3-(1-(11-Aminoundecyl)-1,2,3,6-tetrahydropyridin-4-yl)-1*H*-indole-5-carbonitrile (IVc). 11-(4-(5-Methoxy-1*H*-indol-3-yl)-5,6-dihydropyridin-1(2*H*)-yl)undecan-1-amine (0.8 g, 1.5 mmol) was dissolved in ethanol (50 mL) and hydrazine monohydrate (5 mL) was added. The mixture was stirred at ambient temperature for 2 h and then evaporated. Methylene chloride (100 mL) was added and the solution was stirred at ambient temperature for 18 h. The solution was filtered and evaporated, and the product was recrystallized from acteonitrile to give 0.37 g of (**IVc**) as a pale yellow solid in a 60% yield.

IDT-319. BOC-PEG3400-NHS (0.8 g) was dissolved in methylene chloride (20 mL) and 2-(4-(5-methoxy-1*H*-indol-3-yl)-5,6-dihydropyridin-1(2*H*)-yl)ethanamine (0.6 g, 0.025 mmol) was added. The solution was stirred at ambient temperature for 18 h and evaporated. The resulting t-BOC-protected intermediate was washed with diethyl ether (5 × 100 mL) and dried under reduced pressure. The intermediate was dissolved in methylene chloride (50 mL), and trifluoroacetic acid (2 mL) was added. This solution was stirred at ambient temperature for 18 h and evaporated to yield 0.076 g of IDT-319 which was used without further purification.

IDT-320. 0.086 g of IDT-320 was obtained using the same synthetic protocol employed for the synthesis of IDT-319, substituting compound (**IVb**) in place of (**IVa**), and was used without further purification.

IDT-352. Mono-amino-methoxy-terminated PEG2000 (0.5 g, 0.25 mmol) and octanoic acid (28.6 mg, 0.25 mmol) were placed in a 100 mL round-bottom flask equipped with a stir bar, and methylene chloride (50 mL) was added. *N*-Hydroxysuccinimide (0.03 g, 0.26 mmol) was added, and the solution was cooled to 0 °C. Then, a solution of dicyclohexylcarbodimide (0.054 g, 0.25 mmol) dissolved in methylene chloride (10 mL) was added dropwise, and the solution was stirred overnight. The solution was filtered to remove the resulting urea and evaporated under reduced pressure. The crude product was washed with diethyl ether (5 × 100 mL) resulting in 0.5 g of IDT-352, which was used without further purification.

IDT-353. Mono-amino-methoxy-terminated PEG2000 (0.2 g) was placed in a 100 mL round-bottom flask equipped with a magnetic stir bar. To this, methylene chloride (50 mL) and indole-3-butyric acid NHS ester (0.33 g, 1.1 mmol) was added. The solution was stirred at ambient temperature for 18 h, evaporated, and washed with diethyl ether (5 × 100 mL). This gave 0.15 g of IDT-353 as a colorless solid which was used without further purification.

IDT-363. Biotin-PEG5000-NHS (0.15 g) was dissolved in methylene chloride (50 mL) and dodecan-1-amine (1 g, 5.4 mmol) was added. The solution was stirred at ambient temperature for 18 h, evaporated, and the resulting material was washed with diethyl ether (5 × 100 mL). This gave 0.13 g of IDT-363 as a colorless solid, which was used without further purification.

IDT-361. 0.16 g of 11-(4-(5-cyano-1*H*-indol-3-yl)-5,6-dihydropyridin-1(2*H*)-yl)undecan-1-amine (**IVc**) was added to biotin-PEG5000-NHS (0.2 g) dissolved in methylene chloride (50 mL). The solution was stirred at ambient temperature for 18 h, evaporated, and washed with diethyl ether (5 × 100 mL). This gave 0.13 g of IDT-361 as a pale yellow solid, which was used without further purification.

QD Conjugate Preparation. Covalent attachment of amine-terminated ligands was performed through the use of an EDC coupling reaction. We have previously reported optimized coupling conditions which result in PEG ligand attachment while retaining optimal fluorescent QD emission (*20*). These optimized conditions were retained with a slight modification; the conjugation reaction was performed with a higher ratio of ligands in order to ensure complete QD surface coverage. Consequently, EDC couplings were performed in borate buffer by reacting 8000 mol equiv of amine-terminated ligand with 6000 mol equiv of both EDC and NHS to each molar equivalent of quantum dots. The reaction was allowed to proceed for 1 h with stirring at room temperature.

While the EDC coupling reaction is intended to result in a covalent attachment of the ligand's terminal amine to a carboxylic acid on the polymeric QD coating, we also demonstrate surface modification in the absence of added coupling reagents. For these self-assembly reactions, 8000 mol equiv of ligand for each molar equivalent of quantum dot were stirred together in borate buffer for 1 h at room temperature. Surface modifications resulting from this approach cannot be due to covalent attachment, due to a lack of added coupling reagents. Through the testing of a variety of PEG derivatives, each with differing terminal functionalities, we have demonstrated that this self-assembly results from hydrophobic interactions with the QD surface.

Gel Electrophoresis Characterization. Ligand conjugation to the QD surface was confirmed using agarose gel electrophoresis. Gels were prepared at a concentration of 1% agarose in TAE buffer, and run for 80 min at a constant 80 V in TAE running buffer. Fluorescent images of gels were acquired on an AlphaImager 2000 imaging station (Alpha Innotech Corp.). Since surface modification acts both to passivate charged residues on the QD surface and increase the overall probe size, successful ligand attachment results in an overall reduction of the observed electrophoretic mobility.

Since PEG-QD conjugates exhibit a significantly reduced electrophoretic mobility in agarose gels, subsequent protein adsorption does not result in any observable electrophoretic difference. Consequently, a nondenaturing polyacrylamide gel electrophoresis (PAGE) approach was developed to verify protein adsorption to the QD surface. PAGE provides the capability to initially separate QDs from any unadsorbed protein and subsequently stain to determine protein distribution. Native, nondenaturing polyacrylamide gels were prepared according to established protocols (*27*) utilizing a 2.5% polyacrylamide stacking gel with a 10% polyacrylamide resolving gel. QD conjugates, with and without added albumin, were run at a constant 25 mAmp for 2.5 h. A fluorescent image was then recorded using the AlphaImager 2000 imaging station to verify location of QD bands present in the gel. The gel was subsequently removed from its glass cassette and stained for protein distribution using a Coomassie Blue staining solution overnight as per manufacturer's instructions (note: fluorescent images of the gel must be acquired prior to protein staining since the Coomassie solution quenches the QD fluorescence). A bright field image following gel destaining provides a colorimetric determination of protein content throughout the gel. Protein adsorption to the QD surface is clearly resolved using this approach, as it results in protein bands which colocalize with the previously observed QD bands.

NMR Spectroscopy. ^{1}H NMR experiments were performed to provide spectroscopic proof of QD-ligand complexes. For these reactions, QD conjugation was carried out as before, with and without EDC coupling reagents, for both IDT-319 and IDT-320 ligands. Following conjugation, the reaction mixtures were run through Sephadex G-50 columns to help eliminate any

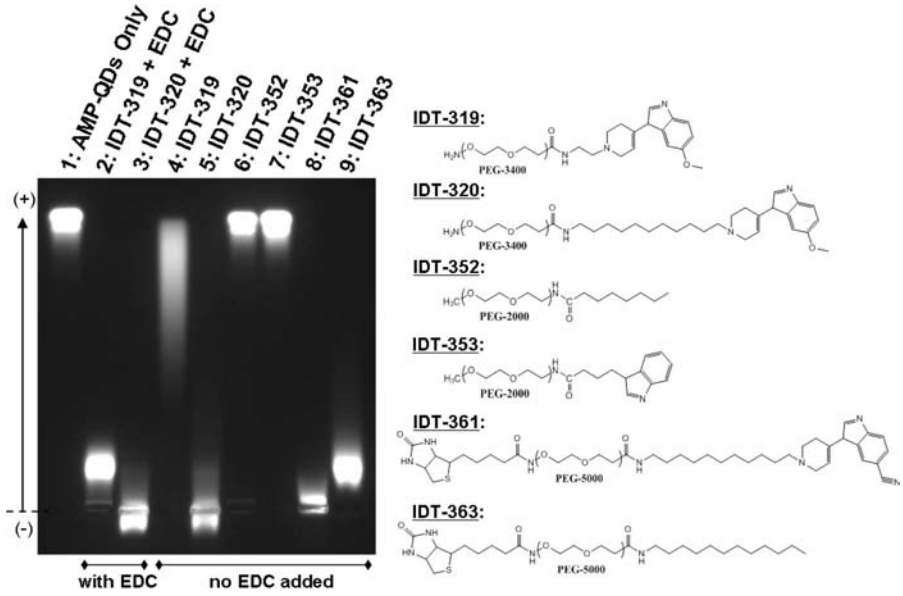

Figure 2. Agarose gel electrophoresis demonstrating assembly of PEG derivatives to QD surface. QD conjugates were run on a 1% agarose gel in TAE buffer for 80 min with a constant applied potential of 80 V. Unconjugated AMP-QDs (lane 1) have a characteristic electrophoretic mobility due to the deprotonated carboxylic acid residues on their surface. Ligand conjugation to the QD surface retards the observed electrophoretic mobility, as seen for both IDT-319 conjugates (lane 2) and IDT-320 conjugates (lane 3). A diminished electrophoretic mobility is also observed for these ligands without added EDC coupling reagent, indicative of self-assembly to the QD surface. Simply mixing IDT-319 with QDs (lane 4) results in conjugates which streak on the gel, indicating differential ligand loading; while IDT-320 completely passivates the QD surface without covalent attachment (lane 5). Other ligands were assayed in an attempt to understand the chemical functionality required to drive surface modification. PEG derivatives with either a short alkyl chain (IDT-352, lane 6) or an indole terminus (IDT-353, lane 7) both failed to drive surface modification in the absence of added coupling reagent. Self-assembly is driven by added hydrophobicity at the PEG terminus, as illustrated for both IDT-361 (lane 8) and IDT-363 (lane 9). Structures of various compounds are illustrated on the right.

unconjugated PEG ligands, and only the fluorescent QD fraction was collected. These QD solutions were then concentrated by means of 100K molecular weight centrifugal filters (Millipore), with one added rinse to ensure complete removal of any unbound ligand, to a final volume of ~20 μL. This concentrated QD solution was then diluted in deuterium oxide to a final concentration of 200 nM, and UV−vis absorption measurements were then made to ensure identical QD concentrations for each NMR sample. All ^{1}H spectra were then recorded on a Bruker 501 spectrometer at ambient temperature in D_2O. A small portion of the residual H_2O signal was suppressed. The resulting spectra were analyzed using *TopSpin 2.0* software.

Cell Culture. LLC-PK1 cell cultures were supplied as a gift from the laboratory of Dr. Randy Blakely (Vanderbilt University, Nashville, TN) and maintained according to established protocols (*28*). Briefly, cells cultured in Dulbecco's Modified Eagle's Medium (DMEM, GIBCO) supplemented with 10% fetal bovine serum, 2 mM L-glutamine, 100 units/mL penicillin, and 100 mg/mL streptomycin were maintained at 37 °C with 5% CO_2. For fluorescent microscopy experiments, cells were initially plated on coverglass bottom cell culture dishes (MatTek Corp., Ashland, MA) approximately 24−48 h prior to imaging, and allowed to reach ~80% confluency. Once cells reached the desired confluency, they were rinsed once with PBS and exposed to a 10 nM solution of QD conjugates for 30 min at room temperature. Cells were then rinsed three times with cold PBS and imaged immediately.

Fluorescence Microscopy. Fluorescent imaging was carried out using a Zeiss Axiovert 200 M inverted fluorescent microscope equipped with a Photometrics HQ2 high-resolution CCD camera, a HBO-100 mercury arc lamp for fluorescent excitation, and Metamorph image analysis software. Bright field images were acquired using differential interference contrast microscopy, while fluorescent images were obtained using a filter set designed for optimal QD detection (XF304−1, Omega Optical) All images were acquired using an oil-immersion 100× objective (Zeiss) and thresholded equivalently for clear comparison.

RESULTS AND DISCUSSION

Initial efforts were focused on the development of small molecule QD conjugates which would specifically interact with the serotonin transporter (SERT) membrane bound receptor. As such, custom ligands were synthesized to include a SERT selective terminus as well as a reactive amine terminus on either side of a PEG spacer. The amine functionality permitted covalent attachment to the carboxylic acid functionality on the surface of commercially available water-soluble ITK QDs, while the SERT selective small molecule would presumably be able to interact with its biological target. Agarose gel electrophoresis was used as verification of successful QD surface modification subsequent to covalent attachment of PEG ligands. As illustrated in Figure 2, the addition of PEG ligands acts both to decrease QD surface potential, by derivatizing negatively charged carboxylic acid residues, as well as increase the overall probe volume, cumulatively resulting in a decreased electrophoretic mobility. Consequently, unconjugated QDs (lane 1) have an increased electrophoretic mobility in a 1% agarose gel as compared to IDT-319 (lane 2) or IDT-320 (lane 3) QD-conjugates. Unexpectedly, however, there was an observable difference between the relative mobility of IDT-319 and IDT-320 QD-conjugates. The only difference between these two ligands is a nine carbon alkyl linker between the PEG and the SERT-selective terminus, a seemingly negligible difference which should not result in any sizable disparity in electrophoretic mobilities, especially given the large overall molecular weight (~3400 Da) of the PEG ligand. This electrophoretic difference could therefore be attributed to differential ligand loading at the QD surface for these two similar ligands, perhaps mediated by added hydrophobicity at the IDT-320 terminus.

To verify the possibility that a hydrophobic terminus could interact with the QD surface and cause self-assembly, the

conjugation reaction was carried out without added EDC or NHS. EDC is a reagent that enables the formation of an amide bond between the terminal amine of the PEG ligand and carboxylic acid functionalities at the QD surface. Consequently, any observed surface modification in the absence of these coupling reagents would have to result from interactions with the ligand's more hydrophobic SERT-selective region. The absence of added coupling reagents, presumably resulting in no ligand attachment, should result in products with the same electrophoretic mobility of unconjugated AMP-QDs. However, it is apparent that QD surface modifications do occur in the absence of added coupling reagents, most notably for increasingly hydrophobic PEG ligands (lanes 4−9, Figure 2). QDs mixed with IDT-319 only resulted in partial surface modification (lane 4), suggesting that ligand attachment is at least partially dependent upon amide bond formation. The streaking observed in the IDT-319 QD product in the absence of EDC and NHS is indicative of differential ligand loading at the QD surface. The IDT-320 QD product (lane 5), however, results in complete surface modification and faithfully reproduces the electrophoretic mobility observed when the conjugation was carried out in the presence of EDC and NHS (lane 3). This indicates that IDT-320 assembles independent of covalent ligand attachment and acts to passivate the reactive AMP-QD surface.

Additionally, alternate PEG ligands were synthesized to further elucidate the chemical functionality required to drive the self-assembly of PEG ligands to the AMP-QD surface in the absence of coupling reagents. PEG ligands terminated with either a seven-carbon alkyl chain (IDT-352, lane 6) or an indole ring (IDT-353, lane 7) did not result in QD surface modification. A PEG derivative with a longer twelve-carbon alkyl chain (IDT-363, lane 9), however, did result in ligand assembly to the QD surface, as illustrated by a characteristic retardation of electrophoretic mobility. Taken together, these data indicate that this self-assembly of PEG ligands to the QD surface is driven by hydrophobic/hydrophilic interactions, and not a result of a specific chemical functionality present in the SERT-selective termini. Additionally, an alternate SERT-selective cyano derivative (IDT-361, lane 8), with a chemical functionality similar to IDT-320 but synthesized via different intermediates, results in self-assembly to the QD surface; this further corroborates the importance of added hydrophobicity for driving assembly of PEG ligands to the QD surface.

While agarose gel electrophoresis characterization qualitatively indicate the self-assembly of hydrophobic PEG derivatives to the QD surface, additional spectroscopic proof of this interaction is certainly necessary for verification of any such claims. As a result, a NMR experiment was devised to provide spectroscopic characterization of these QD-ligand structures and help quantify ligand coverage to verify any conclusions drawn from electrophoretic mobility measurements. Given the large number of structurally equivalent hydrogen atoms in their long PEG chains, the ^{1}H NMR spectra of IDT-319 and IDT-320 predominately consist of a single large peak around 3.64 ppm (Supporting Information, Figure S2). The ^{1}H spectrum of unconjugated AMP-QDs (also Supporting Information Figure S2) has no such feature present at that chemical shift, indicating the utility of this spectral feature in assessing ligand conjugation to the QD surface. NMR samples were diluted into deuterium oxide following QD conjugation to either IDT-319 or IDT-320, carried out as before both with and without added EDC coupling reagents, and special care was taken to eliminate any unbound ligand following conjugation (see Experimental Methods section). The ^{1}H NMR spectra of IDT-319 and IDT-320 conjugates, presented in Figure 3, illustrate IDT-320 conjugation to the QD regardless of any coupling reagents, an indication that the observed differences in electrophoretic mobilities result directly from PEG surface modifications. A large PEG peak is apparent for both the IDT-319 and IDT-320 QD-conjugates synthesized in the presence of EDC coupling reagents (Figure 3A). While this peak remains for IDT-320 conjugates synthesized in the absence of any added coupling reagents, a demonstration that these hydrophobic PEG derivatives self-assemble to the QD surface, the IDT-319 peak is significantly diminished in the absence of EDC (Figure 3B). The presence of additional peaks from the AMP-QD, presumably due to protons present in its ampiphilic polymer coating, permit normalization of integral areas with respect to QD concentration and facilitate straightforward sample-to-sample comparisons for determination of relative ligand loading. As expected, the integral areas for these

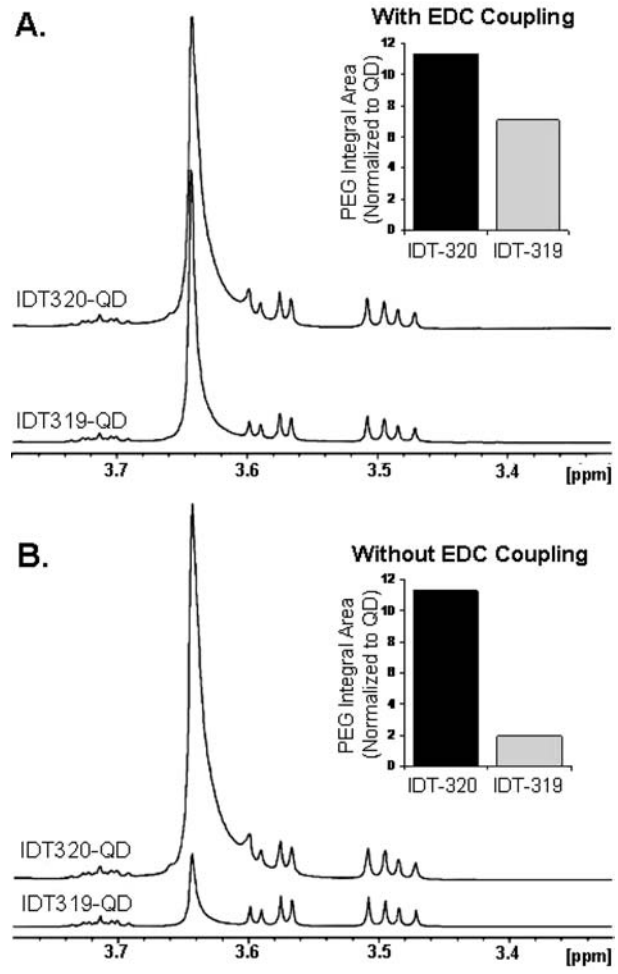

Figure 3. ^{1}H NMR characterization of QD-ligand conjugates. QD conjugation reactions to either IDT-319 or IDT-320 were carried out (A) with the addition of EDC coupling reagents or (B) in the absence of any coupling reagents; conjugates were then purified of any unbound ligand before analysis. Consequently, the presence of a peak at 3.64 ppm in the ^{1}H NMR spectra, due to the long PEG chain present in each ligand, is indicative of ligand attachment to the QD surface. (A) In the presence of EDC coupling reagents, both IDT-320 (upper spectrum) and IDT-319 (lower spectrum) present a spectral feature indicating ligand attachment. (B) Without added coupling reagents, the feature is still clearly present for the IDT-320 conjugates (upper spectrum), while this peak is greatly diminished for IDT-319 conjugates (lower spectrum). The integral area of each PEG peak, which is directly proportional to the amount of ligand present, is therefore indicative of ligand loading, but all areas must be first be normalized to a QD feature to permit any sample-to-sample comparison. (Inset) Quantification of integral areas, each normalized to the AMP-QD doublet of doublets at 3.5 ppm, clearly demonstrate equivalent ligand loading for IDT-320 conjugates regardless of added coupling reagents, while the IDT-319 conjugates demonstrate a roughly 4-fold decrease in ligand attachment in the absence of coupling reagents.

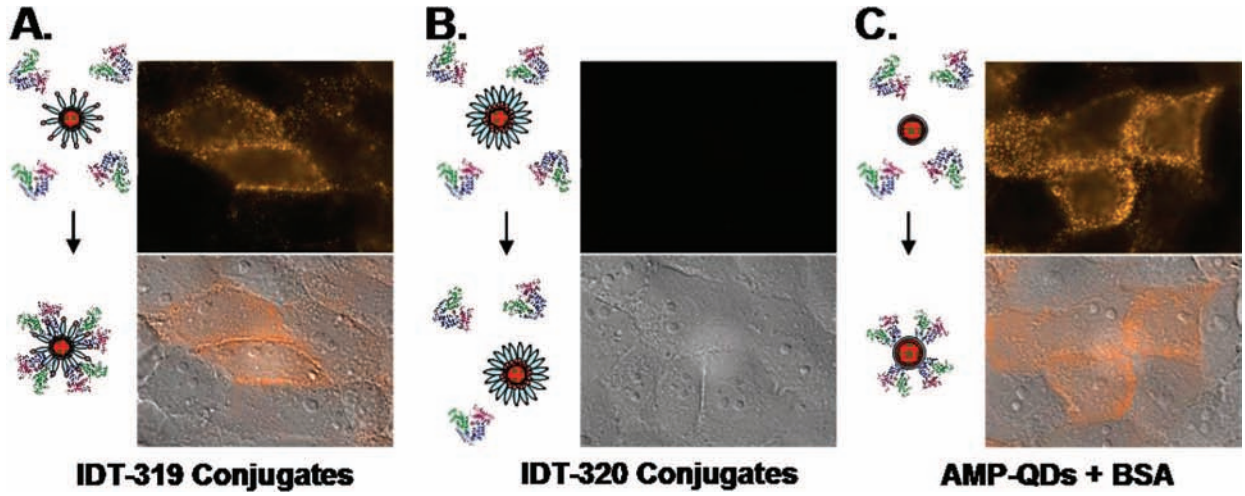

Figure 4. Cellular imaging with QD conjugates. SERT-expressing LLC-PK1 cells were incubated with various QD conjugates in the presence of BSA, a standard blocking agent. QD fluorescence micrographs (top) and corresponding bright field composite overlay images (bottom) are shown for IDT-319 QD-conjugates (A), IDT-320 QD-conjugates (B), and unconjugated AMP-QDs (C). The fluorescent staining observed for the IDT-319 conjugates is not ligand-mediated, since the same pattern is observed with unconjugated AMP-QDs; rather, this artifactual staining is apparently the result of albumin adsorption (illustrated schematically at left). No such albumin associated artifactual staining is observed for IDT-320 QD conjugates, owing to the improved passivation of the IDT-320 QD surface.

QD-conjugates, each normalized to a doublet of doublets at 3.47 ppm from the AMP-QD, clearly indicate a similar ligand loading for IDT-320 regardless of coupling reagents, while the IDT-319 conjugates have approximately a 4-fold decrease in ligand loading without covalent attachment (Figure 3, inset). These results are obviously consistent with the results of the agarose electrophoresis experiment, in which any added ligand loading results in a diminished electrophoretic mobility. Taken together, these data provide an unambiguous demonstration of the attachment of PEG derivatives to the QD surface and provide an additional means to determine and compare ligand loading.

The utility of this surface modification approach, and the improved QD surface passivation, could be of great importance to biological imaging applications. Our own efforts have been focused toward the development of small molecule conjugated QDs for biological imaging application, and these custom PEG ligands should ultimately facilitate specific QD recognition of SERT. An initial attempt to demonstrate specific targeting of SERT in a cellular assay using these custom PEG derivatives, however, produced intriguing results. For this assay, SERT-expressing LLC-PK1 cells were incubated with either IDT-319 or IDT-320 ligand-conjugated QDs in a bovine serum albumin (BSA) blocking solution for 30 min at 37 °C, rinsed three times with cold PBS, and immediately imaged with a fluorescent microscope at 100× magnification. The observed fluorescent staining pattern for IDT-319 QD conjugates (Figure 4A) was dramatically different from the negligible fluorescent staining observed for IDT-320 conjugates (Figure 4B). This staining pattern observed for the IDT-319 conjugates was not uniform across the field of view, but isolated to individual cells, an indication of specificity and apparently not the result of nonspecific QD interactions with the cellular membrane. This labeling, however, could not be blocked with the selective serotonin reuptake inhibitor paroxetine, and was apparent in parental cell lines which do not express SERT (data not shown), a clear demonstration that the custom PEG ligands were not mediating specific labeling of SERT. Additional imaging experiments indicated that the observed QD staining pattern involved active intracellular transport, demonstrated a cell cycle dependence, and could not be blocked with free ligand (Supporting Information). It became apparent that albumin was mediating this effect when AMP-QDs, without any added surface modification, recapitulated the same fluorescent staining pattern following an initial incubation in a solution containing BSA (Figure 4C). Taken together, these data indicate that BSA adsorption (illustrated schematically in Figure 4) to AMP-QDs and IDT-319 QD conjugates result in an endosomally associated fluorescent staining pattern, while improved surface passivation of IDT-320 QD conjugates prevent protein adsorption and any associated artifactual cellular labeling.

QD-BSA conjugates are reportedly photostable endosomal markers (*22*), but it was assumed that PEG surface modification would passivate the reactive QD surface and eliminate any undesirable protein associations. Our own prior investigation has highlighted the utility of PEG to significantly reduce nonspecific interactions of AMP-QDs in live cell assays (*20*), but these previous results were collected in the absence of serum protein blocking conditions and any potential protein interference was consequently not explored. It is now apparent that nontargeted PEG-QDs result in an endosomal fluorescent staining pattern for cellular assays where serum protein blocking conditions are employed (Supporting Information Figure S4). These cellular imaging results seem to indicate that BSA adsorption occurs despite PEG modification; yet, this protein adsorption to the QD surface must first be verified in order to validate these assumptions. Gel-filtration chromatography has previously been employed as an analytical tool to assess serum protein interactions with QD surfaces (*23*), and has proven useful in identifying electrostatic interactions as the most likely cause of serum protein adsorption to QD surfaces (*29*). We have focused instead on an alternate approach using polyacrylamide gel electrophoresis (PAGE) to assess protein−QD interactions, without the added expense of gel-filtration chromatography instrumentation. Previous work has identified the utility of PAGE for characterization of QDs covalently modified with BSA (*30*, *31*), but these studies focused on denaturing SDS-PAGE given the covalent nature of the QD surface modification. A nondenaturing, native gel was chosen for our assay in order to maintain the interaction which causes albumin adsorption to reactive QD surfaces. This approach initially facilitates electrophoretic separation of QDs from unconjugated protein, owing to a significant size difference; additionally, the resulting resolved gel can subsequently be stained to assess protein localization. Colocalization of a protein band, visualized via colorimetric detection, with the QD band, as determined by fluorescence, is therefore indicative of a protein−QD interaction;

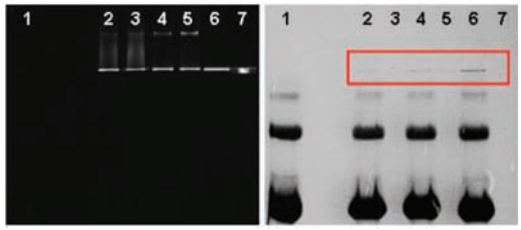

Figure 5. Polyacrylamide gel electrophoretic determination of albumin adsorption to reactive QD surfaces. A fluorescent image (left) illustrates QD accumulation at the interface between the 2.5% stacking gel and the 10% resolving gel. A bright field image following Coomassie Blue staining (right) confirms protein localization. Unassociated BSA is evident in the resolving gel as three characteristic bands. Albumin adsorbed to the QD surface, however, colocalizes with the QD fluorescent bands (highlighted with a red box). Lane 1: BSA without any QDs. Lane 2: IDT-320 QDs with BSA. Lane 3: IDT-320 QDs, no BSA. Lane 4: IDT-319 QDs with BSA. Lane 5: IDT-319 QDs, no BSA. Lane 6: AMP-QDs with BSA. Lane 7: AMP-QDs, no BSA. The passivated IDT-320 QD show minimal albumin adsorption (lane 2) compared to IDT-319 conjugates (lane 4), while AMP-QDs show the highest degree of albumin association (lane 6).

conversely, complete separation of protein from QDs occurs in the absence of any protein−QD interaction.

Protein analysis is routinely performed using PAGE and frequently incorporates both a lower percentage polyacrylamide stacking gel with a higher percentage resolving gel. The QD characterization technique developed in this study makes use of a 2.5% polyacrylamide stacking gel and a 10% resolving gel. As large particles experience a decreased electrophoretic mobility with increasing polyacrylamide concentration, the initial 2.5% gel facilitates QD migration and protein separation, while the 10% resolving gel acts a barrier to the QDs, concentrating them to an individual band (Figure 5, left). A Coomassie Blue stain after electrophoretic separation subsequently permits colorimetric determination of protein localization (Figure 5, right). Using this approach, free BSA separates into three distinct bands, characteristic of albumin monomers, dimers, and globulins (Figure 5, lane 1), but BSA adsorbed to the QD surface appear as an additional band coincidental with the QD fluorescence (highlighted with red box). Of particular notice, the dark band associated with AMP-QDs (lane 6) indicates a large degree of albumin association. Additionally, IDT-319 conjugates (lane 4) have an increased albumin adsorption as compared to their IDT-320 counterparts (lane 2), consistent with the cellular imaging observations. The covalent PEG attachment for the IDT-319 conjugates does act to reduce the amount of albumin adsorption as compared to AMP-QDs, but apparently this minimal amount of protein is still sufficient to cause the observed artifact in fluorescent imaging experiments. Control samples consisting of QD conjugates without added BSA (lanes 3, 5, and 7) provide verification that the observed staining is not due to QD interferences. While this PAGE characterization may lack the sensitivity of a comparable gel-filtration approach, it does serve as a facile tool to quickly assess potential protein interactions at the QD surface without any significant instrumentation expenditure.

CONCLUSIONS

In this report, we have demonstrated that increasingly hydrophobic ligands will self-assemble to the QD surface, presumably through an interaction with the hydrophobic organic capping ligands present on the QD surface. Our own small molecule approach to specifically target membrane-associated receptors is critically dependent upon ligand presentation at the QD surface, and it is now apparent that increasingly hydrophobic targeting molecules will be unavailable to interact with their intended targets due to this unexpected association with the QD surface. An improved architecture for optimal ligand presentation on the surface of AMP-QDs must therefore incorporate a less hydrophobic targeting compound, as is the case for our own $GABA_c$ receptor-specific muscimol−QD derivatives (*18*). In the instance that a biological target requires a hydrophobic compound for effective labeling, a two-step labeling approach can be employed, utilizing biotinylated ligands to initially facilitate a specific interaction, and subsequently be recognized by a streptavidin-conjugated QD (*32*). Alternately, effective presentation of these hydrophobic drug derivatives may ultimately be accomplished through a complete displacement of any organic capping ligands, although issues regarding diminished colloidal stability and fluorescence quenching are still of concern for these type of conjugates (*33*, *34*). In addition to these observations regarding ligand presentation, we have demonstrated the improved passivation resulting from self-assembly of PEG derivatives, which have proven to be even less reactive than covalently modified PEG-QDs. These self-assembled conjugates may ultimately provide a useful platform for biological applications owing to their ability to eliminate unwanted protein adsorption and other associated interferences.

Previous reports have focused on identifying appropriate blocking strategies and surface modifications which limit biological recognition of nanoparticles and reduce their nonspecific binding to cellular membranes. We have demonstrated the potential interference protein adsorption can cause in cellular assays which incorporate QD probes, despite efforts to limit QD reactivity through PEG surface modification, and it is apparent that the observed endosomal staining could easily be mistaken for a specific interaction. Serum protein adsorption, and in particular albumin adsorption, is likely to occur in any *in vivo* analysis and is also likely to occur in numerous *in vitro* assays, where serum blocking is widely employed to limit unwanted fluorescent background staining. While the use of serum proteins is generally accepted in biological protocols, and furthermore necessary for maintaining long-term cellular viability, their potential reactivity with QD probes is frequently neglected. At least one study has demonstrated the importance of selecting an appropriate blocking solution for effective and specific QD labeling (*35*), and our results provide further insight into the persistent nature of this problematic interference. An alternate report has highlighted a potential application utilizing protein adsorption on gold nanoparticles to facilitate intracellular delivery and mediate materials transfection (*36*), consistent with the intracellular staining observed with our own albumin-modified QDs. Consequently, protein adsorption can present either a desirable result or an unwanted interference, depending on the nature of the biological assay in question, highlighting the importance of improved approaches to control the QD surface and mediate biomolecule attachment.

ACKNOWLEDGMENT

We would like to thank Brian O. Bachman for providing access to gel imaging equipment and Frederick R. Haselton for access to a Nanodrop spectrophotometer. We would also like to thank Randy D. Blakely for helpful discussion throughout the course of this work and providing us with the LLC-PK1 cell line employed in this study. This work was supported by the National Institutes of Health under Grants EB003728 and GM72048-02. M.R.W. gratefully acknowledges a fellowship from the Vanderbilt Institute of Nanoscale Science and Engineering (VINSE) and additional funding through the Vanderbilt Institute for Integrative Biosystems Research and Education (VIIBRE).

Received March 20, 2008; Revised Manuscript Received May 15, 2008

Integrins, especially integrin $\alpha_v\beta_3$, are attractive receptors for vascular targeting strategies. Recently, a divalent RGD peptidomimetic, E-[c(RGDfK)$_2$], has been described that demonstrates increased uptake in human ovarian carcinoma OVCAR-3 xenograft tumors. Inspired by these results, we set out to develop doxorubicin conjugates with E-[c(RGDfK)$_2$] by binding two different maleimide derivatives of doxorubicin to E-[c(RGDfK)$_2$] that was thiolated with iminothiolane. In this way, two water-soluble derivatives were obtained, E-[c(RGDfK)$_2$]-DOXO-1 and E-[c(RGDfK)$_2$]-DOXO-2. In E-[c(RGDfK)$_2$]-DOXO-1, doxorubicin was bound to the peptide through a stable amide bond, and in E-[c(RGDfK)$_2$]-DOXO-2, a MMP-2/MMP-9 cleavable octapeptide was introduced between doxorubicin and the peptide. The rationale for a MMP-2/MMP-9-cleavable linker was that MMP-2 and MMP-9 bind to integrin $\alpha_v\beta_3$ and both are overexpressed in tumor vasculature. In addition, analogous control doxorubicin-containing peptides bearing c(RADfK) that does not bind to integrin $\alpha_v\beta_3$ were synthesized, i.e., c(RADfK)-DOXO-1 and c(RADfK)-DOXO-2. Whereas E-[c(RGDfK)$_2$]-DOXO-2 was cleaved effectively by MMP-2 and in OVCAR-3 tumor homogenates releasing a doxorubicin-tetrapeptide or doxorubicin as the final cleavage product, no release of doxorubicin was observed for E-[c(RGDfK)$_2$]-DOXO-1. Proliferation of HUVEC in the presence of MMP-2-cleavable doxorubicin-containing peptides exhibited 6- to 10-fold increased inhibition compared to the amide-linked doxorubicin-containing peptides. In addition, inhibition of HUVEC sprouting during a 24 h exposure was approximately 3-fold stronger for E-[c(RGDfK)$_2$]-DOXO-2 and 20-fold stronger for the reference peptide conjugate c(RADfK)-DOXO-2 than for doxorubicin alone. *In vivo* studies in an OVCAR-3 xenograft model demonstrated no or only moderate antitumor efficacy for either E-[c(RGDfK)$_2$], E-[c(RGDfK)$_2$]-DOXO-1, E-[c(RGDfK)$_2$]-DOXO-2, or c(RADfK)-DOXO-2, even at doses of 3 × 24 mg/kg doxorubicin equivalents, compared to an improved antitumor effect for doxorubicin at 2 × 8 mg/kg.

INTRODUCTION

Vascular targeting agents interact with receptors on endothelial cells and, unlike antiangiogenic drugs that inhibit the formation of new vessels, destroy or occlude pre-existing blood vessels of solid tumors (*1*). Vascular targeting agents can act as inhibitors of endothelial growth such as combretastatins or receptor antagonists or they comprise ligand-based drugs consisting of a targeting moiety and an effector molecule. Suitable receptors on endothelial cells for ligand-directed approaches are the VEGF[1] receptors, the fibronectin ED-B domain, endoglin, NG2 proteoglycan, prostate-specific membrane antigen (PSMA), as well as cell adhesion receptors such as vascular cell adhesion molecule 1 (VCAM-1), E-selectins, and integrins (*1–4*). The latter have perhaps been the most intensely studied as endothelial targets for vascular targeting agents (*5*). Integrins are heterodimeric cell surface receptors of which several such as integrin $\alpha_v\beta_3$, $\alpha_v\beta_5$, and $\alpha_5\beta_1$ are overexpressed in the blood vessels of solid tumors and mediate adhesion between cells and the extracellular matrix, thus promoting tumor cell migration and tumor growth (*3*). A characteristic feature of integrins is their high binding affinity for arginyl-glycyl-aspartic acid (RGD) sequences exposed on endogenous or exogenous ligands. Using an *in vivo* phage display technology, Arap and co-workers discovered cyclic RGD-4C peptides that bind avidly to integrin $\alpha_v\beta_3$ and $\alpha_v\beta_5$ (*6, 7*). A number of doxorubicin conjugates have been developed with a divalent RGD-4C peptide (ACDCRGDCFCG). The first by Arap et al. who coupled the 3′-amino position of doxorubicin to one or two of the free carboxylate groups of RGD-4C by activating the latter with 1-ethyl-3-(3,3-dimethylaminopropyl)carbodiimide and *N*-hydroxysuccinimide. This conjugate showed improved activity and toxicity profile over doxorubicin in a MDA-MB-435 mammary carcinoma model

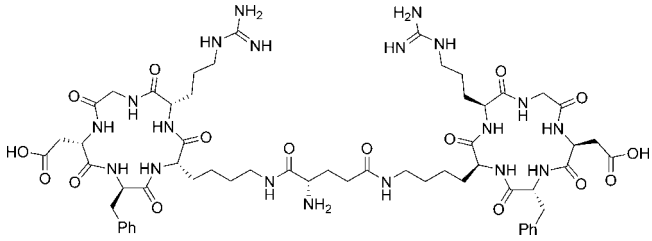

Figure 1. Structure of E-[c(RGDfK)$_2$].

in which integrin $\alpha_v\beta_3$ is expressed in the tumor vessels as well as on the tumor cell themselves (*7, 8*). Superior efficacy of the RGD-4C-doxorubicin conjugate was confirmed in another model (hepatoma) in which the tumor cells did not express integrin $\alpha_v\beta_3$ suggesting that a direct endothelial effect was responsible for tumor growth inhibition (*8*). The precise structure and mode of action of these conjugates has not been reported, but conjugation at the 3′-amino group seems likely resulting in a stable amide bond between doxorubicin and the divalent peptide which presumably cannot be readily cleaved *in vivo*. This led de Groot et al. to develop a prodrug with RGD-4C and a plasmin-cleavable substrate D-Ala-Phe-Lys that showed comparable *in vitro* cytotoxicity to doxorubicin after activation by plasmin (*9*). Unfortunately, no *in vivo* efficacy has been reported for this conjugate. Due to the presence of two disulfide bridges in the structure of RGD-4C that are prone to cleavage during synthesis or in biological media, a stable peptide derivative E-[c(RGDfK)$_2$] based on the integrin $\alpha_v\beta_3$ antagonist Cilengitide has been developed that shows specific tumor targeting properties (*10–13*). The presence of the glutamic acid residue makes it an ideal ligand for further chemical conjugation. Burkhart et al. conjugated a doxorubicin prodrug, doxsaliform, to this position and showed that the resulting conjugate bound specifically to vitronectin and that *N*-methylhydroxyl-doxorubicin is released by hydrolysis as the highly cytotoxic doxorubicin derivative, but no *in vivo* data were reported (*14*).

Further diagnostic studies by Janssen et al. demonstrated that a dimeric form of c(RGDfK) (Figure 1), i.e. E-[c(RGDfK)$_2$], has improved tumor targeting properties over the monomeric form (*12, 14*). Subsequent biodistribution studies with radiolabeled E-[c(RGDfK)$_2$] showed an uptake of up to 7.5% injected dose/g in OVCAR-3 xenograft tumors (*12*).

Inspired by these results, we set out to develop doxorubicin conjugates with E-[c(RGDfK)$_2$]. Our aim was to (a) develop a stable drug derivative as well as a prodrug with RGD peptides, (b) to establish the *in vitro* properties of these drug conjugates including analogously constructed conjugates with the nonintegrin $\alpha_v\beta_3$ binding control peptide c(RADfK), and (c) to compare the *in vivo* efficacy of the RGD doxorubicin conjugates in the human ovarian carcinoma OVCAR-3 xenograft model which was used by Janssen et al. for biodistribution studies with E-[c(RGDfK)$_2$], in the hope of answering some of the open questions regarding cleavability and *in vivo* potential that have arisen in this particular area of doxorubicin conjugates.

As starting materials for the intended doxorubicin RGD-based peptide conjugates, we used the 6-maleimidocaproyl amide derivative of doxorubicin **1** as a stable derivative and the maleimidotriethylene glycol peptide derivative **2** that contains an octapeptide that is cleaved by matrix metalloproteases 2 and 9 (MMP-2 and MMP-9) (Figure 2). A MMP-2/-9 cleavable prodrug seemed suitable for our vascular targeting strategy considering that MMP-2 and MMP-9 bind to integrin $\alpha_v\beta_3$ and both are overexpressed in tumor vasculature (*15–17*) which could ensure that sufficient amounts of these proteases are present at the molecular target after binding of the doxorubicin RGD peptides to integrin $\alpha_v\beta_3$. In addition, compound **2**, developed as an albumin binding prodrug, demonstrated superior *in vivo* efficacy compared to doxorubicin in a melanoma xenograft model (*18*).

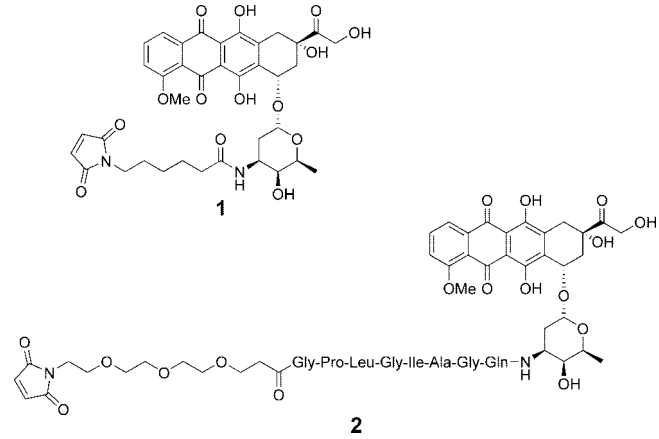

Figure 2. Stable 6-maleimidocaproyl amide derivative of doxorubicin **1** and the MMP-2 cleavable maleimidotriethylene glycol peptide derivative **2**.

EXPERIMENTAL PROCEDURES

Materials and Instrumental. Doxorubicin hydrochloride was purchased from Yick-Vic (Hong Kong, PRC); E-[c(RGDfK)$_2$] and c(RADfK) were purchased from Peptides International (Louisville, KY, USA); organic solvents: HPLC grade (Labscan Ltd., Dublin, Ireland; Roth, Karlsruhe, FRG; Merck, Darmstadt, FRG). Compound **2** was prepared as described in the literature (*18*). All other chemicals used were at least reagent grade and obtained from Sigma-Aldrich (Deisenhofen, FRG), Roth, or Merck and used without further purification; buffers were vacuum-filtered through a 0.2 μm membrane (Sartorius, Göttingen, FRG) and thoroughly degassed with nitrogen prior to use. ^{1}H, ^{13}C NMR: Bruker AM 400 (internal standard: TMS); analytical HPLC were performed with a Kontron 422 pump and a Kontron 430 detector (at 495 and 254 nm). For peak integration, *Geminyx* software (v 1.91 by Goebel Instrumentelle Analytik, FRG) was used; column: Machery-Nagel, 100 Å, Nucleosil 100−5 C18 [4 × 250 mm] with precolumn; chromatographic conditions: flow: 1.0 mL/min, mobile phase A: AcN/0.05% aq. TFA (30/70, v/v), mobile phase B: AcN/0.05% aq. TFA (70/30, v/v), gradient: 0−1.5 min 100% mobile phase A; 1.5−40 min increase to mobile phase B; 40−46.5 min decrease to initial mobile phase A; injection volume: 20 μL. Cleavage studies with MMP-2 and in OVCAR-3 tumor homogenates were performed following a modified method according to the literature (*18*) with a Kontron 422 pump and a Merck F-1050 fluorescence spectrophotometer (EX 490 nm, EM 540 nm). For peak integration, *Geminyx* software was used; column: Waters WAT106151, Symmetry 300, C18 5 μ [4.6 × 250 mm] with precolumn WAT106166; chromatographic conditions: flow: 1.0 mL/min, mobile phase A: AcN/0.05% aq. TFA (25/75, v/v), mobile phase B: AcN/0.05% aq. TFA (55/45, v/v), gradient: 0−25 min 100% mobile phase A; 25−40 min increase to mobile phase B; 40−50 min 100% mobile phase B; 50−60 min decrease to initial mobile phase A; injection volume: 20 μL. Preparative HPLC for the separation of E-[c(RGDfK)$_2$]-DOXO-1, E-[c(RGDfK)$_2$]-DOXO-2, c(RADfK)-DOXO-1, and c(RADfK)-DOXO-2 was performed with a BioLogic Duo-Flow System from Biorad (München, FRG) which was connected with a Lambda 1010 visible monitor from Bischoff (at λ = 495 nm); UV-detection at λ = 254 nm from Biorad; column: Machery-Nagel, 100 Å, Nucleosil 100−7 C18 [21 × 250 mm] with precolumn; chromatographic conditions: flow: 10 mL/min,

mobile phase A: AcN/0.05% aq. TFA (30/70, v/v), mobile phase B: AcN/0.05% aq. TFA (70/30, v/v), gradient: 0−1 min 100% mobile phase A; 1−44 min increase to mobile phase B; 41−46 min decrease to initial mobile phase A; injection volume: 2 mL. MALDI-TOF mass spectra were acquired on a Reflex III mass spectrometer (Bruker Daltonik GmbH, Bremen, FRG) in the reflector mode (positively charged ions) with external calibration. Samples were prepared with an adapted thin-layer technique (*19*). α-Cyano-4-hydroxycinnamic acid (97%, Aldrich, Taufkirchen, FRG) was used as matrix and nitrocellulose (Biorad, Trans-Blot Transfer Medium) as additive. The samples were washed with 0.1% TFA. Monoisotopic peaks were used for data analysis. ESI-TOF mass spectra were acquired on an Agilent 6210 system, consisting of an Agilent 1100 HPLC system with a diode array detector and an ESI-MSD TOF by Agilent Technologies (Böblingen, FRG).

Synthesis of 6-Maleimidocaproylamide Derivate of Doxorubicin 1. Doxorubicin hydrochloride (500 mg, 0.86 mmol, 1 equiv), 6-maleimidocaproylic acid *N*-hydroxysuccinimide ester (292 mg, 0.95 mmol, 1.1 equiv), and triethyl amine (239 μL, 1.74 mmol, 2 equiv) were dissolved in DMF (30 mL) and stirred for 2 h at room temperature. The solution was precipitated in diethyl ether (10 mL), washed with dry diethyl ether (2 × 5 mL), filtered and dried *in vacuo* to obtain red crystals in 91% yield (574 mg, 0.78 mmol); HPLC analysis: 14.4 min, 96% of peak area, 495 nm; MS (ESI-TOF) m/z = 775.21 $[M + K]^+$, 759.24 $[M + Na]^+$.

General Procedure for the Synthesis of E-[c(RGDfK)$_2$]-DOXO-1, E-[c(RGDfK)$_2$]-DOXO-2, c(RADfK)-DOXO-1, and c(RADfK)-DOXO-2. The doxorubicin derivatives **1** (20 mM solution in DMF) or **2** (1 equiv) and E-[c(RGDfK)$_2$] or c(RADfK) (1 equiv) were dissolved in 10 mM sodium phosphate buffer (8−20 mL, containing 1 mM EDTA, pH 7.5). A 72.7 mM solution of 2-iminothiolane (1 equiv) in 10 mM sodium phosphate buffer (containing 1 mM EDTA, pH 7.5) was added to the clear red solution and the mixture was kept overnight at room temperature. The solvent was removed *in vacuo*; the residue was dissolved in 2 mL AcN/0.05% aq. TFA (30/70, v/v) and purified by preparative HPLC.

E-[c(RGDfK)$_2$]-DOXO-1. Red crystals were obtained in 44% yield (42 mg, 0.017 mmol). HPLC analysis: 10.3 min, >97% of peak area, 495 nm; MS (TOF) m/z = 2177.90 $[M + Na]^+$, 2155.93 $[M + H]^+$, 1759.84 $[C_{79}H_{119}N_{22}O_{22}S]^+$.

E-[c(RGDfK)$_2$]-DOXO-2. Red crystals were obtained in 62% yield (60 mg, 0.018 mmol). HPLC analysis: 12.1 min, 95% of peak area, 495 nm; MS (TOF) m/z = 2939.35 $[M + H]^+$, 2543.27 $[C_{113}H_{176}N_{31}O_{34}S]^+$.

c(RADfK)-DOXO-1. Red crystals were obtained in 29% yield (43 mg, 0.026 mmol). HPLC analysis: 11.3 min of peak area, 95%, 495 nm; MS (TOF) m/z = 1455.61 $[M + H]^+$, 1059.55 $[C_{48}H_{75}N_{12}O_{13}S]^+$.

c(RADfK)-DOXO-2. Red crystals were obtained in 43% yield (81 mg, 0.033 mmol). HPLC analysis: 12.9 min, 91% of peak area, 495 nm; MS (TOF) m/z = 2261.04 $[M + Na]^+$, 2239.06 $[M + H]^+$, 1842.97 $[C_{82}H_{132}N_{21}O_{25}S]^+$.

Cleavage Studies of E-[c(RGDfK)$_2$]-DOXO-2 with 58.8 mU/μL Activated MMP-2. A 200 μM solution of E-[c(RGDfK)$_2$]-DOXO-2 in 50 mM Tris·HCl buffer (pH 7.5) was prepared. A 10 mM stock solution of *p*-aminophenylmercuric acetate (APMA, 3.9 mg) in 0.1 M NaOH (1 mL) was diluted with 50 mM Tris·HCl buffer (3 mL, pH 7.5) to obtain a 2.5 mM APMA solution which was adjusted to pH 7.2. MMP-2 (58.8 mU) was activated for 30 min at 37 °C with 7.5 μL of the 2.5 mM APMA solution. 100 μL of the E-[c(RGDfK)$_2$]-DOXO-2 stock solution (200 μM) were mixed with activated MMP-2 and incubated at 37 °C. Samples were collected and analyzed by HPLC over 3 h.

Cleavage Studies of E-[c(RGDfK)$_2$]-DOXO-2 with OVCAR-3 Tumor Homogenates. For preparing the tumor homogenates, tissues of OVCAR-3 xenografts were cut into small pieces, and 200 mg samples were transferred in a 2 mL Eppendorf tube to which was added 800 μL of buffer (50 mM Tris·HCl buffer, pH 7.4, containing 1 mM monothioglycerol). Homogenization was carried out with a microdissmembrator at 2000 rpm for 2 × 10 min with the aid of glass balls. Subsequently, the samples were centrifuged at 10 000 rpm for 10 min at 4 °C. The supernatant was aliquoted and kept frozen at −78 °C prior to use.

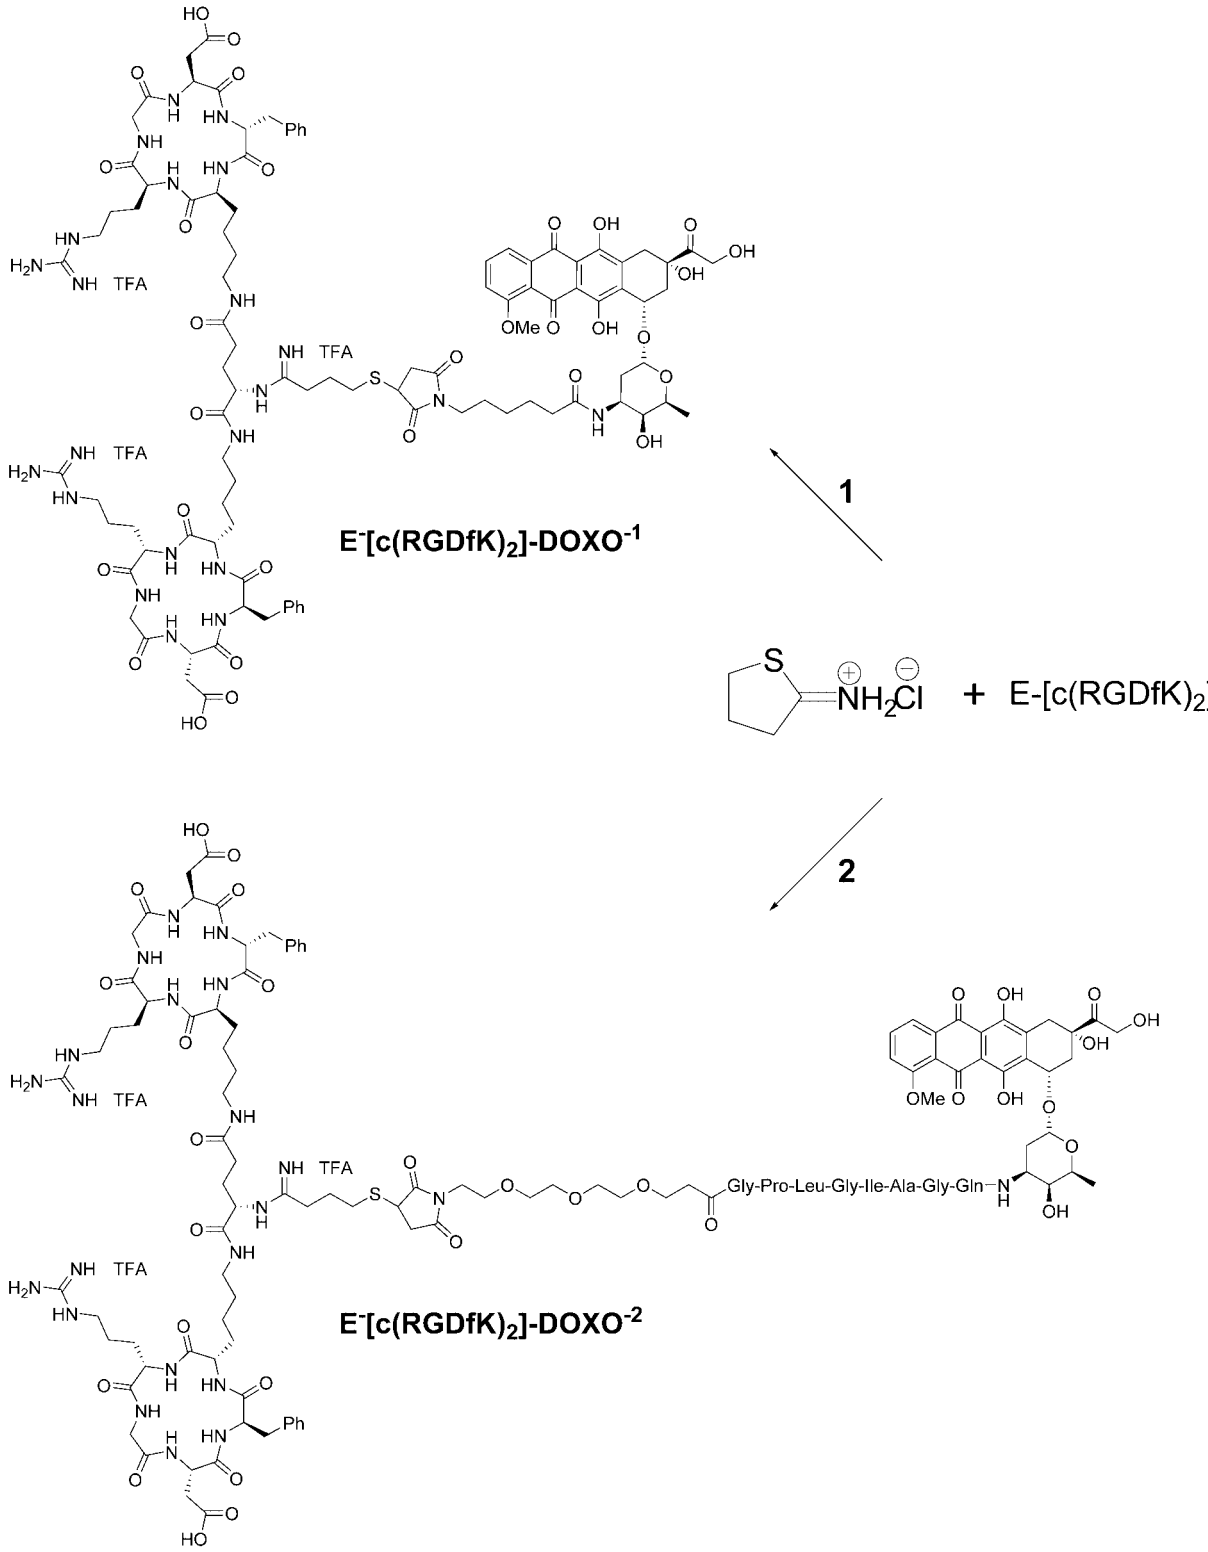
100 μL of the E-[c(RGDfK)$_2$]-DOXO-2 stock solution (200 μM) were mixed with OVCAR-3 tumor homogenate at pH 7.4 and incubated at 37 °C. Samples were collected and analyzed by HPLC over 75 min.

Endothelial Cell Proliferation Assay. HUVEC were plated onto 24-well plate (1.5×10^4 cells/well) in EBM-2 medium (Clonetics, Walkersville, MD, USA) supplemented with 5% FBS and incubated for 24 h (37 °C; 5% CO_2). On the following day, the cultured medium was removed and cells were exposed to serial dilutions of doxorubicin derivatives prepared in a fresh mixture of EBM-2 medium and EGM-2 complete medium (Clonetics) (1:1, v/v). Cell proliferation was assessed after 72 h by means of direct counting using a Z1 Coulter Particle Counter (Beckman Coulter, Luton, England). As positive control, cells were grown without treatment. Each treatment was assayed in triplicates and the experiment was repeated independently. Proliferation of endothelial cells was normalized to percent cell growth compared to the cell growth of the positive untreated control cells. Error bars represent the standard deviation of the mean.

Endothelial Cell Sprouting Assay. HUVEC were purchased from PromoCell (Heidelberg, FRG) and used at passage 3−4. The experiments were pursued in modification of the originally published protocol (*20, 21*). In brief, spheroids were prepared as described by pipetting 500 endothelial cells (EC) in a hanging drop on plastic dishes to allow overnight spheroid aggregation. 50 EC spheroids were then seeded in 0.9 mL of a collagen solution and pipetted into individual wells of a 24 well plate to allow polymerization. The test compounds were added after 30 min by pipetting 100 μL of a 10-fold concentrated working dilution on top of the polymerized gel in combination with VEGF-A (25 ng/mL, ProQinase, Freiburg, FRG). Plates were incubated at 37 °C for 24 h and fixed by adding 4% paraformaldehyde. Sprouting intensity of EC spheroids was quantitatively determined by the cumulative sprout length per spheroid using an inverted microscope and the digital imaging software *Analysis 3.2* from Soft Imaging System (Münster, FRG). The mean of the cumulative sprout length of 10 randomly selected spheroids was analyzed as an individual data point and the relative inhibition by the test compounds determined. Fitting of IC_{50} curves and calculation of IC_{50} values was performed with *GraphPad Prism 5.01*.

***In Vivo* Experiments.** For the *in vivo* testing of E-[c(RGDfK)$_2$], E-[c(RGDfK)$_2$]-DOXO-1, E-[c(RGDfK)$_2$]-DOXO-2, and c(RADfK)-DOXO-2 in comparison with doxorubicin female NMRI: nu/nu mice (M&B A/S, Ry, Denmark) were used. The mice were held in laminar flow shelves under sterile and standardized environmental conditions (25 ± 2 °C room temperature, 50 ± 10% relative humidity, 12 h light−dark rhythm). They received autoclaved food and bedding (ssniff, Soest, FRG) and acidified (pH 4.0) drinking water *ad libitum*. All animal experiments were performed under the auspices of the German Animal Protection Law. Orientating toxicity study with E-[c(RGDfK)$_2$]-DOXO-2 was carried out at doses of 8, 16, and 24 mg/kg doxorubicin equivalents. E-[c(RGDfK)$_2$]-DOXO-2 was dissolved in glucose phosphate buffer (10 mM

Scheme 1. Preparation of E⁻[c(RGDfK)$_2$]-DOXO^{-1} and E⁻[c(RGDfK)$_2$]-DOXO^{-2}



sodium phosphate, 5% D-(+)-glucose, pH 5.8) at a concentration of 3 mM and administered intravenously (i.v.) in a weekly schedule. For experiments in tumor-bearing animals, 10^7 cells of human ovarian cancer cells OVCAR-3 from *in vitro* culture were transplanted subcutaneously (s.c.) into the flank region of anaesthetized (40 mg/kg i.p. Radenarkon, Asta Medica, Frankfurt, FRG) mice on day zero. Mice were randomly distributed to the experimental groups (8 mice for control, 6 mice each for the treatment groups). When the tumors were grown to a palpable size, treatment was initiated (Figure 8). Mice were treated intravenously at day 10, 17, and 24 with glucose phosphate buffer (10 mM sodium phosphate, 5% D-(+)-glucose, pH 5.8), E-[c(RGDfK)$_2$], dissolved in glucose phosphate buffer (10 mM sodium phosphate, 5% D-(+)-glucose, pH 5.8) at a concentration of 7 mM (3 × 54.5 mg/kg), doxorubicin (2 × 8 mg/kg), E-[c(RGDfK)$_2$]-DOXO-1, dissolved in glucose phosphate buffer (10 mM sodium phosphate, 5% D-(+)-glucose, pH 5.8) at a concentration of 4 mM (3 × 24 mg/kg), E-[c(RGDfK)$_2$]-DOXO-2, dissolved in glucose phosphate buffer (10 mM sodium phosphate, 5% D-(+)-glucose, pH 5.8) at a concentration of 3

mM (2 × 8 mg/kg, 3 × 24 mg/kg), or c(RADfK)-DOXO-2, dissolved in glucose phosphate buffer (10 mM sodium phosphate, 5% D-(+)-glucose, pH 5.8) at a concentration of 6 mM (3 × 24 mg/kg) freshly dissolved in glucose phosphate buffer.

Tumor size was measured twice weekly with a caliper-like instrument in two dimensions. Individual tumor volumes (V) were calculated by the formula $V = (\text{length} + [\text{width}]^2)/2$ and related to the values on the first day of treatment (relative tumor volume, RTV). Statistical analysis was performed with the U-test (Mann and Whitney) with $p < 0.05$. The body weights of mice were determined every 3 to 4 days.

RESULTS

Chemistry. A series of acid-sensitive and enzymatically cleavable maleimide drug derivatives have been developed in our group that react specifically and selectively with thiol groups, e.g., with the cysteine-34 position of circulating albumin (*18, 22–28*). Maleimide doxorubicin derivatives were therefore an obvious choice for developing conjugates with E-[c(RGDfK)$_2$]. The precursor **1** for the stable conjugates was obtained by reaction of doxorubicin hydrochloride and 6-maleimidohexanoic acid *N*-hydroxysuccinimide ester. By introducing a thiol group with 2-iminothiolane (Traut's reagent) at the α-amino position of the glutamic acid moiety of E-[c(RGDfK)$_2$], we discovered that doxorubicin conjugates with **1** and **2** could be conveniently synthesized in a one-pot reaction of 2-iminothiolane, E-[c(RGDfK)$_2$], and the respective 6-maleimide derivate **1** or **2**. Subsequently, the resulting conjugates were isolated by preparative HPLC, thus obtaining E-[c(RGDfK)$_2$]-DOXO-1 and E-[c(RGDfK)$_2$]-DOXO-2 (Scheme 1). The analogously constructed doxorubicin conjugates with the control peptide c(RADfK), c(RADfK)-DOXO-1, and c(RADfK)-DOXO-2 were obtained in the same manner (Figure 3 and Experimental Procedures section). The conjugates showed good water solubility in glucose phosphate buffer (10 mM sodium phosphate, 5% D-(+)-glucose, pH 5.8) of ~10 mg/mL for E-[c(RGDfK)$_2$]-DOXO-1, c(RADfK)-DOXO-1, and c(RADfK)-DOXO-2 and ~20 mg/mL for E-[c(RGDfK)$_2$]-DOXO-2. The conjugates were characterized by analytical HPLC and MALDI TOF (see Experimental Procedures section).

Stability and Cleavage Properties of RGD Doxorubicin Conjugates. Stability of E-[c(RGDfK)$_2$]-DOXO-2 was studied at pH 7.0 (FPLC buffer; 150 mM NaCl, 4 mM Na_2HPO_4) at room temperature. Chromatograms were recorded over a period of 24 h showing minor decomposition of 17% (data not shown).

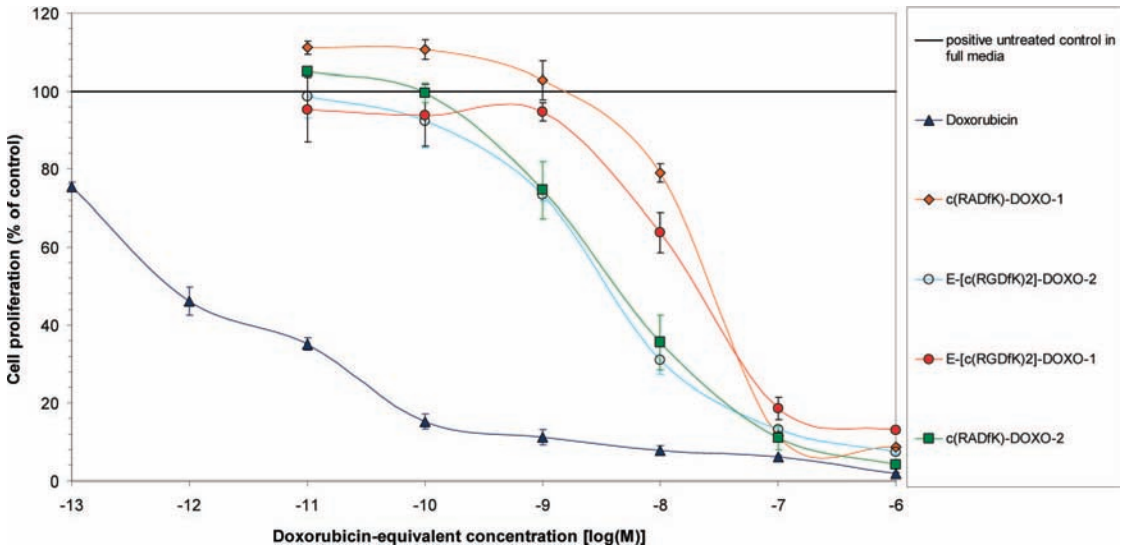

Figure 6. HUVEC proliferation assay treated with free doxorubicin (closed triangles, mean IC_{50} = 700 fM) and doxorubicin derivatives: E-[c(RGDfK)$_2$]-Doxo-1 (closed circles, mean IC_{50} = 20 nM), E-[c(RGDfK)$_2$]-Doxo-2 (open circles, mean IC_{50} = 3.5 nM), c(RADfK)-Doxo-1 (closed diamond, mean IC_{50} = 28 nM), and c(RADfK)-Doxo-2 (closed squares, mean IC_{50} = 4.2 nM). Solid line represents positive control of HUVEC proliferation in the presence of growth factors. Data represents mean ± standard deviation of the mean. HUVEC proliferation was significantly inhibited by free doxorubicin, while it was inhibited to a lesser extent by doxorubicin derivatives.

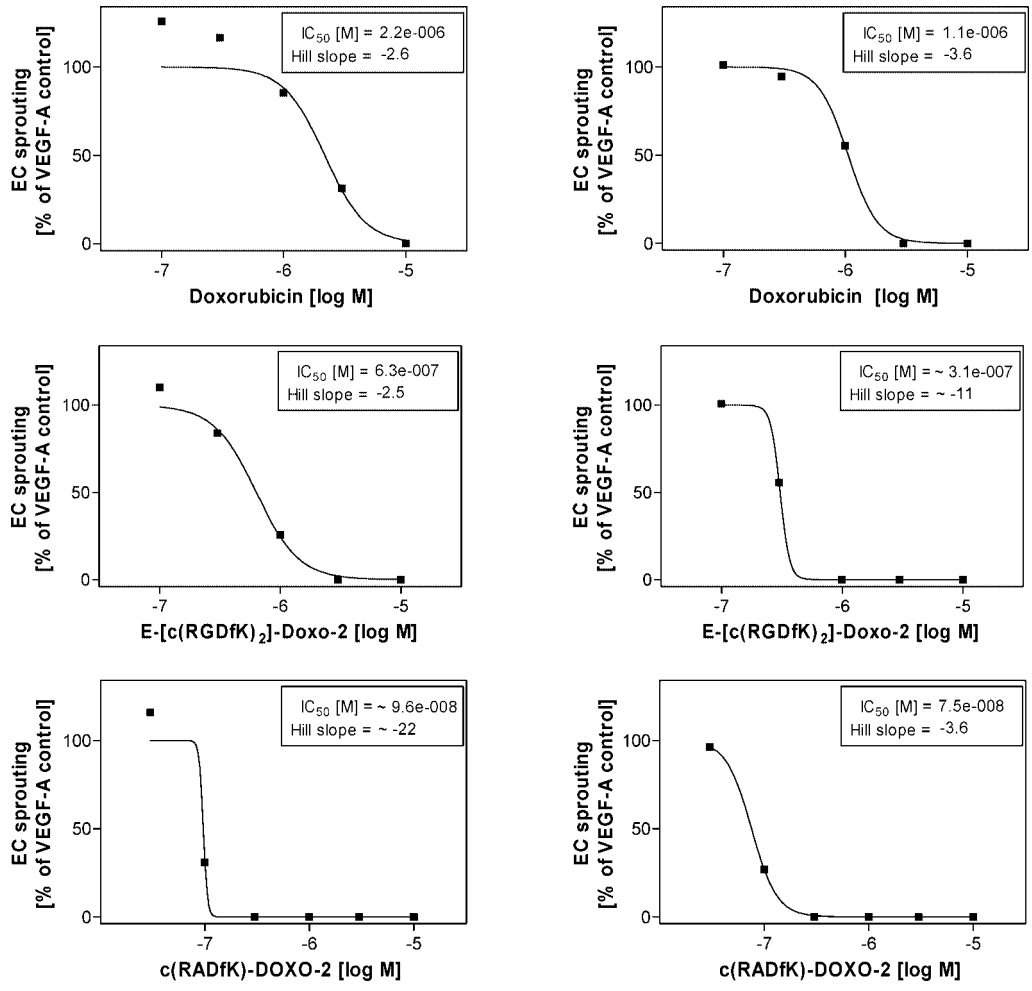

Figure 7. 3D spheroid-based angiogenesis assay. HUVEC spheroids were embedded in a 3D collagen gel, stimulated with VEGF-A [25 ng/mL], and treated for 24 h with different concentrations of doxorubicin, E-[c(RGDfK)$_2$]-DOXO-2, and c(RADfK)-DOXO-2 (in [log *M*], as indicated). The cumulative sprout length of 10 randomly selected spheroids per data point was analyzed and the relative inhibition by the test compounds determined. Two independent experiments were performed. Fitting of IC_{50} curves and calculation of IC_{50} values was performed with *GraphPad Prism 5.01*. HUVEC sprouting was inhibited approximately 3.5-fold more strongly with E-[c(RGDfK)$_2$]-DOXO-2 [mean IC_{50} = 470 nM] and approximately 20-fold stronger with c(RADfK)-DOXO-2 [mean IC_{50} = 86 nM] compared to doxorubicin [mean IC_{50} = 1700 nM].

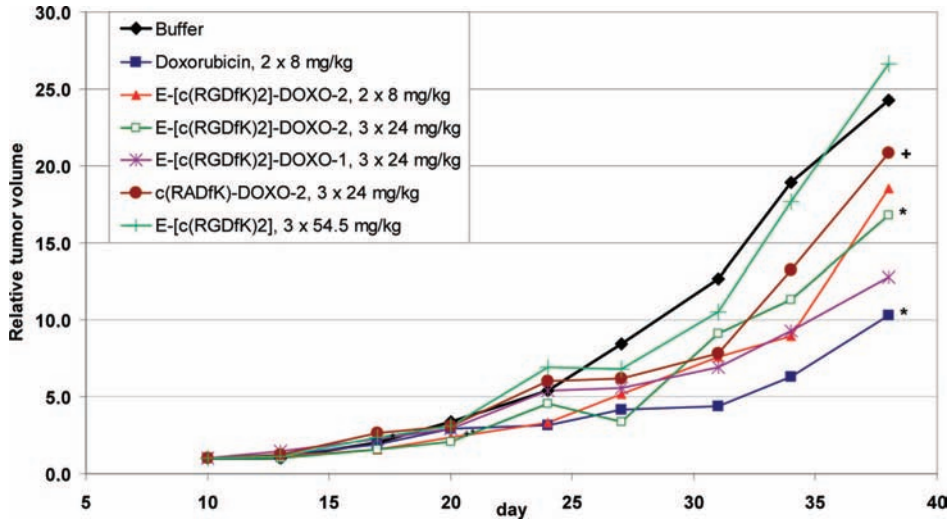

Figure 8. Curves depicting tumor growth inhibition of subcutaneously OVCAR-3 xenografts under therapy with RGD- and RAD-doxorubicin derivatives, doxorubicin, and E-[c(RGDfK)$_2$]; * significant to control; + significant to doxorubicin $p < 0.05$.

Table 1. Dose Schedule, Mortality, Body Weight Change, and Antitumor Activity of RGD- and RAD-Doxorubicin Derivatives, Doxorubicin, and E-[c(RGDfK)$_2$] against Human Ovarian Cancer Xenografts (OVCAR-3) *in Vivo*

substance	nu/nu mice	treatment (d)	dose (mg/kg/inj.)	toxic deaths (d)	BWC (%) d 10−17	optimum T/C (%) [at day]
5% Glucose-P-Buffer	8	10, 17, 24			−2	
Doxorubicin	6	10, 17	8	0	−2	33 [34][a]

[a] Significant to control. [b] Significant to doxorubicin $p < 0.05$.

Subsequent cleavage studies of E-[c(RGDfK)$_2$]-DOXO-2 were carried out following a modified method of Mansour et al. (*18*). The octapeptide Gly-Pro-Leu-Gly-Ile-Ala-Gly-Gln in **2** is specifically cleaved by MMP-2 and MMP-9 releasing the doxorubicin-tetrapeptide Ile-Ala-Gly-Gln-DOXO as previously shown (*18, 29*). Incubation studies of E-[c(RGDfK)$_2$]-DOXO-2 with activated MMP-2 showed a major peak at 27 min for E-[c(RGDfK)$_2$]-DOXO-2 min in the HPLC chromatogram after 5 min incubation time which decreased with time and an unidentified peak at 18 min (Figure 4). Furthermore, a peak at 13 min was observed which increased during 3 h and which we assigned as Ile-Ala-Gly-Gln-DOXO by comparison with our data from refs (*18, 29*). In OVCAR-3 tumor homogenates, the major cleavage product was doxorubicin after 75 min incubation (Figure 5). Identification of doxorubicin as the cleavage product was verified with a doxorubicin standard and spiking with doxorubicin in the cleavage experiment. In contrast, no release of doxorubicin was observed for E-[c(RGDfK)$_2$]-DOXO-1 in OVCAR-3 tumor homogenates (data not shown).

***In Vitro* Activity.** *Endothelial Cell Proliferation and Sprouting Is Inhibited by Doxorubicin-Containing RGD Peptides.* The effect of doxorubicin, and the doxorubicin derivatives E-[c(RGDfK)$_2$]-DOXO-1, E-[c(RGDfK)$_2$]-DOXO-2, c(RADfK)-DOXO-1, and c(RADfK)-DOXO-2 on endothelial cells was tested in two independent assays. First, the ability of doxorubicin derivatives to inhibit HUVEC proliferation was assessed using a standard 72 h proliferation assay. Free doxorubicin inhibited HUVEC proliferation more efficiently than the four peptide-containing doxorubicin derivatives, demonstrating an IC_{50} value of 700 fM compared to 20 nM for E-[c(RGDfK)$_2$]-DOXO-1, 3 nM for E-[c(RGDfK)$_2$]-DOXO-2, 30 nM for c(RADfK)-DOXO-1, and 5 nM for c(RADfK)-DOXO-2 (Figure 6). The E-[c(RGDfK)$_2$] peptide inhibited HUVEC proliferation by itself but only at high concentrations of 100−1000 nM. c(RADfK) peptide showed no effect even at those high concentrations (data not shown).

In a second assay, HUVEC spheroids were embedded in a 3D collagen gel, stimulated with VEGF-A, and treated for 24 h with different concentrations of doxorubicin, E-[c(RGDfK)$_2$]-DOXO-2, and c(RADfK)-DOXO-2 (in [log *M*], as indicated). As shown in Figure 7, HUVEC sprouting was inhibited ~3.5-fold stronger with E-[c(RGDfK)$_2$]-DOXO-2 [mean IC_{50} = 470 nM] and ~20-fold stronger with c(RADfK)-DOXO-2 [mean IC_{50} = 86 nM] compared to doxorubicin [mean IC_{50} = 1700 nM]. In contrast, the free peptides E-[c(RGDfK)$_2$] and c(RADfK) as well as the stable doxorubicin amide derivatives E-[c(RGDfK)$_2$]-DOXO-1 and c(RADfK)-DOXO-1 showed no activity at the highest concentration of ~10 000 nM (data not shown).

***In Vivo* Activity.** Subsequently, the *in vivo* antitumor efficacy of E-[c(RGDfK)$_2$], doxorubicin, and the doxorubicin derivatives E-[c(RGDfK)$_2$]-DOXO-1, E-[c(RGDfK)$_2$]-DOXO-2, and c(RADfK)-DOXO-2 was evaluated in xenografted nu/nu mice (human ovarian carcinoma OVCAR-3), this model being chosen because Janssen et al. showed a high uptake of radiolabeled E-[c(RGDfK)$_2$] of up to 7.5% ID/g in subcutaneously growing OVCAR-3 tumors (*11*).

Based on an orientating toxicity study with E-[c(RGDfK)$_2$]-DOXO-2 that showed a maximum tolerated dose (MTD) of 24 mg/kg doxorubicin equivalents, the following doses were chosen: doxorubicin (2 × 8 mg/kg), E-[c(RGDfK)$_2$]-DOXO-1 (3 × 24 mg/kg doxorubicin equivalents), E-[c(RGDfK)$_2$]-DOXO-2 (2 × 8 mg/kg, and 3 × 24 mg/kg doxorubicin equivalents), c(RADfK)-DOXO-2 (3 × 24 mg/kg doxorubicin equivalents), and E-[c(RGDfK)$_2$] (3 × 54.5 mg/kg, corresponding to the amount present in 3 × 24 mg/kg E-[c(RGDfK)$_2$]-DOXO-2) (Table 1). The results of the xenograft experiment are summarized in Table 1 and Figure 8. Treatment with

doxorubicin resulted in a moderate, but statistically significant, antitumor effect at its optimal dose in nu/nu mice models of 2 × 8 mg/kg (T/C max. 33%). In contrast, the free peptide E-[c(RGDfK)$_2$] and the stable amide derivative E-[c(RGDfK)$_2$]-DOXO-1 were inactive, with the latter also being toxic with a mortality of 50%. The prodrug E-[c(RGDfK)$_2$]-DOXO-2 at 2 × 8 mg/kg and 3 × 24 mg/kg showed a very moderate inhibition of tumor growth, which was statistically significant versus control only for the high-dose group. One animal died in this group. The prodrug c(RADfK)-DOXO-2 with the nonintegrin $\alpha_v\beta_3$ binding control peptide showed a high mortality at 3 × 24 m/kg and doxorubicin equivalents (50%). The remaining three animals showed a slightly better antitumor efficacy than the five animals treated with E-[c(RGDfK)$_2$]-DOXO-2, although this antitumor effect was not statistically significant compared to the control.

DISCUSSION

Integrins, especially integrin $\alpha_v\beta_3$, have served as an attractive target for designing drug delivery systems ranging from RGD-based liposomes (*30*, *31*), protein (*32*) or polymer conjugates (*33*), and nanoparticles (*34*).

A key result in this field was the discovery of the divalent RGD-4C peptide using a phage-display library (*7*). Subsequent development and evaluation of doxorubicin conjugates with RGD-4C have, however, not resulted in a clear picture of the structural requirements that a doxorubicin RGD conjugate should have for effective *in vivo* vascular targeting. In this work, we therefore developed doxorubicin conjugates with the divalent RGD peptide, E-[c(RGDfK)$_2$], which is more stable than RGD-4C and meanwhile commercially available. Synthesis of the conjugates was achieved by thiolating the free amino group of E-[c(RGDfK)$_2$] or of the control peptide c(RADfK) and reacting the stable maleimide doxorubicin derivative **1** or a MMP-2 cleavable doxorubicin derivative **2** with the introduced thiol group yielding E-[c(RGDfK)$_2$]-DOXO-1 and E-[c(RGDfK)$_2$]-DOXO-2, c(RADfK)-DOXO-1, and c(RADfK)-DOXO-2. E-[c(RGDfK)$_2$]-DOXO-2 was effectively cleaved by MMP-2 and in OVCAR-3 tumor homogenates releasing a doxorubicin-tetrapeptide or doxorubicin as the final cleavage product demonstrating a clear prodrug nature for **2**. In contrast, E-[c(RGDfK)$_2$]-DOXO-1 was stable in OVCAR-3 tumor homogenates. In a cytotoxicity assay against HUVEC, E-[c(RGDfK)$_2$]-DOXO-1 and E-[c(RGDfK)$_2$]-DOXO-2 as well as their c(RADfK) analogues showed cytotoxicity in the low nanomolar range, the cytotoxicity being more dependent on the cleavability than the nature of the RGD peptide (Figure 6). Surprisingly, in a HUVEC sprouting assay the doxorubicin prodrug with the control peptide, c(RADfK)-DOXO-2, was more active than E-[c(RGDfK)$_2$]-DOXO-2 (Figure 7), whereas E-[c(RGDfK)$_2$]-DOXO-1 and c(RADfK)-DOXO-1 were inactive, indicating that interactions with other membrane-associated targets besides integrin $\alpha_v\beta_3$ could be important.

In vivo, neither doxorubicin conjugates with E-[c(RGDfK)$_2$] nor c(RADfK) showed convincing antitumor efficacy. This result is disappointing considering that much larger doses (3 × 24 mg/kg doxorubicin equivalents) than the MTD of doxorubicin in nu/nu mice models (2 × 8 mg/kg) were administered. In contrast, the albumin-binding prodrug **2** has shown superior efficacy compared to doxorubicin in a melanoma xenograft model (*18*). There are a number of reasons that could explain the lack of efficacy of our new conjugates: (1) The targeting potential of the new conjugates is insufficient, although this explanation does not seem likely considering the convincing evidence of tumor uptake that Janssen et al. has collected with radiolabeled E-[c(RGDfK)$_2$] in the OVCAR-3 xenograft model (*12*), the same that model that we used in our studies. (2) After binding of E-[c(RGDfK)$_2$] to endothelial cells, the doxorubicin conjugates are taken up rapidly by endocytosis that would prevent the cleavage of E-[c(RGDfK)$_2$]-DOXO-2 by the extracellular proteases MMP-2 and MMP-9. There are data supporting an internalization of RGD peptides in integrin $\alpha_v\beta_3$ expressing and nonexpressing melanoma cells by an integrin-independent fluid-phase endocytosis pathway (*35*). Our own investigations do not support cleavage of the MMP-2 cleavable octapeptide when tumor homogenates at pH 5.0 are used that preserve activity of lysosomal proteases (*36*). (3) The potency of doxorubicin is not sufficient for receptor targeting of integrin $\alpha_v\beta_3$. The interaction of E-[c(RGDfK)$_2$]-DOXO-2 with integrin might be limited due to an insufficient receptor density on endothelial cells or a rapid clearance of E-[c(RGDfK)$_2$]-DOXO-2 leading to low amounts of doxorubicin reaching endothelial cells. Thus, targeting of integrin $\alpha_v\beta_3$-expressing cells could be improved by using highly potent cytotoxic drugs in line with the clear trend of using such agents for the development of drug antibody conjugates that are designed for receptor or antigen targeting (*37*, *38*).

In our current work, we are addressing the nature of the enzymatically cleavable linker as well as the drug component on RGD-based drug conjugates.

Synthesis and Characterization of Star Poly(ε-caprolactone)-*b*-Poly(ethylene glycol) and Poly(L-lactide)-*b*-Poly(ethylene glycol) Copolymers: Evaluation as Drug Delivery Carriers

Fei Wang,*,† Tatiana K. Bronich,‡ Alexander V. Kabanov,‡ R. David Rauh,† and Jacques Roovers§

EIC Laboratories, Incorporated, 111 Downey Street, Norwood, Massachusetts 02062, and Department of Pharmaceutical Science, University of Nebraska Medical Center, 986025 University Medical Center, Omaha, Nebraska 68198-6025. Received November 20, 2007; Revised Manuscript Received May 22, 2008

Two types of 32 arm star polymers incorporating amphiphilic block copolymer arms have been synthesized and characterized. The first type, stPCL-PEG_{32}, is composed of a polyamidoamine (PAMAM) dendrimer as the core with radiating arms having poly(ε-caprolactone) (PCL) as an inner lipophilic block in the arm and poly(ethylene glycol) (PEG) as an outer hydrophilic block. The second type, stPLA-PEG_{32}, is similar but with poly(L-lactide) (PLA) as the inner lipophilic block. Characterization with SEC, ^{1}H NMR, FTIR, and DSC confirmed the structure of the polymers. Micelle formation by both star copolymers was studied by fluorescence spectroscopy. The stPCL-PEG_{32} polymer exhibited unimolecular micelle behavior. It was capable of solubilizing hydrophobic molecules, such as pyrene, in aqueous solution, while not displaying a critical micelle concentration. In contrast, the association behavior of stPLA-PEG_{32} in aqueous solution was characterized by an apparent critical micelle concentration of ca. 0.01 mg/mL. The hydrophobic anticancer drug etoposide can be encapsulated in the micelles formed from both polymers. Overall, the stPCL-PEG_{32} polymer exhibited a higher etoposide loading capacity (up to 7.8 w/w % versus 4.3 w/w % for stPLA-PEG_{32}) as well as facile release kinetics and is more suitable as a potential drug delivery carrier.

INTRODUCTION

Micelles formed from amphiphilic block copolymers have recently attracted significant attention in diverse fields of medicine and biology. In particular, polymeric micelles have been developed as drug and gene delivery systems (*1*–*3*) as well as carriers for various contrast agents in diagnostic imaging applications (*4*). In an aqueous environment, the hydrophobic blocks of the copolymer are expected to segregate into the core of the micelle, while the hydrophilic blocks form the corona or outer shell. Such a core−shell architecture is essential for the utility of the polymeric micelles as functional materials for pharmaceutical applications. The hydrophobic micelle core serves as a microenvironment for the incorporation of various therapeutic compounds, while the corona, the outer shell, serves as a stabilizing interface between the hydrophobic core and the external medium. As a result, polymeric micelles can be used as effective "nanocontainers" for reagents with poor solubility and/or low stability in physiological environments (*5*, *6*). Interest in polymeric micelles for drug delivery has increased rapidly since the late 1980s (*7*). Most of the work has focused on classical micelles formed by intermolecular aggregation of amphiphilic block copolymers as the drug delivery vehicle, and the advantages of using their micelle structures as drug delivery systems have been demonstrated (*8*, *9*).

The major factors that influence the performance of polymeric micelles for drug delivery are loading capacity, release kinetics, circulation time, biodistribution, size, stability, and stability on dilution (*2*). One of the approaches to improve the micelles' stability is to develop star-shaped molecules in which the lipophilic components are covalently bound together within the micelle core. Core polymerization is an effective method to prevent dissociation of the block copolymer micelle. Kataoka's group has successfully employed this idea (*10*). In their study, the micelles were prepared from an amphiphilic block copolymer in which the hydrophobic block contained a polymerizable end group. After micellation, the end groups on the hydrophobic block were polymerized to form a stable core for the star-shaped polymer structure. The resulting micelles showed fairly high stability and maintained their small size. As anticipated, the core-polymerized micelle showed excellent solubilization of rather large molecules such as taxol (*11*). Another approach was reported by Uhrich et al. (*12*) with a star-shaped polymer composed of mucic acid substituted with a fatty acid as the lipophilic inner block and PEG as the hydrophilic outer block. This new type of molecule was capable of encapsulating a hydrophobic model drug in aqueous media.

The increased interest in amphiphilic star polymers for drug delivery has been demonstrated by several more recent publications. One paper (*13*) described the synthesis of a 4 arm star block copolymer of PCL and PEG using chemistry similar to that reported in this manuscript. Another report (*14*) described the preparation of a 4 arm star PCL-b-PEG polymer using a diethyl zinc catalyst. However, the molecular weight distribution of the block copolymer was unacceptably wide. Allen et al. (*15*) described the synthesis of a 6 arm star poly(δ-valerolactone)-*b*-PEG copolymer via a cationic polymerization method using fumaric acid as a catalyst. The micelle formation and biocompatibility of the star copolymer were demonstrated.

In a previous report (*16*), we described the synthesis and characterization of a 16 arm star PCL-PEG copolymer. The star structure of the polymers was confirmed by several physicochemical methods. The micellar properties of the star amphiphilic polymer in aqueous media were characterized by

fluorescence techniques and dynamic light scattering (DLS). A series of entrapment experiments showed that various drugs could be incorporated in such micelles. These results indicate that the star-PCL-PEG micelle system is a promising drug carrier for the delivery of lipophilic drugs. The aggregation from unimolecular micelles into larger associated micelles was observed by DLS and pyrene fluorescence studies. It is likely that the 16 arm star polymer forms a relatively loose outer PEG shell, which is not sufficient to hinder the intermolecular association of the inner hydrophobic PCL blocks. It is expected that more stable unimolecular micelles may be obtainable by increasing the number of block copolymer arms. It has been demonstrated that when the number of arms reaches 64, star polymers exhibit characteristics of a hard sphere, and the repulsion between the star molecules becomes much stronger (*17*).

In this paper, we describe the synthesis and characterization of two types of 32 arm star polymers composed of amphiphilic block copolymer arms. The first type, stPCL-PEG_{32}, is composed of a polyamidoamine (PAMAM) dendrimer as the core with radiating arms having poly(ε-caprolactone) (PCL) as an inner lipophilic block in the arm and poly(ethylene glycol) (PEG) as an outer hydrophilic block. The second type, stPLA-PEG_{32}, is similar but with poly(L-lactide) (PLA) as the inner lipophilic block. The micelle formation of both star copolymers was studied by fluorescence spectroscopy. The affinity of the star polymer micelles for solubilizing small hydrophobic molecules was assessed by determining the aqueous partition coefficient of the lipophilic fluorescence probe pyrene. Finally, solubilization of the anticancer drug etoposide into the 32 arm star polymer micelles was studied to evaluate the relevance of such systems for drug delivery.

EXPERIMENTAL SECTION

Materials and Methods. PEG (M_n = 5000) with methoxy and carboxymethyl terminal groups was used as received from Nektar. ε-Caprolactone from Sigma-Aldrich was dried by stirring with CaH_2 and distilled before use. L-Lactide was from Lancaster and was recrystallized twice from ethyl acetate before use. Dichloromethane was dried by stirring over and distilling from P_2O_5. All other reagents and solvents were used as received from Sigma-Aldrich.

^{1}H NMR spectra were recorded on a Hitachi R-1500 FT-NMR spectrometer at 60 MHz. Infrared spectra were recorded on a Nicolet 750 FTIR spectrometer. UV−vis spectra were recorded on a HP 8452A UV−vis diode array spectrophotometer. Size exclusion chromatography (SEC) was used to determine the molecular weights, polydispersity, and degree of branching of the synthesized polymers. SEC measurements were conducted using a Hewlett-Packard series 1050 HPLC equipped with one Polymer Laboratories PL gel 5 μ mixed-D column and a Hewlett-Packard 1047A refractive index detector as well as Viscotek T60 light scattering (LS) and viscosity detectors. Tetrahydrofuran was used as the eluting solvent at a flow rate of 1 mL/min. Data analysis was performed using Viscotek Trisec GPC software version 3.0.

The thermal transitions of the polymers were determined using a Perkin-Elmer DSC7 differential scanning calorimeter under nitrogen purge. The samples were heated and cooled at a rate of 10 °C/min.

Synthesis of the 32 Arm Star-PCL Polymer (stPCL_{32}). A 100 mL three-neck flask equipped with a condenser and argon gas inlet was charged with PAMAM-OH Dendrimer Generation 3 with 32 terminal OH groups (20 wt % solution in methanol, 5.26 g, 0.151 mmol). Methanol was then removed under vacuum. A predetermined amount of ε-caprolactone (14.42 g, 126 mmol) followed by 15 mL toluene were added into the reaction flask. The mixture was heated to reflux using a Dean−Stark trap for 30 min, and the toluene was distilled off. The heating of the reaction mixture up to 145 °C resulted in the dissolution of the dendrimer in ε-caprolactone. After cooling the reaction mixture to 130 °C, 5 mg (0.012 mmol) of tin(II) 2-ethylhexanoate ($Sn(Oct)_2$) was introduced, followed by stirring at 115−120 °C for 20 h. The reaction mixture was cooled to room temperature, dissolved in THF, and precipitated into cold methanol. After drying, 15.3 g (99% yield) of the white solid product was obtained. The polymer was further purified by fractionation. 3.6 g of polymer was dissolved in 70 mL of THF in a round-bottom flask, and methanol was added until the solution became cloudy. The solution was heated in a water bath at 60 °C and became clear. About 10 mL of methanol was added to reach a cloudy point, and the mixture was transferred into a hot separation funnel and allowed to stand at room temperature for three days. The polymer solution separated into two layers, and the top layer was removed without disturbing the lower layer. The lower layer was diluted with THF and precipitated into cold methanol. 2.76 g of polymer was obtained. ^{1}H NMR ($CDCl_3$): δ = 4.07 (t, 2H, OCH_2), 2.31 (t, 2H, $COCH_2$), 1.1−2 (m, 6H, $(CH_2)_3$). The characteristic peaks of dendrimer and polymer were overlapping, and peak integration was inconclusive.

Synthesis of the 32 Arm Star-PCL-PEG Polymer (stPCL-PEG_{32}). The $stPCL_{32}$ (1.3 g, 0.0152 mmol), PEG (2.64 g, 0.527 mmol), and 4-(dimethylamino)pyridinium 4-toluenesulfonate (DPTS) (0.155 g, 0.527 mmol) were dissolved in 80 mL of dry CH_2Cl_2 by stirring at room temperature. Then diisopropylcarbodiimide (DIPC) (0.2 g, 1.58 mmol) was added into the reaction mixture via syringe. The reaction mixture was stirred overnight at room temperature. An additional amount of DIPC (0.15 g) was added to the reaction mixture followed by stirring for a total of 7 days. The reaction was stopped, and fractionation was used to purify the Star-PCL-PEG. Briefly, 20 mL CH_2Cl_2 was added to dilute the product. Hexane was slowly added to the resulting solution at a water bath of 45 °C until the appearance of cloudiness. Then the mixture was transferred into a hot separation funnel and was allowed to stand at room temperature. The top layer was removed, and the lower layer refractionated by the same procedure. Finally, the lower layer was diluted with CH_2Cl_2 and precipitated into hexane. After drying, 3.1 g (83% yield) of white solid product was obtained. ^{1}H NMR ($CDCl_3$): δ = 4.07 (t, 2H, $COOCH_2$), 3.64 (s, 18.8H, OCH_2CH_2O), 2.31 (t, 2H, $COCH_2$), 1.1−1.9 (m, 6H, $(CH_2)_3$).

Synthesis of the 32 Arm Star-PLA polymer (stPLA_{32}). A 100 mL three-neck flask equipped with a condenser and argon gas inlet was charged with PAMAM-OH Dendrimer Generation 3 (20 wt % solution in methanol, 5.26 g, 0.151 mmol). Methanol was then removed under vacuum. A predetermined amount of L-lactide (14.71 g, 102 mmol) followed by 15 mL toluene was added into the reaction flask. The mixture was heated to reflux using a Dean−Stark trap for 30 min and toluene was distilled off. Heating of the reaction mixture up to 135 °C resulted in the dissolution of the dendrimer in L-lactide. After cooling the reaction mixture to 125 °C, 5 mg (0.012 mmol) of $Sn(Oct)_2$ was introduced, followed by stirring at 105 °C for 20 h. The reaction mixture was cooled to room temperature, dissolved in THF, and precipitated into cold methanol. After drying, 15.4 g (97% yield) of the white solid product was obtained. SEC analysis indicated that there were some low molecular weight impurities mixed with the star polymer. The polymer was further purified by fractionation using THF as the solvent and methanol as the nonsolvent. However, after repeated trials, including the use of chloroform as the solvent, the fractionation was found to be unsuccessful. Low molecular weight materials remained in the star polymer. ^{1}H NMR ($CDCl_3$): δ = 5.17 (q, 1H,

-CH(CH_3)-), 1.57 (d, 3H, CH_3). The characteristic peaks of the dendrimer were too broad and integration was inconclusive.

Synthesis of the 32 Arm Star-PLA-PEG Polymer (stPLA-PEG$_{32}$). The stPLA$_{32}$ (1.2 g, 0.0141 mmol), PEG (2.6 g, 0.52 mmol), and DPTS (0.155 g, 0.527 mmol) were dissolved in 80 mL of dry CH_2Cl_2 by stirring at room temperature. Then DIPC (0.2 g, 1.58 mmol) was added into the reaction mixture via syringe. The reaction mixture was stirred overnight at room temperature. An additional amount of DIPC (0.15 g) was added to the reaction mixture followed by stirring for total of 7 days. The product was purified by fractionation twice with CH_2Cl_2 as the solvent and hexane as the nonsolvent. After workup and drying, 2.53 g (72% yield) of white solid product was obtained. ^{1}H NMR ($CDCl_3$): $\delta = 5.18$ (q, 1H, -C**H**(CH_3)-), 3.64 (s, 12.6H, OCH_2CH_2O), 1.58 (d, 3H, -CH_3).

Synthesis of Linear-PLA (l-PLA). A linear PLA was synthesized in a similar procedure using L-lactide (5.1 g, 35.4 mmol), di(ethylene glycol) benzyl ether (0.05 g, 0.25 mmol) as an initiator, and two drops of Sn(Oct)$_2$. Isolation was conducted with the same procedure as described previously. After drying, 4.8 g (95% yield) of the white solid product was obtained.

Preparation of Polymer Micelles. Aqueous dispersions of stPCL-PEG$_{32}$ and stPLA-PEG$_{32}$ were prepared using the dialysis technique. Initially, the copolymer was dissolved in *N*,*N*-dimethylformamide (DMF) at polymer concentrations ranging from ~100−200 mg/mL. Next, distilled water was added to the mixture dropwise in a very slow fashion (25 μL of water per 2−3 min) until the desired water content was achieved (67−87.5 vol %). Finally, the water−organic mixture was dialyzed against 3 L distilled water using Membra-Cel MD-25−03.5 membrane tubing. The water was changed every hour for the first 4 h and then every 4−6 h for the next two days. The concentration of the star copolymers after dialysis was determined gravimetrically.

Micelle Characterization. Dynamic laser light scattering (DLS) measurements on polymer micelles were carried out using a "ZetaPlus" Zeta Potential Analyzer (Brookhaven Instrument Co.) equipped with the Multi Angle Option and with a 30 mW solid state laser operated at a wavelength of 635 nm. The sizing measurements were performed at 25 °C at an angle of 90°. All solutions were filtered repeatedly through Millipore membranes with pore sizes of 0.45 and 0.22 μm prior to measurements. Software provided by the manufacturer was used to calculate the effective hydrodynamic diameters of the micelles. DLS measurements were also used to monitor the aggregation stability of micelle solutions. Consequently, size measurements were carried out every 2−3 days over a one month period. Steady-state fluorescence spectra were recorded using a Shimadzu RF5000U spectrofluorophotometer with a bandwidth of 2.5 nm for both excitation and emission. For fluorescence emission spectra, λ_{ex} was 336 nm, and for excitation spectra, λ_{em} was 390 nm. Negative staining was used for the transmission electron microscopy (TEM) studies. A drop of the filtered (0.22 μm filter) sample solution was allowed to settle on a Formvar precoated copper grid for one minute. Excess solution was wicked away with filter paper, and a drop of 1% uranyl acetate solution was allowed to contact the sample for one minute. The samples were studied using a Phillips 410LS electron microscope with a digital imaging camera. The diameters of the particles were determined using 127 measurements randomly collected from TEM images using the Image Pro program (Media Sybernetics).

Drug Encapsulation and Release. The two star copolymers with different lipophilic components were evaluated to determine which structure was more suitable for the delivery of etoposide. A micelle extraction method (*2*) was used to encapsulate etoposide into the 32 arm star polymer micelles. 100 μL of etoposide stock solution (20 mg/mL) in acetonitrile was added to the empty vial, and the solvent was evaporated to dryness. Then 1 mL of micelle solution was added to the vial and agitated for 2 days. The concentration of micelle solution was varied from 2 mg/mL to 15 mg/mL. The solution was centrifuged (5 min at 10 000 × *g*) to remove any insoluble drug. It should be noted that centrifugation of the polymer micelle solutions under these conditions did not change the polymer content in the supernatant. The etoposide concentration in the supernatant was determined by HPLC using a Shimadzu LC-10AT system equipped with a reverse-phase C18 column (4.6 mm × 15 cm), mobile phase: 25% (acetonitrile/1% acetic acid)/75% (water/1% acetic acid), flow rate at 1 mL/min, $T = 32$ °C. The detection of etoposide was performed by UV absorption at 230 nm.

The release of etoposide from the polymer micelles was evaluated by the dialysis method. The polymer micelles loaded with etoposide in phosphate buffered saline (PBS, pH 7.4, 0.14 M NaCl, 1 mL) were transferred to a dialysis bag (molecular weight cutoff 3500). The dialysis bag was immediately placed in 20 mL of PBS. At regular time intervals, 1 mL of release medium was sampled and replaced with an equal volume of PBS. The release experiments were performed at room temperature. The concentration of etoposide present in the dialysate was monitored using HPLC as described above.

RESULTS AND DISCUSSION

Synthesis of Star Copolymers. The synthesis of stPCL-PEG$_{32}$ was carried out following the synthetic scheme shown in Scheme 1. The expected PEG formula weight is 5000 D and the PCL formula weight is 3000 D, corresponding to $m = 26$. PAMAM-OH Dendrimer Generation 3 was used as the initiator core. Starting from this core, the star-PCL polymer with 32 arms was synthesized by the ring-opening polymerization of ε-caprolactone with Sn(Oct)$_2$ as the catalyst. The stPCL$_{32}$ product was obtained in almost quantitative yield. After two fractionations, the pure star polymer was obtained. Next, PEG polymers were attached to the stPCL$_{32}$ polymers using a commercial product from Nektar. The structure of this product is a PEG polymer (5000 D), with one end capped by a methoxy and the other end by a carboxylic acid group. The carboxylic acid endgroup on the PEG was esterified by the terminal hydroxyl groups in the stPCL$_{32}$ polymer to produce the desired final star polymer stPCL-PEG$_{32}$. Excess PEG polymer was used, and the reaction was allowed to continue for seven days. After the reaction was complete, the product was purified twice by fractionation to remove the excess PEG and other impurities. The final stPCL-PEG$_{32}$ polymer was obtained in 83% yield.

Using a similar approach, a 32-arm stPLA-PEG$_{32}$ was synthesized as shown in Scheme 1. Here, we started with a PAMAM-OH Dendrimer Generation 3 as the initiator to polymerize *l*-lactide, using Sn(Oct)$_2$ as a catalyst. Similar to the polymerization of ε-caprolactone, the reaction was well-controlled, and the final star-PLA polymer had an arm length determined by the feed ratio of monomer/initiator. The reaction yield was 97%. SEC analysis indicated that the star-PLA polymer contained some low molecular weight side products. Purification by fractionation was attempted but unsuccessful, possibly because of interfering crystallization (see DSC study below). The impure stPLA$_{32}$ polymer was therefore used in the next step, with the expectation that the low molecular weight side product will be removed when purifying the final product. The stPLA-PEG$_{32}$ polymer was prepared by the same esterification reaction described above. The stPLA-PEG$_{32}$ polymer was purified by two fractionations, and the yield was 72%. The low molecular weight impurity was completely removed, and pure stPLA-PEG$_{32}$ product was obtained.

To verify that L-lactide polymerization under Sn(Oct)$_2$ catalysis conditions can produce PLA with a narrow molecular

Scheme 1. Synthesis of Star Polymers

[a] When calculating the molecular weights, the integration was limited only to the major star polymer peak.

weight distribution, a linear PLA polymer was synthesized using di(ethylene glycol) benzyl ether as the initiator. The yield was 94%. SEC analysis confirmed that this linear-PLA polymer indeed has a very narrow molecular weight distribution (shown in Table 1).

Characterization of Star Polymers. Spectroscopic measurements confirmed the structures of the star polymer products. In the ^{1}H NMR spectrum of $stPCL_{32}$ (shown in Figure 1), four major peaks were observed: the triplet peak at 3.98 ppm is assigned as (-C***H***$_2$-O-) protons; the triplet at 2.23 ppm is assigned as (-C***H***$_2$-CO-) protons; the multiple peak at 1.57 ppm are the protons of (-O-CH_2-C***H***$_2$-CH_2-C***H***$_2$-CH_2-CO-); the multiple peak at 1.30 ppm are the protons in the middle. The peaks from the dendrimer core have a low intensity due to the low content. The small triplet peak at 3.58 ppm is assigned as the chain end terminal protons (-C***H***$_2$-OH). The integration ratio of this peak vs peaks at 3.98 ppm is used to estimate the degree of polymerization of the PCL polymer arms and was found to be about 1/26. This corresponds to a PCL block formula weight of about 3000 D. However, this estimation is based on the ratio of a very small terminal proton peak to a large polymer peak.

In the ^{1}H NMR spectrum of $stPCL\text{-}PEG_{32}$, in addition to the peaks from PCL, the single peak at 3.56 ppm is assigned as the (-O-CH_2CH_2-O-) of the PEG unit. The integration ratio between PEG and PCL reflects the component ratio in the block copolymers and is consistent with the SEC results. The ^{1}H NMR spectrum of $stPLA\text{-}PEG_{32}$ is consistent with the structure, with a quartet peak observed at 5.08 ppm due to the (-C***H***(CH_3)-) proton; a doublet at 1.49 ppm due to the (-CH(CH_3)-) protons; and single peak at 3.56 ppm due to the (-O-CH_2CH_2-O-) in the PEG unit.

The molecular weights of the synthesized polymers were determined by SEC and are summarized in Table 1. The system is equipped with refractive index, viscosity, and light scattering detectors. The combination of these three detectors can provide the absolute molecular weights of the star polymers. The polydispersity of the star polymers was narrow ($M_w/M_n < 1.08$). All the star polymer samples had relatively low intrinsic viscosities and small radii of gyration, confirming their highly branched, compact structure. As shown in Table 1, all of the polymers had lower molecular weights than the theoretical values. This may reflect some uncertainty in the SEC-LS method. There are two possible explanations for this: (1) the polymer arms are shorter than expected; (2) the number of star polymer arms is less than desired. Data from the ^{1}H NMR study indicate that the $stPCL_{32}$ product had an arm length close to the expected value of about 3K. However, as discussed before, such an estimation is not precise. Some OH-containing impurities exist in the system that initiate the polymerization of monomer, as is evident from the low molecular weight polymer impurities in the PCL and PLA stars. These low molecular weight impurities consume some of the monomers, which can result in star polymers with shorter arms than the theoretical value. The ^{1}H NMR analysis of $stPCL\text{-}PEG_{32}$ indicates that the PEG/PCL ratio is 1.81, higher than the theoretical 1.67. This excludes a deficiency in the esterification reaction. It is also possible that our batch of PAMAM-OH dendrimer had some defects, so that the number of surface -OH groups available for polymerization was less than 32. Therefore, both shorter arms and a reduced number of arms may contribute to the overall lower molecular weight of the final star polymer. The number of arms equal to 27.8 is derived from $[M_w(stPCL\text{-}PEG_{32}) - M_w(stPCL_{32})]/M_w(PEG)$. Similarly, for $stPLA\text{-}PEG_{32}$ the calculated number of arms is 28.6. Taking into account the various uncertainties, the estimated number of arms in these star polymers is in the range 26−30.

Thermal Behavior. The thermal properties of the polymers were investigated using differential scanning calorimetry (DSC) to determine the glass transition temperature (T_g) and melt temperature (T_m). For the $stPCL_{32}$ and $stPCL\text{-}PEG_{32}$ polymers, the thermal behavior was simple: $T_m = 50$ °C was observed for $stPCL_{32}$ and $T_m = 57$ °C for $stPCL\text{-}PEG_{32}$. For the PLA polymers, interesting thermal behavior was observed. The DSCs of $stPLA_{32}$ and the linear PLA are shown in Figures 2 and 3, respectively. The heating trace for $stPLA_{32}$ shows a T_g at about

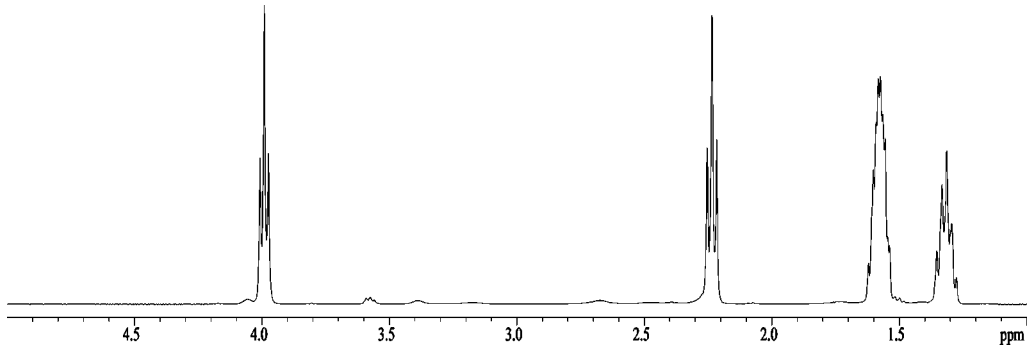

Figure 1. ^{1}H NMR spectrum of stPCL$_{32}$.

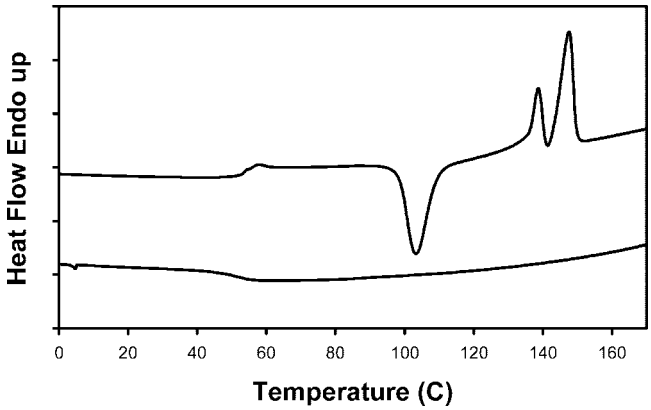

Figure 2. DSC of stPLA$_{32}$: top trace is heating and lower trace is cooling.

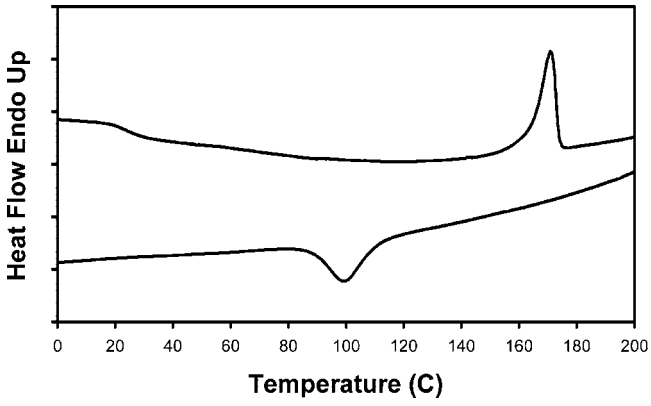

Figure 3. DSC of linear-PLA: top trace is heating and lower trace is cooling.

56 °C, a crystallization transition temperature at 103 °C, and two melting transition peaks at 139 and 148 °C. The cooling trace shows no crystallization transition, and the T_g is at about 50 °C. In contrast, the heating trace for the linear-PLA shows no T_g, and a single melting transition is observed at 171 °C. The cooling trace shows a crystallization transition at 98 °C and no T_g. The linear-PLA polymer can reorganize more freely and has a higher molecular weight of 19K. This indicates a high proportion of crystalline phase in the sample and a small amorphous phase. For the stPLA$_{32}$, the polymer chain is shorter (3K), and one end is bound to the dendrimer core. This means that it has less freedom to reorganize and therefore forms less perfect crystals and a larger amorphous fraction, leading to the observed T_g. In the cooling process, the nucleation of the crystallization (which dominates) is slow at high temperatures (above T_m), so the sample stays amorphous until it passes the T_g. In the heating process, the polymer chains become mobile

Table 2. Characterization of Star Polymer Micelles

	effective diameter[a], nm	polydispersity index
stPCL-PEG$_{32}$	19.0	0.19
stPLA-PEG$_{32}$	24.7	0.20

[a] Effective diameter denotes averaged value calculated from three measurements performed on each sample. The effective diameter values are within ±5 nm. Polymer concentration is 15 mg/mL.

(kinetics dominate) above the T_g. Nucleation is then very fast at low temperature (below T_m), and crystallization occurs. Since it forms less perfect crystals, the two peak melting profiles may be due to two types of crystals, or there may be a partial melting/recrystallization followed by complete melting.

The DSC of stPLA-PEG$_{32}$ in Figure 4 shows interesting behavior as well. The heating trace exhibits a large T_m at 54 °C and a small T_m at 97 °C. The cooling trace shows corresponding transitions at lower temperatures. The unusual thermal behavior of stPLA$_{32}$ was not observed here. The highly crystalline nature of the PEG plays a major role in this case. The sample may contain two types of crystals; one is the PEG crystal and the other is the less perfect PLA crystal. The majority PEG crystal melts at lower temperature and gives the large peak. The smaller amount and less perfect PLA crystals melt at a higher temperature and give a relatively small peak.

Micellar Properties of the Star Polymers. The dialysis method was employed to prepare polymeric micelles. Their effective hydrodynamic diameter was measured by DLS. The measurements performed immediately after dialysis revealed the formation of dispersions of star polymer particles with very broad distributions (polydispersity indices were more than 0.3). Removal of the large aggregates by repeated filtration (membranes with pore sizes of 0.45 and 0.22 μm) resulted in the substantial decrease of the concentration of micellar dispersions (ca. 30−50%). The effective diameters of the polymer micelles in solutions prepared by dialysis are presented in Table 2. The micelle size distribution was rather broad in all cases and varied in the range 0.13−0.21, indicating the possible existence of some aggregated species. As an example, a DLS graph of size

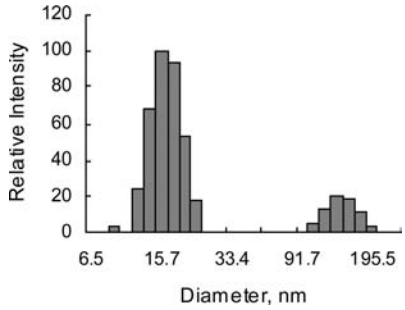

Figure 5. DLS graph of the stPCL-PEG_{32} micelle size distribution. Concentration of stPCL-PEG32 was 15 mg/mL.

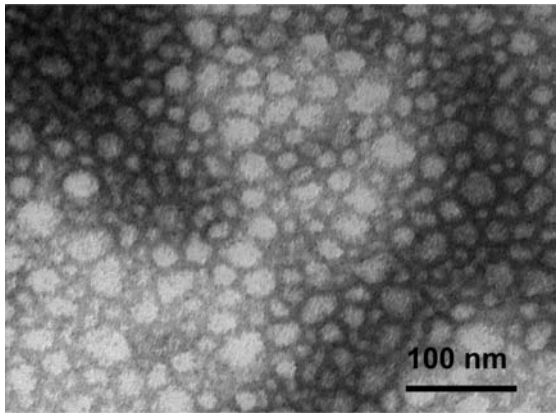

Figure 6. TEM micrograph of stPCL-PEG32 micelles obtained using uranyl acetate staining.

distribution of stPCL-PEG_{32} micelles in a polymer solution with a concentration of 15 mg/mL is shown in Figure 5. It is a bimodal distribution with a smaller size component of ~15.7 nm (85%) and a large size component of ~134 nm (15%). The size and aggregation stability of the star polymer micelles in aqueous dispersions depended on the water content in the water−organic mixture at the start of the dialysis. Specifically, micelles prepared by dialysis from the water−organic mixtures with higher water content (87.5 vol %) were characterized as having both larger particle size and polydispersity, as well as a lower degree of stability. Formation of aggregates followed by phase separation was observed in these solutions within 2−3 days. The most stable stPCL-PEG_{32} and stPLA-PEG_{32} aqueous dispersions were obtained with 67% water content in the initial dialysis mixture. Subsequent measurements of these stPCL-PEG_{32} and stPLA-PEG_{32} samples showed that the size of the particles remained practically unchanged for several weeks. Furthermore, it should be noted that the size and size distribution of the micelles formed from the same batch of polymer varied slightly due to variations in the processing parameters such as stirring conditions, rate of water addition, and so forth.

The morphology of the star polymer micelles was further examined by transmission electron microscopy (TEM) using negative staining. A representative micrograph of the stPCL-PEG_{32} micelles is presented in Figure 6. The micelles are close to spherical and have a mean number-average diameter of 11.5 ± 0.4 nm. Analysis of TEM images revealed the broad size distribution of the polymer micelles as well as the presence of large aggregates with diameters between 25 and 45 nm (frequency from 6% to 1%). The diameters of the particles determined from the TEM data were less than the effective diameter determined by DLS. This is not surprising, since the DLS determines the hydrodynamic diameter or the "equivalent sphere diameter" in solution, while TEM images were obtained in the absence of the solvent. Nevertheless, both methods exhibited the same trend in the particle sizes of the micelles.

The star polymer micelles were further characterized by fluorescence spectroscopy to determine the partition coefficient of the model hydrophobic probe pyrene between the polymer micelles and the aqueous compartment. Several aspects of the pyrene spectroscopic properties were changed as the polymer concentration increased: the total fluorescence intensity increased, and the vibrational fine structure of the emission spectra changed. This type of behavior is indicative of the partitioning of the pyrene into the more hydrophobic environment. However, the extent of these changes as a function of polymer concentration was drastically different for the polymers studied. For stPCL-PEG_{32}, the total fluorescence intensity increased steadily even in very dilute polymer solutions, and the vibrational fine structure (I_1/I_3) changed from 1.8 to 1.32. These results suggest that in dilute solutions the intact stPCL-PEG_{32} molecules formed unimolecular micelles. The calculated value for the partition coefficient (P) for pyrene between stPCL-PEG_{32} micelles and water at 22 °C was 4150, nearly double than that found for a 16 arm star-PCL-PEG polymer (P = 2410) (*16*). In contrast, the onset of the changes in the fluorescence spectra of pyrene in the stPLA-PEG_{32} aqueous dispersions was detected at a polymer concentration of ~0.01 mg/mL. The partition coefficient for pyrene in this system was found to be ~600. Furthermore, the stPLA-PEG_{32} micelle solutions were found to have an I_1/I_3 ratio of 1.6. This value is higher than the 1.32 value determined for stPCL-PEG_{32} micelles. These data suggest that the PLA cores of stPLA-PEG_{32} micelles are more polar compared to the PCL cores. As a result, the environment of the pyrene molecule in the PLA core is less hydrophobic, decreasing the solubilization capacity of stPLA-PEG_{32} micelles.

Similar studies were conducted for star polymer micelles in phosphate buffer saline (PBS). In the case of stPCL-PEG_{32}, the total fluorescence intensity steadily increased even in the very dilute polymer solutions, suggesting the presence of stPCL-PEG_{32} molecules as unimolecular micelles. The onset of the changes in the fluorescence spectra of pyrene in the stPLA-PEG_{32} aqueous dispersions was detected at a polymer concentration of ~0.067 mg/mL. The calculated values for the partition coefficient for pyrene under these conditions were 1440 for stPCL-PEG_{32} micelles and 470 for stPLA-PEG_{32} micelles.

Encapsulation and Release of Etoposide in Copolymer Micelles. Two general drug-loading methods were explored for encapsulating etoposide in stPCL-PEG_{32} micelles. In the first method (dialysis), etoposide (2 mg) was dissolved in acetonitrile and then mixed with stPCL-PEG_{32} polymer (5 mg) dissolved in DMF (1 mL). Next, distilled water was slowly added dropwise to the mixture (25 μL of water per 2−3 min) to achieve a water content of 67 vol %. Drug precipitation was not observed upon mixing water with the drug−polymer solution. The obtained water−organic solvent mixture containing etoposide and polymer was then dialyzed against water. No etoposide was detected in the final dispersions. Therefore, this technique is not applicable, possibly due to the water solubility of etoposide (ca. 0.12 mg/mL).

In the second method, micelle extraction (*2*) was used to encapsulate etoposide into the star micelles. Briefly, an aliquot of etoposide stock solution in acetonitrile was added to the empty vial, the solvent was evaporated to dryness, and 1 mL micelle solution was added to the vial and agitated for 2 days. Polymer concentrations ranging from 2 mg/mL to 15 mg/mL were used. The solution was then centrifuged to remove insoluble drug, and the etoposide concentration in the solution was determined by HPLC. The loading levels of etoposide into the copolymer micelles are presented in Table 3. The maximum etoposide loading (7.8 w/w % for stPCL-PEG_{32} and 4.3 w/w

Table 3. Etoposide Loading in stPCL-PEG$_{32}$ and stPLA-PEG$_{32}$ Polymers

	15	0.43	2.8

[a] The etoposide concentration values are within ± 3%.

% for stPLA-PEG$_{32}$, respectively) was achieved at a polymer concentration of ca. 3 mg/mL. Further increase in the polymer concentration resulted in a decrease in the drug loading level. Such complex solubilization behavior is typical of systems where there is a strong interaction between the drug and the micelle core (*3*, *18*, *19*). In this case, the solubilization capacity might increase to a saturation level with increasing polymer concentration. As a result, the relative drug loading in the micelles will decrease. It is noteworthy that the incorporation of drug did not affect the size of the star polymer micelles. The etoposide/star polymer dispersions remained stable over several days. Furthermore, they could be stored at 4 °C for at least 24 h without precipitation of etoposide.

The drug release from the etoposide/stPCL-PEG$_{32}$ system (polymer concentration 5 mg/mL) was evaluated in phosphate buffered saline (pH 7.4, 0.14 M NaCl) by the dialysis method. About 60% of the loaded etoposide (an averaged value calculated based on three experiments) was released from the micelles during the first 24 h. Overall, these studies suggested that etoposide can be loaded and efficiently released from star polymer micelles.

Concluding Remarks. In summary, we have successfully synthesized two types of amphiphilic star-polymers with PCL and PLA as the lipophilic components. The star polymer structures were confirmed by SEC, spectroscopic, and thermal characterizations. The micelle properties of the polymers were investigated by various techniques. The formation of unimolecular micelles from the stPCL-PEG$_{32}$ has been demonstrated by pyrene fluorescence studies. The results from fluorescence, DLS, and TEM experiments have shown that unimolecular micelles and aggregated multimolecular micelles coexist in the water solution. A systematic study revealed the optimal condition for etoposide encapsulation by the polymer micelles. The stPCL-PEG$_{32}$ has a higher etoposide loading capacity than stPLA-PEG$_{32}$. This may be due to the more lipophilic properties of the PCL core. The overall etoposide loading capacity of the 32 arm star polymer is lower than the 16 arm star polymer we reported previously (*16*). One possible reason for this may be due to the higher PCL polymer density in the 32 arm star polymer micelle interior, therefore leaving less space for drug loading. The *in vivo* testing for tumor treatment by the etoposide/star polymer formulation will be report in separate paper.

The successful use of peptides as potential radiopharmaceuticals essentially requires the modification of the bioactive peptide hormones to introduce chelators for radiolabeling. In this study, four Y_1/Y_2 receptor-selective NPY analogues with different receptor subtype specificities have been investigated. For *in vitro* studies, the cold metal surrogate was used. Gallium and indium complexes were introduced by using 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid as bifunctional chelator. The peptides were synthesized by solid-phase peptide synthesis (SPPS), the chelator was coupled either at the N-terminus or at the N^{ε} side chain of Lys^4 of the resin-bound peptide, and the labeling was performed in solution after cleavage. Competitive binding assays showed high binding affinity of the receptor-selective analogues at NPY receptor expressing cells. To test internalization of the novel peptide analogues and the metabolic stability in human blood plasma, the corresponding 5(6)-carboxyfluorescein (CF) analogues were prepared and investigated. One of the most promising analogues, the Y_1-receptor selective [Lys(DOTA)^4, Phe^7, Pro^{34}]NPY was labeled with ^{111}In and injected into nude mice that bear MCF-7 breast cancer xenografts, and biodistribution studies were performed. *In vitro* and *in vivo* studies suggest that receptor-selective analogues of NPY have promising characteristics for future applications in nuclear medicine for breast tumor diagnosis and therapy.

INTRODUCTION

The use of radiolabeled receptor-mediated peptide analogues for the treatment of primary and metastatic tumors, namely, targeted radionuclide therapy, has been an important alternative to conventional therapeutic regimens. Receptor-avid peptides have been chosen as vehicles to selectively deliver cytotoxic radiation-emitting radionuclides to tumor cells, resulting in tumor cell death (*1*).

Neuropeptide Y (NPY)[1] is a 36 amino acid peptide amide of the pancreatic polypeptide family. It is expressed in the peripheral and central nervous system and is one of the most abundant neuropeptides in the brain (*2*). NPY acts peripherally as a vasoconstrictor and modulates the activity of further neurotransmitters. Several other physiological activities such as induction of food intake, inhibition of anxiety, increase in memory retention, etc., have also been attributed to NPY (*3*). Its receptors are produced in a number of neuroblastoma and cell lines derived thereof, which suggest them as optimal targets for tumor scintigraphy. So far, five receptor subtypes (Y_1, Y_2, Y_4, Y_5, y_6) have been cloned that bind NPY with nanomolar affinity (*4*). They all belong to the large family of G-protein-coupled receptors (GPCRs) with their typical seven transmembrane helix structure (*5*).

Previous studies showed that there is a molecular basis for a putative role of NPY in tumors, e.g., neuroendocrine tumors, glioblastomas, and breast cancers (*6–9*). The strong predominance of Y_1 receptors in breast carcinomas compared to Y_2 in normal breast tissue suggests that neoplastic transformation can switch the NPY receptor expression from the Y_2 to the Y_1 receptor subtype. The high incidence of Y_1 in *in situ*, invasive, and metastatic breast cancers therefore allows the possibility to target them for diagnosis and therapy with NPY Y_1 receptor-selective analogues by using an appropriate metalloradiopharmaceutical that contains, e.g., a metallic radionuclide (e.g., ^{67}Cu, ^{90}Y, ^{99m}Tc, ^{111}In, ^{177}Lu, ^{186}Re, or ^{212}Bi). Additionally, the targeting biomolecule requires a bifunctional chelator (BFC), either directly or separated by a spacer molecule to coordinate the metallic radionuclide.

We focused on the development of gallium- and indium-labeled NPY receptor-selective analogues chelated by DOTA, since this chelator is capable of forming stable complexes with various 3^+-charged radiometals, as demonstrated by the successful development of Ga-labeled somatostatin analogues (*10*). The effect on receptor binding properties was studied by labeling the DOTA-NPY analogues with nonradioactive Ga and In.

All peptides were tested for receptor binding affinity at various NPY receptor expressing cells, e.g., human neuroepithelioma (SK-N-MC), human breast adenocarcinoma (MCF-7), human neuroblastoma (SMS-KAN), and human endometrial carcinoma (HEC) cells. The SK-N-MC and MCF-7 cells selectively express NPY Y_1 receptors, while SMS-KAN cells selectively express NPY Y_2 receptors and HEC-1B$-Y_5$ cells were stable transfected with Y_5 receptors (*11*). All cell lines have frequently been used to investigate binding as well as signal transduction of NPY (*12*).

Here, we report on the influence of the linker chelator 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) and conjugates of four different NPY analogues with respect to ligand binding. Interestingly, the position of the labeling of linker was of significant interest regarding the binding to the receptor. Moreover, we present the first series biodistribution data of one of the most potent Y_1 receptor selective NPY analogues [Lys(DOTA)^4, Phe^7, Pro^{34}]NPY. The peptide was successfully labeled with ^{111}In and accordingly confirms the proof of the principle. The *in vivo* characteristic of the peptide was studied in nude mice that bear MCF-7 breast cancer xenografts.

EXPERIMENTAL PROCEDURES

Materials. The N^α-Fmoc-protected amino acids were obtained from Alexis (Läufelfingen, Switzerland) and Novabiochem (Läufelfingen, Switzerland). The side chain protecting groups were *tert*-butyl for Asp, Glu, Ser, Thr, and Tyr; *tert*-butyloxycarbonyl (Boc) for Lys; trityl for Asn, Gln, and His; and 2,2,5,7,8-pentamethylchroman-6-sulfonyl (Pmc) for Arg. The 4-(2′,4′-dimethoxyphenyl-Fmoc-aminomethyl)-phenoxy (Rink Amide) resin was obtained from Novabiochem. *N*,*N*-Dimethylformamide, dichloromethane, methanol, and diethyl ether were purchased from Scharlau (La Jota, Barcelona, Spain). Physiological sodium chloride was obtained from Braun (Melsungen, Germany). 5(6)-Carboxyfluorescein (CF), 1-hydroxybenzotriazole (HOBt), thioanisole, *p*-thiocresol, piperidine, diisopropylethylamine, hydrazine monohydrate, and *tert*-butanol were purchased from Fluka (Buchs, Switzerland). *N*,*N*′-Diisopropylcarbodiimide (DIC) was purchased from Aldrich (Buchs, Switzerland). Acetonitrile (ACN) was obtained from Romil (Cambridge, England) and Merck (Darmstadt, Germany). Trifluoroacetic acid was obtained from Fluka (Buchs, Switzerland) and Merck. Ethanol (70%), water for chromatography, sodium acetate buffer, and saline solution were purchased from Merck. Dulbecco's MEM/NutMix F12 medium (50:50, v/v), Minimum Essential Medium (MEM) with Earl's salts, Dulbecco's PBS, sodium pyruvate, phosphate buffered saline (NaCl/Pi), fetal calf serum, glutamine, nonessential amino acids, and trypan blue were purchased from Gibco (Life Technologies, Basel, Switzerland). Trypsin-EDTA was obtained from Gibco (Life Technologies, Basel, Switzerland) and Biochrom (Berlin, Germany). Isofluran Curamed was purchased from Cura MED Pharma (Karlsruhe, Germany) and MatrigelTM Matrix was obtained from Becton & Dickinson (Heidelberg, Germany). Bacitracin and BSA were from Sigma (Buchs, Switzerland), while EDTA, Pefabloc SC, and all other chemicals were from Fluka. [^{3}H]propionyl-NPY and $^{111}InCl_3$ were obtained from Amersham (Buckinghamshire, United Kingdom).

Automatic Peptide Synthesis. The peptides were synthesized by fluorenylmethoxycarbonyl/*tert*-butyl (Fmoc/t-Bu) strategy with an automated multiple peptide synthesis robot system (Syro, MultiSynTech, Bochum, Germany) using Rink amide resin (30 mg, 450 μmol). Each amino acid was coupled by a double coupling procedure (two times coupling with 40 min incubation) using a 10-fold excess of N^α-Fmoc-protected amino acids and *in situ* activation with DIC and 500 μL HOBt (0.5 M in DMF) within 15 min incubation time at room temperature (*13*). The removal of the Fmoc-group was carried out with 40% piperidine in DMF (*13*). Cleavage of the peptide from the resin and of the side-chain protecting groups was accomplished in one step with 90% trifluoroacetic acid (TFA) in the presence of 10% scavengers (thioanisole/thiocresol 1:1) for 3 h. The peptides were precipitated from ice-cold diethyl ether and collected by centrifugation, resuspended in ether, and centrifuged again. This procedure was repeated four times. The identification of the products was confirmed by matrix-assisted LASER desorption ionization-time-of-flight (MALDI-ToF) mass spectrometry. The purification of the peptides was performed by a preparative RP-HPLC on a Shimadzu RP18-column (12.5 $\times$ 250 mm; 5 μm/300 Å). The pure products were characterized by analytical RP-HPLC on a Vydac RP18-column (4.6 $\times$ 250 mm; 5 μm/ 300 Å, Merck Hitachi, Darmstadt, Germany) by using a linear gradient of 0.1% TFA in water (A) and 0.08% TFA in acetonitrile (B) from 10% to 60% B in A over 30 min at a flow rate of 0.6 mL/min^{-1}. The following peptides were synthesized: NPY, [Phe^7, Pro^{34}]NPY, [Ahx$^{5-24}$]NPY, and [Ahx$^{8-20}$]NPY. The analytical data of the peptides are summarized in Table 1.

For the modification of the N^ε side chain of Lys^4, this residue was protected with 4,4-dimethyl-2,6-dioxocyclohex-1-ylideneethyl (Dde group) by using Fmoc-Lys(Dde), whereas the N-terminus was protected by the Boc-protecting group. After complete synthesis of the peptide sequence, the Dde protecting group was selectively removed from the resin by repeated washing steps with 2% hydrazine in DMF (*14*) followed by a 10 min incubation time at room temperature. The peptide remained still bound to the resin and all acid labile protecting groups remain fully protected under these conditions. After this, Lys (*4*) was labeled with the respective group (chelator or 5(6)-carboxyfluorescein), followed by the cleavage of the labeled peptide from the resin as described above.

Labeling with 5(6)-Carboxyfluorescein (CF). Prior to cleavage of the peptides, the peptides were labeled with 5(6)-carboxyfluorescein, following the procedure described by Weber et al. (*15*), in which a 10-fold excess of the CF group was used. HOBt and DIC were dissolved in DMF to give a 250 mM solution and an incubation period of 2 h was applied. Then, the resin was washed three times with 1 mL of DMF, DCM, MeOH, and Et_2O each and dried *in vacuo*. Cleavage of the peptides from the resin and identification of the CF-labeled peptides was performed as described above. The following peptides were produced: CF-NPY, [Lys(CF)^4]NPY, CF-[Phe^7, Pro^{34}]NPY, [Lys(CF)^4, Phe^7, Pro^{34}]NPY, CF-[Ahx$^{5-24}$]NPY, [Lys(CF)^4, Ahx$^{5-24}$]NPY, CF-[Ahx$^{8-20}$]NPY, and [Lys(CF)^4, Ahx$^{8-20}$]NPY.

Conjugation with DOTA. A protected DOTA analogue (DOTA-3tBu) was activated in a separate vial by 3 equiv HOBt and 3 equiv DIC in 250 μL DMF. It was transferred to the resin-bound peptide and incubated at room temperature for 2 h. The resin was washed three times with 1 mL of DMF, DCM, DMF, MeOH, and Et_2O each and dried *in vacuo*. The following peptides were synthesized: DOTA-NPY, Lys(DOTA)^4-NPY, DOTA-[Phe^7, Pro^{34}]NPY, Lys(DOTA)^4-[Phe^7, Pro^{34}]NPY, DOTA-[Ahx$^{5-24}$]NPY, Lys(DOTA)^4-[Ahx$^{5-24}$]NPY, DOTA-[Ahx$^{8-20}$]NPY, and Lys(DOTA)^4-[Ahx$^{8-20}$]NPY.

Labeling of DOTA-NPY Analogues with Ga. A mixture of 500 μg (340 μmol) of DOTA-NPY in 500 μL of 0.4 M sodium acetate buffer (pH 5) was incubated with 102 μL of a

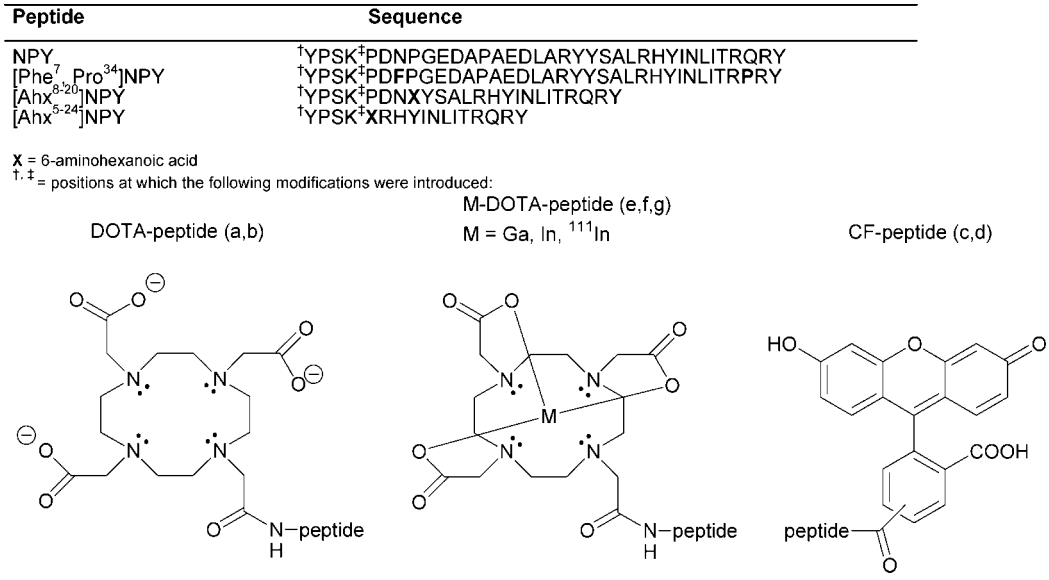

Figure 1. Sequences and modifications of the peptides used in this study: (a) modification with DOTA at the N-terminus, (b) modification with DOTA at the N^{ε} side chain of Lys^4, (e,f) modification with Ga/In, (g) modification with ^{111}In, (c) modification with CF at the N-terminus, (d) modification with CF at the N^{ε} side chain of Lys^4.

0.01 M aqueous solution of nonradioactive $Ga(NO_3)_3$ for 30 min at 37 °C and cooled to room temperature. Lys(DOTA)^4-[Phe^7, Pro^{34}]NPY was labeled with Ga to produce [Lys(Ga-DOTA)^4, Phe^7, Pro^{34}]NPY.

Labeling of DOTA-NPY Analogues with In. A mixture of 500 μg (340 μmol) of DOTA-NPY in 500 μL of 0.4 M ammonium acetate buffer (pH 5) was incubated with 100 μL of a 0.01 M aqueous solution of nonradioactive $InCl_3$ for 30 min at 37 °C and cooled to room temperature. Lys(DOTA)^4-[Phe^7, Pro^{34}]NPY was labeled with In to produce [Lys(In-DOTA)^4, Phe^7, Pro^{34}]NPY.

Labeling of DOTA-NPY Analogues with ^{111}In. A mixture of 25 μg (1 mg/0.5 mL saline solution (2.5 M)) of NPY analogue in 12.5 μL of saline solution (2.5 M) was incubated with 100 μL of $^{111}InCl_3$ (41 MBq) in 0.04 M HCl and 20 μL of a 2.5 M sodium acetate buffer (pH 5.6) for 15 min at 75 °C and cooled for 10 min (*16*). The product was analyzed by radio-HPLC. Analysis was performed on the HPLC system Agilent (Luna column 5 μm, C18, 250 × 4.6 mm), by using a linear gradient of 0.1% TFA in water (A) and 0.1% TFA in acetonitrile (ACN) (B) from 25% to 50% B in A in 30 min with a flow of 1.0 mL/min. Lys(DOTA)^4-[Phe^7, Pro^{34}]NPY was labeled with ^{111}In to produce [Lys(^{111}In-DOTA)^4, Phe^7, Pro^{34}]NPY.

Cell Culture. Cells were grown in 75 cm^2, 175 cm^2, and 225 cm^2 culture flasks at 37 °C, 5% CO_2, in a humidified atmosphere. SK-N-MC cells were cultivated in MEM with Earl's salts supplemented with 10% (v/v) heat-inactivated fetal calf serum (FCS), 4 mM L-glutamine, 0.2 mM nonessential amino acids, and 1 mM sodium pyruvate. SMS-KAN cells were grown in DMEM/nutrient mix Ham's F12 (1:1) with 15% v/v FCS, 4 mM L-glutamine, and 0.2 mM nonessential amino acids. MCF-7 cells were cultivated in DMEM/nutrient mix Ham's F12 (1:1) with 10% (v/v) FCS and 2 mM L-glutamine. All cells were grown to confluence before use.

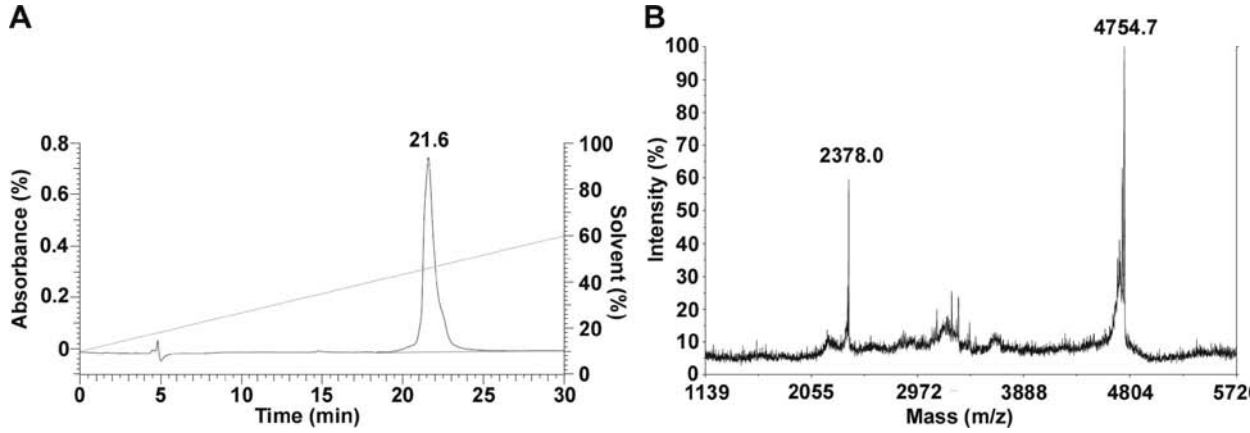

Figure 2. Typical analytical data of compound **2f** [Lys(In-DOTA)^4, Phe^7, Pro^{34}]NPY (A) HPLC chromatogram from 10% to 60% ACN in 30 min, (B) MALDI spectrum of the compound.

Receptor Binding Affinity Assays. Cells were resuspended in incubation buffer (minimal essential medium with Earl's salts containing 0.1% bacitracin, 50 mM Pefabloc SC, and 1% bovine serum albumin). A total of 200 μL of the cell suspension containing approximately 60 000 cells was incubated with 25 μL of a 10 nM solution of ^{3}H-propionyl-NPY and 25 μL of NPY or analogue in a concentration range of 10 μM to 10 pM in 1% BSA. Nonspecific binding (NSB) was defined in the presence of 1 μM unlabeled NPY. After incubating the cells for 90 min at room temperature, the incubation was terminated by centrifugation at 2000 $\times$ *g* and 4 °C for 5 min. The pellets were washed twice with 400 μL PBS (137 mM NaCl, 8 mM Na_2HPO_4/KH_2PO_4, pH 7.4), centrifuged, and resuspended in 100 μL PBS. The cell suspension was mixed with 3 mL scintillation cocktail and radioactivity was determined by using a beta-counter.

IC_{50} values of the binding curves were calculated by nonlinear regression on a sigmoidal dose−response based model by using GraphPad Software *PRISM 3.0*. Each experiment was performed 2−3 times in triplicate and $K_i \pm$ SEM values were calculated, using the Cheng-Prusoff equation (*17*). The following K_D values of the radioligand ^{3}H-NPY at the respective receptors were used: 0.18 nM at the Y_1 receptor, 0.45 nM at the Y_2 receptor, and 1.8 nM at the Y_5 receptor.

Confocal Laser Scanning Microscopy (CLSM). For confocal laser scanning microscopy, the cells were grown on Falcon Cell Culture Inserts with Cyclopore membranes or a Laboratory-Tak Chamber Slides for the observation of unfixed cells. In order to perform measurements, the Leica Confocal System TCS SP2 was used at excitation/emission wavelengths of 488/514 nm argon laser, respectively.

Metabolic Stability in Human Blood Plasma. The proteolytic degradation of the CF-labeled peptide was determined *in vitro* in human blood plasma obtained from healthy donors. 0.1 mL of plasma was incubated at 37 °C with 10 μM CF-labeled peptide for 0, 3, 6, 12, and 24 h. Then, samples were precipitated with 40 μL acetonitrile/ethanol (50:50, v/v) by incubation in ice for 30 min followed by centrifugation at 8000 rpm at 4 °C for 15 min. The supernatant was filtered through HPLC certified 220 μm filters, analyzed by HPLC on a Vydac RP18-column (4.6 $\times$ 250 mm; 5 μm/ 300 Å, Merck Hitachi, Darmstadt, Germany), and monitored by fluorescence detection. A linear gradient with 0.1% TFA in water (A) and 0.08% in acetonitrile (B) from 25% to 50% B in A over 60 min at a flow rate of 600 μL min^{-1} was used. The fluorescence labeled metabolites collected from each HPLC chromatogram were identified by MALDI-ToF as possible cleavage sites from the parent peptide.

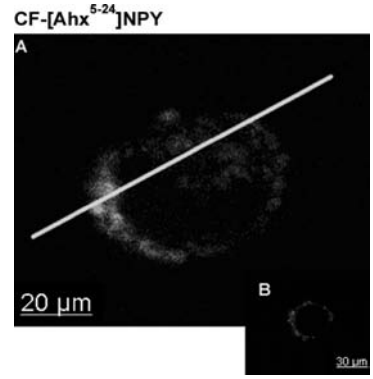

Figure 3. (A) Cellular uptake of CF-[Ahx$^{5-24}$]NPY in SMS-KAN cells. Cells were incubated with the CF-labeled peptide at a final concentration of 1 μm at 37 °C for 120 min. The CLSM view shows a slice at 3.08 μm from Z-scans (from −4.50 to 2.04 μm with an increment interval of 0.38 μm). (B) For the determination of nonspecific adsorption of the ligand, BHK cells which do not express NPY receptors were used as negative control. They were treated in parallel and observed in CLSM under the same parameters.

Inoculation of MCF-7 Tumor Cells in Immunodeficient Mice. In general, for biodistribution studies nude mice (female); app. 18 g NMRI nu/nu were used. First of all, three days before tumor cell inoculation, subcutaneous implantation of estrogen pellet in the left shoulder was affected. Mice were anesthesized with Isofluran Curamed. MCF-7 cells were resuspended in Dulbecco's PBS with Ca^{2+}/Mg^{2+} and Matrigel Matrix with growth factor. Subcutaneous injection of 100 μL of the cell suspension containing similarly 2 $\times$ 10^7 cells occurred in the right shoulder of the mice 16 days before biodistribution.

Biodistribution of Lys(^{111}In-DOTA)^4-[Phe^7, Pro^{34}]NPY in MCF-7 Tumor-Bearing Mice. The biodistribution of Lys(^{111}In-DOTA)^4-[Phe^7, Pro^{34}]NPY was studied in nude mice bearing MCF-7 tumors. Adjacent to the induction of light anesthesia with Isofluran Curamed, the animals were injected with the radiolabeled peptide via a lateral tail vein at a radioactive dose of 88 kBq ^{111}In. Following injection, animals were individually housed in metabolism cages with food and water to allow separate collection of voided urine and feces. Animals were killed after 0.5 h, 1.0 h, 2.0 h, 4.0 h, and 24 h by decapitation under anesthesia with Isofluran Curamed. Each carcass was dissected and the organs and tissues assayed for radioactivity (*18*).

RESULTS

Synthesis and Labeling of NPY Analogues. For our studies, we used the three NPY analogues [Phe^7, Pro^{34}]NPY,

[Ahx$^{5-24}$]NPY, and [Ahx$^{8-20}$]NPY as well as NPY. It has been shown that [Phe^7, Pro^{34}]NPY significantly binds to Y_1 receptors with subnanomolar affinity (*19*). For [Ahx$^{5-24}$]NPY and [Ahx$^{8-20}$]NPY, selectively binding to Y_2 receptors has been observed (*13*, *20*). The peptides were produced with either a DOTA or a CF group (Figure 1). The labels were introduced manually to the resin-bound peptides either at the N-terminus or at the selectively deprotected N$^{\varepsilon}$ side chain of Lys^4 while they were still bound to the resin. The most potent DOTA-conjugated peptide was chelated with $Ga(NO_3)_3$ and $InCl_3$. The optimum conditions at which we could obtain the Ga-DOTA-NPY analogue with a maximum yield (42%) and the In-DOTA-NPY analogue with a maximum yield (96%) included the incubation of DOTA-conjugated peptide in 0.4 M sodium acetate buffer and 0.4 M ammonium acetate buffer with 0.01 M aqueous solution of $Ga(NO_3)_3$ or $InCl_3$ for 30 min at 37 °C. All peptides were purified and analyzed by RP-HPLC and the identity was confirmed by MALDI-ToF. A typical analytical data of the compound **2f** are shown in Figure 2. In total, 23 peptides were produced and their sequences and analytical data are listed in Table 1. Numbering was performed according to the scheme described in Figure 1.

Receptor Binding Affinity. The receptor affinity was tested at cell lines that selectively express single NPY receptor subtypes by the displacement of 1 nM [^{3}H]propionyl-NPY. The experimental data showed an IC_{50} value of 2.0 ± 0.1 nM for NPY at Y_1 receptor expressing SK-N-MC cells that was transferred to a K_i value of 0.3 ± 0.02 nM, by using the Cheng-Prusoff equation (*17*). Evaluation of the binding data obtained with the modified or labeled analogues is summarized in Table 1. As shown in Table 1, the unlabeled NPY showed maximum binding at all NPY receptor expressing cells.

To test the effect of the chelator on receptor binding properties, compounds **2**−**4** were labeled with DOTA. The labeling of compound **2** as well as of NPY at the N$^{\varepsilon}$ side chain of Lys^4 with DOTA showed better binding affinities at Y_1/Y_2 receptor expressing cells compared to the labeling at the N-terminus (compound **2a** with pK_i values 8.6 ± 0.2 vs **2b** with 9.5 ± 0.2). A reversed effect was observed with compounds **3a** and **3b** at Y_2 receptors with pK_i values 8.8 ± 0.1 vs 8.5 ± 0.1, respectively.

Although some loss in affinity was found for compound **2e** (pK_i = 8.8 ± 0.1), nanomolar affinity was still found for the Ga-DOTA-labeled peptide. The same affinity could be observed for the In-DOTA-labeled peptide, compound **2f** (pK_i = 8.8 ± 0.1).

Furthermore, the DOTA conjugated compound **2a** showed constant selectivity at Y_1 receptor expressing SK-N-MC and MCF-7 cells compared to Y_2 and Y_5 receptor expressing SMS-KAN and HEC-1B−Y5 cells (compound **2a** with pK_i values of 8.6 ± 0.2 at SK-N-MC vs 6.5 ± 0.1 and 7.1 ± 0.3 at SMS-KAN and HEC-1B−Y5 cells). Same results could be observed for the compound **2b** with DOTA at N$^{\varepsilon}$ side chain of Lys^4 (compound **2b** with pK_i values of 9.5 ± 0.2 at SK-N-MC vs 7.2 ± 0.1 and 7.5 ± 0.1 at SMS-KAN and HEC-1B−Y5 cells).

To determine whether the fluorescently labeled NPY analogues had any effect on receptor affinity, CF labeled peptides were tested as well. Interestingly, the binding was found to significantly dependent on the position of the labeling, as the NPY receptor selective N-terminally labeled peptides as well as NPY were found to be mostly more biologically active at the corresponding NPY Y_1 or Y_2 receptor. The effect was pronounced at the Y_1 receptors especially in MCF-7 cells (compounds **1c** and **1d** with pK_i values of 9.3 ± 0.2 vs 7.2 ± 0.1, respectively). Similar results were also obtained with Y_2 receptor selective analogues at SMS-KAN cells (compounds **3c** and **4c** with pK_i values of 8.2 ± 0.1 and 8.8 ± 0.1 vs pK_i values of 8.0 ± 0.1 and 7.7 ± 0.1 of compounds **3d** and **4d**). All of these binding data at various receptors are summarized in Table 1. These fluorescent labeled compounds were further used in confocal microscopy for visualization of the receptor−ligand interaction in internalization assays to investigate uptake of compounds into the cells. For all analogues, receptor subtype selective uptake could be demonstrated. Figure 3 shows the cellular uptake of compound **3c** into SMS-KAN cells by using confocal laser scanning microscopy (CLSM).

Metabolic Stability in Human Blood Plasma. The metabolic stability and the main cleavage product in human blood plasma of [Lys(CF)^4, Phe^7, Pro^{34}]NPY, compound **2d**, was determined. The intact peptide found after 3 h incubation was about 95%, after 6 h as 88%, after 12 h as 74%, and after 24 h about 71%. Only one main cleavage product could be detected for the NPY analogue after 24 h, [Lys(CF)^4, Phe^7, Pro^{34}]NPY(1−35) with about 25−30%. Figure 4 shows the analytical data of metabolic degradation in human blood plasma after 24 h and the time course of degradation of [Lys(CF)^4, Phe^7, Pro^{34}]NPY.

Radiolabeling. [Phe^7,Pro^{34}]NPY has been shown to be the compound with the most significant Y_1-receptor preference with subnanomolar affinity (*19*). Accordingly, we used this NPY analogue for radiolabeling and biodistribution studies in MCF-7 tumor-bearing mice for detection of breast cancers. ^{111}In-DOTA radiolabeling of [Lys(DOTA)^4, Phe^7, Pro^{34}]NPY is also dependent on different labeling conditions, like temperature, pH, and reaction time. Optimized conditions were found for the incubation of DOTA-NPY analogue in 2.5 M saline solution and $^{111}InCl_3$ (41 MBq) in 0.04 M HCl for 15 min at 75 °C with a radiochemical yield of 80%. In contrast, a longer incubation time of 20 min and a temperature of 70 °C led to a radiochemical yield of only 6% (Figure 5A). The radiolabeled peptide was analyzed by radio-HPLC. A typical radio-HPLC chromatogram of the compound **2g** is shown in Figure 5B.

Biodistribution. The evaluation of [Lys(^{111}In-DOTA)^4, Phe^7, Pro^{34}]NPY for *in vivo* receptor targeting was performed by using biodistribution in MCF-7 tumor-bearing mice. Therefore, the nude mice were successfully inoculated with the Y_1 receptor expressing MCF-7 cell line in the right shoulder. The animals were injected with the ^{111}In-labeled peptide via a lateral tail vein (inject dose of 87.67 kBq). The radiolabeled peptide was not removed from the unlabeled peptide. Separated organs, tissues, and the blood were weighed and assayed for radioactivity using a gamma-counter for detection of ^{111}In after 0.5 h, 1.0 h, 2.0 h, 4.0 h, and 24 h respectively. Microsoft *Excel* analysis program was applied to calculate %ID/g (percent of injected dose per gram organ, tissue, or blood). The biodistribution study data of the compound **2g** demonstrated extensive accumulation in the kidney and a low tumor uptake. After intravenous injection of the ^{111}In-labeled peptide, maximum tumor uptake of 1.7%ID/g was reached after 30 min. A significant accumulation of 86.8%ID/g after 4 h was reached in the kidney. Furthermore, an increase in the uptake was found in the bone with a maximum of 1.62%ID/g after 24 h. A relatively lower concentration was detected in spleen (1.10%ID/g after 24 h). In the adrenals and blood, ^{111}In-labeled peptide concentration decreased over 24 h. The complete results of the biodistribution study are summarized in Table 2.

DISCUSSION

The prerequisite for radiolabeled receptor-binding peptides as diagnostic or therapeutic agents include therapeutic efficacy and favorable pharmacokinetics, such as rapid and high tumor uptake, extended tumor retention, high organ ratio of tumor to normal organ, and rapid whole-body clearance (*21*). In a metalloradiopharmaceutical, the targeting biomolecule is only one part of the whole molecule and the development of an efficient BFC and new

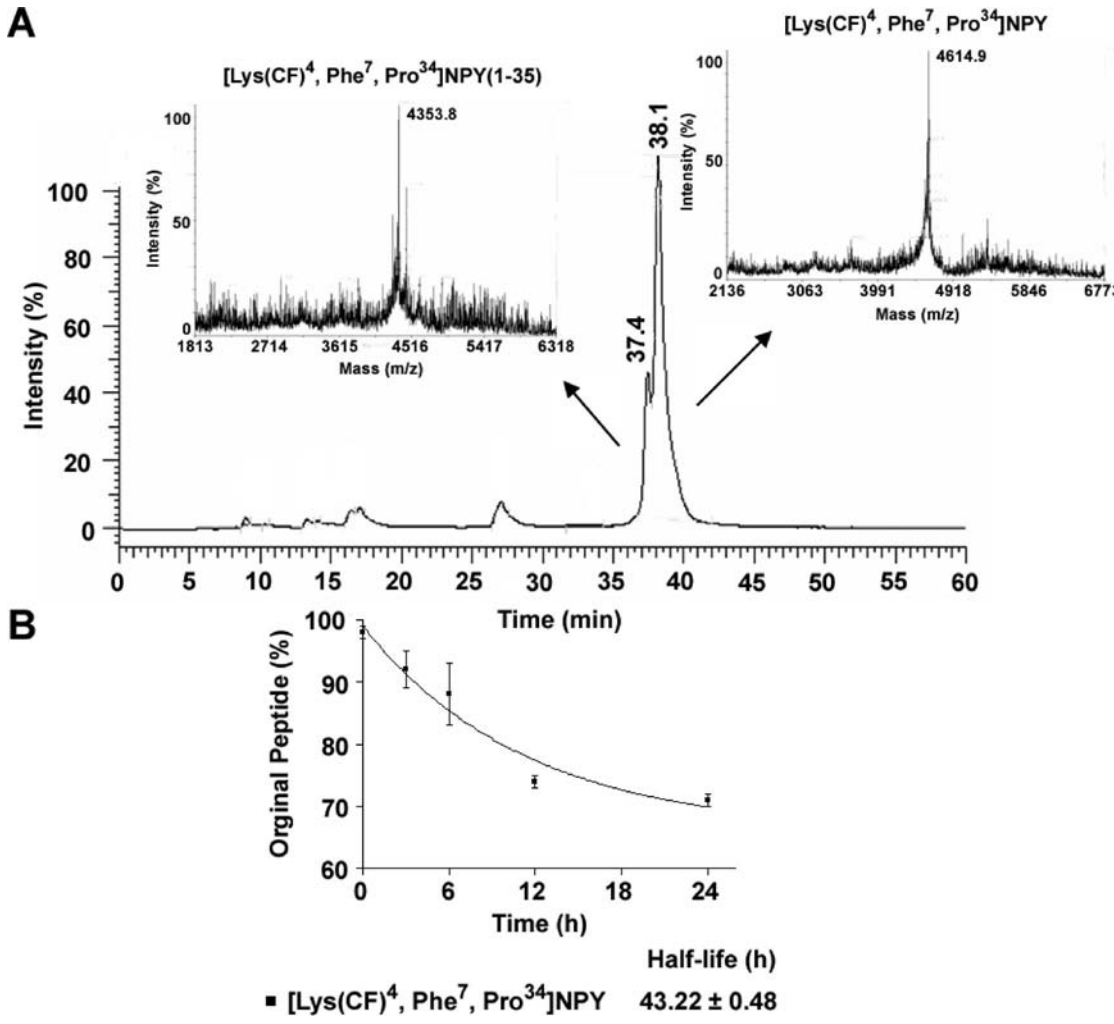

Figure 4. (A) HPLC chromatogram from 20% to 50% ACN in 60 min and MALDI spectra of fluorescence labeled metabolites of [Lys(CF)^4, Phe^7, Pro^{34}]NPY, compound **2d** after 24 h incubation at 37 °C in human blood plasma. (B) Time course of degradation after incubating compound **2d** with blood plasma at 37 °C.

radiolabeling technologies is equally important. For the receptor-based therapeutic radiopharmaceuticals, it is very important to remember that the receptor population is often limited. The use of a large amount of unlabeled bifunctional chelator−biomolecule (BFC-BM) conjugate may block the binding of the radiolabeled BFC-BM conjugate at the receptor sites. Therefore, the BFC must have very high labeling efficiency (fast and high-yield labeling) and form metal complexes with high specific activity. The choice of BFC is largely dependent upon the nature and oxidation state of the metal ion and requires a good understanding of the coordination chemistry of any given radiometal. Another point of fundamental concern in the design of radiometallated peptide constructs is to ensure the *in vivo* stability of the radiometal incorporated by the ligand framework. *In vivo* stability can be controlled by virtue of the high thermodynamic stability and the kinetic inertness of a specific metal chelation framework (*22*–*24*).

Because the DOTA macrocyclic ligand system is well-known to form kinetically inert and thermodynamically stable chelates with indium, yttrium, and lanthanides, it has received wide acceptance for *in vivo* applications with several trivalent radiometals, not only for scintigraphy but also for peptide receptor radionuclide therapy (PRRT) (*25*–*27*). Peptide ligands can be derivatized with DOTA without loss of receptor specificity and binding affinity. Recently, [DOTA^0, Tyr^3]-octreotate, labeled with the β- and γ-particle-emitting radionuclide ^{177}Lu, was reported to be very successful in terms of tumor regression and animal survival in a rat model (*28*).

Bifunctional chelating agents (BFCAs) can be incorporated into peptides by using either the prelabeling or postlabeling approach. In the postlabeling approach, a BFCA is first attached to the peptide and then the radionuclide is coupled to the free chelating group of the BFCA (*29*). This approach can be combined with the advantages of solid-phase peptide synthesis (SPPS). Applying a molar excess of BFCA, complete coupling to the resin-bound peptide can be achieved, and unreacted BFCA is easily washed away. Subsequent cleavage from the resin yields the highly pure BFCA−peptide conjugate.

Accordingly, NPY receptor-selective derivatives on Rink amide resin were synthesized, selectively deprotected N$^\varepsilon$ side chain of Lys^4 by hydrazine in DMF and coupled the BFCA either at the N$^\varepsilon$ side chain of Lys^4 or at the N-terminus, by using the postlabeling approach. Furthermore, by incorporation of Phe^7 and Pro^{34} into NPY sequence, Y_1 receptor subtype selectivity (*19*) and by replacing the sequence (5−24)NPY or (8−20)NPY with the spacer 6-aminohexanoic acid (Ahx), Y_2 receptor subtype selectivity were achieved (*30*). This can be confirmed by the binding data of compounds **2** and **3** determined with SK-N-MC and SMS-KAN cells with (pK_i values 10.3 ± 0.2 vs 7.6 ± 0.1) and (pK_i values 6.8 ± 0.1 vs 9.2 ± 0.3), respectively.

The compounds conjugated with DOTA at the N$^\varepsilon$ side chain of Lys^4 showed higher affinity compared to the N-terminally conjugated compounds with respect to native NPY and the NPY Y_1 receptor selective analogue. These effects could be due to

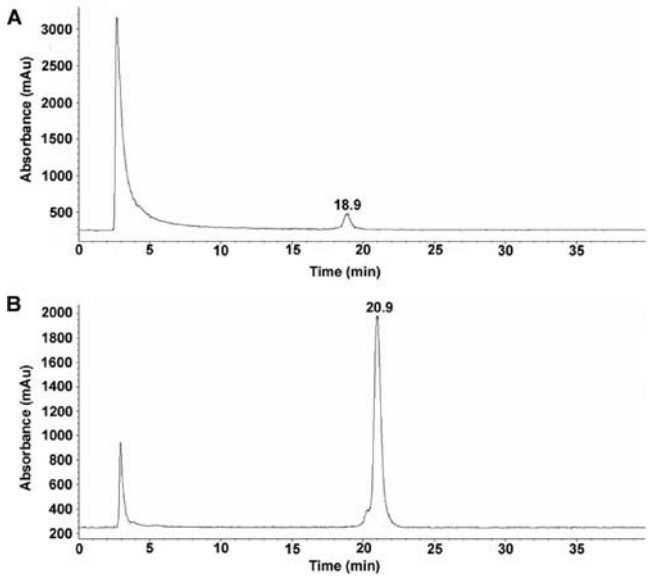

Figure 5. (A) Radio-HPLC chromatogram from 25% to 50% ACN in 30 min of [Lys(^{111}In-DOTA)^4, Phe^7, Pro^{34}]NPY, compound **2g**, after 20 min incubation at 70 °C. The radio-HPLC chromatogram shows a radiochemical yield of only 6%. (B) Radio-HPLC chromatogram from 25% to 50% ACN in 30 min of [Lys(^{111}In-DOTA)^4, Phe^7, Pro^{34}]NPY, compound **2g**, after 15 min incubation at 75 °C. The radio-HPLC chromatogram shows a radiochemical yield of 80%.

less steric hindrance encountered by more spatial availability of the N-terminus produced by labeling of the chelator at the N$^\epsilon$ side chain of Lys^4. Our results show that N-terminal flexibility is a crucial factor for the interaction of the bioconjugate with the receptor. Otherwise, the N-terminally DOTA-conjugated NPY Y_2 receptor selective analogue showed higher affinity than that conjugated at the N$^\epsilon$ side chain of Lys^4. These data can be explained by the reduced influence of the truncated N-terminus of [Ahx$^{5-24}$]NPY in receptor binding compared to NPY or [Phe^7, Pro^{34}]NPY.

Carboxyfluorescein possesses two carboxyl groups as possible reaction centers, the intrinsic carboxyl group of fluorescein in position 2 and the additional carboxyl group in position 4(5). Since the fluorescence-properties of fluorescein depend on the presence of the free carboxyl-group in position 2, this group has to remain unmodified during reaction. Our data show that the peptides labeled with CF at the N-terminus showed mostly higher affinity compared to the CF-labeling at the N$^\epsilon$ side chain of Lys^4. This also suggests that the type of modifier is involved in the Y-receptor−ligand interaction.

A metabolic stability study in human blood plasma of [Lys(CF)^4, Phe^7, Pro^{34}]NPY was performed. The peptide was found to be enzymatically more stable than native NPY (half-life of 24.66 ± 1.38 h) *in vitro* (*31*). In addition, only one main cleavage product [Lys(CF)^4, Phe^7, Pro^{34}]NPY(1−35) could be detected after 24 h incubation (*31*).

Furthermore, first results of the *in vivo* behavior of the Y_1 receptor selective neuropeptide Y (NPY) analogue [Phe^7, Pro^{34}]NPY could be obtained. Our data show that [Lys-(DOTA)^4, Phe^7, Pro^{34}]NPY was successfully labeled with ^{111}In at 75 °C for 15 min with a radiochemical yield of 80%. In contrast, by using a temperature of 70 °C and an incubation time of 20 min only a radiochemical yield of 6% could be observed. This result suggests that higher reaction temperatures could lead to more flexibility of the cage-like structure of DOTA followed by a better complexation of ^{111}In. However, higher temperatures could lead to degradation of the peptide. Different retention times in radio-HPLC (20.9 min vs 18.9 min) could be explained by distinct concentrations of the unlabeled peptide.

In the past, strong predominance of the Y_1 receptor subtype was shown in breast carcinomas (*9*). Thus, the nude mice for the biodistribution study were inoculated with the Y_1 receptor expressing MCF-7 breast cancer cell line. Our results demonstrate a high accumulation of the ^{111}In-DOTA-labeled [Phe^7, Pro^{34}]NPY in the kidney with 86.8% ID/g after 4 h. This is a common phenomenon for radiometal-chelated peptides, especially for peptides with DOTA as BFC (*32*). On the other hand, our biodistribution results show a low tumor uptake of the peptide with 1.7% ID/g after 30 min. These data indicate that the interaction between the ^{111}In-labeled peptide and the breast cancer tumor, which expresses the Y_1 receptor subtype, was disturbed by the faster accumulation in the kidney. Another reason for the low tumor uptake could be the lack of separation of the unlabeled peptide, which might have resulted in binding competition of the unlabeled and ^{111}In-labeled peptide *in vivo*. Moreover, it has been shown that the native ligand NPY exhibits rapid proteolysis in humans with a half-life of only 4 min (*33*). The differences between the metabolic stability in the body

and the blood can be confirmed by our results of the fast degradation of the ^{111}In-DOTA-labeled [Phe^7, Pro^{34}]NPY in mice compared to the half-life of [Lys(CF)^4, Phe^7, Pro^{34}]NPY in human blood plasma. The development of metabolically more stable NPY analogues is a crucial step for radiopharmaceutical application.However, Y_1 receptor selective NPY analogues show good capability for future applications in tumor targeting and therapy, confirmed by some tumor uptake of [Lys(^{111}In-DOTA)^4, Phe^7, Pro^{34}]NPY.

Accordingly, we clearly could demonstrate a novel application of modified BFCA-conjugated NPY Y_1/Y_2 receptor selective analogues. Competitive binding assays showed surprisingly high affinity to the desired receptors. Based on structure−activity relationships of NPY, we found potential candidates for metal complexation. By using SPPS, stable, well-defined BFCA DOTA conjugated analogues for Ga or In and ^{111}In complexation were synthesized. These analogues are stable and selectively maintained the binding with the desired receptor. Our data show that, in spite of replacement/substitution of amino acids, introduction of spacer, and incorporation of an organometallic moiety, the binding potency of the ligand at the receptor was only slightly influenced. Moreover, the *in vivo* data show the possibility of using NPY Y_1 receptor selective analogues for future applications in tumor therapy and diagnosis, because some, although still low, tumor uptake in MCF-7 tumor-bearing mice was observed. Our *in vitro* and *in vivo* data demonstrate that modified NPY analogues are expandable candidates for further developments in the field of tumor targeting.

Novel Bimodal Bifunctional Ligands for Radioimmunotherapy and Targeted MRI

Hyun-Soon Chong,*,† Hyun A. Song,† Xiang Ma,† Diane E. Milenic,‡ Erik D. Brady,‡ Sooyoun Lim,† Haisung Lee,† Kwamena Baidoo,‡ Dengfeng Cheng,† and Martin W. Brechbiel‡

Chemistry Division, Biological, Chemical, and Physical Sciences Department, Illinois Institute of Technology, Chicago, Illinois, Radioimmune and Inorganic Chemistry Section, Radiation Oncology Branch, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, Maryland. Received February 8, 2008; Revised Manuscript Received April 22, 2008

The structurally novel bifunctional ligands *C*-NETA and *C*-NE3TA, each possessing both acyclic and macrocyclic moieties, were prepared and evaluated as potential chelates for radioimmunotherapy (RIT) and targeted magnetic resonance imaging (MRI). Heptadentate *C*-NE3TA was fortuitously discovered during the preparation of *C*-NETA. An optimized synthetic method to *C*-NETA and *C*-NE3TA including purification of the polar and tailing reaction intermediates, *tert*-butyl *C*-NETA (**2**) and *tert*-butyl *C*-NE3TA (**3**) using semiprep HPLC was developed. The new Gd(III) complexes of *C*-NETA and *C*-NE3TA were prepared as contrast enhancement agents for use in targeted MRI. The T_1 relaxivity data indicate that Gd(*C*-NETA) and Gd(*C*-NE3TA) possess higher relaxivity than Gd(*C*-DOTA), a bifunctional version of a commercially available MRI contrast agent; Gd(DOTA). *C*-NETA and *C*-NE3TA were radiolabeled with ^{177}Lu, ^{90}Y, ^{203}Pb, $^{205/6}$Bi, and ^{153}Gd; and *in vitro* stability of the radiolabeled corresponding complexes was assessed in human serum. The *in vitro* studies indicate that the evaluated radiolabeled complexes were stable in serum for 11 days with the exception being the ^{203}Pb complexes of *C*-NETA and *C*-NE3TA, which dissociated in serum. *C*-NETA and *C*-NE3TA radiolabeled ^{177}Lu, ^{90}Y, or ^{153}Gd complexes were further evaluated for *in vivo* stability in athymic mice and possess excellent or acceptable *in vivo* biodistribution profile. $^{205/6}$Bi-*C*-NE3TA exhibited extremely rapid blood clearance and low radioactivity level at the normal organs, while $^{205/6}$Bi-*C*-NETA displayed low radioactivity level in the blood and all of the organs except for the kidney where relatively high renal uptake of radioactivity is observed. *C*-NETA and *C*-NE3TA were further modified for conjugation to the monoclonal antibody Trastuzumab.

INTRODUCTION

Radioimmunotherapy (RIT) (*1*) and magnetic resonance imaging (MRI) (*2*) are promising techniques for targeted treatment or imaging of numerous cancer types. Both modalities require the use of either radioactive or nonradioactive metals, either of which can be very toxic when deposited in normal tissues *in vivo*, causing life-threatening side effects (*3*). Therefore, the success of clinical applications of both RIT and MRI depends heavily on the performance of the metal-binding ligands. RIT employs a monoclonal antibody (mAb) for selective delivery of a cytotoxic radionuclide to tumor cells while minimizing toxicity due to nonselective exposure of the radionuclide to the normal healthy cells (*4, 5*). The RIT scenario requires three components: a radionuclide, a mAb, and a bifunctional ligand (*6*). The first RIT drug, Zevalin, consists of an anti-CD20 antibody, 1B4M-DTPA (2-(4-nitrobenzyl)-6-methyl-diethylenetriaminepentaacetic acid), and ^{90}Y, and has proven to have significant potency against B-cell non-Hodgkin's lymphoma (*7, 8*). The radionuclides ^{177}Lu, ^{90}Y, ^{212}Pb, ^{212}Bi, and ^{213}Bi are all recognized as promising metallic radionuclides for effective RIT (*5, 6*). An effective bifunctional ligand conjugated to a sensitive mAb that can rapidly form a stable complex with a short-lived radionuclide must be employed to minimize toxicity due to either dissociation of metal complex or radiolytic damage resulting from extended exposure of the protein during radiolabeling (*9–11*). Although numerous RIT using the radioisotopes have been explored to treatment of various cancers, less progress has been made on development of new bifunctional ligands that might address limitations of the currently available bifunctional ligands, *C*-DOTA (2-(4-nitrobenzyl)-1,4,7,10-tetraazacyclododecane tetraacetic acid) and *C*-DTPA (2-(4-nitrobenzyl)-diethylenetriamine pentaacetic acid), that are related to slow complexation kinetics and low complex stability, respectively (*12*).

MRI is a powerful diagnostic medical tool that provides noninvasive and high-resolution imaging for a variety of applications (*2, 13*). MRI gives distribution of the MR signal intensity resulting from the longitudinal (T_1) and the transverse (T_2) magnetic relaxation times of water protons. Images with a clear contrast between tissues with different relaxation times of water protons can be obtained with MRI (*2*). The lanthanide Gd(III) is known to be an optimal paramagnetic metal for MRI due to high electronic spin (7/2) and slow electronic relaxation rate (*14*). Stable Gd(III) complexes with low toxicity and efficient excretion profiles are required for *in vivo* use since free Gd(III) is toxic causing severe side effects (*15*). A number of Gd(III) complexes such as Gd(DOTA) and Gd(DTPA) are clinically approved for use in MRI (*2*). However, most contrast agents have nonspecific extracellular distribution and the disadvantages of low relaxivity, low tissue specificity, and rapid clearance. Considerable research efforts have been directed toward developing safe Gd(III)-based MR contrast agents with high tissue specificity and sensitivity. Development of bifunctional

ligands with a functional unit for conjugation to a targeting moiety that can tightly sequester Gd(III) is required for targeted MRI with high sensitivity and specificity.

Previously, we reported NETA to be a promising chelate for RIT and MRI applications (*16*–*18*). The bimodal ligand NETA ({4-[2-(bis-carboxymethyl-amino)-ethyl]-7-carboxymethyl-[1,4,7]triazonan-1-yl}-acetic acid) possesses a parent macrocyclic ligand and a flexible acyclic multidentate pendant arm and is designed to integrate the advantages of the macrocyclic DOTA (1,4,7,10-tetraazacyclododecane-tetraacetic acid) and acyclic DTPA (diethylenetriaminepenta acetic acid) frameworks and with this hybridization to provide high thermodynamic stability and favorable formation kinetics for complexation of metal ions of interest. Indeed, nonfunctionalized NETA displayed significantly enhanced complexation kinetics with Y(III) (*16*), Lu(III) (*19*), and Bi(III) (*19*) as compared to DOTA. The NETA complexes radiolabeled with ^{90}Y (*16*), ^{177}Lu (*17*), or ^{153}Gd (*18*) exhibited excellent *in vitro* serum stability and demonstrated excellent or acceptable *in vivo* biodistribution profiles. NETA was also evaluated as the chelate of Gd(III) for MRI. NETA-Gd(III) complex displayed enhanced relaxivity comparable to that of DOTA-Gd(III) (*18*). NETA radiolabeled with ^{153}Gd was exceptionally stable in serum and mice (*18*). With the proven potential of NETA for RIT and MRI, we have moved forward with synthesis of a bifunctional version of NETA and NETA analogue possessing a linker for conjugation to a targeting moiety for RIT and for targeted MRI. In this paper, we describe the synthesis and evaluation of a bifunctional version of NETA, *C*-NETA ({4-[2-(bis-carboxymethyl-amino)-3-(4-nitro-phenyl)-propyl]-7-carboxymethyl[1,4,7]triazonan-1-yl}-acetic acid) and its heptadentate analogue *C*-NE3TA ({4-carboxymethyl-7-[2-(carboxymethyl-amino)-3-(4-nitro-phenyl)-propyl]-[1,4,7]triazo-nan-1-yl}-acetic acid) for RIT and MRI.

EXPERIMENTAL PROCEDURES

Instruments and Methods. ^{1}H and ^{13}C NMR spectra were obtained using a Bruker 300 MHz instrument and chemical shifts are reported in ppm on the δ scale relative to TMS, TSP, or solvent. Elemental microanalyses were performed by Galbraith Laboratories, Knoxville, TN. Fast atom bombardment (FAB) high-resolution mass spectra (HRMS) were obtained on JEOL double sector JMS-AX505HA mass spectrometer (University of Notre Dame, IN). Analytical HPLC was performed on Agilent 1200 instrument (Agilent, Santa Clara, CA) equipped with a diode array detector (λ = 254 and 280 nm), thermostat set at 35 °C, and a Zorbax Eclipse XDB-C18 column (4.6 × 150 mm, 80Å, Agilent, Santa Clara, CA). The mobile phase of a binary gradient (0−100% B/40 min; solvent A = 0.05 M AcOH/Et_3N, pH 6.0; solvent B = CH_3CN for method 1) or solvent A = 0.05 M AcOH/Et_3N, pH 6.0; solvent B = CH_3OH for method 2; (0−50% B/30 min solvent A = 0.05 M AcOH/Et_3N, pH 6.0; solvent *B* = CH_3OH for method 5) or a binary gradient and isocratic (0−100% B/40 min and 100% B/40−50min; solvent A = 0.05 M AcOH/Et_3N, pH 6.0; solvent B = CH_3CN for method 6) at a flow rate of 1 mL/min was used. Semiprep HPLC was performed on an Agilent 1200 equipped with a diode array detector (λ = 254 and 280 nm), thermostat set at 35 °C, and a Zorbax Eclipse XDB-C18 column (9.4 × 250 mm, 80 Å). The mobile phase of a binary gradient (0−100% B/160 min; solvent A = 0.05 M AcOH/Et_3N, pH 6.0; solvent B = CH_3CN for method 3 or 0−50% B/30 min, solvent A = H_2O; solvent B = methanol for method 4) at a flow rate of 3 mL/min was used. Size exclusion HPLC (SE-HPLC) chromatograms were obtained on a Laboratory Alliance isocratic system (model: QGrad, State College, PA) with a Waters 717plus autosampler (Milford, MA), a Gilson 112 UV detector (Middleton, WI), and an in-line IN/US γ-Ram model 2 radiodetector (Tampa, FL), fitted with a TSK G3000PW column (Tosoh Biosep, Montgomeryville, PA).

Reagents. All reagents were purchased from Sigma-Aldrich (St. Louis, MO) and used as received unless otherwise noted. Phosphate buffered saline (PBS), 1×, pH 7.4, consisted of 0.08 M Na_2HPO_4, 0.02 M KH_2PO_4, 0.01 M KCl, and 0.14 M NaCl. ^{90}Y in the chloride form was purchased from Perkin-Elmer Life Sciences (Shelton, CT). ^{177}Lu in the chloride form was obtained from NEN Perkin-Elmer. ^{86}Y,^{205,6}Bi, and ^{203}Pb were produced using a CS30 cyclotron (PET Dept, Clinical Center, NIH) and purified as described previously (*17*, *18*). *C*-DOTA was purchased from Macrocyclics (Dallas, TX). ^{153}Gd was obtained from Isotope products (Valencia, CA). ^{157}Gd and ^{115}In were obtained from Sigma-Aldrich (St. Louis, MO).

***tert*-Butyl {4-*tert*-Butoxycarbonylmethyl-7-[2-(*tert*-butoxycarbonylmethyl-amino)-3-(4-nitrophenyl)-propyl]-[1,4,7]triazonan-1-yl}-acetic Acetate (3).** To a slurry of **1** (*26*) as an acidic salt (2.27 g, 5 mmol) in DMF (50 mL) at 0 °C was added DIPEA (6.5 g, 50.25 mmol) and KI (996 mg, 6 mmol). *tert*-Butyl bromoacetate (3.22 g, 16.5 mmol) was added dropwise over 20 min. The resulting mixture was stirred for 2 h at 0 °C and for 2 h at room temperature. The reaction mixture was heated to 50 °C and stirred for 19 h after which time the reaction mixture was cooled to room temperature and then to 0 °C. 6 M HCl (3.5 mL) and heptane (30 mL) were sequentially added to the solution. The resulting solution was vigorously stirred for 5 min, and the heptane layer was separated. The aqueous layer was extracted with heptane (2 × 30 mL), and treated with 10% Na_2CO_3 (45 mL). Additional heptane (30 mL) was added into the aqueous solution, the resulting mixture was stirred for 30 min, and the heptane layer was separated. The combined heptane layers were washed with water (10 mL), dried ($MgSO_4$), filtered, and concentrated *in vacuo*. The residue was eluted on a silica gel (220−400 mesh) column with 20−30% CH_3OH/CH_2Cl_2 and 0.5 mL Et_3N in 20−30% CH_3OH/CH_2Cl_2 starting from CH_2Cl_2 to provide pure **3** (2.21 g, 68%): ^{1}H NMR ($CDCl_3$) δ 1.41 (s, 27 H), 2.30−2.52 (m, 2 H), 2.63−2.94 (m, 15 H), 3.20−3.36 (m, 6 H), 7.36 (d, J = 8.01 Hz, 2 H), 8.15 (d, J = 8.01 Hz, 2 H); ^{13}C NMR ($CDCl_3$) δ 28.98, 28.09, 39.32, 49.83, 55.84, 56.04, 56.92, 59.48, 62.62, 80.36, 80.76, 123.32, 130.11, 146.36, 147.47, 171.07, 171.40; HRMS (positive ion FAB): Calcd for $C_{33}H_{56}N_5O_8$ $[M+H]^+$ *m*/*z* 650.4129. Found: $[M+H]^+$ *m*/*z* 650.4110. Analytical HPLC (t_R = 32.6 min, method 6). Isolation of **3** from the reaction mixture was achieved using semiprep HPLC (method 3). The mixture was dissolved in 1 mL of CH_3OH, and the fractions from 79−101 min were collected, evaporated, dissolved in CH_2Cl_2, treated with H_2O, and adjusted to pH 7. The organic layer was dried, filtered, evaporated, and concentrated *in vacuo* to afford the desired **3**.

{4-Carboxymethyl-7-[2-(carboxymethyl-amino)-3-(4-nitrophenyl)-propyl]-[1,4,7]triazonan-1-yl}-acetic Acid (C-NE3TA). Compound **3** (60 mg, 0.09 mmol) was treated with 4 M HCl in 1,4-dioxane (5 mL) at 0 °C. The resulting mixture was gradually warmed to room temperature and stirred for 24 h. Diethyl ether (100 mL) was added into the reaction mixture, and the resulting mixture was placed in the freezer for 2 h. The precipitate was filtered, immediately dissolved in water (10 mL), and washed with diethyl ether (20 mL). The aqueous layer was lyophilized to provide pure *C*-NE3TA as a light brownish solid (54 mg, 95%): ^{1}H NMR (D_2O) δ 2.42−2.60 (m, 1 H), 2.80−3.39 (m, 14 H), 3.68−3.92 (m, 8 H), 7.45 (d, J = 7.9 Hz, 2 H), 8.16 (d, J = 7.9 Hz, 2 H); ^{13}C NMR (D_2O) δ 36.6, 47.5, 51.4, 52.3, 54.3, 58.6, 61.1, 126.8, 132.9, 145.7, 149.6, 171.6, 174.0. HRMS (positive ion FAB): Calcd for $C_{21}H_{32}N_5O_8$ $[M+H]^+$ *m*/*z* 482.2251. Found: $[M+H]^+$ *m*/*z* 482.2274. Analytical HPLC (t_R = 9.96 min, method 2).

***tert*-Butyl {4-[3-(4-Aminophenyl)-2-(bis-*tert*-butoxycarbonylmethylamino)-propyl]-7-*tert*-butoxycarbonylmethyl-[1,4,7]triazanonan-1-yl}-acetate (4).** To a solution of **2** (*26*) (90 mg, 0.12 mmol) in MeOH (10 mL) was added 10% Pd/C catalyst (20 mg). The resulting mixture was subjected to hydrogenolysis by agitation with excess H_2 (g) at 15 psi in a Parr hydrogenator apparatus at ambient temperature for 14 h. The reaction mixture was filtered through Celite, and the filtrate was concentrated *in vacuo* to provide pure **4** (81 mg, 92%). ^{1}H NMR ($CDCl_3$) δ 1.42 (s, 9 H), 1.44 (s, 18 H), 1.47 (s, 9 H), 2.02−2.60 (m, 5 H), 2.65−2.96 (m, 12 H), 3.30−3.80 (m, 8 H), 6.60 (d, 2 H), 6.91 (d, 2 H); ^{13}C NMR ($CDCl_3$) 28.1, 34.7, 51.6, 52.2, 53.0, 53.2, 56.8, 57.7, 60.2, 80.5, 80.7, 115.2, 128.9, 129.9, 144.3, 170.0, 170.6, 170.8. HRMS (positive ion FAB): Calcd for $C_{39}H_{67}N_5O_8$ $[M+H]^+$ *m/z* 734.5068. Found: $[M+H]^+$ *m/z* 734.5029. Analytical HPLC (t_R = 29.82 min, method 1).

***tert*-Butyl {4-[3-(4-Aminophenyl)-2-(*tert*-butoxycarbonylmethylamino)-propyl]-7-*tert*-butoxycarbonylmethyl-[1,4,7]triazonan-1-yl}-acetate (5).** To a solution of **3** (180 mg, 0.28 mmol) in MeOH (20 mL) was added 10% Pd/C catalyst (36 mg). Compound **5** (167 mg, 97%) was isolated using the same procedure described for synthesis of **4**. ^{1}H NMR ($CDCl_3$) δ 1.37−1.50 (m, 36 H), 2.24−2.49 (m, 5 H), 2.61−2.94 (m, 12 H), 3.28−3.47 (m, 8 H), 6.60 (d, 2 H), 6.92 (d, 2 H); ^{13}C NMR ($CDCl_3$) 28.05, 28.15, 38.23, 49.53, 55.09, 55.41, 56.74, 59.11, 62.23, 80.60, 80.75, 115.19, 128.38, 129.91, 144.76, 171.16, 171.41; HRMS (positive ion FAB): Calcd for $C_{33}H_{58}N_5O_6$ $[M+H]^+$ *m/z* 620.4387. Found: $[M+H]^+$ *m/z* 620.4385. Analytical HPLC (t_R = 29.82 min, method 1).

{4-[3-(4-Aminophenyl)-2-(bis-carboxymethyl-amino)-propyl]-7-carboxymethyl-[1,4,7]triazanonan-1-yl}-acetic Acid (6). Compound **4** (50 mg, 0.07 mmol) was treated with 4 M HCl in 1,4-dioxane (5 mL) at 0 °C. The resulting solution was lyophilized to provide pure **6** as a pale yellow solid (44 mg, 93%): ^{1}H NMR (D_2O) δ 2.90−3.20 (m, 6 H), 3.30−3.57 (m, 11 H), 3.72 (t, 2 H), 3.92−4.22 (m, 7 H), 4.39 (d, 1 H), 7.37 (dd, 4 H); ^{13}C NMR (D_2O) δ 33.5, 48.5, 50.2, 50.7, 51.0, 52.0, 52.7, 52.91, 53.4, 53.9, 55.9, 60.8, 123.7, 129.3, 131.0, 135.6. HRMS (positive ion FAB): Calcd for $C_{23}H_{36}N_8O_8$ $[M+H]^+$ *m/z* 510.2587. Found: $[M+H]^+$ *m/z* 510.2564. Analytical HPLC (t_R = 5.45 min, method 2; t_R = 4.74 min, method 1).

{4-[3-(4-Amino-phenyl)-2-(carboxymethylamino)-propyl]-7-carboxymethyl-[1,4,7]triazonan-1-yl}-acetic Acid (7). Compound **5** (55 mg, 0.09 mmol) was treated with 4 M HCl in 1,4-dioxane (5 mL) at 0 °C. Compound **7** (48 mg, 97%) was obtained using the same procedure described for **6**. ^{1}H NMR (D_2O) δ 2.42−2.53 (m, 2 H), 2.75−3.22 (m, 14 H), 3.51 (s, 1 H), 3.75−3.95 (m, 8 H), 7.29 (dd, 4 H); ^{13}C NMR (D_2O) δ 33.7, 44.9, 48.7, 49.5, 50.9, 51.6, 55.9, 56.3, 56.7, 58.7, 123.7, 129.1, 130.8, 136.4, 169.1, 171.1, 171.8. HRMS (positive ion FAB): Calcd for $C_{21}H_{34}N_5O_6$ $[M+H]^+$ *m/z* 452.2509. Found: $[M+H]^+$ *m/z* 452.2491. Analytical HPLC (t_R = 1.70 min, method 2).

{4-[2-(Bis-carboxymethyl-amino)-3-(4-isothiocyanatophenyl)propyl]-7-carboxymethyl-[1,4,7]triazanonan-1-yl}-acetic Acid (8). To a solution of **6** (20 mg, 0.031 mmol) in water (2 mL) was added a 1 M solution of thiophosgene in $CHCl_3$ (0.39 mL). The resulting mixture was stirred for 4 h at room temperature. The aqueous layer was decanted, and the $CHCl_3$ layer was separated and washed with water (2 × 1 mL). The combined aqueous layers were lyophilized to provide **8** as a pale yellow solid (18 mg, 85%): ^{1}H NMR (D_2O) δ 2.95−4.40 (m, 27 H), 7.18−7.42 (s, 4 H). HRMS (positive ion FAB): Calcd for $C_{24}H_{34}N_5O_8S$ $[M+H]^+$ *m/z* 552.2117. Found: $[M+H]^+$ *m/z* 552.2128. Analytical HPLC (t_R = 14.56 min, method 2).

{4-Carboxymethyl-7-[2-(carboxymethylamino)-3-(4-isothiocyanatophenyl)-propyl]-[1,4,7] triazonan-1-yl}-acetic Acid (9). To a solution of **7** (20 mg, 0.031 mmol) in water (2 mL) was added a 1 M solution of thiophosgene in $CHCl_3$ (0.39 mL). Compound **9** (19 mg, 88%) was isolated using the same procedure described for **3**. ^{1}H NMR (D_2O) δ 2.52−2.60 (m, 2 H), 2.85−3.32 (m, 15 H), 3.74−3.88 (m, 8 H), 7.21 (dd, 4 H). HRMS (positive ion FAB): Calcd for $C_{22}H_{32}N_5O_6S$ $[M+H]^+$ *m/z* 494.2073 Found: $[M+H]^+$ *m/z* 494.2081. Analytical HPLC (t_R = 16.0 min, method 1).

General Procedure for the Preparation of Gd(III) Complexes (C-DOTA, C-NETA, or C-NE3TA). The Gd^{3+} complexes were prepared by reacting the aqueous solution of the appropriate ligand (2 mM, 1 mL, *C*-NETA, *C*-NE3TA, or *C*-DOTA) and $GdCl_3$ (2 mM, 0.9 mL) at a 1:0.9 mol ratio at 90 °C overnight, and the pH of the resulting solution was adjusted to ∼7 using 1 M NaOH. No unbound Gd(III) was detected in the solution as evidenced by AAIII assay and TLC analysis. The Gd complexes were purified using semi-HPLC (method 4). Fractions centered at 20.4, 18.0, and 14.5−15.1 min were collected to provide the Gd(III) complexes of *C*-NETA, *C*-NE3TA, and *C*-DOTA, respectively. Analytical HPLC of the isolated complexes (method 5) was performed, and the data were compared to those of free ligands (Gd-*C*-NETA, t_R = 20.4 min; Gd-*C*-NE3TA, t_R = 18.0 min; Gd-*C*-DOTA, t_R = 15.4 min; *C*-NETA, t_R = 11.2 min; *C*-NE3TA, t_R = 14.2 min; *C*-DOTA, t_R = 21.6 min).

Procedure for Detection of Free Gd(III) Using AAIII Assay. AAIII assay was used for the determination of the free Gd(III) in the complex solution (*27*). A solution of AAIII (10 μM) was prepared in the acetate buffer (NH_4OAc, 0.15 M, pH 7). Droplets of AAIII (100 μL) were arranged in a 96 well plate, and a droplet of reaction mixture (5 μL) was added to AAIII solution in each well. The presence of free Gd(III) was indicated by the immediate color change from pink to green.

ICP-MS. To verify the concentration of Gd(III) in the purified complexes, ICP-MS was performed using a computer-controlled Thermo Elemental (now Thermo Fisher) PQ ExCell inductively coupled plasma mass spectrometer. Samples were prepared by nitric acid digestion (9:1 nitric acid:sample) in a 65 °C water bath. The digested samples were diluted into 15 mL conical vials with a final concentration of 3% (v/v) nitric acid. Gd(III) standards were prepared in 3% (v/v) nitric acid with values 0.1, 0.25, 0.5, 1, 5, 10, 25, and 50 ng/mL Gd(III). Indium was spiked into every sample (including standards) for a final indium concentration of 5 ng/mL. Isotopes ^{157}Gd and ^{115}In were used for determination.

Relaxivity Measurements. Relaxivity measurements were acquired by taking the slope of a plot of $1/T_1$ (s^{-1}) versus concentration (mM). The longitudinal water proton relaxation times (T_1) were determined using a Bruker mq60 NMR (Bruker Canada, Milton, ON, Canada) analyzer operating at 59.97 MHz and 37 °C. The agent was added to Millipore water and serially diluted by 0.5 to give a series of 5 concentrations (500 μL total volume) for each relaxivity trial. The T_1 relaxivity was determined using an inversion recovery pulse sequence with 10 different pulse separations per sample, 4 repetitions per echo time, phase cycling, and a recycle delay that is ≥5 times the T_1 of each given sample. All curves were fit using a monoexponential curve fitting formula.

Radiolabeling of Ligands. Each of the radionuclides (1−3 mCi in 10−20 μL of 0.1 M HCl solution) was added to 100 μL of 0.15 M NH_4OAc buffer solution (pH 4.5). 5 M NH_4OAc (pH 7.3) was added as needed to adjust pH to 4.5, and the volume of the solution was brought up to 200 μL. Separate tubes containing 7 μmol of each of the ligands were prepared, and the solids were dissolved in 200 μL of NH_4OAc (pH 4.5). The ligand solution was added to the radionuclide solution and the resulting tube was capped. The reactions were heated at 80 °C

[a] The data were cited for comparison (*26*).

for 12 h, after which they were loaded onto a column of Chelex-100 resin (100−200 mesh, Na^+ form, Biorad, Richmond, CA; 1 mL volume bed, equilibrated with PBS, pH 7.4). The complexes were eluted from the resin with PBS, pH 7.4, while the resin retained the free metals.

***In Vitro* Stability of the Radiolabeled Metal Complexes.** The stability of the purified radiolabeled complexes was evaluated in human serum (Gemini Bioproducts, Woodland, CA) for up to 11 days (Table 1). The serum stability of the radiolabeled complexes was assessed by measuring the transfer of the radionuclide from each complex to serum proteins using SE-HPLC methods. Radiolabeled complexes were diluted to an appropriate volume that allowed for preparation of multiple samples containing 5−10 μCi and were filter-sterilized using a Millex-GV 0.22 μm filter. This stock solution was then mixed with 1400 μL of sterile normal human serum. Aliquots (200 μL) were drawn and separated into individual tubes for subsequent analysis using aseptic technique. The samples were incubated at 37 °C, and at designated intervals, subjected to analysis by SE-HPLC. Samples were loaded onto the HPLC and eluted with PBS, pH 7.4 isocratically at 1 mL/min. Radioactivity still associated with the chelate typically displayed a retention time of ∼8.5 min at this flow rate. Radioactivity associated with a transfer to serum proteins generally appeared at ∼6 min.

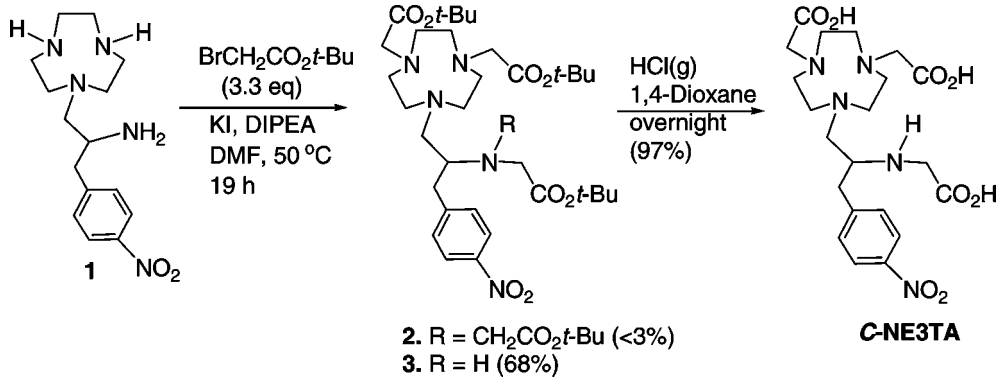
***In Vivo* Biodistribution Studies of the Radiolabeled Metal Complexes.** Female athymic mice were obtained from Charles River Laboratories (Wilmington, MA) at 4−6 weeks of age. The pH of the radiolabeled ligands was adjusted to pH ∼7.0 with 0.5 M sodium bicarbonate (pH 10.5) and diluted in phosphate-buffered saline. The radiolabeled ligands (5−10 μCi for ^{86}Y, $^{205/6}$Bi, ^{177}Lu, and ^{203}Pb) were administered to the mice in 200 μL of solution *via* tail vein injection. The mice (5 per data point) were sacrificed by exsanguination at 0.5, 1, 4, 8, and 24 h. Blood and the major organs were harvested, wet-weighed, and the radioactivity measured in a γ-scintillation counter (1480 Wizard, Perkin-Elmer). The percent injected dose per gram (% ID/g) was determined for each tissue. The values presented are the mean and standard deviation for each tissue. All animal experiments were performed in compliance with current regulations and guidelines of the U.S. Dept. of Agriculture and approved by the NCI Animal Care and Use Committee.

General Procedure for Spectroscopic Determination of Ligand to Protein Ratio. A stock solution of the Cu(II)-AAIII reagent was prepared in 0.15 M NH_4OAc, pH 7.0, by adding an aliquot of a 5.00×10^{-4} M Cu(II) atomic absorption solution (to afford a 5 μM solution of copper) to a 10 μM solution of arsenazo III. This solution was stored in the dark to avoid degradation over time. A UV/vis spectrometer was zeroed against a cuvette filled with 1.0 mL of a 0.15 M NH_4OAc solution at pH 7.0 with a window open from 250 to 700 nm. The acetate solution was removed and replaced with 1.0 mL of the Cu(II)-AAIII reagent, a spectrum was collected, and the absorbance values at 280 and 652 nm noted. 50 μL of the Cu(II)-AAIII reagent were removed and discarded. The ligand−antibody conjugate of interest was added (50 μL) and the spectrum was immediately collected. Spectra were then collected periodically until no further change was noted for the peaks at 280 and 652 nm (less than 30 min for the Cu(II)-AAIII reagent with the ligands detailed in this paper). A series of calculations detailed in the discussion allow for the determination of the concentration of ligand in the sample.

Spectroscopic Determination of Ligand to Protein Ratio. All absorbance measurements were obtained on an Agilent 8453 diode array spectrophotometer equipped with a 8-cell transport system (designed for 1 cm cells). Metal-free stock solutions of all buffers were prepared using Chelex-100 resin (100−200 mesh, Bio-Rad Laboratory, Hercules, CA). Chelex resin (5 g) was added into the buffer solution (500 mL) and the mixture was shaken for 1 h in a shaker, stored in the refrigerator overnight, and filtered through a Corning filter system (#430513, pore size 0.2 μM). Disposable PD-10 Sephadex G-25 M columns (GE Healthcare, Piscataway, NJ) were rinsed with 25 mL of the appropriate buffer prior to addition of antibody or its ligand conjugates. Centricon C-50 (50 000 MWCO) Centrifugal Filter Devices were purchased from Amicon Bioseparations (Millipore, Bedford, MA) and were rinsed several times with DI H_2O prior to use. Trastuzumab was purchased from Genentech Inc. (South San Fransico, CA). The initial concentration of Trastuzumab was determined by the Lowry method (*24*). Phosphate buffered saline (PBS) was purchased from Gibco as a 1× solution at pH 7.4 and was used as received. Ammonium acetate (0.15 M, pH 7.0, and 0.15 M, pH 4.5), bicarbonate buffer (50 mM $NaHCO_3$, 150 mM NaCl, 10 mM EDTA, pH 8.5), and conjugation buffer (50 mM HEPES, 150 mM NaCl, pH 8.6) were prepared as 10× solutions, chelexed, and then diluted to 1× solutions for use as needed with DI H_2O. Phosphate buffered saline (PBS), 1×, pH 7.4 consisted of 0.08 M Na_2HPO_4, 0.02 M KH_2PO_4, 0.01 M KCl, and 0.14 M NaCl.

Conjugation of C-NETA-NCS to Trastuzumab. Trastuzumab (9.5 mg) was added to a PD-10 column previously charged with bicarbonate buffer. Additional buffer was added in 0.5 mL portions to the PD-10 column to exchange the buffer solution of the antibody. The buffer solution collected between 3.5 and 5.0 mL was combined following confirmation of the presence of Trastuzumab via analysis of the UV/vis spectrum at 280 nm. To a sterile test tube containing the recovered Trastuzumab (5 mg) was added a 20-fold excess of *C*-NETA-NCS. The resulting solution was gently agitated overnight at room temperature. The following day, this solution was placed on a Centricon C-50 membrane and spun down to reduce volume. PBS (3 × ∼2 mL) was added to the remaining solution of the C-NETA−Trastuzumab conjugate, followed by centrifugation in order to remove unreacted ligand. The volume of purified, conjugate antibody was brought to 2.00 mL with PBS. The ligand to protein (*L*/*P*) ratio was determined by measuring the absorbance of the solution at 280 nm, which indicated that 1.45 mg (9.67×10^{-6} M, 29%) of the Trastuzumab remained after centrifugation. An aliquot of the C-NETA−Trastuzumab conjugate (50 μL) was added to the cuvette containing the Cu(II)-AAIII reagent (950 μL) and the absorbance at 652 nm was monitored over time. The reaction was complete after 20 min, and the concentration of *C*-NETA-NCS was calculated

Scheme 1. Synthesis of *C*-NE3TA



(1.48 × 10^{-5} M). The *L*/*P* for the C-NETA−Trastuzumab conjugate was found to be 1.5 to 1.

Conjugation of C-NE3TA-NCS to Trastuzumab. Trastuzumab (6.0 mg, 2.5 mL) was added to a PD-10 column previously charged with conjugation buffer. Additional conjugation buffer (3.5 mL) was added to PD-10 column to exchange the buffer solution of the antibody. The collected antibody solution (5.9 mg, 98.0%) was then added to a 10-fold excess of *C*-NE3TA-NCS. The solution was gently agitated for 24 h at room temperature. The reaction solution was then placed on a Centricon C-50 membrane and spun down to reduce volume. PBS (3 × 2 mL) was added to the remaining solution of the *C*-NE3TA−Trastuzumab conjugate, followed by centrifugation to remove unreacted ligand. The volume of purified conjugate antibody was brought to 1 mL with PBS. The analysis of the absorbance of the solution at 280 nm indicated that 5.71 mg (38.8 × 10^{-5} M, 96.8%) of the Trastuzumab remained after the processing.

A stock solution of the Cu(II)-AAIII reagent was prepared in 0.15 M NH_4OAc, pH 7.0, by adding an aliquot of a 5 μM Cu(II) atomic absorption solution to a 10 μM solution of AAIII. This solution was stored in the dark to avoid degradation over time. A UV/vis spectrometer was zeroed against a cuvette filled with 2.0 mL of a 5 μM AAIII solution at pH 4.5 with a window open from 200 to 1100 nm. The AAIII solution was removed and replaced with 2.000 mL of the Cu(II)-AAIII reagent, a spectrum was collected, and the absorbance values at 610 nm noted. Solutions of *C*-NE3TA-NO_2 were then used for generating the calibration graph. Various concentration of *C*-NE3TA-NO_2 solution (50 μL) was reacted with 1.95 mL of the Cu(II)-AAIII reagent at room temperature. Abosrbance measurements at 610 nm were taken after 5 min. An aliquot of the *C*-NE3TA−Trastuzumab conjugate (50 μL) was added to a cuvette containing the Cu(II)-AAIII reagent (1.95 mL) and the absorbance at 610 nm was monitored over time. Spectra were then collected periodically until no further change was noted for the peaks at 280 and 610 nm. The reaction was complete after 30 min, and the concentration of *C*-NE3TA was calculated (9.7 × 10^{-5} M). The *L*/*P* for the *C*-NE3TA−Trastuzumab conjugate was found to be 2.5 to 1.

RESULTS AND DISCUSSION

Synthesis of *C*-NETA and *C*-NE3TA. *C*-NE3TA was serendipitously discovered during the synthesis of *C*-NETA. *C*-NE3TA contains four amines and three carboxylates as potential donor groups. The heptadentate *C*-NE3TA forms a neutral complex with Y(III), Lu(III), Bi(III), and Gd(III) that requires no counterion and thus these formed complexes have an advantage of less protein interaction and a potentially more favorable *in vivo* tissue distribution. Synthesis of *C*-NE3TA is shown in Scheme 1. As an initial attempt to prepare *tert*-butyl *C*-NETA **2** (*26*), the free amino groups in **1** were reacted with *tert*-butyl bromoacetate in CH_3CN in the presence of diisopropylethylamine (DIPEA) as a base. However, the reaction afforded **2** in low (<35%) and nonreproducible yields. The reaction also provided a significant amount of a polyalkylated byproduct very difficult to differentiate from **2** by TLC as confirmed by NMR. To improve the synthesis of **2**, starting material **1** as a HCl salt instead of free amine was directly reacted with *tert*-butyl bromoacetate in DMF at 50 °C (Scheme 1) (*20*). Surprisingly, the reaction provided *tert*-butyl *C*-NE3TA (**3**) in 68% yield as the major product along with a small amount of **2**. This result was taken as an indication that the formation of **2** requires an elevated reaction temperature. Indeed, when starting material **1**, still as a HCl salt, was reacted with *tert*-butyl bromoacetate in DMF at 90 °C (*26*), **2** was obtained in an improved yield (54%). Although not described in detail in this paper, the preparation of **2** and **3** was not straightforward. Numerous reaction conditions varying solvents, bases, temperatures, and mole ratios of the reagents were investigated. Purification of **2** and **3** using flash silica gel (or alumina) column chromatography was found to be quite challenging due to the presence of byproduct, specifically a polyalkylated byproduct, which could not be resolved from the desired ligands by TLC. A significant amount of solvents were consumed even in small-scale column chromatographic purifications of **2** (∼100 mg) using a very gradual increase of solvent polarity. With the challenge encountered in isolation of **2** and **3** in high purity, research focused on development of a reliable and efficient purification method available for preparation of these intermediates, **2** and **3**, in high purity so that, after deprotection of the *tert*-butyl groups, the water-soluble per-acid products could be cleanly isolated. Semipreparative HPLC of the reaction mixture containing **2** and **3** eluted with a binary gradient (solvent A = 0.05 M AcOH/Et_3N, pH 6.0, and solvent B = CH_3CN) successfully separated **2** and **3** in high purity. The desired ligands, *C*-NETA (*26*) and *C*-NE3TA were then obtained by removal of the *tert*-butyl groups of **2** and **3** using HCl(g) in 1,4-dioxane. Synthesis of *C*-NE3TA-NCS and *C*-NETA-NCS having a functional linker for conjugation to an antibody is shown in Scheme 2. The nitro groups in **2** and **3** were transformed into the amino group to provide **4** and **5**, respectively. Removal of the *tert*-butyl groups in **4** and **5** followed by reaction with thiophosgene provided the desired ligands with the linker for conjugation to antibody, *C*-NETA-NCS (**8**) and *C*-NE3TA-NCS (**9**).

Relaxivities. The Gd(III) complexes of the new chelates in the nitro form were prepared and purified. The T_1 relaxivity of Gd(*C*-NETA) and Gd(*C*-NE3TA) was measured and compared to that of Gd(*C*-DOTA). Previously, we reported the Gd(III) complex of nonfunctionalized bimodal ligand NETA to be stable both in serum and *in vivo* and displayed

considerably enhanced T_1 relaxivity compared to Gd(DOTA) where the Gd(III) is coordinated to the eight donor atoms of the ligands with one vacant coordination site available to bind a water molecule ($q = 1$) (*2*). The increase in relaxivity of Gd(NETA) as compared to Gd(DOTA) was proposed to be ascribed to a decrease in ligand denticity from eight- to seven-coordinate by one of the flexible acyclic pendant coordinating groups not being coordinated at all or from an "on"−"off" mechanism of one of the pendant coordinating groups and thus resulting in an increase in q value of the Gd(NETA) complex to an intermediate state between one coordinated water molecule ($q = 1$) and two coordinated water molecules ($q = 2$) (*18*). In the present study, the Gd(III) complexes of bifunctional ligands *C*-NETA and heptadentate *C*-NE3TA were prepared as potential MRI contrast agents. Heptadentate *C*-NE3TA was expected to provide enhanced relaxivity due to increase in hydration number (q) when compared to *C*-NETA and *C*-DOTA. The Gd(III) complexes of the bifunctional ligands were prepared and purified using semipreparative HPLC, while the presence of free Gd(III) ions was detected using an ArsenazoIII (AAIII) assay (*27*). Relaxivity of the aqueous Gd(III) complexes (∼pH 7) were measured on a Bruker MQ60 NMR analyzer, and the concentration of the Gd(III) complexes was measured by ICP-MS. The relaxivity data indicate that Gd-*C*-NETA (4.77 mM^{-1} s^{-1}) and Gd-*C*-NE3TA (5.89 mM^{-1} s^{-1}) complexes provided higher relaxivity as compared to the DOTA complex (3.96 mM^{-1} s^{-1}). Introduction of a functional nitro group into the NETA backbone did not impact the T_1 relaxivity of NETA. The difference of T_1 relaxivity (∼1 MHz) between *C*-DOTA and *C*-NETA was similar to that between DOTA and NETA. As mentioned above, the on and off binding to Gd(III) of one of the pendant coordinates would have resulted in enhanced relaxivity of Gd(*C*-NETA) as compared to Gd(*C*-DOTA). Among the evaluated Gd(III) complexes, Gd(*C*-NE3TA) gives the highest T_1 relaxivity at 60 MHz, probably due to an increase in q (*21*). The relaxation rates for the Gd(III) chelates are dominated by the inner-sphere dipolar coupling between the coordinated water molecule and the paramagnetic Gd(III). The measured relaxivities arise from the exchange between the coordinated water molecule and the surrounding water molecules in solution (*21*). An increase in the number of coordinated water molecules to the Gd(III), which could have occurred with dissociation of Gd(III) from the chelate in solution, would have resulted in a significant increase in the measured relaxivities. No indication of Gd(III) dissociation is evident from the relaxivity data, which is in agreement with the *in vitro* serum stability and *in vivo* biodistribution studies.

***In Vitro* Serum Stability.** *C*-NETA and *C*-NE3TA were radiolabeled with ^{90}Y,^{177}Lu, ^{203}Pb, $^{205/6}$Bi, or ^{153}Gd as previously described (*17, 18*). *In vitro* serum stability of the radiolabeled complexes purified via ion-exchange chromatography was performed to determine if *C*-NETA or *C*-NE3TA labeled with the radionuclides remained stable without transchelation or loss of their respective radionuclide in human serum. This was assessed by measuring the transfer of radionuclide from the complex to serum proteins over the course of 11 days. *C*-NETA and *C*-NE3TA radiolabeled with^{90}Y,^{177}Lu, $^{205/6}$Bi, and ^{153}Gd were stable in serum for up to 11 days with no measurable loss of radioactivity. However, considerable release of radioactivity into serum (∼17%) over 7 days was observed with the ^{203}Pb-labeled *C*-NETA. ^{203}Pb-*C*-NE3TA was also unstable by this assay as indicated by significant amounts of ^{203}Pb (∼40%) dissociating within 1 day.

***In Vivo* Biodistribution.** The *in vivo* stability of the radiolabeled complexes was evaluated by performing biodistribution studies in normal athymic mice. The results of the

biodistribution studies for the radiolabeled complexes are shown in Tables 2–5. Selected organs and the blood were harvested at 5 time points, 0.5, 1, 4, 8, and 24 h postinjection. *C*-NETA (*26*) and *C*-NE3TA radiolabeled with ^{177}Lu have similar biodistribution profiles, and both complexes were rapidly cleared from the blood and displayed low radioactivity levels in all organs (<0.8% ID/g at 24 h; Table 2). ^{86}Y-*C*-NETA and ^{86}Y-*C*-NE3TA resulted in rapid blood and liver clearance (Table 3). ^{86}Y-*C*-NETA displayed relatively higher uptake at the femur as compared to that of ^{86}Y-*C*-NE3TA at all time points (0.78 ± 0.07% ID/g vs 0.08 ± 0.02% ID/g at 24 h, respectively). Low radioactivity levels in other organs were observed with both complexes. *C*-NE3TA radiolabeled with $^{205/6}$Bi was rapidly cleared from the blood, lung, heart, and femur and displayed a higher radioactivity level in the kidney when compared to the other organs (Table 4). The radioactivity level of $^{205/6}$Bi-*C*-NE3TA in the kidney peaked at 5.05 ± 0.24% ID/g at 0.5 h and decreased to 0.73 ± 0.19% ID/g by 24 h. $^{205/6}$Bi-*C*-NETA exhibited extremely rapid blood clearance and low radioactivity levels at all of the organs except the kidney (<1.0% ID/g at all time points), while radioactivity in the kidney decreased rather slowly starting from 24.9 ± 3.48% ID/g to 6.06 ± 0.19% ID/g at 24 h (*26*). *C*-NE3TA radiolabeled with ^{153}Gd almost completely cleared from the blood, liver, spleen, lung, heart, and femur in less than 4 h, where the radioactivity level in the kidney was 0.16 ± 0.11% ID/g at 24 h postinjection (Table 5).

^{153}Gd-*C*-NETA also displayed extremely rapid blood clearance and low uptake at spleen, lung, and heart, while relatively increased radioactivity levels in the liver, kidney, and femur at 24 h (2.98 ± 0.44% ID/g, 2.18 ± 0.14% ID/g, 2.31 ± 0.40% ID/g, respectively) were observed with this complex (Table 5).

Conjugation of *C*-NETA-NCS and *C*-NE3TA-NCS to Trastuzumab and Determination of *L*/*P* Ratio Based on Cu(II)-AA(III) Assay. HER2 are receptors overexpressed in a variety of epithelial tumors making this an attractive target. Trastuzumab, a monoclonal antibody that selectively targets the HER2 protein and blocks its overexpression function (*22*) and has been shown to enhance a survival rate of metastatic breast cancer patients was chosen as a tumor targeting biomolecule (*23*) for the present study. *C*-NETA was conjugated with Trastuzumab by an established method (*24*). Protein concentration was quantified by the method of Lowry (*25*). The Cu(II)-AAIII based UV−vis spectrophotometric assay as described previously (*24*) was used for the determination of the number of *C*-NETA ligands linked to Trastuzumab (*L*/*P* ratio). The *L*/*P* ratios for *C*-NETA−Trastuzumab and *C*-NE3TA conjugates were found to be 1.5 and 2.5, respectively.

CONCLUSIONS

The novel bifunctional ligands, octadentate *C*-NETA and heptadentate *C*-NE3TA, were synthesized for use in RIT and MRI applications. The T_1 relaxivities of their corresponding Gd(III) complexes are reported. At clinically relevant field strength, the relaxivities of Gd(*C*-NETA) and Gd(*C*-NE3TA) are higher than that of a bifunctional version of the clinically used contrast agent, Gd(DOTA). The *in vitro* serum stability and *in vivo* biodistribution data of the ^{153}Gd-labeled complexes, Gd(*C*-NETA) and Gd(*C*-NE3TA), indicate that *C*-NETA and *C*-NE3TA bind ^{153}Gd with high complex stability. *C*-NETA and *C*-NE3TA were evaluated as chelators of ^{177}Lu, ^{90}Y, ^{212}Pb, ^{212}Bi, or ^{213}Bi for RIT applications. *C*-NETA and *C*-NE3TA radiolabeled with ^{177}Lu, ^{90}Y, and $^{205/6}$Bi were extremely stable without loss of any radioactivity from the metal complex in human serum for up to 11 days. Both ^{203}Pb-*C*-NETA and ^{203}Pb-*C*-NE3TA underwent significant dissociation of the metal from the complexes. *In vivo* biodistribution of *C*-NETA and *C*-NE3TA labeled with ^{177}Lu or ^{90}Y using athymic mice indicate that the radiolabeled complexes exhibited rapid blood clearance and relatively low radioactivity levels in the normal organs and possess a favorable biodistribution profile. $^{205/6}$Bi-*C*-NE3TA exhibited extremely rapid blood clearance and low radioactivity level in the normal organs at 24 h. $^{205/6}$Bi-*C*-NETA displayed a minimum amount of uptake of the activity in the normal organs except for the kidney. High renal uptake of the activity at all time points was observed with $^{205/6}$Bi-*C*-NETA. The bifunctional ligands, *C*-NETA and *C*-NE3TA, were successfully conjugated to trastuzumab with respective *L*/*P* product ratios of 1.5 and 2.5 as determined using a UV/vis spectrophotometric AAIII assay. The results of T_1 relaxivity, *in vitro* serum stability, and *in vivo* biodistribution studies suggest that the novel bifunctional ligands, *C*-NETA and *C*-NE3TA, are promising bifunctional ligands for disease-specific Gd(III)-based MRI and RIT of ^{177}Lu and ^{90}Y.

Simple Modifications of Branched PEI Lead to Highly Efficient siRNA Carriers with Low Toxicity

Arkadi Zintchenko,* Alexander Philipp, Ali Dehshahri, and Ernst Wagner

Center for Drug Research, Department of Pharmacy, Pharmaceutical Biology-Biotechnology, and Center for NanoScience (CeNS), Ludwig-Maximilians-University, Butenandstr. 5-13, D-81377 Munich, Germany. Received February 19, 2008; Revised Manuscript Received May 7, 2008

Polymer carriers like PEI which proved their efficiency in DNA delivery were found to be far less effective for the applications with siRNA. In the current study, we generated a number of nontoxic derivates of branched PEI through modification of amines by ethyl acrylate, acetylation of primary amines, or introduction of negatively charged propionic acid or succinic acid groups to the polymer structure. The resulting products showed high efficiency in siRNA-mediated knockdown of target gene. In particular, succinylation of branched PEI resulted in up to 10-fold lower polymer toxicity in comparison to unmodified PEI. Formulations of siRNA with succinylated PEI were able to induce remarkable knockdown (80% relative to untreated cells) of target luciferase gene at the lowest tested siRNA concentration of 50 nM in Neuro2ALuc cells. The polyplex stability assay revealed that the efficiency of formulations which are stable in physiological saline is independent of the affinity of siRNA to the polymer chain. The improved properties of modified PEI as siRNA carrier are largely a consequence of the lower polymer toxicity. In order to achieve significant knockdown of target gene, the PEI-based polymer has to be applied at higher concentrations, required most probably for sufficient accumulation and proton sponge effects in endosomes. Unmodified PEI is highly toxic at such polymer concentrations. In contrast, the far less toxic modified analogues can be applied in concentrations required for the knockdown of target genes without side effects.

INTRODUCTION

Since double-stranded RNA molecules were identified as the mediator of gene silencing in *C. elegans* (*1*), RNA interference (RNAi) has become a powerful strategy for intervention also in mammalian cell processes and treatment of various diseases, due to its ability to silence gene expression in a sequence-specific manner (*2–4*).

Polycations such as polyethylenimine (PEI)[1] have been introduced as nonviral gene carriers with a capability of forming stable complexes by electrostatic interactions with nucleic acids. The polyplex formation leads to improved protection of the genetic material from enzyme-mediated digestion and enhanced intracellular delivery. PEI, although it is known to be a powerful agent in plasmid-based gene delivery (*5, 6*), has been shown to be less effective in siRNA-mediated gene silencing (*7, 8*). Moreover, it is known to be toxic when applied at higher doses. The toxicity is mainly associated with a strong positive charge of this polycation, which leads to strong interaction of PEI with cell surfaces and their damage. Therefore, modifications of polymeric backbone that reduce the positive charge of PEI might be useful in order to reduce the toxicity of the polymer.

Several approaches have already been investigated in this direction. Different polymeric forms of PEI are available, the linear form (obtained via polyisoxazoline precursors) or the branched form (obtained from acid-catalyzed polymerization of aziridine), both in various degrees of polymerization that influence their biological activities (*9–12*). Backbone modification of linear PEI 22 kDa, which on its own is one of the most potent transfection agents (*6*), have reduced the high gene transfer activity (*13*). In fact, it was demonstrated that the high activity depends on complete removal of propionamide residues from the polyisoxazoline precursor polymer (*14*). Linear PEI22 on its own has limited efficiency in siRNA delivery (*7*); the activity however can be enhanced with concatemerizing "sticky" siRNA (ssiRNA) applied for polyplex formation (*15*).

Experiences with branched PEI 25 kDa gave different trends. Interestingly, partial acetylation of PEI amino groups was shown to enhance gene transfer activity (*16*). N-Acylation of PEI lowered its toxicity (*17*). Also, conjugation of acetate, butanoate, and hexanoate to branched PEI at low degree of substitution (below 25%) resulted in moderate improvement of transfection activity as demonstrated by Putnam and colleagues (*18*). The same research group compared different (linear and branched) PEIs for siRNA transfer activity; only branched PEI within a narrow window of conditions was able to mediate in vitro gene silencing in a (HR5-CL11) cell line (*8*). Reducing the surface charge of polyplexes by PEGylation of PEI positively affected the siRNA delivery capacity in the absence (*19*) or in the presence of a cell targeting molecule (*20*).

In this work, using relatively simple modification strategies, we were able to produce a number of branched PEI derivates, which were aimed at screening the positive charge of the polymer. In particular, negative charges were introduced into the polymer backbone by modification with succinic anhydride or Michael addition of ethyl acrylate followed by ester hydrolysis. Alternatively, amino groups were modified by acetylation or addition by ethyl acrylate. As was expected, all the products showed reduced toxicity in comparison to unmodified PEI. Moreover, we found that several modifications were able to greatly improve the siRNA/PEI formulation characteristics and

silencing activities, thereby presenting easy access to promising siRNA transfection reagents.

EXPERIMENTAL SECTION

Materials. Ethyl acrylate (EA), acetic anhydride, and succinic anhydride were obtained from Sigma (Munich, Germany). The plasmid pEGFPLuc (Clontech Laboratories, Heidelberg, Germany) containing a CMV promoter-driven fusion of the genes encoding for enhanced green fluorescent protein and luciferase was used for generation of stably transfected cells. Branched PEI with an average molecular weight of 25 kDa (PEI) was obtained from Sigma-Aldrich (Munich, Germany). PEI was used as a 1−10 mg/mL stock solution neutralized with HCl. All other chemicals were purchased by Sigma-Aldrich (Munich, Germany). Cell culture media, antibiotics, and fetal calf serum (FCS) were purchased from Invitrogen (Karlsruhe, Germany). Ready to use siRNA duplexes were purchased from MWG-Biotech (Ebersberg, Germany), namely, luciferase-siRNA; GL3 luciferase duplex; 5′-CUUACGCUGAGUACUUCGAdTdT-3′; control-siRNA; nonspecific control duplex with similar GC content as antiluciferase-siRNA; 5′-AUUGUAUGCGAUCG-CAGACdTdT-3′.

Modification of PEI by Ethyl Acrylate (EA). About 1 g of PEI was dissolved in chloroform. The solution was heated to 40 °C. The desired amount of acrylate was added to the solution with stirring. The reaction proceeded for at 40 °C. After 4 h, the chloroform was removed by rotary evaporator. The waxy product was dissolved in 15 mL water and neutralized by HCl to the pH 4−5 and freeze-dried. The modification degree was analyzed by ^{1}H NMR in D_2O on a Jeol JNMR-GX400 (400 MHz) or Jeol JNMR-GX500 (500 MHz) spectrometer from the ratio between the peaks of PEI (δ 2.6−3.6 ppm) and methyl acrylate (δ = 1.3 ppm). The modification degree was expressed as a number of modifications per monomer unit of PEI × 100%. According to FTIR spectra recorded on a Jasco FT/IR-410 spectrometer (Jasco Labor- and Datentechnik GmbH, Germany), a pronounced ester peak (1730 cm^{-1}) was detected. No significant amide band (1652 cm^{-1}) was found.

Synthesis of Acetylated and Succinylated PEI. PEI (0.5 g) was dissolved in 8.5 mL of water and 1.5 mL of NaCl solution (3 M) and then adjusted to pH 5 using 1 M HCl. The desired amounts of acetic or succinic anhydride were dissolved in DMSO and added dropwise to PEI solution. The reaction was carried out at room temperature for 3 h. The crude products dialyzed (18 000 cutoff, Spectra/Por membrane) first against 0.25 M NaCl solution to remove unreacted acetate or succinate, and then twice against water at 4 °C to remove salt. After the dialysis, the aqueous solution was lyophilized. The modification degree was analyzed by ^{1}H NMR in D_2O from the ratio between the peaks of PEI (δ 2.6−3.6 ppm) and methylene of succinate (δ = 2.5 ppm) or methyl of acetate (δ = 2.1 ppm). The modification degree was expressed as a percentage of modified amines of PEI under the assumption that each amine is able to react.

Synthesis of Propionic Acid Modified PEI by Hydrolysis of EA Modified PEI. About 0.3 g of PEI-EA polymer was dissolved in 1 M HCl. The solution was incubated at 40 °C for 3 days. The final product was dialyzed against water (18 000 cutoff, Spectra/Por membrane) and freeze-dried. The extent of reaction was controlled by ^{1}H NMR in D_2O. No ethyl peak was found for all samples, indicating complete hydrolysis of the ester bond. Neither ester (1730 cm^{-1}) nor amide (1652 cm^{-1}) peak was detected by FTIR.

Polyplex Formation. In all studies, the composition of polyplexes was characterized by the w/w ratio of the polymer to nucleic acid in the mixture. The weight of unmodified PEI represents a weight of the polymer in base form. The weight of modified PEI represents the weight of lyophilized product, which was previously neutralized to pH of about 4−5 and, therefore, includes the mass of counterions (chloride). Formulations for pDNA and siRNA delivery were prepared in HBG (20 μL) as follows: First, different concentrations of the nucleic acid and PEI derivatives were diluted at various polymer/nucleic acid ratios (w/w: weight/weight) in separate tubes in HBG (HEPES-buffered glucose solution; 20 mM HEPES, 5% glucose). Then, the HBG solution of PEI was added to the HBG solution of the nucleic acid, mixed, and incubated for 30 to 40 min at room temperature to form stable polymer/nucleic acid complexes.

EtBr Exclusion Assay. The ability of the products to condense DNA or siRNA was studied using an ethidium bromide (EtBr) assay. Polymer solution was added stepwise to the solution of nucleic acid (10 μg/mL) in HBG containing EtBr (0.4 μg/mL). After each step, fluorescence intensity was monitored (λ_{ex} = 510 nm, λ_{em} = 590 nm). The fluorescence intensity of the EtBr solution in the presence of free nucleic acid corresponded to 0% condensation, whereas the fluorescence intensity without nucleic acid corresponded to 100% condensation.

Polyplex Stability Assay. Polyplexes were mixed with DNA or siRNA in HBG at a final concentration of 20 μg/mL of nucleic acid and a 1:1 w/w ratio. The particle sizes were monitored by dynamic laser light scattering using a Malvern Zetasizer 3000HS (Malvern Instruments, Worcestershire, UK). After this, 3 M NaCl solution was added stepwise to the polyplex solution. After each step, the correlation functions and scattering intensities were monitored. The dissociation of polyplexes led to the drop of scattering intensity to the level of the salt buffer and changes in correlation function (Supporting Information Figure 1). The NaCl concentration at which the dissociation of the polyplexes occurred was related to the stability of the polyplexes.

Cell Culture. For pDNA and siRNA delivery experiments, mouse melanoma cells B16F10, mouse glioblastoma cells Neuro2A, Neuro2A/EGFPLuc cells, and HUH7/EGFPLuc cells stably transfected with the EGFPLuc gene (see below) were used. B16F10 cells and Neuro2A/EGFPLuc cells were grown in Dulbecco's modified Eagle's medium (DMEM) and HUH7/EGFPLuc were grown in DMEM/Ham's F-12 medium, whereby all media were supplemented with 10% FCS, 4 mM stable glutamine, 100 U/mL penicillin, and 100 μg/mL streptomycin. All cells were seeded 24 h prior to pDNA or siRNA delivery using 5000 cells per well in 96-well plates for analysis of protein expression.

For the generation of stably transfected cells, the vector pEGFPLuc (Clontech) was linearized using the restriction enzyme Dra III, and cells were then transfected with this linearized vector using linear polyethylenimine 22 kDa (PEI 22lin; Euromedex, Souffelweyersheim, France).

Following gene transfer, Neuro2A or HUH7 cells were incubated in fresh medium for 72 h prior to selection of the stably transfected cells with 200 to 2000 μg/mL G418 (geneticine; Invitrogen, Karlsruhe, Germany). After several days, surviving cells were seeded at low density into 6-well plates in order to generate separate colonies. Single cell clones were then isolated and expanded. The generated clones were analyzed for the percentage of EGFP-positive (EGFPLuc stably transfected) cells by flow cytometry. Clones with the highest number of EGFP-positive cells were then further selectively grown up under the above-described selective conditions, and this procedure was repeated until all cells were positive for EGFP. These stably transfected cells expressing approximately 60 ng luciferase per million cells were then used for siRNA delivery experiments.

In Vitro Gene Transfer. In vitro transfection efficiency of the polymers was evaluated in B16F10 or Neuro2A cells using

pEGFPLuc (200 ng pDNA per well). In all experiments, pDNA delivery was performed in 96-well plates with 5000 cells (B16F10) or 10 000 cells (Neuro2A) per well in triplicates. Cells were seeded 24 h prior to transfection and then medium was replaced with 80 μL fresh growth medium containing 10% FCS. Transfection complexes for pDNA delivery (20 μL in HBG) at different w/w ratios were added to each well and incubated at 37 °C. After 4 h, the medium was replaced by fresh growth medium. The cells were treated with 50 μL cell lysis buffer (25 mM Tris, pH 7.8, 2 mM EDTA, 2 mM DTT, 10% glycerol, 1% Triton X-100) 24 h following pDNA transfection. Luciferase activity in cell lysate (20 μL) was measured using a luciferase assay kit (100 μL Luciferase Assay buffer, Promega, Mannheim, Germany) on a luminometer for 10 s (Lumat LB9507 instrument, Berthold, Bad Wildbad, Germany).

In Vitro Gene Silencing with siRNA. In vitro gene silencing experiments were performed in stably transfected Neuro2A/EGFPLuc and HUH7/EGFPLuc cells using LucsiRNA and MutsiRNA as a control. In all experiments, siRNA delivery was performed in 96-well plates with 5000 cells per well in triplicate. Cells were seeded 24 h prior to transfection, and then medium was replaced with 80 μL fresh growth medium containing 10% FCS. Transfection complexes for siRNA delivery (20 μL in HBG) at different w/w ratios were added to each well and incubated at 37 °C without medium change. Cells were washed with phosphate-buffered saline (PBS) and treated with 50 μL cell lysis buffer (25 mM Tris, pH 7.8, 2 mM EDTA, 2 mM DTT, 10% glycerol, 1% Triton X-100) 48 h following siRNA transfection. Luciferase activity in cell lysate (20 μL) was measured using a luciferase assay kit (100 μL luciferase assay buffer, Promega, Mannheim, Germany) on a luminometer for 10 s (Lumat LB9507 instrument, Berthold, Bad Wildbad, Germany). The relative light units (RLU) were related to untreated control cells.

Cytotoxicity Assay. Neuro2A cells were seeded into 96-well plates at a density of 1×10^4 cells/well. After 24 h, the culture medium was replaced with 100 μL/well of serial dilutions of polymer stock solutions in growth medium. Alternatively, transfection complexes for pDNA delivery (20 μL in HBG) at different C/P ratios were added. All studies were made in triplicate. After 4 h incubation, the medium was replaced by the fresh one.

After 24 h, MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) (Sigma-Aldrich, Germany) was dissolved in phosphate buffered saline at 5 mg/mL, and 10 μL aliquots were added to each well reaching a final concentration of 0.5 mg MTT/mL. After an incubation time of 1 h, unreacted dye with medium was removed. The purple formazan product was dissolved in 100 μL/well dimethyl sulfoxide and quantified by a plate reader (Tecan, Groedig, Austria) at 590 nm with background correction at 630 nm. The relative cell viability (%) relative to control wells containing cell culture medium without polymer was calculated by [A] test/[A] control $\times$ 100.

RESULTS

Synthesis of the Polymers. The strategies for modification of branched PEI 25 kDa are presented in Figure 1. In EA and PROP series, the primary amines of PEI were transformed to the secondary amines by Michael addition. In AC and SUC series, the primary amines were acetylated to amides. Additionally, PROP and SUC series have carboxylic group in the structure.

Syntheses and characterization are described in Materials and Methods and Supporting Information. PEI was modified with ethyl acrylate via Michael addition performed at 40 °C and relatively short incubation time. Table 1 shows the degrees of modification (12−31%) depending on the ratios in the feed.

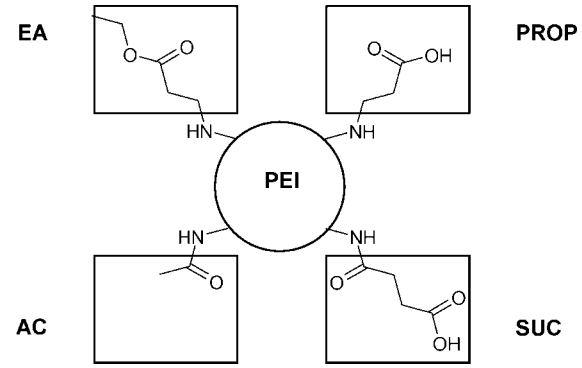

Figure 1. Strategies for modification of branched PEI.

