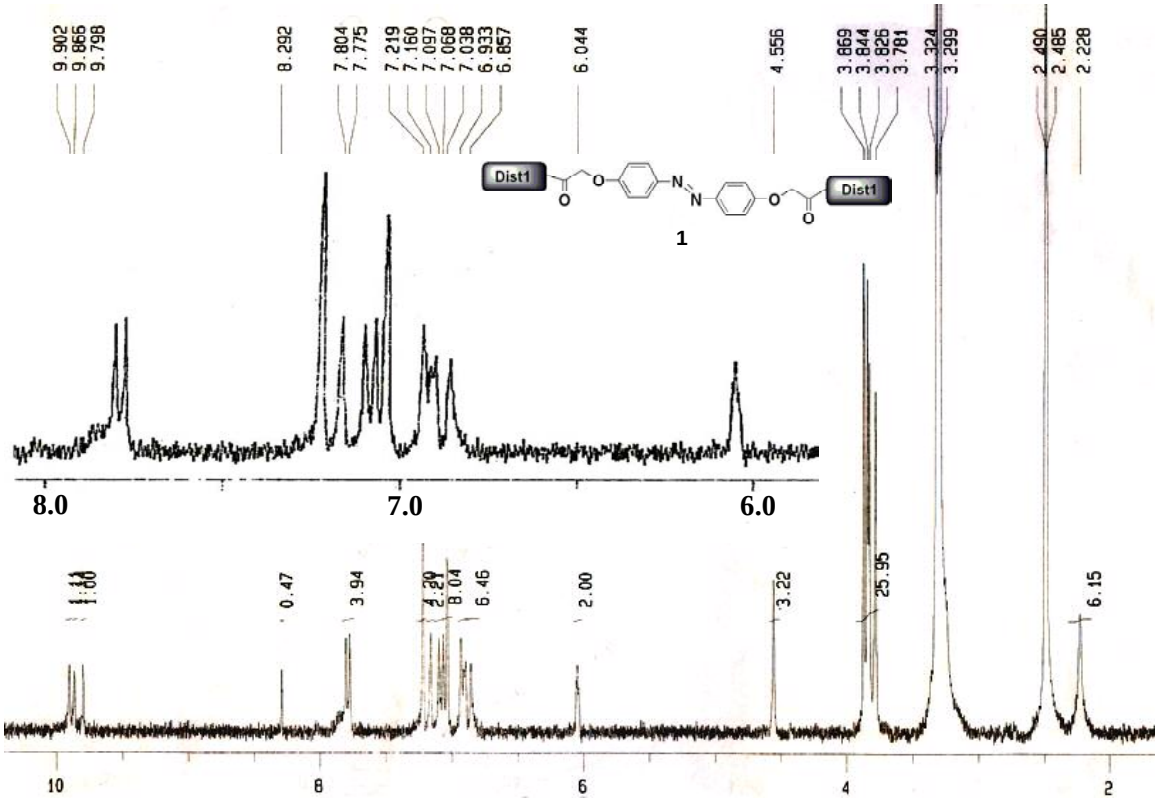
Spectral Characterization data of Final Compounds: **1, 2, and 3 (^{1}H-NMR, and ^{13}C-NMR Spectra) (Fig. SI-1, SI-2, SI-3)**	SI-3-5
^{1}H-NMR spectra of 2 before and after photoirradiation at ~360 nm (Fig. SI-4)	SI-6
Competition for DNA minor groove, Hoechst displacement Assay (Fig. SI-5)	SI-7
Docking and free binding energies of all the ligands (Dist-1 Dist-2 and 1, 2, 3) (Table SI-1)	SI-8
Melting temperatures (T_m) at fixed [D]/[P] ratio of 0.5 obtained from binding of different forms of 1, 2 and 3, with poly [d(A-T).d(T-A)]. (Table SI-2)	SI-9
The single point and relative energies of the lowest docked structure of *trans* and *cis* forms for the ligands 1-3 (Table SI-3)	SI-10
The total energies (hartree) and the cartesian coordinates of optimized structures of ligands (Dist-1 Dist-2, Hoechst, and 1, 2, 3)	SI-11
The total energies in hartree and the cartesian coordinates of the structures 17a, 17b, 18a and 18b at MP2/6-31+G* level of theory	SI-19

Materials and Methods. All reagents used in this study were of highest purity available and were used without purification. Thin-layer chromatography (TLC) was performed using silica gel-G and preparative column chromatography was done on silica gel (60–120 mesh size). Solvents such as CH_2Cl_2, $CHCl_3$ were dried over P_2O_5, Et_3N was dried over KOH, THF using sodium and benzophenone ketyl and DMF was vacuum distilled over anhydrous $MgSO_4$. ^{1}H-NMR spectra were recorded on a 300 or a 400 Hz spectrometer and ^{13}C-NMR spectra were recorded on a 500 Hz spectrometer. Chemical shifts (δ) are reported in ppm downfield from the internal standard (TMS). Electrospray ionization (ESI) mass spectra were used to characterize synthesized compounds. Abbreviations for the structures of azobenzene-distamycin conjugates **1-3** are given in the main manuscript.

A



B

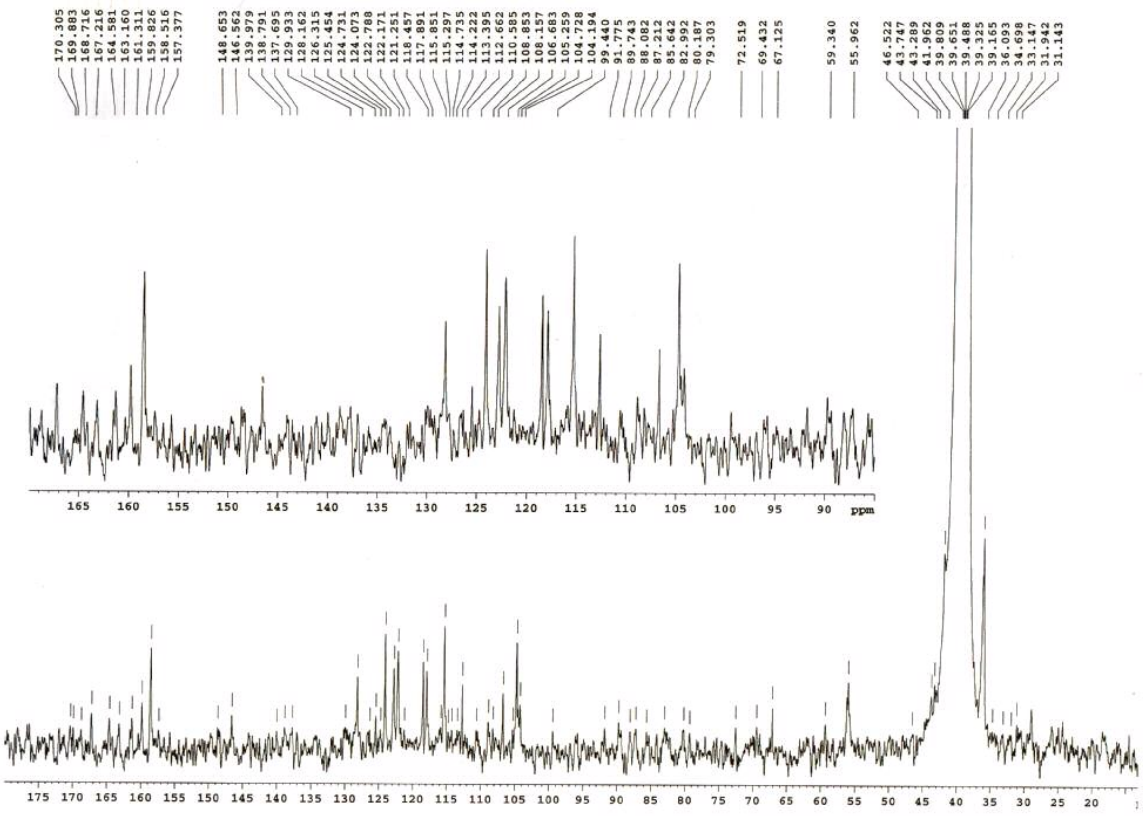


Figure S1. (A) ^{1}H-NMR (300 MHz, DMSO-d_6); (B) ^{13}C-NMR (125 MHz, DMSO-d_6) of **1**.

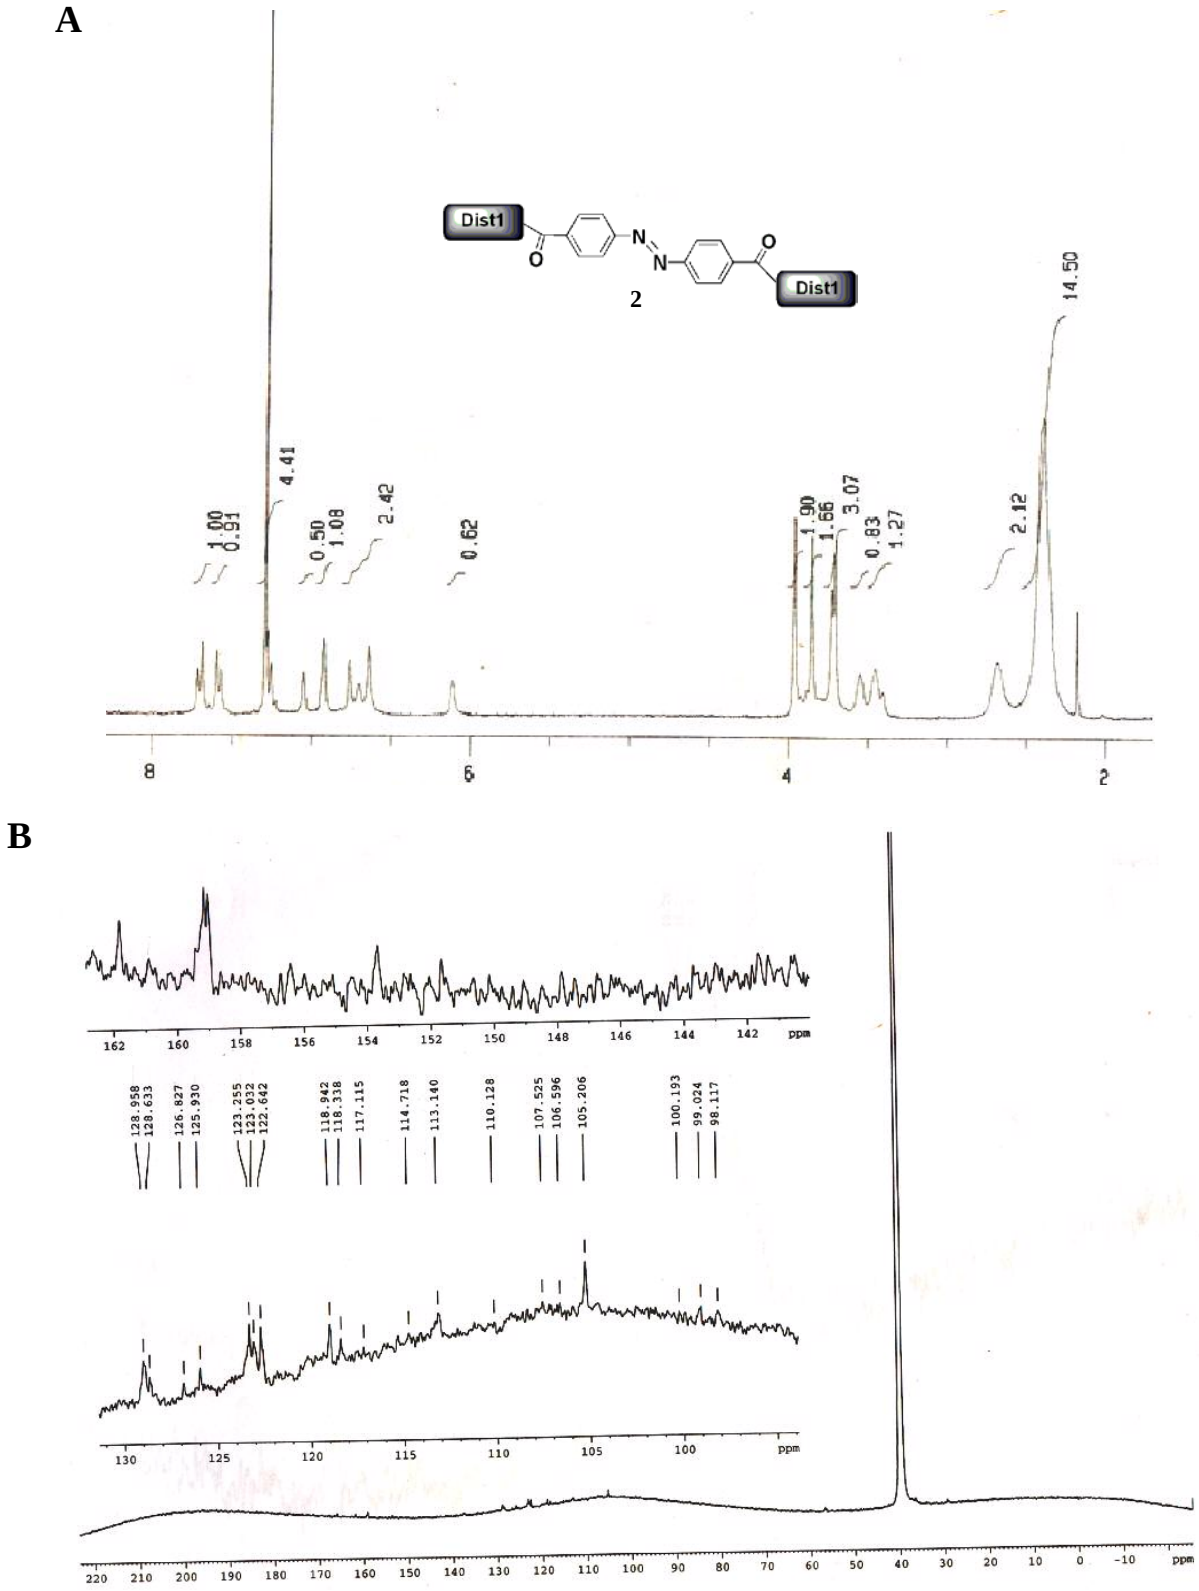

Figure S2. (A) ^{1}H-NMR (300 MHz, DMSO-d_6); (B) ^{13}C-NMR (125 MHz, DMSO-d_6) of **2**.

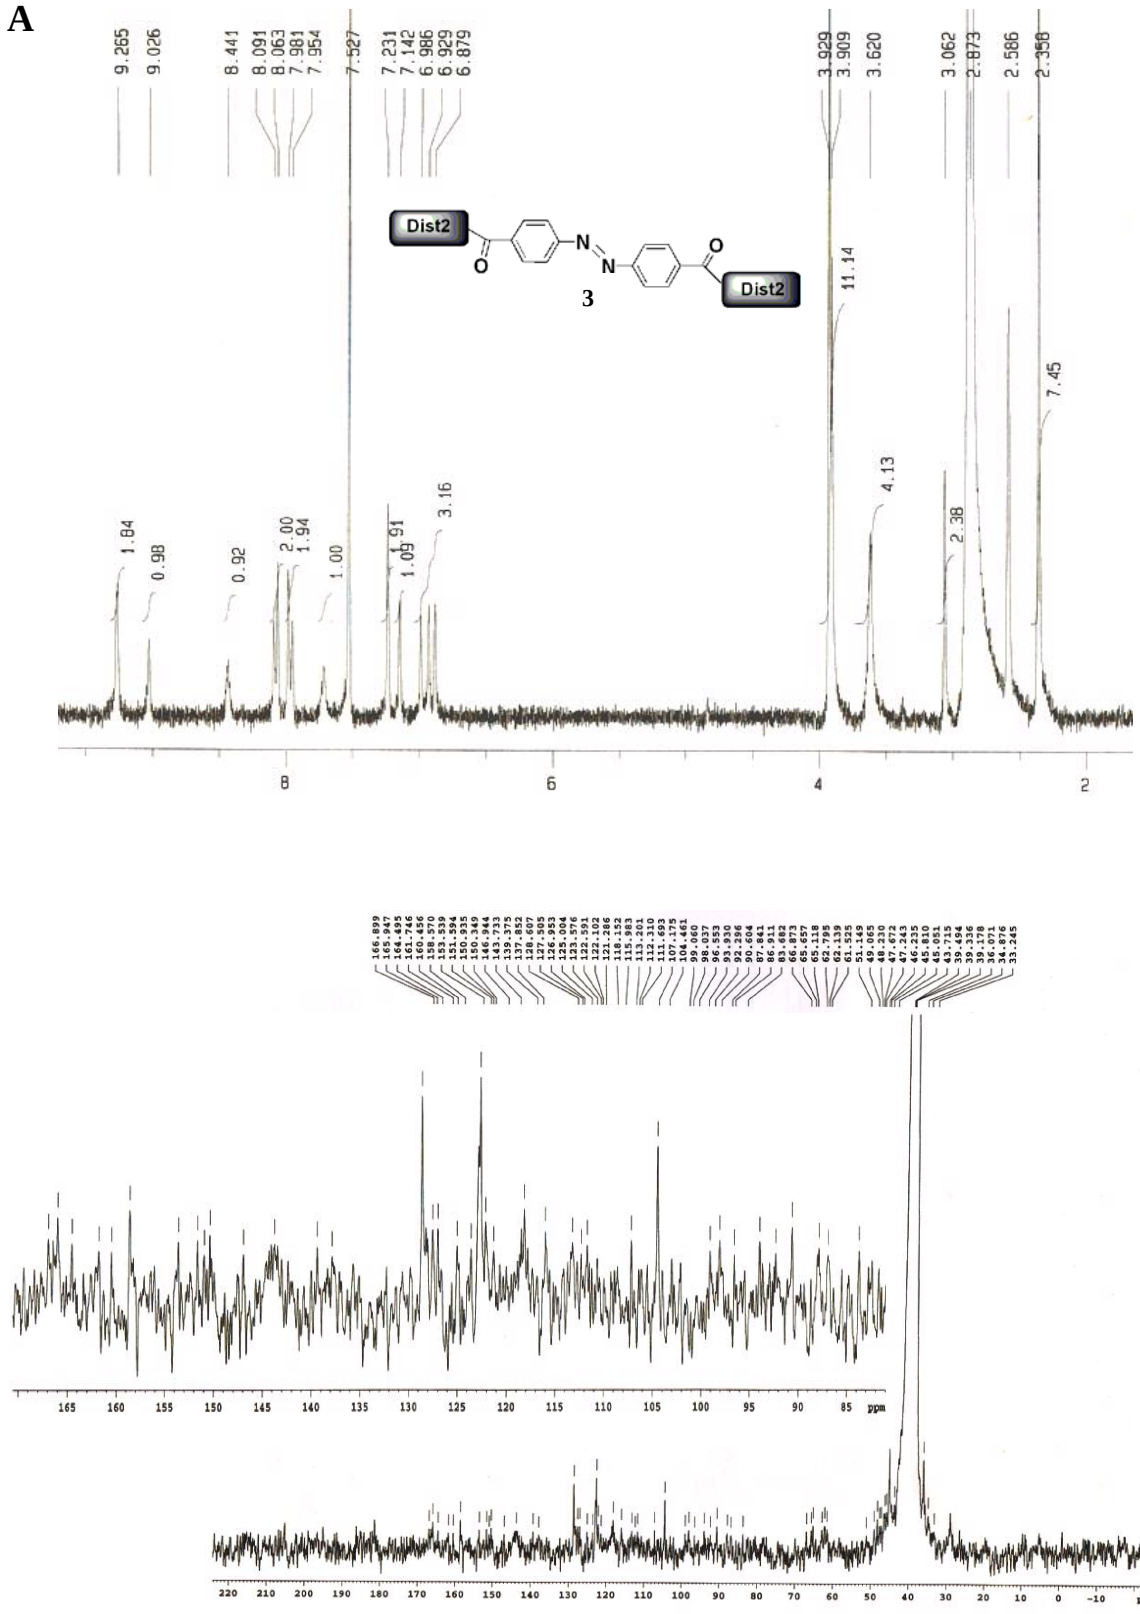

Figure S3. (A) ^{1}H-NMR (300 MHz, DMSO-d_6); (B) ^{13}C-NMR (125 MHz, DMSO-d_6) of **3**.

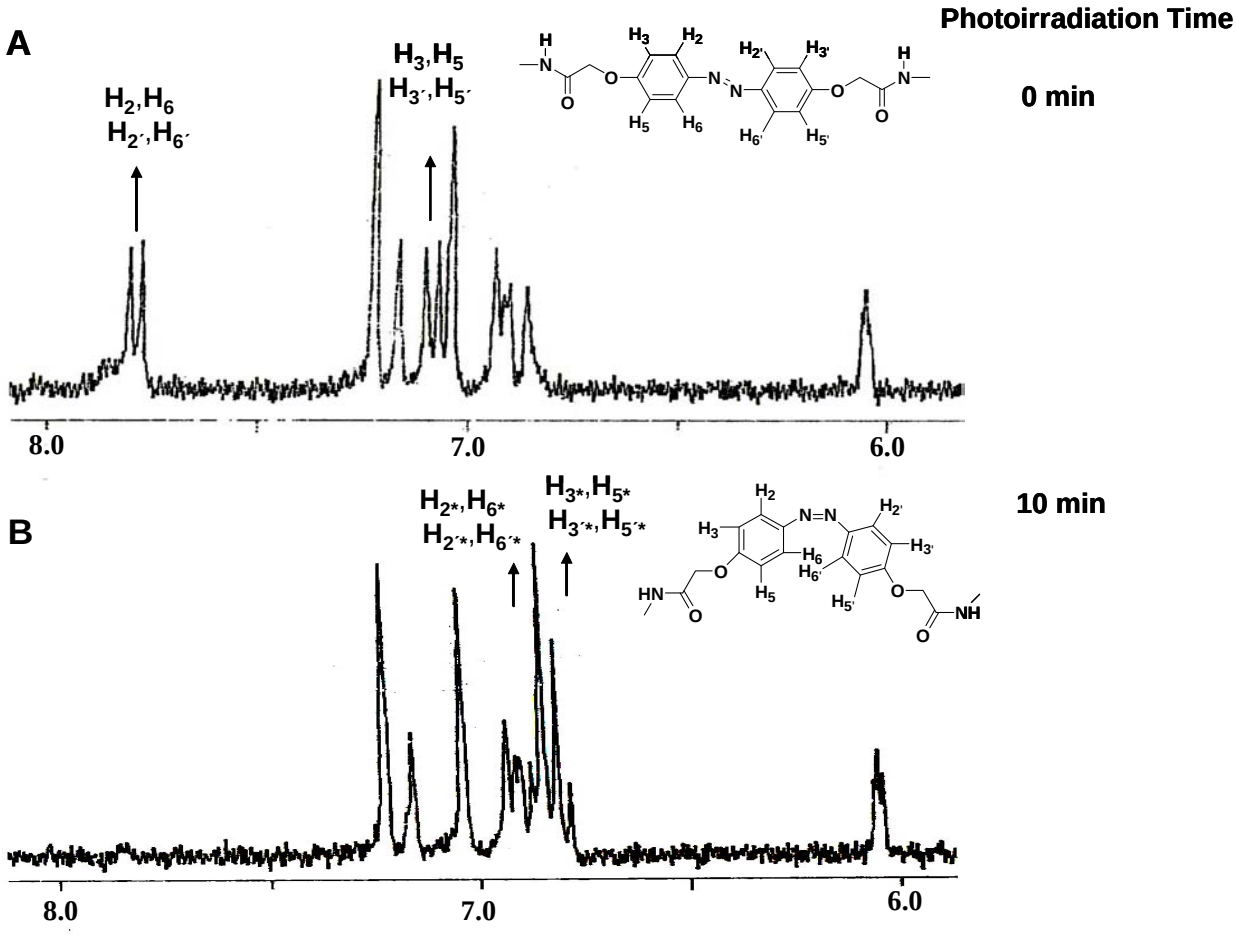

Figure S4. ^{1}H-NMR spectra of a d_6-DMSO solution of **1** (1 mM) before (A) and after (B) 10 min of photoirradiation at ~360 nm. Chemical shifts of the respective azobenzene protons before and after irradiation are indicated with respect to TMS as standard. The symbol '*' refers to the sample after irradiation.

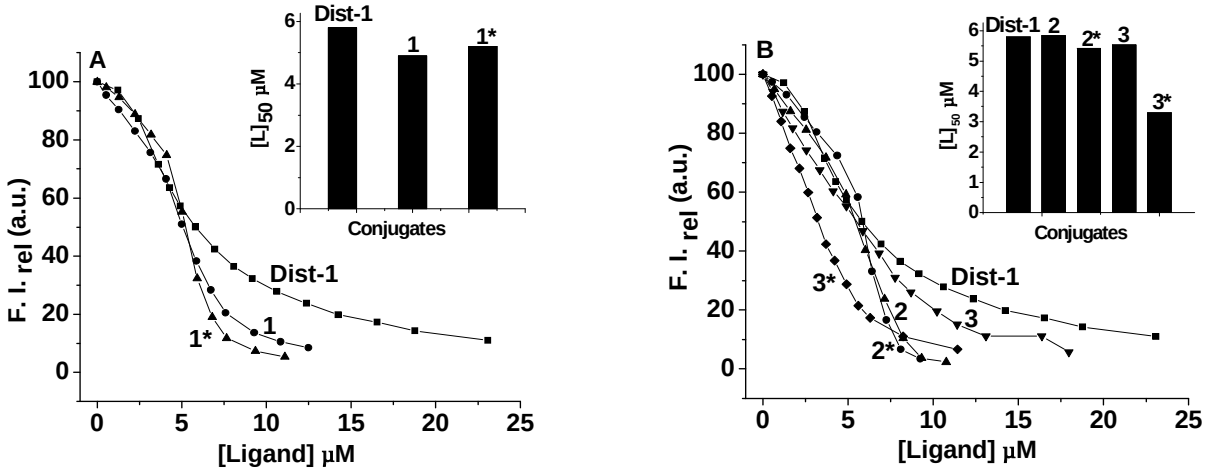

Figure S5. Changes in the fluorescence intensity of Hoechst 33258 upon addition of different azobenzene-distamycin conjugate into the saturated Hoechst-poly [d(A-T).d(T-A)] complex in NaCl buffer at 25 ^{o}C. Inset: Y-axis of the bar correspond to various ligand concentrations ($[L]_{50}$) to displace 50% Hoechst from DNA minor groove surface. Apparent binding constants (K_{app}) were calculated from the respective $[L]_{50}$ values and considering *Ka* (Hoechst) = 1.5×10^{7} M^{-1}, and [Hoechst 33258] = 250 nM. Here different isomeric compositions of the ligands are same as mentioned above.

Table SI-1. The docked and free binding energies (ΔG), number of rotable bonds, cluster (number of similar conformations) and number of amide bond contacts with DNA bases obtained form Autodock calculations of **Dist-1**, **Dist-2, Hoechst** and different photoisomeric forms of **1**, **2**,and **3** with modeled duplex $[d(GC(AT)_{10}CG)]_2$ DNA are tabulated.

Ligands	ΔG (kcal/mol)	Docked energy (kcal/mol)	Rotable bonds	Cluster	The bond distance between ligand and DNA bases (Å)
Dist-1	-7.0	-11.3	0	1	2.50, 2.74, 2.32, 2.54
Dist-2	-7.1	-11.5	0	1	2.21, 2.39, 2.53, 2.52, 2.11
Hoechst	-12.1	-13.0	0	1	2.26, 2.18
1a	-7.5	-7.5	0	1	
	-7.7	-19.9	10	1	
	-8.2a	**-21.9**	**0**	**1**	**3.35, 5.29, 6.54, 2.74, 4.61, 5.63**

	-13.7	-25.7	6	1	
	-14.1	**-25.9**	**0**	**20**	

[a]The values in bold obtained by rigid docking of the lowest docked conformation of the ligands initially obtained from the flexible docking studies.

Table SI-2. Melting temperatures (T_m) at fixed [D]/[P] ratio of 0.5 obtained from binding of different forms of **1**, **2** and **3**, with poly [d(A-T).d(T-A)].

DNA + Ligands	T_m(°C)[a]	ΔT_m(°C)[b]
Poly [d(A-T). d(T-A)] alone	64.7	-
+ 1	76.2	11.5
+ 1*	78.0	13.3
+ 2	81.3	16.6
+ 2*	83.7	19.0
+ 3	89.0	24.3
+ 3*	>90	>25.3

[a]T_m indicates the average melting temperature value of two independent melting experiments that has been done with the complexes of poly [d(A-T).d(T-A)] in the presence of different ligands in 150 mM NaCl, 10 mM Na_2HPO_4, 0.1 mM EDTA, pH = 7.4 at the saturated [D]/[P] ratio, The error is within ± 0.2 °C. [b]ΔT_m corresponds to the difference in T_m between DNA alone and DNA-ligand complexes.

Table SI-3: The single point and relative energies of the lowest docked structure of *trans* and *cis* forms for all the ligands **1-3** at HF/3-21g level of theory using Gaussian 03 program are given. The D1 and D2 are the distance around the azobenzene and azobenzene and spacer moiety as shown in scheme 4.

Ligand	Total energy in hartree	Relative energy in (kcal/mol)	D1 (Å)	D2 (Å)
1a (*trans*)	−4920.77349	0.0	11.62	21.53
1b (*cis*)	−4920.74933	15.2	8.02	14.06
2a	−4694.29540	0.0	11.91	19.40
2b	−4694.28781	4.8	8.17	11.91
3a	−4203.73143	0.0	11.91	17.05
3b	−4203.63689	59.3	7.53	8.30

The coordinates of docked conformation of these isomers can be obtained from the authors.

The total energies in hartree and the cartesian coordinates of optimized structures at HF/3-21g level of theory using Gaussian 03 program package are given.

Received April 25, 2008; Revised Manuscript Received September 5, 2008

We developed multifunctional fluorescent nanoparticles suitable for the nonviral delivery of negatively charged molecules like RNA. Therefore, we incorporated the recently developed branched hCT-derived carrier peptide hCT(18−32)-k7 on the surface of luminescent quantum dots (QDs). Besides detailed characterization of our QD−peptide conjugates concerning stability, toxicity, and uptake mechanism. we used them for efficient RNA delivery into different cell lines. The results of our studies indicate the involvement of more than one endocytotic uptake pathway in the internalization process. Furthermore, we could show that the QD−peptide bioconjugates exhibit no effect on cell viability and possess high stability inside living cells. The efficacy of our newly designed constructs for oligonucleotide drug delivery is highlighted by the successful intracellular transport of Cy-3 labeled RNA. Moreover, by using the chemotherapeutic chloroquine the efficient release of the assemblies out of endosomes was demonstrated. These results prove that our multifunctional platforms are versatile tools for diagnostic and therapeutic imaging purposes applicable for biologically active siRNA or aptamer sequences.

INTRODUCTION

During the past decades, a large amount of potential drug candidates and future drug targets have been developed. Our main focus should now rest on the understanding and investigation of the biological action and processes these compounds exert and cause. For this reason, it is not only important to figure out how a probe enters a cell but also to follow its fate within the cell interior. Recently, a series of multifunctional nanoparticles has been developed that can be used in biomedical and pharmaceutical applications for diagnosis and therapy. Thereby, these probes can not only serve as vehicles for the delivery of therapeutic agents to their targets, but they can also act as tools for imaging. The latter can be realized by the use of luminescent semiconductor nanocrystals, also known as quantum dots (QDs). Due to unique spectroscopic properties, this new class of materials has attracted much attention (*1, 2*). Quantum dots have narrow, size-tunable emission spectra and possess a high quantum yield. They are excitable within a broad wavelength range and are exceptionally resistant to photobleaching and chemical degradation. All these advantages make them superior to conventionally used fluorophor systems like small organic dyes or fluorescent proteins. For this reason, they are widely applied as an alternative in many fluorescent-based (cell-) assays preferably when performing long-term and multicolor labeling experiments (*3*). However, certain requirements should be fulfilled by these particles: they should not exhibit any cytotoxicity, and they should be attached to a targeting moiety allowing them not only to penetrate the cell membrane but also to reach their target site within the cell interior.

Coating QDs with peptides is one approach that has become more and more accepted. For instance, attachment of cell-penetrating peptides (CPP) (*4, 5*), such as polyarginine and TAT-derived peptides, to the QD surface has allowed translocating QDs into cells (*6, 7*). Recently, CPP have become widely used vectors for the cellular delivery of molecules in basic and applied biomedical research. With their help, it is possible to introduce membrane-impermeable substances like peptide nucleic acids (PNA) (*8*), proteins (*9*), oligonucleotides (*10*), or nanoparticels (*11, 12*) into mammalian cells. There is a growing attraction in using CPP for drug delivery because many pharmacologically interesting molecules have often only poor bioavailability. Additionally, the attachment of the bioactive compound is easily achieved by covalent coupling or via complexation strategies. Cell-penetrating properties of the human hormone calcitonin (hCT) have been described recently. Human calcitonin, a 32 amino acid long peptide amide, is physiologically secreted by the thyroid gland and involved in the regulation of the calcium metabolism. Owing to a high permeability through the nasal epithelium, it is applied as an intranasal therapeutic (*13*). Structure−activity studies revealed that the truncated sequence hCT(9−32) can translocate through cell membranes, although the calcitonin receptor activating N-terminus (aa 1−8) of hCT is lacking (*14, 15*). By using hCT(9−32), efficient transport of different cargoes into cells like the antiproliferative drug daunorubicin, fluorophors, or even large proteins has been achieved (*16, 17*). Until now, several different hCT-derived carrier peptides have been developed and successfully used in internalization studies (*18, 19*). Moreover, we previously reported on branched hCT-derived analogues that very effectively transfected several cell lines, as well as primary cells, with plasmid DNA encoding the protein EGFP (*20, 21*). This branched design successfully combined the cell-penetrating properties of the hCT moiety with a positively charged side chain suitable for complexation of negatively charged molecules like oligonucleotides. However, so far little is known about the uptake mechanism of hCT-derived CPP. From several studies, it is known that the uptake is mediated by endocytosis. Recently, Foerg et al. postulated a lipid raft dependent pathway for hCT(9−32) and its branched derivative hCT(9−32)-br into cells (*22*). For future applications, a further careful analysis of the uptake mechanism is crucial. In particular, the correlation between attached cargoes and the entry pathway should be

investigated carefully. Results from these studies should help to design best-fitted hCT-derivatives.

The focus of this work was the design and characterization of a QD−peptide-based delivery system suitable for imaging and delivery purposes. Therefore, we covalently coupled a branched hCT-derived peptide to QD nanoparticles of different colors. For the first time, we present the successful delivery of nanoparticles with our hCT-derived CPP. Furthermore, the newly generated constructs were investigated concerning cellular toxicity, stability, and uptake mechanism. Additionally, we focused on the cellular transport of potent oligonucleotide drugs and chose Cy-3-labeled RNA for tracking the fate of the cargo in the cytoplasm. By using fluorescence microscopy, we could demonstrate an effective uptake of these QD−peptide−RNA conjugates and that the complex between the RNA and the QD−peptide conjugate is quite stable. Moreover, by the addition of chloroquine, a substance that assists the release out of endosomes, the assemblies of RNA and QD−peptide conjugates diffused in the cytoplasm.

EXPERIMENTAL PROCEDURES

Materials. Piperidine, thioanisole, ethanedithiole, trifluoroacetic acid (TFA) (HPLC grade), tris(2-carboxyethyl)phosphine (TCEP), Trypan blue, Hoechst 33342, and 5(6)-carboxyfluorescein (CF) were purchased from Fluka (Buchs, Switzerland). *N*,*N*-Diisopropylethylamine (DIEA), *O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU), thiocresol, ethylenediaminetetraacetic acid (EDTA), methyl-β-cyclodextrin, wortmannin, chlorpromazine, 5-(*N*-ethyl-*N*-isopropyl)amiloride (EIPA), nystatin, and sulfosuccinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (sulfo-SMCC) were obtained from Sigma-Aldrich (Steinheim, Germany). Quantum Dots (T2-MP-EviTags) from Evident Technologies (New York, USA), diethyl ether from Merck (Darmstadt, Germany), and acetonitrile (ACN) were purchased from VWR Prolabo (Darmstadt, Germany). 4-(2′,4′-Dimethoxyphenyl-Fmoc-aminoethyl)-phenoxy resin (Rink amide) and N^{α}-Fmoc-protected amino acids were purchased from NovaBiochem (Läufelingen, Switzerland) and Iris Biotech (Marktredwitz, Germany). *N*,*N*′-Diisopropylcarbodiimide (DIC), *N*-hydroxybenzotzriazole (HOBt), and trifluoroacetic acid (TFA) (peptide grade) were obtained from Iris Biotech (Marktredwitz, Germany). *N*,*N*′-Dimethylformamide (DMF) and dichloromethane (DCM) were purchased from Biosolve (Valkenswaard, The Netherlands).

The following side chain protecting groups were chosen: trityl (Trt) for Cys and His; 2,2,4,6,7-pentamethyldihydrobenzofurane-5-sulfonyl (Pbf) for Arg; *tert*-butyl (tBu) for Thr and Glu; *tert*-butyloxylcarbonyl (Boc) or 1-(4,4-dimethyl-2,6-dioxocyclohex-1-ylidene)ethyl (Dde) according to the synthesis strategy.

For cell culture and colocalization studies, the following media, supplements, and substances were used: RPMI 1640 (with L-glutamine), Dulbecco's modified Eagle's medium (DMEM), trypsin/EDTA (1 × concentrate, 1:250 in PBS, trypsin 0.5 mg/mL, EDTA 0.22 mg/mL, pH 7−7.5), Dulbecco's phosphate buffered saline (PBS, pH 7.4), and fetal calf serum (FCS) were purchased from PAA Laboratories (Pasching, Austria), OptiMEM and Hank's balanced salt solution (HBSS) from Gibco/Invitrogen (Auckland, NZ). Transferrin from human serum as Texas Red or Alexa Fluor 488 conjugate and cholera toxin subunit B (recombinant) Alexa Fluor 488 or 647 conjugate were from Molecular Probes (Eugene, Oregon, USA). Cell culture flasks (75 cm^2) and 24-well plates were obtained from TPP (Trasadingen, Switzerland). 8-well chamber slides for microscopy were from ibidi (Munich, Germany). Human embryonic kidney (HEK 293) and human cervix carcinoma (HeLa) cell lines were obtained from the American type Culture Collection (ATCC).

Peptide Synthesis and Purification. Synthesis of the hCT derivatives was performed by automated multiple solid-phase peptide synthesis (SPPS) (Syro, MultiSynTech, Bochum, Germany) using orthogonal Fmoc/^{t}Bu strategy as described previously (*23*). All peptides were synthesized as C-terminal amides by using the Rink amide resin (30 mg, resin loading 0.45 mmol g^{-1}).

At first the sequence, hCT(19−32) was synthesized automatically. Then, (Dde)-Lys(Fmoc)-OH was introduced manually and elongated via the side chain of Lys (*18*) to obtain the branched peptides. Therefore, double-coupling reactions were carried out (1 h each) using 3-fold excess of amino acid, HATU, and DIEA. Afterward, the fragment was elongated automatically and (Dde)-hCT(18−32)-k7 was obtained, whereas the N-terminus of the side chain k7 was protected with Boc. After cleavage of the Dde protecting group with 2% hydrazine in DMF (v/v; 10 × 10 min at room temperature), the peptide was either modified with (5,6)-carboxyfluorescein (CF) or cysteine in order to obtain CF-hCT(18−32)-k7 or [C^{17}]-hCT(18−32)-k7, respectively. CF-coupling was performed for 2 h using a 1.5-fold excess of CF, HATU, and DIEA in DMF. Introduction of cysteine was performed as described above for (Dde)-Lys(Fmoc)-OH. For synthesis of a double-labeled conjugate, CF-labeling of the side chain occurred as described above. Subsequently, the hydroxyl groups of CF were protected with trityl by using 4 equiv of trityl chloride and DIEA in DCM for 16 h. Then, cysteine at position 17 was introduced after cleavage of the Dde protecting group.

Finally, the peptides were cleaved from the resins within 3 h at room temperature. Peptides without Cys were treated with TFA/thioanisol/thiocresol (90:5:5 v/v) and peptides containing Cys were treated with TFA/thianisol/ethanedithiol (90:7:3 v/v). Then, the peptides were precipitated from ice−cold diethyl ether, collected by centrifugation, lyophilized from water/*tert*-butyl alcohol (3:1 v/v), and analyzed by analytical RP-HPLC on a Vydac RP18-column (4.6 × 250 mm; 5 μm/300 Å) using linear gradients of 10−60% B in A (A = 0.1% TFA in water; B = 0.08% TFA in ACN) over 30 min and a flow rate of 0.6 mL min^{-1}. Purification of the peptides was achieved by preparative HPLC on a RP18 column (Waters, 5 μm, 25 × 300 mm) by using a linear gradient of 10−40% B in A over 50 min and a flow rate of 15 mL min^{-1}. Identification was performed by MALDI-TOF mass spectrometry (Voyager RP, Perseptive Biosystems), and purity was confirmed again by analytical RP-HPLC as described before.

The following peptides were synthesized: CF-hCT(18−32)-k7, [C^{17}]-hCT(18−32)-k7, and [C^{17}]-hCT(18−32)-k7(CF). Sequences and analytical data are shown in Table 1.

Preparation of QD−Peptide Conjugates. To obtain QD-[C^{17}]-hCT(18−32)-k7 conjugates, amine-functionalized quantum dots (QD; purchased from EvidentTech) were at first activated by adding approximately 1 mg of sulfo-SMCC to 200 μL of amine quantum dots (QD_{514}: $n = 2.3$ nmol) in 200 μL of 50 mM sodium phosphate pH 7.4. After shaking at room temperature for 60 min, the excess of the cross-linker was removed using a PD-10 desalting column equilibrated with conjugation buffer (1 mM EDTA, 0.1 M phosphate, 0.15 M NaCl, pH 7.2). Fractions containing the QD were collected, identified by tracking the fluorescence (Horiba Jobin Yvon Fluorolog-3), and combined. Coupling of the peptide was performed by first incubating the peptide with TCEP to obtain free sulfhydryl groups. Then, [C^{17}]-hCT(18−32)-k7 was mixed with the maleimide-activated QD in conjugation buffer (1 mM EDTA, 0.1 M phosphate, 0.15 M NaCl, pH 7.2) and incubated at 4 °C overnight. Afterward, the solution was concentrated using an Amicon filter device (MWCO 10 000). The conjugate was then purified by size exclusion chromatography with a

[a]CF: 5(6)-carboxyfluorescein.

Superdex200 resin. At least 25−30 fractions were collected. The fluorescence of the fractions was recorded at the QD emission peak wavelength of 514 nm, and the peptide amount in each fraction was measured by Bradford assay. The Bradford readings and the fluorescence values at the QD emission peak wavelength were plotted vs the fraction number to generate elution profiles and to identify the fractions containing QD−peptide conjugate.

The same procedure was used to conjugate [C^{17}]-hCT(18−32)-k7 and [C^{17}]-hCT(18−32)-k7(CF) to QD_{617} (n = 2.4 nmol). QD−peptide conjugates with a QD to peptide ratio of 1:100 up to 1:300 were prepared.

Cell Culture. Cells were grown in 75 cm^2 culture flasks to confluence at 37 °C and 5% CO_2 in a humidified atmosphere (95%). HeLa cells were grown in supplemented RPMI 1640 (with L-glutamine) with 10% heat-inactivated fetal calf serum. HEK 293 cells were cultured in Dulbecco's modified Eagle's medium/Ham's F12 (without L-glutamine) containing 15% heat-inactivated fetal calf serum.

Resazurin-Based Cell Viability Assay. HEK 293 or HeLa cells were seeded in 96-well plates (15 000 and 50 000 cells/well, respectively). To investigate the influence of the inhibitors, peptides, and QD−peptide bioconjugates on the cell viability, we used the fluorimetric resazurin-based cell viability assay as described recently in ref *21*. The peptide or rather the QD−peptide bioconjugate was diluted to appropriate concentrations (0.01−2 μM for the QD−peptide bioconjugate, 100 μM of [C^{17}]-hCT(18−32)-k7 and CF-hCT(18−32)-k7) in standard cell culture medium. For testing the inhibitors, dilutions of wortmannin (200 nM), EIPA (100 μM), chloropromazine (20 μM), nystatin (27 μM), or methyl-β-cyclodextrin (10 mM) in serum free medium were prepared. For each data point, a triplicate of wells was prepared. Cells were incubated for 24 h with the peptide and QD−peptide solutions and for 60 min with the inhibitor solutions, and afterward, the resazurin-based *in vitro* toxicity assay was performed.

Untreated cells were investigated as the negative control, whereas cells incubated with a solution of 70% alcohol for 10 min were used as the positive control. Afterward, a freshly prepared resazurin solution (1:5 v/v in serum-free cell culture medium) was added (1:1 v/v), and the cells were incubated for 2 h under standard growth conditions. The cell viability was finally analyzed fluorimetrically by using a multiwell plate reader (Spectrafluor plus, Tecan, Crailsheim, Germany). The metabolic conversion of resazurin to the reduced resofurin by the living cells was measured at 595 nm (after excitation at 550 nm).

Fluorescence Microscopic Imaging. To characterize the peptide uptake by fluorescence microscopic imaging, living, unfixed cells were investigated. HeLa and HEK 293 cells seeded in 8-well chamber slides (40 000 and 100 000 cells/well, respectively) were incubated with 25 μM CF-hCT(18−32)-k7 for 30 and 60 min. 10 min prior to the end of the peptide incubation, Hoechst 33342 was added to a final concentration of 5 μg/mL for nuclear staining. To monitor the intracellular fate, cells were coincubated with either Alexa Fluor 647 labeled cholera toxine (final concentration of 10 μg/mL) or Texas Red labeled transferrin (final concentration of 50 μg/mL). To distinguish between internalized and cell surface-bound peptides, the remaining extracellular fluorescence was quenched with an acidic Trypan blue buffer (300 μM in glycine buffer, pH 4.5) for 1 min. Subsequently, cells were washed 3 times with PBS, suspended in HBSS (pH 7), and inspected by fluorescence imaging. The peptide uptake was analyzed using a Zeiss Axiovert 200 inverse phase-contrast fluorescence microscope provided with an ApoTome and a 63×/1.4 oil immersion objective.

Additionally, HeLa and HEK 293 cells, seeded in 8 well chamber slides (40 000 and 100 000 cells/well, respectively) were incubated with QD_{617}-[C^{17}]-hCT(18−32)-k7 (0.02 μM QD) for 45 up to 90 min as described above and simultaneously incubated with either cholera toxin Alexa Fluor 488 (10 μg/mL) or transferrin Alexa Fluor 488 (50 μg/mL). Finally, the cells were washed with PBS for several times, diluted in HBSS (pH 7), and imaged.

Flow Cytometry. HeLa and HEK 293 cells were seeded in 24-well plates (100 000 and 250 000 cells/well, respectively) and grown under standard growth conditions. Subconfluent cells were incubated with CF-hCT(18−32)-k7 (20 μM in serum free medium) for 60 min or with QD_{617}-[C^{17}]hCT(18−32)-k7 (0.01 μM QD in serum free medium) for 90 min. Then, cells were incubated with Trypan blue (300 μM in glycine buffer, pH 4.5) for 1 min in order to quench potentially remaining extracellular fluorescence caused by CF. Additionally, cells were washed with PBS (3 × 300 μL). Afterward, the cells were detached by incubation with trypsin/EDTA for 1 min. The catalytic activity of trypsin was stopped by addition of cell culture medium supplemented with 10% FCS (HeLa)/15% FCS (HEK 293). Then, trypsin/EDTA was removed, and the cells were resuspended in PBS and analyzed by a flow cytometer (Partec GmbH, Münster, Germany). At least 10 000 cells per sample were analyzed in order to get reproducible results. The mean fluorescence intensity of peptide-labeled cells was compared with untreated cells as control.

For inhibition of endocytosis pathways, cells were pretreated for 30 min with wortmannin (200 nM), EIPA (100 μM), chloropromazine (20 μM), nystatin (27 μM) or methyl-β-cyclodextrin (10 mM) (all inhibitor dilutions were prepared in serum free medium) prior to incubation with CF- or QD_{617}-

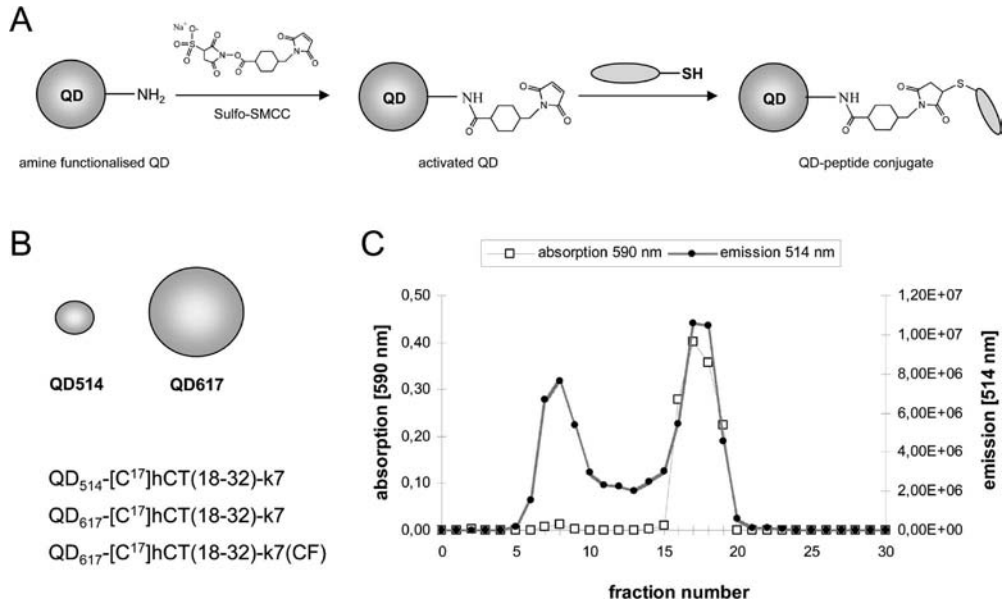

Figure 1. Synthesis of QD−peptide assemblies. (A) Amine-functionalized QDs were activated with sulfo-SMCC, subsequently followed by reaction with the thiol group of the peptide. (B) Two different QDs were used for bioconjugate generation. The double-labeled conjugate was created by coupling the CF-labeled peptide to QD_{617}. (C) Fractions collected by a Superdex200 column were measured by Bradford assay (absorption) and fluorescence spectroscopy (emission). QD−peptide fractions are represented by peaks with overlapping fluorescence and absorption spectra.

labeled hCT derivatives. All experiments were performed twice or triply in duplicate or triplicate.

The flow cytometric data were evaluated by using the software *FlowMax 3.0* (Partec).

Stability of QD-hCT-Peptide Conjugates. To determine the stability of the newly synthesized QD-hCT-peptide conjugates, HeLa and HEK 293 cells, respectively, were seeded in 8 well chamber slides (40 000 and 100 000 cells/well, respectively) and grown under standard growth conditions. Subconfluent cells were incubated with the double-labeled QD_{617}-[C^{17}]-hCT(18−32)-k7(CF) (0.02 μM QD) for 1.5 and 4 h. After 4 h incubation, the QD-hCT-peptide conjugate solution was removed and cell media were added. Fluorescence imaging was performed after 1.5, 4, and 24 h shortly after washing the cells 3−5 times with 200 μL HBSS (pH 7). At least 100 μL HBSS was added for fluorescence imaging that was performed using a Zeiss Axiovert 200 inverse phase-contrast fluorescence microscope provided with an ApoTome and a 63×/1.4 oil immersion objective.

Peptide-Mediated RNA Delivery. We complexed Cy-3-labeled RNAs of different lengths with QD_{514}-hCT-peptide conjugates: 83 base long RNA (5′-GGGAGAATTCCGACCA-GAAGAUUGAGAAGGGCGAUCUUCCGGCCGGACCUCA-ACCGGCGUAUGUGGCUCUACAUGGAUCCUCA-3′) and 101 base long RNA (sequence: 5′-GGAGCUCAGCCUUCA-CUGCCGGAGUGCAUUGUUGGCUGGGUGAUCGUGGU-GGAGACCUUACCCCUCUACGGGGGGGUGGAGGGCA-CCACGGUCGGAUCCAC-3′). Final concentrations at the cells were 0.4 μM RNA and QD_{514}-[C^{17}]-hCT(18−32)-k7 (0.04 μM QD) in 200 μL OptiMEM.

Prior to the peptide−RNA complexation, the RNA was de- and renatured. Therefore, the required volume of RNA stock solution was diluted with RNase- and DNase-free distilled water to a final volume of 10 μL, heated up to 70 °C for 5 min and slowly cooled down to room temperature. Then, the required volume of QD_{514}-[C^{17}]-hCT(18−32)-k7 solution was added and the noncovalent peptide−RNA complexation was carried out for 1 h at 37 °C. Afterward, preheated serum-free OptiMEM was added to reach a final volume of 200 μL. The QD-peptide-RNA solution was added to the cells and incubated for 1.5 and 6 h, respectively, at 37 °C. For nuclear staining, Hoechst 33342 was added to a final concentration of 5 μg/mL 10 min prior to the end of complex incubation. Finally, after 1.5 or 6 h the QD−peptide−RNA solution was removed and the cells were washed four times with 200 μL OptiMEM. 100 μL HBSS was added to the cells, and fluorescence microscopic imaging was performed as described above.

The influence of chloroquine was investigated as follows: prior to the addition of the QD−peptide−RNA solution, the cells were preincubated with 100 μL chloroquine (100 μM). After 1.5 h incubation, the QD−peptide−RNA solution was removed, and the cells were treated as described above.

RESULTS

Synthesis of QD-hCT-Peptide Conjugates. Peptides were coupled covalently to green (514 nm emission maximum, QD_{514}) and red (617 nm emission maximum, QD_{617}) emitting QDs. For efficient cell delivery, we incorporated the branched hCT-derivative hCT(18−32)-k7 on the surface of the QDs. We recently were able to show that this branched peptide was internalized very effectively in several cell lines (*21*). Furthermore, owing to the cationic sequence of the side chain an efficient complexation of negatively charged structures like oligonucleotides is possible. Synthesis of the QD−peptide conjugates was performed according to the manufacturer's protocol. Briefly, we first coupled the bifunctional cross-linker sulfo-SMCC to PEG-NH_2 functionalized QDs. Then, the peptide was introduced as [C^{17}]-hCT(18−32)-k7 that reacted selectively with the maleimide of the cross-linker (see Figure 1A for reaction scheme). We prepared QD−peptide conjugates with a QD to peptide ratio of 1:100 up to 1:300. Additionally, we synthesized a double-labeled conjugate where the peptide was labeled with 5(6)-carboxyfluorescein (CF) at the N-terminus of the side sequence k7 (see Figure 1B for details).

The coupling efficiency was determined by performing either a Bradford assay or, in the case of the double-labeled conjugate, by measuring the fluorescence of CF. For the red-emitting QDs, the assays revealed about 100 peptide molecules per quantum dot, whereas for the smaller green-emitting QDs, ratios of about 1:50 QD to peptide were determined.

Cellular Uptake in HeLa and HEK 293 Cells. Cellular uptake was studied in two different cell lines, HeLa and HEK

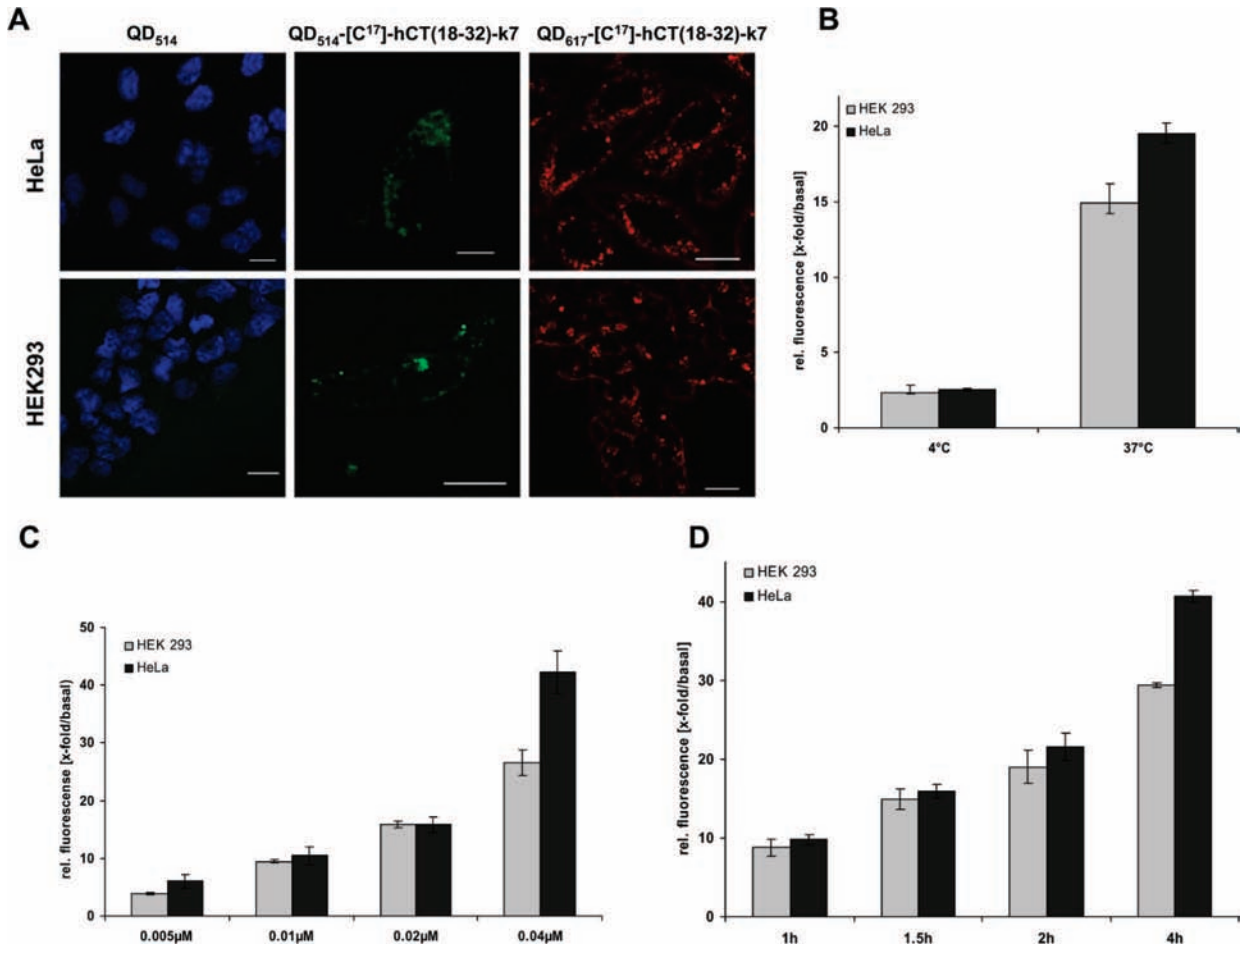

Figure 2. Internalization of QD−hCT carrier peptide conjugates in HeLa and HEK 293 cells. (A) Representative fluorescence microscopy images of QD_{514}-solution only (0.25 μM), QD_{514}-[C^{17}]-hCT(18−32)-k7 (0.04 μM QD concentration) and QD_{617}-[C^{17}]-hCT(18−32)-k7 (0.02 μM QD concentration). The scale bar is 20 μm. (B,C,D) Uptake of QD_{617}-[C^{17}]-hCT(18−32)-k7 (0.02 μM QD concentration) in HEK 293 and HeLa cells as determined by flow cytometry at either 37 or 4 °C for 90 min (B), at different concentrations for 90 min at 37 °C (C) and after incubation the cells up to 4 h at 37 °C.

293 cells, because these cell lines have often been used in recent reports (*6*, *22*, *23*). After incubation with nonconjugated QDs, we observed no detectable intracellular fluorescence, indicating that the nanoparticles were not able to enter the cells by themselves (shown for QD_{514} in Figure 2A). Cell internalization of the $QD_{617/514}$-[C^{17}]-hCT(18−32)-k7 conjugates was slow and occurred efficiently after 90 min of incubation. A punctuate and vesicular uptake pattern was observed in both cell lines pointing to an endocytotic entry pathway (Figure 2A). Subsequently, we studied in more detail the uptake of QD_{617}-[C^{17}]-hCT(18−32)-k7 conjugates in both cell lines by using flow cytometry. Uptake was significantly reduced at 4 °C (Figure 2B), supporting an energy-dependent internalization mechanism. This is in agreement with previously published results on QD−peptide delivery in both HEK 293 (*6*) and HeLa (*23*) cells. In addition, internalization of the QD−peptide bioconjugates is both concentration- (Figure 2C) and time-dependent (Figure 2D) in HEK 293 as well as in HeLa cells.

To get more insight into the entry mechanism, we investigated the uptake by the simultaneous delivery of AlexaFluor 488-conjugated cholera toxin subunit B (AF488-CtxB) or AlexaFluor 488-conjugated transferrin (AF488-Tf) into the cells. Like other microbial toxins, the active part of cholera toxin subunit B is internalized by an endocytosis pathway that is independent of clathrin and involves lipid rafts (*24*, *25*). However, labeled transferrin is commonly used to monitor clathrin-dependent uptake in cells (*26*). Therefore, cells were preincubated with the appropriate marker, and subsequently, the QD−bioconjugates were added. We inspected the cells after 45 min, the time point at which we assumed that cell entry of the QD−peptide assemblies occurred. Figure 3A,B shows the uptake of QD_{617}-[C^{17}]-hCT(18−32)-k7 conjugates in HeLa cells. No colocalization was found for QD−peptide conjugates and AF488-Tf, whereas after incubation with AF488-CtxB, colocalization of internalized QD−peptide conjugate and CtxB was evident as seen by the merged fluorescence on the plasma membrane. Quite different results were obtained after incubating HEK 293 cells with the QD−peptide conjugate and the two endocytosis markers (Figure 3C,D). Here, no colocalization within the cell was observed. Moreover, it seems that the entry of the markers into this cell line occurs very fast, while the QD−peptide conjugate is mostly present on the plasma membrane and only to a minor fraction in the cell interior. Even after inspecting the cells at different time points (15, 30, 60, 90, 120 min), we did not detect any degree of overlap in the fluorescence pattern (data not shown).

Inhibition of Endocytotic Pathways. To further characterize the uptake mechanism of the QD−peptide bioconjugates, we preincubated HeLa as well as HEK 293 cells with different inhibitors interfering with individual endocytotic pathways (*25*−*30*). After 30 min preincubation with these different inhibitors, we analyzed the cellular uptake of the QD−peptide conjugates (cells were incubated with bioconjugates for 90 min) by flow cytometry. Additionally, we tested the influence of the same inhibitors on the uptake of 5(6)-carboxyfluorescein (CF)-labeled hCT(18−32)-k7 in both cell lines to get some insights into the

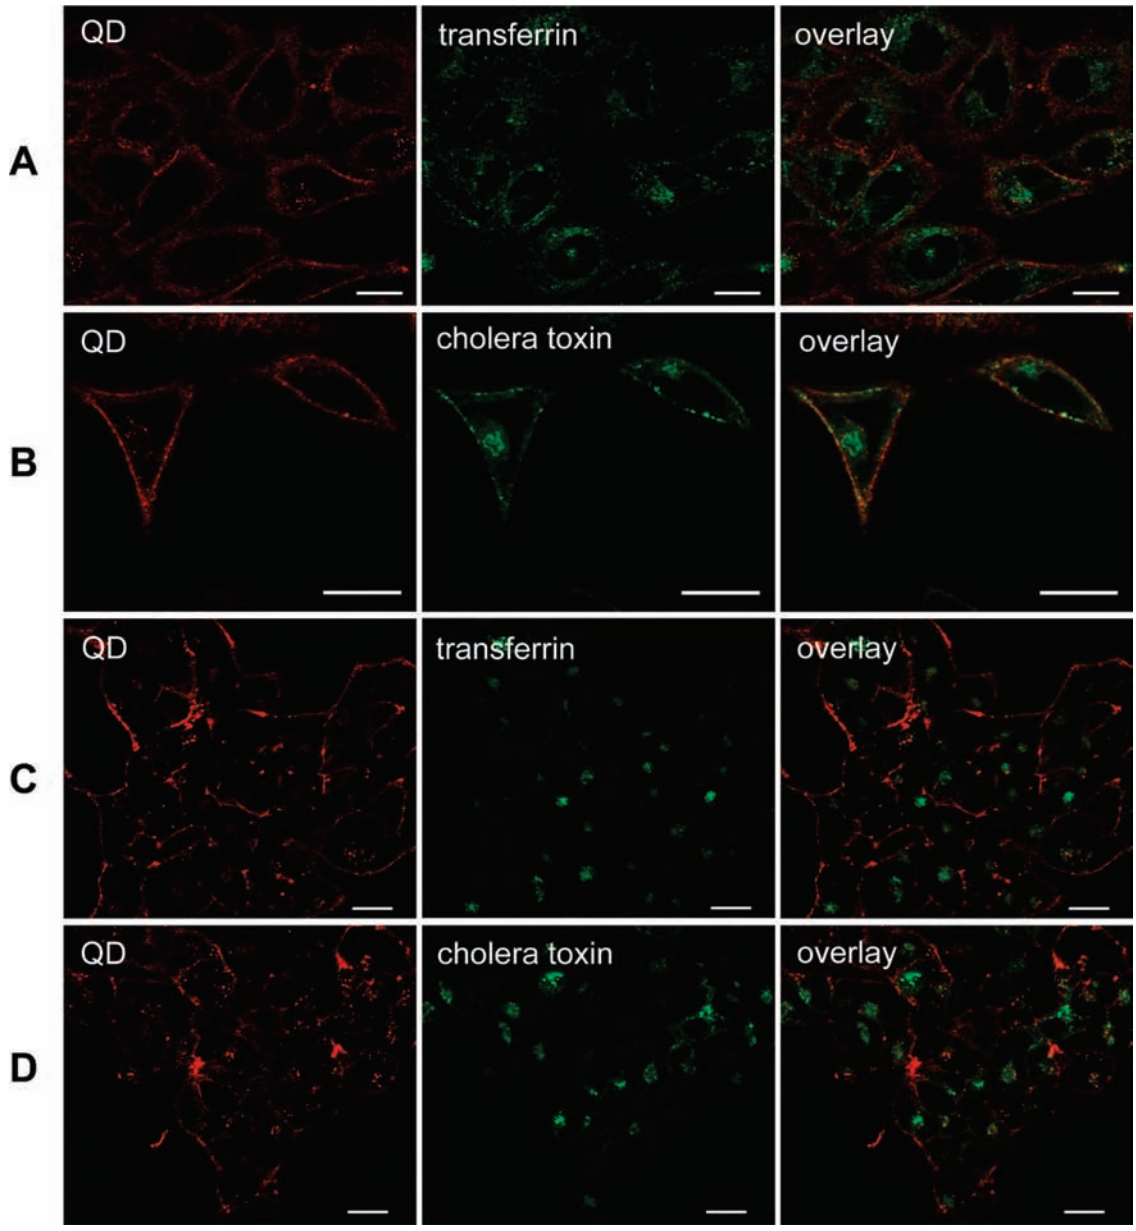

Figure 3. Colocalization study of QD_{617}-[C^{17}]-hCT(18−32)-k7 in HeLa (A,B) and HEK 293 (C,D) with transferrin or cholera toxin, respectively. Colocalized vesicels are visible in yellow, QD_{617}-[C^{17}]-hCT(18−32)-k7 conjugate in red, and endocytosis markers (transferrin and cholera toxin) in green. For colocalization studies with transferrin, cells were incubated with QD_{617}-[C^{17}]-hCT(18−32)-k7 and simultaneously stained with 50 μg/mL Alexa Fluor 488-conjugated transferrin for 45 min at 37 °C (A,C). For colocalization studies with Alexa Fluor 488-conjugated cholera toxin, cells were preincubated with 10 μg/mL cholera toxin at 4 °C, and the marker was then replaced by QD_{617}-[C^{17}]hCT(18−32)-k7 for 1 h at 37 °C (B,D). The scale bar is 20 μm.

influence of the cargo size on the internalization process. Unspecific bound peptides were detached from the outer leaflet of the cell membrane by trypsin digestion. Figure 4A,B demonstrates the uptake of QD_{617}-[C^{17}]-hCT(18−32)-k7 and CF-hCT(18−32)-k7 in HeLa and HEK 293 cells, respectively. We found out that the uptake of the QD−peptide conjugate in HeLa cells seems to follow two different pathways (see Figure 4A). The decreased uptake after depletion of cholesterol through MβCD proves the results from the colocalization studies and points to a lipid raft-dependent entry pathway. The second way is obviously mediated by macropinocytosis, a fact that is indicated by the influence of 5-(*N*-ethyl-*N*-isopropyl)amiloride (EIPA). Interestingly, the uptake of CF-hCT(18−32)-k7 is realized by a third pathway in HeLa cells that is clathrin-dependent. Upon preincubation with chlorpromazine, a marker that inhibits this endocytosis pathway, the uptake was decreased (see Figure 4A). The same pathways seem to be involved in the internalization process of CF-hCT(18−32)-k7 in HEK 293 cells (see Figure 4B). Surprisingly, the uptake of QD_{617}-[C^{17}]-hCT(18−32)-k7 was not negatively influenced after preincubating HEK 293 cells with any of the tested inhibitors. In contrast, here we observed an increase in uptake (see Figure 4B).

To eliminate influence of the tested inhibitors on cell viability and thus impair the results of the inhibition studies, we performed resazurin-based cell viability assays. As demonstrated in Figure 4C, the impact of the inhibitors on cell viability was negligible for HeLa as well as for HEK 293 cells in the tested concentration range.

Stability. By using the double-labeled compound, we investigated the stability of the QD−peptide bioconjugates after cell entry. Hence, we incubated HeLa and HEK 293 cells for 24 h with the conjugate QD_{617}-[C^{17}]-hCT(18−32)-k7(CF) and visualized the cells by fluorescence microscopy after 1.5, 4, and 24 h.

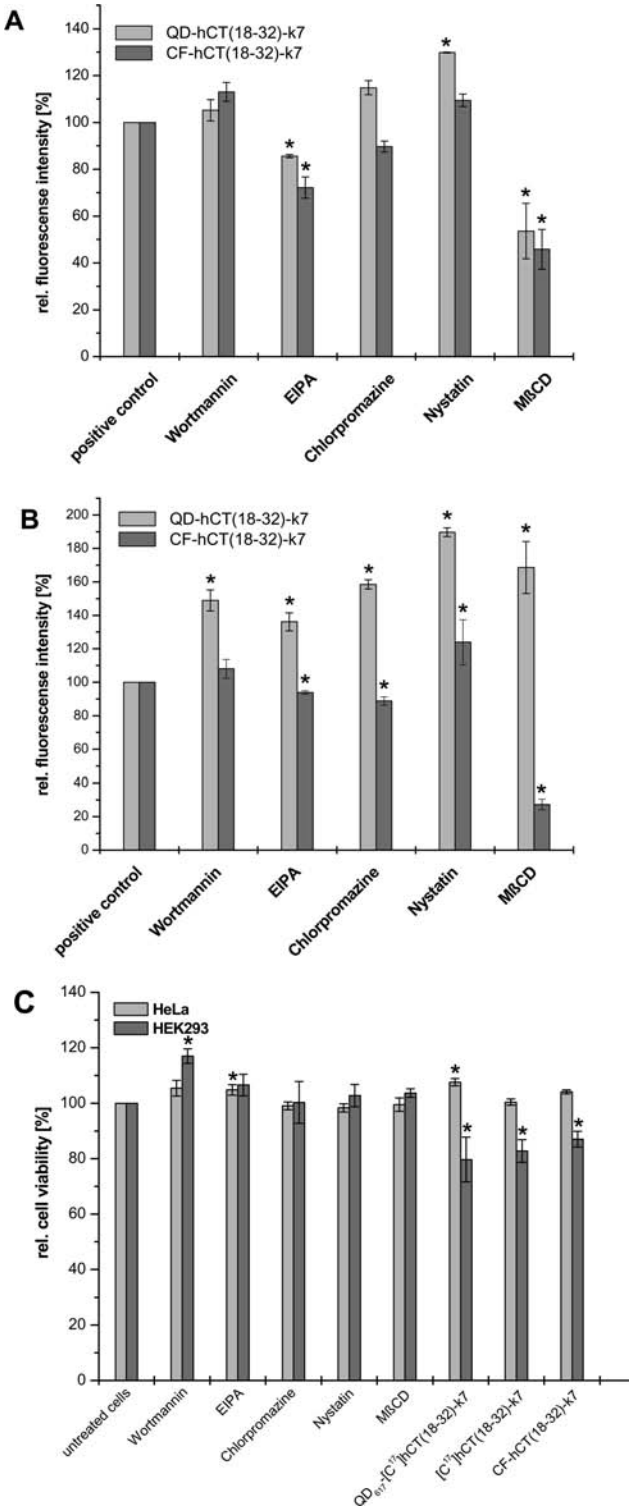

Figure 4. Endocytosis inhibition and toxicity studies. Panels A and B show uptake and endocytosis inhibition of CF-hCT(18−32)-k7 and QD_{617}-[C^{17}]-hCT(18−32)-k7 in HeLa (A) and HEK 293 (B) cells as determined by flow cytometry. The inhibition of endocytosis was performed by pretreating cells with 200 nM wortmannin, 100 μM EIPA, 20 μM chlorpromazine, 27 μM nystatin, and 10 mM methyl-β-cyclodextrin (MβCD) before incubation with QD_{617}-[C^{17}]-hCT(18−32)-k7 (0.02 μM QD) for 90 min or 20 μM CF-hCT(18−32)-k7 for 60 min. Cells incubated only with peptide or QD−peptide conjugate were used as control cells and set as 100%. Panel C shows relative cell viability of HeLa and HEK 293 cells after treatment with inhibitor for 60 min and peptide or QD−peptide solutions for 24 h (for details, see Experimental Section). Data are normalized to untreated cells (100% viability). Means were compared using Student's *t* test. A *P* value of <0.05 was considered significant and is indicated by an asterisk symbol (*).

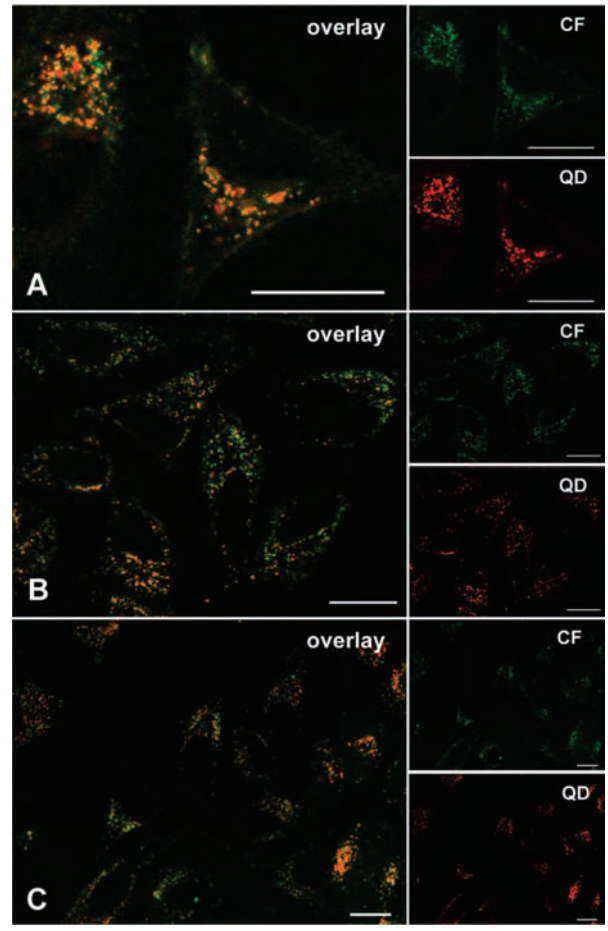

Figure 5. Stability of the new QD−hCT−peptide bioconjugates in HeLa cells. Colocalized vesicles are visible in yellow, carboxyfluorescein in green, and QDs in red. Cells were incubated with the double-labeled conjugate QD_{617}-[C^{17}]-hCT(18−32)-k7(CF) (0.02 μM QD concentration) for 1.5 h (Panel A) or 4 h (Panel B), and fluorescence imaging was performed at 1.5 h (Panel A), 4 h (Panel B), and 24 h (Panel C). The scale bar is 20 μm.

The merged fluorescence of the two fluorophors even after 24 h demonstrates that the conjugate seemed to be mostly intact (see Figure 5 for HeLa cells). In addition, it can be seen that the peptide-labeled nanoparticles were still entrapped in vesicles. The same results were obtained for HEK 293 cells (see Supporting Information Figure 2).

Furthermore, potential cytotoxic effects of the QD-CPP assemblies were assessed using a cell proliferation assay. The results confirmed no influence on cell viability for the QD−peptide conjugates in HeLa cells relative to untreated control cells (see Figure 4C). In contrast, cell viability was slightly reduced to 80% after incubating HEK 293 cells with the conjugate for 24 h.

Cargo Delivery. The main focus of this study was to create multifunctional particles for both imaging and transport of bioactive molecules. A major difference between this work and earlier studies is that the conjugated carrier peptides simultaneously function for the delivery of both the QD and an attached cargo. Furthermore, by complexing the cargo directly to the carrier peptide our approach circumvents the tradeoffs in the number of attached species on the QD surface. Since negatively charged oligonucleotides are not able to translocate the cell membrane by themselves, there is a great demand on effective delivery systems for siRNA or aptamers in gene regulation strategies. Therefore, as proof of our concept, we chose to transport Cy-3 labeled RNA into HeLa and HEK 293 cells. The Cy-3 label served for visualizing the fate of the cargo after cell

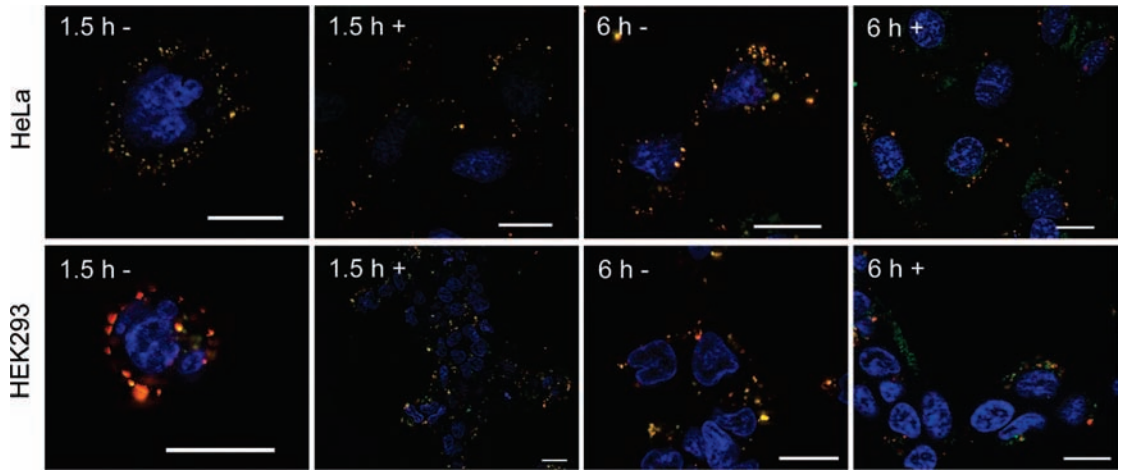

Figure 6. RNA delivery mediated by the QD_{514}-[C^{17}]-hCT(18−32)-k7 bioconjugate. Delivery of the 83 base long RNA in HeLa and HEK 293 cells. Colocalization is visible in yellow, Cy-3 labeled RNA in red, QD_{514}-[C^{17}]-hCT(18−32)-k7 in green, and the nucleus was stained with Hoechst 33342 in blue. The cells were incubated with QD-peptide-RNA either for 1.5 h (1.5 h -) or 6 h (6 h -). The influence of the pretreatment with 100 μM chloroquine for 1 h is shown in panels marked with +. The scale bar is 20 μm.

entry. Thus, we complexed QD_{514}-[C^{17}]-hCT(18−32)-k7 with RNAs of different lengths (either 83 or 101 bases long).

One major problem when using CPP for cargo delivery is their enclosure in endosomes after cell entry. The results from our internalization studies clearly showed entrapment of the QD−peptide conjugates in vesicles that may be endosomes or lysosomes. To overcome this difficulty, we also treated the cells with the antimalaria drug chloroquine. This cell-permeable base is described to neutralize the acidic environment in the endosomes leading to reduction of endolysosomal hydrolytic degradation and destabilization of the complex between carrier and cargo (*31*). Figure 6 shows HeLa (upper row) and HEK 293 (lower row) cells after incubation of complexes formed from QD_{514}-[C^{17}]-hCT(18−32)-k7 and the 83 base long RNA. Cells were inspected after 1.5 and 6 h. As described above, cellular distribution was monitored in preparations with or without the addition of chloroquine. It is evident that the complex is still intact after 6 h in both cell lines, whereas upon the addition of chloroquine, most of the substances have distributed into the cytoplasma. Only the green fluorescence coming from the QD−peptide conjugates was visible. The red fluorescence from the RNA was only merely seen. Therefore, we conclude that the RNA must have been detached from the complex with the peptides coupled to the QD surface. The same results were obtained after incubation of complexes formed from QD_{514}-[C^{17}]-hCT(18−32)-k7 and the 101 base long RNA in both tested cell lines (data not shown).

DISCUSSION

Over the past two decades there has emerged an immense interest in quantum dots as fluorescent probes for biomolecular and cell imaging owing to their unique spectroscopic properties. Several examples are now available demonstrating successful *in vitro* and *in vivo* applications of QDs in tissue staining and cell labeling. Here, different strategies for cell internalization have been followed, like nonspecific or specific binding to the cell surface or the use of antibody-coated QDs (*32*, *33*). Another promising approach for realizing effective cell uptake is the attachment of cell-penetrating peptides to the QD surface. This class of peptides is able to penetrate the cell membrane in a receptor-independent way and shuttle various cargoes into the cell at the same time. Recent advances have shown the applicability of CPP in an impressive mode, and until now, a series of different biomolecules has been successfully transported into diverse cell lines. Nevertheless, only a few studies exist that have investigated peptide-coated quantum dots especially for their stability, toxicity, and internalization mechanism. Recently, Ruan et al. published data concerning cellular uptake and intracellular fate of Tat-functionalized QDs (*23*). They observed an engulfment of Tat-QDs in vesicles where they were bound to the inner membrane, and the subsequent transport of these vesicles to the perinuclear region. Furthermore, they found vesicles loaded with Tat-QDs on the outer membrane resulting from vesicle shedding. Moreover, it was assumed that the Tat peptide-conjugated QDs are internalized by macropinocytosis. Another paper from the same group dealt with PEG/PEI-coated QDs. Herein, the authors could show an improvement concerning the escape from intracellular acidic organelles (*34*). A general major drawback in such applications is, however, the toxicity of PEI that was minimized in this study by grafted PEG segments.

Our work focused on the development of transport systems that contain photostable markers like QDs and are useful as fluorescent probes for imaging, tracking, and delivery purposes. Furthermore, we were interested in the stability and toxicity of the new constructs and their internalization mechanism. Therefore, we generated different QD−peptide bioconjugates by attaching cysteine-modified [C^{17}]-hCT(18−32)-k7 to the surface of PEG-coated QD. We also synthesized a double-labeled compound by coupling [C^{17}]-hCT(18−32)-k7(CF) to red emitting QD_{617}. By measuring the fluorescence of the second fluorophor CF and comparing it with a calibration curve, it was possible to determine the amount of peptides per QD_{617} to a ratio of about 100:1. In our experiments, this value barely differed from the one we obtained by Bradford assay. Generally, this ratio is in good agreement with values obtained in previous studies where peptides were attached on a QD surface (*11*). Moreover, by introducing a second fluorophor the determination of the amount of peptides on the QD surface is achieved in an easy way. Thus, long-time stability can simply be monitored. We determined that the double-labeled QD−peptide conjugate was stable at least over a period of one year (data not shown). A similar approach to quantify the number of peptides attached per QD was adopted by Derfus et al. (*35*). The disulfide bond of a cleavable cross-linker between FITC-labeled peptides and nanoparticles was reduced by 2-mercaptoethanol and the amount of FITC-labeled peptide was then quantified by fluorescence. However, our approach differs from other strategies where the therapeutic and delivery entities are simultaneously attached to

the QD surface. Thus, our newly formed constructs can directly serve as delivery and imaging tools.

Next, we analyzed the uptake and distribution of our QD−peptide conjugates in two cell lines, HEK 293 and HeLa. The first internalization experiments using fluorescence microscopy showed that the generated bioconjugates were able to cross the lipid barrier of the cells. Both HeLa and HEK 293 cells efficiently took up the peptide-coated QDs. Also, we detected no uptake of the QDs alone. This is in agreement with the study of Delehanty et al. on self-assembled quantum dot−peptide bioconjugates (*6*). Furthermore, the vesicular distribution pattern suggests an endocytotic mechanism. This was confirmed by investigating the uptake of QD_{617}-[C^{17}]-hCT(18−32)-k7 using flow cytometry. We found that uptake is reduced at 4 °C pointing to an energy-dependent internalization. Additionally, internalization of the studied QD−peptide conjugates is concentration- and time-dependent. Interestingly, these results were similar to previous studies using carboxyfluorescein (CF)-labeled hCT-derived peptides (*22*). In addition, recent studies on HEK 293 cells revealed that the uptake of CF-hCT(18−32)-k7 is temperature-, concentration-, and time-dependent. Here, it was also found that the uptake could not be displaced by the addition of unlabeled hCT(18−32)-k7 peptide, pointing to a receptor-independent uptake mechanism (*36*).

Accordingly, we studied the uptake in more detail because CPP are known to use several endocytotic pathways for cell internalization. For instance, most of the cationic peptides investigated so far enter the cells via clathrin-independent pathways including macropinocytosis (*37*−*39*). Therefore, we started with colocalization experiments by using fluorescent-labeled transferrin and cholera toxin subunit B to distinguish at first between clathrin-dependent (transferrin) and lipid raft-dependent (CTxB) endocytosis. Since we were interested in the processes of cell entry, we inspected the cells to an early stage, after 45 min, when most of the QD−peptide bioconjugates were passing the cell membrane, and only few constructs stayed inside the cell. From fluorescence imaging studies of HeLa cells incubated with QD_{617}-[C^{17}]-hCT(18−32)-k7 and AlexaFluor 488 labeled CTxB, we assume a lipid raft dependent uptake mechanism due to clear colocalization of both substances. It is known that HeLa cells have decreased caveolin-1 expression. Therefore, internalization of cholera toxin subunit B can occur via the clathrin-mediated pathway, too, but it was found out that the significant fraction is internalized via clathrin-independent pathways (*40*−*42*). For HEK 293 cells, the results were not as clear, since we could not detect any colocalization of our QD−peptide conjugates with neither transferrin nor CTxB. In both cases, the marker was very rapidly taken up by HEK 293 cells. However, we were additionally interested in the influence of the cargo size on the internalization process and compared the results of the QD−peptide bioconjugates to the uptake of CF-labeled hCT(18−32)-k7. In contrast to the QD−peptide conjugate, we detected colocalization with both markers transferrin and CTxB in HeLa cells (see Supporting Information Figure 1) indicating that CF-hCT(18−32)-k7 is internalized by both clathrin-dependent and -independent pathways. Again, we observed no colocalization after incubating HEK 293 cells with the peptides and either transferrin or CTxB.

Therefore, we decided to extend our studies by using several endocytotic inhibitors. We preincubated the cells with inhibitors for clathrin-dependent and -independent pathways, as well as for caveolin-dependent endocytosis and macropinocytosis. Our results show that the import of the conjugates was never fully blocked after preincubation with the inhibitors. Besides, we did not find any influence of wortmannin. Since wortmannin is reported to also affect the sorting pathways like recycling and degradation, it may have happened that internalization per se was not reduced but the fate of the peptides inside the cells was influenced. This has to be investigated further.

For HeLa cells, we conclude that the QD−peptide−bioconjugates appear to enter by macropinocytosis and lipid raft-dependent pathways. We could assess a strong influence of methyl-β-cyclodextrin (MβCD) to the amount of intracellular fluorescence. MβCD perturbs the function and organization of lipid rafts and is therefore a marker for raft processes. The results from the colocalization studies were consistent with this observation because they demonstrated simultaneous entrapment of hCT-QDs and cholera toxin subunit B also pointing to a lipid raft-dependent pathway. By using the inhibitor 5-(*N*-ethyl-*N*-isopropyl)amiloride (EIPA), the uptake of the bioconjugate was to some extent reduced as well, indicating that the internalization of the conjugate may occur by a second pathway that is macropincocytosis. Interestingly, when treating with the inhibitors we did not detect any decrease in uptake for the peptide-coated QDs in HEK 293 cells. Moreover, the inhibition of the pathways led to a dramatic increase in uptake in all cases. Recently, this effect was also reported by Duchardt et al. They detected a high increase in cellular fluorescence (4- to 7-fold) by flow cytometry after treatment with MβCD. They explained this observation on the one hand with the strong enrichment of the tested peptides at the plasma membrane. This fraction was also resistant to trypsin digestion (*38*). On the other hand, it may be that the inhibitors promote the uptake leading then to a more rapid internalization pathway. This could also be the case for the internalization of the QD−peptide conjugates in HEK 293 cells. Another explanation could be the retention of the QD−peptide conjugate inside the endosomal compartment and thus an inhibition of the rapid exit of its fragments out of the cytosol. Since we determined no relevant cytotoxicity for all tested inhibitors in the evaluated concentration range, we exclude the possibility that the increased uptake observed is due to any negative influence on cell viability.

In contrast, the CF-labeled peptide seemed to follow three different entry pathways in HeLa and HEK 293 cells. Additionally, the evaluation of the inhibition studies demonstrated strong evidence that EIPA, chlorpromazine, and MβCD influence the uptake. In HeLa cells, this is consistent with the observations we made by fluorescence microscopy where colocalization was found with fluorescent-labeled transferrin as well as with cholera toxin subunit B, pointing to both clathrin-dependent and -independent endocytosis. In addition, we detected reduced peptide uptake in the dependence of the particular inhibitors tested. Therefore, we assume that the most dominant entry pathway is lipid raft-dependent and that only a minor fraction of CF-hCT(18−32)-k7 peptides are internalized by clathrin-mediated endocytosis or macropinocytosis. The strong influence of MβCD to the uptake of CF-hCT(18−32)-k7 in HEK 293 cells is in our opinion not remarkable, since it is known that depletion of cholesterol can generally affect most of the endocytotic uptake pathways (*43*).

Interestingly, it seems that both tested substances labeled with cargoes of different sizes use more than one entry pathway. However, regarding the relatively high concentrations that are normally used to study CPP it is likely that the peptides enter through multiple pathways, i.e., fluid phase or nonspecific adsorptive endocytosis. In fact, Duchardt et al. concluded that peptide concentration is a key experimental condition when analyzing peptide uptake (*38*). In another study, it was hypothesized that, in HeLa cells, macropinocytosis operates at a low basal rate. Thus, an inhibition of clathrin- and caveolae-mediated pathways could result in the stimulation of macropinocytosis (*44*). However, the differences in the uptake of the QD−peptide conjugates concerning HEK 293 and HeLa cells could be explained on one hand by the involvement of a yet unknown

uptake pathway in HEK 293 cells. On the other hand, there is general disagreement regarding to what extent the exact uptake pathway can be elucidated by inhibition studies. This is because the sensitivity of a certain cell line to various inhibitors of endocytic uptake pathways is different. In fact, the results of these studies can only give some indication of how the uptake of a certain molecule or complex could happen. Nevertheless, in conclusion, our findings contribute to the understanding of how CPP and especially hCT-derived carrier peptides are able to enter the cell interior and how the attached cargo can influence the adopted pathway. Anyway, the dissection of such mechanistic aspects is crucial in the further development and application of such drug delivery vectors for pharmaceutical purposes.

Furthermore, we demonstrated that our newly developed QD-CPP assemblies exert no cytotoxic effects on HeLa cells and have only a minor influence on cell viability after incubation of HEK 293 cells for 24 h with the constructs. This could be due to aggregation of the QD−peptide conjugates after 24 h in the cell interior. The toxic influence of the CF-hCT(18−32)-k7 peptides may be due to their rapid internalization in this cell line (as observed by fluorescence microscopy), an effect that was also described by Delehanty et al. (*6*). Furthermore, we assessed the stability of the QD−peptide nanoparticles after exposure of the double-labeled QD−peptide conjugate for 24 h to both cell-lines. Still after 24 h, the constructs of QD and peptide seemed to be mostly intact, as indicated by the merged fluorescence. From this, we conclude that the QD surface can effectively help to protect the peptides from degradation. Considering future *in vivo* applications, this could be important because one major drawback in using peptides is often the lack of metabolic stability that restricts many *in vivo* experiments.

The past years have sparked great interest in the therapeutic potential of gene regulation and gene silencing. As a result, there have been great efforts in the development of different strategies to deliver siRNA or aptamers into mammalian cells. The aim of this work was therefore to provide tools that are not only helpful in imaging but also in drug delivery applications. According to this, our results from the delivery studies with Cy-3 labeled RNA demonstrate the versatility of our peptide−QD conjugates. RNA of different length was efficiently transported into HeLa and HEK 293 cells. Furthermore, with the help of chloroquine it was possible to deliver the conjugates into the cytosol. Recently, we were able to demonstrate that the addition of chloroquine is useful in improving transfection rates in several cell lines and does not influence cell viability in the tested concentrations (*21*). Other approaches like the addition of cationic lipids are common for achieving endosomal escape (*35*). However, depending on whether chloroquine was added or not the complex of QD−peptide conjugates and RNA persisted in vesicles or was discharged in the cytoplasma. Interestingly, upon release out of the vesicles it seems that the RNA has dissociated from the QD−peptide assembly. After 6 h, only the green fluorescence was visible in the cytosol originating from the QD-bioconjugate. The red fluorescence from the RNA was only merely seen. Therefore, it must be assumed that the RNA dissociated from the positively charged peptides coupled to the QDs. Since we could show that the QD−peptide conjugate was stable for at least 24 h, the green fluorescence is in fact assumed to derive from the intact QD−peptide bioconjugate. The problem in the use of QDs is that they are sequestered in vesicles after cell entry. Thus, they are not available for molecular recognition or targeting. By using our approach, this obstacle can be overcome, and the delivery of therapeutic RNA to its target can be realized. Therefore, our delivery systems could be very useful tools for the transport and monitoring of other structures like siRNA or aptamers.

CONCLUSION

The aim of this study was to develop fluorescent nanoparticles suitable for the nonviral delivery and monitoring of therapeutic oligonucleotides. Therefore, we incorporated in a first step hCT-derived carrier peptides on the surface of luminescent quantum dots. Second, we carefully characterized these new systems and could demonstrate that they are nontoxic and possess high stability inside cells. Furthermore, we found some key factors concerning their uptake mechanism. The last step demonstrated that our QD−peptide conjugates successfully deliver complexed RNA into cells. This explored approach could be easily adapted to the transport and tracking of other biologically active molecules important in gene therapy.

ACKNOWLEDGMENT

The authors thank R. Reppich-Sacher for recording the MALDI mass spectra and K. Löbner for help in cell culture experiments. Cy-3 labeled RNA was a gift from Prof. Dr. U. Hahn and is kindly acknowledged. I. Neundorf thanks Prof. Dr. A. G. Beck-Sickinger for generous access to all resources of the institute.

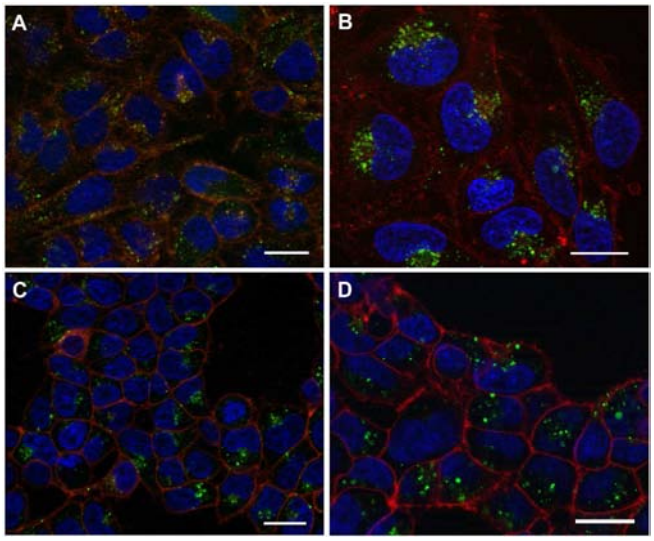

Figure 1. Cellular uptake of CF-hCT(18-32)-k7. Co-localisation study of CF-hCT(18-32)-k7 with either transferrin or cholera toxin in HeLa and HEK 293 cells. Co-localised vesicles are yellow, CF-labelled peptide is visible in green and endocytosis markers (transferrin or cholera toxin) are red. Panel A and B shows Hela and Panel C and D HEK 293 cells. For co-localisation studies with transferrin (A, C) cells were simultaneously incubated with 25 µM CF-hCT(18-32)-k7 for 30 min at 37°C and transferrin (50 µg/ml). For co-localisation studies with cholera toxin (B, D) cells were pre-incubated with 10 µg/ml cholera toxin (B: 30min at 4°C, D: 15 min at 37°C) and then incubated with 25 µM CF-hCT(18-32)-k7 (B: 1 h at 37°C, D: 15 min at 37°C). The scale bar is 20 µm.

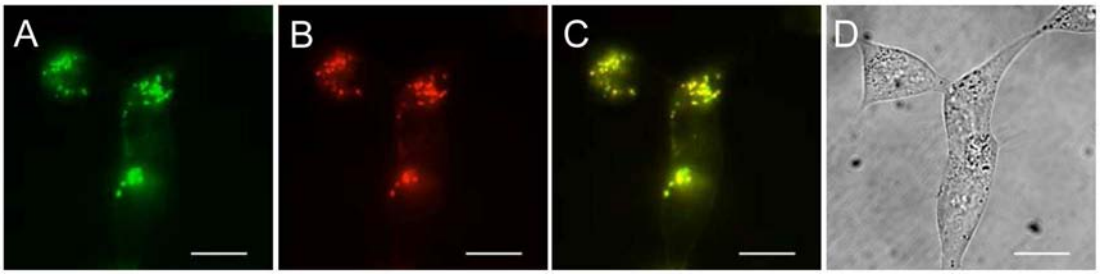

Figure 2. Stability of the QD-peptide bioconjugates in HEK 293 cells. Cells were incubated with the double-labelled conjugate QD_{617}-[C^{17}]-hCT(18-32)-k7(CF) for 4 h. QD-peptide solution was replaced by cell culture medium and fluorescence imgaging was performed after 24 h. (A) CF fluorescence, (B) QD fluorescence, (C) merge, (D) bright field. Synthesis and Complexation Ability of a Novel Bis-(guanidinium)-tetrakis-(β-cyclodextrin) Dendrimeric Tetrapod as a Potential Gene Delivery (DNA and siRNA) System. Study of Cellular siRNA Transfection

S. Menuel,[†] S. Fontanay,[†] I. Clarot,[†] R. E. Duval,[†] L. Diez,[‡] and A. Marsura*[,†]

UMR 7565 SRSMC and UMR 7564 LCPME, CNRS, Nancy-Université, Faculté de Pharmacie 5 rue A. Lebrun, BP 80403, 54001 Nancy Cedex, France. Received May 14, 2008; Revised Manuscript Received October 6, 2008

The facile synthesis of a novel bis-(guanidinium)-tetrakis-(β-cyclodextrin) tetrapod, the first example of a new host family, was described, and the ability of the cyclodextrin CyD tetrapod to form molecular association with siRNA and DNA guest molecules was demonstrated. Affinity capillary electrophoresis was used to determine the binding constant with the evaluation of the shift in the electrophoretic mobility μ of injected siRNA when various CyD tetrapod concentrations were added to the run buffer. A significant association constant (K_a =16 000 M^{-1}) was obtained with borate buffer when double-stranded siRNA was primarily opened with the help of temperature. An efficient cellular transfection of siRNA into human embryonic lung fibroblasts was observed by fluorescence microscopy.

INTRODUCTION

Developing new, highly efficient, and nontoxic gene delivery carriers in cells remain an important challenge both in basic sciences and in clinical research fields. At the present time, viral vectors (clinical tests using adenoviruses, adeno-associate viruses, retroviruses, etc.) have been successfully applied, but their side effects such as severe pathogenicity limited further application (*1*). Besides, nonviral (cationic polymers, lipids, dendritic polymers, polyplexes, etc.) vectors have been studied as an alternative strategy for gene delivery because of their lower toxicity, non-immunogenicity, and convenient handling (*2*). However, the remaining difficulties with nonviral vectors remain with their relatively lower transfection efficiency than viral vectors. The poor performance was also due to polyplex aggregation as a consequence of decreasing water solubility induced by charge neutralization arising when electrostatic interaction between polyanionic DNA and polycationic vectors occurs (*3*).

Significant efforts for DNA delivery and more recently siRNA in cells have been conducted the past ten years through different nonviral approaches using macromolecular systems as carriers (*4*−*6*). Prosaically, two families of molecules are represented, on one hand nanoparticulate systems (*7*−*10*) and on the other hand polymeric systems (*11*−*15*).

Early in 1995, cyclodextrins (CyDs) and derivatives were introduced as potent carriers for phosphorothioate−ODN delivery. It was demonstated that cellular uptake was concentration and time dependent (*16*). Further, numerous contributions appear from that time in which either native and modified cyclodextrins were evaluated as ligands for nucleotides, oligonucleotides, and DNA (*17*−*19*).

Our first report on the subject suggested early in 1997 monothiogalactosyl and heptakis-thiogalactosyl-β-cyclodextrins as novel nonpolymeric efficient vectors for small antisense-ODN (*20*). Some other examples have been reported in the literature on complexes of CyD-DNA as, e.g., CyD−PAMAM dendrimeric conjugates (*21*) or bis-amidinium-CyDs polymers (*22, 23*) and their corresponding PEG derivatives, including monosaccharidyl inclusion polyplexes (*24*). The latter has been demonstrated further as totally biocompatible and efficient to transfect DNA in cells. In the same way, some liganded-CyDs cluster-organized, and dendrimers have been found able to form molecular associations with ODNs (*25, 26*). Furthermore recently, a family of sophisticated systems based on polymer−Cyd associations such as nanostructured multilayers using polylysine−CyD multilayers (*27*), polyelectrolyte multilayers (*28*), low weight or linear polyethyleneimine−CyD polymers (*29, 30*), or amphiphilic cationic CyDs (*31*) were successfully tested as *in vitro* nonviral gene delivery vectors. In parallel, the "molecular umbrella" tetrameric design and synthesis of nonviral noncyclodextrinyl vectors, notably based on the bottom-up construction of supramolecular systems, has been developed and has been shown to be able to cross the membrane of living cells and concentrate at the nucleus and therefore could be considered interesting molecular systems for nuclear drug targeting (*32*−*34*).

Here, we report in this way the synthesis of a novel bis-(guanidinium)-tetrakis-(β-cyclodextrin) dendrimeric tetrapod as a discrete molecular system, characterization of its self-assembly with a short interfering RNA (siRNA) oligonucleotide and single-stranded DNA, ability of the tetrapod to form molecular association with siRNA and DNA by affinity capillary electrophoresis, and siRNA *in vitro* transfection results.

EXPERIMENTAL SECTION

Materials. Chemicals for the synthesis, benzyl alcohol, and all other chemicals and solvents for electrophoresis experiments were of analytical grade and were purchased from Sigma-Aldrich. Ultrapure-grade water was obtained in a Milli-Q system from Millipore (Bedford, MA). MRC-5 cells (human pulmonary embryonic fibroblasts, ATCC CCL-171) were obtained from BioMerieux (France). The short interfering RNA (siRNA) oligonucleotide used is a 21 bp random duplex siRNA, purified and desalted, with no known homology to any mammalian

sequence, labeled by Cy3 fluorochrome. siRNA stock solution was provided by Eurogentec (siRNA 633790−637791 SCB-1, Eurogentec, France) at a concentration of 100 μM. Modified essential medium (MEM, 41090, Invitrogen) supplemented with 10% decomplemented fetal bovine serum (FBS, 10270, Invitrogen, lot 40Q5150K).

Synthesis. The pure tetrapod **5** was obtained in fairly good yield (96%) and in two steps from a carbodiimide-β-cyclodextrin dimer **3**, which is afforded by the "phosphine imide" strategy from the monoazido-CyD (Scheme 1). Compounds **1**, **2**, and **3** have been synthesized by known procedures in the literature (*35*, *36*).

Synthesis of 6-Monoguanidino-(bis-β-cyclodextrin) Dimer 4. Carbodiimide **3** (1.40 g; 0.615 mmol) (*35*) was dissolved in dichloromethane/methanol (5:1 by volume, 60 mL) and the solution was stirred at 25 °C under NH_3 for 18 h. After evaporation of the solvent, the residue was dissolved in methanol (5 mL) and precipitated with diethyl ether, filtered, and evaporated to dryness to give pure **4** (92%). FTIR (KBr): ν = 3374.5 cm^{-1} (OH);1736−1663 cm^{-1} (N═C−(NH_2)−NH). ESMS: 2292 [M + H^+]. ^{1}H NMR (400 MHz, D_2O, 25 °C, TMS): δ = 5.07 (m, 14H; H1), 3.95 (m, 14H; H3), 3.90−3.80 (m, 26H; H6a; H5), 3.71−3.62 (m, 16H; H6b; H2), 3.51 (m, 14H; H4). ^{13}C NMR (100 MHz, D_2O, 25 °C, TMS): δ = 175.1 (N═C−(NH_2)−NH), 102.2 (C1), 81.5 (C4), 73.4 (C2), 72.3 (C3), 72.2 (C6), 60.6 (C5).

Synthesis of the Bis-guanidinium-tetrakis-β-cyclodextrin Tetrapod 5. 6-Monoguanidino-(bis-β-cyclodextrin) dimer **4** (0.622 g; 0.271 mmol) and 1,2-dibromoethane (0.025 g; 0.135 mmol; 0.5 equiv) was dissolved in DMSO (25 mL), and the solution was stirred at 50 °C for 18 h under argon. The reaction was stopped by precipitation with diethyl ether (100 mL) at 25 °C and filtered. The residue was dissolved in methanol/water (1:2 by volume, 53 mL). This solution was concentrated to dryness, and the residue was dissolved in water (100 mL). After lyophilization, this solution gave pure **5** (96%). Found: C, 33.02; H, 6.53; N, 1.58; S, 5.31. $C_{127}H_{286}Br_2N_6O_{136}$, 10DMSO, 19$H_2O$ requires C, 32.96; H, 7.23; N, 1.57; S, 5.99. FTIR (KBr): ν = 3359.7 cm^{-1} (OH);1737 cm^{-1}; ($^+$NH═*C*−(NH_2)−NH, Br^-) 1639 cm^{-1}. ESMS: 3662 [M − (β-CyD−NH)$^+$]. MALDI-TOF: 4591 [M − 18]$^+$, 2292 [dipode **4** + H]$^+$. ^{1}H NMR (400 MHz, D_2O, 25 °C, TMS): δ = 5.10 (m, 28H; H1), 3.99 (m, 28H; H3), 3.95−3.81 (m, 52H; H6a; H5), 3.74−3.65 (m, 32H; H6b; H2), 3.50 (m, 28H; H4), 3.17 (m, 4H; CH_2). ^{13}C NMR (100 MHz, D_2O, 25 °C, TMS): δ = 174.0 (NHBr═*C*−(NH_2)−NH), 102.3 (C1), 81.6 (C4), 73.6 (C2), 72.4 (C3), 72.3 (C6), 60.7 (C5), 22.3 (CH_2).

Capillary Electrophoresis. All experiments were performed on a Beckman P/ACE 5500 model (Beckman, Fullerton, USA) equipped with a diode array detector (190−600 nm). Capillary temperature was controlled by coolant at 25.0 °C. An untreated

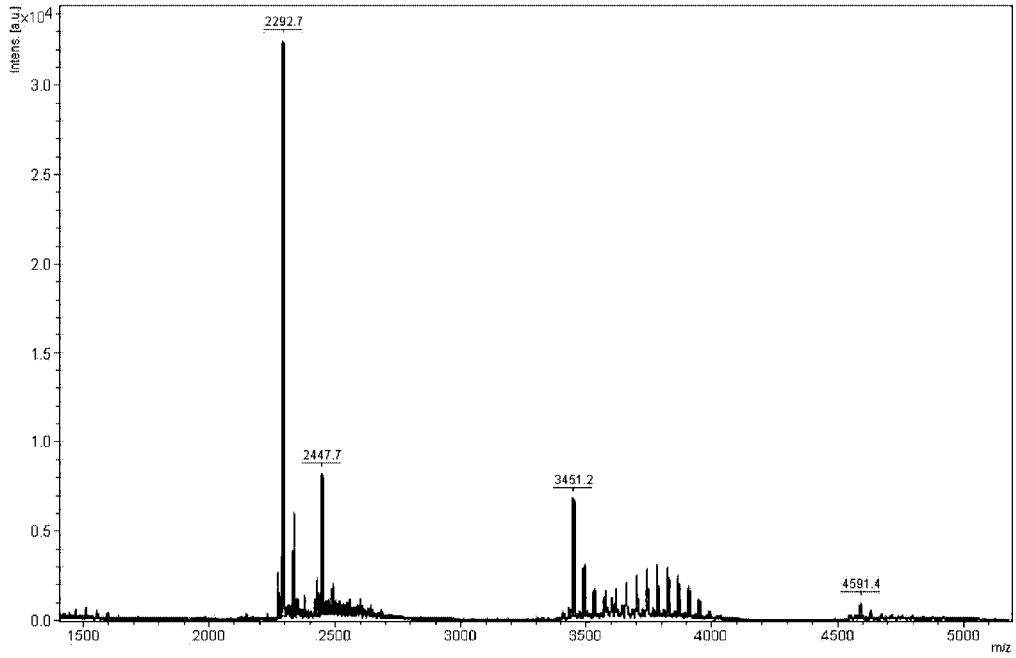

Figure 1. MALDI-TOF MS of Tetrapod **5**.

fused-silica capillary 75 μm i.d. with a total length of 47 cm (effective length 40 cm) was employed. All samples were injected in the hydrodynamic mode (10 s under pressure) at 20 kV. The experimental setup, data acquisition, and processing were governed using Beckman P/ACE Station software. The background electrolyte (BGE) was prepared by dissolving 2 μmol to 50 μmol of CyD tetrapod **5** in the appropriate borate buffer (25 mM, pH 9.3). Everyday, at the beginning of a run batch, the capillary was rinsed with 0.1 M sodium hydroxide (20 min) and ultrapure water (20 min). Before each injection, the capillary was successively rinsed with 0.1 M sodium hydroxide (2 min), ultrapure water (2 min), and BGE (2 min). All solutions introduced in the capillary were first percolated through an Alltech (Tampleuve, France) regenerated cellulose filter (0.45 μm pore size).

Electrophoresis Sample Preparation. Sample solutions were obtained by dissolving biological material in ultrapure water at the final concentration of 2 μM. Double-stranded siRNA was opened with temperature (94 °C) in the presence of CyD tetrapod **5** and diluted in run buffer at 0.2 μM before injection.

Cell Line, Cell Culture. The MRC5 cell line was cultured in Modified Essential Medium without antibiotics at 37 °C, 5% CO_2, under a humid atmosphere. Cell viability was determined by the trypan blue dye exclusion method. MRC-5 cells were plated at 5×10^5 cells/slide flask (170920, Nunc). For all experiments, cells were allowed to adhere and grow for 24 h in culture medium prior to siRNA transfection.

Transfection Complex (CyD Tetrapod/siRNA). First, we prepared an aqueous solution of tetrapod **5** at a final concentration of 2.5 mg/mL. The solution was sterilized through a 0.22 μm filter (SLGP033RS, Millipore). Second, we added 57.2 μL of this aqueous solution of CyD **5** to 12 μL of siRNA stock solution. After that, the solution was heated at 94 °C during 3 min, and then we controlled the cooling (less 0.8 °C per 5 s) until a final temperature of 2 °C was reached. This step is supposed to permit siRNA and CyD tetrapod **5** to complex together. Finally, we added this solution to 12 mL of MEM supplemented with 2% decomplemented fetal bovine serum in order to obtain our transfection solution.

***In Vitro* Transfection.** To start the transfection reaction, culture medium was replaced by 2 mL of this preparation (assay). Negative controls were transfected with either (i) CyD tetrapod **5** in the absence of any siRNA or (ii) siRNA in the absence of any CyD tetrapod **5**. Then, slides were incubated 37 °C, 5% CO_2, under a humid atmosphere, until appropriate times.

Table 1. Linear Regression Obtained with Equation 1 and Corresponding Binding Constants *K* for Single Stranded (ss) DNA in Phosphate Conditions (phos.) and for Single-Stranded DNA and Double- (ds) and Single-Stranded siRNA in Borate Conditions (bor.)

analyte	slope	intercept	corr. coef.	$K \pm$ s.d. M^{-1}
ss DNA phos.	1.818	7730.294	0.9996	4250 ± 750
ss DNA bor.	1.513	9189.418	0.9927	6050 ± 1550
ds siRNA bor.	~0	–	–	–
ss siRNA bor.	0.630	10187.151	0.9992	16150 ± 3700

^{1}H NMR and ^{13}C NMR Spectroscopy. ^{1}H NMR and ^{13}C NMR spectra were obtained using a Bruker DRX-400 (400 MHz and 100 MHz, respectively).

Fluorescence Microscopy. In order to perform fluorescent microscopy analysis, cells were fixed with a 4% formaldehyde solution (in PBS) for 1 min and subsequently washed 3 times with PBS. Then, cells were counterstained with Hoechst 33342 for 1 min and washed 3 times in PBS. Cells were mounted in PBS and examined by fluorescence microscopy with appropriate filters (microscope Axioskop SIP 48843, Zeiss, and camera AxioCam MRC, Zeiss). Observations were made after 6, 12, and 24 h of exposure with a 400× magnification.

RESULTS AND DISCUSSION

Synthesis and Characterization of CyD Tetrapod 5. Tetrapod **5** was synthesized according to our previous report (*37*) using the "phosphine imide" efficient strategy (also named Staudinger-Aza-Wittig tandem reaction) developed by our team in four steps from the monoazido-β-CyD (*35*). Scheme 1 shows the entire synthetic procedure of the tetrapod **5** available in a large-scale batch. The structure of **5** was confirmed by FTIR, ^{1}H and ^{13}C NMR, MALDI-TOF, and elemental analysis. Figure 1 shows the MALDI-TOF MS of **5**.

Self-Assemblies of CyD Tetrapod 5 and siRNA or DNA. Numerous analytical methods have been developed and applied in the study of the interactions between small ligands and biomacromolecules. Among them, some chromatographic

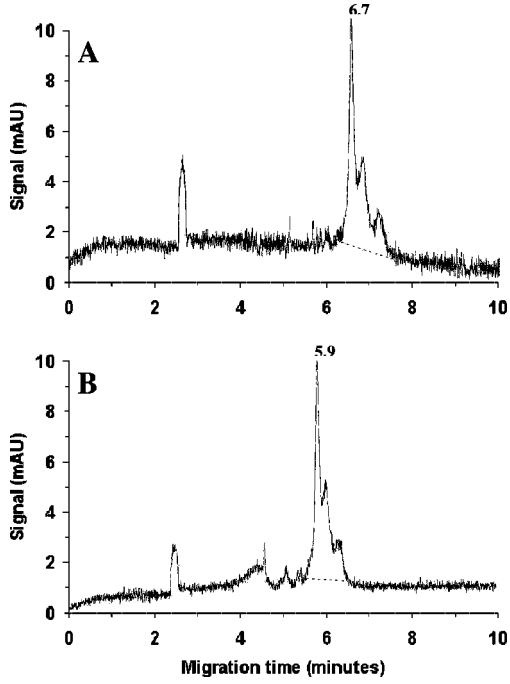

Figure 2. Electrophoregrams of single-stranded siRNA with background electrolyte containing 0 (A) and 25 μM of CyD (B). (Electrophoretic conditions were described in the Experimental Section).

methodologies, such as affinity chromatography or size exclusion, have also been employed to determine binding parameters (*38, 39*). Capillary electrophoresis (CE) is an attractive method for such determination. Low sample consumption, rapid analysis speed, and high efficiency are advantages that make this technology a major tool of association constant measurement. Several CE modes are available for such measurement, such as affinity capillary electrophoresis (ACE), Hummel-Dreyer method (HD), vacancy affinity capillary electrophoresis (VACE), vacancy peak method (VP), frontal analysis (FA), or frontal analysis continuous capillary eletrophoresis (FACCE) (*40*−*43*). Measurement in the ACE mode is based on the change in electrophoretic mobility of the biomolecule due to complexation to the ligand added at various concentrations in the background electrolyte. Both DNA and siRNA were used in this work to demonstrate the ability of **5** to form stable complexes with oligonucleotides.

The binding constants were estimated by the changes in the migration time of the analytes based on the different additions of **5** (2 to 50 μmol) in running buffers. For 1:1 association, the change in solute mobility with changing ligand concentration is related to the following equation (double reciprocal plot) (*44*).

$$\frac{1}{(\mu_i - \mu_f)} = \frac{1}{(\mu_c - \mu_f)K}\frac{1}{[\mathrm{CyD}]} + \frac{1}{(\mu_c - \mu_f)} \qquad (1)$$

where μ_i is the experimentally measured electrophoretic mobility of the solute, μ_f is the mobility of the free (uncomplexed) solute, μ_c is the electrophoretic mobility of the solute−ligand complex, K is the binding constant, and [CyD] is the equilibrium ligand concentration. Binding constants can be estimated by varying the ligand concentration at constant solute concentrations and fitting the data by linear regression to eq 1. To develop and optimize the electrophoresis methodology, a single-stranded DNA primer was primarily used. It is well-known that capillary electrophoresis of biological material such as DNA with BGE containing borates could lead to inappropriate complexation study. In a first approach, the single-stranded DNA under evaluation was used with two electrolyte conditions: borate 25 mM pH 9.3 and phosphate 50 mM pH 9.0. As illustrated in Table 1 lines 1 and 2, both conditions lead to equivalent binding constants (similar order) indicating that borates have no influence on the association process with the CyD tetrapod **5**.

SiRNA was first used without temperature treatment (double strand not open), and no binding constant could be determined as no modification of the analyte migration time was observed (Table 1, line 3). When siRNA was opened (single-stranded configuration), the addition of CyD to the background electrolyte led to a significant decrease of the electrophoretic mobility, as

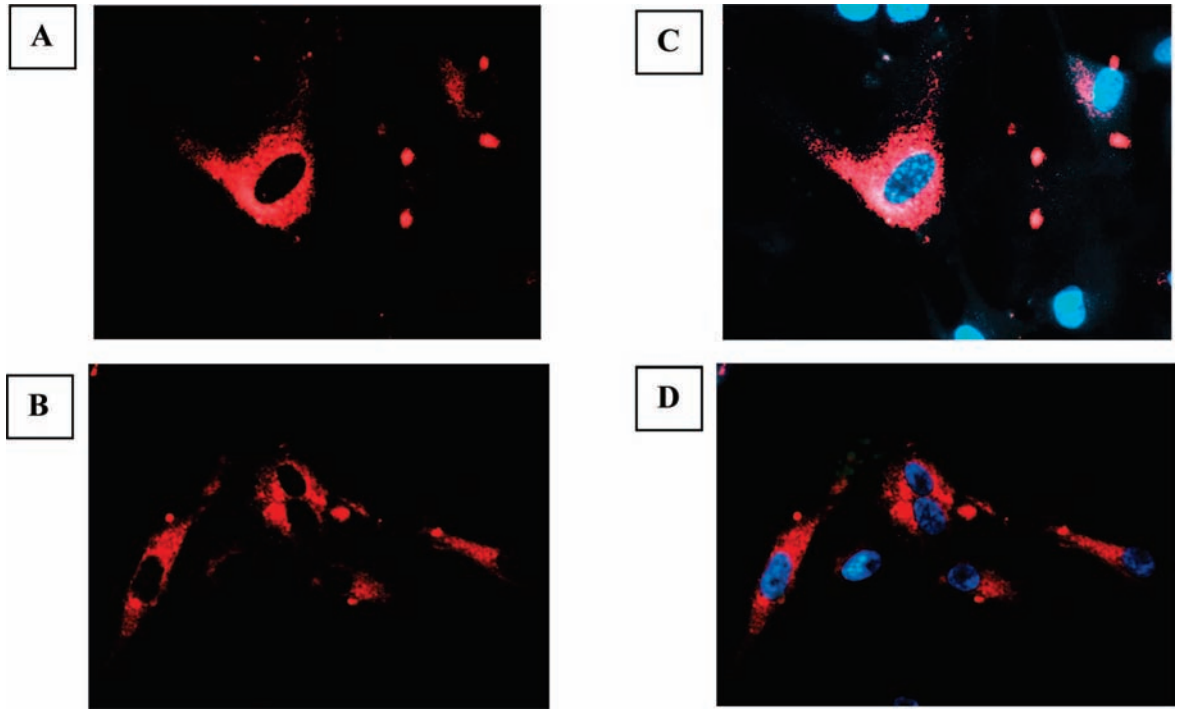

Figure 3. (A) Cy3-labeled siRNA at 6 h after injection; (B) after 12 h; (C) Cy3-labeled siRNA at 6 h after injection with Hoechst counterstained nuclei; (D) Cy3-labeled siRNA at 12 h after injection with Hoechst counterstained nuclei.

illustrated in Figure 2 for 0 and 25 μM of CyD added. The association constant obtained (16 150 M^{-1}, Table 1, line 4) indicates the ability of ligand **5** to form a strong association with such a biological molecule.

Toxicity Experiments. Toxicity experiments on tetrapod were performed *in vitro*, by measuring cellular viability (e.g., MTT assay) in the presence of increasing amounts of tetrapod. We have demonstrated that the tetrapod was poorly cytotoxic on MRC-5 cells, with a greater toxic effect for prolonged exposure times (e.g., 168 h), and concluded that it weakly affects MRC-5 cell viability (*37*).

Transfection Experiments. For transfection experiments, we used an siRNA labeled with Cy3 (see Experimental Section) to investigate the intracellular delivery and traffic of siRNA by the CyD tetrapod **5** in MRC-5 cells. Negative controls (see Experimental Section for details) showed no Cy3 labeling (data not shown), while numerous Cy3-stained cells, showing an intense red fluorescence, were detected in tetrapod-siRNA transfected MRC-5 cells, and thus until 6 h post-transfection (Figure 3A,C).

Hence, we demonstrated that a final concentration of 100 μM of scrambled siRNA is sufficient for an efficient cell transfection until 6 h of incubation with our tetrapod (Figure 3A). Nevertheless, the transfection reaction is clearly time-dependent, with a more intense fluorescence for 12 h transfected cells (Figure 3C). We observed the same staining at 24 h post-transfection. Figure 3B,D, showing parallel Hoechst 33342 (e.g., blue fluorescence) and Cy3 (e.g., red fluorescence) staining on the same field, at both 6 and 12 h, respectively. Hoechst labeling was used to counterstain nuclei of MRC-5 cells. Hence, we demonstrated a, siRNA transfection and/or localization in the cytoplasm (e.g., at the periphery of nucleus) of transfected MRC-5 cells.

We have also demonstrated that the efficiency of CyD tetrapod **5** is comparable to these of commercial compounds, i.e., PEI as previously described by Ikeda (*45*) and Ou (*46*); but it is noteworthy that CyD tetrapod **5** is also clearly less toxic than such compounds.

In summary, this novel tetrapod has high gene transfection efficiency, low cytotoxicity, and great potential for gene delivery *in vitro*. From the above data, bis(guanidinium)-tetrakis-(β-CD) **5** has a significantly high gene transfection in primary human lung fibroblast cell line (MRC-5), and it could be a promising gene carrier in many other primary cancer or stem cells. We actually attempted to validate the efficiency of delivery by silencing cellular "housekeeping" gene.

CONCLUSION

We synthesized a novel bis-(guanidinium)-tetrakis-(β-cyclodextrin) dendrimeric tetrapod for gene delivery systems. The compound presented here is the first example of a new molecular family including future CyD linear oligomeric analogues (penta-, hexapod, etc.) presently in progress. Tetrapod **5** could form 1:1 supramolecular water-soluble complexes with single-stranded DNA and siRNA as shown by capillary electrophoresis, and a better association with siRNA instead DNA was demonstrated. Elsewere, efficiency of siRNA and DNA transfection in cells is comparable to existing polyplex or polycationic systems. Toxicity experiments reveal that CyD tetrapod **5** is less cytotoxic than existing PEI cationic polymers. Finally, we can conclude that CyD tetrapod **5** is efficient not only for complexation of nucleic acids, but also for transfection of siRNA.

ACKNOWLEDGMENT

We thank the CNRS, MESR, and District of Nancy for financial supports. Pr. J.J. Gaumet for MALDI-TOF spectrum registration, Pr. A. Nicolas for providing electrophoresis facilities and discussion, Pr. C. Finance for Biological facilities, and Mr. E. Dubs for technical assistance in the synthesis of a cyclodextrin starting product. The service commun of NMR (UHP) is also acknowledged.

Comparison of Cellular Uptake Using 22 CPPs in 4 Different Cell Lines

Judith Mueller, Ines Kretzschmar, Rudolf Volkmer, and Prisca Boisguerin*

Institut für Medizinische Immunologie, Charité - Universitätsmedizin Berlin, Hessische Str. 3−4, 10115 Berlin, Germany.
Received May 15, 2008; Revised Manuscript Received October 21, 2008

Cell-penetrating peptides (CPPs) are short peptides able to penetrate cell membranes and translocate different cargoes into cells. Although recently the topic of many research articles, to our best knowledge no single systematic study of CPPs has been carried out as yet, meaning information can only by gathered piece by piece from different sources. We therefore decided to start analytical screening of CPP specificity in cell lines. We used 22 different CPPs, which have all been published before, and present the first analytical screen in 4 selected cell lines (MDCK, HEK293, HeLa, and Cos-7). Furthermore, we examined the influence of different conditions, such as protease inhibitors, incubation conditions, endocytosis inhibitors, temperature, and cytotoxicity. We clearly demonstrate that the 22 CPPs can be classified into 3 groups based on their internalization properties, even after trypsinization. Moreover, we show that additional agents, which should increase cellular uptake or dissolve endosomal/lysosomal entrapped CPPs, only have low effects. Our intensive screening under standardized conditions provides the opportunity to compare cellular uptake of CPPs, an important step for the use of CPPs as peptidic vectors in the medical field.

INTRODUCTION

Over the past decade, intracellular drug delivery has become an emerging area of research in medical and pharmaceutical fields. However, cell membranes are impermeable to most molecules not actively imported by living cells, including practically all macromolecules and even many small molecules whose physicochemical properties prevent passive membrane diffusion. An increasingly popular class of membrane translocating agents is the cell penetrating peptides (CPPs) (reviewed in *refs 1, 2*).

Many CPPs (also known as "protein transduction domains") have now been characterized, revealing remarkable properties of cell penetration either on their own or as conjugates with a range of other types of biomolecules, such as peptides, proteins, liposomes, and nanoparticles (reviewed in ref *3*). The mechanism by which CPPs enter cells is not clear, although many recent papers have indicated different forms of endocytosis, implicating the involvement of well-characterized clathrin-mediated endocytosis (*4*), caveolae-mediated endocytosis (*5, 6*), or macropinocytosis (*7, 8*). Most likely, CPPs utilize multiple internalization mechanisms in combination (*9*).

Work in the CPP area stemmed from the discovery that the third helix of the Antennapedia homeodomain, pAntp (43−58) (*10*) and the trans-activating transcriptional activator, Tat, a protein encoded by HIV-1 (*11, 12*), can cross biological membranes. Within the last two decades, the number of peptides assigned to the family of CPPs has increased to about 100 (*13*). Nowadays, they can be divided into three classes: protein-derived peptides, model peptides, and designed peptides (*13, 14*). Protein-derived CPPs usually comprise the minimal effective sequence segment of the parent translocation protein and are also known as protein transduction domains or membrane translocation sequences. Examples are the Tat peptide (48−60) derived from the 86-mer Tat protein (*15*) or penetratin (43−58) derived from the homeodomain of *Drosophila* Antennapedia. Model CPPs comprise sequences designed with the aim of producing well-defined amphipathic α-helical structures or mimicking the structures of known CPPs. Examples are the model amphipathic peptide (MAP) (*16*) or polyarginine sequences (*17*). Designed CPPs are usually chimeric peptides comprising a hydrophilic and a hydrophobic domain of different origins, such as transportan, a fusion peptide of galanin and mastoparan (*18*). Here, we used 22 representative CPPs of these classes, as shown in Table 1.

No unambiguous definition of CPPs has been proposed, but generally, they comprise less than 30 amino acids. All known CPPs have a net positive charge at physiological pH and contain between approximately 17% (e.g., hCT(9−32)) and 100% (polyarginines) positively charged amino acids. With the exception of polyarginines, all other CPPs are amphipathic. Some of them acquire amphipathic characteristics when adopting an α-helical structure, as, for instance, the model peptide MAP, while others have distinct hydrophobic and hydrophilic parts, such as transportan.

However, the endocytic mechanism used (clathrin-mediated endocytosis, caveolar uptake, or macropinocytosis) defines the migration of these peptides into cells and depends on parameters such as the nature of the cationic agent itself and complex formation with cargo, as well as the nature and distribution of proteoglycans expressed on the cell surface (*9, 19*).

To the best of our knowledge, only a few studies comparing CPP cellular uptake have been performed up to now (*20*−*22*). Nevertheless, differences in numerous variables relating to the experimental procedures used by various groups make it hard to compare studies and form any conclusions, especially about the mechanism of internalization. These variables include the following: different sources and purity of CPP, label or cargo used, concentration of CPP, cell-type, density and stage of cell cycle, incubation time, and final end point or readout.

Since there has been no large-scale systematic attempt to determine which CPP sequence shows optimal cellular uptake, we decided to compare the uptake of 22 different CPPs in 4 cell lines, Cos-7, HEK293, HeLa, and MDCK (reasons for cell line selection are given in Experimental Procedures). In a first step, we defined standard conditions allowing direct comparison

[a] CPPs were N-terminally labeled with FITC. Number of amino acids (no. AA), theoretical isoelectric points (pI), and molecular weights (MW) were calculated using the Protparam tool (http://www.expasy.ch/cgi-bin/protparam).

of the measured cellular uptake. Thereafter, we systematically analyzed the properties of the CPPs by changing one of the conditions, such as trypsinization, endocytosis modulators, or temperature. The resulting information, which includes determining the CPPs showing the highest cellular uptake, represents an important step for using CPPs in the clinical applications.

EXPERIMENTAL PROCEDURES

Peptides. The peptides used for the binding studies were automatically synthesized (Syro II, MultiSynTech) according to the Fmoc standard protocol. Peptides with a C-terminal carboxyl group were generated using TentaGel S PHB-aa-Fmoc (Rapp Polymere). For standard synthesis, Fmoc-aa-OH was used with the following side-chain protections: E-, D-(OtBu); S-, T-, Y-(tBu); K-, W-(Boc); N-, Q-, H-(Trt); R-(Pbf) (Novabiochem; Bachem). 5(6)-Carboxyfluorescin (FITC, Fluka) coupling was achieved using 1 equiv *N*-hydroxybenzotriazole (HOBt) and 1 equiv di-isopropylcarbodiimide (DIC) as activators, as reported in ref *23*.

The crude peptides were purified to >95% by preparative HPLC (Waters), and their identity was determined by analytical RP-HPLC (Waters) and MALDI TOF mass spectrometry (LaserTec BenchTopII, PerSeptive Biosystems).

Cell Culture. African green monkey kidney (Cos-7), human embryonal kidney (HEK293), human cervix carcinoma (HeLa), and Madin-Darby canine kidney (MDCK) cells were cultured in phenol red-free Dulbecco's modified Eagle medium (DMEM, Invitrogen) supplemented with 10% fetal bovine serum (FBS, Invitrogen) and 1% penicillin/streptomycin (pen/strep, Biochrom AG). The cells were seeded 1×10^5 cells/mL in 1.5 mL media in 6-well culture plates (Falcon, BD Biosciences) and allowed to grow until ~80% confluence. Unless otherwise indicated, 37 °C solutions were used and all incubations were performed at 37 °C, 5% CO_2.

Cell line selection was the result of intense screening of more than 90 papers published between 2000 and 2008, which determined CPP uptake in over 54 different cell lines. The cell lines mostly used were HeLa (46%), CHO (9%), MDCK (9%), Cos (7%), HEK293 (7%), MCF-7 (5%), Jurkat (5%), and NIH-3T3 (5%). All other cell lines are under the threshold of 5%. By screening the cellular uptake of CPPs in HeLa, Cos-7, HEK293, and MDCK cells, we intend to cover the commonly used cell lines.

Cellular Uptake. The cell layers were rinsed twice with PBS to completely remove the medium. One milliliter of a 100 μM peptide solution in PBS-G (PBS + 1% glucose) was applied for 30 min at 37 °C, 5% CO_2 (final CPP concentration 10 μM). Excess CPPs were removed by two rinses with PBS buffer (37 °C). Unless otherwise indicated, the cells were trypsinated for 10 min at 37 °C with 200 μL trypsin (0.05% trypsin /0.02% EDTA (w/v) solution (Biochrom AG)) before lysis. Then, cells were washed with 10 mL followed by 5 mL of PBS buffer, and centrifuged at 4000 rpm at 4 °C for 10 min (Eppendorf centrifuge 5810 R). The cell pellets were resuspended in 500 μL RIPA (50 mM Tris, 1 mM EDTA, 150 mM NaCl, 1% (v/v) NP40, 0.5% (v/v) deoxycholat, 0.1% (w/v) SDS, pH 7.5; Complete Mini, EDTA-free (Roche Diagnostica GmbH) freshly added) for lysis. The lysates were transferred into 1.5 mL Eppendorf tubes and incubated for 1 h at 4 °C. Finally, the samples were centrifuged at 8200 rpm at 4 °C for 10 min (Eppendorf centrifuge 5415 R).

The CPP concentrations were determined using 100 μL of lysat to measure FITC emission (Nunc 96 well plates U96 PP) on a microplate reader (FLUOstar Optima (excitation: 485 nm and emission: 520 nm)). The total protein contents were determined by a BCA assay. Five microliters of the sample and 200 μL of the BCA-reagent (reagent A: 1% (w/v) BCA-Na_2, 2% (w/v) Na_2CO_3, 0.16% (w/v) Na_2−Tatrat, 0.4% NaOH, 0.95% (w/v) $NaHCO_3$, pH 11.25. reagent B: 4% (w/v) $CuSO_4 \cdot 5H_2O$; A/B = 50:1) were mixed in a 96-well plate (Nunc Maxi Sorb) and incubated for 30 min at 37 °C. The solution was measured using a microplate reader (FLUOstar Optima (absorbance at 620 nm)), and thereafter, the concentration was calculated using a bovine serum albumin (BSA, Sigma-Aldrich) calibration curve.

Protease Inhibitor Test. The protease inhibitors (Sigma-Aldrich) were diluted in 900 μL DMEM (+1% pen/strep, without FBS) and mixed with 100 μL CPPs in PBS-G (final concentration 10 μM). The solutions were applied to the HeLa cells and incubated for 30 min at 37 °C, 5% CO_2. Peptides and inhibitors were omitted in the control sample. After 30 min incubation, CPPs and inhibitors were removed by two rinses with PBS (37 °C) buffer, and cells were lysed with RIPA as described above.

We used the following protease inhibitor concentrations: 50 μM leupeptin, 1 mM aprotinin, 1 mM glycerolphosphate,

10 μM phenanthroline, 1 mM ethylene diamine tetraacetic acid (EDTA), and 10 μM E-64 dissolved in H_2O; 20 μM MG-132 and 10 μM bestatin dissolved in dimethyl sulfoxide (DMSO) and 1 mM phenylmethylsulfonylfluoride (PMSF) dissolved in isopropanol. All inhibitors were purchase from Sigma-Aldrich or Calbiochem.

To determine the degradation product, cell lysates were analyzed by HPLC (Waters) equipped with a 5 μm (150 $\times$ 4.6 mm) C18 column, a precolumn containing the same adsorbent, and a fluorescence detector. HPLC conditions are described in ref *29*.

Endocytosis Inhibitor Test. The protease inhibitors (20 μM MG-132 and 1 mM EDTA) were diluted in 900 μL DMEM (+1% pen/strep, without FBS) and added to the cells at 37 °C. After 1 h, the endocytosis inhibitors were added and incubated for 30 min. Thereafter, 100 μL CPPs (100 μM in PBS-G) were applied to the different inhibitors (final CPP concentration 10 μM) and incubated for 30 min. Excess CPPs and inhibitors were removed by two rinses with PBS (37 °C), and then the cells were trypsinated and lysed with RIPA as described above.

All inhibitors were purchased from Sigma-Aldrich, and we used the following inhibitor concentrations: 30 μM chlorpromazine hydrochloride, 100 μM chloroquine diphosphate salt, 10 μM heparin sodium salt all dissolved in H_2O, as well as 100 μM nystatin dehydrate and 100 nM wortmannin dissolved in DMSO.

Besides the 37 °C incubation, we also performed incubations at 4 °C with the protease inhibitors (20 μM MG-132 and 1 mM EDTA) and the CPPs. To minimize possible side effects, we ensured that all solutions were pre-chilled to 4 °C.

Confocal Laser Scanning Microscopy. Confocal images were acquired with an inverted IX81 fluorescence microscope equipped with a Fluoview 1000 scanhead (Olympus, Tokyo, Japan) and a 60$\times$ (N.A. 1.35) oil-immersion objective at 25 °C. The green FITC fluorescence was excited with the 488 nm laser line of an Ar-ion laser, while the red trypan blue fluorescence was excited with a 543 nm He−Ne laser. The system was run in sequential scanning mode, where only one laser was active at a time, to avoid spectral overlap. The emission of FITC was recorded between 500 and 530 nm. For trypan blue, the emission was recorded from 570 to 670 nm. All measurements of peptide uptake were performed with living, nonfixed cells grown in a glass-bottom dish (World Precision Instruments). Cells were seeded at a density of 1×10^5/well 1 day before the experiment and cultured in DMEM (+1% pen/strep, without FBS).

Viability Assay. 100 μL containing 5×10^5 cells were seeded in 96-well microtiter plates (Falcon) and cultivated overnight. The next day, cells were rinsed twice with PBS, and subsequently, 100 μL DMEM (+1% pen/strep, without FBS) was added. Then, 10 μL of different peptide solution concentrations were applied, and cells were incubated for 2 h at 37 °C. Finally, cell viability was measured using colorimetric MTT dye.

After washing the cells with PBS, they were incubated with 10 μL of CCK-8 solution (Fluka) and 100 μL of DMEM (1% pen/strep) for 4 h, and cell viability was determined by measuring the absorbance of each sample due to the formazan product at 570 nm using a microplate reader (FLUOstar Optima).

RESULTS

Determining the Main Conditions. For our analytical evaluation of CPP uptake, we selected 22 different peptides (Table 1) corresponding to the three representative CPP families. Screening the literature revealed CPP concentrations varying from 1 μM to 50 μM (*24, 25*); a range over which the CPPs are normally not toxic (*9, 26*). Moreover, Duchardt et al. (*9*) demonstrated that CPP internalization could be enhanced by using concentrations of $\geq$10 μM. Time-dependent assays performed to determine the optimal incubation duration showed that 30 min is largely sufficient to measure cellular uptake. Longer incubation times (45 or 60 min) only increase the signal intensities by a factor of 1.4 (data not shown). For that reason, and also due to toxicity, we chose a CPP concentration of 10 μM and an incubation time of 30 min for all assays, unless stated otherwise.

To avoid artifacts during fluorescence measurements, some precautions had to be considered. For FACS (fluorescence activated cell sorting) or microplate reader measurements, the electrostatic interaction between the positively charged CPPs and the negatively charged plasma membrane have to be removed by trypsin treatment (*12, 27*). However, visualizing CPP cell translocation by microscopy using live cells is now standard procedure.

Influence of Protease Inhibitors on Cellular Uptake. A few studies have investigated the metabolic stability or the pattern of degradation of the CPPs (*28*−*31*). Proteolytic processing of the peptides could result in membrane-impermeable products, showing the importance of protease inhibiting agents. In uptake experiments with incubation time points up to 1 h or longer, the peptides need to be stable outside the membrane and should not be degraded within this time. Hence, evaluating peptide stability is an important parameter (*29*).

An attempt was made to inhibit degradation using several protease inhibitors covering the most common proteases, namely, phenanthroline, which inhibits matrix metalloproteases (MMPs); ethylenediaminetetraacetic acid (EDTA) as an inhibitor for metalloproteases; MG-132 as a proteasome inhibitor; bestatin, which inhibits aminopeptidase B and leucine aminopeptidase; E-64 as a broadband irreversible covalent cysteine protease inhibitor; phenylmethylsulfonyl fluoride (PMSF), which inhibits serine proteases; and finally, aprotinin, an inhibitor of serine proteases, particularly trypsin (see Table 1 in Supporting Information). All these protease inhibitors are often represented in commercially available protease inhibitor cocktails. In addition, we analyzed the influence of bovine serum albumin (BSA), which should saturate the proteases in order to increase amounts of intact peptides. Cells were incubated with inhibitors or BSA 2 h before CPP incubation and together with the CPPs for 30 min at 37 °C. Figure 1A shows the results using $S4_{13}PV$ as an example CPP in HeLa cells. In most of the cases, the protease inhibitors have a low or even negative influence on cellular uptake. Phenanthroline and bestatin have no influence, whereas E-64, PMSF, and aprotinin seem to reduce cellular uptake, probably due to toxic effects on the cells. Using BSA, we observed the greatest decrease in internalization. Only EDTA, MG-132, and the combination of both increased cellular uptake by preventing extracellular and intracellular peptide degradation. Neither protease inhibitor is toxic for the cells, either alone or in combination (Figure 1, B). To confirm the inhibitory effect of EDTA/MG-132, we analyzed the cell lysate of HeLa cells incubated with $S4_{13}PV$ (Figure 1C). Measurements of the peak areas revealed a reduction of the peaks at 14.03 and 26.76 min by more than 60% in the presence of EDTA/MG-132. On the other hand, the double peak (19.84 and 20.12 min) increased, which corresponds to cis−trans isomers of $S4_{13}PV$.

Despite the fact that the proteolytic activity strongly depends on the cell line, Trehin et al. (*30*) found that degradation patterns between different cell lines were comparable. Since our own observations agree with this result (data not shown), we choose EDTA and MG-132 as standard conditions for further analyses in different cell lines.

Figure 1. Effects of protease inhibitors on CPP cellular uptake. (A) HeLa cells were preincubated for 2 h with the respective protease inhibitor followed by incubation with CPP $SV_{13}PV$ for 30 min at 37 °C. The data represent the mean of three independent experiments ± SEM. The best result is obtained using 1 mM EDTA and 20 μM MG-132 (last bar). The red line represents 100% internalization corresponding to the control without inhibitor. The data represent the mean of 2−3 independent experiments ± SEM. (B) Measurement of viability using the CCK-8 solution (Fluka): HeLa cells were preincubated for 2 h with either 20 μM MG-132 or 1 mM EDTA, or both together. The red line shows 100% viability, which corresponds to no toxic effect of the protease inhibitors. The data represent the mean of 2−3 independent experiments ± SEM. (C) Cell lysates of HeLa cells incubated with $S4_{13}PV$ in the presence or absence of the protease inhibitor (EDTA/MG-132) analyzed by HPLC. #: Peak at 8.60 min is due to medium impurity. *: The double peak at 19.84 and 20.12 min represents CPP-$S4_{13}PV$ and is due to proline cis−trans isomerization. Products at 14.03 and 26.78 min are potential degradation products, which are reduced by the protease inhibitors. The data represent the mean of 3 independent experiments ± SEM.

Quantitative Analyses of 22 Different CPPs and the Influence of Trypsinization. The CPPs listed in Table 1 were tested in Cos-7, HEK293, HeLa, and MDCK cells, and cellular uptake was quantified by fluorescence measurements using a microplate reader (Figure 2). Although all 22 CPPs are known from the literature and are supposed to have cell penetrating properties, they do not show the same degree of cellular uptake. In the first data set (Figure 2A - without trypsin), we could discriminate three groups of CPPs. The first group (<1000 SI/mg) comprises the nearly unmeasurable uptake of polyomavirus Vp1, poly-P, NF-kB, SV40 T antigen, HATF3, and hCT(9−32). The second group (between 1000 SI/mg and 10 000 SI/mg) includes SynB1, DPV6, HIV-1 Tat-(48−60), Pep-1, Bac1−15, MPG, integrin, and pVEC-scrambled. The third group comprises CPPs with high cellular uptake (>10 000 SI/mg), such as penetratin, $S4_{13}PV$, transportan, MAP, R7, R9, HIV-1 Rev-(34−50), and pVEC. Comparing one individual CPP among the four cell lines, we could determine approximately the same amount of uptake. Interestingly, three CPPs seem to be specific for one cell line: integrin for HEK293 cells (4-fold higher), $S4_{13}PV$ (3-fold higher), and MAP (2-fold higher) for HeLa cells (Figure 2A).

Flow cytometry and a microplate reader are both conventional tools to quantify cellular association of fluorochrome-tagged CPPs. However, neither method could discriminate between membrane-bound and internalized fluorochrome. To differentiate between CPPs that are within the cells and those stuck on the cell surface, we included a trypsinization step before cell lysis. Using this protocol, we could clearly demonstrate a more than 10-fold to over 100-fold decrease in signal intensities in most cases. Figure 2B shows that the CPPs with the highest internalization after trypsinization are the commonly used CPPs such as penetratin, $S4_{13}PV$, transportan, MAP, and R9, whereby MAP seems to be slightly more specific for HeLa. However, in most cases only up to 20% of the CPPs are within the cells after trypsinization (Figure 2C). Curiously, we could not measure high cellular uptake of HIV-1 Tat-(48−60), which is often reported to be within the same range as penetratin or R9. However, we could clearly confirm the efficiency of R9 compared to R7, which is in accordance with Tunnemann et al. (*26*).

Interestingly, integrin is still specific for HEK293 cells even after trypsinization (3-fold higher SI/mg protein compared to the other cells; details in Table 2). Likewise, we could observe penetratin specificity for HeLa cells (3-fold higher, details in Table 3 in the Supporting Information).

Altogether, in the majority of cases, the CPPs are located on the cell surface, and less than 10% are actually found within the cells. One exception is transportan, which shows high cellular uptake even after trypsinization. In HEK293 cells, we observed only a 6-fold decrease in signal intensity and only 2- to 3-fold reductions in Cos-7, HeLa, or MDCK cells. Some CPPs, such as NF-kB, SV40 T antigen, HATF3, and hCT(9−32), which previously showed very low internalization (without trypsin) also display low internalization after trypsin treatment.

Comparing both panels of Figure 2 clearly demonstrates that measurements in the absence of trypsin treatment always overestimated cellular uptake. The extent of the overestimation varied according to the cell lines and peptides. Moreover, the efficiency of the trypsin treatment is shown with integrin, which

Figure 2. Comparison of CPP cellular uptake with or without a trypsinization step in Cos-7, HEK293, HeLa, and MDCK cells. (A) Cellular uptake without trypsin: Cells were preincubated for 2 h with the protease inhibitor (EDTA/MG-132) followed by incubation with CPPs for 30 min at 37 °C. After washing steps, the cells were lysed and analyzed by a microplate reader. The data represent the mean of 3−5 independent experiments ± SEM. Measured values and standard deviations are given in Supporting Information. (B) Cellular uptake with trypsin: Cells were preincubated for 2 h with the protease inhibitor (EDTA/MG-132) followed by incubation with CPPs for 30 min at 37 °C. The cells were treated with trypsin (10 min at 37 °C) before cell lysis. The data represent the mean of 3−5 independent experiments ± SEM. Measured values and standard deviations are given in Supporting Information. (C) For a better overview, the real CPP translocations within the cells were calculated as the relative percentage of internalization: (A[SI/mg protein]/B[SI/mg protein] · 100%). Gray boxes represent cellular uptake between 10% and 20%; black boxes over 20%.

[a] CPPs were N-terminally labeled with FITC. Theoretical isoelectric points (pI) were calculated using the Protparam tool (http://www.expasy.ch/cgi-bin/protparam). Cells were cultured as described in Experimental Procedures. The given values represent the signal intensity per mg cell protein (SI/mg cell protein). The data represent the mean of 3−5 independent experiments ± S.E.M.

is not a trypsin substrate. Trypsin is supposed to remove surface-bound peptide by the digestion of peptide and/or membrane proteins. This phenomenon could be clearly demonstrated by showing a decrease of 19-fold for Cos-7 cells, 3-fold for MDCK cells, and 2-fold for HEK293 cells. For HeLa cells, we only observed a 1.5-fold decrease, revealing the specificity for this cell line (see Supporting Information Table 3).We therefore used a standard protocol including a trypsin treatment before analysis of cell lysates by a microplate reader in all subsequent experiments.

Comparing CPP Distribution. Conflicting evidence has been presented concerning the role of individual endocytic pathways (*32*, *33*). We supposed that the apparent discrepancies were a consequence of the different experimental conditions with respect to cell lines, incubation times, and peptide concentrations. To investigate this, we performed experiments using a subset of the previously analyzed CPPs.

We used polyomavirus Vp1 as an example of a CPP with low cellular uptake (Figure 2B). Penetratin, HIV-1 Tat-(48−60), and R9 were used, since they are well-known in the literature. Furthermore, we used transportan, MPG, and integrin due to their high measured cellular uptake even after trypsinization (compare Figure 2A,B).

Figure 3 summarizes the distribution of the CPPs within the four cell lines. We only compared data from experiments using the same cell numbers and same incubation time. In the control picture (without CPPs), no self-fluorescence of the cells could be measured (Figure 3A, first panel). Additionally, to avoid misinterpretation due to extracellular fluorescence bound to cell membranes or working materials, we added trypan blue solution during each CLSM measurement. Trypan blue is unable to translocate intact cell membranes, which makes it a selective quencher for extracellular bound fluorophores (*34*−*36*). The trypan blue staining is only shown in the control of Figure 3A or in special cases revealing diverging phenomenon (Figure 3B).

First of all, by subjectively comparing the fluorescence pictures we could clearly reproduce the results obtained by the microplate reader (Figure 2). The three postulated groups of CPPs can be deduced with polyomavirus Vp1 showing the lowest cellular uptake (group 1), HIV-1 Tat-(48−60), MPG, and integrin with medium internalization (group 2) and penetratin, R9, transportan, and MAP with the highest adsorption (group 3).

Looking in detail at the CPP distribution, we observed that the CPPs were within the cells in all cases, even if a low cellular uptake was measured by the microplate reader. We detected low cytoplasmic dissemination only in the case of polyomavirus Vp1 (Figure 3A, second panel) and medium internalization in the case of integrin (Figure 3A, eighth panel) for all analyzed cell lines, which correspond to the low and medium results of Figure 2. CPPs such as penetratin, R9, MAP, and FP-NLS (MPG), which show good cellular uptake measured by the microplate reader—even after trypsinization—also revealed high cellular internalization (Figure 3A,B).

HIV-1-Tat-(48−60) mainly shows a vesicular distribution in all cells, and furthermore, a cytoplasmic and additionally nucleic localization (10−20%) in the case of HeLa and MDCK cells (Figure 3A, third panel). In general, the HIV-1 Tat-(48−60) distribution in cells seems to be more diffuse, showing a combination of punctuated fluorescence and more diffuse fluorescence in the cytoplasm and nucleus. Due to the additional cytoplasmic and nucleic distribution in HeLa and MDCK cells, the quantity of internalized CPP seems to be higher than in the other two cell lines, which does not correspond to the approximately equal distribution measured by the microplate reader (Figure 2). At this juncture, we could only postulate that the nuclear-located CPP could not be extracted and measured after cell lysis.