Table 1. Composition of Modified PEIs[a]

polymer	reagent/amine*100%, feed	modification degree, %
PEI-EA 12	13%	11.5%
PEI-EA 18	26%	17.6%
PEI-EA 31	52%	31%
PEI-PROP 12	n.a.	11.5%
PEI-PROP 18	n.a.	17.6%
PEI-PROP 31	n.a.	31%
PEI-AC 12	10%	12.3%
PEI-AC 22	20%	21.8%
PEI-SUC 9	10%	8.9%
PEI-SUC 19	20%	19.4%

[a] The nomenclature of the polymers is expressed as follows: PEI-*X Y*, where *X* represents the reagent by which PEI was modified (EA, ethyl acrylate; SUC or AC, succinic or acetic anhydride, respectively) or functional group (PROP for 3-propionic acid) and *Y* represents the modification degree of the amines measured by NMR.

Longer incubation times are known to cause aminolysis of ester bond and lead to cross-linking of PEI (*21*). No amide peak was found on FTIR spectra of all polymer samples of PEI-EA series (data not shown). Therefore, no aminolysis was observed, excluding the cross-linking of PEI. No double bond peak was present in ^{1}H NMR for all samples, indicating the complete evaporation of unreacted acrylate during freeze-drying procedure and its absence in the final products.

The 3-propionic acid-modified B-PEI (PEI-PROP) was generated by acid hydrolysis of PEI-EA polymers. Complete hydrolysis was verified by disappearance of the ester protons in the NMR spectra and characteristic FTIR-band at 1730 cm^{-1}. The degrees of PEI modification with carboxylic groups were assumed to be the same as in nonhydrolyzed precursor polymers. An absence of the amide peak on FTIR spectra (1652 cm^{-1}) reveal no significant cross-linking during hydrolysis.

The modification of PEI with acetic anhydride and succinic anhydride was performed in the presence of salt in the reaction solution to avoid precipitation of the polymer. The purification of polymers via dialysis was performed against salt buffer to ensure complete exchange of acetic or succinic acid, respectively, against chloride. At low reagent/amine feed ratios (10−20%), nearly quantitative modification of PEI was achieved (Table 1).

The yields were typically 80−120%. The neutralization of the products and, consequently, the weight gain due to counterions (chloride), which was not taken into account by calculation of theoretical yields, was the reason for some of the yields being above 100%.

The pH titrations of the polymers demonstrated that the pH5 to pH7 buffer capacity did not significantly change after modification (data not shown).

Toxicity of the Polymers. The cell culture cytotoxicity profiles of modified PEIs (Figure 2) are shifted to higher polymer concentrations in comparison to PEI, demonstrating a

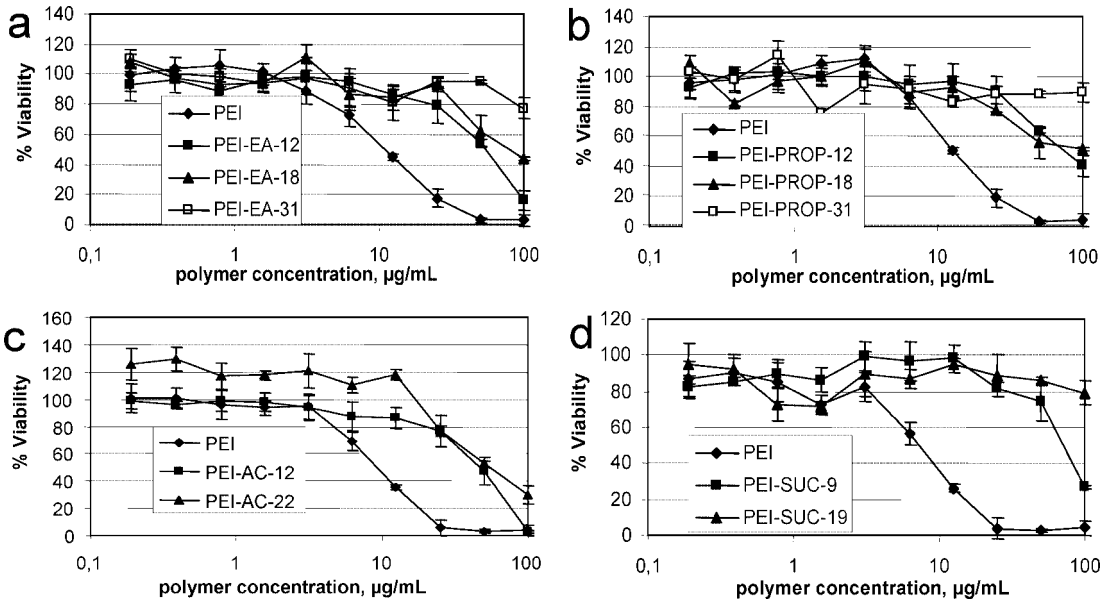

Figure 2. Cell viability of Neuro2A cells as a function of concentration of modified PEI polymers in the medium. (a) PEI-EA series, (b) PEI-PROP series, (c) PEI-AC series, (d) PEI-SUC series.

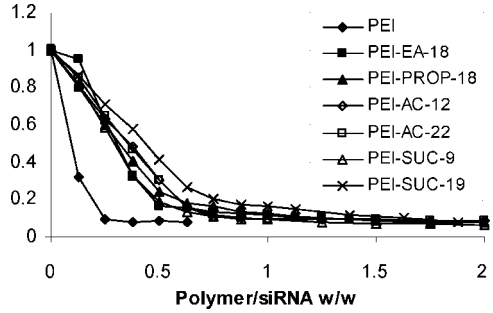

Figure 3. EtBr exclusion assay of the polymers with siRNA in HBG buffer.

decrease in toxicity. Relatively soft neutral modifications (EA and AC) have shown only moderate improvement of cell viability, whereas the incorporation of negative charges on PEI led to polymers with far less toxicity.

Chemical and Biophysical Properties of Polyplexes. In salt-free buffer, all polymers were effective in binding of siRNA (Figure 3) as well as DNA (data not shown). In comparison to PEI, the binding required higher polymer to siRNA and DNA (w/w) ratios. Such a difference is caused by the fact that for modified PEI w/w ratio was calculated from the base form. Modified PEIs were weighed in neutralized form; therefore, the counter ions (chloride) markedly contribute to mass per charge ratio. Nevertheless, at w/w ratio of 2 even the polymers with a high degree of modification show the reduction of EtBr fluorescence to less than 10%. No significant difference in binding between products of different modifications was observed in this assay. Agarose gel electrophoresis data confirmed these results (data not shown).

The analysis of the polyplex solutions mixed in HBG at w/w ratios of 2 and 4 by photon correlation spectroscopy did not show the formation of nanoparticles in the usual 30−300 nm range of standard DNA/PEI polyplexes. The scattering intensity from polyplex solution at a concentration of 5 μg/mL based on siRNA was close to that of HBG buffer, which indicates very small polyplex sizes and low aggregation number of the polymer chains. Such behavior of siRNA/PEI polyplexes has recently been shown by Meyer et al. (*22*) where particle sizes of around 25 nm were detected by fluorescent correlation spectroscopy.

The increase of the salt concentration in this solution to 150 mmol NaCl led to continuous aggregation of the initial polyplexes and formation of nanoparticles (around 500 nm after 30 min) in the case of modified PEI. Unmodified PEI without siRNA did not show any aggregation at physiological saline.

Plasmid-Based Gene Transfer. Most of the polymers were found to be effective gene transfer agents and showed transfection efficiencies comparable to branched PEI on B16F10 and Neuro2A cells (Supporting Information Figure 2). Only PEI-PROP-31 displayed relatively low efficiency. All others showed transfection efficiencies comparable to PEI. The polyplexes generated with the modified PEIs induce much less toxicity than PEI. As can be seen from Supporting Information Figure 2b,c, at w/w ratio of 4 the cell viabilities are above 80% for the modified PEI and only 20−40% for the unmodified PEI.

Gene Silencing with siRNA. Modified PEIs were found to be good DNA transfection agents. However, it is known from literature that efficient carriers of plasmid DNA are not necessarily effective for siRNA delivery (*23*). Linear polyethylenimine 22 kDa and branched polyethylenimine 25 kDa (PEI), the powerful DNA delivery agents, showed only limited efficiency in siRNA delivery (*7, 8*). Therefore, the modified PEIs were tested for their efficiency in siRNA delivery using a neuroblastoma cell line stably transfected with a luciferase marker gene. The results are presented in Figure 4. Luciferase activities were determined for cells treated either with LUC siRNA (directed against the target mRNA) or with a control siRNA (Mut siRNA), and compared with the luciferase activity of untreated control cells. Knockdown effects are real when expression decreases with Luc siRNA but not Mut siRNA. If luciferase expression decreases with both target and control siRNA, "knockdown" is mainly due to unspecific carrier toxicity. siRNA formulations with PEI were not able to facilitate knockdown of reporter gene without toxicity. High toxicity was observed for the formulations above w/w ratio of 1, indicated by decrease of luciferase level for formulations with mismatched siRNA.

Most modified PEIs (except PEI-PROP-31 and PEI-SUC-19) showed up to 80−90% of luciferase knockdown, when formulated with Luc-siRNA. The effect cannot be attributed to the toxicity of polyplexes, since the luciferase level by the formulations with mismatched siRNA was close to the control.

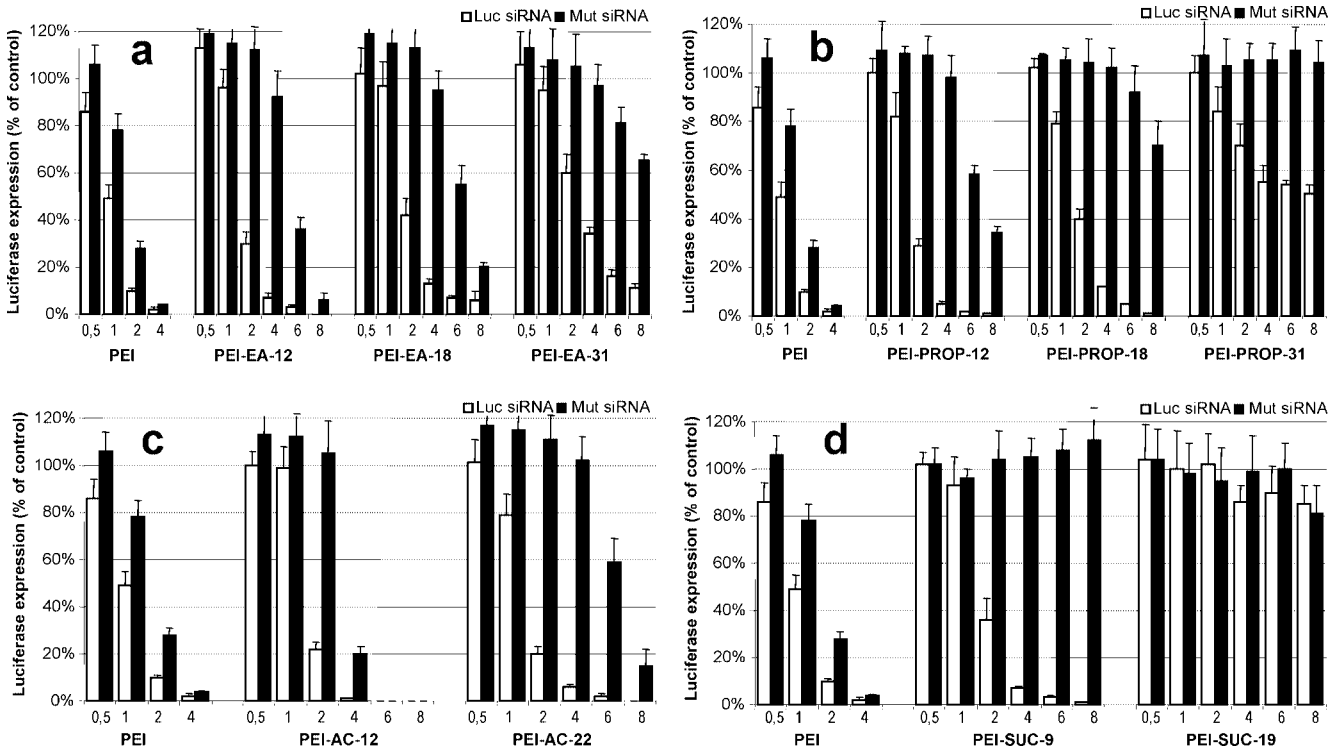

Figure 4. siRNA delivery to Neuro2A/EGFPLuc cells using modified PEI: (a) EA series, (b) PROP series, (c) AC series, (d) SUC series. The numbers on the *x*-axis represent the polymer/siRNA w/w ratios. The final siRNA concentration in culture medium was 380 nM. White bars, LucsiRNA; black bars, MutsiRNA. Luciferase expression levels are presented in % relative to untreated control cells. Luciferase expression was measured 48 h after transfection without change of the medium.

The best knockdown was achieved with PEI-SUC-9. Being nontoxic at all studied mixing ratios, it showed the gene silencing to almost less than 10% relative to the control. Further increase of the negative charge on PEI led to inactivation of this polymer; PEI-SUC-19 did not show any gene knockdown at all w/w ratios. Interestingly, PEI-EA-31 showed significant knockdown at w/w of 4 and 6, whereas the hydrolyzed analogue PEI-PROP-31 was inactive. Thus, low amounts of negatively charged groups on the polymer were able to improve the efficiency of PEI in siRNA delivery, whereas high amounts of negative charges resulted in nontoxic but also ineffective polymers.

Even with lower amounts of siRNA significant knockdown was achieved, if the polymer amount remained on the same level (Figure 5). At concentration of the polymers in transfection medium of 20 μg/mL and siRNA concentration of 50 nM, it was possible to achieve 50−80% knockdown of the luciferase gene. Decrease of siRNA concentration led to a certain increase of the toxicity of the formulations with most of the polymers, which was caused by an increasing amount of uncomplexed PEI in the transfection medium. Only PEI-SUC-9 was able to show up to 80% knockdown without any sign of toxicity at 50 nM siRNA concentration. Unmodified PEI at concentration of 2.5 μg/mL was taken as a control. As is seen, PEI was not efficient at any siRNA concentration. Higher concentrations showed unspecific knockdown due to the toxicity of the carrier.

PEI-SUC-9, as the most promising candidate, was additionally tested for siRNA delivery to another stably transfected cell line HUH7Luc (Supporting Information Figure 3). Also on this cell line, high efficiency and low toxicity of this carrier were demonstrated.

Bolcato-Bellemin et al. (*15*) postulated that the limited efficiency of PEI/siRNA formulations might be caused by low binding affinity of polycation to nucleic acid. Therefore, if the binding to PEI could be increased, the formulation with siRNA would gain efficiency. The modifications of PEI used in the

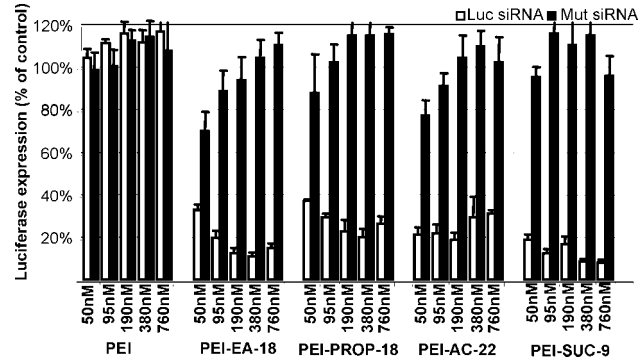

Figure 5. siRNA delivery to Neuro2A/EGFPLuc cells using modified PEI. The numbers on the *x*-axis represent the concentration of siRNA in culture medium. The concentration of PEI-EA-18, PEI-PROP-18, PEI-AC-22, and PEI-SUC-9 was kept constant at 20 μg/mL. The concentration of unmodified PEI was kept at 2.5 μg/mL. White bars, LucsiRNA; black bars, MutsiRNA. Luciferase expression levels are presented in % relative to untreated control cells. Luciferase expression was measured 48 h after transfection without change of the medium.

present paper were not expected to increase the binding with siRNA. Nevertheless, several of the modified polymers showed strongly improved siRNA activity in comparison to that of PEI. To study this discrepancy and further define the influence of PEI modification on the binding between polymer and siRNA, the stability of the polyplexes against dissociation induced by salt was studied.

Electrostatic interactions between polycations and nucleic acids are largely responsible for the stabilization of polyplexes. Contrary to long nucleotide sequences (like plasmids), for relatively short oligomers the stabilization is expected to be dependent on the number of charges per nucleic acid molecule. Low molecular salt is able to screen the electrostatic interactions and, at certain concentration, cause the dissociation of poly-

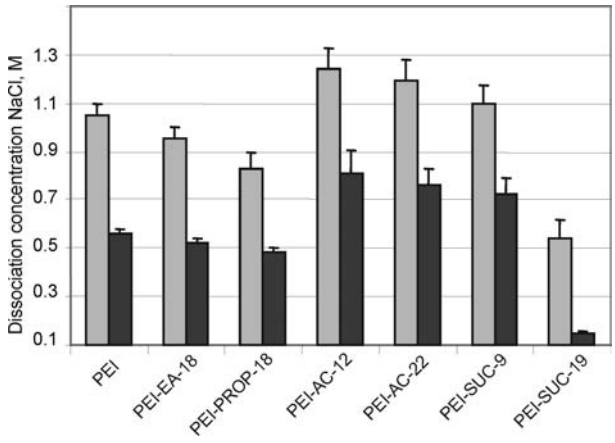

Figure 6. NaCl concentrations required for dissociation of polyplexes: gray bars, polyplexes with DNA; black bars, polyplexes with siRNA. For details, see Experimental Section and Supporting Information. Complexes were formed at concentration of 20 ug/mL nucleic acid and 1/1 w/w ratio.

plexes. The salt concentration required for the dissociation could be attributed to the stability of polyplexes. Photon correlation spectroscopy was used to detect the dissociation point. The polyplexes formed in salt-free buffer were titrated with NaCl. After each step, dynamic light scattering measurements were performed. Addition of NaCl to the polyplex solution led to aggregation of small polyplex particles, increase of scattering intensity, and shift of the correlation function to the slow-motion range (Supporting Information Figure 1). Further increase in NaCl concentration led to the dissociation point, where the scattering intensity drops to the level of NaCl buffer. The residual correlation is mainly caused by the statistically low number of foreign particles in the solution (i.e., dust) (Supporting Information Figure 1).

The NaCl concentrations required for the dissociation of the polyplexes with DNA and siRNA are presented in Figure 6. As expected, polyplexes with DNA dissociate at near two times higher salt concentration than polyplexes with siRNA. However, no correlation between the stability and knockdown efficiency within siRNA polyplexes was found, since all series of PEI modifications were found to show the efficient knockdown of the luciferase gene. According to the stability data, EA and PROP series showed lower stability than PEI, whereas in case of AC and SUC series, the stability was higher. The same dependence could be also attributed to the polyplexes with DNA. The reasons for the increased stability of the polyplexes in AC and SUC series are not clear. Additional stabilization of the polyplexes might be mediated through the hydrogen bonding between the amides in these structures and the nucleic acids (*24*).

Interestingly, the PEI-SUC-19 was able to transfect the cells, but was completely inefficient in inducing knockdown with siRNA (Figure 4d). Data from Figure 6 explain this behavior. While being relatively stable with DNA, siRNA polyplexes of this polymer are unstable at physiological salt concentration and not able to induce knockdown.

DISCUSSION

In this study, a number of PEI-based polymers were synthesized, which showed significantly lower toxicity in comparison to branched PEI. Since toxicity of PEI is mainly associated with the high positive charge of the polymer, the screening of PEI amines was performed in different ways. The Michael addition of ethyl acrylate (EA series) represents a relatively soft modification, which results in transformation of primary amines of PEI to secondary. Also, a bulky EA group is introduced to the structure, which could represent a steric barrier for interaction of PEI with negatively charged surfaces. The AC modification reduces the positive charges of PEI due to acetylation of primary amines. In the PROP series, the transformation of primary to secondary amines was combined with the introduction of negatively charged proionic acid residues. Finally, SUC series represent the strongest reduction of the positive charge of PEI by combination of acylation of primary amines and introduction of negative charges into the polymer.

As expected, the toxicity of the polymers was greatly reduced by the modifications. Even the softer PEI modifications (EA, AC) reduced the toxicity, although to a lower extent in comparison to the PROP and SUC series. These data fit very well with literature, where several modifications of branched PEI led to decreased charge and lower toxicity of the polymer (*17*, *25*). The reduction of positive charge, however, might also reduce activity of polycation in nucleic acid transfer as previously reported (*13*, *14*, *19*). Within our series of modifications, only two products with the highest degrees of modification showed inactivation: PEI-PROP-31 for both DNA and siRNA transfer, and PEI-SUC-19 for siRNA transfer. Reduced polyplex stability due to the increased density of negative charges on the cationic polymer chain is presumably responsible for this. For example, polyplexes of siRNA and PEI-SUC-19 dissociated in physiological saline. All other modified PEI products were found to show transfection efficiency with DNA comparable to that of unmodified PEI. Importantly, in contrast to unmodified PEI, they were able to induce efficient siRNA-mediated knockdown. PEI-SUC-9 was found to be the most effective delivery agent for siRNA. Low toxicity and high efficiency in knockdown, also at low concentrations of siRNA, make this PEI modification very promising for in vitro delivery of siRNA.

Possible reasons for the low efficiency of unmodified PEIs in siRNA delivery despite their high efficiency in DNA transfer might be associated with the stability of the polyplexes. Requirements for delivery of DNA and siRNA are different. DNA transfer requires nuclear uptake with subsequent unpacking and release of the plasmid. Relatively strong binding of the carrier to the pDNA might prevent the unpacking and degradation of pDNA in the cytoplasm. In case of siRNA delivery, an effective dissociation from the carrier is required within the cytoplasm. Therefore, the modifications should aim at a lower affinity of the polymer to siRNA in comparison to DNA polypexes. Another hypothesis postulates that lower affinity of siRNA to the carrier as compared to plasmid DNA may be the reason for insufficient knockdown due to polyplex instability. Therefore, in order to achieve effective knockdown formulations, the stability of the polyplexes with siRNA should be increased.

Neither of the two hypotheses seems to be true. According to the data of the present investigation, the stability of the polyplexes with siRNA is lower in comparison to the polyplexes with DNA. Although all PEI modifications in this study were expected to reduce the electrostatic affinity to nucleic acids, certain series (AC and SUC) showed even higher stability of polyplexes in comparison to unmodified PEI. Taking into account that all modification types were able to induce significant knockdown, AC and SUC series do not fit the first hypothesis as well as EA and PROP series to the second. The stability of siRNA formulations could possibly play a role during in vivo applications; however, for in vitro efficacy the extent of polyplex stability has minor importance, unless the polyplex is sufficiently stable to survive in the culture medium.

The most probable reason for the improved properties of modified PEIs in siRNA delivery in comparison to unmodified PEI is the lower toxicity of the carrier, which enables higher

amounts of PEI for transfection. This hypothesis is also supported by DNA transfection data with unmodified PEI; the increase of w/w ratio from 0.8 to 4 led to increased transfection efficiency (and toxicity). Higher amounts of PEI in the formulation and subsequently in endosomal compartments may increase escape to the cytosol due to a stronger proton sponge effect (*26, 27*). Therefore, the transfection properties of PEI can be boosted by increasing the amount of polymer.

The concentration of PEI plays a major role for efficient siRNA delivery. At small concentrations, unmodified PEI is not able to facilitate significant knockdown (Figure 5). Higher concentrations lead to high toxicity of the carrier. In the case of modified PEIs, in particular, PEI-SUC-9, higher concentrations of PEI could be applied without toxicity. At these concentrations, even small amounts of siRNA could be applied to decrease the activity of the target gene. Therefore, the reduction of the toxicity has a really decisive role for the efficiency of siRNA formulations with modified PEI.

CONCLUSIONS

The amino group modifications of branched PEI with acetamide, β-propionic acid and ethyl ester, or succinic acid as presented in this study strongly increase the efficiency in siRNA delivery. For example, PEI-SUC can mediate knockdown at siRNA concentrations as low as 50 nM. The stability of polyplexes did not correlate with the efficiency. The most probable reason for the improved characteristics is the strongly reduced cytotoxicity of the modified PEI, which allows the administration of polyplexes formulated with a larger amount of polymeric carrier.

Solid-Phase Synthesis of Europium-Labeled Human INSL3 as a Novel Probe for the Study of Ligand−Receptor Interactions

Fazel Shabanpoor,[†,‡] Richard A. Hughes,[§] Ross A. D. Bathgate,[†,||] Suode Zhang,[†] Denis B. Scanlon,[⊥] Feng Lin,[†] Mohammed Akhter Hossain,[†] Frances Separovic,[‡] and John D. Wade*[,†,‡]

An efficient solid-phase synthesis protocol has been developed which, together with regioselective sequential formation of the three disulfide bonds, enabled the preparation of specifically monolanthanide (europium)-labeled human insulin-like peptide 3 (INSL3) for the study of its interaction with its G-protein-coupled receptor, RXFP2, via time-resolved fluorometry. A commercially available chelator, diethylene triamine pentaacetic acid (DTPA), was coupled to the N-terminus of the INSL3 A-chain on the solid phase, and then a coordination complex between europium ion and DTPA was formed using $EuCl_3$ to protect the chelator from production of an unidentified adduct during subsequent combination of the A- and B-chains. The labeled peptide was purified in high yield using high-performance liquid chromatography with nearly neutral pH buffers to prevent the liberation of Eu^{3+} from the chelator. Using time-resolved fluorometry, saturation binding assays were undertaken to determine the binding affinity (pK_d) of labeled INSL3 for RXFP2 in HEK-293T cells stably expressing RXFP2. The dissociation constant of DTPA-labeled INSL3 (9.05 ± 0.03, $n = 3$) that was obtained from saturation binding experiments was comparable to that of ^{125}I-labeled INSL3 (9.59 ± 0.09, $n = 3$). The receptor binding affinity (pK_i) of human INSL3 was determined to be 9.27 ± 0.06, $n = 3$, using Eu-DTPA-INSL3 as a labeled ligand, which again is similar to that obtained when ^{125}I-INSL3 was used as labeled ligand (9.34 ± 0.02, $n = 4$). This novel lanthanide-coordinated, DTPA-labeled INSL3 has excellent sensitivity, stability, and high specific activity, properties that will be particularly beneficial in high-throughput screening of INSL3 analogues in structure−activity studies.

Insulin-like peptide 3 (INSL3), also referred to as Leydig-insulin-like (Ley-I-L) and relaxin-like factor (RLF) (*1*) is a circulating peptide hormone belonging to the relaxin-insulin superfamily of peptides. The heterodimeric peptide hormone INSL3 consists of two chains (A and B) connected via three disulfide bonds (*1–3*). INSL3 and its G-protein coupled receptor (GPCR), RXFP2 (also known as LGR8), have been shown to play important roles in the reproductive system including testicular descent during fetal development as a result of INSL3-mediated gubernacular growth (*4–6*) and meiotic progression of arrested oocytes in the female and suppression of male germ cell apoptosis (*7*). Additionally, recent studies have shown the pathological involvement of INSL3 in certain cancers, as its expression is up-regulated in human thyroid carcinoma, neoplastic Leydig cells, and mammary epithelial cells (*8*).

Recent structure−activity relationship studies have provided considerable insight into the molecular interaction of INSL3 with its receptor associated with reproductive processes. The rapidly emerging physiological and pathological importance of INSL3 has led to efforts to develop antagonists which prevent binding and signaling of INSL3. The structure-based development and discovery of such antagonists requires the design and synthesis of various analogues. In order to test these analogues for their receptor binding affinity, radioactive ^{125}I-labeled INSL3 has typically been employed. However, the use of this peptide has drawbacks including its short half-life, high cost, and the need for its preparation immediately prior to use. Additionally, there are safety concerns associated with the use of radionuclides. To overcome these problems, we undertook the development of efficient methods for the preparation of an INSL3 labeled with a lanthanide for evaluation and use in a time-resolved fluorescence receptor binding assay.

The development of such lanthanide-based assays to study ligand−receptor interactions provides an attractive alternative to the traditional radionuclide-based assays. Due to their unique fluorescent properties, chelates of specific trivalent lanthanide ions (Eu^{3+}, Tb^{3+}, and Sm^{3+}) have been coupled to molecules of biological interest and the resultant labeled molecules used as probes in various biological assays such as kinase assays (*9*), immunofluorometric detection assays (*10*), and ligand−receptor interaction assays (*11*). Normally, aqueous solutions of Eu^{3+}, Tb^{3+}, or Sm^{3+} produce such a weak fluorescence that it cannot be detected by a regular fluorometer (*12*). However, these rare earths form stable coordination complexes with appropriate signal-enhancing ligands and, following irradiation with near-ultraviolet light, the ligand is excited (*13*). Then by intersystem crossing (known as an antenna effect), energy is transferred from the signal-enhancing ligand to the central lanthanide ion, which becomes excited (*13*). When the excited lanthanide ion returns to the ground state, it emits a strong fluorescence. The signal-enhancing ligands enhance the fluorescent emission of lanthanide ions by shielding them from the quenching effects of water (*14*).

The emitted fluorescence has four attractive characteristics: (1) the emission wavelength is barely affected by the structure of the ligand. (2) It has a long fluorescence lifetime (∼ms) which

allows measurement of fluorescence signal to be made after the decay of short-lived (micro- to picoseconds) background fluorescence from plates, cells, and reagents that are often a source of background in many fluorescence measurements (*10*, *15*, *16*). (3) It is characterized by a large Stokes shift (difference between the excitation maximum and emission maximum) compared to the short Stokes shift of organic fluorescent dyes in which the excitation and emission spectrum often overlap. (4) It exhibits a sharp emission peak which causes a large emission intensity that is easily detectable. These factors contribute to the low background and high sensitivity of lanthanide time-resolved fluorescence, making it comparable to that of radionuclide detection.

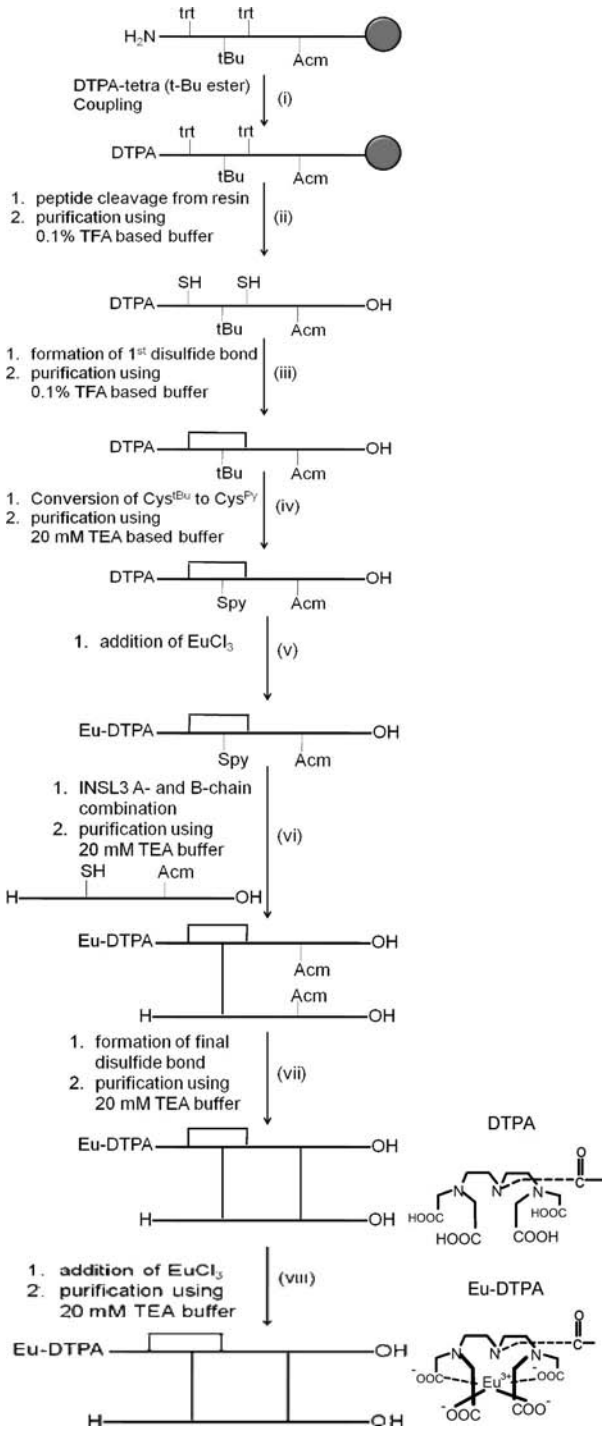
In this study, we have developed an efficient solid-phase synthesis technique to prepare specifically monolabeled peptide, which was subsequently shown to possess biophysical properties that render it suitable for receptor binding studies. INSL3 was labeled specifically at the *N*-terminus of the synthetic A-chain with the chelator, diethylenetriamine-*N*,*N*,*N*′′*N*′′-tetra-*tert*-butyl acetate-*N*′-acetic acid (DTPA). The labeled peptide was subsequently combined with the B-chain via regioselective disulfide bond formation. After chemical characterization of labeled INSL3, we performed saturation binding assays to determine maximum specific binding (B_{max}) and the receptor binding affinity of Eu-DTPA-labeled INSL3 (pK_d). We then performed competition binding assays to determine the binding affinity (pK_i) of the native INSL3 for RXFP2 in HEK 293 cell line using Eu-DTPA-INSL3 as labeled ligand.

EXPERIMENTAL PROCEDURES

Materials. 9-Fluorenylmethoxycarbonyl (Fmoc) protected L-α-amino acids; 1-[bis(dimethylamino)methylene]-1*H*-benzotriazolium hexafluorophosphate (HBTU), *N*,*N*-dimethylformamide (DMF), piperidine, and trifluoroacetic acid (TFA) were obtained from Auspep (West Melbourne, Australia). Fmoc-L-Tyr(tBu)-PEG-PS and Fmoc-L-Ala-PEG-PS resins with substitution of 0.20 mmol/g were purchased from Applied Biosystems (Melbourne, Australia). Methanol, diethyl ether, dichloromethane, Merck (Kilsyth, Melbourne, Australia), 3,6-dioxa-1,8-octanedithiol (DODT), triisopropylsilane (TIPS), diisopropylethylamine (DIPEA), 1,2,4,5-benzene-tetracarboxylic dianhydride (Sigma-Aldrich, Sydney, Australia), 2,2′-dipyridyl disulfide (DPDS), (Fluka-Switzerland); diethylenetriamine-*N*,*N*,*N*′′,*N*′′-tetra-*tert*-butyl acetate-*N*′-acetic acid (DTPA) (Macrocyclic, USA). N^1-(*p*-isothiocyanatobenzyl)-diethylenetriamine-*N*, N^2, *N*, N^3-tetraacetic acid (Eu-DTTA) (Perkin-Elmer, Australia). Acetonitrile and NH_4HCO_3, $(NH_4)_2CO_3$: BDH laboratory supplies, (Poole, UK) and trifluoromethanesulfonic acid (TFMSA) (MP Biomedicals, Seven Hills NSW Australia). All other reagents: Sigma Castle Hill, NSW. Dulbecco's modified Eagles' medium (DMEM), RPMI 1640 medium, 2 mM L-glutamine, fetal calf serum, and penicillin/streptomycin were all obtained from Trace Biosciences (Castle Hill, New South Wales). All other reagents were obtained from Sigma-Aldrich (New South Wales, Australia).

Peptide Synthesis. All linear precursor peptides were solid-phase synthesized (*17*) as C-terminal acids on PAC-PEG-PS resin (0.2 mmol/g loading) using Fmoc chemistry. They were assembled on a CEM Liberty microwave peptide synthesizer (Ai Scientific, Queensland, and Australia). The side chain protecting groups of trifunctional amino acids were trifluoroacetic acid labile, except for acetamidomethyl (Acm)-protected cysteines in positions A24 and B22, and *tert*-butyl (tBu)-protected cysteine in position A11. All peptides were synthesized on a 0.1 mmol scale using a 5-fold molar excess of Fmoc-protected amino acids (0.5 mmol) that were activated by using 5-fold excess of HBTU in the presence of DIEA (*18*, *19*). N^{α}-Fmoc protecting groups were removed by treating the resin-attached peptide with piperidine (20% v/v) in DMF. The coupling and deprotection were carried out at 75 °C using 25 W microwave power for 5 min and 60 W microwave power for 3 min, respectively. The chelator, DTPA-tetra(tBu ester) (3 equiv, 0.3 mmol), was coupled to the N-terminus of the solid-phase bound A-chain. The 2,4,6-trinitrobenzenesulphonic acid (TNBSA) test (*20*) was carried out to determine the success of coupling the DTPA. Each resin-bound polypeptide chain was cleaved from the solid support by treatment with a cocktail of trifluoroacetic acid (TFA)/3,6-dioxa-1,8-octanedithiol (DODT)/H_2O/triisopropylsilane (TIPS) (94%/2.5%/2.5%/1%, 20 mL) for 90 min. The cleaved peptide was precipitated in ice-cold diethyl ether and centrifuged at 3000 rpm for 3 min. The pellet was washed by resuspending it in ice-cold diethyl ether and centrifuging it again. This washing process was repeated at least three times. The stepwise synthesis of disulfide bonds was carried out by first forming the intra-A-chain disulfide bond between cysteines at positions A10 and A15. The cysteines were oxidized by first dissolving the linear A-chain in 0.1 M NH_4HCO_3 (1 mg/3 mL) to which a 1 mM solution of 2,2′-dispyridyl disulfide (DPDS) (*21*) in methanol (0.2 mL/ 1 mg peptide) was added while stirring. An aliquot of the mixture was analyzed by RP-HPLC to monitor the oxidation process. The oxidized INSL3 A-chains were analyzed and purified by preparative RP-HPLC on Waters XBridge columns (4.6 × 250 mm, C18, 5 μm) and (19 × 150 mm, C18, 5 μm), respectively, using two different buffer systems. INSL3 A-chain was purified using 0.1% trifluoroacetic acid in water (solvent A) and 0.1%

Scheme 1. Schematic Diagram of Synthesis of Eu-DTPA-INSL3 and Its Reagents and Conditions[a]



[a] (i) DTPA (3 equiv), HBTU (3 equiv), DIEA (3.5 equiv); (ii) TFA:DoDt:H_2O:TIPS (94:2.5:2.5:1); (iii) 1 mg peptide/0.2 mL of 1 mM DPDS; (iv) peptide:DPDS (1:4 μmol) dissolved in TFA: thioanisole (9:1) in 50 μg/μL, chilled on ice to 0 °C and then similar volume of TFA:TFMSA (4:1) was added; stirred for 1 hr at 0 °C and then purificaion of DTPA-INSL3 A-chain using 20 mM TEA buffer, pH 6.5, (v) DTPA-INSL3 A-chain and $EuCl_3$ (2 equiv) were dissolved in H_2O and stirred at room temperature for 30 min; (vi) Eu-DTPA-INSL3 A-chain dissolved in NH_4CO_3 mixed with INSL3 B-chain in water (1:1 mol) and stirred for 30 min; (vii) 60 mM HCl, acetic acid (2 mg/ mL), 20 mM I_2 (23 equiv/Acm), 1 h at rt, peptide was purified using 20 mM TEA based buffer, (viii) Eu-DTPA-INSL3 and $EuCl_3$ (2 equiv) were dissolved in H_2O and stirred at room temperature for 30 min and then final product was purified using 20 mM TEA based buffer to prevent the liberation of Eu^{3+} from the chelation with DTPA chelator.

trifluoroacetic acid in 100% acetonitrile (solvent B) running from 20% to 50% B at a flow rate of 10 mL/min over 30 min. In order to form the first interchain disulfide bond, the *tert*-butyl protecting group on cysteine in position A11 was converted to 2-pyridylsulfenyl derivative by dissolving the A-chain and DPDS (1:4 μmol) in TFA and thioanisole (9:1 v/v) (50 μg/ μL). The mixture was chilled on ice after which a similar volume of TFMSA in TFA (1:4 v/v) was added and the reaction continued for 45 min at 0 °C (*22*). The A-chain was precipitated with cold diethyl ether, and the pellet collected by centrifugation and washed 4 times to remove excess DPDS. The INSL3 A-chain derivative was purified using 0.1% TFA based buffers whereas the INSL3 A-chain with DTPA attached was purified using 20 mM triethylammonium acetate (TEA), pH 6.5, (solvent A) and 20 mM TEA in 90% acetonitrile (solvent B) with gradient of 20−50% B in 30 min. The first interchain disulfide bond was formed by reacting equimolar amounts of purified INSL3 B-chain with thiol-activated A-chain. The A-chain was dissolved in NH_4HCO_3, pH 8.5 and the B-chain, dissolved in water, was then added with stirring. The progress of the reaction was monitored using RP-HPLC. The reaction was complete after 30 min and the combined A- and B-chains were then purified by RP-HPLC using 0.1% TFA based buffers. In the case of INSL3 A-chain with the DTPA chelator at the N-terminus, the A-chain was first dissolved in NH_4HCO_3, pH 8.5, and then a 2-fold excess of europium chloride ($EuCl_3$) solution in water was added and the reaction was stirred for 10 min to form the complex of Eu-DTPA-A-chain before adding the equimolar amounts of INSL3 B-chain. The combined INSL3 Eu-DTPA-A-chain and B-chain was purified using 20 mM TEA based buffers. The formation of the last disulfide bond was achieved by oxidative removal of the acetamidomethyl groups in positions A24 and B22 by dissolving the peptide in 60 mM HCL (5% v/v) and acetic acid (2 mg/mL) followed by addition of 20 mM iodine (23 equiv/Acm). The reaction was stirred at room temperature for 1 h during which the progress was assessed by analytical RP-HPLC. After the completion of reaction, the mixture was poured onto chilled diethyl ether to precipitate the peptide, which was collected by centrifugation. The peptide was dissolved in water and 20 mM ascorbic acid to quench the remaining traces of iodine and then purified by preparative RP-HPLC on a Waters XBridge column (19 × 150 mm, C18, 5 μm) using 20 mM TEA-based buffers as described above. The solvent was removed by lyophilization which left a yellow oily peptide that was relyophilized in 50% acetonitrile in water to give a white powder. After purification, the labeled INSL3 containing the DTPA chelator was redissolved in H_2O and then 2 equiv of europium chloride was added and stirred for an hour. The formation of complex between europium and DTPA chelator was monitored by RP-HPLC and MALDI-TOF/TOF mass spectroscopy. The labeled INSL3 was then purified by RP-HPLC using 20 mM TEA-based buffer.

Postsynthesis Labeling of INSL3. The postsynthesis labeling of INSL3 with Eu-DTTA complex was attempted using a 10-fold excess of Eu-DTTA over peptide at three different reaction conditions: (1) 50 mM $NaHCO_3$ + 150 mM NaCl, pH 8.5 (*23*), (2) 100 mM Na_2CO_3, pH 9.2 (according to the DELFIA labeling kit form PerkinElmer), (3) 100 mM Na_2CO_3, pH 6.5. The reactions were carried out at 4 °C overnight.

Peptide Characterization. Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF/TOF MS, Bruker Daltonics, Germany) was used to characterize the peptides at each intermediate step using sinapinic acid, α-cyano-4-hydroxycinnamic acid, and 2,5-dihydroxy benzoic acid (Bruker Daltonics, Germany) based on the molecular size of the peptide. The matrices were made up in 50% acetonitrile containing either 0.05% TFA or 0.05% formic acid. The peptide

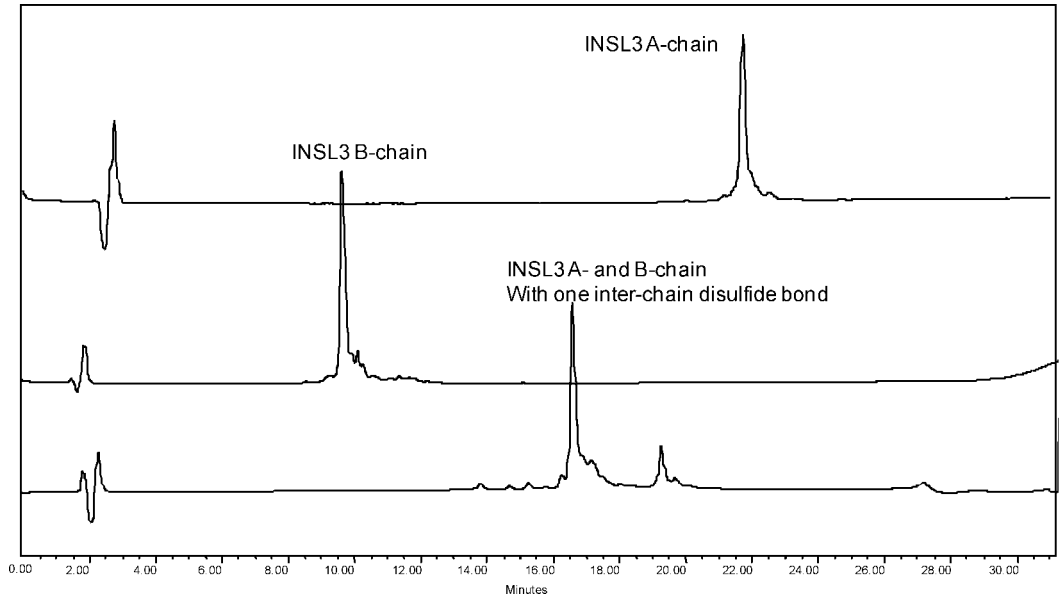


Figure 4. RP-HPLC monitoring of DTPA-INSL3 A-chain combination with INSL3 B-chain. The single-chain peptides each have a correct molecular mass as determined by MALDI-TOF/TOF. However, the combined A- and B-chain product had a *m*/*z* 55.2 higher than the expected monoisotopic mass (see Figure 5).

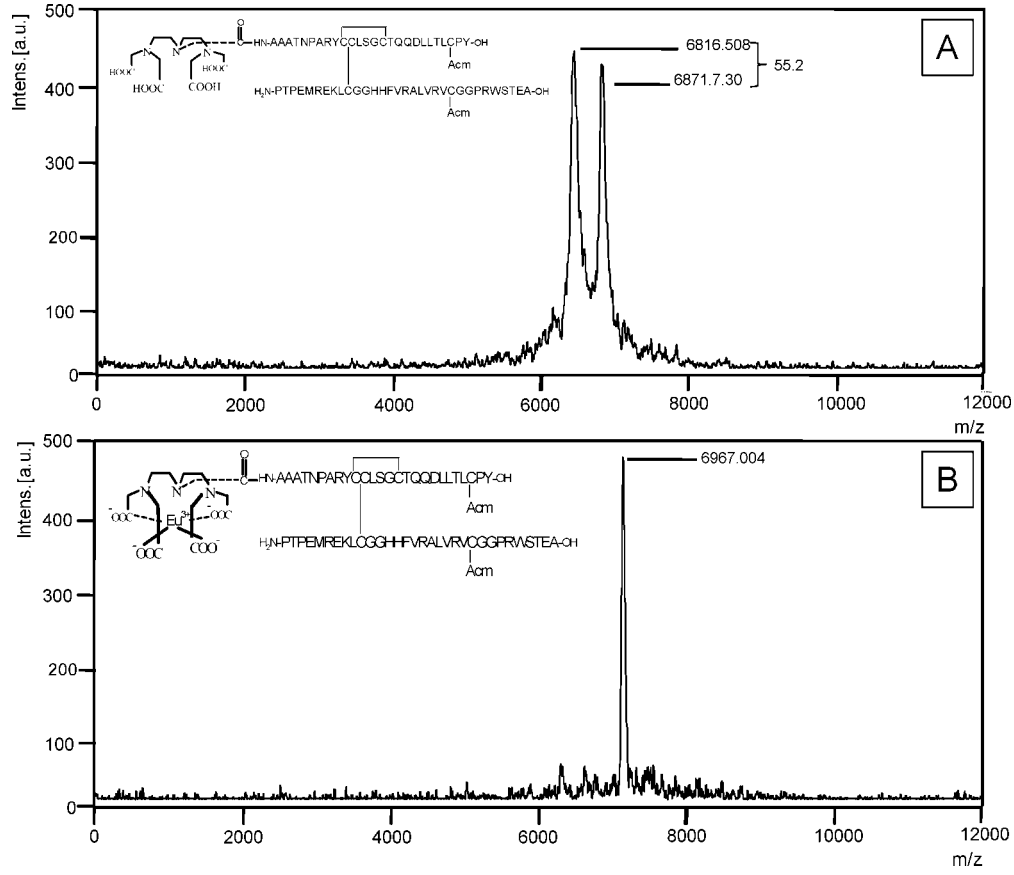

Figure 5. (A) Mass spectrum of DTPA-labeled INSL3 after the formation of first interchain disulfide bond which showed a *m*/*z* of 55.2 Da higher ($[M + H]^+ = 6724.244$) than the expected monoisotopic mass ($[M + H]^+ = 6668.989$). (B) Protection of the DTPA on the A-chain with Eu^{3+} prior to combination with B-chain gave a labeled INSL3 with the correct monoisotopic mass (expected $[M + H]^+ = 6966.85$).

content was determined using vapor-phase acid hydrolysis in 6 M HCL containing 2% phenol at 110 °C for 24 h. The individual amino acids were converted to stable, fluorescent derivatives using a Waters AccQ.Tag kit (Waters, Sydney, Australia). The derivatized amino acids were separated using a Shim-Pak XR-ODS (3 × 75 mm, 2.2 μm) column on Shimadzu RP-HPLC system (Shimadzu, Victoria, Australia).

Circular Dichroism Spectroscopy. The peptides were made up to a concentration of 0.1 μM in phosphate buffered saline (PBS: 10 mM potassium phosphate buffer containing 137 mM NaCl pH 7.4). The far UV circular dichroism (CD) spectra of peptides were acquired using a Jasco J815 spectropolarimeter between the wavelengths of 195−250 nm at room temperature with a resolution of 0.1 nm, bandwidth of 0.1 nm, and a cell of

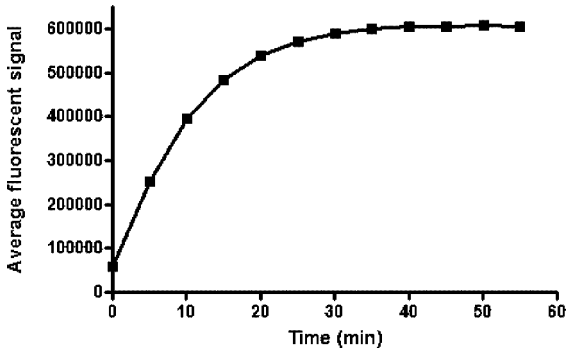

Figure 6. Measurement of Eu release from DTPA chelate. 10 μL of 10 nM Eu-DTPA-INSL3 peptide was mixed with enhancement solution in triplicate and the fluorescence was measured at 5 min interval for 60 min. The signal reached its maximum at ~600 000 average fluorescent units (AFU) at time 40 min.

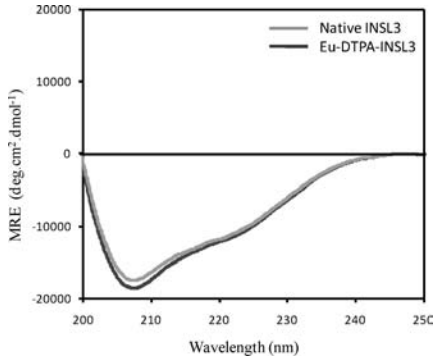

Figure 7. CD spectra of human INSL3 (solid gray line) and Eu-DTPA-INSL3 (solid black line) measured at a concentration of 0.1 μM in PBS (pH 7.4) at room temperature. The two peptides showed similar spectra and a calculated helicity of approximately 33%.

0.1 cm path length. The recorded spectra in millidegrees of ellipticity (θ) were converted to mean residue ellipticity (MRE) in deg.cm^2 dmol^{-1}.

Cell Culture and Ligand Binding Assays. Subcultures of human embryonic kidney cells (HEK 293T) stably transfected with RXFPR2 (LGR8) were plated out at a density of 80 000 cells per 200 μL per well in a 96 well Isoplate with white wall and clear bottom precoated with poly(L-lysine). The binding assay was carried out using a modification of a method previously described by us (*24*). Briefly, at the start of each experiment, cell culture medium was removed and the cells were washed with phosphate buffer saline (PBS) (250 μL per well). 1% BSA in receptor binding buffer (250 μL) was then added to each well and allowed to stand at room temperature for 1 h. The appropriate concentration of INSL3 and Eu-labeled INSL3, in 1% BSA in receptor binding buffer, was added to each well in triplicate and incubated at room temperature for 1 h. The cells were washed with PBS (250 μL) once, and then 100 μL of enhancement solution (purchased from Perkin-Elmer, composed of β-NTA, TOPO and 0.1% (w/v) Triton X-100 in 0.1 M acetic acid adjusted to pH 3.2) was added to each well, and after 45 min, the fluorescent measurement was carried out on a Victor^3 Plate Reader (Perkin-Elmer, USA) at excitation of 340 nm and emission of 614 nm with the delay time and counting time of 400 μs each.

Data Analysis. The CD spectra data were first transformed from machine unit θ to $\Delta\varepsilon$ using Graphpad *PRISM 4* (Graphpad Ins., San Diego, USA) with user-defined formula ($\varepsilon = \theta \times (0.1 \times \text{MRW})/(\text{P} \times \text{C}) \times 3298$). The converted values were then submitted to the DichroWeb server (*25–28*) for calculation of secondary structure using the CDSSTR (*29*) and K2D (*30*)

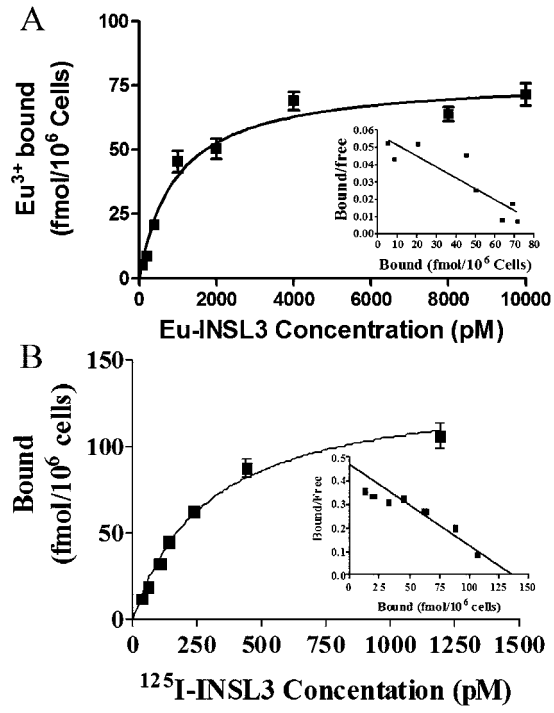

Figure 8. Saturation binding curves of Eu-DTPA-INSL3 and ^{125}I-INSL3 in HEK293T cells stably transfected to express RXFP2. Different concentrations of labeled peptides were added to cells and incubated at room temperature for 60 min. Nonspecific binding was determined in the presence of 500 nM INSL3. The pK_d and B_{max} of the labeled peptides were determined to be 9.05 $\pm$ 0.03 (n = 3); 78074 (receptors/cell) $\pm$ 15834 SEM (n = 3); and 9.59 $\pm$ 0.09; 83518 (receptors/cell) $\pm$ 13061 SEM, respectively. GraphPad *Prism* software was used to fit the data using the nonlinear regression and one site binding model.

analysis algorithms. Graphpad *PRISM 4* was used to analyze the receptor-binding assays data, which were expressed as mean $\pm$ SEM of percentage specific binding of Eu-chelate-labeled INSL3 from triplicate treatments from at least three independent experiments. The value for the dissociation constant (k_d) was determined by fitting saturation binding data to a one-site hyperbolic model. The inhibition constants were determined from IC_{50} values using the Cheng-Prusoff equation (*31*).

RESULTS AND DISCUSSION

Molecular Design and Postsynthesis Labeling. Human INSL3 has two chains (a 26 residue A-chain and a 31 residue B-chain) each containing a free terminal α-amino group. There is also an ε-amino group on the side chain of lysine B8 (Figure 1). We initially undertook postsynthesis labeling of synthetic native human INSL3 with commercially available activated Eu-DTTA chelate, N^1-(*p*-isothiocyanato benzyl)-diethylenetriamine-N,N^2,N,N^3-tetraacetic acid (Figure 2A). First, we synthesized human INSL3 by Fmoc chemistry using standard solid-phase techniques that have been optimized in our laboratory (*32*), employing regioselectively S-protecting groups for the sequential formation of each of the three disulfide bonds. The postsynthesis labeling of INSL3 was then carried out using different reaction conditions, each of which yielded a mixture of mono- and multilabeled peptides, as well as unlabeled INSL3 (Figure 3). Although it was possible to identify some of the species present in the complex mixture obtained, they were poorly resolved making their complete deconvolution and purification exceptionally difficult. As the determination of precise binding parameters requires knowledge of the true specific activity of a ligand, we thus sought an alternative approach to develop a molecularly defined Eu-labeled INSL3.

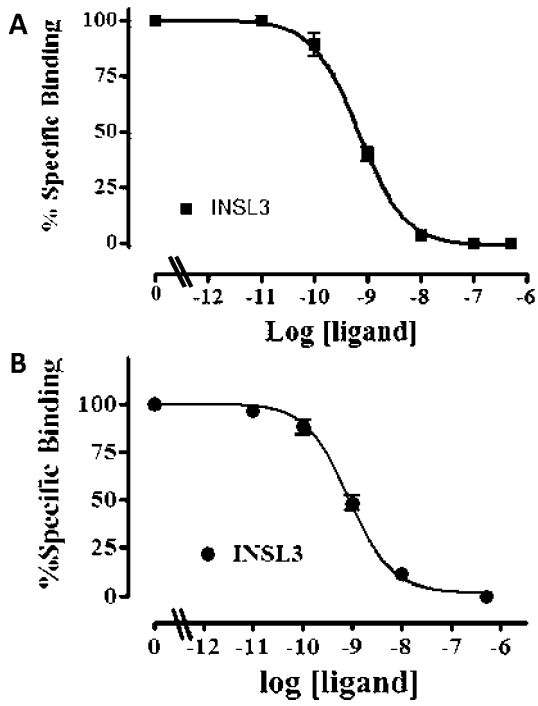

Figure 9. Competition binding curves of INSL3 using Eu-DTPA-INSL3 (A) and ^{125}I-INSL3 (B) as labeled ligand in HEK293T cells stably transfected to express RXFP2. Different concentrations of INSL3 were added to cells and incubated at room temperature for 60 min. INSL3 was competed off the receptor with 0.5 nM of Eu-DTPA-INSL3. The pK_i of INSL3 was determined to be 9.27 ± 0.06 (n = 3) using Eu-DTPA-INSL3 as labeled ligand and 9.34 ± 0.02 (n = 4) when ^{125}I-INSL3 used as labeled ligand. GraphPad *Prism* software was used to fit the data using the nonlinear regression and one site competition model.

Synthesis of INSL3 and Incorporation of DTPA Chelator on Solid Phase. Structure−activity relationship studies with INSL3, relaxin, and other members of this superfamily of peptide hormones which each have a similar core tertiary structure have shown that the N-terminus of the A-chain is tolerant to a range of chemical modifications (*33*). We thus chose to prepare a Eu-chelate labeled INSL3 in which the chelator was incorporated specifically and solely at the N-terminus of the A-chain. To do this, we first synthesized human INSL3 A-chain on the solid phase and concluded this by coupling the empty chelator DTPA (Figure 2B) (Scheme 1). Our plan was that this would allow us to use standard TFA-based HPLC buffers—these are not compatible with Eu-loaded chelates, as the chelates are unstable at low pH—rather than the less well-resolving TEA acetate buffers. Following the removal of the chelator-labeled A-chain from the solid support, the intrachain disulfide bond was formed via 2-pyridyldisulfide-mediated oxidation (*21*). The resulting modified peptide, which possessed a *tert*-butyl protecting group on the thiol of Cys 11 and a Acm group on the thiol of Cys 24, was then subjected to treatment with 2-pyridyldisulfide in TFMSA/TFA to convert the tert-butyl functionality to an S-pyridinyl group. In subsequent preliminary experiments, despite the apparent successful combination of the A- and B-chains via thiolysis of the S-pyridinyl by the free thiol of Cys 10 of the B-chain (Figure 4), MALDI-TOF MS showed the resulting product to have a molecular mass that was 55.2 higher than the expected monoisotopic mass ($[M + H]^+$= 6668.98) (Figure 5A) group. Although this modification did not hinder formation of the final disulfide bond (via iodine oxidation of the Acm groups on Cys A24 and B22), the resulting DTPA-peptide failed to form a complex with the Eu^{3+} when treated with an excess of $EuCl_3$. This suggested that the modification was of the DTPA moiety itself. In order to overcome this, we modified the protocol by loading the DTPA on the A-chain with Eu^{3+} prior to combining the two chains. This strategy effectively protected the four free carboxylic groups on the DTPA chelator during chain combination, and the resulting chain-combined peptide could thus be obtained with the correct monoisotopic mass (Figure 5B). The final stage of the synthesis (the formation of second interchain disulfide bond using iodine in acetic acid) is carried out at low pH, conditions which might be expected to lead to the loss of Eu^{3+} from the DTPA. Although MS analysis indicated that only a small proportion of Eu^{3+} was lost during the final disulfide bond formation, we nevertheless chose to reload the chelate with Eu^{3+} after this step to ensure that the final product was completely Eu-chelated. The formation of the complex between europium and DTPA-labeled INSL3 was monitored by RP-HPLC and MALDI-TOF/TOF MS. The final desired Eu-chelate labeled INSL3 was then purified by RP-HPLC buffer using TEA acetate buffer at near-neutral pH (6.5) to prevent the liberation of europium from the DTPA.

The peptide purity was shown by analytical RP-HPLC to be greater than 95%, and to have a peptide content of 64% as assessed by amino acid analysis. A monoisotopic m/z of 6821 corresponding to the singly Eu-coordinated DTPA-labeled INSL3 was obtained using MALDI-TOF MS, which contrasts to previous studies on synthetic lanthanide complexes of synthetic peptides, in which multiple isomers were obtained (*34*). The overall yield of synthesis was 7.7%, which compares favorably to that obtained for native human INSL3 (10%) obtained using a similar synthesis protocol (*35*).

In order to monitor the time that it takes for the fluorescent signal of Eu-coordinated DTPA INSL3 (as a result of the liberation of Eu^{3+} from chelation with DTPA) to reach its maximum, the release of Eu^{3+} from DTPA chelate was monitored by measuring the fluorescence of 10 μL of 10 nM Eu-DTPA-INSL3 in 100 μL of enhancement solution in triplicate at 5 min intervals for 60 min (Figure 6). The signal reached its maximum at ∼600 000 average fluorescence units (AFU) at time 40 min. This time was used in the subsequent assays as the end point for liberation of europium before measurement of fluorescent signal.

Circular Dichroism Spectroscopy. The CD spectra of synthetic native human INSL3 and DTPA-labeled INSL3 were measured in PBS (pH 7.4) (Figure 7). The two peptides showed a similar CD spectroscopic profile with calculated helicity of approximately 33%. This indicated that the coupling of DTPA to the N-terminus of the INSL3 A-chain had no apparent influence on the secondary structure of INSL3 and is therefore unlikely to have perturbed its tertiary structure.

Whole Cell Receptor Binding Assay. Eu-chelate-labeled and ^{125}I-labeled INSL3 were compared under identical saturation binding conditions using HEK293T cells stably transfected to express the INSL3 receptor RXFP2. To determine the total binding, cells were incubated with different concentrations of Eu-DTPA-INSL3 and ^{125}I-INSL3 in a 96 well plate for 60 min at room temperature to reach equilibrium. To measure the nonspecific binding, 500 nM unlabeled INSL3 was used to competitively dissociate Eu-chelate-labeled INSL3. The nonspecific binding was found to be less than 15% of total binding at any concentration of Eu-DTPA-INSL3 used. Like ^{125}I-INSL3, Eu-DTPA-INSL3 binds in a specific and saturable manner and it was best fitted to a one-site binding model (Figure 8). The calculated dissociation constant (pK_d) for Eu-DTPA-INSL3 was 9.05 ± 0.03 (n = 3) and maximal binding B_{max} was 78074 ± 15834 receptors/cell (n = 3). The pK_d and B_{max} determined for Eu-DTPA-INSL3 agreed with the pK_d (9.59 ± 0.09, n = 3) and B_{max} (83518 ± 13061 receptors/cell) values for ^{125}I-INSL3. There was a slight decrease in pK_d of Eu-DTPA-INSL3

compared to ^{125}I-INSL3 that is statistically significant ($p < 0.005$). This decline in affinity of Eu-DTPA-INSL3 for its receptor RXFP2 is possibly due to the relatively large size of the DTPA moiety compared to the smaller ^{125}I atom. This phenomenon of a slight loss in ligand−receptor affinity has also been reported in other cases where DTPA labeling of bioactive peptides has been described (*36*–*38*). Assays using the Eu-chelate-labeled INSL3 were highly reproducible, showed excellent signal-to-noise ratios, and were faster than radioisotopic-based binding assays, as the measurement can be made directly in the same plate as the assay (in the case of radionuclei-based assays, the cells need to be transferred for signal measurement).

Once the Eu-DTPA-INSL3 was characterized by saturation binding experiments, it was then used as a labeled ligand in competition binding assays (Figure 9) to determine the receptor binding affinity (pK_i) of native human INSL3 for RXFP2. INSL3 displaced Eu-DTPA-INSL3 (0.5 nM) with pK_i value of 9.27 ± 0.06 ($n = 3$), which was similar to those previously obtained using ^{125}I-INSL3 (9.34 ± 0.02, $n = 4$) (*3*).

CONCLUSION

The use of lanthanide-labeled ligands to study ligand−receptor interactions has become increasingly popular over the past decade. Such peptides have a longer shelf life compared to radiolabeled peptides, offering greater reproducibility of results, since the same stock of labeled ligand can be used over a long period of time. In this study, we have demonstrated a novel and efficient methodology for effective preparation of Eu-coordinating, DTPA-lableled INSL3 via solid-phase synthesis. The site-specific incorporation of DTPA chelator on the solid phase gives a monolabeled peptide with high yield and purity compared to the postsynthesis labeling using DTTA chelator. Eu-DTPA-labeled INSL3 showed binding properties that are comparable to that of ^{125}I-INSL3. Lanthanide detection methods are presently being applied to other members of the relaxin-insulin superfamily of peptide hormones.

ACKNOWLEDGMENT

We thank Sharon Layfield for carrying out the cell culture and Tania Ferrero for help with binding assays. This work was funded by National Health and Medical Reseach Council of Australia Project grants 350245 and 509048 to J.D.W., R.A.D.B., and R.A.H.

Design and Synthesis of Dendritic Molecular Transporter that Achieves Efficient *in Vivo* Delivery of Morpholino Antisense Oligo

Yong-Fu Li* and Paul A. Morcos

Gene Tools, LLC, One Summerton Way, Philomath, Oregon 97370. Received April 4, 2008; Revised Manuscript Received May 15, 2008

Safe and efficient *in vivo* delivery of Morpholino antisense oligos was probably the last and most difficult challenge for the broad application of antisense in animal research and therapeutics. Several arginine-rich peptides effective for *in vivo* delivery of Morpholino antisense oligos require rather complex and expensive procedures for synthesis and conjugation. This work describes the design and synthesis of a dendritic transporter in a most concise manner where the selection of the core scaffold, functional group multiplication, orthogonal protecting group manipulation, solid phase conjugation, and off-resin perguanidinylation of the transporter structure are all orchestrated for efficient assembly. We utilized triazine as a core to provide a site for on-column conjugation to the Morpholino oligo and to anchor functional side arms which, after extension, multiplication, and deprotection, are subsequently converted from primary amines to the eight guanidinium headgroups that serve for transport across cell membranes. Intravenous administration of the delivery-enabled Morpholino into a splice-reporter strain of transgenic living mice results in *de novo* expression of splice-corrected green fluorescent protein in a broad range of tissues and organs in those treated mice. This rigorously demonstrates that this new dendritic transporter achieves effective delivery of a Morpholino oligo into the cytosol/nuclear compartment of cells systemically *in vivo*. The practical conjugation process may overcome any availability limitation for routine use by the scientific community, and the efficient delivery ability of this transporter may advance the application of Morpholino antisense technology in animals.

INTRODUCTION

Unlike other types of antisense oligos including siRNA, PNA, mPNA, S-DNA, and LNA, Morpholinos provide all the desired properties of stability, nuclease resistance, high efficacy, long-term activity, water solubility, low toxicity, and exquisite specificity (*1*, *2*). However, biological barriers typically limit or preclude uptake, and therefore therapeutic benefit, of large polar structures such as antisense oligos (*3*). Advanced antisense oligo types faced the lack of a safe and effective delivery component which could transport oligos into the cytosol/nuclear compartment of cells of living animals, and this constituted the last major hurdle before antisense oligos could be introduced for the treatment of a broad range of currently intractable diseases such as splice-modifying genetic defects and viral diseases. The development of novel guanidinium-rich compositions that facilitate cellular uptake of a variety of physiologically and therapeutically active biomolecules started with discovery that HIV-Tat peptide and other arginine-rich derivatives could achieve efficient intracellular delivery (*4–8*). These and other cell-permeable arginine-rich oligopeptides were capable of transporting various types of cargo, such as small polar molecules, oligonucleotides, plasmid DNA, and proteins, across the membranes of most types of animal cells (*9–15*). Structural variations on the arginine-rich peptides have shown that the length of the backbone and the spacing and composition of the side chains can be varied to adjust the uptake efficiency (*16–19*). Testing structural modifications on the arginine-rich peptides and peptoids have demonstrated that the guanidinium headgroups of the arginine residues are principally responsible for the uptake into cells, backbone chirality is not critical for cellular uptake, and about 7 to 15 guanidine headgroups are optimal for efficient uptake (*20–22*).

Arginine-rich peptides have been covalently conjugated with Morpholino antisense oligos and the conjugates were shown to enter the cytosol and nucleus of cells (*23–26*). Because of the peptidic nature, however, degradation of the peptide portion of the conjugates was found to be time- and tissue-dependent ((*27*) and references cited therein). In addition, the intensively studied cell-penetrating peptides [(R-AhxR)$_4$AhxB] showed different degrees of toxicity depending on the dose, dose frequency, and route of administration. From a practical point of view, the application of such arginine-rich peptide transporters is somewhat limited due to their high cost, scalability, and stability. Usually, these peptide transporters are prepared using a solid-phase synthesizer. Although this approach is readily automated and allows for efficient synthesis and purification of the transporter peptides, the approach suffers drawbacks including limited scalability and the need for resin attachment and cleavage and off-column attachment. Importantly, the use of peptides risks an immune response to the conjugates, which would prevent repeated administrations for diseases requiring long-term treatment.

To develop an efficient delivery composition which is cost-effective, is not immunogenic, and is stable under physiological conditions, we sought to exploit nonlinear, nonpeptidic, and non-natural architectures. Relatively few attempts have been made to use guanidine groups in branched or dendritic structures, but those attempts have produced some useful data that helped our development process. For example, polyguanidino dendrimers using triamine-based diamino acid monomeric units to form a series of octa-guanidine dendrimers show differences in uptake efficiency related to the structural flexibility of the dendritic architecture (*28*). Branched-chain arginine peptides translocate through cell membranes and bring exogenous proteins into cells; eight arginine residues was the number that exhibited the most

efficient internalization (*29*). Dendritic oligoguanidines based on amino triol subunits translocate through the cell membrane (*30*). An alternative architecture based on an amino triacid scaffold demonstrated that dendritic molecular transporters can not only enable transport of bioactive cargo across the cell membrane, but can also direct the delivery into particular intracellular compartments (*31*). However, the reported syntheses of dendritic oligoguanidines are lengthy or involve expensive reagents for their assembly. We directed our efforts to developing a dendritic structure which mimics features of branched octaguanidines but provides cost-effective synthesis, convenient conjugation with bioactive molecules (Morpholino in this study), and superior performance in transporting compounds across biological barriers.

For a molecular transporter to possess the aforementioned features, we proposed that the constitution of the dendritic scaffold should allow assembly of the oligoguanidine through a variant of a segment-multiplying strategy and had to allow attachment of a bioactive substance to its orthogonal functional site. We chose triazine as a trifunctional entity on which two sites could be used for branching side arms while a Morpholino oligo could be linked to its third functional site. To construct the molecular transporter in a cost-effective manner, we used diethanolamine to displace two chlorine atoms, yielding a tetra-alcohol intermediate. After formation of a tetra-carbonate from the corresponding alcohols, a secondary amine from a triamine moiety in which the two terminal primary amines are in a protected form was contacted with the tetra-carbonate to give octa-amine, thus providing eight side chains each containing a terminal primary amino group in a protected form. To the third functional site of triazine, a reactive linking group which could conjugate with a Morpholino oligo was installed. Conjugation on synthesis resin allowed convenient removal of excess reagents, and the conjugate thus formed was cleaved from the synthesis resin by ammonia treatment. This ammonia treatment simultaneously generated an unprotected octa-amine intermediate which was subsequently converted to octa-guanidine by a single perguanidinylation step, yielding a conjugate of Morpholino with a transporter containing a triazine as the core scaffold (Scheme 1). These conjugates which are enabled for *in vivo* delivery are referred to as "Vivo-Morpholinos". We conjugated the transporter with a Morpholino oligo targeted to block a mutant RNA splicing site whose blockage leads to normal translation of an enhanced green fluorescent protein (EGFP) reporter. Using the signal from this reporter gene, relative *in vivo* delivery efficacies were determined for a variety of tissues in transgenic mice.

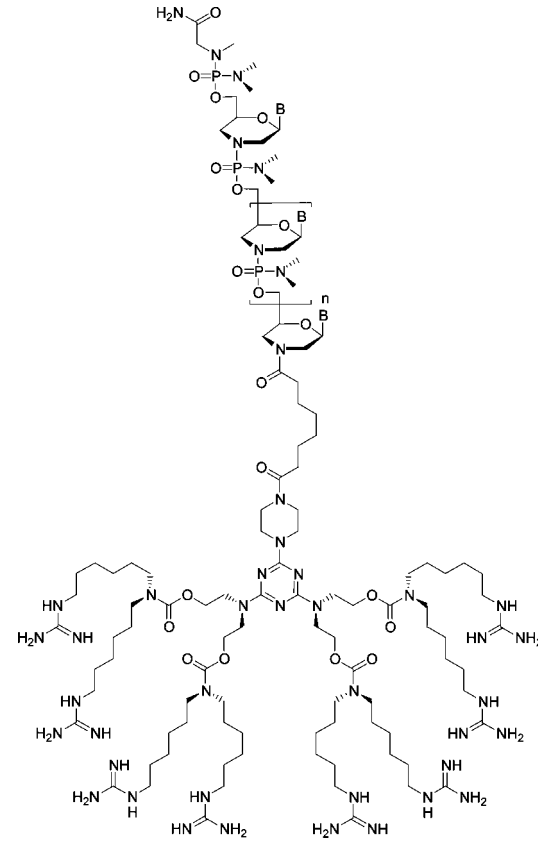
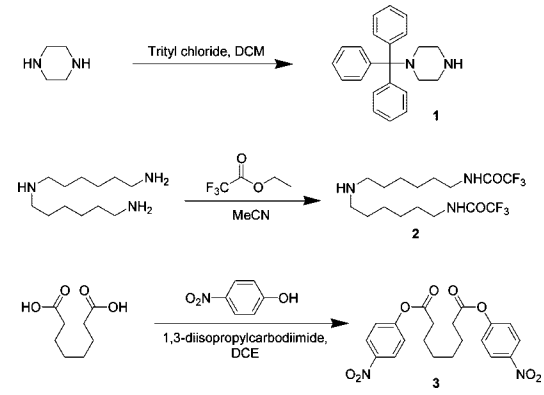


Scheme 2. Synthesis of Building Components for the Transporter Composition



EXPERIMENTAL PROCEDURES

Materials and Methods. All reagents and solvents were purchased from commercial sources and were used as received. Components of the transporter were synthesized from readily available starting materials (Scheme 2). Analytical TLC was carried out on Baker-flex silica gel IB2-F and spots were located by UV illumination. Column chromatography was conducted through silica gel (60−200 mesh) from Fisher Scientific. All NMR spectra were measured on a 400 MHz Bruker FT-NMR spectrometer. MALDI-TOF MS were carried out on an Applied Biosystems Voyager using a matrix of 2′,4′,6′-trihydroxyacetophenone (THAP). Oasis HLB LP extraction cartridges (Waters Corporation, Milford, MA, USA) were used for purification of Vivo-Morpholino.

Synthesis of *N*-Tritylpiperazine (1). Piperazine (107.5 g, 1.25 mol) was dissolved in dichloromethane (500 mL). Trityl chloride (69.7 g, 0.25 mol) was added to the mixture cooled in an ice bath. After addition, the mixture was kept at room temperature for 30 min. The mixture was washed with water (500 mL, three times) and the organic layer was separated and dried over sodium sulfate. The solution was concentrated to ca. 100 mL and added to hexane (1 L). The solid was removed by filtration. The filtrate was evaporated to dryness to give a white solid (80 g, 97%). ^{1}H NMR (400 MHz, $CDCl_3$) $\delta = 1.31$ (br, 1H), 3.04 (br, 8H), 7.17−7.52 (m, 15H).

Synthesis of Bis(trifluoroacetamidohexyl)amine (2). To a stirred solution of bis(hexamethylene)triamine (8.62 g, 40 mmol) in acetonitrile (120 mL) cooled in an ice bath was added water (0.864 mL) and ethyl trifluoroacetate (16.7 mL, 140 mmol). After addition, the mixture was refluxed for 16 h. The solvents were removed by evaporation. The residue solidified upon storing at room temperature and was used without further purification.

Synthesis of Di(4-nitrophenyl) Suberate (3). Suberic acid (8.71 g, 50 mmol) and 4-nitrophenol (14.61 g, 105 mmol) were dissolved in dichloroethane (100 mL). 1,3-Diisopropylcarbo-

diimide (16.28 mL, 104 mmol) was added to the mixture. The mixture was kept at room temperature for 16 h. The solid was removed by filtration. The filtrate was loaded on a silica gel column (silica gel 140 g), eluting with dichloromethane. After removal of the solvent, a white solid was obtained (18.4 g, 88%). ^{1}H NMR (400 MHz, $CDCl_3$) δ = 1.54 (m, 4H), 1.84 (m, 4H), 2.66 (t, 7.44 Hz, 4H), 7.31 (d, 9.39 Hz, 4H), 8.30 (d, 9.20 Hz, 4H).

Synthesis of 2-(4-Tritylpiperazinyl)-4,6-bis(diethanolamino)triazine (4). Cyanuric chloride (922 mg, 5 mmol) was dissolved in a solution of tetrahydrofuran (10 mL) containing *N*,*N*-diisopropylethylamine (1.74 mL, 10 mmol). *N*-Tritylpiperazine (**1**) (1.642 g, 5 mmol) dissolved in tetrahydrofuran (10 mL) was added to the mixture cooled in an ice bath. The mixture was kept at 0 and 25 °C for 30 min, respectively. Diethanolamine (5 mL, 52 mmol) was added to the mixture. The mixture was heated at 70 °C for 16 h. The volatile materials were removed by evaporation. The residue was dissolved in ethyl acetate (200 mL) and washed with sodium bicarbonate (150 mL) and water (200 mL × 2) and dried over sodium sulfate. After removal of the solvent, a white solid was obtained (2.82 g, 92%). ^{1}H NMR (400 MHz, $CDCl_3$) δ = 2.36 (br, 2H), 3.70 (br, 8H), 3.71 (br, 12H), 3.83 (br, 2H), 4.01 (br, 2H), 4.39 (br, 2H), 7.17−7.50 (m, 15H).

Synthesis of 2-(4-Tritylpiperazinyl)-4,6-bis[di(4-nitrophenyloxycarbonyloxyethyl)amino]triazine (5). 2-(4-Tritylpiperazinyl)-4,6-bis(diethanolamino)triazine (**4**) (2.82 g, 4.59 mmol) was dissolved in acetone (40 mL). Triethylamine (1 mL) was added to the mixture, followed by bis(4-nitrophenyl) carbonate (8.4 g, 27.54 mmol). The mixture was kept at room temperature for 48 h. The solvent was then removed. The product was obtained by column purification to give a yellowish solid (4.8 g, 82%). ^{1}H NMR (400 MHz, DMSO-d_6) δ = 2.45 (br, 2H), 3.94 (m, 14H), 4.51 (m, 8H), 6.87 (d, 9.19 Hz, 8H), 7.17−7.49 (m, 15H), 8.07 (d, 9.19 Hz, 8H).

Synthesis of 2-(4-Tritylpiperazinyl)-4,6-bis{di[di(trifluoroacetamidohexyl)aminocarbonyloxyethyl]amino}triazine (6). 2-(4-Tritylpiperazinyl)-4,6-bis[di(4-nitrophenyloxycarbonyloxyethyl)amino]triazine (**5**) (2.03 g, 1.6 mmol) was dissolved in acetone (40 mL). *N*,*N*-Diisopropylethylamine (2.8 mL, 16 mmol) was added to the mixture, followed by bis(trifluoroacetamidohexyl)amine (**2**) (4.16 g, 8 mmol). The reaction mixture was kept at room temperature for 16 h. The volatile materials were removed by evaporation. The residue was chromatographed to give an oily foam (3.28 g, 87%). ^{1}H NMR (400 MHz, DMSO-d_6) δ = 1.21 (br, 32H), 1.42 (br, 32H), 3.07 (br, 8H), 3.15 (br, 32H), 3.72 (br, 8H), 4.08 (br, 8H), 7.19−7.45 (m, 15H), 9.35 (s, 8H). MALDI MS: calculated for $C_{102}H_{143}F_{24}N_{19}O_{16}$, 2347.3; found, 2356.9.

Synthesis of 2-[(4-Nitrophenyl)oxycarbonylhexamethylenecarbonylpiperazinyl]-4,6-bis{di[di(trifluoroacetamidohexyl)-aminocarbonyloxyethyl]amino}triazine (8). 2-(4-Tritylpiperazinyl)-4,6-bis{di[di(trifluoroacetamidohexyl)aminocarbonyloxyethyl]amino}triazine (**6**) (1.0 g, 0.43 mmol) was dissolved in methanol (3.2 mL) and the solution was mixed with 5% cyanoacetic acid in 2,2,2-trifluoroethanol (5 mL). The mixture was kept at room temperature for 10 min. The solvents were removed by evaporation. The residue was then diluted with dichloromethane (50 mL) and washed with saturated sodium bicarbonate (30 mL). The organic layer was separated and dried over sodium sulfate. After removal of the solvent, the crude product **7** was dissolved in acetone (10 mL). *N*,*N*-Diisopropylethylamine (0.4 mL, 2.3 mmol) was added to the mixture, followed by di(4-nitrophenyl) suberate (**3**) (732 mg, 1.76 mmol). The reaction mixture was kept at 50 °C for 2 h. The solvents were removed and the product was isolated from silica gel column chromatography to give an oily paste (0.95 g, 93%). ^{1}H NMR (400 MHz, DMSO-d_6) δ = 1.23 (br, 34H), 1.45 (br, 34H), 1.54 (m, 2H), 1.67 (m, 2H), 2.35 (t, 7.23 Hz, 2H), 2.64 (t, 7.43 Hz, 2H), 3.15 (m, br, 32H), 3.47 (br, 4H), 3.64 (br, 2H), 3.69 (br, 2H), 3.76 (br, 8H), 4.14 (br, 8H), 7.44 (d, 9.19 Hz, 2H), 8.31 (d, 9.19 Hz, 2H), 9.36 (s, br, 8H). MALDI MS: calculated for $C_{97}H_{144}F_{24}N_{20}O_{21}$, 2382.3; found, 2390.6.

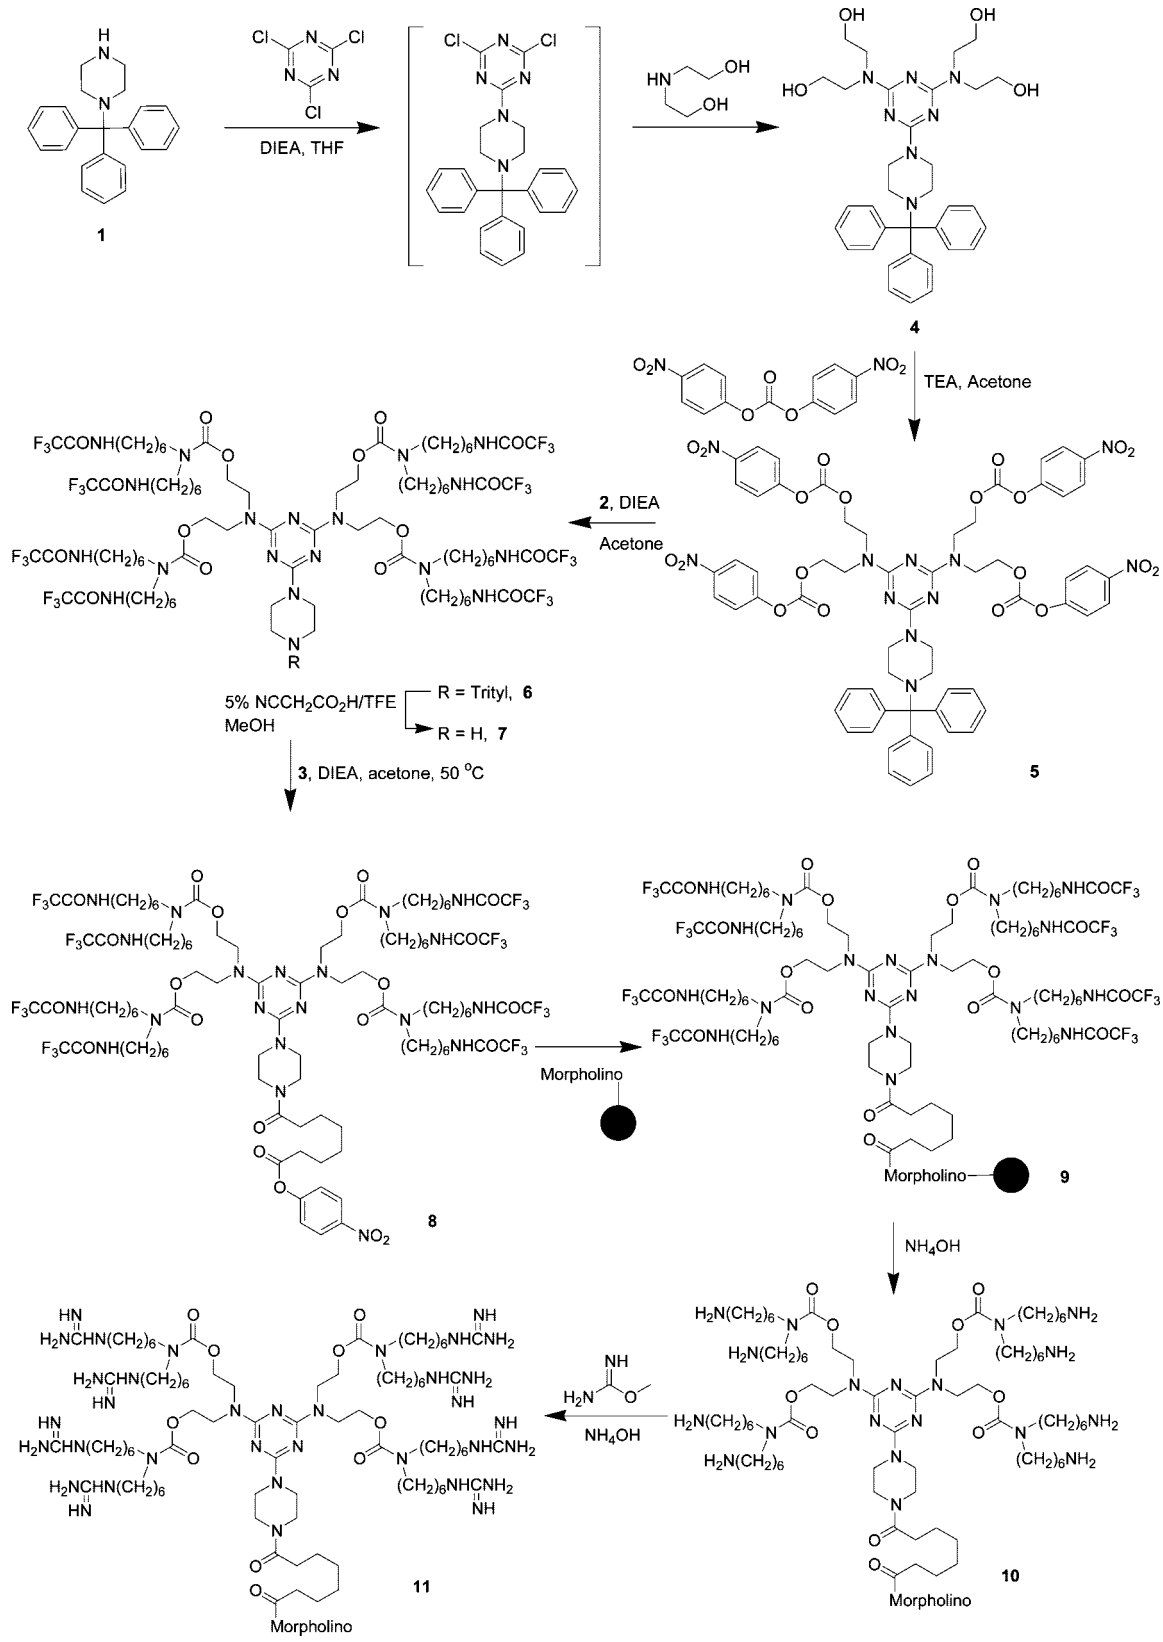
General Procedure for Synthesis of Vivo-Morpholino 11, a Conjugate Containing the Transporter Composition and a Morpholino Antisense Oligo. The precursor transporter composition **8** (50 mg) in 1,3-dimethyl-2-imidazolidinone (0.18 mL) containing 5% of 1-hydroxybenzotriazole as catalyst and 5% of triethylamine was incubated with Morpholino (300 nmol) at 60 °C for 2 h. After removal of the solvent, concentrated ammonia (0.30 mL) was added and the mixture was incubated at 50 °C for 5 h. 18% ammonia (0.30 mL) was added to the mixture, followed by *O*-methylisourea hydrochloride (100 mg). The mixture was incubated at 65 °C for 45 min. Water was added to dilute the mixture, and the product was isolated by using Oasis HLB LP extraction cartridge to give Vivo-Morpholino.

Functional Quantitative Assessment of Delivery *in Vivo* of a Conjugate Comprising the Transporter Composition with a Morpholino. Intravenous injections of Vivo-Morpholino were carried out in Ryszard Kole's laboratory by Peter Sazani using transgenic mice that ubiquitously express a modified enhanced green fluorescent protein (EGFP) pre-mRNA containing an aberrantly spliced β-globin intron (IVS2−654) (*32*). The Vivo-Morpholino oligo called VM654−25 with the sequence 5′-TTGCTATTACCTTAACCCAGAAATT was injected i.v. into mice at 12.5 mg/kg for 4 consecutive days, sacrificed on day 5, and analyzed as described previously (*32*).

RESULTS AND DISCUSSION

We set out to design a transporter composition which could be constructed very efficiently. Therefore, many factors such as scaffold core selection, functional group multiplication, orthogonal protecting group manipulation, and methods for formation of guanidine headgroups had to be taken into consideration for overall economy of process. We chose triazine architecture since it provides three functional sites, one for installing a linking group to covalently conjugate with a Morpholino oligo and the other two for anchoring the dendritic arms. Importantly for the selection of triazine, it is unnatural and robust in the living system. This increases the likelihood of avoiding problems such as antigenicity and toxicity and improving properties such as bioavailability, stability, and safety for use *in vivo*. The synthesis uses readily available starting materials (Scheme 2). Monotritylated piperazine **1** is obtained by treating trityl chloride with an excess amount of piperazine. Reaction of bis(hexamethylene)triamine with ethyl trifluoroacetate selectively protects the two terminal primary amines and gives the intact secondary amine **2**. Homobifunctional linker **3** is obtained by formation of the nitrophenyl ester of suberic acid. The whole scheme for assembly of Vivo-Morpholino is illustrated in Scheme 3. The protected piperazine **1** reacts with cyanuric chloride to give monosubstituted dichlorotriazine. The dichloride is then treated with diethanolamine to give tetra-alcohol **4**. The hydroxyl groups are activated with bis(4-nitrophenyl) carbonate to provide tetra-carbonate **5**. The tetra-carbonate **5** is treated with a secondary amine **2** to form tetra-carbamate **6** containing octa-amine in a protected form. The secondary amine of piperazine **7** is regenerated by acidic deprotection, which reacts with the homobifunctional linker **3** to give the transporter moiety **8** with an active functional moiety at one terminus. This activated ester functional group **8** couples with a Morpholino oligo on the synthesis resin to give conjugate

Scheme 3. Synthetic Scheme for Assembly of Vivo-Morpholino



9. Exposure of **9** to concentrated ammonia cleaves the conjugate from the synthesis resin and removes all the protecting groups on the Morpholino oligo bases and the protecting groups on the octa-amines to give conjugate **10**. Perguanidinylation with *O*-methylisourea quantitatively converts all the amino groups on the dendritic scaffold to guanidine headgroups, furnishing the assembly of Vivo-Morpholino **11**.

Triazine Core and Functional Group Multiplication. Dendrimers represent an attractive transporter scaffold offering economical assembly of oligoguanidine transporters through a segment-multiplying strategy. The ease of displacement of chloride atoms in cyanuric chloride by various nucleophiles in the presence of a hydrochloride acceptor (usually tertiary amines) makes this reagent useful for preparation of mono-,

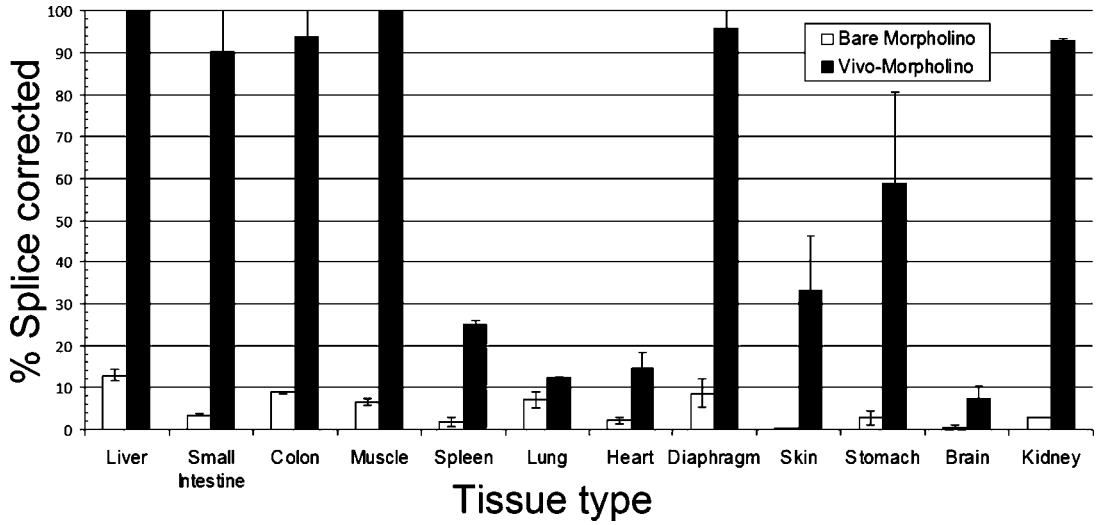


Figure 1. Densitometric analysis of RT-PCR transcripts of splice correction by Vivo-Morpholino in comparison with bare Morpholino. The data is collected from four mice, two injected with Vivo-Morpholino and two injected with bare Morpholino at 12.5 mg/kg/day i.v. for four days, followed by sacrifice and RT-PCR one day after the final injection.

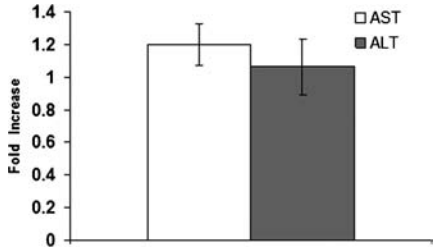

Figure 2. Assessment of liver toxicity. No significant changes in aspartate aminotransferase (AST) or alanine aminotransferase (ALT) levels in the liver were detected with Vivo-Morpholinos delivered at 12.5 mg/kg/day i.v. for four days. Data shown as fold AST or ALT over prebleed, one day after final injection.

di-, and trisubstituted 1,3,5-triazine (*33*). The substitution of chloride can be controlled by temperature to run in a stepwise manner. In this study, the first amino group from *N*-tritylpiperazine **1** was introduced to give monosubstituted triazine at 0 °C in the presence of *N*,*N*-diisopropylethylamine as base. The other two chloride atoms of the triazine were displaced at 70 °C by diethanolamine which was used in excess as base to neutralize the hydrogen chloride generated. The trityl group serves as the protecting group which, after removal at a later stage, generates an amino group for installing an active linking group to be used for conjugation with a Morpholino oligo. The formation of this intermediate provides the core scaffold on which the tetra-alcohol **4** not only extended the side-arms and doubled the number of the functional groups, but also paved the way for further multiplication of side arms. We activated the hydroxyl groups to form reactive carbonate **5**. By contacting a secondary amine of a triamine moiety in which the two terminal primary amines are in a protected form, the tetracarbonate **5** yielded an eight side chain entity **6**, each of which contains a terminal protected primary amine which forms a guanidine headgroup after deprotection and guanidinylation.

Protecting Group Manipulation. We chose bis(hexamethylene)triamine so that its secondary amine, after selective protection of two terminal primary amines, could contact reactive carbonate **5** to form carbamate **6** and double the number of side arms. The methylene units of this commercially available triamine link and spatially separate the three nitrogen atoms. After the primary amino groups are converted to guanidine headgroups, the side arms are flexibly spaced which could be beneficial for efficient contact with cell membrane surface and consequently efficient intracellular uptake. Trifluoroacetyl is selected for protecting terminal primary amines, based on the following four critical reasons: (a) Since methyl or ethyl trifluoroacetate are mild and selective reagents to protect primary amines in the presence of secondary amines (*34*), the secondary amine can remain intact while the primary amines are protected so that the secondary amine can be used to contact the carbonate **5**. (b) An orthogonal strategy has to be used since a different amino group must be selectively deprotected for ultimate conjugation with a Morpholino oligo. Acid-labile trityl group is selected for this amino group since trifluoroacetyl group is labile toward basic conditions but stable toward acidic conditions. (c) Trifluoroacetyl protecting groups on the amines can be cleaved by ammonolysis, a condition previously serving the double duty of removing protecting groups on Morpholino oligo bases and cleaving the oligo from the synthesis resin. Therefore, exposure of ammonia fits into the normal Morpholino synthesis process. This strategy proved very useful since the coupling of the transporter composition can be carried out with Morpholino antisense oligo while it is still on the synthesis resin, and subsequent ammonolytic treatment not only removes all the protecting groups on the Morpholino oligo and the oligoamine moiety, but also cleaves the Morpholino with its conjugated precursor transporter composition from the synthesis resin. The advantage of this triple duty maneuver is simple and economic production. (d) Ammonia is also a basic reagent for converting an amino group to a guanidine in the presence of a guanidinylation agent, *O*-methylisourea hydrochloride. Therefore, without any purification, the ammonia used for cleavage from resin and deprotection of protecting groups of the Morpholino oligo bases and the dendrimeric amine can be carried over for the subsequent guanidinylation. By choosing the selected protecting group (trifluoroacetyl) and the selected protecting group removal agent (ammonia), the whole process for producing a conjugate containing a Morpholino oligo and transporter composition is significantly simplified.

Perguanidinylation. In principle, guanidino groups can be installed before the whole transporter composition is conjugated with a Morpholino oligo. However, because of the nature of the guanidine moiety, it requires expensive reagents for the conversion from primary amines and for the protection of the guanidines thus formed. In this study, we adopted a postperguanidinylation performed in solution phase after deprotection and cleavage of the conjugate from the solid support with

ammonia. Without any purification, the mixture thus obtained was treated further with *O*-methylisourea hydrochloride, giving Vivo-Morpholino, the conjugate of transporter composition with a Morpholino oligo. *O*-Methylisourea hemisulfate could also be used for the conversion, but side products corresponding to the incomplete guanidinylation were observed, which was in agreement with the reported results (*35*). We did not find any side reactions toward the other amino groups present in the bases of Morpholino oligo under the guanidinylation conditions. This off-resin method to convert amino functions quantitatively into guanidines proves a concise and straightforward means to obtain the target compounds.

Systemic Delivery of Vivo-Morpholino in Transgenic Mice. Kole and co-workers have developed a strain of transgenic mice modeled after their test system used in cell culture (*36*) but replacing the luciferase component with enhanced green fluorescent protein (EGFP) (*37*). That RNA transcript, expressed in all tissues of the mice, contains a globin intron mutation that causes a splicing error which prevents expression of the EGFP. Annealing an appropriate Morpholino antisense oligo to the mutant splice site corrects the splicing error and results in the expression of EGFP. Thus, the technology of visualizing green fluorescence in a specific tissue or evaluating the corrected transcript by RT-PCR has been used to rigorously assess cytosolic delivery into cells of that tissue *in vivo*.

The ability of Vivo-Morpholinos to achieve cytosolic delivery *in vivo* was assessed by administering a Vivo-Morpholino targeting the splice mutation site. This was introduced by intravenous injection at 12.5 mg/kg for 4 consecutive days into two of the transgenic mice harboring the splice mutation, followed by sacrifice on day 5. Delivery was assessed by densitometric RT-PCR analysis of RNA transcripts isolated from various tissues (Figure 1). Nearly complete splice correction was observed in liver, small intestine, colon, skeletal muscle, diaphragm, and kidney, indicating excellent delivery with Vivo-Morpholinos. Delivery into the spleen and stomach was also high, although not sufficient for complete splice correction at the concentration tested. Modest delivery was achieved in lung, heart, skin, and brain. The AST-ALT data were also collected (Figure 2), indicating that the Vivo-Morpholinos were not toxic to the liver in mice at 12.5 mg/kg over 4 days. These striking results show that Vivo-Morpholinos are capable of achieving a quantifiable level of delivery in all tissues tested from repeated i.v. injections. This suggests that Vivo-Morpholinos are both achieving a high level of access to the cytosol of cells within tissues and able to avoid the inhibitory effects of serum and other cellular components.

CONCLUSION

In this report, we described synthesis of a novel dendritic molecular transporter and its conjugate with a Morpholino oligo and investigated intracellular uptake of the conjugate in transgenic mice by quantitative functional assessment. The transporter composition is a compact, biocompatible dendritic scaffold with guanidine headgroups spaced in a flexible framework. The assembly of the core structure exploits trifunctional triazine both for installing a linking site for ultimate conjugation with a Morpholino oligo and for anchoring the side arms which were then multiplied to extend the number of side chains. This structure was demonstrated to provide efficient delivery into cells of transgenic mice with minimal toxicity. Further investigations will involve the studies of tissue distribution, biological stability, and pharmacokinetics of delivery-enabled Morpholino oligos. Our present results show that the synthetic approach of this molecular transporter and its highly efficient delivery ability have advanced Morpholino antisense technology into a stage where cost-effective production of delivery-enhanced Morpholino oligos for studies in living animals is now practical.

ACKNOWLEDGMENT

We would like to thank Dr. James E. Summerton for his insightful discussion. Mrs. Chandell L. Terwilliger and Mrs. Jeannine M. Turner are thanked for their analytical assistance. We are grateful to Dr. Jon D. Moulton for his critical proofreading of the manuscript.

Monosaccharide-Based Water-Soluble Fluorescent Tags

Alan R. Katritzky,* Janet Cusido, and Tamari Narindoshvili

Center for Heterocyclic Compounds, Department of Chemistry, University of Florida, Gainesville, Florida 32611-7200. Received April 9, 2008; Revised Manuscript Received May 2, 2008

Monosaccharides are fluorescently labeled under microwave irradiation by *N*-(coumarin-3-carbonyl)benzotriazole **4**. 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose **9** gives **12** (90%), 1,2:5,6-di-*O*-isopropylidene-D-glucose **10** gives **13** (89%), 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose **11** gives **14** (65%) (all by *O*-acylation) and 2,3,4,5-tetra-*O*-pivaloyl-*β*-D-galactopyranosylamine **15** gives **16** (60%) (by *N*-acylation). Similarly, the coumarin-containing activated lysine derivatives **7** and **8** afford the L-lysine-scaffold based coumarin labeled sugars **17**, **18a**,**b**, and **19** (67−85%) which, after removal of the diisopropylidene groups, provide water-soluble fluorescent derivatives.

INTRODUCTION

Carbohydrate moieties have pivotal roles in numerous biological processes including cell−cell communication (*1–3*), cell adhesion (*4, 5*), and protein folding and are implicit in various diseases (*6*) such as chronic inflammation, microbial infections, and cancer (*7–11*).

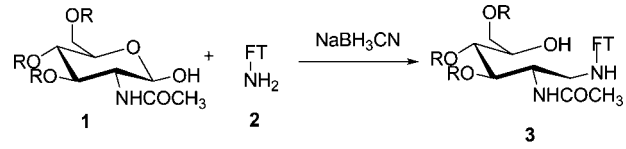
Glycosylation is a very common post-translational modification of proteins; in eukaryotic systems, over 50% of all protein sequences are glycosylated (*12, 13*). Glycosylated lipids constitute up to 5−10% of the membrane content in animal cells, and are involved in a wide array of pathological disorders (*14*).

Sequencing and structural analysis of an oligosaccharide chain of a glycoprotein or glycolipid is more complicated than DNA or protein sequencing because glycolipid molecules are frequently branched and each linkage between sugar residues introduces a new α or *β* stereocenter. Preferred analytical approaches (*15, 16*) detect oligosaccharides either by mass spectrometry (MS) or by pulsed amperometry. Before release from glycoproteins or glycolipids by chemical or enzymatic methods, oligosaccharides are frequently labeled at the reducing end to increase detection sensitivity (*17*). The insertion of a fluorescent tag (*18*) followed by chromatography or electrophoresis is a common analytical practice.

Primary amine-containing fluorescence tags (FT) can be introduced by reductive amination at the reducing end of sugar chains (*11, 19–23*). Thus, saccharides **1** react with **2** containing, e.g., a 2-aminopyridine and sodium cyanoborohydrate (or sodium borohydride) to give a glycamine **3** (Scheme 1). Similar procedures are used to determine glycosyl transferase activities (*24*). However, these methods cleave the cyclic structure at the reducing end of the sugar chain, thus changing the properties of the sugar moieties.

Labeling amino groups of mono- and diaminosaccharides with a fluorescent tag is an alternative method of measuring glycosyltransferase activities (*25–27*). Coupling of 7-hydroxycoumarin-3-carboxylic acid to glycosylamine was carried out in DMF by HBTU/HOBT/DIEA (*25*). Amino-rich polysaccharides have also been labeled with the fluorescein derivative 5-([4,6-dichlorotriazine-2-yl] amino)-fluorescein (DTAF) (*26, 27*). However, classical labeling procedures applied to proteins, based on acylation of NH_2 groups, are not useful for many sugars because of the absence of free amino groups in many saccharide structures.

Scheme 1. Fluorescent Labeling of Saccharides by Reductive Amination



FT - Fluorescent Tag

Fluorescence detection depends on the physical characteristics of the dyes employed. Many dyes with high extinction coefficients and high quantum yields are of limited utility because of (i) poor photostability and/or (ii) poor aqueous solubility. Solubility characteristics affect the degree of self-interaction in solution of chromophores conjugated to substrates and therefore light absorption and emission properties (*28*). Bright fluorescent reagents of good aqueous solubility and affording low nonspecific staining are needed. Incorporation of sugar units confers useful water solubility to organic fluorophores without significant changes in absorption and fluorescent properties (*29, 30*).

We have disclosed *N*-(coumarin-3-carbonyl)benzotriazole **4** as a useful starting material for convenient and reliable fluorescent labeling of amino acids and dipeptides (*31*). Such coumarin-labeled lysines, including N^{ϵ}-coumarin-labeled N^{α}-protected-L-lysines **5**,**6** (*31*) are of considerable interest for the design and synthesis of fluorogenic substrates for the analysis of matrix metalloproteinases (MMP) (*32–34*). Our successful labeling of amino acids in solution phase also utilized **7** (*31*), a benzotriazole-activated **5** (Scheme 2).

We recently reported efficient *O*-acylations of diisopropylidene-protected sugars with readily available *N*-(Cbz-α-aminoacyl)benzotriazoles under microwave irradiation (*35*). We now present the convenient and efficient fluorescent labeling of disopropylidene-protected sugars **9**−**11** by *O*-acylation and of pivaloyl-protected amino sugar **15** by *N*-acylation utilizing as acylating agents (i) *N*-(coumarin-3-carbonyl)benzotriazole **4** and (ii) **7**, **8**, the benzotriazole derivatives of N^{ϵ}-coumarin-labeled N^{α}-protected-L-lysines **5**, **6**. Acylation reactions were carried out at 60 °C under microwave irradiation or at ambient temperature. Monosaccharide-containing Fmoc-lysine fluorescent building blocks could be useful as water-soluble organic fluorophores for peptide labeling at the C-terminus in inverse solid-phase peptide synthesis (SPPS) (*36*).

EXPERIMENTAL PROCEDURES

General Procedure for the Preparation of *O*-(Coumarin)Diacetonide Sugars 12−14 under Microwave Irradiation. A dried, heavy-walled Pyrex tube containing a small stir bar was charged with *N*-coumarinoylbenzotriazole **4** (1.0 mmol), sugar (**9**−**11**) (1 mmol), DMAP (1 mmol), and CH_2Cl_2 (1 mL). The reaction mixture was exposed to microwave irradiation (100 W) for 45 min to obtain products (**12**−**14**) at a temperature of 60 °C. After the irradiation, the reaction mixture was allowed to cool until the temperature had fallen below 30 °C (ca. 10 min). CH_2Cl_2 (20 mL) was added to the reaction mixture, and the whole washed with 4 N HCl soln (3 × 15 mL), brine (10 mL), and dried over $MgSO_4$. The solution was concentrated under reduced pressure and the crude product was crystallized from CH_2Cl_2/hexanes for elemental analysis.

General Procedure for the Preparation of L-Lysine Scaffold Based Coumarin Labeled Sugars 17, 18a,b, 19, 20 at 20 °C. To a mixture of sugar (**9**, **10**, **11**, **12**) (1.0 mmol), N^{ϵ}-coumarin-3-carbonyl-N^{α}-Cbz-L-lysine benzotriazole **7** (to obtain **18a**) or N^{ϵ}-coumarin-3-carbonyl-N^{α}-Fmoc-L-lysine benzotriazole **8** (to obtain **17**, **18b**, **19**, **20**) (1.0 mmol) and DMAP (1.0 mmol), was added dry CH_2Cl_2 (3−5 mL), and the mixture stirred at room temperature for 16−24 h. The reaction mixture was then diluted by 30 mL of CH_2Cl_2 and washed with 4 N HCl (3 × 15 mL), brine (20 mL), and dried over $MgSO_4$. The solution was concentrated under reduced pressure and crude product was crystallized from CH_2Cl_2/hexanes mixture for elemental analysis.

General Procedure for the Cleavage of Diisopropylidene Group Present in Coumarin Labeled Glycoconjugates 13, 17. TFA-H_2O (4−0.2 mL) mixture was added to **13**, **17** (0.100 g) at room temperature and the reaction mixture was stirred until **13**, **17** were completely consumed as monitored by TLC (5−7 min). Solvent was then removed under reduced pressure, followed by subsequent washing with acetonitrile and diethyl ether (2−3 times). The residue solid was filtered off and dried to give **21**, **22** in yields of 97−98%.

RESULTS AND DISCUSSION

Preparation of N^{ϵ}-Coumarin-Labeled N^{α}-Fmoc-L-Lysine Benzotriazolide 8. N^{ϵ}-Coumarin-3-carbonyl-N^{α}-Fmoc-L-lysine benzotriazole **8** (Scheme 2) was prepared (87%) from coumarin-labeled N^{α}-Fmoc-protected lysine **6** according to the benzotriazole methodology optimized in our laboratories (*37*–*43*), by reaction with 1*H*-benzotriazole and thionyl chloride in CH_2Cl_2 at 20 °C for 2 h.

Preparation of coumarin-O-tagged monosaccharides: *O*-(coumarin-3-carbonyl)diisopropylidene sugars 12, 13, 14. *O*-Coumarin-labeled diisopropylidene sugars **12**, **13**, **14** were prepared by coupling of **4** with the 6-OH of 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose **9**, 3-OH of 1,2:5,6-di-*O*-isopropylidene-α-D-glucose **10**, and 1-OH of 2,3:5,6-di-*O*-

Scheme 6

[a] Determined in 95% methanol.

isopropylidene-α-D-mannofuranose **11**, respectively, in CH_2Cl_2 utilizing 1 equiv of DMAP, under 100 W microwave irradiation at 60 °C for 45 min (Scheme 3). The products were isolated after simple acid workup without chromatography in 65−90% yields.

Preparation of Coumarin-N-Tagged Monosaccharide: *N*-(Coumarin-3-Carbonyl)Tetrapivaloyl Sugar 16. 2,3,4,6-Tetra-*O*-pivaloyl-*β*-D-galactopyranosylamine **15** couples with *N*-(coumarin-3-carbonyl) benzotriazole **4** in dry CH_2Cl_2 in the presence of 1 equiv of DMAP during 24 h at 20 °C (Scheme 3). After acid workup and silica-gel column chromatography using EtOAc /hexane (1:2) as eluent, product **16** was isolated in 60% yield.

Preparation of *O*- and *N*-(N^{ϵ}-Coumarin-3-Carbonyl-N^{α}(Fmoc or Cbz-L-lys)-Protected Sugars 17, 18a,b, 19, 20. L-Lysine scaffold-based coumarin-labeled sugars **17**, **18a**,**b**, **19**, and **20** were synthesized by *O*-acylation of the free OH groups of diacetonide-protected sugars **9**, **10**, and **11** and *N*-acylation of the NH_2 group of **15** by N^{ϵ}-coumarin-3-carbonyl-N^{α}-Cbz or Fmoc-L-lysine benzotriazoles **7**, **8** (Scheme 4).

Coupling reactions were carried out in dry CH_2Cl_2, in the presence of 1 equiv of DMAP, at room temperature for 16−24 h. After washing with 4 N HCl, products **17** and **18a**,**b** were obtained without chromatography in 67−85% yields. Compounds **19** and **20** were isolated using chromatography in 74% and 40% yields, respectively. Under microwave irradiation at 60 °C, the preparation of **18a** (yield 83%) took 1 h; however, for the other products **17**, **18b**, **19**, and **20** lower yields in comparison to those obtained with room-temperature conditions were obtained.

Deprotection of the Diisopropylidene Groups of O-(Coumarin-Labeled) Diisopropylidene Sugars 13 and 17. Deprotection of the diacetonide groups of **13** and **17** were achieved in aqueous TFA at 20 °C in 5−7 min. The coumarin-free sugar **21** (Scheme 5) and coumarin-L-lysine-free sugar conjugates **22** (Scheme 6) were obtained in quantitative yields and characterized by ^1H and ^{13}C NMR spectroscopy, elemental analysis, melting point, and ORP.

Absorption ($\lambda_{Abs.}$) and fluorescence ($\lambda_{Em.}$) wavelength maxima were measured for each compounds (Table 1).

In conclusion, we have demonstrated a convenient and efficient *O*-fluorescent labeling of diisopropylidene protected sugars **12**−**14** and *N*-labeling of pivaloyl protected amino sugar **15** in yields of 60−90% by *N*-(coumarin-3-carbonyl)benzotriazole **4**. Fmoc and Cbz protected L-lysine scaffold-based coumarin-labeled protected sugars **17**, **18a**,**b**, **19**, and **20** were obtained from **7** and **8**. Deprotection of diisopropylidene groups from **13** and **17** provide water-soluble conjugates **21** and **22** in quantitative yields. Sugar-Fmoc-lysine fluorescent building blocks **17** and **18b** and **19** are expected to be useful fluorescent markers for peptide labeling in SPPS; deprotection of diisopropylidene protecting groups will provide better water solubility of coumarin-labeled peptides.

Supporting Information Available: Procedures for preparation and compound characterization data for **4**−**8** and characterization data for **14**, **16**, **19** and **20**. This material is available free of charge via the Internet at http://pubs.acs.org.

TECHNICAL NOTES

Synthesis of a Cross-Bridged Cyclam Derivative for Peptide Conjugation and ^{64}Cu Radiolabeling

Received January 30, 2008; Revised Manuscript Received May 28, 2008

The increased use of copper radioisotopes in radiopharmaceutical applications has created a need for bifunctional chelators (BFCs) that form stable radiocopper complexes and allow covalent attachment to biological molecules. Previous studies have established that 4,11-bis-(carbo-*tert*-butoxymethyl)-1,4,8,11-tetraazabicyclo[6.6.2]hexadecane (H_2CB-TE2A), a member of the ethylene "cross-bridged" cyclam (CB-cyclam) class of bicyclic tetraaza macrocycles, forms highly kinetically stable complexes with Cu(II) and is less susceptible to *in vivo* transchelation than its nonbridged analogue, 1,4,8,11-tetraazacyclotetradecane-1,4,8,11-tetraacetic acid (TETA). Herein, we report a convenient synthesis of a novel cross-bridged BFC that is structurally analogous to CB-TE2A in that it possesses two coordinating acetate arms, but in addition possesses a third orthogonally protected arm for conjugation to peptides and other targeting agents. Application of this strategy to cross-bridged chelators may also enable the development of even further improved agents for ^{64}Cu-mediated diagnostic positron emission tomography (PET) imaging as well as for targeted radiotherapeutic applications.

INTRODUCTION

The syntheses of 1,4,8,11-tetraaza-bicyclo[6.6.2]hexadecane (CB-cyclam) and related cross-bridged tetraamine ligands having non-adjacent nitrogens connected by an ethylene (CH_2CH_2) bridge (Figure 1) have been reported by Weisman and Wong (*1–3*). These ligands are remarkably efficient proton sponges and form complexes with small metal ions including Cu(II) by adopting low-energy conformations having all four nitrogen lone pairs convergent upon a three-dimensional cleft (*1*). Several related cross-bridged Cu(II) complexes have been synthesized (*2*), including those bearing pendant carboxymethyl arms that fully envelop the six-coordinate cation and neutralize its dicationic charge (*3*). Additional ethylene cross-bridged Cu(II) complexes have been explored by Busch (*4–7*), while other bridged bicyclic ligands have been reported by Springborg (*8–11*) and Micheloni (*12–16*). The coordination chemistry of bicyclic tetraaza ligands has been thoroughly reviewed by Springborg (*17*).

Copper-64 is an attractive radionuclide for use in both positron emission tomography (PET) imaging and targeted radiotherapy due to its half-life ($t_{1/2}$ = 12.7 h), its decay characteristics (β^+ (19%); β^- (39%)) and its compatibility with large-scale production at high specific activities using a biomedical cyclotron (*18*). Increased use of ^{64}Cu and other copper radioisotopes in nuclear medicine and in preclinical applications has produced a need for copper chelators with high stability against metal loss (*19–23*). Development of optimal metal chelators is a critical step in designing systems for the *in vivo* delivery of copper radioisotopes (*21, 23–25*).

1,4,8,11-Tetraazacyclotetradecane-1,4,8,11-tetraacetic acid (TETA) has been extensively used as a BFC for copper radionuclides in clinical imaging and therapy studies involving both antibodies and peptides (Figure 1) (*19, 20*). Seminal work performed by Moi, Denardo, Meares, and co-workers pursued the development of TETA-based bifunctional chelators for attaching the low-energy β-emitting isotope ^{67}Cu to monoclonal antibodies for targeted radioimmunotherapy of lymphoma (*26–29*). Despite widespread use, TETA is not an optimal BFC for biomedical applications, as Anderson and co-workers have demonstrated the dissociation of ^{64}Cu from TETA-D-Phe^1-octreotide (TETA-OC) in rat liver and subsequent binding to superoxide dismutase (SOD) (*25, 30*). Copper complexes of the cross-bridged cyclam derivative CB-TE2A (Figure 1) were shown to possess superior *in vivo* stability over TETA (*25*), and a ^{64}Cu-labeled peptide conjugate of CB-TE2A demonstrated superior imaging characteristics over the corresponding TETA−peptide conjugate (*31*). However, one of the two metal coordinating carboxylic acid arms was sacrificed in order to achieve CB-TE2A peptide conjugation (*31*), leaving the Cu(II) in a less than ideal coordination geometry, as both carboxylic acid moieties would be necessary in order to fully saturate the coordination sphere of the six-coordinate cation and neutralize its +2 charge (*3*).

A recent investigation by Sprague and co-workers evaluated both the structure and the *in vivo* behavior of 4-acetamido-11-carboxymethyl-1,4,8,11-tetraazabicyclo[6.6.2]hexadecane (CB-TEAMA), a hybrid monoamide analogue of CB-TE2A, as a model for a CB-TE2A−peptide conjugate (*32*). X-ray crystallography studies have revealed a distorted octahedral coordination geometry for both Cu(II)-CB-TE2A (*3*) and Cu(II)-CB-TEAMA (*32*), with coordination from the carbonyl oxygen of the amide pendant arm in the latter case (*32*). Interpretation of the corresponding *in vivo* data for ^{64}Cu-CB-TEAMA, however, must be approached with great caution due to differences in complex lipophilicity (log *P*) as well as the potential scenario (proposed by the authors) of hepatic enzymatic hydrolysis of ^{64}Cu-CB-TEAMA to ^{64}Cu-CB-TE2A, secretion of the radiometabolite(s) into blood, and subsequent clearance via the kidneys (*32*). In any event, an orthogonal bifunctional chelator having two pendant negatively charged carboxylic acid groups and a third arm for the sole purpose of conjugation would (1) saturate the Cu(II) coordination sphere while neutralizing its dicationic charge and (2) simplify conjugation chemistry by providing a selective site for peptide conjugation. The current study addresses these issues through the synthesis and development of a novel cross-bridged bifunctional chelator *via* a monopendant-armed cross-bridged tetraamine intermediate. This approach allows greater control of conjugation chemistry and may also serve to enhance metal complex *in vivo* stability in diagnostic and therapeutic applications involving copper radionuclides.

EXPERIMENTAL SECTION

General Methods. ^{1}H NMR and ^{13}C NMR spectra were obtained using a Varian Gemini 300 MHz instrument, and the chemical shifts are reported in ppm on the δ scale relative to internal TMS or TSP. Proton chemical shifts are annotated as follows: ppm (multiplicity, integration). Resonance assignments are established with the aid of NOESY, COSY, or HETCOR. Electrospray ionization time-of-flight mass spectra were obtained on a Waters LCT Premier time-of-flight mass spectrometer using electrospray ionization (ESI/TOF/MS) operated in positive ion mode. The electrospray capillary voltage was 3 kV, and the sample cone voltage was 60 V. The desolvation temperature was 225 °C, and the desolvation nitrogen gas flow rate was 300 L/h. Accurate masses were obtained using the lock spray mode with Leu-Enkephalin as the external reference compound. Fast-atom bombardment (FAB) mass spectra were run on a VG 7070E-HF double-focusing mass spectrometer and were obtained in positive ion mode except where noted. A sample matrix of either glycerol (GLY) or 3-nitrobenzyl alcohol (NBA) was employed and ionization was effected by a beam of xenon atoms generated in a saddle-field ion gun at 8.0 ± 0.5 kV. Nominal mass MS were obtained at a resolution of 1200, while accurate mass analysis (high-resolution FAB/MS) was carried out at a resolution of approximately 5000. For the latter, a limited-range V/E scan was employed under control of a MASPEC-II data system for Windows (MasCom GmbH, Bremen, Germany). For these analyses, 1.0 μL 1.0 N KCl in 90% methanol/H_2O was added to the sample before mixing with the NBA matrix so that the matrix-derived ions, utilized as the internal mass references for accurate mass determinations, also included K^+ adducts. In these analyses, molecular identity could usually be confirmed by formation of a $[M + K]^+$ species. Both ^{1}H and ^{13}C NMR data, in conjunction with the observed isotopic distribution of $[M + H]^+$, were used to set constraints for the calculation of all possible elemental compositions within 20 ppm of the measured accurate mass. In all cases, a unique molecular formula could be determined by consideration of the molecular ion species and appropriate fragment ions. Positive ion MALDI mass spectra were obtained on a Shimadzu-Biotech Axima-CRF time-of-flight mass spectrometer using α-cyano-4-hydroxycinnamic acid as the sample matrix. Peptide standards of appropriate molecular weight to bracket the mass of the sample were used to provide internal mass reference peaks for accurate mass measurement. In all cases, the number of significant figures reported is determined by the experimental precision expressed in ppm and is related to the resolution and performance characteristics of the instrument used as well as the internal mass references employed in accurate mass measurement.

Semipreparative reversed-phase HPLC was performed using two Gilson model 303 pumps, a Gilson 803C manometric module, a Gilson 811B dynamic mixer, a Knauer ultraviolet detector, and an INUS λ-Ram radioactive detector all connected through a Gilson 506C system interface module and operated by *UniPoint* version 1.65 software. Analytical HPLC of synthetic products **4**, **5**, and **6** and all peptide conjugates was achieved with a Hamilton Prp-1 polymer reversed-phase semipreparative column (10 μm, 7.0 mm × 30.5 cm) using a flow rate of 3 mL/min; purification of all peptide conjugates was performed using identical conditions. Size-exclusion HPLC (SE-HPLC) was performed using the same system in a single pump mode using a Tosohaas G3000SW, 10 μm, 7.8 mm × 30 cm column with phosphate buffered saline solution as the eluent (0.5 mL/min).

Materials. Solvents were used as purchased. *tert*-Butyl bromoacetate, *N*-hydroxysuccinimide, *N*-ethyl-*N*′-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDCI), and peptide sequence grade trifluoroacetic acid were purchased from the Aldrich Chemical Co. Sodium borohydride powder and 10% Pd/C were purchased from Lancaster Synthesis, Incorporated. CB-cyclam (*3*) and 2-bromo-pentanedioic acid 5-benzyl ester 1-*tert*-butyl ester (*33*) were prepared as reported in the literature. The integrin $\alpha_v\beta_3$-binding peptide c(RGDfK(S)) was purchased from Peptides International. All experiments with moisture- and/or air-sensitive compounds were carried out under a dry Ar atmosphere. For column chromatography, Merck 60 Silica Gel (70−230 mesh) was used. Thin-layer chromatography (TLC) was performed on silica gel 60 F-254 plates from EM Reagents. All water used was purified using a Hydro Ultrapure Water Purification system.

2-(1,4,8,11-Tetraaza-bicyclo[6.6.2]hexadec-4-yl)-pentanedioic Acid 5-Benzyl Ester 1-*tert*-Butyl Ester (3). To a solution of CB-cyclam (**1**) (1 g, 4.42 mmol) in anhydrous CH_3CN was added K_2CO_3 (0.914 g, 6.61 mmol). The solution was shielded from light, and a solution of 2.36 g (6.63 mmol) of 2-bromopentanedioic acid 5-benzyl ester 1-*tert*-butyl ester in CH_3CN was added dropwise *via* an addition funnel over 1 h with constant stirring. The resulting mixture was allowed to react for 24 h in darkness under argon with constant stirring. Excess salt was removed by filtration and solvent removed by rotary evaporation. The resulting residue was dissolved in minimal CH_2Cl_2 and subjected to flash chromatography using a slowly increasing gradient from 100% CH_2Cl_2 to 15% MeOH in CH_2Cl_2. The relevant fractions were identified by ^{1}H NMR spectroscopy, combined, and solvent removed (0.43 g of protonated (HBr) product). The resulting residue was dissolved in $CHCl_3$, chilled, and quickly extracted once with 20% NaOH (aq) at 0 °C. The organic phase was dried with Na_2SO_4 and solvent removed to yield **3** as a pale yellow oil (0.36 g, 16.2% yield). ^{1}H NMR (300 MHz, $CDCl_3$, TMS) δ 1.45 (s, 9H), 1.38−1.62 (m, 7H), 1.80−1.96 (m, 1H), 1.97−2.12 (m, 1H), 2.13−2.24 (m, 2H), 2.28−3.40 (m, 16H), 3.12−3.34 (m, 2H), 4.78−4.98 (br s, 1H), 5.12 (s, 2H), 7.33−7.37 (m, 5H); ^{13}C NMR (75 Hz, $CDCl_3$, TMS) δ 25.08, 25.91, 27.46, 28.26, 31.36, 48.63, 48.68, 48.86, 49.17, 51.74, 53.89, 54.05, 57.65, 58.88, 60.17, 61.63, 66.12, 80.79, 128.12, 128.45, 135.88, 172.22, 172.85. High resolution ESI/TOF/MS: $[M + H]^+$ for $C_{28}H_{47}N_4O_4$ 503.3597, found 503.3604.

2-(11-*tert*-Butoxycarbonylmethyl-1,4,8,11-tetraaza-bicyclo[6.6.2]hexadec-4-yl)-pentanedioic Acid 5-Benzyl Ester 1-*tert*-Butyl Ester (4). To a solution of **3** (0.180 g, 0.360 mmol) in dry CH_3CN was added K_2CO_3 (0.0494 g, 0.357 mmol) and *tert*-butyl bromoacetate (0.070 g, 0.359 mmol) in one portion. The mixture was constantly stirred in darkness for 24 h under argon. Salts were removed by filtration, and the solvent removed by rotary evaporation. The residue was placed under reduced pressure to give the HBr salt of **4** with no further purification necessary to proceed to the next step in the synthesis. For characterization, the residue was dissolved in $CHCl_3$ and quickly extracted once with 20% NaOH (aq) at 0 °C. The organic phase was dried with Na_2SO_4 and solvent removed to yield **4** as a pale yellow oil (0.21 g, 95.0% yield). ^{1}H NMR (300 MHz, $CDCl_3$, TMS) δ 1.45 (d, 18H), 1.22−1.52 (m, 7H), 1.78−1.92 (m, 1H), 1.93−2.10 (m, 1H), 2.30−3.25 (m, 22H), 5.12 (s, 2H), 7.27−7.37 (m, 5H); ^{13}C NMR (75 Hz, $CDCl_3$, TMS) δ 26.14, 27.84, 27.88, 28.32, 28.44, 31.45, 51.13, 51.38, 52.83, 53.01, 55.99, 56.39, 56.57, 57.69, 59.13, 59.18, 61.72, 66.23, 80.43, 80.73, 128.24, 128.26, 128.59, 136.08, 171.80, 172.62, 173.20. High-resolution FAB/MS: $[M + H]^+$ for $C_{34}H_{57}N_4O_6$ 617.4281, found 617.4276.

2-(11-*tert*-Butoxycarbonylmethyl-1,4,8,11-tetraaza-bicyclo[6.6.2]hexadec-4-yl)-pentanedioic Acid 1-*tert*-Butyl Ester (5). To a solution of **4** (0.350 g, 0.568 mmol)) in dry MeOH (15 mL) was added 88% HCO_2H (0.0594 g, 1.3 mmol) followed by 0.10 g of Pd/C (Degussa type E101 NE/W). The round-bottom flask with magnetic stir bar was sealed using a rubber septum. The flask was evacuated and recharged three times using a balloon filled with H_2 gas. The mixture was maintained under the balloon of H_2 for 4 h with constant stirring. The mixture was filtered through Celite 535 prewetted with MeOH, and solvent removed to yield **5** as a pale yellow solid (0.300 g, >99% yield). ^{1}H NMR (300 MHz, $CDCl_3$, TMS) δ 1.46 (d, 18H), 1.45−2.11 (m, 7H), 2.48−3.59 (m, 22H), 3.90−4.08 (br m, 1H), 4.10−4.80 (br s, 2H); ^{13}C NMR (75 Hz, $CDCl_3$, TMS) δ 22.77, 24.96, 27.81, 27.87, 31.21, 47.82, 48.25, 49.46, 50.20, 50.67, 52.89, 55.39, 55.85, 58.10, 59.24, 61.75, 81.94, 81.76, 169.98, 171.10, 174.96. High-resolution FAB/MS: $[M + H]^+$ for $C_{27}H_{51}N_4O_6$ 527.381, found 527.3794.

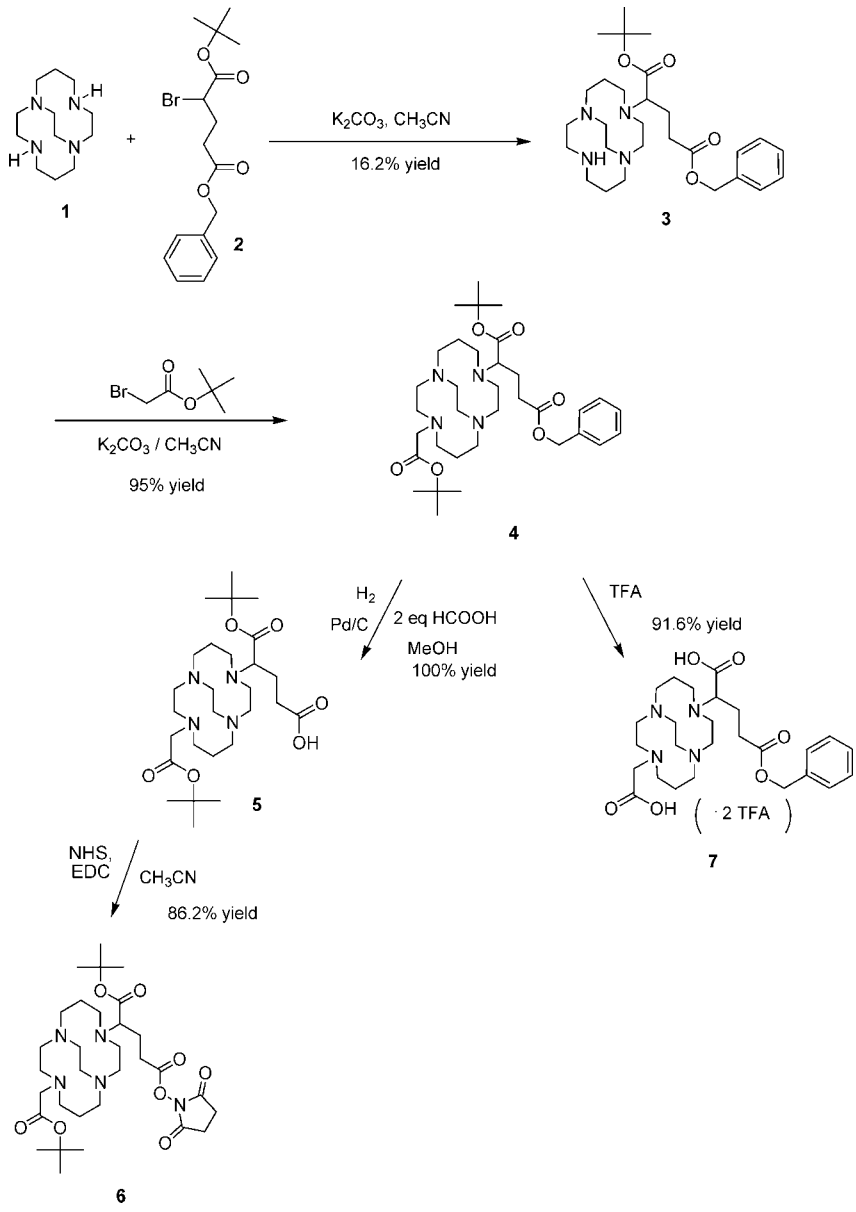
2-(11-*tert*-Butoxycarbonylmethyl-1,4,8,11-tetraaza-bicyclo[6.6.2]hexadec-4-yl)-pentanedioic Acid 5-*tert*-Butyl Ester 1-(2,5-dioxo-pyrrolidin-1-yl) Ester (6). To a solution of **5** (0.100 g, 0.190 mmol) in dry CH_3CN was added *N*-hydroxysuccinimide (0.026 g, 0.23 mmol) and EDCI (0.044 g, 0.23 mmol) in one portion. The resulting solution was maintained under argon for 10 h with constant stirring. Solvent was removed under reduced pressure, and the residue was dissolved in $CHCl_3$. The solution was extracted twice with brine and once with water. Solvent was removed from the organic phase by rotary evaporation to yield **6** as a pale yellow solid (0.102 g, 86.1% yield). ^{1}H NMR (300 MHz, $CDCl_3$, TMS) δ 1.41 (d, 18H), 1.50−2.15 (m, 5H), 2.40−3.65 (m, 28H), 3.65−3.80 (m, 1H), 3.80−4.00 (m, 1H); ^{13}C NMR (75 Hz, $CDCl_3$, TMS) δ 22.80, 23.23, 25.59, 25.60, 25.73, 28.13, 28.21, 28.32, 48.14, 48.38, 50.21, 50.42, 51.23, 53.55, 53.70, 55.54, 55.95, 56.43, 57.62, 59.89, 61.47, 82.15, 82.36, 168.20, 169.22, 170.40, 170.70. High-resolution FAB/MS: $[M + H]^+$ for $C_{31}H_{54}N_5O_8$ 624.3973, found 624.3941; $[MH\text{-}C_4H_3O_2N]^+$ 527.383, found 527.381; $[MH\text{-}2C_4H_8]^+$ 512.271, found 512.272.

2-(11-Carboxymethyl-1,4,8,11-tetraaza-bicyclo[6.6.2]hexadec-4-yl)-pentanedioic Acid 5-Benzyl Ester (7). Neat trifluoroacetic acid (15 mL) was added to **4** (0.100 g, 0.162 mmol) in a round-bottom flask. The mixture was stirred for 10 h under argon. Excess acid was removed by rotary evaporation. The residue was dissolved in CH_2Cl_2 (20 mL) and solvent removed by rotary evaporation; this process was repeated exhaustively to remove residual acid. The resulting yellow oil was triturated with Et_2O and by submerging the flask into an ultrasonicating bath. Upon solidification, the solid was allowed to settle, and the ethereal wash was carefully pipetted away from the product. Residual solvent was removed to give a hygroscopic pale yellow solid **7** (0.109 g, 91.6% yield including 1.5 associated TFA molecules and 1 H_2O). ^{1}H NMR (300 MHz, CD_3CN) δ 1.60−2.35 (m, 8H), 2.45−3.40 (m, 20H), 3.40−3.85 (m, 3H), 5.24 (s, 2H), 7.48−7.53 (m, 5H), 9.00−9.60 (br s, 2H); ^{13}C NMR (75 Hz, CD_3CN) δ 23.11, 24.53, 25.16, 32.33, 48.79, 49.61, 51.49, 52.75, 53.98, 56.74, 57.84, 58.22, 60.24, 65.03, 67.35, 116.13, 118.69, 120.00, 129.50, 129.92, 137.84, 161.25, 172.83, 173.96, 174.11. Elemental analysis calculated for $C_{26}H_{40}N_4O_6 \cdot (TFA)_{1.5}(H_2O)$: C, 50.20; H, 6.32; N, 8.08. Found: C, 49.95; H, 6.09; N, 7.99.

CB-TE2A Di-*tert*-butyl Ester-(propionamide linker)-c(RGDfK(S)). To c(RGDfK(S)) (0.025 g, 0.036 mmol) in DMF (250 μL) was added **6** (0.0282 g, 0.045 mmol) in one portion. The reaction mixture was stirred at 25 °C for 16 h under argon. The mixture was subjected to purification by semipreparative reversed-phase HPLC using a gradient from 100% 0.1% TFA in H_2O (pH 2.5) to 60% 0.1% TFA in CH_3CN over 30 min. Solvent was removed under reduced pressure, and the remaining aqueous solution was lyophilized to give fluffy white solid CB-TE2A di-*tert*-butyl ester-(propionamide linker)-c(RGDfK(S)) (0.017 g, 39.2% yield). ^{1}H NMR (300 MHz, D_2O, TSP) δ 0.95−1.05 (br s, 3H), 1.12−2.05 (m, 7H), 1.53 (d, 18H), 2.18−2.40 (br s, 4H), 2.40−2.65 (br s, 3H), 2.75−2.90 (m, 2H), 2.90−4.00 (m, 33H), 4.15−4.25 (m, 1H), 4.30−4.8 (m, 5H), 7.18−7.45 (m, 5H). High resolution MALDI/MS: $[M + H]^+$ for $C_{57}H_{95}N_{14}O_{14}$ 1199.72, found 1199.74.

CB-TE2A-(propionamide linker)-c(RGDfK(S)). Neat trifluoroacetic acid (15 mL) was added to CB-TE2A di-*tert*-butyl ester-(propionamide linker)-c(RGDfK(S)) (0.012 g, 0.010 mmol), and the reaction was stirred at 25 °C under for 16 h under argon. Excess acid was removed by rotary evaporation. The residue was dissolved in CH_2Cl_2 (20 mL) and solvent removed by rotary evaporation; this process was repeated exhaustively to remove

Scheme 1. Synthetic Route to the Cross-Bridged Cyclam Bifunctional Chelator



residual acid. A 20 mL aliquot of Et_2O was added to the residue to induce solidification. Solvent removal under reduced pressure gave 0.013 g (>99% assuming two associated TFA molecules) of fluffy white solid CB-TE2A-(propionamide linker)-c(RGDfK(S)). ^{1}H NMR (300 MHz, D_2O, TSP) δ 0.80−1.10 (br s, 2H), 1.30−2.00 (m, 12H), 2.22−2.45 (m, 3H), 2.45−2.60 (m, 2H), 2.65−2.85 (m, 3H), 2.90−4.00 (m, 33H), 4.00−4.30 (m, 2H), 4.35−4.45 (m, 2H), 4.65−4.75 (m, 1H), 7.20−7.45 (m, 5H). High resolution MALDI/MS: $[M + H]^+$ for $C_{49}H_{79}N_{14}O_{14}$ 1087.59, found 1087.55.

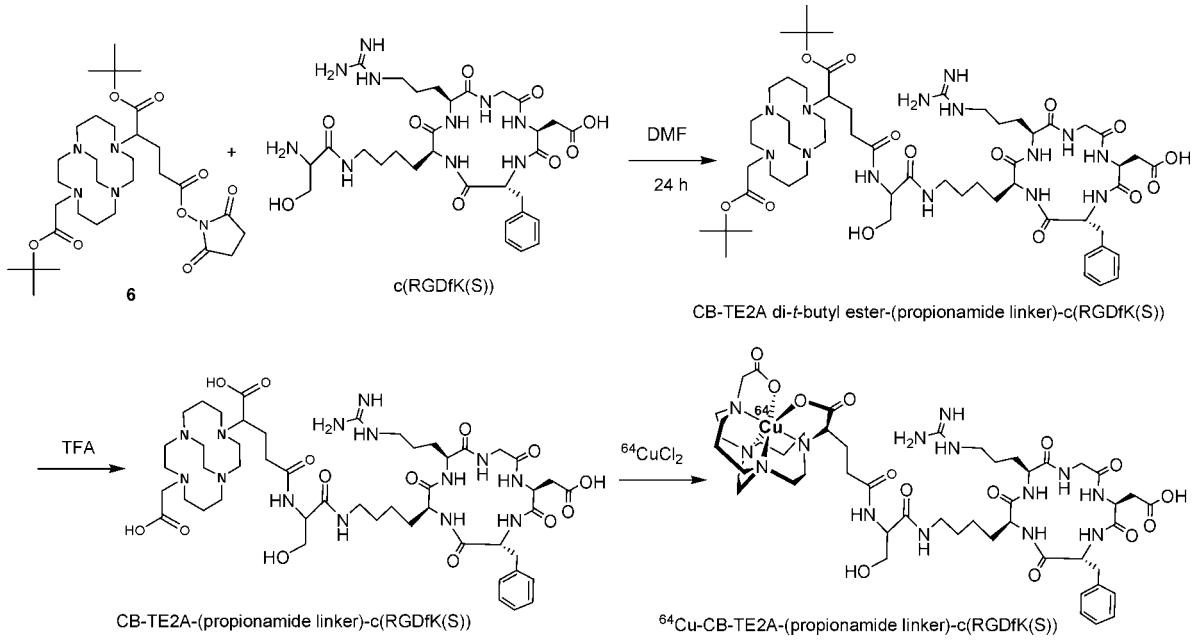
Radiochemistry—Synthesis of ^{64}Cu-CB-TE2A-(propionamide linker)-c(RGDfK(S)). *Caution: ^{64}Cu ($t_{1/2}$ = 12.7 h) is a (β^+ (19%); β^- (39%)) emitting radionuclide. Appropriate shielding and handling protocols should be in place when using this radionuclide.* $^{64}CuCl_2$ was purchased from MDS Nordion (Vancouver, BC, Canada). To CB-TE2A-(propionamide linker)-c(RGDfK(S)) (15 μg) in 0.1 M NH_4OAc (200 μL) (pH 8.0) was added $^{64}CuCl_2$ (1 mCi in 0.1 M HCl). The reaction mixture was heated for 1 h at 95 °C. Unchelated ^{64}Cu was removed from ^{64}Cu-CB-TE2A-(propionamide linker)-c(RGDfK(S) by ion exchange chromatography using Chelex-100 (100−200 mesh, Na^+ form, Bio-Rad Laboratories, Hercules, CA). The radiochemical yield was 64%. To generate analytical radio-HPLC data, a portion of the purified radiolabeled peptide was subjected to reversed-phase HPLC using a gradient from 100% 0.1% TFA in H_2O (pH 2.5) to 60% 0.1% TFA in CH_3CN over 30 min. In addition, the resulting peak fraction was collected, frozen, lyophilized, and subjected to analytical radio-HPLC using the same column and flow rate but different solvent conditions: 0.15 M NH_4OAc (pH 7.0) with 0% to 80% MeOH over 30 min (Supporting Information).

Serum Stability. An aliquot of ^{64}Cu-CB-TE2A-(propionamide linker)-c(RGDfK(S)) (3 μCi) was added to 25 μL of human serum (NHS Gemini Cat # 100−110) or to 25 μL of saline in a 100 μL microcentrifuge tube for each time point. The samples were capped and placed in a 37 °C incubator. At the appropriate time points, samples were analyzed by SE-HPLC. The % radioactivity associated with protein versus low molecular weight species was determined by integration.

RESULTS AND DISCUSSION

Ligand Synthesis and Rationale. The overall synthetic approach is presented in Scheme 1, wherein the bifunctional

Scheme 2. Conjugation of Cyclic Peptide, c(RGDfK(S)), to the Succinimidyl Ester 6 and Subsequent TFA Deprotection of the Resulting Peptide−Chelate Conjugate



chelator derivative of CB-TE2A is synthesized for the ultimate purpose of conjugation to peptides and subsequent targeted PET imaging of tumor receptors using ^{64}Cu. It should be noted, however, that targeted radiotherapy of small to medium tumor burden may also be realized through use of the low energy β-emitting sister isotope, ^{67}Cu ($t_{1/2}$ = 61.92 h; β^- ($E_{\beta[avg]}$= 141 keV; R_{mean}= 0.24 mm)). For the synthesis of a bifunctional chelator derivative of CB-TE2A compatible with solid-phase peptide synthesis, an orthogonally protected, bromide-functionalized glutamic acid derivative (**2**) was synthesized as previously described by Mäcke and co-workers (*33*). Reaction of cross-bridged cyclam (*3*), **1**, with **2** resulted in the formation of the desired hybrid-arm construct (**3**) (Scheme 1). Our previous attempts at coupling **2** with the bisaminal resulting from condensation of cyclam with glyoxal were unsuccessful (data not shown). Reversing the sequence, alkylating **1** with **2** after reacting with *tert*-butyl bromoacetate, was found to be less desirable (data not shown). Steric effects greatly reduced the reaction yield, and the initial alkylation results in a statistical mixture of products. Unlike the more statistical product distribution achieved by alkylation with *tert*-butyl bromoacetate, alkylation of **1** using **2** tends to greatly favor the 1:1 macrocycle-arm product, even in the presence of excess alkylating agent. Interestingly, the alkylation of **3** proceeds even in $CHCl_3$ without the use of a carbonate base (data not shown); however, use of K_2CO_3 in CH_3CN reduces the reaction time from 3 days to 1 day and increases the yield of **4**.

Debenzylation of **4** was achieved by catalytic hydrogenolysis in the presence of formic acid to yield monoacid **5**. Our initial hydrogenation attempts in the absence of formic acid were completely unsuccessful, resulting in unexpected partial intramolecular transfer of the benzyl group to macrocyclic amines with concomitant formation of ethyl ester when the reaction was performed in EtOH (data not shown). This behavior was attributed to the remarkable basicity of the amines, and formic acid was chosen to acidify the reaction and to act as an additional hydrogen source for the hydrogenation. Subsequent reaction of **5** with NHS and EDCI gave the desired bifunctional chelating agent, succinimidyl ester **6**, ready for immediate conjugation to peptides. Purification of **6** was achieved by solvent extraction as described in the Experimental Methods section. The purity of this ester was acceptable by NMR and HPLC; therefore, no further purification was pursued. We observed a broad peak at ~10 ppm in the ^{1}H NMR spectrum of **6**; a similar peak was also observed for the HBr salts of **3** and **4** following column chromatography but prior to basic extraction into $CHCl_3$ (data not shown). We therefore attribute this peak to protonation of these remarkably basic amines. We are unsure of whether the proton is inside the "clamshell" cavity or not, but this is a possibility. Following the basic extraction workup of **3** and **4**, the peak at ~10 ppm was not present (Supporting Information). Unfortunately, it is impossible to use extraction to deprotonate **5** and **6** due to a polar carboxylic acid and a base-sensitive succinimidyl ester, respectively.

Compound **7** was synthesized for two reasons: (1) to further demonstrate the orthogonality of our protection scheme and (2) in hopes that crystals of Cu(II)-**7** might be obtained for structure determination. Successful deprotection of the *tert*-butyl esters using neat TFA was achieved with retention of the benzyl protection on the third pendant carboxylic acid arm. Unfortunately, all attempts at forming Cu(II)-**7** for crystallization were thwarted by partial benzyl deprotection due to the requisite complexation conditions, namely, the addition of NaOH followed by reflux in ethanol.

We have previously used a similar approach to synthesize a bifunctional chelator derivative of the acyclic ligand, CHX-A″-DTPA, that is likewise compatible with off-line tagging of peptides following Fmoc solid-phase peptide synthesis (*34*) Synthesis of a carbon backbone-functionalized isothiocyanate-bearing bifunctional chelator derivative of CB-TE2A has been reported by Archibald and co-workers (*35*, *36*). This work involved a relatively high yielding six-step synthesis of a C-functionalized nitrobenzyl bisaminal intermediate (*35*), that was further reacted to a diacid, monoisothiocyanate bifunctional chelating agent in seven additional steps (*ca.* 20% overall yield from the bisaminal) followed by conjugation to biotin (*36*). While isothiocyanate derivatives of chelators are routinely used by our laboratory and others for antibody/protein conjugation, the orthogonally protected bifunctional chelator presented here may offer advantages in peptide synthesis studies due to the clean reactions afforded by succinimidyl ester coupling chemistry. In addition, fewer synthetic steps are involved in the current approach: only four steps from **1**, which is accessible from commercially available cyclam in only four steps (*3*). The

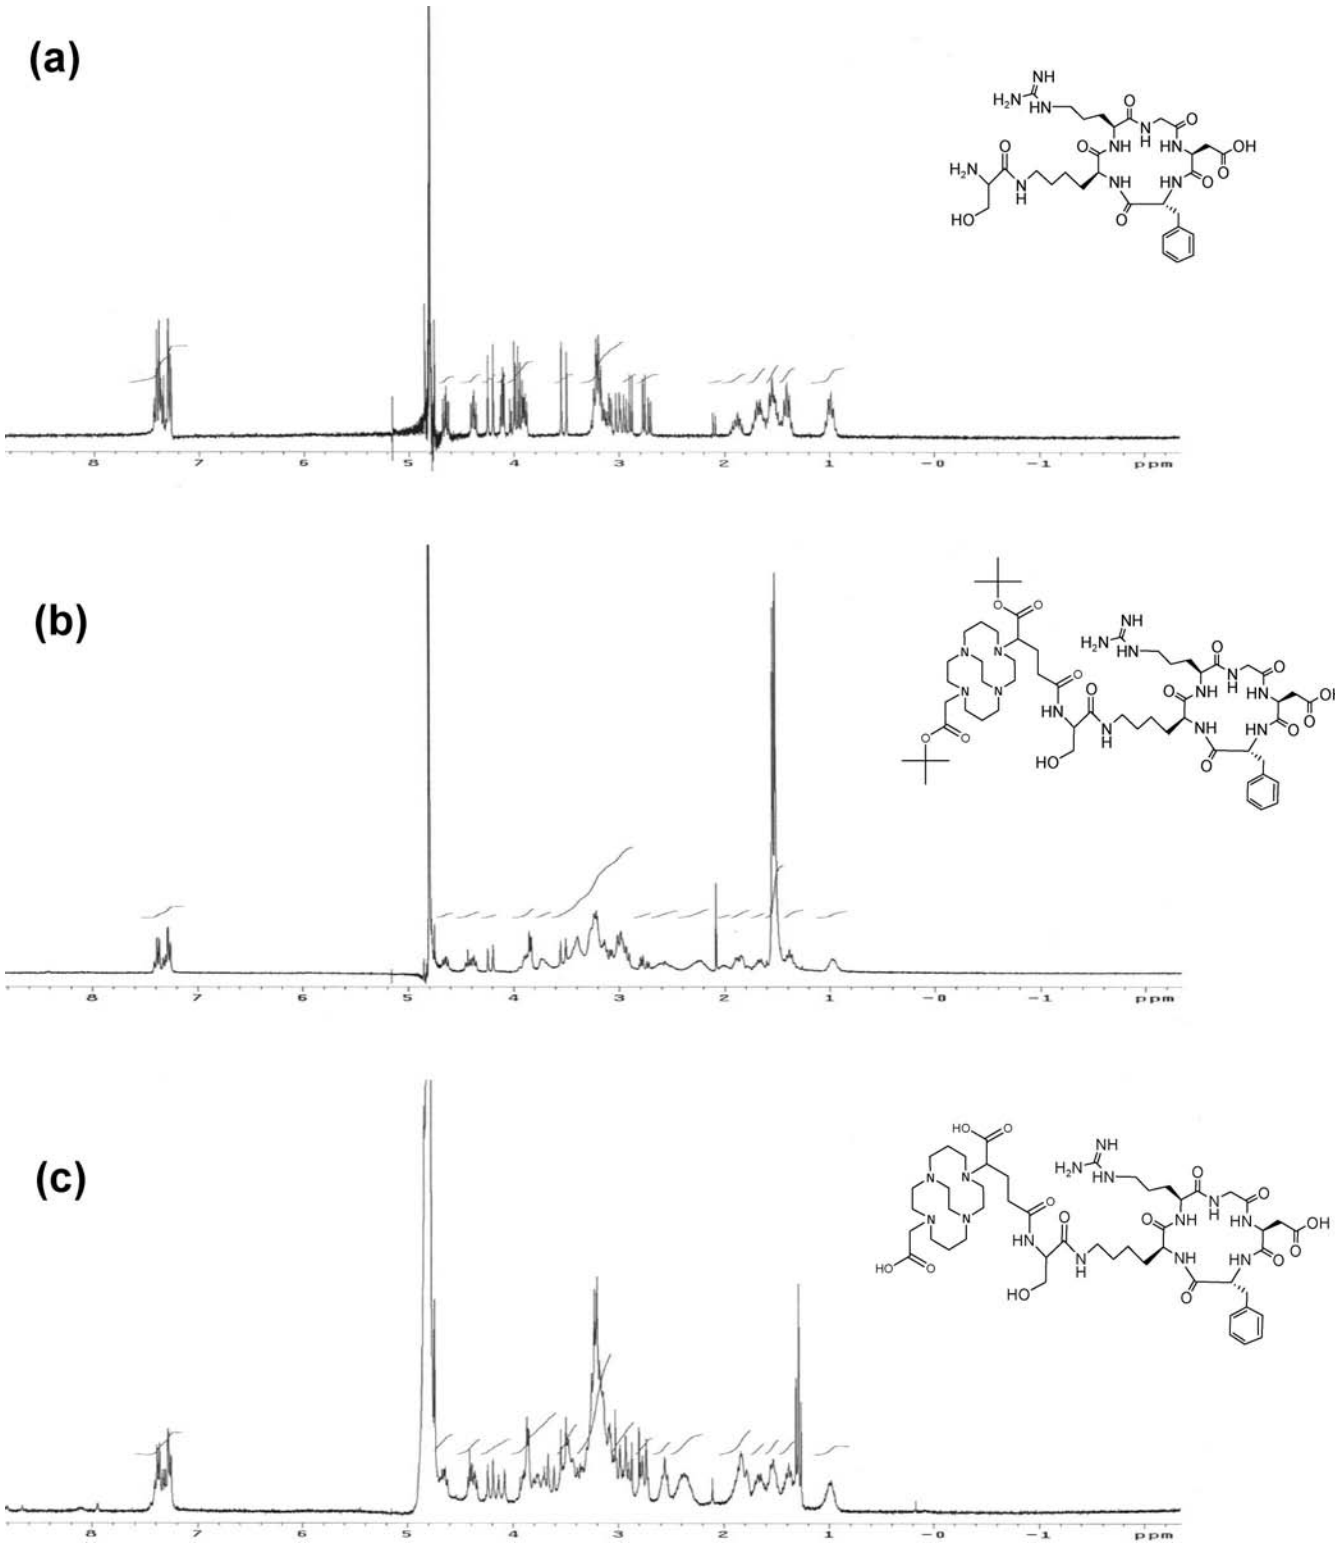


Figure 2. ^{1}H NMR spectra in D_2O of (a) c(RGDfK(S)), (b) CB-TE2A-c(RGDfK(S)) di-*tert*-butyl ester, and (c) CB-TE2A-c(RGDfK(S)) after TFA deprotection.

only major disadvantage of the current approach is the low yield obtained for the coupling reaction of CB-cyclam to the bifunctional glutamic acid-derived arm (*ca.* 16%). This low yield reflects the necessity of column chromatography to separate the desired product **3** from a structurally related analog that is also formed during the alkylation (data not shown). This side product is a quaternary ammonium compound having the same mass where alkylation on one of the bridgehead (tertiary) amines instead of on a secondary (NH) amine has occurred. Formation of significant amounts of this product is attributed to steric factors as the alkylating agent **2**, a secondary bromide, is somewhat bulky.

Peptide Conjugation, Radiolabeling with ^{64}Cu, and Serum Stability Studies. To validate the utility of our agent, we chose to conjugate our novel bifunctional cross-bridged cyclam chelator **6** to a cyclic RGD peptide, c(RGDfK(S) (Scheme 2). The peptide−chelator conjugate readily formed in DMF and, following chromatographic purification, was characterized by

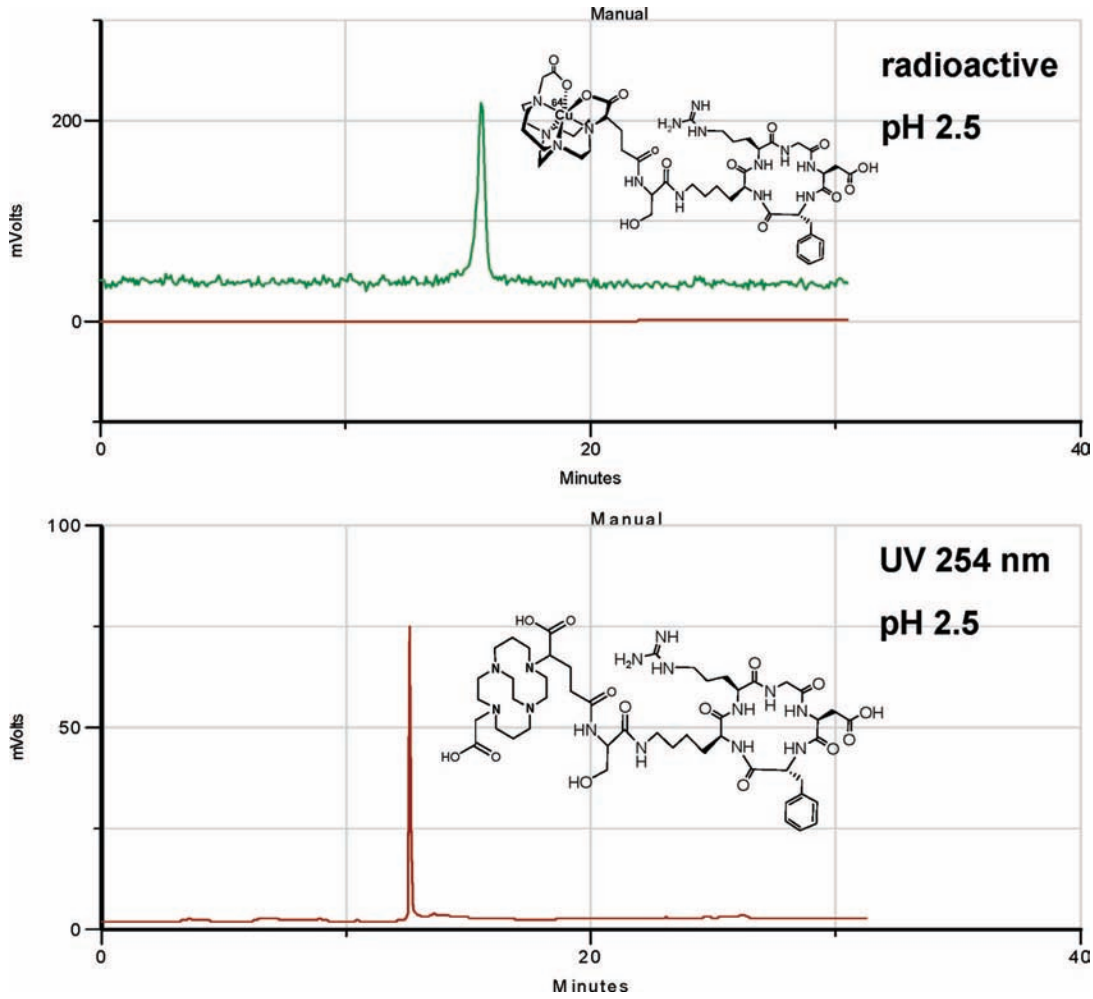

Figure 3. Radio-HPLC chromatogram of ^{64}Cu-CB-TE2A-c(RGDfK(S)) including the radioactive trace (top) and the corresponding UV trace due to CB-TE2A-c(RGDfK(S)) (bottom) on a C18 column at 3 mL/min flow rate with the following gradient: 0.1% TFA in H_2O with 0% to 60% 0.1% TFA in CH_3CN over 30 min.

NMR spectroscopy (Figure 2). This conjugate was amenable to acid deprotection of the *tert*-butyl esters and subsequent radiolabeling with ^{64}Cu (Scheme 2) as demonstrated by the ^{1}H NMR spectra (Figure 2) and HPLC data (see Figure 3 and Supporting Information), respectively. In addition, *in vitro* evaluation of the radiolabeled peptide conjugate in human serum demonstrated a stably complexed radiocopper ion with no evidence of transchelation of ^{64}Cu into serum proteins for up to 48 h (Supporting Information).

The radiochemical yield obtained was 64%. We did not attempt to optimize the radiolabeling since our overall goal in demonstrating the conceptual functionality of our bifunctional chelator was achieved. The incorporation of ^{64}Cu into our peptide conjugate was lower than previously reported for a CB-TE2A-somatostatin analogue under the same conditions (*31*). Many factors may have contributed to our lower yield, including the nature of the peptide (structure, solubility, etc.), the structural difference in our novel chelate relative to the parent CB-TE2A, and possible noncovalent intramolecular interactions between the chelate and the peptide.

Identical radiolabeling conditions (1 h, pH 8, 95 °C) were previously used to radiolabel the CB-TE2A conjugate of a somatostatin peptide analogue (*31*). Although many immunoglobulins can tolerate pH 8 and even slightly more alkaline conditions, this temperature requirement unfortunately precludes the use of cross-bridged cyclam chelators for conjugation and subsequent radiolabeling of antibodies and other heat-sensitive biological macromolecules. By using our bifunctional chelator, however, it may be possible to first form the ^{64}Cu complex using the two closest free acids and then activate the third, more distant carboxylate group unused for Cu chelation for subsequent coupling to proteins; the possibility of this approach warrants further investigation.

In vitro evaluation of the radiolabeled peptide conjugate in human serum demonstrated a stably complexed radiocopper ion with no evidence of transchelation of ^{64}Cu into serum proteins for up to 48 h (Supporting Information). This is consistent with *in vitro* stability data for the structurally related complex, ^{64}Cu-CB-TE2A, which showed no evidence of transchelation of ^{64}Cu into serum proteins for up to 24 h (*37*). A true test of *in vivo* kinetic stability, however, would require future *in vivo* metabolism studies to test for radiometal transchelation into blood and liver proteins. For example, previous studies within our laboratory have revealed that ^{64}Cu-TETA exhibits high *in vitro* serum stability (*38*): however, the situation for ^{64}Cu-TETA *in vivo* is much different in that transchelation of ^{64}Cu to superoxide dismutase and other proteins has been reported (*25, 30, 39*).

CONCLUSSIONS

A cross-bridged BFC derivative of CB-TE2A has been synthesized in four steps with reasonable (*ca.* 13 %) overall yield from CB-cyclam. The novel agent is directly structurally analogous to the parental CB-TE2A in that it possesses the identical ligand donor set arranged in the same geometry for high kinetic stability with Cu(II) radionuclides, while also

featuring a third orthogonally protected arm for conjugation to peptides and other targeting agents. This work may also enable the development of improved agents for diagnostic positron emission tomography (PET) imaging as well as for targeted radiotherapeutic applications.

Improved Procedure for Direct Coupling of Carbohydrates to Proteins via Reductive Amination

Jeffrey C. Gildersleeve,*,† Oyindasola Oyelaran,† John T. Simpson,‡ and Benjamin Allred†

Laboratory of Medicinal Chemistry, Center for Cancer Research, National Cancer Institute, NIH, 376 Boyles Street, Building 376, Room 109, Frederick, Maryland 21702, and Protein Chemistry Laboratory, Advanced Technology Program, SAIC — Frederick, Inc., NCI — Frederick, Frederick, Maryland 21702. Received April 14, 2008; Revised Manuscript Received May 29, 2008

Carbohydrate-protein conjugates are utilized extensively in basic research and as immunogens in a variety of bacterial vaccines and cancer vaccines. As a result, there have been significant efforts to develop simple and reliable methods for the construction of these conjugates. While direct coupling via reductive amination is an appealing approach, the reaction is typically very inefficient. In this paper, we report improved reaction conditions providing an approximately 500% increase in yield. In addition to optimizing a series of standard reaction parameters, we found that addition of 500 mM sodium sulfate improves the coupling efficiency. To illustrate the utility of these conditions, a series of high mannose BSA conjugates were produced and incorporated into a carbohydrate microarray. Ligand binding to ConA could be observed and apparent affinity constants (K_ds) measured using the array were in good agreement with values reported by surface plasmon resonance. The results show that the conditions are suitable for microgram-scale reactions, are compatible with complex carbohydrates, and produce biologically active conjugates.

INTRODUCTION

Carbohydrate−protein conjugates play a key role in basic and applied research (for some recent reviews, see refs *1–5*). Several polysaccharide−protein conjugate vaccines such as Prevnar, Menactra, and HIBTiter are FDA approved and used routinely for the prevention of invasive bacterial infections. Many others are in clinical trials for the prevention of infections and for treatment of cancer (*1, 6*). In basic research, carbohydrate−BSA (bovine serum albumin) conjugates have been used for years to study molecular recognition of carbohydrates (*7, 8*). As a result, there has been significant effort to develop simple and efficient methods to covalently couple carbohydrate molecules to proteins (*7, 9*); however, existing methods are not ideal and pursuit of improved methods remains an active area of research.

Carbohydrate−protein conjugates are frequently made via multistep procedures involving modification of the carbohydrate to introduce reactive functionality (e.g., addition of a linker, oxidation of hydroxyls) followed by coupling to the protein. One of the most appealing strategies is direct coupling of oligosaccharides to proteins in a single step. Glycans containing a free reducing end can be covalently attached to protein amino groups via reductive amination (*10*). The reducing end of a sugar exists as an equilibrium mixture composed of the cyclic hemiacetal form (lactol) and the open-chain aldehyde form (see Scheme 1). Under suitable conditions, amine groups will condense with the aldehyde to form an iminium ion which can be reduced to an amine. The process results in ring opening of the reducing end monosaccharide. When coupling to proteins, this reaction is carried out in aqueous buffer.

Several factors make reductive amination of sugars to proteins challenging. First, the reducing agent must be stable in water, unreactive with aldehydes, and yet reactive with iminium ions. Sodium cyanoborohydride meets these requirements and is by far the most common reducing reagent used for reductive amination of aldehydes to proteins. Second, the equilibrium between aldehyde and lactol form of sugars highly favors the lactol; therefore, the concentration of free aldehyde is low. Third, the high concentration of water in aqueous buffer sets up an equilibrium that disfavors release of a water molecule, a process that is required to form the iminium ion. Due to the second and third features, reductive amination of carbohydrates directly to proteins is slow and inefficient. As a result, one typically uses large excesses of sugar (∼300 equiv), high concentrations (∼60 mM), and long reaction times. Therefore, direct reductive amination has been limited to sugars that are readily available in large quantities.

Our group has been using carbohydrate−protein conjugates and glycoproteins for the construction of carbohydrate microarrays (*11–14*). Carbohydrate microarrays contain diverse sets of glycans immobilized on a solid support in a spatially defined arrangement (*15–21*). Using a carbohydrate microarray, one can evaluate binding of a protein, cell, or virus to all of the carbohydrate ligands simultaneously. While reductive amination is an attractive approach for obtaining glycoconjugates, many biologically interesting carbohydrates such as N-linked sugars are very difficult to obtain. Microgram amounts of these sugars (20−200 μg) can be very expensive or require considerable time and effort to isolate and purify from natural sources; therefore, one cannot afford to use 300 equiv and waste >95% of the material in the coupling process. Moreover, the volume of buffer required to achieve high concentrations can be completely impractical when working with micrograms of material. For example, to obtain a 60 mM solution starting with 100 μg of Man9, one would require a final reaction volume of only 1 μL. Clearly, methods to improve the efficiency and facilitate coupling on a small scale were needed. Improved conditions would also be beneficial for the development and production of carbohydrate−protein conjugate vaccines.

MATERIALS AND METHODS

General. Unless indicated otherwise, all chemicals and reagents were purchased from Sigma-Aldrich (St. Louis, MI)

and used without further purification. LNT, LSTa, and Man8D1D3 were purchased from Glycotech (Gaithersburg, MD). Tetra-*N*-acetylchitotetraose, Man3, Man7D1, and Man7D3 were purchased from Dextra laboratories (Reading, UK). Man6 was purchased from IsoSep (Tullinge, Sweden). Man5 and Man9 were generous gifts from Dr. Lai-Xi Wang.

General Procedure for Reductive Amination. Bovine serum albumin (BSA; 2 μL of a 150 mg/mL solution; fraction V), sodium borate (5.5 μL of a 400 mM solution, pH 8.5), sodium sulfate (3.7 μL of a 3 M solution, 50 °C), oligosaccharide (3.3 μL of a 20 mM solution for 15 equiv), H_2O (5.3 μL), and sodium cyanoborohydride (2.2 μL of a 3 M solution) were combined in a 200 μL PCR tube. The tube was capped and then incubated in a PCR thermal cycler at 56 °C for 96 h with a heated lid. The reaction was diluted with H_2O (100 μL), transferred to a 500 μL dialysis tube (MWCO 10 000, Slide-A-Lyzer MINI Dialysis Unit, Pierce, Rockford, IL), and then dialyzed against H_2O (2.5 L) three times. Conjugates were diluted with H_2O to a final concentration of 1 mg/mL and then analyzed by matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) to determine the extent of conjugation.

Mass Spectrometric Analysis of Glycoconjugates. MALDI-TOF mass spectrometric analysis of the glycoconjugates was performed on an Applied Biosystems Voyager-DE Pro time-of-flight mass spectrometer. The accelerating voltage was 25 kV, guide wire 0.15% and grid voltage 91.5%. The instrument was operated in linear mode under positive ion conditions. A nitrogen laser was used at 337 nm with 250 laser shots averaged per spectrum. Sinapinic acid (3,5-dimethoxy-4-hydroxycinnamic acid, Aldrich Chemicals, St. Louis, MO) was used as the matrix for all experiments. Matrix was prepared as a saturated solution in 50% acetonitrile/0.1% trifluoroacetic acid (v/v). Sample preparation was a modified "dried droplet" procedure (*22*), whereby 0.3 μL of sample was spotted onto the MALDI target followed by 0.3 μL of matrix. The mixture was then allowed to air-dry prior to analysis. External calibration was performed using bovine serum albumin as a standard. Data analysis was carried out using *Data Explorer* software resident on the Voyager mass spectrometer. Representative spectra can be found in the Supporting Information.

Evaluation of Neoglycoconjugate Activity by Enzyme-Linked Lectin Assay (ELLA). BSA conjugates (50 μL of a 10 μg/mL solution in PBS) were added to wells of a 96 well plate (white Maxisorp, Nunc, Rochester, NY) and incubated for 2 h at room temperature. Liquid was removed and the wells were blocked with BSA (200 μL/well of a 3% solution in PBS). After removal of the liquid, the wells were incubated with various concentrations of biotinylated wheat germ agglutinin (WGA; Vector laboratories, Burlingame, CA) diluted in 3% BSA/PBS solution. After 2 h, wells were emptied and washed 3 times with PBS. Next, wells were incubated with streptavidin−alkaline phosphatase (2 μg/mL in 3% BSA/PBS) for 1 h and then washed 7 times with PBS. Wells were then incubated with methyl umbelliferryl phosphate (50 μL of a 100 μM solution in Tris buffer at pH 9.0). After 15 min of incubation, the fluorescence intensities for each well were measured using an FL_X800 plate reader.

Carbohydrate Microarray Fabrication. Carbohydrate arrays were printed with Stealth Micro Spotting Pins (SMP3; TeleChem, Sunnyvale, CA) using a robotic array spotter (Genomic Solutions, BioRobotics MicroGrid II 600/610). Conjugates and glycoproteins were distributed into 384-well plates at 4 wells per sample and 20 μL per well. Each component was prepared at 125 μg/mL in print buffer (1× PBS: 140 mM NaCl, 3 mM KCl, 10 mM Na_2HPO_4, 2 mM KH_2PO_4, pH 7.4), 2.5% glycerol, 0.006% Triton-X 100) onto ArrayIt SuperEpoxy 2 Protein glass slides. The pins were dipped into the sample wells and blotted 10 times before printing. The humidity level in the arraying chamber was maintained at about 65% during printing. Each of the components was printed in duplicate in a grid of 110 μm diameter spots with 220 μm pitch. Sixteen complete arrays were printed on each slide. Printed slides were allowed to dry, protected from light, for about 14 h at room temperature, and then stored at −20 °C until use.

Carbohydrate Microarray Binding Assay. The binding experiment was carried out in triplicate. Slides were assembled on 16-well slide holders (ProPlate, Grace Bio-Laboratories) and blocked with 3% BSA/PBS overnight at 4 °C, then washed 6 × 200 μL PBST0.05 (PBS with 0.05% Tween 20). A dilution series of biotinylated Concanavalin A (ConA) was prepared in 25 mM Tris, 124 mM NaCl, pH 7.6, at concentrations ranging from 0.03 nM to 48 μM. Lectin solutions were added to arrays, covered tightly with a seal strip, and allowed to incubate for 1 h at room temperature. After washing unbound lectin with 3 × 200 μL PBST0.05, detection of bound lectin was carried out by incubating with Cy3-streptavidin in 3% BSA/PBS (5 μg/mL) for 30 min at room temperature. Slides were then washed 7 × 200 μL PBST0.05, removed from holders, immersed in wash buffer for 5 min, and then centrifuged at 453*g* for 5 min.

Image Processing and Calculation of Apparent Dissociation Constant. Slides were scanned with a Genepix 4000B microarray scanner (Molecular Devices Corporation, Union City, CA) at PMT voltage settings where no saturated pixels were obtained. Image analysis was carried out with *Genepix Pro 6.0* analysis software (Molecular Devices Corporation, Union City, CA). Spots were defined as circular features with maximum diameter of 100 μm. Local background subtraction was performed and features were allowed to be resized to 70 μm as needed. The background-corrected median feature intensity, *F532median-B532*, was used for initial data processing, which was performed with Microsoft *Excel*. The means for replicate

spots for each array component was calculated, and then the mean and standard deviations for the 3 replicate experiments were obtained and used for subsequent K_d determination.

Apparent dissociation constants were determined using the scientific graphing and analysis software *Origin* (OriginLab). For each glycoconjugate, the mean intensity of 3 replicate experiments was plotted as a function of ConA concentration on a logarithmic scale. Nonlinear line-fitting to the equation

$$F_{obs} = \frac{F_{max}}{\frac{K_D}{[L]} + 1} \quad (1)$$

was performed, where F_{obs} is the mean intensity of the replicate spots for ConA binding at a particular concentration, F_{max} is the maximum fluorescence intensity, K_d is the apparent dissociation constant for interaction between lectin and immobilized glycoconjugate, and [L] is the concentration of ConA. For each glycoconjugate, the reported values are the apparent K_d of the mean ± the standard deviation of 3 replicate experiments.

RESULTS AND DISCUSSION

The protocol most frequently used for direct reductive amination of carbohydrates was developed by Roy et al. (*23*). Typical reaction conditions involve coupling protein (200 μM) with sugar (60 mM) in the presence of $NaBH_3CN$ (300 mM) and aqueous sodium borate buffer (200 mM, pH 9.0) for 10−24 h at 37−50 °C. Borate buffer appears to significantly enhance the yield of coupling when compared to other buffers, although the exact role of borate is not well understood.

We began by evaluating reactions of several sugars with bovine serum albumin (BSA) under the Roy conditions but with only 15−30 equiv of sugar (3−6 mM). In addition, the reaction volume was limited to 20−50 μL to assess couplings on the small scale. The extent of conjugation was evaluated by MALDI-TOF MS. Initially, reactions were carried out in Eppendorf tubes heated either in a water bath or on a heat block. Due to the small volumes, evaporation with condensation on the lid became a serious problem resulting in highly variable results. To avoid this problem, all subsequent reactions were carried out in PCR tubes and heated in a PCR thermal cycler with a heated lid. Under these conditions, results were much more reproducible and evaporation was not observed.

After surveying a variety of oligosaccharides, the yield was found to be highly dependent on the identity of the reducing end sugar. Cummings group has also observed substrate-dependent coupling efficiency (*24*). Saccharides with a reducing end glucose residue such as maltose, LNT, and LSTa (see Figure 1) coupled efficiently. For example, reactions utilizing 30 equiv of sugar produced conjugates with an average of 10 oligosaccharide chains per molecule of BSA (after 24 h at 50 °C). In contrast, sugars with mannose (Man), *N*-acetylglucosamine (GlcNAc), or galactose (Gal) at the reducing end coupled much less efficiently yielding conjugates with an average of 0−1 oligosaccharide chain per molecule of BSA. These results were disheartening since many interesting N-linked oligosaccharides have a GlcNAc at the reducing end (see Man3−9, Figure 1); therefore, efforts to improve efficiency were investigated.

To increase the yield, a number of reaction parameters such as the temperature, time, and pH were systematically varied. While conceptually straightforward, it was not known if changes such as higher temperatures and longer reaction times would compromise the biological activity of the resulting conjugates. Tetra-*N*-acetylchitotetraose, a sugar containing GlcNAc at the reducing end (see Figure 1), was used as a model oligosaccharide in couplings to BSA. Differences in pH ranging from 8.5 to 10.0 had no effect on the ratio (data not shown), but changes to the time and temperature led to improvements. Increasing the reaction time from 24 to 96 h improved the ratio about 2-fold (see Table 1). Raising the temperature from 50 to 56 °C led to a 1.5-fold increase. Further increases in temperature resulted in precipitate formation, presumably due to denaturation of the protein. Changes to the concentration of $NaBH_3CN$ from 50−500 mM had no effect.

Formation of the key imine intermediate requires expulsion of a molecule of water. In an aqueous solution, this equilibrium is highly disfavored. It was anticipated that high salt concentrations might make the expulsion of water somewhat less

unfavorable, facilitating formation of the imine. In addition, high salt concentrations can have a substantial effect on protein structure and solubility. For example, high salt concentrations are reported to reduce the rate of aggregation of BSA (*25*); therefore, a series of salt additives was examined next.

As a first test case, NaCl was added at concentrations of 0.5 M, 1.0 M, and 2.0 M. A measurable increase in conjugation ratio was observed, with 1.0 M giving the best result. A number of other salt additives were investigated (see Table 1) and many improved the yield of the reaction. Overall, addition of 0.5 M Na_2SO_4 produced the best results. A 1.0 M Na_2SO_4 solution occasionally produced even higher ratios but frequently resulted in precipitate formation and unrecoverable protein. The added salt also improved the conjugation efficiency at lower temperatures; at 37 °C, added salt produced a nearly 3-fold increase in conjugation efficiency relative to the absence of salt (compare entries 19 and 20, Table 1). This result indicates that addition of salt may be especially useful when coupling sugars to proteins that are sensitive to high temperatures.

Overall, the combination of higher temperatures, longer reaction times, and added salt produced about a 5-fold increase in the amount of sugar conjugated to BSA and an overall yield of about 33% with 15 equiv of sugar. Higher ratios could be obtained with 30 equiv of sugar, albeit with slightly lower yield (based on sugar). This level of incorporation and efficiency was judged to be suitable for making a variety of BSA conjugates for the array.

To determine whether the altered reaction conditions affect the biological activity or binding capacity of the final conjugate, binding of biotinylated wheat germ agglutinin (WGA) was measured over a range of concentrations using an ELLA assay. Binding could be detected down to concentrations of 10 ng/mL (277 pM). For comparison, a conjugate with a similar ratio of tetra-*N*-acetylchitotetraoses to BSA (9.2/BSA) was prepared using the Roy conditions (entry 21, Table 1). Both conjugates displayed similar binding by ELLA (see Figure 2) indicating that the modified reaction conditions do not reduce the biological activity of the conjugate.

Next, the modified reaction conditions were applied to a series of biologically interesting high-mannose oligosaccharides. 30 equiv (200−300 μg, 100−200 nmol) of Man3, Man5, Man6, Man7D1, Man7D3, Man8D1D3, and Man9 were coupled to BSA (250−400 μg, 3.5−6 nmol) in 20−25 μL reactions containing 100 mM sodium borate at pH 8.5, 300 mM sodium cyanoborohydride, and 500 mM sodium sulfate. Reactions were incubated in the PCR thermal cycler at 56 °C for 96 h and then dialyzed extensively with water. MALDI-TOF MS analysis (see Supporting Information) showed that the resulting glycoconju-

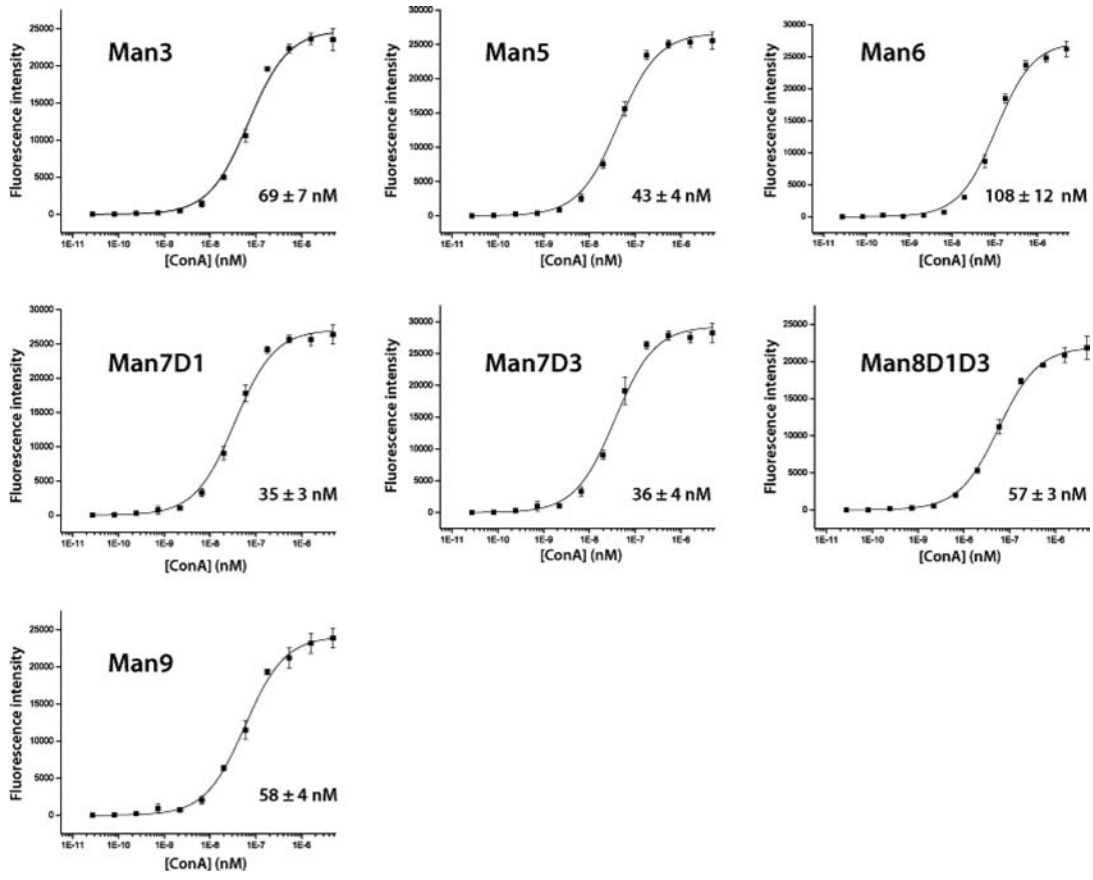

Figure 3. Binding of ConA to high mannose oligosaccharides on the carbohydrate microarray. Biotinylated ConA was incubated on the carbohydrate microarray at various concentrations. After washing, the array was incubated with Cy3-labeled streptavidin and fluorescence intensities were measured using a Genepix microarray scanner. The apparent K_ds for each high-mannose sugar are listed in the bottom right corner of each panel.

gates contained an average of 7 oligosaccharide chains per molecule of BSA. The results verify that the improved conditions for reductive amination can be successfully applied to a variety of expensive, complex oligosaccharides on a microgram scale. Using our current printing conditions for the carbohydrate microarrays, 250 μg of BSA conjugate is sufficient for over 100 000 array experiments.

To verify that the high-mannose sugars were structurally intact and suitable for use in a carbohydrate microarray, binding to concanavalin A was examined. Con A is a mannose binding lectin that has been used extensively as a research tool for detection of mannose containing glycans. It has been studied at length and is frequently used as a test lectin to validate assays. Mannose conjugates were printed on epoxide-coated glass microscope slides as reported previously (*11–13*). Binding was assessed by incubating the array with a range of concentrations of biotinylated ConA, washing away excess lectin, and incubating the array with Cy3-labeled streptavidin. After washing, fluorescent spots were detected and intensities quantitated using a DNA microarray scanner with GenePix software. Apparent K_ds were determined on the array using the method of MacBeath (*26*). K_d values are shown in Figure 3 and are in good agreement with values previously obtained for ConA with related sugars measured by surface plasmon resonance (*27*), frontal affinity chromatography (*28*), and carbohydrate microarray (*29*). Thus, the neoglycoconjugates appear to retain appropriate bioactivity.

CONCLUSSIONS

In summary, improved conditions for the direct conjugation of oligosaccharides to proteins using reductive amination are described. The conditions are compatible with microgram quantities of sugar and provide biologically active conjugates suitable for use in ELISA/ELLA assays and incorporation into microarrays. The conditions were successfully applied to a series of mannose containing oligosaccharides and these neoglycoconjugates were shown to bind to ConA. Improved conditions for reductive amination should prove useful for the preparation of glycoconjugates for both basic and applied research.

ACKNOWLEDGMENT

We thank Lai-Xi Wang for the generous gift of high mannose sugars. This research was supported by the Intramural Research Program of the NIH, NCI. This project has been funded in whole or in part with federal funds from the National Cancer Institute, National Institutes of Health, under contract N01-CO-12400. Minimal Chemical Modification of Reductive End of Dextran to Produce an Amphiphilic Polysaccharide Able to Incorporate onto Lipid Nanocapsules

Antoine Richard,[†] Alexandre Barras,[†] Amena Ben Younes,[‡] Nicole Monfilliette-Dupont,*[,†] and Patricia Melnyk[†]

Laboratoire de Chimie et MicroNanotechnologie à Visée Thérapeutique, UMR 8161 CNRS-Université de Lille 2-Université de Lille 1-Institut Pasteur de Lille, and INSERM IFR 142 Institut Pasteur de Lille-Institut de Biologie de Lille, Institut de Biologie de Lille, 1 Rue du Pr. Calmette, 59021 Lille cedex, France. Received December 4, 2007; Revised Manuscript Received May 19, 2008

In order to graft an amphiphilic polysaccharide to lipid nanocapsules, we present here a new method of dextran lipidation. The lipidation strategy is based on the formation of an oxime linkage between the amphiphilic hydroxylamine $\mathbf{C_{16}E_{20}ONH_2}$ and the reductive end of a 40 kDa dextran. This chemoselective reaction allows us to control the lipidation site and the number of lipid introduced on the dextran molecule. This new amphiphilic dextran was used to coat the surface of lipid nanocapsules. The coating efficiency was followed by dynamic light scattering and the presence of the polysaccharide was confirmed by ^{1}H NMR and observed by electronic microscopy.

INTRODUCITON

Since the development of liposomes, many other drug carriers in the nanometer range have been in development: polymer particles, solid lipid nanoparticles, lipid nanocapsules, and dendrimers (*1*). In order to extend the release of a drug and/or to address nanoparticles to the target cells or organ to treat, much attention has been devoted to increasing the blood half-time of these nanocarriers. Indeed, due to their interaction with the reticulo-endothelial system, their blood half-life is very low (*2, 3*). Toward this aim, nanoparticles were usually covered by a hydrophilic polymer, often a poly(ethylene glycol) (PEG). The longer the PEG, the more the blood half-time increases. Usually, medium molecular weight PEGs (2000−5000 Da) were used (*2, 3*).

Instead of PEG, biopolymers like polysaccharides can be used. Some authors reported the coating of liposome with dextran or chitosan (*4–9*). In order to anchor the polymer onto the liposome surface, a chemical modification of the polysaccharide with a hydrophobic function is necessary. These hydrophobic moieties, such as cholesteryl derivatives, were generally grafted in a statistically random manner on hydroxyl or amine functional groups present on the carbohydrate (*4, 5, 10*). By modulating the polysaccharide/lipophilic molecule ratio, it is possible to control the number of lipid moieties attached to the polysaccharide. Nevertheless, the reaction could occur anywhere on the reactive functions of the polymer.

We propose here a lipidation method of a dextran to attach a single lipid molecule at the polysaccharide reductive end. This coupling was achieved by forming an oxime bond as described by Dumy et al. (*11–13*) The oxime formation was achieved by reaction of a hydroxylamine with native dextran in aqueous medium. This chemoselective method can be used while maintaining biological properties (aqueous solubility, molecular recognition, etc.) and chemical functions which can be present on the polysaccharide chain. Moreover, by anchoring the sugar by one of its ends on the particle, we take advantage of its full length, which is impossible with statistical "lipidation" on the polymer.

As a proof of concept, the amphiphilic derivative **3** of dextran T40 (40 kDa) was synthesized and was anchored onto lipid nanocapsules. These nanocapsules consist of an oily liquid triglyceride core surrounded by a tensioactive cohesive interface. This tensioactive cohesive interface was mainly constituted of solutol HS15 which exposes a medium PEG chain containing an average of 15 ethylene glycol units (*14, 15*). To minimize the nanocapsule disturbance by the carbohydrate moiety, a PEG chain of an average of 20 ethylene glycol units was introduced between the polysaccharide and a C16 alkyl chain.

EXPERIMENTAL SECTION

Chemicals and Materials. Mass spectra were recorded on a Perspective Biosystems Voyager-DE STR, Biospectrometry Workstation MALDI-TOF spectrometer, and measurements were acquired after deposition on a dihydroxybenzoic acid (DHB) matrix. NMR spectra were recorded on a 300 MHz Bruker spectrometer. Chemicals reagents were purchased from Sigma-Aldrich. Lipid nanocapsules were made of labrafac lipophile WL 1349, soy lecithin Phospholipon 90G, and Solutol HS 15 were generously provided by Gattefossé SA, Phospholipid, and BASF, respectively.

Anchor Synthesis. Compound **1**: Under nitrogen atmosphere, 1 g (0.89 mmol, 1 equiv) of Brij-58P, 0.698 g (2.66 mmol, 3 equiv) of PPh_3, and 0.349 g (2.14 mmol, 2.4 equiv) of *N*-hydroxyphthalimide were dissolved in 20 mL of THF freshly distilled over sodium in the presence of benzophenone. 560 μL (2.66 mmol, 3 equiv) of DIAD were then added dropwise. The reaction medium was stirred for 3 h under nitrogen atmosphere and was concentrated under vacuum. The residue was precipitated in 50 mL of dry diethyl ether at 4 °C and then centrifuged. The resulting solid was collected and triturated twice with diethyl ether. The white solid obtained was dried under vacuum in the presence of P_2O_5 overnight. 952 mg of the phthalimide derivative was collected. Yield: 84%. ^{1}H NMR, $CDCl_3$, ppm: 7.83 (m, 2H); 7.76 (m, 2H); 4.38 (t, 4.5 Hz, 2H); 3.88 (t, 5 Hz, 2H); 3.65 (s, 42H); 3.44 (t, 6.8 Hz, 2H); 1.57 (m, 2H); 1.25 (s, 28H); 0.88 (t, 6.7 Hz, 3H).

Compound **2**: 952 mg (0.75 mmol, 1 equiv) of compound **1** was dissolved in 20 mL of absolute ethanol and 1 mL (20 mmol, 27 equiv) of hydrazine hydrate was added. After 4 h, the reaction medium was filtered and the solvent was evaporated under reduced pressure. The crude product was dissolved in diethyl

ether, precipitated at 4 °C, and centrifuged. The solid was collected, dissolved in CH_2Cl_2, and precipitated twice with diethyl ether. The white solid obtained was then dried overnight under vacuum in the presence of P_2O_5. 789 mg of the hydroxylamine derivative **2** was collected. Yield: 92%. MALDI-TOF MS: Two Gaussian distributions of peaks separated by $m/z = 44$ corresponding to ethylene glycol monomer. The first Gaussian corresponds to the $[M + H^+]$ centered on $m/z = 1138.9$ and the second one corresponds to the $[M + Na^+]$ centered on $m/z = 1160.9$. ^{1}H NMR, $CDCl_3$, ppm: 3.84 (t, 4.6 Hz, 2H); 3.65 (s, 88H); 3.57, (m, 2H); 3.44 (t, 6.8 Hz, 2H); 1.54 (m, 2H); 1.25 (s, 28H); 0.88 (t, 6.7 Hz, 3H). ^{13}C NMR, $CDCl_3$, ppm: 74.9; 71.7; 70.7; 70.2; 69.7; 32.1; 29.8; 29.6. 29.5; 26.2; 22.8; 14.3.

Dextran Coupling. Compound **3**: 1.6 g (40 μmol, 1 equiv) of dextran T40 and 174 mg (140 μmol, 3.5 equiv) of **2** were dissolved in 3 mL of a 100 mM acetate buffer pH 5.5. After 72 h, the reaction medium was poured onto 50 mL of methanol and centrifuged. The solid was dissolved twice in water, precipitated again in methanol, and centrifuged. Finally, the amphiphilic dextran was dissolved in water and lyophilized. 1.531 g of a white powder was collected. Yield: 93%. ^{1}H NMR: 7.47 (d, 6.2 Hz, 0.8H); 6.83 (d, 6.6 Hz, 0.2H); 4.85 (d, 3.3 Hz, 247H); 3.8 (m, 443H); 3.6 (m, 564H); 3.4 (m, 400H); 1.45 (s, 2H); 1.18 (s, 30H); 0.79 (t, 6.1 Hz, 3H).

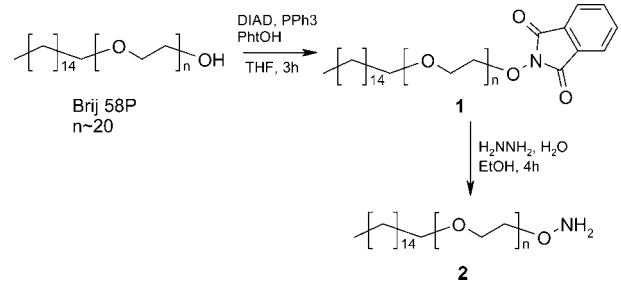
Nanocapsules. The preparation of lipid nanocapsules was based on a phase inversion method that allows the preparation of very small nanocapsules by thermal manipulation of an oil/water system as described by Heurtault et al. (*14*). Briefly, 420 mg of labrafac, 37.5 mg of phospholipon P90, 240 mg of solutol, 22 mg of NaCl, and 540 μL of distilled water were mixed at 80 °C. The mixture was subjected to 3 temperature cycles from 70 to 90 °C under magnetic stirring; then, it was cooled to 78 °C, 3.3 mL of 0 °C water were added, and the suspension was stirred at room temperature.

Lipodextran Insertions into Preformed Nanocapsules. Lipodextran nanocapsules were obtained by two postinsertion methods. First method: plain nanocapsules (15 mg LN/mL) were incubated for 24 h with lipodextran (10 mg/mL of LN) under magnetic stirring at room temperature. Second method: plain nanocapsules (15 mg LN/mL) were incubated for 120 min with 100 μL/mL of LN of an aqueous micellar solution of lipodextran (100 mg/mL) under magnetic stirring at 60 °C. The suspension was then dialyzed (pore size: 300 000 Da) against distilled water overnight to remove any uninserted lipodextran from the external volume of nanoparticles.

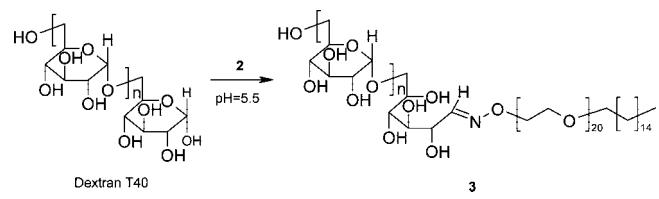
Lipid Nanoparticle Characterization. The average diameter and polydispersity of the particle were determined by photon correlation spectroscopy at 25 °C using a DynaProMS800. Nanoparticle suspensions were diluted at 1/2000 (v/v) in distilled water and filtered over 0.22 μm. Mean results were given for 100 acquisitions, and measurements were performed in triplicate. The zeta potential was determined with a Malvern Zetasizer Nano ZS (Malvern Instruments S.A., Worcestershire, UK).

Electron Microscopy. Samples were studied using a slightly modified version of the negative staining method as previously described by Op De Beeck et al. (*16*); 20 μL droplets of free and covered nanocapsule preparations were adsorbed for 1 min onto Formvar carbon-coated nickel grids (400 mesh, Electron Microscopy Science, Washington, PA). The grids were dried by absorption with a filter paper, stained for 1 min on a drop of 2% uranyl acetate stain, air-dried for less than 2 min, and immediately examined under a transmission electron microscope (TEM, Hitachi 7500, Japan) at 80 kV and HR conditions. Because of their rapid degradation, every sample is processed for electron microscopy and immediately examined under TEM.

Scheme 1. Synthesis of the Amphiphilic Hydroxylamine $C_{16}E_{20}ONH_2$



Scheme 2. Coupling of Dextran to Amphiphilic Hydroxylamine 2



RESULTS AND DISCUSSION

Synthesis. The amphiphilic hydroxylamine moiety **2** was synthesized in two steps. First, the hydroxylamine function was introduced by coupling the *N*-hydroxyphthalimide by means of a Mitsunobu reaction. Second, the phthalimide group was

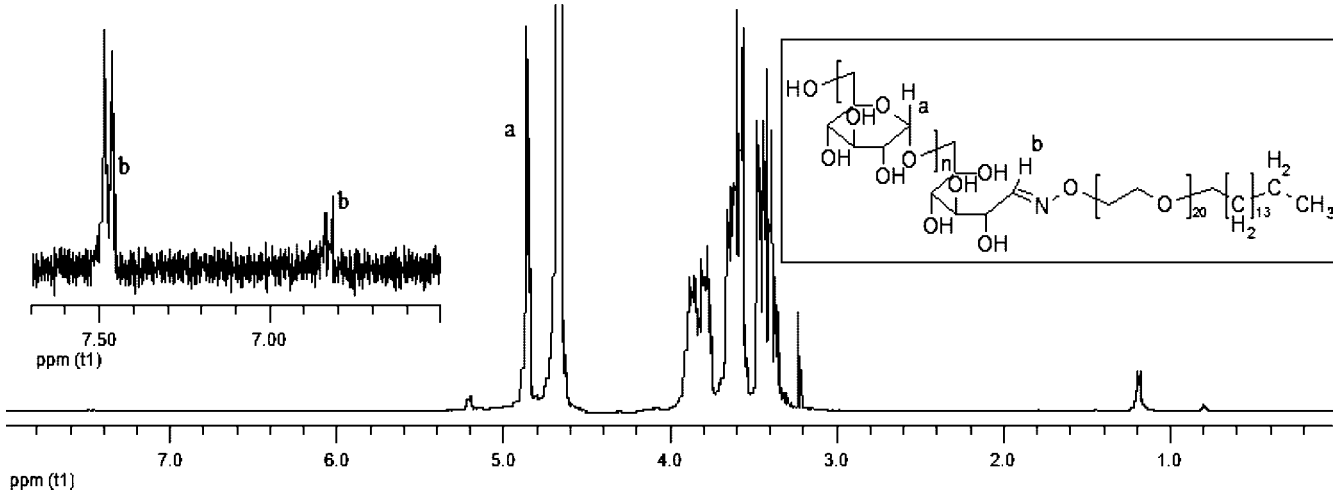


Figure 1. Analysis of oxime ^{1}H of amphiphilic dextran **3** by NMR spectroscopy.

Table 1. Fitting Results of the Evolution of Nanocapsule Mean Diameter with Eq 1 in the Presence of Amphiphilic Dextran 3

postinsertion	room temperature		60 °C	
parameter	value	error	value	error
A	58.03 nm	0.7 nm	58.53 nm	0.6 nm
B	18.3 nm	0.9 nm	13.7 nm	0.7 nm
τ	5.4 h	0.7 h	0.2 h	0.03 h
R^2	0.9978	-	0.9945	-

removed by hydrazinolysis (Scheme 1). The starting product was the commercial nonionic detergent Brij 58P which consists of a C16 alkyl chain bearing a PEG chain of an average of 20 ethylene glycol units with a free hydroxyl group at the chain end.

The coupling of hydroxylamine **2** with dextran T40 occurs in an aqueous solvent at high concentration (at less than 10 mM) with an excess of compound **2** (Scheme 2). The hydroxylamine reacts with the reductive end of dextran in 72 h at room temperature to form the corresponding oxime compound. Taking advantage of dextran insolubility in methanol, buffer salt and excess reagent can be removed by precipitation in methanol to give the amphiphilic dextran **3** in an overall yield of 72% for the three steps.

^{1}H NMR of compound **3** shows the presence of a doublet at 7.47 ppm and another one at 6.83 ppm, which confirms the presence of the oxime link between the dextran and the hydroxylamine **2** (Figure 1). Moreover, taking the acetal proton (4.85 ppm) of the glucose unit of dextran (247 H for Dextran T40) as integration reference, the doublet at 7.47 ppm integrates for roughly 0.8 H and the one at 6.83 ppm for roughly 0.2 H. It is thus concluded that the oxime link is in E configuration at 80% and in Z at 20%.

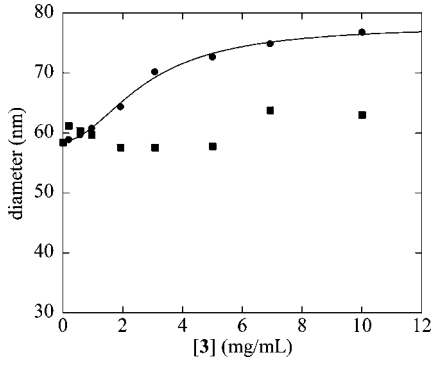

Figure 3. Evolution of nanocapsules mean diameter as a function of dextran concentration: •, amphiphilic dextran; ■, commercial dextran of 40 kDa.

Table 2. Lipid Nanoparticles Characterization (NP, lipid nanoparticles without amphiphilic dextran; and Dextran NP, lipid nanoparticles with amphiphilic dextran).

			zeta potential	
	mean particle size (nm)	polydispersity (nm)	peak (mV)	width (mV)
NP	59.2 ± 2.9	6.8 ± 1.6	−4.08	10.4
Dextran NP (RT)	71.9 ± 1.5	6.2 ± 1.4	−2.86	6.0
Dextran NP (60 °C)	73.8 ± 2.1	9.4 ± 1.4	−1.67	3.5

After three consecutive dialyses (1:1000 in water), NMR spectra do not change (data not shown), which allows us to conclude that the oxime link is stable.

Dextran Incorporation onto Nanocapsules. The dextran T40 average diameter was measured by dynamic light scattering at 9 nm. So, if we anchor this polysaccharide uniformly on the nanocapsules surface, their mean diameter should grow by approximately 20 nm. The size of our nanocapsules, initially close to 58 nm, which were suspended in an amphiphilic dextran solution at 10 mg/mL in water, was in accordance with this hypothesis (Figure 2).

The increase of particle mean diameter with time could be well fitted by a monoexponential curve as defined in eq 1

$$\bar{d} = A + B \cdot \left[1 - \exp\left(-\frac{t}{\tau}\right)\right] \quad (1)$$

in which d is the mean diameter, A the starting diameter of nanoparticles (without dextran), B the mean diameter raise, and τ the characteristic time of dextran insertion.

The fitting results of this equation are given in Table 1.

We found an increase in diameter of 18.3 ± 0.9 nm. This is in accordance with a full coverage of nanocapsules by a 40 kDa dextran. The anchorage of amphiphilic dextran was complete in 24 h when postinsertion was realized at room temperature with a characteristic time of 5 h 20 min ± 42 min and was complete in 45 min when postinsertion was realized at 60 °C with characteristic time of 12 min ± 1.8 min.

For a second time, taking advantage of the hydroxylamine reactivity in aqueous medium, we tried to form the oxime **3** directly on to the nanoparticles. This strategy was already employed to link peptides to lipid vesicles by an oxime bond (*17*). To this end, compound **2** was first incorporated during the formulation of nanocapsules. These nanocapsules were suspended in dextran solution, but the dextran concentration required (around 10 mM) for the reaction to occur with the hydroxylamine carried by particles was incompatible with nanocapsule stability. Furthermore, the coformulation of the amphiphilic dextran **3** with other components does not yield the expected particles. Thus, the postinsertion method seems to be the most efficient to coat these lipid nanocapsules with our dextran.

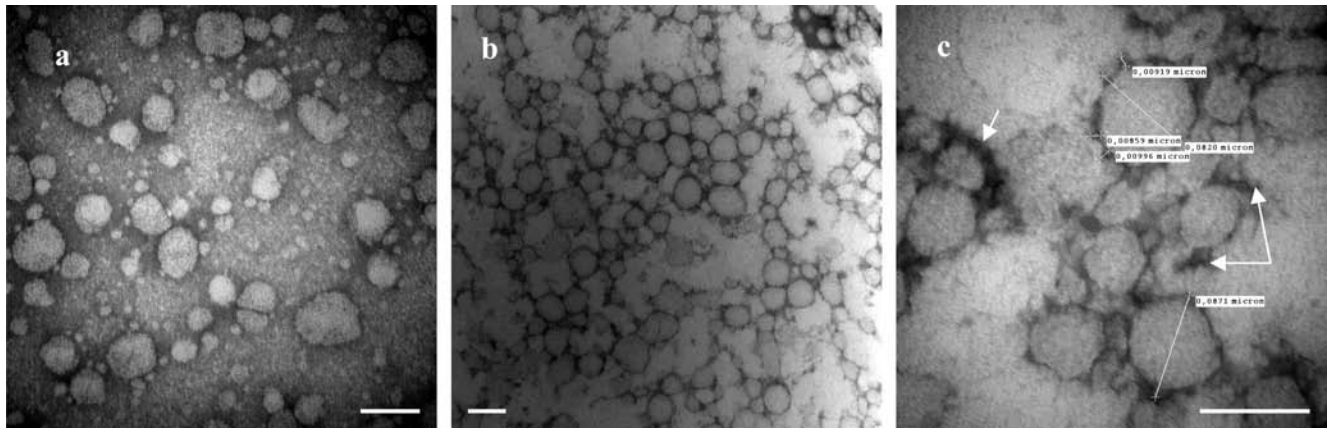

Figure 4. TEM visualization of lipid nanocapsules. Bar scale represents 100 nm. (a) Lipid nanocapsules without dextran. (b) Lipid nanocapsules in the presence of 5 mg/mL of amphiphilic dextran **3**. (c) Enlargement of (b); white arrows show a deposit attributed to dextran.

The presence of the C16 alkyl chain is a necessary condition to achieve the nanoparticles coverage: only polysaccharide **3** brings about a significant increase of nanocapsules diameter. But, as can be seen in Figure 3, a sufficient polysaccharide concentration was needed to obtain a size increase of 18 nm, corresponding to an entire coverage of particles by dextran. In our case, the concentration should be greater than 5 mg/mL to complete the postinsertion.

As shown in Table 2, the zeta potential of the nanoparticles measured was slightly influenced by the presence of dextran on the surface. Zeta potential of almost neutral value (−2.86 and −1.67 mV for postinsertion at room temperature and 60 °C, respectively) was measured for the nanoparticles prepared by postinsertion with amphiphilic dextran, which is a neutral polysaccharide.

To confirm this result, the nanocapsules were observed by transmission electron microscopy using the negative staining method (Figure 4). A dark deposit dense to electrons was observed on the nanocapsules surface only if the nanocapsules were incubated with amphiphilic dextran. The same experiment was carried out with the nanocapsules in the presence of lipodextran without incubation or free dextran T40 and no dark deposit dense to electrons was observed. This observation suggests that the amphiphilic dextran coats the surface of lipid nanocapsules. In addition, the size of this deposit, as determined from the TEM micrograph, corresponds to the size of 40 kDa dextran.

To corroborate our direct observation by electron microscopy, we wanted to have a spectrometric signature of the dextran presence on the nanocapsules surface. Thus after gel filtration through a sephacryl 500HR column, a ^{1}H NMR spectrum of the nanocapsule fraction in H_2O/D_2O 95/5 solvent was acquired. As the NMR spectra show (Figure 5), specific signals of dextran were detected (in the region between 3.8 and 4.0 ppm) with amphiphilic dextran. In the control experiment with commercial dextran T40, no dextran peak was found on nanoparticles NMR spectrum. Thus, the lipid tail link to dextran allows the polysaccharide fixation onto the surface of nanocapsules. The quantification of lipodextran has been investigated by the ^{1}H NMR method (see Supporting Information for quantitative analysis of lipodextran incorporation onto nanocapsules by ^{1}H NMR). Integration of the signals indicates the quantity of lipodextran on the surface of nanocapsules (5.1% mass incorporation of nanocapsules at RT and 10.1% mass incorporation of nanocapsules at 60 °C). The results indicate that the postinsertion method at 60 °C allows us to introduce approximately twice as much lipodextran on the surface of nanocapsules as at RT.

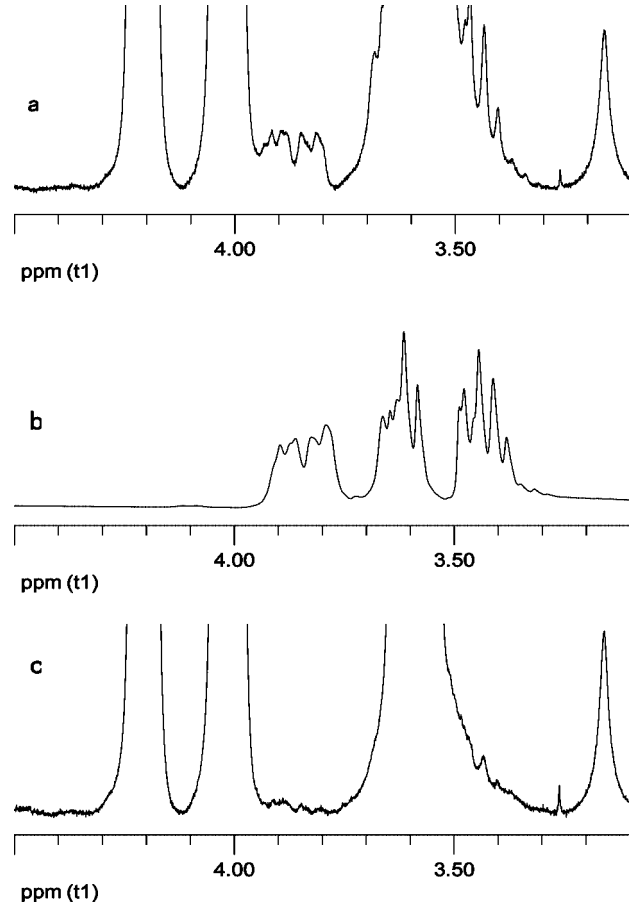

Figure 5. NMR spectra in H_2O/D_2O 95/5 of (a) nanocapsules in the presence of amphiphilic dextran **3** after gel filtration, (b) commercial dextran T40, and (c) nanocapsules in the presence of commercial dextran T40 after gel filtration.

Full Conclusion. We have developed here an efficient and convenient method to anchor a polysaccharide onto the surface of lipid nanocapsules. The formation of amphiphilic dextran as well as the formulation of nanocapsules were performed under aqueous conditions without organic solvent. This is an important parameter when biological or pharmaceutical applications are engaged. We have shown that only one alkyl C16 chain is sufficient to anchor a 40 kDa dextran. Moreover, the postinsertion of this carbohydrate can be achieved under mild conditions: at room temperature in less than one day. This method could constitute an attractive alternative to the use of

PEG and could be useful for decorating lipid particles with functionalized polysaccharide with the aim of active cell targeting.

Synthesis of ^{64}Cu-Labeled Magnetic Nanoparticles for Multimodal Imaging

Benjamin R. Jarrett, Björn Gustafsson, David L. Kukis, and Angelique Y. Louie*

Department of Biomedical Engineering, University of California-Davis, Davis, California 95616. Received March 13, 2008; Revised Manuscript Received May 21, 2008

Complementary imaging modalities provide more information than either method alone can yield and we have developed a dual-mode imaging probe for combined magnetic resonance (MR) and positron emission tomography (PET) imaging. We have developed dual-mode PET/MRI active probes targeted to vascular inflammation and present synthesis of (1) an aliphatic amine polystyrene bead and (2) a novel superparamagnetic iron oxide nanoparticle targeted to macrophages that were both coupled to positron-emitting copper-64 isotopes. The amine groups of the polystyrene beads were directly conjugated with an amine-reactive form (isothiocyanate) of aza-macrocycle 1,4,7,10-tetraazacyclo-dodecane-1,4,7,10-tetraacetic acid (DOTA). Iron oxide nanoparticles are dextran sulfate coated, and the surface was modified to contain aldehyde groups to conjugate to an amine-activated DOTA. Incorporation of chelated Cu-64 to nanoparticles under these conditions, which is routinely used to couple DOTA to macromolecules, was unexpectedly difficult and illustrates that traditional conjugation methods do not always work in a nanoparticle environment. Therefore, we developed new methods to couple Cu-64 to nanoparticles and demonstrate successful labeling to a range of nanoparticle types. We obtained labeling yields of 24% for the amine polystyrene beads and 21% radiolabeling yield for the anionic dextran sulfate iron oxide nanoparticles. The new coupling chemistry can be generalized for attaching chelated metals to other nanoparticle platforms.

1. INTRODUCTION

Challenges in diagnostic imaging have led to an explosion of interest in combining modalities to more accurately interpret disease and abnormalities in vivo. Combinations of imaging modalities are being investigated for a synergistic effect, and the combination of positron emission tomography/magnetic resonance imaging (PET/MRI) has raised expectations for highly sensitive and high-resolution imaging (*1*, *2*). PET and MRI are complementary to each other given the high anatomical spatial resolution of MRI and the unparalleled sensitivity and functional imaging of PET (*3*). Noninvasive monitoring of physiological abnormalities in vivo promises to greatly enhance our knowledge and treatment of diseases.

Concomitant with the development of dual-mode imaging systems has been an increase in interest for dual-mode molecular imaging probes that are targeted for very specific clinical applications, e.g., imaging of tumors and atherosclerotic plaques (*4*–*7*). Most of the reported dual-mode agents have been combinations of either PET or MRI agents with optical agents (*6*, *8*–*12*). Reports of SPIOs with dual-modality properties are increasing in the literature, with the focus primarily on probes with magnetic and optical properties suitable for imaging (*13*–*18*). Very recently, a trimodal PET/CT/optical agent based on iron oxide nanoparticles was developed (*19*). In this work, we describe development of a combined MRI/PET agent composed of iron oxide nanoparticles coupled to chelated positron emitting ions.

A commonly used method to radiolabel macromolecular targeting agents for imaging with any PET active metal is to chelate the metal to a bifunctional polyazacarboxylate- (*20*) or a tetraaza-macrocycle (*21*). The isotope ^{64}Cu, with a half-life of 12.7 h, has expanded in use as a positron emitter (*22*) for PET and metabolic radiotherapy (*23*, *24*) due to the additional high-energy β^- particle and Auger electron emissions of this nucleus. The ligand−cage pairs of polyazacarboxylate- or tetraaza-macrocycle form thermodynamically stable complexes with Cu^{2+} ($\log K = 20-28$) (*25*, *26*). The copper chelate could then be conjugated to the superparamagnetic iron oxide nanoparticle to develop a dual-modality probe for MRI and PET imaging. We found that the development of an iron oxide conjugated to a copper chelate was synthetically difficult using traditional bioconjugation methods.

Herein, we report ^{64}Cu radiolabeling of dextran sulfate coated superparamagnetic iron oxide nanoparticles; these are targeted toward inflammatory events, such as atherosclerotic plaques. The labeling was done by coordination of the ^{64}Cu to the chelating bifunctional ligand *S*-2-(4-isothiocyanatobenzyl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (*p*-SCN-Bz-DOTA) and then conjugation to the nanoparticle. We also describe a synthetic route for a ^{64}Cu-radiolabeled model imaging probe utilizing an aliphatic amine polystyrene microsphere as another example for radiolabeling of nanoparticles.

water (18.0 MΩ·cm) was from a Barnstead nanopure filtration unit. Dextran (10 095 MW, Sigma (St. Louis, MO)) was reduced and purified according to Paul et al. (*27*).

2.2. Preparation of Polystyrene Beads and Dextran Sulfate Coated Iron Oxide Nanoparticles Labeled with "Cold" Copper. *2.2.1. Prechelation of "Cold" Copper into p-SCN-Bz-DOTA Followed by Conjugation to Polystyrene Beads.* $CuCl_2$ (1.29 mg; 9.57 μmol in 20 μL nanopure H_2O) was added to p-SCN-Bz-DOTA (5.26 mg; 7.656 μmol in 1.0 mL nanopure H_2O) and stirred for 2 h. The reaction solution was then purified by size exclusion chromatography (SEC) on a Sephadex G-25 column. UV−vis spectra of the purified product were used to determine the fraction corresponding to the *p*-SCN-Bz-DOTA(Cu^{2+}) complex based on the absorption of the benzyl group and copper ion. UV−vis was not used to assess the purity of the product. The *p*-SCN-Bz-DOTA-Cu solution was then added to tetramethylammonium phosphate solutions (pH 8) of both 78 nm and 1 μm sized polystyrene beads in molar ratios of approximately 5000:1 and 218 000:1, respectively. The reactions were stirred at room temperature overnight and purified by dialysis against 4 L nanopure water for ~2 days with 6 changes of water. Inductively coupled mass spectrometry (ICP-MS) was used to determine amounts of conjugated copper.

2.2.2. Labeling of ADIO Nanoparticles with "Cold" Copper to Determine Affect of Labeling on Particle Size. Dextran sulfate coated iron oxide nanoparticles (anionic dextran sulfate iron oxide, ADIO) were synthesized as described previously (*28*). It was found that amination of the ADIO nanoparticles leads to cross-linking as the ethylenediamine is bifunctional (Scheme 1); therefore, we sought to avoid particle cross-linking by attaching the ethylenediamine to the *p*-SCN-Bz-DOTA instead. In this way, any dimer formation of *p*-SCN-Bz-DOTA-amine complexes would be unreactive and not contribute to particle aggregation. Synthesis of copper-labeled dextran sulfate nanoparticles was achieved by conjugation of an amine reactive *p*-SCN-Bz-DOTA with the dextran sulfate coating.

The *p*-SCN-Bz-DOTA (9.82 mg; 16.70 μmol in 14.28 mL DMSO), was mixed in a 1:1 molar ratio with a solution of $CuCl_2$ (1.92 mg of $CuCl_2$ in 0.465 mL nanopure water) and incubated at room temperature for 15 min. Next, the *p*-SCN-Bz-DOTA-Cu was amine-activated by coupling ethylenediamine to the *p*-SCN-Bz-DOTA to form a urea bond (Scheme 2). A 0.1 M triethanolamine acetate (TEAA) (pH 8) buffer was added to the *p*-SCN-Bz-DOTA-Cu solution (7 mL added, 0.032 M TEAA final) and ethylenediamine (1 μL) was mixed in a 1:1 molar ratio with the *p*-SCN-Bz-DOTA and incubated at room temperature for 15 min. To couple the amine group to the particle surface (Scheme 3a), the dextran sulfate particles were prepared by the ring-opening reaction with periodic acid (*29*). Depending on the amount of labeling desired, 1% periodic acid was mixed with a 1.41 mM Fe solution (2 mL particles) of dextran sulfate particles in an Fe/HIO_4 molar ratio of 15.2:1, 5:1, or 2.5:1 (4.25, 12.75, 25.5 μL HIO_4, respectively). Then, 0.404 mL, 1.212 mL, or 2.424 mL of the amine-activated *p*-SCN-Bz-DOTA-Cu (Fe/*p*-SCN-Bz-DOTA molar ratio of 11.4:1, 3.8:1, 1.9:1) was added to the particles and stirred at room temperature for 2 h. Next, 0.6 mL ethylene glycol was added to quench the reaction, followed by 15 min of stirring. This was followed by the addition of ~5 to 15 mg solid sodium cyanoborohydride to reduce the imine bond (Schiff base) and stirred for an additional 20 min. The product was purified by gel chromatography on a Sephadex G-25 (fine bead size, Sigma (St. Louis, MO)) column equilibrated with 1× phosphate buffered saline (PBS). Fractions corresponding to the particles were collected and pooled together.

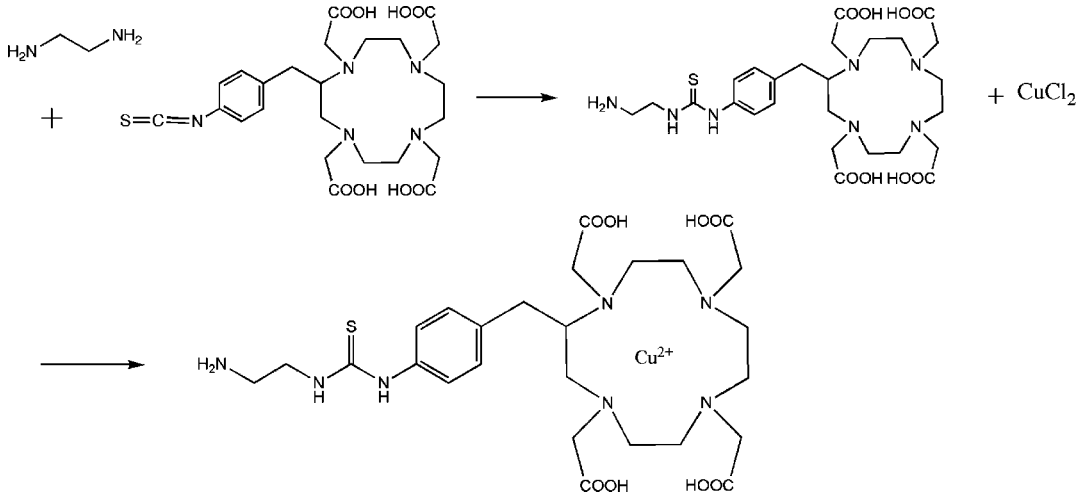
2.3. Preparation of Copper-64 Labeled Polystyrene Beads and Dextran Sulfate Coated Iron Oxide Nanopart icles (ADIO-(DOTA-Cu)). *2.3.1. Labeling of Polystyrene Beads with Copper-64.* $^{64}CuCl_2$ (2.35 mCi, approximately 0.6 nmol, in 50 μL of 10 mM HCl) was buffered with 1 M TEAA buffer, pH 8 (5 μL), then added to *p*-SCN-Bz-DOTA (0.120 μmol in 6 μL of 0.1 M TEAA buffer, pH 8). Pure triethanolamine (1 μL) was added to adjust the final pH to 8. This reaction mixture was then incubated for 20 min at 40 °C and added to a solution of polystyrene beads (1 μm; 5.2 mg in 440 μL of 0.1 M TEAA buffer, pH 8), and incubated for 2 h at 40 °C. After incubation, 10 mM EDTA (100 μL) was added to scavenge any free metal ions. To purify, the beads were centrifuged at 7500 rpm for 5 min, the supernatant was drawn off, and the beads were resuspended in water (300 μL). The purification procedure was performed three times.

2.3.2. Labeling of ADIO Nanoparticles with Copper-64 for Multimodal Imaging. The protocol described for the "cold" copper in section 2.3.1 was used with the following modifications. Ethylenediamine (at least 1 μL was used) was mixed in a 1:1, 2:1, or 30:1 molar ratio with the *p*-SCN-Bz-DOTA and incubated at room temperature for 4 h to generate amine-Bz-DOTA (2-*p*-(3-aminopropylthioureido)benzyl-1,4,7,10-tetraazacyclododecane-tetraacetic acid). If a 2:1 or 30:1 molar ratio was used, the product was purified by size exclusion gel chromatography (SEC) on a Sephadex G-25 column equilibrated with 50 mM ammonium bicarbonate. To couple the amine group to the particle surface (Scheme 3b), the dextran sulfate particles were prepared by the ring-opening reaction with periodic acid (*29*).

Briefly, amine-Bz-DOTA was synthesized by combining a buffered solution of *p*-SCN-Bz-DOTA (2.8 mg; 4.07 μmol dissolved in 408 μL 0.1 M carbonate buffer (pH 9.2)) with ethylenediamine. Within 1 min of preparation of the aqueous *p*-SCN-Bz-DOTA, ethylenediamine (8.2 μL; 122.4 μmol, 30 equiv) was added and stirred at room temperature for 4 h. The product was then purified by SEC on a Sephadex G-25 column equilibrated with 50 mM ammonium bicarbonate. Fractions corresponding to amine-Bz-DOTA were pooled (confirmed spectrophotometrically by a broad absorbance at 260−280 nm). Second, the ADIO polysaccharide surface was modified with aldehyde groups by mixing 0.5 mL ADIO (5.64 mM Fe) with 0.25 mL 1% HIO_4 (3.9 equiv) at room temperature for 4 h. The modified particles were then purified by SEC on a Sephadex G-25 column equilibrated with nanopure water. The purified amine-Bz-DOTA was then mixed with 930 μCi (~0.2 nmol) $^{64}CuCl_2$ at room temperature for 20 min. The amine-Bz-DOTA(^{64}Cu) was then added to the aldehyde-ADIO particles and stirred at room temperature for 1.5 h. The reaction was completed by the addition of ~3 mg solid sodium cyanoborohydride to reduce the imine bond formed. The labeled nanoparticles were then purified by SEC on a Sephadex G-25 column equilibrated with 1× PBS.

2.3.3. Comparison of p-NH_2-Bz-DOTA with the Synthesized Amine-Bz-DOTA for Labeling of ADIO Nanoparticles with Copper-64. *S*-2-(4-Aminobenzyl)-1,4,7,10-tetraazacyclododecane tetraacetic acid (*p*-NH_2-Bz-DOTA) was used in parallel

Scheme 2. Amine "Activation" of the *p*-SCN-Bz-DOTA for Coupling to the Dextran Sulfate Coated Nanoparticles



with amine-Bz-DOTA for comparison of labeling efficiency. Amine-Bz-DOTA was synthesized by reacting *p*-SCN-Bz-DOTA (1.09 μmol, 10 mM) with 30 mol equiv of ethylenediamine in 0.1 M sodium bicarbonate buffer (pH 9.0) for 3 h at room temperature (RT). The amine-Bz-DOTA product was then purified by SEC on a Sephadex G-25 column equilibrated with 50 mM ammonium bicarbonate using the Panofsky method (centrifuge at 2000 rpm for 2 min). This was repeated 2 times to yield amine-Bz-DOTA.

Next, aldehyde-terminated ADIO nanoparticles were generated by incubating 1 mol equiv (Fe/HIO_4) of 1% HIO_4 with ADIO nanoparticles at RT for 3 h (6.36 μmol Fe, 85 μL of a 74.8 mM Fe solution in 0.9% NaCl). The product was purified by SEC on a Sephadex G25 column equilibrated with nanopure water using centrifugation (2000 rpm, 2 min). This was repeated 2 times to yield the aldehyde-modified ADIO nanoparticles.

Then, copper-64 was chelated by *p*-NH_2-Bz-DOTA or amine-Bz-DOTA by first mixing $^{64}CuCl_2$ in 10 mM HCl (30 μL) with 1 M triethanolamine acetate (pH 8, 7 μL) to form a ^{64}Cu-actetate complex in a solution with a pH of 8.0. Then, the *p*-NH_2-Bz-DOTA (1.07 μmol) in 50 mM ammonium bicarbonate or amine-Bz-DOTA ($\sim$1.09 μmol) in 50 mM ammonium bicarbonate was mixed with 37 μL of the copper acetate solution at RT for 30 min.

The aldehyde-ADIO nanoparticles (110 μL) were then reacted with either *p*-NH_2-Bz-DOTA(^{64}Cu) (263 μCi) or amine-Bz-DOTA(^{64}Cu) (246 μCi) at RT for 2 h. Then, 0.5 mg solid $NaCNBH_3$ was added and allowed to incubate with the nanoparticles for an additional 20 min at RT to reduce the imine bond formed between the chelator and the nanoparticle to form a stable product. The nanoparticles were then purified by SEC on a Sephadex G25 column equilibrated with 0.9% NaCl using centrifugation (2000 rpm, 2 min). This was repeated 3 times to yield ADIO-DOTA(^{64}Cu) using either *p*-NH_2-Bz-DOTA or amine-Bz-DOTA. The activity was then measured and the radiolabeling yield determined.

2.4. Characterization. *2.4.1. Iron and Copper Quantification.* The iron and copper content of the labeled ADIOs was determined by atomic absorbance spectroscopy (AAS) using a Varian SpectrAA 220FS (Varian (Palo Alto, CA)) to verify iron concentration and the number of "cold" copper coordinated *p*-SCN-Bz-DOTA ligands were conjugated to each ADIO particle. The AAS samples were prepared in 3% HCl and five standard solutions with known iron and copper concentrations were used to generate standard curves.

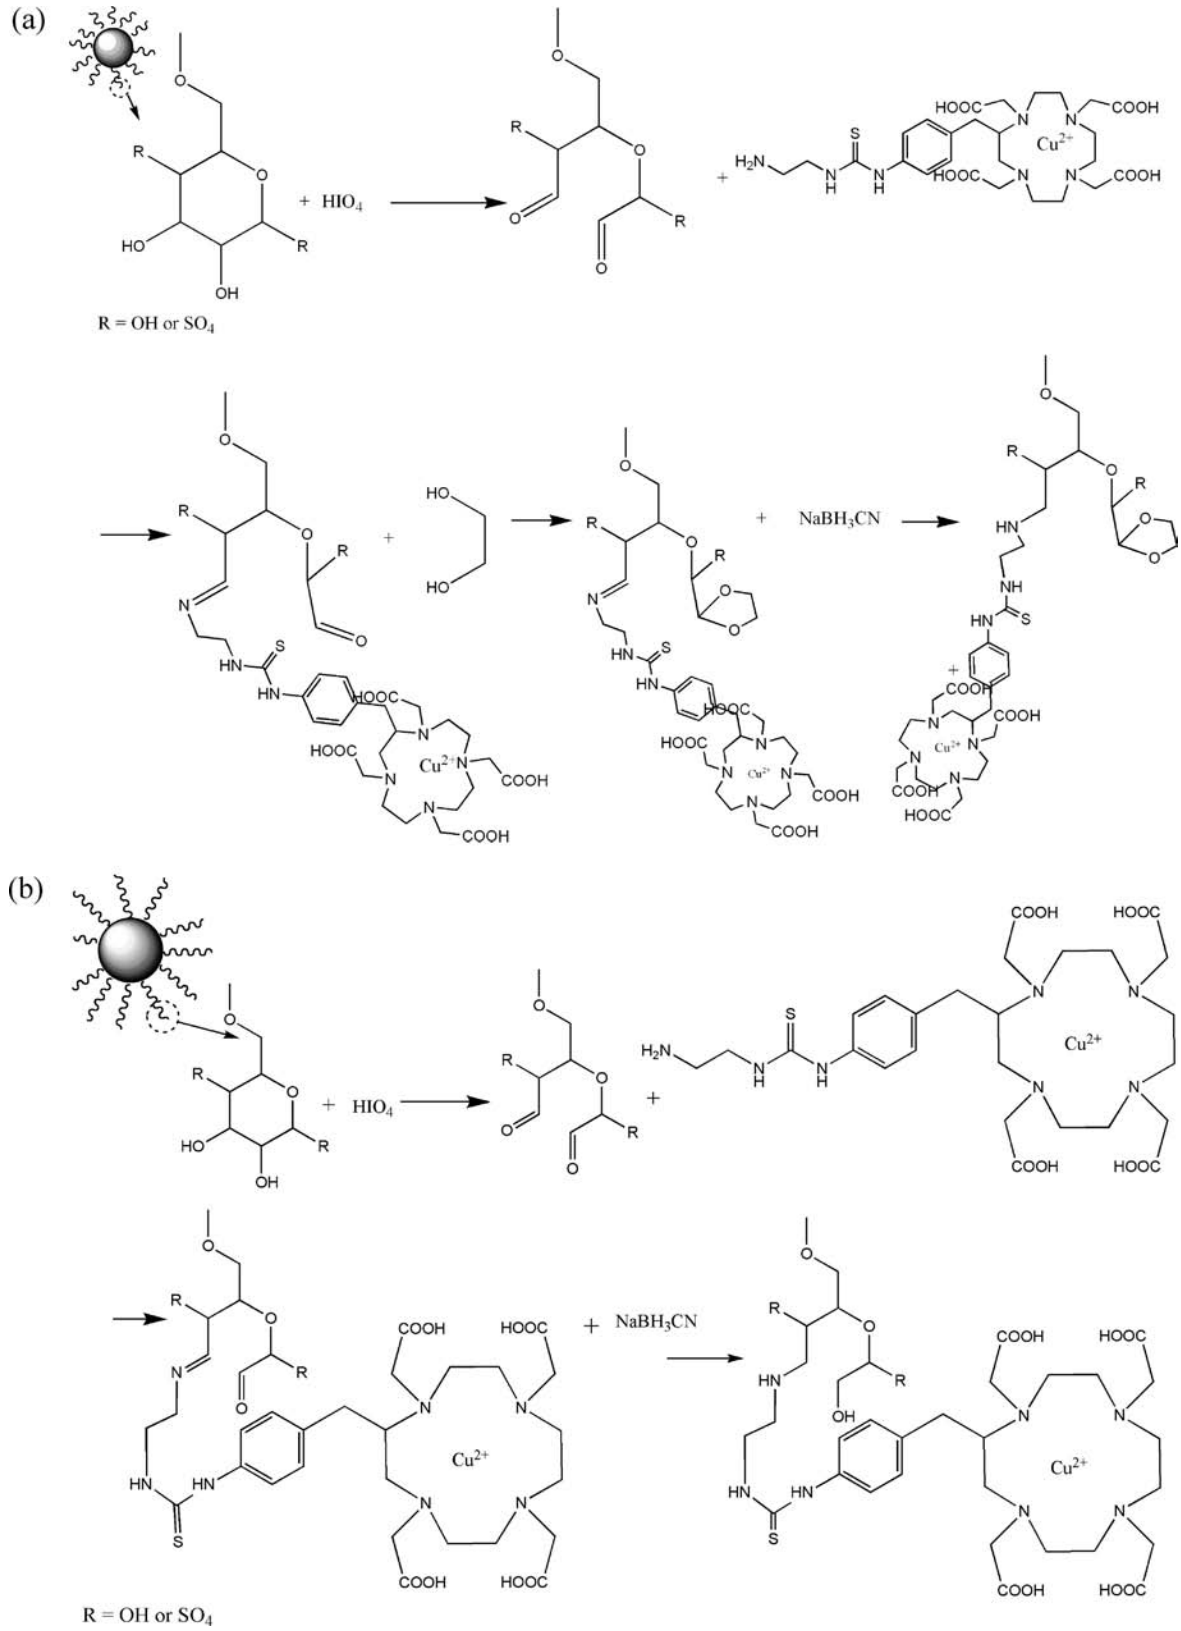
Copper content of the polystyrene bead comparable experiments with "cold" copper were analyzed by inductively coupled plasma mass spectrometry (ICP-MS) on an Agilent 7500a (Agilent Technologies (Santa Clara, CA)) quadrupole ICP-MS. The ICP-MS samples were prepared as 10 mL triplicates in 3% HNO_3. In order to correct for instrumental drift during analysis, germanium solution was mixed with all sample and standard solutions as an internal standard.