Penetratin (Figure 3A, fourth panel) displays a punctuated dispersion within the cells, as is also observed for the smac-penetratin construct used in HeLa cells (*21*). We observed an equal distribution of R9 with an additional cytoplasmic distribution found most strongly in MDCK cells (Figure 3A, fifth panel).

CLSM pictures of MAP (Figure 3A, sixth panel) demonstrated in most cases that the fluorescence appeared evenly distributed throughout the cytosol and nucleus, accompanied by a punctuated pattern, suggesting that non-endocytotic as well as endocytotic modes of uptake are involved. FP-NLS (MPG) (Figure 3A, seventh panel) show a comparable uptake to MAP but 2-fold lower as shown in Figure 2B. Integrin seems to be mostly located close to the cell membrane, especially in Cos-7 and HeLa cells, which is in agreement with Zhang et al. (*37*) (Figure 3A, eighth panel). The low internalization does not correspond to the middle signals in Figure 2B. The observed discrepancy between both methods could be explained by the pH-induced quenching effect of the FITC moiety within vesicles (*38*).

Transportan plays a special role in cellular uptake. Using the microplate reader, we recorded extremely high incorporation even after trypsinization. Images of confocal microscopy showed not only cytoplasmic vesicles but also intense cell damage (Figure 3B). 20−30% of the cells revealed a huge accumulation of transportan, correlating with the vital dye trypan blue staining, independent of the cell types. This lytic characteristic is also clearly demonstrated in the viability test showing a high cytotoxic effect with a transportan concentration up to 25 μM (Supporting Information Table 2). The same phenomenon could be observed in 5% of the HeLa cells incubated with MAP (data not shown).

Viability Test of the 22 Different CPPs. We also examined the cellular toxicity of the 22 different CPPs, since this is crucial to their use as effective delivery vehicles. To provide information about acute toxicity, we incubated cells for 2 h with all 22 FITC-labeled CPPs, at concentrations of 1 μM to 50 μM (Table 2 in Supporting Information). Most of the CPPs showed no cytotoxicity even at high concentrations (100% ± 20% viability). Using the three peptides $S4_{13}PV$, transportan, and MAP, we did observe a decrease in cell viability at a concentration of 25 μM. $S4_{13}PV$ seems the more critical candidate with a viability of 63−50% for Cos-7 and HEK293, complete cytotoxicity at 25 μM for HeLa and even at 10 μM for MDCK cells. Transportan caused decreased viability at 25 μM for Cos-7, HeLa, and MDCK cells (20−0%) but had a lower effect on HEK293 cells (~50%). MAP was only toxic at 25 μM for Hela

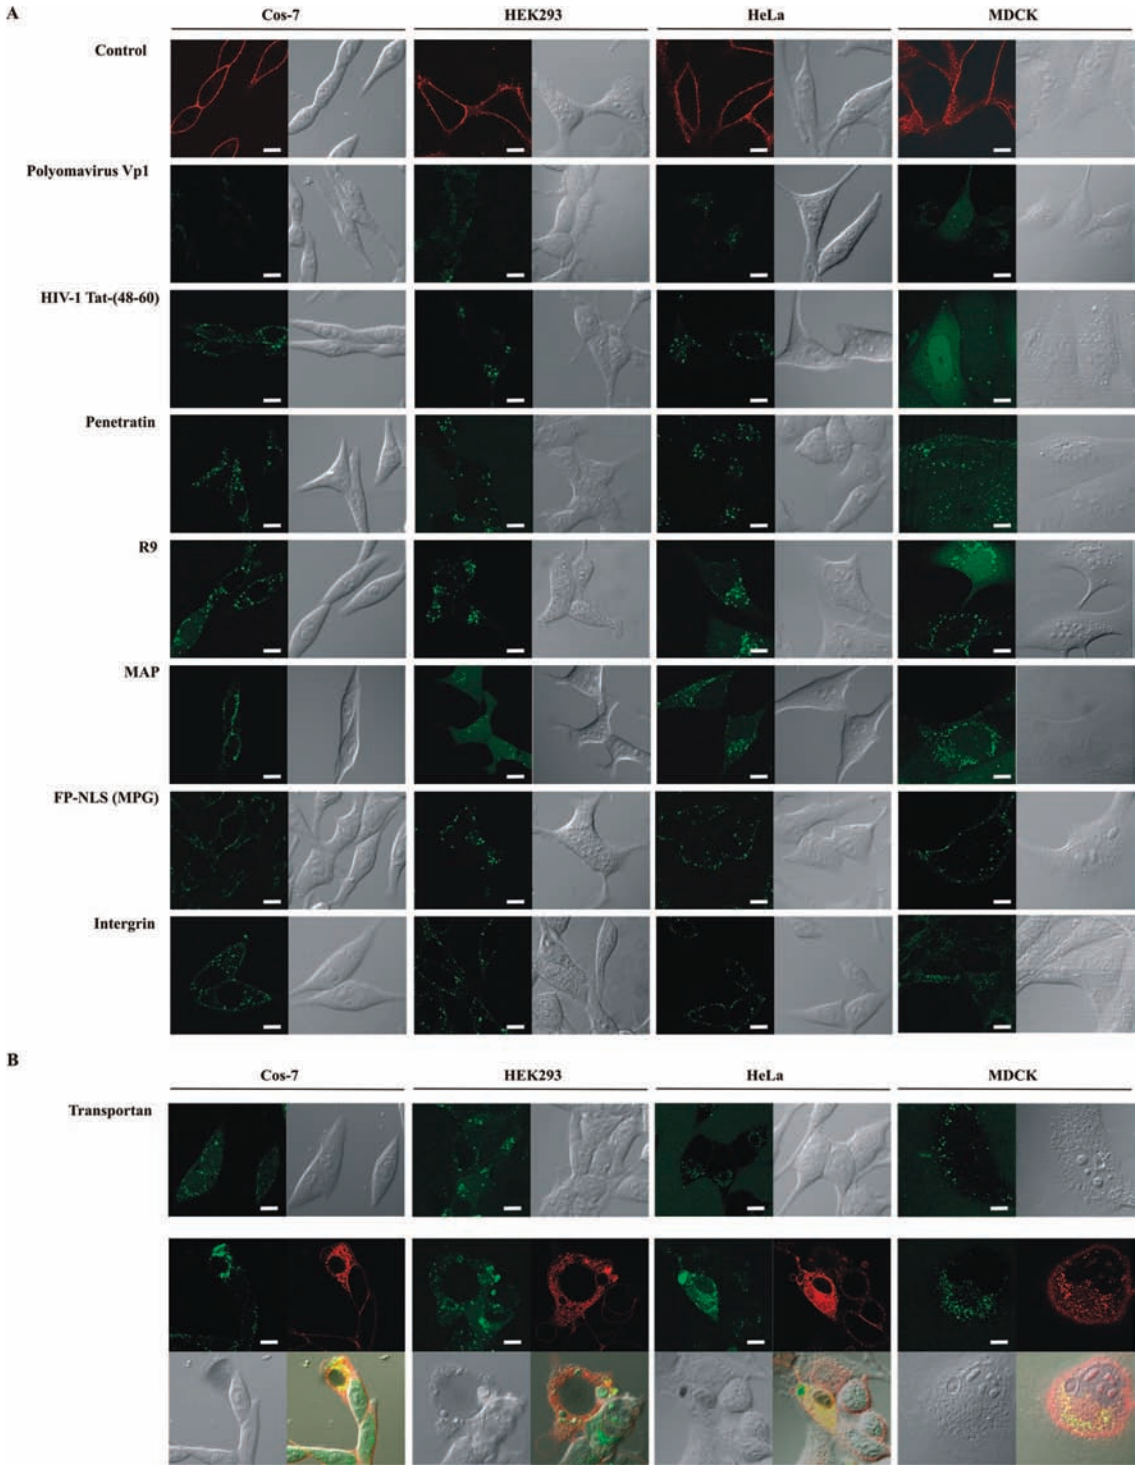

Figure 3. Example of CPP cellular uptake in Cos-7, HEK293, HeLa, and MDCK cells. As control, the four cell lines without peptides are shown as an overlay of the FITC staining (488 nm) and the trypan blue staining (543 nm) with the corresponding phase contrast images. Thereafter, the four different cell types are treated with 10 μM of the FITC-labeled CPPs for 30 min. For each condition, we show the fluorescence (488 nm) and phase contrast images. (A) Trypan blue staining is only shown to demonstrate the artifact as exemplified by transportan. Here, we additionally show the vital trypan blue staining and the corresponding merged images (B). The white bars represent 10 μm.

cells, whereas it had low or even no effect on Cos-7, MDCK, and HEK293 cells. The effect of decreasing cell viability by these three CPPs is not surprising because they are postulated to penetrate the cell by pore formation (*39*).

Because $S4_{13}PV$ shows some toxic effects, we further analyzed its cytotoxicity more precisely at a concentration of 10 μM. We used HeLa cells because their reduced viability (64 $\pm$ 24%) lies between the values of Cos-7 (89 $\pm$ 17%), HEK293 (95 $\pm$ 6%), and MDCK (33% $\pm$ 16%) cells. HeLa cells were incubated for 30 and 60 min with $S4_{13}PV$. Neither incubation time showed any cytotoxic effects on the cells (30 min, 100 $\pm$ 11%; 60 min, 102 $\pm$ 3%).

Altogether, these results substantiated our standard conditions (10 μM CPP for 30 min) as not affecting cell viability.

Influence of Endocytosis Inhibitors on the Cellular Uptake. To gain more insight into the mechanism(s) by which CPPs are taken up by cells, we selected the 8 CPPs from Figure 3 as well as 4 others from the 22 CPPs and tested them with

[a] The cells were treated with the reagents at the given concentrations, and later, CPPs (10 μM) were added to the medium. The cells were incubated for another 30 min and subjected to quantification (for more details see Experimental Procedures). The data represent the mean of 3−5 independent experiments. The results at the standard condition (37°C) are set at 1.00 with the other results relative to this value. As a control, we used cells with reagents but without CPPs. To quantify the significance of reagent effects, we determined a significant increase at >2.00 (black boxes) or a significant decrease at <0.50 (white boxes). On the right, we calculated the overall average effect (%) of the different reagents (positive effect = % of black boxes; negative effect = % of white boxes). The numbers marked in red represent the conditions used for confocal microscopy (see Figure 4 and Supporting Information Figure 1). Measured values and standard deviations are given in Supporting Information.

chemical inhibitors to block specific endocytotic pathways. We treated cells with the inhibitors (see Supporting Information Table 1) before adding the CPPs and then analyzed them using a microplate reader. Besides the standard conditions at 37 °C, we tested energy-dependent pathways by measuring at 4 °C. As direct endocytosis inhibitors, we used chlorpromazine as a clathrin-dependent endocytosis inhibitor and nystatin, which disrupts caveolar structures and functions. As endocytosis modulators, we utilized chloroquine inhibiting the acidification of endosomes and the fungal metabolite wortmannin inhibiting fluid-phase uptake and the homotypic fusion of early endosomes (*32*). Furthermore, heparin was used as a competitor of cell membrane-associated heparin sulfate proteoglycans (HSPGs).

The effects of the endocytosis inhibitors used are summarized in Table 3. Each box corresponds to a decimal number based on the standard condition (37 °C, no inhibitor) set to 1.00, with the threshold set at <0.50 for negative (white boxes) and >2.00 for positive effects (black boxes). All gray squares represent no difference, likened to the standard condition (raw data are given in the Supporting Information).

The overall effect of each inhibitor or condition for all the CPPs tested was calculated such that the percent of black boxes gives the average positive effect and the percent of white boxes the average negative effect (Table 3, right column).

By comparison of the four cell lines, the chosen conditions seem to have more positive effects on Cos-7 cells: 26 black boxes compared to 14 white boxes. The most positive effects were seen with heparin (58%), chloroquine (58%), and, curiously, at 4 °C (48%), suggesting an energy-independent pathway for uptake. Opposite effects were observed with HEK293 cells: 10 black boxes to 26 white boxes. The most frequent negative effects here were observed with 4 °C (58%), Nystatin (50%), and Wortmannin (58%).

For HeLa and MDCK cells, we found a more equal distribution of positive and negative effects (12 black boxes to 15 white boxes for HeLa and 13 black boxes to 8 white boxes for MDCK). HeLa and MDCK cells only showed an increase in cellular uptake using specific CPP/inhibitor combinations (no average positive effect ≥50%).

Altogether, most of the inhibitors used seem to have weak consequences for the cells: 44% of the conditions used have no effects on Cos-7, 50% on HEK293, 63% on HeLa, and 70% on MDCK cells (numbers of gray boxes).

To confirm the different activity of certain inhibitors, we used CLSM imaging to reevaluate the potential redistribution of some CPPs (Table 3, numbers marked in red; Figure 4 and Supporting Information Figure 1). Fluorescence images show the differences between the cellular uptake of selected CPPs without and with inhibitor. We again proved a reduced cellular uptake in the same cases as observed in Table 3, such as R9 with heparin in HeLa cells. On the other hand, we could only show an increase in cellular uptake when we previously found an increase over 2.00, such as integrin with wortmannin in MDCK cells or HIV-1 Tat-(48−60) with heparin in Cos-7 cells. Altogether, we could

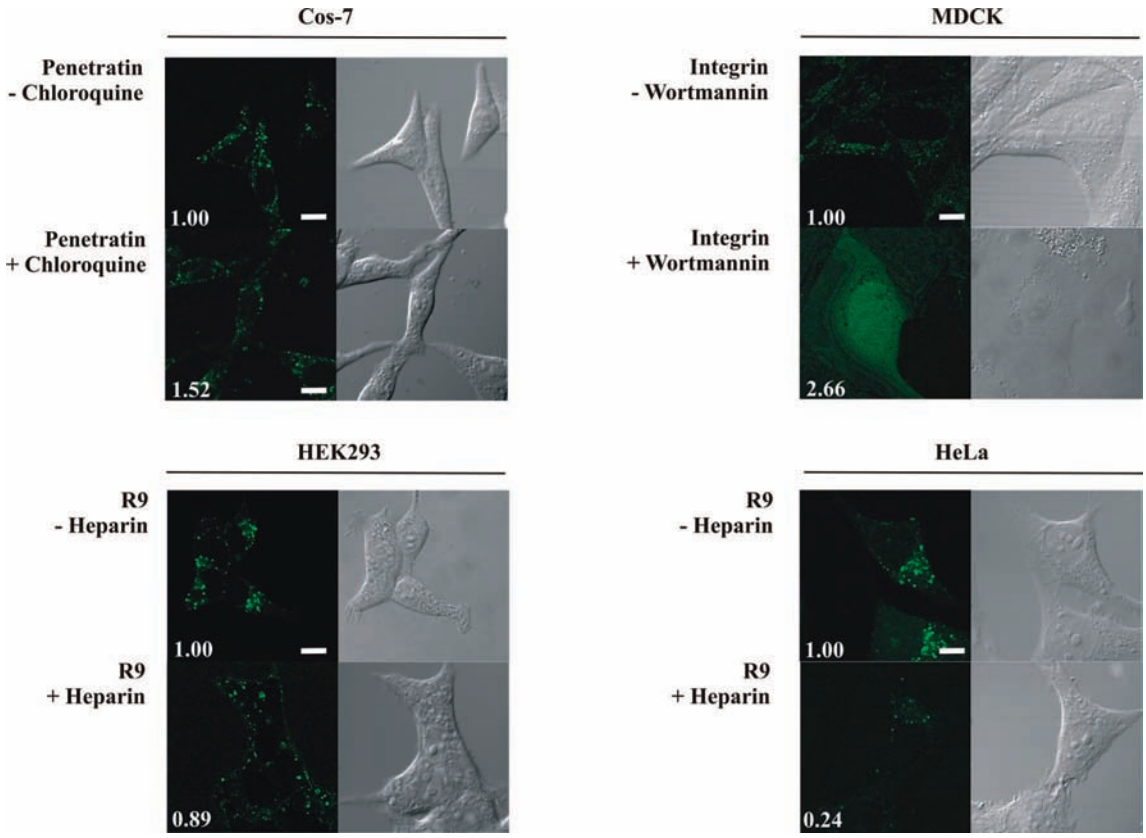

Figure 4. Example of cellular uptake and endocytosis inhibitors in Cos-7, HEK293, HeLa, and MDCK cells. Confocal microscopy sections of the four different cell types were treated with the endocytosis inhibitors for 30 min and afterward with 10 μM of FITC-labeled CPPs together with the inhibitors for an additional 30 min. For each condition, we show the fluorescence and phase contrast images. The percentage of cellular uptake measured by the microplate reader is given in the left lower corner of the fluorescence images. The white bars represent 10 μm.

visualize the same effects of the inhibitors by microscopy as observed in the microplate reader experiments.

DISCUSSION

In the past few years, defined experimental conditions have been established for the measurements of cellular uptake, a necessary step for reproducibility and avoiding artifacts. Approximately 100 000 cells (depending on the cell line) should be seeded in 6-well plates two days before the experiment in order to reach about 80% confluence on the day of measurement. Within one experiment, the same number of cells should always be seeded, since the uptake of CPPs depends on the peptide to cell ratio (*40*). To acquire images for confocal microscopy, the cells should not be confluent (40−60% is preferable). For example, endocytotic internalization was remarkably reduced especially in confluent Madin-Darby canine kidney (MDCK) epithelial cells. This effect was shown to be compound-unspecific, since also other compounds (FITC-dextran, TRITC-transferin, etc.), known to be internalized by endocytosis, lost their internalization efficiency (*41*).

To prevent extra- or intracellular degradation, we determined a combination of EDTA/MG-132 as the most efficient protease inhibitors (Figure 1). Although EDTA is known to interfere with many processes inside the cell, it has no toxic effect on the cells used in this study (see Figure 1B). The same was found for MG-132. Furthermore, the combination of both inhibitors has no influence on cell viability and morphology (see control experiment in Figure 3A, first panel). Curiously, BSA dramatically reduced CPP internalization. This is in contradiction to Palm et al. (*29*) who postulated the saturation of the proteases by BSA. Our results are in agreement with the function of BSA acting as a universal protein/peptide transporter in the serum. Therefore, it is most likely that BSA masks the CPPs and prevents their interaction with the cell membrane as reported by Kosuge et al. (*42*).

Toxic effects should be kept at a minimum if CPPs are used as drug delivery vehicles. For that reason and as deduced form literature, we used a final CPP concentration of 10 μM and an incubation time of 30 min by default. Applying these conditions, we observed no cytotoxicity, clearly demonstrated by the viability tests (Supporting Information Table 2). In general, at high concentrations toxic effects were observed on cell membranes and organelles as shown for MAP and especially for transportan. 20−30% of the cells revealed a huge accumulation of transportan (Figure 2B), which correlated with the vital dye trypan blue staining independently of the cell type. This is not surprising, since transportan penetrates the cell membrane by creating short-lived pores (*39*). The same phenomenon could be observed in 5% of the HeLa cells incubated with MAP (data not shown). Furthermore, the lytic property is clearly demonstrated in the viability test showing a high cytotoxic effect with transportan at a concentration up to 25 μM and also with MAP, but with lesser effects (Supporting Information Table 2).

Our analytical evaluation of the CPP internalization results in a classification into three groups: (1) CPPs with low cellular uptake [such as polyomavirus Vp1, poly-P, NF-kB, SV40 T antigen, HATF3, and hCT(9−32)]; (2) CPPs with medium internalization [e.g., SynB1, DPV6, HIV-1 Tat-(48−60), Pep-1, Bac1−15, MPG, and pVec-scrambled]; (3) CPPs with high cellular uptake [such as penetratin, $S4_{13}PV$, transportan, MAP, R7, R9, HIV-1 Rev-(34−50), and pVec]. This relationship found between the investigated CPPs is significantly influenced by additional trypsinization of the cells (Figure 2).

Nevertheless, comparing all results confirms that it is still a great challenge to predict a CPP's properties based only on primary sequences. CPPs with similar isoelectric points (pI) show different uptake activities. For example, penetratin (pI = 12.31) shows high cellular internalization in comparison to the low activity of poly-P with the same pI value (pI = 12.30). These results demonstrate that the positive charges of CPPs (pI = 10−12), which are postulated to be important for the interaction with HSPGs on the cell surface, are not always the portal guiding endocytosis (*19*). On the other hand, we also found CPPs with a low pI such as integrin (pI = 5.49), which revealed good internalization, especially with HEK293 cells.

The only point that can be ruled out is the correlation of the amino acid order within the primary sequence. pVEC could be detected, e.g., in HeLa cells (SI/mg = 239 ± 140), whereas the scrambled version showed practically no uptake (SI/mg = 77 ± 50). A similar effect could be observed with $S4_{13}PV$ (ALWKTLLKKVLKA-PKKKRKV; SI/mg = 10.000−39.000) and SV40 T antigen (PKKKRKV; SI/mg = 160−310): only the addition of the N-terminal sequence induces the cell penetrating properties of the sequence (*43*). These results imply that the sequence length and conformation of the CPP plays a more important role in cellular uptake than the accumulation of positive charge. However, it is also difficult to argue with the three-dimensional structure, since α-helices (e.g., transportan (*44*)) as well as β-structures (e.g., penetratin (*45*)) are reported to be important for cellular internalization via membrane perturbation.

Comparing our results, we could find some agreements with published reports, but also some basic differences. For example, the commonly used CPPs such as penetratin, MAP, and R9 also show the highest signal intensities in our analytical measurements, which is in agreement with the literature. Curiously, we could not measure high cellular uptake of HIV-1 Tat-(48−60), which often ranks in the same range as penetratin or R9 according to earlier published observations (*31*). Similarly, poly-P is less internalized compared to HIV-1 Tat-(48−60), penetratin, or polyarginines (*25*).

CPP-mediated delivery into the cytoplasm can be achieved by at least two independent mechanisms: (i) adsorptive endocytosis and subsequent release of the enclosed compounds from endosomes or lysosomes (*4, 8, 46*); and (ii) rapid crossing of the membrane by a seemingly energy-independent, not well understood mechanism referred to as transduction (*9, 47, 48*). For the 22 presented CPPs (Table 1), there is a consensus that different endocytosis pathways strongly contribute to cellular uptake, since only small effects could be detected after treatment with endocytosis inhibitors. 43−57% of the tested conditions showed no effects on the CPP internalization (gray boxes in Table 3) These results are in accordance with Duchardt et al. (*9*) showing that chlorpromazine seems to have no special effect using 10 μM CPPs or with Oehlke et al. (*49*) who demonstrated that chloroquine had no effect upon the internalization of MAP peptides.

However, chloroquine seems to have a special role as an endocytic modulator. Chloroquine is a lysosomotropic amine acting as a buffering agent and preventing endosome acidification. Chloroquine also slows down endocytosis, thus leaving more time for endosomal escape. Finally, by preventing the acidification of endocytic compartments, it inhibits associated degradative activities. This endocytic modulator has no clear increasing effect on the cellular uptake, but could significantly increase conjugate activity implying endocytic uptake of at least a portion, if not all, of the internalized conjugate (*50, 51*).

Furthermore, nystatin has no influence on the CPP internalization in HEK293, HeLa, and MDCK cells, as was also observed in human hepatoma cells (HepG2) and in buffalo green monkey (BGM) cells (*52*).

Treatment with heparin has been shown to inhibit CPP cellular uptake by capping the interaction between the negatively charged proteoglycan and the positively charged peptide (*19*). Nevertheless, the influence of heparin seems not as significant as predicted previously (*6, 46, 53*). The small differences observed between the cells could be due to differential expression of cell surface-expressed HPSGs. In fact, although all tissues express proteoglycans, the level of expression is determined by the state of differentiation and growth of the cell, and specific HPSG isoforms are known to be differentially expressed in different cell types (*54*).

Finally, wortmannin, which inhibits endosome fusion, seems to have a negative effect in combination with penetratin and R9, whereas it has no effect with HIV-1 Tat-(48−60) as described by Fischer et al. (*31*). All wortmannin treated cells show the typical phenomenon of enlarged endosomes, even without FITC-labeled CPPs, caused by inhibiting fusion with lysosomes (Supporting Information Figure 1).

Altogether, the endocytosis inhibitors had little effect on the cellular uptake of the 12 tested CPPs in Cos-7, HEK293, HeLa, and MDCK cell lines. Probably, the avoidance of endocytic routes could be achieved using higher CPP peptide concentrations between 25 and 40 μM as recommended by Tunnemann et al. (*26*) or Duchardt et al. (*9*). The equilibrium between the different states of internalization could be shifted to the cytoplasmic one by increasing the HIV-1 Tat-(48−60) concentration, as reported previously (*9, 55*). The uptake of R9 (endocytosis versus transduction) was shown to be dependent on the CPP concentration, as demonstrated with HeLa cells (*9*) and mouse C2C12 myoblasts (*26*).

CONCLUSION

Despite the high number of biological applications using CPPs, the precise mechanism of entry still appears controversial and certainly requires further investigation. Contradictory results are often reported and could stem from experimental variations: e.g., diversity of the CPP sequences, the wide variety of cell lines studied, the differing protocols applied to investigate the entry mechanism, etc.

Therefore, we performed a comparative screen using 22 CPPs in four cell lines under standardized conditions. Our results clearly revealed that the CPPs could be categorized by their behavior into three main groups showing high, medium, and low cellular uptake. This phenomenon still applies even after trypsinization. The use of endocytosis modulators to manipulate cellular uptake seemed to have fewer effects than often reported. Therefore, we propose a more sophisticated approach to modulate the cellular localization by varying the concentration, sequence length, and/or 3D structure of the analyzed CPP. Furthermore, even if the CPPs are trapped in endosomal/lysosomal vesicles, we believe that the quantity of available cytosolic CPPs is enough to initiate a biological reaction such as reported in Abes et al. (*56*). Chloroquine treatment, which does not lead to a significant redistribution of CPPs, as shown by fluorescence microscopy in our experiments (see also ref *50*), led to a concomitant improvement in oligonucleotide activity of the internalized CPP−conjugate, as shown in splicing correction experiments (*50, 51*). Another way to promote endosomal escape could be the conjugation of a viral fusion peptide such as the N-terminus of hemagglutinin (HA2), which has a better *in vivo* potential (*51*).

Having now in our hand a subset of CPPs with high cell penetrating properties, our future directions will include screening various CPPs together with or fused to elements (e.g., CPP

and peptidic inhibitors) to determine structure−activity relationships (SAR).

Supporting Information

Tabel 1: Consequences of protease inhibitors and endocytosis modulators

Effect of the	Treatment	Conc.	Consequences
Protease	Phenanthroline	10 µM	Inhibition of metallo proteases
	EDTA	1 mM	Inhibition of metallo proteases
	MG-132	20 µM	Inhibition of proteasom activity
	Bestatin	10 µM	Inhibition of aminopeptidase B and leucine aminopeptidase
	E-64	10 µM	Inhibition of cysteine proteases
	BSA	1%	For protease saturation
	PMSF	1 mM	Inhibition of serine proteases by sulfonylation
	Aprotinin	2 µg/ml	Inhibition of serine proteases especially trypsin
Endocytosis	37°C	-	Standard condition
	4°C	-	Inhibition of energy-dependent process
	Chlorpromazine	30 µM	Inhibition of clathrin-dependent endocytosis
	Chloroquine	100 µM	Inhibits acidification of endosomes
	Nystatin	100 µM	Disrupt caveolar structure and function
	Heparin	10 µM	Competitor of cell membrane-associated HSPGs
	Wortmannin	100 nM	Inhibits endosome fusion

Footnote: The concentrations given in the table are the concentrations used in this study. Additionally, a brief description of the proposed exerted effect on protease/endocytosis is given for each substance. EDTA: ethylenedinitrilotetraacetic acid, PMSF: phenylmethanesulphonylfluoride, BSA: bovine serum albumin, Glycerol-P: β-glycerol phosphate, HSPGs: heparin sulfate proteoglycans

Footnote: Measurement of the viability using the CCK-8 solution (Fluka). 100% shows no influence of the CPPs. Four different CPP concentrations were used (1 µM, 10 µM, 25 µM, and 50 µM) for each cell lines. The data represent the mean of 3-5 independent experiments ± S.E.M.; bold data indicated a viability ≤50%.

Cells were pre-incubated for 2 h with the protease inhibitors (EDTA/MG-132) followed by incubation with CPPs for 30 min at 37°C. After washing steps the cells were lysed and analyzed by a microplate reader. For assays with trypsin, the cells were treated with trypsin (10 min at 37°C) before cell lysis. The data represent the mean (M) of 3-5 independent experiments with the corresponding standard deviation (SD) and correlation value (CV). The CV values for all cell assays are below the threshold of 30%.

The cells were treated with the reagents at the given concentrations and later CPPs (10 µM) were added to the medium. The cells were incubated for another 30 min and subjected to quantification (for more details see Experimental Procedures). The data represent the mean (M) of 3-5 independent experiments with the corresponding standard deviation (SD) and correlation value (CV). The CV values for all cell assays are below the threshold of 30%.

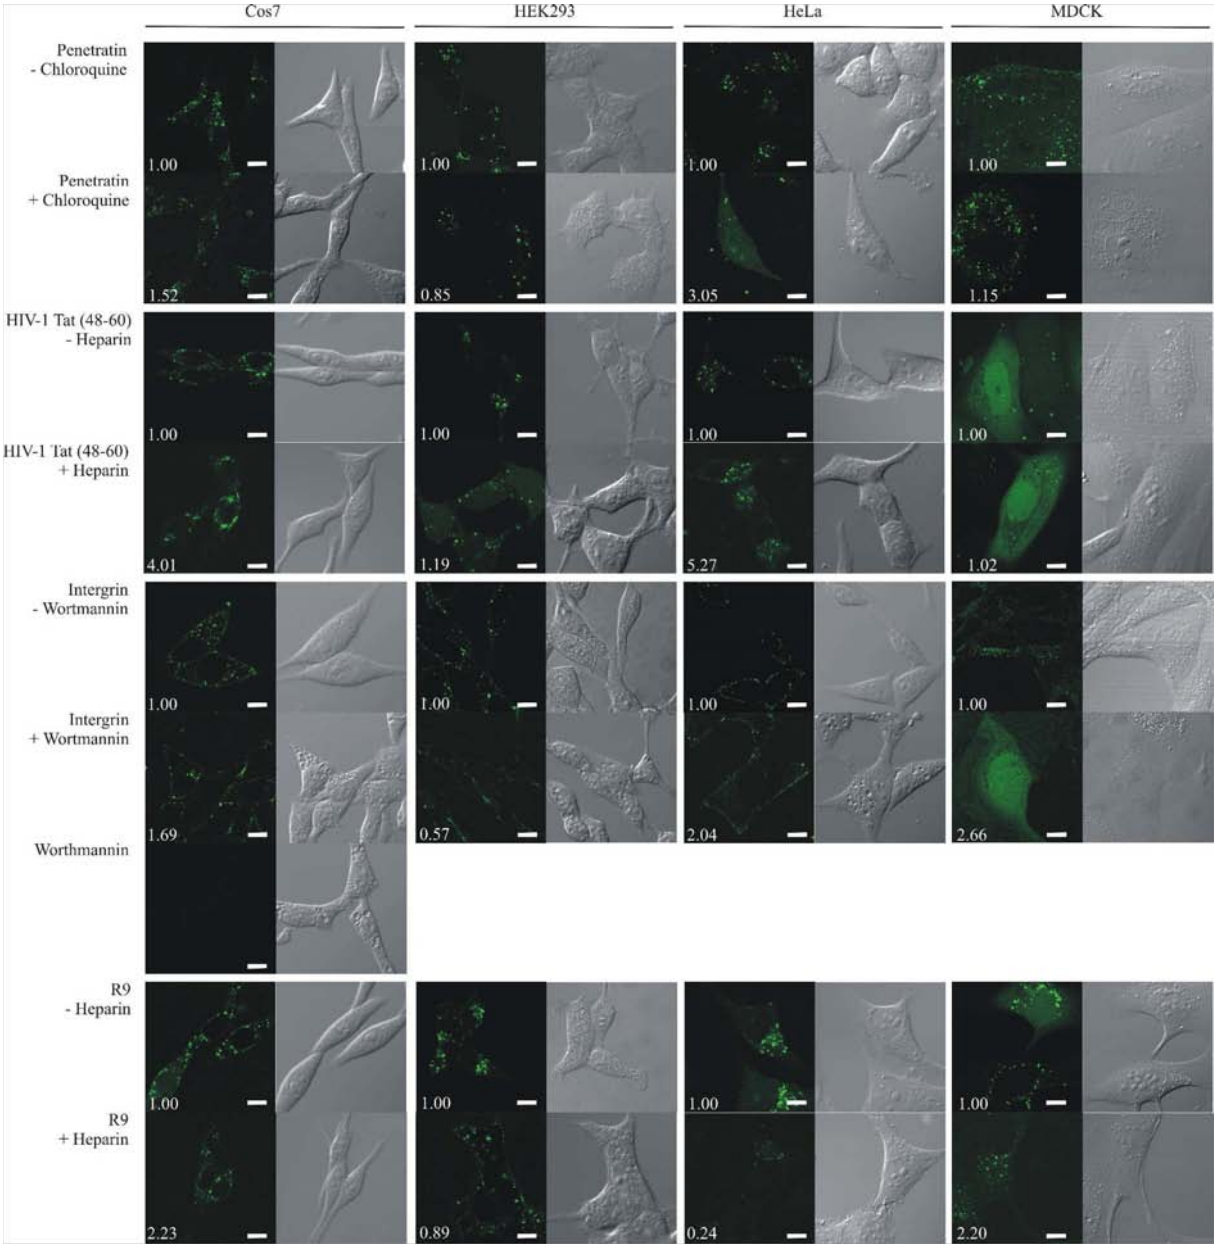

Figure 1: Example of cellular uptake and endocytosis modulators in Cos-7, HEK293, HeLa, and MDCK cells. Confocal microscopy sections of the four different cell types treated with the endocytosis modulators (concentrations see Experimental Section) for 30 min and afterwards with 10 µM of the FITC-labelled CPPs together with the inhibitors for additional 30 min. For each condition we show fluorescence and the phase contrast images. In the left upper corner of the fluorescence images the percentage of the cellular uptake measured by microplate reader is given (Table 3). The white bars represent 10 µm.

Enhanced Cell Uptake of Superparamagnetic Iron Oxide Nanoparticles Functionalized with Dendritic Guanidines

Amanda L. Martin,[†] Lisa M. Bernas,[II,§] Brian K. Rutt,[II,§] Paula J. Foster,[II,§] and Elizabeth R. Gillies*[,†,‡]

Received May 20, 2008; Revised Manuscript Received October 14, 2008

Magnetic resonance imaging (MRI) is a powerful tool for the diagnosis of disease and the study of biological processes such as cancer metastasis and inflammation. Superparamagnetic iron oxide (SPIO) nanoparticles have been shown to be effective contrast agents for labeling cells to provide high sensitivity in MRI, but this sensitivity depends on the ability to label cells with sufficient quantities of SPIO, which can be challenging for nonphagocytic cells such as cancer cells. To address this issue, a novel cell-penetrating polyester dendron with peripheral guanidines was developed and conjugated to the surface of SPIO. The functionalized nanoparticles were characterized by transmission electron microscopy, infrared spectroscopy, and dynamic light scattering, and it was found that the surface functionalization reaction proceeded to completion and did not have any adverse effects on the SPIO. In GL261 mouse glioma cells, the dendritic guanidine exhibited remarkably similar cell-penetrating capabilities to the HIV-Tat_{47-57} peptide for the transport of fluorescein, and when conjugated to SPIO, it provided significantly enhanced uptake in comparison with nanoparticles having no dendron or dendrons with hydroxyl or amine peripheries. This uptake led to substantial decreases in the transverse relaxation time (T_2) of labeled cells relative to control cells. While the nanoparticles functionalized with dendritic guanidines exhibited somewhat greater toxicity than those functionalized with dendrons having hydroxyl or amine peripheries, they were still relatively nontoxic at the low concentrations required for labeling.

INTRODUCTION

Magnetic resonance imaging (MRI) is an important noninvasive technique for the diagnosis of disease and the study of biological processes. Since the inception of MRI, several million contrast agent injections have been performed. These agents increase the signal contrast between normal and diseased tissues by altering the nuclear relaxation times of water molecules in their vicinity. In addition to low molecular weight complexes based on gadolinium (Gd^{3+}) (*1*), a class of contrast agents of growing importance is superparamagnetic iron oxide (SPIO) nanoparticles (*2*). These nanoparticles induce local inhomogeneities in the magnetic field, resulting in regions of hypointensity in T2-weighted MR images. Several SPIO agents are clinically approved by the United States Food and Drug Administration for use in liver and spleen imaging, as well as gastrointestinal imaging (*3*). In vivo administration of SPIO has been investigated primarily by two routes. In some applications, SPIO is injected intravenously and reaches the target site either passively or by the conjugation of an active targeting group to the SPIO surface (*4, 5*). Alternatively, for the study of biological processes such as metastasis and stem cell transplantation, cells can be labeled with SPIO in vitro then tracked by MRI following in vivo injection (*6*−*8*). Recent work by Heyn and co-workers has demonstrated that even single SPIO labeled cells can be detected in vivo by MRI, thus illustrating the immense promise of this technique (*9*).

The ability to detect labeled cells by MRI depends on the quantity of SPIO in the cells. Thus, the efficiency with which cells can be loaded with SPIO is a major determinant for MR sensitivity at the single cell level. For biological applications, SPIO is typically coated with a water soluble polymer such as dextran (*10*) or poly(ethylene oxide) (*11, 12*) in order to provide water solubility and biocompatibility, but these polymers are not designed to significantly enhance the uptake of SPIO into cells. While cells such as macrophages can be readily labeled with adequate quantities of SPIO due to their inherent capability to phagocytose material in the extracellular medium, many other cell lines, including cancer cells do not readily phagocytose SPIO. This challenge can be overcome in some cases by the use of complexes formed between SPIO and transfection agents such as Superfect, Lipofectamine, and poly(L-lysine) (*13*); however, this is a multistep process that must be optimized on a case by case basis and care must be taken to control the size and polydispersity of the resulting complexes. An alternative approach that has been investigated involves the direct conjugation of cell-penetrating peptides such as HIV-Tat (*14, 15*) or protamine (*7*) to the SPIO surface. This method provides a well-defined agent that can be used to label cells in a single step, but a limitation is the availability of peptides on a large scale due to the expense of peptide or protein synthesis and concerns regarding immunogenicity when they are isolated from natural sources. In addition, due to the many reactive functional groups present in peptides, their conjugation to the nanoparticle surface is nontrivial, involving first activation and then conjugation via a multistep process. Thus, the goal of this work was the development of a simple and versatile process for modulating the cell uptake of SPIO via functionalization of the nanoparticle surface.

Well-defined branched molecules called dendrimers were anticipated to be an ideal backbone for the covalent functionalization of the SPIO surface in order to modulate biological properties and cell uptake (*16, 17*). Dendrimers are prepared

by a stepwise synthetic sequence providing molecules with well-defined molecular weight and composition. They can frequently be prepared on a multigram scale by exploiting very high yielding reactions and using a minimal number or even no chromatographic purification steps. Thus far, there have been a couple of reports of dendrimer coated SPIO for cell labeling, but in these cases, carboxyl terminated dendrimers were used as a stabilization agent during the nanoparticle synthesis and the mode of attachment of the dendrimer to the nanoparticle surface is still not well understood (*6, 18, 19*). For this work, it was proposed that by using wedges of dendrimers, commonly referred to as dendrons, the multiple functional groups at the dendron's periphery could allow for the introduction of multiple biological ligands in a well-defined display to modulate properties such as cell uptake and targeting, while the dendron's focal point would provide a site for attachment to the nanoparticle surface. Recent work by the groups of Goodman (*20*), Wender (*21*), and Harth (*22*) has demonstrated that dendrons functionalized at their peripheries with guanidines can significantly enhance the uptake of chromophores into cells in a manner similar to cell-penetrating peptides such as HIV-Tat (*23*) and protamine (*24*), which contain high levels of the amino acid arginine. However, the ability of these dendritic molecules to deliver large and challenging cargo such as nanoparticles into cells has not yet been demonstrated. With the aim of modulating the uptake of SPIO by cells for in vitro cell labeling, we describe here the preparation of a polyester dendron having multiple peripheral guanidine groups and its conjugation to SPIO. This new dendritic guanidine was found to have a cell penetrating capability very similar to that of the HIV-Tat_{47-47} peptide, and upon conjugation to SPIO, it was found to significantly enhance the cell uptake of the nanoparticles, leading to substantial changes in T2 in MR images. Its effect on the toxicity of the nanoparticles was also investigated.

EXPERIMENTAL PROCEDURES

General Procedures and Materials. All chemicals were purchased from commercial sources and used without further purification unless otherwise noted. Anhydrous acetonitrile, dichloromethane, and *N*,*N*-dimethylformamide (DMF) were obtained from a solvent purification system. Triethylamine was distilled from CaH_2. Column chromatography was performed using silica gel (0.063−0.200 mm particle size, 70−230 mesh). Dialysis was performed using a Spectra/Por regenerated cellulose membrane. Ultrafiltration was carried out using a 300 KDa molecular weight cutoff (MWCO) membrane of regenerated cellulose purchased from Amicon. Infrared spectra were obtained as thin films on NaCl plates or as KBr pellets. ^{1}H NMR spectra were obtained at 400 or 600 MHz, and ^{13}C NMR spectra were obtained at 100 or 150 MHz. Chemical shifts are reported in ppm and are calibrated against residual solvent signals of $CDCl_3$ (δ 7.26, 77.2) or CD_3OD (δ 3.31, 49.15). All coupling constants (*J*) are reported in Hertz. Transmission electron microscopy (TEM) was carried out using a carbon Formvar grid and a Phillips CM10 microscope operating at 80 kV with a 40 μm aperture. Dynamic light scattering (DLS) was performed at a concentration of 1 mg of iron/mL in water using a Malvern Zetasizer Nano-S instrument.

Quantification of Accessible Amine Groups on the Nanoparticle Surface. Amine functionalized, cross-linked dextran coated Fe_3O_4 nanoparticles (**1**) were prepared as previously reported (*7, 25*). The nanoparticles (0.81 mg of Fe, as determined spectrophotometrically following treatment with HCl and H_2O_2 (*7*)) were then diluted into 0.5 mL of 25 mM pH 7.4 citrate buffer, and the rhodamine derivative **2** (*26*) (18 mg, 0.025 mmol) was added, followed by diisopropylethylamine (DIPEA) (20 μL). The reaction mixture was stirred overnight in the dark at room temperature and then dialyzed against water for 24 h with several water changes. The UV−visible absorbance of the resulting solution was measured, and the concentration of conjugated dye **2** was calculated based on the extinction coefficient of the dye in water ($\varepsilon = 96100$ M cm^{-1}, $\lambda = 567$nm).

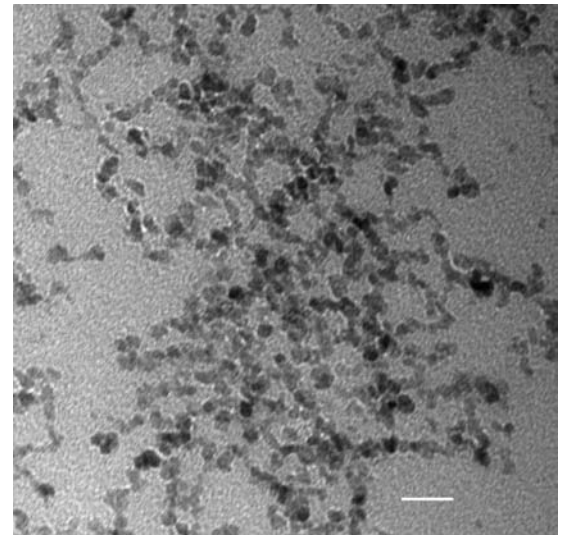

Figure 1. TEM image of nanoparticle **1** (scale bar = 20 nm).

Synthesis of Water Soluble Linker 4. Under a nitrogen atmosphere 2-(2-(2-(2-azidoethoxy)ethoxy)ethoxy)acetic acid **3** (*27*) (0.50 g, 2.2 mmol, 1.0 equiv), *N*-hydroxysuccinimide (0.25 g, 2.2 mmol, 1.0 equiv), and DCC (0.47 g, 2.3 mmol, 1.1 equiv) were dissolved in 20 mL of anhydrous acetonitrile. This solution was stirred at 65 °C for 6 h and then was cooled to room temperature, and the dicyclohexylurea byproduct was removed by filtration. The solvent was removed under reduced pressure to provide 0.69 g (96%) of the product **4** as a colorless oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 4.53 (s, 2H), 3.81−3.79 (m, 2H), 3.73−3.65 (m, 8H), 3.39 (t, 2H, $J = 5.1$), 2.85 (br s, 4H). ^{13}C NMR (400 MHz, $CDCl_3$) δ: 169.2, 166.3, 71.5, 70.8, 70.2, 66.7, 50.9, 25.8. IR (cm^{-1}, thin film from CH_2Cl_2): 3330, 2930, 2870, 2110, 1820, 1790, 1740. MS calcd for $[M + H]^+$ ($C_{12}H_{19}O_7N_4$): 331.1. Found: (ES+) 331.1.

Conjugation of Linker 4 and Dye 2 to Nanoparticles (Synthesis of Nanoparticles 5). To a solution of nanoparticle **1** (10 mg of Fe) in 1.1 mL of 25 mM pH 7.4 citrate buffer was added linker **4** (8.2 mg, 25 μmol) in 0.25 mL of 1:1 DMSO/H_2O followed by the rhodamine derivative **2** (1.7 mg, 2.5 μmol) and DIPEA (50 μL). The solution was stirred overnight in the dark and then dialyzed against pure water for 24 h to provide nanoparticle **5**. The presence of the azide group on the nanoparticle surface was verified by IR spectroscopy (KBr pellet) (Figure 3a), while the amount of conjugated dye was quantified by UV−visible spectroscopy to be 0.21 μmol/mg of Fe.

Synthesis of *N*,*N*′-Bis(*tert*-butoxycarbonyl)-6-guanidinylcaproic Acid (8). 6-Aminocaproic acid (**6**) (0.51 g, 3.9 mmol, 1.0 equiv) was dissolved in 10:1 CH_3CN/H_2O (60 mL), and NEt_3 (4.0 mL) was added. At 0 °C, *N*,*N*′-bis(*tert*-butoxycarbonyl)-1H-pyrazole-1-carboxamidine (**7**) (1.0 g, 3.2 mmol, 0.83 equiv) was added and the mixture was stirred overnight. The reaction was then diluted with EtOAc (100 mL) and washed with saturated $NaHCO_3$ (2 × 50 mL), 1 M $KHSO_4$ (2 × 50 mL), and finally brine (50 mL). The organic phase was dried with $MgSO_4$ and filtered, and the solvent was removed under reduced pressure to yield 1.1 g (90%) of **8** as a white solid. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.32 (t, 1H, $J = 4.6$), 3.41−3.36 (m, 2H), 2.34 (t, 2H, $J = 7.4$), 1.67−1.62 (m, 4H), 1.49 (s, 18H), 1.43−1.38 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ:

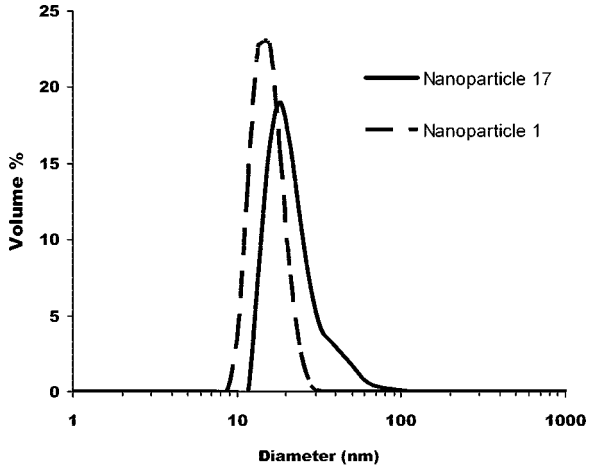

Figure 2. Hydrodynamic diameters of the nanoparticles prior to and after surface functionalization via the "click" reaction, as determined by dynamic light scattering.

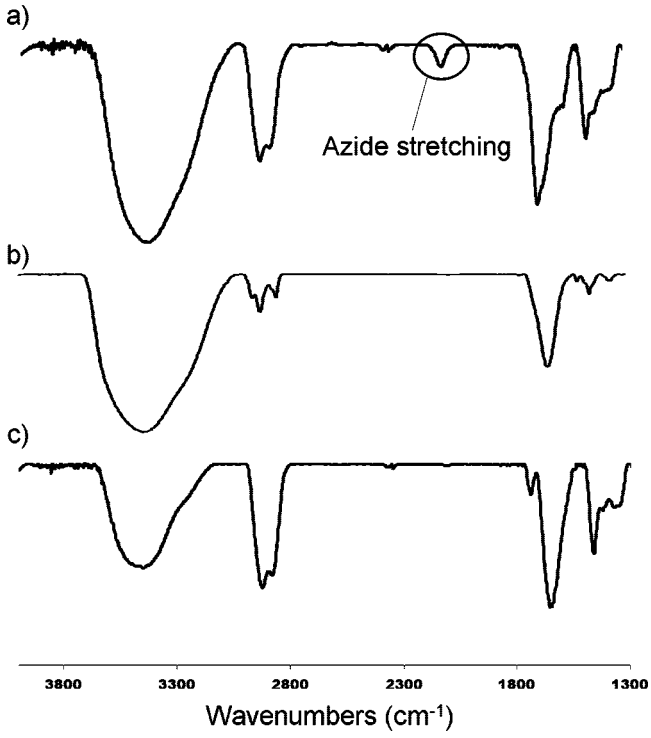

Figure 3. Infrared spectra of (a) nanoparticle **5**, (b) dendron **13**, and (c) functionalized nanoparticle **19**.

163.71, 156.34, 153.49, 83.27, 79.48, 40.92, 28.92, 28.47, 28.26, 28.17, 26.55, 24.67. IR (cm^{-1}, thin film from CH_2Cl_2): 3330, 3140, 2980, 2935, 1720, 1640, 1620. MS calcd for $[M + H]^+$ ($C_{17}H_{31}O_6N_3$): 373.5. Found: (ES+) 373.2.

Synthesis of Dendron 12. Dendron **11** (*28*) (50 mg, 21 μmol, 1.0 equiv) and the acid **8** (0.14 g, 0.38 mmol, 18 equiv) were dissolved in anhydrous *N*,*N*-dimethylformamide (DMF) (4.0 mL), and *O*-benzotriazole-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HBTU) (0.14 g, 0.38 mmol, 18 equiv) was added, followed by 1-hydroxybenzotriazole (HOBt) (51 mg, 0.38 mmol, 18 equiv) and DIPEA (74 μL, 0.43 mmol, 20 equiv). The reaction mixture was stirred under nitrogen for 48 h. The product was purified by dialysis against DMF followed by silica gel chromatography using EtOAc and then 1:1 CH_2Cl_2/MeOH to provide 60 mg (65%) of **12** as a colorless oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 11.48 (s, 8H), 8.30 (t, 8H, $J = 4.8$), 6.57−6.54 (m, 6H), 4.73 (d, 2H, $J = 2.2$), 4.31−4.16 (m, 28H), 3.51−3.47 (m, 16H), 3.39−3.35 (m, 16H), 2.60−2.64 (m, 1H), 2.55 (t, 16H, $J = 6.1$), 2.18 (t, 16H, $J = 7.4$), 1.66−1.54 (m, 24H), 1.49 (s, 144H), 1.37−1.33 (m, 16H), 1.27 (s, 3H), 1.25 (s, 6H), 1.23 (s, 12H). ^{13}C NMR (150 MHz, $CDCl_3$): δ 173.1, 171.9, 171.8, 171.7, 156.1, 153.2, 82.9, 80.0, 77.3, 75.8, 65.2, 65.0, 64.8, 53.0, 46.7, 46.5, 46.4, 40.7, 36.2, 34.9, 34.1, 28.6, 28.3, 28.0, 26.5, 26.0, 25.2, 17.8, 17.5, 17. 4. IR (cm^{-1}, thin film from CH_2Cl_2): 3330, 2980, 2930, 2120, 1740, 1735, 1725, 1640, 1615. MS: calcd for $[M + H]^+$ ($C_{198}H_{341}N_{32}O_{70}$): 4287.3. Found: (ES+) 4282.2.

Synthesis of Dendron 13. Dendron **12** (77 mg, 18 μmol) was dissolved in 2 mL of 1:1 trifluoroacetic acid/CH_2Cl_2, and the solution was stirred at room temperature for 2 h. The solvent was removed under reduced pressure to yield 63 mg (98%) of **13** as a colorless oil in the form of its TFA salt. ^{1}H NMR (600 MHz, CD_3OD): δ 4.77 (d, 2H, $J = 2.2$), 4.22 (m, 28H), 3.43 (t, 16H, $J = 6.7$), 3.16 (t, 16H, $J = 7.1$), 2.93 (t, 1H, $J = 2.3$), 2.56 (t, 16H, $J = 6.7$), 2.20 (t, 16H, $J = 7.4$), 1.64−1.55 (m, 24H), 1.41−1.37 (m, 16H), 1.35 (s, 3H), 1.29 (s, 6H), 1.26 (s, 12H). ^{13}C NMR (600 MHz, CD_3OD): δ 174.6, 174.1, 173.1, 173.0, 172.3, 77.0, 75.5, 65.0, 52.5, 46.2, 46.1, 46.0, 39.9, 35.8, 35.2, 34.9, 33.2, 28.5, 25.8, 24.9, 16.8. IR (cm^{-1}, thin film from THF/MeOH): 3400, 2930, 2120, 1650, 1460. MS: calcd for $[M + H]^+$ ($C_{118}H_{205}N_{32}O_{38}$): 2677.5. Found: (MALDI-TOF) 2678.4.

Synthesis of Dendron 14. Dendron **12** (25 mg, 5.8 μmol, 1.0 equiv) was dissolved in 0.5 mL of 1:1 THF/H_2O. To this was added 3-amino-1-azidopropane (*29*) (5.9 mg, 58 μmol, 10 equiv), $CuSO_4$ (15 μL of a 0.5 M solution in H_2O, 7.5 μmol, 1.3 equiv), sodium ascorbate (200 μL of a 0.5 M solution in H_2O, 100 μmol, 17 equiv), and finally bathophenanthrolinedisulfonic acid disodium salt (5.0 mg, 8.5 μmol, 1.5 equiv). The reaction mixture was stirred for 24 h at room temperature. The product was purified by dialysis against DMF to provide 15 mg (60%) of **14** as a viscous colorless oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 11.49 (s, 8H), 8.32 (s, 8H), 6.61 (br s, 8H), 5.26 (br s, 2H), 4.25−4.16 (m, 28H), 3.65 (s, 2H), 3.50−3.46 (m, 16H), 3.40−3.36 (m, 16H), 2.57−2.54 (m, 16H), 2.43−2.40 (m, 1H), 2.21−2.17 (m, 16H), 1.66−1.54 (m, 24H), 1.49 (s, 144H), 1.37−1.33 (m, 16H), 1.25−1.21 (m, 24H). ^{13}C NMR (600 MHz, $CDCl_3$): δ 180.0, 173.2, 171.9, 171.8, 171.6, 156.1, 138.1, 83.0, 79.2, 70.5, 64.9, 64.8, 58.0, 46.4, 46.2, 40.7, 36.4, 36.2, 34.9, 34.1, 31.4, 28.8, 28.2, 28.0, 26.5, 25.3, 17.9, 17.8, 17.7. IR (cm^{-1}, thin film from CH_2Cl_2): 3330, 2980, 2935, 2240, 2100, 1740, 1735, 1645, 1615, 1575, 1455. MS: calcd for $[M + H^+]^+$ ($C_{201}H_{341}N_{36}O_{70}$): 4379.8. Found: (ES+) 4379.2.

Synthesis of Fluorescein Functionalized Dendron 16. Dendron **14** (10 mg, 2.3 μmol, 1.0 equiv) and fluorescein isothiocyanate isomer 1 (FITC) (3.5 mg, 9.2 μmol, 4.0 equiv) were dissolved in 2 mL of dry DMF. The resulting solution was cooled to 0 °C, and then 1 mL of dry triethylamine was added and the reaction mixture was stirred in the dark for 24 h. The product was purified by dialysis against DMF to provide 10 mg (95%) of the protected product as a viscous yellow oil. The protected derivative (10 mg, 2.2 μmol) was then dissolved in 2 mL of 1:1 trifluoroacetic acid/CH_2Cl_2, and the solution was stirred at room temperature for 2 h. The solvent was removed under reduced pressure to yield 8 mg (90%) of **16** as a viscous yellow oil. ^{1}H NMR (600 MHz, $CD_3OD/CDCl_3$ 1:1): δ 8.26 (d, 2H, $J = 9.4$), 8.09 (d, 2H, $J = 9.4$), 7.46 (d, 1H, $J = 8.8$), 7.39 (d, 1H, $J = 8.8$), 7.20−7.14 (m, 1H), 6.85 (d, 2H, $J = 9.4$), 5.24 (br s, 2H), 4.22−4.17 (m, 28H), 3.80 (br s, 2H), 3.43−3.40 (m, 16H), 3.23 (br s, 2H), 3.13−3.10 (m, 16H), 3.03 (br s, 2H), 2.70 (br s, 1H), 2.55−2.53 (m, 16H), 2.19−2.16 (m, 16H), 1.59−1.55 (m, 24H), 1.37−1.33 (m, 16H), 1.24−1.21 (m, 24H). ^{13}C NMR (600 MHz, $CDCl_3$): δ 174.5, 171.5, 170.9, 165.8, 162.0, 157.1, 156.0, 145.6, 129.7, 125.9, 125.1, 121.9, 121.8, 115.3, 70.1, 64.9, 64.8, 64.6, 48.9, 46.5, 40.9, 35.5, 34.9, 33.6,

28.1, 25.8, 24.9, 17.3, 17.1. IR (cm^{-1}, thin film from CH_2Cl_2/MeOH): 3369, 2980, 2930, 2102, 1739, 1681, 1674, 1652, 1594, 1526, 1456, 1436. MS: calcd for $[M + Na]^+$ ($C_{142}H_{234}NaN_{37}O_{41}S$): 3168.7. Found: (ES+) 3167.7.

Conjugation of Dendrons 9, 11, and 13 to Nanoparticle 5 (Synthesis of Nanoparticles 17, 18, and 19). The desired dendron (**9**, **11**, or **13**) (10 μmol, 2 equiv per azide) was dissolved in a minimum volume of water and was added to a solution of nanoparticle **5** (2 mg of Fe in 1 mL of water). To this was added sodium ascorbate (4 mg, 20 μmol) followed by $CuSO_4$ (1.2 mg, 5 μmol), and the reaction mixture was stirred overnight under a nitrogen atmosphere. The resulting solution was dialyzed against 10 mM ethylenediaminetetraacetic acid (EDTA), followed by pure water. IR spectroscopy (KBr pellet) on a lyophilized sample showed disappearance of the peak corresponding to the azides on the nanoparticles, confirming completion of the reaction (Figure 3c and the Supporting Information).

Cell Culture. GL261 mouse glioma cells obtained from the NCI-Frederick Cancer Research National Tumor Repository were maintained at 37 °C and 5% CO_2 in RPMI-1640 medium (Gibco) supplemented with 10% fetal bovine serum (FBS, Gibco).

Evaluation of the Cell Uptake of Dendron 16. Cells were plated at 8×10^5 cells/well in 6-well plates and allowed to adhere for 24 h. At this point, the medium was aspirated to remove dead cells and replaced with 1 mL of fresh medium to which dendron **16** or FITC-Tat_{47-57} (Ana Spec) was added at concentrations of 0.1, 1.0, or 10 μM. The cells were incubated at 37 °C for either 10 min or 1 h. At this point, the cells were washed twice in the plates with Hank's Buffered Salt Solution (HBSS, Gibco), detached using trypsin-EDTA for 3 min, quenched with RPMI/10% FBS, and then resuspended in 0.5 mL of HBSS and kept on ice until analysis. The cells were analyzed for fluorescein fluorescence by flow cytometry on a BD FACSCalibur flow cytometer (BD Biosciences, USA). Basal fluorescence was given by GL261 cells that were not incubated with the agents.

Evaluation of Cell Uptake of Nanoparticles 5, 17, 18, and 19. In order to assess cellular uptake of the nanoparticle agents, the experiment was carried out as described above, except that the agents were added at a concentration of 25 μg Fe/mL, and the cells were incubated for 30 min or 2 h and then analyzed by flow cytometry for rhodamine fluorescence.

Confocal Microscopy. Cells were plated on collagen-coated coverslips (BD Biosciences) in 6-well plates at a density of 5×10^5 cells/well and allowed to adhere overnight. Agents were then added at 25 μg of Fe/mL in 1 mL of fresh media, and the cells were incubated at 37 °C for 2 h. The cells were then washed with HBSS, fixed with 10% formalin for 10 min, washed again, and turned onto glass slides for confocal microscopy. Images were obtained using a confocal laser scanning microscope (LSM 510, Carl Zeiss Inc.) using a 63× (N.A. = 1.4) objective and an excitation wavelength of 543 nm (He−Ne laser).

Evaluation of Agent Toxicity. The cytotoxicity of the agents was evaluated using a colorimetric MTT assay (Sigma). Cells were plated at 5×10^4 cells/well in 50 μL in a 96-well plate and allowed to adhere overnight. Iron oxide agents were then added at varying concentrations up to ~200 μg Fe/mL, giving a total volume of 100 μL/well. After 24 h, the MTT reagent (10 μL) was added to the cells and the cells were returned to 37 °C for 3 h, during which time the MTT reagent was metabolized by viable cells, resulting in the formation of insoluble purple formazan crystals. The crystals were then solubilized by the addition of a detergent, and the plate was incubated for 4 h in the dark at room temperature. The absorbance read on a plate reader at 590 nm and normalized to the background at 650 nm is proportional to the number of viable cells.

Magnetic Resonance Imaging of Labeled Cells. GL261 cells were plated in T75 flasks and allowed to reach 80% confluency. Nanoparticle **19** was incubated with the cells at a concentration of 12 μg of iron per mL for 2 h. Control cells were incubated in the absence of nanoparticles. The cells were then washed in the flasks four times with HBSS, detached, and washed once more by resuspension in 5 mL of HBSS and centrifugation. The cells were transferred to mini NMR tubes (New Era Enterprises, Inc.) and centrifuged at 10000*g* for 5 min to form dense pellets. T2 measurements of unlabeled and labeled cell pellets were made using a spin echo sequence (TE = 12−300 ms, TR = 2500 ms, 2 mm slice thickness) on a 3T MRI scanner (GE).

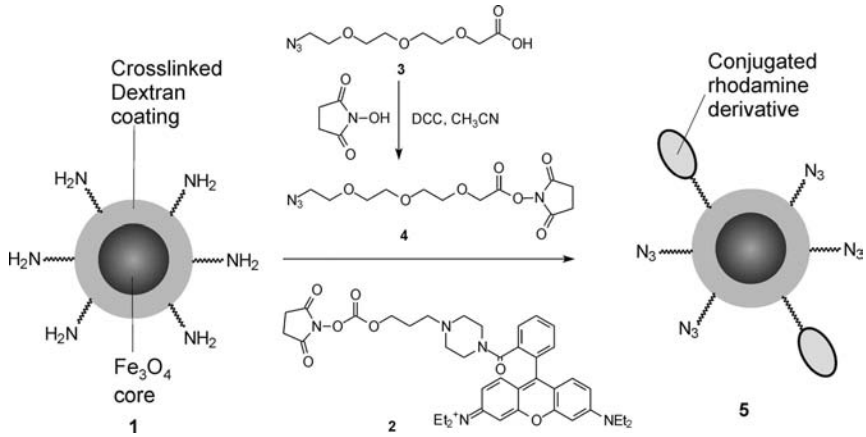
RESULTS AND DISCUSSION

Preparation of Nanoparticles for Functionalization. A number of synthetic protocols ranging from aqueous to high temperature thermal decomposition methods have been reported for the synthesis of SPIO (*30*). For this work, the procedure involving the decomposition of $FeCl_2$ and $FeCl_3$ in the presence of ammonium hydroxide and dextran was used, as it readily provided water soluble nanoparticles for further functionalization (*25*). Treatment with epichlorohydrin followed by ammonium hydroxide, as described by Weissleder and co-workers, provided nanoparticle **1**, with a cross-linked dextran shell and surface amine groups (*7*).

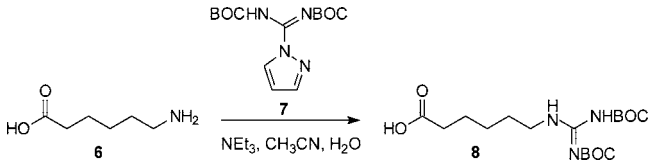
These nanoparticles were characterized by transmission electron microscopy (TEM) (Figure 1), and the size of the iron oxide core was found to be approximately 5 nm, as previously reported (*31*). Dynamic light scattering was used to determine that the total hydrodynamic diameter of the nanoparticles, including the dextran coating, was 16 nm (Figure 2). The polydispersity index for the nanoparticles was relatively low at 0.26. The concentrations of iron in nanoparticle solutions were determined spectrophotometrically following nanoparticle degradation with hydrochloric acid and hydrogen peroxide (*7*). In addition, the dextran was quantified using the phenol sulfuric acid assay (*32*), and it was found that the mass ratio of dextran/iron in the nanoparticles was approximately 1.9:1, similar to what was expected based on previous reports (*31*). As the surface amine groups are critical for further functionalization of **1**, it was important to quantify the number of amine groups that were available for potential derivatization. By treatment of the nanoparticles with a large excess of the *N*-hydroxysuccinimidyl carbonate activated rhodamine derivative **2** (*26*), followed by removal of excess dye by dialysis, it was found that there were 23 μmol of amine available for functionalization per milligram of iron based on quantification of the dye by UV−visible spectroscopy. Although the concentration of reactive amines on the nanoparticle surface has not been explicitly quantified in this way before, conjugations to SPIO have generally been carried out at ratios on the order of micromoles of agent per milligrams of iron, thus indicating that nanoparticle **1** has more than enough amines available (*7, 33, 34*).

Amines provide good functional handles for bioconjugation reactions with a number of functional groups including carboxylic acids, *N*-hydroxysuccinimidyl esters, and isothiocyanates in water. However, when the biological ligands of interest have internal amines or other nucleophilic functional groups, the preparation and conjugation of the above derivatives can be problematic. Therefore, in order to develop a highly general technique to introduce dendrons with a wide variety of functional groups on their peripheries, surface amines on **1** were converted to azides using a water soluble linker (Scheme 1). Azides allow

Scheme 1



Scheme 2



for highly chemoselective and functional group tolerant Cu(I) catalyzed "click" cycloaddition reactions with alkynes to be carried out on the nanoparticle surface under aqueous conditions (*35*). These cycloaddition reactions have been found to be very high yielding, even in the presence of significant steric hindrance (*36*), and are therefore ideal for the conjugation of macromolecules such as dendrons. This reaction has previously been demonstrated to be effective for conjugating molecules to the surface of SPIO (*37, 38*). As shown in Scheme 1, the linker **4** was prepared by the reaction of 2-(2-(2-(2-azidoethoxy)ethoxy)-ethoxy)acetic acid (*27*) (**3**) with *N*-hydroxysuccinimide using *N*,*N*′-dicyclohexylcarbodiimide in acetonitrile. This linker was then reacted with nanoparticle **1** in pH 7.4 citrate buffer at a ratio of 2.5 μmol of linker per milligram of iron to provide **5**. Due to the large excess of amines on the nanoparticle surface, the number of surface azides was limited by the quantity of linker added. The presence of the azide groups on the nanoparticle surface was verified using infrared (IR) spectroscopy by the presence of the distinctive azide stretch at 2100 cm^{-1} (Figure 3a).

In addition to the azide functional handles for conjugation of the dendrons, a fluorescent probe was required in order to characterize the biological properties of the nanoparticles, such as their cellular uptake and intracellular trafficking. This was accomplished in the same step using the rhodamine derivative **2** at a ratio of 0.25 μmol/mg of iron. After the reaction, all residual small molecules and salts were removed by dialysis. The quantity of conjugated dye on **5** was determined by UV−visible spectroscopy to be 0.21 μmol/mg of iron, thus verifying the high yield of the nanoparticle amine derivatization using *N*-hydroxysuccinimidyl derivatives. In addition, by comparison of the fluorescence with a sample having a normalized absorbance at 567 nm, it was determined that fluorescence quenching of the rhodamine by the nanoparticles was negligible.

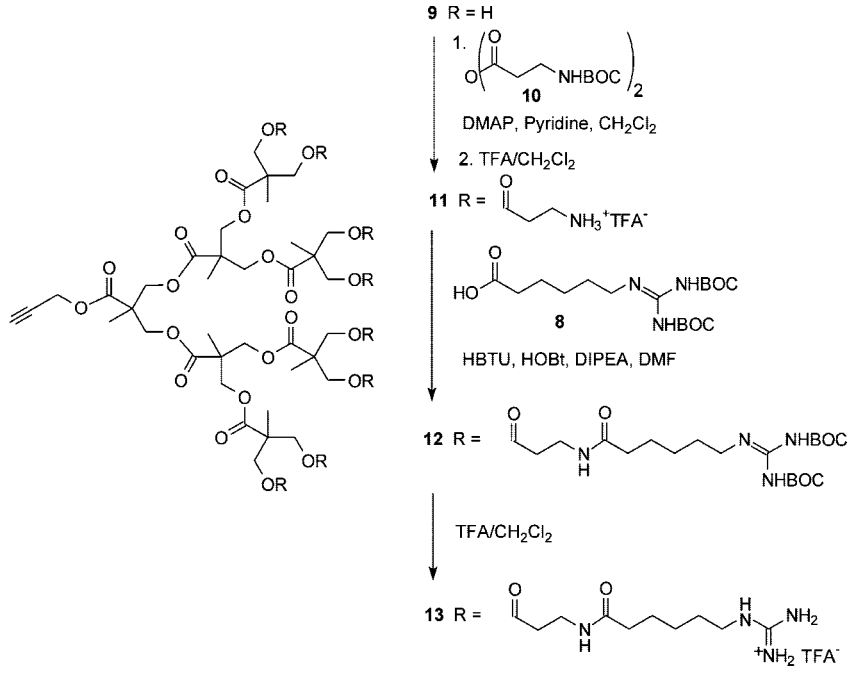
Synthesis of a Dendritic Guanidine. For preparation of the dendritic guanidine transporter, a guanidine derivative with a carboxylic acid functional handle was prepared. 6-Aminocaproic acid (**6**) was reacted with *N*,*N*′-bis(BOC)-1-amidinopyrazole (**7**) to provide *N*,*N*′-bis(BOC)-6-guanidinylcaproic acid (**8**) as shown in Scheme 2. Selection of this linker length was based on previous reports demonstrating that guanidine functionalized dendrons with more flexible spacers exhibited increased cell-penetrating capabilities relative to those that were less flexible (*21*).

A polyester dendron based on 2,2-bis(hydroxymethyl)propionic acid was selected as the dendritic scaffold due to its ease of synthesis, biodegradability, and biocompatibility (*39*, *40*). The alkyne functionalized dendron **9** was prepared as previously reported (*41*), and then the peripheral hydroxyl groups were converted to amines by reaction with anhydride **10** followed by deprotection to provide **11**, with more nucleophilic functional handles for further derivatization (Scheme 3) (*28*). The guanidine derivative **8** was then coupled to the peripheral amines using *O*-benzotriazole-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HBTU) and hydroxybenzotriazole (HOBt). Excess **8** and other byproducts were removed by dialysis and standard column chromatography to provide dendron **12**. Removal of the BOC protecting groups using 1:1 trifluoroacetic acid/dichloromethane provided dendron **13** with eight peripheral guanidine groups in the form of their trifluoroacetate salts. Overall, this synthetic route is simple and amenable to scale up, as no HPLC and only one standard column chromatography purification step is required throughout the entire synthesis.

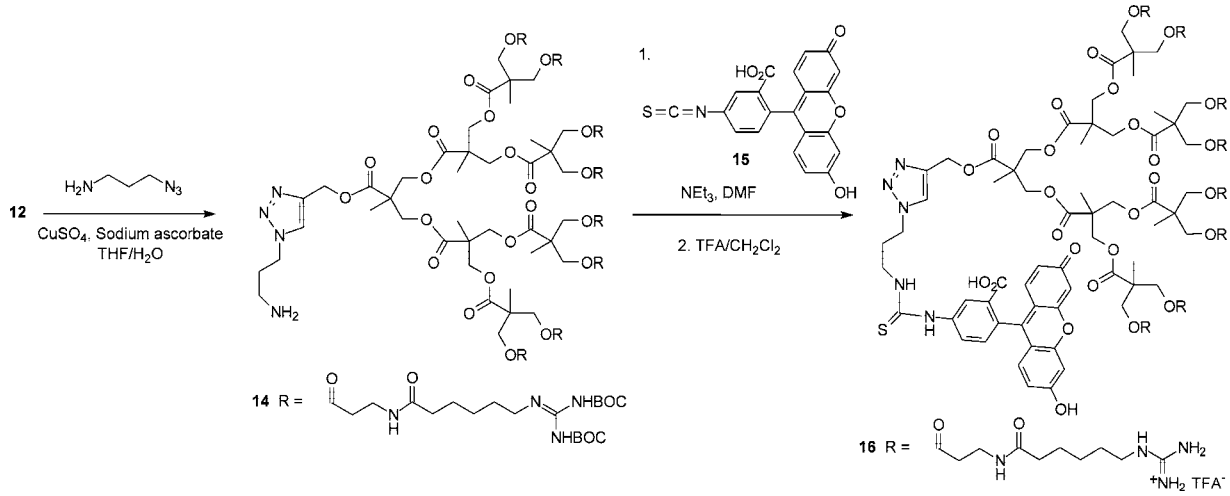
In order to investigate the efficacy of the dendritic guanidine relative to the well established molecular transporter HIV-tat_{47-57}, a fluorescein labeled dendron was prepared. As shown in Scheme 4, an amine was introduced to the focal point of dendron **12** by reaction of the focal point alkyne with 3-amino-1-azidopropane (*29*) to provide **14**. This amine was then reacted with fluorescein isothiocyanate (FITC) (**15**). Excess FITC was removed by dialysis, and then dendron **16** was obtained upon removal of the BOC protecting groups.

Conjugation of Dendrons to Nanoparticles. With dendrons having peripheral hydroxyls (**9**), amines (**11**), or guanidine groups (**13**) in hand, each was conjugated to the surface of nanoparticle **5** to provide functionalized nanoparticles **17**, **18**, and **19**, respectively. As shown in Scheme 5, each coupling was carried out using click reaction conditions consisting of **5**, 5 mM $CuSO_4$, 20 mM sodium ascorbate, and 2 equiv of the dendron per azide group on the nanoparticle. After 24 h, excess reagents were removed by dialysis against 10 mM EDTA followed by water. The EDTA dialysis was critical in removing residual copper salts. In the absence of this step, high levels of toxicity were observed in preliminary work. Characterization of the resulting nanoparticles by TEM verified that the iron oxide core was not degraded during the conjugation and that the size remained approximately 5 nm. DLS showed that only a small increase in the hydrodynamic diameter of the nanoparticles was observed following conjugation, accompanied by a small increase in the polydisperity index to 0.28, which is consistent

Scheme 3



Scheme 4

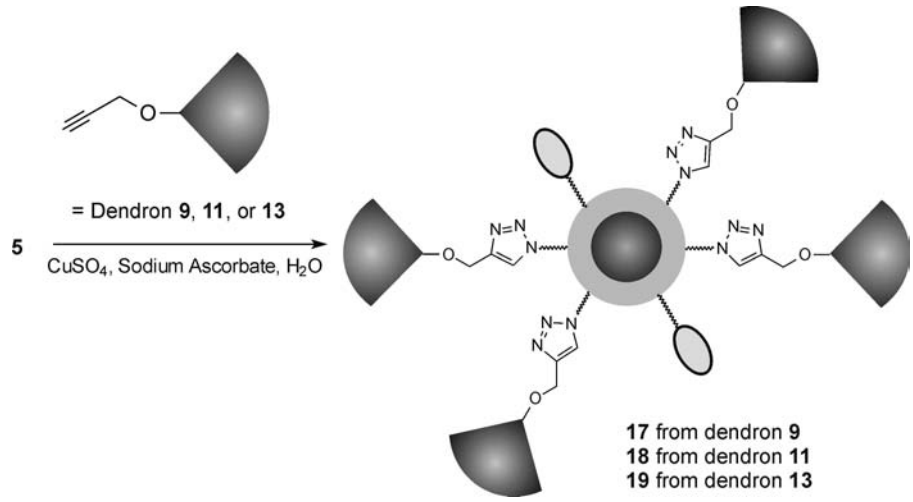


with the small size of the dendron relative to the initial nanoparticles and very minimal aggregation (Figure 2). IR spectroscopy on dried samples of the nanoparticles showed that, in the case of all three dendrons, the click reaction proceeded to completion with complete disappearance of the peak at 2100 cm^{-1} corresponding to the azide group. In addition, changes in the region of the spectrum corresponding to C═O stretching and N—H bending (~1500−1700 cm^{-1}) were observed, which is consistent with the introduction of the dendrons bearing multiple ester and amide groups (Figure 3b and c). In contrast, subjecting nanoparticle **5** to the click conditions in the absence of dendron did not lead to any change in the IR spectrum. Thus, the click reaction proved to be highly effective for the conjugation of dendrons having a variety of functional groups on their peripheries.

Biological Evaluation. GL261 mouse glioma cells were selected for biological studies because they are nonphagocytic cells, which are generally challenging to load with SPIO in the absence of a transfection agent. It is of significant interest to be able to track cancer cells using MRI in order to reach a better understanding of the cell invasion process, so the development of nanoparticles that are capable of more effectively labeling such cells would contribute significantly to the imaging studies. First, the efficacy of the fluorescein labeled dendritic guanidine transporter **16** was compared to that of a fluorescein labeled HIV-Tat_{47-57} oligopeptide (FITC-LC-YGRKKRRQRRR-NH_2) using flow cytometry. The effects of both incubation time and concentration were investigated. As shown in Figure 4, it was found that, at a concentration of 1.0 μM, dendron **16** and Tat_{47-57} exhibited very similar levels of uptake at both 10 min and 1 h time points. At a concentration of 10 μM, very similar uptake was observed after 10 min, while the uptake of Tat_{47-57} was approximately 2-fold higher after 1 h. Overall, both cell-penetrating agents exhibited time- and concentration-dependent uptake, and the similarity in the uptake of the new dendritic guanidine compared to Tat_{47-57} is remarkable, given that it does not contain a specific amino acid sequence and is an unoptimized structure.

Next, the cellular uptake of the functionalized SPIO nanoparticles **5**, **17**, **18**, and **19** was investigated. The cells were incubated for 30 min or 2 h with the nanoparticles at a concentration of 25 μg of iron per mL, and then cell uptake

Scheme 5



was assessed by flow cytometry based on the fluorescence of the rhodamine dye that was conjugated at the same density on each set of nanoparticles. After 30 min, only nanoparticle **19** gave rise to a new population of cells with increased fluorescence (Figure 5a) while the fluorescence of all other cells remained identical to that of control cells that were not exposed to any nanoparticles. After 2 h, cells incubated with nanoparticle **19** exhibited significantly increased fluorescence, as shown in Figure 5b, while cells incubated with all other nanoparticles remained at background levels. This result indicates that the dendritic guanidines specifically enhance the uptake of SPIO into GL261 cells and that the effect is not simply due to a cationic charge on the nanoparticles.

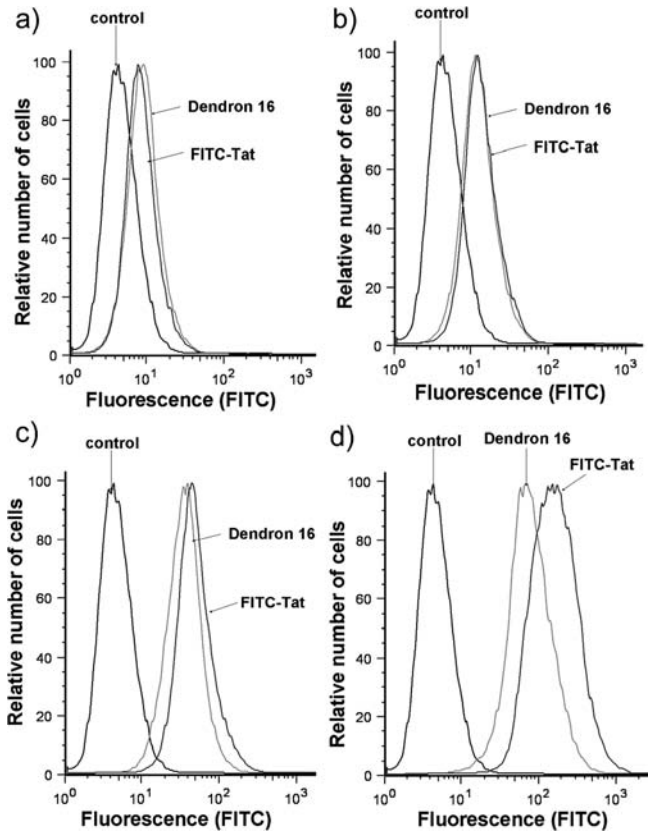


Figure 4. Flow cytometry analyses of GL261 cells following incubation with dendron **16** or HIV-Tat$_{47-57}$: (a) 1.0 μM for 10 min; (b) 1.0 μM for 1 h; (c) 10 μM for 10 min; (d) 10 μM for 1 h.

To verify the flow cytometry results, confocal microscopy was performed on cells following 2 h incubations with nanoparticles **5**, **17**, **18**, and **19** at a concentration of 25 μg of iron per mL. As shown in Figure 6, cells incubated with nanoparticle **19** were strongly fluorescent, while control cells and cells incubated with nanoparticles **5**, **17**, and **18** did not show any fluorescence using the same microscope settings. Based on the confocal images, it is difficult to determine the exact intracellular location of the nanoparticles or whether it is even a single compartment. Thus, further detailed microscopy studies will need to be carried out to determine this, as well as the effects of cell type, incubation time, and fixation (*42*). Dendritic guanidines have been demonstrated to provide delivery to different intracellular compartments depending on subtle differences in the dendritic structure (*22*), but it is not yet clear how a nanoparticle-based cargo may affect the intracellular trafficking. For this work, the location of the SPIO within cells is not a critical aspect of its ability to provide contrast, unless it causes undesirable alterations in the behavior of the labeled cells. No signs of nanoparticle toxicity were observed in the cells during this study.

To show that the enhanced uptake observed using flow cytometry and confocal microscopy results in an enhanced MRI response, GL261 cells were incubated with nanoparticle **19** at a concentration of 12 μg of iron per mL for 2 h, washed, and pelleted. T2 measurements of unlabeled and labeled cell pellets were made using a spin echo sequence on a 3T MRI scanner. T2 values were 65 and 6.1 ms for unlabeled and labeled cell

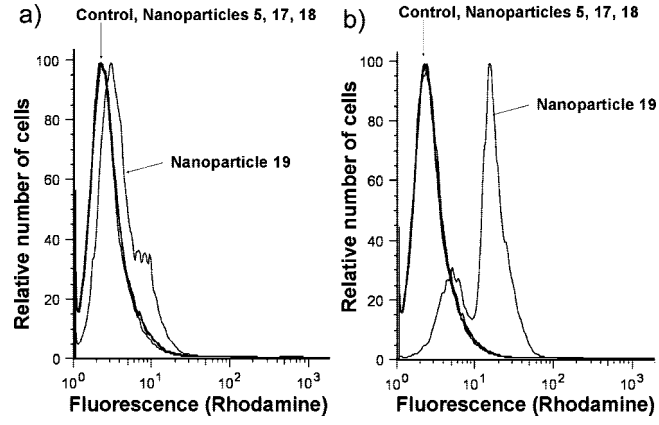

Figure 5. Flow cytometry analyses of GL261 cells following incubation with nanoparticles **5**, **17**, **18**, or **19** at a concentration of 25 μg Fe/mL for (a) 30 min or (b) 2 h.

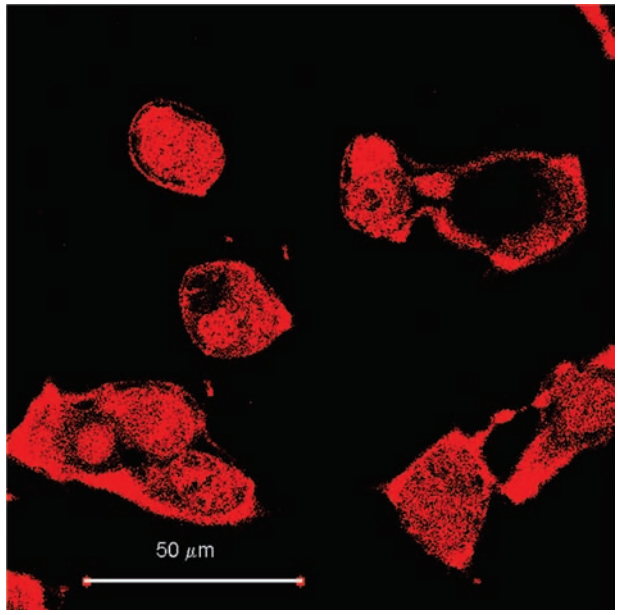

Figure 6. Confocal laser scanning microscopy image of GL261 cells following a 2 h incubation with nanoparticle **19** at a concentration of 25 μg of Fe/mL.

pellets, respectively (Figure 7). This significant difference in T2 values illustrates the utility of these nanoparticles for labeling cells for detection by MRI.

Finally, to investigate the toxicities of the nanoparticles as a function of their surface coating, the GL261 cells were incubated with varying concentrations of nanoparticles **5**, **17**, **18**, and **19** for a 24 h period, and then an MTT assay was performed to quantitatively assess cell viability. The results of this assay are shown in Figure 8. Consistent with previous experiments demonstrating the high biocompatibilities of dendrimers based on 2,2-bis(hydroxymethyl)propionic acid (*39*, *43*), nanoparticle **17** exhibited a relatively similar toxicity profile to the underivatized nanoparticle **5** which is similar to those that have been widely used in a number of cell labeling applications (*44*−*46*). Nanoparticle **18**, prepared from the dendron **11** with peripheral amines, also had a similar toxicity profile. Guanidine functionalized nanoparticle **19** did exhibit somewhat increased toxicity, but it remained relatively nontoxic at the low concentrations used for cell labeling. It is possible that its toxicity at higher concentrations arises from their ability to penetrate and create defects in cell membranes, as has been observed for various

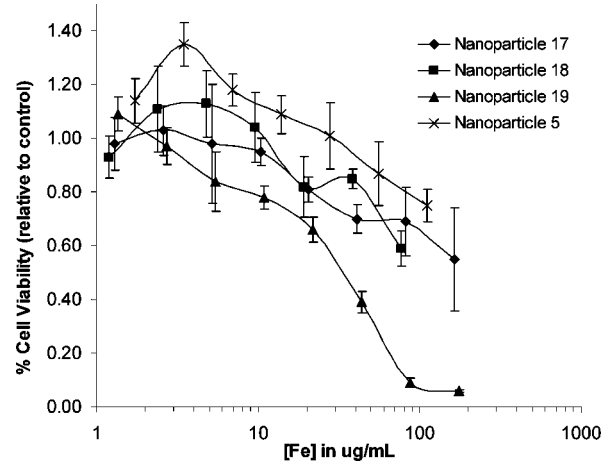

Figure 8. Viability of GL261 cells after a 24 h incubation with nanoparticles **5**, **17**, **18**, and **19**, as measured by the MTT assay. Error bars represent standard deviations on three measurements.

polycationic nanoparticles and transporters (*47*). It is likely that the toxicity of the nanoparticles can be modulated in the future by tuning the ratio of dendron to nanoparticles as well as the length and hydrophobicity of the linker used to conjugate the guanidine groups to the dendron periphery.

CONCLUSIONS

In conclusion, SPIO with surface azide groups was prepared and used to conjugate dendrons having various peripheral functional groups and focal point alkynes. In particular, a new dendritic guanidine was prepared and was found to have a cell penetrating capability remarkably similar to that of the HIV-Tat_{47-57} oligopeptide. Upon conjugation to the nanoparticle surface, this dendron provided significantly enhanced uptake of SPIO into GL261 mouse glioma cells in comparison to dendrons with hydroxyl or amine peripheries. This level of uptake was demonstrated to provide a decrease in the T2 of labeled cells relative to control cells by an order of magnitude. At the concentrations used for cell labeling, the functionalized nanoparticles were found to be relatively nontoxic. It is also noteworthy that the nanoparticles at all stages of synthesis were found to be stable over periods of months when stored at 4 °C in neutral solutions. This represents the first successful example of the transport of a biologically relevant nanoparticle cargo by a dendritic guanidine transporter and promises to provide improved labeling of cells with SPIO for enhanced sensitivity in cellular MRI. In the future, this dendron will also be investigated for its ability to transport other challenging cargo such as quantum dots and polymer assemblies. In addition, as this work demonstrates that dendrons are an effective means of presenting biologically relevant functionality on the nanoparticle surface, it is anticipated that this surface functionalization approach can be expanded to include other biological targeting ligands such as carbohydrates that can also benefit from a multivalent dendritic display.

ACKNOWLEDGMENT

We thank NSERC, the Canada Research Chairs Program, and the Ontario Institute for Cancer Research One Millimetre Cancer Challenge Program for funding this work. Influence of Ligand Valency on the Targeting of Immature Human Dendritic Cells by Mannosylated Liposomes

Institut Gilbert Laustriat, UMR 7175-LC01 CNRS/Université Louis Pasteur, Département de Chimie Bioorganique, Laboratoire de Chimie Enzymatique et Vectorisation, Faculté de Pharmacie, 74 route du Rhin, 67400 Illkirch, France, Centro Galénico, Facultad de Farmacia, Universidad de Navarra, Pamplona, Spain, and Unité INSERM U748, Institut de Virologie, Université Louis Pasteur, 3 Rue Koeberlé, 67000 Strasbourg, France. Received June 24, 2008; Revised Manuscript Received September 9, 2008

An important challenge for the development of new generations of vaccines is the efficient delivery of antigens to antigen presenting cells such as dendritic cells. In the present study we compare the interaction of plain and targeted liposomes, containing mono-, di-, and tetraantennary mannosyl lipid derivatives, with human monocyte-derived immature dendritic cells (iDCs). Whereas efficient mannose receptor-mediated endocytosis by iDCs was observed for the mannosylated liposomes, in contrast, only nonspecific interaction with little uptake was observed with plain liposomes. In accordance with the clustering effect, liposomes prepared with multibranched mannosylated lipids displayed higher binding affinity for the mannose receptor than vesicles containing the monomannosylated analogs. Importantly, we have found that dimannosylated ligands present at the surface of the liposomes were as efficient as tetramannosylated ones to engage in multidentate interactions with the mannose receptor of iDCs, resulting in both cases in an effective uptake/endocytosis. This result will greatly facilitate, from a practical standpoint, the design of mannose-targeted vaccination constructs. Moreover, we showed that mannose-mediated uptake of liposomes did not result in an activation of iDCs. Altogether, our results suggest that antigen-associated targeted liposomes containing diantennary mannosylated lipids could be effective vectors for vaccines when combined with additional DC activation signals.

INTRODUCTION

Dendritic cells (DCs) are the most effective antigen presenting cells that play a key role in adaptive immunity against pathogens or tumor cells (*1, 2*). Immature dendritic cells (iDCs) present in peripheral tissues very actively endocytose exogenous antigens (*3*), after which these cells begin a maturation process that involves a down-regulation of their phagocytic ability and an up-regulation of antigen processing (reviewed by Guermonprez et al.) (*3*). This process is followed by the migration of iDCs to secondary lymphoid organs, where they turn into efficient antigen-presenting cells to naïve T-cells, via the MHC-I and MHC-II molecules, resulting in the activation of T-cells and in the initiation of antigen-specific immune responses or immunological tolerance (*4, 5*). In view of the antigen uptake and presentation competence of DCs, targeting of these cells might be a rational strategy for improving vaccine efficacy. Furthermore, enhancement of the interaction between the vaccine formulation bearing specific antigens and DCs could also be a potential method for increasing vaccine effectiveness.

Recognition and uptake of antigens by iDCs involves receptor-mediated endocytosis/phagocytosis via nonspecific pattern recognition receptors such as Toll-like receptors (TLR) and C-type lectins (*3*). C-type lectins are able to recognize specific pathogen-associated carbohydrate structures. Within the lectins superfamily, the mannose receptor family, composed of four members that include the mannose receptor (MR/CD206), DEC-205(CD205), Endo180, and the M-type phospholipase A2 receptor (*6*−*9*), is of particular importance (*10*). MR has been implicated in the recognition of mannose residues exposed on the surface of specific pathogens and in the internalization of mannosylated antigens, resulting in their enhanced presentation to T-cells (*11*). Furthermore, a recent study has demonstrated that the immunostimulatory properties of KLH (keyhole limpet hemocyanin), a xenoantigen widely used as a vaccine component, are partially triggered by its interaction with MR (*12*). Thus, mannosylation of peptide or protein antigens was shown to result in a 200−10,000-fold enhanced potency for the stimulation of specific T-cell clones, when compared with their nonmannosylated counterparts (*13*). As reviewed by Keler et al., MR-targeted vaccines present a promising approach (*14*). Consequently, the recent generations of antigen delivery systems to DCs involve the formulation of glycosylated antigen carriers such as liposomes, nanoparticles, or niosomes (*15*−*19*). Among the different vaccination vectors, liposomes are particularly attractive structures that are characterized by a marked absence of toxicity and a low intrinsic immunogenicity. These vesicles also offer a wide range of options for the design of vaccination constructs that include the size and (phospho)lipid composition of the vesicles, the mode of association of antigens, adjuvants, e.g. lipopeptide TLR ligands, and cytokines (IL-2...) (*20*−*22*).

Our group has previously synthesized a mannosylated amphiphilic derivative which was optimized to present a high affinity for MR and which could be easily incorporated into the bilayers of liposomes (*23*). This compound was composed of a tetramannosyl headgroup connected, via a polyethylene glycol spacer, to a lipid moiety. The tetramannosylated derivatives, when exposed on the surface of liposomes, showed a much higher affinity for concanavalin A than their monomannosylated analogs (*23*). In the present study, we have now synthesized and investigated a simplified ligand that contains only two mannose residues (Scheme 1). Our aim was to define the optimal

degree of ligand mannosylation (i.e., valency equal to 1, 2, or 4), yielding an efficient interaction and uptake of fluorescently labeled small unilamellar liposomes by human iDCs. The interaction of the mannosylated liposomes with the target cells was assessed by flow cytometry (*18*, *24*). In a second approach, clodronate, a nonpermeant cytotoxic molecule, was encapsulated in the mannosylated liposomes to explore their ability to interact with iDCs and to deliver intracellularly an active molecule. Collectively, our results indicate the following: (i) that targeting via mannosylated molecules is needed to observe an efficient internalization of liposomes by human iDCs, (ii) that targeted liposomes are able to release an active drug into iDCs without their activation, (iii) that, to target iDCs, multibranched mannosylated ligands are more efficient than monomannosylated ones, and, importantly, (iv) that targeting with dimannosylated ligands is as effective as targeting with tetramannosylated ones, thus greatly simplifying the design of DC targeted liposomes.

EXPERIMENTAL PROCEDURES

General. Reagent grade solvents were used without further purification. Egg yolk L-α-phosphatidylcholine (PC), L-α-phosphatidyl-DL-glycerol (PG) transesterified from egg yolk PC, cholesterol (recrystallized in methanol), dichloromethylenebisphosphonate (clodronate), yellow-colored 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), and mannan were purchased from Sigma-Aldrich (Saint-Quentin-Fallavier, France). 5(6)-Carboxyfluorescein (CF) was purchased from Eastman Kodak company (Rochester, NY) and purified according to Silvander et al. (*25*). The Hepes buffer used in this study corresponds to 10 mM Hepes containing 150 mM NaCl at pH 7.4. The mono- and tetramannosylated lipids, described in Scheme 2 (Man_1DOG and Man_4DOG), were synthesized according to (*23*). ^1H NMR and ^{13}C NMR spectra were recorded on a Bruker DPX 200 (200 MHz) and DPX 300 (300 MHz). Mass spectrometry was performed using a ESI/TOF Mariner spectrometer.

Synthesis. *$(ManAc)_2DOG$.* $(ManAc)_2KCOOH$ (50 mg, 44 μmol) (*23*), $DOGP_4NH_2$ (34 mg, 44 μmol) (*23*), DCC (10 mg, 48.4 μmol), and NHS (1 mg) were dissolved in 2 mL of anhydrous methylene chloride. After 1 h, the formed precipitate was removed by filtration and the organic phase was then washed with 3 × 6 mL of 5% (w/v) citric acid in water followed by 3 × 6 mL of water. After drying over $MgSO_4$, the solvent was evaporated to dryness. The reaction product $(ManAc)_2DOG$ (35 mg; yield 42%) was obtained after purification by chromatography on silica gel eluted with CH_2Cl_2/MeOH (30/1). ^1H NMR (δ ppm, $CDCl_3$/MeOD 1:1): 0.91 (t; 6H, $J = 6.6$ Hz, 2 × CH_3), 1.32 (m, 44H, 2 × 11 CH_2 allyl), 1.56 (m, 4H, 2 × OCH_2CH_2), 1.69−2.15 (m, 14H, $CH(CH_2)_3CH_2$ lys, 2 × $CH_2CH{=}CHCH_2$), 1.94, 1.97, 2.06, 2.15 (s, 24H, $OC(O)CH_3$), 2.80−3.03 (m, 4H, 2 × SCH_2), 3.30−3.82 (m, 39H, $CH(CH_2)_3CH_2$ lys, $NHCH_2(CH_2OCH_2)_4CH(CH_2O)O$, 2 × $SCH_2CH_2O(CH_2)_2$, 2 × $OCH_2(CH_2)_7$), 3.98−4.45 (m, 11H, CH_α-lys, 2 × $H_{4,6}$Man, 2 × $OCH_2C(O)NH$), 5.17−5.49 (m, 10H, 2 × $CH{=}CH$, 2 × $H_{2,3,5}$Man), 5.47 (d, 1H, $J = 1.76$ Hz, H_1Man), 7.8 and 8.1 (*NH*). ^{13}C NMR (δ ppm, $CDCl_3$/MeOD 1:1): 14.56 (CH_3), 20.59 − 20.69 − 20.75 and 20.78 ($OC(O)CH_3$), 23.74 (CH_2CH_3), 24.09 ($CH(CH_2)_3CH_2$lys), 27.24, 27.32 ($OCH_2CH_2CH_2$), 28.17 ($CH_2CH{=}CHCH_2$), 30.17, 30.32, 30.36, 30.47, 30.58, 30.63, 30.66, 30.80, 30.85, 31.17, 31.37, 31.52 (SCH_2, $OCH_2CH_2CH_2(CH_2)_4CH_2$, $CH{=}CHCH_2(CH_2)_4$-$CH_2CH_2CH_3$), 33.07, 33.63 ($OCH_2CH_2(CH_2)_6CH{=}CH(CH_2)_5$-$CH_2$), 33.38 ($C(O)NHCH_2CH_2$lys), 39.68, 40.41 ($C(O)NH$-$CH_2CH_2O$, $C(O)NHCH_2CH_2$lys), 53.86 ($C_\alpha$lys), 63.58 (C_6Man), 67.41, 70.38, 70.92, 72.14 (C_{2-5}Man), 70.48 ($CHCH_2O(CH_2)_8$), 71.08 − 71.11 − 71.17 − 71.28 − 71.42 − 71.47 − 71.54 − 71.58 − 71.90 − 71.98 − 72.08 − 72.53, 73.24 (SCH_2-$(CH_2OCH_2)_2C(O)$, $NHCH_2(CH_2OCH_2)_4$), 79.26 (OCH_2CHO), 83.76 (C_1Man), 130.82, 130.87 ($HC{=}CH$), 171.37, 171.44, 172.19, 172.29, 172.47, 172.54, 173.67 ($C(O)$). ESI-TOF MS (*m*/*z*), calculated for $C_{93}H_{161}N_3O_{31}S_2$ 1881.4, found ($M + Na^+$) 1904.0.

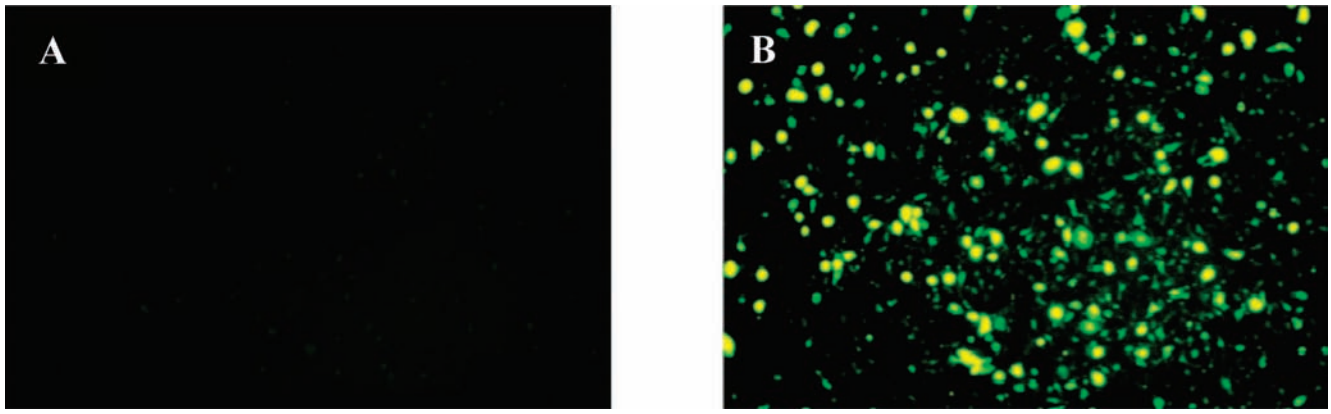

Figure 1. Epifluorescence images of human iDCs incubated at 37 °C for 2 h with 5(6)-carboxyfluorescein-encapsulated in plain (A) or Man_4-liposomes (6 mol % mannose) (B). Cells were observed with a Nikon Diaphot TMD inverted microscope with an epifluorescence attachment.

Man_2DOG. $(ManAc)_2$DOG (35 mg, 19 μmol) and potassium carbonate (7 mg, 50 μmol) were dissolved in 10 mL of anhydrous methylene chloride. After 3 h at room temperature and stirring, the organic phase was evaporated to dryness. The reaction product Man_2DOG (28 mg; yield 97%) was obtained after purification by chromatography on silica gel eluted with CH_2Cl_2/MeOH (7/3). ^{1}H NMR (δ ppm, $CDCl_3$/MeOD 1:1): 0.91 (t, 6H, $J = 6.6$ Hz, 2 × CH_3), 1.29 (m, 44H, 2 × 11 CH_2allyl), 1.58 (m, 4H, 2 × OCH_2CH_2), 1.73−2.15 (m, 14H, $CH(CH_2)_3CH_2$lys, 2 × $CH_2CH{=}CHCH_2$), 2.68−2.95 (m, 4H, 2 × SCH_2), 3.26−4.05 (m, 55H, $CH(CH_2)_3CH_2$lys, $NHCH_2(CH_2OCH_2)_4CH(CH_2O)O$, 2 × $SCH_2CH_2O(CH_2)_2O$, 2 × $OCH_2(CH_2)_7$, 2 × H_{2-6}Man, 2 × $OCH_2C(O)NH$), 4.41 (m, 1H, CH_αlys), 5.33−5.36 (m, 6H, 2 × C$H{=}$CH, 2 × H_1Man). ^{13}C NMR (δ ppm, $CDCl_3$/MeOD 1:1): 14.54 (CH_3), 23.75 (CH_2CH_3), 24.16 ($CH(CH_2)_3CH_2$lys), 27.25, 27.31 (OCH_2CH_2-CH_2), 28.16 ($CH_2CH{=}CHCH_2$), 30.18, 30.36, 30.48, 30.62, 30.80, 30.86, 31.16, 31.33 (SCH_2, $OCH_2CH_2CH_2(CH_2)_4CH_2$-$CH{=}CHCH_2(CH_2)_4CH_2CH_2CH_3$), 33.07, 33.63 ($OCH_2CH_2$-$(CH_2)_6CH{=}CH(CH_2)_5CH_2CH_2CH_3$), 33.30 ($C(O)NHCH_2$-$CH_2$lys), 39.72, 40.42 ($C(O)NHCH_2CH_2O$, $C(O)NHCH_2$lys), 53.11 ($C_\alpha$lys), 62.82 (C_6Man), 70.47, 71.12, 71.19, 71.43, 71.56, 71.70, 71.81, 71.95, 72.07, 72.17, 72.53 ($SCH_2(CH_2O$-$CH_2)_2C(O)$, $NHCH_2(CH_2OCH_2)_4$), 68.88, 73.08, 73.55, 75.03 (C_{2-5}Man), 79.28 (OCH_2CHO), 86.33 (C_1Man), 130.85 ($HC{=}CH$), 172.49, 172.62, 173.85 (C(O)). ESI-TOF MS (*m*/*z*) calculated for $C_{77}H_{145}N_3O_{23}S_2$ 1543.9, found ($M + Na^+$) 1567.9.

Liposome Preparation. Liposomes were prepared by mixing, in a round-bottom flask, phospholipids (PC, PG) and cholesterol (75/20/50 molar ratio), in chloroform with the appropriate mannosylated lipid at 0−16 mol % mannose content. After solvent evaporation under high vacuum, the dried lipid film was hydrated by vortex mixing after addition of 1 mL of Hepes buffer (for 10 μmol of lipids) containing 150 mM clodronate or 40 mM CF. The resulting suspension was sonicated at 25 °C for 1 h (5 s cycles interrupted for 1.25 s) under a continuous flow of nitrogen, using a 3 mm diameter probe sonicator (Vibra Cell, Sonics and Material Inc., Danbury, CT) at 300 W. The SUV (Small Unilamellar Vesicles) preparations were finally centrifuged for 10 min at 10,000*g* to remove the titanium dust originating from the probe. The liposomes were separated from unencapsulated CF or clodronate by passage through a 1 × 10 cm Sephadex G-75 column equilibrated with Hepes buffer. The size of the vesicles was determined by a photon correlation spectroscopy technique, using a Coulter (model N4SD) submicron particle analyzer (Coulter Electronics, FL). The liposomes were analyzed for phosphorus (*26*) and sugar content (*23*). All the liposome formulations were freshly prepared and sterilized (Millex filters 0.22 μm) before use with the cells. This formulation led to a clodronate concentration of 4.8 mM in the final liposome suspension. Encapsulated CF was quantified according to Barbet et al. (*27*). Mannosyl residues associated with the liposomes are expressed in mol % relative to the phospholipids: for example, four times more Man_1DOG molecules were used compared to the case of Man_4DOG to achieve the same mannose content.

Generation of Human Immature Dendritic Cells. iDCs were obtained by differentiation of monocytes isolated by countercurrent elutriation of peripheral blood mononuclear cell (PBMC) separated from the blood of healthy donors. Accordingly, the monocytes were then cultured in RPMI 1640 medium (GIBCO BRL, France) containing 10% fetal bovine serum (FBS) (GIBCO BRL, France), 1000 IU/mL GM-CSF, and 500 IU /mL IL-4 (PeproTech, USA) for 6 days. Cells were again fed with fresh medium containing cytokines on day 1 and with fresh cytokines on day 4. At day 6, the resulting cells, which were semi- to nonadherent, displayed DC morphology and their phenotype was analyzed as described below.

Uptake of 5(6)-Carboxyfluorescein-Encapsulated Liposomes by iDCs. Immature human dendritic cells were plated at 4 × 10^5 cells/mL in 6-well plates and incubated with (manno)liposomes containing CF for 30 min (2 h for microscopy and fluorometric experiments) at 37 °C with 5% CO_2. The medium used was RPMI 1640 supplemented with 5% heat inactivated FBS. After the incubation period, the cells were washed twice with cold PBS and finally fixed with 1.5% paraformaldehyde before flow cytometry analysis (FACS). Mannan was used in a competitive inhibition assay to confirm the specificity of the uptake of the ligands. Accordingly, the cells were preincubated for 10 min with 10 μg/mL of mannan followed by the liposomal formulation for an additional 30 min. The cells were then treated as above for FACS analysis (Figure 2). For spectrofluorometric analysis (Figure 3), after cold PBS treatment, the cells were lyzed with 1% Triton in PBS. The fluorescence was measured at $\lambda_{em} = 530$ nm (λ_{ex} 485 nm) with a fluorometer (Shimadzu, RF-5301, Kyoto, Japan). The relation between liposomal phospholipids and total CF fluorescence (Figure 3) was determined similarly after detergent lysis of the CF-loaded vesicles.

Microscopy. Epifluorescence microscopy of human iDCs was performed at 37 °C after 2 h of incubation with 5(6)-carboxyfluorescein encapsulated in plain or Man_4 liposomes (6 mol % mannose). Cells were observed with a Nikon Diaphot TMD inverted microscope with an epifluorescence attachment (FITC filter set: DM 510 B-2A) and equipped with a 10× magnification.

Effect of Mannosylated Liposomes on the Phenotype of iDCs. To evaluate the induction of maturation of iDCs by mannosylated liposomes, adherent and nonadherent cells were

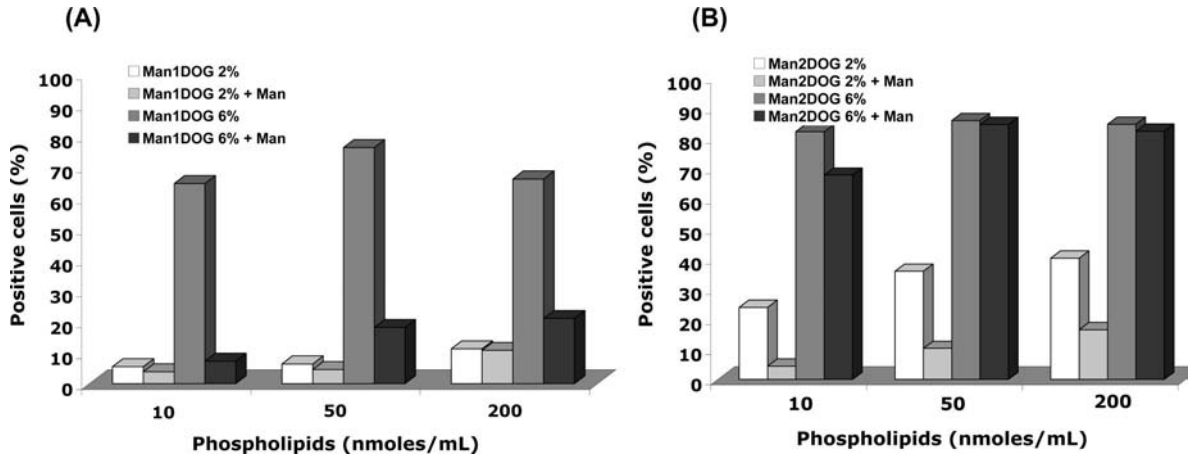

Figure 2. Quantification of fluorescently labeled iDCs observed after incubation with 5(6)-carboxyfluorescein-encapsulated liposomes targeted with Man_1DOG (A) or Man_2DOG (B). The cells were incubated at 37 °C for 30 min with varying concentrations (expressed in nmol/mL of phospholipids) of CF-liposomes containing the indicated amounts (expressed in mol % mannose) of Man_1DOG or Man_2DOG. (+) Man: mannan inhibition experiments. The cells were preincubated for 10 min with 10 μg of mannan/mL followed by an incubation with Man_1- or Man_2-liposome formulations for 30 min. The percentage of positive cells in the presence of plain liposomes was <10%. The data are from a representative experiment carried out twice with similar results.

harvested from T-75 flasks with cold PBS-EDTA. These cells were then recultured at 4×10^5 cells/mL in 6-well plates in media prepared with one volume of fresh RPMI containing 5% FBS and one volume of monocyte-conditioned medium (MCM) corresponding to cytokine-enriched medium from a 6-day culture of monocytes. After addition of LPS (1 μg/mL) or the different mannosylated formulations (0.1−50 nmol of phospholipids/mL), the cells were further incubated for 24−48 h before phenotypic analysis by flow cytometry.

Intracellular Activity of Clodronate Encapsulated in Liposomes on iDCs. Immature human dendritic cells generated as above were plated at 4×10^5 cells/mL in 48-well plates and incubated with (manno)liposomes containing clodronate for 48 h at 37 °C with 5% CO_2. The medium used was RPMI 1640 supplemented with 5% heat inactivated FCS. After the incubation, the cells were washed twice with cold PBS and their viability was evaluated as indicated below.

Cytotoxicity Assay. Cell viability was measured with the colorimetric MTT assay (*28*). Briefly, 5×10^5 DCs/mL, maintained in one volume of MCM and one volume of RPMI 1640 containing 5% FCS, was incubated in the presence of different concentrations of liposomes for 24, 48, or 72 h at 37 °C. Half of the medium was removed before addition of 60 μL of MTT (7.5 mg/mL in PBS lacking Ca^{2+} and Mg^{2+}) for 2 h at 37 °C. Solubilization of the formazan crystals was achieved by aspiration of 300 μL of supernatant followed by addition of 200 μL of 10% (v/v) Triton-X100 in acidified (0.4% concentrated HCl) isopropanol. The absorbance of quadruplicates at 540 nm was measured using a plate reader. The clodronate concentration versus cells was estimated considering a clodronate concentration of 4.8 mM in the final liposome suspension.

Phenotype Analysis by Flow Cytometry. Phenotypic characterization of dendritic cells was carried out by flow cytometry using a FACScan (Becton Dickinson). Cells resuspended in PBS (Becton Dickinson) were incubated for 15 min at 4 °C with saturating concentrations of the following panel of PE-labeled monoclonal antibodies: anti-CD83, anti-CD86, and anti-HLA DR. Specific anti-immunoglobulin isotypes mAbs (anti-IgG1 and anti-IgG2) were used as control. The percentage of positive cells was determined regarding the isotypic control (Figure 5) The mean fluorescence intensity (MFI) was determined for the cells stained with the specific marker antibody (Figure 5).

Statistical Analysis. The data of Figure 5 were analyzed using the Mann−Whitney test (SigmaStat, version 2.0, Jandel GmbH, Erkrath, Germany). Results were considered significantly different when $p < 0.05$.

RESULTS AND DISCUSSION

Synthesis of the Amphiphilic Dimannosyl Conjugate Man_2DOG. Our group has previously synthesized mono- and tetra-mannosylated derivatives which, when incorporated in liposomes, were promising molecules to target cells expressing mannose receptors (*23*). In the present work we first performed the synthesis of a dimannosylated derivative to investigate the influence of the mannose valency on the *in vitro* iDCs' targeting. The synthesis of Man_2DOG (Scheme 1) first required the production of lipid $DOGP_4NH_2$. This compound was synthesized in 6 steps starting from glycerol, tetraethylene glycol, and oleyl alcohol according to the procedure described previously by Espuelas et al. (*23*). Compound $(ManAc)_2KCOOH$ was obtained by introduction of two mannose groups on a L-lysine backbone as described (*23*). The carboxylic acid function of $(ManAc)_2$-KCOOH was activated with dicyclohexylcarbodiimide and *N*-hydroxysuccinimide at room temperature in the presence of diisopropylethylamine. $DOGP_4NH_2$ in CH_2Cl_2 was then added and the reaction was carried out for 12 h to give $(ManAc)_2DOG$. The final product, Man_2DOG, was obtained after removal of the acetyl protecting groups of the mannose residues with potassium carbonate in methanol.

Characterization of the Mannosylated Liposomes. Liposomes have been described as tools for the efficient presentation of ligands to cell surface receptors, which require multivalent interactions (*23*). Moreover, antigens associated with such vesicles were also shown to be more efficiently captured/endocytosed and presented by antigen presenting cells than free antigens in solution (*29*). We consequently formulated small unilamellar liposomes incorporating various amphiphilic mannosylated derivatives in their phospholipidic bilayers. The main characteristics of plain and mono- and tetramannosylated liposomes (see Scheme 2 for structures) have been previously reported (*23*). The sugar residues associated with these vesicles, determined by the resorcinol−sulfuric acid method, increased proportionally with the amount of mannosyl lipids added during liposome preparation (*23*). Mono- and tetramannosylated lipids were consequently found to be stably inserted into the bilayer of liposomes, leading to Man_1- and Man_4-liposomes, respectively (*23*). In the present work, Man_2-liposomes have been prepared by incorporation of the presently described Man_2DOG.

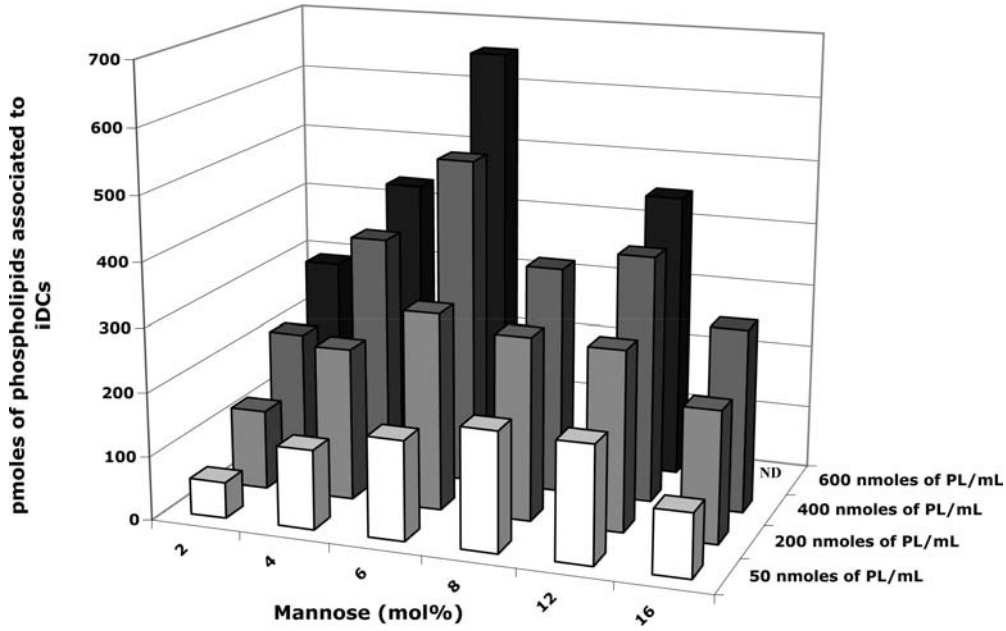

Figure 3. Quantification of cell-associated vesicles after incubation of iDCs with 5(6)-carboxyfluorescein-encapsulated liposomes containing varying amounts (2−16 mol % mannose) of Man_4DOG. The cells were incubated at 37 °C for 2 h with the given concentrations (in nmol/mL of phospholipids) of targeted CF-liposomes. The cell-associated vesicles (expressed as picomoles of phospholipids) were quantified by determination of the fluorescence of CF at $\lambda_{em} = 530$ nm (λ_{ex} 485 nm) after lysis of the cells with 1% Triton X-100. The results are expressed as picomoles phospholipids associated to iDCs as a function of nanomoles of liposomal phospholipids/mL of cell medium. Data are means of three experiments (SD < 10%). ND, not determined.

Scheme 2. Structures of the Mono- and Tetramannosylated Lipid Derivatives

Abbreviation	Structures
Man_4DOG	Man_1DOG	
The size of the liposomes ranged between 70 nm for the plain vesicles and 110 nm for the liposomes containing the highest proportion of the tetramannosylated lipid (i.e., equivalent to 16 mol % mannose). Compared to plain vesicles, the presence of the mannosylated lipids had no apparent influence on their stability. Thus, about 60% retention of the encapsulated marker CF was observed after incubation of the different liposome populations for 24 h in a cell culture medium (RMPI in the presence of 5% heat-inactivated serum) at 37 °C.

Interaction of Targeted Liposomes Containing 5(6)-Carboxyfluorescein with Immature Human Dendritic Cells. The ability of the liposomes to interact with iDCs has been assessed with vesicles having encapsulated CF. Upon release of the CF in the cytoplasm, the fluorescence is dequenched and visible inside the cell. Figure 1 illustrates the dramatic difference between the fluorescence emitted by the cells after incubation with plain (Figure 1A) and targeted Man_4-liposomes (Figure 1B). In Figure 2, the cell-associated fluorescence has been expressed as percentage of CF positive cells (Figure 2A and 2B) after incubation with plain and Man_1- and Man_2-liposomes. The percentage of CF positive cells was <10% after incubation with plain liposomes. At this point it should be mentioned that although iDCs are known to display high endocytic/phagocytic activities (*3*) and to capture plain liposomes (*15, 18, 24, 30*), this uptake remains quite low for short incubation times such as the 2 h used in our study (*15, 30, 31*).

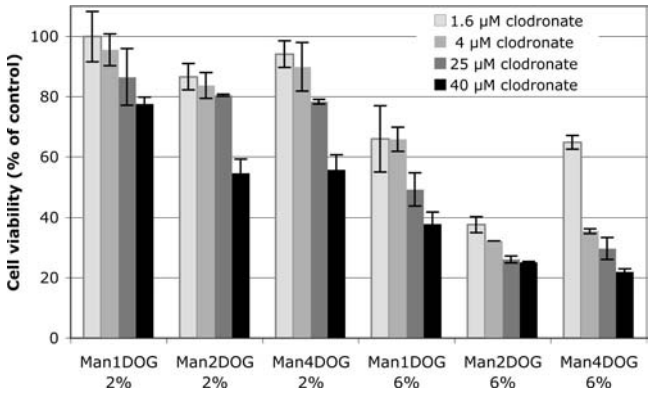

Figure 4. Cytotoxicity assay. Cytotoxicity of clodronate encapsulated in mannose-targeted liposomes. Human iDCs, plated at 4×10^5 cells/mL RPMI supplemented with 5% heat-inactivated FBS in 48-well plates, were incubated with the indicated liposomal formulations for 48 h. The cytotoxicity was measured with a MTT test. Data represent means of triplicates ± SEM.

As shown in Figure 2A, no significant fluorescence was found associated with iDCs after incubation with Man_1-liposomes at 2 mol % mannose, whereas for higher mannose densities (e.g., 6 mol %), about 60−70% of the cells were fluorescent, irrespective of the liposome concentration (10−200 nmol/mL). For the same mannose content, the behavior of the Man_2-liposomes was very different (Figure 2). Thus, about 20−40% of the cells were already fluorescent at a low dimannose density (2 mol %); moreover, the number of positive cells increased as a function of the concentration of liposomes. In the presence of Man_2-liposomes containing a mannose density of 6 mol %, the percentage of positive cells was about 80% regardless of the concentration of liposomes. Related to these points, which indicate that in agreement with literature (*32*−*34*) the mannose density and valency have a major impact on DC targeting, we have shown previously with galactosylated liposomes that lectin−sugar interactions were highly dependent on the surface density of monovalent ligands, with the occurrence of a threshold value of about 5 mol % (*35*). Accordingly, monomannosylated lipids inserted into the outer layer of the targeted liposomes could generate above a critical concentration—via lateral diffusion—a multivalent platform which adopts a favorable arrangement for high-affinity interaction with the MR receptor (*36*).

Incubation of iDCs with plain and Man_4-liposomes (6 mol % mannose) was performed at 4 °C (to determine binding) and 37 °C (to evaluate binding and endocytosis). For plain liposomes, after 2 h of incubation, only low levels of cell-associated fluorescence were observed (<10% of positive cells, Figure 1A) and no significant difference was found between 4 and 37 °C (data not shown). For the targeted liposomes, with concentrations varying from 0 to 330 nmol of phospholipids/mL, a low saturable binding was observed at 4 °C, reaching 600 MFI for the highest vesicle concentration; in contrast, at 37 °C, no saturation was found and a value of 1270 MFI was reached at the highest concentration used (data not shown). These results suggest that under our conditions the cell-associated fluorescence measured at 37 °C is predominantly due to vesicle uptake via endocytosis.

To demonstrate the specificity of the interaction of the targeted liposomes with mannose receptors (most likely the MR) present at the surface of DCs, we have performed competition experiments in the presence of free mannan. At a concentration of 10 μg/mL, mannan substantially inhibited the uptake of Man_1-liposomes (Figure 2A), indicating that these vesicles were predominantly endocytosed by DCs via a mannose-specific receptor. Inhibition of the uptake of constructs containing multivalent mannosyl ligands required, however, much higher mannan concentrations (up to 1 mg/mL) (data not shown). This observation confirms the occurrence of increased binding affinities resulting from multivalent interactions that are triggered by clustering effects (*32*−*34*).

In Figure 3, the cell-associated fluorescence was measured and reported in picomoles of phospholipids (PL) associated to iDCs as a function of nanomoles of PL/mL for the Man_4-liposomes. Increasing the concentration of targeted liposomes from 50 to 600 nmol of PL/mL resulted in an increase of fluorescence associated to iDCs regardless of the ligand density used (2−16 mol % mannose). Consequently, in this vesicle concentration range no uptake saturation could be observed during the 30 min of incubation. Furthermore, Figure 3 indicates that the optimal tetramannose density for liposome association with iDCs is reached around 6−8 mol %.

Cytotoxicity of Clodronate-Loaded Mannosylated Liposomes. Clodronate, a small hydrosoluble and cytotoxic molecule, does not readily enter cells. However, when encapsulated into liposomes, this drug was shown previously to be delivered intracellularly and this formulation was used extensively to selectively deplete mononuclear phagocytic cells such as macrophages (*37*). Under our experimental conditions, free clodronate was indeed found to become cytotoxic for iDCs at only very high concentrations, with an $IC_{50} \approx 2$ mM (data not shown). However, and in sharp contrast with macrophages, when human monocyte-derived iDCs were incubated for 48 h with clodronate encapsulated in plain liposomes, no toxicity could be detected in the concentration range tested (0−40 μM of clodronate) (data not shown). As already noted above (Figure 1A), this observation might be related to a lower ability of dendritic cells, compared to macrophages, to spontaneously capture particles either by phagocytosis or endocytosis (*38*) and consequently to a decreased intracellular delivery of the cytotoxic drug. Related to that latter point, macrophage depletion experiments have generally been performed with larger liposomes, i.e. 200−300 nm vs 70 nm in this study, and thus with a higher clodronate load; moreover, macrophages are also known for a great intrinsic sensitivity to the effect of this drug (*39*).

In sharp contrast, however, iDC viability was highly affected by clodronate entrapped in targeted liposomes (Figure 4). Thus, incorporation of our synthetic mono-, di-, and tetramannosylated lipids into clodronate-loaded liposomes was able to dramatically enhance the uptake of the vesicles by iDCs and, consequently, the cytotoxicity of the drug. Moreover, and in line with observations made above, the clodronate study confirmed that Man_1-liposomes were efficient only at the highest mannose density (6 mol %). Interestingly, at constant drug concentration, the cytotoxicity of liposomal clodronate increased with the density of the mannose residues present at the surface of the targeted vesicles and also with the valency of the branched mannosylated lipids, for Man_1 and Man_2 but not for Man_4 (Figure 4). It is possible that the dimannosyl lipid could cluster on the surface of the liposome in a topology as favorable for a multivalent interaction with the receptor as the tetramannosyl ligand.

As shown in Figure 4, a clodronate dose-dependent increase of toxicity was only observed with Man_1-liposomes (at 2 and 6 mol % mannose) and with multibranched lipids at low mannose densities (e.g., 2 mol %). With the di- or tetramannosylated lipids at the highest mannose density used (i.e., 6 mol %), very high toxicities were observed at already very low clodronate concentrations. The higher affinities of the multivalent constructs were confirmed by the competition studies with mannan. Thus, about 100-fold higher concentrations of the polysaccharide were needed to inhibit the interaction uptake of the multivalent-targeted liposomes with the DCs compared to Man_1-liposomes.

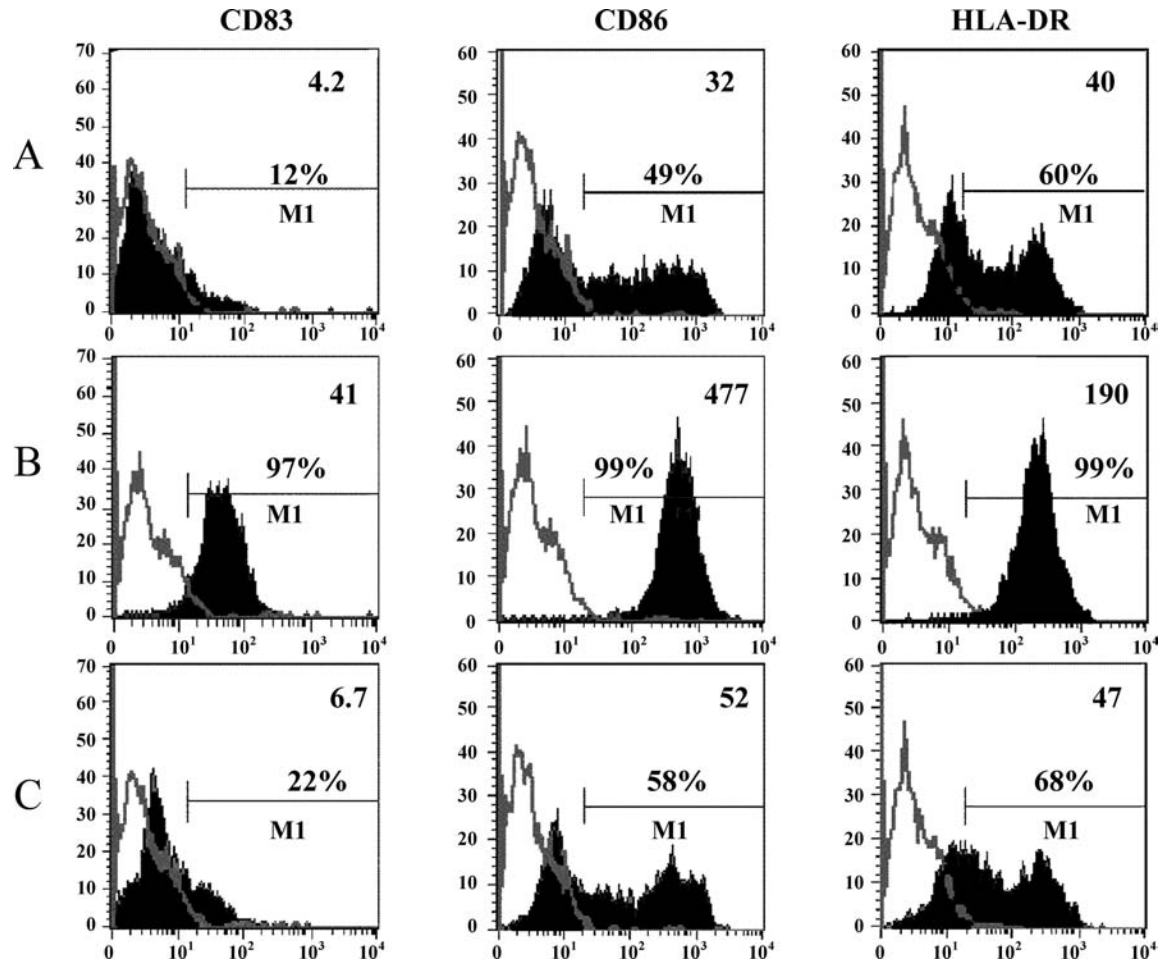

Figure 5. Absence of phenotypic maturation of human iDCs incubated in the presence of Man_4-liposomes. Monocytes maintained in culture for 6 days to differentiate into dendritic cells were cultured for an additional 24 h in the absence of stimuli (A) or in the presence of 1 μg/mL LPS (B) and Man_4-liposomes (200 nmol of phospholipids/mL. (C) Cells were stained with PE-conjugated Abs specific for the marker indicated (filled histogram) or an isotype-matched color Ab (thick gray line). Values indicated on histograms (M1) are the percentage of positive cells of the cells stained with the marker-specific Ab. In the right upper corners, the mean fluorescence intensities (MFI) are indicated. The results represent a single experiment with the same donor and are representative of five experiments that gave similar results: (A) untreated cells; (B) cells incubated with 1 μg/mL LPS; (C) cells incubated in the presence of Man_4-liposomes (6 mol % mannose). Compared to control cells (A), the presence of LPS as maturation agent, lead to a significant increase of surface markers ($p < 0.01$ at least for the three markers) while no significant modification of marker levels was observed ($p > 0.05$ for the three markers) for the cells incubated in the presence of Man_4-liposomes (C).

These results are in agreement with the ability of multivalent branched constructs to bind with increased affinity with the CRD (carbohydrate recognition domains) of the MR (*33*).

Several C-type lectins that recognize mannosyl moieties have been identified on the surface of human monocyte-derived DCs, such as MR and DC-SIGN (*14*). Whereas DC-SIGN binds internal mannose residues of linear N-linked oligosaccharides, MR shows a greater affinity for the terminal sugars in branched structures (*40*). We can thus hypothesize that the uptake of clodronate-loaded mannosylated liposomes via endocytosis is probably mediated by MR, although additional experiments would be necessary to prove this point.

The conclusions reached with the present studies corroborate the results obtained above with flow cytometric analysis of the fluorescence associated with iDCs after incubation with 5(6)-carboxyfluorescein loaded liposomes. A dramatic increase of fluorescence was thus observed for the targeted Man_1- and Man_2-constructs when the mannose surface density was increased from 2 to 6 mol % (Figure 2).

Taken together, our results indicate that the nontargeted liposomes used in our study are poor vectors to deliver nonpermeant molecules, such as clodronate, into iDCs. This diverges with the known uptake of plain liposomes by phagocytic cells used for the treatment of intramacrophage pathogens (*41, 42*). In contrast, however, targeted liposomes designed to interact with the mannose receptors present at the surface of DCs proved to be excellent carriers. In this respect, we have shown that the relatively simple diantennary mannosylated, when incorporated into liposomes, was as efficient as the more complex tetraantennary lipid. This might be explained by the ability of the diantennary ligand to engage into multivalent/multidentate interactions, favored by lateral diffusion at the surface of the vesicle. Importantly, this observation will simplify the chemical approach for the design of such targeted liposomes.

Activation/Maturation of Immature Dendritic Cells. DCs are capable of evolving from antigen-capturing cells (immature) to antigen-presenting cells (mature). This maturation, which represents a major step in the initiation of an immune response (*3*), would be of great interest if it could also be triggered by vaccination constructs. Related to this point, some studies have hinted that mannosylation of antigens might represent an effective means of triggering the maturation and enhancing the functional capacity of DCs *in vitro* (*43*). We were consequently interested in the evaluation of the impact of our mannosylated molecules, incorporated into liposomes, on the maturation of human iDCs.

Most typical features of immature dendritic cells were obtained after culturing monocytes for 6 days (Figure 5A, upper

row). DC maturation is accompanied by the expression of CD83 and the up-regulation of CD80 and CD86. After treatment of iDCs for 24 or 48 h with mannosylated liposomes, the levels of surface markers were determined and compared with those induced by LPS (1 mg/mL), used as a maturation control (Figure 5B, middle row). As shown in Figure 5C (lower row), the incubation of iDCs with Man_4-liposomes (6 mol %) did not induce any significant change ($p > 0.05$) in the phenotypic expression of surface markers typical of immature cells. Levels of MHC-II and costimulatory molecule CD86 did not change (Figure 5). Similar results were obtained for plain liposomes (data not shown).

We can conclude that, whereas the role of MR in antigen uptake is well documented (*44*, *45*), the suggestion that this receptor might also be endowed with signaling functions (*46*), resulting in DC maturation and activation, still needs solid experimental proof (*40*). A similar lack of dendritic cells' activation has been observed previously with other mannosylated liposomes prepared with branched trimannoside structures (*18*, *24*). However, as suggested before, immune responses generated by antigen delivery through mannosylated constructs might also need additional signals provided, for example, by TLR agonists (*47*−*49*).

CONCLUSION

Mannosylated liposomes are highly valuable vehicles to specifically deliver drugs or antigens to cells such as DCs, and this strategy shows great promise in the design of vaccines (*24*, *50*). Although monovalent mannosyl ligands, when inserted above a certain threshold in the bilayer of liposomes, can yield good interactions with mannose receptors, multivalent ligands that have higher affinities in accordance with the cluster effect, are more efficient for targeting. In this respect, the observation made in the present study that di- and tetraantennary ligands, when exposed at the surface of clodronate-loaded liposomes, exhibited similar cell delivery efficiencies with iDCs, is of practical value from a chemical standpoint. Indeed, the synthesis of a diantennary mannosyl ligand such as the one illustrated in Scheme 1 is much more straightforward than the tetraantennary equivalent. Based on the present work, we have recently applied with success the *in vivo* targeting to DCs of antitumor vaccination constructs (*51*) that codeliver MHC-I/II peptide epitopes and immune response activators such as TLR ligands (J.-S. Thomann et al., to be published).

Investigation of Insulin Loaded Self-Assembled Microtubules for Drug Release

Marsiyana M. Henricus, Karen T. Johnson, and Ipsita A. Banerjee*

Department of Chemistry, Fordham University, 441 East Fordham Road, Bronx, New York 10458. Received June 25, 2008; Revised Manuscript Received September 22, 2008

Self-assembled microtubules were used to entrap insulin for the preparation of new drug delivery devices. The interactions of insulin with the microtubules were probed by circular dichroism, zeta potential analysis, as well as FTIR spectroscopy. The morphologies of the insulin-loaded tubules were examined by AFM and TEM. We found that insulin loading was both pH- as well as concentration-dependent. The circular dichroism analysis indicated that, at pH range 6−7, the conformation change in the presence of the microtubules was minimal and hence would be the most appropriate conditions for insulin loading. The entrapment efficiency and release of insulin was found to be pH-dependent. Further, the controlled drug release studies indicated that, under acidic conditions, insulin release was extremely slow, and it is likely that the insulin is protected inside the microtubules. Thus, the microtubules may potentially protect the insulin from aggregation and release at lower pH (gastric pH) *in vivo*. However, at pH 6.5 (closer to intestinal pH) a sustained release was observed. Such new materials may inhibit the aggregation of peptides under suitable conditions and potentially be used for drug delivery, in particular, for other peptide-based drugs.

INTRODUCTION

Over the past several years, attention has been focused on research related to the development of nanomaterials for numerous applications such as biosensors, optoelectronics, catalysts, and drug delivery systems (*1*−*4*). In addition to their small size, nanomaterials can be altered to facilitate attachments to specific components, in order to improve biocompatibility and allow for more accurate intracellular and intercellular targeting (*5*−*7*). Nanoparticles consisting of polymers, ceramics, metals, as well as biological materials have been constructed to form various types of structures that offer unique characteristics to aid drug delivery (*8*−*11*). Many of the polymeric nanoparticles that have been developed are biodegradable, preventing the accumulation of the nanoparticles in the body in addition to ensuring the constant drug release over a period of time. Soft delivery systems such as surfactant micelles, liposomes engineered from phospholipids, and vegetable oil based materials have also been used to carry various types of biological materials and lipophilic drugs. In lieu of this, several lipid formulations have been developed to transport protein drugs and allow for their sustained release (*12*−*22*).

A rapidly growing drug delivery approach is the use of microtubules and nanotubes because of their large relative internal volumes, which can be functionalized on the internal and the external surface. Self-assembled lipid microtubes and carbon nanotubes (CNTs) have been utilized as drug delivery agents (*23*−*27*). Nanotubes and microtubules self-assembled from peptide bolaamphiphiles exhibit several properties that make them promising biomaterials, including facile self-assembly in aqueous solutions, biocompatibility, and ability to be functionalized (*28, 29*). For example, self-assembled peptide nanotubes have been used to immobilize enzymes such as lipase, which upon immobilization showed improved stability (*30*).

In this work, the peptide drug, insulin, was entrapped within self-assembled peptide microtubules. Insulin is an important hormone for the regulation of blood glucose levels and is implicated in diseases such as Diabetes type I and type II (*31*). Aggregation of insulin and consequent precipitation has been a major barrier to the development of long-term delivery methods for insulin (*32, 33*). Many methods have been used to protect insulin and other peptide drugs from physical inactivation, such as the addition of stability-enhancing additives, surfactants, and phenols (*34, 35*). Nanomaterials such as poly(alkyl cyanoacrylate), PLGA, poly(vinyl alcohol) gel spheres, hydroxypropyl methylcellulose phthalate microspheres, Eudragit L100 microspheres, and poly(γ-glutamic acid) nanoparticles shelled with chitosan have been functionalized with insulin for purposes of drug delivery (*36*−*40*). It is well-known that dicarboxylic amino acids have been successfully used to prevent agitation-induced aggregation in insulin (*41*). However, the rich potential of self-assembled tubular assemblies formed from synthetic amino acid bolaamphiphiles (two amino acid head groups connected by a hydrophobic tail group) for diminution of aggregation, entrapment of insulin, and preparation of a potential drug delivery device is yet to be explored. Here, we have examined highly biocompatible microtubules self-assembled from bis(*N*-α-amidotyrosyl-tyrosyl-tyrosine)-1,5-pentane dicarboxylate for controlled drug release of insulin. The main objective of the present study was to examine the interactions of insulin with the microtubule, determine entrapment efficiency, and study their release behavior. Such materials may potentially be useful for the encapsulation of other peptides and drugs and promote longer circulation times *in vivo*.

EXPERIMENTAL SECTION

Materials. 1-Hydroxy-benzotraizole hydrate, Tyr-Tyr-Tyr-methyl ester, DMF, EDAC (dimethylaminopropyl-*N*-ethylcarbodiimide hydrochloride), chloroform, methanol, TEA (triethyl amine), $NaHCO_3$, NaOH, HCl, and insulin from Porcine pancreas (≥27 USP units/mg) were purchased from Sigma Aldrich. Phosphate buffer solutions of various pH values were

prepared, and the pH was adjusted by adding either HCl or NaOH as required; Brillant Blue G-250, 95% ethanol, and phosphoric acid were purchased from Fisher Scientific. All chemicals were used as received.

Methods. *Growth and Self Assembly of Microtubules.* The bolaamphiphile was synthesized and self-assembled according to previously established methods (*28, 29, 42*). Briefly, the bis(*N*-α-amido-tyr-tyr-tyrosine)-1,5-pentane dicarboxylate (8 mM) was self-assembled into microtubules at pH 5 over a period of two weeks. The assembled tubules were then sonicated, washed, and centrifuged twice at 4000 rpm for 3 h before incorporation of insulin.

Preparation of Insulin-Loaded Microtubules. Various concentrations of insulin in the range of 0.1 mg/mL to 2 mg/mL were incubated with the microtubules for a period of 72 h at 4 °C while mildly agitating the samples. The samples were then centrifuged and washed twice with nanopure water to remove any un-entrapped insulin. In order to determine the optimum pH for entrapment of insulin, the experiments were carried out in the pH range 4−10.

Measurement of Entrapment Efficiency. The amount of insulin loaded into the peptide microtubules was determined by measuring the difference between the total amount of insulin added into the peptide microtubules and the amount of unloaded insulin present in the supernatant after the loading process. In general, a concentration of 0.5 mg/mL of insulin was used in order to carry out the entrapment efficiency studies. The studies were carried out in varying pH, to determine the effect of pH on the loading capacity. The loaded microtubules (500 μL) were centrifuged at 4500 rpm at 4 °C for 5 h, and then the amount of free insulin in the clear supernatant was measured by the Bradford method (*43*). The entrapment efficiency was calculated using the following equation: $(X_1 - X_2/X_1) \times 100\%$, where X_1 is the concentration of the amount of insulin and X_2 is the concentration of the unloaded insulin. Therefore, entrapment efficiency of insulin in microtubules

$$= \frac{\text{total amount of insulin used} - \text{free insulin in supernatant}}{\text{total amount of insulin used}} \times 100 \quad (1)$$

Drug Release Studies of Insulin. The insulin-loaded microtubules (formed at pH 6) were washed and centrifuged thoroughly before conducting the release studies. In order to determine the pH effect on the release studies of insulin from the microtubules, we investigated the release of insulin at varying pH. Insulin-loaded microtubules (500 μL) were added to 1.5 mL of respective buffer solutions (pH 4−10) and the amount of insulin released was measured via the Bradford method. Measurements were carried out for a period of 5 h at 37 °C. All measurements were carried out in triplicate.

Characterization. *Circular Dichorism (CD) Spectroscopy.* CD measurements were carried out using a JASCO J-720 spectropolarimeter. Samples were scanned at least five times at the rate of 200 nm/min with a 0.5 nm step, 1 nm bandwidth, and then averaged. The path length of the quartz cell was 2 mm. In the experiments, a blank run made with buffer alone was subtracted from the experimental spectra for correction. The 190−250 nm spectra were used for analysis. All the spectra were smoothed and converted to the mean residue ellipticity $[\theta]$ in deg*cm^2/dmol.

FTIR Spectroscopy. In order to confirm the incorporation of insulin onto the microtubules, FTIR analyses were performed using Matteson Infinity IR equipped with DIGILAB, ExcaliBuv HE Series FTS 3100 software. The samples were dried at room temperature and mixed with KBr to make pellets and then analyzed. All spectra were taken at 4 cm^{-1} resolution with 50 scans taken for averaging. Sample measurements were carried between 400 and 4000 cm^{-1}.

Absorbance Spectroscopy. To determine the protein concentration using the Bradford method, absorbance measurements were carried out at λ_{max} of 595 nm using a Varian Cary 3 UV−visible spectrophotometer. Samples were diluted with appropriate amounts of buffer or nanopure water.

Zeta Potential Analysis. A NICOMP 380 ZLS zeta potential/particle sizer system (Santa Barbara, CA) was used to determine the zeta potential of the samples. Measurements of ζ-potential of the samples were carried out at 25 °C and at varying pH. The concentrations of the suspensions were adjusted within the operational limits of the instrument, and the suspension pH was adjusted by the addition of standard buffer solutions. The reported ζ-potential values are the average of at least five measurements (spread of values ± 5% of the reported mean values).

Atomic Force Microscopy. Atomic force microscopy was carried out using a Quesant Universal SPM Instrument by the tapping mode in air using a silicon nitride cantilever.

Transmission Electron Microscopy (TEM). The morphologies of the samples were analyzed by TEM (JEOL 120 EX) operated at 100 kV. Samples were washed twice and air-dried on carbon-coated copper grids before analysis.

RESULTS AND DISCUSSION

The microtubules were self-assembled in aqueous solution at pH 5. Both hydrogen bonding interactions between the amide and carboxyl groups as well as the hydrophobic interactions allowed for the facile self-assembly of the bolaamphiphile. The microtubules formed via self-assembly at room temperature within a period of two weeks. Details of the self-assembly of the microtubules are described elsewhere (*29*). A TEM image of a self-assembled microtubule before entrapment of insulin

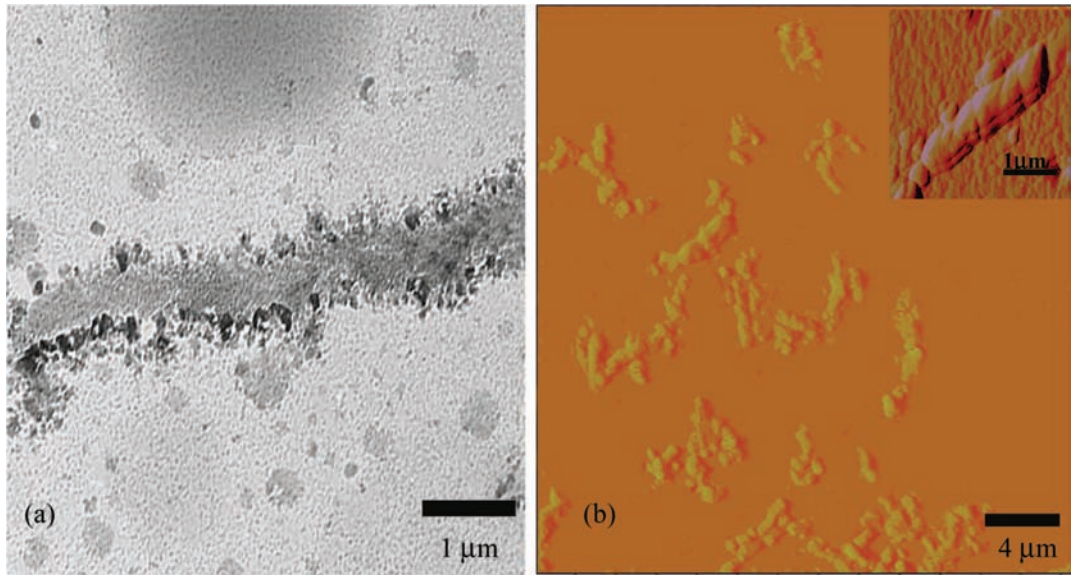

Figure 2. (a) TEM image of insulin-coated microtubules on the outside wall, at 1 mg/mL concentration of insulin. (b) AFM amplitude image of insulin-coated microtubules. Inset shows a single coated microtubule in the presence of a high concentration of insulin (1 mg/mL).

is shown in Figure 1a. The morphologies of the tubules after incorporation of insulin were examined by transmission electron microscopy and atomic force microscopy. On an average, we used tubules with an inner diameter of 500 nm to entrap the insulin. In order to determine optimum conditions for incorporation of insulin, it was incubated with the microtubules at varying pH for different periods of time. The concentration of insulin was also varied. By and large, we observed that, after 72 h, insulin was entrapped within the microtubules. The results obtained indicate that the incorporation of insulin was found to be not only pH-dependent but also concentration-dependent. At concentrations between 0.5 mg/mL and 0.6 mg/mL, at a pH range between 4 and 7, after incubation for 72 h, insulin was entrapped inside the microtubules. Figure 1a shows the TEM image of a microtubule before incubation with insulin. Figure 1b shows the TEM image of a microtubule after incubation for 72 h at pH 6 when the sample was incubated with 0.2 mg/mL insulin, while Figure 1c shows the TEM image of a microtubule where in the insulin is uniformly encapsulated after 72 h at pH 6 in the presence of 0.5 mg/mL insulin. As shown in figures 1b and 1c, the insulin appeared as darker areas in the microtubules (*44*). We also observed that, at higher pH, insulin tended to form aggregates and was not incorporated uniformly within the microtubules even at low concentrations (data not shown). At higher concentrations (between 0.8 mg/mL and 2 mg/mL), the insulin bound to the outside surface of the microtubules as well (Figure 2). The TEM image of insulin−microtubule (Figure 2a) shows the incorporation of insulin within the microtubules as well as formation of aggregates on the outside walls of the tubules. Those studies were also carried out after 72 h. The concentration of insulin used therein was 1 mg/mL. Figure 2b shows the AFM image of insulin-coated microtubules at pH 6, when the samples were incubated with 1 mg/mL of insulin. The inset shows a single microtubule, whose outside walls are coated with insulin. Thus, at lower concentrations, it appears that the inside loading mechanism of insulin may be similar to incorporation of nanoparticles via capillary effect as observed in previous work where the trends were similar (*45*, *46*), while at higher concentrations, they tend to adsorb onto the outside walls of the microtubules as well. Although the exact mechanism of entrapment of insulin is not clear yet, it is likely that, as the microtubules are exposed to the insulin solution, it diffuses inside due to a concentration gradient as well as due to capillary action. Hydrophobic interactions between the tyrosines of the

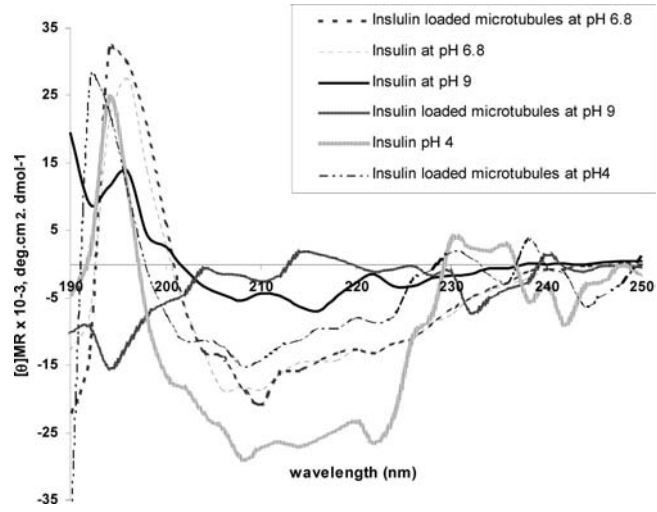

Figure 3. Comparison of CD spectra of insulin and insulin-loaded microtubules at varying pH.

bolaamphiphiles and the hydrophobic residues of insulin may also be involved. In addition, electrostatic interactions and hydrogen bonding also play a critical role.

Circular Dichroism. The conformational changes of insulin upon association with microtubules was evaluated using CD spectroscopy. Figure 3 indicates the CD spectra obtained in the presence and absence of microtubules under different pH conditions. At pH 4, the CD spectrum of insulin shows negative ellipticity at 208 and 222 nm as well as a positive band with a maximum at 192 nm. These peaks are indicative of typical α-helical structure (*47*). After incubation with the microtubules, however, there is a decrease in the negative ellipticity at 222 nm as well as 208 nm. This decrease in intensity upon binding is indicative that there is a reduction in the α-helical content; further, this indicates that interaction of insulin with microtubules at pH 4 may result in partial unfolding of the protein structure. Increasing the pH to 6.8 showed a reduction in the α-helical content of insulin by itself compared to that observed at pH 4; however, when bound to the microtubules, we did not observe significant changes in the secondary structure, except that there is a shift in the negative ellipticity band from 208 to 206 nm and a reduction in the intensity of the positive maxium

Table 1. Zeta Potential Analysis Comparison of Insulin Loaded Microtubules

pH	Zeta Potential of Microtubules (mV)	Zeta Potential of Insulin-Loaded Microtubules (mV)
pH 4	5.96	6.22
pH 5	5.51	6.72
pH 6	1.24	2.19
pH 7	0.18	2.17
pH 9	−1.81	−1.69

observed at 194 nm. At pH 9, however, upon incorporation of the microtubules, the protein seems to undergo unfolding, forming a random coil like structure, with a negative ellipticity band at 194 nm, and its structure is significantly different from that observed for insulin by itself in solution at pH 9. Also, at pH 9, the α helix content of insulin appears to be significantly less than that observed at lower pH and the CD spectrum becomes one that is more typical of that observed for β-sheet structures, characterized by a minimum in the ellipticity at 216 nm and a maxima at 196 nm. This trend is similar to previous observations of insulin CD studies (*48*). These studies indicate that the optimum pH for entrapping insulin within the microtubules would be around pH 6−7, as the conformation change was relatively minimal under those conditions.

Zeta Potential Analysis. The pH dependence on the ζ-potential of the tubules before and after entrapment of insulin is shown in Table 1. We observed that the ζ-potential of insulin-entrapped tubules was slightly higher compared to those of the tubules by themselves. Although changes in the ζ-potential are evident, no drastic changes were observed, which indicate that insulin was encapsulated within the tubules and not adsorbed on the outside as well. This effect is similar to those observed in the case of polymeric nanocapsules, wherein ζ-potential changes were negligible upon encapsulation (*49*). We observed that under basic conditions the ζ-potential of the insulin−tubules remained negative. Since the isoelectric point of insulin is 5.5, above its pI, insulin becomes negatively charged, resulting in favorable electrostatic interactions between microtubule and insulin and increased loading up to pH 7. At basic pH, the negatively charged insulin would have less attraction toward the negatively charged microtubules, resulting in significantly less incorporation of insulin due to the presence of deprotonated residues of insulin as well as the COO^- groups of the microtubules.

Infrared Spectroscopy. In order to confirm the incorporation of insulin, the samples were also analyzed by FTIR spectroscopy. Figure 4 shows the comparison of IR spectra of insulin and insulin-loaded tubules obtained at pH 6, when 0.5 mg/mL concentration of insulin was used. In the insulin-loaded tubules, peaks at 1293 cm^{-1} and 1269 cm^{-1} due to the C−O stretching vibrations are slightly blue-shifted compared to those observed for insulin at 1286 cm^{-1} and 1261 cm^{-1} due to C−O−H hydrogen bonding interactions (*50, 51*) between the microtubules and insulin. Peaks at 1487 cm^{-1} due to C═C aromatic stretching vibration seen in insulin are shifted to 1485 cm^{-1} in the insulin-loaded tubules. This peak is further shifted from the weak C═C aromatic stretching peak observed for the microtubules by themselves at 1492 cm^{-1} due to the presence of the tyrosine moieties in the microtubules. Peaks at 1592 cm^{-1} and 1569 cm^{-1} due to the amide N−H (1°-amide) II band and N−H (2°-amide) II band observed in the case of insulin-loaded microtubules are also blue-shifted to a small extent compared to those of insulin at 1590 cm^{-1} and 1567 cm^{-1}, respectively. Characteristic asymmetric stretching due to COO^- occurring in the region 1410−1460 cm^{-1} and a small peak at 1562 cm^{-1} are seen due to the amide II N−H bend of the microtubules. In the case of insulin alone (Figure 4a), an intense peak is observed at 1659 cm^{-1}, which is attributed to the amide I stretching

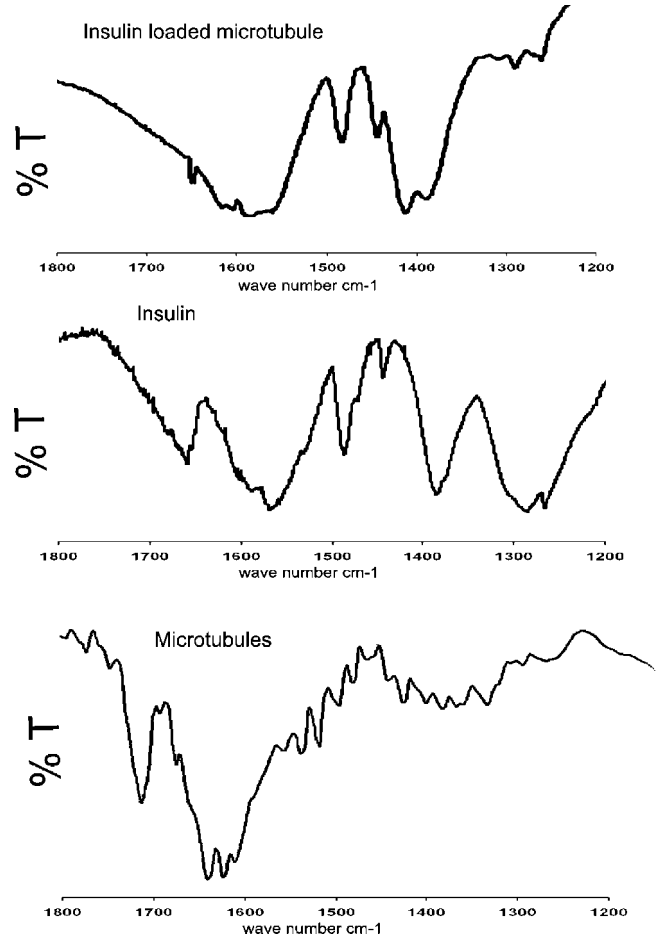

Figure 4. Comparison of FTIR spectra of insulin-loaded microtubules, insulin, and microtubules.

vibration and typical for α-helix conformation (*52*). This peak is also seen in the case of insulin-loaded tubules at 1652 cm^{-1}, though less intense due to interactions with the tubules indicating that the conformation of insulin is relatively similar in the microtubules. Overall, the broad peak centered around 1620 cm^{-1} for the insulin-loaded microtubules is mostly due to the combined contributions of both insulin and the microtubules, particularly the amide I C═O stretches (free and H-bound) at 1654 $cm^{-1}$and 1639 cm^{-1}, as well as the carboxylate peak at 1721 cm^{-1} of the microtubules. No distinct peak at 1721 cm^{-1} is observed for the insulin-loaded microtubules, indicating the involvement of COOH−HOOC interactions with insulin. It is to be noted that similar shifts were observed in the case of pH 4 samples as well (data not shown). These results further confirm that the insulin was loaded in the microtubules.

Entrapment Efficiency and *in Vitro* Release Behavior of Insulin Microtubules. The drug carrying capacity or entrapment efficiency of delivery systems is vital when determining the efficacy of a particular system. The entrapment efficiency of insulin within the microtubules was examined at various pH. The concentration of insulin was kept constant at 0.5 mg/mL, and the amounts of insulin encapsulated at various pH were calculated. As expected, the entrapment efficiency was found to be pH-dependent. This effect is shown in Figure 5. It was observed that the entrapment efficiency was highest in the pH 6−7 range At pH 6.8, the entrapment efficiency was found to be 80.5%, which was calculated to be 0.382 mg/mL. Subsequently, the entrapment efficiency became less at basic pH. It is most likely that there is charge repulsion between the deprotonated carboxylate groups of the microtubules and deprotonated amino acids of insulin at basic pH, leading to lesser

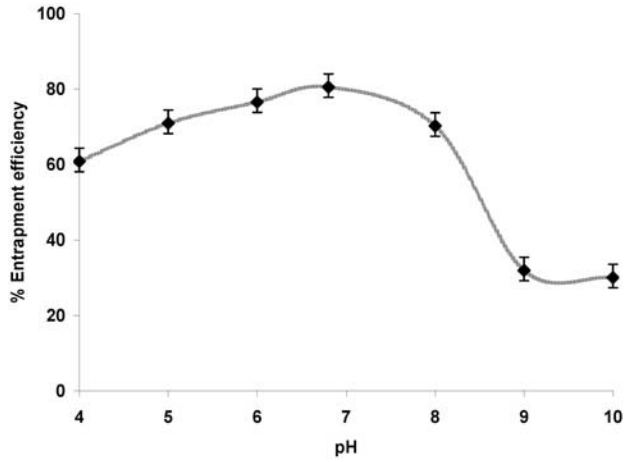

Figure 5. Effect of pH on the entrapment efficiency of insulin in the microtubules.

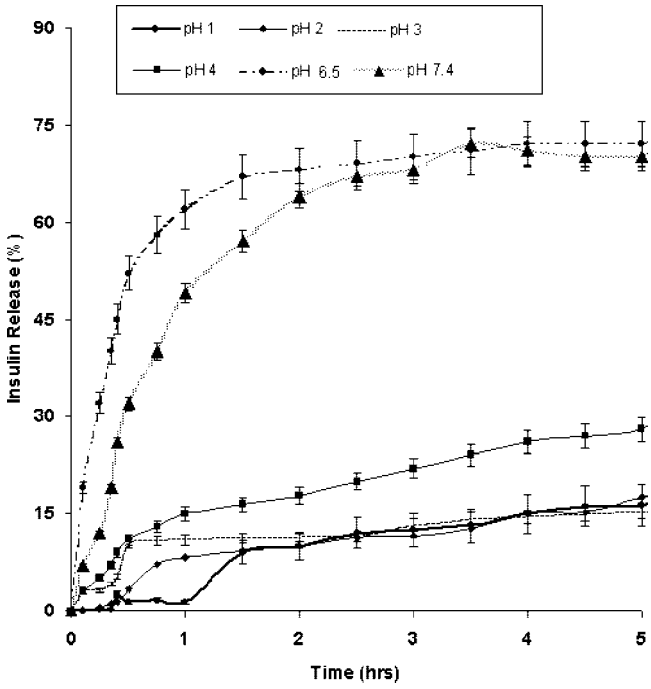

Figure 6. Effect of pH on the *in vitro* release of insulin from microtubules.

entrapment efficiency. Further, at higher pH, insulin tends to aggregate, making it more difficult for incorporation into the microtubules. A key benefit of this process is that insulin loading can be accomplished without the use of organic solvents or the addition of external additives.

The release of insulin was studied over a period of 5 h at 37 °C at varying pH. The *in vitro* release profiles of insulin from the microtubules at different pH are shown in Figure 6. In general, some of the drawbacks of peptide drugs include degradation in the stomach and inactivation by proteolytic enzymes in the luminal cavity. In order to mimic the conditions in the stomach, we studied the insulin release patterns at low pH (pH 1−3). We observed that, at low pH, the release was significantly slower, whereas a sustained release pattern was obtained at a pH of 6.5 (closer to the conditions in the duodenum). At pH 7.4 (closer to conditions at ileum), we observed a similar trend as that observed at pH 6.5, although the initial release was relatively faster. Overall, the release pattern of insulin was found to be pH-dependent and was characterized by an initial rapid release during the first hour (for pH 6.5 and 7.4) followed by a relatively sustained release. It appears that insulin release takes place via disassociation of insulin from the microtubules. At low pH, the dissociation of insulin is relatively less as the microtubules are highly protonated, and the strong hydrogen bonding interactions may allow for less insulin to be released. As the pH is increased, the release of insulin increases. Although *in vivo* conditions may vary, the microtubules appear to have higher insulin retention capacity at low pH, and thus, it is likely that under acidic conditions (for example, in gastric environment) the insulin may be protected inside the microtubules and may be more likely to release at intestinal pH (pH 6−7) where the absorption and action of the drug are necessary. Such materials may be applicable for insulin drug delivery systems. In order to further improve the conformational stability of the insulin within the microtubules while optimizing their delivery, future work will involve spray freeze−drying the insulin-loaded microtubules. The rapid freezing of the insulin-loaded microtubules may prevent phase separation of the drug, thwart crystalline growth in frozen water, and result in a more stable insulin delivery system. Further *in vivo* studies are ongoing and will be published separately.

CONCLUSIONS

In this work, we have utilized self-assembled microtubules formed from the peptide bolaamphiphile bis(*N*-α-amidotryosyl-tyrsol-tyrosine)-1,5-pentane dicarboxylate for entrapment of insulin. The interactions of insulin with the self-assembled microtubules were probed by circular dichroism, zeta potential analysis, as well as FTIR spectroscopy. The morphologies of the insulin-loaded tubules were examined by AFM and TEM. We found that insulin loading was both pH as well as concentration-dependent. The circular dichroism analysis indicated that, at pH 6−7, the conformation change upon interaction with microtubules was relatively minimal and hence would be the most appropriate conditions for insulin loading. The entrapment efficiency and release of insulin was found to be pH-dependent. Further, we also carried out controlled drug release studies, which indicated that, under acidic conditions, the insulin release was extremely slow, and it is likely that the insulin is protected inside the microtubules. However, at pH 6.5−7.4, a sustained release pattern was observed.

ACKNOWLEDGMENT

The authors thank Dr. Areti Tsiola at the Queens College Core Facilities Center for Biomolecular imaging for the use of the transmission electron microscope and Ed Nieves at the Albert Einstein School of Medicine for the use of the Circular Dichroism spectropolarimeter. Signal Transduction of Hyaluronic Acid−Peptide Conjugate for Formyl Peptide Receptor Like 1 Receptor

Eun Ju Oh,[†] Jung-Wook Kim,[‡] Ji-Hyun Kong,[†] Sung Ho Ryu,[‡] and Sei Kwang Hahn*[,†]

Department of Materials Science and Engineering and Department of Life Science, Pohang University of Science and Technology (POSTECH), Pohang, Kyungbuk 790-784, Korea. Received June 25, 2008; Revised Manuscript Received October 13, 2008

Agonistic and antagonistic peptides for formyl peptide receptor like 1 (FPRL1) receptor have been investigated as novel drug candidates for inflammatory diseases such as sepsis, asthma, and rheumatoid arthritis. In this work, a novel protocol for the synthesis of hyaluronic acid (HA)−peptide (CWRYMVm) conjugate for FPRL1 receptor was successfully developed for further clinical applications of peptide drugs. Aminoethyl methacrylated HA (HA-AEMA) was synthesized by the coupling reaction of tetrabutyl ammonium salt of HA (HA-TBA) and AEMA using benzotriazol-1-yloxy-tris(dimethylamino) phosphonium hexafluorophosphate (BOP) in dimethyl sulfoxide (DMSO). Then, HA-AEMA was conjugated with CWRYMVm in water via Michael addition reaction between methacrylate group of HA-AEMA and thiol group in cysteine. The formation of HA−peptide conjugate was confirmed by ^{1}H NMR and gel permeation chromatography (GPC). The average number of conjugated peptide molecules could be controlled from 5 to 23 per single HA chain. The HA−peptide conjugate showed serum stability longer than four days. *In vitro* signal transduction activity of the HA−peptide conjugate for FPRL1 receptor was confirmed from the elevated levels of phospho-extracellular signal-regulated kinase (pERK) and calcium ion in FPRL1 overexpressing RBL-2H3 cells. The partially decreased biological activity of HA−peptide conjugates by the steric hindrance of HA was recovered after its degradation by hyaluronidase treatment.

INTRODUCTION

The formyl peptide receptor like 1 (FPRL1) receptor is one of the chemoattractant receptors encompassing G protein-coupled seven transmembrane domains. It is mostly expressed in phagocytic leukocytes and stimulates innate immunity, such as chemotactic migration, pro-inflammatory cytokine secretion, and degranulation (*1*). When inflammation and infection occur, chemotactic factors bind to specific heterotrimeric G protein-coupled receptors (GPCRs) such as FPRL1 receptor on the leukocyte surface (*2*). Activation of these receptors leads to directed migration, granule mobilization, and activation of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase (*3*). The reactive oxygen species generated by the oxidase are important for microbial killing and for intercellular signaling in astrocytoma cell lines, neutrophils, monocytes, T cells, and HUVECs (*1*, *3*). Several agonistic and antagonistic peptide sequences for the FPRL1 receptor have been investigated as drug candidates for inflammatory diseases such as sepsis, asthma, and rheumatoid arthritis (*4*−*6*). Trp-Lys-Tyr-Met-Val-DMet (WKYMVm) is one of the widely studied agonist peptides that selectively binds to and activates the FPRL1 receptor in FPRL1 overexpressing RBL-2H3 cells (*4*, *5*). Trp-Arg-Trp-Trp-Trp-Trp (WRWWWW) is an FPRL1 antagonist peptide that down-regulates the activation of FPRL1 by agonistic peptides, resulting in the complete inhibition of the intracellular calcium increase, extracellular signal-regulated kinase activation, superoxide generation, and chemotactic migration of cells toward agonistic peptides (*6*).

Recently, the bioconjugation technology using synthetic and natural polymers like poly(ethylene glycol) [PEG] and hyaluronic acid (HA) has been widely used for the development of various biopharmaceuticals with feasible pharmacokinetic characteristics (*7*). The chemical attachment of PEG to the biopharmaceuticals, such as protein and peptide drugs, has been reported to increase the drug efficacy by reducing renal clearance, decreasing the immunoresponse and alleviating the enzymatic degradation in the body. There are several commercialized PEGylation products, such as Neulasta (pegfilgrastim) by Amgen, Somavert (pegvisomant) by Pfizer, PEGASYS (peginterferon alfa-2a) by Roche, and so on. However, the negative effect of PEGylation has been also reported (*8*, *9*). A repeated injection of PEGylated liposomes has been reported to result in their diminished long-circulating characteristics by a so-called "accelerated blood clearance" (ABC) phenomenon (*8*). In addition, PEGylation of glucagon like peptide - 1 (GLP-1) has been reported to bring about a significant decrease in its cAMP activity (*9*). The branch-type PEGylation with a molecular weight of 43 000 Da caused even greater biological activity loss (*9*). As an alternative to replace the roles of PEG, HA has been investigated as a novel drug carrier for various protein and peptide drugs (*10*−*13*). HA is a natural linear polysaccharide composed of alternating disaccharide units of D-glucuronic acid and *N*-acetyl-D-glucosamine with $\beta(1\rightarrow4)$ interglycosidic linkage (*10*). HA is the only nonsulfated glycosaminoglycan (GAG) which is abundant in synovial fluid and extracellular matrix (ECM) (*10*). The fact that HA molecules from different sources have the same primary structure explains the molecular basis for its natural biocompatibility (*14*). HA plays important roles in the regulation of cell behavior including cell migration and proliferation (*15*−*18*). CD44 (*19*), RHAMM (*15*, *20*), and LYVE-1 (*21*) have been identified as HA receptors. Because of the various biological functions and unique physicochemical properties, HA and modified HA have been widely used for drug delivery (*11*, *12*), arthritis treatment (*22*), ophthalmic surgery (*23*), and tissue engineering (*24*). Especially for drug delivery applications, HA with a high molecular weight over 2 million was used for the

sustained-release formulation of human growth hormone (*11*), and selectively cross-linked HA hydrogels were used for the encapsulation of erythropoietin (*12*). HA was also used for the conjugation with active cytotoxic agents, such as paclitaxel (*25*) and doxorubicin (*26*).

In this work, a novel bioconjugation protocol for FPRL1 peptide therapeutics was developed to make them suitable for *in vivo* applications. Bioconjugation of the peptide drug to HA increases its half-life in circulation contributing for a high efficacy. In contrast to PEGylation, HA can be conjugated with various numbers of peptide drug molecules per single HA chain, which enables multiple action of peptide drugs. The peptide drug used in this study was one of the agonistic peptides for FPRL1 receptor with a sequence of WRYMVm. In order to introduce a thiol group to the peptide molecule, cysteine was added to the end of the peptide sequence. Aminoethyl methacrylated HA (HA-AEMA) was newly synthesized in DMSO using the tetra-*n*-butylammonium salt of HA (HA-TBA) and benzotriazol-1-yloxy-tris(dimethylamino)phosphonium hexafluorophosphate (BOP), and *N*,*N*-diisopropylethylamine (DIPEA). CWRYMVm was conjugated to HA-AEMA via the Michael addition reaction between the methacryloyl group of HA-AEMA and the thiol group in cysteine. Michael addition, between electron-poor olefins and nucleophiles such as thiols, has been used for the bioconjugation of various biomolecules (*27*, *28*). The stability of peptide in fetal bovine serum (FBS) was investigated before and after its conjugation to HA. Since the binding of agonistic peptide to FPRL1 receptor induces the elevation of phospho-extracellular signal-regulated kinase (pERK) and calcium ion levels (*1*), the biological activity of HA−peptide conjugates was assessed from the intracellular level of pERK and calcium ion in FPRL1 overexpressing RBL-2H3 cells. RBL-2H3 cells have no FPRL1 showing similar characteristics to the other immune cells with FPRL1. Therefore, FPRL1 overexpressing RBL-2H3 (RBL-2H3/FPRL1) cells are a very good model system to check the FPRL1 downstream signaling such as pERK level.

MATERIALS AND METHODS

Materials. Sodium hyaluronate, the sodium salt of hyaluronic acid (HA), with a molecular weight of 200 000 was obtained from Denkikagaku Kogyo Co. (Tokyo, Japan). Peptide with a sequence of Cys-Trp-Arg-Tyr-Met-Val-DMet (CWRYMVm) was purchased from Peptron (Daejeon, Korea). Dowex 50WX8−40 ion-exchange resin, benzotriazol-1-yloxy-tris(dimethyl-amino)phosphonium hexafluorophosphate (BOP), 2-aminoethyl methacrylate hydrochloride (AEMA), *N*,*N*-diisopropylethylamine (DIPEA), tris(2-carboxyethyl) phosphine hydrochloride (TCEP), trifluoroacetic acid (TFA), and hyaluronidase from *Streptomyces hyalurolyticus* were purchased from Sigma-Aldrich (St. Louis, MO). Tetra-*n*-butylammonium hydroxide (TBA-OH) was obtained from Alfa Aesar (Ward Hill, MA). Dimethyl sulfoxide (DMSO) was obtained from Junsei Chemical Co. (Tokyo, Japan) and acetonitrile from J. T. Baker (Phillipsburg, NJ). Anti-rabbit polyclonal antibody to phospho-ERK was purchased from Cell Signaling Technology (Danvers, MA) and anti-mouse monoclonal antibody to GAPDH from Biogenesis (Poole, UK). Goat anti-rabbit IgG or goat anti-mouse IgG antibody conjugated to horseradish peroxidase was obtained from KPL (Gaithersburg, MD). Double-distilled water was used for the following experiments. All chemicals were used without further purification.

Synthesis of HA-AEMA. Ion exchange resin of Dowex 50WX-8−400 (25 g) was washed with 500 mL of water and filtered to remove the supernatant three times. Then, 1.5 molar excess of TBA-OH (48.9 mL) was added to the Dowex resin and mixed for 30 min. The filtered Dowex-TBA resin was washed with 500 mL of water and filtered again three times. Sodium salt of HA (MW = 200 K, 5 mmol) was dissolved in 200 mL of water, which was poured into the prepared Dowex-TBA (25 mmol) resin. After mixing for 3 h, the supernatant was filtered through 0.45 μm filter and lyophilized for 3 days. The resulting HA-TBA was dissolved in DMSO. Then, BOP, 2-AEMA and *N*,*N*-DIPEA were added to the solution and mixed for a day. Finally, the reaction product was dialyzed against a large excess amount of water and lyophilized for three days. The obtained HA-AEMA was characterized with ^{1}H NMR (NMR, DPX300, Bruker, Germany).

Synthesis of HA−Peptide Conjugates. Agonistic peptide for FPRL1 receptor (CWRYMVm) was dissolved in water. For the reduction of the disulfide bond between peptide molecules, 10-fold molar excess of TCEP as a reducing reagent was added to the peptide solution and mixed for 10 min. HA-AEMA was also dissolved in water. After complete dissolution, the HA-AEMA solution was mixed with the peptide solution. The number of peptide molecules per single HA chain in the feed was 5, 9, 19, 28, and 56, respectively. After the pH of the reaction mixture was adjusted to 8.74 by the addition of 1 N NaOH, the mixed solution was incubated at 37 °C for 16 h. Then, the reaction was stopped by dropping the pH to 7.0 with 1 N HCl. The solution was finally lyophilized for three days. HA−peptide conjugate was purified by fractionation using gel permeation chromatography (GPC). GPC analysis was performed using the following systems: Waters 1525 binary HPLC pump, Waters 2487 dual λ absorbance detector, Waters 717 plus autosampler, Superdex Peptide 10/300 GL column. The eluent was 30 vol % acetonitrile (ACN)/0.1 vol % trifluoroacetic acid (TFA), and the flow rate was 1 mL/min. The detection wavelengths were 210 nm for HA and 280 nm for the peptide, respectively. Three replicates were carried out to assess the average peptide content in HA−peptide conjugate and the bioconjugation efficiency (%).

Quantification of Peptide Content in HA−Peptide Conjugates. A peptide stock solution at a concentration of 1 mg/mL was used to prepare peptide standard solutions with concentrations of 10, 20, 40, 80, 160, and 320 μg/mL, respectively. HA−peptide conjugate solutions were also prepared by dissolving 1 mg of each HA−peptide conjugate sample in 1 mL of water. GPC analysis was carried out as described above. From the peak areas detected at 280 nm, a linear standard curve for peptide was obtained and used for the determination of the amount of peptide in HA−peptide conjugates.

***In Vitro* Serum Stability Test of HA−Peptide Conjugates.** In order to investigate the effect of HA conjugation on the serum stability of peptide, raw peptide and three HA−peptide conjugates were dissolved in 0.5 mL of water and mixed with 0.5 mL of fetal bovine serum (FBS), respectively. In HA−peptide conjugates, the number of peptide molecules per single HA chain was 5, 19, and 33, respectively. Because the peptide was not dissolved in serum completely, 50 vol % serum solution was used for the serum stability test. Then, the solutions were incubated at 37 °C for 96 h. The remaining amount of peptide was measured by GPC analysis after incubation for 12, 24, 48, 72, and 96 h. Three replicates were carried out.

Hyaluronidase Treatment of HA−Peptide Conjugates. In order to investigate the effect of HA conjugation on the signal transduction activity of peptide, three kinds of peptide samples were prepared, the raw peptide, HA−peptide conjugates, and HA−peptide conjugates after hyaluronidase treatment. In the HA−peptide conjugates, the number of peptide molecules per single HA chain was 5, 8, and 23, respectively. Each HA−peptide conjugate sample (0.4 mL, 1 mg/mL) was divided into two aliquots. One aliquot was mixed with 0.2 mL of hyaluronidase solution (400 units/mL), and the other was mixed with 0.2 mL

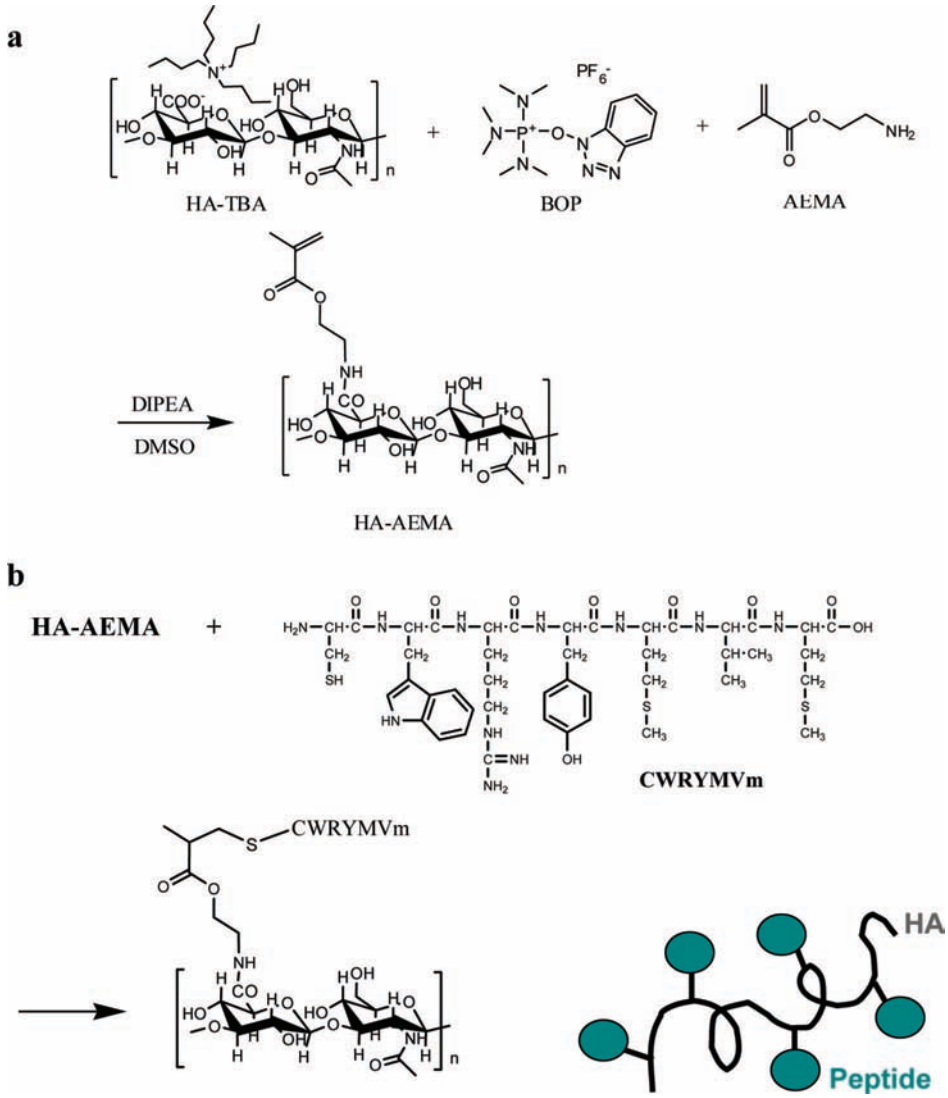

Figure 1. Schematic representations (a) for the synthesis of aminoethyl methacrylated hyaluronic acid (HA-AEMA) using *N*,*N*-diisopropylethylamine (DIPEA) and benzotriazol-1-yloxy-tris(dimethyl-amino)phosphonium hexafluorophosphate (BOP) and (b) for the conjugation of HA-AEMA with the peptide (CWRYMVm) for formyl peptide receptor like 1 (FPRL1) receptor.

of water. Then, the solutions were incubated at 37 °C overnight for the complete enzymatic degradation of HA. Three replicates were carried out for the following bioactivity tests measuring the intracellular level of pERK and calcium ion.

RBL-2H3 and RBL-2H3/FPRL1 Cell Cultures for Western Blot. RBL-2H3 cells and FPRL1 overexpressing RBL-2H3 (RBL-2H3/FPRL1) cells were cultured at 37 °C in a humidified incubator containing 5% CO_2, as described elsewhere (*29*). Dulbecco's modified Eagle's medium (DMEM) was supplemented with 20 vol % heat-inactivated FBS and 200 μg/mL of G418. The cells were subcultured every 3 days.

Stimulation of RBL-2H3/FPRL1 Cells with Peptide Samples. The prepared cells were aliquoted into 1×10^6 cells and stimulated with a control (no treatment), peptide (CWRYMVm), HA-AEMA, the mixture of peptide and HA-AEMA, and three HA−peptide conjugate samples with and without hyaluronidase treatment. For comparison, the peptide content in HA−peptide conjugate samples was adjusted to have the same amount as the peptide sample. The stimulation time varied from 0 to 30 min. After stimulation, the cells were washed with serum-free DMEM and lysed in lysis buffer at pH = 7.4 containing 0.5 M NaCl, 20 mM Tris-Cl, 0.25% Triton X-100, 1 mM EDTA, 1 mM EGTA, 10 mM β-glycerphosphate, 10 mM NaF, 1 mM benzamidine, 10 μg/mL aprotinin, 10 μg/mL leupeptin, 10 μg/mL pepatatin, 1.5 mM Na_3VO_4, 1 mM phenylmethylsulfonyl fluoride (PMSF), and 1 mM DTT. The detergent-insoluble material was pelleted by centrifugation at 12 000 *g* and 4 °C for 15 min, and the soluble supernatant fraction was used immediately or stored at −80 °C before use. Protein concentrations in the lysates were determined by Bradford protein assay. Three replicates were carried out.

Electrophoresis and Immunoblot Analysis for Western Blot. Protein samples were subjected to electrophoresis using 12 wt % SDS−polyacrylamide gel and the buffer system described by King and Laemmli (*30*). After the electrophoresis, the proteins were blotted onto nitrocellulose membrane and blocked by incubating with Tris-buffered saline, 0.05% Tween 20 containing 5% nonfat dried milk. Then, the membranes were incubated for 12 h with anti-rabbit polyclonal antibody to pERK (1/1000 dilution) or anti-mouse monoclonal antibody to GAPDH (1/2000 dilution) and washed with Tris-buffered saline. After incubating the membrane with a 1/5000 diluted goat anti-rabbit IgG or goat anti-mouse IgG antibody conjugated to horseradish peroxidase for 1 h, the antigen−antibody complexes were visualized by using the enhanced chemiluminescence (ECL) detection system. The phosphorylation of pERK was analyzed using the *Image J* 1.38 X program.

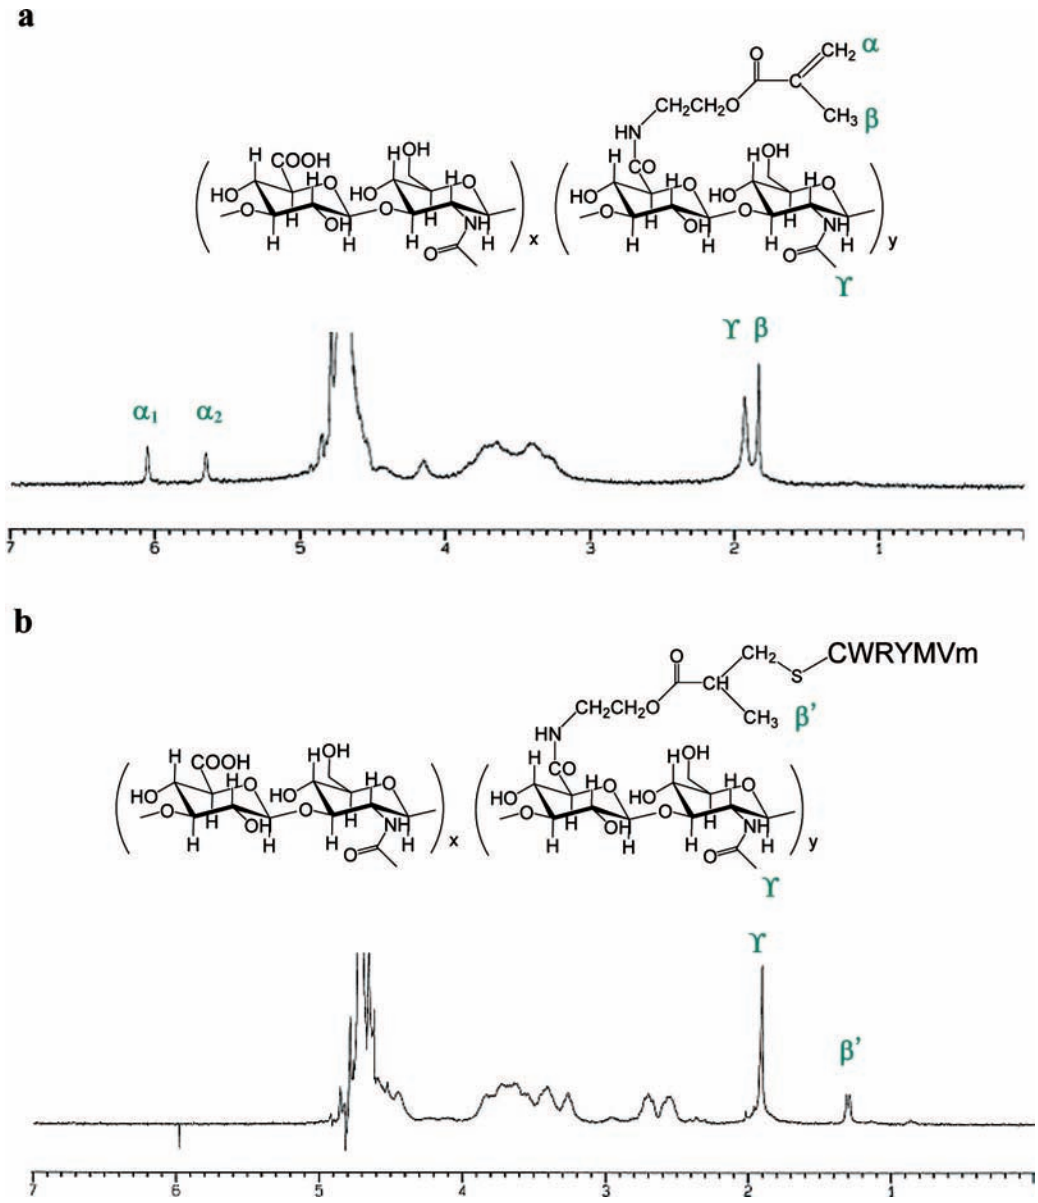

Figure 2. ^{1}H NMR spectra of (a) aminoethyl methacrylated hyaluronic acid (HA-AEMA) and (b) HA−peptide conjugate of HA-$(CWRYMVm)_{23}$ for formyl peptide receptor like 1 (FPRL1) receptor.

Calcium Imaging of the Cells. The intracellular calcium level was determined using fura-2-acetoxymethyl ester (Fura-2/AM) as described by Bae et al. (*31*). Briefly, the prepared cells were incubated in serum-free RPMI 1640 medium with 3 μM of Fura-2/AM at 37 °C for 50 min under continuous stirring. For each measurement, 2×10^6 cells were aliquoted in Ca^{2+}-free Locke's solution (154 mM NaCl, 5.6 mM KCl, 1.2 mM $MgCl_2$, 5 mM HEPES, pH 7.3, 10 mM glucose, and 0.2 mM EGTA). Changes in the fluorescence ratio were measured at the dual excitation wavelengths of 340 and 380 nm and emission wavelength of 500 nm, and the fluorescence images were also obtained.

Statistical Analysis. The data are expressed as means ± SD from several separate experiments. Statistical analyses and comparisons were carried out via *t*-test, and a value for $p < 0.05$ was considered statistically significant.

RESULTS AND DISCUSSION

Synthesis of HA−Peptide Conjugates for FPRL1 Receptor. The chemical modification of HA with AEMA was successfully carried out using the novel protocol as schematically shown in Figure 1a. HA-AEMA was synthesized by the coupling reaction of TBA salt of HA (HA-TBA) with AEMA using BOP in DMSO. DIPEA was used to release the free primary amine of AEMA. The chemical structure of HA-AEMA was analyzed by ^{1}H NMR. The methyl resonance of acetamido moiety of HA at $\delta = 1.85-1.95$ ppm was used as an internal standard (γ in Figure 2). The degree of AEMA modification was ca. 57 mol %, which was determined from the peak areas of methacrylate unit of AEMA at $\delta = 6.1$ and 5.6 ppm (α_1 and α_2 in Figure 2a). By changing the amount of AEMA added for the reaction, we could control the degree of AEMA modification in HA-AEMA up to 85 mol %. The peptide for FPRL1 receptor having a sequence of WRYMVm was modified with cysteine to prepare CWRYMVm with thiol groups. HA-AEMA was conjugated with CWRYMVm via the Michael addition reaction between methacryloyl groups in HA-AEMA and thiol groups in CWRYMVm (Figure 1b). ^{1}H NMR analysis of HA−peptide conjugate, HA-$(CWRYMVm)_{23}$, confirmed the formation of HA−peptide conjugate (Figure 2b). Before conjugation, there were double peaks at $\delta = 6.1$ and 5.6 ppm corresponding to two hydrogens on methacryloyl groups of HA-AEMA (α_1 and

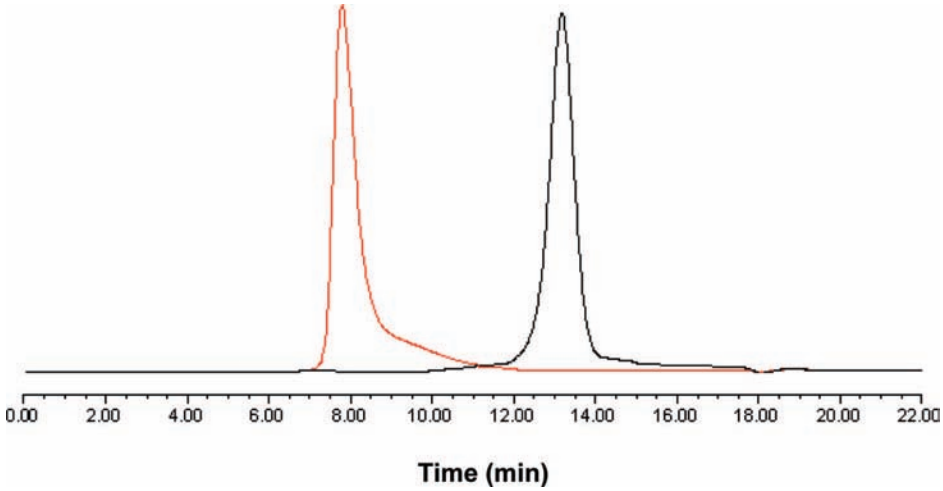

Figure 3. Gel permeation chromatograms (GPC) of the peptide (CWRYMVm) for formyl peptide receptor like 1 (FPRL1) receptor at a right peak and hyaluronic acid (HA)−peptide conjugate at a left peak detected at 280 nm.

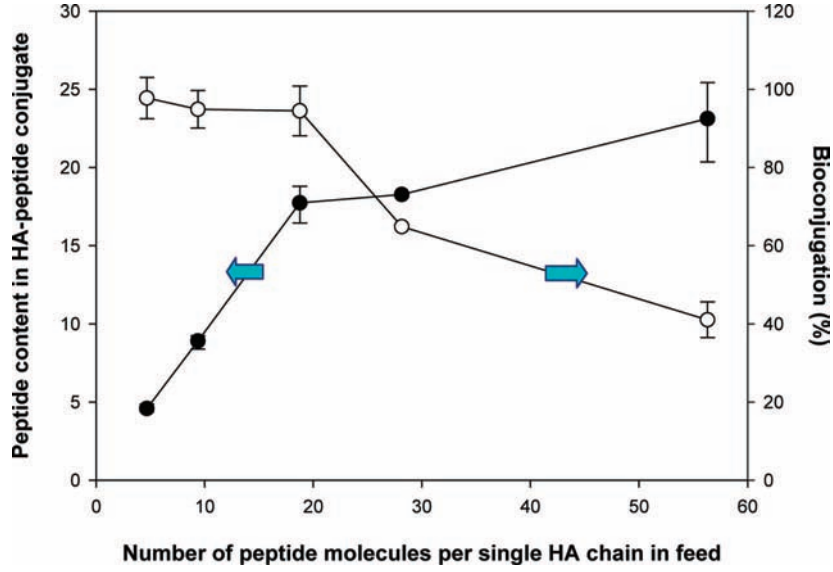

Figure 4. The content of peptide (CWRYMVm) for formyl peptide receptor like 1 (FPRL1) receptor in hyaluronic acid (HA)−peptide conjugates (the number of peptide molecules per single HA chain) (•, ⟸) and the resulting bioconjugation efficiency (%) (○, ⟹). The results are presented as means ± SD of three independent experiments.

α_2). After Michael addition reaction, the peaks at $\delta = 6.1$ and 5.6 ppm disappeared and the peak corresponding to -CH_3 of the methacryloyl group at $\delta = 1.8$ ppm (β) was shifted to the peak at $\delta = 1.3$ ppm (β'). The results from ^{1}H NMR analysis corroborated the successful formation of HA-AEMA and the subsequent HA−peptide conjugate.

Characterization of HA−Peptide Conjugates for FPRL1 Receptor. The formation of HA−peptide conjugate for FPRL1 receptor was also confirmed by GPC analysis as shown in Figure 3. The peak of HA−peptide conjugate appeared at a retention time of 8 min, while that of intact peptide appeared at a retention time of 13 min. The peak shift to the early retention time revealed that the peptide was conjugated to HA with a high molecular weight of 200 000 Da. The number of peptide molecules added per single HA chain in the reaction solution for the synthesis of HA−peptide conjugate was 5, 9, 19, 28, and 56, respectively. The resulting peptide contents in HA−peptide conjugate were quantified by measuring the peak area on GPC detected at 280 nm. Because HA is not detected at a wavelength of 280 nm, the peaks of HA−peptide conjugates at 280 nm resulted solely from the peptide molecules. The peptide content in HA−peptide conjugates at a retention time of 8 min increased with the feeding ratio of peptide molecules

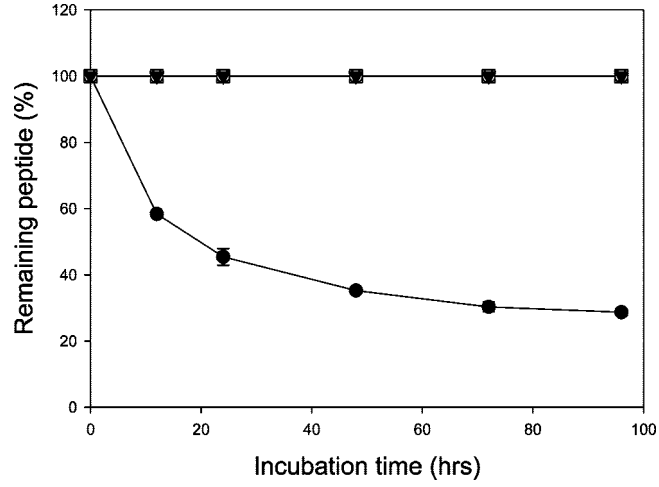

Figure 5. *In vitro* serum stability of peptide (CWRYMVm, ●) and hyaluronic acid (HA)−peptide conjugates in fetal bovine serum (FBS, 50 vol %) solution. The number of peptide molecules per single HA chain was 5 (○), 19 (▼), and 33 (□), respectively. The results are presented as means ± SD of three independent experiments.

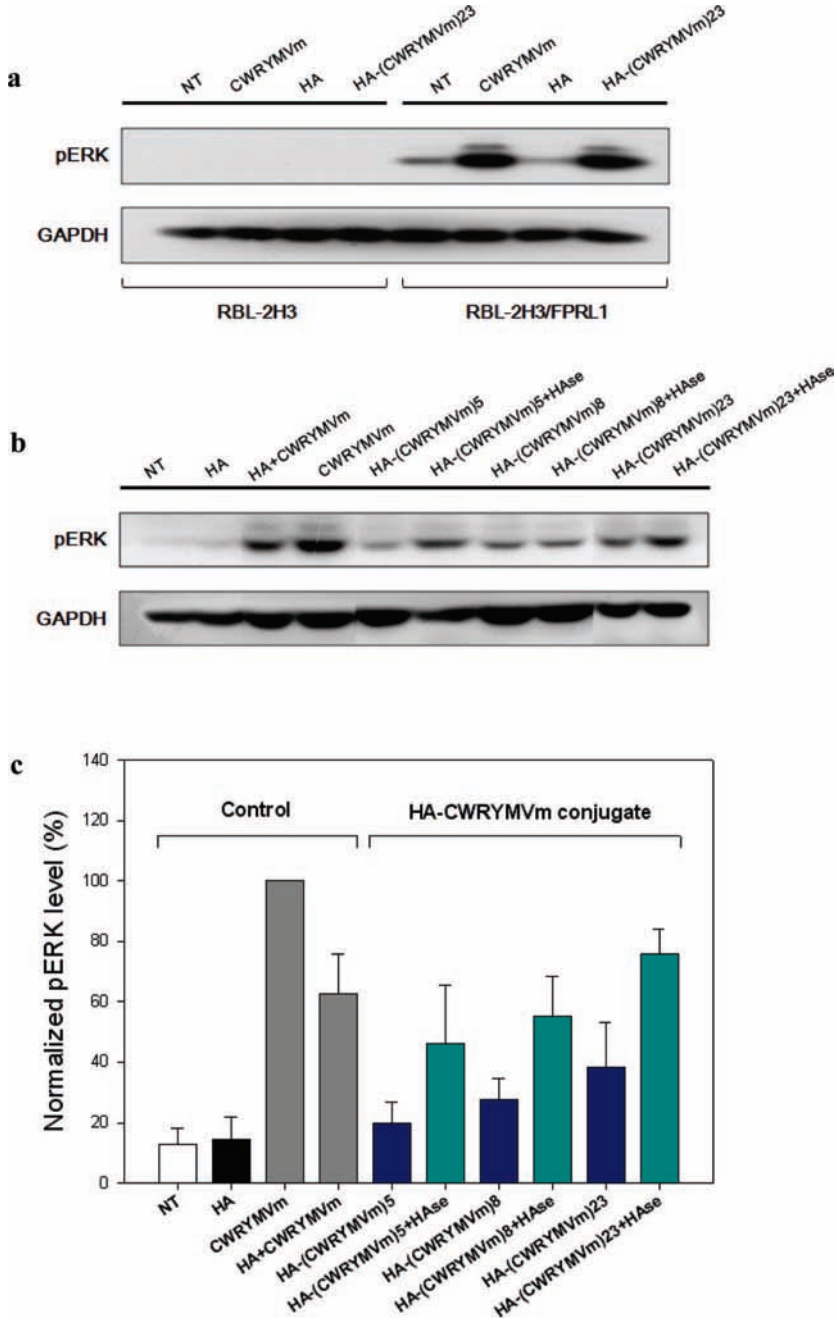

Figure 6. (a) Western blots for phospho-extracellular signal-regulated kinase (pERK) levels in the RBL-2H3 cells and formyl peptide receptor like 1 (FPRL1) overexpressing RBL-2H3 cells after stimulation for 5 min with a control (no treatment), peptide (CWRYMVm), aminoethyl methacrylated hyaluronic acid (HA-AEMA), and HA−peptide conjugate of HA-$(CWRYMVm)_{23}$ having 23 peptide molecules per single HA chain. (b) Western blots for pERK levels in the FPRL1 overexpressing RBL-2H3 cells after stimulation for 5 min with a control (no treatment), HA-AEMA, peptide (CWRYMVm), a mixture of HA-AEMA and peptide (HA + CWRYMVm), and three HA−peptide conjugate samples (HA-CWRYMVm) with and without hyaluronidase (HAse) treatment. The numbers 5, 8, and 23 represent the number of peptide molecules per single HA chain in HA−peptide conjugates. (c) Densitometry of Western blot bands for the samples in (b). The results were presented as means ± SE of three independent experiments.

to single HA chain (Figure 4). However, the degree of bioconjugation (%) decreased with increasing peptide content in the reactants. The bioconjugation (%) represents the molar ratio of peptide molecules in the HA−peptide conjugate to the total peptide molecules added initially for the conjugation reaction. When the number of peptide molecules per single HA chain in the feed was less than 19, the bioconjugation efficiency (%) was higher than 90%. The average number of conjugated peptide molecules could be controlled from 5 to 23 per single HA chain, as schematically shown in Figure 1b.

***In Vitro* Serum Stability of HA−Peptide Conjugates for FPRL1 Receptor.** Although several agonistic and antagonistic peptides for FPRL1 receptor have been identified in our group as promising new drug candidates for the inflammatory diseases such as sepsis, asthma, and rheumatoid arthritis (*4*−*6*), their short half-lives in the body should be elongated for further clinical applications. As expected, the peptide with a sequence of CWRYMVm was quite unstable in serum. After incubation in 50 vol % FBS solution for 3 days, only less than 30 wt % of the peptide remained with a big initial degradation of over 50 wt % in a day (Figure 5). However, HA−peptide conjugate showed notably increased serum stability in 50 vol % FBS solution. The peptide conjugated to HA did not degrade at all even after incubation for 4 days. The increased stability of peptide in serum by HA conjugation was the same for all three HA−peptide conjugates with different peptide contents. As the serum stability of the peptide drug is essential for the

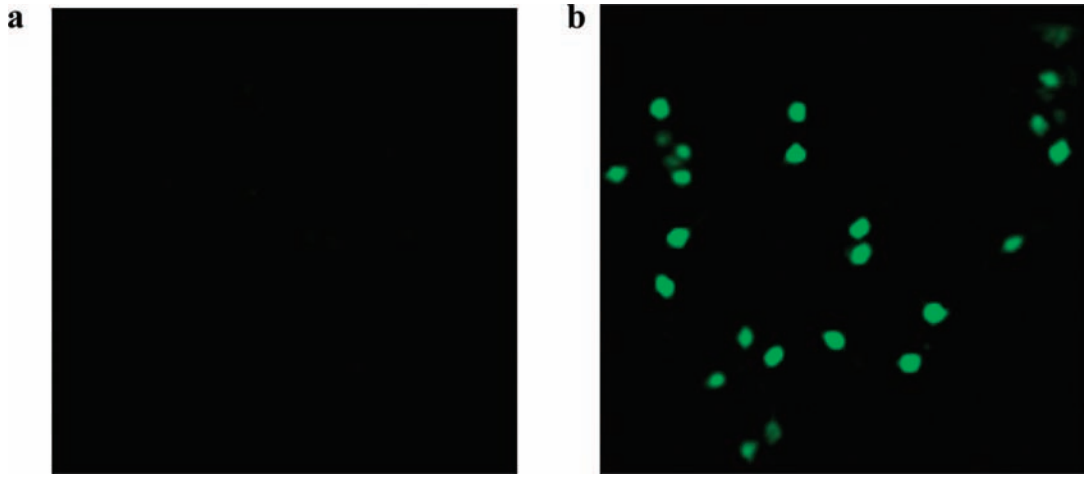

Figure 7. Calcium fluorescence imaging of the formyl peptide receptor like 1 (FPRL1) overexpressing RBL-2H3 cells after stimulation with (a) a control (no treatment) and (b) HA−peptide conjugate sample of HA-$(CWRYMVm)_{23}$ for FPRL1 receptor. The number of peptide molecules per single HA chain was 23.

application *in vivo*, the protocol for the conjugation of peptide to HA via Michael addition would be usefully exploited for the development of peptide therapeutics with good solubility and a feasible long half-life.

***In Vitro* Signal Transduction of HA−Peptide Conjugates for FPRL1 Receptor.** The signal transduction activity of HA−peptide conjugate for the FPRL1 receptor was assessed by measuring the elevation level of phospho-extracellular signal-regulated kinase (pERK) (Figure 6) and calcium ion (Figure 7) in RBL-2H3/FPRL1 cells. The band intensity was normalized to GAPDH to get the pERK level. When the cells were stimulated with the peptide or HA−peptide conjugate for FPRL1 receptor up to 30 min, the elevation of intracellular pERK level on Western blot was the highest at a stimulation time of 5 min in both cases. Therefore, the stimulation time was fixed at 5 min for the following cell activity tests. Figure 6a compares the pERK levels on Western blots in RBL-2H3/FPRL1 cells with those in RBL-2H3 cells after stimulation with a control (no treatment), peptide (CWRYMVm), HA-AEMA (HA), and HA−peptide conjugate having 23 peptide molecules per single HA chain. As there is no receptor for CWRYMVm in RBL-2H3 cells, the pERK levels were not elevated at all even after stimulation with peptide alone. However, in RBL-2H3/FPRL1 cells, the pERK levels elevated significantly after stimulation with both peptide alone and HA-$(CWRYMVm)_{23}$ samples. Figure 6b shows the pERK levels on Western blots after stimulation with a control (no treatment), HA-AEMA (HA), peptide (CWRYMVm), a mixture of HA-AEMA and peptide (HA + CWRYMVm), HA−peptide conjugates (HA-CWRYMVm), and hyaluronidase-treated HA−peptide conjugates (+HAse). The numbers 5, 8, and 23 represent the number of peptide molecules per single HA chain in HA−peptide conjugates. As a control, the pERK level by peptide alone was set to be 100% and the other data were normalized for comparison (Figure 6c). In the mixture of HA-AEMA and peptide, the pERK level decreased to ca. 63% compared with that of peptide alone. Moreover, the bioactivity of HA−peptide conjugates decreased to ca. 20%, 28%, and 38% depending on the amount of peptide per single HA chain. However, the bioactivity could be recovered up to ca. 76% after degradation of HA molecules by hyaluronidase treatment (+HAse). The decrease in the signal transduction activity of peptide molecules after being conjugated to HA might have resulted from the "steric hindrance" of HA chain reducing the access of peptide molecules to FPRL1 receptor. For the same reason, HA−peptide conjugate with a low peptide content of 5 per single HA chain [HA-$(CWRYMVm)_5$] showed a lower pERK level than HA-$(CWRYMVm)_{23}$, despite using the same peptide content for the Western blot analysis. After the hyaluronidase treatment (+HAse), however, the steric hindrance was thought to be alleviated, contributing to the increase of intracellular pERK level. There was a positive correlation between the pERK level and the content of peptide in HA−peptide conjugates with and without hyaluronidase treatment. According to the *t*-test, the *p*-value between HA-AEMA (HA) and [HA-$(CWRYMVm)_5$ + HAse] was 0.194, which means no significant elevation of pERK level after treatment with [HA-$(CWRYMVm)_5$ + HAse]. However, as the content of peptide in HA−peptide conjugates increased to 9 and 23, the *p*-value decreased to 0.056 and 0.004, respectively. The decreased *p*-value indicates that the biological activity of HA-CWRYMVm after hyaluronidase treatment significantly increased with the peptide content in HA-CWRYMVm conjugates. Bioconjugation of multiple peptides to a single HA chain might contribute to the development of long-acting formulation of peptide therapeutics. Previously, we have reported the effect of chemical modification of HA on its degradation (*32*, *33*). The chemical modification of carboxyl groups on HA was thought to make it more stable to enzymatic degradation by hyaluronidase contributing to the elongation of its half-life. The half-life of HA−peptide conjugate will be assessed by *in vivo* tests for further applications. Calcium imaging showed the same tendency as the Western blot analysis. Unlike the control, the RBL-2H3/FPRL1 cells treated by HA−peptide conjugate showed a bright fluorescence under UV light demonstrating its biological activity (Figure 7). Altogether with the stimulation test results of RBL-2H3/FPRL1 cells with agonistic peptides and HA−peptide conjugates, we could confirm the signal transduction activity of HA−peptide conjugates for the FPRL1 receptor. The novel protocol for the conjugation of HA-AEMA with the peptide of CWRYMVm would be usefully applied for various protein and peptide drugs with thiol groups. The HA−peptide conjugate for the FPRL1 receptor will be investigated further in murine models of inflammatory diseases such as sepsis, asthma, and rheumatoid arthritis for clinical applications to immunotherapeutics.

CONCLUSIONS

HA-AEMA was successfully synthesized and conjugated with CWRYMVm, one of the agonistic peptide drugs for the FPRL1 receptor, via Michael addition between the methacryloyl group of AEMA and the thiol group of cysteine. The formation of the HA−peptide conjugate was confirmed by ^{1}H NMR and GPC. HA−peptide conjugate could be prepared to have 5−23 peptide molecules per single HA chain by changing the initial feed ratio of peptide to HA repeat unit. The conjugation of peptide to HA molecules resulted in significantly enhanced serum stability. The signal transduction activity of HA−peptide

conjugate was confirmed by measuring the elevation level of pERK and calcium ion in FPRL1 overexpressing RBL-2H3 cells. The bioconjugation protocol using HA derivatives might be successfully applied for the development of peptide therapeutics with an elongated half-life and a feasible biological activity. *In vivo* tests of HA−peptide conjugate for FPRL1 receptor will be carried out in murine models of inflammatory diseases such as sepsis, asthma, and rheumatoid arthritis for further clinical applications to immunotherapeutics.

Influence of the Molecular Charge on the Biodistribution of Bombesin Analogues Labeled with the [^{99m}Tc(CO)$_3$]-Core

Elisa García Garayoa,*[,†] Christian Schweinsberg,[†] Veronique Maes,[‡] Luc Brans,[‡] Peter Bläuenstein,[†] Dirk A. Tourwé,[‡] R. Schibli,[†] and P. August Schubiger[†]

Paul Scherrer Institute, Centre for Radiopharmaceutical Science, CH-5232 Villigen PSI, Switzerland, and Department of Organic Chemistry, Vrije Universiteit Brussel, 1050 Brussels, Belgium. Received June 27, 2008; Revised Manuscript Received September 26, 2008

The overexpression of Bombesin (BBS) receptors on a variety of human cancers make them interesting targets for tumor imaging and therapy. Analogues of the neuropeptide BBS have been functionalized with the (N$^{\alpha}$His)-chelator for labeling with the ^{99m}Tc-tricarbonyl core. The introduction of a βAla-βAla linker between the stabilized BBS binding sequence and the chelator led to increased tumor uptake but still rather unfavorable *in vivo* properties. Novel polar linkers, with different charge, have been introduced in the molecule and tested for their influence on the biodistribution. The new analogues showed a shift in hydrophilicity from a Log D = 0.9 to Log D values between 0.4 and −2.2. All compounds kept the increased stability in both human plasma ($t_{1/2}$ > 16 h) and in tumor cells ($t_{1/2}$ = 30−40 min). The compounds with Log D values between +1 and −1 showed the highest binding affinities with K_d values of <0.5 nM, as well as the highest cellular uptake. However, higher hydrophilicity (Log D < −1.8) led to lower affinity and a substantial decrease of internalization. The introduction of a positive charge (β^3hLys) resulted in unfavorable biodistribution, with increased kidney uptake. The introduction of an uncharged hydroxyl group (β^3hSer) improved the biodistribution, resulting in significantly better tumor-to-tissue ratios. The compound with one single negative charge (β^3hGlu) showed a significant increase in the tumor uptake (2.1 ± 0.6% vs 0.80 ± 0.35% ID/g in comparison to the βAla-βAla analogue) and also significantly higher tumor-to-tissue ratios. The specificity of the *in vivo* uptake was confirmed by coinjection with natural BBS. Moreover, the analogue provided a much clearer image of the tumor xenografts in the SPECT/CT studies. The introduction of a single negative charge may be useful in the development of new BBS analogues to obtain an improved biodistribution profile, with increased tumor uptake and better imaging.

INTRODUCTION

A variety of human carcinomas show an overexpression of peptide receptors for which natural neuropeptides feature high affinities. Thus, peptide-based radiopharmaceuticals exhibit a great potential for imaging and therapy of cancer (*1*−*5*). Their small size allows good penetration into tumor tissue and promotes more rapid blood clearance compared to other macromolecular carriers such as antibodies (*4*). This can result in high specific uptake and optimal tumor-to-background ratios for the visualization of tumors and small metastases as well as for therapeutic applications, depending on the radionuclide used (*4*). Peptides are readily synthesized and can withstand harsh conditions for labeling. Their chemical characteristics offer a broad range for functionalization and modification like the introduction of chelating systems and pharmacokinetic modifiers (*4*−*6*). There is evidence that for some cancer types not only one but several peptide receptors may be overexpressed in varying levels and regions in the tumor tissue (*7*). Therefore, it is of great interest to develop more than one peptide radiopharmaceutical to cover a broader range of possible targets as well as to obtain a more homogeneous distribution of the activity within the tumor mass.

Bombesin (BBS) is a tetradecapeptide with high affinity for the mammalian gastrin-releasing peptide receptor (GRP-R), a subtype of the BBS receptor superfamily, which is overexpressed in most human prostate and breast tumors as well as small-cell lung cancer and several other cancer types (*8*−*10*). A variety of BBS analogues has been designed, based either on the complete original peptide sequence or on the fragment (7−14). Several BBS analogues containing the appropriate chelating systems for radiolabeling with different radionuclides (e.g., ^{99m}Tc or ^{186}Re/^{188}Re, ^{64}Cu, ^{111}In, ^{177}Lu, and ^{18}F) show promising pharmacological properties (*4*−*6*, *11*−*14*). Of the different radionuclides useful in nuclear medicine, ^{99m}Tc is still the one with the broadest clinical application due to its favorable dosimetry, high specific activity, low cost, and ready availability from a ^{99}Mo/^{99m} Tc-generator. Its physical properties ($t_{1/2}$ = 6 h, energy γ = 140 keV, 98% abundance) are optimal for imaging using single photon emission computed tomography (SPECT) (*15*−*17*). In addition, a metal chelator applicable for ^{99m}Tc is usually also suitable for the therapeutic radionuclides ^{186}Re and ^{188}Re due to their similar chemical properties. Thus, a successful candidate for targeting GRP-R with ^{99m}Tc could be interesting for radiotherapeutic applications with Re isotopes (*16*). Our group successfully established a chelating system for both ^{99m}Tc(I) and ^{186}Re/^{188}Re(I) in the form of a tridentate chelator, the retro(N$^{\alpha}$His)Ac-chelator, for labeling of biomolecules with the tricarbonyl technique (*18*, *19*).

Some modifications of the BBS amino acid sequence, such as the exchange of Met^{14} with norleucine (Nle) and Leu^{13} with cyclohexylalanine (Cha), resulted in an improved stability in human plasma and in prostate and breast cancer cells. These modifications did not affect the binding affinity and cell internalization, but led to increased tumor-to-background ratios, although tumor uptake did not significantly change (*20*, *21*).

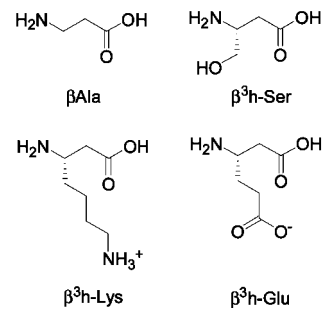

Figure 1. Chemical structure of the new BBS analogues.

Smith et al. reported on the positive influence of aliphatic spacers on the uptake of ^{99m}Tc-labeled BSS analogues into GRP-R-expressing tissues (*14*). With the introduction of a βAla-βAla[1]linker, we showed an additional improvement of the *in vivo* tumor uptake of stabilized BBS analogues labeled with the ^{99m}Tc-tricarbonyl core (*20*). Likewise, other recent papers report on the positive effects of polar linker moieties on ^{64}Cu-labeled DOTA-, NOTA-, and ^{99m}Tc(III)-labeled BBS conjugates (*22*−*24*). The BBS analogues with the ^{99m}Tc(CO)$_3$-His complex are more lipophilic than the above-mentioned peptides, since the His-imidazole residue (pK = 6) is not protonated at physiological pH values. An increase of the hydrophilicity of the molecule as well as the presence of charges may lead to new analogues with improved biodistribution profiles. New BBS derivatives were synthesized with different polar linkers inserted between the stabilized binding sequence and the retro(N$^\alpha$His)Ac-chelator. The spacers contain different β-amino acids (*25, 26*) either neutral or with a positive or negative charge in the side chain. In this study, we investigated the influence of these polar linkers and charges on the *in vitro* and *in vivo* behavior of new ^{99m}Tc(I)-labeled BBS analogues.

EXPERIMENTAL PROCEDURES

Chemicals and Equipment. Cell culture media DMEM GLUTAMAX-I, trypsin/EDTA, bovine serum albumin, and soybean trypsin inhibitor were obtained from Invitrogen (Basel, Switzerland), fetal calf serum (FCS), and antibiotic/antimycotic solution were obtained from Bioconcept (Allschwil, Switzerland). Bacitracin, HEPES, and Chymostatin were purchased from SIGMA (Buchs, Switzerland). All other chemicals were obtained from Fluka (Buchs, Switzerland) or Merck (Dietikon, Switzerland). For the determination of protein concentrations, a Pierce BCA Protein Assay kit from Socochim (Lausanne, Switzerland) was used. Na[^{99m}TcO$_4$] was eluted from a Mallinckrodt ^{99}Mo/^{99m}Tc generator (Tyco Healthcare, Petten, The Netherlands) using 0.9% saline. Sodium boranocarbonate was a gift from the provider of the generator. The radioactivity of *in vitro* and *in vivo* experiments was measured with a NaI-γ-counter (Packard Canberra Cobra II, Meriden, USA) or a NaI ionization chamber. The Fmoc-β^{3}homoamino acids were purchased from Fluka.

Peptide Synthesis and Radiolabeling with ^{99m}Tc. Peptide solid-phase synthesis was carried out on a Rink Amide Resin using the Fmoc-strategy as previously described (*20*). Purification of the peptides was done on a semipreparative HPLC system (Gilson) on a reversed-phase C_{18} column (DiscoveryBIO SULPELCO Wide Pore, 25 cm × 2.21 cm, 5 μm) with a linear gradient of 3% B to 100% B (solvent A = H_2O + 0.1% TFA and solvent B = CH_3CN + 0.1% TFA) in 30 min, a flow rate of 1 mL/min, and UV detection at 215 nm.

Each of the new spacers introduced between the binding sequence and the chelator contained three β-amino acids in form of a β-alanine (βAla), β^3-homoserine (β^{3}hSer), β^3-homolysine (β^{3}hLys), or β^3-homoglutamic acid (β^{3}hGlu). The (N$^\alpha$His)Ac moiety (retro[N^α-carboxymethyl-histidine]) was coupled to the N-terminus for labeling to [^{99m}Tc(CO)$_3$] (Figure 1) (*25, 26*).

Radiolabeling of the analogues was performed as previously described (*20*). For analyses and purification of the labeled peptides from the unlabeled compounds, a Macherey-Nagel CC Nucleosil 100−5 C_{18} RP column (5 μm, 250 × 4.6 mm) was used. Preparative HPLC for purification of the labeled peptides was performed using a Merck-Hitachi L-7100-system with an equipped two-channel scintillation detector interface (John Caunt Scientific Ltd., Eynsham, England) and a Rainin Dynamax absorbance detector model UV-1. HPLC solvents consisted of H_2O + 0.1% TFA (solvent A) and CH_3OH + 0.1% TFA (solvent B). The separation was performed with a linear gradient 50% A/50% B to 20% A/80% B in 25 min (1.0 mL/min). For the analytical HPLC of the labeled peptides, a Varian ProStar system was used with a Varian ProStar 230 Solvent Delivery Pump, a Varian Photodiode Array Detector model 330, a Varian ProStar Autosampler model 410, and a radiomatic Flo-one Beta Detector (Packard Canberra). HPLC solvents consisted of CH_3CN + 0.1% TFA (solvent A) and H_2O + 0.1% TFA (solvent B). The labeling control was performed with a linear gradient of 30% A/70% B to 80% A/20% B in 25 min (1.0 mL/min).

Octanol/Water Partition Coefficient Study. To compare the polarity of the different new analogues, the octanol/water partition coefficients were determined at pH = 7.4 by measuring the distribution of the radiolabeled peptides in 1-octanol and

[1]βAla is the exception to the general nomenclature of the β amino acids according to Abele and Seebach (*25, 26*)

PBS. Five microliters containing 500 kBq of radiolabeled compound in PBS were added to a vial containing 1.2 mL 1-octanol and PBS (1:1). After vortexing for 1 min, the vial was centrifuged for 5 min at 10 000 rpm to ensure complete separation of layers. Then, 40 μL of each layer were taken in a preweighed vial and measured in the γ-counter. Counts per unit weight of sample were calculated, and log D values were obtained using the formula

$$\log_{10}\mathrm{D} = \log_{10}\left(\frac{\text{counts in 1 g of octanol}}{\text{counts in 1 g of water}}\right)$$

Cell Culture. PC-3 human prostate cancer cell line was obtained from the European Collection of Cell Cultures (Salisbury, United Kingdom). Cells were maintained in Dulbecco's MEM with GLUTAMAX-I supplemented with 10% FCS, 100 IU/mL penicillin G sodium, 100 μg/mL streptomycin sulfate, and 0.25 μg/mL amphotericin B. Cells were incubated at 37 °C in an atmosphere containing 5% CO_2 and subcultured twice a week after detaching with trypsin-EDTA.

Metabolic Stability in Human Plasma and in PC-3 cells. The degradation of the radiolabeled analogues was investigated *in vitro* in human plasma from healthy donors. The analogues (3 MBq/mL, 1.5−2 pmol/mL) were incubated for different time periods (from 0 to 24 h) at 37 °C. After incubation, proteins were precipitated as follows: 250 μL of sample + 750 μL of acetonitrile/ethanol (1:1) and TFA (0.01%). The mixture was vortexed and centrifuged (10 min, 20 000 *g*) at 4 °C. The supernatant was filtered and analyzed by RP-HPLC equipped with a radioactivity detector. The stability in cell culture was evaluated with 2×10^6 cells in PBS. The analogues (3 MBq/mL, 1.5−2 pmol/mL) were incubated from 0 to 5 h at 37 °C. Afterward, proteins were precipitated, and the supernatant filtered and analyzed as above. All experiments were carried out 2−3 times. Different peaks corresponding to the intact peptide and the different degradation products were obtained in the radioactivity chromatograms. The percentage of intact peptide was determined for each incubation time.

Receptor Inhibition Studies. One day prior to the assay, PC-3 cells at confluence were placed in 48-well plates. Cells were incubated in a special binding buffer (50 mM HEPES, 125 mM NaCl, 7.5 mM KCl, 5.5 mM $MgCl\cdot 6H_2O$, 1 mM EGTA, 5 g/L BSA, 2 mg/L Chymostatin, 100 mg/L Soybean Trypsin inhibitor, 50 mg/L Bacitracin, pH 7.4) with increasing concentrations of the BBS analogues (0−30 000 nM) in the presence of 4 kBq of ^{99m}Tc-BBS(7−14), which is known to express a high binding affinity to the GRP receptor. After 1 h incubation at 37 °C, the cells were washed twice with cold PBS. Bound radioactivity was recovered by solubilizing the cells in 1 N NaOH (2×400 μL). The radioactivity was measured in the γ-counter. All experiments were carried out 2−3 times in triplicate.

Receptor Saturation Studies. One day prior to the assay, PC-3 cells at confluence were placed in 48-well plates and incubated for 1 h at 37 °C in the binding buffer described above with increasing concentrations of the labeled BBS analogues (0.01−2 nM). The concentration of total technetium-labeled peptide was calculated according to Bauer et al. (*15*). Nonspecific binding was determined by coincubation with 1 μM natural BBS. After incubation, the cells were washed twice with cold PBS, solubilized in 1 N NaOH (2×400 μL), and the radioactivity was measured in the γ-counter. Experiments were performed 2−3 times in triplicate.

Internalization. One day prior to the assay, PC-3 cells at confluence were placed in 6 well plates. Cells were incubated with the labeled analogues (4 kBq/well) in binding buffer for 5, 15, 30, 60, and 120 min at 37 °C to allow binding and internalization. Nonspecific binding was determined in the presence of 1 μM natural BBS. After incubation, cells were washed twice with cold PBS. Surface-bound activity was removed by acid wash (50 mM glycine/HCL, 100 mM NaCl, pH 2.8, 2×600 μL for 5 min at room temperature). Afterward, the plates were neutralized with 600 μL PBS and cells were lysed with 1 N NaOH (2×600 μL). Surface-bound and internalized activities were measured in the γ-counter. The protein concentration was determined and results were calculated as percentage of total added radioactivity per milligram of protein. All experiments were carried out 2−3 times in triplicate.

Externalization. One day prior to the assay PC-3 cells at confluence were placed in 6 well plates. Cells were incubated with the labeled analogues (20 kBq/well) in culture medium for 1 h at 37 °C to allow binding and maximal internalization. After incubation, the supernatant was discarded and each well washed twice with cold PBS. Afterward, the cells were incubated again at 37 °C in 2 mL culture medium for 30, 60, 150, or 300 min. At each time point, the supernatant was collected, the cells were washed twice with cold PBS, and the radioactivity remaining in the cells was recovered by lysing the cells with 1 N NaOH (2×600 μL). Radioactivity in the supernatant (released activity) and in the lysate (internalized activity) was determined in the γ-counter. Results are expressed as the percentage of the total activity associated with the cells. The protein concentration was determined, and results were calculated as the percentage of total added radioactivity per milligram protein. All experiments were carried out 2−3 times in triplicate.

Biodistribution Studies. All animal experiments were conducted in compliance with the Swiss animal protection laws and with the ethical principles and guidelines for scientific animal trials established by the Swiss Academy of Medical Sciences and the Swiss Academy of Natural Sciences. Female CD-1 nu/nu mice 6−8-week-old (Charles River Laboratories, Sulzfeld, Germany) were subcutaneously injected with 8×10^6 cells in 150 μL culture medium without supplements. About 3 weeks after tumor implantation, the mice (3−6 per group) were injected i.v. with 3.7 MBq of the radiolabeled peptides (peptide amount of 0.2 pmol/mouse). At 0.5 h, 1.5 or 5 h postinjection (p.i.), the animals were sacrificed by cervical dislocation. The different organs (heart, lung, spleen, kidneys, pancreas, stomach, small intestine, large intestine, liver, muscle, bone) and blood were collected from the animals, weighed, and the radioactivity measured in a γ-counter. To determine specificity of the *in vivo* uptake, one group of mice received a coinjection of 100 μg of unlabeled natural BBS and the radiolabeled analogue and sacrificed 1.5 h p.i. Results are presented as a percentage of injected dose per gram of tissue (%ID/g).

SPECT/CT Studies. Single photon emission computed tomography/X-ray computed tomography (SPECT/CT) images were performed postmortem 1.5 h after i.v. injection of the ^{99m}Tc-BBS analogues (20 MBq). Images were obtained on an X-SPECT-system (Gamma Medica Inc.) equipped with a single head SPECT device and a CT-device. SPECT data were acquired and reconstructed with *LumaGEM* (version 5.407). CT data were acquired by an X-Ray CT-system (Gamma Medica) and reconstructed with the software *Cobra* (version 4.5.1). Fusion of SPECT and CT data was performed with IDL *Virtual Machine* (version 6.0). Images were generated with *Amira* (version 3.1.1).

Statistical Analysis. All data are presented as the mean ± SD. Differences in the *in vivo* uptake in the biodostribution studies were analyzed by one-way ANOVA followed by Dunnett's comparison test. Differences between blocked and

control groups were analyzed by unpaired *t* test. $P \leq 0.05$ was considered statistically significant.

RESULTS

Peptide Synthesis and Radiolabeling. In the peptide syntheses, yields of 50−58% were obtained for the cold purified peptides (Table 1, Supporting Information). The labeling yields with the ^{99m}Tc-tricarbonyl core were higher than 90%. Pertechnetate and tricarbonyl represented a maximum of 3% and 5%, respectively. For both *in vitro* and *in vivo* studies, labeled and unlabeled peptide were separated by preparative RP-HPLC. After the separation, the labeled analogue was analyzed with analytical RP-HPLC and corresponded to more than 98% of the radioactivity.

Octanol/Water Coefficient. The reference compound (**1**) with the linker βAla-βAla showed a rather lipophilic character with a Log D of +0.9. The introduction of a hydroxyl group (**2**) changed the polarity to +0.4. The insertion of additional positive or negative charges resulted in a clear increase of hydrophilicity up to −2.2 for compound **6** (bearing three negative charges) (Table 1).

Metabolic Stability. All new analogues, based on the fragment BBS(7−14) with the same changes at positions 13 and 14 (Cha and Nle for Leu and Met, respectively) showed increased stability compared to the unmodified sequence with a $t_{1/2}$ of approximately 16 h in human plasma. Stability in PC-3 tumor cells was also higher for the new analogues ($t_{1/2} = 30-40$ min) especially for compound **4**, which showed a clear increase in cell stability with a $t_{1/2}$ of 80 min.

Binding Assays. The binding affinity was tested for both the labeled and the unlabeled analogues. In inhibition experiments, compounds **1** and **2** showed the highest affinity, with IC_{50} values of 5.1 and 6.8 nM, respectively. Compounds **3** to **5** had slightly lower affinities, whereas compound **6** showed a high decrease of affinity ($IC_{50} = 634$ nM) (Table 1). The ^{99m}Tc-labeled compounds **1** to **5** exhibited a saturable and highly specific binding. These analogues had high affinity for GRP receptors, with K_d values in the subnanomolar range under 0.5 nM (Table 1). Under the set conditions, the binding of the labeled compound **6** was very low in the range of unspecific binding and the K_d value was not determined.

Internalization/Efflux. For compounds **1** to **5**, more than 80% of the activity bound to PC-3 cells was internalized after 30 min. Internalization of compounds bearing a neutral spacer (**2**) or a single negative charge in the spacer (**3**) was comparable to the reference peptide **1** after 1 h (30% of total dose/mg protein). Compound **4** (with a single positive charge) showed the highest internalization value (40% of total dose/mg protein after 1 h), whereas compound **5** and especially compound **6** showed a lower internalization (15% and 1% of total dose/mg protein after 1 h, respectively). Results are depicted in Figure 2A. Due to its low affinity and internalization, compound **6** was not tested for externalization.

In the externalization experiments with analogues **3**, **4**, and **5**, the radioactivity was rapidly externalized with a release of approximately 70% in the first 2.5 h after maximal internalization. Release of compounds **1** and **2** was slower (45% of the internalized activity was released in the first 2.5 h). Percentages of 20−30% of analogues **3**, **4**, and **5** remained in the cells after 5 h, whereas the retention for analogues **1** and **2** was slightly higher with 40% of activity still associated with the cells at this time (Figure 2B).

Biodistribution and SPECT/CT Studies. The neutral or negatively charged compounds (analogues **1**, **2**, **3**, and **5**) were further tested in mice with PC-3 tumor xenografts (Table 2). Compound **4** with a positive charge was excluded from these studies due to the unfavorably high retention in kidneys and liver found in previous biodistribution studies in normal mice (Supporting Information Table 2).

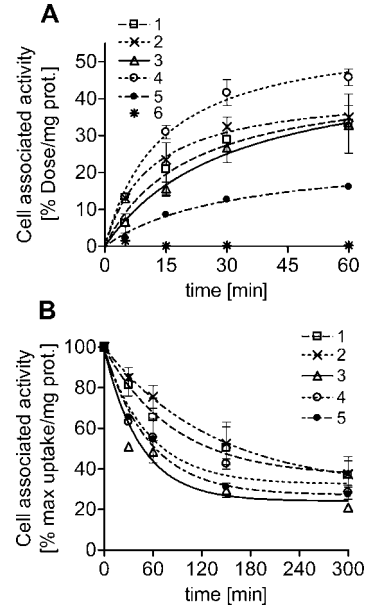

Figure 2. Time-course internalization (**A**) and externalization after maximal internalization (**B**) of the ^{99m}Tc-labeled BBS analogues in PC-3 cells after incubation at 37 °C. Data represent the percentage of internalized activity per milligram protein related to the total activity added to the cells ($n = 2-3$).

Compared to compound **1**, analogues **2** (neutral) and **3** (one negative charge) showed higher uptake in the receptor-expressing tissues (pancreas, colon, and tumor) at 0.5 h p.i. time (Table 2). Interestingly, the tumor uptake was significantly higher for analogue **3** compared to the reference **1** ($P \leq 0.05$), and the activity was retained longer (1% ID/g at 5 h p.i.) than for the other analogues (∼0.5% ID/g at 5 h p.i.).

Analogues **2**, **3**, and **5** showed a highly significant decrease in liver accumulation compared to the reference peptide **1** ($P \leq 0.01$) (Table 2). In spite of the higher kidney uptake of all new peptides at 0.5 h p.i., the activity washout from this organ was very fast, with the exception of compound **5**. Thus, the activity in the kidneys at later p.i. times was lower than 1% ID/g and similar for compounds **1**, **2**, and **3** (Table 2).

The higher tumor uptake in combination with a lower liver uptake and a faster clearance from blood and normal tissues led to high tumor-to-nontumor ratios for the new analogues especially for compound **3** after 1.5 h (tumor/kidney = 2.3 ± 0.8, tumor/liver = 6.3 ± 0.6) and 5 h (tumor/kidney = 3.5 ± 0.5, tumor/liver = 11.1 ± 1.3) (Figure 3).

In the blocking experiments, an excess of natural BBS was coinjected with the labeled analogues at 1.5 h p.i., and the uptake in the receptor-positive tissues pancreas, colon, and tumor was significantly reduced, thus indicating clearly a specific accumulation of radioactive tracer in these tissues (Table 2).

SPECT/CT images were acquired with compounds **1**, **3**, and **5** at 1.5 h p.i. The visualization of the tumor xenograft was clearer with **3** than with **1** and **5**, which corroborated the results obtained in the biodistribution studies (Figure 4). Compound **1** exhibited high uptake in the abdominal cavity due to the high hepatic, pancreatic, and intestinal uptakes (Figure 4A). The radioactivity in the abdominal area for compound **5** would be determined by the uptake in the kidneys, pancreas, and bowel (Figure 4C). Compound **3** showed lower renal and hepatic uptakes, and the abdominal activity would correspond to the uptake in pancreas and intestinal tract (Figure 4B).

The *in vivo* studies were performed with the HPLC purified analogues. We found that injection of nonpurified analogues

[a] n.d. = non-determined.

led to higher uptake in blood and normal tissues (namely, kidney, lung, spleen, and liver) compared to the corresponding HPLC-purified analogues (unpublished data). No statistically significant differences were found in the uptake in receptor-positive tissues, which indicates that the presence of an excess of unlabeled peptide was not sufficient to block the receptors *in vivo*. Moreover, the injection of the HPLC-purified analogues with an amount of the corresponding unlabeled peptide similar to the nonpurified samples (100 pmol) resulted in biodistributions comparable to those of the HPLC-purified analogues. This demonstrated that the increased nonspecific uptake in healthy tissues was not due to the presence of unlabeled analogue but to other radioactive species that are not detected in the HPLC chromatogram and are eliminated after HPLC purification.

DISCUSSION

A variety of BBS analogues have been labeled with different radionuclides to investigate their potential for the detection and therapy of GRP-R-expressing neoplasms (*4*−*6*, *11*, *13*, *14*, *22*−*24*, *27*).

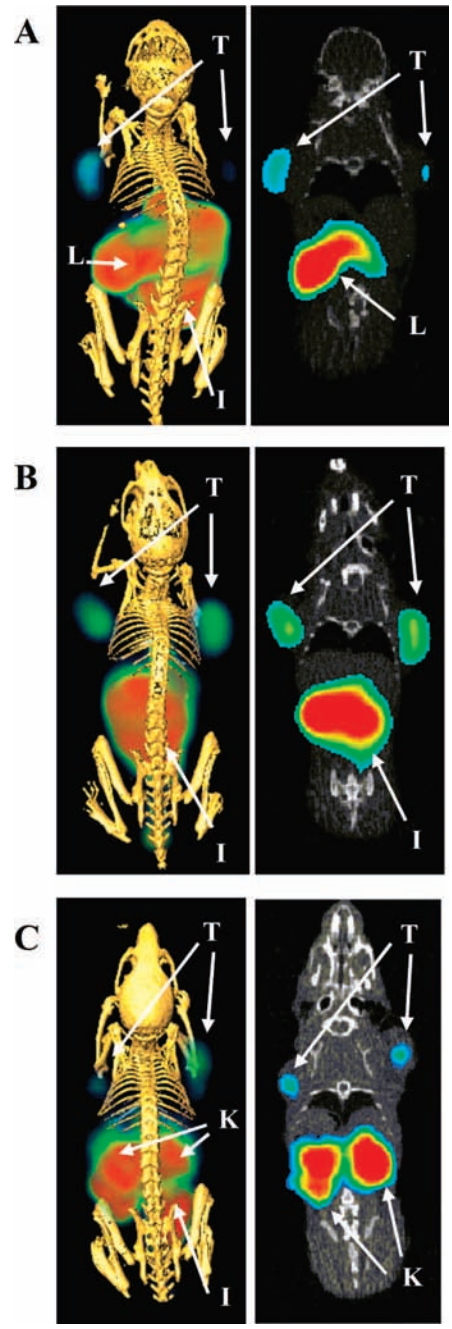

Figure 4. SPECT/CT image of nude mice bearing PC-3 tumor xenografts at 1.5 h p.i. of 20 MBq of the ^{99m}Tc-labeled BBS analogue. (**A**) Three-dimensional image (left) and coronal slice (right) of compound **1** (neutral). (**B**) Three-dimensional image (left) and coronal slice (right) of compound **3** (one negative charge). (**C**) Three-dimensional image (left) and coronal slice (right) of compound **5** (two negative charges). T = tumor; K = kidney; L = liver; I = intestinal activity.

Our work is focused on the development and characterization of new BBS derivatives radiolabeled with ^{99m}Tc using the tricarbonyl labeling technique (*18*, *19*). The amino acid sequence of our peptides is based on the fragment 7−14 of BBS (Figure 1), which has been modified as previously published to increase the stability (replacement of Leu^{13} with Cha, and Met^{14} with Nle). The additional introduction of a βAla-βAla linker (**1**) led to improved *in vivo* tumor uptake (*14*, *20*). However, the accumulation of activity in the liver increased, and the tumor-to-nontumor ratios were still rather low. High uptake in the liver and in the kidneys has also been reported for other ^{99m}Tc-labeled BBS analogues (*11*, *23*) and may obscure the detection of lesions in the abdomen. Moreover, high renal uptake could also induce

Table 2. Biodistribution of the ^{99m}Tc-labeled BBS analogues (3.7 MBq/mouse i.v.) in mice bearing PC-3 xenografts. The animals of the blocked group received a co-injection of 0.1 mg natural BBS. Data (mean ± SD) are expressed as percentage of injected dose per gram of tissue (n = 3-4)[a]

[a] n = 13 for compound 1 (21); * ($P \leq 0.05$), ** ($P \leq 0.01$) vs. reference compound 1 (one-way ANOVA and Dunnett's post hoc test); § ($P \leq 0.05$), §§ ($P \leq 0.01$) vs. unblocked group (unpaired t-test).

radiation nephrotoxicity. The modification of the polarity can change the pharmacokinetics of biomolecules and have a significant impact on the biodistribution as reported for several radiolabeled peptides (*21, 22, 28*−*30*). Therefore, new hydrophilic amino acid linkers were introduced into our BBS analogues to improve the *in vivo* distribution and to increase the tumor-to-background ratios. To avoid the introduction of new enzymatic cleavage sites, β^3homoamino acids were chosen for the syntheses of these linkers (Figure 1) (*26*). All new peptides showed a higher hydrophilicity compared to our reference peptide **1** (Table 1). A single hydroxyl group (β^3hSer, **2**) resulted only in a slight increase of polarity. The insertion of β^3hGlu (**3**) and β^3hLys (**4**) provided the molecule with a single negative and a single positive charge, respectively, and resulted in higher hydrophilicity. As expected, the increase in polarity was even more evident for analogues **5** and **6**, with two and three negative charges.

The linkers did not influence the metabolic stability of the peptides, which showed high plasma stability *in vitro* ($t_{1/2}$ = 16 h) as well as in PC-3 cells ($t_{1/2}$ = 30−40 min), similar to that of stabilized BBS analogues recently published (*21*). Besides a high stability, compounds **2** to **5** exhibited high binding affinities for GRP-R, in the range of ^{125}I-BBS and our previous BBS analogues (Table 1) (*21*), while the affinity of the unlabeled compound **6** was more than 100-fold lower than that of the reference **1**.

In vitro internalization studies in human prostate carcinoma PC-3 cells reflected an agonistic behavior for the new conjugates, which is consistent with data previously reported for BBS constructs with a similar amino acid sequence (Figure 2A) (*11,21,23,29*). The internalization of the analogues **1**, **2** (neutral), and **3** (one negative charge) was comparable, with a maximum of 30% of the total dose/mg protein. Since these three BBS analogues showed big differences in the molecular polarity and no differences in both affinity and internalization, polarity does not seem to be crucial for the internalization. However, analogue **4** (one positive charge) showed a slightly higher internalization than **1** to **3**, whereas the internalization of analogue **5** (two negative charges) was significantly decreased and that of compound **6** (three negative charges) was negligible. These results would indicate that a positive charge may favor internalization of the tricarbonyl-labeled analogues, while more than one negative charge would have an adverse influence, which is consistent with the results Parry et al. reported for the insertion of one and two glutamic acids into the linker of a ^{64}Cu-labeled DOTA-BBS(7−14). The Cu-labeled DOTA-complex already bears a single negative charge, and the introduction of the additional charges also led to a loss of binding affinity and internalization (*22*). This would underscore that not only the linker but also the chelating system may affect the properties of biomolecules, which has already been discussed by Decristoforo et al. for ^{99m}Tc-labeled peptides (*31*). Furthermore, the influence of different polar groups might be specific for each particular labeling approach. The results of the *in vitro* studies indicate that the number and position of negative charges may have a strong influence on the binding affinity and internalization of radiolabeled BBS analogues.

Biodistribution studies were performed in mice bearing PC-3 tumor xenografts to investigate the influence of the charge on the *in vivo* uptake into human tumor cells. The highest tumor

uptake at 0.5 h p.i. was obtained with analogue **3**, being similar to that of a previously reported analogue (*21*). Although compound **2** only showed a slightly lower tumor uptake, it was more rapidly cleared than analogue **3** (Table 2). The fast washout of analogue **3** from normal tissues together with a longer residence time in the tumor tissue resulted in more favorable tumor-to-tissue ratios (Figure 3). The uptake in pancreas and colon was higher than that in tumor for all analogues (Table 2), which is consistent with the presence of high amounts of GRP receptors in these tissues. Specific uptake in normal receptor-positive organs may preclude the use of peptide-based radiopharmaceuticals in clinics. In this respect, no colon uptake is to be expected in men, since human colon does not express GRP receptors. Human pancreas expresses bombesin receptors and might be a dose-limiting organ in radionuclide therapy. However, the levels of GRP receptors are lower than in murine pancreas. Furthermore, human pancreas is not a highly radiosensitive organ, and interestingly, analogue **3** showed a faster washout from pancreas than from tumor. The pancreas uptake observed with the radiolabeled analogues showed a good correlation with their binding affinity. However, no correlation was found between affinity and tumor uptake. This discrepancy may be due to a combination of a polarity-dependent tumor penetration and the affinity for the receptors. Thus, although a higher polarity seems to favor tumor penetration, the different affinity would determine the final binding to the receptors. The hydrophilic character of the analogues **2**, **3**, and **5** translated into a highly significant reduction of activity in the liver, which was comparable to or even clearly lower than that of other recently published ^{99m}Tc-labeled BBS analogues (*11, 21, 23, 32*). The increased polarity also resulted in higher kidney uptake, especially for analogue **5**. The biodistribution of **5** was less favorable, since it showed not only high uptake and retention in the kidneys but also lower uptake in receptor-positive tissues, which confirmed the *in vitro* results. In contrast, compounds **2** and **3** exhibited a much faster clearance from kidney, which led to the highest tumor-to-kidney ratios reported for ^{99m}Tc-labeled BBS agonists (*11, 29*). Analogue **3** also showed higher tumor-to-liver ratios (Figure 3), thus indicating that a single negative charge would be more favorable. Compound **4** was not included in these experiments because of its unsatisfying *in vivo* behavior in preliminary biodistribution studies in normal mice (Supporting Information Table 2). This analogue showed high kidney uptake and slow washout. The influence of the charge on renal uptake has been reported for radiolabeled peptides (*30, 33, 34*). It is known that interaction between positively charged peptides and the negatively charged surface of the proximal tubular cells may increase renal accumulation (*33, 34*). The positive charge on the Lys side chain of analogue **4** may contribute to the higher and persistent accumulation of radioactivity in the kidneys. High renal uptake may cause radiation nephrotoxicity, the most important dose-limiting factor that reduces the therapeutic index of radiopeptides.

Analogue **3** provided a better imaging of the tumor xenografts with a SPECT/CT system than analogues **1** and **5** (Figure 4), with an enhanced delineation of the xenografts and decreased radioactivity in the abdominal area. High abdominal accumulation of radioactivity may obscure the detection of tumors and metastases localized in this region, and it is a general observation reported not only for ^{99m}Tc-labeled BBS analogues (*11, 14, 29, 35*) but also for ^{64}Cu-labeled DOTA-BBS(7−14) (*22*), ^{64}Cu-NOTA-8-Aoc-BBN(7−14)NH_2 (*24*), or ^{68}Ga-labeled DOTA-BBS(6−14) (*36*). Therefore, in order to increase the potential of new radiolabeled BBS analogues in tumor targeting, it is very important to reduce the abdominal uptake.

In conclusion, we evaluated five new BBS analogues for their usefulness in imaging GRP-R-expressing neoplasms and could confirm the great impact of the polarity and charge on their *in vivo* behavior. Different linkers, consisting of polar β^3homoamino acids, were introduced between the binding sequence and the retro(N$^{\alpha}$His)Ac-chelator. A positive charge in the linker resulted in higher uptake and retention in kidney and liver. A hydroxyl group and especially a single negative charge in form of a β^3homoglutamic acid considerably ameliorated the biodistribution profile, with higher tumor uptake and retention, and significantly improved tumor-to-background ratios. However, additional negative charges led to a loss of binding affinity and internalization, and unfavorable biodistribution. The introduction of polar groups seems to be of great interest to improve the *in vivo* properties of ^{99m}Tc- or $^{186/188}$Re-labeled BBS analogues and increase their potential for imaging of GRP-R-expressing tumors. Further preclinical studies with therapeutic radionuclides will help to determine their potential use as radiotherapeutics.

ACKNOWLEDGMENT

The authors thank Ms. Olga Gasser, Dr. Alexander Hohn, and Mr. Alain Blanc for their technical assistance. This work was funded by an Oncosuisse grant (Nr. OCS 01311-02-2003) and by the Fund for Scientific Research-Flanders, Belgium, (grant nr. G.0036.04). V. Maes is a Postdoctoral Researcher of the Fund for Scientific Research-Flanders; Luc Brans thanks the "Institute for the Promotion of Innovation through Science and Technology in Flandres (IWT-Vlaanderen)" for a grant.

Department of Applied Biological Science, Genome and Drug Research Center, and Faculty of Pharmaceutical Sciences, Tokyo University of Science, 2641 Yamazaki, Noda, Chiba 278-8510, Japan. Received July 2, 2008; Revised Manuscript Received October 26, 2008

We investigated the application of resins used in solid-phase synthesis for affinity purification. A synthetic ligand for FK506-binding protein 12 (SLF) was immobilized on various resins, and the binding assays between the SLF-immobilized resins and FK506-binding protein 12 (FKBP12) were performed. Of the resins tested in this study, PEGA resin was the most effective for isolating FKBP12. This matrix enabled the isolation of FKBP12 from a cell lysate, and the identification of SLF-binding peptides from a phage cDNA library. We confirmed the interaction between SLF and these peptides using a cuvette type quartz crystal microbalance (QCM) apparatus. Our study suggests that PEGA resin has great potential as a tool not only for the purification and identification of small-molecule binding proteins but also for the selection of peptides that recognize target molecules.

INTRODUCTION

To elucidate the mechanism of action of biologically active small molecules, it is important to identify their target proteins (*1*). Affinity purification with ligand-immobilized beads has greatly contributed to screening for small molecule target proteins (*2*). Generally, agarose is used as a matrix for affinity purification. Unfortunately, however, agarose has a tendency to cause nonspecific binding of proteins, which can lead to problems during the screening procedure. Moreover, the yield as well as the variety of small ligands immobilized on an agarose matrix are limited because agarose is unstable in organic solvents. Several kinds of matrices, including a glycidyl methacrylate (GMA)-covered GMA-styrene copolymer (*3*−*7*), poly(methacrylate) polymers (*8*−*11*), and poly(acrylamide) polymers (*12*−*16*), have been developed to circumvent these problems (*2*). We are interested in applying resins used in solid-phase synthesis to the affinity purification of proteins (*17*). The resins have several attractive features as potential affinity matrices, including significant stability in both organic and aqueous media, chemical and physical stability, and high capacity loading of ligand. We have previously reported the affinity purification of a mammalian DNA polymerase β using its inhibitor-immobilized TentaGel resin.

In earlier studies, the fluorescent, radioisotope, or biotin-labeled derivatives immobilized on affinity beads were used as tools for identification of the target proteins derived from cell lysates (*18*−*21*). Indeed, several target proteins of small molecules, such as methotrexate (*7*, *22*, *23*), FK506 (*1*, *5*, *8*−*11*, *24*), and cyclosporin A (*25*−*27*), were isolated by these methods. Recently a phage-based method was reported (*28*). Phage particles can display a huge combinatorial library encoding peptides or proteins, which are derived from foreign DNA inserts as fusions of the phage capsid. Phage clones that specifically bind to the target molecules are first selected from the library. The corresponding amino acid sequences expressed on the phage surface can then be identified by sequencing the insert DNA of the phage clones. This method allows the rapid selection and identification of the ligand-binding peptides or proteins and has been successfully applied to the determination of binding proteins for FK506 (*29*), doxorubicin (*30*), HBC (*31*), and paclitaxel (*32*−*34*). Moreover, phage display technology can be used to efficiently identify the specific drug-binding site of the identified protein (*33*, *35*−*37*).

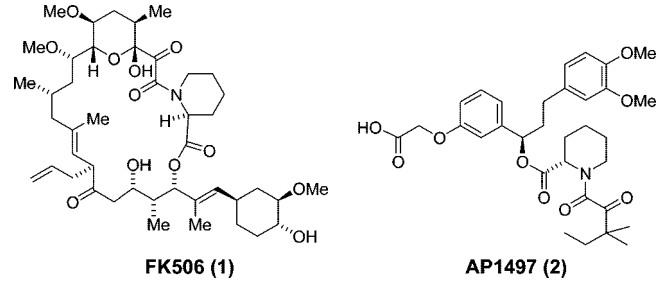

Figure 1. Structure of FK506 (**1**) and AP1497 (**2**). AP1497 is one of the synthetic ligands for FKBP12 (SLFs).

To evaluate the suitability of resins used in organic synthesis as affinity matrices, we focused on synthetic ligands for FK506-binding protein 12 (SLFs) as a model system (Figure 1). AP1497 (**2**) is one such SLF, which tightly binds to FK506 binding protein 12 (FKBP12) with a dissociation constant (K_D) of 20 nM (Figure 1) (*38*, *39*). Previous studies demonstrated that FK506-immobilized matrices captured FKBP12 from cell lysates (*1*, *5*, *8*−*11*, *24*) and that a biotinylated SLF derivative enabled the isolation of clones encoding FKBP12 from a T7 cDNA phage-display library (*40*, *41*). Thus, SLF is considered an ideal model ligand to evaluate matrices for affinity purification of target proteins from both cell lysates and phage cDNA libraries.

In this article, we have evaluated several resins used for organic syntheses as candidate affinity matrices for the identi-

fication of small molecule-binding proteins. We isolated FKBP12 protein from Jurkat cell lysates using SLF-immobilized PEGA resin. We also isolated two SLF-binding phage clones, which displayed full-length FKBP12 and a SLF-binding peptide, from a phage cDNA library using SLF-immobilized PEGA resin.

EXPERIMENTAL PROCEDURES

General Chemistry. Dichloromethane was distilled from P_2O_5 prior to use. *N*,*N*-Dimethylformamide was distilled from calcium hydride prior to use. All other reagents were commercially available and used without further purification. All reactions were monitored by TLC, which was carried out on Silica Gel 60 F_{254} plates (Merck, Darmstadt, Germany). Flash chromatography separations were performed on PSQ 100B (Fuji Silysia Co., Ltd., Japan). ^{1}H and ^{13}C NMR spectra were recorded on Avance DRX-600 or DRX-400 (Bruker BioSpin, Rheinstetten, Germany), using $CDCl_3$ (with TMS for ^{1}H NMR and chloroform-*d* for ^{13}C NMR as the internal reference) solution, unless otherwise noted. Chemical shifts were expressed in δ (ppm) relative to Me_4Si or residual solvent resonance, and coupling constants (*J*) were expressed in Hz. Optical rotations were recorded on a P-1030 digital polarimeter (JASCO, Tokyo, Japan) at room temperature. Infrared spectra (IR) were recorded on a FT/IR-410 spectrometer (JASCO) using NaCl (neat) or KBr pellets (solid) and were reported on wavenumbers (cm^{-1}). Mass spectra (MS) were obtained on an ABIQSTAR pulsar i mass spectrometer (Applied Biosystems, Foster City, CA) under high resolution conditions, using poly (ethylene glycol) as internal standard. Amino HypoGel200 (loading, 0.92 μmol/mg; size, 90 μm) and amino HypoGel400 (loading, 0.70 μmol/mg; size, 90 μm) were purchased from RAPP plolymere (Tübingen, Germany). Amino NovaSyn resins (loading, 0.29 μmol/mg; size, 90 μm), amino NovaGel (loading, 0.83 μmol/mg; size, 75−150 μm), amino PEGA (loading, 0.40 μmol/mg; size, 150−300 μm), amino polystyrene (loading, 0.90 μmol/mg; size, 75−150 μm), and hydroxyamino Wang resins (loading, 2.0 μmol/mg; size, 100−200 μm) were purchased from novabiochem (San Diego, CA). AffiGel 102 Gels (loading, 15 μmol/mL; size, 70−300 μm) were purchased from Bio-Rad Laboratories (Hercules, CA). EAH Sepharose 4B (loading, 7−12 μmol/mL; size, 45−165 μm) was purchased from GE Healthcare Bio-Science Corp (Piscataway, NJ). The peptide (LSCLWAELSGKLWPLPAAQ) was purchased from GENIX TALK (Osaka, Japan).

General Biology. Fetal bovine serum (FBS) was purchased from Biowest (Loire Valley, French). Kanamycin sulfate, dimethyl sulfoxide (DMSO), and biotin were purchased from Wako Pure Chemical Industries (Tokyo, Japan). RPMI 1640 and 2-Mercaptoethanol were purchased from Nacalai Tesque (Kyoto, Japan). Protease inhibitor cocktail was obtained from Sigma-Aldrich (ST. Louis, MO). Streptavidin agarose gel was purchased from GE Healthcare (Buckinghamshire, U.K.).

(1*R*)-1-[3-[2-(4-Nitrophenoxy)-2-oxoethyl]phenyl]-3-(3,4-dimethoxyphenyl)-1-propanyl (2*S*)-1-(3,3-dimethyl-1,2-dioxopentyl)-2-piperidinecarboxylate (3). Compound **3** was prepared in ca. 4:1 tautomeric mixture according to our previous report (*41*). Major tautomer: $[\alpha]_D^{24} = -7.2$ (*c* 1.8, $CHCl_3$); ^{1}H NMR (600 MHz, $CDCl_3$) δ 8.27 (2H, m), 7.33 (2H, m), 7.31 (1H, m), 7.03 (1H, d, J = 7.7 Hz), 7.00 (1H, *br*s), 6.93 (1H, dd, J = 8.2 Hz, 2.5 Hz), 6.77 (1H, m), 6.68 (2H, m), 5.80 (1H, dd, J = 7.9 Hz, 5.7 Hz), 5.32 (1H, *br*d, J = 5.3 Hz), 4.96 (2H, s), 3.85 (6H, s), 3.35 (1H, brd, J = 12.7 Hz), 3.16 (1H, td, J = 13.1 Hz, 2.9 Hz), 2.57 (2H, m), 2.36 (1H, m), 2.24 (1H, m), 2.07 (1H, m), 1.72 (5H, m), 1.45 (1H, m), 1.35 (2H, m), 1.22 (3H, s), 1.21 (3H, s), 0.88 (3H, t, J = 7.4 Hz); ^{13}C NMR (100 MHz, $CDCl_3$) δ 207.8, 169.7, 167.3, 166.6, 157.7, 154.6, 148.9, 147.4, 145.6, 141.8, 133.3, 129.9, 125.3 (× 2), 122.2 (× 2), 120.4, 120.1, 114.6, 113.1, 111.7, 111.3, 76.4, 65.3, 55.9, 55.8, 51.2, 46.7, 44.1, 38.0, 32.4, 31.2, 26.3, 24.9, 23.4, 23.1, 21.1, 8.7; IR (neat) 3021, 2937, 2861, 1786, 1738, 1701, 1640, 1592, 1521, 1444, 1348, 1210, 1143, 1082, 1029, 992, 921, 864, 756 cm^{-1}; HRMS (ESI) calcd for $C_{38}H_{44}N_2O_{11}$ ($[M + Na]^+$) *m*/*z* 727.2837, found 727.2800.

General Method for the Preparation of SLF-Immobilized Resins (5). Dry resins (1 equiv) were swollen in pyridine. To the suspension of the resins was added a solution of **3** (0.3−1.9 equiv) and DMAP (1.2 equiv) in CH_2Cl_2. After the mixture was stirred at r.t. for 19 h, the mixture was filtrated and washed with CH_2Cl_2 five times. The filtrate was concentrated, and the residue was purified by silica gel chromatography (hexane/EtOAc = 4:1 to 1:1) to give the recovered AP1497 *p*-nitrophenyl ester. The amount of SLF immobilized on the dry resins was estimated by the amount of the recovered **3**.

The SLF-immobilized resins were suspended in Ac_2O-pyridine (1:1), and the suspension was stirred at r.t. for 3 h. Then the suspension was filtered and washed with CH_2Cl_2 three times, MeOH three times, and CH_2Cl_2 twice. The resulting resins were dried in vacuo.

The amount of SLF immobilized on 1 mg of dry PEGA resin (**5e**) was 0.19 μmol. Because the swelling volume of PEGA in water is reported to be 16 mL/g in the manufacturer's instruction, 1 g of PEGA resin swells up to 16 mL. Thus, the amount of SLF immobilized on 1 mL of wet PEGA resin (**5e**) was estimated to be 11−12 μmol.

General Method for the Preparation of Acetylated Resins (Control Resins) (6). Dry resins were swollen in pyridine (5.0 mL). To the suspension of the resins was added Ac_2O (5.0 mL), and the suspension was stirred at r.t. for 3 h. Then the suspension was filtered and washed with CH_2Cl_2 three times, MeOH three times, and CH_2Cl_2 twice. The resulting resins were dried in vacuo.

Synthesis of SLF-Immobilized AffiGel. Affigel 102 Gel was washed with DMF five times and swollen in DMF (*5*). To the suspension of the gel was added a solution of **3** (1.2 equiv) and DMAP (1.2 equiv) in DMF. After the mixture was stirred at r.t. for 16 h, the mixture was filtrated and washed with DMF five times. The filtrate was concentrated, and the residue was purified by silica gel chromatography (hexane/EtOAc = 4:1 to 1:1) to give the recovered **3**. The amount of SLF immobilized on the gel was estimated to be 15 μmol/mL by the amount of recovered **3**. The SLF-immobilized AffiGel were suspended in 20% DMF solution of Ac_2O, and the suspension was stirred at r.t. for 3 h. Then the suspension was filtered and washed with DMF three times and 20% aqueous solution of EtOH three times.

Synthesis of Acetylated AffiGel. Affigel 102 Gel was washed with DMF five times. The gel was suspended in 20% DMF solution of Ac_2O, and the suspension was stirred at r.t. for 3 h. Then the suspension was filtered and washed with DMF three times and 20% aqueous solution of EtOH three times.

Synthesis of SLF-Immobilized Sepharose 4B. EAH Sepharose 4B was washed with 1 mM aqueous solution of HCl three times and in 0.5 M aqueous NaCl, and swollen in dioxane/H_2O (1:1). To the suspension of the resins was added a solution of **3** (1.2 equiv) and DMAP (1.2 equiv) in dioxane/H_2O (1:1). After the mixture was stirred at r.t. for 16 h, the mixture was filtrated and washed with dioxane/H_2O (1:1) five times. The filtrate was concentrated, and the residue was purified by silica gel chromatography (hexane/EtOAc = 4:1 to 1:1) to give recovered **3**. The amount of SLF immobilized on the beads was estimated to be 7 μmol/mL by the amount of recovered **3.** The SLF-immobilized Sepharose 4B were suspended in 5% Ac_2O in dioxane, and the suspension was stirred at r.t. for 3 h. Then the suspension was filtered and washed with dioxane/H_2O five times and H_2O three times.

Synthesis of Acetylated Sepharose 4B. EAH Sepharose 4B was washed with 1 mM aqueous solution of HCl three times and in 0.5 M aqueous NaCl, and swollen in dioxane/H_2O (1:1). The gels were treated with 5% Ac_2O in dioxane, and the suspension was stirred at r.t. for 3 h. Then the suspension was filtered and washed with dioxane/H_2O five times and H_2O three times.

Bis(SLF-PEG-undecyl)disulfide (7). Compound **7** was prepared in ca. 4:1 tautomeric mixture from compound **3** according to our previous report (*41*). Major tautomer: $[\alpha]_D^{24} = -3.6$ (*c* 0.67, $CHCl_3$); ^{1}H NMR (600 MHz, $CDCl_3$) δ 7.31 (1H × 2, t, $J = 7.9$ Hz), 7.05 (1H × 2, *br*t, $J = 5.6$ Hz), 7.00 (1H × 2, *br*d, $J = 7.7$ Hz), 6.93 (1H × 2, *br*s), 6.86 (1H × 2, dd, $J = 7.9$ Hz, 2.0 Hz), 6.78 (1H × 2, m), 6.68 (1H × 2, *br*s), 6.67 (2H × 2, m), 6.09 (1H × 2, *br*m), 5.77 (1H, dd, $J = 7.9$ Hz, 5.6 Hz), 5.31 (1H × 2, d, $J = 5.4$ Hz), 4.50 (2H × 2, s), 3.86 (3H × 2, s), 3.85 (3H × 2, s), 3.63 (8H × 2, *br*s), 3.60 (2H × 2, m), 3.57 (2H × 2, m), 3.52 (2H × 2, m), 3.44 (2H × 2, m), 3.37 (1H × 2, *br*d, $J = 12.3$ Hz), 3.18 (1H × 2, td, $J = 13.1$ Hz, 2.9 Hz), 2.67 (2H × 2, t, $J = 7.4$ Hz), 2.61 (1H × 2, m), 2.53 (1H × 2, m), 2.38 (1H × 2, *br*d, $J = 13.7$ Hz), 2.25 (1H × 2, m), 2.15 (2H × 2, t, $J = 7.4$ Hz), 2.05 (1H × 2, m), 1.80−1.60 (12H × 2, m), 1.50 (1H × 2, m), 1.35 (4H × 2, m), 1.27 (10H × 2, brs), 1.23 (3H × 2, s), 1.21 (3H, s), 0.89 (3H × 2, *t*, $J = 7.4$ Hz); ^{13}C NMR (100 MHz, $CDCl_3$) δ 207.8 (× 2), 173.2 (× 2), 169.7 (× 2), 168.1 (× 2), 167.3 (× 2), 157.4 (× 2), 148.9 (× 2), 147.4 (× 2), 141.9 (× 2), 133.3 (× 2), 130.0 (× 2), 120.1 (× 2), 120.1 (× 2), 114.2 (× 2), 113.3 (× 2), 111.3 (× 2), 76.5 (× 2), 70.5 (× 4), 70.3 (× 2), 70.2 (× 2), 70.0 (× 2), 69.7 (× 2), 67.4 (× 2), 55.9 (× 2), 55.8 (× 2), 55.8 (× 2), 51.3 (× 2), 46.7 (× 2), 44.1 (× 2), 39.12 (× 2), 39.10 (× 2), 38.8 (× 2), 36.7 (× 2), 32.5 (× 2), 31.2 (× 2), 29.7 (× 2), 29.5 (× 2), 29.42 (× 2), 29.36 (× 2), 29.3 (× 2), 29.21 (× 2), 29.20 (× 2), 28.5 (× 2), 26.4 (× 2), 25.7 (× 2), 24.5 (× 2), 23.5 (× 2), 23.2 (× 2), 21.2 (× 2), 8.7 (× 2); IR (neat) 3342, 2928, 2857, 1738, 1645, 1517, 1444, 1351, 1261, 1141, 1030, 992 cm^{-1}; HRMS (ESI) calcd for $C_{102}H_{56}N_6O_{24}Na_2S_2$ 979.5198 ($[M + 2Na]^{2+}$), found 979.5220. Calcd for $C_{102}H_{56}N_6O_{24}NaS_2$ *m*/*z* 1936.0504 ($[M + Na]^+$), found 1936.0549.

Bis(Acetyl-PEG-undecyl)disulfide (Bis 11-(*N*-acetyl-3,6,9-trioxaundecyl-*N*-carbamoylundecyl)disulfide) (8). A solution of bis(amino-PEG-undecyl)disulfide (13.4 mg, 13.3 μmol) in Ac_2O (1 mL) and pyridine (1 mL) was stirred at r.t. for 20 h. Then the mixture was concentrated, and the residue was purified by silica gel chromatography ($CHCl_3$/MeOH = 20:1) to give **7** (10.4 mg, 90%) as a white solid. Mp = 88−89 °C; ^{1}H NMR (600 MHz, $CDCl_3$) δ 6.22 (1H ×2, *br*s), 6.11 (1H × 2, *br*s), 3.65 (8H × 2, *br*s), 3.57 (4H × 2, t, $J = 5.1$ Hz), 3.45 (4H × 2, m), 2.68 (2H × 2, t, $J = 7.3$ Hz), 2.17 (2H, x 2, t, $J = 7.9$ Hz), 1.99 (3H × 2, s), 1.69−1.60 (4H × 2, m), 1.37 (2H × 2, m), 1.27 (10H × 2, *br*s); ^{13}C NMR (100 MHz, $CDCl_3$) δ 173.2 (× 2), 170.0 (× 2), 70.39 (× 2), 70.38 (× 2), 70.1 (× 4), 69.9 (× 2), 69.8 (× 2), 39.2 (× 2), 39.1 (× 2), 39.0 (× 2), 36.6 (× 2), 29.36 (× 2), 29.33 (× 2), 29.27 (× 2), 29.2 (× 2), 29.1 (× 4), 28.4 (× 2), 25.6 (× 2), 23.1 (× 2); IR (neat) 3298, 3082, 2921, 2849, 1643, 1557, 1463, 1414, 1377, 1286, 1232, 1143, 997, 952 cm^{-1}; HRMS (ESI) calcd for $C_{42}H_{82}N_4O_{10}NaS_2$ 889.5364 ($[M + Na]^+$), found 889.5364.

Expression of Six Histidine-Tagged FK506-Binding Protein 12 (FKBP12). The cDNA encoding human FKBP12 was cloned into the expression vector pET28a(+) (Novagen) and was transformed into *Esherichia coli* BL21(DE3). A single colony was inoculated into 15 mL of LB medium containing 1% glucose and 50 μg/mL kanamycin, and cultured at 30 °C. The cells were grown overnight and then were transferred into 1 L of the same medium at 37 °C. After incubation for 3 h, the expression of FKBP12 was induced by adding IPTG to 1 mM. The culture was then continued for further 3 h at 37 °C. The cultured cells were harvested by centrifugation at 1500*g* for 10 min at 4 °C. The cells were resuspended in PBS and centrifuged at 1100*g* for 10 min at 4 °C. After removal of the supernatant, the cells were frozen using liquid N_2 and then stored at −80 °C.

Purification of His-Tagged FKBP12. The FKBP12-producing cells were sonicated in buffer A (50 mM phosphate (pH. 8.0), 300 mM NaCl, 10 mM imidazole, 1 mM phenylmethylsulfonyl fluoride (PMSF), 1 μg/mL leupeptin, and 1 μg/mL pepstatin A) and then centrifuged at 20400*g* for 30 min at 4 °C. The supernatant was filtered through a PVDF membrane (Millex, pore size 0.45 μm, Millipore, Billerica, MA) and then loaded onto a Ni-NTA resin (GE Healthcare) pre-equilibrated with buffer A. The column was washed with buffer B (50 mM phosphate (pH. 8.0), 300 mM NaCl, 20 mM imidazole), and buffer C (50 mM phosphate (pH. 8.0), 300 mM NaCl, and 30 mM imidazole). Bound proteins were then eluted with buffer D (50 mM phosphate (pH. 8.0), 300 mM NaCl, and 250 mM imidazole). The fractions containing the His-tagged FKBP12 were collected and dialyzed into TEMG buffer (50 mM Tris-HCl (pH 7.5), 1 mM EDTA, 50 mM NaCl, 10% glycerol, and 5 mM 2-mercaptoethanol) for purification by FPLC. The protein was loaded onto HiTrap DEAE column pre-equilibrated with TEMG buffer, and the flow-through fraction was then subjected to HiTrap SP column. The flow-through fraction was collected and dialyzed into FKBP buffer (25 mM Tris-HCl (pH 7.5), 50 mM NaCl, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 10% glycerol, 5 mM 2-mercaptoethanol, and 0.05% Nonidet P-40) and then stored at −80 °C until use.

Binding Analysis between FKBP12 and the Resins. Each resin (4 mg) was pre-equilibrated with the FKBP12 buffer (400 μL) overnight. Then 600 μL of recombinant FKBP12 (1.61 mg/mL, 0.97 mg) was added to the resins. The resins were incubated at 4 °C for 4 h. The amount of FKBP12 in the supernatant was determined by the Bradford assay, with absorbance measured at 595 nm. The amount of FKBP12 bound to the resins was calculated by subtracting the amount of FKBP12 in the supernatant from the amount of total FKBP12. After the resins were washed with the FKBP12 buffer (850 μL) 5 times, the resulting resins were boiled at 90 °C in 250 μL of SDS−PAGE loading buffer (0.25 mM dithiothreitol, 0.5% SDS, 20 mM Tris-HCl (pH6.8), 2.5% glycerol, and 0.01% Bromo phenol blue). The supernatant of each sample was separated on a 15% acrylamide gel, visualized by CBB staining, and quantified using the ImageJ program.

Affinity Purification of FKBP12 from Jurkat Cell Lysates by the SLF-Immobilized PEGA Resin. All procedures were performed at 4 °C. Frozen Jurkat cells (1×10^7 cells) were suspended in 1 mL FKBP buffer containing protease inhibitors (1 mM phenylmethyl sulfonyl fluoride, 1 μg/mL leupeptin, and 1 μg/mL pepstatin A), sonicated twice for 5 s, and incubated on ice for 25 min. The cells were centrifuged at 15000 rpm for 20 min at 4 °C, and the supernatant was kept as cell lysate. After SLF-immobilized PEGA resin (4 mg) and control PEGA resin (4 mg), pre-equilibrated with FKBP buffer containing protease inhibitors, the resulting beads were added to 450 μL of Jurkat cell lysate. The mixtures (1 mL) were rotated gently for 4 h. The resins were washed 3 times with 850 μL of FKBP buffer containing protease inhibitors and were boiled at 90 °C in 50 μL of SDS−PAGE loading buffer (1.25 mM dithiothreitol, 2.5% SDS, 100 mM Tris-HCl (pH6.8) 12.5% glycerol, and 0.01% bromo phenol blue). Each sample was separated on a 15% acrylamide gel and visualized by silver staining. FKBP12 bound to the resins was detected by Western blotting with anti-FKBP12 goat polyclonal antibody (Santa Cruz Biotechnology, Inc., Santa Cruz, CA) and alkali phosphatase-conjugated antigoat IgG.

Construction of FKBP12 Phage Clone. Full length gene encoding human FKBP12 protein was obtained from a phage cDNA library by PCR with the two primers, FKBP-up (5′-GAATTCGATGGGAGTGCAGGTGGAAAC-3′) and FKBP-down (5′-AAGCTTTCATTCCAGTTTTAGAAGCTCC-3′). The amplified DNA was double digested with *Eco*R I and *Hin*d III endonucleases and concentrated by ethanol precipitation. The purified DNA was then ligated into T7-Select10-3b vector (Novagen) and subsequently packaged into phagemid (Novagen). The FKBP12 phage clone was amplified by infection into *E. coli* strain BLT5615.

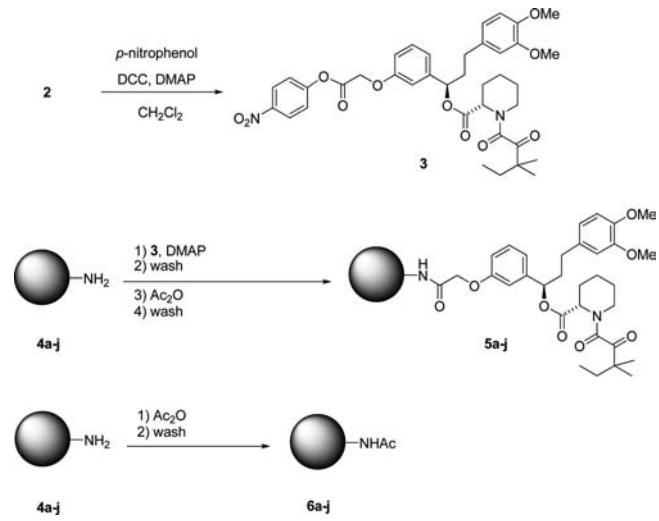
Binding Analysis of FKBP12 Phage Clone to the SLF-Immobilized Resin or Control Resin. Each resin (100 μg) was pre-equilibrated with TBS (25 mM Tris-HCl, pH 7.5, 50 mM NaCl, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 10% Glycerol, and 0.05% Nonidet P40) for 12 h at 4 °C. The FKBP12 phage clone was amplified by infection into *E. coli* strain BLT5615 as host cells, and the amplified phage clone (1×10^{10} plaque forming units (pfu)/mL) was added to the resin. After incubation at room temperature for 1 h, the resin was precipitated and the phage solution removed. The resin was then washed 10 times with Wash buffer (25 mM Tris-HCl, pH 7.5, 50 mM NaCl, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 10% Glycerol, 0.05% Nonidet P40, and 5 mM 2-mercaptoethanol). Bound phage particles were subsequently removed from the resin by 15 min incubation in 1% SDS in TBS buffer. The eluted phage particles were amplified by infection into *Escherichia coli* strain BLT5615, and the titers of the phage particles from each resin were calculated. The phage clone with no inserted cDNA fragment (No Ins phage) was used in the same binding assay as the negative control.

Construction of T7 cDNA Phage Library. The T7 phage library was constructed using cloning kits for T7 phage display (T7 Select 10-3 OrientExpress cDNA Cloning System, Random Primer, Novagen) and cDNA derived from Colo205 cells according to the method given by the manufacturer. The primary titer of this T7 phage library was 3.3×10^5 pfu. The library was amplified with a titer of 1×10^{10} pfu/mL for screening.

Affinity Selection of SLF-Binding Phage Clones from T7 cDNA Phage Library Using the SLF-Immobilized PEGA Resin. A modified version of the biopanning technique given in the manufacturer's instructions (Novagen) was used in this study. The resin (100 μg) pre-equilibrated with TBS (25 mM Tris-HCl, pH 7.5, 50 mM NaCl, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 10% glycerol, and 0.05% Nonidet P40) for 12 h at 4 °C. The T7 cDNA display library (1 mL, approximately 1×10^{10} pfu/mL) was added to the resin. After incubation at room temperature for 1 h, the resin was precipitated and the phage solution removed. The resin was then washed 10 times with Wash buffer (25 mM Tris-HCl, pH 7.5, 50 mM NaCl, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 10% glycerol, 0.05% Nonidet P40, and 5 mM 2-mercaptoethanol). Adsorbed phage particles were subsequently removed from the resin by 15 min of incubation in 1% SDS solution. The eluted phage particles were amplified by infection into *E. coli* strain BLT5615 as host cells. The amplified phage was applied to subsequent rounds of biopanning. The titer was monitored at each panning step. The eluted phage solution at each step was used for the immediate infection of host cells. Incubation with shaking at 37 °C was continued until lysis was observed. Amplified phage titers of each round were estimated to be approximately $1-6 \times 10^{10}$ pfu/mL. After each round, the eluted phage titers were compared to those of the previous round.

Characterization of Binding Phage. After the seventh round, the eluted phage particles were applied to Luria−Bertani (LB) plates containing 50 μg/mL carbenicillin. Sixteen clones were randomly selected from the plate, and each clone was dissolved in phage extraction solution (20 mM Tris-HCl pH 8.0, 100 mM NaCl, and 6 mM $MgSO_4$). Phage DNA carrying insert cDNAs was amplified by PCR using a forward primer (5′-TGCTAACT-TCCAAGCGGACC-3′) and a reverse primer (5′-TTGCCCA-GAACTCCCCAA-3′). The PCR products were purified with ExoSAP-It (GE Healthcare) and used for cycle sequence PCR with a BigDye Terminator 3.1 Cycle Sequence Kit (Applied BioSystems). The resulting fragments were precipitated with ethanol. The purified PCR products were sequenced on an ABI PRISM 3100 Genetic Analyzer (Applied BioSystems). From the results, the deduced amino acid sequence present on the T7 phage capsid was determined.

Scheme 1. Synthesis of SLF-Immobilized Supports (5a−j) and Control Supports (6a−j)[a,b]



[a] (**a**) HypoGel 200, (**b**) HypoGel 400, (**c**) TentaGel, (**d**) NovaSynTG, (**e**) PEGA, (**f**) NovaGel, (**g**) polystyrene resins, (**h**) Wang resins (**i**) AffiGel, (**j**) Sepharose 4B. [b] The loading of SLF on **5** was estimated from the amount of the recovered **2**, resulting in **5a** (0.48 μmol/mg), **5b** (0.49 μmol/mg), **5c** (0.23 μmol/mg), **5d** (0.19 μmol/mg), **5e** (0.19 μmol/mg), **5f** (0.48 μmol/mg), **5g** (0.48 μmol/mg), **5h** (0.48 μmol/mg), **5i** (15 μmol/mL), and **5j** (7 μmol/mL).

Kinetic Analysis of the Binding between SLF and FKBP12 or SLF-Binding Peptide by QCM Apparatus. Kinetic analyses were performed by a 27 MHz QCM system (Affinix Q, Initium Inc., Tokyo, Japan). Disulfide linked SLF dimer or acetylated diulfide was immobilized on the gold electrode of the sensor chip (*41*). The sensor chip was set on the QCM apparatus and soaked in buffer (8 mL, 10 mM Tris-HCl, pH 8.0, and 200 mM NaCl). The frequency of the QCM was defined as zero position after equilibrium (3 min). Then an 8 μL aliquot of His-tagged FKBP12 or 20 amino acid peptide sequence (SLSCLWAELSGKLWPLPAAQ) was sequentially injected into the cuvette. The changes of the frequency were monitored over time. The kinetic analysis was performed by AQUA ver. 1.5 software (Initium Inc.).

RESULTS

Syntheses of SLF-Immobilized Supports and Control Supports. AP1497 (**2**) was immobilized on resins (**4a**−**h**), which are normally used for solid-phase syntheses, and commercially available agarose matrices (**4i** and **4j**) by two steps via its nitrophenyl ester **3** (Scheme 1) (*38*, *41*). After immobilization of **2** onto the resins, the residual amino groups were blocked with acetic anhydride, yielding SLF-immobilized supports (**5a**−**j**). The loading of the SLF molecule was estimated from the amount of recovered **3**. Typically, the SLF-immobilized supports were prepared with a loading of 0.007−0.49 μmol/mg. In addition, control matrices (**6a**−**j**) were prepared by acetylation of **4** with Ac_2O to check the binding specificity.

HypoGel200 (**4a**), Hypogel400 (**4b**), TentaGel (**4c**), and NovaSyn TG (**4e**) are polystyrene−polyethylene glycol graft polymers (*42*). The molecular masses of polyethylene glycol (PEG) in HypoGel200 and Hypogel400 are 200 and 400 Da, respectively. TentaGel and NovaSynTG resins have PEG chains with a molecular mass of about 2000−3000 Da. The major difference between TentaGel and NovaSyn TG is the structure of the linkers. The PEG chains in TentaGel are linked to the polystyrene core via benzyl ether or in the case of NovaSyn TG via ethyl ether. NovaGel (**4f**), (4′-*O*-methylpolyethyleneglycoxycarbonylaminomethyl)polystyrene, was prepared from a modified aminomethylated polystyrene by partial derivatization with PEG chains. NovaGel has PEG chains with a molecular mass of about 2000 Da. PEGA (**4e**) is a copolymer of dimethylacrylamide and PEG (*43*). The molecular mass of the PEG chains in PEGA resin is about 800 Da. Wang resin (**4h**) was linked to the polystyrene core via the hydroxymethylphenoxy group. AffiGel (**4i**) and Sepharose 4B (**4j**) are commercially available agarose supports and are usually used for target identification of biologically active compounds. All of the supports used in this paper had a similar particle size (45−300 μM).

Binding Analyses between FKBP12 and the SLF-Immobilized Supports. Binding analyses between recombinant FKBP12 and the resins for organic synthesis were performed by the Bradford method for protein quantification (Figure 2A) (*17*, *44*). An excess amount of FKBP12 (0.97 mg) was applied to each SLF-immobilized resin (**5a**−**h**) or control resin (**6a**−**h**). After incubation at 4 °C for 4 h, the amount of FKBP12 in the supernatant was determined using the Bradford assay. The amount of FKBP12 bound to the resins was calculated by subtraction of the amount of free FKBP from that of total FKBP12. As shown in Figure 2A, only SLF-immobilized PEGA resin (**5e**) bound a significant amount of FKBP12 (0.53 mg), i.e., >25-fold greater than that bound by the control PEGA resin (**6e**) (0.02 mg). After washing away the unbound FKBP12 with buffer 5 times, the resins were boiled with SDS sample buffer. Any eluted FKBP12 was detected by SDS−PAGE and visualized using CBB staining. Figure 2B shows that FKBP12 was eluted only from **5e**. In contrast, no bound FKBP was detectable using the other resins, even after loading in the presence of abundant quantities of FKBP. The binding specificity was also confirmed by a competition assay with free SLF (Supporting Information). Similarly, we compared the amount of FKBP12 binding to SLF immobilized on PEGA resin (**5e**) with that to AffiGel (**5i**), which is one of the matrixes widely utilized for affinity purification of proteins (Figure 2C). SDS−PAGE analyses indicated that very similar amounts of FKBP12 were captured by the SLF on both resins in significantly low background. We confirmed that both **5e** and **5i** absorbed almost the same amount of FKBP12 (approximately 180 μg/4 mg resin). Because the amount of SLF immobilized on **5e** and **5i** was 11−12 and 15 μmol/mL, respectively (see Experimental Procedures and ref *45* for details), these data indicate that FKBP12 specifically bound to SLF immobilized on PEGA resin with efficiency similar to that of the AffiGel matrix. In addition, we confirmed that the PEGA resin with other ligands, such as lithocolic acid (LCA, a DNA polymerase β inhibitor) and glutathione (GSH), was applicable for affinity purification (Supporting Information).

We next sought to isolate FKBP12 from Jurkat cell lysates with the SLF-immobilized PEGA resin (**5e**) in a small scale. After incubation with the cell lysates, the resins were washed and then bound proteins were analyzed by SDS−PAGE. A 12-kDa protein was detected in the eluted proteins from **5e** in the silver-stained gel but not in those from **6e** (Figure 3A). In addition, a polyclonal antibody against FKBP12 cross-reacted

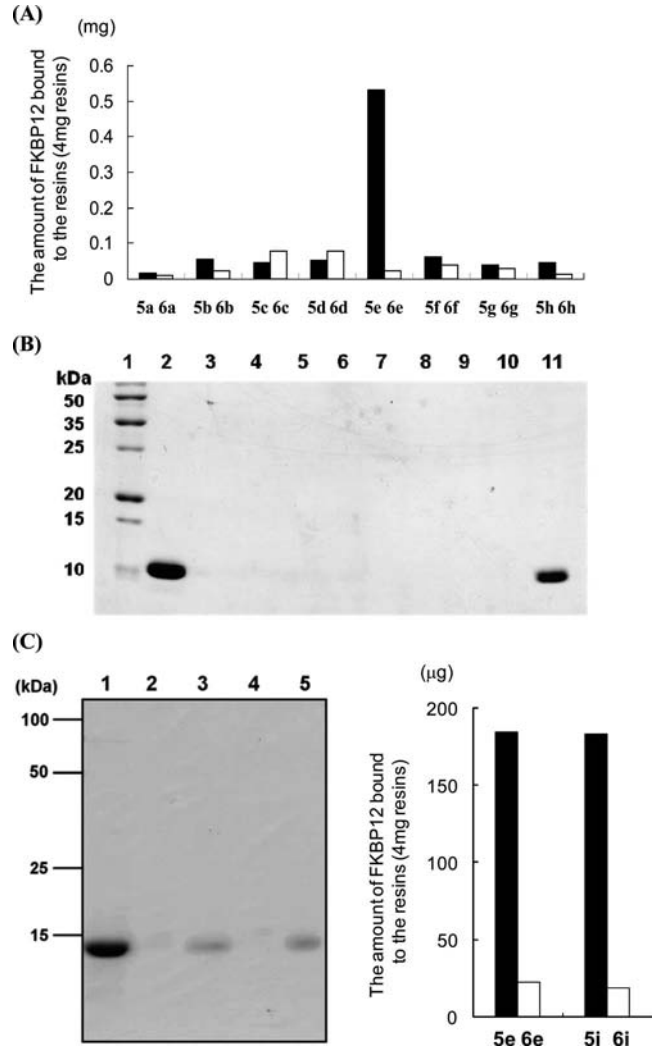


Figure 2. Binding analysis between recombinant FKBP12 and SLF-immobilized resins. (A) The amount of FKBP12 binding to resins **5a**−**h** and **6a**−**h**. A total of 0.97 mg of FKBP12 was applied onto **5a**−**h** and **6a**−**h**. After equilibrium, the amount of FKBP12 in the supernatant was determined by the Bradford assay. The amount of FKBP12 binding to resins **5a**−**h** and **6a**−**h** was calculated by subtraction of the amount of FKBP12 in the supernatant from the input FKBP12. (B) SDS−PAGE of FKBP eluted from **5a**−**h** and **6e**. After washing the resins to remove unbound FKBP12, the resins were boiled with SDS sample buffer. The eluted FKBP12 was analyzed by SDS−PAGE and visualized by CBB staining. Lane 1, molecular weight marker; lane 2, input FKBP12 (20%); lane 3, **5a**; lane 4, **5b**; lane 5, **5c**; lane 6, **5d**; lane 7, **5f**; lane 8, **5g**; lane 9, **5h**; lane 10, **6e**; lane 11, **5e**. (C) Comparison of FKBP12 binding between SLF-immobilized PEGA resin (**5e**) and AffiGel (**5i**). The bound FKBP12 protein on each resin was separated on a SDS−polyacrylamide gel (right) and quantified using ImageJ software (left). Lane 1, input FKBP12 (100%); lanes 2−5, elution from **6e** and **5e**, and **6i** and **5i**, respectively.

with this protein band (Figure 3B), indicating that the SLF-immobilized PEGA resin efficiently captured FKBP12 from the cell lysate.

Binding Analysis between FKBP12 Phage Clone and SLF-Immobilized PEGA Resin. To explore the suitability of PEGA resin as an affinity matrix for phage display, we conducted a T7 phage display screen using the SLF-immobilized PEGA resin. The binding of the T7 phage expressing FKBP12 clone (FKBP12 phage) to the SLF-immobilized PEGA resin was examined (Figure 4A). The phage particles were incubated with the SLF-immobilized PEGA (**5e**) or the control PEGA resins (**6e**). After removal of unbound phage, the bound phage particles were eluted and counted by infection into *E. coli*. The

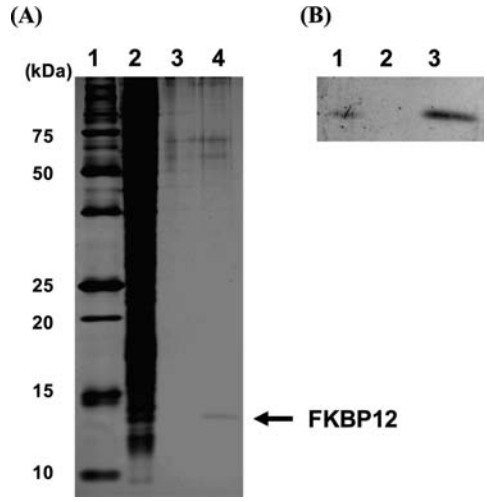

Figure 3. Affinity purification and detection of FKBP12 from Jurkat cell lysates using the SLF-immobilized PEGA resin. (A) SDS−PAGE analysis of the eluted samples from SLF-immobilized PEGA resin (**5e**) and control PEGA resin (**6e**). The protein bands on the gel were visualized after silver staining. Lane 1, molecular weight marker; lane 2, cell lysate; lane 3, elution from **6e**; lane 4, elution from **5e**. (B) Immunoblotting analysis for FKBP12. The eluted fractions were subjected to immunoblotting analysis using antihuman FKBP12 antibody. Lane 1, cell lysate; lane 2, elution from **6e**; lane 3, elution from **5e**.

recovery rate of the eluted phage particles from **5e** or **6e** is shown in Figure 4. **5e** trapped 600-fold more FKBP12 phages than **6e**. In contrast, there was little difference between the recovery rates of the phage with no insert cDNA (No Ins phage) from the two resins (i.e., **5e** and **6e**). These results indicate that the FKBP12 phage clone specifically binds SLF immobilized on the PEGA resin. We conducted the same binding analyses using AffiGel and Sepharose 4B (Figure 4 B and 4C). The SLF-immobilized AffiGel (**5i**) trapped 144-fold more FKBP12 phages than the acetylated AffiGel (**6i**), although the recovery rate was quite lower than that in the case of **5e** (Figure 4B). By contrast, the SLF-immobilized Sepharose 4B (**5j**) absorbed the FKBP12 phage clone with significantly high background. Our results indicate that PEGA resin may be a useful matrix for phage display screening.

Affinity Selection of SLF-Binding Phage Clones from the T7 Phage cDNA Library Using the SLF-Immobilized PEGA Resin. Isolation of FKBP12 phage from a phage cDNA library using the SLF immobilized PEGA resin was examined (Figure 5A). The T7 phage cDNA library was prepared with total RNA from Colo205 cells. The primary T7 phage library contained approximately 3.3×10^5 individual phage clones. The phage cDNA library was incubated with the SLF-immobilized PEGA (**5e**) or control PEGA resin (**6e**). After removal of unbound phage particles, the bound phage particles were eluted and amplified in *E. coli*. The resulting phages were then used in the next round of selection. Using **5e**, the recovery rate of eluted phage particles against input phage particles increased with each round of biopanning (Figure 5). By contrast, this ratio displayed little variation during each round of biopanning using **6e** (Figure 5). After the seventh round, we randomly selected 13 clones out of the eluted phage clones from **5e**. We then analyzed the deduced amino acid sequences displayed on the phage surface (Table 1A). Three clones (clone 1) encoded full-length FKBP12 including the 5′-terminal untranslated region. The other 9 clones displayed 20 amino acids (SLSCLWAELSGKLWPLPAAQ) on the phage surface, which are derived from a frameshift of the inserted cDNA. We also randomly selected 15 clones from the phages binding to **6e** and analyzed the corresponding sequences. Fourteen out of 15 clones binding to

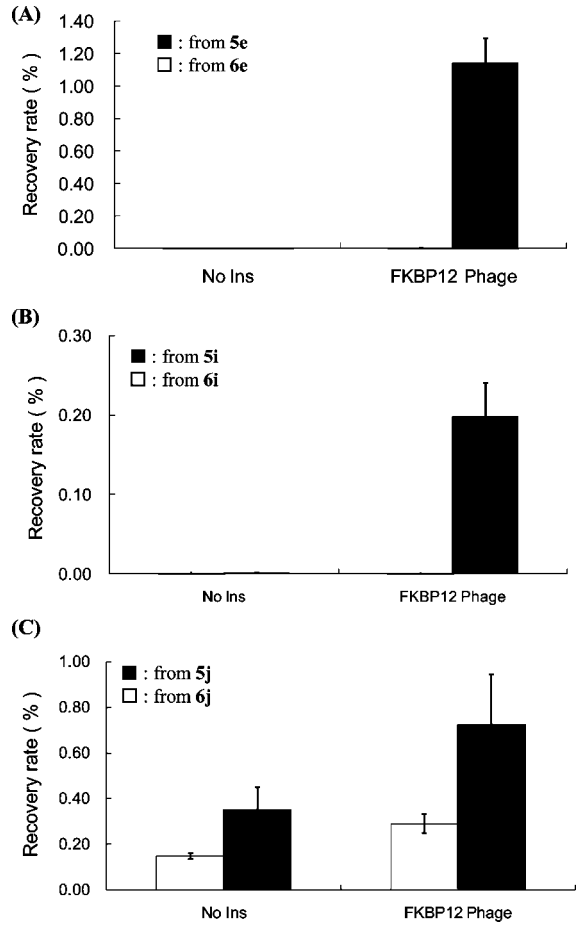

Figure 4. Binding analysis between FKBP12 phage clone and SLF-immobilized PEGA resin (A), AffiGel (B), or Sepharose 4B (C). Recovery rate of FKBP12 phage particles to the input phage particles from SLF-immobilized beads (filled column) or control beads (open column) is indicated. The phage clone with no insert cDNA (No Ins phage) was used in the same binding assay as the negative control. Values are the mean ± SD ($n = 6$).

6e encoded an individual short peptide, but no consensus sequences were identified.

Specific binding of clone 2 onto **5e** was confirmed using the same procedures as for FKBP12 phage (Figure 6). The recovery rate of clone 2 from **5e** was 9.5-fold higher than that from **6e**. However, there are no differences between the recovery of No Ins phage clone by **5e** and **6e**. These results indicate that clone 2 specifically recognizes SLF immobilized on the PEGA resin. Taken together, these results indicate that affinity selection of SLF-binding phage clones from the cDNA library was successfully achieved by the use of the SLF-immobilized PEGA resin. We searched for human genes homologous to the clone 2 peptide using PSI-BLAST (position-specific iterative BLAST). The clone 2 peptide displayed homology to various human gene products, but showed a relatively higher level of similarity to the 13 amino-acid sequence of group E Sox proteins (SoxE) (Supporting Information). This result suggests that SLF may bind to many kinds of proteins in human cells and that SoxE members are passive targets of SLF in vivo.

Kinetic Analysis of the Binding between SLF and the SLF-Binding Peptide Using a QCM Apparatus. We performed a kinetic analysis of the interaction between SLF and the clone 2 peptide (SLSCLWAELSGKLWPLPAAQ) using a cuvette type quartz crystal microbalance (QCM) apparatus (Affinix Q, Initium). Disulfide linked with SLF (Bis(SLF-PEG-undecyl)disulfide; **7**) or acetylated disulfide (bis(Acetyl-PEG-undecyl)disulfide; **8**) was immobilized onto the gold surface of

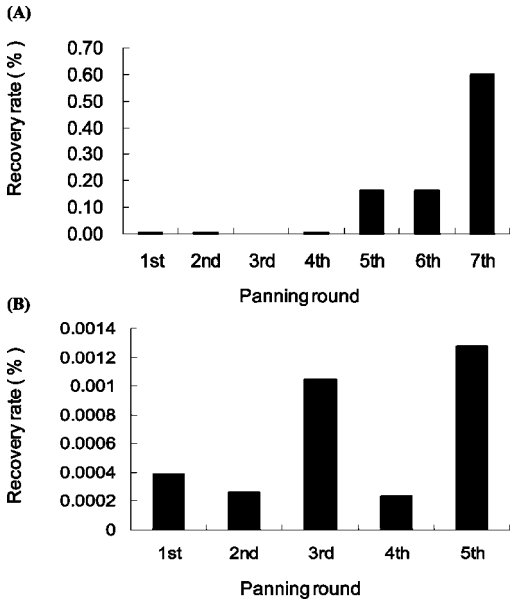

Figure 5. Recovery rate of SLF-binding phage particles after each round of biopanning. (A) The recovery rate obtained from the SLF-immobilized PEGA resin (**5e**). (B) The recovery rate obtained from the control PEGA resin (**6e**). The phage cDNA library derived from Colo205 cells was applied to **5e** or **6e**. After removal of unbound phage particles, bound phage particles were eluted and amplified by infection of *E. coli*. The resulting phage particles were used in the next round of selection. At each round, the recovery rates of the eluted phage particles to the input phage particles from the resins were calculated.

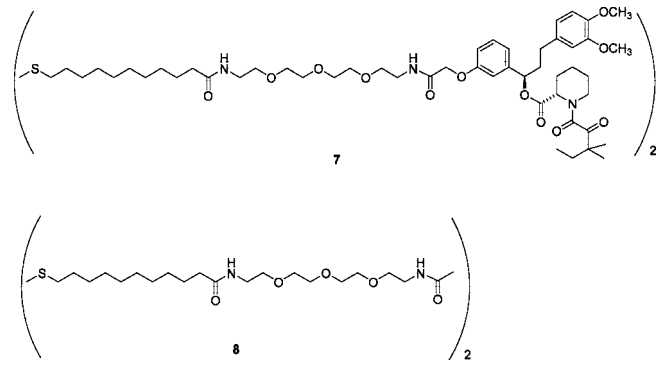

Figure 7. Structure of the disulfide linked with SLF (**7**) and acetylated disulfide (**8**).

the sensor chip (Figure 7). After washing the gold surface, the resulting sensor chip was mounted onto the QCM apparatus. As a positive control, recombinant FKBP12 was injected into the cuvette, and the QCM frequency shifts caused by the binding between the protein and small molecules conjugated to the sensor chip were monitored (red line in Figure 8A). The injection of protein significantly varied the frequency on the SLF-immobilized sensor chip. However, these frequency changes were only slight on the compound **8**-immobilized sensor chip, which was used as a negative control (Figure 8A, black line). Similarly, the addition of clone 2 peptide caused substantial frequency changes on the SLF-immobilized sensor chip but almost no change on the compound **8**-immbilized sensor chip (Figure 8B). The binding of FKBP12 or the clone 2 peptide against compound **7** was analyzed using the Langmuir adsorption model (Figure 9). The K_D values of the recombinant FKBP12 and clone 2 peptide with compound **7** were 0.027 μM and 5.8 μM, respectively. These results indicate that the clone 2 peptide (SLSCLWAELSGKLWPLPAAQ) specifically binds to SLF in vitro.