2.4.2. Characterization of Amine-Bz-DOTA (2-p-(3-aminopropylthioureido)Benzyl-1,4,7,10-Tetraazacyclododecane-Tetraacetic Acid). Amine-Bz-DOTA was generated by reacting 8.26 mg *p*-SCN-Bz-DOTA with 30 mol equiv of ethylenediamine in 0.1 M sodium carbonate buffer (pH 9.0, 10 mM DOTA solution). After purification by SEC on a Sephadex G-25 column equilibrated with 50 mM ammonium bicarbonate, the amine-Bz-DOTA product was then dialyzed (MWCO = 100) against 4 L of nanopure water for 18 h with 2 water changes to remove salts. The product ($\sim$3.3 mg, 40% yield) was then lyophilized ($-$48 °C, 0.002 mTorr, 3 days) and analyzed by ^{1}H NMR and mass spectrometry. A small portion was dissolved in nanopure water for ESI^+ MS. The instrument was a Thermo LCQ ion trap (San Jose, CA) operated with an electrospray source in positive ion mode under standard conditions. The remaining sample (3.3 mg) was resuspended in D_2O (750 μL) for ^{1}H NMR (500 MHz, 300 K, Bruker, Billerica, MA). The *p*-SCN-Bz-DOTA was also dissolved in nanopure water for ESI^+ MS and DMSO-d_6 for ^{1}H NMR.

The ^{1}H NMR spectra for the final product, amine-Bz-DOTA (2-*p*-(3-aminopropylthioureido)benzyl-1,4,7,10-tetraazacyclododecane-tetraacetic acid), is presented in Supporting Information Figure S1. Amine-Bz-DOTA, ^{1}H NMR (D_2O): δ 1.9$-$2.4 (4H, m, CH_2), δ 2.4$-$2.7 (4H, m, CH_2), δ 2.745 (1H, s, CS-NH-Ar), δ 2.78$-$2.9 (4H, m, N-CH_2 and Ar-CH_2), δ 2.9$-$3.9 (21H, m, CH_2), δ 7.128 (2H, s, ArH), δ 7.225 (2H, s, ArH). ESI^+ MS (100% H_2O): *m/z* found 612.5 (100%, calc. M + H = 612.67), 634.5 (12%, M + Na^+, calc. 635.66), 306.8 (22%, [M + H]$^{2+}$, calc. 306.34), 552.5 (5%, *p*-SCN-Bz-DOTA calc. 552.4), 1223.8 (6%, dimmer + NaCl, calc. 1221.77). The ^{1}H NMR of *p*-SCN-Bz-DOTA is presented in Supporting Information Figure S2. *p*-Bz-DOTA, ^{1}H NMR (DMSO-d_6): δ 2.6$-$4.2 (43H, m, CH_2), δ 7.424 (4H, s, ArH), δ 12.5$-$14 (3H, m, COOH). ESI^+ MS (100% H_2O): *m/z* found 552.4 (100%, calc. M + H = 552.4).

2.4.3. Size Measurements. Dynamic light scattering (DLS) was used to determine the overall particle size in solution (expressed as the volume weighted diameter) with a Nanotrac 150 particle size analyzer (Microtrac, Inc. (Montgomeryville, PA)). A geometric eight-root regression, with no residuals, was used to fit the data. The Nanotrac 150 has a built-in thermometer

Scheme 3. Conjugation of *p*-SCN-Bz-DOTA-Copper to the Dextran Sulfate Coated Nanoparticles[a]



[a] (a) Initial synthesis where ethylene glycol was used to quench the HIO_4. (b) No ethylene glycol is used and SEC is used to purify the aldehyde modified nanoparticles and the final product after reduction of the imine bond between the amine-Bz-DOTA(^{64}Cu) and the nanoparticles.

to measure the cell temperature, from which the viscosity is calculated; the nanorange option was enabled and a scan time of 30 s was used. Particle size is expressed as the mean volume diameter ± one standard deviation.

3. RESULTS AND DISCUSSION

In previous work, the synthetic strategy for conjugating fluorescent dyes to nanoparticles has been to form an amide

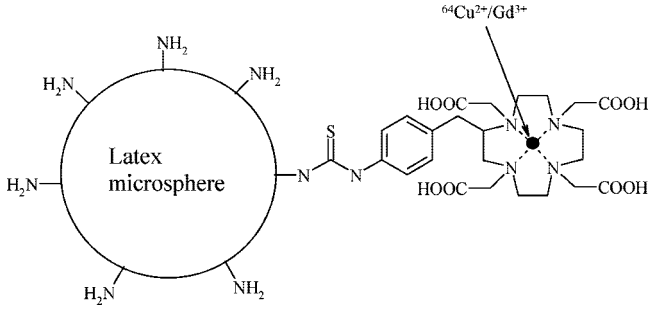


Figure 1. A schematic illustration of the conjugation of the metal chelating ligand to the surface of a polystyrene bead.

bond between the dye and the amine sites on the coating of the SPIO, or a linker connecting to the SPIO through a disulfide or a thioether linkage (*9, 13*). Our initial labeling approach was based on a similar theory. For the dextran sulfate coated nanoparticles, the particle surface is modified to contain aldehyde groups, which can be conjugated to the amine-reactive *p*-SCN-Bz-DOTA chelator. For the polystyrene beads, the chelating ligand is directly conjugated to the aliphatic amine groups on their surfaces.

3.1. Nanoparticles are Not Labeled if DOTA is Conjugated to the Particle before Chelation of Copper. *3.1.1. Polystyrene Beads As a Model Compound: Conjugation of DOTA to the Particle Surface.* To conveniently explore and develop the chemistry of the labeling of surface-modified nanoparticles, we utilized a system consisting of aliphatic amine polystyrene beads. The polystyrene beads are inexpensive, commercially available, and mimic the surface environment of amine-functionalized ADIO nanoparticles, or alternatively, different functionality if the ADIO particles are aldehyde-terminated. Because the polystyrene beads are fundamentally different from the aldehyde-modified ADIO nanoparticles (size, surface charge, and functional groups), labeling of these particles presents an opportunity to create a labeling method that can be applied to a broad range of nanoparticle systems.

The amine-reactive, metal chelating ligand (*p*-SCN-Bz-DOTA) was attached by direct linkage to the amine groups of the bead by the formation of a thiourea bond (Figure 1) described earlier by Mirazdeh et al. (*30*). We found for the aliphatic amine polystyrene bead system that labeling is not achieved if the chelator is conjugated to the nanoparticles before the copper is introduced. This has previously been observed for the 1,4,8,11-tetraazacyclotetradecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (TETA) chelator by other researchers (*31*). In the study, by Moi et al. labeling antibodies with copper-64 TETA, it was found that labeling was only achievable if the copper was preinserted into the TETA before conjugation to the antibody (*31*).

In our polystyrene system, for example, if 0.5 mL of the 1 μm PS beads were first coupled to *p*-SCN-Bz-DOTA ($\sim$20 400 DOTA molecules per bead), purified and then mixed with a Cu^{2+} chloride solution (molar ratio of Cu^{2+}/*p*-SCN-Bz-DOTA = 2.1:1), no copper was detected in the product after purification. We believe that that lack of coupling is due to competition for binding of copper by the numerous free amines available at the surface. Each nonconjugated 1 μm sized bead had an average of 157 000 amines on the surface. Even with a 100% conjugation of the *p*-SCN-Bz-DOTA (in this case 20 400 per bead), the free surface amine groups remaining on each bead could bind up to approximately 130 000 copper(II) ions and might thereby compete with, and prevent, chelation by the DOTA groups. Therefore, prechelation of the copper ion must first be performed in a separate step.

3.1.2. Conjugation of DOTA to the ADIO Particles before Chelation of Copper Did Not Result in Labeling. The ADIOs were previously shown to have small size and good magnetic properties to work as a MR imaging contrast enhancing agent. The relaxivities were determined to $r_1 = 14.46\ mM^{-1}\ s^{-1}$ and $r_2 = 72.55\ mM^{-1}\ s^{-1}$ at 60 MHz, 37 °C, and the overall particle diameter was measured as 32.3 $\pm$ 11.8 nm (*28*).

A literature procedure for coupling fluorescein isothiocyanate was modified to couple *p*-SCN-Bz-DOTA to the nanoparticles after amination of the dextran (sulfate) coating (Scheme 1) (*29*). After amination of the ADIO particles, *p*-SCN-Bz-DOTA was conjugated to the nanoparticles through the amine groups.

We found that, for both nanoparticle systems, aliphatic amine polystyrene beads and dextran sulfate coated iron oxides, labeling with copper was not possible if the metal chelator was conjugated to the nanoparticle surface before chelation; only after preinsertion of the metal into the chelator before conjugation to the nanoparticle surface was labeling achievable. As observed for the polystyrene bead system, if the *p*-SCN-Bz-DOTA was first conjugated to the particle surface before the chelation of copper, there was inhibition of the labeling (Table 1). In agreement with the previous study by Moi et al., for our nanoparticle systems, we found that prechelation of copper-64 was necessary for both polystyrene beads and dextran sulfate coated iron oxide nanoparticles (*31*).

Table 1. Radiolabeling of ADIO Nanoparticles[a]

particle[b]	E.D.:*p*-SCN-Bz-DOTA	% yield (^{64}Cu)
ADIO	1:1	0[c]
ADIO	1:1	1
ADIO	2:1	5.2
ADIO	30:1	21.5

[a] The yield was determined by measuring the activity level before conjugation and then after purification of the final product. Size was determined by DLS. [b] Particle size of the ADIO before labeling was 32 $\pm$ 11.8 nm as determined by DLS and was 26.6 $\pm$ 7.3 nm after labeling with copper-64 (for the product that had a yield of 21.5%. [c] Copper-64 was not prechelated into the *p*-SCN-Bz-DOTA and no labeling was achieved.

Table 2. Conjugation of *p*-SCN-Bz-DOTA-Cu to the Polystyrene Bead Surface[a]

size of PS-bead	*p*-SCN-Bz-DOTA:bead	number DOTA-Cu/bead	% yield (Cu)
78 nm	4 968: 1	150	3
1000 nm	218 000:1	40 000	18

[a] The amount of Cu was determined by ICP-MS after particle purification. Particle size was given by the manufacturer and confirmed by DLS.

3.2. Chelation of the Copper by the DOTA before Conjugation to the Nanoparticles Results in Some Labeling at Low Yield. *3.2.1. Preinsertion of Copper into the p-SCN-Bz-DOTA Resulted in Labeling of Polystyrene Beads.* By first chelating the copper ion in the DOTA complex, and then conjugating the *p*-SCN-Bz-DOTA(Cu) to the PS, bead labeling was achieved (Table 2). The higher degree of labeling for the 1 μm PS beads (18%) compared to the 78 nm beads (3%) could have been due to several factors. First, the amount of *p*-SCN-Bz-DOTA was 43 times greater for the 1 μm beads, and this may have resulted in the higher labeling efficiency. Another possible explanation for the higher labeling efficiency of the larger beads could have been due to the surface density of the amine groups. For a 1 μm particle (surface area of 3 141 593 Å^2), the surface density for 157 000 amines would be approximately 1 amine group every 20 Å^2. For the 78 nm beads (1 911 345 Å^2), the surface density of 54 000 amines would be 1 amine every 36 Å^2. The surface charge of the larger particles has a greater charge density and therefore may result in a more efficient attraction and subsequent coupling between the chelator and the bead.

Table 3. Conjugation of *p*-SCN-Bz-DOTA-Cu to ADIO Surface[a]

molar ratio Fe/*p*-SCN-Bz-DOTA	particle size	number *p*-SCN-Bz-DOTA-Cu/ADIO	% yield (Cu)
11.4: 1	31.6 ± 9.1	7.0	0.8
3.8: 1	33.1 ± 8.4	16.1	0.6
1.9: 1	36.5 ± 10.4	328.8	6.0

[a] The amount of Fe and Cu were determined by AAS after particle purification. The amount of iron per core was calculated based on an average particle size of 7.9 nm and one core per ADIO particle was assumed. Particle size in solution was determined by DLS.

3.2.2. Preinsertion of Copper into the p-SCN-Bz-DOTA Resulted in Labeling of ADIO Nanoparticles, But Cross-Linking Lead to Aggregation. A literature procedure for coupling fluorescein isothiocyanate was modified to couple *p*-SCN-Bz-DOTA to the nanoparticles after amination of the dextran (sulfate) coating (Scheme 1) (*29*). After amination of the ADIO particles, *p*-SCN-Bz-DOTA was conjugated to the nanoparticles through the amine groups. We found that amination of the ADIO particles led to irreversible cross-linking and flocculation. The cross-linking is most likely due to the ethylenediamine being equally reactive at both ends. The ADIO nanoparticles were 32 nm before surface modification and 133 nm after amination.

Particle size plays an integral role in clearance from the body, and iron oxide particles larger than 50 nm have been shown to be rapidly cleared by the liver (*32–34*). To target specific sites of interest, particle size is to be kept small, smaller than ~30 nm, to increase circulation time to allow the particles to reach targets of interest (*32, 35, 36*). To avoid the irreversible cross-linking of the ADIO nanoparticles, we opted to modify the synthesis by introducing amine groups to the *p*-SCN-Bz-DOTA rather than the ADIO nanoparticles (Scheme 2). In this revised chemistry, we attach the ethylenediamine to the *p*-SCN-Bz-DOTA rather than the ADIO surface. If dimers of the DOTA form, they cannot react with the nanoparticles, and can be removed by purification, and thus the aggregation seen with functionalizing the ADIO nanoparticles was avoided.

3.2.3. Cross-Linking of ADIO Nanoparticles Avoided by Amination of the p-SCN-Bz-DOTA but Cu Labeling Yield Remains Low. After preinsertion of the copper into the *p*-SCN-Bz-DOTA (Scheme 2), the chelator was conjugated to the nanoparticle surface (Scheme 3a). The *p*-SCN-Bz-DOTA was modified to have an amine group and this could then react with the aldehyde group on the ADIO surface (Scheme 3a). By coupling the ethylenediamine to the *p*-SCN-Bz-DOTA instead of the ADIO nanoparticles, we were able to avoid the cross-linking of the particles. Results for the degree of "cold" copper labeling of the ADIO nanoparticles are shown in Table 3. As expected, the degree of labeling increased with additional HIO_4 (more binding sites) and the addition of extra *p*-SCN-Bz-DOTA(Cu^{2+}). Approximately 7 *p*-SCN-Bz-DOTA(Cu^{2+}) molecules were conjugated to the particle surface with a Fe/*p*-SCN-Bz-DOTA molar ratio 11.4:1 and the number of conjugated *p*-SCN-Bz-DOTA(Cu^{2+}) molecules increased to 328 with a Fe/*p*-SCN-Bz-DOTA molar ratio of 1.9:1 (Table 3). Interestingly, a 3-fold increase in the *p*-SCN-Bz-DOTA, from 11.4:1 to 3.8:1, did not result in an increased labeling yield (Table 3); only when a 6-fold increase in *p*-SCN-Bz-DOTA (1.9:1) was used did the labeling yield increase from 0.8% to 6%. The DOTA/HIO_4 was kept constant in all three instances, approximately 1:1; therefore, the increase in labeling yield (6%) for the highest concentration of HIO_4 (25.5 μL HIO_4, Fe/*p*-SCN-Bz-DOTA = 1.9:1) must have been more efficient compared to lower concentrations of HIO_4 for creating more reaction sites in the dextran coating on the nanoparticles. The higher acid concentration (25.5 μL HIO_4) may have been necessary to decrease the pH significantly to drive the ring opening reaction (on the polysaccharide nanoparticle coating) (Scheme 3a).

Table 4. Radiolabeling of Polystyrene Beads[a]

size of PS bead	*p*-SCN-Bz-DOTA:bead	activity used (mCi ^{64}Cu)	labeled activity (mCi ^{64}Cu)	% yield (^{64}Cu)
78	1.13×10^6: 1	2.35	0.571	24
78	1.31×10^6: 1	2.9	0.639	22
1000	1.54×10^8: 1	4.02	0.272	6.8

[a] The yield was determined by measuring the activity level before conjugation and then after purification of the final product.

The particle size increased slightly as the amount of *p*-SCN-Bz-DOTA added increased (Table 3). The size of the particles with 7 DOTA(Cu^{2+}) moieties attached was 31.6 nm and was 36.5 nm for particles with 329 DOTA(Cu^{2+}) attached. This was most likely the result of an added hydration layer due to the nitro and carboxyl groups added by the additional DOTA moieties. Dynamic light scattering measures the hydrodynamic radius, the particle size plus surface-bound water, and therefore as the number of DOTA moieties increased the hydration layer also increased, resulting in a larger particle diameter (Table 3).

3.3. Modification of the Chemistry Resulted in Greater Labeling Yields for Both Nanoparticle Systems. Initially, by attempting conjugation of *p*-SCN-Bz-DOTA chelator to an amine-coated nanoparticle, polystyrene beads or dextran sulfate coated nanoparticles, before insertion of the metal (Cu^{2+}) no labeling was achievable. By preinserting the copper into the DOTA chelator before conjugation to the nanoparticle surface, labeling was accomplished. However, for each system, there were limitations in labeling efficiency that warranted improved chemistry. In the polystyrene bead system, labeling with copper took several days, which is not desirable for a radionuclide with a limited lifetime. Therefore, we sought to obtain similar labeling yields (at least 18%) of the polystyrene beads with more rapid chemistry and purification. For the ADIO nanoparticle system, labeling was achievable and particle cross-linking avoidable by generating a amine-Bz-DOTA(Cu) complex to conjugate to the ADIO surface; however, the yields were very low, <1% for ^{64}Cu, and therefore we sought to improve the chemistry to obtain higher labeling yields.

3.3.1. Radiolabeling of Polystyrene Beads with Improved Chemistry. The radiolabeling for the polystyrene beads with copper-64 was modified from the "cold" copper labeling to minimize the reaction time to avoid unnecessary decay of the radionuclide. For the "cold" copper labeling, the copper was incubated with the DOTA at a 1.25:1 molar ratio for 2 h in diH_2O at room temperature and then purified by SEC. As for the copper-64, it was supplied in a 10 mM HCl solution, and we therefore adjusted the pH to 8 with TEAA and incubated at 40 °C for 20 min (compared to 2 h). The solution was buffered, as it is known that the stability of the copper-DOTA complex decreases as the pH decreases (*37, 38*). Furthermore, no SEC was used for purification after chelation of the copper-64 by DOTA as the *p*-SCN-Bz-DOTA was in excess. The use of an acetate buffer, TEAA, in this work is similar to the work by Sun et al. in which copper-64 was chelated by 1,4,8,11-tetraazacyclododecane-1,4,8,11-tetraacetic acid (TETA) in ammonium acetate (pH 7) at 43 °C for 2 h (*39*).

The conjugation of the *p*-SCN-Bz-DOTA(^{64}Cu) to the polystyrene beads was done at 40 °C and the incubation was 2 h compared to overnight for labeling the PS beads with the "cold" copper. Finally, similar to the work by Sun et al. (*39*), we used centrifugation to purify the radiolabeled beads in favor of dialysis.

These time reduction steps, utilizing an elevated temperature, resulted in a radiolabeling yield for the [(*p*-SCN-Bz-DOTA)-^{64}Cu] on the polystyrene beads of 7% to 24% (Table 4). The radiolabeling for the 78 nm particles increased to 22−24% (Table 4), compared to the 3% labeling with the "cold" copper (Table 2). This increase

in labeling yield was most likely due to the increased *p*-SCN-Bz-DOTA/bead ratio for the radiolabeling. However, the radiolabeling of the 1 μm PS beads was only ~7% compared to 18% for the "cold" copper (Tables 1 and 3). This may have been due to a large change in pH during the addition of the buffer with a large amount of the copper-64, 4.02 mCi, compared to the smaller amount used for the 78 nm PS beads.

3.3.2. Labeling of ADIO with Modification of the Chemistry Resulted in Greater Labeling Yields. As was the case with the "cold" copper labeling of ADIO particles and PS beads, if the copper-64 was not chelated by the *p*-SCN-Bz-DOTA before conjugation to the nanoparticle there was no labeling achieved (Table 1). Following the preinsertion scheme and molar ratios of starting materials developed during the cold copper experiments (ratio of ethylenediamine/*p*-SCN-Bz-DOTA = 1:1) (Schemes 2 and 3a), labeling the ADIO nanoparticles with copper-64 had a yield of 1% (Table 1). This was most likely due to the dimerization of *p*-SCN-Bz-DOTA and was alleviated by increasing the amount of ethylenediamine.

The amine-Bz-DOTA was purified by SEC (Schemes 2 and 3b) and excess ethylenediamine removed before addition to the aldehyde-modified nanoparticles or the excess ethylenediamine would react with adjacent nanoparticles and cause flocculation. A molar ratio of the ethlyenediamine/*p*-SCN-Bz-DOTA of 2:1 and purification with SEC increased the labeling yield from 1% to ~5% (Table 1). By further increasing the ratio to 30:1, the labeling yield increased to ~20% (Table 1). After the radioactivity had decayed, the particles that had the ~20% yield were sized by DLS and found to be 26.6 ± 7.3 nm in diameter, which is of similar size to the starting ADIO material (32 ± 11.8 nm). This demonstrates that the radiolabeling did not affect the overall particle size. Due to the low yields, the other labeled particles were not sized by DLS.

The increase in yields using SEC to purify the aldehyde-modified ADIO nanoparticles and amine-Bz-DOTA (Scheme 3b) had a strong affect on radiolabeling. The amine-Bz-DOTA was purified by SEC purification not only to remove excess ethylenediamine, but also for the removal of sodium to avoid competition between the copper-64 and sodium by the DOTA macrocycle. Additionally, by using SEC to purify the aldehyde-modified ADIO nanoparticles, the HIO_4 could be removed without the use of ethylene glycol, which could have had two effects on the outcome of the labeling.

Chromatography ensured the removal of all HIO_4 so that the solution was not acidic during the conjugation of the *p*-SCN-Bz-DOTA complex to the nanoparticle. It is known that if the pH drops below about 4 the DOTA can no longer conjugate the copper as the amines in the ring become protonated. Second, by avoiding ethylene glycol any dioxane formation at the aldehyde groups on the nanoparticle surface was avoided, which would block reaction sites for the amine-Bz-DOTA(^{64}Cu).

Low labeling yields, around 1−5%, were observed for both the cold-copper and copper-64 labeling in TEAA buffer and a 1:1 ethylenediamine/*p*-SCN-Bz-DOTA molar ratio (Tables 2 and 4). The reaction between the aldehyde group on the nanoparticle and the amine of the amine-Bz-DOTA is more efficient at a higher pH, around 9, compared to neutral or slightly basic (conditions seen with the TEAA, pH 8). We therefore used a more basic buffer, sodium carbonate buffer, pH 9.2 (versus pH 8 for the TEAA), for ethylenediamine/*p*-SCN-Bz-DOTA molar ratios of 2:1 and 30:1 (Scheme 3b). By increasing the ratio of ethylenediamine to *p*-SCN-Bz-DOTA and increasing the pH of the reaction during the copper-64 labeling, the highest labeling yield, ~20%, was achieved without an increase in particle size.

Table 5. Radiolabeling Yield for ADIO-DOTA(^{64}Cu)[a].

chelator	labeling yield (%)
p-NH_2-Bz-DOTA	6.2
amine-Bz-DOTA	9.1

[a] Running the labeling procedure in parallel using the same batch of ^{64}CuCl, the radiolabeling was more efficient (32%) using the synthesized amine-Bz-DOTA.

3.4. Labeling of ADIO with the Synthesized Amine-Bz-DOTA Resulted in a Greater Labeling Yield Compared to the Commercially Available *p*-NH_2-Bz-DOTA. The two chelators, amine-Bz-DOTA and the commercially available *p*-NH_2-Bz-DOTA, were incubated with ^{64}Cu and then conjugated to the ADIO nanoparticles in parallel (Scheme 3b). The radiolabeling using each of the DOTA derivatives is shown in Table 5, and the labeling efficiency for the amine-Bz-DOTA was ~32% greater than that of the *p*-NH_2-Bz-DOTA. This could have been due to the ethylenediamine linker, which may decrease the steric hindrance between the DOTA and the nanoparticle.

4. CONCLUDING REMARKS

From iron oxides for magnetic resonance imaging (MRI) to quantum dots for optical imaging, nanotechnology has come to play an important role in many imaging applications. The highly complementary nature of MRI and PET has resulted in great interest in combined MR/PET imaging (*2, 40*); however, there are very few reports of multimodal PET/MRI contrast agents (*5, 19*). Our recent successes in synthesizing dextran sulfate coated iron oxide nanoparticles (ADIO) (*28*) and acquiring simultaneous PET and MR images (*1*), as well as the scarcity of suitable imaging probes for PET/MR imaging made it desirable to synthesize nanoparticles labeled with ^{64}Cu. Labeling was recalcitrant to traditional coupling methods and new syntheses had to be developed to achieve labeling of nanoparticles with ^{64}Cu.

In summary, radiolabeling was not achievable for either nanoparticle system if the metal (Cu^{2+}) was not first chelated in the DOTA before conjugation. Radiolabeling yields for the polystyrene beads was 24% and was achieved by conjugating the *p*-SCN-Bz-DOTA(Cu^{2+}) to the amines on the polystyrene surface. For the ADIO nanoparticles, however, amine groups had to be introduced onto the *p*-SCN-Bz-DOTA to avoid the cross-linking that occurred when the bifunctional ethylenediamine was used functionalize the ADIO surface. Radiolabeling of the aldehyde-functionalized ADIO nanoparticles with amine-Bz-DOTA(Cu^{2+}) was improved from 1% to 5% by using SEC instead of ethylene glycol to remove the HIO_4 during purification of the aldehyde-functionalized ADIO nanoparticles. Further improvement of radiolabeling of the ADIO nanoparticles was achieved by increasing the molar ratio of ethylenediamine to *p*-SCN-Bz-DOTA to 30:1 from 1:1. Furthermore, the synthesized amine-Bz-DOTA [2-*p*-(3-aminopropylthioureido)benzyl-1,4,7,10-tetraazacyclododecane-tetraacetic acid] had a radiolabeling yield that was 32% more efficient compared to the commercially available *p*-NH_2-Bz-DOTA. This increase in labeling of the amine-Bz-DOTA was most likely due to the extended linker that the ethylenediamine provided, compared to the NH_2 group directly off of the benzyl group of the commercial compound, and thus resulted in less steric hindrance. The radiolabeling yield for the *p*-SCN-Bz-DOTA on the ADIO was ~21%, which is ample for our imaging applications; due to the extreme sensitivity of PET, even modest levels of labeling are sufficient for detection of the compound.

It is important to note that the presence of amines on a surface does not guarantee that traditional amine-coupling methods will work, as we found with the nanoparticles of two different types. The nanoparticle environment posed an unexpected challenge

for conjugation. For example, compared to the dextran-coated particles described by Nahrendorf et al., where the authors first chelate the DTPA to the nanoparticle surface and then purify the nanoparticle-DTPA(^{64}Cu) by centrifugation (*19*), we found that, if the DOTA was chelated to the nanoparticle (e.g., polystyrene) and then incubated with ^{64}Cu, centrifugation alone did not remove surface-bound (not chelated) ^{64}Cu. In our polystyrene system, this surface-bound ^{64}Cu was easily removed by chromatography. The stability constants for DTPA or DOTA complexes with copper are similar, 21.5 and 22.25, respectively (*25, 41*), but slightly higher for DOTA. It is possible for the polystyrene bead system that the large number of amine groups at the particle surface presented a competition binding site for the Cu^{2+}; if the metal was not preinserted into the chelator before conjugation to the nanoparticle surface, then the Cu^{2+} bound to the surface of the nanoparticle rather than the DOTA and could be removed by chromatography. Similarly, the Cu^{2+} could have interacted with high negative charge on the surface of dextran sulfate coated particles (ADIO) rather than the DOTA, which could explain why in our ADIO system we had to preinsert the Cu^{2+} into the DOTA before conjugation compared the method used by Nahrendorf et al. with the more neutral charge of the dextran-coated particles.

Additionally, for the polysaccharide-coated (dextran sulfate) iron oxide nanoparticles there were several parameters that had to be considered, including the affect of surface modification on particle aggregation (e.g., functionalizing ADIO surface with ethylenediamine) and preinsertion of the metal into the chelator before conjugation to the nanoparticle surface. The ethylenediamine used here to introduce amine groups most likely resulted in cross-linking between nanoparticles as a result of the bifunctionality of the ethylenediamine and numerous aldehyde groups present on the nanoparticle surface.

The methods developed here can be applied to other nanoparticle systems with amine-functionalized surfaces, or it can be used with other functional groups such as *N*-hydroxysuccinimide esters, thiol, or carboxyl functional groups. One can envision the use of the multimodal contrast agent developed here for whole body screening using PET to identify potential lesions, then applying MRI to obtain detailed information on plaque structure and composition. We are currently applying these probes for multimodal imaging in an animal modal of atherosclerosis.

A β-Cyclodextrin "Click Cluster" Decorated with Seven Paramagnetic Chelates Containing Two Water Exchange Sites

Joshua M. Bryson,[†] Wen-Jang Chu,[§] Jing-Huei Lee,[‡,§] and Theresa M. Reineke*[,†]

The Department of Chemistry at Virginia Tech, Blacksburg, Virginia 24061, and the Departments of Psychiatry, and Biomedical Engineering, at the University of Cincinnati, Cincinnati, Ohio 45221. Received May 18, 2008; Revised Manuscript Received June 19, 2008

The development of novel macromolecular contrast agents that offer enhanced relaxivity profiles at high magnetic fields have the potential to greatly improve the diagnosis, understanding, and treatment of disease. To this end, we have designed a monodiperse paramagnetic β-cyclodextrin click cluster decorated with seven paramagnetic arms. A novel alkyne-functionalized diethylenetriaminetetraacetic acid (DTTA) chelate (**6**) has been created and coupled to a per-azido-β-cyclodextrin core (**7**) to yield the precursor macromolecule (**8**). After removal of the protecting groups and titrating with Gd^{3+}, the final paramagnetic click cluster, **Gd10**, was obtained. Luminescence measurements were carried out in H_2O and D_2O on an analogous structure, **Eu10**, and indicated that at each lanthanide has an average of 1.8 water exchange sites, which is important for enhancing relaxivity and MRI resolution. This discrete paramagnetic click cluster yields a high relaxivity profile (43.4 mM^{-1} s^{-1} per molecule and 6.2 mM^{-1} s^{-1} per Gd^{3+} at 9.4 T) and enhanced contrast on a human MRI scanner as compared to a commercial agent, Magnevist (3.2 mM^{-1} s^{-1} at 9.4 T). Moreover, the useful inclusion properties exhibited by β-cyclodextrin also make this an excellent host scaffold to functionalize via noncovalent assembly with receptor specific targeting moieties for biomolecular imaging.

Advancements in the design of novel imaging agents have the potential to transform biomedical research. Indeed, the ability to diagnose a disease at the earliest stage of onset and to understand the pathophysiological and treatment mechanisms of disease *in vivo* could revolutionize medicine. With such potential, magnetic resonance imaging (MRI) is a safe yet powerful diagnostic technique for visualizing soft tissue often with the aid of paramagnetic contrast agents (*1–3*). Chelate structures that contain Gd^{3+} improve imaging contrast by increasing the longitudinal relaxation time (T_1) of proximal water protons, which appear brighter in the T_1-weighted image (*4*). To further increase resolution, MRI scanners are rapidly being developed with higher magnetic field strengths (*5*, *6*). Considerable efforts to create innovative agents that exhibit high relaxivities ($\mathbf{r}_1$) and tissue contrast at higher magnetic fields must follow suit (*1–6*).

Although current FDA-approved small molecule Gd^{3+}-chelates provide some contrast enhancement, they do not have optimal relaxivity profiles at high magnetic fields (*5*, *6*). Likewise, small agents do not provide contrast at very low concentrations, which is essential for biomolecular and targeted imaging (*1–6*). Conversely, macromolecular contrast agents show great promise for enhancing contrast, sensitivity, and diagnostic imaging time, as they reveal slow vascular diffusion

and clearance rates, and they can house multiple lanthanide chelates (*7–12*). However, a major drawback of existing paramagnetic macromolecules is that they suffer from polydispersity and difficulties in characterization, which could drastically affect clinical approval for diagnostic use (*9–13*).

To this end, we present our efforts toward designing a novel macromolecular MRI contrast agent that is completely monodisperse, has a multivalent loading of Gd^{3+} chelates that house two water exchange sites (Figure 1), and reveals a high relaxivity profile at high magnetic fields. This architecture has been inspired by the biocompatibility of our polycationic β-cyclodextrin "click clusters", which are highly efficient nucleic acid delivery vehicles previously created by our laboratory (*13*). The structure has also been motivated by the interesting inclusion properties of the β-cyclodextrin scaffold. The hydrophobic cup can act as a host, endowing this macromolecule with a versatile modification method via noncovalent inclusion of hydrophobic guests that are linked to receptor-specific biomolecules (*14, 15*). This potentially allows a multitude of targeted imaging applications for visualizing specific cell and tissue types, biomarkers, or receptors, and enhancing diagnosis and treatment monitoring. Indeed, it is no surprise that others have realized the potential of the cyclodextrin scaffold with related designs (*16*), particularly in a recently published paper developed in parallel to our work (*17*).

A convergent synthetic approach was designed to yield our target structure. The synthesis of the novel dendrons, the alkyne functionalized Gd^{3+} chelates, was inspired by the works of Merbach et al. (*18*). Their studies have shown that DTTA-type ligands have high lanthanide binding stability, fast water exchange, and multiple water coordination sites, which yield excellent relaxivity profiles (*18, 19*). In addition to the multivalent architecture, the key feature of our structure is the design of the arms, which consist of a chelate structure that has two open water exchange sites on the lanthanide for enhancing relaxivity. Scheme 1 was initialized with an amino bis-ethylphthalimide (**1**), which was prepared as previously reported (*20*). Next, the secondary amine was protected with a benzyl carbomate (Cbz) group (**2**) and the primary amines were liberated via hydrazine hydrate in acetronitrile, affording the diamine, **3**. This structure was then reacted with *t*-butyl bromoacetate, creating the functionalized tertiary amine (**4**), and the CBz removed via hydrogenation yielding the chelate precursor (**5**). It is worth mentioning that *t*-butyl bromoacetate was utilized in this synthetic route as the related *n*-methyl bromoacetate analogue (potentially milder basic deprotection) allowed an intramolecular cyclization to occur with the free secondary amine upon CBz removal, which could not be carried forth in the reaction scheme. A simple nucleophilic addition of **5** to 6-bromohexyne resulted in the desired protected DTTA-hexyne dendron (**6**). A crucial step in the formation of these *monodisperse* click clusters is the synthesis of the acetylated per-azido-β-cyclodextrin core (**7**) moiety. It is important to note here that the commercially available per-halogenated β-cyclodextrin analogues have an unacceptable percentage of lesser substituted impurities (up to 10%, as noted by the manufacturer), which ultimately lead to contamination of the final structure with lesser-substituted products. Because of the negative implication of a polydisperse final product, it was important to synthesize the pure acetylated per-azido-β-cyclodextrin core (**7**) according to previous reports, which produces a monodisperse final product (*vide infra*) (*13, 21, 22*).

The key step in the assembly of the target click cluster was carried out via the click reaction, which promotes regiospecific coupling in high yield even in sterically hindered environments (*23, 24*). As shown in Scheme 2, the protected DTTA-hexyne dendron (**6**) was coupled to the acetylated per-azido-β-cyclodextrin (**7**). The clean formation of the fully substituted 1,4-regioisomer (**8**) was evidenced by mass spectra (Figure 2) and NMR (see Supporting Information). Because both the DTTA carboxylates and the β-cyclodextrin hydroxyls are protected, chelation of copper from the catalyst and retention of this metal in the final product was not found. Next, the acetyl and *t*-butyl groups on the click cluster were deprotected via conventional methods creating **9**, which was then titrated with $GdCl_3$, yielding the target paramagnetic macromolecule, **Gd10**. This β-cyclodextrin click cluster was purified via exhaustive dialysis in ultra pure water. Quantification of Gd^{3+} loading and full chelation was revealed via mass spec and ICP-MS analysis, which showed the presence of seven loaded chelates without lower chelation products or excess Gd^{3+}.

Contrast agent efficacy is influenced by the chelation environment and water coordination number (q). To gain insight into the average q value, **9** was chelated with Eu^{3+}, creating **Eu10**, a luminescent analogue of **Gd10**. As Eu^{3+} and Gd^{3+} have identical coordination chemistry (*25*), q can be determined with **Eu10** from the proportionality between the luminescence decay in H_2O and D_2O via the Horrocks equation [$q = 1.11\ (kH_2O - kD_2O - 0.31)$] (*26*). Typically, Gd^{3+} and Eu^{3+} prefer nonadentate coordination and the DTTA-like chelate usually forms a heptadentate complex; therefore, a q value of 2 is predicted. From this experiment, a q value of 1.8 was calculated, which is within reasonable error of the predicted value. It has been shown that hydroxyls on adjacent groups can block water coordinate sites within related lanthanide chelates (*27*). However, this study of the analogous **Eu10** structure suggests that the two open coordination sites on the lanthanide chelates are available for water exchange, which is essential for maximal relaxivity enhancement, particularly at higher fields.

The relaxivity for **Gd10** was determined at a high magnetic field (9.4 T, 400 MHz, 37 °C) by measuring the T_1 values of several aqueous solutions and plotting $1/T_1$ versus concentration. As a control, the results were compared to Magnevist ($Gd\text{-}DTPA^{2-}$), a common clinically approved contrast agent. As shown in Figure 3a, at this high magnetic field, Magnevist has a relaxivity value of 3.2 $mM^{-1}\ s^{-1}$. However, the molecular relaxivity calculated for the entire **Gd10** cluster was found to be 43.4 $mM^{-1}\ s^{-1}$, which is an exceptionally high value. When we calculated the relaxivity value on a per Gd^{3+} basis for **Gd10**, it was found to be 6.2 $mM^{-1}\ s^{-1}$. This value represents a 94% increase in the relaxation efficiency over Magnevist at 9.4 T and is likely related to the higher q value and larger molecular size that can increase the rotational correlation time (*10–13*). It

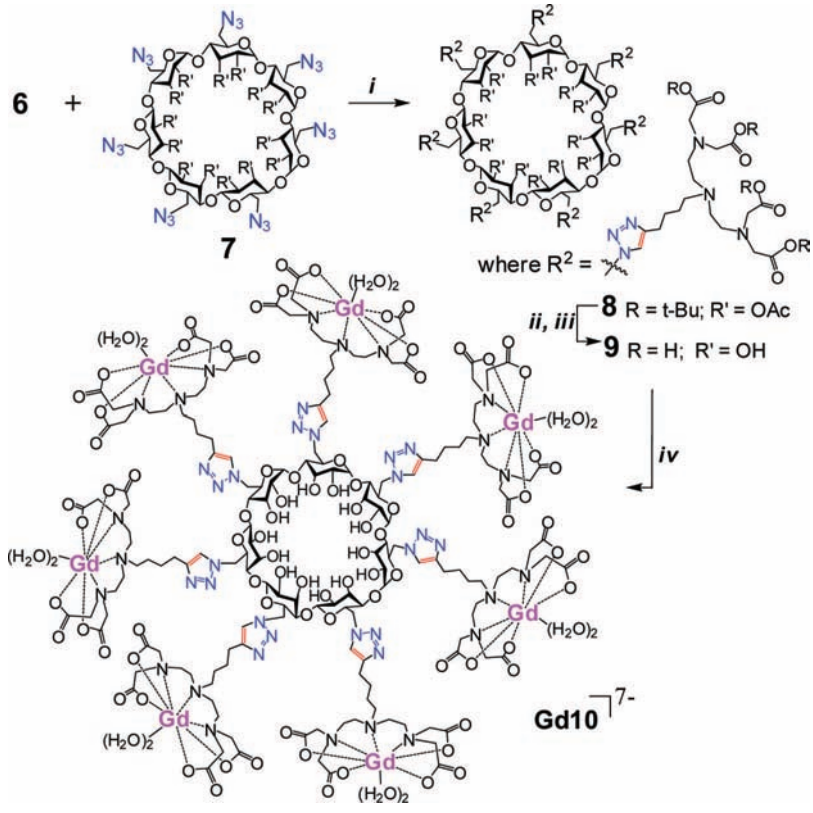
Scheme 2. Synthesis of the Paramagnetic Click Cluster, Gd10[a]



[a] (*i*) $CuSO_4 \cdot 5H_2O$, Sodium Ascorbate, THF:H_2O (1:1), 60°C; (*ii*) NaOMe, MeOH, 24 h; (*iii*) TFA, 3 h; (*iv*) $GdCl_3$, $NaHCO_3$, pH = 6−8.

should be noted that these values are predicted to be much higher at lower magnetic fields by the Solomon-Bloembergen-Morgan (SBM) equations (*1–4, 21*). To directly visualize the enhanced relaxivity for **Gd10** and potential for increasing resolution, we imaged 25 mL vials filled with Magnevist, **Gd10,** and water together on a Varian 4T human MRI scanner, keeping the gadolinium concentration constant, $[Gd^{3+}] = 1.11$ mM (Figure 3b). With respect to water, Magnevist reveals a higher contrast; however, **Gd10** clearly reveals the brightest signal and highest contrast even at a low macromolecule concentration.

In summary, the development of novel macromolecular contrast agents that offer enhanced relaxivity profiles at high magnetic fields have the potential to greatly improve the diagnosis, understanding, and treatment of disease. For this purpose, a novel β-cyclodextrin click cluster has been creatively endowed with seven paramagnetic arms that each contain two

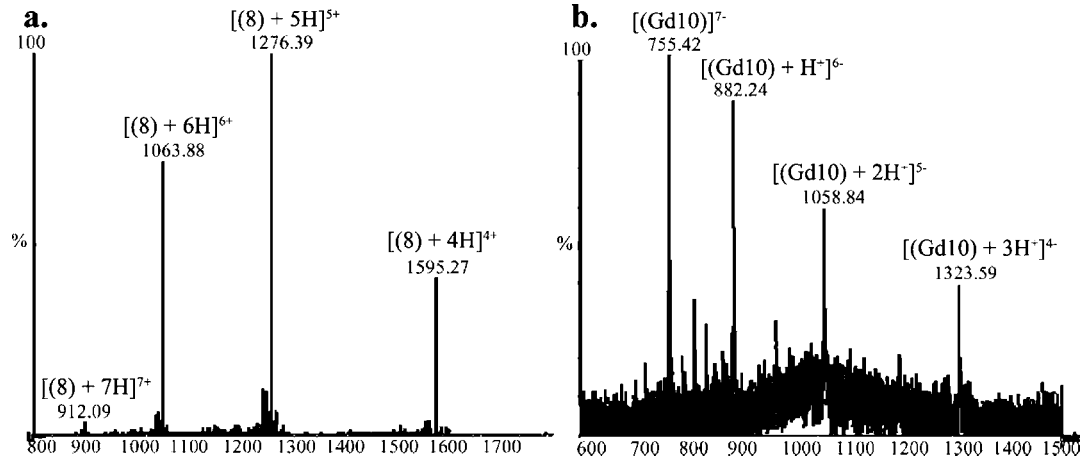


Figure 2. (a) ES-MS (positive ion mode) of **8** showing the observed monoisotopic ions. The M_{obs} {[**8** + H^+] calculated *m*/*z*: 6377.70, found *m*/*z*: 6377.38} is a deconvoluted mass of the compound from the multiply charged ions, and (b) ES-MS (negative ion mode) of **Gd10** showing the ionic distribution of 7-, 6-, 5-, and 4- species.

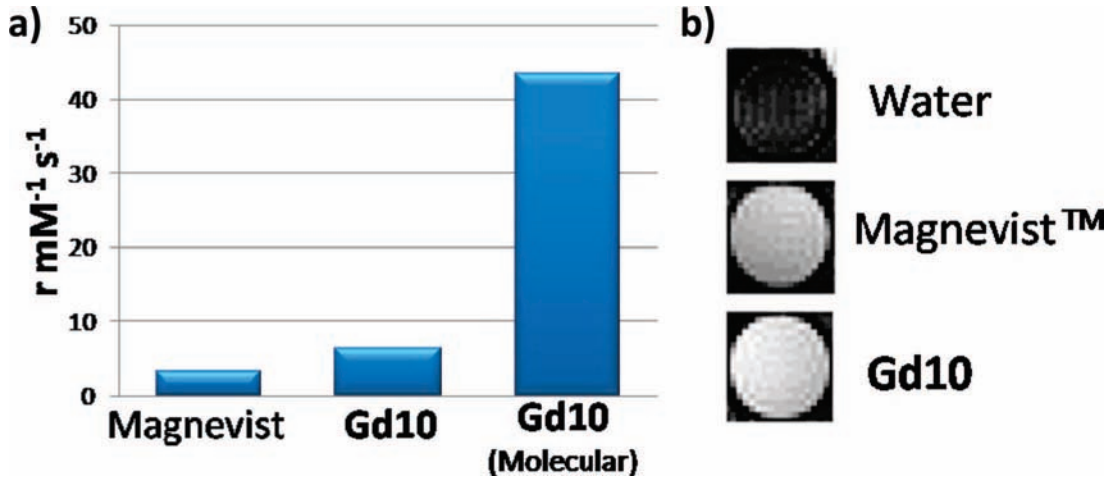

Figure 3. Relaxivity of Magnevist and **Gd10**. (a) The bars reveal the relaxivities at 9.4 T. (b) The inset images show the T_1-weighted MR images of water, Magnevist, and **Gd10** solutions acquired on a 4 T MRI scanner.

water exchange sites. This discrete paramagnetic agent yields an exceptionally high relaxivity profile (43.4 mM^{-1} s^{-1} at 9.4 T) and enhanced contrast on a human MRI scanner. Moreover, the useful inclusion properties exhibited by β-cyclodextrin also make this an excellent host scaffold to functionalize via noncovalent assembly with biological receptor-specific targeting moieties. Investigations are underway to study the limitless potential of this contrast agent for targeted MRI applications.

ACKNOWLEDGMENT

We thank Kirk Lokits for ICP-MS, Andrew Wolf for some synthetic studies, and Dr. Stephan Macha for ESI-MS acquisitions. This work was supported by the National Institutes of Health (1-R21-EB007244-01), the University of Cincinnati, and the Alfred P. Sloan Foundation.

The Departments of Chemistry,[‡] Psychiatry,[§] and Biomedical Engineering[€] at the University of Cincinnati, Cincinnati, OH 45221

General. β-cyclodextrin was purchased from Wacker Chemie AG (Munich, Germany) and 6-bromohexyne was acquired from ChemSampCo (Philadelphia, PA). All other chemicals unless specified otherwise were purchased from Alfa Aeser Chemical Co. (Boston, MA) and were used without further purification. Acetylated per-azido-β-cyclodextrin, **7**, was synthesized according to a published procedures (*1*). The mass spectra were obtained on an IonSpec HiResESI mass spectrometer. NMR spectra were collected on a Bruker AV-400MHz spectrometer and relaxivity measurements were carried out on a Bruker AMX-400MHz spectrometer. Determination of the percentage of gadolinium content was determined with a Perkins-Elmer ELAN 6000 Inductively-Coupled Plasma Mass Spectrometer. Luminescence studies were performed using a Varian Cary Eclipse Fluorescence Spectrophotometer. Thin-layer chromatography (TLC) was performed using TLC plastic sheets (silica gel 60 F_{254}) from Merck (Darmstadt, Germany). Dialysis membranes [1000 molecular weight cutoff (MWCO)] were manufactured by Spectrum Laboratories, Inc. (Rancho Dominguez, CA). Magnetic resonance images were acquired with a Varian 4 Tesla MRI/MRS human scanner (170.35MHz).

Synthesis.

N^1,N^3-Bis(phthalimido)-N^2-benzoxycarbonyl-diethylenetriamine (2). 1,7-Bis(phthalimido)-1,4,7-triazaheptane, **1** (9.21g, 25.2 mmol), prepared by a previously published procedure (*2*), was slurried in 80ml of dichloromethane at 0°C under brisk stirring. 4-Dimethylaminopyridine (1.25g, 10.2 mmol) and diisopropylethylamine (4.85g, 37.5 mmol) were then added to the slurry. Benzylchloroformate (5.12g, 30.0 mmol) was separately dissolved in 30ml of dichloromethane and added dropwise to the slurry over a period of 10 min, after which the reaction mixture became clear. The solution was then allowed to stir an additional 18h, after which the mixture was washed several times with 3 x 75ml acidic water (pH adjusted to 4 with 1M HCl), with saturated bicarbonate (1 x 75ml), and finally with ultrapure water (1 x 75ml). The washed organic fraction was dried over sodium sulfate and evaporated to give the crude product as an off-white solid. The crude solid was slurried in anhydrous diethylether, filtered, and washed again with ether (200mL) to remove the benzylchloroformate starting material. The final product was recovered and dried *in vacuo* yielding **2** a white solid (7.22g, 57.5%). ^{1}H-NMR ($CDCl_3$, 400MHz): δ = 3.62 (t, 4H), 3.91 (dt, 4H), 4.84 (s, 2H), 7.19 (d, 2H), 7.30 (m, 3H), 7.64 - 7.83 (m, 8H). ^{13}C-NMR ($CDCl_3$, 100MHz): δ = 35.7, 45.8, 67.3, 123.3, 127.6, 127.7, 128.3, 131.8, 134.0, 136.2, 156.1, 168.2. ES-MS positive ion mode: calculated *m/z* 520.148, [**2** + H^+]. Found *m/z*: 520.127.

N^2-Benzoxycarbonyl-diethylenetriamine (3). Compound **2** (7.22g, 14.5 mmol), was slurried in 25ml of acetonitrile. Hydrazine hydrate (5.80g, 116 mmol) was added to the mixture and after 10min of stirring, the solution became clear. After stirring the solution for approximately 4h, a precipitate formed, and after 24h, the reaction was complete (as determined via TLC). The white precipitate was filtered from the solution and washed thoroughly with acetonitrile. The initial solution was combined with the washings and dried *in vacuo* yielding the final product, **3**, as a viscous orange oil. (3.20g, 95.1%). ^{1}H-NMR ($CDCl_3$, 400MHz): δ = 1.93 (bs, 4H), 2.91 (s, 4H), 3.38 (s, 4h), 5.13 (s, 2H), 7.37 (m,

5H). ^{13}C-NMR ($CDCl_3$, 100MHz): δ = 38.4, 53.1, 67.3, 127.1, 127.6, 130.0, 136.1, 152.1. ES-MS positive ion mode: calculated *m/z* 238.156, [**3** + H^+]. Found *m/z*: 238.120.

N^2-Benzoxycarbonyl-diethylenetriamine-tetra-*t*-butylacetate (4). Compound **3** (3.20g, 13.5mmol) was dissolved in 22ml of DMF containing $KHCO_3$ (7.02g, 70.1 mmol) under stirring at room temperature. *Tert*-butyl-bromoacetate (13.7g, 70.1 mmol) was added directly to the stirred solution, which caused mild heat evolution. The reaction was allowed to stir for 48h at room temperature and then for an additional 2h at 60°C. The solution was then partitioned between diethyl ether and saturated sodium bicarbonate (50ml of each). After stirring for 5 min, the ether layer was retained and washed with ultrapure water (2 x 50ml), dried over anhydrous sodium sulfate, and evaporated to yield the crude product as a light yellow oil. The crude product was loaded onto a silica column and eluted using a solvent gradient (CH_2Cl_2 to 10% EtOAc : 90% CH_2Cl_2). The fractions containing the final product (second elution band) were combined and dried in vacuo yielding **4** (5.48g, 58.5%). ^{1}H-NMR ($CDCl_3$, 400MHz): δ = 1.46 (s, 36H), 2.88 (m, 4H), 3.40 (s, 8H), 3.47 (m, 4H), 5.12 (s, 2H), 7.36 (m, 5H). ^{13}C-NMR ($CDCl_3$, 100MHz): δ = 28.2, 46.5, 52.7, 56.1, 67.0, 80.9, 127.8, 127.9, 128.5, 137.1, 156.0, 170.6. ES-MS positive ion mode: calculated *m/z* 694.428, [**4** + H^+]. Found *m/z*: 694.448.

Diethylenetriamine-tetra-*t*-butylacetate (5). A 50ml round bottom flask containing a solution of **4** (3.34g, 4.8 mmol) dissolved in 25ml of MeOH, was purged with $Ar_{(g)}$ to remove dissolved $O_{2\ (g)}$. To remove the Cbz groups, catalyst (334 mg of Pd/C) was added to the flask which was again purged with $Ar_{(g)}$. Next, a balloon containing $H_{2\ (g)}$, fitted with a syringe, was used to bubble several liters of $H_{2\ (g)}$ through the solution at room temperature, and the solution was then allowed to stir overnight. The solution was then filtered through celite to remove the catalyst and dried *in vacuo,* yielding compound **5** (2.43g, 90%) as a yellow oil. ^{1}H-NMR ($CDCl_3$, 400MHz): δ = 1.47 (s, 36H), 2.68 (t, 4H), 2.87 (t, 4H),

3.45 (s, 8H). ^{13}C-NMR ($CDCl_3$, 100MHz): δ = 28.0, 47.9, 54.3, 56.3, 80.8, 170.8. ES-MS positive ion mode: calculated *m/z* 560.390, [**5** + H^+]. Found *m/z*: 560.394.

N^2-(Hex-5-yne)-diethylenetriamine-tetra-*t*-butylacetate (6). Compound **5** (629mg, 1.12 mmol), 6-bromohexyne (322mg, 1.69 mmol), and $KHCO_3$ (113mg, 1.12mmol) were dissolved in 2 ml of DMF. The solution was allowed to stir for 48h at room temperature and then for 2h at 60°C. This solution was then added to a partition of diethyl ether and saturated sodium bicarbonate solution and stirred for 5 min. The ether layer was recovered and washed with ultrapure water (2 x 50ml), dried over anhydrous sodium sulfate, and evaporated *in vacuo* affording the crude product as a light yellow oil. The crude product was purified via silica gel flash chromatography using a solvent gradient (CH_2Cl_2 → 20% EtOAc: 80% CH_2Cl_2 →45% EtOAc: 45% CH_2Cl_2: 10% MeOH). The final compound was eluted out with the final gradient system, and the corresponding fractions were combined and dried *in vacuo* yielding **6** (324mg, 45.2%) as a yellow oil. ^{1}H-NMR ($CDCl_3$, 400MHz): δ = 1.47 (s, 36H), 1.54 (m, 4H), 1.95 (s, 1H), 2.20 (m, 2H), 2.48 (t, 2H), 2.61 (t, 4H), 2.80 (t, 4H), 3.46 (s, 8H) ^{13}C-NMR ($CDCl_3$, 100MHz): δ = 14.1, 18.2, 21.0, 26.2, 28.1, 52.9, 56.2, 60.3, 68.4, 80.8, 170.6. ES-MS positive ion mode: calculated *m/z* 640.454, [**7** + H^+]. Found *m/z*: 640.456.

Heptakis{2,3-di-*O*-acetyl-6-*N*-[(diethylenetriamine-tetra-*t*-butylacetate)butyl]-6-(1,2,3-triazole)} cyclomaltoheptaose (8). Compounds **6** (69.5mg, 1.09 x 10^{-4} mol) and **7** (29.4mg, 1.55 x 10^{-5} mol) were dissolved in 2.6 ml of a 1:1 THF:water solution. Fresh solutions of 1M $CuSO_4 \cdot 5H_2O$ and 1M sodium ascorbate were prepared and used to introduce the catalyst 5% $CuSO_4$ and 10% sodium ascorbate (as molar percent of **6**) to the reaction mixture to promote the click coupling reaction using similar conditions developed by Hawker, Frechét and coworkers (*3*). This mixture was stirred briefly at 60°C to promote dispersion and was then stirred at room temperature until the solution became turquoise-blue (after about 8h), which signified reaction completion. The reaction mixture was then

partitioned between water and dichloromethane (10ml of each) and stirred for 2 min. The dichloromethane layer was retained and washed with a 0.1M Na^+ EDTA solution (2 x 10ml) and ultrapure water (2 x 10mL). The organic layer was dried over sodium sulfate and evaporated *in vacuo* yielding **8** (95mg, 96%) as a viscous yellow oil. ^{1}H-NMR ($CDCl_3$, 400MHz): δ = 1.23 (m, 14H), 1.42 (s, 252H), 1.53 (m, 14H), 1.61 (m, 14H), 1.98 (s, 21H), 2.03 (s, 21H), 2.48 (d, 14H), 2.59 (bs, 28H), 2.77 (bs, 28H), 2.95 (m, 14H), 3.41 (s, 56H), 4.44 (m, 7H), 4.70 (d, 7H), 4.91 (m, 7H), 5.31 (m, 7H), 5.59 (s, 7H), 7.53 (s, 7H). ^{13}C-NMR ($CDCl_3$, 100MHz): δ = 20.8, 25.6, 25.7, 27.4, 27.9, 28.2, 29.7, 50.9, 52.2, 53.1, 54.8, 67.9, 70.9, 80.7, 96.2, 100.0, 123.5, 148.3, 168.2, 170.6. ES-MS positive ion mode M_{obs}: Calculated *m/z* 1595.43, [**8** + $4H^+$]. Found *m/z*: 1595.27. Calculated *m/z*: 1276.54, [**(8)** + $5H^+$]. Found *m/z*: 1276.40. Calculated *m/z* 1063.95, [**(8)** + $6H^+$]. Found *m/z*: 1063.88. Calculated *m/z* 912.107, [**(8)** +$7H^+$]. Found *m/z*: 912.028. Deconvolution of spectrum: Found *m/z*: 6377.38. Calculated *m/z* 6377.70, [**8** + H^+].

Heptakis{6-*N*-[(diethylenetriamine-tetraaceticacid)butyl]-6-(1,2,3-triazole)} cyclomaltoheptaose (9). Compound **8** (85mg, 1.33 x 10^{-5} mol) was dissolved in 2ml of MeOH, the solution was adjusted to a pH = 8 with NaOMe, and the mixture was allowed to stir overnight. The pH was brought back to neutral using Amberlyst® strong cation exchange resin, the resin was filtered from the mixture, and the solvent was removed to yield the deacetylated product. This product was then redissolved in 2ml of dichloromethane and cooled to 0°C. Triethyl silane (TES) was added (100µl), followed by 1ml of trifluoroacetic acid (TFA). The solution was warmed to room temperature and stirred for 3h, after which the TFA/TES mixture was removed *in vacuo* leaving a viscous oil. Anhydrous ether was added to the oil and allowed to sonicate for 5 min, yielding a fine white precipitate. The white powder was recovered and dissolved in 2ml of water, brought to pH = 7 with $NaHCO_3$ and dialyzed extensively

against ultrapure water in a 1000 MWCO membrane. The purified solution was lyophilized to dryness yielding **9** (41mg, 73%) as a fluffy white solid. It should be noted that this product (**9**) is very hygroscopic and rapidly uptakes water from the air if not stored in a dessicator. ^{1}H-NMR (D_2O, 400MHz): δ = 1.80 (bs, 14H), 1.86 (bs, 14H), 1.92 (bs, 14H), 2.07 (bs, 14H), 2.39 (s, 14H), 2.30 (bs, 28H), 3.32 (bs, 28H), 3.44 (m, 7H), 3.58 (m, 7H), 3.84 (m, 7H), 3.93 (m, 7H), 3.99 (m, 7H), 4.16 (s, 56H), 7.87 (s, 7H). ^{13}C-NMR (D_2O, 100MHz): δ = 20.5, 24.8, 27.4, 48.1, 52.1, 52.8, 57.3, 58.0, 70.1, 70.6, 71.4, 76.8, 95.5, 125.1, 135.4, 170.8, 172.8. ES-MS positive ion mode deconvoluted mass [9 + H^+]$^{1+}$: Calculated *m/z* 4216.79, Found *m/z*: 4217.97. FT-IR: (KBr pellets, cm^{-1}) 3430.7, 2910.2, 1681.75, 1600.2, 1404.6, 1204.6, 1136.8, 1049.0.

Heptakis{6-*N*-[(Gd(III)-diethylenetriamine-tetraaceticacid)butyl]-6-(1,2,3-triazole)} cyclomaltoheptaose (Gd10). Compound **9** (25.2mg, 5.98 x 10^{-6}mol) was dissolved in 5ml of ultrapure water and the solution was adjusted to pH=7 with sodium bicarbonate. Gadolinium chloride hexahydrate (15.6mg, 4.18 x 10^{-5}mol) was dissolved in 1ml of ultrapure water and added to the solution of **9** in 3 separate aliquots. After the addition of each aliquot, the pH was adjusted back to a pH between 8-9 using a 0.1M potassium carbonate solution. The solution was allowed to stir for 30min to allow for Gd chelation to occur, dialyzed against ultrapure water for 18h, and lyophilized to yield **Gd10** as a fluffy white solid (27.3mg, 78%). ICP-MS: %Gd(III): theoretical for {$C_{168}H_{238}Gd_7K_7N_{42}O_{84}$ + $(H_2O)_{14}$} = 18.9%; Found 18.8%. The ES-MS for **Gd10** is displayed below in Figure S2. ES-MS negative ion mode: calculated *m/z* 755.863 [**(Gd10)**]$^{7-}$. Found *m/z*: 755.421. Calculated *m/z:* 882.070 [**(Gd10)** + H^+] $^{6-}$. Found *m/z*: 882.239. Calculated *m/z:* 1058.61 [**(Gd10)** + $2H^+$]$^{5-}$. Found *m/z*: 1058. 84. Calculated *m/z:* 1323.51 [**(Gd10)** + $3H^+$] $^{4-}$. Found *m/z*: 1323.59. FT-IR: (KBr pellets, cm^{-1}) 3422.5, 2935.9, 1750.0, 1609.9, 1402.7, 1248.9, 1048.0.

Heptakis{6-*N*-[(Eu(III)-diethylenetriamine-tetraaceticacid)butyl]-6-(1,2,3-triazole)} cyclomaltoheptaose (Eu10). Compound **9** (2.10mg, 4.98 x 10^{-7} mol) was dissolved in 0.5ml of ultrapure water and the solution was adjusted to pH=7 with sodium bicarbonate. A freshly prepared 1mM solution $EuCl_3 \cdot 6H_2O$ (498µl, 4.98 x 10^{-7} mol) was added to the solution of compound **9** in a similar manner to **Gd10**. The pH was then adjusted back to 7 - 8 using a 0.1M potassium carbonate solution. The solution was dialyzed against water and lyophilized to give **Eu10** (1.7mg, 65%) as a fluffy white solid. ICP-MS: %Eu(III): Theoretical for $\{C_{168}H_{238}Eu_7K_7N_{42}O_{84} + (H_2O)_{14}\}$ = 18.4%; Found = 22.0%. ES-MS negative ion mode: calculated *m/z* 750.717 [**(Eu10)**]$^{7-}$. Found *m/z*: 750.352. Calculated *m/z:* 875.838 [**(Eu10)** + H^+] $^{6-}$. Found *m/z*: 875.732. Calculated *m/z:* 1051.21 [**(Eu10)** + $2H^+$]$^{5-}$. Found *m/z*: 1051.42. Calculated *m/z:* 1314.26 [**(Eu10)** + $3H^+$] $^{4-}$. Found *m/z*: 1314.33. FT-IR: (KBr pellets, cm^{-1}) 3421.1, 2936.1, 1750.0, 1610.1, 1401.8, 1248.8, 1047.9.

ICP-MS for Lanthanide Quantification

$GdCl_3$ and $EuCl_3$ 1,000ppm lanthanide standard solutions in 1% HNO_3 (Aldrich, St. Lois, MO) were used to prepare a stock solution containing 1.00 ppm of both Eu^{3+} and Gd^{3+}, which was used to prepare 500, 250, 100, 50, 10, and 5 ppb solutions. These solutions were analyzed for four Gd^{3+} isotopes (156, 157, 158, 160), and 2 Eu^{3+} isotopes (151, 153). This data was used to generate a calibration curves for both Gd(III) and Eu(III). Solutions of **Gd10** and **Eu10** (100 ppb) were prepared, analyzed, and the lanthanide content was determined for each sample according to the calibration curve. The Gd^{3+} content in **Gd10** was found to be 18.8 ppb and the Eu^{3+} content for **Eu10** was found to be 22.0 ppb.

Determination of the water coordination number (*q*) (*4*)

Determination of the luminescence lifetime (τ) of **Eu10** was performed in both H_2O and D_2O (5.0×10^{-5} M) with a delay time of 0.05 ms, a gate time of 0.2 ms, λ_{ex} = 395, and λ_{em} = 614 nm. Excitation and emission slits were set to 10 nm. Calculations of *q*, were carried out in Graphpad prism v10.0 using the equation of $q = 1.11 [k_{H2O} - k_{D2O} - 0.31]$, where k is the rate of luminescence decay.

Relaxivity Measurements

Stock solutions of Magnevist™ and **Gd10** (2.95mM = $[Gd^{3+}]$) were prepared in H_2O and diluted to make 1.48 mM and 0.738 mM solutions. The longitudinal relaxation time (T_1) for the six solutions and water were measured using an inversion recovery pulse sequence (180° – d_t – 90° – acquire) carried out on a Bruker AMX-400 MHz spectrometer at 310K. Arrayed data ($n(d_t) = 14$) was processed using NUTS software and fit to a three-parameter model. Relaxivity was acquired from a linear least squares fit of the slope of the line obtained from plotting $1/T_1$ vs. [Gd].

T_1 weighted Images

Solutions of Magnevist™ and **Gd10**, were prepare so $[Gd^{3+}]$ = 1.11mM, and put in 25mL vials to be imaged. The images were acquired with gradient echo pulse sequence using a TEM (transverse electromagnetic) volume coil. Acquisition parameters are as follows: TR (repetition time) = 50 msec, TE (echo time) = 5 msec, FOV (field of view) = 200x200 mm and matrix size = 128x128. Contrast was adjusted relative to the controls.

Cellular Entry and Nuclear Targeting By a Highly Anionic Molecular Umbrella

Mohamed Mehiri,[†] Bingwen Jing,[†] Danielle Ringhoff,[†] Vaclav Janout,[†] Lynne Cassimeris,[‡] and Steven L. Regen*[,†]

Departments of Chemistry and Biological Sciences, Lehigh University, Bethlehem, Pennsylvania 18015. Received May 6, 2008; Revised Manuscript Received July 14, 2008

A fluorescently labeled, persulfated molecular umbrella (**1**) has been synthesized from cholic acid, lysine, spermine, and Coumarin 343 and found capable of entering live HeLa cells. The distributions of **1** throughout the cytoplasm and the nucleus were diffuse and punctate, respectively. This finding, together with its ability to cross liposomal membranes by passive diffusion, suggests that passive diffusion plays a significant role in the ability of **1** to enter cells. The fact that **1** is concentrated at the nucleus raises the possibility that molecular umbrellas of this type could be used for the nuclear targeting of drugs.

Molecular umbrellas are a unique class of conjugates that are composed of two or more facial amphiphiles that are covalently bound to a central scaffold. Such molecules have been found to possess the ability of crossing liposomal membranes by passive diffusion (*1*−*4*). Our working hypothesis has been that the amphiphilic "wings" of a molecular umbrella first bind to the surface of the liposomal membrane, that translocation proceeds through a shielded conformation in which the hydrophilic faces of the molecule point toward one another as it passes through the hydrocarbon interior, and that the umbrella is then released from the adjacent monolayer into the adjoining aqueous phase. In Scheme 1, we illustrate our current model for umbrella transport of a hydrophilic agent across a lipid bilayer. Here, the shaded and unshaded rectangles represent hydrophobic and hydrophilic faces of the facially amphiphilic units, respectively, and the lightly shaded oval represents a covalently attached, hydrophilic agent. Thus, the umbrella first approaches the membrane in a fully exposed conformation (structure **A**). Hydrophobic interactions with the membrane interior then lead to an adsorbed state in which the hydrophilic faces are in contact with the polar headgroup region and the hydrophobic faces are in intimate contact with the hydrocarbon region of the lipid bilayer (structure **B**). Subsquent absorption into the interior of the membrane, being driven by hydrophobic forces, then affords structure **C**. Translocation to the adjoining leaflet, 180° rotation, and reversal of steps **B** and **A** (not shown) then releases the conjugate from the other side of the membrane. In essence, we have postulated that the molecular umbrella masks its own hydrophilicity as well as that of an attached polar agent as it crosses the hydrocarbon interior of the bilayer.

In the work that is reported herein, we sought to answer a long-standing question that bears directly on the potential of molecular umbrellas as drug carriers. Specifically, can a molecular umbrella that is capable of crossing liposomal membranes also cross cellular membranes? To address this question, we designed a fluorescently labeled molecular umbrella (**1**) and investigated its interaction with live HeLa cells (Chart 1). We also compared the transport properties of **1** with a non-umbrella analogue that is similar in size and charge, but devoid of facial amphiphilicity (i.e., **2**). Previously, we showed that a nonfluorescently labeled form of **1** escapes the aqueous interior of liposomes, leaving behind a much smaller, hydrophilic peptide (i.e., glutathione) (*4*). This selective release established that the much larger molecular umbrella crosses lipid bilayers without damaging them.

In Scheme 2, we outline the method that was used to prepare **1**. Thus, activation of the carboxyl group of Coumarin 343, followed by condensation with α-*t*-BOC-lysine afforded **3**. Subsequent formation of the corresponding *N*-hydroxylsuccinate ester and acylation of one of the terminal amino groups of spermine produced **4**. Finally, deprotection to give **5**, total acylation with lysine dicholamide [activated with 3-hydroxy-1,2,3-benzotriazin-4(3H)-one] to give **6**, and persulfation with pyridine sulfur trioxide afforded **1** (6683 Da). Scheme 3 shows the approach that was used to prepare **2** (5 ± 1 kDa). Thus, activation of PRO 2000 (a gift from Indevus Pharmaceuticals, Lexington, MA) with sulfonyl chloride, followed by condensation with less than 1 mol % of a monoconjugate made from Courmarin 343 and putrescine (i.e., **7**) and subsequent hydrolysis afforded **2**.

Before examining the ability of **1** and **2** to enter HeLa cells, we first compared their ability to cross liposomal membranes by passive diffusion. Using experimental methods similar to those previously described, liposomes (200 nm, extrusion) were prepared from 40 mg of a mixture of 1-palmitoyl-2-oleyol-*sn*-glycero-3-phosphocholine (POPC) and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphatidylglycerol (POPG) [POPC/POPG, 95/5, mol/mol] and 2 mL of phosphate buffered saline [10 mM phosphate, 150 mM NaCl, pH 7.4, PBS] that was 0.5 mM in **1** or **2** (*4*). After dialysis for 52 h at 23 °C, the percentage of liposome-entrapped **1** or **2** was monitored as a function of time (Figure 1). In contrast to **1**, which exhibited a first-order release, liposome-entrapped **2** showed no detectable release.

To determine whether **1** can enter live HeLa cells, confocal microscopy was used to section optically through the cellular volume to ascertain whether the fluorescent label was dispersed within the cell and not bound to its outer surface. Cells were also labeled with Syto-59 to mark their nucleus and their cytoplasm. After a 90-min incubation period with 4 μM of **1**, the molecular umbrella was detected inside the cells (Figure 2). Similar micrographs were observed after 10 min. That **1** had been internalized within the cells was confirmed from profile views that were obtained by computer-based rotation of the image stacks (Figure 2, bottom). Here, the red fluorescence of Syto-59 marks each cell, the fluorescence of Coumarin 343 is

shown in green, and the overall cell is revealed by the differential interference contrast (DIC) micrographs. Both the Coumarin 343 and merged micrographs in Figure 2 show a distribution of **1** that is diffuse in the cytoplasm and punctate in the nucleus. The former is generally considered to be an indication of cellular entry via passive diffusion (*5*, *6*). In addition, the molecular umbrella that was found in the nucleus was bound in spots that colocalize with nucleoli within the nucleus. At present, the nature of this binding is unclear, although we believe that the high density of the sulfate groups within each facial amhiphile is likely to play a key role. It should be noted that no cellular damage of any sort was ever observed in any of these experiments. Specifically, the cells appeared healthy throughout these experiments, as indicated by the fact that they did not retract and that they maintained attachments to the substrate. It is also noteworthy that incubation with **1** for 30 min showed negligible toxicity (<5% cell death) as judged by propidium iodide exclusion measurements. Related studies that have been carried out with CaSki cells, which were fixed with 4% paraformaldehyde, have also shown nuclear localization after 15 min of incubation with **1** (*7*).

In sharp contrast to **1**, which was consistently taken up by the HeLa cells in more than 20 independent experiments, the internalization of **2** was variable. *In most cases no cellular uptake was observed!* When cellular uptake was found, **2** entered all of the cells; that is, its uptake was either all or none. Another peculiar feature of **2** was that it induced a redistribution of Syto-59 within the HeLa cells. Examples of cellular uptake of **2**, in those few cases where internalization was observed, are shown in Figure 2. In contrast to **1**, the distribution of **2** within the cytoplasm and the nucleus was punctate and diffuse, respectively. The former implies that **2** enters HeLa cells by a fundamentally different pathway,

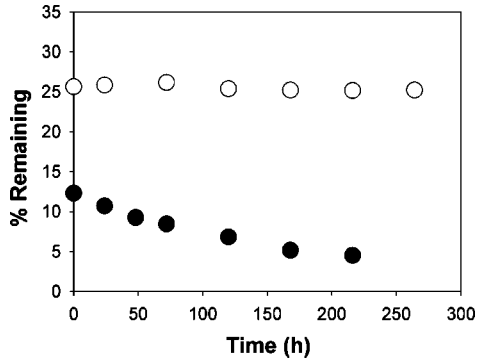

Figure 1. Plot of percentage of liposome-entrapped **1** (●) and **2** (○) remaining as a function of dialysis time at 23 °C, after an initial dialysis of 52 h. Experimental methods used were similar to those previously described (*4*). Here, release of **1** was monitored by removing aliquots of the liposomal dispersion during dialysis, destroying the liposomes with an ethanolic solution of sodium dodecyl sulfate, and analyzing for residual Cascade Blue (460 nm). The half-lives for **1** and **2** diffusing across the dialysis membrane were 3.5 and 7 h, respectively.

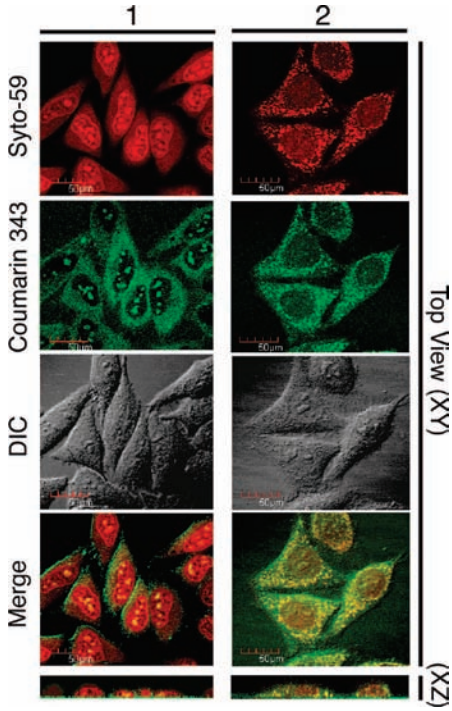

Figure 2. Confocal micrographs of HeLa cells incubated with 4 μM of **1** or **2** for 90 min. Living cells were treated with Syto-59 (red in the merged image to mark the nuclei and cytoplasm) and Coumarin 343-labeled **1** or **2** (green in merged images). Single image planes from the centers of the cells are shown. Syto-59 (red), Coumarin 343 (green), and DIC are shown in the $X-Y$ dimension (top view) and in the $X-Z$ dimension (profile, bottom). NOTE: The addition of **2** (but not **1**) to HeLa cells led to a redistribution of Syto-59.

most probably via endocytosis. Because of the poor reproducibility of cellular internalization by **2**, and because it led to a peculiar redistribution of Syto-59, this *non-umbrella* analogue was not investigated further.

The fact that **1** is capable of crossing liposomal membranes, together with its diffuse distribution within the cytoplasm, suggests that passive diffusion plays an important role in its cellular entry. The reason for the slow rate at which **1** is released from liposomes relative to the rapid internalization by cells is not presently clear. Since cell membranes are rich in proteins, one explanation for this difference would be that lipid/protein interfaces provide a pathway for the molecular umbrellas to "slip across" the membrane, possibly via some type of protein-induced "flip-flop" mechanism. Alternatively, rapid cellular entry of **1** could be related to a higher intrinsic affinity of **1** to cellular membranes. In addition, we cannot rule out the possibility that other mechanisms may be contributing to the cellular entry of **1**. In preliminary studies, treatment of HeLa cells with NaN_3 and 2-deoxyglucose (to deplete ATP production) only modestly inhibited the cellular uptake of **1** (see Supporting Information). Control experiments that were carried out under similar conditions with fluorescently labeled transferrin, however, showed a very substantial inhibition of endocytotic uptake. This finding is fully consistent with passive diffusion of **1** across lipid bilayers. Although no cellular uptake of **1** was found at 4 °C, which is consistent with an endocytotic pathway for cellular entry, we believe that the ATP-depletion experiment is a more reliable indicator of probable mechanism of cellular entry. Specifically, we believe that the lowering of the temperature to 4 °C is a more severe perturbation of cellular conditions than ATP-depletion, since it is likely to result in a major reorganization of the two-dimensional structure of the plasma membrane.

The ability of this highly *anionic* molecular umbrella (**1**) to enter live cells is in sharp contrast to many cationic cellular delivery systems that have been reported in the literature; e.g., arginine-rich, cell-penetrating peptides (*8*). This anionic character may well be responsible for the ability of **1** to concentrate at the nucleus of cells. Efforts currently in progress are aimed at defining the relationships that exist between the structure and composition of molecular umbrellas and their ability to diffuse across hydrophobic barriers, enter cells, and concentrate at the nucleus of cells. The results of these studies will be reported in due course.

ACKNOWLEDGMENT

We are grateful to the National Institutes of Health (PHS Grants GM51814 to SLR and GM58025 to LC) for support of this research and to Prof. Susan Fueshko Perry (Lehigh) for valuable discussions.

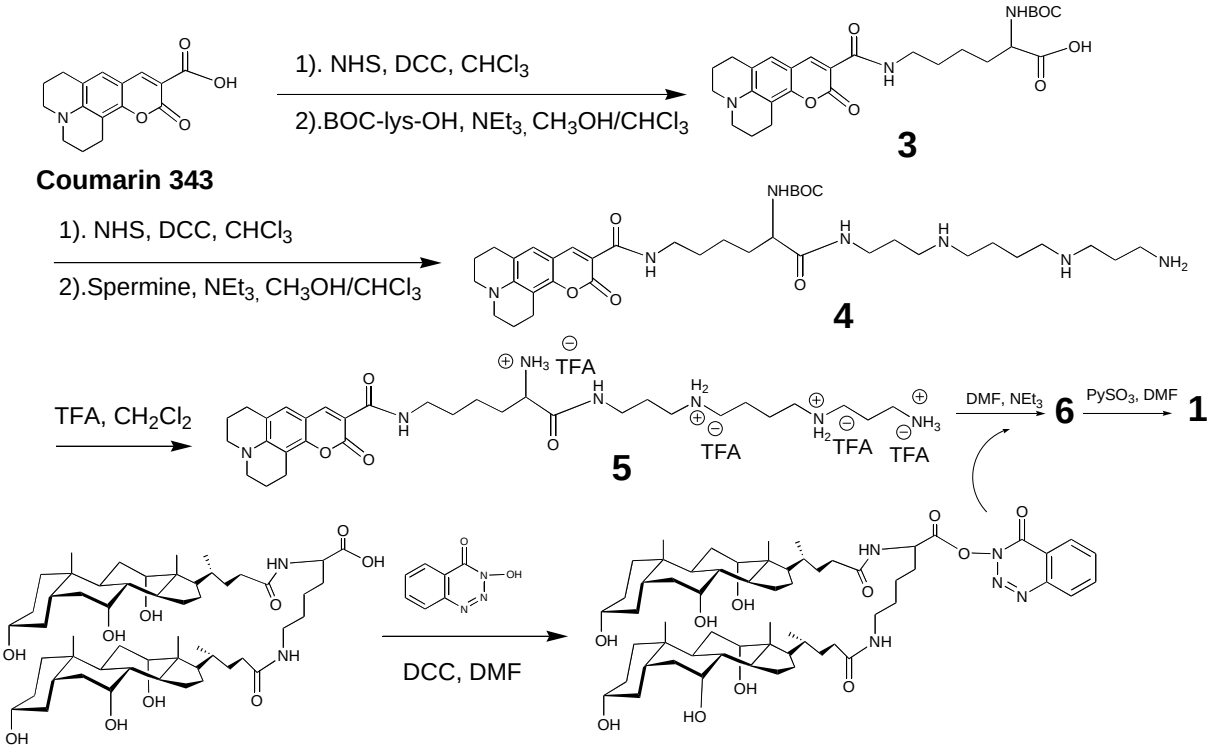
Supporting Information

Materials. Coumarin 343 (Sigma-Aldrich) and PRO 2000 (Indevus Pharmaceuticals, Lexington, MA) were used as obtained. BOC-lys-OH was obtained from Fluka.



Coumarin 343-BOC–lysine (3). To a solution that was made from 300 mg (1.05 mmol) of Coumarin 343, 145 mg (1.26 mmol) of N-hydroxyl succinimide and 20 mL of chloroform was added 260 mg (1.26 mmol) of DCC. After stirring for 3 h at room temperature, the insoluble urea was removed by filtration, and the filtrate was concentrated to ca. 10 mL. The resulting chloroform solution, which contained the NHS-ester of Coumarin, was then added to a solution that was made from 271 mg (1.1mmol) of BOC-lys-OH and 460 µL (3.3 mmol) of triethylamine in 4 mL of methanol. The reaction mixture was stirred at room temperature overnight. Removal of solvent under reduced pressure and purification of the crude product by silica gel column chromatography using chloroform/methanol (10:1, v/v, R_f=0.24) as the eluant afforded 274 mg (51%) of **5** as a yellow solid and ^{1}HNMR ($CDCl_3$): 1.40-2.0(m, 19H), 2.73(t, 2H), 2.83(t, 2H), 3.30-3.50(m, 6H), 4.29(br, 1H), 5.34(s, 1H, -OCON**H**-), 6.99(s, 1H), 8.66(s, 1H). MALDI-TOF MS: *m/z* **514** ($[M+H]^+$).

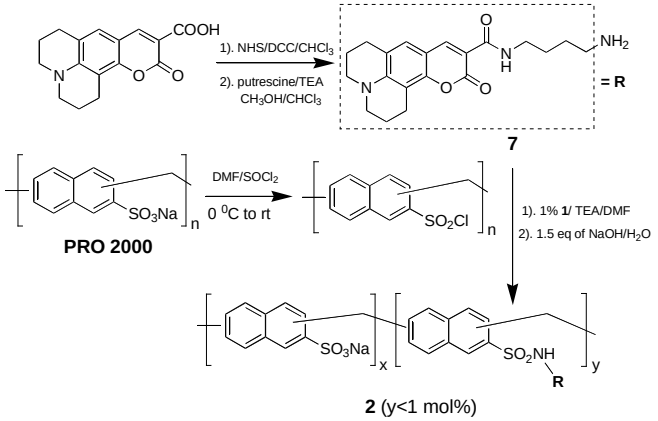
Coumarin 343-BOC-lysine-spermine (4). An activated form of **3** was prepared by dissolving 205 mg (0.4 mmol) of the conjugate in 20 mL of chloroform along with 51 mg (0.44 mmol) of N-hydroxysuccinimide and 91 mg (0.44 mmol) of DCC. After stirring at room temperature for 3 h, the insoluble urea was removed by filtration and the filtrate then added, dropwise, to a stirred solution that was made from 405 mg (2 mmol) of spermine, 167 µL (1.2 mmol) of triethylamine and 50 mL of methanol. The mixture was then stirred for 1 h at room temperature, and the solvent removed under reduced pressure. The resulting residue was purified by silica gel column chromatography using chloroform/methanol/ammonium hydroxide (30%) (60/40/10, v/v/v) as the eluant, affording 187 mg (67%) of **4** having a R_f of 0.28 and ^{1}HNMR (CD_3OD): 1.40-1.80(m, 23H), 1.96(m, 4H), 2.55-2.86(m, 14H), 3.18-3.29(m, 2H), 3.33-3.45(m, 6H), 3.95(s, 1H), 7.06(s, 1H), 8.45(s, 1H). MALDI-TOF MS: *m/z* **698** ($[M+H]^+$).

Coumarin 343-lysine-spermine-TFA salt (5). A solution was prepared by dissolving 151 mg (0.216 mmol) of **4** in 2 mL of a 1/1 mixture of trifluoroacetic acid/chloroform (v/v) at 0°C, and the mixture then stirred at room temperature for 5 h. Removal of solvent under reduced pressure and subsequent

freeze drying overnight afforded 230 mg (91%) of **5** having ^{1}HNMR (CD_3OD): 1.35-2.10(m, 18H), 2.72-2.78(m, 4H), 3.00-3.15(m, 10H), 3.30-3.50(m, 8H), 3.84(t, 1H), 7.03(s, 1H), 8.41(s, 1H). MALDI-TOF MS: *m/z* **598** ($[M+H]^+$).

Conjugate 6. A solution was prepared by dissolving 300 mg (0.323 mmol) of lysine dicholamide, 56 mg (0.344 mmol) of 3-hydroxy-1,2,3-benzotriazin-4(3H)-one, and 72 mg (0.349 mmol) of DCC in 1.5 mL of DMF.[1] The mixture was stirred at room temperature for 3 h, followed by the addition of 71 mg (0.0608 mmol) of **5** and 94 μL (0.674 mmol) of triethylamine. The resulting solution was stirred at room temperature overnight and then poured into 10 mL of an aqueous saturated sodium bicarbonate solution. The precipitate was collected by filtration and purified by silica gel column using chloroform/methanol/ammonium hydroxide (30%) (40/10/1, v/v/v) as the eluant to give 134 mg (52%) of **6**, which was further purified by preparative TLC (silica gel), using the same eluant as that which was used in the column chromatography. Conjugate **6** had an R_f=0.31 and ^{1}HNMR (CD_3OD): 0.69(s, 24H), 0.90-2.40(m, 282H), 2.79(t, 2H), 2.84(t, 2H), 3.16(m, 12H), 3.32-3.50(m, 22H), 3.8(s, 8H), 3.93(s, 8H), 4.16-4.40(br, 3H), 4.76(br, 2H), 7.13(s, 1H), 8.51(s, 1H). MALDI-TOF MS: *m/z* **4258** ($[M+Na]^+$).

Conjugate 1. To 1 mL of DMF was added 67 mg (0.018 mmol) of **6** and 182 mg (1.143 mmol) of pyridine sulfur trioxide at 0 ^{0}C. The reaction mixture was stirred at room temperature overnight and neutralized by addition of cold saturated sodium bicarbonate having a pH of ca. 10. After removal of solvent under reduced pressure, the residue was purified by silica gel column using chloroform/methanol/water (50/50/10, v/v/v) as the eluant to give 90 mg (85%) of **1** having R_f=0.42 ($CHCl_3/CH_3OH/H_2O$, 4/4/1, v/v/v) and ^{1}HNMR (CD_3OD): 0.75-2.40(m, 306H), 2.80(t, 2H), 2.86(t, 2H), 3.14(m, 12H), 3.33-3.50(m, 14H), 4.13(s, 8H), 4.26(br, 3H), 4.44(s, 8H), 4.65(s, 8H), 4.76(br, 2H), 7.15(s, 1H), 8.55(s, 1H).



1, 4'-Aminobutylcoumarin 343 amide (7). To a solution that was prepared by dissolving 200 mg (0.7 mmol) of Coumarin 343 in 10 mL of chloroform was added 100 mg (0.87 mmol) of N-hydroxylsuccinimide and 180 mg (0.87 mmol) of DCC. After stirring for 5 h at room temperature, the insoluble urea was removed by filtration. The filtrate was then diluted with 50 mL of chloroform and the resulting solution added in a dropwise manner (within 1 h) to a stirred solution made from 176 mg (1.4 mmol) of putrescine and 293 µL (2.1 mmol) of triethylamine in 100 mL of methanol. After stirring for 3 h at room temperature, the solvent was removed under reduced pressure and the residue purified by silica gel column chromatography using chloroform/methanol/ammonium hydroxide (30%) (50/10/1, v/v/v, R_f=0.7) affording 133 mg 53% of **7** having ^{1}HNMR (500 MHz, CD_3OD, rt): 1.78(m, 4H), 2.05(m, 4H), 2.81(t, 2H), 2.88(t, 2H), 3.03(t, 2H), 3.42(m, 4H), 3.50(m, 2H), 7.17(s, 1H), 8.57(s, 1H). MALDI-TOF MS: *m/z* **356** ($[M+H]^+$).

Fluorescent Labeling of PRO 2000 (2). The procedure that was used for activating PRO 2000 was similar to that used for forming chlorosulfonate derivatives of aromatic compounds.[2,3] Thus, a suspension that was prepared from 200 mg of PRO 2000 in 1 mL of DMF was cooled to 0°C, followed by addition of 200 µL (2.75 mmol) of thionyl chloride. After stirring for 10 min, the mixture was allowed to reach room temperature and stirred for an additional 5 h. The product mixture was poured into 25 mL of ice water, vortex mixed for 5 min, and centrifuged. The aqueous solution was then removed and an additional 25 mL of ice water added to the precipitate. Further centrifugation and

removal of the aqueous phase, followed by freeze drying overnight to give 180 mg of a chlorosulfonated form of the polymer as a pale powder.

To a solution that was prepared by dissolving 80 mg of this activated form of PRO 2000 in 1 mL of DMF was added 0.5 mL of a DMF solution containing 1.2 mg (0.00337 mmol) of **7**, (corresponding to less than 1% mol of the pendant sulfonate groups present in solution) plus 100 µL (0.717 mmol) of triethylamine. This solution was stirred at room temperature for 4 h, followed by addition of an alkaline solution that was prepared by dissolving 25 mg (0.628 mmol) of NaOH in 1 mL of water. After stirring the solution for an additional 2 h, the solvent was removed under reduced pressure. The residue was dissolved in 1 mL of water and passed through a C-18 reverse-phase column using pure water as eluant. The first fraction (yellow) that was eluted from the column was concentrated under reduced pressure. Additional purification of this residue was carried out by preparative thin layer chromatography (silica gel, two chromatographs) using chloroform/methanol/water (40/40/10, v/v/v) as the eluant. The polymer was then dialyzed against pure water for 24 h, using dialysis tubing having a 500 MW cutoff. Concentration of the dialyzed product under reduced pressure afforded 53 mg of **2** as a yellow powder.

Binding to Liposomal Membranes. Binding of **1** to liposomal membranes was measured via an equilibrium dialysis cell having 2.0 mL compartments (Fisher Scientific, Bel-Art Scienceware), using a Nuclepore membrane (100 nm diameter pores) to separate the two compartments. To the "source" side was added 0.5 mL of a 500 µM solution of **1** in PBS plus 0.5 mL of a liposomal dispersion made from 10 mg of POPC/POPG (95/5, mol/mol, 200 nm diameter, extrusion) in PBS. To the "receiving side" was added 1.0 mL of PBS. The UV absorption (460 nm) in the "receiving" side of the cell was then monitored as a function of time at room temperature with gentle rocking of the cell until equilibrium was reached (24 h). Under these conditions, the amount of the molecular umbrella that was bound to the liposomes corresponded to 0.002 mole of **1** per mole of phospholipid.

Cell Entry Experiments. HeLa (human epithelial cervical carcinoma) cells were cultivated in Minimum Essential Medium (MEM, Invitrogen) supplemented with 10% fetal bovine serum (FBS) at

37°C in a humidified atmosphere containing 5% CO_2. For all experiments, exponentially growing cells were detached from the culture flasks using a trypsin-0.125% EDTA solution, counted using a hemocytometer and the trypan blue dye. The cell suspension was seeded at a concentration of 20×10^4 cells/cm^2 onto a 42 mm glass round coverslip (Hemogenix). Experiments were carried out 24 h later, at a confluence level of approximately 60%-70%. To ensure consistency in uptake, cells were passaged biweekly and discarded after 20 passages.

Compound **1** or **2** was dissolved in PBS Ca^{2+} and Mg^{2+} free (Invitrogen) at a concentration of 150 µM. Before all experiments, compound **1** or **2** stock solutions were diluted to a concentration of 4 µM in 2 mL of DMEM (Invitrogen) lacking both phenol red and fetal bovine serum.

In a typical experiment, the coverslip with the monolayer of HeLa cells was mounted in a POC chamber (PeCon GmbH, Erbach, Germany) and washed three times with 2 mL PBS of Ca^{2+} and Mg^{2+} free to remove nonadherent cells. The attached cells were then labeled with 1 µM Styo-59 (Molecular Probes) in 2 mL of DMEM at 37 °C in CO_2 atmosphere for 20 min. Cells were imaged to measure their autofluorescence prior a cellular entry experiment. The medium was then discarded and the cells were incubated with 2 mL of 4 µM of compound **1** or **2** in DMEM at 37 °C for the indicated time prior image acquisition.

Confocal laser scanning microscopy was performed with an Olympus Fluoview 1000 confocal microscope (Olympus FV 1000, Tokyo, Japan) using a 60X/1.4 NA plan-apochromatic objective. Coumarin 343 was excited by both the 458 nm and 488 nm lines from an argon ion laser. Syto-59 was excited using a 543 nm HeNe laser. The microscope settings were maintained identical for both compounds. Images, usually 1024 x 1024 or 512 x 512 pixels, were acquired using 2-line mean averaging. Optical sections have a depth of 0.75 µm. The background from a region lacking cells was subtracted from each image. The fluorescence intensity (measured using Image J software) within each cell was measured from single optical sections located at the center of the cell (Z dimension). The autofluorescence of the cells was subtracted from each measurement. For presentation, image stacks

were converted to maximum intensity projections using the Olympus Fluoview ver.1.6 viewer software. The Fluoview software was also used to rotate 3-D projections to visualize the X – Z dimension. Images were exported as TIFF files and printed using Photoshop 7.0 (Adobe).

Similar procedures were used for experiments in which cells were depleted of ATP.[4-6] In this case, the cells were incubated in saline containing 5 mM NaN_3 and 1 mM 2-deoxyglucose for 4-5 minutes.[6] The efficiency of inhibition of energy-dependent endocytosis was determined by incubation in saline containing 10 mM Alexa Fluor 488-labeled transferrin (5 mM stock solution in 1x PBS; Molecular Probes) for 3 min, fixation in 2% *p*-formaldehyde, and microscopic examination of either ATP-depleted or untreated cells.

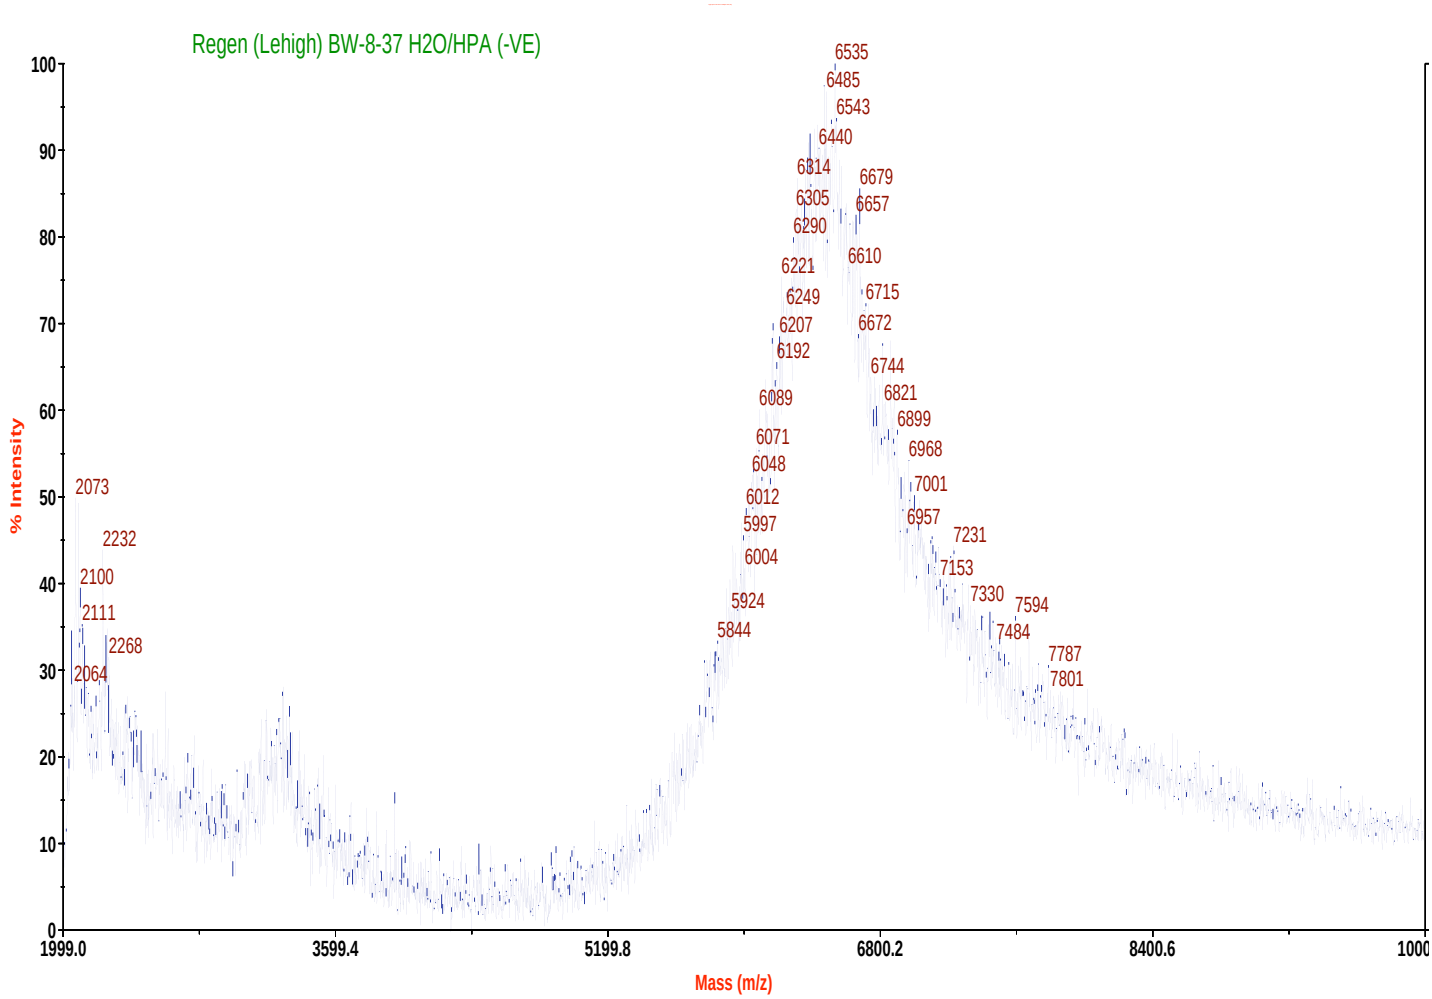
Low Res. Mass Spectrum for Compound 1



Moving Known Libraries to an Addressable Array: A Site-Selective Hetero-Michael Reaction

Melissae Stuart,[†] Karl Maurer,[‡] and Kevin D. Moeller*[,†]

Department of Chemistry, Campus Box 1134, Washington University, St. Louis, Missouri 63130, and CombiMatrix Corporation, 6500 Harbor Heights Parkway, Suite 301, Mukilteo, Washington 98275. Received January 21, 2008; Revised Manuscript Received June 6, 2008

A two-step, Michael reaction-based strategy for site-selectively placing molecules by unique electrodes in an addressable microelectrode array has been developed. The strategy is compatible with the use of polypeptide nucleophiles and works with microelectrode arrays having either 1024 electrodes/cm^2 or 12 544 electrodes/cm^2. The chemistry should allow for the transfer of existing molecular libraries to microelectrode array devices for analysis.

INTRODUCTION

Microarray technology allows for the placement of a molecular library in a small area and simultaneous screening of the library members for binding to a receptor (*1–4*). Our group is interested in using addressable microelectrode arrays as a platform for these efforts (*5, 6*). The goal is to build molecular libraries so that each unique member of the library is located next to unique, individually addressable microelectrodes in the array. The electrodes can then be used to monitor the binding of molecules in the library with biological receptors as the events happen (in "real time") (*7*).

With this in mind, we have been developing synthetic methodology for site-selectively building molecules on microelectrode arrays (*8–12*). In these efforts, the array is first coated with a porous polymer. The microelectrodes in the array are then used to covalently attach substrates to the polymer proximal to every electrode. The substrates are then site-selectively manipulated by using the microelectrodes to generate reagents that effect chemical reactions involving the polymer-bound substrates. The site-selectivity is achieved by covering the entire array with a solution containing a second substrate that destroys the reagent generated at the microelectrodes. The result is a competition between generation of a reagent at the microelectrodes and destruction of the reagent in solution. Reactions involving the polymer-bound substrate near a microelectrode occur when generation of the reagent at the electrode overwhelms the solution phase reaction. In this way, the location of reactions on the array is controlled by the selection of electrodes used.

In addition to building molecules on the microelectrode arrays, we would like to have the capability to move existing small, targeted molecular libraries to the arrays so that their binding to biological receptors can also be monitored in "real time". Accomplishing this goal requires transferring the library to the microelectrode array in a manner that places each individual member of the library proximal to a single microelectrode. For this purpose, we selected the known coupling between a thiol and either a maleimide or acrylate Michael acceptor. This reaction is often used to attach peptides, sugars, or DNA to a functionalized surface because it occurs quickly with simple incubation at neutral pH in aqueous buffer (*13–15*).

However, how can this coupling reaction be performed site-selectively on a microelectrode array having either 1024 electrodes/cm^2 (1K-chip) or 12 544 electrodes/cm^2 (12K-chip)? The more dense 12K-chips are required for analytical screening (*7*). In this case, the overall strategy involves a two-step sequence (attachment of the Michael acceptor to the polymer and then thiol addition (Scheme 1)) and hence two possible steps for effecting site-selectivity. Since the Michael reaction will occur without a catalyst (*16, 17*), it appeared that the best step for controlling the site-selectivity of the process was the step placing the Michael acceptor onto the polymer. We report here that this step can be controlled with an extremely high degree of site-selectivity.

We began our investigation with two different Michael acceptors, *N*-acryloxysuccinimide **1** and *N*-succinimidyl-3-maleimidopropionate **2** (Figure 1). In the first experiment, *N*-acryloxysuccimide **1** was placed on the surface of an agarose coated 1K-chip using the electrochemically generated base conditions employed previously for placing substrates by all of the microelectrodes in the array. However, in this case, a checkerboard pattern of electrodes was selected for the reaction. The base was generated by using the microelectrodes as cathodes to reduce vitamin B_{12}, catalyzing a transesterification between the activated ester substrate and the hydroxyls on the surface of the agarose coating the chip (Scheme 1).

The site-selectivity of the process was controlled by using a high concentration (20 mM) of activated ester in the experiment. Deprotonation of an alcohol by the radical anion of vitamin B_{12} can be expected to occur quickly. Hence, any migration of base away from the region surrounding a selected electrode would involve the formation of methoxide, either by direct deprotonation of the methanol solvent by the vitamin B_{12} radical anion or as a result of equilibration between the alkoxides generated on the surface of the agarose by the radical anion and methanol. In either case, the excess activated ester in solution would be expected to react with the methoxide to generate a methyl ester and prevent migration of the base to remote locations on the array.

The success of the reaction was determined by conducting a subsequent Michael reaction using the same electrogenerated base conditions and the same checkerboard pattern of selected electrodes. Pyrene-thiol **3** was used as the nucleophile for this test because of its fluorescence properties. Along these lines,

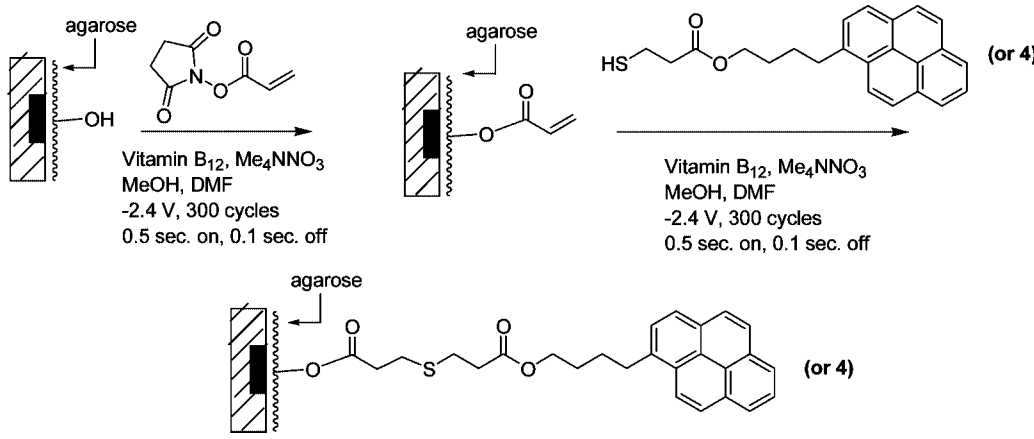
Scheme 1. Site-Selective Michael Reaction



imaging the microelectrode array with a fluorescence microscope showed a bright checkerboard pattern (Figure 2A). Clearly, the two-step procedure led to the desired site-selectivity.

A control experiment confirmed that placing the Michael acceptor on the agarose was indeed necessary for attachment of the thiol to the agarose polymer. When an agarose coated chip without the Michael acceptor was treated with the pyrene-thiol **3** and electrochemically generated base, there was no reaction between the thiolate generated and the agarose polymer; no fluorescent spots were observed.

The argument that the site-selectivity of the two-step process originated with placement of the Michael acceptor and not the Michael reaction itself was supported with a second control experiment. In this study, the Michael acceptor was placed by every microelectrode in an array and then the thiolate nucleophile for the Michael reaction was generated in a checkerboard pattern. The result was the generation of Michael product and the appearance of bright fluorescent spots by every electrode in the array.

Since the site-selectivity of the process does not depend on the Michael reaction, the thiolate addition does not need to be electrochemically catalyzed. For example, an acrylic acid-patterned chip can be incubated in a solution containing the pyrene-thiol **3** to add the pyrene to the surface of the microelectrode array. Although these conditions do work, most organic solvents damage or dissolve the agarose polymer used to fix the substrates to the surface of the array during the time frame needed for the coupling reaction. Hence, for libraries that are soluble in organic solvents it is still best to use the electrochemical conditions to accelerate the coupling step and minimize damage to the agarose polymer.

To screen libraries for binding to a receptor using a microelectrode array, the libraries need to be placed on a 12K-array (*7*). While moving to a microelectrode array with a larger density of electrodes can present a problem for the site-selectivity of a reaction, in the current case the optimal conditions with the acrylate linker that gave confinement on a 1K-chip (95 μm electrode diameter) also gave confinement to a single electrode on a 12K-array (45 μm electrode diameter) (Figure 2B). When the maleimide linker **2** was used, the reaction was not confined to a single electrode. Instead, the fluorescent spot observed was roughly the same size as an electrode on a 1K-array. Since the use of the acrylate linker led to cleaner reactions, it was selected for use in subsequent studies.

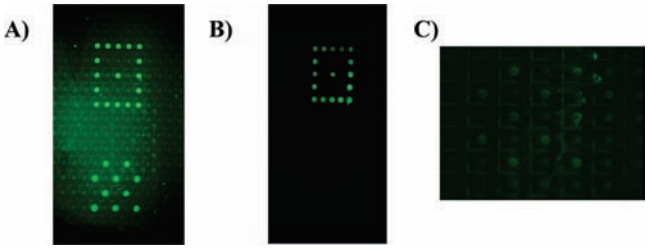

Figure 3. (A) Two patterns with acrylate linker **2** and peptide **4** as the thiol source. (B) Control experiment using 10 mM 2-hydroxyethane thiol as the initial nucleophile for the checkerboard pattern. (C) Blow-up of the checkerboard region of the array in B at longer exposure time.

Having established that the hetero-Michael reaction can be used to put a small organic molecule onto the surface of a microelectrode array, we turned our attention to the placement of water soluble biomolecules such as peptides, proteins, or DNA onto the microelectrode arrays. In these cases, it is best to site-selectively functionalize the polymer coating the array with the Michael acceptor and then incubate the functionalized array with an aqueous solution having a pH consistent with a thiol being more nucleophilic than alcohols or amines (*17*), a scenario that favors the cysteine moiety serving as the nucleophile for the hetero-Michael reaction. For example, consider the placement of a short RGD-based peptide onto a microelectrode array. Peptides containing a RGD sequence are known to bind to integrins, cell-surface receptors that mediate cell attachment (*18–20*). The peptide H-K(FAM)GGRGDSPC-NH_2, with 5(6)-carboxyfluorescein attached to the amine of the lysine side chain (**4**), was synthesized using Fmoc solid phase peptide synthesis. The acrylate acceptor **1** was placed on the surface of a microelectrode array in a checkerboard pattern using 10 electrodes of a 1K-microelectrode array. The chip was then incubated in a 7.6 mM solution of the peptide in 5 × PBS, pH 6.0. Following this step, the acrylate placement was repeated this time to give a box and dot pattern. The peptide was then placed onto the newly selected microelectrodes by incubating the array in a 7.6 mM solution of peptide in 10 × PBS, pH 4.0, while using the selected electrodes as cathodes (*21*). The change in pH for the second step was made in order to maximize the stability of the peptide already placed onto the array. The use of the selected microelectrodes as cathodes effectively raises the pH of the solution proximal to the electrodes thereby assisting the addition step in those regions. Following the second addition, the microelectrode array was imaged using a fluorescence microscope (Figure 3A). Clearly, multiple reactions can be performed with this coupling strategy, allowing attachment of different thiol-containing library members to the polymer above selected electrodes in the array.

One control experiment is very important for supporting this conclusion. In this experiment, the sequence of events used to generate the image in Figure 3A was repeated. However, in this case the initial peptide substrate used to make the checkerboard pattern was replaced with 10 mM 2-hydroxyethane thiol. The second step to make the box and dot pattern was repeated just like before using peptide **4**. The microelectrode array was then imaged using a fluorescence microscope as before (Figure 3B). A faint checkerboard pattern could be observed, although it is not observable unless the initial region of the chip is exposed for longer time periods (Figure 3C). Quantitative analysis of the spots revealed that the "bleed-over" of the peptide to the original set of electrodes was minimal.

The small amount of "bleed-over" observed could be explained by either the presence of unreacted Michael acceptor after placement of the 2-hydroxyethane thiol on the microelectrode array, or an equilibration of the product on the array following the second step. In order to address this issue, a second control study was performed. In this experiment labeled peptide was placed on the array using either the maleimide- or acrylate-based hetero-Michael reaction. A second step was then used to place a Michael acceptor at remote sites on the array. The resulting chip was incubated for 45 min in the buffer solution used for the Michael reaction, and then the array imaged to see if the peptide migrated from its original location to the remote sites. In this experiment, use of the maleimide acceptor did lead to a small amount of peptide migration. However, no such migration was detected when the acrylate acceptor was employed. Hence, the "bleed-over" observed during the previous

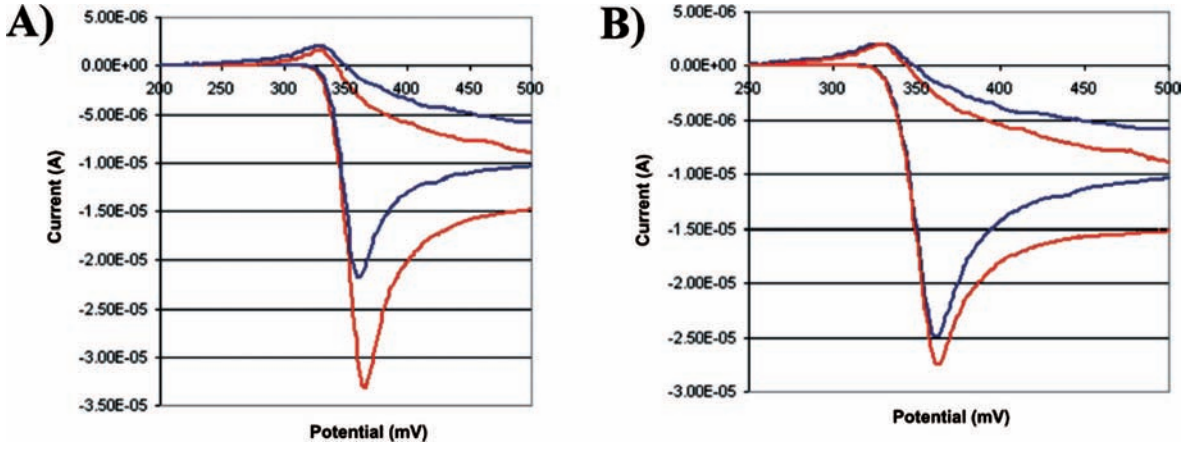

Figure 4. Red line, no receptor; blue line, with receptor. (A) CV data for the best binding peptide H-K(FAM)GGRGDSPC-NH_2 (**4**). (B) CV data for the weaker binding peptide H-K(FAM)GGRADSPC-NH_2 (**5**). In each case, 10 microelectrodes on a 12K-microelectrode array were used for the experiment. The experiments used 8 mM $K_3Fe(CN)_6$ in 30% glycerol, 100 mM NaCl, 20 mM Tris-HCl, 1 mM $CaCl_2$, and a scan rate of 10 mV/s.

study was due to a small amount of unreacted Michael acceptor in the first step, a situation that can most likely be avoided by optimizing the percent conversion of the first Michael reaction.

Peptides placed on the surface of the array using the chemistry described are available for binding ligands in solution. This was demonstrated with the electrochemical impedance experiment illustrated in Figure 4. In this experiment, a 12K-microelectrode array was functionalized with two peptides each being placed next to 10 microelectrodes. The first, peptide **4**, is known to bind the integrin receptor well (*22*). The second, peptide H-K(FAM)GGRADSPC-NH_2 (**5**), is known to bind weakly to the integrin receptor. After placing the peptides onto the array, the array was inserted into an electrolysis solution containing potassium ferricyanide along with a Pt wire auxiliary electrode. Current was then passed through the solution using the microelectrode array as the anode and the Pt wire as the cathode. The current associated with the oxidation of ferrous ion in solution (made at the cathode) was measured and the red line in both Figure 4A and Figure 4B recorded.

To the solution was then added an integrin receptor (Integrin $\alpha_{IIb}\beta_{III}$ (GPIIb/IIIa)). In an impedance experiment, the binding of a receptor to molecules on the surface of the microelectrode array blocks the ferrous ion from the neighboring microelectrode causing a dropoff in the current measured. The binding between the solution phase integrin receptor and the microelectrode array bound **4** can be seen in Figure 4A by observing the dropoff in current associated with the blue line (measured for the oxidation of ferrous ion after addition of the integrin receptor) relative to the initial red line. The significantly smaller dropoff observed in Figure 4B indicates the weaker binding event occurring next to the electrodes associated with the second peptide.

In conclusion, we have found that the base catalyzed placement of Michael acceptors on a microelectrode array can be accomplished in a highly site-selective fashion. The placement of peptides onto the array can then be accomplished in a selective fashion with a minimal amount of crossover (5%) between sites on the array. The resulting array can be used to monitor binding events between the peptides placed on the array and a receptor in solution. Work to optimize the selectivity of the placement reactions and establish the utility of the microelectrode arrays for monitoring the binding behavior of molecules in a library with a biological receptor is underway.

ACKNOWLEDGMENT

We thank Dr. Joshua Maurer for his help with the solid phase peptide synthesis and fluorescent imaging. This work is generously supported by the National Science Foundation (CHE-9023698). Synthetic Procedures

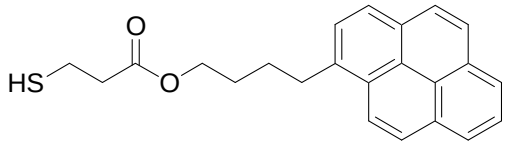
General:

3-Mercaptopropionic acid, 1-pyrenebutanol, *p*-toluenesulfonic acid, benzene, *N*-acryloxysuccinimide, vitamin B_{12} (cyanocobalamin), tetramethylammonium nitrate, diisopropylethylamine, piperidine, DMF, MeOH, CH_2Cl_2, HPLC-grade H_2O and MeCN were purchased from Aldrich and used as received. *N*-Succinimidyl 3-maleimidopropionate was purchased from VWR. Boc-Lys(Fmoc)-OH, Fmoc-Gly-OH, Fmoc-Arg(Pbf)-OH, Fmoc-Asp(OBut)-OH, Fmoc-Ser(But)-OH, Fmoc-Pro-OH, Fmoc-Cys(Trt)-OH, Fmoc-Ala-OH, HBTU, and Rink resin SS (200-400 mesh) were purchased from Advanced ChemTech. HOAT was purchased from AKScientific (Mountain View, CA) and PyAOP was purchased from Oakwood Products, Inc. (West Columbia, SC). 5(6)-Carboxyfluorescein was purchased from Acros. Integrin $\alpha_{IIb}\beta_{III}$(GPIIbIIIa) was purchased from Calbiochem. The peptides were synthesized on a CS Bio Company solid phase peptide synthesizer (model CS136XT). ^{1}H and ^{13}C NMR were obtained on a Varian Mercury (300 MHz). Analytical HPLC was performed on a HP1100 instrument with a UV detector. Fluorescence images in Figure 2 and 3 (A and B) were taken with an Olympus IX70 epifluorescence microscope (pyrene filter excitation wavelengths 320-400 nm, emission 420-540 nm; fluorescein filter excitation wavelengths 475-525 nm, emission 530 nm). The fluorescence image in Figure 3C was taken with a Nikon TE-2000E epifluorescence microscope. Cyclic voltammetry was performed using the ElectraSense Reader (Combimatrix, Mukilteo, WA, http://www.combimatrix.com/products_electrasense.htm) connected to a Bioanalytical System 100B/W potentiostat (Bloomington, IN) running proprietary software.



4-(pyren-2-yl)butyl 3-mercaptopropionate (3):

3-mercaptopropionic acid (261 µL, 3 mmol), 1-pyrenebutanol (0.822 g, 3 mmol), *p*-toluenesulfonic acid (0.050 g, 0.3 mmol) were added to a flame-dried three-neck flask fitted with a Dean-Stark trap under argon. The reaction mixture was dissolved in 6 mL benzene and heated to reflux. When the starting materials were consumed as indicated by thin-layer chromatography, the reaction was cooled to room temperature. The benzene was removed *in vacuo* and the residue was dissolved in 10 mL CH_2Cl_2. The organic layer was washed twice with 10 mL 5% aqueous $NaHCO_3$, twice with 10 mL H_2O, dried over Na_2SO_4, and concentrated. The crude residue was purified by silica gel chromatography (6:1 hexane: EtOAc) to provide the desired compound (0.850 g, 75% yield). IR (thin film, KBr plate): 3041, 2935, 2892, 2567, 1725, 841, 763, 710 cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$): δ = 8.27 (d, J = 9.3 Hz, 1H), 8.19-8.12 (m, 4H), 8.04 (AB, J =9.0 Hz, 2H), 8.00 (t, J = 7.8 Hz, 1H), 7.87 (d, J = 7.8 Hz, 1H), 4.20 (t, J = 6.3 Hz, 2H), 3.40 (t, J = 7.5 Hz, 2H), 2.75 (dt, J = 9.6, 5.1 Hz, 2H), 2.64 (t, J = 6.6 Hz ,2H), 1.96-1.91 (m, 2H), 1.88-1.78 (m, 2H), 1.6 (t, J = 8.4 Hz,1H) ppm; ^{13}C NMR (75 MHz, $CDCl_3$): δ = 171.9, 136.5, 131.7, 131.1, 130.1, 128.8, 127.7, 127.5, 127.4, 126.9, 126.1, 125.4, 125.1, 125.03, 124.96, 123.5, 64.8, 38.7, 33.2, 28.8, 28.3, 20.0 ppm.
HR MS (FAB) *m/z* calculated for $C_{23}H_{22}O_2S$: 369.1495, measured: 369.1488.

Fmoc solid phase synthesis of *KGGRGDSPC (4) and *KGGRADSPC (5):

Rink amide resin SS, 200-400 mesh, (0.2148g, 0.1074 mmol) was swelled in 5.0 mL DMF three times. After washing with 2 x 5.0 mL DMF, the resin was treated with 4.0 mL 20% piperidine in DMF and mixed for 5 min. The resin was then treated with another 4.0 mL 20% piperidine in DMF, mixed by inversion for 20 min, and washed with 2 x 4.0 mL DMF, 2 x 5.0 mL CH_2Cl_2, and 2 x 5.0 mL DMF. Then a solution of 0.4 mmol (4 eq.) protected amino acid and 0.4 mmol HBTU in 5.0 mL DMF was mixed with 3.0 mL 0.16M DIPEA (8 eq.) in DMF. This solution was added to the resin and mixed by inversion for 45 min. The resin was then washed with 2 x 5.0 mL DMF, 5.0 mL CH_2Cl_2, and 5.0 mL DMF. The cycle began again with the Fmoc deprotection step followed by amino acid coupling. The last step, coupling the 5(6)-carboxyfluorescein, used the more reactive coupling agents HOAt and PyAOP (0.4 mmol, 4 eq. of each) instead of HBTU. Following the synthesis, the resin was collected and dried by vacuum filtration. The resin was added to a cleavage cocktail containing 9.5 mL TFA, 0.5 mL triisopropylsilane, 0.3 mL H_2O in a 15 mL conical tube. The mixture was shaken in the dark for 2 hours. After that time, the mixture was vacuum filtered and the filtrate was collected in a 50 mL conical tube. To the tube was added 40 mL ice cold Et_2O was added, yielding a yellow precipitate. The mixture was centrifuged at 10,000 rpm for 5 min and the liquid was decanted. The yellow pellet was washed twice with 30 mL cold Et_2O, centrifuging each time as before. After the final centrifugation, the yellow pellet was dissolved in 5 mL diH_2O, transferred to a tared 100 mL round bottom flask, and rolled in a dry ice/acetone bath for 10 minutes to shell freeze the liquid. The flask was connected to a vacuum line overnight, yielding 90 mg lyophilized peptide.

ESI-MS *m/z* calculated for $C_{54}H_{68}N_{14}O_{18}S$ **(4)**: 1232.45, measured: 1233.5
ESI-MS *m/z* calculated for $C_{55}H_{70}N_{14}O_{18}S$ **(5)**: 1246.47, measured: 1247.4

RP-HPLC of peptides:

Column: Supelco Discovery HS C18 column, 5 µm, 4.6 × 250 mm. MeCN and H_2O, each with 0.1% TFA added, were used as eluents. 20 µL of peptide in H_20 was injected and a linear gradient was run from 10-40% MeCN over 20 minutes, flow rate 1.0 mL/min. UV detection was at 214 nm.

t_R = 5.22 (unlabeled), 11.04, 11.21 (labeled, 2 isomers of FAM) min for **4**
t_R = 5.81 (unlabeled), 14.98, 15.30 (labeled, 2 isomers of FAM) min for **5**

General procedure for conducting Michael additions on a 1K chip:

1. A chip containing 1000 electrodes/cm^2 was spin coated (3000 rpm, 60s) with freshly prepared 3% agarose in water and let to dry for 1 hour. For the electrolysis, 6.0 mg *N*-acryloxysuccinimide (30 µmol) was dissolved in 100 µL DMF in a 1.7 mL Eppendorf tube. To this solution was added 1.5 mL MeOH containing 2.77 mg Vitamin B_{12} and 13.6 mg tetramethylammonium nitrate. The chip was immediately exposed to this solution and selected electrodes were pulsed at -2.4V for 0.5 sec and 0V for 0.1 sec for 300 cycles. The chip was then washed with an excess of EtOH, H_2O, and EtOH and let to dry. For the other Michael acceptors, 9.6 mg N-succinimidyl 6-maleimidocaproate (30 µmol) or 8.1 mg N-succinimidyl 3-maleimidopropionate (30 µmol) were used.

2. For the Michael addition, the procedure was followed as above except 5.0 mg **3** was dissolved in 100 µL DMF instead of *N*-acryloxysuccinimide. Following this reaction, the counter electrode was polished with alumina to remove tarnish. The chip was visualized with a fluorescence microscope and a pyrene filter.

3. For the Michael addition with the peptide, N-acryloxysuccinimide (9.1 mg) was placed on the chip in a small checkerboard pattern as above. Following the electrolysis, the chip was washed with EtOH, H_2O, and 5xPBS. The chip was incubated in a 7.6 mM solution of the peptide (or 10 mM β-mercaptoethanol) in 1.7 mL 10xPBS, pH 7, for 45 minutes. Following the incubation, the chip was washed with 5xPBS and visualized using a fluorescence microscope. Then, the same Michael acceptor (10.2 mg) was attached to the array in box and dot pattern following the same procedure as above. The chip was washed with H_2O and 5xPBS. The chip was then placed in a 7.6 mM solution of the peptide in 10xPBS, pH 4 and the same electrodes (box and dot pattern) were activated as cathodes. The chip was washed with H_2O and visualized as above.

General procedure for conducting Michael additions on a 12K chip:

A plasma-cleaned chip containing 12,000 electrodes/cm^2 was spin coated (1500 rpm, 30s) with freshly prepared 3% agarose in 9:1 DMF:H_2O and let to dry for 1 hour. The electrolysis solution for the coupling of the Michael acceptor, either *N*-acryloxysuccinimide or N-succinimidyl 3-maleimidopropionate, was prepared as above. The slide was exposed to 100 µL of the reaction solution and selected electrodes were grounded, while a potential of +1.5 V was applied to the auxiliary electrode (making the microelectrode array negative) for 60 s. The washing procedure

was the same as above. The electrolysis solution for the addition of **3** was prepared as above. The slide was exposed to this solution and selected electrodes were grounded, while a potential of +1.5 V was applied to the auxiliary electrode for 60 s. The chip was washed as above and visualized with a fluorescence microscope.

Cyclic voltammetry:

1. A 12K chip, cleaned with 9:1 3% H_2O_2: conc. H_2SO_4 for 30 min at 65°C, was coated as above. The chip was treated with 100 µL of the base electrolysis solution containing 8.0 mg N-acryloxysuccinimide using the electrolysis conditions as above for the 12K chip, selecting only 10 electrodes. Following reaction, the chip was washed with EtOH and H_2O. The chip was then incubated in 100 µL of 7.6 mM solution of peptide **4** in 5xPBS (pH 7) for 45 minutes. After this time, the chip was washed with H_2O and let to dry. The Michael acceptor placement was repeated as above using a neighboring 10-electrode block, the chip was washed as before, and put to soak in 100 µL of 7.6 mM solution of peptide **5** in 5xPBS (pH 7) for 45 minutes. The chip was then washed and visualized using a fluorescence microscope to confirm placement of each peptide.

2. The chip was covered with 200 µL of a solution containing 8 mM $K_3Fe(CN)_6$, 30% glycerol, 100mM NaCl, 20 mM Tris-HCl, 1 mM $CaCl_2$, pH 7.2 and was placed in the ElectraSense reader. One 10-electrode block was activated and cyclic voltammetry was performed, scanning from 700-0 mV to generate some Fe(II), then cycling from 0-750 mV with a scan rate of 10 mV/s. The counter electrode was a platinum plate of area of 0.75 cm^2 and held 650-800 µm away from the chip by an O-ring. The background scan was repeated with the other 10-electrode block. Next, the chip was covered with 200 µL of the same solution above, also containing 30 µg integrin $\alpha_{IIb}\beta_{III}$ and cyclic voltammetry was repeated as above for each block. The same protein solution was used while each block was scanned.

Images used for fluorescence quantification:

Images were taken with an EXFO X-CITE lamp at 12% power and a FITC filter with excitation wavelengths of 465-495 nm and emission at 515-555 nm. The images are 12-bit with no binning and exposure time of 700 ms.

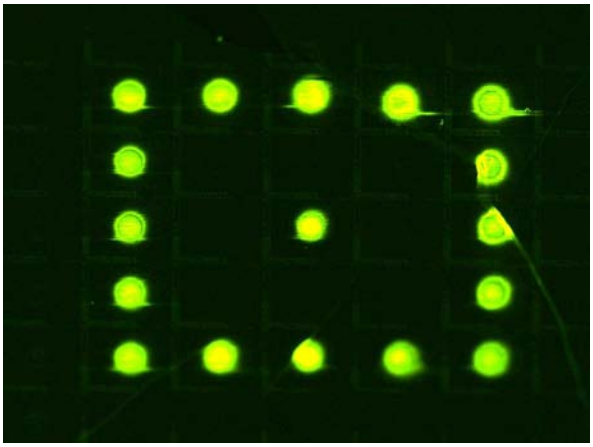


Figure S1: Box and dot pattern of chip prepared as in Figure 3B. Mean intensity of whole pattern corrected for background 700 ± 100.

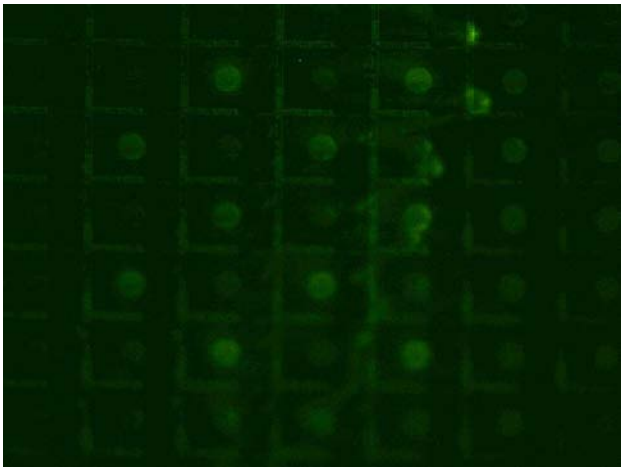

Figure S2: Checkerboard pattern on chip prepared as in Figure 3B. Mean intensity of whole pattern corrected for background 20 ± 10.

Control Experiments:

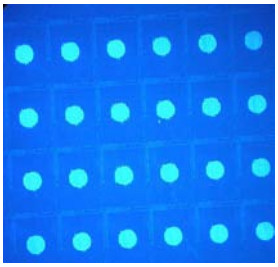

Figure S3: *Selectivity of Michael addition*
Following the above procedure for electrochemical deposition of the Michael acceptor on a 1K chip, 8.0 mg N-succinimidyl 3-maleimidopropionate was placed over every electrode. After washing as above, 5.5 mg **4** was reacted as above in a checkerboard pattern. Fluorescence was observed over every electrode, where the maleimide linker was placed. Similar results were obtained when N-acryloxysuccinimide was used as the linker.

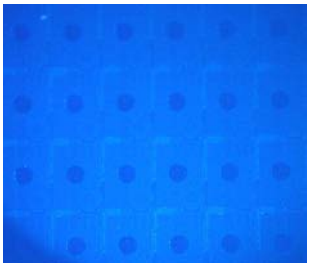

Figure S4: *Reaction of thiolate with agarose (No Michael acceptor):*
A 1K chip, coated as above, was reacted with 5.3 mg **3** under the same electrochemical conditions as above. No fluorescence was observed on any electrodes.

Other linker:

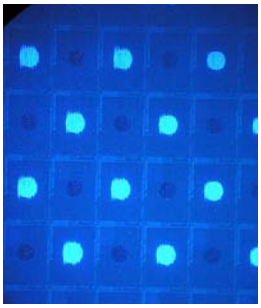

Figure S5: *Linker 2, N-succinimidyl 3-maleimidopropioate*
Following procedure for reaction on a 1K chip, using 8.1 mg N-succinimidyl 3-maleimidopropioate and 5.4 mg **3**

Synthesis and in Vitro Characterization of a Dendrimer−MORF Conjugate for Amplification Pretargeting

Xiangji Chen, Shuping Dou, Guozheng Liu, Xinrong Liu, Yi Wang, Ling Chen, Mary Rusckowski, and Donald J. Hnatowich*

Division of Nuclear Medicine, Department of Radiology, University of Massachusetts Medical School, 55 Lake Avenue North, Worcester, Massachusetts 01655. Received March 11, 2008; Revised Manuscript Received June 12, 2008

Amplification pretargeting can play an important role in molecular imaging by significantly increasing the accumulation of signal in target tissues. Multiple-step amplification pretargeting offers the potential to greatly improve target localization of effector molecules through the intermediate use of polymers conjugated with multiple copies of complementary oligomers. In this study, PAMAM dendrimer generation 3 (G3) was conjugated with multiple copies of a phosphorodiamidate morpholino (MORF) oligomer. Characterization of the conjugate by native-PAGE and SE-HPLC demonstrated that the conjugation was successful. The average numbers of MORF groups in the G3-MORF conjugate, both attached and accessible to the ^{99m}Tc labeled complementary MORF (cMORF), were determined. The antitumor antibody CC49 was conjugated with both MORF and cMORF (collectively (c)MORF) at an average of about one group per molecule. Nine of the 32 carboxyl groups of the dendrimer were modified with MORF, of which 90% were accessible in solution to ^{99m}Tc-cMORF. After purification, the G3-MORF was radiolabeled with tracer ^{99m}Tc-labeled cMORF (i.e., G3-MORF/^{99m}Tc-cMORF) and added to the antibody CC49 previously conjugated with cMORF (i.e., CC49-cMORF/G3-MORF/^{99m}Tc-cMORF), the complex demonstrated a single peak on SE-HPLC as evidence of complete hybridization between G3-MORF/^{99m}Tc-cMORF and CC49-cMORF. The CC49-(c)MORF were bound to both Protein G and Protein L coated plates, and G3-MORF was added to hybridize with CC49-cMORF before the ^{99m}Tc-cMORF was added to test amplification pretargeting. In comparison to conventional pretargeting without the G3-MORF, the signal was amplified about 6 and 14 times, respectively, showing that the G3-MORF participated in amplifying the signal. Further amplification studies using the CC49-(c)MORF for LS174T tumor cells in tissue culture also demonstrated clear evidence of signal amplification.

INTRODUCTION

Conventional nuclear medicine imaging with radiolabeled tumor specific agents such as antitumor antibodies can provide high tumor/nontumor ratios but usually with slow signal localization and clearance. Pretargeting is one approach that provides useful tumor/nontumor radioactivity ratios more rapidly by placing the effector carrying the radioactivity or other label on a small molecule designed to clear from the circulation and whole body rapidly (*1*). Pretargeting requires at least two steps in which the targeting macromolecule, usually an antibody, is administered first followed by the radioactive effector. The pretargeting approaches that have been reported thus far use (strep)avidin, bispecific antibodies, or oligonucleotides (*2*–*5*). One advantage of (strept)avidin for pretargeting is the 4-fold valency of this protein for biotin, providing the potential of modest signal amplification (*2*). However, a polymer conjugate with multiple copies of oligomers such as peptide nucleic acids (PNAs) or phosphorodiamidate morpholinos (MORFs), administered intermediately between the antitumor antibody and the small effector, provides a potential for amplification far in excess of four (*6*–*8*). In comparison to conventional pretargeting, the three-step amplification pretargeting approach is obviously more complex, but with the potential to greatly increase the localization of radioactivity in the target. Multivalent bispecific antibody and enzyme catalytic systems have also been considered for signal amplification (*9*, *10*).

The choice of polymer is critical for successful amplification pretargeting. It should be large enough to carry sufficient numbers of oligomers; after conjugation it should be water soluble and stable in vivo; it should have favorable pharmacokinetics; and the oligomers must be arranged on the polymer in such a way that they can be easily accessed by their effector. In our previous amplification pretargeting studies, polylysine (PL) and poly(methyl vinyl ether-*alt*-maleic acid) (PA) and other linear polymers provided lower amplification factors than expected. However, the concept has now been shown to be feasible (*6*–*8*), although further studies for optimization are required.

Recently, there has been interest in exploring dendrimers as potential drug delivery vehicles (*11*–*19*). Dendrimers are branched polymers with highly reactive pendant functional groups (Figure 1) that can be used for covalent conjugation of drugs, ligands, and antibodies for targeted delivery (*20*–*34*).

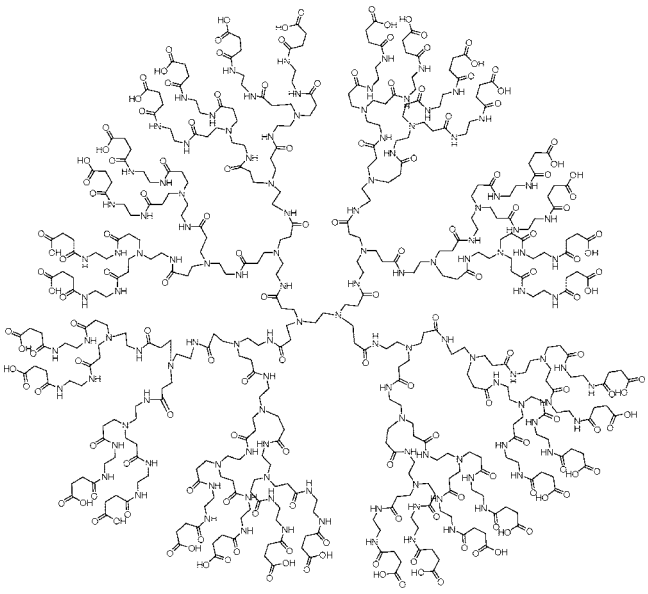

Figure 1. Two-dimentional representation of a PAMAM-succinamic acid dendrimer generation 3 with 32 carboxyl groups on its surface.

Unlike the linear PA and PL polymers, steric hindrances diminishing the accessibility of the conjugated oligomers to their complements should be minimal in the case of dendrimers because of their spherical geometry. The goal of this investigation was to use a dendrimer to achieve a higher degree of amplification pretargeting. As the first step toward this goal, a small dendrimer, generation 3 (G3) with 32 carboxyl groups on its surface, was conjugated with MORF and the in vitro properties of the conjugated polymer evaluated for amplification pretargeting.

EXPERIMENTAL PROCEDURES

Materials and Instruments. The 18-mer MORF and its complement, cMORF (collectively (c)MORF), were purchased from Gene-Tools (Philomath, OR) with 3′-amine modification and with the same base sequences used in this laboratory in connection with conventional pretargeting (*35, 36*). The base sequences and molecular weights were: MORF, 5′-TCTTC-TACTTCACAACTA-3-C-linker-amine, 6059 Da; cMORF, 5′-TAGTTGTGAAGTAGAAGA-3-C-linker-amine, 6317 Da. The cDNA phosphorothioate oligomer was purchased from IDT (Coralville, IA). PAMAM-succinamic acid dendrimer generation 3 (10111 Da), 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide methiodide (EDC-methiodide) and antimouse $F(ab')_2$ fragment-R-phycoerythrin antibody were purchased from Sigma-Aldrich (St. Louis, MO). *N*-hydroxysuccinimidyl S-acetylmercaptoacetyl-triglycine (NHS-MAG_3) was synthesized in house (*37*) and its structure was confirmed by elemental analysis, proton magnetic resonance, and mass spectrometry. The human colon cancer cell line (LS174T) was obtained from the American Type Culture Collection (Manassas, VA). Microcon YM-30 centrifugal filter devices were purchased from Millipore Corporation (Bedford, MA). Tris-glycine gradient precast polyacrylamide gels (4−20%) were purchased from Bio-Rad Laboratories (Hercules, CA). The antiTAG-72 IgG antibody CC49 was prepared by Strategic Biosolutions (Newark, DE) from the CC49 murine hybridoma cell line, a gift from Jeffery Schlom Ph.D. (Laboratory of Tumor Immunology and Biology, Center for Cancer Research, NCI, NIH, Bethesda, MD). The Hydralink kit was purchased from Solulink (San Diego, CA). The P-4 resin (Bio-Gel P-4, medium) was purchased from Bio-Rad and the Sephadex G-100 resin from Pharmacia Biotech (Piscataway, NJ). Protein G and Protein L coated plates were obtained from Pierce (Rockford, IL). All other chemicals were reagent grade and were used without purification. The ^{99m}Tc-pertechnetate was eluted from a ^{99}Mo-^{99m}Tc generator (Bristol-Myers Squibb Medical Imaging, N. Billerica, MA). The SE-HPLC system is consisted of one Waters 515 pump, one 2487 dual λ absorbance detector and one radioactivity detector. The Superose 12/30 HR column was purchased from GE Healthcare (Piscataway, NJ) and the mobile phase was 0.2 M phosphate buffer (pH 7.0).

Preparation of ^{99m}Tc-Labeled cMORF. The conjugation of cMORF with MAG_3 and subsequent labeling were as previously described (*38*). Briefly, the cMORF was first conjugated with S-acetyl NHS-MAG_3 via the 3′-derivatized amine in pH 8.0 HEPES buffer. After purification on a P-4 column with NH_4OAc buffer, the peak fractions were pooled and underwent a preliminary purification procedure consisting of the labeling procedure described below but without radioactivity followed by another P-4 column purification. For radiolabeling, 10 μL of ^{99m}Tc-pertechnetate generator eluate was introduced into a solution consisting of 3 μL (0.88 μg) of MAG_3-cMORF in pH 5.2 NH_4OAc buffer, 4 μL of 50 μg/μL sodium tartrate in a pH 9.2 buffer, and 1.5 μL of 4 μg/μL $SnCl_2 \cdot 2H_2O$ in ascorbate−HCl solution (1 μg/μL sodium·ascorbate in 10 mM HCl). The solution was heated to 100 °C for 20 min. The labeling efficiency was routinely greater than 95% as determined by SE-HPLC.

G3-MORF Conjugation. To 2.4 mg of EDC-methiodide (8.1 μmol) was added 10 μL of 1% PAMAM-succinamic acid dendrimer G3 (10 nmol). The mixture was gently vortexed at ambient temperature for 2 min and a 1 nmol/μL solution of MORF in distilled water was added at five different MORF/dendrimer molar ratios. Each conjugation mixture was incubated at ambient temperature overnight.

Native polyacrylamide gel electrophoresis (PAGE) conditions similar to those described elsewhere for analysis of dendrimers were used for the analysis of G3-MORF polymers (*31, 39, 40*). The free MORF, free dendrimer, and one of the G3-MORF conjugation mixtures (prepared at a 16:1, MORF/dendrimer molar ratio) before purification were analyzed using a 4−20% Tris-glycine gradient gel under native conditions. The running buffer was 2.5 mM Tris and 19.2 mM glycine at pH 8.2. Since MORF is uncharged, negatively charged cDNA (cDNA) was added to form a charged duplex that would migrate in the gel and also can be stained with ethidium bromide. Ten microliters of each of the three samples were mixed with 10 μL PBS containing equal molar cDNA at room temperature for 20 min. To each mixture, 10 μL of 50% sucrose and 1% bromophenol blue was added. The gel was run at low voltage (80 V) on a vertical gel electrophoresis system and then stained with ethidium bromide solution (0.5 μg/mL) at ambient temperature in the dark. After staining, the gel was first imaged with UV light on a Kodak Imaging Station 440CF (Eastman Kodak Co., New Haven, CT). The gel was then stained with 2.5% Coomassie Blue-R250 solution in 10% acetic acid and 50% methanol at room temperature for 2 h and destained in 10% acetic acid with 50% methanol for 4 h at room temperature and then in water overnight.

The absorbance at 265 nm of an aliquot of the conjugation mixture before purification was used to determine the average number of MORFs bonded to each dendrimer (i.e., groups of MORF per conjugate molecule (GPM)) by SE-HPLC analysis. Since the dendrimer does not appreciably absorb in the UV at 265 nm, unlike MORF, the UV peak areas of free MORF and the MORF coupled dendrimer were used to calculate the attached GPM. Since GPM accessible to radiolabled cMORF is a more important parameter than the attached GPM, the average number of MORFs accessible in solution was determined by a SE-HPLC shift assay in which ^{99m}Tc-cMORF at

Table 1. Experimental Procedures for Amplification Pretargeting and Conventional Pretargeting on Protein G and Protein L Coated Plates

	amplification pretargeting	nonspecific amplification	conventional pretargeting	nonspecific pretargeting
1st incubation	CC49-cMORF	PBS	CC49-MORF	PBS
2nd incubation	G3-MORF	G3-MORF	PBS	PBS
3rd incubation	^{99m}Tc-cMORF	^{99m}Tc-cMORF	^{99m}Tc-cMORF	^{99m}Tc-cMORF

trace concentration was added to the conjugation mixture before purification. The hybridization was carried out for 20 min at room temperature followed by SE-HPLC analysis to measure the radioactivity bound to free MORF and that bound to the G3-MORF. The areas of G3-MORF/^{99m}Tc-cMORF and MORF/^{99m}Tc-cMORF peaks on the radioactivity trace were compared with the corresponding peaks on the UV trace. Since accessibility of the ^{99m}Tc-cMORF to free MORF is assumed to be 100%, the identical ratio of G3-MORF to free MORF by radioactivity and UV detection would imply that the accessibility of the ^{99m}Tc-cMORF to G3-MORF was also 100%.

Since the free MORF (MW 6 KDa) and the coupling reagent EDC-methiodide (MW < 400 Da) are of low molecular weight, they could be removed from the high molecular weight product by filtration. The reaction mixture was repeatedly centrifuged using the Microcon YM-30 (MWCO 30 KDa) centrifugal filter devices to near dryness with water added between centrifugations until there was no evidence of free MORF or coupling agents by SE-HPLC. Stability of the conjugation mixture at room temperature in water was measured by monitoring the UV signal on SE-HPLC for more than one week.

Preparation of CC49-(c)MORF. The CC49 antibody was conjugated with either MORF or cMORF using a commercial Hydralink linker following the instruction of the manufacturer and experiences in this laboratory (*41*). Briefly, the antibody was first modified with succinimidyl 4-hydrazinonicotinate acetone hydrazone, while the (c)MORF was modified with succinimidyl 4-formylbenzoate. After purification, combining the hydrazine-modified antibody and the benzaldehyde-modified (c)MORF resulted in hydrazone formation. Purification of the antibody-(c)MORF from the free (c)MORF was achieved on Sephadex G-100 1 × 30 cm Econo-column using 100 mM PBS (pH 7.2) as eluent. The GPM was determined by SE-HPLC using the UV signal at both 265 and 280 nm. Under the assumption that the absorption coefficients of CC49 (280 nm) and (c)MORF (265 nm) do not change after conjugation, the concentration of CC49 and the (c)MORF GPM was calculated as described previously (*41, 42*).

Preserved immunoreactivities of CC49-(c)MORF were confirmed by flow cytometry with native CC49 as the positive control and the incubation medium as the negative control. Briefly, 2×10^5 LS174T cells in 100 μL of PBS were incubated with each antibody (3 μg) at room temperature for 30 min in the dark. The cells were washed three times using PBS, then gently resuspended in ice cold PBS, and phycoerythrin labeled secondary antibody, sheep antimouse F(ab′)$_2$, in 100 μL of 3% BSA/PBS was added. After 30 min incubation at room temperature in the dark, the cells were washed with PBS three times and resuspended in ice cold 3% BSA/PBS for analysis of immunoreactive fraction on a Becton-Dickinson FACSCalibur system (San Jose, CA). Background fluorescence was measured on a set of cells treated with secondary antibody alone. The immunoreactive fraction was well known to be the percentage of antibody preserving the immunoreactivity after conjugation compared with unmodified antibody. The percentage of fluorescence shift in the FACS study was used to calculate the immunoreactive fraction.

Hybridization in Solution. To confirm that the G3-MORF can link the CC49-cMORF and ^{99m}Tc-cMORF together in solution, the G3-MORF (4.75 μg, 2.5 μL) was mixed with 5 μL of ^{99m}Tc-cMORF (0.13 μg, 82.5 μCi) at room temperature and, after 30 min, 2 μL of the mixture was added to 40 uL of CC49-cMORF (4.3 μg). After a further 30 min, the mixture was analyzed by SE-HPLC by monitoring both radioactivity and UV signals.

Signal Amplification on Plates. The experimental procedure is outlined in Table 1. Both the CC49-(c)MORF antibodies were first immobilized on both the Protein G and Protein L coated 96-well flat-bottomed plates, via their Fc and VLκ regions, respectively, according to the manufacturer's instructions and the plates were rinsed three times using 200 μL of washing buffer (0.1 M PBS, pH 7.2, with 0.05% Tween-20). To two sets of wells was added 100 μL of each CC49-(c)MORF solution (about 3.3 μg/mL) containing the same amount of (c)MORF (2 pmol). As controls, to an equal number of wells only PBS was added in place of the antibodies. The plates were incubated for 60 min at room temperature and then rinsed with 3 × 200 μL of washing buffer. To the wells containing CC49-cMORF and one set of PBS control wells, 100 μL of G3-MORF (2.4 μg/mL in PBS, pH 7.2, containing 1% BSA) was added. The plates were incubated for 30 min at room temperature and then rinsed with 3 × 200 μL of washing buffer. To each well, 50 μL of ^{99m}Tc-cMORF (2 μCi in PBS, pH 7.2, containing 1% BSA) was added. The plates were incubated for another 30 min at room temperature and the free ^{99m}Tc-cMORF was removed with 3 × 200 μL of washing buffer. The radioactivity bound to the plates was removed with 2 × 200 μL of 1% sodium dodecyl sulfate (SDS) in 0.2 N NaOH and 200 μL of 2 M hydrochloride for counting in a NaI(Tl) well counter. To the wells containing CC49-MORF rather than CC49-cMORF and one set of PBS control wells was added 100 μL of PBS (pH 7.2, containing 1% BSA). The plates were incubated for 30 min at room temperature before the wells were rinsed with 3 × 200 μL of washing buffer. To each well 50 μL of ^{99m}Tc-cMORF was added and the studies performed as described above. The amplification factor (AF) was calculated from the percentage of bound radioactivity removed from the wells of all four studies. AF = (Amplification pretargeting − Nonspecific amplification)/(Conventional pretargeting − Nonspecific pretargeting). An identical study was performed on the Protein L coated plate.

Signal Amplification on Cells. The cell amplification pretargeting was performed similarly to that described in Table 1. Cells were suspended in Minimum Essential Medium (MEM) with 10% FBS and were seeded in 12-well flat-bottomed plates at 1 mL/well. The cells were used when 80% confluence was reached and the medium was changed to MEM with 1% FBS. First, 100 μL of CC49-(c)MORF solution (about 3.3 μg/mL) containing the same amount of (c)MORF (2 pmol) was added to each well in the two groups followed by incubation at 4 or 37 °C for 1 h (the 4 °C incubations were included to evaluate the influence of internalization). Thereafter, 100 μL of G3-MORF (2.4 μg/mL in PBS, pH 7.2, containing 1% BSA) was added to the CC49-cMORF wells and to one set of PBS control wells; 100 uL of PBS without G3-MORF was added to the CC49-MORF wells and one set of PBS control wells. After incubation for 30 min, the cells were rinsed with 2 × 0.5 mL of MEM with 1% FBS and 2 μCi of ^{99m}Tc-cMORF in 50 μL of PBS (containing 1% BSA) was added to each well followed by 30 min incubation. The cell medium was then carefully removed, and the cells were rinsed with 2 × 0.5 mL of cold PBS. The cells were then lysed with 1% SDS in 0.2 N NaOH,

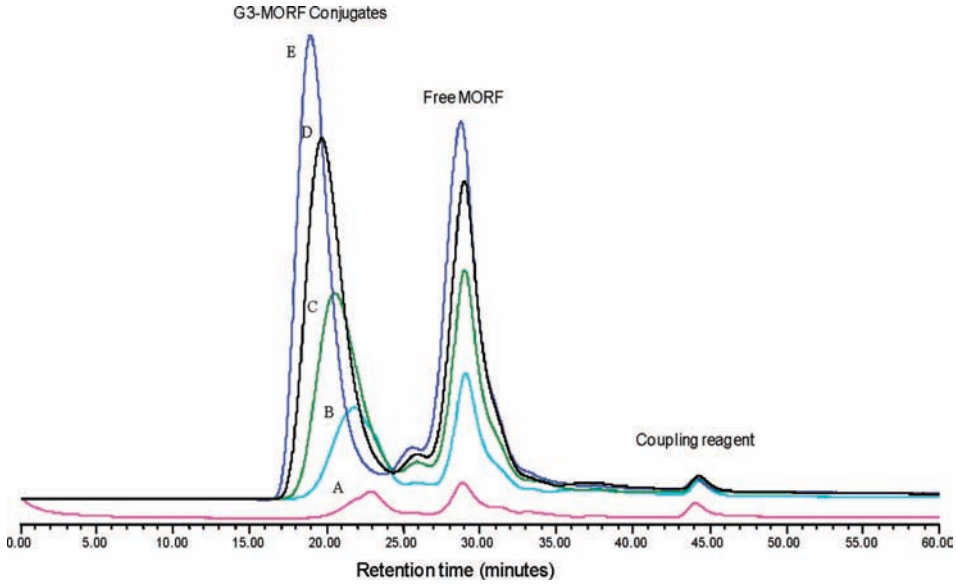

Figure 2. SE-HPLC UV chromatograms at 265 nm of G3-MORF prepared at different molar ratios of MORF to dendrimer: 1:1 (trace A), 2:1 (trace B), 4:1 (trace C), 8:1 (trace D), and 16:1 (trace E). Flow rate was 0.6 mL/min.

and the radioactivity in the medium and cells was measured in the well gamma counter.

RESULTS

G3-MORF Conjugation. In the SE-HPLC UV traces of G3-MORF before purification (Figure 2), the peak at early retention time (18.9−22.9 min) is due to the conjugated G3-MORF while the peak appearing later is due to free MORF. The conjugate prepared at higher molar ratio demonstrated shorter retention time on the SE-HPLC indicating higher molecular weight. Since these traces were obtained before purification, the ratio of peak areas is a measure of the conjugation efficiency (i.e., GPM). As shown, the average GPM increased with increasing molar ratio of MORF to dendrimer as expected. However, molar ratios higher than 16:1 did not further increase the average GPM (data not shown). The possibility that the MORF was bound to the dendrimer noncovalently even in part was excluded by the results of an identical study without coupling agent under the same conditions that demonstrated only individual peaks corresponding to unconjugated dendrimer and free MORF. The conjugate was stable at room temperature for at least one week as monitored by SE-HPLC.

As shown in Figure 3, one conjugation mixture (prepared at a 16:1 MORF/dendrimer molar ratio) was also analyzed by native PAGE following the addition of cDNA and staining with Coomassie Blue (panel A) or ethidium bromide (panel B). The migration of the conjugated dendrimer (lanes 2) was distinctly slowed compared to that of the free dendrimer (lanes 1) indicating a higher molecular weight after conjugation with MORF. The somewhat broad band for the G3-MORF indicates that the conjugate consisted of several G3-MORFs with different GPMs. Both results also demonstrate that there was no unreacted dendrimer left after conjugation. The multiple bands for the free MORF (lane 3) may indicate impurities in the commercial product.

Analysis of the conjugation mixture prepared at the 16:1 molar ratio on SE-HPLC is shown in Figure 4. UV chromatogram (top trace) indicates that this G3-MORF contained an average of 9 GPM. Since there are 32 carboxyl groups on the surface of the G3 dendrimer, the average conjugation efficiency was 28%. After adding a trace level of ^{99m}Tc-cMORF to the conjugation mixture, the ratio of radioactivity peak intensity of G3-MORF/^{99m}Tc-cMORF to MORF/^{99m}Tc-cMORF was compared with that of the UV trace. Since the accessibility of the ^{99m}Tc-cMORF tracer to free MORF may be assumed to be 100%, the comparison shows that about 90% of the MORF groups on the dendrimer formed a duplex with ^{99m}Tc-cMORF. Thus about 8 of the 9 MORF groups in the polymer were accessible to ^{99m}Tc-cMORF in solution.

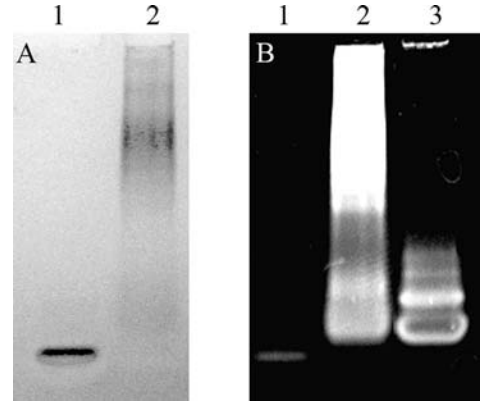

Figure 3. Native PAGE of G3-MORF analyzed before purification and after mixing with cDNA and staining with Coomassie Blue (panel A) or ethidium bromide (panel B). Lane 1 contains free dendrimer, lane 2 contains MORF conjugated dendrimer, and lane 3 (panel B only) contains free MORF.

Preparation of CC49-(c)MORF. The CC49-(c)MORF was successfully synthesized with an average GPM in the range of 1.0−1.3 by the method described previously (*41*). The flow cytometry results of Figure 5 show that both the CC49-MORF and CC49-cMORF retained more than 90% of the immunoreactive fraction of the native CC49.

Hybridization in Solution. The SE-HPLC trace for the CC49-cMORF/G3-MORF/^{99m}Tc-cMORF complex prepared by mixing the ^{99m}Tc-cMORF tracer with the G3-MORF followed by hybridization to the CC49-cMORF is shown in Figure 6. The radioactivity profile shows only a single peak with a high molecular weight retention time of 16.8 min and no evidence of free G3-MORF/^{99m}Tc-cMORF signifying complete hybridization of the G3-MORF/^{99m}Tc-cMORF to the CC49-cMORF antibody. The UV profile also shows only a single peak with the identical 16.8 min retention time (data not presented) and therefore provides further evidence of complete hybridization.

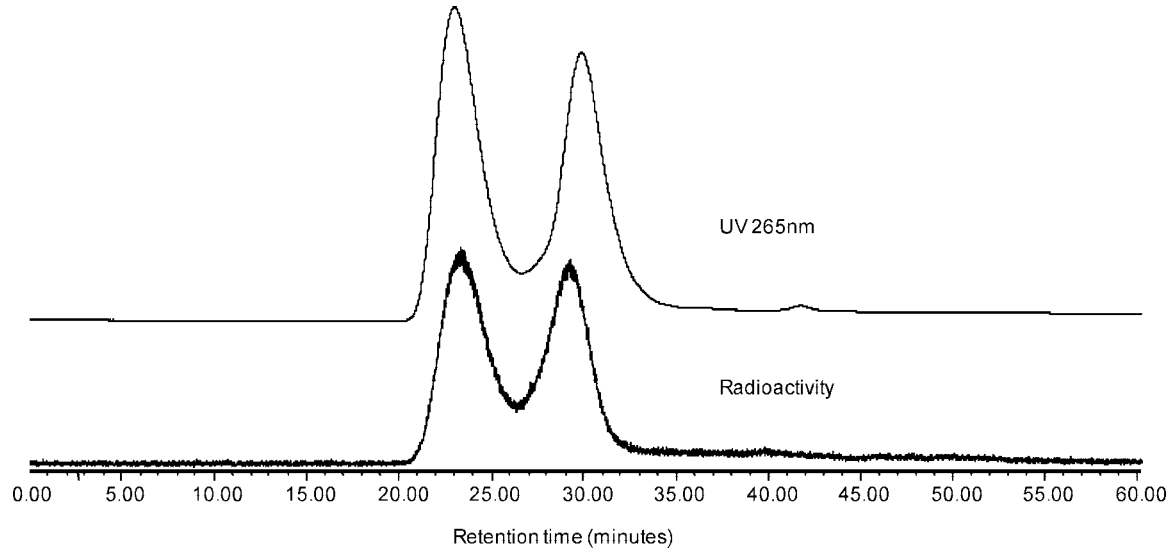

Figure 4. SE-HPLC chromatograms with UV 265 nm detection (top trace) and radioactivity detection (bottom trace) of one G3-MORF (prepared at a 16:1 MORF/dendrimer molar ratio) following addition of trace ^{99m}Tc-cMORF. Flow rate was 0.5 mL/min.

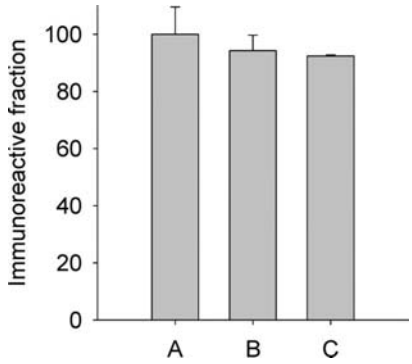

Figure 5. Histograms representing the immunoreactive fractions of native and modified CC49 detected using flow cytometry analysis. A: native CC49. B: CC49-MORF. C: CC49-cMORF. Results are averages, error bars represent 1 s.d ($N = 3$).

Signal Amplification on Plates. Figure 7 presents histograms showing the percentage of radioactivity bound to wells used for amplification pretargeting and conventional pretargeting on Protein G (panel A) and Protein L (panel B) coated plates as described above.

As shown in Figure 7, on Protein G, the amplification factor was about 6 while on Protein L this factor was about 14. The differences between amplification and controls in both cases are significant (Student's *t*-Test, $P < 0.05$). In both cases the G3-MORF therefore played an important role in the accumulation of radioactivity.

Signal Amplification on Cells. The results of the cell signal amplification studies are shown in Figure 8 for incubations at both 4 and 37 °C. Cell accumulations of ^{99m}Tc-cMORF by amplification pretargeting were significantly higher (Student's *t*-Test, $P < 0.05$) at both temperatures by up to 2.5 times that of conventional pretargeting without the G3-MORF. The percentage of radioactivity increased in all study groups except for amplification pretargeting when incubation temperature was increased to 37 °C.

DISCUSSION

In this investigation, a generation 3 PAMAM dendrimer was conjugated with multiple copies of MORF and used in combination with the CC49 antibody conjugated with cMORF and with the cMORF labeled with ^{99m}Tc for in vitro amplification pretargeting. For this investigation, the PAMAM dendrimer, anionic at neutral pH, was selected because anionic dendrimers have shown lower toxicity and a longer clearance time from circulation than cationic dendrimers (*43–46*) and because the carboxyl groups may be readily modified with amine-modified MORF using carbodiimides. Furthermore, PAMAM dendrimers are commercially available in a variety of generations. In addition, the spherical geometry of dendrimers may decrease steric hindrance compared to linear polymers. In this investigation, we determined that increasing the conjugation molar ratio of MORF to dendrimer beyond 16:1 did not increase the number of attached GPM, possibly due to steric hindrance. The maximum average number of MORF that was attached (i.e., GPM) was 9 under the conditions of this investigation. Higher generation dendrimers may therefore be required if higher GPM values are needed. Adding *N*-hydroxysulfosuccinimide (Sulfo-NHS) to improve the degree of conjugation was unsuccessful.

The conjugation was confirmed by native PAGE analysis. As expected, the broad band on native PAGE in Figure 3 indicates that the G3-MORF used in this investigation consisted of conjugates with a range of GPM with an average of 9. Analysis of the dendrimer after conjugation but before purification, when stained with ethidium bromide, provided a G3-MORF band that is much brighter than that of the unconjugated MORF which suggests a high degree of conjugation. The average molecular weight of G3-MORF was about 64 KDa or about 7.2 KDa per MORF, and therefore lower than that of the PA (9.1 KDa/MORF) and PL (10.7 KDa/MORF) polymers studied previously. Although the experimental protocols were very different, the fact that the spherical dendrimer demonstrated higher conjugation efficiency (28%) than the linear PA (19%) or PL (11%) polymers supports a suggestion that the spherical geometry of the dendrimer may be helpful in reducing steric hindrances. Possibly for the same reason, accessibility of the MORF in the G3-MORF conjugate was higher at 90% compared to 50−60% for PL-MORF and PA-MORF conjugate (*7*). As shown in Figure 4, when added at a 1:1 molar ratio, the ^{99m}Tc-cMORF completely hybridized to the G3-MORF and MORF mixture and the G3-MORF completely hybridized to the CC49-cMORF as shown in Figure 6 demonstrating uninhibited accessibility in solution in both cases.

The results presented in Figure 7 clearly demonstrate that the G3-MORF participated in signal amplification on both Protein G and Protein L coated plates in that significantly more

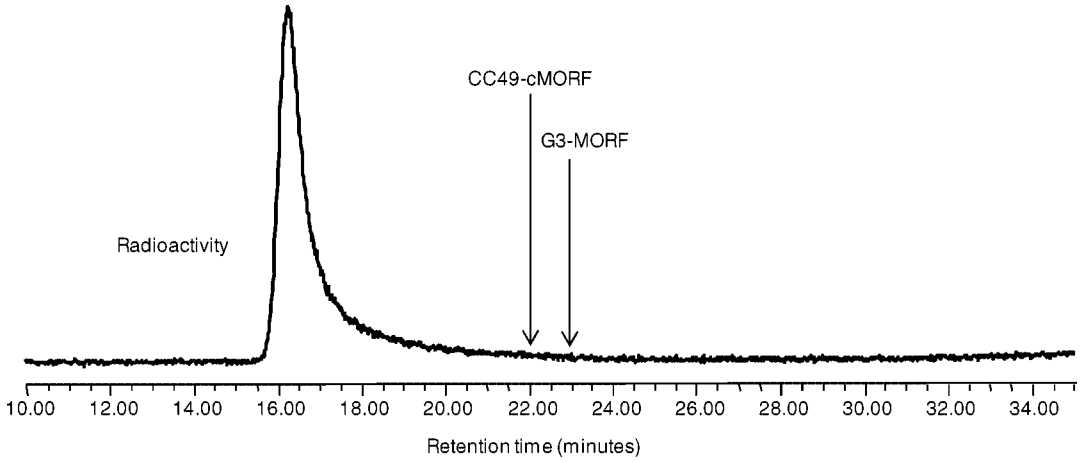

Figure 6. SE-HPLC radioactivity chromatographic profile for the CC49-cMORF/G3-MORF/^{99m}Tc-cMORF complex. The retention times for CC49-cMORF and G3-MORF are indicated by arrows. Flow rate was 0.5 mL/min.

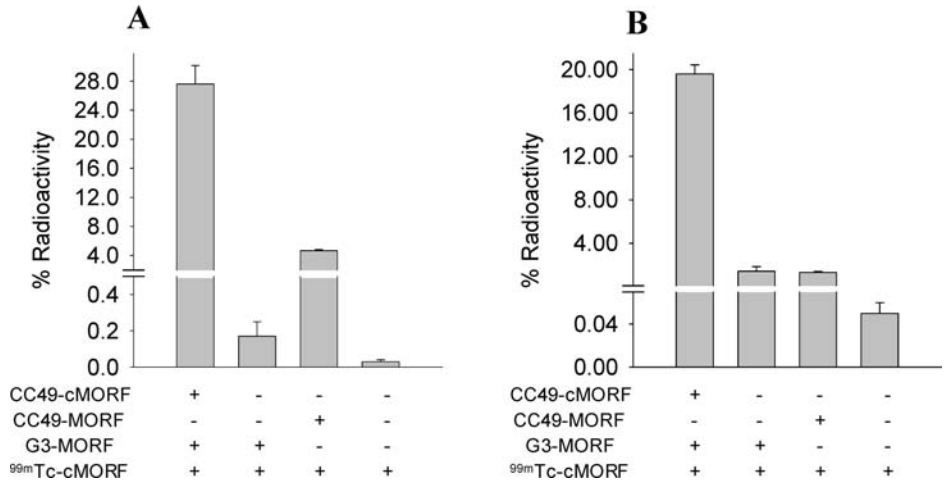

Figure 7. Histograms presenting the percentage on radioactivity obtained in Protein G (panel A) and Protein L (panel B) coated plates by amplification pretargeting and conventional pretargeting and two control studies in which the antibody or both the antibody and the polymer were eliminated. Results are averages; error bars represent 1 s.d ($N = 5$).

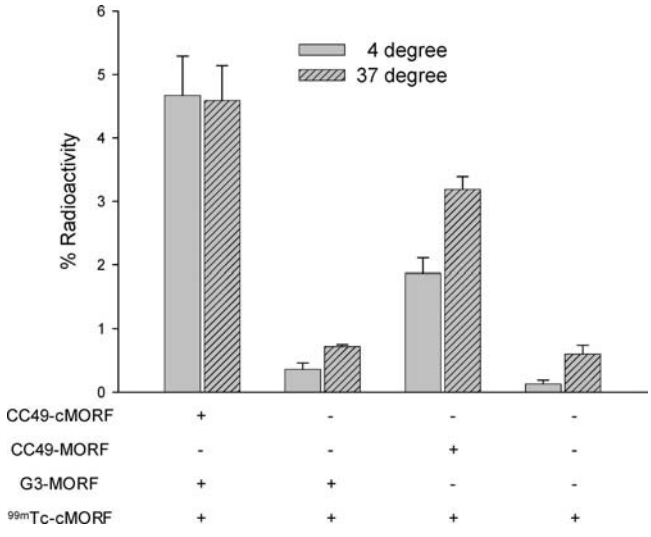

Figure 8. Histograms presenting the percentage of radioactivity accumulated in cells by amplification pretargeting, conventional pretargeting, and their control studies without antibodies, performed at 4 °C (solid bars) and 37 °C (hatched bars). Results are averages; error bars represent 1 s.d ($N = 3$).

^{99m}Tc-cMORF effector accumulated in the amplification studies compared with the conventional pretargeting studies and provided an amplification factor of about 14 in the case of the Protein L coated plate. Because the molecular volume of G3-MORF is fairly large, steric hindrance may restrict its hybridization to CC49-cMORF. The fact that the CC49 antibody was immobilized on Protein G and Protein L coated plates via Fc and VLκ regions, respectively, should result in different orientations of the bound antibodies, which in turn could expose different aspects of the antibody-bound cMORF for G3-MORF binding and may explain the differences in amplification between the two plates.

While the results of studies in cell culture showed that signal was also amplified, the amplification factor was not as high as that on the plates. Studies subsequent to those reported herein suggest that accessibility of the cMORF on antibody to G3-MORF after binding to the antigen may be restricted on the cell membrane compared to the accessibility on either Protein G or Protein L on the plate, although further studies will be required to establish the reason for this observation. As shown in Figure 8, performing the amplification pretargeting at 4 °C to eliminate any influence of internalization made no significant difference to suggest that internalization was not a significant factor in this study.

Measurements of specific binding on plates or cells in wells are usually complicated by the unavoidable contribution of nonspecific binding. It was for this reason that multiple controls were necessary in this investigation. Thus in the plate study,

the nonspecific amplification binding of the ^{99m}Tc-cMORF effector to the intermediate G3-MORF was evaluated by leaving out the CC49-cMORF and the nonspecific conventional pretargeting binding of the ^{99m}Tc-cMORF to the well surface was evaluated by leaving out the G3-MORF and the antibody, as described in Table 1. Fortunately as shown in Figure 7, the nonspecific binding of the G3-MORF in the amplification pretargeting to both Protein G and Protein L coated plates was much lower than the amplification binding. As shown in Figure 8, the identical controls were used in the cell study and again the G3-MORF did not increase the nonspecific binding on cells.

To exclude the possibility that the differences in amplification factors between the plate and cell studies may be due to the different media used, an amplification pretargeting was performed on Protein L coated plate as before but using the cell culture medium as in the cell study. In one additional control group, the protein L coated plates were first incubated with the CC49-MORF instead of CC49-cMORF, followed by the G3-MORF and finally the ^{99m}Tc-cMORF exactly as before, except now in culture media. The results (not presented) showed that the amplification factor was still about 14 as in the former study indicating that the cell culture medium cannot explain the lower amplification factors in the cell study and that the nonspecific binding of G3-MORF to the antibody was very low.

CONCLUSIONS

A G3 dendrimer-MORF conjugate was synthesized with 9 of the 32 surface groups modified with MORF, of which 90% were accessible in solution to ^{99m}Tc-cMORF. The conjugated dendrimer showed unhindered hybridization to ^{99m}Tc-cMORF and CC49-cMORF. On Protein G and Protein L coated plates, the signal was amplified by up to 14-fold that of conventional pretargeting, showing that the dendrimer−MORF conjugate participated in amplifying the signal. Although not as positive, similar studies in the LS174T tumor cells in culture also demonstrated evidence of signal amplification.

ACKNOWLEDGMENT

The authors are grateful to Dr. Schlom (Laboratory of Tumor Immunology and Biology, Center for Cancer Research, NCI, NIH, Bethesda, MD) for providing the CC49 hybridoma. Financial support from NIH (CA 94994 and CA107360) is gratefully acknowledged.

Improved Cellular Activity of Antisense Peptide Nucleic Acids by Conjugation to a Cationic Peptide-Lipid (CatLip) Domain

Uffe Koppelhus,[#,§] Takehiko Shiraishi,[§] Vladimir Zachar,[#] Stanislava Pankratova, and Peter E. Nielsen*

Department of Cellular and Molecular Medicine, The Panum Institute, Faculty of Health Sciences, University of Copenhagen, Blegdamsvej 3c, DK-2200 Copenhagen N, Denmark. Received February 22, 2008; Revised Manuscript Received June 20, 2008

Conjugation to cationic cell penetrating peptides (such as Tat, Penetratin, or oligo arginines) efficiently improves the cellular uptake of large hydrophilic molecules such as oligonucleotides and peptide nucleic acids, but the cellular uptake is predominantly via an unproductive endosomal pathway and therefore mechanisms that promote endosomal escape (or avoid the endosomal route) are required for improving bioavailability. A variety of auxiliary agents (chloroquine, calcium ions, or lipophilic photosensitizers) has this effect, but improved, unaided delivery would be highly advantageous in particular for future *in vivo* applications. We find that simply conjugating a lipid domain (fatty acid) to the cationic peptide (a CatLip conjugate) increases the biological effect of the corresponding PNA (CatLip) conjugates in a luciferase cellular antisense assay up to 2 orders of magnitude. The effect increases with increasing length of the fatty acid (C_8-C_{16}) but in parallel also results in increased cellular toxicity, with decanoic acid being optimal. Furthermore, the relative enhancement is significantly higher for Tat peptide compared to oligoarginine. Confocal microscopy and chloroquine enhancement indicates that the lipophilic domain increases the endosomal uptake as well as promoting significantly endosomal escape. These results provide a novel route for improving the (cellular) bioavailability of larger hydrophilic molecules.

INTRODUCTION

Bioavailability in general and effective cellular delivery in particular are major challenges for nucleic acid derived gene targeting agents and thus for drug discovery and development of such agents. Delivery of large DNA vectors for cellular transfection and gene therapy and of smaller oligonucleotides for antisense and RNA interference approaches is effectively accomplished by lipofection using a variety of cationic lipids (*1–4*). Unfortunately, this method is not without complications for *in vivo* use mainly due to toxicity. Neutral (or positively charged) antisense agents such as peptide nucleic acids (PNAs) (*5*) or morpholino oligomers (*6*) cannot effectively be delivered via lipofection, but codelivery with a partially cDNA oligonucleotide is possible (*7–9*) as is delivery of PNA oligomers conjugated to a variety of lipophilic ligands such a fatty acids (*10*) or polyaromates (*11*).

Several years ago it was discovered that a group of cationic peptides of biological origin as exemplified by the HIV derived Tat-peptide (*12, 13*) and the Antennapedia peptide, penetratin (*14*) (which is contained in a transcription factor form *Drosophila*), are taken up by eukaryotic cells and are able to deliver a conjugated molecular cargo to such cells. These so-called cell penetrating peptides (CPP) (*15*) typically contain multiple arginines, and indeed simple oligoarginines exhibit good cellular delivery activity (*16–18*). Although the first reports claimed that the cellular uptake of CCPs was exclusively a physical phenomenon involving binding to negatively charged sites on the membrane followed by internalization by transient membrane destabilization or by pore formation by the peptides, a range of recent studies have reached the consensus that the major cellular port of entrance for the cationic CPPs is via endocytosis (*19–22*), maybe predominantly macropinocytosis (*23–25*). Consequently, delivery is to endosomes (which eventually turn into lysosomes), and therefore the biological effect is very limited, as the compounds are trapped in these compartments and cannot reach their biological target in the cytoplasm or in the nucleus. Thus one of the major challenges for exploiting CPPs for drug delivery is the discovery of methods or mechanisms that allow efficient endosomal escape of the drugs. This may be accomplished by using auxiliary agents such as chloroquine (*26, 27*), calcium ions (*26*), or lipophilic photosensitizers (*28, 29*), but delivery may also be improved by chemical modification of the peptide. Most obviously, addition of a (viral) endosome disruption domain to the peptide should increase efficiency as already demonstrated (*25*), and more complex "chimeric" peptides such as arginine modified penetratin (*30*) and especially transportan also appear more effective (at least in a PNA context) than simple cationic peptides (*17*), although the mechanism(s) of uptake is still very poorly understood.

The galanin domain of transportan is rather hydrophobic while the mastoparan domain contains the only cationic moieties of this peptide. It would therefore appear that the cellular uptake of transportan could rely more on hydrophobic interactions with the membrane than on electrostatic interactions. It is of course reasonable that both membrane binding as well as membrane penetration should be facilitated by lipophilic ligands. On the other hand a cationic domain would contribute both electrostatic cellular adhesion as well as increased aqueous solubility of the ligand. The efficiency of cationic lipids for cellular delivery of (anionic) oligonucleotides and DNA is well established (*31*), and recently it was shown that fatty acid conjugates of oligoarginines may also be successfully exploited as delivery vehicles for DNA and RNA (*32*). In this case, however, the main function of the cationic peptide most likely is condensation of the anionic nucleic acids. We set out to study the cellular delivery properties of cationic peptides containing a simple lipophilic domain, in the form of a fatty acid. We have

[a] The sequences of the PNAs are written from N-terminal to C-terminal end. Cell penetrating peptides, decanoic acid (Deca) or Lys(Deca) moietiy was covalently linked to PNA at the N-terminal through an ethyleneglycol linker (eg1: 8-amino-3,6-dioxaoctanoic acid) or glycine (Gly) via continuous synthesis. [b] Mismatch PNA for the Tat-Deca-PNA (PNA2534) whereas two mismatches are indicated in bold. Flk, fluorescein (Fl) attached to the ε-amino group of a lysine residue (Lohse, J., Nielsen, P. E., Harrit, N., Dahl, O. (1997) *Bioconjugate Chem. 8*, 503−509).

characterized such two-domain "CatLip" peptides in a PNA antisense context (Table 1) using the quantitative and very sensitive and accurate mRNA splicing correction luciferase pLuc HeLa cell system (*33*, *34*), and we find that adding a fatty acid moiety increases the biological activity of Tat and oligoarginine CPP-PNA conjugates by up to 2 orders of magnitude.

EXPERIMENTAL PROCEDURES

PNA Synthesis. The sequences of the PNAs used are listed in Table 1. PNA synthesis was carried out by the standard Boc strategy as reported previously (*35*). Peptides were linked to the PNA at the N-terminal through an ethylene glycol linker (eg1: 8-amino-3,6-dioxaoctanoic acid) or glycine via continuous solid phase synthesis. The fatty acid was conjugated to the ε-amino group of a lysine moiety during synthesis using orthogonal Fmoc protection. The PNA conjugates were purified by HPLC and characterized by MALDI-TOF mass spectrometry (see Supporting Information). The PNAs were lyophilized and stored at 4 °C until use.

Cell Culture. HeLa pLuc705 cells were purchased from Gene Tools (USA). Cells were grown in RPMI1640 medium (Sigma) supplemented with 10% fetal bovine serum (FBS, Sigma), 1% glutamax (Gibco), 100 U/mL penicillin (Gibco), and 100 μg/mL streptomycin (Gibco) at 37 °C in humidified air with 5% CO_2. For studies of HeLa pLuc705 cells in 96 well plate format, cells were trypsinized and seeded (1.2×10^4 cells/well) 16 h before treatment. For studies in 24-well plate, 7.2×10^4 cells/well were used.

PNA Treatment. The cells, replated in 96 well (Nunc) or 24 well plates (Nunc) 16−24 h earlier, were treated with 100 μL/well (for 96 well plate) or 0.3 mL/well (for 24 well plate) of OPTI-MEM (Gibco) containing the PNA at the desired concentration for 4 h. After PNA treatment, cells were supplemented with the 100 μL/well (for 96 well plate) or 0.3 mL/well (for 24 well plate) of RPMI1640 medium (containing 20% FBS and 1% Glutamax), incubated further for 24 h, and subjected to the desired analysis unless otherwise stated. For the endosome disruption treatments, cells were treated as reported previously (*36*). Briefly, for photochemical internalization (PCI) treatment, cells were plated the day before PNA treatment with the antibiotics free growth medium containing 5 μg/mL aluminum phthalocyanine ($AlPcS_{2a}$, Frontier Scientific, Logan, USA). After the 4 h PNA treatment, the medium was replaced with fresh growth medium (RPMI1640 containing 10%

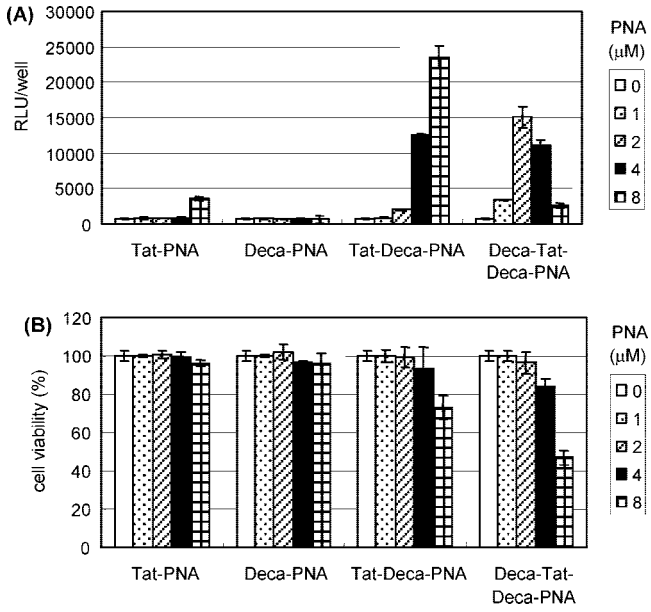

Figure 1. Relative cellular luciferase antisense activity and cellular toxicity in HeLa pLuc705 cells of PNAs conjugated to Tat-peptide and/or decanoic acid (attached to the ε-amino group of a lysine). Cells plated in the 96 well plates were treated with PNAs (Tat-PNA, Deca-PNA, Tat-Deca-PNA, and Deca-Tat-Deca-PNA) for 4 h in OPTI-MEM medium at the designated concentrations (0−8 μM) and incubated further for 24 h after addition of serum-containing growth medium (without removing the PNA solution). The cell samples were then subjected to luciferase analysis and cellular viability test. All tests were performed in triplicate and the results are given as the average values ± standard deviations (SD). (A) Luciferase activities were analyzed by Blight-Gro reagent (Promega) and given as relative light units (RLU/well). (B) Cellular viabilities were analyzed by MTS assay (Promega) and obtained values were normalized to the average value of non-PNA-treated sample.

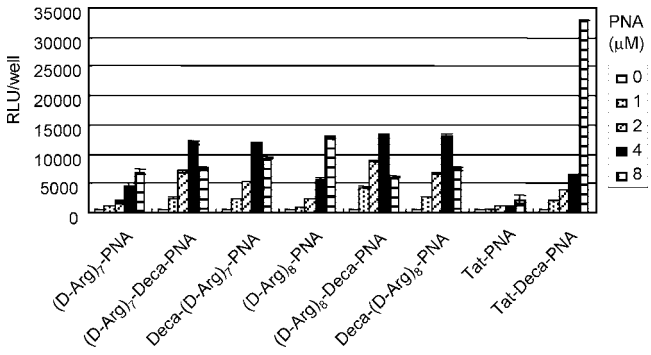

Figure 2. Relative cellular luciferase antisense activity in HeLa pLuc705 cells of PNAs conjugated to a cell penetrating peptide ((D-Arg)$_7$-, (D-Arg)$_8$-, or Tat-) and/or a decanoic acid (attached to the ε-amino group of a lysine). Cells plated in 96 well plate were treated with PNAs (0−8 μM) for 4 h in OPTI-MEM medium and incubated further for 24 h after addition of serum-containing growth medium without removing the transfection solution. Then the cell samples were subjected to luciferase analysis. Luciferase activities were analyzed by Blight-Gro reagent (Promega) and given as relative light units (RLU/well). All tests were performed in triplicate and the results are given as the average values ± standard deviations (SD).

FBS and 1% glutamax) and incubated for 4 h before irradiation with a fluorescence light tube (Alcadia, FO18) at 7.77 μW/cm^2 at 660 nm (15 nm bandwidth). Following irradiation, cells were incubated for additional 24 h before subjected to further analysis. For the chloroquine (CQ) treatment and Ca^{2+} treatment, cells were treated with PNA in OPTIMEM containing 120 μM CQ or 6 mM $CaCl_2$, respectively.

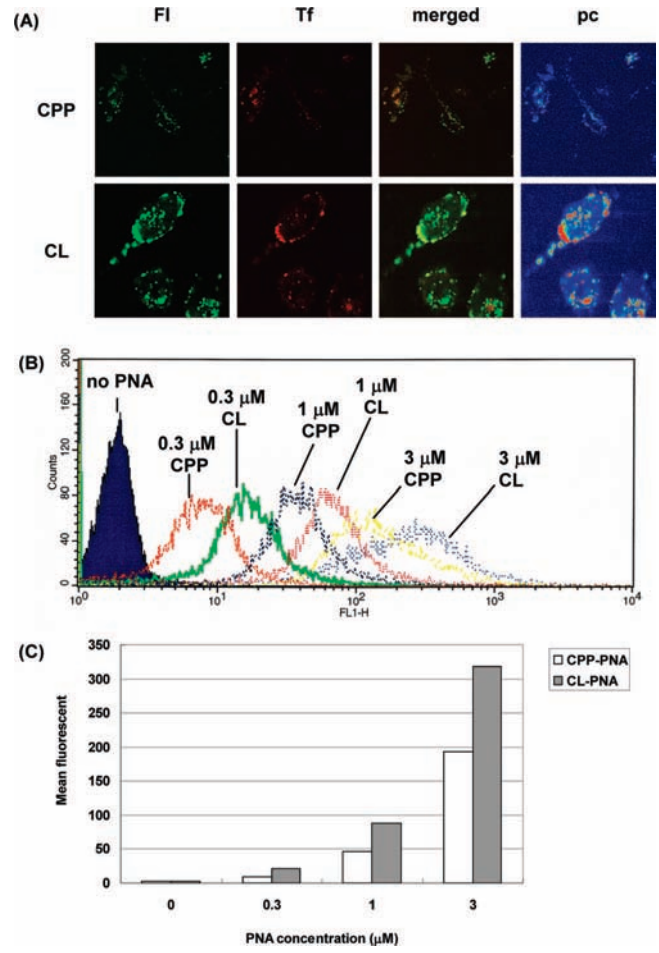

Figure 3. (A) Confocal fluoresence microscopy analysis of the cellular uptake of PNAs in HeLa pLuc705 cells. The fluorescein (Fl)-labeled PNAs (Fl-(Arg)$_8$-PNA (PNA3266) and Fl-(Arg)$_8$-Deca-PNA (PNA3265) were used. The cells were treated with 0.5 μM of PNA together with 20 μg/mL of tranferrin (Tf) for 24 h and analyzed by confocal fluoresence microscopy. Merged images (merged) and pseudocolor (ps) images were created by using the *Lasersharp 2000* software package (BioRad). (B) Flow cytometric analysis of HeLa pLuc705 cells treated with PNAs (Fl-(Arg)$_8$-PNA (CPP) or Fl-(Arg)$_8$-Deca-PNA (CL)) at three different concentrations (0.3, 1, and 3 μM) for 24 h and collected by pipetting using 1% BSA solution (in PBS) for the flow cytometric analysis. Cells (10 000 events for each sample) were analyzed using BD FACSCalibur cytometer and the data were analyzed by the *CellQuest* software. The histogram data of the cells treated with the PNAs at three different concentrations were superimposed. (C) Histogram representation of mean fluorescence of the cells.

Luciferase Assay. At 24 h after the PNA treatment, the cells were subjected to luciferase activity analysis by using the Bright-Glo Luciferase assay system (Promega) or the Luciferase Assay System (Promega) for the cells in 96 well plates or the cells in 24 well plates, respectively. Measurements were performed according to the manufacturer's instructions. Luminescence readings obtained with the Bright-Glo-Luciferase assay system were background-subtracted and are presented as relative light units (RLU/well). For the luciferase assay with the Luciferase Assay System, the cells were lysed with 0.1 mL/well of Passive Lysis Buffer (Promega) and used for both luciferase analysis and RNA extraction as mentioned below. Luminescence readings obtained with the Luciferase Assay System were background-subtracted and normalized by protein concentrations and were presented as RLU/μg protein. Protein concentrations were determined by the BCA protein assay (Pierce) according to the manufacturer's instruction.

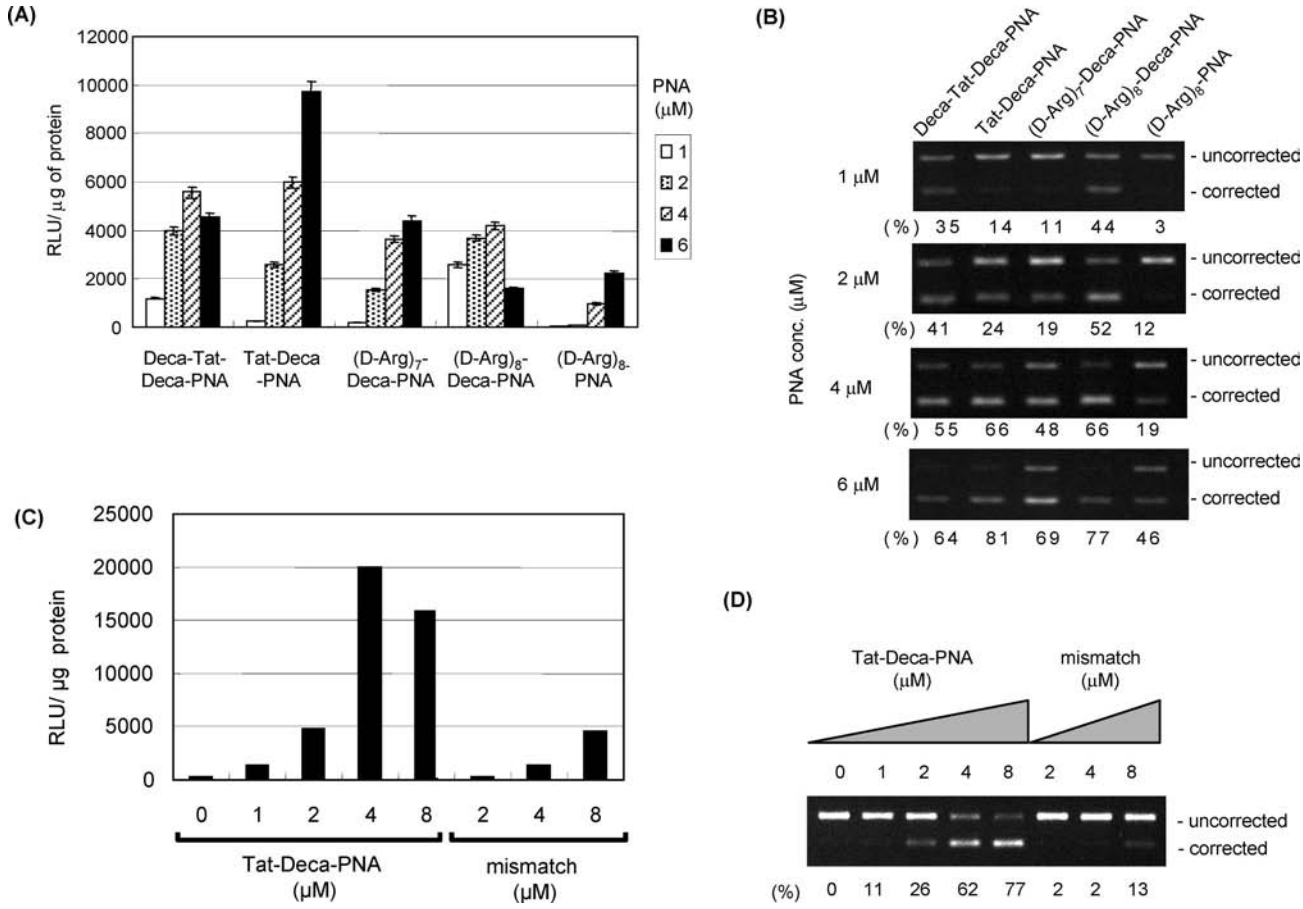

Figure 4. Relative cellular luciferase antisense activity in HeLa pLuc705 cells of PNAs conjugated to a cell penetrating peptide ((D-Arg)$_7$-, (D-Arg)$_8$-, or Tat-) and/or a decanoic acid (attached to the ε-amino group of a lysine). The cells were treated as described in Figure 1. Then cells were subjected to the further analysis. (A and B) PNAs (Deca-Tat-Deca-PNA (PNA2821), Tat-Deca-PNA (PNA2534), (D-Arg)$_7$-Deca-PNA (PNA2801), (D-Arg)$_8$-Deca-PNA (PNA2802), and (D-Arg)$_8$-PNA (PNA2787)) were used at the indicated concentrations (0−6 μM). (A) Luciferase activity was measured by Luciferase assay system (Promega), normalized to protein concentration and given as RLU/ μg of protein. (A) RT-PCR analysis of the splicing correction of pre-mRNAs by PNAs. Total RNA was extracted from the cells after the PNA treatment and subjected to RT-PCR analysis. Uncorrected indicates the 268 bp fragment without mis-splicing correction, and corrected indicates the 142 bp correctly spliced fragment. Numbers under each lane indicate the amount of the corrected form relative to the sum of corrected form and uncorrected form. (C and D) Comparison of Tat-Deca-PNA (PNA2534) with its mismatch PNA (mismatch, PNA2752). PNAs were used at the indicated concentrations (0−8 μM). Analysis was performed as described in (A and B). (C) Luciferase activity was measured and normalized to protein concentration. (D) RT-PCR analysis of mis-splicing correction by PNAs.

Cytotoxicity Test. Cells in 96 well plates were subjected to the MTS assay for cell viability test by using the CellTiter 96 Aqueous Non-Radioactive Cell Proliferation Assay (Promega) according to the manufacturer's instructions. The absorbance is presented as relative cellular viability (absorbance from non-PNA treated cells was set as 100%).

RT-PCR. Total RNA was extracted from the cellular lysate (see the luciferase assay section) by using RNeasy Mini kit (Qiagen) and subjected to RT-PCR analysis. A total of 3 ng RNA was used for each RT-PCR reaction (20 μL). RT-PCR was performed by using OneStep RT-PCR kit (Qiagen) following the manufacture's instructions. Primers for the RT-PCR were as follows: forward primer, 5′-TTGATATGTGGATTTC-GAGTCGTC-3′; reverse primer, 5′-TGTCAATCAGAGT-GCTTTTGG-CG-3′. The RT-PCR program was as follows: [(55 °C, 35 min) × 1 cycle, (95 °C, 15 min) × 1 cycle, (94 °C, 0.5 min; 55 °C, 0.5 min; 72 °C, 0.5 min) × 29 cycles]. RT-PCR products were analyzed on 2% agarose gel with 1× TBE buffer and visualized by ethidium bromide staining. Gel images were captured by ImageMaster (Pharmacia Biotech) and analyzed by UN-SCAN-IT software (Silk Scientific corporation).

Confocal Microscopy. Exponentially growing HeLa pLuc705 cells were plated in 8 well Laboratory-Tek Chambered Coverglass (Nunc) at a cell density of 5×10^4 cells/well the day before transfection. Following 16−24 h incubation, the cells were treated with PNA by incubation in OPTI-MEM medium (0.25 mL/well) containing the fluorescein-labeled PNA at the desired concentration and 20 μg/mL Alexa Fluor 633-conjugated human transferrin (80 kDa, Molecular Probes) for 4 h. Then the cells were incubated further for 20 h after supplement of RPMI 1640 growth medium containing 20% FBS (0.25 mL/well). Subsequently, the cells were washed with Hank's solution and subjected to microscopy analysis in this solution using a MultiProbe 2001 laser scanning confocal system equipped with an argon laser and a red laser diode (excitation wavelength 488 and 638 nm, Radiance2000, BioRad) connected to a Nicon eclipse TE200 microscope (oil immersion 60× 1.4 NA objective, Nikon, Tokyo, Japan). The *Lasersharp 2000* software package (BioRad) was used for image acquisition and processing.

Flow Cytometry. Exponentially growing HeLa pLuc705 cells were plated in 24 well plates at 1.0×10^5 cells/well the day before PNA treatment. After 16−24 h incubation, the cells were treated with fluorescein-labeled PNA as described above. After 24 h, the cells were washed twice with phosphate buffered saline (PBS) containing 1% BSA and collected by pipetting from the BSA/PBS solution. Then the cells were filtered with the cell strainer (70 μM, BD falcon) and subjected to flow cytometric analysis (10 000 events for each samples) using a BD FACS-

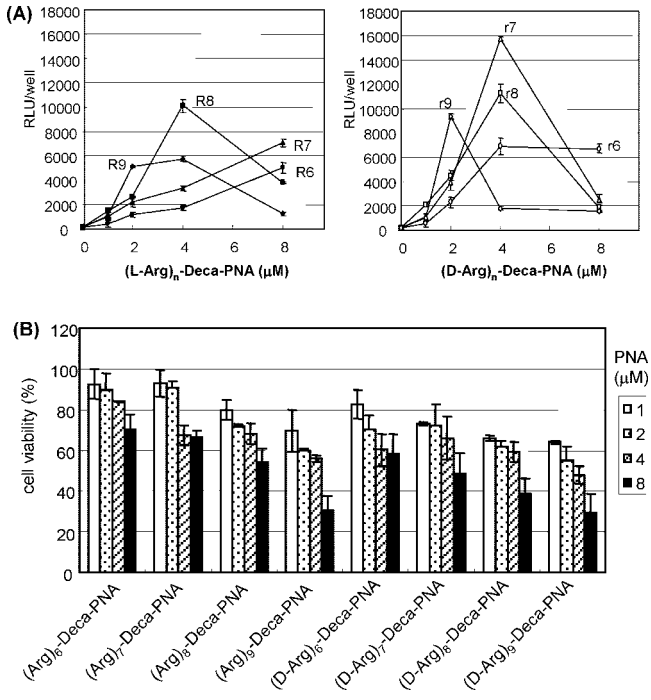

Figure 5. Relative cellular luciferase antisense activity in HeLa pLuc705 cells of PNAs conjugated to decanoic acid and different L-arginine or oligo D-arginine peptides: PNAs 2591 (R6, $(Arg)_6$-Deca-PNA), 3100 (R7, $(Arg)_7$-Deca-PNA); 3101(R8, $(Arg)_8$-Deca-PNA); 2592 (R9, $(Arg)_9$-Deca-PNA); 2739 (r6, $(D\text{-}Arg)_6$-Deca-PNA); 2801 (r7, $(D\text{-}Arg)_7$-Deca-PNA); 2802 (r8, $(D\text{-}Arg)_8$-Deca-PNA), and 2740 (r9, $(D\text{-}Arg)_9$-Deca-PNA) were used. Experimental details as in Figure 1. All tests were performed in triplicate and the results are given as the average values ± standard deviations (SD). (A) Luciferase activities were analyzed by Blight-Gro reagent (Promega) and given as relative light units (RLU/well). (B) Cellular viability was analyzed by the MTS-assay (Promega) and the data were normalized to the average value of non-PNA-treated sample.

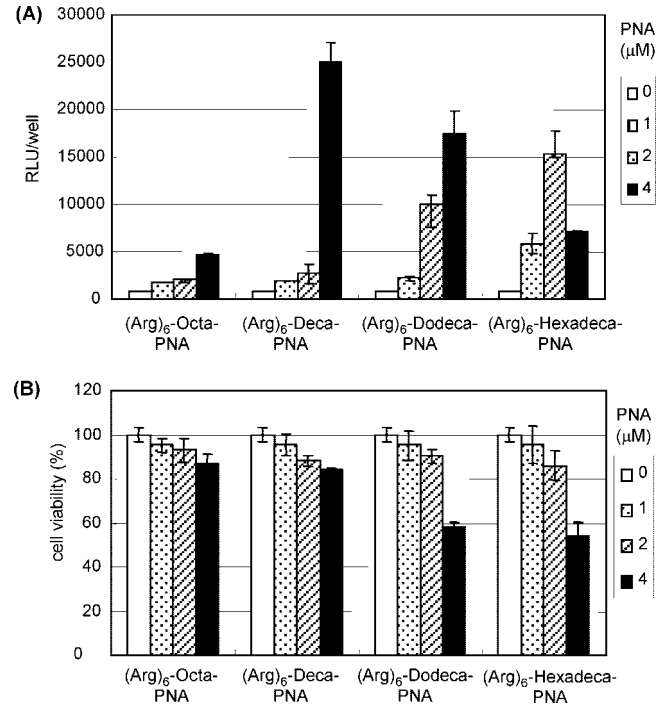

Figure 6. Relative cellular luciferase antisense activity and cellular toxicity in HeLa pLuc705 cells of hexaarginine-PNAs conjugated to different fatty acids (octanoic acid, decanoic acid, dodecanoic acid, or hexadecanoic acid) for the cellular uptake and the cellular toxicity in the HeLa pLuc705 ells. Experimental details as in Figure 1 using PNAs 2646 ($(Arg)_6$-Octa-PNA), 2591 ($(Arg)_6$-Deca-PNA), 2647 ($(Arg)_6$-Dodeca-PNA), and 2648 ($(Arg)_6$-Hexadeca-PNA). All tests were performed in triplicate and the results are given as the average values ± standard deviations (SD). (A) Luciferase activity was analyzed by Blight-Gro reagent (Promega) and is presented as relative light units (RLU/well). (B) Cellular viability was analyzed by MTS assay (Promega) and the data normalized to the average value of non-PNA-treated sample.

Calibur cytometer, and the mean fluorescence signal was calculated by *CellQuest* software.

RESULTS

The Tat peptide belongs to the group of cell penetrating peptides that was originally introduced for cellular delivery (*13*) and for which it has subsequently been shown that, although cellular uptake is quite efficient, this is almost exclusively via an endosomal pathway (*19*, *21*). Thus antisense PNA−Tat conjugates show only very limited activity in cell culture (*17*). However, the activity is dramatically enhanced by endosome disruption agents such as chloroquine (*26*) or lipophilic photosensitizers (*29*), as well as by calcium ions (*26*). Therefore we chose to prepare antisense PNA-Tat-fatty acid conjugates targeted to the aberrant splice site in the engineered luciferase gene in pLucHeLa 705 cells. This antisense assay yields a positive readout (luciferase activation) that is readily quantified with high sensitivity (*33*, *34*), and therefore allows reliable and quantitative comparison of different delivery methods (for antisense agents) (*9*, *11*).

The results presented in Figure 1 clearly demonstrate that while the PNA−Tat conjugate shows only very weak antisense activity in this assay, the analogous conjugate containing a decanoic acid attached to the ε-amino group of a lysine (Tat-Deca-PNA) is dramatically more active. Thus, at 2, 4, and 8 μM, the PNA−Tat conjugate induced luciferase activities of 80, 165, and 2832 RLU; while the corresponding values for the Tat-Deca-PNA were 1275, 11 696, and 22 747, respectively. The activity is further enhanced by having two decanoic acids in the conjugate (Deca-Tat-Deca-PNA) resulting in a luciferase activity of 14 310 at 2 μM—more than 150 times higher than that found for the pure Tat−PNA conjugate at this concentration. However, increased cellular toxicity is observed for the Tat−fatty acid conjugates and this is especially pronounced for the difatty acid compound. Thus, at higher concentrations (4 and 8 μM) the luciferase activation by this conjugate is markedly reduced, due to cellular toxicity. The control fatty acid−PNA conjugate (Deca-PNA) showed no activity.

In order to address whether conjugation of a lipophilic moiety (a fatty acid) to a cationic cell penetrating peptide domain could be a general principle to obtain increased cellular bioavailability we made a series of PNA conjugates based on oligo-arginines. The results presented in Figure 2 show that although hepta- and octa-arginine PNA conjugates as reported previously (*17*) show significantly higher antisense activity than the PNA−Tat conjugate, the activity is further enhanced several fold by fatty acid conjugation, and this enhancement is more pronounced at lower concentrations (1 and 2 μM), but is not seen at 8 μM due to increased toxicity of the fatty acid conjugates (Figures 2 and 5A,B). We also note that although the Tat-Deca-PNA conjugate is slightly less active than the Arg-Deca-PNA conjugates at lower concentrations, it exhibits the highest activity at 8 μM because of lower toxicity. The results also show that the position of the fatty acid relative to the peptide (amino terminal (e.g., Deca-$(D\text{-}Arg)_7$-PNA) or C-terminal between the peptide and the PNA (e.g., $(D\text{-}Arg)_7$-Deca-PNA) does not seem of major importance for activity.

In order to trace the intracellular path of the CatLip PNA a series of experiments were performed using fluorescein labeled

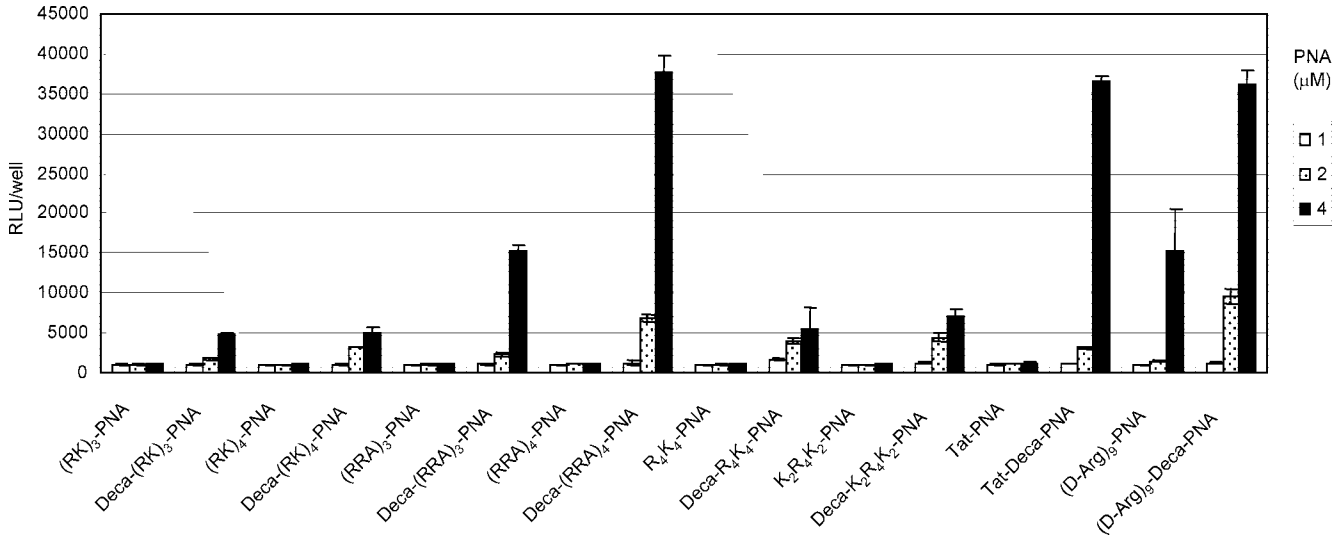

Figure 7. Relative cellular luciferase antisense activity in HeLa pLuc705 cells of PNAs conjugated to a cell penetrating peptide (CPP) or conjugated to both CPP and a decanoic acid. Experimental details as in Figure 1 using PNAs $(RK)_3$-PNA, Deca-$(RK)_3$-PNA, $(RK)_4$-PNA, Deca-$(RK)_4$-PNA, $(RRA)_3$-PNA, Deca-$(RRA)_3$-PNA, $(RRA)_4$-PNA, Deca$(RRA)_4$-PNA, R_4K_4−PNA, Deca-R_4K_4−PNA, $K_2R_4K_2$−PNA, Deca-$K_2R_4K_2$−PNA, Tat-PNA, Tat-Deca-PNA, $(D\text{-Arg})_9$-PNA, $(D\text{-Arg})_9$-Deca-PNA). Luciferase activity was analyzed by Blight-Gro reagent (Promega) and are presented as relative light units (RLU/well). All tests were performed in triplicate and the results are given as the average values ± standard deviations (SD).

octa-arginine PNA conjugates in combination with FACS and fluorescence microscopy analyses. These experiments first of all demonstrate that the lipophilic domain significantly increases the cellular attachment and possibly the uptake of, in this case, the PNA as indicated from the increased intracellular fluorescence observed by confocal fluorescence microscopy (Figure 3A), and quantitatively confirmed by FACS analysis (Figure 3B,C). However, it is quite clear from the fluorescence micrographs that the major part of the fluorescence still appears associated with endosomes, although some increase in diffuse cytoplasmatic and nuclear fluorescence may be present. Therefore, these results would indicate that the enhancing effect of the lipophilic domain on the nuclear antisense activity has contributions from both an increase in cellular (endosomal) uptake as well as a more favorable intracellular distribution with (slightly) reduced endosomal confinement, although even for these improved conjugates, most of the uptake is still within endosomal entrapment (*vide infra*).

The luciferase activity reading is a secondary effect from the molecular event of splicing redirection by the PNA, and we therefore found it important to verify the antisense effect directly at the mRNA level. The results show a very good correlation between the luciferase activity (Figure 4A) and the relative amount of correctly spliced luciferase mRNA (Figure 4B) at PNA concentrations up to 4 μM. However, at 6 μM where toxicity becomes a limiting factor and where the luciferase readings are reduced for two of the conjugates (Deca-Tat-Deca-PNA and $(D\text{-Arg})_8$-Deca-PNA), the RNA data shows increased relative correction activity also for these two PNAs, indicating an expected dose response on splice correction in spite of a decreased amount of total mRNA due to general toxicity.

The RNA data also confirm the strong enhancement exerted by the lipid moiety. Thus at 1 μM a relatively efficient peptide such as $(D\text{-Arg})_8$ only promotes 3% splicing correction when conjugated to the PNA, while $(D\text{-Arg})_8$-Deca-PNA under similar conditions promotes 44% splicing correction, corresponding to more than 10-fold enhancement. At higher concentrations the relative enhancement decreases gradually to less than 2-fold at 6 μM (Figure 4B). The CatLip conjugates are amphiphiles and thus most probably shall form micelles at a well defined cmc (critical micelle concentration). If micelle formation was instrumental for delivery efficiency, a clear concentration threshold (cooperative) effect would be expected. However, the data (e.g., Figure 5) do not specifically support such an effect, although some experiments may hint at nonlinearity of the dose dependence (e.g., Figures 1and 4). Thus more elaborate dose response studies are warranted to specifically address the issue of possible micelle formation by the conjugates and the eventual importance of such putative micelles on cellular uptake and also on toxicity. In this context it is also worth noting that toxicity of the conjugates does appear to be correlated to disruption of the cell membrane integrity as assayed using propidium iodide staining (Supporting Information) (which very much parallel the MTS toxicity assay), thereby indicating a direct physical membrane disturbance by the amphiphilic CatLip conjugates.

As a control for the sequence specificity of the antisense effect we synthesized a double base pair mismatch derivative of identical base composition (two base interchange) of the Tat-Deca-PNA and tested this. As expected, this PNA exhibited dramatically reduced activity both in terms of luciferase activity as well as in terms of mRNA correction activity (Figure 4C,D).

A comparison between D-Arg and L-Arg conjugates (Figure 5A) shows slightly higher activity of the non-natural D-form, clearly arguing against the involvement of specific receptor interactions of the peptide. These data also stress the very fine balance between uptake and toxicity. At 2 μM the activity increases with increasing number of arginines, but as the concentration increases, this order changes as the conjugates of the longer oligo-arginines are relatively more toxic than those of the shorter ones. Finally, the D-Arg conjugates show higher antisense activity but in parallel are also more toxic to the cells (Figure 5B).

This delicate activity/toxicity balance is further illustrated when analyzing the effect of the length of the fatty acid. For this experiment we chose the less active and less toxic hexa-arginine conjugate (Figure 6). Clearly, at lower PNA concentrations (up to 2 μM) the conjugates with longer fatty acid tails are the more active, but as the dodeca- and hexadeca- conjugates are clearly more toxic than the deca- conjugate, the latter shows the highest activity at 4 μM. Thus increased fatty acid length, and thus lipophilicity, produces more potent antisense agents but also compounds of higher cellular toxicity, and decanoic acid appears as a good compromise. A small series of arginine-rich peptides were tested for enhancement by fatty acid acylation

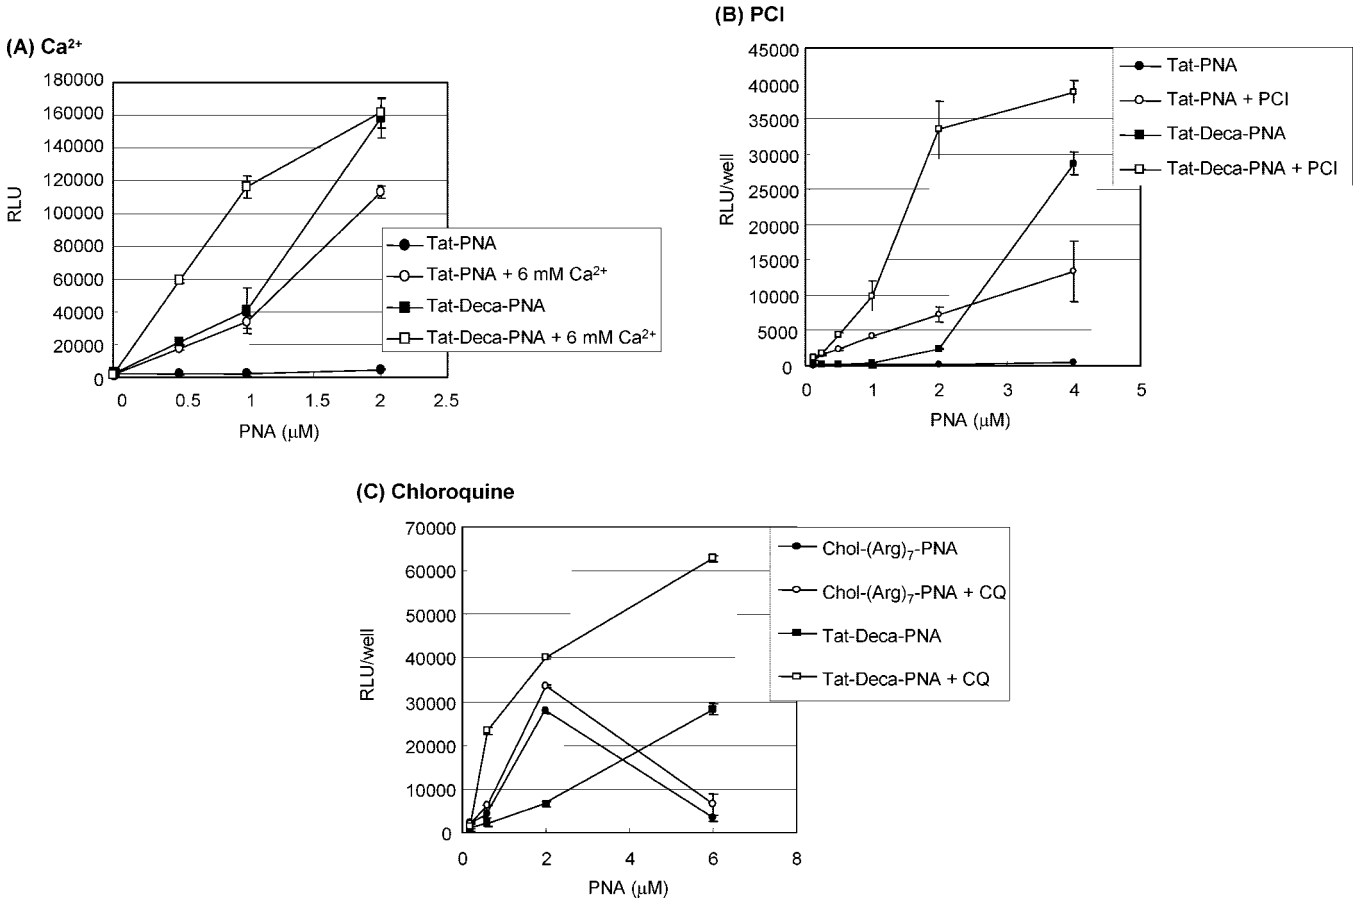

Figure 8. Effects of the endosome disruption agents on the cellular luciferase antisense activity in HeLa pLuc705 cells of PNA conjugates. HeLa pLuc705 cells (plated in the 96 well plate) were treated with the PNA in combination with one of the endosome disruption treatments (chloroquine (CQ), photochemical treatment (PCI) or Ca^{2+} treatment) and subjected to luciferase analysis. Luciferase activity was analyzed by Blight-Gro reagent (Promega) and are presented as relative light units (RLU/well). All tests were performed in triplicate and the results are given as the average values ± standard deviations (SD). (A) Cells were treated with the PNA (Tat-PNA, Tat-Deca-PNA) in combination with the Ca^{2+} treatment. For the Ca^{2+} treatment, cells were incubated with the PNA for 4 h in OPTI-MEM medium containing 6 mM Ca^{2+} and incubated further for 24 h after addition of the serum-containing growth medium without removing the OPTI-MEM medium. (B) Cells were treated with the PNA (2395, Tat-PNA; 2534, Tat-Deca-PNA) in combination with PCI treatment. For the administration of the photosensitizer, cells were incubated with 5 μg/mL $AlPcS_{2a}$ in the growth medium for 16−24 h before being subjected to the PNA treatment. Cells were then treated with the PNA for 4 h in OPTI-MEM medium and incubated further for 4 h after the replacement of the PNA solution with fresh serum-containing growth medium. Then cells were subjected to 10 min red light irradiation and incubated further for 24 h before being subjected to the luciferase analysis.

as illustrated by the data presented in Figure 7. It is clear that for all conjugates the acylated form exhibits superior activity relative the nonacylated form, but it is also noteworthy that the relative enhancement differs significantly for the various peptides as already demonstrated by the difference between the Tat and oligo-arginine conjugates. In particular, the very dramatic enhancement (up to 2 orders of magnitude) of the $(Arg\text{-}Arg\text{-}Ala)_4$ conjugate upon fatty acid conjugation is interesting in terms of the molecular mechanism(s) of the cellular uptake as this conjugate resembles the behavior of the Tat peptide more than that of the oligo-arginines. These data indicate a clear possibility for optimizing the peptide-fatty acid (CatLip) moiety in terms of delivery/toxicity ratio.

We have previously found that the antisense activity of CPP−PNA conjugates is significantly augmented in the presence of submillimolar concentrations of chloroquine or millimolar concentrations of calcium ions (*26*) or by photochemical internalization (PCI) using photosensitizers (*29*), agents that all promote endosome disruption. In order to address whether these agents could also enhance the effect of the fatty acid conjugates, we studied the effect of chloroquine, Ca^{2+}, and PCI treatment on the antisense activity of the Tat-Deca-PNA conjugate. In all cases a significant enhancement was observed especially at lower concentrations (Figure 8). However, the relative enhancement is much more pronounced for the Tat-PNA (10−25-fold) than for the Tat-Deca-PNA (1−15-fold) (Figure 8A), possibly indicating that the fatty acid moiety is facilitating endosomal escape or is supporting a nonendosomal pathway for uptake. Interestingly, we note that a CatLip construct based on a cholesterol ester (PNA 3016) which exhibits considerably higher antisense activity than the Tat−decanoic acid conjugate (PNA 2534) (but also higher cellular toxicity) is not enhanced by chloroquine (Figure 8C). Further studies are needed to determine whether this very interesting behavior is due to a nonendosomal route of entry or to efficient endosomal escape by this type of CatLip conjugates.

CONCLUSIONS

The present results clearly demonstrate that the nuclear antisense activity of PNA oligomers can be dramatically enhanced by conjugation to a CatLip domain consisting of a cationic peptide and a fatty acid, and that this enhancement (dependent on the specific peptide) is up to 2 orders of magnitude higher than that obtained by using the peptide alone. The antisense effect of the CatLip PNAs is further enhanced by endosome disruptive agents but the enhancing effect is significantly less than that seen for the corresponding PNA−peptide conjugates, thereby giving a clear indication that part, but not all, of the effect of the lipophilic domain is due to facilitation of endosomal escape. Obviously the lipophilic

domain supports the interaction of the PNA conjugates with the cellular (and endosomal) membranes and most likely contributes to membrane destabilization (as also indicated by the increased cellular toxicity of these conjugates), which could also facilitate nonendosomal, direct passage through the membrane. Increased cellular association was indeed observed through FACS and fluorescence microscopy analyses. These experiments also illustrate that even for the most effective CatLip conjugates a major part of the antisense agent was still trapped in endosomes and increased activity could be obtained using endosome releasing agents such as chloroquine. The cholesteryl conjugate (which also exhibit high toxicity) could be an example of a conjugate for which the endosomal route is not the more significant one. Clearly, the present results open the door to a new family of drug delivery conjugates, and further studies will reveal the interplay between different (peptidic as well as nonpeptidic) cationic domains and lipophilic domains in terms of cellular delivery potency, mechanism(s) of cellular entry and toxicity in various cell types. Furthermore, the behavior of such conjugates for increasing the *in vivo* bioavailability of potential drugs could be very interesting. Finally, there is little doubt that the delivery properties of CatLip domains may be optimized far beyond the limited examples studied so far.

ACKNOWLEDGMENT

This work was supported by the Lundbeck Foundation, The Danish Cancer Foundation and the European Commission (6th FP EMIL and SNIPER contracts LSHC-CT-2004−503569 & LSHB-CT-2004−005204). The authors would like to acknowledge Dr. Anders E. Pedersen for help with flow cytometry, Dr. Darya Kiryushko for help with confocal laser microscopy, and Ms. Jolanta Ludvigsen and MSc. Nadia Bendifallah for synthesizing the PNA conjugates.

Supporting Information

PNA cellular uptake studies with propidium iodide (PI) counter staining. For uptake analysis, exponentially growing HeLa pLuc705 cells were plated in 4-well chamber slides (Nunc) the day before treatment. The cells were treated with the fluorescein-labeled PNA (Fl-CPP-PNA(3266), Fl-CL-PNA(3265)) by incubating with the PNAs (0.6, 2 and 6 μM) in OPTI-MEM medium (serum free) for 4 h and further 20 h after adding the equal volume of growth medium (including 20% FBS) without removing the PNA solutions. After 24 h the cells were counter stained with 1 μg/ml PI for 10 min at 37 ^{o}C before subjected to microscopy. Living cells (without fixation) were visualized using a fluorescence microscope (DIALUX 22EB, LEITZ WETZLAR (Germany)) at 500x magnification with appropriate filter blocks (I2/3 and N2 respectively for PI and FITC).

[a)]The sequences of cell-penetrating peptides are written using the standard one-letter amino acid symbols. The sequences of PNA conjugates are written from N-terminal-end to C-terminal –end. eg1 (8-amino-3,6-dioxaoctanoic acid) is an ethylene glycol linker. [b)]98 corresponds to single peak; 95 corresponds to single peak with slight foot; 90 corresponds to single peak with slight foot and/or shoulder peak; 75 corresponds to single peak with significant foot and/or shoulder/satellite peaks; # the HPLC analysis showed a close, sharp double peak, whereas the MALDI analysis showed only one signal of the expected mass. [c)] Flk is a monomer with fluorescein (Fl) attached to the ε-amino group of a lysine residue (Lohse J, Nielsen PE, Harrit N, Dahl O *Bioconjugate Chemistry* 1997, 8: 503-509.).

Octa-Substituted Anionic Porphyrins: Topoisomerase I Inhibition and Tumor Cell Apoptosis Induction

Baoping Zhai,[†,‡] Li Shuai,[†,‡] Li Yang,[‡] Xiaocheng Weng,[‡] Lin Wu,[‡] Shaoru Wang,[‡] Tian Tian,[‡] Xiaojun Wu,[‡] Xiang Zhou,*[,‡,§] and Congyi Zheng[§]

College of Chemistry and Molecular Sciences, State Key Laboratory of Virology, and School of Life Science, Wuhan University, Hubei, Wuhan 430072, PR China. Received December 17, 2007; Revised Manuscript Received March 30, 2008

β-Octabromo-*meso*-tetra(4-carboxyl)phenyl porphyrin **6** and β-octaphenyl-*meso*-tetra(4-carboxyl)phenyl porphyrin **8** were synthesized and fully characterized by ^{1}H NMR, UV, and HRMS. Their cytotoxicities to tumor cells were tested using MTT assays. One kind of tumor cell apoptosis induced by these anionic porphyrins under irradiation was examined by flow cytometric analysis. The inhibition of Topo I (Topoisomerase I) indicates that Topo I preferentially binds to the synthesized compounds, thus blocking the interaction between Topo I and DNA. The results implied that compounds **4**, **6**, and **8** are potential inhibitors to Topo I, which might be one of the important factors inducing apoptosis of tumor cells.

INTRODUCTION

Porphyrins have found wide application in catalysis, materials, and medicine (*1–6*) because of their physical, chemical, and biological properties. When porphyrin molecules are modified by the use of peripheral substitutents, they could show very interesting functions due to the change in electronic and steric properties (*7–9*). Therefore, the substitution at β-positions is of extraordinary importance. It has been found that substitutents at the β-positions of porphyrins exert much larger steric and electronic effects on the porphyrin ring than substiutents at the *meso*-aryl positions. What's more, β-substitutents can induce the porphyrin ring into a nonplanar conformation, which might mimic control of the the biological properties in tetrapyrrole systems like the photosynthetic centers, vitamin B12 and P-450 (*10–12*).

Since Fiel and collaborators studied the interaction between porphyrins and nucleic acid (*13*), a variety of porphyrins have been synthesized and their abilities to bind to DNA have been confirmed (*14–16*). Several kinds of porphyrins have been found to induce cell apoptosis (*17*). Nevertheless, so far most reported works concerning either the interaction between porphyrins and DNA or the induction of tumor cell apoptosis are chiefly concentrated on cation porphyrins such as TMPyP (tetra-(4-*N*-methylpyridium)porphyrin). In fact, as is proven in previous work, negatively charged porphyrins are more membrane permeable than cation porphyrins, which makes the porphyrin molecules biologically more active (*18*). Recently, Vicente and co-workers (*19*) have reported the cellular uptake and animal toxicity of a anionic porphyrin, tetra(carboranylphenyl)-tetrabenzoporphyrin. Their results suggest that anionic porphyrins might have more favorable abilities to interact with tumor cells. In this paper, we have designed and synthesized a series of anionic porphyrins with β-octabromo or β-octaphenyl substitution; meanwhile, carboxyl groups are introduced onto the *meso*-aryl positions. Some initial studies on the inducement of tumor cell apoptosis by the synthesized compounds have also been carried out. The results reveal that the inhibition of topoisomerase I activity by the synthesized compounds might be one of the key points to tumor cell apoptosis, which is in accord with the reported fact that DNA topoisomerases are responsible for cell death via the apoptosis pathway (*20, 21*).

EXPERIMENTAL PROCEDURES

Synthesis of Test Compounds. Desired compounds were synthesized according to the procedures shown in Scheme 1. Compound **5** was synthesized with reference to Day's report (*8*). The synthesis of β-octasubstituted-*meso*-tetra-(4-carboxyl)phenyl porphyrin **6** and **8** was involved in Suzuki coupling chemistry starting from β-octabromoporphyrin. Porphyrins **3** (*22*) and **4** (*23*) were obtained from mixing methyl 4-formylbenzoate **1** or 4-carboxybenzaldehyde **2** and pyrrole in refluxing propionic acid with yields of 22.4% and 10.5%, respectively. β-Octabromo-substituted porphyrin **5** was prepared from porphyrin **3**. Porphyrins **6** and **8** were traced by HPLC (Supporting Information, Figure S1).

Synthesis of β-octabromo-*meso*-tetrakis (4-carboxyphenyl)porphyrin methyl ester (**5**). Porphyrin **3** (400 mg, 0.47 mmol) was dissolved in 150 mL of chloroform followed by the addition of $Cu(OAc)_2 \cdot H_2O$ (760 mg, 3.81 mmol, 8 equiv). The reaction mixture was stirred at reflux for 30 min. After complete conversion to copper porphyrin as detected by TLC, 4 mL liquid Br_2 was added to the reaction mixture directly. The solution was continually stirred for about 1 day at room temperature. Aqueous solution of sodium thiosulfate was added to quench the reaction. After removal of the excessive bromine, the reaction mixture was washed by H_2O several times, and then 30 mL of perchloric acid was added to the solution. The reaction mixture was stirred for about 12 h for demetallization. The organic layer was separated and washed with aqueous and a solution of sodium bicarbonate and water, and dried over anhydrous Na_2SO_4. The organic mixture was rotary-evaporated to give a solid. The crude product was purified by column chromatography on silica gel using chloroform/ethyl acetate 60:1 as eluent to give porphyrin **5** (478 mg, 68.4% yield). ^{1}H NMR

Synthesis of β-octaphenyl-*meso*-tetrakis(4-carboxyphenyl)porphyrin methyl ester (**7**). A 100 mL Teflon-stoppered flask was charged with porphyrin **5** (400 mg 0.27 mmol), $PhB(OH)_2$ (656 mg, 5.4 mmol, 20 equiv), $(Ph_3P)_4Pd$ (96 mg, 0.08 mmol, 0.3 equiv), anhydrous K_2CO_3 (1500 mg, 10.8 mmol, 40 equiv), DMF (6 mL), and toluene (54 mL). The brown suspension was degassed by the freeze−pump−thaw method (three cycles), and then was heated at 90−100 °C under N_2 for 7 days. The reaction mixture was worked up by extracting with 50 mL $CHCl_3$ and washed with water and brine. The organic layer was dried over anhydrous Na_2SO_4 and rotary-evaporated to dryness. The crude product was purified by column chromatography on silica gel using chloroform/ethyl acetate 20:1 as eluent to give porphyrin **7** (208 mg, 52.9% yield). ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm), 7.63−7.60 (d, J = 7.2 Hz, 8 H), 7.40−7.37 (d, J = 9.1 Hz, 8 H), 6.69−6.67 (m, 40 H), 3.99 (s, 12 H). UV−vis ($CHCl_3$): λ_{max} (nm, log ϵ) = 467 (5.19), 562 (4.03), 611 (3.96). ESI HRMS for $C_{100}H_{70}N_4O_8$ [M^+ + H] calcd 1455.5266, found 1455.5310.

Synthesis of β-octabromo-*meso*-tetrakis(4-carboxyphenyl)porphyrin (**6**). Porphyrin **5** (30 mg, 0.02 mmol) was dissolved in 5 mL of THF and 3 mL of a 2 M aqueous solution of potassium hydroxide was added. The solution was stirred in a sealed flask at room temperature, for 3 days. The aqueous phase was collected and the pH lowered, using a 1 M solution of hydrochloric acid, until precipitation of the porphyrin. The precipitate was washed with water and dried under vacuum to

Synthesis of β-octaphenyl-*meso*-tetrakis (4-carboxyphenyl)porphyrin (**8**). Porphyrin **7** (36 mg, 0.025 mmol) was dissolved in 5 mL of THF and 3 mL of a 2 M aqueous solution of potassium hydroxide was added. The solution was stirred in a sealed flask at room temperature, for 3 days. The aqueous phase was collected and the pH lowered, using a 1 M solution of hydrochloric acid, until precipitation of the porphyrin. The precipitate was washed with water and dried under vacuum to give porphyrin **8** (32 mg, 92.1% yield). ^{1}H NMR ([d^6]-DMSO, 300 MHz): δ (ppm), 8.36 (s, 4 H), 7.41−7.38 (d, J = 9.0 Hz, 8 H), 7.22−7.19 (d, J = 9.0 Hz, 8 H), 6.70 (s, 40 H). Cell Incubation and Cell Survival Assay (*24*). The SGC7901 cells were obtained from China Center for type Culture Collection (CCTCC) and grown in MEM supplemented with 10% FBS (fetal bovine serum), incubated at 37 °C in a 5% CO_2, 95% air atmosphere, and were subcultured every two to three days as necessary. The cells (about 3×10^3) were added to a 96-well plate and incubated for 24 h at 37 °C in a 5% CO_2 incubator. Then, the as-synthesized porphyrins at various concentrations were added. After incubation for 4 h at 37 °C in a 5% CO_2 incubator, the cells were irradiated for 30 min by a 50 W high-pressure mercury lamp at a distance of 13 cm. Then, the cells were allowed to incubate for another 72 h. MTT formazan (10 μL, 5 mg/mL) was added to each well and incubated for another 4 h. The cells were centrifuged at 2000 rpm for 10 min, and then the medium was removed. With addition of 100 μL of DMSO to each well, the values of OD were detected at 570 nm. The cytotoxicity data were presented as IC_{50} values.

Flow Cytometric Determination of Apoptosis (*17*). The cells were cultured as above. 5×10^4 cells of each well were seeded in a 24-well plate. After 24 h, various concentrations of porphyrins were added and trireplicated. Then, the plate was irradiated for 30 min by a 50 W high-pressure mercury lamp. After 72 h, the cells of each well were harvested by using typsin. After centrifugation and being washed two times with PBS, these cells were fixed in an ice-cold 70% ethanol solution at −20 °C overnight. The 100 μL of suspended single cell solution in PBS were obtained by further centrifugation and washing. Sample wells prepared for the flow cytometry analysis were treated with RNase (1 mg/mL) for 30 min at 37 °C. The mixture was suspended in 1 mL of PBS solution containing propidium iodide PI (100 μg/mL). Then, the cells were incubated for 1 h at room temperature in the dark and analyzed on a flow cytometer (Beckmen Coulter Eltra flow cytometer). The linear DNA content data were analyzed by MultiCycle DNA Content and Cell Analysis software for cell cycle analysis. Cell apoptosis was measured as a sub-G0-G1 hypodiploid peak and indicated with the fluorescence intensity of FITC.

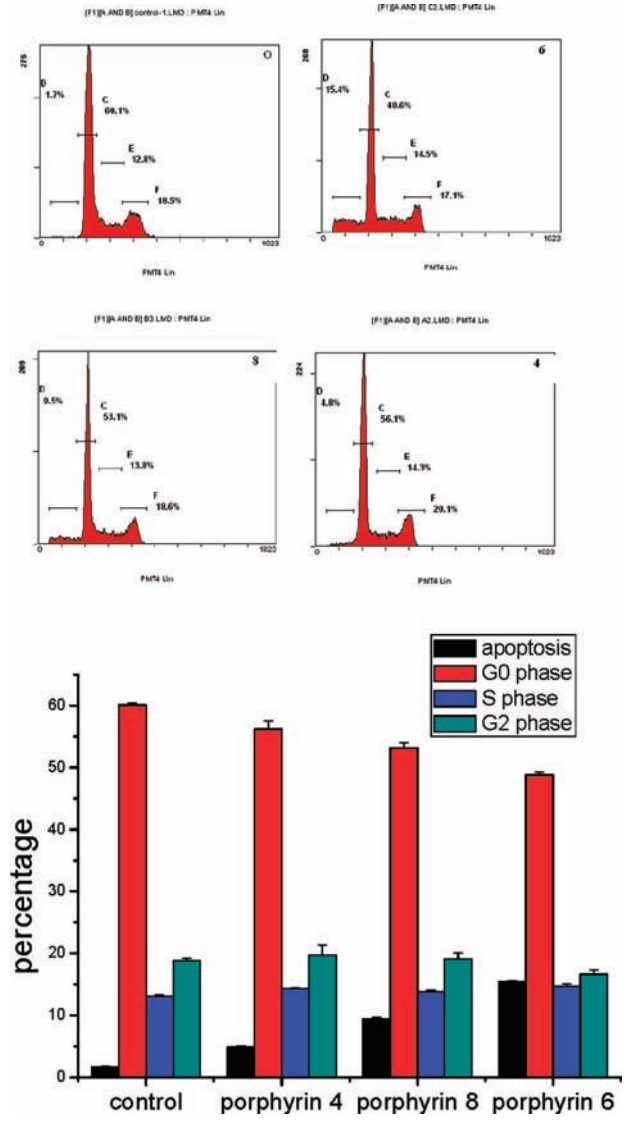

Figure 1. The histogram drug-induced cell cycle arrest and apoptosis of porphyrin (10 μM) in 7901 cells as measured by flow cytometric analysis. The *x*-axis is the DNA content and the *y*-axis is the number of cells with that fluorescence intensity. **6**, **8**, and **4** represent cells that were treated with 10 μM porphyrins **6**, **8**, and **4**, respectively, for 72 h (O is control) and irradiated by light for 30 min, respectively. The rate of apoptosis: 15.4 ± 0.15%, 9.5 ± 0.25%, and 4.8 ± 0.21%, respectively.