DISCUSSION

In this study, we investigated whether the resins used for solid-phase syntheses were suitable for affinity purification. To evaluate the capacity of the resins to act as an affinity matrix, synthetic ligand for FKBP12 (SLF), which specifically and tightly binds to FKBP12, was used as a model system. The efficacy of the SLF-immobilized resins was evaluated by affinity purification of FKBP12 from both a cell lysate and a phage cDNA library. Among the resins tested in this study, SLF-immbolized PEGA resin was the most effective at capturing FKBP protein. This result suggested that the favorable swelling

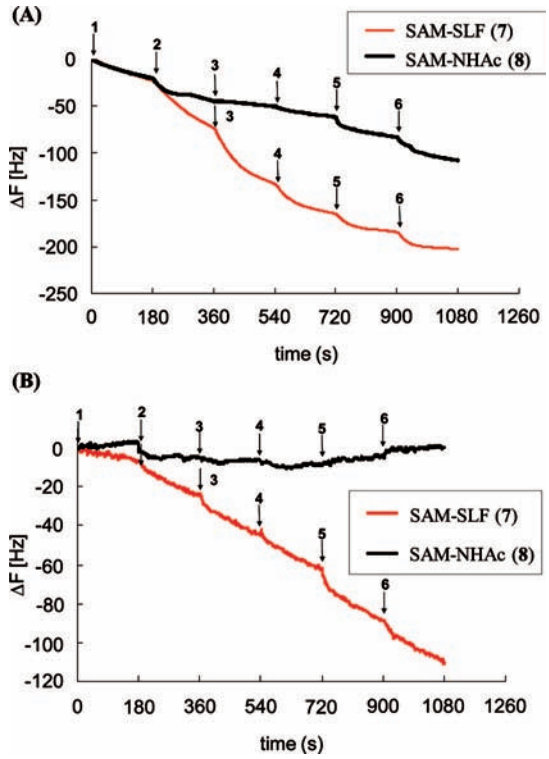

Figure 8. Kinetic analyses of the binding between SLF and SLF-binding peptides by using the QCM apparatus. (A) Time course of the frequency change of the SLF-immobilized (red) or control (black) sensor chip, responding to the addition of FKBP12. Various concentrations of FKBP12 were added to the cuvette. The resulting overall concentrations of FKBP12 in the cuvette were as follows: 1, 7.2 nM; 2, 21.6 nM; 3, 50.3 nM; 4, 79.0 nM; 5, 107.7 nM; 6, 136.4 nM. (B) Time course of the frequency change of the SLF-immobilized (red) or control (black) sensor chip, responding to the addition of clone 2 peptide. Various concentrations of the peptide were added to the cuvette. The resulting overall concentrations of the peptide in the quvette were as follows: 1, 0.3 μM; 2, 0.8 μM; 3, 1.3 μM; 4, 1.8 μM; 5, 4.8 μM; 6, 6.8 μM.

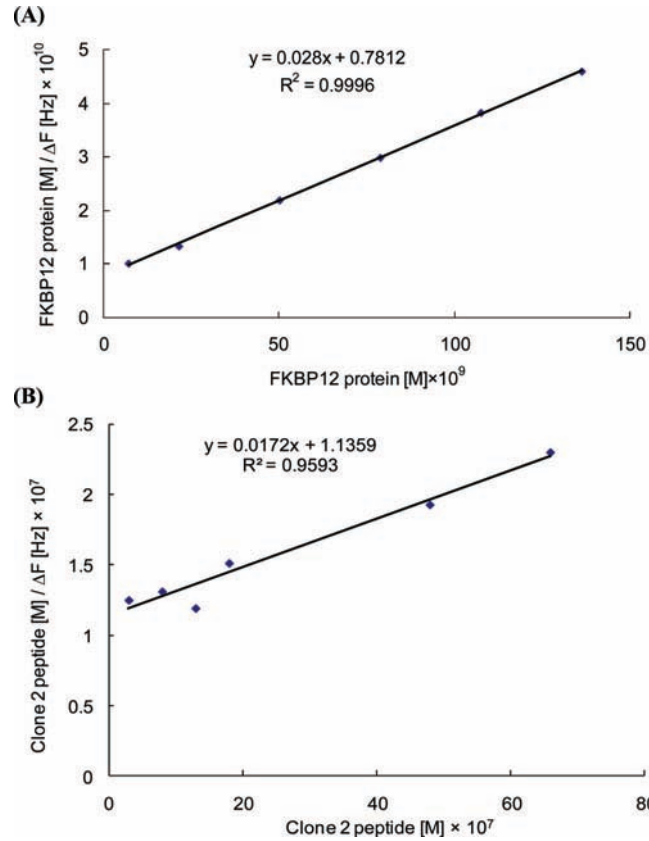

Figure 9. Langmuir isotherm plots for (A) FKBP12 and (B) clone 2 peptide binding with SLF-SAM (**7**) by QCM analyses.

properties of PEGA resin (16 mL/g) in aqueous media enabled affinity purification with high binding capacity and specificity. The swelling properties of the other resins are less favorable (e.g., 4 mL/g for TentaGel and NovaSyn TG resin in water). Furthermore, the hydrophilic nature of the PEGA matrix afforded easy access of the protein to the immobilized ligand on the resin.

Our previous report showed that TentaGel, which is PEG-coated polystyrene beads, was an effective resin for purifying DNA polymerase β. DNA polymerase β was purified from a Molt4 nuclear extract by LCA-immobilized TentaGel. In the present study, TentaGel was found to be unsuitable for purifying FKBP12. Tamura and co-workers also failed to isolate FKBP12 from a cell lysate with FK506-immobilized TentaGel, although the background itself was very low (*8*). These results suggest that hydrophobic ligands are poorly displayed on the surface of TentaGel resin, probably because the ligands have a tendency to form hydrophobic interactions with the polystyrene core by distorting the long flexible PEG chains (Mw 2000−3000 Da) (*8*). The very long PEG chains of TentaGel are not suitable for a spacer as affinity matrix when the hydrophobic ligands are immobilized on TentaGel. By contrast, DNA polymerase β binds to LCA-conjugated TentaGel because the hydrophilic carboxylic acid groups of LCA might prevent direct interaction with the polystyrene core.

Here, we demonstrate that SLF-immobilized PEGA resin can be used to purify FKBP12 from using Jurkat cell lysates with a low background. To our knowledge, this is the first case to exemplify that the target protein could be isolated from a cell lysate with a small ligand-immobilized PEGA resin. The hydrophilic PEG chains (Mw 800 Da) on the surface chains may act as a suitable linker not only to display the hydrophobic ligand on the surface but also to reduce nonspecific binding of proteins on the core. Auzanneau et al. reported that an antibody against *Streptococcus* Group A trisaccharide recognized the small molecule on PEGA resin (*14*). Sucholeiki et al. revealed that methotrexate-immobilized PEGA magnetic matrix specifically captured the folate binding protein from several kinds of proteins (bovine albumin, chicken albumin, folate binding protein, lysozyme, lactferrin, and lactoperoxidase precursor) (*16*). Taken together with our results, these observations indicated that PEGA resin could be applicable for affinity purification using small molecules with a variety of chemical properties as ligands.

We also investigated the application of the resins for phage display screening. Recently, several groups have succeeded in determining the ligand-binding site of the target protein by this screening method (*29*−*37*), where an avidin-coated matrix with a biotinylated compound was generally utilized. We found that the T7 phage displaying FKBP12 specifically bound the SLF immobilized on PEGA resin and that the PEGA matrix as well as AffiGel showed better signal-to-noise ratio than Sepharose 4B. These observations indicate that the PEGA resin is a useful matrix not only for affinity purification of proteins but also for phase display screening.

Using the SLF-immobilized PEGA resin, we successfully isolated 2 different clones out of the phage cDNA library derived from Colo205 cells. One clone (clone 1) encoded full length FKBP12 with the untranslated region, and the other phage clone (clone 2) displayed the 20 amino acid peptide (SLSCLWAELS-GKLWPLPAAQ, clone 2 peptide). We verified that the dissociation constant of the clone 2 peptide was 5.8 μM using the QCM apparatus, whereas interaction of the peptide with the

acetylated disulfide was barely detectable (K_D = 10.1 mM). Although the interaction between the peptide and SLF was weaker than that between FKBP12 and SLF (0.027 μM), these results suggest that the peptide specifically binds to SLF.

We also found that human SoxE proteins contain a region homologous to the clone 2 peptide. The SoxE proteins include Sox8, 9, and 10, which regulate transcription in various developmental processes, such as chondrogenesis, male sex determination, neural crest development, and gliogenesis (*46*−*48*). The 13 amino acids of SoxE proteins showing similarity to the clone 2 peptide are located in helix 2 of the HMG domain. This helix contacts the base pairs of the target DNA site and is followed by the C-terminal region of the HMG domain, including helix 3 and the C-terminal tail, which are required for interaction with numerous transcription factors (*49*−*51*). From these observations, we propose that SLF interferes with the binding between SoxE proteins and DNA and/or that the protein−protein interactions with transcription factors are inhibited by the conformational change of the C-terminal region of SoxE proteins due to the binding of SLF to the helix 2 domain. Therefore, although SLF does not exhibit a significant cellular response, it is possible that SLF might block certain cell differentiation pathways in which the SoxE proteins are involved.

In summary, we investigated the application of the resins used in solid-phase synthesis for affinity purification. Since resins used in solid-phase synthesis are chemically and physically stable, various approaches for synthesis and immobilization of small ligands are available by using the resins. Of the resins tested in this study, PEGA resin was the most effective for isolating FKBP12. This matrix enabled the isolation of FKBP12 from a cell lysate, and the identification of SLF-binding peptides from a phage cDNA library. Moreover, PEGA resin displayed as appropriate properties for affinity protein purification and phage display as AffiGel in our experimental conditions. Our study suggests that PEGA resin has great potential as a tool not only for the purification and identification of small-molecule binding proteins but also for the evolution and selection of peptides or antibodies that recognize target molecules. Further proteomics applications of PEGA resin are currently underway.

1. Binding competition assays of FKBP12 absorption on SLF-immobilized PEGA resin

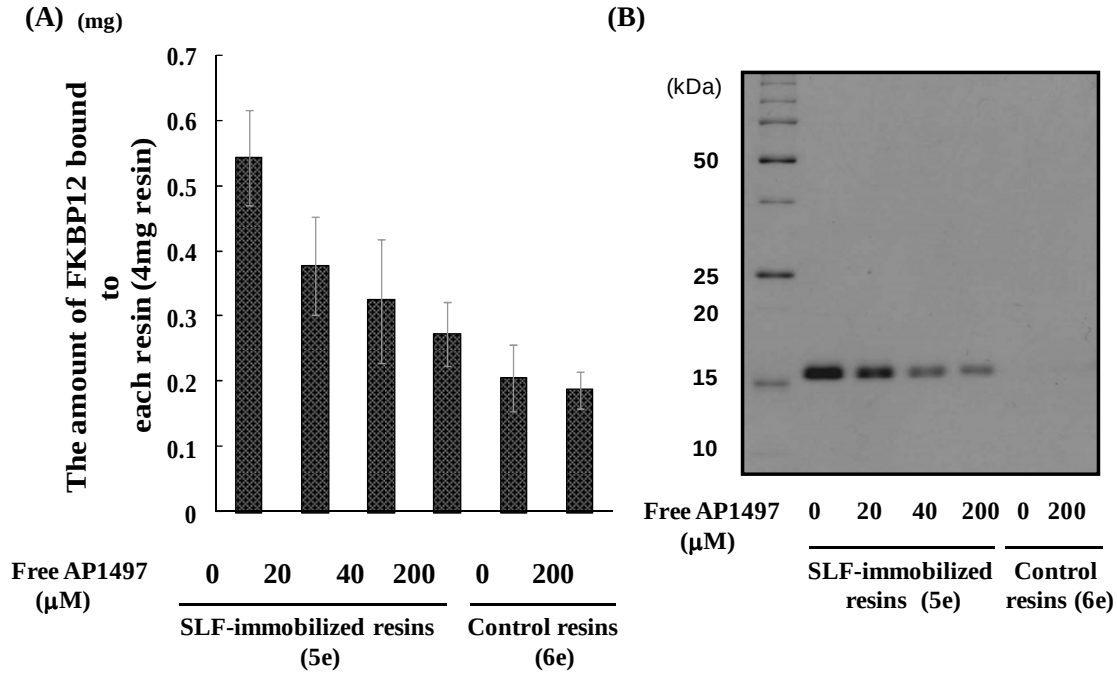

Figure S1. Binding competition assays of FKBP12 absorption on SLF-immobilized PEGA resin. The amount of FKBP12 bound to SLF-immobilized PEGA (**5e**) in the absence or presence of increasing concentration of free AP1497. As a control, the amount of FKBP12 bound to control PEGA (**6e**) is indicated. These experiments were performed according to the procedure described in text. (A) Total 0.97 mg of FKBP12 was applied to **5e** and **6e** in the absence or presence of increasing concentration of free AP1497. After equilibrium, the amount of FKBP12 in the supernatant was determined by Bradford assay. The amount of FKBP12 binding to resins **5e** and **6e** was calculated by subtraction of the amount of FKBP12 in the supernatant from that of input FKBP12. (B) SDS-PAGE of FKBP eluted from **5e** and **6e**. After washing the resins to remove unbound FKBP12, the resins were boiled with SDS sample buffer. The eluted FKBP12 was analyzed by SDS-PAGE and visualized by CBB staining. Values are mean±S.D. of a representative result conducted in triplicates.

A New PEG−β-Alanine Active Derivative for Releasable Protein Conjugation

Gianfranco Pasut,*[,†] Anna Mero,[†] Francesca Caboi,[‡] Silvia Scaramuzza,[‡] Luigi Sollai,[‡] and Francesco M. Veronese[†]

Department of Pharmaceutical Sciences, University of Padua, via F. Marzolo 5, 35131 Padua, Italy, and Bio-Ker S.r.l., Piscinamanna 09010 Pula (CA), Italy. Received July 7, 2008; Revised Manuscript Received November 3, 2008

A new PEGylating agent, PEG-βAla-NHCO-OSu, has been studied for protein amino conjugation using human growth hormone (hGH) and granulocyte colony stimulating factor (G-CSF) as model therapeutic proteins. This new activated PEG possesses a convenient property for protein modification when compared to other activated carboxylate PEGs, namely, lower reactivity. When this polymer reacts with a protein, its features lead to fewer PEG−protein conjugate isomers because it preferentially binds the most nucleophilic and exposed amines. Furthermore, the conjugates obtained with PEG-βAla-NHCO-OSu showed an interesting slow release of polymer chains upon incubation under physiological conditions. Further investigations determined that the PEG chains released are those coupled to histidine residues, and this finally yields less PEGylated species as well as free protein. This release allows a partial recovery of protein activity that is often remarkably and permanently reduced after stable PEGylation, and it occurs in water or blood without the involvement of enzymes. On the other hand, the rate of PEG release, tuned by the chemical structure of this new PEGylating agent, is not too high, and therefore, the achievement of a desired prolongation of protein half-life in vivo is still feasible. The pharmacokinetics of hGH-PEG6k-βAla conjugate was compared to that of native hGH in rats and monkeys, and the blood residence times were increased by 10- and 7-fold, respectively. The conjugate potency was evaluated in hypophysectomized rats demonstrating a superior pharmacodynamic profile with respect to native hGH.

INTRODUCTION

Biotechnology products are becoming more successful as therapeutic agents because of the important role of monoclonal antibodies (*1*). Besides important and promising results, several proteins still present relevant limitations for a safe therapeutic use, such as (i) the tendency to promote an immunological response, particularly in the case of heterologous proteins but also for human proteins administered at high doses (*2*), (ii) the physicochemical instability, both during shelf storage and in vivo after administration, and (iii) the short body residence time, especially for proteins with molecular weights below the kidney clearance threshold. Most of these problems can be overcome by PEGylation (the chemical link of polyethylene glycol), because it increases molecular weight of native drugs, shields critical protein sites (epitopes or amino acid sequences degraded by enzymes), reduces aggregation, and enhances water solubility (*3*−*6*). Altogether, these advantages lead to improved therapeutics that can be less frequently administered with respect to parent drugs, thus increasing patient compliance. PEGylation has already reached important results as demonstrated by the eight marketed PEG−protein conjugates (*5*). Despite its potentials, PEGylation is not devoid of open problems, such as the marked activity reduction of conjugated proteins that can in some cases prevent the exploitation of a conjugate, although this is often counterbalanced by the greater prolongation of conjugate in vivo half-life. A typical example is PEGylated interferon α-2a (PEGASYS), which retains only 7% of the native protein activity, but because of the half-life increase from 2.1 to 15 h, it has become a product with enhanced therapeutic value (*7*). Several research groups are now addressing this problem with interesting "releasable PEGs", although none of the conjugates reported so far entered the market. These PEGs take advantage of cleavable spacers that allow and control the release of conjugated protein in its fully active native form. Often, these systems are based on ester bonds which trigger the release, and the rate can be tuned by changing the neighboring chemical groups (*8*−*11*).

We recently developed a new PEGylating derivative, PEG-βAla-NHCO-OSu, which exhibited lower reactivity toward amines and higher stability in alkaline solutions, as compared to other *N*-hydroxysuccinimide activated PEGs (*12*). For protein PEGylation, this derivative was found useful because it preferentially reacts with the most nucleophilic and solvent-exposed protein amino groups, yielding a less heterogeneous mixture of conjugate isomers. This behavior was investigated with two therapeutic proteins, namely, human growth hormone (hGH) and granulocyte colony stimulating factor (G-CSF). Interestingly, the conjugates obtained with this PEGylating agent possess the property to slowly release some polymer chains, forming either fewer PEGylated protein isomers or native proteins also. To better understand the release mechanism, PEG-βAla-NHCO-OSu was conjugated to simple models revealing that the polymer is released when coupled to histidines. The PEG release rate was slow enough to ensure the conjugate half-life prolongation obtained by PEGylation.

The hGH conjugate was also investigated for the pharmacokinetic profile, in rats and monkeys, and the potency in hypophysectomized rats. It is worth noting that a single weekly

subcutaneous injection of hGH-PEG-βAla was equally potent to a daily subcutaneous injection of native hGH.

MATERIALS AND METHODS

Lyophilized rh-GH and rh-G-CSF were supplied by Bio-Ker (Pula, Cagliari, Italy). PEG-NH_2 of different molecular weights was purchased from Nektar (Huntsville, AL). *N*,*N*-Dicychlohexylcarbodiimide (DCC), *N*-hydroxysuccinimide (NHS), 2,4,6-trinitrobenzensulfonic acid (TNBS), *p*-nitrophenyl chloroformate, and organic solvents were purchased from Aldrich Chemie (Steinheim-West-Germany). Salts of analytical grade were from Merck. β-Alanine (βAla) was a Fluka product. Boc-NH-βAla-NHS was purchased from Novabiochem (Germany).

Gel filtration chromatography was performed with a Shimadzu (Kyoto, Japan) analytical HPLC system, using a Zorbax GF250 column (250 × 4.6 mm). Elution was carried out at a flow rate of 0.3 mL/min with 0.1 M PBS, 0.3 M NaCl containing 20% of acetonitrile. The effluent was monitored by recording the absorbance at 226 nm or at 280 nm.

Conjugate purification was carried out using an ion exchange SP-Sepharose fast flow (GE Healthcare, Uppsala, Sweden) loaded column (300 × 25 mm), with a Shimadzu HPLC (Kyoto, Japan). Elution was carried out at flow rate of 0.5 mL/min with a linear gradient of 0.1 M NaCl in water from 0% to 100% in 60 min. The effluent was monitored by recording the absorbance at 226 nm.

Protein concentrations were determined spectrophotometrically on a Perkin-Elmer Lambda-25 spectrophotometer. The concentrations of stock solutions of proteins and PEG−protein conjugates were evaluated from their absorbance at 280 nm. Extinction coefficients at 280 nm for PEG−proteins were considered unchanged from the native proteins.

PEG-βAla-NHCO-OSu Synthesis. PEG-βAla-NHCO-OSu was synthesized as previously reported (*12*). Briefly, PEG-NH_2 6 kDa (0.05 mmol), dissolved in CH_2Cl_2, reacted with Boc-NH-βAla-NHS (0.15 mmol) in the presence of Et_3N (0.1 mmol) to yield PEG-βAla-NH-Boc, which was purified by precipitation in Et_2O. The Boc protection group was removed by TFA hydrolysis, forming PEG-βAla-NH_2 that was recovered by evaporation of the solvent in a Rotavap, followed by precipitation in Et_2O. The dried PEG-βAla-NH_2 (0.042 mmol) dissolved in DMSO and reacted with di(*N*-succinimidyl) carbonate (0.21 mmol), for 12 h at 50 °C, gave the desired PEG-βAla-NHCO-OSu that was recovered by precipitation from Et_2O (yield 72%).

The degree of PEG activation was evaluated as reported elsewhere (*13*); briefly, an equimolar solution of PEG-βAla-NHCO-OSu and Gly-Gly was reacted and the unreacted amino groups determined by Snyder assay (*14*). The percentage of PEG-βAla-NHCO-OSu activation was 81%. Percentages of PEG dimer (below 5%), formed during the last step of the synthesis, and unreactive PEG (without the amino group, about 7%), present in the commercial batch of PEG-NH_2, were also determined. This may account for the reported percentage of PEG-βAla-NHCO-OSu activation.

^{1}H NMR ($CDCl_3$, 300 MHz) analysis of PEG-βAla-NHCO-OSu (PEG-βAla-NHCO-OSu) was performed by irradiating the sample with a pulse of 1444 Hz to suppress the signal of PEG$(OCH_2CH_2)_n$ hydrogens: σ 2.466 (t, 2H, NH-CO-CH_2-CH_2), σ 2.797 (s, 4H, -CH_2-, NHS), σ 3.364 (s, 3H, CH_3O), σ 3.538 (q, 2H, NH-CO-CH_2-CH_2).

Protein Conjugation with PEG-βAla-NHCO-OSu. PEG-βAla-NHCO-OSu was conjugated to either hGH or G-CSF as follows: a solution of 5 mg/mL of protein in 10 mM phosphate buffer pH 7 was left to react for 3 h at 4 °C with 3 molar excess of PEG-βAla-NHCO-OSu per each protein's amino group. The reaction was monitored by gel permeation chromatography (GPC), and after 3 h, the total amount of protein had reacted with PEG, as determined by GPC and MALDI-TOF analysis (see Supporting Information). The PEG−protein conjugate mixtures were fractionated by ion exchange chromatography, and the conjugate fractions were pooled and concentrated by ultrafiltration. The conjugate purity was checked by GPC, and the samples were eventually further purified by a second chromatographic step. The final solution was dialyzed against water, and a solution of trehalose was added to reach a ratio of 0.2 mg of trehalose for 0.8 mg of protein and lyophilized. Characterization was carried out by gel filtration chromatography.

PEG Release from Conjugates. The purified conjugate mixtures were dissolved in physiological buffer (10 mM Na_2HPO_4, 0.15 M NaCl; pH 7.4), at a concentration of 1 mg/mL (expressed as protein content) and incubated for 96 h at room temperature. At predetermined times, samples were withdrawn and analyzed by GPC using a Zorbax GF250 column (250 × 4.6 mm). Elution was carried out at a flow rate of 0.3 mL/min with 0.1 M PBS, 0.3 M NaCl, containing 20% of acetonitrile. The effluent was monitored by recording the absorbance at 226 nm or at 280 nm. The degree of PEG release was evaluated by both the variation in the peak area of the conjugates and the appearance of free protein peak. Solutions of hGH and G-CSF were studied under the same conditions.

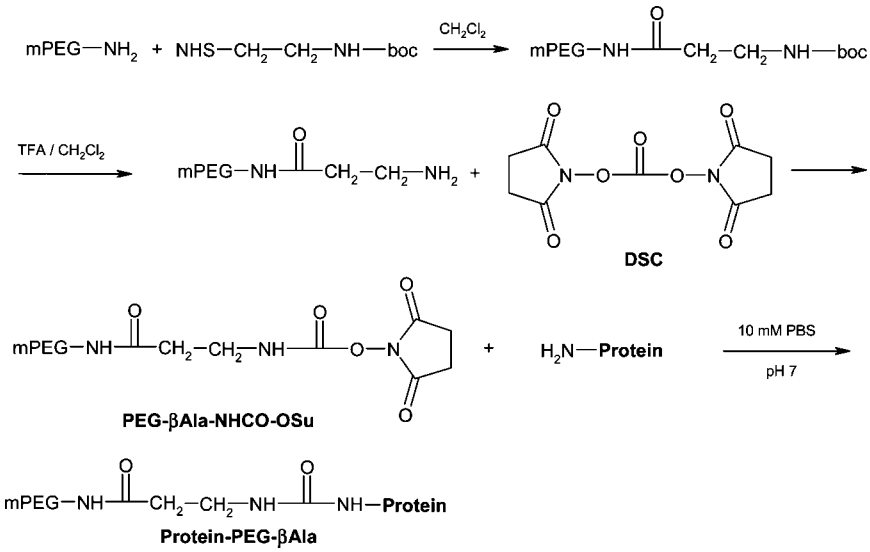
Peptide Model Conjugation with PEG-βAla-NHCO-OSu. Triptorelin (pGlu-His-Trp-Ser-Tyr-DTrp-Leu-Arg-Pro-Gly-NH_2), Boc-Tyr, and Gly-Phe-Leu-Gly were used as models to evaluate the reactivity of the secondary amine of histidine, the tyrosine hydroxyl group, and the N-terminal amino group, respectively. Each peptide or protected amino acid (1 equiv) was dissolved in DMSO, and PEG-βAla-NHCO-OSu (0.33 equiv) was added under stirring. After dissolution, 1.5 equiv of Et_3N was added, the reaction was allowed to proceed for 12 h, diluted 1:1 with CH_2Cl_2, and finally washed with acidic water. The organic phase, dried over anhydrous sodium sulfate, was precipitated in diethyl ether. The product was recovered by filtration, dried under vacuum, and incubated in a solution of 10 mM Na_2HPO_4, 0.15 M NaCl, pH 7.4, at room temperature. The conjugate stability was evaluated by GPC or by RP-HPLC.

Animal Studies. All animal experiments were performed in accordance with the procedure described in the Guide for the Care and Use of Laboratory Animals.

Pharmacokinetic Study in Rats. Pharmacokinetic study in rats has been performed on male Sprague−Dawley rats, weighing about 300−350 g (Harlan Nossan). hGH content in serum samples was quantified by ELISA, using the Active Human Growth Hormone Elisa Kit supplied by Diagnostic System Laboratories Inc. (DSL), 445 Medical Centre Boulevard, Webster, TX. Four rats (group 1) have been administered once with 2.5 mg/kg b.w. of hGH-PEG-βAla subcutaneously on the back. Blood has been withdrawn at predose and 1, 2, 4, 8, 24, 32, 48, and 72 h after PEGylated h-GH administration. Four rats (group 2) have been administered once with 0.5 mg/kg b.w. of reference product (native hGH). Blood has been withdrawn at predose and 5, 15, 30, 60, and 90 min and 2, 3, 4, and 6 h after hGH administration. hGH content in serum samples was quantified by ELISA.

Pharmacokinetic Study in Monkeys. Pharmacokinetic study in monkeys has been done on young adult male rhesus monkeys (*Macaca mulatta*) 4 years old (4−7 kg). hGH content in the serum was quantified by ELISA as reported above. Three monkeys (group 1) have been administered once with 1.5 mg/kg b.w. of hGH-PEG-βAla, by subcutaneous injection. Blood (at least 1.0 mL) has been withdrawn at predose and 0.5, 1, 2, 4, 8, 12, 18, 24, 32, and 48 h after administration and every 24 h for 1 week. Three monkeys (group 2) have been administered once with 0.5 mg/kg b.w. of the reference product (native hGH), by subcutaneous injection. Blood (at least 1.0

Scheme 1. Synthesis of PEG-βAla-NHCO-OSu and Its Coupling with a Protein



mL) has been withdrawn at predose, 5, 15, and 30 min, and 1, 1.5, 2, 3, 4, 6, 8, 10, 12, and 24 h after administration. hGH content in serum samples was quantified by ELISA.

Pharmacodynamic Study in Hypophysectomized Rats (Weight Gain Test). Pharmacodynamic study in rats was performed by treating hypophysectomized Sprague−Dawley rats, weighing 80−100 g. Animals were divided in three groups, eight rats in each: the first group was administered once with 240 μg/rat (protein equiv) of hGH-PEG-βAla by subcutaneous route on the back. The second group received daily 60 μg/rat/day of native hGH for 6 days by subcutaneous route on the back. The third was treated with vehicle by subcutaneous route on the back. Animal weight was monitored every two days until the end of the study.

RESULTS AND DISCUSSION

Preparation and Characterization of hGH and G-CSF Conjugates with PEG-βAla-NHCO-OSu. In Scheme 1, the synthesis of PEG-βAla-NHCO-OSu and the subsequent conjugation to protein amino groups are shown. Coupling reactions between PEG-βAla-NHCO-OSu and hGH or G-CSF were monitored by gel permeation chromatography (GPC) as reported in Figure 1 (panels A and B). After 3 h of incubation, nearly all protein amounts disappeared from the reaction mixture, yielding two new peaks that, on the basis of GPC and MALDI-TOF analysis, corresponded to mono- and di-PEGylated conjugates with traces of tri-PEGylated species (for MALDI-TOF analysis, see Supporting Information). In order to purify the conjugates from the excess of unreacted polymer and the free protein, a cationic exchange chromatography was carried out and purified reaction mixtures were checked by GPC.

The lower reactivity of PEG-βAla-NHCO-OSu with respect to the PEG-O-CH_2COOSu (PEG-SCM), a well-known PEGylating agent, was confirmed by studying both their chemical stability in alkaline solution and the conjugate isomers obtained after a coupling reaction with hGH (see Supporting Information). In particular, the half-life of NHS hydrolysis was 6.35 and 1.05 min for PEG-βAla-NHCO-OSu and PEG-O-CH_2COOSu, respectively. When PEG-SCM was conjugated to hGH under the same conditions of PEG-βAla-NHCO-OSu, diPEGylated and triPEGylated isomers were formed to a considerable degree while PEG-βAla-NHCO-OSu formed mainly monoPEGylated conjugates (see Supporting Information).

PEG Release from the Conjugates. The stability of hGH and G-CSF conjugates was assessed by GPC following incubation in PBS buffer at pH 7.4; Figure 2 shows the free protein release. After 96 h, the amount of released free hGH or G-CSF was found to be 21% and 29% of the starting conjugated proteins, respectively. In both cases, the GPC analysis revealed a decrease of diPEGylated species peak area during the time of

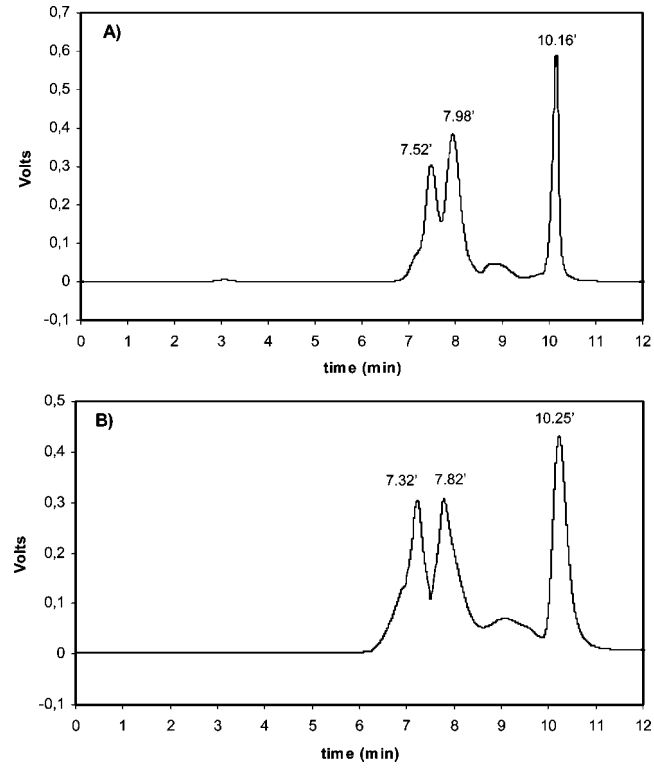


Figure 1. Gel filtration profile of reaction mixture of hGH (panel A) and G-CSF (panel B) with PEG-βAla-NHCO-OSu, after 3 h of reaction. (A) PEG/hGH reaction: peak at T_R = 7.52 min is di-PEGylated hGH conjugates, and peak at T_R = 7.98 min is mono-PEGylated hGH conjugates (as determined by MALDI-TOF analysis). (B) PEG/G-CSF reaction: peak at T_R = 7.32 min is di-PEGylated G-CSF conjugates, and peak at T_R = 7.82 min is mono-PEGylated G-CSF conjugates. The peaks at 10.16 min and 10.25 min are *N*-hydroxysuccinimide. The shoulders eluting with the first peaks of each chromatogram correspond to the tri-PEGylated conjugates. In both chromatograms, the peaks at about 9 min correspond to the unreacted protein.

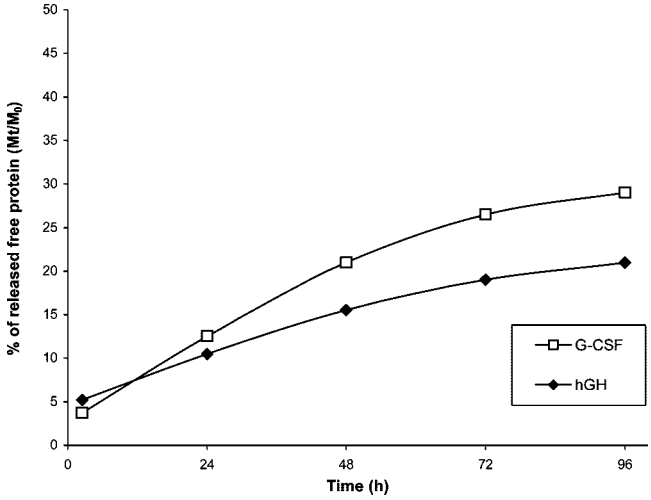

Figure 2. Protein release from hGH-PEG-βAla (♦) and G-CSF-PEG-βAla (□) conjugates during incubation in a solution of 10 mM Na_2HPO_4, 0.15 M NaCl, pH 7.4 at room temperature. The released hGH or G-CSF were evaluated by GPC analysis.

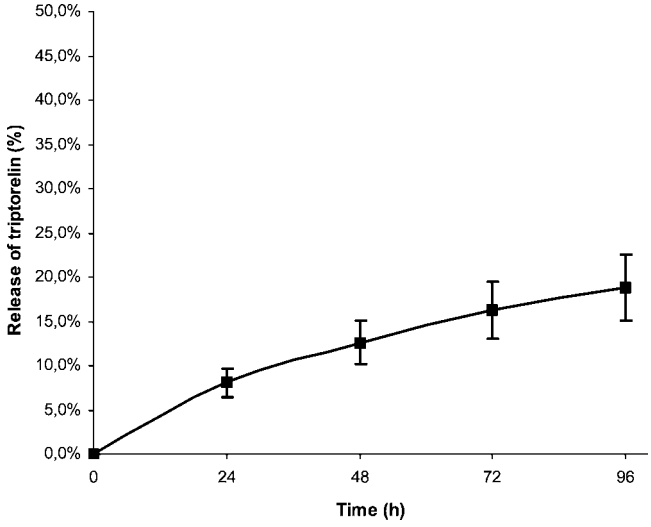

Figure 3. Triptorelin release after incubation of triptorelin-PEG-βAla conjugate in a solution of 10 mM Na_2HPO_4, 0.15 M NaCl, pH 7.4 at room temperature. The release was determined by GPC on the basis of formation of free peptide and decrease of conjugate amount.

the experiment with a concomitant small increase of mono-PEGylated conjugates and the formation of a peak of free protein.

PEG Release from Peptide Models. To gain insight into the release mechanism of PEG-βAla-NHCO-OSu, this polymer was studied with suitable models, namely, Triptorelin (pGlu-His-Trp-Ser-Tyr-DTrp-Leu-Arg-Pro-Gly-NH_2), Gly-Phe-Leu-Gly, and Boc-Tyr used to mimic the conjugation at His side chain; N-terminal amino group, and hydroxyl group of Tyr, respectively. The conjugate stability was studied following incubation in PBS. The Gly-Phe-Leu-Gly and Boc-Tyr conjugates showed negligible PEG release after 5 days of incubation, demonstrating the stability of the amide or carbamate bond between PEG-βAla-NHCO-OSu and the amine group of Gly or the hydroxyl group of Tyr, respectively. On the other hand, a release was observed in the case of triptorelin, where PEG is linked to the histidine secondary amine (see Figure 3). We expect that the coupling of PEG-βAla-NHCO-OSu to the Tyr hydroxyl group of a protein will probably occur to a very limited extent during common reaction conditions in water solutions,

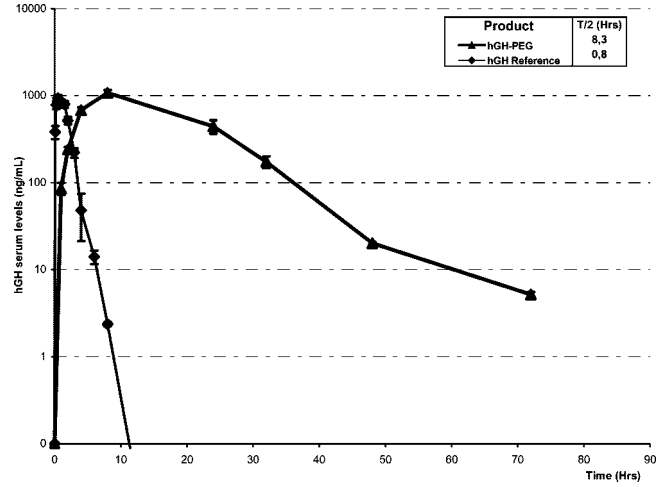

Figure 4. Pharmacokinetic profile of native hGH and hGH-PEG-βAla in rats (dose 2.5 mg/kg). PEGylation raised the hGH half-life from 0.8 to 8.3 h.

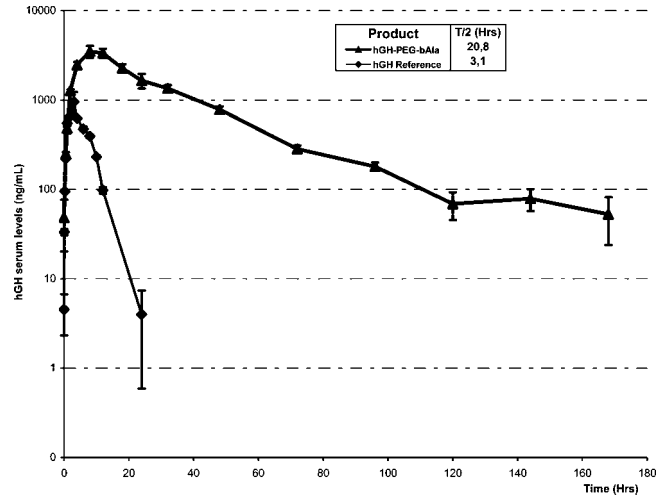

Figure 5. Pharmacokinetic profile of native hGH and hGH-PEG-βAla in monkeys (dose 1.5 mg/kg). As shown, after PEGylation the hGH half-life increased from 3.1 to 20.8 h.

where stronger nucleophiles are present, e.g., amino groups of lysines and N-terminal amino acid.

Pharmacokinetic Studies of hGH-PEG-βAla Conjugate in Rats and Monkeys. Pharmacokinetics studies were carried out in rats and monkeys for the hGH-PEG-βAla diconjugate fraction separated by cation exchange chromatography. The conjugation led to a great increase in blood residence time in both animal models; in fact, hGH half-life increased from 0.8 to 8.3 h in rats and from 3.1 to 20.8 h in monkeys, as shown in Figures 4 and 5, respectively. These data are comparable to those reported by other authors on hGH-PEG obtained by stable PEGylation (*15*), although a thorough comparison is difficult because several parameters are different in these two studies, as, for instance, the mass of PEG.

In Vivo Activity of hGH-PEG-βAla in Animal Model. The biological activity of hGH-PEG-βAla conjugate mixtures and their pharmacodynamic profiles were tested in hypophysectomized rats by evaluating the weight gain during one week observation of animals. A single subcutaneous injection of hGH-PEG-βAla (1 × 240 μg/rat, protein equiv) was found to be similar or slightly more potent than the same total amount of free hGH but given daily over a period of six days (6 × 40 μg/rat) (see Figure 6). Clark and co-workers reported similar results for hGH conjugated to 5 PEG 5 kDa chains (*15*). The

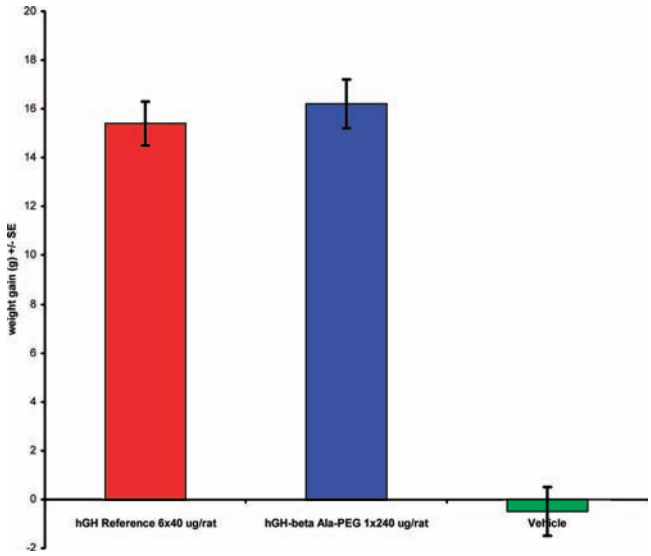

Figure 6. Weight gain in hypophysectomized rats given daily subcutaneous injections of hGH (6 × 40 μg/rat) or one weekly dose of hGH-PEG-βAla (1 × 240 μg/rat, protein equiv).

hGH−$(PEG)_5$ conjugate prepared by these authors had a half-life longer (15 h) than the hGH-PEG-βAla reported here (8.3 h), thus extending theoretically the protein activity over a longer period. The activity of these two different hGH−PEG conjugates are comparable, and this seems more in favor of the new hGH−PEG, which is still able to lead to a great pharmacodynamic response although showing a shorter half-life. Probably, this relevant response is partially due to the ability of this new PEG−βAla conjugate to slowly release in part the PEG chains, yielding either fewer PEGylated species or native hGH that are in any case more biologically active than the starting conjugate. Furthermore, the rate of PEG release does not compromise the beneficial half-life increase of the protein obtained after PEGylation.

CONCLUSION

Our study demonstrates that the new PEGylating agent, PEG-βAla-NHCO-OSu, can enhance the potential of PEG−protein conjugation. In fact, this polymer showed a higher stability in water at alkaline pH values, six times higher than that of PEG-SCM, and a lower reactivity toward amines that direct the coupling only toward the strongest and most solvent-exposed nucleophiles of a protein (*12*). Therefore, it forms fewer PEG−protein isomers than other commonly used PEG reagents. Furthermore, this PEG derivative showed the propensity to be slowly released from the protein conjugate when the polymer is attached to the side chain of histidine. As it is a phenomenon extremely relevant to recovering the protein activity that is often markedly reduced in the conjugated protein, this is one of the major limitations of PEGylation. The possibility to address this problem by using a simple approach, such as the coupling with PEG-βAla-NHCO-OSu, is particularly needed, and it could lead to the preparation of improved protein bioconjugates. In fact, beside the advantage of a prolonged in vivo half-life, these conjugates will possess the ability to recover the protein activity by slowly releasing the PEG chains attached.

The pharmacokinetic and pharmacodynamic data presented here support the effectiveness of PEG-βAla-NHCO-OSu as a new PEGylating agent for protein modification.

SUPPLEMENTARY INFORMATION

Experimental conditions of hGH conjugation with PEG-SCM 3

MALDI-TOF mass spectrometry analysis 3

Stability of PEG derivatives in alkaline solution 4

Figure A 5

Figure B 6

Figure C 7

Experimental conditions of hGH conjugation with PEG-SCM. A hGH solution of 5 mg/ml in 10 mM phosphate buffer pH 7 was left to react for 3 hours at 4°C with 3 molar excess of PEG-SCM per each protein's amino group. The reaction was monitored by gel permeation chromatography (GPC) and after three hours the total amount of protein reacted with PEG, as determined by GPC and MALDI-TOF analysis.

MALDI-TOF Mass Spectrometry analysis. Measurements were performed on a REFLEX time-of-flight instrument (Bruker-Franzen Analytik, Bremen, Germany) equipped with a SCOUT ion source operating in positive linear mode. Ions, formed by a pulsed UV laser beam (nitrogen laser, λ = 337 nm), were accelerated to 25 kV. Sinapinic acid (saturated solution in acetonitrile:water (50:50 v:v)) was used as a matrix. Samples were dissolved in 0.1% trifluoroacetic acid aqueous solution. 5 µl of the diluted sample solution was mixed with the same volume of matrix solution, and 1 µl of the resulting mixture was deposited on a stainless steel sample holder and allowed to dry before introduction into the mass spectrometer.

In figure A is shown the MALDI-TOF spectrum of PEG-βAla-NHCO-OSu as a single peak centered in 6101 Da. The mass spectrometry analysis of PEG-βAla-NHCO-OSu / hGH reaction mixture confirmed the results obtained from GPC. In fact, PEG-βAla-NHCO-OSu reacting with hGH formed mainly monoPEG-hGH (peak at 28151 Da) and diPEG-hGH (peak at 34261 Da) as shown in figure B. A small amount of free protein is still present (peak at 22144). The lower reactivity of PEG-βAla-NHCO-OSu as amino PEGylating agent with respect the most known and used PEG-SCM is also demonstrated by the MALDI-TOF analysis of PEG-SCM / hGH reaction mixture. PEG-SCM, reacting in the same conditions as PEG-βAla-NHCO-OSu, formed hGH-PEG conjugates with higher degree of PEGylation (figure C).

Stability of PEG derivatives in alkaline solutions. A concentrated solutions of PEG-βAla-NHCO-OSu and PEG-SCM were prepared in 1,4-dioxane at 20 mg/ml. 100 µl of these solutions were taken and diluted with 900 µl of 0.1M borate buffer pH 8, respectively. The increment of UV absorption at 260 nm of these solutions, due to NHS release from the polymer, was followed until reaching the steady state. The half-life of NHS hydrolysis was calculated using first order reactions mathematical model. The hydrolysis t½ was 6.35 min for PEG-βAla-NHCO-OSu, a value significantly higher than that of the commonly used PEG-SCM (t½ = 1.05 min).

Figure A: MALDI-TOF spectrum of new active PEG-βAla-NHCO-OSu derivative (from ref. 12).

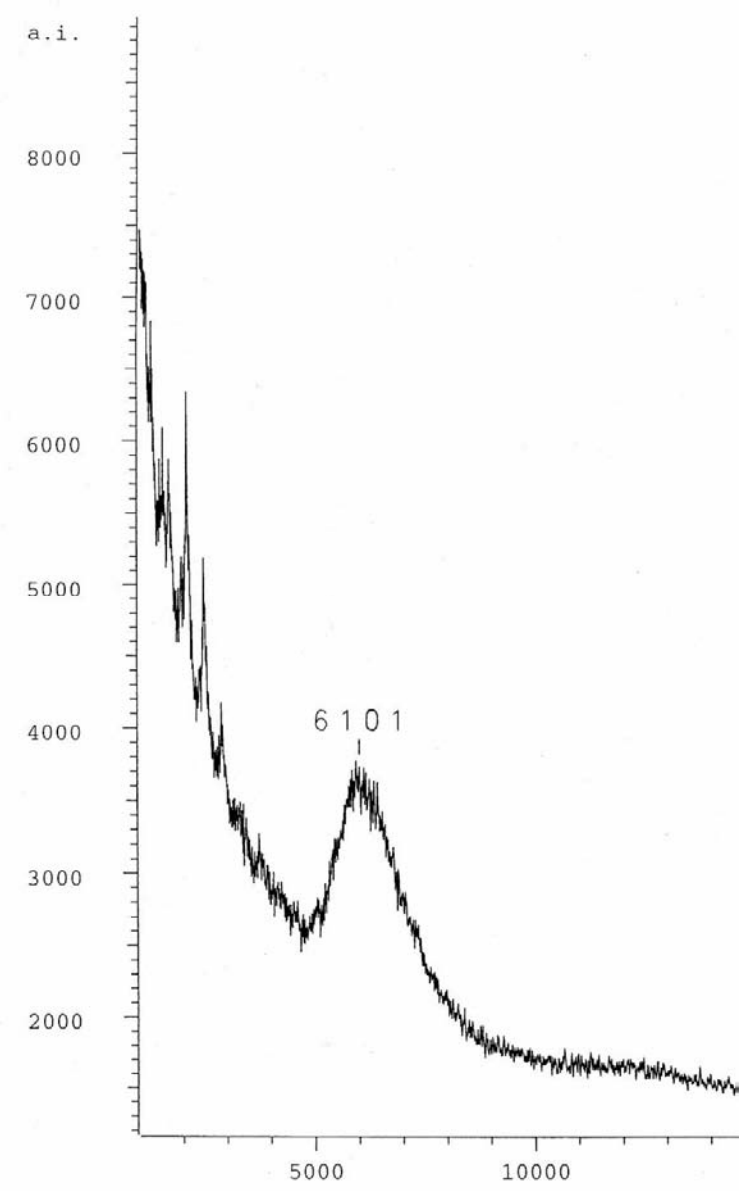

Figure B: MALDI-TOF spectrum of PEG-βAla-NHCO-OSu / hGH reaction mixture. The peak at 22144 m/z is the protein hGH, peak at 28151 m/z is the monoPEG hGH, peak at 34261 m/z is the diPEG-hGH (from ref. 12).

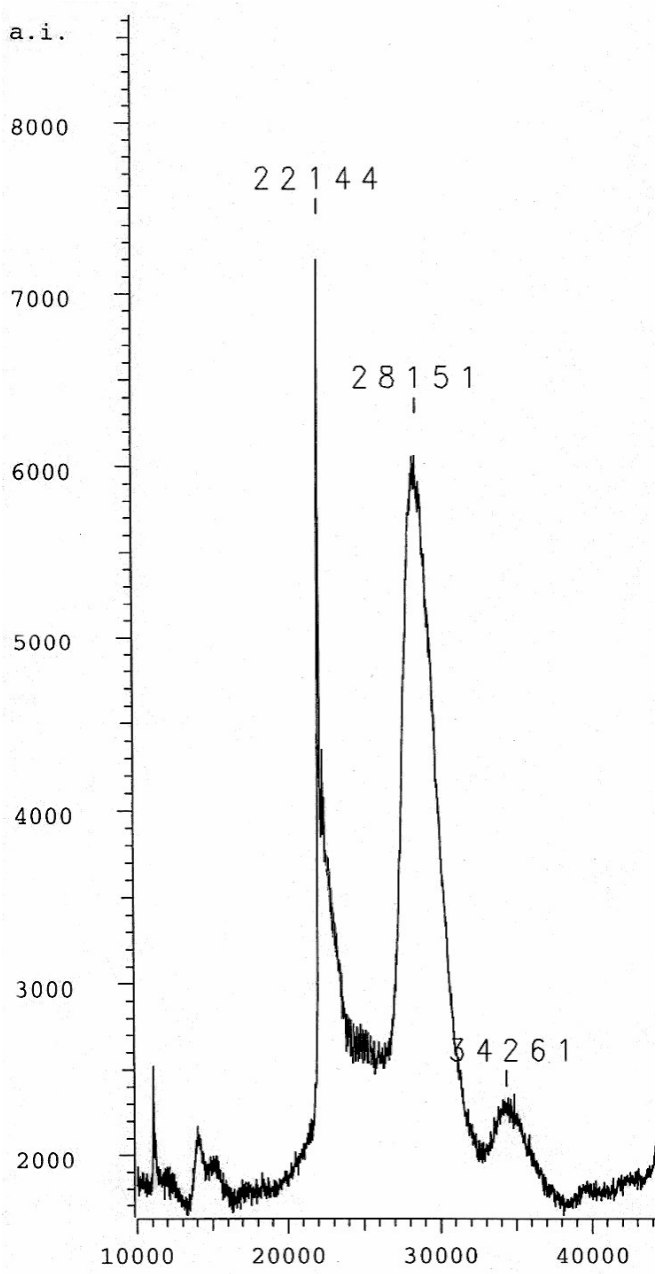

Figure C: MALDI-TOF spectrum of reaction mixture of PEG-SCM / hGH. The peak at 29033 m/z is the monoPEG-hGH, peak at 34814 m/z is the diPEG-hGH and peak at 40428 m/z is the triPEG-hGH (from ref. 12).

Received July 25, 2008; Revised Manuscript Received October 14, 2008

Radiolabeled bombesin (BBS) analogues are promising pharmaceuticals for imaging of cancer cells expressing gastrin-releasing peptide receptors (GRPR). However, most of the radiolabeled BBS derivatives show a high accumulation of activity in the liver and a strong hepatobiliary excretion, both unfavorable for imaging and therapy of abdominal lesions. For this reason, we introduced hydrophilic carbohydrated linker moieties into our BBS analogues to reduce the abdominal accumulation and to improve the tumor-to-background ratios. A stabilized BBS(7−14) sequence bearing the (N$^{\alpha}$His)Ac-chelator was modified with amino acid linkers containing a lysine or propargylglycine residue. The ε-amino group of a lysine was either coupled to shikimic acid or reacted with glucose to form the Amadori conjugate. Alternatively, a glucose was attached to the peptide via "click" chemistry with the propargylglycine side chain. The peptides were synthesized on Rink amide resin using solid-phase peptide synthesis and labeled with ^{99m}Tc using the tricarbonyl technique. Binding and degradation were tested *in vitro* in GRPR-expressing PC-3 cells. Biodistribution and SPECT/CT imaging studies were performed in nude mice bearing PC-3 tumor xenografts. The new peptides showed a log *D* between −0.2 and −0.5 and kept the high affinity for GRPR with K_d values of <0.5 nM. *In vitro*, they were rapidly internalized into the tumor cells and showed an increased cellular retention and stability ($t_{1/2}$ > 35 min). *In vivo*, all new compounds exhibited higher tumor-to-background ratios compared to the nonglycated reference. Thus, the best results were obtained with the triazole coupled glucose with a 4-fold increased uptake and retention in tumor tissue (3.6 and 2.5%ID/g at 1.5 h and 5 h p.i, respectively) and a significantly reduced accumulation in the liver (0.6 vs 2.4%ID/g, 1.5 h p.i., respectively). Apart from higher tumor-to-liver ratios (17-fold, 1.5 h p.i.), both tumor-to-kidney and tumor-to-blood ratios could be significantly improved by a factor of 1.5 and 2.7, respectively (1.5 h p.i., $P < 0.05$). The imaging studies proved the reduction of abdominal background, and tumor xenografts could clearly be visualized. In conclusion, the introduction of a carbohydrated linker substantially improved the biodistribution properties of BBS analogues labeled with the ^{99m}Tc-tricarbonyl core.

INTRODUCTION

Modified neuropeptides have gained increasing attention for radiopharmaceutical applications like peptide receptor imaging (PRI) and peptide receptor radiotherapy (PRRT) (*1*−*5*). They bind with high affinity and selectivity to their corresponding receptors, which are overexpressed on a considerable number of cancers (*1*, *5*, *6*). Apart from somatostatin (sst) analogues like ^{111}In-DTPA-Octreotide (OctreoScan) or ^{90}Y- and ^{177}Lu-DOTA-TOC, which already are successful in the clinical treatment of neuroendocrine tumors and gastrinomas (*7*−*10*), additional receptor ligands are under investigation for targeting a broader range of tumor types. The tetradecapeptide bombesin (BBS) has recently been studied intensively due to its high affinity for the mammalian gastrin-releasing peptide receptor (GRPR) (*11*). GRPR shows high expression in most human prostate and breast tumors as well as small-cell lung, ovarian, endometrial, and other cancers (*12*−*14*). BBS derivatives have been labeled with various radionuclides like ^{99m}Tc, ^{64}Cu, ^{68}Ga, ^{111}In, ^{177}Lu, or ^{18}F and proved to be successful candidates for both PRI and PRRT (*15*−*21*). However, the modification of their pharmacokinetic profile is of high interest to reduce their frequent high hepatic accumulation and hepatobiliary excretion, which is problematic for imaging and therapy of abdominal lesions (*15*, *16*, *18*, *20*−*23*). Different modifiers offer the possibility to influence these unfavorable *in vivo* properties. Smith et al. investigated the positive effects of aliphatic and amino acid linkers for BBS analogues (*18*, *24*, *25*). Moreover, glycation by the Amadori reaction has been reported to provide radiohalogenated sst analogues with excellent physicochemical characteristics (*26*−*28*). These compounds were more hydrophilic but still exhibited a high receptor binding affinity, improved tumor uptake and tumor-to-nontumor ratios, and reduced hepatobiliary transfer and liver accumulation (*26*, *28*−*31*). Recent studies with ^{111}In- and ^{177}Lu-labeled DOTA-sst analogues confirmed the positive effects of glycation via Amadori rearrangement for radiolabeled metallopeptides (*32*), and interestingly, in addition the modification of neurotensin (NT) with the glycomimetic 3,4,5,-trihydroxyl-1-cyclohexene-1-carboxylic acid (shikimic acid) induced a reduction of both hepatic uptake and renal retention (*33*). Our group could already show an improvement of ^{99m}Tc-labeled BBS analogues by the introduction of a double β-alanine sequence and recently published the first promising results of a linker coupled to shikimic acid (*34*).

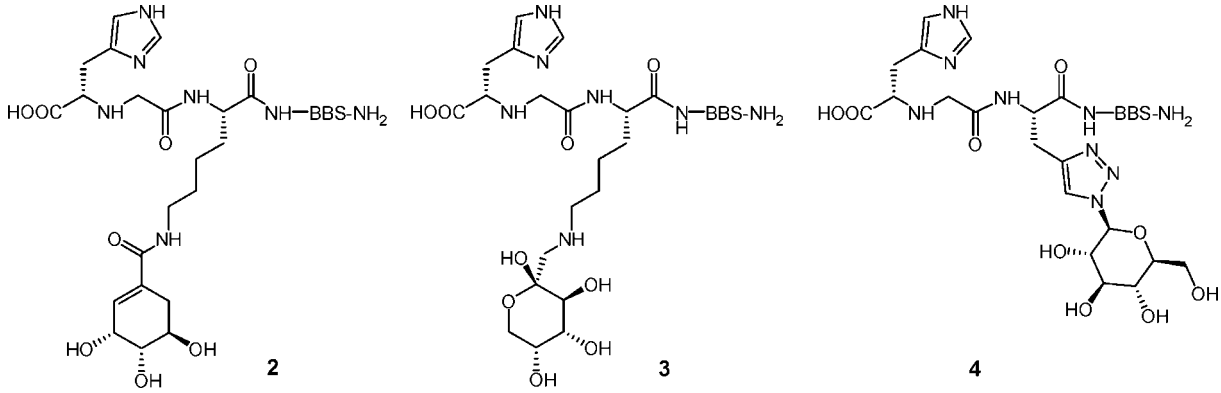

Figure 1. Chemical structure of the carbohydrated groups introduced into the linker sequence of the BBS analogues. **2** = Lysine-coupled shikimic acid; **3** = Amadori-product; **4** = triazole-coupled glucose.

Surprisingly, so far no further data of glycated BBS analogues have been published.

In this study, we investigated for the first time the influence of glycation on the biodistribution profile of radiolabeled BBS derivatives. We inserted carbohydrated linker moieties between the stabilized binding sequence BBS(7−14) and the N^{α}histidine-chelator by the application of established methods like the Amadori reaction, by the formation of a stable triazole bond via "click" chemistry, and by coupling of shikimic acid to a lysine residue (*33*, *35*, *36*). The peptides were labeled with ^{99m}Tc ($t_{1/2}$ = 6 h, 140 keV γ photon energy, 89% abundance) featuring a favorable dosimetry, high specific activity, low cost, and ready availability from a ^{99}Mo/^{99m}Tc-generator, and radiochemical properties optimal for single photon emission tomography (SPECT) (*37*). Moreover, the chemical similarities of the "matched pair" ^{99m}Tc/^{188}Re offer the opportunity to use successful ^{99m}Tc-labeled candidates for tumor targeting also for therapeutic applications labeled with ^{188}Re ($t_{1/2}$ = 17 h; 2.12 MeV $\beta^{-}{}_{max}$-radiation) (*37*). The new compounds were tested *in vitro* for binding affinity, internalization, efflux, and metabolic stability in the GRPR-expressing human prostate carcinoma cell line PC-3. *In vivo* biodistribution and SPECT/CT studies were performed in nude mice bearing PC-3 tumor xenografts.

MATERIALS AND METHODS

Chemicals and Equipment. All chemicals were obtained from Fluka (Buchs, Switzerland) or Merck (Dietikon, Switzerland). Cell culture media DMEM GLUTAMAX-I, trypsin/EDTA, bovine serum albumin, and soybean trypsin inhibitor were obtained from Invitrogen (Basel, Switzerland); fetal calf serum (FCS) and antibiotic/antimycotic solution were obtained from Bioconcept (Allschwil, Switzerland). Bacitracin, HEPES, and Chymostatin were purchased from SIGMA (Buchs, Switzerland). For the determination of protein concentrations, a Pierce BCA Protein Assay kit from Socochim (Lausanne, Switzerland) was used. Na[^{99m}TcO$_4$] was eluted from a Mallinckrodt ^{99}Mo/^{99m}Tc generator (Tyco Healthcare, Petten, The Netherlands) using 0.9% saline. Sodium boranocarbonate was a gift from the provider of the generator. The radioactivity of *in vitro* and *in vivo* experiments was measured with a NaI-γ-counter (Packard Canberra Cobra II, Meriden, USA) or a NaI ionization chamber.

Peptide Synthesis and Radiolabeling with ^{99m}Tc. The peptide solid-phase synthesis was carried out on a Rink Amide Resin with the Fmoc-strategy as previously described (*23*). The introduction of different carbohydrates (Figure 1) in the form of glucose or shikimic acid was performed as recently published (*33*, *35*, *36*, *38*). The purification of the peptides was done on a semipreparative HPLC system (Gilson) on a reverse-phase C_{18} column (Discovery BIO SULPELCO Wide Pore, 25 cm × 2.21 cm, 5 μm) with a linear gradient of 3% B to 100% B (solvent A = H_2O + 0.1% TFA and solvent B = CH_3CN + 0.1% TFA) in 30 min, a flow rate of 1 mL/min, and UV detection at 215 nm. Radiolabeling of the peptides with [^{99m}Tc(OH$_2$)$_3$(CO)$_3$]$^+$ was performed as previously described (*23*). For analyses and purification of the labeled peptides from the unlabeled compounds, a Macherey-Nagel CC Nucleosil 100−5 C_{18} RP column (5 μm, 250 = 4.6 mm) was used. Preparative HPLC for peptide purification was performed using a Merck-Hitachi L-7100-system with an equipped two-channel scintillation detector interface (John Caunt scientific Ltd., Eynsham, England) and a Rainin Dynamax absorbance detector model UV-1. HPLC solvents consisted of H_2O + 0.1% TFA (solvent A) and CH_3OH + 0.1% TFA (solvent B). The separation was performed with a linear gradient 50% A/50% B to 20% A/80% B for 25 min (1.0 mL/min). For the analytical HPLC of the labeled peptides, a Varian ProStar system was used with a Varian ProStar 230 Solvent Delivery Pump, a Varian Photodiode Array Detector model 330, a Varian ProStar Autosampler model 410, and a radiomatic Flo-one Beta Detector (Packard Canberra). HPLC solvents consisted of CH_3CN + 0.1% TFA (solvent A) and H_2O + 0.1% TFA (solvent B). The labeling control was performed with a linear gradient of 30% A/70% B to 80% A/20% B for 25 min (1.0 mL/min).

Octanol/Water Partition Coefficient Study. The octanol/water partition coefficients were determined at pH = 7.4. 5 μL containing 500 kBq of the radiolabeled compound in PBS was added to a vial containing 1.2 mL 1-octanol and PBS (1:1). After vortexing for 1 min, the vial was centrifuged for 5 min at 10 000 rpm to ensure complete separation of layers. Then, 40 μL of each layer was taken in a preweighed vial and measured in the γ-counter. Counts per unit weight of sample were calculated, and log D values were calculated as described by Pillarsetty et al. (*39*) using the formula

$$\log_{10} D = \log_{10}\left(\frac{\text{counts in 1 g of octanol}}{\text{counts in 1 g of water}}\right)$$

Cell Culture. PC-3 human prostate cancer cell line was obtained from European Collection of Cell Cultures (Salisbury, United Kingdom). Cells were maintained in Dulbecco's MEM with GLUTAMAX-I supplemented with 10% FCS, 100 IU/mL penicillin G sodium, 100 μg/mL streptomycin sulfate, and 0.25 μg/mL amphotericin B. Cells were incubated at 37 °C in an atmosphere containing 5% CO_2 and subcultured twice a week after detaching with trypsin-EDTA.

Metabolic Stability in PC-3 Cells. The stability in cell culture was evaluated with 2 × 10^6 cells in PBS. The analogues (3 MBq/mL, 1.5−2 pmol/mL) were incubated for 0.5, 1, 2.5, and 5 h at 37 °C. Afterward, proteins were precipitated as follows: 250 μL of sample + 750 μL of CH_3CN /ethanol (1:1)

Table 1. Sequence of BBS Analogues with New Carbohydrated Groups in the Linker[a]

and TFA (0.01%). The mixture was vortexed and centrifuged (10 min, 20 000 g) at 4 °C. The supernatant was filtered and analyzed by RP-HPLC equipped with a radioactivity detector. All experiments were carried out 2−3 times.

Receptor Inhibition Studies. One day prior to the assay, PC-3 cells at confluence were placed in 48 well plates. Cells were incubated in a special binding buffer (50 mM HEPES, 125 mM NaCl, 7.5 mM KCl, 5.5 mM $MgCl\cdot 6H_2O$, 1 mM EGTA, 5 g/L BSA, 2 mg/L Chymostatin, 100 mg/L Soybean Trypsin inhibitor, 50 mg/L Bacitracin, pH 7.4) with increasing concentrations of the BBS analogues (0−30 000 nM) in the presence of 4 kBq of ^{99m}Tc-BBS(7−14). After 1 h incubation at 37 °C, the cells were washed twice with cold PBS. Bound radioactivity was recovered by solubilizing the cells in 1 N NaOH (2 × 400 μL). The radioactivity was measured in the γ-counter. All experiments were carried out 2−3 times in triplicate.

Receptor Saturation Studies. One day prior to the assay, PC-3 cells at confluence were placed in 48 well plates and incubated for 1 h at 37 °C in the binding buffer described above with increasing concentrations of the labeled BBS analogues **2**−**4** (0.01−2 nM). The concentration of total technetium-labeled peptide was calculated according to Bauer et al. (*40*). Nonspecific binding was determined by coincubation with 1 μM BBS(1−14). After incubation, the cells were washed twice with cold PBS, solubilized in 1 N NaOH (2 × 400 μL), and the radioactivity measured in the γ-counter. Experiments were performed 2−3 times in triplicate.

Internalization and Externalization. One day prior to the assay, PC-3 cells at confluence were placed in 6 well plates. For internalization studies, cells were incubated with the labeled analogues (4 kBq/well) in binding buffer for 5, 15, 30, 60, and 120 min at 37 °C to allow binding and internalization. Nonspecific binding was determined in the presence of 1 μM BBS(1−14). After incubation, cells were washed twice with cold PBS. Surface-bound activity was removed by acid wash (50 mM glycine/HCL, 100 mM NaCl, pH 2.8, 2 = 600 μL for 5 min at room temperature). Afterward, the plates were neutralized with 600 μL PBS, and cells were lysed with 1 N NaOH (2 × 600 μL). Surface-bound and internalized activities were measured in the γ-counter. The protein concentration was determined and results were calculated as a percentage of total added radioactivity per milligram protein.

For externalization studies, PC-3 cells were incubated with the labeled analogues (20 kBq/well) in culture medium for 1 h at 37 °C to allow binding and maximal internalization. After incubation, the supernatant was discarded and each well washed twice with cold PBS. Afterward, the cells were incubated again at 37 °C in 2 mL culture medium for 30, 60, 150, or 300 min. At each time point, the supernatant was collected, the cells were washed twice with cold PBS and the radioactivity remaining in the cells was recovered by lysing the cells with 1 N NaOH (2 × 600 μL). Radioactivity in the supernatant (released activity) and in the lysate (internalized activity) was determined in the γ-counter. Results are expressed as a percentage of the total activity associated with the cells. The protein concentration was determined, and results were calculated as a percentage of total added radioactivity per milligram protein. All experiments were carried out 2−3 times in triplicate.

Biodistribution Studies. All animal experiments were conducted in compliance with the Swiss animal protection laws and with the ethical principles and guidelines for scientific animal trials established by the Swiss Academy of Medical Sciences and the Swiss Academy of Natural Sciences. Female CD-1 nu/nu mice 6−8 week-old (Charles River Laboratories, Sulzfeld, Germany) were subcutaneously injected with 8×10^6 PC-3 cells in 150 μL culture medium without supplements. About 3 weeks after tumor implantation, the mice (3−6 per group) were injected i.v. with 3.7 MBq radiolabeled peptides. At 0.5 h, 1.5, or 5 h postinjection (p.i.), the animals were killed by cervical dislocation. The different organs (heart, lung, spleen, kidneys, pancreas, stomach, small intestine, large intestine, liver, muscle, bone) and blood were collected, weighed, and the radioactivity measured in a γ-counter. Results are presented as the percentage of injected dose per gram of tissue (%ID/g). To determine the specificity of the *in vivo* uptake, one group of mice received a coinjection of 100 μg of unlabeled BBS(1−14) and the radiolabeled analogue and sacrificed at 1.5 h p.i.

SPECT/CT Studies. Single photon emission computed tomography/X-ray computed tomography (SPECT/CT) images were performed postmortem 1.5 h after i.v. injection of the ^{99m}Tc-BBS analogues (20 MBq). Images were obtained on an X-SPECT-system (Gamma Medica Inc.) equipped with a single head SPECT device and a CT device. SPECT data were acquired and reconstructed with LumaGEM (version 5.407). CT data were reconstructed with the software *Cobra* (version 4.5.1). Fusion of SPECT and CT data was performed with *IDL Virtual Machine* (version 6.0). Images were generated with *Amira* (version 3.1.1).

Statistical Analysis. All data are presented as the mean ± SD. Differences in the *in vivo* uptake in the biodostribution studies were analyzed by one-way ANOVA followed by Dunnett's comparison test. Differences between blocked and control groups were analyzed by unpaired *t* test. $P \leq 0.05$ was considered statistically significant.

RESULTS AND DISCUSSION

The modification of the biodistribution profiles of BBS analogues toward a reduction of abdominal accumulation is of high interest for both diagnostic and therapeutical applications. In this study, we investigated the influence of different glycated linkers on the *in vivo* behavior of ^{99m}Tc(CO)$_3$-labeled BBS derivatives. The amino acid sequence of the new peptides was based on the fragment 7−14 of BBS (Table 1), which had been successfully modified as previously published to increase the metabolic stability in human plasma and PC-3 tumor cells (replacement of Leu^{13} with Cha, and Met^{14} with Nle) (*23, 34*). The additional introduction of a βAla-βAla linker (compound **1**) led to improved *in vivo* tumor uptake (*18, 23*). However, the accumulation of activity in the liver was increased and the tumor-to-tissue ratios were still rather poor (tumor-to-blood = 4.3 ± 3.4; tumor-to-kidney = 0.9 ± 0.3; tumor-to-liver = 0.4 ± 0.3; at 1.5 h p.i.). A significant impact of polar linker moieties on the biodistribution was reported for several radiolabeled peptides, and in particular, carbohydrated compounds exhibited clearly improved pharmacokinetics (*21, 26, 34, 41, 42*). Therefore, we set out to synthesize three glycated BBS analogues (**2**, **3**, and **4**) for comparison with the unglycated

Table 2. Characteristics of the New BBS Analogues: Retention Time and Polarity (log *D*) of the ^{99m}Tc-Labeled Peptides, And Binding Affinity for GRP Receptors in PC-3 Cells of the Labeled (K_d Values) and Unlabeled (IC_{50} Values) Compounds ($n = 2-4$)

compound	HPLC γ − trace t_R [min]	log *D*	K_d [nM]	IC_{50} [nM]	$t_{1/2}$ in PC-3cell [min]

3	16.7	−0.5 ± 0.1	0.18 ± 0.03	3.7 ± 1.7	37 ± 8
4	16.8	−0.5 ± 0.1	0.29 ± 0.16	3.2 ± 1.2	38 ± 5

^{99m}Tc(CO)$_3$-labeled compound **1**, which has recently been characterized by our group (*23*) (Table 1).

Compound **2** was modified with a linker bearing a lysine coupled to the glycomimetic shikimic acid at the ε-amino group, as recently published (*33*). Compound **3** was glycated by the "Amadori rearrangement", the Schiff base reaction of an aldose with a free amino group, known to form extremely stable carbohydrated peptide derivatives (*36, 43*). Finally, we investigated a clicked, carbohydrated BBS(7−14) analogue by the formation of a stable triazole bond between an alkyne in the linker and an azido glucose derivative (*35*) (Figure 1).

Radiolabeling of these novel carbohydrated peptides with $[^{99m}Tc(OH_2)_3(CO)_3]^+$ was performed at ligand concentrations of 10^{-5} M for 1 h at 75 °C. The HPLC traces of the ^{99m}Tc(CO)$_3$ complexes showed a general shift to longer retention times (16.4−16.9 min) compared to the unlabeled peptides (∼14.5 min) and the precursor $[^{99m}Tc(OH_2)_3(CO)_3]^+$ (∼9 min). Radiolabeling yields were higher than 95% for all derivatives, and the active complexes **2**−**4** were successfully separated from the unlabeled peptides to avoid a saturation of the GRPR in subsequent *in vitro*/*in vivo* experiments.

To compare the polarity of the $[^{99m}Tc(CO)_3]$-labeled new analogues **2**−**4**, the octanol/water partition coefficients were determined. The reference compound **1** bearing only the βAla-βAla-linker showed a rather lipophilic character with a log *D* of +0.9. The introduction of the shikimic acid changed the polarity of peptide **2** to −0.2, while the coupling to glucose resulted in log *D* values of −0.5 for both analogues **3** and **4** (Table 2).

***In Vitro* Studies.** The *in vitro* experiments were performed with PC-3 cells, which express a high level of GRPR. In order to investigate the potential of our three novel carbohydrated peptides **2**−**4** for specific targeting of GRPR, studies on receptor binding (Table 2) and cell internalization/cellular efflux (Figure 2) were performed. Additionally, the metabolic stability in tumor cells was investigated (Table 2). We already published an increased stability in PC-3 cells for compound **1** compared to the unmodified sequence (30 ± 6 min vs 5 ± 2 min, respectively) (*34*). The $t_{1/2}$ values of the novel peptides **2** (35 ± 11 min), **3** (37 ± 8 min), and **4** (38 ± 5 min) were slightly higher than for reference **1**, but the differences were not statistically significant (Table 2).

The affinity of the unlabeled analogues for GRPR was tested in inhibition experiments in competition with 4 kBq of ^{99m}Tc-BBS(7−14), which is known to express a high affinity for this receptor (*44*). All peptides exhibited a similar high affinity with IC_{50} values between 3 and 7 nM (Table 2). Furthermore, the receptor binding of the new analogues proved to be saturable and highly specific after radiolabeling with the ^{99m}Tc(CO)$_3$-core, with K_d values lower than 0.5 nM (Table 2). Interestingly, peptide **2** showed the highest affinity ($K_d = 0.02 \pm 0.01$ nM), about ten times higher than reference **1** ($K_d = 0.18 \pm 0.12$ nM) and the new peptides **3** ($K_d = 0.18 \pm 0.03$ nM) and **4** ($K_d = 0.29 \pm 0.16$ nM).

The internalization experiments showed a similar, rapid uptake into PC-3 cells reaching a plateau between 60 and 120 min (Figure 2). We found 29−37% of the total radioactivity per milligram of protein in the cell lysate after stripping the surface-bound activity off the cells with acidic buffer (pH 2.8). These results would reflect an agonistic behavior for the new compounds and are consistent with recently published BBS analogues with similar amino acid sequences (*15, 20, 34, 41*). The nearly complete blockade (<1% of the added radioactivity per milligram protein) by coincubation with an excess of BBS(1−14) demonstrated the high specificity for all new glycated BBS radiotracers. Variations in the bound radioactivity among the new peptides were statistically not significant. Additionally, efflux studies revealed a similar intracellular retention of the internalized activity of ∼35% up to 5 h for all new peptides **2**−**4** and the reference compound **1** (Figure 2). These results are in agreement with the similar metabolic stability of the new peptides we found in the degradation experiments with PC-3 cells (Table 2).

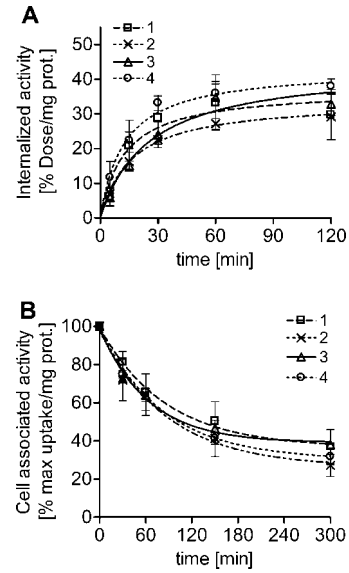

Figure 2. Time-course internalization (**A**) and externalization after maximal internalization (**B**) of the ^{99m}Tc-labeled BBS analogues in PC-3 cells after incubation at 37 °C. Data represent the percentage of internalized activity per milligram of protein related to the total activity added to the cells ($n = 2-3$).

Biodistribution Studies. Time-dependent biodistribution studies with the new radiotracers **2**−**4** have been performed in athymic mice, bearing PC-3 tumor xenografts. The new peptides **2** and **4** exhibited higher blood levels at 0.5 h p.i. (2.1 ± 0.7%ID/g and 1.8 ± 0.2%ID/g, respectively) than reference **1** (0.6 ± 0.2%ID/g). However, the clearance from the blood pool was fast and efficient for all new derivatives, providing low levels at 1.5 h p.i. for all new compounds (≤0.4% ID/g), similar to those published for the nonglycated ligand **1**.

All three new ligands **2**−**4** showed a relatively low liver uptake between 2.3 ± 0.3%ID/g (peptide **2**) and 1.3 ± 0.3%ID/g (peptide **3**) after 0.5 h. Peptides **2** and **4** showed a rapid elimination of activity from this organ (0.6 ± 0.1%ID/g and 0.6 ± 0.3%ID/g at 1.5 h p.i., respectively). Peptide **3** showed a slightly slower washout with 1.0 ± 0.1%ID/g (1.5 h p.i.) and 0.6 ± 0.2%ID/g (5 h p.i.). However, the uptake and retention of the carbohydrated peptides was significantly lower than the data reported for the nonglycated analogue **1** (5.3 ± 1.3 ID/g at 0.5 h p.i. and 2.1 ± 0.4%ID/g at 5 h p.i.).

Maximal tumor uptake was found at 0.5 h for all complexes. Compound **4** featured the highest accumulation at all p.i. times (5.6 ± 2.1, 3.6 ± 1.1, and 2.5 ± 1.3%ID/g at 0.5 h, 1.5, and 5 h p.i., respectively), which was significantly higher than that reported for peptide **1** ($P < 0.01$) (Table 3). Interestingly, the retention of **4** in the tumor was significantly higher than that of

Table 3. Biodistribution of the ^{99m}Tc-Labeled BBS Analogues (3.7 MBq/mouse i.v.) in Mice Bearing PC-3 Xenografts[a]

[a] The animals of the blocked group received a coinjection of 0.1 mg BBS(1−14). Data (mean ± SD) are expressed as percentage of injected dose per gram of tissue ($n = 3-4$). [b] $n = 13$. [c] $n = 6$. * ($P \leq 0.05$). ** ($P \leq 0.01$) vs reference compound **1** (one-way ANOVA and Dunnett's posthoc test). [§] ($P \leq 0.05$). [§§] ($P \leq 0.01$) vs unblocked group (unpaired *t* test).

the other new peptides **2** and **3** and the reference **1**. Thus, in the case of complex **4**, 45% of the tumor-localized activity after 0.5 h still remained inside the tumor at 5 h p.i., compared to 16−29% for the other analogues.

Besides the increased tumor uptake, we observed high uptake of the radiopeptides in pancreas and colon, which are known to express GRPR in mice. The highest values in both organs were obtained for peptide **4** at 0.5 h p.i. (pancreas = 63%ID/g and colon 13.0% ID/g). Moreover, the specificity of tracer accumulation in GRPR-positive tissues was determined by coinjection with 0.1 mg BBS(1−14) per mouse. These experiments showed a clear reduction of radioactivity in the tumor xenografts and in pancreas and colon (Table 3), which would confirm that the *in vivo* uptake was due to receptor-specific interaction.

Despite the higher kidney uptake found for the new carbohydrated BBS analogues at early p.i. times (due to their increased hydrophilicity), it rapidly decreased, and the activity in the kidneys at later p.i. times was relatively low for all peptides (<1% ID/g, at 1.5 and 5 h p.i.) (Table 3). This would indicate that the tracers were not trapped in the renal tissue and renal excretion of the radiopeptides was very fast.

The increased hydrophilicity of the new peptides resulted in a decrease in hepatic activity. However, a relatively high and unspecific accumulation of activity was observed in the small intestine, which would indicate that hepatobiliary excretion partially contributes to the overall tracer elimination (Table 3). Biodistribution experiments in normal mice have been reported for ^{99m}Tc(III)-labeled BBS analogues, all modified with different lipophilic linkers, and, in the case of two compounds, an additional carboxylic group. All these complexes featured high uptake in hepatic tissue (7.2−9.4%ID/g) and relatively high renal accumulation between 1.8 and 6.0%ID/g at 1 h p.i (*20*).

Calculation of tumor-to-blood, tumor-to-liver, and tumor-to-kidney ratios (Figure 3) allowed comparisons with other radiolabeled BBS analogues, recently described in the literature. The highest tumor-to-blood ratios corresponded to compound **4** and were significantly higher than those of the reference peptide **1** at 1.5 h p.i. (11.5 ± 4.8 vs 4.3 ± 3.4, respectively; $P < 0.05$) and at 5 h p.i. (33.4 ± 4.2 vs 1.9 ± 0.5, $P < 0.01$). Compounds **2** and **3** showed similar tumor-to-blood ratios compared to peptide **1** at 0.5 and slightly higher at 1.5 and 5 h p.i. time, but the differences were not statistically significant, with the exception of compound **3** at 1.5 h (13.0 ± 7.1 vs 4.3 ± 3.4, respectively; $P < 0.01$).

Interestingly, compound **4** featured significantly increased tumor-to-kidney ratios already at 1.5 h p.i. (1.4 ± 0.4 for **4** vs 0.9 ± 0.3 for **1**; $P < 0.05$) but more remarkably at 5 h p.i. (2.6 ± 0.4 for **4** vs 1.1 ± 0.3 for **1**; $P < 0.01$). Tumor-to-kidney ratios for peptides **2** and **3** were not significantly different compared to the reference **1** at any p.i. time (Figure 3).

The most notable finding was the improvement of tumor-to-liver ratios for all new glycated radiotracers at all p.i. times compared to the nonglycated peptide **1** (Figure 3). This indicates a significant impact of carbohydration on tracer accumulation in the liver, which is particularly important since high accumulation of radioactivity in the liver has been reported not only for ^{99m}Tc-labeled BBS analogues but also for ^{64}Cu-DOTA-BBS(7−14), ^{64}Cu-NOTA-8-Aoc-BBN(7−14)NH_2, and ^{68}Ga-DOTA-BBS(6−14) (*19*, *21*, *22*). The positive effect of carbohydration on liver accumulation has already been published for other peptides, e.g., radiolabeled sst analogues. Carbohydrated conjugates of Tyr^3-octreotide (TOC) showed a significant decrease of tracer accumulation in the liver and the intestines, without any effect on the binding affinity and similar or even increased uptake in sst receptor expressing tissues and tumor xenografts (*26*).

A direct comparison of the *in vivo* results with other ^{99m}Tc-labeled BBS analogues published in the literature is somehow difficult, since no glycated BBS analogues have yet been described and most of the reported analogues are based on the unmodified BBS(7−14) sequence. Smith et al. reported on the biodistribution in SCID mice with PC-3 tumor xenografts of BBS analogues radiolabeled with the bidentate ^{99m}Tc(X)(CO_3)-DPR-complex (X = H_2O or $P(CH_2OH)_3$ and DPR = 2,3-diaminopropionic acid) (*24*). Maximal tumor uptake at 1 and 4 h p.i. (3.7 and 2.7%ID/g, respectively) was comparable to our glycated BBS analogue **4** (3.6 and 2.5%ID/g at 1.5 and 5 h p.i., respectively). However, the accumulation in the liver and kidneys was higher, and thus, tumor-to-liver and tumor-to-kidney ratios were lower compared to our glycated compound **4**. Alves et al. published *in vivo* data in PC-3 tumor xenografted SCID mice for a series of pyrazolyl BBS conjugates labeled with the ^{99m}Tc(I)-tricarbonyl-core (*41*). In this case, maximal tumor uptake (1.8%ID/g at 1 h p.i.), as well as tumor-to-tissue ratios, was lower than those of analogue **4**. Interestingly, they tested the effect of several linkers between the chelator and the binding sequence. They found that the polar seryserylserine featured a longer retention in the tumors at 4 h p.i. compared to two rather lipophilic linkers consisting of β-Ala or glycylglycylglycine. This supports the results obtained with our polar glycated compounds and indicates a general positive influence of polar linkers on the biodistribution of ^{99m}Tc(I)-triycarbonyl-

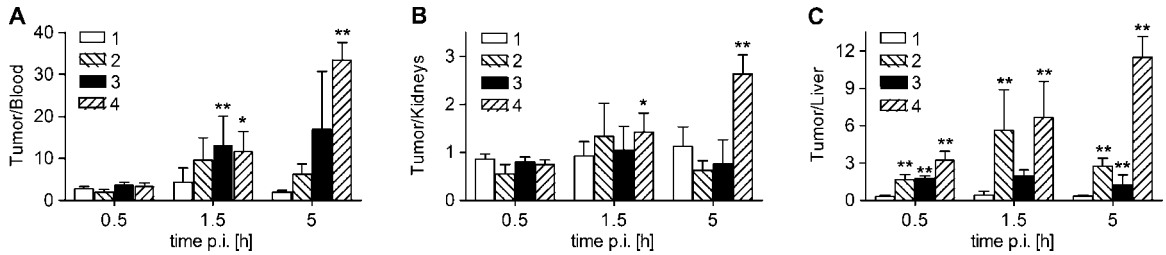

Figure 3. Tumor-to-tissue ratios of the ^{99m}Tc-labeled BBS analogues in mice bearing PC-3 tumor xenografts (3.7 MBq/mouse i.v.) ($n = 3-13$). (A) Tumor-to-blood. (B) Tumor-to-kidney. (C) Tumor-to-liver. * ($P \leq 0.05$), ** ($P \leq 0.01$) vs reference compound **1** (one-way ANOVA and Dunnett's posthoc test).

labeled BBS analogues. The same group reported recently a study with similar analogues incorporating 2-(*N,N′*-Bis(*tert*-butoxycarbonyl)diethylenetriamine) acetic acid (DTMA) as chelator for ^{99m}Tc (*45*). The *in vivo* behavior of the DTMA-BBS analogues was comparable to that of the pyrazolyl conjugates. Our results are also in agreement with a recent study with HYNIC and diphosphine BBS analogues (*46*). The authors found higher tumor uptake and better tumor-to-tissue ratios for the HYNIC analogue compared to the more lipophilic diphosphine tracer. Our analogue **4** showed slightly higher tumor uptake than the HYNIC conjugate (3.6%ID/g vs 3.0%ID/g at 1.5 h p.i., respectively). However, kidney and liver uptakes were lower, and consequently, tumor-to-kidney and tumor-to-liver ratios higher. Nock et al. reported on *in vivo* data for several ^{99m}Tc(V)-labeled BBS(1−14) analogues either with a hydrophilic or with a lipophilic character. Their results also indicated a strong impact of the polarity on the accumulation of the tracers in liver, kidneys, and tumors (*15*), the hydrophilic peptides showing the best tumor-to-nontumor ratios. Tumor-to-liver and tumor-to-blood ratios were comparable to those of our best compound (**4**). However, the glycated ^{99m}Tc(I)-labeled peptide **4** showed higher tumor-to-kidney values than the ^{99m}Tc(V)-labeled compound, which could be of interest for therapeutical applications with $^{186/188}$Re-labeled BBS.

SPECT/CT Imaging Studies. High accumulation of activity in the liver and gastrointestinal tract may hide the localization of cancerous lesions in the abdomen. Therefore, the reduced abdominal uptake by introduction of carbohydrates in addition to the increased tumor uptake is able to increase the potential of radiolabeled BBS, in general, and of ^{99m}Tc(CO)$_3$-labeled peptides, in particular. The new glycated analogues were further evaluated *in vivo* in SPECT/CT imaging experiments. Representative SPECT/CT images of the novel glycated radiotracer **4** and the nonglycated ligand **1** are depicted in Figure 4. The new conjugate **4** clearly provided a better imaging of the tumor xenografts than the reference compound **1**. The higher tumor uptake of conjugate **4** led to a clearer visualization of the xenografts compared to the nonglycated **1**. Furthermore, the lower liver and kidney uptakes resulted in decreased radioactive background in the abdominal area. Accumulation in small intestines due to hepatobiliary excretion as well as uptake in the GRPR-positive pancreatic and colon tissue were still high, in accordance with our *ex vivo* biodistribution data.

CONCLUSION

We evaluated three novel carbohydrated BBS derivatives for their usefulness in imaging GRPR-expressing neoplasms, and we could confirm the positive impact of glycation on the *in vivo* behavior of BBS analogues. In summary, the introduction of the polar carbohydrates had no effect on internalization, efflux, or metabolic stability *in vitro* but led to a significant reduction of abdominal accumulation, higher tumor uptake, and improved tumor-to-background ratios *in vivo*. The best results were obtained with a triazole coupled glucose, which ameliorated the biodistribution profile significantly. In this respect, the easy glycation via click reaction, using commercially available reagents, clearly offers an opportunity to improve the pharmacokinetic profiles of ^{99m}Tc- or ^{188}Re-labeled BBS analogues and increase their potential for imaging and therapy of GRPR-expressing tumors.

Protease-Specific Nanosensors for Magnetic Resonance Imaging

Eyk Schellenberger,* Franziska Rudloff, Carsten Warmuth, Matthias Taupitz, Bernd Hamm, and Jörg Schnorr

Department of Radiology, Charité - Universitätsmedizin Berlin; Charitéplatz 1; 10117 Berlin, Germany. Received August 1, 2008; Revised Manuscript Received October 27, 2008

Imaging of enzyme activity is a central goal of molecular imaging. With the introduction of fluorescent smart probes, optical imaging has become the modality of choice for experimental *in vivo* detection of enzyme activity. Here, we present a novel high-relaxivity nanosensor that is suitable for *in vivo* imaging of protease activity by magnetic resonance imaging. Upon specific protease cleavage, the nanoparticles rapidly switch from a stable low-relaxivity stealth state to become adhesive, aggregating high-relaxivity particles. To demonstrate the principle, we chose a cleavage motif of matrix metalloproteinase 9 (MMP-9), an enzyme important in inflammation, atherosclerosis, tumor progression, and many other diseases with alterations of the extracellular matrix. On the basis of clinically tested very small iron oxide particles (VSOP), the MMP-9-activatable protease-specific iron oxide particles (PSOP) have a hydrodynamic diameter of only 25 nm. PSOP are rapidly activated, resulting in aggregation and increased T2*-relaxivity.

INTRODUCTION

The advent of fluorescent smart sensor probes activatable by proteases ignited the development of reporter probes (*1*) and instrumentation (*2*) establishing optical imaging as the modality of choice for *in vivo* detection of enzyme activity (*3*).

To take advantage of the high resolution and deep-tissue imaging capabilities of magnetic resonance imaging (MRI), suitable for whole-body imaging of humans, as well as the absence of radiation exposure, several new probe designs were introduced. Meade and co-workers developed a reporter probe activatable by β-galactosidase on the basis of a paramagnetic contrast agent and demonstrated its successful use for the visualization of gene transfer by MRI (*4*).

A paramagnetic polymerization probe was presented by Bogdanov et al., which allowed imaging of tissue peroxidase activity by MRI (*5*). Josephson and co-workers introduced magnetic relaxation switches sensing enzymatic activity based on superparamagnetic high-relaxivity probes for *in vitro* MRI (*6*). Upon protease activation, these sterically stabilized cross-linked iron oxide particles (CLIO) switch from large clustered high-relaxivity aggregates to smaller low-relaxivity single particles. This technique is not suitable for *in vivo* application, since the nonactivated clustered particles are too large to have a favorable bioavailability and, more importantly, activation by elevated enzyme activity in the target tissue *reduces* the relaxivity and consequently the contrast effect.

Here, we describe a new design of protease-sensitive nanosensors, which are based on electrostatically stabilized, citrate-coated very small iron oxide particles (VSOP) with a hydrodynamic diameter of 7.7 ± 2.1 nm (Figure 2a) instead of larger sterically stabilized nanoparticles (over 20 nm). We have previously developed a pharmacologically formulated variant of these superparamagnetic particles (VSOP-C184) for magnetic resonance angiography, which was successfully tested in a clinical phase 1 trial and currently undergoing clinical phase 2 testing (*7*).

As cleavage motif, we chose a recognition site for MMP-9 and MMP-2, which was previously used to prepare a MMP-9-activatable fluorescent probe (*8*, *9*). MMPs have been identified as important regulators of pathological remodeling of extracellular matrix in cancer and inflammation (*10*). Using fluorescent smart probes, Bremer et al. developed a new concept to monitor the success of MMP inhibition in cancer by *in vivo* imaging, which may ultimately enable monitoring of therapeutic responses in the large spectrum of diseases with alterations of the extracellular matrix (*11*).

EXPERIMENTAL PROCEDURES

Synthesis. (1) The synthesized fluorescein-labeled MMP-9 peptide NH_2-GG*PRQITA*G-K(FITC)-GGGG-RRRRR-G-RRRRR-amide (the italicized amino acids correspond to the MMP-9 substrate (*9*)) was confirmed by MALDI-TOF (MALDI 2, Shimadzu). The molecular weight was within 1 Da of the expected value. 1 mg of the MMP-9 peptide (in 100 μL DMSO) was reacted with 31 mg NHS-mPEG (*O*-[(*N*-succinimidyl)succinyl-aminoethyl]-*O*′-methyl-poly(ethylene glycol) 5000, Fluka) in 300 μL 0.1 M HEPES, pH 7.5, overnight at 4 °C. The resulting MMP-9-peptide-mPEG copolymer was purified by gel filtration with BioGel P6 (BioRad, in 10 mM HEPES, 140 mM NaCl, pH 7.5). The absence of unreacted MMP-9 peptide was confirmed by HPLC using a reverse-phase C18 column with acetonitrile/water gradient. The concentration of the peptide-mPEG copolymers was determined spectrophotometrically by measuring peptide-bound fluorescein absorption (absorption at 494 nm, extinction coefficient of 72 000 M^{-1} cm^{-1}).

(2) VSOP (VSOP-C200) was provided by Ferropharm GmbH. To prepare 6×-MMP-9-PSOP (with six peptide-mPEG copolymers per VSOP), 1.25 nmol VSOP (3.25 μmol Fe assuming 2600 iron atoms per particle, data from Ferropharm GmbH) in 250 μL HEPES buffer (10 mM HEPES, 140 mM NaCl, pH 7.5) were mixed with 7.5 nmol peptide-mPEG in 250 μL HEPES buffer and stirred immediately. Other ratios (3 to 16) were prepared accordingly. Hydrodynamic diameters of MMP-9-PSOPs were determined by dynamic light scattering (Zetasizer Nano ZS, Malvern Instruments) in the same buffer. Relaxivities were measured with an MR spectrometer at 0.94 T (Bruker, Minispec MQ 40) according to the manufacturer's instructions.

For quenching experiments (Figure 3), 50 pmol VSOP was mixed with different amounts of the peptide-mPEG copolymers (150 pmol to 800 pmol) in 200 μL and subjected to fluorescence

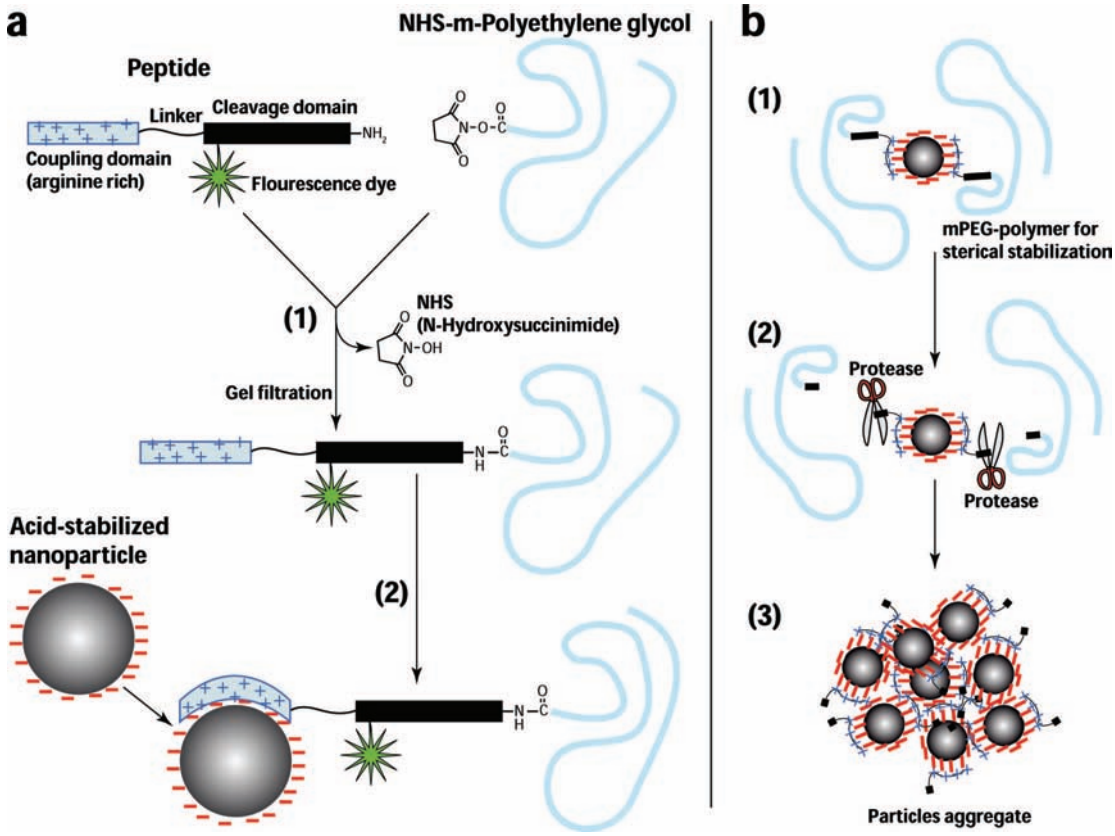

Figure 1. Synthesis and function of MMP-9-PSOP. (a) Synthesis. In step (1), the 25 amino acid peptides consisting of an arginine-rich coupling domain and a cleavage domain with the recognition site for MMP-9 linked by a glycine bridge are reacted with NHS-methyl-poly(ethylene glycol) (NHS-mPEG). The resulting peptide-mPEG copolymers are purified by gel filtration to remove unreacted mPEG and NHS. In step (2), peptide-mPEG are mixed with VSOPs, yielding MMP-9-PSOP. (b) Function. When sterically stabilized PSOP with an intact mPEG shell (1) are exposed to a protease specific to the cleavage motif, the peptide-mPEG are cut at the cleavage domain, resulting in a loss of sterical stabilization (2). The remaining particles aggregate due to the magnetic attraction of the iron oxide cores and the electrostatic attraction of the positive (arginine-rich coupling domain) and negative charged surface areas (acid shell).

measurements (excitation/emission 494/521 nm, Hitachi fluorescence spectrophotometer F-7000). Ratios of these quenched fluorescences and corresponding unquenched fluorescences of equal copolymer concentrations without VSOP addition were calculated and compared with the fluorescence of free fluorescein dye mixed with VSOP accordingly.

Enzyme Activation. To demonstrate the ability of MMP-9 to activate MMP-9-PSOP (0.125 nmol particles in 50 μL), hydrodynamic size measurements were carried out before and after adding MMP-9 (7.4 U MMP-9, human, Calbiochem) at 37 °C. For experiments with enzyme inhibition, MMP-2/MMP-9 Inhibitor II (30 μM final concentration, Calbiochem) was added before the addition of MMP-9 enzyme. The hydrodynamic diameters (Zetasizer) were monitored for 2 h. The incubation buffer for enzyme experiments was 10 mM HEPES, 140 mM NaCl, 1.3 mM $CaCl_2$, and 50 μM $ZnCl_2$, pH 7.5.

MR Imaging. For the MR experiments (Figure 4b), four different particle concentrations of 6×-MMP-9-PSOP (300 nM, 150 nM, 75 nM, and 38 nM particle concentration) were incubated with 1.3 U MMP-9 in 200 μL incubation buffer (see above) at 37 °C. All inhibitor experiments (Figure 4c,d) were done under identical conditions using a particle concentration of 300 nM. All enzyme reactions were imaged with a clinical 1.5-T MR scanner (Siemens Sonata). The gradient echo sequence with 12 echo times (TR = 100 ms, TE = 3.1−44.8 ms) was repeated 200 times over 50 min. The images were analyzed with OsiriX DICOM viewer, ImageJ (National Institutes of Health, USA), and Prism 5 (GraphPad Software). Curve fits for T2 calculation and enzyme inhibition (logarithmic inhibitor response curve, standard slope) were done with Prism 5.

Molecular Modeling. The 5 nm octahedral magnetite core of VSOP-C200 with approximately 2600 iron atoms and 75 citrate shell molecules per core (data provided by Ferropharm GmbH) was generated with CrystalMaker (CrystalMaker Software). Molecular modeling of MMP-9-PSOP was done based on the size measurements and the sequence of the MMP-9 peptide and NHS-mPEG (MW 5000) using the PyMOL Molecular Graphics System (*12*).

RESULTS

To add enzyme-sensing capability, we designed a construct shown in Figure 1a consisting of a peptide and a methyl-poly(ethylene glycol) polymer (mPEG, molecular weight 5000). The peptide consists of a cleavage domain with the enzyme recognition motif and a highly positively charged, arginine-rich coupling domain, which are connected by a linker sequence. For analysis by fluorescence methods, a fluorescine is coupled to the peptide. In a first step, this peptide was reacted with NHS-mPEG at the end of the cleavage domain. In a second step, after purification by gel filtration and HPLC control for purity, these peptide-mPEG copolymers were mixed in different ratios with the VSOP. A ratio of 6 peptide-mPEG per VSOP yielded MMP-9-PSOP with a hydrodynamic diameter of 24.9 ± 7.0 nm (Figure 2b). Mixtures with ratios between 6 and 16 peptide-mPEG consistently yielded particles with sizes around 24 nm,

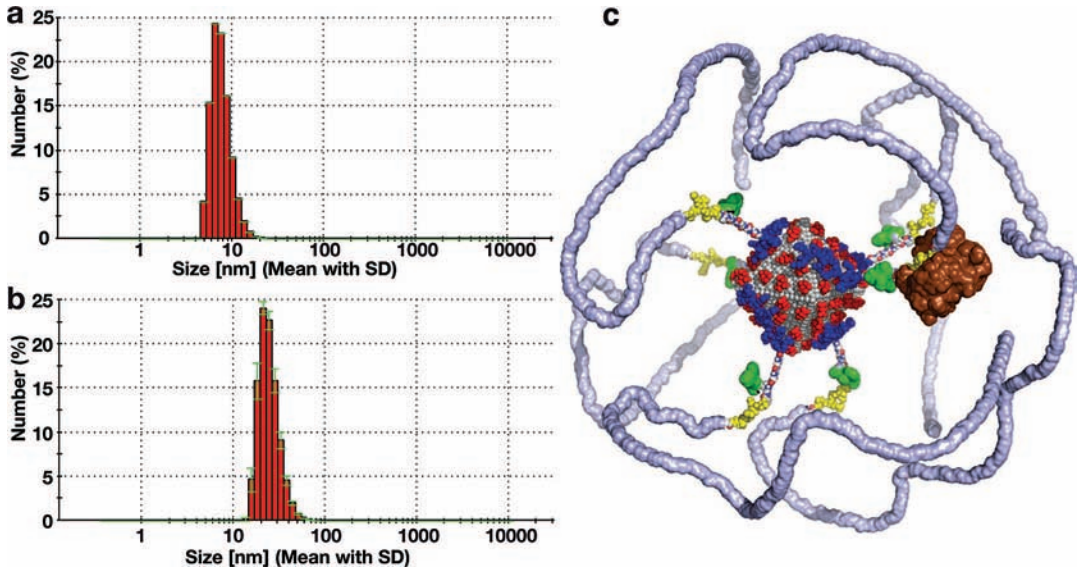

Figure 2. Size and model of MMP-9-PSOP. The hydrodynamic size distribution of the parent VSOP with 7.7 ± 2.1 nm is shown in (a). With the copolymers attached to the surface, the PSOP are still small at 25 nm with a narrow size distribution (b). For illustration, a model of MMP-9-PSOP based on the peptide sequence, the structure of mPEG, and the size measurements is shown in (c). The parent VSOP consists of a 5 nm magnetite core (gray) covered by a negatively charged citrate shell (red). The peptide-mPEG copolymers are electrostatically bound by the positively charged coupling domains (blue). The mPEG polymers (light blue) are linked to the coupling domain via the cleavage domain (yellow) and a linker peptide. A model of MMP-9 (*22*) (brown) is shown for size comparison at the cleavage domain. Fluorescein dyes (green).

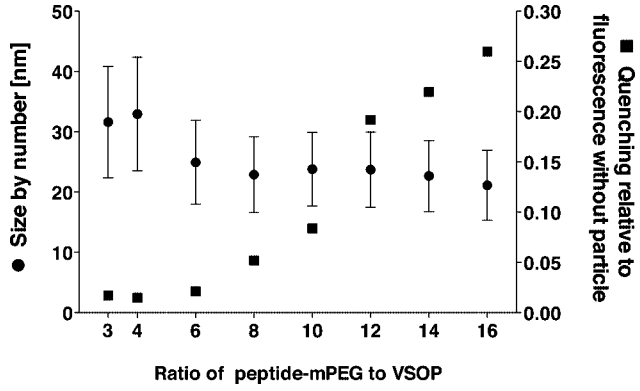

Figure 3. Dependence of size and fluorescence quenching on the ratio of peptide-mPEG copolymers to VSOP. Left axis: With an increasing number of peptide-mPEG copolymers per VSOP, the hydrodynamic size (mean of distribution by number, SD) of MMP-9-PSOP decreases slightly up to a ratio of 6 peptide-mPEG per VSOP and stays constant around 24 nm up to a ratio of 16. An average ratio of 6 peptide-mPEG per VSOP seems to be necessary for good steric stabilization. Below that ratio, the particles most likely form more dimers or multimers. Right axis: Due to the proximity of the copolymer-coupled fluorescein dyes to each other and to the nanoparticle cores, strong quenching of fluorescence can be observed for PSOP with ratios up to 8, proving nearly complete binding of the copolymers to the VSOP. With higher ratios, the quenching effect decreases, indicating incomplete coupling of copolymers due to saturation of the VSOP surface with peptide-mPEG copolymers.

whereas ratios below 6 resulted in particles over 30 nm in size, probably due to insufficient steric stabilization (Figure 3 and Table 1).

To evaluate the level of copolymer coupling to the VSOP surface, we measured the fluorescence quenching effect of the peptide-bound fluorescein, which is caused by nonradiative energy transfer due to the proximity of the dyes to each other and to the iron oxide cores (*13*). Compared with the fluorescence of the peptide-mPEG complexes without the particles, the fluorescence was strongly quenched up to ratios of 8 complexes per VSOP (Figure 3). PSOP with 6 complexes per VSOP had a quenched relative fluorescence of 0.02, indicating nearly complete coupling of the complexes to the VSOP surface. Higher ratios of complexes to particle cores showed a decreasing quenching effect, revealing incomplete coupling, most likely due to saturation of the VSOP surface. When free fluorescein was mixed with the particles (6 fluorescein dyes per VSOP) as control, the fluorescence was only reduced to 0.78, confirming that the reduction of copolymer fluorescence was not only caused by light absorption by the particles. Therefore, 6 peptide-mPEG copolymers per particle was considered a good ratio for further experiments.

For illustration, a model of MMP-9-PSOP (6 peptide-mPEG per particle), based on the sequence of the peptide-mPEG complexes and particle size measurements, is shown together with a crystal structure of MMP-9 in Figure 2c.

The function of the particles is explained in Figure 1b. When the sterically stabilized MMP-9-PSOP (1) are exposed to MMP-9, the protease cleaves the peptide at the recognition site (2), resulting in loss of the sterically stabilizing mPEG shell. Due to the superparamagnetic properties of the iron oxide cores and the ambivalent surface of the remaining particles with positively (coupling domains) and negatively (citrate coat of VSOP) charged areas, the particles aggregate driven by magnetic and electrostatic attraction (3).

This process has two important consequences: First, clustering of the superparamagnetic nanoparticles causes a substantial increase in R2-relaxivity, called magnetic switch (*6*). Second, the particles are converted from mPEG-covered stealth particles into highly aggregative particles with strongly charged surfaces (*14*). Conveniently, mPEG-5000 has been shown to be optimal for achieving stealth properties for nanoparticles (*15*). Consequently, once injected, the intact PSOP should remain for a long time in the blood circulation until they reach an MMP-9 expressing target tissue, where they are converted into aggregative particles and accumulate.

In contrast to mPEG-5000, peptide-mPEG copolymers made of mPEG-2000 (molecular weight 2000) or of branched mPEG-2000 did not yield stable particles but precipitating aggregates, presumably due to insufficient steric stabilization (data not

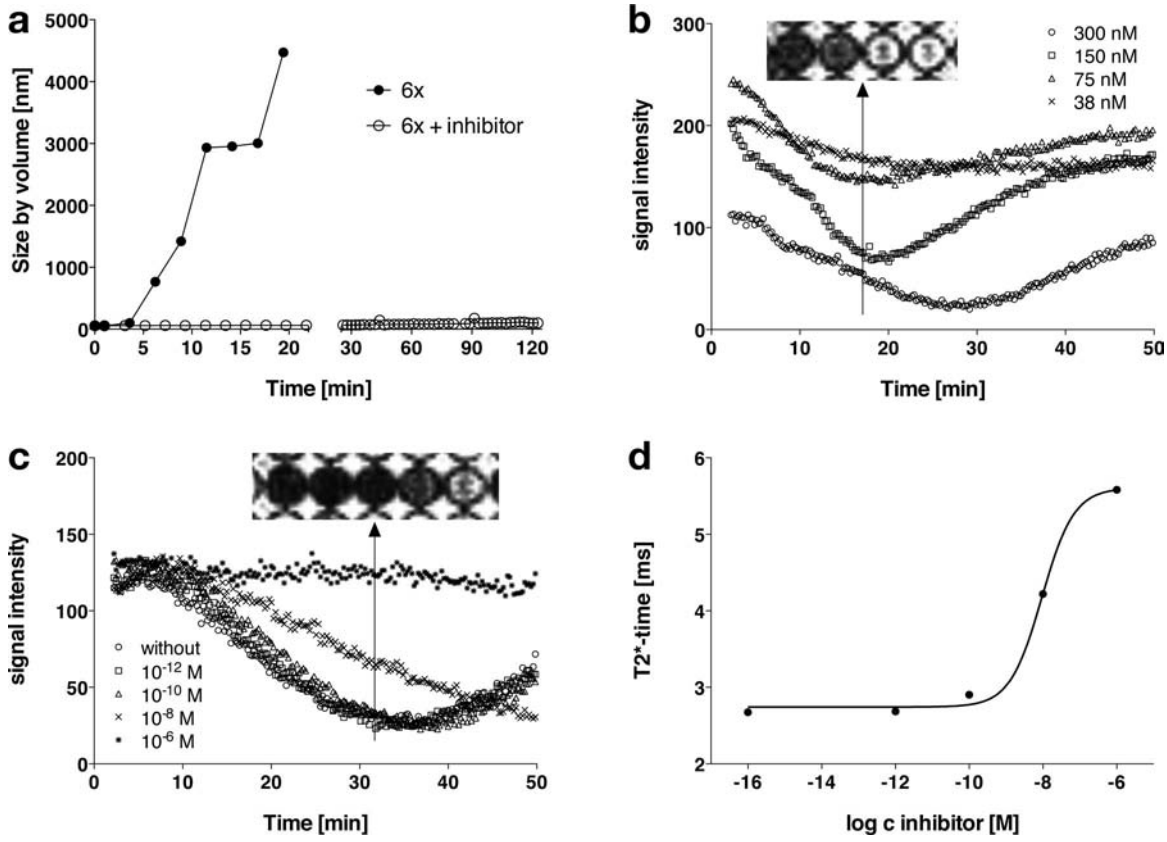

Figure 4. Function of PSOP. (a) Hydrodynamic size measurements. Time course of aggregation-induced size increase of the MMP-9-PSOP probe (0.125 nmol particles) induced by enzyme activation with 7.4 U of MMP-9. There was no probe activation when the experiments were done in the presence of 30 μM MMP-9-inhibitor. (b−c) MRI experiments. (b) Time course of activation of MMP-9-PSOP at four different particle concentrations. As aggregates form, the T2*-relaxivity of these particles increases, causing a drop in signal intensities on the gradient echo sequences to a minimum until no further decrease occurs because continuing aggregation and precipitation reduce the amount of water protons affected. MR image obtained at the time point indicated by the arrow. (c) Time course of signal intensities of MMP-9-PSOP (300 nM particle concentration) incubated with different concentrations of a MMP-9-inhibitor. (d) Inhibition of the T2*-time-shortening at the time point indicated by the arrow in (c). The 50% inhibitory concentration in this assay is approximately 10 nM. MR experiments were done with 1.3 U MMP-9 in 200 μL buffer.

Table 1. Properties of MMP-9-PSOP

size [nm]	24.9 ± 7.0
Peptide-mPEG copolymers per particle	6
R1 relaxivity [mM $Fe^{1-}s^{-1}$]	8.9
R2 relaxivity [mM $Fe^{1-}s^{-1}$]	41
Fe atoms per particle*	2600

shown). Another control experiment with uncoupled peptide and mPEG-5000 did not result in stable particles either (data not shown).

To demonstrate the function of MMP-9-PSOP, we measured the changes in size and T2* contrast in MRI following activation by MMP-9. Results are shown in Figure 4. First, we tested the activation of MMP-9-PSOP by monitoring hydrodynamic diameters (Figure 4a). Incubation of MMP-9-PSOP (6 peptide-mPEG per particle) with MMP-9 caused dramatic aggregation already after a few minutes leading to particle sizes exceeding the micrometer range. When the experiment was repeated in the presence of a MMP-9 inhibitor, the size remained almost unchanged over a period of 2 h.

To monitor the activation using MRI, we prepared 200 μL reactions with different concentrations of MMP-9-PSOP (300 nm, 150 nM, 75 nM, and 38 nM) and 1.3 U MMP-9 each. Approximately every 15 s, T2*-weighted images (gradient echo sequences with 12 echo times (TE) between 3.1 and 44.8 ms and a repetition time (TR) of 100 ms) were acquired over a period of 50 min. Figure 4b shows the time course of the signal intensities (for a TE of 10.6 ms). Depending on the concentration, the signal intensities decrease and reach a minimum at about 15 min for a concentration of 75 nM concentration and at about 27 min for 300 nM. The signal decrease was about 79% for 300 nM and 24% for 38 nM. The differences in the time it took to reach the signal minimum can be explained by the different amounts of peptide substrates to be cleaved by the MMP-9. The MR image in Figure 4b represents a snapshot taken at 17.6 min. Figure 4c shows the time course of signal intensities measured under the same conditions for 300 μM-MMP-9-PSOP incubated with different concentrations of a MMP-9-inhibitor. The signal drop is delayed at a concentration of 10 nM and nearly completely suppressed for the observation period of 50 min at a MMP-9-inhibitor concentration of 1 μM. T2* relaxation times for the different inhibitor concentrations were calculated from the MR images obtained at 32 min and analyzed using an inhibition function of Prism 5 software (log(inhibitor) vs response curve with standard slope, $R^2 = 0.996$). The 50% inhibitory concentration in this assay was 9.3 nm (95% confidence interval 4.2 nM to 21 nM).

DISCUSSION

After mixing with the VSOP, the peptide-mPEG copolymers adsorb at the strongly negatively charged VSOP citrate surface with their positively charged coupling domains. The resulting protease-specific iron oxide particles (PSOP) with the copolymers at the surface are no longer electrostatically but sterically stabilized, i.e., the natural tendency of superparamagnetic magnetite nanocores to aggregate is countered by the thick mPEG coat and not by the negatively charged surface of the

VSOP as before. Instead of PEG, other macromolecules such as dextran could provide sterical stabilization as well.

The results of the size measurements and *in vitro* MRI experiments presented here confirm the specific protease-sensing function of these newly developed PSOP. Upon incubation with MMP-9, the nanosensors start clustering after a few minutes, as can be shown by dynamic laser light scattering and MRI. This activation by protease activity was largely suppressed by preincubation with an MMP-2/MMP-9 inhibitor. Inhibition occurred in a typical, concentration-dependent manner (Figure 4d), proving that activation was due to the protease activity of MMP-9.

The PSOP comprise several key characteristics making them a good candidate for an enzyme reporter probe for *in vivo* MRI: Synthesis of the particles is fairly straightforward. They can be adapted to any proteases or possibly other cleaving enzymes. Poly(ethylene glycol)s have been proven to be biocompatible (listed in the pharmacopeia) and provide stealth properties, which is a prerequisite for a sufficiently long circulation time *in vivo* (*15*). Together with the nanosensors' small diameter of about 25 nm, these properties ensure good bioavailability in the desired target tissues. Unlike the caspase-3-sensitive nanosensors presented by Josephson and co-workers (*6*), which are clusters of approximately 45 nm sized CLIO monomers before activation and are cleaved into monomers by caspase-3, leading to a *decrease* in relaxivity and contrast effect, PSOP become larger upon activation and relaxivity increases. This property allows the *in vivo* application of the nanoparticles. The parent VSOP has been shown to be safe in preclinical (*16*) and clinical trials (*7*). In contrast to near-infrared fluorescence imaging, MRI with PSOP is a potential candidate for whole-body imaging of protease activity in humans. Moreover, the particles could be used to deliver therapeutics, or the accumulating magnetic cores themselves could serve as "theranostics" in clinical magnetic thermotherapy of cancer, which currently requires direct injection of magnetic nanoparticles into the tumor (*17*).

The *in vitro* experiments performed in this study have some limitations: First, the size measurements yielded meaningful results only until the aggregates started to precipitate, thereby dropping out of the measurement field of the zetasizer. In the MR experiments, the T2* contrast effect also started to decrease at a certain point in time, which is partially attributable to precipitation as well. Additionally, the fraction of water protons influenced by the magnetic field of the particles also decreases from a certain time onward as the aggregates continue to increase in size while their number decreases (*18*). Although precipitation due to aggregation is problematic for these *in vitro* settings, it is an intended and important mode of function for *in vivo* application. The accumulation of the particles in protease-expressing target tissues following the switch from a PEGylated stealth state to a highly surface-charged, aggregative state cannot be demonstrated with the types of experiments used here and remains to be shown *in vivo*. Although the aggregation effect and consequently the magnetic switch would be desirable for an enhanced contrast effect in the *in vivo* situation, it is not a necessity, since a particle binding to the target tissue due to the exposed charged surface is sufficient to produce a strong contrast effect (*19*−*21*).

We are convinced that the nanosensors presented here have great potential as reporter probes for assessing enzyme activity of proteases by *in vivo* MRI and can thus help diagnose diseases with pathologically altered protease activity or monitor protease inhibitor therapies.

N-Acetyl-L-cysteine (NAC) is an antioxidant and anti-inflammatory agent with significant potential in clinical applications including stroke and neuroinflammation. The drug shows high plasma binding upon IV administration, requiring high doses and associated side effects. Through the use of an appropriate delivery vehicle, the stability and efficacy of NAC can be significantly improved. Dendrimers are an emerging class of nanoscale drug delivery vehicles, which enable high drug payloads and intracellular delivery. Poly(amidoamine) (PAMAM) dendrimer−NAC conjugates having cleavable disulfide linkages are designed for intracellular delivery based on glutathione levels. We have successfully synthesized two conjugates with a cationic G4-NH_2 and an anionic G3.5-COOH PAMAM dendrimer with NAC payloads of 16 and 18 per dendrimer, respectively, as confirmed by ^{1}H NMR and MALDI-TOF analysis. NAC release from the conjugates at intracellular and extracellular glutathione (GSH) concentrations were evaluated by reverse phase HPLC (RP-HPLC) analysis, and ∼70% of NAC payload was released within one hour at intracellular GSH concentrations (∼10 mM), whereas negligible NAC release was observed at extracellular GSH levels (2 μM). FITC-labeled conjugates showed that they enter cells rapidly and localize in the cytoplasm of lipopolysaccharide (LPS)-activated microglial cells (the target cells *in vivo*). The significantly improved efficacies of dendrimer−NAC conjugates in activated microglial cells was confirmed by measuring the nitrite inhibition in the cell culture medium, which is an indication of the antioxidative property of the drug. Both G4-NH_2 and G3.5-COOH conjugates showed significantly better nitrite inhibition both at 24 and 72 h compared to free NAC, by as much as a factor of 16. The results indicate that PAMAM dendrimer conjugates produce higher local NAC concentration inside the cells, with GSH-sensitive disulfide linker enabling efficient and rapid cellular release of the drug.

INTRODUCTION

N-Acetyl cysteine (NAC) is a clinically important antioxidant, antiapoptotic, and anti-inflammatory drug used in the treatment of neuroinflammation, AIDS, colon cancer, and detoxification of heavy metals (e.g., lead, mercury, arsenic) (*1*−*6*). NAC has been extensively studied as both a therapeutic agent and direct cysteine precursor (*7*). In the treatment of neuroinflammation, it acts at multiple neuroprotective sites and has recently been demonstrated to attenuate amniotic and placental cytokine responses after maternal infection induced by lipopolysaccharide (LPS) (*8*) and to restore the maternal fetal oxidative balance and reduce fetal death and preterm birth (*9*, *10*). Further, a higher dose of NAC remains a primary treatment for acetaminophen overdose and exposure to toxic chemicals and is routinely used in hospitals (*11*−*14*). However, the use of NAC requires higher and repeated dosing. This is due to the poor bioavailability and blood stability, caused by the presence of free sulfhydryl groups in NAC, which are capable of spontaneous oxidation and forming disulfide bonds with plasma proteins (*15*). Early pharmacokinetic studies have demonstrated low oral bioavailability of NAC (between 6% and 10%), which were attributed to low blood concentrations of NAC (*16*, *17*). The need for high doses can lead to cytotoxicity and side effects, including increased blood pressure (*18*). NAC is one of the very few drugs being explored for treating neuroinflammation in perinatal applications, where side effects can be very critical.

The design of appropriate dendrimer−NAC conjugates can improve the stability and bioavailability, and at the same time enable intracellular release. These are especially important in our eventual interest in perinatal and neonatal applications of dendrimers and NAC. The unique design of conjugates involves linking of the NAC via disulfide bonds to spacer molecules attached to dendrimers. The resulting structure of the conjugates described here achieves two major objectives to ensure efficacy: (a) it may restrict the protein binding of NAC, as the free sulfydryl groups are involved in disulfide linkages; (b) it may enable higher intracellular levels of NAC and better release of NAC from the conjugate, resulting from disulfide linkages that are cleaved in the presence of intracellular glutathione (GSH). The results on *in vitro* release and the cellular efficacy toward reducing neuroinflammation in activated microglial cells shows the improved efficacy of the conjugates.

Over the past few decades, polymeric carriers have been extensively explored for controlled delivery of drugs intracellularly and to targeted tissues (*19*). Dendrimers are emerging as a viable class of polymeric vehicles (∼5−15 nm) because of the large density of reactive functional groups and well-defined structure and monodispersity (*20*, *21*). This enables a

high drug payload, but the steric hindrance at the dendrimer surface can make drug release a challenge when ester or amide linkers are used, especially at higher generations (*22*). Active molecules could be encapsulated (*23*), complexed (*24*), or covalently linked (*25*) to the polymeric carrier. The polymer can improve the solubility, stability, and blood circulation times. Despite several significant achievements of the polymeric conjugates, clinical applications still remain elusive, partly due to the issues of drug release over an appropriate time interval. Common approaches in conjugate design involve the use of ester or amide linkers, which are cleaved hydrolytically or enzymatically (*26*). For practical applications in drug delivery, increasing the drug payload and engineering the drug release at the appropriate tissue are two key aspects in the design of polymer conjugates. For intravenous applications, it is highly desirable to design a linker that is stable during circulation but enables drug release when it reaches the target site. There is a need to design efficient polymer conjugates having cleavable bonds or linkers, with high drug payloads and appropriate release profiles.

Recently, specific chemical reactions, such as the disulfide reduction, have emerged as alternative mechanisms for drug release (*27, 28*). Polymeric delivery systems offer an avenue for GSH responsive targeted delivery of drugs to tumor tissue (*29, 30*). Various carriers such as gold nanoparticles (*31*), gold nanorods (*32*), mesoporous silica nanorods (*27*), nanoparticle inhibited β- galactosidase (*33*), poly (2-dimethylaminoethyl methacrylate) (PDMAEMA) (*34*), carbon nanotubes for siRNA delivery (*28*), poly (β-amino ester) (*35*), gelatin nanoparticles (*36*), methyl acryloylglycylglycine 4-nitrophenyl ester for DNA delivery (*37*) have been used in this regard with reductively cleavable disulfide spacers. Furthermore disulfide bonds have been incorporated in the synthesis of cleavable delivery systems for plasmid DNA (*38*), antisense oligonucleotides (*39*), peptide nucleic acids (*40*), toxins (*41*), and anticancer drugs (*42*) Therefore, in the present investigation we have combined a dendrimer-based delivery system with disulfide chemistry, to develop a GSH-responsive release system with a high drug payload. The disulfide bonds are easily cleavable, and hence the drug release is not compromised. The glutathione (GSH)-mediated release of biomolecules from monolayer-protected gold nanoparticle surfaces and manipulation of their bioactivity *in vitro* has been demonstrated (*31*). GSH is the most abundant thiol species in the cytoplasm and the major reducing agent in biochemical processes, providing a potential *in situ* releasing source in living cells. The intracellular GSH concentration (1−10 mM) is substantially higher than extracellular levels (0.002 mM in plasma) (*31*). More importantly, the GSH levels in cancer tissues can be many-fold higher than those in normal tissues (*30, 31*). Therefore, a GSH responsive linker will limit plasma release and can promote targeted release.

EXPERIMENTAL PROCEDURE

The experimental protocols, characterization methods, and NMR and MALDI spectra for the various compounds discussed in the paper are provided as part of the Supporting Information (R-I to R-XI).

Stability of Conjugates. Stabilities of NAC alone, GSH alone, GSH and NAC when they are present together, were evaluated as controls. The NAC and GSH concentrations used for stability studies were 0.2 mg/mL and 3 mg/mL (10 mM), respectively. The concentrations of GSH and NAC in these studies were chosen in relevance to the conjugate stability studies. Stability of conjugates was analyzed in physiological pH (PBS buffer) and in the presence of two different GSH concentrations (10 mM and 2 mM). The stability studies were carried out for a period of 17 h at 37 °C. The conjugates were dissolved at 1 mg/mL concentrations in 1 mL of PBS solution and required amount of GSH was added to trigger disulfide exchange reactions, resulting in the release of NAC from the conjugate. At specific time intervals, 30 μL samples were withdrawn and analyzed with HPLC. All experiments were run in triplicate for statistical analysis.

Flow Cytometry Analysis. Immortalized mouse microglial cells (BV-2 cells obtained by courtesy of Dr. Kuhn, Wayne State University) (passage 16) were grown overnight in 6-well plates using DMEM cell culture medium supplemented with 10% FBS and 1% penicillin−streptomycin. When the cells were 70% confluent, they were treated with FITC-labeled-PMAM-NH-CO-propionyl S-S-*N*-acetyl-cysteine conjugated (FITC PAMAM-NH-CO-Pr-S-S-NAC compound **2**) (equivalent to 10 μg/mL of FITC-PAMAM-NH-CO-Pr-S-S-NAC) for 15, 60, and 120 min. The cells were washed with phosphate buffered saline (PBS, pH = 7.4), trypsinized, and centrifuged at 1500 rpm for 5 min to obtain a cell pellet. The cells were then rinsed with PBS buffer, spun down three times, and resuspended in 1% formaldehyde, and analyzed using a flow cytometer (FACS caliber, Becton Dickinson) by counting 10 000 events. The mean fluorescence intensity of cells was calculated using the histogram plot.

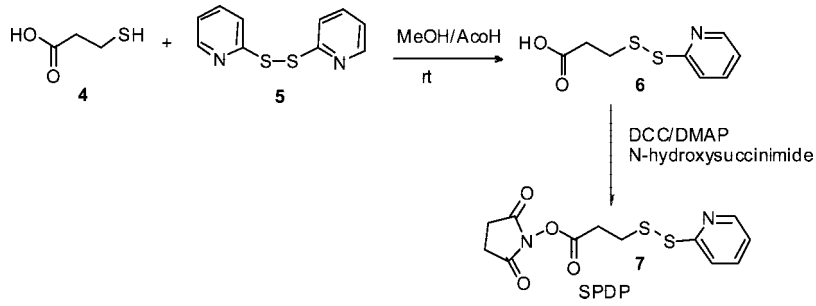
Confocal Laser Scanning Microscopy. The procedure for cell culture and drug treatment was the same as described in the previous section. After treating BV-2 cells for 2 h with FITC PAMAM-NH-CO-Pr-S-S-NAC conjugate (equivalent to 10 μg/mL of FITC PAMAM-NH-CO-Pr-S-S-NAC), the cells were washed with PBS three times and fixed with 4% *para*-formaldehyde for 20 min. Images were captured under the confocal microscope (Zeiss LSM 310) using a magnification of 630×. The emission and excitation wavelengths were 488 and 518 nm for FITC.

Detection of Nitrite Production. The presence of L-PS induces nitrite production, and the subsequent suppression of this by the dendrimer conjugates is used to assess the efficacy. BV-2 cells (passage 16) were seeded in 24-well plates at 10^5/ml/well and incubated for 24 h. The medium was removed and 500 μL of fresh serum-free medium was added. The cells were exposed to 100 ng/mL of lipopolysaccharide (LPS) and various concentrations of dendrimer conjugates for 3 h. The medium was removed again, and 500 μL of fresh, serum-free medium containing 100 ng/mL of LPS was added. The cells were incubated for 24 and 72 h, and the culture medium was removed for analysis. Control treatments with various concentrations of free NAC, positive controls with LPS induction and no treatment, and negative controls without any LPS induction were also studied.

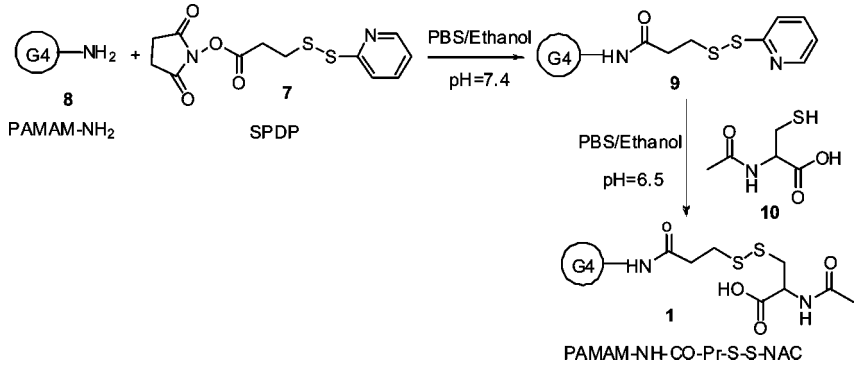
Accumulation of nitrite in the culture medium was used as a measure of NO formation. The nitrite concentration was determined by using the Griess reagent system (Cayman) that uses sulfanilamide and *N*-(1-naphthyl)ethylene diamine. In brief, 100 μL of supernatant from BV-2 cells exposed to different treatments was incubated with 50 μL of Griess reagent 1 (sulfanilamide) and 50 μL of Griess reagent 2 (*N*-(1-naphthyl)-ethylenediamine) for 10 min at room temperature. The absorbance at 540 nm was then measured, and nitrite concentration was determined using a curve calibrated with nitrite standards.

Intracellular GSH Measurement. Levels of intracellular reduced glutathione (GSH) was assessed spectrofluorimetrically by monochlobimane staining (*13*). Briefly, the procedure for culture and drug treatment was the same as described in the previous section. Cells seeded in collagen I coated 96-well plates were washed once with PBS and incubated with 50uM monochlobimane diluted in phenol red free medium. The fluorescence intensity was measured after 15 min at 37 °C. Excitation and emission wavelengths were 380 and 485 nm, respectively. Intracellular GSH reduced rate was calculated

Scheme 1



Scheme 2



according to the following formula: [reduced rate (%) = (fluorescence intensity of EMEM control − fluorescence intensity of treatment group)/fluorescence intensity of EMEM control × 100%].

RESULTS AND DISCUSSION

This therapeutic efficacy of polymer conjugates can be enhanced, and side effects reduced, if intracellular drug release can be enhanced. This is especially true in neonatal applications of NAC, where high doses of NAC are used. To attain this objective, we have developed GSH-responsive dendrimer NAC conjugates incorporating a connecting disulfide spacer. Use of the disulfide spacer can provide extracellular stability with rapid degradation once internalized in cells, releasing the free NAC. In the present investigation, we have successfully synthesized and evaluated two dendrimer conjugates, a cationic PAMAM-NH-CO-Pr-S-S-NAC and an anionic G3.5-CO-Glutathione-S-S-NAC (G3.5-CO-GS-S-NAC) conjugate, for the first time in dendrimers with a disulfide bond between the drug and the dendrimer through a different spacer. The drug will be released at a rate dependent on GSH concentration.

PAMAM-NH-CO-Pr-S-S-NAC Conjugate Synthesis (1). To conjugate the NAC to dendrimers, the linker SPDP was appended to the dendrimer with the thiopyridine termination. The NAC was covalently attached to the PDP linked dendrimer by the formation of disulfide bonds. Synthesis of *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) was performed by a two-step procedure (Scheme 1). First, 3-mercaptopropionic acid was reacted by thiol−disulfide exchange with 2,2′-dipyridyl disulfide to give 2-carboxyethyl 2-pyridyl disulfide (Scheme 1, Supporting Information R-V). To facilitate linking of amine-terminated dendrimers to SPDP, the succinimide group was appended on SPDP to obtain *N*-succinimidyl 3-(2-pyridyldithio)propionate (Scheme 2, Supporting Information R-VI), by esterification with *N*-hydroxysuccinimide by using *N*,*N*′-dicyclohexylcarbodiimide. To introduce sulfhydryl-reactive groups, PAMAM-NH_2 dendrimers were reacted with the heterobifunctional cross-linker SPDP (Scheme 2, Supporting Information R-VI). The *N*-succinimidyl activated ester of SPDP couples to the terminal primary amines to yield amide-linked 2-pyridyldithiopropanoyl (PDP) groups (Scheme 2). After reaction with SPDP, PAMAM-NH-PDP was analyzed using RP-HPLC (data not shown) to determine the extent to which SPDP had reacted with dendrimers.

The samples were compared to unmodified PAMAM-NH_2 dendrimers. Samples were initially run on a linear gradient from 100:0 H_2O (0.1 wt % TFA)/acetonitrile to 10:90 H_2O (0.1 wt % TFA)/acetonitrile over 32 min. During this gradient, PAMAM-NH_2 was eluted after (13.1) compared to the modified PAMAM-NH-PDP dendrimer (data not shown). The increased retention time is in line with the addition of hydrophobic PDP groups. The slight broadening of the peaks and appearance of shoulder peaks for both PAMAM dendrimers and PAMAM-NH-PDP might reflect structural defects that occurred during synthesis of the dendrimer, for example, by incomplete alkylation of the primary amines or intramolecular cyclization. The absence of amine-terminated dendrimer in the pyridyl disulfide-modified dendrimers indicates the completion of the reaction as reflected from the HPLC analysis. The PAMAM-NH-PDP so obtained was reacted with water soluble NAC to get the desired conjugate. The linking of NAC to dendrimer via the formation of a disulfide bond was confirmed by HPLC, NMR, and MALDI-TOF (Table 1, Supporting Information R-VII). The NMR and the MALDI data for the drug payload agree very well with each other, as summarized in Table 1. The HPLC chromatogram reflected decreased retention time (Figure 2B) (15.0 min) with the addition of hydrophilic groups. The shift in retention times for the dendrimer conjugates confirms the conjugation with NAC; further, the shift to higher retention times indicates the hydrophobic nature imparted due to the spacer molecules and the NAC. The absence of the peaks corresponding to NAC and NAC-NAC and SPDP in the chromatogram for the conjugates confirms the purity of the compound synthesized. The chromatogram of the PAMAM-NH-CO-Pr-S-S-NAC conjugate showed the presence of a very small fraction of NAC-NAC as indicated by the slight hump at 8.2 min. Further, the appearance of methyl groups in NMR at 1.94 ppm confirms

the formation of disulfide bonds between the PAMAM-NH-PDP and NAC. The attachment of multiple copies of NAC to PAMAM-NH-PDP dendrimers was determined by MALDI-TOF. Analysis of the unmodified G4 dendrimer gave a broad M+ peak at 14.1 kDa (Figure 1A), which closely corresponds to the theoretical molecular mass of the dendrimer 14.2 kDa. Coupling of the G4 terminal amine groups with NAC resulted in a shift in the major peak to 18.3 kDa (Figure 1B, Table 1, Supporting Information R-VII). Each thiopropanoyl NAC group has a molecular mass of 250 Da. Therefore, these data indicate an average of 16 NAC molecules per dendrimer molecule (16 thiopropanoyl NAC groups per dendrimer molecule containing 64 amine terminal groups, $n = 3$; number of independent experiments, Table 1, Supporting Information R-VII). The PAMAM-NH-CO-Pr-S-S-NAC conjugate was tagged with fluorescent dye FITC (Scheme 3) for a cell uptake study (data not shown). The drug payloads in the conjugates have been kept moderate, in order to enable high solubilities of the conjugate for *in vivo* experiments.

PAMAM-CO-GS-S-NAC Conjugate Synthesis. *S*-(2-Thiopyridyl)glutathione, was prepared from the reaction of 2,2′-dithiodipyridine in excess and the corresponding peptide in a mixture of methanol and water at room temperature (Scheme 4). Upon completion of the reaction, methanol was removed *in vacuo* and the residue was washed with dichloromethane. The aqueous solution was subjected to reverse phase (RP) HPLC purification, and lyophilization of the eluent gave the pure product as a white solid (Supporting Information R-IX). This compound was reacted with NAC in PBS in pH = 7.4 to get the desired glutathione-*N*-acetyl cysteine (GS-S-NAC) (Scheme 4) intermediate and purified. The formation of a disulfide bond was confirmed by NMR and ESI-MS (Table 1, Supporting Information R-X). The appearance of methyl groups in NMR at 1.90 ppm indicates the formation of disulfide bond between

the GSH and NAC. To introduce the GS-S-NAC, PAMAM-COOH was reacted with GS-S-NAC in the presence of PyBop/DIEA to give the desired PAMAM-CO-GS-S-NAC conjugate (Scheme 4, Supporting Information R-XI). Introduction of GS-

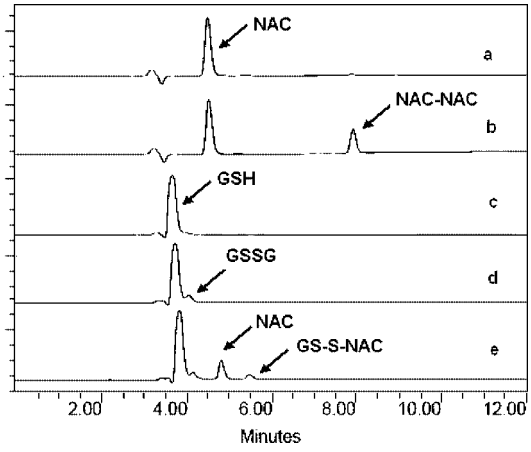

Figure 5. RP-HPLC UV absorbance chromatograms at 210 nm (arbitrary AU units) (a) NAC; (b) NAC and NAC-NAC; (c) GSH; (d) GSH and GSSG; (e) GSH, GSSG, NAC, and GS-S-NAC.

S-NAC was confirmed HPLC, NMR, and MALDI. The same type of MALDI analysis yielded approximately 19.7 kDa (Figure 3B, Supporting Information R-X) (18 GS-S-NAC groups for the PAMAM-COOH dendrimers). The number of GS-S-NAC groups was also determined via NMR analysis and the appearance of methyl protons at 1.70 and 1.92 ppm (Supporting Information R-XI) indicates the formation of GS-NAC conjugate with dendrimer. The NMR and MALDI data for the drug payload agree very well with each other, as summarized in Table 1.The yields of PAMAM-conjugates are high and reproducible.

Release Studies. The release of NAC from the conjugates was investigated in the presence of GSH at intracellular and extracellular concentrations (*31*). It was assumed that the release of NAC would occur by the disulfide exchange reaction. GSH and its oxidized form (GSSG) are responsible for forming the intracellular redox buffer. Intracellularly, GSH takes the role of attacking thiolate moiety and gets oxidized in the process while cleaving the existing disulfide bonds. Disulfide exchange reactions do not change the total number of disulfide bonds but rather shuffle the species forming them. In the present study, the release of NAC from the conjugates by disulfide exchange reaction was confirmed by the HPLC analysis and is discussed in detail in the following sections.

Free NAC had an elution time of 4.7 min (Figure 5a), whereas GSH eluted at 3.8 min (Figure 5c). Oxidized forms of NAC and GSH were also analyzed by HPLC and the oxidized form of NAC eluted (NAC-NAC) at 8.2 min (Figure 5b), while oxidized GSH (GSSG) eluted at 3.9 min (Figure 5d). The GSSG peak was very close to the GSH peak, and when both were injected together, GSSG appeared as a shoulder on the GSH peak (Figure 5d). On the other hand, NAC-NAC is more hydrophobic than NAC, as indicated by the higher elution times for the former than NAC in the chromatogram (Figure 5b). Hydrophilicity of NAC can be associated with its thiol group, and when this group is occupied, the molecule is rendered more hydrophobic, as suggested by the significant increase in its retention time when NAC-NAC (Figure 5b) was formed. A similar shift to higher retention was observed for GSSG, as indicated by the appearance of a shoulder on the peak seen for retention of GSH (Figure 5d). However, this shift in retention time of GSSG is not as significant (Figure 5d) as that seen for NAC-NAC (Figure 5b). The retention time of GS-S-NAC (Figure 5e) was 5.3 min, which was longer than both GSH (3.8 min) and NAC (4.7 min). This suggests that occupation of thiol groups reduces the hydrophilicity of both NAC and GSH.

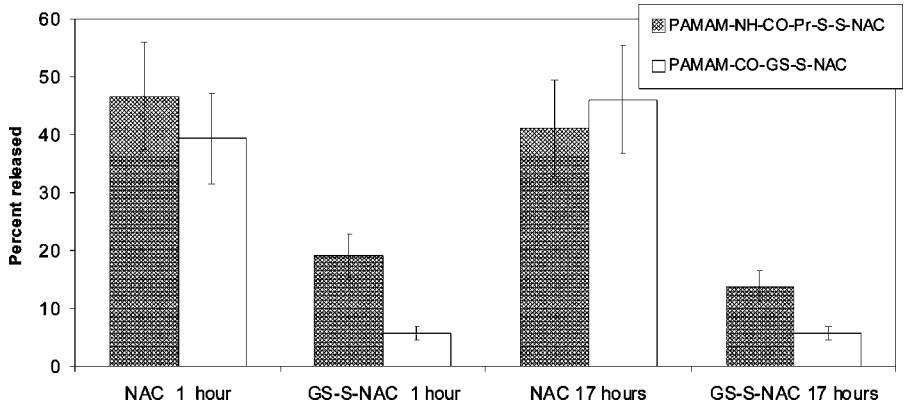

Figure 6. Release of NAC and GS-S-NAC from conjugates (in PBS with 10 mM GSH).

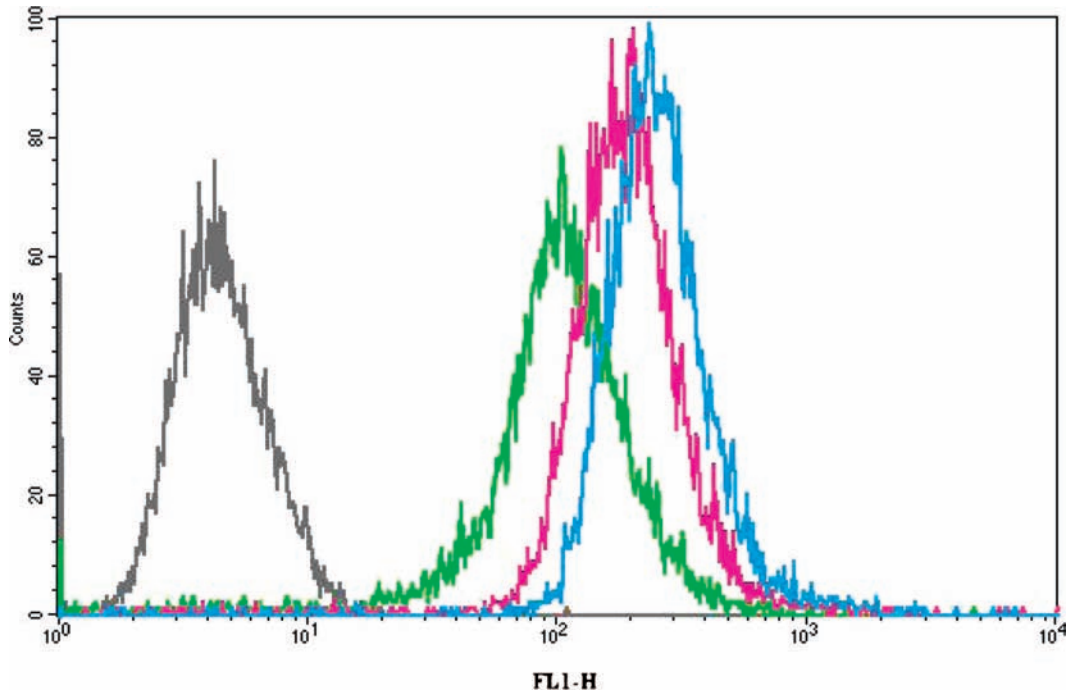

Figure 7. Flow cytometry of the cell entry dynamics of FITC-PAMAM-NH-CO-Pr-S-S-NAC- conjugate in the BV-2 microglial cell line. The log of FITC absorption intensity (FL1-H on *x*-axis) is plotted against the number of cells (counts on *y*-axis). The rapid increase in the cellular uptake of FITC-PAMAM-NH-CO-Pr-S-S-NAC within 15 min is evident.

Stability analysis of free NAC and free GSH suggests that both GSH and NAC go through slow oxidation and form their dimers (NAC-NAC and GSSG) by disulfide bond formation when dissolved in PBS. The rate of disulfide bond formation was relatively slow at 25% of NAC and GSH being converted to their oxidized form over 17 h. It was determined that, in addition to their dimers, when NAC and GSH were present together, they formed GS-S-NAC as well. The formation rates of GS-S-NAC were in agreement with the oxidation rates determined for both NAC and GSH separately. When NAC and GSH were present together where GSH was in excess, no detectable NAC-NAC was formed. The conjugates were also analyzed in the absence of GSH to verify the stability of the disulfide linkage at physiological pH. When the conjugates were placed in PBS buffer and analyzed for 17 h, both conjugates were stable and did not release any of the NAC they carried. The stability of the disulfide linkage shows that they are capable of carrying their payload without any release due to instability in aqueous media at physiological pH. The extent of the release of drug from both dendrimer−NAC conjugates was also analyzed at plasma and intracellular GSH concentrations. The conjugates and the GSH in required amounts were added to PBS solution, and the solution was analyzed at various time intervals by HPLC for up to 17 h. UV absorbance peak areas were used to determine the concentrations of each of the species in the solution, based on appropriate calibration curves. At plasma GSH concentration (2 μM), both G3.5-CO-GS-S-NAC and G4-NH-CO-Pr-S-S-NAC conjugates were very stable and they did not release any detectable levels of free NAC within a 17 h period. For both conjugates, 1% of the NAC payload was found in the release medium in reduced GS-S-NAC or NAC-NAC forms (data not shown). The limited release of NAC in reduced GS-S-NAC or NAC-NAC forms was very rapid and competed within 1 h. The remaining NAC stayed intact throughout the release study due to depletion of the reduced GSH in the media. This suggests that NAC releases from the conjugate rapidly but the amount of NAC released will be governed by the amount of reduced GSH available.

The expected release mechanisms of both PAMAM-NH-CO-Pr-S-S-NAC and PAMAM-CO-GS-S-NAC conjugates should be similar, with the only difference being the linker used. In the presence of excess GSH, the conjugates containing disulfide bonds can get shuffled by GSH in two possible ways. The conjugates may release NAC in the free form, while a GSH will attach onto the dendrimers forming the disulfide bond. The other possible way includes releasing of GS-S-NAC while the dendrimers have a free thiol group. The GS-S-NAC formed can be further shuffled by excess GSH present and can yield GSSG and NAC. The shuffling reactions will reach equilibrium where the concentration of each species is stabilized. These fast shuffling reactions will not change the total number of disulfide linkages, while slow oxidation reactions can also take place forming new disulfide bonds.

Both conjugates were analyzed for their release characteristics at intracellular GSH concentration (10 mM). The results suggest that both conjugates were able to release significant amounts of free NAC within an hour (Figure 6). PAMAM-NH-CO-Pr-S-S-NAC conjugate released 47% of the NAC payload in free form within 1 h. Additionally, 19% of NAC payload was found in GS-S-NAC oxidized form. The total NAC that was detached from the dendrimers within 1 h was 66%. The extent of NAC released did not change significantly after the initial release within 1 h; 41% of NAC payload was found in the free form and 14% was found as GS-S-NAC. The slight decrease in NAC content was most likely due to the error in concentration determination, and it was within standard error limits. Similarly, PAMAM-CO-GS-S-NAC conjugate released 39% of NAC in free form and another 6% in GS-S-NAC form within 1 h, yielding a 45% total NAC release. At 17 h, the free NAC content was determined as 46%, and 6% of NAC payload was in the GS-S-NAC form. At intracellular GSH concentration, no NAC-NAC was formed throughout the release studies. Absence of NAC-NAC can be explained by the excess amount of GSH present in the media, which can transfer the disulfide linkage onto either GSSG or GS-S-NAC by disulfide exchange reactions. After the initial rapid release of NAC, the concentrations

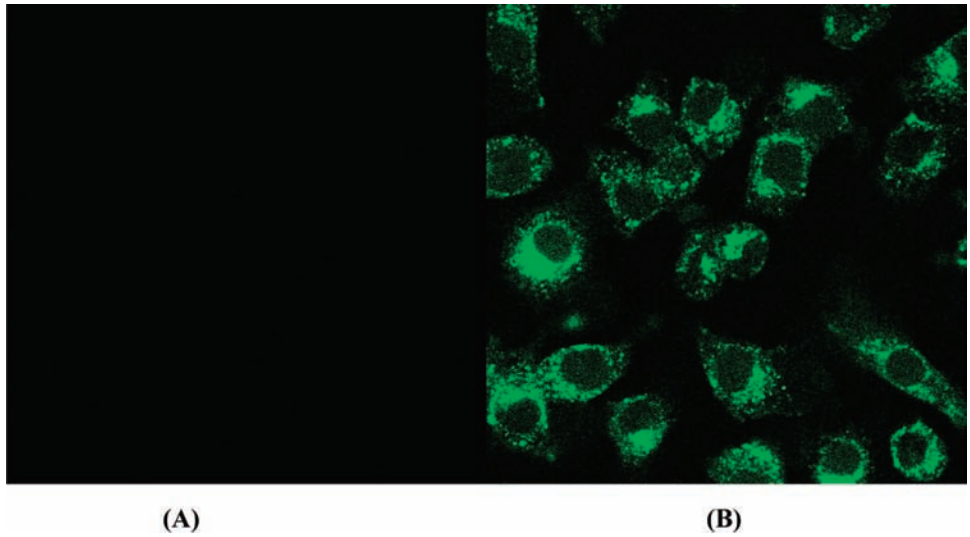

Figure 8. Confocal microscopy images (630×) after 2 h of treatment with (A) control and (B) FITC-PAMAM-NH-CO-Pr-S-S-NAC. The FITC-PAMAM-NH-CO-Pr-S-S-NAC conjugates appear to be mainly localized in the cytoplasm, while the nucleus appears to be relatively free of the presence of any fluorescence at this time scale.