Assessment of Intracellular Caspase-3 Activity (*25*). The CaspGLOW Fluorescein Active Caspase-3 Staining Kit was used to monitor the intracellular caspase-3 activities according to the manufacturer's recommendations (Biovision, USA). The assay utilizes the caspase-3 inhibitor DEVD-FMK conjugated

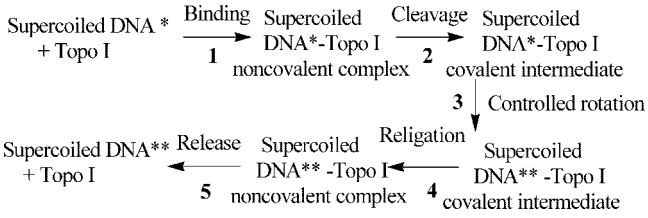

Figure 2. Mechanism of human topoisomerase I. * means the τ of this supercoiled DNA is n. ** means the τ of this supercoiled DNA is $n - 1$.

to FITC (FITC-DEVD-FMK) as the fluorescent in situ marker. FITC-DEVD-FMK is cell-permeable, nontoxic, and irreversibly binds to activated caspase-3 in apoptotic cells. The FITC label allows for direction of activated caspases in apoptotic cells by flow cytometry. The cells were cultured as above. 2×10^5 cells of each well were seeded in a 6-well plate. After 24 h, various concentrations of porphyrins were added and trireplicated. The cells were irradiated for 30 min by a 50 W high-pressure mercury lamp at a distance of 13 cm after incubation for 4 h at 37 °C in a 5% CO_2 incubator. The cells of each well were harvested by using typsin at given time intervals. Aliquots (300 μL) of each treatment were added into microtubes. With the addition of 1 μL of FITC-DEVD-FMK, the tubes were incubated for 0.5 h at 37 °C in an incubator with 5% CO_2. Cells were centrifuged at 3000 rpm for 5 min and supernatant was removed. The cells were then resuspended in 0.5 mL of wash buffer, and centrifuged again. For flow cytometric analysis, cells were resuspended in 500 μL of wash buffer. Samples were put on ice and analyzed by flow cytometry (Beckman-Coulter, Eltra flow cytometer) using the FL-1 channel.

Measurement of Relaxation Activity Topo I (*26*). Functional activity of Topo I[1] was assayed by relaxation of supercoiled plasmid DNA. Briefly, relaxation of 50 ng of supercoiled DNA pBR322 (0.1 U of Topo I) was performed in 10 μL of Topo I relaxation buffer (20 mM Tris pH 7.5, 0.1 mM Na_2EDTA, 10 mM $MgCl_2$, 50 mg/mL acetylated-BSA, 100 mM KCl) at 37 °C for 30 min in the presence or absence of the porphyrins dissolved in DMSO solution. Control groups were either DNA alone or DNA treated with Topo I only. Incubation at 37 °C for time course was terminated by addition of 0.5% (w/v) SDS and proteinase K. The mixtures were run in a 0.8% agarose gel. Gels were stained with ethidium bromide (EB) and visualized by UV and photographed using Vilber Lourmat video system.

Measurement of Topo I Mediated DNA Cleavage (*27*). With addition of excessive enzymes (i.e., 0.3 U of Topo I), topoisomerase I reactions were performed in topoisomerase I relaxation buffer at 37 °C for 30 min. Reactions were terminated with 0.5% (w/v) SDS. After digestion with proteinase K, open circular and linear DNA were separated from intact supercoiled and relaxed forms by agarose gel electrophoresis in the presence of 0.5 mg/mL of EB under the same conditions as for the relaxation assay. CPT was used as the reference drug.

Analysis of Binding with Topo I and pBR 322 (*28*). The supercoiled DNA pBR322 (50 ng) or the Topo I enzyme (0.2 U) was preincubated at 4 °C for 15 min in Topo I relaxation buffer with the indicated concentrations of compound **6**. Then, Topo I (0.2 U) or supercoiled DNA pBR322 (50 ng) was added and incubated with compound **6** for 30 min at 37 °C and analyzed on 0.8% agarose gels at 4.5 V/cm. The control shows the electrophoretic mobility of pBR 322 DNA alone.

Analysis of Topoisomerase−DNA Binding by Electrophoretic Mobility Shift Assay (EMSA) (*28*). During analysis of Topo I/DNA binding by EMSA, supercoiled DNA pBR322 was incubated with 0.3 U of topoisomerase I for 1 min at 37

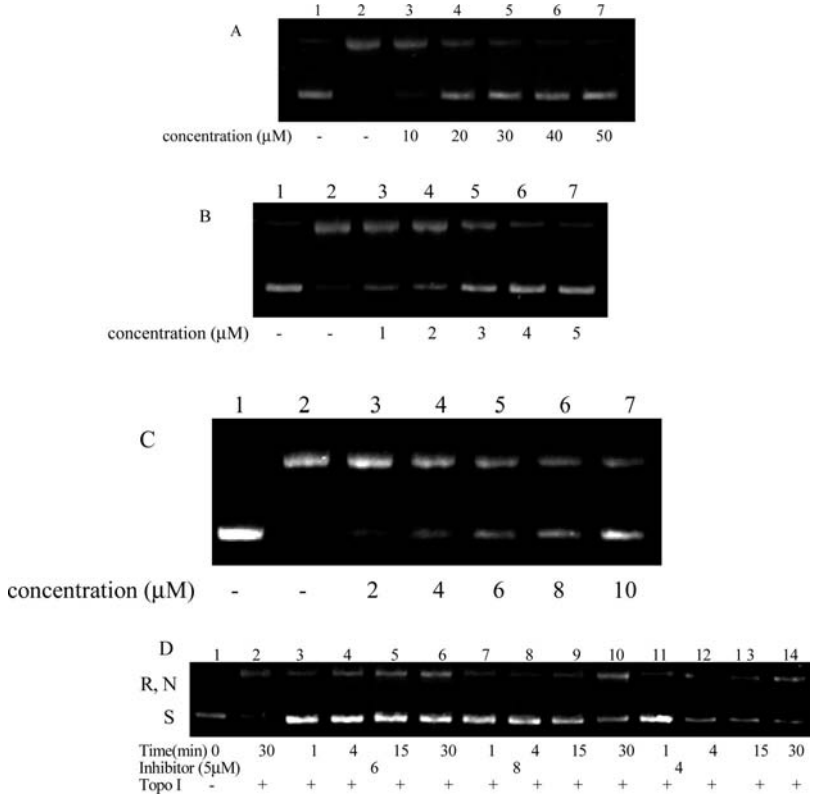

Figure 3. (A) The gradient agarose gel assays of compound **4**. (B) The gradient agarose gel assays of compound **6**. (C) The gradient agarose gel assays of compound **8**. (D) Activity inhibition of Topoisomerase I. Agarose gel electrophores from 1 to 30 min. Relaxed DNA (R) and nicked DNA (N) slowly migrate in the gel for a cell free DNA relaxation assay of a pBR322 DNA treated with Topo I inhibitors as compared to supercoiled DNA (S).

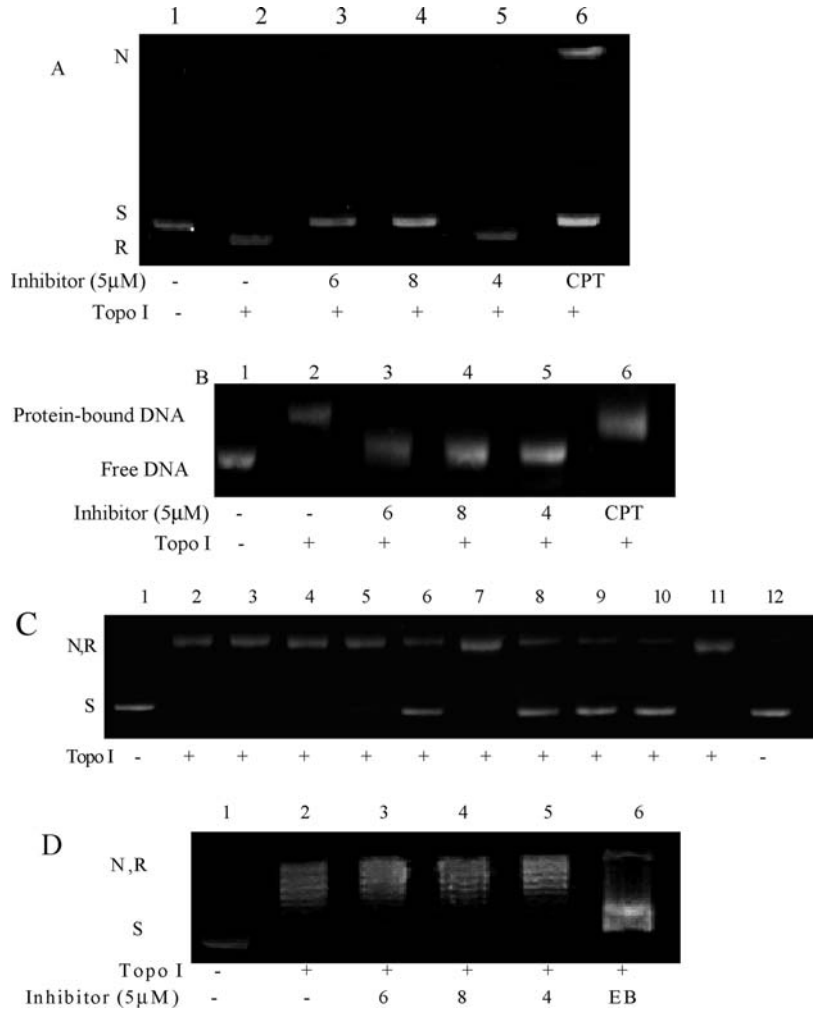

Figure 4. Mechanism of Topo I inhibition. (A) Representative image of agarose gel electrophoresis of the cleavage assay. pBR322 DNA (50 ng) was incubated in the presence of Topo I (0.1 U) and with or without Topo I inhibitors. Only CPT induced the formation of a slowly migrating complex formed by enzyme, drug, and DNA; whereas drug **6**, **8**, and **4** were unable to interfere. (B) Prevent binding of Topo I to substrate DNA. EMSAs of Topo I incubated with appropriate DNA are shown. Samples contained pBR322 DNA (50 ng), each inhibitor, and excess of topoisomerase I (0.3 U) to allow the strongest possible DNA shift. (C) Inhibition of Topo I catalyzed pBR 322 DNA relaxation by compound **6**. Relaxation of 50 ng of pBR 322 DNA by 0.2 units of human topoisomerase I was incubated with compound **6** for 30 min at 37 °C and analyzed on 0.8% agarose gels. The DNA−substrate (lanes 1 to 6) or the enzyme (lanes 7 to 12) were preincubated at 4 °C for 15 min with the indicated concentrations of compound **6**. (D) interaction of drug **6**, **8**, and **4** with DNA was measured in an unwinding assay. All experiments were repeated three times with similar results.

°C. SDS denaturation and proteinase K digestion were omitted. Samples were immediately loaded onto the 0.8% agarose gel with 0.5 mg/mL of ethidium bromide in TBE buffer and separated by electrophoresis for 6 h.

Measurement of DNA Intercalation (*29, 30*). DNA intercalation was measured with the unwinding assay. Supercoiled pBR322 DNA was relaxed with 0.3 U of Topo I at 37 °C for 10 min in Topo I relaxation buffer. To confirm full relaxation of DNA, the sample was terminated with SDS after 10 min. Porphyrins were added and the mixture was allowed to incubate for another 30 min. A parallel experiment ensured that Topo I retained its activity in the presence of the compounds used. The reaction was terminated by addition of 0.5% (w/v) SDS and followed by digestion with proteinase K as described above. Excess porphyrins were removed by extraction with chloroform/isoamyl alcohol (24:1). Reaction samples were loaded onto the 0.8% agarose gel. At this moment, EB was used as the reference.

CT DNA topoisomerase I (Topo I) (20 U/μL) and supercoiled pBR322 plasmid DNA were purchased from Toyobo (Osaka, Japan). Camptothecin (CPT) was purchased from Acros. Human gastric carcinoma cell line SGC7901 was obtained from China Center for Type Culture Collection (CCTCC).

RESULTS

Cell Survival Assay. For initial investigation, we chose tumor cell line 7901 as the target to study the anticancer abilities of the synthesized porphyrins. The effect of the compounds on proliferation of cancer cell lines was determined using the standard MTT assay under irradiation (*24*). All the stock solutions were dissolved in DMSO and diluted with water, and the final DMSO concentration is less than 0.1%. Results from MTT assay are shown in Table 1.

Cell Cycle and Apoptosis analysis. In further research, we investigated the effects of anionic porphyrins on the growth of tumor cells through cell cycle and apoptosis analysis. Normally, there is a cell cycle in the proliferation of cells. If the cell cycle was perturbed and was not successfully repaired by itself, the cell will go to death (necrosis or apoptosis). Apoptosis is a physiological "cell suicide" program, and is the normal pathway for clearance of defective or aged cells in the body (*31, 32*). It is also the key pathway in animal development (*33*). The

apoptosis analysis was conducted by flow cytometry assay staining with propidium iodide (Figure 1).

Assessment of Intracellular Caspase-3 Activity. Caspase-3 is a member of the cysteine aspartic-acid-specific protease family. As the enzyme takes part in the execution phase of programmed cell death, it plays a key role in early phases of apoptosis in mammalian cells (*34*). Therefore, the activity of the enzyme is an important biochemical indicator of the apoptosis procedure. We studied the enzymatic activity of caspase-3 in cells incubated with the synthesized compounds using the CaspGLOW Fluorescein Active Caspase-3 Staining Kit.

Inhibition of Topoisomerase I Activity. The mechanism of human Topo I (topoisomerase I) has been well-established, as is shown in Figure 2 (*35*). CPT (camptothecin) binds to the supercoiled DNA*−Topo I covalent intermediate after cleavage and inhibits subsequent religation. It means that CPT can inhibit step 4 in the procedure. Our results indicate that porphyrins **4**, **6**, and **8** could bind to free Topo I and subsequently inhibit the binding of the free enzyme to the DNA cleavage site, and thus prevent all following steps of the catalytic cycle. Such a hypothesis is supported by CT DNA (calf thymus DNA) Topo I activity in a cell-free system was evaluated with relaxation assay. We tested whether these compounds could inhibit Topo I relaxation activity of a supercoiled DNA pBR322. The experimental data are shown in Figure 3. Figure 3A,B,C are gradient agarose gel assays which show the inhibition of these compounds. The IC_{50} value for the inhibition of the catalytic activity of Topo I by **6**, **8**, and **4** were 2.34 μM, 3.40 μM, and 11.75 μM, respectively.

Mechanism of Interaction between Topo I and Porphyrins. It is known that Topo I is a single-stranded endonuclease and ligase. CPT, which is used as our control, is known to inhibit ligase without affecting the cleavage step (*36*, *37*). Therefore, CPT shows a slowly migrating complex, which is named a cleavable complex, formed with the enzyme and drug and DNA, As we have found that **4**, **6**, and **8** could inhibit Topo I activity, we try to understand their working sites of compounds **4**, **6**, and **8** either as pure catalytic inhibitors or as topoisomerase poisons, stabilizing the cleavable complex (*27*). Figure 4A shows that CPT could stabilize the Topo I cleavable complex, resulting in the generation of open-circle plasmid DNA (*28*). In contrast, open-circle DNA was not observed with **4**, **6**, or **8**.

These findings encouraged us to consider that **4**, **6**, and **8** might exert their effect on Topo I before DNA cleavage (*29*). To verify such a hypothesis, we performed the EMSA (electrophoretic mobility shift assay) experiments between supercoiled pBR322 DNA and Topo I and investigated the impact of these compounds on Topo I. We used CPT as a control, which inhibits the ligase activity without interfering with the binding of the enzyme to DNA. Figure 4B demonstrates that **4**, **6**, and **8** inhibit the formation of these enzyme−DNA complexes. In contrast, DNA binding of Topo I is not affected by CPT (Figure 4B, lane 6). These observations are inconsistent with the mechanism of CPT, and thus we suggested that drugs could interfere in the binding of Topo I to DNA (*30*).

DISCUSSION

As expected, data in Table 1 show good abilities of porphyrins **6**, **8**, and **4** to inhibit the growth of the 7901 cell line at low concentrations. Under light irradiation, the IC_{50} values of **6**, **8**, and **4** are 13.6 ± 1.5, 18.7 ± 0.7, and 3.7 ± 0.4 μM, respectively; while the values in the absence of light irradiation are 24.6 ± 1.6, 21.6 ± 0.9, and 17.5 ± 1.1 μM. These data indicate that light irradiation has not resulted in significant changes in the IC_{50} values; i.e., the inhibitory efficiency of **4** and **6** with irradiation are 5 times and 2 times higher than in the dark. For compound **6** at a concentration of 10 μM, as seen in Table 1, the proliferation of cells is inhibited to 52% in the light, whereas the inhibitory percentage is only 4.9% in the dark, which shows good photoactivity of this compound. To further elucidate the mechanism of the cytotoxicity of these compounds, their abilities to induce apoptosis are investigated.

Table 2. Caspase-3 Activity Induced by Compound 6[a]

samples	control 1	control 2	22 h	44 h	96 h
10 μM	0%	2.2%	9.5%	13.6%	25.8%
20 μM	0%	2.2%	14.8%	27.2%	34.6%

[a] Percentages refer to the ratio of caspase-3-activated cells. Control 1: cells without any compounds or Z-VAD-FMK. Control 2: cells with Z-VAD-FMK but without compounds.

The apoptosis analysis indicated that compound **6** can significantly induce apoptosis of 7901 cells at a 10 μM concentration, while under the same conditions, compounds **8** and **4** have much slighter effects as compared to **6**. From the analysis of the cell cycle, we found that all three compounds can disturb the cell cycle of the 7901 cell line, which is shown with the decreased G0−G1 phase and increased S phase. Obviously, compound **6** has the most significant effect on cell cycle compared to the other two compounds. The G0−G1 phase percentage of **6** decreases from 60.1 ± 0.35% to 48.6 ± 0.40%. The apoptosis of tumor cells 7901 resulting from porphyrins causes the decrease of cells in the G0 phase. This is because the activation of endonucleases following the apoptosis of cells plays a direct and important role in DNA fragmentation, which results in the decrease of cells in the G0 phase (*38*). The outstanding inhibiting ability of compound **6** might be attributed to the electron-deficient property of the molecule resulting from the strong electron-withdrawing effect of the eight bromine atoms at β-positions.

The preliminary results of intracellular caspase-3 activity have shown that cells incubated with **6** exhibits significant caspase-3 activity as compared to the negative control (Table 2). Data in Table 2 also show that the caspase-3 activity increases with prolonged the incubation time. After incubating for 96 h, the percentages of apoptosis cells are 25.8% and 34.6%, respectively, with 10 μM and 20 μM of **6**. Another clear trend is that, at the same incubation time, the higher concentration of the compound leads to higher caspase-3 activity. We also examined **8** and **4** with the same method. However, no caspase-3 activity was detected in the cells incubated with these two compounds. Thus, it is concluded that the cell death induced by **6** is via an apoptosis pathway.

Mechanism of interaction between Topo I and porphyrins has been studied and experimental data shown in Figure 4A,B give a clear indication that the inhibition of the catalytic activity of Topo I by **4**, **6**, and **8** is due to the inhibition of the DNA binding of the enzyme. The effect of **4**, **6**, and **8** could be achieved by intercalation of these compounds into partially relaxed plasmid DNA or by a direct interaction of the drugs with the enzyme itself. To distinguish between these possibilities and further elucidate the mechanism of topoisomerase inhibition, we carried out further experiments with the results shown in Figure 4C,D (*25*, *30*, *31*). Upon preincubation of **6** with enzyme, effective inhibition of topoisomerase I-catalyzed pBR 322 DNA relaxation could be obviously observed at 1 μM concentration, whereas in the case when the porphyrin was preincubated with pBR322, 3 μM **6** was needed to observe the DNA relaxation. Results in Figure 4C further indicate that the enzyme preferentially combines with the drug molecule; hence, the interaction of enzyme with DNA is blocked and the enzymatic activity is weakened. The inhibitory effect of **4**, **6**, and **8** on Topo I-mediated DNA relaxation can be enhanced by preincubation with the enzyme before addition of the DNA plasmid. On the

other hand, we employed a DNA unwinding assay to assess any possible impact of **4**, **6**, and **8** on the superhelical state of closed circular DNA. This assay is based on the ability of intercalating compounds to unwind the DNA duplex and thereby change the DNA twist. These drug-induced changes in DNA twist also induce structural tension in the DNA backbone, and this tension can be relieved by topoisomerases (*35*). On removal of both topoisomerase and intercalating agent, the unwinding effect of the intercalating compound is no longer present and the DNA returns to a supercoiled state. Figure 4D shows that **4**, **6**, and **8** were unable to modulate DNA unwinding, whereas EB, used as a positive control, did it. These findings therefore indicate that the mechanism through which **4**, **6**, and **8** inhibit topoisomerases was independent of DNA intercalation. Taken together, these data suggest that **4**, **6**, and **8** bind directly to Topo I. For porphyrin **6**, it has a potent ability to inhibit Topo I comparing with porphyrins **4** and **8**.

In all, we have synthesized two β-substituted anionic porphyrinsm, and their bioactivities were evaluated. Through MTT and flow cytometric analysis, their abilities to induce cell apoptosis and kill tumor cells were investigated. The β-octabromo porphyrin **6** was preliminarily proven to potentially be a strong anticancer agent. Meanwhile, we found that compound **6** has a stronger ability to inhibit Topo I, and it might be one of the factors that induce tumor cell apoptosis. Further research concerning the mechanism of inducing apoptosis as well as factors affecting the induction are currently in process.

For antibody therapeutics to succeed when intracellular target molecules are involved, a strategy must be applied to increase the delivery of antibodies into cells to reach their targets. Antibody cationization by chemical conjugation of a polyamine could be one such strategy. Both natural polyamines with increasing net charge valencies (putrescine, PUT; spermidine, SPD; and spermine, SPM) and a synthetic polyamine (hexamethylenediamine, HMD) can be used to cationize antibodies, but no comparison of the respective effects of these polyamines on intracellular delivery of antibodies has been performed yet. This study describes the covalent modification of antitetanus $F(ab')_2$ with these four polyamines using different reaction conditions, and compares the effects of these modifications on antibody interaction with cultured HL60 cells. The cationized antibodies retained ≥80% of the binding activity of the unmodified $F(ab')_2$ with regard to tetanus toxin, as measured by an antigen-binding capture enzyme immunoassay. This same method was used to quantify the amount of cell-associated $F(ab')_2$ following incubation with HL60 cells. Cationization was shown to enhance cell interaction of the $F(ab')_2$: the higher the number of coupled polyamine molecules, the greater the amount of antibody associated with the cells. Moreover, coupling the $F(ab')_2$ to the SPD and SPM polyamines had greater effect on cell interaction than coupling the $F(ab')_2$ to the PUT and HMD diamines. Internalization of the cationized antibodies by the HL60 cells was demonstrated by confocal microscopy. This technique also showed that SPD and SPM were more effective than PUT and HMD in terms of intracellular delivery of the $F(ab')_2$. It follows from all these results that electrostatic interaction involving charge density plays a predominant role in the endocytic transport mechanism of the $F(ab')_2$ modified with these polyamines. However, coupling the $F(ab')_2$ to SPM and SPD yielded the same maximum effects in terms of cell interaction, although coupling SPM was expected to increase the antibody net charge valency more than coupling SPD. This finding suggests that the effective global charge for the cell interaction and uptake of polyamine-modified antibodies does not simply correspond to the addition of the ionizable amine functions on the coupled polyamines, and that other factors may come into play.

INTRODUCTION

The potential of antibodies as diagnostic and therapeutic agents is limited, especially when intracellular target molecules are involved, because antibodies are poorly internalized by cells. Indeed, these hydrophilic molecules cannot cross the lipid matrix of the cell plasma membrane efficiently, and so cannot gain access to the cell interior or the different cellular compartments to reach the target molecules.

The high adsorptive property of cationic proteins to anionic sites present on all cell surfaces has provided the basis for the development of cationization strategies for delivering proteins into cells (*1*, *2*). Proteins can be cationized through the chemical conversion of their surface carboxylic acid groups into basic moieties by covalent coupling of polyamines. Not only can the positively charged proteins thus formed bind to the various negatively charged plasma membrane components surrounding the cells, but the bound proteins are also internalized into cells in a receptor- and transporter-independent manner, by adsorptive-mediated endocytosis (AME[1]) (*3*).

The ability of cationized antibodies or fragments to undergo enhanced cellular uptake (*3*–*6*) and exert intracellular activity (*7*, *8*) has been demonstrated in different in vitro cell models.

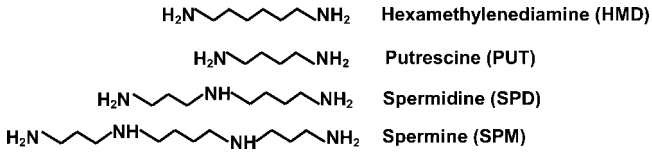

Figure 1. Structures of the synthetic diamine, hexamethylenediamine (HMD), and of the natural polyamines, putrescine (PUT), spermidine (SPD), and spermine (SPM). Due to coupling, each polyamine is found with one less primary amino group, i.e., one less positive charge, at neutral pH.

Moreover, it has also been shown that cationized antibodies can be transported across complex physiological barriers, such as the blood-brain barrier (*1*), indicating that cationization is a strategy able to increase both target cell endocytosis and *trans*-endothelial migration of antibodies.

Antibody cationization has most generally been accomplished by coupling antibodies to the synthetic diamine molecule known as hexamethylenediamine (HMD) (Figure 1). In addition, a different type of protein cationization involving the covalent attachment of putrescine (PUT), spermidine (SPD), and spermine (SPM), a series of endogenously occurring polyamines with increasing net charge valencies (Figure 1), has also been described (*9*). The covalent modification of a variety of proteins with PUT, SPD, and/or SPM has been shown to facilitate the delivery of these proteins into the brain in vivo. More specifically, a remarkable increase in brain transfer was observed for PUT-modified immunoglobulin G (IgG) relative to the native protein (*9*). However, no comparison of the respective effects of PUT, SPD, and SPM on the cellular internalization of antibodies in vitro or their brain transfer in vivo has been performed yet. The same holds true for HMD in that it has yet to be shown whether synthetic polyamines are more, less, or equally effective as natural polyamines. Therefore, we chose to perform a study which included all of the aforementioned polyamines for antibody cationization in order to investigate these questions and to select the most effective polyamine in terms of intracellular delivery.

Using polyclonal antitetanus $F(ab')_2$ fragments as an antibody model, the present study describes their covalent modification with HMD, PUT, SPD, and SPM and the effects of these modifications on antibody cell interaction and internalization in an in vitro model with HL60 cells. Optimization of the conditions of modification yielded two sets of $F(ab')_2$ with increasing net charge valencies: one set with an increasing number of coupled polyamine molecules, and the other with increasing charge densities associated with the polyamines after antibody modification. We then measured the antigen-binding activity of the modified $F(ab')_2$ samples, and quantitatively analyzed their interaction with the HL60 cells by an ELISA method which has been especially developed for these measurements (*10*). Finally, the distribution of these antibodies at the cellular level was visualized by confocal microscopy.

EXPERIMENTAL PROCEDURES

Materials. The antitetanus toxoid horse polyclonal $F(ab')_2$ fragments (batch no U-5000-2) and the tetanus anatoxin were gifts from Aventis-Pasteur (Marcy l'Etoile, France). The HL60 (Human Caucasian promyelocytic leukemia) cell line was obtained from the European Collection of Animal Cell Cultures (Salisbury, Wiltshire, UK). Putrescine • 2HCl, spermidine • 3HCl, spermine • 4HCl, hexamethylenediamine, and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) were from Fluka (Saint-Quentin Fallavier, France). [2,3-^{3}H-(*N*)]putrescine (1243.2 GBq/mmol; 185 MBq/mL) and [terminal methylenes-^{3}H-(*N*)]spermidine (919.5 GBq/mmol; 185 MBq/mL) were obtained from PerkinElmer Life Sciences (Boston, MA), and [1,4-^{14}C]spermine (4.07 GBq/mmol; 1.85 MBq/mL) from GE Healthcare (Orsay, France). Alkaline phosphatase-labeled streptavidin, *p*-nitrophenyl phosphate, protamine base, and 2-(*N*-morpholino)ethanesulfonic acid (Mes) were purchased from Sigma-Aldrich (Saint-Quentin Fallavier, France). Rabbit biotin conjugated affinity purified antihorse IgG ($F(ab')_2$ specific) was from Rockland (Gilbertsville, PA). The following chemicals were obtained from Invitrogen (Cergy Pontoise, France): streptavidin conjugated to Alexa Fluor 488, toto-3 iodide, Roswell Park Memorial Institute 1640 medium (RPMI 1640), Hepes buffer solution 1 M, Hanks' balanced saline solution (HBSS), and 7.5% (w/v) bovine serum albumin (BSA) solution. All other chemicals were of the purest grade available and purchased from VWR (Fontenay-sous-Bois, France) unless otherwise noted. Milli-Q Plus purified water (Millipore, Bedford, MA) was used throughout.

Preparation of Polyamine-Modified Antitetanus $F(ab')_2$. The method used for antibody modification was similar to that described previously (*10*). The polyamines, HMD, PUT, SPD, and SPM, respectively, were covalently attached to carboxylic acid groups of the $F(ab')_2$ using EDC. A sample of the native $F(ab')_2$ diluted in 0.1 M Mes buffer with a pH of 4.5, 5.5, or 6.5 was added to the desired polyamine in water while stirring. This was followed by the addition of water-soluble EDC, and the modification reaction was allowed to proceed for 4 h at 4 °C in the dark. The concentrations of tested polyamine, EDC, and antibody in the EDC(+) mixture (50 mL) were 50 mM, 0.96 mg/mL, and 0.5 mg/mL, respectively. The reaction was quenched with the addition of an equal volume of 0.1 M sodium acetate buffer, pH 5.0. To remove the excess of polyamine and EDC, the product was first filtered on Omega-50 membrane filter with a MWCO of 50 000 (Pall/Gelman Sciences, Ann Arbor, MI), and then on Bio-Gel 10DG column (Bio-Rad, Marnes-la-Coquette, France), and finally dialyzed against water with multiple changes for 60 h at 4 °C using Spectra/Por CE membrane with a MWCO of 25 000 (VWR). Concurrently, $F(ab')_2$ samples were treated under the same conditions as those described above, except that water was used in place of EDC. These EDC(−) $F(ab')_2$ samples were used as controls throughout this study. The cationized and the control antibody preparations were analyzed for protein content using the Bio-Rad DC Protein Assay kit with bovine IgG as a standard (Bio-Rad). The antibody solutions were then individually aliquoted and stored at −20 °C for subsequent use. These aliquots were stable over a one-year storage period at this temperature.

Estimation of the Polyamine Substitution Ratio of the $F(ab')_2$. The polyamine, PUT, SPD, or SPM, was added to two samples of the $F(ab')_2$ in 0.1 M Mes buffer with the desired pH, ranging from 4.5 to 6.5, and the samples spiked with known amounts of [^{3}H]PUT, [^{3}H]SPD, or [^{14}C]SPM. Then, EDC was added to one $F(ab')_2$ sample (EDC(+)) and water to the other (EDC(−)). The concentrations of polyamine and $F(ab')_2$ in the EDC(+) and EDC(−) samples (each 5 mL), and the concentration of EDC in the EDC(+) sample were the same as those used above. The concentration of radioactive polyamine in each sample was 2 μM for [^{3}H]PUT and for [^{3}H]SPD and 10 μM for [^{14}C]SPM. After incubation followed by the addition of 0.1 M sodium acetate buffer, pH 5.0 (5 mL), the EDC(+) and EDC(−) $F(ab')_2$ samples were individually filtered and dialyzed as described. Dialysis was stopped when no radioactivity was detected in the EDC(−) sample (generally after 48−60 h dialysis), indicating that all free polyamine had been removed from both samples. Radioactivity counting was performed using liquid β-scintillation spectrometry (Tri-Carb 1900-TR model, Packard Instruments, Les Ulis, France). The dialyzed EDC(+) $F(ab')_2$ sample was analyzed for radioactivity and protein

content to determine its polyamine substitution ratio (i.e., the number of coupled polyamine molecules per antibody molecule).

Characterization of the Polyamine-Modified $F(ab')_2$ by Electrophoresis. The control $F(ab')_2$ and the polyamine-modified $F(ab')_2$ samples were analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), using gels with an acrylamide monomer concentration of either 12% or 8% T and 2.67% C, and a Tris-glycine buffer system (*11*). Protein samples were solubilized in SDS under reducing conditions with 2-mercaptoethanol, and under nonreducing conditions. This step was followed by electrophoresis and staining with Coomassie Blue R-250. Gels were run at constant voltage with the Mini-Gel apparatus (Bio-Rad), according to the manufacturer's instructions. Protein standards used were the Precision Plus protein standards from Bio-Rad or the high molecular weight calibration kit from GE Healthcare. Isoelectric focusing (IEF) was performed as described previously (*10*), using ampholine polyacrylamide gel plates of 1mm thickness, with acrylamide monomer concentration of 5% T and 3% C and 2.2% carrier ampholytes pH 3.5−9.5 (GE Healthcare). IEF standards from GE Healthcare were used containing 11 proteins with isoelectric points in the range of 3.5−9.3. The proteins were visualized with Coomassie Blue R-250.

Determination of the Antigen-Binding Activity of the Antitetanus $F(ab')_2$. An antigen-binding capture enzyme-linked immunosorbent assay (ELISA) for the antitetanus $F(ab')_2$ (*10*) was performed on preparations of control and polyamine-modified antitetanus $F(ab')_2$ to determine their binding activity. The protocol followed was the same as that reported in ref (*10*). Briefly, the method used tetanus anatoxin coated on microtiter plates as capture antigen (0.5 μg/well) to bind the $F(ab')_2$, with the amount of antibody binding being quantified using, first, a rabbit biotinylated antihorse $F(ab')_2$ (60 ng/well), and then a streptavidin-alkaline phosphatase conjugate (0.15 μg/well). Substrate for making the color reaction was *p*-nitrophenyl phosphate (100 μg/well). A solution of HBSS supplemented with 0.2% (w/v) BSA (HBSS/BSA) was used as assay diluent for the $F(ab')_2$ samples. Each dilution of samples (over the concentration range 2.5−25 ng/mL for both the control and polyamine-modified $F(ab')_2$) was assayed in duplicate. Blanks (HBSS/BSA) were included in each assay. The color was developed for 60 min in the dark at room temperature and the enzyme reaction stopped with 1 M NaOH (100 μL/well). Plates were read on a Bio-Tek ELX 800 microplate reader (Winooski, VT) at a wavelength of 405 nm.

Linear regression curves were determined by plotting the concentrations of the control or polyamine-modified $F(ab')_2$ versus the absorbance according to the following equation:

$$y = a \times x + b \tag{1}$$

where y is the absorbance at 405 nm, x the antibody concentration in ng/mL, and a and b are the slope and intercept of the curve, respectively.

HL60 Cell Assays and Measurement of Cell-Associated $F(ab')_2$. HL60 cells were grown in suspension cultures as reported (*6*), using a RPMI 1640 medium with 10% fetal calf serum, and maintained in a logarithmic growth phase at a maximum density of $\sim 1.5 \times 10^6$ cells/mL by subculturing every 3 days. For the assays with the polyamine-modified and control $F(ab')_2$, the HL60 cells were harvested from cultures by centrifugation at 200 × *g* (5 min, room temperature), washed three times with RPMI 1640 containing 10 mM Hepes buffer (pH 7.0) and 0.2% (w/v) BSA, and suspended to a density of $\sim 2 \times 10^6$ cells/mL. The cell suspension was divided between two sample sets of polypropylene centrifuge tubes (1 mL/tube): one set was incubated at 4 °C and the other at 37 °C. To each tube was then added 1 mL of dilutions of either the polyamine-modified or the control $F(ab')_2$ prepared in RPMI 1640/10 mM Hepes/0.2% (w/v) BSA. Dilutions of each antibody were made up to give $F(ab')_2$ concentrations of 5, 12.5, 25, or 50 μg/mL. Each antibody level was tested in duplicate. The tubes were then incubated for 120 min at 4 or 37 °C. Kinetic experiments using SPD-$F(ab')_2$ showed that cellular antibody concentrations reached steady state at 120 min of incubation at 37 °C. The kinetic results were similar to those obtained with PUT-$F(ab')_2$ in a previous study (*10*). After incubation, the cells were immediately centrifuged at 200 × *g* (5 min, 4 °C) and washed three times with ice-cold HBSS to remove the unbound antibody. Cells were then suspended in 1 mL of ice-cold HBSS and finally lysed on ice by ultrasound sonication for 10 s. Blank cell lysates from HL60 cells incubated without antibodies were prepared as stated above. Each cell lysate was then separated into two parts, the first part for the cellular protein assay and the second for the measurement of cell-associated $F(ab')_2$. The term cell-associated $F(ab')_2$ includes the surface-bound antibody plus the internalized antibody, if any. Protein determination was performed in duplicate as described above, using BSA (Bio-Rad) as a standard. The concentrations of the antitetanus $F(ab')_2$ in total cell lysates were determined by ELISA. Prior to this, the total lysates were supplemented with BSA (0.2%, final w/v), and dilutions ranging from 1/2 to 1/50 were then prepared in HBSS also containing 0.2% BSA. The dilutions were assayed by ELISA concurrently with dilutions of a $F(ab')_2$ standard, i.e., the same $F(ab')_2$ as that used for the assays with the HL60 cells. Standards were prepared in HBSS/BSA over the concentration range 2.5−25 ng/mL for both the control and the polyamine-modified $F(ab')_2$. Blanks (HBSS/BSA) were included in each assay. The plates were then processed as described above. A linear regression curve was calculated for the standard and used to compute antibody levels in cell lysates. The amount of cell-associated $F(ab')_2$ was normalized to milligrams of cell proteins.

Inhibition Assays. HL60 cells ($\sim 2 \times 10^6$ cells in RPMI 1640/10 mM Hepes/0.2% (w/v) BSA) were incubated for 120 min at 37 °C with 50 μg/mL of control or SPD-modified $F(ab')_2$ and different concentrations of inhibitor, SPD, or protamine base. SPD was used in the concentration range 1.25−1250 μg/mL, and protamine in the range 0.205−1025 μg/mL. After incubation, the cells were centrifuged and washed with ice-cold HBSS to remove the excess unbound antibody and inhibitor. The cells in each tube were then suspended in 1 mL HBSS and lysed using ultrasound sonication. Each cell lysate was analyzed for protein content and its antitetanus $F(ab')_2$ level as already described. The amount of cell-associated $F(ab')_2$ was normalized to milligrams of cell proteins.

The relationship between the amount of cell-associated $F(ab')_2$ (C) and the concentration of inhibitor (I_t) was modeled with the following equation

$$C/C_{max} = IC_{50}/(IC_{50} + I_t) \tag{2}$$

where C_{max} is the maximum amount of cell-associated antibody measured in the absence of inhibitor, and IC_{50} is the theoretical concentration of inhibitor producing a 50% decrease in C_{max}. IC_{50} was estimated with its standard deviation by nonlinear regression analysis using Micro-Pharm software (*12*).

Confocal Laser Microscopy. The polyamine-modified and control $F(ab')_2$ (each used at a concentration of 50 μg/mL) were incubated with HL60 cells at either 4 or 37 °C, as described above. Following incubation, the cells were centrifuged and washed with ice-cold HBSS to remove the unbound antibody. The cells ($\sim 2 \times 10^6$ cells/tube) were then fixed with 1 mL of 4% (w/v) paraformaldehyde in 10 mM phosphate buffer/138 mM NaCl/2.7 mM KCl, pH 7.4, (PBS) for 60 min. All subsequent steps were performed at room temperature, and PBS was used as washing buffer between each step. After washing,

the cells were suspended in 0.4 mL PBS and then immobilized on the glass surface of Lab-Tek II chambers (Nunc, Roskilde, Denmark) previously coated with 0.1% (w/v) poly(L-lysine) (Sigma-Aldrich) in water. The immobilized cells were permeabilized with 0.2% (v/v) Triton X-100 in PBS for 10 min, and the free aldehyde groups then blocked with 0.8% (w/v) glycine in PBS for 30 min. Thereafter, the cells were successively incubated with 2% (v/v) rabbit serum (Sigma-Aldrich) in PBS for 30 min, rabbit biotinylated antihorse $F(ab')_2$ (8 μg/mL in PBS containing 2% (v/v) rabbit serum) for 60 min in the dark, and finally with a streptavidin-Alexa Fluor 488 conjugate (2 μg/mL in PBS containing 1% (w/v) BSA) for 30 min in the dark. The biotinylated secondary antibody was the same antibody as that used in ELISA. For specific nuclear labeling, the cells were incubated with toto-3 (1 μg/mL in PBS) for 10 min in the dark. The internalization of antibodies was examined using a confocal microscope (Zeiss LSM 510) and a 63/1.4× oil immersion objective. Confocal optical sections were obtained through the nuclear plane of the cells. As controls, we used HL60 cells which were incubated without antitetanus $F(ab')_2$ at either 4 or 37 °C. These cells were then treated in exactly the same way as those incubated with antibodies.

Statistical Analysis. Data analyzed with the Triomphe software (*13*) are presented as mean ± standard deviation (S.D.). Coefficient of variation (C.V. = S.D./mean) was used to evaluate variation between measures. To study the variation in antigen binding activity between the different $F(ab')_2$ preparations, we used a two-way analysis of variance (*14*) to compare mean values of antibody binding, and an analysis of covariance (*15*) to compare the slopes of the titration curves of the $F(ab')_2$. The analysis of variance studied the effects of the reaction pH on the $F(ab')_2$ cell interaction, as well as the effects of cationization at the different pH values, for each temperature and each antibody. It also studied the variation in amount of cell-associated antibody between the different $F(ab')_2$, and between temperatures for each antibody. Statistical significance was set at the $p < 0.05$ level.

RESULTS

Polyamine Modification of the Antitetanus $F(ab')_2$. The antitetanus $F(ab')_2$ was covalently modified with PUT, SPD, SPM, or HMD, by activating carboxylic acid groups to the reactive ester with water-soluble carbodiimide (EDC), and then by reacting with each polyamine as the nucleophilic reagent (*16*). A large excess of the polyamines was used in the reaction to ensure that only one primary amine group of the molecules would couple with one carboxylic acid group on the antibody, and thus avoid intermolecular cross-linking and the formation of $F(ab')_2$ polymers (*2*). Following the reaction, the excess of polyamine was removed from the polyamine-$F(ab')_2$ conjugates using a three-step purification procedure.

The conditions for the carbodiimide-mediated amidation of the $F(ab')_2$ carboxylic acid groups were optimized as follows. Because the initial phase of the reaction depends on the ionization of carboxylic acid, preliminary experiments using PUT and [^{3}H]PUT were conducted to adjust the ionization of the $F(ab')_2$ carboxylic acid groups with pH. As illustrated in Figure 2, reactions at different pH values decreasing from 7.0 to 4.5 demonstrated increasing degrees of modification of the $F(ab')_2$ which reached a maximum value of ~3 molecules of PUT coupled per antibody molecule at pH 4.5. Decreasing the pH to values below 4.5 did not further increase the amount of coupling and led to the risk of antibody denaturation. Another variable that can influence the extent of cationization of a protein is the molar excess of polyamine relative to the carboxyl groups (*17*). Therefore, experiments were conducted where the $F(ab')_2$ was modified with PUT and [^{3}H]PUT at pH 4.5, using different molar ratios of polyamine over antibody. The amount of coupling was shown to increase almost linearly from 0.02 to 3.2 molecules of PUT per $F(ab')_2$ molecule when the molar ratio of polyamine over antibody increased from 100 to 10 000. The use of PUT/$F(ab')_2$ ratios higher than 10 000 resulted in a contamination of the antibody conjugate by free polyamine which could not be removed by two successive filtrations on Omega-50 membrane filter and Bio-Gel 10DG column, followed by dialysis, even when dialysis was continued for more than 7 days.

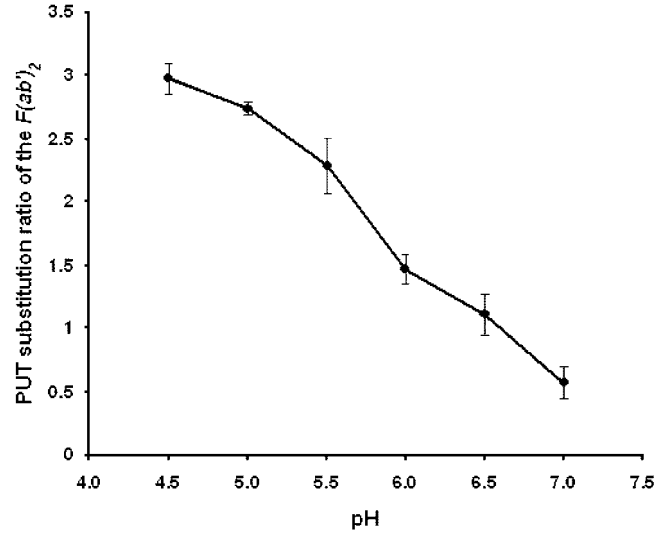

Figure 2. The effect of pH on the EDC-mediated polyamine modification of the antitetanus $F(ab')_2$. The average number of PUT molecules coupled per $F(ab')_2$ molecule (●) estimated at each pH value is shown along with its S.D., and is the result of five independent experiments.

Table 1. Polyamine Substitution Ratio of the Antitetanus $F(ab')_2$[a]

polyamine	pH of the reaction	cationized antibody	substitution ratio
PUT	6.5	PUT-$F(ab')_2$	1.11 ± 0.16
PUT	5.5	PUT-$F(ab')_2$	2.29 ± 0.22
PUT	4.5	PUT-$F(ab')_2$	2.98 ± 0.12
SPD	4.5	SPD-$F(ab')_2$	2.68 ± 0.11
SPM	4.5	SPM-$F(ab')_2$	2.89 ± 0.19
HMD	4.5	HMD-$F(ab')_2$	*nd*[b]

[a] The results are presented according to the polyamine and pH used in the modification reaction. The substitution ratio of the $F(ab')_2$ corresponds to the number of polyamine molecules coupled per antibody molecule. Mean values are shown in all cases along with their S.D., and are the results of five independent experiments. [b] *nd*, not determined.

On the basis of these results, the antitetanus $F(ab')_2$ was modified with PUT at pH 6.5, 5.5, and 4.5. Table 1 shows that these modifications resulted in substitution ratios of roughly 1, 2, and 3 coupled PUT molecules per antibody molecule, yielding a set of antibodies with increasing positive charge valencies due to the number of coupled polyamine molecules. Using the same maximized reaction conditions as for PUT, the $F(ab')_2$ was modified with either HMD, SPD, or SPM, resulting in a second set of antibodies with different charge valencies due to the different number of corresponding protonated amino groups left after coupling (Figure 1). The substitution ratios determined for the $F(ab')_2$ modified with SPD and SPM at pH 4.5 and using a molar polyamine/antibody ratio of 10 000 were both close to 3 (Table 1). The coupling was reproducible in all cases (C.V. <15%). As no radioisotope for HMD is commercially available, it was assumed that similar results of coupling obtained for PUT, SPD, and SPM at pH 4.5 could also be obtained for HMD coupled to the $F(ab')_2$ (i.e., 3 coupled HMD molecules per antibody molecule).

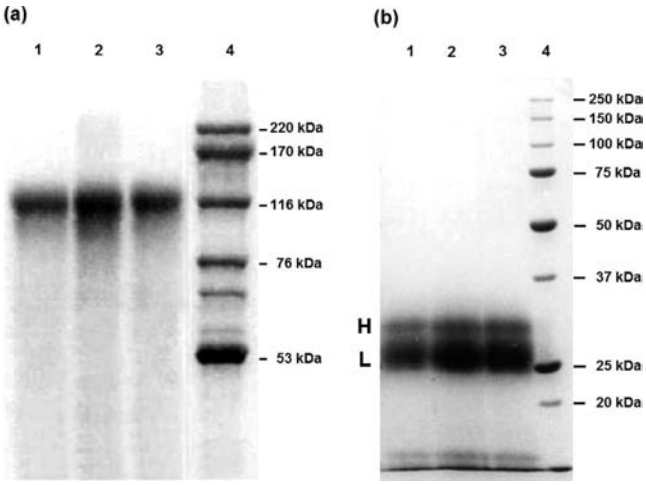

Figure 3. Analysis of polyamine-modified antitetanus $F(ab')_2$ by SDS-PAGE. (a) Coomassie Blue stain of nonreducing SDS-PAGE of PUT-$F(ab')_2$ after modification at pH 4.5 (lane 1), the corresponding control $F(ab')_2$ (lane 2), and the native $F(ab')_2$ (lane 3). (b) Coomassie Blue stain of reducing SDS-PAGE of PUT-$F(ab')_2$ modified at pH 4.5 (lane 1), the corresponding control $F(ab')_2$ (lane 2), and the native $F(ab')_2$ (lane 3). The migration of the heavy chain fragments (H) and light chains (L) of the $F(ab')_2$ is shown on the left-hand border. Five micrograms of each $F(ab')_2$ was applied to the gel, along with molecular weight standards (lanes 4 in (a) and (b)). The molecular weights of the standards are shown on the right-hand border. Reducing and nonreducing SDS-PAGE analysis of all the other polyamine-modified $F(ab')_2$ and the corresponding control $F(ab')_2$ yielded similar results, respectively, to those shown for the PUT-$F(ab')_2$ and its control.

For both the cationized and control $F(ab')_2$, the amount of antibody recovered after the reaction followed by purification represented ≥75% of the amount of $F(ab')_2$ in the starting material. The loss observed for both the cationized and control antibodies was tolerable and likely due to the nonspecific adsorption of these antibodies to the ultrafiltration or dialysis membranes, or the gel particles (or to all three), which were used in the three-step purification procedure.

SDS-PAGE and IEF Analysis of the Polyamine-Modified Antitetanus $F(ab')_2$. When SDS-PAGE was performed under nonreducing conditions, both the control and cationized $F(ab')_2$ migrated with one single protein band at a molecular weight of ~110 kDa, which was identical to that exhibited by native antitetanus $F(ab')_2$ (Figure 3a). This result indicates that polyamine modification of the $F(ab')_2$ and the conditions used therein did not result in any intermolecular cross-linking of the antibody, nor in its degradation. In addition, the results of SDS-PAGE under reducing conditions demonstrated two protein bands at molecular weights of ~30 and ~25 kDa for both the control and modified forms of the $F(ab')_2$, which corresponded to the monomeric heavy chain fragments and to the light chains of the native $F(ab')_2$ (Figure 3b).

As determined by IEF, the isoelectric point (pI) of the native antitetanus $F(ab')_2$ varied over a wide pI range 5.2−8.4, with a predominant distribution in the high pI range (Figure 4). The control $F(ab')_2$ samples also had multiple species whose pIs and distribution were similar to those of the native antibody, indicating that the conditions used in the reaction caused minimal changes in the antibody pI forms. Very different IEF results were obtained with the cationized $F(ab')_2$. Modification with PUT at pH 6.5, 5.5, and 4.5 resulted in a graded shift to increasing pIs that was in the order of pH 6.5 < 5.5 < 4.5 (Figure 4a). Concurrently, the proportions of residual unmodified isoforms gradually decreased. These results were consistent with the increasing amounts of coupling determined at these three pH values (Table 1). The IEF profiles of the $F(ab')_2$ modified with HMD, SPD, and SPM at pH 4.5 (Figure 4b) were similar to that of the PUT-$F(ab')_2$ modified at the same pH value. All these antibodies showed two major isoforms: one had an average pI of ~8.8 and the other a pI ≥ 9.3. They also contained some minor isoforms in the pI range ~7.4−8.6.

Antigen-Binding Activity of the Polyamine-Modified Antitetanus $F(ab')_2$. The effects of HMD, PUT, SPD, and SPM modifications on the biological activity of the $F(ab')_2$ were evaluated by assaying dilutions of decreasing concentrations of the polyamine-modified and control antibodies by a specific ELISA method (*10*). Because this assay was also intended to be used for the quantitative analysis of the $F(ab')_2$ in HL60 cell lysates, a HBSS solution with 0.2% BSA (HBSS/BSA) was used as assay diluent. Representative examples of the titration curves obtained for the polyamine-modified and control $F(ab')_2$ are presented in Figure 5. Linear dose-response curves were obtained for all the antibodies when titration was performed over the concentration range 2.5−25 ng/mL. Linearity was determined by checking five titration curves over five days for each antibody (duplicate measurements per level on each day). For all the antibodies assayed, the coefficients of correlation of the titration curves were ≥0.9951. The slope of each titration curve reflects the antigen binding activity of the antibody. As illustrated in Figure 5, low background levels (≤0.107 absorbance units) were measured in both the assays using the polyamine-modified $F(ab')_2$ and the control $F(ab')_2$, indicating that the ELISA was not affected by nonspecific adsorption of these antibodies to the coated plates (*10*). The precision for concentrations at 5, 7.5, 10, 12.5, 15, 17.5, and 20 ng/mL on these curves was always C.V. ≤15%, and the accuracy within the interval of ±15% of the nominal values. The precision for both the lower and upper concentrations on the curves (2.5 and 25 ng/mL, respectively) was C.V. ≤20%, and the accuracy within ± 20% of the nominal values. These results satisfactorily met current acceptance criteria for validation of standard curves (*18*), so these curves were used to determine the concentrations of polyamine-modified and control $F(ab')_2$ in cell lysate samples.

As shown by the slopes of the titration curves for the PUT-$F(ab')_2$ (Figure 5), the antigen binding activity of the antibody decreases with the pH of the modification reaction: the decrease did not exceed 3% of the control when modification was performed at pH 6.5, and reached values up to ~20% by reducing the pH to 4.5 ($p < 0.01$ in all cases). Modification of the $F(ab')_2$ with SPD, SPM, and HMD at pH 4.5, respectively, also resulted in a decrease of roughly 20% in antigen binding activity, as compared with the corresponding control antibodies ($p < 0.001$ in all cases) (not illustrated). Furthermore, the similar results obtained with the $F(ab')_2$ modified with PUT, SPD, SPM, and HMD at pH 4.5 ($p = 0.305$) indicated that the type of coupled polyamine did not influence the antigen-binding activity of the $F(ab')_2$. Only small and nonsignificant differences were observed among the activities of the control antibodies ($p > 0.500$). Moreover, these activities were very similar to that determined for the native antitetanus $F(ab')_2$ in a previous study (*10*), also using HBSS/BSA as assay diluent.

Quantification of Antitetanus $F(ab')_2$ in HL60 Cell Lysates by ELISA. The quantitative analysis of cationized and control $F(ab')_2$ which were associated to the HL60 cells following incubation at 4 and 37 °C, respectively, was performed with an ELISA method (*10*) using total cell lysates. Thus, all cell-associated $F(ab')_2$, including surface-bound and internalized antibodies, were measured. Because this method is an antigen-binding capture ELISA, the antibodies measured are necessarily active antibodies. The results for the PUT-$F(ab')_2$ and the corresponding control $F(ab')_2$ are presented in Figure 6, and those for the HMD-, SPM-, and SPD-$F(ab')_2$ and their respective controls in Figure 7.

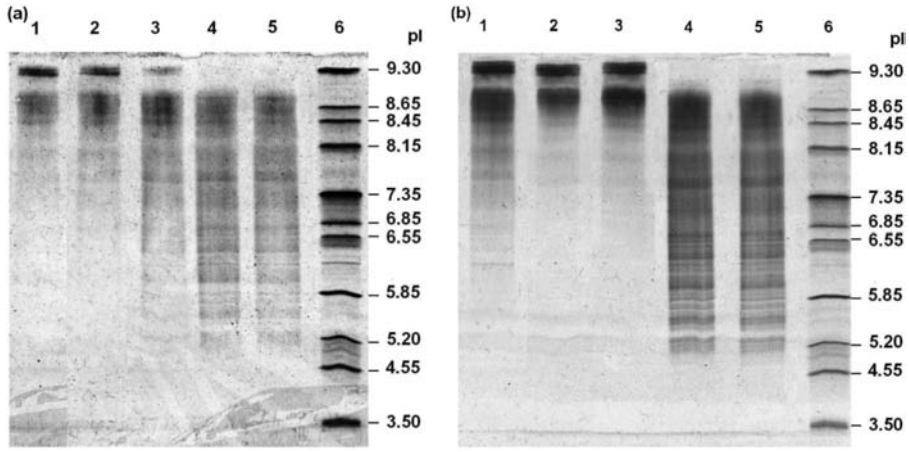

Figure 4. Analysis of polyamine-modified antitetanus $F(ab')_2$ by IEF. (a) Coomassie Blue stain of polyacrylamide gel IEF of PUT-$F(ab')_2$ modified at pH 4.5 (lane 1) along with the corresponding control $F(ab')_2$ (lane 4), and PUT-$F(ab')_2$ modified at pH 5.5 (lane 2) and pH 6.5 (lane 3), and the native $F(ab')_2$ (lane 5). (b) Coomassie Blue stain of polyacrylamide gel IEF of HMD-$F(ab')_2$ (lane 1), SPD-$F(ab')_2$ (lane 2), SPM-$F(ab')_2$ (lane 3) along with the corresponding control $F(ab')_2$ (lane 4), and the native $F(ab')_2$ (lane 5). Twenty micrograms of each $F(ab')_2$ were applied to the gel in (a), and 25 μg in (b), along with pI standards (lanes 6 in (a) and (b)). The pIs of the standards are shown on the right-hand border.

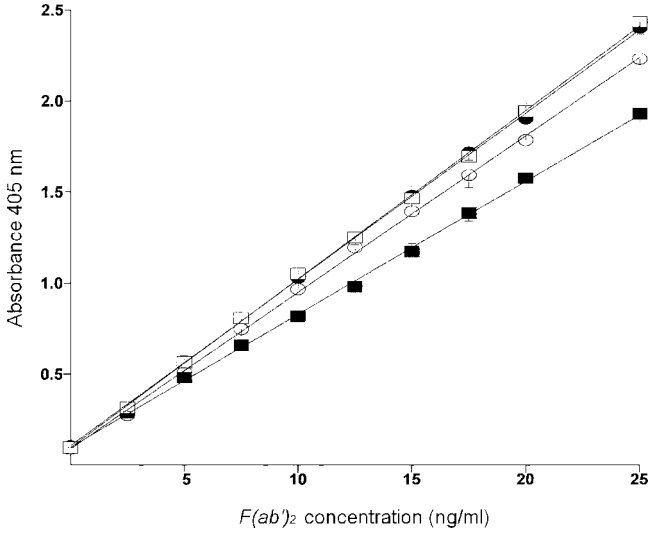

Figure 5. Titration curves measured by ELISA for the PUT-$F(ab')_2$ modified at pH 6.5 (●), pH 5.5 (○), and pH 4.5 (■), along with the control $F(ab')_2$ (□) corresponding to the latter. All antibodies were assayed at concentrations of 2.5, 5, 7.5, 10, 12.5, 15, 17.5, 20, and 25 ng/mL (duplicate measurements per level). Each titration curve was determined from the data of five different ELISA experiments. The experimental points correspond to mean values which are shown along with their S.D.. The solid lines are computer-estimated values. The equations of the titration curves for the PUT-$F(ab')_2$ modified at pH 6.5 and 5.5 are $y = -0.0913x + 0.107$ and $y = -0.0860x + 0.090$, respectively. The coefficients of correlation (r) of these curves were 0.9985 and 0.9976. The equations of the curves for the PUT-$F(ab')_2$ modified at pH 4.5 and the corresponding control are $y = -0.0729x + 0.099$ ($r = 0.9977$) and $y = -0.0925x + 0.097$ ($r = 0.9988$). x is the concentration of the $F(ab')_2$ in ng/mL, and y is the absorbance. The titration results for the SPD-, SPM-, and HMD-$F(ab')_2$ modified at pH 4.5 were not significantly different from those obtained with the PUT-$F(ab')_2$ modified at pH 4.5. No significant differences were found between the various control samples.

The amounts of cell-associated $F(ab')_2$ were greater at 37 than at 4 °C for the cationized and the control antibodies ($p < 0.001$). The amounts also increased as the initial antibody concentration was increased in the incubation medium ($p < 0.001$), the effect of concentration being greater at 37 °C than at 4 °C ($p < 0.001$ for the temperature-concentration interaction). No $F(ab')_2$ was measured in the blank cell samples (no antibody present).

Effect of the Degree of Antibody Modification on Cell Interaction. As shown in Figure 6, the amounts of PUT-$F(ab')_2$ associated with the cells increased as the number of coupled PUT molecules increased. The amounts measured at 4 or 37 °C for the $F(ab')_2$ coupled with three PUT molecules (the antibody modified at pH 4.5) were approximately 1.5 times higher, on average, than that measured for the $F(ab')_2$ coupled with two PUT molecules (the antibody modified at pH 5.5) and 2 times higher than that coupled with one PUT molecule (the antibody modified at pH 6.5). All the differences observed were significant ($p < 0.05$). The cell-associated amounts of all the PUT-$F(ab')_2$ were significantly higher than those of the corresponding control $F(ab')_2$ at each temperature and antibody level tested ($p < 0.05$). When the pH of the modification reaction decreased from 6.5 to 4.5, the variation between the cationized and control antibodies was accentuated. Small, albeit statistically significant, differences in cell-associated amounts were observed between the various control $F(ab')_2$ at both 4 and 37 °C ($p < 0.05$ for each temperature). These differences increased as the pH decreased. This suggests that the accessibility and/or relative distribution of amino acid side-chain groups on the antibody surface may be slightly changed by the pH of the reaction, thus mildly affecting the interaction of the control antibodies with the cells. Nonetheless, this was seen to have minimal effect on the IEF profiles of the control $F(ab')_2$ and none on their antigen-binding activities relative to the native antibody.

Effect of the Charge Valency of $F(ab')_2$ Coupled Polyamine. The amounts of cell-associated antibody measured for the $F(ab')_2$ modified with HMD, SPD, and SPM at pH 4.5 are shown in Figure 7. These antibodies had substitution ratios of approximately 3 coupled polyamine molecules per antibody molecule, which were similar to that of the PUT-$F(ab')_2$ modified at pH 4.5 (Table 1). Since 1 protonated amino group is left on a HMD or PUT molecule after coupling, and 2 and 3 of these groups are left on SPD and SPM molecules, respectively (Figure 1), the expected number of positive charges associated with these polyamines after coupling should increase in the order of HMD or PUT < SPD < SPM, with a corresponding increase in the antibody net charge valency of +3, +6, and +9, respectively. At all antibody concentrations tested, both at 4 and at 37 °C, the amounts of cell-associated HMD-$F(ab')_2$ (Figure 7) were similar to those measured for the PUT-$F(ab')_2$ modified at pH 4.5 (C.V. <18%) (Figure 6). These amounts were ~2.5 times lower, on average, than those measured for the $F(ab')_2$ modified with SPD or SPM at each temperature (p

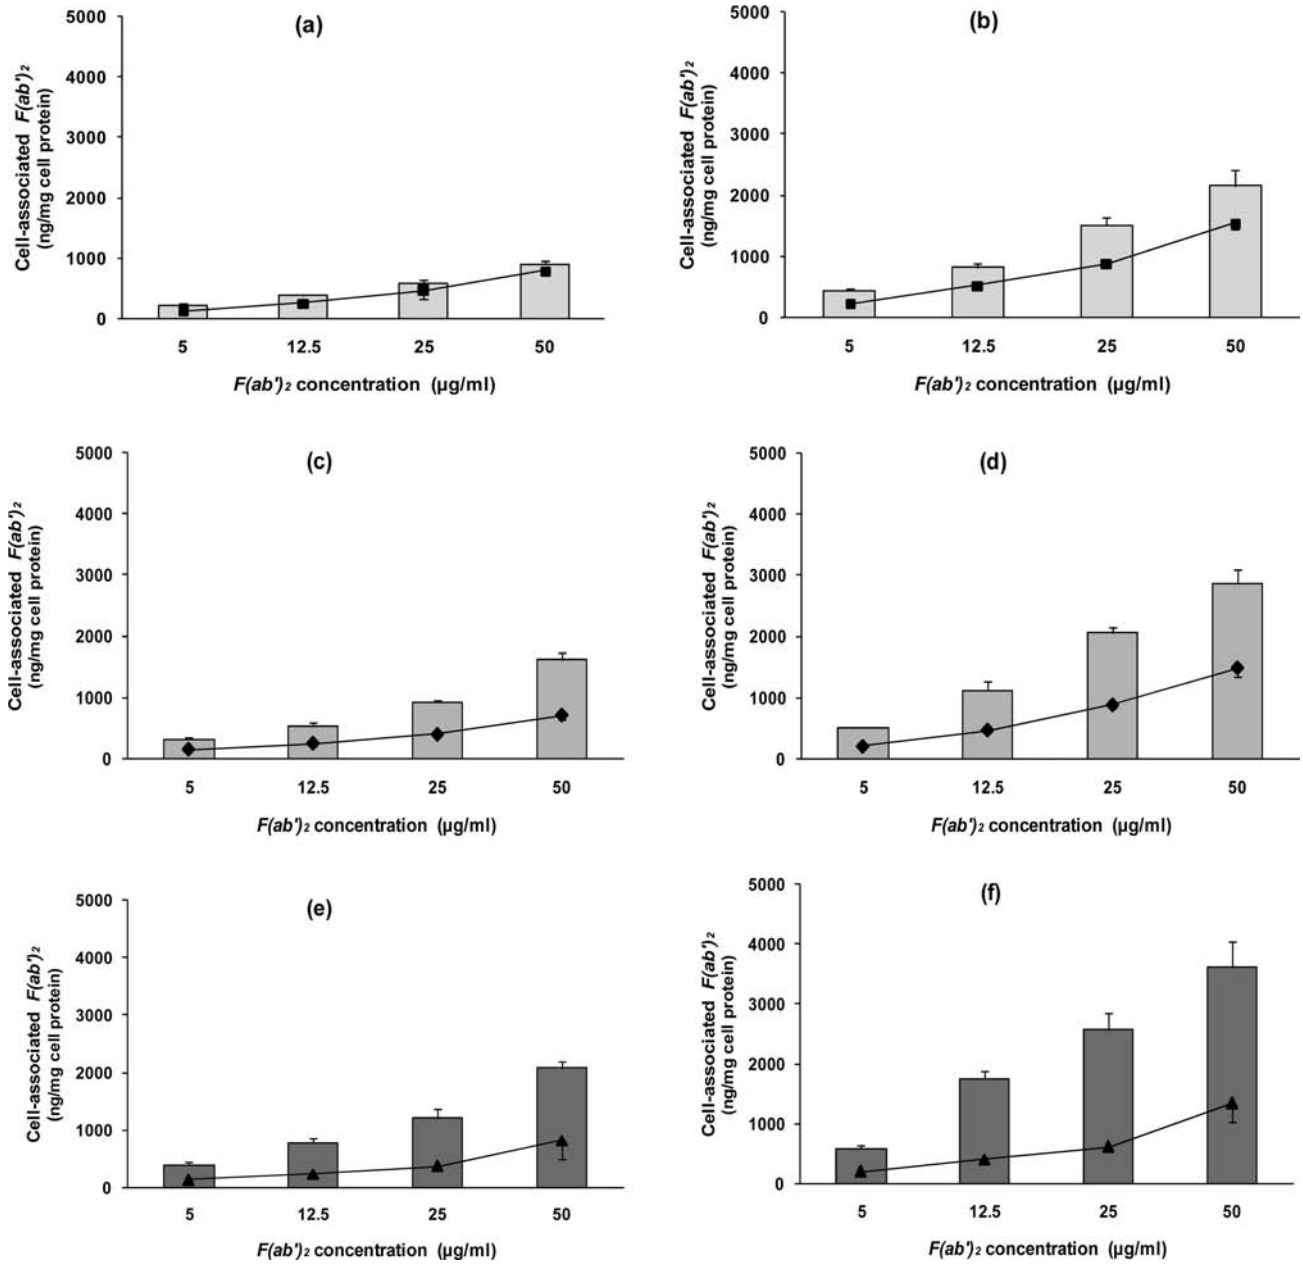

Figure 6. Cell-associated PUT-$F(ab')_2$ and control-$F(ab')_2$ measured by ELISA following incubation with HL60 cells at 4 and 37 °C. Cells were incubated for 120 min with different concentrations (5, 12.5, 25, or 50 μg/mL) of the PUT-$F(ab')_2$ modified at pH 6.5 (a and b), pH 5.5 (c and d), and pH 4.5 (e and f), at either 4 °C (a, c, and e) or 37 °C (b, d, and f). The figures also show the amounts of cell-associated antibody measured for the corresponding control $F(ab')_2$ (■, ◆, and ▲, respectively) after incubation with HL60 cells at these two temperatures. The results for the cationized $F(ab')_2$ are presented in bar graphs where the different shades of gray indicate different antibodies. The corresponding control $F(ab')_2$ are superimposed (-■-,-◆-, or -▲-). Mean values for the cationized $F(ab')_2$, as well as for the control $F(ab')_2$, are shown along with their S.D. These values are the results of three to seven independent experiments (each antibody level tested in duplicate in each experiment).

< 0.05 in each case) (Figure 7). However, the SPD-$F(ab')_2$ and SPM-$F(ab')_2$ showed similar cell-associated amounts at either 4 or 37 °C (C.V. <7%), indicating that an increase in the $F(ab')_2$ charge valency from +6 to +9 after coupling of SPD and SPM does not further increase the interaction of the antibody with the HL60 cells. In comparison, the cell-associated amounts of all three control antibodies for the HMD-, SPD-, and SPM-$F(ab')_2$ were significantly lower ($p < 0.05$ at each temperature and antibody concentration). Indeed, the amounts for the control antibodies corresponding to the SPD- and SPM-$F(ab')_2$ were up to 8 times lower, on average, when compared to the cationized antibodies. Only small differences were observed among all three control antibodies at either 4 or 37 °C (C.V. <13%). The cell viability checks performed throughout these experiments by Trypan blue exclusion indicated that none of the antibodies used at the present doses exerted cellular toxicity (cell viability ≥90% in all cases).

Inhibition of the Interaction of the Polyamine-Modified $F(ab')_2$ with HL60 Cells. Figure 8 illustrates the inhibition of the cell interaction of SPD-$F(ab')_2$ and that of the corresponding control $F(ab')_2$ by addition of (free) SPD and protamine. Higher concentrations of (free) SPD (Figure 8a) were needed to decrease the amounts of cell-associated SPD-$F(ab')_2$ relative to protamine (Figure 8b): the IC_{50} values calculated for these inhibitors were 568 ± 17 and 348 ± 10 μg/mL, respectively. Much lower inhibitory potencies were found for SPD and protamine when they were used to inhibit the cell interaction of the control $F(ab')_2$, with IC_{50} values of 1807 ± 61 and 988 ± 44 μg/mL. Moreover, the amounts of cell-associated antibody were reduced by only 50% for the control $F(ab')_2$ versus 75%

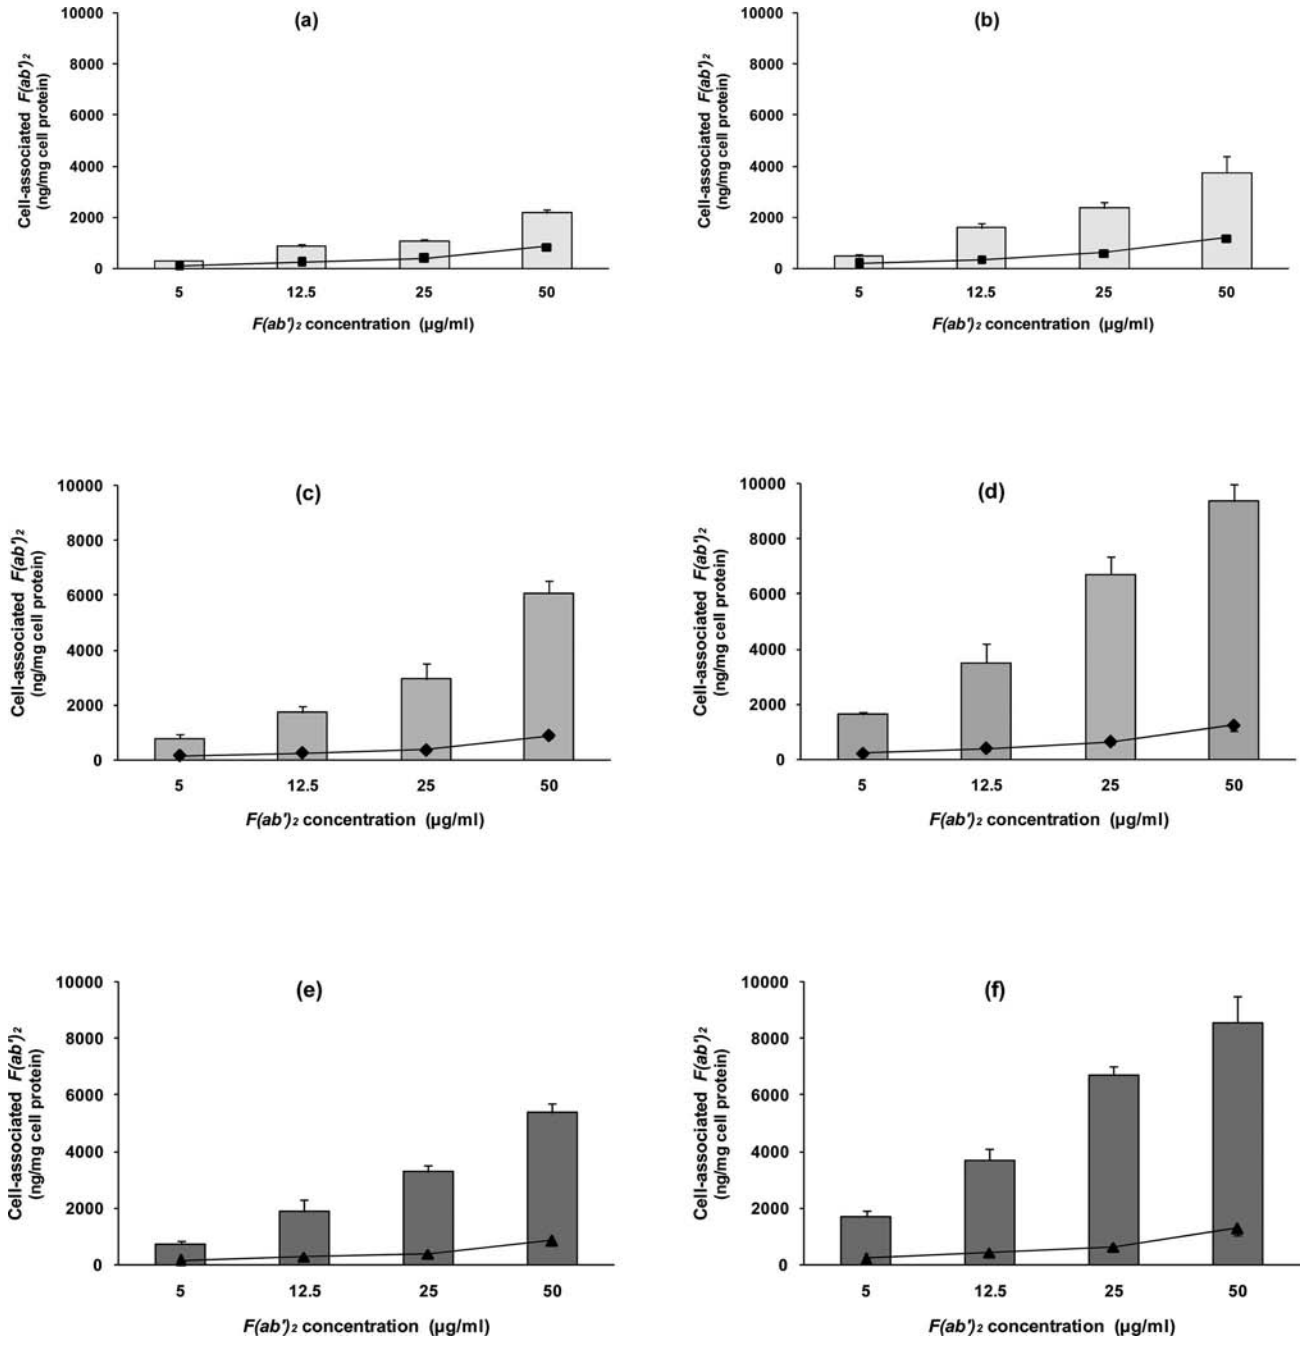

Figure 7. Cell-associated HMD-, SPD-, and SPM-$F(ab')_2$ and corresponding control-$F(ab')_2$ measured by ELISA following incubation with HL60 cells at 4 and 37 °C. Cells were incubated for 120 min with different concentrations (5, 12.5, 25, or 50 μg/mL) of the HMD-$F(ab')_2$ (a and b), SPD-$F(ab')_2$ (c and d), and SPM-$F(ab')_2$ (e and f), at either 4 °C (a, c, and e) or 37 °C (b, d, and f). The pH used in the modification reaction of the $F(ab')_2$ with HMD, SPD, or SPM was 4.5. The figures also show the amounts of cell-associated antibody measured for the corresponding control $F(ab')_2$ (■, ◆, ▲, respectively) after incubation with HL60 cells at these two temperatures. The results for the cationized $F(ab')_2$ are presented in bar graphs where the different shades of gray indicate different antibodies. The corresponding control $F(ab')_2$ are superimposed (-■-,-◆-, or -▲-). Mean values for the cationized $F(ab')_2$, as well as for the control $F(ab')_2$, are shown along with their S.D. These values are the results of three to seven independent experiments (each antibody level tested in duplicate in each experiment). Note that the scale on the *y*-axis is two times greater than that in Figure 6.

or more for the polyamine-modified antibody, at the highest inhibitor concentrations used.

Confocal Microscopic Studies. Two different antibody detection procedures were tested in preliminary experiments: a one-step procedure using a secondary antihorse $F(ab')_2$ conjugated to Texas red, and a two-step procedure that used first a secondary biotinylated antihorse $F(ab')_2$ and then a streptavidin-Alexa Fluor 488 conjugate. The two-step detection procedure gave better results than the other in terms of sensitivity, probably because of the signal amplification effect brought about through the biotin-streptavidin system. This procedure also had the advantage of using the same secondary antibody as in the ELISA assays. Figure 9 shows representative confocal microscopy images of HL60 cells incubated with either polyamine-modified or control $F(ab')_2$, using the biotin-streptavidin system for detection.

Wide-field images at low magnification (×10) of all the HL60 cells incubated with the various cationized $F(ab')_2$ at 37 °C gave comparable results in that all incubated cells showed the presence of associated antibodies which included both surface-

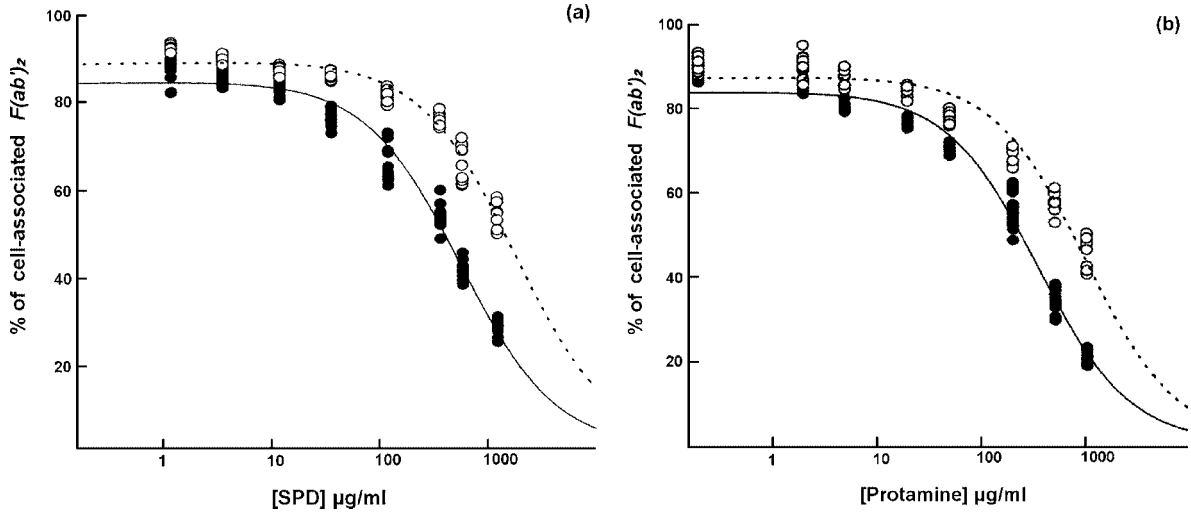

Figure 8. Inhibition of the interaction of SPD-$F(ab')_2$ (●; solid line) and corresponding control $F(ab')_2$ (○; dotted line) with HL60 cells by addition of free SPD (a) and protamine (b). Each antibody used at a concentration of 50 μg/mL was incubated with the cells in the presence of increasing concentrations of (free) SPD or protamine for 120 min at 37 °C. The inhibitor concentrations were 1.25, 3.75, 12.5, 37.5, 125, 375, 600, and 1250 μg/mL for SPD, and 0.205, 2.05, 5.125, 20.5, 51.25, 205, 512.5, and 1025 μg/mL for protamine. The percentage shown of cell-associated $F(ab')_2$ is the ratio of the cell-associated amount in the presence of inhibitor to the cell-associated amount in the absence of inhibitor. All the values shown are mean values from five independent experiments for the SPD-$F(ab')_2$ and four experiments for the control $F(ab')_2$ (each inhibitor concentration tested in duplicate in each experiment). The solid or dotted lines are computer-estimated values. The IC_{50} values of the inhibitors calculated from the inhibition data are given in the text along with their S.D.

bound and internalized $F(ab')_2$. However, a more detailed examination of the fluorescence pattern at ×40 or ×63 magnification, in combination with Nomarski images of the cells, showed specific differences between the cells incubated with the PUT- and HMD-$F(ab')_2$ conjugates and those incubated with the SPD- and SPM-$F(ab')_2$ conjugates. An intense punctured fluorescence was observed in the cytoplasm of the cells incubated with the various conjugates (Figures 9b and d), indicating that all of these conjugates were actually internalized at 37 °C. However, the fluorescence in cells incubated with the SPD-$F(ab')_2$ (Figure 9d) or the SPM-$F(ab')_2$ (not illustrated) was greater than the fluorescence in cells incubated with the PUT-$F(ab')_2$ (Figure 9b) or the HMD-$F(ab')_2$ (not illustrated). The different fluorescent intensities observed suggested that the HL60 cells internalized more of the antibodies cationized with SPD or SPM. This observation was consistent with the greater amounts of cell-associated antibody measured for the SPD- and the SPM-$F(ab')_2$ by ELISA relative to the PUT- and HMD-$F(ab')_2$ (Figures 6 and 7). For all internalized polyamine-$F(ab')_2$, fluorescence was localized in vesicular-like structures which may correspond to endosomes and/or lysosomes. In contrast to the results at 37 °C, fluorescence was associated only with the plasma membrane of the cells incubated with the cationized $F(ab')_2$ at 4 °C (Figure 9a,c). On the other hand, in HL60 cells incubated with the control $F(ab')_2$ at either 4 °C (Figure 9e) or 37 °C (Figure 9f), the fluorescence was very weak, and no fluorescence was detected in the cytoplasm, demonstrating that the $F(ab')_2$ did not undergo significant endocytosis when it was not cationized. No fluorescence was detected in the blank HL60 cells incubated without antitetanus $F(ab')_2$ but with all other reagents.

Estimation of Internalized Amounts of the Cationized $F(ab')_2$. Considering the ELISA results in light of those obtained by microscopy, we concluded that the cationized $F(ab')_2$ which were associated with the cells at 4 °C corresponded to surface-bound antibodies only (endocytosis is blocked at 4 °C (*19*)), while those at 37 °C corresponded to internalized antibodies as well as surface-bound antibodies. The cell-associated amounts of control $F(ab')_2$ at 4 °C was ascribed to nonspecific binding, and the amounts at 37 °C ascribed to nonspecific binding and perhaps nonspecific endocytosis (the contribution due to non-specific endocytosis must be small, since no control $F(ab')_2$ was detected inside the cells (Figure 9f)).

Using the ELISA measurements (Figures 6 and 7), we estimated the cell-internalized amounts of HMD-, SPD-, and SPM-$F(ab')_2$ as well as those for PUT-$F(ab')_2$ cationized at pH 4.5, all having the same maximum coupling. We did not include the PUT-$F(ab')_2$ modified at pH 5.5 and 6.5 because the interaction of these antibodies with the HL60 cells was less successful. For these calculations, the amounts of cell-associated control $F(ab')_2$ at 37 and 4 °C were subtracted from the amounts of cell-associated cationized $F(ab')_2$ at 37 and 4 °C, respectively, to eliminate any possible contribution due to nonspecific binding and/or nonspecific endocytosis. The amount of internalized cationized $F(ab')_2$ was then calculated as the difference between the cell-associated amounts at 37 °C and those at 4 °C. This calculation assumes that the amounts of cationized $F(ab')_2$ bound to the HL60 cell surface via electrostatic interaction were similar at both 4 and 37 °C, which seems reasonable because, as far as electrostatic interaction is concerned, the binding of cationic substances to anionic surfaces slightly increases when the temperature decreases if the process is enthalpy-driven (*20–22*). Therefore, this assumption could only lead to an underestimation of the amount of internalized antibody.

The results corresponding to these calculations are presented in Figure 10. The endocytosis of the cationized $F(ab')_2$ was concentration-dependent, but the relationship between the amount of antibody taken up by the cells and the corresponding concentration of cationized $F(ab')_2$ was not linear: the amount of internalized $F(ab')_2$ increased for concentrations ranging from 5 to 25 μg/mL, but reached a plateau for concentrations greater than 25 μg/mL. This could reflect a saturation in the internalization process of these antibodies by HL60 cells. The maximum amounts of SPD- and SPM-$F(ab')_2$ internalized by the cells were similar and amounted to ~3000 ng/mg cell protein. These values were approximately three times higher than those calculated for the PUT-$F(ab')_2$ as well as for the HMD-$F(ab')_2$. These results indicate that coupling the antitetanus $F(ab')_2$ to SPD and SPM in order to deliver this antibody into HL60 cells is more efficient

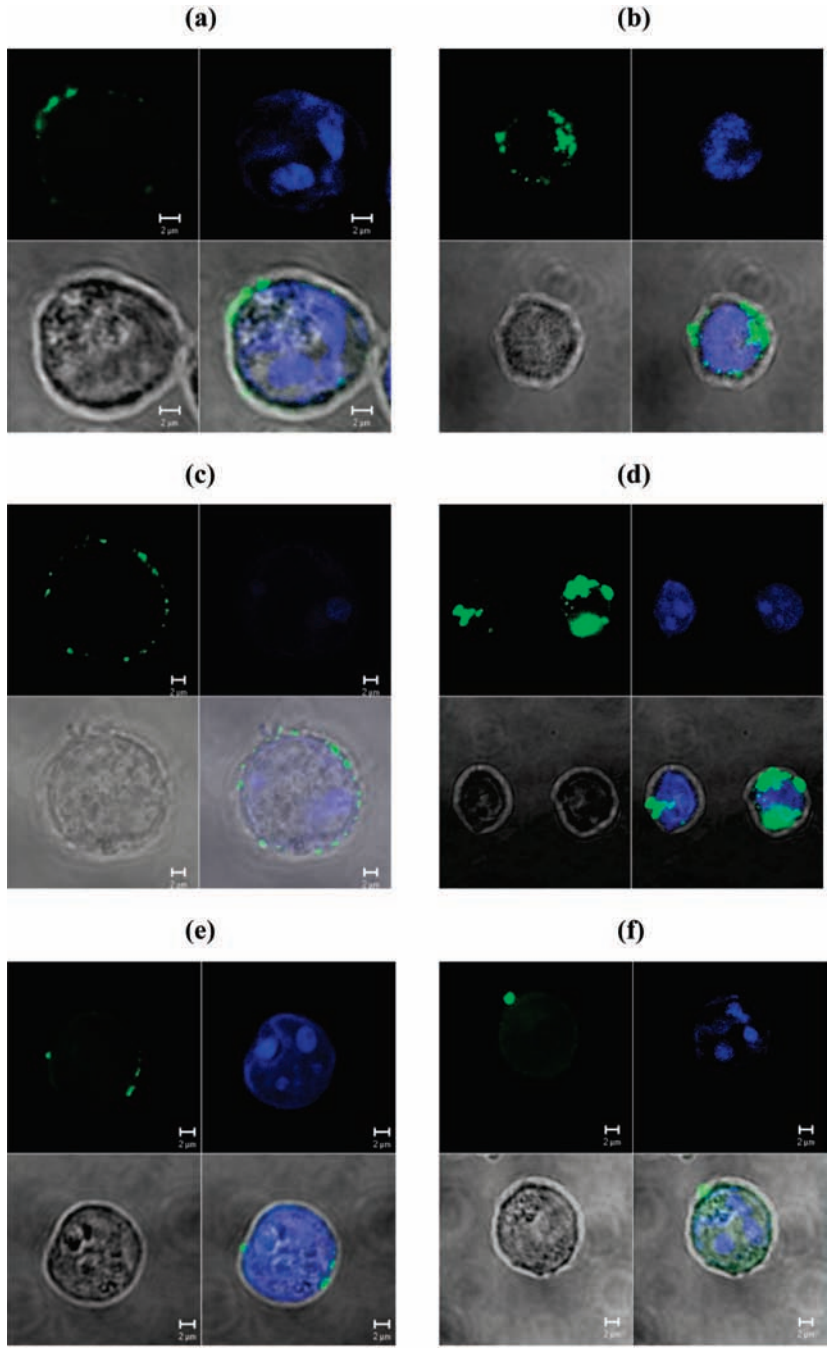

Figure 9. Internalization of cationized antitetanus $F(ab')_2$ fragments by HL60 cells, and effect of modification with different polyamines. Cells were incubated for 120 min with PUT-$F(ab')_2$ (a and b), SPD-$F(ab')_2$ (c and d), and control unmodified $F(ab')_2$ (e and f), at either 4 °C (a, c, and e) or 37 °C (b, d, and f). Bound and internalized $F(ab')_2$ fragments (green) were detected by immunofluorescence confocal microscopy using a biotinylated antihorse $F(ab')_2$ antibody/streptavidin−Alexa 488 conjugate system. Nuclear labeling (blue) was performed using toto-3. Nomarski images were used to visualize the cells. Scale bar = 2 μm.

than coupling to PUT and HMD, probably owing to the larger number of positive charges left after coupling on SPD and SPM.

DISCUSSION

As was stipulated in the introduction, our aim was to compare both the natural PUT, SPD, and SPM polyamines and the synthetic HMD polyamine after antibody cationization in order to, at the outcome, select the most effective polyamine in terms of antibody intracellular delivery. To this end, we used a systematic approach that encompassed (i) the cationization of polyclonal antitetanus $F(ab')_2$ with these polyamines, (ii) the degree of modification of the $F(ab')_2$ conjugates, (iii) their biological activity, and (iv) their interaction with HL60 cells. For these last two points, we used an ELISA method especially developed both to measure antibody binding activity after cationization and to quantify cell-associated antibodies after interaction with HL60 cells (*10*). Our choice of HL60 cells as a model is justified in that these cells have already shown their viability in other cellular internalization studies, one using antitetanus $F(ab')_2$ cationized with PUT (*10*), and another concerning IgG and its *Fab* fragments cationized with HMD (*6*).

By coupling HMD, PUT, SPD, or SPM to surface carboxyl groups of the $F(ab')_2$, we showed that the degree of modification of the antibody could be controlled by varying the pH of the reaction or the molar excess of polyamine relative to the

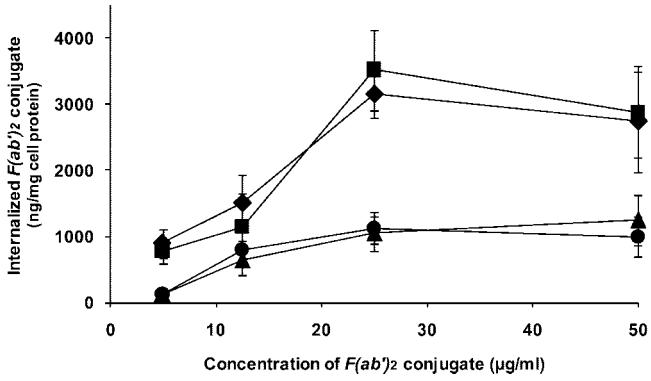

Figure 10. Internalization of cationized $F(ab')_2$ in HL60 cells estimated from ELISA-based measurements: effect of antibody cationization at pH 4.5 with various polyamines. The amounts of internalized PUT-$F(ab')_2$ modified at pH 4.5 (●) and HMD- (▲), SPD- (■), and SPM-$F(ab')_2$ (◆) were calculated from the data shown in Figures 6 and 7. The values of internalized antibody amounts are mean values, and are shown along with their standard deviation. Details of the calculations are described in the text.

antibody carboxyl groups, yielding a coupling of one, two, or three polyamine molecules per $F(ab')_2$ molecule. This study has taken protein cationization one step further compared to other studies where the different stages of cationization were evaluated only by the increase in the protein pI (*6, 17, 23–25*). In our study, we developed a procedure that quantitatively determines the degree of polyamine coupling of the antitetanus $F(ab')_2$. A definite cationization of the $F(ab')_2$ was achieved by high excess of polyamine, thus reducing the risk of cross-linking between $F(ab')_2$ molecules. Dialysis used alone was not found to be a sufficient method in eliminating the excess polyamine from the $F(ab')_2$ following cationization, as seen in other studies (*17*). Therefore, we were very careful in purifying the cationized $F(ab')_2$. Purification was obtained by a three-step procedure: ultrafiltration, gel filtration, and dialysis of the reaction products. The maximum coupling of three polyamine molecules per antitetanus $F(ab')_2$ molecule was relatively low. This result may not be surprising since, in its native form, this polyclonal antibody is characterized by a large content of high pI forms, indicating a low abundance of accessible carboxyl groups. The shift to high pIs observed after polyamine modification confirmed that the $F(ab')_2$ was readily cationized. In addition, this shift was more pronounced in the acidic $F(ab')_2$ species than in the other ones, and also when the antibody was modified at pH 4.5 rather than at higher pH levels.

The antigen-binding activity of cationized antibodies is critical to their use as potential drugs. Because cationization may compromise the antibody activity, we came up with an antigen-binding capture ELISA (*10*) which would quantify the biological activity of the cationized $F(ab')_2$, as well as the HL60 cellular interaction and the active amounts of cell-associated antibodies. There was a gradual decrease in the activity of the $F(ab')_2$ when cationized at decreasing pH values. The highest decrease observed was comparable to that reported for other cationized polyclonal antibodies (*26*) and stayed within tolerable limits. It was also consistent with the absence of structural changes in the antibody that would have altered mobility on SDS-PAGE. Accordingly, there was no need to perform cationization with antibody site protection.

To sum up, the HL60 cellular interaction of the cationized and control $F(ab')_2$ was quantified by ELISA, and the localization of these antibodies at the cellular level was visualized by confocal microscopy. The ELISA-based measurements showed that cationization of the $F(ab')_2$ significantly enhanced the interaction of the antibody with the cells, compared to control $F(ab')_2$. They also highlighted an increasing cell interaction of the polyamine-modified $F(ab')_2$ when the degree of polyamine coupling increased. Moreover and for similar degrees of coupling, the $F(ab')_2$ modified with the polyamines SPD and SPM (+6 and +9 positive charges, respectively, expected after modification) exhibited higher interactions with the HL60 cells than the antibodies modified with the diamines PUT and HMD (+3 positive charges expected for each). The HL60 cellular interaction was seen to depend on both temperature and antibody concentration. Furthermore, the confocal microscopy studies demonstrated clear internalization of the cationized $F(ab')_2$ by the HL60 cells at 37 °C, but not at 4 °C. In addition, the relationship between the estimated amount of internalized antibody and the tested dose of cationized $F(ab')_2$ indicated that the cell uptake of these antibodies reached a plateau. These results were consistent with those of previous studies which also showed that the internalization of HMD-cationized IgG and *Fab* fragments by HL60 cells (*6*), and the cell uptake of other HMD-modified antibodies using other cell models (*3, 5, 27*) was inhibited at low temperatures, and could become saturated. In contrast, and in spite of the preponderance of alkaline isoforms, the control antitetanus $F(ab')_2$, like the native $F(ab')_2$ (*10*), bound only in small amounts to the surface of the cells and did not undergo detectable endocytosis, showing that a basic pI in this context is not sufficient to cause significant antibody internalization, as observed in other studies (*4, 5*).

Taken together, these results suggest that the mechanism involved in cellular internalization of the polyamine-modified $F(ab')_2$ is an adsorptive-mediated endocytosis (AME). Indeed, AME is a temperature- and concentration-dependent transport process (*1, 28*) which depends predominantly on charge-charge interaction between the transported molecule and the cell surface (*3*). It typically becomes saturated and/or inhibited at higher doses than receptor-mediated endocytosis (*1*). These features are consistent with the particularly high concentrations of SPD and protamine needed to inhibit the HL60 cellular interaction of SPD-$F(ab')_2$. Moreover, the greater IC_{50} value determined for SPD in relation to protamine showed that protamine was a more potent inhibitor of the SPD-$F(ab')_2$ interaction with the HL60 cells than SPD, probably owing to its larger number of positive charges. Nonetheless, if the cationized $F(ab')_2$ enter the HL60 cells by virtue of charge interaction, our results raise the question as to why no further increase in cell uptake was observed when the number of ionizable amine groups left on the polyamine after protein coupling increased from +6 (for the SPD-$F(ab')_2$) to +9 (for the SPM-$F(ab')_2$), coupling to these two polyamines having the same maximum effect.

As has been established (*29, 30*), the protonation schema of (free) SPD and SPM showed normal first and second protonation reactions of their amine functions, while for the third protonation (and also the fourth for SPM) the basicity of the amine functions decreased. These variations of the macro-ionization constants are consistent with the difficulty of adding another positive charge on a molecule that is already positively charged, owing to repulsive interactions between electric charges of the same sign accumulating in a confined space (*29*). According to the pK_a values reported for SPD (10.8, 9.58, and 7.82) and for SPM (10.7, 9.7, 8.31, and 7.18), an SPD molecule will carry 2.8 positive charges at neutral pH, and an SPM molecule only 3.3 charges, although these values can change when electrolytes are present in the medium (*29, 30*). After protein coupling, the SPD molecule is expected to carry 2 positive charges, and an SPM molecule a maximum of 2.8 charges since the third protonation of coupled SPM remains difficult for electrostatic reasons. Moreover, the proximity of the third ionizable amine function of SPM to the site of coupling can decrease its accessibility to the solvent and affect its protonation, possible interaction of this function with vicinal charged amino acid side

chain groups on the protein surface notwithstanding. Owing to this, the global charge of SPM after protein coupling may only be due to the protonation of its two most external amine functions. In this case, the effective global charge brought about by coupling of SPM to $F(ab')_2$ would be similar to that of SPD; the respective effects thereof on antibody cell interaction and uptake would also be similar.

Due to the abundance of polyanions that surround cells, cationization of proteins is a reasonable method to endow them with the ability to penetrate cells via AME. In this study, we explored the idea of cationization via the carbodiimide-mediated amidation of the $F(ab')_2$. Nevertheless, other successful cationization methods have also been described, involving the chemical conjugation of proteins to polycationic polymers or to arginine/lysine-rich peptides (*2*). Another strategy for improving the cell entry of proteins is the covalent attachment of these molecules to cell-penetrating peptides (CPPs) (*31*). These peptides are heterogeneous in size and sequence, but they have an obvious common feature in their cationic nature. The uptake mechanisms of CPPs still remain ambiguous in that different CPPs can utilize diverse uptake mechanisms, depending on their cargo and biophysical properties. However, several studies have highlighted the crucial role of CPPs' basic residues in the translocating ability of these peptides (*31*). Various CPPs, including the Tat-derived peptides (*31*) and Syn-B peptides (*32*), have been associated with AME. There is experimental evidence that heparan sulfate proteoglycans (HSPG) (*33*), as well as other negatively charged cell surface components (*31*), are involved in the cell uptake of these peptides, thus reinforcing the possibility of an adsorptive endocytic process for some CPPs.

In conclusion, this is the first study, to our knowledge, which uses both synthetic and natural polyamines for antibody cationization and compares the effects of these modifications on antibody cell interaction and uptake. Modification of the antitetanus $F(ab')_2$ with the synthetic diamine HMD was as effective as with the natural diamine PUT, in terms of intracellular delivery. In comparison, modification with SPD or SPM gave better results, indicating that the increase in cell uptake observed after polyamine modification was, to a certain degree, dependent on the charge density associated with the coupled polyamine. The similar results for SPD- and SPM-$F(ab')_2$ suggest that the effective global charge for the cell uptake of polyamine-modified antibody may not simply correspond to the addition of the ionizable amine functions in the polyamine, but may also be related to differences in protonation between these functions, and to the reduced accessibility of the most internal amine function of SPM when it is coupled to $F(ab')_2$. In view of this, both the intrinsic properties of polyamines and the effect of protein coupling on the accessibility/protonation of their amine functions should be taken into account when planning to use these molecules as vectors to improve the intracellular delivery of proteins. Finally, a good example of a potential use for cationized antibodies would be a treatment for tetanus. This severe disease, caused by a bacterial toxin targeting the central nervous system (*34*), is currently treated with antitoxin antibodies. But while these antibodies can neutralize the toxin in the blood, they are ineffective when the toxin enters the nerve cells (*35*). It has been shown that cationization has the potential to facilitate transcytosis of antitetanus $F(ab')_2$ across an in vitro blood-brain barrier model (*36*). The present study showed robust internalization of this antibody following cationization with SPD and SPM, with retention of antigen binding activity after uptake. The cationized $F(ab')_2$ were localized in vesicle-like structures which may correspond either to endosomes or to lysosomes. The exact fate of cationized $F(ab')_2$ after internalization is unknown, but some of these proteins may be released by vesicular disruption and may gain access to the cytoplasm where they can bind and neutralize the toxin. Although these studies are encouraging, there is much to be learned before any cationization-mediated strategy can be developed to deliver antitetanus antibodies across the blood−brain barrier and into nerve cells, and also before the potential of cationized antitetanus antibodies as therapeutic substances for the treatment of tetanus can be pharmacologically exploited.

ACKNOWLEDGMENT

We would like to thank Dr. Charles Lutsch and the Aventis-Pasteur Company (Marcy l'Etoile, France) for providing us with the antitetanus $F(ab')_2$ fragments and tetanus anatoxin. This work was supported by a grant from INSERM.

Received February 6, 2008; Revised Manuscript Received June 18, 2008

We present structure, photoexcited triplet-state property, and singlet oxygen ($^1O_2$) generation capability of human serum albumin complexed with a tris(dicarboxymethylene)[60]fullerene C_3-isomer (HSA−CF). Small angle X-ray scattering measurements showed that a globular size-dimension and surface charge distribution of HSA were unaltered by monomolecular complexation of CF into the hydrophobic cavity. Laser flash photolysis to the HSA−CF solution yielded a photoexcited triplet state of the CF chromophore (^{3}CF*) with lifetime of 46 μs. In the presence of O_2, energy transfer occurred from HSA−^{3}CF* to O_2 to generate $^1O_2$; the quenching rate constant [$k_q(O_2)$] was determined to be 2.2×10^8 M^{-1} s^{-1}. The HSA−CF showed strong photoresistence relative to HSA complexed with a protoporphyrin IX. The quantum yield of $^1O_2$ production for this artificial protein was compared to those of other photosensitizing agent. The HSA−CF did not show a dark cytotoxicity, but induced cell death efficiently under visible light irradiation.

INTRODUCTION

Photodynamic therapy (PDT) is a nonsurgical cancer treatment that combines a photosensitizing medication with exposure to visible light (*1, 2*). Highly cytotoxic singlet oxygen ($^1O_2$) formed by energy transfer from photoexcited sensitizer to molecular O_2 has been implicated as an intermediary species leading to cell death in tumors. To accelerate this $^1O_2$ generation, a range of organic dyes, especially porphyrin compounds, have been synthesized as photosensitizers (*3*). The most widely used reagent in clinical PDT is Photofrin, which is a heterogeneous mixture of hematoporphyrin oligomers (*1, 2, 4*). Several porphyrin or chlorin derivatives are also being tested as second generation (*1, 2, 5, 6*). Another well-known agent approved by the FDA is Levulan; 5-aminolevulinic acid (ALA) (*7–9*). ALA-induced photosensitization is unique approach that utilizes the heme biosynthetic pathway to produce endogenous protoporphyrin IX (PP). When ALA enters cancer cells, it triggers the synthesis of PP, which acts as an active sensitizer. Wavelengths typically used in PDT are between 600 and 800 nm, because light below 600 nm is absorbed by tissues and hemoglobin (Hb). Photofirin is normally excited by a red light (630 nm) using an Excimer dye-laser (*1, 2*). The ALA-PDT also uses the 630 nm laser, while the irradiation using a metal halide lamp or xenon arc lamp is still popular, because this is reasonable in comparison to the expensive laser pulse system and suitable for irradiation of the wide area of the diseased part (*9*). In fact, the light source approved in the U.S. for ALA-PDT was halogen lamp (λ_{exc} = 410 nm). Buckminster[60]fullerene (C_{60}) produces $^1O_2$ by energy transfer with extremely high quantum yield (Φ_Δ: 0.96, λ_{exc} = 532 nm) (*10, 11*) and generally shows strong photoresistance compared to the porphyrins. Consequently, various water-soluble fullerenes and fullerene−polymer hybrids have been prepared as a new class of photosensitizer for $^1O_2$ production (*11–16*). However, we would like to emphasize herein that most exogenous compounds administered into our bloodstream are immediately captured by human serum albumin (HSA, Mw: 66.5 kDa), which is the major protein component in our blood plasma (*17, 18*). To evaluate the biological performance of the fullerene, we must investigate the structure and function of the HSA−fullerene complex. Despite that necessity, photochemistry of the HSA−fullerene complex has never been studied to date. In this paper, we report for the first time the structure and photoexcited triplet-state properties of HSA complexed with a tris(dicarboxymethylene)[60]fullerene C_3-isomer (HSA−CF) and highlight its photoinduced energy transfer to O_2 to produce $^1O_2$. Furthermore, cytotoxicity of HSA−CF in vitro has also been evaluated. It is known that CF acts as a neuroprotective agent (*19*) and binds to HSA (*20*), but its photophysical behavior and cytotoxicity under visible light irradiation have not been elucidated.

EXPERIMENTAL PROCEDURES

Materials and Apparatus. All reagents were purchased from commercial sources as special grades and used without further purification. Recombinant HSA expressed in *Pichia pastoris* was purchased from Sigma-Aldrich Corp. Tris(dicarboxymethylene)-[60]fullerene C_3-isomer (CF) was purchased from Axxora LLC and 2-[4-(2-hydroxyethoxy)phenyl]-1,3-dioxolo-4*a*,5*a*-[60]fullerene (HF) was purchased from FLOX Corp. Protoporphyrin IX (PP), protoporphyrin IX dimethyl ester (PPDME), and [60]fullerene (C_{60}) were purchased from Sigma-Aldrich Corp. The water was deionized using a Millipore Elix and Simpli Laboratory-UV. The UV−vis absorption spectra for the potassium phosphate buffered (PB) solution (pH 7.0, 50 mM) of the HSA−fullerene complex (normally 20 μM) were recorded using an Agilent 8453 UV−visible spectrophotometer with an Agilent

89090A temperature control unit. The CD spectra for the PB solution of the HSA−fullerene complex were measured using a JASCO J-820 circular dichrometer. The concentration of the HSA sample was 2 μM and a quartz cuvette with a 2.0 mm thickness was used for measurements in the range 195−250 nm. Mass spectroscopic analyses were performed using a JEOL JMS-T100CS ESI-TOF mass spectrometer.

Preparations of HSA−Fullerene Complexes. Typically, 3.92 mL of a PB solution (pH 7.0, 50 mM) of HSA (0.25 mM) was mixed with 1.0 mL of 0.98 mM CF in PB (CF/HSA molar ratio of 1:1) and incubated for 12 h with rotation in the dark at room temperature. The complex was then diluted with 50 mM PB solution and concentrated to the initial volume using a Vivaspin 20 centrifuge filter (5 kDa MW cutoff) at 4000 × *g* using a Beckman Coulter Allegra X-15R centrifuge. In the case of HSA−HF, 4.29 mL of PB solution (pH 7.0, 50 mM) of HSA (42 μM) was mixed with 0.67 mL of 0.267 mM HF in DMSO (HF/HSA molar ratio of 1:1) and incubated for 12 h with rotation in the dark at room temperature ([DMSO] = 13.5 vol %). The complex was then diluted using 50 mM PB solution and concentrated to the initial volume using a Vivaspin 20 centrifuge filter at 4000 × *g*. These dilution/concentration cycles were repeated to reduce the DMSO concentration to <0.1 vol %. The obtained protein solution was loaded on a Superdex 75 g gel-permeation column by elution of 50 mM PB using an ÄKTA Prime Plus FPLC system; only one band was observed during the chromatography. The PB solutions (pH 7.0, 50 mM) of HSA−CF and HSA−HF ([HSA]: 20 μM) in a 10-mm-path length optical quartz cuvette sealed with a rubber septum was degassed and purged using N_2 prior to use. The HSA complexed with PP (HSA−PP) was also prepared by the same procedure as HSA−HF.

HPLC. HPLC measurement of the HSA−fullerene complex was carried out using an HPLC system consisted of a Shimadzu LC-8A pump and a Shimadzu SPD-10A UV detector. A Shodex Protein KW-803 column was used with PB (pH 7.0, 10 mM) as the mobile phase at 22 °C (1.0 mL min^{-1}).

Isoelectric Focusing (IEF). The IEF was performed using an Amersham Biosciences Electrophoresis Power Supply EPS 301 with an Invitrogen Novex pH 3−7 IEG Gel. The protein marker used was a GE Healthcare IEF calibration kit Low Range *p*I (pH 2.5−6.5). The voltage was gradually raised to 300 V for 4 h. The gels were stained by a Daiichi Pure Chemicals PAGE Blue 83 and distained by washing with aqueous ethanol/acetic acid and 10% acetic acid.

Small-Angle X-ray Scattering (SAXS). SAXS experiments were carried out using an Anton Paar SAXSess camera in the *q*-range 0.10−9.0 nm^{-1}. Deionization of the protein sample was performed by dilution/concentration cycles with pure water using Vivaspin 20 centrifuge filter (5 kDa MW cutoff) at 4000 × *g*, giving an aqueous solution of the HSA−CF complex. Washing with phosphate buffered saline (PBS) solution (pH 7.4, 150 mM) gave the PBS solution of the protein. The scattered intensity $I(q)$ was generally given as $I(q) = nP(q)S(q)$ for globular particle system, where n is the particle number density, $P(q)$ is the form factor, and $S(q)$ is static structure factor. The measured intensities were normalized to give the uniform primary intensity at $q = 0$ and converted into absolute scale using water as a secondary standard. A model-independent collimation-correction procedure was made via an indirect Fourier transformation (IFT) technique. The pair-distance distribution functions $p(r)$ of HSA and HSA−CF in solution, which are given as inverse Fourier transformations of the form factor $P(q)$ into real space, were obtained using IFT technique for a highly diluted sample ($S(q) \sim 1$) and its generalized version (GIFT) for $c > 1$ g dL^{-1}. The GIFT technique enables splitting of $I(q)$ into $P(q)$ and $S(q)$, letting $P(q)$ and the resulting $p(r)$ virtually model free, where we assumed a screened Coulomb (Yukawa) potential and Rogers-Young (RY) closure relation. We made a complementary analysis to deduce the experimental structure factor, $S(q)^{exp}$, by dividing the normalized intensity $I(q)/c$ by the experimental form factor $P(q)^{exp}$ determined at very low concentration, which confirms the validity of the GIFT results.

Laser Flash Photolysis. The transient absorption spectra and triplet lifetime measurements were carried out using a Unisoku TSP-1000WK time-resolved spectrophotometer with a Spectron Laser Systems SL803G-10 Q-switched Nd:YAG laser, which generated a second-harmonic (532 nm) pulse of 6 ns duration (10 Hz) (*21*). The samples (20 μM) of the PB solutions (50 mM, pH. 7.0) of HSA−CF, HSA−HF, HSA−PP, THF solution of PPDME, and toluene solution of C_{60} were held in a quartz cuvette (optical path length; 10 mm); experiments were carried out at 22 °C. The gas mixture with the desired partial pressure of O_2/N_2 prepared by a KOFLOC Gasbrender GB-2C was flowed into the sample cuvette for 20 min for equilibration.

Near-Infrared Photo-Counting Measurement. The emission spectrum of $^1O_2$ ($^1\Delta_g \rightarrow {}^3\Sigma_g^-$) was measured using a Hamamatsu Photonics C8282W Near-Infrared Photo-Counting System equipped with a Hamamatsu Photonics R5509 photomultiplier and a Q-switched Nd:YAG laser, which generated a second-harmonic (532 nm) pulse (20 Hz, 60 μJ/pulse at the sample position). The gate time width was 2−100 μs. The samples (40 μM) were held in a quartz cuvette (optical path length 10 mm). The experiments were carried out in air at 22 °C. Quantum yield of $^1O_2$ (Φ_Δ) production by HSA−CF was determined using rose bengal as the standard compound.

In Vitro Cytotoxicity Evaluation. The LY80 tumor cell, a variant of the Yoshida sarcoma, was kindly gifted from Dr. Katsuyoshi Hori, Tohoku University. The cells were grown at 37 °C in DMEM supplemented with 10% fetal bovine serum (FBS) and penicillin (100 IU/cm^3) in 95% air−5% CO_2 humidified incubator. The cell solution (2.5×10^5 cells/mL, 0.16 mL) was mixed with PBS (0.04 mL) or PBS solution of HSA−CF (100 μM, 0.04 mL) in a Corning Costar 3596 cell culture plate (96 well) and incubated in the dark. Then the plate was irradiated by visible light using a 500 W halogen lamp in conjunction with a HOYA HA30 heart absorption filter (330−700 nm). The power at the cell level was monitored using a Gentec Power Meter and adjusted to 20 mW cm^{-2}. The temperature was kept at 36 ± 1 °C during the irradiation. As a negative control, we examined another PBS group in the same culture plate without light irradiation. After 2 h, the cell numbers were counted using microscopy under tripan blue staining.

RESULTS AND DISCUSSION

Structure of HSA−Fullerene Complexes. The HSA−fullerene complexes were prepared essentially as described previously for HSA−hemin complexes (*21*). A phosphate buffered (PB) solution (pH 7.0, 50 mM) of HSA was mixed with PB solution of CF (CF/HSA molar ratio of 1:1) and incubated for 12 h. The complex was then concentrated to the initial volume using a centrifuge filter (Figure 1 inset photograph). The filtrate was colorless during the centrifugation. The gel permeation chromatogram (Superdex 75 g) of the orange-colored protein exhibited only a single elution peak. These results indicate that CF is efficiently incorporated into HSA. For comparison, hydrophobic fullerene, 2-[4-(2-hydroxyethoxy)-phenyl]-1,3-dioxolo-4a,5a-[60]fullerene (HF), was also complexed with HSA to give HSA−HF. The obtained HSA−fullerene solutions can be concentrated up to 3.75 mM (25 g dL^{-1}); they were stable for a year without precipitation.

The UV−vis absorption spectroscopic features of the HSA−CF solution are the sum of those from the individual HSA and CF (Figure 1), which indicates that CF is monomolecularly

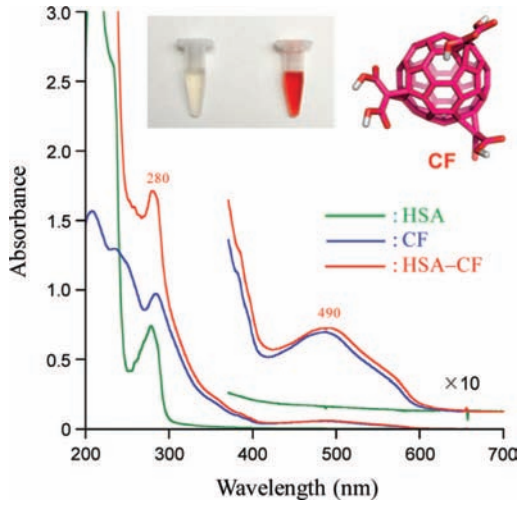

Figure 1. UV−vis absorption spectrum of HSA−CF complex, CF and HSA (20 μM) in PB solution (pH 7.0, 50 mM) at 22 °C. Inset photographs are 5 g dL^{-1} HSA (left) and HSA−CF (right) solutions.

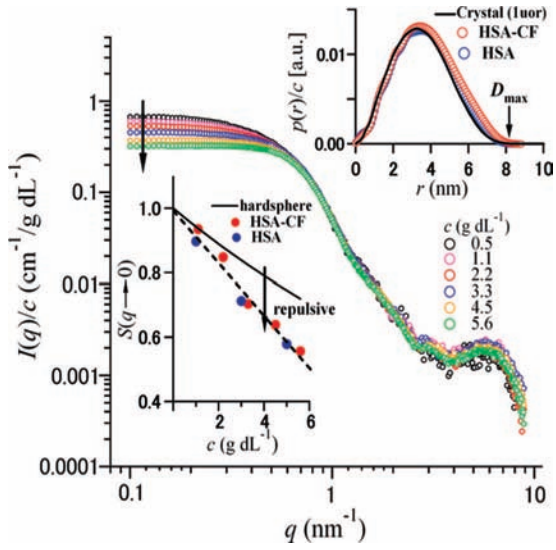

Figure 2. Normalized SAXS intensities [$I(q)/c$] of HSA−CF complex in 150 mM PBS solutions (c = 0.5−5.6 g dL^{-1}). The upper and lower insets show pair-distance distribution functions [$p(r)$] and extrapolated structure factors [$S(q\to 0)$] of HSA−CF and HSA, respectively.

incorporated into HSA and no specific interaction between the two molecules at the ground state. In contrast, the absorption spectrum of the brown-colored HSA−HF solution did not coincide with the superposition of the HSA and HF spectra (Figure S1). The increased absorbance at 380−550 nm suggests the formation of HF clusters in the protein (*11, 16*).

The HSA−CF complex was sufficiently stable to apply the HPLC measurement. In the elution profile, a single peak appeared at a retention time of 7.64 min, which was slightly earlier than that of HSA itself (7.75 min) (Figure S2). The ratio of the peak intensity monitored at 280 nm (based on HSA) and at 490 nm (based on CF) (I_{280}/I_{490} = 30) was exactly the same as the absorbance ratio at 280 and 490 nm in the UV−vis absorption spectrum (A_{280}/A_{490}) of HSA−CF, which implies that all CF molecules were eluted within the HSA fraction.

The ESI-TOF mass spectroscopy of HSA−CF showed a distinct ion peak at 67 587 Da, which corresponds to the mass of the equivalent complex of HSA−CF. On the other hand, two separated peaks were observed in the HSA−HF spectrum at 66 585 (free HSA) and 68 296 Da, that reveals 1:2 stoichiometry for HSA/HF and the formation of HF clusters in the protein. The CD spectral patterns and intensities of HSA−CF and HSA−HF were identical to those of HSA (Figure S3). We inferred that fullerene binding did not change the highly ordered structure of the host HSA.

The incorporation of negatively charged CF having hexacarboxyl groups might influence the surface charge distribution of albumin. However, isoelectric focusing of HSA−CF indicated the same isoelectric point (*p*I) with HSA. This contrasts sharply to the fact that fatty acid binding induced the reduction of the *p*I value because of partial neutralization of the molecular charge (*22*). We then used small-angle X-ray scattering (SAXS) to evaluate the globular particle structure and protein−protein interactions of HSA−CF (Figure 2) (*23*). The pair-distance distribution functions [$p(r)$] of HSA−CF and HSA were almost identical to the curve calculated from crystallographic data of HSA (1uor) (Figure 2 upper inset). It demonstrates that the maximum diameter (D_{max}: *ca.* 8 nm) and three-dimensional particle shape of HSA were unaltered by complexation of CF. The normalized SAXS intensities [$I(q)/c$] of HSA−CF at the low q range [$I(q\to 0)/c$] monotonously decreases with increasing protein concentration. In the PBS solution, the long-range electrostatic repulsion between HSA−CFs is efficiently screened, so that the suppressed forward intensity could be mainly due to excluded volume effect. However, the extrapolated structure factors [$S(q\to 0)$] of HSA−CF and HSA, which reflect the net repulsive forces between the protein molecules, were systematically lower than that predicted for hardsphere with an identical volume fraction (Figure 2 lower inset). The negative deviations are attributed to the electrostatic repulsion between the proteins. It is remarkable that the plots of $S(q\to 0)$ for HSA−CF and HSA perfectly lie on the same line, suggesting that HSA preserves its surface net charges upon the CF binding. On the basis of these results, we conclude that (i) CF is accommodated into the deep hydrophobic cavity of HSA with internal charge neutralization, and (ii) it does not induce marked changes in the globular particle size and surface charge distribution of HSA.

Photoexcited Triplet State of HSA−CF Complex and $^1O_2$ Formation. Photoexcitation of the fullerenes generates the singlet state, which undergoes intersystem crossing to the triplet state in high yield (*10, 11*). Laser flash photolysis (SHG of Nd:YAG, 532 nm, 6 ns) of the HSA−CF solution under an N_2 atmosphere gave a triplet−triplet (T-T) absorption spectrum of the ^{3}CF* chromophore (λ_{max} = 740 nm) (Figure 3) (*11, 13, 24*). The time course of the absorbance decay was composed of a single exponential kinetics with a lifetime (τ_T) of 46 μs (Figure 3 inset). The peaks of maximum absorption and τ_T value resembled those of the aqueous CF solution (τ_T: 43 μs). These observations again support that CF is held monomolecularly within the HSA interior.

Although HF in DMSO exhibited clear triplet absorption (τ_T: 31 μs), HSA−HF showed no signals in this wavelength range (Figure S4). The extremely short triplet lifetime of HSA−HF is probably attributed to T-T annihilation of the HF aggregates in the protein (*11*). If this is the case, the lifetime should become longer when the laser pulse energy is decreased. However, the decay was too fast to analyze precisely even under the weak laser flash photolysis.

In the presence of O_2, the triplet lifetime of HSA−CF significantly decreased. Energy transfer occurred from HSA−^{3}CF* to the O_2 molecule to generate active $^1O_2$. The Stern-Volmer plot clearly depicts a linear correlation for O_2 concentrations of 0−1.0 mM, giving the Stern-Volmer constant (K_{SV}) and quenching rate constant [$k_q(O_2)$] (Figure 4) [Note: $\tau_T^0/\tau_T = K_{SV}[O_2]$ (τ_T^0 and τ_T represent triplet lifetimes in the absence and presence of O_2)].The $k_q(O_2)$ of HSA−CF was 2.2 $\times$ 10^8 M^{-1} s^{-1}, which is one-seventh that of the monomeric

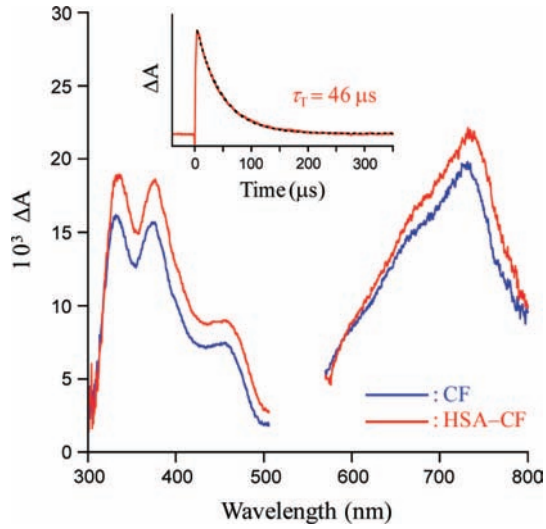

Figure 3. Triplet−triplet absorption spectra of HSA−CF complex and CF in PB solution (pH 7.0, 50 mM) under N_2 atmosphere at 22 °C; Ex. at 532 nm. The inset shows absorption decay of HSA−^{3}CF* complex at 734 nm, which was fitted by single exponential relaxation curve (black dotted line).

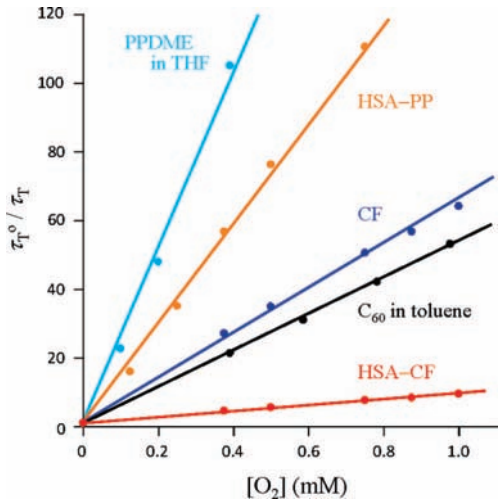

Figure 4. Stern-Volmer plots of triplet state quenching of HSA−CF complex and other compounds by O_2 at 22 °C. The HSA−CF, HSA−PP, and CF were in PB solution (pH 7.0, 50 mM).

Table 1. Quenching Rate Constants of the Photoinduced Excited Triplet States of HSA−CF Complex and Other Compounds by O_2 at 22 °C

compound	solvent	$k_q(O_2)$ (M^{-1} s^{-1})
HSA−CF	PB (pH 7.0, 50 mM)	2.2×10^8
CF	PB (pH 7.0, 50 mM)	1.6×10^9
HSA−PP	PB (pH 7.0, 50 mM)	1.3×10^8
PPDME	THF	1.6×10^9

		1.9×10^{9a}

[a] ref 10.

CF solution (1.6×10^9 M^{-1} s^{-1}) (Table 1). The HSA−PP complex in PB also showed smaller $k_q(O_2)$ (1.3×10^8 M^{-1} s^{-1}) compared to that of the protoporphyrin IX dimethylester (PPDME) in THF (*25*). The slow $k_q(O_2)$ values of the protein systems suggest that the quenching reaction is almost diffusion controlled. The intensity of the visible band of HSA−CF (λ_{max} = 490 nm) did not changed after 10^3 laser flash photolysis (λ_{ex} = 532 nm, 0.5 W) in air, indicating no photodegradation of the CF chromophore. In contrast, the Soret band of HSA−PP was

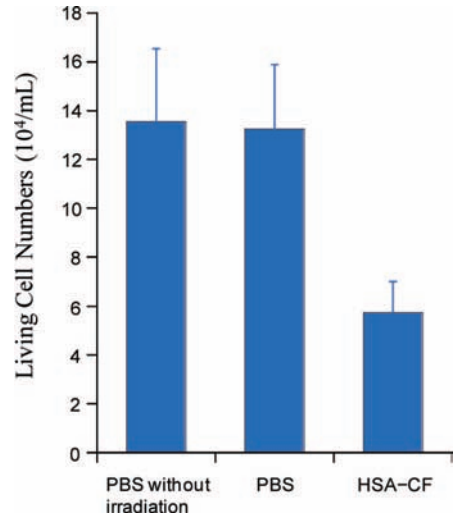

Figure 5. Living cell numbers of LY80 with HSA−CF and PBS after visible light irradiation (20 mW cm^{-2}, 2 h, 36 ± 1 °C). Each value represents the mean ± SD (n = 4).

≈6% photobleached after the identical flash irradiations. It can be concluded that the light resistance of CF is significantly higher than that of PP, which is an active photosensitizer in ALA-PDT.

We observed the near-infrared luminescence of the produced $^1O_2$ (λ_{max} 1270 nm) and evaluated the quantum yield of $^1O_2$ production (Φ_Δ) for HSA−CF from the value of emission intensity at 1270 nm (I) using rose bengal as a standard (*26*). The Φ_Δ value of HSA−CF (0.46) was in the same range as those of monomeric CF (0.48), methylene blue (0.52), PPDME in benzene (0.59) (*26*), and substituted fullerenes in organic solvent (*27, 28*), but somewhat lower than those of rose bengal (0.75), hematoporphyrin in methanol (0.74) (*29*), and C_{60} (0.96) in benzene (*10*). It is known that the substitution of the pristine C_{60} causes a perturbation of the electronic structure of the fullerene core, and thereby results in a decrease in the quantum yield for the $^1O_2$ formation (*27, 28*).

Cytotoxicity of HSA−CF Complex. Finally, we measured the cytotoxicity and photodynamic activity of the HSA−CF complex to the LY80 tumor cells in vitro. The cell cultures were first incubated for 24 h in the dark with HSA−CF (20 μM) at 37 °C under 5% CO_2. The cell numbers after the incubation were identical to that of control group with the PBS solution, indicating that the HSA−CF complex does not have dark cytotoxicity. The cell culture plates were then exposed to visible light of 350−600 nm (20 mW cm^{-2}) for 2 h at 36 ± 1 °C. Some of the cells mixed with HSA−CF showed abnormal shape after the light irradiation, whereas the PBS group did not show any morphological changes of the cells. The living cell numbers of the PBS groups with and without light irradiation were almost the same (Figure 5), which means that the light exposure did not affect the LY80 tumor cells in this experimental condition. On the other hand, the living cell numbers of the HSA−CF group were markedly lower than that of the PBS group; 57% cell death occurred by visible light irradiation. This result clearly implies that the HSA−CF complex acts as a photosensitizer for PDT.

CONCLUSIONS

The HSA−CF complex having identical molecular shape and surface charge distribution with HSA is easily excited by visible light and shows a high charge transfer rate constant for molecular O_2. The efficiency of the $^1O_2$ production of this artificial protein is in the same range as well-known dye

sensitizers, such as methylene blue and PPDME. In general, water-soluble drugs administrated into our bloodstream are quickly eliminated from the body. On the contrary, the HSA hybrid can remain in the circulatory system and/or tissues with a long persistence; therefore, the $^1O_2$ generation by albumin-based photosensitizer might be of clinical importance for photodynamic cancer therapy. The HSA−CF complex does not show dark cytotoxicity, but engenders cell death efficiently under visible light irradiation. Recombinant HSA is currently manufactured on an industrial scale using yeast species *Pichia pastoris* (*30*), which allows the use of the HSA−fullerene complex in practical applications.

Antibody targeting of drug substances can improve the efficacy of the active molecule, improving distribution and concentration of the drug at the site of injury/disease. Encapsulation of drug substances into polymeric nanoparticles can also improve the therapeutic effects of such compounds by protecting the molecule until its action is required. In this current study, we have brought together these two rationales to develop a novel immuno-nanoparticle with improved therapeutic effect against colorectal tumor cells. This nanoparticle comprised a layer of peripheral antibodies (Ab) directed toward the Fas receptor (CD95/Apo-1) covalently attached to poly(lactide-*co*-glycolide) nanoparticles (NP) loaded with camptothecin. Variations in surface carboxyl density permitted up to 48.5 μg coupled Ab per mg of NP and analysis of nanoparticulate cores showed efficient camptothecin loading. Fluorescence visualization studies confirmed internalization of nanoconstructs into endocytic compartments of HCT116 cells, an effect not evident in NP without superficial Ab. Cytotoxicity studies were then carried out against HCT116 cells. After 72 h, camptothecin solution resulted in an IC_{50} of 21.8 ng mL^{-1}. Ab-directed delivery of NP-encapsulated camptothecin was shown to be considerably more effective with an IC_{50} of 0.37 ng mL^{-1}. Calculation of synergistic ratios for these nanoconstructs demonstrated synergy of pharmacological relevance. Indeed, the results in this paper suggest that the attachment of anti-Fas antibodies to camptothecin-loaded nanoparticles may result in a therapeutic strategy that could have potential in the treatment of tumors expressing death receptors.

INTRODUCTION

Targeting of tumor-associated antigens using specific antibodies forms the basis of a drug delivery strategy to circumvent difficulties and side effects associated with nonspecific drug dosing. In the design of any immuno-nanoparticulate system, the choice of peripheral antibody, its conjugation chemistry, and therapeutic payload will depend on the intended target cell and associated cell-surface biomarker. One such cell-surface target, amenable to binding by antibodies, is the Fas (CD95/Apo-1) receptor. Fas is a 45 KDa type 1 membrane protein and a member of the tumor necrosis factor (TNF) super family. It is found on the plasma membrane of a variety of cancer cell lines (*1*) and has been identified as a target for antibodies that induce apoptosis in various human cell lines (*2, 3*). Fas is present on the cell surface as a homotrimer (*4*). Upon Fas ligand (FasL) or agonist antibody binding, activation of the Fas receptor trimer results in recruitment of the death inducing signaling complex (DISC) to its intracellular domain leading to activation of pro-caspase 8 (*5, 6*). Pro-caspase 8 is autocatalytically activated (*6*), and in turn cleaves and activates several downstream substrates including the effector caspases 3 and 7, cumulating in a proteolytic cascade that leads to the death of the cell (*7*).

The cell surface expression of Fas has been shown to be modulated by treatment of cells with drugs such as the quinoline-based plant alkaloids found in the wood, bark, and fruit of the Asian tree *Camptotheca acuminate*. The most utilized of these is camptothecin (CPT) which selectively inhibits mammalian topoisomerase I, a DNA replication enzyme overexpressed in a wide range of tumors, including advanced human colon, ovarian, and esophageal carcinomas (*8*). CPT exhibits antitumorigenic effects by trapping topoisomerase-I with DNA in topoisomerase I-cleavage complexes (*9*). This inhibition results in the stalling of DNA replication, subsequent S-phase arrest, and initiation of apoptotic cell death in tumor cells (*10*). Previously, it has been observed that agonistic Fas antibodies potentiated the cytotoxicity caused by CPT treatment (*11*). Specifically, results demonstrated that sublethal concentrations of CPT up-regulated Fas and other pro-apoptotic proteins, such as Fas ligand, Bax, and p21. Similarly, Xia and co-workers demonstrated that CPT significantly increased the glioblastoma cell death response to Fas receptor activation using agonist antibodies (*12*). Furthermore, a study using CPT-11 (irinotecan), a water-soluble, semisynthetic prodrug of CPT, found up-regulation of cell-surface Fas expression in colorectal cancer cells, independent of *p53* status. Interestingly, by combination treatments with CPT-11 and agonistic Fas antibody, it was shown that this surface up-regulation could be exploited to produce synergistic tumor cell cytotoxicity (*13*).

Despite the demonstration that CPT has efficacious activity toward tumor cells, drawbacks remain with its clinical application. CPT is particularly active when in its lactone form, but is easily converted at physiological conditions to a less active carboxylate form, which gives rise to increased side effects (*14–16*). Moreover, human serum albumin binds to the carboxylate form preferentially, driving the equilibrium in favor of carboxylate formation in the systemic circulation (*17, 18*).

Additionally, CPT is poorly water-soluble (*19*), and formulations frequently require addition of cosolvents, such as poly(ethylene glycol) (PEG) 400, prior to administration (*20*). It is believed that these drawbacks contribute to the considerable variability in patient response after oral or intravenous administration, observed for the entire CPT drug class (*21*). Furthermore, as an S phase-specific drug, CPT requires prolonged exposure to the tumor to ensure efficacy (*11, 22, 23*). *In vivo* studies examining the pharmacokinetic profile of CPT have shown that large doses administered over extended intervals are poorly effective when compared to continual low doses or frequently fractioned dosing (*24*). Consequently, irinotecan (CPT-11) was developed in an effort to circumvent these problems. Although intentionally more water-soluble than CPT, it exhibits much lower antitumor activity, with an IC_{50} of 1200 μM compared to CPT with an IC_{50} of 23 μM in L1210 murine leukemia cells. Furthermore, CPT-11 has a lower activity on topoisomerase-I inhibition, with an $IC_{50} > 100$ μM, compared to an IC_{50} of 0.6−1.4 μM for CPT (*25*).

Although clinically effective, the reduced potency of CPT-11 means that the ability to use CPT still remains an attractive goal for cancer therapy. As an alternative to cosolvent approaches, the *in vitro* antitumor activity of CPT has been enhanced by loading into colloidal drug delivery systems, such as mixed micellar systems (PEG)-phosphatidylethanolamine conjugate with D-α-tocopheryl poly(ethylene glycol) 1000 succinate (*26*) and sterically stabilized phospholipid micelles (*23*). Similarly, the improved efficacy of CPT-loaded methoxy-poly(ethylene glycol)-poly(DL-lactic acid) nanoparticles (NP) lead to a combination of longer plasma retention times with more efficient tumor localization (*27*).

In this present study, the application of antibody-targeted nanoparticle conjugates containing CPT has been investigated. It was hypothesized that a nanoparticulate system containing CPT and bearing antibodies toward Fas would be simultaneously beneficial. The study aimed to investigate if the combination of Fas targeting and intracellular CPT delivery would improve the efficacy of the drug over solution-based delivery. The results show that entrapment of CPT within the NP improves their efficacy toward tumor cells which is further improved by direct targeting and triggering of receptor-mediated endocytosis via antibody directed interaction with Fas receptor to deliver CPT intracellularly to its site of action.

EXPERIMENTAL PROCEDURES

Materials. (*S*)-(+)-CPT was purchased from Sigma-Aldrich, Germany. PLGA (Resomer RG 502 H) with an acid value of 9 mg KOH per g PLGA, molecular weight 12 kDa and inherent viscosity of 0.22 dL g^{-1} at 0.1% (w/v) in chloroform at 25 °C, was a generous gift from Mr. Markus Weingärtner, Boehringer Ingelheim, Germany. PLGA (Resomer RG 505 S) with an acid value of <1 mg KOH per g PLGA, molecular weight 80 kDa and inherent viscosity of 0.7 dL g^{-1} at 0.1% (w/v) in chloroform at 25 °C, was purchased from Boehringer Ingelheim, Germany. A water-soluble carbodiimide, *N*-ethyl-*N*(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC), was obtained from Fluka, Slovakia. *N*-Hydroxysuccinimide (NHS) and poly(vinyl alcohol) (PVA), 87−89% hydrolyzed with molecular weight 13−23 kDa, were obtained from Aldrich, Germany. Magnesium chloride hexahydrate ($MgCl_2 \cdot 6H_2O$), 2-morpholinoethanesulfonic acid monohydrate (MES), polyoxyethylenesorbitan monooleate (Tween 80), and 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT reagent) were obtained from Sigma, Germany. Anti-Fas human mAb and IgG Isotype mAb were supplied by Fusion Antibodies Ltd., Northern Ireland. The microBCA kit was purchased from Pierce, USA. Acridine Orange dye was obtained from Sigma, USA. Acetone (Fisher Scientific, UK) was used as a water-miscible solvent during NP preparation, while dichloromethane (DCM) (Riedel-de Haën, Germany) was used as a water-immiscible solvent. Dimethyl sulfoxide (DMSO) and acetonitrile were from (BDH, UK). Phenol Red-free medium (RPMI 1640 with L-glutamine) and McCoy's 5A medium with L-glutamine were obtained from Invitrogen USA. A human colorectal cancer cell line (HCT116) was obtained from the American Tissue Culture Collection. All chemicals were used without further purification.

Preparation of CPT-Loaded and AO-Loaded PLGA NP. CPT-loaded NP were prepared by dissolving CPT (0.2 mg) in 200 μL DCM and 100 μL DMSO to give the 100:1 PLGA/CPT weight ratio nanoparticulate formulation. DMSO was introduced as a cosolvent to ensure complete CPT dissolution in the organic phase. NP with the 10:1 weight ratio were prepared by addition of 2.0 mg CPT to the DCM/DMSO phase. The CPT solution was added to a 500.0 μL organic solution of acetone containing 20 mg PLGA. The ratio of total water-miscible organic solvents (acetone/DMSO) to DCM was maintained at 3:1 v/v. The organic phase (ice-cold) was injected under moderate stirring into 3.0 mL of ice-cold pH 5.0 MES buffer (25 mM) solution containing 2.5% (w/v) PVA and 45% (w/v) $MgCl_2 \cdot 6H_2O$. Both phases were then sonicated in an ice bath for three minutes, at 50−55 W in pulse mode. An additional 5.0 mL of pH 5.0 MES buffer (25 mM) solution containing 2.5% (w/v) PVA was added under moderate stirring to initiate acetone-DMSO diffusion. Samples were kept stirring overnight to allow organic solvent evaporation.

NP were prepared using RG 502 H alone (NP-100), which gave a maximum carboxylic acid density on the peripheral surface. Also, a 20% w/w blend of RG 502 H with 80% w/w RG 505 S (NP-20), which gave a lower peripheral carboxylic acid density, was prepared. Blank NP were prepared as described above, but without CPT. Acridine Orange (AO)-loaded NP without CPT incorporation were prepared using the procedure described above, with AO replacing CPT in the organic phase.

NP Purification. NP were filtered through a No. 1 sintered glass filter, centrifuged at 50 000 × *g* for 1 h at 10 °C, then washed using suspension-spin cycles with pH 5.0 MES buffer. NP loaded with AO were washed repeatedly, until a clear supernatant was evident, to eliminate any loosely adsorbent materials, be it CPT or free dye. Nanoparticulate pellets were resuspended to give 1.0 mg NP mL^{-1} in pH 5.0 MES buffer prior to further use.

CPT Entrapment Efficiency. The purified nanoparticulate pellet was dissolved in DMSO and acetonitrile (ACN) added to bring the volume ratio to 1:1 (DMSO/ACN). Samples were diluted further using this 1:1 volume ratio solvent (DMSO/ACN) and measured using UV−vis spectrophotometry at 365 nm. Results were compared to a standard calibration curve of CPT solution in DMSO/ACN at a 1:1 volume ratio. Entrapment efficiency was calculated using eq 1.

$$\text{Entrapment efficiency (\%)} = \frac{\text{Mass of drug determined (mg)}}{\text{Mass of drug added (mg)}} \times 100 \quad (1)$$

***In Vitro* Evaluation of CPT Release from PLGA NP.** Release profiles of CPT from nanoparticulate suspensions (100:1 weight ratio loading) were determined using a dialysis-based procedure. CPT-loaded NP were dispersed in a release medium (phosphate buffered saline (PBS), pH 7.4 containing 2% (w/v) Tween 80) (*28*) with the amount of available CPT for release and the volume of release medium adjusted so as to maintain optimal sink conditions. A mass of NP, equivalent to 300 μg CPT, was dispersed in 12 mL of a pH 7.4 PBS solution containing 2% (w/v) Tween 80. This was injected into a Slide-A-Lyzer dialysis cassette with a 10K molecular weight cutoff

(Pierce, USA) and immersed in 138 mL of a pH 7.4 PBS solution containing 2% (w/v) Tween 80 under conditions of continuous stirring. Samples (5.0 mL) of receiver phase were withdrawn at selected time points and replaced with equivalent volumes of fresh medium. CPT concentration in the receiver medium was measured using spectrofluorometry (emission at 435 nm and excitation at 374 nm) and compared with a calibration curve for standard CPT solutions prepared under similar conditions.

The diffusion of CPT from a standard solution across the dialysis membrane served as a control, representing a situation where formulation-based sustained effects were not exerted. In this study, 300 μg CPT was dissolved in 12 mL of a pH 7.4 PBS containing 2% (w/v) Tween 80 and introduced into the dialysis cassette. Sample were withdrawn and analyzed as described above.

Particle Size and Zeta Potential Measurements. Nanoparticulate size and zeta potential were measured using photon correlation spectroscopy (ZetaSizer 3000 HS, Malvern instruments, UK). Measurements were carried out using monochromatic coherent He−Ne laser light of fixed wavelength (633 nm) at 90° and at room temperature (25 °C), with each sizing determination done in triplicate and an average particle size expressed as the mean diameter (Z_{ave}).

NP Activation with NHS and Carbodiimide. Purified NP (100:1 weight ratio loading) were used as the core platform for antibody conjugation and subsequent *in vitro* evaluations. They were suspended in 20 mL pH 5.0 MES buffer and activated using NHS-carbodiimide chemistry, as described previously (*29*). Briefly, activation was achieved by adding 200 μL of 0.1 M EDC and 200.0 μL of 0.7 M NHS, both dissolved in pH 5.0 MES, to the nanoparticulate suspension, which was kept at room temperature for 1 h under conditions of moderate stirring. Samples were centrifuged at 50 000 × *g* for 1 h at 10 °C, and the NP collected, washed three times in pH 7.4 PBS using suspension-spin cycles to eliminate unused adsorbent reagents, and finally resuspended at 1 mg mL^{-1} in PBS.

Peripheral Anti-Fas mAb and IgG Isotype mAb Conjugation. Anti-Fas human mAb (100 μL of 1.0 mg mL^{-1} solution) or IgG isotype mAb, which was used as a control for anti-Fas mAb (100 μL of 1.0 mg mL^{-1} solution), were added to a 1 mL suspension of 1 mg mL^{-1} activated NP in 1.5 mL Eppendorf tubes. Samples were vortexed and incubated at 4 °C overnight, centrifuged at 22 000 × *g* (Sigma 3−18 K Centrifuge) for one hour at 10 °C and washed twice with PBS using suspension-spin cycles to remove excess unconjugated antibody. Antibody conjugation was quantified spectrophotometrically at 562 nm (Tecan Spectra III, Austria) using a microBCA kit (Pierce, USA) as per the manufacturer instructions.

Fluorescence Microscopy Imaging. HCT116 cells were cultured in Phenol Red free medium (RPMI 1640) containing L-glutamine, sodium pyruvate (5 mM), and 10% v/v fetal calf serum. Cells were grown to a confluency of 70% before seeding in six-well plates at 1.0 × 10^5 cells per well. This was followed by 90 min of incubation at 37 °C and 5% CO_2 with 100.0 μL dispersion of 1.0 mg mL^{-1} AO-loaded NP-100 conjugated to anti-Fas human mAb suspended in PBS. All NP preparations were diluted 10-fold, where 10.0 μL of 1.0 mg mL^{-1} of NP suspension was made up to 100.0 μL using PBS. Naked AO-loaded NP-100 were used as corresponding controls. Cells were washed three times with ice-cold PBS before observation using fluorescence microscopy (Nikon Eclipse TE 300, Japan). The *X*/*Y Y*/*Z* section analysis was performed using confocal scanning laser microscopy (Leica Confocal TCS Sp2, Germany). Excitation was done using laser illumination at 450 nm for green fluorescence and 540 nm for red fluorescence.

Table 1. Glossary and Summary of Different NP Preparations Prepared for Cell-Based Assays

abbreviation	loading[a]	antibody conjugated
20% RG 502 H (w/w) - Low Carboxylic Acid Density on NP Surface		
NP-20	none	none
NP-20-CPT	CPT	none
NP-20-CPT-CtrlAb	CPT	IgG Isotype control antibody
NP-20-Fas	none	Anti-Fas mAb
NP-20-CPT-Fas	CPT	Anti-Fas mAb
100% RG 502 H (w/w) - High Carboxylic Acid Density on NP Surface		
NP-100	none	none
NP-100-CPT	CPT	none
NP-100-CPT-CtrlAb	CPT	IgG Isotype control antibody
NP-100-Fas	none	Anti-Fas mAb
NP-100-CPT-Fas	CPT	Anti-Fas mAb

[a] CPT = camptothecin.

***In Vitro* Antitumor Activity of CPT-Loaded NP.** HCT116 cells were plated in 96-well microplates at 5.0 × 10^3 cells per well in 190.0 μL of complete medium and allowed to adhere under incubation at 37 °C and 5% CO_2. Twenty-four hours later, 10.0 μL of medium containing different CPT solutions or nanoparticulate suspensions were added to wells and incubated for 24, 48, and 72 h. Preparations were made for anti-Fas human mAb, either as solutions or conjugated to the surface of NP, which were themselves either blank or CPT-loaded (Table 1). IgG1 isotype control mAb were presented to cells after being conjugated to the surface of CPT-loaded NP to act as a control for corresponding anti-Fas conjugated NP. CPT was presented either as a solution in 10.0% (v/v) DMSO or loaded in NP, either naked or conjugated to antibody (Table 1). Wells containing control cells for all preparations were treated with 10 μL of medium, except for CPT solution preparations, where 10 μL medium containing 10% (v/v) DMSO was used resulting in a final concentration of 0.5% (v/v) DMSO in the medium. At this concentration the DMSO had no measurable effect on cell viability.

Percentage cell survival after each time point was determined by the MTT colorimetric assay. The medium was replaced by 200 μL of MTT solution prepared in media to give a final concentration of 0.5 mg mL^{-1}. This was incubated for 2 h at 37 °C and 5% CO_2 to allow for the formation of purple water-insoluble formazan. MTT solution was replaced with 100 μL DMSO and incubated at 37 °C and 5% CO_2 for 2 h to dissolve formazan. Optical density was measured at 570 nm using a microwell plate reading spectrophotometer (Tecan Spectra III, Austria) and compared to control cells. Cell survival was then expressed as a percentage of the control cells, which were taken to represent the 100% cell survival for each respective time point.

***In Vitro* Caspase 8 Activation.** Cultured HCT116 cells were seeded in flat-bottomed, 6-well plates (250 000 cells/well) and allowed to adhere overnight. Cells were treated with a solution of blank NP coated with anti-Fas mAb or isotype IgG mAb (0.18 mg PLGA per well, corresponding to 0.1 μg of conjugated mAb per 1000 cells) for 48 h. Cells were harvested and centrifuged at 2000 × *g* for 10 min at 4 °C and the pellet resuspended in 10 μL of PBS and stored at −80 °C until required.

Whole cell lysates (25 μL) were electrophoresced on 10% Tris-SDS-PAGE gels (Bio-Rad Laboratories, Hercules, CA) and electroblotted onto a polyvinylidene difluoride (PVDF) membrane (Bio-Rad Laboratories) using standard techniques. The PVDF membrane was blocked with 3% (w/v) bovine serum albumin in PBS prior to detection with anticaspase-8 (1:700) (Alexia Corporations, San Diego, CA) and a HRP-conjugated goat antimouse secondary antibody (1:3000, BioRad, Hercules,

CA, USA) followed by visualization using Supersignal West Femto Chemiluminescent Substrate (Pierce, Rockford, IL).

Data Analysis. Statistical analyses were performed using analysis of variance (one-way and two-way ANOVA), with either followed by Bonferoni's test to compare all pairs of preparations (Graph-Pad Prism, San Diego, CA, USA). Rejection of the null hypothesis was considered when the P value is <0.05. IC_{50} values, defined as the concentration of a preparation which will result in a 50% cell survival, were used to compare potency of different preparations. The IC_{50} value for a preparation was obtained by plotting log(concentration) against percentage cell survival and then applying a nonlinear sigmoidal dose response curve fitting function (Graph-Pad Prism, San Diego, CA, USA).

The nature of the interaction obtained by conjugating anti-Fas human mAb to CPT-loaded NP was determined by calculating the synergistic ratio (SR) (*30*), as shown in eq 2

$$\mathrm{SR} = \frac{S_{\mathrm{exp}}}{S_{\mathrm{obs}}} \quad (2)$$

where the expected HCT116 cell survival (S_{exp}) was defined as the product of the HCT116 cell survival observed for CPT-loaded NP alone and the HCT116 cell survival observed for anti-Fas mAb conjugated to the surface of blank NP alone.

$$S_{\mathrm{exp}} = (\text{Survival CPT-loaded NP}) \times (\text{Survival anti-Fas mAb conjugated to blank NP}) \quad (3)$$

The actual HCT116 cell survival observed for anti-Fas mAb conjugated to the surface of CPT-loaded NP was defined as S_{obs}. Synergy was defined as an SR greater than unity (SR > 1.0). SR values of 1.0 or less indicated the absence of synergy. A synergistic interaction may be of pharmacological interest when SR values are around 2.0 (*31*).

RESULTS

The evaluation of CPT entrapped in PLGA NP and anti-Fas conjugated PLGA NP was undertaken, using different blends of PLGA polymer. Changes in particle size, zeta potential, CPT entrapment efficiency, and antibody conjugation of NP prepared from different PLGA blends were analyzed (Table 2). Modulation of non-end-capped density by way of variation of PLGA composition had a significant effect ($P < 0.05$) on the NP size and amount of antibody conjugation, but did not affect CPT entrapment efficiency. NP-100, prepared using 100% (w/w) RG 502 H, were significantly smaller when compared to NP-20, prepared using 20% RG 502 H ($P < 0.05$). Entrapment efficiencies for both the 100:1 and 10:1 CPT loadings where

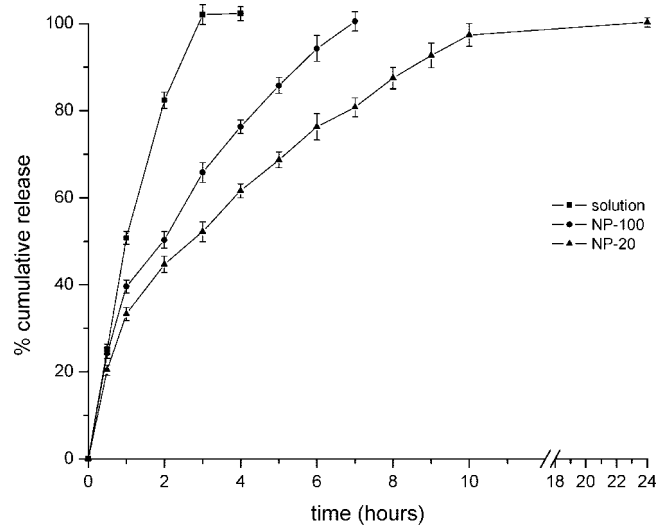

Figure 1. The effect of PLGA composition on *in vitro* release of CPT from the 100:1 weight ratio loading, showing cumulative release from NP formulations, NP-100 (▲), NP-20 (•), and from CPT solution (□), which was used as a control for equilibrium across the dialysis membrane. (Results are mean ± SD, $n = 3$).

shown to be almost complete, with PLGA composition not affecting this parameter. As expected, antibody conjugation was more effective when the 100% (w/w) RG 502 H composition was used as this formulation exposes more peripheral carboxyl coupling functionality in comparison to the to the 20% RG 502 H variant. This was demonstrated by conjugation levels in NP prepared using 100% RG 502 H polymer, which resulted in 48.3 μg coupled antibody per mg of NP, in comparison to NP prepared with only 20% RG 502 H, giving instead only 12.4 μg antibody per mg NP (Table 2). These results show clearly that the amount of anti-Fas mAb that could be conjugated to the NP using a two-step carbodiimide activation was dependent on the ratio of non-end-capped to endcapped PLGA types. In addition, it was observed that anti-Fas conjugation was not affected by CPT loading with no significant differences observed between conjugation to blank NP or those loaded with CPT.

CPT release profiles from the 100:1 weight ratio NP formulations, evaluated by a dialysis procedure, enabled determination of free CPT concentration without the need for prolonged centrifugation. Care was taken to ensure sink conditions and that the maximum concentration possible of CPT remained below 10% of the solubility of CPT in the release medium, previously reported as 79 μg mL^{-1} (*28*). Calibration procedures showed a linear correlation between fluorescent emission intensity and CPT concentration in the range of 20 ng mL^{-1} to 80 ng mL^{-1} ($r^2 = 0.992$). The effect of both PLGA compositions on *in vitro* cumulative release profiles from NP prepared using either 100% RG 502 H or 20% RG 502 H is shown in Figure 1. In both formulations, a rapid initial release of CPT was observed. However, beyond 60 min distinct differences in drug release were observed with 34% CPT release observed for 20% RG 502 H NP compared with 39% in 100% RG 502 H NP. By 3 h, the observed release was 50% for the 20% RG 502 H NP, compared to 65% from 100% RG 502 H NP. Both types of PLGA NP had achieved almost 100% release by 10 h. Although not instantaneous, the equilibrium of the CPT control solution across the dialysis membrane was more rapid, reaching an approximate value of 82% (w/v) CPT diffused into the receiver phase after 2 h.

The application of mAb-NP formulations were then examined in cell-based assays using the HCT116 colorectal carcinoma cells, previously shown to express Fas (*33*). To permit the visualization of the mAb-NP conjugates in association with cells,

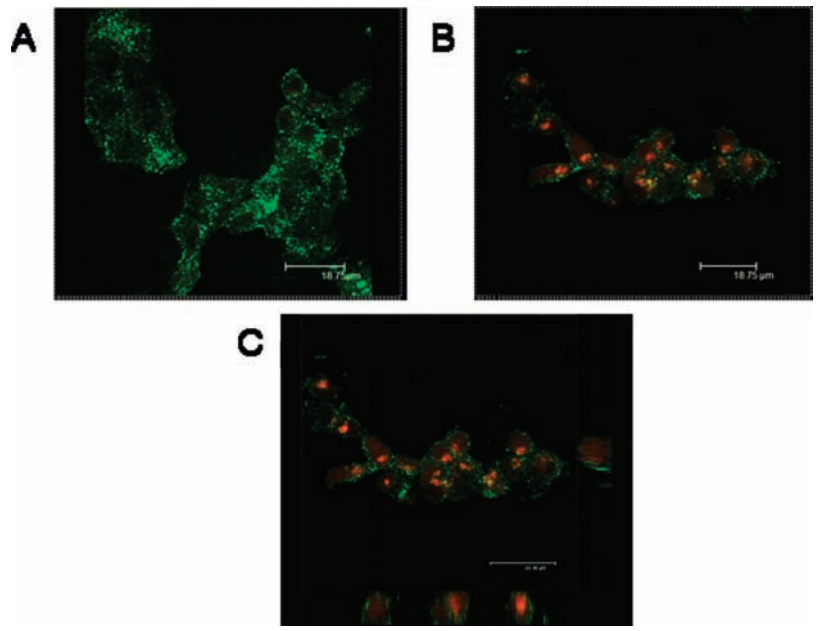

Figure 2. Fluorescence microscopy images for HCT116 cells incubated with (A) a 100 μL suspension of naked AO-loaded NP-100 in PBS, (B) a 100 μL suspension of AO-loaded NP-100 with 4.67 μg of conjugated anti-Fas mAb, and (C) *X*/*Y Y*/*Z* confocal section analysis of HCT116 cells incubated with a 100 μL PBS dispersion of AO-loaded NP-100 with anti-Fas mAb conjugated peripherally. Cells were exposed to NP dispersions over a 90-min incubation period at 37 °C and 5% CO_2. Cells were washed three times with ice-cold PBS before observation using confocal laser scanning microscopy with excitation at 450 nm for green fluorescence and 540 nm for red fluorescence.

NP were prepared containing acridine orange (AO), as employed previously to visualize uptake of the conjugates into cells using fluorescence microscopy (*33*). Furthermore, results have determined that the release of AO from the PLGA NP *in vitro* amounts to approximately 10% of the total encapsulated AO over 4 h (data not shown), barely detectable at concentrations and length of study (90 min) employed in these cellular studies presented here. Therefore, the intense fluorescence arising from endosomal space is almost exclusively AO still entrapped within PLGA cores. AO fluoresces in a pH-dependent manner, with a green emission spectra at neutral or basic pH, shifting to red/orange fluorescence in acidic conditions (*34*, *35*). Substantial differences in subcellular fluorescence was observed in HCT116 cells, dependent on the nature of the conjugate applied, with the presence of red fluorescent foci in cells treated with mAb-NP, which was not observed in the presence of unconjugated NP (Figure 2a,b). This finding is consistent with internalization of the antibody-conjugated particles localizing in acidic vesicles, suggesting that binding of anti-Fas conjugated NP to the surface of HCT116 cells leads to internalization into endocytic acidic compartments. Further analysis of this internal fluorescence was undertaken using an *X*/*Y Y*/*Z* confocal section analysis confirming the intracellular localization of the AO-loaded NP (Figure 2c). Conversely, in the control nonconjugated particles, only green fluorescence is visualized suggesting that these NP, at the concentrations and mild washing conditions employed here, have adhered or internalized into the cells in a nonspecific nonreceptor mediated manner. Crucially, however, and in line with our previous findings (*33*), is the difference in fluorescence observed with the two formulations indicating the receptor specific nature of the internalization with antibody-conjugated NP.

Next, the ability of the nanoparticle formulations were analyzed in their ability to attenuate the proliferation of tumor cells. HCT116 cells were exposed to CPT as a solution in 10% (v/v) DMSO (CPT solution) or CPT-loaded NP prepared with 100% (NP-100-CPT) or 20% (NP-20-CPT) RG 502H. NP were either naked or conjugated with anti-Fas monoclonal antibody (NP-100-CPT-Fas or NP-20-CPT-Fas), or conjugated with isotype IgG control antibody (NP-100-CPT-ContAb or NP-20-CPT-ContAb). As a further control, Anti-Fas mAb alone was presented to cells either in solution (Fas solution) or conjugated to non-drug-loaded NP (NP-100-Fas or NP-20-Fas). The viability of cell populations were then assessed at 24 h, 48 h, and 72 h time points. After 24 h, no significant variances in cell viability were measured with the formulations (Table 3), but by 48 h the dose-dependent cytotoxic effect of the CPT solution was evident cumulating in approximately 25% HCT116 survival at 100 ng mL^{-1} with an IC_{50} of 21.8 ng mL^{-1} after 72 h (Figure 3 and Table 3). The incorporation of CPT into the NP resulted in significant improvements in potency of both PLGA formulations examined (*P* value <0.01). However, the full extent of the cytotoxic potency of CPT-loaded NP was found to be dependent on the PLGA blend used to prepare the NP and concentration of available CPT. After 72 h of incubation, the

Table 3. IC_{50} Values Calculated after Nonlinear Dose-Response Curve Fitting of the HCT116 Cell Survival Results

NP formulation	time from treatment	IC_{50} (ng mL^{-1})
CPT solution	24 h	<450
	48 h	231.2 (±10.2)

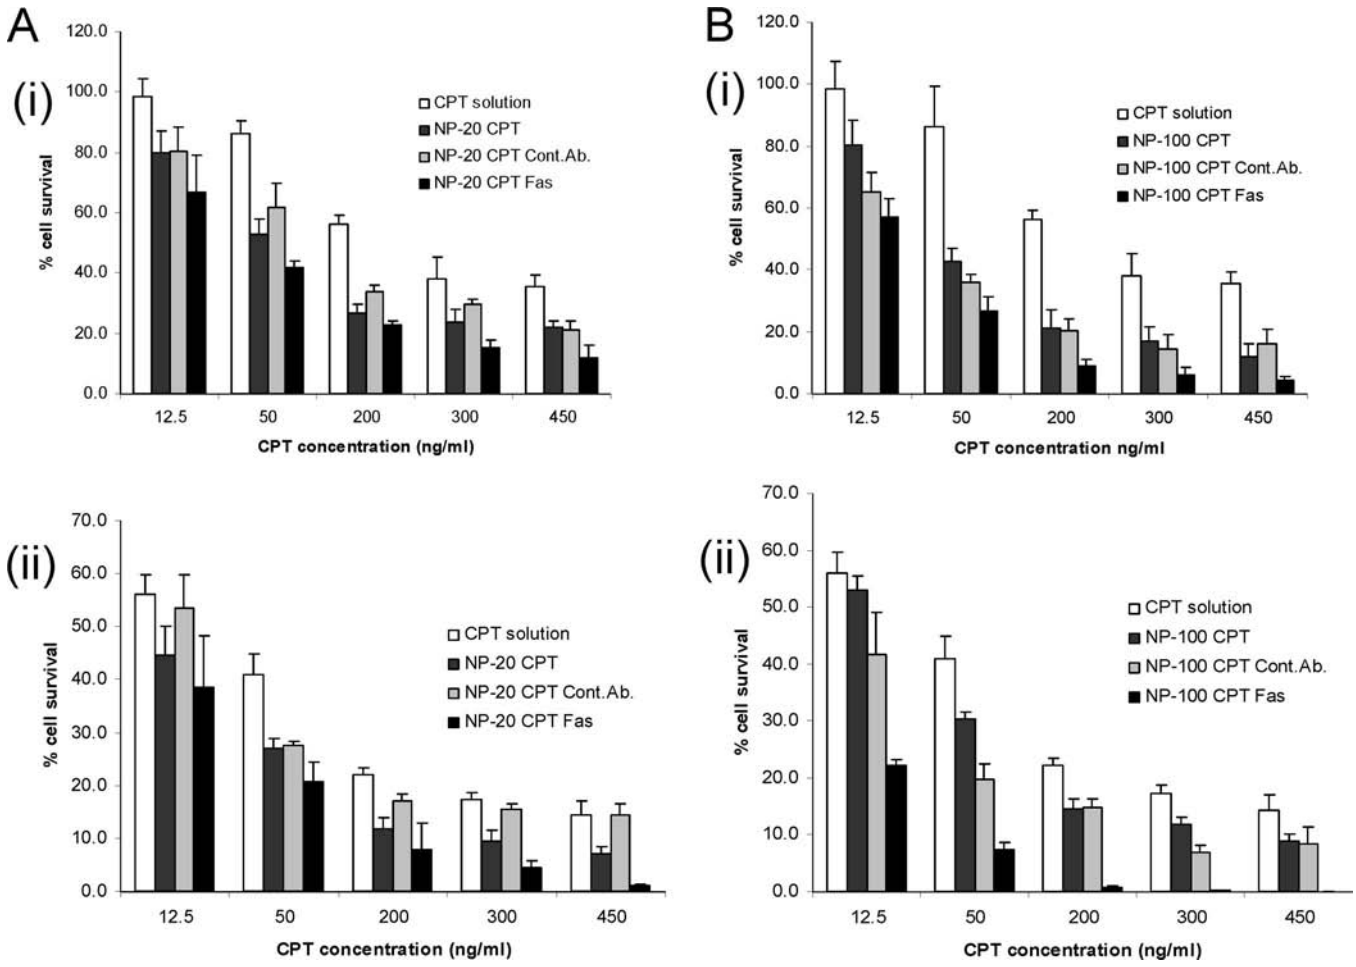

Figure 3. Percentage HCT116 cell survival (MTT assay) after treatment with different formulations of CPT and/or anti-Fas mAb. (A) Graphs show the determined survival for NP-20 prepared using 20% RG 502 H at 48 (panel i) and 72 h (panel ii). (B) Graphs show the determined survival for NP-100 prepared using 100% RG 502 H at 48 (panel i) and 72 h (panel ii). (Results are mean ± SD, $n = 5$).

NP-20-CPT formulation was found to be significantly more potent than NP-100-CPT ($P < 0.05$), as demonstrated by the calculated NP-20-CPT IC_{50} of 7.8 ng mL^{-1} in comparison to 15.8 ng mL^{-1} for NP-100-CPT (Figure 3A panel (ii); Figure 3B panel (ii), and Table 3).

The attachment of antibodies to the surface of the CPT-loaded particles resulted in further improvements in cytotoxic effects over both CPT solution and CPT containing NP. This was particularly evident at the 72 h time point, with cytotoxicity at 200 ng mL^{-1} reaching almost 100% (IC_{50} of 0.37 ng mL^{-1}) using NP-100-CPT-Fas (Figure 4A). Use of the NP-20-CPT-Fas formulation resulted in similar cytotoxicity trends, but with a less potent IC_{50} of 5.6 ng mL^{-1} (Table 3).

The possible cytotoxic effects mediated by the antibodies themselves on the surface of the NP conjugates were also examined using blank NP-mAb conjugates comprising cores made using both polymer ratios (NP-20-Fas and NP-100-Fas). Results demonstrated that the conjugated antibodies on their own had a minimal effect. Over 24 and 48 h of incubation, there was no effect on cell viability (data not shown). At the 72 h time point, a small divergent effect is seen at higher antibody concentrations in both NP polymer formulations, with up to 20% cell death (Figure 4A). Due to the high density of the IgG antibody on the surface of the NP, it was hypothesized that this antibody could be promoting the cross-linking of the Fas receptor and activation of the extrinsic apoptotic pathway through activation of caspase 8. To examine this, anti-Fas NP and anti-isotype control NP conjugates were incubated for 48 h in the presence of HCT116 and whole cell lysates were analyzed by Western blot for activation of caspase 8 (Figure 4B). It was found that caspase 8 cleavage was evident in these cells treated with the Fas-conjugated NP, indicative of its activation.

Analysis of the cytotoxicity results, by calculation of a synergistic ratio (SR), showed that the combined effects of CPT and anti-Fas antibodies were indeed synergistic, as shown by SR results in excess of unity (Figure 5). Pharmacologically relevant SR (values above 2, indicated by dashed line, Figure 5), showed that, after 72 h exposure with both formulations of NP, synergy could be seen with higher concentrations of CPT in the NP-20 formulations, but in the NP-100 formulations, which present higher concentrations of anti-Fas antibody (Table 2), the pharmacologically relevant synergy was observed at all concentrations used, demonstrating the effectiveness of this combination of antibody and chemotherapy in NP formulations.

DISCUSSION

Although numerous targeting methodologies have been proposed and reviewed at length, such as those based on immunoliposomes (*36*) and polymeric constructs (*37*), the evaluation of novel nanoparticulate systems remains an area of active investigation (*38*). In this present study we have investigated the application of the chemotherapeutic agent CPT in targeted immunoconjugates. CPT and derivatives are therapeutic chemotherapeutics with potent antitumor activity that has been shown previously to up-regulate the expression of the death receptor Fas on the surface of tumor cells (*11–13*); exploitable by the application of agonist anti-Fas antibodies to trigger

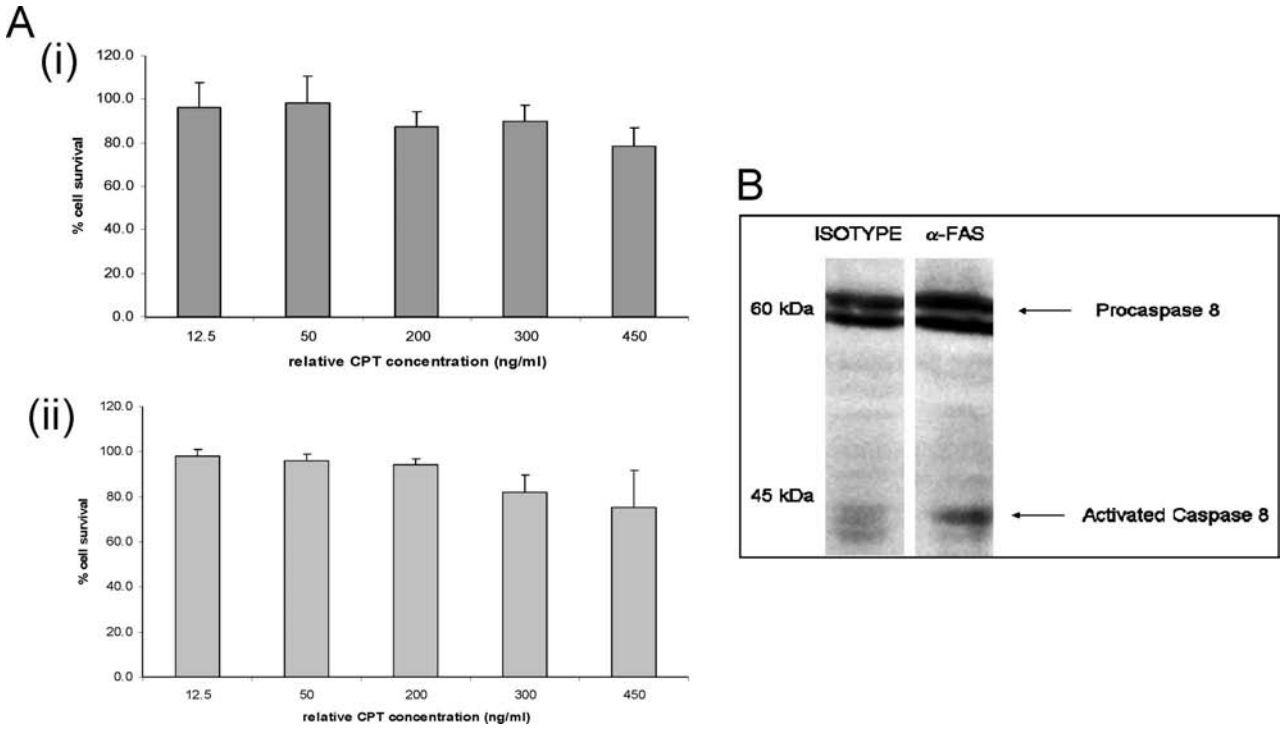

Figure 4. (A) Cell survival in the presence of "empty" NP-20 coated with anti-Fas antibody at 72 h (panel i) or NP-100 (panel ii). The *X* axis represents the relative CPT concentration that would be present if the NP were loaded with CPT as in Figure 3. (Results are mean ± SD, $n = 5$). (B) Caspase 8 activation following exposure of blank NP coated with anti-Fas antibody, demonstrating activation of Fas receptor and initiation of extrinsic apoptotic pathway.

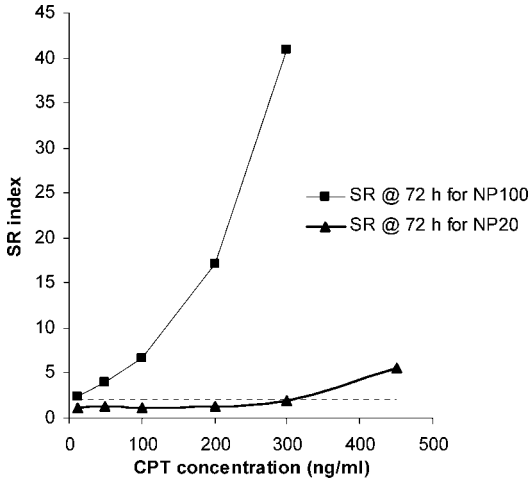

Figure 5. Synergistic ratio (SR) values after 72 h of exposure. SR values were calculated based on HCT116 cell survival obtained in Figure 3 for NP-100 CPT Fas in comparison with NP-100 loaded with CPT and "empty" NP-100 Fas (□) and NP-100 CPT Fas in comparison with NP-100 loaded with CPT and "empty" NP-100 Fas (▲). Pharmacological relevance (SR ≥ 2) is represented as the dashed line.

extrinsic apoptotic cell pathways to improve cytotoxicity over treatment with CPT alone. Therefore, the application of these two therapeutic approaches was pursued in the form of a immunoconjugate consisting of a nanoparticle, loaded with CPT and coated in anti-Fas antibodies.

The initial focus of this work was to incorporate CPT into PLGA NP. A novel aspect to this work was the simultaneous use of two PLGA polymers, one with a low molecular weight and high acid value (RG 502 H) and the other with a higher molecular weight variant with low acid value (RG 505 S). This enables the manufacture of NP with different matrix properties, but more importantly, with different densities of superficial carboxyl functionality. Conjugation of anti-Fas human monoclonal antibodies to PLGA NP using a water-soluble carbodiimde/NHS procedure was found to be dependent on carboxylic acid density on the NP surface (Table 2). NP made with 100% RG 502 H (low molecular weight) permitted increased antibody conjugation than NP made from the 20/80 blend (NP-20), which possessed less peripheral -COOH. This relationship between carboxylic acid density on the NP surface and amount of conjugated antibody indicated that chemical linkage is dominant over nonspecific physical adsorption.

The entrapment efficiency of CPT into NP manufactured from both PLGA blends, and at the two loading ratios tested, was essentially 100% within the concentration ranges analyzed here and did not depend on the PLGA compositions used. Further investigations revealed that the nature of the initial organic solution of CPT affected incorporation, with DMSO a requisite solvent during this process. In the absence of DMSO, entrapment efficiency fell to approximately 60% (data not shown). Previously, it has been shown that CPT exists in a crystalline form at 10% w/w of CPT loaded in PLGA microspheres and is molecularly dispersed at 1.2% w/w of CPT loaded in PLGA microspheres (*19*). The formation of a crystalline state of CPT in the initial organic solution could explain the observations see in Table 2, where larger NP were obtained as the drug loading was increased from 100:1 to 10:1. The subsequent release of entrapped CPT, loaded at 100:1 weight ratio was shown to be dependent on the PLGA composition (Figure 1). Similar release profiles generated using the 10:1 loading (not shown) were generally more prolonged and were not ideally suited to the time frame used during the *in vitro* cellular exposures. For this reason, the 100:1 PLGA:CPT weight ratio was the preferred loading. In all NP preparations tested, 100% RG 502 H (NP-100) showed a faster release when compared to 20% RG 502 H, as its low molecular weight and high acid value results in faster hydration when compared to the high molecular weight, low acid value RG 505 S, which forms the majority (80% w/w) of NP prepared using 20% RG 502 H (NP-20).

Importantly, though, once entrapped within a PLGA-based NP, the CPT is exposed to an acidic microclimate, which has been shown to stabilize the active lactone structure of this compound (*39*). The approach taken in this work, whereby CPT is loaded into PLGA NP, is expected to maintain CPT in its active lactone form for sustained periods of time and also to protect it from blood and human serum albumin, which readily hydrolyze CPT into its carboxylate form with a hydrolysis half-life of 54 min (*40*). The carboxylate form also has a high binding affinity to human serum albumin (*41*) enhancing its formation and resulting in reduced activity (*15*) and increased side effects (*14*). Particulate delivery of CPT was reported to enhance *in vitro* antitumor effects, such as seen with PLGA microspheres (*42*). Thus, stabilizing the lactone form and sustaining its release may explain the higher potency observed for NP-100-CPT (IC_{50} of 47.9 and 15.8 ng mL^{-1} after 48 and 72 h exposure, respectively) and NP-20-CPT (IC_{50} of 48.9 and 7.8 ng mL^{-1}, respectively) compared to CPT solution (IC_{50} of 231.2 ng mL^{-1} and 21.8 ng mL^{-1}, respectively). The ability of NP-20-CPT to show longer sustained release may also explain its higher potency when compared to NP-100-CPT. Similar improvements have previously been observed with poly(ϵ-caprolactone) microspheres (*28*), poly(ethylene glycol)-CPT conjugates (*43*), water-soluble poly(L-glutamic acid)-Gly-CPT conjugates (*44*), and long-circulating polymeric micelles (*20*).

Internalization of antibody-conjugated NP was examined by fluorescent microscopy, which indicated the selective localization of NP unto the surface of the HCT116 cells using an anti-Fas monoclonal antibody. Furthermore, the NP localization within acidified lysosomes, as shown in Figure 2, was in accordance with the findings of Algeciras-Scimnich et al. (*45*),who reported internalization of activated Fas through an endosomal pathway. Interestingly, localization of CPT NP in lysosomes may improve the stability of CPT as the acidic pH in this compartment will help maintain the lactone form of the drug.

Although this work has shown that NP can sustain CPT release and induce NP uptake through targeting of the Fas receptor, it is possible that the targeting of the Fas receptor with a CPT-loaded delivery system has added advantages. It was hypothesized that the display of anti-Fas antibody on the surface of the NP may enhance Fas-mediated caspase 8 activation. The detection of caspase 8 cleavage in the presence of "empty" particles displaying anti-Fas antibodies suggest that the NP conjugates promote their cytotoxic effects via activation of both the intrinsic and extrinsic apoptotic pathways with CPT initiating DNA damage and the antibody initiating caspase 8 activation.

Previously, studies using HCT116 cells demonstrated that the application of the cross-linking IgM anti-Fas antibody CH11 could be used in combination with CPT-11 to produce a synergistic cytotoxic effect (*13*). In agreement with these previous studies, it was shown in this current work that a combination of a CPT-loaded PLGA NP and a peripheral coating of anti-Fas mAb resulted in significant synergetic cytotoxicity. NP-20-CPT-Fas showed less significant potency and a lower SR values when compared to NP 100, as shown in Figure 5. This may be due to lower amounts of anti-Fas human monoclonal antibody conjugated to the NP surface. This lower density of antibody presentation on the NP may result in lower Fas activation, but this observation and the full intent of exstrinic apoptosis induction through Fas will require further investigation.

In conclusion, this work has demonstrated the application of CPT using PLGA NP coated with an antibody targeting Fas. This drug delivery system directs and selectively targets cells expressing Fas receptor and through receptor-mediated internalization results in the uptake of the drug-loaded NP. Furthermore, as well as mediating its cytotoxic effect through DNA damage induced by CPT, these particles may result in the activation of Fas receptor and initiation of the extrinsic apoptotic pathway. Furthermore, as it is known that CPT up-regulates Fas cell surface expression, this antibody drug conjugate further potentiates cytotoxicity through two independent mechanisms resulting in synergy that could be pharmaceutically useful. This study paves the way for examination of other drug and receptor relationships were combinations of antibody and drug payload could produce conjugates with improved targeting and efficacy for treatment of cancer and other conditions.

The *in vivo* fate of nanomaterials strongly determines their biomedical efficacy. Accordingly, much effort has been invested into the development of library screening methods to select targeting ligands for a diversity of sites *in vivo*. Still, broad application of chemical and biological screens to the *in vivo* targeting of nanomaterials requires ligand attachment chemistries that are generalizable, efficient, covalent, orthogonal to diverse biochemical libraries, applicable under aqueous conditions, and stable in *in vivo* environments. To date, the copper(I)-catalyzed Huisgen 1,3-dipolar cycloaddition or "click" reaction has shown considerable promise as a method for developing targeted nanomaterials *in vitro*. Here, we investigate the utility of "click" chemistry for the *in vivo* targeting of inorganic nanoparticles to tumors. We find that "click" chemistry allows cyclic LyP-1 targeting peptides to be specifically linked to azido-nanoparticles and to direct their binding to p32-expressing tumor cells *in vitro*. Moreover, "click" nanoparticles are able to stably circulate for hours *in vivo* following intravenous administration (>5 h circulation time), extravasate into tumors, and penetrate the tumor interstitium to specifically bind p32-expressing cells in tumors. In the future, *in vivo* use of "click" nanomaterials should expedite the progression from ligand discovery to *in vivo* evaluation and diversify approaches toward multifunctional nanoparticle development.

INTRODUCTION

The ability to target nanomaterials to precise biological locations would have wide-ranging impact in biology and medicine. In living systems, highly controlled transportation networks continually shuttle payloads to and from specific molecular addresses. The efficiency of these systems provides strong motivation for the advancement of targeted nanoparticle technologies, particularly for the diagnosis and treatment of human diseases. Toward this goal, high throughput strategies for ligand discovery have generated a multitude of chemical and biological motifs with the potential to direct nanomaterials to specific biomolecular targets. However, translation of these ligands toward *in vivo* nanoparticle targeting has been limited by the number of nanoparticle attachment methods that are efficient, generalizable, aqueous compatible, chemically orthogonal to broad ranges of functional groups, and suitable for *in vivo* applications.

Previous work has demonstrated that *in vivo* bacteriophage display may be used to select for peptide sequences that mimic the ability of endogenous shuttles to target vascular and parenchymal tissue addresses (*1*–*5*). Already, linear peptide candidates of phage screens, as well as small molecule targeting candidates, have been translated toward nanomaterial targeting (*6*–*9*), primarily via use of exogenous or nonessential thiols, carboxylic acids, or amines. Still, some of the most powerful targeting motifs developed to date are those that contain essential thiol, amine, and carboxyl groups, thereby prohibiting their specific attachment via traditional methods. In particular, conformationally constrained, disulfide-cyclized targeting peptides are desirable for their enhanced affinity to biological receptors (*10*, *11*), and resistance to proteolytic degradation *in vivo* relative to their linear counterparts (*12*, *13*). However, specific intramolecular cyclization makes it difficult to add exogenous cysteine residues, while essential amines and carboxyl groups prohibit selective conjugation via exogenous lysine, aspartic acid, or glutamic acid residues. Additionally, noncovalent methods of ligand attachment relying on hydrophobic or electrostatic effects, although widely used *in vitro* (*14*–*16*), are unlikely to remain stable in blood or to resist rapid clearance *in vivo*. Recently, copper(I)-catalyzed "click" chemistry has emerged as an extraordinarily selective chemistry and an attractive solution in applications where commonly used thiol-reactive (maleimide, 2-pyridyldithio, iodoacetyl) or amine-reactive (NHS, epoxy, aldehyde, EDC) chemistries are not suitable (*17*). *In vitro* "click" chemistry has been utilized to generate functionalized polymers, (*18*–*20*), surfaces (*21*–*23*), and nanoparticles (*24*–*32*), and meets the previously mentioned criteria for broad utility in nanoparticle functionalization (chemical orthogonality, aqueous efficiency, applicability for diverse substrates). However, the use of "click" nanoparticles for *in vivo* applications has not been investigated. Particularly, as opposed to small molecule reagents with circulation times on the order of minutes (*8*), ligand attachments on long circulating nanomaterials must remain stable against *in vivo* degradation for hours while nanoparticles circulate systemically and identify molecular targets.

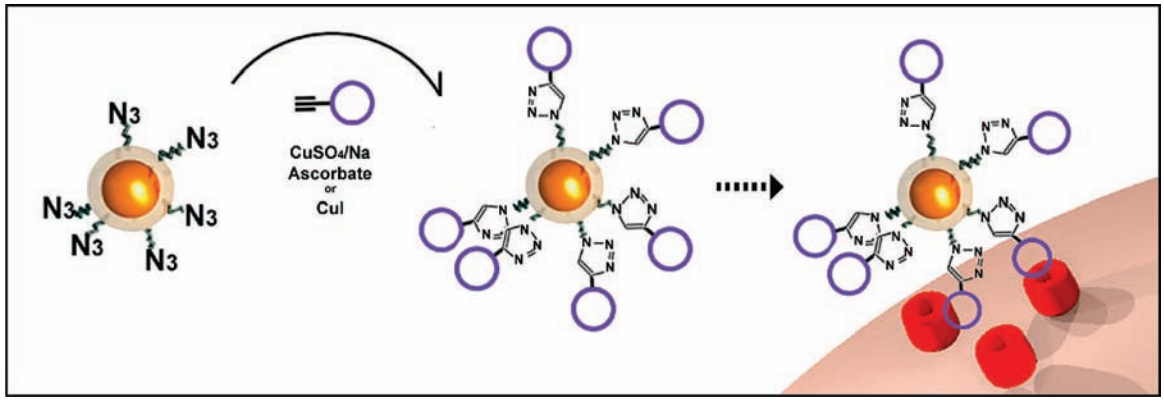
Scheme 1. Design of a "Click" Nanoparticle That Targets Tumor Cells *in Vitro* and *in Vivo*[a]



[a] Cross-linked, fluorescent, superparamagnetic iron oxide nanoparticles are modified to display azido-PEG groups. Conjugation of cyclic targeting peptides (purple circles) bearing pendant alkynes to azido-PEG nanoparticles via the copper(I)-catalyzed Huisgen 1,3-dipolar cycloaddition ("click" reaction) allows specific targeting of the nanoparticles to cells expressing the receptor (red).

Here, we find that alkyne-azide "click" chemistry provides a facile, single-step method for specifically linking the cyclic tumor-targeting peptide LyP-1 (CGNKRTRGC (*1*, *33*);), which contains essential thiol and amine groups, to polymer-coated magnetofluorescent nanoparticles. LyP-1 binds to p32, a mitochondrial proteins that is both overexpressed and aberrantly localized at the cell surface of tumor cells, macrophages and lymphatic endothelial cells in certain experimental tumors and in human cancers (*34*, *35*). We find that "click" LyP-1 nanoparticles are able stably traverse the systemic circulation, extravasate into tumors, and penetrate the tumor interstitium to specifically bind to receptors on p32-expressing cells in the tumors. Together, these results provide strong motivation for future use of "click" functionalization as a strategy for developing nanoparticles for *in vivo* biomedical applications (Scheme 1).

EXPERIMENTAL SECTION

Unless otherwise stated all reagents were purchased from Sigma-Aldrich and all reactions were performed at room temperature.

Iron Oxide Nanoparticle Synthesis. Cross-linked, aminated, fluorescent, superparamagnetic iron oxide nanoparticles were synthesized according to the published protocol (*36*, *37*). Briefly, dextran-coated iron oxide nanoparticles were synthesized, purified, and subsequently cross-linked using epichlorohydrin. After exhaustive dialysis, particles were aminated by adding 1:10 v/v ammonium hydroxide (30%) and incubated on a shaker overnight. Aminated nanoparticles were subsequently purified from excess ammonia using a Sephadex G-50 column and concentrated using a high-gradient magnetic-field filtration column (Miltenyi Biotec). The near-infrared-fluorochrome VivoTag 680 was added to remotely detect particle accumulation *in vitro* and *in vivo* by reacting in 0.1 M HEPES buffer with 0.15 M NaCl at pH 7.2. DMSO-solubilized fluorochromes were added into particle solutions at 4 °C under mixing and allowed to warm to room temperature to react for 2 h. The yield was approximately 10 fluorochromes per nanoparticle for all experiments.

Succinimidyl 4-Azidobutyrate Synthesis (Scheme 2A). *Ethyl 4-azidobutyrate (***1***).* To a solution of ethyl 4-bromobutyrate (5.85 g, 30 mmol) in dimethyl sulfoxide (DMSO, 20 mL), sodium azide (2.925 g, 45 mmol) was added with stirring. The reaction mixture was stirred for 22 h at 55 °C, and cooled to room temperature. Water was added to the reaction mixture and extracted with ethyl ether (3 × 30 mL). The combined organic layer was washed with water and brine, and reduced in vacuo to afford 3.80 g of the azido compound **1**.

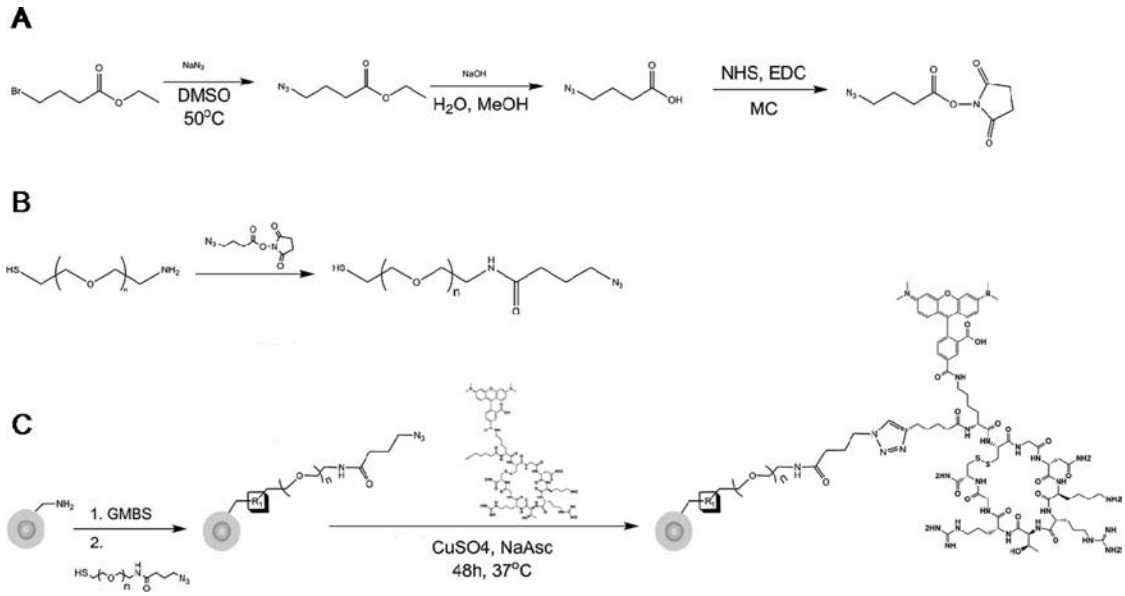
*4-Azidobutyric acid (***2***).* Ethyl 4-azidobutyrate **1** (3.14 g, 20 mmol) was dissolved in aqueous sodium hydroxide solution (1 N, 24 mL) with a minimum amount of methanol to make the solution homogeneous. The reaction mixture was stirred for 3 h at room temperature. After removal of methanol *in vacuo*, the aqueous solution was acidified to pH 0 with HCl and extracted with ethyl ether (3 × 50 mL). The ether layer was then dried over sodium sulfate and filtered. Removal of solvent gave the acid **2** (2.25 g).

*Succinimidyl 4-Azidobutyrate (***3***).* To a solution of *N*-hydroxyl succinimide (1.65 g, 14.3 mmol) in methylene chloride (100 mL) was added acid **2** (1.68 g, 13 mmol) followed by 1-ethyl-3-[3-dimethylaminopropyl]carbodiimide hydrochloride (EDAC, 2.74 g, 14.3 mmol). After stirring for 4 h at room temperature, the reaction mixture was washed with water and brine, dried over sodium sulfate, and filtered. Solvent was removed under reduced pressure to yield 1.15 g of the succinimidyl 4-azidobutyrate **3**.

Peptide Synthesis. Peptides were synthesized in the MIT Biopolymers Laboratory and their composition was confirmed via HPLC and mass spectrometry. The LyP-1 and LyP-1CTL peptides were synthesized with either heptynoic acid or propargylglycine at the N-terminus for conjugation. Each peptide is also labeled with a TAMRA fluorophore (Anaspec) via a lysine residue separated by an aminohexanoic acid (Ahx) spacer. (final sequence for LyP-1: Heptynoic acid or propargylglycine-K(Tamra)[Ahx]-CGNKRTRGC; for LyP-1CTL: Heptynoic acid or propargylglycine-K(Tamra)[Ahx]-CRVRTRSGC). Peptides were cyclized by bubbling air into 10 μM aqueous peptide solutions overnight. Finally, peptide solutions were lyophilized for subsequent use.

"Click" Attachment of Peptides to Nanoparticles. Succinimidyl 4-azidobutyrate was linked to 5 kDa thiol-PEG-amine polymers in 0.1 M HEPES 0.15 M NaCl pH 7.2 for 1 h at a 2:1 molar ratio between linker and polymer. Simultaneously, amino-modified, fluorochrome-labeled nanoparticles were activated with *N*-[γ-maleimidobutyryloxy] succinimide ester (GMBS) (dissolved in DMSO) cross-linker under similar conditions at a 200:1 molar ratio between cross-linker and nanoparticles. To remove excess GMBS, nanoparticle samples were filtered on a G50 column into 50 mM Na phosphate buffer at pH 7.2 supplemented with 10 mM EDTA. Purified nanoparticles were then combined with the polymer reaction mixture and allowed to react at room temperature overnight. Azido-PEG-nanoparticles were then purified from excess polymer and succinimidyl 4-azidobutyrate on a size exclusion column (ACA-44 media: Pall) into 0.1 M HEPES pH 7.2 buffer. Finally, the

Scheme 2. Synthesis of LyP-1-Coated Nanoparticles Using "Click" Chemistry[a]



[a] (A) Synthesis of succinimidyl 4-azidobutyrate. (B) Synthesis of azide-PEG-thiol by linking succinimidyl 4-azidobutyrate to a 5 kDa thiol-PEG-amine. (C) Aminated, cross-linked, fluorochrome-labeled superparamagnetic iron-oxide nanoparticles are activated with GMBS, filtered, and then reacted with the thiol-PEG-azide from (B) to yield azido-PEG bearing nanoparticles. After purification, the particle solutions were reacted with alkyne-bearing LyP-1 peptides with $CuSO_4$/Na Ascorbate as catalysts to yield LyP-1-coated nanoparticles for *in vitro* and *in vivo* use.

azide-PEG-bearing particles were concentrated using Amicon Ultra-4 (Millipore) filters and stored at 4 °C.

To optimize catalyst concentrations for the "click" reaction by HPLC, a 10-fold excess of azido-PEG-NH_2 or *O*-(2-aminoethyl)-*O′*-(2-azidoethyl)pentaethylene glycol (Polypure) was added to a 100 μM peptide solution. $CuSO_4$ and Na ascorbate were dissolved in H_2O and added to the reaction mixture to final concentrations of 1 mM/5 mM and 10 mM/50 mM $CuSO_4$/Na Ascorbate. This mixture was shaken at 37 °C for various times (1 day to 3 days), after which it was characterized via HPLC.

Alkyne-bearing peptides (70:1 peptide/nanoparticle molar ratio), $CuSO_4$ (1 mM), and sodium ascorbate (5 mM) in H_2O were added to a solution of particles and the mixture was shaken at 37 °C for 48 h. Following the reaction, nanoparticles were purified from copper catalyst and excess peptides by filtration in ACA-44 size exclusion media into 0.1 M HEPES 0.15 M NaCl pH 7.2 buffer.

Cell Culture. Cell uptake experiments were performed using a human MDA-MB-435 cancer cell line. Grow media was minimum essential medium eagle (Invitrogen) with fetal bovine serum (10%; Invitrogen). Cells were passaged into 96-well plates and used at 60−80% confluency.

For peptide uptake experiments (Figure 1), LyP-1 or LyP-1CTL peptides were added to cell monolayers in serum-containing media at a final concentration of 10 μM. After 45 min of incubation at 37 °C, cells were washed with media, PBS, treated with trypsin (0.25%) and EDTA, and resuspended in 1% BSA (in PBS) for flow cytometry (BD LSRII). Fluorescence data on 10 000 cells was collected for each sample.

For nanoparticle uptake experiments (Figure 2), particles bearing an LyP-1, LyP-1CTL, or terminal azides were added to the cells in serum media at a final concentration of 100 nM. After 2 h of incubation, cells were trypsinized and assayed for particle fluorescence by flow cytometry. For peptide inhibition experiments, free LyP-1 peptides (10 μM to 100 μM) were first incubated with the cells for 1 h. The cells were then washed with media and 100 nM of LyP-1-coated nanoparticles were added to the cell culture. For imaging, cells were washed with PBS and observed using a 20× objective. Images were captured with a CCD camera mounted on a Nikon TE200 inverted epifluorescence microscope.

In Vivo Studies of Nanoparticle Targeting. Nude athymic mice were inoculated subcutaneously with human cancer cells (MDA-MB-435). After tumors had reached ~0.5 cm^3 in size, LyP-1- and azide-bearing nanoparticles were injected intravenously in the tail vein (1 mgFe/kg). Twenty-four hours after the injection, tumor tissues were excised, snap−frozen, and cut into 15 μm histological sections. Rat antimouse CD-31 (1:50, BD Pharmingen) and polyclonal anti-p32 antibody (1:200 (*34*)) were used for immunohistochemical staining of frozen tissue sections. The corresponding secondary antibodies were added and incubated for 1 h at room temperature: Alexa Fluor 594 goat antirat IgG (1:500, Invitrogen) for CD-31 and Alexa Fluor 594 goat antirabbit IgG (1:500, Invitrogen) for p32 antibody. The slides were washed three times with PBS and mounted in Vectashield Mounting Medium with DAPI (Vector Laboratories). The stained tumor sections were observed with a fluorescence microscope (Nikon, Tokyo, Japan). Histological quantitation of nanoparticles localization was done using *ImageJ* software. Stacks of CD31-stained sections and nanoparticle fluorescence images were utilized for intra- and extravascular particle distribution quantitation. Regions with CD31-staining were selected to denote intravascular accumulation of nanoparticles and surrounding areas were classified as extravascular. The net nanoparticle fluorescence signal above background was quantified for each of these regions to determine the approximate percent of nanoparticle fluorescence localized to the vasculature vs the extravascular space. Three sections from each set of mice were randomly chose for analysis.

RESULTS AND DISCUSSION

In order for "click" chemistry to be applied to the development of peptide-targeted nanomaterials, peptides must be able to harbor pendant alkyne or azide moieties without abating peptide activity. To investigate the efficacy of targeting peptides harboring pendant alkyne moieties, LyP-1 peptide (CGNKRTRGC) and untargeted cyclic control peptide, LyP-1CTL (CRVRTRSGC) in which the essential NKRTR motif is replaced with

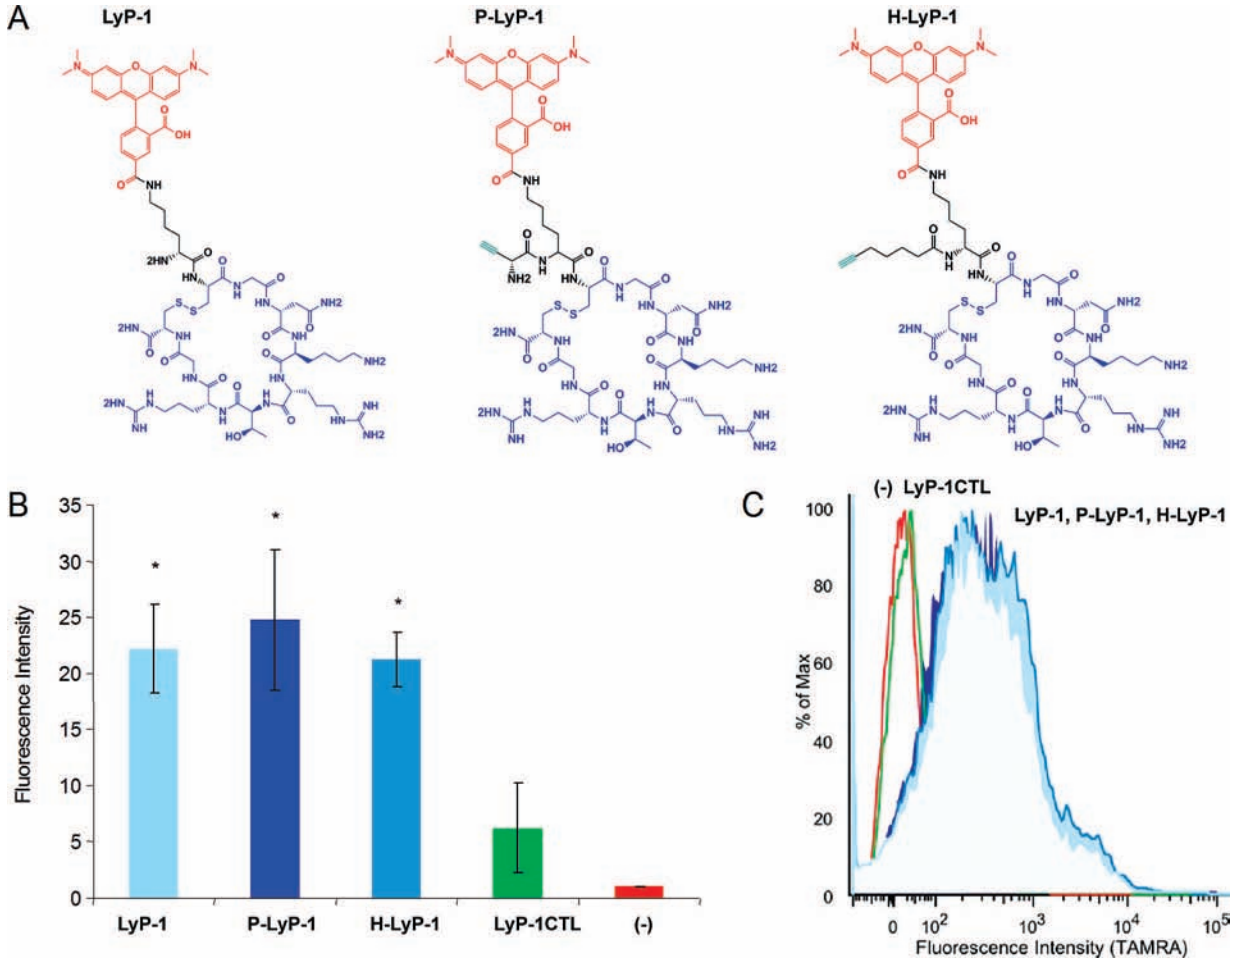


Figure 1. Native and alkyne-bearing LyP-1 peptides target p32-expressing MDA-MB-435 cells *in vitro*. (A) Structures of LyP-1, propargylglycine-LyP-1, and heptynoic acid-LyP-1, all labeled with a TAMRA fluorophore (red). The cyclic nonapeptide is in blue. The pendant alkyne moieties were conjugated to the N-terminus of the peptide during standard FMOC peptide synthesis. (B) Flow cytometry shows that peptides bearing different alkyne groups target MDA-MB-435 cancer cells similarly, while a scrambled control (LyP-1CTL) do not target (P = propargylglycine, H = 6-heptynoic acid, $*p < 0.01$, unpaired Student's *t*-test). **(**C) Flow cytometry histogram shows LyP-1, P-LyP-1, and H-LyP-1 peptides (in different shades of blue) target MDA-MB-435 cells *in vitro*, while LyP-1CTL peptide (green) did not show targeting relative to peptide-free control cells (red).

RVRTR to maintain net charge but abate p32 targeting (*33*), were synthesized to incorporate either of two alkyne moieties (the unnatural amino acid propargylglycine or 6-heptynoic acid) and a 5,6-carboxytetramethylrhodamine fluorophore (TAMRA) (Figure 1A; spectra: Supporting Information Figure 1). Because the alkyne moieties provide molecularly small chemical handles that may be incorporated in FMOC synthesis to either the N- or C-terminal of essential peptide sequences, we hypothesized their presence could be tailored to allow chemical attachment to azido-nanomaterials without interfering with LyP-1 peptide activity. In previous investigations, we found that N-terminal addition of visible and near-infrared fluorophores do not disrupt peptide binding to its receptors (*1, 33*). Accordingly, we reasoned alkyne moieties located near the N-terminus would be well-tolerated by the peptide (Figure 1A). To verify the specificity and efficacy of alkyne-LyP-1 targeting, 10 μM of LyP-1, bearing propargyl glycine, heptynoic, or no alkyne group were incubated for 45 min on monolayers of MDA-MB-435 human tumor cells, which have been shown to bind and internalize LyP-1 and express p32 at the cell surface (*33, 34*), LyP-1CTL peptides were included as a control sequence to verify targeted enhancement of uptake over nonspecific cyclic peptide structures. Cellular uptake of LyP-1 peptide was quantified via flow cytometry (Figure 1B) and plotted as the populational fluorescent intensity, relative to cells incubated with vehicle alone. *In vitro* targeting of LyP-1 peptides bearing either propargylglycine or 6-heptyoic acid was similar to that of native LyP-1 and control peptides (Figure 1C), indicating that alkyne modifications N-terminal to targeting sequences were innocuously chaperoned by peptides and did not affect cell binding.

We next probed the effect of three variables on "click" reaction conditions between our peptides and an azido-PEG-amine (catalyst, catalyst concentration, and reaction time). Azido-PEG-amine was chosen to emulate the azido-PEG surface of the nanoparticles to be used subsequently and to provide a model reaction amenable to HPLC quantitation of product formation. Copper(I) catalyst was added either directly as an iodinated salt (Cu(I)I), or indirectly as soluble copper sulfate ($Cu(II)SO_4$) and reduced by sodium ascorbate *in situ*. The degree of product formation was measured via HPLC with mass spectrometric verification of product identity. The addition of the azido-PEO-amine rendered peptides more hydrophilic and decreased retention times compared to unconjugated peptides. As shown in Supporting Information Table S1, product formation proceeded more completely in the tested reaction conditions for the heptynoic acid-LyP-1, likely due to reduced steric hindrance provided by the extended hydrocarbon chain. Optimal reaction conditions were found to be either 1 mM $CuSO_4$/5 mM Na ascorbate or 1 mM −100 mM CuI for 72 h. Notably, the reaction yields with 10 mM $CuSO_4$ levels were dramatically

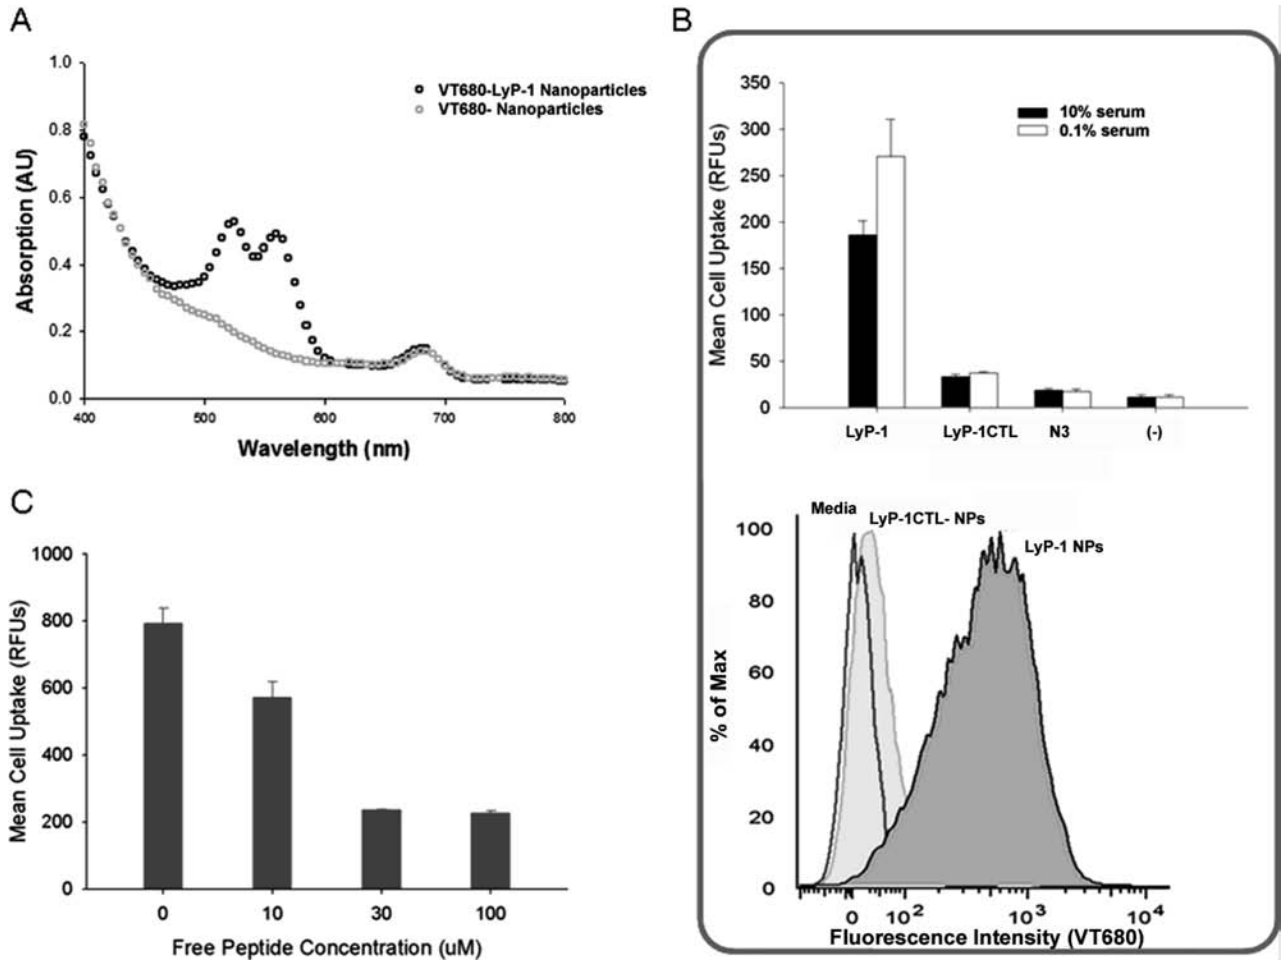

Figure 2. LyP-1-conjugated nanoparticles target p32-expressing MDA-MB-435 cells *in vitro*, while nanoparticles conjugated to control cyclic peptides (LyP-1CTL) do not target. (A) The amount of peptide bound per particle was quantified spectrophotometrically by measuring the absorbance of the TAMRA dyes added following the click reaction. With the addition of catalyst $CuSO_4$/Na ascorbate (dark circles), the TAMRA absorbance at 555 nm was quantified to equal approximately 30 peptides per particle, whereas no TAMRA signal was observed without catalyst (light circles). (B) LyP-1-nanoparticles or control LyP-1CTL-nanoparticles (both at ~30 peptides per particle), or parent azido-bearing particles (N3), were added to MDA-435-MB cancer cells in normal 10% serum (black bars) and 0.1% serum-starved (light bars) conditions. Flow cytometry histogram shows marked increase in uptake of LyP-1-nanoparticles (black contour) vs LyP-1CTL-nanoparticles (light gray contour) and particle-free control cells (dark gray contour). Each error bar represents 6 parallel experiments. (C) Addition of free LyP-1 peptides at concentrations from 10 to 100 uM inhibited cellular uptake of LyP-1-coated nanoparticles, suggesting that the LyP-1 peptide and LyP-1-labeled particles target the same receptor.

lower than 1 mM, likely due to global precipitation of reduced Cu(I) in solution. Nevertheless, we found 1 mM $CuSO_4$ reactions to yield more reliable conjugations than 1 to100 mM CuI reactions, possibly because the insolubility of CuI in aqueous solutions produced variations in the amount of available catalyst delivered to the reactions. Therefore, the optimal conditions for subsequent nanoparticle modification were determined to be 1 mM $CuSO_4$ and 5 mM Na ascorbate. Under these conditions, we did not observe any reduction of peptide disulfide bonds due to copper catalyst or Na ascorbate reduction as determined by MALDI mass spectrometry and HPLC analysis (data not shown).

Having verified that alkyne-bearing LyP-1 peptides could effectively target p32-expressing MDA-MB-435 cancer cells and become linked to azido-bearing PEG polymers, we next developed a protocol for linking these peptides onto azido-PEG bearing, near-infrared fluorochrome-labeled (VivoTag 680) iron oxide nanoparticles. Dextran-caged iron oxide nanoparticles were used as the parent formulation to provide a highly stable, relatively noncytotoxic, and *in vivo*-tested nanoparticle scaffold. Briefly, a heterobifunctional linker bearing an azide on one end an N-hydroxysuccinimide leaving group on the other was synthesized and attached to an amine-PEG-thiol polymer (MW 5000 Da) via its terminal amine (Scheme 2A,B). Azido-PEG-thiol polymers were subsequently linked to surface of cross-linked, aminated, and fluorochrome-labeled dextran-coated iron oxide nanoparticles via the linker *N*-[γ-maleimidobutyryloxy] succinimide ester (GMBS) (Scheme 2C). Long PEG polymers were utilized to carry pendant azide groups in order to enhance particle circulation time *in vivo* and to provide a generalizable nanoparticle surface, whereby optimized "click" attachment conditions might be applicable to other PEG-coated organic and inorganic nanomaterials in the future. Azido-PEG particles were purified from excess polymer and linked to alkyne-bearing peptides in 1 mM $CuSO_4$, 5 mM Na ascorbate. Finally, the conjugated nanoparticles were purified and sterile filtered for *in vitro* and *in vivo* applications.

Peptide valency on nanoparticles was assessed spectrophotometrically by quantifying the number of TAMRA dyes added onto nanoparticles following "click" reaction (Figure 2A). In the presence of catalyst, approximately 30 peptides were added per nanoparticle for both LyP-1 and LyP-1CTL peptides, whereas no addition was observed in the absence of catalyst (Figure 2A). LyP-1 nanoparticles, LyP-1CTL nanoparticles, or azide nanoparticles were incubated over MDA-MB-435 tumor cells for 2 h and nanoparticle accumulation was quantified using flow cytometry (Figure 2B). LyP-1-nanoparticles showed significant tumor cell accumula-

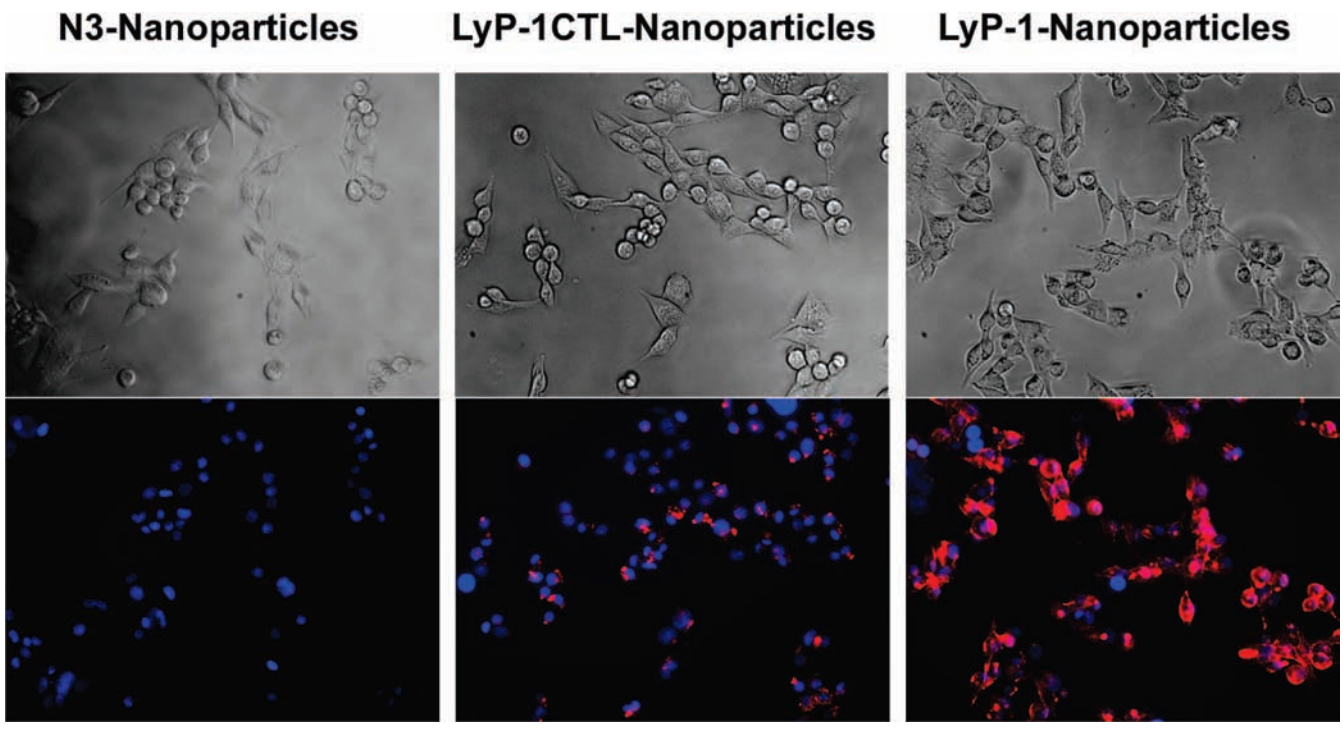

Figure 3. LyP-1-nanoparticles target MDA-MB-435 cancer cells (right). Fluorescence imaging of cells incubated with LyP-1-nanoparticles showed increased near-infrared fluorescence (red). Uptake of azido-bearing or scrambled control peptide (LyP-1CTL)-bearing nanoparticles are not visible or show minor background (left and middle).

tion, while LyP-1CTL-nanoparticles or azide-nanoparticles displayed minimal cell uptake (Figure 2B). The effect of serum on nanoparticle uptake was also studied, as low serum levels enhance the stress-induced expression of the p32 receptor (*33*). The slight increase in LyP-1-nanoparticle targeting in lower serum levels provided further validation of receptor-specific targeting, as decreased serum protein concentrations lowers the likelihood of nonspecific serum protein mediated uptake. To further confirm the uptake specificity of LyP-1-nanoparticles, free LyP-1 peptide was added to cells along with LyP-1-particles (Figure 2C). Dose-dependent inhibition of uptake was observed with LyP-1 peptide concentrations from 10 to 100 μM, suggesting the free LyP-1 and LyP-1-labeled particles share common cellular receptors. We attribute the large excess of free peptide required for inhibition compared to the concentration of nanoparticles used (100 nM) to the presence of multiple copies of the LyP-1 peptide on each nanoparticle, thus improving nanoparticle avidity to receptors through polyvalent binding (*38*). In order to visualize LyP-1 peptide-mediated cell uptake, nanoparticles bearing pendant LyP-1 peptides, control LyP-1CTL peptides, or azides were incubated over MDA-MB-435 cells for 30 min, washed, incubated with a nuclear stain, and imaged via epifluorescence microscopy (Figure 3). LyP-1-nanoparticles were seen associated with cells, while markedly less binding of azide-bearing or control peptide-bearing nanoparticles was not observed. If the same staining procedure was instead performed at 24 h post-incubation, LyP-1-nanoparticles were seen in punctate locations consistent with sequestration in endosome-like compartments (Supporting Information Figure 2). To assess the cytotoxicity of "click" nanoparticles, NH_2-PEG-, azido-PEG-, and peptide-conjugated nanoparticles were incubated for 24 h above HeLa cell cultures (Supporting Information Figure 3). In all three formulations, the TC50 is >7 mM Fe, or over 16 times higher than maximal blood concentrations during *in vivo* experiments performed here and 32 times higher than concentrations used *in vitro* here.

Having found that "click" attachment of homing peptides could mediate the targeting nanoparticles *in vitro*, we evaluated the ability of "click" chemistry to direct nanoparticle targeting to specific tumor cells *in vivo*. Again, near-infrared fluorochrome-labeled (VivoTag 680) nanoparticles were "clicked" to LyP-1 peptides, resulting on average of ~30 LyP-1 peptides per particle, while the parent azido-PEG nanoparticles were used as a negative control. Each population of nanoparticles was injected intravenously into mice bearing human MDA-MB-435 cancer xenografts. Nanoparticles were allowed to circulate and distribute in mice for 24 h, after which the mice were sacrificed and organs collected for immunohistochemical or whole organ fluorescence analysis. Vascular staining with anti-CD31 antibodies showed that azide nanoparticles in tumors remained localized within the immediate periphery of blood vessels (Figure 4B). This perivascular distribution of untargeted nanomaterials is in agreement with previous histological and intravital observations of passive liposomal accumulation in tumors (*39, 40*). By contrast, LyP-1 "click" nanoparticles appeared to have extravasated from the tumor vasculature, penetrated into the interstitial space of the tumor, and bound to p32-expressing cells (Figure 4B,C). As a result, the fraction of LyP-1 nanoparticles that get sequestered beyond the perivascular space was significantly higher than that of azido nanoparticles (Figure 4D) ($P < 0.005$). This pattern was observed in all injected mice and is characteristic of LyP-1 peptide and phage homing observed previously (*1*). Interestingly, previous LyP-1 bacteriophage experiments showed that the LyP-1-expressing phage concentrate in nonvascularized sites of tumors within minutes after injection while insertless phage do not reach these regions (*1*). Thus, there may be unique transportation pathways within tumors that are exploited by this ligand after extravasation that are not available to untargeted materials. In the future, the localization of LyP-1 nanoparticles in avascular tumor regions may be of use for directing therapeutics into hypoxic regions of tumors, where most nanoparticle therapies do not reach. Whole organ assessment

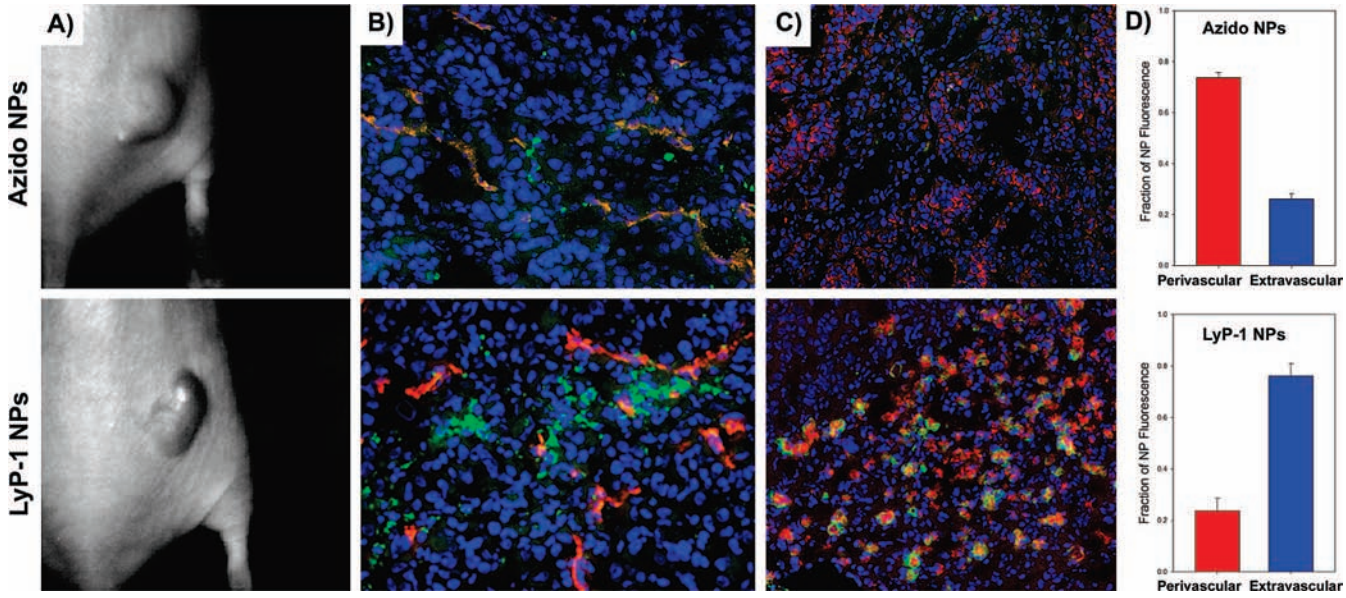

Figure 4. "Click" LyP-1-nanoparticle targeting to tumor cells *in vivo*. Nanoparticles bearing only azide groups (top) or labeled with LyP-1 peptides (bottom) that are matched in circulation time were injected intravenously via the tail vein into mice bearing human MDA-MB-435 cancer xenografts. Histological sections were obtained 24 h postinjection. (A) Light reflectance images of mice bearing the tumor xenografts. (B) Fluorescent LyP-1-nanoparticles (VT680 fluorescence pseudocolored as green) did not colocalize with CD31, a blood vessel marker (red), while untargeted azide-PEG nanoparticles remained localized to the blood vessels or their immediate periphery. (C) LyP-1-nanoparticles (green) accumulated in regions of high p32 expression (red), whereas untargeted, azido-bearing nanoparticles did not accumulate in these areas. (D) Histological quantitation using CD31 stain to assess nanoparticle localization to immediate periphery of blood vessels. The fraction of LyP-1 nanoparticles outside of the perivascular space of CD31-stained blood vessels is significantly higher than azido-nanoparticles ($P < 0.005$) as assessed from three randomly chosen views in each set of mice ($n = 3$). Together, LyP-1-coated nanoparticles penetrate into the tumor interstitium to target p32-expressing cells.

of near-infrared tumor fluorescence demonstrated that, despite the distinct microscopic behavior of LyP-1 nanoparticles, the macroscopic tumor accumulation of LyP-1 nanoparticles and PEG-azide nanoparticles was similar (Supporting Information Figure 4), indicating that the targeted accumulation of LyP-1-nanoparticles was on par with passive delivery, whereby long-circulating materials accumulate in tumors via their hyperporous vasculature over time (*41*, *42*). These results are in accordance with data showing that the development of targeted nanoparticle formulations that amplify the macroscopic accumulation in tumors requires systematic *in vivo* optimization of multiple material parameters, including target avidity, circulation time, and particle size (*43*, *44*). Experiments of this kind are ongoing in order to probe the power of the LyP-1 targeting ligand for amplifying the accumulation and efficacy of nanoparticle-based imaging and therapeutic agents.

CONCLUSION

In this work, we have demonstrated that "click" chemistry may be used to develop nanoparticles that seek out specific cells *in vivo* based on their surface expression of protein markers. Ultimately, these findings suggest that "click" chemistry meets the criteria of being applicable under aqueous conditions, efficient, orthogonal to thiol- and amine-containing targeting motifs, and stable in the complex *in vivo* environments of the blood and tumor milieu. In the future, this work may empower the development of "click" nanomaterials that seek out specific tumor cell types, including tumor stem cells and angiogenic endothelial cells, or amplify the macroscopic accumulation of imaging agents or therapeutics in tumors. Further, the modularity of this "click" attachment strategy should allow it to be adapted to a diversity of *in vivo* nanoparticle platforms and both biological and synthetic ligands, potentially empowering novel on-nanoparticle screen approaches to targeted nanomaterial development.

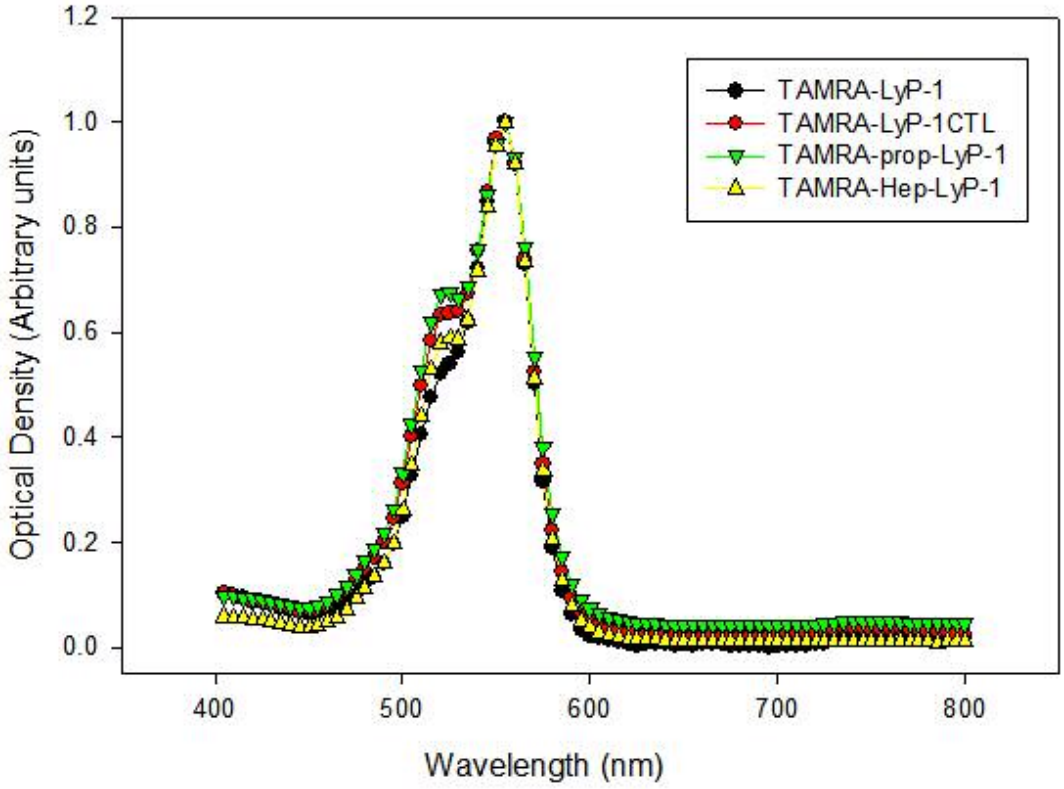
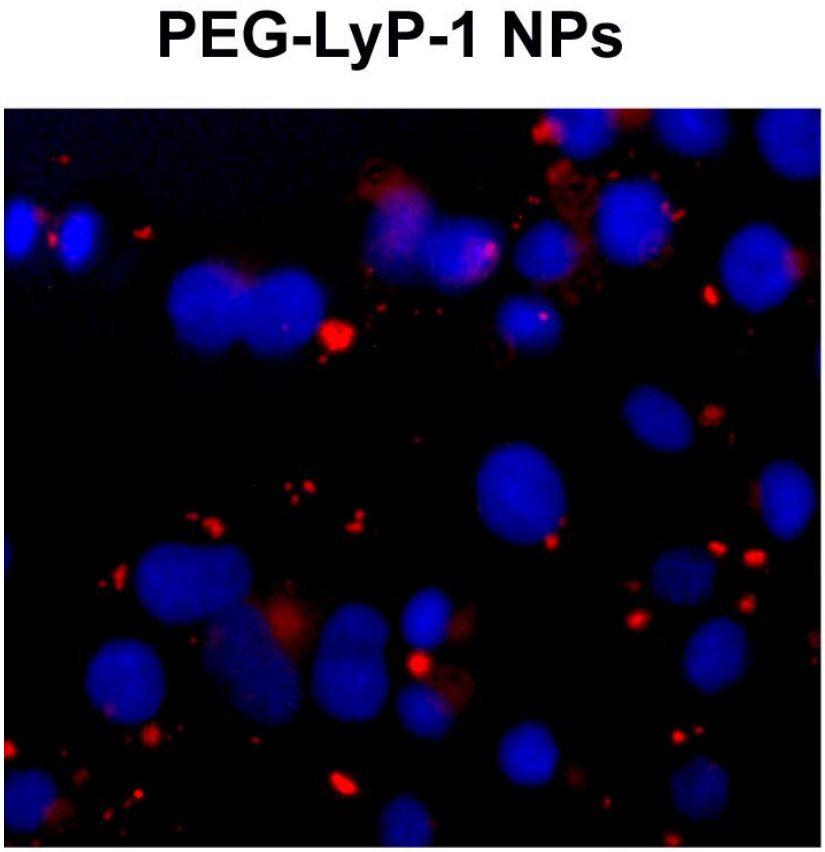
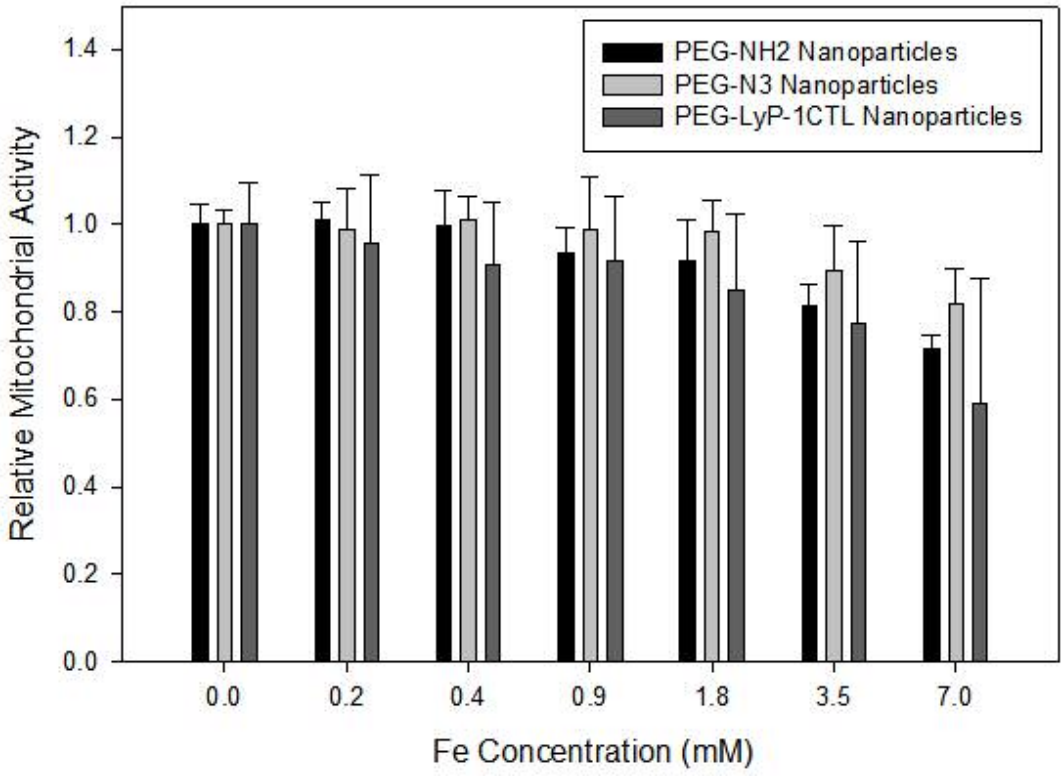
Table S1. Optimization of the "click" reaction. The rate of product conversion in the "click" reaction is measured as a function of product formation in HPLC. The reaction is performed in various catalysts (CuSO4 or CuI) and concentrations, in 24h or 72h reactions, using LyP-1 peptides bearing either propargylglycine or 6-heptynoic-acid.



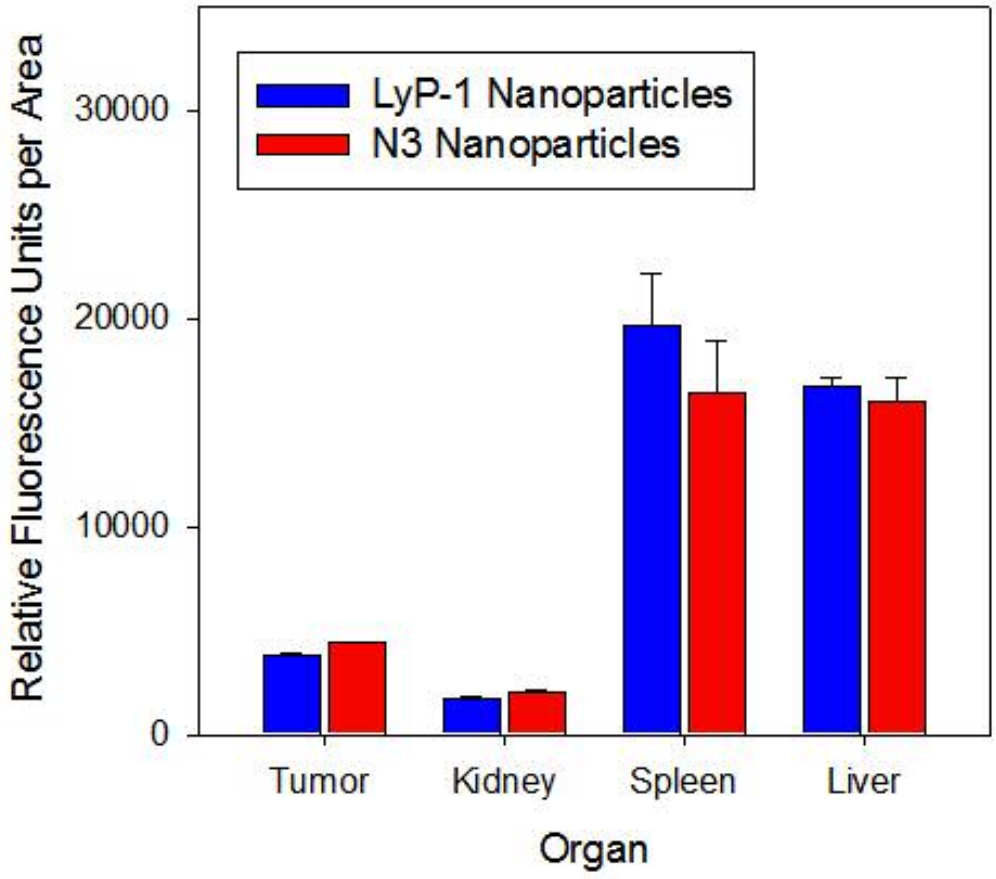
Supplementary Figure 1. *Fluorophore-labeled LyP-1 Peptide Spectra.* UV-Vis spectra for LyP-1 and LyP-1CTL peptides synthesized with varying pendant alkyne groups (prop= propargylglycine; Hep=heptynoic acid)



Supplementary Figure 2. LyP-1-nanoparticles target MDA-MB-435 cancer cells and become localized in endosome-like compartments over 24hrs in vitro. Cells were incubated with LyP-1-nanoparticles for 30min, washed, and incubated for 24hrs before nuclear staining and imaging. PEG-LyP-1 nanoparticles no longer show diffuse membranous staining, but have become localized into punctuate compartments, implying endosomal sequestration away from cell surface.