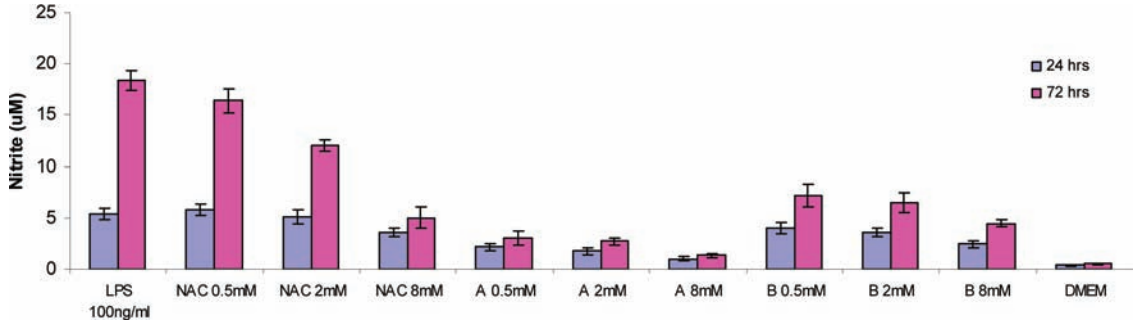

Figure 9. Efficacy assay of dendrimer−NAC conjugates. BV-2 cells were treated with 100 ng/mL of LPS and the indicated concentration of NAC, PAMAM-NH-CO-Pr-S-S-NAC (A) conjugate and PAMAM-CO-GS-S-NAC (B) conjugate for 3 h, and then incubated with 100 ng/mL of LPS for 24 and 72 h. Nitrite in culture medium was measured using Griess reagent system. Data are mean ± SD of three samples per group, and assessed by *t* test.

of analytes did not change significantly, which suggests that the cleavage is by fast exchange reactions which reach equilibrium within 1 h. The difference in drug release of the two conjugates may be explained by the different types of linkers used for attachment of NAC.

Our study shows fast release of NAC from the conjugates in intracellular GSH levels and the stability at plasma GSH levels; these results suggest the similar release mechanism for NAC from the conjugates. This study demonstrates that PAMAM dendrimer-based NAC delivery systems can be developed for various applications. The above results have significant implications in designing dendrimer-based drug delivery systems. Enzymatic release of drugs from dendritic delivery systems is challenging. Smaller generations were shown to be capable of enzymatic cleavage, but lower generations lack the enhancements higher generations have to offer, whereas higher generations face steric hindrance issues (*43, 44*). Commonly used pH-responsive release systems usually provide slower drug release over longer time periods unless the release takes place at a very low pH (*24, 44*). The two GSH-responsive delivery systems described here have very fast release kinetics at intracellular conditions and demonstrate that GSH can be used as a reliable releasing agent in dendrimer-based delivery systems. Interestingly, the thiol-containing drugs are capable of forming disulfide bonds, and this is one major contributing factor for their enhanced protein binding and reduced bioavailability. Further, this study shows that the covalent linking of the thiol-containing drugs by disulfide bonds would provide a means of releasing these drugs from the carrier systems at the targeted sites.

Cell Entry of Conjugates in BV-2 Microglial Cell. Cellular entry of FITC-PAMAM-NH-CO-Pr-S-S-NAC conjugate was evaluated using flow cytometry and confocal microscopy. The flow cytometry shows a significant fluorescence intensity increase within 15 min, as evidenced by a two order of magnitude increase in the fluorescence intensity (Figure 7). Subsequently, there was a moderate increase in fluorescence noted until 120 min. This shows that the FITC-PAMAM-NH-CO-Pr-S-S-NAC conjugates entered the cells rapidly.

The cellular entry was also visualized using confocal microscopy (Figure 8). It is evident that the FITC-PAMAM-NH-CO-Pr-S-S-NAC conjugate enters the cells and localizes mostly in the cytoplasm, while the nucleus appears to have relatively less fluorescence at this time scale. The cells without any treatment show no fluorescence. From the above results, it appears that FITC-PAMAM-NH-CO-Pr-S-S-NAC conjugates are transported inside the cells efficiently, perhaps by endocytosis (*45*).

Efficacy Assay of Conjugates. NAC exerts its therapeutic effects by decreasing the production of pro-inflammatory cytokines and reactive oxygen and nitrogen species. In our *in vivo* studies, we seek to use NAC to treat neuroinflammation induced by activated microglial cells in perinatal brain injury. Therefore, we evaluated the cellular efficacy of these conjugates in the BV-2 mouse microglial cell line that is activated by LPS.

Microglial cells activated by LPS release the free radical NO that can result in damage to membranes and DNA of the surrounding cells leading to cell death. The antioxidative properties of the conjugates were tested by measuring the nitrite levels as a marker of free radical NO production in the cell supernatant. Free NAC inhibited nitrite production in a dose-dependent manner after 72 h of incubation. At 24 h, a time point at which a relatively lower amount of NO is produced, only the highest concentration of free NAC (8 mM) inhibited nitrite release. Both PAMAM-NH-CO-Pr-S-S-NAC and PAMAM-CO-GS-S-NAC conjugates showed significant inhibition of nitrite production even at the lowest equivalent dose of NAC (0.5 mM). In fact, in both conjugates, with anionic and cationic terminal groups, 0.5 mM NAC in the conjugated form showed equivalent efficacy to 8 mM of free NAC. The conjugates did not show a significant dose dependence, at the three concentrations equivalent to free NAC, perhaps because significant suppression (>60%−80%) was seen even at the lowest concentrations (Figure 9) for both conjugates. Perhaps, the use of even lower concentration of conjugates may enable us to find dose dependence, but detailed dose dependence is beyond the scope of this study. At equivalent concentrations, the cationic PAMAM-NH_2-NAC conjugate showed slightly better efficacy than the anionic PAMAM-COOH-NAC conjugate. From these results, it appears that improved intracellular uptake and high drug payload in the dendrimer conjugate may be producing a high local drug concentration inside the cell to elicit a significant therapeutic response. It also suggests that an appreciable amount of the drug is released intracellularly even at these relatively short time intervals (especially for polymer conjugates).

The above results have significant implications in both understanding and manipulating drug release mechanisms and achieving controlled intracellular drug release in dendrimer-based delivery systems. The results suggest that GSH can be used as a reliable *in vivo* releasing agent in dendrimer-based delivery systems. As the most abundant thiol species in living cells, GSH is the most likely candidate for the disulfide reduction in previously reported drug delivery systems. The relatively rapid drug release at intracellular GSH levels is key in dendrimer-based conjugates where drug release is typically much slower. The manipulation of GSH concentration in living cells as demonstrated here conclusively proves that GSH-mediated release is a viable mechanism for releasing payloads from dendrimer conjugates.

CONCLUSIONS

We have developed dendrimer−NAC conjugates as drug delivery systems for the treatment of neuroinflammation associated with cerebral palsy in perinatal applications. The PAMAM dendrimer-based intracellular drug delivery system uses a linker that uses GSH as the releasing agent. Two conjugates were prepared, one based on an anionic PAMAM G3.5-COOH dendrimer and one based on a cationic PAMAM-G4-NH_2 dendrimer. NMR, MALDI, and HPLC showed that the conjugate synthesis was effective and successful. *In vitro* release studies at different GSH levels have shown that GSH is responsible for releasing payloads from a dendrimer carrier in buffer. Flow cytometry and confocal microscopy revealed that the conjugates enter the cells rapidly and localize in the cytoplasm. The efficacy was assessed in activated microglial cells using nitrite inhibition. Both conjugates showed significant efficacy even at drug levels 16 times lower than that of the free drug. These studies address a key challenge that relates to drug release from polymer in general, and dendrimers in particular. We have recently reported the intrinsic ability of PAMAM dendrimers to target activated microglial cells in animal models of neuroinflammation (*44*). Combined with the findings of these studies, which allow us to tailor the intracellular release based on glutathione levels, we will be able to design dendrimer−drug conjugates with increased *in vivo* efficacy.

Materials(R-I):

Ethylenediamine-core poly(amidoamine) [PAMAM] dendrimers (Diagnostic grade generation 3.5 with -COOH end groups, and generation-4 with -NH_2 groups) were purchased from Dendritech. Other reagents were obtained from assorted vendors in the highest quality available. These include benzotriazol-1-yl-oxytripyrrolidinophosphonium hexafluorophosphate (PyBop, Aldrich), Diisopropyl ethylamine (Aldrich) dimethyl sulfoxide, (DMSO, Aldrich), dicyclohexylcarbodiimide (DCC, Aldrich), *N*-hydroxysuccinimde (Aldrich), 2, 2^1 –Dipyridyldisulfide (Aldrithiol, Aldrich) dimethylformamide (DMF, Aldrich) Ethanol (Aldrich) (N-Acetyl Cysteine (NAC, Aldrich), Glutathione (GSH, Aldrich), Acetonitrile (Aldrich) phosphate buffer saline (PBS, pH, 7.4, Aldrich) and Spectra/Por dialysis membrane (MWCO 1000).

Methods (R-II):

All ^{1}H and ^{13}C NMR spectra were recorded on Varian Mercury spectrometer 400MHz in DMSO. MALDI-TOF spectra were recoded on a Bruker Ultraflex system equipped with a pulsed nitrogen laser (337 nm), operating in positive ion reflector mode, using 19 kV acceleration voltage and a matrix of 2, 5 dihydroxybenzoic acid

Reverse Phase-HPLC Characterization (R-III)

HPLC characterization of conjugates was carried out with Waters HPLC instrument equipped with two pumps, an autosampler and dual UV detector interfaced to Breeze software. The mobile phase used was Acetonitrile / Water (both 0.14% TFA by w.) and water phase had a pH of 2.25. Mobile phases were freshly prepared, filtered and degassed prior to the use. Supelco Discovery BIO Wide Pore C5 HPLC Column (5 μm particle size, 25 cm × 4.6 mm length × I.D.) equipped with two C5 Supelguard Cartridges (5 μm particle size, 2 cm × 4.0 mm length × I.D.) was used for characterization of the conjugates as well as stability studies. Gradient method used for analysis was (100:0) Water: Acetonitrile to (60:40) Water-Acetonitrile in 25 minutes followed by returning to initial conditions in 5 minutes. The flow rate was 1 mL/min. The dual U.V. absorbance detector was used at 210 nm and 280 nm simultaneously. Calibration curves were prepared for NAC, GSH and their oxidized forms, based on UV absorbance peak area at 210nm. These calibrations were used in characterization and stability analysis.

Cell Culture (R-IV)

Mouse microglial cell line (BV-2) was obtained from Children's Hospital of Michigan Cell Culture Facility. Cells were grown in 75 mm^2 culture flasks using Dulbecco's Modified Eagle Medium (DMEM, Invitrogen) supplemented with 10% fetal bovine serum (FBS, Invitrogen) and 1% penicillin-streptomycin at 37^oC with 5% CO_2 in an incubator. The cells were subcultured every 48 hours and harvested from subconfluent cultures (60-70%) using 0.05% trypsin-EDTA (Invitrogen).

Preparation of 3-(2-Pyridyldithio)-propanoic acid (PDP) (6) (R-V)

3-(2-Pyridyldithio)-propanoic acid (**6**) was synthesized as a precursor for the generation of *N*- succinimidyl 3-(2-pyridyldithio)-propanoate (**7**) (SPDP). 2, 2^1 –Dipyridyldisulfide (**5**) (2.745 g, 0.0124 mol) was dissolved in 20 mL anhydrous ethanol. Acetic acid (0.75 mL) and 3-mercapto-propanoic acid (0.66 g, 0.0062 mol) were added and the solution was stirred at room temperature for 2 hours and subsequently the solvent was removed under reduced pressure to yield a viscous yellow oil, which was placed under high vacuum to remove all traces of acetic acid. The crude product was purified by a basic Al_2O_3 column using a 3:2 mixture of dichloromethane and ethanol as eluent. Once the yellow band corresponding to the thione by-product had eluted from the column, 4 mL of acetic acid per 100 mL solvent was added to elute the desired product. Fractions containing this compound were pooled and the solvent removed under reduced pressure. The resulting viscous oil was placed on a high vacuum line to remove all traces of acetic acid and yield the title compound (**6**) (1.04 g, 0.0048 mol, 78% yield). Calculated mass: 215.01; ESI: *m/z* 214.04 (M-1), 238.03 (M + Na). ^{1}H NMR (300 MHz; d_6-DMSO) δ, 2.59 (2H, t, J = 7.0), 2.98 (2H, t, J = 7.0), 7.23 (1H, ddd, J = 7.1, 4.8, 1.2), 7.75 (1H, d, J = 8.0), 7.8 (1H, td, J = 7.9, 1.4), 8.4 (1H, d, J = 4.9). ^{13}C NMR (75MHz, d_6-DMSO) δ 33.6, 33.7, 119.2, 121.1, 137.7, 149.5, 159.0, 172.7.

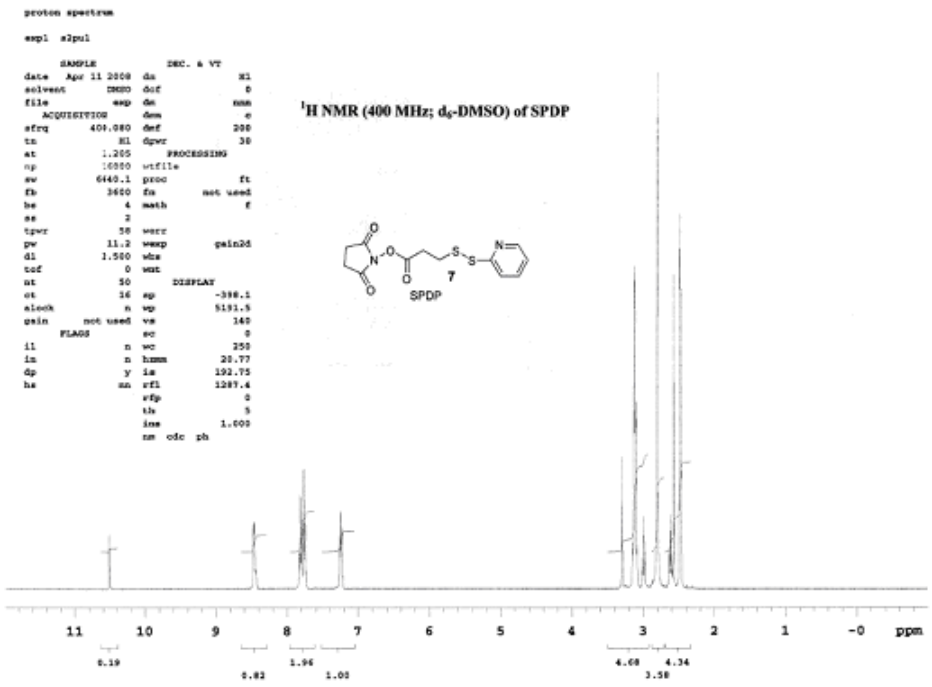
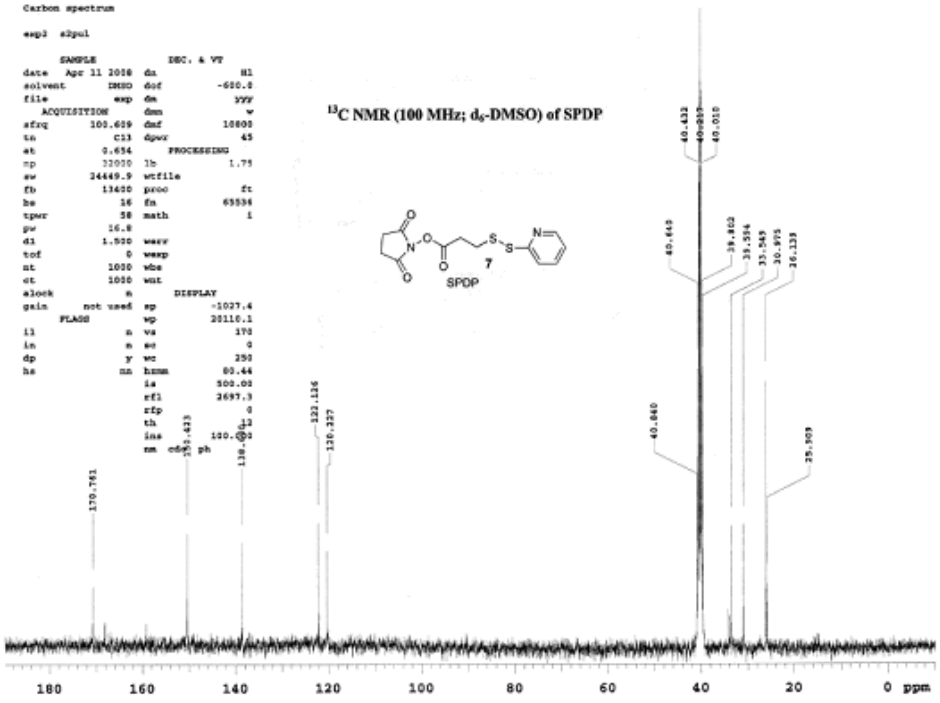
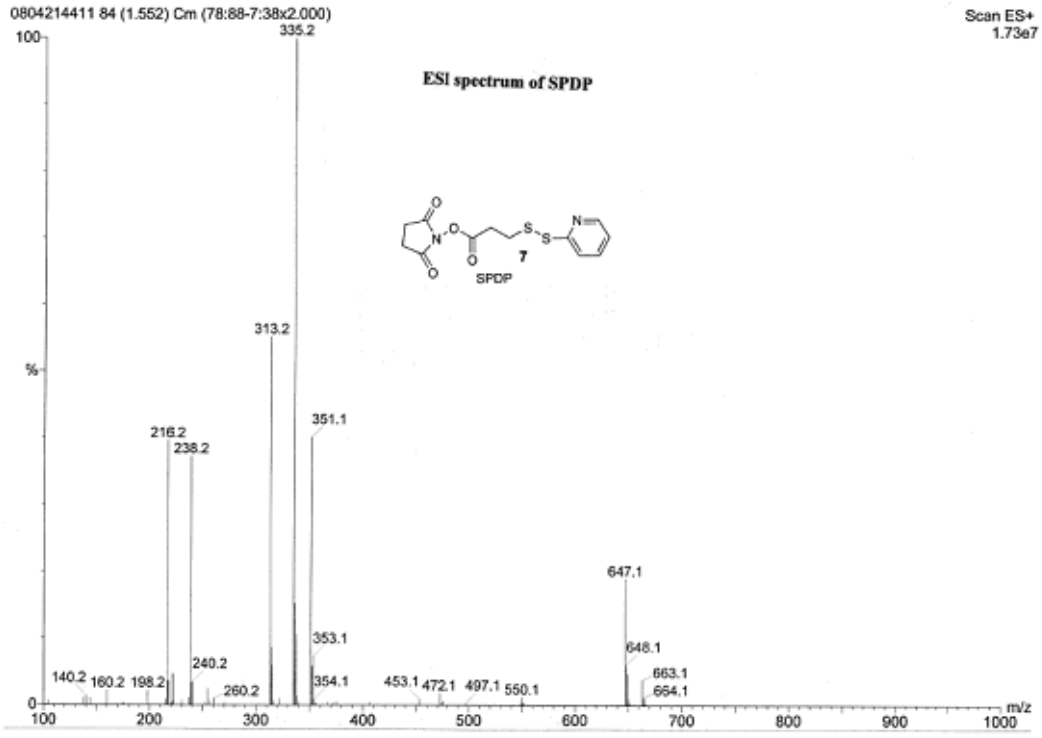
Preparation of *N*-Succinimidyl 3-(2-pyridyldithio)-propanoate (SPDP) (7) (R-VI)

3-(2-Pyridyldithio)-propanoic acid (**6**) (0.862 g, 0.004 mol) in anhydrous DCM (5 mL) was cooled to 0°C in an ice bath. *N*-hydroxysuccinimde (0.507 g, 0.0044 mol) was added followed by dicyclohexylcarbodiimide (0.91 g, 0.0044 mol), both in anhydrous DCM (2 mL). The solution was brought back up to room temperature and left stirring for 3 hours. The formation of a product was followed by silica gel TLC. After the reaction had reached completion the solution was filtered under vacuum from the urea precipitate and the solvent removed from the filtrate under reduced pressure to yield yellow oil. This crude material was purified via silica gel column chromatography using a 50:2 mixture of dichloromethane and methanol as the eluent. The fractions containing the product were combined and the solvent removed to yield colorless oil that crystallized overnight at -20°C (1.025 g, 0.0032 mol, 82% yield). Calculated mass: 312. ESI *m/z* 313.35 (M+H), 335.2 (M + Na). ^{1}H-NMR (300 MHz, d_6-DMSO) δ/ppm 2.81-2.83 (2H, m), 2.80 (H_2O, brs) 2.99-3.03(1H, m), 3.12-3.16 (5H, m), 7.25 (1H, ddd, J = 6.4, 4.8, 1.6), 7.76 (1H, d, J

= 7.1), 7.82 (1H, td, J = 7.5, 1.6), 8.48 (1H, d, J = 4.9). ^{13}C NMR (75, MHz; d_6-DMSO) δ/ppm 25.90, 30.97, 33.54, 120.22, 121.12, 138.60, 150.42, 159.5, 167.4, 170.76.







Preparation of PAMAM -NH-CO-Pr-S-S-NAC conjugate (1) (R-VII)

For the preparation of PAMAM-PDP (**9**) generation 4, SPDP (**7**) (351 mg, 1.126 mol) in ethanol (10 mL) was added to a solution of PBS buffer pH 7.4 (20 mL) and PAMAM-NH_2 dendrimer (**8**) (500 mg, 2.25 mol) to provide sufficient modification whilst preventing loss of product due to the precipitation of highly modified dendrimer. Reaction was stirred at room temperature for 2h. To this reaction N-Acetyl cysteine was added (**10**) (273 mg, 1.67 mol) at once, and stirred the reaction at room for 4 h. The reaction was monitored with HPLC. After completion of reaction, the reaction mixture was diluted with water and lyophilized to get *crude* product. The solid *crude* product was diluted with water and dialyzed against DMSO followed by PBS (pH = 7.4) to remove by-products and the excess of reactants and then replaced with deionized water (1 times 4l) for 12h days to remove salts. The water was lyophilized to get pure product in good yield(71%).

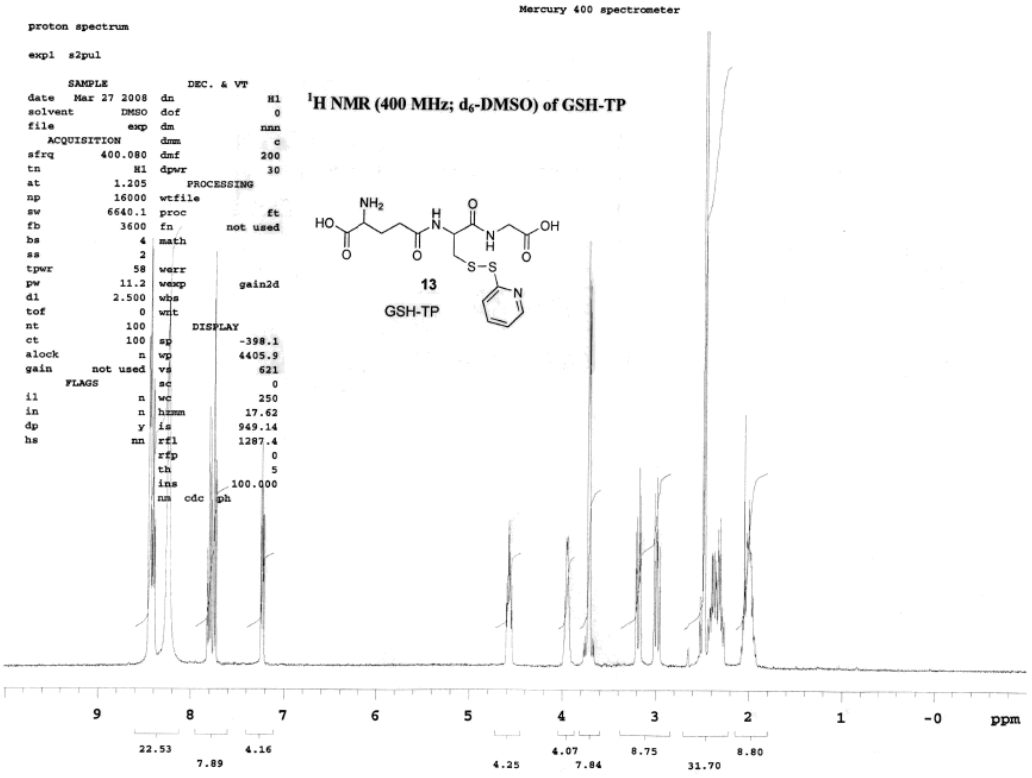
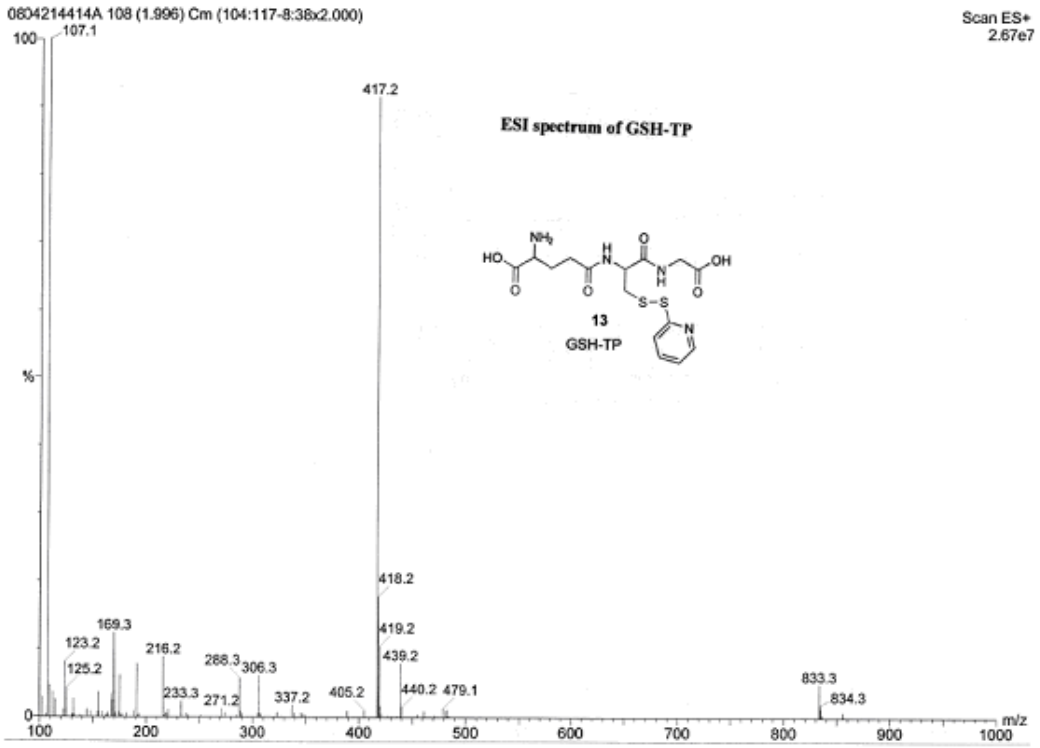
Synthesis of FITC-PAMAM –NH-CO-Pr-S-S-NAC conjugate for imaging (2) (R-VIII)

To a stirred solution of **PAMAM –CO-PR-S-S-NAC** (**1**) (50 mg, 2.73 mmole) in DMSO (2 mL) FITC was added (2.12 mg, 5.44 mmole) and the reaction was continued for 12h at room temperature in dark. Reaction was analyzed using RP-HPLC to determine the extent to which FITC had reacted with PAMAM-MPA-NAC conjugate (**1**). The samples were compared to unmodified dendrimer-conjugate. Samples were initially run on a linear gradient from 100: 0 H_2O/acetonitrile(0.1 wt % TFA) to 10:90 H_2O/acetonitrile (0.14 wt % TFA) over 32 min. During this gradient, dendrimer conjugate was eluted after 15 min compared to the modified FITC-dendrimer- conjugate (**2**) was eluted after 16.0 min. After completion of reaction the compound was dialyzed against DMSO followed by PBS to remove excess of reactants and then replaced with deionized water. The water was lyophilized get pure product in 88% yield.

_S_-(2-thiopyridyl) glutathione (13) (R-IX)

_S_-(2-thiopyridyl) glutathione (**13**) is prepared from the reaction of 2, 2[1]-dithiodipyridine (2.8 g, 0.0127 mol) and GSH (2 g, 0.0065 mol) in a mixture of methanol and water (1:1) stirred for 15h at room temperature. Upon completion of the reaction (monitored by TLC), most of methanol was removed in vacuo and the residue was dissolved in water washed with dichloromethane. The aqueous solution was subjected to reverse phase (RP) HPLC purification, and lyophlization of the eluent gave the pure product as a white solid in 80% yield. Calculated mass: 416. ESI _m/z_ 417 (M+H). ^{1}H-NMR (300 MHz, d_6-DMSO) δ/ppm 1.98-2.11(2H, m), 2.22-3.02 (2H, m), 2.98-3.08(1H, m), 3.18-3.22(1H, m), 3.65-3.71(2H, m), 3.95-402(1H, m), 4.57-4.62(1H, m), 7.0-7.07(1H, m), 7.72-7.87(2H, m), 8.24(2H, br.s., NH), 8.42-8.48(3H, m, NH_2, aromatic)





N-Acetyl –glutathione (14) (R-X)

S-(2-thiopyridyl) glutathione (**13**) (0.8 g, 0.0019 mol) was dissolved in PBS buffer pH= 7.4 (5 mL) and added NAC (**10**) (0.313 g, 0.0019 mol) at once, and the reaction mixture was stirred at room temperature for 2 h. After completion of reaction dichloromethane was added and the organic layer was separated to remove the corresponding thione by-product, this process was repeated five times. The aqueous solution was subjected to reverse phase (RP) HPLC purification, and lyophilization of the eluent gave the pure product as a white solid in 79% yield. Calculated mass: 468. ESI *m/z* 467 (M-H). ^{1}H NMR (300 MHz, d_6-DMSO) δ/ppm, 1.81 (3H, s), 1.90-2.0(2H, m), 2.28-2.37(2H, m), 2.79-2.86(3H, m), 3.07-3.17(2H, m), 3.69-3.78(2H, m), 4.40-4.46(1H, m), 4.52-4.58(1H, m). ^{13}C-NMR (75, MHz d6-DMSO) δ/ppm, 22.35, 26.09, 30.86, 51.26, 51.32, 51.64, 52.02, 169.36, 169.44, 170.89, 171.27, 172.02, 172.07.

Preparation of PAMAM –CO-GS-S-NAC conjugate (3) (R-XI)

The anionic PAMAM-COOH generation-3.5 dendrimer (0.5 g, 0.043 mmol) was dissolved in DMSO/DMF (3:2, 20 mL) and DIEA (557 µL, 0.0059 mol) and PyBop (1.44 g, 0.0027 mol) were added and the reaction stirred for 1h. To this a solution of N-Acetyl-glutathione (**14**) (1.391 g, 0.0027 mol) was added in DMSO (10 mL) was stirred for 12 h at room temperature. The reaction was monitored with HPLC. After completion of reaction, it was diluted with water and lyophilized to get crude product. The solid crude product was diluted with water and dialyzed against DMSO followed by PBS (pH =7.4) to remove by-products and the excess of reactants and then replaced with deionized water for 12h to remove salts. The water was lyophilized get pure product in 78% yield .

Enhancement of Electrochemical Signal on Gold Electrodes by Polyvalent Esterase−Dendrimer Clusters

Martin Humenik, Christopher Pöhlmann, Yiran Wang, and Mathias Sprinzl*

Laboratorium für Biochemie, Universität Bayreuth, Universitätstrasse 30, 95440 Bayreuth, Germany. Received August 18, 2008; Revised Manuscript Received October 14, 2008

5′-Maleimide-oligodeoxynucleotide was conjugated with single sulfhydryl group of cystamine core poly(amidoamine) dendrimers of different generations. Amino groups on the dendrimer moiety were modified with maleimide and coupled to the cysteine 118 of esterase 2 from *Alicyclobacillus acidocaldarius* in a site-specific manner. Polyvalent esterase-dendrimer-oligodeoxynucleotide clusters were hybridized to capture oligodeoxynucleotides immobilized on a gold electrode. The amperometric signal of *p*-aminophenol was detected following the esterase-catalyzed hydrolysis of *p*-aminophenylbutyrate. The multiple anchoring of the esterase reporter via generation 3- and generation 5-derived clusters exhibited 10- and 100-fold signal enhancement, respectively, as compared to monovalent esterase−oligonucleotide conjugate. The polyvalent and monovalent reporters were comparable in their abilities regarding mismatch discrimination.

INTRODUCTION

Electrochemical sensors for the detection of DNA hybridization combine nucleic acid layers with electrochemical reporters to generate electrical signals. This type of sensors simplifies the data collection and makes it suitable for construction of portable DNA biosensors (*1, 2*). The improvement of biosensor sensitivity remains, however, a challenging task. Enhancement of the signal has been achieved by optimization of sensor design and performance of enzyme reporters. The physical optimization via minimization of the sensor surface (*3, 4*) and redox-recycling of electro-active substrate (*5, 6*) has improved detection limits dramatically. Nowadays, most frequently used reporter enzymes are alkaline phosphatase and horseradish peroxidase (*7*). The important task is to increase stability and specific activity of enzymes (*8, 9*), and to improve the quality of enzyme conjugation to the DNA hybridization event. Conjugation can be achieved either via interaction of streptavidin−enzyme and biotinylated ODN[1] (*6, 10*) or directly via covalently conjugated enzyme−ODN (*8, 11*).

We recently developed a sensitive enzyme−ODN reporter for electrochemical detection of DNA hybridization (*8*), which uses thermostable esterase 2 from *Alicyclobacillus acidocaldarius* (*12*) as a reporter enzyme. Single-chain esterase 2 provides the possibility for site-specific conjugation of the protein and ODN. EST−ODN conjugate with a 1:1 ratio of protein to oligonucleotide allowed the detection of attomoles of DNA (*8*). It is expected that the sensitivity of detection will be substantially improved if several reporter enzyme molecules are attached to one ODN. In the present study, we describe a site-specific chemistry for the preparation of ODN reporters equipped with multiply coupled esterase via dendrimer branching. We employed commercially available PAMAM dendrimers of generation 3 and generation 5 (Figure 1A), which differ in diameter, multivalency, and surface group density (*13, 14*). These polyvalent EST-dendrimer-ODN clusters were used in a DNA-directed immobilization assay on a gold electrode (Figure 1B). The capacity of signal enhancement and the ability of mismatch discrimination were determined and compared to monovalent EST−ODN conjugate (*8*).

MATERIALS AND METHODS

General. The organic bifunctional reagents sulfosuccinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate and succinimidyl-[(*N*-maleimidopropionamido)-diethylene glycol] ester were purchased from Pierce (Rockford, IL, USA); G3 and G5 cystamine core PAMAM dendrimers and tris(2-carboxyethyl)phosphine were from Aldrich (Taufkirchen, Germany). 5′-Amino and 5′-sulfhydryl modified ODNs, equipped with C6 linker, were obtained from Biomers (Ulm, Germany). Biogel-P6 was from Biorad (München, Germany). SepPak C18 columns (Waters Corp., Eschborn, Germany) were used for desalting of oligonucleotides. Microcon YM10 centrifuge tubes (Millipore, Schwalbach, Germany) were used for desalting and concentration of dendrimer−ODN probes. Gel permeation chromatography was performed by using Pharmacia FPLC system on Sephacryl S-200 HR column (Pharmacia, Freiburg, Germany).

Preparation of Esterase 2 (C97S, E118C). Plasmid pET30a-EstC97S_E118C was derived from pT7-SCII-Est2 plasmid DNA (*12*) to replace Cys97 to Ser and Glu118 to Cys in esterase 2. The gene was expressed in *E. coli* BL21 (DE3). Esterase was purified according to published procedure (*12*) and stored at −20 °C in 100 mM Tris/HCl, pH 7.5, 20 mM $MgCl_2$, 200 mM KCl, 1 mM β-mercaptoethanol, and 50% glycerol. The esterase was dialyzed against 0.1 M Na-Pi, pH 7.2, before conjugation with oligonucleotides.

5′-Maleimide-ODN. 5′-Amino-modified ODN (50 nmol) in 0.1 M Na-Pi, pH 8.0, (100 μL) was treated with sulfo-SMCC (2.5 μmol, 50 μL in DMF). The reaction mixture was left at RT for 1 h and the 5′-maleimide-ODN was precipitated with ethanol and isolated by centrifugation. The pellet was dissolved in 0.1 M Na-Pi buffer, pH 7.4, (500 μL) and desalted on a Biogel P6 column. The procedure yielded typically 90% of 5′-

maleimide-ODN as determined by A_{260} absorption. The purity and identity of the product were analyzed by HPLC and MALDI-TOF (Supporting Information).

Dendrimers−ODN Conjugates. Dendrimer G3 (100 nmol, 7.7 μL, in methanol) was added into triethylamine solution in DMF (25 μL, 123 mM) followed by solution of acetic anhydride in DMF (25 μL, 93 mM). The reaction mixture was left at RT for 2 h and used without purification for next steps. The acetylation of G5 PAMAM was performed under similar conditions, where 100 nmol of dendrimers (33.6 μL in methanol) was diluted with DMF to the end volume of 100 μL and treated with 0.9 μL of acetic anhydride (9.5 μmol) and 1.5 μL of triethylamine (11.5 μmol). The reaction mixture of acetylated dendrimer was then diluted with 3 volumes of buffer (50 mM Na-Pi, 150 mM NaCl, 5 mM EDTA, pH 6.3) treated by 1 μmol of TCEP (100 mM solution in the same buffer), followed by incubation at 37 °C for 1 h. The freshly prepared reaction mixture of sulfhydryl-activated dendrimer was combined with 100 nmol of 5′-maleimide-ODN (40 μM in 50 mM Na-Pi, 150 mM NaCl, 5 mM EDTA, pH 6.3). The reaction mixture was left at RT for 1 h and subsequently filtered through YM10 centrifuge tubes. The retained product was washed twice with 0.1 M Na-Pi buffer, pH 8.0, and collected in the same. Typically, 70% yield was obtained for dendrimer−ODN conjugates of generations 3 and 5. The reaction course was followed by urea-PAGE and HPLC. Product was characterized by MALDI-TOF (Supporting Information).

Maleimide Activation of Dendrimer−ODN Conjugates. Dendrimer−ODN conjugates in 0.1 M Na-Pi, pH 8.0, (15 nmol, 150 μL) were treated with bifunctional reagent SMEG (4.5 μmol, 90 μL in DMF) at RT for 1 h. Excess of the reagent was removed by a Biogel-P6 column affording 50% of maleimide-dendrimer-ODN of generation 3. G5-derived conjugate was isolated by 4× repeated filtration in YM10 centrifuge tubes against 50 mM Na-Pi, 150 mM NaCl, 5 mM EDTA, pH 6.3, yielding typically 70% maleimide-dendrimer-ODN conjugate.

Preparation of EST-Dendrimer-ODN Cluster. Esterase 2 (C97S, E118C) in 0.1 M Na-Pi buffer, pH 7.2, (70 μM) was treated with 1.4 mM TCEP at 37 °C for 30 min and isolated by filtration in YM10 centrifuge tubes removing TCEP. The esterase was collected in 50 mM Na-Pi, 150 mM NaCl, 5 mM EDTA, pH 6.3, and 360 μL of the protein solution (0.2 mM) was treated with G3 maleimide-dendrimer-ODN conjugate (0.1 mM, 90 μL in the same buffer) at 37 °C for 16 h. Product was purified by gel permeation chromatography on Sephacryl S-200 HR column (2 × 70 cm), eluted with 10 mM Tris/HCl, 10 mM KCl, pH 7.5, at a flow rate of 1 mL/min. The main peak of the product was collected (10−12 mL), concentrated under vacuum to one-fifth of the volume, and reloaded on the same column for the second round of chromatography.

Electrochemical Detection on Gold Electrodes. Chip modules and potentiostat were obtained from Siemens Corporate Technology (Erlangen, Germany). Each chip (11 mm × 13 mm) consisted of 8 individual 0.85-mm-diameter (0.6 mm^2) gold electrodes with spaces of 2.0 mm between the positions. Four electrodes were treated with a silver/silver chloride solution and served as reference electrodes. For measurements, a U-shaped 10 μL flow chamber was placed over the electrodes, and the printed circuit board of the chip was connected to the multi-potentiostat device. The potentiostat was connected to a PC through a serial interface SCB-68. *Labview 6.0* software was used to control the potentiostat, collect the data, and plot figures.

Immobilization of DNA on Gold Electrodes. The gold electrodes were rinsed with water and ethanol, and dried under air stream. The thiol group of the capture ODN (0.2 μM) was first reduced by treatment with 2 mM TCEP in 10 mM Na-Pi, 300 mM NaCl, pH 7.0, at 37 °C for 5 min. Activated capture ODN (1 μL) was spotted onto electrodes and incubated at ambient temperature in a humidity chamber for 16 h. Individual electrodes were washed three times with the same buffer. The sequences of the used capture ODNs are listed in Table 1S (Supporting Information).

EST Activity Measurements on the Gold Electrodes. Detection limits were estimated by serial dilution of EST−ODN conjugate or EST-dendrimer-ODN clusters in 20 mM Na-Pi, 300 mM NaCl, 2 mM EDTA, 0.05% Tween 20, 1 mg/mL BSA,

Table 1. Apparent Michaelis−Menten Constants Obtained from the Kinetic Measurement of Esterase Reporter Immobilized via Hybridization of Corresponding ODN Conjugate or Dendrimer−ODN Cluster on the Gold Electrode

	EST−ODN	EST-dendrimer-ODN	
		G3	G5
K_M^{app} [mM]	0.7 ± 0.1	0.9 ± 0.1	1.1 ± 0.4
I_{max} [nA s^{-1}]	6.6 ± 1.8	31.7 ± 3.6	57.8 ± 12.6
k_{cat} [nA s^{-1} nM^{-1}]	1.3 ± 0.3	6.3 ± 0.7	11.5 ± 2.5

pH 7.4. Different concentration of EST conjugates (1 μL) was applied onto each electrode equipped with immobilized perfect match capture ODN and incubated at 25 °C for 20 min. The electrodes were washed three times with 100 μL of 5 mM Na-Pi, 75 mM NaCl, 0.5 mM EDTA, 0.05% Tween 20, pH 7.4. The same experimental procedure was used for mismatch determination. Different capture ODNs comprising 1 to 3 mismatches were used. After hybridization at 50 °C and washing steps, the chip was placed into a potentiostat and 1 mM substrate, *p*-aminophenylbutyrate, in 0.1 M Na-Pi, pH 7.0, was pumped through a flow chamber at flow rate of 50 μL/min for 1 min. The flow was stopped and the current slope was measured to assay the EST activity (*8*).

Measurement of enzyme kinetics was conducted by using EST−ODN conjugate and EST-dendrimer-ODN clusters (5 nM) to hybridize with perfect match capture ODN on gold electrodes. Different concentrations of *p*-aminophenylbutyrate in 0.1 M Na-Pi, pH 7.0, were delivered over gold electrodes, and signal was recorded as described above.

RESULTS AND DISCUSSION

Preparation and Characterization of EST-Dendrimer-ODN Clusters. Primary amino groups on the surface of G3 and G5 PAMAM cystamine core dendrimers (*14*) had to be partially acetylated (*15*) to prevent the unspecific binding of the positively charged dendrimers to oligonucleotide polyanion. Approximately 60% acetylation ratio, estimated by MALDI-TOF (Supporting Information, Figures 3S and 4S), was found as an optimal shield of positive charge on the dendrimer surface and at the same time provides sufficient amount of free amino groups for further multiple EST coupling. The partially acetylated dendrimers were reduced and conjugated to 5′-maleimide-ODN (*16*). Bifunctional linker sulfo-SMCC was used to activate 5′-amino-ODN for monovalent conjugation as previously described (*8*). The free amino groups on the surface of dendrimer−ODN conjugate allow further modification with a maleimide linker. Multiple binding of nonpolar linkers such like SMCC decreases the solubility in aqueous environment. Therefore, ethylene glycol linker SMEG, which provides both better solubility and spacing between dendrimer and protein surface, was used. The formation of dendrimer products with different extent of maleimide activation was evident from smear on urea-PAGE and from peak broadening on HPLC (Supporting Information, Figures 1S and 2S). MALDI-TOF spectra also revealed broad molecular peaks, typical for dendrimers (*17, 18*) and dendrimer−ODN conjugates (*16*) and did not allow precise molecular mass determination of the product (Supporting Information, Figures 3S and 4S).

The wild-type esterase 2 contains only one cysteine at position 97, which is buried inside the structure and is not accessible for modification (*19*). Thus, replacements of cysteine 97 by serine and glutamine 118 by cysteine were performed to expose a reactive sulfhydryl group on the protein surface. EST-dendrimer-ODN clusters (Figure 2) were prepared by reaction of 8- and 16-fold excess of EST with maleimide-activated dendrimer−ODN of generations 3 and 5, respectively. Statistical mixtures of clusters (Figure 3A,B, lane 1), as reported also for other protein−dendrimer conjugates (*20, 21*), were obtained. The higher molecular mass clusters were separated from unreacted esterase and dendrimer−ODN conjugate by gel permeation chromatography on Sephacryl S 200 HR (Figure 3A,B). Monovalent EST−ODN conjugate was also prepared and purified as described (*8*).

The relative protein content of the purified clusters was determined from absorbance ratio at 260 and 280 nm, defined as

$$\frac{A_{260}}{A_{280}} = \frac{\varepsilon_p^{260} c_p + \varepsilon_o^{260} c_o}{\varepsilon_p^{280} c_p + \varepsilon_o^{280} c_o} \quad (1)$$

where A is absorbance at 260 or 280 nm and ε represents extinction coefficient, while c_p and c_o represent the concentration of protein and ODN, respectively. Experimental A_{260} and A_{280} values from different mixtures of esterase 2 and 5′-amino-modified ODN (from 0:1 to 18:1) were fitted to a hyperbolic curve (Figure 4). The resulting calibration curve allowed us to deduce the composition of the G3 cluster (7:1) and the G5 cluster (10:1). G3 and G5 PAMAMs significantly differ in the number of surface amino groups (4-fold) (*14*), whereas the observed loading difference between G3 and G5 dendrimer−ODN with the esterase was less than 2-fold. The different reactivities of smaller G3 and larger G5 maleimide-dendrimer-ODN conjugate toward bulky protein are probably reasons for observed deviations.

The amount of the esterase anchored on the gold electrode via hybridization between capture ODN and either monovalent EST−ODN conjugate or polyvalent G3/G5 clusters (Figure 1B) was tested. The intensities of the electrical signal in the presence of varied concentrations of *p*-aminophenylbutyrate were measured. Apparent kinetic parameters (Table 1) were calculated from the electrochemical version of the Lineweaver−Burk equation (eq 2) (*22*).

$$\frac{1}{I_{slope}} = \frac{K_M^{app}}{I_{max}} \times \frac{1}{[S]} + \frac{1}{I_{max}} \quad (2)$$

The apparent Michaelis−Menten constant (K_M^{app}) is a reflection of both the enzymatic affinity and the ratio of microscopic constants including diffusion of the product to the electrode surface. I_{slope} represents the increase of the current after the addition of substrate (this value was determined the first 5 s in stopped flow mode (*8*)), [S] is the bulk concentration of substrate, and I_{max} is the maximum current measured under substrate saturation. Different values of current slope against substrate concentration, with obvious similarity to Michaelis−Menten kinetics (Supporting Information, Figure 5S), were observed using 5 nM EST−ODN, G3 and G5 EST-dendrimer-ODN clusters. With the G3 and G5 clusters, the increase in maximal current I_{max} (Table 1) demonstrates that more esterase is brought to the electrode surface by a hybridization event if compared with monovalent EST−ODN. Additionally, catalytic efficiency k_{cat} corresponds with EST/ODN ratio obtained from the A_{260}/A_{280} dependence depicted in Figure 4.

Signal Enhancement on Gold Electrodes Using Multivalent EST-Dendrimer-ODN Clusters. The influence of polyvalent G3 and G5 EST-dendrimer-ODN clusters on signal enhancement was compared with monovalent EST−ODN conjugate (*8*). Different concentrations of EST bound ODN probes were assayed on the gold electrodes uniformly modified with perfectly matched capture ODN and resulted in linear dependences in all experiments (Figure 5). The lowest detectable ODN concentration using the EST−ODN conjugate was 3 pM, which is in agreement with results reported previously (*8*). The G3 and G5 EST-dendrimer-ODN clusters revealed upon the same experimental arrangement the lowest detectable target

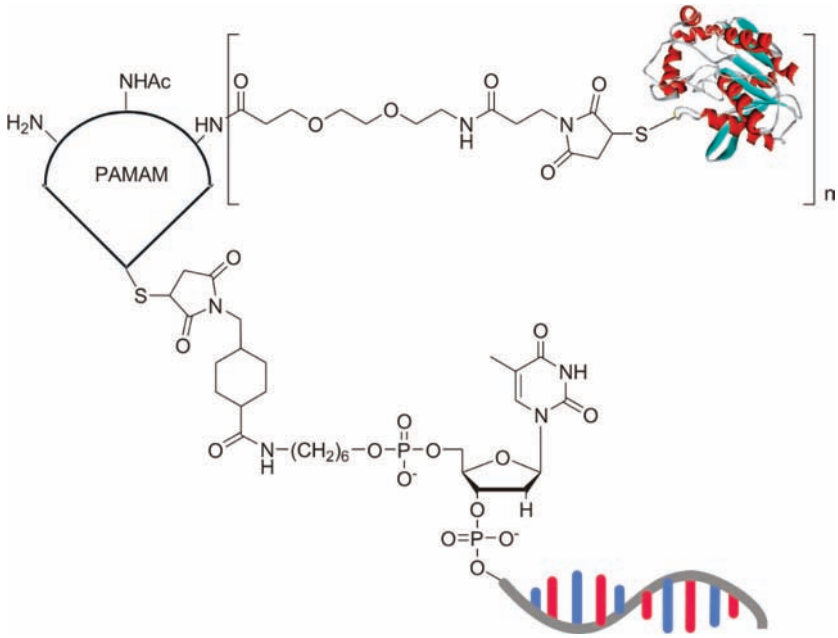

Figure 2. Schematic representation of esterase-dendrimer-ODN cluster. SMCC linker connects ODN and sulfhydryl group of PAMAM. Esterase is attached to the dendrimer surface via ethylene glycol linker in a site-specific manner (Cys118).

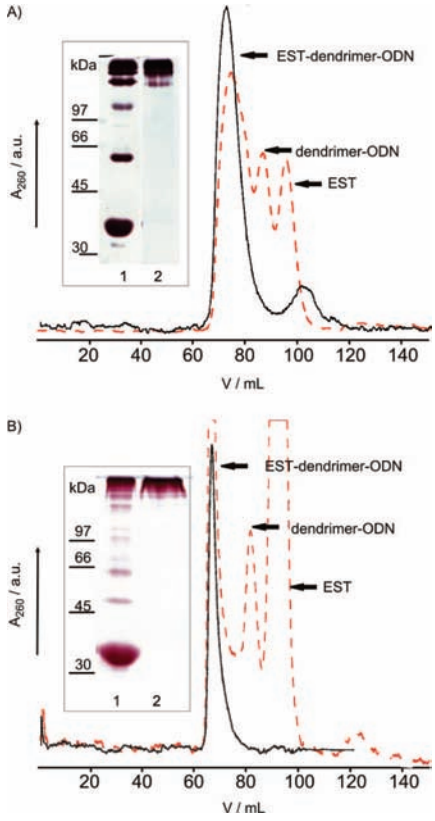

Figure 3. Purification of the EST-dendrimer-ODN cluster by gel permeation chromatography on Sephacryl 200 HR; clusters derived from G3 (A) and G5 PAMAM (B) were eluted in the void volume of the column. First (- -) and second (—) round of purification are presented. concentrations of 0.3 pM (Figure 5A) and 0.02 pM (Figure 5B), respectively. Strong enhancement of the signal were achieved at low concentrations of clusters (<10 pM), whereas at concentrations of >10 nM, no signal enhancement was observed. It is conceivable that at higher concentrations the

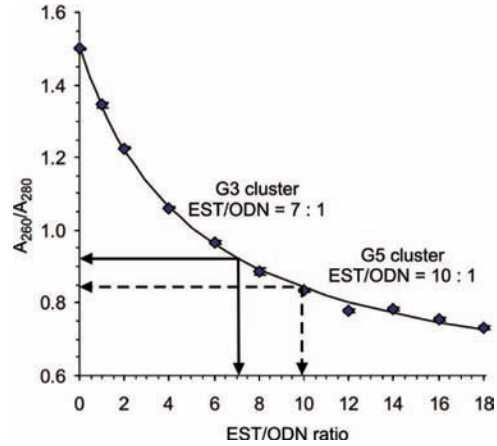

Figure 4. Estimation of the molecular EST/ODN ratio for EST-dendrimer-ODN cluster derived from G3 and G5 PAMAM; UV absorption was recorded at 260 and 280 nm for different mixtures of esterase 2 and 5′-amino-ODN (◆). The data were fitted to the hyperbolic plot (—). UV absorption of G3 (full line with arrows) and G5 cluster (dashed line with arrows) correspond to EST/ODN ratio 7:1 and 10:1, respectively.

advantage of the multiple esterase attachment was compromised by a large hydrodynamic volume of polyvalent EST−dendrimer moiety. On the other hand, at lower concentration levels, where most of the capture ODNs became unoccupied, the multiple enzyme binding significantly enhanced the signal. G3 and G5 clusters have comparable protein content (Figure 4), whereas diameters and corresponding areas of dendrimers differ significantly (4× and 8×, respectively) (*14*). Apparently, the dense protein loading of the G3 dendrimer surface may alter proper protein folding and substrate accessibility/diffusion summed in observed enzyme activity. Thus, G3 and G5 EST-dendrimer-ODN clusters differ by 10× in their signal enhancement abilities. The controlled spotting of G3 and G5 clusters either onto a bare gold electrode or onto an electrode layered with non-matched capture ODN excluded any possible unspecific binding of higher PAMAMs onto the gold surface (*23*) or to capture oligonucleotides (*24*).

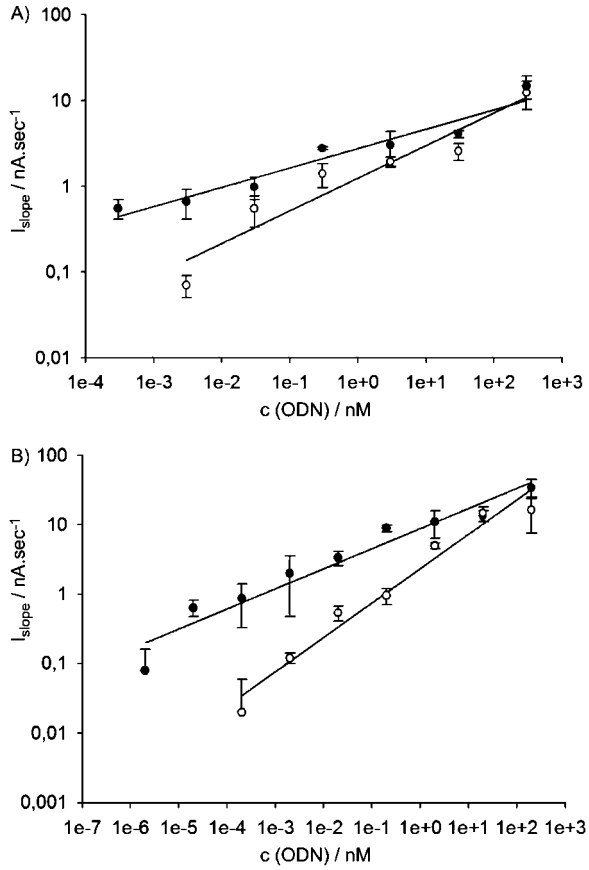

Figure 5. Detection of DNA hybridization on the gold electrodes equipped with uniform capture ODN. (A) Correlation of the signal with ODN concentration of G3 EST-dendrimer-ODN clusterd (•) and monovalent EST−ODN conjugate (○). (B) Analogous comparison for the G5 cluster.

Specificity of DNA hybridization and mismatch detection are important parameters of DNA analysis on biosensors. In order to test these parameters, gold electrodes were prepared with immobilized capture ODNs resulting in a perfect match and one, two, and three mismatched base pairs. The EST−ODN conjugate and EST-dendrimer-ODN clusters were then hybridized to these immobilized capture ODNs. Monovalent EST−ODN and polyvalent G3 and G5 clusters distinguished the perfect from the mismatched probes (Figure 6). The discrimination efficiency increased with the number of the nonmatched base pairs when EST−ODN and G3 clusters were assayed. However, the G5 cluster was not able to discriminate among the numbers of mismatches as efficiently as the G3 cluster.

CONCLUSION

In summary, we prepared EST-dendrimer-ODN clusters derived from G3 and G5 cystamine core PAMAM dendrimers. Efficient sulfhydryl−maleimide chemistry to connect ODN and dendrimer, which was polyvalently functionalized with esterase 2, was exploited. Although mutivalency of dendrimers was already applied in the construction of protein (*20*, *21*, *25*−*27*) and ODN (*16*, *28*, *29*) nanoscale devices, according to our knowledge the synthesis of polyvalent enzyme-dendrimer-ODN clusters had not yet been reported. DNA-directed hybridization of the presented polyvalent clusters on gold electrodes revealed 10- and 100-fold shifts of the detection limit to lower concentrations if compared among G3 and G5 clusters and monovalent EST−ODN conjugate (*8*). Hence, the multivalent binding of esterase to capture ODN resulted in detection limits of 3×10^{-13} M and 2×10^{-14} M for G3 and G5 dendrimer clusters, respectively. These detection limits are comparable with alternative methods of electrochemical DNA detection, which use horseradish peroxidase bound liposomes (*30*), ferrocene multiple labeling of gold nanoparticles (*31*), and cyclic DNA probes (*32*). The simple and efficient preparation and fairly improved detection limits emphasize the potential of the presented esterase 2-dendrimer-ODN construct in electrochemical detection of DNA.

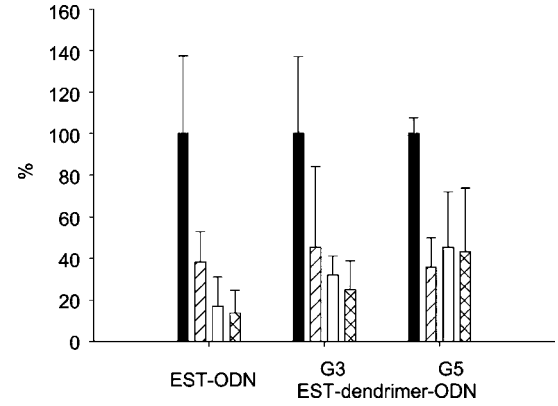

Figure 6. Mismatch discrimination ability of the EST−ODN conjugate and G3 and G5 clusters compared in the amperometric detection of immobilized capture probes. Perfectly matched capture and one, two, and three mismatches are presented as black, dashed, open, and crossed bars, respectively; the signal values for perfectly matched capture was set as 100%.

PAGE analysis of G3 and G5 dendrimers and related ODN conjugates

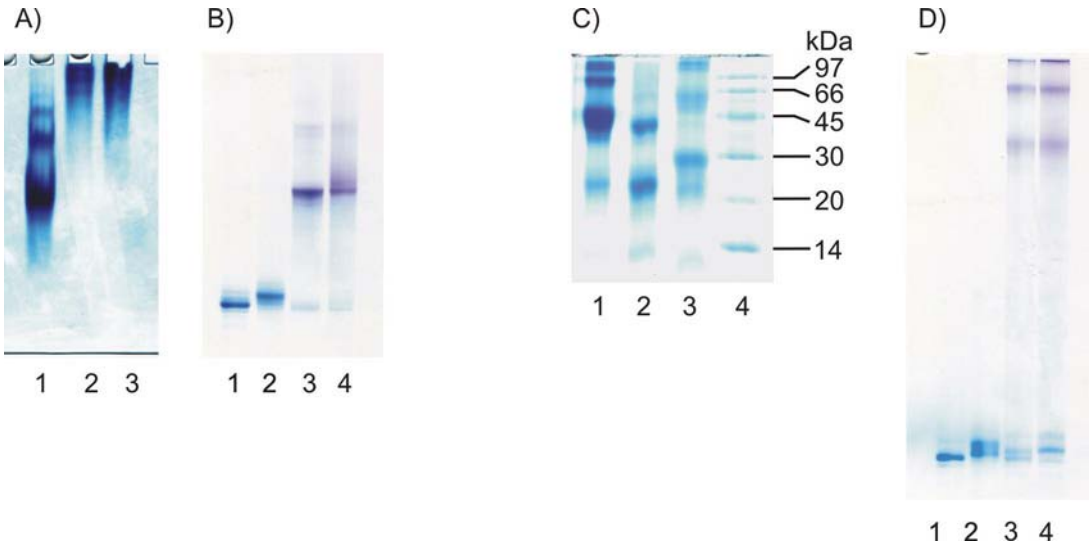

Figure 1S.: PAGE analysis of G3/G5 dendrimer-ODN preparations; A) Native PAGE (15%) of the G3 dendrimer acetylation; lane 1: G3 PAMAM dendrimer; lane 2: preparation of acetylated analog; lane 3: reduction of cystamine core of dendrimer by TCEP; B) Urea-PAGE (15%) of G3-ODN conjugation; lane 1: 5´-amino-ODN; lane 2: 5´-maleimide-ODN; lane 3: G3-ODN; lane 4: maleimide-G3-ODN; C) SDS-PAGE (20%) of G5 acetylated dendrimers and dendrimer-ODN conjugate; lane 1: acetylated dendrimer; lane 2: reduction of cystamine core of dendrimer by TCEP; lane 3: G5-ODN conjugate; lane 4: protein mass standard: D) Urea-PAGE analysis of G5 dendrimer ODN conjugation; lane 1 and lane 2 identical with B; lane 3 and lane 4 analogous to B in terms of G5 conjugation. Generally main band of the G3/G5 dendrimer (A and C, lane 1) is accompanied by trailing generation (half of molecular mass) and by oligomers originated from PAMAM synthesis (*S1*).

HPLC analysis of 5´-modiefied ODNs and dendrimer-ODN conjugates

High-pressure liquid chromatography was carried out on Beckman Gold HPLC system (Beckman Coulter GmbH, Krefeld, Germany) with variable-wavelength detector. Oligonucleotide conjugates were analyzed by reverse phase chromatography on Jupiter C-18 column (250×4.6 mm, 5 µm, Phenomenex, Aschaffenburg, Germany). Buffer A contained 0.01 M triethylammoniumacetate (TEAA) in water, pH = 6.8, buffer B contained 0.01 M TEAA in water, pH = 6.8 and 90% of CH_3CN. Elution was performed by gradient of B 5-50% over 30 min. Flow rate was 1 ml/min, detection by absorbance at 260 nm. Alternatively, ODN-dendrimer conjugates were analyzed by Gemini C6-Phenyl column (250×4.6 mm, 5 µm, Phenomenex, Aschaffenburg, Germany). Buffer A contained 0.1% TFA in water, buffer B contained 0.1% TFA in water and 90% of CH_3CN. Elution was performed by a gradient of B 0-50% over 30 min.

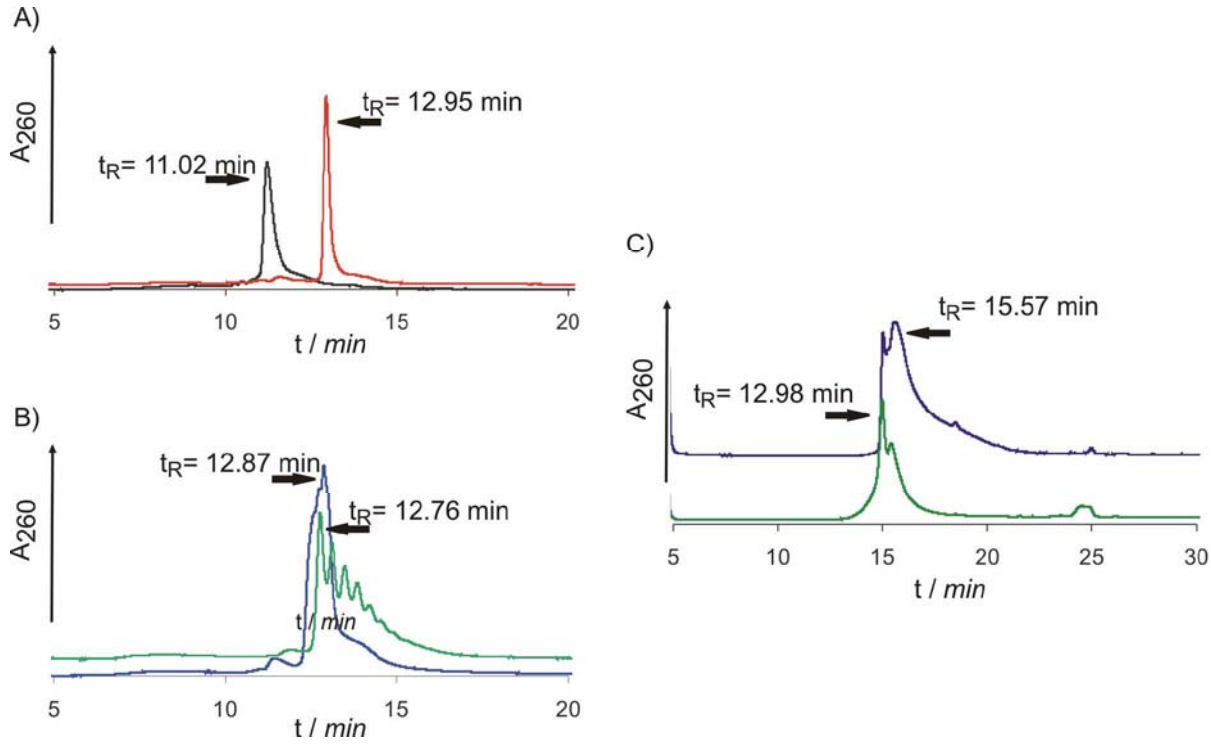

Figure 2S.: HPLC analysis of G3/G5 dendrimer ODN conjugation: A) 5´-amino-ODN, t_R = 11.02 min and 5´-maleimide-ODN, t_R = 12,95 min; B) G3-ODN, t_R = 12.87 min and maleimide-G3-ODN, $t_R \geq$ 12.76 min; A and B analyzed by C18 column and TEAA/CH_3CN elution buffer; C) G5-ODN, t_R = 12.98 min and maleimide-G5-ODN, $t_R \geq$ 15.57 min; analyzed by C6-Phenyl column and 0.1%TFA/H_2O/CH_3CN elution buffer.

Although, PAMAM dendrimers are protein like polyamides, it should be mentioned that G3 dendrimer-ODN conjugate was likely detectable under ODN like conditions (Urea-PAGE and HPLC on C18 reverse phase column and triethylammonium acetate / acetonitril system). However, G5 dendrimer-ODN conjugate, where dendrimer became a prevalent structural moiety, was better

analyzable under protein like conditions (SDS-PAGE and HPLC on C6 reverse phase colmn and 0.1 % TFA / H_2O / acetonitryl system).

MALDI-TOF analysis of ODNs, dendrimers and their conjugation products

MALDI-TOF mass spectrometry was performed on a Bruker Reflex III equipped with a 337 nm N_2 laser in the linear mode and 20 kV acceleration voltage.

Purchased G3 and G5 PAMAM dendrimers were diluted with MeOH to end concentration of 1 mM and reaction mixtures of acetylated dendrimers respectively were mixed with Sinapinic acid matrix (20 mg/ml, 50 % CH_3CN, 0.1% TFA in H_2O) to final concentration 0.1 mM. 0.5 µL was spotted onto target plate.

ODNs and G3/G5 dendrimer-ODN conjugates were desalted on SepPak C18 column eluted with 50 % CH_3CN in ddH_2O, dried and redissolved in matrix solution composed from 9 parts of 3-hydroxypicolinic acid (50 mg/ml in 50% CH_3CN / H_2O) and 1 part of diammonium citrate (50 mg/ml in H_2O) to final concentration 50-100 µM.

Fluorine-18 Click Radiosynthesis and Preclinical Evaluation of a New ^{18}F-Labeled Folic Acid Derivative

Tobias L. Ross,* Michael Honer, Phoebe Y. H. Lam, Thomas L. Mindt,† Viola Groehn,‡ Roger Schibli,† P. August Schubiger, and Simon M. Ametamey

Animal Imaging Center - PET, Center for Pharmaceutical Science of ETH, PSI and USZ, and Department of Chemistry and Applied Biosciences, ETH Zürich, 8093 Zürich, Switzerland, and Merck Eprova AG, 8200 Schaffhausen. Received August 20, 2008; Revised Manuscript Received October 24, 2008

The folate receptor (FR) is highly expressed on most epithelial cancer cells, while normal cells show only restricted expression of FR. As a result, the FR is an ideal target for receptor-based molecular imaging and therapy of cancer and has become a promising target in oncology. To date, several folate-based chemotherapeutics and imaging probes such as radiopharmaceuticals for single photon emission computed tomography (SPECT) have been developed. However, an ^{18}F-labeled folic acid derivative suitable for positron emission tomography (PET) imaging that can be routinely applied is still lacking. In this study, a new fluorinated and radiofluorinated folic acid derivative, $^{18/19}$F-click folate, was synthesized using click chemistry. In a convenient and very efficient two-step radiosynthesis, the isolated ^{18}F-click folate was obtained in good radiochemical yields of 25−35% with a specific activity of 160 ± 70 GBq/μmol after ≤90 min synthesis time. The new compound was pharmacologically evaluated *in vitro* and *in vivo*. The affinity of the non-radioactive ^{19}F-click folate to the FR was determined in displacement studies with FR expressing KB tumor cells using ^{3}H-folic acid. In these *in vitro* binding studies, a nanomolar affinity with a K_i of 9.76 ± 3.13 nM was found for ^{19}F-click folate. The ^{18}F-labeled click folate derivative was then applied for *in vivo* PET studies and *ex vivo* biodistribution experiments using nude mice bearing KB tumor xenografts. The *post mortem* dissection experiments showed a high specific uptake of ^{18}F-click folate derivative in FR-expressing tissues. Uptake in KB tumor xenografts and kidneys (FR-positive tissue) amounted to 3.13%ID/g (94% specific blockade) and 16.53%ID/g (75% specific blockade), respectively. PET imaging using ^{18}F-click folate permitted a visualization of KB tumors, and blockade studies confirmed the specific accumulation of the radiotracer *in vivo*. However, strong hepatobiliary excretion of the new tracer led to elevated accumulation of radioactivity in the abdominal region. In conclusion, the click chemistry approach is convenient to accomplish and provided high radiochemical yields of ^{18}F-click folate. The new tracer showed good *in vitro* but limited *in vivo* properties. Ultimately, the ^{18}F-click folate emphasizes the potential of ^{18}F-labeled folates for receptor-based tumor PET imaging.

INTRODUCTION

Folic acid **1** (see Scheme 1) is an essential dietary vitamin, namely, vitamin B_9. In eukaryotic cells, folic acid is needed in the one-carbon metabolism and *de novo* nucleotide production for DNA synthesis (*1*). In normal cells, folates are directly internalized by the ubiquitously expressed reduced-folate carrier (RFC), a membrane-spanning protein. The RFC has only a low, micromolar affinity to the oxidized forms of folic acid, but it has a high affinity to reduced forms of folic acid (*2*). Another possibility of folic acid uptake into cells is the endocytosis by a glycoprotein receptor, the folate receptor (FR) (*3*). The FR shows a high affinity (K_D ~1 nM) to oxidized forms of **1** (*4*−*7*). In highly proliferating cells, which have an increased demand of folate due to their amplified growth rate, the FR is considered to play a role in mediating elevated folate uptake (*1, 2, 6, 8, 9*). Furthermore, many malignant human endothelial cancer cells highly express the FR, while in normal tissue, only a restricted expression is found (*10, 11*). The degree of overexpression of the FR on human epithelial cancer cells ranges from 30-fold (ovarian carcinoma) up to 1400-fold (endometrial cancer) (*10*). Under physiological conditions, the FR is notably expressed only in choroid plexus, thyroid, and kidney. Hence, the FR is a very attractive molecular target for receptor-based tumor imaging and therapy (*12, 13*).

Over the past decade, several folate-based radiopharmaceuticals have been developed and have proven their potential as diagnostic tools for imaging FR-positive tumors and tissues (*14*). Most of them have been labeled with ^{111}In or with ^{99m}Tc, and some are currently in (pre)clinical studies for potential application as radiopharmaceuticals in diagnostic nuclear medicine (*15, 16*).

The folic acid structure offers two positions for derivatization, the α- and γ-carboxylic acid. Whether or not the binding affinity and *in vivo* pharmacological behavior is dependent on the site of derivatization and conjugation is still debated in the literature (*12, 14, 17*). The first findings in biological studies using folate-based drugs and (radio-)imaging agents indicated the necessity of a free α-carboxyl function to retain binding affinity to the receptor (*18*−*20*). Consequently, the γ-carboxyl group became the preferred site for derivatization for folate conjugates (*12, 14, 21*). In contrast, other studies reported that both the α- and γ-regisomer of a folate derivative showed almost no significant difference in binding affinity to the FR (*12, 14, 16, 17*). Furthermore, there is also evidence of unaltered FR binding affinity and successful endocytosis of drugs after omission of the whole glutamic acid residue (*16, 17, 22*).

Regarding PET imaging, fluorine-18 is the most commonly used radionuclide due to its excellent physical characteristics

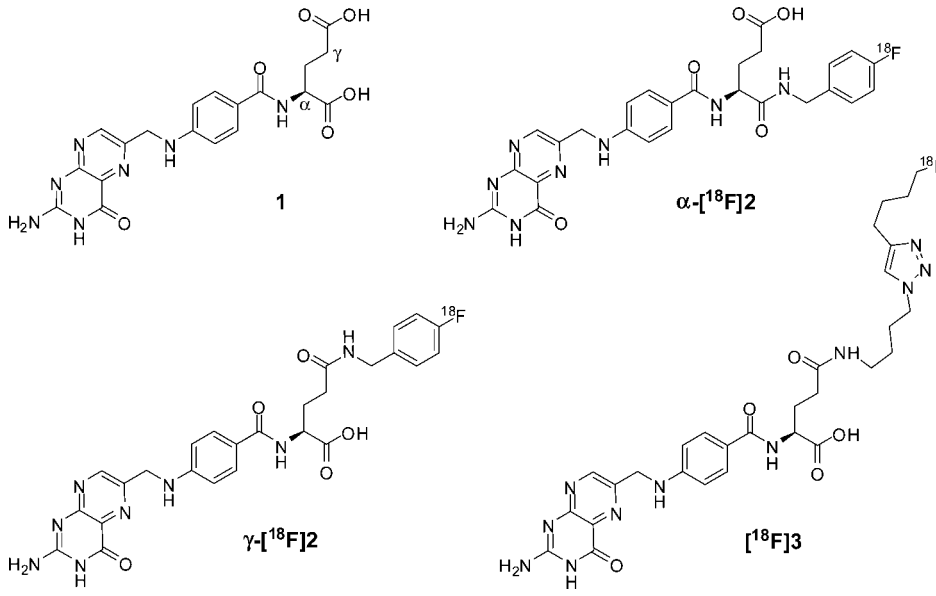
Scheme 1. Structures of Folic Acid (1) and [18]F-Labeled Folic Acid Derivatives, [18]F-Click Folate ([[18]F]3), α- and γ-[[18]F]FBA-Folate (α- and γ-[[18]F]2)



for imaging. The half-life of F−18 of 110 min allows complex radiosyntheses, extended pharmacological *in vivo* studies, and further offers the possibility of distribution and delivery of ^{18}F-radiopharmaceuticals to PET centers without radiochemistry laboratories. Moreover, the β^+-energy of only 635 keV reduces the range of the emitted positron before annihilation and thus provides high spatial resolution for PET imaging. Hence, an ^{18}F-labeled folate-based radiopharmaceutical would be of great interest.

We recently developed the first ^{18}F-labeled folate, the α/γ-[^{18}F]FBA-folate (**α/γ-[^{18}F]2**; see Scheme 1), using the prosthetic group 4-[^{18}F]fluorobenzylamine (4-[^{18}F]FBA), (*23*) which was coupled to native folic acid (*24*). Although the **α/γ-[^{18}F]2** showed promising results in *in vivo* PET studies, it was not suited for routine PET imaging due to unfavorable radiochemistry (*24*). The multistep radiosynthesis of **α/γ-[^{18}F]2** included the three-step preparation of 4-[^{18}F]fluorobenzylamine and the coupling with the activated esters of native folic acid. Subsequently, the **α/γ-[^{18}F]2** was isolated in radiochemical yields of only ∼5% by means of semipreparative HPLC. Moreover, the use of native folic acid caused the formation of both regioisomers of the activated ester and thus resulted in the formation of both the **α-** and **γ-[^{18}F]2**, which could not be separated by semipreparative HPLC. However, *in vitro* cell assays revealed similar binding affinities of the separately synthesized reference compounds, **α-2** and **γ-2** (IC_{50} (**α-2**), 71 ± 8 nM; IC_{50} (**γ-2**), 62 ± 6 nM).

Another approach by Al Jammaz et al. was also based on prosthetic group labeling, but no pharmacological data have been provided so far (*25*).

In 2002, a Cu(I)-catalyzed version of the Huisgen 1,3-dipolar cycloaddition of terminal alkynes and azides has been discovered, which dramatically enhances yields and reduces reaction times from days to hours (*26, 27*). In addition, the new catalyzed variant leads only to one regioisomer, the 1,4-triazoles, while the classic alkyne−azide cycloaddition gave a mixture of 1,4- and 1,5-triazoles. Due to an extraordinary efficiency and selectivity, the new variant of this cycloaddition had such a huge impact on various fields of chemistry that it has become the most famous representative of the so-called click reactions (*28, 29*). The first use of this click cycloaddition in PET chemistry was reported by Marik and Sutcliffe in 2006, who used ^{18}F-labeled alkynes for a click reaction with azide-functionalized peptides (*30*). Since then, several studies have proven its accessibility toward ^{18}F-labeling with high efficiency and outstanding robustness (*31*).

The aim of this study was to develop a new ^{18}F-labeled folic acid derivative as a potential radiopharmaceutical for routine PET imaging of FR-positive tumors. In order to develop a robust and high-yielding ^{18}F-labeling, which is suitable for large-scale routine productions, the click chemistry approach was chosen. On the basis of the report of Marik and Sutcliffe (*30*), the click approach was expanded to ^{18}F-labeling of folates. Furthermore, click chemistry provides a regiospecific coupling with the ^{18}F-labeled moiety and exclusively leads to one regioisomer, in this study, to the γ-isomer. As mentioned before, literature data are controversial and do not exclusively indicate one of the regioisomers. We chose the γ-isomer, as in our previous studies, we found slightly better FR affinity for this regioisomer (*24*). The new "^{18}F-click folate" (**[^{18}F]3**; see Scheme 1) was evaluated *in vitro* and *in vivo* using nude mice bearing FR-positive KB tumor xenografts.

EXPERIMENTAL PROCEDURES

General. Reagents and solvents were purchased from Sigma-Aldrich Co. or Merck AG. All chemicals were used as supplied unless stated otherwise. The *N2-N,N*-dimethylaminomethylene-10-formylpteoric acid was generously provided by Merck Eprova AG, Schaffhausen, Switzerland. ^{3}H-Folic acid (**[^{3}H]1**) was purchased from Moravek Biochemicals Inc. (USA). Nuclear magnetic resonance spectra were recorded with a Bruker 400 or 500 MHz spectrometer with the corresponding solvent signals as an internal standard. Chemical shifts are reported in parts per million (ppm) relative to tetramethylsilane (0.00 ppm). Values of the coupling constant, *J*, are given in hertz (Hz); the following abbreviations are used in the experimental section for the description of P^{1P}H-NMR spectra: singlet (s), doublet (d), triplet (t), multiplet (m), doublet of doublets (dd). The chemical shifts of complex multiplets are given as the range of their occurrence. Low-resolution mass spectra (LR-MS) were recorded with a Micromass Quattro micro API LC-ESI. Water-sensitive reactions were run under argon in flame-dried glassware. Reactions were monitored by thin layer chromatography (TLC, performed on EM Science 0.25-mm-thick, precoated silica gel 60 F-254 glass-supported plates) or HPLC. HPLC was

performed on a Merck-Hitachi L-7000 system equipped with a L-7400 tunable absorption detector. Analytical HPLC was performed with a reversed-phase column (XBridge C18, 5 μm, 4.6 × 150 mm, Waters AG) using the following solvent system: 0.1% TFA_{aq} (solvent A), acetonitrile (solvent B); flow, 1 mL/min; 0-1 min, 95% A; 1-15 min, 95% → 5% A; 15-20 min, 5% A; 20-22 min, 5% → 95% A; 22-25 min, 95% A. Semipreparative HPLC was performed with a reversed-phase semipreparative column (XBridge C18, 5 μm, 10 × 150 mm, Waters AG), flow, 3 mL/min; isocratic NH_4HCO_3 solution (10 mM, 88%)/CH_3CN (12%).

Analytical radio-HPLC was performed on an Agilent 1100 series HPLC system equipped with a GabiStar (Raytest) radiodetector using a reversed-phase column (Gemini 5 μ C18, 250 × 4.6 mm, Phenomenex) with a solvent system and gradient as follows: 10 mM NH_4HCO_3 solution (solvent A), methanol (solvent B); flow, 1 mL/min; 0−30 min, A 90% → 40%; 30−40 min, A 40%; 40−45 min, A 40% → 90%. Semipreparative radio-HPLC was carried out on an HPLC system equipped with a Merck-Hitachi L-6200A intelligent pump, a Knauer Variable Wavelength Monitor UV-detector, and an Eberline RM-14 radiodetector using a reversed-phase column (Gemini 5 μ C18, 250 × 10 mm, Phenomenex) with a solvent system and gradient as follows: 10 mM NH_4HCO_3 solution (solvent A), ethanol (solvent B); flow, 2 mL/min; 0−30 min, A 90% → 40%; 30−40 min, A 40%; 40−45 min, A 40% → 90%. Determination of relative lipophilicity was perfomed on the Agilent 1100 system using the reversed-phase Gemini 5 μ C18 (250 × 4.6 mm, Phenomenex) column and an isocratic solvent system as follows: 80% water (pH 2 with H_3PO_4) and 20% acetonitrile.

PET imaging was performed with the 16-module variant of the quad-HIDAC tomography (Oxford Positron Systems). This small animal PET camera system provides an ultrahigh resolution of less than 0.9 mm^3 (*32*, *33*).

Synthesis of 6-[^{19}F]fluoro-1-hexyne (5). 5-Hexyne-1-yl *p*-tosylate (**4**) (330 mg, 1.3 mmol) (prepared by tosylation of 5-hexyne-1-ol according to the procedure described by van Hest et al. (*34*)), Kryptofix 2.2.2 (620 mg, 1.6 mmol), and KF (97 mg, 1.6 mmol) in dry THF (12 mL) were stirred at reflux for 20 h. Fractionated distillation of the volatile components at ambient pressure gave **5** as a 42% solution in THF (200 mg, 62%): Bp. 65−70 °C/1 atm.

^{1}H NMR ($CDCl_3$) δ 4.51 (t, 1H, J = 6.0 Hz), 4.40 (t, 1H, J = 6.0 Hz), 2.23 (dt, 2H, J = 7.6 and 2.8 Hz), 1.95 (t, 1H, J = 2.8 Hz), 1.80−1.73 (m, 2H), 1.65−1.61 (m, 2H) ppm.

Synthesis of γ-(4-Azido-butyl)-folic Acid Amide (6). 6 was prepared according to the procedure described by Mindt et al. (*35*).

N-BOC-amino-butane-azide was prepared from mono-BOC-diaminobutane according to the procedure described by Link et al. (*36*). After deprotection in CH_2Cl_2/TFA (20%) at room temperature overnight, the TFA salt of 4-azido-butane-amine was obtained as a colorless oil (0.44 g, 94%). The activated ester of α-protected glutamic acid, BocGluOMe, was formed by the use of 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluroniumhexafluorophosphate (HBTU). The activated ester was coupled to the TFA salt of 4-azido-butane-amine to furnish BOC-Glu(4-azido-butyl)-OMe as colorless oil (330 mg, 92%). After deprotection in CH_2Cl_2/TFA (20%) at room temperature overnight, the TFA salt of Glu(4-azido-butylamide)OMe was obtained as a pale yellow oil (740 mg, quantitative). The activated ester (HBTU) of *N2*-*N*,*N*-dimethylaminomethylene-10-formyl-pteroic acid was coupled to the TFA salt of Glu(4-azido-butylamide)OMe to furnish the *N2*-*N*,*N*-dimethylaminomethylene-10-formyl-α-*O*-methyl-γ-(4-azido-butyl) folic acid amide as a yellow solid (290 mg, 92%). After deprotection in 1 M NaOH at room temperature overnight, the pH was adjusted to ∼2 to precipitate the penta-hydrochloride salt of **6** as a yellow powder (75 mg, quantitative).

Synthesis of γ-(4-(4-[^{19}F]fluorobutyl)triazo-1-yl)butyl-folic Acid Amide (^{19}F-click folate, 3). 6 (penta-hydrochloride salt, 14 mg, 0.02 mmol) was suspended in ^{t}BuOH/H_2O (1:1, 2 mL), and **5** (48 mg, 0.2 mmol), $Cu(OAc)_2$ (0.8 mg, 20 mol %) and sodium ascorbate (1.5 mg, 40 mol %) were added. The mixture was stirred at 75 °C until HPLC indicated complete conversion of the azide starting material (∼30 min). The mixture was cooled to room temperature, and the resulting suspension was dissolved by addition of a few drops 1 M NaOH. Adjustment of pH to 2 by addition of 1 M HCl resulted in precipitation of the product. The mixture was centrifuged (10 min at 3500 rpm) and the pale yellow supernatant decanted. Drying of the solid provided a brown powder (20 mg). The crude product was dissolved in 0.1 M NaOH (0.4 mL) and purified by semiprep HPLC. The collected fractions containing the product were concentrated under reduced pressure and the residue dissolved in 1 M NaOH (1 mL). Adjustment to pH 2 by addition of 1 M HCl resulted in precipitation of **3**. Centrifugation (10 min at 3500 rpm), decantation of the pale yellow supernatant, and drying of the solid provided the penta-hydrochloride salt of **3** as a yellow powder (9 mg, 53%).

^{1}H NMR (DMSO-d_6) δ 12.02−11.85 (bs, 1H), 8.66 (s, 1H), 8.19 (d, 1H, J = 7.8 Hz), 7.86−7.80 (m, 2H), 7.65 (d, 2H, J = 8.7 Hz), 7.35−6.95 (broad m, 2H), 6.65 (d, 2H, J = 8.7 Hz), 4.53−4.47 (m, 3H), 4.40 (t, 1H, J = 5.8 Hz), 4.32−4.23 (m, 3H), 3.54−3.32 (bs, 1H), 3.08−2.97 (m, 2H), 2.62 (t, 2H, J = 6.6 Hz), 2.22−2.13 (m, 2H), 2.09−2.00 (m, 1H), 1.98−1.88 (m, 1H), 1.79−1.60 (m, 6H), 1.36−1.26 (m, 2H) ppm. ^{13}C NMR (DMSO-d_6) δ 173.8, 171.5, 166.3, 160.7, 155.0, 153.5, 150.7, 149.1, 148.5, 146.5, 129.0, 128.0, 121.7, 121.4, 111.2, 84.2, 83.0, 52.2, 48.8, 45.9, 37.7, 32.0, 29.3, 27.2, 26.5, 26.1, 24.8, 24.5 ppm. LR-MS: $[M + H]^+$ = 638.24 (calc. for $C_{29}H_{36}FN_{11}O_5$: 637.67). Elemental analysis (calculated % values for $C_{29}H_{36}N_{11}O_5(HCl)_5$ in parenthesis) C 42.72 (42.48), H 5.18 (5.04), N 18.17 (18.79).

Production of n.c.a. [^{18}F]fluoride. N.c.a. [^{18}F]fluoride was produced via the ^{18}O(p,n)^{18}F nuclear reaction at a Cyclone 18/9 cyclotron (IBA, Belgium). Isotopically 97% enriched [^{18}O]water was irradiated by a 18 MeV proton beam using a 2.1 mL liquid target. The [^{18}F]fluoride/[^{18}O]water solution was transferred from the target to a manipulator-equipped syntheses hot cell using a helium stream.

Synthesis of γ-(4-(4-[^{18}F]Fluorobutyl)triazo-1-yl)butyl-folic Acid Amide (^{18}F-click folate, [^{18}F]3). N.c.a. [^{18}F]fluoride (∼20−30 GBq) was trapped on an anion exchange cartridge (Sep-Pak Light Accell Plus QMA, Waters AG), preconditioned with 5 mL 0.5 M potassium carbonate solution and 5 mL water, while the [^{18}O]water was recovered for recycling. The n.c.a. [^{18}F]fluoride was directly eluted into a 10 mL sealed reaction vessel using a solution of potassium carbonate (2 mg) and Kryptofix 2.2.2 (10 mg) in 1.5 mL acetonitrile/water (4:1). At 85−90 °C, the solvents were removed by reduced pressure and a stream of nitrogen. Subsequently, 0.8−1.0 mL of dry acetonitrile was added three times and evaporated to dryness. To the obtained dry [^{18}F]fluoride−cryptate complex, **4** (25 μL) in 1.0 mL acetonitrile was added. The reaction vessel was connected via a PTFE tubing with a second 10 mL reaction vessel containing copper(I)iodide (2.5 mg), and the second reaction vessel was placed in a dry ice/isopropanol cooling bath. The reaction mixture in reaction vessel one was heated to 95−100 °C, while the ^{18}F-labeled product **[^{18}F]5** was co-distilled with acetonitrile to the second reaction vessel (bp (**5**) = 106 °C (*30*)). **[^{18}F]5** was given in a radiochemical yield of 70−85% and a radiochemical purity of 95−99%. After 12 min, the second reaction vessel containing **[^{18}F]5** in 0.6−0.8 mL acetonitrile was

disconnected and allowed to warm to ambient temperature. To this mixture 0.8 mL water, 10 μL DIPEA, 20 μL 2,6-lutidine, and **6** as its penta-hydrochloride salt (1.5 mg, 2 μmol) in 0.2 mL DMF were added successively. The mixture was heated to 80 °C and was allowed to cool down to 60 °C within 20 min. The **[^{18}F]3** content of the crude mixture was 65−80% according to analytical radio-HPLC. The product was isolated by semi-preparative HPLC in radiochemical yields of 25−35%. The HPLC solvents were removed under reduced pressure and a stream of nitrogen at 100 °C. The dry product was then formulated in physiological phosphate buffer solution (PBS, 0.15 M).

***In Vitro* Cell Binding Assays.** Cell binding assays were performed with KB cells, a human nasopharyngeal epidermal carcinoma cell line overexpressing the FR (*3*). Cells were continuously cultured as monolayers in 75 cm^2 flasks at 37 °C in humidified atmosphere (7.5% CO_2). The cells were folate-starved in folate-deficient RPMI 1640 medium supplemented with fetal calf serum (10%, heat-inactivated), L-glutamine, and antibiotics (penicillin, 100 IU/mL; streptomycin, 100 μg/mL). Such compositions, with fetal calf serum as the only folate source in the medium, are known to provide a final folate concentration of ∼3 nmol/mL, which is at the low end of the physiological serum concentration in humans (*37*).

After a growing period of 2−3 days, a cell suspension in pure, ice−cold folate-deficient RPMI 1640 medium (without further additives) was prepared. The cell suspension was distributed to 1.5 mL vials, ∼7000 cells per tube (∼240 μL). A dilution series of eight different concentrations in a range from 5.0×10^{-6} to 5.0×10^{-11} M for native folic acid and in the range from 5.0×10^{-6} to 5.8×10^{-12} M for **3** were prepared. The cells were incubated as triplicates of each concentration together with **[^{3}H]1** (10 μL, ∼25 kBq/μL, specific activity 1.203 GBq/μmol) at 2−4 °C for 30 min. Nonspecific binding was determined in the presence of native folic acid at a concentration of 10^{-3} M. After centrifugation, 10 min at 800 × *g*, and 4 °C, the supernatant was discarded. The cell pellets were resuspended and lysed at the same time using a 1 M NaOH solution (0.5 mL). Preliminary comparative experiments showed that an additional washing step before the lysis is not necessary. The lysed cells were vortexed and transferred into scintillation tubes containing 4 mL of a scintillation cocktail (Ultima Gold, PerkinElmer). Radioactivity in the tubes was recorded by β-counting (LS6500, Beckman USA). The IC_{50} values were determined from the displacement curves using the *Origin 8.0* software (OriginLab Corp., USA). K_i values were calculated according to the Cheng-Prusoff equation (*38*) using a K_D of **[^{3}H]1** of 1 nM.

***In Vitro* Metabolite Studies in Plasma and Liver Microsomes.** The **[^{18}F]3** solution (∼20 MBq, 35 μL) was incubated with human or murine plasma (0.5 mL) in a shaking water bath at 37 °C. Aliquots of 70 μL were taken at different time points over a period of 0−120 min. Plasma proteins were precipitated by addition of 140 μL acetonitrile and removed by centrifugation for 10 min at 10 000 × *g* (room temperature). Aliquots of the supernatant were analyzed by radio-HPLC (analytical HPLC system).

The **[^{18}F]5** solution (∼20 MBq, 35 μL) was incubated with human or murine liver microsomes (BD Gentest, BD Biosciences, USA) in a shaking water bath at 37 °C (0.5 mg protein per mL). Control samples were incubated with heat-inactivated microsomes. Each sample contained 10% 10 mM NADPH solution or PBS for control samples. Proteins were precipitated by addition of 250 μL acetonitrile at different time points over a period of 0−30 min and removed by centrifugation for 5 min at 10 000 × *g* (4 °C). Aliquots of the supernatant were analyzed by radio-HPLC (analytical HPLC system).

***In Vivo* Studies.** *Animals.* Animal studies complied with Swiss and local laws on animal protection and husbandry. Male NMRI nude mice were purchased from Charles River (Germany) and maintained on a folate-deficient rodent diet to reduce their serum folate concentration to a level comparable to human serum levels (*39*). After a 3−4 day acclimatization period, 0.1 mL of a KB tumor cell suspension (50×10^6 cells/mL) was inoculated subcutaneously into the right axilla of each mouse. The cell suspension for inoculation was achieved by cell harvest of subconfluent cells using 1 mM EDTA solution in PBS. Cells were washed once with PBS and after centrifugation (1000 × *g*, 5 min, 20 °C) resuspended in PBS for inoculation. The animal experiments were performed 10−14 days after inoculation, when the tumors had reached weights of 80−300 mg.

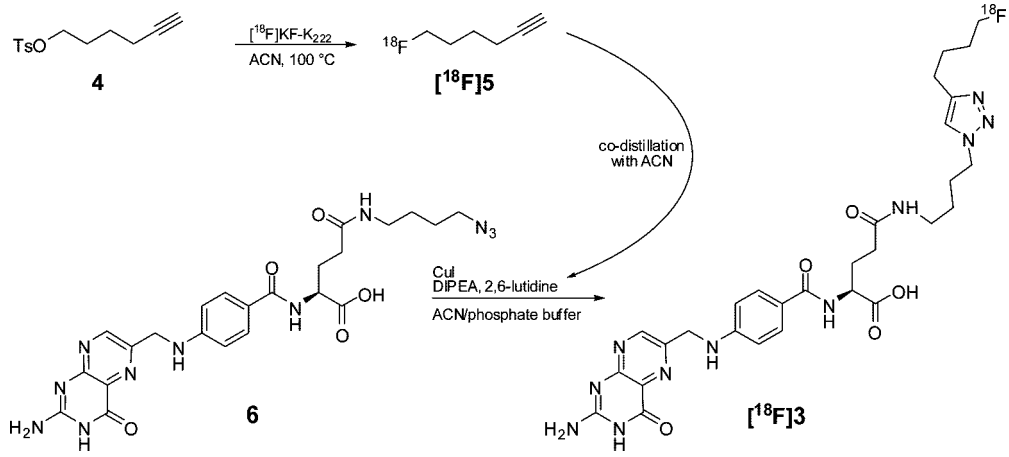
Ex Vivo Biodistribution Studies. Animals were injected with ∼2 MBq, 12.5 pmol, (max. volume 100 μL per injection) of **[^{18}F]3** via a lateral tail vein. In the blockade group ($n = 4$), each animal received 200 μg of native folic acid (2 mg/mL folic acid in PBS) via intravenous injection 10 min prior to the radiotracer injection. The control group ($n = 4$) received an injection of PBS. Animals were sacrificed by decapitation 45 min after radiotracer injection. Tumours, organs, and tissues were dissected and measured in the γ-counter (Wizard, PerkinElmer). The incorporated radioactivity was expressed as percentage injected dose per gram of tissue (%ID/g; ((cpm tissue/g tissue/cpm injected) × 100).

PET Imaging Studies. PET experiments were performed with the 16-module variant of the quad-HIDAC tomograph (Oxford Positron Systems) (*33*). Animals were lightly restrained and injected with 6−12 MBq, 37.5−75.0 pmol of the radiotracer (90−110 μL per injection) via a lateral tail vein. In the blockade group ($n = 3$), each animal received 200 μg of native folic acid (2 mg/mL folic acid in PBS) via intravenous injection 10 min prior to the radiotracer injection, whereas the control group ($n = 3$) received a corresponding volume of PBS. Animals were anesthetized with isoflurane (Abbott) in an air/oxygen mixture and scanned as described previously (*40*). The PET scans were acquired from 15 to 45 min post-injection. For a comparison of [^{18}F]**3** tumor uptake with 2-[^{18}F]fluoro-2-deoxy-D-glucose ([^{18}F]FDG), two animals were rescanned with [^{18}F]FDG four days after the [^{18}F]**3** study. Each animal received ∼9 MBq of [^{18}F]FDG and was scanned 30−60 min after injection.

RESULTS AND DISCUSSION

Radiochemistry. The ^{18}F-labeling is based on a prosthetic group approach using the Cu(I)-catalyzed 1,3-dipolar cycloaddition of alkynes and azides (Scheme 2), also referred to as click chemistry (*26*, *27*). The prosthetic group, 6-[^{18}F]fluoro-1-hexyne **[^{18}F]5**, could be successfully produced from the corresponding *p*-tosylate precursor **4** according to a procedure reported by Marik et al. (*30*). The **[^{18}F]5** was purified by co-distillation with acetonitrile at the same time the ^{18}F-labeling step was carried out. Within 12 min, the ^{18}F-labeled alkyne **[^{18}F]5** was obtained and isolated in excellent radiochemical yields of 70−85% with radiochemical purities of ≥95%. The **[^{18}F]5** was collected by condensation in a second reaction vial, which was placed in a dry ice/*i*-propanol cooling bath. The second reaction vessel already contained CuI as catalyst for the following 1,4-triazole formation by cycloaddition with the γ-azide-functionalized folic acid derivative, γ-(4-azido-butyl)-folic acid amide **6**. This click reaction worked best in a 1:1-mixture of acetonitrile and 0.15 M PBS. Although additional bases are generally not necessary when this click reaction is performed in aqueous systems (*28*), a 1:2 mixture of DIPEA and 2,6-lutidine was found optimal for enhancing coupling efficiency and reducing side-product formation. However, the initial step in the click mechanism is the coordination of the

Scheme 2. Radiosynthesis of ^{18}F-Click Folate ([^{18}F]3) via the 1,3-Dipolar Cu(I)-Catalyzed Cycloaddition of n.c.a. 6-[^{18}F]Fluoro-1-Hexyne ([^{18}F]5) and γ-(4-Azido-Butyl)-Folic Acid Amide (6)[a]



[a] **4**: 5-hexynyl-*p*-tosylate (precursor for **[^{18}F]5**).

Cu(I)-catalyst to the alkyne, forming an acetylide, which is exothermic and favored in aqueous systems, but slightly endothermic in pure organic systems (e.g., in acetonitrile approximately −0.6 kcal/mol), where generally base addition is needed to facilitate this acetylide formation (*41*). Furthermore, previous studies demonstrated that nitrogen bases such as pyridine or 2,6-lutidine suppress side-product formation and often improve yields (*27, 29, 30*). After subsequent addition of PBS, DIPEA, 2,6-lutidine, and finally the γ-azide-functionalized folate **6** in DMF to the reaction mixture, the orange solution was stirred for 20 min at elevated temperatures of 80 → 60 °C. A good conversion of 65−80% to the ^{18}F-click folate **[^{18}F]3** in the reaction mixture was observed by analytical HPLC within 15−20 min. Higher temperatures up to 110 °C increased the coupling yield to some extent, but led to a deteriorated product/side-product ratio. Likewise, elongated reaction times of 45−60 min did not significantly enhance the radiochemical yield. The click chemistry step succeeds without the need for protection groups and directly provides the final product **[^{18}F]3**.

[^{18}F]3 was purified by reversed-phase semipreparative HPLC. The product peak (retention time 17.5 min, full width at half-maximum = 1.0 min) was collected in a reaction vessel, and HPLC solvents (∼3−4 mL) were evaporated under reduced pressure and a stream of nitrogen at 100 °C within 10−15 min. The dry product was redissolved in physiological PBS and formulated for biological applications. After an overall synthesis time of approximately 90 min, the isolated product was obtained in radiochemical yields of 25−35%, with a radiochemical purity of ≥99% and a specific activity of 160 ± 70 GBq/μmol. The **[^{18}F]3** was identified by analytical HPLC by coinjection with its nonradioactive reference compound **3**.

The extraordinary efficiency of the 1,3-dipolar click cycloaddition of alkynes and azides (*28*) could be successfully transferred to ^{18}F-labeling of a new folic acid derivative and has been proven to be very reliable and high-yielding. In comparison to other multistep procedures for preparing ^{18}F-labeled folic acid derivatives (*24, 25*), this two-step click chemistry approach is much more suitable for routine productions. Its robustness and the high radiochemical yields provide sufficient amounts of the ^{18}F-labeled radiotracer within adequate synthesis times. Furthermore, the regiospecific coupling results only in the γ-isomer and precludes complicated separation methods or the use of regioisomeric mixtures. Consequently, this radiosynthetic strategy is particularly suitable for large-scale production of ^{18}F-labeled folates for routine applications in PET imaging.

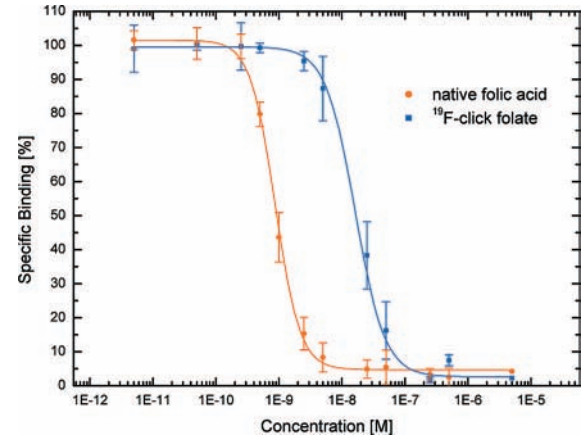


Figure 1. Displacement curves of native folic acid and ^{19}F-click folate (**3**) using ^{3}H-folic acid (1 nM) and human KB cells in cell suspension showing the mean ± SD percentage of specific binding. Nonspecific binding was determined in the presence of native folic acid at a concentration of 10^{-3} M.

***In Vitro* Cell Binding Assays.** Human KB cells (human nasopharyngeal epidermal carcinoma cell line overexpressing the FR) were kept under folate-deficient conditions to reproduce a folate concentration similar to that of human serum. The IC_{50} values of native folic acid and **3** were obtained by displacement studies (Figure 1) using ^{3}H-folic acid (Moravek Biochemicals, USA). The mean IC_{50} of three independent experiments with **3** was determined as 18.0 ± 7.1 nM, which is higher compared to the value for native folic acid (IC_{50} = 1.12 ± 0.44 nM, n = 3). Applying the IC_{50} values to the Cheng-Prusoff equation (*38*) with the assumption that the K_D of ^{3}H-folic acid is 1 nM (*4−7*) gave a K_i value of 9.76 ± 3.13 nM for **3**. Thus, the binding affinity of this new folic acid derivative is in the low nanomolar range but more than 1 order of magnitude lower compared to that of native folic acid (K_i = 0.61 ± 0.19 nM).

***In Vitro* Metabolite Studies in Plasma and Liver Microsomes.** To test the plasma stability of the new tracer, **[^{18}F]3** was incubated in human or murine plasma at 37 °C. Aliquots were taken and analyzed by radio-HPLC over a period of 0−120 min. As PET imaging studies with [^{18}F]-labeled radiotracers are typically performed at early time points after injection, a maximum incubation time of 120 min for the plasma stability study was considered to be sufficient. For all time points examined, no metabolic degradation or defluorination of the radioactive compound was detectable.

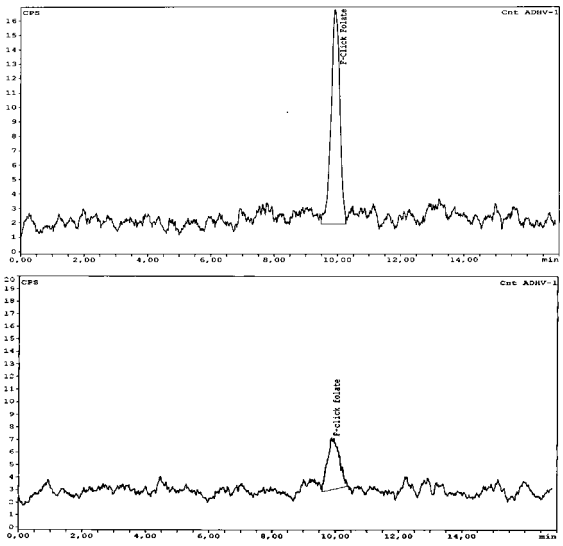

Figure 2. Radio-HPLC chromatograms of the metabolite study using **[^{18}F]3** in human liver microsomes. The first chromatogram shows **[^{18}F]3** at 0 min incubation. In the second chromatogram, only unmetabolized parent compound is detected after 30 min incubation.

[a] Animals were sacrificed 45 min post-injection. Data are expressed as percent injected dose per gram tissue (%ID/g). [b] In the blockade group ($n = 4$), 200 μg native folic acid was injected into each animal 10 min prior to the radiotracer, whereas the control group ($n = 4$) received a corresponding volume of PBS.

Further investigation of the metabolic stability of **[^{18}F]3** *in vitro* was carried out in human and murine liver microsomes. To analyze whether ^{18}F-click folate is degraded by enzymes present in these microsomal preparations, the radiotracer was incubated at 37 °C for 30 min. Radio-HPLC analysis of the samples revealed that **[^{18}F]3** is stable in human and murine liver microsomes, since no radioactive metabolites or defluorination were detected (Figure 2).

Biodistribution Studies. The *in vivo* binding specificity of **[^{18}F]3** to the FR on KB tumor cells was first analyzed by *post mortem* biodistribution studies under control and blockade conditions. The blockade group received 200 μg native folic acid 10 min prior to radiotracer administration, whereas the control animals were injected with a corresponding volume of PBS. Radioactivity accumulation in KB tumors at 45 min post-injection amounted to 3.13 ± 0.79%ID/g, while tracer uptake in blocked animals was reduced by more than 90% to 0.19%ID/g (Table 1). Highly specific uptake of the radiotracer was also identified in the kidneys, which are known to express the FR under physiological conditions (*42*−*44*). Control animals showed a kidney accumulation of 16.53 ± 2.22%ID/g, which was reduced to 3.89 ± 3.52%ID/g in the blockade group (77% specific uptake). Highest nonspecific accumulation of radioactivity was found in the bile, pointing to hepatobiliary elimination of **[^{18}F]3** as the major elimination pathway. Moderate activity accumulation was evident in urine, feces, and intestine.

***In Vivo* PET Imaging.** Mice bearing a FR-expressing KB tumor in the area of their right shoulder were injected with **[^{18}F]3** and scanned 15−45 min post-injection to assess whether tumors can be visualized by PET imaging. As expected from the *ex vivo* biodistribution data, tracer uptake in excretory organs was predominant, but tumors were nevertheless clearly visualized (Figure 3, top row). Tracer uptake in KB tumors was found to be heterogeneous with higher activity accumulation in the rim of the tumors, suggesting better delivery of the radiotracer to the outer portions of the tumor mass. A similar heterogeneous distribution of the radiotracer in KB tumor xenografts was also found in a previous study using **α/γ-[^{18}F]2** (*24*). Due to the fast growth of certain tumor types, the centers of larger xenografts (≥300 mg) are often insufficiently perfused, which may lead to a necrotic tumor center (*45*, *46*). However, there are also indications that KB xenografts, showing a heterogeneous radiotracer uptake, exhibit a homogeneous expression of the FR and good vascularization, and only high intratumoral pressure causes an insufficient radiotracer uptake in the tumor center (*47*).

In agreement with previous studies (*24*, *40*), ^{18}F-FDG uptake in the KB tumor xenografts was negligible (Figure 3, bottom row). The KB tumor model is one example where ^{18}F-FDG PET imaging fails. In such cases, a receptor-based imaging approach using specific ligands such as folic acid derivatives for targeting the FR could overcome these difficulties.

The binding specificity of **[^{18}F]3** to the FR on KB tumor cells was also demonstrated by *in vivo* PET studies under control and blockade conditions. The blockade group received 200 μg native folic acid 10 min prior to radiotracer administration, whereas the control animals were injected with a corresponding volume of PBS. All animals were scanned from 15 to 45 min after radiotracer application. Figure 4 shows a corresponding series of horizontal whole body sections under both experimental conditions. Tumors and kidneys were only visualized in the absence of competing folic acid, supporting the specificity of [^{18}F]3 binding to the FR *in vivo*. The cortex of kidneys (proximal tubules) is known to express the FR under physiological conditions where renal reabsorption of folates takes place (*42*−*44*).

In correspondence to *post mortem* dissection studies (Table 1), PET experiments revealed the highest accumulation of radioactivity in excretory organs of the abdominal region (gall bladder, intestine, urinary bladder, kidneys). The extremely high tracer concentration in bile and, consequently, in the intestines results from the strong hepatobiliary elimination of the radiotracer. A high abdominal accumulation of the radiotracer is undesirable and hampers tumor visualization in this region. Previous studies using the first ^{18}F-labeled folate, **α/γ-[^{18}F]2** (*24*), also showed a prominent hepatobiliary elimination of the radiotracer.

Strong hepatobiliary elimination often correlates with the degree of lipophilicity of a drug. As a consequence, higher lipophilicity generally results in increased hepatobiliary excretion. For comparison of the relative lipophilicity, the retention factors (k'-values) of native folic acid, **α**- and **γ-2** and **3** were determined using a reversed-phase HPLC system (*48*). The k'-value of native folic acid as a reference with the lowest lipophilicity was found to be 0.30. Both regioisomers, **α**- and **γ-2**, gave identical k'-values of 0.67, which indicate an increased lipophilicity in comparison to native folic acid. The k'-value of 2.28 for **3** points to a much higher lipophilicity. Consequently,

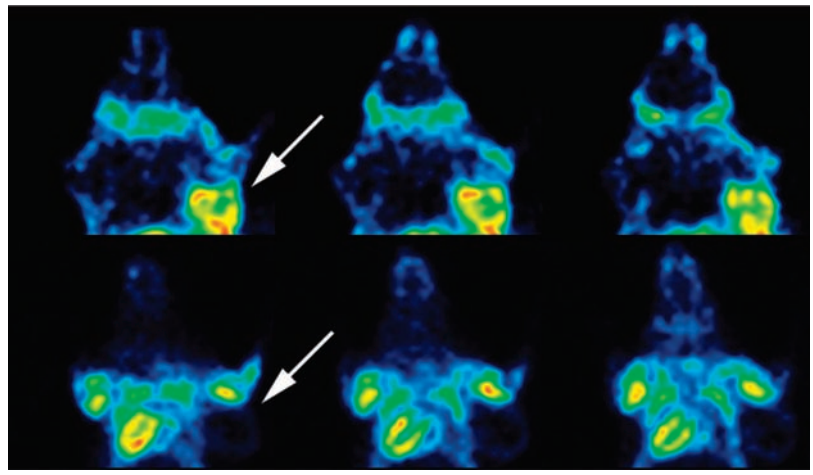

Figure 3. Representative series of horizontal PET images through the head and thorax region of an NMRI nude mouse bearing a KB tumor xenograft next to the right forelimb (arrows). The mouse was injected with **[^{18}F]3** and imaged from 15 to 45 min post-injection (top row). The same mouse was injected with ^{18}F-FDG four days later and scanned from 30 to 60 min post-injection (bottom row). Visualization of the FR-positive tumor was only possible with **[^{18}F]3**.

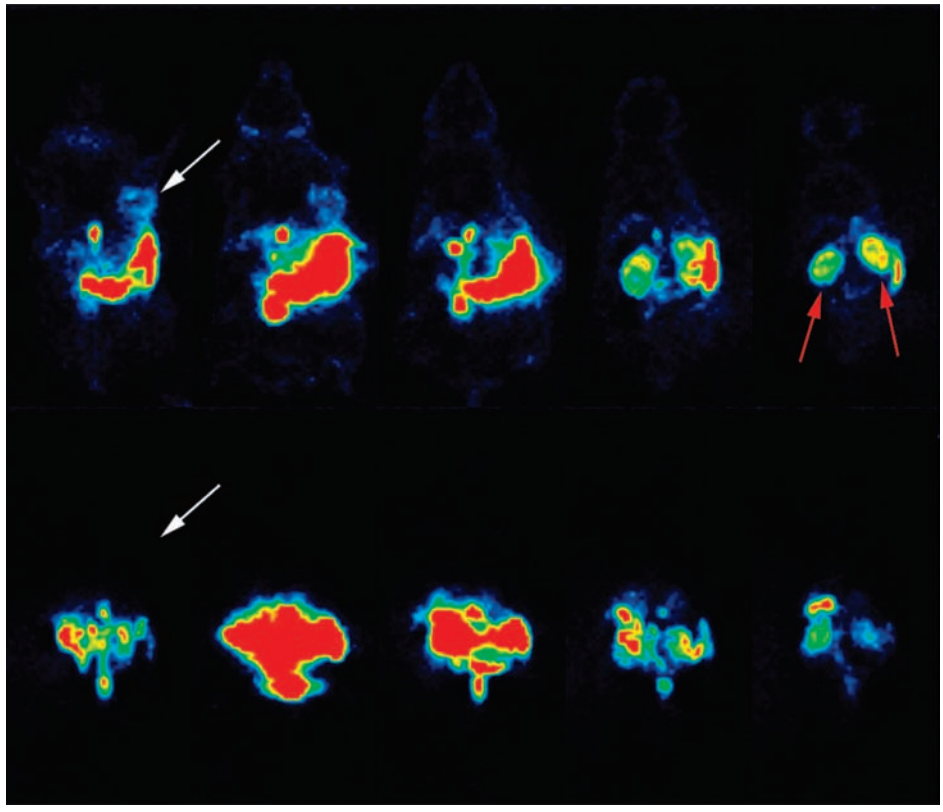

Figure 4. Series of horizontal whole body PET images (ventral to dorsal) of two NMRI nude mice bearing a KB tumor xenograft next to the right forelimb (white arrows). Mice were injected with **[^{18}F]3** under control conditions (top row) or blockade conditions (bottom row) and imaged from 15 to 45 min post-injection. Uptake in FR-positive tumor and kidneys (red arrows) is only present in the control animal demonstrating the specificity of tracer uptake.

the lipophilicity of the fluorinated folates may well correlate with the degree of hepatobiliary elimination.

CONCLUSIONS

On the basis of click chemistry, a new fluorinated folic acid derivative, ^{19}F-click folate, was synthesized and evaluated *in vitro*. ^{19}F-click folate showed nanomolar affinity for the FR on KB tumor cells, which was in a comparable range to that of native folic acid.

The click chemistry approach was successfully applied to the radiolabeling of the corresponding ^{18}F-labeled folic acid derivative. In a two-step radiosynthesis, the ^{18}F-click folate was labeled with fluorine-18 in very good radiochemical yields and high radiochemical purities. The time-saving and robust radiosynthesis and especially the high radiochemical yields are particularly suitable for large-scale productions as needed for routine PET imaging.

In biodistribution studies, a high specificity of ^{18}F-click folate to the FR was observed. High radioactivity accumulation in gall bladder and intestines indicated a pronounced hepatobiliary elimination of ^{18}F-click folate. This finding was confirmed by PET imaging where a high nonspecific accumulation of

radioactivity in the abdominal region was detected. The high specificity of ^{18}F-click folate proves the potential of this class of compounds; however, further investigations toward novel ^{18}F-labeled folates with reduced lipophilicity are warranted.

ACKNOWLEDGMENT

We thank Sabine Baumann, Claudia Keller, and Marianne Kehl for their support with the *in vivo* experiments; Andrea Weber for her help with the *in vitro* tests; and Dr. Cristina Müller for advice and discussion on folates and their pharmacology.

Silica particles as a nanoparticulate carrier material for contrast agents have received considerable attention the past few years, since the material holds great promise for biomedical applications. A key feature for successful application of this material in vivo is biocompatibility, which may be significantly improved by appropriate surface modification. In this study, we report a novel strategy to coat silica particles with a dense monolayer of paramagnetic and PEGylated lipids. The silica nanoparticles carry a quantum dot in their center and are made target-specific by the conjugation of multiple $\alpha v\beta 3$-integrin-specific RGD-peptides. We demonstrate their specific uptake by endothelial cells in vitro using fluorescence microscopy, quantitative fluorescence imaging, and magnetic resonance imaging. The lipid-coated silica particles introduced here represent a new platform for nanoparticulate multimodality contrast agents.

INTRODUCTION

Nanoparticles have been explored for a few decades now as vehicles to deliver therapeutic agents (*1*). Traditionally, nanoparticles composed of naturally occurring molecules, such as bilayered vesicles composed of phospholipids, have been utilized (*2*). The revolution in nanoscience has resulted in the development of a tremendous amount of new materials that hold great potential for biomedical applications (*3*). In the field of diagnostic imaging, nanoparticles also create new possibilities. These include iron oxide nanoparticles for magnetic resonance imaging (MRI) (*4*), carbon nanotubes for MRI (*5*), or gold nanoparticles for computed tomography (CT) (*6*). Semiconductor nanocrystals, also known as quantum dots (QDs), have been recognized as an optical contrast agent due to their outstanding fluorescent properties (*7*). A major advantage of the application of nanoparticles for biomedical purposes is that they can have multiple properties integrated within one single carrier particle. In addition, the possibilities for surface modification create flexibility for a large range of applications. The above-mentioned features of nanoparticles have resulted in the development of nanoparticles that are suitable for both therapeutic and diagnostic purposes (*8*), as well as nanoparticles that can be employed for different imaging modalities, so-called multimodality nanoparticles (*9*).

Silica as a nanoparticulate carrier material has received considerable attention the past few years. The incorporation of nanoparticles in silica has been reported for semiconductor (*10, 11*), metallic (*12, 13*), and magnetic nanocrystals (*14*). In addition, the simultaneous incorporation of magnetic nanoparticles and QDs in silica nanospheres has been reported recently (*15*−*18*). Doping of silica particles with dye molecules is well-established (*19*−*21*), while combinations of dyes with other functionalities within one silica sphere have also been reported (*22*−*24*). The use of these silica-coated nanoparticles and/or dyes as contrast agents for bioimaging applications benefits from the high versatility and well-known surface chemistry of silica nanospheres (*25*). The possibility of combining multiple properties within one silica nanosphere as well as the control over the final particle size over a broad range (20 nm to 5 μm) make these composite particles especially suitable as carriers for multiple diagnostically active materials (*26*−*29*). Most importantly, a key feature for successful application of this material in vivo is biocompatibility, which may be significantly improved by appropriate surface modification.

Two distinct surface modifications to enhance the bioapplicability of silica nanospheres have been reported to date, which both depend on the use of silane coupling agents. In the first method, the silica spheres are terminated by an amine or thiol group using APS or MPS (aminopropyltrimethoxysilane and mercaptopropylmethoxysilane), to which biofunctional groups can be covalently linked (*24, 30*−*34*). The second method involves the modification of the silica surface by molecules that already have a silane group integrated within the molecule (*24, 32, 34, 35*). Most of the aforementioned reports use both strategies simultaneously to attach functional moieties, including antibodies, paramagnetic molecules, and poly(ethylene glycol) (PEG), through an amide bond. Although some variation in surface functionalization is possible, there are several serious drawbacks for these methods. First, due to steric hindrance and differences in reactivity with coupling agents, it is not clear to what extent

and in what ratio the silica surface is covered by the pegylated and biofunctional molecules. Second, the density of the (pegylated) coating around the silica spheres is not well-defined, which limits the optimal use of the surface area payload and may lead to suboptimal biocompatibility. In addition, depending on the pH, this methodology results in the presence of negatively positively charged hydroxyl/amine groups, which may unfavorably affect the stability under physiological conditions. Third, the flexibility of these methods is limited to molecules with reactive groups for the covalent linking step.

In the current study, we report a novel strategy to coat silica particles with a dense monolayer of lipids without the usage of (silane) coupling agents. In the first step, the silica particles are rendered hydrophobic, after which they are coated with both paramagnetic and PEGylated lipids in a second step. This highly flexible and widely applicable coating method for silica particles also allows for the conjugation of target-specific molecules at the surface of the nanoparticle. In the present case, we use highly monodisperse silica particles that have a single core−shell−shell (CSS) QD incorporated into the center and paramagnetic Gd-DTPA-DSA in the lipid coating, to enable their detection with both fluorescence techniques and MRI. As a proof-of-principle, we demonstrate target-specific multimodality imaging of $\alpha v\beta 3$-integrin expression on cultured endothelial cells using our lipid-coated QD/silica nanoparticles.

EXPERIMENTAL PROCEDURES

Materials. 1,2-Distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy(poly(ethylene glycol))-2000] (PEG-DSPE) and 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[maleimide-(poly(ethylene glycol))2000] (Mal-PEG-DSPE) were purchased from Avanti Polar Lipids. Gd-DTPA-bis(stearylamide) (Gd-DTPA-DSA) was obtained from Gateway Chemical Technology. Methanol (anhydrous, 99.8%), octadecanol (99%), Igepal (CO-520), oleic acid (90%), octadecylamine (ODA 97%), and octadecene (ODE, 90%) were purchased from Aldrich. Tetraethyl orthosilicate (TEOS, 99%) was obtained from Johnson Matthey. Acetone (p.a.), chloroform (p.a.), ammonia (25% in water, p.a.), cadmium oxide (>99%), zinc oxide (>99%), and HEPES ($C_8H_{18}N_2O_4S$, >99%) were purchased from Merck. The HEPES buffer contained 2.38 g/L HEPES and 8.0 g/L NaCl (99.8%, Baker), and the pH was adjusted to 6.7 by addition of a NaOH solution. Sulfur powder (99.999%) was obtained from Alfa Aesar, and ethanol (>99.8%) from Riedel de Haën. The cyclic 5-mer RGD (c(RGDf(-S-acetylthioacetyl)K)) was synthesized at a purity of 95% by Ansynth Service BV (The Netherlands).

Synthesis of Silica-Coated QDs. CdSe (core) QDs (3.4 nm in diameter) were synthesized by the conventional organometallic synthesis route, described in detail elsewhere (*36*). The CdSe QDs were coated with 7 monolayers of inorganic shells ($2 \times$ CdS, $3 \times Cd_{0.5}Zn_{0.5}S$, $2 \times$ ZnS) according to a SILAR method that was recently published by Xie et al. (*37*). Addition of these shells was performed by adding precalculated amounts of a 0.1 M precursor solution (Cd oleate, CdZn oleate, Zn oleate, and sulfur in ODE) to 200 nmol CdSe QDs dispersed in a mixture of 4.5 mL ODE and 1.5 mL ODA at 230 °C. Each monolayer was allowed to grow for 10 min before the next precursor solution was added). The CSS-QDs were purified by precipitation and redispersion in a chloroform/acetone mixture 3 times. The resulting core−shell−shell (CSS) QDs increased in size to 7.7 nm (±0.9 nm) and were photostable in air for months, with a QY of 60%. The CSS-QDs were incorporated in silica spheres by a reverse microemulsion method (*10*). In short, 1.3 mL Igepal was added to 10 mL cyclohexane and stirred for 15 min (850 rpm). Subsequently, 2 nmol of QDs (in 100 μL cyclohexane), 80 μL TEOS, and 150 μL ammonia was added with 15 min of stirring in between the additions. After the last addition, the mixture was stirred for 1 min, after which it was placed in the dark for 1 week. The resulting silica-coated QDs were centrifuged and redispersed in ethanol at least 3 times to remove excess reactants from the silica synthesis (i.e., Igepal, TEOS, ammonia, and water).

Lipid Coating of Silica Particles. The silica-coated QDs were subsequently capped with a hydrophobic ligand, by adding an excess of octadecanol (ODOH, 2.5 g in 5 mL of EtOH) to a dispersion of 2 nmol of silica-coated QDs in 5 mL ethanol. This mixture was first heated to 100 °C for 1 h to remove the ethanol, after which the temperature was raised to 170 °C for 3 h to covalently link the ODOH to the silica spheres by a condensation reaction (*38*). The QY of the CSS QDs and ODOH coated QD/silica particles was determined by integrating the emission spectra of these samples (in chloroform) and comparing it to the integrated emission of both Rhodamine 6G and Rhodamine 101 (assuming a QY of 90% and 95% for these dyes, respectively). Each emission spectrum was corrected for the relative absorbance of the sample at the excitation wavelength (497 nm in case of Rhodamine 6G and 528 nm in case of Rhodamine 101). Next, the ODOH-coated silica nanoparticles (with a QD incorporated) were dispersed in chloroform/methanol (20/1, v/v). PEG-DSPE, Mal-PEG-DSPE, and Gd-DTPA-DSA were added in a molar ratio of 0.4/0.1/0.5. The amount of lipids was 25 times higher than the calculated amount of lipids for a monolayer on all nanoparticles. This solution was added to a mildly basic HEPES buffer (20 mM HEPES, 135 mM NaCl, pH 6.7) under vigorous stirring, which led to the formation of an emulsion that was subsequently heated to 110 °C to evaporate chloroform. Upon evaporation of chloroform, the milky suspension converted into a clear dispersion indicative of the total removal of chloroform and the formation of lipid-coated QD/silica nanoparticles. The excess of lipids was removed by centrifugation (3000 rpm) of the lipid-coated QD/silica particles, which were redispersed in HEPES buffer. The cyclic 5mer RGD (c(RGDf(-S-acetylthioacetyl)K)) was conjugated to Mal-PEG-DSPE included in the lipid layer as described previously (*39*). In short, acetyl-protected peptide was deacetylated in 0.05 M Hepes/0.05 M hydroxylamine-HCl/0.03 mM ethylenediamine tetraacetic acid (pH 7.0) for 1 h at room temperature. The activated peptide was added to the Mal-PEG2000-DSPE containing particles. This preparation was stored at 4 °C under N_2 overnight.

Transmission Electron Microscopy (TEM) and Dynamic Light Scattering (DLS). A Tecnai 10 (FEI Company) transmission electron microscope, operated at an acceleration voltage of 100 kV, was used to take bright-field images. Samples were prepared for negative staining by exchanging the buffer for a 0.125 M ammonium acetate and 0.26 mM EDTA adjusted to pH 7.4. This solution was then mixed in a 1:1 ratio with a 2% sodium phosphotungstate negative stain solution (pH 7.4). Formvar-coated nickel grids were dipped in this solution and imaged shortly afterward. The TEM micrographs were processed using TIA software (Tecnai imaging and analysis software). Measurement of the size distribution of the ODOH coated QD/silica particles in chloroform and the Q-SiPaLCs suspended in deionized water was performed with a Malvern HPPS DLS (dynamic light scattering) instrument equipped with a He−Ne laser operating at 633 nm.

In Vitro Targeting Experiments. Human umbilical vein derived endothelial cells (HUVEC) were cultured on gelatin (0.2% in PBS) coated tissue culture flasks (Costar, Cambridge, MA) in culture medium, RPMI-1640 (Life Technologies, Breda, The Netherlands), 10% human serum, and 10% fetal calf serum (HS and FCS; University Hospital Maastricht, The Netherlands), 2 mM glutamine (Life Technologies), 50 U/mL penicillin, and

50 ng/mL streptomycin (ICN Biomedicals, Aurora, OH). For all incubations, 1.5×10^6 cells of passage 2−3 were used for experiments (at least $n = 2$). The cells were incubated for 8 h with RGD conjugated nanoparticles or control nanoparticles at a concentration of 0.07 nmol particles/mL medium. Association of the different nanoparticles to endothelial cells was assessed using fluorescence microscopy and magnetic resonance imaging. A Leica DMIL phase contrast fluorescence microscope (Leica Microsystems, Rijswijk, The Netherlands) equipped with a 20 W G4 HXL64250 Xenophot Halogen lamp (Leica) was used. Parallel phase contrast and red fluorescence (using a BP645−675 filter, Leica) images of the endothelial cell monolayers were taken at 200× magnification. All fluorescence microscopy scans were made with the same settings for laser power and detector sensitivity, allowing direct comparison between different incubations. The cell density for both incubations in Figure 2 was comparable, and therefore, the difference in fluorescence intensity arises from the difference in the level of association.

Fluorescence Imaging and MRI. Fluorescence imaging of cell pellets was performed using the Xenogen IVIS-200 small animal imaging system. A continuous external light source of 365 nm and an emission filter 610−630 nm were used.

MRI experiments were performed on a 6.3 T horizontal bore magnet (Oxford Instruments, England) interfaced to a Bruker (Bruker, Ettlingen, Germany) MR imaging console. A 3 cm quadrature-driven birdcage coil was used. The cups containing cell pellets were placed in a custom-made sample holder, capable of carrying 4 Eppendorf cups. For absolute quantification of T1, an inversion recovery fast T1-mapping sequence was used with 80 different inversion times. In the experiment, TR was 20 s, TE was 9 ms, and the slice thickness was 0.7 mm. For absolute quantification of T2, a multi-spin−echo sequence was used with TR 2000 ms and 32 echos that had a 9 ms echo spacing. A T1-weighted image of cell pellets of the three incubations was generated with a TR of 1500 ms. In this image, cells with a high content of Gd appear brighter than cells with a low content of Gd or no Gd. In all the MRI experiments, the FOV was 3 cm^2, the matrix size 128 × 128 voxels, and the slice thickness 0.7 mm.

RESULTS

Highly photostable and luminescent CdSe/CdS/$Cd_{0.5}Zn_{0.5}S$/ZnS core−shell−shell (CSS) QDs were synthesized according to a SILAR procedure reported by Xie et al. (*37*) Subsequently, a reverse micelle method reported earlier (*10*, *11*) was used to incorporate QDs in the center of highly monodisperse silica particles of 31 nm (±4 nm); see Figure 1A. The synthesis involved the dispersion of hydrophobic QDs in cyclohexane, to which a nonionic surfactant (Igepal), a silane precursor (TEOS, tetraethyl orthosilacate), and catalyst (ammonia) were added. The exact incorporation mechanism and details on the synthesis are published elsewhere (*40*). In short, hydrolyzed TEOS present in the initial reaction mixture (before adding ammonia) replaces the hydrophobic ligands on the QDs. The TEOS-coated QDs are then transferred to the hydrophilic interior of the reverse micelles, where subsequent silica growth takes place. The majority of the silica particles contained a single QD in the center, while only a small fraction of the silica particles contained 2 or more QDs per particle (Figure 1A). Although the QD/silica particles thus obtained are soluble in ethanol or water, the pharmacokinetics of charged surface particles are unfavorable, typically due to a short circulation half-life and/or accumulation in the lungs (*41*, *42*). In order to obtain bioapplicability by a dense lipid coating, the QD/silica particles were first made hydrophobic by an octadecanol (ODOH) coating. This was achieved using a well-known condensation reaction (*38*), where the alcohol group of ODOH reacts with the hydroxyl groups at the silica surface to form a covalent bond, neutralizing the surface charges. The hydrophobic QD/silica particles were subsequently coated with a dense

monolayer of lipids using a simple and fast procedure reported earlier for hydrophobic nanocrystals (*39, 43*). The procedure involves the addition of lipids and water to the hydrophobic QD/silica particles in chloroform, followed by the evaporation

of chloroform, leaving behind a clear suspension of well-dispersed, uncharged silica particles in lipidic micelles. The total synthesis procedure is schematically summarized in Scheme 1. The lipid coating is versatile, because in principle any (functional) amphiphile may be incorporated in this lipid layer. As an example, we have used a combination of Gd-DTPA-based lipids to introduce paramagnetic properties for MRI, pegylated lipids to improve biocompatibility, and maleimide-terminated (pegylated) lipids for conjugation of a biofunctional group. We will refer to the synthesized QDs in silica with a paramagnetic lipidic coating as Q-SiPaLCs.

The nanoparticles were characterized in terms of their size and optical and magnetic properties. We performed transmission electron microscopy (TEM) and negative staining TEM (Figure 1A) as well as dynamic light scattering (DLS) measurements to determine the morphology and size of the silica particles before and after applying the lipid coating. Negative stain TEM (which allows the visualization of hydrophobic substances) images were analyzed, revealing a hydrophobic layer of 3.9 nm ($\pm$0.5 nm) around individual particles, illustrated by the bright corona around the silica particle (Figure 1A, inset). This 4-nm-thick hydrophobic layer confirms the presence of both the ODOH coating around silica ($\sim$2 nm) and the stearyl chains of the lipids ($\sim$2 nm) around the particles. As well as size determinations established by TEM, the size of nanoparticles in an aqueous environment can be estimated using dynamic light scattering (DLS). This so-called hydrodynamic diameter was determined to be 50 nm for ODOH coated QD/silica particles, increasing to 58 nm after the application of the lipid coating (Figure 1B). This increase is in reasonable agreement with what one may expect in the case a single silica nanoparticle is coated with both paramagnetic lipids ($\sim$2 nm) and pegylated lipids ($\sim$10 nm). Figure 1C displays the absorption and emission spectra. The emission spectrum is shown for the final Q-SiPaLCs in HEPES buffer. The absorption spectrum in Figure 1C was measured for the QDs in silica with an octadecanol coating, dispersed in chloroform. The latter system is refractive-index matched (in contrast to the Q-SiPaLCs in water), allowing for a scattering-free absorption measurement and reliable determination of the quantum yield (QY). The absorption spectrum displays multiple absorption features as a result of discrete excitonic transitions in the CSS-QDs, which can be observed due to the high quality and monodispersity of the QDs. The initial QY of the CSS-QDs was 60%, but decreased as a result of the silica coating. This decrease is difficult to measure due to the scattering of the silica particles in ethanol, but it is estimated that the QY after silica coating is 25%. Coating the QD/silica particles with ODOH increased the QY to 35%, which could be accurately determined because of the scattering-free dispersion of the hydrophobic particles in chloroform. The QY of the lipid-coated QD/silica particles in water was slightly lower (by eye), which was again difficult to quantify due to scattering. It should be noted that a significant QY enhancement of the silica-coated QDs is observed upon UV illumination (which was avoided here when determining the QY, to obtain the lower limit). The silica coating and further coating steps did not change the shape of absorption or emission spectra of the QDs. A detailed discussion on the evolution of the QY of the QDs upon incorporation in silica and photoactivation is published elsewhere (*40*). The emission maximum of the CSS QDs lies at 630 nm. This relatively long wavelength is favorable for in vivo fluorescence imaging because of the lower autofluorescence levels of tissue for longer-wavelength excitation and the longer penetration depth into tissue of light with this wavelength.

To make the particle also suitable as an MRI contrast agent, Gd-DTPA-DSA was included in the lipidic coating of the Q-SiPaLCs. This paramagnetic amphiphile consists of Gd-DTPA, a clinically used contrast agent for MRI, and two saturated acyl chains with a chain length of 18 carbon atoms. To evaluate the performance as an MRI contrast agent, the longitudinal relaxation rates R1 of a dilution series were determined at 60 MHz, and Gd contents of these samples were determined by ICP-MS. From these data, the longitudinal relaxivity r1 of the Gd^{3+} ions was calculated to be 14.4 mM^{-1} s^{-1} (Figure 1D), which is a factor of 3$-$4 higher than free Gd-DTPA molecules in solution. This difference is ascribed to the lower tumbling rate of the Gd-lipids in the micelle compared to free Gd-DTPA molecules, enhancing the molar relaxivity (*35, 39, 44*).

As mentioned above, the number of Gd ions was determined by ICP-MS for a dispersion of Q-SiPaLCs. The concentration of Q-SiPaLCs in this dispersion was estimated from the initial number of QDs used for the silica synthesis at 0.24 μM. We found with ICP-MS that the concentration of Gd in the same dispersion was 0.60 mM, which gives a number of 2500 Gd-lipids per silica particle. The estimated maximum number of lipids in a densely packed lipid layer surrounding a 31 nm silica particle is approximately 5000, using a literature value of 60 A^2/lipid (*45*). Since half of the lipids consisted of Gd-DTPA-DSA, the estimated (2500) and experimentally determined (2500) number of Gd-lipids are in excellent agreement, confirming a dense coating of lipids around the Q-SiPaLCs. This is further confirmed by the number of Cd ions that was determined for the same dispersion using ICP-MS, which was found to be 0.50 mM. The number of Cd ions per CSS QD can be estimated to be approximately 2200, by assuming an average wurtzite unit cell volume of 1.1×10^{-28} m^3 (for CdSe, CdS, and CdZnS) with $Z = 2$ and taking into account the presence of Zn ions in the outer shells. Assuming a number of 2200 Cd ions per QD, the concentration of QDs in the dispersion is estimated to be 0.23 μM, which correlates well with the estimation above.

Taking into consideration that the 31 nm Q-SiPaLCs thus carry approximately 2500 Gd-DTPA-DSA lipids per particle (average between calculated and experimentally determined value), the r1 relaxivity per particle was estimated to be 36 000 mM^{-1} s^{-1}. The relaxivity of the Q-SiPaLCs per particle is thereby a factor of 21 higher than for our previously reported lipid-coated QDs (*39*), and a factor of 8$-$12 higher than Gd-wedge-coated QDs that were recently reported (*46*). In another recent report, the relaxivity of Gd-DOTA covalently attached to silica was determined to be 23 mM^{-1} s^{-1}, and apart from the lower tumbling rate, the very high relaxivity was ascribed to a higher water density close to the Gd-DOTA complexes due to the absence of lipids (*35*). However, their maximum relaxivity per particle was still a factor of 3 lower compared to the Q-SiPaLCs due to a lower payload of the paramagnetic complexes per particle. Similarly, the relaxivity per particle of Q-SiPaLCs is a factor of 40 higher than Mn-doped QDs that were recently reported, despite their high molar relaxivity of 18 mM^{-1} s^{-1} (*47*). Other lipid-based particles, such as liposomes (*48, 49*) or microemulsions (*50*), are capable of carrying a much higher payload of Gd-chelates (typically 25 000 to 100 000 molecules) and therefore exhibit a higher relaxivity per particle. On the other hand, such particles are considerably larger (100 to 250 nm). Apart from r1, we also determined the transverse relaxivity r2. The r2/r1 ratio determines whether a contrast agent is more suitable for T1-weighted or for T2-weighted MRI. This value was determined to be 1.6 for our nanoparticulate contrast agent and therefore can be considered an effective T1 agent.

The characterization of the Q-SiPaLCs shows that they form a very promising particle for dual modality imaging. A crucial aspect for application, however, is their ability to be targeted to specific cell types. To demonstrate the targeting potential of

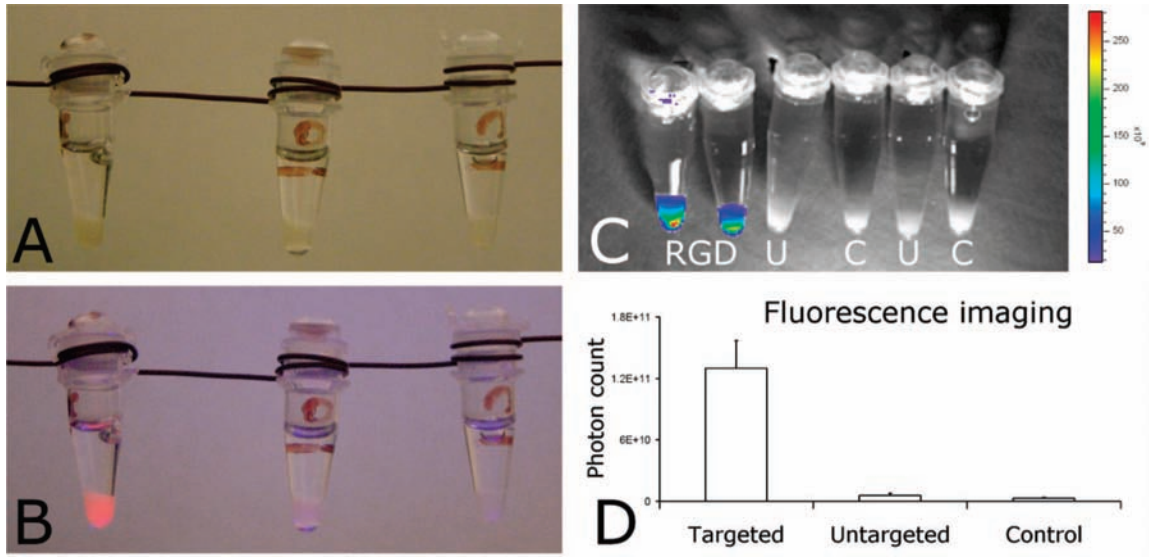

Figure 3. Pellets of cells incubated with RGD-conjugated targeted Q-SiPaLCs (left), non-conjugated untargeted Q-SiPaLCs (middle), and untreated control cells (right) (A) in daylight and (B) illuminated with 365 nm UV. (C) Overlay of a black/white photograph and quantitative fluorescence image of the different cell pellets under UV illumination at 365 nm (RGD = targeted, U = untargeted, C = control cells). The emission intensity from U and C is too low (less than 20×10^9 counts) to be displayed by one of the colors in the scalebar. (D) Mean photon counts of the different cell pellets.

this nanoparticle, it was tested on serum-activated human umbilical vein endothelial cells (HUVEC) in vitro. Nanoparticles can be targeted to these cells by conjugation of multiple RGD-peptides to the maleimide exposing PEG-lipids. These tripeptides specifically bind to $\alpha v\beta 3$-integrin, an adhesion molecule that is expressed by proliferating HUVEC (*51*). This receptor is also predominantly present at angiogenically activated blood vessels, such as those present in tumors (*52*), and has been used for identification of angiogenesis with molecular imaging (*51*). We conjugated ~650 RGD-peptides per particle using a method described previously (*39*). In short, thiol exposing peptides were covalently linked to the distal ends of maleimide-functionalized PEG lipids incorporated in the outer lipid layer of the particle. To assess the specificity of the contrast agent, HUVEC were incubated with either RGD-functionalized nanoparticles (targeted) or non-functionalized nanoparticles (untargeted, no RGD), or they were not incubated with nanoparticles (control). We first established the optimal incubation time on a limited number of cells. Thereafter, incubations were done for 7 h at 37 °C in tissue culture flasks containing $\sim 1.5 \times 10^6$ HUVEC ($n = 2$). Subsequently, cells were washed twice with PBS and fixed with 4% paraformaldehyde solution. In Figure 2A,B, bright-field and fluorescence microscopy images are shown of HUVEC that were incubated with RGD-conjugated nanoparticles. The Q-SiPaLCs are clearly associated with the cells and were found to be internalized at a perinuclear location. Fluorescence images of HUVEC incubated with untargeted Q-SiPaLCs (no functionalization by RGD) showed marginal or no fluorescence (Figure 2C,D), similar to the untreated control cells (not shown). These results demonstrate that lipid-coated QD/silica particles conjugated with RGD peptides are actively taken up by the activated endothelial cells, and that nonspecific uptake (even after 7 h of incubation) is negligible.

Next, the cells were collected and transferred into small Eppendorf cups. In daylight, there is no visual difference between the different loosely packed cell pellets (Figure 3A). Under UV illumination (365 nm), only the cells that had been incubated with RGD conjugated Q-SiPaLCs exhibit a bright red fluorescence and could clearly be distinguished from the two other cell pellets (Figure 3B). In addition, we performed quantitative fluorescence imaging on the different cell pellets (Figure 3C) using the Xenogen IVIS-200. An external illumination source of 365 nm was used, while the photon count was acquired using a spectral imaging filter of 620 nm. In Figure 3D, the mean photon counts of cell pellets incubated with targeted particles, cell pellets incubated with untargeted particles, and control cell pellets are depicted. ~25-fold and ~50-fold differences in photon count were found between the targeted and untargeted cell pellets and the targeted and control pellets, respectively.

Finally, MRI was performed on these cell pellets. A T1-weighted image of the different cell pellets is depicted in Figure 4A and clearly demonstrates higher signal intensity for the pellet of cells incubated with the RGD-conjugated Q-SiPaLCs (the bright white circle) as compared to the control cell pellets (gray circles). In addition, T1 relaxation times were determined in order to allow a more quantitative evaluation of Q-SiPaLCs as a MRI contrast agent. The mean values were 1706 ms, 2189 ms, and 2460 ms, for cells incubated with the targeted particles, cells incubated with untargeted particles, and untreated cells, respectively. The differences in relaxation rate R1 (1/T1) between control cell pellets and cell pellets that were incubated with the nanoparticles correlate with the concentration of contrast agent in the cell pellets. Therefore, we calculated these differences in mean relaxation rates between the control cell pellets and the targeted or untargeted cell pellets. The values clearly demonstrate the effective and specific targeting of this nanoparticulate agent to angiogenically activated endothelial cells (Figure 4B). (Scan parameters are in the Experimental Procedures section.)

DISCUSSION

The Q-SiPaLCs reported here demonstrate the integration of multiple imaging properties in a single bioapplicable nanoparticle and the specific uptake by living cells. This nanoparticulate probe has several advantages over existing agents in terms of detection sensitivity (contrast) due to the high fluorescence quantum yield (35%) and high relaxivity. It presents a new and versatile platform for a wide range of contrast agents suitable for multimodality imaging. Although the QDs were incorporated in silica, more effort needs to be attributed to developing novel stable QD formulations that are not based on Cd to further reduce toxicity. In addition, for in vivo fluorescence imaging

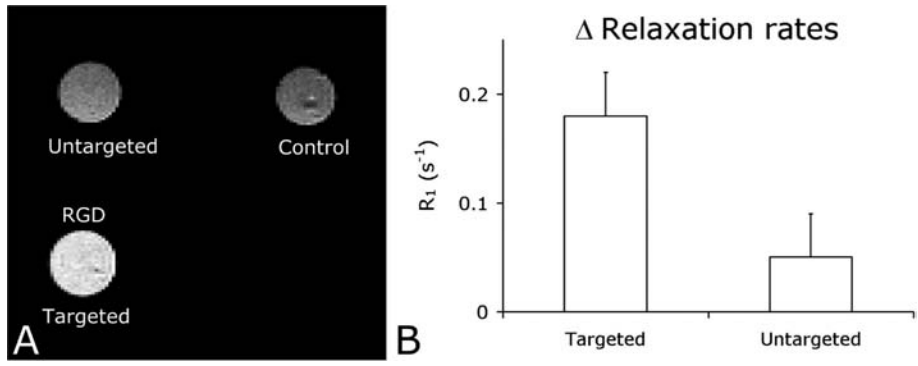

Figure 4. (A) T1-weighted MRI of the different cell pellets (same pellets as displayed in Figure 3) revealed specific uptake of the targeted nanoparticles. (B) Difference in relaxation rates (R1) of the targeted and untargeted cell pellets compared to the relaxation rate of the control cell pellet (set to zero). The differences in relaxation rate reflect the concentration of contrast agent in the untargeted and targeted cell pellets.

purposes, fluorophores that emit photons with a wavelength between 700 and 800 nm have significant advantages, especially for deep tissue imaging (*53*). Therefore, this platform would be more widely applicable if further modified to emit in the near-infrared.

In biomedical research, the two main applications of nanoparticles are their use as carriers for drugs and diagnostic active materials. Their size varies from a few nanometers (QDs, iron oxide nanoparticles, micelles) (*39, 54, 55*) up to hundred nanometers (liposomes) (*2*) and even several hundred nanometers (microemulsions) (*50*) to micrometers (microbubbles) (*56*). Depending on the application and, importantly, the targeted site (vascular versus extravascular), the size may dictate effectiveness. For example, in a study by Stroh et al. it was shown that QD containing silica particles of different sizes (100 nm versus 500 nm) extravasate from the vasculature into the tumor to differing extents (*57*). Furthermore, size also dictates the clearance pathway of nanoparticles and has a significant effect on the circulation half-life. A recent study by Choi et al. (*58*) has revealed renal clearance of particles with a hydrodynamic diameter of less than 5.5 nm. Such small particles are therefore cleared from the circulation relatively fast as compared to, e.g., long-circulating liposomes. The latter platform has a typical size range of 100 to 200 nm and is used extensively in the field of drug targeting, both preclinically and clinically (*2*). The advantage of the current platform in terms of particle size is twofold. First, the nanoparticles are highly monodisperse, as a result of the reverse micelle method used to grow a silica shell of a well-defined thickness. Another great advantage of our particles is that they can be easily and accurately tuned to any desired size from ~20 nm to over 1 μm, by increasing the diameter of the silica spheres. The silica shell is also expected to prevent leaking of Cd and thus reduce the cytotoxicity due to the Cd-containing quantum dots. In addition, any desired fluorescence color or a combination of colors can be chosen to allow for multiplexing or "bar-coding" (*59*), by inserting different kinds of QDs in the silica spheres. Furthermore, due to the high surface area of the Q-SiPaLCs, a high payload of Gd-DTPA-DSA lipids can be integrated per particle. Therefore, the relaxivity per particle is high and can even be increased significantly by increasing the size of the silica particle. Target specificity can be introduced using PEG-lipids with a functional moiety, like maleimide used in this study. The number of functional groups can be varied, which allows the creation of a particle with multiple ligands. This can increase the targeting efficiency of the particle due to multivalent interactions. This is an important issue, since it was recently reported that the target specificity of maleimide-targeted QDs may be poor when a single QD contains less that 1 target peptide per QD, making the uptake highly nonspecific, especially due to the small size of a single QD (*60*). The design of our Q-SiPaLCs solves this problem, because of the possibility of attaching multiple ligands per particle. Furthermore, the nonspecific uptake of the Q-SiPaLCs by HUVEC is shown to be negligible in this study. The nanoparticles as designed in the present report can be applied for imaging of ongoing angiogenesis as a diagnostic tool in the management of cancer. Next to the RGD-peptides used in this study, other ligands, such as antibodies (*61*), antibody fragments (*62*), or proteins (*63*) may be conjugated in a similar fashion. The PEG-lipids that surround the Q-SiPaLCs ensure good pharmacokinetics and an improved biocompatibility of the nanoparticles.