Supplementary Figure 3. *Probing "Click" Nanoparticle Cytotoxicity to Human Cell Cultures.* Human HeLa cervical cancer cells were incubated with parent NH2-PEG-NPs, PEG-N3-NPs, or PEG-LyP-1CTL-NPs at varying concentrations for 24 hrs, rinsed, and incubated with media containing thiazolyl blue tetrazolium bromide (MTT reagent) at 0.5mg/ml. After 3hr, blue precipitates begin to form within cells as a result of mitochondrial activity. Quantitaion of cellular viability via absorbance of DMSO:isopropanol-solubilized MTT reagent showed that all three NP peparations have TC_{50} values of greater than 7mM, which is over 35-times that used in vitro here (100nM NPs used in cell culture and FACS expts = 0.2mM Fe) and greater than sixteen times the maximum blood concentrations during *in vivo* experiments (200nM NP concentration in blood immediately after injection = 0.4mM Fe).



Supplementary Figure 4. *Near-Infrared Fluorescence Analysis of LyP-1- and Azido-Nanoparticle Tumor Accumulation.* Near-infrared fluorochrome-labeled nanoparticles bearing terminal azide groups (red) or LyP-1 peptides (blue) were injected intravenously via the tail vein into mice bearing human MDA-MB-435 cancer xenografts (4 mice). After particles had cleared the systemic circulation (24hrs), mice were sacrificed and tumor, liver, spleen, and kidneys were fluorescently imaged for nanoparticle accumulation (LI-COR Odyssey). As expected for nanoparticles above the renal filtration limit, clearance was predominately via reticuloendothelial system uptake (liver and

spleen). Nanoparticle accumulation in tumors was slightly decreased for peptide-modified nanoparticles, likely due to a decrease in the particle circulation time following cationic peptide attachment and concomitant decrease in the passive targeting.

Evaluation of a Maleimido Derivative of CHX-A″ DTPA for Site-Specific Labeling of Affibody Molecules

Vladimir Tolmachev,[†,‡,§] Heng Xu,[||] Helena Wållberg,[‡] Sara Ahlgren,[§] Magnus Hjertman,[‡] Anna Sjöberg,[‡] Mattias Sandström,[⊥] Lars Abrahmsén,[‡] Martin W. Brechbiel,[||] and Anna Orlova*[,†,‡]

Received March 16, 2008; Revised Manuscript Received May 25, 2008

Affibody molecules are a new class of small targeting proteins based on a common three-helix bundle structure. Affibody molecules binding a desired target may be selected using phage-display technology. An Affibody molecule $Z_{HER2:342}$ binding with subnanomolar affinity to the tumor antigen HER2 has recently been developed for radionuclide imaging *in vivo*. Introduction of a single cysteine into the cysteine-free Affibody scaffold provides a unique thiol group for site-specific labeling of recombinant Affibody molecules. The recently developed maleimido-CHX-A″ DTPA was site-specifically conjugated at the C-terminal cysteine of $Z_{HER2:2395}$-C, a variant of $Z_{HER2:342}$, providing a homogeneous conjugate with a dissociation constant of 56 pM. The yield of labeling with ^{111}In was >99% after 10 min at room temperature. *In vitro* cell tests demonstrated specific binding of ^{111}In-CHX-A″ DTPA-Z_{2395}-C to HER2-expressing cell-line SKOV-3 and good cellular retention of radioactivity. In normal mice, the conjugate demonstrated rapid clearance from all nonspecific organs except kidney. In mice bearing SKOV-3 xenografts, the tumor uptake of ^{111}In-CHX-A″ DTPA-Z_{2395}-C was 17.3 ± 4.8% IA/g and the tumor-to-blood ratio 86 ± 46 (4 h postinjection). HER2-expressing xenografts were clearly visualized 1 h postinjection. In conclusion, coupling of maleimido-CHX-A″ DTPA to cysteine-containing Affibody molecules provides a well-defined uniform conjugate, which can be rapidly labeled at room temperature and provides high-contrast imaging of molecular targets *in vivo*.

INTRODUCTION

Progress in molecular tumor biology is a foundation for increasing specificity of cancer therapy by targeting of molecular structures, which are uniquely expressed or overexpressed on the surface of cancer cells. Since such overexpression occurs only in a fraction of tumors, specific therapy has to be personalized, i.e., patients should be carefully stratified to optimize targeted therapy while avoiding over- or undertreatment. The use of radionuclide molecular imaging can be an important tool for detection of expression of a particular molecular target in the primary tumor and metastases of a patient. Successful molecular imaging depends on the availability of imaging agents that are capable of providing a specific and high contrast imaging of cancer-associated targets *in vivo*.

Three years ago, a preclinical evaluation of a new class of targeting proteins, Affibody molecules, was initiated (*1–3*). Affibody molecules are three helix bundle proteins, derived from staphylococcal protein A. Phage display enables selection of Affibody molecules with a low picomolar affinity (*4*). A small size, about 7 kDa, enables rapid tumor localization of Affibody molecules and their fast clearance from nonspecific compartments. For example, the $Z_{HER2:342}$ Affibody molecule, which binds HER2[1] antigen with an affinity of 22 pM (*4*), demonstrated clear visualization of murine xenografts at 1 h postinjection (pi) (*5*). Recently, Affibody molecules were developed against another tumor-associated target, EGFR (*6–8*).

Successful molecular imaging depends both on a targeting protein providing specific accumulation of radionuclide in the tumor and on a label, i.e., a combination of a particular radionuclide and a linker that provides a stable attachment to the targeting protein. The use of different labeling methods influences not only the stability of the attachment of the radionuclide to the targeting proteins, but also the charge and the lipophilicity of the conjugate, which may influence uptake in healthy tissues and the excretion route. Alternative labeling of Affibody molecules has previously been demonstrated to result in different biodistribution of the radioactivity (*9–16*). Different macrocyclic and acyclic chelators have been evaluated for labeling of Affibody molecules with the radionuclide ^{111}In ($T_{1/2}$ = 2.8 days). Initial evaluation was done using isothiocyanate derivatives of DTPA (*17*), DOTA (*15*), and CHX-A″ DTPA (*18*). Though all these conjugates demonstrated good targeting properties, isothiocyanate-mediated coupling to amino

groups is not site-specific, and the labeled product presented as a distribution of conjugates with chelators at different positions and therefore potentially with different targeting properties. The use of peptide synthesis enabled production of a homogeneous conjugate of the anti-HER2 Affibody molecule $Z_{HER2:342}$ with DOTA attached site-specifically to the *N*-terminal amine (*5*). After labeling with ^{111}In, this conjugate demonstrated excellent targeting of HER2-expressing xenografts in mice (*5*). However, a site-specific method for labeling of Affibody molecules made by recombinant production would be attractive.

One approach to site-specific labeling of recombinant Affibody molecules is based on the fact that the protein lacks cysteines. Therefore, introduction of a single cysteine into the Affibody molecule provides a unique thiol group, which can be used for site-specific labeling. Previously, this approach has been used for labeling of Affibody molecules with radiohalogens for *in vivo* imaging (*9*), and Oregon Green and horseradish peroxidase (HRP) for *in vitro* detection of HER2 (*19*). Recently, we reported the use of this approach for labeling of the anti-HER2 Affibody molecule $Z_{HER2:2395}$-Cys (a variant of anti-HER2 Affibody molecule $Z_{HER2:342}$, which contains a cysteine at C terminus) with ^{111}In using a maleimido-derivative of DOTA (*20*). The resulting conjugate, ^{111}In-DOTA-$Z_{HER2:2395}$-C, demonstrated a tumor-to-blood ratio similar to the ratio observed with the synthetic ^{111}In-DOTA-$Z_{HER2:342}$ conjugate in a murine xenograft model (*5*).

The semirigid acyclic chelator CHX-A″ DTPA, which forms stable complexes with a number of radiometals of interest for radionuclide imaging, might be an alternative to DOTA for labeling of Affibody molecules. Amino-reactive derivatives of CHX-A″ DTPA demonstrated suitability for labeling of proteins and peptides with ^{111}In (*21*, *22*). Of particular importance, the isothiocyanate derivative of CHX-A″ DTPA provided the best tumor-to-blood ratio among all non-site-specifically ^{111}In-labeled Affibody conjugates (*18*). A thiol-reactive derivative of CHX-A″ DTPA, maleimido CHX-A″ DTPA, has recently been reported (*23*) and is now evaluated here for the site-specific conjugation and radiolabeling of Affibody molecules.

The goals of the study were (a) to prepare a maleimido CHX-A″ DTPA conjugate of anti-HER2 Affibody molecule $Z_{HER2:2395}$-Cys; (b) to evaluate targeting properties of the Affibody molecule $Z_{HER2:2395}$ site-specifically labeled with ^{111}In using maleimido CHX-A″ DTPA (^{111}In-CHX-A″ DTPA-Z_{2395}-C); and (c) to compare this product with $Z_{HER2:2395}$ site-specifically labeled with DOTA (^{111}In-DOTA-Z_{2395}-C) and with $Z_{HER2:342}$ nonspecifically labeled using the isothiocyanate derivative of CHX-A″ DTPA (^{111}In-CHX-A″ DTPA-Z_{342}). The chelators used in this study are presented in Figure 1.

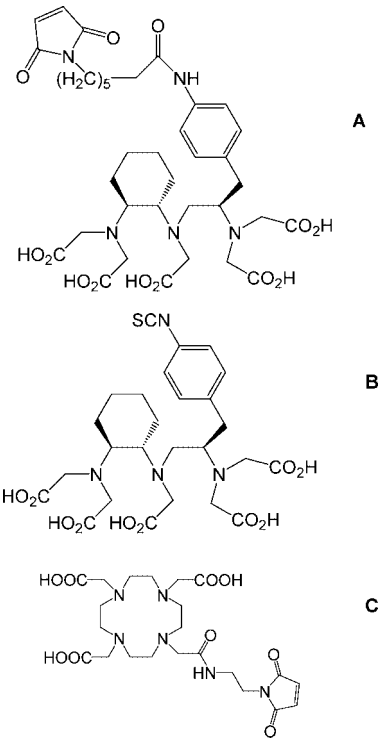

Figure 1. Structures of maleimido-CHX-A″ DTPA (A), CHX-A″ DTPA (B), and maleimido-monoamine-DOTA (C).

MATERIALS AND METHODS

Material. A cysteine-containing variant of $Z_{HER2:342}$, $Z_{HER2:2395}$-C, and its derivatives DOTA-Z_{2395}-C and ^{111}In-DOTA-Z_{2395}-C were produced according to ref (*20*). MMA-DOTA and isothiocyanante-CHX-A″ DTPA were purchased from Macrocyclics (Dallas, TX, USA). The maleimido CHX-A″ DTPA was prepared as previously reported (*23*). A ^{111}In-CHX-A″ DTPA-Z_{342} was produced and labeled according to ref (*18*). Purity and identity of all macromolecules and their conjugates was confirmed using high performance liquid chromatography with on line mass spectrometric detection, as described in the Instrumentation subsection. All purified proteins demonstrated a single peak with a mass, coinciding with the theoretically calculated with an accuracy of ± 1.5 Da, which is within the accuracy of the instrument. Buffers, such as 0.1 M phosphate buffered saline (PBS), pH 7.5, and 0.2 M ammonium acetate, pH 5.5, were prepared using common methods from chemicals supplied by Merck (Darmstadt, Germany). High-quality Milli-Q water (resistance higher than 18 MΩ cm) was used for preparing solutions. Buffers, which were used for conjugation and labeling, were purified from metal contamination using Chelex 100 resin (Bio-Rad Laboratories, Richmond, CA, USA). NAP-5 size exclusion columns were from Amersham Biosciences, Uppsala, Sweden. [^{111}In]indium chloride was purchased from Tyco. Silica gel impregnated glass fiber sheets for instant thin layer chromatography (ITLC SG) were from Gelman Sciences Inc. For cell studies, the HER2-expressing ovarian carcinoma cell line SKOV-3 (ATCC, purchased via LGC Promochem, Borås, Sweden), displaying approximately 1.2×10^6 HER2 receptors per cell (*24*) was used. The cell line was cultured in McCoy's medium (Flow Irvine, UK). The medium was supplemented with 10% fetal calf serum (Sigma, USA), 2 mM L-glutamine, and PEST (penicillin 100 IU/mL and 100 μg/mL streptomycin), all from Biokrom Kg, Germany. Ketalar [ketamine] (50 mg/mL, Pfizer, NY, USA), Rompun [xylazin] (20 mg/mL, Bayer, Leverkusen, Germany), and Heparin (5000 IE/mL, Leo Pharma, Copenhagen, Denmark) were obtained commercially. Data on cellular uptake and biodistribution were analyzed by unpaired, two-tailed *t*-test using GraphPad *Prism* (version 4.00 for Windows GraphPad Software, San Diego, CA, USA) in order to determine any significant differences ($P < 0.05$).

Instrumentation. The radioactivity was measured using an automated gamma counter with 3 in NaI(Tl) detector (1480 WIZARD, Wallac Oy, Turku, Finland). ^{111}In was measured with the use of both photopeaks and summation peak (energy setting from 140 to 507 keV). SDS-PAGE analysis was performed using NuPAGE 4−12% Bis-Tris Gel (Invitrogen) in MES buffer (200 V constant). Distribution of radioactivity along the ITLC strips and SDS-PAGE gels was measured on a Cyclone Storage Phosphor System (further referred to as PhosphorImager) and analyzed using the OptiQuant image analysis software. Cells were counted using electronic cell counter (Beckman Coulter). Affibody samples were analyzed by high performance liquid chromatography with on line mass spectrometric detection (Agilent 1100 HPLC/MSD). The mass spectrometer consisted of a single quadropole mass analyzer with an electrospray

ionization (ESI) interface used in positive ion mode. The software used for analysis and evaluation was Chemstation Rev. B.02.01. (Agilent Technologies). For HPLC-MS analysis, 10 μL sample (1:1 dilution with solution A: 0.1% TFA in Milli-Q water) was loaded onto a Zorbax 300SB-C8 (2.1 × 150 mm, 3.5 μm) RPC-column equilibrated with solution A with 10% solution B (0.1% TFA in acetonitrile) at a flow rate of 0.5 mL/min. After 2 min, the proteins were eluted using a linear gradient, 10−70% solution B in 15 min. For purification, a semipreparative column Zorbax 300SB-C8, 9.4 × 250 mm, 5 μm) was used. The flow rate was 5 mL/min and fractions were collected according to the peak detection settings specified in the chromatographic method.

Preparation and Characterization of ^{111}In-CHX-A″ DTPA-Z_{2395}-C. Conjugation of maleimido CHX-A″ DTPA to $Z_{HER2:2395}$ was performed with calculated chelator to protein ratios of 1:1, 2:1, and 3:1. To reduce any spontaneously forming disulfide bonds, 0.5 mL of $Z_{HER2:2395}$ (stock solution, 3.91 mg/mL) was incubated for 2 h in 30 mM DTT at 37 °C. After incubation, the reduced $Z_{HER2:2395}$ was purified using NAP-5 column pre-equilibrated and eluted with degassed 0.02 M ascorbic acid. Three aliquots of eluant (concentration 2 mg/mL), 200 μL each, were used for coupling. Aliquots were mixed with a precalculated amount of 1 M NH_4OAc, pH 5.5, (degassed by sonication) and with freshly prepared solution of maleimido CHX-A″ DTPA (1 mg/mL in degassed Milli-Q water). The vial was filled with argon gas, and the mixture was incubated at 37 °C for 18 h (overnight). After the end of incubation, the reaction mixture was analyzed using HPLC-MS, as described in the Instrumentation section. Purification of conjugates was performed using semipreparative HPLC, and buffer was changed to 0.2 M NH_4OAc, pH 5.5, using NAP-5 column. Exact concentration of protein was determined by amino acid analysis (Aminosyraanalyscentralen, Uppsala, Sweden). Affinity of conjugate to HER2 was measured using a Biacore 2000 instrument (Biacore, Uppsala, Sweden) according to the method described earlier (*5*).

For a labeling, 180 μL of conjugate solution (containing 20 μg of conjugate in 0.2 M NH_4OAc, pH 5.5) was mixed with 25 μL of ^{111}In in 0.05 M HCl (18 MBq). The mixture was incubated at room temperature. At 10, 20, and 30 min after the start of incubation, a small (0.8 μL) aliquot was taken from the reaction mixture and analyzed using ITLC SG eluted with 0.2 M citric acid. To confirm stable chelation, an aliquot of solution was incubated in 500-fold molar excess of EDTA for 4 h, and then analyzed using ITLC. This stability test was repeated twice.

Binding and Processing of ^{111}In-CHX-A″ DTPA-Z_{2395}-C by HER2-Expressing SKOV-3 Cell Line *in Vitro*. To evaluate cellular processing of ^{111}In-CHX-A″ DTPA-Z_{2395}-C, the labeled conjugate was added in 1 mL complete medium to a series of Petri dishes containing 250 000 cells at an equimolar ratio of Affibody molecules to HER2 receptors. Dishes were incubated for 1 h at 4 °C, and the incubation medium was removed. Cells were washed 3 times with ice-cold serum-free medium and, after addition of 1 mL complete medium, cell dishes were incubated further at 37 °C. At designed times of incubation (0, 0.5, 1, 1.5, 2, 3, 4, 8, and 24 h), one set of 3 dishes was analyzed for cell-associated radioactivity. Medium was collected, and the cells were washed 3 times with ice-cold serum-free medium and treated with 0.5 mL 4 M urea solution in 0.2 M glycine buffer, pH 2.0, with 0.15 M NaCl for 5 min at 4 °C (according to method described in ref (*25*)). Solution was collected and cells were additionally rinsed with 0.5 mL of the same buffer. The radioactivity, which was removed by acid wash, was considered as the membrane bound fraction. After addition of 0.5 mL 1 M NaOH solution, the cells were incubated for 1 h at 37 °C and the solution was collected. Cell dishes were subsequently rinsed with 0.5 mL of alkaline solution. Pooled alkaline fractions represented internalized conjugate. The radioactivity content of the samples was measured using the automated gamma counter.

To confirm that binding of conjugate was receptor-specific, a 100-fold excess of nonlabeled Affibody molecules was added 5 min before the labeled ones to 3 culture dishes and cell-bound radioactivity was measured after treatment with trypsin-EDTA solution (0.25% trypsin, 0.02% EDTA in buffer, Biochrom AG, Berlin, Germany).

To assess the fraction of the conjugate that dissociated intact from the cells, the media was collected after 1, 4, 8, and 24 h of incubation at 37 °C and analyzed using disposable NAP-5 size-exclusion columns (cutoff size 5 kDa) pre-equilibrated with 2.5% bovine serum albumin solution in PBS. Separation on high and low molecular weight fractions was done according to the manufacturer's descriptions. Radioactivity in a high molecular weight fraction was considered intact dissociated conjugate.

Animal Studies. The animal experiments were planned and performed in accordance with the national regulation on laboratory animals' protection. The animal study plans have been approved by the local Ethics Committee for Animal Research in Uppsala. Biodistribution studies in non-tumor-bearing mice were performed in female immunocompetent Naval Medical Research Institute (NMRI) mice. In all experiments on tumor-bearing mice, female outbreed BALB/c nu/nu mice were used. The mice were kept using standard diet, bedding, and environment with free access to food and water. All mice were acclimatized for one week at the Rudbeck Laboratory animal facility before any experimental procedures. Xenografts of HER2-expressing SKOV-3 ovarian carcinoma cell line, 10^7 SKOV-3 cells per animal, were subcutaneously implanted in right hind leg.

In each biodistribution experiment, mice were randomized into groups of four. Animals were injected intravenously (tail vein) with 1 μg conjugate (50 kBq) in 100 μL PBS. At the predetermined time point, a mixture of Ketalar-Rompun (20 μL of solution per gram body weight; Ketalar, 10 mg/mL; Rompun, 1 mg/mL) was intraperitonealy injected and the mice were euthanized by a heart puncture using a 1 mL syringe, prewashed with diluted heparin (5000 IE/mL). Blood as well as lung, liver, spleen, kidneys, tumor (from xenografted mice), samples of muscle and bone, gastrointestinal tract (with its content), and remaining carcass were collected in preweighed plastic vials. Organs and tissue samples were weighed and measured for radioactivity using an automatic gamma counter. The tissue uptake values were calculated as percent injected activity per gram tissue (% IA/g), except for the gastrointestinal tract and the carcass, which were calculated as % IA per whole sample. The radioactivity in the gastrointestinal tract with its content was used as a measure of hepatobiliary excretion.

Biodistributions of the three differentially labeled constructs (two site-specifically labeled at C-terminal, ^{111}In-CHX-A″ DTPA-Z_{2395}-C and ^{111}In-DOTA-Z_{2395}-C, and one labeled using amino-directed chemistry, ^{111}In-CHX-A″ DTPA-Z_{342}) were determined in NMRI mice at 4 and 24 h pi.

Tumor targeting and biodistribution of ^{111}In-CHX-A″ DTPA-Z_{2395}-C at 1, 4, and 24 h pi. were studied in immunodeficient mice bearing SKOV-3 xenografts. To confirm that xenograft accumulation of ^{111}In-CHX-A″ DTPA-Z_{2395}-C was HER2-specific, receptors in one additional group of mice were presaturated by subcutaneous injection of 520 μg of unlabeled $Z_{HER2:342}$ 45 min prior to injection of radiolabeled Affibody molecule. Mice in this group were sacrificed 4 h after injection. For comparison, biodistributions of ^{111}In-DOTA-Z_{2395}-C and ^{111}In-CHX-A″ DTPA-Z_{342} were studied in the same batch of SKOV-3-grafted mice, 4 h pi.

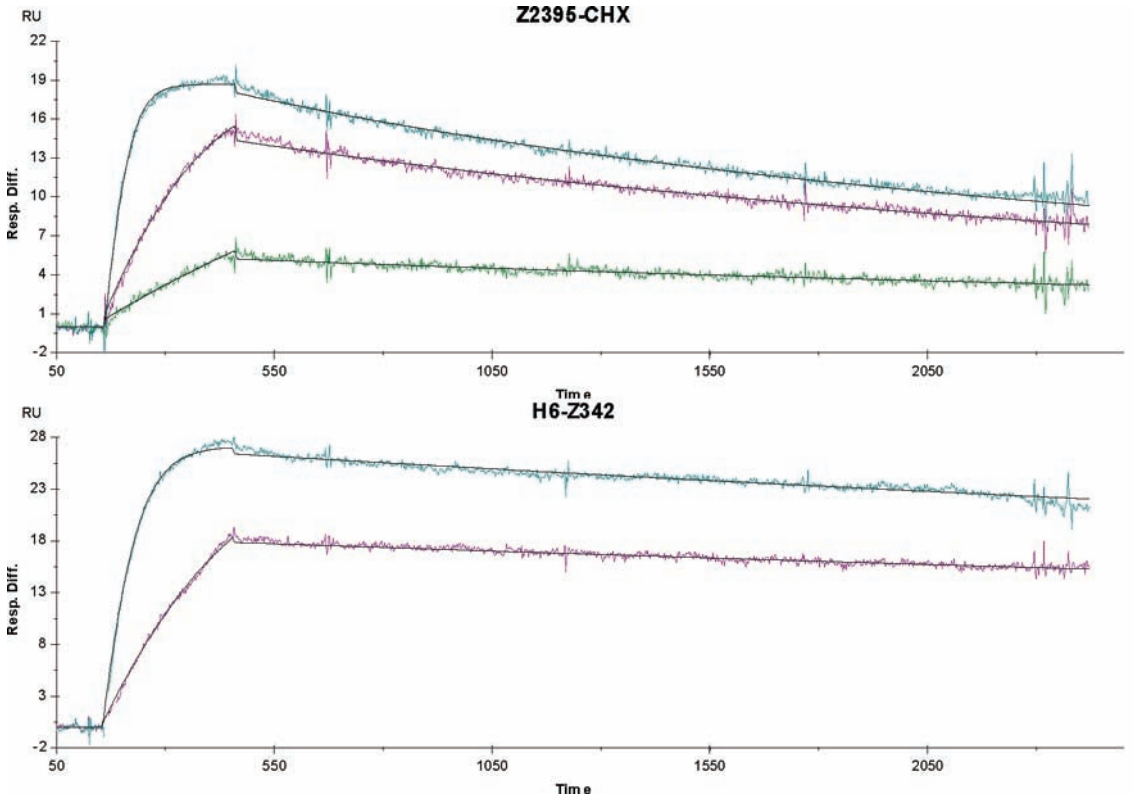

Figure 2. Biosensor binding study using surface plasmon resonance. Sensorgrams obtained after injection of the CHX-A″ DTPA-Z_{2395}-C conjugate (upper panel) and parental His_6-$Z_{HER2:342}$ (lower panel) over a sensor chip flow-cell surface containing amine-coupled HER2-Fc fusion protein. CHX-A″ DTPA-Z_{2395}-C was injected at concentrations of 5 nM, 1.2 nM, and 0.31 nM. His_6-$Z_{HER2:342}$ was injected at concentrations of 6 nM and 1.5 nM. Experimental curves were fitted to a 1:1 (Langmuir) binding model with correction for mass transfer effects.

For gamma camera imaging, four SKOV-3 xenograft bearing mice were injected with 2.7 MBq ^{111}In-CHX-A″ DTPA-Z_{2395}-C (amount of protein 3 μg). 1 and 4 h postinjection, two animals were sacrificed by overdosing Ketalar/Rompun followed by cervical dislocation. After euthanasia, the urine bladders were excised and cadavers were stored on ice until imaging. Imaging was performed at the department of Nuclear Medicine at Uppsala University Hospital using a Millennium GE gamma camera equipped with a medium energy general purpose (MEGP) collimator. Static images (10 min), obtained with a zoom factor of 2, were digitally stored in a 256 × 256 matrix. The evaluation of the images was performed using a Hermes system (Hermes Medical Solutions, Stockholm). In each animal, a region of interest (ROI) was drawn around the tumor. The same region was copied to a contralateral thigh. Tumor-to-contralateral thigh ratios were calculated based on total counts in the ROIs.

RESULTS

Preparation and Characterization of ^{111}In-CHX-A″ DTPA-Z_{2395}-C. HPLC-MS analysis demonstrated that 83% of the $Z_{HER2:2395}$ Affibody molecules were conjugated with chelator, when coupling of maleimido-CHX-A″ DTPA was performed using equimolar amount of chelator and protein. When maleimido-CHX-A″ DTPA was used in a 2- or 3-fold molar excess, no unconjugated Affibody molecules were detected after incubation during 18 h at 37 °C, demonstrating that a uniform 1:1 product was produced. Semi-preparative HPLC using Zorbax 300SB-C8 column provided complete separation from nonconjugated chelator.

Measurement of the binding kinetics of CHX-A″ DTPA-Z_{2395}-C to extracellular domain of HER2 (Figure 2) suggested that the association rate (k_a) was $7.4 \pm 0.5 \times 10^6$ M^{-1} s^{-1} (an average of two measurements ± maximum error of measurement), and dissociation rate $4.1 \pm 0.2 \times 10^{-4}$ s^{-1}, resulting in an equilibrium dissociation constant of 56 ± 6.5 pM. Affinity measurement of His_6-$Z_{HER2:342}$ gave a value of 29 pM, which is in a good agreement with previously published data (22 pM (*4*)). Apparently, coupling of maleimido-CHX-A″ DTPA had no major negative effect on the affinity of the conjugate toward HER2.

Labeling performed at specific radioactivity of 0.9 MBq/μg (6.3 GBq/μmol) provided nearly quantitative yield (99.7 ± 0.3%) after 10 min. Extension of the labeling time to 30 min did not increase the labeling yield. Incubation with 500-fold molar excess of EDTA for 4 h did not decrease conjugate-associated radioactivity, indicating that the labeling was fully mediated by CHX-A″ DTPA, not by any weak chelating pocket that might be formed by amino acid residues.

Binding and Processing of ^{111}In-CHX-A″ DTPA-Z_{2395}-C by HER2-Expressing SKOV-3 Cell Line *in Vitro*. Binding of ^{111}In-CHX-A″ DTPA-Z_{2395}-C to HER2-expressing SKOV-3 cells was specific, since presaturation of receptors with a 100-fold excess of nonlabeled Affibody molecules prevented binding nearly completely, from 35 ± 0.5% to 0.06 ± 0.01% of added radioactivity ($p < 0.0001$).

The results of cellular processing experiments indicated that retention of the conjugate was good; 81 ± 0.5% of radioactivity was still associated with cells 24 h after change of the media (Figure 3, left panel). Interestingly, internalization was rather slow as only 16.6 ± 1.4% of the radioactivity initially associated with cells was internalized at 24 h. Excretion of degraded conjugate was also slow and at early time points the majority of noncell-bound radioactivity was presented by intact conjugates that dissociated from cells. This observation is in agreement with known good intracellular retention of radiometal

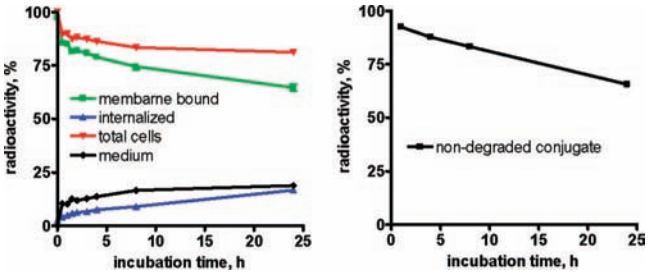

Figure 3. Left panel: cellular retention and internalization of ^{111}In-CHX-A″ DTPA-Z_{2395}-C by HER2-expressing SKOV-3 ovarian carcinoma cell line after inrerrupted incubation. Right panel: percentage of nondegraded conjugate in cell culture media (high-molecular-weight fraction in size-exclusion chromatography using NAP-5 columns) as a function of time after interrupted incubation and media change. Data presented as an average from three cell culture dishes ± SD. Error bars may be not seen since they are smaller than point symbols.

labels (*26*). Excreted radiocatabolites could be detected in the media 24 h after change, but amounted to only 6.5% of the initial radioactivity. Thus, the favorable cellular retention was mainly due to strong binding (very slow off-rate) to cell membrane target.

Animal Studies. To evaluate influence of maleimido-CHX-A″ DTPA conjugation on the biodistribution of the HER2-binding Affibody molecule, the biodistribution of ^{111}In-CHX-A″ DTPA-Z_{2395}-C was compared with that of ^{111}In-DOTA-Z_{2395}-C (site-specifically labeled at the C-terminal using DOTA) and with that of ^{111}In-CHX-A″ DTPA-Z_{342} (labeled via CHX-A″ DTPA coupled using isothiocyanate) in NMRI mice, at 4 and 24 h pi. The results of the biodistribution experiments are presented in Table 1. All conjugates demonstrated rapid clearance from blood and the majority of normal organs and tissues. The renal excretion was dominating, which resulted in a low radioactivity accumulation in the gastrointestinal tract, but high uptake in kidneys. There were, however, some differences. Though radioactivity accumulation in bone was low, the use of DOTA provided lower bone uptake than CHX-A″ DTPA. At the same time, bloodborne radioactivity was higher at both time points for ^{111}In-DOTA-Z_{2395}-C than for both CHX-A″ DTPA-containing conjugates. Hepatic accumulation of the radioactivity was also higher for ^{111}In-DOTA-Z_{2395}-C at 24 h pi. Interestingly, the overall clearance of ^{111}In-CHX-A″ DTPA-Z_{342} from blood and tissues was more rapid than clearance of both site-specifically labeled conjugates.

Targeting of HER2 *in vivo* using ^{111}In-CHX-A″ DTPA-Z_{2395}-C was evaluated in BALB/C nu/nu mice bearing SKOV-3 xenografts (Figure 4 and Tables 2 and 3). The average tumor size was 0.57 ± 0.39 g at the time for the experiment. In agreement with biodistribution data for NMRI mice, ^{111}In-CHX-A″ DTPA-Z_{2395}-C cleared rapidly from normal tissue and blood, with a rather high degree of renal reabsorption. Tumor targeting was also rapid, and already at 1 h pi, the tumor uptake was higher than uptake in any other organ or tissue, except kidney. At 4 h pi, the tumor uptake had not changed significantly in comparison with that at 1 h pi, but tumor-to-organ ratios increased significantly for blood, lung, muscle, and bone due to clearance from normal tissues. Only tumor-to-lung and tumor-to-muscle increased by 24 h pi in comparison with the 4 h pi time point. In order to verify the specificity of ^{111}In-CHX-A″ DTPA-Z_{2395}-C accumulation in HER2-expressing xenografts, its biodistribution (4 h pi) was studied after saturating the binding epitope of HER2 by preinjection of 520-fold molar excess of nonlabeled $Z_{HER2:342}$.The tumor uptake was reduced from 17.3 ± 4.8% to 1.7 ± 0.2% IA/g ($p < 0.001$), demonstrating specific HER2-binding of ^{111}In-CHX-A″ DTPA-Z_{2395}-C in the xenografts.

The targeting properties were assessed at 4 h pi to compare ^{111}In-CHX-A″ DTPA-Z_{2395}-C with the two most favorable HER2-targeting Affibody conjugates, ^{111}In-DOTA-Z_{2395}-C (site-specifically labeled at C-terminal using DOTA (*20*)) and ^{111}In-CHX-A″ DTPA-Z_{342} (labeled via CHX-A″ DTPA coupled using isothiocyanate (*18*)). The results of this comparison are presented in Tables 2 and 3.

Images acquired after the i.v. injection of the ^{111}In-CHX-A″ DTPA-Z_{2395}-C into mice bearing SKOV-3 xenografts confirmed the capacity of this conjugate to visualize HER2-expression (Figure 5). In agreement with the biodistribution data, tumors were clearly visualized already at 1 h pi (tumor-to-contralateral thigh ratio 20 ± 6). By 4 h pi, the contrast of imaging increased due to decrease of the background radioactivity (tumor-to-contralateral thigh ratio 37 ± 8). Due to the renal excretion, high radioactivity was accumulated also in kidneys.

DISCUSSION

Personalizing cancer treatment requires methods for detection of a variety of tumor-specific cell-surface antigens for patient stratification. The Affibody technology of small robust high-affinity binders may be a convenient platform for development of molecular imaging agents to be used for noninvasive assessment of responsiveness to patient-specific therapy (*1–3*). The rapid tumor localization of Affibody-based targeting conjugates and their rapid clearance from blood and healthy tissues (except kidneys) result in high-contrast *in vivo* imaging of tumor biomarkers shortly after injection. However, careful studies on structure−property relationships are required for design of optimal Affibody-based conjugates. Selection of suitable chelators for labeling with radiometals is one important direction for such studies. Thiol-directed chemistry is of particular interest, since it can provide exquisite site-specific coupling of chelators to both chemically and recombinantly produced Affibody molecules having a unique cystein, thereby increasing the flexibility of manufacturing.

HER2 is a transmembrane tyrosine kinase receptor, which is overexpressed in a fraction of breast, ovary and urinary bladder carcinomas (*27–29*). Blocking of HER2 signaling in breast carcinomas using the monoclonal antibody trastuzumab (Herceptin) results in increase of survival and is approved for clinical use both in Europe and North America for patients with HER2-overexpressing tumors. Besides, targeted therapy of HER2-expressing tumors using radionuclides (*30–33*) and drugs (*34*) is under development. Both the American Association of Clinical Oncology (*35*) and the European Group on Tumour Markers (*36*) recommend detecting HER2 expression in each new breast tumor or recurrence in order to select patients who would benefit from trastuzumab therapy. Presently, the assessment of HER2 expression is done based on histopathological examination. Unfortunately, the results of such tests may be affected by sampling errors, discordance in HER2 expression in primary tumors and metastasis, and experience of a laboratory performing analysis (*37*). In contrast, molecular imaging would allow an assessment of the global HER2 expression. An example of clinical utility of radionuclide imaging of HER2 expression in breast cancer patients has been presented by Behr and co-workers (*38*). It was shown that the use of ^{111}In-DTPA-trastuzumab identify not only of patients responding to trastuzumab treatment (alone or in combination with chemotherapy) but also patients who may suffer from cardiac toxicity associated with such treatment.

The choice of the chelator moiety contributes to the overall charge and lipophilicity of the conjugate, and could in addition have an effect on the conformation of the tracer. The present study focused on the effects of different labeling methods on $Z_{HER2:2395}$-C, a cysteine-containing derivative of anti-HER2

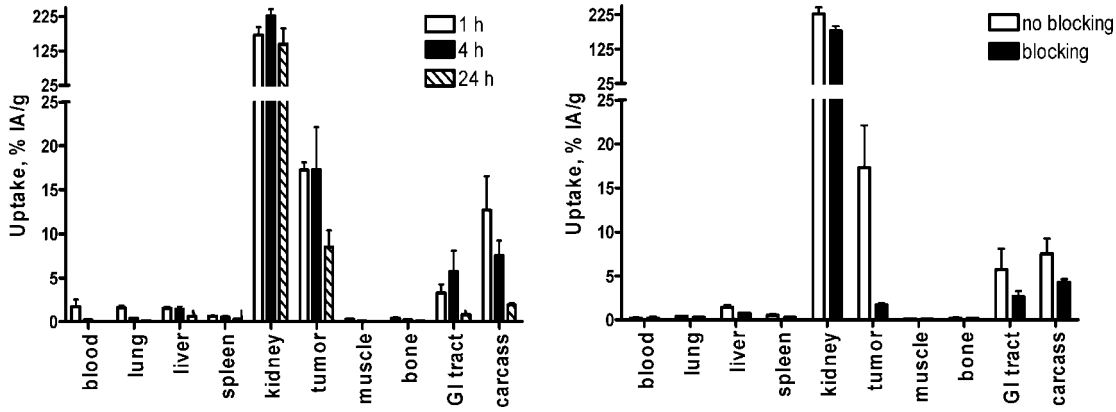

Figure 4. Targeting of HER2-expressing xenografts *in vivo*. Left panel: Biodistribution of ^{111}In-CHX-A″ DTPA-Z_{2395}-C 1, 4, and 24 h pi. Right panel: Specificity of ^{111}In-CHX-A″ DTPA-Z_{2395}-C tumor uptake in SKOV-3 xenografts, 4 h pi. In order to saturate HER2 receptors in tumors, one group of animals was preinjected with 520 μg nonlabeled $Z_{HER2:342}$ 45 min before injection of radiolabeled conjugate (designated as blocking). All animals were injected with 1 μg of labeled Affibody molecules. Data are expressed as % IA/g (percent of injected radioactivity per gram tissue) and presented as an average from four animals ± SD. Data for the gastrointestinal tract (with its content) and for carcass are presented as % IA per whole sample.

[b] For intestine (together with content) and carcass, data presented as percent of injected activity per whole sample (% IA). [c] Significant difference ($p < 0.05$) with ^{111}In-DOTA-Z_{2395}-C at the same time point. [d] Significant difference ($p < 0.05$) with ^{111}In-CHX-A″ DTPA-Z_{342} at the same time point.

Affibody molecule $Z_{HER2:342}$ (*4*). Previous data have shown that coupling with the chelator DOTA followed by labeling with ^{111}In result in a favorable molecular imaging agent, ^{111}In-DOTA-Z_{2395}-C (*20*), superior to ^{111}In-Bz-DOTA- Z_{342}, bearing Bz-DOTA randomly coupled to amino groups (*15*). In contrast to DOTA, CHX-A″ DTPA is a semirigid chelator that provides stable labeling at ambient temperature with a range of medically useful radionuclides (*18*, *21*, *39*, *40*). A maleimido derivative of the CHX-A″ DTPA was developed for use in site-directed maleimide−thiol Michael addition conjugation chemistry (*23*). Site-specific coupling of the maleimido-CHX-A″ DTPA to $Z_{HER2:2395}$-C had no major effect on affinity, suggesting that no major structural changes resulted from the conjugation. The cellular processing was essentially unchanged in comparison with ^{111}In-DOTA-Z_{2395}-C (*20*). Although ^{111}In-CHX-A″ DTPA-Z_{2395}-C demonstrated strong membrane binding, internalization was as slow as for ^{111}In-DOTA-Z_{2395}-C (Figure 3). In normal mice, ^{111}In-CHX-A″ DTPA-Z_{2395}-C as well as ^{111}In-DOTA-Z_{2395}-C and ^{111}In-CHX-A″ DTPA-Z_{342} were rapidly cleared from the blood and the majority of tissues, accompanied by a high degree of renal reabsorption of radioactivity. Interestingly, the ^{111}In-CHX-A″ DTPA-Z_{342} conjugate (with the chelators conjugated via a thiourea bond) cleared more rapidly than the site-specifically labeled conjugates. The same was observed in

[a] Data are presented as an average for four animals ± SD. [b] Significant difference ($p < 0.05$) between tumor-to-organ ratios at 1 and 4 h pi. for ^{111}In-CHX-A″ DTPA-Z_{2395}-C. [c] Significant difference ($p < 0.05$) between tumor-to-organ ratios at 4 and 24 h pi. for ^{111}In-CHX-A″ DTPA-Z_{2395}-C. [d] Significant difference ($p < 0.05$) between tumor-to-organ ratios 4 h pi. for ^{111}In-CHX-A″ DTPA-Z_{2395}-C and ^{111}In-DOTA-Z_{2395}-C. [e] Significant difference ($p < 0.05$) between tumor-to-organ ratios 4 h pi. for ^{111}In-CHX-A″ DTPA-Z_{2395}-C and ^{111}In-CHX-A″ DTPA-Z_{342}. [f] Significant difference ($p < 0.05$) between tumor-to-organ ratios 4 h pi. for ^{111}In-DOTA-Z_{2395}-C and ^{111}In-CHX-A″ DTPA-Z_{342}.

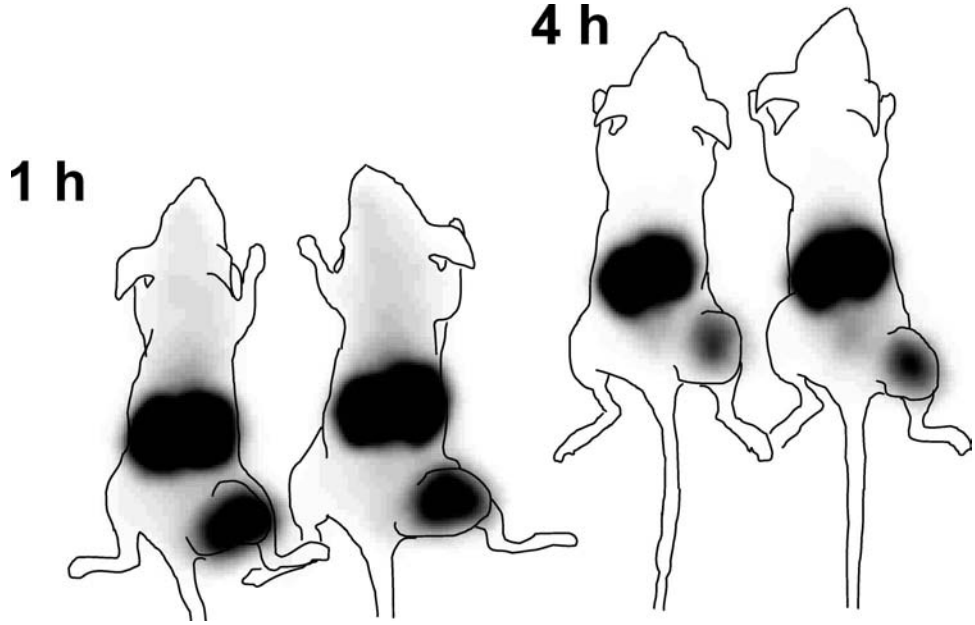

Figure 5. Anterior gamma-camera images of nude mice bearing HER2-expressing SKOV-3 xenografts 1 h (left) and 4 h (right) after injection of ^{111}In-CHX-A″ DTPA-Z_{2395}-C. Contours derived from a digital photographs were superimposed over gamma-camera images to facilitate interpretation. Besides tumors (right hind legs), only kidneys are visualized.

tumor-bearing mice. In our previous study (*20*), an ^{111}In-Bz-DTPA-Z_{342} conjugate with an acyclic chelator randomly amine-coupled demonstrated a more rapid clearance than ^{111}In-DOTA-Z_{2395}-C having DOTA site-specifically coupled. One might hypothesize that a decrease in positive charge resulting from reaction of the isothiocyanate with ϵ-amines of the lysine residues or the N-terminus amine facilitates clearance. In tumor-bearing mice, ^{111}In-CHX-A″ DTPA-Z_{2395}-C displays rapid tumor localization, enabling high tumor-to-organ ratios as early as 1 h pi (Table 3). These results were confirmed by γ-camera imaging (Figure 5). By 4 h pi, the contrast had improved further. Also, the tumor-to-lung and tumor-to-bone ratios were sufficient for imaging at 4 h pi, although these ratios were significantly increased by 24 h. At 4 h pi, the tumor-to-blood ratio of ^{111}In-CHX-A″ DTPA-Z_{2395}-C (86:1) greatly exceeded reported values of any non-Affibody-based HER2-targeting agent, including the ^{111}In-DOTA(GSG)-KCCYSL peptide (tumor-to-blood ratio of 3:1 (*41*)) or ^{111}In-CHX-A″ DTPA-C6.5K-A diabody (tumor-to-blood ratio of 1.34:1 (*21*)).

The high kidney uptake of ^{111}In-CHX-A″ DTPA-Z_{2395}-C might be of some concern, although the radiation dose is most likely not a radiation safety issue. The present data are insufficient for a detailed dosimetry evaluation, but a dose estimate has been performed for another Affibody molecule, ^{111}In-DOTA-$Z_{HER2:342}$, which displayed somewhat higher uptake in kidneys (*5*). Dosimetry modeling suggested that the renal dose from ^{111}In-DOTA-$Z_{HER2:342}$ would be 1.8 mSv/MBq, or 200 mSv if 111 MBq is given to the patient. This is comparable to the 124 mSv/185 MBq for ^{111}In-ProstaScint (data from package insert). It should be noted that renal doses as high as 45 Gy (after more than 90 GBq injected radioactivity) did not cause negative effects on the kidneys in clinical trials using ^{111}In-octreotide for therapy (*42, 43*). The high renal uptake might complicate imaging of metastases close to kidney; however, contemporary reconstruction algorithms may minimize this problem. Handling of renal uptake of radiometal-labeled Affibody molecules is discussed in more detail in a recent publication (*20*).

The chelator CHX-A″ DTPA may be used for labeling with different nuclides. As illustrated here, SPECT studies with ^{111}In are possible. PET imaging is possible after labeling with ^{86}Y, granted that the half-life of only 14.7 h is compatible with the half-life of the tracer (*44*). The half-life of this nuclide would facilitate distribution of radiolabeled conjugates from a central cyclotron-equipped dispensary to satellite PET centers. The use of PET might improve of sensitivity of imaging, including the possibility of visualizing smaller metastases or tumors in the vicinity of kidneys or urinary bladder. The chelator may also be used with a number of therapeutic radionuclides, including ^{90}Y (*21, 22, 45*), ^{114m}In (*18*), ^{177}Lu (*28, 32*), and the α-emitting nuclides ^{212}Bi and ^{213}Bi (*39, 46, 47*). High renal uptake would, most likely, prevent systemic therapy using radiolabeled CHX-

A″ DTPA-Z_{2395}-C. However, locoregional therapy of bladder carcinoma or brain metastases of breast cancer (using short-lived α-emitters) deserves further investigations. The maleimido-CHX-A″ DTPA is of course not limited to the labeling of Affibody molecules, but may be used with any targeting protein containing an unpaired cysteine residue, including Fab′ fragments of monoclonal antibodies and scFv with an engineered cysteine. The final choice of tracer to carry the nuclide will depend on several factors. Besides pharmacokinetics and biodistribution discussed in the present report, multiple administrations may require a low immunogenic response to the tracer. Preliminary data suggest that the Affibody molecules display a low immunogenic potential, possibly due to rapid clearance from the body (*48*).

CONCLUSION

The use of maleimido-CHX-A″ DTPA enables facile and stable site-specific labeling of Affibody molecules with ^{111}In under mild conditions. The conjugate demonstrated preserved binding to HER2-expressing cells and good cellular retention of the radioactivity. In BALB/c nu/nu mice bearing HER2-expressing xenografts, the tumors were clearly visualized 1 and 4 h pi. This suggests that the Affibody molecule-maleimido-CHX-A″ DTPA conjugates possess a high potential for *in vivo* imaging of tumor-associated targets and, possibly, for radionuclide therapy. Apparently, the maleimido-CHX-A″ DTPA can be a suitable chelator for site-specific labeling of other targeting proteins, including Fab′-fragments.

We previously developed potent nonviral vectors based on complexation of lipoplexes and pH-sensitive fusogenic liposomes, which achieve efficient transfection through membrane fusion with intracellular acidic compartments such as endosomes. Because transferrin receptor is known to be overexpressed in cancer cells, in this study, we investigated the effect of transferrin as a ligand for transfection of various cancer-derived cell lines mediated by the liposome−lipoplex hybrid complexes. Results showed that these hybrid complexes with transferrin exhibited higher transfection efficiency toward these cells than complexes without transferrin, but the extent of the transferrin-induced enhancement was dependent on the cell line. Conjugation of transferrin increased their transfection activity for HeLa and KB cells, although it only slightly enhanced transfection for HT1080, HepG2, and K562. Transferrin receptors in HT1080, HepG2, and K562 cells were internalized slowly, whereas those in HeLa and KB cells were internalized quickly and actively. These results indicate that transfection mediated by the ligand-attached hybrid complex does not correlate with the amount of transferrin receptor in the cell surface but correlate with the activity of internalization of transferrin receptor into the cells.

INTRODUCTION

For the establishment of gene therapy, safe and efficient vectors must be developed to deliver DNA into cells to express proteins (*1*–*5*). Although vectors are classified roughly as viral and nonviral vectors, nonviral vectors are attractive because of their low immunogenicity and lack of pathogenicity (*6*, *7*).

To date, several cellular processes have been shown to affect transfection efficiency mediated by nonviral vectors: cellular binding and internalization, transfer from endosome to cytosol, and entry into the nucleus (*8*–*12*). Inefficient internalization and degradation in lysosomes are important problems that must be solved during development of potent nonviral vectors. Modification with appropriate ligands and incorporation of endosomelytic molecules to vectors might overcome these hindrances (*8*, *13*–*19*).

We previously synthesized a pH-sensitive fusogenic polymer, succinylated poly(glycidol) (SucPG), and used it for preparation of pH-sensitive fusogenic liposomes that generate fusion ability under weakly acidic conditions (Figure 1) (*20*, *21*). Because SucPG-modified liposomes are negatively charged, they form a complex with positively charged vector systems, such as lipoplexes, through electrostatic interaction, and impart fusion ability to them (*22*).

Complexation with SucPG-modified liposomes shields positive charges of lipoplexes, reducing their affinity to cell membranes. However, once appropriate ligands are attached to the liposomes, their complexes might exhibit efficient transfection through specific ligand−receptor interaction and fusion with intracellular acidic compartments, such as endosome (*22*, *23*).

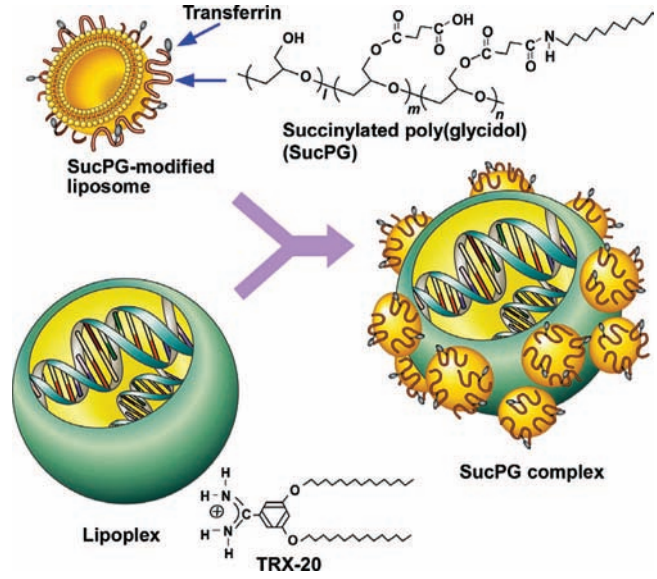

Figure 1. Preparation of SucPG complex.

Transferrin is a glycoprotein transporting iron into cells. Its receptors are expressed on the cell surface and are constitutively taken up through clathrin-dependent endocytosis (*24*, *25*). After internalization, transferrin and its receptors are recycled to the cellular surface via the recycling pathway (*26*, *27*). Therefore, transferrin is considered an appropriate ligand, which provides nonviral vectors with properties of target-specific binding and efficient internalization (*28*).

Complexation of lipoplexes with SucPG-modified liposomes bearing transferrin generates hybrid complexes, which transfect HeLa cells efficiently, as we showed recently (Figure 1) (*22*, *23*).

Considering that many types of cancer cells are known to overexpress transferrin receptors, the transferrin-conjugated hybrid complexes are expected to achieve efficient transfection toward these cancer cells. For the present study, we applied the transferrin-conjugated hybrid complexes, which are termed SucPG complexes, to various types of human cancer-derived cells. We then investigated the relation between their transferrin receptor expression and transfection efficiency. Results showed that attachment of transferrin enhanced the transfection activity of the hybrid complexes, but the extent of the transferrin-induced enhancement was dependent on the cell line. Correlation between the transferrin-induced enhancement of the hybrid complex-mediated transfection and the cellular internalization efficiency of transferrin receptors is described.

EXPERIMENTAL PROCEDURES

Materials. Dioleoylphosphatidyleyhanolamine (DOPE) and egg yolk phosphatidylcholine (EYPC) were kindly donated by NOF Co. (Tokyo, Japan). 3,5-Dipentadecyloxybenzamidine hydrochloride (TRX-20) was kindly donated by Terumo Co. (Kanagawa Japan). Dilauroylphosphatidylcholine (DLPC) was obtained from Wako Pure Chemical Industries (Osaka, Japan). Dulbecco's modified Eagle's medium (DMEM) was from Nissui Pharmaceutical (Tokyo, Japan). Lipofectamine 2000 and SuperFect were purchased from Invitrogen (Carlsbad, CA) and Qiagen (Hilden, Germany), respectively. 1-Ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) was obtained from Dojin Laboratories (Kumamoto, Japan). Bovine serum albumin (BSA) was purchased from Sigma (St. Louis, MO). *N*-(7-Nitrobenz-2-oxa-1,3-diazol-4-yl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine (NBD-PE) was purchased from Molecular Probes Inc., (Eugene, OR). FITC-labeled anti-transferrin receptor was obtained from Dainippon Pharmaceutical Co. (Osaka, Japan). Succinylated poly(glycidol) having *n*-decyl groups (Figure 1) was prepared using poly(glycidol) with the number average molecular weight of 16 400 according to the method previously reported (*20*). Mole percents of glycidol, succinylated glycidol, and *n*-decylamine-attached residues in the SucPG were determined by ^{1}H NMR to be 5, 85, and 10, respectively.

Preparation of Lipoplex and SucPG Complex. Lipoplexes were prepared as reported previously (*29*). To a dry thin membrane of a mixture of TRX-20, DLPC, DOPE (0.26 μmol, 0.26 μmol, 0.52 μmol), 5% glucose solution (2 mL) was added and sonicated for 2 min using a bath-type sonicator to afford a cationic liposome suspension. Plasmid DNA (1.0 μg), p10 (*22*, *23*), which contains a firefly luciferase coding sequence derived from pGL3-basic (Promega) between Raus sarcoma virus LTR and polyadenylation signal, or pEGFP-C1 (Clontech), in 5% glucose solution (25 μL) was added a given volume of the liposome suspension (37.5 μL), and they were incubated for 10 min on ice to afford a lipoplex. SucPG-modified liposomes were prepared by suspending a mixture of SucPG (3 mg) and EYPC (7 mg) in 5% glucose solution (2 mL) using a bath-type sonicator and subsequent extrusion through a polycarbonate membrane with a pore size of 50 nm. To the liposome suspension was added EDC (0.7 mg) at pH 6.0 and stirred for 2 h at 4 °C. Then, transferrin (3 mg) and 0.5 M ferric citrate (5 μL) were added to the liposome suspension, and the suspension was kept at 4 °C overnight. After the liposome suspension was adjusted to pH 7.4, the transferrin-conjugated SucPG-modified liposome was purified using a Sepharose 4B column at 4 °C with 5% glucose. A suspension of SucPG-modified liposome with or without ligand (0−50 μL) was added to the lipoplex suspension and incubated for 10 min in an ice bath.

Cell Culture. HeLa (human cervical cancer cell line), HepG2 (human hepatoma line), KB (human epidermoid adenocarcinoma line), and HT1080 (human fibrosarcoma line) cells were grown in DMEM supplemented with 10% FBS (MP Biomedical, Inc.) and antibiotics at 37 °C. K562 (human leukemia line) cells were grown in RPMI 1640 supplemented with 10% FBS (MP Biomedical, Inc.) and antibiotics at 37 °C.

Transfection. For luciferase assay, transfection to HeLa cells was done according to our previous report (*29*). HeLa cells were seeded in 24 well culture plates at 5.0×10^4 cells per well the day before transfection. The cells were washed with PBS containing 0.36 mM $CaCl_2$ and 0.42 mM $MgCl_2$ [PBS (+)] and then covered with DMEM supplemented with 10% FCS (0.9 mL). The vector solution (62.5−122.5 μL) containing plasmid DNA (1.0 μg) was added and incubated at 37 °C for 4 h. Then, the cells were rinsed with PBS (+), covered with DMEM supplement with 10% FCS, and incubated at 37 °C for 40 h. The cells were washed and lysed by adding 50 μL of Luc-PGC-50 detergent (Toyo Ink, Tokyo, Japan). A 20 μL aliquot from each dish was used for one luciferase assay according to a protocol of a kit (Toyo Ink, Tokyo, Japan) and a Lumat LB9507 luminometer (Berthold, Bad Wildbad, Germany). The protein content of the lysate was measured by Coomassie Protein Assay Reagent (Pierce, IL, USA) using bovine serum albumin as the standard. For GFP expression, the various kinds of cells were seeded in 0.5 mL of DMEM supplemented with 10% FCS in 12-well culture plates at 1.0×10^5 cells per well and allowed to grow for 24 h. The cells were washed with PBS (+) and covered with DMEM supplemented with 10% FCS (1.96 mL). SucPG complexes (36.3 μL) or the lipoplex (31.3 μL) containing pEGFP-C1 (0.5 μg) were added gently to the cells and incubated at 37 °C for 4 h. After that, the cells were washed with PBS three times, followed by the incubation in culture medium at 37 °C for 24 h. Then, GFP-transfected cells were evaluated using flow cytometry (*29*). Superfect (QIAGEN) and Lipofetamine 2000 (Invitrogen) were also used according to the manufacturer's instructions.

Cellular Uptake of SucPG Complex and Inhibition by Free Transferrin. HT1080, HepG2, K562, KB, and HeLa cells (1.0×10^5 cells) cultured for one day in a 12-well plate were washed with PBS (+) and then incubated in the culture medium (1.96 mL). The fluorescence-labeled SucPG complex was prepared by using a lipoplex in which DOPE was substituted by NBD-PE (2 mol %). SucPG complexes (36.3 μL) or the lipoplexes (31.3 μL) containing plasmid DNA (0.5 μg) were added gently to the cells and incubated for 4 h at 37 or 4 °C. In the case of the experiments at 4 °C, cells were preincubated at 4 °C for 2 h. The cells were washed with PBS (+), and detached using trypsin. Then, cellular fluorescence was evaluated by flow cytometry (EPICS XL, Beckman Coulter, Inc.). For inhibition assay, cells were preincubated at varying concentrations of free transferrin for one hour before the incubation with the NBD-PE labeled complexes.

Evaluation of Intracellular Uptake of Transferrin Receptor. HT1080, HepG2, K562, KB, and HeLa cells (1.0×10^5 cells) cultured for one day in a 12-well plate were washed with PBS (+) and then covered with the DMEM supplemented with 10% FCS and 1% BSA (440 μL). FITC-labeled anti-transferrin receptor (60 μL), which was dissolved in the DMEM supplemented with 10% FCS and 1% BSA was added gently to the cells to a final antibody concentration of 6 μg/mL and incubated for 3 h at 37 or 4 °C. In the case of the experiments at 4 °C, cells were preincubated at 4 °C for 2 h. Cells were washed with PBS (+), and harvested using 2 mol % EDTA containing PBS. Fluorescence intensity of cells was evaluated by flow cytometry (EPICS XL, Beckman Coulter, Inc.). Microscopic analysis of

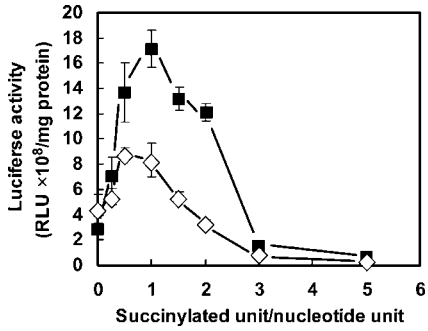

Figure 2. Expression of luciferase in HeLa cells treated with transferrin-conjugated (closed squares) and plain (open diamonds) SucPG complexes with varying compositions. The composition of SucPG complexes was expressed as the ratio of succinylated units of SucPG-modfied liposomes to DNA nucleotide units. The TRX-20 lipoplex with the (±) charge ratio of 1.5 was used for the preparation of SucPG complexes.

these cells was performed using a fluorescence microscopy (BX51WI, Olympus).

RESULTS AND DISCUSSION

Transfection Activity of SucPG Complexes. We have developed hybrid complexes of transferrin-conjugated SucPG-modified liposomes and lipoplexes, designated as SucPG complexes (*22*). Although SucPG complexes have been prepared in PBS, we found recently that SucPG complexes prepared in an aqueous glucose solution generate SucPG complexes with much smaller diameters and much higher transfection activity toward HeLa cells than do complexes prepared in PBS (*29*). Because HeLa cells express transferrin receptors on their cell membrane, specific interaction between transferrin and its receptor might contribute to their high transfection activity. Therefore, we first examined how this specific interaction influences the transfection efficiency.

First, we examined transfection of HeLa cells using the transferrin-conjugated and plain SucPG complexes prepared by complexation of the lipoplex with varying amounts of SucPG-modified liposomes with or without transferrin (Figure 2). Their compositions were expressed as the ratio of succinylated units of SucPG-modified liposomes to nucleotide units of plasmid DNA included in the lipoplex. Transfection activity of the plain SucPG complexes increased with the increasing succinylated unit/nucleotide unit ratio by 0.5. This result suggests that complexation of the SucPG liposomes with the lipoplex indeed enhanced the transfection activity of the lipoplex, probably because their complexation might result in the complex with higher fusion ability under the weakly acidic condition of endosomes (*22*). However, a further increase in the succinylated unit/nucleotide unit ratio decreased the transfection activity. The complex with the succinylated unit/nucleotide unit of 0.5 corresponds to a charge-neutral complex. Therefore, complexes with reduced transfection activity are expected to be negatively charged (*22*). It is likely that the negatively charged surface of the complexes strongly suppressed their association with the cellular surfaces and subsequent internalization into the cells.

The composition dependence of transfection activity for transferrin-conjugated complexes is also shown in Figure 2. Their transfection activity increased concomitantly with the increase in the succinylated unit/nucleotide unit ratio and reached the highest value at the succinylated unit/nucleotide unit ratio of 1, where the activity was twice as high as that without transferrin, as reported previously (*29*). The ligand-conjugated SucPG complexes retained high activity at the succinylated unit/nucleotide unit ratio by 2, where the transferrin-conjugated complex exhibited about four-times-higher efficiency than the plain complex of the same composition. These results indicate that transferrin plays an important role in the enhanced transfection efficiency.

The effect of transferrin conjugation on the transfection activity of the SucPG complex was examined further using EGFP gene. HeLa cells were treated with SucPG complexes with succinylated unit/nucleotide unit ratio of 1, which achieved the highest activity, and expression of EGFP was observed using a fluorescence microscope (Figure 3A,B). More intensive fluorescence was observed for cells treated with the transferrin-conjugated complex than for cells treated with the complex without the ligand. The EGFP expression of HeLa cells treated with the SucPG complexes were also evaluated using flow cytometry (Figure 3C). Although the untreated cells showed very weak fluorescence intensity of less than 10^0, the SucPG complex-treated cells displayed much stronger fluorescence with intensity of around 10^1-10^2. In addition, cells treated with the transferrin-conjugated complex exhibited stronger fluorescence and a higher fraction of EGFP-expressing cells than cells treated with the plain SucPG complex (see also Figure 9). These results demonstrate that the conjugation of transferrin induced both transfection efficiency and elevation of transfection activity induced by the transferrin conjugation.

Cellular Uptake of the SucPG Complex Bearing Transferrin. We next investigated cellular association of these complexes to elucidate the effect of transferrin on transfection. The HeLa cells were treated with the transferrin-conjugated or plain SucPG complexes of varying compositions labeled with fluorescent lipid NBD-PE at 37 °C (*29, 30*). Irrespective of the presence of transferrin, the cellular association of these complexes decreased concomitantly with increasing amounts of SucPG-modified liposomes in the complexes (Figure 4A). Probably, the negatively charged SucPG-modified liposomes shield positive charges of the lipoplex moiety of the complex. We showed in an earlier study that the SucPG complexes at the succinylated unit/nucleotide unit of more than 1 have a negatively charged surface (*29*). However, when SucPG complexes with the same composition were compared, markedly higher amounts of cellular association were observed for transferrin-conjugated complexes, especially those with the succinylated unit/nucleotide unit ratio of 1−1.5, which achieved efficient transfection of HeLa cells (Figure 2).

We also examined internalization of SucPG complexes into the cell by comparing the cellular association of the fluorescent lipid-labeled SucPG complexes at 4 °C, at which cellular endocytosis was blocked, with that at 37 °C (*31, 32*). We used SucPG complexes with the succinylated unit/nucleotide unit ratio of 1, which achieved the highest transfection activity (Figure 2). Figure 4A portrays the mean fluorescence intensity of the cells treated with the SucPG complexes or the parent lipoplex as evaluated using flow cytometry. The cellular fluorescent intensity decreased in the order of lipoplex > transferrin-conjugated SucPG complex > plain SucPG complex at 4 °C, which indicates that positively charged lipoplexes had higher affinity to the cell than SucPG complexes with transferrin.

Intracellular uptake of the complexes was estimated from the difference in fluorescence intensities of the treated cells between 4 and 37 °C (Figure 4B). Calculations show that the amounts of internalization of lipoplex and the transferrin-conjugated SucPG complex were 1.3 and 2.0 times higher, respectively, than that of the plain SucPG complex. In addition, differences in the amounts of the associated complexes between 4 and 37 °C suggest that only 39% of the bound lipoplex particles were internalized into the cell during the cellular treatment, although the amount of internalized transferrin-conjugated SucPG complex particles was 1.6 times that of the SucPG complex bound to the cell surface. This observation indicates that transferrin

(C) Expression of EGFP in HeLa cells treated with transferrin-conjugated (green line) and plain (red line) SucPG complexes detected using flow cytometry. SucPG complexes with the succinylated unit/nucleotide unit ratio of 1 were used.

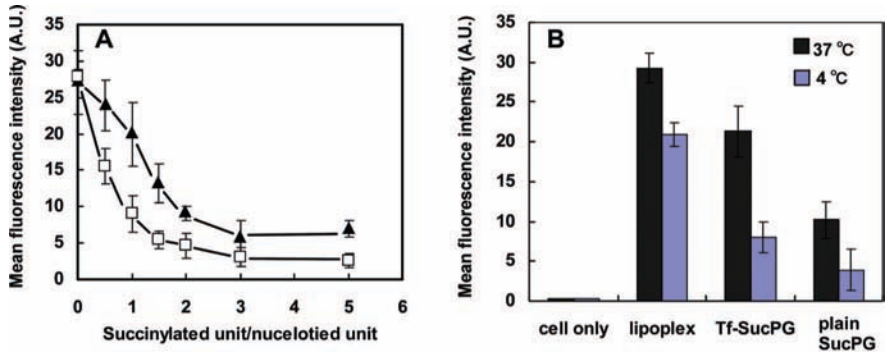

Figure 4. (A) Association of SucPG complexes with HeLa cells. Mean fluorescence intensities of cells treated with fluorescence lipid-labeled transferrin-conjugated (closed triangles) and plain (open squares) SucPG complexes with varying compositions at 37 °C. (B) Mean fluorescence intensities of cells treated with fluorescence lipid-labeled transferrin-conjugated and plain SucPG complexes and the parent lipoplex at 37 °C (black bars) and 4 °C (purple bars). Mean fluorescence intensities of cells without the treatment were also given. SucPG complexes with the succinylated unit/nucleotide unit ratio of 1 was used.

conjugated to SucPG complex enhanced not only its binding to the cell surface but also its internalization into the cell. It is likely that the specific interaction between transferrin and its receptor contributed to these enhancements.

We further examined inhibitory effects of free transferrin on their interaction to confirm the specificity of the interaction between the transferrin-conjugated SucPG complex and HeLa cell. The HeLa cells were treated with the fluorescent lipid-labeled SucPG complex bearing transferrin at varying concentrations of free transferrin. Fluorescence intensities of the treated cells were estimated using flow cytometry (Figure 5A). Apparently, fluorescence intensity of the cells decreased with increasing free transferrin concentration and reached a constant level of fluorescence intensity at free transferrin concentrations greater than 8.8 μM.

The cellular treatment with the fluorescent lipid-labeled SucPG complex without the ligand was also performed at varying concentrations of free transferrin. As presented in Figure 5B, the treated cells displayed almost identical levels of fluorescence intensity, irrespective of free transferrin concentration, indicating that free transferrin does not influence cellular association of the SucPG complex without transferrin. In addition, fluorescence intensities of both the cells treated with transferrin-conjugated SucPG complex at free transferrin concentration greater than 8.8 μM and the cells treated with the plain SucPG complex exhibited similar levels of fluorescence, suggesting that the cellular association of the transferrin-conjugated SucPG complex through the specific interaction with transferrin receptor was blocked by free transferrin under these conditions. These results demonstrate that enhancement of cellular association and uptake was induced by the specific interaction of transferrin conjugated to the SucPG complex with its receptor on the cellular surface and by subsequent internalization through the receptor-mediated endocytosis.

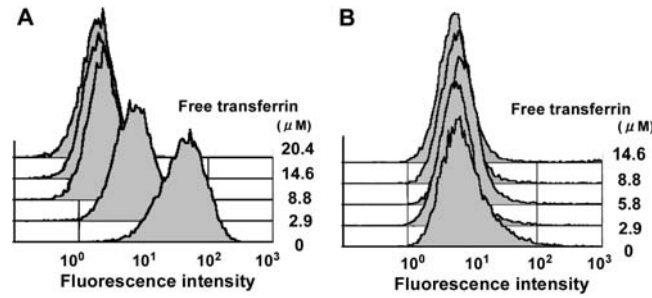

Figure 5. Cellular association of transferrin-conjugated SucPG complex (A) and plain SucPG complex (B) at varying concentrations of free transferrin.

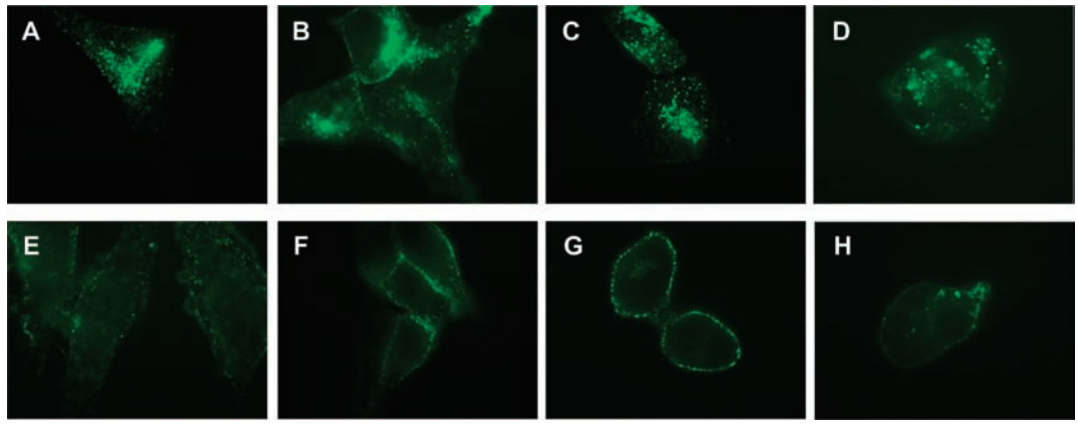

Figure 6. Localization of transferrin receptors in various cells. Fluorescence micrographs of HeLa cells (A,E), KB cells (B,F), HT1080 cells (C,G), and HepG2 cells (D,H) incubated with FITC-labeled anti-transferrin receptor at 37 °C (A−D) and 4 °C (E−H).

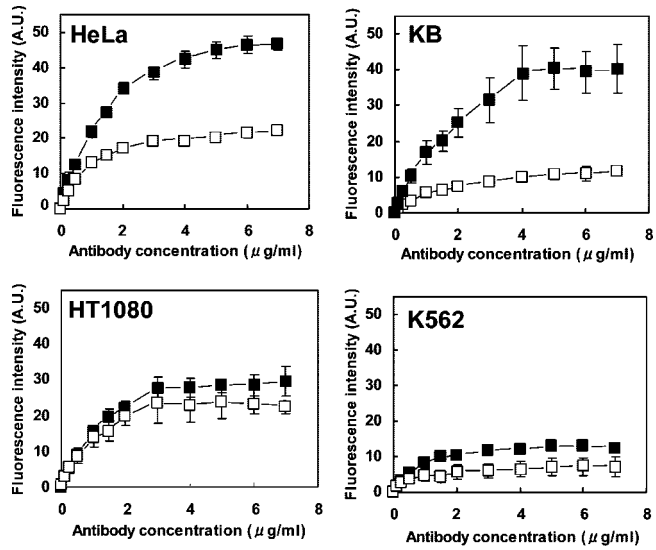

Figure 7. Association of anti-transferrin receptor with various cells. Mean fluorescence intensities of HeLa, KB, HT1080, and K562 cells treated with FITC-labeled anti-transferrin receptor at 4 °C (open symbols) and 37 °C (closed symbols) as a function of antibody concentration. Fluorescence intensity was evaluated using flow cytometry.

Expression of Transferrin Receptors. Because transferrin receptors are known to be overexpressed and actively internalized through clathrin-mediated endocytosis in various types of cancer cells, transferrin has been considered to be a suitable ligand for improving the transfection activity of nonviral vectors toward these cells (*28*). Therefore, we next examined expression and internalization of transferrin receptors in various types of cancer-derived cell lines using FITC-labeled anti-transferrin receptor.

With FITC-labeled anti-transferrin receptor at 37 or 4 °C for 3 h, we incubated five kinds of cancer-derived cells: HeLa, KB, HT1080, and HepG2. Figure 6 depicts fluorescence micrographs of these cells after incubation. Irrespective of the cell lines, at 4 °C, weak fluorescence was observed mainly in the cell periphery; at 37 °C, intensive fluorescence was visible as bright dots inside cells. This observation suggests that transferrin receptor−antibody complexes were localized on the cell surface at 4 °C, and vesicular compartments at 37 °C, which is consistent with the difference in activity of cellular endocytosis between 4 and 37 °C.

We analyzed fluorescence intensities of cells treated with FITC-labeled antibody using flow cytometry. When the FITC-labeled antibody was incubated with cells, we observed that cellular fluorescence intensity increased with time and reached a constant value after 2 h incubation (data not shown). We examined binding of the anti-transferrin receptor to various types of cancer-derived cell lines, HeLa, KB, K562, and HT1080 cells, which were incubated in the presence of various concentrations of the FITC-labeled antibody for 3 h at 37 or 4 °C (Figure 7). The same experiment was also performed for HepG2 cells (data not shown). For all of these cells, cellular fluorescence intensity increased concomitantly with increased labeled antibody concentration and then reached a constant value at labeled antibody concentrations greater than 3−6 μg/mL, which suggests that transferrin receptors on the cell membrane might be fully associated with the labeled antibody at concentrations greater than these.

Mean fluorescence intensities of the cells incubated with the FITC-antibody (6 μg/mL) at 37 and 4 °C are portrayed in Figure 8A. As described above, cellular endocytosis is active at 37 °C but is inactive at 4 °C. Therefore, fluorescence intensities of the cells with treatment at 4 °C might reflect the number of cellular transferrin receptors on the cell surface. It is apparent that expression of transferrin receptors depends on the cell line: expression of transferrin receptors is of a low level for K562 and HepG2 cells, whereas HT1080 and HeLa cells exhibited three-times-higher expression of transferrin receptors than did K562 cells.

Considering that transferrin-conjugated gene vectors, such as SucPG complexes, might deliver a gene into the cell after

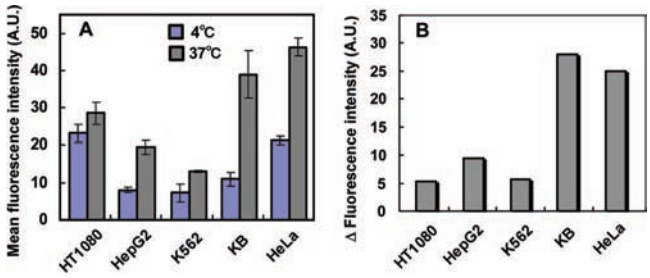

Figure 8. Association of anti-transferrin receptor with various cells. (A) Mean fluorescence intensities of HeLa, KB, HT1080, HepG2, and K562 cells treated with FITC-labeled anti-transferrin receptor at 4 or 37 °C at 6 μg antibody/mL. (B) Difference in cellular fluorescence intensities between 37 and 4 °C. Mean fluorescence intensity was evaluated using flow cytometry.

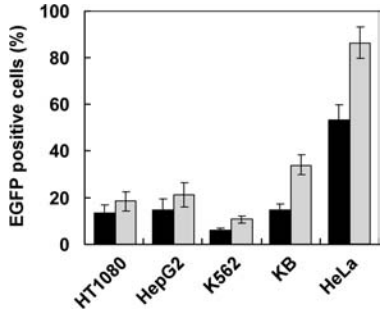

Figure 9. Transfection efficiency of HT1080, HepG2, K562, KB, and HeLa cells treated with transferrin-conjugated (gray bars) and plain (black bars) SucPG complex as evaluated using flow cytometry.

internalization through transferrin receptor-mediated endocytosis, it is likely that cellular activity for internalization of transferrin receptors influences the transfection efficiency of the cells mediated by transferrin-conjugated gene vectors. Therefore, we estimated differences in cellular fluorescence intensities between 4 and 37 °C, which were inferred to reflect the amounts of the receptor−antibody complexes internalized into the cells, at the antibody concentration of 6 μg/mL.

As presented in Figure 8B, KB and HeLa cells exhibited substantial internalization, suggesting high activity for transferrin receptor-mediated endocytosis in these cells. In contrast, much less internalization was observed for HT1080, HepG2, and K562 cells, which is indicative of low activity of the receptor-mediated endocytosis in these three cells. Interestingly, HT1080 cells showed the lowest activity of internalization among these cell species, although their transferrin receptor expression was the highest among them, suggesting that internalization through transferrin receptor-mediated endocytosis might not be induced in HT1080 cells. On the contrary, although KB cells exhibited a low level of transferrin receptors, a very high level of internalization through transferrin receptor-mediated endocytosis might be induced. This fact suggests that the extent of the receptor expression on the cell surface does not always correlate with the activity of the receptor-mediated endocytosis.

Effect of Transferrin on Transfection of Various Cancer-Derived Cells. Results of this study show that cellular expression of transferrin receptors and activity of their internalization varies depending on the cell lines. Indeed, such differences in expression and activity of transferrin receptors might affect their transfection efficiency mediated by the transferrin-conjugated SucPG complex. Therefore, we examined transfection of these cancer-derived cells using transferrin-conjugated SucPG complex and compared those results to those obtained with the plain SucPG complex. Six kinds of cancer-derived cells—HT1080, HepG2, K562, KB, and HeLa—were treated with the SucPG

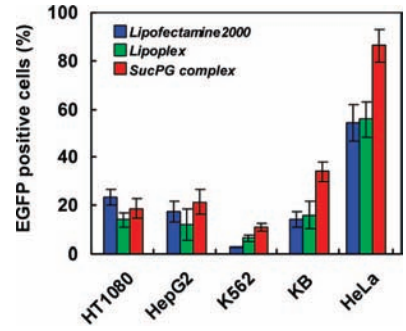

Figure 10. Transfection efficiency of HT1080, HepG2, K562, KB, and HeLa cells treated with transferrin-conjugated SucPG complex, TRX-20 lipoplex, and Lipofectamine 2000 complex as evaluated using flow cytometry.

complexes containing the EGFP gene. Then, EGFP-expressing cells were detected using flow cytometry (see Figure 3).

As presented in Figure 9, a significant difference in transfection efficiency was observed between the transferrin-conjugated complex and the plain complex for HeLa and KB cells, which respectively exhibited differences of 22% and 34% between the transferrin-conjugated and plain complexes. In contrast, HT1080, HepG2, and K562 showed only limited increases in transfection efficiency of ca. 5−6.3% by transferrin conjugation. In connection with the result of Figure 8B, apparently cells that exhibited active internalization of transferrin receptor achieved considerable enhancement of the transfection efficiency. In contrast, the cells with low transferrin receptor-mediated endocytosis displayed only limited enhancement of transfection efficiency.

Transferrin receptor is considered to pass sequentially through early endosomes and perinuclear recycling endosomes before returning to the cell membrane (*27, 33*). Early endosomes are known to be of two distinct populations: a dynamic population, which is highly mobile on microtubules and which matures quickly toward late endosomes; and a static population, which matures much more slowly (*34*). As presented in Figure 8B, in HT1080, HepG2, and K562 cells, internalization of transferrin receptor was low, implying that a large fraction of transferrin receptor was trapped in early endosome of a static nature. Therefore, after receptor-mediated endocytosis, the transferrin-conjugated SucPG complex might be mainly trapped in early endosome of a static nature, which is slowly acidified and hence slowly activates the fusion ability of the SucPG complex.

In contrast, KB and HeLa cells actively internalized transferrin receptor. Consequently, a large fraction of the transferrin receptor might be included in an early endosome of dynamic nature. Therefore, in these cells, the transferrin-conjugated SucPG complex might be trapped in an early endosome of dynamic character, which quickly matures and quickly activates the fusion ability of the SucPG complex. Cellular activity of transferrin receptor-mediated endocytosis is likely to influence the effectiveness of transferrin conjugation on transfection activity of SucPG complex for individual cell lines.

Finally, we compared the transferrin-conjugated SucPG complex with a widely used transfection reagent, Lipofectamine 2000 (*35–37*), which forms a positively charged complex with plasmid DNA. The parent TRX-20 lipoplex was also used as a control. Both the Lipofectamine 2000-plasmid DNA complex and the TRX-20 lipoplex interact with negatively charged cell membranes via nonspecific interaction through electrostatic force. As presented in Figure 10, these positively charged complexes and the transferrin-conjugated SucPG complex exhibited similar transfection efficiency toward HT1080 and HepG2 cells, both of which showed low activity of the transferrin receptor-mediated endocytosis. However, the trans-

ferrin-conjugated SucPG complex achieved much higher transfection efficiency toward KB and HeLa cells, which exhibited higher activity of the transferrin receptor-mediated endocytosis than the positively charged complexes. The transferrin-conjugated SucPG complex showed higher activity than the lipofectamine complex toward K562, whose activity of transferrin receptor-mediated endocytosis was not high. Because K562 cells are nonadhesive cells, the SucPG complex with small size might associate more efficiently with cells suspended in the medium than lipofectamine, which generally form a large aggregate with plasmid DNA. Therefore, the efficacy of the transferrin-conjugated SucPG complex on transfection of cells is related closely with the cellular activity of transferrin-mediated endocytosis.

In conclusion, results of this study show that the effects of conjugation of transferrin to the SucPG complexes on their transfection activity highly depend on cell species. This conjugation improved the transfection efficiency toward cells, which actively internalize transferrin receptor into the cells. However, the transferrin conjugation was not effective for cells with low activity of transferrin receptor-mediated endocytosis. The transferrin-conjugated SucPG complexes achieve significantly higher transfection toward several cancer-derived cells, such as KB and HeLa cells, than a widely used transfection reagent. Therefore, transfection mediated by the ligand-attached hybrid complex does not correlate with the amount of transferrin receptor in the cell surface but correlates with the activity of internalization of transferrin receptor into the cells. Toward further improvement of their transfection activity, selection of the ligand might be important to facilitate cellular internalization and acid-triggered activation of SucPG complexes. The proper ligand might differ depending on the individual cell species, because cellular functions, which affect internalization and intracellular processes of the ligand−receptor complex, might differ among individual cell species. Therefore, conjugation of appropriate ligands to SucPG complexes is expected to generate highly potent nonviral vectors, which achieve transfection of target cells through the ligand−receptor interaction, efficient internalization, and the acid-triggered activation of their fusion ability.

Received April 10, 2008; Revised Manuscript Received June 17, 2008

The interest in using small peptides for therapeutic and diagnostic *in vivo* applications is based on several advantageous features such as good penetration into tissues and rapid clearance from the body. Because of their size, they can easily be synthesized chemically. The recently discovered cell-penetrating peptides (CPP) and among them CPP derived from the native peptide hormone human calcitonin (hCT) could meet these requirements. Therefore, they are nowadays widely used as delivery vectors for a variety of bioactive molecules. However, the knowledge about the distribution and metabolism of CPP *in vivo* is very limited. Hence, evaluation of the pharmacological features of any promising peptide is a crucial challenge in its development process. Herein, we studied the *in vivo* radiopharmacology of ^{68}Ga radiolabeled DOTA-modified, hCT-derived CPP in rats using small animal PET. Furthermore, the arterial blood at different time points and urine were analyzed for radiometabolites. It was shown that D-amino acid modifications of the sequence hCT(9−32) resulted in an increased *in vivo* stability and lower retention in the kidney cortex of this peptide.

INTRODUCTION

During the past decade, the interest in using cell-penetrating peptides (CPP) as vectors for drug delivery has dramatically increased (*1*, *2*). By using CPP, it is possible to introduce membrane-impermeable substances into mammalian cells. There is a growing demand for such delivery strategies since many pharmacologically interesting molecules provide on the one hand promising therapeutic properties *in vitro* but are on the other hand often poorly bioavailable *in vivo*. Because of their physicochemical properties, the transport of such substances into cells and to their biological target is often restricted. That is the reason why during the last few years delivery systems using CPP as drug carriers have been under intense investigation. Meanwhile, a number of different cargos have been transported successfully into various cells, e.g., peptide nucleic acids (PNA) (*3*), proteins (*4*), oligonucleotides (*5*), or nanoparticles (*6*).

Cell-penetrating properties have been described also for the peptide hormone human calcitonin (hCT). Human calcitonin consists of 32 amino acids and is C-terminally amidated and secreted in the thyroid gland. Because of a high permeability through the nasal epithelium, it is applied as an intranasal therapeutic in the treatment of several bone diseases (*7*). Recently, the truncated sequence hCT(9−32) was shown to translocate through cell membranes, although its N-terminal part (residues 1−8) responsible for receptor activation was lacking (*8*). By using hCT(9−32), it was possible to efficiently shuttle different cargos such as the antiproliferative drug daunorubicin, fluorophores, or even large molecules such as the enhanced green fluorescent protein (eGFP) into cells (*9*–*11*).

The interest in using cell-penetrating peptides for therapeutic *in vivo* applications is based on some advantageous features: these small peptides penetrate more readily into tissues, are distributed more uniformly, and disappear more rapidly from the body than larger molecules such as antibodies. However, major drawbacks in using such peptides as *in vivo* therapeutics are their low resistance against proteolytic enzymes and their rapid clearance by the kidneys.

The enzymatic degradation can effectively be inhibited by molecular modifications such as the introduction of D-amino acids or amino-alcohols and the insertion of unnatural amino acids or side chains (*12*). Recently, we modified the N-terminally truncated hCT fragment hCT(9−32) by the introduction of either D-phenylalanine or *N*-methylphenylalanine at positions 12 and 16, which were previously shown to be the initial cleavage sites for an enzymatic digestion *in vitro* (*13*). We could demonstrate that the half-lives of these modified peptides were increased *in vitro* in human blood plasma as well as in the cell culture supernatant (*14*).

Although several examples for successful drug delivery *in vivo* exist (*15*–*18*), so far a careful analysis of the *in vivo* behavior of these hCT-derived peptides as well as for most of the CPP described in the literature is missing. Moreover, in most studies the therapeutic potential of CPP is evaluated by using tissue culture models. However, the evaluation of pharmacological features is a crucial challenge not only in drug discovery but also in the drug development process. Therefore, by detailed studies, it should be possible to design molecules possessing on the one hand the desired biological activity and on the other hand the required pharmacological potency and metabolic stability. Furthermore, the results of such studies could help to decide whether or not a further development of a compound makes sense.

An elegant possibility to investigate the three-dimensional distribution of radiolabeled compounds *in vivo* is the positron emission tomography (PET). PET provides noninvasive and nondestructive quantitative measurements of the time course of biomolecules within living subjects (*19*). The prerequisite for PET studies is the labeling of the compound of interest with a positron-emitting radionuclide, e.g., ^{68}Ga. This isotope has

the advantage of an appropriate half-life of 68 min and can be easily obtained from a $^{68}Ge/^{68}Ga$ radionuclide generator (*20*). For the binding of such trivalent metal cations to peptides, DOTA (1,4,7,10-tetraazacyclotetradecane-*N*,*N*′,*N*″,*N*‴ tetraacetic acid) has proven to be a very suitable chelator (*21, 22*).

The aim of the present work was to evaluate the *in vivo* biodistribution and the metabolic stability of hCT(9−32) and a D-phenylalanine-modified analogue, [$f^{12,16}$]-hCT(9−32). For this purpose, both peptides were equipped with the chelator DOTA and subsequently labeled with the radioisotope ^{68}Ga. By analyzing blood and urine fractions, it was shown that the amino acid modifications indeed improve the *in vivo* stability of the hCT(9−32) analogue.

MATERIALS AND METHODS

Materials. For peptide synthesis, Nα-Fmoc-protected amino acids, 1-hydroxybenzotriazole (HOBt) and 4-(2′,4′-dimethoxyphenyl-Fmoc-aminomethyl)-phenoxy (Rink amide) resin were purchased from NovaBiochem (Läufelfingen, Switzerland). The side chain protecting groups for the amino acids were *tert*-butyl (*t*Bu) for Tyr and Thr; *tert*-butyloxy (*t*BuO) for Asp; trityl (Trt) for Asn, Gln, and His; and either *tert*-butyloxycarbonyl (Boc) or 1-(4,4-dimethyl-2,6-dioxocyclohex-1-ylidene)ethyl (Dde) for Lys according to the synthesis strategy. *N*,*N*′-diisopropylcarbodiimide (DIC) was obtained from Sigma-Aldrich (Taufkirchen, Germany). Trifluoroacetic acid (TFA), *N*,*N*-diisopropylethylamine (DIEA), thioanisole, *p*-thiocresole, hydrazine hydrate solution, and piperidine were purchased from Fluka (Taufkirchen, Germany). Acetonitrile (ACN for HPLC) was obtained from Merck (Darmstadt, Germany). Diethyl ether, dichloromethane and *N*,*N*-dimethylformamide (DMF, peptide synthesis grade) were obtained from Biosolve (Valkenswaard, Netherlands). DOTA (1,4,7,10-tetraazacyclotetradecane-*N*,*N*′,*N*″,*N*‴ tetraacetic acid) was purchased as *t*-Bu-ester from Macrocyclics (Dallas, USA).

Peptide Synthesis. Peptides were synthesized according to the Fmoc-strategy by using an automated multiple solid-phase peptide synthesizer (Syro, MultiSynTech, Bochum, Germany) on Rink amide resin (30 mg, resin loading 0.5 mmol g^{-1}). The following peptides were synthesized as C-terminal amides: hCT(9−32), LGTYTQDFNKFHTFPQTAIGVGAP; [$f^{12,16}$]-hCT(9−32), LGTfTQDfNKFHTFPQTAIGVGAP; and random (rd)-hCT(9−32), FLTAGQNTIQTPVKTGGHFPFADY.

To equip the peptides N-terminally with the chelator DOTA, the preswollen resin was incubated with 3 equiv of DOTA-tris (*t*-Bu-ester), 3 equiv of HOBt, and 3 equiv of DIC for 3 h at room temperature.

Finally, the peptides were cleaved from the resin by using a mixture of TFA/thioanisole/thiocresole (90:5:5, v/v/v) within 3 h at room temperature, simultaneously removing all acid-labile protecting groups. Subsequently, the peptides were precipitated from ice cold diethyl ether, collected by centrifugation, washed four times, and lyophilized from water/*tert*-butyl alcohol (3:1, v/v).

Purification of the peptides was achieved by preparative RP-HPLC on a RP C-18 column (Vydac, 250 × 25 mm, 10 μm) with a gradient of 20−60% B in A (A = 0.1% TFA in water; B = 0.08% TFA in acetonitrile) over 50 min and a flow of 10 mL min^{-1}.

The peptides were analyzed by MALDI-TOF mass spectrometry (Voyager RP, Perseptive Biosystems) and by analytical RP-HPLC on a Vydac RP18-column (4.6 × 250 mm; 5 μm, 300 Å) using a linear gradient of 10−60% B in A over 30 min and a flow rate of 0.6 mL min^{-1}. The experimentally detected masses were in full agreement with calculated masses, and the purity of all peptides was >95% according to analytical RP-HPLC.

Radiolabeling. Two hundred microliters of $^{68}Ga^{3+}$-eluate was added to 60 μL of DOTA-modified peptide (1 mM in 40% propylenglycol). The pH was adjusted to 3.7 − 4.1 by the addition of 0.5 M ammonium acetate. The solution was stirred at 90 °C for 10 min. Then, 10 μL (10 mM) of EDTA was added, the solution was incubated for 10 min at 40 °C, and the success of the ^{68}Ga complexation was controlled by radio-thin layer chromatography (radio-TLC) and radio-HPLC. Analysis by radio-TLC was carried out on Merck-RP-18 sheets using either a 10% aqueous ammonium acetate solution (v/v) or a 4:6 mixture (v/v) of ACN (0.05% TFA) and H_2O (0.05% TFA) as mobile phases. One micorliter of the sample was run on the sheet, subsequently the sheet was dried, and the activity spot was detected by using a Fujifilm Imaging Plate and a Bas Reader 2000 (Fuji, Raytest). The reaction mixture was applied to size exclusion chromatography (HiTrap 5 mL column, elution with isotonic sodium chloride containing 1% propylenglycol), and the radioactive peptide fraction was used in the experiments.

The HPLC system consisted of a Beckman System Gold 125 solvent module equipped with a UV detector (Hewlett-Packard Series 1100) and an external radiochemical detector (RFT 20 046). Analysis was performed on a Zorbax C18 column with a gradient of 10−90% B (ACN with 0.05% TFA) in A (H_2O with 0.05% TFA) over 13 min and a flow of 2 mL min^{-1}.

Animals, Feeding, Husbandry, and Biodistribution Studies in Rats. The animal research committee of the Regierungspräsidium Dresden approved the animal facilities and the experiments according to institutional guidelines and the German animal welfare regulations. The experimental procedure used conforms to the *European Convention for the Protection of Vertebrate Animals used for Experimental and other Scientific Purposes (ETS No. 123)*, to the *Deutsches Tierschutzgesetz*, and to the *Guide for the Care and Use of Laboratory Animals* published by the US National Institutes of Health (DHEW Publication No. (NIH) 82−23, Revised 1996, Office of Science and Health Reports, DRR/NIH, Bethesda, MD 20205).

Wistar rats (Wistar Unilever, HsdCpb:Wu, Harlan Winkelmann GmbH, Borchen, Germany) were housed under standard conditions with free access to standard food and tap water. Animals were between 7 and 9 weeks of age. The rats were housed in an Animal Biosafety Level 1 (ABSL-1) acclimatized facility with a temperature of 23 ± 2 °C and humidity of 55 ± 5%. Animals were under a 12 h light cycle in temperature (27 ± 1 °C)-controlled airflow cabinets. The animals had free access to standard pellet feed and water. Four animals (body weight 191 ± 9 g) for each time point were intravenously injected into a tail vein with approximately 55 μCi (2 MBq) ^{68}Ga-DOTA-hCT(9−32), ^{68}Ga-DOTA-[$f^{12,16}$]-hCT(9−32), or ^{68}Ga-DOTA-rd-hCT(9−32) in 0.5 mL of electrolyte solution E-153 (Serumwerk Bernburg, Germany) supplemented with 0.1% (w/v) human serum albumin (Serumwerk Bernburg, Germany). Animals were euthanized at 5 and 60 min post injection. Blood and the major organs were collected, wet-weighed, and counted in a Wallac WIZARD Automatic Gamma Counter (PerkinElmer, Germany). The radioactivity of the tissue samples was decay-corrected and calibrated by comparing the counts in tissue with the counts in aliquots of the injected tracer that had been measured in the gamma counter at the same time. The activity in the selected tissues and organs was expressed as percent-injected dose per organ (% ID) or as standardized uptake value (SUV) according to the following equation:

$$SUV = \frac{tissue_tracer_concentration}{injected_dose} \times body_weight = \frac{(Bq/g)}{Bq} \times g = \frac{\%ID/g}{100\%} \times g$$

The values are quoted as the means ± standard deviation (mean ± SD) for each group of four animals.

PET Imaging. General anesthesia of rats was induced with inhalation of desflurane 9% (v/v) (Suprane, Baxter, Germany) in 40% oxygen/air (gas flow 1 L/min), and was maintained with desflurane 6% (v/v). For arterial blood sampling, a 3.5 Fr umbilical vessel catheter prefilled with heparinized saline was inserted into the right carotid artery, and 200 μL blood samples were taken at 1.5, 3, 5, 10, 20, 30, and 60 min after tracer application. The volume was substituted by E-153. In the PET experiments, 0.5 mCi (18 MBq) of ^{68}Ga-DOTA-hCT(9−32), ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32), or ^{68}Ga-DOTA-rd-hCT(9−32) in 0.5 mL was administered intravenously over 1 min into a tail vein. PET imaging in rat was performed over 60 min with a microPET P4 scanner (Siemens CTI Molecular Imaging Inc., Knoxville). Data acquisition was performed in 3D list mode. A transmission scan was carried out prior to the injection of the radiolabeled peptides using a ^{57}Co point source. Emission data were collected continuously for 60 min after injection of the ^{68}Ga-labeled peptides. The list mode data were sorted into sinograms using a framing scheme of 15 × 10 s, 5 × 30 s, 5 × 60 s, 4 × 300 s, and 4 × 600 s frames. The data were attenuation corrected, and frames were reconstructed by Ordered Subset Expectation Maximization applied to 3D sinograms (OSEM3D) with 14 subsets, 6 OSEM3D iterations, 2 maximum a posteriori (MAP) iterations, and 0.05 β-value for smoothing. The pixel size was 0.3 by 0.3 by 1.21 mm in a matrix of 256 × 256 × 63, and the resolution in the center of field of view was 1.85 mm. No correction for recovery and partial volume effects was applied. The image files were processed using the *ROVER* software (ABX GmbH, Radeberg, Germany). Summed frames from 30 to 90 s post injection (p.i.) and 30 to 90 min p.i. were used to define the regions of interest (ROI). The data were normalized to the injected radioactivity by using standards from the injection solution measured in a γ-well counter (Isomed 2000, Dresden, Germany) cross-calibrated to the PET scanner and expressed in %ID or SUV.

Statistical Analysis. The data are expressed as the means ± SD. One-way analysis of variance (ANOVA) was used for statistical evaluation. Means were compared using Student's *t*-test. A P value of <0.05 was considered significant and indicated by an asterisk symbol (*), hash mark (#), or paragraph (§) symbol dependent on the compared data sets.

Metabolite Analysis. The 0.5 mCi (18 MBq) of ^{68}Ga-DOTA-hCT(9−32), ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32) or ^{68}Ga-DOTA-rd-hCT(9−32) in 0.5 mL were injected intravenously, and seven arterial blood samples were drawn at 90, 180, 300, 600, 1200, 1800, and 3600 s after application. Aliquots (50 μL) of arterial blood samples were taken for the total blood activity measurement. The blood plasma was separated by centrifugation (11,000g × 3 min) from the blood cells. Plasma proteins were precipitated by mixing of 1 volume plasma with 2 volumes acetonitrile followed by freezing in liquid nitrogen. After thawing, the samples were centrifuged (11,000g × 3 min), the clear supernatant was used for radio-HPLC analysis, and aliquots were measured for ^{68}Ga-activity determination. The hematocrit was determined from the blood sample 1 (90 s p.i.) with the classical capillary centrifugation method. The hematocrit was calculated as the mean of four determinations.

The chromatographic system of Agilent 1100 LC series, Agilent Technologies, Germany consisted of an autosampler with a 0.9 mL sample loop, a quaternary pump with degasser, thermostat column compartment, VWD detector and a radio-chromatography detector RAMONA (raytest Isotopenmessgeräte GmbH, Germany). The samples were analyzed using a ZORBAX III 300SB-C-18 250 × 9, 4 mm, 5 μm column with a binary gradient (eluent A, water with 0.05% TFA; eluent B, acetonitrile with 0.04% TFA; 20 min from 5 to 70% B, 1 min to 90% B, 9 min at 90% B). The flow was constant at 3 mL/min, the UV-signals were measured at 210 and 254 nm, and the radioactivity was registered with a time constant of 1 s. The data were expressed as the metabolite fraction in the rat plasma. These data were used to calculate the amount of original compounds in the arterial blood.

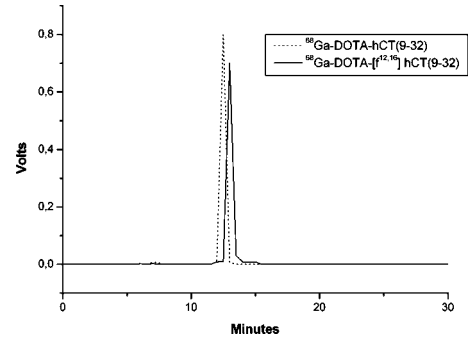

Figure 1. Radio-HPLC elution profiles of ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32) and ^{68}Ga-DOTA-hCT(9−32).

MALDI-TOF Analysis of the Metabolites. The RP-HPLC system (Agilent series), applied for metabolite analysis, was equipped with an UV detector and an external radiochemical detector (RFT 20 046). HPLC was performed by using a Zorbax C18 column with a gradient of 10−90% B (ACN with 0.05% TFA) in A (H_2O with 0.05% TFA). The plasma and urine samples were detected by their radioactive signals. Peaks appearing in the urine samples were collected, and after activity was decayed, they were examined by MALDI-TOF mass spectrometry on a Voyager-DE RP workstation (Perseptive Biosystems).

RESULTS

Peptide Synthesis and Radiolabeling. The hCT-derived peptides hCT(9−32), [f^{12,16}]-hCT(9−32) as well as a random sequence were prepared with high yields by automated solid-phase peptide synthesis according to standard Fmoc/*t*Bu-methodology. The Rink amide resin was used to obtain C-terminal peptide amides. After completion of the solid-phase synthesis, the bifunctional chelator DOTA was manually introduced at the N-terminus of the peptides by activating the *tert*-butyl ester of DOTA with HOBt/DIC. After deprotection and cleavage from the resin with trifluoroacetic acid, the labeled peptides were purified by preparative RP-HPLC. The purity (>95%) and identity was controlled by RP-HPLC and MALDI-TOF mass spectrometry, respectively.

Subsequently, the DOTA-labeled peptides were complexed with ^{68}Ga in 0.5 ammonium acetate (containing approximately 230 MBq), at pH 3.5−4.2 for 10 min at 90 °C. The reaction mixtures were analyzed by radio-TLC and radio-HPLC (see Figure 1 for ^{68}Ga-DOTA-hCT(9−32) and ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32)). The radiochemical yield of 32% ± 5 (decay-corrected) was obtained with a radiochemical purity of >90% for all preparations according to the radio-HPLC measurements.

Biodistribution. ^{68}Ga-DOTA-hCT(9−32), ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32), and the ^{68}Ga-labeled random peptide were injected intravenously into a tail vein in male Wistar rats. After 5 and 60 min postinjection, the rats were euthanized, and the radioactivity of the blood and the tissue samples were determined. The results of the biodistribution studies are summarized in Figure 2 (see Supporting Information for detailed data Tables 1−4).

The activity in the selected tissues and organs was expressed as percent-injected dose (%ID) (see Figure 2A) or as standardized uptake value (SUV) (see Figure 2B). It can be seen that the peptides left the blood stream immediately after injection and that the general retention in the body was low. However,

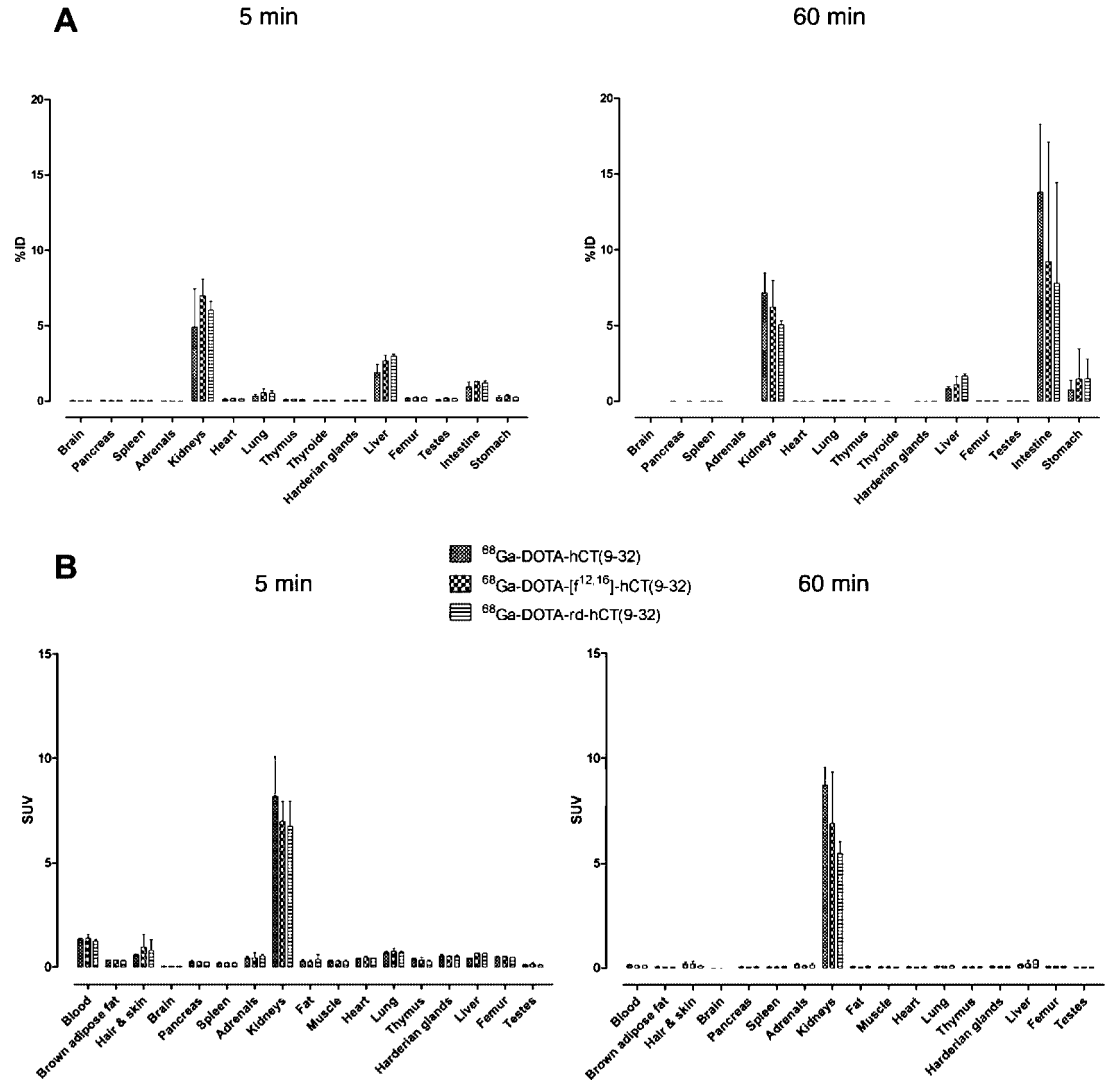

Figure 2. Biodistribution of ^{68}Ga-DOTA-hCT(9−32), ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32), ^{68}Ga-DOTA-rd-hCT(9−32) in male Wistar rats 5 and 60 min after single intravenous application represented as %ID ± SD (A) and as SUV ± SD (B) (4 animals per time point).

they were rapidly taken up by kidneys and liver and substantially excreted into the intestine. High activity was observed after 5 min in the kidneys (4.90 ± 2.55%ID per gram tissue for ^{68}Ga-DOTA-hCT(9−32), 6.99 ± 1.09%ID g^{-1} for ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32) and 6.03 ± 0.60%ID g^{-1} for ^{68}Ga-DOTA-rd-hCT(9−32)). Interestingly, ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32) had a lower retention in the kidney cortex, and the activity of the parent ^{68}Ga-DOTA-hCT(9−32) peptide increased here after 60 min i. v. injection to 7.17 ± 1.30%ID g^{-1}. Some amount of the peptides was metabolized by the hepatobiliary tract too, as was indicated by the detected activities in the liver (1.91 ± 0.52%ID g^{-1} for ^{68}Ga-DOTA-hCT(9−32), 2.67 ± 0.39%ID g^{-1} for ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32), and 2.98 ± 0.14%ID g^{-1} for ^{68}Ga-DOTA-rd-hCT(9−32)).

No relevant accumulation in other tissues was observed. Furthermore, as detected by the low activities in the brain none of the tested peptides was able to cross the blood-brain barrier.

PET Imaging Studies. Dynamic PET studies were carried out to validate the data from the biodistribution experiments and to study the kinetics of the radiolabeled hCT-derived peptides. Therefore, whole body PET scans were carried out over 60 min postinjection of ^{68}Ga-DOTA-hCT(9−32), ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32), and ^{68}Ga-DOTA-rd-hCT(9−32). A fast clearance out of the body was observed (see Supporting Information, Figure 1 for PET maximum intensity projections of ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32) distribution at different time points). Figure 3A and B show coronal PET images of the three peptides distribution in male Wistar rats 45 min after single intravenous application. High activity accumulations were observed in the kidneys.

Furthermore, the *in vivo* kinetic of the labeled peptides was analyzed within regions-of-interest (ROI). Figure 3C displays time−activity curves of ^{68}Ga-DOTA-hCT(9−32), ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32), and ^{68}Ga-DOTA-rd-hCT(9−32) in the kidneys of male Wistar rats after single intravenous application in SUV as calculated from kidney ROI. These data were in agreement with the corresponding results obtained from biodistribution experiments and show again the activity retention in the kidneys. The increasing activity in the kidneys of ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32) in the second half of the measurement was a result of low urine flow in this rat and not a sign of changed metabolism.

Additionally, we determined metabolite corrected blood time−activity curves of the three radiolabeled injected peptides. The data were calculated from heart ROI and the metabolite fraction in the blood at seven different time points after tracer application (see Figure 4). We could estimate that the blood clearance of the original peptides reached terminal half-lives of ^{68}Ga-DOTA-hCT(9−32) 15.9 min, ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32) 20.9 min, and ^{68}Ga-DOTA-rd-hCT(9−32) 15.8 min.

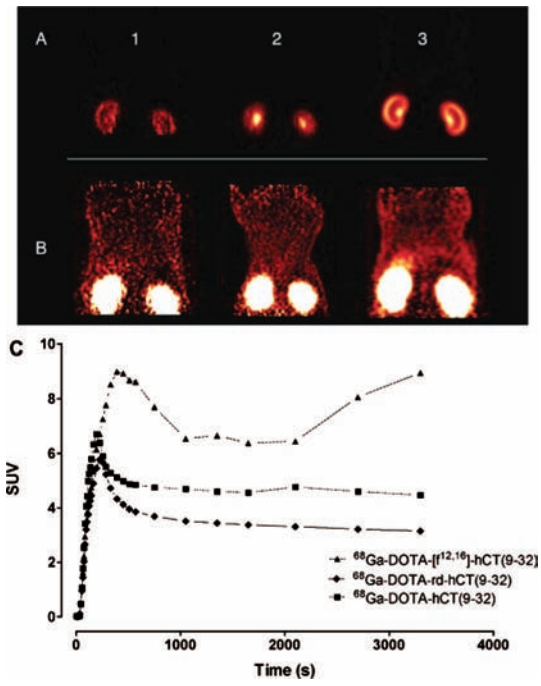

Figure 3. (A and B) Coronal PET images of ^{68}Ga-DOTA-hCT(9−32) (1), ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32) (2), and ^{68}Ga-DOTA-rd-hCT(9−32) (3) distribution in male Wistar rats 45 min after single intravenous application. The color scales of the upper images (A) are normalized to the maximum, and the color scales of the lower images (B) are expanded to show the background activity distribution. (C) Time−activity curves of ^{68}Ga-DOTA-hCT(9−32) (■), ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32) (▲), and ^{68}Ga-DOTA-rd-hCT(9−32) (♦) in the kidneys of male Wistar rats after single intravenous application in SUV. The data were calculated from kidney ROI.

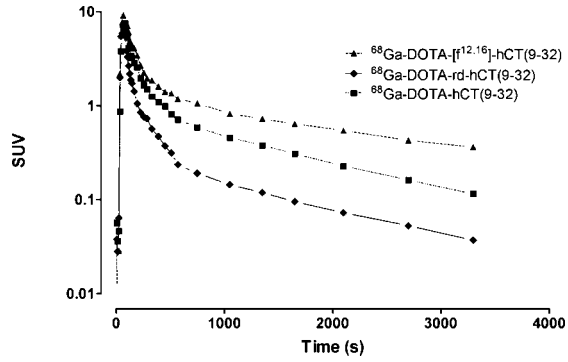

Figure 4. Metabolite corrected blood time−activity curves of ^{68}Ga-DOTA-hCT(9−32) (■), ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32) (▲), and ^{68}Ga-DOTA-rd-hCT(9−32) (♦) in male Wistar rats after single intravenous application in SUV. The data were calculated from heart ROI and metabolite fraction in the blood at 1, 3, 5, 10, 20, 30, and 60 min after tracer application.

Metabolite Analysis in Blood Samples. Metabolic stability of the parent radiometal-labeled peptides was determined in arterial blood samples at seven different time points (1.5, 3, 5, 10, 20, 30, and 60 min postinjection). Analysis by radio-HPLC showed different cleavage patterns for the distinct peptides (see Supporting Information, Figure 2). Unfortunately, the concentrations of the collected peaks from the radio-HPLC were too low for further mass spectrometric analysis of the evolved metabolites. However, the random peptide was cleaved very rapidly in a set of metabolites. After 30 min postinjection, the HPLC-chromatograph revealed seven different peaks, whereas one could be attributed to the original compound ^{68}Ga-DOTA-rd-hCT(9−32). In contrast to this, the cleavage patterns of the two peptides ^{68}Ga-DOTA-hCT(9−32) and ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32) displayed fewer radio-metabolites. After 30 min postinjection, three major peaks arose (in which one could be related to the parent compound) but to different extents, indicating the higher metabolic stability of the D-Phe-modified hCT peptide.

Analysis of the Metabolites in the Urine. We also analyzed the urine for metabolite content by using radio-HPLC. The metabolite patterns found in the urine samples of rats injected with ^{68}Ga-DOTA-hCT(9−32) allowed a differentiation of eight peaks with retention times from 5.5 min−11.2 min (data not shown), whereas no unaffected peptide could be found (12.8 min, see Figure 1). The main peak was detected at 7.0 min. Unfortunately, the fractionated peptide concentrations were too low for mass spectrometric metabolite analysis.

In contrast, the radio-HPLC of urine samples derived from rats injected with ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32) showed only three peaks, eluting from 12.0 to 13.1 min. These peaks were collected and analyzed by MALDI-TOF mass spectrometry. As presented in Figure 5, three major metabolites were identified: ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−17), ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−18), and ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−19) (see also Table 1).

DISCUSSION

During the past decade, the successful application of a number of peptides in *in vitro* studies has raised the hope of their therapeutic and diagnostic application *in vivo*. Indeed, the demand on such small peptides as therapeutic or diagnostic agents is increasing, for instance as delivery vectors for membrane-impermeable drugs (*1*) or as radiopharmaceuticals in nuclear medicine (*23*). However, even if a peptide is well characterized *in vitro*, the prediction of its *in vivo* behavior is difficult because of the countless factors that may influence the route of the peptide inside the body, its structural integrity, or its clearance. Therefore, it is likely that a careful investigation of the pharmacological features of a promising peptide is one major prerequisite for its possible future application *in vivo*. Concerning the family of cell-penetrating peptides, until now only few studies exist that investigated these features (*2, 24, 32*). Thus, the true potential of CPP *in vivo* remains to be elucidated.

One of the major problems in the application of peptides is often their short biological half-life due to proteolytic cleavage. Also for the parent hormone human calcitonin, poor absorption and rapid proteolytic degradation are described. Therefore, the oral route is limited by extensive proteolytic degradation in the GI lumen and low intrinsic intestinal membrane permeability (*25*). However, it was shown that enzymatic degradation can be inhibited by modifications of the peptide sequence, e.g., by replacement of L-amino acids by D-amino acids (*26*) or the insertion of unnatural amino acids or side chains (*12*). Accordingly, we modified recently the cell-penetrating peptide hCT(9−32) by the introduction of D-phenylalanine at amino acid positions 12 and 16. *In vitro* stability tests in heparinised human blood plasma revealed a significantly increased metabolic stability of the resulting novel peptide [f^{12,16}]-hCT(9−32) (*14*). But although the *in vivo* stability of peptides in blood might be well modeled by *in vitro* stability tests in heparinised plasma (*27, 28*), this approach neglects for instance the renal and hepatic clearance that will occur *in vivo*. Therefore, the aim of this work was a systematic examination of the *in vivo* stability and biodistribution of the hCT-derived cell-penetrating peptides hCT(9−32) and [f^{12,16}]-hCT(9−32). To exclude any artifacts, we also investigated the tissue distribution of a radiolabeled random hCT(9−32) sequence.

Therefore, the two peptides as well as the random sequence were N-terminally labeled with DOTA and subsequently complexed with ^{68}Ga. We recently showed for the peptides DOTA-

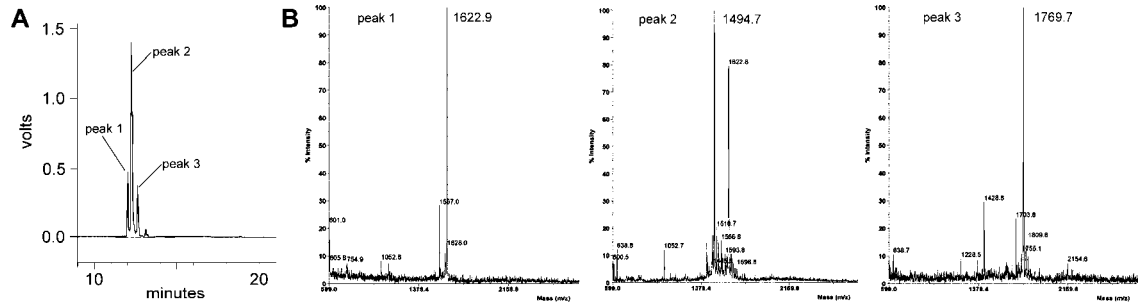

Figure 5. (A) Radio-HPLC of urine samples derived from rats injected with ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32). (B) MALDI-TOF analysis of the collected peaks.

Table 1. Peptide Sequences as Well as Calculated and Experimentally Determined Molecular Weights of the Cleavage Products of ^{68}Ga-DOTA-[f^{12,16}]-hCT(9-32) Found in Urine Samples by MALDI-TOF Analysis

peak	name	sequence	$MW_{exp.}$	$MW_{calc.}$
1	Ga-DOTA-[f^{12,16}]-hCT(9−18)	Ga-DOTA-LGTfTQDfNK	1622.8	1621.9
2	Ga-DOTA-[f^{12,16}]-hCT(9−17)	Ga-DOTA-LGTfTQDfN	1494.7	1493.8
3	Ga-DOTA-[f^{12,16}]-hCT(9−19)	Ga-DOTA-LGTfTQDfNKF	1769.7	1769.0

hCT(9−32) and DOTA-[f^{12,16}]-hCT(9−32) complexed with cold gallium that they are still internalized in HEK 293 and HeLa cells, respectively (*29*). Hence, we conclude that the labeling did not influence the cell-penetrating properties of the two peptides when applied in *ex vivo* studies.

The radiolabeled peptides were then injected in male Wistar rats, and their tissue distribution was determined. A relatively high kidney uptake is typical for all radioconjugates, which are small enough to pass through glomerular membranes and hydrophilic enough to undergo renal clearance (*30*). This was the case for ^{68}Ga-DOTA-hCT(9−32) and for the modified analogue ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32). Also, the random sequence was excreted mostly by the renal pathway. All peptides were metabolized to some extent by the hepatobiliary tract too and showed some excretion into the intestine. It was important for us to demonstrate that our CPP are not nonselectively accumulated in a specific tissue. Accumulation in the reticuloendothelial system is often observed for large or aggregated structures and can cause side effects in future *in vivo* applications (*31*). Recently, studies with a fusion protein of TAT and β-galactosidase showed distribution to all tissues in mice, including the brain (*2, 24*). In our experiments, no delivery over the blood−brain barrier was observed. Another preliminary study concerning the *in vivo* behavior of the sweet arrow peptide demonstrated uptake in blood cells (*32*). Whether our peptides have been indeed taken up in blood cells or in liver or kidney cells has not been elucidated yet. From *in vitro* studies with HT-29 colon carcinoma cells, we know that hCT(9−32) can transfer the ^{68}Ga-DOTA label effectively into the cell interior (data not shown). However, the transfer of bioactive cargos *in vivo* will be the focus of future studies.

All the results observed in the biodistribution studies could be confirmed by using small animal PET imaging. Strong ^{68}Ga activities in the kidneys and the bladder were detected that indicate renal peptide elimination. The corresponding kinetic supports this picture and demonstrates a very rapid peptide clearance from the blood and the kidneys. Furthermore, with the calculated time−activity curves in blood we could demonstrate the higher stability of the ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32) peptide. The estimated terminal half-life of 20.9 min was clearly higher than that of ^{68}Ga-DOTA-hCT(9−32) (15.9 min).

To analyze the metabolic stability of the peptides, radio-HPLC was used to identify the labeled compounds in blood as well as in urine samples. Because of the low peptide content, the blood samples could not be further characterized by MALDI-TOF mass spectrometry. But this is not surprising since a very rapid peptide clearance from the blood was observed. Nevertheless, from the radio-HPLC chromatographs it was concluded that the random peptide was relatively fast degraded in blood in a lot of metabolites. In contrast to this, the original CPP ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32) and ^{68}Ga-DOTA-hCT(9−32) were metabolically more stable, whereas the D-Phe modified hCT-analogue had the highest stability. These results confirm well our recently performed *in vitro* studies (*14*).

More results about the cleavage pattern were obtained from urine fractions that were collected 60 min postinjection. By using radio-HPLC, in the case of ^{68}Ga-DOTA-hCT(9−32) eight radiolabeled peaks were detected with retention times between 5.5−11.2 min. Since the retention time of 12.8 min of the unaffected peptide was lacking, this result indicates the complete proteolytic degradation of ^{68}Ga-DOTA-hCT(9−32). The obviously low metabolic stability of this peptide is in good agreement with previous *in vitro* studies (*13, 14*). Unfortunately, it was not possible to identify any cleavage products of ^{68}Ga-DOTA-hCT(9−32) by using MALDI-TOF mass spectrometry. Therefore, an enzymatic cleavage at the former *in vitro* identified labile positions 12 and 16 can neither be proven nor excluded.

However, in the case of the D-amino acid-modified ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32), radio-HPLC revealed three ^{68}Ga-labeled compounds in urine. The smallest peak (retention time 13.0 min) might be the uncleaved parent compound, but because of its low peptide content, this could not be confirmed by MALDI-TOF mass spectrometry. Nevertheless, HPLC analysis indicated that the parent compound was proteolytically degraded resulting in at least three ^{68}Ga-labeled metabolites. By analyzing these metabolites with MALDI-TOF mass spectrometry, three cleavage products were identified: ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−17), ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−18), and ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−19). As the major cleavage product, ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−17) was found. Interestingly, the same metabolite was recently detected by our group in preliminary *in vitro* studies (*14*). However, the *in vivo* identified cleavage sites after Lys^{18} and Phe^{19} were not observed in the *in vitro* study. Probably ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32) is proteolytically cleaved *in vivo* between Asn^{17}-Lys^{18} by an endopeptidase resulting in the fragment ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−17). In addition, two cleavage sites in the C-terminal part of the peptide (Gln^{24}-Thr^{25} and Ala^{26}-Ile^{27}) that were found *in vitro* were not detected in the present *in vivo* study. But more interestingly, no further N-terminal cleavage site was observed, probably indicating the increased stability of the modified hCT(9−32) analogue, which would be in good agreement with our *in vitro*

data. It is obvious that a peptide modification with D-amino acids can provide protection against metabolic degradation not only *in vitro* but also *in vivo*.

CONCLUSIONS

The results of the presented *in vivo* examination show that ^{68}Ga-DOTA-hCT(9−32) and ^{68}Ga-DOTA-[f^{12,16}]-hCT(9−32) do not accumulate in a specific tissue. As other investigated radiolabeled peptides, they were relatively rapidly excreted out of the body mostly by the renal system. The blood clearance and the elimination of the ^{68}Ga-DOTA-peptides were relatively high and may be decreased by further structural changes. This will be investigated in more detail in future studies. In addition, we could prove the increased metabolic stability of the modified peptide [f^{12,16}]-hCT(9−32) peptide. Furthermore, the results of this *in vivo* degradation study supported very well the results we gained in previous *in vitro* experiments. All in all, these studies demonstrate that it is very important to define the pharmacokinetic characteristics of an assumed biologically active compound. The future application of CPP *in vivo* will hardly depend on such pharmacological issues.

ACKNOWLEDGMENT

We gratefully thank R. Herrlich for performing the biodistribution studies, A. Suhr for performing the analysis of the metabolites, and R. Reppich-Sacher for the MALDI-TOF measurements. I.N. thanks Professor Dr. A. G. Beck-Sickinger for generous access to all facilities of the institute.

Biophysical and Biochemical Approach to Locating an Inhibitor Binding Site on Cholesteryl Ester Transfer Protein

David Cunningham, Wen Lin, Lise R. Hoth, Dennis E. Danley, Roger B. Ruggeri, Kieran F. Geoghegan, Boris A. Chrunyk, and James G. Boyd*

Pfizer Global Research and Development, Groton, Connecticut 06340. Received April 22, 2008; Revised Manuscript Received June 20, 2008

Cholesteryl ester transfer protein (CETP) transfers neutral lipids between different types of plasma lipoprotein. Inhibitors of CETP elevate the fraction of plasma cholesterol associated with high-density lipoproteins and are being developed as new agents for the prevention and treatment of cardiovascular disease. The molecular basis of their function is not yet fully understood. To aid in the study of inhibitor interactions with CETP, a torcetrapib-related compound was coupled to different biotin-terminated spacer groups, and the binding of CETP to the streptavidin-bound conjugates was monitored on agarose beads and in a surface plasmon resonance biosensor. CETP binding was poor with a 2.0 nm spacer arm, but efficient with polyethyleneglycol spacers of 3.5 or 4.6 nm. The conjugate based on a 4.6 nm spacer was used for further biosensor experiments. Soluble inhibitor blocked the binding of CETP to the immobilized drug, as did preincubation with a disulfide-containing covalent inhibitor. To provide a first estimate of the binding site for torcetrapib-like inhibitors, CETP was modified with a disulfide-containing agent that modifies Cys-13 of CETP. Mass spectrometry of the modified protein indicated that a single half-molecule of the disulfide was covalently bound to CETP, and peptide mapping after digestion with pepsin confirmed previous reports based on mutagenesis that Cys-13 was the site of modification. Modified CETP was unable to bind to the biosensor-mounted torcetrapib analog, indicating that the binding site on CETP for torcetrapib is in the lipid-binding pocket near the N-terminus of the protein. The crystal structure of CETP shows that the sulfhydryl group of Cys-13 resides at the bottom of this pocket.

INTRODUCTION

Cardiovascular disease is the major cause of premature death in Western societies (*1*). Decades of epidemiological analysis has led to the recognition of multiple distinct risk factors for this syndrome, among which unhealthful elevation of the level of low-density lipoprotein (LDL) cholesterol is the best-known example. This can be treated successfully with statins, which block cholesterol production in the liver, but it still represents only about 30% of the total risk for acquiring the disease. There remains an urgent need for therapies that reduce other elements of the risk burden.

One example is suboptimal levels of high-density lipoprotein (HDL) cholesterol. HDL collect cholesterol from the vascular periphery, and return it (as cholesteryl esters) to the liver for excretion. Despite some advances, there are not yet any approved drugs that elevate the level of HDL cholesterol successfully enough (and in a manner sufficiently free of undesirable side effects) to make major inroads against atherosclerotic disease. Currently, however, there are intensive efforts to evaluate inhibitors of cholesteryl ester transfer protein (CETP) for this purpose.

CETP is a circulating hydrophobic glycoprotein with a polypeptide molecular mass of 53 kDa and three or four N-linked glycans. It transfers neutral lipids between lipoproteins of different classes (other functions await recognition), and reductions in this activity by drug action or genetic change lead to an elevation of HDL cholesterol. When a CETP inhibitor (torcetrapib) was coadministered with atorvastatin, quite dramatic changes in the plasma lipid profile were obtained of a kind corresponding to a highly desirable shift in the levels of both biomarkers (*2*). Torcetrapib, unfortunately, was recently withdrawn from development because of surprising adverse events (*3*), but it continues to be medically and scientifically important to elucidate the function of CETP at a molecular level and the manner in which its inhibitors bind to it and block its function.

Kinetic analysis of CETP function indicated that it is a shuttle protein (*4*), optionally binding to lipoproteins of different classes, extracting a small number of molecules of their predominant neutral lipids in exchange for lipids previously bound, and presumably existing as a soluble protein when not bound to a lipoprotein. A recent report of its crystal structure suggested how these functions might occur, showing that neutral lipids are carried in a 6 nm tunnel formed inside the protein's elongated body, while each orifice of the tunnel is plugged with an amphiphilic phospholipid (*5*). Keen interest now centers on how CETP inhibitors bind to the protein and affect its function as a lipid shuttle.

Several important clues are already available. Torcetrapib has been shown to increase the relative affinity of CETP for HDL by a factor of 5 (*6*). As a shuttle carrier must have finely balanced relative affinities for the different states that it populates, this effect is clearly sufficient to disable lipid transfer by CETP. It is also known that torcetrapib binds to CETP with 1:1 stoichiometry (*6*), but the binding pocket that it occupies on CETP has not been determined.

CETP possesses two large binding pockets for neutral lipids which form a continuous interior cavity within the protein (*5*), but are demarcated from each other by a constriction in the cavity that has been termed the neck. To date, there have been no direct reports of the structures of CETP-inhibitor complexes, but there has been biochemical and mutagenesis-based evidence that two distinct disulfide containing inhibitors each modify Cys-

13 in the N-terminal region of CETP (*7*, *8*). Another report suggested that a mercurial cholesterol analog inhibits by modifying Cys-333 in the C-terminal lipid binding region (*9*). In the present study, a close analog of torcetrapib was adapted for use in a biosensor instrument by coupling it to biotin-terminated spacers of different lengths, and the resulting conjugates were characterized for their ability to bind CETP. The ability to measure the binding of CETP to an immobilized inhibitor provided a basis for experiments probing the ability of different inhibitors to compete with one another for binding sites, and has led to the discovery that torcetrapib apparently occupies the same pocket as one of the covalent inhibitors for which the site of action was previously implied by mutagenesis and was directly determined in the present study.

EXPERIMENTAL SECTION

CETP Mutant 444. A mutant form of CETP (C1A, C131A, N88D, N240D, N341D) was prepared as described (*5*). The expressed protein, designated CETP 444, was composed of the 493-residue polypeptide given in Genbank accession M30185 with the five mutations as listed. Amino-acid numbering (including the mutations) refers to mature CETP lacking the 17-residue signal sequence, i.e., the eighteenth residue of the gene product is designated Cys-1. The mutant showed activity equal to that of recombinant wild-type CETP in cholesteryl ester transfer assays. For mass spectrometry of the intact protein, it was deglycosylated using peptide N-glycosidase F.

Reagents and Conditions. Guanidine hydrochloride (Sigma Ultra) and iodoacetamide were purchased from Sigma (St Louis, MO). Hydrochloric acid and Tris base were from J. T. Baker (Phillipsburg NJ). DTT was from BioVectra (PEI, Canada). TFA was from Applied Biosystems (Foster City, CA). All other solvents were from J. T. Baker or Applied Biosystems were used as purchased. Phosgene (2.0 M in toluene) was purchased from Fluka (St. Louis, MO), and 6-amino-1-hexanol and *tert*-butyl dicarbonate were from Aldrich. *N*-Fmoc-8-Amino-3,6-dioxaoctanoic acid was from Chem-Impex (Wood Dale, IL). 1-Amino-11-azido-3,6,9-trioxoundecane was from Toronto Research Chemicals (North York, Ontario, Canada). NHS-LC-Biotin and TFP-PEO-Biotin were purchased from Pierce (Rockford, IL). Boc-6-Amino-1-hexanol was prepared from commercially available *tert*-butyl dicarbonate and amino alcohol as described (*10*).

NMR was performed on a 400 MHz field strength spectrometer from Varian Inc. (Palo Alto, CA) in CD_3OD or $CDCl_3$. Chemical shifts are reported in parts-per-million (ppm). Residual solvent was used as reference (CD_3OD = 3.32 ppm, $CDCl_3$ = 7.27 ppm). Preparative HPLC was performed using a BISCHOFF (Atlanta, GA) C_{18} column (50 × 20 mm, part # B025 0F185PS050), eluting with a linear slope gradient of water/acetonitrile/TFA (95:5:0.1 to 20:80:0.1) over 10 min, then isocratic 80% acetonitrile for 5 min, and flow rate of 10 mL/min). Analytical samples for liquid chromatography electrospray mass spectrometry (LC ESMS) were dissolved in methanol. 5−10 μL each of these were injected onto a Phenomenex 4.6 × 50 mm C_{18} Jupiter column and eluted using a linear gradient from 0.1% TFA, 5% acetonitrile in water to 100% acetonitrile over 10 min with a flow rate of 1 mL/min. Mass detection was performed using a Micromass LCT spectrometer employing external calibration with sodium iodide/cesium iodide clusters to determine experimental masses. Observed peaks were evaluated by summing those scans at one-half peak height. Compound purity was assessed by C_{18} reversed phase HPLC (RP HPLC) methods using diode array UV detection. Biotinyl compounds were >89% pure when measured at 214 nm and >99% pure when measured at 250 nm.

Preparation of Affinity Columns. A stock solution of biotinyl ligand was prepared by dissolving compound **8**, **9**, or **13** (0.5 μmol) in 2.5 mL ethanol and diluting with 7.5 mL phosphate buffered saline (pH 7.0). An aliquot of the stock solution (5 μL) was diluted with 95 μL methanol and set aside as an HPLC standard. A 1 mL HiTrap Streptavidin HP column (GE Healthcare, catalog # 17−5112−01) was pre-equilibrated with 10 mL of 20% ethanol in pH 7.0 phosphate buffer. The 10 mL of ligand stock solution was passed over the column using a syringe at a flow rate of about 1 mL/min and the flow-through fraction collected. The column was washed with 10 mL of 20% ethanol in phosphate buffer and the eluant collected. The stock solution, flow-through, and wash fractions were assayed by RP HPLC. No ligand was detected in the eluants indicating complete loading on the column.

(±) Benzyl [(2*R*,4*S*)-2-ethyl-6-(trifluoromethyl)-1,2,3,4-tetrahydroquinolin-4-yl]carbamate (1). 4-Trifluoromethylaniline (1.2 g, 7.4 mmol) and propionaldehyde (0.5 g, 8.6 mmol) were combined in dichloromethane (30 mL) and treated with anhydrous sodium sulfate (2.5 g). After stirring 1 h at room temperature, the reaction mixture was filtered and to the resulting solution was added *N*-vinyl-*O*-benzylcarbamate (1 equivalent) and a drop of borontrifluoride etherate. After stirring for 90 min at room temperature the reaction mixture was concentrated onto silica gel employing a rotary evaporator and purified by silica gel chromatography eluting with 5−10% ethyl acetate in hexanes to afford 1.0 g of the racemic product (47%). ^{1}H NMR ($CDCl_3$): δ 7.32 − 7.41 (m, 5H), 7.22 (dd, 1H, *J* = 8.3, 2.1 Hz), 6.46 (d, 1H, *J* = 8.51 Hz), 5.18 (s, 2 H), 5.03 (td, 1H, *J* = 10.5, 5.5 Hz), 4.87 (d, 1H, *J* = 9.6 Hz), 4.06 (bs, 1H), 3.35 − 3.45 (m, 1H), 2.32 (ddd, 1H, *J* = 12.3, 5.5, 2.6 Hz), 1.54 (d, 1H, *J* = 6.4 Hz), 1.51 − 1.58 (m, 1 H), 1.45 (td, 1H, *J* = 11.6 Hz), 0.98 (t, 3H, *J* = 7.5 Hz).

Benzyl [(2*R*,4*S*)-2-ethyl-1-(trifluoroacetyl)-6-(trifluoromethyl)-1,2,3,4-tetrahydroquinolin-4-yl]carbamate (2). Compound **1** (1.0 g, 2.6 mmol) and triethylamine (1 mL, 7.2 mmol) were dissolved in 30 mL of dichloromethane and cooled in an ice/water bath as trifluoroacetic anhydride (0.5 mL, 3.5 mmol) was added. After 4 h, the reaction mixture was combined with an aqueous 1 N HCl solution, and the organic phase washed with a saturated aqueous $NaHCO_3$ solution, dried over $MgSO_4$, filtered and concentrated under reduced pressure to afford the racemic product (85%). The enantiomers were separated by regular phase HPLC using a Chiralcel OD column eluting with 20% isopropanol in heptane. The later eluting peak contains the desired THQ enantiomer with the (2*R*, 4*S*) stereochemistry. ^{1}H NMR ($CDCl_3$): δ 7.60 (s, 1 H), 7.57 (d, 1 H, *J* = 7.5 Hz), 7.39 (m, 6 H), 5.19 (s, 2 H), 4.97 (d, 1 H, *J* = 9.1 Hz), 4.79 (bs, 1 H), 4.66 (bs, 1 H), 2.69 (m, 1 H), 1.48 (m, 1 H), 1.37 (m, 2 H), 0.97 (t, 3 H, *J* = 7.5 Hz).

(2*R*,4*S*)-2-Ethyl-1-(trifluoroacetyl)-6-(trifluoromethyl)-1,2,3,4-tetrahydroquinolin-4-amine (3). Compound **2** (1.0 g, 2.1 mmol) was dissolved in 30 mL each of absolute ethanol and cyclohexene. The resulting solution was treated with 10% Pd on carbon (200 mg, 50% by weight with water) and heated at reflux. After 1 h, the reaction mixture was filtered through a pad of Celite and concentrated under reduced pressure to afford the title compound. ^{1}H NMR ($CDCl_3$): δ 7.82 (s, 1H), 7.58 (ddd, 1H *J* = 8.3, 1.4, 0.7 Hz), 7.33 (bs, 1H), 4.71 (bs, 1H), 3.83 (dd, 1H, *J* = 11.4, 5.2 Hz), 2.64 (ddd, 1H, *J* = 12.5, 8.8, 5.3 Hz), 1.42 − 1.51 (m, 1H), 1.29 − 1.41 (m, 1H), 1.18 (bs, 1H), 0.88 (t, 3H, *J* = 7.5 Hz).

***N*-[3,5-Bis(trifluoromethyl)benzyl]-*N*-[(2*R*,4*S*)-2-ethyl-1-(trifluoroacetyl)-6-(trifluoromethyl)-1,2,3,4-tetrahydroquinolin-4-yl]acetamide (4).** Compound **3** (0.5 g, 1.5 mmol) and 3,5-(bis)trifluoromethylbenzaldehyde (0.36 g, 1.5 mmol) were combined in 40 mL of 1,2-dichloroethane at room temperature. After 1 h, sodium triacetoxyborohydride (0.21 g, 7.5 mmol) was added and the mixture stirred for 18 h. An aqueous 2 N

KOH solution was added to the reaction mixture, the organic phase was separated, dried over $MgSO_4$, filtered and concentrated under reduced pressure to afford 0.65 g crude amine. The amine was dissolved in 1.0 mL pyridine and 20 mL dichloromethane, and the resulting mixture cooled with an ice/water bath. Acetyl chloride (0.5 mL, 7.0 mmol) was added slowly by syringe and the reaction stirred at room temperature for 4 h. Aqueous 1 N HCl solution was added to the reaction mixture, the organic layer was separated, washed once with an aqueous saturated sodium bicarbonate solution, dried over magnesium sulfate, filtered and concentrated under reduced pressure. The resulting material was purified by chromatography on silica eluting with 20% ethyl acetate in hexanes to afford the title compound (44%). ^{1}H NMR ($CDCl_3$): [~2:1 mixture of rotamers] δ 7.74 − 7.88 (m, 1H), 7.67 (s, 1H), 7.65 − 7.73 (m, 1H), 7.48 (bs, 1H), 7.27 (s, 1H), 5.59 (d, 1H, J = 16 Hz), 4.84 (dd, 1H, J = 11.9, 4.7 Hz), 4.55 − 4.71 (m, 1H), 3.96 (d, 1H, J = 16.2 Hz), 2.35 (bs, H), 2.26 (bs, 1H), 2.24 (s, 2H), 2.08 (s, 1H), 1.43 − 1.61 (m, 1H), 1.27 − 1.43 (m, 2H), 0.78 (t, 3H, J = 7.4 Hz).

***N*-[3,5-Bis(trifluoromethyl)benzyl]-*N*-[(2*R*,4*S*)-2-ethyl-6-(trifluoromethyl)-1,2,3,4-tetrahydroquinolin-4-yl]acetamide (5).** Compound **4** (400 mg, 0.66 mmol) was dissolved in 10 mL THF, combined with 5 mL of an aqueous 2 N LiOH solution, and stirred at room temperature for 4 h. The reaction mixture was concentrated under reduced pressure, the residue diluted with water and $MgSO_4$, filtered, and concentrated under reduced pressure to afford the title compound. ^{1}H NMR ($CDCl_3$): [~2:1 mixture of rotamers] δ 7.54 − 7.83 (m, 3H), 7.21 − 7.27 (m, 1H), 6.92 − 7.01 (m, 1H), 6.49 − 6.57 (m, 1H), 5.26 (dd, 1H, J = 11.8, 5.6 Hz), 4.59 − 4.89 (m, 1H), 3.99 − 4.14 (m, 1H), 3.99 − 4.29 (m, 1H), 3.40 (bs, 1H), 2.38 (s, 2H), 2.14 (s, 1H), 1.94 − 2.09 (m, 1H), 1.37 − 1.66 (m, 3H), 0.93 (t, 2H, J = 7.4 Hz), 0.89 (t, 1H, J = 7.7 Hz).

(6-[(*tert*-Butoxycarbonyl)amino]hexyl) (2*R*,4*S*)-4-{acetyl[3,5-bis(trifluoromethyl)benzyl]amino}-2-ethyl-6-(trifluoromethyl)-3,4-dihydroquinoline-1(2H)-carboxylate (6a). To a solution of 300 mg compound **5** in 5 mL toluene was added 3 mL of 20% phosgene (6 mmol) in toluene. The reaction was refluxed for 6 h, cooled to room temperature, and the excess phosgene was driven into a trap by a stream of nitrogen. The residual solvent was evaporated on rotovap followed by high vacuum, leaving the carbamoyl chloride as a waxy solid. LCMS showed it to be a mixture of 95% carbamoyl chloride and 5% **5,** which is stable at room temperature for at least 30 days (ESMS: calculated m/z for $[M+H]^+$ = 575.11, found = 575.22). To 50 mg carbamoyl chloride (0.087 mmol) was added 1.0 mL toluene, 95 mg Boc-6-amino-1-hexanol (0.44 mmol) and 0.1 mL DIEA. The reaction was refluxed for 24 h, cooled, evaporated, dissolved in 0.5 mL methanol and directly purified by preparative HPLC as described in Reagents and Conditions. Collected fractions were analyzed by analytical LCMS and those judged as having adequate purity were pooled and lyophilized. The purity of the product was 90% as determined by HPLC at 215 nm. Yield = 15 mg (23%). ^{1}HNMR (CD_3OD): δ 7.92 (s, 2H), 7.84 (s, 1H), 7.6 (dd, 2H), 7.06 (s, 1H), 5.3 (d, 1H, J = 16 Hz), 5.14 (dd, 1H), 4.35 (m, 1H), 4.29 (d, 1H, J = 16 Hz), 4.16 (t, 2H), 2.99 (t, 2H), 2.28 (m, 1H), 2.26 (s, 3H), 1.67 (m, 4H), 1.5−1.3 (m, 8H), 1.40 (s, 9H), 0.72 (t, 3H). ESMS: calculated m/z for $[M+H]^+$ = 756.30, found = 756.51.

6-Aminohexyl (2*R*,4*S*)-4-{acetyl[3,5-bis(trifluoromethyl)benzyl]amino}-2-ethyl-6-(trifluoromethyl)-3,4-dihydroquinoline-1(2*H*)-carboxylate (6b), TFA Salt. Boc protected urethane **6a** (15 mg) was treated with 0.5 mL TFA for 10 min at room temperature. The TFA was evaporated under a stream of nitrogen, then at high vacuum. The purity of the amine TFA salt was 90% as determined by HPLC at 214 nm. Yield = 15 mg (100%). ESMS: calculated m/z for $[M+H]^+$ = 656.25, found = 656.38. HRMS: calculated m/z for $[M+H]^+$ = 656.2529, found = 656.2526.

(6-({[2-(2-Aminoethoxy)ethoxy]acetyl}amino)hexyl) (2*R*,4*S*)-4-{acetyl[3,5-bis(trifluoromethyl)benzyl]amino}-2-ethyl-6-(trifluoromethyl)-3,4-dihydroquinoline-1(2*H*)-carboxylate (7), TFA Salt. To a solution of 7.0 mg (18 μmol) Fmoc-8-amino-3,6-dioxaoctanoic acid in 36 μL of a 0.5 M DMF solution of HOBT/HBTU (18 μmol) was added 10 μL (60 μmol) DIEA. After 2 min, 6.0 mg (9.1 μmol) of TFA salt **6b** was added and the solution allowed to react for 1 h. The reaction solution was diluted with 10 mL ethyl ether, and washed with 0.1 M HCl, 0.1 M $NaHCO_3$, saturated NaCl, and dried over $MgSO_4$. The ether was filtered and concentrated to an oily solid. The solid was treated with 0.1 mL 30% piperidine/DMF for 20 min, then 30 μL acetic acid was added to quench the reaction. The solution was fractionated by direct injection onto a C_{18} preparative HPLC column as for **5**, and appropriate fractions were pooled and lyophilized. Yield = 2.0 mg (28%). ESMS: calculated m/z for $[M+H]^+$ = 801.33, found = 801.36.

(6-{[6-({5-[(3a*S*,4*S*,6a*R*)-2-Oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl]pentanoyl}amino)hexanoyl]amino}hexyl)(2*R*,4*S*)-4-{acetyl[3,5-bis(trifluoromethyl)benzyl]amino}-2-ethyl-6-(trifluoromethyl)-3,4-dihydroquinoline-1(2*H*)-carboxylate (8). To a solution of 5.0 mg (7.6 μmol) TFA salt **6b** in 50 μL DMF was added 10 mg (22 μmol) NHS-LC-Biotin and 5 μL DIEA. After 1 h, the product was purified by direct injection onto a C_{18} preparative HPLC column as for **5**. Appropriate fractions were pooled and lyophilized. HPLC purity at 214 nm = 94%, at 250 nm >99%. Yield = 6.2 mg (65%). ESMS: calculated m/z for $[M+H]^+$ = 995.41, found = 995.61. HRMS: calculated m/z for $[M+H]^+$ = 995.4145, found = 995.4142.

(8,11,27-Trioxo-31-[(3a*S*,4*S*,6a*R*)-2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl]-16,19,22-trioxa-7,12,26-triazahentriacont-1-yl) (2*R*,4*S*)-4-{acetyl[3,5-bis(trifluoromethyl)benzyl]amino}-2-ethyl-6-(trifluoromethyl)-3,4-dihydroquinoline-1(2*H*)-carboxylate (9). To a solution of 4.0 mg (6.1 μmol) TFA salt **6b** in 50 μL DMF was added 16 mg (23 μmol) TFP-PEO-Biotin (Pierce, catalog # 21336) and 5 μL DIEA. After 1 h, the product was purified by direct injection onto a C_{18} preparative HPLC column as for **5**. Appropriate fractions were pooled and lyophilized. HPLC purity at 214 nm = 89%, at 250 nm >99%. Yield = 4.0 mg (55%). ESMS: calculated m/z for $[M+H]^+$ = 1184.51, found = 1184.75. HRMS: calculated m/z for $[M+2H]^{+2}$ = 592.7609, found = 592.7632.

(8,17,20,36-Tetraoxo-40-[(3a*S*,4*S*,6a*R*)-2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl]-10,13,25,28,31-pentaoxa-7,16,21,35-tetraazatetracont-1-yl) (2*R*,4*S*)-4-{acetyl[3,5-bis(trifluoromethyl)benzyl]amino}-2-ethyl-6-(trifluoromethyl)-3,4-dihydroquinoline-1(2*H*)-carboxylate (10). TFP-PEO-Biotin was allowed to react with 2.0 mg (2.2 μmol) of TFA salt **7** as described for the synthesis of **9**. HPLC purity at 214 nm = 94%, at 250 nm >99%. Yield = 1.5 mg (51%). ESMS: calculated m/z for $[M+H]^+$ = 1329.73, found = 1329.59. HRMS: calculated m/z for $[M+2H]^{+2}$ = 665.2979, found = 665.3000.

Methyl [(2*S*,4*R*)-1-(13-azido-5,8,11-trioxa-2-azatridecan-1-oyl)-2-ethyl-6-(trifluoromethyl)-1,2,3,4-tetrahydroquinolin-4-yl]carbamate (12). In a 1.5 mL Eppendorf tube 150 mg (0.50 mmol) of methyl [(2*S*,4*R*)-2-ethyl-6-(trifluoromethyl)-1,2,3,4-tetrahydroquinolin-4-yl]carbamate (**11**) (*11*) was dissolved in 0.10 mL THF. *p*-Nitrochloroformate (200 mg, 2.0 equiv) was added and the resulting solution was shaken at 40 °C for 16 h. The THF was evaporated and residue was dissolved in 1.5 mL methanol, 0.35 mL DIEA. 400 mg (4.0 equiv) 1-amino-11-azido-3,6,9-trioxoundecane was added and the resulting solution was shaken at 70 °C for 48 h. The product was purified by

direct injection onto preparative HPLC as for compound **5** except a shallower solvent gradient to 50% acetonitrile was employed. Yield = 99 mg (36%). ESMS: calculated *m*/*z* for $[M+H]^+$ = 547.25, found = 547.24.

Methyl [(2*S*,4*R*)-1-{15,22-dioxo-26-[(3a*S*,4*S*,6a*R*)-2-oxohexahydro-1H-thieno[3,4-d]imidazol-4-yl]-5,8,11-trioxa-2,14,21-triazahexacosan-1-oyl}-2-ethyl-6-(trifluoromethyl)-1,2,3,4-tetrahydroquinolin-4-yl]carbamate (13). 4.2 mg (7.7 μmol) of compound **12** was dissolved in 2 mL THF. Three mg Pd/C was added and the mixture shaken under 50 psi H_2 for 5 h. The reaction was filtered through a plug of celite and evaporated. LCMS showed >99% conversion of the azide to the amine (ESMS: calculated *m*/*z* for $[M+H]^+$ = 521.26, found = 521.22). The amine was dissolved in 100 μL DMF and 10 μL DIEA. NHS-LC-Biotin (14 mg, 4.0 equiv) was added and the solution shaken for 1 h at room temperature The product was purified by direct injection onto preparative HPLC as for compound **5**. HPLC purity at 214 nm = 95%, at 250 nm >99%. ESMS: calculated *m*/*z* for $[M+H]^+$ = 860.42, found = 860.57. HRMS: calculated *m*/*z* for $[M+H]^+$ = 860.4198, found = 860.4196.

Covalent Modification of CETP. CETP (18 μM) was incubated with **14** (50 μM) in 20 mM Tris, 150 mM NaCl, pH 7.5 for 36 h at room temperature, after which it was dialyzed exhaustively against the same buffer at 4 °C.

Biosensor Analyses. SPR measurements were performed using a Biacore 3000 system (GE Healthcare, Piscataway, NJ). In typical experiments, biotinylated drug analogs were immobilized onto standard Biacore streptavidin-coated biosensor chips. CETP binding was measured at 25 °C in 20 mM Tris pH 7.4, 150 mM NaCl, 0.005% Tween 20, 1% DMSO using a flow rate of 100 μL/min. The underivatized streptavidin surface was used as a reference. Surfaces were regenerated between injections by two sequential three-second pulses of 0.1% SDS. Data were processed using Scrubber 2 software (BioLogic Software) to y-zero, x-align and double reference against buffer injections and a streptavidin surface lacking any immobilized ligand. Kinetic analyses were conducted using BIAeval software (GE Healthcare, Piscataway, NJ.).

Acetone Precipitation of CETP. HCl (0.005 mL, 0.5 M) was added to 0.042 mL of CETP (2.4 mg/mL) to give a final HCl concentration of 0.05 M. 0.150 mL of cold acetone was added and the sample was allowed to stand at −20 °C for 2 h, after which the sample was centrifuged for 10 min at 14,000 rpm in a microfuge. The supernatant was discarded and the pellet was dried in a centrifugal concentrator to remove residual acetone.

Peptic Digestion/Reduction. The acetone precipitate (~0.1 mg CETP) was dissolved in 0.1 mL of 0.05 M HCl, 8 M guanidine hydrochloride, and incubated at 50 °C for 15 min. The sample was diluted to 3 M guanidine hydrochloride, 0.001 mL of pepsin at 2 mg/mL was added, and the sample was digested for 19 h at 23 °C. The samples was then divided into two portions: (i) Nonreduced, non-neutralized sample: 0.002 mL water was added to 0.010 mL of the pepsin digest. (ii) Reduced sample: 0.001 mL 1 M Tris base and 0.001 mL 1 M DTT was added to 0.01 mL of the pepsin digest.

Reversed-Phase Liquid Chromatography−Mass Spectrometry. Peptide mapping by reversed-phase HPLC-MS was conducted by capillary HPLC using a Vydac type 218MS5.510 column (0.5 × 100 mm) running at 0.005 mL/min on an Agilent 1100 chromatograph based on a Model G1376A capillary pump and interfaced with a Thermo Finnigan LCQ ion-trap mass spectrometer. The HPLC solvents were: A, 0.02% TFA; B, 0.02% TFA in acetonitrile. From initial conditions of 1.6% B (0−2 min), the gradient consisted of steps from 1.6−35% B (2−100 min), and 35−80% B (100−110 min). The standard Finnigan electrospray interface was modified by replacing the sample needle with a coated fused silica tip (TaperTip; part number TT150−50−50-CE-5, New Objective Inc., Woburn, Massachusetts). The LCQ was controlled by Xcalibur 1.2 software (Thermo Finnigan) and set to perform data-dependent MS/MS analysis ("triple play") as described. Peptides were identified by searching the Swiss-Prot sequence database using Sequest as implemented under license by Thermo Finnigan (Sequest Browser), or the Mascot search engine (Matrix Sciences) (*12*).

Size-Exclusion Chromatography−Mass Spectrometry. SEC-MS was conducted with a Phenomenex Bio-SEC-S3000 column (300 × 4.6 mm) run at 0.2 mL/min on an Agilent 1100 chromatograph based on a Model G1312A binary pump and interfaced with a Micromass LCT electrospray/time-of-flight mass spectrometer. The HPLC solvent was 0.045% TFA in 40% acetonitrile. The LCT was controlled by MassLynx 4.0 software (Waters).

RESULTS

Affinity Ligand Synthesis. Compound **4**, a close-in analog of torcetrapib (Scheme 1), was selected as the starting structure for elaboration to potential affinity ligands. Internal (unpublished) torcetrapib SAR had shown that the methoxycarbonyl at the tetrahydroquinoline (THQ) 4-amino position could be replaced with acetyl without loss of affinity for CETP. More importantly for the present investigations, replacement of the ethyl chain of the THQ 1 position carbamate with longer alkyl chains only slightly reduced CETP binding. Hence, we investigated the value of placing different biotin-terminated spacer arms in this substituent. Condensation of 4-trifluoromethylaniline with propionaldehyde followed by addition to *N*-vinyl-*O*-benzylcarbamate provided a direct route to racemic cis-4-aminocarbobenzyloxy (Cbz) protected THQ **1**. Trifluoroacetylation of the THQ 1-amine affords an intermediate that can be readily separated into its constitutive enantiomers by chiral HPLC methods. Thus **2** was obtained, which following hydrogenation provides the suitably protected primary amine **3**. Reductive coupling of **3** with 3,5-bis-trifluoromethylbenzaldehyde followed by acetylation of the alkylated 4-amino group led to intermediate **4**. Removal of the trifluoroacetyl group with lithium hydroxide delivered key THQ **5**. Reaction of **5** with phosgene in toluene followed by evaporation of the solvent provided a carbamoyl chloride crude product in about 95% purity. We found that the THQ carbamoyl chloride reacted readily with amines, but the product ureas had significantly reduced affinity for CETP. Synthesis of high affinity urethane compounds was significantly more difficult, but reaction with excess *N*-Boc protected 6-aminohexanol in refluxing toluene did provide compound **6a** in modest yield. Finally, removal of the Boc group of compound **6a** with TFA afforded amine salt **6b**.

Putative CETP affinity ligands were prepared as shown in Scheme 2. TFA salt **6b** was coupled directly with a long chain *N*-hydroxysuccinimidyl ester of biotin (NHS-LC-Biotin) to produce compound **8**, which was purified by reverse phase HPLC. Similarly, **6b** was coupled to Fmoc-8-amino-3,6-dioxaoctanoic acid with HBTU activation, and the resulting intermediate was deblocked with piperidine/DMF and purified by preparative HPLC to provide amine salt **7**. Amines **6b** and **7** were allowed to react with the tetrafluorophenyl (TFP) ester of a PEG-biotin reagent (TFP-PEO-Biotin) to prepare compounds **9** and **10**, respectively. Control urea compound **13** was prepared from chiral THQ **11** (*11*), which features the opposite THQ stereochemistry of torcetrapib (Scheme 3). Activation of the THQ nitrogen of **11** with *p*-nitrophenylchloroformate followed by reaction with a commercially available heterobifunctional linker provided urea azide **12**, a compound that lacks

Table 1. Effects of Immobilization and Spacer Arm Length on CETP Binding

compound	phase	IC50[b] (μM)	% CETP bound[c]	capacity (μg/mL)	spacer length[e] atoms[d]	spacer length[e] nm
6a	solution	1.5	NA[a]	NA	NA	NA
8	agarose	2.3	20	75	16	2.1
9	agarose	2.6	>98	1100	28	3.5
10	solution	0.72	NA	NA	37	4.6
12	solution	>300	NA	NA	NA	NA
13	agarose	ND	19	70	21	2.5
none	agarose	NA	<3	<10	NA	NA

[a] NA = not applicable; ND = not determined. [b] Average of two determinations. [c] Reported as the percent missing from the flow-through fraction and washings as measured by SDS−PAGE, and absorbance at 280 nm following a 0.375 mg load. Additional 0.375 mg aliquots of CETP were used to determine column capacity. [d] Number of atoms between the THQ 1 position and the carboxyl group of the biotin affinity handle. [e] Estimated for fully extended conformation using average bond length = 1.48 Å and the formula (average bond length)(cos 35)(# atoms + 1).

to LDL or VLDL in 90% human plasma (*13*). All three compounds showed similar affinities for CETP, with IC_{50} values in the low micromolar range (Table 1). By comparison, the reported IC_{50} value for torcetrapib is 47 nM (*6*), indicating that the aminohexanol-derived spacers caused a 30- to 50-fold loss in binding affinity. Control compound **12,** which had the opposite stereochemistry of torcetrapib and lacked the 3,5-(bis)trifluoromethylbenzyl group, did not inhibit CETP.

Biotinyl compounds **8**, **9**, and **13** were evaluated as potential ligands for immobilization of CETP. A 0.5 mg sample of each compound was allowed to bind to 1 mL of Streptavidin Sepharose, a maximum loading density of 0.5 mg/mL agarose (~0.5 mM). Solutions of purified CETP were passed over the columns as well as over a column of Streptavidin Sepharose containing no biotinyl ligand, and the flow-through fractions were assayed for protein using SDS-PAGE and absorbance at 280 nm. When 0.37 mg of CETP was passed over Streptavidin Sepharose lacking affinity ligand, >97% of the protein was recovered from the flow-through and wash fractions, indicating no detectable binding to the matrix (Table 1). When 0.37 mg of CETP was passed over the column prepared with ligand **8**, 0.30 mg (81%) was recovered in the flow-through. Additional aliquots of protein were passed over the column of immobilized **8**, but no additional CETP bound, indicating that its total capacity for CETP was 0.07 mg/mL. This result was essentially identical to that seen with a column made from biotinylated

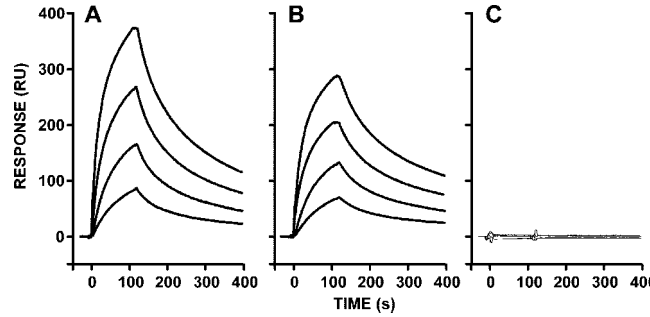

Figure 1. The effect of spacer arm length on the binding of CETP to immobilized inhibitor. Wild-type CETP at 1.7, 0.56, 0.18, and 0.06 μM was injected over (A) compound **10** (spacer 4.6 nm); (B) compound **9** (spacer 3.5 nm), and (C) compound **8** (spacer 2.9 nm). Each compound was immobilized to give a surface density of ~150 RU on the streptavidin biosensor surfaces.

control compound **13**, and suggests that CETP binding to columns of immobilized **8** and **13** was compound-dependent but nonspecific, and likely due to hydrophobic interaction with the THQ rather than to specific binding of the immobilized torcetrapib analog. In contrast, when CETP was passed over columns of immobilized **9**, essentially all of the protein bound to the column and none was detected in the flow-through fraction. By passing additional aliquots of protein over a column of **9** until overloading occurred, the CETP capacity was determined to be about 1.1 mg/mL. When dissolved in plasma, ligands **8** and **9** had similar potencies in the CE transfer assay, but **8** did not specifically bind CETP when immobilized. This strongly suggested that there was a dependence on linker length, and that the 16-atom spacer of **8** was too short for the THQ group to access the torcetrapib binding pocket when the biotin residue was bound to streptavidin.

Biosensor Analysis. Initial SPR experiments evaluated the effect of spacer length on CETP binding. When CETP was injected over biotinyl compounds **8**, **9**, and **10** immobilized on a streptavidin-coated biosensor, binding results were similar to those seen when the compounds were immobilized on Streptavidin Sepharose. No specific CETP binding was observed with **8** (Figure 1), confirming that its 16-atom spacer is too short to allow the THQ group to reach the torcetrapib binding pocket. While both **9** and **10** bound CETP (Figure 1), compound **10** had approximately 25% greater binding capacity than **9**, suggesting that the 37-atom spacer of **10** allowed greater access to the torcetrapib site than did the 28-atom spacer of **9**. All subsequent SPR experiments used immobilized **10**. A kinetic analysis of CETP binding at concentrations ranging from 2.8 μM to 0.1 μM indicated that binding was somewhat complex. However, a reasonable global fit could be made using the 1:1 Langmuir model that indicated a K_D of approximately 0.3 μM with an on-constant of 22 000 ± 200 $M^{-1}s^{-1}$ and an off-constant of 0.0064 ± 0.0001 s^{-1} (data not shown). This value correlated well with the IC_{50} of 0.7 μM obtained for **10** in the transfer assay (Table 1). Though IC_{50} is dependent on the conditions of the assay, which are different from those used in the SPR assay, a value consistent in magnitude to the calculated K_D suggests that the assay is relevant to specific binding of the compound and target. For a competitive inhibitor K_D relates to IC_{50} by the equation $K_D = IC_{50}/(1+[S]/K_m)$. When CETP was preincubated with an equimolar concentration of either torcetrapib (not shown) or its close analog CP-532,623 (*14*), binding to **10** was substantially inhibited (Figure 2), providing good evidence that immobilized **10** binds specifically to CETP in the same pocket as torcetrapib.

The test of ability to bind to immobilized **10** could then be used to survey inhibitors for evidence of binding in the

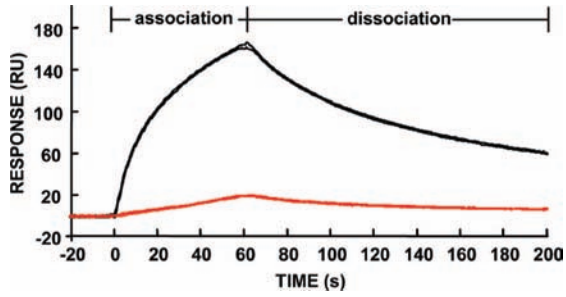

Figure 2. Preincubation with inhibitor prevents CETP binding to immobilized torcetrapib analog. Mutant CETP 444 at 1 μM was preincubated 30 min with (red) or without (black) torcetrapib analog CP-532,623 (1 μM) and injected in duplicate over immobilized 10.

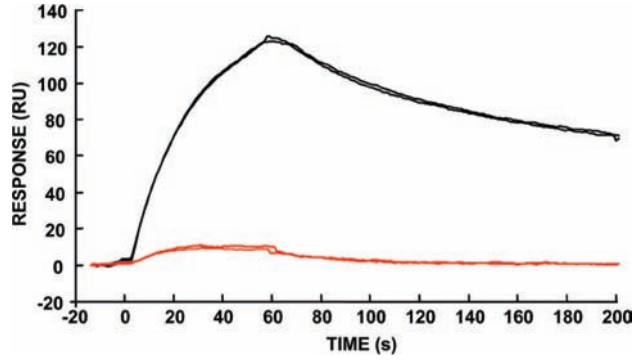

Figure 3. Modification with **14** prevents CETP binding to immobilized torcetrapib analog. Mutant CETP 444 modified with compound **14** (red) or unmodified control (black) each at 1 μM was injected in duplicate over immobilized compound **10**.

14

torcetrapib pocket. When the reportedly covalent disulfide inhibitor **14** (compound 4 of reference (*7*)) was preincubated with CETP, it blocked binding of CETP to immobilized **10** (Figure 3) and lowered its cholesteryl ester transfer activity by >90% (data not shown). The action of this compound was investigated in more detail to enhance its value as an indicator of the binding site of torcetrapib.

Stoichiometry of Modification. Site-directed mutagenesis implicated Cys-13 as the reaction site on CETP for **14** (*7*) (see Scheme 4 for structure), but could not exclude the possibility of additional modifications at other cysteine residues. To check the stoichiometry of modification, modified CETP 444 was subjected to electrospray/time-of-flight mass spectrometry using size-exclusion chromatography in 40% acetonitrile as the desalting method (Figure 4). To obtain interpretable spectra, it was necessary to remove the lone glycan on Asn-296 of CETP 444 using peptide N-glycosidase F. For unmodified CETP 444, the mass of 53 052 Da (Figure 4A) agreed acceptably well with the theoretical value of 53 046 Da, which assumes a disulfide bond between Cys-143 and Cys-184 and conversion of Asn-296 to Asp-296 during deglycosylation. The minor peak came from protein lacking residues 1−3, as verified by Edman sequencing (mass obsd. 52 765 Da; mass theor. 52 760 Da)

Peaks in the mass spectrum of CETP 444 treated with **14** gained 326 Da (major) and 321 Da (minor), respectively,

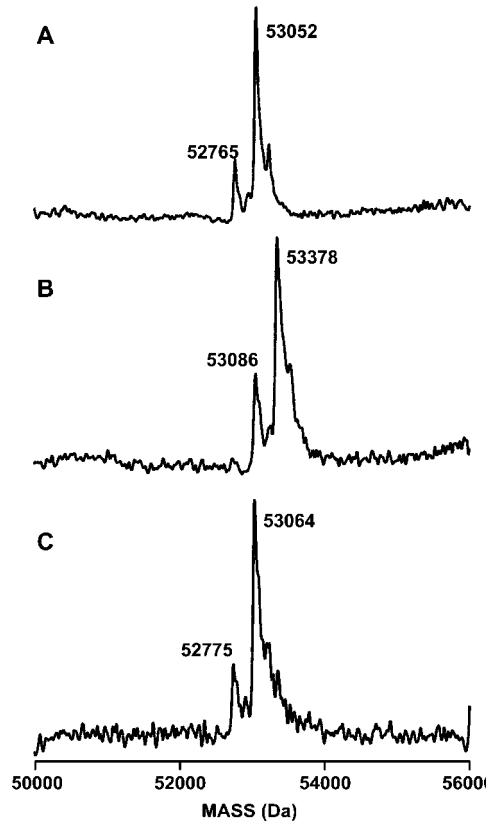

Figure 4. Mass spectrometry of CETP 444 (A) before and (B) after modification with **14** and (C) after treatment of the modified protein with dithiothreitol. The theoretical mass for deglycosylated unmodified CETP 444 (major peak) was 53046 Da, and for the same protein lacking amino acids 1−3, it was 52760 Da. The theoretical mass increase resulting from the formation of a mixed disulfide with a half-molecule of **14** was 317 Da.

consistent in this method with addition of a single half-molecule of **14** as a mixed disulfide with a protein thiol (theoretical increase 317 Da) (Figure 4B). Treatment with dithiothreitol reversed the modification, supporting the interpretation (Figure 4C).

Site of Modification by 14. The site at which **14** modified CETP 444 was determined by peptide mapping, using pepsin as the agent of digestion. Pepsin was chosen not only for its broad specificity and preference for hydrophobic sites, but also because digesting CETP at pH 2 lowered the risk of disulfide interchange reactions. In the map of the modified protein (Figure 5), new peaks in the 100−108 min range (see asterisks in Figure 5B) were attributed on the bases of novelty, mass and MS/MS-derived sequencing (not shown) to fragments containing Cys-13 disulfide-linked to the half-molecule of **14**. The peaks at 100, 104 and 108 min were attributed to fragments 1−20, 4−20 and 11−20 of CETP 444, respectively, each modified by the addition of 317.5 Da at Cys-13. Also detected, but in much lower abundance, were the modified peptides 1−21, 4−21 and 11−21. No other cysteine was modified. Peptides from unmodified CETP 444 containing Cys-13 as a free thiol were absent from the digest of the modified form (not shown). Treating the digest of the modified protein with dithiothreitol abolished the modification, confirming that it was based on a disulfide (Figure 5C).

DISCUSSION

SPR-based biosensors detect changes in refractive index that occur when molecules in solution bind to their immobilized partners in the molecular layer adjacent to the biosensor surface

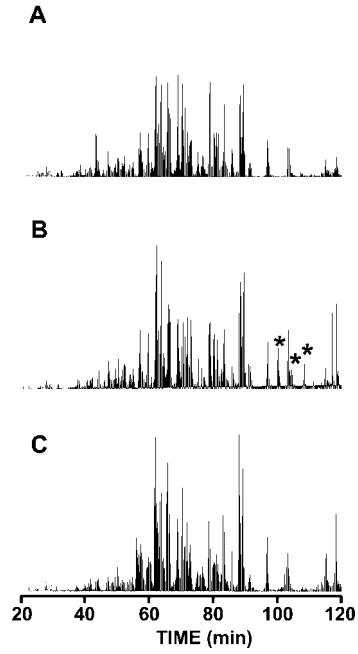

Figure 5. Base peak chromatograms from LC-MS peptide mapping analysis of (A) CETP 444; (B) CETP 444 after modification with **14**; and (C) after treatment of the modified CETP with dithiothreitol. Asterisks in panel B mark the three major peaks attributed to peptides containing the mixed disulfide bond between Cys-13 of CETP and one-half-molecule of **14**. From left to right, the three marked peaks were attributed to peptides 1−20, 4−20, and 11−20 of CETP 444 (see Table 2 for data related to the identifications).

(*15*). Early SPR technology was limited to detecting the capture of macromolecules, but refinements now make it possible to detect directly the binding of small molecules to immobilized proteins in many systems. Largely because of the availability of this technology, kinetic analyses of interactions between candidate drugs and their targets are an increasingly important aspect of drug discovery (*16*). Biosensors can now provide these analyses for a wide variety of targets beyond the classical cases of slow-binding enzyme inhibitors (*17*) and membrane-bound receptors. However, in some cases development of a method for direct biosensor kinetics is hindered by difficulties in obtaining stable and active immobilized protein or by problems associated with compound aggregation or compound binding to fluidics and reference surfaces. CETP and its inhibitors presented all of these of difficulties. (D. Cunningham, unpublished).

When direct kinetic biosensor methods are not possible, indirect inhibitor affinity data can sometimes be obtained from solution affinity experiments in which protein and ligand are mixed at various ligand concentrations and the mixtures are allowed to come to equilibrium. When the mixtures are injected over an immobilized ligand, the initial rate of protein binding to the immobilized ligand is proportional to the free (unliganded) protein concentration. For optimum results, the free protein must bind the immobilized compound to give a sufficiently robust signal when present in concentrations at or below the K_d for the competing inhibitor.

While immobilized small molecule approaches can circumvent the problems listed above, their use in SPR techniques has been limited due to the need to synthesize tagged ligands that retain useful receptor affinity when bound to SPR chips (for examples see *18–25*). In general, ligand development is an empirical process but it is aided greatly by the availability of direct structural information or compound series SAR. In the present examples we drew upon in-house (unpublished) SAR in the torcetrapib series which suggested that CETP could accommodate long linear spacer groups at the torcetrapib THQ 1 position. Thus compound **6a** was synthesized and found to exhibit an IC_{50} of 1.5 μM in a cholesteryl ester transfer assay (Table 1). The measured IC_{50} for torcetrapib in this assay is near 50 nM (*13*) indicating that **6a** suffers a 30-fold reduction in binding affinity for CETP, perhaps due to some unfavorable interactions with the protein. Nonetheless, low micromolar affinity was judged sufficient for further ligand development.

Hydrophilic spacers of different lengths were placed between biotin and the drug-like component to generate affinity ligands **8**, **9**, and **10**. In solution these ligands showed similar affinities for CETP as measured by the transfer assay but the length of the spacer arm proved to be critical for efficient CETP binding when immobilized. When the conjugates were bound to streptavidin, either on agarose matrices or biosensor surfaces, it was found that a 2.1 nm (extended length) polyethyleneglycol-based spacer was not long enough to reach the torcetrapib pocket in CETP (Figure 1). While both the 3.5 nm spacer of compound **9** and the 4.6 nm spacer of compound **10** were sufficient to allow binding to a biosensor surface, the 4.6 nm linker apparently allowed better access and provided the greatest CETP binding capacity. Preincubation of CETP with free torcetrapib analog prevented binding to immobilized **10** on a biosensor surface (Figure 2), suggesting that binding was specific and based on occupancy of the site that accommodates torcetrapib. Although the binding of CETP to the immobilized compound appeared to be complex (data not shown), a reasonable fit could be obtained using a simple 1:1 binding analysis. CETP bound to immobilized **10** with an affinity that was very similar to its affinity for **10** in solution (K_d = 0.3 μM, as compared to a transfer assay IC_{50} of 0.7 μM). This binding proved to be more than adequate for use in an affinity resin, where high immobilization densities and relatively low flow rates contribute to extensive rebinding, However, when **10** was immobilized in a biosensor for the solution affinity measurements for which it was designed, the signal was not robust at the low CETP concentrations required. This may have been in part due to variable losses of the hydrophobic CETP to instrument fluidics when injected at low concentrations.

The linker lengths reported in Table 1 are for fully extended *anti* conformations of all sp^3 hybridized linker atoms, but it is *gauche* conformations that predominate for polymers of ethylene

oxide (*26*). Dynamics simulation experiments performed on PEG-based linkers have shown that extended linker lengths are often overestimated and that the effective linker length of PEG linkers is probably 60−80% of that calculated here (*27*). Even taking this adjustment into account, the magnitude of the linker length dependence observed for compounds **8**, **9**, and **10** is still striking. One can rationalize this result by referring to the recently published crystal structure of CETP (*5*). The structure reveals a 6.0 nm long tunnel which traverses the length of the protein and binds two molecules of cholesteryl ester and two molecules of phospholipid. The tunnel can be accessed by either of two openings which allow entry and egress of lipid cargo molecules. The linker length data reported here support a model where torcetrapib affinity analogs enter through an opening and bind deep in the tunnel. When immobilized on an avidin support, the linker of **8** is not long enough to allow the tethered drug to reach the torcetrapib binding site (Figure 1 and Table 1). The lower CETP binding capacity observed for compound **9** relative to **10** may indicate that 3.5 nm linker length of **9** is near the minimum needed to access the torcetrapib binding site.

Despite this, the tethered torcetrapib analog proved quite valuable in another SPR application for surveying inhibitors of various chemotypes for evidence of binding either in the torcetrapib pocket or in distinct pockets (D. Cunningham, unpublished work). These experiments revealed that **14** blocks wild-type CETP binding to immobilized **10.** As **14** was thought to be a covalent inhibitor (*7*), it then became a convenient tool for the focus of the present study to locate primary sequence in proximity to the torcetrapib binding site. While a previous report provided indirect evidence for the involvement of Cys-13 in disulfide formation with a thioester closely related to **14**, the results presented demonstrated that **14** inactivates CETP by reacting with Cys-13. Mass spectrometry of the intact modified molecule demonstrated that **14** modified the simplified mutant CETP 444 with one-half-molecule of disulfide only, and peptide mapping after digestion with pepsin confirmed that the modified residue was Cys-13. Mutant CETP 444 so modified was inhibited for binding to immobilized torcetrapib analog, suggesting that torcetrapib also binds in the vicinity of Cys-13. The crystal structure of CETP (*5*) shows that indeed Cys-13 resides in the bottom of the N-terminal pocket that forms one end of the lipid-binding tunnel. This study shows that immobilized inhibitors can be useful probes in SPR even when the immobilized inhibitor has a relatively weak affinity for the target protein.

ACKNOWLEDGMENT

We are grateful to George Perkins for expert HRMS analyses.

Received May 5, 2008

Ion channel-forming peptides and proteins offer tremendous opportunities for fundamental and applied studies of function on individual molecules. An ongoing challenge in ion channel research is the lack of simple and accessible synthetic methods to engineer pores with tailored chemical and physical properties. This paper describes a practical synthetic route to rapidly generate C-terminally modified derivatives of gramicidin A (gA), an ion channel-forming peptide, through the use of two chemically reactive gA-based building blocks. These amine- and azide-containing building blocks can react readily with typical substrates for amidation and 1,3-dipolar cycloaddition ("click") reactions to present molecules with desired structure and functionality near the opening of a gA pore. These derivatives of gA are stable under typical aqueous conditions for ion channel recordings and retain characteristic single ion channel conductance properties in planar lipid bilayers. Additionally, the synthetic methods described here afford useful quantities of these gA derivatives in good purity and yield with minimal purification. We demonstrate that derivatives of gA can be used for studying, *in situ*, a change in conductance through a channel upon performing a "click" reaction on an azide moiety attached to the gA pore. We also demonstrate that these gA-based building blocks can be used to construct sensors for the recognition of specific protein−ligand binding interactions in solution. This widely accessible, enabling synthetic methodology represents a powerful new tool to study relationships between chemical structure and function on the single molecule level.

INTRODUCTION

Semisynthetic ion channels derived from natural peptides and proteins have gained increasing interest in recent years as functional nanotransducers that can amplify a signal through the transport of ions across a lipid bilayer membrane (*1–23*). Ion channels can conduct more than 10^3 ions per millisecond from a single channel opening event (*24*), making it possible to detect the ion conducting functional properties of individual supramolecular structures. This high gain amplification makes ion channels promising for fundamental studies of structure−function relationships on the single molecule level (*2–4, 25–35*) and for sensing applications (*9, 19, 36–42*). Among the most significant challenges for the development of ion channel-based probes is the lack of widely accessible, reliable, and cost-effective methods to modify these pores chemically with tailored functional groups (*43*). Here, we present a method to formally convert the C-terminal alcohol on gramicidin A (gA, **1**, a natural ion channel forming peptide) to a reactive amine or azide functionality in order to make gA readily accessible for facile and selective synthesis of ion channel-based molecular probes. We demonstrate that these two gA-based building blocks, which we call gramicidamine (**2**) and gramicidazide (**3**), are readily amenable to conventional synthetic derivatization to produce robust and active ion channels carrying tailored chemical functionality. Starting from these two building blocks, we introduce four additional, novel derivatives of gA and characterize them electrophysiologically on a single channel level. Additionally, we illustrate the usefulness of these reactive gA building blocks for development of ion channels that can be used for monitoring a "click" reaction, *in situ*, or for detecting a specific protein−ligand interaction in solution.

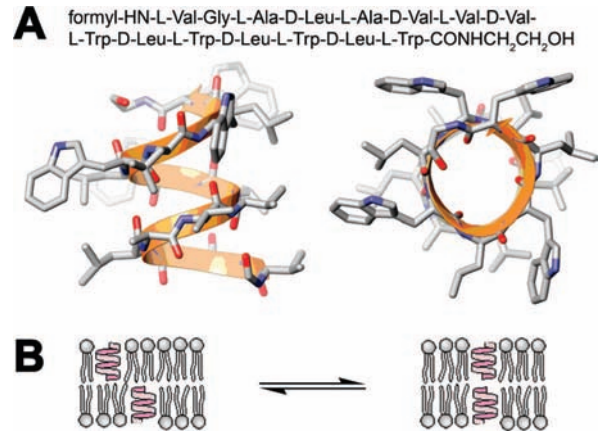

Figure 1. Cartoon showing the amino acid sequence and structure of a monomer of gramicidin A (gA) (adapted from the crystal structure of gA, 1GRM) and the reversible dimeric assembly of a gA pore in a lipid bilayer. (A) Sequence and helical structure (side view on the left and top view on the right) of gA. (B) Pore formation of gA: the reversible dimerization of two gA molecules at their N-termini via hydrogen-bonding produces an open pore that spans the lipid bilayer and conducts monovalent cations. This ion flux results in distinct and measurable conductance levels that are characteristic for certain derivatives of gA (*2, 4, 26, 43, 100, 101*).

Gramicidin A is a natural 15-amino-acid peptide (isolated from *Bacillus brevis*) that self-incorporates into lipid bilayers and facilitates a transmembrane flux of monovalent cations upon reversible head-to-head dimerization within a membrane (Figure 1). At least eight reasons make this peptide attractive as a practical molecular platform for the development of ion channel-based nanoprobes: (1) its ion conducting properties can measur-

ably amplify a signal by monitoring a flux of ions through a single pore; (2) its current levels are distinct and quantized, which facilitate the measurement of changes in conductance on a single pore level; (3) its C-terminus is conducive to derivatization without compromising function (*2, 3, 9–12, 44–48*); (4) its availability in gram quantities from commercial sources makes it possible to generate tailored derivatives on practical scales; (5) its self-incorporation into lipid bilayers makes its use straightforward as opposed to most ion channel proteins that require incorporation into bilayers through proteoliposome fusion (*49–52*); (6) its electrophysiological characteristics are well explored, which makes it an excellent model for fundamental biophysical studies of pores in membranes; (7) its size is nanoscale, which is conducive to miniaturized device designs and may enable parallel assays developed in a high density format; and (8) its activity is localized in a membrane, a property useful for applications where control of location is important.

Figure 1A shows the sequence and helical structure of gA. Gramicidin A reversibly dimerizes in a bilayer (Figure 1B), forming an N-terminus to N-terminus dimeric structure held together by a network of hydrogen bonds (*53–55*). The C-termini in these dimeric structures are exposed to the aqueous solutions on either side of a bilayer, and C-terminal modifications affect (but do not destroy) the conductance properties of the peptide (*3, 9, 10, 12, 17*).

To date, two major synthetic approaches to install modifications at the C-terminus of gA have been employed: solid phase peptide synthesis or direct functionalization of the C-terminal alcohol of native gA. Although solid phase peptide synthesis can afford small quantities of tailored gA derivatives (*12, 27, 56–60*), esterification or carbamoylation of the C-terminal alcohol of native gA has been the dominant reported synthetic approach for constructing gA-derivatives (*3, 9–11, 25, 44, 46*). This choice of synthetic approach is presumably due to simplicity, available equipment and facilities, and cost. The poor chemical reactivity of the C-terminal alcohol on native gA, however, restricts the use of native gA for construction of gA derivatives carrying tailored functionality (*60*).

In order to develop an improved method to generate C-terminally modified derivatives of gA, we developed a practical procedure to convert large quantities of native, commercial gA to gA-based building blocks carrying reactive C-terminal functional groups. We developed a protocol to generate these gA-based building blocks with the following five goals in mind: (1) the synthetic steps must afford desired products in good purity and yield, (2) the protocol must be amenable to conversion of commercial gA on a scale of at least 100 mg, (3) the protocol must not require any HPLC purification steps (to make these gA-based building blocks readily accessible to non-synthetic laboratories), (4) the new chemical functionality introduced on the C-terminus of gA must be readily amenable to selective and chemically stable conjugation, and (5) the new chemical functionality on the C-terminus must be as close to the opening of the pore as possible (a characteristic that is, for instance, important for charge-based sensing applications *9, 10*).

Within these design constraints, we describe here a practical synthetic procedure for preparing gramicidamine **2** and gramicidazide **3**. We used these building blocks to synthesize four novel derivatives of gA and characterized them functionally by single channel recordings. We confirmed that **2** and **3** are more reactive than native gA toward desired chemical derivatization. We also demonstrated the expected increased stability under conventional ion channel recording conditions of the amide and triazole groups generated from derivatization of **2** and **3** compared to previously reported ester linkages on gA (*9–11, 25*).

To highlight the engineered, selective reactivity of the azide group in **3**, we used single channel recordings to monitor, *in situ*, a "click" reaction between **3** and propargyl sulfonate under typical conditions for 1,3-dipolar cycloaddition reactions (*61*). In addition, we demonstrated an example of a biochemically relevant sensing application of a molecule derived from **3** that reports the interaction between a sulfonamide moiety and carbonic anhydrase. Finally, we confirmed specificity of this protein−ligand interaction by competitive displacement of a gA derivative carrying a sulfonamide (**11**) with 4-carboxybenzene sulfonamide.

EXPERIMENTAL PROCEDURES

Materials. We purchased all reagents and chemicals from Sigma-Aldrich unless otherwise stated. Gramicidin A (gA) was purchased as gramicidin D from Sigma Aldrich and purified by silica chromatography using a literature procedure (*62*) (to afford a final purity of 97% of gA). Carbonic anhydrase II (CA, bovine, EC 4.2.1.1) was from Sigma-Aldrich, Inc. We purchased 1,2-diphytanoyl-*sn*-glycero-3-phosphocholine (DiPhyPC) lipids from Avanti Polar Lipids, Inc. All analyses by HPLC were performed on an Agilent Zorbax C-18 column (4.6 μm × 25 cm) using a gradient of 60% to 100% MeOH in H_2O over 52 min (flow rate = 1 mL min^{-1}.

Synthesis of 2-Aminoethyl Gramicidate (4). Gramicidin A (142 mg, 75 μmol) was added to 10 mL of acetonitrile (ACN). Phosphorus oxychloride (287 μL, 3 mmol) was added dropwise to the solution of gA and the reaction was stirred at 23 °C for 4 h. The reaction mixture was concentrated to dryness and 10 mL of a 4:1 mixture of ACN/H_2O was added. The mixture was stirred for 20 min, concentrated to dryness, and dissolved in 5 mL of a 2:1 mixture of dichloromethane (DCM)/methanol (MeOH). This mixture was added dropwise to a stirred beaker containing 200 mL of H_2O. The resulting precipitate was collected by filtration. The crude yield was 96% by weight. The retention time by HPLC was 34.7 min. ESI-MS (*m*/*z*) calculated for $C_{99}H_{140}N_{20}O_{17}$ (M^+), 1882.07; found $(M-H)^-$, 1880.85.

Synthesis of *N*-Formyl-2-aminoethyl Gramicidate. Anhydrous formic acid (0.55 mL, 14.4 mmol) was combined with acetic anhydride (1.36 mL, 14.4 mmol) and heated to 65 °C for 30 min. After cooling the formic acid/acetic anhydride solution to 23 °C, the mixture was added to 2-aminoethyl gramicidate **4** (139 mg, 72 μmol) that was dissolved in 20 mL of dry tetrahydrofuran (THF). The reaction was stirred for 3.5 h followed by concentration to dryness. We dissolved the crude product in a minimal volume of a 2:1 mixture of DCM/MeOH at 23 °C (until the solution was clear) and added this solution dropwise to a stirred beaker containing 200 mL of H_2O. The resulting precipitate was collected by filtration and taken to the next step without further purification. Note: When performing these reactions on smaller scales (<100 mg of peptides), it is possible to isolate the product by silica chromatography using DCM/MeOH (9:1) as the eluent to afford *N*-formyl-2-aminoethyl gramicidate as a white powder in 72% isolated yield. ESI-MS (*m*/*z*) calculated for $C_{100}H_{140}N_{20}O_{18}$ (M^+), 1910.07; found $(M+Na)^+$, 1932.97.

Synthesis of Desethanolamine gA (5). The crude product of *N*-formyl-2-aminoethyl gramicidate (150 mg, 78 μmol) was dissolved in 25 mL of THF. In a separate flask, $LiOH \cdot H_2O$ (327 mg, 7.8 mmol) was dissolved in 25 mL of H_2O. The two mixtures were combined and stirred at 23 °C for 3 h, followed by slow addition of 1 M HCl until the solution had a pH of 2. The reaction mixture was concentrated *in vacuo* to dryness and redissolved in 15 mL of 2:1 DCM/MeOH. The mixture was added dropwise to 150 mL of H_2O while stirring. The resulting precipitate was collected by filtration and purified by silica chromatography. The eluent initially consisted of a mixture of $CHCl_3$/MeOH/H_2O:acetic acid (750:75:10:2.5) to elute the less-polar impurities. After confirming by thin layer chromatography

(TLC) that the impurities had eluted, the eluent was changed to $CHCl_3$/MeOH/H_2O/acetic acid (200:30:4:1). The fractions containing desethanolamine gA **5** were concentrated *in vacuo*, and the resulting gel was redissolved in 15 mL of 2:1 DCM/MeOH. The mixture was added dropwise to 150 mL of H_2O while stirring. The resulting precipitate was collected by filtration to yield 93 mg of **5** (65% yield over two steps from **4**). ESI-MS (*m*/*z*) calculated for $C_{97}H_{135}N_{19}O_{17}$ $(M)^+$, 1839.03; found $(M+Na)^+$, 1861.94. The retention time by HPLC was 40.7 min.

Synthesis of Gramicidamine (2). Desethanolamine gA **5** (25 mg, 13.6 μmol) and triethylamine (7.6 μL, 54.4 μmol) were added to 1 mL of anhydrous THF and the resulting mixture was stirred and cooled to 0 °C. After adding ethyl chloroformate (5.20 μL, 54.4 μmol) to the cooled mixture, the reaction was stirred for 3.5 h at 0 °C. Mono-*tert*-butyloxycarbonyl (BOC) ethylenediamine (8.6 μL, 54.4 μmol, purchased from Alfa Aesar) was dissolved in 0.2 mL of THF and cooled to 0 °C. This solution was added to the mixture containing desethanolamine gA **5** and the resulting solution was stirred for an additional 30 min at 0 °C, followed by stirring at 23 °C for 8 h. After concentrating to dryness, the BOC-protected gramicidamine was purified using preparative silica chromatography (using a 9:1 mixture of DCM/MeOH as eluent). ESI-MS (*m*/*z*) calculated for $C_{104}H_{149}N_{21}O_{18}$ (M^+), 1981.14; found $(M-H)^-$, 1979.66. A mixture containing 1 mL of DCM, 1 mL of trifluroacetic acid (TFA), 0.1 mL of dimethylsulfide, and 0.05 mL of ethanedithiol was prepared and cooled to 0 °C. BOC-protected gramicidamine (22.4 mg, 11.3 μmol) was dissolved in the cooled mixture. The reaction was allowed to warm up to 23 °C and stirred for 3 h. The reaction mixture was concentrated *in vacuo* to dryness and purified by silica chromatography. The eluent initially consisted of a mixture of DCM/MeOH (9:1) to elute the less-polar impurities. After confirming by thin layer chromatography (TLC) that the impurities had eluted, the eluent was changed to DCM/MeOH (9:2). HR-MS (*m*/*z*) calculated for $C_{99}H_{141}N_{21}O_{16}$ $(M+H)^+$, 1881.0937; found $(M+H)^+$, 1881.0943. The retention time by HPLC was 40.5 min. The overall yield was 74% (19 mg) from desethanolamine gA **5**.

Synthesis of 7. Gramicidamine **2** (1.2 mg, 0.64 μmol), (N-BOC-protected) glycine *N*-hydroxysuccinimidyl ester (0.52 mg, 2 μmol), and diisopropylethylamine (DIEA, 0.32 μL, 2 μmol) were dissolved in 0.4 mL of THF. The reaction was stirred for 14 h at 23 °C. The product was purified by HPLC. The isolated yield of **7** was 76%. The retention time by HPLC was 43.3 min. HR-MS (*m*/*z*) calculated for $C_{106}H_{152}N_{22}O_{19}$ $(M+H)^+$, 2038.1676; found $(M+H)^+$, 2038.1661.

Synthesis of 9. Gramicidamine **2** (1.2 mg, 0.64 μmol), 4-carboxybezenesulfonamide *N*-hydroxysuccinimidyl ester (0.57 mg, 2 μmol), and DIEA (0.32 μL, 2 μmol) were dissolved in 0.4 mL of THF. The reaction was stirred for 14 h at 23 °C. The product was purified by HPLC. The isolated yield of **9** was 41%. The retention time by HPLC was 37.6 min. HR-MS (*m*/*z*) calculated for $C_{106}H_{146}N_{22}O_{19}S$ $(M+H)^+$, 2064.0928; found $(M+H)^+$, 2064.1015.

Synthesis of Sodium Propargyl Sulfonate (*63*). Propargyl bromide (1 mL, 9 mmol), purchased from Acros Organics as a solution containing 80 wt % in toluene, and sodium sulfite (1.43 g, 11.35 mmol) were dissolved in 3.5 mL of H_2O and 3.5 mL of MeOH. The mixture was stirred for 7 h at 65 °C. MeOH (60 mL) was added and the resulting precipitate was filtered and removed. The filtrate was diluted in acetone and the resulting precipitate was collected as white crystals (1.3 g, 81% yield). ESI-MS (*m*/*z*) calculated for $C_3H_3O_3S$ $(M)^+$, 118.98; found $(M)^+$, 119.04. ^{1}H NMR (D_2O, 400 MHz): δ 3.849 (d, 2H, 1.4 Hz), 2.714 (t, 1H, 1.4 Hz).

Synthesis of 2-Azidoethylammonium Chloride (*64*). Sodium azide (236 mg, 3.6 mmol) and 2-bromoethylammonium bromide (200 mg, 0.98 mmol) were dissolved in 1 mL of H_2O. The reaction was refluxed at 95 °C for 1 h. After cooling the solution to 23 °C, 1 M NaOH was added to the solution until the pH was 12. The resulting 2-azidoethylammonium chloride was then co-distilled with H_2O, acidified to pH 4 with 1 M HCl, and lyophilized to provide 76 mg of product as a white powder (65% yield). ESI-MS (*m*/*z*) calculated for $C_2H_6N_4$ $(M)^+$, 86.06; found $(M+H)^+$, 86.99. ^{1}H NMR (D_2O, 400 MHz): δ 3.414 (t, 2H, 5.6 Hz), 3.301 (t, 2H, 5.6 Hz).

Synthesis of Gramicidazide (3). Desethanolamine gA **5** (20 mg, 10.8 μmol) and DIEA (7.6 μL, 43.4 μmol) were added to 2 mL of anhydrous THF and the resulting mixture was stirred and cooled to 0 °C. After adding ethyl chloroformate (4.6 μL, 43.4 μmol) to the cooled mixture, the reaction was stirred for 3.5 h at 0 °C. Separately, 2-azidoethylammonium chloride (5.3 mg, 43.4 μmol) was dissolved in 0.2 mL of 1 M NaOH and cooled to 0 °C. This solution was added to the mixture containing desethanolamine gA and the resulting solution was stirred for an additional 30 min at 0 °C and then at 23 °C for 8 h. After concentrating to dryness, the product was purified using preparative silica chromatography (using a mixture of 9:1 DCM/MeOH as eluent) to give 14.2 mg of **3** (69% yield). HR-MS (*m*/*z*) calculated for $C_{99}H_{139}N_{23}O_{16}$ $(M+H)^+$, 1907.0842; found $(M+H)^+$, 1907.0782. The retention time by HPLC was 42.4 min.

Synthesis of 10. Gramicidazide **3** (10 mg, 5.2 μmol) and sodium propargyl sulfonate (1.2 mg, 8.6 μmol) were dissolved in 2 mL of *tert*-butanol (t-BuOH). Sodium ascorbate (8.2 mg, 41.4 μmol) was dissolved in 0.5 mL of H_2O, and $CuSO_4 \cdot 5H_2O$ (2.6 mg, 10.4 μmol) was dissolved separately in 0.5 mL of H_2O. The solution of sodium ascorbate was added to the solution of gramicidazide **3**, followed by addition of the solution of $CuSO_4 \cdot 5H_2O$. The reaction was stirred at 23 °C for 14 h. The solution was then concentrated *in vacuo* and purified by HPLC to give 32% yield of **10**. The retention time by HPLC was 36.1 min. HR-MS (*m*/*z*) calculated for $C_{102}H_{143}N_{23}O_{19}S$ $(M-H)^-$, 2025.0578; found $(M-H)^-$, 2025.0512.

Synthesis of *N*-Propargyl-4-sulfamoylbenzamide (*65*). Propargyl amine (34 μL, 0.497 mmol) and 4-carboxybenzenesulfonamide (100 mg, 0.497 mmol) were dissolved in 2 mL of dry dimethylformamide. *N*-Hydroxybenzotriazole (44.7 mg, 0.33 mmol), *O*-(benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (188 mg, 0.497 mmol) and DIEA (79.4 μL, 0.497 mmol) were added in this order to the stirred solution. After 4 h, the solution was evaporated to dryness and 30 mL of ethylacetate was added. The solution was washed twice with 30 mL of H_2O and with 30 mL of brine, dried over Na_2SO_4, filtered, and concentrated to dryness. The compound was purified by column chromatography using a 1:4 mixture of DCM/ethyl acetate as eluent, affording 52 mg (44% yield) as a white solid. ^{1}H NMR (DMSO-d_6, 400 MHz): δ 9.148 (t, 1H, 5.6 Hz), 8.003 (d, 2H, 8.4 Hz), 7.902 (d, 2H, 8.4 Hz), 7.506 (s, 2H), 4.075 (m, 2H), 3.172 (t, 1H, 2.4 Hz).

Synthesis of 11. Gramicidazide **3** (1.5 mg, 0.79 μmol) and *N*-propargyl-4-sulfamoylbenzamide (0.30 mg, 1.26 μmol) was dissolved in 0.2 mL of *t*-BuOH. To the solution of **3**, a solution of sodium ascorbate (1.1 mg, 5.5 μmol) dissolved in 0.05 mL of H_2O was added, followed by addition of a solution of $CuSO_4 \cdot 5H_2O$ (700 μg, 2.8 μmol) dissolved in 0.05 mL of H_2O. The reaction was stirred for 3 days. The solution was then concentrated *in vacuo* and purified by HPLC to give an 88% yield of **11**. HR-MS (*m*/*z*) calculated for $C_{109}H_{149}N_{25}O_{19}S$ $(M+H)^+$, 2145.1254; found $(M+H)^+$, 2145.1216. The retention time by HPLC was 37.6 min.

Formation of Planar Lipid Bilayers. We formed most planar lipid bilayers by the "folding technique" (*10*). Briefly, we used a Teflon film (Eastern Scientific Inc., pore diameter

0.1−0.2 mm) that we pretreated on both sides of the pore with 2 μL of 5% (v/v) hexadecane in pentane. This film was mounted using vacuum grease (Dow Corning, high vacuum grease) to a custom-made Teflon chamber separating two buffer compartments each with a volume capacity of 4 mL (*66*). After addition of 1 mL of electrolyte (20 mM KCl buffered with 0.2 mM HEPES pH 7.4 or 140 mM KCl buffered with 10 mM phosphate pH 8.0) to each compartment, we spread lipids at the air−water interface of the electrolyte solution in both compartments (specifically, we added 5 μL from a 25 mg mL^{-1} solution of 1,2-diphytanoyl-*sn*-glycero-3-phosphatidylcholine, DiPhyPC, in pentane). Three additional milliliters of the same electrolyte solution were added to each compartment to raise the liquid level above the aperture in the Teflon film. We formed the bilayers on the pore of the Teflon film by aspirating the electrolyte solution into a 3 mL syringe, followed by dispensing the electrolyte solution back into each compartment. This cycle of raising and lowering the liquid levels was repeated until we obtained a bilayer that had a minimum capacitance of 70 pF and that was stable (i.e., no significant current fluctuations above the baseline noise level) at 100 mV of applied potential for at least 2 min.

Ion Channel Measurements. We performed single channel recordings in "voltage clamp mode" using Ag/AgCl pellet electrodes (Warner Instruments) in each compartment of the bilayer setup. Data acquisition and storage was carried out using custom software in combination with an EPC-7 patch clamp amplifier from Heka (set at a gain of 10 mV pA^{-1} and a filter cutoff frequency of 3 kHz). The data acquisition board for the amplifier was set to a sampling frequency of 15 kHz. All current traces shown in the figures were further filtered using a digital Gaussian low-pass filter with a cutoff frequency of 4 Hz.

We performed the analysis of the single channel current traces by computing histograms of the currents from the original current versus time traces with *ClampFit 9.2* software from Axon Instruments. From these histograms, we extracted the main current values by fitting a Gaussian function to the peaks in the histograms. All gramicidin molecules showed a predominant conductance and occasionally subconductance states (i.e., single channel currents that were smaller than the main current values). Single channel conductances reported in this paper always refer to the main conductance state (i.e., to the dominant peaks in the current histograms). All conductance values were obtained from the slopes of current versus voltage ($I-V$) curves taken at −75, −50, +50, and +75 mV.

Monitoring a 1,3-Dipolar Cycloaddition ("Click") Reaction *in Situ* Using Single Ion Channel Recordings. We added 3 μL (from a 100 ng mL^{-1} solution in ethanol) of **3** (to afford a final concentration of 40 pM of **3**) to each compartment of a bilayer setup containing as electrolyte 20 mM KCl and 0.2 mM HEPES buffer. Solutions of sodium ascorbate and sodium propargyl sulfonate were added to both compartments to bring the final concentration of each molecule to 2 mM. We added a solution of $CuSO_4 \cdot 5H_2O$ to each compartment to a final concentration of 0.5 mM. The final pH of this solution was 6.9. In order to facilitate the analysis of single ion channel traces, we kept the concentration of **3** low (40 pM) during the reaction to minimize the possibility for multichannel events (i.e., opening of two or more channels simultaneously). This strategy made it possible to observe measured currents that would frequently return to baseline (i.e., current steps separated by no observed channel events). Consequently, we observed a small number of events over time, and thus analyzed the data over a window of time rather than at specific time points. Events were recorded over time windows of 4−15, 90−104, and 150−165 min throughout the course of the reaction. The percent composition of **3** and **10** in the reaction mixture in each time window were estimated by manually counting the number of observed single ion channel events corresponding to the conductance of **3** or **10.** For the 4−15 min time window, we measured 26 total channel events. For the 90−105 and 150−165 min time windows, we recorded 15 total channel events. Since the number of total channel events from each time window was limited to 15−26 events, the reported percent of conversion of starting material to product are estimated values. The capacitance of the folded membranes throughout the course of these studies ranged 70−88 pF. The conductivities of the buffer before and after the reaction were 323 and 336 mS cm^{-1}, respectively.

Detection of Protein−Ligand Binding Interactions Using Ion Channel Measurements. We added 1 μL (from a 100 ng mL^{-1} solution in ethanol) of **11** (to afford a final concentration of 12 pM of **11**) to each compartment of a bilayer setup containing as electrolyte 140 mM KCl and 10 mM phosphate buffer (pH 8.0). The conductance was recorded at 100 mV. Upon addition of bovine carbonic anhydrase II (CA, EC 4.2.1.1) to the trans compartment to bring the final concentration of CA to 50 μM, the membrane broke and was refolded. We recorded the conductance through the refolded membrane for 40 min to ensure that the observed reduction of ion channel activity was due to the interaction of CA with **11**. We then added 4-carboxybenzenesulfonamide (to give a final concentration of 1.5 mM of inhibitor) to the trans compartment of the bilayer setup, and again observed that the membrane broke during this addition. After refolding the membrane, we rapidly observed (within 20 s of reestablishing a planar lipid bilayer) the reemergence of significant ion channel activity. The capacitance of all folded membranes throughout the course of these studies ranged from 84−88 pF.

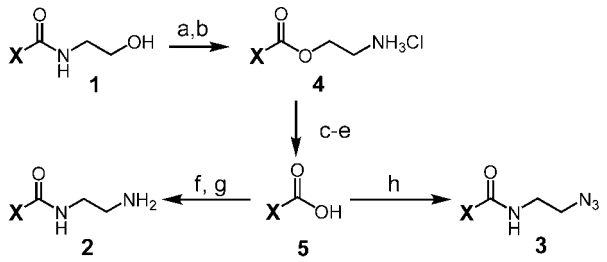
RESULTS AND DISCUSSION

Synthesis of Chemically Reactive Derivatives Gramicidamine 2 and Gramicidazide 3 from Native gA. In order to develop a general route to prepare functional molecular probes based on gA, we synthesized two derivatives of gA carrying chemically reactive groups on the C-terminus of the peptide. We envisioned that these reactive gA derivatives could be used as common building blocks for the synthesis of ion channels with tailored chemical functionality. One of these gA-based building blocks carried a reactive, primary amine functionality. Amines can be conjugated to readily synthesized or commercially available substrates that bear an activated ester group to form stable amide linkages (*67*). The other gA-based building block carried a C-terminal azide functionality on gA. Azides can be used as a reactive chemical group for conjugation to biomolecules due to the well-known reactivity of azides with terminal alkynes under mild conditions to furnish cycloaddition products in good yield (*61*).

To formally convert the C-terminal alcohol of native gA to an amine or azide functionality, we began with a strategy that removed the entire C-terminal ethanolamine residue of gA to afford desethanolamine gA (**5**, Scheme 1). To this end, we reacted native gA with excess $POCl_3$ to convert the C-terminal ethanolamine to a putative oxazoline intermediate, followed by treatment with H_2O in acetonitrile to afford the amino ester **4** (Scheme 1). To hydrolyze the ester in **4**, we reacted the primary amine in **4** with a formyl group (to prevent it from converting rapidly back to gA under alkaline conditions), and hydrolyzed the ester group of this *N*-formyl derivative of **4** with LiOH to give desethanolamine gA (**5**).[1] Finally, we reacted **5** with

[1]We improved on a previously reported procedure for the synthesis of **5** to afford this molecule in greater purity and with fewer purification steps compared to the original method (*J. Am. Chem. Soc.* **2007**, *129*, 9737−9745).

Scheme 1. Synthesis of Gramicidamine (2) and Gramicidazide (3)[a]



[a] (a) $POCl_3$, acetonitrile (ACN); (b) H_2O, ACN (96% yield, 2 steps); (c) acetic anhydride, formic acid, tertrahydrofuran (THF) (72% yield); (d) LiOH, H_2O, THF; (e) HCl, H_2O (65% yield, 2 steps); (f) $ClCO_2CH_2CH_3$ ($ClCO_2Et$), $N(CH_2CH_3)_3$ (NEt_3), dichloromethane (DCM) followed by *N-tert*-butyloxycarbonyl-ethylenediamine (N-BOC-ethylenediamine); (g) trifluoroacetic acid (TFA), ethanedithiol (EDT), dimethyl sulfide (Me_2S), DCM (74% yield, 2 steps); (h) $ClCO_2Et$, NEt_3, THF followed by 2-azidoethylammonium chloride, H_2O, NaOH (69% yield). All yields correspond to isolated yields.

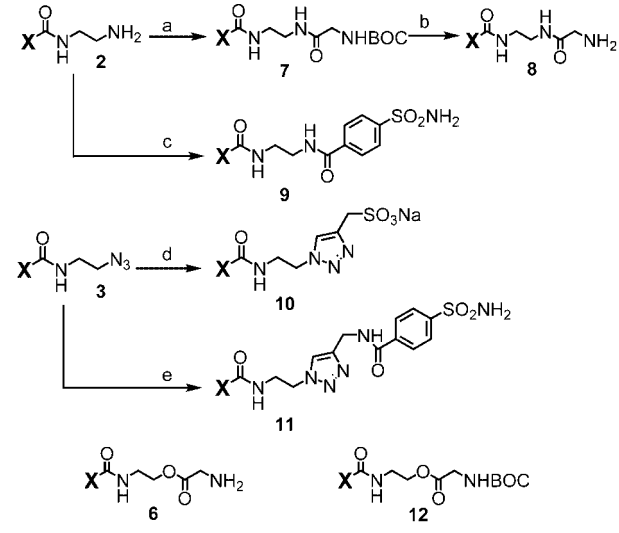
N-BOC-ethylenediamine (followed by acidic deprotection of the BOC group) to afford the desired gramicidamine **2** or with azidoethylammonium chloride to afford the desired gramicidazide **3**.

Although the overall yields of 48% for **2** and 45% for **3** from native gA are relatively modest, we were able to convert 150 mg of native gA to 38 mg of **2** and 28 mg of **3** in two days without the need for HPLC purification (the ability to work with gA derivatives at scales above 20 mg significantly facilitates the purification of intermediates and final products by precipitation and flash column chromatography, and therefore circumvents the need for HPLC purification). Furthermore, the purities of **2** (85%) and **3** (95%) obtained from these comparably (*9, 10*) large-scale preparations were sufficient to explore the synthetic utility of these gA-based building blocks for development of four additional, novel ion channel-based probes.

Chemical Reactivity of Gramicidamine 2 and Gramicidazide 3. In order to examine whether gramicidamine **2** and gramacidazide **3** can be readily derivatized using conventional chemical methods, we tested their chemical reactivity using a set of molecules that represent typical substrates for conjugation to amine or azide groups. For gramicidamine **2**, we examined the reactivity of the amine functionality with molecules containing activated ester groups. Scheme 2 shows that **2** reacts in good yield with the *N*-hydroxysuccinimidyl (NHS) ester of *N-tert*-butyloxycarbonyl-protected (BOC-protected) glycine and with the NHS ester of 4-sulfonamidobenzoate in the presence of diisopropylethylamine (as a base catalyst). We demonstrated in several organic solvents that these common amidation conditions afforded the expected products in good yield (here, demonstrated in the case of the NHS ester of BOC-protected glycine) (Table 1), suggesting that issues of substrate solubility, which are often problematic (*68*), should not limit the ability to synthesize desired gA derivatives. For comparison, we demonstrated that native gA had little to no reactivity with the NHS ester of BOC-protected glycine in the presence of a base catalyst in a variety of organic solvents (Table 1).

Although in a few examples we and others have succeeded in esterifying the C-terminal alcohol of native gA (*9–11, 25*), these ester derivatives of gA can have limited stability under typical aqueous conditions for ion channel measurements

Scheme 2. Synthesis of gA Derivatives from gA-Based Building Blocks 2 and 3 and the Structures of Two Ester Derivatives of gA (6 and 12) Derived from Native gA[a]



[a] (a) NHS ester of BOC-protected glycine, diisopropylethylamine (DIEA), THF; (b) TFA, Me_2S, EDT, DCM (62% yield over 2 steps); (c) NHS ester of 4-sulfonamidobenzoate, DIEA, THF (41% yield); (d) *N*-propargyl-4-sulfonamidobenzamide, $CuSO_4 \cdot 5H_2O$, sodium ascorbate, H_2O, *tert*-butanol (t-BuOH) (88% yield); (e) propargyl sulfonate, $CuSO_4 \cdot 5H_2O$, sodium ascorbate, H_2O, t-BuOH (32%).

(especially over a wide range of pH). To confirm the limited stability of ester derivatives of gA, we synthesized gramicidyl glycine (*9*) (**6**, Scheme 2) and tested its stability in acidic (pH 3.5) and in basic solutions (pH 10.4). In acidic solutions, we did not observe hydrolysis of the ester moiety of **6** after 24 h at 23 °C. We did, however, observe the expected complete hydrolysis of the ester of **6** after 3 h at 23 °C in the basic solution (as determined by HPLC analysis). For comparison, **8**, which was prepared using the method presented here and hence contained an amide linkage between the gramicidamine and a glycine group (Scheme 2) as opposed to the ester in **6**, was stable toward hydrolysis under acidic (pH 3.4) and basic (pH 10.4) conditions over a period of 24 h at 23 °C. These results highlight two important advantages of molecules derived from **2**: first, the synthetic route to molecules derived from **2** is simplified and proceeds in reasonable yield compared to molecules derived from native gA (*44*), and second, the stability of molecules derived from **2** in aqueous solutions extends the range of applications of ion channel-based probes compared to ion channels generated through direct esterification of native gA.

In addition to synthesizing gramicidamine (**2**) for direct comparison of reactivity and stability with gA, we synthesized gramicidazide (**3**) containing an azide group that is expected to have orthogonal reactivity to the C-terminal alcohol in native gA or the C-terminal amine in gramicidamine (**2**). Since organic azides undergo 1,3-dipolar cycloaddition reactions with terminal alkynes under mild conditions in water (*61*), we tested the reactivity of gramicidazide (**3**) with propargyl sulfonate and *N*-propargyl-4-sulfamoylbenzamide as representatives of typical, terminal alkyne substrates (Scheme 2). As expected, reaction of **3** with these two alkyne susbtrates in the presence of Cu^I as metal catalyst afforded triazole cycloaddition products **10** and **11** in modest to good yield (Table 1). These yields are in agreement with similar "click" reactions under comparable experimental conditions (*61*). We confirmed, as expected, that the triazole linkage in **10** resulting from conjugation of the

Table 1. Summary of Reactions of Native gA (1), Gramicidamine (2), And Gramicidazide (3) with Molecules That Represent Typical Substrates for Conjugation to Amines and Azides

[a] The concentration of **1** and **2** was 1.6 mM in all cases. The concentration of **3** was 1.7 mM when reacted with sodium propargyl sulfonate and 2.6 mM when reacted with *N*-propargyl-4-sulfamoylbenzamide. [b] All reactions with **1** and **2** contained 1.5 equiv of diisopropylethylamine (DIEA) and 2 equiv of the NHS ester. The reaction between **3** and sodium propargyl sulfonate contained 8 equiv of sodium ascorbate, 3 equiv of $CuSO_4 \cdot 5H_2O$, and 1.6 equiv of sodium propargyl sulfonate. The reaction between **3** and *N*-propargyl-4-sulfamoylbenzamide contained 7 equiv of sodium ascorbate, 3.5 equiv of $CuSO_4 \cdot 5H_2O$, and 1.6 equiv of *N*-propargyl-4-sulfamoylbenzamide. [c] NHS = *N*-hydroxysuccinimidyl. [d] The solvent was a 2:1 mixture of t-BuOH:H_2O. [e] Yields were determined by HPLC.

terminal alkyne to gramicidazide is stable to acidic (pH 3.4) and basic (pH 10.4) solutions over a period of 24 h at 23 °C.

In order to demonstrate that molecules derived from **2** and **3** retained their activity as functional ion channels, we measured the single channel conductance of **2**, **3**, **7**, and **9**−**11** in planar lipid bilayers. Figure 2 shows representative single channel traces of current versus time of these gA derivatives under an applied potential of 100 mV. These current recordings illustrate that **2** and **3**, as well as derivatives generated from **2** and **3**, all retained well-defined ion channel activity.

Monitoring a "Click" Reaction *in Situ* Using Single Ion Channel Recordings. We recently reported that chemical analytes that react with (and change the charge of) functional groups attached to the opening of a gA pore can be detected using single ion channel recordings (*9, 10*). Here, we use conductance measurements to highlight the reactivity of the azide group of **3** toward reaction with terminal alkynes in the presence of a Cu^I catalyst and to demonstrate the capability to follow the course of this chemical reaction on individual pores. We used single ion channel conductance measurements to monitor, *in situ*, the conversion of the azide group in **3** to a negatively charged triazole cycloaddition product **10** (Figure 3). Since we (*10*) and others (*25, 56*) have previously shown that derivatives of gA carrying a negative charge near the opening of the pore have increased conductance compared to uncharged derivatives of gA (under conditions of low ionic strength in the recording electrolyte (*10*)), we expected the product of cycloaddition **10** to have a larger conductance than **3**. Measurement of the conductance of pure samples of **10** and **3** confirmed this prediction, indicating a single channel conductance (γ) of 4.3 ± 0.1 pS for **10** and 3.3 ± 0.1 pS for **3** under the recording conditions used to monitor the cycloaddition reaction shown in Figure 3. By making the simplifying assumption that **3** and **10** distribute equally between the bilayer and the aqueous media, we can use the difference in conductance between **3** and **10** to estimate the relative conversion of starting material **3** to product **10** throughout the course of the reaction (Figure 3).[2]

We added **3** to a final concentration of 40 pM to both 4 mL chambers of a stirred lipid bilayer setup comprised of zwitterionic 1,2-diphytanoyl-*sn*-glycero-3-phosphatidylcholine (DiPhyPC) lipids that separated two compartments containing 20 mM KCl, 0.2 mM HEPES buffer, 2 mM sodium ascorbate (as a reducing agent for Cu^{II}), and 2 mM propargyl sulfonate. The final pH of this solution was 6.9. We added $CuSO_4$ (to give a final concentration of Cu^{II} of 0.5 mM) to both chambers of the bilayer setup and recorded the single ion channel activity over time. Although we added the substrate and catalyst to both chambers of the bilayer setup, we previously showed that only changes in the chemical properties of molecules attached near the *entrance* of the pore (and not the *exit* of the pore) affect the conductance through gA-based ion channels (*3, 10*). Since we monitored this cycloaddition reaction at a constant applied potential of +75 mV, these experiments only revealed the chemical reactions on **3** occurring on the positively polarized side of the membrane (which represents the *entrance* of the pore). The table in Figure 3 summarizes the results from ion channel conductance measurements throughout the course of this reaction. When we analyzed the conductance values from ion channel events in a time window from the fourth to 15th minute after the start of the reaction, we observed that approximately 20% of the ion channel events corresponded to an ion channel with conductance value significantly higher than **3**, which we attribute to the presence of product **10.** Measurement of ion channel events over a window of time between 90−104 min of incubation revealed that the reaction between **3** and propargyl sulfonate had proceeded to give approximately 60% product. Analysis of the channel events from the reaction mixture between 150−165 min showed the same ratio of product **10** to starting material **3** as observed in the time window 90−104 min, suggesting the reaction was complete after ∼90 min. Although these reaction conditions were not optimized for this 1,3-dipolar cycloaddition reaction (*69, 70*), these results illustrate the utility of tailored gA derivatives for monitoring the progress of synthetic reactions using single ion channel conductance measurements.

Design and Synthesis of an Ion Channel-Based Sensor for Detection of Protein−**Ligand Interactions.** In order to illustrate the synthetic utility of gA-based building blocks **2** and **3** for construction of ion channel-based sensors, we carried out a proof-of-principle study for the detection of a protein−ligand interaction using ion channel recordings. In Scheme 2, we show that molecules **2** and **3** can be used to synthesize gA derivatives **9** and **11**, which both carry benzenesulfonamide moieties. Benzenesulfonamides are well-known ligands for carbonic anhydrase II (CA, EC 4.2.1.1), a Zn^{2+}-containing protein (*71–78*).

[2]This assumption is very rough since we would expect the negatively charged product **10** to partition significantly less in the membrane due its increased solubility in water compared to the neutrally "charged" starting material **3**. The yields shown in Figure 3B are, therefore, likely to be an underestimate due to the likely difference in partitioning between **3** and **10** in the membrane.

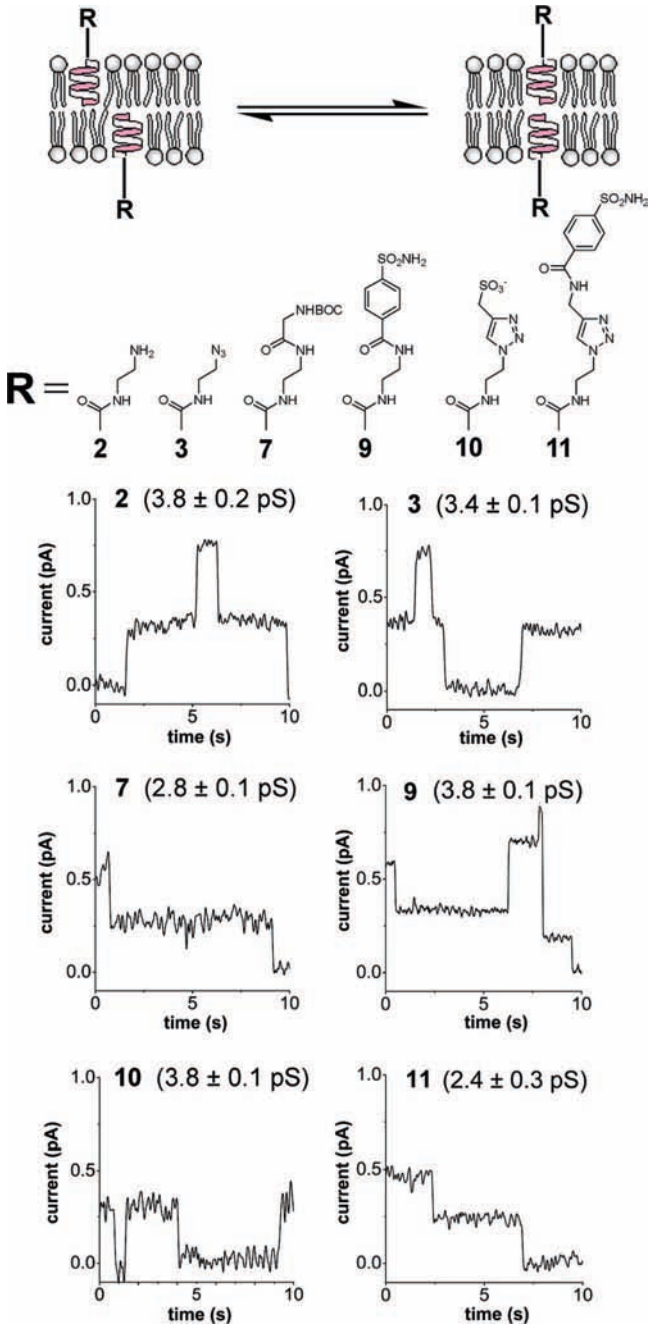

Figure 2. Cartoon illustrating the reversible dimerization of six different derivatives of gA (**2**, **3**, **7**, **9**−**11**) and original single channel traces of current versus time of all six derivatives. The applied potential was 100 mV and the electrolyte solution contained 20 mM KCl and 0.2 mM HEPES (pH 7.4) in all experiments. The conductance values (listed on top of every current trace) were determined from the slopes of current versus voltage (*I*−*V*) curves. The traces shown here were selected for clarity. Complete analysis of traces over long periods of time showed occasional subconductance states (shown here, for example, in the case of **9**). Conductance values are mean values determined from linear best fits of the *I*−*V* curves of the main conductance states in the linear range from −75 mV to +75 mV. All current traces were filtered with an analogue filter with a cutoff frequency of 3 kHz followed by filtering with a digital Gaussian filter with a cutoff frequency of 4 Hz.

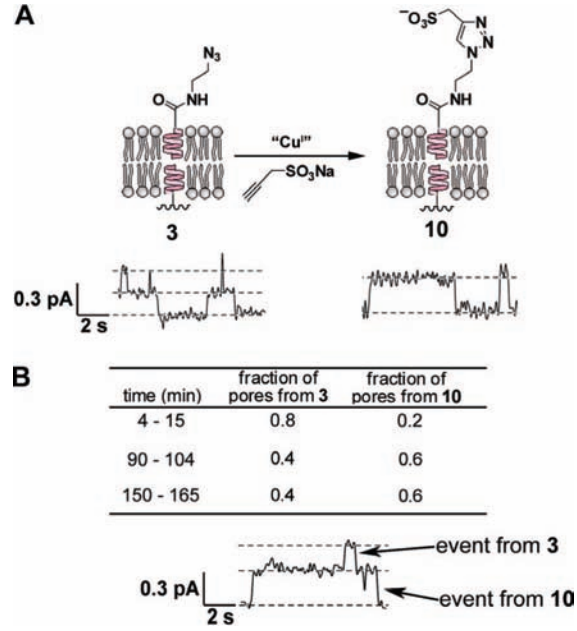

Figure 3. Conversion of gramicidazide **3** to a negatively charged triazole sulfonate **10**. (A) Cartoon of ion channels comprised of **3** and **10** in a membrane and their corresponding single ion channel conductance traces. As expected, the single channel conductance of **10** (4.3 ± 0.1 pS) was larger than the single channel conductance of **3** (3.3 ± 0.1 pS) when measured in low ionic strength recording media. (B) The table indicates the fraction of observed ion channel events that corresponded to the starting material (gramicidazide **3**) and the product of the reaction (triazole sulfonate **10**) over time windows 4−15, 90−104, and 150−165 min throughout the course of the reaction. The current versus time trace in B shows a time window during the course of the reaction where an ion channel event from **3** occured at the same time as an ion channel event from **10**. All current versus time traces were generated at an applied voltage of +75 mV in recording media containing 20 mM KCl, 0.2 mM HEPES (pH 7.4), 2 mM sodium ascorbate, 2 mM propargyl sulfonate, and 0.5 mM $CuSO_4$. The pH of the solution was 6.9. The initial concentration of **3** was 40 pM. Note: the single channel conductances of **3** and **10** are different from conductances reported in Figure 2 due to the differences in the recording buffer.

We, therefore, examined whether a derivative of gA carrying a benzenesulfonamide group could be used to detect the presence of CA in solution. In previous work, Cornell (*11*), Antonenko (*48*, *79*), and Futaki (*12*) showed the use of biotinylated derivatives of gA to detect streptavidin or an anti-biotin antibody. Here, we demonstrate that gramicidazide **3** makes it possible to expand the scope of biological interactions that can be explored using ion channel measurements by focusing on a protein−ligand interaction with a binding constant that is typically found in biology ($K_d = 10^{-6}$−10^{-9} M) such as the association of CA with a benzenesulfonamide ligand (*80*).

Figure 4A shows the conductance of multiple, simultaneous openings of pores of **11** (at a concentration of 12 pM) in a bilayer made from DiPhyPC lipids. Upon addition of CA to one side of the bilayer to give a final concentration of CA of 50 μM, we observed nearly complete suppression of ion channel activity (Figure 4B). Since the K_d for binding of benzenesulfonamides to CA can range from 10^{-6} to 10^{-9} M (*80*), it is reasonable to expect that a significant fraction of **11** would be associated with CA at these concentrations of protein and gA derivative. Two potential mechanisms can explain the decrease in observed channel activity upon binding of CA to **11** (*43*): (1) CA may have associated with **11** and caused the CA-bound **11** to partition less in the membrane compared to **11** alone (i.e., binding of CA may have extracted **11** from the bilayer), or (2) CA may have associated with membrane-bound **11** and sterically blocked ions from entering or exiting the channel (Figure 4B). Both mechanisms would result in the observed strong reduction in channel activity and they may act in parallel.

To test whether the observed strong reduction in ion channel activity shown in Figure 4B was indeed due to a specific and reversible protein−ligand binding event, we added an excess of a competitive inhibitor, 4-carboxybenzenesulfonamide, to the

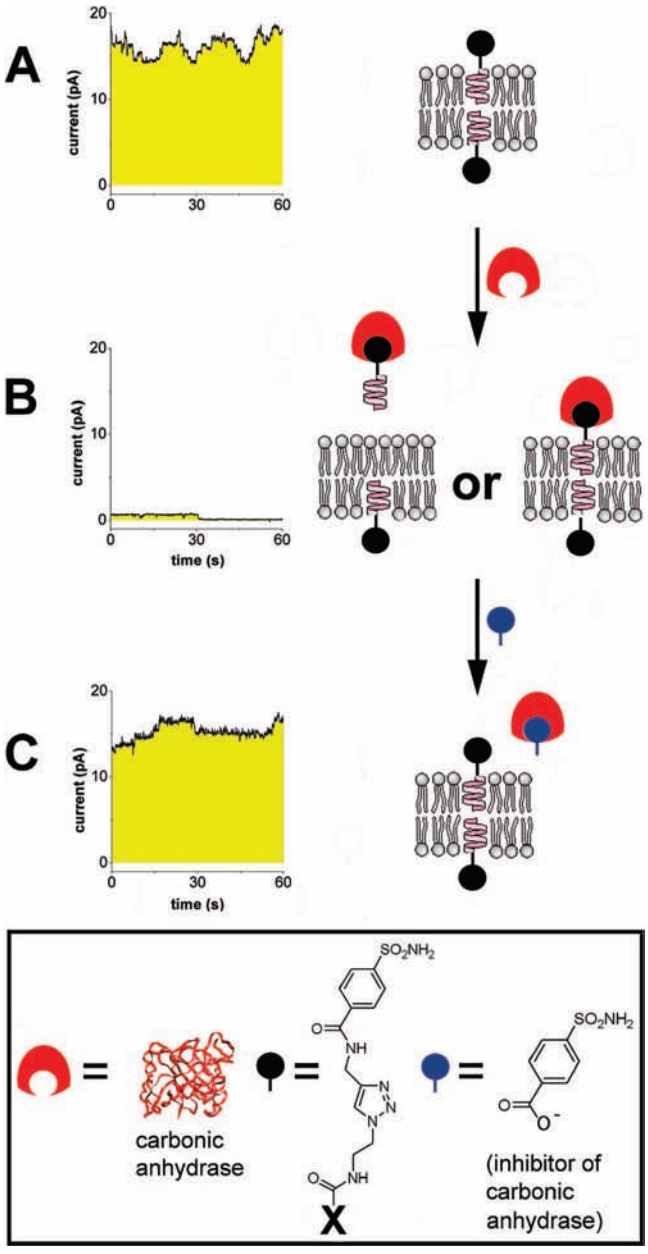

Figure 4. Detection of carbonic anhydrase (CA) with gA derivative **11**. (A) Cartoon of two molecules of **11** that dimerize to form an open pore across a membrane. The accompanying current versus time trace shows the conductance of multiple, simultaneous opening events in the membrane. (B) Binding of gA-sulfonamide **11** by CA almost completely abolished the observed transmembrane ion flux through **11**. This dramatic reduction in observed conductance could be caused either by extraction of the gA derivative from the bilayer upon binding to CA or by steric blockage of the pores by CA. (C) Addition of a competitive inhibitor of CA (4-carboxybenzenesulfonamide) restored ion channel activity and hence demonstrated specificity of binding of **11** to CA. The recording electrolyte contained 140 mM KCl and 10 mM phosphate buffer (pH 8.0). The current traces were recorded at 100 mV. **X** = HCO-Val-Gly-Ala-Leu-Ala-Val-Val-Trp-Leu-Trp-Leu-Trp-Leu-Trp-.

aqueous solution to displace **11** from CA. Upon addition of the competitive inhibitor, we observed a rapid restoration (within 20 s) of ion channel activity (Figure 4C), confirming the specificity of the interaction between CA and **11**. These results illustrate the utility of gA-based building blocks **2** and **3** for constructing specific and sensitive nanoprobes for fundamental studies of protein−ligand interactions in membranes as well as for sensing applications.

In conclusion, this paper demonstrates a practical method to synthesize chemically reactive gA-based building blocks from commercially available native gA. These amine- and azide-containing building blocks can be used to rapidly generate stable, C-terminally modified derivatives of gA that retain single channel conductance properties, and can, therefore, serve as an enabling tool for basic and applied studies on ion channels. For instance, these gA-based building blocks make it possible to tune the chemical and physical properties at the opening of the pore, which is useful for basic biophysical studies of ion channels on the single molecule level (*1*, *25*, *31*, *81*–*86*). These synthetic methods also make it possible to rapidly gain access to derivatives of gA for sensing applications, where changes in the ion flux through gA derivatives in response to a specific external stimulus can be detected using ion channel conductance measurements (*9*, *11*, *12*, *44*, *60*, *87*, *88*). Recent advances in bilayer recording technology and microfabrication (*66*, *89*–*98*) address many of the non-synthetic challenges that have also previously limited studies on ion channels such as limited mechanical stability of membranes (*6*, *19*, *66*, *89*, *99*) and poor signal-to-noise ratios for conductance measurements (*66*). A convenient and general synthetic procedure to rapidly produce gA derivatives that display specific chemical functionality, along with the availability of improved and increasingly automated commercial planar lipid bilayer setups, could make such fundamental and applied studies on ion channels accessible to a broad scientific community.

Acetal Linked Oligoethylenimines for Use As pH-Sensitive Gene Carriers

Veronika Knorr,[†,‡] Verena Russ,[†,‡] Lars Allmendinger,[§] Manfred Ogris,[†,‡] and Ernst Wagner*[,†,‡]

Pharmaceutical Biology - Biotechnology and Pharmaceutical Chemistry, Department of Pharmacy Ludwig-Maximilians-Universität München, Butenandtstr. 5-13, D-81377 Munich, Germany. Received May 7, 2008; Revised Manuscript Received June 7, 2008

Two types of acid-degradable nonviral gene carriers, OEI-MK and OEI-BAA, were synthesized by polymerizing oligoethylenimine of 800 Da (OEI800) with the pH-sensitive acetone ketal cross-linker 2,2-bis(*N*-maleimidoethyloxy) propane (MK) or the 4-methoxybenzaldehyde bisacrylate acetal cross-linker 1,1-bis-(2-acryloyloxy ethoxy)-[4-methoxy-phenyl]methane) (BAA). Corresponding acid-insensitive counterparts (OEI-BM and LT-OEI-HD) were synthesized as well, representing control polymers. Kinetics of hydrolysis were measured and confirmed the pH-dependent degradation profile of the acetal functions, with short half-lives of 3 min at pH 5.0, and 5 h (OEI-MK) or 3.5 h (OEI-BAA) at physiological pH 7.4 and 37 °C. DNA polyplexes of a luciferase expression plasmid were tested for gene transfer efficiency and biocompatibility in two cell lines (B16F10 and Neuro2A). Polyplexes with acid-labile polymers showed an improved toxicity profile compared to those made with acid-stable polymer analogues. At low cation/plasmid (c/p) w/w ratios the transfection efficiency of pH-sensitive polymers was slightly reduced, but it became similar or superior to the efficiency of acid-stable polymers at higher c/p ratios. An improved *in vivo* biocompatibility of the acid-degradable polymers over the stable control polymers was confirmed by liver histology after systemic administration of polymers in Balb/c mice.