Finally, the presently reported contrast agent design offers numerous possibilities to integrate a wide range of properties for multimodality imaging. We have successfully demonstrated a general and effective pathway for making silica (nano)spheres bioapplicable and target-specific. We have recently investigated the biocompatibility and biodistribution properties of the Q-SiPaLCs. In vitro, an elevated cell vitality was shown for the lipid-coated particles as compared to the bare particles, while in vivo the lipid-coated QD/silica particles displayed increased circulation half-lives as a result of a diminished reticuloendothelial system clearance rate (*64*). In the future, this method can be applied to any combination of contrast agents incorporated in silica to make them suitable for biomedical applications. For example, magnetite nanoparticles (for MRI detection), gold or bismuth nanoparticles (for CT or EM detection), or fluorescent materials (QDs, dyes, phosphor nanocrystals) can readily be integrated in silica and can be made bioapplicable through the procedure reported here. Additional properties may be added to the particle by inserting paramagnetic or fluorescent amphiphiles in the lipidic coating, for example. Drug delivery and gene targeting may also be functionalities that can be accomplished using this biocompatible silica nanoparticle platform.

In summary, we have developed a new method for making bioapplicable silica nanoparticles that can serve as a contrast agent for target-specific multimodality imaging. The nanoparticle is composed of a QD incorporated in a silica sphere of 31 nm. First, the silica surface is made hydrophobic, and subsequently, it is surrounded by pegylated, paramagnetic, and biofunctional lipids. This results in a highly monodisperse, fluorescent, and paramagnetic contrast agent suitable for both fluorescence imaging and MRI studies, and it shows a highly specific uptake by HUVEC. The use of the presently reported method for creating biocompatible and target-specific silica nanoparticles opens a new platform for multimodality imaging contrast agents by integrating any desired combination of contrast agents in the silica nanoparticle and inserting (combinations of) functional amphiphiles in the lipidic coating.

Circularly Permutated Bioluminescent Probes for Illuminating Ligand-Activated Protein Dynamics

Sung Bae Kim, Moritoshi Sato, and Hiroaki Tao*

Research Institute for Environmental Management Technology, National Institute of Advanced Industrial Science and Technology (AIST), 16-1 Onogawa, Tsukuba 305-8569, Japan, and Graduate School of Arts and Sciences, The University of Tokyo, 3-8-1 Komaba, Meguro-ku, Tokyo 153-8902, Japan. Received September 5, 2008; Revised Manuscript Received November 3, 2008

Engineered bioluminescent enzymes provide a creative approach for illuminating the intracellular molecular events. We demonstrate a new strategy for molecular imaging of bioactive small molecules using circularly permutated luciferases (cpLuc), derived from *Gaussia princeps* (GLuc), *Photinus pyralis* (FLuc), and *Pyrearinus termitilluminans* (CBLuc): (i) the luciferases were first dissected into two fragments, (ii) the original N- and C-termini were linked with a GS linker and the new termini were created in an appropriate site, and (iii) the new ends were correspondingly linked with proteins of interest, e.g., a ligand-binding domain (LBD) and an LBD-recognition protein. When the ends of the cpCBLuc were linked with LBD of estrogen receptor (ER) and Src homology 2 domain of Src (SH2 of Src), the estrogen can trigger an intramolecular ER LBD-Src SH2 binding. This assembly subsequently provokes an approximation of the adjacent fragments of cpCBLuc recovering the enzyme activity. These probes were surprisingly stable in the mammalian cells and largely exhibited a decreased background luminescence (e.g., 1000 times in case of cpGLuc) and improved signal-to-noise ratios, compared with the non-CP indicators. This study offers a new strategy for luciferase-aided probing systems. Our study is the first to fabricate circular permutation (CP) in luciferases for tracing the molecular dynamics of proteins.

INTRODUCTION

Engineered functional proteins have provided major contributions to advancements in the bioindustry and have brought a breakthrough in the treatment of human diseases. Manipulation of enzymes as functional proteins is largely governed by the knowledge of the principles that direct enzyme catalysis and enzyme structures, elucidated by X-ray crystallography (*1*). Recent revolutionary advances in enzyme manipulation technologies now allow researchers to carry out quantitative examination of the molecular dynamics and cell signaling in living cells (*2*). While the green fluorescent protein (GFP) that acts as an excellent functional protein has been widely used, enzymes catalyzing light emission are currently proving their distinguished advantages in the quantitative, specific, signal-enhanced, noninvasive, and real-time investigation of intracellular molecular events (*3*−*9*).

As a creative approach for probing molecular events, a circular permutation (CP) of bioluminescent enzymes can be an effective technique. Many of the beetle-derived bioluminescent enzymes are members of a superfamily of acyl-adenylate forming enzymes and consist with larger N-terminal and smaller C-terminal domains (*10*, *11*). When the active-site region between the domains is dissected into two fragments, the activity of the enzyme may be temporally lost. A dissected active site can be placed in the opposite side of the other dissected site in the probe backbone, by CP. Upon stimulation of the ligand, the fragmented luciferase recovers its activity via an intramolecular complementation. As the possibility of encounter between the fragmented active sites by CP is rare, we can expect a dramatic decrease in the background activity of the enzyme and an enhancement of the signal-to-background ratios. The molecular structure is illustrated with the firefly luciferase (FLuc), as shown in Figure 1.

On the basis of this speculation, the feasibility of an indicator with circularly permutated luciferases was explored with the luciferases derived from *Gaussia princeps* (Gaussia luciferase (GLuc); Nanolight), *Photinus pyralis* (firefly luciferase (FLuc); Promega), and *Pyrearinus termitilluminans* (click beetle luciferase (CBLuc); Promega).

We first examined the circularly permutated CBLuc (cpCBLuc) for illuminating the phosphorylation of estrogen receptor (ER), and cpFLuc for imaging the ligand-stimulated protein−protein interactions. The original N- and C-termini of CBLuc were linked with a GS linker, and the new N- and C-termini were constructed between I439 and K440 of CBLuc. Each end of the cpCBLuc was extensively linked with the ligand binding domain of the estrogen receptor (ER LBD) and the Src homology 2 domain of Src (Src SH2). This fusion protein was surprisingly expressed stably in mammalian cells and tolerated the insertion of ER LBD and Src SH2. The probe was sensitive to 4-hydroxytamoxifen (OHT) and emitted the characteristic bioluminescence. Similarly, we synthesized a bioluminescent probe that traces the real-time dynamics of Ca^{2+} as a representative second messenger in living mammalian cells.

In Figure 1, the current mechanism of the CP of enzymes is illustrated with the structure of FLuc, as the crystal structures of CBLuc and GLuc were not presented. It should be noted that Ca^{2+} and estrogen are a typical second messenger and a major steroid hormone, respectively. Thus, the above-mentioned examples of GLuc and CBLuc demonstrate the general applicability of the current CP concept in illuminating the protein dynamics in living mammalian cells.

EXPERIMENTAL PROCEDURES

Plasmid Construction. The respective cDNA fragments consisting of circularly permutated luciferase probes were generated by the polymerase chain reaction (PCR) to introduce each unique restriction site at each end of the fragments, using adequate primers and templates. For example, a plasmid carrying Yellow

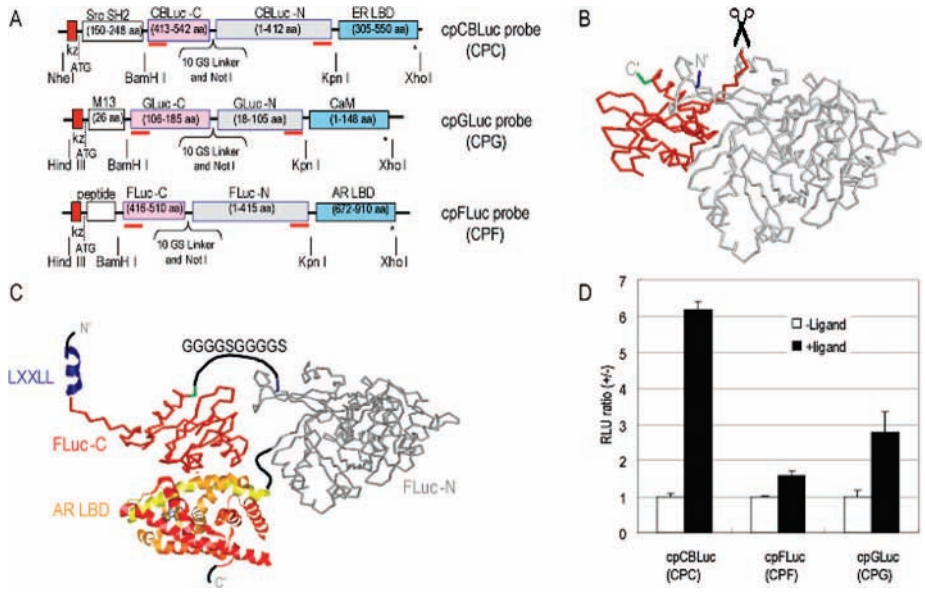

Figure 1. (A) Schematic diagram of circularly permutated luciferase probes. The original N- and C-terminals of CBLuc, GLuc, and FLuc were fused with a 10 GS linker. On the other hand, their new terminal ends were created at I439, Q105, and D415, respectively. Abbreviations: Src SH2, SH2 domain of Src; CBLuc-N and -C, N- and C-terminal fragment of click beetle luciferase; ER LBD, ligand binding domain of estrogen receptor; M13, a 26-residue calmodulin-binding peptide of myosin light-chain kinase; CaM, calmodulin. (B) The crystal structure of firefly luciferase (FLuc). N- and C-terminal fragments are colored gray and red, respectively. The scissors mark shows the dissected point (D415) in the structure. (C) Comprehensive illustration of the molecular structure of CPF as an example. (D) Comparison of the ligand sensitivities of the present CP probes. The luminescence intensities from COS-7 cells carrying each probe were determined in the presence or absence of the specific stimulators, i.e., OHT for CPC, DHT for CPF, histamine for CPG.

Cameleon-3.1 (YC3.1), donated by Dr Miyawaki (*12*), was utilized as a template for amplifying *Xenopus laevis* CaM, by using PCR. A cDNA encoding humanized *Gaussia princeps* luciferase (GLuc; Nanolight) was consumed as a template of PCR for generating the N- and C-terminal fragments, where the known N-terminal secretion signal (1−17 AA) of GLuc was excluded for confining GLuc to the cytoplasm as determined before (*6*, *13*). The synthesized constructs are illustrated in Figure 1A. The enzyme-restricted cDNA fragments were tandemly ligated, as shown in Figure 1A, and subcloned into pcDNA 3.1(+) (Invitrogen). The plasmids were named pCPC (cpCBLuc probe), pCPG (cpGLuc probe), and pCPF (cpFLuc probe), according to the type of luciferases that were circularly permutated in the single-chain probes. The expressed fusion probes may be called CPC, CPG, and CPF, respectively.

In addition, the cDNA of ER LBD in pCPC was point-mutated at Y537 from TAT to TTT, i.e., Y537F. The construct was subcloned into the pcDNA 3.1(+) backbone. This plasmid was named pCPC-mut. As another reference to our cpCPC probe, a probe with straight-ordered fragments of luciferase was similarly constructed, as shown in Figure 3B. The N- and C-terminal fragments were tandemly fused in the straight order, where a 10 GS linker was intervened between the fragments. Then, the N- and C-terminal ends of chimera cDNA were flanked with cDNAs of Src SH2 and ER LBD, respectively. The plasmid with this construct was named pCPC-ctrl. In addition, an integrated-molecule-format (IMF) probe was constructed in parallel, as illustrated in Figure 3D. The plasmid was named pSMC. As a reference to CPG, an IMF probe was constructed, as shown in Figure 5B. The plasmid encoding this probe was named pCPG-ctrl.

All the plasmids constructed for this study were sequenced to ensure fidelity, using a BigDye Terminator Cycle Sequencing kit and a genetic analyzer ABI Prism310 (Applied Biosystems).

Comparison of Relative Luminescence Intensities by CPC, CPF, or CPG. The relative luminescence intensities by CPC, CPF, or CPG were compared in the presence or absence of each ligand (Figure 1(D)). COS-7 cells derived from African green monkey kidney were cultured in a 24-well plate with Dulbecco's modified Eagle's medium (DMEM; Sigma), supplemented with 10% steroid-free fetal bovine serum (FBS) and 1% penicillin−streptomycin (P/S) at 37 °C in a 5% CO_2 cell incubator (Sanyo). The COS-7 cells were transiently transfected with pCPC, pCPF, or pCPG (0.2 μg per well) using a transfection reagent, TransIT-LT1 (Mirus). The cells were extensively incubated in the CO_2 incubator for 16 h.

The cells carrying pCPC or pCPF were stimulated with 10^{-6} M of OHT or dihydrotestosterone (DHT) (final concentration). The luminescence intensities were developed with a Bright-Glo substrate solution (Promega) and integrated for 15 s using a luminometer (Minilumat LB9506; Berthold). The brief procedure for the use of the Bright-Glo substrate solution is as follows: The mammalian cells were washed once with PBS, 20 min after stimulation with a ligand. 40 μL of the substrate (D-leuciferin) solution was added to each well of the plates. Three minutes after substrate addition, the plate was tapped gently, and the subsequent cell lysates were transferred to a test tube for determination of the luminescence intensities.

One the other hand, the cells carrying pCPG were harvested by trypsinization and centrifugation. The cells were gently mixed with a 40 μL substrate (coelenterazine) solution containing 1 mM histamine or PBS. The luminescence intensities were then determined with the luminometer (Minilumat LB9506).

Comparison of the Ligand Sensitivity of CPC and CPC-mut. We examined whether the phosphorylation of ER LBD at Y537 motivated the intramolecular interaction between Src SH2 and ER LBD in the CPC and CPC-mut, as illustrated in Figure 2B. COS-7 cells cultured in a 24-well plate were transiently transfected with pCPC or pCPC-mut. Sixteen hours after transfection, the cells were stimulated with various ligands (10^{-6} M) for 20 min. The ligands used were as follows: vehicle (0.1% DMSO; final concentration), OHT, estrone, E_2, DHT, and cortisol. The subsequent luminescence intensities were estimated with the luminometer.

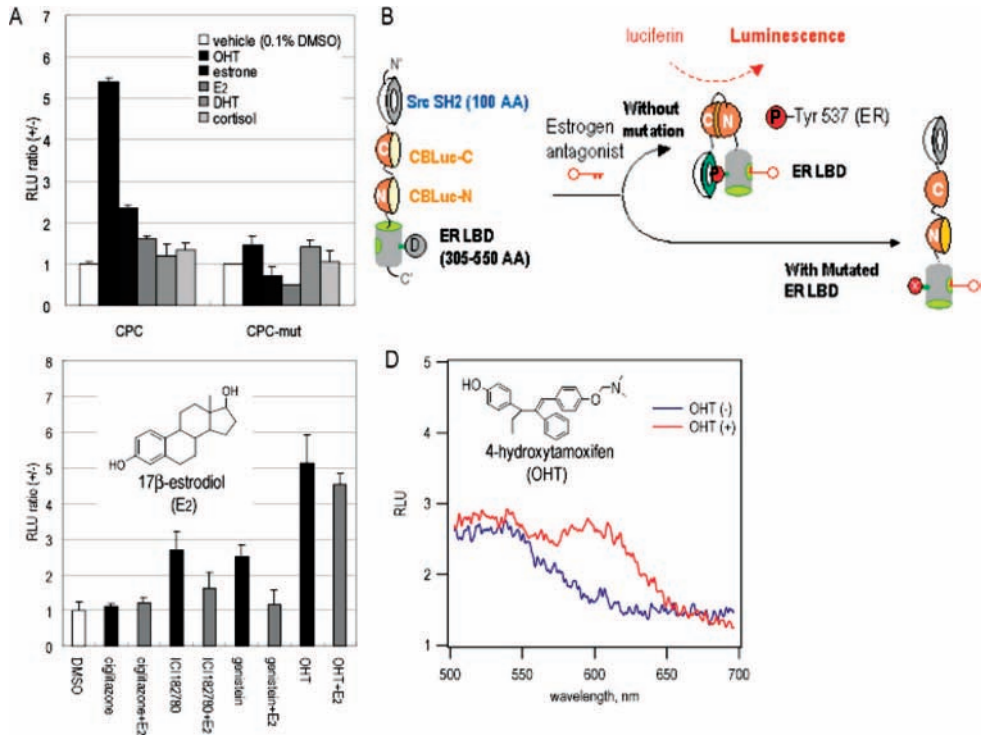

Figure 2. (A) Mutagenesis study for the association of ER LBD with Src SH2 domain. Tyrosine 537 in ER LBD is replaced with lysine, and the plasmid is named pCPC-mut. The luminescence intensities from COS-7 cells carrying pCPC or pCPC-mut are compared in response to various ligands ($n = 3$). (B) Comprehensive illustration of ligand-sensing mechanisms of CPC and CPC-mut. OHT−ER LBD binding exerts phosphorylation of ER LBD at Y537, which subsequently triggers Src SH2−ER LBD interactions. On the other hand, mutation at Y537 demolishes this interaction. (C) Relative sensitivity of CPC to various antagonists. E_2 competed with the antagonists for binding ER LBD. (D) Spectra from the COS-7 cells carrying CPC before and after stimulation of OHT.

Comparison of Inhibitory Effects of E_2 to Antagonist-Bound CPC. On the basis of the result that CPC is sensitive to ER antagonists, and not to the agonists, the inhibitory effects of E_2 to the antagonized CPC were examined (Figure 2C). COS-7 cells cultured in 24-well plates were transiently transfected with pCPC. Sixteen hours after transfection, the cells were prestimulated with 10^{-5} M E_2 for 5 min. The cells were additionally incubated with one of the following nuclear receptor antagonists (10^{-6} M: final concentration): ciglitazone, ICI182780, genistein, or OHT. The resulting luminescence intensities were compared with those from the cells stimulated with an antagonist alone.

Comparison of the Ligand Sensitivity of CPC and CPC-ctrl. The ligand sensitivity of CPC was compared with the CPC-ctrl (Figure 3A). COS-7 cells cultured in 24-well plates were transiently transfected with pCPC or pCPC-ctrl. Sixteen hours after transfection, the cells were stimulated with varying concentrations of E_2 or OHT for 20 min. The resulting luminescence intensities were recorded with the luminometer.

Dose−Response Curves of CPC to Ligands and the Comparison with CPC-ctrl. Ligand sensitivity of CPC in COS-7 cells was examined with varying concentrations of steroids (Figure 3C). COS-7 cells cultured in the 24-well plates were transiently transfected with pCPC. Sixteen hours after transfection, the cells were stimulated with varying concentrations of ligands. The developed luminescence intensities were recorded with the luminometer (Minilumat LB9506).

As another reference to CPC, the sensitivity of SMC was examined in parallel with the same experimental condition as CPC. COS-7 cells carrying pSMC were stimulated with varying concentrations of OHT, and the resulting luminescence intensities were determined with the luminometer (Minilumat LB9506).

Kinetics of Ligand−Probe Binding. The kinetic aspects of ligand−probe binding were estimated with COS-7 cells carrying pCPC (Figure 4). COS-7 cells cultured in 12-well plates were transiently transfected with pCPC and incubated for another 16 h. The luminescence intensities were recorded at 2, 5, 10, 20, and 30 min after the addition of 10^{-6} M OHT or vehicle (0.1% DMSO).

In the meantime, relaxation of the OHT−CPC binding was examined by refreshing the culture medium after OHT stimulation (Figure 4B). The cells carrying pCPC were stimulated with 10^{-6} M OHT or vehicle (0.1% DMSO) for 20 min, and the culture media were then replaced with fresh, ligand-free media. The luminescence intensities at 10, 20, and 60 min after medium replacement were developed with a Bright-Glo substrate solution. The intensities at each time period were compared with those from the cells mock-stimulated with the vehicle (0.1% DMSO).

Comparison of Relative Luminescence Intensities after Being Screened by Bandpass Filters. The wavelengths of light emitted from COS-7 cells were examined by using a series of bandpass filters (Figure 4C). COS-7 cells cultured in a 24-well, glass-bottom plate were transfected with pCPC and incubated for 16 h. The cells were saturated with a 500 μL Hank's balanced salt solution (HBSS) buffer containing coelenterazine and one of the following stimulators: vehicle (0.1% DMSO), 10^{-6} M E_2, or 10^{-6} M OHT. Twenty minutes after stimulation with the ligand, the relative luminescence intensities from the cells were monitored with a series of bandpass filters, whose wavelengths were as follows: 510 ± 10 nm, 535 ± 10 nm, 540 ± 10 nm, 560 ± 10 nm, and 610 ± 10 nm.

Determination of the Ca^{2+} Dynamics in COS-7 Cells with CPG. The dynamics of the cytosolic Ca^{2+} in COS-7 cells were monitored with CPG and CPG-ctrl (Figure 5A). COS-7 cells cultured in a black, glass-bottom plate (24-well) were transfected with pCPG or pCPG-ctrl, and incubated in a cell incubator for 16 h. The cells were saturated with 300 μL HBSS buffer

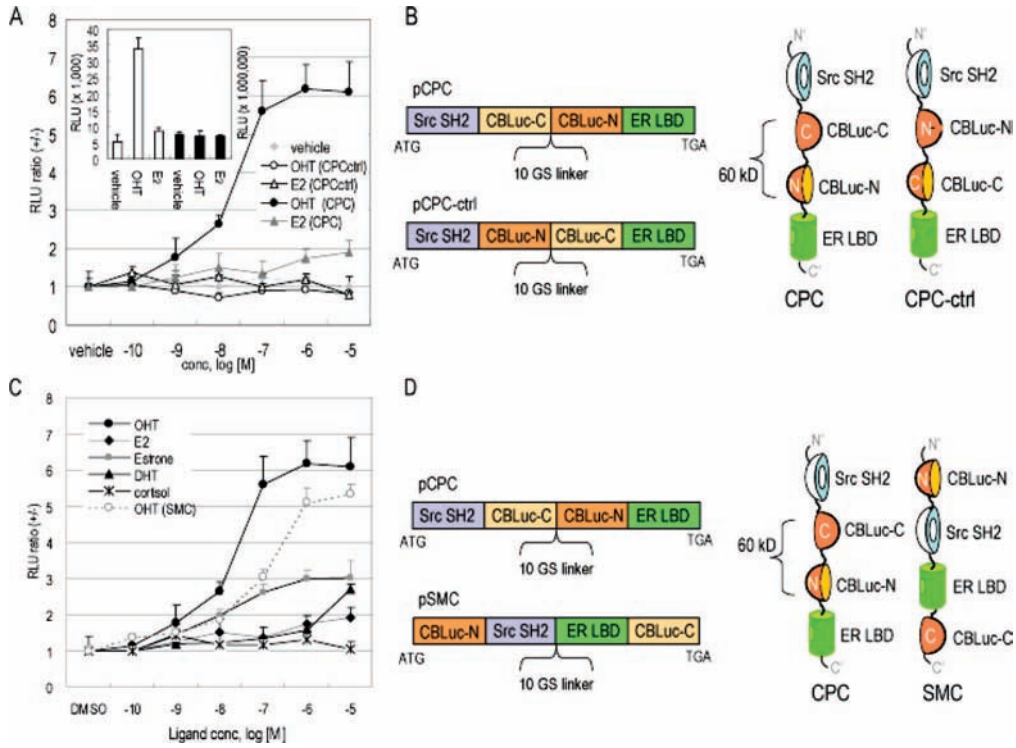

Figure 3. Ligand sensitivity of CPC. (A) Comparison of ligand sensitivity of CPC and CPC-ctrl. Inset shows the absolute luminescence intensities from the cells carrying CPC and CPC-ctrl in response to OHT and E_2. The left *X*-axis shows the luminescence intensities by CPC (open bars), whereas the right *X*-axis indicates the intensities by CPC-ctrl (closed bars). (B) Comprehensive illustration of the molecular structures of CPC and CPC-ctrl. Abbreviations: OHT, 4-hydroxytamoxifen; E_2, 17β-estradiol; DHT, dihydrotestosterone; Src SH2, Src homology 2 (SH2) domain of Src; ER LBD, ligand binding domain of estrogen receptor; CBLuc-N and -C, N- and C-terminal domains of click beetle luciferase. (C) Dose−response curves of CPC in response to varying concentrations of ligands. (D) Illustrative comparison of the molecular structures of CPC and SMC.

containing coelenterazine. The luminescence variances were monitored with a bioluminescence plate reader (Mithras LB 940; Berthold) every 30 s before and after the addition of histamine in the range 0.1−1 mM.

RESULTS

Structural Basis of CPC and Its Phosphorylation Recognition. The Y537 in ER LBD was phosphorylated upon the stimulation of ER ligands, which is sensitively recognized by the Src SH2 domain (*14*). We utilized this typical non-genomic interaction of ER with Src in constructing our CP probe. This phosphorylation-mediated binding was compared with a reference probe carrying point-mutated ER LBD at Y537F (CPC-mut) (Figure 2A,B). CPC recognized various steroids and was particularly sensitive to an estrogen antagonist, OHT, whereas CPC-mut was insensitive to all the ligands (Figure 2A). The results show that (i) the intramolecular interactions occur via phosphorylation of ER LBD at Y537, (ii) Y537 in ER is phosphorylated ligand-dependently, (iii) the luminescence intensities by CPC are capable of indexing the antagonistic activities of ligands, and (iv) from an analytical point of view, signal-to-noise ratios are large enough to discriminate among the non-genomic activities of the ligands. It was previously debated on whether 17β-estradiol (E_2) exerts phosphorylation of ER at Y537. Our experiment reveals that not only E_2 but also OHT could induce phosphorylation of ER at Y537. Although both E_2 and OHT phosphorylate ER LBD, OHT may induce more favorable conformational changes of ER LBD in the recovery of CBLuc activity than E_2. This observation is analogous to an earlier luciferase study on ER antagonists (*5*).

We also examined the influence of E_2 on CPC-antagonist binding (Figure 2C). E_2 negatively contributed to the luminescence intensities developed by the antagonists. The results show that the (i) antagonists compete with E_2 in binding ER LBD, and (ii) OHT is the most efficient antagonist barely influenced by 10× excess of E_2.

Luminescence spectra were obtained for examining whether the recovery of the red−orange light is selective to OHT (Figure 2D). The spectra showed that red−orange light was enhanced by OHT and the λ_{max} was the same as that of intact CBLuc. This result was in concordance with the results with bandpass filters in Figure 4C and also with the result of our previous study (*9*).

Comparison of Ligand Sensitivity of CPC with That of Its Non-CP Controls. The ligand sensitivities of CPC were examined with varying doses of steroids (Figure 3). CPC selectively sensed OHT and even responded to 10^{-9} M of OHT. The half-maximal effective concentration (EC_{50}) was approximately 5×10^{-8} M. On the other hand, CPC-ctrl did not show any luminescence variance in response to OHT or E_2 (Figure 3A). The reason was found to be in the extremely high background luminescence, even in the absence of stimulators. The background luminescences by CPC-ctrl were ca. 1000 times higher than those by CPC. This resulted in poor signal-to-noise ratios, as shown in Figure 3A.

CPC showed a 10-fold enhanced detection limit, when compared with a CP-free probe (SMC) (Figure 3C). The structural difference between CPC and SMC is illustrated in Figure 3D. Even in the absence of a stimulator, SMC emitted a background luminescence that was seven times stronger than CPC, i.e., 38 500 vs 5500 RLU ($n = 3$). The reason for the improved detection limit is explained by the fact that CP of CBLuc decreases the basal interactions between the ER LBD and SH2 in the absence of a ligand.

Kinetics of CPC−Ligand Binding. The ligand-sensing kinetics of CPC was monitored with COS-7 cells carrying pCPC (Figure 4). The luminescence intensities by CPC were greatly enhanced from 5 min after OHT addition and reached a plateau

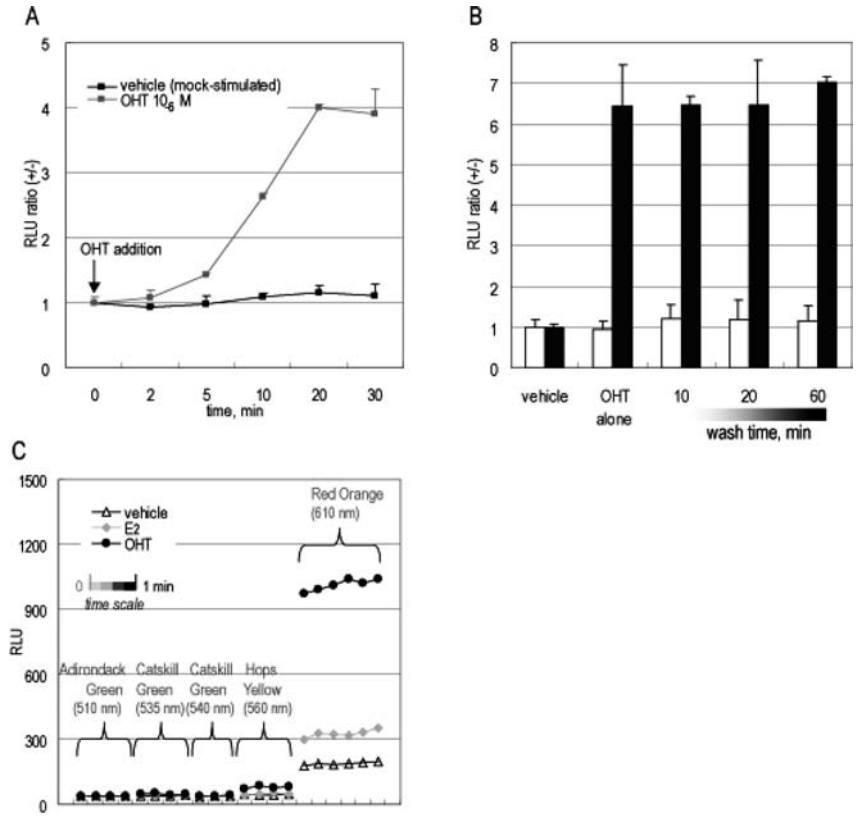

Figure 4. Ligand-binding kinetics of CPC. (A) Time course of OHT-CPC binding was examined. At 2, 5, 10, 20, and 30 min after OHT−CPC binding, the luminescence variances were monitored. (B) Cancellation of OHT−CPC binding by medium replacement was determined. The luminescence intensities were retained until 60 min after medium replacement. (C) Relative luminescence intensities after being screened by bandpass filters. The light from the cells carrying CPC passed well through a 610 nm bandpass filter, indicating that the signal is red−orange light.

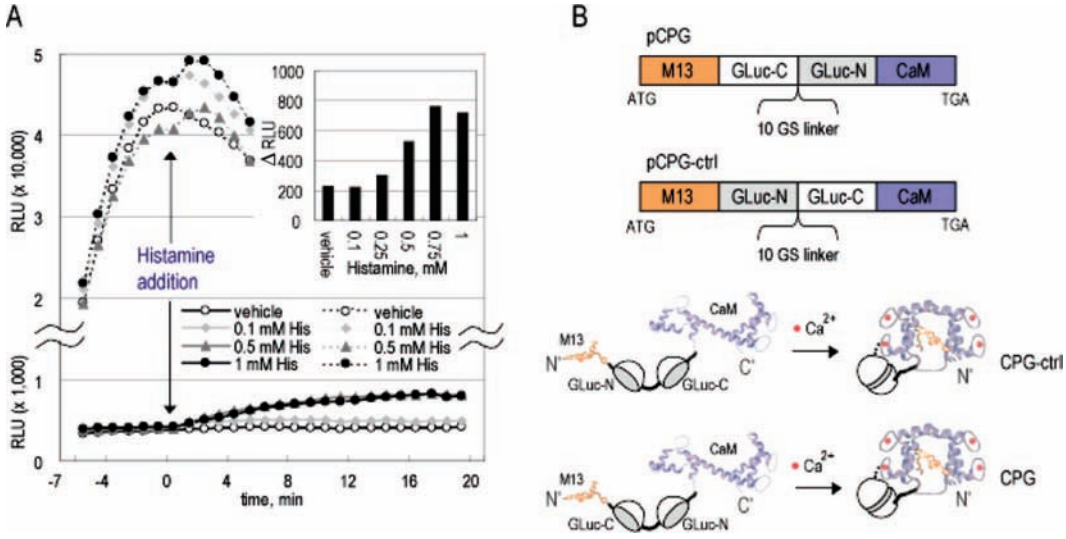

Figure 5. (A) Comparison of ligand-binding kinetics of CPG (solid lines) with that of SMG (dot lines). Inset shows the increased luminescence intensities due to histamine ($n = 3$). (B) A cartoon diagram showing the Ca^{2+} recognition and conformation changes of CPG and CPG-ctrl. Abbreviations: GLuc-N and -C, N- and C-terminal fragments of *Gaussia* luciferase; ΔRLU, change in the amount of luminescence intensity in the presence or absence of histamine; M13, calmodulin-binding peptide of myosin light-chain kinase; CaM, calmodulin.

in 20 min. The total response time, 20 min, comprised the total time for (i) penetration of OHT across the plasma membrane, (ii) OHT−ER LBD binding and conformation change of ER LBD, (iii) subsequent binding of ER LBD with Src SH2, and (iv) intramolecular complementation between the fragments of CBLuc. Using cell-free assays, it was previously proven that the net ligand−ER binding and conformation change of ER were completed within 1 min (*15*). Therefore, it can be considered that the large portion of the total response time, 20 min, was consumed during the penetration of OHT into the cytosol. This response time is considerably slower than those shown by our previous probes (*10*, *16*). Hydrophilicity of OHT, when compared with other steroids, may cause the late plasma membrane penetration.

Dissociation kinetics of CPC-ligand binding was examined with COS-7 cells carrying pCPC (Figure 4B). First, the cells were stimulated with OHT for 20 min. The culture medium was then replaced with a fresh, OHT-free medium. The

luminescence intensities within 1 h after the change of the medium were not decreased considerably. Even washout for 60 min did not weaken the luminescence intensities from the cells. These results show that OHT-triggered Src SH2−ER binding can be endured for quite a long time.

Wavelengths of Light Emitted from COS-7 Cells Carrying pCPC. The wavelengths and intensities of light from COS-7 cells carrying pCPC were determined with a series of bandpass filters after the stimulation of ligands (Figure 4C). The light from COS-7 cells efficiently passed a 610 ± 10 nm filter, which indicates that the probe emits red−orange light. The luminescence intensities by OHT were five times stronger than those by the vehicle (0.1% DMSO), whereas the intensities by E_2 were merely 1.8 times stronger. These results show that OHT selectively elevates the red−orange light, and thus, the light can be a specific index of antagonistic activities of ligands to ER.

Ligand-Sensing Chemistry of CPG. As a representative of second messengers, cytosolic Ca^{2+} levels in living mammalian cells were estimated with our CPG (Figure 5). *Gaussia princeps*-derived luciferase was dissected at Q105, and the fragments were circularly permutated with a 10 GS linker. The outer terminals were fused with M13 and CaM, respectively. A control probe, CPG-ctrl, was synthesized in parallel with the same components but in different order (CP-free; Figure 5B). In response to 1 mM histamine, CPG quickly increased its luminescence intensities, which reached a plateau in approximately 10 min. The inset in Figure 5A shows the dose−response curve ($n = 3$). The probe was even sensitive to 0.25 mM of histamine, and the linear range was found between 0.25 and 0.75 mM of histamine. On the other hand, CPG-ctrl was unstable in emitting light and exhibited approximately 100× higher background intensity than the CPG, even in the absence of histamine. Stimulation with 1 mM histamine seldom increased the luminescence intensities. Only the substrate coelenterazine was saturated in the COS-7 cells within 8.5 min (Supporting Information Figure S1(C)). These results conclude that the CP of GLuc favors the decrease in background intensities, as shown in the case of CPC and CPC-ctrl. The decreased basal luminescence enabled us to firmly determine the dynamics of free Ca^{2+} levels triggered by histamine.

DISCUSSION

The concepts of CP were previously introduced with green fluorescent protein (GFP) variants, where the hydrophobicity of the chromophore varied according to a stimulator (*17, 18*). It is interesting to compare the ligand-sensing mechanism of our CP-based probes with that of the conventional CP-based fluorescent probes. The on/off system of fluorescent probes with cpGFP is considered to depend on the altered quantum yield of fluorescence by solvent penetration into the chromophore (*19, 20*). Particularly, an insertion of peptides at the β-sheet linkers temporarily disrupts fluorescence, owing to solvent penetration within the protein core, which interferes with the fluorophore−β-sheet interactions. The inhibitory action is relieved by condensive interaction between the inserted peptides. On the other hand, the recovery of luminescence in our probes is based on the physical approximation after dissociation between the completely separated fragments of a split luciferase, and not on the hydrophobicity variance like cpGFP.

Conventionally, real-time imaging of dynamics of second messengers relied heavily on the fluorescence resonance energy transfer (FRET) (*12, 21, 22*). The FRET between GFP variants can be detectable with a fluorescence microscope. However, only few cells can be observed by this method with autofluorescence. Our cpGLuc probe (CPG) provides a simple whole-cell assay and real-time imaging, and is useful for tracing the molecular dynamics in mammalian cells. Our study was the first example to determine the ligand-triggered dynamics of a second messenger with a bioluminescent probe in the living cells.

The probe with cpCBLuc (CPC) was sensitive to antagonists and exhibited a 1000× lower background luminescence when compared with a non-CP probe (CPC-ctrl). This dramatic decrease of basal luminescence intensity can be explained as follows: the CBLuc is considered to consist of two major domains, between which the active site may probably exist (*10, 11*). In our study, the potential active site region was divided into two fragments, causing a temporary loss of activity. A dissected active site of CBLuc was located in the opposite side of the other dissected site in the single-chain probe backbone, with respect to CP. In this conformation, the encountering chance between the fragmented active sites should be extremely decreased in the basal conditions. This structural reason may contribute to (i) the dramatic decrease of the basal activity of the probe and (ii) the improved signal-to-background ratios in the study.

It was previously debated whether the 17β-estradiol (E_2) exerts phosphorylation of estrogen receptor (ER) at Y537 (*23, 24*). Our experiment revealed that not only E_2 but also 4-hydroxytamoxifen (OHT) could induce phosphorylation of ER at Y537. Although both E_2 and OHT phosphorylate ER LBD, OHT modulates a more appropriate conformation change on ER LBD for recruiting the adjacent SH2 domain than E_2. Previously, an intramolecular folding sensor was developed, where a single-component protein (i.e., ER LBD), and not a two-component protein like ours, was sandwiched between the fragments of split-*Renilla* luciferase (RLuc) (*5*). It is interesting that their probe was similarly sensitive only to antagonists and was believed to be controlled by the conformational variances of ER LBD.

On the whole, we synthesized efficient bioluminescent probes with circularly permutated fragments of luciferases. Our probes were surprisingly stable in the mammalian cells after permutation, and the permutated positions were tolerant to the insertion of the detector proteins. The probes were sensitive to their respective ligands and exhibited a dramatically decreased background luminescence and improved signal-to-background ratios, when compared with the CPC-ctrl. This study offers a new strategy for the enzyme-aided probing systems that overcomes the limitations of the conventional probes. Our study was the first to fabricate CP in the enzymes. Any protein−protein interactions and molecular dynamics may be examined with these probes by simply replacing the detector proteins.

Supporting Information Available: Washout effects of ligand-elevated Ca^{2+} levels in COS-7 cells carrying pCPG. were specified in Figure S1(A). Kinetics of coelenterazine saturation in COS-7 cells were examined with the cells carrying CPG-ctrl (Figure S1(C)). This material is available free of charge via the Internet at http://pubs.acs.org.

Washout effects of ligand-elevated Ca^{2+} levels in COS-7 cells carrying pCPG. Washout effects of the elevated Ca^{2+} levels by various ligands were examined with CPG in COS-7 cells (Suppl. Figure 1). After stimulation with ligands, the COS-7 cells carrying pCPG were washed with PBS for removing the ligands in the medium. This washout terminates the external stimulation of ligands in elevating cytosolic Ca^{2+} levels. The resulting luminescence intensities shown in Suppl. Figure 1 are interpreted as follows: since histamine and ATP cannot pass the plasma membrane, they bind their specific receptors on the membrane. The elevated cytosolic Ca^{2+} levels by histamine or ATP alone are quickly decreased by Ca^{2+} pumping of the cells. Additional supplementation of thapsigargin, known as an endoplasmic reticulum Ca^{2+} pump inhibitor, retained the luminescence intensities elevated by histamine or ATP. On the other hand, co-stimualtion of cyproheptadine, when added with histamine, selectively blocked the elevation of cytosolic Ca^{2+} levels. This is because cyproheptadine acts as an anti-histamine reagent and blocks the effects of histamine. Ionomycin triggers the influx of exogenous Ca^{2+} into the cytosol, which resulted in retaining certain levels of Ca^{2+} in the cytosol in spite of the Ca^{2+} pump.

These results reveal that the current CPG provides a bioluminescent measure for exploring the dynamics of Ca^{2+}-related molecular events in living mammalian cells, which was not examined previously with a bioluminescent probe.

Retention of Ca^{2+} levels after washout, which were elevated by various ligands. Retention of cytosolic Ca^{2+} levels were monitored on the basis of the luminescence intensities from COS-7 cells carrying pCPG (Suppl. Figure 1). COS-7 cells cultured in a 24-well plate were transiently transfected with pCPG and extensively incubated for 16 h. The cells were stimulated with the following ligands for 20 min: (i) vehicle (PBS), (ii) 0.5 mM histamine, (iii) 0.5 mM histamine plus 10 μM cycloheptadine, (iv) 0.5 mM histamine plus 1 μM thapsigargin, (v) 0.5 mM ATP, (vi) 0.5 mM ATP plus 10 μM cycloheptadine, (vii) 0.5 mM ATP plus 1 μM thapsigargin, and (viii) 2 μM ionomycin.
The cells were washed twice with PBS, and harvested by trypsinization and centrifugation. The cells were resuspended with a 40 μL substrate buffer carrying coelenterazine, and then transferred to a test tube to determine the luminescence using a luminometer (Minilumat LB9506).

Kinetics of substrate saturation in COS-7 cells carrying pCPG-ctrl. The kinetics of coelenterazine saturation in COS-7 cells were monitored with COS-7 cells carrying pCPG-ctrl (Suppl. Figure 1(C)). COS-7 cells cultured in a 24-well plate were transiently transfected with pCPG-ctrl and incubated for another 16 h. The cells on the plate were washed once with HBSS buffer, and then suspended on 500 μL HBSS buffer. After addition of coelenterazine, the variance of luminescence intensities was traced with a bioluminescence plate reader (Mithras LB940; Berthold).

Monofunctional Carbocyanine Dyes for Bio- and Bioorthogonal Conjugation

Fangwei Shao, Ralph Weissleder, and Scott A. Hilderbrand*

Center for Molecular Imaging Research and Center for Systems Biology, Massachusetts General Hospital/Havard Medical School, Room 5404, Building 149, 13th Street, Charlestown, Massachusetts 02129. Received September 30, 2008; Revised Manuscript Received October 22, 2008

A facile synthetic route to prepare monofunctional carbocyanine dyes for biological application is developed. Three pentamethine carbocyanine dyes have been successfully modified with a variety of functional groups such as: carboxylic acids, azides, or alkynes. The new dyes are characterized by strong NIR fluorescence emission, high extinction coefficients and good quantum yields. The azide and alkyne dyes have potential utility as components in bioorthogonal labeling schemes via [2 + 3] dipolar cycloaddition "click" reactions. The application of one derivative, CyAM-5 alkyne, for bioorthogonal labeling is demonstrated. Fluorescence microscopy shows coupling of CyAM-5 alkyne to Chinese hamster ovary (CHO) cells preincubated with azide modified glycans.

INTRODUCTION

Near-infrared (NIR) fluorescence-based imaging is becoming a key tool for early disease diagnosis, therapeutic applications, and biochemical analysis, due to the high sensitivity, excellent temporospatial resolution, and potential for multichannel imaging (*1, 2*). There is currently a need for improved, bright near-infrared, water-soluble dyes containing diverse functional groups for conjugation to biomolecules (*3, 4*). Asymmetric monofunctional carbocyanine dyes containing carboxylic acids were first reported in the early 1990s (*5, 6*). Due to their bright fluorescence and NIR emission, these fluorophores are receiving considerable interest as components of new NIR optical imaging agents (*5*−*7*). For example, the Cy5.5 and Cy7 dyes have been used for labeling a variety of biological/biomedical macromolecules and nanoparticles (*8, 9*). Two major synthetic strategies are currently employed in the preparation of functionalized carbocyanine dyes. One is a stepwise synthetic route to prepare asymmetric cyanine dyes, in which different indoleninium or benzindoleninium moieties are condensed to a polymethine chain (*5, 6*). Although many commonly used monofunctional cyanine dyes are prepared through this route, synthetic yields are often less than 10% and significant amounts of the undesired symmetric dyes are formed (*10*). A second synthetic route for incorporating functional groups into symmetric heptamethine cyanine dyes also has been developed (*11*). This route proceeds via reaction of nucleophiles with commercially available chloro-substituted cyanine dyes to give a variety of aryl ether, thiol ether, and aryl thioether modified tricarbocyanine fluorophores often in greater than 90% yield (*12*−*14*). More recently, a modified Suzuki-Miyaura coupling was proposed to prepare *meso*-aryl, aryl ether, and arylamino tricarbocyanine dyes in good yields (*15*). Unfortunately, many of these compounds have lower quantum yields (often $\Phi < 0.1$) than canonical Cy7 ($\Phi = 0.27$) or are chemically unstable (*16*). Furthermore, the physical behavior of these carbocyanine derivatives can be altered significantly by their functional substituents. For example, aryl ether modified dyes can show an increased tendency to aggregate in aqueous solution (*12*). There are several criteria that need to be met for design of dyes that are useful for bioconjugation and bioimaging applications. These include universal requirements, such as bright fluorescence emission, water solubility, chemical stability, as well as far-red/NIR absorption and emission. In addition to these parameters, a flexible high-yielding synthetic methodology is desirable. In order to achieve these requirements and circumvent the shortcomings of existing synthetic routes, we present in this paper a new procedure based on modification of the malonaldehyde dianil dye precursors for preparation of monofunctional far-red/NIR pentamethine carbocyanine dye derivatives. This synthetic paradigm can be extended to incorporate a variety of functional groups, such as carboxyl, azido, and alkynyl groups, into the cyanine fluorochromes. Azido and alkynyl groups are two essential reagents in the click reaction. In the presence of Cu(I) catalyst, azide and alkyne containing molecules combine in a [3 + 2] dipolar cycloadditon to form a stable triazole moiety (*17, 18*). Since there are few, if any, azides or alkynes that occur naturally in biology, the click reaction is receiving increased attention as a potential bioorthogonal conjugation scheme (*19*−*21*). However, to date there has been little effort to develop NIR fluorophores modified with azides or alkynes that are suitable for biological and *in vivo* imaging applications.

EXPERIMENTAL PROCEDURES

General Materials and Methods. All chemicals were purchased from Aldrich or TCI and were used as received. All of the solvents were at least of reagent grade and were used without further purification. All of the dyes for characterization were purified by high-performance liquid chromatography (HPLC) on a Varian 210 instrument equipped with a 335 diode array detector. If not otherwise noted, HPLC buffer A is 0.1% trifluoroacetic acid (TFA) in water and buffer B is acetonitrile with 10% water and 0.1% TFA. ^{1}H (400 MHz) and ^{13}C NMR (100 MHz) spectra were collected on a Bruker Advance-400 NMR spectrometer at ambient temperature. The chemical shifts were measured versus tetramethylsilane (TMS) as an internal standard. High-resolution electrospray ionization (ESI) mass spectra were obtained on a Bruker Daltonics APEXIV 4.7 T Fourier transform ion cyclotron resonance mass spectrometer (FT-ICR-MS) in the Department of Chemistry Instrumentation Facility at the Massachusetts Institute of Technology.

[a] Reaction conditions: (a) $C_2O_2CI_2$/DMF/$C_2H_2CI_2$,70 °C; (b) 4 M NaOH; (c) R-NH_2CI/10% HCI_{aq}; (d) HOAc/0.5% TEA 115 °C. A. (Upper) Synthesis of malonaldehyde dianil intermediates. B. (Lower) Synthesis of monofunctional carbocyanine dyes.

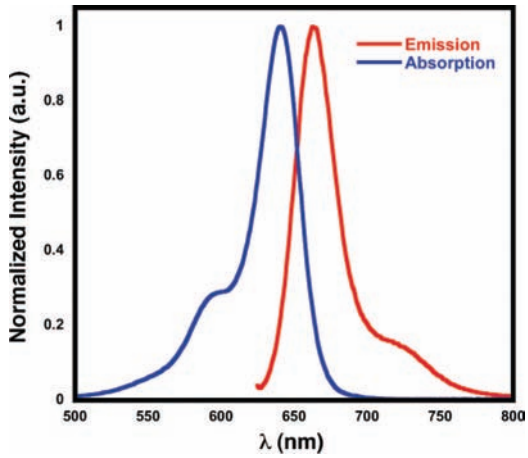

Figure 1. Normalized absorption and emission spectra of CyAM-5 acid in PBS, pH 7.0.

mmol) and oxalyl chloride (1.26 g, 10 mmol) were added sequentially into 30 mL anhydrous dichloromethane (DCM) in an acetone/dry ice bath. The mixture was allowed to warm to room temperature over 15 min. Methyl 5,5-dimethoxyvalerate (881 mg, 5 mmol) was then added dropwise to the reaction solution followed by heating at 70 °C for 2 h, allowing the DCM to evaporate. The resulting yellow oil was dissolved in 5 mL of 4 M NaOH and was heated at 70 °C for 1 h. Before their use, the aniline derivatives (4-aminobenzoic acid, 4-azidoaniline, 3-ethynylaniline) were converted to their corresponding chloride salts on a 10 mmol scale by dissolving the aniline in acetone and precipitating its salt by addition of excess concentrated aqueous HCl. After removing the solvent under vacuum, the appropriate aniline chloride salt (10 mmol), dissolved in 5 mL water, was added to the basic, crude reaction solution and was allowed to stir at room temperature for 1 or more hours, until the reaction was complete. The final malonaldehyde dianil hydrochloride salts were precipitated as light yellow solids after the addition of 5 mL of 10% aqueous HCl and were collected by filtration. The products were above 95% pure and used directly in the dye synthesis without further purification if not mentioned specifically.

Table 1. Optical Properties of Pentamethine Carbocyanine Dyes

	λ_{abs} (nm)[a]	λ_{em} (nm)	ε ($M^{-1}cm^{-1}$)[b]	Φ[c]
CyAM-5 acid	642	656	215 000	0.17
CyAM-5 azide	641	658	222 000	0.20
CyAM-5 alkyne	641	657	240 000	0.20

[a] Spectra were obtained in phosphate buffered solution, pH 7.0. Details are listed in Experimental Procedures. [b] Extinction coefficients at 640 nm are averaged over at least three sets of equivalent experiments. Details are listed in Experimental Procedures. [c] Emission spectra were excited at 620 nm. Details are listed in Experimental Procedures.

*Carboxylic Acid Intermediate (**3a**).* Yield 65%, 1.22 g. ^{1}H NMR (400 MHz, DMSO-d_6): δ 11.65 (b, 2H), 8.80 (s, 2H), 8.08 (d, 4H, J = 8.8 Hz), 7.63 (d, 4H, J = 8.8 Hz), 2.90 (t, 2H, J = 7.6 Hz), 2.48 (t, 2H, J = 7.9 Hz). ^{13}C NMR (100 MHz, DMSO-d_6): δ 174.78, 167.50, 160.44, 143.41, 131.97, 128.74, 119.31 112.49, 32.75, 18.35. HRMS-ESI $[M + H]^+$ m/z calcd. for $[C_{20}H_{18}N_2O_6]^+$ 383.1238, found 383.1231.

*Azide Intermediate (**3b**).* 4-Azidoaniline hydrochloride was used as received. Yield 61%, 1.24 g. ^{1}H NMR (400 MHz, DMSO-d_6): δ 8.92 (s, 2H), 7.68 (d, 4H, J = 8.8 Hz), 7.23 (d, 4H, J = 8.7 Hz), 2.94 (t, 2H, J = 7.3 Hz), 2.46 (t, 2H, J = 7.8 Hz). ^{13}C NMR (100 MHz, DMSO-d_6): δ 173.82, 158.22, 137.04, 136.31, 125.27, 120.45, 109.95, 31.88, 17.45. HRMS-ESI $[M + H]^+$ m/z calcd. for $[C_{18}H_{16}N_8O_2]^+$ 377.1469, found 377.1473.

*Alkyne Intermediate (**3c**).* Crude precipitates were purified on a silica column starting from 5% MeOH in DCM. The pure product eluted at 15% MeOH in DCM. Yield 24%, 440 mg. ^{1}H NMR (400 MHz, DMSO-d_6): δ 8.19 (s, 2H), 7.41 (s, 2H), 7.37 (d, 2H, J = 7.2 Hz), 7.34 (d, 2H, J = 8.0Hz), 7.20 (d, 2H, J = 6.8), 4.24 (s, 2H), 2.79 (t, 2H, J = 7.5 Hz), 2.44 (t, 2H, J = 7.8 Hz). ^{13}C NMR (100 MHz, DMSO-d_6): δ 174.43, 154.61, 145.14, 129.78, 126.82, 122.78, 120.66, 119.14, 113.33, 83.31, 80.98, 32.13, 18.51. HRMS-ESI $[M + H]^+$ m/z calcd. for $[C_{22}H_{18}N_2O_2]^+$ 343.1441, found 343.1443.

Dye Synthesis (CyAM-5 acid, CyAM-5 azide and CyAM-5 alkyne). *General Synthetic Route.* 1-Ethyl-2,3,3-trimethylindoleninium-5-sulfonate (**4**) was prepared according to literature

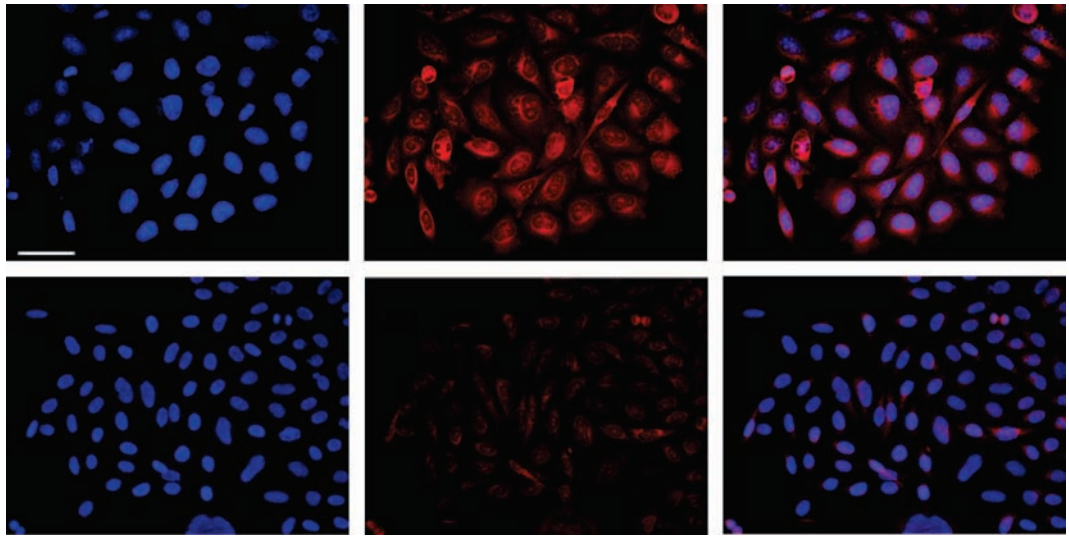

Figure 2. Fluorescene microscopy of CHO cells labeled with CyAM-5 alkyne. Cells incubated with azido-sugar supplimented media (top) or unsupplimented media (bottom) after treatment with CyAM-5 alkyne in the presence of Cu(I)/TBTA as catalyst. Experimental details and additional controls are shown in the supporting material. Fluorescence signal from the nuclear stain, DAPI, colored blue (left), CyAM-5 alkyne colored red (center), and the merged images (right) are shown. The scale bar represents 50 μm.

procedures (*5*). Indoleninium **4** (4 equiv) and intermediate **3a**, **b**, or **c** (1 equiv) were dissolved in 5 mL acetic anhydride with 0.5% v/v triethylamine. The reaction solution was heated at 115 °C for 1 h in a sealed flask. The crude product was then precipitated by the addition of diethyl ether and washed with additional diethyl ether. Preparative HPLC (Varian Pursuit XRs 10 C18 250 × 21.2 mm column, 0−25% buffer B over 30 min at a flow rate of 21 mL/min) was applied to purify **CyAM-5-acid** giving the blue dye as the free acid. The other dyes (**CyAM-5 azide** and **CyAM-5 alkyne**) were isolated as their ammonium salts by preparative HPLC over the same gradient but with buffer A as 50 mM NH_4OAc in water and buffer B as 100% acetonitrile.

*CyAM-5 Acid (***5a***).* Yield 66%, 252 mg starting with 0.5 mmol of **3a**. ^{1}H NMR (400 MHz, DMSO-d_6): δ 10.30 (s, 1H), 8.21 (d, 2H, J = 14.1 Hz), 7.86 (d, 2H, J = 8.7 Hz), 7.84 (s, 2H), 7.72 (d, 2H, J = 8.8 Hz), 7.66 (d, 2H, J = 8.2 Hz), 7.35 (d, 2H, J = 8.4 Hz), 6.33 (d, 2H, J = 14.2 Hz), 4.21 (m, 4H), 2.99 (t, 2H, J = 6.7 Hz), 2.60 (t, 2H, J = 7.1 Hz), 1.71 (s, 12H), 1.30 (t, 6H, J = 7.1 Hz). ^{13}C NMR (100 MHz, DMSO-d_6): δ 173.43, 172.03, 167.51, 154.11, 145.75, 143.81, 142.19, 141.40, 133.99, 130.99, 126.73, 125.62, 120.61, 118.98, 110.63, 100.36, 49.61, 39.67, 36.10, 27.46, 20.58, 12.69. HRMS-ESI $[M]^+$ m/z calcd. for $[C_{39}H_{44}N_3O_9S_2]^+$ 762.2513, found 762.2539.

*CyAM-5 Azide (***5b***).* Yield 64%, 116 mg starting with 0.24 mmol of **3b**. ^{1}H NMR (400 MHz, DMSO-d_6): δ 10.08 (s, 1H), 8.20 (d, 2H, J = 14.2 Hz), 7.83 (s, 2H), 7.66 (d, 2H, J = 8.9 Hz), 7.64 (d, 2H, J = 8.7 Hz), 7.34 (d, 2H, J = 8.4 Hz), 7.03 (d, 2H, J = 8.9 Hz), 6.32 (d, 2H, J = 14.2 Hz), 4.20 (m, 4H), 2.98 (t, 2H, J = 6.7 Hz), 2.54 (t, 2H, J = 6.8 Hz), 1.70 (s, 12H), 1.29 (t, 6H, J = 7.1 Hz). ^{13}C NMR (100 MHz, DMSO-d_6): δ 173.73, 171.74, 154.46, 146.15, 142.49, 141.71, 137.42, 134.65, 133.61, 127.05, 121.55, 120.94, 120.31, 110.93, 100.73, 49.91, 39.63, 36.23, 27.79, 21.04, 13.02. HRMS-ESI $[M]^+$ m/z calcd. for $[C_{38}H_{43}N_6O_7S_2]^+$ 759.2629, found 759.2630.

*CyAM-5 Alkyne (***5c***).* Yield 65%, 114 mg starting with 0.2 mmol of **3c**. ^{1}H NMR (400 MHz, DMSO-d_6): δ 10.08 (s, 1H), 8.19 (d, 2H, J = 14.2 Hz), 7.82 (s, 2H), 7.79 (s, 1H), 7.64 (d, 2H, J = 8.4 Hz), 7.48 (d, 1H, J = 8.8 Hz), 7.33 (d, 2H, J = 8.4 Hz), 7.25 (t, 1H, J = 7.9 Hz), 7.07 (d, 1H, J = 7.6 Hz), 6.38 (d, 2H, J = 14.2 Hz), 4.21-4.18 (m, 4H), 4.05 (s, 1H), 2.98 (t, 2H, J = 6.8 Hz), 2.54 (t, 2H, J = 6.8 Hz), 1.68 (s, 12H), 1.14 (t, 6H, J = 7.3 Hz). ^{13}C NMR (100 MHz, DMSO-d_6): δ 172.81, 171.24, 153.59, 145.20, 141.57, 140.79, 139.28, 132.49, 129.14, 126.39, 126.13, 122.19, 121.91, 119.99, 119.77, 110.03, 99.83, 83.33, 80.47, 48.98, 38.70, 35.49, 26.84, 22.55, 12.11. HRMS-ESI $[M]^+$ m/z calcd. for $[C_{40}H_{44}N_3O_7S_2]^+$ 742.2615, found 742.2612.

Optical Properties. Absorption spectra and extinction coefficients of the fluorophores were obtained on a Varian Cary 50-Bio UV−visible spectrophotometer. Extinction coefficients were measured in phosphate-buffered saline (PBS), 10 mM phosphate buffer pH 7.0, 27 mM potassium chloride, and 137 mM sodium chloride and were averaged over at least three sets of parallel experiments. For each trial, 2−3 mg of the HPLC-purified dyes were weighed on a Mettler AT201 analytical balance with an error of ±0.01 mg and were dissolved in deionized water using a 10 mL volumetric flask to prepare the stock solutions. Emission spectra were collected on a Varian Cary Eclipse fluorescence spectrophotometer. Quantum yield measurements were performed on at least eight trials for each dye derivative with the maximum absorption for each sample less than 0.1, using Cy5 as a standard (Φ = 0.27) (*5*). The standard deviation for both the extinction coefficient and quantum yield measurements is less than 5%. Photostability data were collected on a Horiba Jobin Yvon Fluorolog-3 spectrofluorometer (Edison, NY) equipped with a 450 W xenon lamp (Ushio Inc., Japan). Dye photobleaching was observed by monitoring the fluorescence emission of absorbance-matched dye samples (absorbance <0.1) at an excitation wavelength 620 nm for 60 min.

Fluorescence Labeling and Cell Imaging. Chinese hamster ovary (CHO) cells were maintained in a 5% CO_2, water-saturated atmosphere and grown in F12 HAMS medium supplemented with 10% FBS, 1% penstrep, and 1% L-glutamine. For biolabeling experiments, the cells were incubated for 2−3 days in the regular medium or medium supplemented with 100 μm ManNAz (Molecular probes) in an eight-well LabTek II chamber slide (Nunc). The medium was gently aspirated, and the cells were fixed at −20 °C with methanol for 10 min and then acetone for 1 min. The cells then were washed with 500 μL of PBS (pH 7.0) three times and were treated with a bioorthogonal reaction solution containing 20 μM CyAM-5 alkyne, 100 μM $CuSO_4$/100 μM Tris[(1-benzyl-1*H*-1,2,3-triazol-4-yl)methyl]amine (TBTA) if mentioned and 1 mM sodium ascorbate in PBS (pH 7.0) at room temperature for 1−2 h. Immediately prior to imaging, Vectra Shield mounting medium

containing DAPI (Vector Laboratories) was applied to the cells. Fluorescent images were captured on a Nikon Eclipse TE2000-S fluorescence microscope with 40× objective equipped with a Photometrics Cascade 512B CCD camera using excitation and emission filters from Chroma Technology. Exposure times of 200 and 1000 ms, for the nuclear stain and carbocyanine dye channels, respectively, were used for image collection. All images from the carbocyanine dye channel were processed with identical leveling.

RESULTS AND DISCUSSION

Our design of monofunctional dyes focuses on symmetric carbocyanine scaffolds, as shown in Scheme 1. These dyes have two identical monosulfonated indoleninium moieties (**4**) and are prepared in simple one-stage dye condensation reactions, which typically have significantly higher yields than reactions reported for asymmetric cyanine dye synthesis (*5*, *6*). The two sulfonate groups on the aromatic rings confer excellent water solubility to the final dyes. The acid, azide, and alkyne handles are introduced onto the central carbon atom of the polymethine chain through an alkyl chain followed by an arylamide linkage that is formed during the dye synthesis.

The desired functional groups are incorporated into the malonaldehyde dianil intermediates (**3a**−**c**) (Scheme 1a). These malonaldehyde dianil derivatives are prepared via carboxylic acid intermediate, (**2**), which is synthesized from methyl 5,5-dimethoxyvalerate (**1**) via a Vilsmeier−Haack−Arnold amino-formylation followed by basic hydrolysis. An aniline moiety containing a carboxylic acid, alkyne, or azide in either the *para* or *meta* position is then added to reaction solution to yield the modified malonaldehyde dianil derivatives. Compounds **3a**−**c**, which are isolated in 24−65% yield as their chloride salts after acidic workup, are of sufficient purity for subsequent use in the dye condensation reactions. The unique pathway for preparation of the malonaldehyde dianil intermediates in this report allows for facile introduction of a variety of functional groups onto the final cyanine dyes. By using different indoleninium and benzindolinium derivatives, these malonaldehyde dianil derivatives can be applied to prepare not only Cy5 dyes but also their monofunctional Cy5.5 analogues.

Synthesis of the monofuctional carbocyanine fluorophores is achieved by combining 1 equiv of intermediate (**3**) and 4 equiv of 1-ethyl-2,3,3-trimethylindoleninium-5-sulfonate (**4**) in acetic anhydride with 0.5% triethylamine. During the dye condensation, one of the two aniline groups on the malonaldehyde derivatives undergoes an intramolecular nucleophilic attack, reacting with the carboxylic acid of the malonaldehyde derivative forming an amide bond, as shown in Scheme 1b. This unique intramolecular rearrangement occurs during the synthesis of all the three dyes. The intramolecular rearrangement allows for facile installation of diverse functional groups onto the polymethine chain of the cyanine dye scaffold in a one-stage reaction to give a variety of cyanine dyes suitable for conjugation reactions. In combination with the simple isolation of the dyes by precipitation from diethyl ether, the overall yields for the dye condensations are all near 65% even after HPLC purification.

Regardless of the functional groups attached to the polymethine scaffold, the spectroscopic profiles of the three dye derivatives, CyAM-5 acid (**5a**), CyAM-5 azide (**5b**), and CyAM-5 alkyne (**5c**) are nearly identical. Absorption and emission spectra of CyAM-5 acid are shown in Figure 1. CyAM-5 acid has optical features of a typical pentamethine cyanine dye with absorption and emission maxima at 642 and 658 nm, respectively. The absorption and emission maxima of all three dyes are blue-shifted by approximately 5 nm in comparison to those of Cy5, whereas the Stokes shifts are nearly identical to that of Cy5, ∼16 nm. Table 1 summarizes the optical properties of the monofuctional dyes. All three of the new dyes are extremely bright with extinction coefficients greater than 215 000 M^{-1} cm^{-1} and quantum yields of 0.17 or higher. Furthermore, the new dyes have better photostability than typical cyanine derivatives that have unsubstituted polymethine chains. As shown in Supporting Information Figure S2, after an hour of irradiation, CyAM-5 acid shows 28% less photobleaching when compared to Cy5.

Due to their bright fluorescence, long-wavelength absorption, and emission, as well as the ability to accommodate a variety of functional groups for conjugation reactions, this new class of cyanine dyes should find use in many biological labeling and imaging applications. For example, CyAM-5 acid can be conveniently converted to its corresponding activated succinimidyl ester (*22*) for conjugation to amine-containing molecules. CyAM-5 azide and alkyne have a variety of potential uses in which they can be employed as a component in the click reaction. In addition, the aryl azide of CyAM-5 azide may find use in photo-cross-linking experiments.

Recently, fluorescence labeling methods based upon click chemistry have been developed for visualization of glycoproteins in cells incubated with azide-containing sugars (*19*−*21*). We have adapted this sugar labeling system to demonstrate the ability of our monofunctional dyes to undergo efficient bioorthogonal coupling in a biorelevant system. Azide sugar modified Chinese hamster ovary (CHO) cells were first prepared by incubation of the cells with azidoacetylmannosamine containing media for 3 days. These cells then are fixed with methanol/acetone and are labeled with CyAM-5 alkyne in the presence of copper (I) as a catalyst. The cells bearing azido sialic acid in their glycoprotein show increased fluorescence signal when compared to control cells that were not incubated with the azido-mannosamine, as shown in Figure 2, indicating the labeling of the cells with CyAM-5 alkyne via formation of a triazole linkage. The enhancement of fluorescence signal is only observed in the presence of both catalyst Cu(I) and azido glycans (Supporting Information Figure S3). The Cu(I) chelating ligand, trisbenzyltriazolylmethylamine (TBTA), facilitates the reaction, but is not necessary for efficient labeling of the cells. The requirement of both Cu(I) and azido-sugar treatment for fluorescent labeling of CHO cells with CyAM-5 alkyne indicates that the resulting click reaction is a selective, bioorthonogal method for cell labeling.

In conclusion, a unique, general strategy for synthesizing monofunctional carbocyanine derivatives has been developed that is amenable to the preparation of far-red/NIR cyanine dyes with high yields containing acid, alkyne, or azide synthetic handles. These dyes are expected to have a variety of potential applications in bio- and bioorthogonal labeling schemes. Furthermore, using this synthetic approach, installation of additional useful functional groups such as amines, thiols, and maleimides should be feasible.

ACKNOWLEDGMENT

This work is supported by NIH grant 1-U01-HL080731. We thank Dr. Neal Devaraj for helpful discussion on click chemistry.

Micelles from amphiphilic star-block copolymers, having a hydrophobic hyperbranched core and amphiphilic fluoropolymer arms, were constructed as drug delivery agent assemblies. A series of polymer structures was constructed from consecutive copolymerizations of 4-chloromethylstyrene with dodecyl acrylate and then 1,1,1-trifluoroethyl methacrylate with *tert*-butyl acrylate, followed by acidolysis to release the hydrophilic acrylic acid residues. These structures were labeled with cascade blue as a fluorescence reporter. The series of materials differed primarily in the ratio of 1,1,1-trifluoroethyl methacrylate to acrylic acid units, to give differences in fluorine loading and hydrophobicity/hydrophilicity balance. Doxorubicin (DOX) was used as a therapeutic to study the loading, release, and cytotoxicity of these micellar constructs on an U87-MG-EGFRvIII-CBR cell line. The micelles, with TEM-measured diameters ranging 5−9 nm and DLS-measured hydrodynamic diameters 20−30 nm, had loading capacities of ca. 4 wt % of DOX. The DOX-loaded micelles exhibited potent cytotoxicity with cell viabilities of 60−25% at 1.0 μg/mL effective DOX concentrations, depending upon the polymer composition, as determined by MTT assays. These cell viability values are comparable to that of free DOX, suggesting an effective release of the cargo and delivery to the cell nuclei, which was further confirmed by fluorescence microscopy of the cells. ^{19}F-NMR spectroscopy indicated a partial degradation of the surface-available trifluoroethyl ester linkages of the micelles, which may have accelerated the release of DOX. ^{19}F-NMR spectroscopy was also employed to confirm and to quantify the cell uptake of the micelles. These dual fluorescent- and ^{19}F-labeled and chemically functional micelles may be used potentially in a variety of applications, such as cell labeling, imaging, and therapeutic delivery.

INTRODUCTION

Nanoscopic systems that can incorporate combined imaging and therapeutic capabilities are the focus of intensive research for applications in the growing field of nanomedicine (*1*−*7*). Such systems offer the possibility to increase diagnostic accuracy and therapeutic effectiveness, while minimizing side effects from treatment. Nanoscopic polymeric assemblies from dendrimers (*8, 9*), polymer micelles (*5, 10, 11*), shell cross-linked knedel-like (SCKs) nanoparticles (*12*−*14*), and other polymer assemblies (*15, 16*) are promising candidates for such multifunctional therapeutic platforms, since these materials are conveniently synthesized, variably functionalized, and can be assembled to a range of sizes and compositions.

Such polymeric assemblies usually have an amphiphilic composition, in which the hydrophobic component serves as a reservoir for therapeutic cargo and/or imaging agents, and the hydrophilic component provides stability in solution and can be tailored for attaching imaging agents and/or targeting ligands. Therapeutic cargos, usually packed through hydrophobic−hydrophobic interactions, when not covalently attached, can be released through passive diffusion (*12*) or as a response to external stimuli such as pH (*8*−*10, 17*), temperature (*17*−*19*), and light (*19*). In order to utilize polymer assemblies for systemic delivery of therapeutics, it is important to maximize the loading capacity to minimize injection volume for *intravenous* delivery and also to achieve sustained and controlled release.

Our group has long been interested in developing polymers for the construction of multifunctional nanoscopic assemblies for imaging and drug delivery purposes (*12, 14, 16, 20, 21*). One such system is the 1,4,7,10-tetraazocyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA)-conjugated SCKs that can chelate ^{64}Cu for labeling and in vivo PET imaging (*14, 22*). Extension of the SCKs to serve as a therapeutic delivery system has also been reported (*12*). Recently, we developed fluorinated hyperbranched star-like polymers that can serve as ^{19}F magnetic resonance imaging (MRI) agents (*23*). The multicompartmental amphiphilicity of these structures gave rise to the hypothesis that they are capable of therapeutic agent packaging while also providing for detectable imaging or labeling for tracking of the nanoparticle locations. In this study, utilization of these materials as ^{19}F and fluorescence dual-labeled imaging assemblies as well as nanocarriers for chemotherapeutic cargos was explored. ^{19}F NMR/MRI techniques were successfully applied to track and quantify cell migration and uptake. Due to near-zero background, the technique is highly sensitive. In this study, ^{19}F NMR was applied to quantify the number of micelles taken up by the cells and to determine the micelle stability. Doxorubicin (DOX) was selected as the therapeutic agent, and the loading, release, and cytotoxicity of the nanocarrier constructs was investigated in depth and compared against the behaviors of the host nanomaterial and the small molecule drug, each individually and together. DOX has been studied extensively in micellar delivery strategies (*5, 8, 24, 25*) and is a common therapeutic for the treatment of a range of cancers (*26*). It also exhibits

antibiotic properties and may provide benefits toward other diseases that involve a need for reduction in cell growth, such as interfering with restenosis by using drug eluting stents (*27*). Most importantly, for these fundamental studies, DOX is a viable model drug, due to its inherent UV−vis/fluorescence characteristics. We found that these polymer micelle assemblies were capable of packaging DOX and that the DOX−micelle constructs exhibited cytotoxicity against U87-MG-EGFRvIII-CBR cancer cells that nearly matched that of the free DOX. The successful construction of dual-labeled micelles may find applications in the area of drug delivery, wherein monitoring their migration and uptake activity require careful monitoring.

EXPERIMENTAL PROCEDURES

Materials and Methods. All chemicals were purchased from Sigma−Aldrich Chemical Co., unless otherwise noted. Cascade Blue (CB) ethylenediamine trisodium salt and MTT assay kit were purchased from Invitrogen Co. The amphiphilic hyperbranched polymer materials, **1a**−**c**, were prepared as previously reported (*23*).

U87-MG-EGFRvIII-CBR cells (a human glioblastoma cell line modified to express the mutant EGFRvIII receptor and click beetle red luciferase) have been previously reported (*12*).

^{1}H NMR spectra were recorded on a 500 MHz Varian Inova 500 spectrometer, with the solvent proton signal as the standard. ^{19}F-NMR spectra were recorded at 470 MHz on a Varian Inova 500 spectrometer equipped with a fluorine-observe 5 mm probe (Nalorac Co. CA) with trifluoroacetic acid (TFA) as an internal standard.

Dynamic light scattering (DLS) measurements were acquired using a Brookhaven Instruments (Worcestershire, U.K.) system, including a model BI-200SM goniometer, a model BI-9000AT digital correlator, a model EMI-9865 photomultiplier, and a model 95−2 Ar ion laser (Lexel, Corp.; Farmindale, NY) operated at 514.5 nm. Measurements were made at 25 ± 1 °C. Prior to analysis, solutions were filtered through a 0.22 μm Gelman Nylon Acrodisc 13 membrane filter to remove dust particles. Scattered light was collected at a fixed angle of 90°. The digital correlator was operated with 522 ratio spaced channels, and initial delay of 5 μs, a final delay of 100 ms, and a duration of 10 min. A photomulitplier aperture of 400 μm was used, and the incident laser intensity was adjusted to obtain photon counting of between 200 and 300 kcps. The calculations of the particle size distributions and distribution averages were performed with the ISDA software package (Brookhaven Instruments Co.), which employed single-exponential fitting, cumulants analysis, and non-negatively constrained least-squares (NNLS) and CONTIN particle size distribution analysis routines. The data are presented as the average values from four measurements.

Transmission electron microscopy (TEM) measurements were conducted on a Hitachi H600 microscope. Micrographs were collected at 100 000× magnification and calibrated using a 41 nm polyacrylamide bead from NIST. Carbon-coated copper grids were treated with oxygen plasma prior to deposition of the micellar samples. The samples were stained with 1% phosphotungstic acid (PTA) for 1 min, and then the solution was wicked away and the samples were allowed to dry under ambient conditions. The number-average particle diameters (D_{av}) and standard deviations were generated from the analysis of a minimum of 100 particles from at least three different micrographs.

UV−vis spectroscopy was acquired on Varian Cary 1E UV−vis system (Varian Inc., Palo Alto, CA) using PMMA cuvettes.

Synthesis. *Preparation of Cascade Blue-Conjugated Micelles [***2a**−**2c***].* To three solutions of polymers **1a**−**c** (20 mg each of **1a**−**1c**, 0.20, 0.22, and 0.21 μmol for **1a**−**1c**) in DMF (5 mL) was added HBTU (3.8 mg, 1×10^{-2} mmol) and HOBT (1.4 mg, 1×10^{-2} mmol). The solutions were allowed to stir under argon for 1 h. DIPEA (4 mg, 4×10^{-2} mmol) and Cascade Blue (0.63 mg, 1×10^{-3} mmol) were added. The reactions were stirred under argon overnight. DMF (15 mL) was added and the solutions were dialyzed (MWCO 30 kDa) against nanopure water for 84 h. Micellar solutions were thereby obtained and the amounts of Cascade Blue (CB) were determined by UV−vis (400 nm, $\varepsilon = 28\,000$ M^{-1} cm^{-1} from manufacturer's manual). A portion of the micelle solution was lyophilized to dryness for ^{1}H and ^{19}F NMR analyses.

2a. 3.4 CB/polymer (68%), micelle concentration, 0.33 mg mL^{-1}. ^{1}H NMR (500 MHz, DMSO-d_6): δ 0.8−2.3 (br, m, *CH*$_2$ and *CH* of backbone), 4.3−4.7 (s, br, *CH*$_2$CF$_3$, Ph*CH*$_2$), 6.4−7.5 (m, br, *ArH*), 7.6−8.0 (m, br, *ArH* of CB), 8.2 (*ArH* of CB), 8.6 (s, *ArH* of CB), 9.0 (s, *ArH* of CB), 9.9 (s, *ArH* of CB), 12.0−12.5 (s, br, COO*H*) ppm. ^{19}F NMR (470 MHz, DMSO-d_6): δ 2.7 (s) ppm. TEM: D_{av} 9 ± 2 nm. DLS: $D_{h(n)}$ 21 ± 2 nm, $D_{h(v)}$ 29 ± 4 nm, $D_{h(i)}$ 129 ± 20 nm.

2b. 4.2 CB/polymer (84%), micelle concentration 0.35 mg mL^{-1}. ^{1}H NMR (500 MHz, DMSO-d_6): δ 0.8−2.3 (br, m, *CH*$_2$ and *CH* of backbone), 4.3−4.7 (s, br, *CH*$_2$CF$_3$, Ph*CH*$_2$), 6.4−7.5 (m, br, *ArH*), 7.6−8.0 (m, br, *ArH* of CB), 8.2 (*ArH* of CB), 8.6 (s, *ArH* of CB), 9.0 (s, *ArH* of CB), 9.9 (s, *ArH* of CB), 12.0−12.5 (s, br, COO*H*) ppm. ^{19}F NMR (470 MHz, DMSO-d_6): δ 2.7 (s) ppm. TEM: D_{av} 8 ± 2 nm. DLS $D_{h(n)}$ 26 ± 4 nm, $D_{h(v)}$ 29 ± 6 nm, $D_{h(i)}$ 135 ± 25 nm.

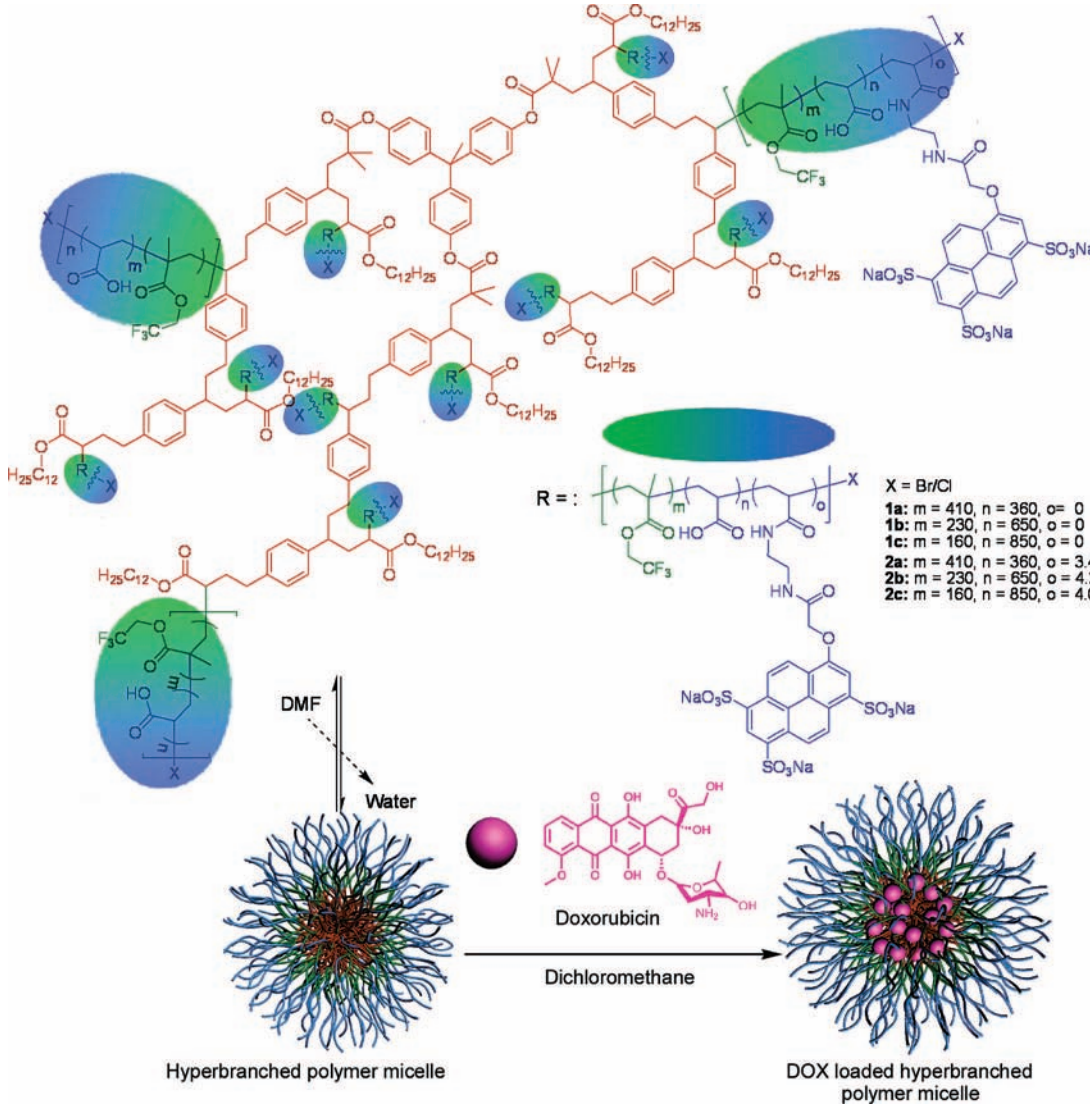
2c. 4.0 CB/polymer (80%), micelle concentration 0.32 mg mL^{-1}. ^{1}H NMR (500 MHz, DMSO-d_6): δ 0.8−2.3 (br, m, *CH*$_2$ and *CH* of backbone), 4.3−4.7 (s, br, *CH*$_2$CF$_3$, Ph*CH*$_2$), 6.4−7.5 (m, br, *ArH*), 7.6−8.0 (m, br, *ArH* of CB), 8.2 (*ArH* of CB), 8.6 (s, *ArH* of CB), 9.0 (s, *ArH* of CB), 9.9 (s, *ArH* of CB), 12.0−12.5 (s, br, COO*H*) ppm. ^{19}F NMR (470 MHz, DMSO-d_6): δ 2.7 (s) ppm. TEM: D_{av} 5 ± 1 nm. DLS: $D_{h(n)}$ 29 ± 3 nm, $D_{h(h)}$ 33 ± 6 nm, $D_{h(n)}$ 135 ± 20 nm.

General Procedure for DOX Loading. A solution of DOX (2.7 mg mL^{-1} in CH_2Cl_2 and 3 equiv of triethylamine, 30 w/w % with respect to the micelle) was added to a vial containing a magnetic stir bar and the micelle (4 mL, polymer concentration ∼0.30 mg mL^{-1}). The solution were protected from light and stirred without a cap in a well-ventilated fume hood for 16 h. Insoluble DOX was removed by centrifugation (3000 rpm × 10 min), and the supernatants were transferred to a centrifugal filter device (Amicon Ultra 4, 30 kDa MWCO, Millipore Corp., Billerica, MA, USA) and washed extensively with 5 mM PBS pH 7.4 buffer at 37 °C to remove all unincorporated DOX. After eight washing cycles, the filtrate was analyzed by UV−vis (488 nm) to confirm the successful removal of the free DOX. The DOX-loaded micelle solutions were then reconstituted to a final volume of 4 mL. The amount of incorporated DOX was determined by UV−vis (480 nm, $\varepsilon = 12\,500$ M^{-1} cm^{-1} determined by a calibration curve in DMF/PBS 4:1) in a 4:1 v/v mixture of DMF and DOX−micelle solution.

General Procedure for the Release Experiments. DOX−micelle solutions (2 mL) were transferred to a presoaked dialysis cassette (Slide-A-Lyzer, 10 kDa MWCO, Pierce Biotechnology, Rockford, IL, USA). The cassettes were then stirred in a beaker containing 4 L of 5 mM PBS at pH 7.4 and 37 °C for a period of 48 h. Samples (∼100 μL) were removed from the cassette at 0, 1, 2, 3, 4, 8, 16, 24, and 48 h and analyzed by UV−vis (488 nm, $\varepsilon = 12\,500$ M^{-1} cm^{-1} determined by a calibration curve in PBS). All release experiments were conducted in triplicate.

Cell Cytotoxicity Assay on U87-MG-EGFRvIII-CBR Cells. Cell cytotoxicity assay was conducted using MTT assay kit and followed the manufacturer's protocol. Briefly, 5000 cells/

Scheme 1. Chemical Structures and Compositions for Micelles 1a−1c and 2a−2c, and Schematic Illustrations of the Amphiphilic Star-Like Structure, Assembled as Uni- or Multi-Molecular Aggregates, and the Loading of DOX into Those Nanostructures



well of the U87-MG-EGFRvIII-CBR cells were plated in triplicate in 96-well plate for 24 h before treatment. Cells were then washed twice with sterile PBS and exposed to different doses of either free DOX or DOX−micelles at 37 °C for 2 h in 10% FBS α-MEM. After 2 h of incubation, the cells were washed again twice with sterile PBS and refed with fresh media and further incubated at 37 °C for 72 h before the MTT assay was performed. To assess cell viability, 10 μL of MTT (5 mg mL^{-1}) solution was added into each well and the mixture incubated at 37 °C for 4 h. The reaction was terminated with 10% SDS stop solution. Absorbance was read at 570 nm using a μQuant plate reader (Bio-Tek Instruments Inc.), and viability was calculated as the percentage of control (cells receiving no treatment).

In Vitro Fluorescent Microscopy Study. U87-MG-EGFRvIII-CBR cells were treated for 24 h with either 1 μg mL^{-1} of DOX or DOX-loaded micelles. Afterward, cells were washed twice with PBS buffer and fixed with 4% paraformaldehyde. Fluorescence was observed using Zeiss fluorescence microscope equipped with a appropriate filter set (Axioskop plus, Carl Zeiss, Germany), and pictures were taken using 63× oil lenses.

Micelle Stability Studies by ^{19}F NMR. U87-MG-EGFRvIII-CBR cells (1 million) suspended in 200 μL PBS buffer were mixed with micelles in PBS buffer, and this cell solution was then placed in a 5 mm NMR tube. TFA (0.050 mg/mL) was used as an internal reference. The pH was measured to be 7.4 before the kinetics studies. The degree of hydrolysis was calculated on the basis of relative integration value of the trifluoroethyl ester at 2.7 ppm and the integration value of trifluoroethanol at −1.2 ppm. In a control study, PBS buffer, instead of the cell solution, was used and the protocol was identical. The parameters used were: d1= 10 s, sw = 19 189.3 Hz, nt = 378, lb = 5 Hz, temp = 37 °C.

Cell Uptake Studies by ^{19}F NMR. U87-MG-EGFRvIII-CBR cells (4 million) were plated on a 6-well plate and then treated with 500 μL of micelle solution for 2 h at 37 °C. Afterward, the cells were washed 3 times with PBS buffer and lifted by trypsin. Cells were washed again with PBS buffer and centrifuged 3 times (3000 rpm × 5 min). Cell pellet was collected and fixed with 4% paraformaldehyde and resuspended into 250 μL PBS buffer. The cells were sonicated for 1 min; 100 μL of D_2O and 10 μL of 0.050 mg/mL TFA solution were added. The solution was transferred into a water-compatible BMS-005TJ Advanced NMR microtube (Shigemi Inc., PA) and subjected to ^{19}F NMR spectroscopic analysis. In a control study, PBS buffer instead of micelle solution was used and the protocol was identical. The

RESULTS AND DISCUSSION

Synthesis and Micellization of the Cascade Blue-Conjugated Fluoropolymers. The polymers **1a**−**1c** (*23*) were functionalized with Cascade Blue (CB) ethylene diamine to give CB-functionalized polymers (Scheme 1). Coupling of CB ethylene diamine to the pre-established macromolecules, having a hyperbranched hydrophobic core and amphiphilic copolymer arms comprising trifluoroethyl methacrylate and acrylic acid residues, was facilitated by the addition of standard peptide coupling reagents, *N*-hydroxybenzotriazole (HOBt), and *O*-benzotriazol-1-yl-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HBTU) in *N*,*N*-dimethylformamide (DMF), to give an amide linkage between the CB and the macromolecule acrylic acid sites. Initially, polymers with *ca.* two CB units per polymer chain were prepared, but the corresponding micelles failed to produce adequate fluorescence microscopy images with our instrumental resolutions. Therefore, the theoretical number of CBs per polymer was increased to *ca.* five during the coupling reactions, which afforded CB/polymer values of 3.3, 4.2, and 4.0 per polymer for samples **2a**, **2b**, and **2c**, corresponding to conjugation efficiencies of 69%, 82%, and 79%, respectively, as determined by UV−vis spectroscopy.

Recently, we reported that purification and micellization can be performed simultaneously (*28*), thus, after the conjugations of CB, additional DMF was added to the reaction mixtures and the solutions were dialyzed subsequently against nanopure water for 84 h to induce self-assembly into polymeric micelles while removing noncovalently linked CB. The polymers readily formed micelles, as determined by transmission electron microscopy (TEM) and dynamic light scattering (DLS) studies (Figure 1 and Table 1). Compared to the original micelles of the precursors, **1a**−**1c** (*23*), conjugation of CB did not change the TEM size of the micelles significantly (Table 1). The DLS data showed slight increases in number-average hydrodynamic diameter (D_h) values.

DOX Loading and Release Profiles. DOX was incorporated into the micelles using a similar procedure published previously (*8*). Dichloromethane was used as the organic solvent to solvate the DOX and to swell the core of the micelle, facilitating the loading of the therapeutic. The amount of DOX in the micelle solutions were determined by UV−vis measurements. The loading capacities for micelles **2a**−**2c** were 3.6 ± 0.5, 4.9 ± 0.6, and 4.0 ± 0.7 wt % based on polymer mass, respectively (Table 1). During the preparation of the micelles, we noticed that the micelle solution **2a** precipitated after *ca.* one week of storage, while micelles **2b** and **2c** were storage stable for months, indicating that a high fluorine content adversely affected the formation and stability of the micelles, which may be a reason for its low loading capacity. The balance of fluorine and carboxylic acid content also affected the DOX release profiles. The release of the DOX was assessed by monitoring the decrease of UV−vis absorbance over time (*8, 12*). Samples were withdrawn from dialysis cassettes at progressive time intervals and analyzed by UV−vis spectroscopy. In this release model, DOX molecules are first released from the micelles, and then pass through the dialysis membrane. Since the rate-determining step is the rate that DOX is released from the micelles (Figure 2), the overall rate can be considered as the rate that DOX was released from the micelles. Using this release model, the DOX release behavior was similar for **2b** and **2c**, but **2a** exhibited a faster release rate (Figure 2), possibly due the fact that **2a** does not have a stable micelle structure. For **2b** and **2c**, a release of ca. 25% of the cargo was observed in 8 h, followed by a slow, sustained release over the course of 48 h. At the end of 48 h, 66%, 45%, and 51% of DOX had released from micelles **2a**, **2b**, and **2c**, respectively. The release profiles were slower than those observed for highly branched dendritic constructs (*8*) loaded with DOX, but similar to release rates from shell cross-linked nanoparticles (*12*).

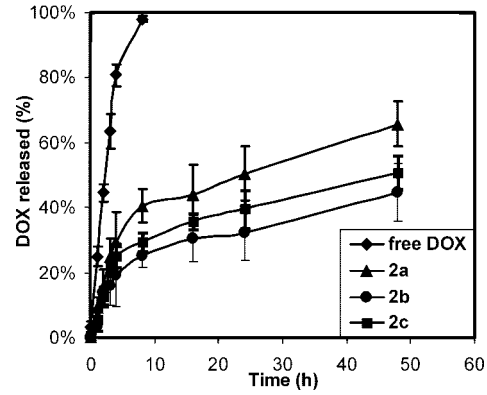

Figure 2. Release profiles of DOX from a dialysis cassette (control labeled as free DOX in the legend) and from dialysis cassettes containing micelles of **2a**−**2c** over time in PBS buffer (5 mM, pH 7.4) at 37 °C.

Cell Cytotoxicity Studies. The cytotoxicities of **2a**−**2c** were studied by incubating U87-MG-EGFRvIII-CBR cells with varying concentrations of the micelles. Cell viability was assessed using a Vibrant MTT cell proliferation assay kit. Cells were first incubated with DOX-loaded and nonloaded micelles for 2 h; subsequently, the cells were washed twice with PBS buffer and refed with fresh media. After 72 h of incubation, MTT assays were conducted. No significant toxicity was observed at concentrations up to 100 000 ng mL^{-1} for the nonloaded micelles (Figure 3, top). In comparison, the DOX-loaded micelles exhibited potent cytotoxic effects (Figure 3, bottom). At 1000 ng mL^{-1}, only 30% of the cells treated with DOX-loaded micelles survived (sample **2b**), which is comparable to free DOX at the same dose concentration (20% survived, Figure 3, bottom), indicating that this nanocarrier can achieve excellent cytotoxic effect on this glioma cell line. Interestingly, compared to glassy amorphous SCK nanoparticles derived from poly(acrylic acid)-*b*-poly(styrene) (PAA-*b*-PS) (*12*), the micelles in this study have lower loading capacity of DOX, but showed significantly greater cytotoxicity. The improvement of therapeutic efficacy is possibly due to a higher extent of release of DOX in these systems (45−66% after 48 h, compared to the

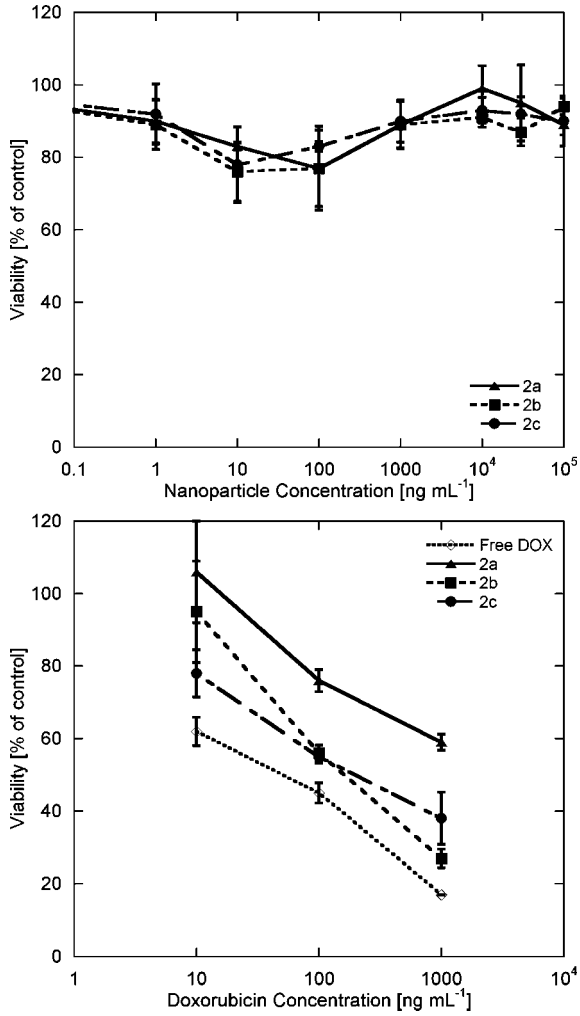

Figure 3. Cell viability studies using MTT assay. U87-MG-EGFRvIII-CBR cells were incubated with **2a**−**2c** without (top) and with DOX (bottom) loading at varied concentrations.

SCK system that retains more cargo, with only 30−55% release after 48 h), as this new system was designed to contain an integrated mixing between the hydrophobic pockets and hydrophilic domains, giving a more open, multicompartment structure, in contrast to the core−shell structure of SCK nanoparticles.

We also noticed that, in the presence of cells, a partial degradation of the trifluoroethyl ester moiety occurred, which may further enhance the release of DOX. The substantial chemical shift difference between trifluoroethyl ester and trifluoroethanol and the zero-background of ^{19}F-NMR signal allows real-time monitoring of the hydrolysis of these fluorinated micelles, upon cellular incubation. As seen in Figure 4, the trifluoroethyl esters in the micelle exhibited a broad ^{19}F resonance at 2.7 ppm, and the degradation product, trifluoroethanol, gave a sharp triplet at −1.2 ppm with a $^3J_{H-F} = 8.5$ Hz. While the micelle solutions were very stable in water and PBS (for months), as monitored by ^{19}F NMR spectroscopy, incubation with cells resulted in quick release of trifluoroethanol. Within 1 h, ca. 2% of trifluoroethanol was detected by ^{19}F NMR spectroscopy. The hydrolysis proceeded rapidly up to ca. 4 h, with a total of ca. 8% degradation. Afterward, a sudden halt of degradation was observed, resulting in a nonlinear degradation profile (see Supporting Information). A halt in degradation may be due to a loss of enzymatic activity. Alternatively, the hydrolysis may be limited to the surface-available trifluoroethyl ester groups, while others remain stable beneath the surface of

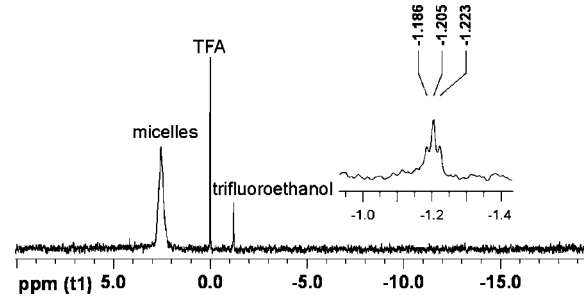

Figure 4. ^{19}F NMR spectra demonstrating partial hydrolysis of the trifluoroethyl ester units of **2b** (470 MHz, H_2O/D_2O, with TFA as an internal standard, 4 h after incubation of micelles with cells at 37 °C).

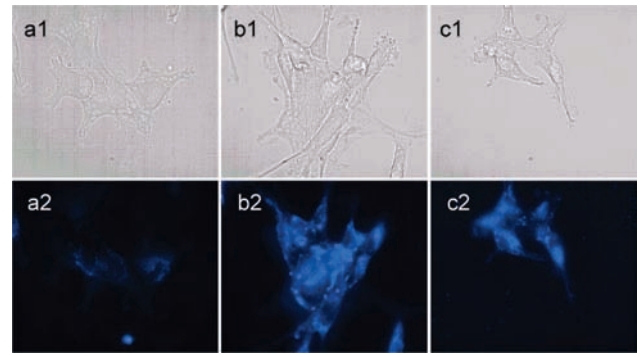

Figure 5. Cellular uptake of micelles by fluorescence microscopy study. U87-MG-EGFRvIII-CBR cells were incubated with micelle solutions of **2a**, **2b**, and **2c**, respectively. 1: phase contrast. 2: blue fluorescence. The cells were treated with micelles (0.1 mg/mL) for 2 h at 37 °C, followed by repeated washings, and then fixed with 4% paraformaldehyde.

the polymer or polymer micelle assembly. A thorough study of the hydrolysis of these micellar constructs using lipases and enzymatic inhibitors is currently underway. Nevertheless, the partial hydrolysis of trifluoroethyl ester during the cell incubation may result in a faster and more complete release of DOX in vitro, as compared to release data from the dialysis model. Although the hydrolysis product, trifluoroethanol, may be toxic to cells, we did not observe a significant negative effect on the viability of the cells incubated with the control micelle solutions (Figure 3, top).

Fluorescence Microscopy Studies. The cellular uptake of the polymer micelles was also studied by fluorescence microscopy. We took advantage of the blue fluorescence from CB and red autofluorescence from DOX to study the cellular uptake of the polymeric micelles and localization of DOX within the cells delivered by these polymers. As shown in Figure 5, cells treated with all three control micelles (**2a**−**2c**) demonstrated significant amounts of blue fluorescence, mostly in the cytoplasm. This intracellular trafficking is in contrast to that of free CB dye as a small molecule, which binds strongly to the nucleus (data not shown), confirming that the fluorescence observed arises from polymer−dye conjugates. At this moment, the mechanism of cellular uptake of these micelles is not clear and remains to be investigated. However, the blue fluorescence clearly indicated that cell uptake indeed occurred.

Because micelles **2b** showed the best cell viability reduction (Figure 3, bottom), we chose micelles **2b** for further microscopy studies on DOX localization. As seen in Figure 6, within 2 h treatment, DOX molecules were already delivered inside the cells, although mostly present in the cytoplasm surrounding the nucleus (Figure 6, a2). In contrast, after 24 h treatment, DOX was located within the nucleus (Figure 6, b2); the nuclei are

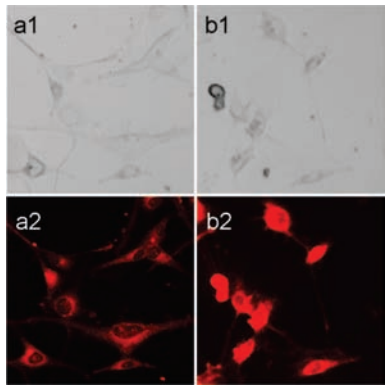

Figure 6. Localization of DOX upon treatment of DOX-loaded micelles by fluorescence microscopy. U87-MG-EGFRvIII-CBR cells were incubated with DOX-loaded micelle **2b**. 1: phase contrast. 2: red fluorescence. a: 2 h after treatment. b: 24 h after treatment, more DOX were incorporated into the nucleus.

brighter, indicating more DOX molecules have been incorporated. These images indicated efficient deliveries of DOX to the nucleus, which may be responsible for cell viability reductions.

^{19}F NMR Studies on the Cellular Uptake of the Micelles. Fluorine-containing nanoscopic assemblies have been used for cell uptake and cell trafficking studies using ^{19}F NMR spectroscopy or ^{19}F MRI (*7, 29, 30*). Since there is no background signal, the ^{19}F NMR/MRI technique is highly sensitive, with detection limits on the nanogram scale. In this study, ^{19}F NMR spectroscopy was employed to confirm and quantify cell uptake of **2b** in U87-MG-EGFRvIII-CBR cells. This micelle was selected because it had good loading capacity, desired release profile (Figure 2), and the best cytotoxicity result (Figure 3). Cells (4 million) were first incubated with the micelle solution for 2 h, followed by repeated washings with fresh PBS buffer and centrifugation to remove any free micelles. The cells were harvested and sonicated to lyse the cells. Trifluoroacetic acid (TFA) was used as an internal standard to quantify the fluorine concentration. Since the CF_3 groups on the micelles have much shorter T_1 relaxation times (*ca.* 500 ms) than that of TFA (*ca.* 2.5 s), it was necessary to adopt a long relaxation delay (10 s) to ensure that both fluorine species were fully relaxed before the next acquisition scan. However, with such long delay times, *ca.* 24 h scanning time was required to acquire a spectrum with reasonable resolution (Figure 7). Using the same method as reported by Ahrens and co-workers (*30*), it was possible to calculate that the total amount of fluorines in each cell was *ca.* 4.6×10^8 fluorines, indicating about 0.1% cell uptake efficiency. This very low cell uptake is possibly due to the negatively charged micelle that limits cell uptake compared to neutral nanoemulsions, wherein the cell uptake of fluorine species can reach concentrations of $10^{11}-10^{13}$ (*30*). Nevertheless, even with limited cell uptake, these nanostructures loaded with DOX exhibited a significant ability to reduce cell viability.

CONCLUSIONS

In conclusion, we have successfully constructed fluorine and CB dual-labeled nanostructures, studied their loading and release characteristics for therapeutic guests, and applied ^{19}F NMR and fluorescence microscopy as tools to study their cellular uptake and cell viability reduction. The nanostructures were designed to possess an amphiphilic, multicompartment morphology for packaging of therapeutic guests, based upon a hyperbranched-linear hybrid star-like structure that assembled into uni- or multimolecular micelles having optimum hydrodynamic diameters of 20−30 nm. Reasonable quantities of DOX could be

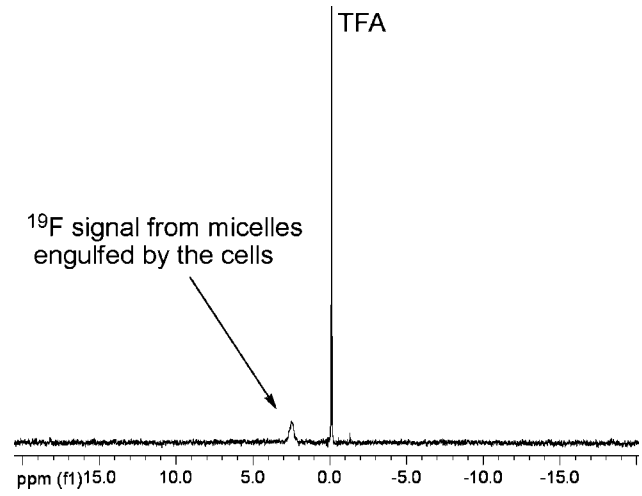

Figure 7. ^{19}F NMR spectrum of U87-MG-EGFRvIII-CBR cell suspensions. ^{19}F signal from micelles, engulfed by the cells, appears at 2.7 ppm.

loaded into the structures, and they exhibited differential release profiles, in terms of rates and ultimate amounts, depending upon their composition. These DOX-loaded nanostructures exhibited potent cytotoxicity on U87-MG-EGFRvIII-CBR cells. We anticipate that the incorporation of ligands for cell targeting will improve the DOX delivery even further. ^{19}F NMR spectroscopy showed a partial degradation of the surface available fluorinated polymer segments, which could accelerate the release of DOX from the micelles *in vitro* and *in vivo*. The successful construction of this dual-labeled, multifunctional nanocarrier may find promising applications in nanomedicine. The key unmet challenge is to now prepare such nanoscale constructs with cell-specific targeting groups so that therapeutics can be efficiently delivered with minimal side effects (*5, 15, 31*).

Structural and Formulation Factors Influencing Pyridinium Lipid-Based Gene Transfer

Lin Zhu, Yan Lu, Duane D. Miller, and Ram I. Mahato*

University of Tennessee Health Science Center, Memphis, Tennessee 38103. Received September 19, 2008; Revised Manuscript Received November 6, 2008

A series of pyridinium lipids containing a heterocyclic ring and a nitrogen atom were synthesized to determine the structure−activity relationship for gene delivery. Pyrylium chloroaluminate was synthesized by monoacylation of mesityl oxide and converted into pyrylium hexafluorophosphate, which was used as the key intermediate for reaction with different primary amines, to yield hydroxyethylpyridinium hexafluorophosphate and aminoethylpyridinium hexafluorophosphate. Acylation of these pyridinium salts with different types of fatty acid chlorides afforded the final pyridinium lipids, which were mixed with a co-lipid, such as L-α-dioleoylphosphatidylethanolamine (DOPE) and cholesterol (Chol) to prepare cationic liposomes by sonication. These liposomes were mixed with plasmid DNA encoding enhanced green fluorescent protein (pCMS-EGFP) or luciferase (pcDNA3-Luc) and transfected into Chinese hamster ovary (CHO) cells. Several factors including hydrophobic anchor chain length, anchor chain type, configuration of double bond, linker type, co-lipid type, cationic lipid/co-lipid molar ratio, charge ratio (N/P), and cell type had significant influence on transfection efficiency and cytotoxicity. Pyridinium lipids with amide linker showed significantly higher transfection efficiency compared to their ester counterparts. Liposomes prepared at a 1:1 molar ratio of pyridinium lipid and co-lipid showed higher transfection efficiency when either DOPE or cholesterol was used as a co-lipid to prepare cationic liposomes for complex formation with plasmid DNA at 3:1(+/−) charge ratio. Pyridinium liposomes based on a hydrophobic anchor chain length of 16 showed higher transfection efficiency and lower cytotoxicity. The pyridinium lipid with a trans-configuration of the double bond in the fatty acid chain showed higher transfection efficiency than its counterpart with cis-configuration at the same fatty acid chain length. In the presence of serum, C16:0 and Lipofectamine significantly decreased their transfection efficiencies, which were completely lost at a serum concentration of 30% and higher, while C16:1 trans-isomer still had high transfection efficiency under these conditions. In conclusion, pyridinium lipids showed high transfection efficiency and have the potential to be used as transfection reagents in vitro and in vivo.

INTRODUCTION

Cationic liposomes are the most commonly used synthetic carriers for delivery of oligonucleotides, siRNAs, and plasmid DNA. The three basic components of a cationic lipid, which affect gene expression or silencing, include (i) a hydrophobic lipid anchor group, such as fatty acid chains of various lengths and unsaturation states, or cholesterol, which helps in forming liposomes and exchanging lipids in cell membrane (*1*), (ii) a linker group, such as an ester, ether, amide, or carbamate, which binds the polar group to the lipid moiety and determines the stability and biodegradability of the cationic lipid (*2*), and (iii) a positively charged hydrophilic headgroup, such as mono- or polyamine group, which interacts with pDNA via electrostatic interaction, leading to its condensation and enhanced the cellular uptake (*3, 4*). Understanding these structural parameters is essential for the rational design of efficient cationic lipid-based transfection reagents. Transfection efficiency of cationic liposomes greatly depends on (i) the extent of DNA condensation, (ii) increased cellular uptake due to ionic and/or hydrophobic interaction with negatively charged biological surfaces, and (iii) membrane fusion via transient membrane destabilization to achieve delivery into the cytoplasm while avoiding degradation in the lysosomal compartment (*5, 6*).

* Corresponding authors. Ram I. Mahato, Ph.D., Department of Pharmaceutical Sciences, University of Tennessee Health Science Center, 19 Manassas, RM224, Memphis, TN 38103-3308. Tel: (901) 448-6929, Fax: (901) 448-2099, E-mail: rmahato@utmem.edu, http://cop.utmem.edu/rmahato.

Significant progress has been made in the design and function of cationic lipids since the introduction in 1987 of the transfection reagent Lipofectin, which is a 1:1 w/w mixture of the cationic lipid *N*-[1-(2,3-dioleoyloxy)propel]-*N*,*N*,*N*-trimethylammonium (DOTMA) and DOPE (*7*). Many cationic lipids bearing either a single tertiary or quaternary ammonium headgroup or that contain protonatable polyamines linked to dialkyl or cholesterol anchors have been designed for transfection of a variety of cell types in culture (*8*−*10*). Commercially available cationic lipids used as liposomes or alone for gene delivery include DOTMA (Lipofectin); 2,3-dioleyloxy-*N*-[2-spermine carboxamide] ethyl-*N*,*N*-dimethyl-1- propanammonium trifluoroacetate (DOSPA, Lipofectamine); 1,2-dioleoyl-3-trimethylammonium-propane (DOTAP); *N*-[1-(2,3-dimyristyloxy)propyl]-*N*,*N*-dimethyl-*N*-(2-hydroxyethyl) ammonium bromide (DMRIE), 3β-[*N*-(*N*,*N*′-dimethylaminoethane) carbamoyl] cholesterol (DC-Chol); dioctadecyl amidoglyceryl spermine (DOGS, Transfectam); and dimethyldioctadecylammonium bromide (DDAB) (*6, 7, 10*−*15*). A few such compounds have also been used in initial clinical studies. However, many of the cationic lipids used in early clinical trials such as DC-Chol, DMRIE, and GL-67, although effective in vitro, have proven inefficient in vivo, especially when compared with viral vectors (*16, 17*).

Various heterocyclic cationic lipids had been studied and used for gene delivery. Some of them showed higher transfection efficiency and lower cytotoxicity compared to cationic lipids with linear primary amines or polyamines as

10.1021/bc8004039 CCC: $40.75 © 2008 American Chemical Society
Published on Web 12/03/2008

the headgroup (*18*). Pyridinium heterocyclic ring in the cationic amphiphile, which had antiseptic and antibiotic properties, was first introduced in the 1940s (*19*, *20*). With the invention of pyridinium-based cationic lipids, a series of these lipids have been developed, and some of them have been reported to reach or surpass the transfection efficiency of commercial cationic lipid formulations, both in vitro and vivo, while maintaining low cytotoxicity (*21*−*25*).

In this study, we synthesized a series of pyridinium lipids containing a heterocyclic positively charged ring linked to different types of fatty acids via ester or amide spacers. Following purification and characterization of these cationic lipids using ^{1}H NMR, ^{13}C NMR, and mass spectrometry, cationic liposomes were prepared using DOPE or cholesterol as a co-lipid, followed by determination of particle size and zeta potential. Reporter gene expression and cytotoxicity were determined after transfection of Chinese hamster ovary (CHO) cells, hepatocarcinoma (CRL1830) cells, and prostate cancer (C4−2) cells with green fluorescent protein (GFP) or luciferase expression plasmid DNA after complex formation with cationic liposomes. Factors influencing gene transfer, including charge ratio (N/P) between cationic liposomes and pDNA, cationic lipid/co-lipid ratio, linker type, fatty acid carbon chain length, degree of saturation, configuration of double bond, the presence of serum, and cell type were studied.

EXPERIMENTAL PROCEDURES

Materials. 1,2-Dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE) was purchased from Avanti Polar Lipids (Alabaster, AL). Lipofectamine, DMEM, and RPMI1640 were purchased from Invitrogen Corporation (Carlsbad, CA). Heat-inactivated fetal bovine serum (FBS) and penicillin (10 000 units/mL penicillin G sodium)−streptomycin solution (10 000 μg/mL streptomycin sulfate) in 0.85% saline were purchased from Mediatech, Inc. (Herndon, VA). Luciferase Assay Kit and Cell Culture Lysis Reagent 5X (CCLR) were procured from Promega Corporation (Madison, WI). QIAfilter plasmid maxi kit was purchased from Qiagen, Inc. (Valencia, CA); BCA protein assay kit from Pierce (Rockland, IL); pCMS-EGFP plasmid was procured from BD Biosciences Clontech (Palo Alto, CA), and pcDNA3-Luc plasmid was a kind gift from Expression Genetics, Inc. (Huntsville, AL). All reagents used for lipid synthesis were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO) and Fisher Scientific (Pittsburgh, PA) and were used without further purification.

Synthesis of Pyridinium Lipids. *General Methods.* Routine thin layer chromatography (TLC) was performed on aluminum-backed Uniplates. (Analtech, Newark, DE). ^{1}H NMR spectra were obtained on a Bruker AX 300 (Billerica, MA) or Varian Inova-500 (Palo Alto, CA) spectrometer. Chemical shifts for ^{1}H NMR were reported as parts per million (ppm) relative to tetramethylsilane (TMS) in deuterated chloroform ($CDCl_3$) as internal standard. ^{13}C NMR spectra were obtained on a Bruker AX 300 spectrometer, operating at 75.5 MHz. To make sure the final results are reliable, we used both conventional mass and high-resolution mass (HRMS) spectrophotometers to characterize the synthesized pyridinium lipids. Conventional mass spectral data were collected on a Bruker ESQUIRE electrospray/ion trap instrument in positive and negative ion modes. High-resolution mass measurements were obtained using a Micromass Q-TOF2 mass spectrometer. HRMS samples were dissolved in 50% acetonitrile, 0.1% formic acid, and were infused by syringe (0.4 μL/min).To make this article easier to read, we only listed the HRMS data.

Pyridinium amide cationic lipids **4**−**13** and pyridinium ester cationic lipids **14**−**18** were synthesized as described by Ilies et al. (*25*), and their visual structures with minimized energy were simulated with the *Chem3D Pro* software, v 10.0 (ChemOffice, CambridgeSoft Corp.) using MM2 molecular mechanics routine toward a 0.1 rms gradient, which are shown in Table 1. Figure 1 outlines a synthesis route via the corresponding pyrylium salts. Mesityl oxide was monoacylated with fatty acid chloride in the presence of aluminum chloride to yield pyrylium chloroaluminate, which was subsequently converted into more stable hexafluorophosphate **1**, for using as a key intermediate to react with different primary amines, yielding aminoethylpyridinium hexafluorophosphate **2** and hydroxyethylpyridinium hexafluorophosphate **3**. Acylation of these pyridinium salts with different types of fatty acid chlorides afforded the final pyridinium amide cationic lipids **4**−**13** and pyridinium ester cationic lipids **14**−**18**, which were purified with chromatography on silica gel and recrystallized from ethanol.

Synthesis of Pyridinium Amide Cationic Lipids **4**−**13.** Aminoethylpyridinium hexafluorophosphate **2** and compounds **4** and **5** were synthesized as described by Ilies et al. (*25*), and the spectra were the same as those reported by these scientists.

4,6-Dimethyl-2-tetradecyl-1-[2-(9Z)-hexadec-9-enoylamidoethyl] Pyridinium Hexafluorophosphate **6.** Yield: 89.9%. ^{1}H NMR ($CDCl_3$), δ, ppm: 7.41 (s, 1H, H-5 pyridinium), 7.38 (s, 1H, H-3 pyridinium), 6.75 (t, 1H, J = 6.0 Hz), 5.33 (m, 2H, J = 5.4 Hz), 4.56 (t, 2H, J = 6.9 Hz), 3.63 (dt, 2H, J = 6.9 Hz, 6.6 Hz, CONHC$\underline{H}_2$), 3.17 (t, 2H, J = 7.5 Hz, CαPy-C$\underline{H}_2$), 2.90 (s, 3H, C$\underline{H}_3$ α-pyridinium), 2.55 (s, 3H, C$\underline{H}_3$ γ-pyridinium), 2.18 (t, 2H, J = 7.5 Hz, NHCOC$\underline{H}_2$), 1.99 (4H, br), 1.72 (quint., 2H, CαPy-CH$_2$C$\underline{H}_2$), 1.47 (m, 2H, NHCOCH$_2$C$\underline{H}_2$), 1.25 (s, 38H, C$\underline{H}_2$ from both of alkyl chains), 0.88 (t, 6H, C$\underline{H}_3$ of alkyl chains). ^{13}C NMR (300 M, $CDCl_3$), 175.23 (C═O), 159.07, 158.14, 155.05 (C-2, C-4, and C-6 pyridium), 130.41, 130.28 (CH═CH), 128.68, 127.32 (C-3 and C-5 pyridium), 50.55 (CαPy-$\underline{C}$H$_2$), 38.25 (CβPy-$\underline{C}$H$_2$), 35.97, 33.25, 32.59, 32.57, 31.92, 31.75, 29.70, 29.69, 29.65, 29.64, 29.63, 29.63, 29.59, 29.39, 29.34, 29.29, 29.29, 29.24, 29.21, 29.06, 29.03, 28.84, 25.40, 22.67, 22.63, 21.73, 21.51, 14.05, 14.05. HRMS calcd for $C_{39}H_{71}N_2O^+$, 583.5566, found 583.5568.

4,6-Dimethyl-2-tetradecyl-1-[2-(9E)-hexadec-9-enoylamidoethyl] Pyridinium Hexafluorophosphate **7.** Yield: 81.5%. ^{1}H NMR (300 M, $CDCl_3$), δ, ppm: 7.42 (s, 1H, H-5 pyridinium), 7.37 (s, 1H, H-3 pyridinium), 6.75 (t, 1H, J = 6.0 Hz), 5.37 (m, 2H), 4.55 (t, 2H, J = 6.6 Hz), 3.62 (dt, 2H, J = 6.6 Hz, 6.3 Hz, CONHC$\underline{H}_2$), 3.17 (t, 2H, J = 7.5 Hz, CαPy-C$\underline{H}_2$), 2.90 (s, 3H, C$\underline{H}_3$ α-pyridinium), 2.54 (s, 3H, C$\underline{H}_3$ γ-pyridinium), 2.17 (t, 2H, J = 7.5 Hz, NHCOC$\underline{H}_2$), 1.95 (4H, br), 1.72 (quint., 2H, CαPy-CH$_2$C$\underline{H}_2$), 1.46 (quint., 2H, NHCOCH$_2$C$\underline{H}_2$), 1.25 (s, 38H, C$\underline{H}_2$ from both of alkyl chains), 0.87 (t, 6H, C$\underline{H}_3$ of alkyl chains). ^{13}C NMR (300 M, $CDCl_3$), 174.67 (C═O), 158.47, 157.54, 154.51 (C-2, C-4, C-6 pyridinium), 129.37, 129.25 (CH═CH), 128.11, 126.72 (C-3 and C-5 pyridium), 49.97 (CαPy-$\underline{C}$H$_2$), 37.64 (CβPy-$\underline{C}$H$_2$), 36.38, 32.67, 31.35, 31.21, 29.17, 29.11, 29.09, 29.08, 29.07, 29.02, 28.82, 28.77, 28.72, 28.70, 28.69, 28.65, 28.60, 28.55, 28.49, 28.40, 26.66, 26.65, 24.83, 22.09, 22.06, 21.14, 20.92, 13.49, 13.48. HRMS calcd for $C_{39}H_{71}N_2O^+$, 583.5566, found 583.5562.

4,6-Dimethyl-2-tetradecyl-1-(2-octadecanoylamidoethyl) Pyridinium Hexafluorophosphate **8.** Yield: 87.5%. ^{1}H NMR ($CDCl_3$), δ, ppm: 7.41 (s, 1H, H-5 pyridinium), 7.38 (s, 1H, H-3 pyridinium), 6.77 (t, 1H, J = 6.0 Hz), 5.37 (m, 2H, J = 19.2 Hz), 4.55 (t, 2H, J = 6.9 Hz), 3.62 (dt, 2H, J = 6.9 and 6.0 Hz, CONHC$\underline{H}_2$), 3.17 (t, 2H, J = 7.2 Hz, CαPy-C$\underline{H}_2$), 2.90 (s, 3H, C$\underline{H}_3$ α-pyridinium), 2.54 (s, 3H, C$\underline{H}_3$ γ-pyridinium), 2.17 (t, 2H, NHCOC$\underline{H}_2$), 1.95 (4H, br), 1.72 (quint., 2H, CαPy-CH$_2$C$\underline{H}_2$), 1.48 (quint., 2H, NHCOCH$_2$C$\underline{H}_2$), 1.25 (s, 50H, C$\underline{H}_2$ from both of alkyl chains), 0.88 (t, 6H, C$\underline{H}_3$ of alkyl chains).

Table 1. Energy-Minimized Structures and Melting Points of Pyridinium Lipids

Carbon chain legnth and type	Compound ID	Amide	M.P.	Compound ID	Ester	M.P.
C14:0	4		73.6 °C	14		72.3 °C
C15:0				15		81.7 °C

4,6-Dimethyl-2-tetradecyl-1-(2-oleoylamidoethyl) Pyridinium Hexafluorophosphate **9.** Yield: 62.3%. ^{1}H NMR ($CDCl_3$), δ, ppm: 7.41 (s, 1H, H-5 pyridinium), 7.38 (s, 1H, H-3 pyridinium), 6.77 (t, 1H, J = 6.0 Hz, CONH), 5.33 (2H, t, HC=CH), 4.56 (t, 2H, J = 6.9 Hz), 3.63 (dt, 2H, J = 6.9 and 6.0 Hz, $CONHCH_2$), 3.17 (t, 2H, J = 7.5 Hz, CαPy-CH_2), 2.90 (s, 3H, CH_3 α-pyridinium), 2.55 (s, 3H, CH_3 γ-pyridinium), 2.18 (t, 2H, $NHCOCH_2$), 1.99 (q, 4H), 1.72 (quint., 2H, CαPy-CH_2CH_2), 1.47 (quint., 2H, $NHCOCH_2CH_2$), 1.25 (s, 42H, CH_2 from both of alkyl chains), 0.88 (t, 6H, CH_3 of alkyl chains). ^{13}C NMR (300 M, $CDCl_3$), 175.20 (C=O), 159.07, 158.13, 155.05 (C-2, C-4, C-6 pyridinium), 129.95, 129.81 (CH=CH), 128.68, 127.31 (C-3 and C-5 pyridium), 50.55 (CαPy-CH_2), 38.24 (Cβ Py-CH_2), 35.96, 33.24, 31.91, 31.90, 29.78, 29.75, 29.68, 29.67, 29.66, 29.64, 29.63, 29.58, 29.51, 29.38, 29.33, 29.32, 29.29, 29.28, 29.28, 29.26, 29.25, 29.24, 29.18, 29.06, 27.23, 25.39, 22.66, 21.71, 21.49, 14.05, 14.05. HRMS calcd for $C_{41}H_{75}N_2O^+$, 611.5879, found 611.5872.

4,6-Dimethyl-2-tetradecyl-1-[2-(9E)-octadec-9-enoylamidoethyl] Pyridinium Hexafluorophosphate **10.** Yield: 56.5%. ^{1}H NMR ($CDCl_3$), δ, ppm: 7.42 (s, 1H, H-5 pyridinium), 7.37 (s, 1H, H-3 pyridinium), 6.76 (t, 1H, J = 6.3 Hz), 5.37 (t, 2H, HC=CH, J = 19.2 Hz), 4.57 (t, 2H, J = 6.9 Hz), 3.63 (dt, 2H, J = 6.9 and 6.3 Hz, $CONHCH_2$), 3.17 (t, 2H, J = 7.8 Hz, CαPy-CH_2), 2.90 (s, 3H, CH_3 α-pyridinium), 2.56 (s, 3H, CH_3 γ-pyridinium), 2.18 (t, 2H, $NHCOCH_2$), 1.99 (br, 4H), 1.74 (quint., 2H, CαPy-CH_2CH_2), 1.46 (quint., 2H, $NHCOCH_2CH_2$), 1.25 (s, 42H, CH_2 from both of alkyl chains), 0.87 (t, 6H, CH_3 of alkyl chains). ^{13}C NMR (300 M, $CDCl_3$), 175.14 (C=O), 158.98, 158.06, 155.02 (C-2, C-4, C-6 pyridinium), 130.36, 130.21 (CH=CH), 128.63, 127.23 (C-3 and C-5 pyridium), 50.47 (CαPy-CH_2), 38.16 (Cβ Py-CH_2), 35.91, 33.17, 32.54, 32.51, 31.86, 31.84, 29.62, 29.63, 29.62, 29.61, 29.60, 29.59, 29.58, 29.53, 29.42, 29.34, 29.28, 29.23, 29.24, 29.20, 29.18, 29.15, 29.01, 28.98, 25.34, 22.60, 22.61, 21.65, 21.41, 13.99, 13.99. HRMS calcd for $C_{41}H_{75}N_2O^+$, 611.5879, found 611.5870.

4,6-Dimethyl-2-tetradecyl-1-[2-(11Z)-eicos-11-enoylamidoethyl] Pyridinium Hexafluorophosphate **11.** Yield: 79.8%. ^{1}H NMR ($CDCl_3$), δ, ppm: 7.41 (s, 1H, H-5 pyridinium), 7.38 (s, 1H, H-3 pyridinium), 6.78 (t, 1H, J = 6.3 Hz), 5.34 (m, 2H, HC=CH), 4.56 (t, 2H, J = 6.6 Hz), 3.63 (dt, 2H, J = 6.6 and 6.3 Hz, $CONHCH_2$), 3.17 (t, 2H, J = 7.8 Hz, CαPy-CH_2), 2.90 (s, 3H, CH_3 α-pyridinium), 2.55 (s, 3H, CH_3 γ-pyridinium), 2.18 (t, 2H, $NHCOCH_2$), 1.99 (br, 4H), 1.72 (quint., 2H, CαPy-CH_2CH_2), 1.57−1.42 (m, 2H, $NHCOCH_2CH_2$), 1.25 (s, 46H, CH_2 from both of alkyl chains), 0.88 (t, 6H, CH_3 of alkyl chains). ^{13}C NMR (300 M, $CDCl_3$), 175.23 (C=O), 159.06, 158.13, 155.06 (C-2, C-4, C-6 pyridinium), 129.90, 129.90 (CH=CH), 128.69, 127.31 (C-3 and C-5 pyridium), 50.54 (CαPy-CH_2), 38.23 (Cβ Py-CH_2), 35.97, 33.24, 31.92, 31.90,

29.81, 29.80, 29.78, 29.69, 29.67, 29.65, 29.64, 29.59, 29.54, 29.52, 29.50, 29.39, 29.35, 29.32, 29.30, 29.29, 29.29, 29.28, 29.24, 29.06, 27.25, 27.23, 25.41, 24.78, 22.66, 21.72, 21.49, 14.05, 14.05. HRMS calcd for $C_{43}H_{79}N_2O^+$, 639.6192, found 639.6193.

4,6-Dimethyl-2-tetradecyl-1-[2-(11E)-eicos-11-enoylamidoethyl] Pyridinium Hexafluorophosphate **12.** Yield: 58.8%. ^{1}H NMR ($CDCl_3$), δ, ppm: 7.41 (s, 1H, H-5 pyridinium), 7.38 (s, 1H, H-3 pyridinium), 6.78 (t, 1H, J = 6.0 Hz), 5.38 (t, 2H, HC=CH), 4.57 (t, 2H, J = 6.6 Hz), 3.64 (dt, 2H, J = 6.9 and 6.0 Hz, CONHCH$_2$), 3.17 (t, 2H, J = 7.8 Hz, CαPy-CH$_2$), 2.90 (s, 3H, CH$_3$ α-pyridinium), 2.56 (s, 3H, CH$_3$ γ-pyridinium), 2.18 (t, 2H, NHCOCH$_2$), 1.96 (br, 4H), 1.71 (quint., 2H, CαPy-CH$_2$CH$_2$), 1.48 (quint., 2H, NHCOCH$_2$CH$_2$), 1.25 (s, 42H, CH$_2$ from both of alkyl chains), 0.87 (t, 6H, CH$_3$ of alkyl chains). ^{13}C NMR (300 M, $CDCl_3$), 175.27 (C=O), 159.11, 158.16, 155.04 (C-2, C-4, C-6 pyridinium), 130.36, 130.36 (C=C), 128.68, 127.35 (C-3 and C-5 pyridium), 50.59 (CαPy-CH$_2$), 38.27 (CβPy-CH$_2$), 35.98, 33.28, 32.60, 31.92, 31.91, 29.70, 29.69, 29.69, 29.68, 29.68, 29.67, 29.67, 29.66, 29.65, 29.64, 29.59, 29.49, 29.49, 29.39, 29.35, 29.32, 29.30, 29.29, 29.19, 29.07, 25.40, 25.40, 22.66, 22.66, 21.74, 21.54, 14.05, 14.05. HRMS calcd for $C_{43}H_{79}N_2O^+$, 639.6192, found 639.6196.

4,6-Dimethyl-2-tetradecyl-1-[2-(2-heptyl-undecanoyl)-amidoethyl] Pyridinium Hexafluorophosphate **13.** Yield: 77.3%. ^{1}H NMR ($CDCl_3$), δ, ppm: 7.41 (s, 1H, H-5 pyridinium), 7.37 (s, 1H, H-3 pyridinium), 6.78 (1H, t, 1H, J = 6.3 Hz), 4.55 (t, 2H, J = 6.6 Hz), 3.66 (dt, 2H, J = 6.6 and 6.6 Hz, CONHCH$_2$), 3.22 (t, 2H, J = 6.9 Hz, CαPy-CH$_2$), 2.93 (s, 3H, CH$_3$ α-pyridinium), 2.55 (s, 3H, CH$_3$ γ-pyridinium), 2.12 (quint., 1H, NHCOCH), 1.71 (quint., 2H, CαPy-CH$_2$CH$_2$), 1.46 (quint., 4H, NHCOCH(CH$_2$)$_2$), 1.25 and 1.23 (s, s, 46H, CH$_2$ from both of alkyl chains), 0.88−0.84 (m, 9H, CH$_3$ of alkyl chains). ^{13}C NMR (300 M, $CDCl_3$), 178.24 (C=O), 159.01, 158.01, 155.21 (C-2, C-4, C-6 pyridinium), 128.71, 127.25 (C-3 and C-5 pyridium), 50.51 (CαPy-CH$_2$), 47.17 (C_9H_{19}CHC$_7$H$_{15}$), 38.03 (CβPy-CH$_2$), 33.27, 32.68, 31.91, 31.89, 31.84, 29.72, 29.68, 29.67, 29.66, 29.65, 29.65, 29.61, 29.61, 29.60, 29.53, 29.42, 29.34, 29.33, 29.30, 29.71, 29.11, 29.06, 27.45, 27.38, 27.42, 26.77, 22.65, 22.62, 21.65, 21.44, 14.04, 14.04. HRMS calcd for $C_{41}H_{77}N_2O^+$, 613.6035, found 613.6037.

Synthesis of Pyridinium Ester Cationic Lipids **14**−**18.** Hydroxyethylpyridinium hexafluorophosphate **3** and compounds **14** and **16** were synthesized per the described method (*25*), and the spectra are the same as those reported in ref *25*.

4,6-Dimethyl-2-tetradecyl-1-(2-pentadecanoylhydroxyethyl) Pyridinium Hexafluorophosphate **15.** Yield: 72.0%. ^{1}H NMR ($CDCl_3$), δ, ppm: 7.44 (s, 1H, H-5 pyridinium), 7.39 (s, 1H, H-3 pyridinium), 4.80 (t, 2H, J = 5.7 Hz, COOCH$_2$), 4.47 (t, 2H, J = 5.7z), 3.04 (t, 2H, J = 7.8 Hz, CαPy-CH$_2$), 2.87 (s, 3H, CH$_3$ δ-pyridinium), 2.55 (s, 3H, CH$_3$ γ-pyridinium), 2.25 (t, 2H, J = 7.5 Hz, COCH$_2$), 1.79 (cv, 2H, J = 7.5 Hz,), 1.48 (cv, 2H, COCH$_2$CH$_2$), 1.25, 1.26 (s, 44H, CH$_2$ from both of alkyl chains), 0.88 (t, 6H, CH$_3$ of alkyl chains). ^{13}C NMR (300 M, $CDCl_3$), 173.00 (C=O), 158.63, 158.56, 155.43 (C-2, C-4, C-6 pyridinium), 128.81, 126.90 (C-3 and C-5 pyridium), 60.68 (CαPy-CH$_2$), 49.94 (CβPy-CH$_2$), 33.76, 33.38, 31.92, 29.68, 29.68, 29.67, 29.67, 29.66, 29.66, 29.65, 29.65, 29.64, 29.60, 29.59, 29.59, 29.58, 29.45, 29.36, 29.35, 29.34, 29.22, 29.19, 29.06, 28.37, 24.64, 22.67, 21.77, 21.63, 14.06, 14.06. HRMS calcd for $C_{38}H_{70}NO_2^+$, 572.5406, found 572.5404.

4,6-Dimethyl-2-tetradecyl-1-(2-octadecanoylhydroxyethyl) Pyridinium Hexafluorophosphate **17.** Yield: 70.1%. ^{1}H NMR ($CDCl_3$), δ, ppm: 7.43 (s, 1H, H-5 pyridinium), 7.40 (s, 1H, H-3 pyridinium), 4.81 (t, 2H, J = 6.0 Hz, COOCH$_2$), 4.49 (t, 2H, J = 6.0z), 3.06 (t, 2H, J = 7.5 Hz, CαPy-CH$_2$), 2.89 (s, 3H, CH$_3$ α-pyridinium), 2.57 (s, 3H, CH$_3$ γ-pyridinium), 2.26 (t, 2H, J = 7.5 Hz, COCH$_2$), 1.81 (quint., 2H, CαPy-CH$_2$CH$_2$), 1.49 (quint., 2H, COCH$_2$CH$_2$), 1.26, 1.27 (s, 50H, CH$_2$ from both of alkyl chains), 0.88 (t, 6H, CH$_3$ of alkyl chains). ^{13}C NMR (300 M, $CDCl_3$), 173.00 (C=O), 158.64, 158.55, 155.43 (C-2, C-4, C-6 pyridinium), 128.80, 126.90 (C-3 and C-5 pyridium), 60.68 (CαPy-CH$_2$), 49.95 (CβPy-CH$_2$), 33.76, 33.38, 31.92, 31.92, 29.70, 29.69, 29.69, 29.69, 29.68, 29.68, 29.67, 29.66, 29.65, 29.65, 29.64, 29.60, 29.58, 29.45, 29.35, 29.35, 29.34, 29.22, 29.19, 29.06, 28.37, 24.65, 24.65, 22.67, 22.67, 21.77, 21.63, 14.05, 14.05. HRMS calcd for $C_{41}H_{76}NO_2^+$, 614.5875, found 614.5880.

4,6-Dimethyl-2-tetradecyl-1-(2-oleoylhydroxyethyl) Pyridinium Hexafluorophosphate **18.** Yield: 69.5%. ^{1}H NMR ($CDCl_3$), δ, ppm: 7.43 (s, 1H, H-5 pyridinium), 7.39 (s, 1H, H-3 pyridinium), 5.33 (m, 2H, CH from double bond in oleyl group), 4.80 (t, 2H, J = 6.0 Hz, COOCH$_2$), 4.47 (t, 2H, J = 6.0 Hz), 3.05 (t, 2H, J = 7.5 Hz, CαPy-CH$_2$), 2.87 (s, 3H, CH$_3$ α-pyridinium), 2.55 (s, 3H, CH$_3$ γ-pyridinium), 2.25 (t, 2H, J = 7.8 Hz, COCH$_2$), 1.99 (q, 4H), 1.79 (quint. 2H, CαPy-CH$_2$CH$_2$), 1.48 (quint., 2H, COCH$_2$CH$_2$), 1.26 (s, 44H, CH$_2$ from both of alkyl chains), 0.88 (t, 6H, CH$_3$ of alkyl chains). ^{13}C NMR (300 M, $CDCl_3$), 172.99 (C=O), 158.75, 158.62, 155.52 (C-2, C-4, C-6 pyridinium), 130.15 129.59 (CH=CH), 128.76, 126.90 (C-3 and C-5 pyridium), 60.70 (CαPy-CH$_2$), 50.09 (CβPy-CH$_2$), 33.75, 33.42, 31.92, 31.90, 29.76, 29.68, 29.68, 29.67, 29.67, 29.65, 29.63, 29.57, 29.51, 29.44, 29.35, 29.34, 29.33, 29.29, 29.20, 29.19, 29.12, 29.07, 29.02, 28.41, 27.25, 27.16, 24.64, 22.66, 21.79, 14.04, 14.04. HRMS calcd for $C_{41}H_{74}NO_2^+$, 612.5719, found 612.5725.

Determination of Lipid Phase Transition Temperature and Melting Point. Differential scanning calorimetry (DSC) studies were carried out to find the phase transition temperature and melting point with a DSC Q2000, TA Instruments (UK). About 5 mg of pyridinium lipid or lipid mixture was scanned from 0 to 100 °C at a scan rate of 2 °C/min. Data were analyzed using Universal Analysis software provided by TA Instruments.

Preparation of Pyridinium Liposomes and Lipoplexes. A pyridinium lipid was dissolved in chloroform with a co-lipid, DOPE or Chol, at the molar ratio of 1:1, 2:1, and 4:1 to reach a final concentration of 1 mg/mL for the charged species. The solvent was removed by rotary evaporation and further dried under vacuum overnight to generate a thin lipid film. The lipid film was hydrated in sterile water at 60 °C and vortexed to form a cationic liposome suspension. Since lipid molecules form a lipid bilayer upon solvent evaporation, no free lipids should appear in the aqueous solution. Therefore, we did not make any attempt to isolate free lipids which may be present in the liposome suspension. The particle size of these liposomes was further reduced by probe sonication (Sonication s-4000, MISONIX) at the amplitude of 60 for 5 min. Pyridinium liposomes were characterized for DNA condensation efficiency, particle size distribution, and ζ-potential as described previously (*3*). The particle size and ζ-potential of cationic liposomes and lipoplexes were determined at 25 °C by dynamic light scattering using a Malvern Zetasizer (Malvern Instruments, UK). Briefly, DNA condensation was determined by 0.6% agarose gel electrophoresis at 10 v/cm for 100 min in 1× TBE buffer, followed by ethidium bromide (EtBr) staining.

In Vitro Transfection. CHO cells were seeded in 24-well plates and maintained in 0.5 mL of RPMI 1640 medium containing 10% fetal bovine serum (FBS) under 5% CO_2 at 37 °C for 24 h. The cell number was about 4×10^4 cells per well. GFP or luciferase expression plasmid (pCMS-EGFP or pDNA3-Luc) and cationic liposomes (different formulations) were diluted to 25 μL by Opti-MEM I medium, respectively, and incubated for 5 min at room temperature. Lipoplexes were prepared by mixing plasmid and liposomes in equal volume,

and incubated for 20 min at room temperature to allow complex formation. Immediately before transfection, the media was removed, and cells were washed gently with sterile phosphate buffered saline (PBS). Lipoplexes were added to each well, diluted to 0.5 mL by Opti-MEM I medium, and the plate was incubated under 5% CO_2 at 37 °C for 6 h. Following transfection, the culture medium was replaced with RPMI 1640 medium containing 10% FBS. GFP gene expression was observed under fluorescence microscopy (Olympus, Japan).

For luciferase expression, the cells were collected and lysed. The cell lysate was measured for luciferase gene expression by Luciferase Assay Kit (Promega, Madison, WI). The total protein concentration was measured by bicinchoninic acid (BCA) protein assay reagent (Pierce, Rockford, IL). Luciferase activity was normalized by the total protein content and expressed as relative light unit (RLU) per μg of protein (RLU/μg protein).

To determine whether the presence of serum in the culture media affects the transfection efficiency of pyridinium lipids, we used RPMI 1640 culture medium containing 0%, 5%, 10%, 15%, 20%, 30%, and 40% FBS for transfection of CHO cells with pyridinium lipid-based lipoplexes, and their transfection efficiencies were determined.

To determine the effect of cell types on gene transfer, two more cell lines were used to determine transfection efficiency and cytotoxicity. Murine hepatocarcinoma cells (CRL 1830) were seeded with 0.5 mL of DMEM medium containing 10% FBS under 5% CO_2 at 37 °C. Human prostate cancer cells (C4−2) cells seeded with RPMI 1640 medium containing 10% FBS under 5% CO_2 at 37 °C. The cell number was about 4×10^4 cells per well for 24 well plate for both of them. Luciferase expression and cytotoxicity were measured at the end of the transfection.

Cytotoxicity Assay. The cytotoxicity of lipoplexes at 48 h post-transfection was determined using 3-[4,5-dimethylthiazol-2-yl]-2,5- diphenyltetrazolium bromide (MTT) assay in CHO cells. Briefly, 5 mg/mL stock solution of MTT in PBS was diluted 10 times with complete growth medium. Four hours before the end of transfection study, cell culture medium was removed and replaced by this MTT medium to achieve a final concentration of 0.5 mg/mL MTT. The plate was then incubated at 37 °C in 5% CO_2 for 4 h. The medium was removed, blotted dried, and 200 μL of DMSO was added to each well to dissolve the formazan crystals. Finally, the plate was read spectrophotometrically at 560 nm using a microplate reader (Bio-Rad, Hercules, CA). The relative cell viability was calculated as $[Abs]_{sample}/[Abs]_{control} \times 100\%$.

Statistical Analysis. Data were expressed as the mean ± standard deviation (SD). The difference between any two groups was determined by ANOVA. $P < 0.05$ was considered statistically significant.

RESULTS

Synthesis of Pyridinium Lipids. The goal of this study was to synthesize a series of pyridinium lipids to determine the structure−activity relationship for enhanced gene delivery. All of these cationic lipids contain a heterocyclic pyridinium ring linked to a single alkyl chain fatty acid of different alkyl chain lengths (C14, C15, C16, C18, and C20), types (cis−trans isomers), and branched chain via ester and amide spacers. We synthesized not only the saturated and unsaturated even-numbered carbon chain length, but also carbon chain length of 15 (odd number) saturated analogue and branched carbon chain saturated analogue. The synthesis scheme of pyridinium lipids is shown in Figure 1. Briefly, mesityl oxide was monoacylated to yield pyrylium chloroaluminates, which were converted into pyrylium hexafluorophosphates (**1**) by hexafluorophosphoric acid. Pyrylium hexafluorophosphate was used as a key intermediate for reaction with different primary amines to form a pyridinium heterocyclic ring with different linkers in the final structure. Acylation of these pyridinium salts with different lengths and types of fatty acid chlorides afforded the final pyridinium lipids. Intermediate and final products of these pyridinium lipids were characterized by ^{1}H NMR, ^{13}C NMR, and high-resolution mass spectrometry (HRMS), and these results are included in the Experimental Procedures section.

Table 2. Determination of Lipid Phase Transition Temperature (°C) by Differential Scanning Calorimetry (DSC)[a]

type of hydrophobic anchor chain	linker		lipid with amide linker/co-lipid (molar ratio 1:1)	
	ester	amide	DOPE	CHOL
C14:0	45.5−47 5	38.9−44 9	18.2−21 4	32.9−35 2
C16:0	63.5−66.1	39.3−41.4	37.8−40.0	40.2−42.1
C16:1, cis		29.7−31.1		
C16:1,trans		35.7−36.7		
C18:0	73.4−74.1	45.4−48.7	24.2−26.3	42.1−46.5
C18:1, cis		31.4−32.1		
C18:1,trans		34.1−37.9		
C20:1, cis		36.7−39.6		
C20:1,trans		37.4−41.3		

[a] Values are "onset to peak temperature".

The structures with minimized energy of these lipids are listed in Table 1. Two side chains are much closer in energy-minimized structures of unsaturated lipids than those of saturated lipids, which may facilitate the formation of lipid bilayers in liposomes. The melting points of these lipids are listed in Table 1. More than half of these pyridinium lipids have melting points of more than 60 °C. An increase in fatty acid chain length increased the melting point. Saturated lipids have higher melting points than unsaturated lipids, except branched ones. For unsaturated lipids, the melting point of the trans-isomer is higher than that of the cis-isomer of the same fatty acid chain length. Lipid phase transition temperatures of pure pyridinium lipids and lipid mixture are listed in Table 2. The lipids with amide linker showed lower phase transition temperature compared to lipids with an ester linker. An increase in hydrophobic carbon chain length increased the phase transition temperature. At the same carbon chain length, the phase transition temperature of the trans-isomer was higher than that of the cis-isomer. The phase transition temperature was higher when formulated with cholesterol than that when formulated with DOPE. A higher phase transition temperature makes liposome preparation difficult by rehydration of lipid films and extrusion. Therefore, probe sonication was used to produce small unilamellar vesicles (SUV) at 60 °C. Sterile water was used as the suspension medium in cationic liposome preparation so as to prevent cationic liposome aggregation in long-term storage in electrolytic buffer.

Preparation and Characterization of Lipoplexes. Transfection efficiency of lipoplexes is known to depend on the particle size and surface charge of liposomes and lipoplexes (*26*, *27*). Therefore, we determined the mean particle size, particle size distribution (PSD), and ζ-potential of pyridinium liposomes prepared using different co-lipids and molar ratios of cationic lipid/co-lipid. The mean particle size of these liposomes was about 97.98 ± 4.31 nm, with the polydispersity index (PDI) of 0.32 ± 0.03, and ζ-potential was 41.33 ± 4.10 mV (Table 3). This suggests little difference in particle size and ξ-potential among different liposome preparations. Pyridinium liposomes were stable, and no aggregation was observed at 4 °C during the experimental period. Lipoplexes were formed by simply mixing pyridinium liposomes and plasmid DNA. The degree of DNA condensation increased with the increase in charge ratio.

Table 3. Particle Size and ζ-Potential of Pyridinium Cationic Liposome and Lipoplexes[a]

	pyridinium cationic liposomes	lipoplexes (0 h)	lipoplexes (10 h)
particle size (nm)	97.98 ± 4.31	124.33 ± 2.08	128.33 ± 1.53
PDI	0.32 ± 0.03	0.17 ± 0.02	0.15 ± 0.02
PSD (<200 nm)	>95%	>90%	>80%
ζ-potential (mV)	41.33 ± 4.10	28.07 ± 5.12	31.17 ± 5.50

[a] PDI: polydispersity index. PSD: particle size distribution. Values are mean ± SD.

However, migration of some free DNA was seen when lipoplexes were prepared at 0.5/1 to 2.5/1(+/−). At a charge ratio of 3:1(+/−) or above, plasmid DNA was completely condensed in all the formulations, as evidenced by no band shift upon agarose gel electrophoresis of lipoplexes (data not shown). Upon lipoplex formation, the particle size, polydispersity index, and ζ-potential of lipoplexes were determined and found to be 124.33 ± 2.08 nm, 0.17 ± 0.02, and 28.07 ± 5.12 mV, respectively. Particle size distribution of lipoplexes (<200 nm) was more than 90% at 0 h and more than 80% after 10 h. There was no significant change in the particle size, particle size distribution, and ζ-potential even at 10 h post-incubation at room temperature, suggesting that these lipoplexes are fairly stable on storage.

Factors Influencing Transfection Efficiency. The effect of various structure and formulation parameters on in vitro transfection efficiency of pyridinium lipids in CHO cells was examined as a function of linker (ester vs amide), hydrophobic carbon chain length (14, 16, and 18) and type (single vs double), configuration of double bond (cis-isomer vs trans-isomer), co-lipid type (DOPE vs Chol), cationic lipid/co-lipid molar ratio (1:1, 2:1 and 4:1), and cationic lipid/DNA (+/−) charge (1:1, 3:1, and 5:1) ratio. Lipofectamine is one of the most commonly used transfection reagents, and thus we selected this as the positive control for screening our pyridinium lipids. Our aim was to optimize our own cationic liposome formulations, not the transfection conditions of Lipofectamine. Therefore, we formulated Lipofectamine/plasmid complexes at 3/1(+/−) charge ratio, which is in the range of the recommended conditions by the manufacturer. Transfection efficiency was reported as relative light units (RLU) per μg of total protein content.