INTRODUCTION

The design of vectors that mediate gene transfer efficiently but do not cause appreciable toxic side-effects is still a major challenge in the field of nonviral gene delivery. High transfection efficiency is almost always associated with high vector toxicity. For example, polyethylenimines (PEI) of molecular weight around 22−25 kDa mediate gene transfer very effectively (*1*, *2*) but cause considerable toxic effects (*3*, *4*) and are not degradable into small excretable degradation products. In contrast, shorter polyethylenimines such as 800 Da OEI possess just negligible toxicity, but exhibit only very poor gene transfer capacity. Therefore, one approach toward safer vectors designs biodegradable polycations of adequate sizes, which allow gene transfer as effective as their stable PEI counterparts, but with time or upon a specific stimulus, decompose into nontoxic degradation products. Researchers have inserted diverse degradable functions into their polymers, including disulfide bonds (*5–9*), ester bonds (*6*, *10–12*), imines (*13*), or phosphoesters (*14*, *15*).[1]

In the current work, we focused on developing gene carriers containing acid cleavable acetal functions. Acetal groups have already been introduced into polymers (*16*, *17*) to allow triggered degradation at a slightly acidic pH such as the endosomal pH. Thus, drug carriers can be produced that are sufficient stable at physiological pH of 7.4 to mediate efficient drug delivery to the target cell. Upon endocytosis, degradation of the acid-sensitive polymeric carriers in the maturing and acidifying endosome should result in small decomposition products with enhanced biocompatibility. In this article we present the synthesis and characterization of two acetal linked polymer types: OEI-MK is generated from 800 Da oligoethylenimine (OEI) and 2,2-bis(*N*-maleimidoethyloxy) propane (MK) as pH-sensitive ketal linker (*18*), and OEI-BAA is synthesized from OEI and the 1,1-bis (2-acryloyloxy ethoxy)-[4-methoxy-phenyl]methane) (BAA) linker (*19*). To investigate a possible advantage of the pH sensitivity, the pH-labile polymers were compared with homologous acid-insensitive polymers OEI-BM and LT-OEI-HD, with the acid-sensitive functions being replaced by a stable ether or a hydrocarbon moiety, respectively.

EXPERIMENTAL SECTION

Chemicals and Reagents. Dimethylsulfoxide purissimum (DMSO) and dichloromethane purissimum (DCM) were obtained from Fluka (Fluka Chemie GmbH, Deisenhofen, Germany). Acetone and *n*-heptane were distilled prior to use. Oligoethylenimine with an average molecular mass of 800 Da (OEI800), branched PEIs with average molecular weights of 2, 10, 25, and 50 kDa (PEI2K, PEI10K, PEI25K, PEI50K), 1,6-hexanediol diacrylate (HD), *p*-methoxybenzaldehyde, 2-hydroxyethyl acrylate, *p*-toluene sulfonic acid, and triethylamine (TEA) were purchased from Sigma-Aldrich (Munich, Germany). 1,8-Bis-maleimidodiethyleneglycol (BM) was purchased from

Pierce Biotechnology, Inc., Rockford, USA. 2,2-Bis(*N*-maleimidoethyloxy) propane (MK) can be synthesized as described (*18*) and was purchased from Organix Inc., Woburn, Massachusetts, USA. 1,1-Bis-(2-acryloyloxy ethoxy)-[4-methoxyphenyl]methane) (BAA) was synthesized as described (*19*). The resulting crude product was purified by flash column chromatography on silica gel equilibrated with the eluent (*n*-heptane/acetone 8.2/1.8 + 1% TEA) and BAA was obtained as a colorless oil with 100% purity as confirmed by ^{1}H NMR. Linear PEI of 22 kDa (PEI22K) was synthesized by acid-catalyzed deprotection of poly(2-ethyl-2-oxazoline) (50 kDa, Aldrich) in analogous form as described in ref (*20*). Superdex 75 preparative grade and Superdex 200 preparative grade were obtained from GE Healthcare Europe GmbH (Freiburg, Germany). Cell culture media, antibiotics, and fetal calf serum (FCS) were purchased from Life Technologies (Karlsruhe, Germany). Plasmid pCMVLuc (*Photinus pyralis* luciferase under control of the CMV enhancer/promoter) described in ref (*21*) was purified with the EndoFree Plasmid Kit from Qiagen (Hilden, Germany). Dialysis was performed with Spectra/Por membranes (molecular mass cutoff 3.5 kDa; Spectrum Laboratories Inc., Rancho Dominguez, CA, USA) at 4 °C. Water was used as purified, deionized water. Silica gel column chromatography was performed on silica gel 60 Å (35−70 μm) from Acros (Acros Organics, Geel, Belgium). Infrared spectra were recorded on a Jasco FT/IR-410 spectrometer (Jasco Labor und Datentechnik GmbH, Germany). ^{1}H NMR spectra were recorded on a Jeol JNMR-GX400 (400 MHz) or a Jeol JNMR-GX500 (500 MHz) spectrometer. Chemical shifts are reported in ppm; data are reported as s = singlet, d = doublet, t = triplet, m = multiplet; br = broad.

Synthesis of pH-Stable Polymer OEI-BM. BM (15.4 mg; 50 mg/mL in anhydrous DMSO) was added dropwise and under vortexing to OEI800 (40 mg; 400 mg/mL in anhydrous DMSO) and reacted for 22 h at 22 °C under constant shaking. Prior to purification, the reaction mixture was diluted 1:4 with 1 M Hepes buffer pH 7.5 containing 4 M sodium chloride. Dialysis was carried out at 4 °C in 20 mM Hepes buffer pH 7.5 containing 0.25 M sodium chloride using a Spectra/Por membrane (molecular mass cutoff 3.5 kDa). After 4 h, the buffer was exchanged against water; water was then replaced twice by fresh water. After a total dialysis duration of 26 h, the purified product was lyophilized (yield 48%) and stored at −80 °C in dry form. According to NMR analysis, the molar ratio of BM to OEI800 in the product was 1.3/1.

^{1}H NMR (500 MHz, D_2O): δ = 3.77 (t, 4H, NCH_2CH_2O), 3.69 (s, 4H, OCH_2CH_2O linker ethylene), 3.64 (t, 2H, COCHCH_2 of linker succinimide), 3.59−2.35 (br m; 72H NCH_2 of OEI ethylenes; 4H NCH_2CH_2O of linker ethylenes and 4H COCH_2CH of linker succinimide).

Synthesis of Acid-Degradable Polymer OEI-MK. MK (16.1 mg; 50 mg/mL in anhydrous DMSO) was added dropwise under vortexing to OEI800 (40 mg; 400 mg/mL in anhydrous DMSO) and the mixture was reacted for 22 h at 22 °C while shaking constantly. Purification and lyophilization were performed as indicated above for OEI-BM (yield 40%). The dry polymer was stored at −80 °C. According to NMR analysis the molar ratio of MK-linker versus acetone ketal versus OEI800 in the product was 1.03/0.93/1.

^{1}H NMR (400 MHz, D_2O): δ = 3.75 (t, 4H, OCH_2), 3.72−2.30 (br m; 72H NCH_2 of OEI ethylenes; 10H NCH_2 of linker ethylene and COCHCH_2 of linker succinimide), 1.45−1.25 (m, 6H, CH_3 linker of acetone ketal).

Synthesis of Acid-Degradable Polymers OEI-BAA. BAA (14 mg at 50 mg/mL in anhydrous DMSO for the synthesis of OEI-BAA-1 polymers, 28 mg at 50 mg/mL for the synthesis of OEI-BAA-2, or 17.5 mg at 500 mg/mL for the synthesis of BAA-1.25) was added dropwise under vortexing to OEI800 (32 mg; 400 mg/mL in anhydrous DMSO) and reacted for 3 days (OEI-BAA-1−3d, OEI-BAA-2−3d), 1.5 days (OEI-BAA-1−1.5d) or 45 min (OEI-BAA-1−45m, OEI-BAA-1.25−45m) at 22 °C with constant shaking. Purification and lyophilization were performed as indicated above for OEI-BM, with the difference that total dialysis duration at 4 °C was only 15 h to prevent degradation. The yields were 40%, 56%, and 70% in the cases of OEI-BAA-1−3d, −1.5d, and 1−45m, respectively; 50% yield in the case of OEI-BAA-2−3d; and 58% in the case of OEI-BAA-1.25−45m. Polymers were stored at −80 °C. According to NMR analysis the molar BAA/OEI800 ratios and the content of intact diester in the products were 0.3/1 and 26% for (OEI-BAA-1−3d), and 0.7/1 and 26% for OEI-BAA-2−3d. Reduction of reaction time (to 1.5 days or 45 min) increased intact BAA incorporation, providing a 0.4/1 BAA/OEI ratio with a 40% diester content for OEI-BAA-1/1−1.5d, a 0.44/1 ratio with 75% diester for OEI-BAA-1−45m, and a 0.56/1 ratio with 60% diester for OEI-BAA-1.25−45m.

^{1}H NMR (400 MHz, D_2O): δ = 7.50−7.37 (m, 2H, CHCHCOCH$_3$ of aromatic ring), 7.08−6.96 (m, 2H, CHCOCH$_3$ of aromatic ring), 5.68−5.53 (m; 1H, acetal H), 4.35−4.28 (m, COOCH_2; 2H, monoester* or 4H, diester), 4.00−2.30 (br m; 72H, NCH_2 of OEI ethylenes; 3H, OCH_3; 4H, OCH_2CH$_2$OCO; 2H, OCH$_2$CH_2OH*; 8H, OOCCH_2CH_2 and NOCCH_2CH_2*). (*Due to partial ester aminolysis, resulting in corresponding alcohol and the carboxamide).

Analysis of the Kinetics of Aminolysis by ^{1}H NMR. Synthesis of OEI-BAA-1 was performed analogously as indicated above in DMSO-d_6. The reaction mixture was analyzed by ^{1}H NMR at different time points between 0.5 h and 24 d. The degree of aminolysis was calculated by analyzing the signal of the acetal proton at 5.5 ppm, which is shifted toward the higher field when aminolysis occurs.

Synthesis of LT-OEI-HD Polymer. Synthesis of LT-OEI-HD was performed following the protocol of Kloeckner et al. (*22*). HD-linker and OEI800 were employed in the synthesis at a molar ratio of 1.2/1 (HD/OEI800) in anhydrous DMSO at 22 °C. After purification by dialysis at 4 °C using a 3.5 kDa molecular mass cutoff membrane and freeze-drying, LT-OEI-HD was obtained in 65% yield. As determined by ^{1}H NMR, the HD to OEI ratio was 1.25/1, with 77% of esters remaining intact.

Structural Analysis by FT-IR. Infrared spectra of the polymers were recorded from potassium bromide (KBr) pellets on a Jasco FT/IR-410 spectrometer.

Size Exclusion Chromatography (SEC) of Polymers. Gel filtration was performed using HR 10/30 columns containing Superdex 75 or a Superdex 200 material (GE Healthcare Bio-Sciences AB, SE-75184 Uppsala), with an HPLC 600 controller equipped with a photodiode array detector 996 from Waters (Waters GmbH Eschborn, Germany). Prior to use, column material was preconditioned with PEI25K and then washed with running buffer. A 20 mM Hepes buffer pH 7.4 with 0.25 M NaCl was chosen as running buffer. Chromatography was performed at a flow rate of 1 mL/min and sample detection was carried out at λ = 225 nm. Calibration with standard polymers of known molecular weights and of comparable chemical structure, OEI800, PEI2K, PEI10K, PEI25K, and PEI50K was performed. The term "size exclusion chromatography (SEC)" is used in the following text to describe gel filtration analysis performed on Superdex material using the described neutral buffer and equipment.

Determination of Polymer Molecular Weights by Gel Permeation Chromatography (GPC). Analysis of acid stable polymers (OEI-BM and LT-OEI-HD) was performed using an Agilent 1200 series HPLC system (Agilent Technologies, Waldbronn, Germany) equipped with a MALLS and a refractive

index detector, a NOVEMA 10-μm precolumn and a NOVEMA 300 analytical column (10 μm, 8 $\times$ 300 mm) (PSS, Mainz, Germany). The mobile phase was maintained in formic acid and sodium chloride (0.1% (v/v) HCOOH, 0.1 M NaCl, pH 2.8) at a flow rate of 1 mL/min. Samples were dissolved in the mobile phase at a concentration of 6 mg/mL; 10 μL of methanol were added to 1 mL of sample as internal standard. Results were evaluated using PSS WinGPC Unity software. Molecular weights were measured relative to Pullulan molecular weight standards that were used for preparing a standard calibration curve. This was necessary, as the d*n*/d*c* was not available for the analyzed polymers. The term "gel permeation chromatography (GPC)" is used in the following text to describe gel filtration analysis performed on NOVEMA 300 material using the described acidic buffer and GPC equipment.

Hydrolysis Assay. Aliquots of OEI-MK or OEI-BM were dissolved either in 1 mL 20 mM Hepes buffer pH 7.4 containing 0.25 M NaCl or in 1 mL 0.2 M sodium acetate buffer pH 5.0 containing 0.25 M NaCl. After incubation at 37 °C for different time periods, samples were applied to a gel filtration column (Superdex 75) either directly (pH 7.4 samples) or after neutralization with sodium hydroxide to stop hydrolysis (pH 5.0 samples). SEC was performed as indicated above. For calculation of the degradation rates, the monitored curves were segmented into three fractions: fraction I containing the polymer portion of the highest m.w., fraction II consisting of midsized m.w., and fraction III including the degradation end-products (OEI800 monomers). These fractions were integrated, and as a function of time the decrease of the AUC of fraction I and the increase of the AUC of fraction III, respectively, were set into relation. Out of this, the half-life was determined. For OEI-BAA polymers, kinetics of acetal hydrolysis was measured by monitoring the UV absorption of the emerging hydrolysis product (*p*-methoxybenzaldehyde) at 300 nm. Therefore, the polymer was diluted with 0.2 M sodium acetate buffer pH 5.0, or 0.2 M Hepes buffer pH 7.4. Samples were incubated at 37 °C and absorption was determined on a GENESYS 10 series spectrometer (Thermo Electron Corporation, Pittsford, NY) at different time points. Hydrolysis of LT-OEI-HD was monitored by ^{1}H NMR analysis, as the polymer lacks appropriate UV absorbing functions. The polymer was incubated in D_2O at pH 7.4 and 37 °C. After different periods of time (up to 14 days), NMR spectra were recorded and the decrease of the ester signal was analyzed.

Ethidium Bromide (EtBr) Exclusion Assay. Aliquots of the respective polymer were added sequentially to a DNA solution (20 μg/mL) in HBG (Hepes buffered glucose; 20 mM Hepes pH 7.4 plus 5% w/v glucose) containing 400 ng/mL EtBr, and the decrease of fluorescence was measured in a Varian Cary Eclipse fluorescence spectrometer (Varian, Mulgrave, Australia). EtBr/DNA fluorescence (λ_{ex} 510 nm and λ_{em} 590 nm) was set to 100% prior to addition of polycation.

Formation of Polyplexes. Plasmid DNA (pDNA) was mixed with the polycation at indicated cation/pDNA (c/p) ratios (w/w). PEI22K was applied at $c/p = 0.78$ which presents N/P = 6. Polycation/DNA polyplexes were prepared as described in ref (*23*) at final DNA concentrations of 100 μg/mL for biophysical analysis on the Zetasizer (see below) and 20 μg/mL for transfection experiments. Briefly, indicated amounts of pDNA and polycation were each diluted in HBG or HBS pH 7.4 and mixed rapidly by pipetting. Polyplexes were incubated at room temperature for 20 min prior to use.

Particle Size and Zeta Potential Analysis. Particle size and surface charge of polycation/DNA complexes were measured by laser-light scattering using a Malvern Zetasizer Nano ZS (Malvern Instruments, Worcestershire, UK). For measurements, the complexes (preparation in HBG pH 7.4) were diluted with the indicated buffer (HBG or HBS pH 7.4) to a final DNA concentration of 10 μg/mL (total volume 1 mL).

Cell Culture. B16F10 murine melanoma cells (kindly provided by I. J. Fidler, Texas Medical Center, Houston, TX) and murine neuroblastoma Neuro2A cells (ATCC CCI-131) were cultured in DMEM (1 g of glucose/L) supplemented with 10% FCS (v/v) and 1% penicillin/streptomycin (v/v). The cells were grown at 37 °C in 5% CO_2 humidified atmosphere.

Luciferase Reporter Gene Expression and Metabolic Activity of Transfected Cells. *In vitro* transfection experiments were performed on either B16F10 or Neuro2A cells. Two parallel transfection series were carried out in separate 96-well plates (TPP), one for the determination of reporter gene expression and one for the determination of metabolic activity. 24 h prior to transfection cells were seeded with a density of 5×10^3 (B16F10) or 1×10^5 cells (Neuro2A) in 200 μL of culture medium (DMEM supplemented with 1 g of glucose/L, 10% FCS (v/v) and 1% penicillin/streptomycin) per well. Immediately before transfection, medium was removed and 100 μL of a dilution of transfection complexes (200 ng pDNA/well) in culture medium were added to the cells. After 4 h of incubation at 37 °C complex containing medium was replaced by 100 μL of fresh medium. Transfection efficiency was evaluated 24 h after treatment by measuring luciferase reporter gene expression from cell lysates using a luminometer (Lumat LB 9507; Berthold Technologies, Bad Wildbad, Germany) as described previously (*24*). Values are given as relative light units (RLU) and represent the luciferase activity per 10^4 cells. Two ng of recombinant luciferase (Promega, Mannheim, Germany) corresponds to 10^7 light units.

Relative metabolic activity of cells was determined 24 h after transfection by the methylthiazoletetrazolium (MTT)/thiazolyl blue assay as described in ref (*25*). Optical absorbance was measured at 590 nm (reference wavelength 630 nm) using a micro plate reader (Spectrafluor Plus, Tecan Austria GmbH, Grödig, Austria). Metabolic activity was expressed relative to the metabolic activity of untreated control cells, defined as 100%.

***In Vivo* Biocompatibility Study.** Animal experiments were performed according to National Regulations and were approved by the Local Animal Experiments Ethical Committee. Female Balb/c mice were purchased from Janvier (Le Genest St Isle, France). Animals were housed in individually vented cages; food and water were provided *ad libitum*. For toxicity studies, polymers were dissolved in HBG and injected into the tail vain of the 8-week-old mice. The polymers were applied at amounts of 100 or 50 μg/20 g mouse, in an injection volume of 250 μL. At 48 h after polymer treatment, mice were killed and perfusion-fixed with formalin solution (4% paraformaldehyde in phosphate-buffered saline). Main organs were taken and embedded in paraffin. Sections of 5 μm thickness were cut and stained with hematoxylin-eosin for histological investigations. Microscopic pictures were taken with a Framos Infinity 2−3C, CCD-camera on an Axiovert 200 inverted microscope (Carl Zeiss) using a $\times$40 LC Achroplan objective.

Statistical Analysis. Results are presented as mean $\pm$ sd. Data were evaluated by variance analysis (ANOVA) using the Duncan test. *p*-values smaller than 0.05 were considered to be significant; * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$.

RESULTS

Polymer Syntheses and Structural Analysis. OEI800-based polymers were generated by Michael addition of OEI800 amines with four different bifunctional linkers (Figure 1). Maleimido-functionalized linkers, (a) the pH-labile ketal MK or (b) the nonhydrolyzable diether BM linker, were mixed with OEI800 at equimolar ratio and reacted for 22 h at 22 °C in anhydrous

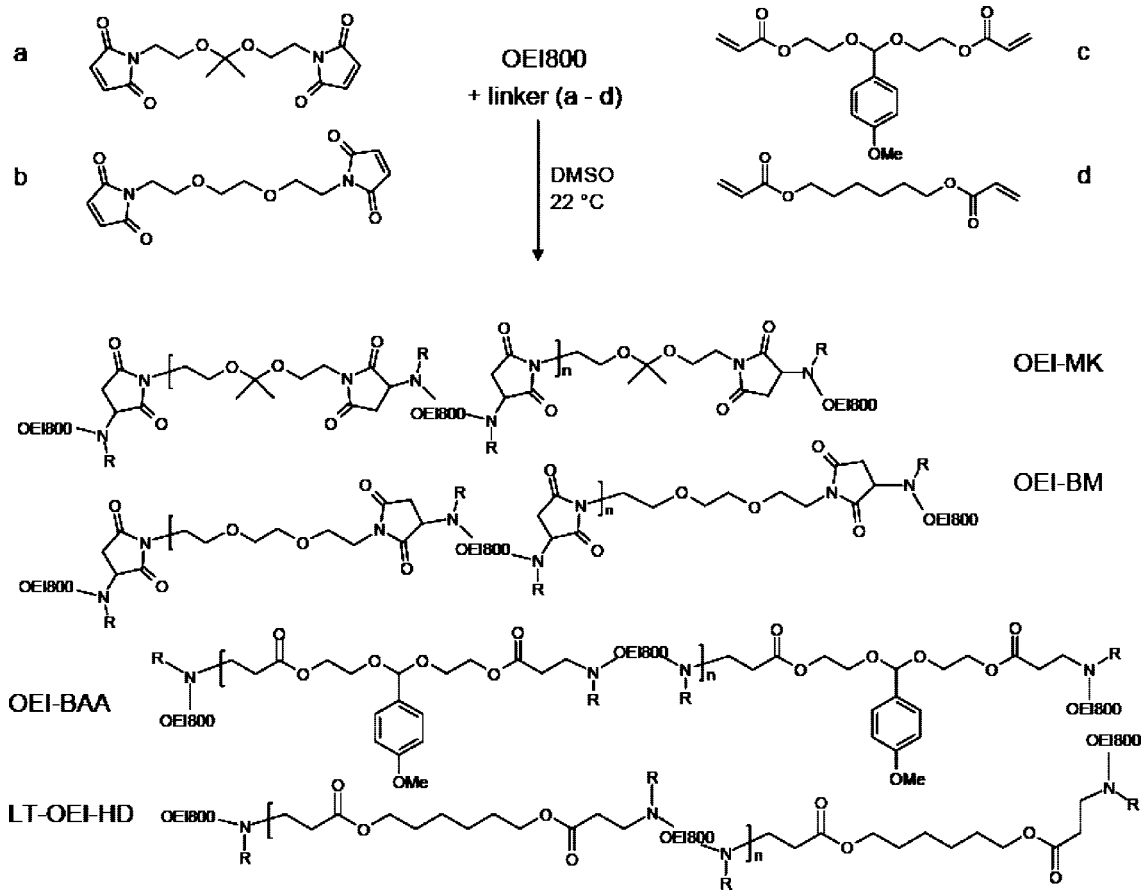

Figure 1. Syntheses of the oligoethylenimine based polymers: acid-degradable acetal-linked OEI-MK, OEI-BAA, and control polymers OEI-BM and LT-OEI-HD. (a) acid-labile MK-linker; (b) acid-stable BM-linker; (c) acid-labile BAA-linker; (d) acid-insensitive HD-linker.

Table 1. Chemical and Structural Data of OEI800 Based Conjugates[a]

			Feed Product Intact Linker [%]		
Polymer	Yield [%]	Mp [kDa]		Linker/OEI	[molar ratio]
OEI-MK	40	8−10	1	1.03	93
OEI-BM	48	8−10; 40	1	1.3	100
OEI-BAA-1−3d	40	2−3	1	0.3	26
OEI-BAA-1−1.5d	56	2−3	1	0.4	40
OEI-BAA-1−45m	70	2−3	1	0.44	75
OEI-BAA-1.25−45m	58	2−3	1.25	0.56	60
OEI-BAA-2−3d	50	4; 8−10	2	0.7	26
LT-OEI-HD	65	8−10	1.2	1.25	77

[a] Yields are given as weight to product/weight to educts [w/w] percent. Molecular weights were determined by SEC using a Superdex 75 and 200 columns.

DMSO. Purification of the products from solvent and unreacted starting material was achieved by dialysis at 4 °C using a 3.5 kDa molecular mass cutoff membrane and freeze-drying. Polymers OEI-BM and OEI-MK were then analyzed by ^{1}H NMR to investigate their linker to OEI ratio and confirm the preservation of the labile acetal functions during synthesis and purification (Table 1). For OEI-BM a linker to OEI ratio of 1.3/1 was found. For OEI-MK the linker to ketal to OEI ratio was 1.03/0.93/1, indicating a <10% hydrolysis of ketal groups in the product after workup.

To generate OEI polymers, which may degrade via acetal and ester bond cleavage, the methoxybenzaldehyde acetal diacrylate ester BAA (c) was applied, whereas 1,6-hexanediol diacrylate HD (d) was applied to synthesize the acetal-free control polymer LT-OEI-HD. LT-OEI-HD had a HD to OEI ratio of 1.25/1, with 77% of esters remaining intact. In our previous work (*22*) we found that the low temperature (LT, i.e., 22 °C, 4 days) is critical to avoid aminolysis of the ester bonds by OEI amines. For this reason also OEI-BAA synthesis was performed at 22 °C with BAA/OEI molar input ratios of 1, 1.25, and 2. Nevertheless, NMR analysis of products resulting from 3 day reactions (OEI-BAA-1−3d, OEI-BAA-2−3d) demonstrated significant aminolysis (Figure 2), resulting in polymers that contain acetal, ester, and amide bonds (see Table 1). The kinetics of the amide formation was monitored by ^{1}H NMR during a synthesis of OEI-BAA-1 performed in DMSO-d_6. By analyzing the signal of the acetal protons (5.6−5.5 ppm) the ratios of diester/monoester/diol were determined (Figure 2). Based on this analysis, and the finding that the Michael addition between BAA linker and OEI800 was largely completed within 45 min at room temperature, additional OEI-BAA polymers were synthesized by reducing the reaction time to 1.5 days and also as short as 45 min. For the OEI-BAA polymers this reduced reaction time increased the content of intact diester in the linker molecules (from 26%) to up to 75%. Infrared analysis of OEI-BAA-1−45min, OEI-BAA-1−1.5d, and OEI-BAA-2−3d confirmed the presence of amides in the polymers as well as their increase with the elongation of reaction time.

Molecular weight distribution of polymers is shown in Table 1 as analyzed by SEC. For detailed information on molecular weight determined by GPC (using a Novema 300 column) and SEC (using Superdex 75 and Superdex 200 columns) see Supporting Information (Figure S1 and Table S1). In short, GPC analysis of the pH-stable polymers OEI-BM and LT-OEI-HD displayed molecular weight distributions of $M_n = 8.5$ kDa, $M_w = 36$ kDa and $M_n = 4.9$ kDa, $M_w = 21$ kDa, respectively. These data correlated well with SEC analysis displaying peak molecular weights M_p of 8−10 kDa. Based on this good correlation

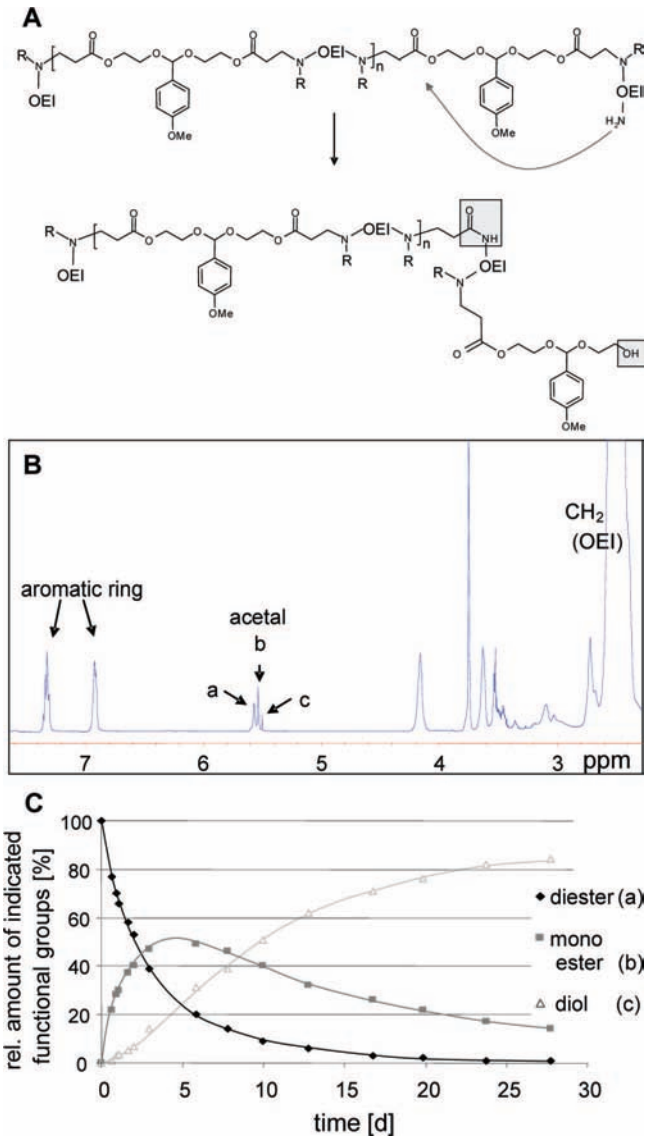

Figure 2. Structural analysis of OEI-BAA-1−3d during polymer synthesis. (A) Scheme of aminolysis reaction. (B) ^{1}H NMR spectra were recorded at different time points (shown here: reaction time 48 h) during the reaction at 22 °C in DMSO-d_6 and the degree of aminolysis was calculated on the basis of the acetal signal (5.6−5.5 ppm). This signal shows three different chemical shifts; for the intact diester at 5.57 ppm (a), for the monoester (aminolysis on one side of the linker) at 5.54 ppm (b), for the diol (aminolysis on both linker sides) at 5.50 ppm (c). (C) Diagram of the ^{1}H NMR based kinetics of BAA aminolysis over 24 days.

and the fact that the established GPC required the use of a pH 2.8 mobile phase, molecular weight distribution of the pH-labile polymers was analyzed by SEC only. Polymer OEI-MK displayed a M_p of 8−10 kDa, OEI-BAA-2−3d a main M_p of 4 kDa with a minor M_p of 8−10 kDa, and the other OEI-BAA polymers a smaller M_p range of 2−3 kDa.

Degradation Study of OEI-MK and OEI-BAA Polymers. To evaluate the pH dependency of the hydrolysis of OEI-MK and OEI-BAA polymers, degradation kinetics was measured at 37 °C and physiological pH 7.4 as well as at pH 5.0 (Figure 3). The half-life of OEI-MK was determined by detection of polymer fragments by SEC using Superdex 75 (Figure 3A). At pH 5.0, polymer hydrolysis was almost complete (98%) after 15 min, whereas at pH 7.4, the half-life was about 5 h at 37 °C. In contrast, control polymer OEI-BM was stable even after 20 h of incubation at both pH conditions and 37 °C (data not shown). Degradation of the acetal function in OEI-BAA

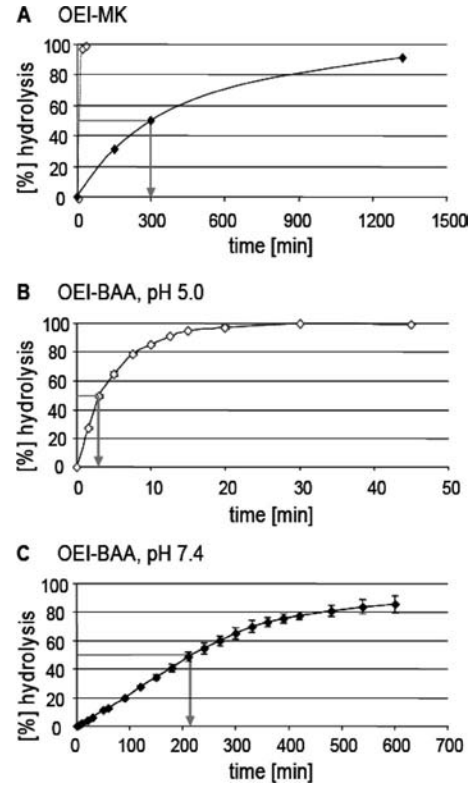

Figure 3. Kinetics of hydrolysis of acid labile polymers at 37 °C. Grey arrows mark the half-lifes of the polymers. (A) Degradation of OEI-MK at pH 5.0 (open diamonds) and at pH 7.4 (closed diamonds), values calculated from Superdex 75 SEC data (AUC at different time points after incubation). (B) Hydrolysis of OEI-BAA polymers at 37 °C, pH 5.0 and (C) at pH 7.4. UV absorbance (λ 300 nm) of the arising hydrolysis product was measured at indicated time points. Each point represents the mean ± sd of three independent experiments.

polymers was analyzed by measuring the increase of UV-absorbance of the released aromatic benzaldehyde. At pH 5.0 (Figure 3B), hydrolysis proceeded with a half-life of about 3 min and was complete in less than 30 min, while at pH 7.4, the half-life was about 3.5 h (Figure 3 C). The slower hydrolysis of the ester bonds is not detectable in this assay. It was analyzed by ^{1}H NMR using the ester bond containing control polymer LT-OEI-HD. The half-life was found to be 2 days at pH 7.4, 37 °C. At pH 5, ester-based polymers would hydrolyze significantly more slowly (*22*).

The presence of amide linkages in OEI-BAA polymers influences the size of fragments obtained by acid-catalyzed hydrolysis (see Supporting Information, Figure S2). OEI-BAA-1−45m, the polymer with the highest diester acetal linker content, degraded completely into fragments of the size of OEI800 monomers and dimers. OEI-BAA-2−3d (the polymer with the highest nonhydrolyzable amide content) hydrolyzed to monomers, dimers (M_p around 2 kDa) and considerable amounts of oligomers. Nevertheless, very profound degradation took place for all polymers, eliminating any high molecular weight fraction.

DNA Binding Assay. All polymers were analyzed for their DNA binding affinity by EtBr exclusion assay in HBG (Figure 4). The OEI-BM and -MK polymers bound to DNA more strongly than native OEI800. This was also the case for LT-OEI-HD at higher *c*/*p* ratios, while at low *c*/*p* ratios EtBr exclusion was weaker. OEI-BAA polymers showed slightly reduced binding capacity compared to OEI800.

Particle Size and Zeta Potential. Polyplexes with pDNA were formed at different *c*/*p* ratios in HBG buffer and were analyzed for their size and surface charge. Polymers formed

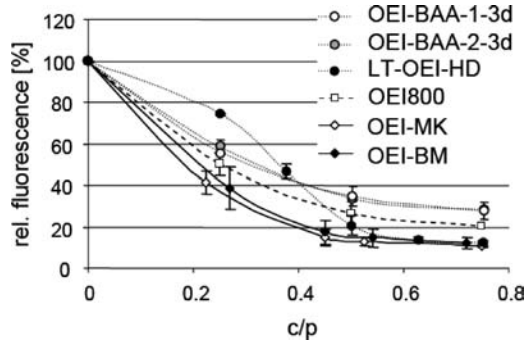

Figure 4. DNA binding affinity of polymers determined by ethidium bromide exclusion assay in HBG pH 7.4. OEI800, open squares; OEI-MK, open diamonds; OEI-BM, solid diamonds; OEI-BAA-1−3d, open circles; OEI-BAA-2−3d, gray diamonds; LT-OEI-HD, solid circles. Each point represents the mean ± sd of three independent experiments.

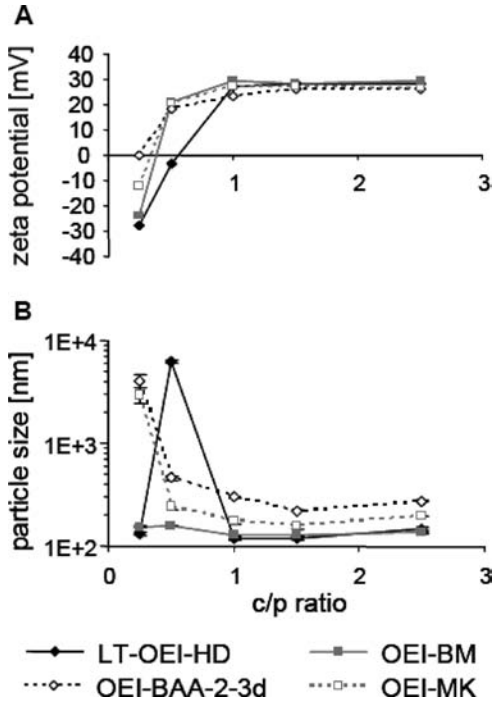

Figure 5. Surface charges (A) and sizes (B) of DNA polyplexes with OEI-MK, OEI-BM, OEI-BAA-2−3d, and LT-OEI-HD at different *c*/*p* ratios (in HBG, pH 7.4). Experiments were performed in triplicate.

polyplexes of small size (OEI-BM, OEI-MK: 130−200 nm; LT-OEI-HD, OEI-BAA: 150−300 nm) and positive surface charge (23−30 mV) at *c*/*p* ratios of 1 and higher (Figure 5), with the exception for OEI-BAA-1−3d where polyplexes aggregated with time. For lower *c*/*p* ratios of 0.5 or 0.25, surface charges of polyplexes became lower or even negative and all polymers particles tended to aggregate. Additionally, the influence of ionic strength on particle stability was investigated (data not shown). Upon the addition of salt (HBS), aggregation of particles occurred in the case of polymers with weaker DNA binding ability, i.e., OEI-BAA polymers (all *c*/*p* ratios tested) and LT-OEI-HD (for *c*/*p* ratios of 1 or less).

Luciferase Reporter Gene Expression and Metabolic Activity of Transfected Cells. In order to investigate the influence of polymer degradability on transfection efficiency and cytotoxicity, B16F10 (Figure 6) and Neuro2A cells (Figure 7) were transfected with pCMVLuc reporter gene polyplexes with the acid-labile polycations or their acid-insensitive counterparts at different *c*/*p* ratios prepared in HBG. PEI22K previously established as the gold standard was used for comparison at its optimal *c*/*p* ratio (*c*/*p* 0.78, corresponding to N/P 6) (*12*). Linear PEI22K was selected as transfection control (instead of the structurally more related branched PEI25K) because of its higher transfection activity over PEI25K in the investigated cell lines (*12*).

For B16F10 cells, the maximum transfection efficiency of both degradable OEI-MK and its stable analogue OEI-BM reached values of about 1 log unit below PEI22K (Figure 6A). For maximum efficiency, higher *c*/*p* ratios (≥5) of OEI-MK were required than for OEI-BM (optimal transfection at a *c*/*p* ratio of 2.5). For OEI-BM, further increase in *c*/*p* resulted in a reduction of transfection efficiency. This can be explained by significant cytotoxicity (Figure 6B) caused by OEI-BM at *c*/*p* ≥5. In contrast, no cytotoxicity was observed for pH-labile OEI-MK up to *c*/*p* 7.5. Consequently, at high *c*/*p* ratios the acid-labile polymer OEI-MK became superior. The starting material OEI800 shows no cytotoxicity but also no transfection efficiency, independent from the *c*/*p* ratio. PEI22K shows only moderate cytotoxicity at optimal *c*/*p* ratio of 0.78, but strong toxicity at higher *c*/*p* ratios, with relative metabolic viability of less than 50% for *c*/*p* 2 (*12*).

The OEI-BAA polymers and its acetal-free ester analogue LT-OEI-HD (Figure 6C,D) were also evaluated on B16F10 cells. Here, OEI-BAA-1−3d was the most promising polymer, with an optimal transfection efficiency at *c*/*p* of 7.5 significantly exceeding even PEI22K (Figure 6C). The acetal-free control polymer LT-OEI-HD could not reach the transfection levels of OEI-BAA-1−3d and OEI-BAA-2−3d. Although the ester-based degradable polymer LT-OEI-HD is far less cytotoxic than PEI22K, it showed some toxicity at c/*p* ≥ 5. The acetal- and ester-containing OEI-BAA counterparts showed the best biocompatibility (Figure 6D).

OEI-BAA polymers that differ in their diester acetal-linker content (i.e., low amide content) were compared in their transfection efficiency and cytotoxity profiles (Supporting Information Figure S3). A fine balance between maximum gene transfer activity and maximum biocompatibility was observed. In short, OEI-BAA-2−3d, the polymer with a considerable amide content, displayed the highest transfection activity and reduced metabolic activity of transfected cells at *c*/*p* of ≥10. The polymers with the highest diester acetal content and lower molecular weight displayed the best biocompatibility even at *c*/*p* of 20, but were least effective in gene transfer. Polymer OEI-BAA-1−1.5 was less effective as OEI-BAA-2−3d at low *c*/*p* ratios, but became almost equal at *c*/*p* 20, while remaining completely nontoxic. Therefore, within the OEI-BAA series the polymers containing acetal diesters and significant amide linkages provided the best activity and biocompatibility profile.

Transfections were also carried out with Neuro2A cells as a second cell line. In this cell line, transfection efficiencies of all polyplexes (including also the standard PEI22K) prepared in HBG buffer were low (Figure 7A, solid bars). In contrast, transfection efficiency was improved for several polymers if formulations were generated in salt-containing HBS buffer (Figure 7A, striped bars). All OEI-BAA polymers (including also those not shown in Figure 7) and PEI22K responded to this procedure with strongly (approximately 100-fold) elevated transfection levels. Cytotoxicity (Figure 7B) was not influenced remarkably by the presence of salt, except for PEI22K where metabolic activity of treated cells decreased by 20%. Interestingly, HBS had only little influence on the transfection efficiency of LT-OEI-HD and no influence on the more stable OEI-MK and OEI-BM polyplexes (data not shown).

***In Vivo* Biocompatibility Studies.** As the acid-degradable polymers showed promising results concerning biocompatibility *in vitro*, we also examined their *in vivo* toxicity. Different

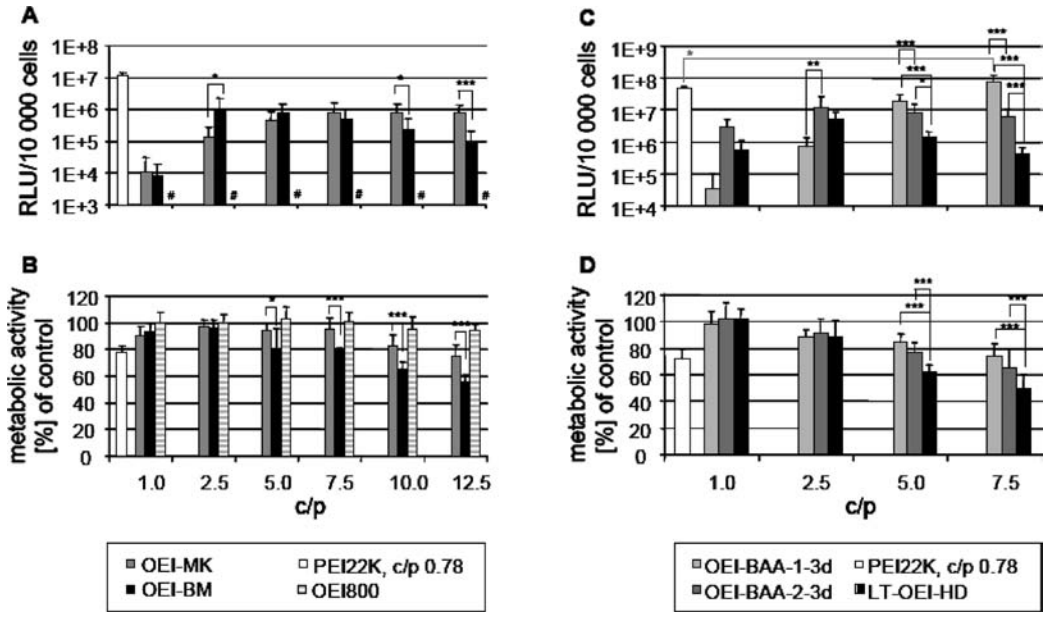

Figure 6. Transfection efficiency (luciferase assay, A,C) and metabolic activity (MTT assay, B,D) in B16F10 cells. Cells were treated with polyplexes of OEI-MK and OEI-BM in comparison to OEI800 and PEI22K (A,B), or with OEI-BAA and LT-OEI-HD (C,D). #, OEI800 <1000 RLU for all *c*/*p* ratios.

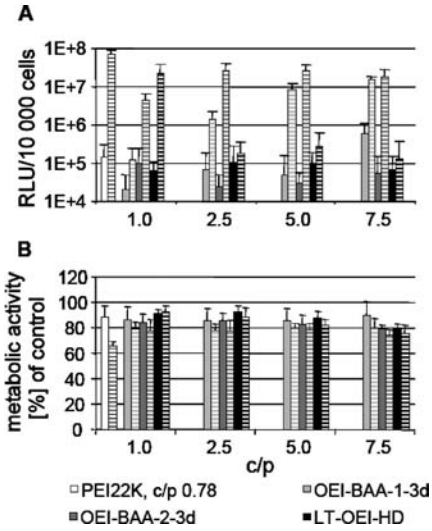

Figure 7. Transfection of Neuro2A cells. Influence of ionic strength (solid bars, HBG; striped bars, HBS) on transfection efficiency (luciferase assay, A) and cytotoxicity (MTT-assay, B). Sequence of polymer formulations (from left to right): PEI22K, *c*/*p* 0.78; OEI-BAA-1−3d; OEI-BAA2−3d; LT-OEI-HD.

amounts of selected plain polymers (OEI-BAA-2−3d, OEI-MK, or stable controls OEI-BM, LT-OEI-HD, PEI25K) were administered to 8-week-old female Balb/c mice via tail vain injection. As control polymer, branched PEI25K was chosen, because it is structurally more related to the branched OEI800 based polymers than the linear PEI22K. After PEI25K treatment, all three animals died when treated with 50 μg/20 g body weight. The dosage had to be reduced to 25 μg PEI25K/20 g mouse. Even then hepatocytes lost their normal shape indicating necrotic changes (Figure 8). Acetal comprising polymers were well-tolerated by mice at amounts of 50 μg/20 g mouse, and no changes in liver tissue were detectable (Figure 8, upper two pictures on the left). Doubling the polymer amount to 100 μg/20 g mouse was still well-tolerated for OEI-BAA-2−3d and no pathological alterations in the analyzed liver tissue were found; for OEI-MK this was also the case for two out of three mice, while one of the mice showed the first slight signs of developing a fatty liver at the 100 μg dose. In contrast, stable OEI-BM and LT-OEI-HD polymers had already caused fatty livers at 50 μg/20 g mouse (Figure 8, upper two pictures on the right), and the 100 μg dosage was lethal in the case of OEI-BM.

DISCUSSION

The aim of this study was to design degradable polycations as nucleic acid carriers, which are composed of small oligocation units linked via acid-sensitive acetal linkages. While maintaining their high molecular weight in the extracellular space, providing efficient protection and tight packaging of the nucleic acid and mediating its uptake into the cell, these polymeric carriers should degrade intracellularly into small, biocompatible decomposition products. Different approaches (i.e., vectors decomposing with different velocities upon different stimuli) have already been investigated, but currently the required optimal specific timing (minutes, hours, or days) and location (*26, 27*) of such a degradation (vesicles, cytoplasm, nucleus) remain to be determined. For example, vector decomposition that depends on endosomal milieu has to proceed fast enough to ensure that polymer degradation occurs before endosomal release into the pH-neutral cytoplasm. This might occur on a quite short time scale (minutes to less than an hour), because an efficient endosomal release of polyplexes must take place before the endosome matures into an endolysosome destroying the delivered nucleic acid. Too rapid degradation of the polymeric carrier which protects the nucleic acid would also be counterproductive. In essence, concerted polymer degradation and endosomal release is hypothesized to be preferred for pH-sensitive carriers. However, it is difficult to make specific statements on optimal location and timing, as the demands depend on the particular objective and target (nuclear DNA delivery/cytoplasmic RNA delivery) and also on the cell type. It also remains to be determined which molecular triggers for degradation, cleavage upon endosomal acidification (*16, 17, 28–31*), reductive cleavage of disulfide bonds (*27, 32*), hydrolysis of ester bonds (*6, 10, 11, 33*), alone or in combination, are most suitable for polyplex delivery.

In the current work we focused on the acidification of endosomal compartments as a specific trigger for polymer degradation. For this purpose two different acetal-based linkers were chosen for cross-linking OEI800 units into larger acid-

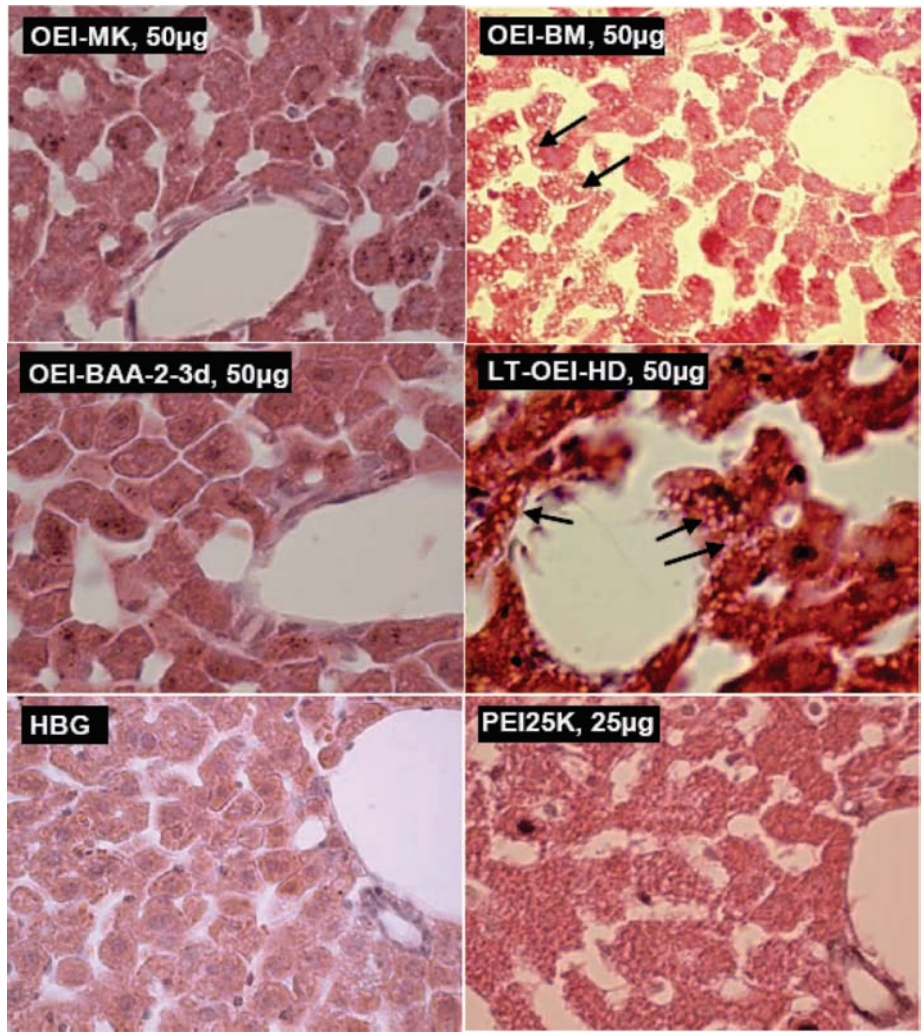

Figure 8. *In vivo* study on toxicity of the free polymers in Balb/c mice. Histological examination on liver tissue (hematoxylin and eosin staining) 48 h after i.v. administration of indicated amounts of free polymer per 20 g mouse. Application of 50 μg of acid-labile polymers OEI-MK and OEI-BAA-2 induced no histopathological changes in the liver compared to HBG-treated control animals. In contrast, the same dosage of OEI-BM and LT-OEI-HD polymers resulted in the development of fatty livers (black arrows indicate lipid droplets in hepatocytes after OEI-BM and LT-OEI-HD treatment). Mice treated with 25 μg of PEI25K even showed necrotic changes in liver tissue, which can be seen by the impaired morphology of hepatocytes in the lower right picture.

hydrolyzable polymers OEI-MK and OEI-BAA. The acetone ketal-containing linker MK (*18*) was previously introduced as reversible protein cross-linking agent, and the *p*-methoxybenzaldehyde acetal diacrylate ester BAA (*19*) previously applied in acid-cleavable polymer particles. In the case of BAA, the obtained OEI-BAA polymers contain both the acid-labile acetal groups and hydrolyzable ester groups. If polyplexes were not degraded completely until they are released from the endosome, the remaining polymer can be hydrolyzed in the cytosol at neutral pH.

The acetal containing polymers OEI-MK and OEI-BAA degrade in a pH-dependent manner, with very fast degradation kinetics (approximately 3 min half-life at 37 °C) in the acidic environment of pH 5 and much slower degradation (3.5 to 5 h half-life) at physiological pH 7.4. In contrast, the control polymers OEI-BM (as control for OEI-MK) and LT-OEI-HD (control for OEI-BAA) degraded under the same acidic conditions either very slowly (LT-OEI-HD) or not detectable at all (OEI-BM).

With regard to their application as gene vectors, DNA binding and compacting capacity of the polymers was determined by ethidium bromide (EtBr) exclusion assay and polyplex particle size and zeta potential analysis. At *c*/*p* ratios >1, stable, positively charged particles (i.e., sizes of 100−300 nm, positive zeta potential of 23−30 mV)) were obtained in salt-free buffer. The EtBr exclusion assay correlated well with the size measurements: for polymers that showed weaker DNA-binding affinity (e.g., OEI-BAA polymers) in the EtBr assay, slightly larger particles were detected by size measurements than for those made from polymers with high DNA-binding ability (e.g., OEI-MK). The firmer the DNA was condensed by the polycation, the smaller the polyplex was in size. Sizes of polyplexes from polymers with strong DNA binding (OEI-MK, OEI-BM) were not influenced by the addition of salt, while those prepared from weakly DNA-binding polymers (OEI-BAA polymers, at low *c*/*p* also LT-OEI-HD) started to grow in size and aggregated, as is also known for standard PEIs (*34*, *35*). Overall, the polyplexes showed biophysical characteristics in the range of PEI22K particles and thus should be suitable for use as gene vectors.

Polyplex transfection efficiency and toxicity were tested using B16F10 and Neuro2A cells. Concerning the biocompatibility of the formulations, the acid-degradable polymers showed a clear advantage over acid-stable analogues: the acetal containing polymers (OEI-MK and OEI-BAA) were significantly less toxic than their stable controls. This effect became more apparent with increasing *c*/*p* ratios. Regarding gene transfer efficiency, we found that polymerization of the very poorly transfecting

OEI800 to larger polycations boosts transfection efficiency levels dramatically, both for acid-stable linkages (OEI-BM, LT-OEI-HD) as well as for the acid-degradable (OEI-MK, OEI-BAA) ones. Due to better biocompatibility, for acid-labile polymers the *c*/*p* ratios leading to maximum transfection efficiency were slightly higher than those for the stable counterparts.

The OEI-BAA polymer series, containing both the acid-labile methoxybenzaldehyde acetal and hydrolyzable β-aminopropionic ester bonds, displayed the most encouraging potential as transfection agent. For example, polymer OEI-BAA-2−3d mediated gene transfer more effectively than the control ester polymer LT-OEI-HD (with similar molecular weight) at all *c*/*p* ratios tested. The smaller polymer OEI-BAA-1−3d which showed lower transfection efficiency at low *c*/*p*, exceeded OEI-BAA-2−3d with increasing *c*/*p* ratio and also the gold standard linear PEI22K. It is worth noting that the stability of the OEI-BAA polymer can be modulated by incorporation of additional amide linkages by an aminolysis process as described in the chemistry section of the paper.

In Neuro2A cells, a generally low transfection efficiency of medium-sized polyplexes (formed in HBG) is observed, presumably resulting from a generally insufficient polyplex cellular uptake. This can be overcome by salt-induced aggregated polyplexes of PEI22K and OEI-BAA polymers. Once more, the BAA polymers provided highest gene expression levels, at lowest cytotoxicity.

In vivo toxicity studies with the free polymers confirmed the encouraging biocompatibility of the acetal containing polymers. Dosages (100 μg/20 g mouse) which are lethal in case of OEI-BM, PEI25K, or PEI22K polymer and cause damage in liver tissue in the case of LT-OEI-HD, were well-tolerated in the case of OEI-MK and OEI-BAA-2−3d polymers. This emphasizes the advantage of acid degradable polymers over the controls *in vivo* also and makes them interesting candidates for use as more biocompatible gene transfer agents.

Taken together, these data clearly show an advantage of degradable acetal-linked polymers compared to acid-stable ones. The chosen acetal linkages exhibit favorable kinetics of hydrolysis: the synthesized polymers provide adequate stability for DNA polyplex formation resulting in efficient gene transfer, but also sensitivity toward a slight decrease in pH in endosomes, which causes polymer degradation and thus improved biocompatibility. The presented work did not address significant additional bottlenecks beyond biodegradability. Endosomal release is still a major limit even for PEI-type polymers despite their proton sponge activity (*36*), but might be overcome by incorporation of endosomally active components (*37, 38*). Inadvertent particle aggregation may be prevented by pH-responsive PEGylation (*31, 37, 39*). Insufficient endocytosis of polyplexes might be overcome by the integration of suitable ligands to boost specific polyplex uptake into the target cells. Such strategies remain to be investigated in the context of the polymeric carriers presented in this paper, to yield polyplexes with suitable characteristics for *in vivo* gene transfer.

ACKNOWLEDGMENT

We thank Olga Brück for skillful assistance in preparing the manuscript and Wolfgang Rödl for help with the GPC analysis. This work was supported by the DFG SFB 486, SPP1230, excellence cluster Nanosystems Initiative Munich (NIM), and by the European Community project 'GIANT'.

1. Determination of Polymer Molecular Weight by GPC and SEC.

Gel Permeation Chromatography (GPC). Analysis of acid-stable polymers (OEI-BM and LT-OEI-HD) was performed using an Agilent 1200 series HPLC system (Agilent Technologies, Waldbronn, Germany) equipped with a MALLS and a refractive index detector, a NOVEMA 10-µm precolumn and a NOVEMA 300 analytical column (10 µm, 8 x 300 mm) (PSS, Mainz, Germany). The mobile phase was maintained in formic acid and sodium chloride (0.1% (v/v) HCOOH, 0.1 M NaCl, pH 2.8) at a flow rate of 1 mL/min. Samples were dissolved in the mobile phase at a concentration of 6 mg/mL; 10 µl of methanol were added to 1 mL of sample as internal standard. Results were evaluated using PSS WinGPC Unity software. Molecular weights were measured relative to Pullulan molecular weight standards that were used for preparing a standard calibration curve.

Size Exclusion Chromatography (SEC). Gel filtration was performed using HR 10/30 columns containing Superdex 75 or a Superdex 200 material (GE Healthcare Bio-Sciences AB, Uppsala, Sweden), with an HPLC 600 controller equipped with a photodiode array detector 996 from Waters (Waters GmbH Eschborn, Germany). Prior to use, column material was preconditioned with PEI25K and then washed with running buffer. A 20 mM Hepes buffer pH 7.4 with 0.25 M NaCl was chosen as running buffer. Chromatography was performed at a flow rate of 1 mL/min and sample detection was carried out at $\lambda = 225$. Calibration with standard polymers of known molecular weights and of comparable chemical structure, OEI800, PEI2K, PEI10K, PEI25K and PEI50K, was performed.

Figure S1. (A) GPC elution profiles of acid-stable OEI-BM and LT-OEI-HD on a Novema 300 column. 2. Degradation Study for Different OEI-BAA Polymers.

Aminolysis in the OEI-BAA polymer synthesis generates amide linkages which do not degrade as fast as the acetal linkages. Therefore, dependent on their different acetal diester and amide contents, acid catalyzed hydrolysis of OEI-BAA polymers results in end-products of different sizes. To investigate this in more detail, polymers were diluted in 20 mM Hepes and adjusted at pH 1 by the addition of HCl. Samples were incubated at 37 °C for 1 h, and neutralized with NaOH. The degradation products were analyzed by SEC using a Superdex 75 column with 20 mM Hepes pH 7.4, 0.25 M NaCl as running buffer (**Figure S2**). OEI-BAA-1-45m, the polymer with the highest diester acetal linker content, degraded completely into fragments of the size of OEI800 monomers and dimers. OEI-BAA-1-1.5d (with a slightly lower acetal diester content) showed a degradation product profile shifted towards the dimers and minor amounts of oligomers. OEI-BAA-2-3d (the polymer with the highest non-hydrolyzable amide content) hydrolyzed to monomers, dimers and considerable amounts of oligomers. Despite the amide content very profound hydrolysis of the polymer took place, eliminating the high m.w. fraction of the polymer (compare Figure S1D).

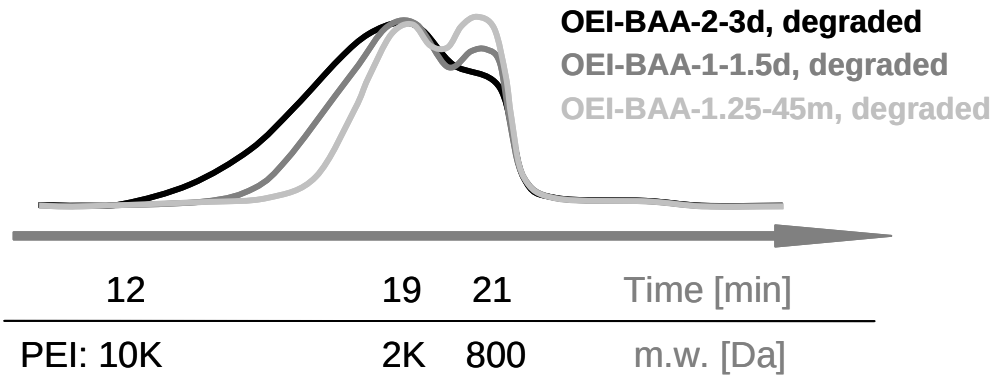

Figure S2. SEC elution profiles (Superdex 75) of degraded OEI-BAA polymers after acid treatment.

3. Comparison of Different OEI-BAA Polymers for Transfection Efficiency and Metabolic Activity of Transfected Cells.

OEI-BAA polymers that differ in their diester- and acetal-linker content were compared in their transfection efficiency (**Figure S3A**) and cytotoxity (**Figure S3B**) profiles. OEI-BAA-2-3d, OEI-BAA-1-1.5d, OEI-BAA-1-45m and OEI-BAA-1.25-45m were evaluated which form polyplexes of comparable size and surface charge. High c/p ratios (up to 20) were also tested in this experiment, to make any significant toxicity visible. A clear relationship between the content of acid degradable diester acetal linker in the polymer and its biocompatibility (i.e. low cytotoxicity) was observed. OEI-BAA-2-3d, the polymer with the lowest diester content among the tested OEI-BAAs, reduced metabolic activity of transfected cells at c/p of ≥10. Nevertheless, biocompatibility was far better than for PEI22K or the acetal-free ester analog LT-OEI-HD (see also Figure 6) and optimum transfection activity was observed at the much lower c/p 2.5. Polymers with higher acetal content (OEI-BAA-1-1.5d, OEI-BAA-1-45m, OEI-BAA-1.25-45m) displayed no detectable cytotoxicity even at the highest c/p ratio tested. These polymers however showed also the lowest transfection levels. OEI-BAA-1-1.5 was inferior to OEI-BAA-2-3d at low c/p ratios but became almost equal at higher concentrations, while still being completely non-toxic.

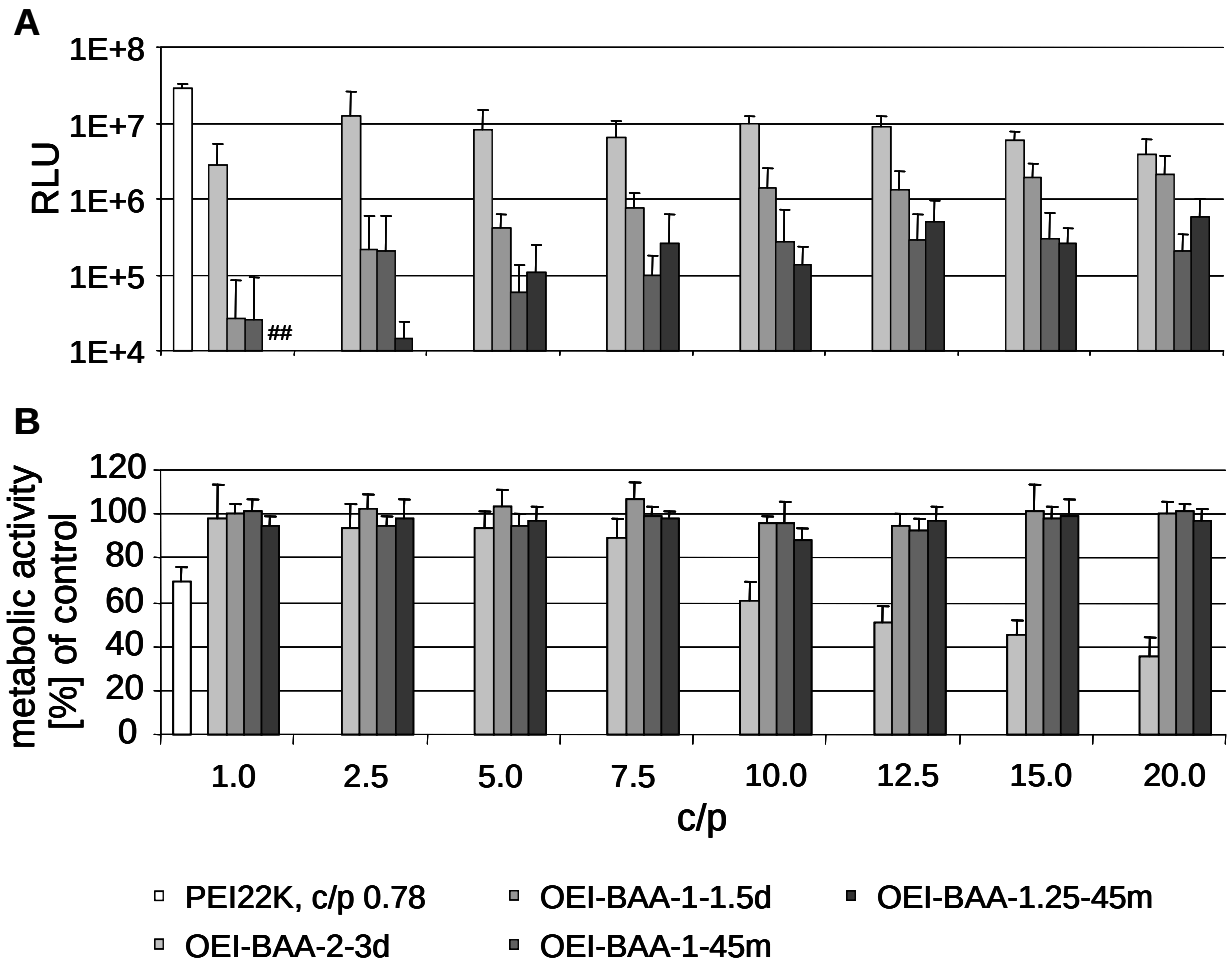

Figure S3. Influence of acetal linker content in the OEI-BAA polymers on transfection efficiency (E) and toxicity (F). ## 4540 RLU ± 920.

Near Infrared Fluorescence-Based Bacteriophage Particles for Ratiometric pH Imaging

Center for Molecular Imaging Research and Center for Systems Biology, Massachusetts General Hospital/Harvard Medical School. Received May 9, 2008; Revised Manuscript Received June 11, 2008

Fluorogenic imaging agents emitting in the near-infrared are becoming important research tools for disease investigation *in vivo*. Often pathophysiological states such as cancer and cystic fibrosis are associated with disruptions in acid/base homeostasis. The development of optical sensors for pH imaging would facilitate the investigation of these diseased conditions. In this report, the design and synthesis of a ratiometric near-infrared emitting probe for pH quantification is detailed. The pH-responsive probe is prepared by covalent attachment of pH-sensitive and pH-insensitive fluorophores to a bacteriophage particle scaffold. The pH-responsive cyanine dye, HCyC-646, used to construct the probe, has a fluorogenic pK_a of 6.2, which is optimized for visualization of acidic pH often associated with tumor hypoxia and other diseased states. Incorporation of pH-insensitive reference dyes enables the ratiometric determination of pH independent of the probe concentration. With the pH-responsive construct, measurement of intracellular pH and accurate determination of pH through optically diffuse biological tissue is demonstrated.

INTRODUCTION

The *in vivo* investigation of biological processes at a molecular level has received considerable attention for its potential application in early diagnosis and treatment of disease. Although the disruption of acid/base homeostasis is associated with a variety of diseases such as cancer, cystic fibrosis, and immune dysfunction (*1–4*), our understanding of the direct and indirect effects of these environments is limited. Due to their sensitivity and noninvasive nature, fluorescence-based imaging methodologies are well suited for investigation of pH in biological systems.

In order to obtain useful *in vivo* pH data, methods need to be employed in which the pH response of the probe is determined in a ratiometric fashion, allowing for measurement of local pH in a probe concentration independent manner. Even though small molecule (*5–10*) and nanoparticle (*11–15*) based systems have been employed for ratiometric pH determination in solution and *in vitro*, none are suitable for *in vivo* imaging applications. These probes typically use fluorescein (*6, 8–10, 13–15*) or other pH-sensitive lumophores (*5, 7, 11, 12*) with emission in the visible region. For efficient *in vivo* optical imaging, fluorophores that emit in the NIR are necessary due to the increased optical transparency and minimal tissue autofluorescence in this regime (*16*). There are currently few reports of NIR pH-responsive fluorophores in the literature (*17–21*). These dyes have suboptimal optical and solubility properties for imaging pH *in vivo*. Often the diseased states result in pH changes that are only slightly lower than that of physiological pH. For example, typical extracellular pH values reported for tumors are between 6.3 and 7.0 (*3*). Current NIR probes are not ideal for biological imaging because they are either irreversible (*21*) or have fluorogenic pK_a values that are too high (*17, 20*) or too low (*18*) for effective imaging. Recently, we reported a new strategy for tuning the pK_a of pH-responsive cyanine dyes to address these issues (*22*).

Probes based on a nanoscaffold possess several advantages over small molecule pH sensors. Particle based approaches can easily incorporate a pH-insensitive reporter dye allowing for the determination of H^+ concentration independent of the probe concentration. In addition, multiple copies of the reference and pH-responsive dyes can be appended to a single particle, effectively increasing the brightness of the individual probe nanoparticle. Our research group has reported the development of targeted M13 bacteriophage particles functionalized with several hundred copies of NIR fluorophores for *in vitro* and *in vivo* receptor targeted imaging applications (*23, 24*). The M13 bacteriophage is a flexible heterofunctional nanoplatform (*25*) with a well investigated *in vivo* biodistribution profile (*26*). Individual bacteriophage particles are approximately 880 × 6.6 nm in size and contain 2700 copies of the p8 coat protein with their amino termini exposed to the solvent. These amine groups are available for bioconjugation (*23, 27*). The preparation of nanoscale pH-sensitive imaging agents based on these bacteriophage imaging platforms using optimized pH-responsive and pH-insensitive NIR fluorophores for potential *in vivo* imaging is detailed in this report.

EXPERIMENTAL PROCEDURES

General Considerations. All chemicals were purchased from Sigma-Aldrich (Milwaukee, WI), TCI America (Portland, OR) or Acros Organics USA (Morris Plains, NJ) and were used as received. The starting indoles, 2,3,3-trimethylindolenine-5-sulfonic acid and 1-(ε-carboxypentyl)-2,3,3-trimethylindolenium-5-sulfonate, were prepared according to published procedures (*28*). The succinimidyl esters of Cy 7 and Cy 5 were purchased from GE Lifesciences (Piscataway, NJ). All solvents, including anhydrous DMF, were purchased from Sigma-Aldrich. High performance liquid chromatography (HPLC) was performed on a Hitachi D-7000 instrument equipped with a L-7455 diode array detector. Nuclear magnetic resonance (NMR) spectra were acquired on a Bruker DPX-400 spectrometer at ambient temperature and referenced to tetramethylsilane (TMS) as an

internal standard. Absorption spectra were collected on a Varian Cary 50-Bio UV/visible spectrophotometer (Palo Alto, CA). The extinction coefficient measurements for dye **2** were determined in 50 mM glycine buffer, pH 3.0, and were performed in triplicate using reverse phase C-18 and cation exchange chromatography purified dye. For determination of the extinction coefficient, of protonated **2**, fresh stock solutions of the dye were prepared for each trial by dissolution of 2−3 mg portions of the dyes, weighed on a Mettler AT201 analytical balance with an error of ±0.01 mg, in 50 mM glycine buffer, pH 3.0, using a 10 mL volumetric flask. The extinction coefficient of the deprotonated form of **2** was determined in an analogous manner using aqueous NaOH, pH 10.0. Standard deviations for the extinction coefficient measurements were 5% or less. Fluorescence data were collected on a Horiba Jobin Yvon Fluorolog-3 spectrofluorometer (Edison, NJ) and were corrected for the detector sensitivity. Quantum yield measurements of the protonated form of **2** in 50 mM glycine, pH 3.0, were performed in triplicate following published procedures (*29*) and were collected using dilute samples (absorbance ≤0.10 OD) with Cy 5 ($\Phi = 0.27$) (*28*) in phosphate buffered saline as a standard. All samples for quantum yield determinations were excited at 610 nm. High-resolution electrospray ionization (ESI) mass spectra were collected on a Bruker Daltonics APEXII 3 T Fourier transform mass spectrometer in the Department of Chemistry Instrumentation Facility (DCIF) at the Massachusetts Institute of Technology. Low-resolution ESI mass spectra were obtained using a Waters/Micromass ZQ 4000 mass spectrometer.

Fluorescence microscopy was performed on Zeiss Axiovert 100 TV microscope with a 40X objective using filter sets from Omega Optical. The NIR reference dye, Cy 7 was imaged using a 740 ± 12.5 nm band-pass filter for excitation and a 780 nm long-pass filter for emission. The pH-sensitive dye was imaged using a 610 ± 10 nm band-pass filter for excitation and a 670 ± 20 nm band-pass filter for emission.

Fluorescence reflectance imaging (FRI) data were acquired on a Maestro imaging system from CRi (Woburn, MA). The pH-responsive HCyC-646 (**2**), was imaged using a 590 to 645 nm band-pass excitation filter and the LCD emission filter tuned to 670 nm. The pH-insensitive reference, Cy 7, was imaged using a 690 to 750 nm band-pass excitation filter and the LCD emission filter tuned to 775 nm. All Cy 7 images were exposed for 97 ms and all images using dye **2** were exposed for 68 ms.

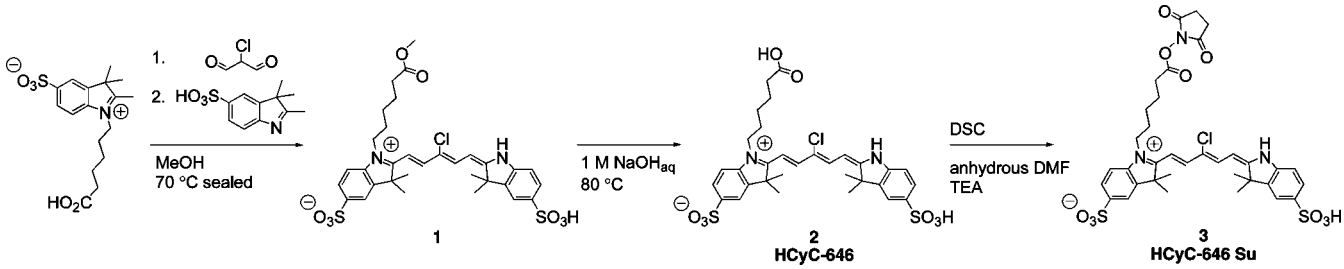
HCyC-646 Methyl Ester, 1. To a solution of 1-(ε-carboxypentyl)-2,3,3-trimethylindoleninium-5-sulfonate (884 mg, 2.5 mmol) was added chloromalonaldehyde (266 mg, 2.5 mmol) in 15 mL of MeOH. This solution was sealed in a thick-walled glass pressure reactor and heated at 70 °C for 30 min giving a yellow-green solution. After cooling, 2,3,3-trimethylindolenine-5-sulfonic acid (598 mg, 2.5 mmol) was added, the pressure reactor was resealed, and the solution was heated at 70 °C for an additional 5 h giving a dark blue solution. After cooling to room temperature, the solvent was removed by rotary evaporation. The crude blue solid was subjected to reverse-phase C-18 column chromatography (Isolute 70 g RPC18 cartridge) eluting with increasing concentrations of CH_3CN (0, 5, and 10%) in H_2O to afford **1** (163 mg, 9.6%). HPLC analysis of the final product indicates >97% purity with dye **2** being the major contaminant. ^{1}H NMR (400 MHz, DMSO-d_6): δ 13.1 (broad s, 1H), 8.39 (d, 1H, $J = 13.8$ Hz), 8.27 (broad d, 1H, $J = 12.8$ Hz), 7.85−7.84 (two overlapping singlets, 2H), 7.67−7.63 (two overlapping doublets, 2H), 7.40 (d, 1H, $J = 8.3$ Hz), 7.23 (d, 1H, $J = 8.1$ Hz), 6.37 (broad d, 1H, $J = 13.8$ Hz), 4.13 (t, 2H, $J = 6.4$ Hz), 3.55 (s, 3H), 2.30, (t, 2H, $J = 7.3$ Hz), 1.76−1.33 (m, 18H). MS-ESI $[M+H]^+$: calcd for $C_{32}H_{38}ClN_2O_8S_2^+$ 677.2, found 677.2.

HCyC-646, 2. Intermediate **1** (102 mg, 0.15 mmol) was added to 5 mL of 1 M NaOH and heated at 80 °C for 1.5 h. After cooling, the solution was acidified by addition of 10% aqueous HCl and the solvent was removed by rotary evaporation. The blue solid was purified by reverse-phase C-18 column chromatography (Isolute 70 g RPC18 cartridge) eluting with increasing concentrations of CH_3CN (0%, 10%, and 15%) in H_2O. Following solvent removal, the product was subjected to cation exchange chromatography (Dowex 50WX8 hydrogen form resin) to give pure **2** (88 mg, 88%). ^{1}H NMR (400 MHz, DMSO-d_6): δ 13.1 (broad s, 1H), 8.39 (d, 1H, $J = 13.8$ Hz), 8.28 (d, 1H, $J = 12.7$ Hz), 7.85 (two overlapping singlets, 2H), 7.67−7.63 (two overlapping doublets, 2H), 7.40 (d, 1H, $J = 8.3$ Hz), 7.23 (d, 1H, $J = 8.1$ Hz), 6.37 (broad d, 1H, $J = 13.4$ Hz), 6.24 (d, 1H, $J = 13.4$ Hz), 4.14 (t, 2H, $J = 5.9$ Hz), 2.20 (t, 2H, 7.2 Hz), 1.76−1.37 (m, 18H). HRMS-ESI $[M+H]^+$: calcd for $C_{31}H_{36}ClN_2O_8S_2^+$ 663.1596, found 663.1613.

HCyC-646 Su, 3. To a solution of **2** (19.9 mg, 0.03 mmol) in 1 mL of anhydrous DMF was added 11.5 mg (0.045 mmol) of *N*,*N*′-disuccinimidyl carbonate (DSC) and triethylamine (31 μL, 0.225 mmol). After stirring for 4 h, the product was precipitated by addition of *tert*-butyl methyl ether to give a blue solid. This material was further purified by preparative reverse phase HPLC chromatography using a gradient of 100% H_2O with 0.1% TFA to 60% CH_3CN in H_2O with 0.1% TFA to yield **3** (18.9 mg, 83%) as a blue solid. HPLC analysis of the product indicates the presence of approximately 5% dye **2** as an impurity. ^{1}H NMR (400 MHz, DMSO-d_6): δ 13.1 (broad s, 1H), 8.38 (d, 1H, $J = 13.8$ Hz), 8.27 (broad d, 1H, $J = 13.5$ Hz), 7.85−7.84 (two overlapping singlets, 2H), 7.65−7.63 (two overlapping doublets, 2H), 7.39 (d, 1H, $J = 8.3$ Hz), 7.22 (d, 1H, $J = 8.1$ Hz), 6.37 (broad d, 1H, $J = 13.7$ Hz), 6.23 (d, 1H, $J = 13.4$ Hz), 4.14 (broad t, 2H), 2.80 (s, 4H), 2.69 (t, 2H, $J = 7.2$ Hz), 1.77−1.37 (m, 18H). HRMS-ESI $[M-H]^-$: calcd for $C_{35}H_{37}ClN_3O_{10}S_2^-$ 758.1614, found 758.1592.

Bacteriophage Preparation and Labeling. Wild type M13 bacteriophage were amplified by infection in *Escherichia coli* and their titer was determined according to published procedures (*30*). Following titer determination, the bacteriophage were labeled simultaneously with the succinimidyl esters of Cy 7 and HCyC-647 using a modified literature procedure (*31*). Briefly, Cy 7 succinimidyl ester (40 μL of a 5 μg/μL stock solution in anhydrous DMSO) and HCyC-646 (20 μL of a 5 μg/μL stock solution in anhydrous DMSO) were added to 1×10^{13} plaque forming units (pfu) of wild type M13 bacteriophage in 2 mL of 100 μM bicarbonate buffer, pH 8.3. The resulting solution was allowed to incubate for 1 h at room temperature in the dark. Following incubation, the labeled bacteriophage was precipitated by addition of 350 μL of a PEG 8000/2.5 M NaCl solution (40% w/v PEG 8000) and allowed to stand on ice for 30 min. The bacteriophage was then pelleted by centrifugation at 10 000 *g* for 15 min. After removal of the supernatant, the pellet was resuspended in 833 μL of DPBS buffer. This suspension was then subjected to two additional rounds of the PEG precipitation using 166 μL of the PEG 8000/2.5 M NaCl solution. The final labeled bacteriophage was resuspended in 1000 μL of DPBS. The concentration of the labeled bacteriophage (in pfu) was determined by comparing the absorbance values of 10-fold dilutions of the initial unlabeled bacteriophage (5×10^9 pfu/μL) to the labeled bacteriophage at 280 nm. The degree of labeling for both dyes was determined from a 10-fold dilution of the stock labeled bacteriophage in 100 μM PBS, pH 8.0, using the extinction coefficients of Cy 7 ($\varepsilon = 200\,000$ M^{-1} cm^{-1} at 750 nm) (*28*) and deprotonated HCyC-646 ($\varepsilon = 50\,000$ M^{-1} cm^{-1} at 506 nm). Typical dye labeling using this procedure gives 400−500 copies of each dye per bacteriophage particle.

Scheme 1. Synthesis of the pH-Responsive Cyanine Derivative



Sensor Calibration. The pH-dependent response of the sensor was determined based on the ratio of the fluorescence emission bands of the Cy 7 and HCyC-646 fluorophores on the bacteriophage particles in a series of 50 mM phosphate/citric acid buffer solutions from pH 4.9 to 9.3. For the *in vitro* calibrations, Cy 7 was excited at 715 nm and the fluorescence emission was integrated from 730 to 825 nm, whereas HCyC-646 was excited at 610 nm and the fluorescence emission was integrated from 630 to 725 nm.

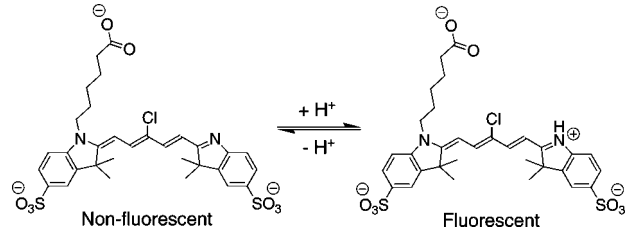
For the cell imaging experiments, *in situ* standard curves were generated on the same day that the imaging was performed using a procedure modified from the literature (*5*). The ionophore nigericin was used for intracellular pH equilibration of all samples (*5*). Briefly, RAW cells on 24 well plates were first incubated at 37 °C with the pH-responsive bacteriophage (at a final concentration of 1 μM Cy 7 on the bacteriophage) in DPBS, pH 7.4 for 1 h. Following removal of the pH-sensitive bacteriophage-containing buffer, the cells were washed 2 × 100 μL with the appropriate pH nigericin solutions. Nigericin solutions were prepared by adding 100 μL of a 10× nigericin stock solution (100 μg/mL nigericin, 1.3 M KCl, and 10 mM $MgCl_2$ in distilled water) to 900 μL of 50 mM phosphate/citric acid solutions with pH values between 5.0 and 7.5 in increments of 0.5 pH units. The cells were then incubated in the different pH nigericin solutions at 37 °C for 30 min to equilibrate the intracellular pH with the buffer pH and were then imaged by fluorescence microscopy. Images of at least three cells were used to acquire the fluorescence ratio between Cy 7 and HCyC-646 at each pH value for generation of the standard curve.

In the mouse imaging experiments, standard curves were generated by acquiring fluorescence images of the Cy 7 and HCyC-646 signals from 50 μL volume phantom tubes containing the pH-responsive bacteriophage. For all phantoms, the bacteriophage was adjusted to a Cy 7 concentration of 1 μM. The bacteriophage probe was suspended in a series of 50 mM phosphate/citric acid buffer solutions with pH values between 5.0 and 7.0 in increments of 0.5 pH units. The phantoms were inserted subcutaneously into a mouse, which had been previously sacrificed, prior to imaging in order to correct for differences in light attenuation through tissue between the Cy 7 and HCyC-646 imaging channels. The fluorescence signals from the individual imaging channels were further corrected for background fluorescence by subtracting the average fluorescence intensity from a region of interest (ROI) adjacent to the bacteriophage-probe phantoms from the average signal intensity of ROIs covering the entire phantom. As with the *in vitro* and intracellular-based standard curves, the Cy 7/HCyC-646 ratios were used to generate a standard curve used for subsequent imaging experiments.

RESULTS AND DISCUSSION

The water-soluble pH sensitive dye, HCyC-646 used in this report was prepared by the condensation of 1-(ε-carboxypentyl)-2,3,3-trimethylindoleninium-5-sulfonate and 2,3,3-trimethylindolenine-5-sulfonic acid with chloromalonaldehyde and then converted to its activated succinimidyl ester for bioconjugation (Scheme 1). In acidic environments, HCyC-646, exists primarily in its protonated emissive form with absorption at 646 nm and fluorescence emission at 670 nm (Scheme 2, and Figure S1 Supporting Information). The protonated dye has an extinction coefficient of 200 000 M^{-1} cm^{-1} at 646 nm and a quantum yield of 8% in aqueous media. At neutral or basic pH, however, deprotonation of the indole nitrogen is accompanied by a large hypsochromic shift in the absorption maximum to 506 nm and loss of NIR fluorescence emission. With a pK_a of 6.2, HCyC-646 is ideally suited for potential imaging of biologically relevant acidic environments such as those found in tumors (*3*) and other disease states (*32, 33*). In addition, the long wavelength absorption and emission of HCyC-646 lie within the optimal window for *in vivo* imaging between approximately 650 and 900 nm (*16*).

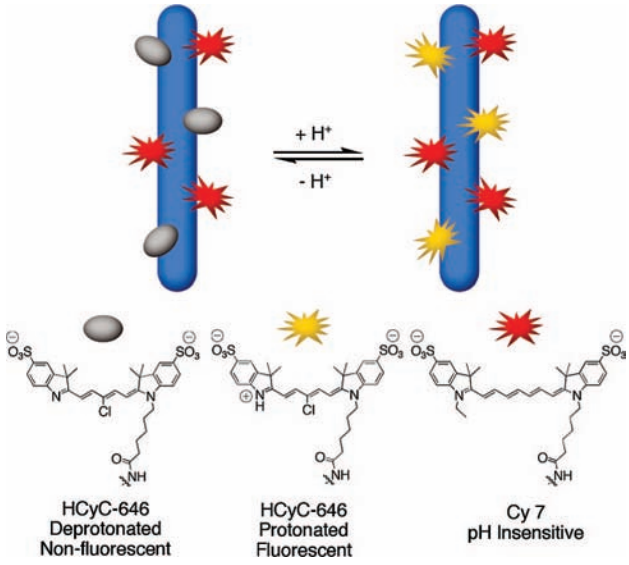
Scheme 2. pH-Dependent Equilibrium of HCyC-646



To prepare the ratiometric bacteriophage probe, the succinimidyl esters of the pH-sensitive dye and an additional pH-insensitive reference dye, Cy 7, were conjugated to the surface of the bacteriophage particles. In a typical labeling procedure approximately 400−500 copies of each dye could be attached to the surface of the bacteriophage particles. Once labeled, the bacteriophage respond to pH in a ratiometric manner with the HCyC-646 emission signal varying with pH and the Cy 7 signal remaining stable from pH 5 to 9 (Scheme 3 and Figure 1). This pH range matches well with the expected pH values in biological systems.

The labeled bacteriophage can be used for intracellular pH imaging. Incubation of the pH-responsive probe with RAW cells for one hour results in internalization of the phage particles into acidic intracellular vesicles. Cells were imaged with filter sets optimized for HCyC-646 and Cy 7. To obtain pH map data, the ratios of the Cy 7 and HCyC-646 signals were taken and then correlated to an *in situ* standard curve. Using this approach, it is possible to visualize intracellular pH (Figure 2). The cellular pH readings were found to lie between 6.5 and approximately 5.0. These values agree well with reported pH ranges for acidic intracellular vesicles such as endosomes, phagosomes, and lysosomes (*34*). These data are also in good agreement with intracellular pH readings from a recently published fluorescein-based ratiometric pH probe (*13*). In addition to the ability of the pH-responsive bacteriophage to image intracellular pH, the probe can be used to image through optically diffuse biological tissue.

Scheme 3. Fluorophore Labeled Bacteriophage Particles



To demonstrate the ability of the phage particles for imaging through tissue, pH adjusted phantoms containing a 50 μL solution of the probe adjusted to a concentration of 1 μM with respect to Cy 7 were inserted subcutaneously into mice and visualized by fluorescence reflectance imaging (Figure 3). As with the cell imaging experiments, the fluorescence signals were ratioed and mapped to a standard curve to generate the pH maps.

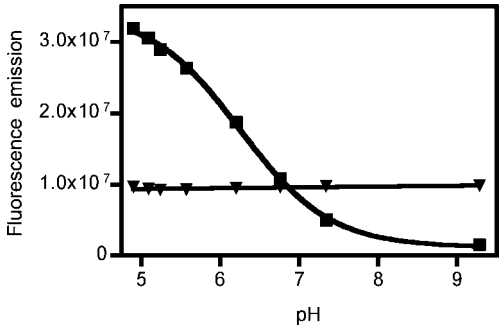


Figure 1. Fluorescence response of the labeled bacteriophage in a series of different pH 50 mM phosphate/citric acid buffers. The emission from the conjugagted HCyC-646 (squares) varies with pH, whereas the Cy 7 signal (triangles) is pH-insensitive. Excitation for HCyC-646 was at 610 nm and the emission signal was integrated from 630 to 725 nm. Excitation for Cy 7 was at 715 nm and the emission signal was integrated from 730 to 825 nm. The probe was adjusted to a concentration of 1 μM with respect to Cy 7.

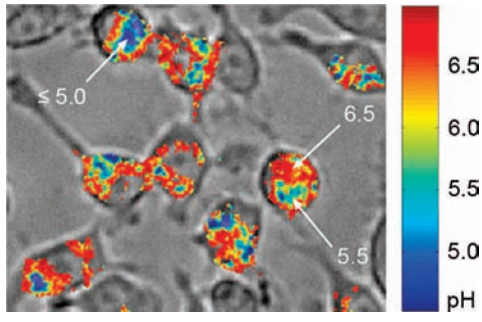

Figure 2. Intracellular ratiometric pH imaging in RAW cells with the pH-responsive bacteriophage particles. Prior to imaging, the cells were incubated with the ratiometric imaging probe in PBS, pH 7.4 adjusted to a final probe concentration of 1 μM with respect to Cy 7. The fluorescence images from the HCyC-646 and Cy 7 were ratioed and correlated to the standard curve to generate the pH map.

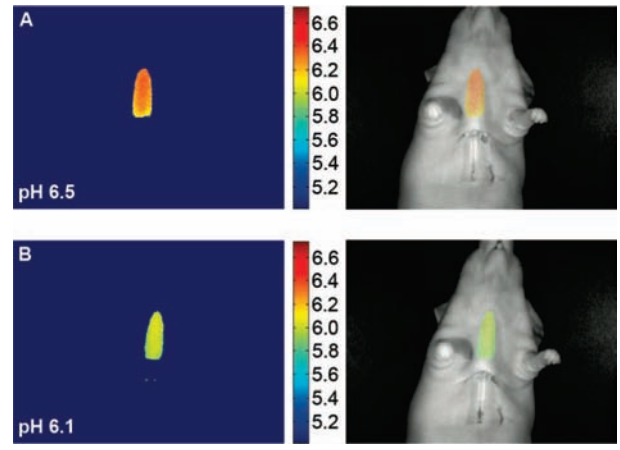

Figure 3. Fluorescence ratio pH maps through optically diffuse tissue of 50 μL phantoms containing the pH-responsive probe adjusted to a concentration of 1 μM with respect to Cy 7 in 50 μM phosphate/citric acid buffers. The left and right panels show the recconstructed pH ratio maps from the phantoms and the pH maps overlaid on the bright field images, respectively. The ratiometrically determined pH values of 6.5 (A) and 6.1 (B) match well with the corresponding pH electrode measurements of 6.60 and 6.16.

There is excellent correlation between the ratiometrically based pH readings and the electrode measured pH values of the phantoms. For example, the ratiometrically measured pH of the phantom in Figure 3a of 6.5 compares well with the actual pH of 6.60. In Figure 3b, a ratiometrically measured pH of 6.1 matches well with the actual pH of 6.16. The ability to clearly visualize different pH values in this range should prove invaluable for *in vivo* imaging of pathophysiological processes associated with acidic pH. One current limitation of this system arises from differences in the tissue penetrating ability of light at the emission wavelengths of the two fluorophores (Table S1, Supporting Information). The shorter wavelength fluorescence emission at ~670 nm from HCyC-646 shows stronger tissue absorbance than the ~775 nm emission from Cy 7. To correct for the light penetrating abilities at the different imaging wavelengths, fluorescence data for the standard curve were obtained under identical conditions to those in which the unknown pH phantoms were imaged.

In summary, we report the development of a new nanoscaffold for fluorescence-based pH imaging, both intracellular and through optically diffuse biological tissue. The pH-sensitive cyanine dye, HCyC-646, used in this report has a pK_a of 6.2, which is optimized for visualization of pH in a biologically relevant range. Through coupling of several hundred copies pH sensitive HCyC-646 and Cy 7, a pH-insensitive dye, to the surface of bacteriophage particles, a bright pH-responsive ratiometric imaging platform was obtained. With this platform, it is possible to make intracellular pH measurements as well as determine pH through optically diffuse tissue. Current research is focused on development of new nanoparticle scaffolds, for preparation of additional ratiometric pH-sensitive systems. We are also exploring strategies in which correcting for differences in light penetration through diffuse biological tissue at the different imaging wavelengths would not be necessary. One potential approach is through the use of fluorescence lifetime-based measurements using pH-sensitive and -insensitive dyes, which have identical absorption and emission wavelengths, but different fluorescence lifetimes. Once these hurdles are overcome, *in vivo* fluorescence-based imaging of pH in disease will be feasible. Such systems could prove invaluable for identification and diagnosis of tumors and other diseased states.

ACKNOWLEDGMENT

This research was funded in part by NIH grants CA119349, CA92782, and HL080731 (to R.W.).

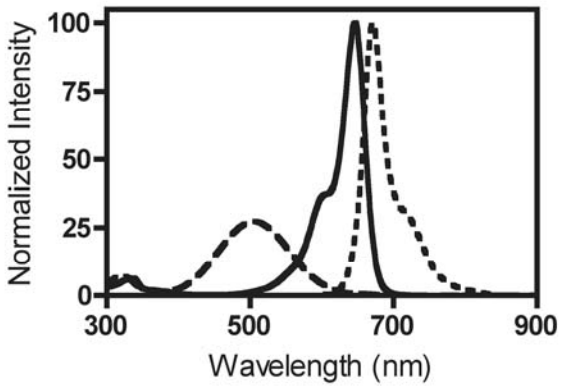

Figure S1. Normalized absorption and fluorescence emission data for 1 µM HCyC-646 in aqueous media. The absorbance trace of the deprotonated dye in pH 10.0 aqueous NaOH solution (dashed line) and the absorbance of the protonated dye in 50 mM glycine buffer, pH 3.0 (solid line) are shown. The fluorescence emission (dotted line) was obtained by excitation of the protonated dye at 610 nm in 50 mM glycine buffer, pH 3.0.

Table S1. Raw fluorescence emission signals from the Cy 7 and HCyC-646 dye labeled bacteriophage alone or through tissue (subcutaneous) collected on the Maestro imaging system showing differences in the attenuation of the two signals through tissue. For the Cy 7 data, the LCD emission filter of the imaging system was set to 775 nm, whereas for the HCy-646 data, the emission filter was set to 670 nm. The same phantom solution, 1 µM probe with respect to Cy 7 at pH 5.12, was used for the data with and without the optically diffuse tissue.

Synthesis and Gene Transfection Efficacies of PEI−Cholesterol-Based Lipopolymers

Avinash Bajaj,[†] Paturu Kondaiah,[‡] and Santanu Bhattacharya*[,†,§]

Department of Organic Chemistry, and Department of Molecular Reproduction, Development, and Genetics, Indian Institute of Science, Bangalore 560 012, India, and Chemical Biology Unit of JNCASR, Bangalore 560 064, India. Received October 14, 2007; Revised Manuscript Received March 18, 2008

Nine lipopolymers based on low molecular weight polyethyleneimines (PEI) and cholesterol via an ether linkage between the polymer amine and the cholesterol backbone have been synthesized. Different percentage of cholesterol moieties have been grafted on three types of PEI of molecular weights 800, 1200, and 2000. These lipopolymers were studied for gene transfection activities in HeLa cells. All the lipopolymers were first optimized for enhanced transfection efficacies as coliposomes with DOPE. All lipopolymers are better transfecting agents and highly serum compatible than commercially available PEI-25KDa. Transfection efficacies and serum compatibility of lipopolymers were found to be dependent upon the MW of PEI used for lipopolymer synthesis and percentage of cholesterol grafting on lipopolymers. Cell viability assay showed that PEI-25KDa is highly toxic as compared to all the lipopolymers. Lipopolyplexes were characterized by transmission electron microscopy, which showed the presence of spherical aggregates.

INTRODUCTION

Gene Therapy (*1*), which involves the transfer of a desired gene to a target cell, is a new hope for various disorders like cystic fibrosis (*2, 3*), diabetes, cancer (*4, 5*), AIDS (*6*), and so forth (*7*−*9*). The first major challenge of the use of gene therapy for curing disorders is to deliver the desired gene efficiently with the least toxicity and low immunogenicity. A second major challenge is to transfer such genes to the specific cells (*10*−*13*). Viruses are very potent carriers for delivery of the gene, but due to toxicity, strong immunogenicity, and its limitation to carry less DNA, various researchers are trying to develop different kinds of nonviral vectors for efficient gene delivery (*14*−*17*).

Among nonviral vectors, cationic lipids (*18, 19*), polymers (*20*), and lipopolymers (*21*) are a major focus for researchers to develop new vectors for efficient gene delivery. Various kinds of cationic lipids have been developed and investigated for their gene transfection activity (*22*−*25*). Over the past few years, we have been investigating the aggregation, transfection, and mechanistic studies of various lipid-based formulations (*26*−*32*). Among polymers, polyethylenimine (PEI[1]) (*33*), polylysine, polyornithine (*34, 35*), and so forth have been examined for gene delivery (*36*). Behr and co-workers demonstrated for the first time the transfection efficacy of PEI (*33*). PEI is also one of the main focus systems for gene delivery in many research groups because of its early endosomal release of DNA, which prevents the DNA from degradation in late endosomes (*37*). This is because of the different pK_a values of the primary, secondary, and tertiary amines in it, which give the PEI a good buffer capacity that does not allow it to lower the pH of early endosomes, which is suitable for various enzymes to act (*37*).

PEIs of different molecular weights ranging 0.6−800 kDa have been examined in gene transfection studies (*37*). PEIs of higher molecular weights (70−800 kDa) were found to be better transfecting agents for *in vitro* studies, whereas low MW PEIs have been known to show better gene delivery activity with intravenous administration. Cytotoxicities of PEI increase with increase in molecular weight. However, low MW PEIs are found to be less cytotoxic, although they are not effective as gene delivery agents. To further improve their transfection potential, PEI had been derivatized with various ligands including sugars (*10*), amino acids (*36*), poly(ethylene glycol) (*37*), long hydrocarbon chains (*38*), and even cholesterol (*39*). Hydrophobic anchors are essential for gene delivery vehicles because of increased cellular uptake and enhanced DNA stability against the bloodstream (*37*). Klibanov et al. had shown the effect of various chemical modifications of nitrogen atoms on the efficiency of PEIs as synthetic vectors for the delivery of plasmid DNA (*38*).

One of the major problems associated with the nonviral vectors for clinical application is their inefficiency in serum conditions (*40*−*43*). It has already been mentioned that a hydrophobic part is essential to enhance the stability of the lipoplex in the bloodstream and gene transfer, as the cellular uptake would be increased by favorable hydrophobic groups of gene carrier and cell membrane. Various kinds of long-chain alkyl and cholesteryl groups have been attached to PEI to enhance the efficiency of gene transfer. Modification of PEI of M_w 1800 with cholesterol at the primary amine has been shown to dramatically increase the transfection efficacy of PEI (*44*). Modification of secondary amines in PEI with cholesterol moieties was also shown to furnish better transfection activities (*45*). Kim and co-workers have shown the DNA delivery abilities of modified linear PEI (MW 25 kDa) with cholesterol (*46*). Park et al. studied the transfection properties of cholesterol and myristate-conjugated PEI (*39*). Recently, dexamethasone-conjugated low molecular weight PEI was reported for gene transfection efficacies as well (*47*).

We have previously reported the aggregation and transfection properties of different types of cationic lipids (*48*−*52*). We also

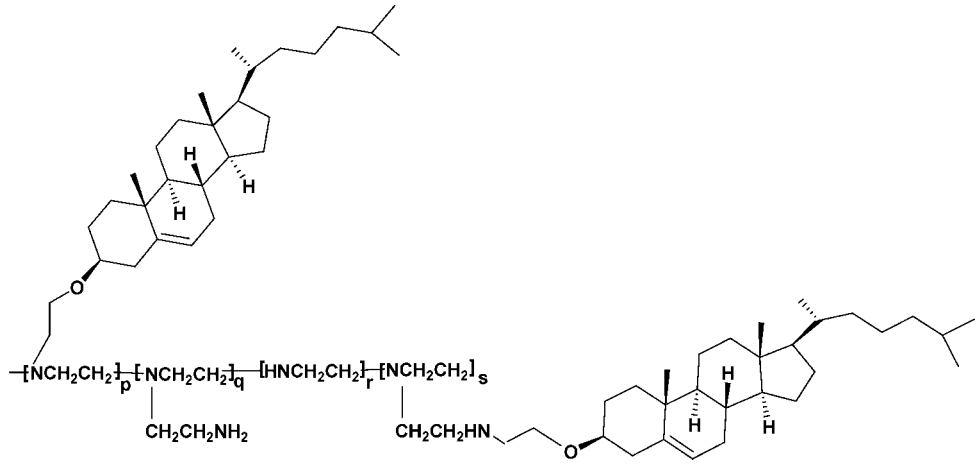

Figure 1. General structure of the PEI−cholesterol-based lipopolymers used for the study.

probed the interaction of cholesterol in membranes with cationic and phospholipids (*53, 54*). Cholesterol accordingly was used in the design of various cationic lipids and lipopolymers due to its natural occurrence, which make the vectors biocompatible. It has already been reported from this laboratory that the nature of the linkage between the hydrophobic cholesterol backbone and the headgroup plays an important role in regulating the transfection activities of cationic lipids (*55*−*59*). Thus, the cholesterol lipids possessing ether-based linkages between the cationic headgroup and steroid skeleton significantly enhanced transfection activities as compared to its ester- or urethane-based counterparts. Recently, we also showed the serum-compatible gene transfection activities of cholesterol-based gemini lipids differing in the length and nature of the spacer between the headgroups (*42, 43*).

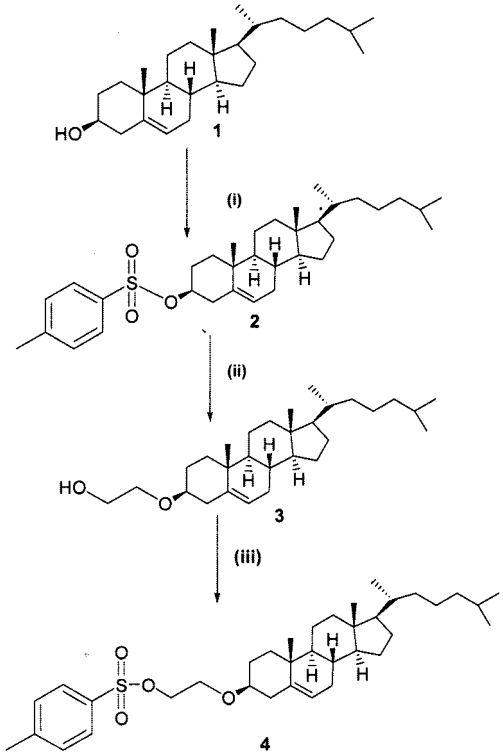
Although few PEI−cholesterol conjugates have been reported (*39, 45, 46*), the PEI−lipid conjugates based on ether-linked cholesterol units have never been described and examined for transfection activity. Accordingly, we have synthesized nine lipopolymers with variable extent of cholesterol units to three different low molecular weight PEIs (M_w = 800 (**P8**), M_n = 1200 (**P12**), and M_w = 2000 (**P20**)) via ether-based links. We also characterized such cholesterol−PEI-based lipopolymers (Figure 1) and finally investigated their transfection efficiencies.

EXPERIMENTAL PROCEDURES

Materials and Methods. All reagents, solvents, and chemicals used in this study were of the highest purity available. The solvents were dried prior to use. Column chromatography was performed using 60−120 mesh silica gel. NMR spectra were recorded using Jeol JNM λ−300 (300 MHz for ^{1}H) spectrometer. The chemical shifts (δ) are reported in ppm downfield from the internal standard: TMS, for ^{1}H NMR. Mass spectra were recorded on a MicroMass ESI-TOF spectrometer or ESI-MS (HP1100LC-MSD). Infrared (IR) spectra were recorded on a Jasco FT-IR 410 spectrometer using KBr pellets or neat.

Synthesis (Scheme 1). *Cholest-5-en-3β-tosylate (2).* To an ice-cooled solution of cholesterol (**1**) (5.0 g, 0.013 mmol) in dry pyridine (5 mL) and dry chloroform (5 mL), *p*-tosyl chloride (3.7 g, 0.02 mmol) was added. A catalytic amount of DMAP was also added. The reaction mixture was then allowed to stir at 0 °C for 6 h, chloroform (35 mL) was added, and the resulting reaction mixture was washed with 1 N HCl (2 × 50 mL), water (50 mL), and brine (50 mL); the organic layer was separated and dried over anhydrous Na_2SO_4. Chloroform from this solution was evaporated to leave a residue. From the residue, cholest-5-en-3β-tosylate (**2**) was recrystallized using chloroform and methanol. Yield: White solid, 6.49 g., 0.012 mmol, 92.8%. m.p: 133 °C. lit m.p: 132−133 °C (*55*). IR (neat) (cm^{-1}): 2949, 2867, 1598, 1495, 1467, 1366, 1188, and 1174. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 0.65 (s, 3H), 0.84−2.29 (m, 41H), 2.44 (s, 3H), 4.32 (m, 1H), 5.30 (d, 1H, J = 4.5 Hz), 7.31−7.34 (d, 2H, J = 8.1 Hz), 7.78 −7.81 (d, 2H, J = 8.1 Hz).

Scheme 1[a]



[a] Reaction conditions: (i) *p*-TsCl/Py/$CHCl_3$, 0 °C, 6 h; (ii) ethylene glycol, 1,4-dioxane, 4 h, reflux; (iii) *p*-TsCl/Py/$CHCl_3$, 0 °C, 6 h.

Cholest-5-en-3β-oxyethane (3). Chlolest-5-en-3β-tosylate (**2**) (3.5 g, 6.5 mmol) was taken in anhydrous dioxane. To this, dry ethylene glycol (10 g, 0.16 mol) was added and the mixture was refluxed under nitrogen for 4 h. The solution was cooled and solvent was removed under vacuum. A white residue was obtained which was dissolved in chloroform (50 mL) and washed with water. The organic layer was separated; washed with $NaHCO_3$ (50 mL), water (50 mL), and brine (50 mL); and dried over anhydrous Na_2SO_4. Finally, from this solvent was removed *in vacuo*, and the product cholest-5-en-3β-oxyethane (**3**) was purified by column chromatography over silica gel using a mixture of hexane and ethyl acetate. Yield: white solid, 2.3 g,

P20C3	2000	17.17	3	26.36	1:0

[a] More then 100% cholesterol grafting indicates that the primary amines in PEI get alkylated with two cholesteryl moieties.

5.3 mmol, 85%. m.p: 99−100 °C. lit mp: 97−98 °C (*60*). IR (neat) (cm^{-1}): 3438, 2936, 2868, 1466, and 1376. ^1H NMR ($CDCl_3$, 300 MHz): δ 0.67 (s, 3H), 0.85−2.35 (m, 41H), 3.20 (m, 1H), 3.57−3.60 (t, 2H), 3.72 (t, 2H), 5.34 (d, 1H). ESI-MS: 453 ($M + Na^+$).

Cholest-5-en-3β-oxyethane tosylate (4). To an ice-cooled solution of cholest-5-en-3β-oxyethan-2-ol (**3**) (2.2 g, 5.1 mmol) in dry pyridine (5 mL) and dry chloroform (5 mL), *p*-tosyl chloride (1.5 g, 7.86 mmol) was added. The reaction mixture was allowed to stir at 0 °C for 6 h, chloroform (40 mL) was added, and then the reaction mixture was washed with 1 N HCl (2 × 50 mL), water (50 mL), and brine (50 mL). Finally, the organic layer was separated and dried over anhydrous Na_2SO_4. Solvent was removed using a rotary evaporator, and the product cholest-5-en-3β-oxyethane tosylate (**4**) was purified by column chromatography over silica gel using a mixture of hexane and ethyl acetate. Yield: 2.68 g, 7.04 mmol, 90.0%. IR (neat) (cm^{-1}): 2935, 2886, 1598, 1465, 1360, 1189, and 1177. ^1H NMR ($CDCl_3$, 300 MHz): δ 0.67 (s, 3H), 0.85−2.25 (m, 41H), 2.44 (s, 3H), 3.06−3.13 (m, 1H), 3.63−3.66 (t, 2H), 4.13−4.16 (t, 2H), 5.31 (d, 1H), 7.32−7.35 (d, 2H), 7.79−7.82 (d, 2H). ESI-MS: 607 ($M + Na^+$).

Lipopolymer Synthesis (Scheme 2). Cholest-5-en-3β-oxyethane-tosylate (**4**) (170 mg, 0.29 mmol) was taken in 3 mL of dry toluene. Desired amounts of PEI solutions (2−8 equiv) from the stock solution of PEI in dry MeOH were added to reaction mixture. The reaction mixture was refluxed, the reaction was monitored by TLC, and reflux was continued until the disappearance of cholest-5-en-3β-oxyethane-tosylate (**4**). The reaction mixture was evaporated, and 30 mL of chloroform was added to the crude mixture. The chloroform layer was washed with 5 mL of 1 N NaOH, water (5 mL), and brine solution (5 mL). The organic layer was passed through dry K_2CO_3 and evaporated to get lipopolymer. All the lipopolymers were characterized by ^1H NMR.

Transmission Electron Microscopy. Freshly prepared aqueous suspensions of lipopolymer−DNA complexes were examined under transmission electron microscopy with negative staining using 1% uranyl acetate. A 10 μL sample of the suspension was loaded onto Formvar-coated 400 mesh copper grids and allowed to remain for 1 min. Excess fluid was wicked off the grids by touching their edges to filter paper, and 10 μL of 1% uranyl acetate was applied on the same grid after which the excess stain was similarly wicked off. The grid was air-dried for 30 min, and the specimens were observed under TEM (JEOL 200-CX) operating at an acceleration voltage of 120 keV. Micrographs were recorded at a magnification of 5000−20 000×.

Plasmid DNA. pEGFP-c3 (Clontech, USA), which encodes for an enhanced green fluorescence protein (GFP) under a CMV promoter, was amplified in *Escherichia coli* (DH5α) and purified using Qiagen Midi Prep Plasmid Purification protocol (Qiagen, Germany). Purity of the plasmid was checked by electrophoresis on 1.0% agarose gel. Concentration of the DNA was estimated spectroscopically by measuring the absorption at 260 nm and confirmed by gel electrophoresis. The plasmid preparations showing a value of $OD_{260}/OD_{280} > 1.8$ were used.

Cell Culture. Cells (HeLa) were cultured in Dulbecco's Modified Eagle's Medium (DMEM; Sigma) supplemented with 10% fetal bovine serum (FBS) in T25 culture flasks (Nunc, Denmark) and were incubated at 37 °C in a humidified atmosphere containing 5% CO_2. Cells were regularly passaged

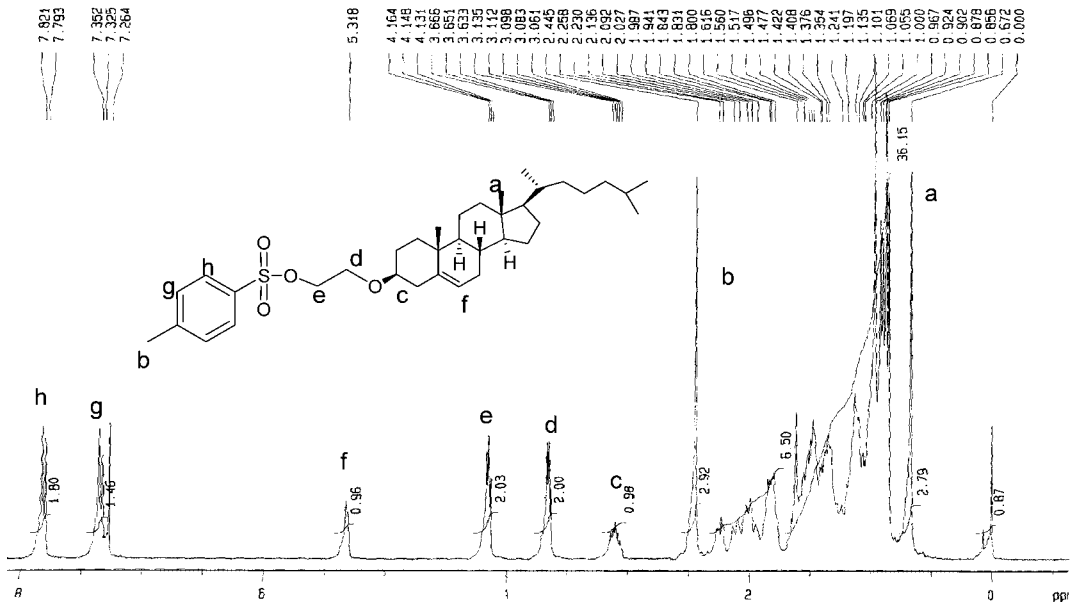

Figure 2. Representive ^{1}H NMR (300 MHz) of cholest-3β-oxyethan-tosylate.

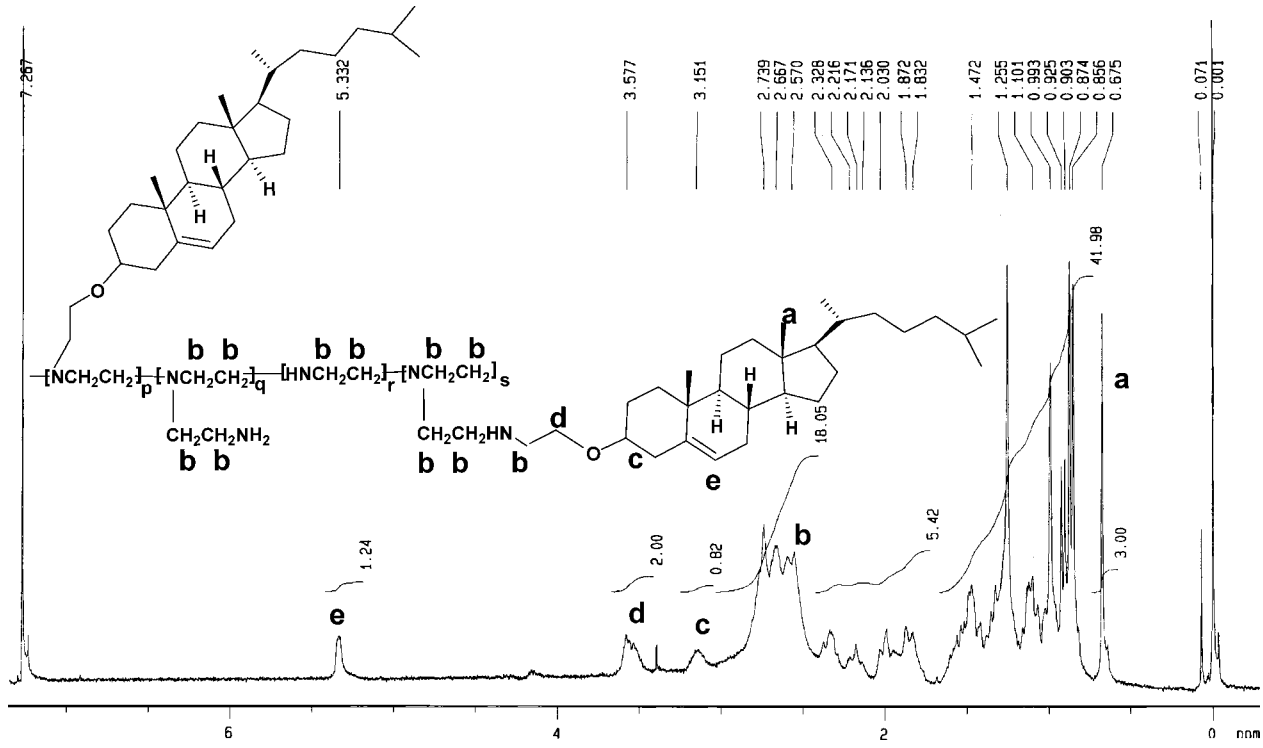

Figure 3. Representive ^{1}H NMR (300 MHz) of one lipopolymer molecule.

by trypsinization with 0.1% trypsin (EDTA 0.02%, dextrose 0.05%, and trypsin 0.1%) in PBS (pH 7.2).

Cytotoxicity. Toxicity of each lipopolymer formulation toward HeLa cells was determined using 3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyltetrazolium bromide reduction assay following literature procedures (*61, 62*).

Cytotoxicity of the lipopolymer formulations optimal for transfection experiments was determined under conditions exactly the same as transfection conditions. Nearly 12 000 cells/well were plated in 96 well plates. After 24 h, optimized lipopolymer/DOPE formulations were complexed with 0.2 μg of the DNA at various N/P ratios for 30 min. DNA−lipopolymer complexes were added to the cells in the absence of serum. After 6 h of incubation, lipoplexes were removed and 200 μL of media with 10% FBS was added. After 42 h, 20 μL of MTT solution was added and the cells were incubated further for 6 h. Blue formazan crystals were seen when checked under microscope. Media was removed and 200 μL of DMSO was added per well. The absorbance was measured using a microtiter plate reader. The % viability was then calculated as [{A_{590}(treated cells) − background]/[A_{590}(untreated cells) − background}] × 100.

Transfection Procedure. All transfection experiments were carried out in HeLa Cells in antibiotic-free media unless specified otherwise. In a typical experiment, 24 well plates were seeded with 45 000 cells/well in antibiotic-free media 24 h before transfection such that they were at least ~70% confluent at the time of transfection. For transfection, lipopolymer

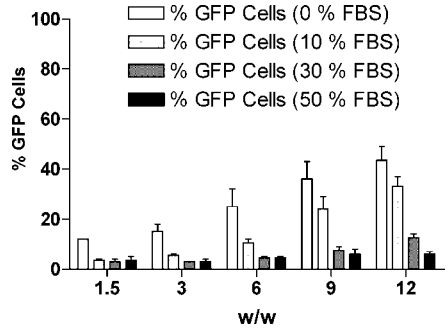

Figure 4. Transfection efficiency of PEI-25KDa at different polymer/DNA weight ratios (w/w) using EGFP-c3 plasmid in the presence of different percentages of serum.

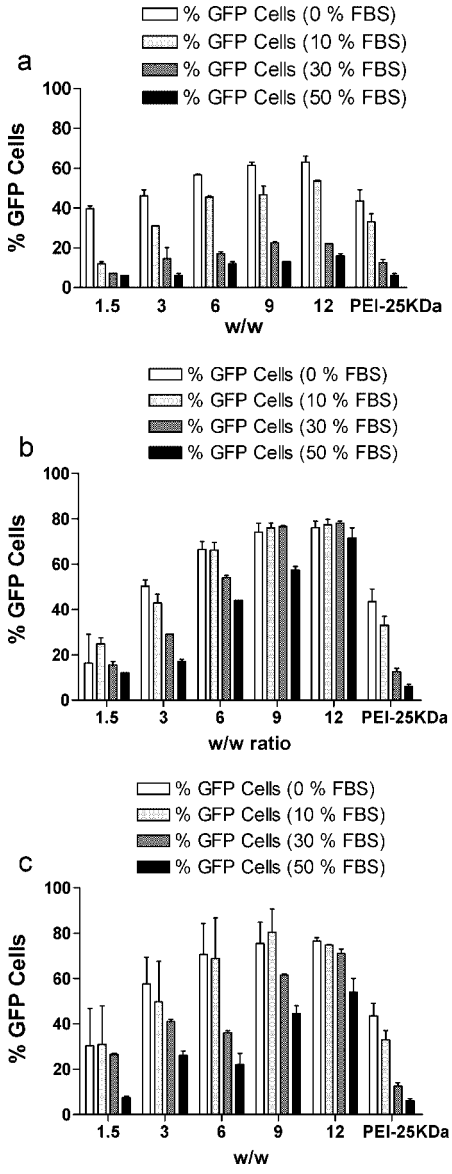

Figure 5. Transfection efficiencies of lipopolymers at different lipopolymer/DNA weight ratios (w/w) using EGFP-c3 plasmid in the presence of different percentages of serum using optimized lipopolymer/DOPE ratio: (a) **P8C1**; (b) **P8C2**; (c) **P8C3**.

formulation and DNA were serially diluted separately in DMEM containing no serum to have the required working stocks. DNA was used at a concentration of 0.8 μg/well unless specified otherwise. The lipopolymer and DNA were complexed in a volume of 200 μL by incubating the desired amount of lipopolymer formulation and DNA together at room temperature for about 30 min. The lipopolymer concentrations were varied so as to obtain the required lipopolymer/DNA (w/w) charge ratios. After 30 min of complexation, 200 μL of media was added to the complexes. Old medium was removed from the wells, cells were washed with DMEM, and lipopolymer−DNA complexes in 200 μL media were added to the cells. The plates were then incubated for 6 h at 37 °C in a humidified atmosphere containing 5% CO_2. At the end of incubation period, medium was removed, and cells were washed with DMEM, and then 500 μL of DMEM containing 10% FBS was added per well. Plates were further incubated for a period of 42 h before checking for the reporter gene expression. GFP expression was examined by fluorescence microscopy and was quantified by flow cytometry analysis. All the experiments were done in duplicate, and results presented are the average of at least two such independent experiments done on two different days.

For transfections in the presence of serum, lipopolymer and DNA were separately diluted in serum-free media as already mentioned, and the complexation was done in serum-free media (200 μL) for 30 min. The complex was then diluted to 400 μL with DMEM containing 20% FBS so as to achieve a final serum concentration of 10%. The cells were then incubated with this complex for 6 h. At the end of the incubation period, medium was removed and cells were washed with DMEM, and 500 μL of DMEM containing 10% FBS was added per well. For transfections at 30% and 50% of serum concentrations, complexes were diluted with DMEM containing 60% FBS or with neat FBS, respectively.

Flow Cytometry. The reporter gene expression was examined by fluorescence microscopy at regular intervals and was quantified 48 h post-transfection by flow cytometry. The percentages of transfected cells were obtained by determining the statistics of cells fluorescing above the control level where nontransfected cells were used as the control. Approximately 10 000 cells were analyzed to generate the statistical data, which have been presented as the average of at least two independent measurements. For the flow cytometry analysis, ~48 h post-transfection, old medium was removed from the wells; cells were washed with PBS and trypsinized by adding 100 μL of 0.1% trypsin. To each well, 200 μL of PBS containing 20% FBS was added. Duplicate cultures were pooled and analyzed by flow cytometry immediately using Becton and Dickinson flow cytometer equipped with a fixed laser source at 488 nm.

FACS Analysis. FACS data were analyzed by public domain *WinMDI* software to eliminate data from cell debris (particles smaller than cells), dead cells, and clumps of two or more cells. Subcellular debris and clumps can be distinguished from single cells by size (estimated by the intensity of low angle forward scatter). Dead cells have lower forward-scatter and higher side-scatter than living cells. The FACS scans were configured to display the fluorescence signals only from those particles with a specified set of scatter properties, namely, living single cells. This is called a scatter-gated fluorescence analysis. Therefore, the data from dead cells had been eliminated by gating out brightly fluorescent cells. We have presented the representative FACS scans (as well as scatter plots) for the transfection experiments using lipopolymers and the respective FACS scans (as well as scatter plots) of the untransfected cells in the Supporting Information. We have set up the baseline in FACS scans, so that we observed only 1−3% transfection in the untreated cells as shown by the FACS scans presented in the Supporting Information. Baseline setup for the representative FACS scans has been shown in the Supporting Information.

RESULTS

Synthesis and Characterization. Nine PEI−cholesterol-based lipopolymers were synthesized using different molecular

weight polyethylenimines as starting materials (Figure 1, Table 1). Different percentages of cholesteryl units were incorporated covalently on PEI by its reaction with cholest-5-en-3β-oxyethane tosylate (**4**). First, cholesterol (**1**) was tosylated using *p*-toluenesulfonyl chloride in pyridine−chloroform (v/v: 1/1) with a catalytic amount of DMAP for 6 h at 0 °C in 92% yield. Cholesterol tosylate (**2**) was then subjected to a reaction with ethylene glycol in dioxane under reflux for 4 h to afford cholest-5-en-3β-oxyethan-2-ol (**3**) in 85% yield. Compound **3** was then tosylated with *p*-toluenesulfonyl chloride in pyridine−chloroform (v/v: 1/1) for 6 h at 0 °C to get **4** in 90% yield. Reaction of the tosylate (**4**) with PEI of different molecular weights in different mole ratios resulted in the formation of PEI−cholesterol-based lipopolymers. All the lipopolymers were characterized by ^{1}H NMR studies (*47*).

Characterization of Lipopolymers. Figure 2 displays the ^{1}H NMR of cholest-3β-oxyethan-tosylate (**4**). The ^{1}H peak at δ of 0.67 is due to the angular methyl group directly linked to cyclohexane and cyclopentane rings of the cholesterol backbone (signal a designated by proton a). The chemical shifts at δ 3.64 and δ 4.14 were attributed to protons d and e, respectively. The ^{1}H peaks of δ 3.09 and δ 5.3 were associated with the $-CH-$O$-$ (proton c, signal c) and $-CH=$C$-$ (proton f, signal f) protons of cholesterol, respectively. Singlets at δ 2.3 (proton b, signal b) and δ 7.3, 7.8 (protons g and h, signal g and h) were due to methyl and aromatic protons of the tosylate group. The ratio of the peak areas was determined to be 3:3:1:2:2:1:2:2 for signals/protons a:b:c:d:e:f:g:h, confirming the successful synthesis of cholest-3β-oxyethan-tosylate (**4**).

The successful synthesis of lipopolymers was evidenced by ^{1}H NMR spectra as shown in Figure 3. The ^{1}H NMR of lipopolymers illustrates peaks at δ 0.67, 3.14, and 5.3 because of the presence of protons a, c, and e due to the cholesterol moiety. Various peaks at 0.7−1.2 were also attributed to the presence of cholesterol units with polymer. The peak at 5.38 arose from the proton of =CH− in the cholesterol units (signal e). The peak at δ 0.7 was from the methyl group directly linked to the cyclic hydrocarbon (signal a). The broad peak in the

region δ 2.0−2.5 was because of the protons of the PEI backbone (signal b, protons b), which also includes the protons of $-CH_2-$ from the $-CH_2-CH_2-O-$ group of the cholesterol unit attached to the PEI backbone by alkylation. Disappearance of the peaks at δ 2.3 and δ 7−8 in ^{1}H NMR of lipopolymers (Figure 3) (signals b, g, and h observed in the case of the ^{1}H NMR spectra of cholest-3β-oxyethan-tosylate (Figure 2)) confirms the substitution of the tosylate group by the amine of PEI. The information provided by the ^{1}H NMR spectrum of lipopolymers proved that the cholesteryl group was successfully grafted onto the PEI main chain.

Degree of Cholesterol Grafting in PEI. The grafting degree was obtained from the ^{1}H NMR spectra. The degree of cholesterol grafting has been defined as the relationship of the number of amines alkylated by the cholesterol moiety to the total number of amines on the PEI chain. The signal at 0.67 is due to the protons attached to the $-CH_3$ group directly linked to the hexane and pentane cycles of the cholesterol backbone (signal a, proton a). The broad peak in the region δ 2.0−2.5 is attributed to $-CH_2-$ of the PEI backbone as well as the protons of $-CH_2-$ from the $-CH_2-CH_2-O-$ group attached to the cholesterol backbone, which are now attached to PEI backbone by alkylation. The ratio of the protons due to $-CH_3$ at δ 0.67 and $-CH_2$ from the $-CH_2-CH_2-O-$ group attached to the cholesterol backbone, which are now attached to the PEI backbone by alkylation is 3:2, or 1.5:1. Therefore, the area of the curve in the region δ 2.0−2.5 (ΔA_{pei}) also includes the area (ΔA_c/1.5) which is due to $-CH_2$ from the $-CH_2-CH_2-O-$ group attached to the cholesterol backbone, which are now attached to the PEI backbone by alkylation. Therefore, the actual area of the PEI backbone would be ($\Delta A_{pei} - \Delta A_c$/1.5). The percentage of grafting may be estimated as follows:

$$R_g = \frac{\Delta A_c \times N_{pei}}{\left(\Delta A_{pei} - \frac{\Delta A_c}{1.5}\right) \times N_c}$$

where ΔA_c is the area of the selected peak from the cholesterol backbone, ($\Delta A_{pei} - \Delta A_c$/1.5) is the area of the selected peak of the PEI backbone, N_c is the number of hydrogen atoms from the selected region of cholesterol backbone, and N_{pei} is the number of hydrogen atoms from the selected region of the PEI backbone. Only suitable protons from the pendant chain and the main chain of the polymers were selected in the calculation. The proton signal selected should not overlap with the signals from other protons. On the basis of the peak area of the signals a and b, R_g for lipopolymers was estimated as given in Table 1.

Transfection Efficacy. *Optimization of the Lipopolymer/DOPE Ratio.* Incorporation of the helper lipid, DOPE, is known to enhance the transfection efficiencies of many of cationic lipid-based formulations (*63*). Therefore, we first decided to investigate the optimized lipopolymer/DOPE mole ratios for our newly synthesized lipopolymers. These data were obtained from flow cytometric analysis (*64*). In order to determine the most effective formulations, transfections were performed with identical amounts of the DNA and lipopolymer upon variation of mole ratios of lipopolymers in DOPE. Optimized lipopolymer/DOPE mole ratios were found to depend upon the percentage of cholesterol grafting and the molecular weight of PEI. The optimized lipopolymer/DOPE ratios for all lipopolymers are given in Table 1. Lipopolymers (**P8C1**, **P12C1**, **P20C1**) with highest cholesterol drafting showed optimized transfection at lipopolymer/DOPE ratio of 1:1. In contrast, lipopolymers **P20C2** and **P20C3** showed maximum transfection activities in the absence of DOPE. In further studies, we used these optimized lipopolymer/DOPE formulations. All the optimized lipopolymer formulations were examined for transfection studies using EGFP-c3 plasmid in HeLa cells at different DNA/lipoolymer weight ratios. The transfection experiments were performed in the absence and in the presence of serum. To get further insight, we investigated the transfection activities at higher serum concentrations as well. The transfection experiments have also been performed with the unmodified polymers. We have not observed any transfection activity with these polymers. It is also well-known in the literature that low molecular weight PEI does not show transfection. Kim et al. (*45*) reported only <1% transfection efficiency of PEI of molecular weight 1800, and transfection efficiencies increases with increase in molecular weight. PEI-25KDa was found to be the best commercially available PEI polymer, and we have compared the transfection efficacies of lipopolymers with PEI-25KDa.

Optimization of Lipopolymer/DNA Ratio. After optimization of lipopolymer/DOPE mole ratio for each lipopolymer, all the lipopolymers were tested by taking an identical amount of DNA (0.8 μg) and varying the amount of lipopolymer using the respective optimized lipopolymer/DOPE ratio. We have also examined the transfection efficacies of commercially available PEI 25KDa. It showed nearly 40% GFP positive cells by FACS analysis, and even in the presence of 10% serum, nearly 30% transfection efficacy was observed (Figure 4). At higher serum concentrations of 30% and 50%, transfection activity decreases drastically. Only ∼5% transfection activity was observed in the presence of 50% serum.

Formulation from the **P8C1** lipopolymer was able to transfect nearly 60% of the cells in the absence of serum and in the presence of 10% serum; there was little decrease in the transfection activity to 50% (Figure 5). At high serum concentrations of 30% and 50%, nearly 10−20% GFP-positive cells were found by FACS analysis. Formulations based on lipopolymers **P8C2** and **P8C3** showed nearly 70% transfection activity. In the case of **P8C3** formulation, there was a decrease in the activity at higher serum concentrations, whereas in case of **P8C2** formulation, there was some decrease in the activity in the presence of 50% serum concentrations. Nearly 60% GFP-positive cells were observed at a w/w ratio of 12 at 50% serum concentrations in the case of lipopolymer **P8C2**, whereas in case of lipopolymer **P8C3**, nearly 50% transfected cells were observed.

In the case of formulations **P12C1** and **P12C2**, there was no decrease in the transfection activities at high serum concentrations (Figure 6). Nearly 50−60% transfection activities were observed in the cases of both formulations at all serum concentrations. In the case of **P12C3** formulation, transfection efficacy decreases at high serum conditions. Nearly 20−30% transfection activity was observed at 50% serum conditions, whereas 50−60% cells had been found to be positive by FACS analysis in the absence of serum.

There was a gradual decrease in the transfection efficacy with increase in the serum concentrations in the case of **P20C1** and **P20C3** formulations, where in the case of formulation **P20C2**, there was little decrease in the transfection activity at 50% serum conditions (Figure 7). Only 20−30% transfection efficiency was observed at 50% serum conditions for formulations **P20C1** and **P20C3**, whereas **P20C2** showed ∼60% efficacy at 50% serum conditions.

Figure 8 shows the comparative gene transfection efficacies of lipopolymers and PEI-25KDa in the presence of various percentages of serum, which clearly shows that all lipopolymers are better transfecting agents and highly serum compatible than PEI-25KDa. Transfection efficacy and serum compatibility are dependent upon the MW of PEI used for lipopolymer synthesis and % of cholesterol grafting on lipopolymers

Cytotoxicity. Percentage cell viabilities of PEI-25KDa and lipopolymers at different concentrations are shown in Figure 9.

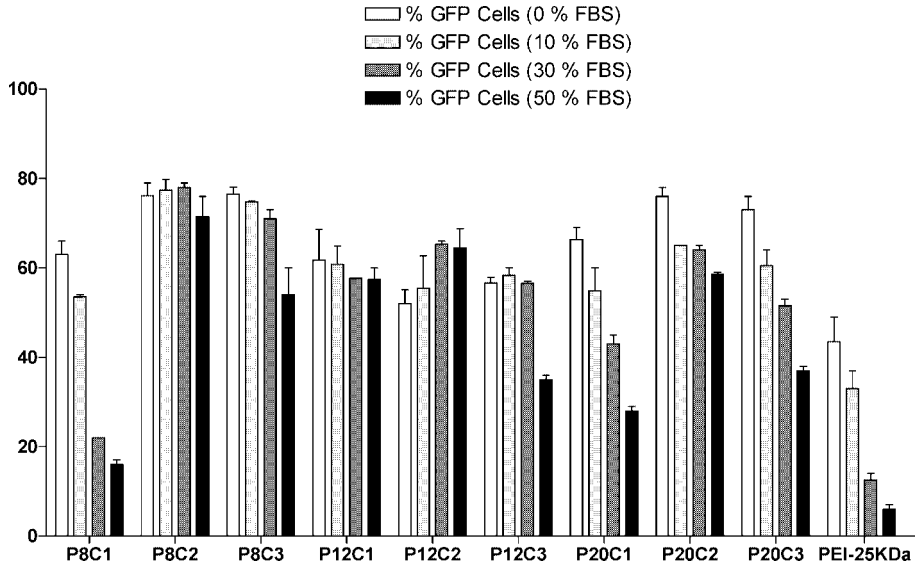

Figure 8. Comparative gene transfection efficacies of lipopolymers and PEI-25KDa in the presence of various percentages of serum using EGFP-c3 plasmid DNA at w/w ratio of 12 using optimized lipopolymer/DOPE ratio.

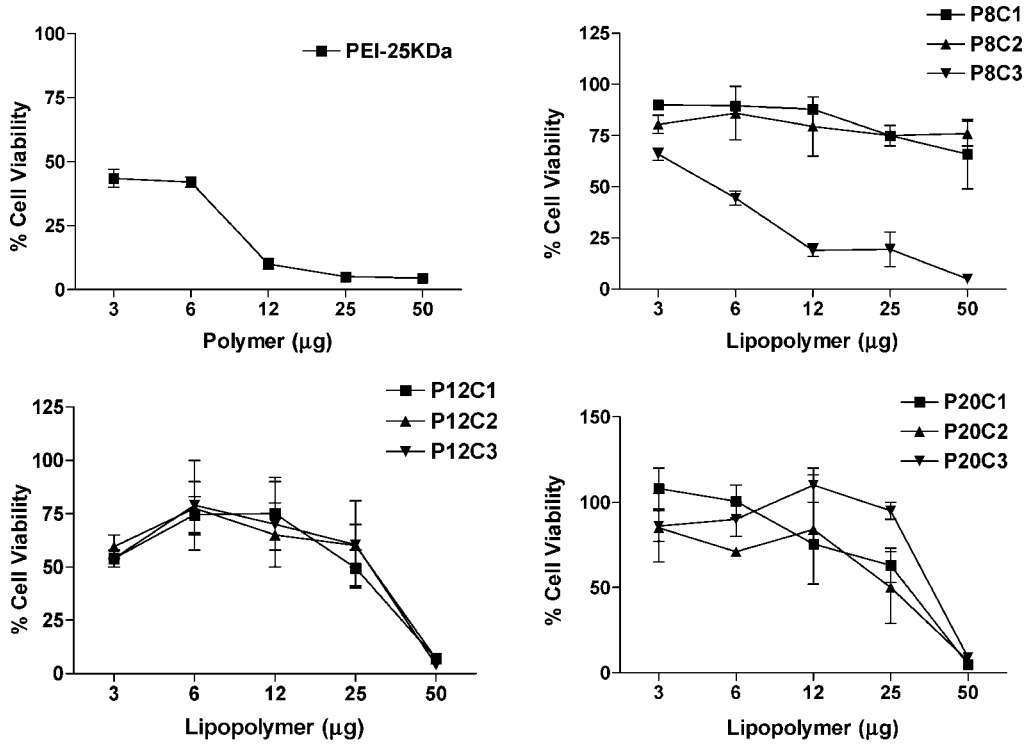

Figure 9. Percentage cell viabilities of PEI-25KDa and lipopolymers in HeLa cells at different concentrations of lipopolymers.

PEI-25KDa was found to be highly toxic as compared to all the lipopolymers. There was nearly complete cell death at 12 μg of the PEI-25KDa. In the case of lipopolymers **P8C1**, **P8C2**, and **P8C3**, % viability increases with increase in cholesterol grafting, and **P8C3** shows complete cell death at 50 μg concentration, whereas 75% cell viability was observed in the case of **P8C1** and **P8C2**. Other lipopolymers showed no cell viability at 50 μg concentration. Therefore, cell viability assays of lipopolymer formulations clearly showed that all lipopolymer formulations are much less toxic as compared to commercially available PEI-25KDa. After studying the cytotoxicity of lipopolymer formulations, we studied the cell viabilities of lipopolyplexes (lipopolymer/DNA complexes) using optimized lipopolymer/DOPE formulations at different w/w ratios at which transfection experiments were performed. Cell viabilities of lipopolyplexes at different w/w ratios are shown in Figure 10. This clearly showed that all lipopolyplexes possessed more than 80% cell viability, whereas formulations **P20C1** and **P20C2** were found to be toxic at lipopolymer/DNA weight ratio of 12, where 50% cell viability was observed.

Characterization of Lipopolyplexes. To get further insight into the lipopolymer−DNA complexes, we performed transmission electron microscopy of the lipopolymer−DNA complexes using the optimized lipopolymer/DOPE formulations. Representive electron micrographs of lipopolymer−DNA complexes have been shown in Figure 11. Most of the lipopolymer formulations formed spherical lipopolymer−DNA complexes. Lipopolymer **P8C3** formulation forms polyplexes of uniform size, whereas other lipopolymer−DNA complexes (of lipopolymers **P20C1** and **P20C2**) were found to be irregular in shape. **P8C2**

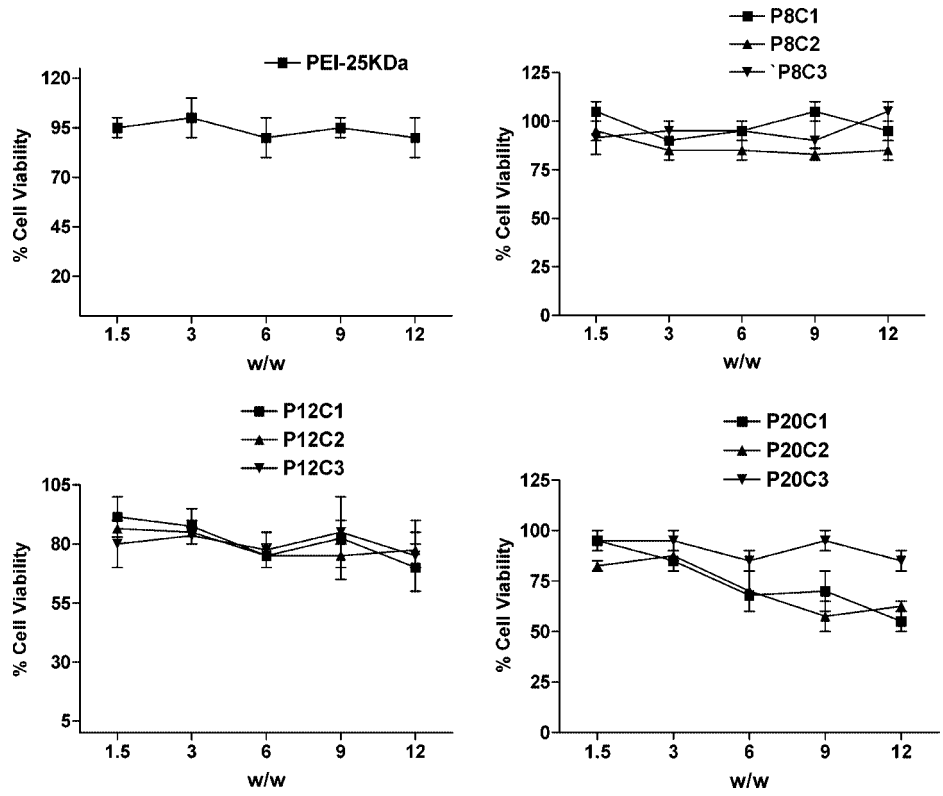

Figure 10. Percentage cell viabilities of lipopolyplexes using PEI-25KDa and lipopolymers at different lipopolymer/DNA weight ratios (w/w) using EGFP-c3 plasmid DNA in HeLa cells at different weight ratios of lipopolymers and DNA.

lipopolymer-based polyplexes showed small spherical loose aggregates. Large spherical aggregates were formed from polyplexes of lipopolymers **P8C1** and **P20C1**.

DISCUSSION

PEIs of different molecular weights have been studied for their gene delivery efficacies since the discovery of its gene transfection potential by Behr and co-workers (*33*). Various structure−activity investigations have been reported with the modification of different types of PEI to enhance the transfection activity and to reduce the toxicity. In this report, we present the effect of cholesterol modification on three different low molecular weight PEIs on cytotoxicity and gene transfection properties, as low molecular weight has been known to show low transfection activity and low cytotoxicity. We synthesized nine PEI−cholesterol-based lipopolymers by alkylation of PEI with cholest-5-en-3β-oxyethane tosylate using three PEIs of different molecular weights. Ether functionality has been incorporated between the amine backbone and cholesterol moiety, as prior studies indicated advantages from transfection with such linkages. Different amounts of cholesterol have been grafted on the PEI backbone. The transfection properties of all the lipopolymers and PEI-25KDa have been studied in HeLa cells. One of the major drawbacks of nonviral vectors for their *in vivo* use is in the inhibition of the transfection in the presence of serum (*65, 66*). Maintenance of the transfection efficiency in the absence of serum even for *in vitro* experiments is also cumbersome often due to the toxic nature of the synthetic formulations. Therefore, we have also studied the effect of the different concentrations of serum on the transfection activities of the lipopolymer formulations and compared that with commercially available PEI-25KDa. PEI-25KDa showed nearly 40% transfection efficacy, but as expected with the increase in serum concentration, the transfection efficacy decreased drastically. This is expected as the highly positively charged PEI interacts with negatively charged serum proteins, thereby triggering dissociation of the PEI−DNA complex resulting in the reduction in transfection activity. Cholesterol-based lipopolymers showed enhanced gene transfection activity as compared to PEI-25KDa. In most of the lipopolymers, gene transfection efficacies decreased expectedly with increase in the serum concentrations in the case of **P8C2**, **P12C1**, and **P12C2** lipopolymer formulations. There is no effect of the high percentages of serum on transfection activities of **P8C2** and **P12C1** lipopolymer formulations, whereas in the case of the **P12C2** lipopolymer formulation, serum was found to enhance the transfection activity. Among all the formulations, **P8C2** showed highest transfection activity. The greater serum compatibility of these lipopolymers might be caused by the cholesterol grafting, as the presence of cholesterol moieties might prevent the serum proteins to dissociate from the lipopolymer−DNA complexes. It is well-known in literature that, with increase in the molecular weight of the PEI, transfection efficiency as well as cytotoxicity increases. The unmodified low molecular weight PEIs of molecular weights 800, 1200, and 2000 do not show any transfection activity, which is consistent with the reports by Kim et al., where <1% transfection activity was reported with PEI of molecular weight 1800 (*45*). The commercially available PEI-25KDa which is known to show high transfection activity was found to be highly toxic as well. The cytotoxicity studies have shown that the presently developed lipopolymers are much less toxic as compared to the commercially available PEI-25KDa. All the lipopolymer−DNA complexes also showed low levels of cell toxicity except **P20C1** and **P20C2**, which may be because of the high molecular weight of the PEI used for these lipopolymers. Although the DNA delivery to eukaryotic cells involves several steps and the mechanism of many of these steps is not very clear at the molecular level (*31, 32, 67*−*69*), it would be important to note the high transfection properties,

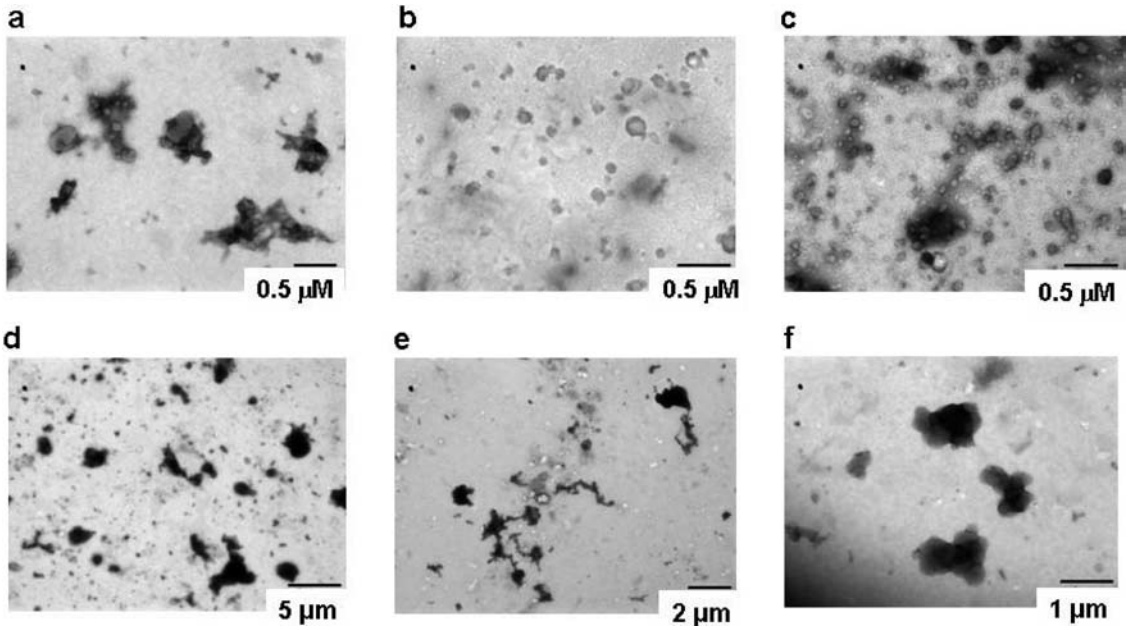

Figure 11. Representative transmission electron micrographs of the lipopolyplexes prepared from optimized lipopolymer/DOPE liposome/DNA complexes at the optimized w/w ratio of 12.0: (a) **P8C1**; (b) **P8C2**; (c) **P8C3**; (d) **P12C1**; (e) **P12C2**; (f) **P20C1**.

low cytotoxicities, and high serum compatibilities of these lipopolymer formulations.

CONCLUSIONS

PEI has been of interest to many scientists for its use in gene delivery applications. PEI can be easily derivatized with different ligands to enhance the biocompatibility and efficacies of the PEI derivatives. Toward this end, we synthesized nine PEI−cholesterol-based conjugates based on ether linkage between the polymer amine backbone and the cholesterol unit. Three low molecular weight PEIs were used for the synthesis of lipopolymers. Cholesterol tethering to PEI render them suitable for partitioning into phospholipid membranes (*70*). The transfection studies in HeLa cells showed high potency and low cytotoxicity of these lipopolymers as compared to the commercially available PEI. Commercially available PEI of molecular weight 25 kDa was found to be very toxic and less effective as compared to lipopolymers. The transfection efficacy of PEI-25 kDa decreased in the presence of high percentage of serum, whereas PEI−cholesterol-based lipopolymers were found to be effective even in the presence of high percentages of serum. The transfection efficacies and cytotoxicities of the lipopolymers were found to depend upon the percentage of cholesterol grafting and the molecular weight of PEI used for the synthesis of lipopolymers. Optimized lipopolymer−DOPE formulations were found to show higher cell viability as compared to PEI-25 kDa. All lipopolymer−DNA complexes except **P20C1** and **P20C2** formulation based lipopolyplexes showed more than 80% cell viability. Most of the lipopolymer formulations formed spherical lipopolymer-DNA complexes. The transfection activities reported in the present study manifest one of the highest efficiency among nonviral delivery reagents known. The retention of high transfection efficiency even in the presence of serum should be of interest to the researchers working in this area.

University, Budapest, Hungary, and Department of Experimental and Health Sciences, Universitat Pompeu Fabra, Barcelona, Spain. Received December 17, 2007; Revised Manuscript Received May 25, 2008

Two conjugates with epitope peptide ^{278}LLEDPVGTVA^{287} derived from glycoprotein D (gD-1) of Herpes simplex virus (HSV) were synthesized for analysis of the effect of conjugation on protection against enzymatic degradation. In this design, the turn-forming epitope core ^{281}DPVG^{284} was positioned in the central part of the peptide and elongated by three amino acids from the native sequence at both termini. Conjugation was achieved by the introduction of amide bond or thioether linkage between the C-terminal of the HSV peptide and the side chain of four lysine residues of the oligotuftsin derivative used as carrier molecule. We compared the proteolytic stability of the conjugates in diluted human sera as well as in rat liver lysosomal preparation. The data obtained in lysosomal preparation at two pH values (pH 3.5 and 5.0) show that the type of covalent bond between the carrier and the epitope peptide had no significant effect, as compared to the stability of the free, unconjugated peptide. Based on the identification of degradation fragments by mass spectrometry we found marked differences in the lengths and amounts of oligopeptides obtained. In contrast, in 10% and 50% human serum the conjugation provided full protection against enzymatic hydrolysis over 96 h, while the free peptide was decomposed quickly.

INTRODUCTION

One of the major limitations in the use of peptides as effective subunit vaccines is their instability in biological matrices, which is mainly due to the rapid degradation by proteases. To protect biologically active peptides from enzymatic decomposition there are various possible approaches, e.g., alteration of the peptide bond (*1*), cyclization (*2*), conjugation to carrier molecules (*3*), and incorporation of nonproteinogenic amino acids such as β-Ala (*4*) or D-amino acids (*5–7*). Conjugation could have several favorable effects on peptides: it can enhance the solubility, improve cellular uptake (*8*), provide prolonged blood circulation, alter biodistribution, and also in some cases it can diminish toxicity. Different strategies can be utilized for conjugation: the biologically active compound can be attached directly to the carrier molecule, or it is possible to use a spacer structure in between. This method is applied when the cargo has to be released on the effect of pH (for example by using a spacer sensitive to pH (*9*)) or enzymatic cleavage (e.g., by using a spacer sensitive to enzymes) and the biologically active compound can exercise its effect in the targeted compartment. When conjugated directly to a carrier molecule, different bonds could be considered: for example, amide bond formation between the amino group of the N-terminus of the cargo peptide and a side-chain carboxyl group (Glu/Asp) of the partner molecule, or between the carboxyl group of the C-terminus of the peptide and a side-chain amino group (Lys) of the carrier. A thioether link could be formed between the SH- side chain of the N- or C-terminal cystein residue of the cargo peptide and the chloroacetylated amino group of a side-chain of the carrier molecule (*10*); a disulfide bridge could be established between Cys residues present in both parties (*11*).

Literature studies mainly report on the drug release from conjugates on enzymatic effect; the enzymatic degradation of conjugates is not discussed as we know. Searle et al. studied the release of ellipticine derivative (6-(3-aminopropyl)-ellipticine) conjugated to *N*-(2-hydroxyprolyl)methacrylamide copolymer through GFLG and GG linker peptides in tritosomes (rat liver lysosomal enzymes) (*12*). Subr et al. used rat liver lysosomal preparation and cathepsin B to study the effect of Gly-Gly, Gly-Leu-Gly, and Gly-DL-Phe-Leu-Gly spacers on the release of methotrexate conjugated to hexamethylenediamine (*13*). Release of daunorubicin conjugated to succinylated serum albumin via one to four amino acids (L, AL, LAL, or ALAL) was studied in lysosomal preparation and in 95% calf serum (*14*).

Herpes simplex virus (HSV), with two closely related serotypes, HSV-1 and HSV-2, is one of the most common infectious agents in humans. Glycoprotein D (gD) of HSV type 1 or 2 is a major envelope protein, and appears to be the major target for the immune response. It has been shown that peptides from the N-terminal region of HSV-1 gD (gD-1) can induce both B and T cell responses (*14*), and the resulting antibodies are proven able to neutralize HSV-1 *in vitro* (*15–18*). Another epitope of gD-1 has been identified by monoclonal antibodies and located in the 268−287 region (*19, 20*). It was shown that the minimal epitope of this region in the HSV gD-1 was the

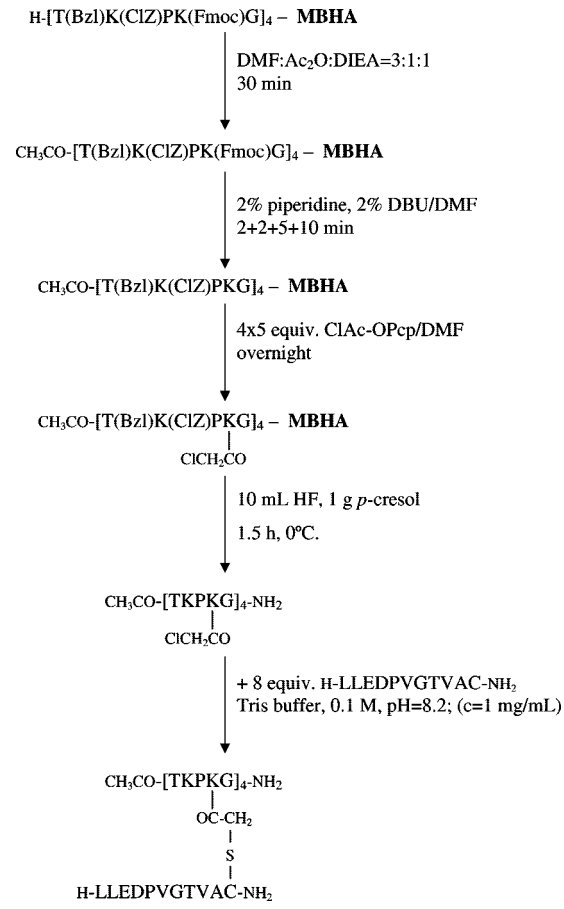
^{281}DPVG^{284} sequence (*21*) representing a turn structure that is important in the immunological recognition, as has been proven in the case of another sequence of the same protein (*22*).

The aim of this study was the analysis of the effect of conjugation on the enzymatic degradation of carrier attached epitope peptide. Therefore, conjugates containing oligotuftsin derivative as carrier and epitope peptide 278−287 with ^{281}DPVG^{284} in the central position were synthesized with amide bond or thioether link. Amide bond formation was achieved between the carboxyl group of the C-terminus of the oligopeptide and the ε-amino group of the side chain of the lysine residues in the carrier molecule (Scheme 1). For introduction of the thioether linkage, first we have elongated the peptide epitope by a C-terminally added cysteine residue. The carrier part of the conjugate was chloroacetylated and used for coupling (Scheme 2). Here we report on our findings on the enzymatic stability of the conjugated epitope peptide in complex biological fluids. The enzymatic hydrolysis of the constructs was investigated in diluted human sera (10% and 50%) and also in rat liver lysosomal preparation at two pH values (pH 3.5 and pH 5). Our data indicate that conjugates show high resistance against proteolytic degradation in diluted human sera but these compounds are degraded in lysosomal preparation.

EXPERIMENTAL PROCEDURES

Materials. Amino acid derivatives were purchased from NovaBiochem (Läufelfingen, Switzerland) and Reanal (Budapest, Hungary). 4-Methyl-benzhydrylamine (MBHA) resin was from NovaBiochem. All chemicals for coupling and cleavage (hydrogen fluoride (HF), thioanisole, *m*-cresol, *p*-cresol, *p*-thiocresol, *N,N′*-dicyclohexylcarbodiimide (DCC), 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), 1-hydroxybenzotriazole (HOBt), trifluoracetic acid (TFA), *N*-ethyldiisopropylamine (DIEA)) were obtained from Fluka (Buchs, Switzerland). All solvents for the synthesis and purification as well as $Na_2HPO_4 \cdot 2H_2O$, KH_2PO_4, Na-acetate$\cdot 3H_2O$, and acetic acid were from Reanal.

Scheme 2. Outline of the Synthesis of Thioether Bond Containing Conjugate of LLEDPVGTVA of gD-1 of HSV



Synthesis of Conjugate with Amide Bond. Amide bond containing conjugate was prepared by solid phase methodology using 0.5 g 4-methyl-benzhydrylamine resin (1.04 mmol/g). The following side-chain protected amino acid derivatives were used: Boc-Thr(Bzl)-OH, Boc-Asp(OcHex)-OH, Boc-Glu(OcHex)-OH, Boc-Lys(Fmoc)-OH, and Boc-Lys(ClZ)-OH. Coupling was carried out by using DCC/HOBt *in situ* active ester method in 4:1 (v/v) DCM/DMF mixture. 3 equiv of amino acid derivatives and coupling reagents were used. N^{α}-Boc group was removed with 33% TFA in DCM. For neutralization 10% DIEA in DCM was applied. The success of the coupling was monitored by ninhydrine reaction (*23*) or isatine assay (*24*). The following protocol was applied: DCM washing (3 × 0.5 min); deprotection with 33% TFA/DCM (2 × 20 min); DCM washing (5 × 0.5 min); neutralization with 10% DIEA/DCM (4 × 0.5 min); DCM washing (4 × 0.5 min); coupling (60 min); DMF washing (2 × 0.5 min); DCM washing (2 × 0.5 min); ninhydrine or isatine reaction. After removal of the N^{α}-Boc group, the side-chain protected tetratuftsin derivative ([T(Bzl)K(ClZ)PK(Fmoc)G]$_4$) was acetylated at the N-terminus using a mixture of acetic anhydride and DIEA in DMF 1:1:3 (v/v/v) for 30 min. Then the Fmoc groups were removed with 2% piperidine, 2% DBU in DMF four times for 2 + 2 + 5 + 10 min. The sequence of LLEDPVGTVA decapeptide was built up stepwise on the ε-amino group of the Lys residues using suitable protected amino acids by Boc strategy. The conjugate was cleaved from the resin by the aid of anhydrous HF-*p*-cresol (10 mL/1 g) at 0 °C for 1.5 h, precipitated with dry diethyl ether, filtered, and washed several times with diethyl ether. The conjugate was dissolved in 10% acetic acid and freeze-dried.

Synthesis of Conjugate with Thioether Bond. The oligotuftsin derivative as well as peptide H-LLEDPVGTVAC-NH_2

was prepared by solid phase methodology using Boc strategy on 0.5 g 4-methyl-benzhydrylamine resin (1.04 mmol/g). The following side-chain protected amino acid derivatives were used: Boc-Cys(Mbzl)-OH, Boc-Thr(Bzl)-OH, Boc-Asp(OcHex)-OH, Boc-Glu(OcHex)-OH, Boc-Lys(Fmoc)-OH, Boc-Lys(ClZ)-OH. Synthesis was performed as described above. After the removal of the Fmoc group from the ε-amino group of the Lys residues tetratuftsin derivative was chloroacetylated at the side chain of the Lys residues. The chloroacetyl group was introduced by using chloroacetic acid pentachlorophenyl ester in 4 × 5 equiv excess (5 equiv per lysine residue) in DMF overnight at room temperature (*9*). The chloroacetylated peptide was cleaved from the resin by the aid of anhydrous HF in the presence of *m*-cresol-*p*-thiocresol (10 mL/0.5 mL/0.5 g) at 0 °C for 1.5 h (*25*).

RP-HPLC-purified chloroacetylated tuftsin oligopeptide derivative was dissolved in Tris buffer (0.1 M, pH = 8.2) at c = 1 mg/mL. Peptide H-LLEDPVGTVAC-NH_2 was added to this solution in 8 equiv excess little by little. Reaction was followed by RP-HPLC (Supelcosil C_{18} 5 μm; 4.6 mm × 250 mm column) using gradient elution. After sample application an isocratic elution with 20% eluent B was applied for 2 min, then a linear gradient from 20% to 45% eluent B was generated over 25 min at room temperature with a flow rate of 1 mL/min (eluent A, 0.1% TFA in water; eluent B, 0.1% TFA in acetonitrile−water (80:20, v/v %)). UV detection was performed at λ = 214 nm. Reaction was considered complete when no change in the position and intensity of peaks on the chromatogram was observed.

Purification by RP-HPLC. The crude products (peptides and conjugates) were purified by RP-HPLC on a Phenomenex Jupiter C_{18} column (10 μm; 300 Å, 10 mm × 250 mm), using gradient elution, where eluent A was 0.1% TFA in water, while eluent B was 0.1% TFA in acetonitrile−water (80:20, v/v %). After sample application an isocratic elution with 15% eluent B was applied for 2 min, then a linear gradient from 15% to 40% eluent B was generated over 25 min at room temperature with a flow rate of 4 mL/min. UV detection was performed at λ = 214 nm.

RP-HPLC Analysis. The homogeneity of peptides and conjugates was analyzed by RP-HPLC on a Symmetry C_{18} 3.5 μm, 4.6 mm × 150 mm column (for peptides) or on a Supelcosil C_{18} 5 μm, 4.6 mm × 250 mm column (for conjugates). After sample application an isocratic elution with 20% eluent B was applied for 2 min, then a linear gradient from 20% to 45% eluent B was generated over 25 min at room temperature with a flow rate of 1 mL/min: eluent A, 0.1% TFA in water; eluent B, 0.1% TFA in acetonitrile−water (80:20, v/v%). UV detection was performed at λ = 214 nm.

Amino Acid Analysis. The amino acid composition of compounds was determined by amino acid analysis using a Beckman model 6300 analyzer (Fullerton, CA). Prior to analysis, samples were hydrolyzed in 6 M HCl in sealed and evacuated tubes at 110 °C for 24 h.

Mass Spectrometry. Mass spectrometric experiments were performed on a Bruker Daltonics Esquire 3000plus (Germany) ion trap mass spectrometer, equipped with electrospray ionization source. Spectra were aquired in positive ionization mode, in the 50−2000 *m/z* region. Samples were dissolved in acetonitrile/water = 1:1 (v/v) mixture, containing 0.1% acetic acid. Samples were introduced into the mass spectrometer using a syringe pump, at a flow rate of 10 μL/min.

Enzymatic Digestion. *Lysosome Preparation.* For a detailed description of the lysosome preparation see Tugyi et al. (*7*). Briefly, rat livers were homogenized in 0.3 M sucrose, diluted with 0.3 M sucrose, and centrifuged. The supernatant was centrifuged again, and rehomogenized in sucrose containing 1 mM $CaCl_2$. After incubation at 37 °C for 5 min, 50% Percoll solution was added and homogenate was centrifuged again. The lysosomal fraction was obtained as a hard brown pellet. The enzymatic activity of the preparation was determined according to Dingle (*26*).

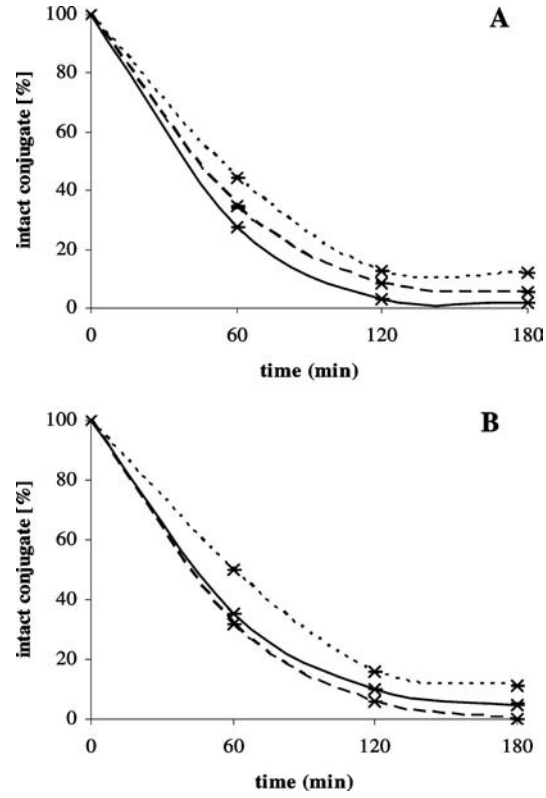


Figure 1. Degradation profile of the free peptide (H-LLEDPVGTVA-NH_2) (−x−), and its conjugates with amide (− −x− −) or thioether bond (---x---) in lysosomal preparation at pH = 3.5 (A) and at pH = 5.0 (B).

Digestion of Peptides and Conjugates in Lysosome Homogenates. Control peptide was dissolved at c = 2.5 mg/mL in 0.1 M acetate buffer, pH = 3.5 or pH = 5.0, while conjugate concentration was c = 3.76 mg/mL and c = 3.82 mg/mL for thioether and for amide conjugate, respectively. Afterward, the lysosome fraction was added ($c_{lysosomal}$ = 22 μL/mL), and peptide or conjugate samples were incubated at room temperature for 180 min. Aliquots of 100 μL were taken at 30 s and 60, 120, and 180 min. The enzymatic reaction was stopped by the addition of 5 v/v% perchloric acid. Samples were centrifuged at 4600 rpm for 5 min at 4 °C and the concentration of the intact peptide in the supernatant was determined by RP-HPLC (Supelcosil C_{18} 5 μm; 4.6 mm × 250 mm column), using calibration curves. For RP-HPLC analysis eluent A (0.1% TFA in water) and eluent B (0.1% TFA in acetonitrile−water (80:20, v/v)) were applied. A gradient 20−45% eluent B in 25 min was generated. Each sample was injected twice, and each digestion experiment was performed twice. Standard deviation of the twice-injected samples was negligible, while standard deviation for the independent studies was calculated and provided in Figure 1 and Table 2.

Digestion of Peptides and Conjugates in Human Serum. Human serum was obtained from National Institute of Haematology and Immunology (Budapest, Hungary). Control peptide was dissolved in 0.1 M phosphate buffer (pH = 7.2) containing 0%, 10%, or 50% human serum, at c = 2.5 mg/mL, while conjugate concentration was c = 3.76 mg/mL for compound with thioether linkage, and 3.82 mg/mL for the construct with amide bond. Conjugates were incubated at 37 °C up to 96 h. Samples (100 μL for 0% and 10% human sera and 140 μL for 50% human sera) were taken after 0, 24, 48, 72, and 96 h. All

digestion experiments were performed under sterile conditions. Further treatment of the samples was identical to that described for the lysosomal digestion above.

Isolation and Identification of Degradation Fragments. Samples of the digests were analyzed by RP-HPLC using analytical column (Supelcosil C_{18} 5 μm; 4.6 mm × 250 mm column). For the RP-HPLC analysis eluent A (0.1% TFA in water) and eluent B (0.1% TFA in acetonitrile−water (80:20, v/v)) were applied. A gradient 20−45% eluent B in 25 min was generated. Fragments were collected in Eppendorf tubes and freeze-dried. Molecular mass of the fragments was detemined by mass spectrometry (see above).

RESULTS AND DISCUSSION

In order to study the effect of covalent coupling of epitope peptide on the enzymatic degradation, conjugates with an oligopeptide derived from the glycoprotein D of Herpes simplex virus were prepared. As carrier a tetratuftsin derivative composed of four tuftsin-like units, TKPKG, was used. Human tuftsin is a tetrapeptide (TKPR) present in the Fc receptor of the IgG molecule (*27*). TKPK is the canine tuftsin sequence (*28*) and the presence of the second Lys offers a new possibility to conjugate even two different entities. Both human and canine tuftsins exhibit immunostimulatory effect (*29*).

In conjugates prepared for the present study amide or thioether linkage was established between the carrier and the cargo epitope. In both cases oligopeptide ^{278}LLEDPVGTVA^{287} was attached to the tetratuftsin derivative through the C-terminal amino acid residue (Scheme 1). When a thioether bond was formed peptide 278−287 was elongated with a Cys at the C-terminal and its SH group was utilized in the conjugation (Scheme 2). The stability of conjugates with thioether link or amide bond was studied in two complex biological matrices possessing enzymatic activity. For the investigation of stability in serum we used two concentrations of the human serum (10% and 50%) under aseptic conditions. The conjugates and the free epitope peptide 278−287 were also incubated with lysosomal preparation at two different pH values (pH = 3.5 and 5.0). In experiments performed we determined the amount of intact compound. Based on the comparative analysis of these data we have documented the capability of conjugates to resist against enzymatic degradation.

Synthesis of Conjugates. The ^{278}LLEDPVGTVA^{287} region of HSV gD-1 contains the ^{281}DPVG^{284} epitope core (*21*) adopting turn structure under appropriate conditions (*30*). For our studies we have elongated the tetramer core by three amino acids from the native sequence at both termini. The amide bond containing conjugate was prepared on MBHA resin by tandem solid phase peptide synthesis. After the cleavage of all four Fmoc protecting groups from Lys residues in the carrier molecule Ac-[T(Bzl)K(ClZ)PKG]$_4$-R, the synthesis was continued using the liberated ε-amino groups of the semiprotected carrier. Thus, four copies of the decapeptide ^{278}LLEDPVGTVA^{287} were assembled as branches using the Boc strategy (Scheme 1).

For the preparation of conjugate with thioether bond, first the epitope peptide with C-terminal Cys (LLEDPVGTVAC) and the semiprotected tetratuftsin derivative carrier Ac-[T(Bzl)K(ClZ)PKG]$_4$-R was synthesized also by solid phase synthesis on MBHA resin. In this case the free side chain of four Lys residues of the carrier molecule was chloroacetylated using chloroacetic acid pentachlorophenyl ester (*11*). Finally, the chloroacetylated carrier Ac-[T(Bzl)K(ClZ)PK(ClCH$_2$CO)G]$_4$-NH_2 as well as the Cys-containing peptide, H-LLEDPVGTVAC-NH_2, were cleaved from the resin by HF. After RP-HPLC purification the oligopeptide was conjugated with the purified carrier molecule under slightly alkaline condition (0.1 M Tris buffer, pH = 8.2). Tetratuftsin derivative was dissolved at c = 1 mg/mL, then peptide H-LLEDPVGTVAC-NH_2 was added in 8 equiv excess in small portions to avoid the risk of dimerization (Scheme 2). The conjugation reaction was followed by RP-HPLC analysis. Conjugates and the free peptide used for the enzymatic studies were characterized by amino acid composition, by relative molar mass determined by ESI-MS, and by RP-HPLC retention time values (Table 1).

Enzymatic Stability of Conjugates. For *in vitro* enzymatic stability studies of peptides authors have utilized in the literature mainly isolated enzymes like carboxypeptidase A, aminopeptidase M, proteinase A, carboxypeptidase Y (*31*), α-chymotrypsin, or carboxypeptidase Y (*32*), or complex biological fluids, like human serum and urine (*33*), human plasma (*34*), or rat liver lysosomes (*35*). It is interesting to note that only a limited number of studies on peptide conjugates has been reported so far and only the liberation of the free drug has been investigated.

We have studied the enzymatic stability of two conjugates with different linkages as well as the corresponding oligopeptide, H-LLEDPVGTVA-NH_2, as control, in diluted human sera and in rat liver lysosomal preparation. We have isolated and identified the degradation products and propose a hypothesis on the involvement of potential enzymes. The data are summarized in Tables 2 and 3. The degradation profiles of all three compounds in lysosomal preparation at pH 3.5 and pH 5.0 (Figure 1A,B) are also shown.

Table 3. Effect of Conjugation on the Stability of Epitope Peptide LLEDPVGTVA in Diluted Human Serum

	intact compound [%][a] after digestion with human serum									
	10%					50%				
peptide/conjugate	0 h	24 h	48 h	72 h	96 h	0 h	24 h	48 h	72 h	96 h

$[TKPK(LLEDPVGTVA)G]_4$	100	100	100	100	100	100	100	100	100	100
$[TKPK(LLEDPVGTVAC)G]_4$	100	100	100	100	100	100	100	100	100	100

[a] Compound [%] = c_{intact}/c_{total}. The concentration of intact compound was calculated from the AUC (area under the curve) of the corresponding peak obtained after HPLC analysis as described in Experimental Procedures.

First we have analyzed the stability of the two conjugates and compared with that of the free linear peptide, H-LLEDPVGTVA-NH_2 in rat lysosomal preparation, containing various proteolytic enzymes. Considering the lack of consensus in the literature about the pH within the lysosome we have selected two pH values (pH 3.5 and pH 5.0) to perform the assay. Harada et al. reported on a value of pH 4 (*36*); Bach et al. observed that the pH in lysosomes varies between 4.3 and 4.5 (*37*). Other groups found a different level of acidity between pH 4.5 and pH 5.0 (pH 4.5 (*38*, *39*), 4.67 (*40*), 4.75 (*41*), 5.0 (*42*)). It is also known that the optimal pH for the main lysosomal enzyme, Cathepsin D, is pH 3.5 (*43*).

Data obtained are summarized in Table 2 and Figure 1. We observed that both conjugates degraded in lysosomal preparation with a fairly similar degradation profile, in a nearly identical way to that the free peptide. However, it is interesting to note that the rate of the enzymatic hydrolysis was slightly dependent on the type of linkage present in conjugates: 88% and 89% of the amide bond containing conjugate degraded at pH = 3.5 and 5.0, respectively, while 95% and 100% of the thioether containing conjugate disappeared at pH = 3.5 and 5.0, respectively.

In the next series of experiments we have studied the enzymatic degradation of the compounds in 10% and in 50% human sera. Data, summarized in Table 3, showed no degradation when peptide was conjugated to oligotuftsin derivative as carrier under the conditions applied. However, the control linear peptide degraded along the amide bonds in 24 h even in 10% human serum.

Identification of Fragments in Lysosomal Preparation. In order to gain insight into the degradation process, fragments present in the reaction mixture were identified by mass spectrometry. We found that the fragmentation of the two conjugates differ from each other and also from that of the free peptide.

The main fragment of peptide H-LLEDPVGTVA-NH_2 is H-DPVGTVA-NH_2, but we have also detected the presence of smaller fragments like H-LLE-OH, H-DPVG-OH, and H-EDPVG-OH. The change of the pH from 3.5 to 5.0 has no significant effect on the number and composition of fragments formed.

Similarly, the pH has essentially no effect on the fragmentation profile of the amide bond containing conjugate. The quantity, number, and composition of the fragments are almost identical at the pH values used. The predominant fragment appearing at the highest quantity is a truncated conjugate missing one N-terminal LLE tripeptide unit (M: 5729.8) (Figure 2A). In marked quantity we found conjugates without (a) two LLE trimer (M: 5374.4), (b) one LLE and one LLEDPVG units (M: 5006.0), or (c) three LLE tripeptides (M: 5018.7). Accordingly we have isolated the tripeptide H-LLE-OH (M: 373.9) from the digests (Figure 2A).

In the case of the thioether conjugate the degradation was faster and the number of fragments formed was higher. In addition we observed pH-dependent fragmentation. The degradation rates of the different fragments were also pH-dependent. At pH = 3.5 the quantity of most of the fragments present after

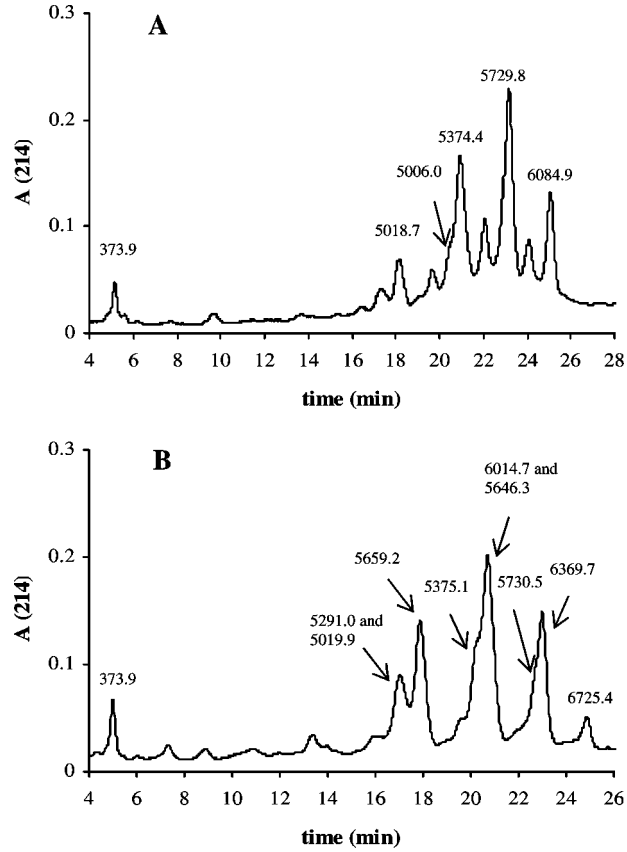

Figure 2. RP-HPLC chromatogram of digest obtained after treatment with lysosomal preparation of conjugate with amide bond at pH = 5.0 after 120 min (A); and conjugate with thioether linkage at pH = 3.5 after 120 min (B). Molecular masses of fragments identified are shown on the peaks.

60 min was increased after 120 and 180 min (Figure 3A). In contrast at pH = 5.0 the amount of the majority of the fragments present at 60 min was decreased until the end of the period studied (Figure 3B). However, the predominant fragments were found to be identical at both pH values. These are the following (see also Figure 3B): conjugate missing one, two, or three LLE tripeptides (M: 6369.7, 6014.7, and 5659.2, respectively) or one LLE tripeptide plus one LLEDPVG unit (M: 5646.3) or two LLE plus one LLEDPVG unit (M: 5019.9). The H-LLE-OH tripeptide (M: 373.9) is detectable at both pH as well as in the case of the amide bond containing conjugate. At pH = 5.0 fragments missing a full LLEDPVGTVA sequence (one LLEDPVGTVA, M: 5730.5; one LLEDPVGTVA and one LLE, M: 5375.1; one LLEDPVGTVA and two LLE, M: 5019.9) were also detectable in minor quantity. Interestingly at this pH the fragment H-LLEDPVGTVA-OH was also detectable (data not shown). The cleavage of the bond between the E and D amino acids observed in all three cases (the two conjugates and free peptide) is probably due to the presence of tripeptidyl peptidase

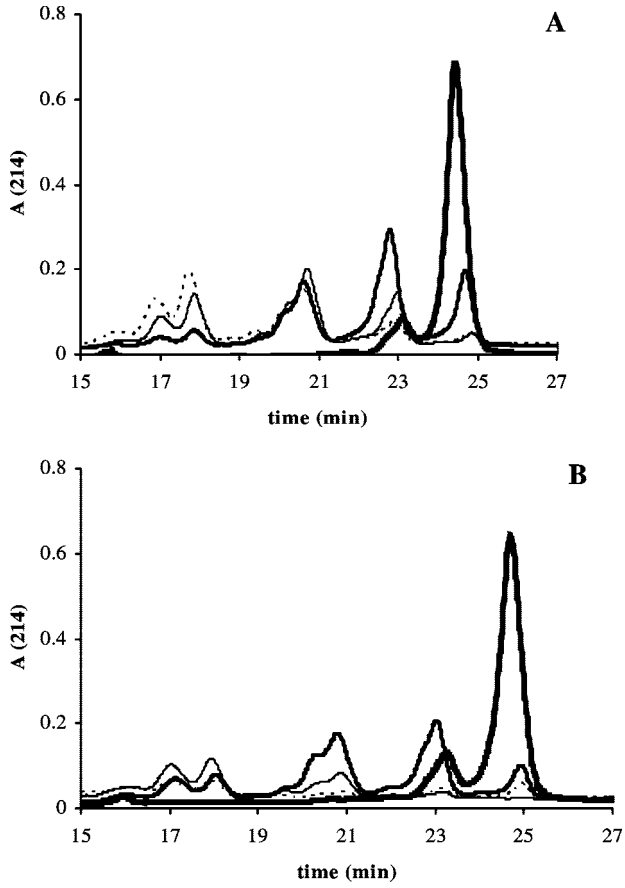

Figure 3. RP-HPLC chromatogram of digest obtained after treatment with lysosomal preparation of amide bond containing conjugate (A) and thioether linkage containing conjugate (B) after 0 (thick line), 60 (-), 120 (-), and 180 min (---).

I (*44*). The split of GT as well as AC bonds could be due presumably to the enzyme Cathepsin D (*45*).

CONCLUSION

In this study we reported on the synthesis and on proteolysis of two ^{278}LLEDPVGTVA^{287} conjugates with amide or thioether bond. We compared the stability of these conjugates in diluted human sera and in rat lysosomal preparation. The data obtained in human sera show that conjugation enhanced the stability of the epitope peptide as compared to its free form. It should be noted that the type of linkage between the peptide and the carrier part of the conjugate essentially did not influence the degradation pattern. These results also show that in diluted human sera the conjugation of an oligopeptide could provide full protection against enzymatic hydrolysis. Comparing the degradation of the two conjugates in lysosomal preparation, we found only modest differences. In the case of the conjugate with an amide bond the rate of the degradation was somewhat lower and the number of fragments were also limited as compared to the conjugate with a thioether bond. The fragment without an LLEDPVGTVA sequence appears only in the digest of the thioether conjugate. This difference could be explained by the fact that for the formation of this fragment in the case of the amide conjugate, the cleavage of the amide bond between the α-carboxyl group of Ala residue of the epitope and the ε-amino group of the Lys of the carrier molecule would be required. This cleavage probably is prevented by the fact that this is an isopeptide bond and perhaps also by steric restriction, while in the thioether conjugate the amide bond between the Ala and the Cys residue is a peptide bond and it could be more accessible because the Cys residue enhances the distance between the carrier and the peptide side chain. It is interesting to note that there is no detectable fragment from the carrier backbone of the conjugate. This observation could be explained by the conformation of the tetratuftsin derivative used as carrier (*46*), but it is more likely that the attachment of four copies of the epitope peptide to the side chains of the carrier limits the accessibility of backbone amid bonds for proteolytic enzymes.

Taken together, our results indicate that conjugation of the epitope peptide studied fully protected its degradation in diluted human sera as compared to the free linear epitope peptide, which decomposed quickly. This observation might be useful for the design of artificial immunogens. We have also demonstrated that the fragments derived from the thioether conjugate can possess the full-size epitope peptide in contrast to the amide conjugate from which only one fragment with the epitope core (DPVG) was produced. It is attractive to speculate that complete epitope peptide released from the thioether conjugate in the lysosome might be available for MHC for antigen presentation. Considering this finding, one can propose to design an amide conjugate in which a spacer unit could provide an appropriate distance between the epitope peptide and the carrier. Thus endopeptidases could have access to amide bonds and release the "full" epitope sequence.

Systematic Investigation of Polyamidoamine Dendrimers Surface-Modified with Poly(ethylene glycol) for Drug Delivery Applications: Synthesis, Characterization, and Evaluation of Cytotoxicity

Yoonkyung Kim,*,† Athena M. Klutz, and Kenneth A. Jacobson*

Molecular Recognition Section, Laboratory of Bioorganic Chemistry, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland 20892. Received January 2, 2008; Revised Manuscript Received May 21, 2008

Surface modification of amine-terminated polyamidoamine (PAMAM) dendrimers by poly(ethylene glycol) (PEG) groups generally enhances water-solubility and biocompatibility for drug delivery applications. In order to provide guidelines for designing appropriate dendritic scaffolds, a series of G3 PAMAM-PEG dendrimer conjugates was synthesized by varying the number of PEG attachments and chain length (shorter PEG_{550} and PEG_{750} and longer PEG_{2000}). Each conjugate was purified by size exclusion chromatography (SEC) and the molecular weight (MW) was determined by ^1H NMR integration and matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS). NOESY experiments performed in D_2O on selected structures suggested no penetration of PEG chains to the central PAMAM domain, regardless of chain length and degree of substitution. CHO cell cultures exposed to PAMAM-PEG derivatives (≤ 1 μM) showed a relatively high cell viability. Generally, increasing the degree of PEG substitution reduced cytotoxicity. Moreover, compared to G3 PAMAM dendrimers that were *N*-acetylated to varying degrees, a lower degree of surface substitution with PEG was needed for a similar cell viability. Interestingly, when longer PEG_{2000} was fully incorporated on the surface, cell viability was reduced at higher concentrations (32 μM), suggesting increased toxicity potentially by forming intermolecular aggregates. A similar observation was made for anionic carboxylate G5.5 PAMAM dendrimer at the same dendrimer concentration. Our findings suggest that a lower degree of peripheral substitution with shorter PEG chains may suffice for these PAMAM-PEG conjugates to serve as efficient universal scaffolds for drug delivery, particularly valuable in relation to targeting or other ligand−receptor interactions.

INTRODUCTION

Synthetic macromolecules are often employed as drug carriers to improve overall pharmacokinetic properties of monomeric drugs and to enhance their therapeutic effects (*1, 2*). For instance, one of the most successful tumor targeting approaches greatly benefits from therapeutics with macromolecules by implementing their ability to readily extravasate from the leaky tumor blood vessels and accumulate in the tumor interstitium through the enhanced permeability and retention (EPR) effect (*3*). As originally proposed by Ringsdorf and others, synthetic macromolecular carriers facilitate the incorporation of various functional units such as solubility enhancers, targeting units, and visualizing groups, in addition to the particular drug moieties of interest (*4*). Unfortunately, these carriers may suffer from an elevated toxicity and immunogenicity (i.e., low biocompatibility). Accordingly, additional modification of the structure might be necessary for a synthetic macromolecular drug delivery system to minimize undesirable properties for practical applications.

The dendrimer, one of the latest additions to the polymer family, has a globular shape and a relatively predictable size as represented by the hydrodynamic volume in a given solvent (*5–8*). Indeed, the virtue of using these (nearly) monodisperse dendrimers as drug carriers over the conventional polymeric agents relies heavily on their robust shape and controllable size and physical properties—to result in consistent biological effects—that can be attained by routine organic synthesis (*9–18*). Characteristics of dendritic structures, including toxicity, interactions with foreign objects (e.g., cells, opsonins), routes for cellular uptake, and intracellular fate will most likely be governed by the imparted surface groups (*19–21*). In contrast, such properties of conventional polymeric carriers may vary depending on their preferred folding pattern in a particular environment. Thus, a judicious choice of surface groups is crucial to optimize the pharmacological effects of a dendrimer-based drug delivery system.

Linear poly(ethylene glycol) (PEG) dissolves in water and most organic solvents and manifests crystalline properties in the solid state. Its strong but neutral hydrophilic nature without any significant toxic effect has found many applications in drug delivery as a structural modifier (*22–25*). In general, attachment of PEG (i.e., PEGylation) improves water solubility, reduces toxicity, decreases enzymatic degradation, and increases the in vivo half-lives of small-molecule drugs. A possible reduction in drug potency due to the sterics imparted by a long flexible PEG chain can be compensated by a reduced renal elimination rate.

Numerous reports described examples of attaching PEG to dendrimers through different types of *bond* formations to create hybrids of various *geometries*, among which the application for drug delivery has been most prevalent (*26*): (i) by forming either covalent (*27–33*) or electrostatic bonds (*34*) between a dendrimer and PEG groups; (ii) by attaching either linear PEG derivatives to the dendrimer periphery (i.e., unimolecular micelle) (*29, 32, 35*) or mono/multifunctional PEG derivatives to one or more core units of dendrons to form linear/branched-dendritic block

copolymers (*27, 31, 33, 36–43*). Physical properties of these PEG-dendrimer conjugates were often dependent on the weight contribution of each block and the solvent used, occasionally exhibiting semicrystalline morphologies by phase-segregation (*37, 40, 42, 43*). Some examples involving self-assembly of amphiphilic PEG-dendritic block copolymers allowed the controlled release of electrostatically bound (*27, 44*) and/or hydrophobically encapsulated (*32, 45–47*) therapeutic agents. Intriguingly, a fully surface-PEGylated ($M_n = 2000$) dendrimer with a basic interior efficiently retained and slowly released hydrophobic anticancer drugs with acidic functionalities, in aqueous medium of a low ionic strength (*32*). Alternatively, when ligands are covalently attached (i.e., activation without chemical cleavage) to the termini of a dendrimer, the neighboring surficial PEG chains may impose a substantial steric barrier to impede the direct accessibility of ligands to their receptors. Therefore, strategies to covalently connect ligands to these dendrimer conjugates involved presenting them at the surface through peripheral PEG groups as long spacers (*28, 48, 49*) or degradable linkages (*50–53*). However, it is noteworthy that hydrophobic molecules were not well-encapsulated into a dendrimer when most of the periphery was derivatized by shorter PEG chains ($M_n = 550/750$), suggesting a relatively loose cavity (i.e., a low steric barrier) (*32, 54*).

Despite their known structural defects (*55*), poly(amidoamine) (PAMAM) dendrimers have been widely used for biomedical applications due to their commercial availability and relatively biocompatible nature (*56*). Each layer (i.e., generation) of PAMAM dendrimer is formed by a two-step procedure of double Michael addition with methyl acrylate followed by the chain extension with ethylenediamine, to present amide and tertiary amine functionalities in the interior. Of many PAMAM variations, the popularity of the amine-terminated PAMAM dendrimer, especially for oligonucleotide delivery (*27,30,33,57–62*), may arise from its unique cationic properties—a pH-dependent two-stage swelling behavior in aqueous solutions (*62, 63*). Under physiological conditions, the peripheral amino groups of PAMAM dendrimers are predominantly charged—the pK_a values of the terminal primary amine and the internal tertiary amine are 6.9 and 3.9, respectively. This is advantageous to form a charge complex with anionic drugs to allow entry into the cell mainly by endocytosis and their release under lysosomal pH conditions (*20, 21*). Unfortunately, these polycationic PAMAM dendrimers are toxic (*19, 29, 64–66*), and various strategies have been applied to conceal the terminal amino groups. Partial acetylation of the PAMAM surface, where a fraction of the toxic amino groups was left uncovered to achieve desired properties, affected water solubility and reduced the hydrodynamic volume (*67–69*). Partial conversion into lauroyl end groups increased membrane permeability and reduced cytotoxicity (*29,65*). However, this modification may increase hydrophobicity and promote aggregation in water through the attached aliphatic chains. Other examples, such as modifying into small alkyl alcohol groups, reduced the cytotoxicity and maintained water solubility (*70, 71*). Overall, PAMAM surface modification by relatively small functional groups required complex tuning of the stoichiometry for each appended functional moiety to achieve both the desired physicochemical and pharmacological properties. With the recent success of gene delivery across the blood–brain barrier (*72*), a PAMAM scaffold with peripheral PEG modifications may still be among the safest and most versatile dendritic drug carriers. Here, the synthesis, characterization, and evaluation of cytotoxicity of a series of third-generation (G3) PAMAM-PEG conjugates are explored in the context of drug delivery applications. PEG groups were attached to the surfaces of amine-terminated PAMAM dendrimers by varying their size (i.e., $M_n = 550$, 750, and 2000) and number of attachments. Each PAMAM-PEG conjugate was characterized by NMR and mass spectrometry. The cytotoxicity of each PAMAM-PEG dendrimer was evaluated in Chinese hamster ovary (CHO) cell cultures, which was compared with the cytotoxicity of acetylated G3 PAMAM structures and the commercial anionic PAMAM dendrimers of different generations.

EXPERIMENTAL PROCEDURES

Materials and Methods. Glassware was oven-dried and cooled in a desiccator before use. All reactions were carried out under a dry nitrogen atmosphere. Solvents were purchased as anhydrous grade and used without further purification. Suppliers of the commercial compounds are listed as follows: amine-terminated G3 PAMAM dendrimer and carboxylate-terminated PAMAM dendrimers of G2.5, G3.5, and G5.5, all with the ethylenediamine as an initiator core (*8*), poly(ethylene glycol) methyl ether (M_n = 550, 750, and 2000), acetic anhydride (Ac_2O), 4-nitrophenyl chloroformate, triethylamine, *N*,*N*-diisopropylethylamine (DIEA), dimethyl sulfoxide (DMSO), methanol (MeOH), and chloroform ($CHCl_3$) were purchased from Aldrich; *N*,*N*-dimethylformamide (DMF) and tetrahydrofuran (THF) were purchased from Acros; DMSO-d_6, chloroform-*d* ($CDCl_3$), and D_2O were purchased from Cambridge Isotope Laboratories.

Preparative SEC was performed on Bio-Beads S-X1 beads (BIO-RAD, MW operating range 600−14 000 Da), 200−400 mesh, with DMF (Aldrich 99.8%, anhydrous) as an eluent at ambient pressure.

NMR spectra were recorded on either a Varian Inova 300 or a Bruker DRX-600 spectrometer at 25.0 °C under an optimized parameter setting for each sample, unless otherwise mentioned. ^{1}H NMR chemical shifts were measured relative to the residual solvent peak at 2.50 ppm in DMSO-d_6, at 7.26 ppm in $CDCl_3$, and at 4.80 ppm in D_2O. ^{13}C NMR chemical shifts were measured relative to the residual solvent peak at 39.51 ppm in DMSO-d_6 and at 77.23 ppm in $CDCl_3$. Complete NMR peak assignments were made possible with 2D COSY and NOESY experiments. For dendrimer conjugates, integrals were reported only for the peaks clearly resolved (i.e., with a relatively good baseline-separation) in the ^{1}H NMR spectra. Detailed methods for NMR analysis including peak labeling and assignments, integration, determination of the stoichiometry, and estimation of average MWs for dendrimer conjugates are described in the Supporting Information.

The electrospray ionization (ESI) MS experiments were performed on a Waters LCT Premier mass spectrometer at the Mass Spectrometry Facility, NIDDK, NIH. MALDI-TOF MS experiments were performed on an Applied Biosystems Voyager-DE STR spectrometer at the Mass Spectrometry Laboratory, University of Illinois. 2,5-Dihydroxybenzoic acid (DHB) or 2,4,6-trihydroxyacetophene (THAP) was used as the matrix for the MALDI samples. Average MWs determined by MALDI are listed in Tables 1 and 2.

[a] M_n of PEG monomethylether **5** originally used to prepare the corresponding carbonate precursor **7**. M_n values were taken from the Aldrich bottle. [b] Based on ^{1}H NMR integration determined in DMSO-d_6. [c] PAMAM dendrimer **1** used for calculation here was assumed to have 32 peripheral amino groups and no structural defects. [d] Number-average molar mass. [e] Weight-average molar mass. [f] Polydispersity index. [g] Mass range selected for the average MW calculations contained (a part of) the peak region corresponding to the half-size of each desired compound.

General Procedure for Acetylation of PAMAM G3 Dendrimer. To a 2.68 mM DMSO solution of PAMAM G3 **1** was added slowly the corresponding amount of Ac_2O in DMSO (10%, v/v) with stirring. Reaction was stirred continuously for >24 h. Ca. 50 μL of each reaction mixture was taken, dried *in vacuo* for >2 h, and dissolved in 650−700 μL of DMSO-d_6 to determine the degree of acetylation by ^{1}H NMR. Later, it was found that the stoichiometric control of the acetylation reaction was better achieved if methanol was removed from commercial PAMAM dendrimer **1** *in vacuo*, then the dried sample was dissolved in DMSO-d_6 (ca. 1 mM), and the corresponding amount of Ac_2O (ca. 1 M in DMSO-d_6) was slowly added to the dendrimer solution. The reaction was stirred for 20−24 h, and the NMR spectrum was readily obtained by diluting an aliquot of the reaction mixture with DMSO-d_6.

Acetylated PAMAM Dendrimers 2 and 3. G3 PAMAM dendrimer **1** (2.68 mM, 5.40 mL, 14.5 μmol) was treated with Ac_2O (10% (v/v); 220 μL, ca. 233 μmol for **2**; 330 μL, ca. 349 μmol for **3**) in DMSO (total volume: 6.00 mL) and stirred for 40 h to yield a colorless glassy solid. ^{1}H NMR (600 MHz, DMSO-d_6) **2**: δ 8.15−7.81 (m, 73.18H, NH_{G0}, NH_{G1}, NH_{G2}, NH_{G3}, and NH_{Ac}), 3.09−3.07 (m, 179.31H, H_d, H_f, H_{fAc}, and H_{gAc}), 2.64−2.60 (m, 153.29H, H_b and H_g), 2.42 (m, 62.74H, H_e and H_a), 2.19−2.18 (m, 120.00H, H_c), 1.88 (s, 24.69H, CH_3CO^-), 1.79 (s, 40.60H, H_h); **3**: δ 8.14−7.81 (m, 75.79H, NH_{G0}, NH_{G1}, NH_{G2}, NH_{G3}, and NH_{Ac}), 3.09−3.07 (m, 187.24H, H_d, H_f, H_{fAc}, and H_{gAc}), 2.65−2.61 (m, 138.75H, H_b and H_g), 2.42 (m, 62.77H, H_e and H_a), 2.19−2.18 (m, 120.00H, H_c), 1.89 (s, 30.78H, CH_3CO^-), 1.79 (s, 59.22H, H_h).

Acetylated PAMAM Dendrimer 4. G3 PAMAM dendrimer **1** dried *in vacuo* (20.7 mg, 3.00 μmol) was dissolved in 1.50 mL of DMSO-d_6 and treated with Ac_2O (13.7 μL, 145 μmol). The reaction was stirred for 24 h and the ^{1}H NMR of the crude mixture was taken. Additionally, a portion of reaction mixture was purified by SEC (H 39 cm × O.D. 3.0 cm) in DMF to give **4** as a colorless glassy solid, and its ^{1}H NMR was acquired. ^{1}H NMR (600 MHz, DMSO-d_6) δ 7.94 (s, NH_{G3}), 7.88 (s, 35.05H, NH_{Ac}), 7.80 (br s, 26.41H, NH_{G0}, NH_{G1}, and NH_{G2}), 3.09−3.07 (m, 189.64H, H_d, H_{fAc}, and H_{gAc}), 2.65 (m, 116.29H, H_b), 2.42 (m, 59.60H, H_e and H_a), 2.18 (m, 120.00H, H_c), 1.79 (s, 96.34H, H_h).

General Procedure for Synthesis of PEG carbonate 7. PEG carbonate **7** was prepared following the modified procedure of Kojima et al. (*32*). To a mixture of poly(ethylene glycol) monomethyl ether **5** and 4-nitrophenylchloroformate (2 equiv) in THF was added triethylamine or DIEA (2 equiv). The reaction was stirred at room temperature for >5 d. Solvent was removed under reduced pressure, and the crude mixture was loaded on a SEC column for purification. The SEC column fractions were collected in small portions, and those verified to contain only the desired compound by ^{1}H NMR were combined. Purification by SEC was repeated, if necessary.

PEG Carbonate 7a. The reaction of poly(ethylene glycol) monomethyl ether **5a** (M_n = 550, 0.500 mL, 0.990 mmol), 4-nitrophenylchloroformate (398 mg, 1.92 mmol), and triethylamine (0.280 mL, 2.01 mmol) in THF (28 mL) gave the activated PEG carbonate **7a** as a sticky yellowish solid. ^{1}H NMR (300 MHz, $CDCl_3$) δ 8.26 (d, 2H, J = 9.5 Hz, H-3 of *p*-nitrophenol), 7.38 (d, 2H, J = 9.1 Hz, H-2 of *p*-nitrophenol), 4.42 (m, 2H, OCH_2CH_2OCO), 3.79 (m, 2H, OCH_2CH_2OCO), 3.72−3.52 (m, 55H, satellites J = 70.1 Hz, OCH_2CH_2O and OCH_2CH_2O), 3.36 (s, 3H, CH_3O); ^{13}C NMR (75 MHz, $CDCl_3$) δ 155.7, 152.6, 145.5, 125.5, 122.0, 72.1, 70.9, 70.7, 68.8, 68.5, 59.2; HRMS (ESI) Calcd for $C_{32}H_{59}N_2O_{17}$ (m = 12, M + NH_4^+): 743.3814, Found: 743.3785.

PEG Carbonate 7b. The reaction of poly(ethylene glycol) monomethyl ether **5b** (M_n = 750, 793 mg, 1.06 mmol), 4-nitrophenylchloroformate (438 mg, 2.11 mmol), and DIEA (0.370 mL, 2.12 mmol) in THF (40 mL) gave the activated PEG carbonate **7b** as a sticky yellowish solid. *The desired compound was contaminated with an inert PEG derivative, which was removed in the next step. The contaminant is suspected to be a methyl carbonate derivative of **7b** which has formed by the methanol (ca. 1 mL) added at the end of the reaction to quench the activity of excess 4-nitrophenylchloroformate. Methanol was not added for the other two reactions to make **7a** and **7c**. ^{1}H NMR (300 MHz, $CDCl_3$) δ 8.27 (d, 2H, J = 9.2 Hz, H-3 of *p*-nitrophenol), 7.38 (d, 2H, J = 9.4 Hz, H-2 of *p*-nitrophenol), 4.43 (m, 2H, OCH_2CH_2OCO), 3.80 (m, 2H, OCH_2CH_2OCO), 3.72−3.53 (m, *126H, satellites J = 70.8 Hz, OCH_2CH_2O and OCH_2CH_2O), 3.37 (s, 3H, CH_3O); ^{13}C NMR (75 MHz, $CDCl_3$) δ 125.5, 122.0, 72.1, 70.9, 70.8, 68.8, 68.5, 61.9, 59.2; HRMS (ESI) Calcd for $C_{40}H_{75}N_2O_{21}$ (m = 16, M + NH_4^+): 919.4862, Found: 919.4877.

PEG Carbonate 7c. The reaction of poly(ethylene glycol) monomethyl ether **5c** (M_n = 2000, 2.00 g, 1.00 mmol), 4-nitrophenylchloroformate (404 mg, 1.95 mmol), and triethylamine (0.280 mL, 2.01 mmol) in THF (100 mL) gave the activated PEG carbonate **7c** as a pale yellow solid. ^{1}H NMR (600 MHz, $CDCl_3$) δ 8.27 (d, 2H, J = 9.0 Hz, H-3 of

p-nitrophenol), 7.38 (d, 2H, $J = 9.2$ Hz, H-2 of *p*-nitrophenol), 4.43 (m, 2H, OCH_2CH_2OCO), 3.80 (m, 2H, OCH_2CH_2OCO), 3.69−3.53 (m, 186H, satellites $J = 70.4$ Hz, OCH_2CH_2O and OCH_2CH_2O), 3.37 (s, 3H, CH_3O); ^{13}C NMR (75 MHz, $CDCl_3$) δ 125.5, 122.0, 72.1, 70.8, 68.8, 68.5, 60.1; HRMS (ESI) Calcd for $C_{98}H_{187}N_2O_{50}Na$ ($m = 45$, $M + Na^+$): 2201.2019, Found: 2201.1978.

General Procedure for Synthesis of PAMAM-PEG Conjugates. The commercial G3 PAMAM dendrimer **1** (30−90 μL) was dried *in vacuo* to remove methanol and was weighed (50 μL gave ca. 9 mg, Aldrich). The dried dendrimer **1** was dissolved in DMSO and the corresponding amount of the activated PEG carbonate **7** was added slowly either as a solution (for PEG_{550} and PEG_{750}) in DMSO or as a solid (for PEG_{2000}). The final concentration of the dendrimer solution was ca. 1.3−1.5 mM and the reaction was stirred at room temperature for ≥4 d. The crude mixture was loaded directly on a SEC column and the fractions containing the desired product were identified by ^1H NMR. The first and last SEC fractions confirmed to contain minor amounts of the desired dendrimer by NMR were eliminated deliberately to reduce the polydispersity of the PAMAM-PEG dendrimer conjugates. In general, the yield of the each reaction calculated on the basis of the NMR-determined MW (Table 2) was nearly quantitative.

PAMAM-PEG_{550} Dendrimer Conjugate 8. To a stirred solution of G3 PAMAM dendrimer **1** (16.62 mg, 2.41 μmol) in DMSO (1.33 mL) was added PEG carbonate **7a** (6.88 mg, 9.62 μmol) in DMSO (275 μL). The mixture was continued to stir for 4 d and the crude mixture was loaded on a SEC column (H 38 cm × O.D. 4.5 cm) to isolate the desired dendrimer conjugate **8** (17.8 mg). ^1H NMR (600 MHz, DMSO-d_6) δ 8.16−7.83 (m, 57.62H, NH_{G0}, NH_{G1}, NH_{G2}, and NH_{G3}), 7.24 (br s, 3.77H, NH_{PEG} of major isomer), 6.83 (br s, 0.23H, NH_{PEG} of minor isomer), 4.03 (t, 8.47H, $J = 4.5$ Hz, H_h), 3.62−3.39 (m, 203.76H, satellites $J = 70.6$ Hz, H_i, H_j, and H_k), 3.24 (s, H_l), 3.09−3.05 (m, H_d, H_f, H_{fPEG}, and H_{gPEG}), 2.65, 2.57 (m, 157.75H, H_b and H_g), 2.43 (m, 58.97H, H_e and H_a), 2.19 (m, 120.00H, H_c).

PAMAM-PEG_{550} Dendrimer Conjugate 9. To a stirred solution of G3 PAMAM dendrimer **1** (15.7 mg, 2.27 μmol) in DMSO (1.08 mL), was added PEG carbonate **7a** (13.0 mg, 18.2 μmol) in DMSO (520 μL). The mixture was continued to stir for 4 d and the crude mixture was loaded on a SEC column (H 43 cm × O.D. 4.5 cm) to isolate the desired dendrimer conjugate **9** (21.2 mg). ^1H NMR (600 MHz, DMSO-d_6) δ 8.06−7.84 (m, 56.29H, NH_{G0}, NH_{G1}, NH_{G2}, and NH_{G3}), 7.24 (br s, 6.88H, NH_{PEG} of major isomer), 6.83 (br s, 0.54H, NH_{PEG} of minor isomer), 4.03 (t, 13.87H, $J = 4.7$ Hz, H_h), 3.62−3.38 (m, 338.47H, satellites $J = 70.9$ Hz, H_i, H_j, and H_k), 3.24 (s, 25.79H, H_l), 3.08−3.04 (m, 144.64H, H_d, H_f, H_{fPEG}, and H_{gPEG}), 2.64, 2.56 (m, 149.14H, H_b and H_g), 2.42 (m, 59.52H, H_e and H_a), 2.19 (m, 120.00H, H_c).

PAMAM-PEG_{550} Dendrimer Conjugate 10. To a stirred solution of G3 PAMAM dendrimer **1** (9.88 mg, 1.43 μmol) in DMSO (950 μL) was added PEG carbonate **7a** (16.5 mg, 23.1 μmol) in DMSO (150 μL). The mixture was continued to stir for 13 d and the crude mixture was loaded on a SEC column (H 38 cm × O.D. 3 cm) to isolate the desired dendrimer conjugate **10** (18.6 mg). ^1H NMR (600 MHz, DMSO-d_6) δ 7.97−7.86 (m, 60.53H, NH_{G0}, NH_{G1}, NH_{G2}, and NH_{G3}), 7.27 (br s, 13.07H, NH_{PEG} of major isomer), 6.85 (br s, 1.26H, NH_{PEG} of minor isomer), 4.03 (t, 27.31H, $J = 4.1$ Hz, H_h), 3.62−3.38 (m, 649.88H, satellites $J = 70.7$ Hz, H_i, H_j, and H_k), 3.23 (s, 42.76H, H_l), 3.08−3.01 (m, 158.09H, H_d, H_f, H_{fPEG}, and H_{gPEG}), 2.64, 2.54 (m, 144.01H, H_b and H_g), 2.42 (m, 57.85H, H_e and H_a), 2.19 (m, 120.00H, H_c); ^1H NMR (600 MHz, D_2O) δ 4.20, 4.16 (m, 28.00H, H_h, two isomers), 3.77−3.53 (m, 691.77H, H_i, H_j, and H_k), 3.34 (s, 46.20H, H_l), 3.25−3.20 (m, 153.89H, H_d, H_f, H_{fPEG}, and H_{gPEG}), 2.78 (m, 145.01H, H_b and H_g), 2.58 (m, 60.70H, H_e and H_a), 2.40−2.37 (m, 120.00H, H_c).

PAMAM-PEG_{550} Dendrimer Conjugate 11. To a stirred solution of G3 PAMAM dendrimer **1** (5.62 mg, 0.813 μmol) in DMSO (210 μL), was added PEG carbonate **7a** (37.4 mg, 52.3 μmol) in DMSO (340 μL). The mixture was continued to stir for 23 d and the crude mixture was loaded on a SEC column (H 38 cm × O.D. 3 cm) to isolate the desired dendrimer conjugate **11** (14.7 mg). ^1H NMR (600 MHz, DMSO-d_6) δ 7.94 (s, 33.53H, NH_{G3}), 7.79 (br s, 28.10H, NH_{G0}, NH_{G1}, and NH_{G2}), 7.23 (s, 30.00H, NH_{PEG} of major isomer), 6.80 (br s, 2.60H, NH_{PEG} of minor isomer), 4.03 (t, 63.13H, $J = 4.1$ Hz, H_h), 3.61−3.38 (m, 1540.42H, satellites $J = 69.0$ Hz, H_i, H_j, and H_k), 3.23 (s, 99.29H, H_l), 3.08−3.00 (m, 231.53H, H_d, H_{fPEG}, and H_{gPEG}), 2.64 (m, 121.74H, H_b), 2.41 (m, 58.91H, H_e and H_a), 2.17 (m, 120.00H, H_c).

PAMAM-PEG_{750} Dendrimer Conjugate 12. To a stirred solution of G3 PAMAM dendrimer **1** (11.3 mg, 1.64 μmol) in DMSO (960 μL) was added PEG carbonate **7b** (24.2 mg, 26.4 μmol) in DMSO (140 μL). The mixture was continued to stir for 23 d and the crude mixture was loaded on a SEC column (H 43 cm × O.D. 4.5 cm) to isolate the desired dendrimer conjugate **12** (18.3 mg). ^1H NMR (600 MHz, DMSO-d_6) δ 8.08−7.86 (m, 59.30H, NH_{G0}, NH_{G1}, NH_{G2}, and NH_{G3}), 7.26 (br s, 8.56H, NH_{PEG} of major isomer), 6.85 (br s, 0.51H, NH_{PEG} of minor isomer), 4.03 (t, 17.80H, $J = 4.1$ Hz, H_h), 3.62−3.38 (m, 551.24H, satellites $J = 71.1$ Hz, H_i, H_j, and H_k), 3.23 (s, 29.99H, H_l), 3.08−3.00 (m, 157.03H, H_d, H_f, H_{fPEG}, and H_{gPEG}), 2.64, 2.54 (m, 142.08H, H_b and H_g), 2.42 (m, 59.26H, H_e and H_a), 2.19 (m, 120.00H, H_c).

PAMAM-PEG_{750} Dendrimer Conjugate 13. To a stirred solution of G3 PAMAM dendrimer **1** (5.63 mg, 0.815 μmol) in DMSO (270 μL) was added PEG carbonate **7b** (48.3 mg, 52.8 μmol) in DMSO (280 μL). The mixture was continued to stir for 13 d and the crude mixture was loaded on a SEC column (H 38 cm × O.D. 4.5 cm) to isolate the desired dendrimer conjugate **13** (16.8 mg). ^1H NMR (600 MHz, DMSO-d_6) δ 7.94 (s, 34.61H, NH_{G3}), 7.79 (br s, 28.15H, NH_{G0}, NH_{G1}, and NH_{G2}), 7.23 (s, 29.94H, NH_{PEG} of major isomer), 6.81 (br s, 2.56H, NH_{PEG} of minor isomer), 4.03 (t, 63.72H, $J = 4.2$ Hz, H_h), 3.62−3.38 (m, 1949.61H, satellites $J = 70.4$ Hz, H_i, H_j, and H_k), 3.23 (s, 96.44H, H_l), 3.08−3.00 (m, 207.73H, H_d, H_{fPEG}, and H_{gPEG}), 2.64 (m, 121.55H, H_b), 2.41 (m, 59.85H, H_e and H_a), 2.17 (m, 120.00H, H_c).

PAMAM-PEG_{2000} Dendrimer Conjugate 14. A mixture of G3 PAMAM dendrimer **1** (17.0 mg, 2.45 μmol) and PEG carbonate **7c** (21.2 mg, 9.79 μmol) in DMSO (1.6 mL) was continued to stir for 5 d. The crude mixture was loaded on a SEC column (H 38 cm × O.D. 4.5 cm) to isolate the desired dendrimer conjugate **14** (35.0 mg). ^1H NMR (600 MHz, DMSO-d_6) δ 8.04−7.84 (m, 54.97H, NH_{G0}, NH_{G1}, NH_{G2}, and NH_{G3}), 7.24 (br s, 3.68H, NH_{PEG} of major isomer), 6.83 (br s, 0.19H, NH_{PEG} of minor isomer), 4.03 (t, 8.45H, $J = 4.6$ Hz, H_h), 3.62−3.39 (m, 712.46H, satellites $J = 70.8$ Hz, H_i, H_j, and H_k), 3.24 (s, H_l), 3.09−3.01 (m, 136.94H, H_d, H_f, H_{fPEG}, and H_{gPEG}), 2.64, 2.55 (m, 155.18H, H_b and H_g), 2.42 (m, 57.90H, H_e and H_a), 2.19 (m, 120.00H, H_c); ^1H NMR (600 MHz, D_2O) δ 4.20, 4.16 (m, 8.87H, H_h, two isomers), 3.78−3.54 (m, 773.85H, H_i, H_j, and H_k), 3.34 (s, 16.59H, H_l), 3.27−3.20 (m, 132.80H, H_d, H_f, H_{fPEG}, and H_{gPEG}), 2.78−2.72 (m, 158.64H, H_b and H_g), 2.58 (m, 61.43H, H_e and H_a), 2.40−2.38 (m, 120.00H, H_c).

PAMAM-PEG_{2000} Dendrimer Conjugate 15. A mixture of G3 PAMAM dendrimer **1** (15.6 mg, 2.25 μmol) and PEG carbonate **7c** (38.9 mg, 18.0 μmol) in DMSO (1.6 mL) was continued to stir for 5 d. The crude mixture was loaded on a SEC column (H 43 cm × O.D. 4.5 cm) to isolate the desired

dendrimer conjugate **15** (50.1 mg). ^{1}H NMR (600 MHz, DMSO-d_6) δ 8.02−7.83 (m, 59.93H, NH_{G0}, NH_{G1}, NH_{G2}, and NH_{G3}), 7.23 (br s, 7.63H, NH_{PEG} of major isomer), 6.82 (br s, 0.66H, NH_{PEG} of minor isomer), 4.03 (t, 15.03H, J = 4.3 Hz, H_h), 3.62−3.39 (m, 1406.73H, satellites J = 70.7 Hz, H_i, H_j, and H_k), 3.24 (s, 30.32H, H_l), 3.09−3.00 (m, 149.47H, H_d, H_f, H_{fPEG}, and H_{gPEG}), 2.64, 2.55 (m, 158.48H, H_b and H_g), 2.42 (m, 58.93H, H_e and H_a), 2.19 (m, 120.00H, H_c).

PAMAM-PEG$_{2000}$ Dendrimer Conjugate 16. A mixture of G3 PAMAM dendrimer **1** (11.2 mg, 1.62 μmol) and PEG carbonate **7c** (56.2 mg, 26.0 μmol) in DMSO (1.1 mL) was continued to stir for 25 d. The crude mixture was loaded on a SEC column (H 43 cm × O.D. 4.5 cm) to isolate the desired dendrimer conjugate **16** (53.1 mg). ^{1}H NMR (600 MHz, DMSO-d_6) δ 7.98−7.83 (m, 66.70H, NH_{G0}, NH_{G1}, NH_{G2}, and NH_{G3}), 7.25 (br s, 15.80H, NH_{PEG} of major isomer), 6.83 (br s, 1.23H, NH_{PEG} of minor isomer), 4.03 (br s, 32.67H, H_h), 3.62−3.38 (m, 3002.14H, satellites J = 70.7 Hz, H_i, H_j, and H_k), 3.23 (s, 59.22H, H_l), 3.09−3.00 (m, 166.13H, H_d, H_f, H_{fPEG}, and H_{gPEG}), 2.64, 2.55 (m, 134.95H, H_b and H_g), 2.41 (m, 58.40H, H_e and H_a), 2.18 (m, 120.00H, H_c).

PAMAM-PEG$_{2000}$ Dendrimer Conjugate 17. A mixture of G3 PAMAM dendrimer **1** (5.64 mg, 0.816 μmol) and PEG carbonate **7c** (113 mg, 52.2 μmol) in DMSO (550 μL) was continued to stir for 13 d. The crude mixture was loaded on a SEC column (H 43 cm × O.D. 4.5 cm) to isolate the desired dendrimer conjugate **17** (12.5 mg). ^{1}H NMR (600 MHz, DMSO-d_6) δ 7.93 (s, 35.70H, NH_{G3}), 7.79 (br s, 28.60H, NH_{G0}, NH_{G1}, and NH_{G2}), 7.22 (s, 29.53H, NH_{PEG} of major isomer), 6.80 (br s, 2.88H, NH_{PEG} of minor isomer), 4.03 (br s, 64.23H, H_h), 3.62−3.38 (m, 5633.29H, satellites J = 70.8 Hz, H_i, H_j, and H_k), 3.23 (s, 100.03H, H_l), 3.07−3.00 (m, 289.19H, H_d, H_{fPEG}, and H_{gPEG}), 2.63 (m, 121.87H, H_b), 2.41 (m, 58.47H, H_e and H_a), 2.17 (m, 120.00H, H_c).

Cytotoxicity Assays. Typically, a stock solution of dendrimer derivative was prepared by dissolving 0.5 μmol of a vacuum-dried solid sample in 50 μL of DMSO (10 mM solution). Dendrimers **2** and **3** used for cytotoxicity studies were not purified by SEC, in order not to disrupt the average MWs. Thus, samples **2** and **3** contained some acetic acid, and were used as reaction mixtures after drying *in vacuo* extensively. All other synthesized PAMAM-PEG dendrimer conjugates were purified by SEC. To ensure the dissolution, each 50 μL dendrimer sample in DMSO was heated at 80 °C for 30 min and then allowed to cool to room temperature. A partial gelation appeared with dendrimer conjugate **8** (see Results and Discussion section), and thus the actual concentration of assay samples of **8** may be lower. 5 mL of DMEM/F12 media (Mediatech Inc.) containing 10% fetal bovine serum and antibiotics was added to this 50 μL solution to make 1% (v/v) DMSO as a total content, which was then heated at 37 °C for another 30 min to ensure homogeneity. Any further dilutions used the media supplemented with 1% (v/v) DMSO, which was shown in control experiments not to affect the cell growth.

Serial dilutions were carried out to prepare samples of the following concentrations: 0.32, 1.0, 3.2, 10, and 32 μM for dendrimers **1**−**4** and **8**−**17**; 1.0, 3.2, 10, and 32 μM for dendrimers **18**, **19**, and **20**. 1.6 mL of each dilution was added to a six-well plate, and 30 000 cells were seeded per well. A well containing the 1.6 mL of media with 1% (v/v) DMSO was prepared simultaneously as a control along with each dendrimer series, which was seeded with the same number of cells. Two plates for each dendrimer compound were prepared so that one plate could be used for cell counting and the other plate could be used for hematoxylin staining. The cells grew for a period of 5 d, when the control well was 90% confluent. Subsequently, the media was aspirated and 1 mL of phosphate buffer saline (PBS) was added to each well and then removed. To count the cells, the cells were detached with 0.2 mL of trypsin and diluted with 2 mL of media (without the DMSO). The cell density in each well was measured using a hemocytometer to determine the effect of the added dendrimer derivative on cell survival, as an indication of cytotoxicity. Each well was homogenized and three counts were made to determine the accuracy. Thus, the percent cell survival is determined by normalizing each cell count against the value obtained from the corresponding control and is reported as mean ± standard error. For the hematoxylin staining, cells were fixed with methanol for 10 min. After PBS wash (×3) for 5 min each, the cells were stained with 4 g/L hematoxylin (containing 35.2 g/L aluminum sulfate and 0.4 g/L sodium iodate) for 10 min. The cells were washed (×3) with PBS for 5 min, allowed to air-dry, and then treated with glycerol. The image was visualized using a Zeiss bright-field microscope (*73*).

RESULTS AND DISCUSSION

Acetylation of PAMAM Dendrimers. We began our studies by preparing acetylated G3 PAMAM dendrimers. Partial acetylation of PAMAM dendrimers has been commonly applied as a way to enhance water solubility and reduce cytotoxicity of amine-terminated PAMAM dendrimers for drug delivery applications. Recent studies suggested that the partial acetylation altered the surface properties of the PAMAM dendrimer and led to a more compact structure, allowing it to better expose the attached ligands—and thus improved targeting—by suppressing the potential of backfolding (*67*, *69*). In general, commercial PAMAM dendrimers are somewhat heterogeneous, displaying a distribution of structures (i.e., defects), mainly caused by incomplete coupling and purification in each step of the divergent layer growth. Accordingly, we performed simple acetylation reactions to understand the stoichiometry involving heterogeneity and to establish the characterization method based on the ^{1}H NMR integration (Table 1). Furthermore, these partially acetylated PAMAM dendrimers may serve as controls to compare with the PEGylated PAMAM dendrimers of similar degrees of substitutions for their cytotoxic effects.

Dendrimer conjugates were synthesized from G3 PAMAM dendrimer **1** (Figure 1) with ethylenediamine as an initiator core ((*8*), Scheme 1). Initially, a stock solution of PAMAM dendrimer **1** in DMSO was prepared. In order to accurately determine the concentration of the stock solution, six individual batches containing the same volume of PAMAM stock solution, treated with different amounts of acetic anhydride in DMSO, were subjected to analysis of ^{1}H NMR integrals. Here, addition of organic base was not necessary for the acetylation reaction in DMSO, possibly due to the self-neutralizing effect of PAMAM dendrimers, which can form an ionic complex with acetic acid, the byproduct, at either the remaining peripheral amine (pK_a 6.9) or the tertiary amine (pK_a 3.9) in the interior (*62*). Next, the PAMAM dendrimer in DMSO was treated with ca. 16, 24, or 48 equiv of acetic anhydride. Typically, when the peripheral amino groups of PAMAM dendrimers were acetylated by acetic anhydride, a singlet corresponding to the methyl of acetamide appeared at 1.79 ppm ("h", Figure S1, Supporting Information) in DMSO-d_6, and a methyl peak from acetate anion was found at ca. 1.90 ppm which disappeared upon purification. When the integrals were normalized against the methylene peak of PAMAM at 2.18 ppm ("c", 120H), the internal standard of PAMAM for ^{1}H NMR integration, these dendrimers were found to contain 14, 20, and 32 acetamide groups on average, respectively (**2**, **3**, and **4**; Table 1). In fact, prior attempts to exhaustively acetylate the peripheral amino groups of PAMAM G3 dendrimers indicated that the number of terminal amino groups was close to the theoretical value of

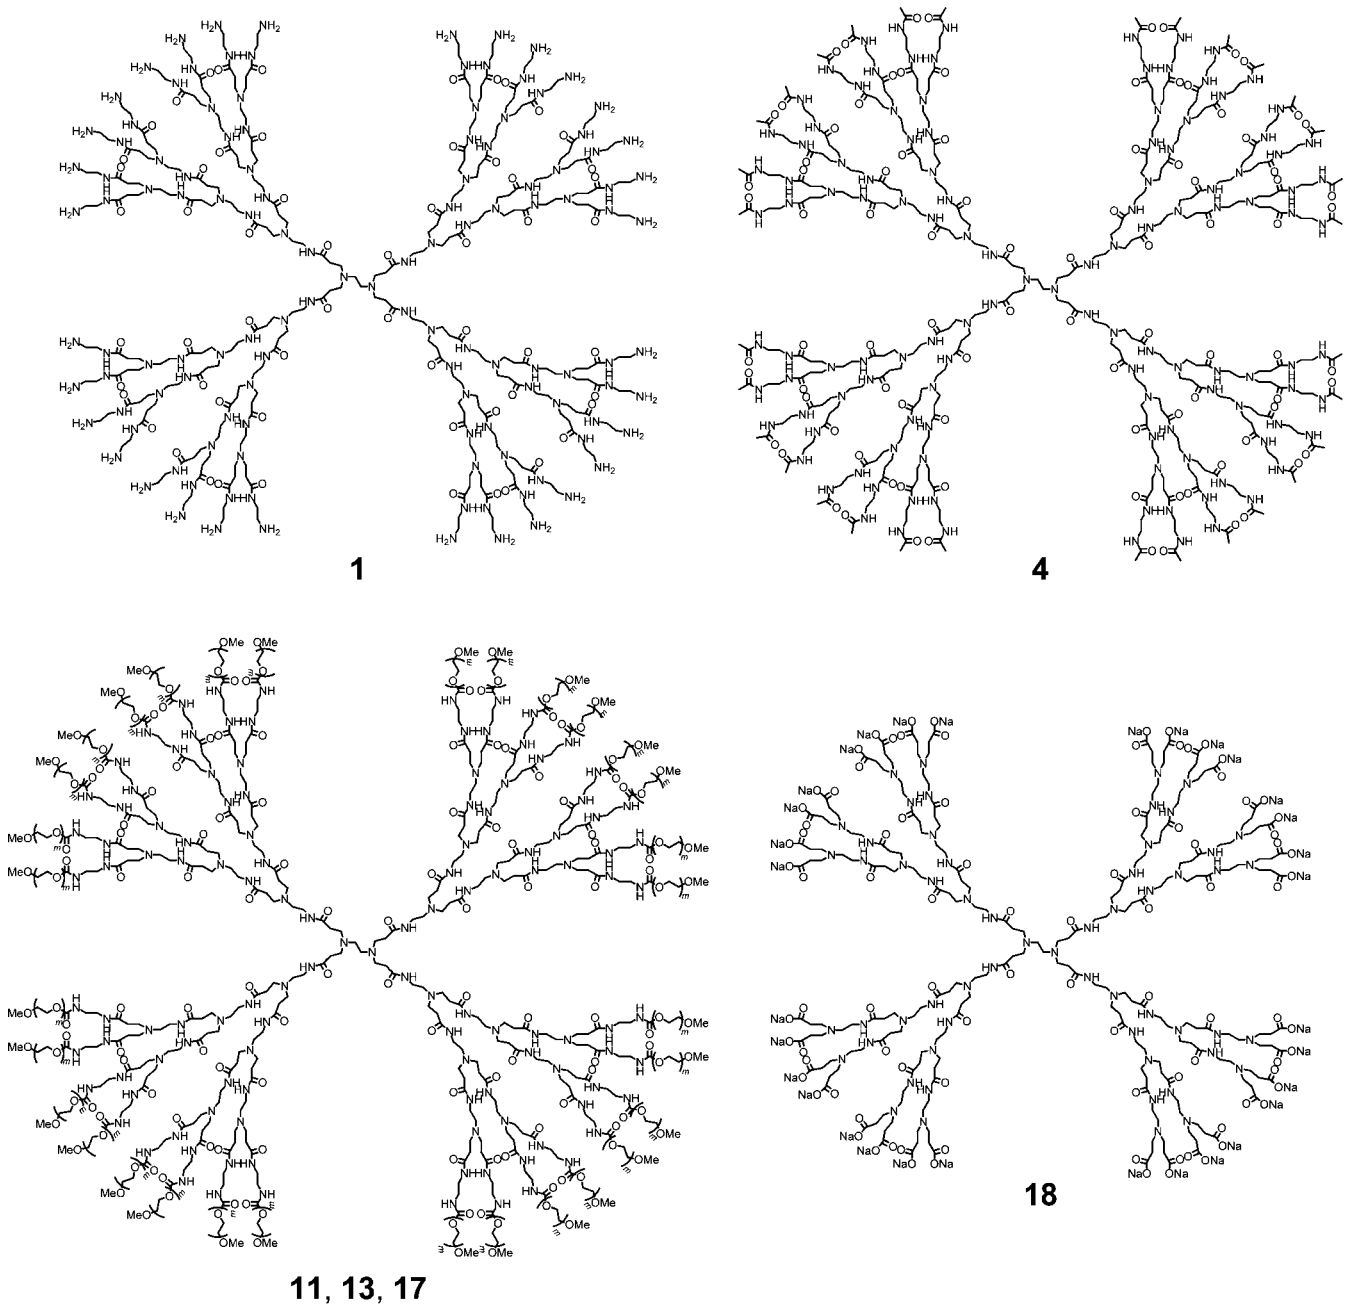

Figure 1. Structures of PAMAM dendrimer derivatives with homogeneous end groups: a commercial G3 PAMAM (**1**), acetylated G3 PAMAM (**4**), PEGylated G3 PAMAM (**11** from PEG_{550}, **13** from PEG_{750}, and **17** from PEG_{2000}), and a commercial G2.5 PAMAM with carboxylate terminal groups (**18**).

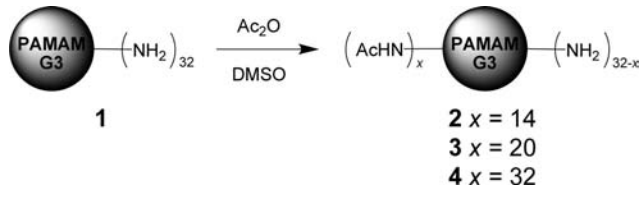
Scheme 1



32 by this normalization method based on the internal standard "c" after purification by SEC. Thus, 32 peripheral groups were assumed for PAMAM G3 dendrimers for the remainder of our structural analysis based on the ^{1}H NMR integration. Interestingly, when a portion of either of the partially acetylated PAMAM dendrimer reaction mixtures, **2** or **3**, was passed through a SEC column in DMF, the average number of acetamide groups shifted toward higher values by ^{1}H NMR integration, whereas the value for the fully acetylated PAMAM **4** remained the same. This may have resulted from the poorer solubility of PAMAM dendrimers with a lower degree of acetylation in DMF, reducing the relative recovery after SEC compared to the recovery of dendrimers bearing more acetamide groups in the same batch.

Various matrices and conditions were attempted to obtain the mass spectra of the acetylated PAMAM dendrimers by MALDI (see Supporting Information). As reported previously, MALDI spectra obtained with either DHB or THAP as a matrix generally gave the best results for our analysis (*74*). A relatively broad major peak was observed for each acetylated dendrimer, **2**, **3**, or **4**, spanning up to the mass range corresponding to the fully acetylated PAMAM. In either matrix, the overall pattern of the peak distribution was more or less the same between these three acetylated dendrimers. A secondary broad peak region corre-

sponding to the half-size of the desired MW was detected in the MALDI spectra of acetylated dendrimers, **2**, **3**, and **4**, as well as for the commercial PAMAM **1**. This half-size peak may have originated from the fragmentation near the tertiary amine of the core (*75*) and/or may indeed represent G2 PAMAM derivatives which were formed by the reagents carried over to the next step without removal in the commercial PAMAM synthesis. The average MWs of **2**, **3**, and **4** determined by MALDI in either matrix were lower than those determined by ^{1}H NMR (Table 1). Unlike the analysis based on ^{1}H NMR, average MWs estimated by MALDI slightly varied depending on the specific conditions applied (e.g., sample preparation, scanned mass range, laser intensity, etc.) or by the chemical nature of samples affecting fragmentation pattern and the tendency to form matrix/salt adducts. Overall, the MALDI-estimated average MWs increased (except for **4** with DHB matrix) in both matrices as the degree of acetylation increased from **1** to **4**.

Synthesis, Purification, and Characterization of PAMAM-PEG Conjugates. In order to systematically study the influence of PEG, relative to its size and abundance on reducing the cytotoxic effect of PAMAM dendrimers, conjugates were prepared starting from three different lengths of monomethyl PEG ether **5** (i.e., M_n 550, 750, and 2000; Scheme 2) by varying the degree of PEGylation. Preparation of the activated PEG carbonate **7** followed the modified procedure of Kojima et al. (*32*). As reported previously, contamination of the commercial monomethyl PEG ether by its diol derivative produced a mixture of mono- and diactivated PEG carbonates (*23, 76*). Diactivated PEG carbonate analogue of **7** (structure not shown) may result in unwanted intra- and intermolecular cross-links, and thus a tedious and cumbersome purification was necessary to remove these species by SEC in DMF. SEC fractions verified to contain only the desired PEG derivative **7** by ^{1}H NMR were combined and were used for the next step. The average MW of each PEG derivative **7** was determined on the basis of analysis of ^{1}H NMR and MS (Table 2). Here, each purification carried out by SEC slightly shifted the distribution of PEG derivative **7** to affect the average MW. Strangely, even after repeated purification, analysis of **7b** (from PEG_{750}) by ^{1}H NMR integration indicated the number of repeat units to be approximately twice the anticipated value. Despite the suggested contamination, the mass spectrum of **7b** displayed the desired peak distribution as a major entity, and thus **7b** was used for next step (Figure S7, Supporting Information). Unlike **7a** or **7c**, conjugation of **7b** to PAMAM indeed created some discrepancies in stoichiometry (*vide infra*); however, the contaminant was successfully removed by SEC at this later step without causing any further contamination.

Next, G3 PAMAM dendrimer **1** was treated with different amounts of PEG carbonate **7** (Scheme 3). Stoichiometry of the conjugation was generally well-managed when methanol was removed *in vacuo* from the commercial PAMAM G3 dendrimer **1**, and then the corresponding amount of the activated PEG **7** was added relative to the mass of dry PAMAM **1**. Preparation of ten different PAMAM-PEG derivatives was planned by adding: 4, 8, 16, and 64 equiv of **7a** (from PEG_{550}); 16 and 65 equiv of **7b** (from PEG_{750}); 4, 8, 16, and 64 equiv of **7c** (from PEG_{2000}). Reaction was generally performed in the concentration range 1.3−1.5 mM per dendrimer, and upon addition of **7**, the colorless reaction mixture instantly turned an intense yellow color, indicating the appearance of *p*-nitrophenolate species. After stirring for ≥4 d, the reaction mixture was loaded on a SEC column with DMF as an eluent, and the desired fractions were combined after careful analyses of ^{1}H NMR spectra. Here, the first and last SEC fractions confirmed to contain minor amounts of the desired dendrimer by NMR were eliminated deliberately. This was intended to reduce the polydispersity and thus to achieve more reliable biological effects by restricting the range of structural dissimilarity in the distribution, which is a limitation of the partial derivatization method commonly applied in PAMAM dendrimer chemistry.

The stoichiometry of PAMAM-PEG conjugates was established by ^{1}H NMR integration in DMSO-d_6 (Table 2, Figures 2 and 3). Detailed methods used for the analysis of NMR data are described in the Supporting Information. In summary, PAMAM dendrimer conjugates were characterized to contain the following: 4 (**8**), 7 (**9**), 14 (**10**), and 32 (**11**) of PEG_{550} chains; 9 (**12**), and 32 (**13**) of PEG_{750} chains; 4 (**14**), 8 (**15**), 17 (**16**), and 32 (**17**) of PEG_{2000} chains. Except for the PEG_{750} derivative **12,** which was prepared from a contaminated PEG derivative **7b** (*vide supra*), stoichiometric control of the conjugation reaction was elaborately executed as planned. In addition, the NMR-based MW estimation of PAMAM-PEG derivatives in DMSO-d_6 is summarized in Table 2. Alternatively, selected structures **10** and **14** were characterized similarly by ^{1}H NMR in D_2O, to give nearly identical results (Figure S4, Supporting Information).

Overall, these PAMAM-PEG conjugates were hygroscopic and exhibited relatively good water solubility except for dendrimer **8**, which was substituted with four short chains of PEG_{550}. Surprisingly, a severe irreversible gelation occurred for a portion of compound **8**, hampering any further usage of the batch. Gelation phenomena from amine-terminated PAMAM dendrimers were noticed previously, especially with lower substitution, and neither sonication nor the treatment with various organic solvents, water, acid/base, or heat restored them to the solution state (*77*).

Next, to help predict the solution conformation of PAMAM-PEG conjugates under physiological conditions, NOESY experiments were carried out in D_2O (Figures S5 and S6, Supporting Information). Dendrimer **10** with multiple numbers of short PEG chains ($14PEG_{550}$) and dendrimer **14** substituted with fewer long PEG chains ($4PEG_{2000}$) were chosen to explore the influence of PEG chain length and population on the overall geometry in solution. No NOE cross-peaks were observed from either structure between peaks from PAMAM and PEG regions in D_2O. This strongly suggests that, in water, the terminal hydrophilic PEG groups are entirely segregated from the central PAMAM domain (i.e., no backfolding) regardless of PEG chain length studied here. Thus, the geometry of PAMAM-PEG conjugates in aqueous media may closely resemble that of the phase-separated micelle. Indeed, the concept of a dendritic/hyperbranched "unimolecular micelle" with hydrophilic end groups was introduced earlier mainly for the entrapment of small hydrophobic molecules (*35, 54, 78–82*).

MALDI mass spectra of PAMAM-PEG conjugates were obtained using 2,5-dihydroxybenzoic acid (DHB) and 2,4,6-trihydroxyacetophene (THAP) as matrices (Figure 4, Supporting Information). Generally, the desired peaks were better resolved when the MALDI scan range was narrowed. Average MWs were calculated from the mass range encompassing the desired major peak. Again, the peaks corresponding to the half-size of the desired MW were detected in all cases. In certain cases, parts of these half-size peaks were included in the mass range for MW calculation to further underestimate the MW of the

desired, especially when the expected (i.e., NMR-determined) MWs of conjugates were relatively low(<25000 Da). Overall, when the half-size peak was not included, MALDI underestimated the MW of PAMAM-PEG conjugates by 7−18% compared to the MW determined by NMR. Again, broadening of peaks may have originated from random fragmentation under applied MALDI conditions (e.g., between the carbon−nitrogen bond at the interior tertiary amine), structural defects from the commercial starting material, or formation of matrix/salt adducts (*74*). Interestingly, MALDI of conjugates derivatized with fewer PEG_{2000} chains, **14** and **15**, displayed individual broad peaks separated by ca. 2000 Da, corresponding to PAMAM dendrimers with increasing numbers of PEG substitutions. MALDI-estimated average MWs of the PAMAM-PEG dendrimer conjugates in each matrix are listed in Table 2.

***In Vitro* Cytotoxicity of PAMAM Dendrimer Derivatives.** Evaluation of the cytotoxicity of PAMAM dendrimer derivatives with various surface modifications has been reported. A relevant study compared the cytotoxicity and hemolytic potential of the melamine-based dendrimers each bearing cationic (amine, guanidine), anionic (carboxylate, sulfonate, phosphonate), or neutral (PEG) hydrophilic surface group (*83*). Unfortunately, only limited systematic studies were performed to date along these lines that may provide guidelines to estimate the proper degree of peripheral substitutions needed when a particular functional group is used. Here, we examined the cytotoxic effects of dendrimer derivatives with several commonly used end groups in PAMAM-based drug delivery-acetamide, carboxylate, and PEG. Our systematic approach included varying the degree of terminal substitution for each functionality (acetamide, PEG), the size of PEG chains (PEG_{550}, PEG_{750}, and PEG_{2000}), and the generation of dendrimer (carboxylate). We investigated near the micromolar concentration range where somewhat marked differences in cytotoxicity between studied dendrimers were elicited. CHO cells were chosen as our target which were often used in our laboratory for studies on G protein-coupled receptors ((*74*) and references therein).

First, the cytotoxicity of PAMAM dendrimers with acetylated peripheries was examined (Figure 5A). Dendrimer **2** carried 14 acetamide groups (ca. 44% substitution) as analyzed by ^{1}H NMR integration method, dendrimer **3** had 20 acetamide groups (ca. 63% substitution), and dendrimer **4** was fully acetylated (100% substitution) leaving no free primary amino groups at the periphery. As expected, dendrimers with a higher degree of acetylation showed less toxicity. For instance, fully acetylated

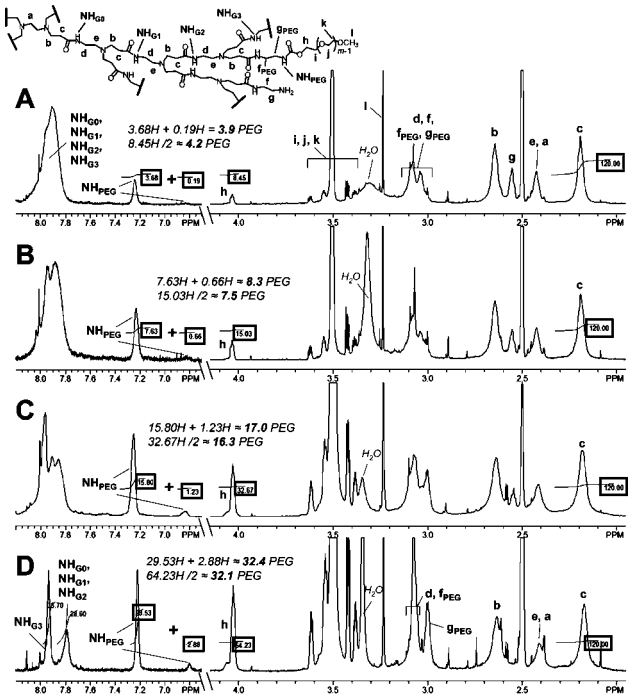

Figure 3. ^{1}H NMR spectra of PAMAM-PEG dendrimer conjugates (A) **14**, (B) **15**, (C) **16**, and (D) **17** in DMSO-d_6.

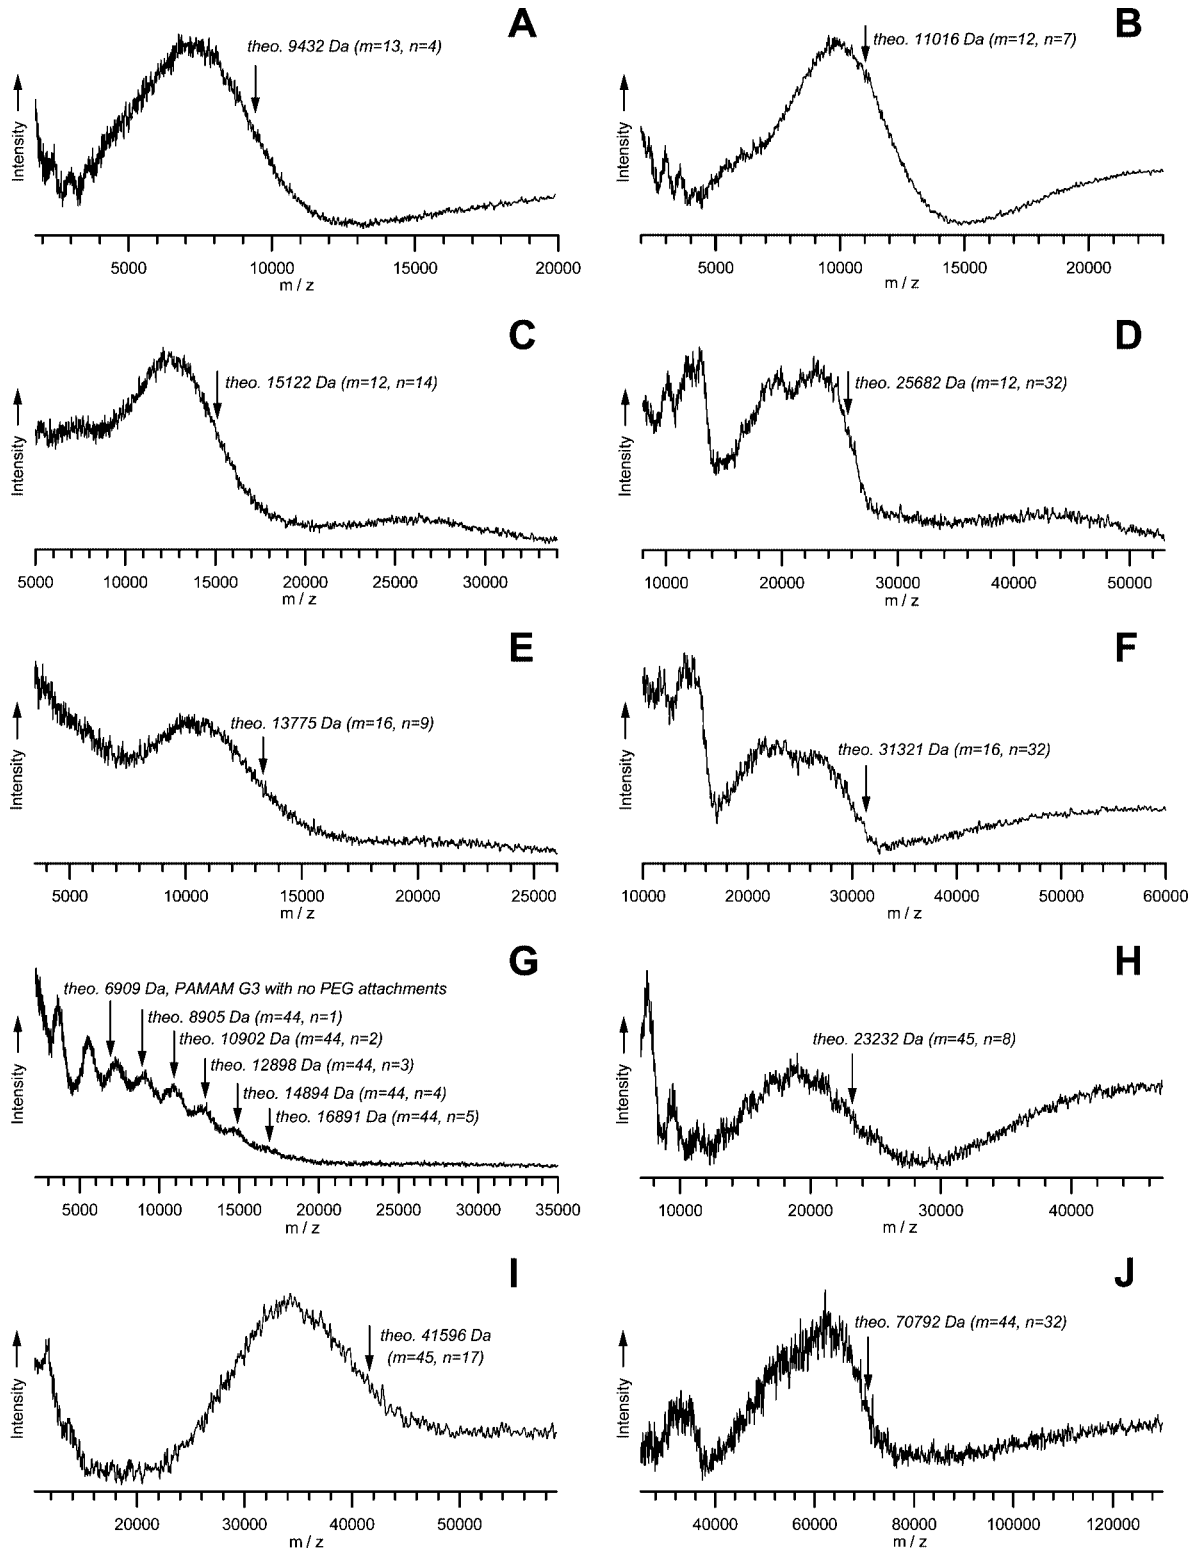

Figure 4. MALDI-TOF MS spectra of PAMAM-PEG dendrimer conjugates using DHB as a matrix: (A) **8**; (B) **9**; (C) **10**; (D) **11**; (E) **12**; (F) **13**; (G) **14**; (H) **15**; (I) **16**; (J) **17**.

dendrimer **4** exhibited ca. 75% cell survival at 32 μM (the highest concentration tested), whereas the unsubstituted PAMAM **1** and a nearly half-acetylated dendrimer **2** showed only ca. 5% cell survival. All dendrimer derivatives including the commercial PAMAM **1** exhibited >70% cell survival at $\leq$1 μM under the applied assay conditions. Recently, a similar systematic study was reported on acetylated G2 and G4 PAMAM dendrimers, which manifested concentration-dependent cytotoxic effects in Caco-2 cell cultures (*84*).

Next, our synthesized PAMAM-PEG dendrimer conjugates **8**−**17** were subjected to cytotoxicity evaluation under the same conditions in CHO cell cultures (Figure 5B,C). Generally, the cytotoxic effects of PAMAM-PEG conjugates decreased with increasing numbers of peripheral substitutions with respect to the same PEG chain length (i.e., PEG_{550}, PEG_{750}, or PEG_{2000}). Almost no cytotoxic effects were observed up to 1 μM concentration with dendrimers having a lower degree of PEG-substitution (22−28%), **9**, **12**, and **15**, which all exhibited similar

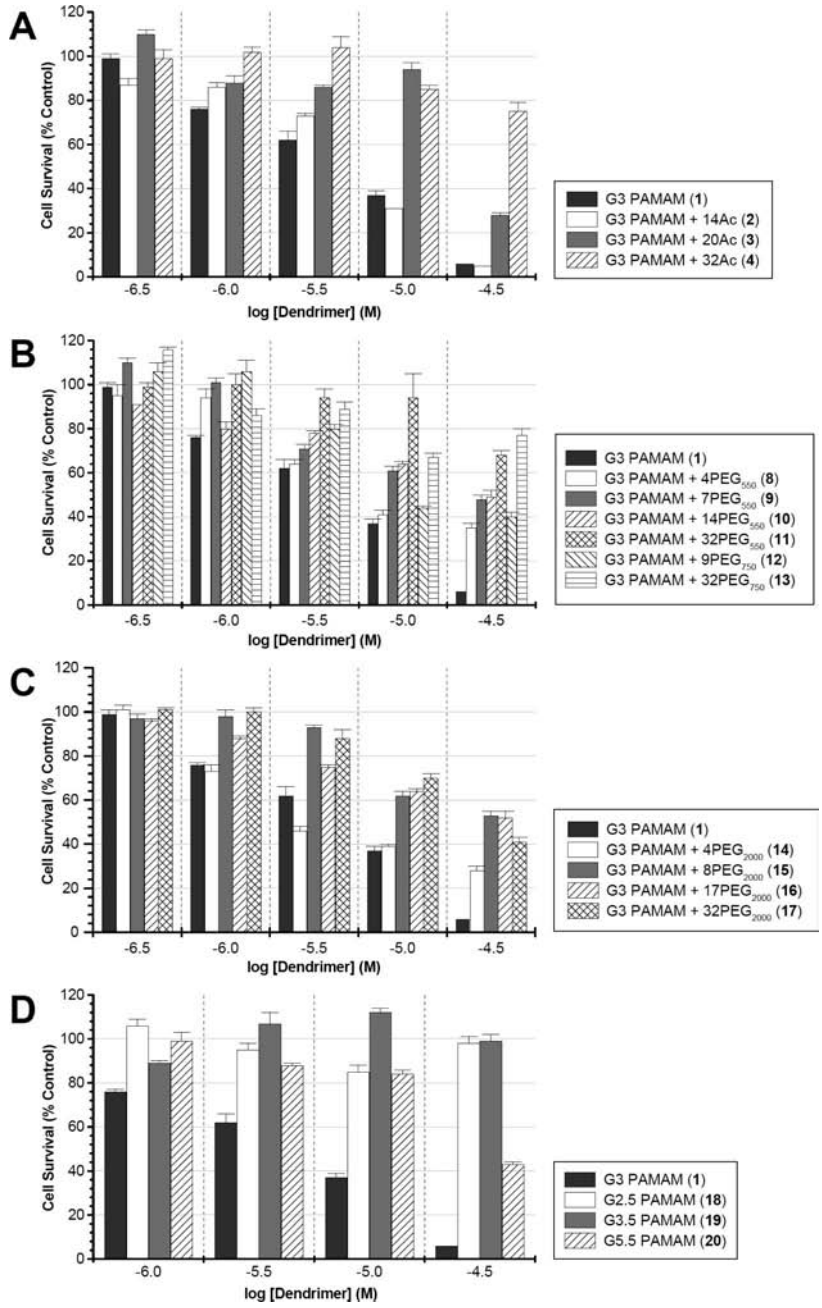

Figure 5. Cytotoxicity of dendrimers in CHO cell cultures: (A) acetylated G3 PAMAM dendrimers, G3 PAMAM dendrimers derivatized with (B) shorter PEG chains (PEG_{550}/PEG_{750}) or (C) a longer PEG chain (PEG_{2000}), and (D) anionic carboxylate PAMAM dendrimers (G2.5, G3.5, and G5.5). Each dendrimer sample was prepared using DMEM/F12 media (Mediatech, Inc.) containing 10% fetal bovine serum and antibiotics with 1% (v/v) DMSO. 30 000 cells were seeded per six-well plate containing dendrimer media, and the cells were counted after a 5 d incubation. Cell survival is reported by normalizing the cell counts to the value obtained from a control well with 1% (v/v) DMSO, which did not contain the dendrimer. Cell survival is reported as mean ± standard error.

cytotoxic values at higher concentrations within the permitted error range. Despite the limited experimental trials, when the cytotoxicity was compared between fully substituted PAMAM-PEG dendrimers, **11**, **13**, and **17** (Figure 1), interestingly, only **17** with the longest PEG groups showed a sudden drop in cell survival rate at the highest concentration of 32 μM. This dendrimer **17** was more toxic at 32 μM than the less substituted analogues, **15** and **16**, of the same chain length (PEG_{2000}). A previous report proposed the possibility of the intermolecular agglomeration and interpenetration for fully substituted PAMAM conjugates with longer PEG chains (PEG_{5000}) at higher concentrations, deterring efficient encapsulation (i.e., solubilization) of small hydrophobic molecules (*54*). Similarly, this potential agglomeration of dendrimer **17** may negatively affect cell viability at higher concentrations.

The cytotoxicity of PAMAM-PEG conjugates were then compared with that of acetylated dendrimers. At the highest concentration studied (32 μM), partially PEGylated dendrimers (**8**−**10**, **12**, and **14**−**16**) with 13−53% peripheral substitution were generally less toxic (28−53% cell survival) regardless of their chain length, compared to the partially acetylated dendrimers **2** and **3** (44−63% peripheral substitution, 5−28% cell survival). More specifically, the cytotoxicity profile of nearly half-substituted PAMAM-PEG derivatives, **10** and **16**, was more or less the same over the entire concentration range studied, suggesting negligible effects of chain length (PEG_{550} vs

PEG_{2000}). However, when these two medium-range PEG substitutions were compared to acetylated PAMAM **2** with 14 acetyl groups, cytotoxicity was significantly lower at ≥ 10 μM (49−64% cell survival for **10** and **16**; 5−31% cell survival for **2**). On the other hand, except for the dendrimer **17** with longer PEG chains, cell survival rates of fully substituted and relatively nontoxic dendrimers **4** (acetamide), **11** (PEG_{550}), and **13** (PEG_{750}) were similar. Taken together, PAMAM dendrimer with a lower degree (ca. 25% or less) of short PEG substitutions may substantially reduce the cytotoxicity of amine-terminated PAMAM dendrimers at a micromolar concentration range with good water solubility. In contrast, the smaller acetamide groups may require a higher degree of surface masking to achieve similar cell viability, limiting the number of available peripheral amino groups for further attachments of other functional moieties for drug delivery applications (e.g., drugs, targeting units, markers, etc.). Furthermore, water solubility of the final dendrimer with a partially acetylated surface may be governed more by the physical properties of these other appended moieties compared to the PEGylated surface, requiring additional fine-tuning of the stoichiometry.

Carboxylate-terminated anionic PAMAM dendrimers possess excellent water solubility. However, these derivatives have been used less frequently for drug delivery compared to the amine-terminated PAMAM dendrimers. In the same manner, we evaluated the cytotoxicity of commercial G2.5 (**18**, Figure 1), G3.5 (**19**), and G5.5 (**20**) PAMAM dendrimers with the ethylenediamine as an initiator core, which contain 32, 64, and 256 carboxylate end groups, respectively, in theory (Figure 5D). Essentially, no cytotoxic effect was observed from lower generation dendrimers, **18** and **19**, at all concentrations studied. Interestingly, for G5.5 PAMAM **20**, a sudden increase in cytotoxicity was observed at the highest concentrations (32 μM). Similar to the result obtained for dendrimer **17**, this relatively large dendrimer **20** with multiple hydrophilic end groups may aggregate intermolecularly (or alone) to display an increased level of cellular toxicity at elevated concentrations. Thus, for carboxylate PAMAM series, usage of G5.5 or higher generations may be limited to lower concentrations (≤ 10 μM) for drug delivery applications.

CONCLUSION

Attachment of PEG chains to macromolecular therapeutics generally alters the surface properties, leading to excellent water solubility and biocompatibility. PAMAM dendrimers are frequently used for dendrimer-based drug delivery applications due to their known relative biocompatibility and commercial availability. PEGylation has been applied to PAMAM dendrimers as a way to reduce toxicity of their amine termini and to offer a sufficient steric barrier for the efficient encapsulation of a drug or gene. Despite its advantageous effects, overcrowding the surface of these carriers by longer PEG chains may cause intermolecular aggregation, increase cytotoxicity, and prohibit intracellular drug release by deterring the uptake process (*9*). An estimation of minimally required PEG substitution is crucial when other functional moieties are appended on the PAMAM surface, especially when targeting or other ligand−receptor interaction is involved. Accordingly, to provide guidelines in designing PAMAM-based drug delivery agents, a series of PAMAM-PEG conjugates were prepared varying the degree of substitution and PEG chain length. Each dendrimer was purified by SEC and characterized by NMR and MALDI. A careful analysis of ^{1}H NMR integrals allowed the complete characterization of PAMAM-PEG conjugates for MW determination. NOESY experiments in D_2O confirmed the absence of back-folding of the peripheral PEG regardless of its size and population on the PAMAM surface, suggesting a micellar geometry.

The cytotoxicity of PAMAM-PEG derivatives was evaluated in CHO cell cultures. In comparison to the acetylated G3 PAMAM dendrimers, a lower degree of surface substitution was needed when PEG was present in order to achieve similar cell viability. Our systematic investigation indicated that a relatively low degree of surface modification (ca. 25% or less) by shorter PEG chains (PEG_{550}/PEG_{750}) may significantly reduce the cytotoxicity of amine-terminated PAMAM dendrimers while maintaining good water solubility.

In summary, PAMAM-PEG dendrimer conjugates may serve as universal scaffolds to build efficient and more versatile drug carriers. Current findings led us to further explore the influence of PEG chain length and number of attachments on eliciting potential pharmacological effects of ligands attached to the dendrimer surface involving receptor interactions, which will be reported in a separate manuscript.

ACKNOWLEDGMENT

This research was supported in part by the Intramural Research Program of the NIH, NIDDK. We thank Dr. Haijun Yao at the Mass Spectrometry Laboratory of the University of Illinois, for numerous attempts to obtain MALDI spectra of our PAMAM dendrimer derivatives. We are grateful to Rick Dreyfuss at ORS, NIH, who helped us to obtain the images for the cytotoxicity results. Y.K. thanks the Can-Fite Biopharma for financial support.

Supporting Information Available: ^{1}H NMR and MALDI-MS spectra, a complete list of cytotoxicity values, and selected images of cell cultures containing dendrimers used for cytotoxicity experiments. This material is available free of charge via the Internet at http://pubs.acs.org/BC.

NMR ANALYSIS OF PAMAM DENDRIMER CONJUGATES

General Methods. Since each PAMAM dendrimer conjugate was not unimolecular,[1] characterization by NMR represented the average value from its polymeric distribution. The integration value of each peak was reported in two decimal places as determined by the ^{1}H NMR analysis. For G3 PAMAM dendrimer-based conjugates, a methylene peak at 2.18 ppm ("c", see Figure S2) was used as an internal standard (set at 120 H) for the integration, assuming 32 peripheral groups without any defects in the structure. Assignments of peaks were based on the labeling method shown in Figure S1 for the acetylated PAMAM dendrimers and Figure S2 for the PEGylated PAMAM dendrimers.

Determination of Stoichiometry. The stoichiometry of PAMAM-PEG conjugates was established by ^{1}H NMR integration in DMSO-d_6 (Table 2, Figures S2 and S3). A distinct methylene peak from PEG next to the carbamate bond appeared at 4.03 ppm ("h"). Similar to the integration method applied for the acetylated G3 PAMAM dendrimers, the number of PEG attachments (*n*) was determined by the integrals of peak "h" relative to the PAMAM internal standard "c" at 2.18 ppm (120 H). A methyl peak from the PEG terminus at 3.23 ppm, often used to determine the number of PEG attachments (*n*) elsewhere, was not clearly resolved in DMSO-d_6 due to the adjacent broad peaks. Alternatively, the number of PEG chains (*n*) was estimated by summing the integrals of carbamate NH peaks ("NH_{PEG}") from two conformational isomers (i.e., conformers) found at ca. 7.24 ppm (major) and ca. 6.82 ppm (minor, 5-9%), which closely matched with the values determined through the methylene peak at 4.03 ppm ("h"). In fact, the peak integrated as "h" at 4.03 ppm included a small shoulder peak (minor conformer); however, quantification of its integral was difficult due to the significant overlap with the major peak. Characterization of the *E*- and *Z*-isomers from the carbamate linkages (e.g., *tert*-butoxycarbonyl (Boc)-protected amino acids) by ^{1}H NMR and IR spectroscopic methods was described previously,[2] and the composition of isomers generally varied depending on the temperature, solvent, concentration, and adjacent substituent groups. Consequently, by taking the average of integration values determined through two different methods described here, PAMAM dendrimer conjugates were characterized to contain: 4 (**8**), 7 (**9**), 14 (**10**), and 32 (**11**) of PEG_{550}

chains; 9 (**12**), and 32 (**13**) of PEG_{750} chains; 4 (**14**), 8 (**15**), 17 (**16**), and 32 (**17**) of PEG_{2000} chains.

Estimation of Average MWs. Each purification by SEC slightly shifted the distribution of these polymeric mixtures, affecting not only the number of PEG attachments (*n*), but also the average PEG chain length (i.e., number of repeat units, *m*). In an attempt to estimate the MW of PAMAM-PEG conjugates by NMR, the total number of repeat units (*mn*) was determined by integrating the entire PEG methylene peaks (Figures S2 and S3). The major peak of PEG appeared at 3.50 ppm, and its satellite peaks were observed at 3.62 ppm and 3.38 ppm, symmetrical to each other. Unfortunately, integration of the satellite peak at 3.38 ppm was often encumbered by the presence of a nearby water peak. Thus, the same integration value as for the other at 3.62 ppm was assumed. After combining the integrals of all PEG methylene peaks including "h", the total number of repeat units (*mn*) was estimated by dividing this integral by four (number of protons from a single repeat unit). Furthermore, the number of repeat units per PEG chain (*m*) was determined by dividing the total number of repeat units (*mn*) by the number of PEG attachments (*n*) for each conjugate. Similarly, selected structures **10** and **14** were characterized in D_2O by ^1H NMR, to give nearly identical results (Figure S4). The NMR-based MW estimation of PAMAM-PEG derivatives in DMSO-d_6 is summarized in Table 2.

[a] The actual concentration of **8** used for cytotoxicity studies may not be accurate due to the lower water-solubility and partial gelation. [b] Assumed to contain theoretical numbers of peripheral groups and no structural defects. [c] Exactly, carboxylate-terminated PAMAM dendrimers were not made by the peripheral substitution, but by stopping the two-step iterative PAMAM dendrimer layer-growth after the first step. [d] Percent cell survival is reported by normalizing each cell count against the value obtained from the corresponding control without the dendrimer, and reported as mean ± standard error (see Experimental Procedures for details).

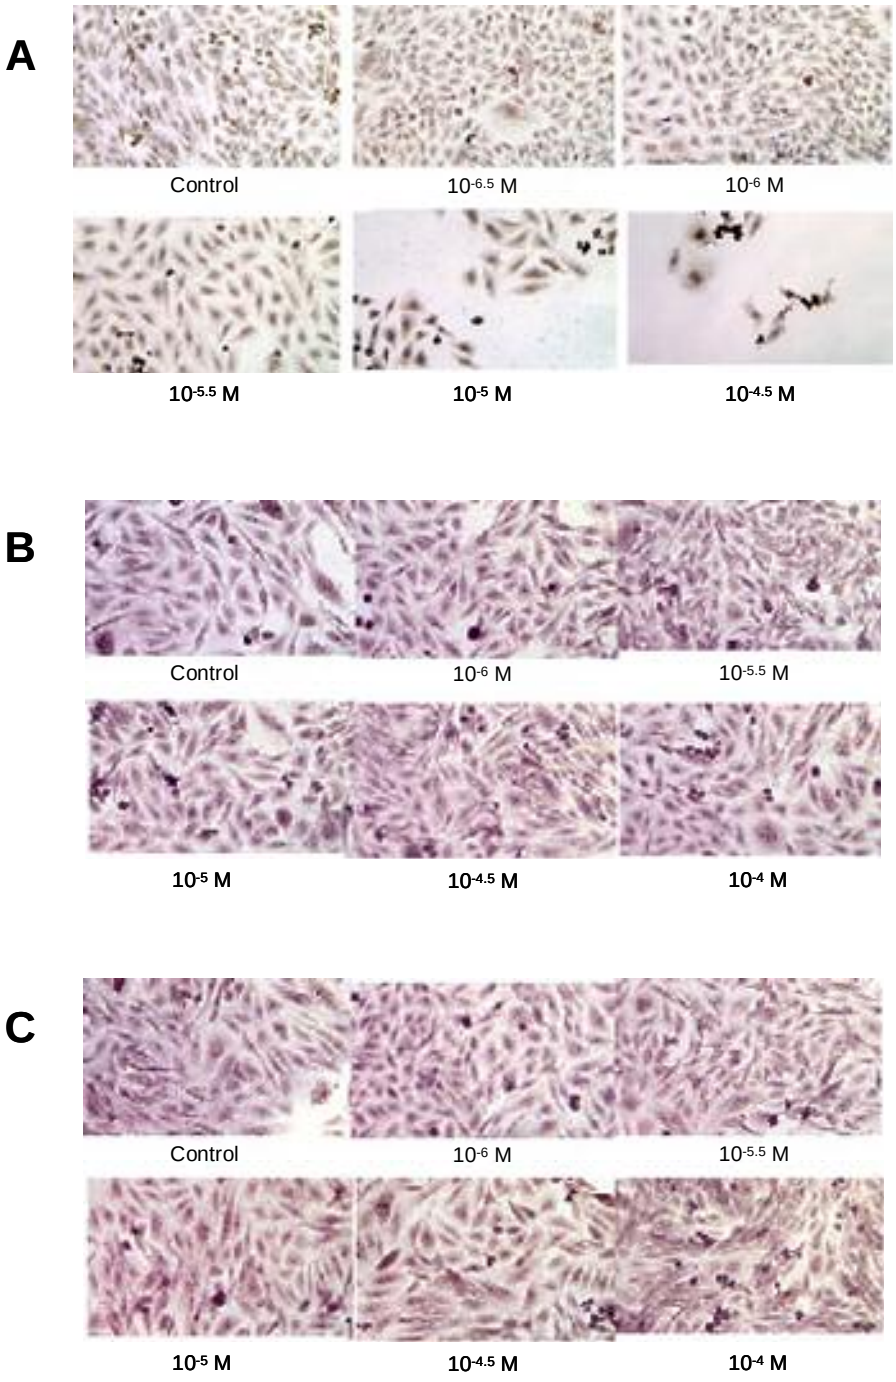

Figure S23. Cytotoxicity micrographs of (A) PAMAM G3 (**1**), (B) PAMAM G2.5 (**18**), and (C) PAMAM G3.5 (**19**) on CHO cells. Concentration of the corresponding dendrimer for control was 0 M.

Anti-CD22-MCC-DM1 and MC-MMAF Conjugates: Impact of Assay Format on Pharmacokinetic Parameters Determination

CD22 represents a promising target for antibody−drug conjugate therapy in the context of B cell malignancies since it rapidly internalizes, importing specifically bound antibodies with it. To determine the pharmacokinetic parameters of anti-CD22-MCC-DM1 and MC-MMAF conjugates, various approaches to quantifying total and conjugated antibody were investigated. Although the total antibody assay formats gave similar results for both conjugates, the mouse pharmacokinetic profile for the anti-CD22-MCC-DM1 and MC-MMAF appeared significantly different depending on the conjugated antibody assay format. Since these differences significantly impacted the PK parameters determination, we investigated the effect of the drug/antibody ratio on the total and conjugated antibody quantification using multiple assay formats. Our investigations revealed the limitations of some assay formats to quantify anti-CD22-MCC-DM1 and MC-MMAF with different drug load and in the context of a heterogeneous ADC population highlight the need to carefully plan the assay strategy for the total and conjugated antibody quantification in order to accurately determine the ADC PK parameters.

INTRODUCTION

Antibody−drug conjugate (ADC)[1] therapy, also known as antibody-targeted chemotherapy, is a therapeutic strategy designed to specifically or preferentially deliver a cytotoxic agent to tumor cells through conjugation to a monoclonal antibody that binds to a tumor-associated antigen (*1–3*). Each component of an ADC is important to achieve efficacy with minimal toxicity. First, the antibody should recognize a specific cell surface tumor antigen with no or minimal expression in vital tissue, and should preferentially trigger the internalization of its antigen. Second, the chemical linker between the antibody and the drug must be highly stable in the circulation (*4*), yet exhibit efficient release of the active drug either within the tumor cell or in its vicinity in order to mediate targeted antitumor activity. Multiple types of linker have been developed over the years, from the acid-labile hydrazones and reducible disulfides (*5–8*) to the valine-citrulline dipeptide linkers cleaved by cathepsin (*8, 9*) and the noncleavable more stable linker like the thioether (*10*) and maleimidocaproyl (*9*) linkers designed for maximum serum stability. Finally, the drug itself should be highly potent and remain active after conjugation and release from the ADC. Although the development of an efficacious ADC is in part based on rational design, it is key to keep in mind that each ADC will behave differently in terms of efficacy, toxicity, and pharmacokinetics depending on the tumor cell target. Therefore, multiple combinations of antibodies, linkers, and drugs should be investigated in order to develop the best therapeutic ADC candidate. Reliable determination of the pharmacokinetic profiles of these combinations is, therefore, a critical aspect of ADC characterization.

CD22 is a 140 kDa cell surface glycoprotein of the Siglec (sialic acid-binding immunoglobulin (Ig)-like lectins) family (*11, 12*). CD22 is expressed on the surface of B lymphocytes only during mature stages of differentiation and on their malignant counterparts, but not on other non-B lineage cells or on hematopoietic stem cells (*13–16*). Rapidly internalized, CD22 represents an attractive target for antibody−drug conjugate therapy to treat B-cell malignancies and has been investigated as such in several studies (*17–19*). We targeted CD22 using an anti-CD22 monoclonal antibody conjugated to the antitubulin agents maytansinoid (DM1) (*20, 21*) or monomethyl auristatin F (MMAF) (*9*). Both DM1 and MMAF were conjugated to the antibody through relatively stable linkers. DM1 was conjugated to the lysine residues of the antibody through a thioether linker, succinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (MCC) (*10*) (anti-CD22-MCC-DM1), while MMAF was coupled via a maleimidocaproyl group to the interchain cysteines (*9*) (anti-CD22-MC-MMAF). To evaluate the stability of these anti-CD22 ADCs *in vivo*, we developed two types of ELISA-based strategies allowing us to measure either the total antibody (conjugated or not) or the drug-conjugated antibody exclusively.

To measure the total anti-CD22 antibody defined as the ADC with a drug/antibody ratio higher or equal to 0, recombinant CD22 extracellular domain (ECD) was used to capture, while a goat anti-human IgG Fc horseradish peroxidase conjugated antibody (GxhFc-HRP) was used for detection. This specific total antibody assay format, which will be referred to as CD22/GxhFc-HRP, was initially compared with a generic human Fc

IgG assay format. To measure the drug-conjugated anti-CD22 antibody defined as the ADC with a drug/antibody ratio greater than or equal to 1, recombinant CD22 ECD was used to capture, while an anti-DM1 or anti-MMAF biotinylated antibody followed by streptavidin HRP was used for detection (formats that will be referred to as CD22/xDM1-Biotin and CD22/xMMAF-Biotin assays, respectively). This assay was compared with an anti-DM1 or anti-MMAF antibody coat using biotinylated CD22-ECD combined with streptavidin-HRP to detect (later referred as xDM1/CD22-Biotin and xMMAF/CD22-Biotin assays, respectively). Noticeably, these assays generated significantly different PK profiles in a way that affected the calculation of several critical PK parameters, especially for the conjugated antibody. One critical characteristic of the conventional ADC to consider in our interpretation of the different PK assay results is the fact that maytansine and monomethyl auristatin ADC chemistry results in both positional and stoichiometric heterogeneity. Therefore, we generated anti-CD22-MCC-DM1 enriched mixtures as well as purified anti-CD22-MC-MMAF fractions with various drug loads to investigate the impact of the drug/antibody ratio on the quantification of the anti-CD22 ADCs using different total and conjugated antibody assay formats. Our investigations allowed us to define the advantages and disadvantages of each assay format depending on the anti-CD22 ADC and to highlight the limitations of some assays in their current format to solely and accurately determined the ADC concentration.

EXPERIMENTAL PROCEDURES

Preparation of Anti-CD22-ADCs. Anti-CD22 antibody (10F4v3; huIgG1) (Genentech, Inc. South San Francisco, CA, USA) was generated (*22–25*) and conjugated with SMCC-DM1 (*26*) or MC-MMAF (*9*) as previously described. The average drug to antibody ratio for both ADCs was 3.4 (Table 1).

Preparation of Anti-CD22-MCC-DM1 Enriched Mixtures. Succinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (SMCC)-*N*(2′)-deacetyl-*N*(2′)-(3-mercapto-1-oxopropyl)-maytansine (DM1) conjugation of anti-CD22 (10F4v3) was performed as described previously (*26*). Although SMCC-DM1 was used for the anti-CD22 antibody conjugation, the ADC is referred to here as anti-CD22-MCC-DM1 to more accurately reflect the chemical structure. The DM1 conjugation reaction was performed using various DM1/Ab ratios in order to generate anti-CD22-MCC-DM1 enriched mixtures with average DARs equal to 0, 1, 4.2, and 8.5 DM1 per Ab. The different preparations were diafiltered with PBS (20×) before characterization as described elsewhere (*26*). The 1 and 4.2 DM1/Ab enriched mixtures were analyzed by mass spectrometry. Mixing the 1 and 4.2 drug/Ab anti-CD22-MCC-DM1 enriched preparations at 2:1 and 1:2 ratios generated the 2.1 and 3.1 drug/Ab enriched mixtures, respectively. Mixing equal amounts of the 4.2 and 8.5 drug/Ab anti-CD22-MCC-DM1 enriched preparations generated the 6.3 drug/Ab enriched mixture.

Isolation of Specific DAR Species from the anti-CD22-MC-MMAF ADC. The separation of the different anti-CD22-MC-MMAF DAR species was performed with a Phenyl-5PW hydrophobic interaction chromatography column (PIN 07573, 7.5 × 75 mm, 10 μm (Tosoh Biosciences Inc., South San Francisco, CA, USA) on an Agilent 1100 HPLC system equipped with a fraction collector (Agilent Technologies Inc., Santa Clara, CA, USA). A linear gradient from 75% of mobile phase A (25% mobile phase B) to 100% mobile phase B over 16 min was used. Mobile phase A was composed of 25 mM sodium phosphate and 1.5 M ammonium sulfate at pH = 6.95. Mobile phase B contained 75% 25 mM sodium phosphate at pH = 6.95 and 25% isopropyl alcohol. The flow rate was 1 mL/min and the column was maintained at 25 °C. The anti-CD22-MC-MMAF sample loading was 1 mg for the preparative scale and 50 μg for the analytical scale. A control DAR = 0 sample was prepared by injecting 150 μg of the unconjugated anti-CD22 antibody and collecting the peak. This amount was approximately the same as that corresponding to the DAR = 0 peak (15% of the total peak area) in a 1 mg injection of the ADC. The peaks of interest (DAR = 0, 2, 4a, 4b, and 6) were collected and reinjected on the analytical column for confirmation of their purity and identity. The anti-CD22-MC-MMAF ADC, the HIC-fractionated peaks and the unconjugated anti-CD22 antibody were reduced at 2 mg/mL with 100 mM DTT in 100 mM Tris-HCl, pH 8.0, for 15 to 30 min at 37 °C. The reduced samples were analyzed on a polymeric reverse phase column (PIN 1912−1502, PLRPS 1000 Å, 50 × 2.1 mm, 5 μm (Varian Inc., Palo Alto, CA, USA)). The sample loading was 2 μg/injection. The separation was achieved at 78 °C using a linear gradient from 25% B to 50% B in 25 min at a flow rate of 0.25 mL/min. Mobile phase A was 0.05% trifluoroacetic acid in water and mobile phase B was 0.04% trifluoroacetic acid in acetonitrile. The fractionated peaks were buffer-exchanged into 10 mM sodium succinate, 10% trehalose, 0.1% PS20 at pH = 5.0 with NAP 5 Columns (GE Healthcare Life Sciences, Piscataway, NJ, USA) following collection.

Sample Generation for Pharmacokinetic Studies. Plasma pharmacokinetic study was conducted at Genentech, Inc., in compliance with National Institutes of Health guidelines for the care and use of laboratory animals and approved by the Institutional Animal Care and Use Committee (IACUC). The study was conducted in non-tumor-bearing CB-17 SCID mice. Mice were randomized into 5 groups of 20 animals such that the mean body weight was not statistically different. Animals were fasted overnight before dosing with anti-CD22 naked antibody at 5 mg/kg, anti-CD22-MCC-DM1 (DAR = 3.4)(Table 1A,B) or anti-CD22-MC-MMAF (DAR = 3.4)(Table 1C,D) at 0.5 and 5 mg/kg as a single intravenous dose. After dosing, mice (4 mice per time point, 3 time points per mouse) were anesthetized by isoflurane inhalation, and blood (200 μL) was collected, by puncture of the retro-orbital plexus at 5 min, 1 and 6 h, and 1, 2, 3, 4, 8, 10, 14, 21, 28, 35, and 44 days after injection. Blood was transferred to lithium heparin tubes and

For the conjugated antibody assay various materials were used as coat reagent: CD22-ECD (Schematic C) with anti-DM1-Biotin (C1) or anti-MMAF-Biotin (C2) as detection reagents; anti-DM1 (D1, E1, E2) with CD22-ECD-Biotin (Schematic D), GxhFc-HRP (schematic E) or GxhF(ab′)$_2$-HRP as detection reagents, respectively; anti-MMAF (D2, E3, E4) with CD22-ECD-Biotin (Schematic D), GxhFc-HRP (Schematic E) or GxhF(ab′)$_2$-HRP as detection reagents, respectively.

immediately placed on ice until centrifugation for collection of the plasma samples.

Total Antibody Pharmacokinetic ELISA-Based Assays. Microtiter plates (96 wells) (Nunc, Rochester, NY, USA) were coated with human CD22 (beta) extracellular domain HIS-tagged (Genentech, Inc.) at 1 μg/mL in coat buffer (0.05 M carbonate/bicarbonate buffer pH 9.6) for the CD22 coat/AffiniPure F(ab′)$_2$ fragment goat anti-human IgG, Fcγ fragment specific HRP conjugated detection (CD22/GxhFc-HRP, format A1, Table 2) and CD22 coat/AffiniPure F(ab′)$_2$ fragment goat anti-human IgG, F(ab′)$_2$ fragment specific HRP conjugated detection (CD22/GxhF(ab′)$_2$-HRP, format A2, Table 2) total assay formats. Microtiter plates (96 wells) were coated with the AffiniPure F(ab′)$_2$ fragment rabbit anti-human IgG, Fcγ fragment specific (RxhFc)(Jackson ImmunoResearch Laboratory, West Grove, PA, US) at 1 μg/mL in coat buffer for the AffiniPure F(ab′)$_2$ fragment rabbit anti-human IgG, Fcγ fragment specific coat/AffiniPure F(ab′)$_2$ fragment goat anti-human IgG, Fcγ fragment specific HRP conjugated detection (RxhFc/GxhFc-HRP, format B1, Table 2) and for the AffiniPure F(ab′)$_2$ fragment rabbit anti-human IgG, Fcγ fragment specific coat/AffiniPure F(ab′)$_2$ fragment goat anti-human IgG, F(ab′)$_2$ fragment specific HRP conjugated detection (RxhFc/GxhF(ab′)$_2$-HRP, format B2, Table 2) total assay formats. After an overnight incubation at 4 °C, assay plates were washed and treated with block buffer (PBS/0.05% Tween 20/0.05% Proclin 300 pH 7.4) for 1 to 2 h before 2 h incubation with anti-CD22-MCC-DM1 or anti-CD22-MC-MMAF standards and samples diluted in sample diluent (PBS/0.5% BSA/10 ppm Proclin/0.05% Tween 20/0.2%BGG/0.25% CHAPS/5 mM EDTA/0.35 M NaCl, pH7.4). Assay plates were first washed 6 times with wash buffer (PBS/0.05% Tween 20) and then incubated for 1 h with the AffiniPure F(ab′)$_2$ fragment goat anti-human IgG, Fcγ fragment specific HRP conjugated (GxhFc-HRP) (Jackson ImmunoResearch Laboratory) diluted to 20 ng/mL (for CD22/ GxhFc-HRP and RxhFc/ GxhFc-HRP) or the AffiniPure F(ab′)$_2$ fragment goat anti-human IgG, F(ab′)$_2$ fragment specific HRP conjugated (GxhF(ab′)$_2$-HRP)(Jackson ImmunoResearch Laboratory) diluted to 80 ng/mL (for CD22/ GxhF(ab′)$_2$-HRP and RxhFc/ GxhF(ab′)2-HRP) in assay buffer (PBS/0.5% BSA/10 ppm Proclin/0.05% Tween 20, pH7.4). After washing (6 times), detection step was done using tetramethylbenzidine (TMB) substrate (Moss, Passadena, MD, USA). Absorbance was measured at 450 nm against a reference wavelength of 620 nm.

DM1-Conjugated Antibody Pharmacokinetic ELISA-Based Assays. Microtiter plates (96 well) (Nunc) were coated either with 1 μg/mL of human CD22 (beta) extra-cellular domain HIS-tagged (Genentech, Inc.) in coat buffer for CD22 coat/biotinylated anti-DM1 antibody detection (CD22/xDM1-Biotin, format C1, Table 2) assay format or anti-DM1 antibody in coat buffer (ImmunoGen, Inc., Cambridge, MA) for anti-DM1 antibody coat/biotinylated CD22 detection (xDM1/CD22-Biotin, format D1, Table 2), anti-DM1 antibody coat/AffiniPure F(ab′)$_2$ fragment goat anti-human IgG, Fcγ fragment specific HRP conjugated detection (xDM1/GxhFc-HRP, format E1, Table 2), and anti-DM1 antibody coat/AffiniPure F(ab′)$_2$ fragment goat anti-human IgG, F(ab′)$_2$ fragment specific HRP conjugated detection (xDM1/GxhF(ab′)$_2$-HRP, format E2, Table 2) assay formats. After an overnight incubation at 4 °C, assay plates were washed and treated with block buffer for 1 to 2 h before 2 h incubation with anti-CD22-MCC-DM1 standards and samples diluted in sample diluent. Assay plates were washed 6 times with wash buffer and incubated for 1 h with either biotinylated anti-DM1 antibody at 13 ng/mL followed by streptavidin-HRP (GE Healthcare Life Sciences) (for CD22 /xDM1-Biotin assay format), human CD22 (beta) extracellular domain HIS-tagged biotinylated followed by streptavidin-HRP (for xDM1/CD22-Biotin), GxhFc-HRP diluted to 20 ng/mL (for xDM1/GxhFc-HRP) or GxhF(ab′)$_2$-HRP diluted to 40 ng/mL (for xDM1/ GxhF(ab′)$_2$-HRP) in assay buffer. After washing (6 times), detection step was carried out using TMB substrate (Moss). Absorbance was measured at 450 nm against a reference wavelength of 620 nm.

MMAF-Conjugated Antibody Pharmacokinetic ELISA-Based Assays. Microtiter plates (96 well) (Nunc) were coated with 1 μg/mL of human CD22 (beta) extracellular domain HIS-tagged (Genentech) in coat buffer for CD22 coat/biotinylated anti-MMAF antibody clone 3.247 detection (Seattle Genetics, Bothell, WA, USA) (CD22 /xMMAF-Biotin, format C2, Table 2) assay format. Microtiter plates (96 well) (Nunc) were coated with 1 μg/mL of anti-MMAF antibody clone 3.247 in coat buffer for anti-MMAF antibody coat/biotinylated CD22 detection (xMMAF/CD22-Biotin, format D2, Table 2), anti-MMAF antibody coat/AffiniPure F(ab′)$_2$ fragment goat anti-human IgG, Fcγ fragment specific HRP conjugated detection (xMMAF/GxhFc-HRP, format E3, Table 2), and anti-MMAF antibody coat/AffiniPure F(ab′)$_2$ fragment goat anti-human IgG, F(ab′)$_2$ fragment specific HRP conjugated detection (xMMAF/GxhF(ab′)$_2$-HRP, format E4, Table 2) assay formats. After an overnight incubation at 4 °C, assay plates were washed and treated with block buffer for 1 to 2 h before 2 h incubation with anti-CD22-MC-MMAF standards and samples diluted in sample diluent. Assay plates were first washed 6 times with wash buffer and then incubated for 1 h with either biotinylated anti-MMAF antibody clone 3.247 at 2.4 ng/mL followed by streptavidin-HRP (GE Healthcare Life Sciences) (for CD22/ xMMAF-Biotin assay format), human CD22 (beta) extracellular domain HIS-tagged biotinylated followed by incubation with streptavidin-HRP (for xMMAF/CD22-Biotin), GxhFc-HRP diluted to 20 ng/mL (for xMMAF/GxhFc-HRP) or GxhF(ab′)$_2$-HRP diluted to 40 ng/mL (for xMMAF/GxhF(ab′)$_2$-HRP) in

Figure 1. (A) Mouse plasma pharmacokinetic analysis. Mice were injected with a single IV dose of anti-CD22-MCC-DM1 (a, b) or anti-CD22-MC-MMAF (c, d) at 0.5 (a, c) and 5 mg/kg (b, d) and plasma samples collected over time up to 44 days. Sample analysis was conducted using two different total assay formats: CD22/GxhFc-HRP (format A1, Table 1) (—●—) or RxhFc/GxhFc-HRP (format B1, Table 1) (—○—), and two different conjugated antibody assay formats: CD22/anti-drug-Biotin (format C1 & C2, Table 1) (--■--) or anti-drug/CD22-Biotin (format D1 & D2, Table 1) (——). For each time point the average concentrations in ng/mL ± STDEV for 4 animals is shown. Total antibody concentrations measured using CD22/GxhFc-HRP format (A1, Table 1) were compared to concentrations measured using RxhFc/GxhFc-HRP format (B1, Table 1). +, $P < 0.05$; ++, $P < 0.01$; +++, $P < 0.001$. Conjugated antibody concentrations measured using CD22/anti-drug-Biotin format (C1 & C2, Table 1) were compared to concentrations measured using anti-drug/CD22-Biotin format (D1 & D2, Table 1). *, $P < 0.05$; **, $P < 0.01$; ***, $P < 0.001$. (B) Mouse pharmacokinetic parameters. Based on the total and conjugated antibody concentrations measured using two different total assay formats (CD22/GxhFc-HRP and RxhFc/GxhFc-HRP) and two different conjugated antibody assay formats (CD22/anti-drug-Biotin and anti-drug/CD22-Biotin), pharmacokinetic parameters were calculated for anti-CD22-MCC-DM1 and anti-CD22-MC-MMAF (*CL*, $t_{1/2}$,V_1, and AUC).

assay buffer. After washing (6 times), detection step was done using TMB substrate (Moss). Absorbance was measured at 450 nm against a reference wavelength of 620 nm.

Pharmacokinetic Analysis. The mean total and conjugated 10F4v3-MCC-DM1 and 10F4v3-MC-MMAF time−concentration data were analyzed using a two-compartmental analysis (Model 200, WinNonlin-Pro, Version 5.0.1; Pharsight Corporation; Mountain View, CA) to obtain the clearance (*CL*), elimination half-life ($t_{1/2}$), volume of distribution (V_1), and drug exposure (AUC).

Statistical Analysis. Assessments of the difference between the total antibody concentrations determined using the CD22/GxhFc-HRP and RxhFc/GxhFc-HRP assay formats, and the difference between the conjugated antibody concentrations determined using the CD22/anti-drug-Biotin and anti-drug/CD22-Biotin assay formats were conducted by applying mixed-effect regression analysis of the log-ratios of the measurements from the two assay formats over the time points. Significance was defined as $P < 0.05$.

RESULTS

Mouse Plasma Pharmacokinetic Analysis Using Various Total and Conjugated Antibody Assay Formats. SCID mice received a single intravenous dose of anti-CD22-MCC-DM1 (DAR = 3.4) (Table 1A,B) or anti-CD22-MC-MMAF (DAR = 3.4) (Table 1C,D) at 0.5 (Figure 1A, panels a and c, respectively) or 5 mg/kg (Figure 1A, panels b and d, respectively). Blood was collected and plasma samples prepared at different times after injection up to 44 days. Samples were subsequently analyzed using two types of ELISA-based assays to either measure the total anti-CD22 antibody (with or without drug) or the drug-conjugated anti-CD22 antibody (defined as the ADC). Initially, two assay formats were investigated as potential total antibody assays (Figure 1A, solid lines). These assays either used CD22-ECD (Format A1, Table 2) or RxhFc to capture (Format B1, Table 2). Both of these total assays used a GxhFc-HRP for detection (see Experimental Procedures section). For both anti-CD22-MCC-DM1 and anti-CD22-MC-MMAF the two total assay formats gave similar pharmacokinetic profiles (Figure 1A). Although the total antibody concentrations measured by the RxhFc/GxhFc-HRP assay (Format B1, Table 2) were consistently slightly higher and significantly different for later time points than those measured by the CD22/GxhFc-HRP assay (Format A1, Table 2), the pharmacokinetic parameters calculated from the different total antibody profiles including clearance (*CL*), elimination half-life ($t_{1/2}$), volume of distribution (V_1), and drug exposure (AUC) were fairly equivalent (Figure 1B). As an example, for anti-CD22-MCC-DM1 the total antibody clearance was 7.5 and 5.9 mL/day/kg at 0.5 and 5 mg/kg, respectively, when assayed with CD22/GxhFc-HRP and 6.2 and 5.3 mL/day/kg at 0.5 and 5 mg/kg, respectively, when assayed with RxhFc/GxhFc-HRP (Figure 1B). Similarly, for anti-CD22-MC-MMAF the total antibody clearance was 7.5 and 7.4 mL/day/kg at 0.5 and 5 mg/kg, respectively, when assayed with CD22/GxhFc-HRP and 5.6 and 6.1 mL/day/kg at 0.5 and 5 mg/kg, respectively, when assayed with RxhFc/GxhFc-HRP (Figure 1B).

Two conjugated antibody assay formats were also implemented (Figure 1A, dotted lines) coating CD22-ECD and detecting through the biotinylated anti-drug antibody (Format C1 and C2, Table 2) or conversely coating the anti-drug antibody and detecting with biotinylated CD22-ECD (Format D1 and D2, Table 2). For both drug types (DM1 or MMAF), the ADC concentrations measured by the CD22/anti-drug-Biotin (Format

C1 and C2, Table 2) were significantly lower than those measured by the anti-drug/CD22-Biotin assays (Format D1 and D2, Table 2) (Figure 1A).

For anti-CD22-MCC-DM1, the conjugated antibody concentrations measured by the two assay formats were significantly different as early as 24 and 48 h at 0.5 and 5 mg/kg, respectively (Figure 1A, panel a and b, respectively). Anti-CD22-MCC-DM1 at 0.5 mg/kg quantified at 3.24 ± 0.46 and 4.06 ± 0.27 μg/mL (mixed-effect regression analysis $P < 0.001$) with CD22/anti-drug-Biotin and anti-drug/CD22-Biotin assay formats, respectively, after 24 h. Anti-CD22-MCC-DM1 at 5 mg/kg quantified at 32.3 ± 7.2 and 49.4 ± 10.8 μg/mL (mixed-effect regression analysis $P < 0.001$) with CD22/anti-drug-Biotin and anti-drug/CD22-Biotin assay formats, respectively, after 48 h. For later time points, the difference between the concentrations measured using the two assays increased. For example, anti-CD22-MCC-DM1 at 0.5 mg/kg quantified at 0.08 ± 0.01 and 0.31 ± 0.05 μg/mL (mixed-effect regression analysis $P < 0.001$) with CD22/anti-drug-Biotin and anti-drug/CD22-Biotin assay formats, respectively, after 35 days. Anti-CD22-MCC-DM1 at 5 mg/kg quantified at 0.9 ± 0.15 and 3.1 ± 0.47 μg/mL (mixed-effect regression analysis $P < 0.001$) with CD22/anti-drug-Biotin and anti-drug/CD22-Biotin assay formats, respectively, after 35 days. These significant differences between the anti-CD22-MCC-DM1 concentrations measured with the two conjugated assay formats resulted in marked difference in calculated PK parameters, especially for the clearance (*CL*) and the drug exposure (AUC) (Figure 1B). The calculated clearance for anti-CD22-MCC-DM1 was 17 and 14 mL/day/kg at 0.5 and 5 mg/kg, respectively, when assayed with CD22/anti-drug-Biotin and 8.3 and 7.2 mL/day/kg at 0.5 and 5 mg/kg, respectively, when assayed with anti-drug/CD22-Biotin. The drug exposure for anti-CD22-MCC-DM1 was 30 and 370 dayxμg/mL at 0.5 and 5 mg/kg, respectively, when assayed with CD22/anti-drug-Biotin and 61 and 700 day/μg/mL at 0.5 and 5 mg/kg, respectively, when assayed with anti-drug/CD22-Biotin.

For anti-CD22-MC-MMAF, the conjugated antibody concentrations measured by the two assay formats were significantly different as early as day 2 and 4 at 0.5 and 5 mg/kg, respectively (Figure 1A, panel c and d, respectively). Anti-CD22-MC-MMAF at 0.5 mg/kg quantified at 2.6 ± 0.15 and 3.5 ± 0.22 μg/mL (mixed-effect regression analysis $P < 0.001$) with CD22/anti-drug-Biotin and anti-drug/CD22-Biotin assay formats, respectively, after 2 days. Anti-CD22-MC-MMAF at 5 mg/kg quantified at 15.2 ± 2.13 and 21.7 ± 3.0 μg/mL (mixed-effect regression analysis $P < 0.001$) with CD22/anti-drug-Biotin and anti-drug/CD22-Biotin assay formats, respectively, after 4 days. For later time points, the difference between the concentrations measured using the two assays increased. For example, anti-CD22-MC-MMAF at 0.5 mg/kg quantified at 0.04 ± 0.007 and 0.08 ± 0.02 μg/mL (mixed-effect regression analysis $P < 0.001$) with CD22/anti-drug-Biotin and anti-drug/CD22-Biotin assay formats, respectively, after 35 days. Anti-CD22-MC-MMAF at 5 mg/kg quantified at 0.6 ± 0.04 and 1.2 ± 0.06 μg/mL (mixed-effect regression analysis $P < 0.001$) with CD22/anti-drug-Biotin and anti-drug/CD22-Biotin assay formats, respectively, after 35 days. These significant differences between the anti-CD22-MC-MMAF concentrations measured with the two conjugated assay formats resulted in marked difference in calculated PK parameters, especially for the clearance (*CL*) and the drug exposure (AUC) (Figure 1B). The calculated clearance was 23 mL/day/kg at 0.5 and 5 mg/kg, when assayed with CD22/anti-drug-Biotin and 15 and 16 mL/day/kg at 0.5 and 5 mg/kg, respectively, when assayed with anti-drug/CD22-Biotin. The drug exposure for anti-CD22-MC-MMAF was 22 and 210 day/μg/mL at 0.5 and 5 mg/kg, respectively, when assayed with CD22/anti-drug-Biotin and 33 and 310 day/μg/mL at 0.5 and 5 mg/kg, respectively, when assayed with anti-drug/CD22-Biotin.

From these initial investigations, we concluded that ELISA-based strategies that use different capture or detection modalities especially for the conjugated antibody assay could yield different pharmacokinetic profiles for the anti-CD22-MCC-DM1 or anti-CD22-MC-MMAF ADCs and therefore impact the calculation of critical PK parameters such as clearance and drug exposure.

Impact of the Total Antibody Assay Format on Anti-CD22-MCC-DM1 Enriched Mixtures Measurement. The differences observed between the mouse plasma pharmacokinetic profiles generated using different total and conjugated antibody assays combined with the fact that conventional ADCs are heterogeneous by nature (Table 1) prompted us to further investigate the impact of the assay format on the detection of anti-CD22-MCC-DM1 enriched mixtures with different DARs. Four total antibody assay formats using either CD22-ECD or RxhFc as coat reagents and GxhFc- or GxhF(ab′)$_2$-HRP conjugates as detection reagents were implemented (Table 2). Four conjugated antibody assay formats were also implemented for each ADC type using either CD22-ECD or anti-drug antibody as coat reagent and biotinylated anti-drug antibody, biotinylated CD22-ECD, GxhFc-HRP, or GxhF(ab′)$_2$-HRP conjugates as detection reagents (Table 2).

Enriched mixtures of anti-CD22-MCC-DM1 with average DAR equal to 0, 1, 3.1, 4.2, 6.5, and 8.5 were generated as described in the Experimental Procedures section and analyzed in four different total antibody assays. The heterogeneity of the anti-CD22-MCC-DM1 enriched mixtures at 1 and 4.2 DM1/Ab were analyzed by mass spectrometry (Figure 2A, panel a and b, respectively). For the 1 DM1/Ab enriched mixture, the range of conjugation was from 0 to 4 drugs/Ab, with the 0 and 4 DAR representing 45% and 0.32% of the entire preparation, respectively (Figure 2A, panel a). For the 4.2 DM1/Ab enriched mixture, the range of conjugation was from 0 to 9 drugs/Ab, with the 0 and 9 DAR representing 2.8% and 0.18% of the entire preparation, respectively (Figure 2A, panel b). Interestingly, similar results were observed with the CD22/GxhFc-HRP (Format A1, Table 2) (Figure 2A, panel c), CD22/GxhF(ab′)$_2$-HRP (Format A2, Table 2) (Figure 2A, panel d), and RxhFc/GxhF(ab′)$_2$-HRP (Format B2, Table 2) (Figure 2A, panel f) assay formats. With these three assay formats, increase in DM1/Ab ratio resulted in a decrease in assay signal (Figure 2A, panel c, d, and f). In addition, the biggest separation in terms of signal for the different preparations was observed with the CD22/GxhF(ab′)$_2$-HRP assay (Format A2, Table 2) (Figure 2A, panel d) with the lowest signal at 39.8% of the 0 DAR maximum absorbance, while the lowest signal was at 56.4% and 67.6% for the CD22/GxhFc-HRP (Format A1, Table 2) (Figure 2A, panel c) and RxhFc/ GxhF(ab′)$_2$-HRP (Format B2, Table 2) (Figure 2A, panel f) assays, respectively. By contrast, the assay format B1 (RxhFc/GxhFc-HRP) (Table 2) was less sensitive to drug load than the other three formats (Figure 2A, panel e). The maximum signal was observed with the anti-CD22-MCC-DM1 enriched mixture with a DM1/Ab ratio of 0 (no drug), while the lowest signal was observed with the mixture at 8.5 DM1/Ab (highest drug load). In the RxhFc/GxhFc-HRP assay (Format B1, Table 2) (Figure 2A, panel e), the different mixtures produced similar results with an average signal equal to 93.4% ± 5.5% of the 0 DAR maximum absorbance.

In conclusion, increasing DM1 load onto the anti-CD22 antibody negatively impacted the CD22/GxhFc-HRP, CD22/GxhF(ab′)$_2$-HRP, and RxhFc/ GxhF(ab′)$_2$-HRP total antibody assay formats but not the RxhFc/GxhFc-HRP assay. This result suggests that increasing stoichiometry of DM1 conjugation

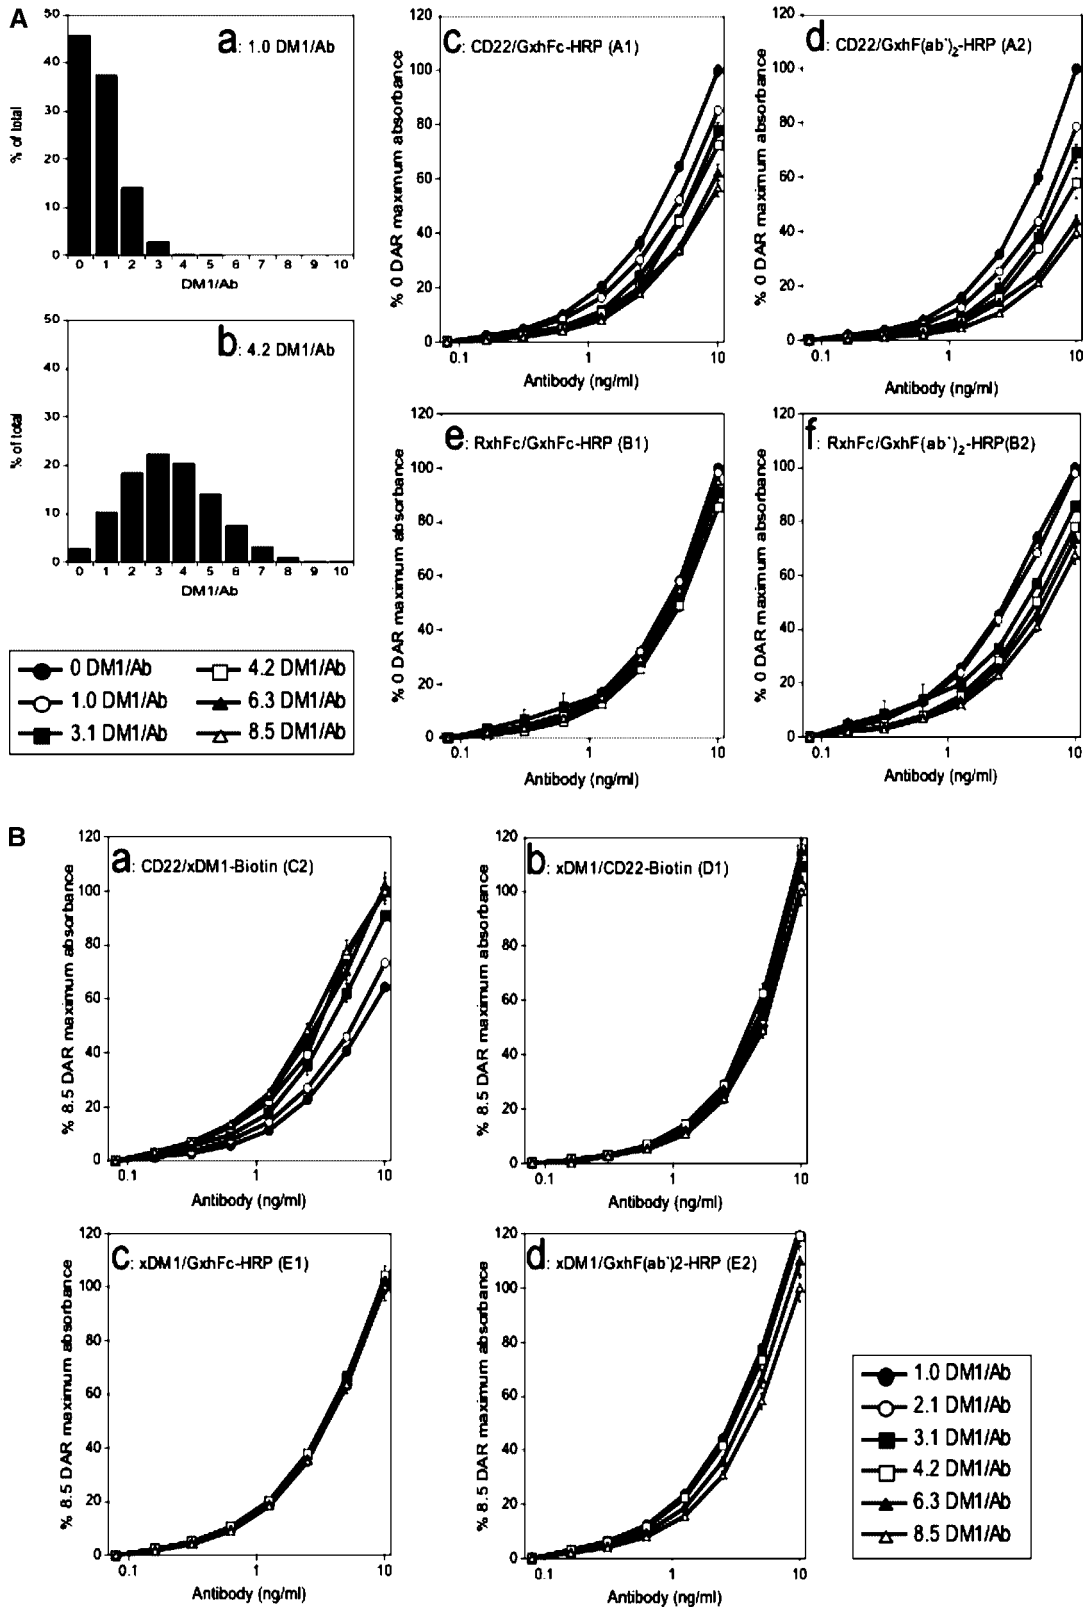

Figure 2. (A) Performances of anti-CD22-MCC-DM1 enriched mixtures in different total antibody assay formats. The heterogeneity of the anti-CD22-MCC-DM1 enriched mixtures at 1 (a) and 4.2 (b) DM1/Ab were analyzed by mass spectrometry. Anti-CD22-MCC-DM1 enriched mixtures with an average drug load of 0 (●), 1.0 (○), 3.1 (■), 4.2 (□), 6.3 (▲), and 8.5 (Δ) DM1 per antibody were assayed using various total antibody assay formats: CD22/GxhFc-HRP (c), CD22/GxhF(ab′)$_2$-HRP (d), RxhFc/GxhFc-HRP (e), RxhFc/ GxhF(ab′)$_2$-HRP (f). For the different anti-CD22-MCC-DM1 mixtures assayed from 0.16 to 10 ng/mL (1/2 serial dilution) plus blank, assay results were expressed as percentage of the maximum absorbance of 0 DM1/Ab fraction. (B) Performances of anti-CD22-MCC-DM1 enriched mixtures in different conjugated antibody assay formats. Anti-CD22-MCC-DM1 enriched mixtures with an average drug load of 1.0 (●), 2.1 (○), 3.1 (■), 4.2 (□), 6.3 (▲), and 8.5 (Δ) DM1 per antibody were assayed using various total antibody assay formats: CD22/xDM1-Biotin (a), xDM1/CD22-Biotin (b), xDM1/GxhFc-HRP (c), xDM1/ GxhF(ab′)$_2$-HRP (d). For the different anti-CD22-MCC-DM1 mixtures assayed from 0.16 to 10 ng/mL (1/2 serial dilution) plus blank, assay results were expressed as percentage of the maximum absorbance of 8.5 DM1/Ab fraction.

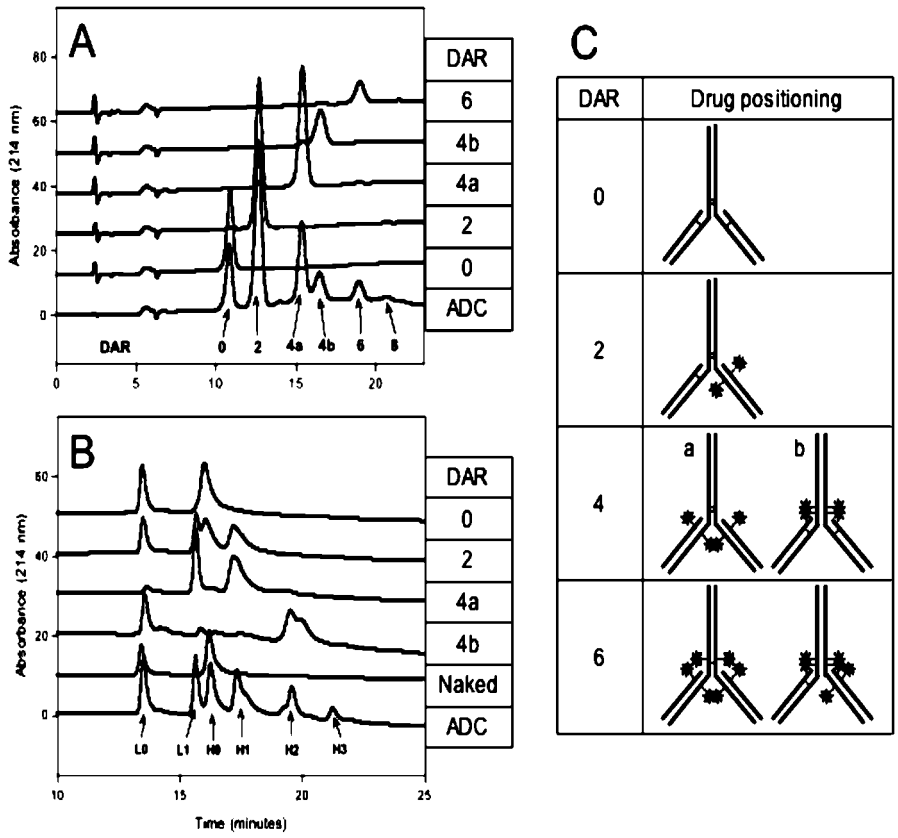

Figure 3. (A) HIC chromatograms of the anti-CD22-MC-MMAF ADC and the individual fractionated peaks at 0, 2, 4a (earlier retention time), 4b (later retention time), and 6 MMAF/Antibody. (B) RP-HPLC elution profiles of HIC purified fractions. The bottom chromatogram is the profile of the DTT reduced anti-CD22-MC-MMAF ADC. The labels L0, L1, H0, H1, H2, and H3 for the ADC profile are the free light chain, light chain with 0 drug-linker, light chain with one drug-linker, free heavy chain, heavy chain with one, two and three drug-linkers, respectively. (C) Schematic of the MMAF conjugation in different anti-CD22-MC-MMAF DAR species.

reduced binding of the anti-CD22-MCC-DM1 to CD22-ECD coat as well as binding of the GxhF(ab′)$_2$-HRP to the captured ADC.

Impact of the Conjugated Antibody Assay Format on Anti-CD22-MCC-DM1 Enriched Mixtures Measurement. The same set of anti-CD22-MCC-DM1 enriched mixtures with different DARs was analyzed using four different conjugated antibody assay formats: CD22/xDM1-Biotin (Format C1, Table 2) (Figure 2B, panel a), xDM1/CD22-Biotin (Format D1, Table 2) (Figure 2B, panel b), xDM1/GxhFc-HRP (Format E1, Table 2) (Figure 2B, panel c), and xDM1/ GxhF(ab′)$_2$-HRP (Format E2, Table 2) (Figure 2B, panel d). Regardless of the conjugated antibody assay format, no signal was observed with the 0 DM1/Ab fraction that went through the conjugation process but was not drug-modified (data not shown). In the CD22/xDM1-Biotin assay (Figure 2B, panel a), the signal increased when the ADC drug load increased. Reduction of the drug load from 3.1 to 2.1 and 1 DM1/Ab resulted in a decrease in absorbance with top signal at 10 ng/mL of ADC equal to 90.7%, 73.4%, and 64.4% of the 8.5 DAR maximum absorbance, respectively (Figure 2B, panel a). In this assay, the 8.5, 6.3, and 4.2 DM1/Ab preparations behaved similarly with an average signal equal to 100.5% ± 1.2% of the 8.5 DAR maximum absorbance. Results were markedly different when the anti-DM1 antibody was used as the coating reagent. All the differently loaded preparations behaved essentially the same in the xDM1/CD22-Biotin assay (Figure 2B, panel b) as well as in the xDM1/GxhFc-HRP assay (Figure 2B, panel c). Interestingly, some separation was observed between mixtures when GxhF(ab′)$_2$-HRP was used instead of GxhFc-HRP to detect the anti-DM1 captured ADC (Format E2, Table 2) (Figure 2B, panel d). Specifically, the two highly loaded anti-CD22-MCC-DM1 mixtures (8.5 and 6.3 DAR) generated the lowest OD signal while all the less loaded preparations (1, 2.1, 3.1, and 4.2 DM1/Ab) generated an average signal at 10 ng/mL equal to 120.3% ± 1.2% of the 8.5 DAR maximum absorbance, suggesting the GxhF(ab′)$_2$-HRP binding could be impaired by high drug load.

As expected, the signal in the CD22/xDM1-Biotin assay increased with the anti-CD22-MCC-DM1 drug load. Other assay formats were not affected by the ADC drug load except the xDM1/ GxhF(ab′)$_2$-HRP. In this assay, binding of the GxhF(ab′)$_2$-HRP appeared to be negatively impacted when the average drug load was higher or equal to 4.2 DM1/Ab.

Isolation and Characterization of Individual DAR Species from the anti-CD22-MC-MMAF ADC. Similar differences in mouse plasma pharmacokinetic profiles were observed for anti-CD22-MC-MMAF depending on the different total and conjugated antibody assays implemented (Figure 1). Since MMAF ADC is heterogeneous by nature (Table 1C,D), we investigated the impact of the assay format on the detection of ADC fractions with specific DARs purified from the anti-CD22-MC-MMAF (DAR = 3.4) use in the mouse PK study. We isolated different DAR species from the anti-CD22-MC-MMAF ADC by hydrophobic interaction chromatography. As shown in Figure 3A, anti-CD22-MC-MMAF used for this study contained 9.1%, 35.6%, 27.9%, 13.6%, and 10.4% of DAR species with 0, 2, 4a, 4b, and 6 MMAF/Ab, respectively. The individual fractions were then reduced with DTT and analyzed by reverse phase chromatography (Figure 3B) and their identities were confirmed by LC-MS (data not shown). The shoulder, which is seen at the trailing edge of the heavy chain with one drug-linker (referred to as H1, Figure 3B), and the leading as well as trailing edge of the heavy chain with two drug-linkers (referred to as H2, Figure 3B) are likely due to incomplete

reduction. The second profile from the bottom is the unconjugated anti-CD22 antibody (naked) and shows the retention times associated with reduced light and heavy chains without drug (L0 and H0). The top chromatogram (0 DAR) is identical to that of the naked anti-CD22 antibody (see above) run under the same conditions, demonstrating that there is no linker or drug attached to this fraction. The DAR 2 peak showed equal amounts of light chain and light chain with one drug-linker, as well as equal quantities of heavy chain and heavy chain with one drug-linker. Therefore, the 2 DAR species is composed of antibody with one of the two heavy chain−light chain disulfide bonds modified with drug-linker (Figure 3C) while the other disulfides are intact. Peak 4a (earlier retention time than 4b) (third profile from top, Figure 3B) showed predominantly light chain with one drug-linker and heavy chain with one drug-linker. This implies that peak 4a corresponds to an ADC in which both disulfide bonds between heavy and light chains are labeled, while the two disulfide bonds between the heavy chains at the hinge region remain intact (Figure 3C). The HIC profile of the fractionated peak 4a shows a slight contamination with the 2 DAR species (Figure 3A) that leads to the presence of the small peaks of L0 and H0. The reverse phase chromatography profile of peak 4b (later retention time than 4a) shows primarily unmodified light chain and heavy chain with two drug-linkers, with a few very minor peaks (due to some contamination of the peak with the 4a species as seen in Figure 3A). This implies that 4b corresponds to a form where both of the hinge disulfide bonds between the heavy chains are labeled, while the two disulfide bonds between heavy and light chain are unmodified (Figure 3C). Finally, characterization of the 6 drugs/Ab peak could not be conclusively performed by this technique, as the recoveries of this minor form were very low. For this fraction, assuming that only interchain disulfide bonds are involved, we hypothesize that one disulfide bond between the two heavy chains at the hinge region and both disulfide bonds between heavy and light chain or both disulfide bonds between the two heavy chains at the hinge region and one disulfide bond between heavy and light chain could be conjugated to MMAF (Figure 3C).

Impact of the Total Antibody Assay Format on Detection of Anti-CD22-MC-MMAF Fractions with Different DARs. The above purified fractions of anti-CD22-MC-MMAF ADC with drug loads of 0, 2, 4a, 4b, and 6 MMAF/Ab were assayed along with the naked anti-CD22 antibody in four different total antibody assay formats: CD22/GxhFc-HRP (Format A1, Table 2) (Figure 4A, panel a), CD22/GxhF(ab′)$_2$-HRP (Format A2, Table 2) (Figure 4A, panel b), RxhFc/GxhFc-HRP (Figure B1, Table 2) (Figure 4A, panel c), and RxhFc/GxhF(ab′)$_2$-HRP (Format B2, Table 2) (Figure 4A, panel d). In all assay formats and in the range of concentrations tested (0.16 to 10 ng/mL), these fractions generated comparable absorbance signals compared to the unmodified anti-CD22 antibody regardless of their DAR. The average signal at 10 ng/mL was 88.7% ± 6.7%, 96.3% ± 10.6%, 101.6% ± 5.3%, and 98.8% ± 5.6% of the naked antibody maximum absorbance in CD22/GxhFc-HRP (Figure 4A, panel a), CD22/ GxhF(ab′)$_2$-HRP (Figure 4A, panel b), RxhFc/GxhFc-HRP (Figure 4A, panel c), and RxhFc/ GxhF(ab′)$_2$-HRP (Figure 4A, panel d) assays, respectively.

In conclusion, increasing stoichiometry of MMAF conjugation to the anti-CD22-MC-MMAF ADC did not have any effect on the different total antibody assay tested.

Impact of the Conjugated Antibody Assay Format on Detection of anti-CD22-MC-MMAF Fractions with Different DARs. The same anti-CD22-MC-MMAF ADC purified fractions were assayed in four different conjugated antibody assay formats: CD22/xMMAF-Biotin (Format C2, Table 2) (Figure 4B, panel a), xMMAF/CD22-Biotin (Format D2, Table 2) (Figure 4B, panel b), xMMAF/GxhFc-HRP (Format E3, Table 2) (Figure 4B, panel c), and xMMAF/ GxhF(ab′)$_2$-HRP (Format E4, Table 2) (Figure 4B, panel d). As expected, regardless of the conjugated antibody assay format, no signal was observed with the 0 MMAF/Ab fraction that went through the conjugation process but was not drug-modified. In the CD22/xMMAF-Biotin assay, the signal increased when the ADC drug load increased (Figure 4B, panel a). The maximum signal was observed with the 6 MMAF/Ab fraction while signals equal to 65.3%, 57.9%, and 12% of the 6 DAR maximum absorbance was observed with the 4a, 4b, and 2 MMAF/Ab fractions, respectively. Surprisingly, in the xMMAF/CD22-Biotin assay similar signals were observed with fractions with drug loads equal to 6, 4a, and 4b MMAF/Ab with an average of 107% ± 8.5% of the 6 DAR maximum absorbance, while signal for the fraction at 2 DAR was markedly lower at 29.2% of the 6 DAR maximum absorbance (Figure 4B, panel b). In the xMMAF/GxhFc-HRP assay, a clear separation of the different fractions was observed with a signal at 77.4%, 60.3%, and 17.5% of the 6 DAR maximum absorbance with the 4b, 4a, and 2 MMAF/Ab purified fractions, respectively (Figure 4B, panel c). In the xMMAF/GxhF(ab′)$_2$-HRP assay, a separation of the different purified fractions was also observed (Figure 4B, panel d). Interestingly, the highest signal was observed with the 6 and 4b MMAF/Ab fractions while the signal for the 4a fraction was 62% lower than the one observed for the 6 MMAF/Ab fraction at 10 ng/mL. Finally, in this assay the 2 MMAF/Ab fraction also generated the lowest signal compared to the other fractions with higher DARs (Figure 4B, panel d).

To conclude, the signal generated in the CD22/xMMAF-Biotin assay was positively correlated to the anti-CD22-MC-MMAF drug load. Surprisingly, the xMMAF/GxhFc-HRP and xMMAF/GxhF(ab′)$_2$-HRP assays did not detect the ADC with 4 MMAF/Ab as efficiently as the 6 MMAF/Ab. None of the conjugated antibody assays tested efficiently detected the ADC with 2 MMAF/Ab.

DISCUSSION

As promising therapeutic candidates, the reliable determination of the pharmacokinetic profile of anti-CD22-MCC-DM1 and anti-CD22-MC-MMAF ADCs is a critical aspect of their preclinical evaluation and selection. In this study we investigated the impact of the assay format on PK parameters determination.

In mouse plasma, the two total antibody assay formats gave similar results although the CD22/GxhFc-HRP assay format measured consistently less ADCs than the RxhFc/GxhFc-HRP format. In contrast, very significant differences were observed when two conjugated antibody assay formats relying on either CD22-ECD or anti-drug antibody capture were used to quantify the ADCs. For both conjugates the CD22-ECD coat format resulted in a lower quantification of the conjugated antibody compared to the one achieved in the anti-drug antibody coat format. This difference prompted us to further investigate the impact of the assay format on ADCs quantification.

Using enriched mixtures of anti-CD22-MCC-DM1 with various DARs we demonstrated that increasing DM1 loads resulted in lower quantification of the antibody in total antibody assay formats relying on CD22-Biotin or GxhF(ab′)$_2$-HRP detection while the RxhFc/GxhFc-HRP assay was not affected. Because none of the total antibody assay formats involve the anti-DM1 antibody, this result came out as unexpected and strongly suggests that DM1 conjugation to the anti-CD22 antibody could interfere with the antigen binding ability of the antibody. This effect was observed for enriched mixtures with an average drug load as low as 1 DM1/Ab; however, considering the heterogeneity of this fraction we conclude that a conjugation ratio between 1 and 4 DM1/Ab would be sufficient to negatively

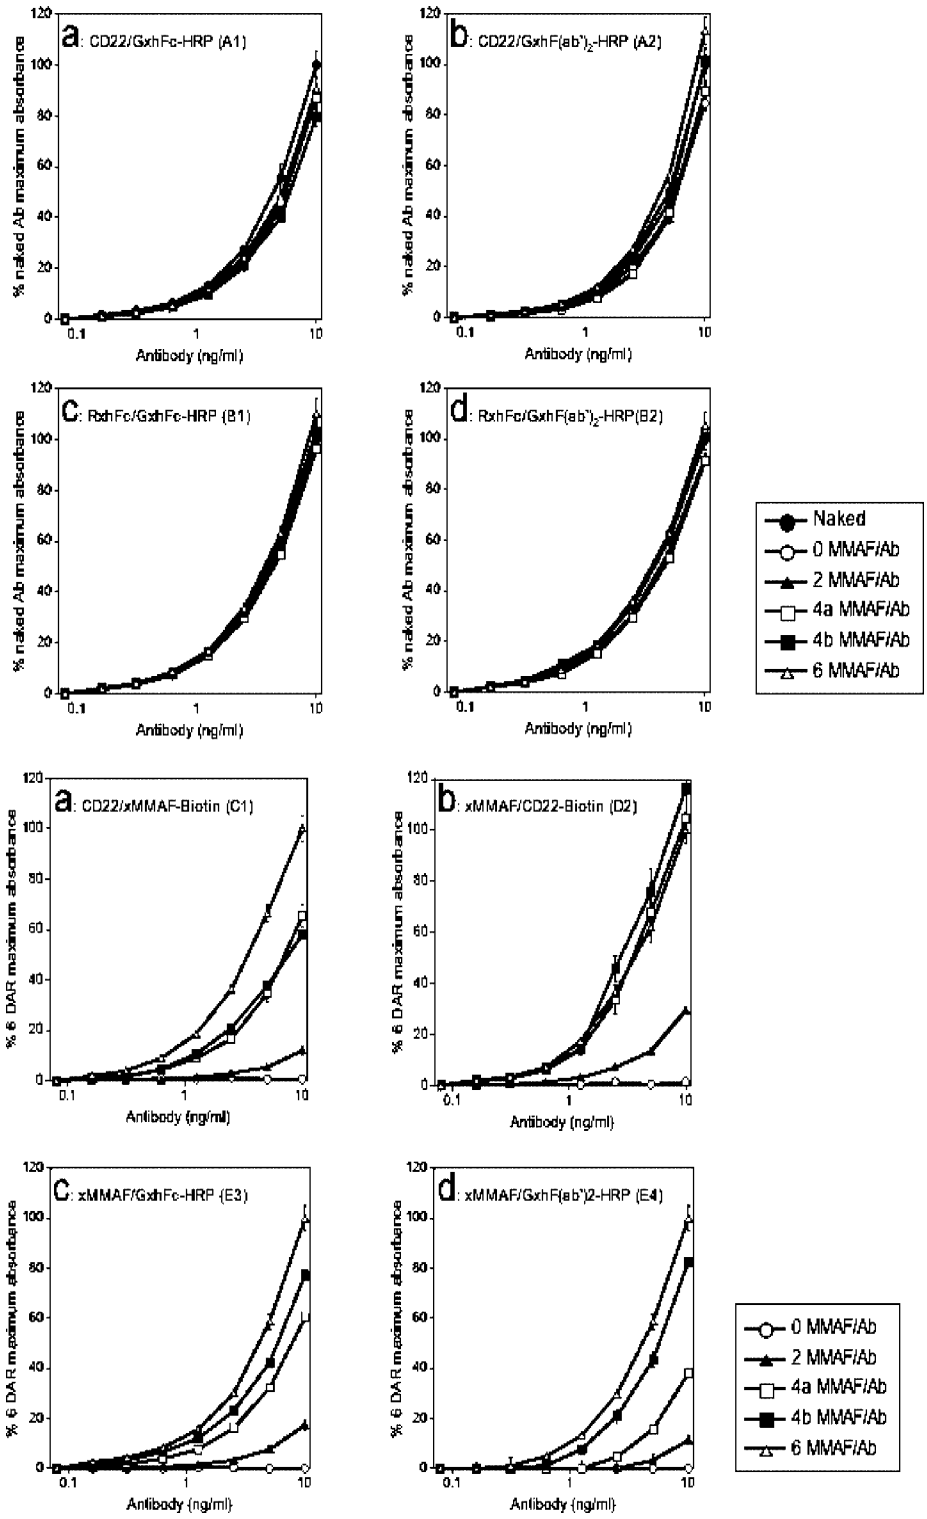

Figure 4. (A) Performances of anti-CD22-MC-MMAF HIC purified fractions in different total antibody assay formats. Unmodified anti-CD22 (●) and anti-CD22-MC-MMAF fractions with a drug load of 0 (○), 2 (▲), 4a (□), 4b (■), and 6 (Δ) MMAF per antibody were assayed using various total antibody assay formats: CD22/GxhFc-HRP (a), CD22/GxhF(ab′)$_2$-HRP (b), RxhFc/GxhFc-HRP (c), RxhFc/GxhF(ab′)$_2$-HRP (d). For the different anti-CD22-MC-MMAF fractions assayed from 0.16 to 10 ng/mL (1/2 serial dilution) plus blank, assay results were expressed as percentage of the maximum absorbance of naked antibody. (B) Performances of anti-CD22-MC-MMAF enriched fractions in different conjugated antibody assay formats. Anti-CD22-MC-MMAF fractions with a drug load of 0 (○), 2 (▲), 4a (□), 4b (■), and 6 (Δ) MMAF per antibody were assayed using various total antibody assay formats: CD22/xMMAF-Biotin (a), xMMAF/CD22-Biotin (b), xMMAF/GxhFc-HRP (c), xMMAF/GxhF(ab′)$_2$-HRP (d). For the different anti-CD22-MC-MMAF fractions assayed from 0.16 to 10 ng/mL (1/2 serial dilution) plus blank, assay results were expressed as percentage of the maximum absorbance of 6 MMAF/Ab fraction.

impact the binding of the antibody onto immobilized CD22. Based on this data, any accelerated clearance of the high DAR anti-CD22-MCC-DM1 fractions or progressive DM1 loss from these fractions would result in the CD22/GxhFc-HRP assay quantifying more than the RxhFc/GxhFc-HRP assay when using the 3.4 DAR anti-CD22-MCC-DM1 standard curve. Interestingly, this scenario does not correlate with the mouse PK data where the CD22/GxhFc-HRP assay measured consistently

slightly less total ADC than the RxhFc/GxhFc-HRP format, especially at later time points. Therefore, we hypothesized that changes in the high DAR anti-CD22-MCC-DM1 fractions would have a minor effect on the overall PK profile since these fractions represent a small percentage of the total ADC. However, changes that would result in a decrease of the anti-CD22 mAb carrying less than 3.4 DM1/Ab could affect the PK profile with the CD22/GxhFc-HRP assay quantifying less total ADC than the RxhFc/GxhFc-HRP assay when the 3.4 DAR anti-CD22-MCC-DM1 standard is use as observed in the mouse PK study.

In these conditions, our data raise the question about the best total assay format to implement to accurately evaluate the PK profile of the anti-CD22-MCC-DM1 conjugate. Although an assay format relying on antigen binding is preferred, it appeared that in this case, considering the heterogeneous nature of the anti-CD22-MCC-DM1 ADC, this type of assay could potentially introduce a bias in the total antibody quantification. Based on our data, the RxhFc/GxhFc-HRP assay format appears the most accurate in evaluating anti-CD22-MCC-DM1 pharmacokinetic profile in rodents. This total assay format was also chosen in the context of other DM1 ADCs such as Cantuzumab Mertansine (huC242-DM1), a conjugate that recognizes the tumor-selective carbohydrate epitope CanAg present on the membrane-associated mucin MUC1 (*5*). For monkey and human pharmacokinetic studies, background could interfere with the RxhFc/GxhFc-HRP assay, and therefore, the CD22/GxhFc-HRP assay format would be the best to implement although it could potentially underestimate the total circulating anti-CD22-MCC-DM1 especially at later time points.

For the conjugated antibody assays, the CD22/xDM1-Biotin assay was the only format where the signal was dependent on the drug load. This result was expected since detection of the immobilized anti-CD22-MCC-DM1 is achieved through the anti-DM1 antibody and therefore the assay signal was anticipated to be positively correlated to drug load. The other assay formats relying on the immobilized anti-DM1 antibody, assay signal was not expected to be dependent on the drug load since 1 DM1/Ab was supposed to be sufficient to optimally capture the ADC. However, in the xDM1/ GxhF(ab′)$_2$-HRP assay the signal slightly dropped for the highest DARs. This result suggests that high DM1 load could result in some modification of the anti-CD22-MCC-DM1 FAb region that impairs the GxhF(ab′)$_2$-HRP binding to the ADC captured onto the assay plate and could correlate with the total assay results suggesting that DM1 conjugation negatively impacts the binding of the antibody to the immobilized CD22. CD22/xDM1-Biotin assay would have the advantage of being able to monitor the relative circulating conjugated DM1. However, it could potentially introduce a bias in the conjugated antibody quantification, since the heterogeneous nature of the conjugate might change *in vivo* compared to the standard material. The observation that the profile generated from the xDM1/CD22-Biotin assay format separates from the total antibody profiles after 20 days indeed suggests that DM1 could be lost from the ADC, thus increasing over time the ADC fraction with 0 drug per antibody. Therefore, the xDM1/CD22-Biotin assay appears to be the format of choice to accurately quantify the anti-CD22-MCC-DM1 conjugate in circulation. A similar conjugate assay format with anti-DM1 antibody coat was also implemented by Xie et al. (*5*) to measure Cantuzumab Mertansine (huC242-DM1) in mouse plasma. In conclusion, the RxhFc/GxhFc-HRP and the xDM1/CD22-Biotin appeared to be the best assay formats to quantify the total and conjugated antibody in plasma, respectively, and interestingly these two assay formats provided similar pharmacokinetic profiles in mouse up to 20 days postinjection, suggesting that the anti-CD22-MCC-DM1 ADC defined as the antibody carrying at least one DM1 drug is relatively stable in mouse circulation at the doses studied.

Fractions of anti-CD22-MC-MMAF with 0, 2, 4, and 6 MMAF/Ab were purified using hydrophobic interaction chromatography and subsequently characterized by reverse phase chromatography. These fractions were used to investigate the impact of the MMAF load and position on the ADC quantification. Interestingly, the MMAF load on the anti-CD22 antibody did not have any major impact on the antibody quantification in any of the total antibody assay formats tested, most likely because the drug is coupled via interchain cysteines and so by definition is not near the antigen binding site. Therefore, the CD22/GxhFc-HRP assay format would be the preferred total antibody assay format to evaluate anti-CD22-MC-MMAF pharmacokinetic profiles in human, monkey, and rodent serum or plasma. This assay format relying on a specific antibody capture and an HRP-labeled anti-human IgG Ab detection was also implemented for other auristatin antibody-drug conjugates such as cAC10-Val-Cit-MMAE, an anti-CD30 MMAE conjugate, for which an anti-idiotype cAC10 monoclonal antibody was used to specifically capture the total ADC (*27*).

As expected with the conjugated antibody assay CD22/xMMAF-Biotin, the signal was positively correlated to the MMAF load. Surprisingly, similar results were observed with all other conjugated assay formats relying on immobilized anti-MMAF antibody, with a dramatic decrease in signal for the anti-CD22-MC-MMAF fraction with a DAR of 2. In addition, the position of the drug on the anti-CD22-MC-MMAF ADC affected the performance of the xMMAF/GxhF(ab′)$_2$-HRP assay suggesting that the binding of the GxhF(ab′)$_2$ antibody is clearly affected by the presence of the MMAF in the Fab region (fraction 4a), but less in the hinge region (fraction 4b). This suggests some perturbation of the antibody structure that affect more the GxhF(ab′)-HRP binding than the GxhFc-HRP binding. Our data also suggest that the anti-MMAF antibody used in our assay strongly relies on an avidity effect to capture the anti-CD22-MC-MMAF ADC. In this context, the difference between the mouse pharmacokinetic profiles generated with CD22/xMMAF-Biotin and xMMAF/CD22-Biotin assay formats was most probably due to different abilities to detect the 4 and in lesser extent the 2 MMAF/Ab fractions. Regardless of the ADC clearance mechanism, the different conjugated antibody assays described here will underestimate any increase in the proportion of circulating anti-CD22-MC-MMAF with 2 drug/Ab potentially compromising the accurate determination of the ADC PK profile and the subsequent calculation of critical PK parameters. Considering our results, either CD22/xMMAF-Biotin and xMMAF/CD22-Biotin assays could be implemented, but considering the limitations mentioned above, neither of these two assay formats will be entirely satisfying without the implementation of a conjugated MMAF assay in order to precisely determine the amount of drug associated with the circulating anti-CD22-MC-MMAF. Others implemented this strategy such as Sanderson et al. (*4*) who used a conjugated antibody assay relying on the anti-auristatin antibody to detect cAC10-Val-Cit-MMAE. Similar to our results with the CD22/anti-drug assay format, a significant reduction in assay signal was observed for the 2 DAR cAC10-Val-Cit-MMAE ADC compared to the 4 DAR, although these two fractions quantified similarly in their total assay. Interestingly, this group also determined the amount of conjugated MMAE associated with cAC10-Val-Cit-MMAE ADC using a free MMAE competition ELISA after treatment of the samples with cathepsin B (*4*).

The work presented here suggests that different total and conjugate assay formats could provide significantly different ADC PK profiles and subsequently results in the calculation of different PK parameters. Using anti-CD22-MCC-DM1 enriched

mixtures and anti-CD22-MC-MMAF purified fractions, our investigations allowed us to better understand the impact of the assay formats on the determination of the ADC PK profile and to highlight the advantages and disadvantages of various total and conjugate assay formats. The understanding of the behavior of these various assays with regard to the ADC drug load will be critical to interpret future studies geared toward the understanding of anti-CD22-MCC-DM1 and anti-CD22-MC-MMAF ADCs clearance mechanism.

ACKNOWLEDGMENT

We thank Ruth Moser and Dr. Damon Meyer (Seattle Genetics, Inc., Bothell, WA, USA) for providing us with the anti-CD22-MC-MMAF; Xingye C. Lei for her statistical analysis of the PK data; and Dr. Laura DeForge, Dr. Suzie Scales, and Dr. Lino Gonzalez for their useful comments on the manuscript.

Annexin V is useful in detecting apoptotic cells by binding to phosphatidylserine (PS) that is exposed on the outer surface of the cell membrane during apoptosis. In this study, we examined the labeling of annexin V-128, a mutated form of annexin V that has a single cysteine residue at the NH_2 terminus, with the thiol-selective reagent ^{18}F-labeling agent N-[4-[(4-[^{18}F]fluorobenzylidene)aminooxy]butyl]maleimide ([^{18}F]FBABM). We also examined the cell binding affinity of the ^{18}F-labeled annexin V-128 ([^{18}F]FAN-128). [^{18}F]FBABM was synthesized in two-step, one-pot method modified from literature procedure. (Toyokuni et al., *Bioconjugate Chem*. **2003**, *14*, 1253−1259). The average yield of [^{18}F]FBABM was 23 ± 4% (n = 4, decay-corrected) and the specific activity was ~6000 Ci/mmol. The total synthesis time was ~92 min. The critical improvement of this study was identifying and then developing a purification method to remove an impurity *N*-[4-[(4-dimethylaminobenzylidene)aminooxy]butyl]maleimide **4**, whose presence dramatically decreased the yield of protein labeling. Conjugation of [^{18}F]FBABM with the thiol-containing annexin V-128 gave [^{18}F]FAN-128 in 37 ± 9% yield (n = 4, decay corrected). Erythrocyte binding assay of [^{18}F]FAN-128 showed that this modification of annexin V-128 did not compromise its membrane binding affinity. Thus, an *in vivo* investigation of [^{18}F]FAN-128 as an apoptosis imaging agent is warranted.

INTRODUCTION

Apoptosis, or programmed cell death, is an essential component for embryogenesis and homeostasis. Dysregulation of apoptosis is associated with many diseases such as cancer, autoimmunity, and neurodegenerative disorders (*1*). Many anticancer therapies exert their therapeutic effects by inducing apoptosis in tumor cells. A suitable *in vivo* marker for noninvasive imaging of apoptosis would be useful for both clinical care and drug development.

One of the early characteristics of apoptosis is the externalization of phosphatidylserine (PS) molecules on cell membranes, which promotes recognition and phagocytic removal (*2, 3*). In culture, once apoptosis is triggered, the PS externalization begins to occur within one hour (*2*). Annexin V, a 36 kDa endogenous cytoplasmic protein, binds with high affinity (K_d ~10 nM) to membrane-bound PS in a Ca^{2+}-dependent manner (*4*). Annexin V staining has been a standard practice for the assessment of apoptosis *in vitro* for the past decade. More recently, radiolabeled annexin V has been actively investigated to image cell death (*5–8*). ^{99m}Tc-labeled annexin V showed promising results in early clinical SPECT studies (*9–11*), but its low sensitivity has limited its broader application. To take advantage of the higher resolution and more accurate quantification of PET, labeling annexin V with short half-life positron-emitters such as ^{18}F is of particular interest.

We (*12*) and others (*13, 14*) have reported the labeling of wild-type annexin V with *N*-succinimidyl-4-^{18}F-fluorobenzoate ([^{18}F]SFB). We have also demonstrated that the ^{18}F-labeled annexin V ([^{18}F]fluoroannexin or [^{18}F]FAN) showed increased uptake in rat liver proportional to apoptosis after apoptosis was chemically induced (*15*). The rapid blood clearance and urinary excretion of [^{18}F]FAN suggest its potential as a PET imaging agent. This radiotracer, however, has its own disadvantages. The predominant renal clearance increases the radiation burden to the kidneys and bladder, and a patient would have to be catheterized if the diagnostic area of interest were in the abdomen (*15*). Moreover, this labeling method for annexin V is nonspecific, as the reaction is between the prosthetic group ([^{18}F]SFB) and any available NH_2 groups in this protein. There are at least 23 potential sites for this reaction to occur in each annexin V molecule, some near the active binding site of the protein. A recent report confirms that amine-directed chemical modification of annexin V reduces its membrane-binding activity even at low stoichiometries (*16*). Multiple substitutions of annexin V with [^{18}F]SFB could mean disproportional signaling by low-affinity molecules in PET imaging. Therefore, a site-specific method to label annexin V with only one substitution per molecule should have an advantage over the [^{18}F]SFB-modified version.

An alternative strategy to label proteins involves targeting the free thiol groups that are present only in cysteine residues. Thiol reactive agents such as N-substituted maleimides and iodoacetamide can be used to modify proteins at cysteines at specific sites (*17–20*). Annexin V-128 is a mutated form of annexin V containing only one cysteine. The initiator Met at position one is deleted and a six amino acid extension containing one cysteine is added at the N-terminus. The N-terminus does not play a role in the binding activity of annexin V and so this modification does not change the binding affinity of annexin V-128 for PS. Site-specific labeled (with ^{99m}Tc) annexin V-128 derivatives showed twice as much *in vivo* apoptosis-specific uptake in rat liver models as did amine-derivatized forms of annexin V (*16*). A previous approach to label thiol-containing molecules with *N*-[4-[(4-[^{18}F]fluorobenzylidene)aminooxy]butyl]maleimide ([^{18}F]FBABM) used a two-step/two-pot synthesis that was labor intensive and gave low yield with larger biomolecules such as 5′-S-ODN (*21*). In this paper, we report an improved synthesis and efficient purification of [^{18}F]FBABM,

and the production of [^{18}F]annexin V-128 ([^{18}F]FAN-128) with this thiol-reactive reagent. The PS binding affinity of [^{18}F]FAN-128 and its potential as a PET imaging agent for cell death are also discussed.

MATERIALS AND METHODS

General. All reagents and solvents were purchased from Aldrich Chemical Co. (Milwaukee, WI) as reagent grade and were used without purification unless otherwise noted. The labeling precursor, 4-trimethylammoniumbenzaldehyde triflate **1**, was prepared as described by Haka et al. (*24*) and stored in a sealed vial over desiccant in the refrigerator. The coupling precursor, *N*-[4-(aminooxy)butyl]maleimide **3**, as a HCl salt was synthesized according to Toyokuni et al. (*21*) with modifications and stored over desiccant in the refrigerator. Enriched (97%) [^{18}O]water was obtained from Medical Isotopes, Inc. (Pelham, NH). Chromafix 30-PS-HCO_3 ^{18}F separation cartridges were obtained from GE Medical Systems and C-18 SepPak (light) cartridges were obtained from Waters Corp. (Milford, MA). The first part of the radiosynthesis (the production of the radioprecursor [^{18}F]FBABM) was performed using a GE Tracerlab FX_{FN} automatic synthesis module. The second part of the radiosynthesis (the radio-labeling of annexin V-128) was done manually outside the GE box. ^{1}H NMR data were obtained with a Varian 300 MHz NMR instrument. Quality control of the purified radioactive product was performed on a Waters 2690 HPLC module coupled with an in-line Micromass ZMD mass spectrometer.

Preparation of Annexin V-128. Annexin V-128 (~2 mg/mL in 20 mM HEPES sodium, 100 mM NaCl, pH 7.4) was prepared and purified as described (*26*). The protein was reduced with 1 mM dithiothreitol (DTT) for 15 min at 37 °C and then applied to a Sephadex G-25 column equilibrated with deoxygenated buffer (20 mM HEPES-sodium, 100 mM NaCl, pH 7.4) to remove the reductant. Protein concentration was measured by absorbance at 280 nm and the reduced protein was used for labeling within 6 h.

Synthesis of *N*-[4-[(4-Dimethylaminobenzylidene)aminooxy]butyl]maleimide 4. A solution of 4-dimethylaminobenzaldehyde (17 mg, 0.1 mmol) and **3**·HCl (20 mg, 0.09 mmol) in anhydrous DMF (1 mL) was stirred at r.t. for 16 h. The reaction mixture was then poured into water and extracted with diethyl ether. After drying over anhydrous Na_2SO_4, the ether solution was decanted, concentrated under reduced pressure, and then loaded onto a silica TLC plate (Alltech Silica Gel 60 F_{254} 5 × 20 cm). The TLC plate was developed with 40% diethyl ether in hexanes (v:v) and the product (R_f ~ 0.34) was washed off with ether as a yellowish solid (14 mg, 0.05 mmol, 50%). mp 51 °C. ^{1}H NMR ($CDCl_3$, 300 MHz) δ 1.65−1.75 (m, 4H), 2.99 (s, 6H), 3.57 (t, J = 6.0 Hz, 2H), 4.12 (t, J = 6.0 Hz, 2H), 6.66 (d, J = 9.0 Hz, 2H), 6.67 (s, 2H), 7.43 (d, J = 9.0 Hz), 7.97 (s, 1H). MS (ESI+): 316 $[M+H]^+$ HRMS (ESI+): $[M+Na]^+$ Calc. 338.1475; Found: 338.1481.

Synthesis of FBABM. A solution of 4-fluorobenzaldehyde (31 μL, 0.29 mmol) and **3**•HCl (41 mg, 0.18 mmol) in DMF (2 mL) was stirred at r.t. for 30 min. The reaction mixture was then poured into water and extracted with diethyl ether. After drying over anhydrous Na_2SO_4, the ether solution was decanted and concentrated under reduced pressure, and then loaded onto a silica flash chromatography column and eluted with 40% diethyl ether in hexanes (v:v) to give FBABM (50 mg, 0.17 mmol, 91%) as a white solid. mp 81 °C.(Lit. (*21*) 79−81 °C) ^{1}H NMR (CD_3OD, 300 MHz) δ 1.55−1.70 (m, 4H), 3.49 (t, J = 6.0 Hz, 2H), 4.09 (t, J = 6.0 Hz, 2H), 6.74 (s, 2H), 7.07 (dd, J = 9.0 Hz, 9.0 Hz, 2H), 7.57 (dd, J = 9.0 Hz, 6.0 Hz, 2H), 8.03 (s, 1H). MS (ESI+): 291 $[M+H]^+$.

Radiosynthesis of [^{18}F]FBABM. Cyclotron-produced [^{18}F]fluoride in $H_2{}^{18}O$ was forced through a Chromafix ^{18}F separation cartridge with helium pressure using a GE Tracerlab FX_{FN} automated synthesis unit. The concentrated $^{18}F^-$ on the cartridge was then eluted with 1.4 mg K_2CO_3 in 0.5 mL 1:1 (v:v) acetonitrile/water solution into the reaction vessel of the FX_{FN} box. A solution of 7.5 mg Kryptofix[2,2,2] in 2 mL anhydrous acetonitrile was then added to the same reaction vessel and the whole mixture was azeotropically evaporated to dryness under heat and reduced pressure. A solution of 4−5 mg 4-trimethylammoniumbenzaldehyde triflate **1** in 1 mL anhydrous acetonitrile was then pushed into the reactor, pressurized (~200 mbar), and heated at 100 °C. After 15 min, the reaction vessel was cooled to r.t. before 8−9 mg **3** in 1.5 mL methanol was added. After stirring at r.t. for 15 min, the mixture was slowly evaporated to <0.5 mL with heat (50 °C) under vacuum. After cooling to r.t., 1.5 mL of 45% ethanol in water (v:v) was added to the reaction vessel and the whole mixture was transferred to the HPLC loop. Semipreparative HPLC was performed with a C18 column (Phenomenex Prodigy ODS(3), 5 μm, 250 × 10 mm) eluted with 45% ethanol/water (v:v) at 3 mL/min and 50 °C. The chemically and radiochemically (>99%) pure fraction containing [^{18}F]FBABM was collected (~12 mL; t_R ~ 38−40 min). The chemical and radiochemical purity was assessed with a C18 analytical HPLC column (Phenomenex Inertisil ODS-3, 100 × 2.1 mm, 5 μm, eluted with 55% methanol/water (v:v) at 0.3 mL/min flow rate and 40 °C with in-line mass detection.

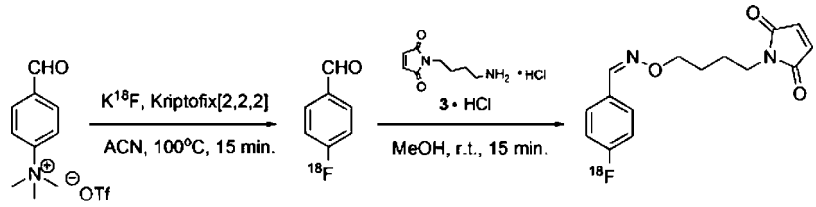
Labeling of Annexin V-128 with [^{18}F]FBABM. Purified [^{18}F]FBABM from the previous step (~12 mL) was diluted with water (~50 mL) and passed through a Waters C18 SepPak that had been preconditioned with 5 mL ethanol and 5 mL water. The SepPak was washed with additional 10 mL water and the excess water was expelled with a push of air. 2 mL of ether was then pushed through the SepPak to elute the product into a clean 5 mL glass test tube. The ether phase of the biphase mixture was drawn out and transferred into a clean 5 mL BD Vacutainer test tube. The ether was then removed by evaporation under a gentle flow of argon at 50 °C. After cooling to r.t., approximately 0.7 mg freshly prepared annexin V-128 in 0.5 mL buffer (20 mM HEPES, 100 mM NaCl, pH 7.4) was carefully added to the residual film and incubated for 15 min with periodic gentle agitation. Labeled [^{18}F]fluoroannexin V-128 ([^{18}F]FAN-128) was isolated by a semipreparative size-exclusion column (BioSep SEC-S 2000, 300 × 7.8 mm) eluted at 1 mL/min with 10 mM phosphate/150 mM NaCl (pH = 7). [^{18}F]FAN-128 was the first radioactive peak eluted from the column with a retention time of ~7−9 min.

Cell-Binding Assay of [^{18}F]FAN-128. The membrane binding affinity of [^{18}F]FAN-128 was determined following the procedure described by Tait et al. (*22, 16*) Briefly, mixtures of red blood cells (RBCs) with exposed PS on the outer surface of the cell membrane (Coulter "4C Plus" Cell Control, Fullerton, CA), [^{18}F]FAN-128 (diluted to a final concentration of 1 nM) in buffer (100 mM NaCl, 50 mM Hepes-Na, pH 7.4, 0.02% NaN_3, 1 mg/ml BSA) and $CaCl_2$ at precise concentrations (between 0 and 3 mM) were prepared. The mixtures were incubated for 10 min. at r.t. After centrifugation, the supernatant was discarded. Then the RBCs with bound [^{18}F]FAN-128 were washed with the same buffer containing $CaCl_2$ at the same concentrations and recentrifuged and the supernatant was discarded. Membrane-bound [^{18}F]FAN-128 was then released with assay buffer containing 5 mM EDTA and counted in the gamma counter.

RESULT AND DISCUSSION

Chemistry. Our synthesis of [^{18}F]FBABM builds on the approach reported by Toyokuni et al. (*21*) (Scheme 1). Briefly, triflate **1** was heated with dried [^{18}F]KF in anhydrous acetonitrile in the presence of Kryptofix[2,2,2] to generate [^{18}F]FBA **2**,

Scheme 1. Synthesis of [^{18}F]FBABM



1 **2** **[^{18}F]FBABM**

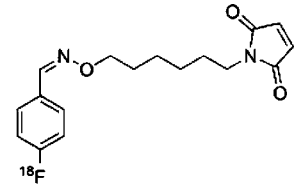
Table 1. Yield of FBA (2) under Different Reaction Conditions[a]

solvent	amt. of precursor **1** (mg)	temperature (°C)	yield (%)[c]
DMSO	8	100	90
THF	4	80[b]	0
CH_3CN	2	100[b]	10
CH_3CN	3	100[b]	20
CH_3CN	4	100[b]	75
CH_3CN	8	100[b]	90

[a] All reactions were carried out by heating the precursor in 1 mL solvent for 15 min in a closed reaction vessel in a GE Tracerlab FX_{FN} automated synthesis module. [b] Heated under helium pressure (200 mbar). [c] Determined from radio-HPLC chromatograms of the crude product. Data represent an average of 3 runs.

followed by the addition of maleimide **3** in methanol and purification by HPLC. Their two-step/two-pot synthesis of [^{18}F]FBABM was used to label the thiol-containing tripeptide glutathione (GSH) and a 5′-thiol-functionalized oligodeoxynucleotide (5′-S-ODN). This synthesis started with the generation of **2** followed by a C18 SepPak purification. After coupling to the heterobifunctional linker *N*-[4-(aminoxy)butyl]maleimide **3** using the oxime O-ether formation reaction and HPLC purification, [^{18}F]FBABM was formulated in acetonitrile and successfully labeled GSH or 5′-S-ODN. This method, however, has disadvantages for routine protein labeling. First, the synthesis of [^{18}F]FBABM was labor-intensive, with a two-pot setup and a C18 SepPak purification step in between. Second, although the labeling of GSH gave good yield (70% decay corrected), the yield in labeling larger biomolecules such as 5′-S-ODN (5% decay corrected) was low. The concentrations of the GSH or the 5′-S-ODN in these reactions were 6 mM and 0.1 mM, respectively. The radiochemical yield of radiolabeled peptides/proteins or other biomolecules via prosthetic groups typically decreases as the concentration of the biomolecule decreases. For an even larger molecule such as annexin V-128, which is usually obtained in ~30 μM concentration, the radiochemical yield might be even lower than 5%. Indeed, our initial attempts to label annexin V-128 with [^{18}F]FBABM synthesized by closely following the literature procedure (*12*) gave no yield. In addition to the slow rate of reaction associated with dilute conditions, the presence of nonradioactive maleimide-containing impurities, which would compete with [^{18}F]FBABM for the available thiol groups, could be an important factor that results in the dramatic decrease in yield. In the Toyokuni report, there was little information on the chemical purity of the [^{18}F]FBABM produced. We focused our investigation on simplification of the radiosynthesis and purification of the [^{18}F]FBABM.

We found that the C18 SepPak purification was not required for [^{18}F]FBABM synthesis; the two-step reactions proceed smoothly in one pot. Starting with ~850 mCi [^{18}F]fluoride, 110 ± 14 mCi (n = 4) of purified [^{18}F]FBABM was obtained in ~92 min (23 ± 4% decay corrected radiochemical yield) with >99% radiochemical purity and a specific activity of ~6000 Ci/mmol. This yield is comparable to that from the two-pot procedure (*21*), but with a process that can be automated. Although theoretically, [^{18}F]FBABM could be formed as both *E*- and *Z*-isomers, we observed only one isomer (tentatively assigned to possess the *E*-configuration) (*21*) under our reaction condition. This was confirmed by coeluting with the cold standard of FBABM, whose NMR spectrum revealed only one isomer, on HPLC. During the preparation of this manuscript, Berndt et al. reported a one-pot method to prepare a similar thiol-reactive labeling agent *N*-[6-(4-[^{18}F]fluorobenzylidene)-aminooxyhexyl]maleimide ([^{18}F]FBAM) with similar yield to ours (*23*). Their method, however, includes an extra prepurification step using solid-phase extraction on LiChrolut RP18 cartridge before semipreparative HPLC purification.

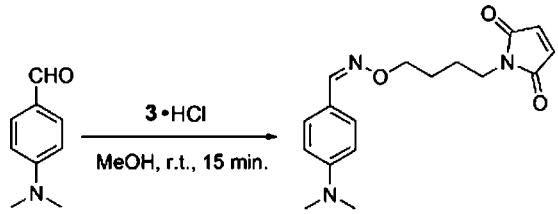


[^{18}F]FBAM

The synthesis of [^{18}F]FBA **2** from the triflate precursor **1** was traditionally carried out by heating the dried [^{18}F]KF/Kryptofix[2,2,2] in a high-boiling polar aprotic solvent such as DMSO (*24, 25*). We chose the lower boiling acetonitrile because it could be easily removed by evaporation. Compared with DMSO, the use of acetonitrile did not compromise the yield of [^{18}F]FBA (Table 1). Similar yields were obtained while the same amounts of precursors were used. A smaller amount of precursors resulted in decreased yields of **2**. Using 4 mg triflate precursor struck a balance between reasonably high yield and acceptably lower quantity of material introduced into the system. Compared to the Toyokuni report (*21*), the yield of the coupling reaction dropped from ~70% to ~40% (calculated from the yield of the first step and the overall yield), but the advantage of easier production of this radiotracer outweighed this reduction of yield. It is important to note that, because FBA is a volatile compound at elevated temperature, it is crucial to cool the reaction mixture to r.t. before opening the reaction vessel to add the coupling precursor.

The critical factor for optimal protein labeling with [^{18}F]FBABM is the chemical purity of the product. We suspected that a maleimide side product was present that would compete with [^{18}F]FBABM for reaction with thiol groups. HPLC-MS was used to identify this major contaminant as *N*-[4-[(4-dimethylaminobenzylidene)aminooxy]butyl]maleimide (**4**) (estimated >100 μg from a typical run described above) derived from the 4-dimethylaminobenzaldehyde formed inevitably during the initial nucleophilic fluorination step (Scheme 2). In a typical run, about 300 μg 4-dimethylaminobenzaldehyde was detected after this first step. The identity and quantity was determined by HPLC-MS analysis, in comparison to an authentic sample. Our initial attempt to label annexin V-128 with [^{18}F]FBABM containing **4** gave no yield, presumably due to a competition for the single thiol group by the vast molar excess of the alternative maleimide contaminant **4**. In a typical labeling reaction, the molar ratio of FBABM to annexin V-128 (generally 0.6 mg was used)

Scheme 2. Formation of 4



4

was approximately 1:1, whereas that of **4** was greater than 20:1. Attempts to remove the undesired 4-dimethylaminobenzaldehyde after the first step with a C18 SepPak were unsuccessful. The removal of **4** from the final product [^{18}F]FBABM proved to be challenging. The calculated log *P* values for FBABM and **4** are 1.91 and 1.85, respectively (Molinspiration program: http://www.molinspiration.com/cgi-bin/properties). The two compounds coeluted using the HPLC method from the literature (*21*). We developed a useful separation by using Phenomenex Prodigy ODS(3) 5 μm 250 × 10 mm column. At 50 °C and 45% ethanol/water as the eluent at 3 mL/min, **4** was completely removed from [^{18}F]FBABM (impurity t_R(**4**) ∼ 26−28 min, t_R(FBABM) ∼ 34−38 min). A typical semipreparative HPLC chromatogram is shown in Figure 1. No detectable amount of **4** was present in the purified [^{18}F]FBABM product. We realize that, in this isocratic HPLC method, although a complete separation of impurity **4** was achieved, the long retention time of the [^{18}F]FBABM is disadvantageous for routine production. We are currently investigating alternative purification method with gradient HPLC.

Annexin V-128 (*26*) contains one cysteine in its N-terminus. The single naturally occurring cysteine residue in its interior domain has been mutated to a serine in order to eliminate the possibility of modification by thiol-reactive prosthetic conjugating agents. Annexin V-128 is freshly reduced immediately prior to each labeling study with DTT to ensure that the free thiol is fully accessible. The protein is purified of excess DTT by eluting through a Sephadex column.

The purified [^{18}F]FBABM was concentrated onto a C18 SepPak, washed off with diethyl ether, and taken to dryness. After evaporation, the [^{18}F]FBABM was incubated with annexin V-128 in HEPES buffer (pH = 7.4, 0.5 mL). It is noted that the number of liquid transfers and the contact surface area with the reaction vessel should be minimized to reduce unnecessary loss of annexin V-128 due to surface adsorption of the protein. Even using a careful transfer technique, approximately 1/3 of the total radioactivity is typically lost in transfers for injection onto the size-exclusion column (SEC). After HPLC purification, radiochemically pure

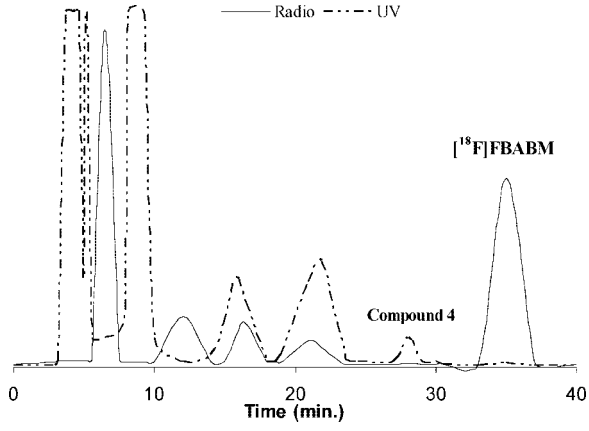


Figure 1. A typical semipreparative HPLC chromatogram for [^{18}F]FBABM purification. (Phenomenex Prodigy ODS-3, 250 × 10 mm, 5 μm, eluted with 45% ethanol/water v:v at 3 mL/min and 50 °C).

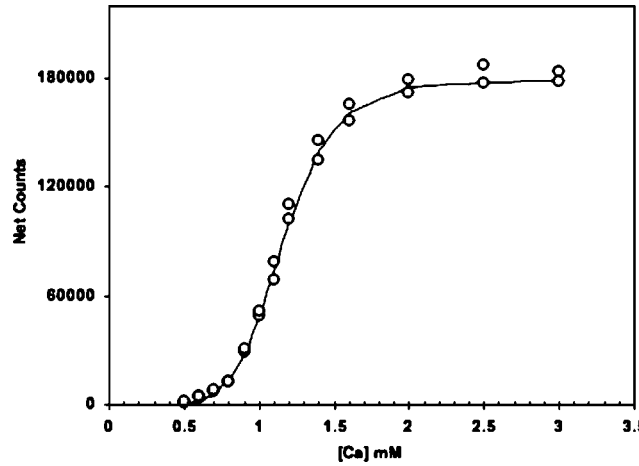

Figure 2. Typical binding curve of [^{18}F]FAN-128 to PS-enriched membranes. Typical binding curve of [^{18}F]FAN-128 as a factor of calcium concentration. [^{18}F]FAN-128 is held constant well below its K_d (at 1 nM), while calcium is titrated between 0 and 3 mM (maximal binding is observed at 2−2.5 mM Ca^{2+}). The membrane-bound radioactivity is plotted versus the concentration of Ca^{2+} present. p*K* value is calculated from slope (N) and midpoint of titration curve (EC_{50}) (*16*). Two measurements are done for each data point.

(>98%) [^{18}F]FAN-128 was obtained with 37 ± 9% yield (n = 4, decay-corrected) from [^{18}F]FBABM. The total recovery of radioactivity from the SEC was >90% with the radioactive peak at 7−9 min being [^{18}F]FAN-128. The unreacted [^{18}F]FBABM was retained for >1 h on the SEC column.

As a negative control, we repeated the reaction under the same condition using wild-type annexin V instead of mutated annexin V-128. Wild-type annexin V has one internal cysteine but it does not have a free thiol group on its N-terminus. In this reaction, the yield of ^{18}F-labeled protein was negligible (<0.2%). This result shows that, under our reaction conditions, [^{18}F]FBABM does not react with other nucleophiles such as the free NH_2 groups in annexin V, and the single cysteine residue that is present in the interior domain of wild-type annexin V is not readily accessible for maleimide binding. Therefore, we are able to conclude that the [^{18}F]FBABM labeling of annexin V-128 is site-specific. The mutation of Cys-316 to Ser in annexin V-128 may not be necessary for future annexin V based tracer design.

[^{18}F]FAN-128 PS Binding Assay. The *in vitro* membrane-binding affinity of [^{18}F]FAN-128 was determined by erythrocyte binding using the method reported by Tait et al. (*16*) The commercially available RBCs had exposed PS on their outer surfaces of the cell membranes because of the preservatives used (*27*). Annexin binding to PS is calcium dependent. By titrating calcium instead of protein, this method allows an accurate measurement of annexin binding at <1% occupancy, a value similar to that for *in vivo* imaging where the membrane is far from saturated with protein. A typical binding curve for [^{18}F]FAN-128 is presented in Figure 2. The binding affinity was measured by determining EC_{50} and slope from this experimental titration curve (*22*). The negative log of the binding constant, p*K*, is equal to $-(n \log_{10}EC_{50} + \log_{10}[\text{membrane}])$, where n is the number of Ca^{2+} ions interacting with each annexin V molecule, the EC_{50} is the molarity of Ca^{2+} at which cell binding is half of the maximal value, and [membrane] is the concentration of annexin V-binding sites in the assay (*16*). Seven batches of [^{18}F]FAN-128 gave an average p*K* of 28.5 ± 1.8, an EC_{50} of approximately 1 mM, and a slope (Hill coefficient) between 7 and 8. This compares favorably with reported values for wild-type annexin V of a p*K* around 30, EC_{50} close to 1, and a slope of 8 (*26*, *16*). These data indicate that the *in vitro* binding activity

of this site-specific, monosubstituted protein was not significantly different from that of the wild-type and an *in vivo* investigation of [^{18}F]FAN-128 as an apoptosis imaging agent is warranted.

CONCLUSION

We have developed an improved, one-pot synthesis of the thiol-reactive labeling reagent [^{18}F]FBABM. It gives satisfactory radiochemical yield and can be automated for routine production. The critical improvement was identifying and then developing a purification method to remove the impurity *N*-[4-[(4-dimethylaminobenzylidene)aminooxy]butyl]maleimide (**4**). The presence of this impurity in [^{18}F]FBABM was dramatically decreasing the yield of labeled protein by competing for the available thiol groups. To our knowledge, this is the first time that this important issue has been addressed. We have also achieved an efficient synthesis of ^{18}F-labeled annexin V-128 ([^{18}F]FAN-128), a 36 kDa protein containing a single thiol group, with the [^{18}F]FBABM radioprecursor. This maleimide modification of annexin V-128 does not compromise its membrane binding affinity.

ACKNOWLEDGMENT

Financial support was provided by NIH CA042045 for this study. We thank Robert Murano and Steve Shoner for radionuclide production.

"Click-to-Chelate": In Vitro and In Vivo Comparison of a $^{99m}Tc(CO)_3$-Labeled N(τ)-Histidine Folate Derivative with Its Isostructural, Clicked 1,2,3-Triazole Analogue

Thomas L. Mindt,[†] Cristina Müller,[‡] Marleen Melis,[§] Marion de Jong,[§] and Roger Schibli*[,†]

Department of Chemistry and Applied Biosciences, ETH Zurich, 8093 Zurich, Switzerland, Center for Radiopharmaceutical Science, ETH-PSI-USZ, Paul Scherrer Institute, 5232 Villigen-PSI, Switzerland, and Department of Nuclear Medicine, Erasmus Medical Center, 3015 CE Rotterdam, The Netherlands. Received May 7, 2008; Revised Manuscript Received June 26, 2008

A side-by-side comparison of the synthesis, radiolabeling, and in vitro and in vivo characterization of two new and isostructural ^{99m}Tc-tricarbonyl folic acid radiotracers comprising either a N(τ)-functionalized histidine (His) chelator or a 1,4-bifunctionalized 1,2,3-triazole His analogue is described. The 1,2,3-triazole-containing folic acid derivative was synthesized in approximately 80% yield by a short reaction sequence including application of click chemistry (the Cu(I)-catalyzed cycloaddition of azides and terminal alkynes). The synthesis of the ligand system and the functionalization of the folic acid derivative were accomplished simultaneously, which prompted us to call this approach "click-to-chelate". In comparison, the reported regioselective synthesis of the N(τ)-His compound provided the final product in only very low yields (<1%). While the efficiency of the syntheses differs considerably, the two isostructural folate derivatives exhibit virtually identical properties with respect to Tc-99m radiolabeling and in vitro and in vivo characteristics as shown by experiments performed with FR-positive KB cells and xenografted mice bearing folate receptor overexpressing tumors. We have demonstrated herein for the first time that a ligand system known to be an excellent chelator for the stable complexation of the organometallic core $[M(CO)_3]^+$ (M = Tc-99m, Re) can be replaced by an isostructural 1,2,3-triazole analogue without influencing the characteristics of the radiometal conjugate. The "click-to-chelate" strategy provides a highly efficient and convenient entry to metal conjugates suitable for diagnostic and potentially therapeutic applications. The described procedures should be readily applicable to any azide-functionalized (bio)molecule and, thus, are likely to represent the method of choice for the future development of radiopharmaceuticals radiolabeled with the organometallic precursors $[M(CO)_3(H_2O)_3]^+$ (M = ^{99m}Tc, ^{188}Re).

INTRODUCTION

A prerequisite for the use of metal probes for application in targeted imaging (using positron emission or single photon emission tomography, magnetic resonance, and fluorescence) (*1–3*) and therapy (with particle emitting radiometals) is their stable attachment to a (bio)molecule via an efficient ligand system. This can be achieved by using bifunctional chelating agents (BFCA), which comprise a ligand system for the stable chelation of the (radio)metal and a second functionality for attachment of the metal chelate to the targeting molecule. However, the preparation of BFCAs generally entails multistep syntheses and their incorporation into (bio)molecules often lacks efficiency and is further complicated by cross-reactivity with other functional groups present. Thus, novel and efficient strategies for the synthesis of metal chelating systems and their incorporation into molecules of biological interest are needed.

The organometallic precursor $[^{99m}Tc(CO)_3(H_2O)_3]^+$ (*4*) has been extensively evaluated for the radiolabeling of (bio)molecules (*5–7*). A variety of tridentate ligand systems have been reported for complexation of the Tc-99m tricarbonyl core (*6*) including examples of bifunctional chelators derived from natural amino acids or synthetic analogues (*8–10*). For example, histidine (His) derived ligand systems have been shown to be extraordinarily good chelators for the efficient and stable coordination of "$M(CO)_3$" (M = Tc-99m, Re) (*11, 12*). Unfortunately, the synthesis of BFCAs based on N(τ)-functionalized His is not straightforward. Direct alkylation of the imidazole moiety of His derivatives generally yields mixtures of N(τ)-alkylated His along with the analogous, undesired N(π)-alkylated product (Figure 1, path A) (*13*). The formation of isomers makes tedious separations necessary even if one alkylation product is formed preferentially. An elegant strategy has been reported for the regioselective preparation of N(τ)-His derivatives via alkylation of a cyclic N(π)-urea intermediate and subsequent alcohol-mediated ring opening of the resulting quaternary amine (path B) (*12, 14, 15*). However, the efficiency of the alkylation step and the ring opening reaction depends on the nature of the reagents employed, and yields of isolated N(τ)-functionalized His can vary.

We have recently reported that the imidazole heterocycle of N(τ)-functionalized histidines can be replaced with a 1,4-disubstituted 1,2,3-triazole without altering the excellent chelating properties of the ligand system with regard to complexation of "$M(CO)_3$" (M = Tc-99m, Re) (*16*). Ligand design based on a 1,2,3-triazole scaffold takes advantage of the selectivity and efficiency of the Cu(I)-catalyzed [3 + 2] cycloaddition of terminal alkynes and azides, a transformation which has been termed a "click reaction" (*17–19*). For instance, click reaction of an azide with commercial L-propargyl glycine (**1**) (*20*) quantitatively yields optically pure triazoles which are isostructural to N(τ)-functionalized histidines (Figure 1, path C). The click product derived from propargyl glycine proved to be an excellent tripodal ligand system for "$M(CO)_3$" forming stable

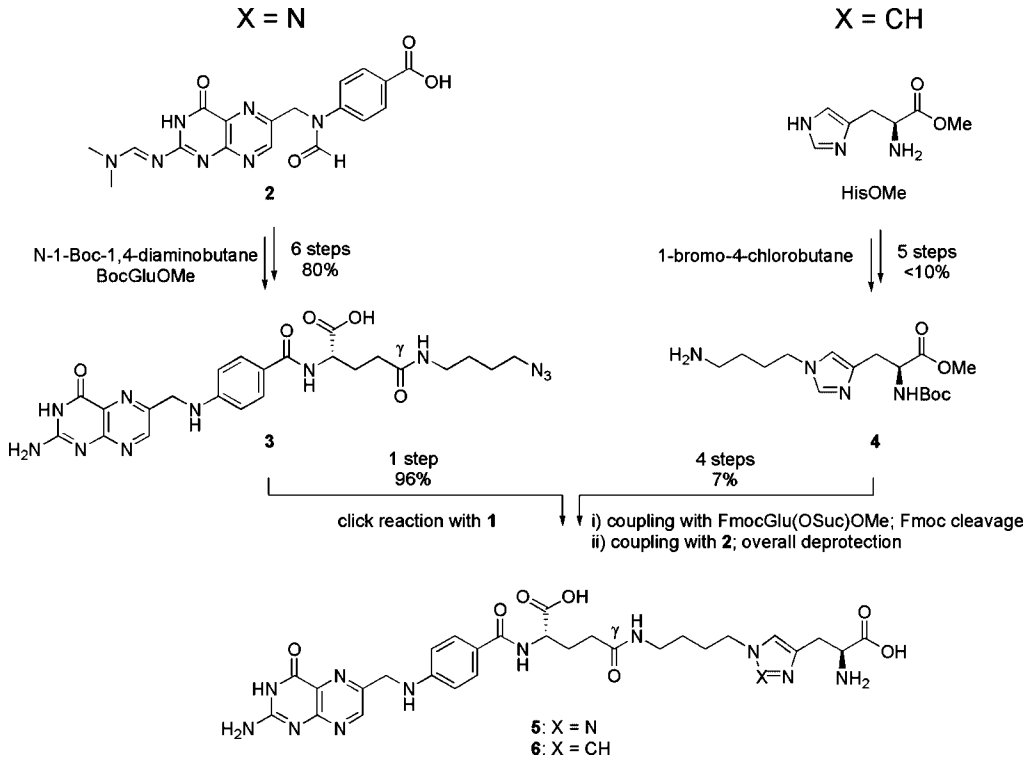

Figure 2. Comparison of the syntheses of two isostructural folic acid derivatives equipped with a 1,2,3-triazole containing chelator obtained by click chemistry (X = N) and a N(τ)-His ligand system (X = CH).

complexes by preferential coordination of the metal via nitrogen N(3) (rather than N(1) or N(2)) of the heterocycle (*16*). It is noteworthy that the synthesis of the chelating system and its attachment to a (bio)molecule is achieved simultaneously in a single step, a feature which has prompted us to call this new strategy "click-to-chelate".

In the meantime, we have reported a number of examples of the "click-to-chelate" approach for applications in radiopharmacy (*16, 21, 22*). However, a direct comparison of an N(τ)-His (radio)chelate with its 1,2,3-triazole analogue that demonstrates the chemical equivalence of the two isostructural ligand systems is still missing. We now wish to report the synthesis, Tc-99m labeling, and in vitro and in vivo characteristics of a folic acid Tc-99m radiotracer comprising a His-mimicking 1,2,3-triazole ligand system, and a side-by-side comparison with a folate conjugate equipped with a N(τ)-His chelate, the synthesis and in vivo evaluation of which has recently been described (see Figure 2) (*23, 24*).

EXPERIMENTAL PROCEDURES

Syntheses. *General Methods.* Melting points were taken on a Büchi-535 apparatus and are uncorrected. Infrared spectra were recorded on a Jasco FT/IR-6200 ATR-IR. Nuclear magnetic resonance spectra were recorded with a Bruker 400 or 500 MHz spectrometer with the corresponding solvent signals as an internal standard. Chemical shifts are reported in parts per million (ppm) relative to tetramethylsilane (0.00 ppm). Values of the coupling constant, *J*, are given in hertz (Hz); the following abbreviations are used in the experimental section for the description of ^{1}H-NMR spectra: singlet (s), doublet (d), triplet (t), quartet (q), multiplet (m), doublet of doublets (dd), and bs (broad singlet). The chemical shifts of complex multiplets are given as the range of their occurrence. For signal assignment, H/D exchange and 2D-NMR experiments (COSY, HSQC, HMBC) were performed for all new compounds. Low resolution mass spectra (LR-MS) were recorded with a Micromass Quattro micro API LC-ESI and high resolution mass spectra (HR-MS) with a Bruker FTMS 4.7 T BioAPEXII (ESI).

All water sensitive reactions were performed under argon in flame-dried glassware. Reactions were monitored by thin layer chromatography (TLC, performed on EM Science 0.25 mm thick, precoated silica gel 60 F-254 glass supported plates) or HPLC. HPLC was performed on a Merck-Hitachi L-7000 system equipped with an L-7400 tunable absorption detector and a Berthold LB 506 radiometric detector. The following systems were used for analytical HPLC: HPLC System 1: XBridge column (C18, 5 μm, 4.6 × 150 mm, Waters); 0.1% aq. TFA (solvent A), acetonitrile (solvent B); 0−1 min, 95% A; 1−15 min, 95→5% A; 15−20 min, 5% A; 20→22 min, 5→95% A; 22→25 min, 95% A; flow rate: 1 mL/min. HPLC System 2: Identical to system 1 but because of the solubility of deprotected folic acid derivatives, 10 mM NH_4HCO_3 was used instead of 0.1% aq. TFA. HPLC system 3: Tc-99m complexes were analyzed and compared with Re-analogues using a Nucleosil 5 C18 column (5 μm, 4.6 × 250 mm, Macherey-Nagel) with the following solvent system: Aqueous 0.05 M triethylammonium phosphate buffer, pH 2.25 (solvent A), methanol (solvent B), the HPLC system started with 95% A, with a linear gradient to 20% A and 80% B over 15 min, followed by 5 min of 100% A, with a flow rate of 1 mL/min. Semi preparative HPLC was performed with an XBridge column (C18, 5 μm, 10 × 150 mm, Waters) using the solvent system as indicated in the description of the individual experiments; flow rate of 3 mL/min.

[Na][$^{99m}TcO_4$] was eluted from a $^{99}Mo/^{99m}Tc$-generator (Mallinckrodt-Tyco, Petten, The Netherlands) with a 0.9% saline solution. Protected pteroic acid **2** was provided by Merck Eprova AG, Switzerland. All other commercially available reagents and solvents were purchased from Sigma-Aldrich and used as supplied unless stated otherwise. For a detailed description of the synthesis of compound **3**, see the Supporting Information.

Compound **5.** Azido folate **3** (36 mg, 0.05 mmol) was suspended in $^tBuOH/H_2O$ (1:1, 3 mL); and L-propargyl glycine (**1**, 6 mg, 0.053 mmol), $Cu(OAc)_2$ (2 mg, 20 mol %), and sodium ascorbate (4 mg, 40 mol %) were added. The mixture was stirred at 80 °C for 20 min after which HPLC (HPLC system 3) indicated completed conversion of substrate **3** and formation of a single product. The brown suspension was dissolved by addition of 2−3 drops of NaOH (1 M) and cleared by filtration through Celite. The product was precipitated by adjusting the pH of the solution to pH 2−3 with aq. HCl (1 M). The resulting suspension was centrifuged (10 min at 3500 rpm), the supernatant was decanted, and the solid was dried under reduced pressure to give the pentahydrochloride salt of triazolyl folate **5** as a orange powder (40 mg, 96%; purity according to HPLC >95%): mp >250 °C (decomposition); elemental analysis (calculated % values for $C_{28}H_{34}N_{12}O_7(HCl)_5$ in parenthesis), C 40.20 (40.37), H 5.12 (4.72), N 20.63 (20.18), O (13.45); chloride content determined by titration, 20.32 (calc. 21.28). For spectroscopic analysis, a sample of the crude product (10 mg) was purified by semipreparative HPLC (isocratic CH_3CN (10%), 0.1% aq. TFA (90%)). Lyophilization provided the tris-TFA salt, monohydrate of product **5** as a yellow powder (5 mg; purity according to HPLC >98%): IR (neat) ν 3253, 3085, 2936, 2787, 1683, 1631, 1604, 1507, 1302, 1227, 1180, 1125, 834 cm^{-1}; ^1H NMR (DMSO-d_6, using a water-signal suppressing program) δ 8.68 (bs, 1H), 8.27 (bs, 2H, exchange with D_2O), 8.20 (d, 1H, exchanges with D_2O, J = 6.8 Hz), 7.92 (s, 1H), 7.85 (t, 1H, exchanges with D_2O, J = 5.7 Hz), 7.65 (d, 2H, J = 8.1 Hz), 7.5−7.0 (multiple bs, 2H, exchange with D_2O), 6.64 (d, 2H, J = 8.1 Hz), 4.50 (s, 2H), 4.35−4.20 (m, 5H, one proton exchanges with D_2O), 3.23−3.13 (m, 2H), 3.09−2.94 (m, 2H), 2.50 (bs, 2H, exchange with D_2O), 2.18 (t, 2H, J = 8.2 Hz), 2.10−1.98 (m, 1H), 1.93−84 (m, 1H), 1.80−1.72 (m, 2H), 1.45−1.27 (m, 2H) ppm; ^{13}C NMR (DMSO-d_6) δ 173.8, 171.5, 170.1, 166.3, 160.4, 158.5, 153.5, 150.7, 149.6, 148.3, 140.4, 129.0, 127.9, 123.6, 121.4, 111.2, 52.1, 51.8, 49.0, 45.8, 37.7, 32.0, 27.2, 26.6, 26.1, 26.0 ppm; HR-MS $[M+H]^+$ = 651.2738 (calc. for $C_{28}H_{35}N_{12}O_7$ 651.2752); elemental analysis (calculated % values for $C_{28}H_{34}N_{12}O_7(TFA)_3(H_2O)$ in parenthesis), C 40.30 (40.40), H 4.20 (3.98), N 16.86 (16.63), O (22.16); fluoride content determined by titration, 15.95 (calc. 16.63).

*Compound [$^{99m}Tc(CO)_3$(**5**)]*. The precursor $[^{99m}Tc(H_2O)_3(CO)_3]^+$ was prepared according to the literature (*25*). In brief, $[^{99m}TcO_4]^-$ in 0.9% NaCl from a $^{99}Mo/^{99m}Tc$ generator was added to the IsoLink kit (Mallinckrodt-Tyco, Petten, The Netherlands) via the septum. The reaction mixture was heated for 20 min at 100 °C. The solution was cooled on ice and neutralized (pH 7.2) with 1 M phosphate buffer pH = 7.4 and 1 M HCl (1:1 mixture).

Synthesis 1: 50 μL of a stock solution of folic acid conjugate **5** (pentahydrochloride salt; 10^{-3} M in phosphate buffered saline (PBS), pH 7.4) was added to a solution of $[^{99m}Tc(CO)_3(OH_2)_3]^+$ (100 μL; ∼1 GBq/mL). PBS (pH 7.4) was added to adjust the final concentration of the ligand (10^{-4}−10^{-9} M) and the reaction mixture was heated for 30 min at 100 °C. Radiolabeling yields were determined by HPLC (γ-detection). Radiolabeling of the isostructural compound **6** was performed using the same procedure.

Synthesis 2 (one-pot, two-step procedure): Aqueous solutions azido folate **3** (100 μL, 10^{-3} M), copper (II) acetate (40 μL, 10^{-2} M), sodium ascorbate (80 μL, 10^{-2} M), and L-propargyl glycine (**1**, 150 μL, 10^{-3} M) were combined and heated at 100 °C for 30 min. After cooling to rt, $[^{99m}Tc(OH_2)_3(CO)_3]^+$ (100 μL in PBS pH 7.4; ∼1 GBq/mL) was added and the mixture was incubated at 100 °C for 30 min after which HPLC (γ-detection) indicated clean formation of product $[^{99m}Tc(CO)_3$(**5**)] (>90% purity according to HPLC).

*Compound [Re(CO)$_3$(**5**)]*. Folic acid derivative **5** (pentahydrochloride salt, 12.5 mg, 0.015 mmol) and $[Re(Br)_3(CO)_3][Et_4N]_2$ (11.5 mg, 0.015 mmol) were dissolved in water (2 mL). The pH of the solution was adjusted from pH 3 to pH 8 by addition of dilute aq. NaOH. After stirring at 50 °C for 1 h, HPLC indicated complete conversion of substrate **5** and formation of a single product. The reaction mixture was cleared by filtration through Celite and the product was precipitated at pH 2−3 by addition of dilute aq. HCl. The resulting suspension was centrifuged (10 min at 3500 rpm), the supernatant decanted, and the crude product was purified by semipreparative HPLC (isocratic CH_3CN (15%), 10 mM NH_4HCO_3 (85%)). Lyophilization provided the ammonium salt of [Re(CO)$_3$(**5**)] as a yellow solid (9.5 mg, 70%; purity according to HPLC >98%): mp >250 °C (decomposition); IR (neat) ν 3253, 3095, 2932, 2014, 1873, 1631, 1602, 1507, 1022, 821 cm^{-1}; ^1H NMR (DMSO-d_6) δ 10.55 (bs, 1H; exchanges with D_2O), 8.64 (s, 1H), 8.26 (s, 1H), 7.97 (t, 1H, J = 5.4 Hz; exchanges with D_2O), 7.80 (bs, 1H; exchanges with D_2O), 7.58 (d, 2H, J = 9.0 Hz), 7.24 (bs, 2H; exchange with D_2O), 6.91 (t, 1H, J = 5.9 Hz; exchanges with D_2O), 6.65 (d, 2H, J = 9.0 Hz), 5.95−5.91 (m, 1H, exchanges with D_2O after 5 days), 5.29 (d, 1H, J = 11.5 Hz; exchanges with D_2O after 5 days), 4.50−4.45 (m, 2H, becomes singlet (4.48 ppm) after D_2O exchange), 4.40 (t, 2H, J = 7.2 Hz), 4.12−4.03 (m, 1H; becomes triplet (4.09 ppm, J = 5.1 Hz) after D_2O exchange), 3.88−3.80 (m, 1H; becomes triplet (3.85 ppm, J = 3.9 Hz) after D_2O exchange), 3.18 (d, 2H, J = 5.0 Hz), 3.08−3.00 (m, 2H), 2.19−2.08 (m, 2H), 2.07−1.93 (m, 1H), 1.90−1.74 (m, 3H), 1.42−1.33 (m, 2H) ppm; ^{13}C NMR (DMSO-d_6) δ 199.0, 198.0, 197.3, 180.8, 174.7, 172.4, 166.2, 161.8, 156.8, 154.7, 151.1, 149.0, 148.8, 142.8, 129.1, 128.4, 126.0, 122.2, 111.7, 51.1, 51.0, 50.9, 46.4, 38.1, 32.6, 27.4, 26.5, 26.4 ppm (one CH_2 is not observed presumably due to overlapping signals); HR-MS: $[M+H]^+$ = 921.2077

(calc. for $C_{31}H_{34}N_{12}O_{10}Re$: 921.2078); elemental analysis (calculated % values for $C_{31}H_{36}N_{13}O_{10}Re$ in parenthesis) C 39.43 (39.74), H 4.02 (3.87), N 18.96 (19.23).

Determination of log *P*. The log *P* values of the Tc-99m folate tracers [$^{99m}Tc(CO)_3$(**5**)] and [$^{99m}Tc(CO)_3$(**6**)] were determined by a published procedure (*26*). In brief, samples of the HPLC-purified radiotracers (250 kBq) were mixed with equal amounts (1.5 mL) of PBS (pH 7.4) and octanol and the resulting biphasic system was mixed vigorously for 1 min. The two phases were separated by centrifugation and 0.5 mL aliquots were taken from each layer and counted for radioactivity in a γ-counter. The partition coefficient is expressed as the ratio of radioactivity (cpm) in the octanol phase to the one in the PBS phase and represents the mean (± standard deviation) of eight measurements for both compounds.

In Vitro Cell Uptake of ^{99m}Tc-Labeled Complexes. KB cells (human nasopharyngeal carcinoma cell line) were purchased from ATCC (CCL-17; American type Culture Collection, Manassas, USA). The cells were cultured as monolayers at 37 °C in a humidified atmosphere containing 5% CO_2. Importantly, the cells were cultured in FFRPMI cell culture medium (modified RPMI medium, without folic acid, vitamin B_{12}, and phenol red; Cell Culture Technologies GmbH, Gravesano/Lugano, Switzerland). FFRPMI medium was supplemented with 10% heat-inactivated fetal calf serum (FCS, as the only source of folate), L-glutamine, and antibiotics (penicillin/streptomycin/fungizone).

Eighteen hours prior to the experiment, the cells were seeded in 12-well plates (7.5×10^5 cells/well) to form confluent monolayers overnight. The experiments were performed in triplicate. Cell binding experiments of the radiofolates [$^{99m}Tc(CO)_3$(**5**)] and [$^{99m}Tc(CO)_3$(**6**)] were performed according to the following procedure: Cell monolayers were rinsed twice with PBS (pH 7.4). Pure FFRPMI medium (without FCS/L-glutamine/antibiotics, 975 μL) was added into each well. Blocking studies were performed with FFRPMI medium (475 mL) and a folic acid solution (200 μM, 500 μL). The well plates were preincubated at 37 °C for 40 min. A solution of the corresponding radiotracer (25 μL, 1.5 MBq/mL) was added, and the well plates were incubated for 1 h at 37 °C. Then, after removal of the radiotracer, the monolayers were washed two times with PBS (pH 7.4): radioactivity counted in these samples could be ascribed to the sum of FR-bound radiotracer on the cell surface and the internalized fraction. Other triplicate cell samples washed two times with stripping buffer (an aqueous solution of 0.1 M acetic acid and 0.15 M NaCl, pH 3) after the PBS wash in order to release radiotracers from FRs on the cell surface enabled determination of radioactivity of the internalized fraction only (*27*, *28*). The monolayers were lysed in 1 N NaOH (1 mL), transferred into 4 mL tubes, and homogenized by vortex. The radioactivity of each sample was measured in a γ-counter. The concentration of proteins was determined (using a commercially available kit of BioRad, Veenendaal, The Netherlands) for each sample in order to normalize measured radioactivity of the samples with respect to the averaged sample protein content. The raw data were converted from counts per minute (cpm) into percentage of total radioactivity added.

Biodistribution in Tumor Bearing Mice. All animal experiments were approved by the governing Animal Welfare Committee and conducted in accordance with the regulations of the Erasmus Medical Center, Rotterdam, The Netherlands. 8−10-week-old male, athymic nude mice (NMRI nu/nu) were purchased from Charles River Laboratories (Maastricht, The Netherlands). The animals were acclimatized and fed with a folate-deficient rodent diet starting 5 days prior to the tumor cell inoculation (*29*). The mice were inoculated subcutaneously with KB tumor cells (suspension of 5×10^6 cells in 100 μL PBS) on each shoulder. Radiofolate biodistribution studies were carried out in triplicate 14 days after tumor cell inoculation when the tumors reached a size of 0.5−1.5 cm^3. For biodistribution studies, mice were injected into a lateral tail vein with 1.5 MBq of HPLC-purified [$^{99m}Tc(CO)_3$(**5**)] and [$^{99m}Tc(CO)_3$(**6**)] respectively, in 100 μL PBS. The animals were sacrificed at 1, 4, or 24 h postinjection (p.i.) of the radiofolate. Blocking experiments were performed 4 h p.i. with mice (co)injected with excess folic acid (100 μg) shortly before injection of the radiotracer. Selected tissues and organs were removed, weighed, and counted for radioactivity in a γ-counter (Wizard, 1480, Perkin-Elmer). The results were expressed as percentage of the injected dose per gram of weight tissue [% ID/g], using reference counts from a definite sample of the original injectate counted at the same time.

RESULTS AND DISCUSSION

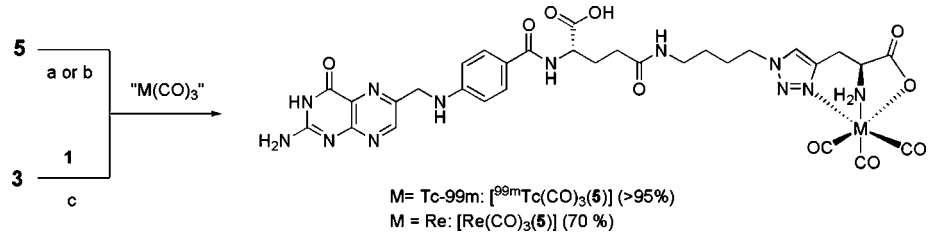
Folic acid is an essential dietary vitamin required by eukaryotic cells for the biosynthesis of nucleotide bases. As a consequence, acquirement of the vitamin is essential for cell survival and proliferation. A number of cancer cell lines exhibit high levels of the cell surface folate receptor (FR) while its expression is highly restricted in most normal tissues. In the past, folic acid conjugates have been successfully used to deliver specifically a variety of diagnostic and therapeutic agents to FR-positive tumors (*30*, *31*). For example, we and others have reported the attachment of radiometal chelates to folic acid for diagnostic and therapeutic applications (*32*–*38*). Although preclinical data are promising, the sometimes lengthy and inefficient syntheses of folic acid/radio metal conjugates may impede future development for radiopharmaceutical applications.

For the synthesis of compound **5**, we employed a fragment coupling strategy including as a key step the condensation of a protected pteroic acid derivative with an appropriate glutamic acid counterpart. The latter fragment was modified regioselectively at the γ-position with an azide functionality, hence providing a handle for the subsequent incorporation of a triazole-containing ligand system by click chemistry.

The synthesis of the folic acid derivative **5** is summarized in Figure 2. The required azido precursor **3** was synthesized in 6 steps and 80% yield from derivatives of glutamic acid and 1,4-diaminobutane and protected pteroic acid **2** (see Supporting Information for details). The Cu(I)-catalyzed functionalization of intermediate **3** was performed with unprotected L-propargyl glycine (**1**) (*20*) using reaction conditions similar to those initially reported by the Sharpless group (*17*). Thus, an aqueous solution of the click substrates alkyne **1** and azide **3** in the presence of catalytic amounts of in situ generated Cu(I) was heated to 80 °C for 20 min, after which HPLC indicated complete conversion of the substrates and formation of a single product. Alternatively, product **5** can be obtained at rt after stirring of the reaction mixture overnight. Conveniently, the HCl salt of triazole **5** could be isolated from the aqueous reaction mixture in pure form and in high yield by precipitation at decreased pH. Thus, precursor **5** for metal labeling was prepared in 7 steps and an overall yield of approximately 80%. In comparison, the regioselective synthesis of isostructural folate derivative **6** equipped with the N(τ)-functionalized His chelating system **4** (prepared via synthetic path B; see Figure 1) required 9 steps and provided the final product with an overall yield of <1% (Figure 1B) (*23*). Clearly, application of click chemistry led to a significant improvement of the synthetic efficiency of the preparation of functionalized folic acid derivatives.

Nonradioactive labeling of folic acid conjugate **5** was performed with the precursor $[Re(CO)_3(Br)_3][Et_4N]_2$ (*39*) using previously described procedures (Scheme 1) (*16*, *32*). Rhenium complex [$Re(CO)_3$(**5**)] was obtained as a single product and

Scheme 1. Synthesis of Folic Acid Metal Conjugates[a]



[a] (a) For $[^{99m}Tc(CO)_3(\mathbf{5})]$:$[^{99m}Tc(CO)_3(H_2O)_3]^+$, 0.15 M PBS, pH 7.4, 100 °C, 30 min; (b) For $[Re(CO)_3(\mathbf{5})]$:$[Re(Br)_3(CO)_3][Et_4N]_2$, H_2O, pH 8, 50 °C, 1 h; (c) **1**, 10 mol % $Cu(OAc)_2$/sodium ascorbate (1:2), H_2O, 30 min 100 °C, then $[^{99m}Tc(CO)_3(H_2O)_3]^+$, 30 min, 100 °C.

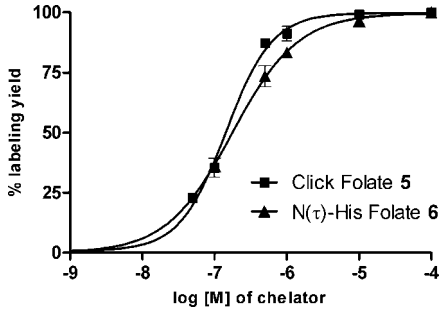


Figure 3. $^{99m}Tc(CO)_3$ labeling efficiency of the clicked 1,2,3-triazole chelator **5** and the corresponding isostructural N(τ)-His ligand system **6**, respectively, at varying concentrations (number of experiments $n = 3$).

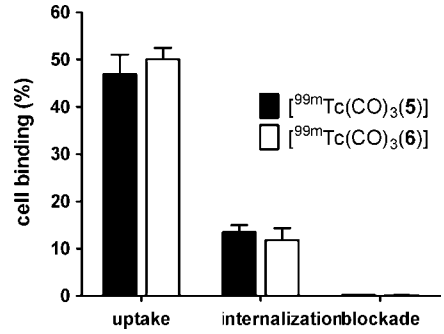

Figure 4. Uptake and internalization of complexes $[^{99m}Tc(CO)_3(\mathbf{5})]$ and $[^{99m}Tc(CO)_3(\mathbf{6})]$ using FR-positive KB cancer cells. Almost complete blockage (<1% of total added radioactivity) was found after addition of excess folic acid.

fully characterized by spectroscopic methods (NMR, MS, IR) and elemental analysis. In agreement with reported complexes of "$Re(CO)_3$" and 1,2,3-triazole-containing ligand systems (*16, 21*), NMR analysis of compound $[Re(CO)_3(\mathbf{5})]$ supports a $\kappa N(3),\kappa O,\kappa N(\alpha)$ coordination.

Derivative **5** (and **6**) could also be readily radiolabeled with $[^{99m}Tc(CO)_3(H_2O)_3]^+$ at 100 °C. Identity of $[^{99m}Tc(CO)_3(\mathbf{5})]$ was confirmed by comparison of the HPLC γ-trace with the UV-trace of $[Re(CO)_3(\mathbf{5})]$ (see Supporting Information). The labeling efficiency of folate **5** with a 1,2,3-triazole-containing chelating system was assessed and compared with the isostructural folic acid derivative **6**. Varying the concentration of the ligands gave rise to step-sigmoid curves which allowed a comparison of the labeling capacities of the two chelators (Figure 3). With both compounds, 50% labeling yield of $^{99m}Tc(CO)_3$ was achieved at ligand concentrations of $\sim 10^{-7}$ M. This demonstrates again that the N(τ)-functionalized His chelator and the 1,4-disubstituted 1,2,3-triazole analogue are equally potent ligand systems with respect to complexation of $[^{99m}Tc(CO)_3(H_2O)_3]^+$ (*16, 21*). Importantly, folic acid SPECT tracer $[^{99m}Tc(CO)_3(\mathbf{5})]$ could also be obtained directly from azide **3** by a one-pot, two-step protocol without isolation and purification of the intermediate **5**, therefore simplifying further the synthetic procedure (Figure 1, path D) (*16*). Thus, heating of an aqueous solution of azide **3** and L-propargyl glycine (**1**) in the presence of Cu(I) catalyst for 30 min followed by addition of $[^{99m}Tc(CO)_3(H_2O)_3]^+$ and heating for 30 min provided the final compound $[^{99m}Tc(CO)_3(\mathbf{5})]$ in pure form and identical in all respects to the product obtained from isolated and purified precursor **5**.

Because the lipophilicity of a radiotracer could affect the fate of the compounds after systemic administration, the log *P* values of both radiofolates $[^{99m}Tc(CO)_3(\mathbf{5})]$ and $[^{99m}Tc(CO)_3(\mathbf{6})]$ were determined. The Tc-99m complex of **5** revealed a log *P* value of -3.41 ± 0.06, whereas that of **6** was found to be -3.47 ± 0.05 (both measured at pH = 7.4). Thus, the Tc-99m complexes of compounds **5** and **6** exhibit virtually identical hydrophilic characters.

In Vitro and In Vivo Assessment. We have recently reported the assessment of a $^{99m}Tc(CO)_3$-labeled bombesin derivative which was functionalized via click chemistry (*16*). The in vitro and in vivo results were largely comparable to that of a bombesin analogue equipped with a N^{α}-AcHis chelating system. While the amino acid sequence of both peptides was identical, they differed with respect to the spacer entity (βAla vs βAla-βAla) and the site of functionalization of the chelating system (N^{α}-amino group of His vs N(1) of the 1,2,3-triazole heterocycle). In addition, the bombesin derivatives were tested in vivo at a single time point only, which did not allow a comparison of their pharmacokinetic profiles. With the isostructural folic acid derivatives $[^{99m}Tc(CO)_3(\mathbf{5})]$ and $[^{99m}Tc(CO)_3(\mathbf{6})]$ available, a more thorough and accurate evaluation and comparison in vitro and in vivo became possible.

$[^{99m}Tc(CO)_3(\mathbf{5})]$ and $[^{99m}Tc(CO)_3(\mathbf{6})]$ were assessed in vitro using FR-positive KB tumor cells (Figure 4). For both Tc-99m complexes, a cell uptake of approximately 50% of total added radioactivity was observed of which roughly one-third was found internalized. Blocking experiments with excess folic acid resulted in a decrease of cell-associated radioactivity to less than 1%, proving FR-specific uptake.

In order to assess and compare the in vivo behavior of $[^{99m}Tc(CO)_3(\mathbf{5})]$ and $[^{99m}Tc(CO)_3(\mathbf{6})]$, time-dependent biodistribution studies were performed with nude mice bearing KB tumor xenografts (Figure 5; see Supporting Information for details). On average, the two radiofolate tracers revealed a very similar biodistribution pattern. Both complexes showed a fast clearance from the blood and retention in nontargeted (FR-negative) organs and tissues was generally below 1% ID/g (4 h p.i.). Despite their almost identical lipophilicity, complex $[^{99m}Tc(CO)_3(\mathbf{6})]$ accumulated in the liver at early time points to a greater extent than $[^{99m}Tc(CO)_3(\mathbf{5})]$ (9.73 ± 1.32% ID/g vs 2.95 ± 1.02% ID/g, respectively; 1 h p.i.). However, radioactivity was completely cleared from the liver in both cases after 24 h (<1% ID/g). Tumor uptake of $[^{99m}Tc(CO)_3(\mathbf{5})]$ and $[^{99m}Tc(CO)_3(\mathbf{6})]$ 1 h after intravenous injection was 3.94 ± 0.71% ID/g and 2.63 ± 0.43% ID/g and peaked at 4 h p.i. with 4.84 ± 0.10% ID/g and 4.29 ± 0.67% ID/g, respectively. After 24 h p.i., tumor-associated radioactivity was still 3.51 ± 0.37%

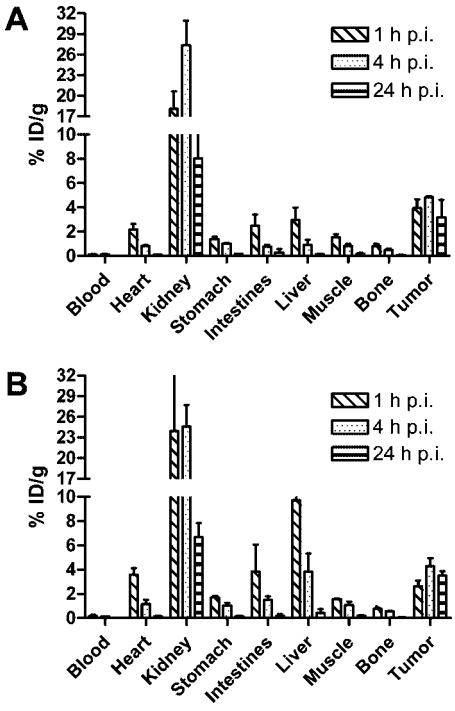

Figure 5. Time-dependent biodistribution data in selected organs and tissues at 1, 4, and 24 h p.i. of complex [^{99m}Tc(CO)$_3$(**5**)] (A) and [^{99m}Tc(CO)$_3$(**6**)] (B), respectively. Specific accumulation of the radiofolate is observed only in FR-positive tumors and kidneys. Data for compound [^{99m}Tc(CO)$_3$(**6**)] are taken from ref (*24*).

ID/g in the case of the N(τ)-His compound and 3.18 ± 1.45% ID/g for the click-derivative ($p > 0.5$). Besides in the tumor xenografts, substantial amounts of radioactivity were found in the FR-positive renal tissue. In both cases, a maximal fraction of the radiotracers was observed in the kidney at 4 h p.i. (24.56 ± 3.17% ID/g for [^{99m}Tc(CO)$_3$(**6**)] and 27.33 ± 3.61% ID/g for [^{99m}Tc(CO)$_3$(**5**)]). High renal retention of radiofolate is a known phenomenon due to substantial expression of the folate receptor at the luminal site of the proximal tubule (*40*). Biodistribution experiments performed after coinjection of excess folic acid (100 μg/mouse) confirmed specific, FR-mediated uptake of both radiofolates in the tumors and kidneys. Almost complete attenuation (<1% ID/g) of the uptake of the radiotracers was observed under these conditions (see Supporting Information).

CONCLUSIONS

A side-by-side comparison of the synthesis and in vitro and in vivo characteristics of two isostructural, organometallic ^{99m}Tc-folate radiotracers provide the final piece of evidence that (i) the "click-to-chelate" strategy improves considerably the efficiency of the preparation of Tc/Re(CO)$_3$-bioconjugates, the synthesis of which can be challenging by alternative approaches; (ii) the efficient N(τ)-derivatized histidine ligand system well suited for radiolabeling with [M(CO)$_3$(H$_2$O)$_3$]$^+$ (M = ^{99m}Tc, ^{188}Re) can be substituted by an isostructural 1,4-bifuctionalized 1,2,3-triazole-containing analogue without influencing the characteristics of the conjugate with respect to radiolabeling efficiency, in vitro uptake and internalization in a FR-overexpressing tumor cell line, and in vivo tumor-targeting capacity and pharmacokinetics.

The herein described procedures are efficient, easy to conduct, and should be readily applicable to any other type of (bio)molecule into which an azide functionality can be incorporated. It is likely that the attractive features of the "click-to-chelate" approach will make this strategy the method of choice for future development of targeted radiopharmaceuticals radiolabeled with the organometallic precursors [^{99m}Tc(CO)$_3$(H$_2$O)$_3$]$^+$ and [^{188}Re(CO)$_3$(H$_2$O)$_3$]$^+$.

ACKNOWLEDGMENT

We thank Merck Eprova AG, Switzerland for providing protected pteroic acid **2** and a sample of N(τ)-histidine folate **6**, Satish Boedhoe (Erasmus MC) for technical assistance, and Dr. Bernhard Pfeiffer and Dr. Aileen Höhne (ETH Zurich) for NMR spectroscopic measurements.

Supporting Information Available: Detailed description of the synthesis of azido folate **3**, ^{1}H and ^{13}C NMR spectra of all new compounds, HPLC chromatograms of Tc-99m and Re complexes, and complete biodistribution data of complex [^{99m}Tc(CO)$_3$(**5**)] and [^{99m}Tc(CO)$_3$(**6**)] at 1 h, 4 h, and 24 h p.i. This material is available free of charge via the Internet at http://pubs.acs.org.

Materials and Methods. Common chemicals and solvents in addition to bromoacetic acid 3*H*-1,2-benzodithiol-3-one 1,1-dioxide, Et_3N, *i*-Pr_2NEt, tripropargyl amine, benzyl azide, sodium azide, 2,6-lutidine, *O*-(2-cyanoethyl)-*O*-[3-(4,4'-dimethoxytrityl)oxy-1-propyl]-*N*,*N*-diisopropylphosphoramidite, 2-cyanoethyl-*N*,*N*-diisopropylchlorophosphoramidite, *O*-(2-cyanoethyl)-*O*-(5-hexyn-1-yl)-*N*,*N*-diisopropylphosphoramidite, bis(*N*,*N*-diisopropylamino)chlorophosphine, *O*-(2-cyanoethyl)-*O*-[6-(4-methoxytrityl)amino-1-hexyl]-*N*,*N*-diisopropylphosphoramidite, 500Å Long Chain Alkylamine Controlled-Pore Glass (CPG), tetrakis(acetonitrile)copper(I) hexafluorophosphate, copper(II) sulfate pentahydrate, sodium ascorbate, 2',4',6'-trihydroxyacetophenone monohydrate, 3-hydroxypicolinic acid, ammonium citrate tribasic, 1-methylimidazole, hydrazine hydrate, argon gas cylinder, and lecture bottles of NH_3 and CH_3NH_2 gases were all purchased from commercial sources and used without further purification. Azido acetic acid was prepared from the reaction of bromoacetic acid and sodium azide as described by Dyke, J. M. et al. (*J. Am. Chem. Soc.* **1997**, *119*, 6883-6887). Anhydrous solvents (MeCN, CH_2Cl_2, C_6H_6, pyridine, THF) and deuterated solvents (C_6D_6,) were obtained from reputable sources and used as received.

Reagents for oligonucleotide synthesis including the 5'-Deblocking solution (3% TCA in CH_2Cl_2), the Activator solution (0.25 M 5-ethylthio-1*H*-tetrazole or 0.4 M 1*H*-tetrazole in MeCN), Cap A solution (Ac_2O/pyridine/THF), Cap B solution (10% 1-methylimidazole in THF), and the Oxidizing solution (0.02 M iodine in THF/pyridine/water) were purchased from commercial sources and used as received. Succinyl long chain alkylamine controlled-pore glass functionalized with 5'-*O*-(4,4'-dimethoxytrityl)-2'-deoxythymidine as the leader nucleoside was also obtained from commercial sources and used as is. 2 M Triethylammonium acetate buffer was purchased from Applied Biosystem and diluted to 0.1 M with HPLC grade water prior to use. Snake venom phosphodiesterase (*Crotallus adamanteus*) and bacterial alkaline phosphatase were commercially available and used without further purification.

Preparative chromatographic purifications were performed on glass columns (2.5, 5.0 or 6.5 cm I.D.) packed with silica gel 60 (230-400 mesh), whereas analytical thin-layer chromatography (TLC) analyses were conducted on 2.5 cm × 7.5 cm glass plates coated with a 0.25 mm thick layer of silica gel 60 F_{254}.

RP-HPLC analyses were performed using a 5 μm Supelcosil LC-18S column (25 cm × 4.6 mm) according to the following conditions: starting from 0.1 M triethylammonium acetate pH 7.0, a linear gradient of 1% MeCN/min is pumped at a flow rate of 1 mL/min for 40 min or as indicated. Peak heights are normalized to the highest peak, which is set to 1 arbitrary unit.

All NMR experiments were performed using spectrometers at fields of 300.13 and 700.13 MHz for ^1H, 75.47 and 176.06 MHz for ^{13}C, and 121.5 MHz for ^{31}P. One-dimensional; ^1H, ^{31}P, $^1H/^{31}P$ decoupled ^{13}C, ^1H decoupled ^{13}C, and two-dimensional ^1H-^{13}C correlation (HSQC) data were acquired using a 5 mm QXI (quadruple resonance; ^1H, ^{15}N, ^{13}C, ^{31}P inverse) probe with actively shielded XYZ gradients

on the spectrometer operating at 700 MHz. ^{1}H-^{1}H total correlation (TOCSY) experiments were performed using the spectrometer operating at 300 MHz that is equipped with a TXI (triple resonance; ^{1}H, ^{15}N, ^{13}C inverse) probe with actively shielded XYZ gradients. Samples were maintained at a temperature of 298 °K. All spectra were recorded in C_6D_6 and chemical shifts δ were reported in parts per million (ppm) relative to appropriate internal references.

Accurate mass determination of each deoxyribonucleoside phosphorodiamidite **4** was performed using atmospheric pressure electrospray ionization (APESI) in the positive mode (ES^+). Samples dissolved in MeCN (~60 μg/mL) were infused directly at 2.5 mL/h into a stream of MeCN that flowed at 0.5 mL/min to obtain adequate signal intensity. A calibrant containing known ion of 922 m/z was nebulized into the chamber simultaneously with each sample. Software calibration was performed prior to the analysis to re-align the 922.0098 calibrant mass to the theoretical value. The TOF mass spectrometer was set to accurately measure masses over the range 100 to 1500 m/z. Accurate mass measurements for each sample are reported as the average of five injections.

MALDI-TOF mass spectrometric analyses were performed operating in delayed extraction reflector mode, using 3-hydroxypicolinic acid [50 mg/mL in MeCN/H_2O (1:1 v/v)] or 2',4',6'-trihydroxyacetophenone monohydrate [10 mg/mL in MeCN/H_2O (1:1 v/v)] as a matrix and ammonium citrate (50 mg/mL in H_2O) as a cation exchanger.

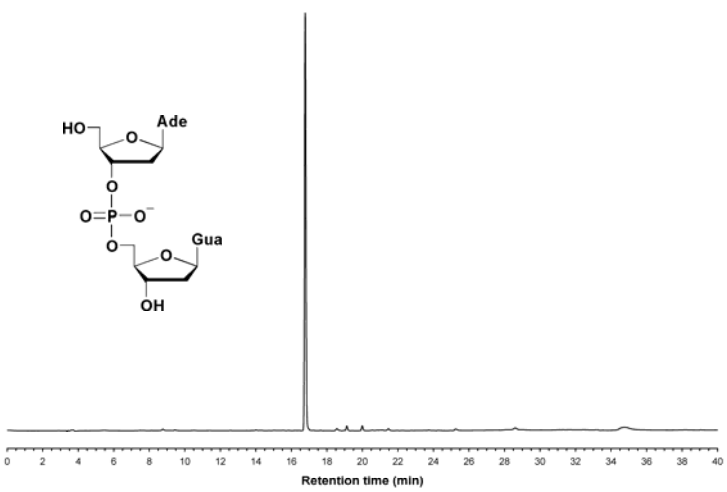
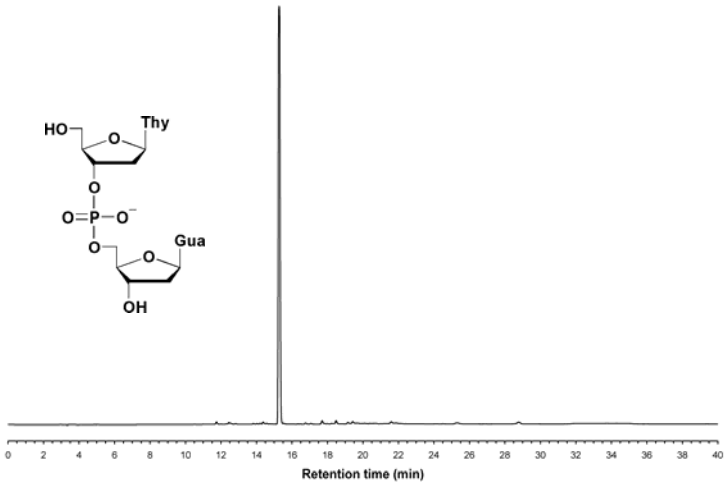
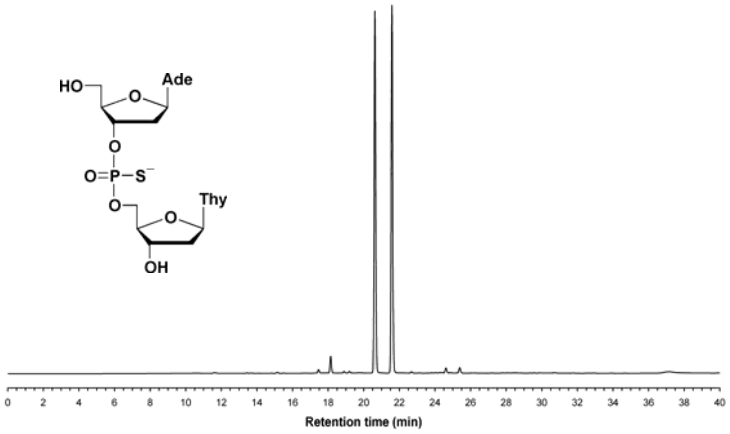
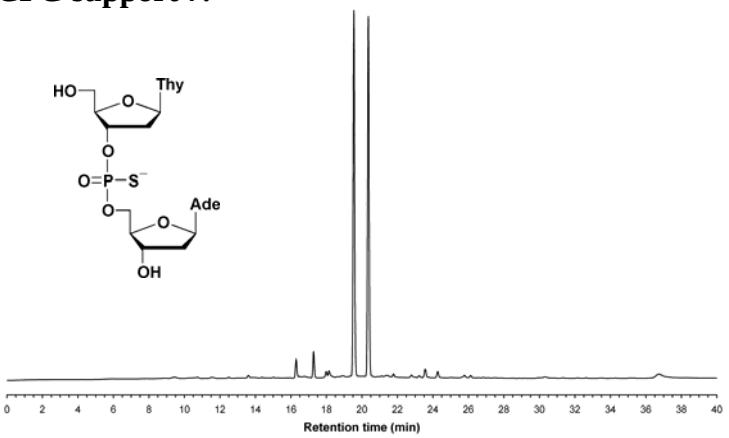
RP-HPLC chromatograms of dinucleoside phosphate diesters that were thermolytically released from the CPG support 7

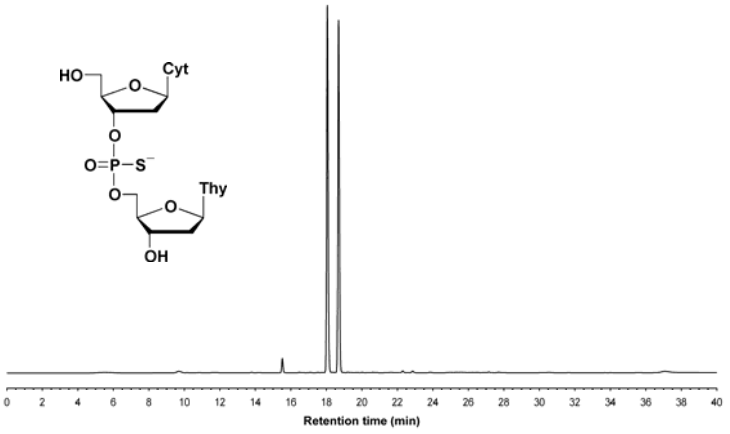


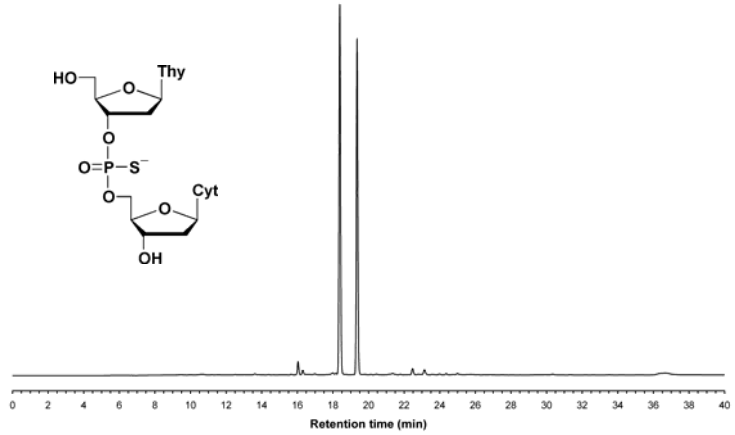


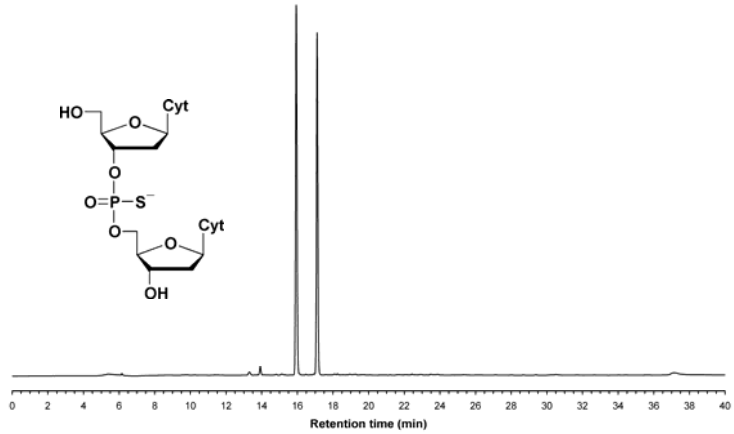
RP-HPLC chromatograms of dinucleoside phosphorothioates that were thermolytically released from the CPG support 7.

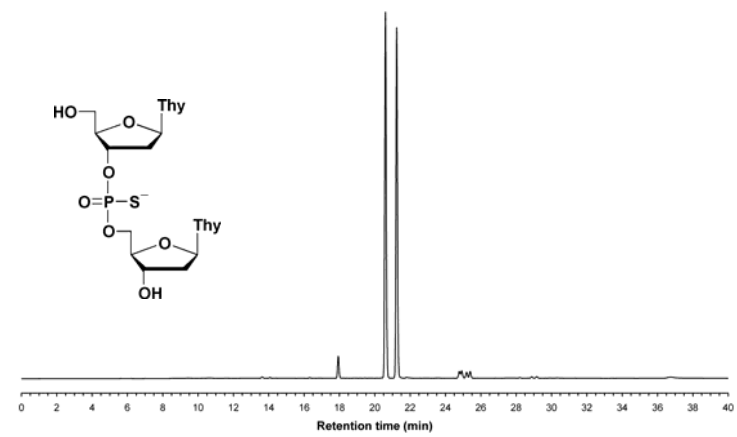


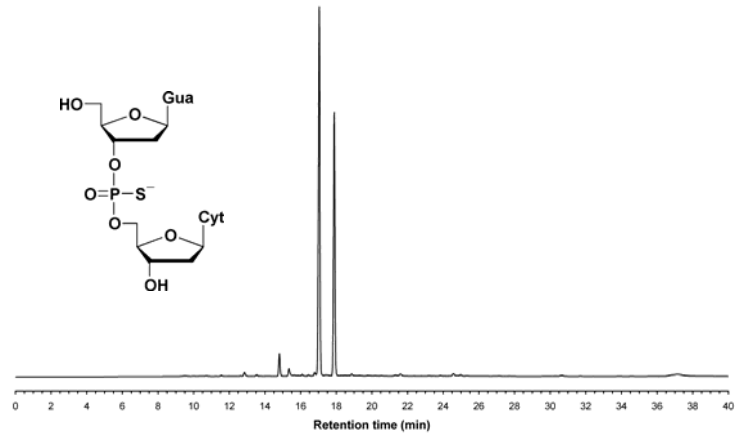


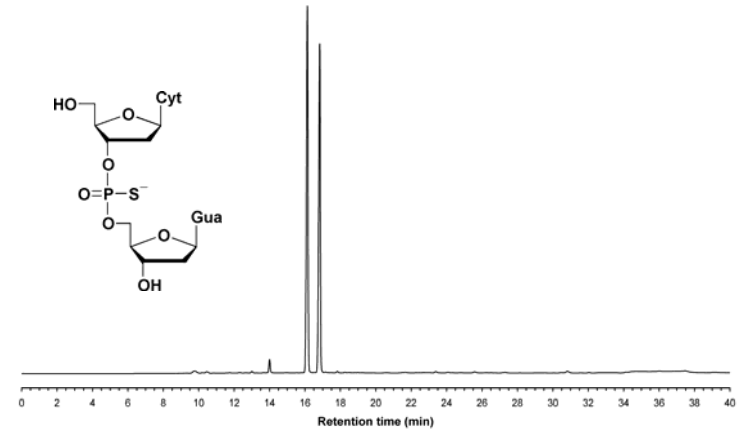




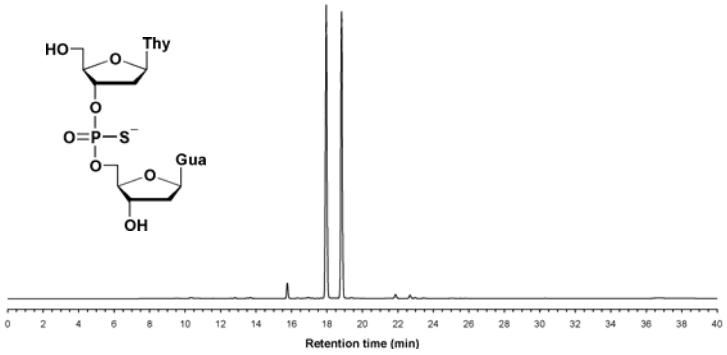


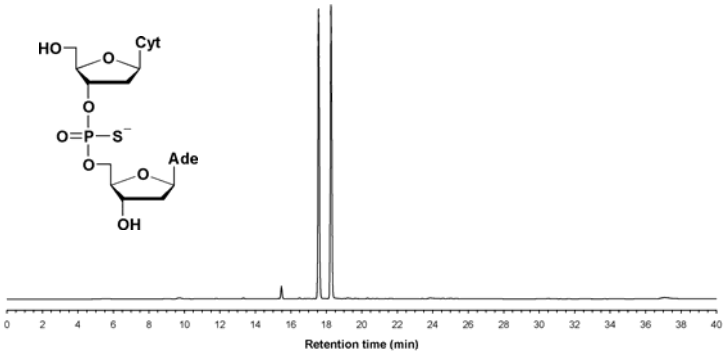


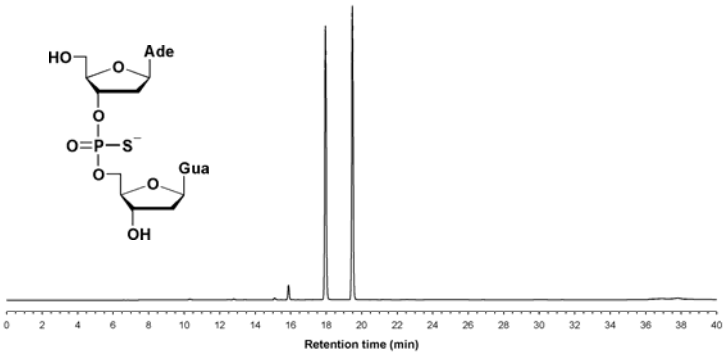


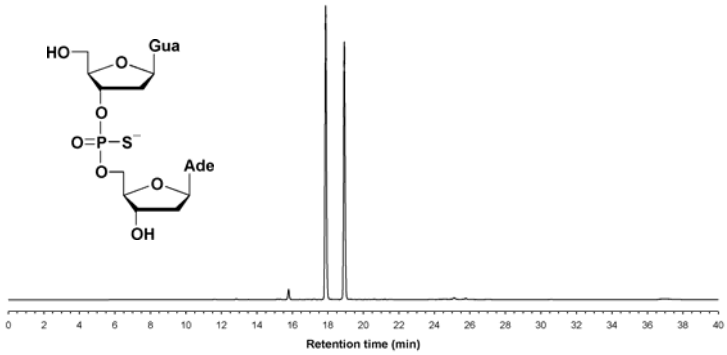


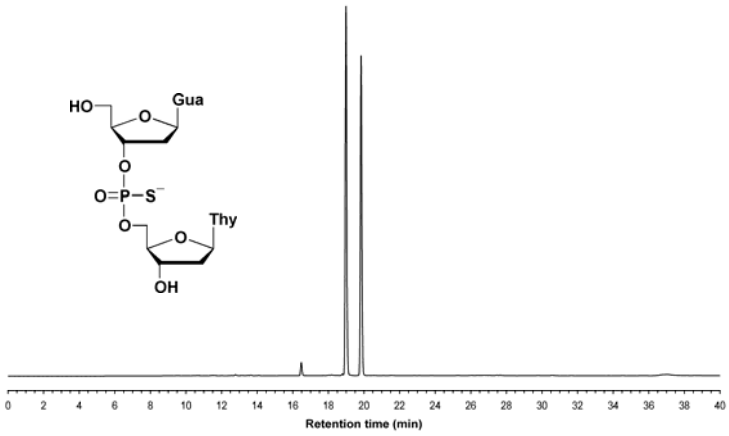
RP-HPLC chromatograms of dinucleoside phosphorothioates that were thermolytically released from the CPG support 7.

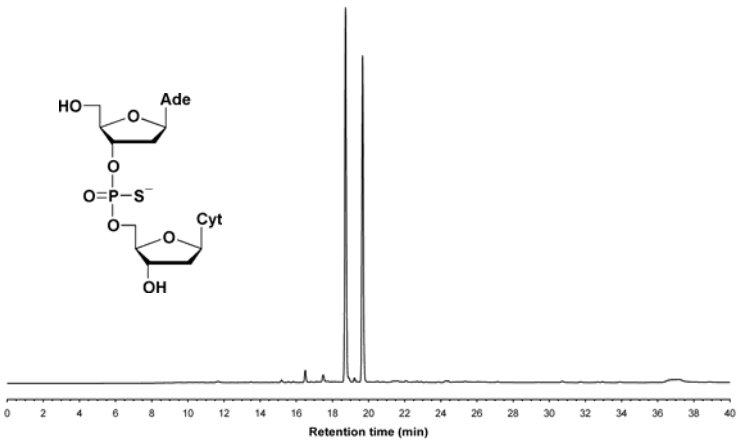


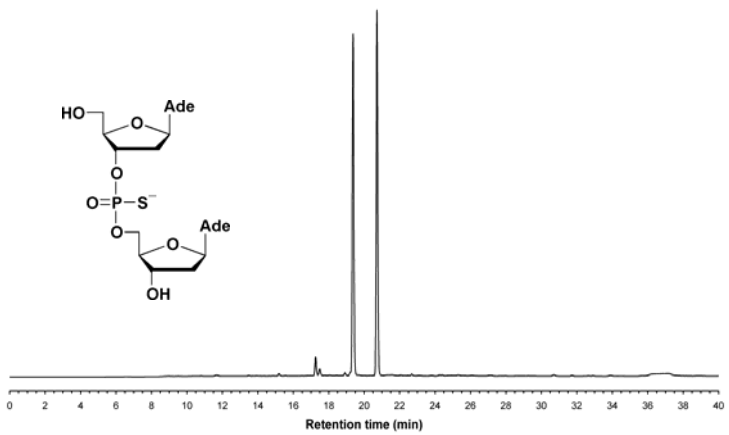


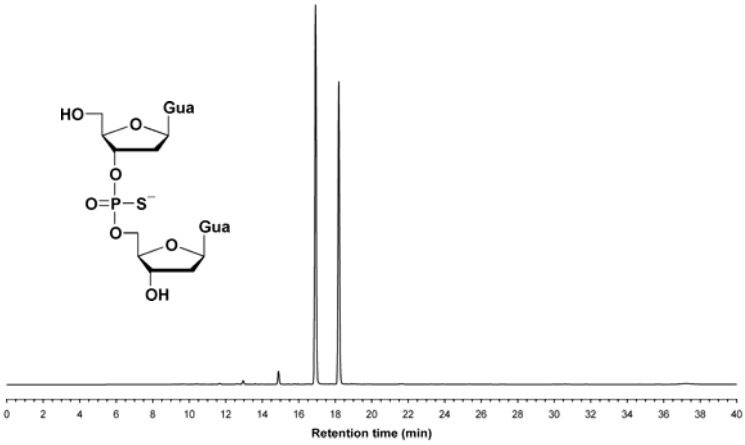


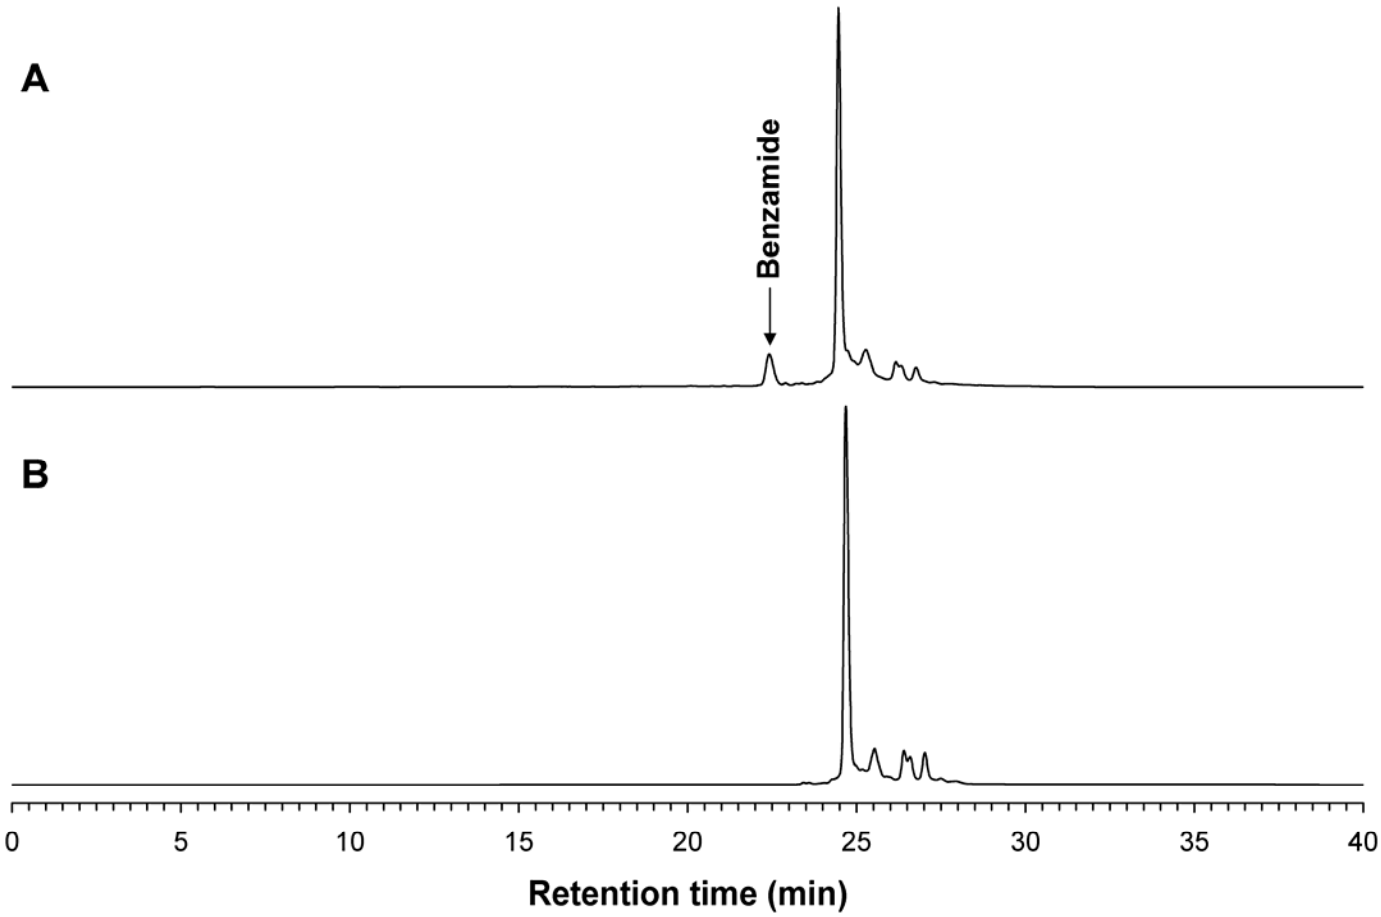




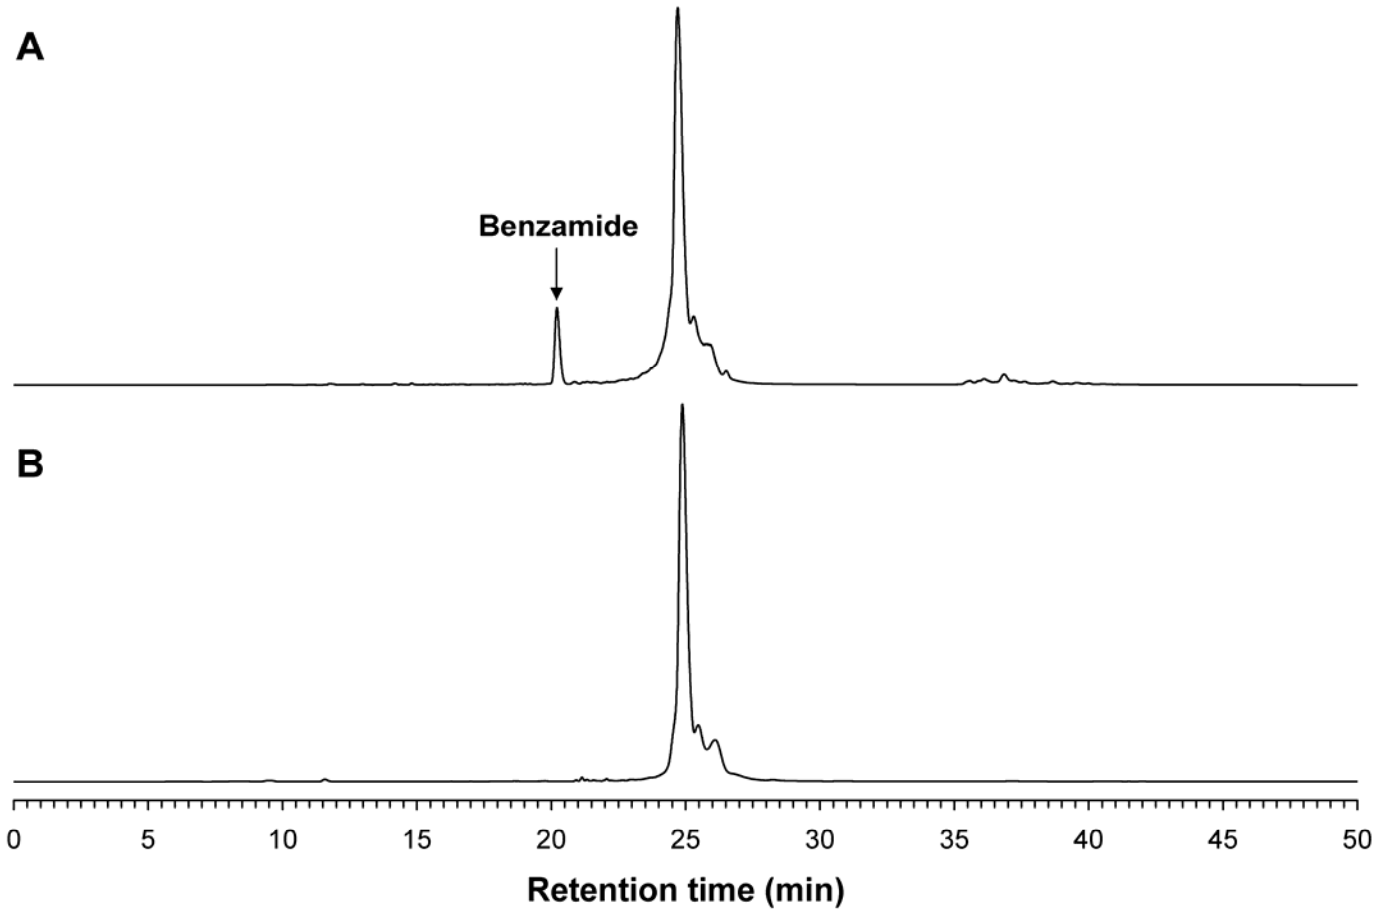








Enlarged Figure 1. RP-HPLC analysis of unpurified 5'-d(CGACTGTGAATCGATGCCAT). **A:** Chromatogram of the native 20-mer that was synthesized employing commercial CPG under standard conditions. Nucleobase and phosphate deprotection, and release of the oligomer from the support were effected by treatment with pressurized NH_3 gas (~10 bar) over a period of 16 h at 25 ºC, as described in the Experimental section. **B:** Chromatogram of the 20-mer that was synthesized using the CPG support **7** under standard conditions. After nucleobase and phosphate deprotection under the conditions described in **A**, the deprotection side products were washed away from the CPG support **8** with MeCN:H_2O (1:1 v/v). The 20-mer was thermolytically cleaved from **8** upon heating at 90 ºC in 1× PBS (pH 7.2) for 2 h. RP-HPLC analyses were performed using a 5 μm Supelcosil LC-18S column (25 cm × 4.6 mm) according to the following conditions: starting from 0.1 M triethylammonium acetate pH 7.0, a linear gradient of 0.7% MeCN/min was pumped at a flow rate of 1 mL/min for 30 min and was followed by a linear gradient of 4% MeCN for 5 min, which was held isocratically for 5 min. Peak heights are all normalized to the highest peak, which is set to 1 arbitrary unit.



Enlarged Figure 2. RP-HPLC analysis of unpurified 5'-d($C_{PS}G_{PS}A_{PS}C_{PS}T_{PS}G_{PS}T_{PS}G_{PS}A_{PS}A_{PS}T_{PS}C_{PS}$ $G_{PS}A_{PS}T_{PS}G_{PS}C_{PS}C_{PS}A_{PS}T$). **A:** Chromatogram of the fully phosphorothioated 20-mer that was synthesized employing commercial CPG under standard conditions. Nucleobase and thiophosphate deprotection was effected by treatment with pressurized NH_3 gas (~10 bar) over a period of 16 h at 25 ºC, as described in the Experimental section. **B:** Chromatogram of the 20-mer that was synthesized using the CPG support **7** under standard conditions. After nucleobase and thiophosphate deprotection under the conditions described in **A**, the deprotection side products were washed away from the CPG support **8** with MeCN:H_2O (1:1 v/v). The 20-mer was thermolytically cleaved from the support **8** upon heating at 90 ºC in 1× PBS (pH 7.2) for 2 h. RP-HPLC analyses were performed using a 5 µm Supelcosil LC-18S column (25 cm × 4.6 mm) according to the following conditions: starting from 0.1 M triethylammonium acetate pH 7.0, a linear gradient of 1% MeCN/min was pumped at a flow rate of 1 mL/min for 40 min. Peak heights are all normalized to the highest peak, which is set to 1 arbitrary unit.

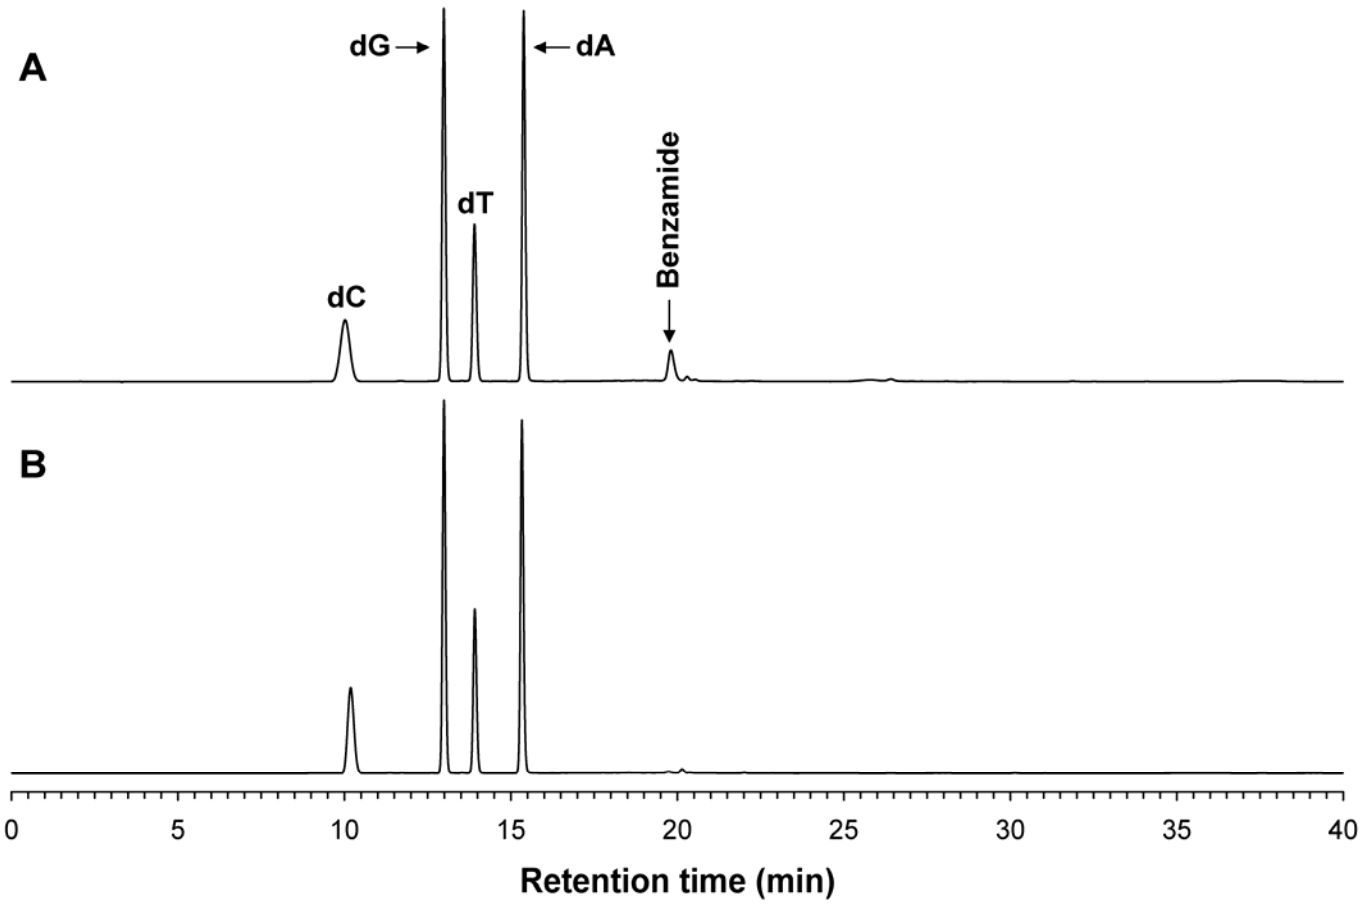


CHART 1. RP-HPLC analysis of unpurified 5'-d(CGACTGTGAATCGATGCCAT) after treatment with snake venom phosphodiesterase and bacterial alkaline phosphatase. **A:** Chromatogram of the enzymatic digest of the 20-mer described in Figure 1A. **B:** Chromatogram of the enzymatic digest of the 20-mer described in Figure 1B. Chromatographic conditions are identical to those described in the legend of Enlarged Figure 2. **dC**, 2'-deoxycytidine; **dG**, 2'deoxyguanosine; **dT**, 2'deoxythymidine; **dA**, 2'-deoxyadenosine.

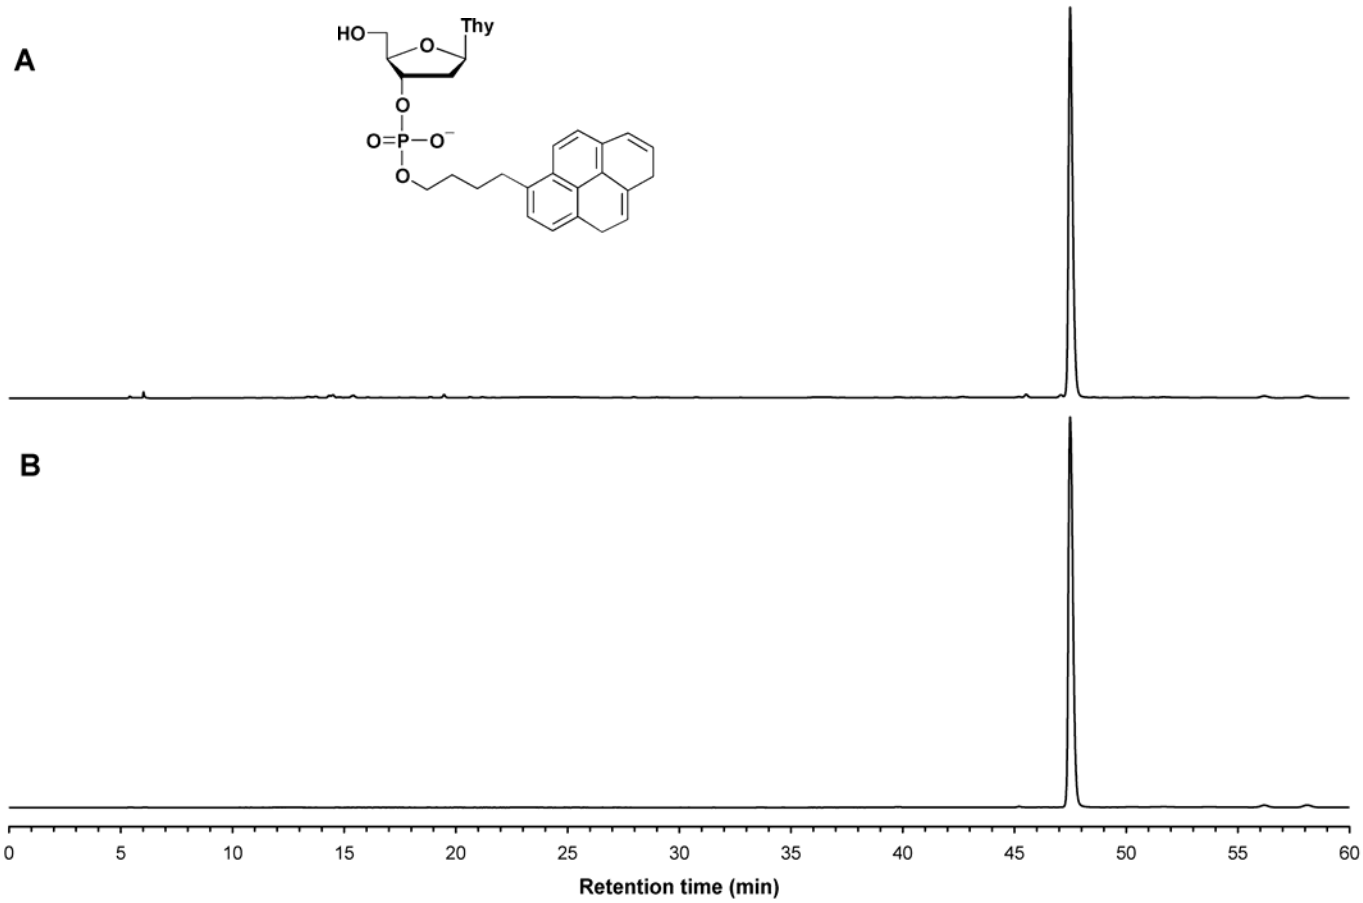

CHART 2. RP-HPLC chromatograms of unpurified thymidine 3'-*O*-(1-pyrenebutyl) phosphate that was thermolytically released from the CPG support **12**. **A:** Chromatogram of thymidine 3'-*O*-(1-pyrenebutyl) phosphate recorded at 260 nm. **B:** Chromatogram of thymidine 3'-*O*-(1-pyrenebutyl) phosphate recorded at 340 nm. RP-HPLC analyses were performed under conditions identical to those described in the legend of Enlarged Figure 2.

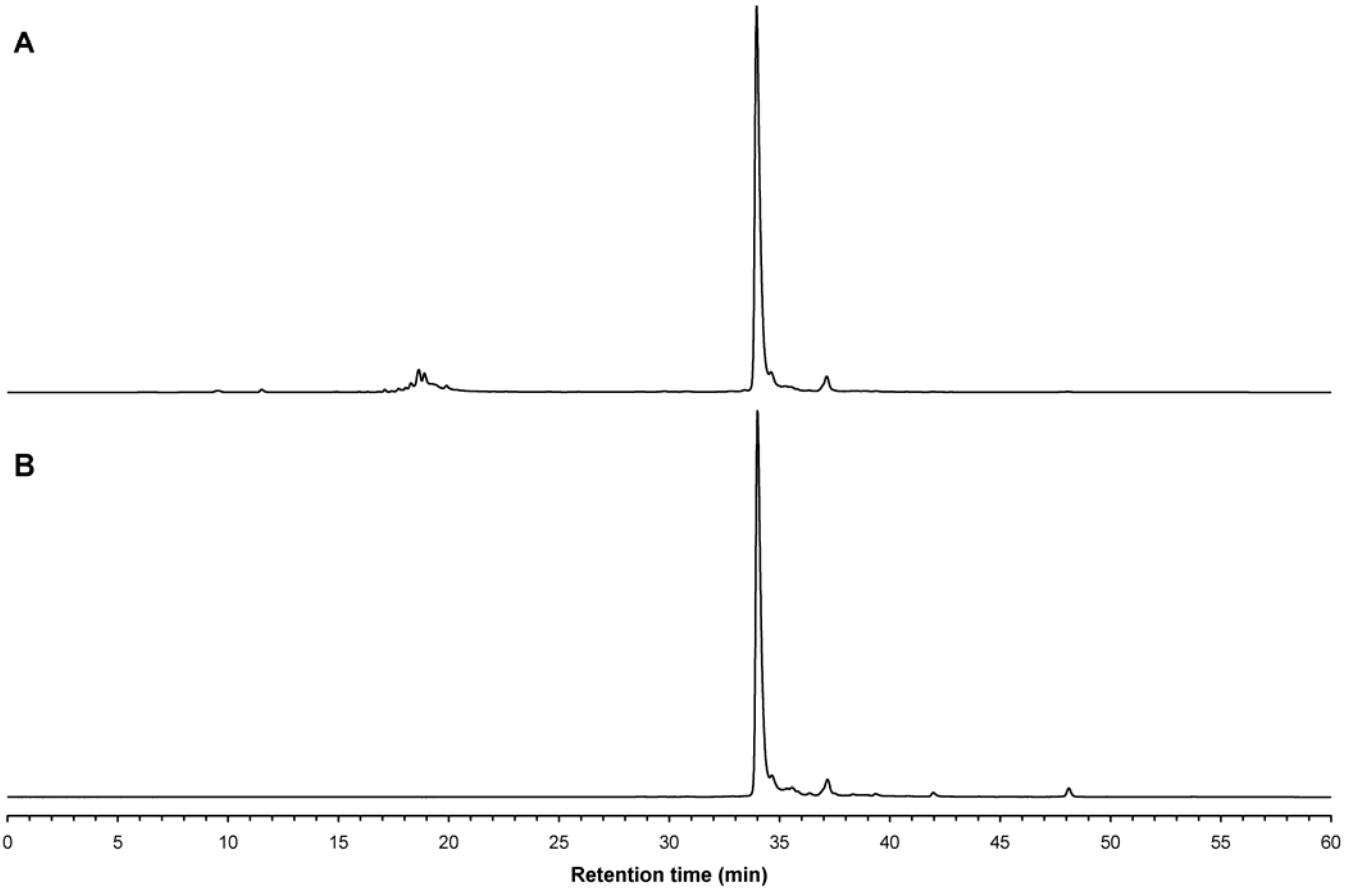

CHART 3. RP-HPLC analysis of unpurified 3'-pyrenylated DNA oligonucleotide **14**. **A:** Chromatogram of **14** recorded at 260 nm. **B:** Chromatogram of **14** recorded at 340 nm. RP-HPLC analyses were performed under conditions identical to those described in the legend of Enlarged Figure 2.

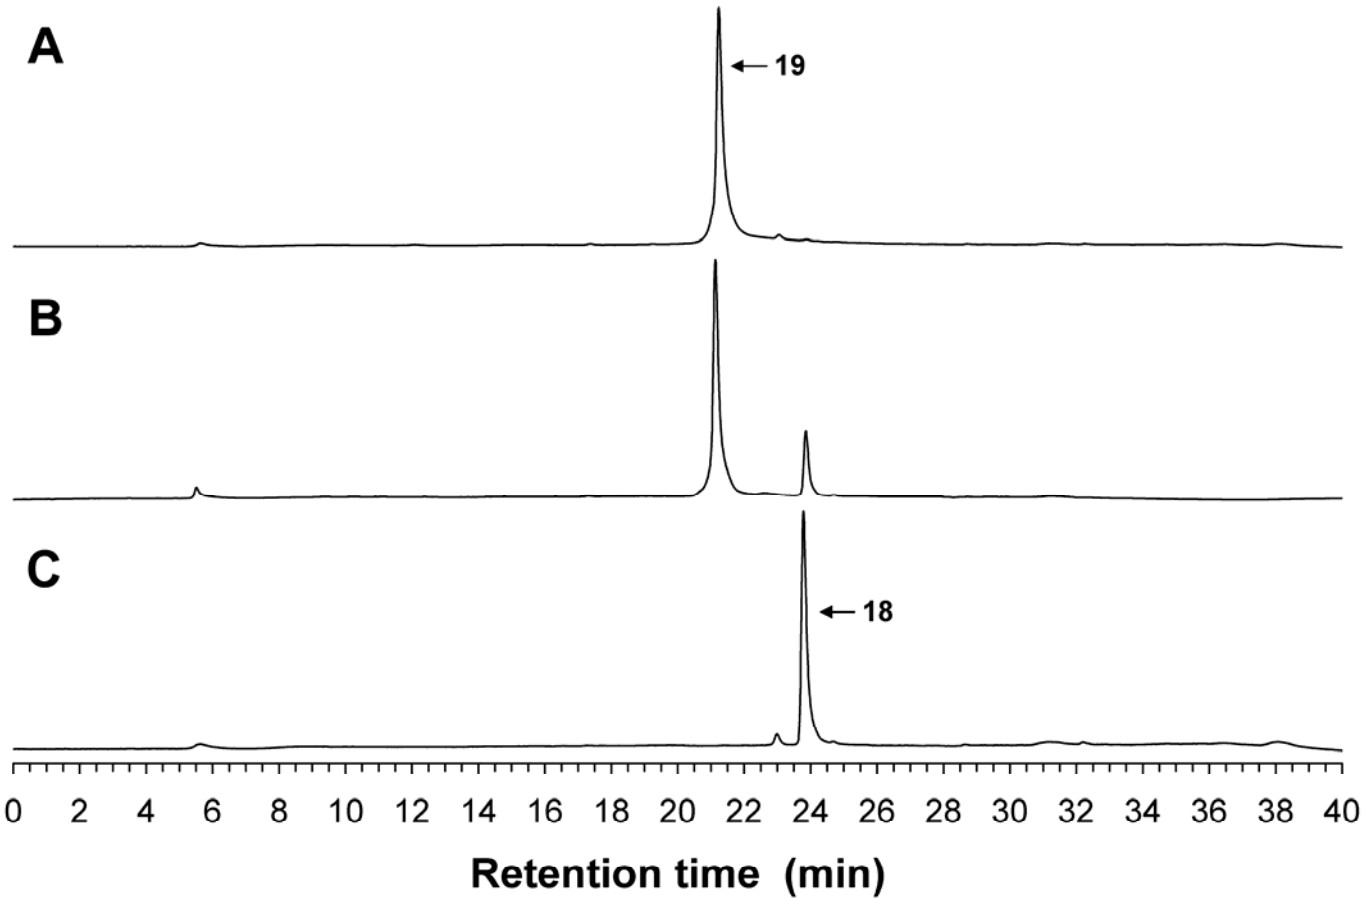

CHART 4. RP-HPLC analysis of the conversion of the (5',3')-heteroconjugated DNA oligonucleotide **18** to the circular DNA oligonucleotide **19** under "click chemistry" conditions. **A:** RP-HPLC-purified circular DNA oligonucleotide **19** (MALDI-TOF MS: calcd for $C_{209}H_{249}N_{79}O_{125}P_{21}$ $(M–H)^-$ 6517, found 6521). **B:** Chromatogram of a co-mixture of RP-HPLC-purified **19** and **18** (4:1). **C:** RP-HPLC-purified (5',3')-heteroconjugated DNA oligonucleotide **18** (MALDI-TOF MS: calcd for $C_{209}H_{249}N_{79}O_{125}P_{21}$ $(M–H)^-$ 6517, found 6522). RP-HPLC analyses were performed under conditions identical to those described in the legend of Enlarged Figure 2.

Thermolytic Release of Covalently Linked DNA Oligonucleotides and Their Conjugates from Controlled-Pore Glass at Near Neutral pH†

Received May 12, 2008; Revised Manuscript Received June 5, 2008

The functionalization of long chain alkylamine controlled-pore glass (CPG) with a 3-hydroxypropyl-(2-cyanoethyl)thiophosphoryl linker and its conversion to the support **7** has led to the synthesis of DNA oligonucleotides and their 3′- or (3′,5′)-conjugates. Indeed, CPG support **7** has been successfully employed in the synthesis of both native and fully phosphorothioated DNA 20-mers. Unlike conventional succinylated CPG supports, this distinctively functionalized support allows oligonucleotide deprotection and removal of the deprotection side products to proceed without releasing the oligonucleotide into the aqueous milieu. When freed from deprotection side products, the DNA oligonucleotide is thermolytically released from the support within 2 h under nearly neutral conditions (pH 7.2, 90 °C). The quality of these oligonucleotides is comparable to that of identical oligonucleotides synthesized from succinylated CPG supports in terms of shorter than full length oligonucleotide contaminants and overall yields. The versatility of the thermolytic CPG support **7** is further demonstrated by the synthesis of a DNA oligonucleotide (20-mer) and its conjugation with an azido and alkynyl groups at both 5′-and 3′-termini, respectively. The functionality of the (3′,5′)-heteroconjugated oligonucleotide **18** is verified by its circularization to the DNA oligonucleotide **19** under "click" chemistry conditions.

INTRODUCTION

Solid supports have revolutionized the synthesis of natural products such as peptides (*1, 2*), oligonucleotides (*3–6*), and carbohydrates (*7, 8*), and that of organic compounds through the development of combinatorial chemistries (*9*). The functionality of solid-supported syntheses is however critically dependent on the design and implementation of linkers for the covalent attachment of organic building blocks to solid supports (*10*). When employed in the solid-phase synthesis of oligonucleotides and their analogues or conjugates, the solid support must be functionalized efficiently with a linker designed to allow synthesis to proceed while maintaining the availability of both 5′- and 3′-terminal hydroxyls for subsequent conjugation with various functional groups. The junction linker-to-oligonucleotide and linker-to-support should ideally be stable to the reagents and conditions used during oligonucleotide synthesis and conjugation in addition to those employed for oligonucleotide deprotection. Such an attribute would facilitate the removal of side products resulting from the cleavage of nucleobase and phosphate/thiophosphate protecting groups, including those generated from terminal 5′-/3′-hydroxyl and/or functional group deprotection, by simply washing the solid support. Release of the oligonucleotide, its conjugate or analogue, from the solid support would be effected under mild and neutral thermolytic conditions, free from side products. To the best of our knowledge, the thermolytic release of oligonucleotides with free 5′- and 3′-hydroxyls from solid supports under nearly neutral conditions has not, as yet, been described in the literature. Given that modified oligonucleotides and their conjugates are valuable tools for mechanistic investigations and for therapeutic or diagnostic applications (*11–13*), we have instigated the use of versatile supports designed to enable the preparation of oligonucleotides, conjugated or not with functional groups at either the 3′-terminus or both 3′- and 5′-termini. Specifically, nucleoside or dinucleotide precursors are covalently linked to long chain alkylamine controlled-pore glass (CPG) through either a 3′- or an internucleotidic phosphotriester function. After synthesis and deprotection, release of the oligonucleotides from the support is triggered by a thermolytic intramolecular cyclodeesterification reaction (*14*) in an aqueous buffer at pH 7.2. Details regarding the functionalization of CPG and the thermolytic release of dinucleotide models are outlined in Schemes 1 and 2, respectively. The solid-phase synthesis and thermolytic release of native and modified DNA oligonucleotides in addition to oligonucleotides conjugated with functional groups at the 3′-terminus or at both 3′-and 5′-termini are also described in this report.

EXPERIMENTAL PROCEDURES

Preparation of Functionalized CPG Support 3. CPG (500 Å, 500 mg) was suspended in Et_3N/MeCN (1:1 v/v, 2 mL) in a 4 mL glass vial and was manually agitated over a period of 2 min. The suspension was vacuum-filtered using a glass sintered funnel of coarse porosity. The CPG support was washed with MeCN (10 mL) and then dried under vacuum (3 min). The support was transferred to an 8 mL glass vial, which was stoppered with a rubber septum. The vial and its contents were flushed with a flow of dry argon prior to sequentially adding, by syringe, a solution of *O*-(2-cyanoethyl)-*O*-[3-(4,4′-dimethoxytrityl)oxy-1-propyl]-*N*,*N*-diisopropylphosphoramidite (**1**, 250

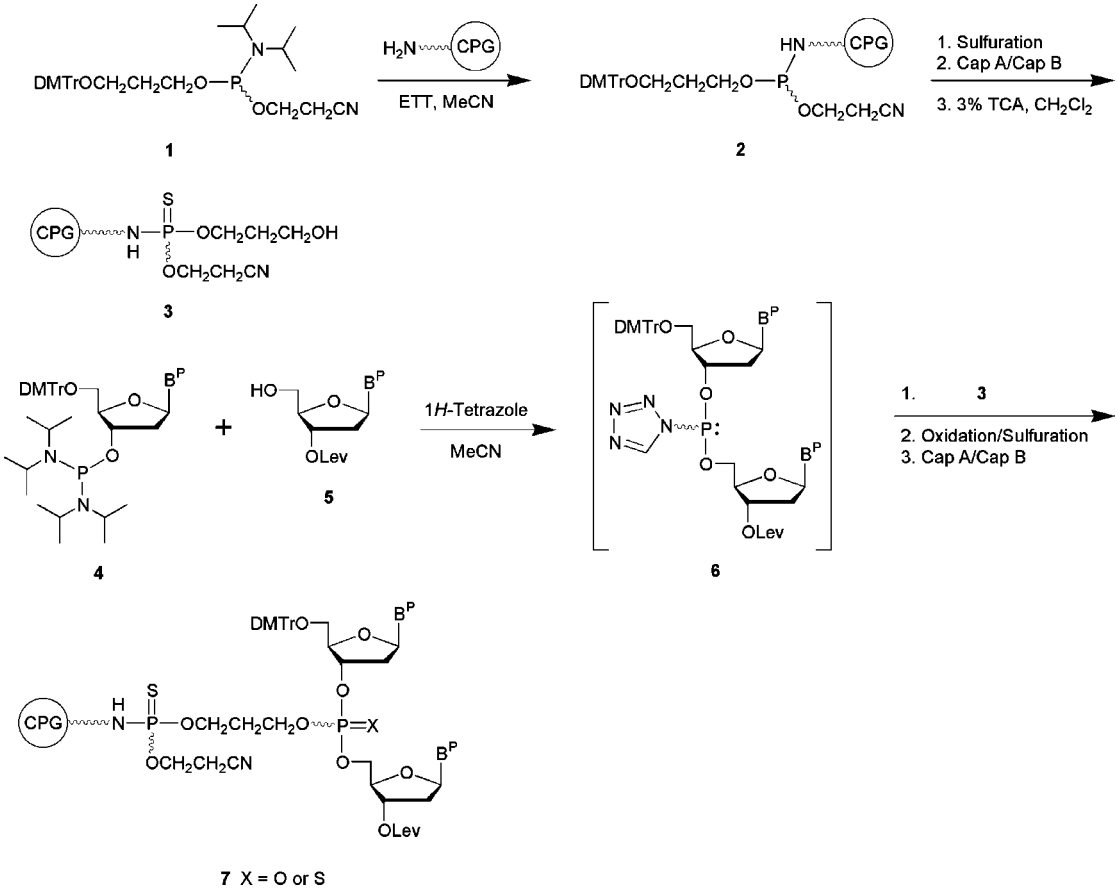
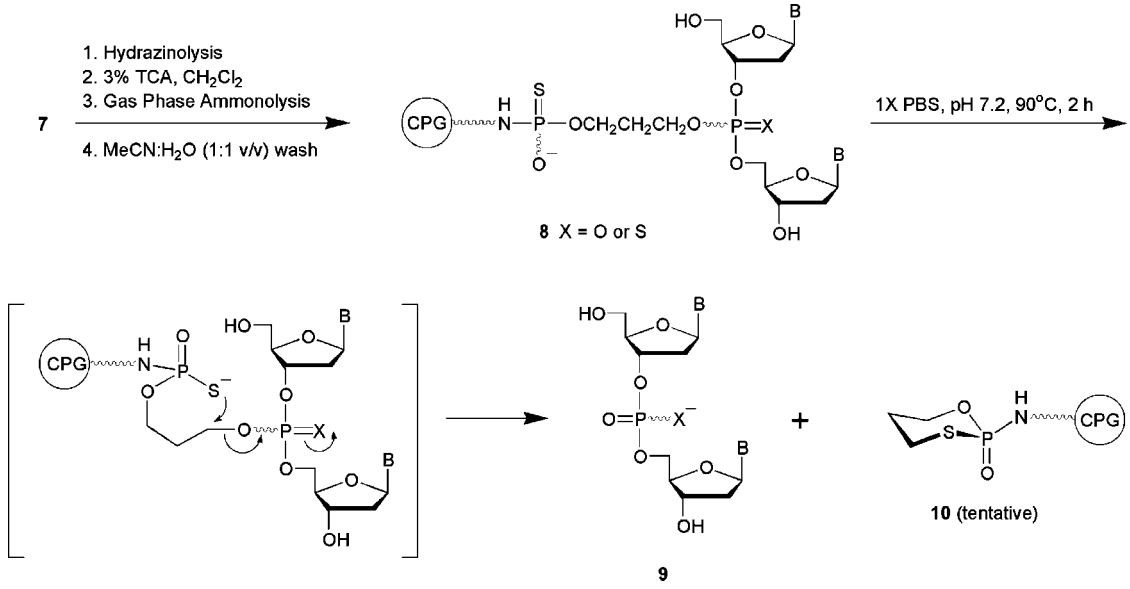
Scheme 1. Preparation of CPG Support 3 and Its Conversion to Support 7[a]



[a] Keys: DMTr, 4,4′-dimethoxytrityl; CPG, 500 Å long chain alkylamine controlled-pore glass; ETT, 5-ethylthio-1*H*-tetrazole; Cap A, acetic anhydride/pyridine/THF; Cap B, 10% 1-methylimidazole in THF; TCA, trichloroacetic acid; B^P, Thy (thymin-1-yl), Cyt^{Bz} (N^4-benzoylcytosin-1-yl), Ade^{Bz} (N^6-benzoyladenin-9-yl), or Gua^{iBu} (N^2-isobutyrylguanin-9-yl); Lev, levulinyl.

Scheme 2. Thermolytic Release of Dinucleoside Phosphate/Thiophosphate Diesters from CPG Support 8[a]



[a] Keys: B, thymin-1-yl, cytosin-1-yl, adenin-9-yl or guanin-9-yl; PBS, phosphate buffered saline.

mg, 0.43 mmol) in dry MeCN (1.2 mL) and 0.25 M 5-ethylthio-1*H*-tetrazole in dry MeCN (3.2 mL, 0.80 mmol). The suspension was agitated, manually, for 15 min under a positive pressure of argon and filtered under vacuum using a glass sintered funnel of medium porosity. The CPG support **2** was washed with MeCN (10 mL) and exposed, while in the funnel, to 0.1 M 3*H*-1,2-benzodithiol-3-one 1,1-dioxide (5 mL) for 15 min. Excess sulfuration reagent was removed from the support by vacuum filtration. The functionalized CPG support was washed with MeCN (10 mL) and was then suspended in a solution of Cap A (THF/pyridine/Ac_2O, 2.5 mL) and Cap B (1-methylimidazole/THF, 2.5 mL) for a period of 10 min. Excess capping

reagents was removed by filtration; the support was washed with MeCN (10 mL) and dried under vacuum. Dedimethoxytritylation of the support by treatment with 3% TCA (trichloroacetic acid) in CH_2Cl_2 (3 mL, 3 min) afforded the functionalized CPG support **3**. Spectrophotometric determination of the 4,4′-dimethoxytrityl cation at 498 nm revealed a hydroxyl concentration of 69 μmol/g of **3**.

General Procedure for the Preparation of Deoxyribonucleoside Phosphorodiamidites (4) (*15*). A 5′-*O*-(4,4′-dimethoxytrityl)-2′-deoxyribonucleoside (T, C^{Bz}, A^{Bz}, or G^{iBu}, 2.0 mmol) was dried by coevaporation with anhydrous pyridine (3 × 10 mL) under reduced pressure and was finally dissolved in a solution of anhydrous CH_2Cl_2 (15 mL) and *i*-Pr_2NEt (3.48 mL, 20.0 mmol). To the stirred solution was added bis((*N*,*N*-diisopropylamino)chlorophosphine (587 mg, 2.20 mmol). Progress of the reaction was monitored by TLC, which showed complete phosphinylation within 2 h at ∼25 °C. The reaction was quenched upon addition of water (15 mL); the mixture was vigorously stirred for ∼5 min prior to being transferred to a separatory funnel. The organic layer was collected and rotoevaporated to an oil under reduced pressure. The material was dissolved in a minimal amount (∼4 mL) of benzene/Et_3N (9:1, v/v) and loaded onto the top of a column packed with silica gel (∼30 g) pre-equilibrated in benzene/Et_3N (9:1, v/v). Elution of the reaction product was achieved using benzene/Et_3N (9:1, v/v) as the eluent. Fractions containing the product were identified by TLC and were pooled together. The solvent was removed by rotoevaporation under reduced pressure to afford the phosphoramidite **4** as a white foam. The material was dissolved in dry benzene (10 mL) and the resulting solution was frozen in a dry ice−acetone bath. The frozen solution was then lyophilized under high vacuum for ∼16 h to give triethylamine-free **4** as a white powder in yields of 85−95%.