Charge Ratios. Pyridinium lipid (C16:0, amide linker) was mixed with Chol at the cationic lipid/co-lipid molar ratio of 1:1 to prepare cationic liposomes, and lipoplexes were prepared by mixing with luciferase plasmid at the charge ratios of 1:1, 3:1, and 5:1 (+/−). Luciferase gene expression (Figure 2A) and cytotoxicity (Figure 2B) in CHO cells were determined at 48 h post-transfection. Luciferase gene expression levels increased with an increase in lipid/DNA charge ratios from 1:1 to 5:1, while cell viability decreased slightly with an increase in charge ratio to 5:1(+/−). Compared to Lipofectamine, a much higher transfection efficiency was observed at the charge ratios of 3:1 and 5:1(+/−) groups, but there was no significant difference between 3:1 and 5:1. Further, there was no significant difference in cytotoxicity between pyridinium liposomes and Lipofectamine.

Type of Linkers. Pyridinium lipids (C16:0 with ester and amide linkers) were used to prepare liposomes with DOPE and Chol at the cationic lipid/co-lipid molar ratio of 1:1. Following transfection of CHO cells with lipoplexes (3:1, +/−), GFP-positive CHO cells were visualized under fluorescence microscopy at 48 h post-transfection. The cationic lipids with amide linkers significantly increased transfection efficiency in all liposomal formulations in CHO cells compared to their counterparts with ester linker, as evidenced by much higher levels of green fluorescence (Figure 3).

Cationic Lipid/Co-lipid Molar Ratios. Pyridinium lipid with C16:0 fatty acid chain and amide linker was used to formulate liposomes with cholesterol at cationic lipid/co-lipid molar ratios of 1:1, 2:1, and 4:1, and lipoplexes were prepared at the charge ratio of 3:l(+/−). At 48 h post-transfection, luciferase gene expression (Figure 4A) and cytotoxicity (Figure 4B) were measured. Pyridinium liposomes prepared at 1:1 and 2:1 cationic lipid/co-lipid molar ratios showed higher transfection efficiency compared to 4:1 molar ratio and Lipofectamine. Cell viability slightly decreased when the molar ratio of pyridinium lipid to Chol increased but was no different compared to Lipofectamine. So, we decided to select a 1:1 cationic lipid/co-lipid molar ratio to prepare liposomes for further studies.

Type of Co-Lipids. Pyridinium lipids with amide linker but different fatty acid chain (C16:0 and C18:0) were used to prepare liposomes by mixing with DOPE and Chol at the molar ratio of 1:1, and lipoplexes were prepared at the charge ratio of 3:l(+/−). After 48 h post-transfection, luciferase gene expression (Figure 5A) and cytotoxicity (Figure 5B) were measured. Chol as a co-lipid showed higher transfection efficiency in C16:0 amide lipid; on the contrary, DOPE as a co-lipid showed higher transfection efficiency in C18:0 amide lipid. Both of the formulations showed higher transfection efficiency than Lipofectamine/pDNA complexes formulated at 3:1(+/−) charge ratio. No difference in cytotoxicity was seen between pyridinium liposomes and Lipofectamine.

Alkyl Chain Length. Pyridinium lipids with amide linker and different alkyl chain length (C14:0, C16:0, and C18:0) were used to formulate liposomes with cholesterol at cationic lipid/co-lipid molar ratio of 1:1. At 48 h post-transfection of CHO cells with lipoplexes, the luciferase level was determined at 3:1(+/−) charge ratio (Figure 6A). Cytotoxicity data were shown in Figure 6B. Pyridinium lipid with C14:0 and C16:0 showed much higher transfection efficiency compared to C18:0 and also higher than Lipofectamine at 3:1(+/−) ratio. There was no difference in cytotoxicity compared to Lipofectamine for all the formulations except C14:0 lipid with amide linker, which showed the lowest level of cell viability. We also found that an odd number (C15:0) and C18:0 branched carbon chain analogues could not increase the transfection efficiency (data not shown).

Saturation of Alkyl Chain. Pyridinium lipids (C16:0 and C16:1) were used to prepare cationic liposomes using Chol as a co-lipid at the cationic lipid to co-lipid molar ratio of 1:1. At 48 h post-transfection of CHO cells with lipoplexes (3:1, +/−), luciferase gene expression (Figure 7A) and cytotoxicity (Figure 7B) were measured. The trans-isomer showed slightly higher transfection efficiency than saturated lipid and much higher transfection efficiency than its counterpart the cis-isomer. There was no significant difference in cell viability between pyridinium lipids and Lipofectamine.

Configuration of Alkyl Chain. Pyridinium lipids with different alkyl chain length (C16:1, C18:1, and C20:1) and different configuration (cis and trans) of the double bond were used to formulate cationic liposomes with DOPE at the cationic lipid to co-lipid molar ratio of 1:1. At 48 h post-transfection of CHO cells with lipoplexes (3:1, +/−), luciferase gene expression (Figure 8A) and cytotoxicity (Figure 8B) were measured. The liposomes formulated with trans-configuration lipids showed higher transfection efficiency compared to their counterpart lipids with cis-configuration at the same fatty acid chain length. C16:1 trans isomer has a much higher transfection efficiency than C18:1 and C20:1 trans-isomers at the same type of formulations. There was no significant difference in cell viability between all formulations and Lipofectamine.

Influence of Serum on Gene Transfer. Since serum is known to interfere with the transfection of lipoplexes, we transfected

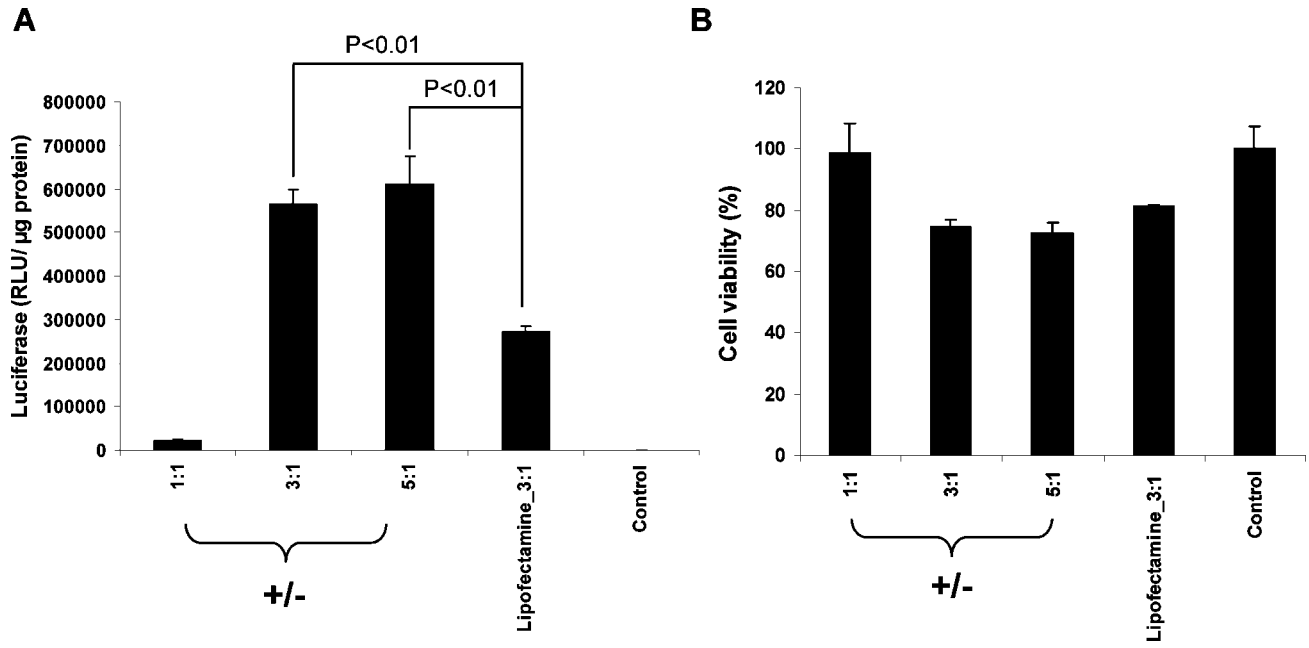

Figure 2. Effect of charge ratios on transfection efficiency (A) and cytotoxicity (B) at 48 h after transfection of lipoplexes. Pyridinium lipid **5** (C16:0, amide linker) was mixed with cholesterol (Chol) at the cationic lipid/co-lipid ratio of 1:1 to prepare cationic liposomes, and lipoplexes were prepared by mixing with luciferase plasmid at the charge ratio of 1:1, 3:1, and 5:1(+/−). Luciferase gene expression and cytotoxicity in CHO cells were determined 48 h post-transfection. The dose of pcDNA3-Luc plasmid was 0.2 μg/well for 4×10^4 cells.

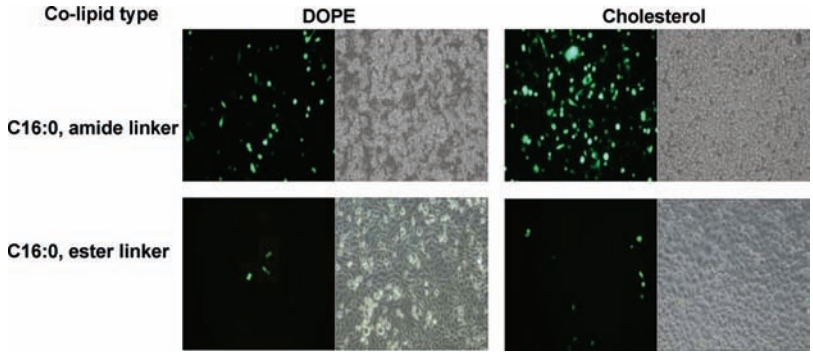

Figure 3. Comparison of gene expression between amide and ester linker. Lipid **5** (C16:0, amide linker) and lipid **16** (C16:0, ester linker) were used to prepare cationic liposomes with co-lipid DOPE and cholesterol at the molar ratio of 1:1. Lipoplexes were formed by mixing with luciferase plasmid at the charge ratio of 3:1(+/−). GFP gene expression was observed 48 h after transfection under fluorescence microscopy and normal light as the control. The dose of pCMS-EGFP plasmid was 0.4 μg/well for 4×10^4 cells.

CHO cells with the lipoplexes prepared using two most potent pyridinium lipid-based liposome formulations {C16:0, amide/cholesterol at 1:1 molar ratio (**5**CH1) and C16:1, amide, trans/DOPE at 1:1 molar ratio (**7**D1)} in the presence of serum (0%, 5%, 10%, 15%, 20%, 30%, and 40%). As shown in Figure 9, the formulation **7**D1 showed significantly higher transfection efficiency compared to the formulation **5**CH1 and Lipofectamine (formulated at 3:1, +/− charge ratio) at each serum concentration. The transfection efficiencies were decreased with an increase in serum concentration. At serum concentrations of 30% and higher, **5**CH1 and Lipofectamine lost their transfection ability when formulated at 3/1(+/−) charge ratio, while **7**D1 still kept high transfection efficiency. The luciferase gene expression in **7**D1 treated cells at the serum concentration of 40% showed similar level compared to those of **5**CH1 and Lipofectamine in the serum-free medium.

Different Cell Lines. Two pyridinium lipid formulations (**5**CH1 and **7**D1) based on cationic /co-lipid molar ratio of 1:1 and complex formation at 3:1 (+/−) charge ratio were tested in two additional cell lines, CRL 1830 and C4−2. At 48 h post-transfection, luciferase gene expression and cytotoxicity in CRL 1830 (Figure 10) and C4−2 (Figure 11) were measured. Both formulations worked very well in these two cell lines as evidence by more than 5−10 times the luciferase level compared to Lipofectamine when formulated at 3:1(+/−) charge ratio. There was no significant difference in cell viability between all formulations and Lipofectamine. These results suggest that the order of magnitude to which pyridinium lipid based formulations exceeds the Lipofectamine 3:1(+/−) formulation is cell-type dependent. Nevertheless, in all cases, much higher transfection efficiency was obtained when transfection was carried out using pyridinium lipid with C16 fatty acid chain and amide linker.

DISCUSSION

The structural and formulation factors, such as lipid/DNA ratio, co-lipid type, and cationic lipid/co-lipid molar ratio, have been shown to influence gene transfer efficiency both in vitro and in vivo (*8*, *26*, *28*). Pyridinium lipids have been shown to display higher transfection efficiency in cells that are not easily transfected by other cationic lipids, such as lipofectin, and transfect a relatively large number of cells (*21*). Therefore, here we report the effect of these parameters on the transfection efficiency of a series of pyridinium lipids.

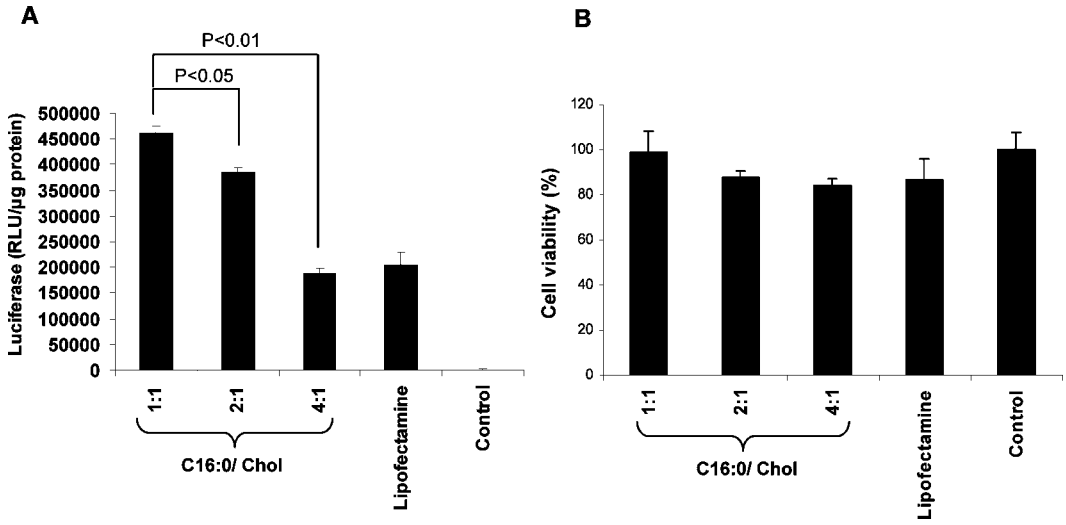

Figure 4. Effect of cationic lipid/co-lipid molar ratios on transfection efficiency (A) and cytotoxicity (B). Lipid **5** (C16:0, amide linker) was used to prepare cationic liposomes with co-lipid cholesterol (Chol) at the molar ratios of 1:1, 2:1, and 4:1. Lipoplexes were formed by mixing with luciferase plasmid at the charge ratio of 3:1(+/−). Luciferase gene expression and cytotoxicity in CHO cells were determined 48 h after transfection. The dose of pcDNA3-Luc plasmid was 0.2 μg/well for 4×10^4 cells.

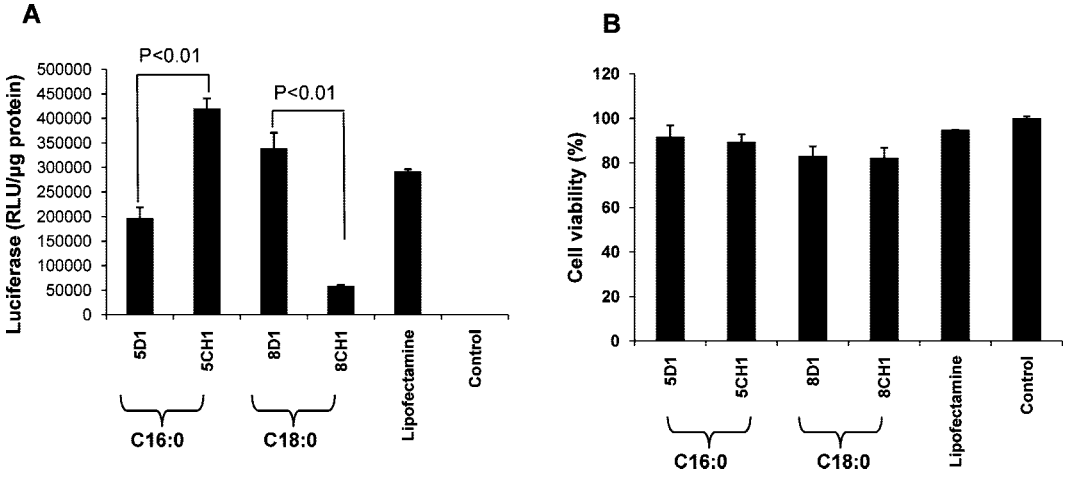

Figure 5. Effect of co-lipid type on transfection efficiency (A) and cytotoxicity (B). Lipids **5** (C16:0, amide linker) and **8** (C18:0, amide linker) were used to prepare cationic liposomes with co-lipid DOPE and cholesterol (Chol) at the molar ratio of 1:1. Lipoplexes were formed by mixing with luciferase plasmid at the charge ratio of 3:1(+/−). Luciferase gene expression and cytotoxicity in CHO cells were determined 48 h after transfection. The dose of pcDNA3-Luc plasmid was 0.2 μg/well for 4×10^4 cells.

The lower phase transition temperature makes the lipid molecule movement (lateral or flip−flop movement) easier within the liposomal bilayer compared to higher phase transition temperature. Generally, the phase transition temperature is influenced by the lipid structure and the liposome composition. In our study, some of the newly synthesized pyridinium lipids have the higher phase transition temperature, especially for the lipids with ester linker, compared to commonly used lipids. The longer the fatty acid chain length, the higher the phase transition temperature is; the higher the degree of saturation, the higher the phase transition temperature is; and the co-lipid will lower the phase transition temperature (Table 2). The high phase transition temperature makes liposome preparation difficult by extrusion even at 65 °C. It needs much higher energy to allow the lipid molecules to move and disperse into aqueous solution to form bilayer structures. Therefore, we chose the probe sonication method to prepare a liposome suspension. Also, the higher phase transition temperature may make phase inversion difficult, further influencing membrane transport of lipids and gene transfer.

In general, transfection efficiency increases with an increase in the charge ratio of lipoplexes until it becomes too toxic to the cells. To determine the structure−activity relationship of pyridinium lipid, we first determined the effect of the cationic lipid/plasmid charge ratio on the transfection efficiency to find the best charge ratio for further evaluations. On the basis of our transfection data, lipoplexes prepared at the charge ratio of 3:1(+/−) showed much higher transfection efficiency compared to 1:1(+/−), but no significant difference compared to 5:1(+/−). There was no significant difference between pyridinium lipids and Lipofectamine in cytotoxicity. Therefore, the charge ratio was fixed to 3:1(+/−) in all the following experiments.

Melting point, phase transition temperature, biodegradability, and transfection efficiency are known to depend on the structure of the linker that binds to the polar headgroup to the hydrophobic lipid chains (*5*). Therefore, we determined the effect of amide and ester linkers on transfection efficiency and cytotoxicity. We used these linkers because they are biodegradable and thus could reduce the cytotoxicity of pyridinium lipids (*25*). As shown in Figure 3, the lipid with an amide linker showed higher transfection efficiency compared to its counterpart with the ester linker regardless of the fatty acid chain length. The high transfection efficiency of amide linker lipids may be caused by their lower phase transition temperature (Table 2) which makes

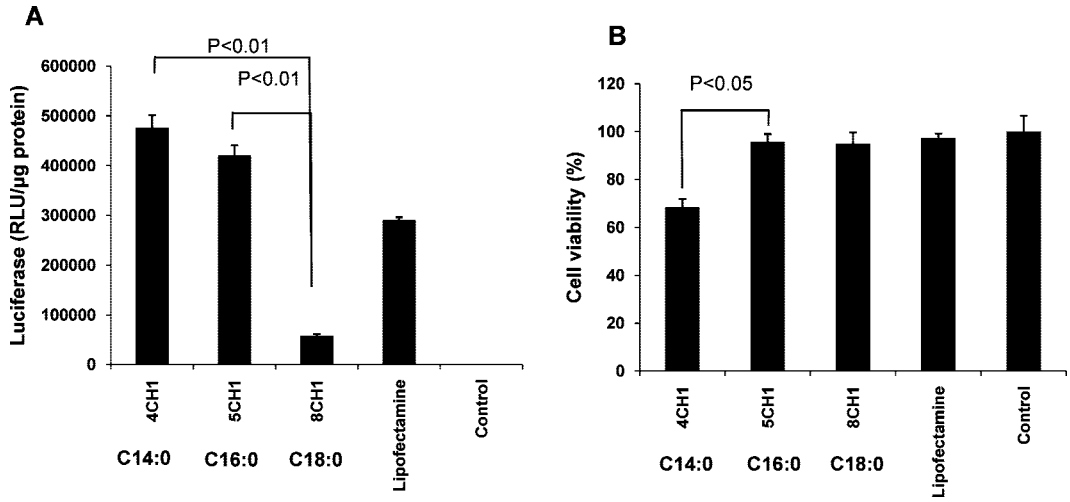

Figure 6. Effect of fatty acid chain length on transfection efficiency (A) and cytotoxicity (B). Lipids **4** (C14:0, amide linker), **5** (C16:0, amide linker), and **8** (C18:0, amide linker) were used to prepare cationic liposomes with co-lipid cholesterol (Chol) at the molar ratio of 1:1. Lipoplexes were formed by mixing with luciferase plasmid at 3:1(+/−) charge ratio. Luciferase gene expression and cytotoxicity in CHO cells were determined 48 h after transfection. The dose of pcDNA3-Luc plasmid was 0.2 μg/well for 4×10^4 cells.

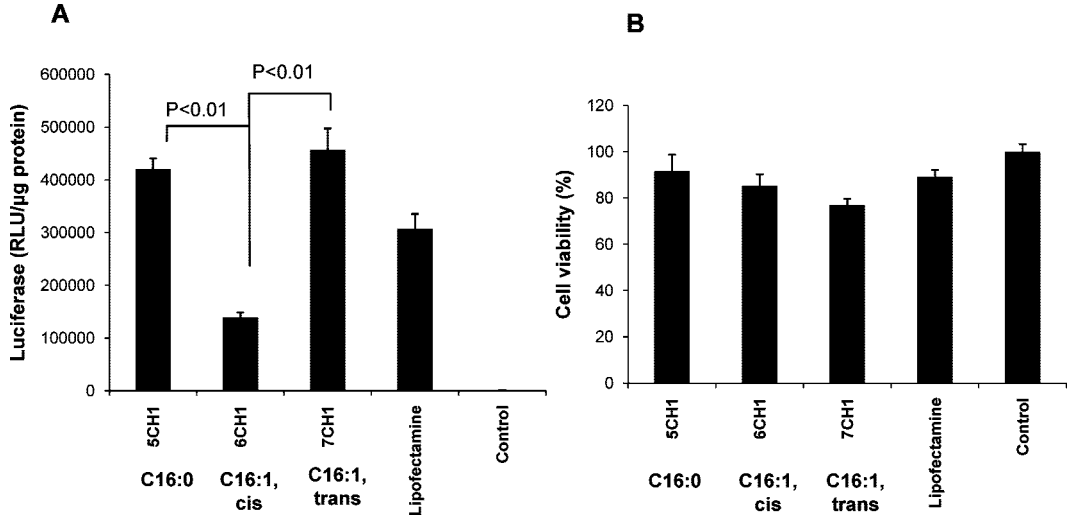

Figure 7. Effect of degree of saturation on transfection efficiency (A) and cytotoxicity (B). Lipids **5** (C16:0, amide linker), **6** (C16:1, amide linker, cis-isomer), and **7** (C16:1, amide linker, trans-isomer) were used to prepare cationic liposomes with co-lipid cholesterol (Chol) at the molar ratio of 1:1. Lipoplexes were formed by mixing with luciferase plasmid at the charge ratio of 3:1(+/−). Luciferase gene expression and cytotoxicity in CHO cells were determined 48 h after transfection. The dose of pcDNA3-Luc plasmid was 0.2 μg/well for 4×10^4 cells.

the liposomal bilayer structure more stable in aqueous solution during the transfection process and storage.

The molar ratio of a cationic lipid to co-lipid is known to affect the phase transition temperature of cationic liposomes and the structure of lipoplexes. Therefore, we prepared cationic liposomes using pyridinium lipid and cholesterol at the molar ratios of 1:1, 2:1, and 4:1, as cholesterol has been reported to be superior to DOPE for pyridinium lipids (*23*). Luciferase gene expression (Figure 4A) and cytotoxicity (Figure 4B) were influenced by the molar ratio of pyridinium lipid to Chol, with the highest transfection efficiency for the liposomes prepared at 1:1 cationic lipid/co-lipid molar ratio. An increase in the amount of Chol slightly decreased the cytotoxicity of pyridinium liposomes. So, we fixed cationic lipid/co-lipid molar ratio to 1:1 in other experiments. These results are in good agreements with the work of Ilies et al. (*23*).

DOPE and Chol are the two most commonly used co-lipids in cationic liposome preparation. The incorporation of fusogenic lipids such as DOPE improves the endosomal release by membrane fusion between the liposomal and endosomal bilayers (*29*, *30*). DOPE has been shown to be a major driving force in promoting transfection efficiency of SAINT-2 cationic lipids, as it gets transformed from its lamellar phase in water to the hexagonal phase when dispersed in a physiological salt solution (*31*). The use of Chol as a co-lipid has been reported to show enhanced in vivo gene expression, as Chol-containing liposomes efficiently interact with the cell membrane in the presence of serum (*32*). On the basis of our data, the use of both DOPE and Chol as co-lipids showed higher transfection efficiency of pyridinium lipids compared to Lipofectamine when lipoplexes were prepared at a 3:1(+/−) charge ratio. The selection of co-lipid was dependent on the type of cationic lipids.

The hydrophobic chain length influences the shape of amphiphiles and supramolecular associations generated through the self-assembling process (*25*). Therefore, we synthesized a series of pyridinium lipids with different lengths of fatty acids to determine the influence of alkyl chain length on gene transfer. Pyridinium lipids with C14:0 and C16:0 fatty acid and amide linker formulated with Chol showed higher transfection efficiency compared to C18:0 lipid with the same linker (Figure 6A). Since C14:0 was more toxic than C16:0 but had similar transfection efficiency, we only synthesized C16:1, C18:1, and

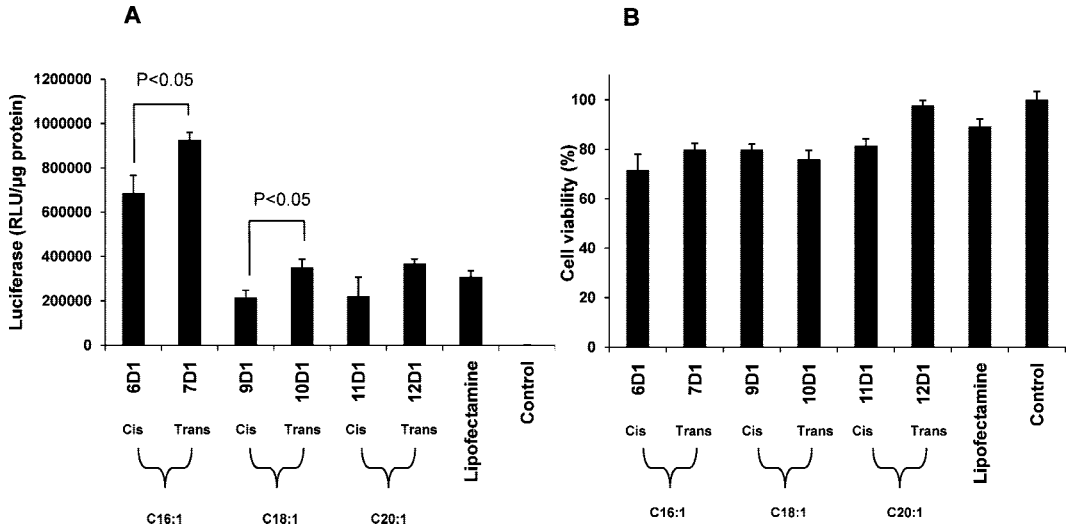

Figure 8. Effect of alkyl chain configuration on transfection efficiency (A) and cytotoxicity (B). Lipids **6** (C16:1, amide linker, cis-isomer), **7** (C16:1, amide linker, trans-isomer), **9** (C18:1, amide linker, cis-isomer), **10** (C18:1, amide linker, trans-isomer), **11** (C20:1, amide linker, cis-isomer), and **12** (C20:1, amide linker, trans-isomer) were used to prepare cationic liposomes with co-lipid DOPE at the molar ratio of 1:1. Lipoplexes were formed by mixing with luciferase plasmid at the charge ratio of 3:1(+/−). Luciferase gene expression and cytotoxicity in CHO cells were determined 48 h after transfection. The dose of pcDNA3-Luc plasmid was 0.2 μg/well for 4×10^4 cells.

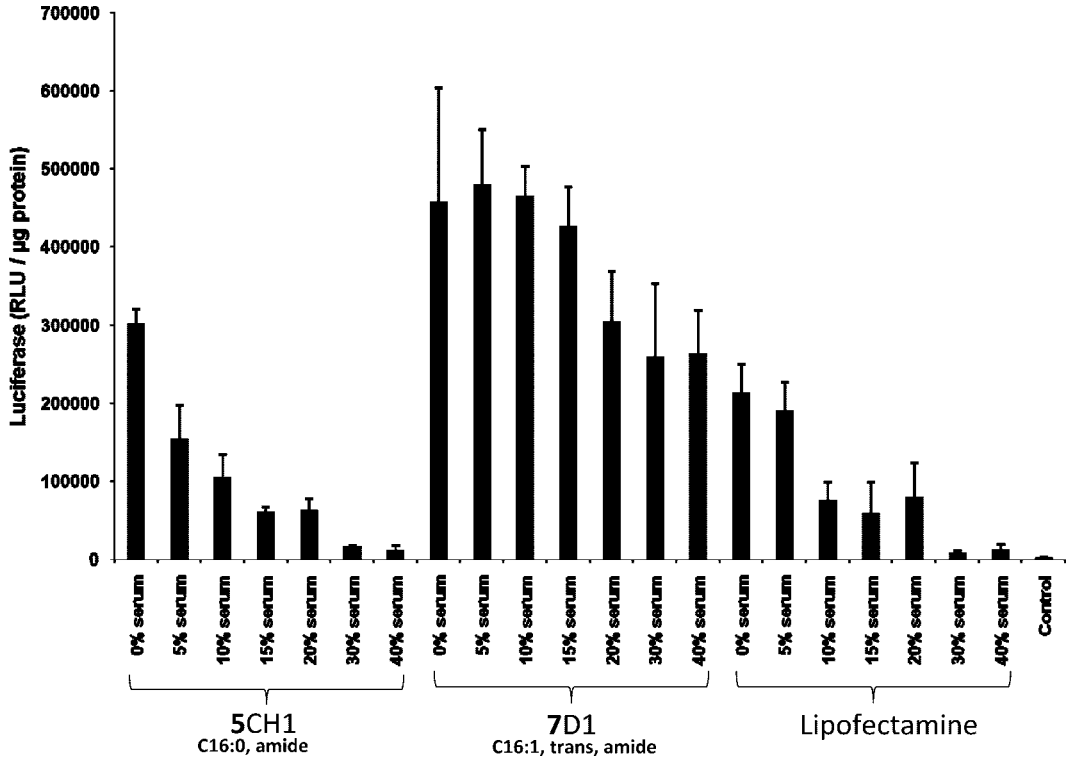

Figure 9. Influence of serum on gene transfer. Lipids **5** (C16:0, amide linker) and **7** (C16:1, amide linker, trans-isomer) were used to prepare cationic liposomes with co-lipid DOPE and cholesterol at the molar ratio of 1:1. Lipoplexes were formed by mixing with luciferase plasmid at the charge ratio of 3:1(+/−). Luciferase gene expression and cytotoxicity in CHO cells were determined 48 h after transfection. The dose of pcDNA3-Luc plasmid was 0.2 μg/well for 4×10^4 cells.

C20:1 for further evaluation. As shown in Figure 8A, C16:1 showed higher transfection efficiency compared to C18:1 and C20:1. Ilies et al. reported similar results (*25*). Van der Woude et al. (*21*) also reported a significant reduction in transfection efficiency and cytotoxicity with the elongation of the alkyl chain length to C18:0 (SAINT-5) relative to that of C16:0 (SAINT-1). Srilakshmi et al. (*33*) demonstrated that the transfection efficiency of cationic lipids was anchor dependent when they studied the cationic lipids containing a hydrophobic anchor chain ranging from C12 to C18. In their study, the lipid containing a 16-carbon chain showed better transfection efficiency among these compounds, while lipids containing less than a 14-carbon anchor chain did not show any transfection, indicating that a minimum of a 14-carbon anchor length is essential for imparting transfection properties to their cationic lipids (*34*). Cationic lipids containing less than a 14-carbon anchor chain do not form stable lipoplexes that are required for efficient cellular uptake of plasmid DNA. Noncondensed plasmid DNA present in the lipoplexes gets degraded by the serum proteins and/or enters into a nonproductive pathway (*34*). On the contrary, the carbon anchor chain will promote strong interaction between DNA and cationic lipid by hydrophobic strength besides electrostatic

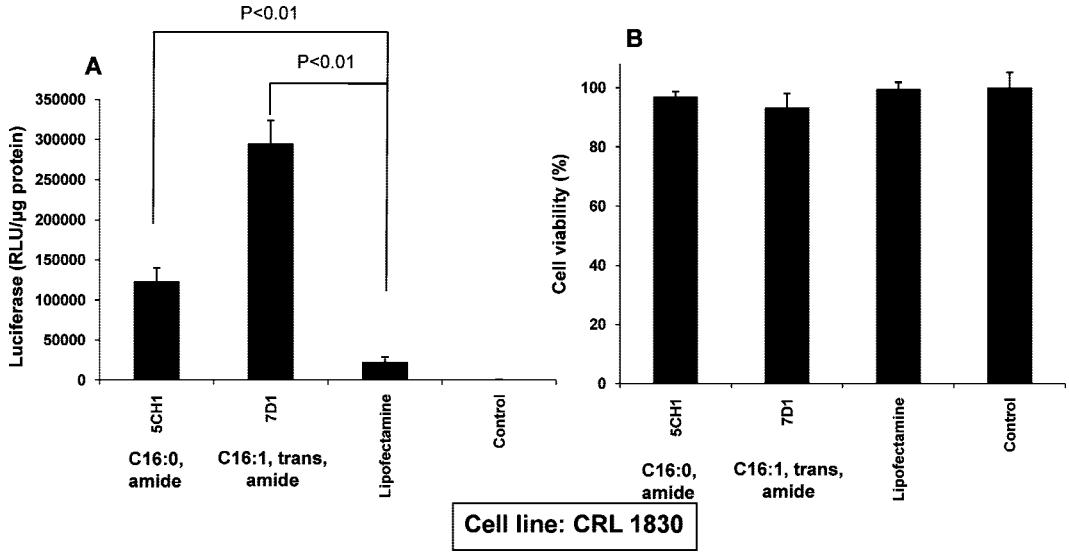

Figure 10. Transfection efficiency (A) and cytotoxicity (B) in hepatocarcinoma cells. Lipids **5** (C16:0, amide linker) and **7** (C16:1, amide linker, trans-isomer) were used to prepare cationic liposomes with co-lipid DOPE and cholesterol at the molar ratio of 1:1. Lipoplexes were formed by mixing with luciferase plasmid at the charge ratio of 3:1(+/−). Luciferase gene expression and cytotoxicity in CHO cells were determined 48 h after transfection. The dose of pcDNA3-Luc plasmid was 0.2 μg/well for 4×10^4 cells.

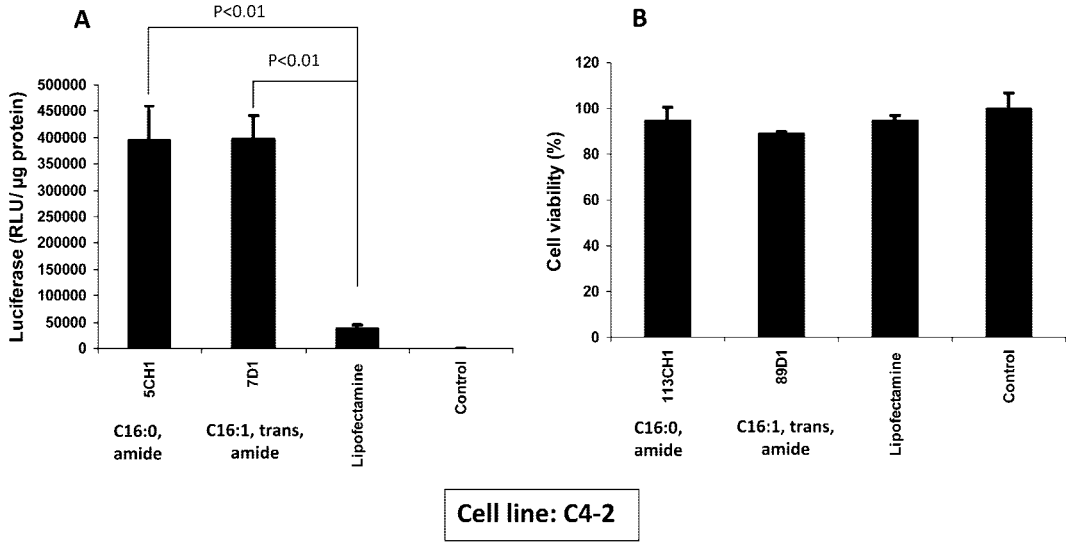

Figure 11. Transfection efficiency (A) and cytotoxicity (B) in prostate cancer cells. Lipids **5** (C16:0, amide linker) and **7** (C16:1, amide linker, trans-isomer) were used to prepare cationic liposomes with co-lipid DOPE and cholesterol at the molar ratio of 1:1. Lipoplexes were formed by mixing with luciferase plasmid at the charge ratio of 3:1(+/−). Luciferase gene expression and cytotoxicity in CHO cells were determined 48 h after transfection. The dose of pcDNA3-Luc plasmid was 0.2 μg/well for 4×10^4 cells.

interaction, which will decrease the release of DNA from cationic liposomes, leading to a further decrease in gene expression (*22*). A balance between the stability of the liposome in the medium and endosomal DNA release into the cytoplasm is important for efficient transfection efficiency (*35*).

The degree of unsaturation and configuration of the hydrophobic anchor chain can affect the transfection efficiency and cytotoxicity (*21*). The degree of unsaturation in the lipid structure affects the fusogenicity of the lipid (L_α/H_{II} transition) (*36,37*). The increase in the chain length of saturated hydrophobic anchors increases the phase transition temperature: 45.5, 63.5, and 73.4 for C14:0, C16:0, and C18:0 of pyridinium lipids with ester linkages; and 38.9, 39.3, and 45.4 for C14:0, C16:0, and C18:0 of pyridinium lipids with amide linkers (Table 2). The increase in phase transition temperature decreases fusogenicity, leading to a decrease in transfection efficiency (*38*). A double bond in the fatty acid carbon chain will also decrease the melting point (Table 1). To investigate the relevance of cis versus trans configuration, we synthesized new lipids with one double bond (cis or trans) in the hydrophobic carbon chain. As is apparent in Figures 7A and 8A, the trans-orientation (C16:1, C18:1, and C20:1) enhances the transfection efficiency compared to cis-oriented alkyl chains of the same length. This trend is in good agreement with the previous report by Van der Woude et al. (*21*). On the basis of our results shown in Figures 5A, 7A, and 8A, we conclude that the trans-isomer worked better than cis and saturated lipids. Since the position and number of double bonds in these unsaturated fatty acid chains may also influence the transfection efficiency of these pyridinium lipids, we plan to synthesize some new compounds to determine the effect of both the position and number of double bonds in the fatty acid chain on transfection efficiency and cytotoxicity.

The stability of the lipoplexes in the presence of serum is important for their in vivo efficacies (*39, 40*). An increase in serum concentration significantly decreased the transfection efficiency (Figure 9). Serum contains nucleases and other enzymes, which

would degrade plasmid DNA, and also contains proteins, such as albumin, which would inhibit the cellular association of the lipoplex (*41*). However, our lipid trans-isomer C16:1 showed excellent performance even at the serum concentration of 30%, and above. Lipofectamine totally lost its tranfection ability when lipoplexes were formulated at a 3:1(+/−) charge ratio. This finding suggests that C16:1 trans-isomer-based liposomes can be used for in vivo gene delivery. Gopal et al. (*22*) also demonstrated good transfection efficiency of glutamide-containing pyridinium lipids in the presence of serum.

A major issue of interest is obviously understanding why pyridinium lipid could improve transfection efficiency. The positively charged pyridinium headgroup plays an important role in improving the transfection efficiency of pyridinium lipids. The antimicrobial activity of alkyl pyridinium salts has been shown to be associated with cell leakage, which is increased with an increase in the number of pyridinium headgroups (*42*). Multiheaded pyridinium amphiphiles have been shown to be more active as compared to their trimethylammonium counterparts (*43*). Woude et al. reported that alkyl pyridinium cationic lipid (SAINT-2) could increase membrane permeability, although this effect is not high enough to ensure lower cytotoxicity compared to DOTMA (*21*). Tucker et al. reported that incubation of cells with alkyl pyridinium sponge toxins could create transient pores on the cell membrane to facilitate cDNA transmembrane movement (*44*). Transient permeabilization of cells with pyridinium cationic lipids was further proven by the evidence of more efficient tissue penetration of pyridinium-based lipoplexes compared to those formed by DOTAP in vivo (*24*). The pores on the cell surface membrane resulted in increased intracellular Ca^{2+}, collapsed membrane potentials, and reduced input resistance (*44*, *45*). DOSPA is a polycation that is the component of Lipofectamine. It has been reported that the polycation could form positively charged loops fixed on DNA molecules. These loops interact with negatively charged lipids on plasma membranes, which probably induces effective nonspecific endocytosis and subsequent cell transformation (*46*). Pore-forming ability combined with ionic interaction, membrane association, and endocytosis may explain why some of our newly synthesized pyridinium cationic lipids showed relatively higher transfection efficiency compared to Lipofectamine.

In conclusion, we have demonstrated that a number of structural and formulation parameters including hydrophobic carbon chain lengths, double bond configuration in the unsaturated aliphatic hydrocarbon tails, lipid/co-lipid ratios, lipid/DNA charge ratios, and cell types play important roles in gene transfer and cytotoxicity of these pyridinium lipids. Important findings include (a) higher transfection efficiencies of pyridinium lipids with the amide linkers compared to their ester counterparts; (b) higher transfection efficiency at 1:1 molar ratio of pyridinium lipid and co-lipid compared to 2:1 and 4:1; (c) efficient transfection with C16 chain length pyridinium lipids; (d) better transfection efficiencies in the presence and absence of serum, compared to that of Lipofectamine, a widely used commercially available liposomal transfection kit; (e) higher transfection efficiencies of pyridinium lipids with the trans orientation in the hydrophobic anchor chain compared to those with cis orientation; and (f) increased efficiency of C16:1 trans-isomer pyridinium lipids in transfection in the presence of a high concentration of serum compared with Lipofectamine when lipoplexes were prepared at a 3:1(+/−) charge ratio.

This study aimed to investigate the effect of cross-linking of a cationic nonviral gene carrier on gene expression. As a precursor for photo-cross-linking, a star-shaped, six-branched cationic polymer of poly(*N*,*N*-dimethylaminopropylacrylamide) (six-branched star vector, SV), which was previously designed as a gene carrier, was synthesized by iniferter-based living radical polymerization. Upon UV irradiation, the number-average molecular weight (M_n) of the SV increased from ca. 28 kDa to ca. 32 kDa (irradiation time, 180 min) and ca. 46 kDa (240 min) with broadness of the polydispersity due to the coupling reaction between the polymer radicals generated at the terminal ends of each branch of the SVs, resulting in the preparation of cross-linked SVs (CSVs) without the use of any chemical cross-linking agents. Irrespective of cross-linking, all the SVs were able to interact with and condense luciferase-encoding plasmid DNA to yield relatively stable polymer/DNA complexes (polyplexes) of approximate diameter 150 nm with ζ-potential of ca. 20 mV. However, a transfection study using several types of cell lines, HeLa, Hep G2, 293, and COS-1, showed that by cross-linking of SVs the luciferase activity increased drastically. The activity with CSV (M_n = ca. 46 kDa) was increased by at least 1 order of magnitude in the original SV (M_n = ca. 28 kDa), which was several-fold that in the SV with the same molecular weight in all cells. In all SVs, no significant cellular cytotoxicity was observed even at a high charge ratio of 45. The SV-based gene transfection was significantly enhanced by the cross-linking of the SVs.

INTRODUCTION

Several successful clinical trials reported thus far have involved viral vector systems (such as retroviruses and adenoviruses) that provide efficient transduction and high levels of gene expression (*1*−*3*). However, their severe immunogenicity and toxicity remain major obstacles in viral vector-mediated gene therapy. For these reasons, nonviral vectors have been introduced as an alternative to such hazardous viral vectors, and they are being studied for their potential in providing safer and more desirable methods of gene delivery and clinical gene therapy (*4*−*8*).

Studies have been conducted in many laboratories to improve the gene delivery efficiency of polymeric gene carriers and to reduce their cytotoxicity. In these studies, nanoarchitectural, macromolecular design of the polymeric carriers by hyperbranching or cross-linking has been attempted as one of the major strategies (*9*−*17*). Starburst polyamideamine dendrimers—a relatively new class of highly branched spherical polymers that are strongly soluble in aqueous solution and have a unique surface of primary amino groups—have been established as one of the core structural components of synthetic gene carriers (*9*−*12*). Further, chemical cross-linking techniques have been used by combining preexisting carriers in order to improve gene delivery efficiency or reduce cytotoxicity. (*14*−*16*) For example, an ester or disulfide bond, which can be cleaved with common reducing agents after conjugation, has been utilized for carrier biodegradation. It has recently been established that branched high-molecular-weight polyethyleneimine (PEI) (>25 kDa) is an effective transfection agent, and recent reports indicate that low-molecular-weight PEI (~10 kDa) has relatively lower toxicity (*18*, *19*). Therefore, low-molecular-weight PEI was cross-linked by biodegradable bonding to obtain high gene delivery efficiency and low toxicity (*15*, *16*).

A branching structure was also introduced to improve the functionality of the carriers (*14*). When naturally occurring polymers or synthetic peptides were attached on the side chains of PEI, a high transfection efficiency was obtained (*20*−*22*). However, in case PEI components were used unmodified, the transfection efficiency of the branched form was generally lower than that of the linear form (*23*). On the other hand, we attempted to investigate the usefulness of a series of star-shaped cationic polymers as a base chemical structure for a novel high-performance gene carrier (*24*−*28*). These polymers, known as star vectors (SVs), were prepared by initiator-transfer agent-terminator (iniferter)-based living radical polymerization (*29*, *30*) of *N*,*N*-dimethylaminopropylacrylamide (DMAPAAm) by using their respective multidithiocarbamate (DC)-derivatized benzenes (multifunctional iniferters). The gene expression efficiency in COS-1 cells improved significantly with an increase in the number of branches and the molecular weight of the SVs (*24*). It was recently shown that attaching each cationic branch in SV with nonionic block chains (*25*) or peptides (*26*) as ligands resulted in a considerable improvement in the gene transfection

efficiency and the targeting of the vector to specific cells such as resting macrophages. Other star-shaped polymers were synthesized by conjugating multiple oligoethyleneimine arms onto an α-cylodextrin core, based on a similar concept used in our molecular design (*31*). These star-shaped polymers, including SVs, are promising new nonviral gene delivery vectors with low cytotoxicity and high gene transfection efficiency that can have gene therapy applications in the future.

The number of branches in SVs enhances the gene expression efficiency as described above (*24*). Therefore, additional complex branching by cross-linking of SVs is expected to further improve gene transfection efficiency. To this end, we synthesized cross-linked SVs (CSVs) by using molecular design wherein we exploited the photoreactive property of DC groups, which theoretically exist at the terminal ends of each branch in SVs after preparation. Further, the effects of the molecular structure and mass of SVs before and after cross-linking on their transfection properties and cytotoxicity were evaluated.

EXPERIMENTAL PROCEDURES

Materials. Chloroform of a special grade was treated with N_2 gas bubbling before use. N_2 gas of G1 grade (Japan Fine Products Co., Kanagawa, Japan) and 99.9999% purity or more was used. Diethyl ether of a special grade was used for polychlorobiphenyl (PCB) analysis; it was stabilized with ethanol and not butylhydroxytoluene (BHT). DMAPAAm purchased from Tokyo Kasei Co. (Tokyo, Japan) was used after distillation (bp 105−110 °C/0.3 mmHg). Other solvents and chemical reagents, all of which were of a special reagent grade, were purchased from Kanto Chemical Co. (Tokyo, Japan) or Aldrich (Milwaukee, WI) and were used without any purification. Purified and DNase-free pyrogen water with a conductance of 18 MΩ or more was prepared using Puric MX-II (Organo Inc., Tokyo, Japan). The 5266-bp pGL3 control vector (Promega Inc., Tokyo, Japan) encoding luciferase was used as luciferase reporter plasmide DNA; it was amplified in competent *Escherichia coli* (Promega Inc.) cells and purified using Maxiprep according to a protocol of QIAGEN (Tokyo, Japan). The purity of the amplified pDNA was assessed by electrophoresis on a 1% agarose gel, and the concentration was determined by UV absorbance at 260 and 280 nm.

Synthesis of 1,2,3,4,5,6-Hexakis(*N,N*-diethyldithiocarbamylmethyl)benzene (Iniferter) (*24, 25*). An ethanol solution (100 mL) of 1,2,3,4,5,6-hexakis(bromomethyl)benzene (1.0 g, 1.6 mmol) and sodium *N,N*-diethyldithiocarbamate trihydrate (6.4 g, 28.2 mmol) was stirred for 96 h at room temperature. The resulting precipitate was filtered, washed three times with approximately 1 L of methanol, and recrystallized using a chloroform/methanol solution. The yield of 1,2,3,4,5,6-hexakis(*N,N*-diethyldithiocarbamylmethyl)benzene was 1.5 g (yield, 90%). ^{1}H NMR (in chloroform-d_1): δ 1.26−1.31 (m, 36H, -CH_2−CH_3), 3.71−3.73 (q, 12H, -N-CH_2-), 3.99−4.01 (q, 12H, -N-CH_2-), 4.57 (s, 12H, Ar-CH_2).

Synthesis of Six-Branched Cationic Polymer (Six-Branched Star Vector, SV) (*24, 25*). 1,2,3,4,5,6-Hexakis(*N,N*-diethyldithiocarbamylmethyl)benzene (45.6 mg, 63 mmol) was dissolved in approximately 20 mL of chloroform. DMAPAAm (7.88 g, 50.5 mmol) was added to the solution. The total volume of the solution with chloroform increased to 50 mL. The concentrations of the iniferter and monomer were 5.0 mM and 1.0 M, respectively. The mixture was poured into a hard-glass cubic cell (4 mm × 40 mm; glass thickness, 3 mm), following which N_2 gas was bubbled into the glass cell at a flow rate of 2 L/min for 10 min to remove the O_2 gas from the solution. The solution was irradiated for 30 min with UV light (light intensity: 2.5 mW/cm^2). The reaction mixture was concentrated to approximately 10 mL by using a rotary evaporator and poured into 1.0 L of diethyl ether to obtain a polymeric precipitate. The diethyl ether solution supernatant was removed by decantation. Reprecipitation was carried out 3 times in a chloroform/diethyl ether system. The final precipitate was dried under vacuum and dissolved in an adequate quantity of H_2O. The resultant aqueous solution was filtered with a disposable syringe filter unit having a pore size of 0.22 um (Mixed Cellulose Ester, Toyo Roshi Ltd., Tokyo, Japan) and freeze−dried for 72 h using a vacuum pump (GCD136X, ULVAC, Tokyo) and freeze−dryer (FUD 2200, EYELA, Tokyo) to yield six-branched poly(D-MAPAAm) powder. The molecular weight was determined by gel permeation chromatography (GPC) analysis: M_n = 28 kDa. ^{1}H NMR (in chloroform-d_1): δ 1.5−1.7 (br, 3H, -C$\underline{H}_2$-CH- and -CH_2-C$\underline{H}_2$-CH_2-), 1.8−2.0 (br, 1H, -C$\underline{H}$-CO), 2.1−2.2 (br, 6H, -N-C$\underline{H}_3$), 2.2−2.4 (br, 2H, -C$\underline{H}_2$-N(CH_3)$_2$), 3.0−3.2 (br, 2H, -NH-C$\underline{H}_2$-), 7.4−7.8 (br, 1H, -NH). In addition, another branched polymer with M_n of 46 kDa was synthesized using a similar procedure by prolonging the irradiation time to 50 min.

Preparation of Cross-linked Star Vector (CSV). Freeze−dried powder of SV (M_n = 28 kDa) was homogenized in a 100-mL hard-glass tube of thickness 2 mm by vigorous stirring on a magnetic stirrer in a closed system. The O_2 gas in the gas phase of the closed system was replaced with N_2 gas. The mist-like SV powder was exposed to UV light for 180 min by using a 300 W Xenon lamp (MAX-301, Asahi Spectra, Tokyo, Japan) under vigorous stirring. The UV light intensity was adjusted to 1.0 mW/cm^2. After light irradiation, the resulting photoirradiated powder was poured into 50 mL of methanol and centrifuged at 10 000 rpm for 5 min at room temperature to remove the insoluble gel-like precipitate that was produced during irradiation. The obtained supernatant was concentrated to approximately 5 mL by using a rotary evaporator and poured into 500 mL of diethyl ether to recover the polymeric precipitate. The diethyl ether solution was removed by decantation. Reprecipitation was carried out 3 times in a chloroform/diethyl ether system. The final polymeric precipitate was dissolved in H_20, filtered with the syringe filter, and freeze−dried to obtain CSV powder. The molecular weight was determined by GPC analysis: M_n = 32 kDa. In addition, another CSV with M_n of 46 kDa was synthesized using a similar procedure by prolonging the irradiation time to 240 min.

General Procedure. The light intensity from a Xenon lam (MAX-301), measured using a photometer (UIT-150 with UVD-405 detector, USHIO, Tokyo), was adjusted to 2.5 mW/cm^2. UV/vis absorption spectra were recorded using a spectrophotometer (UV-1700, Shimadzu, Kyoto). ^{1}H NMR spectra were recorded in chloroform-d_1 with a 300 MHz NMR spectrometer (Varian Gemini-300) using tetramethylsilane (0 ppm) as the internal standard at room temperature. GPC analysis in *N,N*-dimethylformamide with 30 mM lithium bromide was carried out with a high-performance liquid chromatograph system (LC-10Avp, Shimadzu, Kyoto, Japan) and columns (Asahipack GF-710HQ and Asahipack GF-510HQ, Shodex, Tokyo, Japan) that were calibrated for molecular weight with narrow weight distribution poly(ethylene glycol) (PEG) standards.

Preparation of Polyplexes. SVs with or without cross-linking were dissolved in a saline solution at a concentration of 0.79 μg/μL. In a quartz cell (charge ratio 30), 60 μL aliquots of the saline solution were mixed with 90 μL of Tris-HCl buffered saline solution (pH 7.4) containing the pDNA at a concentration of 3.33×10^{-2} μg/μL at room temperature. The solutions (total volume, 150 μL; plasmid concentration, 20 μg/mL) were mixed using a pipet in order to obtain polyplexes. The mean diameters of the polyplexes in the solution were determined by cumulant analysis in a multimodal setting by using the DLS apparatus. During the transfection experiments, which were conducted 10 min after complex formation, 25 μL of the complex solutions

were added into each well of the 24 multiwell dishes (the amount of DNA added to a well, 0.5 μg). Since the data of the particle size were reproducible ($n = 20$, SD < 10%), only the average values have been described.

Biophysical Characterization of Polyplexes. The ζ-potentials and mean diameters of the polyplexes in a saline solution were obtained by employing dynamic light scattering (DLS) on an ELS-8000 system (Otuska Co., Osaka, Japan) equipped with a 10 mW He−Ne laser. The mean diameters were measured at the concentration that was used for transfection at a C/A ratio of 15, and ζ-potentials were measured after dilution with saline solution to 1/10 of the transfection concentration. The mean diameters were determined by cumulant analysis in multimodal setting.

DNase I Protection Assay. The polyplexes prepared from CSV (M_n = ca. 4.6 kDa) and pDNA (0.5 μg) at the C/A ratio of 15 was added with 5 μL (2 unit) of DNase I (Worthington, DPPF grade). After predetermined incubation time (10 min to 24 h) at 42 °C, 50 μL of a stop solution consisting of 4 M ammonium acetate, 20 mM EDTA, and 2 mg/mL glycogen was added, and the reaction mixture was placed on ice. The aliquot of 5.0 μL was electrophoresed for 30 min at 100 V in 1 wt % of agarose gel by 40 mM TAE running buffer. The gel was stained with 0.5 mg/mL ethidium bromide solution for 30 min to visualized the location of plasmid DNA with a Gel Doc 2000 (Bio-Rad Laboratories, Tokyo, Japan).

Cell Lines. COS-1 african green monkey kidney cells, HeLa human cervix carcinoma cells, HepG2 human hepatocellular carcinoma cells, and 293 human kidney transformed cells were purchased from RIKEN CELL BANK (Tsukuba, Japan). COS-1 cells were maintained in DMEM medium (Gibco, Invitrogen Corp., Carlsbad, CA) with 10% fetal calf serum (FCS, Hyclone Laboratories Inc., Logan, UT), HepG2 cells and 293 cells in MEM medium (Gibco) with 10% fetal bovine serum (FBS, Hyclone), and HeLa cells in MEM medium with 10% FCS. All cells were cultured with 200 units/mL penicillin (ICN Biomedicals Inc., Aurora, OH), and 200 mg/mL streptomycin (ICN) in a 5% CO_2 atmosphere at 37 °C.

In Vitro Transfection and Cell Viability Assays. COS-1 cells were seeded at a density of 3×10^4 cells/well in a 24-well plate in medium containing 10% FCS and grown to reach 70−80% confluence prior to transfection for 24 h. HepG2 cells and 293 cells (1×10^5 cells/well) were seeded in a 12-well plate and grown in the same way. Transfections were performed with 0.5 μg of plasmid DNA (pGL3 as control) in 24-well dishes containing 0.2 mL of OPTI-MEM I (Gibco) for COS-1 cells and 1 μg of plasmid DNA in 12-well dishes containing 0.4 mL of OPTI-MEM I. After 3 h of incubation, the cells were washed once with PBS (−) and cultured in 1 mL for 24-well or 2 mL for 12-well of appropriate medium for an additional 48 h. The medium was removed, and the cells were washed twice with PBS (−), lysed with 0.2 mL for 24-well or 0.4 mL for 12-well of cell lysis buffer (Promega, Madison, WI), and mixed by vortexing. The lysate was centrifuged at 15 000 rpm for 1 min at 4 °C, and 5 μL of the supernatant was analyzed for luciferase activity by using a Luminous CT-9000D (Dia-Iatron, Tokyo, Japan) luminometer. The relative light unit (RLU)/s values were converted into the amount of luciferase (pg) by using a standard luciferase curve, which was obtained by diluting recombinant luciferase (Promega) in lysis buffer. The protein concentrations of the cell lysates were measured by performing a Bio-Rad protein assay (BIO-RAD, Hercules, CA) with bovine serum albumin as a standard. The final amount of luciferase was determined as the amount of expressed luciferase (mole quantity) standardized to the total protein content of the cell lysate. Data represent the mean ± the standard deviation (S.D.) of the mean ($n = 5$). Statistical analysis was performed using Student's *t*-test and $p < 0.05$ (*) was accepted to be significant.

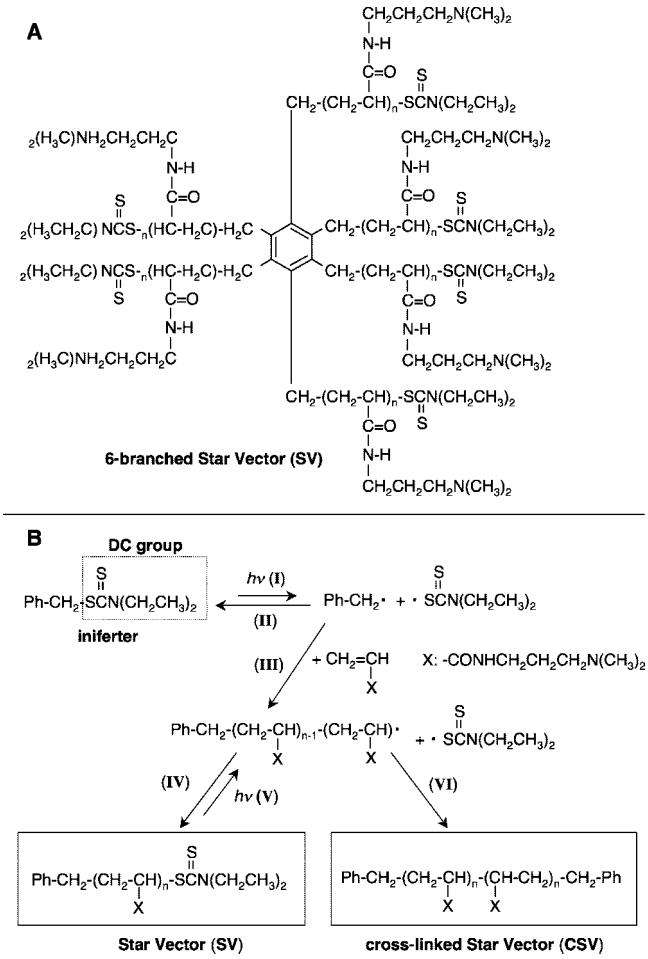

Figure 1. (A) Chemical structure of six-branched star vector (SV). (B) Reaction mechanisms in the preparation of SV through Schemes I, III, and IV from iniferter by photoirradiation in the presence of *N*,*N*-dimethylaminopropyacrylamide, and those involved in the preparation of cross-linked star vector (**C**SV) from SVs through Schemes V and VI by photoirradiation under N_2 atmosphere.

Cytotoxicity was assessed by performing a cell viability assay using the WST-8 method (Dojindo, Kumamoto, Japan). The COS-1 cells were seeded 24 h prior to treatment in 96-well plates at 5000 cells/well. The cells were treated under the same conditions as those used for the luciferase assay; 6.2 μL of the transfection mixture containing 0.124 μg of pDNA was added to each well. The cells were treated under the appropriate conditions for 3 h, washed once with PBS, and cultured in 50 μL of DMEM (Gibco) containing 10% fetal calf serum for an additional 24 h. To each well, 10 μL of WST-8 reagent (5 mmol/L) was added. After 2 h of incubation at 37 °C, the absorbance at 450 nm was determined using a Bio-Rad microplate reader (model 680). Data represents the mean ± the standard deviation (S.D.) of the mean ($n = 5$).

RESULTS AND DISCUSSION

Synthesis and Cross-linking of SV. The two kinds of six-branched SVs with different molecular weights (Figure 1A) were prepared by iniferter-based photoliving radical polymerization via reactions I, III, and IV shown in Figure 1B. The polymerization of a cationic monomer (DMAPAAm) from six-functional iniferter, which was synthesized by the derivatization of DC groups to 1,2,3,4,5,6-hexakis(bromomethyl)benzene, was performed by changing the irradiation time. Following 30 min of

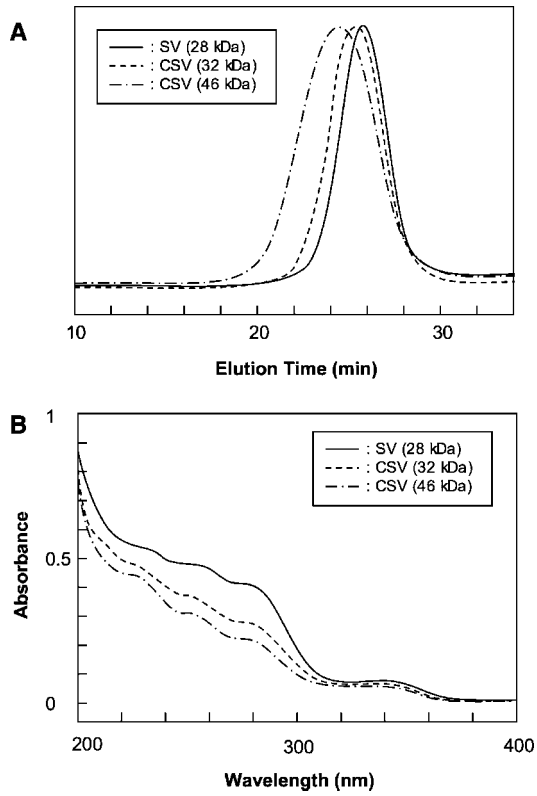

Figure 2. (A) GPC curves and (B) UV absorption spectral changes after photoirradiation of star vectors (SVs) of molecular weight ca. 2.8 kDa to obtain cross-linked star vectors (CSVs) of molecular weight ca. 3.2 kDa (irradiation time, 180 min) and ca. 4.6 kDa (240 min).

UV irradiation, only trace amounts of the SV were observed on GPC, with complete absence of the iniferter (Figure 2A). The obtained SV had a number-average molecular weight (M_n) of ca. 28 kDa with very narrow polydispersity at 1.4 (run 1 in Table 1). By prolonging the irradiation time, the M_n increased to approximately 46 kDa, but the narrow polydispersity (M_w/M_n 1.4) was maintained (run 2).

In the NMR spectrum of the SV with M_n of ca. 28 kDa, after 20 000 cycles, double quartet peaks of two types of *N*-methylene protons appeared at 3.6−3.7 ppm and 3.4−3.5 ppm, indicating the presence of DC groups even after polymerization initiated from the iniferter. On the other hand, the molecular weight of the SV, calculated from the UV spectra (Figure 2B, Table 1), was approximately 32 kDa, which was close to that obtained from GPC measurements (28 kDa). On the basis of these results, we concluded that almost all photoreactive functional DC groups were present at the ω-ends of every branch in the SV.

The mist-like powder of SV with a M_n of ca. 28 kDa was exposed to UV light in a solid phase under a N_2 gas atmosphere in the absence of any monomers. Following 180 min of irradiation, the GPC curve was observed to have shifted slightly to the higher molecular weight side after the gel-like precipitate produced was excluded as a byproduct (Figure 2A). The M_n increased to approximately 32 kDa and the polydispersity broadened (run 1−1 in Table 1). On further increasing the irradiation time to 240 min, a M_n of ca. 46 kDa with an even broader polydispersity was obtained (run 1−2).

Figure 2B shows the UV absorption spectral change of the SVs before and after UV-light irradiation. The specific UV absorption with maximum absorption wavelength at 275 nm originating from the DC group significantly decreased after irradiation. After 240 min of irradiation, the absorption decreased to approximately half the original. The GPC and UV spectral analysis revealed that the SVs were cross-linked by a photoreaction involving the DC groups without the use of any chemical cross-linking agents.

The cross-linking mechanism of the SVs was identified to be as follows. The DC end-capped chain in the SVs finally produced as a precursor was redissociated into a pair of reactive polymer radicals and non- or less-reactive DC radicals by UV irradiation (reaction V in Figure 1B). When there were no monomers in the solid state, simultaneous chain transfer of the generated polymer radicals to the polymer matrix or coupling between the radicals occurred preferentially. Coupling between DC radicals generated *N*,*N*,*N*′,*N*′-tetraethylthiuram disulfide, which is dissociated to dithiocarbamyl radicals by UV irradiation because it is reversible. On the other hand, coupling between polymer radicals generated an SV dimer (reaction VI), which could be not dissociated by UV irradiation. Therefore, the polymer radicals would be selectively consumed by UV irradiation of the SV to generate CSV. As expected, chain transfer of polymer radicals to the polymer matrix also produced CSV in another cross-linking manner, in which the end chains of the SV branch bonded to the side chain of another SV branch. Photoinduced cross-linking with DC groups has previously been performed for the surface modification of medical materials for better biocompatibility (*32*) or polymer design (*33*).

Formation of Polyplexes. Approximately 10 min after mixing a Tris-HCl-buffered solution of pDNA (pGL3-control plasmid) and a saline solution of CSV, the scattering intensity in the DLS measurements was stably observed, indicating that polymer/plasmid complexes (polyplexes) similar to the original SVs had been formed. The effective diameters of the polyplexes prepared from CSV (M_n = ca. 46 kDa), as measured by DLS, were approximately 150 nm at a charge ratio of 15 (Figure 3A). The size was similar to that observed with SVs of almost the same M_n, but it was slightly larger than that with SVs of a low molecular weight (M_n = ca. 28 kDa). All the polyplexes gradually aggregated as incubation proceeded irrespective of whether or not the cross-linking had occurred.

On the other hand, the polyplexes with a higher M_n of ca. 46 kDa were very stable even at a low pH of 4. Up to 180 min after incubation, their small particle size was maintained; however, for the polyplexes from the SV of low M_n (ca. 28 kDa), the particle size increased to approximately 1.5-fold. The particle stability was higher in the polyplexes formed from SVs of a higher molecular weight without any significant dependency on the presence of cross-linking. The moderate ζ-potentials of approximately 20 mV were observed for all particles irrespective of cross-linking and molecular weight (Table 1).

When the polyplexes are formed, it is expected that the digestion of pDNA by DNase I is inhibited. After incubation with DNase I, the polyplexes were analyzed by 1% agarose gel electrophoresis (Figure 4). The pDNA was digested even at 10 min of incubation time. On the other hand, pDNA in the

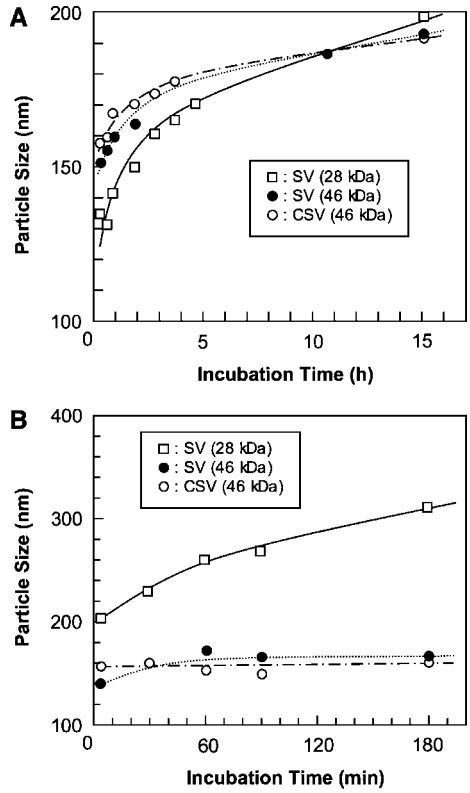

Figure 3. Incubation time-dependent changes in the particle size of polyplexes prepared from luciferase-encoding plasmid DNA nad star vector (SVs) of molecular weight ca. 28 kDa or ca. 46 kDa, or crosslinked star vectors (CSVs) of ca. 46 kDa at pH 7.4 (A) and 4.0 (B). Since the data of the particle size were reproducible (n = 20, S.D. <10%), only the average values have been described.

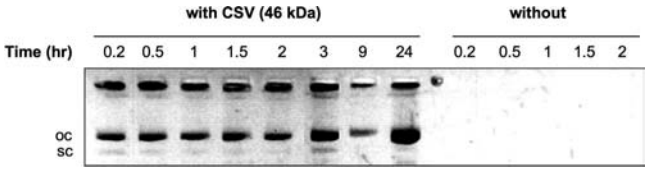

Figure 4. DNase I protection assay. The pDNA with or without CSV at a charge ratio of 15 was treated with DNase I. The position of the open coiled (oc) and supercoiled (sc) forms are indicated on the left.

polyplexes remained even at longer incubation time up to 24 h. The CSV could completely protect the pDNA from digestion of DNase I.

In Vitro Transfection Efficiency. The transfection efficiency of the SVs before and after cross-linking treatment was, at first, tested in the model cell line—COS-1 comprising monkey cells—at a charge ratio of 15 or 30. Since the polyplexes were gradually aggregated as incubation especially in SV with low M_n as indicated in Figure 3, at 10 min after preparation, the polyplexes conducted to the transfection experiments. The cells transfected with the luciferase-encoding plasmid (pGL3) in the absence of any polymer exhibited negligible luciferase expression. In the six-branched SVs, the luciferase expression increased with the molecular weight of the SVs (Figure 5). As shown in Figure 3, the molecular weight dependency may be due to the stability of the polyplexes. A similar dependency was observed for the four-branched SVs, in which a 5-fold increase in molecular weight of the SVs from ca. 10 to 50 kDa induced an approximately 3-fold increase in the luciferase activity. These obtained activities were larger than that in PEI (ExGen 500), which is a major commercially available typical polymeric vector used as a positive control.

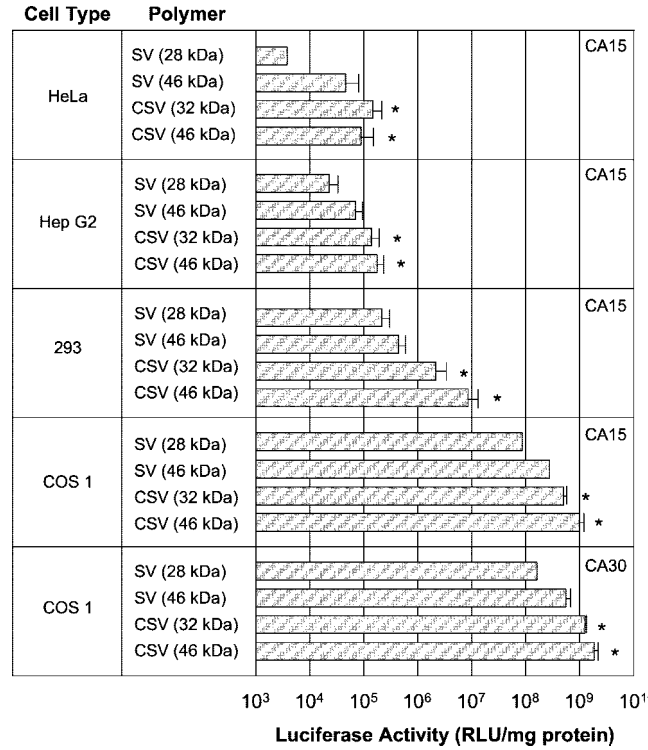

Figure 5. Transfection of four different cell lines using polyplexes prepared by mixing pDNA (pGL3 control, 0.5 μg/24-well plate or 1 μg/12-well plate) and SVs with molecular weight of approximately 28 kDa or 46 kDa, or CSVs with molecular weight of approximately 32 kDa or 46 kDa, at a charge ratio of 15 or 30. For comparison, the transfection efficiency data of polyplexes formed using linear PEI (ExGen 500) at a charge ratio of 5 is also provided. Data represents the mean ± the standard deviation (S.D.) of the mean (n = 5). Statistical analysis was performed using Student's *t*-test and $p < 0.05$ (*) was accepted to be significance.

Interestingly, the transfection activity drastically increased by the cross-linking of the SVs (Figure 5). The activities of CSVs of M_n approximately 32 kDa and 46 kDa at a charge ratio of 15 were approximately 6- and 12-fold the value in the original untreated SV with a M_n of ca. 26 kDa, respectively. For the CSVs with a M_n of ca. 46 kDa, approximately 4-fold higher activity was observed with the cross-linked compound than with the non-cross-linked compound. In addition, an increase in the charge ratio from 15 to 30 induced a further increase in the activity up to approximately 2-fold. Thus, the structural advantage of cross-linking in the SVs was strongly suggested for greater in vitro gene transfection efficiency.

The transfection efficiency was evaluated also in human cell lines—HeLa, human cervix carcinoma cells, HepG2, human hepatocellular carcinoma cells, and 293, human kidney transformed cells. Unfortunately, lower transfection activity was observed in all human cells than that in COS-1 (Figure 5). However, there was a similar drastic increase of transfection activity by cross-linking of SVs. The activity with CSV (M_n = ca. 46 kDa) was at least 1 order of magnitude in the original SV (M_n = ca. 28 kDa). The SV-based gene transfection was significantly enhanced by the cross-linking of the SVs in all cell lines.

Cell Cytotoxicity. The in vitro cytotoxicity of the polyplexes prepared from the regular SVs or photoirradiated SVs was studied as a function of the charge ratio in the range of 5−45 by using the WST assay. As shown Figure 6, in the case of all the polyplexes, the relative cell viability decreased as the charge ratio increased. Polyplexes with a lower charge ratio were considered to have lower cell membrane binding ability, which therefore tended to affect cell viability. In the case of a higher

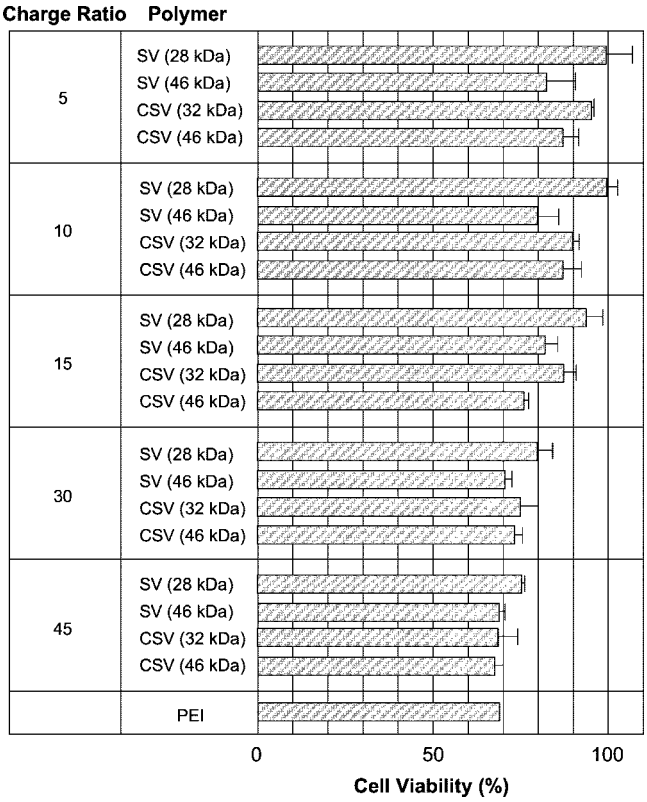

Figure 6. Cytotoxicity of polyplexes prepared by mixing DNA (pGL3 control, 3 μg) and SVs or CSVs at different charge ratios. Cell viability was determined by the WST assay.

charge ratio, it was observed that the polyplexes not only had a higher charge density but also had a higher concentration of the cationic polymer, which was correlated with the cytotoxic effect. Since the molecular weight of the cationic polymer was confirmed as the main parameter affecting its interaction with the cell membrane and, consequently, cell damage, the SVs and photoirradiated SVs of higher molecular weight were considered to have less cytotoxicity at a charge ratio of 30 or 45. However, they might be acceptable, because in these cases, the cell viability was higher than that with polyethyleneimine (PEI) at a charge ratio of 6, and PEI is one of the most popular commercially available gene-delivery agents (Figure 6). There was no significant difference among the polyplexes formed from the SVs and photoirradiated SVs of the same molecular weight. Therefore, it was considered that the photoirradiation treatment of the SVs had no significant disadvantage.

In conclusion, this study successfully demonstrated that SV-based gene transfection was significantly enhanced by the cross-linking of the SVs via any agent except photoirradiation in the solid phase. The M_n of the obtained CSVs increased with increasing irradiation time. With an increase in the M_n of the CSVs, the gene transfection efficiency increased drastically except for HeLa in this study. On cross-linking at charge ratios of both 15 and 30, the transfection activity increased to over 10-fold that of the original SV (M_n = ca. 28 kDa), which in turn was 3-fold that of the SV of the same molecular weight (M_n = ca. 46 kDa). As described in the introduction, nanoarchitectural, macromolecular design of the polymeric DNA carriers by hyperbranching or cross-linking, and so forth, has been attempted as a major strategy for increasing transfection efficiency. Therefore, it was considered that cross-linking of star vector, which could induce an increase in the cationic charge density, would be a key strategy for enhancement of transfection efficiency of cationic polymers. To evaluate the hypothesis, the present study was designed and the effectiveness of the cross-linking of star vector for increasing transfection efficiency was clearly demonstrated. It was considered that the DNA expression using the polyplex was observed by the following five sequential steps: (1) attachment of the polyplexe onto the cell surface, (2) internalization of the polyplexes into the cell, (3) endosomal escape of the polyplex, (4) DNA release from the polyplex, and (5) internalization of DNA into the nucleus. In this study, there were few differences in the ζ-potentials and the mean diameters of all polyplexes, whereas a significant difference was observed in the transfection efficiency between SV and CSV. Therefore, the difference might be greatly induced from the steps after (3).

For further improvement, the CSV-induced gene delivery mechanism should be determined. Although in both SV and CSV excellent colloidal stability with low cytotoxicity was demonstrated, we do not have any additional data to explain the mechanism. In addition, as shown in Figure 2B, a lot of DC groups remained after photo-cross-linking, indicating that the cross-linking only occurred partly. Therefore, it was considered that CSV consisted of a mixture of original SV and cross-linked SV. To purify the CSV, fractionation of the mixture by GPC is ongoing. By using the pure CSV with narrow polydispersity, the mechanism will be explained clearly. Our research in the near future will be directed at optimization of the cross-linking density, macromolecular size and distribution, and combination with other kinds of SVs with different chemical or electrical properties so as to achieve further improvements in the in vitro transfection efficiency for other types of cells and in vivo gene transfection efficiency and in functionalization, including biodegradation ability to obtain low cytotoxicity.

Unimolecular, Soluble Semiconductor Nanoparticle-Based Biosensors for Thrombin Using Charge/Electron Transfer

Marla D. Swain,[†,‡] Jashain Octain,[‡] and David E. Benson*[,‡,§]

Naval Research Laboratory, 4555 Overlook Avenue SW, Washington, DC 20375, Department of Chemistry, Wayne State University, 5101 Cass Avenue, Detroit, Michigan 48202, and Department of Chemistry and Biochemistry, Calvin College, 1726 Knollcrest Circle, SE, Grand Rapids, Michigan 49546. Received September 16, 2008; Revised Manuscript Received November 11, 2008

Duplex DNA was attached to semiconductor nanoparticles providing selective detection of thrombin. Using the method reported here, semiconductor nanoparticles can have selective sensory functions for a host of additional analytes in the future. The system uses one DNA strand that selectively binds an analyte (thrombin), while the complementary DNA strand contains a redox-active metal complex. The accessibility of the metal complex to the nanoparticle surface is increased upon thrombin binding due to unravelling of the duplex DNA secondary structure. Increased interactions between the metal complex and the nanoparticle surface will decrease nanoparticle emission intensity, through charge transfer. Initially, water-soluble nanoparticles with carboxylate-terminated monolayers showed thrombin-specific responses in emission intensity (−30% for 1:1 nanoparticle to DNA, +50% for 1:5). Despite the selective responses, the thrombin binding isotherms indicated multiple binding equilibria and more than likely nanoparticle aggregation. The need for a nonaggregative system comes from the potential employment of these sensors in live cell or living system fluorescence assays. By changing the nanoparticle capping ligand to provide an ethylene glycol-terminated monolayer, the binding isotherms fit a two-state binding model with a thrombin dissociation constant of 3 nM in a physiologically relevant buffer. This article demonstrates the need to consider capping ligand effects in designing biosensors based on semiconductor nanoparticles and demonstrates an initial DNA-attached semiconductor nanoparticle system that uses DNA−analyte binding interactions (aptamers).

INTRODUCTION

Semiconductor nanoparticles, or quantum dots, have a wide array of potential biological applications (*1*−*3*). The benefits of these nanomaterials are the large two-photon cross sections, broad excitation wavelength ranges, sharp emission linewidths, high quantum yields, and high photostability relative to organic and metal−organic fluorophores (*2*). Use of monolayer-protected nanoparticle methods provides water-soluble, biocompatible semiconductor nanoparticles (*4, 5*), which allow the attachment of biological molecules to enhance the function of semiconductor nanoparticles (*6, 7*). Biological molecules add chemical selectivity to the properties of the nanomaterial (*8, 9*). Typically, the biomolecular-induced changes in semiconductor nanomaterial properties are observed by fluorescence-based spectroscopies. Biomolecular-induced changes in photoconductivity are less commonly reported, but have also been observed (*10, 11*). The key to integrating biomolecular function into nanomaterial properties is to use enzymatically generated compounds or a biomolecule-attached reporter compound (*8*). Enzymatically generated compounds that are photo- or electroactive can readily interact with semiconductor nanoparticles to alter the observed fluorescence or photoconductive properties. Such enzymatic signal amplification is similar to ferrocene/glucose oxidase electrode cells for glucose detection (*9*). The use of biomolecule-attached reporter groups link ligand-induced changes in biomolecule conformation (*6, 8, 12*−*14*) or active-site solvation (*15*) to photonic or electrical changes in the semiconductor nanomaterial. Oftentimes, these changes are performed with only the ligand changing the molecular weight of the assembly, called unimolecular or reagentless detection (*12*−*15*). Unimolecular detection facilitates reversible ligand detection in diffusible formats (*16*), such as live-cell fluorescence microscopy. Many semiconductor nanoparticle-based biosensors have been developed with cellular fluorescence microscopy as an extension, but unimolecular versions of these biosensors will be needed for reversible detection.

Protein-attached semiconductor nanoparticles provide unimolecular constructs that function as biosensors (*12*−*15*). It should be noted that localization probes (e.g., antibodies) are omitted from this discussion, since minimal changes in semiconductor nanomaterial properties are typically associated with localization. Using Cy3-attached maltose binding protein (MBP), a reagentless/unimolecular biosensor for maltose was reported (*14*). This report augmented previous work (*17*), where both accounts using multiple fluoropohore-modified MBPs were coordinated per ZnS-coated CdSe (CdSe@ZnS) nanoparticle. Previous studies with this system used displacement assays to demonstrate this phenomenon, where a quencher or fluoropohore was released from the assembly upon maltose binding to MBP (*17*). The unimolecular assembly (*14*) used maltose-induced changes in MBP-attached Cy3 intercalation into or around the maltose binding pocket. The Cy3 intercalation method changed the solvation around Cy3 to alter the Cy3 emission intensity, while the CdSe@ZnS emission remained constant. This strategy, while providing dual emission wavelengths for biosensor concentration-independent detection, relied on organic fluorophore emission. As pointed out already (*1*−*3*), the rationale for semiconductor nanoparticle fluorescence probes is the high photostability as opposed to organic fluorophores.

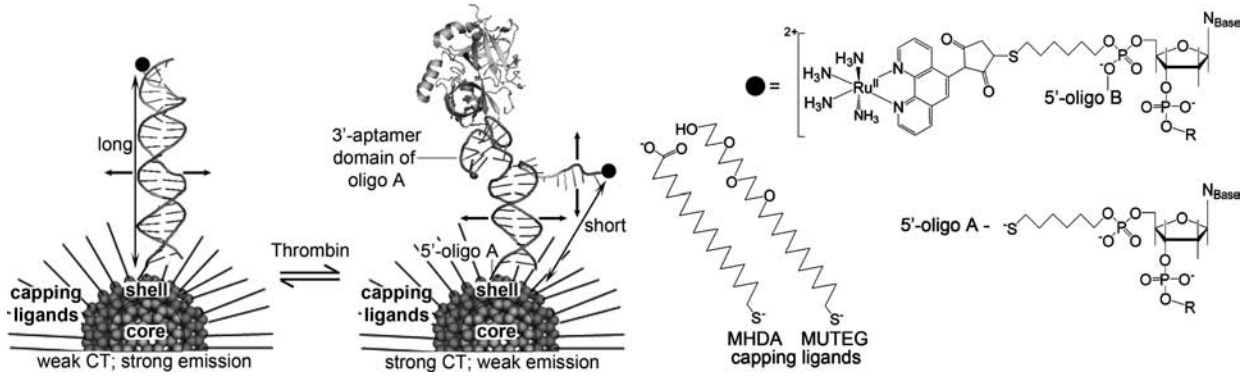

Figure 1. Summary of biosensor components (see Table 1 and experimental for definitions and terms).

Charge/electron transfer reactions provide a unimolecular solution to semiconductor nanoparticle-based biosensors with proteins that alter the semiconductor nanoparticle emission intensity (*8, 12, 13, 15*). MBP was used for these studies as well, where $[Ru(L)(NH_3)_4](PF_6)_2$ (**1**, L = 5-maleimido-1,10-phenanthroline) reduces CdSe@ZnS nanoparticles to render these nanoparticles nonfluorescent (*12, 13*). The rationale for differences between energy and charge/electron transfer methods is that energy transfer has a R_o/r^6 distance dependence ($R_o \sim$ 55 Å) where charge/electron transfer has an $\exp(-\beta r)$ distance dependence ($\beta \sim 1.2$ Å^{-1}). For comparison, a 1 Å interatomic movement in Cy3/complex **1** relative to the CdSe@ZnS nanoparticle surface should result in a 1% change in emission intensity for energy transfer but a 30% change in emission intensity for electron transfer (*8*). Unimolecular semiconductor nanoparticle-based biosensors for fatty acids have also been reported (*15*). For these biosensors, fatty acid-induced changes in solvation around the NH_3 ligands of complex **1** changed electron transfer rates to and emission from CdSe@ZnS nanoparticles. Therefore, both ligand-induced changes in protein conformation or active-site solvation can be used to generate unimolecular biosensors from protein-attached semiconductor nanoparticles.

Despite many reports of unimolecular/reagentless electrochemical biosensors using ligand-induced changes in nucleic acid-attached conformation (*18, 19*), no analogous unimolecular nucleic-attached CdSe@ZnS nanoparticle biosensors have been reported. Nucleic acids that undergo conformational changes upon binding small molecules or proteins are termed aptamers and have been shown in mRNA to regulate protein synthesis (riboswitches) (*20*). Organic fluorophores (*21*) and Au nanoparticles (*22, 23*) have been integrated with CdSe@ZnS nanoparticles to DNA and/or RNA-based aptamers. The only unimolecular nucleic acid-attached semiconductor nanoparticle biosensor was for PbS nanoparticles (*24*). These nanoparticle cores were formed by a thrombin-binding DNA aptamer that quenched the PbS emission when thrombin or prostate-specific antigen (PSA) were added. Despite the lack of a redox active metal complex or organic compound, charge/electron transfer was presumed to be the quenching mechanism for these biosensors. We presume the hole acceptor/electron donor in this formalism would be either a guanine DNA base or a tyrosine side chain from either protein. These effects have not been reported for CdSe or for CdSe@ZnS nanoparticles, which have significantly less surface defect states that link electrostatic changes at the nanoparticle−solution interface to emission intensity changes.

We have found that complex **1**-attached thrombin-binding DNA aptamers provide thrombin-dependent changes in CdSe@ZnS nanoparticle emission intensity (Figure 1). Furthermore, the capping ligands that provide water solubility to the nanoparticle need to be carefully considered to minimize aggregation effects and eliminate alternative/nonspecific binding events. Finally, this report shows an additional avenue for developing semiconductor nanoparticle-based biosensors for new analytes, due to the elegant selection schemes available to aptamers (*25*).

EXPERIMENTAL METHODS

All materials and chemicals were used as received without purification, unless noted. 3-(*N*-Morpholino)propanesulfonic acid (MOPS, 20 mM with 5 mM KCl and 1 mM $MgCl_2$, pH = 7.5) was used to buffer all aqueous solutions except when PSS (physiological salt solution: 21 mM Tris HCl, pH 7.4, 4.4 mM KCl, 2.0 mM $CaCl_2$, 1.2 mM $MgSO_4$, 140.5 mM NaCl, 11.1 mM dextrose) is noted, where the typically used 5% BSA was omitted in most cases. Complex **1** was synthesized and attached to the DNA oligonucloetides similar to reported protein attachment (*12, 13*). 4,4-Difluoro-3,5-bis(4-methoxyphenyl)-8-(4-male-imidylphenyl)-4-bora-3*a*,4*a*-diaza-*s*-indecene (**2**, Bodipy 577/618 maleimide, Invitrogen) was introduced to DNA oligonucleotides similar to previous protein attachment as well (*26*). Heparin, hirudin, lysozyme, and bovine serum albumin (BSA) were purchased from Sigma and purified by gel filtration. Thrombin was obtained from Heamatologic Technologies Inc. (Essex Junction, VT) and diluted (10 mg/mL) to a 250 μM stock. Rat intestinal fatty acid binding protein (IFABP) was prepared from recombinant DNA with *E. coli* expression as before (*15*).

DNA Design, Preparation, and Modification. HPLC-purified oligonucleotides were purchased from Oligos, etc (Wilsonville, OR). Oligo A (5′-CCATCTCCACTT**GGTTGGTGTGGTTGG**-3′) contained the aptamer sequence (bold letters) with the 5′-phosphate terminus modified with 6-mercaptohexanol for nanoparticle attachment (*27*). Oligo B (5′-CCAACTTTTAAGTGGAGATGG-3′) was obtained either without modification (oligo B_0) or with the 5′-phosphate terminus modified with 6-mercaptohexanol for modification with complex **1** (oligo B-**1**) or compound **2** (oligo B-**2**). Oligo C (5′-CCATCTCCACTTGGTGGTGGTTGTGGT-3′) contained a 5′-thiol modification but contained a scrambled sequence relative to the thrombin binding aptamer and was used as a control. The 5′-thiol modified oligos (100 μM) were reduced (dithiothreitol, 1 mM, 30 min) and purified by gel filtration (10DG column, BioRad, Hercules, CA) under anaerobic conditions (anaerobic chamber, Coy laboratories, Grass Lake, MI). The thiol-modified oligo B was then incubated either with 1 equiv of complex **1** (10 mM acetonitrile stock) or 10 equiv of compound **2** (10 mM dimethylformamide stock) for 2 h. After incubation, the modified oligonucleotides were purified by gel filtration and labeling efficiencies (95−100%) were determined by absorbance spectrophotometry. Hybridzation of two complementary oligos (A/B or C/B) was then performed by combining the two oligonucleotide solutions, heating to 70 °C for 10 min,

and slowly cooling the solution back to room temperature. These samples were used immediately, but remained under anaerobic conditions until used.

Nanoparticle Preparation and Capping Ligand Exchange. CdSe@ZnS nanoparticles with 2−3 monolayers of ZnS (CdSe@ZnS_{2-3}) were purchased from NN Laboratories (Fayetteville, AK) as the octadecylamine capped product. Trioctylphosphine oxide capped CdSe@ZnS nanoparticles with 5−6 monolayers of ZnS (CdSe@ZnS_{5-6}) were purchased from Evident Technologies (Troy, NY). These nanoparticles were precipitated (under anaerobic conditions) in an acetone/methanol 1:1 mixture and heated in either neat mercaptohexadecanoic acid (MHDA) or a 50 mM methanolic solution of mercaptoundecyltriethylene glycol (MUTEG) as reported previously (*26, 28*). Potasium *t*-butoxide was added to aqueous suspensions of MHDA-capped nanoparticles to provide water solubility (*26*), while the alkalinity (pH ∼ 10) of MUTEG-capped nanoparticle suspensions was adjusted with tetrabutylammonium hydroxide (3 μM) (*28*). The resulting water-soluble nanoparticles were purified by precipitation in ether and redissolution in water, followed by ultrafiltration (30 000 MW cutoff, Millipore) until minimal fluorescence fluctuations were observed. MHDA-capped CdSe@ZnS nanoparticles were stored in water in the dark and under N_2 for up to two months, while MUTEG-capped nanoparticles were used within one day of the exchange into aqueous solution.

Biosensor Assembly. Modified or unmodified duplex DNA with a single thiol-modified 5′-terminus was mixed with MHDA or MUTEG-capped CdSe@ZnS nanoparticles in buffered solutions. All reactions utilized 25 nM CdSe@ZnS nanoparticles, judged by optical absorbance. Duplex DNA was introduced at various final concentrations. The DNA and nanoparticles were incubated for 1 h at room temperature, when the emission intensity changes saturated. These solutions were used immediately for fluorescence experiments.

Fluorimetry. Emission spectra were obtained using a Fluoromax-3 spectrofluorimeter (Horiba Jobin Yvon Inc., Edison, NJ). Samples were held at room temperature and examined with 363 nm excitation, 3 nm slit widths, and a 1 s integration time. The effect of thrombin and other analytes on the emission intensity was examined by addition of 1−10 μL concentrated analyte stock solutions directly to 1 mL samples in a stirred fluorescence cuvette. Emission spectra were recorded until emission intensities saturated (∼5 min). Quenching analysis were performed in independent samples with increasing **1**-modified duplex DNA concentrations and fit to a modified Stern-Volmer equation (*29*)

$$I/I_0 = \left(\frac{1}{1 + K_a \bullet [\mathbf{1}]} + F_{uq}\right) \quad (1)$$

where I_0 is the initial emission intensity, K_a the Stern-Volmer association constant, [**1**] the concentration of the **1**-modifed duplex DNA, and F_{uq} the fraction of nanoparticle emission intensity that remains unquenched. Analyte-dependent emission intensity changes were reported relative to the 545 nm emission intensity from unmodified duplex DNA attached CdSe@ZnS nanoparticles (fraction intensity).

Titations and Curve Fitting. Thrombin was introduced to the fluorescence cuvette at increasing concentration from a series of stock solutions. Stock solutions were generated by diluting the initial thrombin solution (10 mg/mL) into MOPS or PSS buffer. Stock solutions were introduced to the cuvette in 1 to 5 μL aliquots (Hamilton syringe) and the emission spectrum recorded after emission intensity at 545 nm saturated (∼5 min.). The resulting titration occurred from 10 pM to 1 μM thrombin. The average fraction intensity at 545 nm ($n = 3-5$) was plotted against the thrombin concentration in Igor Pro (Wavemetrics, Portland, OR). Standard deviations of the observed emission intensities determined error bar magnitude. Thrombin-dependent emission intensity changes were represented as the ratio of the observed emission intensity at 545 nm (I) to the emission intensity from the parent (1:1 or 1:5) unmodified system (I_U) and expressed as I/I_U. Graphs of I/I_U vs thrombin concentration were fit to a single binding site isotherm that accounted for the CdSe@ZnS nanoparticle concentration (25 nM)

$$I/I_U = I_{initial} \bullet (I_{final} - I_{initial}) \bullet \frac{([T] + K_d + 25\ nM) - \sqrt{([T] + K_d + 25\ nM) - (4 \bullet [T] \bullet 25\ nM)}}{2 \bullet 25\ nM} \quad (2)$$

where $I_{initial}$ and I_{final} are the initial and final emission intensities, [T] is the thrombin concentration, and K_d is the dissociation constant ($1/K_a$). Analysis of ligand-binding cooperativity was performed by transforming intensity to fraction saturation (Y) using I_o and I_f values. Values of $\log[Y/(1 - Y)]$ were plotted vs log[T], and the slope from nonzero points was determined as the cooperativity (Hill coefficient).

RESULTS

Bionanomaterial Design and Construction. The nucleic acid constructs used by Plaxco and Heeger (*27, 30−32*) were employed to compare charge/electron transfer quenching of semiconductor nanoparticles (*12, 13, 15*) to nucleic acid-based electrochemical biosensors (*27, 30−32*). Two complementary DNA oligonucleotides were synthesized with 6-thiohexanol groups attached to the 5′-phosphate terminus of each strand. One oligonucleotide (A) contained the thrombin-binding aptamer sequence (3′) and a 12-nucleotide region (5′) for invariable association with the complementary oligonucleotide (B). Before DNA hybridization, oligonucleotide B was modified with complex **1** and purified (B-**1**). Oligo B-**1** was hybridized with oligo A to produce the apatmer-containing duplex DNA with complex **1** on the opposite end of the double helix from the 5′-free thiol from oligo A. Duplex DNA containing a single 5′-thiol modification was then adsorbed to MHDA-capped CdSe@ZnS nanoparticles. The resulting system is the basic bionanoparticle assembly reported here (Figure 1, Table 1) where alterations in duplex DNA to nanoparticle stochiometry, reporter group, capping group, and nanomaterial are mentioned.

Emission Responses to Modified Duplex DNA. Complex **1** mediated quenching of MHDA-capped CdSe@ZnS nanoparticles, and thrombin-dependent emission responses were observed for the thrombin-binding aptamer basic assemblies. The amount of CdSe@ZnS emission quenching from duplex DNA-attached complex **1** was determined from comparison to the unmodified system (Table 1, A/B_o duplex). The unmodified duplex DNA bound to CdSe@ZnS nanoparticles decreased

Table 1. CdSe@ZnS Nanoparticle-Based Thrombin Biosensor Systems

biosensor system	oligos[a]	nanoparticle (NP)[b]	NP/oligo stochiometry	capping ligand[c]

[a] Deoxyribonucleotides used for these experiments (see Experimental Section). [b] CdSe@ZnS_{2-3}, CdSe with 2−3 ZnS monolayers; CdSe@ZnS_{5-6}, CdSe with 5−6 ZnS monolayers. [c] MHDA, 16-mercaptohexadecanoate; MUTEG, 11-mercaptoundecyltriethylene glycol.

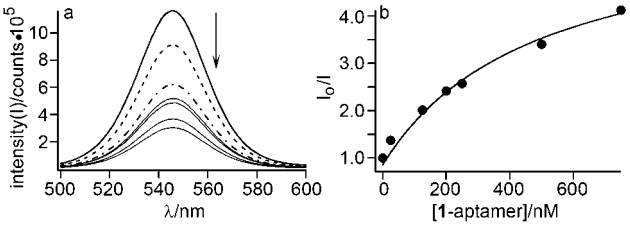

Figure 2. Emission quenching from **1**-modifed duplex DNA. (A) Comparison of emission spectra (thick solid, unmodified (1:1); thick dashed, 1:1 system; thick dash−dotted, 1:5 system, thin solid, higher concentrations). (B) Modified Stern−Volmer analysis (circles, I/I_o, 545 nm; line, fit to eq 1, $K_A = 1.5 \times 10^7$ M^{-1}, $F_{uq} = 0.16$; I_o = emission intensity from 1:1 unmodified system).

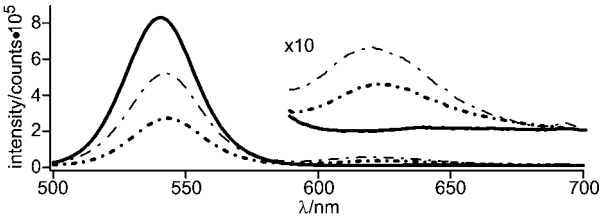

Figure 3. Emission quenching and energy transfer with **2**-modified duplex DNA: thick solid line, 1:5 unmodified system; thick dash−dotted line, 1:5 Bodipy system; thin dash−dotted line, 1:5 Bodipy system with 1 μM thrombin.

emission intensity by 8 ± 2% (Figure 2a, thick solid line) over a variety of DNA concentrations, similar to peptides and proteins (*33*). Addition of 1 and 5 equiv of **1**-modified duplex DNA decreased the nanoparticle emission intensity (Figure 2a, 1:1, 26 ± 3%, thick dashed line; 1:5, 48 ± 2%, thick dash−dotted line) from the emission of the unmodified duplex DNA bound CdSe@ZnS nanoparticles. Direct Stern-Volmer analysis of emission quenching vs **1**-modified duplex DNA showed significant downward curvature, suggesting significant exclusion of complex **1** from the nanoparticle surface. A modified Stern-Volmer analysis (Figure 2b, I_o/I as initial intensity divided by observed intensity) suggested DNA/CdSe@ZnS affinity of 1.5 $\times 10^7$ M^{-1} ($K_d = 67$ nM) with 16% of the emission remaining unaffected by **1**-modified duplex DNA. The initial emission quenching of this system is consistent with the partial complementarity of oligo B to the aptamer sequence from the Plaxco/Heeger system (*19*, *27*) that provided some initial electrochemical (Faradaic) current. The remaining 16% of unaffected emission intensity is reflective of either residual emission from fully "quenched" nanoparticles or steric exclusion of complex **1** from the nanoparticle surface at high DNA concentrations. Despite these effects, two limiting cases were examined to better understand this system: low- and high-density duplex DNA biosensors (1:1 and 1:5 CdSe@ZnS nanoparticle to DNA).

Energy transfer to **2**-modified duplex DNA was examined in the high-density situation (1:5 situation) for comparison to literature reports. Other reports have shown up to 40 equiv of duplex DNA adsorbed to CdSe nanoparticles (*23*); however, these cases have used longer capping groups terminated with streptavidin (~60 Å vs ~8 Å in this system). Ellington and co-workers have used the strongly adsorbing Eclipse quenchers in such systems to achieve almost complete quenching (*21*). Despite the weaker quenching of **2** from decreased spectral overlap, compound **2** was used for comparison to previous protein-attached biosensors based on semiconductor nanoparticles. Addition of **2**-modified duplex DNA to MHDA-capped CdSe@ZnS nanoparticles quenched the nanoparticle emission intensity (545 nm) by 42 ± 2% and increased the **2** emission intensity (625 nm) by 60 ± 5% (Figure 3, thick to thin dash−dotted lines). The degree of energy transfer (via comparison to protein-based systems) is inconsistent with duplex DNA conformation as a rigid helix extending perpendicular to the nanoparticle surface. This model would predict 2−5% nanoparticle emission quenching (~100 Å separation, $n = 5$, 50 Å Förster radius) (*34*). These results indicate initial duplex unwinding along with movement of the DNA duplex (arrows, Figure 1).

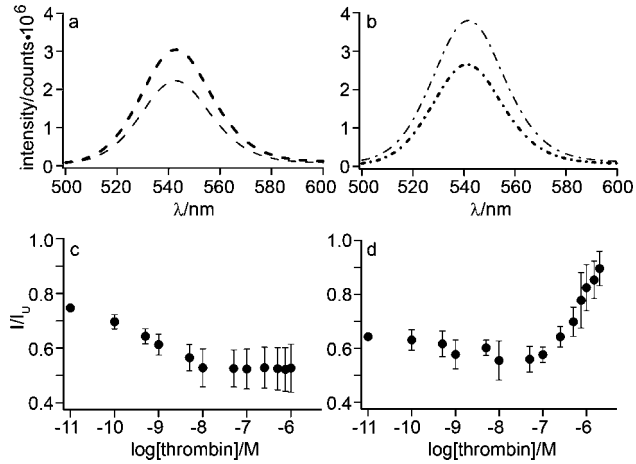

Figure 4. Thrombin-dependent emission responses of MHDA-capped systems. (a,c) 1:1 system, dashed lines; (b,d) 1:5 system, dash−dotted lines. Emission spectra (a,b): Thick lines before thrombin addition, thin lines after thrombin addition (1 μM thrombin). Titration data (c,d): thrombin dependence on emission intensity (545 nm, standard deviation used for error bars, $n = 3$) emission intensity normalized to emission intensity of the parent (c, 1:1; d, 1:5) unmodified systems (defined as I_U) and represented as observed intensity divided by the unmodified intensity (I/I_U).

Emission Response to Thrombin and Alternative Analytes. Thrombin addition to the 1:1 and 1:5 basic biosensor systems provided reproducible but different changes in nanoparticle emission intensity (Figure 4). Introduction of 1 μM thrombin (Figure 4a,b: thin lines; 30−45 min response times) to the 1:1 basic biosensor systems showed a 35 ± 8% quench in emission intensity, while the 1:5 basic biosensor systems showed a 51 ± 2% increase in emission intensity. These emission responses suggested two thrombin-induced **1**-CdSe@ZnS nanoparticle interactions. Thrombin titration curves (Figure 4c,d) for the 1:1 and 1:5 basic biosensor systems are represented as the observed emission intensities (I) relative to the parent (1:1, Figure 4c; 1:5, Figure 4d) unmodified systems (I_U) to compare the relative degree of quenching. Emission quenching at 10 nM thrombin is similar for both the 1:1 and 1:5 biosensor systems; however, the emission intensity 1:5 biosensor system increases at higher thrombin concentrations. These results suggest that the 50% emission intensity increase in the 1:5 biosensor system is an additional state that occurs after an intermediate state. Inspection of even the 1:1 biosensor system thrombin titration curve shows log-linear relationship, which is atypical of a two-state binding site isotherm. A half-maximal signal change occurs at 0.5−1.0 nM thrombin addition but cannot be considered a dissociation constant, since the nanoparticle concentration is 25 nM. The large effect at less than 10% thrombin loadings (<2.5 nM) more than likely occurs by dimerization (via the two binding sites on thrombin) or nonspecific binding. The second phase in the 1:5 biosensor system titration with thrombin (Figure 4d, 10 nM to 10 μM) had difficulties being fit to a single binding site isotherm; however, a reasonable fit to a cooperative binding equation (Hill coefficient of 2.2 ± 0.6, $n = 4$) was obtained. The Hill coefficient suggests **1**-thrombin cooperative interaction from adjacent aptamer-bound thrombins. Evidence for reporter group interactions with thrombin are also seen with the Bodipy system.

Table 2. Emission Quenching of Alternative Systems and Analytes

system	analyte (1 μM)	1:1[a]	1:5[a]
basic	thrombin	−35 (8) %	+51 (2) %
	lysozyme	−1 (1) %	−7 (1) %
	IFABP	−2 (6) %	−8 (1) %
	BSA	+6 (3) %	−17 (1) %
	heparin & hirudin	−8 (4) %	n.d.[b]
basic + heparin & hirudin	thrombin	−4 (5) %	n.d.[b]
basic + thrombin	heparin & hirudin	−4 (3) %	n.d.[b]
scrambled	thrombin	−1 (1) %	+10 (1) %
unmodified	thrombin	−2 (3) %	+9 (1) %
CdSe@ZnS_{5-6}	thrombin	−2 (4) %	−2 (3) %
CdSe@ZnS_{2-3} only	thrombin	−2 (3) %	

[a] Nanoparticle to DNA molar ratio, average change of fraction intensity from analyte addition relative to emission intensity before analyte addition from three to five determinations (standard deviation in parenthesis). [b] Not determined.

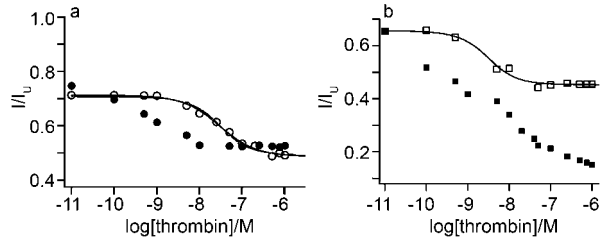

Figure 5. Thrombin-dependent emission responses of additional biosensing systems. Observed emission intensity (545 nm) relative to emission intensity from the 1:1 unmodified system (I/I_U) in the appropriate buffer: Fraction of initial (unmodified system) intensity relative to thrombin added: (A) 1:1 MHDA-capped system with (open circles) and without (filled circles) 25 nM (1.0 equiv) of heparin; (B) 1:1 MUTEG-capped system in MOPS-based buffer (filled squares) and in PSS-based buffer (open squares). The open circles (a) and open squares (b) were fit to a single binding site isotherm ($[NP]_{tot} = 25$ nM; a, $K_d = 28$ nM, $I_{initial} = 71\%$, $I_{final} = 49\%$; b, $K_d = 2.0$ nM, $I_{initial} = 66\%$, $I_{final} = 45\%$).

In this system, thrombin addition (Figure 3, thick to thin lines) caused the emission intensity of the nanoparticle (545 nm), and Bodipy (618 nm, plus blue shift) increased indicating a decrease in polarity of the Bodipy environment while being moved away from the nanoparticle surface. The Bodipy 1:5 system indicates reporter group binding to thrombin in concert with movement away from the nanoparticle surface; such effects in the complex **1** 1:5 biosensor system would cause the observed increase in emission intensity at 1 μM thrombin (Figure 4b). Despite the non-two-state binding isotherms for the 1:5 biosensor system, the MHDA-capped biosensor systems yielded a qualitative assay for thrombin activation.

Selectivity of Thrombin-Mediated Emission Responses. The selectivity of the qualitative thrombin responses from the 1:1 and 1:5 biosensor systems was examined. Addition of 1 μM thrombin to MHDA-capped CdSe@ZnS nanoparticles caused no change in nanoparticle emission within error (Table 2). The electron transfer nature of **1**-mediated quenching was demonstrated when the more insulated CdSe@ZnS_{5-6} nanoparticles showed minimal **1**-modified DNA emission changes and no significant thrombin-mediated emission changes. These observations suggest that thrombin responses of the basic biosensor systems are not due to changes in electrostatics at the nanoparticle surface. Assemblies using **1**-modified duplex DNA that did not contain the aptamer consensus sequence (scrambled) showed no thrombin-mediated change in emission intensity of the 1:1 scrambled system and a small increase in emission intensity of the 1:5 scrambled system. While the response to noncognate proteins was opposite of the thrombin response, the 1:5 basic biosensor system displayed significantly lower selectivity than the 1:1 basic biosensor system. The 1:1 basic biosensor system showed no significant response to lysozyme or IFABP, while bovine serum albumin BSA showed a small effect. Considering the isoelectric points of these proteins (thrombin, 7.3; lysozme, 11.3; IFABP, 5.8; BSA, 5.3), protein electrostatics seems to have minimal contributions to thrombin-selective emission responses.

As the last selectivity test for the 1:1 biosensor system, the effect of two thrombin inhibitors (heparin and hirudin) on the thrombin-mediated responses was examined. Addition of the inhibitors before thrombin addition caused no change in the emission spectrum, while addition of the inhibitors to the thrombin-bound 1:1 biosensor system did not restore the emission intensity. These results suggest that thrombin binding is responsible for the 34% decrease in emission intensity observed with the 1:1 biosensor system. The lack of reversible inhibition suggests that the thrombin−aptamer/nanoparticle affinity is higher than either the thrombin−inhibitor affinities or thrombin-induced irreversible nanoparticle aggregation. A number of variations to the 1:1 biosensor system were examined to obtain a better measurement of the thrombin−aptamer/nanoparticle affinity and to generate a biosensor that could be used for quantitative thrombin measurement.

Solubility Mediates Non-Two-State Binding. Contributions from thrombin-mediated nanoparticle dimerization and aggregation were examined. Following the inhibition studies from above, thrombin titrations were carried out in the presence of one of the two inhibitors, heparin, leaving the fibrinogen exosite and active site of thrombin available for binding the aptamer. The observed thrombin-dependent emission intensities followed a single binding site isotherm with a dissociation constant of 25 nM (Figure 5A, open circles; $K_a = 4.0 \times 10^7$ M^{-1}). The observed thrombin−nanoparticle affinity is consistent with previously reported thrombin−aptamer affinities, but should be considered weaker than the thrombin−aptamer/nanoparticle affinity due to competitive inhibition. More importantly, the introduction of heparin demonstrates that thrombin-mediated nanoparticle dimerization contributes to the non-two-site binding isotherms observed with the MHDA-capped systems.

Thrombin-dependent two-state binding isotherms were observed in the absence of heparin for 1:1 biosensor systems with mercaptoundecyltriethylene glycol (MUTEG) capping ligands. Alcohol/glycol-terminated surfaces are well-known to minimize nonspecific binding and improve solubility in the presence of aqueous mono- and divalent salt solutions (e.g., physiological conditions). MUTEG-capped 1:1 CdSe@ZnS nanoparticles in the low ionic strength MOPS-buffered solutions used for the MHDA-capped systems yielded similar thrombin-dependent results to the 1:1 MHDA-capped system (Figure 5B, filled squares). When the ionic strength was raised (PSS), to increase the solubility of the MUTEG-capped 1:1 CdSe@ZnS nanoparticles, thrombin-dependent results that fit a two-state binding site isotherm (Figure 5B, filled squares; $K_d = 2.0$ nM, $K_a = 5 \times 10^8$ M^{-1}) were observed. Comparison of the low-to-moderate ionic strength conditions suggested that nanoparticle solubility controls the thrombin-mediated aggregative effects seen throughout this study.

DISCUSSION

Generation of soluble unimolecular biosensors based on semiconductor nanoparticles represents the next and necessary iteration in solution DNA/RNA-based biosensors. The majority of aptamer-attached, semiconductor nanoparticle-based biosensors have been based on analyte-dependent aggregation. These aggregative assays generate qualitative analysis and single time

point quantitative analysis. Unimolecular biosensors rely on nonaggregative signaling mechanisms and therefore allow long-term quantitative analysis of analyte concentrations. Long-term monitoring of analyte concentrations would utilize the high photostability of semiconductor nanoparticles, relative to organic fluorophores. Current single-point analysis using semiconductor nanoparticle-based assays take advantage of the high photostabilities and large two-photon cross sections; however, long-term monitoring better demonstrates the high photostability of semiconductor nanoparticles.

In this study, single-stranded DNA seemed to nonspecifically bind other nanoparticles. This nonspecific binding induced aggregation and was a significant impediment to biosensor function. Analysis of thrombin-dependent emission intensities using logarithmic scales were necessary to discern between two-state binding and nonspecific binding/aggregation. Many reports in this area use linear scales, where nonconformity to two-state binding site isotherms is difficult to discern. These nonspecific effects from single-stranded DNA are not expected for electrochemical biosensors due to the use of a bulk material as the detection platform. Nonspecific aggregation does become an issue for nanomaterials diffusing in biological media. We do not suggest that MUTEG or mercaptoundecylhexaethylene glycol capping ligand provides the ultimate solution to nanoparticle solubility; however, MUTEG capping did alleviate the nonspecific aggregation in the initial version of these biosensors. Solubility of semiconductor nanoparticles is becoming an important issue for live cell imaging and toxicity of these inorganic fluorophores (*35*−*37*). This study also suggests a need for careful consideration of capping ligands in semiconductor nanoparticle-based biosensor design.

Translation of aptamer-based electrochemical biosensors to fluorescence imaging using semiconductor nanoparticles was obtained, once nanoparticle aggregation was avoided. Thrombin-dependent changes in nanoparticle emission intensity were observed in all systems that used the redox-active complex **1** attached to aptamer-containing duplex DNA. Emission intensity showed two responses: a 35% decrease in emission intensity (1:1 system) or a 50% increase in emission intensity (1:5 system). The more dilute situation (1:1) operated as expected from the electrochemical biosensor literature (*27*), while the concentrated situation (1:5) showed steric exclusion and sequestration of complex **1** from the nanoparticle surface. The thrombin-dependent emission intensity profiles only fit to two-state binding models in two situations, heparin addition to 1:1 MHDA-capped assemblies and 1:1 MUTEG-capped assemblies in a biocompatible buffer system. Deviation from two-state binding isotherms, more than likely, arose from nanoparticle aggregation. Solubility effects should be expected to play a larger role in thrombin biosensors compared to previous biosensors for lower molecular weight analytes (maltose and palmitate). An additional aspect of aptamer-based sensors, relative to protein-based sensors, is nonspecific nanoparticle binding/aggregation resulting from single-stranded DNA or RNA. Using triethylene glycol terminal groups, quantitative thrombin biosensors were generated using charge/electron transfer quenching of CdSe@ZnS nanoparticles.

These findings demonstrate not only the portability of charge/electron transfer quenching in semiconductor nanoparticle-based biosensors (protein to nucleic acid sensing components), but also the need to carefully consider nanobiosensor solubility in binding profiles. By simply changing the capping ligand for the CdSe@ZnS nanoparticle thrombin-dependent emission profiles moved from multistate/aggregative profiles to two-state profiles depending on the buffer conditions. The nucleic acid surface density on the CdSe@ZnS nanoparticle changed the direction (increase vs decrease) of emission change. The size of thrombin, relative to maltose or palmitate, mediated this new observation in our biosensor systems, where in the 1:5 system the **1**-modified single DNA strand was excluded from the surface. Such an observation points to the need for a 1:1 sensing element to nanoparticle ratios in this class of sensors to remove artifacts from steric hindrance and molecular exclusion. Despite these caveats, this work shows a third principle for constructing soluble, semiconductor nanoparticle-based biosensors; aptamer conformation changes along with protein conformation change and protein binding site water exclusion. Therefore, this work demonstrates a significant advance toward the eventual use of these semiconductor nanoparticle-based biosensors for long-term imaging of analyte fluxes within living cells.

Site-Specific, Thiol-Mediated Conjugation of Fluorescent Probes to Cysteine-Modified Diabodies Targeting CD20 or HER2

Shannon J. Sirk,* Tove Olafsen, Bhaswati Barat, Karl B. Bauer, and Anna M. Wu

Crump Institute for Molecular Imaging, Department of Molecular and Medical Pharmacology, David Geffen School of Medicine at UCLA, Los Angeles, California 90095. Received March 24, 2008; Revised Manuscript Received October 15, 2008

Small, engineered antibody fragments such as diabodies (50 kDa noncovalent dimers of single-chain Fv fragments) are useful alternatives to their larger antibody counterparts. However, due to their size, they are more susceptible to disruption of their antigen binding sites when modified using random conjugation techniques. Previous work has demonstrated the utility of a C-terminal cysteine modification for site-specific radiolabeling of an anti-CEA diabody, resulting in the creation of a cys-diabody (CysDb). In the present work, the adaptability of the CysDb system was explored by creating two additional CysDbs: one specific for CD20 and one for HER2. Purified CysDbs of both specificities demonstrated behavior consistent with stable, covalent dimers harboring a readily reducible disulfide bond. Each CysDb was site-specifically conjugated to three different fluorophores for optical detection: the large fluorescent proteins phycoerythrin (PE) and allophycocyanin (APC), and the small fluorescent molecule Alexa Fluor488. Fluorophore-conjugated CysDbs bound specifically to their targets in both antigen systems and with each different fluorescent tag as determined by flow cytometry. *In vitro* specific antigen binding was observed in the presence of a mixture of specific and nonspecifically conjugated CysDbs. Conjugates retained both specificity and fluorescence, demonstrating the successful expansion of the CysDb repertoire to new targets and to new site-specific conjugation possibilities.

INTRODUCTION

Monoclonal antibodies (mAbs) comprise a unique class of tumor targeting agents capable of specific recognition of cell surface antigens, including cancer biomarkers. Many therapeutic mAbs have been used to target and treat a wide range of diseases, including breast cancer, lymphoma, colorectal cancer, and leukemia (*1*). When conjugated to radionuclides, antibody derivatives specific for cancer biomarkers can be employed for tumor detection using imaging methods such as positron emission tomography (PET) (*2*−*4*). MAbs armed with therapeutic radionuclides or other cytotoxic agents have been used to deliver targeted toxicity to a tumor while minimizing damage to healthy tissue (*5, 6*).

Intact mAbs are highly specific targeting agents but are not suited for every application due to their large size and full Fc domain. Engineered antibody fragments harness the specificity of the variable domains while modifying or deleting the constant domains to suit the intended targeting need (*7, 8*). Single-chain Fvs (scFvs), consisting of the variable light (V_L) and variable heavy (V_H) domains joined by an amino acid linker, are the smallest antibody fragments that still retain specificity and are commonly used antigen-specific probes (*9*−*11*). ScFv linker length influences fragment multimerization, with shorter linkers (3−12 residues) supporting the formation of bivalent diabodies (Dbs) (*12*). Compared to scFvs, Dbs demonstrate superior binding *in vitro* and improved tumor accumulation *in vivo* due to increased avidity and therefore increased functional affinity (*13*).

Targeting applications regularly involve labeling antibodies and antibody fragments, often with a radionuclide. Common techniques involve conjugation via random tyrosine or lysine residues (*14, 15*). Intact antibodies (150 kDa) are large enough to offer several sites that will not disrupt antigen binding when conjugated to a labeling agent. At a fraction of the size of intact antibodies, Dbs (50 kDa) have fewer available conjugation sites, and it is therefore more likely that conjugation will disrupt antigen binding or overall conformation and efficacy of the molecule as a tumor targeting agent.

To address this problem, methods for site-specifically labeling Dbs and bypassing potential adverse effects of random conjugation have been pursued. The addition of C-terminal cysteinyl peptides was originally explored as a method to induce dimerization of scFv molecules (*16, 17*) and provide a defined site for radiometal chelation (*18*). Site-specific PEGylation has been used to adjust the circulating half-life of cysteine-modified scFvs (*19*), and liposomes have been coupled via thiol chemistry to scFvs targeting tumor biomarkers and tumor stromal cells (*20, 21*).

Crystallographic analysis of an anti-carcinoembryonic antigen (CEA) Db revealed that the antigen binding sites are located on opposite sides from the C-termini of the V_H domains (*22*). An anti-CEA Db with a cysteine residue incorporated at the C-terminus of the V_H domain of each scFv monomer was created (CysDb) and expressed in mammalian cell culture, spontaneously yielding stable covalent dimers (*23*). Anti-CEA CysDbs demonstrated excellent binding *in vitro* and, following site-specific chelate conjugation and radiometal labeling, specifically targeted CEA-expressing tumor xenografts in a microPET mouse model (*23*).

On the basis of this initial success, the CysDb format was extended to two additional cancer targets—CD20 (lymphoma) and HER2 (breast cancer). CD20 and HER2 were chosen as candidate antigen systems because there are pre-existing, well-characterized therapeutic antibodies (rituximab and trasuzumab) specific for these targets. Functional CysDbs of both specificities were produced and characterized. Both CysDbs retained specific antigen binding following site-specific conjugation to three different fluorophores. Bifunctionality of each conjugate is

demonstrated through the observed antigen specificity of each CysDb as well as the unique fluorescence profile of each attached fluorophore. Successful expansion of the C-terminal cysteine modification to two new specificities supports the utility of the CysDb format as a generalizable platform for site-specific conjugation of tumor targeting molecules with functional payloads.

EXPERIMENTAL PROCEDURES

Design of Cysteine-Modified Diabodies. Diabodies were constructed from existing gene constructs containing variable regions recognizing HER2 (*4*) or CD20 (Olafsen et al. [abstr.], *J. Nucl. Med.* 47:48P, 2006). Overlap-extension PCR and site-directed mutagenesis (QuikChange XL, Stratagene) were used to create CysDb genes with a five amino acid linker (SGGGG) between the variable light (V_L) and variable heavy (V_H) domains and a C-terminal cysteine modification (GGC) to give the final CysDb construct: (V_L-SGGGG-V_H-GG**C**) in the pEE12 mammalian expression vector (*24*). All constructs were confirmed by DNA sequencing.

Mammalian Expression, Selection, and Purification. 2.5×10^6 NS0 mouse myeloma cells (Sigma) were transfected by electroporation with 10 μg linearized plasmid DNA and selected in glutamine-deficient DMEM (Mediatech Inc.) as described (*24*). Transfectants were screened for CysDb expression by assaying cell culture supernatant by ELISA and/or SDS-PAGE using precast 4−20% gels (Bio-Rad).

ELISA. For anti-CD20 CysDb ELISA, microtiter plate wells were coated with 100 μL (2 μg/mL) goat anti-mouse Fab (Sigma), then blocked with 1% BSA. 100 μL cell culture supernatant was assayed, and anti-CD20 CysDb was detected with 100 μL (0.4 μg/mL) alkaline phosphatase (AP)-conjugated goat anti-mouse Fab (Jackson Immunolabs). Signal was developed using phosphatase substrate tablets (Sigma), and absorbance was detected at 405 nm using a microplate reader (Tecan). The same procedure was performed for anti-HER2 CysDb ELISA, except using Protein L (Sigma) for coating wells and Protein L-horse radish peroxidase (HRP) (Sigma) for detection. Signal was developed with CN/DAB Substrate Kit (Pierce) and analyzed visually for black precipitate.

Gel Electrophoresis and Immunoblotting. SDS-PAGE gels were run with 30 μL cell culture supernatant and either stained with Microwave Blue (Protiga) or transferred to nitrocellulose membrane for Western analysis. Samples were run under both reducing (100 mM DTT) and nonreducing conditions. Anti-CD20 CysDb was detected on Western blot with 0.4 μg/mL goat anti-mouse Fab-AP (Jackson Immunolabs), and color was developed with NBT/BCIP substrate (Promega). Anti-HER2 CysDb was detected on Western blot by Protein L-HRP (Sigma) and color was developed with CN/DAB Substrate Kit (Pierce).

Purification. Clones showing the highest expression were expanded into triple flasks (Corning), and approximately 700 mL cell culture supernatant was collected and filtered on a polyethersulfone (PES) membrane (Corning). Supernatant was loaded onto a Protein L column (Pierce) with a bed volume of 1 mL at a flow rate of 0.4 mL/min in PBS using an ÄKTA Purifier (GE Healthcare Life Sciences). Bound protein was eluted with 0.1 M glycine, pH 2.5, over 20 column volumes. Eluted fractions were neutralized upon collection in 5% final volume 2 M Tris, pH 8.0. Fractions containing protein were identified by SDS-PAGE and combined. Buffer was exchanged to PBS, protein was concentrated using a spin column (Vivaspin 20, 10 kDa cutoff), and protein was stored at 4 °C.

Characterization of Purified CysDbs. Purified, concentrated protein was analyzed by SDS-PAGE followed by Microwave Blue gel staining or Western blot analysis as described above. All molecular weights were approximated by comparison to Kaleidoscope prestained molecular weight standard (Bio-Rad) and a previously characterized anti-CEA CysDb with a known molecular weight of 55 kDa. CysDbs were also subjected to size-exclusion chromatography on a Superdex 75 column (GE Healthcare Life Sciences) in PBS at a flow rate of 0.5 mL/min over one column volume (24 mL) on an ÄKTA Purifier. Protein purity was estimated from size exclusion chromatography data. Anti-CD20 CysDb (only) was analyzed for specific binding by indirect flow cytometry, described below.

Site-Specific Fluorescent Labeling. Cys-diabodies were site-specifically conjugated using thiol chemistry to three different fluorophores: phycoerythrin activated with succinimidyl 4-[*N*-maleimidomethyl]-cyclohexane-1-carboxylate (PE-SMCC, 240 kDa, Prozyme), allophycocyanin (APC)-SMCC (104 kDa, Prozyme), or Alexa Fluor 488 C_5-maleimide (A488, 720 Da, Invitrogen). Each CysDb was conjugated to each fluorophore individually, resulting in six conjugates (3 fluorescent tags × 2 CysDb specificities). Mock conjugation controls were treated under the same conditions, except with no CysDb added. Following the Phycolink conjugation kit guidelines (Prozyme), 150 μg of CysDb in 60 μL PBS was incubated at room temperature with 16 mM DTT for 30 min to reduce disulfide bonds. DTT was removed from reduction reactions using a Micro Bio-Spin 6 chromatography column (Bio-Rad), equilibrated with Exchange Buffer (50 mM MES, 2 mM EDTA, pH 6.0). Reduced CysDb was then incubated with 240 μg activated PE or APC (10 mg/mL in 50 mM MES, 2 mM EDTA, pH 6.0, with 1 μg/mL pentachlorophenol [preservative]), or 12 μg A488 (1 μg/mL, 1.4 mM in water). Molar ratios in the conjugation reactions were approximately 1:3, 1:1.25, and 5.6:1 for PE/CysDb, APC/CysDb, and A488/CysDb, respectively. Addition of fluorophore was followed by incubation in the dark at room temperature for 1 h with occasional mixing. Remaining free sulfhydryls were then blocked with 5.1 μg *N*-ethylmaleimide (NEM, 10 mg/mL in DMSO, Sigma). Reactions were wrapped in foil, incubated at room temperature with occasional mixing for 30 min, and then applied to new spin columns equilibrated with Storage Buffer (10 mM Tris-HCl, 150 mM NaCl, pH 8.2). Fluorophore-conjugated CysDbs were stored in 1.5 mL Eppendorf tubes at 4 °C, wrapped in aluminum foil. Protein yield and conjugation ratios were determined using a UV/visible spectrophotomer (Ultrospec 1100 Pro, GE Healthcare Life Sciences) to measure absorption at 280 and at the peak absorption wavelength of each flurophore.

Flow Cytometry. Flow cytometry was used to evaluate binding of CysDbs to cell-surface antigen before (anti-CD20 CysDb only) and after site-specific fluorescent labeling. Unconjugated anti-CD20 CysDb was tested on 38C13 mouse myeloma cells (ATCC #HB-132) transfected with human CD20 (*25*). Conjugated CysDbs were tested on SKW 6.4 (human B cell lymphoma, CD20-positive, ATCC #TIB-215), Daudi (human B cell lymphoma, CD20-positive, ATCC #CCL-213), and MCF-7 $HER2^+$ (human breast cancer, HER2-transfected, gift of Dr. Dennis Slamon, UCLA School of Medicine) (*26*). Cells were harvested and resuspended in PBS/1% FBS to a final concentration of 1×10^6 cells/mL. For each reaction, 5×10^5 cells (500 μL) were incubated with fluorophore-conjugated CysDb (0.5 or 5 μL) for 1 h on ice with occasional mixing.

38C13-$CD20^+$ cells were incubated first with unconjugated anti-CD20 CysDb, followed by PE-conjugated anti-mouse Fab secondary antibody (Jackson Immunolabs). SKW6.4 cells were incubated with PE-conjugated anti-CD20 CysDb only.

Each fluorescent CysDb and each mock conjugate was incubated in separate reactions with Daudi cells and MCF7-$HER2^+$ cells. Experiments were performed with 0.5 μL (low concentration sample) or 5 μL (high concentration sample) of conjugated CysDb or mock-conjugated dye. Each fluorescent

CysDb was also assayed for specific binding to either Daudi (anti-CD20 CysDbs) or MCF7-HER2$^+$ (anti-HER2 CysDbs) in the presence of other CysDbs. Mixtures were composed of one antigen-specific and two antigen-nonspecific fluorescent conjugates, with every combination represented. Each fluorescent CysDb (3 μL) was incubated with its target cell type in the presence of the other two (nonspecific) CysDb (3 μL each conjugate). Positive control samples were incubated with either anti-CD20 scFvFc (Olafsen et al. [abstr.], *J. Nucl. Med.* 47: 48P, 2006) for Daudi or anti-HER2 scFvFc (*4*) for MCF7-HER2$^+$ cells, and then washed and incubated with each of three fluorescently labeled anti-human-IgG-Fc-specific secondary antibodies (PE- and APC-conjugated, Jackson Immunolabs; Alexafluor 488-conjugated, Molecular Probes). All samples were then washed with PBS/1% FBS, resuspended in 500 μL PBS/1%FBS, filtered, and analyzed on a modified FACScan flow cytometer using *CellQuest* software (BD Biosciences). Fluorescence of 10 000 gated viable cells was collected simultaneously in 3 channels for each sample. A488 signal (519 nm emission wavelength) was detected in FL1, PE signal (578 nm emission wavelength) was detected in FL2, and APC signal (661 nm emission wavelength) was detected in FL4.

RESULTS

Design and Construction of CysDbs. C-terminal GGC modifications were added to anti-HER2 and anti-CD20 scFv gene constructs as shown (Figure 1). Anti-CD20 CysDb gene was constructed from an existing anti-CD20 single chain variable fragment gene (scFv, V_L-SGGGG-V_H), composed of rituximab (Rituxan, Genentech) mouse variable regions (Olafsen et al. [abstr.], *J. Nucl. Med.* 47:48P, 2006). Anti-HER2 CysDb gene was constructed from trastuzumab (Herceptin, Genentech) variable regions, from an existing minibody gene (*4*). The scFv orientation and linker of the anti-HER2 minibody were as follows: V_L-GSTSGGGSGGGSGGGGSS-V_H. Overlap extension PCR was used to shorten the 18 amino acid linker in the anti-HER2 scFv gene to a 5 amino acid linker (SGGGG).

Mammalian Expression. Following transfection of NS0 cells with either anti-CD20 or anti-HER2 CysDb gene construct, positive clones were identified by growth of single colonies in microtiter plates. CysDb-expressing transfectants were screened by ELISA and Western blot (data not shown). Color development verified positive clones by ELISA and allowed ranking of relative expression levels within this group. Bands on Western blots were detected at approximately 50 kDa (nonreduced) and 25 kDa (reduced), providing confirmation of the correct size of both dimer and monomeric subunit forms of the protein.

Purification. Clones expressing anti-CD20 CysDb and clones expressing anti-HER2 CysDb were expanded and CysDb was purified from the media by affinity chromatography on a Protein L column. Final protein yields were 1.6 mg/L of culture supernatant for anti-CD20 CysDb and 3.0 mg/L of culture supernatant for anti-HER2 CysDb. Purities of >99% for anti-CD20 CysDb and >90% for anti-HER2 CysDb were determined from size exclusion chromatography data.

Characterization of Purified CysDbs. *Gel Electrophoresis and Immunoblotting.* SDS-PAGE analysis demonstrated correct size and covalent dimerization of purified CysDbs. Under nonreducing conditions, both proteins migrated near the expected molecular weights of approximately 50 kDa, verifying a population of covalently dimerized molecules in the final purified product. Under reducing conditions, CysDbs migrated at approximately 25 kDa, consistent with the expected scFv monomer (Figure 2). Purified CysDbs were specifically detected by Western blot at approximately 50 kDa (nonreduced) and approximately 25 kDa (reduced) (data not shown).

Size Exclusion Chromatography. Characterization of purified CysDbs by size-exclusion chromatography resulted in elution profiles similar to each other and to previously characterized diabodies (Figure 3). Anti-CD20 CysDb (25.2 min) and anti-HER2 CysDb (22.5 min) both eluted at times similar to the previously characterized anti-CEA CysDb (21.5 min) (*23*) and anti-CD20 Db (23.7 min) (T. Olafsen, unpublished). Anti-CD20 CysDb eluted slightly later than its parental, non-cysteine-modified diabody, suggesting a more compact form of the protein, as expected with covalent dimerization (*23*). Anti-CD20 CysDb eluted later than either of the other CysDbs, consistent with its apparent smaller size as seen by SDS-PAGE (Figure 2).

Flow Cytometry. Specific antigen binding was demonstrated for anti-CD20 CysDb by indirect flow cytometry. Fluorescence of gated viable CD20$^+$ cells showed binding comparable to that of parental, non-cysteine-modified anti-CD20 diabody (data not shown).

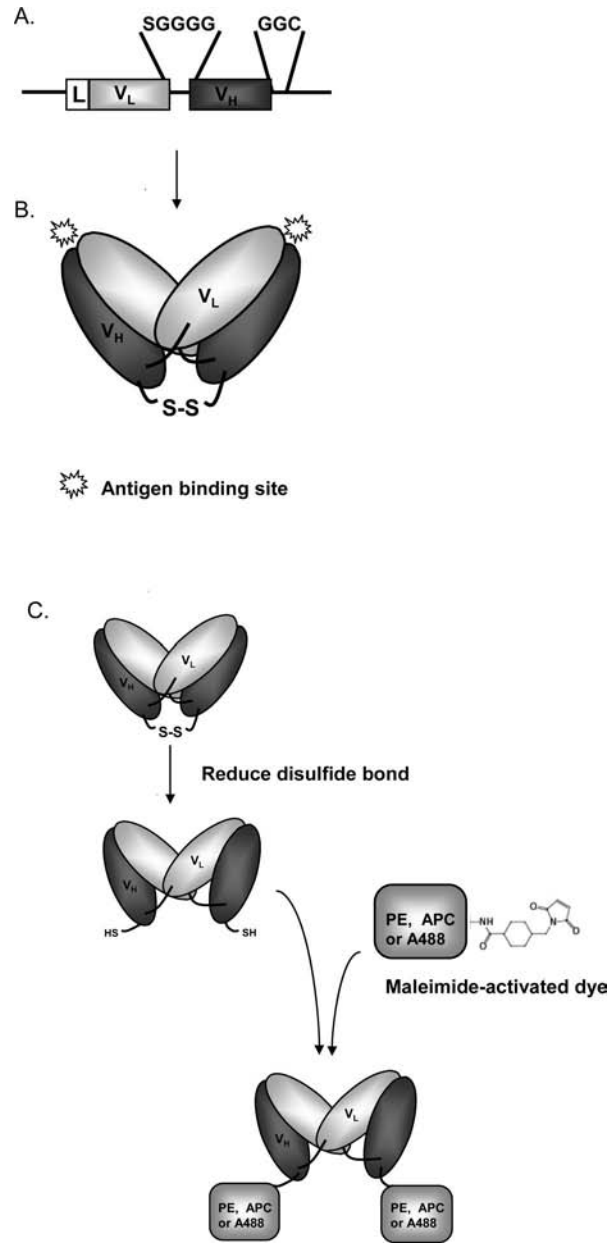

Figure 1. Schematic representation of CysDb. (A) Gene assembly for anti-CD20 and anti-HER2 CysDb (scFv monomer) with 5-aa linker and cysteine modification shown (L, leader sequence for secretion). (B) CysDb with antigen binding sites indicated by starbursts. CysDb is shown in covalent dimer form, with disulfide bond in the predicted location. (C) Conjugation reaction linking cys-diabody to fluorescent probe.

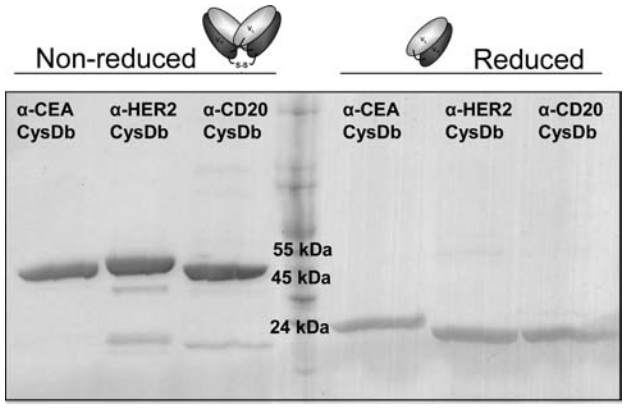

Figure 2. SDS-PAGE of three CysDbs under nonreducing (left) and reducing (right) conditions. Previously characterized anti-CEA CysDb shown for comparison purposes. Nonreduced samples migrate at expected size for covalent dimer (50 kDa), and reduced samples migrate at expected size for monomeric scFv (25 kDa).

Site-Specific Fluorescent Labeling and Specific Binding of Conjugated CysDbs. *Single-Channel Flow Cytometry*. Anti-CD20 CysDbs site-specifically conjugated to the fluorescent dyes PE, APC, or A488 demonstrated specific binding to CD20-positive Daudi cells and not to CD20-negative MCF7-HER2$^+$ cells (Figure 4). Quantities of APC and PE used were half of that suggested in the manufacturer's guidelines, as this modification yielded comparable conjugation efficiency in our hands and conserved reagent. Product guidelines for A488 recommend 10−20 mol of dye per mole of protein when conjugating thiol-reactive probes (Invitrogen). A final value of 5.6 mol of A488 C_5-maleimide per mole of CysDb was used in an attempt to reduce excessive background from unconjugated dye. Dye/protein ratios were calculated for A488 batches only, as this was the only nonprotein fluorophore and therefore gave more consistent quantitative results. The molar ratio of A488/CysDb was calculated to be 2:1.

Single-channel experiments showed binding to Daudi cells of each of the three fluorescent conjugates of anti-CD20 CysDb (Figure 4A). Mock-conjugated fluorophore background showed minimal shift in FL1, FL2 or FL4 compared to the antigen-specific binding shift of the CysDb. PE-labeled anti-CD20 CysDb also demonstrated specific binding to an additional CD20-positive cell line, SKW 6.4, by flow cytometry (data not shown). All three anti-CD20 CysDb conjugates showed a concentration-dependent shift in fluorescence from the low to the high concentration samples, with the APC version exhibiting a higher mean fluorescence in general, across all experiments performed (Figure 4B). All three anti-CD20 CysDb conjugates showed minimal nonspecific background binding to CD20-negative MCF7-HER2$^+$ cells (Figure 4C).

Analogous results were seen with PE-, APC-, and A488-conjugated anti-HER2 CysDbs. All three conjugates showed specific binding to MCF7-HER2$^+$ cells. Fluorescence shifts were seen in the expected channels for each of the conjugated CysDbs, but not for the mock-conjugated dye (Figure 5A). Cells incubated with a low concentration of PE- and APC-conjugated anti-HER2 CysDb showed very little difference in mean fluorescence intensity compared with cells incubated with a high concentration of these CysDbs (Figure 5B). When incubated with HER2-negative Daudi cells, fluorescently conjugated anti-HER2 CysDbs showed minimal background binding (Figure 5C). PE-labeled anti-HER2 CysDb also showed no binding to HER2-negative, CD20-positive SKW 6.4 cells by flow cytometry (data not shown).

Multiple-Channel Flow Cytometry. Figure 6A shows representative plots of three-channel flow cytometry experiments in which Daudi cells were incubated with a cocktail of three different CysDb conjugates: one anti-CD20 CysDb and two anti-HER2 CysDbs, each conjugated to a different fluorophore. Each of the three anti-CD20 CysDb fluorescent conjugates was tested in combination with two anti-HER2 CysDb fluorescent conjugates. For anti-CD20 CysDb-PE, specific binding to Daudi cells was demonstrated by signal in FL2 (upward shift). Minimal background signal was detected in FL4 or FL1 from either APC- or A488-conjugated anti-HER2 CysDb, respectively, as seen by a lack of rightward shift in fluorescence (Figure 6A). Similar results were seen when APC- or A488-conjugated anti-CD20 CysDb was incubated with Daudi cells in a three-conjugate mix with anti-HER2 CysDb and subjected to flow cytometric analysis in all three fluorescence channels (Figure 6B).

Parallel experiments were run with MCF7-HER2$^+$ cells which showed specific binding of conjugated anti-HER2 CysDb when mixed with anti-CD20 CysDb conjugates in three-conjugate cocktail experiments as described above. Figure 6C shows a representative plot demonstrating specific detection in FL2 of PE-conjugated anti-HER2 CysDb bound to MCF7-HER2$^+$ cells, while minimal background signal of APC- or A488-conjugated anti-CD20 CysDb was seen in FL4 or FL1, respectively. Similar results were seen for the other combinations of fluorescent conjugates. For each sample, nearly 100% of the signal was in the channel specific to the anti-HER2 conjugate being detected, while fluorescence from the nonspecific anti-CD20 CysDb was not seen, with the exception of a slightly higher background from the APC-conjugated anti-CD20 CysDb (Figure 6D).

DISCUSSION

Cysteine-modified diabodies were engineered for use as site-specifically modifiable, cancer biomarker-specific antibody fragments. The decision to place the cysteine modification at the C-terminus of the V_L-linker-V_H construct was based on previous success with a similar modification which generated the T84.66 anti-CEA CysDb (*23*). The current work extends the CysDb format from CEA to two additional antibodies recoginizing CD20 and HER2, demonstrating that this format is general. Since the C-termini of the diabody subunits are physically opposite from the antigen-binding sites on the CysDb, following reduction, any further modification to the free sulfhydryls should not interfere with binding activity (*23*). Purified CysDb exists as a stable covalent dimer until subjected to reducing conditions, demonstrating a system with simple and

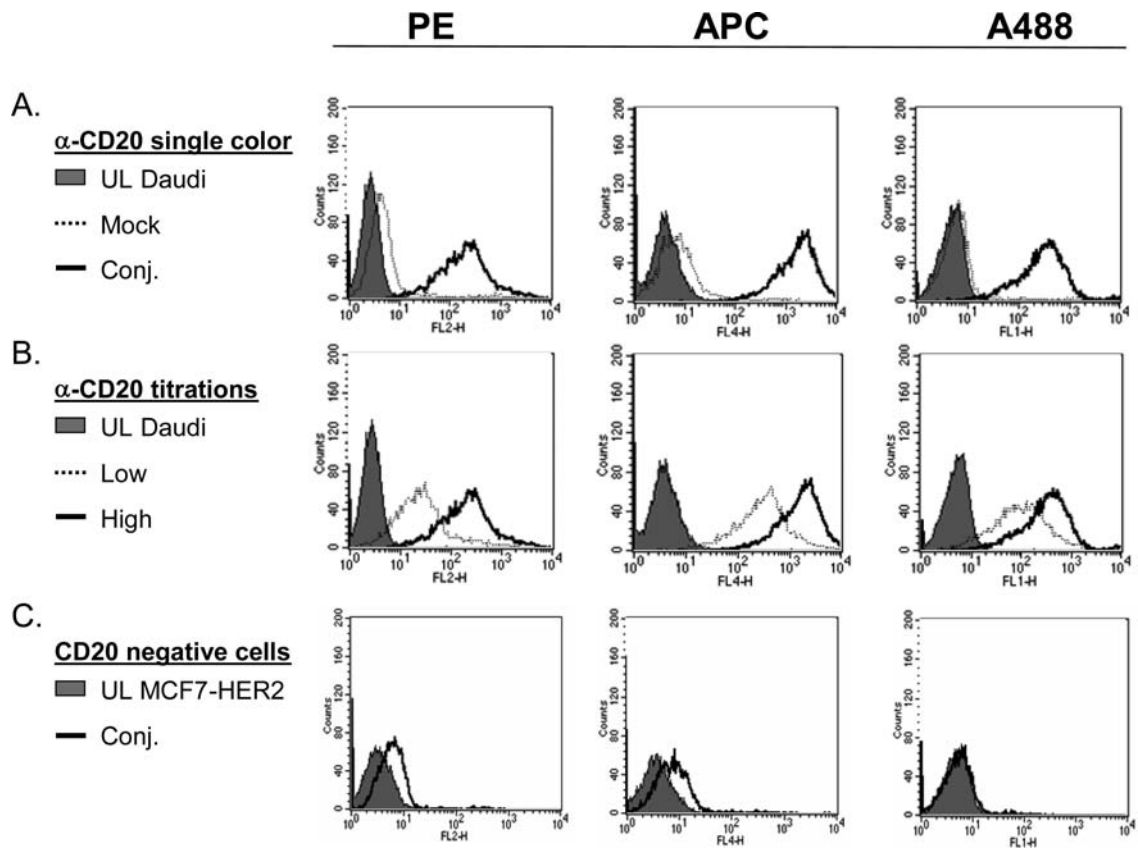

Figure 4. Flow cytometry of single-channel labeling with dye-conjugated anti-CD20 CysDb. Unlabeled cells (UL) shown in solid gray. (A) Three channels of dye-conjugated anti-CD20 CysDb (Conj., thick line) and mock conjugated dye (Mock, dotted line) demonstrating minimal background from nonspecific binding of free dye molecules to $CD20^+$ Daudi cells. (B) Three channels of low (0.5 μL, dotted line) and high (5 μL, thick line) concentrations of dye-conjugated anti-CD20 CysDb demonstrating concentration-dependent shift in mean fluorescence with increasing quantities of conjugated CysDb. reliable control over the availability of free sulfhydryls for thiol-specific conjugation.

The presence of C-terminal cysteine residues clearly induces efficient disulfide bridge formation and a compact overall conformation. Olafsen et al. first observed that the cysteine modification and subsequent disulfide bridge formation caused an anti-CEA CysDb to appear more condensed than the parental diabody (*23*). We also found that, for the two diabody/CysDb pairs examined (anti-CD20, anti-HER2), the cysteine-modified version consistently eluted later on size exclusion chromatography compared to the native diabody (data not shown), consistent with a more closed conformation of the covalent dimer. Elution time by size exclusion appears to be an innate property of each CysDb (Figure 3) and was reproducible among purified batches of the same CysDb. The anti-HER2 CysDb and the anti-CD20 CysDb both have a predicted molecular weight of 50 kDa, although the anti-CD20 CysDb consistently eluted later by size exclusion chromatography (Figure 3). Observed differences in elution times may reflect the sequence difference in the binding sites, as well as the fact that the rituximab framework is murine whereas trastuzumab is humanized. Minor differences in migration were also observed on SDS-PAGE (Figure 2), indicating that mobility was influenced by primary sequence as well as molecular weight.

Reduction of the CysDb disulfide bridges provided a flexible and reproducible approach for site-specific conjugation. Fluorescent dyes spanning a molecular weight range from subkilodalton (A488) to several hundred kilodaltons (PE, APC) were readily coupled to the CD20- and HER2-specific CysDbs to yield six distinct bifunctional conjugates. At the same time, these conjugates retained the ability to bind to antigen, indicating that the internal disulfide bridges in the V regions, characteristic of the conserved immunoglobulin fold, were not disrupted. In addition, spectrophotometric quantitation of the molar conjugation ratio indicated ~2 dye molecules per diabody, consistent with conjugation of fluorophores only onto the two most easily accessible sulfhydryls, at the C-termini.