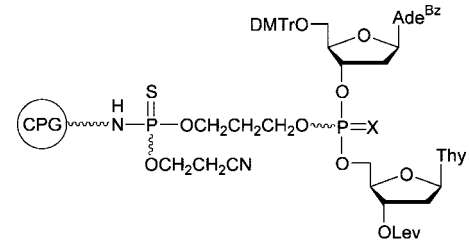
General Procedure for Preparation of Dinucleoside Phosphorotetrazolide Intermediates (6) in Situ and for Their Covalent Attachment to CPG Support 3. Phosphorodiamidite **4** (B^P = Thy, Cyt^{Bz}, Ade^{Bz}, or Gua^{iBu}, 50 μmol), 3′-*O*-levulinyl-2′-deoxyribonucleoside **5** (B^P = Thy, Cyt^{Bz}, Ade^{Bz}, or Gua^{iBu}, 50 μmol), and sublimed 1*H*-tetrazole (11 mg, 150 μmol) were placed in a flame-dried 4 mL glass vial, which was stoppered with a rubber septum and purged with a flow of dry Argon. Anhydrous MeCN (300 μL) was syringed into the vial through the rubber septum. The coupling reaction was allowed to proceed over a period of 10 min at ~25 °C to generate the putative dinucleoside phosphorotetrazolide intermediate **6** (*16*). The reaction mixture was withdrawn from the vial and through a synthesis column filled with CPG support **3** (14.5 mg, 1 μmol) using a luer-tipped syringe connected to one end of the synthesis column and a 16-G hypodermic needle connected to the other end of the synthesis column. The coupling reaction was performed for a period of 10 min. Excess reagent was expelled from the column, which was washed with a solution of 20% 1-methylimidazole in H_2O/MeCN (1:1 v/v) for 2 min. An oxidation reaction was carried out using either 0.05 M 3*H*-1,2-benzodithiol-3-one 1,1-dioxide in MeCN or 0.02 M I_2 in THF/pyridine/H_2O for 2 min. Unreacted hydroxyl groups of support **3** were acylated when exposed to Cap A and Cap B solutions (1 mL each) for 2 min. Excess capping reagents was removed from CPG support **7** by washing with MeCN (10 mL). Spectrophotometric determination (498 nm) of the 4,4′-dimethoxytrityl cation released from **7** under acidic conditions revealed a dinucleoside phosphate triester concentration of 40 μmol/g of support.

General Procedure for the Automated Solid-Phase Synthesis of DNA Oligonucleotides Using CPG Support 7. Solid-phase synthesis of native and phosphorothioated DNA oligonucleotides was performed on a 0.2 μmol scale using a DNA/RNA synthesizer and 2-cyanoethyl deoxyribonucleoside phosphoramidites as 0.1 M solutions in dry MeCN. The reagents and conditions employed for solid-phase synthesis were those recommended by the instrument's manufacturer. However, the preparation of fully thioated oligodeoxyribonucleotides required replacement of the iodine oxidation step in the synthesis cycle with a sulfuration step employing a 0.05 M solution of 3*H*-1,2-benzodithiol-3-one 1,1-dioxide in MeCN, as recommended in the literature (*17, 18*). The capping step was performed before the oxidation step when synthesizing native DNA oligonucleotides and after the sulfuration step when synthesizing phosphorothioated DNA oligonucleotides.

General Procedure for Deprotection, Thermolytic Release, and RP-HPLC Analysis of DNA Oligonucleotides Synthesized from CPG Support 7. 5′-*O*-Dedimethoxytritylated DNA oligonucleotides that were synthesized using CPG support **7** on a 0.2 to 1 μmol scale were subjected to pressurized ammonia gas (~10 bar) for 16 h at 25 °C (*19*) to remove the nucleobase, phosphate/thiophosphate, and 3′-*O*-levulinyl protecting groups. The solid support was washed with 50% aqueous MeCN (1 mL) to eliminate the deprotection side product and was air-dried. The CPG support was transferred to a 4 mL



7 X = O or S

screw-capped glass vial to which was added 1 × PBS (pH 7.2, 0.5 mL); the suspension was heated for 2 h at 90 ± 2 °C. The purity of each unpurified native or phosphorothioated DNA oligonucleotide released in the aqueous buffer was assessed by RP-HPLC and compared with that of identical oligonucleotides prepared from unmodified CPG supports (data shown in Figures 1 and 2). Typically, an aliquot (20 μL) of the PBS solution of each native DNA oligonucleotide was analyzed using a 5 μm Supelcosil LC-18S column (25 cm × 4.6 mm) according to the following conditions: starting from 0.1 M triethylammonium acetate pH 7.0, a linear gradient of 0.7% MeCN/min was pumped at a flow rate of 1 mL/min for 30 min and was followed by a linear gradient of 4% MeCN/min for 5 min, which was held isocratically for 5 min.

An aliquot (60 μL) of the PBS solution of each unpurified phosphorothioated DNA oligonucleotide was analyzed under conditions similar to those used for the native DNA oligonucleotide with the following modification: starting from 0.1 M triethylammonium acetate pH 7.0, a linear gradient of 1% MeCN/min was pumped at a flow rate of 1 mL/min for 40 min. Peak heights were all normalized to the highest peak, which was set to 1 arbitrary unit.

5′-d(CGACTGTGAATCGATGCCAT) [MALDI-TOF MS]: Calcd for $C_{195}H_{227}N_{75}O_{118}P_{19}$ $(M-H)^-$ 6097, found 6102.

5′-d($C_{PS}G_{PS}A_{PS}C_{PS}T_{PS}G_{PS}T_{PS}G_{PS}A_{PS}A_{PS}T_{PS}C_{PS}G_{PS}A_{PS}T_{PS}G_{PS}C_{PS}C_{PS}A_{PS}T$) [MALDI-TOF MS]: Calcd for $C_{195}H_{227}N_{75}O_{99}P_{19}S_{19}$ $(M-H)^-$ 6402, found 6406.

Polyacrylamide Gel Electrophoresis Analysis of DNA Oligonucleotides Synthesized from CPG Support 7. To each unpurified native or phosphorothioated DNA oligonucleotide (0.25 OD_{260}) in a 1.5 mL microfuge tube was added 10 μL of Loading Buffer (10 × Tris Borate EDTA, pH 8.3, in formamide (1:4 v/v) containing 2 mg/mL bromophenol blue). The dark blue solution was vortexed vigorously and centrifuged at 16 000*g* for 5 s. Each DNA solution was syringed into a 2 cm wide well of a 20% polyacrylamide−7 M urea gel (20 cm × 40 cm × 0.75 mm). Electrophoresis was performed at 350 V, using 1 × Tris Borate EDTA (pH 8.3) as the electrolyte, until the bromphenol blue dye traveled 75% of the gel's length. The gel was immersed in a staining solution (250 mL) composed of formamide/isopropyl alcohol/ddH_2O (1:5:20 v/v/v) to which was added a solution (10 mL) of Stains-all (1 mg/mL) in formamide. The gel was stained for ~4 h in the dark. The staining solution was discarded and the gel was rinsed three times with 250 mL distilled water. The gel was exposed to natural light until the purple background disappeared. The native DNA oligonucleotides were visualized as sharp blue bands, whereas fully phosphorothioated DNA oligonucleotides appeared as dark purple bands. Photographs of the gels are shown in Figure 3.

Hydrolysis of Native DNA Oligonucleotides Catalyzed by Snake Venom Phosphodiesterase and Bacterial Alkaline Phosphatase. To 1.0 OD_{260} of lyophilized oligonucleotide was added 1 M Tris·HCl (pH 9.0, 6 μL), 1 M $MgCl_2$ (8 μL), ddH_2O to a total volume of 89 μL, snake venom phosphodiesterase (*Crotallus adamanteus*, 5 μL, 2 U/mL), and bacterial alkaline

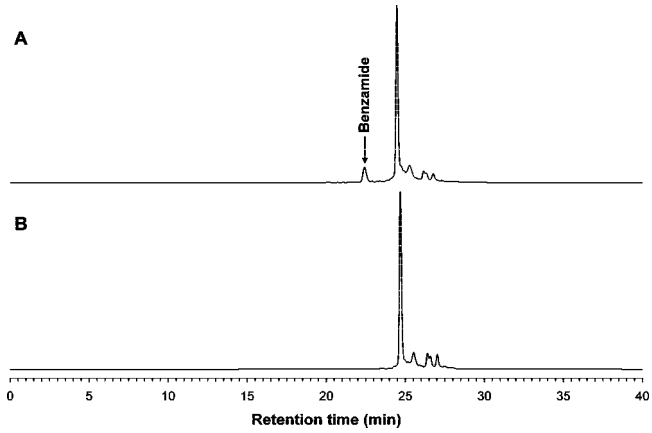


Figure 1. RP-HPLC analysis of unpurified 5′-d(CGACTGTGAATC-GATGCCAT). (A) Chromatogram of the native 20-mer that was synthesized employing unmodified CPG under standard conditions. Nucleobase and phosphate deprotection, and release of the oligomer from the support were effected by treatment with pressurized NH_3 gas (~10 bar) for 16 h at 25 °C, as described in the Experimental Procedures section. (B) Chromatogram of the 20-mer that was synthesized using CPG support **7** under standard conditions. After nucleobase and phosphate deprotection under the conditions described in (A), the deprotection side products were washed away from the modified CPG support with MeCN:H_2O (1:1 v/v). The 20-mer was thermolytically cleaved from the support upon heating at 90 °C in 1 × PBS (pH 7.2) for 2 h. Chromatographic conditions are described in the Experimental Procedures section.

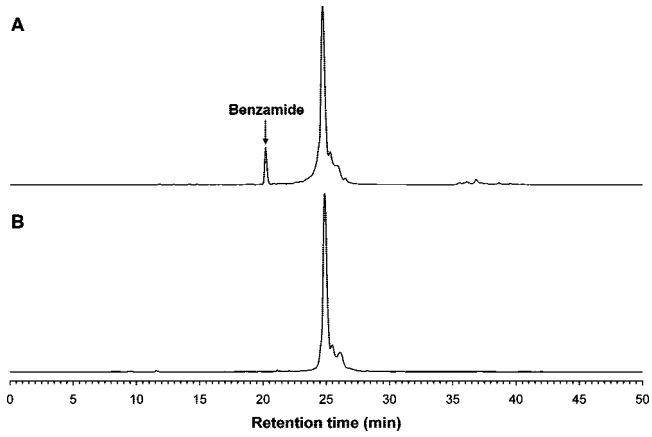

Figure 2. RP-HPLC analysis of unpurified 5′-d($C_{PS}G_{PS}A_{PS}C_{PS}T_{PS}G_{PS}$-$T_{PS}G_{PS}A_{PS}A_{PS}T_{PS}C_{PS}G_{PS}A_{PS}T_{PS}G_{PS}C_{PS}C_{PS}A_{PS}T$). (A) Chromatogram of the fully phosphorothioated 20-mer that was synthesized employing unmodified CPG under standard conditions. Nucleobase and thiophosphate deprotection was effected by treatment with pressurized NH_3 gas (~10 bar) over a period of 16 h at 25 °C, as described in the Experimental Procedures section. (B) Chromatogram of the 20-mer that was synthesized using CPG support **7** under standard conditions. After nucleobase and thiophosphate deprotection under the conditions described in (A), the deprotection side products were washed away from the modified CPG support with MeCN:H_2O (1:1 v/v). The 20-mer was thermolytically cleaved from the support upon heating at 90 °C in 1 × PBS (pH 7.2) for 2 h. Chromatographic conditions are described in the Experimental Procedures section.

phosphatase (6 μL, 0.7 U). The digestion reaction was heated for 16 h in a water bath kept at 37 °C. The digest was finally heated at 100 °C for 1 min to denature the enzymes and was centrifuged at 16 000*g* for 2 min prior to immediate analysis by RP-HPLC. The analysis was performed using a 5 μm Supelcosil LC-18S column (25 cm × 4.6 mm) according to the following conditions: starting from 0.1 M triethylammonium acetate pH 7.0, a linear gradient of 1% MeCN/min is pumped

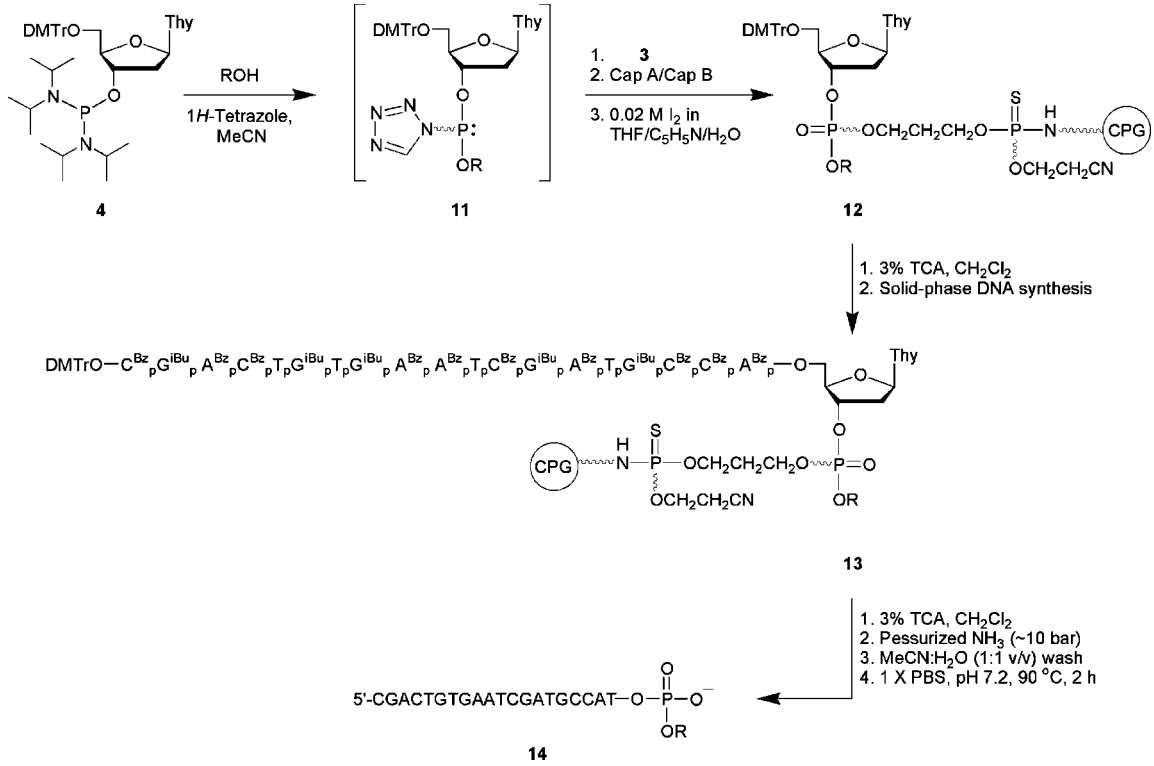
Figure 3. (B) Left lane: electrophoretic profile of the fully phosphorothioated 20-mer that was synthesized employing unmodified CPG and deprotected under standard conditions, as described in the legend of Figure 2. Right lane: electrophoretic profile of the fully phosphorothioated 20-mer that was synthesized using the CPG support **7** under standard conditions and deprotected as recommended in the legend of Figure 2. Electrophoretic conditions are described in the Experimental Procedures section.

at a flow rate of 1 mL/min for 40 min. Peak heights were normalized to the highest peak, which was set to 1 arbitrary unit.

Preparation of CPG-Linked Nucleotide 12. Phosphorodiamidite **4** (B^P = T, 39 mg, 50 μmol), 1-pyrenebutanol (14 mg, 50 μmol), and sublimed 1*H*-tetrazole (11 mg, 150 μmol) were placed in a flame-dried 4-mL glass vial, which was stoppered with a rubber septum and purged with a flow of dry argon. Anhydrous MeCN (300 μL) was syringed into the vial through the rubber septum. The coupling reaction was allowed to proceed for 10 min at ~25 °C to generate the deoxyribonucleoside phosphorotetrazolide intermediate **11** (Scheme 3.) The condensation of **11** with the CPG support **3** (29 mg, 2 μmol) and all subsequent processing steps were performed under conditions identical to those described above for the attachment of dinucleoside phosphorotetrazolide intermediates **6** to CPG support **3**. A fraction of CPG support **12** (2.6 mg, 0.1 μmol) was 5′-dedimethoxytritylated by treatment with 3% TCA in CH_2Cl_2 (3 mL, 3 min), washed with MeCN (10 mL), and suspended in 1 × PBS (pH 7.2, 0.5 mL). The suspension was heated for 2 h at 90 ± 2 °C. The RP-HPLC profile of thymidine 3′-*O*-(1-pyrenylbutyl)phosphate is presented in the Supporting Information.

Preparation of CPG-Linked Oligonucleotide 13. 5′-Dedimethoxytritylation of the support-linked deoxyribonucleoside phosphate triester **12** (26 mg, 1 μmol) was effected by slowly pushing 3% TCA in CH_2Cl_2 (3 mL) through the synthesis column over a period of 3 min. Automated solid-phase oligonucleotide synthesis leading to the CPG-linked oligonucleotide **13** (Scheme 3) was carried out according to the general procedure described above when employing CPG support **7**.

Scheme 3. Preparation of CPG Support 13 for the Solid-Phase Synthesis of DNA Oligonucleotide 3′-Conjugates[a]



[a] Keys: R, 1-pyrenebutyl; p, 2-cyanoethyl phosphoryl.

Oligonucleotide deprotection and thermolytic release from the CPG support were performed following the general procedure described above for DNA oligonucleotides synthesized from CPG support **7**. The purity of the 3′-pyrenylated DNA oligonucleotide conjugate **14** was greater than 90%, as determined by RP-HPLC (data shown in the Supporting Information). The identity of unpurified and desalted **14** was confirmed by MALDI-TOF MS: Calcd for $C_{215}H_{243}N_{75}O_{121}P_{20}$ $(M-H)^-$ 6432, found 6437.

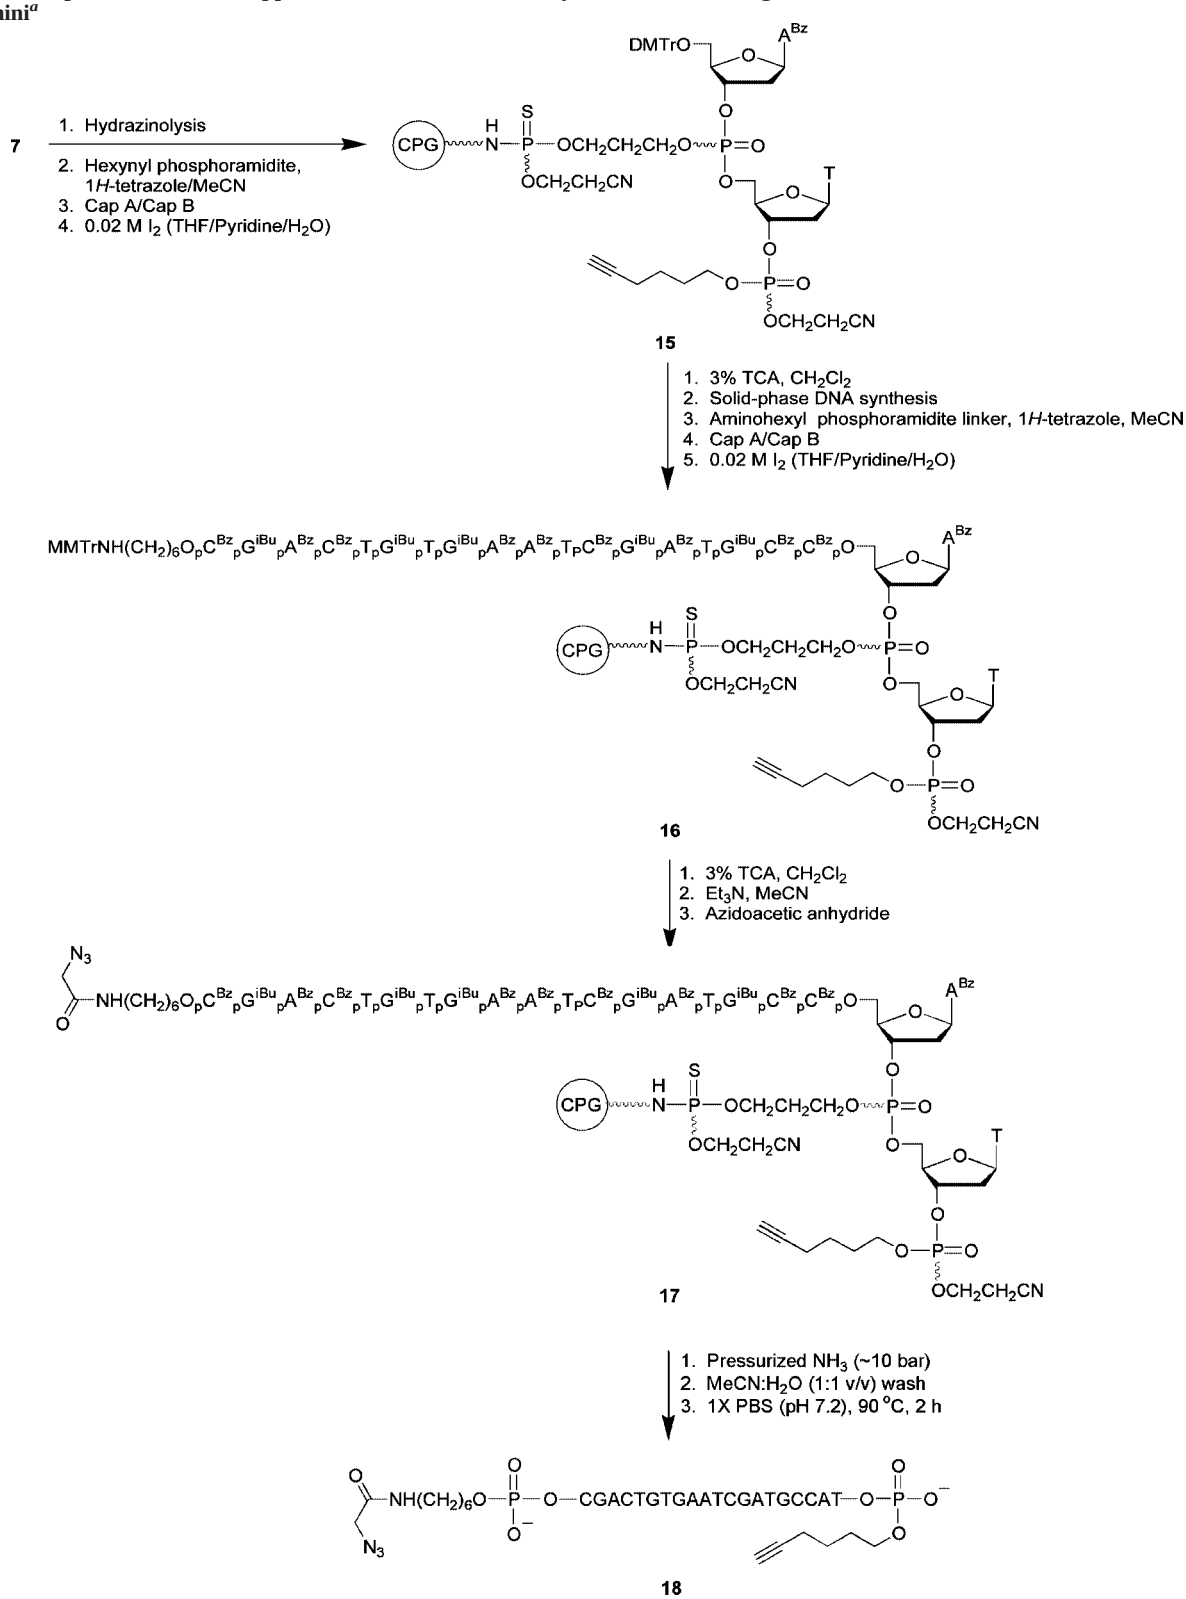
Preparation of CPG-Linked Dinucleotide 15. A solution of 0.5 M hydrazine hydrate in pyridine/acetic acid (3:2 v/v, 2 mL) was pushed through a synthesis column, packed with the support-linked dinucleoside phosphate triester **7** (0.2 μmol), for a period of 30 min to completely remove the 3′-*O*-levulinyl group. Dry MeCN (20 mL) was flushed through the support by syringe to carefully eliminate residual hydrazinolysis reagents and side-product. A premixed solution of 0.1 M *O*-(2-cyanoethyl)-*O*-(5-hexyn-1-yl)-*N*,*N*-diisopropylphosphoramidite (10 μmol) and 0.45 M 1*H*-tetrazole (67 μmol) in dry MeCN was syringed into the synthesis column. The suspension was manually agitated for 3 min. Excess reagents were discarded with MeCN (10 mL) and a premixed solution of Cap A and Cap B reagents (1 mL each) were syringed through the synthesis column. After a total exposure time of 1 min, the capping reagents were replaced with a solution of 0.02 M iodine in THF/pyridine/H_2O (1 mL). An oxidation time of 1 min was sufficient to complete the preparation of the CPG-linked dinucleotide **15** (Scheme 4).

Preparation of CPG-Linked DNA Oligonucleotide 16. 5′-Dedimethoxtritylation of the CPG-linked dinucleotide **15** was carried out by treatment with 3% TCA in CH_2Cl_2 (3 mL) for 3 min. A 4 mL glass vial containing 0.1 M *O*-(2-cyanoethyl)-*O*-[6-(4-methoxytrityl)amino-1-hexyl]-*N*,*N*-diisopropylphosphoramidite in dry MeCN was connected to the synthesizer at position #5 and was incorporated as such into the DNA synthesis program. The automated solid-phase oligonucleotide synthesis was achieved according to the general procedure delineated above when using CPG support **7**.

Preparation of CPG-Linked DNA Oligonucleotide 17. Removal of the terminal 4-methoxytrityl group from **16** was achieved by passing 3% TCA in CH_2Cl_2 (10 mL) through the synthesis column for a period of 10 min. Excess acid was eliminated from the column with an acetonitrile wash (20 mL) followed by a brief (30 s) Et_3N-MeCN (1:1 v/v) wash (3 mL). The resulting free terminal amino group was acylated with a solution (0.5 mL) of azidoacetic anhydride/pyridine/THF (1:1:8 v/v/v) and Cap B (0.5 mL) to produce the CPG-linked DNA oligonucleotide **17** (Scheme 4). Azidoacetic anhydride was prepared in situ from azidoacetic acid (202 mg, 2.00 mmol) and *N*,*N*′-dicyclohexylcarbodiimide (217 mg, 1.05 mmol) in dry THF (3 mL) under conditions similar to those reported for the preparation of levulinic anhydride (*20*). Oligonucleotide deprotection and thermolytic release from the CPG support were performed following the general procedure described above for DNA oligonucleotides synthesized from the CPG support **7**. The (3′,5′)-heteroconjugated DNA oligonucleotide **18** was RP-HPLC purified using the chromatographic conditions outlined above for the analysis of phosphorothioated DNA oligonucleotides; the RP-HPLC profile of **18** is shown in the Supporting Information. Identity of the desalted oligonucleotide **18** was corroborated by MALDI-TOF MS: Calcd for $C_{209}H_{249}N_{79}O_{125}P_{21}$ $(M-H)^-$ 6517, found 6522.

Conversion of Oligonucleotide 18 to Circular DNA Oligonucleotide 19. The circularization of the DNA oligonucleotide **18** was performed essentially as reported by Kumar et al. (*21*). To a solution of *tris*(benzyltriazolylmethyl)amine (1.4 μmol), sodium ascorbate (2.0 μmol), and $CuSO_4 \cdot 5H_2O$ (0.2 μmol) in 0.2 M NaCl (2.4 mL) was added **18** (5 nmol) in 0.2 M NaCl (100 μL). The reaction mixture was left standing at 25 °C for 2 h and was desalted through

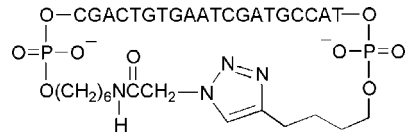
Scheme 4. Preparation of CPG Support 15 for the Solid-Phase Synthesis of DNA Oligonucleotide Functionalized at Both 5′- and 3′-Termini[a]



[a] Keys: MMTr, 4-methoxytrityl.

a PD-10 (Sephadex G-25M) column. The crude circular DNA oligonucleotide **19** was RP-HPLC purified under chromatographic conditions similar to those employed for the analysis of phosphorothioated DNA oligonucleotides. The RP-HPLC profile of the purified circular DNA oligonucleotide **19** is shown in the Supporting Information. The RP-HPLC retention time of **19** (t_R = 21.2 min) is shorter than that of **18** (t_R = 23.8 min) but, as expected, the molecular weight of **19**

(MALDI-TOF MS: Calcd for $C_{209}H_{249}N_{79}O_{125}P_{21}$ $(M-H)^-$ 6517, found 6521) is identical to that of **18**.



19

RESULTS AND DISCUSSION

Functionalization of CPG through 3-Hydroxypropyl Thiophosphoramidation. The amino groups of long chain alkylamine controlled-pore glass (CPG) were first activated by treatment with a solution of Et_3N in MeCN prior to reaction with a 36 mM solution of *O*-(2-cyanoethyl)-*O*-[3-(4,4′-dimethoxytrityl)oxy-1-propyl]-*N*,*N*-diisopropylphosphoramidite (**1**) and 0.25 M 5-ethylthio-1*H*-tetrazole in dry MeCN. The functionalized support **2** (Scheme 1) was washed with MeCN to remove excess reagents and was immersed into a 0.1 M solution of 1,2-benzodithiol-3-one 1,1-dioxide to oxidize the phosphoramidite entity to a thiophosphoramidate function. The unreacted amino groups of CPG were deactivated upon *N*-acetylation with an equal volume of each of the Cap A (THF/pyridine/Ac_2O) and Cap B (1-methylimidazole/THF) solutions. Subsequent dedimethoxytritylation of the support **2** under acidic conditions revealed an essentially quantitative functionalization of CPG based on an hydroxyl concentration of 69 μmol/g of **3**, which was determined by the standard trityl assay.

Attachment of Leader Dinucleoside Phosphate/Thiophosphate to CPG Support 3. The conversion of CPG support **3** to CPG support **7** began with the preparation of the deoxyribonucleoside phosphorodiamidites **4** (Scheme 1), which was reported in the literature more than 20 years ago (*15*). Typically, a 5′-*O*-(4,4′-dimethoxytrityl)-2′-deoxribonucleoside (B^P = Thy, Cyt^{Bz}, Ade^{Bz}, or Gua^{iBu}) was condensed with bis(*N*,*N*-diisopropylamino)chlorophosphine and *N*,*N*-diisopropylethylamine in anhydrous CH_2Cl_2. Complete phosphinylation was accomplished within 2 h, whereupon the crude reaction product was subjected to aqueous extractive workup and subsequent purification by chromatography on silica gel. It was necessary to equilibrate silica gel in benzene/Et_3N (9:1 v/v) to neutralize its inherent acidity and prevent acid-mediated decomposition of the reaction product. The phororodiamidites **4** were isolated as white foams, which were freed from residual moisture and Et_3N by lyophilization from dry benzene. However, depending on the variable amounts of residual moisture and Et_3N contaminating the purified phosphorodiamidites **4**, it is often preferable to precipitate **4** in cold (−78 °C) hexanes followed by lyophilization of the white precipitates from dry benzene to ensure complete removal of these contaminants. Triethylamine-free **4** were obtained as white powders, the yields of which were in the range 85−95%. The phosphorodiamidites **4** were characterized extensively using one-dimensional ^1H, ^1H decoupled ^{13}C, ^1H and ^{31}P decoupled ^{13}C, and ^{31}P NMR techniques, which were complemented with two-dimensional $^1H-^1H$ total correlation (TOCSY) and $^1H-^{13}C$ correlation (HSQC) data, and accurate mass determination by atmospheric pressure electrospray ionization time-of-flight mass spectrometry (APESI-TOF MS). The selection of an appropriate solvent for NMR characterization of the diamidites **4** is critical; the stability of **4** in a nonpolar solvent, such as benzene, is considerably higher than that observed in the relatively polar DMSO. Thus, NMR analysis of the deoxyribonucleoside phosphorodiamidites **4** was carried out in deuterated benzene (C_6D_6). All characterization data are presented in the Experimental Procedures and Supporting Information sections of this report. When pure, each deoxyribonucleoside phororodiamidite **4** is stable for months at −20 °C.

When phosphorodiamidite **4** (B^P = Thy, Cyt^{Bz}, Ade^{Bz}, or Gua^{iBu}), 3′-*O*-levulinyl-2′-deoxyribonucleoside **5** (B^P = Thy, Cyt^{Bz}, Ade^{Bz}, or Gua^{iBu}), and sublimed 1*H*-tetrazole were mixed together in a respective molar ratio of (1:1:3) in anhydrous MeCN, the putative dinucleoside phosphorotetrazolide **6** (Scheme 1) was generated within 10 min. Without isolation, **6** was mixed with support **3** and was allowed to react for 10 min at ∼25 °C. The support was washed with 20% 1-methylimidazole in H_2O/MeCN (1:1 v/v) to cleave any nucleobase adducts that might have been formed during the coupling reaction. Exposure of the support to an oxidant, namely, 0.05 M 3*H*-1,2-benzodithiol-3-one 1,1-dioxide in MeCN or 0.02 M I_2 in THF/pyridine/H_2O gave CPG support **7** (Scheme 1). The unreacted hydroxyl groups of CPG support **3** were deactivated when reacted with equal volumes of Cap A and Cap B solutions. Under these conditions, the concentration of a dinucleoside phosphate/thiophosphate on CPG support **7** averaged 40 μmol/g of support, as determined by the standard trityl assay, and is comparable to the concentration of deoxyribonucleosides linked to unmodified CPG supports.

Deprotection and release of the dinucleoside phosphate/thiophosphate triester covalently attached to CPG support **7** was initiated to evaluate the purity of each of the sixteen combinatorial dinucleoside phosphorothioate diesters and that of two exemplary dinucleoside phosphate diesters (data shown in the Supporting Information). The deprotection steps included: (i) acid-mediated cleavage of the 5′-*O*-DMTr group and (ii) exposure to pressurized ammonia gas to deprotect the nucleobase, 3′-hydroxyl, and eliminate the 2-cyanoethyl group from the phosphorothioamidate linker. The deprotection side products were conveniently eliminated from the support by washing **8** (Scheme 2) with MeCN/H_2O (1:1 v/v). The support-bound dinucleoside phosphate/thiophosphate triester **8** also served as a model for assessing the thermolytic cleavage of oligonucleotides from the CPG support. The support **8** was suspended in 1 × phosphate buffered saline (PBS, pH 7.2) and the resulting suspension was heated in a closed vial at 90 °C for 2 h. This process induced a thermolytic intramolecular cyclodeesterification reaction (*14*, *22*–*28*) resulting in the release of the dinucleoside phosphate/thiophosphate diester **9** in the aqueous buffer, whereas the putative cyclodeesterification side product remained covalently linked to CPG support **10** (Scheme 2).

Reversed-phase high performance liquid chromatography (RP-HPLC) analysis of dinucleoside phosphate/thiophosphate diesters **9** revealed clean reaction products (data shown in the Supporting Information). The purity of the dinucleoside phosphorothioate and dinucleoside phosphate diesters exceeded 95% and 98%, respectively. These encouraging results prompted the solid-phase synthesis of the native DNA oligonucleotide 5′-d(CGACTGTGAATCGATGCCAT) and that of its fully phosphorothioated analogue 5′-d($C_{PS}G_{PS}A_{PS}C_{PS}T_{PS}G_{PS}T_{PS}G_{PS}A_{PS}A_{PS}T_{PS}C_{PS}G_{PS}A_{PS}T_{PS}G_{PS}C_{PS}C_{PS}A_{PS}T$) employing the thermolytic support **7**.

Solid-Phase Oligonucleotide Synthesis on CPG Support 7 and Thermolytic Release of DNA Oligonucleotides from the Modified CPG Support. Solid-phase synthesis of DNA oligonucleotides employing the thermolytic CPG support **7** and the conventional CPG support was carried out under standard conditions (see Experimental Procedures section). Oligonucleotides sharing identical DNA sequences were prepared to demonstrate comparability of the oligonucleotides produced from the two supports in terms of identity, purity, and overall yields. The DNA oligonucleotides synthesized through CPG support **7** and the unmodified CPG support were deprotected on exposure to pressurized ammonia gas at 25 °C (*19*). After

washing away the deprotection side products from the modified support, DNA oligonucleotides were thermolytically released from the support under the conditions outlined in Scheme 2. RP-HPLC analysis of the unpurified oligonucleotides released from the modified support confirmed the absence of deprotection side products (Figures 1B and 2B) when compared to oligonucleotides prepared from the unmodified CPG support showing contamination with benzamide, one of the deprotection side products (Figures 1A and 2A). The RP-HPLC retention times of either the two native oligonucleoside phosphate diesters or the two oligonucleoside phosphorothioate diesters were identical within experimental variability (Figures 1 and 2). The polyacrylamide gel electrophoresis (PAGE) profiles of the two 20-mers produced from the use of support **7** are comparable to those produced when employing the unmodified CPG support on the basis of the amounts of less than full-length oligonucleotides contaminating the DNA oligonucleotide products (Figure 3). Each unpurified oligonucleotide was also characterized by MALDI-TOF mass spectrometry; mass determination results were consistent with the DNA sequence of each oligonucleotide (see Experimental Procedures section).

The unpurified native oligonucleoside phosphate diesters synthesized from either support **7** or the unmodified CPG support were further characterized by treatment with snake venom phosphodiesterase and bacterial alkaline phosphatase. RP-HPLC analysis of the digests revealed the expected deoxyribonucleosides without detectable nucleobase modification. These results collectively demonstrate that the idendity, purity, and overall yield of DNA oligonucleotides synthesized through the thermolytic CPG support **7** are comparable to those of identical oligonucleotides prepared from an unmodified CPG support.

Solid-Phase Synthesis and Thermolytic Release of DNA Oligonucleotides Functionalized with Functional Groups at the 3′-Terminus or at Both 5′- And 3′-Termini. The functionalization of the 3′-terminus or both 5′- and 3′-termini of DNA oligonucleotides with various functional groups is useful in the preparation of bioconjugates or in applications where both termini are required to achieve a specific function. The functionalization of a DNA oligonucleotide (20-mer) synthesized through the use of CPG support **7** was attempted after hydrazinolysis of the 3′-terminal levulinyl group. Phosphinylation of the free 3′-hydroxyl group with a commercial fluorescein-labeled phosphoramidite was unsuccessful presumably due to intermolecular crowding near the surface of the support that is commensurate with the chain length of neighboring oligonucleotides. A convenient method for the functionalization of oligonucleotides at the 3′-terminus consisted of generating a deoxyribonucleoside phosphorotetrazolide functionalized with a ligand, in situ, and covalently attaching the modified phosphorotetrazolide to CPG support **3** (Scheme 3). The ligand must however be compatible with the conditions used during oligonucleotide synthesis, oligonucleotide deprotection, and thermolytic release of the oligonucleotide from the support. Typically, condensation of the deoxyribonucleoside phosphorodiamidite **4** (B^P = Thy) with and equimolar amount of 1-pyrenebutanol and 3 molar equiv of sublimed 1*H*-tetrazole in anhydrous MeCN resulted in the formation of the pyrenylated deoxyribonucleoside phosphorotetrazolide **11** (Scheme 3) within 10 min. The hydroxylated support **3** was mixed with **11** and was allowed to react for 10 min at ~25 °C. The functionalized CPG support **12** was obtained after treatment with 20% 1-methylimidazole in H_2O/MeCN (1:1 v/v) to cleave any nucleobase adducts that might have been formed during the coupling reaction, and after oxidation effected by 0.02 M I_2 in THF/pyridine/H_2O. The unreacted CPG support **3** was suspended in Cap A/Cap B (1:1 v/v) solutions to acetylate any free hydroxyls. 5′-Dedimethoxytritylation of **12** under acidic conditions and spectrophotometric determination of the 4,4′-dimethoxytrityl cation at 498 nm indicated that the concentration of the pyrenylated deoxyribonucleoside phosphate, covalently attached to the CPG support, was 38 μmol/g of **12**. A small fraction of the CPG support **12** was heated in 1 × PBS (pH 7.2) at 90 °C for 2 h to release thymidine 3′-*O*-(1-pyrenebutyl) phosphate, the identity and purity of which was demonstrated by RP-HPLC analysis at 260 and 340 nm (data shown in the Supporting Information). The characteristic UV absorptivity of 1-pyrenebutanol at 340 nm and the absence of absorptivity at 260 nm allows for the unambiguous identification of pyrenylated nucleic acid conjugates.

Solid-phase oligonucleotide synthesis employing the CPG support **12** was carried out on a 0.2 μmol scale using commercial deoxyribonucleoside 3′-phosphoramidites under standard conditions. After the final 5′-*O*-dedimethoxytritylation, oligonucleotide deprotection was initiated by exposing the solid support to pressurized ammonia gas to cleave the nucleobase and the 2-cyanoethyl phosphate protecting groups. Removal of the deprotection side products was effected by washing the CPG support with MeCN/H_2O (1:1 v/v). The support-linked oligonucleotide was heated in 1 × PBS (pH 7.2) at 90 °C for 2 h to release the DNA oligonucleotide conjugate **14**, the identity of which was confirmed by MALDI-TOF mass spectrometry. RP-HPLC profiles of **14** at 260 nm and at 340 nm confirmed the presence of the pyrenyl group in the conjugate and captured the purity of the pyrenylated DNA oligonucleotide, which was 78% based on total peak area at 260 nm (data shown in the Supporting Information).

The versatility of this approach to the preparation of DNA oligonucleotide 3′-conjugates enables one to employ a large variety of commercial hydroxylated ligands or functional groups in the synthesis of these biomolecules, thereby avoiding the restrictions created by the use of commercial supports functionalized with a limited number of ligands or functional groups.

Solid-Phase Synthesis and Thermolytic Release of DNA Oligonucleotides Conjugated with Functional Groups at the 3′-Terminus or at Both 5′- And 3′-Termini. CPG support **7** can also be employed in the solid-phase synthesis of DNA oligonucleotides conjugated with functional groups at both 5′- and 3′-termini (Scheme 4). Hydrazinolysis of **7** followed by condensation of the free 3′-hydroxyl group with *O*-(2-cyanoethyl)-*O*-(5-hexyn-1-yl)-*N*,*N*-diisopropylphosphoramidite and 1*H*-tetrazole in MeCN produced the corresponding 3′-phosphite. Unreacted 3′-hydroxyls were acylated when treated with the Cap A/Cap B solutions and oxidation of the 3′-phosphite to the desired CPG-support **15** was effected by a solution of 0.02 M I_2 in THF/pyridine/water. 5′-Dedimethoxytritylation of **15** was performed under acidic conditions and the solid-phase synthesis of an oligonucleotide sharing a DNA sequence identical to that of conjugate **13** was initiated. Phosphitylation of the terminal 5′-hydroxyl with *O*-(2-cyanoethyl)-*O*-[6-(4-methoxytrityl)amino-1-hexyl]-*N*,*N*-diisopropylphosphoramidite in the presence of 1*H*-tetrazole gave the solid support-bound oligonucleotide **16** after standard capping and oxidation steps. Removal of the 5′-monomethoxytrityl group under acidic conditions followed by acylation of the aminoalkylated oligonucleotide by treatment with azidoacetic anhydride, generated in situ from azidoacetic acid and *N*,*N*′-dicyclohexylcarbodiimide in THF, afforded the CPG-linked oligonucleotide **17** carrying azido and alkynyl groups at the 5′- and 3′-terminus, respectively. Oligonucleotide deprotection was carried out by exposing the solid support to pressurized ammonia gas to remove the nucleobase and phosphate protecting groups, which were discarded by washing the solid support with MeCN/H_2O (1:1 v/v). The deprotected, support-linked oligonucleotide was heated in 1 × PBS at 90

°C for 2 h to release the DNA oligonucleotide **18**. The identity of RP-HPLC-purified **18** was unequivocally confirmed by MALDI-TOF mass spectrometry and the functional characterization of **18** was demonstrated by its circularization through the copper-catalyzed azide-alkyne cycloaddition reaction (*29, 30*). The circularization of **18** was carried out at a concentration of 2 μM in the presence of the Cu(I) catalyst, which was prepared in situ from Cu(II) sulfate pentahydrate, sodium ascorbate, and *tris*(benzyltriazolylmethyl)amine (*30*) in 0.2 M NaCl (*21*). The formation of the cyclic DNA oligonucleotide **19** was assessed by RP-HPLC and MALDI-TOF mass spectrometry (data shown in the Supporting Information).

In summary, the functionalization of long chain alkylamine CPG with an hydroxyalkylated thiophosphoramidate linker produced the CPG support **3**. This support allowed the covalent attachment of combinatorial dinucleoside phosphate/thiophosphate that were generated in situ from activated deoxyribonucleoside phosphorodiamidites (**4**) and 3′-*O*-levulinated deoxyribonucleosides (**5**) to produce the functionalized CPG support **7**, which in turn enabled the solid-phase synthesis of native or modified DNA oligonucleotides. These oligonucleotides can be freed from nucleobase, hydroxyl, and phosphate/thiophosphate protecting groups while being still attached to the support. The very unique feature of CPG support **7** is that fully deprotected DNA oligonucleotides can be released from the support according to a heat-driven cyclodeesterification pathway under nearly neutral conditions. In addition to the orthogonality of oligonucleotide release conditions relative to those employed in conventional solid-phase oligonucleotide synthesis, the versatility of CPG support **7** has been demonstrated in the preparation and full deprotection of a DNA oligonucleotide conjugated with two different functional groups at the 5′- and 3′-termini while still being covalently bound to the support. This approach to the preparation of DNA oligonucleotide conjugates allows the selection of a wide variety of ligands or functional groups in the synthesis of these biomolecules assuming stability of the ligands or functional groups to the conditions employed during synthesis, deprotection, and thermolytic release of the DNA conjugates. The application of the CPG support **3** to the solid-phase synthesis of oligoribonucleotides and their analogues in the context of RNA interference studies is currently being evaluated in our laboratory.

Materials and Methods. Common chemicals and solvents in addition to bromoacetic acid 3*H*-1,2-benzodithiol-3-one 1,1-dioxide, Et_3N, *i*-Pr_2NEt, tripropargyl amine, benzyl azide, sodium azide, 2,6-lutidine, *O*-(2-cyanoethyl)-*O*-[3-(4,4'-dimethoxytrityl)oxy-1-propyl]-*N*,*N*-diisopropylphosphoramidite, 2-cyanoethyl-*N*,*N*-diisopropylchlorophosphoramidite, *O*-(2-cyanoethyl)-*O*-(5-hexyn-1-yl)-*N*,*N*-diisopropylphosphoramidite, bis(*N*,*N*-diisopropylamino)chlorophosphine, *O*-(2-cyanoethyl)-*O*-[6-(4-methoxytrityl)amino-1-hexyl]-*N*,*N*-diisopropylphosphoramidite, 500Å Long Chain Alkylamine Controlled-Pore Glass (CPG), tetrakis(acetonitrile)copper(I) hexafluorophosphate, copper(II) sulfate pentahydrate, sodium ascorbate, 2',4',6'-trihydroxyacetophenone monohydrate, 3-hydroxypicolinic acid, ammonium citrate tribasic, 1-methylimidazole, hydrazine hydrate, argon gas cylinder, and lecture bottles of NH_3 and CH_3NH_2 gases were all purchased from commercial sources and used without further purification. Azido acetic acid was prepared from the reaction of bromoacetic acid and sodium azide as described by Dyke, J. M. et al. (*J. Am. Chem. Soc.* **1997**, *119*, 6883-6887). Anhydrous solvents (MeCN, CH_2Cl_2, C_6H_6, pyridine, THF) and deuterated solvents (C_6D_6,) were obtained from reputable sources and used as received.

Reagents for oligonucleotide synthesis including the 5'-Deblocking solution (3% TCA in CH_2Cl_2), the Activator solution (0.25 M 5-ethylthio-1*H*-tetrazole or 0.4 M 1*H*-tetrazole in MeCN), Cap A solution (Ac_2O/pyridine/THF), Cap B solution (10% 1-methylimidazole in THF), and the Oxidizing solution (0.02 M iodine in THF/pyridine/water) were purchased from commercial sources and used as received. Succinyl long chain alkylamine controlled-pore glass functionalized with 5'-*O*-(4,4'-dimethoxytrityl)-2'-deoxythymidine as the leader nucleoside was also obtained from commercial sources and used as is. 2 M Triethylammonium acetate buffer was purchased from Applied Biosystem and diluted to 0.1 M with HPLC grade water prior to use. Snake venom phosphodiesterase (*Crotallus adamanteus*) and bacterial alkaline phosphatase were commercially available and used without further purification.

Preparative chromatographic purifications were performed on glass columns (2.5, 5.0 or 6.5 cm I.D.) packed with silica gel 60 (230-400 mesh), whereas analytical thin-layer chromatography (TLC) analyses were conducted on 2.5 cm × 7.5 cm glass plates coated with a 0.25 mm thick layer of silica gel 60 F_{254}.

RP-HPLC analyses were performed using a 5 μm Supelcosil LC-18S column (25 cm × 4.6 mm) according to the following conditions: starting from 0.1 M triethylammonium acetate pH 7.0, a linear gradient of 1% MeCN/min is pumped at a flow rate of 1 mL/min for 40 min or as indicated. Peak heights are normalized to the highest peak, which is set to 1 arbitrary unit.

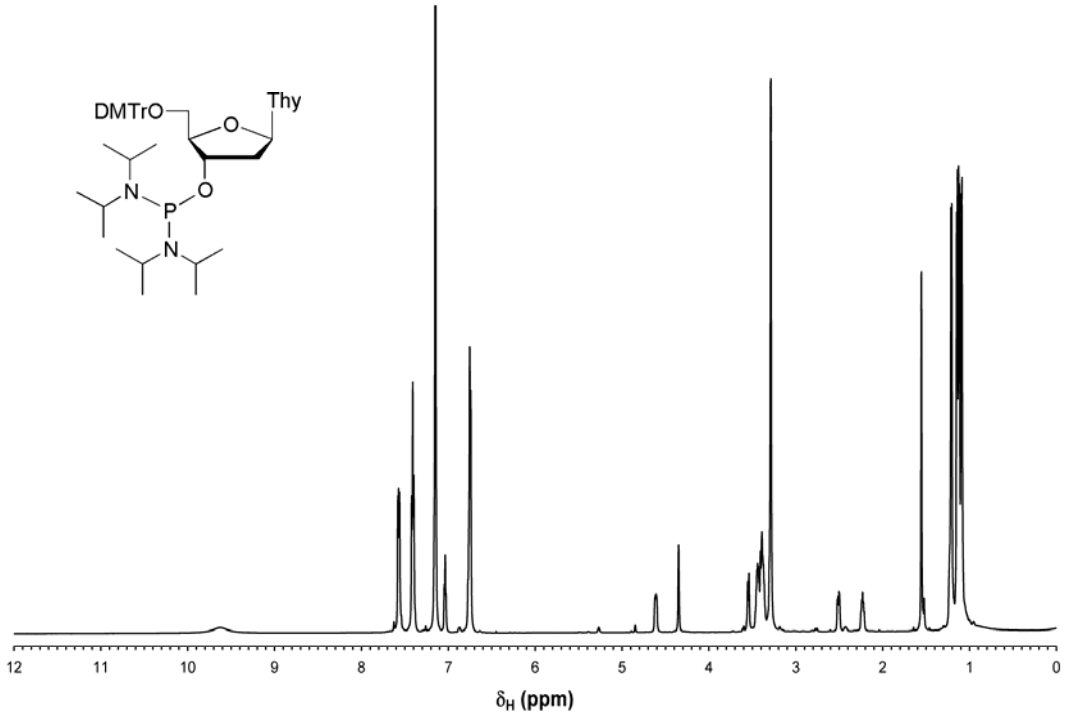
All NMR experiments were performed using spectrometers at fields of 300.13 and 700.13 MHz for ^1H, 75.47 and 176.06 MHz for ^{13}C, and 121.5 MHz for ^{31}P. One-dimensional; ^1H, ^{31}P, $^1H/^{31}P$ decoupled ^{13}C, ^1H decoupled ^{13}C, and two-dimensional ^1H-^{13}C correlation (HSQC) data were acquired using a 5 mm QXI (quadruple resonance; ^1H, ^{15}N, ^{13}C, ^{31}P inverse) probe with actively shielded XYZ gradients

on the spectrometer operating at 700 MHz. ^{1}H-^{1}H total correlation (TOCSY) experiments were performed using the spectrometer operating at 300 MHz that is equipped with a TXI (triple resonance; ^{1}H, ^{15}N, ^{13}C inverse) probe with actively shielded XYZ gradients. Samples were maintained at a temperature of 298 °K. All spectra were recorded in C_6D_6 and chemical shifts δ were reported in parts per million (ppm) relative to appropriate internal references.

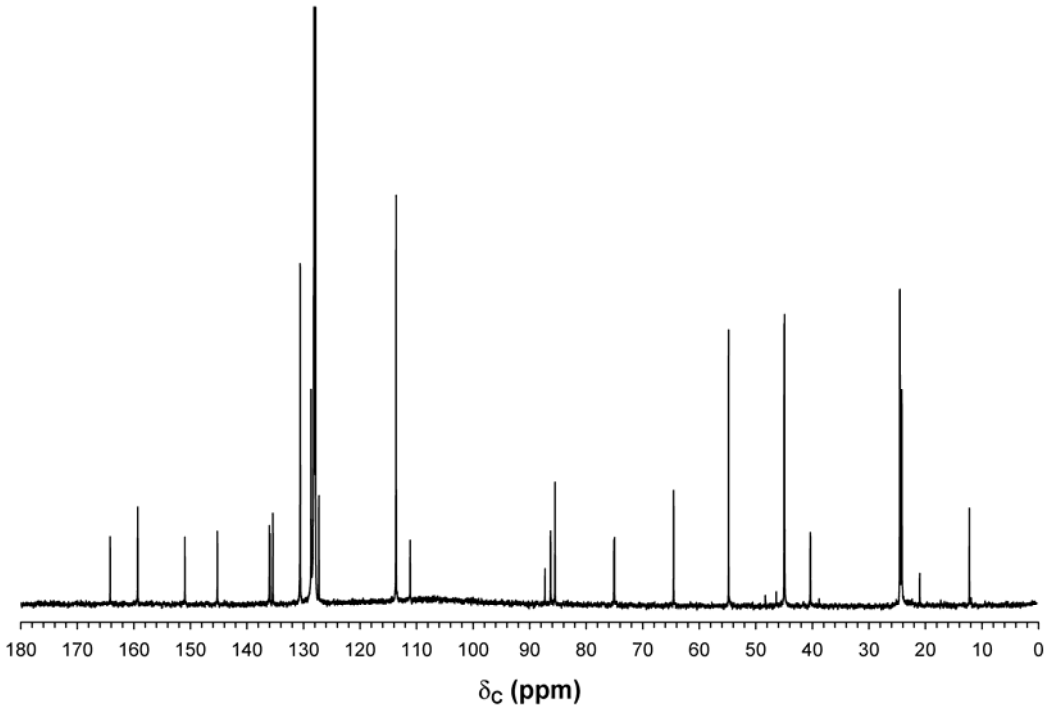
Accurate mass determination of each deoxyribonucleoside phosphorodiamidite **4** was performed using atmospheric pressure electrospray ionization (APESI) in the positive mode (ES^+). Samples dissolved in MeCN (~60 μg/mL) were infused directly at 2.5 mL/h into a stream of MeCN that flowed at 0.5 mL/min to obtain adequate signal intensity. A calibrant containing known ion of 922 m/z was nebulized into the chamber simultaneously with each sample. Software calibration was performed prior to the analysis to re-align the 922.0098 calibrant mass to the theoretical value. The TOF mass spectrometer was set to accurately measure masses over the range 100 to 1500 m/z. Accurate mass measurements for each sample are reported as the average of five injections.

MALDI-TOF mass spectrometric analyses were performed operating in delayed extraction reflector mode, using 3-hydroxypicolinic acid [50 mg/mL in MeCN/H_2O (1:1 v/v)] or 2',4',6'-trihydroxyacetophenone monohydrate [10 mg/mL in MeCN/H_2O (1:1 v/v)] as a matrix and ammonium citrate (50 mg/mL in H_2O) as a cation exchanger.

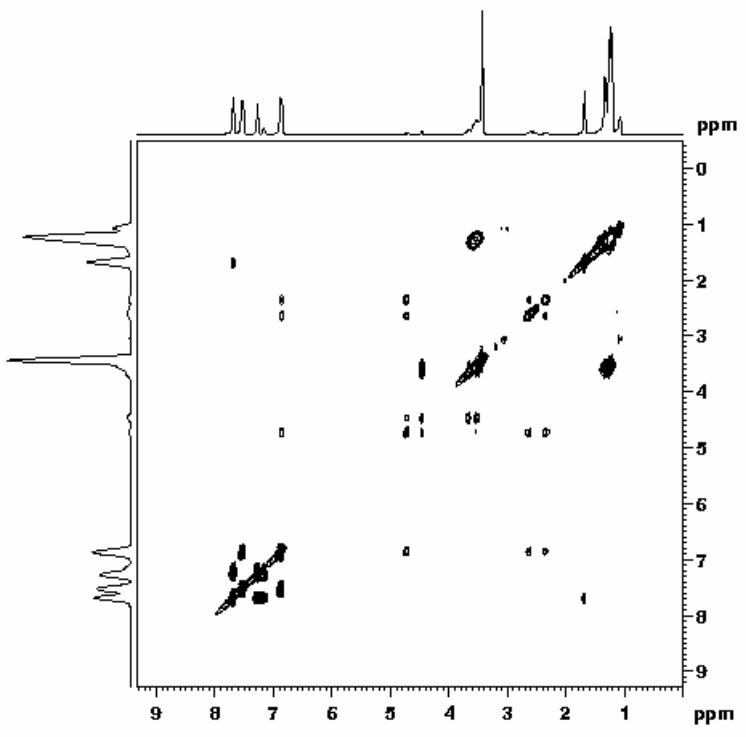
700 MHz ^{1}H NMR spectrum of 5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxythymidine in C_6D_6



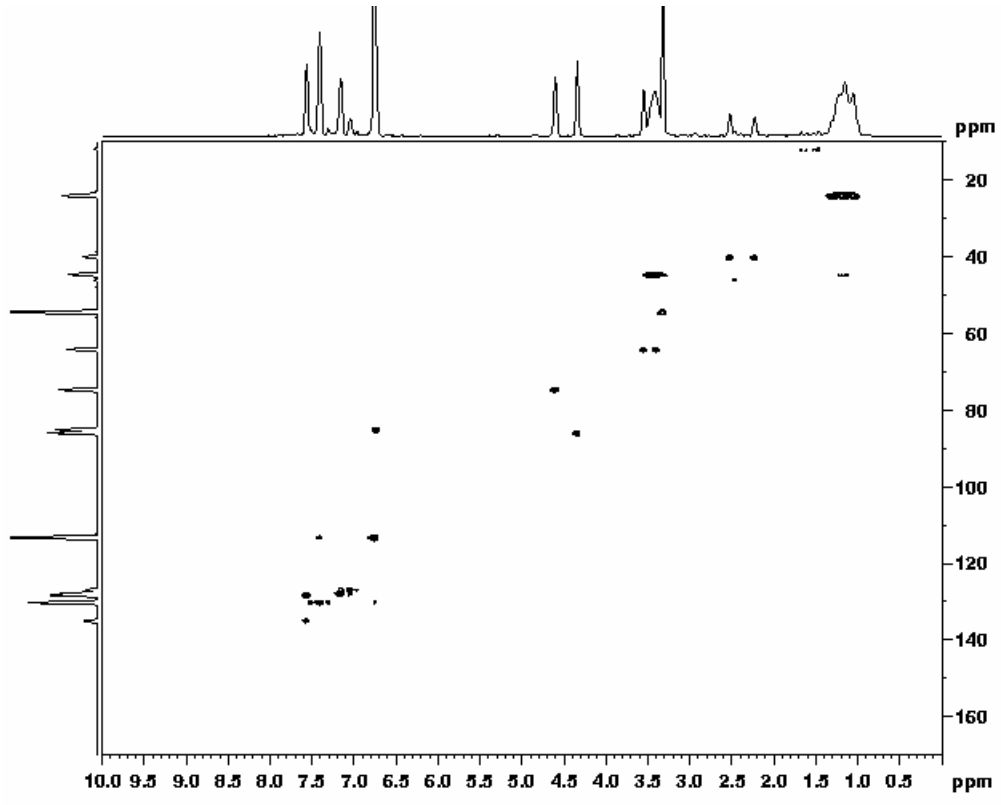
175 MHz ^{13}C NMR spectrum of 5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxythymidine in C_6D_6



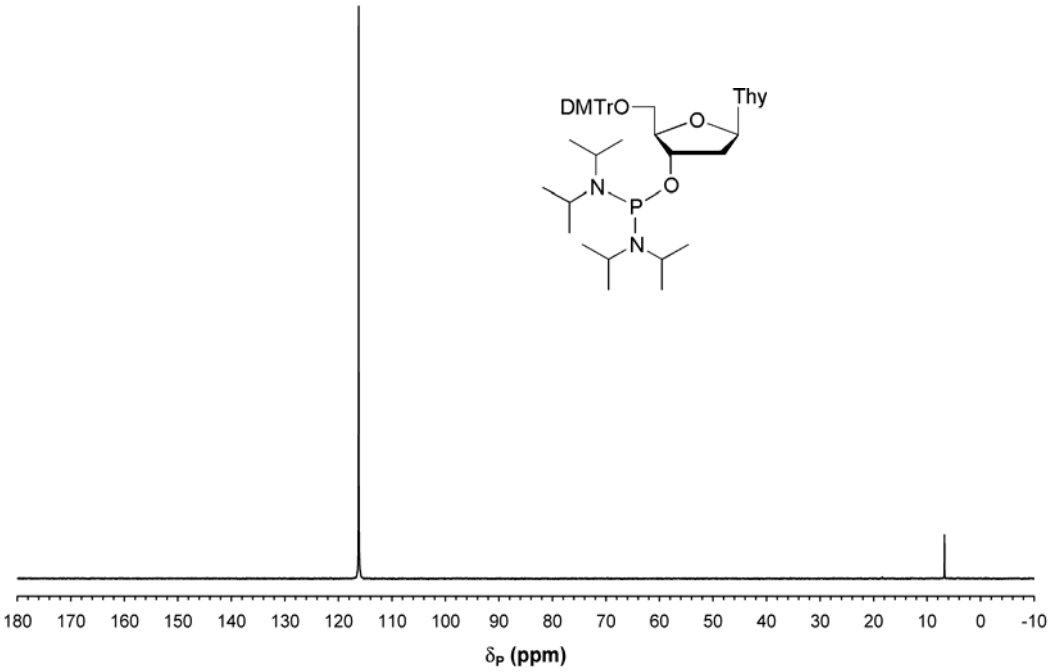
300 MHz ^{1}H-^{1}H TOCSY spectrum of 5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxythymidine in C_6D_6



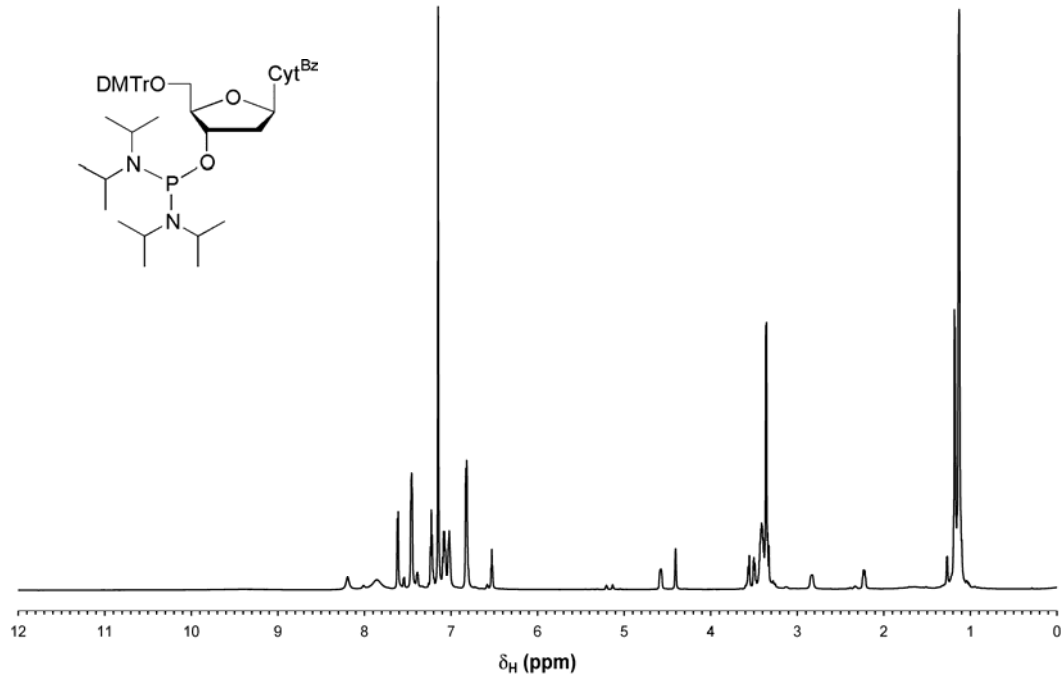
700 MHz ^{1}H-^{13}C HSQC spectrum of 5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxythymidine in C_6D_6



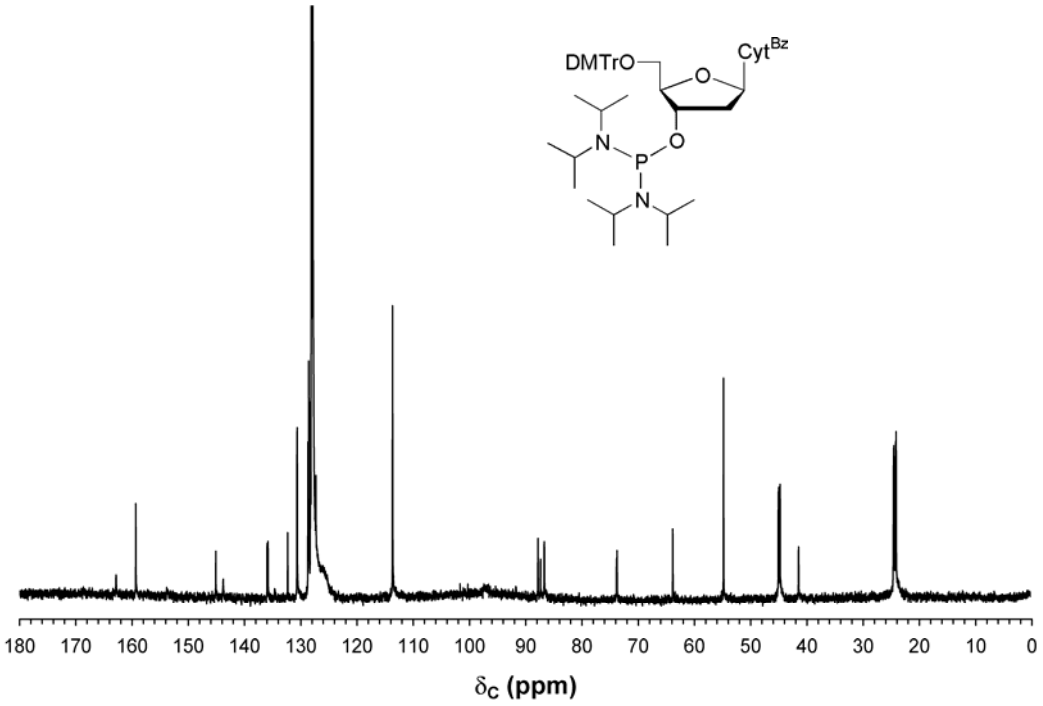
121 MHz ^{31}P NMR spectrum of 5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxythymidine in C_6D_6



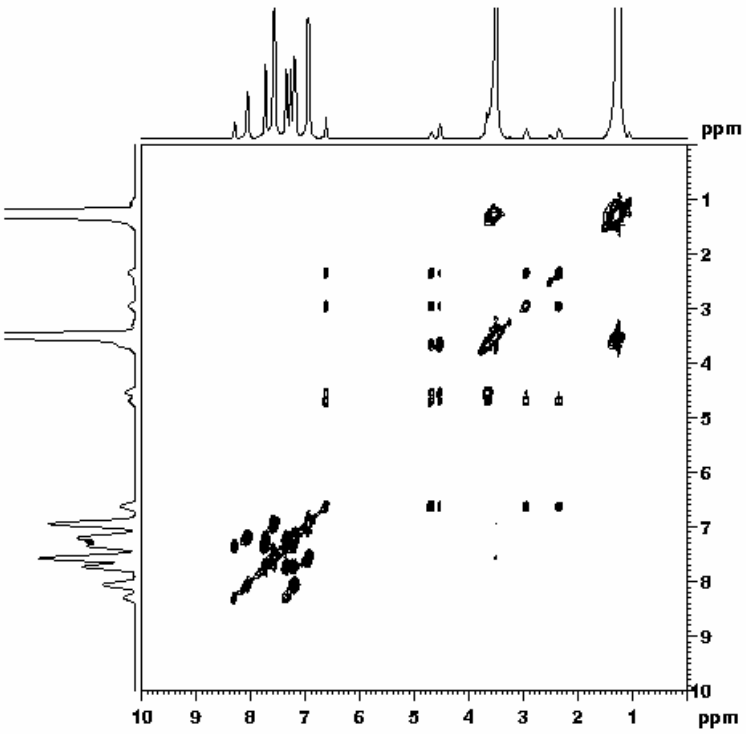
700 MHz ^{1}H NMR spectrum of N^4-benzoyl-5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxycytidine in C_6D_6



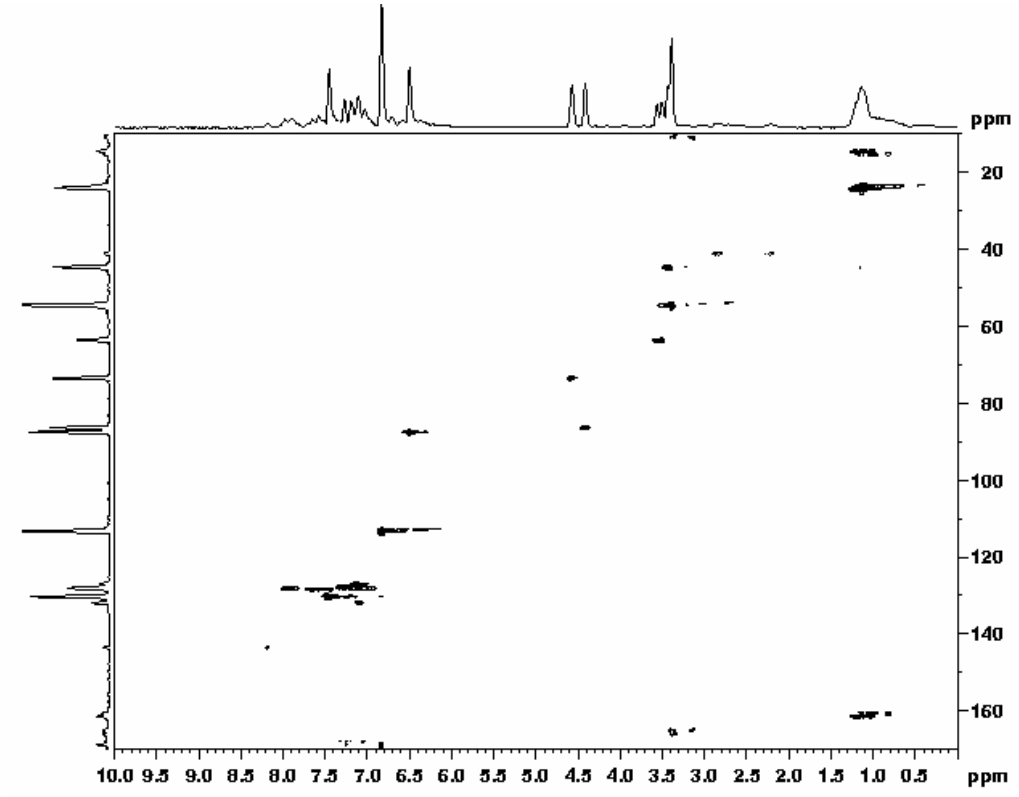
175 MHz ^{13}C NMR spectrum of N^4-benzoyl-5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxycytidine in C_6D_6



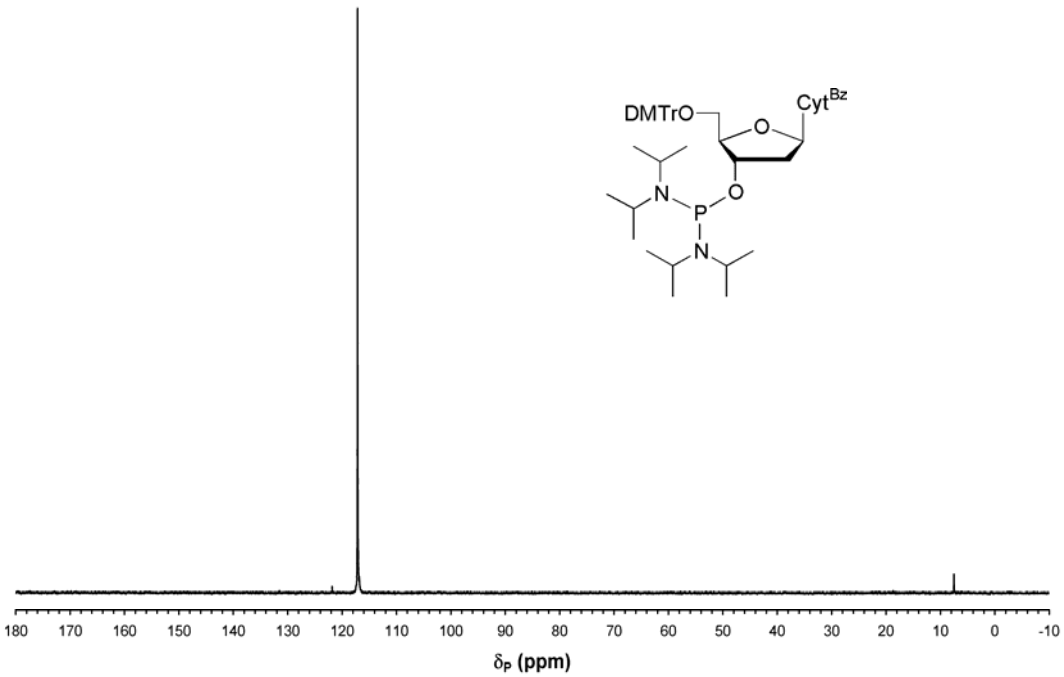
300 MHz ^{1}H-^{1}H TOCSY spectrum of N^4-benzoyl-5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxycytidine in C_6D_6



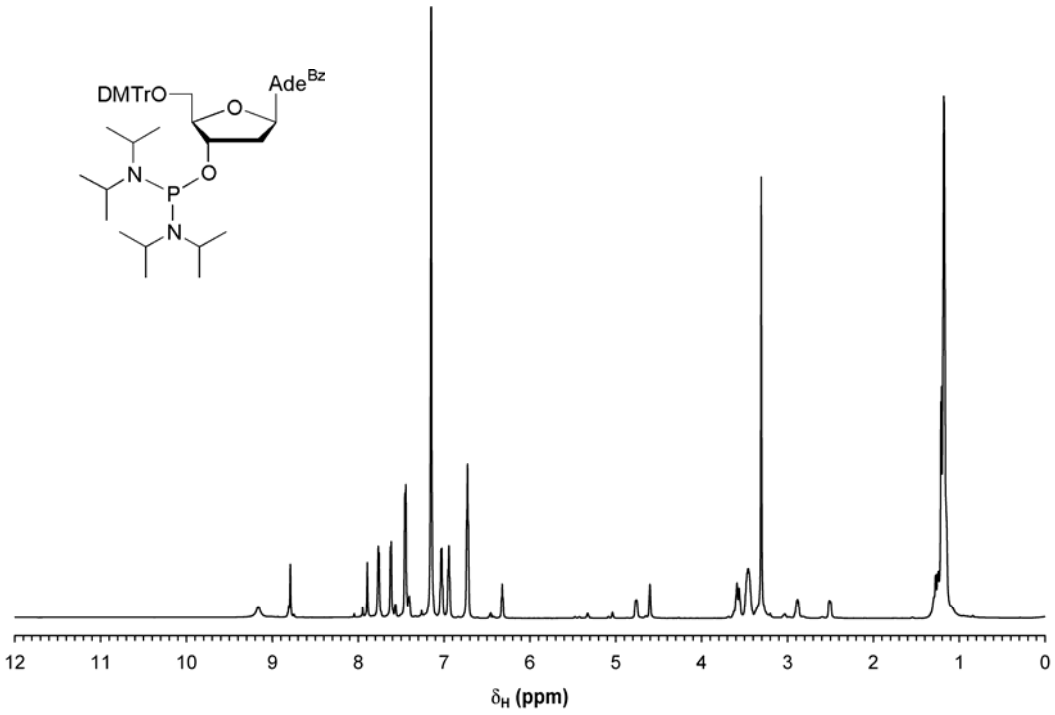
700 MHz ^{1}H-^{13}C HSQC spectrum of N^4-benzoyl-5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxycytidine in C_6D_6



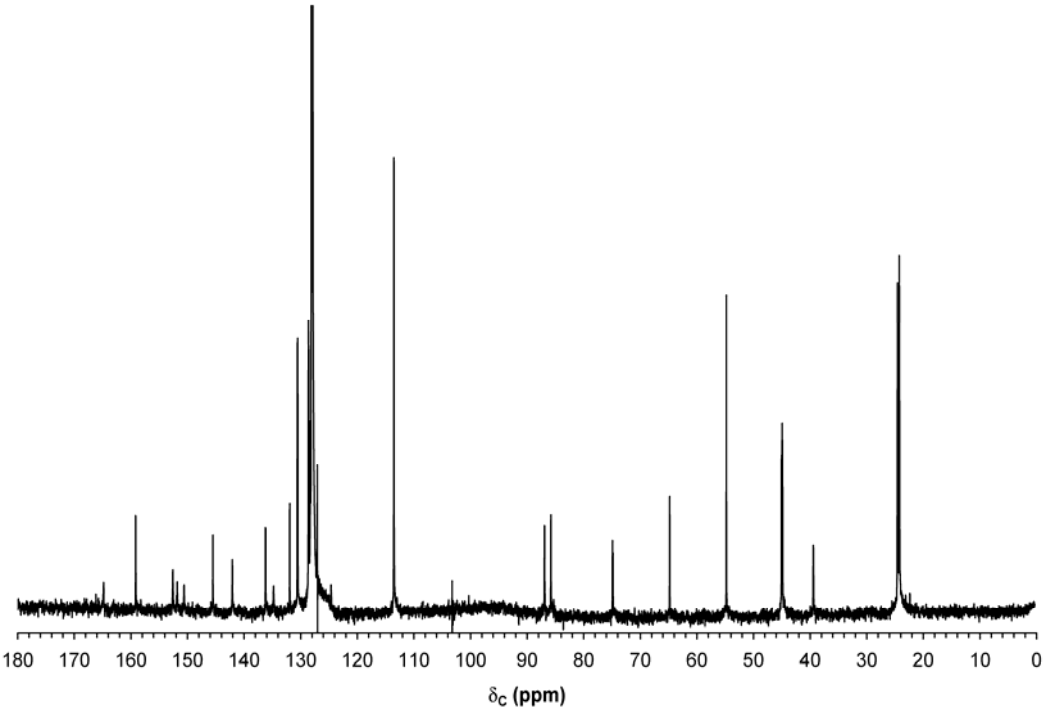
121 MHz ^{31}P NMR spectrum of N^4-benzoyl-5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxycytidine in C_6D_6



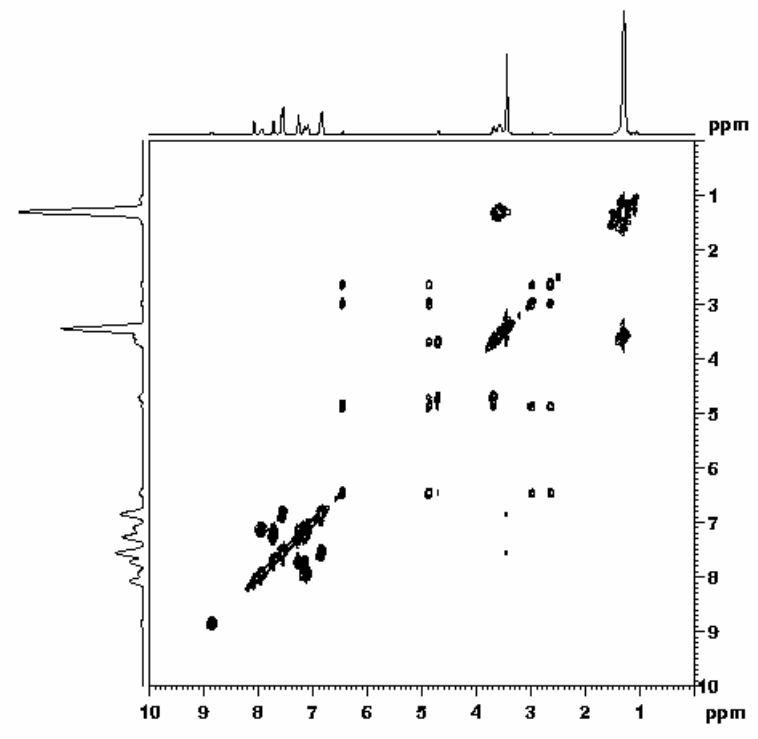
700 MHz ^{1}H NMR spectrum of N^6-benzoyl-5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxyadenosine in C_6D_6



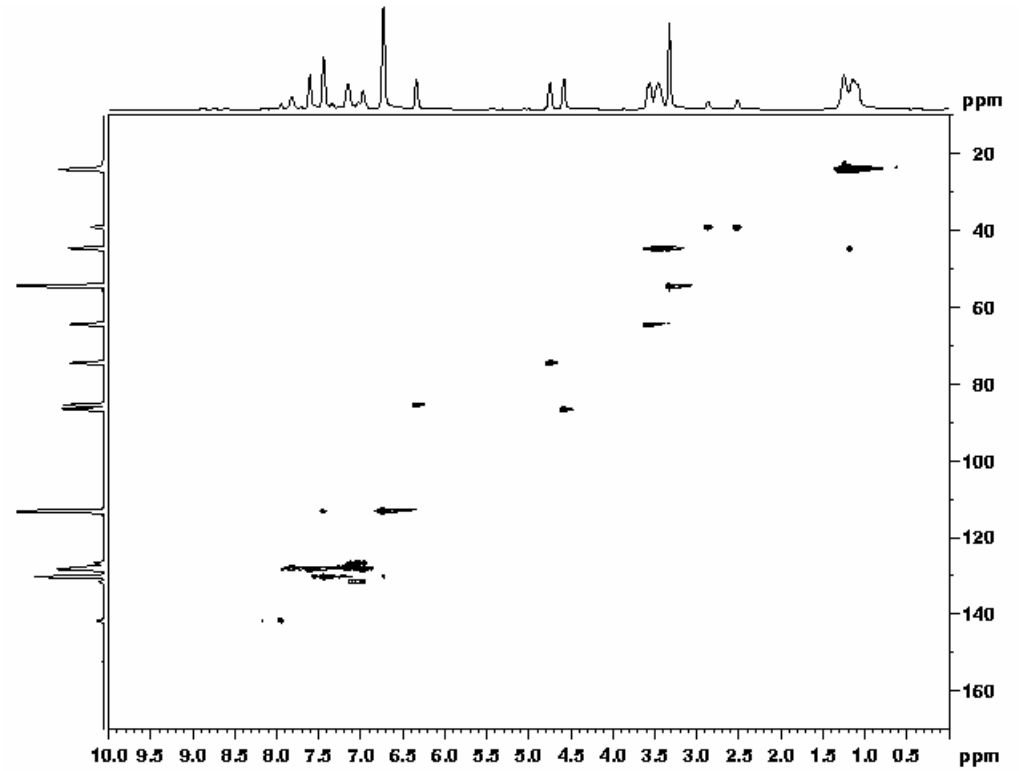
175 MHz ^{13}C NMR spectrum of N^6-benzoyl-5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxyadenosine in C_6D_6



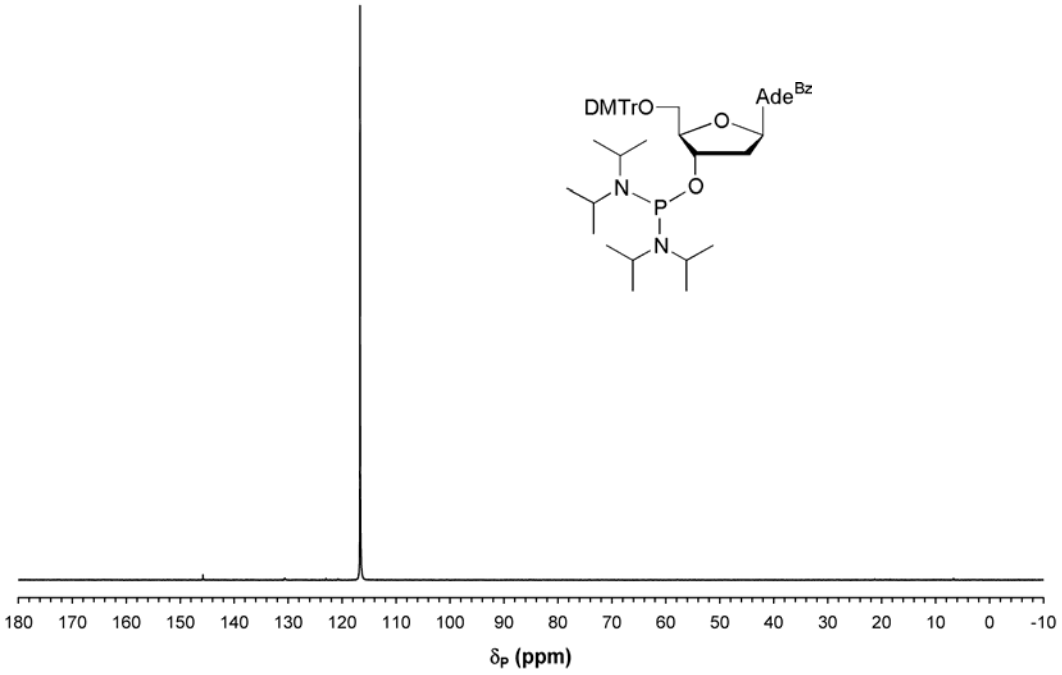
300 MHz ^{1}H-^{1}H TOCSY spectrum of N^{6}-benzoyl-5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxyadenosine in C_6D_6



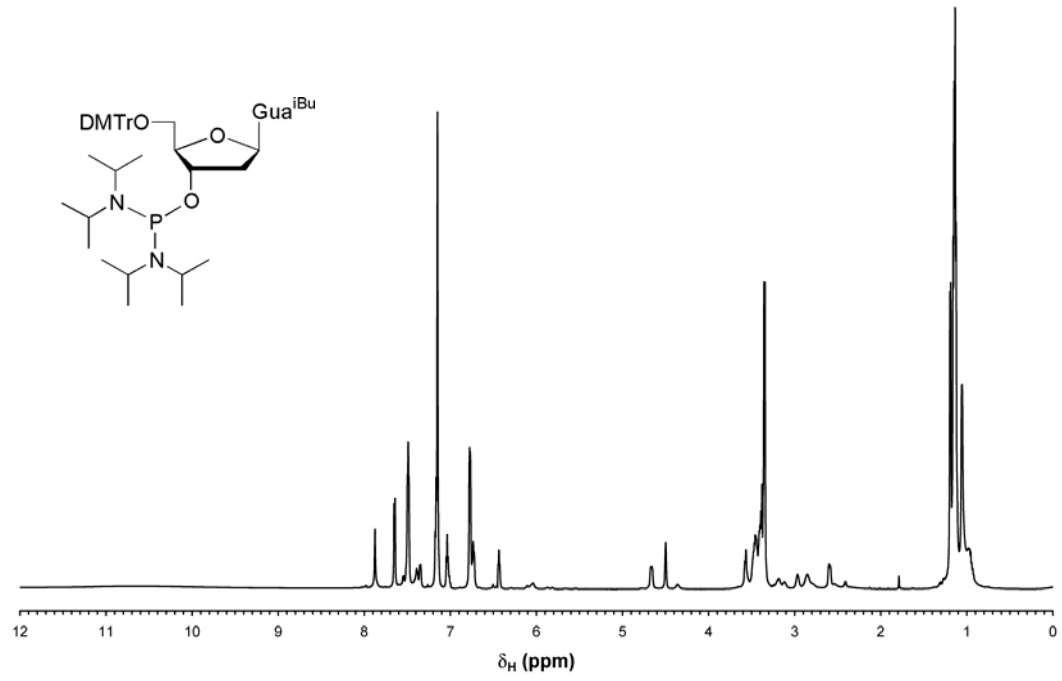
700 MHz ^{1}H-^{13}C HSQC spectrum of N^{6}-benzoyl-5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxyadenosine in C_6D_6



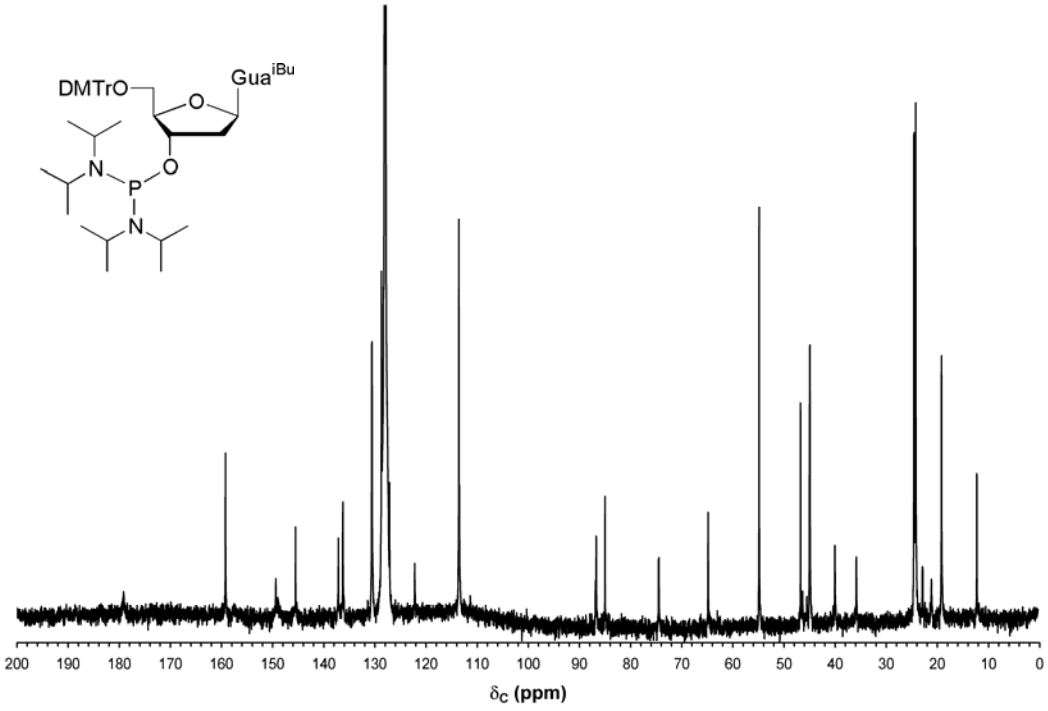
121 MHz ^{31}P NMR spectrum of N^6-benzoyl-5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxyadenosine in C_6D_6



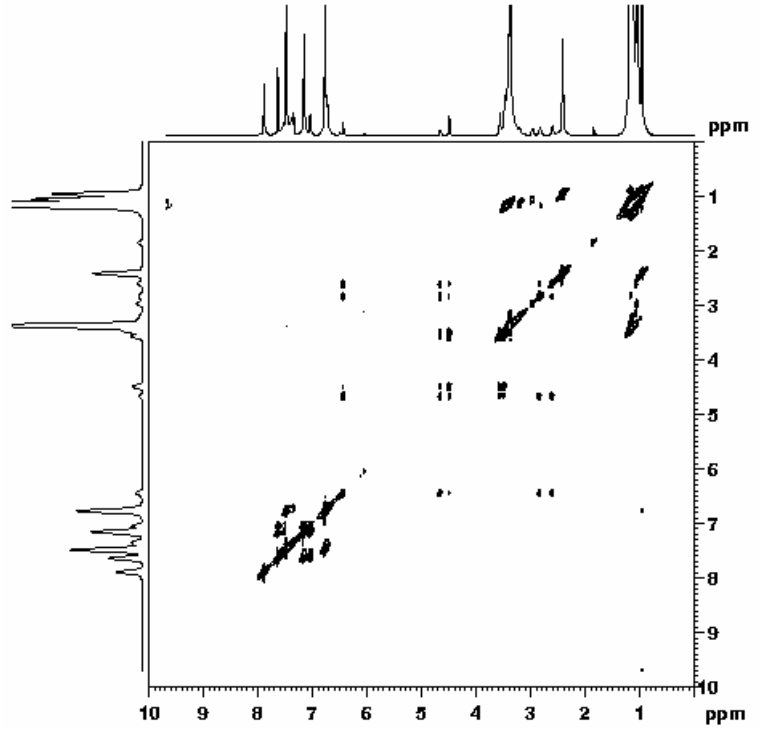
700 MHz ^{1}H NMR spectrum of N^2-isobutyryl-5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxyguanosine in C_6D_6



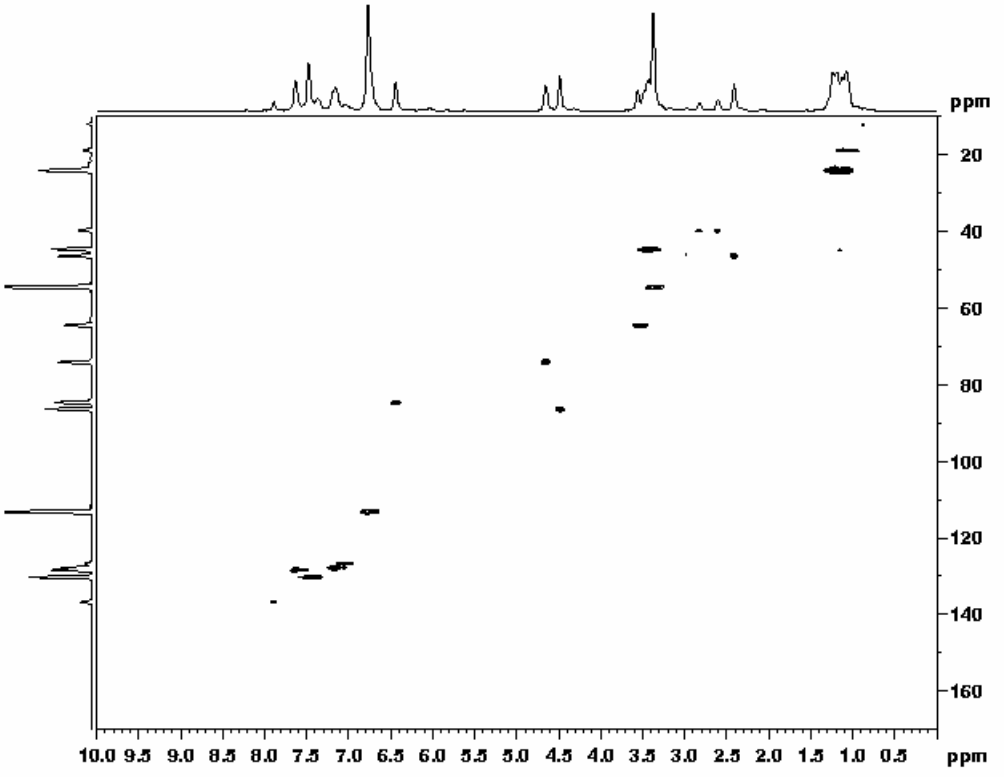
175 MHz ^{13}C NMR spectrum of N^2-isobutyryl-5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxyguanosine in C_6D_6



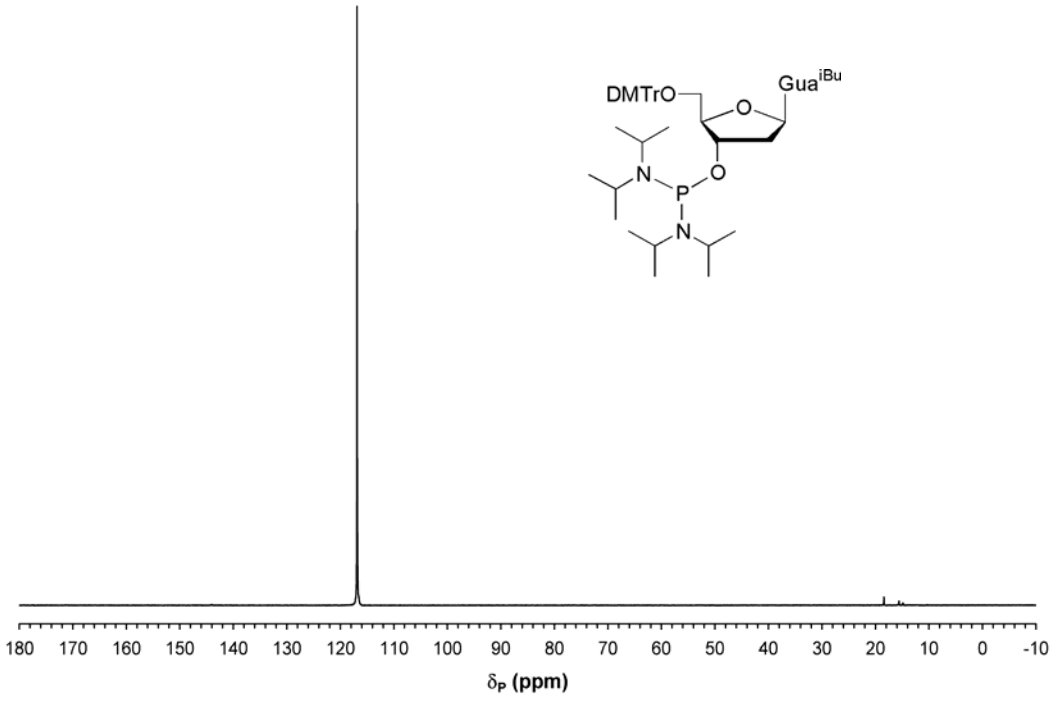
700 MHz ^{1}H-^{1}H TOCSY spectrum of N^2-isobutyryl-5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxyguanosine in C_6D_6



700 MHz ^{1}H-^{13}C HSQC spectrum of *N*^{2}-isobutyryl-5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxyguanosine in C_6D_6



121 MHz ^{31}P NMR spectrum of *N*^{2}-isobutyryl-5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxyguanosine in C_6D_6



APESI-TOF MS spectrum of 5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxythymidine

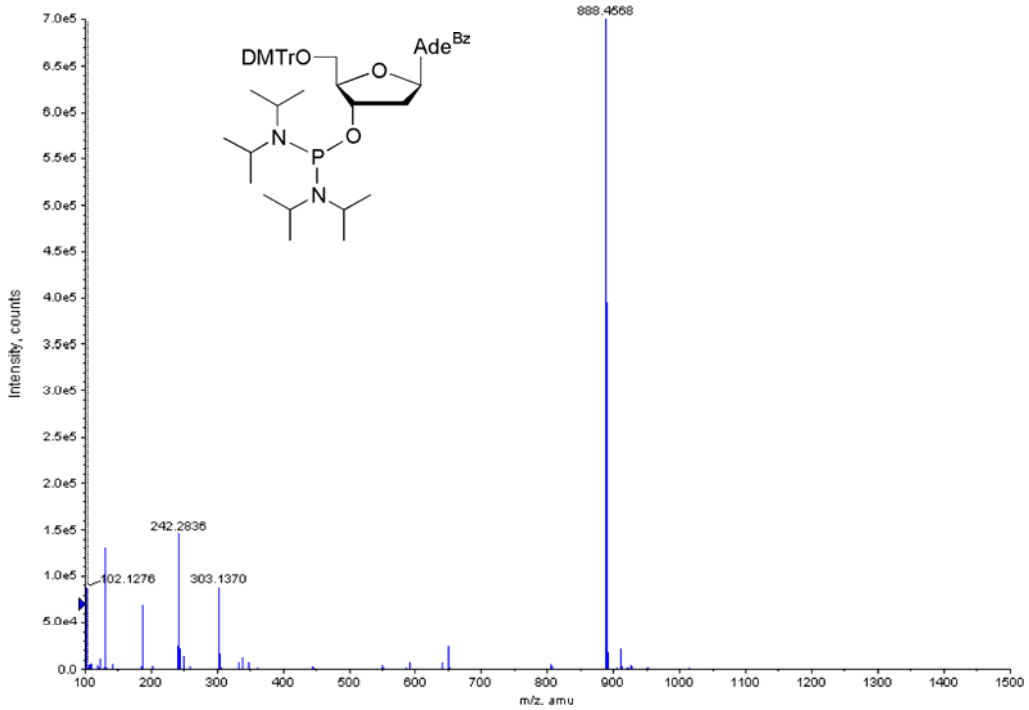
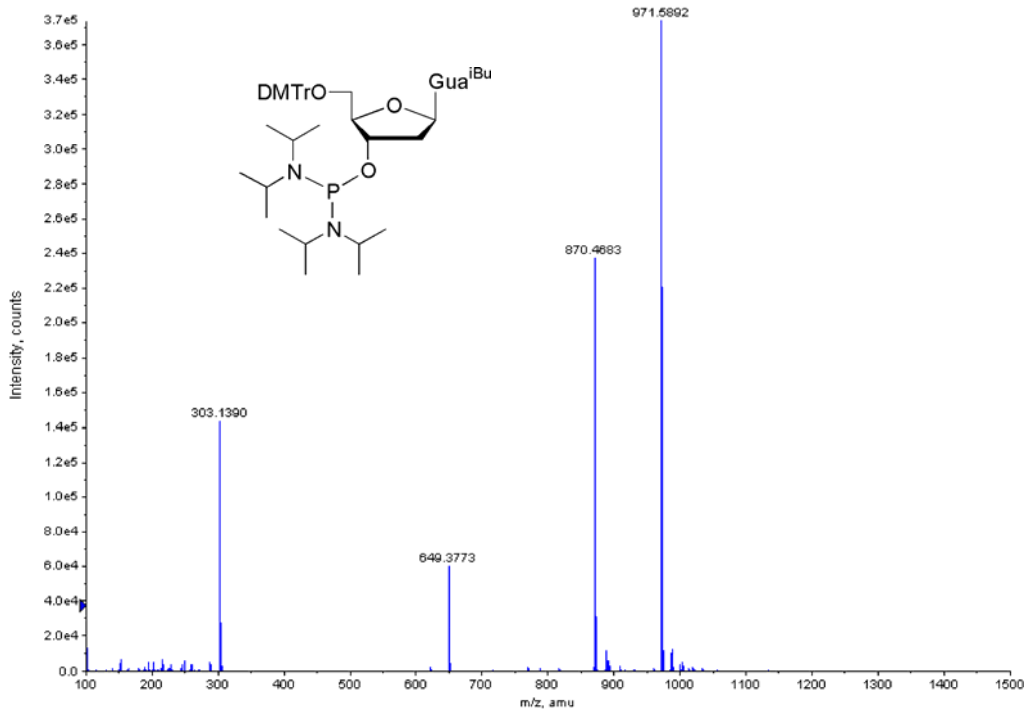
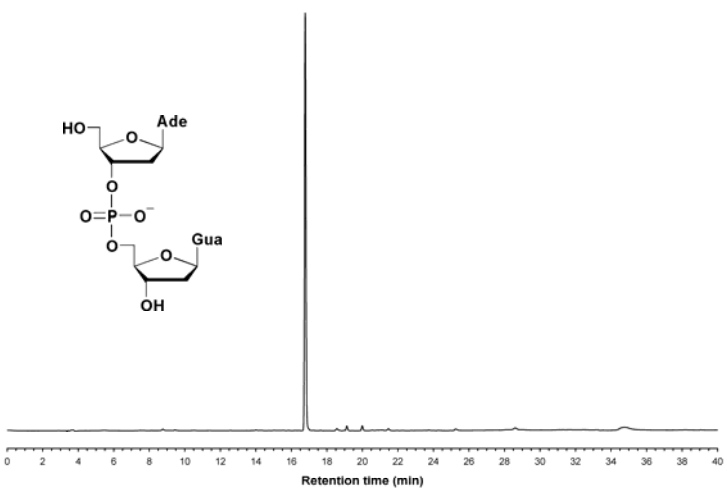
APESI-TOF MS spectrum of N^6-benzoyl-5'-*O*-(4,4'-dimethoxytrityl)- 3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxyadenosine

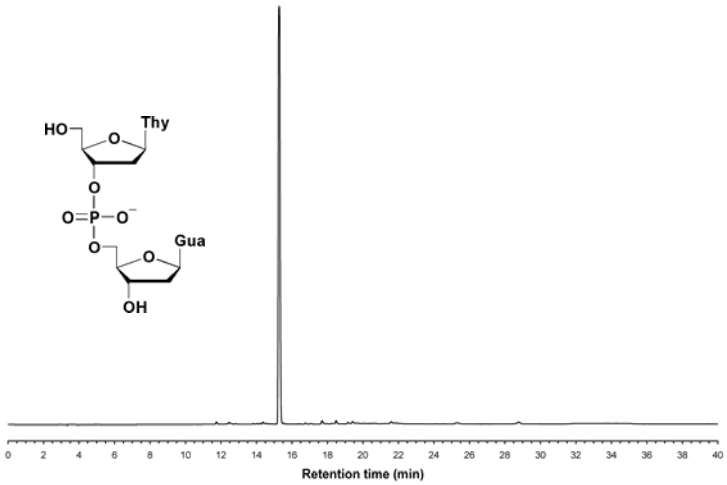


APESI-TOF MS spectrum of N^2-isobutyryl-5'-*O*-(4,4'-dimethoxytrityl)-3'-*O*-bis(*N*,*N*-diisopropylamino)phosphinyl-2'-deoxyguanosine

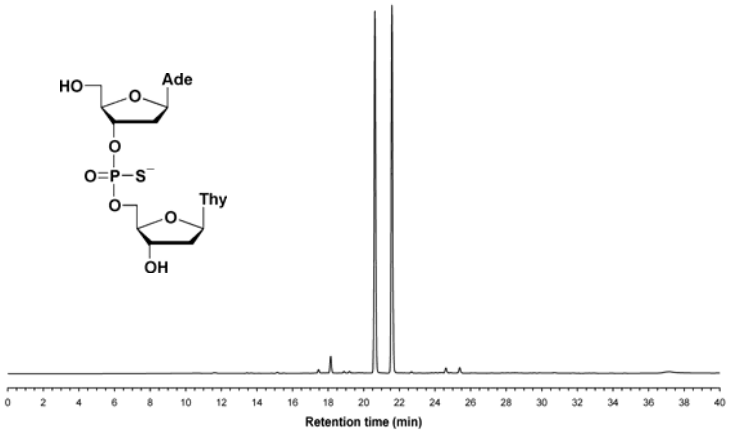


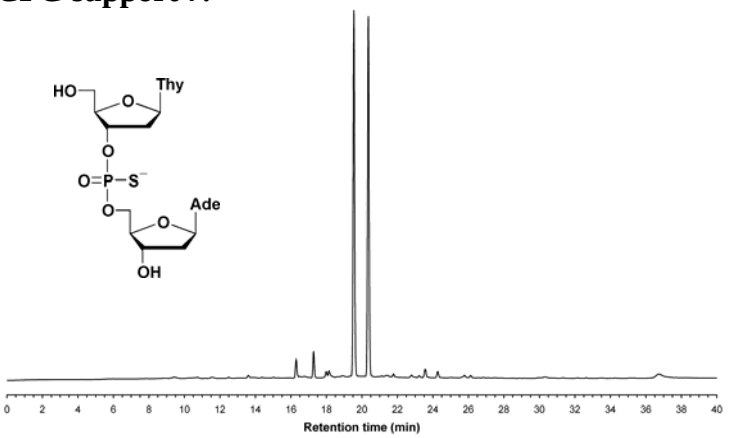
RP-HPLC chromatograms of dinucleoside phosphate diesters that were thermolytically released from the CPG support 7

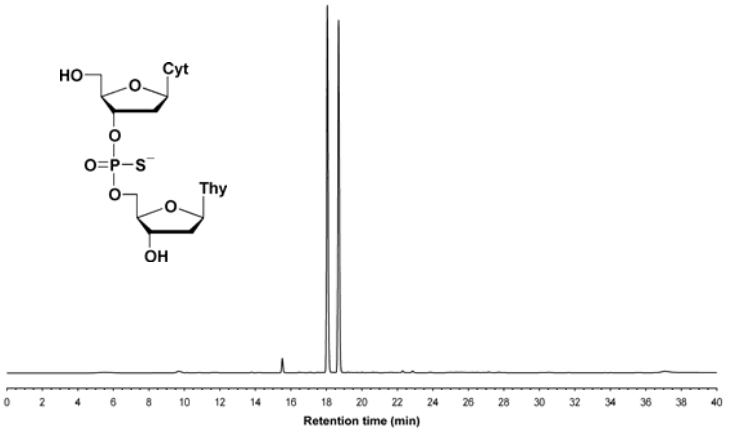


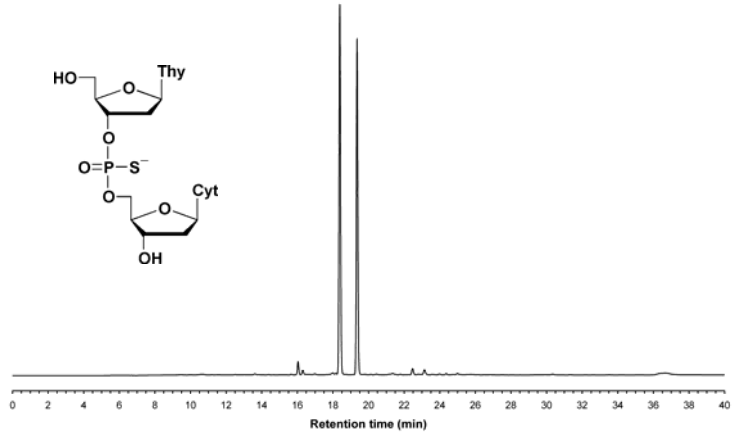


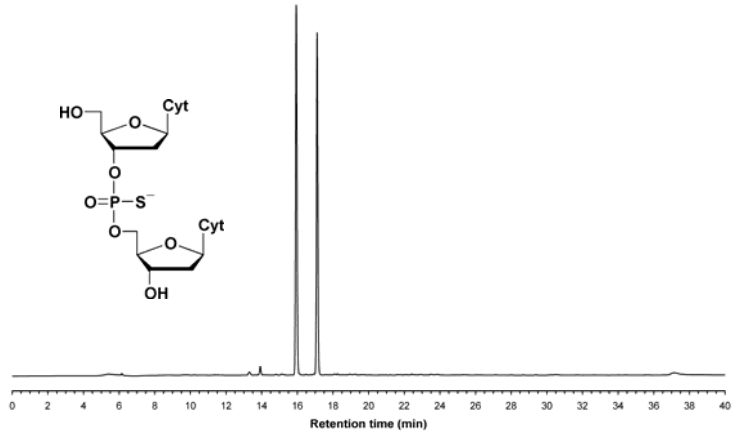
RP-HPLC chromatograms of dinucleoside phosphorothioates that were thermolytically released from the CPG support 7.

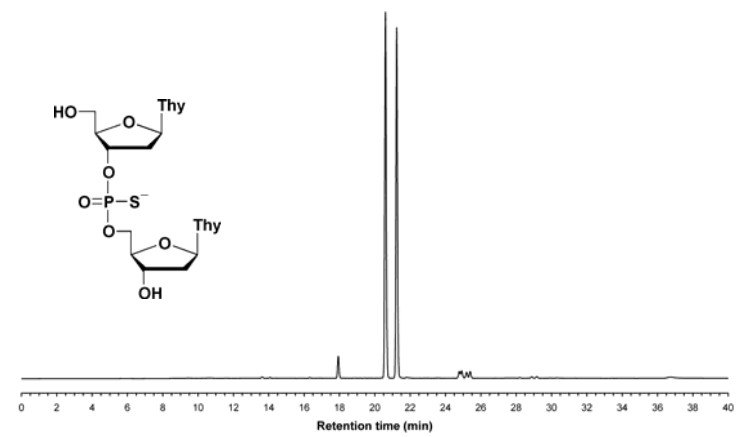


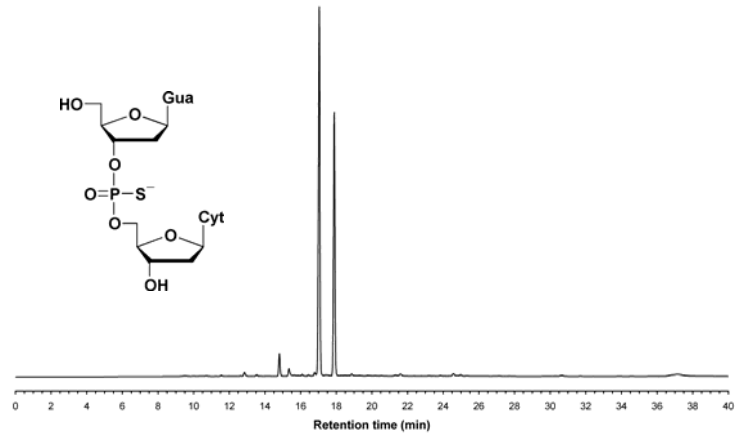


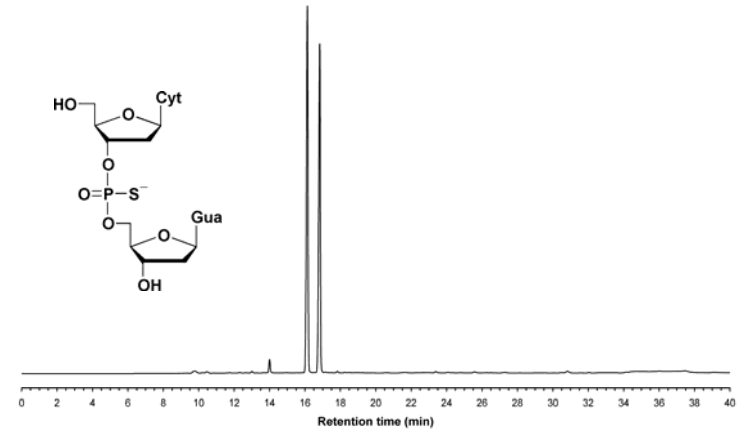




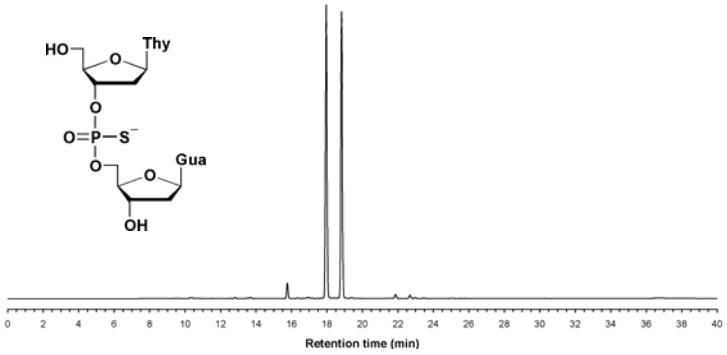


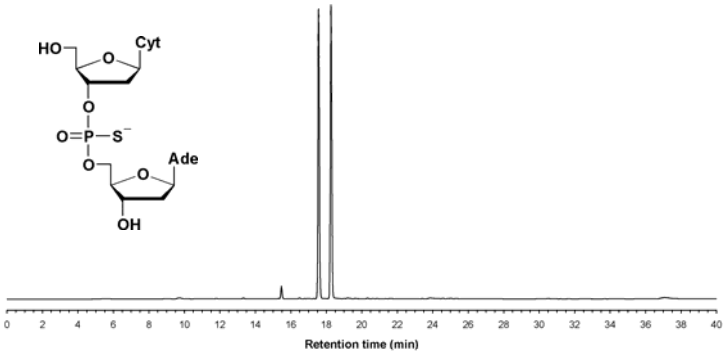


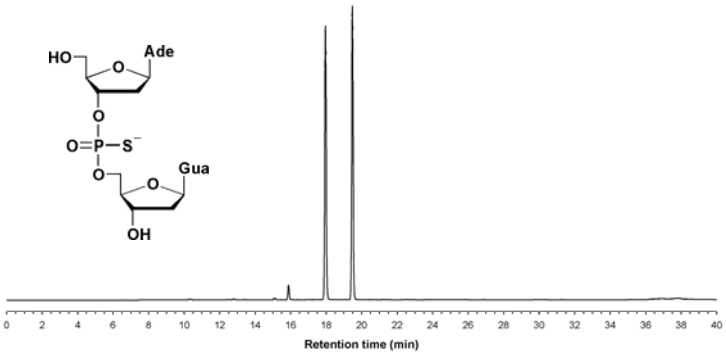


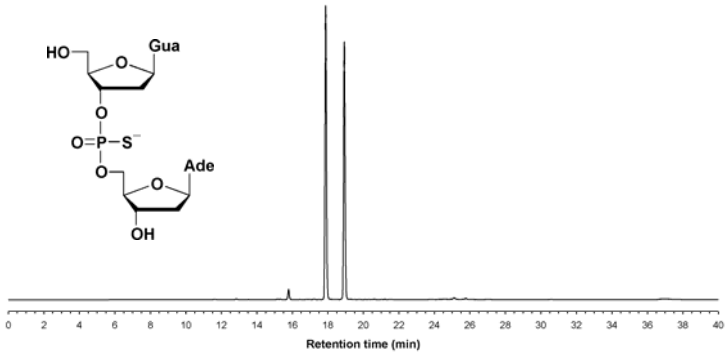


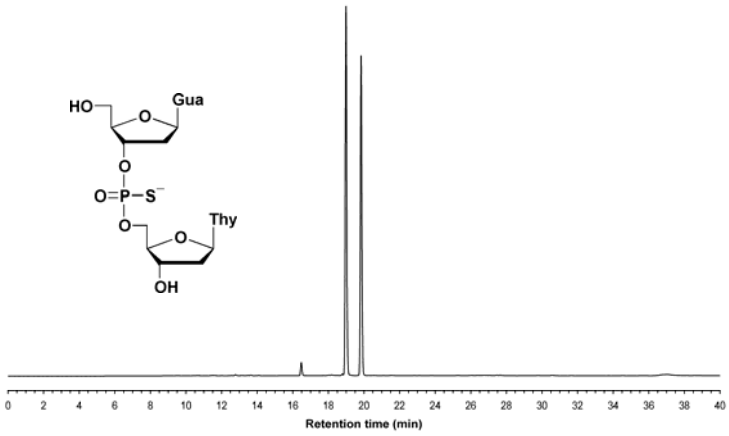
RP-HPLC chromatograms of dinucleoside phosphorothioates that were thermolytically released from the CPG support 7.

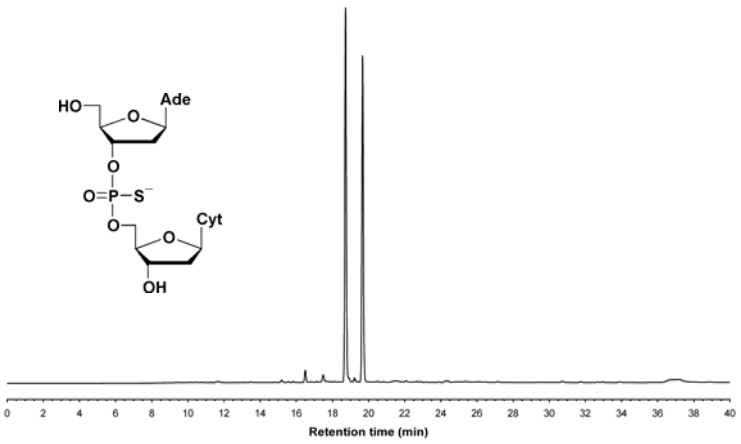


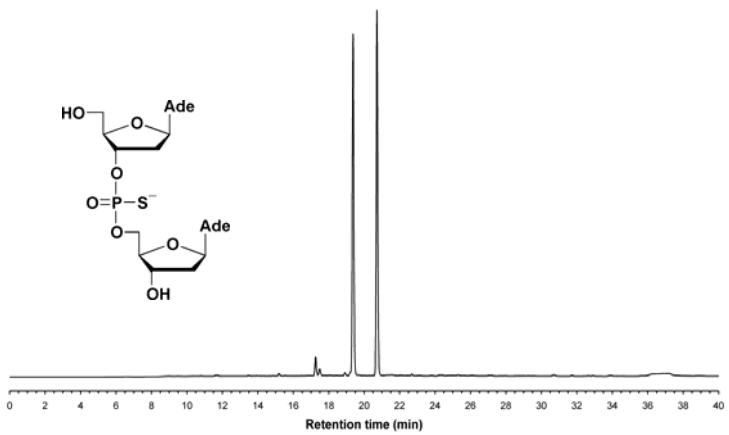


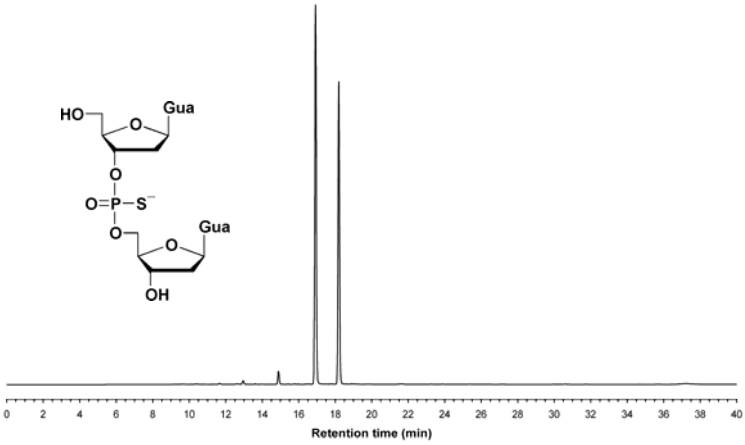


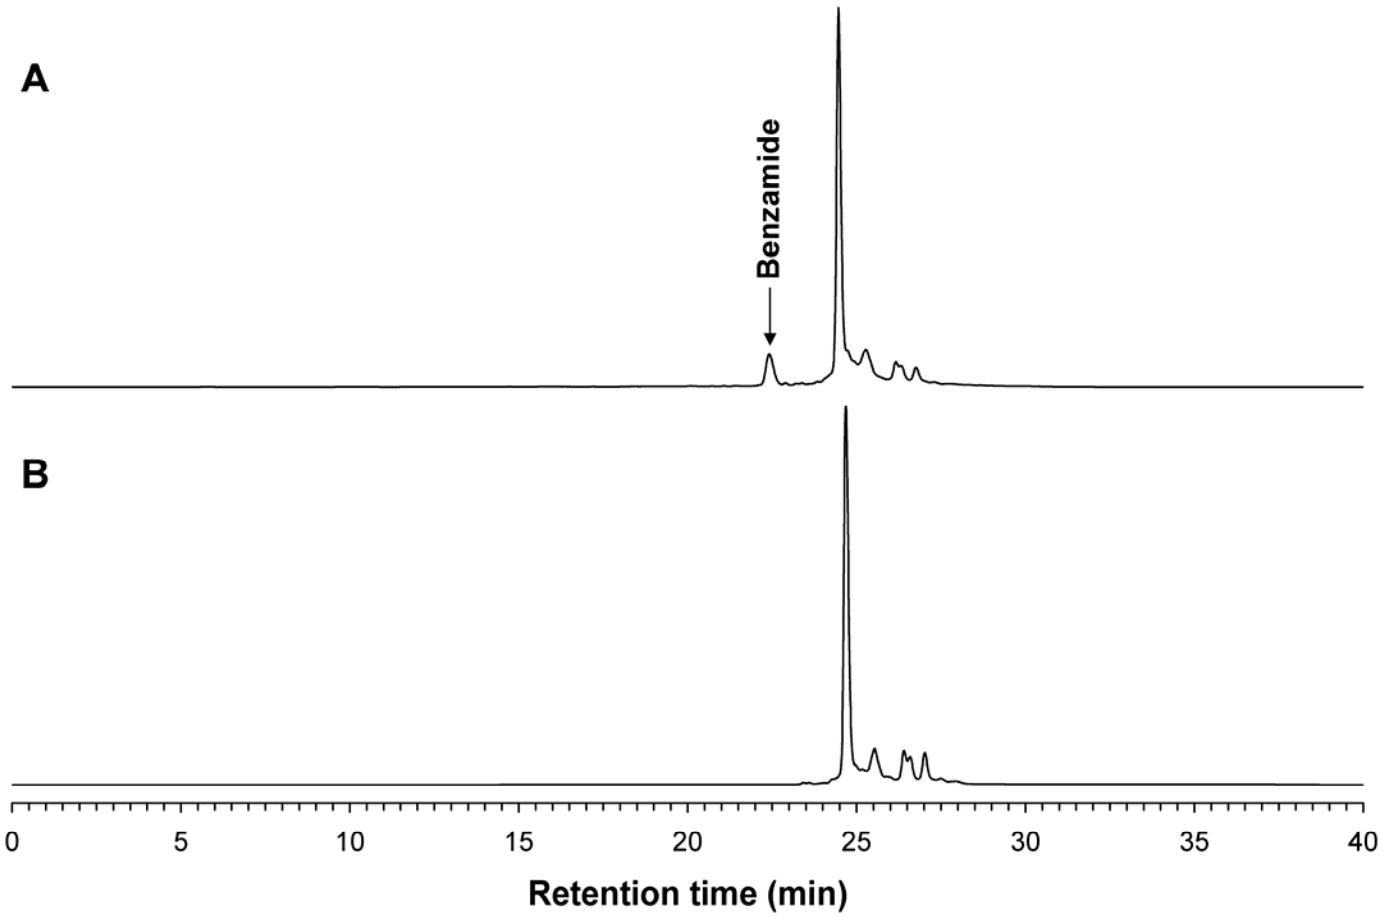




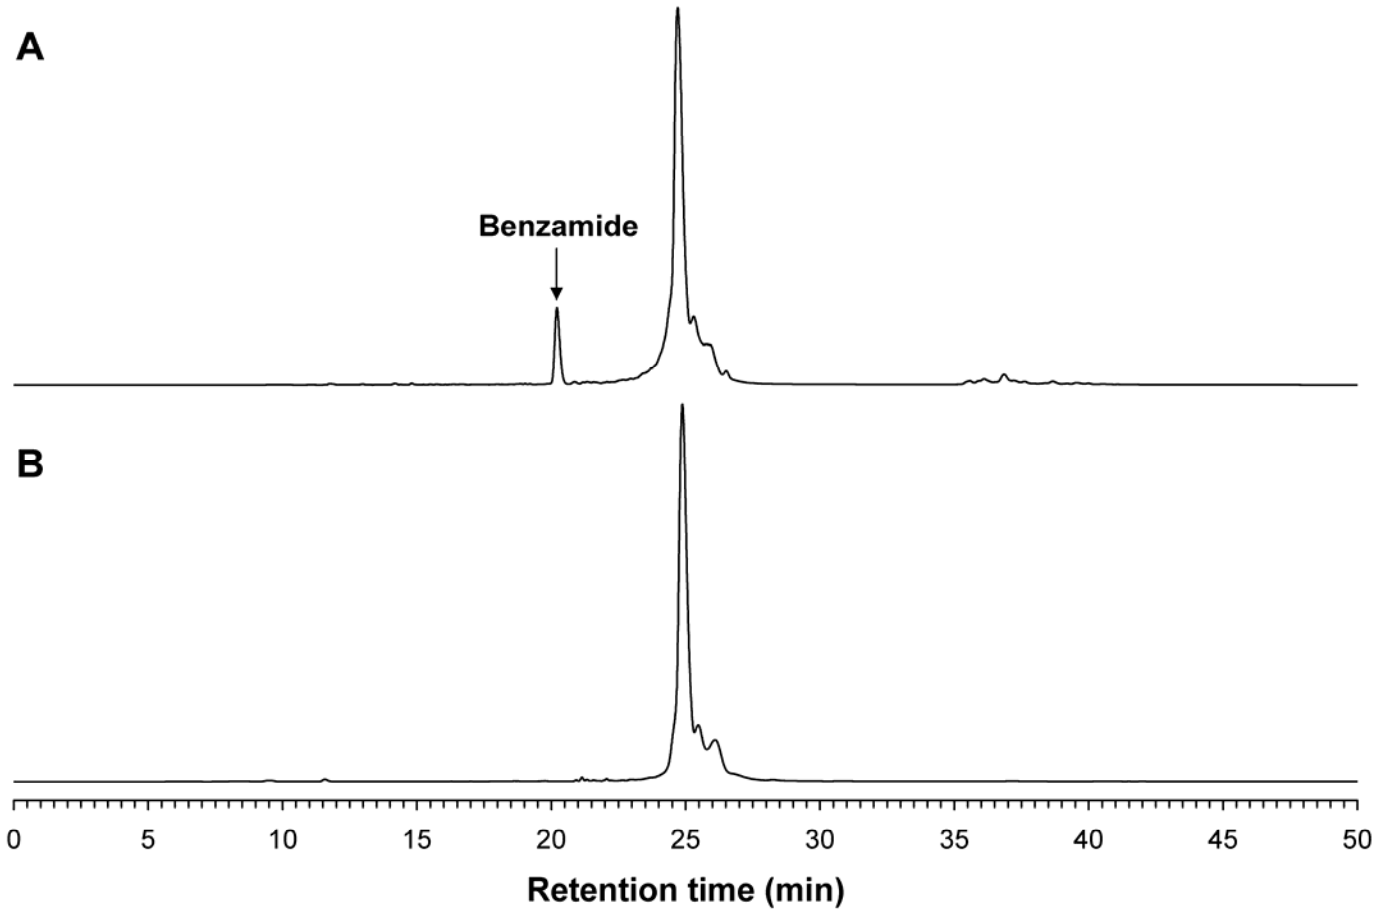








Enlarged Figure 1. RP-HPLC analysis of unpurified 5'-d(CGACTGTGAATCGATGCCAT). **A:** Chromatogram of the native 20-mer that was synthesized employing commercial CPG under standard conditions. Nucleobase and phosphate deprotection, and release of the oligomer from the support were effected by treatment with pressurized NH_3 gas (~10 bar) over a period of 16 h at 25 ºC, as described in the Experimental section. **B:** Chromatogram of the 20-mer that was synthesized using the CPG support **7** under standard conditions. After nucleobase and phosphate deprotection under the conditions described in **A**, the deprotection side products were washed away from the CPG support **8** with MeCN:H_2O (1:1 v/v). The 20-mer was thermolytically cleaved from **8** upon heating at 90 ºC in 1× PBS (pH 7.2) for 2 h. RP-HPLC analyses were performed using a 5 μm Supelcosil LC-18S column (25 cm × 4.6 mm) according to the following conditions: starting from 0.1 M triethylammonium acetate pH 7.0, a linear gradient of 0.7% MeCN/min was pumped at a flow rate of 1 mL/min for 30 min and was followed by a linear gradient of 4% MeCN for 5 min, which was held isocratically for 5 min. Peak heights are all normalized to the highest peak, which is set to 1 arbitrary unit.



Enlarged Figure 2. RP-HPLC analysis of unpurified 5'-d($C_{PS}G_{PS}A_{PS}C_{PS}T_{PS}G_{PS}T_{PS}G_{PS}A_{PS}A_{PS}T_{PS}C_{PS}$ $G_{PS}A_{PS}T_{PS}G_{PS}C_{PS}C_{PS}A_{PS}T$). **A:** Chromatogram of the fully phosphorothioated 20-mer that was synthesized employing commercial CPG under standard conditions. Nucleobase and thiophosphate deprotection was effected by treatment with pressurized NH_3 gas (~10 bar) over a period of 16 h at 25 ºC, as described in the Experimental section. **B:** Chromatogram of the 20-mer that was synthesized using the CPG support **7** under standard conditions. After nucleobase and thiophosphate deprotection under the conditions described in **A**, the deprotection side products were washed away from the CPG support **8** with MeCN:H_2O (1:1 v/v). The 20-mer was thermolytically cleaved from the support **8** upon heating at 90 ºC in 1× PBS (pH 7.2) for 2 h. RP-HPLC analyses were performed using a 5 µm Supelcosil LC-18S column (25 cm × 4.6 mm) according to the following conditions: starting from 0.1 M triethylammonium acetate pH 7.0, a linear gradient of 1% MeCN/min was pumped at a flow rate of 1 mL/min for 40 min. Peak heights are all normalized to the highest peak, which is set to 1 arbitrary unit.

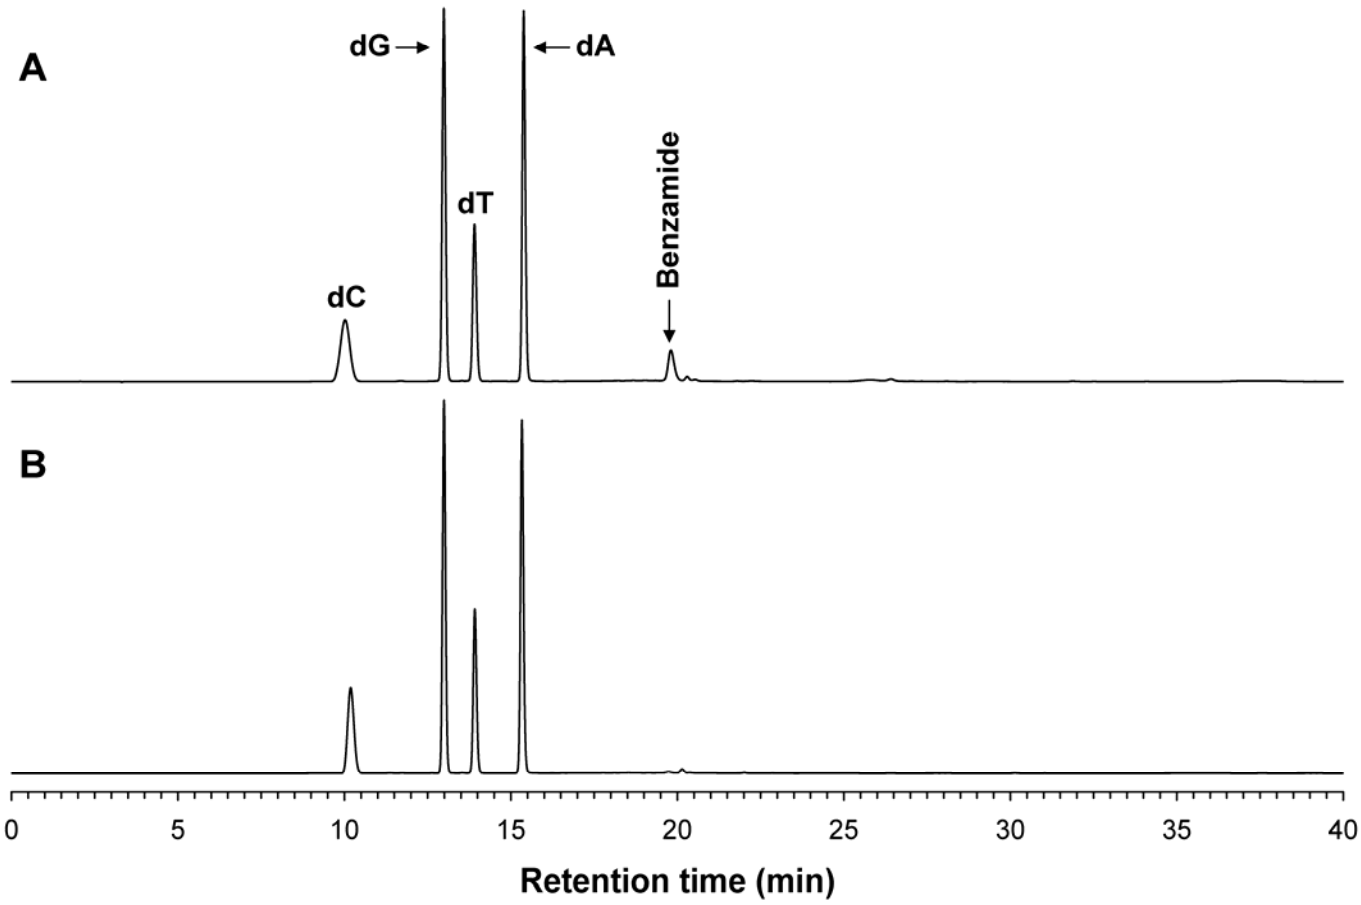


CHART 1. RP-HPLC analysis of unpurified 5'-d(CGACTGTGAATCGATGCCAT) after treatment with snake venom phosphodiesterase and bacterial alkaline phosphatase. **A:** Chromatogram of the enzymatic digest of the 20-mer described in Figure 1A. **B:** Chromatogram of the enzymatic digest of the 20-mer described in Figure 1B. Chromatographic conditions are identical to those described in the legend of Enlarged Figure 2. **dC**, 2'-deoxycytidine; **dG**, 2'deoxyguanosine; **dT**, 2'deoxythymidine; **dA**, 2'-deoxyadenosine.

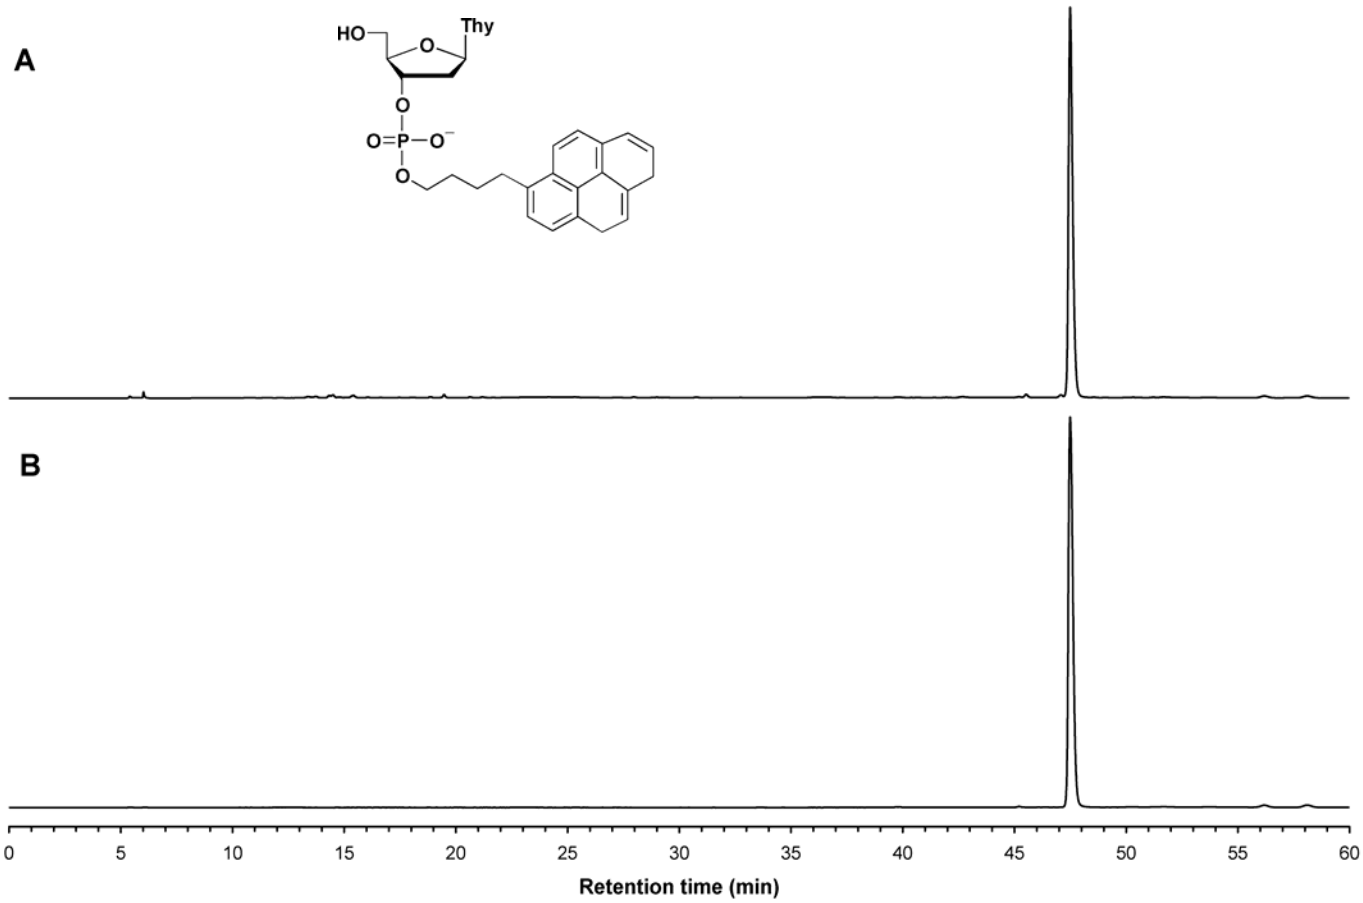

CHART 2. RP-HPLC chromatograms of unpurified thymidine 3'-*O*-(1-pyrenebutyl) phosphate that was thermolytically released from the CPG support **12**. **A:** Chromatogram of thymidine 3'-*O*-(1-pyrenebutyl) phosphate recorded at 260 nm. **B:** Chromatogram of thymidine 3'-*O*-(1-pyrenebutyl) phosphate recorded at 340 nm. RP-HPLC analyses were performed under conditions identical to those described in the legend of Enlarged Figure 2.

Received May 17, 2008; Revised Manuscript Received June 24, 2008

The self-immolative spacer *para*-aminobenzyl alcohol (PABA) was used as a key component in the design of new protease-sensitive fluorogenic probes whose parent phenol-based fluorophore is released through an enzyme-initiated domino reaction. First, the conjugation of the phenylacetyl moiety to 7-hydroxycoumarin (umbelliferone) and 7-hydroxy-9*H*-(9,9-dimethylacridin-2-one) (DAO) by means of the heterobifunctional PABA linker has led to pro-fluorophores **6a** and **6d** whose enzyme activation by penicillin amidase was demonstrated. The second part of this study was devoted to the extension of this latent fluorophore strategy to the caspase-3 protease, a key mediator of apoptosis in mammalian cells. Fluorogenic caspase-3 substrates **11** and **13** derived from umbelliferone and DAO, respectively, were prepared. It was demonstrated that pro-fluorophore **11** is a sensitive fluorimetric reagent for the detection of this cysteine protease. Furthermore, *in vitro* assays with fluorogenic probe **13** showed a deleterious effect of biological thiols on fluorescence of the released acridinone fluorophore DAO that, to our knowledge, had not been reported until now.

INTRODUCTION

Latent fluorophores (or pro-fluorophores) are molecules in which a physical property of the fluorophore is altered upon interaction with an analyte (enzyme, metal cation, reactive oxygen species, and so forth), resulting in a change in the fluorescence spectrum and/or an increase in the fluorescence quantum yield at a particular wavelength, and/or a change in some other fluorescent properties of the molecule (*1*). Most of these fluorogenic probes unmask their intense fluorescence only by a user-designated chemical reaction and so they display a unique selectivity and limited interferences associated with the probe's concentration, excitation intensity, and emission sensitivity (*2, 3*). Thus, they are widely used in many fields because of their powerful ability to improve analytical sensitivity and also because they offer greater temporal and spatial sampling capability. For example, latent fluorophores are valuable tools for modern biochemical and biological research especially for the enzyme-linked immunosorbent assay (ELISA), high-throughput screening of enzyme inhibitors, detection of DNA and RNA, and evaluation of cell viability (*4*). Furthermore, emerging and more challenging biomedical applications such as *in vivo* fluorescence imaging also require the use of such smart fluorogenic probes (*5*). Thus, numerous pro-fluorophores suitable for the vizualization of biologically relevant molecules (H_2O_2 (*6*), $O_2^{-\bullet}$ (*7–9*), $ONOO^-$ (*10*), NO (*6, 11*), cysteine/homocysteine (*12, 13*), glutathione *14–17*), and enzyme activities (esterases *1–3, 18*), caspase-3 (*19, 20*), dipeptidyl peptidase IV substrate (DPP-IV) (*21, 22*), β-galactosidase (*23, 24*), β-lactamases (*25*), phosphatases (*1*) in various *in vitro* and *in cellulo* models, have been developed. However, few of them fulfill all the requirements for *in vivo* use (i.e., far-red or near-IR excitation and emission maxima (*26*), water solubility, serum stability, cell-membrane permeability, and so forth). Inspired by prodrug design (*27–29*), Jones et al. have proposed an attractive approach to develop efficient imaging probes which relies on the conjugation of the recognition unit (responsible for the selective reaction with the target analyte) to a masked aniline-based fluorophore *via* a "self-immolative" spacer (*30*). This latter reactive linker enables the unmasking of the pro-fluorophores through a multistep cascade reaction triggered by the analyte of interest and leading to the release of the free fluorescent molecule. As the target analyte is often a hydrolytic enzyme, the presence of a spacer between the recognition unit and the bulky fluorophore is beneficial to prevent steric hindrance around the cleavage site in order to generate better enzyme substrates. Furthermore, a heterobifunctional spacer permits the conjugation of fluorescent cores that do not necessarily contain the reactive group involved in the enzyme-cleavable bond of the target pro-fluorophore and so widens the scope of fluorescent labels that can be used to prepare the fluorogenic probes (e.g., the use of phenol, thiophenol, or aniline-based fluorophores to prepare protease-sensitive fluorogenic probes). Moreover, phenol-, thiophenol-, and even aniline-based fluorescent species often are good leaving groups: direct ester, thioester, or amide linkage of the fluorescent species at the enzyme-cleavable bond thus frequently gives rise to a

fragile bioprobe (*2, 3*), that often turns out to be sensitive to pH changes, and displays a noticeable nonspecific cleavage, often detrimental when highly sensitive phenomena are targeted. Because of the use of an intermediate self-immolative linker, the chemical functionality leading to the fluorophore release can be tuned in order to reduce drastically the background noise. Such latent fluorophore strategy was recently employed by some academic groups to prepare fluorogenic substrates of several hydrolytic enzymes (i.e., esterases (*31–33*) and β-galactosidase (*34*)) which could potentially be used for *in vivo* imaging. Surprisingly, few published works are devoted to the extension of this strategy to the design and synthesis of protease profluorescent substrates (for recent examples, see the molecular probes with UV−visible and fluorescence outputs for penicillin amidase activity, recently reported by Danieli et al. (*35*), Sicart et al. (*36*), and by us (*37*) and our akin strategy aimed at chemiluminescent probes for protease activity (*38*)). Given their critical role in numerous diseases, the evaluation of specific protease activities *in vivo* is of a great importance especially for diagnostic and therapeutic purposes. In that context, we describe here the synthesis, photophysical characterization, and preliminary biochemical studies of a new generation of fluorogenic probes resulting from the covalent association between a peptide sequence and a phenol-based fluorophore through the self-immolative spacer *para*-aminobenzyl alcohol (PABA). Latent fluorophores from two dyes (blue for **6a** and far-red for **6d**) were suitable for detecting the protease penicillin amidase (also known as penicillin G acylase, PGA) whereas fluorimetric reagents **11** and **13** were initially designed for imaging caspase-3 protease *in cellulo* and *in vivo*, respectively.

EXPERIMENTAL PROCEDURES

Chemicals and Reagents. Column chromatography purifications were performed on silica gel (40−63 μm) from SdS. TLC analyses were carried out on Merck DC Kieselgel 60 F-254 aluminum sheets. Compounds were visualized by one or both of the following methods: (1) spray with a 0.2% (w/v) ninhydrin solution in absolute ethanol, (2) spray with a 3.5% (w/v) phosphomolybdic acid solution in absolute ethanol. Acetonitrile was freshly distilled over CaH_2 under an argon atmosphere prior to use. Dichloromethane was dried by distillation over P_2O_5. Anhydrous NMP (H_2O < 100 ppm) was purchased from Fluka and stored over 4 Å molecular sieves. Pyridine was distilled over KOH and stored over BaO. DIEA and triethylamine (TEA) were distilled from CaH_2 and stored over BaO. 7-Hydroxycoumarin **5a** was purchased from Fluka. (Far)-red emitting phenol-based fluorophores 2-hydroxy Nile Red **5b**, DDAO **5c**, and DAO **5d** were synthesized according to previously reported procedures (*39–41*). The fully protected tetrapeptide Ac-Asp(OTMSE)-Glu(OTMSE)-Val-Asp(OTMSE)-OH and its PABA carboxamide derivative **8** were synthesized by using a multistep synthetic procedure recently reported by us (*38*). Recombinant human caspase-3 enzyme (5.52 U/mg) was purchased from Sigma. Penicillin amidase from *E. coli* and immobilized on Eupergit C (∼100 U/g) was purchased from Fluka. HPLC-gradient grade acetone and CH_3CN were obtained from Acros and Panreac, respectively. Buffers (caspase-3 and phosphate buffers) and aq. mobile phases for HPLC were prepared using deionized water purified with a Milli-Q system (purified to 18.2 MΩ.cm).

Instruments. ^1H and ^{13}C NMR spectra were recorded on a Bruker DPX 300 spectrometer (Bruker, Wissembourg, France). Chemical shifts are expressed in parts per million (ppm) from $CDCl_3$ ($\delta_H = 7.26$, $\delta_C = 77.36$), DMSO-d_6 ($\delta_H = 2.54$, $\delta_C = 40.45$), acetone-d_6 ($\delta_H = 2.09$, $\delta_C = 30.60$, and 205.87), or CD_3OD ($\delta_H = 3.34$, $\delta_C = 49.86$) (*42*). *J* values are expressed in Hz. Infrared (IR) spectra were recorded as thin-film on sodium chloride plates or KBr pellets using a Perkin-Elmer FT-IR Paragon 500 spectrometer. UV−visible spectra were obtained on a Varian Cary 50 scan spectrophotometer. Kinetic parameters were determined using a Molecular Devices fluorometric imaging plate reader FlexStation. Black clear-bottom 96-multiwell plates were purchased from Costar. Fluorescence spectroscopic studies were performed with a Varian Cary Eclipse spectrophotometer. Analytical HPLC was performed on a Thermo Electron Surveyor instrument equipped with a PDA detector. Semipreparative HPLC was performed on a Finnigan SpectraSYSTEM liquid chromatography system equipped with UV−visible 2000 detector. Mass spectra were obtained with a Finnigan LCQ Advantage MAX (ion trap) apparatus equipped with an electrospray source. LC-MS analyses were performed on a Thermo's Surveyor Plus HPLC system coupled with the Finnigan LCQ Advantage MAX (ionization mode, ESI±; capillary temperature, 270 °C; capillary voltage, ±10 V; tube lens offset, 0/−50 V).

HPLC Separations. Several chromatographic systems were used for the analytical experiments, the purification steps and the LC-MS analyses. Each one of these systems was optimized (except System G) in order to improve separation conditions.

System A: RP-HPLC (Thermo Hypersil GOLD C_{18} column, 5 μm, 4.6 × 150 mm) with CH_3CN and 0.1% aq. trifluoroacetic acid (aq. TFA, 0.1%, v/v, pH 2.0) as eluents [100% aq. TFA (5 min), then linear gradient from 0% to 100% (50 min) of CH_3CN] at a flow rate of 1.0 mL/min. Dual UV detection was achieved at 210 and 254 nm.

System B: System A with the following gradient [80% aq. TFA (5 min), then linear gradient from 20% to 100% (40 min) of CH_3CN].

System C1: RP-HPLC (Thermo Hypersil GOLD C_{18} column, 5 μm, 10 × 250 mm) with CH_3CN and 0.1% aq. trifluoroacetic acid (aq. TFA, 0.1%, v/v, pH 2.0) as eluents [80% aq. TFA (5 min), then linear gradient from 20% to 100% (50 min) of CH_3CN] at a flow rate of 5.0 mL/min. Dual UV detection was achieved at 254 and 320 nm.

System C2: System C1 with a Varian Kromasil C_{18} column (10 μm, 21.2 × 250 mm) running at a flow rate of 20.0 mL/min.

System D1: System C1 with visible detection at 450 nm.

System D2: System C2 with visible detection at 450 nm.

System E: RP-HPLC (Thermo Hypersil GOLD C_{18} column, 5 μm, 10 × 250 mm) with CH_3CN and aq. TFA 0.1% as eluents [100% aq. TFA (5 min), then linear gradient from 0% to 5% (10 min), 5% to 10% (10 min), and 10% to 100% (50 min) of CH_3CN] at a flow rate of 3.0 mL/min. Dual UV detection was achieved at 254 and 320 nm.

System F: System E with visible detection at 450 nm.

System G: RP-HPLC (Thermo Hypersil GOLD C_{18}, 5 μm, 2.1 × 150 mm) with CH_3CN and formic acid 0.1% (FA 0.1%) as eluents [90% FA (2 min), then linear gradient from 10 to 50% (13 min) and 50 to 90% (27 min) of CH_3CN] at a flow rate of 0.25 mL/min. UV detection was achieved at 260 nm. ESI-MS detection was achieved in both the positive and negative modes (mass range 75−750 a.m.u., centroid mode).

***N*-(4-(Hydroxymethyl)phenyl)-2-phenylacetamide (3).** *para*-Aminobenzyl alcohol **2** (322 mg, 2.61 mmol) was dissolved in a mixture of dry CH_2Cl_2/DMF (8:1, v/v, 9 mL) and the resulting solution was cooled to 0 °C. Dry pyridine (430 μL, 5.4 mmol) and phenylacetyl chloride **1** (340 μL, 2.57 mmol) were sequentially added and the reaction mixture was stirred at room temperature overnight. Thereafter, the mixture was concentrated under reduced pressure, then CH_2Cl_2 (50 mL) was added and the organic layer was washed with aq. citric acid (10%, w/v, 30 mL) and deionized water (30 mL). The aqueous layer was extracted twice with CH_2Cl_2 (30 mL); the combined organic

layers were dried over Na_2SO_4, filtered, and evaporated to dryness. The resulting residue was purified by chromatography on a silica gel column with a mixture of CH_2Cl_2/AcOEt (7:3, v/v) as the mobile phase, affording phenylacetamide **3** as a white solid (481 mg, 78%). R_f 0.5 (CH_2Cl_2/AcOEt, 7:3, v/v). IR (KBr) 3304, 3202, 3131, 1660, 1606, 1534, 1518, 1411, 1335, 1260, 1141, 1051 cm^{-1}. ^1H NMR (300 MHz, CD_3OD): δ 3.69 (s, 2H, ArCH_2), 4.57 (s, 2H, CH_2OH), 7.30−7.37 (m, 7H, 2 ArH_{PABA} + 5 ArH), 7.56 (d, J = 8.0 Hz, 2H, 2 ArH_{PABA}). ^{13}C NMR (75.4 MHz, CD_3OD): δ 44.7, 64.8, 121.2, 127.9, 128.6, 129.6, 130.1, 136.8, 138.6, 139.0, 172.3. MS (ESI, positive mode): m/z 242.27 $[M + H]^+$, calcd for $C_{15}H_{16}NO_2$ 242.12.

General Procedure for the Synthesis of the PGA Fluorogenic Probes. *(a) Preparation of the Mesylate Ester of* **4.** Alcohol **3** (443 mg, 1.84 mmol) was dissolved in dry acetone (23 mL) and the resulting solution was cooled to 0 °C. Triethylamine (770 μL, 5.5 mmol) and mesyl chloride (425 μL, 5.5 mmol) were sequentially added and the reaction mixture was stirred at room temperature overnight. Thereafter, CH_2Cl_2 (20 mL) was added and the solution was poured into cold 2 N aq HCl. The aqueous layer was extracted with CH_2Cl_2 (30 mL), and the combined organic layers were washed with deionized water (30 mL), dried over Na_2SO_4, filtered, and concentrated under reduced pressure, yielding mesylate ester **4** as a white solid. The crude product was quite unstable and was used without purification in the next step. ^1H NMR (300 MHz, $CDCl_3$): δ 3.62 (s, 3H, CH_3), 3.69 (s, 2H, ArCH_2), 4.49 (s, 2H, CH_2OH), 7.22−7.40 (m, 9H, ArH). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 44.7, 46.2, 52.8, 120.5, 127.8, 129.4, 129.6, 129.7, 133.8, 134.6, 138.0.

(b) Coupling Reaction of **4** *with the Fluorescent Label.* The phenol-based fluorophore was dissolved in dry CH_2Cl_2 (for 7-hydroxycoumarin **5a**, 0.1 M final concentration) or in dry DMF (for 2-hydroxy Nile Red **5b**, DDAO **5c** and DAO **5d**, 0.1 M final concentration). Anhydrous K_2CO_3 (2 equiv) was added and the reaction mixture was stirred at room temperature for 15 min. Then, compound **4** (1 equiv) was added and the reaction mixture was stirred at room temperature overnight. The reaction was checked for completion by RP-HPLC (system B), and evaporated under reduced pressure. CH_2Cl_2 (10 mL) was added and the organic layer was washed with deionized water, dried over Na_2SO_4, filtered, and evaporated to dryness. The crude product was purified by RP-HPLC (system C1 for **6a**, system D1 for **6b**, **6c**, and **6d**) to give after lyophilization the corresponding PGA probe in a pure form.

PGA Fluorogenic Probe (6a). White amorphous powder, overall yield 28%. R_f 0.5 (CH_2Cl_2/AcOEt, 1:1, v/v). ^1H NMR (300 MHz, $CDCl_3$): δ 3.66 (s, 2H, ArCH_2), 4.96 (s, 2H, CH_2OH), 6.15 (d, J = 9.0 Hz, 1H, ArH_{Coum}), 6.74−6.81 (m, 2H, ArH_{Coum}), 7.15−7.31 (m, 8H, ArH + ArH_{PABA} + ArH_{Coum}), 7.39 (d, J = 8.0 Hz, 2H, ArH_{PABA}), 7.54 (d, J = 9.0 Hz, 1H, ArH_{Coum}). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 45.1, 70.4, 102.2, 113.5, 113.6, 120.3, 128.0, 128.7, 129.1, 129.6, 129.8, 132.0, 134.7, 138.1, 143.8, 156.0, 161.6, 162.1, 169.6. MS (ESI, positive mode): m/z 386.33 $[M + H]^+$, calcd for $C_{24}H_{20}NO_4$ 386.14. HPLC (system B): t_R = 29.4 min (purity >95%). UV (CH_3CN, 25 °C): λ_{max} = 275 nm (63 000 M^{-1} cm^{-1}).

PGA Fluorogenic Probe (6b). Red amorphous powder, overall yield 5%. ^1H NMR (300 MHz, DMSO-d_6): δ 1.20 (t, 6H, J = 7.0 Hz, 2 CH_3), 3.55 (q, 4H, J = 7.0 Hz, 2 CH_2CH$_3$), 5.29 (s, 2H, ArCH_2CO), 6.25 (s, 1H, ArH), 6.72 (s, 1H, ArH), 6.84−6.90 (m, 1H, ArH), 7.20−7.42 (m, 6H, ArH), 7.50 (d, 2H, J = 9.0 Hz, ArH), 7.62−7.80 (m, 3H, ArH), 8.05−8.12 (m, 2H, ArH). MS (ESI, positive mode): m/z 558.27 $[M + H]^+$, calcd for $C_{35}H_{32}N_3O_4$ 558.24. HPLC (system B): t_R = 31.7 min (purity 90%). UV−vis (PB/acetone, 8:2, v/v, 25 °C): λ_{max} = 543 nm.

PGA Fluorogenic Probe (6c). Orange amorphous powder, overall yield 7%. R_f 0.5 (CH_2Cl_2/AcOEt, 3:2, v/v). ^1H NMR (300 MHz, $CDCl_3$): δ 1.78 (s, 3H, CH_3), 1.85 (s, 3H, CH_3), 3.77 (s, 2H, ArCH_2), 5.04 (s, 2H, CH_2OH), 6.66−6.69 (m, 1H, ArH_{DDAO}), 7.13 (s, 1H, ArH_{DDAO}), 7.30−7.51 (m, 10H, 5ArH + 4ArH_{PABA} + ArH_{DDAO}), 7.63 (s, 1H, ArH_{DDAO}), 7.75 (s, 1H, NH). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 29.1, 38.4, 45.2, 75.0, 114.1, 114.3, 120.0, 120.3, 128.1, 128.8, 128.9, 129.1, 129.6(6), 129.7, 129.9, 130.6, 132.5, 132.9, 133.7, 134.6, 138.3, 139.8, 140.4, 141.0, 141.3, 148.7, 153.0, 153.5, 169.5, 187.7. MS (ESI, positive mode): m/z 553.33 $[M + Na]^+$, calcd for $C_{30}H_{24}Cl_2NaN_2O_3$ 553.11. HPLC (system B): t_R = 36.8 min (purity 94%). UV−vis (PB/acetone, 8:2, v/v, 25 °C): λ_{max} = 424 nm (15 000 M^{-1} cm^{-1}).

PGA Fluorogenic Probe (6d). Orange amorphous powder, overall yield 14%. ^1H NMR (300 MHz, acetone-d_6): δ 1.57 (s, 6H, 2CH_3), 3.70 (s, 2H, ArCH_2), 5.20 (s, 2H, CH_2OH), 6.55 (dd, J = 2.0 and 10.0 Hz, 1H, ArH_{DAO}), 6.68 (d, J = 2.0 Hz, 1H, ArH_{DAO}), 7.07 (dd, J = 3.0 and 9.0 Hz, 1H, ArH_{DAO}), 7.22−7.48 (m, 9H, 5ArH + 2ArH_{PABA} + 2ArH_{DAO}), 7.60 (d, J = 9.0 Hz, 1H, ArH_{DAO}), 7.71 (d, J = 8.0 Hz, 2H, 2ArH_{PABA}). ^{13}C NMR (75.4 MHz, acetone-d_6): δ 32.2, 37.7, 44.3, 70.3, 113.4, 114.4, 119.6, 127.1, 127.6, 128.8, 129.1, 129.7, 131.3, 132.1, 134.0, 136.4, 137.2, 139.9, 140.2, 142.0, 148.1, 150.8, 161.7, 169.4, 186.8. MS (ESI, positive mode): m/z 463.13 $[M + H]^+$, calcd for $C_{30}H_{27}N_2O_3$ 463.20. HPLC (system B): t_R = 31.6 min (purity 95%). UV−vis (PB/acetone, 8:2, v/v, 25 °C): λ_{max} = 458 nm (17 000 M^{-1} cm^{-1}).

Fully Protected Caspase-3 Latent Blue Fluorophore (10). PABA carboxamide derivative **8** (152 mg, 0.16 mmol) was dissolved in dry acetone (2 mL) and the resulting solution was cooled to 0 °C. Then, triethylamine (67 μL, 0.48 mmol) and mesyl chloride (37 μL, 0.48 mmol) were sequentially added and the resulting reaction mixture was stirred at room temperature overnight. Thereafter, the reaction was quenched by dilution with CH_2Cl_2 (5 mL) and pourring in cold 2 N aq HCl. The aqueous layer was extracted with CH_2Cl_2 (2 × 10 mL). The combined organic layers were washed with deionized water (10 mL), dried over Na_2SO_4, filtered, and evaporated to dryness, affording the mesylate ester **9** as a yellow solid. This crude product was used without purification in the next step. 7-Hydroxycoumarin **5a** (29 mg, 0.18 mmol, 1.1 equiv based on the former step) was dissolved in dry CH_2Cl_2 (2 mL). Anhydrous K_2CO_3 (44 mg, 0.32 mmol, 2 equiv) was added and the mixture was stirred for 20 min, allowing the solution to become yellow-colored. Then, the crude mesylate ester in solution in dry CH_2Cl_2 (2 mL) was added and the reaction mixture was stirred at room temperature overnight. The reaction was checked for completion by RP-HPLC (system B). Thereafter, CH_2Cl_2 (10 mL) was added and the resulting solution was washed with deionized water (10 mL). The organic layer was dried over Na_2SO_4, filtered, and evaporated to dryness. The crude product was purified by RP-HPLC (system C2), to give after lyophilization the corresponding fully protected caspase-3 pro-fluorophore **10** as a white amorphous powder (32 mg, 25%). ^1H NMR (300 MHz, $CDCl_3$): δ 0.02 (s, 9H, Si(CH_3)$_3$), 0.03 (s, 9H, Si(CH_3)$_3$), 0.05 (s, 9H, Si(CH_3)$_3$), 0.96−1.02 (m, 12H, 3CH_2Si + 2CH_{3Val}), 2.07 (s, 3H, CH_3), 2.10−2.20 (m, 2H, CH_{2Glu}), 2.32−2.39 (m, 1H, CHCH$_3$), 2.51−2.62 (m, 2H, CH_2CO$_{Glu}$), 2.85−3.12 (m, 4H, 2CH_{2Asp}), 4.02−4.28 (m, 8H, C*H_{Val} + C*H_{Glu} + 3OCH_2), 4.67−4.73 (m, 1H, C*H_{Asp}), 4.95−5.12 (m, 3H, ArCH_2O + C*H_{Asp}), 6.24 (d, J = 9.0 Hz, 1H, ArH_{Coum}), 6.84−6.92 (m, 2H, 2ArH_{Coum}), 7.09 (d, J = 7.0 Hz, 1H, NH_{Asp}), 7.20 (d, J = 7.0 Hz, 1H, NH_{Val}), 7.34−7.37 (m, 3H, 2ArH_{PABA} + ArH_{Coum}), 7.58−7.64 (m, 2H, ArH_{Coum} + NH_{Asp}), 7.78 (d, J = 8.0 Hz, 2H, ArH_{PABA}), 8.47 (d, J = 3.0 Hz, 1H, NH_{Glu}), 8.67 (s, 1H, NH_{PABA}). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ −1.2 (9C), 17.6

(3C), 18.1, 19.6, 23.3, 25.3, 29.3, 31.6, 36.0, 36.8, 50.3, 51.1, 56.9, 60.7, 63.6, 64.3, 64.4, 70.6, 102.3, 113.0, 113.5, 113.6, 120.6 (2C), 128.6 (2C), 129.0, 131.5, 138.7, 143.8, 156.1, 161.6, 162.2, 169.0, 171.3, 171.4, 171.9, 172.5, 172.8, 172.9, 176.0. MS (ESI, positive mode): *m/z* 1068.40 $[M + H]^+$, calcd for $C_{51}H_{78}N_5O_{14}Si_3$ 1068.49. HPLC (system A): $t_R = 42.0$ min (purity >98%).

Caspase-3 Latent Blue Fluorophore (11). Fully protected pro-fluorophore **10** (12 mg, 11.2 μmol) was dissolved in dry NMP and anhydrous CsF salt (31 mg, 210 μmol) was added. The resulting reaction mixture was stirred at room temperature. Further amounts of CsF (80 equiv and 100 equiv) were added after 16 and 30 h. The reaction was checked for completion by RP-HPLC (system A). Fully protected peptide starting material was completely consumed after 40 h. Finally, the reaction mixture was quenched by dilution with 0.1% aq TFA (3 mL) and purified by RP-HPLC (system E). The product-containing fractions were lyophilized to give the caspase-3 pro-fluorophore **11** as a pale yellow amorphous powder (8.0 mg, quantitative yield). IR (KBr) 3278, 2971, 2883, 1742, 1686, 1664, 1618, 1542, 1490, 1384, 1197, 1140 cm^{-1}. ^1H NMR (300 MHz, DMSO-d_6): δ 0.84−0.89 (m, 6H, 2CH_{3Val}), 1.70−2.10 (m, 6H, CHCH$_3$ + CH_{2Glu} + CH_3), 2.25−2.31 (m, 2H, CH_2CO$_{Glu}$), 2.52−2.80 (m, 4H, 2CH_{2Asp}), 4.15−4.21 (m, 1H, C*H_{Val}), 4.35−4.41 (m, 1H, C*H_{Glu}), 4.50−4.54 (m, 1H, C*H_{Asp}), 4.67−4.73 (m, 1H, C*H_{Asp}), 5.18 (s, 2H, ArOCH_2), 6.33 (d, $J = 9.4$ Hz, 1H, ArH_{Coum}), 7.03 (d, $J = 8.7$ Hz, 1H, ArH_{Coum}), 7.11 (s, 1H, ArH_{Coum}), 7.44 (d, $J = 8.6$ Hz, 2H, 2ArH_{PABA}), 7.66 (m, 3H, ArH_{Coum} + 2ArH_{PABA}) 7.85 (d, $J = 7.5$ Hz, 1H, NH_{Val}), 8.01−8.15 (m, 3H, ArH_{Coum} + NH_{Glu} + NH_{Asp}), 8.42 (d, $J = 6.8$ Hz, 1H, NH_{Asp}), 10.00 (s, 1H, COOH), 12.2−12.5 (m_{Broad}, 2H, 2COOH). MS (ESI, positive mode): *m/z* 768.20 $[M + H]^+$, calcd for $C_{36}H_{42}N_5O_{14}$ 768.27. HPLC (system A): $t_R = 23.6$ min (purity 95%). UV (caspase-3 buffer, 37 °C): λ_{max} = 250 and 320 nm (17 000 M^{-1} cm^{-1}).

Fully Protected Caspase-3 Latent Far-Red Fluorophore (12). 7-Hydroxy-9*H*-(9,9-dimethylacridin-2-one) (DAO) **5d** (10 mg, 42 μmol) was dissolved in dry DMF (800 μL). Anhydrous K_2CO_3 (12 mg, 84 μmol) was added and the resulting reaction mixture was stirred at room temperature for 20 min, allowing the solution to become blue-colored. Then, mesylate ester **9** (35 mg, 35 μmol) was added and the labeling reaction mixture was stirred at room temperature overnight. The reaction was checked for completion by RP-HPLC (system B). Thereafter, CH_2Cl_2 (15 mL) was added and the organic layer was washed with deionized water (7 mL), dried over Na_2SO_4, filtered, and evaporated to dryness. The crude product was purified by RP-HPLC (system D2), to give after lyophilization the corresponding fully protected caspase-3 pro-fluorophore **12** as an orange amorphous powder (4 mg, 13%). ^1H NMR (300 MHz, $CDCl_3$): δ 0.02 (s, 9H, Si(CH_3)$_3$), 0.03 (s, 9H, Si(CH_3)$_3$), 0.05 (s, 9H, Si(CH_3)$_3$), 0.78−1.02 (m, 12H, 3CH_2Si + 2CH_{3Val}), 1.19 (s, 3H, CH_{3DAO}), 1.25 (s, 3H, CH_{3DAO}), 1.95−2.20 (m, 5H, CH_{2Glu} + CH_3), 2.25−2.39 (m, 1H, CHCH$_3$), 2.45−2.62 (m, 2H, CH_2CO$_{Glu}$), 2.80−3.12 (m, 4H, 2CH_{2Asp}), 3.95−4.22 (m, 8H, C*H_{Val} + C*H_{Glu} + 3OCH_2), 4.65−4.72 (m, 1H, C*H_{Asp}), 4.95−5.09 (m, 3H, ArCH_2O + C*H_{Asp}), 6.58−6.66 (m, 3H, 3ArH_{DAO}), 6.93−6.97 (m, 1H, ArH_{DAO}), 7.08−7.12 (m, 2H, NH_{Val} + NH_{Asp}), 7.35−7.41 (m, 3H, ArH_{DAO} + 2ArH_{PABA}), 7.58−7.63 (m, 2H, NH_{Asp} + ArH_{DAO}), 7.77−7.80 (d, 2H, J = 8.7 Hz, 2ArH_{PABA}), 8.47 (d, $J = 4.2$ Hz, 1H, NH_{Glu}), 8.67 (s, 1H, NH_{PABA}). MS (ESI, positive mode): *m/z* 1145.33 $[M + H]^+$, calcd for $C_{57}H_{85}N_6O_{13}Si_3$ 1145.55. HPLC (system A): $t_R = 39.5$ min (purity 90%).

Caspase-3 Latent Far-Red Fluorophore (13). Fully protected peptide **12** (3.0 mg, 2.6 μmol) was dissolved in dry NMP. A large excess of anhydrous CsF salt (79.0 mg, 520 μmol) was added and the deprotection reaction mixture was stirred at room temperature for 48 h. The reaction was checked for completion by RP-HPLC (system A). Finally, the reaction mixture was quenched by dilution with 0.1% aq TFA (3 mL) and purified by RP-HPLC (system F). The product-containing fractions were lyophilized to give the caspase-3 pro-fluorophore **13** as an orange amorphous powder. This fluorogenic caspase-3 substrate was water-solubilized through its conversion into the tris-NH_4^+ salt by brief treatment with 5 μL of 3% aq NH_4OH followed by lyophilization. Quantification was achieved in caspase-3 buffer at $\lambda_{max} = 457$ nm by using the ε value 6500 M^{-1} cm^{-1} (yield after RP-HPLC purification: 82%). MS (ESI, negative mode): *m*/z 843.33 $[M - H]^-$, calcd for $C_{42}H_{47}N_6O_{13}$ 843.32. HPLC (system A): $t_R = 25.8$ min (purity 91%). UV−vis (caspase-3 buffer, 37 °C): λ_{max} = 247 and 457 nm (6500 M^{-1} cm^{-1}).

General Procedure for the *in Vitro* Cleavage PGA Fluorogenic Probes by Immobilized Penicillin Amidase. *(a) Fluorescence Assay.* A solution of PGA fluorogenic probe (final concentration: 2.6 μM for **6a** and 2.2 μM for **6d**) was prepared with a mixture of phosphate buffer (PB, 50 mM, pH 7.4) and acetone (PB/acetone, 8:2, v/v). 1.25 mL of this solution was transferred into a semimicro quartz fluorescence cell (Hellma, 104F-QS, 10 × 4 mm, 1400 μL) and immobilized penicillin amidase (6.4 U, 64 mg) was added. The resulting mixture was incubated at 37 °C. Fluorescence emission of the enzymatically released phenol-based fluorophore (i.e., 7-hydroxycoumarin **5a** at $\lambda = 460$ nm or DAO **5d** at $\lambda = 651$ nm) was monitored over time with measurements every 6 s, after excitation at $\lambda = 360$ nm (for **5a**) or 638 nm (for **5d**). The same conditions were applied to the control sample without adding the enzyme and no significant fluorescence signal was detected.

(b) Characterization of Cleavage by RP-HPLC. PGA fluorogenic probe was dissolved (final concentration: 1.65 mM for **6a** and 1.2 mM for **6d**) in a mixture of phosphate buffer and acetone (PB/acetone 8:2, v/v, 2 mL). For the fluorogenic probe **6d**, 2,6-di-*O*-methyl-β-cyclodextrin (46 mg, 35 μmol) was added to improve the solubility in the aq buffer. Immobilized penicillin amidase (16.7 U, 167 mg for **6a** or 15.0 U, 150 mg for **6d**) was added and the resulting suspension was stirred at 37 °C for 24 h. Periodically, 100 μL of the crude enzymatic mixture were sampled (the biocatalyst was filtered off), dissolved with 300 μL of triethylammonium acetate buffer (TEAA, 100 mM, pH 7.0), and analyzed by RP-HPLC (system A, injection volume: 10 μL). Quantification of **5a**/**6a** (or **5d**/**6d**) was achieved by measurement of the corresponding peak areas at $t_R = 15.6$ and 29.3 min (or $t_R = 21.2$ and 31.5 min).

Optical Properties of DAO 5d. The absorption spectrum of DAO was recorded (220−900 nm) in PBS (0.1 M phosphate, 0.15 M NaCl, pH 7.4) (a 4.2 mM stock solution was prepared in DMSO and diluted with PBS to reach a final concentration of 14.0 μM) at 25 °C. Emission spectrum was recorded under the same conditions after excitation at 610 nm (excitation and emission slit = 5 nm). Relative quantum yield was measured in PBS at 25 °C by a relative method using sulfocyanine dye Cy 5.0 ($\Phi_F = 0.20$ in PBS (*43*)). The following equation was used to determine the relative fluorescence quantum yield:

$$\Phi_F(\text{DAO}) = (A_{Cy5.0}/A_{DAO})(F_{DAO}/F_{Cy5.0})(n_{DAO}/n_{Cy5.0})^2\Phi F_{(Cy\ 5.0)} \quad (1)$$

where A is the absorbance (in the range 0.01−0.1 A.U.), F is the area under the emission curve (620−850 nm after excitation at 610 nm), and n is the refractive index of the solvent (at 25 °C) used in measurements ($n = 1.337$ for PBS). The slopes were determined to be: 9.65×10^4 and 2.43×10^5 ($R^2 = 0.99$) for DAO and Cy 5.0, respectively.

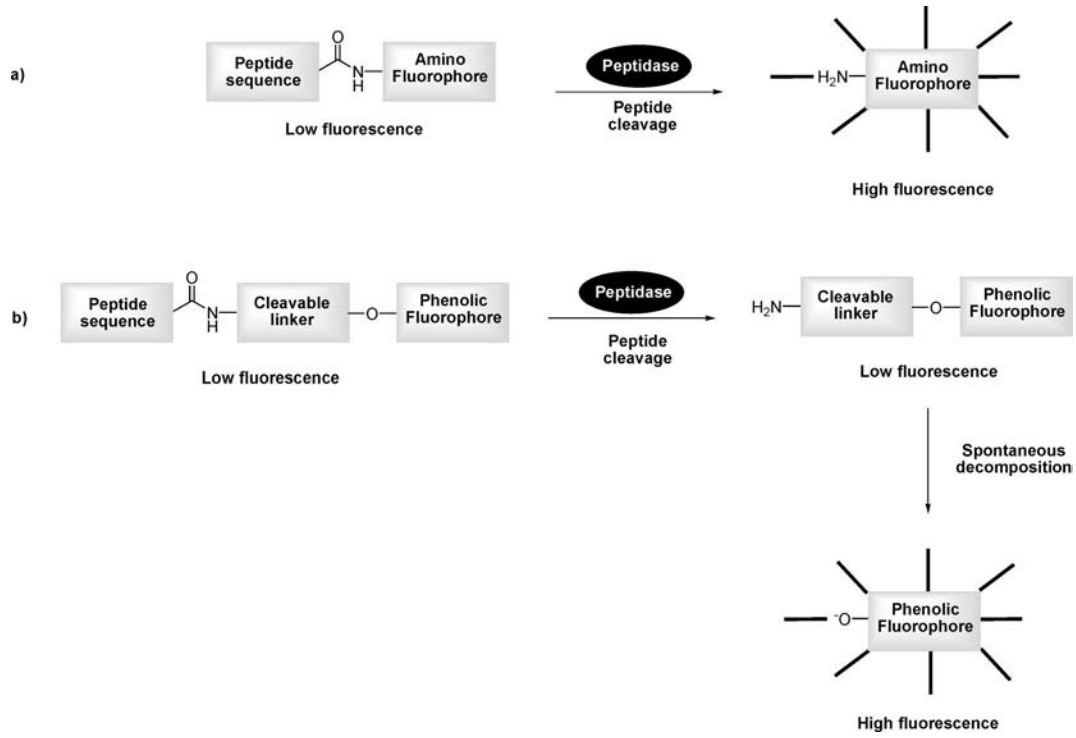

Figure 1. General mechanisms of the activation of pro-fluorophores by proteolytic enzymes. (a) Release of aniline-based fluorophores. (b) Release of phenol-based fluorophores through a self-immolative strategy.

General Procedure for the *in Vitro* Cleavage of Latent Blue and Far-Red Fluorophores 11 and 13 by Recombinant Human Caspase-3. *(a) Fluorescence Assay.* A solution of latent fluorophore (final concentration: 3.0 μM for **11** and 23.0 μM for **13**) was prepared with the following caspase-3 buffer: 100 mM NaCl, 40 mM HEPES, 10 mM DTT, 1 mM EDTA, 10% (w/v) sucrose, and 0.1% (w/v) CHAPS, pH 7.4. 50 μL of this solution were transferred into an ultramicro fluorescence cell (Hellma, 105.51-QS, 3 $\times$ 3 mm, 45 μL), human recombinant caspase-3 (1 μL, 1.6 $\times$ 10^{-3} U for **11** and 2 μL, 3.2 $\times$ 10^{-3} U for **13**) was added and the resulting mixture was incubated at 37 °C. Fluorescence emission of the enzymatically released phenol-based fluorophore (i.e., 7-hydroxycoumarin **5a** at λ = 460 nm or DAO **5d** at λ = 651 nm) was monitored over time with measurements every 5 s, after excitation at λ = 360 nm (for **5a**) or 638 nm (for **5d**). The same conditions were applied to the control sample solution without adding enzyme. No significant fluorescence signal was detected.

(b) Determination of the Kinetic Parameters for the Caspase-3 Hydrolysis of **11.** Latent blue fluorophore **11** was diluted in caspase-3 buffer at the following concentrations 100 μM, 50 μM, 25 μM, 12.5 μM, 6.25 μM, and 3.125 μM and put into a black clear-bottom 96-multiwell plate. Then, 1.0 pmol of recombinant human caspase-3 preheated during 15 min at 37 °C was added (final concentration: 20 nM). The reaction was monitored with FlexStation for 2 h with measurements every 30 s (Ex. λ = 370 nm, Em. λ = 460 nm, 37 °C, cutoff filter λ = 455 nm). A calibration curve using umbelliferone **5a** was used to convert relative fluorescence units in mole of transformed product. Initial velocity V_0 was measured for each substrate concentration, and K_M, V_{max}, k_{cat}, and k_{cat}/K_M values were determined with the double-inverse Lineweaver−Burk relationship. The determination of the kinetic parameters was performed in triplicate; the kinetic constants presented are an average of the values found.

RESULTS AND DISCUSSION

Choice of the Self-Immolative Linker. During the past decade, numerous self-immolative linker strategies have been developed for the design of efficient prodrugs of various pharmaceuticals (*29*) and functionalized solid supports suitable for the synthesis of organic compound libraries through combinatorial or parallel methods (*44–47*). As suggested in some recent publications (*30, 34*), the use of a self-cleavable linker as a spacer unit between the peptidyl substrate and a fluorescent label is potentially beneficial to improve both enzymatic reactivity and spectral properties (especially in the far-red to NIR region) and to reduce the background noise associated with nonspecific hydrolysis of the resulting pro-fluorophore compared to "standard" two-component fluorogenic protease substrates. Indeed, the self-decomposition of the linker through a protease-initiated domino reaction allows the release of a wide range of fluorophores bearing an aniline, a phenol, or a thiophenol moiety (*48*). Therefore, structures more sophisticated than basic carboxamide derivatives of fluorescent amines (i.e., 7-amino-4-methylcoumarin (AMC), rhodamine 110, or cresyl violet) can be envisaged to get protease-activated optical probes with excellent analytical properties (Figure 1). In this context, we first explored the use of the enzyme-labile safety catch linker recently reported by Grether and Waldmann, which allows the release of alcohols or amines through an original enzyme-initiated lactam-cyclization (*49, 50*). A latent blue fluorophore of penicillin amidase derived from this traceless linker was prepared in six steps from homovanilinic acid: however, *in vitro* cleavage experiments (fluorescence and HPLC assays) with PGA have clearly shown the moderate stability of its ester linkage under simulated physiological conditions due to the good leaving-group character of the 7-hydroxycoumarin fluorophore employed. Consequently, we decided to graft the phenol-based fluorophore through a less reactive ether bond by using the commercially available *para*-aminobenzyl alcohol (PABA) as the self-immolative spacer (Figure 2) (*51*). PABA is one of the most popular self-immolative linker applicable in prodrug design (*52*) and its utility in the field of spectroscopic bioprobes was recently demonstrated by Jones et al. through the design of an image contrast agent employing AMC as fluorophore and

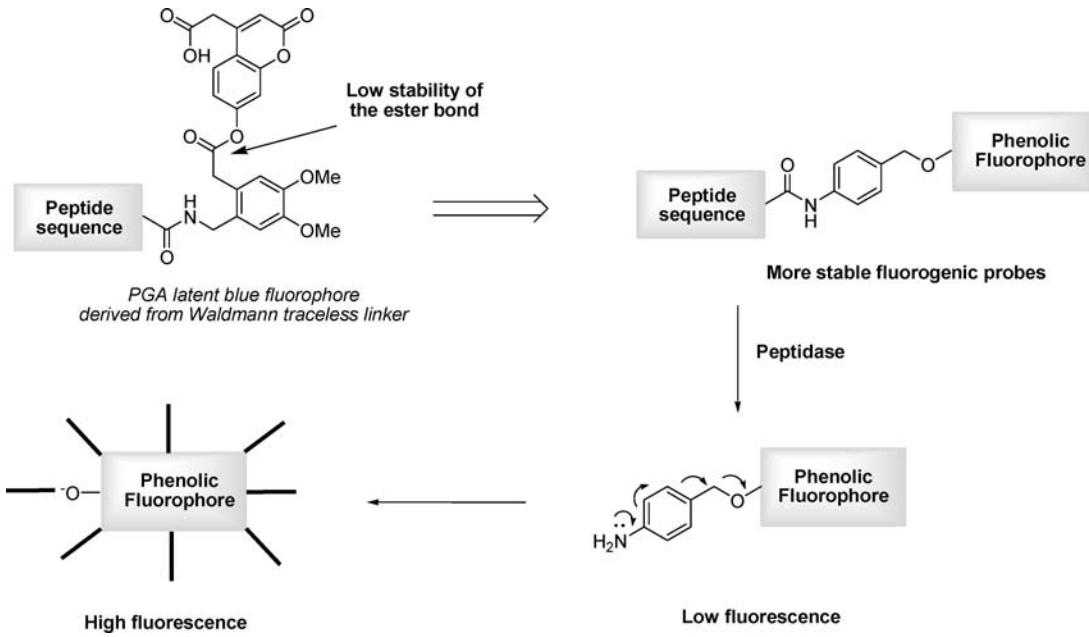

Figure 2. General structure of the first generation peptidase-sensitive pro-fluorophores based on the Waldmann enzyme-labile safety catch linker. General structure of the second generation peptidase-sensitive pro-fluorophores and principle of their activation through the self-immolation of PABA linker.

selective activation by the serine protease prostate specific antigen (PSA) (*30*).

Penicillin Amidase-Sensitive Pro-Fluorescent Probes. To validate our self-immolative approach in the context of protease-sensitive pro-fluorescent probes, we first carried out assays with penicillin amidase (PGA), a commercially available and widely used biocatalyst in the enzymatic synthesis of β-lactam antibiotics, since it allows the deprotection of phenacetyl protected amines (*53*). As this enzyme is inexpensive and readily available under an immobilized form which tolerates the use of an organic cosolvent such as acetone or methanol, it is widely employed as a suitable reagent or catalyst in organic synthesis especially for the selective deprotection of amino groups within complex molecular architectures (dendrimers (*54–56*), peptides (*57*), and so forth), both in solution or on solid phase. Interestingly, the current method for *in vitro* detection of PGA activity relies on the use of phenylacetamide derivatives of fluorescent amines (e.g., AMC) as fluorogenic substrates (*58*). Thus, we synthesized a novel class of PGA-sensitive pro-fluorescent probes in order to check if the PABA moiety inserted between the fluorophore and the protease-reactive group of our latent fluorophores was suitable to fulfill all requirements for biomolecular imaging applications: (1) changes of the fluorescence properties (especially significant increase in emission intensity) upon reaction with enzyme, (2) chemical stability under physiological conditions, and (3) efficiency of the enzyme-initiated fluorophore releasing process. Theoretically, our latent fluorophore strategy is applicable to all labeling dyes having a phenol moiety whose acylation (or alkylation) significantly affects their fluorescence properties. However, as *in cellulo* and *in vivo* applications require the use of fluorescent compounds exhibiting a significant emission in the range 450−750 nm (650−750 nm for *in vivo*) our choice was guided toward four well-known fluorescent phenols, namely, 7-hydroxycoumarin (umbelliferone) **5a**, 2-hydroxy Nile Red **5b**, 7-hydroxy-9*H*-(1,3-dichloro-9,9-dimethylacridin-2-one) (DDAO) **5c**, and 7-hydroxy-9*H*-(9,9-dimethylacridin-2-one (DAO) **5d**. The corresponding PGA-sensitive pro-fluorescent probes were prepared as shown in Scheme 1. condensation of the fluorescent phenol with the phenylacetamide derivative of PABA **3** was achieved by a nucleophilic substitution of the mesylate derivative **4**. Purification of all pro-fluorophores was performed by semipreparative RP-HPLC using 0.1% aqueous trifluoroacetic acid (TFA, pH 2.0) and acetonitrile as eluents (overall yields for two steps 10−28%). The modest isolated yields are explained by the competitive degradation of **4** under basic reaction conditions and the significant loss of fluorogenic substrate during the subsequent chromatographic purification. All spectroscopic data, especially NMR and mass spectrometry, were in agreement with the structures assigned.

The spectral properties of the four novel PGA-sensitive pro-fluorophores were evaluated, compared with those of the corresponding parent phenol-based fluorophore, and collected in Table 1 (for their emission spectra compared with those of free fluorophores, see Supporting Information). The pro-fluorescent probes **6a**, **6c**, and **6d** displayed the expected hypsochromic shift of excitation and emission spectra relative to the free fluorophores and exhibited no significant fluorescence at the maximum emission wavelength of the corresponding parent phenol dye (460 nm for **5a**, 651 nm for **5c** and **5d**). Indeed, the chemical modification of the hydroxyl group (i.e., modification of the phenol either to an ether or an ester) of a fluorescent phenol is known to effectively quench its fluorescence (*59*) and this property has already been used to design efficient fluorogenic probes for detection of β-galactosidase, β-lactamases, and phosphatases (*1*). However, we observed that this particular trend for phenol-based fluorophores was not followed by the benzophenoxazine derivative **6b**, because in our measurements, its fluorescence intensity showed only a 2-fold decrease compared to the parent 2-hydroxy Nile Red and the expected blue-shift of its maximum emission wavelength was not observed. This result is consistent with an earlier report from Briggs et al. showing that the esterification of the hydroxyl group of Nile Red derivatives does not significantly affect their optical properties and prevents the use of such phenol-based fluorophores in the context of fluorogenic probes based on the pro-fluorescence concept (*41*). Furthermore, during the course of our spectroscopic studies, we observed an anomalous behavior of the pro-fluorophore **6c** whose fluorescence significantly increases during incubation with a 8:2 mixture of phosphate buffer (PB, pH 7.4) and acetone. This nonenzymatic fluorescence unveiling of probe **6c** was attributed to the release of the DDAO dye through the hydrolytic cleavage of its ether

Scheme 1. Synthesis of PGA-Sensitive Pro-Fluorescent Probes

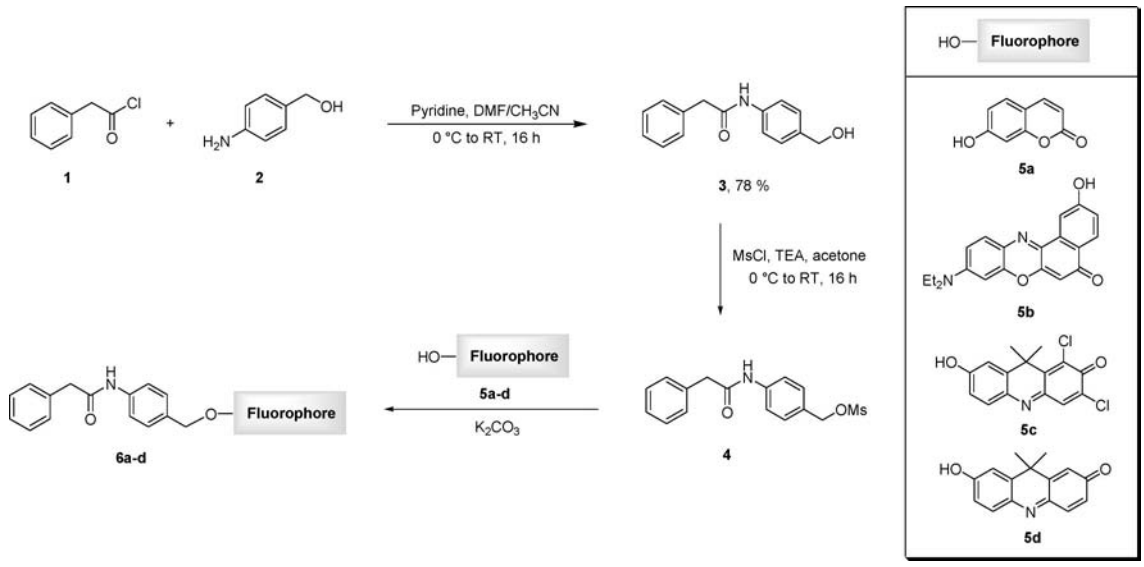

Table 1. Fluorescence Excitation and Emission Wavelengths of PGA-Sensitive Pro-Fluorophores and the Free Phenol Dyes Released by the Enzyme-Initiated Domino Reaction

	PGA pro-fluorophore[a]			free fluorophore[a]	
compound	excitation (nm)	emission (nm)	fluorescence intensity[b]	excitation (nm)	emission (nm)
6a	275	nonfl	nonfl	360	460
6b	530	652	2-fold reduction	582	655
6c	-[c]	-[c]	-[c]	636	651
6d	458	599	8.5-fold reduction	638[d]	651[d]

[a] All spectral properties were determined in a 8:2 (v/v) mixture of phosphate buffer (PB, 50 mM, pH 7.4) and acetone at 25 °C. [b] Calculated by the fluorescence intensity ratio between pro-fluorophore and free fluorophore at the same concentration. [c] Compound **6c** was found to be unstable in the mixture PB/acetone. [d] The fluorescence quantum yield of free DAO **5d** is 0.079 (determined in PBS at 25 °C by using sulfocyanine dye Cy 5.0 (Φ_F = 0.20 in PBS at 25 °C (*43*) as a standard) and the molar exctinction coefficient at λ_{max} = 633 nm is 24 450 M^{-1} cm^{-1}.

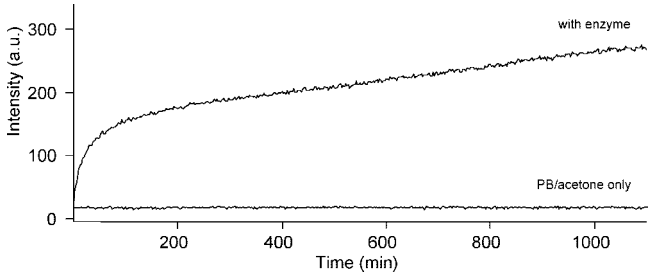

Figure 3. Fluorescence emission time course of pro-fluorescent probe **6d** (concentration 2.2 μM) with immobilized penicillin amidase (6.4 U, incubation time 24 h at 37 °C) in a 8:2 (v/v) mixture of phosphate buffer (50 mM, pH 7.4) and acetone at 651 nm (Ex. λ = 638 nm).

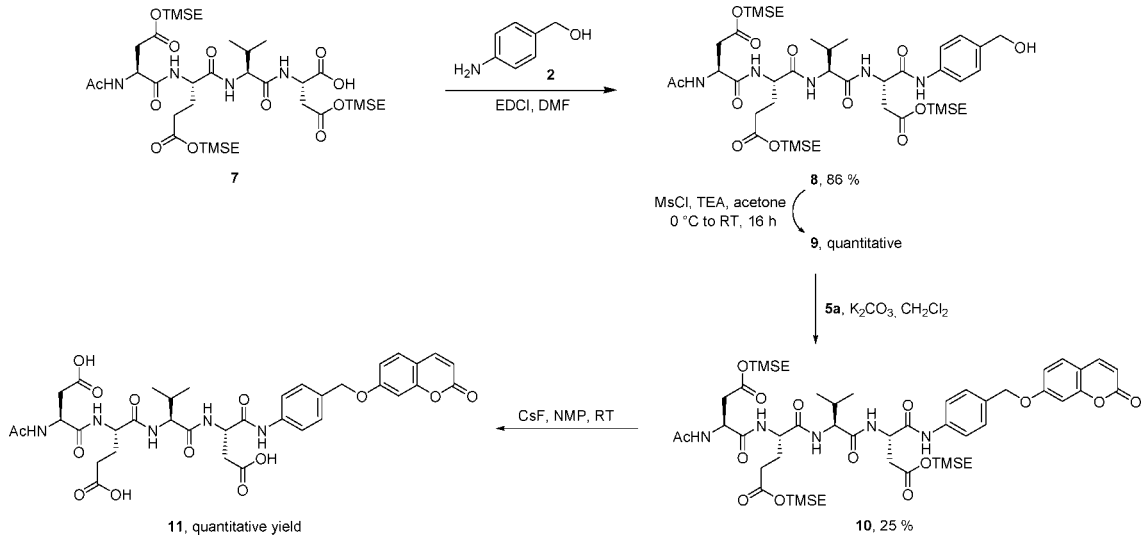
bond in neutral physiological conditions. Due to the presence of two chlorine atoms within its acridin-2-one core, DDAO is too good as a leaving group to be a valuable candidate for the latent fluorophore strategy. Surprisingly, the low chemical stability of fluorogenic substrates using DDAO as a pro-fluorescent label in aqueous solution has never been observed and reported in the literature, whereas some DDAO esters and ether derivatives of biomolecules (i.e., β-D-galactopyranose, nucleotide polyphosphates) have been developed and successfully used to monitor enzyme activities *in vivo* or as reagents for various homogeneous nucleic acid assays (*23, 60*).

Finally, only the two completely quenched and stable pro-fluorophores **6a** and **6d** were tested against immobilized PGA. As an illustrative example, the time-course for the amidase catalyzed hydrolysis of **6d** is shown in Figure 3 (see Supporting Information for results obtained with **6a**). After adding immobilized PGA to the substrate solution, a strong fluorescence signal generated at 651 nm indicated the catalytic cleavage of the carboxamide bond and the release of the free DAO dye. Furthermore, no nonspecific cleavage of the probe was detected in a control reaction where **6d** was incubated only with the mixture PB/acetone (8:2, v/v). Overall, these results confirm that the latent red fluorophore **6d** is a substrate for penicillin amidase. In addition to these spectral measurements, RP-HPLC analyses of the enzymatic hydrolysis mixture of **6d** were performed to prove the identity of the released fluorescent phenol (i.e., DAO, t_R = 15.6 min) and the efficacy of this release process (see Supporting Information). Thus, we validated that the connection of a protease-sensitive substrate to a phenol-base fluorophore through a self-immolative PABA linker is an efficient way to obtain activatable pro-fluorescent probes exhibiting both chemical stability and enzymatic reactivity. We then extended the scope of this approach to the detection of a more challenging protease belonging to the caspase family (i.e., caspase-3) in an attempt to perform *in cellulo* and *in vivo* imaging of apoptosis.

Synthesis of Caspase-3 Sensitive Pro-Fluorescent Probes. Caspases are Cysteine-ASpartic-acid-ProteASES that play a critical role as mediators for apoptotic cell death (*61*). Caspase-3 has been specifically identified as being a key mediator of apoptosis in mammalian cells (*62*): activation of caspase-3 indicates that the apoptotic pathway has progressed to an irreversible stage. As apoptosis disorders are involved in many diseases or malfunctionings such as ischemia, neurodegenerative diseases, or cancers, this protease is an attractive target for diagnostic and therapeutic applications through its detection in biological media using smart optical bioprobes. The main strategy for both *in vitro* and *in cellulo* sensing of caspase-3 relies on the use of fluorescent probes. Numerous

Scheme 2. Synthesis of Caspase-3 Latent Blue Fluorophore 11



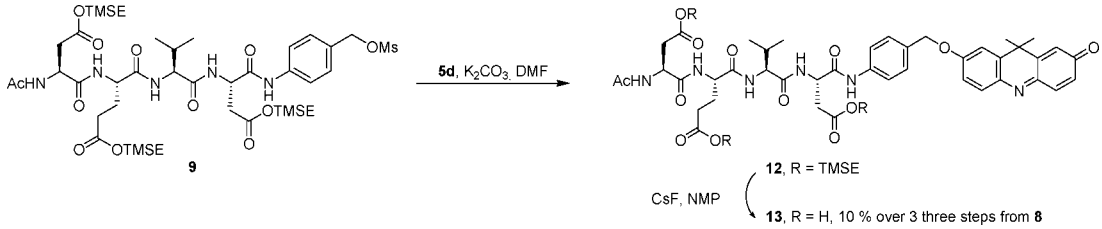
latent blue or green fluorophores (i.e., peptide conjugated to 7-aminocoumarin or rhodamine fluorescent tags) (*19, 20*) and fluorogenic probes based on the fluorescence resonance energy transfer (FRET) mechanism (*63–69*) have been developed, and some of them are routinely used as caspase-3 substrates for enzyme and cell-based fluorescent assays. All these probes are based on the fact that upon binding with caspase-3, protease-mediated cleavage of their peptide substrate occurs after the aspartic acid residue at the C-terminal side. The preferred sequence for caspase-3 cleavage is Asp-Glu-Val-Asp. To our knowledge, only one caspase-3 latent red fluorophore derived from the oxazine dye cresyl violet and marketed under the Magic Red name by ICN Biomedicals and Immunochemistry Technologies has been reported in the literature (*70*). Despite the spectral properties of cresyl violet dye in the far-red region, which enable good tissue penetration and low background noise in biological samples, the poor solubility of this fluorogenic probe in aqueous-based media and its poor kinetics due to the bulky fluorescent moiety prevents its efficient use for *in vivo* real-time imaging of caspase-3 activity. In this context, we wished to develop a novel class of water-soluble and far-red-emitting caspase-3-sensitive pro-fluorescent probes based on the validated "PABA" strategy (*vide supra*). As a first step of this challenging project, we have considered the synthesis of original caspase-3 latent fluorophores from two well-known dyes (umbelliferone **5a** and DAO **5d**), both linked by a PABA moiety to the caspase-3 tetrapeptidyl substrate (Scheme 2). First, the fully protected Ac-Asp(OTMSE)-Glu(OTMSE)-Val-Asp(OTMSE)-OH tetrapeptide **7** was synthesized on the gram scale by solution-phase peptide synthesis according to a multistep procedure developed by us (*38*). The carboxylic acid functionalities of the side chains were protected as 2-trimethylsilylethyl esters (TMSE esters) (*71, 72*). This protecting group is stable to the solution-phase peptide synthesis conditions and can be removed by treatment with various fluoride ion sources under mild conditions fully compatible with the stability of the ether bond linking the fluorescent phenol to the PABA moiety. Thereafter, the PABA linker **2** was introduced at the C-terminal side of **7** and the corresponding benzylic alcohol **8** was obtained in good yield. The introduction of the phenol-based fluorophore was achieved through nucleophilic substitution and required the activation of alcohol **8**. Mitsunobu reaction, bromination with PPh_3/CBr_4, or esterification with tosyl chloride were explored but failed to yield the target phenol-reactive derivative. Finally, we found that the only way to readily activate the alcohol was its conversion into mesylate ester **9**. We suspected that steric hindrance around the benzylic hydroxyl group probably induced by the tetrapeptide folding prevented the introduction of leaving groups bigger than mesylate. The resulting activated derivative was reacted with 7-hydroxycoumarin **5a** under mild basic conditions to give after purification by semipreparative RP-HPLC the fully protected pro-fluorescent probe **10** in 25% yield. Finally, the selective removal of the TMSE side chains protecting groups within the tetrapeptide scaffold was undertaken with different fluoride ion sources. No reaction was observed when an acidic fluoride ion source such as triethylamine-trishydrofluoride (TEA.3HF) was used. Mild basic fluoride ions provided by the tetrabutylammonium fluoride salt (TBAF or silica gel supported TBAF) allowed the complete deprotection of the TMSE esters, but isolation of the caspase-3-sensitive pro-fluorescent probe **11** in a pure form was not possible. Indeed, despite several semipreparative RP-HPLC purification runs (with aq TFA, 0.1% or deionized water as aq mobile phase), pro-fluorophore **11** was always found to be contaminated with significant amounts of tetrabutylammonium salts. This problem was circumvented by the use of tetramethylammonium fluoride (TMAF) or CsF which afforded the caspase-3 latent blue fluorophore **11** in a pure form with a quantitative yield.

To access longer wavelengths, we have applied the same synthetic strategy to the far-red dye DAO **5d** (Scheme 3). Sequential nucleophilic substitution, CsF-mediated deprotection, and final RP-HPLC purification afforded the caspase-3 latent far-red fluorophore **13** in a moderate 10% overall yield. The lower yield obtained for **11** was explained by the lower nucleophilic character of DAO compared to umbelliferone which directly affects the efficacy of the substitution step. To get a water-soluble fluorogenic caspase-3 substrate, **13** was converted into the corresponding tris-NH_4^+ salt by a brief treatment with 3% aq NH_4OH followed by lyophilization.

The structures of latent blue and far-red fluorophores **11** and **13** were confirmed by detailed analytical measurements, including ESI mass spectrometry and ^1H NMR analyses (see Figure 4 and Supporting Information).

Fluorescence Properties and Enzymatic Reactivity. Photophysical properties of fluorogenic probe **11** were evaluated in caspase-3 buffer (for the composition of this buffer, see Experimental Procedures section). This pro-fluorophore displayed the expected hypsochromic (~60 nm) and hypochromic shifts (10-fold diminution of fluorescence intensity) of emission spectrum relative to free umbelliferone (see Table 2 and Supporting Information). As this background fluorescence level

Scheme 3. Synthesis of Caspase-3 Latent Far-Red Fluorophore 13



was not affected by a prolonged incubation of **11** with caspase-3 buffer, the 7-O-substituted derivative of umbelliferone proved to be fully stable in the aq solution. Concerning the reactivity of **11** as a substrate for caspase-3, *in vitro* fluorescence assay was performed with the corresponding recombinant human protease. The increase of fluorescence upon enzyme-induced hydrolytic cleavage of **11** was indicative of single hit kinetics (see Supporting Information). Kinetic constants were calculated to be $k_{cat} = 5.6\ s^{-1}$, $K_m = 65.7\ \mu M$, and $k_{cat}/K_m = 84\,852\ M^{-1}\ s^{-1}$ (Figure 5). Comparison with the apparent kinetic constants from commercially available Ac-Asp-Glu-Val-Asp-AMC fluorogenic substrate ($k_{cat} = 0.75\ s^{-1}$, $K_m = 9.0\ \mu M$, and $k_{cat}/K_m =$ 83 300 $M^{-1}\ s^{-1}$ (*73*)) shows no significant increase in the k_{cat}/K_m value, but a 7.5-fold improvement of the catalytic constant. Thus, the use of PABA linker not only maintained but even improved the recognition of the probe by the targeted enzyme. One can suspect that the beneficial effect of moving away the bulky fluorophore from peptidic substrate should be even more obvious with proteases exhibiting a lower degree of substrate tolerance. Besides this, further experiments aimed at demonstrating the utility of the pro-fluorescent reagent **11** for the measurement of apoptosis in whole cell assays are currently in progress and will be reported elsewhere.

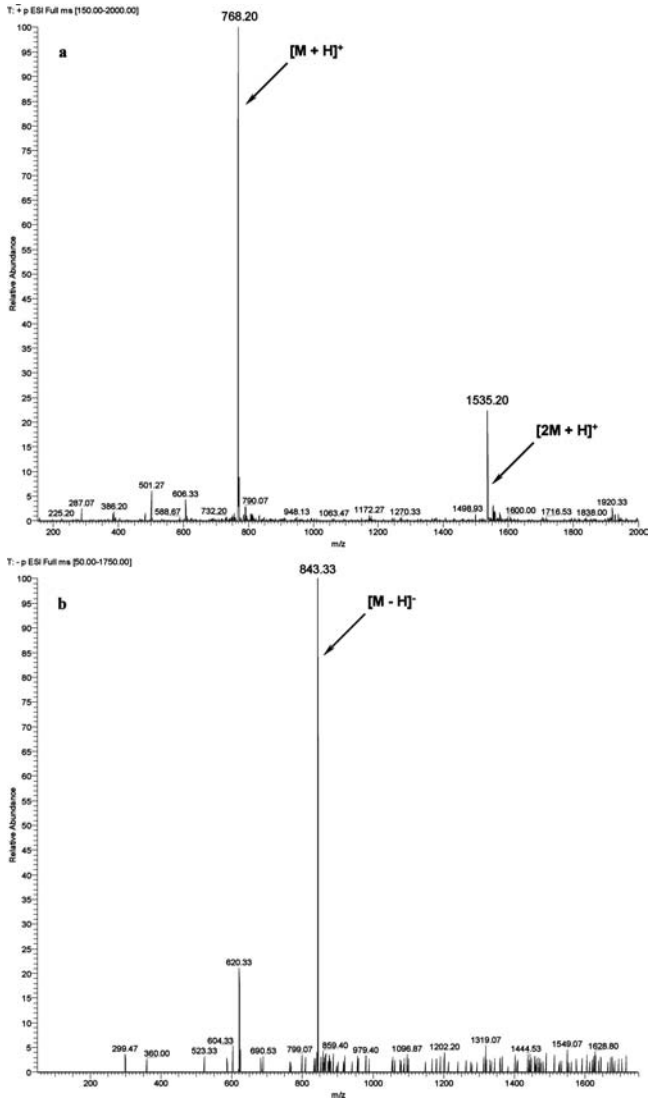


Figure 4. ESI mass spectra of caspase-3 latent fluorophores. (a) positive mode for compound **11** $[M + H]^+$: *m*/*z* calcd mass 768.27, found 768.20. (b) negative mode for compound **13** $[M - H]^-$: *m*/*z* calcd mass 843.32, found 843.33.

Table 2. Fluorescence Excitation and Emission Wavelengths of Caspase-3-Sensitive Pro-Fluorophores and the Free Phenol Dyes Released by the Enzyme-Initiated Domino Reaction

	caspase-3 pro-fluorophore[a]			free fluorophore[a]	
compound	excitation (nm)	emission (nm)	fluorescence intensity[b]	excitation (nm)	emission (nm)
11	320	397	10-fold reduction	360	460
13	460	606	12-fold reduction	638	651

[a] Spectral properties of **5a**/**11** were determined in caspase-3 buffer at 37 °C. Deionized water was used for compounds **5d**/**13** to avoid fluorescence quenching of DAO derivatives by DTT. [b] Calculated by the fluorescence intensity ratio between pro-fluorophore and free fluorophore at the same concentration.

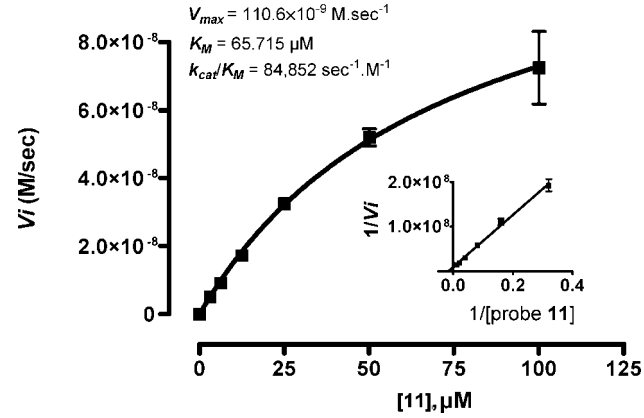

Figure 5. Michaelis−Menten plot for the hydrolysis of pro-fluorophore **11** (100 $\mu M \rightarrow 3.12\ \mu M$) by caspase-3.

The latent far-red flurophore **13** was subjected to the same fluorescence measurements. As expected, alkylation of the 7-OH group of DAO caused a blue-shift of excitation and emission peaks of this acridin-2-one dye (Ex./Em. $\lambda = 460/606$ nm compared to 638/651 nm for DAO). However, contrary to the latent blue fluorophore **11**, the *in vitro* proteolytic cleavage experiment with caspase-3 gave unexpected results. Indeed, dissolution of the pro-fluorophore **13** in caspase-3 buffer resulted in a 12-fold quenching of its residual fluorescence emission at $\lambda = 606$ nm and, after the addition of protease, the red fluorescence of the released DAO dye did appear, but only after a delay correlated with both probe and buffer amounts (around 100 min in the representative experiment displayed in Figure 6). We suspected that one chemical component of the caspase-3

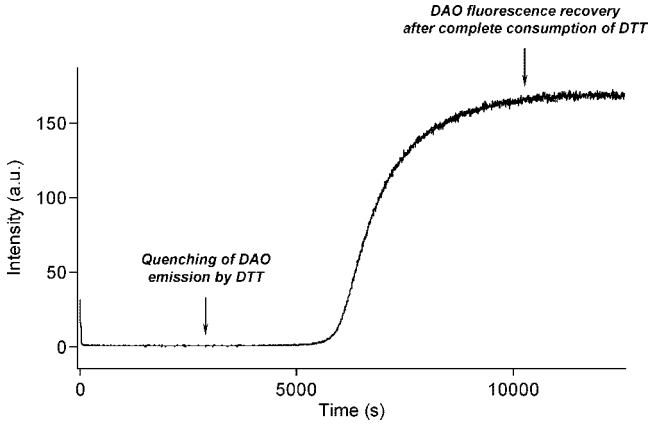

Figure 6. Fluorescence emission time course of pro-fluorescent probe **13** (concentration 23.0 μM) with recombinant human caspase-3 (3.2 10^{-3} U, form: buffered aq glycerol solution containing 100 mM NaCl, 50 mM HEPES pH 7.4, 10 mM DTT, 1 mM EDTA, 10% (w/v) glycerol, and 0.1% (w/v) CHAPS) in deionized water (37 °C) at 651 nm (Ex. λ = 638 nm). (note: The expected level of fluorescence intensity for the released DAO was not reached because of irreversible quenching of some fluorophore molecules through their reaction with DTT.)

buffer should be responsible of this temporary fluorescence extinction. Further experiments have enabled the identification of the dithiol reducing agent DTT as the sole molecule reactive toward DAO dye. LC-MS analyses of the reaction mixture of free DAO **5d** with DTT were performed to check the formation of the nonfluorescent compound and to identify its structure (see Supporting Information). By analogy with the mechanism proposed by Kitson to explain the reaction between some 7-O-substituted derivatives of resorufin and β-mercaptoethanol (*74*), we proposed a pathway compatible with both the observed on/off fluorescence switch of **5d** mediated by the dithiol-reducing agent and the mass value determined for the reaction product (Figure 7): nucleophilic addition of a thiol group of DTT to the α,β-unsaturated imine moiety followed by tautomerization to give the aromatic ring of a phenol as an intermediate nonfluorescent product; this in turn is followed by an oxidation step to reform the acridinone moiety. Thereafter, the same two-step reaction sequence (i.e., nucleophilic addition and tautomerization) occurs with the remaining free thiol group to give the nonfluorescent product **14**. This clock reaction takes place until the complete consumption of reduced DTT which is progressively oxidized either by the atmospheric oxygen dissolved in buffer or through the reverse elimination reaction giving back the fluorescent DAO dye. This unexpected competing reaction does not represent an insuperable defect for *in vitro* applications of pro-fluorescent reagent **11**. However, its evaluation as a reporter molecule for *in cellulo* and *in vivo* imaging of caspase-3 activity cannot be considered due to high levels of thiols (e.g., glutathione) in living organisms.

CONCLUSION

We have demonstrated how common phenol-based fluorophores can be converted to sophisticated molecular tools suitable for protease sensing. The use of a self-cleavable PABA linker provided pro-fluorophores with high chemical stability while maintaining enzymatic reactivity. Furthermore, the modularity of two components of our latent fluorophores (i.e., the dye and the enzyme-reactive group) was demonstrated through the preparation of blue- and far-red-emitting fluorogenic substrates of two different proteolytic enzymes: PGA and caspase-3 protease. Particularly, the implementation of this latent fluorophore strategy to *in vitro* imaging has led us to a ca. 10-fold increase of the enzyme velocity toward the fluorogenic pseudosubstrate **11** as compared to the commercially available pro-fluorophore Ac-Asp-Glu-Val-Asp-AMC. For *in vivo* imaging of protease activities, the self-immolative linker strategy has led us to explore the preparation of the original caspase-3-sensitive far-red-emitting fluorogenic probe **13** by using DAO as a fluorescent phenol. Unfortunately, our preliminary biochemical studies have allowed us to exhibit a yet unprecedented observation: the fluorescence of the enzymatically released acridinone dye is efficiently quenched in the presence of thiols, probably through a nucleophilic addition of these reducing agents to its quinonimine ring. To our knowledge, all known far-red-emitting phenol-based fluorophores (i.e., acridinone and oxazinone derivatives) contain this latter thiol-reactive moiety. Thus, the present study clearly showed the urgent need to design new red-emitting inert phenol-based fluorophores in order to expand the scope of promising latent fluorophore strategies to the visualization of various biologically relevant molecules and activities inside living cells. With this goal in mind, new conjugation-extended 7-hydroxycoumarin NIR dyes are currently under investigation in our laboratory and their use as fluorogenic labels for biomolecular imaging will be reported in due course.

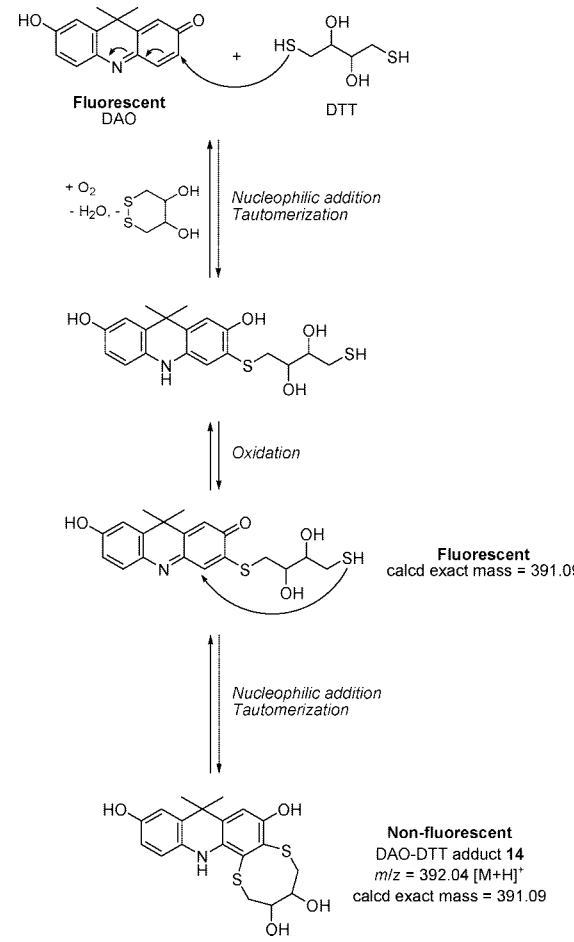

Figure 7. Proposed mechanism to explain the observed on/off fluorescence switch of the DAO dye during the caspase-3 assay with latent far-red fluorophore **13**. (note: As suggested by Kitson et al. (*74*) only the DAO derivatives bearing the quinonimine ring were considered as colored and fluorescent species.)

ACKNOWLEDGMENT

This work was supported by La Région Haute-Normandie, QUIDD and Institut Universitaire de France (IUF). We thank Elisabeth Roger (INSA de Rouen) for IR measurements and

Dr. Christophe Portal (QUIDD) for careful reading and English corrections of the manuscript.

Sequence Dependence of Fluorescence Emission and Quenching of Doubly Thiazole Orange Labeled DNA: Effective Design of a Hybridization-Sensitive Probe

Shuji Ikeda,[†] Takeshi Kubota,[†] Katsuhito Kino,[‡] and Akimitsu Okamoto*[,†]

Advanced Science Institute, RIKEN (The Institute of Physical and Chemical Research), Wako, Saitama 351-0198, Japan, and Kagawa School of Pharmaceutical Sciences, Tokushima Bunri University, Shido, Kagawa 769-2193, Japan. Received May 19, 2008; Revised Manuscript Received June 26, 2008

We have designed a doubly thiazole orange labeled nucleoside showing high fluorescence intensity for a hybrid with the target DNA and effective quenching for a single-stranded state. Knowing how much the fluorescence emission and quenching of this probe depend on the probe sequence and why there is such a sequence dependence is important for effective probe design, we synthesized more than 30 probe sequences and measured their fluorescence intensities. When the probe hybridized with the target DNA strands, there was strong emission, whereas the emission intensity was much weaker before hybridization; however, self-dimerization of probes suppressed fluorescence quenching. In particular, the G/C base pairs neighboring the labeled nucleotide in a self-dimeric structure resulted in a low quenching ability for the probe before hybridization. On the other hand, mismatched base pair formation around the labeled site decreased the fluorescence intensity because the neighboring sequence is the binding site of the tethered thiazole orange dyes. The hybridization enhanced the fluorescence of the probe even when the labeled nucleotide was located at the end of the probe strand; however, the partial lack of duplex structure resulted in a decrease in the fluorescence intensity of the hybrid.

INTRODUCTION

Many fluorescent nucleic acid probes have been developed for observation of the functions of target nucleic acids (*1*−*3*). In particular, a great deal of effort has been invested in the rational design of hybridization-specific DNA detection probes to effectively detect the target DNA using on−off switching of fluorescence depending on hybridization (*4*−*10*). In designing these probes, sensitivity of the dye to the environment, higher-ordered DNA structure caused by the sequence, and quenching by electron transfer from/to nucleobases have a strong influence on fluorescence intensity and sensitivity, and they often impair our predictions.

We have designed a doubly fluorescence labeled nucleoside to achieve high fluorescence intensity for a hybrid with the target DNA and effective quenching for the single-stranded state of the probe (*11*). Two thiazole orange dyes have been linked covalently to a single nucleotide in a DNA probe (Figure 1). An excitonic interaction was produced by the formation of an H-aggregate between dyes, and as a result, emission from the probe before hybridization was suppressed. Dissociation of aggregates by hybridization with the complementary strand resulted in disruption of the excitonic interaction and strong emission from the hybrid. This clear change in fluorescence intensity depending on hybridization is useful for visible gene analysis. However, even this newly designed fluorescent probe exhibited a sequence-dependent change in the ratio of the fluorescence intensities for double- and single-stranded states, for example, $I_{ds}/I_{ss} = 14$ for 5′-d(CGCAAT**X**TAACGC)-3′ (**X**, doubly thiazole orange-labeled nucleoside) and 4.5 for 5′-d(TGAAGGGCTT**X**TGAACTCTG)-3′. To understand how much the fluorescence emission and quenching of these probes depend on the probe sequence and why such a sequence dependence of fluorescence quenching occurs is important. This knowledge facilitates prior estimation of the fluorescence properties of probes and helps in the design of highly hybridization sensitive probes.

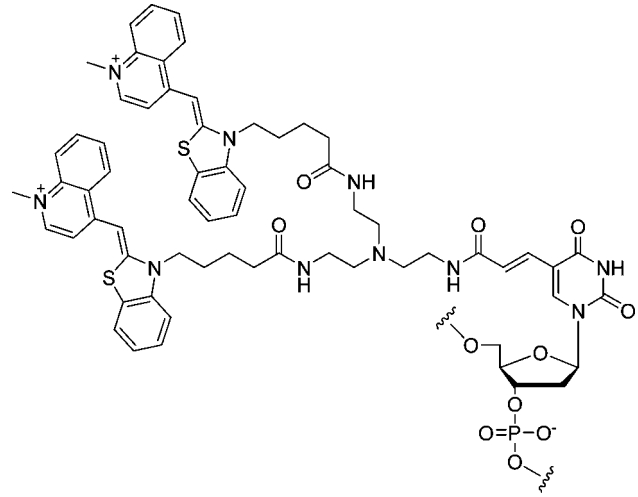

Figure 1. Newly designed nucleotide **X** controlled by excitonic interaction between thiazole orange dyes for an effective hybridization probe.

We herein report the effect of probe sequence on fluorescence emission and quenching. We synthesized a variety of probe sequences including mismatched hybrids and end-labeled probes, and measured their fluorescence intensities. The possibility of self-dimerization and location of the labeling site and mismatched base pair contributing to the fluorescence intensity of the hybrid and quenching efficiency for the single-stranded state

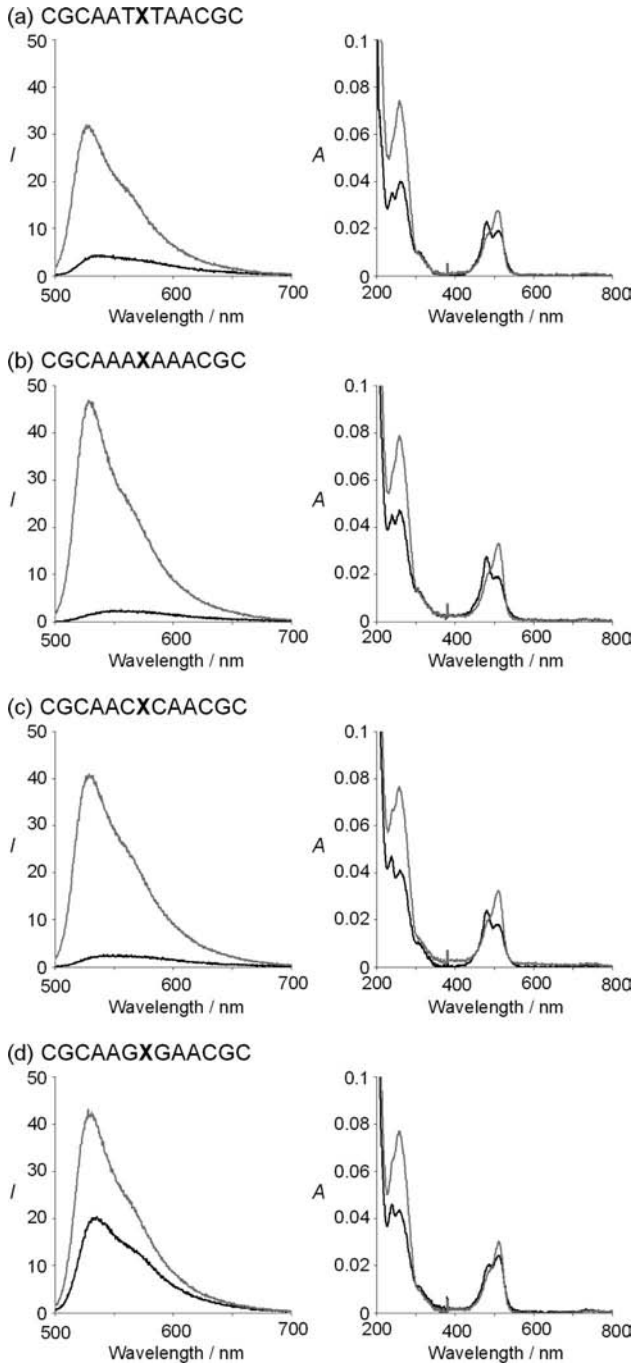

Figure 2. Emission and absorption spectra of CGCAA*N***X***N*AACGC. Emission spectra are shown in the left panels and absorption spectra are shown in the right panels. Spectra were measured in 50 mM sodium phosphate buffer (pH = 7.0) containing 100 mM sodium chloride at 25 °C. Black, spectra before hybridization; gray, spectra after hybridization with the corresponding cDNA. Emission spectra were recorded with excitation at 488 nm.

was investigated. These photophysical data can be used in practical probe design.

EXPERIMENTAL PROCEDURES

Probe Synthesis. DNA oligomers were synthesized by a conventional phosphoramidite method using an Applied Biosystems 392 DNA/RNA synthesizer. Commercially available phosphoramidites were used for dA, dG, dC, and dT. The diamino-modified nucleoside phosphoramidite, which was modified with thiazole orange dyes, was synthesized according to our previous report (*11*). The synthesized DNA oligomer was cleaved from the support with 28% aqueous ammonia and deprotected at 55 °C for 4 h and then at 25 °C for 16 h. After removal of ammonia from the solution under reduced pressure, the DNA was purified by reversed-phase HPLC on a 5-ODS-H column (10 mm × 150 mm, elution with a solvent mixture of 0.1 M triethylamine acetate (TEAA), pH 7.0, linear gradient over 30 min from 5% to 30% acetonitrile at a flow rate of 3.0 mL/min). For determination of the concentration of each DNA, the purified DNA was fully digested with calf intestine alkaline phosphatase (50 U/mL), snake venom phosphodiesterase (0.15 U/mL), and P1 nuclease (50 U/mL) at 25 °C for 16 h. Digested solutions were analyzed by HPLC on a CHEMCOBOND 5-ODS-H column (4.6 mm × 150 mm), elution with a solvent mixture of 0.1 M TEAA, pH 7.0, and flow rate of 1.0 mL/min. The concentration was determined by comparing peak areas with a standard solution containing dA, dC, dG, and dT at concentrations of 0.1 mM.

A solution of the succinimidyl ester of thiazole orange pentanoic acid (*11*) (50 equiv to an active amino group of DNA) in DMF was added to a solution of deprotected DNA in 100 mM sodium carbonate buffer (pH = 9.0), and incubated at 25 °C for 16 h. The reaction mixture was diluted with ethanol. After centrifuging at 4 °C for 20 min, the supernatant was removed. The residue was dissolved with a small amount of water and then the solution was passed through a 0.45 μm filter. The product was purified by reversed-phase HPLC on a 5-ODS-H column (10 mm × 150 mm, elution with a solvent mixture of 0.1 M TEAA, pH 7.0, linear gradient over 30 min from 5% to 30% acetonitrile at a flow rate of 3.0 mL/min). The concentration of the fluorescent DNA was determined by the same method as described in the DNA synthesis. The fluorescent DNA was identified by MALDI-TOF mass spectrometry: CGCAAT**X**TAACGC, calcd for $C_{180}H_{217}N_{56}O_{78}P_{12}S_2$ ($[M - H]^+$) 4848.8, found 4851.4; CGCAAA**X**AAACGC, calcd for $C_{180}H_{215}N_{62}O_{74}P_{12}S_2$ ($[M - H]^+$) 4866.8, found 4866.6; CGCAAC**X**CAACGC, calcd for $C_{178}H_{215}N_{58}O_{76}P_{12}S_2$ ($[M - H]^+$) 4818.8, found 4819.1; CGCAAG**X**GAACGC, calcd for $C_{180}H_{215}N_{62}O_{76}P_{12}S_2$ ($[M - H]^+$) 4898.8, found 4897.8; GCCAAG**X**GAACCG, calcd for $C_{180}H_{215}N_{62}O_{76}P_{12}S_2$ ($[M - H]^+$) 4898.8, found 4898.5; AAAAAA**X**AAAAAA, calcd for $C_{184}H_{215}N_{70}O_{68}P_{12}S_2$ ($[M - H]^+$) 4930.9, found 4930.3; CCCCCC**X**CCCCCC, calcd for $C_{172}H_{215}N_{46}O_{80}P_{12}S_2$ ($[M - H]^+$) 4642.6, found 4643.1; TTTTTA**X**ATTTTT, calcd for $C_{184}H_{225}N_{40}O_{88}P_{12}S_2$ ($[M - H]^+$) 4840.8, found 4841.0; TTTTTC**X**CTTTTT, calcd for $C_{182}H_{225}N_{36}O_{90}P_{12}S_2$ ($[M - H]^+$) 4792.7, found 4793.5; TTTTTG**X**GTTTTT, calcd for $C_{184}H_{225}N_{40}O_{90}P_{12}S_2$ ($[M - H]^+$) 4872.8, found 4872.0; TTTTGT**X**TGTTTT, calcd for $C_{184}H_{225}N_{40}O_{90}P_{12}S_2$ ($[M - H]^+$) 4872.8, found 4872.1; TTTGTT**X**TTGTTT, calcd for $C_{184}H_{225}N_{40}O_{90}P_{12}S_2$ ($[M - H]^+$) 4872.8, found 4873.0; TTGTTT**X**TTTGTT, calcd for $C_{184}H_{225}N_{40}O_{90}P_{12}S_2$ ($[M - H]^+$) 4872.8, found 4871.8; GTCCTC**X**TCGGCA, calcd for $C_{179}H_{218}N_{51}O_{82}P_{12}S_2$ ($[M - H]^+$) 4831.8, found 4832.2; TTTTAG**X**GTTGCG, calcd for $C_{183}H_{221}N_{50}O_{85}P_{12}S_2$ ($[M - H]^+$) 4916.8, found 4916.0; AGAAGA**X**GGTGGC, calcd for $C_{183}H_{216}N_{65}O_{77}P_{12}S_2$ ($[M - H]^+$) 4993.9, found 4994.9; TACCAG**X**CACCAT, calcd for $C_{179}H_{217}N_{54}O_{78}P_{12}S_2$ ($[M - H]^+$) 4808.8, found 4807.4; TATGCG**X**GATTTT, calcd for $C_{183}H_{221}N_{50}O_{84}P_{12}S_2$ ($[M - H]^+$) 4900.8, found 4900.6; CACCAG**X**CACTAC, calcd for $C_{178}H_{216}N_{55}O_{77}P_{12}S_2$ ($[M - H]^+$) 4793.8, found 4792.1; CACCAG**X**CACTGC, calcd for $C_{178}H_{216}N_{55}O_{78}P_{12}S_2$ ($[M - H]^+$) 4809.8, found 4809.1; CCGCTTAA**X**ACTGA, calcd for $C_{190}H_{230}N_{58}O_{85}P_{13}S_2$ ($[M - H]^+$) 5153.0, found 5153.4; AGATCC**X**GACAGA, calcd for $C_{181}H_{216}N_{61}O_{76}P_{12}S_2$ ($[M - H]^+$) 4897.8, found 4897.2; ACCTGCAC**X**ATAAGCAC, calcd for $C_{218}H_{265}N_{72}O_{100}P_{16}S_2$ ($[M - H]^+$) 6053.6, found 6053.1; ACAGTTCT**X**CAACTGGC,

Absorption and Fluorescence Measurements. Absorption and fluorescence spectra of the probes (0.4 μM single-stranded or duplex concentration) were measured in 50 mM sodium phosphate buffer (pH = 7.0) containing 100 mM sodium chloride using a cell with a 1 cm path length. The excitation and emission bandwidths were 1.5 nm. The fluorescence quantum yield (Φ) was determined using 9,10-diphenylanthracene as a reference, with a known Φ = 0.95 in ethanol. The quantum yield was calculated using the following equation:

$$\Phi_{(S)}/\Phi_{(R)} = [A_{(S)}/A_{(R)}] \times (\mathrm{Abs})_{(R)}/(\mathrm{Abs})_{(S)}] \times [n_{(S)}{}^2/n_{(R)}{}^2] \quad (1)$$

Here, $\Phi_{(S)}$ and $\Phi_{(R)}$ are the fluorescence quantum yields of the sample and the reference, respectively. The terms $A_{(S)}$ and $A_{(R)}$ are the areas under the fluorescence spectra of the sample and the reference, respectively, $(\mathrm{Abs})_{(S)}$ and $(\mathrm{Abs})_{(R)}$ are the optical densities of the sample and the reference solution at the wavelength of excitation, respectively, and $n_{(S)}$ and $n_{(R)}$ are the values of the refractive index for the solvents used for the sample ($n_{(S)}$ = 1.333) and the reference ($n_{(R)}$ = 1.383), respectively.

RESULTS AND DISCUSSION

Effect of Neighboring Bases. The influence of bases adjacent to the fluorescence-labeled base has often been discussed as the reason for the sequence dependence of fluorescence intensity. We initially investigated the effect of neighboring bases on the fluorescence intensity using a DNA probe 5′-d(CGCAA*N***X**-*N*AACGC)-3′ (*N* = T, A, C, or G) (Figure 2 and Table 1). When *N* was thymine, the emission spectra were observed at 538 nm as a single, broad band. Hybridization with the complementary strand enhanced the emission intensity, which is clearly distinguishable from the single-stranded state (Φ_{ds}/Φ_{ss} = 4.6). In addition, when *N* was adenine or cytosine, the probe hybridized with the target DNA strands showed strong emission, whereas the emission intensity before hybridization was much weaker. The quenching abilities were slightly higher for the single-stranded state than when *N* was thymine (Φ_{ds}/Φ_{ss} = 12 for A, 9.3 for C). On the other hand, when *N* was guanine, the probe showed a small change in emission intensity before and after hybridization (Φ_{ds}/Φ_{ss} = 1.9). The nonemissive character observed in the single-stranded state is accepted as a general feature of H-aggregates of the dyes (*12*−*14*). The excited state of the dye aggregate splits into two energy levels according to exciton coupling theory (*15*). The transition to the upper excitonic state, which is allowed for the H-aggregates, rapidly deactivates to the lower excitonic state, which is a nonemissive state. Two absorption bands were observed at 400−550 nm for all the probes. An absorption band at shorter wavelength (ca. 480 nm) appeared more strongly when the probes were in a single-stranded state, whereas an absorption band of longer wavelength (ca. 510 nm) became predominant when probes were hybridized with the complementary strands. The shift of the absorption band to 480 nm indicates aggregation of thiazole orange dyes for the single-stranded state of the probe. The ratio of absorbances at 480 and 510 nm (A_{480}/A_{510}) was 1.21, 1.48, 1.34, and 0.83 for *N* = T, A, C, and G, respectively, an order that showed good agreement with the order of Φ_{ds}/Φ_{ss}, suggesting that the aggregation of dyes affects fluorescence quenching for the single-stranded state.

The effect of the neighboring base on fluorescence quenching was also confirmed in the fluorescence measurement of another sequence, 5′-d(TTTTT*N***X***N*TTTTT)-3′ (Figure 3 and Table 2). In contrast to the low quenching ability of 5′-d(CGCAA*N***X**-*N*AACGC)-3′ for a single-stranded state when the *N* base was guanine, 5′-d(TTTTTG**X**GTTTTT)-3′ showed more effective quenching (Φ_{ds}/Φ_{ss} = 25), and aggregation of the dyes was also promoted (A_{480}/A_{510} = 1.54). The fluorescence quenching of probes for the single-stranded state was very effective, although a slight fluorescence emission was observed when *N* was adenine. Therefore, the low quenching ability of 5′-d(CGCAAG**X**GAACGC)-3′ could not be directly attributable to the guanine bases neighboring **X**.

Self-Dimerization. As another working hypothesis for the low quenching efficiency of 5′-d(CGCAAG**X**GAACGC)-3′ observed before hybridization with the target DNA, we next considered the possibility of "self-dimerization" of probes. The probe emits fluorescence when the duplex is formed. Formation of full or partial self-dimerization of the probe may maintain the fluorescence intensity. When the self-dimerized structure of 5′-d(CGCAA*N***X***N*AACGC)-3′ is assumed as the number of possible Watson−Crick base pairs around **X** becomes a maximum, the structures can be drawn as in Figure 4. When *N* is adenine or cytosine, which exhibited a larger Φ_{ds}/Φ_{ss}, two