Fluorescent antibody fragments are regularly used for *in vitro* detection applications and *in vivo* studies in small animals for noninvasive monitoring and radiation-free imaging (*29*). Multichannel flow cytometry experiments in the current work demonstrated antigen-specific binding with the use of a cocktail of fluorescent CysDbs with a spectrum of labels, supporting this format as a robust and easily interchangeable targeting molecule. Increasingly, optically labeled antibody fragments are being used for fluorescence-guided surgery and intraoperative visualization of metastastes (*30*). CysDbs are promising for this application, as their small size should allow them to penetrate a tumor more deeply than a larger, intact antibody. Optical detection and diagnosis using a cocktail of CysDbs recognizing a set of different tumor biomarkers could provide a means for simultaneous evaluation of multiple proteins, subject to the known limitations of detection of visible light in tissues and living organisms.

The CysDb format provides a general approach for combining minimal antibody binding domains with a variety of functional moieties. Previously, the cysteine modification was used for site-specific conjugation of the macrocyclic metal chelator DOTA(1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid), enabling radiolabeling of the anti-CEA CysDb with ^{64}Cu for microPET detection of CEA-expressing LS174T xenografts in mice (*23*). In addition to radiolabeling, site-specific PEGylation

(A) Two representative plots from three-channel experiments demonstrating detection in FL2 of specific binding of PE-conjugated anti-CD20 CysDb with minimal signal in FL1 or FL4 from co-incubated APC- or A488-conjugated anti-HER2 CysDbs, respectively. (B) Bar graph presenting compiled results of all three-channel labeling experiments on Daudi cells, demonstrating consistent, specific detection of all three dye-conjugated anti-CD20 CysDbs and minimal background from nonspecific binding of dye-conjugated anti-HER2 CysDbs. Analogous experiments were performed with dye-conjugated anti-HER2 CysDbs on MCF7-HER2 cells, using dye-conjugated anti-CD20 CysDbs as isotype controls (C,D).

of cysteine-modified scFvs or Dbs has been used to modify the pharmacokinetics of these small antibody formats (*31*). The incremental addition of several kilodaltons of PEG increases serum residence time in a predictable, size-dependent manner (*32*). The ability of the diabodies to accept large payloads is not limited to inert substances such as PEG. Venisnik et al.

fused bioluminescent enzymes to an anti-CEA diabody, demonstrating the ability of the diabody to deliver *Renilla* luciferase and *Gaussia* luciferase to a CEA-expressing tumor *in vivo* (*33, 34*). The success of this fusion protein approach confirms that relatively large functional groups can be linked to the C-termini of diabodies while maintaining binding and targeting capabilities. However, the fusion protein strategy lacks the flexibility of the CysDb approach, as each individual combination requires engineering and expression of a distinct construct.

CysDbs are especially attractive for nanotechnology applications, due to their overall size (diabody dimensions are approximately 5 nm × 7 nm) (*22*), bivalency, and capability for oriented coupling. Nanoparticles such as quantum dots, iron oxide particles, dendrimers, liposomes, and others are emerging as a distinct class of reagents with significant potential for *in vivo* applications (*21, 35, 36*). Several nanoparticles have been developed for use in imaging and therapy, but a general challenge in the field remains the need for targeted *in vivo* delivery (*37*). Oriented conjugation using antigen-specific CysDbs may provide one solution. For example, CysDbs have recently been conjugated to quantum dots, demonstrating specific binding by flow cytomety and confocal microscopy (Barat, B., Sirk, S., et al., submitted). Site-specific thiol coupling of CysDbs to nanoparticles or nanosensor substrates would automatically orient the antigen-binding domains outward to enable interaction with molecules of interest. Furthermore, attachment of CysDbs to nanodevices or nanowires should also shorten the overall interaction distances compared to coupling of intact antibodies (*38, 39*).

These studies show the utility of the CysDb platform as a simple C-terminal modification with the potential to be applied to any existing scFv or diabody. Six fluorescent antibody fragments were produced, demonstrating the versatility and reproducibility of the system. CysDbs are promising as targeting agents for *in vivo* delivery due to their small size and retention of bivalent binding. CysDbs represent a robust and simple method for reliable, site-specific, and oriented conjugation of tumor-targeting proteins to cargo of a range of size and function.

Distinct Uptake Routes of Cell-Penetrating Peptide Conjugates

Per Lundin,[†] Henrik Johansson,[†] Peter Guterstam,[†] Tina Holm,[†] Mats Hansen,[†] Ülo Langel,[†,‡] and Samir EL Andaloussi*[,†,‡]

Department of Neurochemistry, Stockholm University, Sweden, and Laboratory of Molecular Biotechnology, Institute of Technology, Tartu University, Tartu, Estonia. Received May 22, 2008; Revised Manuscript Received October 19, 2008

Cell-penetrating peptides (CPPs) are a growing family of peptides that have opened a new avenue in drug delivery, allowing various hydrophilic macromolecules to enter cells. In accordance with most other cationic delivery vectors, CPPs seem to rely mostly on endocytosis for internalization. However, due to conflicting results the exact endocytic pathways for CPP uptake have not yet been resolved. Here, we evaluated the ability of seven CPPs, with different chemical properties, to convey peptide nucleic acids (PNAs) inside cells. Assays based on both splice correction, generating biologically active read-out, and on traditional fluorescence measurements were utilized. The same assays were employed to assess different endocytic pathways and the dependence on extracellular heparan sulfates for internalization. Both highly cationic CPPs (M918, penetratin, and Tat) and amphipathic peptides (transportan, TP10, MAP, and pVEC) were investigated in this study. Conjugate uptake relied on endocytosis for all seven peptides but splice-correcting activity varied greatly for the investigated CPPs. The exact endocytic internalization routes were evaluated through the use of well-known endocytosis inhibitors and tracers. In summary, the different chemical properties of CPPs have little correlation with their ability to efficiently deliver splice-correcting PNA. However, conjugates of polycationic and amphipathic peptides appear to utilize different internalization routes.

INTRODUCTION

During the past decades, several oligonucleotide (ON)-based methods have been developed with the purpose of manipulating gene expression. So-called antisense strategies, employed to inhibit translation of proteins or to influence splicing patterns, have proven highly potent not only within basic research but also in clinical settings (*1, 2*). However, despite the accumulating knowledge of how to manipulate cellular processes, devising efficient means of delivering these therapeutic agents remains a hurdle.

Cell-penetrating peptides (CPPs) constitute one group of delivery vectors that has gained increasing attention since the initial discovery of penetratin in 1994 (*3*). CPPs have opened a new avenue in drug delivery, allowing the translocation of various cargo molecules into cells (*4*). Even though it is indisputable that CPPs are promising drug delivery candidates, the mechanisms underlying their cellular uptake is a matter of great controversy. Delineating the uptake mechanisms of CPPs is not only important for future development of novel, more efficient peptides but also advantageous in potential clinical trials.

It was previously commonly accepted that internalization did not involve endocytosis, until publications from separate groups revealed that conclusions regarding the translocation could be based on artifacts in the experimental settings (*5, 6*). Although some groups are still reporting on non-endocytic internalization routes for certain peptides, the majority of studies are now emphasizing the importance of endocytosis in the uptake of CPPs (*7*−*9*). For most CPPs evaluated to date, proteoglycans (PGs) on the cell surface seem pivotal for the initial interaction with cells (*8, 10*). Cells lacking heparan sulfate (HS), which is heavily anionic and constitutes parts of the extracellular PGs, display a remarkable decrease in peptide uptake. Despite the consensus that PGs are crucial for cellular uptake and that endocytosis is the main entry mechanism, knowledge regarding this is generally poor and there are conflicting reports of the exact endocytic entry routes.

Most reports evaluating CPP uptake mechanisms have examined the Tat peptide, either per se or conjugated to various cargo molecules (*11, 12*). Usually, internalization mechanisms of CPPs are assessed by using different endocytosis inhibitors that act by selectively blocking specific endocytosis pathways or through the use of fluorescently labeled pathway-specific tracers that are analyzed for colocalization with peptides. Results are divergent, and depending on study, the uptake has been ascribed to classical clathrin-mediated endocytosis (CME) (*11*), lipid raft/caveolae-mediated endocytosis (*12*), macropinocytosis (*13*), or a combination thereof (*9*). The differences in results could in part be explained by the fact that different cargo molecules and treatment concentrations have been used. Furthermore, it is probably a reasonable assumption that different CPPs utilize different mechanisms for translocation into cells. In this study, we utilized three well-known endocytosis inhibitors to distinguish between these pathways. Wortmannin was employed to inhibit both macropinocytosis and CME, whereas cytochalasin D and chlorpromazine inhibit macropinocytosis and CME, respectively.

Fluorophore labels have been used as cargo on a routine basis to allow detection inside cells and to evaluate the CPP internalization mechanisms. Although fluorescence-based methods offer useful information regarding the localization of peptides, there are several concerns hampering their utility. First, different fluorophores can affect the intracellular distribution of peptides differently (*14*). Second, the fluorophore might affect cellular uptake and cytotoxicity of the peptide (*15*). Third, and most importantly, uptake observed with fluorophore-labeled peptides or cargo molecules does not necessarily correlate with

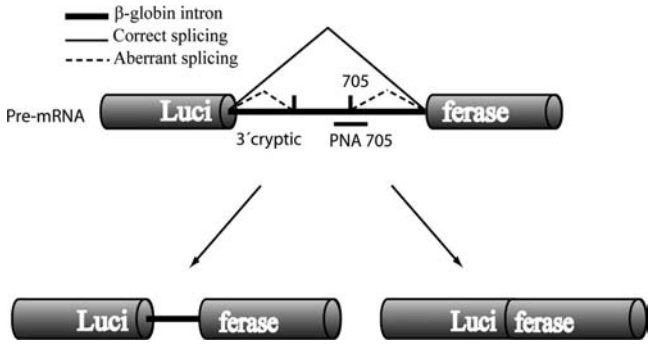

Figure 1. Principle of the splice correction assay. A stably transfected HeLa cell line, HeLa pLuc 705 cells, was used to address nuclear delivery of CPP−PNA conjugates. The cells are stably transfected with a luciferase encoding gene that is interrupted by an insertion of an intron from β-globin pre-mRNA, carrying a cryptic splice site that activates an aberrant splice site, generating nonfunctional luciferase. If the aberrant splice site is masked by PNA, correct splicing is restored and functional luciferase will be produced.

bioavailability of the delivered cargo (*16*). Therefore, it is imperative to complement fluorescence-based methods with functional assays, such as the Cre-recombination assay, which was introduced by Dowdy and colleagues as a screening tool to address nuclear delivery of Tat (*13*). However, Cre-recombinase is a rather large protein (38.5 kDa), which most likely influences the CPP translocation.

In addition to the Cre-recombination assay, a method based on splice correction has emerged to address the ON delivery efficacy of various vectors. This assay is based on a cellular system (HeLa pLuc 705 cells), where a plasmid (pLuc705) carrying the luciferase-coding sequence, interrupted by an insertion of intron 2 from β-globin pre-mRNA, is stably transfected into cells (*17*). The intron contains an aberrant and a cryptic splice site, and, unless the aberrant splice site is masked by an antisense ON, the cryptic splice site will be activated and the pre-mRNA of luciferase will be improperly processed (Figure 1). Various established and new CPPs have been evaluated by measuring luciferase activity after treatment with CPP-delivered ONs targeting this aberrant splice site. This assay has further provided evidence for an endocytic uptake of CPPs, as the lysosomotropic agent chloroquine improves transfections several-fold (*18*−*20*). However, few studies have assessed the endocytic uptake routes in detail by combining a functional assay with the use of endocytosis inhibitors. Furthermore, a parallel study comparing the uptake mechanism of polycationic CPPs and amphipathic CPPs has so far not been conducted.

We recently established a protocol based on splice correction to assess the internalization route of CPPs (*21*). Here, we evaluate the uptake, using that protocol, of polycationic peptides, represented by Tat (*22*), penetratin (*3*), and M918 (*10*), and amphipathic peptides, represented by pVEC (*23*), transportan (*24*), TP10 (*25*), and MAP (*26*), conjugated to a splice-correcting peptide nucleic acid (PNA). Our results suggest that, although most peptides, except M918, are initially dependent on HS on the cell surface for internalization, the subsequent endocytic uptake differ significantly among the peptides. We believe that these data provide new insights into the mechanism of CPP internalization, showing that although the chemical character of CPPs has an impact on the internalization mechanism there is no correlation with the delivery efficacy.

EXPERIMENTAL PROCEDURES

Synthesis of Peptides, PNA, and Conjugates. The peptides Tat, penetratin, TP10, transportan, M918, MAP, and pVEC, and the peptide nucleic acids 705 PNA and inverted 705 PNA were synthesized on Applied Biosystems' stepwise synthesizer model 433A. Both peptides and PNAs were assembled by *t*-Boc chemistry using a 4-methylbenzhydrylamine (MBHA) polystyrene resin generating amidated C-termini. Amino acids were coupled as hydroxybenzotriazole (HOBt) esters, while PNA was coupled with 2-(7-aza-1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU). Cys(Npys) was coupled N-terminally to all peptides, except TP and TP10 where it was coupled to the ε-amino group of Lys^{13} and Lys^{7}, respectively (resulting in branched conformations of these two conjugates). PNA used for uptake studies was labeled with carboxyfluorescein at the ε-amino group of the C-terminal lysine using 5 equiv 5,6-carboxyflorescein, 5 equiv diisopropylcarbodiimide (DIC), 5 equiv HOBt, and 20 equiv diisopropylethylamine (DIEA) dissolved in dimethylsulfoxide/dimethylformamide (DMSO/DMF) 1:1 overnight. After cleavage of peptides and PNAs from the resin using anhydrous hydrogen fluoride (HF), synthesis products were purified by reverse-phase HPLC Supelco C_{18} column and analyzed using Perkin-Elmer prOTOF 2000 MALDI O-TOF mass spectrometer. Conjugation of peptides with 3-nitro-2-pyridinesulphenyl (Npys) to cysteine-coupled PNA via a disulfide bridge was performed overnight in 20% acetonitrile/water containing 0.1% TFA and separated by reverse-phase HPLC. The sequences of the peptides and PNAs are presented in Table 1.

Cell Culture. HeLa pLuc 705 cells, kindly provided by R. Kole and B. Lebleu, were grown at 37 °C, 5% CO_2 in Dulbecco's Modified Eagle's Media (DMEM) with Glutamax supplemented with 0.1 mM nonessential amino acids, 1.0 mM sodium pyruvate, 10% FBS, 100 U/mL penicillin, and 100 mg/mL streptomycin.

Splice Correction Assay. 120 000 or 60 000 cells were seeded 24 h prior to experiments in 24-well or 48-well plates, respectively. Cells were treated for 1 or 4 h in 300 or 150 μL serum-free media including different conjugate concentrations after which the media was replaced with full growth media for an additional 16 h. Thereafter, cells were washed twice with Hepes Krebs Ringer (HKR) buffer, treated with trypsin, and lysed using 100 μL 0.1% Triton X100 in HKR for 15 min at room temperature. Luciferase activity was measured on Flexstation II (Molecular Devices, USA) using Promega luciferase assay system (Promega, Sweden). RLU values were normalized to protein content, and results are displayed as either RLU/mg or fold increase compared to untreated cells or, when inhibitors have been used, as % of splicing compared to conjugate-treated cells. In experiments where general endocytosis was inhibited, cells and solutions were premaintained at 4 °C for 30 min prior to being exposed to conjugates for 1 h at 4 °C. Thereafter, the media was replaced with full growth media, and the cells were transferred back to 37 °C for an additional 16 h.

In experiments with endocytosis inhibitors, cells were pretreated for 30 min prior to addition of 2 or 5 μM conjugates for 1 h. Thereafter, media was replaced and cells were allowed to grow for additionally 16 h in full growth media. Chloroquine is a weak base that buffers the endosomes. Consequently, the fusion with lysosomes is delayed, which provides longer time for endosomal escape, but chloroquine might even destabilize the membrane itself. Hence, this agent is used to promote endosomal escape. Cytochalasin D is an inhibitor of macropinocytosis as it inhibits F-actin elongation. Wortmannin is an inhibitor of phosphatidylinositol 3-kinase (PI3K) and is believed to inhibit both macropinocytosis and CME. Finally, chlorpromazine is an inhibitor of CME, as it disrupts the assembly of adaptor protein 2 and clathrin, which is pivotal for the formation of clathrin-coated vesicles.

[a] Bold letters represent nucleobases. The four underlined bases indicate the inverted sequence within PNA. For building of conjugates, all peptides were synthesized with N-terminal Cys(Npys) except for TP and TP10. [b] Attachment of Cys(Npys) on the ε-amino group of lysine in TP and TP10 (Lys^{13} and Lys^{7}, respectively), resulting in branched conformations. [c] Attachment of carboxyfluorescein on the ε-amino group of the C-terminal lysine on PNA. Conjugates are denoted CPP-PNA and can be illustrated as follows: CPP-Cys-S-S-Cys-**PNA**. Amphipathic moment was calculated (theoretically) in WinPep (*41*).

Quantitative Uptake. For correlation between uptake and splicing efficiency, cells were treated as previously described using fluoresceinyl conjugates (*21*). In experiments analyzing the impact on endocytosis induction following peptide treatments, cells were treated for 1 h with 5 μM unlabeled peptides. Thereafter, media was replaced and incubated with labeled markers for an additional hour. 5 μM FITC-dextran or 25 μg/mL FITC transferrin was used in order to assess the contribution of macropinocytosis and CME, respectively. After treatments, cells were washed twice in HKR before 5 min of trypsination. Cells were centrifuged at 1000 *g* for 5 min at 4 °C, and cell pellets were lysed with 0.1% Triton in HKR. Luminescence and fluorescence measurements were made on the very same cell lysate. Fluorescence was measured at $494_{ex}/518_{em}$ nm on a Spectra Max Gemini XS fluorometer (Molecular Devices, USA) and recalculated to the amount of internalized CPP−PNA conjugate, by using the linearity of fluorescein, and normalized to amount of protein (Lowry BioRad, USA). Fluoresceinyl-labeled conjugates displayed linear correlation between concentration and fluorescence.

Analysis of Luciferase pre-mRNA. Cells were grown and treated with conjugates overnight, lysed with TRIzol (Invitrogen, Stockholm, Sweden), and total cellular RNA extracted according to the manufacturer's protocol. RNA from two wells were pooled and treated with Avian Myeloblastosis Virus reverse transcriptase (Fermentas, Helsingborg, Sweden) according to the manufacturer's protocol. PCR was performed with Taq DNA polymerase, dNTP, forward primer (5′-TTG ATA TGT GGA TTT CGA GTC GTC-3′) and reverse primer (5′-TGT CAA TCA GAG TGC TTT TGG CG-3′). Cycles of PCR proceeded at 94 °C for 30 s, 55 °C for 30 s, and 72 °C for 30 s, for a total of 30 cycles. The PCR products were separated on a 1.7% agarose gel with ethidium bromide at 100 V for 45 min and identified by comparison with bands from 1 kbp DNA ladder. Electrophoresis bands on the agarose gel were visualized by UV light in a Molecular Imager Gel Doc system (Bio-Rad Laboratories, Sundbyberg, Sweden). Bands from the PCR products correspond to the aberrant (268 nucleotides) and the correct (142 nucleotides) mRNA, respectively. The proportion of band intensity was calculated densitometrically with *ImageJ* software (http:/rsb.info.nih.gov/ij/).

Lactate Dehydrogenase (LDH) Leakage. Membrane integrity was assessed using the Promega Cytox-ONE assay. In brief, 10 000 HeLa pLuc 705 cells were seeded in 96-well plates two days before treatment with conjugates in serum-free DMEM. After 1 h, media was transferred to a black fluorescence plate and incubated for 10 min with CytoTox-ONE reagent followed by stop solution. Fluorescence was measured at 560/590 nm.

Wst-1 Assay. In order to determine potential conjugate toxicity, cell proliferation was assessed using the colorimetric Wst-1 assay. The assay measures mitochondrial dehydrogenase activity and is commonly used for evaluating cell viability. HeLa pLuc 705 cells were seeded onto 96-well plates, 10 000 cells/well, two days before treatment. Cells were treated with conjugates in 100 μL serum free DMEM for 24 h and finally exposed to Wst-1, according to the manufacturer's protocol (Sigma, Sweden). Absorbance was measured at 450/690 nm. Untreated cells were defined as 100% viable.

RESULTS

CPP−PNA Conjugates Induce Splice Correction Dose-Dependently with Varying Efficacy. As previously mentioned, all CPPs included in this work have previously been utilized for delivery of various cargo (Table 1). In order to establish whether the conjugates could be used for further mechanistic evaluation, we assessed the acute cytotoxicity, by measuring lactate dehydrogenase (LDH) leakage, and then long-term toxicity by measuring mitochondrial metabolic activity. None of the bioactive conjugates displayed any significant toxicity at 10 μM treatment concentration (Supporting Information). Next, in order to obtain information on the uptake mechanisms of conjugates carrying functional cargo, the splice correction assay (described in Figure 1) was utilized. Thus, the different CPPs were conjugated to splice-correcting PNA and evaluated for their ability to correct aberrantly spliced luciferase pre-mRNA (Figure 2). M918 was the most potent peptide followed by TP10, transportan, and penetratin. The most amphipathic peptide, MAP, with an amphipathic moment of 0.16, according to WinPep (Table 1), was equally or less potent than the polycationic Tat in delivering splice-correcting PNA (Figure 2). pVEC was unable to promote any significant splice correction when conjugated to PNA (Figure 2), despite the high quantitative uptake observed with fluorometry (Figure 4B). This clearly illustrates the necessity of using a functional assay over fluorescence-based methods to determine the delivery efficacy of CPPs. It should, however, be emphasized that a quantitative uptake assay could be useful as an initial screen as some peptides, such as TP10 conjugated to PNA, display a correlation between uptake and splice correction (Figure 4A).

Although luminescence measurements allow for comparisons between different peptide conjugates, it is vital to verify the specificity of the splice correction assay. By using RT-PCR, a confirmation can be obtained regarding the production of luciferase as a result of specific PNA-mediated splice correction. As expected, the positive control TP-PNA restored the correct splicing pattern, whereas no splice correction was detected with the negative control, a conjugate of TP and a PNA with 4 bases inverted in the sequence (Figure 3). Consequently, the RT-PCR corroborates the results obtained from the luciferase assay, showing that the splice correction is a result of a switch in pre-mRNA splicing.

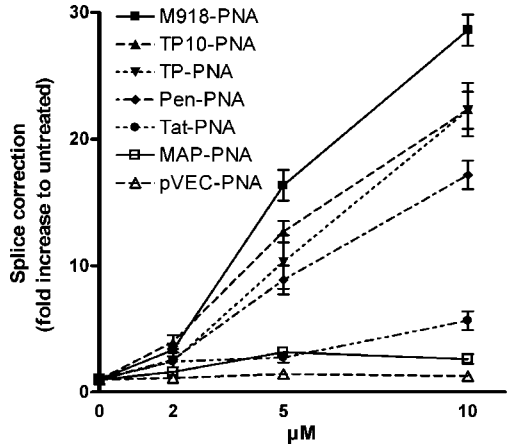

Figure 2. Splice correction by CPP−PNA conjugates. M918, TP10, transportan, and Pen conjugates efficiently corrected splicing while MAP and Tat conjugates displayed minor effects. pVEC conjugate was unable to induce splice correction. HeLa pLuc 705 cells were incubated with indicated conjugates for 4 h in serum-free media followed by exchange to full growth media for an additional 16 h. Cells were lysed and luminescence was normalized to the amount of protein. The values represent the mean of at least three independent experiments done in triplicate (mean ± SEM, $n = 3$).

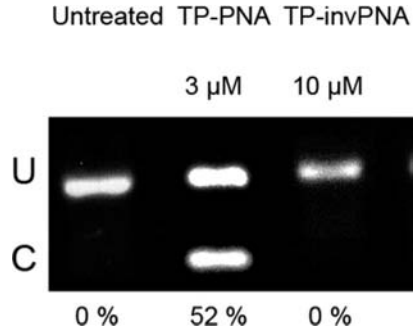

Figure 3. RT-PCR on cells treated with CPP−PNA conjugates. The positive control 3 μM TP-PNA had significant splice-correcting effect on luciferase pre-mRNA, whereas the negative control TP-invPNA (4 bases inverted in the PNA) induced no splice correction even at 10 μM. Upper and lower bands represent RT-PCR products of uncorrected (U) and corrected (C) mRNA, respectively. Cells were treated with conjugates overnight, lysed with TRIzol, total RNA was extracted, converted to cDNA, amplified by PCR, and analyzed on an agarose gel. This gel corresponds to one representative experiment.

Importance of HS for Internalization of Conjugates. HS has in numerous studies been suggested to be an essential cell surface component for internalization of CPPs (*8, 10, 11*). HS involvement is usually assessed by using HS-deficient CHO cells or by co-adding heparin with CPPs for competition analysis. Another approach has been to pretreat cells with heparinase III, which selectively removes HS from PGs, before treatment with CPPs. Again, most results on HS dependence derive from experiments utilizing fluorophore-labeled peptides or peptides conjugated to labeled proteins. Therefore, the splice correction assay was used to address this issue. Prior to exposing cells to CPP−PNA conjugates, cells were treated for 30 min with 1 U/mL of heparinase III in order to remove HS from the cell surface. After 1 h treatment with conjugates, cells were allowed to grow for 16 h prior to analysis. Tat, MAP, and pVEC conjugated to PNA were omitted in these experiments due to the low levels of splice correction observed at 5 μM concentrations. As can be seen in Figure 5, all conjugates, except M918-PNA, were highly dependent on HS for subsequent internalization of bioactive PNA. Intriguingly, after HS removal, the splice correction mediated by M918-PNA was instead significantly enhanced, suggesting that this particular peptide is using another surface component for initial adherence to cells. Overall, there seems to be no correlation between peptide amphipathicity and dependence on HS since the other three peptides rely, at least partially, on HS for internalization.

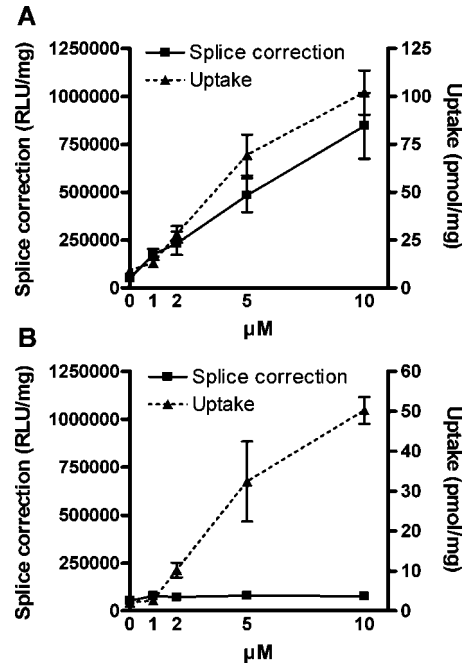

Figure 4. Measurements of CPP−PNA conjugate uptake and splice correction in the same cell lysate. Fluoresceinyl-labeled TP10-PNA (A) displayed a direct correlation between uptake and splice correction, while fluoresceinyl labeled pVEC-PNA (B) displayed concentration-dependent uptake but no correct splicing. Cells were treated as in Figure 2 but removed by trypsination and washed before lysing. In addition to luminescence, fluorescence was measured in the same lysate, recalculated to the number of moles internalized by using the linearity of fluorescein, and normalized to pmol/mg protein. The values represent the mean of three independent experiments done in triplicate (mean ± SEM, $n = 3$).

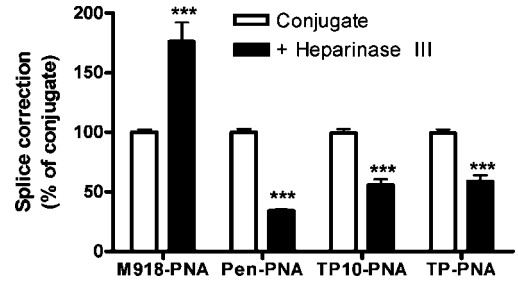

Figure 5. Removal of HS affects CPP−PNA mediated splice correction. CPP−PNA conjugates (5 μM) of Pen, TP10, and TP displayed a significant decrease in splice correction after removal of HS with heparinase III. In contrast, M918-PNA displayed a significant increase in splicing after HS removal. HS were removed by heparinase III (1 U/mL) treatment for 30 min before addition of conjugates, followed by the same procedure as in Figure 2, with the difference that cells were treated for 1 h with conjugates. The values represent the mean of at least three independent experiments done in duplicate (mean ± SEM, $n = 3$). *** $P < 0.001$ (ANOVA Dunnett's).

CPP−PNA Conjugates Are Internalized via Endocytosis. After concluding that HS is a prerequisite for subsequent internalization of most CPP−PNA conjugates, we wanted to confirm the suggested involvement of endocytosis in translocation of CPPs. This was evaluated by premaintaining cells at 4 °C, to inhibit the endocytic machinery, or by pretreating cells with 75 μM chloroquine, to increase release of material from endosomes. As anticipated, chloroquine significantly improved

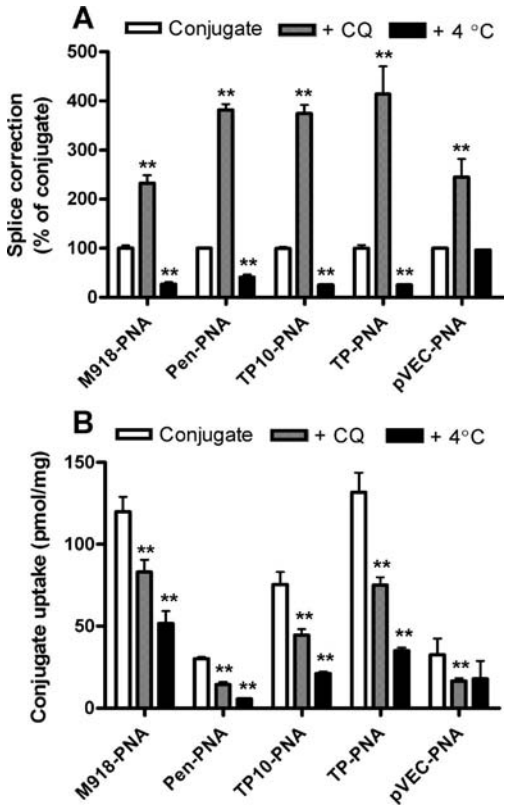

Figure 6. Inhibition of endocytosis and potentiation of endosomal release alter conjugate mediated splicing. Co-incubation of CPP−PNA conjugates (5 μM) with the lysosomotrophic agent chloroquine (75 μM) significantly increased splice correction, while treatment of cells with conjugates at 4 °C significantly decreased splice correction (A). The quantitative uptake decreased significantly for all conjugates after treatment with chloroquine and at 4 °C (B). Experiments were carried out essentially as in Figure 5. The values represent the mean of at least three independent experiments done in triplicate (mean ± SEM, n = 3). ** P < 0.01 (ANOVA Dunnett's).

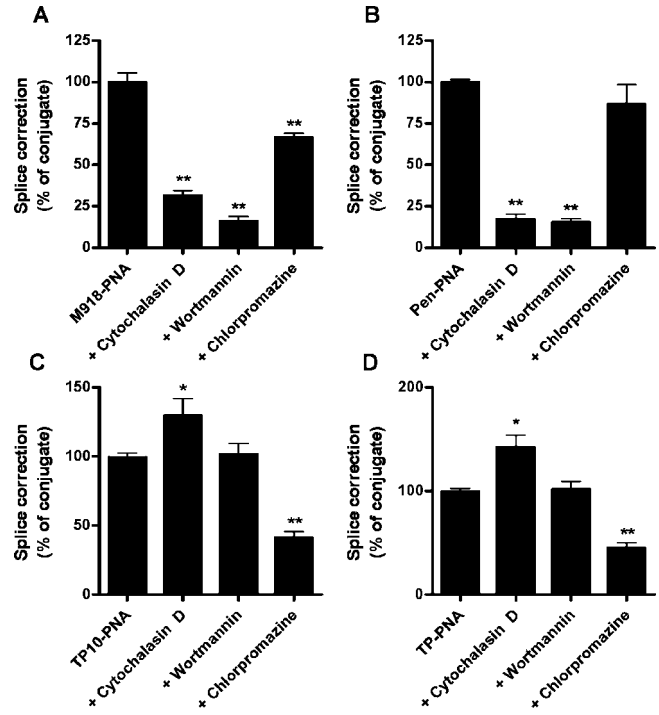

Figure 7. Different endocytic routes depending on CPPs. Cytochalasin D (4 μM) and wortmannin (50 nM) decreased M918-PNA (A) and Pen-PNA (B) splicing, while no effect or increase was observed for TP10-PNA (C) and TP-PNA (D). However, TP10-PNA (C) and TP-PNA (D) splicing was decreased by chlorpromazine (10 μM), which also had a slight inhibitory effect on M918-PNA (A). These results suggest that cationic CPPs exploit macropinocytosis while amphipathic peptides utilize CME for internalization into cells. Cells were pretreated with indicated endocytosis inhibitor for 30 min followed by cotreatment with conjugates (5 μM) for 1 h. Thereafter, the same procedure as in Figure 2 was performed. The values represent the mean of three independent experiments done in triplicate (mean ± SEM, n = 3). * P < 0.05. ** P < 0.01 (ANOVA Dunnett's).

conjugate-mediated splice correction (Figure 6A) while decreasing the quantitative uptake (Figure 6B), which is expected considering that chloroquine also slows down the endocytic machinery (*27*). These experiments were carried out with the conjugates of M918, TP10, transportan, and penetratin, but not with the less potent conjugates of Tat and MAP, as the splice correction values were close to background. pVEC-PNA was included in these experiments in order to illustrate the effects of chloroquine on quantitative uptake and splice correction. For the evaluated peptide conjugates, splicing was reduced significantly at 4 °C, reaching inhibitions up to 75% (Figure 6A). Also, the cellular uptake was decreased significantly at this temperature (Figure 6B). The same results were obtained when performing treatments with 2 μM conjugate concentration (data not shown). Taken together, these results suggest that all peptides rely on endocytosis when conjugated to splice-correcting PNA.

Endocytic Uptake Route Varies Depending on CPP Conjugate. Several previous studies have excellently addressed the endocytic uptake route and intracellular fate of fluorophore-labeled CPPs (*7*−*9*, *11*, *12*). However, in most studies only one or a few CPPs have been evaluated and compared in the same setup. We sought to investigate whether different CPPs utilize different entry routes using the functional splice correction assay. Since most reports to date have indicated that CME or macropinocytosis are the most commonly exploited endocytic pathways by which CPPs enter cells, the endocytosis inhibitors wortmannin (50 nM), cytochalasin D (4 μM), and chlorpromazine (10 μM), were employed to distinguish between these pathways. Cells were treated as previously described with chloroquine, and luciferase expression was assessed. In conjunction with results from Dowdy and co-workers on free Tat peptide and Tat-CRE fusions, splice correction with the polycationic CPPs penetratin and M918 conjugated to PNA was significantly inhibited by the presence of the macropinocytosis inhibitors wortmannin and cytochalasin D (*13*) (Figure 7A,B). In the case of penetratin, the uptake seems to be primarily mediated by macropinocytosis, as the CME inhibitor chlorpromazine was unable to significantly affect splice correction (Figure 7B). Similar results were obtained with the Tat−PNA conjugate, but the RLU values were overall too low for statistical analysis and therefore not further analyzed. M918-PNA-mediated splicing was, however, also significantly reduced with chlorpromazine although not to the same extent, suggesting a slight contribution of CME (Figure 7A). When using the TP10-PNA and TP-PNA conjugates, the opposite effect was observed with the inhibitors: while chlorpromazine significantly reduced splicing, wortmannin had negligible effects on splice correction (Figure 7C,D). In fact, cytochalasin D even increased the transportan splicing significantly. Collectively, these results suggest that cationic peptides conjugated to PNA primarily rely on macropinocytosis for internalization, whereas CME appears to be the pathway employed by amphipathic peptides.

CPPs Promote Cellular Uptake of Endocytic Markers. As conjugation of penetratin and M918 with PNA was strongly inhibited by macropinocytosis inhibitors, we wanted to elucidate whether free peptides could stimulate macropinocytic activity. This was assessed by measuring uptake of the fluid-phase marker

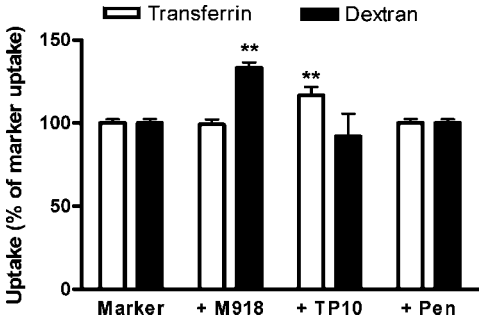

Figure 8. CPPs stimulate endocytic activity. Pretreatment of cells with M918 increased uptake of dextran, while TP10 pretreatment increased transferrin uptake. Cells were pretreated for 1 h with 5 μM peptide after which media was changed to media containing fluoresceinyl-labeled 42 kDa dextran or transferrin for one additional hour. Then, cells were washed, trypsinized, and lysed. Fluorescence was normalized to milligrams protein and expressed as % uptake without peptide preincubation. The values represent the mean of three independent experiments done in triplicate (mean $\pm$ SEM, $n = 3$). ** $P < 0.01$ (ANOVA Dunnett's).

FITC-dextran after 1 h pulsing of cells with 5 μM CPPs. While penetratin was unable to stimulate dextran uptake, M918 significantly promoted cellular internalization of the marker (Figure 8). However, somewhat in disagreement with Figure 7A, M918 had no effect on FITC-labeled transferrin internalization, suggesting that the peptide is not as intimately involved in CME (Figure 8). TP10, on the contrary, significantly stimulated CME, interpreted from the increased FITC-transferrin uptake, without affecting the dextran internalization (Figure 8). These results further support the involvement of CME in the uptake of TP10-PNA, and they are in agreement with previously reported colocalization of fluoresceinyl-labeled TP10 with rhodamine-labeled transferrin (*28*) and partial colocalization of M918 with both markers (*10*).

DISCUSSION

As ON-based approaches for regulation of gene function have gained increasing attention (since the intriguing discovery of splice correcting antisense ONs and siRNAs), so has the search for efficient means of delivery. Several potential therapeutics have entered clinical trials utilizing these effector molecules, but their utility is often restricted due to low bioavailability. CPPs have opened a new avenue in drug delivery, allowing the translocation of peptides, proteins, ONs, plasmids, and nanoparticles into cells both *in vitro* and *in vivo* (*29*). Albeit CPPs can offer an efficient and often nontoxic way of transporting ONs inside cells, their translocation mechanisms have so far not been fully resolved, which would be beneficial for future clinical applications.

It has become increasingly clear that the uptake of CPPs involve endocytosis, at least partially. However, endocytosis is a very wide term, involving several different processes with distinct intracellular fates. In CME, for instance, internalized compounds are often targeted to degradative compartments inside the cells (i.e., lysosomes) (*30*), while in macropinocytosis, and caveolae endocytosis for the most part, compounds bypass the lysosomal pathway (*31*, *32*). Thus, these differences could have a major impact on the intracellular destiny of the internalized compounds. As previously mentioned, most reports to date on CPP uptake mechanisms have been conducted utilizing fluoresceinyl-CPPs, a methodology associated with several drawbacks. Therefore, functional assays are highly desirable, preferably based on positive rather than negative readouts to avoid influence by toxic side effects on cells. The splice correction assay not only provides a positive readout, but also information regarding localization of the delivered cargo, as splicing occurs in the nucleolus of cells. Consequently, we decided to use this previously described assay, with PNA as the bioactive oligonucleotide cargo. The reason for selecting PNA as the functional cargo in these experiments was partially that its synthesis is compatible with classical peptide synthesis. Furthermore, its uncharged backbone alleviates some of the problems associated with RNA and negatively charged analogues, namely, nonspecific electrostatic interactions with CPPs, generating aggregates (*33*). In order for the PNA to be released in the cytoplasm inside cells, a cleavable disulfide bond (*34*) was chosen as a linker between the CPPs and the PNA.

The seven different CPP−PNA conjugates included in this work could be divided into two groups based on the chemical properties of the CPP; one polycationic and one amphipathic group. The amphipathic moments, calculated in WinPep, are given in Table 1. M918, penetratin, and Tat constitute the polycationic group of peptides, with high arginine contents and lower amphipathic moment. pVEC, transportan, TP10, and MAP all have a higher amphipathic moment with sequences more rich in lysines. The PNA was coupled N-terminally to all the peptides, except to TP and TP10 where the PNA was linked to the ε-amino group of the side chains of Lys^{13} and Lys^{7}, respectively. One hypothesis, which is at least partially supported by the results in this paper, was that the mechanism could differ depending on the amphipathicity and the polycationic nature of the peptides.

First, the CPPs were evaluated with regard to their ability to convey splice-correcting PNA inside cells and promote splice correction. As expected, and in accordance with previously reported results, M918, transportan, TP10, and penetratin conjugated to PNA all promoted significant splice correction (Figure 2), whereas neither of the amphipathic peptides MAP nor pVEC conjugated to PNA had any significant splice-correcting ability (Figure 2). This is rather surprising given that both peptides have been used previously for transportation of antisense PNA and cytostatic agents, respectively (*35*, *36*), but it highlights the decisive advantage of the splice correction assay over, e.g., fluorescence-based methods. This is well-illustrated by Figure 4B, where a dose-dependent increase in quantitative uptake of pVEC-PNA was observed but no splice correction. These discrepancies might be an implication of conjugates being retained in endosomes, trapped in the cell membrane, or aggregated on the cell surface, thus producing fluorescence signals but no biological response. Furthermore, one cannot exclude the possibility that the PNA resides in the cytoplasm without reaching the nucleus, although this is unlikely considering that the oligonucleotides delivered using the other peptides seemingly are delivered to the correct cellular compartment.

To verify that the increased production of luciferase emanated from a switch in splicing at the pre-mRNA level, RT-PCR was performed. The positive control 3 μM TP-PNA promoted a significant splice correction, whereas the negative control (10 μM TP-invPNA) had no effect on the splicing pattern (Figure 3). Furthermore, the RT-PCR confirmed the observed impotence of the pVEC−PNA conjugate (data not shown). In conclusion, this assay provided the expected verification of the specificity of the splice correction assay and assisted in excluding the possibility of the occurrence of other cellular events influencing the splicing pattern.

From the splice correction results, it seems that neither the amphipathic moment nor the length of the peptides is the determinant behind high delivery efficacy. Among the four potent peptides, two are amphipathic while two are highly cationic with low amphipathicity. Also, the number of amino acids varies substantially, with penetratin being 16 and transportan 27 residues in length. The four peptides were employed

to investigate the suggested role of HS for internalization of CPPs. In agreement with the common view that HS is a prerequisite for subsequent uptake of CPPs, splicing mediated by TP10, transportan, and penetratin conjugated to PNA was significantly decreased following treatment of cells with heparinase III (Figure 5). Surprisingly, splicing mediated by M918-PNA was instead increased with approximately 90% following HS removal, suggesting another mechanism for initial adherence to cells (Figure 5). A plausible explanation could be that HS prevents M918, through electrostatic interactions, from interacting with its yet unknown target receptor, and after removal of HS, this receptor becomes accessible. These results are in disagreement with the previously reported decrease in uptake of fluoresceinyl M918 in GAG deficient CHO cells, further underscoring the importance of a functional assay (*10*).

The postulated involvement of endocytosis in the uptake of CPPs was confirmed for all tested conjugates (5 μM) since chloroquine improved while 4 °C treatments decreased splice correction significantly (Figure 6A). Interestingly, chloroquine did not have such a pronounced effect on M918-PNA-mediated splicing as on the other conjugates, suggesting that M918 is more effective in escaping the endosomal compartment. The effects seen when treating the cells at 4 °C most likely derive from the experimental setup, as conjugates that potentially remain attached to the cell surface are internalized when the temperature is increased for the additional 16 h incubation. Collectively, these results are in line with previously published results from other groups using other CPPs in the same splice correction assay (*19, 20, 37*).

Albeit several groups have proven endocytic involvement in the uptake of splice-correcting ON-conjugates (*18*−*20*), no study has so far deduced the exact mechanism for entirely different CPP conjugates. In conjunction with previous reports from our group, penetratin appears to almost completely rely on macropinocytosis for internalization (*38*) (Figure 7B). The transportans have recently been reported to utilize a combination of macropinocytosis and CME for internalization, when conjugated to avidin (*39*). However, for translocation of PNA, our results suggest that the transportans exclusively make use of CME, due to the significantly repressed splice correction induced by chlorpromazine treatment (Figure 7C,D). Additionally, TP10 significantly stimulates uptake of transferrin without affecting dextran uptake, further supporting a role of CME (Figure 8). Interestingly, when using the macropinocytosis inhibitor cytochalasin D, a slight but significant increase in splice correction was observed for the transportans. A potential explanation for this could be that the silencing of one pathway (i.e., macropinocytosis) stimulates another endocytic route (i.e., CME), as suggested in ref *40*. Thus, it seems as if amphipathic peptides, such as transportans, and polycationic peptides, like penetratin, exploit different endocytic routes for entry inside cells. Making the picture somewhat more complex, M918-PNA appears to behave analogously to penetratin since both wortmannin and cytochalasin D drastically inhibit splice correction (Figure 7A). However, chlorpromazine also inhibits splicing, although not to the same extent as the other inhibitors, indicating a small contribution of CME. The CME component might on the other hand be questioned, since M918 stimulates dextran uptake but not transferrin uptake (Figure 8). Therefore, we believe that the main entry mechanism of M918 should be ascribed macropinocytosis.

Our results collectively suggest that the amphipathic nature and length of CPPs have little correlation with the ability to convey bioactive PNAs inside cells. However, the amphipathicity seems to affect the uptake route of CPPs; the amphipathic transportans utilize CME, while the cationic peptides penetratin and M918 primarily exploit macropinocytosis for cellular entrance. M918 appears to be unique not only with regard to its superior delivery properties, but also in that the peptide does not need HS for internalization to cells. It is important to clarify that the suggested uptake mechanisms hold for CPP−PNA conjugates but not necessarily for free peptides. However, considering the advantage of using a functional assay over fluorophore moieties and not using, for instance, the large Cre-recombinase as a cargo, but instead a rather inert PNA, we believe that the results from this study are particularly reliable. Finally, since the highest vector potential of CPPs lies within ON-delivery, these results should be the most clinically relevant.

ACKNOWLEDGMENT

The authors would like to thank R. Kole and B. Lebleu for kindly providing the HeLa pLuc 705 cells. This work was supported by the Swedish Science Foundation (VR-NT and VR-MED), VINNOVA, Center for Biomembrane Research, Stockholm University, and Knut and Alice Wallenberg Foundation.

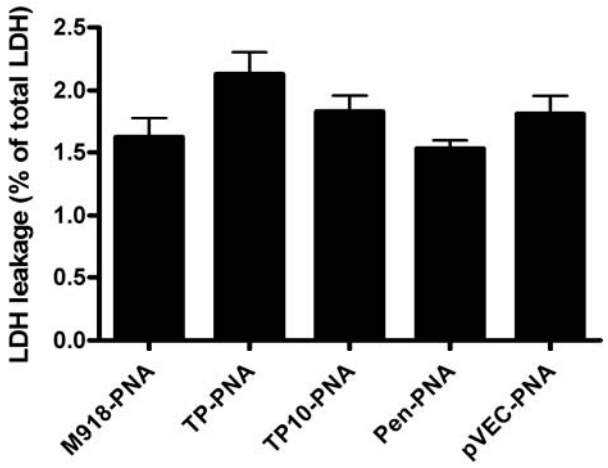

Figure 1. No transient toxicity was detected at 10 µM conjugate concentration
Membrane integrity was measured using the Promega Cytox-ONE^{TM} assay. 10 000 HeLa pLuc 705 cells were seeded in 96-well plates two days before treatment with conjugates (10 µM) in serum free DMEM. After 1 h, media was transferred to a black fluorescence plate and incubated for 10 min with CytoTox-ONE^{TM} reagent followed by stop solution. Fluorescence was measured at 560/590 nm. Neither one of the conjugates exerted any substantial toxic effect on the cells.

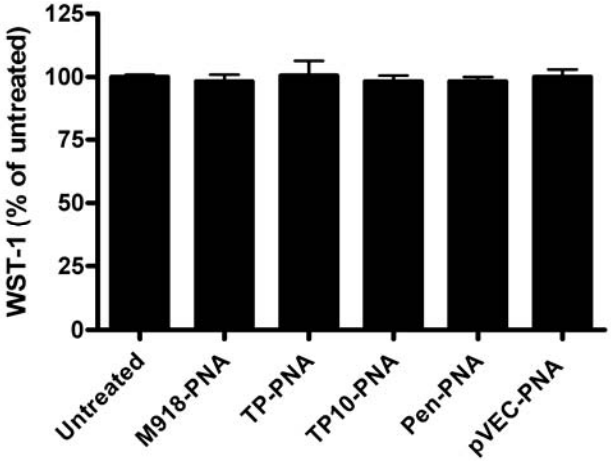

Figure 2. Cell viability was not significantly affected by 10 µM conjugate concentration
HeLa pLuc 705 cells were seeded onto 96-well plates, 10 000 cells/well, two days before the treatment. Cells were treated with conjugates in 100 µl serum free DMEM for 24 h and finally exposed to Wst-1. Absorbance was measured at 450/690nm. Untreated cells were defined as 100% viable. The cell proliferation was not significantly affected by any of the CPP-PNA conjugates.

Rapid Oxime and Hydrazone Ligations with Aromatic Aldehydes for Biomolecular Labeling

Anouk Dirksen and Philip E. Dawson*

Departments of Cell Biology and Chemistry, Skaggs Institute for Chemical Biology, The Scripps Research Institute, 10550 N. Torrey Pines Road, La Jolla, California 92037. Received July 21, 2008; Revised Manuscript Received September 29, 2008

A high-yielding and rapid chemoselective ligation approach is presented that uses aniline catalysis to activate aromatic aldehydes toward two amine nucleophiles, namely, 6-hydrazinopyridyl and aminooxyacetyl groups. The rates of these ligations are resolved for model reactions with unprotected peptides. The resulting hydrazone and oxime conjugates are attained under ambient conditions with rate constants of 10^1-10^3 M^{-1} s^{-1}. These rate constants exceed those of current chemoselective ligation chemistries and enable efficient labeling of peptides and proteins at low μM concentrations, at neutral pH, without using a large excess of one of the components. The utility of the approach is demonstrated by the *p*-fluorobenzylation of human serum albumin and by the fluorescent labeling of an unprotected peptide with Alexa Fluor 488.

INTRODUCTION

Chemoselective ligation chemistries facilitate the site-specific modification and assembly of biomolecules (*1*−*3*). However, the growing demands of research in diverse areas of chemical biology have pushed the limits of current ligation methods, especially in terms of ligation kinetics (*3*). Since biomolecules are often present at low concentrations, their efficient labeling depends on the reaction rate of the ligation chemistry used. The reaction rate constants of current chemoselective ligation chemistries typically range from 10^{-3} to 10^0 M^{-1} s^{-1} under ambient conditions (*3*−*12*). As a result, high concentrations, a large excess of one of the reactants, or elevated temperatures are typically used to compensate for the slow reaction kinetics.

Imine ligations have found significant utility in biomolecular labeling (*13*−*25*). The reaction between an amine and a carbonyl is highly chemoselective and is compatible with other functional groups present in biomolecules. The resulting imine bond is covalent but reversible, and both its stability and dynamics strongly depend on the nature of the amine and the carbonyl. In general, aldehydes are substantially more reactive than ketones, mainly due to steric effects (*26*). Under aqueous conditions, α-effect amines (hydrazines and aminooxy groups) react to form hydrazones and oximes (*11*−*25*). The equilibrium constant (K_{eq}), the ratio between the rate constant of formation k_1 and the rate constant of hydrolysis k_{-1}, is typically in the range 10^4-10^6 M^{-1} for hydrazone linkages and $>10^8$ M^{-1} for oxime bonds. The importance of K_{eq} comes to light when imine ligations are performed at low concentration (low μM range) or when a bioconjugation product is stored at sub-μM concentration. When the K_{eq} is relatively small, as is the case for many hydrazone linkages, the ligation reaction will not go to completion (100% product). Similarly, if a ligation product is stored under too dilute conditions, the system will eventually re-equilibrate and the conjugate will partially dissociate again.

Inspired by the early work of Cordes and Jencks (*27, 28*),we recently reported aniline as a potent nucleophilic catalyst for imine ligation and transimination (*11, 12*). These studies focused on the commonly used glyoxylyl group as the electrophile, and aniline catalysis enhanced the rates of these slow reactions to rates comparable to those of other widely used chemoselective ligation chemistries, including the Staudinger ligation (*4*−*6*), the Cu(I)-catalyzed [3 + 2] azide-alkyne cycloaddition (*7, 8, 29*), the Cu(I)-free click chemistry (*9*), and native chemical ligation (*2, 10, 30*). However, these reactions ($10^{-3}-10^0$ $M^{-1}s^{-1}$) are many orders of magnitude slower than enzymatic labeling methods (*31*), such as the HaloTag technology ($\sim10^6$ M^{-1} s^{-1}) (*32*), noncovalent binding events such as protein−protein interactions ($\sim10^5$ M^{-1} s^{-1}) (*33*) or the biotin−streptavidin interaction ($\sim10^6$ M^{-1} s^{-1}) (*34*). The current limitations are illustrated in Figure 1, which shows simulated second-order reactions at 100 μM reactants. Even with a rate constant of 1 M^{-1} s^{-1}, one needs over 1 day to achieve >90% conversion. As a result, efficient ligation requires the use of higher concentrations, a large excess of one of the reactants, or elevated temperatures. This analysis suggests that, for rapid ligation at 100 μM of each reactant, reaction rate constants of greater than 10 M^{-1} s^{-1} need to be achieved.

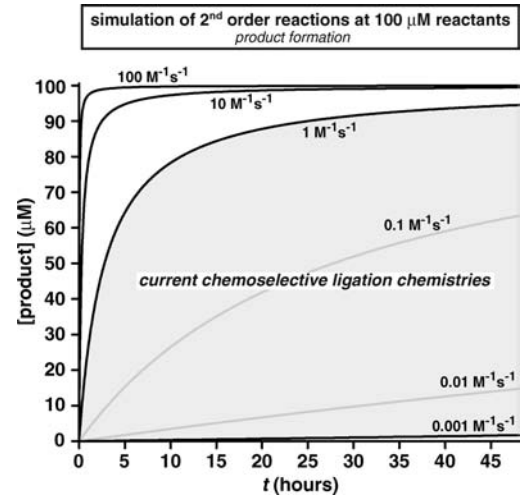

Figure 1. Simulation of second-order reactions between 100 μM reactants showing the formation of product in time as a function of the reaction rate constant. Rate constants of current chemoselective ligation chemistries typically range from 10^{-3} to 10^0 M^{-1} s^{-1}.

In this light, we further explored the scope of aniline-catalyzed imine chemistry by investigating the reaction between aromatic aldehydes and either 6-hydrazinopyridine or aminooxyacetyl

groups. Aromatic aldehydes are potent electrophiles and are more reactive than the ketone and glyoxylyl groups typically used in imine bioconjugation reactions. Aminooxyacetyl groups are readily incorporated into biological macromolecules and chemoselectively form a hydrolytically stable oxime bond, yet the kinetics are slow at neutral pH. An alternative group, 6-hydrazinopyridine, readily forms a hydrazone linkage with aromatic aldehydes to give a chromophore ($\lambda_{max} \sim 350$ nm) that enables direct spectroscopic monitoring of the reaction by UV−vis (*35*). 6-Hydrazinopyridine has similar reactivity to phenylhydrazine, but is less prone to oxidation side reactions (*36*). The 6-hydrazinopyridyl group can be readily incorporated into biomolecules using 6-hydrazinonicotinic acid, also known as HYNIC, a widely used ligand for ^{99m}Tc in radiolabeling (*36*). The ligation between aromatic aldehydes and 6-hydrazinopyridine has been applied to biomolecular labeling (*37*−*40*), but the kinetics of the reaction have not been reported.

EXPERIMENTAL PROCEDURES

Solvents and Starting Materials. Unless stated otherwise, all reagents and solvents were purchased from commercial sources and used without purification.

Note on the Stability of 6-Hydrazinopyridine and Its Hydrazone with Benzaldehyde. In contrast to the hydrazone, the stability of the free hydrazinopyridine is limited. As a solid, the compound is best stored in the freezer protected from light as a salt (HCl/TFA). In solution, the hydrazinopyridine moiety is prone to decomposition due to oxidation in a similar way, but to a lesser extent than phenylhydrazine (*36*). The fast ligation rates observed in the presence of aniline minimize these side reactions. HYNIC-labeled molecules are stored at + 4 or −20 °C, under nitrogen and protected from light. Hydrazone products based on HYNIC and benzaldehyde are stored at a concentration of >50 μM.

Instrumentation. Reversed-phase high-pressure liquid chromatography (RP HPLC) was performed on a HP1050 HPLC system (analytical HPLC) and on a Waters Delta Prep 4000 preparative chromatography system (preparative HPLC), using a Phenomenex Prodigy 5 μ 100 Å (50 × 4.60 mm) and a Phenomenex Jupiter 10 μ Proteo 90Å (250 × 21.2 mm), respectively, for separation. Electrospray ionization mass spectrometry (ESI-MS) was performed on a SCIEX API-I single quadruple mass spectrometer. UV−vis was measured on a GenesysTM 6 spectrophotometer (Thermo Electron Corporation).

Peptide Synthesis. The peptides were obtained *via* manual solid-phase peptide synthesis (SPPS) using the *in situ* neutralization/1*H*-benzotriazolium-1-[bis(dimethylamino)methylene]-5-chloro-hexafluorophosphate-(1-),3-oxide (HCTU) activation procedure for *t*Boc chemistry on a *p*-methylbenzhydrylamine (MBHA) resin (*41*). Detailed procedures are given in the Supporting Information.

Hydrazone Ligations between 6-Hydrazinopyridyl-Peptide 1 and Benzaldehyde. A 2 mM stock solution of HYNIC-peptide **1** (A), a 2 mM stock solution of benzaldehyde (B), and a 200 mM stock solution of aniline (C) were freshly prepared in either 0.1 M NH_4OAc (pH 4.5) or 0.3 M Na phosphate (pH 7). The stock solutions were mixed to give the desired concentrations of **1**, benzaldehyde, and aniline in the final reaction mixture. The reactions at 100 μM were followed by RP HPLC (220 nm, 350 nm), and the reactions at 10 μM were followed by UV−vis (350 nm). Hydrazone product **2** was analyzed by ESI-MS. **2**: ESI-MS calcd. for $C_{68}H_{93}N_{20}O_{25}$ ($[M + H]^+$): 1591.6, found 1591.5 ± 0.7. The data were fitted to the solution of the rate equation of a second-order (reversible) reaction. Details on the kinetics experiments are given in the Supporting Information.

Labeling of HYNIC-HSA with *p*-^{19}F-Benzaldehyde. For the labeling of HYNIC-HSA with *p*-^{19}F-benzaldehyde in the absence of aniline, 350 μL of 0.1 M Na phosphate (pH 7) and 50 μL of a 2.16 mM solution of *p*-^{19}F-benzaldehyde in 0.1 M Na phosphate (pH 7) were subsequently added to 100 μL of a HYNIC-HSA stock solution ([HSA] = 150 μM, on average ∼6 HYNIC/HSA; see Supporting Information). The reaction mixture was vortexed and added into a quartz cuvette. The reaction was followed by UV−vis (370 nm). The final concentration of HYNIC-HSA was 30 μM (2 mg/mL). This concentration of HYNIC-HSA was also used by Chang et al. in a typical procedure for ^{18}F labeling with *p*-^{18}F-benzaldehyde (*40*).

For the labeling of HYNIC-HSA with *p*-^{19}F-benzaldehyde in the presence of 100 mM aniline, 200 μL of 0.1 M Na phosphate (pH 7), 100 μL of a 2.16 mM solution of *p*-^{19}F-benzaldehyde in 0.1 M Na phosphate (pH 7), and 500 μL of a 200 mM stock solution of aniline in 0.1 M Na phosphate (pH 7) were subsequently added to 200 μL of a HYNIC-HSA stock solution ([HSA] = 150 μM, on average ∼6 HYNIC/HSA). The reaction mixture was vortexed and added into a quartz cuvette. The reaction was followed by UV−vis (370 nm). After 1 h, the excess of *p*-^{19}F-benzaldehyde and the aniline catalyst were removed by size-exclusion chromatography over a NAP 5 column. The stability of the hydrazone ligation product was verified by measuring the absorption at 370 nm. No decrease in the absorption of the hydrazone was observed over a period of 20 h.

Labeling of Benzaldehyde−Peptide 4 with Aminooxyacetyl-Alexa Fluor 488 (10 μM Reactants). Aminooxyacetyl-Alexa Fluor 488 is commercially available and is delivered in a vial containing 1 mg of the dye. A stock solution of approximately 1 mM in water was made by adding 1.117 mL of water (A). In addition, a 100 μM stock solution of **4** (B) and a 200 mM stock solution of aniline (C) in 0.1 M Na phosphate (pH 7) were prepared. For the reaction in the absence of aniline, 200 μL of B and 20 μL of A were subsequently added to 1.780 mL of 0.1 M Na phosphate (pH 7). For the reaction in the presence of 100 mM aniline, 1.000 mL of C, 200 μL of B, and 20 μL of A were subsequently added to 780 μL of 0.1 M Na phosphate (pH 7). The reactions were followed by RP HPLC (220 nm, 495 nm; gradient: 5−25% 9:1 v/v MeCN/H_2O in H_2O, 0.1 v % TFA in 20 min; flow: 3 mL/min). The exact concentration of dye in the ligation reactions was determined by measuring the absorption at 495 nm ($\varepsilon = 7.1 \times 10^4$ M^{-1} cm^{-1}) and was calculated to be 13 μM. Oxime product **5** was quantitated by integration (495 nm) and analyzed by ESI-MS. **5**: ESI-MS calcd. for $C_{64}H_{77}N_{15}O_{20}S_2$ ($[M + H]^+$): 1441.5, found 1442.0.

RESULTS AND DISCUSSION

To evaluate the utility of combining aniline catalysis with arylaldehyde electrophiles, we first reacted 6-hydrazinopyridyl peptide **1** and benzaldehyde (Figure 2a) (100 μM each) at pH 4.5, near the pH optimum of imine reactions. The reaction was followed by HPLC (220 nm, 350 nm) and the data were fitted to the rate equation of a second-order reaction. Full conversion to hydrazone product **2** was reached within a day with $k_1 = 3.0 \pm 0.3$ M^{-1} s^{-1} (see Supporting Information), much faster than typical imine ligations used in bioconjugation and matching the fastest chemoselective ligation reactions in the literature. Furthermore, in the presence of 10 mM aniline the reaction reached full conversion within minutes under the same conditions. To fully characterize the k_1, k_{-1}, and K_{eq} of this reaction in the absence and presence of aniline, 6-hydrazinopyridyl-peptide **1** and benzaldehyde were reacted under more dilute conditions. The reactions were followed by absorbance at 350 nm. At 10 μM reactants, the reaction reached an equilibrium

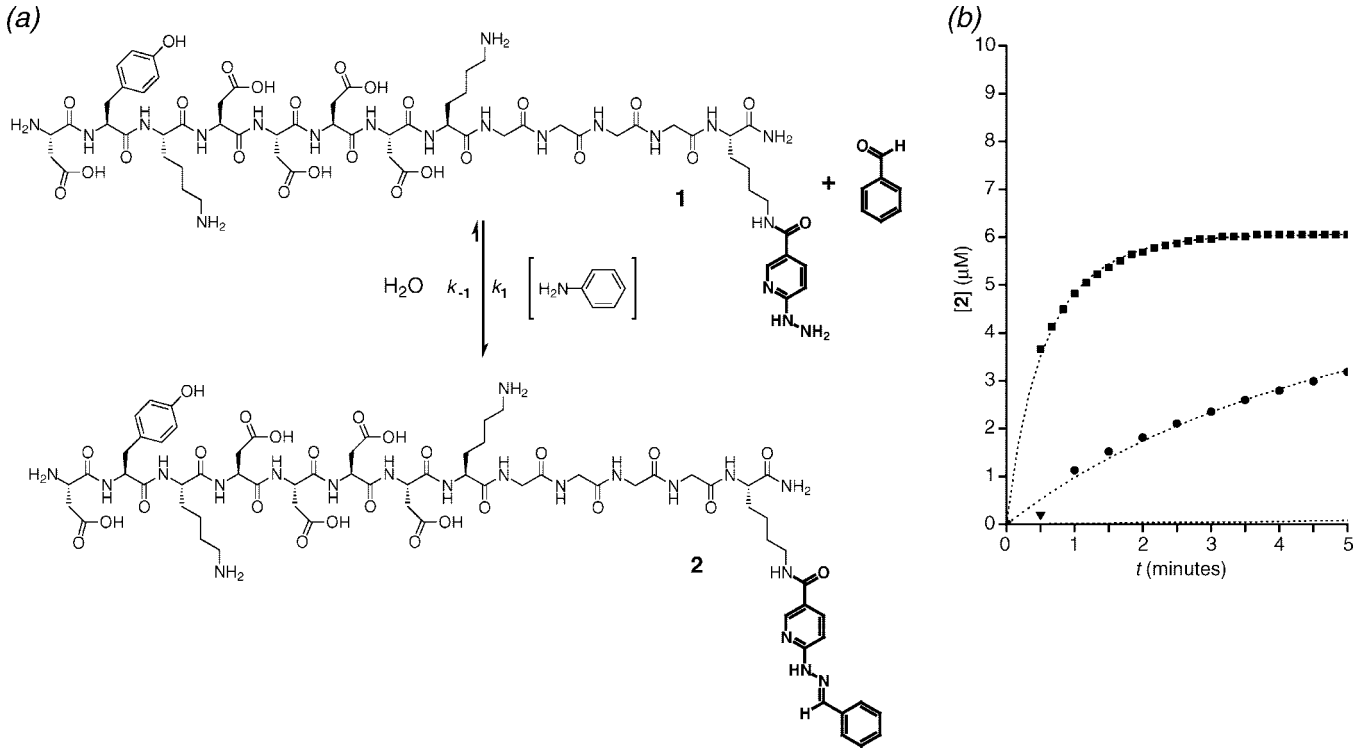

Figure 2. (a) Hydrazone reaction of 6-hydrazinopyridyl-peptide **1** and benzaldehyde in the absence and presence of aniline catalyst. (b) Formation of hydrazone **2** over time at 10 μM reactants in 0.1 M NH_4OAc (pH 4.5) at room temperature in the absence (▼) and in the presence of 10 mM (•) and 100 mM (■) aniline. The dotted lines represent the fit of the data to the rate equation (full data for ▼ is included in Supporting Information Figure 2).

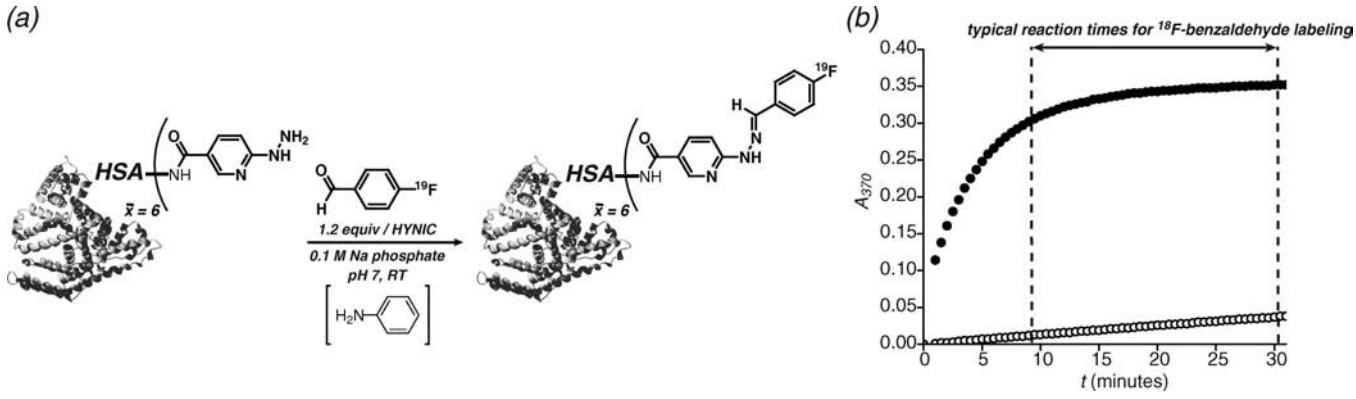

Figure 3. (a) Hydrazone reaction of 6-hydrazinopyridyl-functionalized human serum albumin (HYNIC-HSA; 6 HYNIC per HSA on average) and *p*-^{19}F-benzaldehyde in the absence and presence of aniline catalyst. (b) Labeling of HYNIC-HSA followed in time by UV−vis (370 nm) in the absence (○) and in the presence (•) of 100 mM aniline; [HYNIC-HSA] = 30 μM, [*p*-^{19}F-benzaldehyde] = 216 μM, 0.1 M Na phosphate (pH 7), room temperature.

with ~60% product present (Figure 2b). In accordance with the experiment at 100 μM reactants, the k_1 of the uncatalyzed reaction was 2.6 ± 0.1 M^{-1} s^{-1}. The k_{-1} was found to be (0.03 ± 0.001) × 10^{-3} s^{-1}, giving a K_{eq} of (0.88 ± 0.04) × 10^6 M^{-1}. In the presence of 10 mM aniline, k_1 was enhanced over 70-fold to 190 ± 10 M^{-1} s^{-1} and k_{-1} increased accordingly to (0.81 ± 0.03) × 10^{-3} s^{-1}, giving a K_{eq} = (0.23 ± 0.02) × 10^6 M^{-1}. An additional 10-fold rate enhancement was achieved by using 100 mM aniline: k_1 = 2000 ± 100 M^{-1} s^{-1}, k_{-1} = (5.1 ± 0.1) × 10^{-3} s^{-1}, and K_{eq} = (0.40 ± 0.02) × 10^6 M^{-1}. Despite the very dilute conditions, the reaction reached equilibrium within minutes (Figure 2b).

Many biomolecules are conformationally unstable under acidic conditions and at the same time limited to low concentrations (μM range) owing to their high molecular weight, low availability, and tendency to aggregate. Biomolecular labeling at pH 7 at low concentrations is therefore often desired. At pH 7, the reaction between 6-hydrazinopyridyl-peptide **1** and benzaldehyde (10 μM each) rapidly reaches equilibrium in the presence of 100 mM aniline; k_1 = 170 ± 10 M^{-1} s^{-1}, k_{-1} = (0.08 ± 0.004) × 10^{-3} s^{-1}, and the equilibrium shifts slightly more toward the product (~80% product; K_{eq} = (2.3 ± 0.1) × 10^6 M^{-1}) (see Supporting Information). To the best of our knowledge, the aniline-catalyzed reaction between the 6-hydrazinopyridyl group and benzaldehyde is the fastest chemoselective ligation chemistry that has been described.

The K_{eq} of this reaction implies that at least one of the components should be present at >50 μM in order to shift the equilibrium completely (>99%) toward the product and at >13 μM to reach >90% conversion. When labeling is complete and the excess of one of the components is removed, a new equilibrium will be reached over time, determined by the k_{-1} of the reaction. Consistent with its role as a nucleophilic catalyst, aniline does not affect K_{eq} but does catalyze reequilibration.

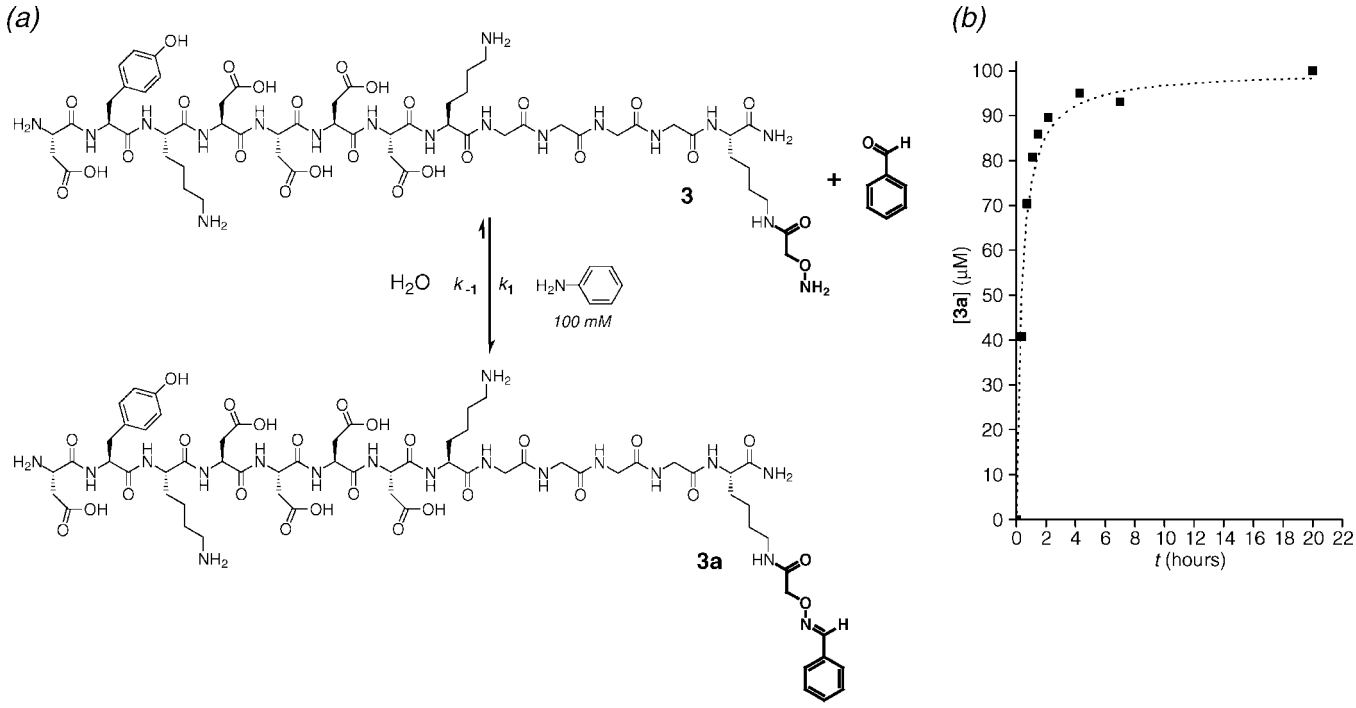

Figure 4. (a) Oxime ligation of aminooxyacetyl-functionalized peptide **3** and benzaldehyde in the presence of aniline catalyst. (b) Formation of oxime **3a** over time at 100 μM reactants in 0.3 M Na phosphate (pH 7) at room temperature in the presence of 100 mM aniline. The dotted line represents the fit of the data to the rate equation.

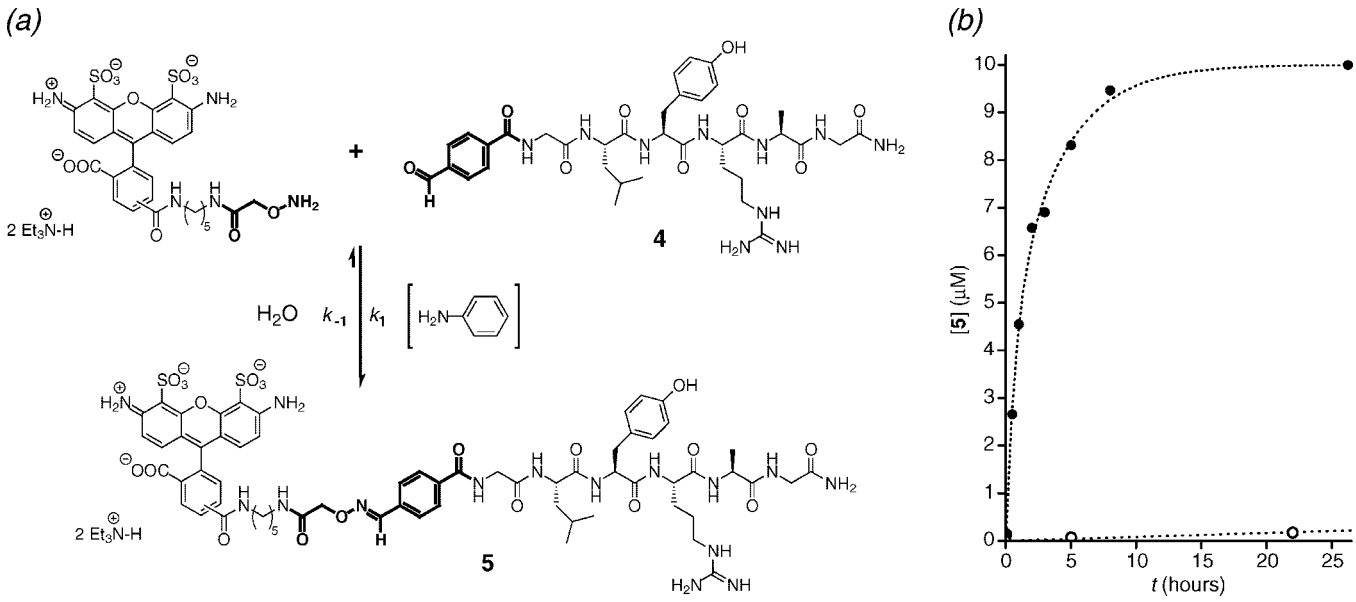

Figure 5. (a) Oxime ligation of aminooxyacetyl-Alexa Fluor 488 and benzaldehyde-functionalized peptide **4** in the absence and presence of aniline catalyst. (b) Formation of oxime **5** over time reacting 10 μM of **4** with 13 μM (1.3 equiv) of aminooxyacetyl-functionalized Alexa Fluor 488 in 0.1 M Na phosphate (pH 7) at room temperature in the absence (○) and in the presence (•) of 100 mM aniline.

However, when the catalyst is removed during workup, re-equilibration would take weeks ($k_{-1} \sim 10^{-6}$ s^{-1} at pH 7).

The rapid ligation between the 6-hydrazinopyridyl group and benzaldehyde in the presence of aniline may be of particular use for radiolabeling, since the time of labeling is strongly limited by the half-life of the radiolabel. Recently, a *p*-^{18}F-benzaldehyde label was developed for positron emission tomography (PET) imaging (*42*). However, high temperatures (50−60 °C) (*40*, *42*) and low pH (*42*) were required to compensate for the slow ligation rates and to achieve optimal labeling within typical reaction times of 10−30 min. To demonstrate the impact of aniline catalysis, the labeling of 6-hydrazinopyridyl-functionalized human serum albumin (HYNIC-HSA) with *p*-^{19}F-benzaldehyde was performed in the absence and presence of 100 mM aniline, using only a slight excess (1.2 equiv per HYNIC) of the label at room temperature (Figure 3a). For this, HSA was functionalized with, on average, 6 HYNIC moieties (see Supporting Information). Labeling was performed at 30 μM HYNIC-HSA, a concentration used in a recently reported optimized protocol for *p*-^{18}F-benzaldehyde labeling (*40*).

As shown in Figure 3b, the labeling of HYNIC-HSA with *p*-^{19}F-benzaldehyde is relatively slow. Less than 10% labeling is achieved within 30 min, consistent with the use of elevated temperatures and acidic conditions in previous labeling protocols for *p*-^{18}F-benzaldehyde. In the presence of aniline, the reaction

kinetics are strongly enhanced and >95% labeling is established within the same amount of time at neutral pH, at room temperature. After removal of the aniline catalyst and the slight excess of label by size exclusion (NAP 5 column), the hydrazone linkage was found to be stable for at least 20 h at room temperature.

In typical radiolabeling experiments with *p*-^{18}F-benzaldehyde, the label is only present in high nM to low μM concentrations, while the biomolecule is in great excess (high μM to low mM). Under these conditions, the labeling reaction will be pseudo-first-order in the biomolecule. If the reaction described above would be performed with the same initial concentration of HYNIC-HSA (6 HYNIC per HSA on average), but with a much lower concentration of *p*-^{19}F-benzaldehyde, this pseudo-first-order reaction would actually reach completion more rapidly than the second-order reaction where an equimolar amount of *p*-^{19}F-benzaldehyde is applied.

Since oximes are more hydrolytically stable than hydrazones, we investigated the combination of the aminooxy nucleophile with benzaldehyde electrophiles. To gain insight into the kinetics of the aniline-catalyzed oxime ligation, aminooxyacetyl-peptide **3** and benzaldehyde (100 μM each) were reacted under ambient conditions at pH 7 in the presence of 100 mM aniline (Figure 4). Although the k_1 of 8.2 $\pm$ 1.0 M^{-1} s^{-1} is 20-fold smaller than the k_1 of the reaction between the 6-hydrazinopyridyl group and benzaldehyde, the K_{eq} of the oxime is at least 2 orders of magnitude larger than the K_{eq} of the hydrazone. This will enable quantitative conjugation at 10 μM within 1 day using only a slight excess of label.

To demonstrate the utility of oxime ligation for labeling, benzaldehyde-functionalized peptide **4** (10 μM) was tagged with the fluorescent label aminooxyacetyl-Alexa Fluor 488 at pH 7 (Figure 5a). As anticipated, labeling was established within 1 day, whereas in the absence of aniline, <5% conversion was reached within the same period of time (Figure 5b).

CONCLUSIONS

Many methods are available to introduce benzaldehyde, 6-hydrazinopyridyl (HYNIC), or aminooxyacetyl groups in a random or site-specific manner into biomolecules (*1*−*3*, *35*, *36*). Aniline catalysis has given the reaction between aromatic aldehydes and α-effect amines a new dimension by exceeding the reaction rates of current chemoselective ligation chemistries and by bringing covalent chemistry one step closer to the rates observed in noncovalent interactions.

Aniline is a weak base that is moderately nucleophilic and does not react with the amino acid side chains of unmodified peptides. Aniline can be readily removed from the conjugation mixture by HPLC or size exclusion chromatography. Aniline may act as a competitive ligand for some metalloproteins, as does imidazole (*43*), a widely used acid−base and nucleophilic catalyst. In addition, aniline will form a reversible Schiff base with aldehyde-containing proteins, which may affect their function. However, for most proteins aniline acts as an organic buffer and is not expected to affect binding or catalysis (*44*). Therefore, we anticipate that the aniline-catalyzed imine chemistry presented in this paper will find wide utility in biomolecular labeling owing to its fast kinetics under mild conditions at neutral pH.

ACKNOWLEDGMENT

We thank Subramanian Yegneswaran (The Scripps Research Institute, USA) for performing the thrombin activity assay and Tilman M. Hackeng (Cardiovascular Research Institute Maastricht, The Netherlands), M. G. Finn (The Scripps Research Institute, USA), and David A. Schwartz (SoluLink Biosciences, Inc., USA) for discussion. PED is a consultant for SoluLink Biosciences, Inc., USA. This work was supported by The Netherlands Organization for Scientific Research (NWO) (A.D.) and NIH GM059380 (P.E.D.).

Supporting Information Available: Detailed procedures on the synthesis of the peptides and the kinetics experiments are given, as well as the activity assay for the serine protease thrombin after incubation with aniline. Rapid Oxime and Hydrazone Ligations with Aromatic Aldehydes for Biomolecular Labeling.

Anouk Dirksen, Philip E. Dawson

Departments of Cell Biology and Chemistry, Skaggs Institute for Chemical Biology, The Scripps Research Institute, 10550 N. Torrey Pines Road, La Jolla, CA 92037, USA.

Peptide synthesis. The peptides were obtained *via* manual solid phase peptide synthesis (SPPS) using an *in situ* neutralization/1*H*-benzotriazolium-1-[bis(dimethylamino)methylene]-5-chloro-hexafluorophosphate-(1-),3-oxide (HCTU) activation procedure for *t*Boc chemistry on a *p*-methylbenzhydrylamine (MBHA) resin.*(1)*

6-Hydrazinopyridyl-peptide 1 (0.05 mmol scale). The Fmoc protecting group of the C-terminal lysine residue of *t*Boc-D(OcHxl)YK(2ClZ)D(OcHxl)D(OcHxl)D(OcHxl)D(OcHxl) K(2ClZ)GGGGK(Fmoc) was removed on the resin by treatment with 20 *v*-% piperidine in DMF (4 × 3 min) followed by a DMF flow wash. 0.1 mmol (25 mg) 6-*t*Boc-hydrazinonicotinic acid (6-BOC-HNA, SoluLink Biosciences, San Diego, CA, USA) was added to a solution of 0.1 mmol (52 mg) benzotriazole-1-yl-oxy-*tris*-pyrrolidino-phosphonium hexafluorophosphate (PyBOP®) and 0.12 mmol (d = 0.742 kgL^{-1}, 21 μL) diisopropylethylamine (DIEA) in 0.5 mL of DMF and the mixture was added to the resin (45 min). The resin was washed with DMF and the *t*Boc groups were removed with trifluoroacetic acid (TFA) (2 × 1 min). The resin was washed with DMF, DCM, and 1:1 *v/v* DCM/MeOH and dried under vacuum. The peptide was cleaved from the resin by HF using 4 *v*-% of anisole as a scavenger. After lyophilization, 6-hydrazinopyridyl-peptide **1** was purified by RP HPLC (gradient: 0 - 25% 9:1 *v/v* MeCN/H_2O in H_2O, 0.1 *v*-% TFA in 80 min; flow: 20 mL/min). **1**: ESI-MS calcd. for $C_{61}H_{89}N_{20}O_{25}$ ($[M+H]^+$): 1503.5, found 1504.0 ± 0.2.

Aminooxyacetyl-peptide 3 (0.1 mmol scale). The Fmoc protecting group of the C-terminal lysine residue of *t*Boc-D(OcHxl)YK(2ClZ)D(OcHxl)D(OcHxl)D(OcHxl)D(OcHxl) K(2ClZ)GGGGK(Fmoc) was removed on the resin by treatment with 20 *v*-% piperidine in DMF

(4 × 3 min) followed by a DMF flow wash. 0.5 mmol (96 mg) *t*Boc-aminooxyacetic acid was activated with 0.5 mmol (d = 0.806 kgL^{-1}, 78 μL) *N*,*N'*-diisopropylcarbodiimide and 0.5 mmol *N*-hydroxysuccinimide in DMF (0.5 mL) (10 min) and the emulsion was added to the resin (2 h). The resin was washed with DMF and the *t*Boc groups were removed with TFA (2 × 1 min). The resin was washed with DMF, DCM, and 1:1 *v/v* DCM/MeOH and dried under vacuum. The peptide was cleaved from the resin by HF using 4 *v*-% of anisole as a scavenger. After lyophilization, aminooxyacetyl-peptide **3** was purified by RP HPLC (gradient: 0 - 25% 9:1 *v/v* MeCN/H_2O in H_2O, 0.1 *v*-% TFA in 80 min; flow: 20 mL/min). **3**: ESI-MS calcd. for $C_{57}H_{87}N_{18}O_{26}$ ($[M+H]^+$): 1441.4, found 1441.0 ± 0.2.

Benzaldehyde-peptide 4. GLY(2BrZ)R(Tos)AG was synthesized by manual SPPS using the *in situ* neutralization/HCTU activation procedure for *t*Boc chemistry on a MBHA resin and cleaved from the resin with HF using 4 *v*-% of anisole as a scavenger. After lyophilization, GLYRAG was purified by RP HPLC (gradient: 5 - 30% 9:1 *v/v* MeCN/H_2O in H_2O, 0.1 *v*-% TFA in 80 min; flow: 15 mL/min). GLYRAG: ESI-MS calcd. for $C_{28}H_{46}N_{10}O_7$ ($[M+H]^+$): 635.7, found 635.5. The N-terminus of GLYRAG was functionalized in solution. For this, 22 mg (0.089 mmol) of *p*-carboxybenzaldehyde succimidyl ester was dissolved in 100 μL of MeCN and added to a solution of 40 mg (0.063 mmol) of GLYRAG in 4.4 mL of 0.1 M Na phosphate (pH 7) (2 h). The product was purified by RP HPLC (gradient: 15 - 40% 9:1 *v/v* MeCN/H_2O in H_2O, 0.1 *v*-% TFA in 80 min; flow: 15 mL/min) and lyophilized to give 21 mg (0.027 mmol, 43.5%) of **4**. **4**: ESI-MS calcd. for $C_{36}H_{50}N_{10}O_9$ ($[M+H]^+$): 767.8, found 767.5.

Hydrazone ligations at pH 4.5 (100 μM reactants). A 2 mM stock solution of 6-hydrazinopyridyl-peptide **1** (A), a 2 mM stock solution of benzaldehyde (B), and a 200 mM stock solution of aniline (C) were freshly prepared in 0.1 M NH_4OAc (pH 4.5). For the reaction in the absence of aniline, 50 μL A and 50 μL B were subsequently added to 900 μL of 0.1 M NH_4OAc (pH 4.5). For the reaction in the presence of 10 mM aniline, 50 μL C, 50 μL A, and 50 μL B were added subsequently to 850 μL of 0.1 M NH_4OAc (pH 4.5). The reactions were followed by RP HPLC (220 nm, 350 nm; gradient: 5 - 20% 9:1 *v/v* MeCN/H_2O in H_2O, 0.1 *v*-% TFA in 15 min; flow: 3 mL/min), hydrazone product **2** was quantitated by integration (350 nm), and analyzed by ESI-MS. **2**: ESI-MS calcd. for $C_{68}H_{93}N_{20}O_{25}$ ($[M+H]^+$): 1591.6, found 1591.5 ± 0.7. The data of the uncatalyzed reaction were fitted to the solution of the rate equation of a 2nd order reaction to resolve k_1 (Figure 1). The reaction in the presence of 10 mM aniline was too fast to resolve accurately k_1.

Hydrazone ligations at pH 4.5 (10 μM reactants). A 2 mM stock solution of 6-hydrazinopyridyl-peptide **1** (A), a 2 mM stock solution of benzaldehyde (B), and a 200 mM stock solution of aniline (C) were freshly prepared in 0.1 M NH_4OAc (pH 4.5). The hydrazone reactions were performed in quartz cuvettes (l = 1 cm). For the reaction in the absence of aniline, 10 μL of A and 10 μL of B were added subsequently to 1.980 mL of 0.1 M NH_4OAc (pH 4.5) (see Figure 2 for full dataset; first 5 minutes shown in Figure 2 of the paper). For the reaction in the presence of 10 mM aniline, 100 μL of C, 10 μL of B, and 10 μL of A were added subsequently to 1.880 mL of 0.1 M NH_4OAc (pH 4.5), and for the reaction in the presence of 100 mM aniline, 1.000 mL of C, 10 μL of B, and 10 μL of A were added subsequently to 980 μL of 0.1 M NH_4OAc (pH 4.5). Time was started as soon as the last component was added and 30 -

60 seconds were taken to vigorously vortex the reaction mixture, transfer it into a cuvette and start the measurement. 0.1 M NH_4OAc containing exactly the same amount of aniline as the reaction mixture was used as a blanc. The reactions were performed at room temperature and monitored by UV-Vis (350 nm). Once the reaction fully reached equilibrium, the total amount of hydrazone product **2** was determined by adding in a 10-fold excess of benzaldehyde (final concentration 110 μM), shifting the equilibrium completely towards the product. The data were fitted to the solution of the rate equation of a 2nd order reversible reaction.*(2)* It should be noted that conditions differ slightly for each reaction (ionic strength, solvent effect of 100 mM aniline). These difference may explain the differences observed in the equilibrium constants. Furthermore, the endpoints were not fixed, which may cause an underestimation of the calculated error in the k_{-1} of the reaction.

Hydrazone ligation at pH 7 (10 μM reactants, 100 mM aniline). This reaction was performed and analyzed analogous to the reaction at pH 4.5. Stock solutions were freshly prepared in 0.3 M Na phosphate (pH 7). The data were fitted to the solution of the rate equation of a 2nd order reversible reaction*(2)* (Figure 3).

Synthesis of HYNIC-HSA. 15 equiv of succinimidyl hydraziniumnicotinate hydrochloride (SHNH, SoluLink Biosciences, San Diego, CA, USA) (0.646 mg) in DMSO (20 μL) were added to a solution of 10 mg of HSA in 0.5 mL of 0.05 M Na phosphate (pH 7.5). The solution was put under nitrogen and protected from light and the reaction was continued for 2 hours at room temperature. The excess of SHNH was removed by size exclusion chromatography over a NAP™ 5 column, preequilibrated with 0.1 M Na phosphate (pH 7). HYNIC-HSA was eluted

from the column with 0.1 M Na phosphate (pH 7). The concentration of HSA in the collected solution was determined to be 150 μM, using the Bradford assay. The concentration of HYNIC was determined by adding 25 μL of the protein solution to 2.475 mL of a 0.5 mM solution of *p*-nitrobenzaldehyde in 0.1 M NH_4OAc (pH 4.5). In time HYNIC reacts with *p*-nitrobenzaldehyde to give a chromophore with $\varepsilon = 2.53 \times 10^4\ M^{-1}cm^{-1}$ at 385 nm.*(3)* After 5 h the absorption at 385 nm was measured and the concentration of HYNIC was calculated to be 893 μM. This corresponds to on average ~6 HYNIC groups per HSA.

Note on the stability of 6-hydrazinopyridine and its hydrazone with benzaldehyde. In contrast to the hydrazone, the stability of the free hydrazinopyridine is limited. As a solid, the compound is best stored in the freezer protected from light as a salt (HCl / TFA). In solution, the hydrazinopyridine moiety is prone to decomposition due to oxidation in a similar way, but to a lesser extent than phenylhydrazine.*(3)* The fast ligation rates observed in the presence of aniline minimize these side reactions. HYNIC labeled molecules are stored at + 4 °C or -20 °C, under nitrogen and protected from light. Hydrazone products based on HYNIC and benzaldehyde are stored at a concentration of > 50 μM.

Oxime ligation at pH 7 (100 μM reactants, 100 mM aniline). A 2 mM stock solution of aminooxyacetyl-peptide **3** (A), a 2 mM stock solution of benzaldehyde (B), and a 200 mM stock solution of aniline (C) were prepared in 0.3 M Na phosphate (pH 7). 500 μL C, 50 μL A, and 50 μL B were added subsequently to 400 μL of 0.3 M Na phosphate (pH 7). The reaction was followed by RP HPLC (220 nm; gradient: 0 - 20% 9:1 *v/v* MeCN/H_2O in H_2O, 0.1 *v*-% TFA in 15 min; flow: 3 mL/min), oxime product **3a** was quantitated by integration (220 nm), and

analyzed by ESI-MS. **3a**: ESI-MS calcd. for $C_{64}H_{91}N_{18}O_{26}$ ($[M+H]^+$): 1529.5, found 1529.5 ± 0.7. The data of the reaction were fitted to the solution of the rate equation of a 2nd order reaction.

Oxime ligation at pH 7 (1 mM reactants, no aniline). The rate constant of the uncatalyzed reaction was determined by reacting **3** with benzaldehyde at 1 mM reactants. For this 250 µL A and 250 µL B were mixed. The reaction was followed by RP HPLC (220 nm; gradient: 0 - 20% 9:1 *v/v* MeCN/H_2O in H_2O, 0.1 *v*-% TFA in 15 min; flow: 3 mL/min), oxime product **3a** was quantitated by integration (220 nm). The data of the reaction were fitted to the solution of the rate equation of a 2nd order reaction and a rate constant of 0.14 ± 0.02 $M^{-1}s^{-1}$ was calculated (Figure 4).

Thrombin activity assay. 150 µl of human α-thrombin (HaemTech, Essex Junction VT) (90 µM) was incubated with either 150 µl of 200 mM aniline and 1 mM benzamidine.HCl or with an equal volume of 1 mM benzamidine.HCl in 50 mM Hepes/150 mM NaCl (pH 7.4) at room temperature for 6 hours. The weak inhibitor benzamidine.HCl was added to prevent self-cleavage of thrombin during incubation. Samples were then dialyzed (1 × 2000 mL) into 50 mM Hepes/150 mM NaCl (pH 7.4) overnight at 4 °C before thrombin activity was evaluated using the chromogenic substrate Pefachrome-TH (Pentapharma, Basel, Switzerland). Briefly, 50 µl of varying concentrations of substrate (0-1600 µM) were added to samples containing 20 nM aniline-treated thrombin or untreated controls. The generation of *p*-nitroaniline was monitored immediately using a 96 well plate reader (Molecular Dynamics, Sunnyvale CA) at 405 nm wavelength (Figure 5).

Hydrazone ligation: 100 μM reactants, no aniline, pH 4.5, room temperature

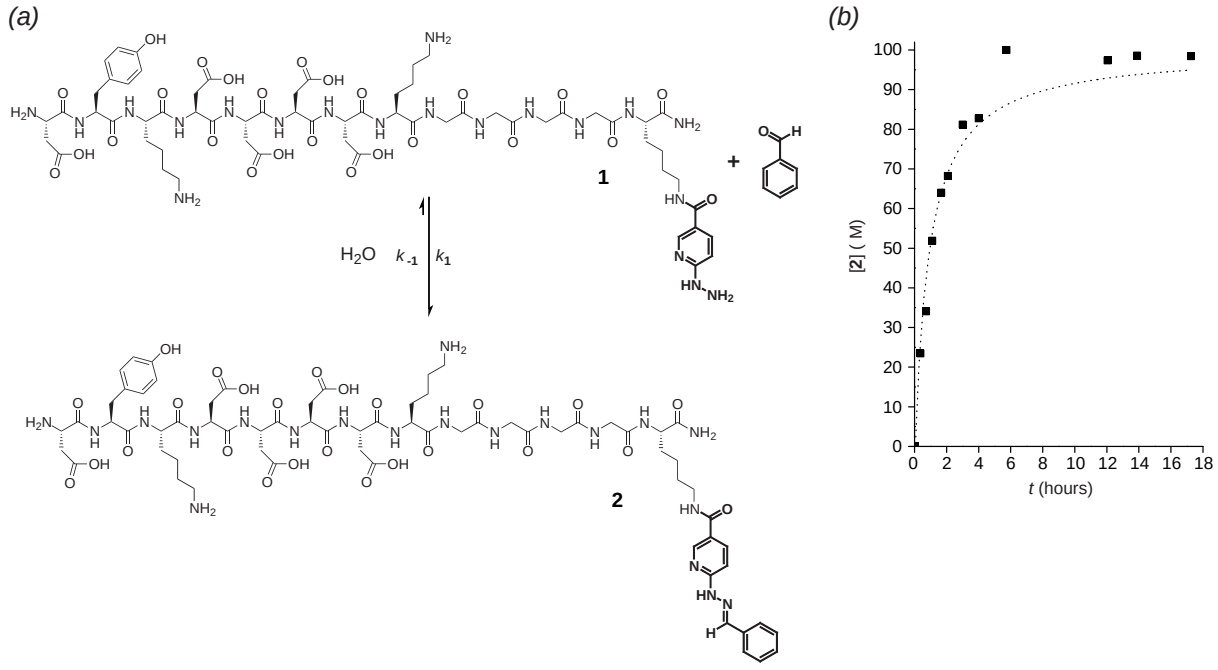

Figure 1. *(a)* Hydrazone reaction of 6-hydrazinopyridyl-peptide **1** and benzaldehyde in the absence of aniline catalyst; *(b)* Formation of hydrazone **2** over time at 100 μM reactants at room temperature in 0.1 M NH_4OAc (pH 4.5). The dotted line represents the fit of the data to the rate equation.

Hydrazone ligation: 10 μM reactants, no aniline, pH 4.5, room temperature (full dataset)

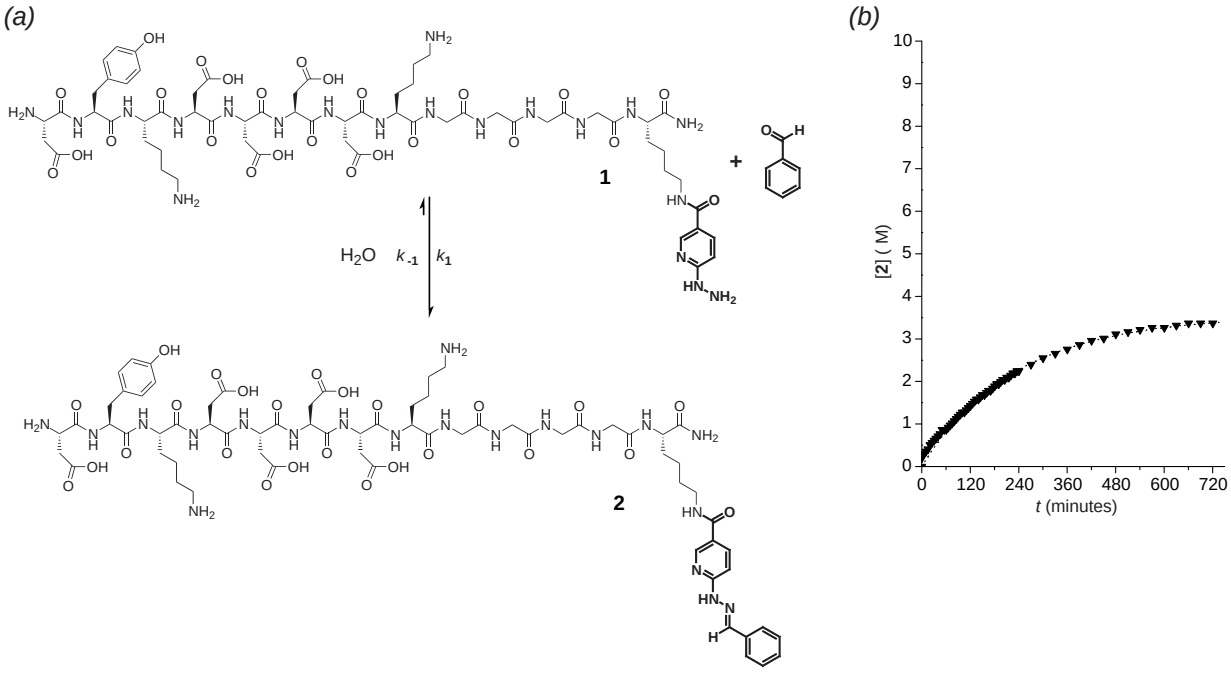

Figure 2. *(a)* Hydrazone reaction of 6-hydrazinopyridyl-peptide **1** and benzaldehyde in the absence of aniline catalyst; *(b)* Formation of hydrazone **2** over time at 10 μM reactants at room temperature in 0.1 M NH_4OAc (pH 4.5). The dotted line represents the fit of the data to the rate equation.

Hydrazone ligation: 10 μM reactants, 100 mM aniline, pH 7, room temperature

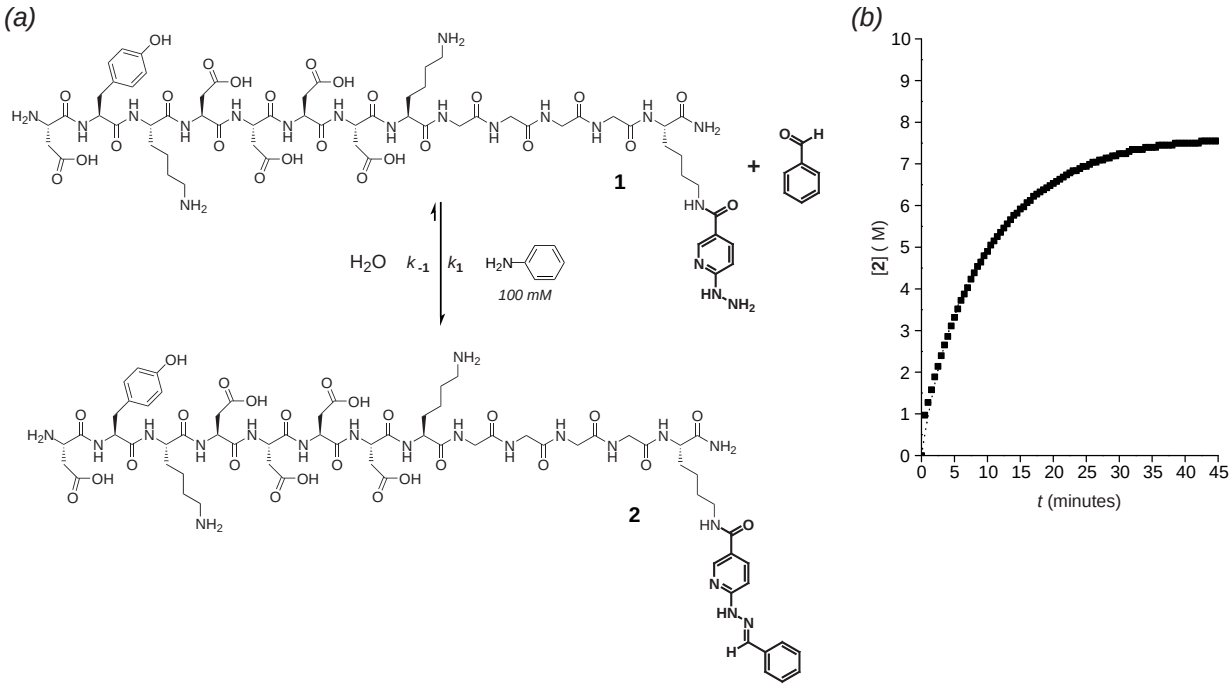

Figure 3. *(a)* Hydrazone reaction of 6-hydrazinopyridyl-peptide **1** and benzaldehyde in the presence of aniline catalyst; *(b)* Formation of hydrazone **2** over time at 10 μM reactants at room temperature in 0.3 M Na phosphate (pH 7) in the presence of 100 mM aniline. The dotted line represents the fit of the data to the rate equation.

Oxime ligation: 1 mM reactants, no aniline, pH 7, room temperature

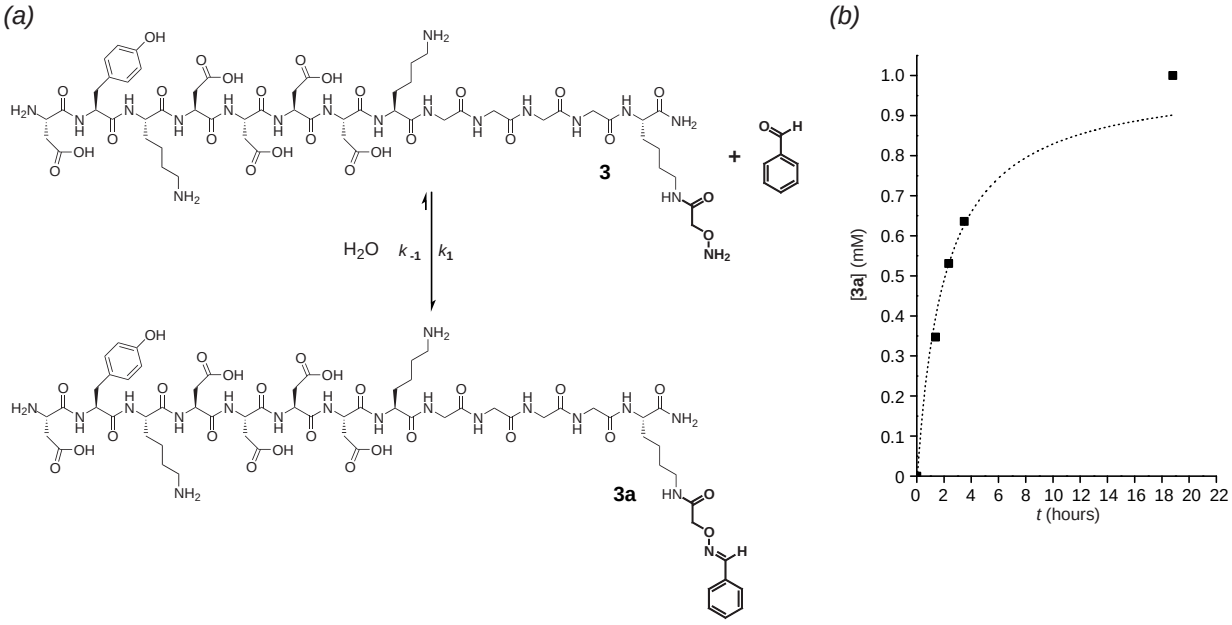

Figure 4. *(a)* Oxime ligation of aminooxyacetyl-functionalized peptide **3** and benzaldehyde in the absence aniline catalyst; *(b)* Formation of oxime **3a** over time at 1 mM reactants at room temperature in 0.3 M Na phosphate (pH 7). The dotted line represents the fit of the data to the rate equation.

Thrombin activity assay

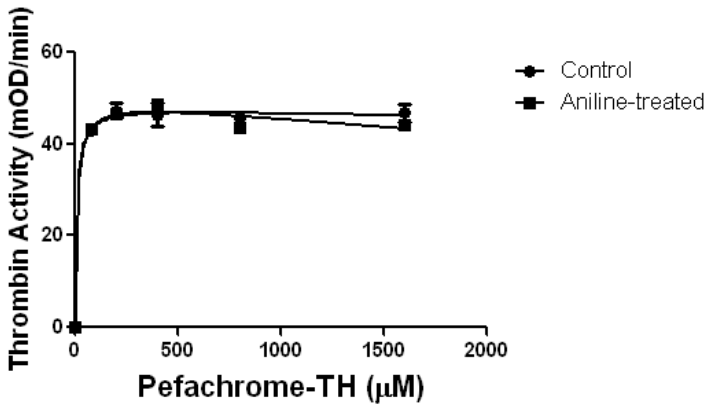

Figure 5. Thrombin activity assay for aniline-treated and untreated thrombin (20 nM) based on the conversion of the substrate Pefachrome-TH (initial concentration ranging from 0-1600 μM) to *p*-nitroaniline in 50 mM Hepes/150 mM NaCl (pH 7.4). The reaction was followed by UV-Vis (405 nm).

Synthesis and Cellular Uptake of Fluorescently Labeled Multivalent Hyaluronan Disaccharide Conjugates of Oligonucleotide Phosphorothioates

Marika Karskela,*[,†] Pasi Virta,[†] Melina Malinen,[‡,§] Arto Urtti,[§] and Harri Lönnberg[†]

Department of Chemistry, University of Turku, FI-20014 Turku, Division of Biopharmaceutics and Pharmacokinetics, Faculty of Pharmacy, and Center for Drug Research, University of Helsinki, P.O. Box 56, FI-00014 University of Helsinki, Helsinki, Finland. Received June 27, 2008; Revised Manuscript Received October 20, 2008

Clustered hyaluronan disaccharides were studied as mediators of cellular delivery of antisense oligonucleotides through receptor-mediated endocytosis. For this purpose, a synthetic route for preparation of an appropriately protected hyaluronic acid dimer bearing an aldehyde tether (**1**) was devised. Up to three non-nucleosidic phosphoramidite building blocks (**2**), each bearing two phthaloyl protected aminooxy groups, were then inserted into the 3′-terminus of the desired phosphorothioate oligodeoxyribonucleotide, and 6-FAM phosphoramidite was introduced into the 5′-terminus. After completion of the chain assembly, the aldehyde-tethered sugar ligands were attached to the deprotected aminooxy functions by on-support oximation. Three fluorescein-labeled phosphorothioate oligonucleotide glycoconjugates (**28**−**30**) containing two, four, or six hyaluronan disaccharides were prepared. The influence of the hyaluronan moieties on the cellular uptake of the thioated oligonucleotides was tested in a cell line expressing the hyaluronan receptor CD44. Specific uptake was not detected with this combination of multiple hyaluronan disaccharides.

INTRODUCTION

Carbohydrate−protein interactions play a major role in recognition of cells by external macromolecules (*1*−*5*). These interactions are multipodal. Although monomeric sugar ligands usually bind only weakly to their receptors, a sufficiently high affinity is achieved by multiple simultaneous interactions, a phenomenon known as a glyco cluster effect (*6*−*12*). Usually, multiantennary carbohydrates anchored to cell membranes recognize extracellular proteins. However, the opposite is also possible (*13*−*15*). Hyaluronic acid, a linear polysaccharide composed of a repeating disaccharide unit of D-glucuronic acid and *N*-acetyl-D-glucosamine, [→3)-*β*-D-GlcNAc-(1→4)-*β*-D-GlcUA-(1→]$_n$, offers a good example. It is the main ligand for a transmembrane glycoprotein CD44 that is overexpressed in many cancers (*16*). Evidently for this reason, hyaluronic acid conjugates of cancer drugs exhibit increased uptake to cancer cells (*17*, *18*). In addition, both high and low molecular weight hyaluronic acid−lipid conjugates have been shown to target liposomes to CD44 expressing cancer cells (*19*−*21*). It has been shown that a hyaluronan octamer is required for high-affinity binding to CD44 (*22*), a tetrameric core region binding to a shallow groove of the protein (*23*). Accordingly, conjugation with hyaluronic acid oligomers may offer a potential means with which to target antisense oligonucleotides to CD44 expressing cells. Enrichment of the oligonucleotide glycoconjugate on the surface, as expected, leads to enhanced internalization by endocytosis and eventually also to increased concentration in the cytoplasm. For comparison, trivalent *N*-acetylgalactosamine (*24*, *25*) and tetravalent galactose (*26*, *27*) conjugates of oligonucleotides, as well as galactosylated PEG conjugates of oligonucleotides (*28*), have been shown to exhibit markedly enhanced cellular uptake by liver cells compared to their non-glycosylated counterpart.

Hyaluronan fragments are used increasingly to study their specific biological activities (*29*). Access to adequate quantities of defined oligosaccharides relies mainly on synthetic methods, since material obtained by enzymatic processing of natural hyaluronan polymers usually consists of a mixture of oligomers. Several hyaluronan oligosaccharides with different lengths and modified sequences have been synthesized over the past decades (*30*−*38*), while the published drug delivery applications have been limited to the use of polymer-sized hyaluronan (*39*).

The underlying idea of the present study was to exploit hyaluronan-mediated binding to the cell surface receptors as a means of internalization of covalently attached oligonucleotide. In more detail, the study was aimed at clarifying whether an oligonucleotide decorated with up to six clustered hyaluronan disaccharides could become recognized by the CD44 receptor instead of a longer hyaluronan oligomer. For this purpose, a synthetic route for preparation of an appropriately protected hyaluronic acid dimer bearing an aldehyde tether (**1**) was devised (Figure 1). For the covalent attachment of these hyaluronan dimers to oligonucleotides, a previously (*40*) developed non-nucleosidic phosphoramidite building block **2** bearing two phthaloyl protected aminooxy groups was utilized. After the assembly of the chain and tethering of a fluorescent dye to the 5′-terminus, the aldehyde-tethered sugar ligands were attached to the deprotected aminooxy groups by on-support oximation. Three fluorescein-labeled phosphorothioate oligonucleotide glycoconjugates (*28*−*30*) were prepared containing two, four, or six hyaluronan ligands. The influence of the hyaluronan moieties on the cellular uptake of the thioated oligonucleotides was tested in a cell line expressing the hyaluronan receptor CD44.

EXPERIMENTAL PROCEDURES

General Methods and Materials. CH_2Cl_2, MeCN, and pyridine were dried over 4 Å molecular sieves. Zinc dust was activated just before use with 5% aqueous HCl, washed with

water, and dried. The NMR spectra of **1**, **4**−**6**, and **9**−**13** were recorded at 500 and 600 MHz. The chemical shifts are given in ppm, using internal TMS or solvent residual signal as a reference (*41*). Appropriate 2D NMR methods, e.g., COSY, HSQC, and HMBC, were used for the assignment of signals. RP HPLC analyses were performed on Thermo Hypersil Hypurity C18 (150 × 4.6 mm, 5 μm, protocol A) or Thermo Hypersil C18 (250 × 4.6 mm, 5 μm, protocol B) analytical columns at a flow rate of 1 mL min^{-1}. A gradient elution from 0% to 30% MeCN in 0.05 mol L^{-1} NH_4OAc buffer over 30 min (protocol A) or a gradient elution from 0% to 50% MeCN in 0.1 mol L^{-1} Et_3NHOAc buffer over 30 min (protocol B) was used. For semipreparative purifications and desalting, a LiChroCART Hypersil ODS column (250 × 10 mm, 5 μm) at a flow rate of 3 mL min^{-1} was used. The detection wavelength was 260 nm. Yields of the purified glycoconjugates **28**−**30** were determined UV-spectrophotometrically at λ = 260 nm using the molar absorptivity calculated for the unstacked oligonucleotides. The molar absorptivity used for the label was 21 000 M^{-1} cm^{-1}. The contributions of the non-nucleosidic building block and saccharide residues to the absorbance at the detection wavelength were ignored.

2-Cyanoethyl 3-(4,4′-Dimethoxytrityloxy)-2,2-bis[3-(phthalimidooxy)propylcarbamoyl]propyl *N*,*N*-Diisopropylphosphoramidite (2). 2 was synthesized as described previously (*40*) except for the following modifications: 2-methoxy-*N*,*N*-bis(3-phthalimidooxypropyl)-1,3-dioxane-5,5-dicarboxamide prepared from *N*,*N*-bis(3-hydroxypropyl)-2-methoxy-1,3-dioxane-5,5-dicarboxamide (9.00 g, 28.1 mmol) by Mitsunobu reaction was purified by crystallization from the reaction mixture (THF) in 65% yield (11.2 g). No recrystallization was carried out. The orthoester protection was then removed by an overnight treatment with 0.1 mol L^{-1} aqueous HCl in dioxane (5:2, v/v). The reaction mixture was neutralized with pyridine and concentrated in vacuo. The product was precipitated by addition of water to obtain 2,2-bis(hydroxymethyl)-*N*,*N*-bis(3-phthalimidooxypropyl)malondiamide in 71% yield (7.28 g). The ^1H and ^{13}C NMR spectra were in accordance with published data (*40*).

Allyl 2,3,4,6-Tetra-*O*-acetyl-β-D-glucopyranoside (3). 3 was synthesized from the commercially available 1,2,3,4,6-penta-*O*-acetyl-β-D-glucopyranose as described in the literature (*42*). The ^1H NMR spectrum was in accordance with the published data.

Allyl 4,6-*O*-Benzylidene-β-D-glucopyranoside (4). Compound **3** (5.33 g, 13.7 mmol) was dissolved in 0.1 mol L^{-1} NaOMe/MeOH solution (50 mL). The mixture was stirred for 1 h, neutralized by addition of strongly acidic cation-exchange resin (Dowex 50WX8−200), and filtered. The filtrate was evaporated to dryness, and the residue was dried in vacuo over P_2O_5. The residue was dissolved in dry MeCN (100 mL), and benzaldehyde dimethylacetal (2.70 mL, 18.0 mmol) and *p*-toluenesulfonic acid (78 mg, 0.41 mmol) were added. The reaction mixture was stirred for 2.5 h, diluted with EtOAc, and washed with water and saturated aqueous $NaHCO_3$. The aqueous layers were extracted with EtOAc, and the combined organic layers were dried over Na_2SO_4, filtered, and evaporated to dryness. The residue was suspended in a small volume of CH_2Cl_2. The product was precipitated (*43*) by addition of ether−hexane (1:2, v/v), filtered, washed with cold ether−hexane, and dried in vacuo to afford **4** as a white solid in 86% yield (3.63 g). ^1H NMR (500 MHz, $CDCl_3$): δ = 7.50−7.47 (m, 2H, Ph); 7.39−7.35 (m, 3H, Ph); 5.94 (m, 1H, CH═); 5.53 (s, 1H, C*H*Ph); 5.34 (m, 1H, ═CH_2); 5.25 (m, 1H, ═CH_2); 4.45 (d, 1H, $J_{1,2}$ = 7.8 Hz, H-1); 4.39 (m, 1H, OC*H*HCH═); 4.34 (dd, 1H, $J_{6a,5}$ = 5.0 Hz, $J_{6a,6b}$ = 10.5 Hz, H-6a); 4.15 (m, 1H, OCH*H*CH═); 3.81 (ddd, 1H, $J_{3,2}$ = 8.9 Hz, $J_{3,4}$ = 9.3 Hz, $J_{3,OH\text{-}3}$ = 2.1 Hz, H-3); 3.78 (dd, 1H, $J_{6b,5}$ = 10.1 Hz, $J_{6b,6a}$ = 10.5 Hz, H-6b); 3.55 (dd, 1H, $J_{4,3}$ = 9.3 Hz, $J_{4,5}$ = 9.3 Hz, H-4); 3.53 (ddd, 1H, $J_{2,1}$ = 7.8 Hz, $J_{2,3}$ = 8.9 Hz, $J_{2,OH\text{-}2}$ = 2.4 Hz, H-2); 3.45 (ddd, 1H, $J_{5,6a}$ = 5.0 Hz, $J_{5,6b}$ = 10.1 Hz, $J_{5,4}$ = 9.3 Hz, H-5); 2.91 (d, 1H, $J_{OH\text{-}3,3}$ = 2.1 Hz, OH-3); 2.78 (d, 1H, $J_{OH\text{-}2,2}$ = 2.4 Hz, OH-2) ppm; ^{13}C NMR (125 MHz, $CDCl_3$): δ = 137.1 (Ph); 133.5 (CH═); 129.4, 128.5, and 126.4 (Ph); 118.6 (═CH_2); 102.2 (C-1); 102.1 (*C*HPh); 80.7 (C-4); 74.6 (C-2); 73.3 (C-3); 70.8 (O*C*H_2CH═); 68.8 (C-6); 66.5 (C-5) ppm; HRMS (EI^+): M^+ requires 308.1260, found 308.1251.

Allyl 2,3-Di-*O*-acetyl-4,6-*O*-benzylidene-β-D-glucopyranoside (5). Compound **4** (3.63 g, 11.8 mmol) was acetylated as described previously (*43*) to give **5** as a white powder in 96% yield (4.43 g). ^1H NMR (500 MHz, $CDCl_3$): δ = 7.45−7.42 (m, 2H, Ph); 7.38−7.34 (m, 3H, Ph); 5.85 (m, 1H, CH═); 5.51 (s, 1H, C*H*Ph); 5.32 (dd, 1H, $J_{3,2}$ = 9.4 Hz, $J_{3,4}$ = 9.6 Hz, H-3); 5.29 (m, 1H, ═CH_2); 5.21 (m, 1H, ═CH_2); 5.04 (dd, 1H, $J_{2,1}$ = 7.9 Hz, $J_{2,3}$ = 9.4 Hz, H-2); 4.64 (d, 1H, $J_{1,2}$ = 7.9 Hz, H-1); 4.37 (dd, 1H, $J_{6a,5}$ = 5.0 Hz, $J_{6a,6b}$ = 10.6 Hz, H-6a); 4.34 (m, 1H, OC*H*HCH═); 4.11 (m, 1H, OCH*H*CH═); 3.81 (dd, 1H, $J_{6b,5}$ = 10.0 Hz, $J_{6b,6a}$ = 10.6 Hz, H-6b); 3.71 [dd, 1H, $J_{4,3}$ = 9.6 Hz, $J_{4,5}$ = 9.5 Hz (average), H-4]; 3.52 [ddd, 1H, $J_{5,4}$ = 9.5 Hz (average), $J_{5,6a}$ = 5.0 Hz, $J_{5,6b}$ = 10.0 Hz, H-5]; 2.07 and 2.05 (2 × s, each 3H, 2 × CH_3, Ac) ppm; ^{13}C NMR (125 MHz, $CDCl_3$): δ = 170.3 and 169.7 (CO, Ac); 136.9 (Ph); 133.4 (CH═); 129.3, 128.4, and 126.3 (Ph); 117.8 (═CH_2); 101.7 (*C*HPh); 100.4 (C-1); 78.5 (C-4); 72.4 (C-2); 71.9 (C-3); 70.4 (O*C*H_2CH═); 68.7 (C-6); 66.5 (C-5); 21.0 and 20.9 (CH_3, Ac) ppm; HRMS (EI^+): M^+ requires 392.1471, found 392.1462.

Allyl 2,3-Di-*O*-acetyl-6-*O*-benzyl-β-D-glucopyranoside (6). Compound **5** (4.43 g, 11.3 mmol) was dissolved in CH_2Cl_2 (45 mL) and cooled to 0 °C. Triethylsilane (8.97 mL, 56.5 mmol) was added, followed by slow addition of trifluoroacetic acid (4.35 mL, 56.5 mmol). After 2 h stirring at the same temperature, CH_2Cl_2 was added and the organic layer was washed with saturated aqueous $NaHCO_3$ and brine. The aqueous layers were extracted with CH_2Cl_2, and the combined organic layers were dried over Na_2SO_4, filtered, and evaporated to dryness. Purification by silica gel chromatography (40% EtOAc in petroleum ether) gave **6** as a colorless oil in 91% yield (4.07 g). ^1H NMR (600 MHz, $CDCl_3$): δ = 7.36−7.29 (m, 5H, Ph); 5.84 (m, 1H, CH═); 5.26 (m, 1H, ═CH_2); 5.18 (m, 1H, ═CH_2); 5.05 (dd, 1H, $J_{3,2}$ = 9.7 Hz, $J_{3,4}$ = 9.2 Hz, H-3); 4.96 (dd, 1H, $J_{2,1}$ = 7.9 Hz, $J_{2,3}$ = 9.7 Hz, H-2); 4.62 (d, 1H, J_{gem} = 12.0 Hz, C*H*HPh), 4.57 (d, 1H, J_{gem} = 12.0 Hz, CH*H*Ph); 4.52 (d, 1H, $J_{1,2}$ = 7.9 Hz, H-1); 4.32 (m, 1H, OC*H*HCH═); 4.08 (m, 1H, OCH*H*CH═); 3.79 (dd, 1H, $J_{6a,5}$ = 5.0 Hz, $J_{6a,6b}$ = 10.5 Hz, H-6a); 3.77 (dd, 1H, $J_{6b,5}$ = 5.0 Hz, $J_{6b,6a}$ = 10.5 Hz, H-6b); 3.75 (m, 1H, H-4); 3.53 (ddd, 1H, $J_{5,4}$ = 9.2 Hz, $J_{5,6a}$ = 5.0

Hz, $J_{5,6b}$ = 5.0 Hz, H-5); 3.01 (br, 1H, OH); 2.08 and 2.05 (2 × s, each 3H, 2 × CH_3, Ac) ppm; ^{13}C NMR (150 MHz, $CDCl_3$): δ = 171.3 and 169.6 (CO, Ac); 137.5 (Ph); 133.5 (CH═); 128.5, 127.9, and 127.8 (Ph); 117.4 (═CH_2); 99.6 (C-1); 75.7 (C-3); 74.0 (C-5); 73.8 (*C*H_2Ph); 71.3 (C-2); 70.9 (C-4); 70.2 (C-6); 69.9 (O*C*H_2CH═); 20.9 and 20.8 (CH_3, Ac) ppm; HRMS (ESI^+): $[M + Na]^+$ requires 417.1525, found 417.1529.

3,4,6-Tri-*O*-acetyl-2-deoxy-2-trichloroacetamido-α-D-glucopyranosyl Trichloroacetimidate (7). **7** was synthesized as described in the literature (*44*). The ^{1}H NMR spectrum was in accordance with published data (*44*)

3,4,6-Tri-*O*-acetyl-2-deoxy-2-(2,2,2-trichloroethoxycarboxamido)-α-D-glucopyranosyl Trichloroacetimidate (8). **8** was synthesized as described in the literature (*45*). The ^{1}H NMR spectrum was in accordance with published data (*46*).

(3,4,6-Tri-*O*-acetyl-2-deoxy-2-trichloroacetamido-β-D-glucopyranosyl)-(1→4)-(allyl 2,3-di-*O*-acetyl-6-*O*-benzyl-β-D-glucopyranoside) (9). Trichloroacetimidate **7** (603 mg, 1.01 mmol) and compound **6** (317 mg, 0.804 mmol) were combined and dried by repeated co-evaporations with toluene. The mixture was dissolved in dry CH_2Cl_2 (9 mL) and cooled to 0 °C, after which trimethylsilyl trifluoromethanesulfonate (TMSOTf) (14 μL, 0.077 mmol) was added. Upon completion of the reaction (40 min), triethylamine (100 μL) was added and the solvents were removed in vacuo. The residue was purified by silica gel chromatography (15% EtOAc in CH_2Cl_2) to give **9** as yellowish foam in 95% yield (630 mg). ^{1}H NMR (500 MHz, $CDCl_3$): δ = 7.47−7.40 (m, 5H, Ph); 6.37 (d, 1H, $J_{NH,2'}$ = 8.6 Hz, NH); 5.84 (m, 1H, CH═); 5.25 (m, 1H, ═CH_2); 5.18 (m, 1H, ═CH_2); 5.14−5.08 (m, 2H, H-3 and H-3′); 4.99−4.95 (m, 2H, H-2 and H-4′); 4.81 (d, 1H, J_{gem} = 12.0 Hz, C*H*HPh); 4.49 (d, 1H, $J_{1',2'}$ = 8.4 Hz, H-1′); 4.47 (d, 1H, $J_{1,2}$ = 7.9 Hz, H-1); 4.45 (d, 1H, J_{gem} = 12.0 Hz, CH*H*Ph); 4.36 (dd, 1H, $J_{6a',5'}$ = 4.5 Hz, $J_{6a',6b'}$ = 12.5 Hz, H-6a′); 4.32 (m, 1H, OC*H*HCH═); 4.07 (m, 1H, OCH*H*CH═); 4.01 (m, 1H, H-4); 3.98 (dd, 1H, $J_{6b',5'}$ = 2.1 Hz, $J_{6b',6a'}$ = 12.5 Hz, H-6b′); 3.72−3.63 (m, 3H, H-2′ and 2 × H-6); 3.44−3.40 (m, 2H, H-5′ and H-5); 2.07 (s, 3H, CH_3, Ac); 2.03 (s, 6H, 2 × CH_3, Ac); 2.01 and 1.98 (2 × s, each 3H, 2 × CH_3, Ac) ppm; ^{13}C NMR (125 MHz, $CDCl_3$): δ = 170.6, 170.6, 170.3, 169.7, and 169.5 (CO, Ac); 161.6 (*C*OCCl_3) 137.8 (Ph); 133.6 (CH═); 129.0, 128.8, and 128.7 (Ph); 117.4 (═CH_2); 99.8 (C-1); 99.0 (C-1′); 92.3 (CCl_3); 74.3 (C-4 and C-5); 73.6 (*C*H_2Ph); 72.8 (C-3); 71.8 (C-5′); 71.6 (C-2); 71.4 (C-3′); 70.0 (O*C*H_2CH═); 68.2 (C-4′); 67.4 (C-6); 61.7 (C-6′); 56.5 (C-2′); 20.8, 20.8, 20.7, 20.7, and 20.6 (CH_3, Ac) ppm; HRMS (ESI^+): $[M + Na]^+$ requires 850.1437, found 850.1457.

[3,4,6-Tri-*O*-acetyl-2-deoxy-2-(2,2,2-trichloroethoxycarboxamido)-β-D-glucopyranosyl]-(1→4)-(allyl 2,3-di-O-acetyl-6-O-benzyl-β-D-glucopyranoside) (10). Trichloroacetimidate **8** (1.00 g, 1.60 mmol) was reacted with **6** (485 mg, 1.23 mmol) as described for **9**. The product was purified by silica gel chromatography (15% EtOAc in CH_2Cl_2) to give **10** as yellow foam in 58% yield (608 mg). ^{1}H NMR (500 MHz, $CDCl_3$): δ = 7.53−7.43 (m, 5H, Ph); 5.84 (m, 1H, CH═); 5.26 (m, 1H, ═CH_2); 5.19 (m, 1H, ═CH_2); 5.10 (dd, 1H, $J_{3,2}$ = 9.8 Hz, $J_{3,4}$ = 9.3 Hz, H-3); 4.96 (dd, 1H, $J_{2,1}$ = 8.0 Hz, $J_{2,3}$ = 9.8 Hz, H-2); 4.92−4.81 (m, 3H, H-4′, C*H*HCCl_3 and H-3′); 4.71 and 4.63 (2 × d, each 1H, J_{gem} = 12.1 Hz, CH_2Ph); 4.46 (d, 1H, $J_{1,2}$ = 8.0 Hz, H-1); 4.39−4.32 (m, 3H, CH*H*CCl_3, H-6a′ and OC*H*HCH═); 4.23 (d, 1H, $J_{1',2'}$ = 8.3 Hz, H-1′); 4.10−4.06 (m, 2H, OCH*H*CH═ and NH); 4.00−3.93 (m, 2H, H-6b′ and H-4); 3.71 (dd, 1H, $J_{6a,5}$ = 2.7 Hz, $J_{6a,6b}$ = 10.9 Hz, H-6a); 3.58 (m, 1H, H-6b); 3.51−3.44 (m, 2H, H-2′ and H-5′); 3.38 (m, 1H, H-5); 2.07, 2.02, 2.02, 1.99, and 1.97 (5 × s, each 3H, 5 × CH_3, Ac) ppm; ^{13}C NMR (125 MHz, $CDCl_3$): δ = 170.7, 170.4, 170.3, 169.7, and 169.6 (CO, Ac); 153.8 (NHCO) 137.5 (Ph); 133.6 (CH═); 129.4, 129.2, and 129.2 (Ph); 117.5 (═CH_2); 100.5 (C-1′); 99.8 (C-1); 95.6 (CCl_3); 75.0 (C-4); 74.6 (*C*H_2PH); 74.2 (C-5); 73.8 (*C*H_2CCl_3); 72.8 (C-3); 72.3 (C-3′); 71.7 (C-2); 71.5 (C-5′); 70.0 (O*C*H_2CH═); 68.5 (C-4′); 66.9 (C-6); 61.8 (C-6′); 56.0 (C-2′); 20.8, 20.8, 20.7, 20.7, and 20.7 (CH_3, Ac) ppm; HRMS (ESI^+): $[M + Na]^+$ requires 880.1543, found 880.1570.

(2-Acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosyl)-(1→4)-(allyl 2,3-di-*O*-acetyl-6-*O*-benzyl-β-D-glucopyranoside) (11). Method A. A solution of **9** (125 mg, 151 μmol) and acetic acid (380 μL) in dry CH_2Cl_2 (9 mL) was treated with freshly activated zinc dust (380 mg). After 72 h, the reaction mixture was filtered and the filtrate was co-evaporated with toluene. The product was purified by silica gel chromatography (3% *i*-PrOH in CH_2Cl_2) to give **11** as white solid flakes in 85% yield (92 mg). ^{1}H NMR (500 MHz, $CDCl_3$): δ = 7.48−7.42 (m, 5H, Ph); 5.84 (m, 1H, CH═); 5.26 (m, 1H, ═CH_2); 5.19 (m, 1H, ═CH_2); 5.11 (dd, 1H, $J_{3,2}$ = 9.7 Hz, $J_{3,4}$ = 9.3 Hz, H-3); 5.03 (dd, 1H, $J_{3',2'}$ = 10.4 Hz, $J_{3',4'}$ = 9.3 Hz, H-3′); 4.95 (dd, 1H, $J_{2,1}$ = 8.0 Hz, $J_{2,3}$ = 9.7 Hz, H-2); 4.94 (dd, 1H, $J_{4',3'}$ = 9.3 Hz, $J_{4',5'}$ = 10.0 Hz, H-4′); 4.87 (d, 1H, $J_{NH,2'}$ = 8.9 Hz, NH); 4.83 (d, 1H, J_{gem} = 12.1 Hz, C*H*HPh); 4.50 (d, 1H, $J_{1',2'}$ = 8.4 Hz, H-1′); 4.47 (d, 1H, $J_{1,2}$ = 8.0 Hz; H-1); 4.45 (d, 1H, J_{gem} = 12.1 Hz, CH*H*Ph); 4.35 (dd, 1H, $J_{6a',5'}$ = 4.5 Hz, $J_{6a'6b'}$ = 12.4 Hz, H-6a′); 4.33 (m, 1H, OC*H*HCH═); 4.08 (m, 1H, OCH*H*CH═); 3.98 (dd, 1H, $J_{6b',5'}$ = 2.2 Hz, $J_{6b',6a'}$ = 12.4 Hz, H-6b′); 3.96 (dd, 1H, $J_{4,3}$ = 9.3 Hz, $J_{4,5}$ = 9.9 Hz, H-4); 3.68 (ddd, 1H, $J_{2',1'}$ = 8.4 Hz, $J_{2',3'}$ = 10.4 Hz, $J_{2',NH}$ = 8.9 Hz, H-2′); 3.63 (d, 2H, $J_{6,5}$ = 2.4 Hz, H-6); 3.50 (ddd, 1H, $J_{5',4'}$ = 10.0 Hz, $J_{5',6a'}$ = 4.5 Hz, $J_{5',6b'}$ = 2.2 Hz, H-5′); 3.45 (dt, 1H, $J_{5,4}$ = 9.9 Hz, $J_{5,6}$ = 2.4 Hz, H-5); 2.06, 2.03, 2.02, 2.00, and 1.98 (5 × s, each 3H, 5 × CH_3, Ac); 1.73 (s, 3H, CH_3, NHAc) ppm; ^{13}C NMR (125 MHz, $CDCl_3$): δ = 170.6, 170.2, 169.8, 169.7, and 169.5 (CO, Ac); 137.8 (Ph); 133.6 (CH═); 129.0, 128.9, and 128.8 (Ph); 117.5 (═CH_2); 100.1 (C-1′); 99.7 (C-1); 74.9 (C-4); 74.3 (C-5); 73.7 (*C*H_2Ph); 72.9 (C-3); 72.5 (C-3′); 71.7 (C-2); 71.5 (C-5′); 69.9 (O*C*H_2CH═); 68.4 (C-4′); 67.3 (C-6); 61.8 (C-6′); 54.7 (C-2′); 23.2 (CH_3, NHAc); 20.8, 20.7, 20.7, and 20.7 (CH_3, Ac) ppm; HRMS (FAB^+): M^+ requires 724.2817, found 724.2807. Method B. A solution of **10** (147 mg, 172 μmol) in acetic anhydride (5 mL) was treated with freshly activated zinc dust (300 mg). The reaction mixture was stirred overnight and filtered. The filtrate was co-evaporated with toluene and the product was purified as described above in Method A to give **11** in 80% yield (99 mg).

(2-Acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosyl)-(1→4)-(allyl 2,3-di-*O*-acetyl-β-D-glucopyranoside) (12). A mixture of benzyl ether **11** (2.04 g, 2.82 mmol) and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) (3.20 g, 14.1 mmol) in dry CH_2Cl_2 (80 mL) was refluxed for 48 h. To cleave the dimeric side product formed during refluxing, water (8 mL) was added and the stirring was continued for 2 h at room temperature. The mixture was diluted with CH_2Cl_2, and the organic layer was washed with saturated aqueous $NaHCO_3$ and brine. The aqueous layers were extracted with CH_2Cl_2, and the combined organic layers were dried over Na_2SO_4, filtered, and evaporated to dryness. Purification by silica gel chromatography (7% *i*-PrOH in CH_2Cl_2) gave **12** as white solid in 90% yield (1.60 g). ^{1}H NMR (500 MHz, $CDCl_3$): δ = 6.21 (d, 1H, $J_{NH,2'}$ = 8.9 Hz, NH); 5.84 (m, 1H, CH═); 5.28−5.18 (m, 2H, ═CH_2); 5.24 [dd, 1H, $J_{3',2'}$ = 10.5 Hz, $J_{3',4'}$ = 9.4 Hz (average), H-3′]; 5.20 (dd, 1H, $J_{3,2}$ = 9.7 Hz, $J_{3,4}$ = 9.2 Hz, H-3); 5.05 [dd, 1H, $J_{4',3'}$ = 9.4 Hz (average), $J_{4',5'}$ = 10.0 Hz, H-4′]; 4.91 (dd, 1H, $J_{2,1}$ = 8.0 Hz, $J_{2,3}$ = 9.7 Hz, H-2); 4.78 (d, 1H, $J_{1',2'}$ = 8.4 Hz, H-1′); 4.54 (d, 1H, $J_{1,2}$ = 8.0 Hz, H-1); 4.37 (dd, 1H, $J_{6a',5'}$ = 4.4 Hz, $J_{6a',6b'}$ = 12.4 Hz, H-6a′); 4.31 (m, 1H, OC*H*HCH═); 4.09 (m, 1H, OCH*H*CH═); 4.04 [dd, 1H, $J_{6b',5'}$ = 2.3 Hz (average), $J_{6b',6a'}$ = 12.4 Hz, H-6b′]; 3.95 (dd, 1H, $J_{4,3}$ = 9.2

Hz, $J_{4,5}$ = 9.9 Hz, H-4); 3.92−3.85 (m, 1H, H-6a); 3.86 (ddd, 1H, $J_{2',1'}$ = 8.4 Hz, $J_{2',3'}$ = 10.5 Hz, $J_{2',NH}$ = 8.9 Hz, H-2′); 3.81−3.70 (m, 1H, H-6b); 3.72 [ddd, 1H, $J_{5',4'}$ = 10.0 Hz, $J_{5',6a'}$ = 4.4 Hz, $J_{5',6b'}$ = 2.3 Hz (average), H-5′]; 3.43 (m, 1H, H-5); 2.61 (br, 1H, OH); 2.08, 2.04, 2.03, 2.02, 2.00, and 1.95 (6 × s, each 3H, 6 × CH_3, Ac) ppm; ^{13}C NMR (125 MHz, $CDCl_3$): δ = 171.2, 170.7, 170.6, 170.2, 169.8, and 169.5 (CO, Ac); 133.5 (CH═); 117.7 (═CH_2); 101.1 (C-1′); 99.8 (C-1); 75.5 (C-4); 75.0 (C-5); 73.0 (C-3); 72.6 (C-3′); 71.9 (C-2); 71.8 (C-5′); 70.3 (O*C*H_2CH═); 68.3 (C-4′); 62.0 (C-6′); 60.5 (C-6); 55.0 (C-2′); 23.3 (CH_3, NHAc); 20.8, 20.8, 20.8, and 20.7 (CH_3, Ac) ppm; HRMS (ESI^+): $[M + H]^+$ requires 634.2347, found 634.2356.

(2-Acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosyl)-(1→4)-(allyl 2,3-di-*O*-acetyl-β-D-glucopyranosiduronic Acid) (13). Compound **12** (520 mg, 0.820 mmol) was dissolved in wet MeCN (5 mL, 0.8 v % water) and cooled to 0 °C. A solution of H_5IO_6/CrO_3 (5 mL, 2.5 equiv/1.1 mol % in 0.8 v % water/MeCN) was added portionwise, and the reaction was allowed to proceed at 0 °C for 3 h. The reaction was quenched by adding aqueous Na_2HPO_4 (1.95 g in 25 mL water). Water was added and organic side products were removed by repeated extractions with CH_2Cl_2. The aqueous layer was acidified to pH 3.0 by addition of 1 mol L^{-1} HCl, and the product was extracted in CH_2Cl_2. The organic layers were combined, dried over Na_2SO_4, filtered, and evaporated to dryness to afford **13** as white solid in 80% yield (423 mg). ^{1}H NMR (500 MHz, $(CD_3)_2SO$): δ = 13.11 (br, 1H, COOH); 7.46 (d, 1H, $J_{NH,2'}$ = 8.9 Hz, NH); 5.83 (m, 1H, CH═); 5.24−5.13 (m, 2H, ═CH_2); 5.20 (dd, 1H, $J_{3',2'}$ = 10.4 Hz, $J_{3',4'}$ = 9.4 Hz, H-3′); 5.15 [dd, 1H, $J_{3,2}$ = 9.5 Hz, $J_{3,4}$ = 9.1 Hz (average), H-3]; 4.83 (d, 1H, $J_{1,2}$ = 7.9 Hz, H-1); 4.79 (dd, 1H, $J_{4',3'}$ = 9.4 Hz, $J_{4',5'}$ = 10.1 Hz, H-4′); 4.75 (d, 1H, $J_{1',2'}$ = 8.3 Hz, H-1′); 4.70 (dd, 1H, $J_{2,1}$ = 7.9 Hz, $J_{2,3}$ = 9.5 Hz, H-2); 4.26 (dd, 1H, $J_{6a',5'}$ = 4.2 Hz, $J_{6a',6b'}$ = 12.4 Hz, H-6a′); 4.20 (m, 1H, OC*H*HCH═); 4.08 (d, 1H, $J_{5,4}$ = 9.4 Hz, H-5); 4.02 (m, 1H, OCH*H*CH═); 3.94 [dd, 1H, $J_{4,3}$ = 9.1 Hz (average), $J_{4,5}$ = 9.4 Hz, H-4]; 3.92 [dd, 1H, $J_{6b',5'}$ = 2.3 Hz (average), $J_{6b',6a'}$ = 12.4 Hz, H-6b′]; 3.79 [ddd, 1H, $J_{5',4'}$ =10.1 Hz, $J_{5',6a'}$ = 4.2 Hz, $J_{5',6b'}$ = 2.3 Hz (average), H-5′]; 3.46 (ddd, 1H, $J_{2',1'}$ = 8.3 Hz, $J_{2',3'}$ = 10.4 Hz, $J_{2',NH}$ = 8.9 Hz, H-2′); 2.00, 1.98, 1.97, 1.94, and 1.89 (5 × s, each 3H, 5 × CH_3, Ac); 1.74 (s, 3H, CH_3, NHAc) ppm; ^{13}C NMR (125 MHz, $(CD_3)_2SO$): δ = 170.0, 169.6, 169.3, 169.3, 169.2, 169.1, and 168.6 (CO, Ac, and CO_2H); 134.0 (CH═); 116.7 (═CH_2); 100.1 (C-1′); 99.1 (C-1); 76.5 (C-4); 73.5 (C-5); 72.2 (C-3′); 71.9 (C-3); 71.1 (C-2); 70.5 (C-5′); 69.4 (O*C*H_2CH═); 68.3 (C-4′); 61.7 (C-6′); 53.8 (C-2′); 22.7 (CH_3, NHAc); 20.4, 20.4, 20.3, and 20.3 (CH_3, Ac) ppm; HRMS (ESI^+): $[M + Na]^+$ requires 670.1959, found 670.1983.

(2-Acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosyl)-(1→4)-(2-oxoethyl 2,3-di-*O*-acetyl-β-D-glucopyranosiduronic Acid) (1). To a solution of allyl disaccharide **13** (381 mg, 0.589 mmol) in dioxane−water (4:1, v/v) (8 mL) OsO_4 (52 μL, 2.5 wt% solution in 2-methyl-2-propanol, 0.0042 mmol) was added. The solution was stirred vigorously for 1 h. The solution turned brownish, which indicated the formation of the osmate ester. $NaIO_4$ (252 mg, 1.18 mmol) was added over 20 min, and stirring was continued for additional 1.5 h. Volatiles were removed, and the residue was dissolved in a small amount of water and acidified to pH 3.0 by the addition of 1 mol L^{-1} HCl. The crude product mixture was evaporated to dryness and purified by silica gel chromatography (20% MeOH in CH_2Cl_2) to give **1** as white solid in 79% yield (304 mg). The product exhibited NMR signals both as a hydrate and as an aldehyde in 9:1 ratio. Only the major form (hydrate) is assigned here (for the structure and atom numbering, see Supporting Information). ^{1}H NMR (500 MHz, 20% D_2O in CD_3CN): δ = 5.12 (dd, 1H, $J_{3',2'}$ = 10.4 Hz, $J_{3',4'}$ = 9.5 Hz H-3′); 5.08 (dd, 1H, $J_{3,2}$ = 9.7 Hz, $J_{3,4}$ = 9.3 Hz, H-3); 4.99 (t, 1H, $J_{2'',1a''}$ = $J_{2'',1b''}$ = 5.0 Hz, H-2"); 4.92 (dd, 1H, $J_{4',3'}$ = 9.5 Hz, $J_{4',5'}$ = 10.0 Hz, H-4′); 4.83 (dd, 1H, $J_{2,1}$ = 8.0 Hz, $J_{2,3}$ = 9.7 Hz, H-2); 4.76 (d, 1H, $J_{1',2'}$ = 8.5 Hz, H-1′); 4.67 (d, 1H, $J_{1,2}$ = 8.0 Hz, H-1); 4.30 (dd, 1H, $J_{6a',5'}$ = 4.1 Hz, $J_{6a',6b'}$ = 12.5 Hz, H-6a′); 4.03 (dd, 1H, $J_{6b',5'}$ = 2.1 Hz, $J_{6b',6a'}$ = 12.5 Hz, H-6b′); 3.95 (dd, 1H, $J_{4,3}$ = 9.3 Hz, $J_{4,5}$ = 9.7 Hz, H-4); 3.81 (ddd, 1H, $J_{5',4'}$ = 10.0 Hz, $J_{5',6a'}$ = 4.1 Hz, $J_{5',6b'}$ = 2.1 Hz, H-5′); 3.78 (d, 1H, $J_{5,4}$ = 9.7 Hz, H-5); 3.67 (dd, 1H, $J_{1a'',2''}$ = 5.0 Hz, $J_{1a'',1b''}$ = 11.0 Hz, H-1a″); 3.65 (dd, 1H, $J_{2',1'}$ = 8.5 Hz, $J_{2',3'}$ = 10.4 Hz, H-2′); 3.54 (dd, 1H, $J_{1b'',2''}$ = 5.0 Hz, $J_{1b'',1a''}$ = 11.0 Hz, H-1b″); 2.03 (s, 6H, 2 × CH_3, Ac); 2.01, 1.97, and 1.95 (3 × s, each 3H, 3 × CH_3, Ac); 1.90 (s, 3H, CH_3, NHAc) ppm; ^{13}C NMR (125 MHz, 20% D_2O in CD_3CN): δ = 173.9 (CO_2H); 173.5 (CONH); 172.0, 172.0, 171.7, 171.4, and 170.9 (CO, Ac); 100.8 (C-1); 100.5 (C-1′); 88.7 (C-2″); 77.9 (C-4); 76.4 (C-5); 73.4 (C-3′); 73.1 (C-1″); 72.8 (C-3); 71.6 (C-2); 71.4 (C-5′); 68.6 (C-4′); 62.2 (C-6′); 54.2 (C-2′); 22.6 (CH_3, NHAc); 20.5, 20.4, 20.3, and 20.3 (CH_3, Ac) ppm; HRMS (ESI^+): $[M + H]^+$ requires 650.1932, found 650.1958.

Table 1. Properties of the Oligothymidine Glycoconjugates (18−21)

entry	oligothymidine glycoconjugate	purity of the crude conjugate[a] [%]	observed mass [g mol^{-1}]	required mass[g mol^{-1}]
1	**18**	46	3279.7	3280.4
2	**19**	43	4189.1	4189.2
3	**20**	47	4493.1	4493.4
4	**21**	30	6009.6	6010.6

[a] Purities according to signal areas in RP HPLC chromatograms of crude mixtures of **18**−**21**.

Oligodeoxyribonucleotide Synthesis. The oligodeoxyribonucleotides were assembled on an Applied Biosystems 392 DNA synthesizer in a 1.0 μmol scale using commercial 1000 Å CPG-succinyl-thymidine support and phosphoramidite chemistry. Phosphoramidite **2** was used as a 0.13 mol L^{-1} solution in dry MeCN with a coupling time of 600 s. After coupling of **2**, 6 additional detritylation cycles were carried out. Otherwise, standard protocols were employed. The coupling efficiencies were followed by DMTr-cation assay.

Synthesis of Oligothymidine Glycoconjugates 18−21. Protected oligonucleotide sequences 5′-d(TXT TTT TT)-3′ (**14**), 5′-d(TXX TTT TT)-3′ (**15**), 5′-d(TXT XTT TTT)-3′ (**16**), and 5′-d(TXT XTX TTT TT)-3′ (**17**), where X stands for the non-nucleosidic building block **2**, were synthesized as described above. Small aliquots of the support-bound oligonucleotides were treated with 0.5 mol L^{-1} hydrazinium acetate solution (0.124/4/1, $NH_2NH_2 \cdot H_2O$/pyridine/AcOH, v/v/v) for 30 min, washed with pyridine and MeCN, and dried. The supports were transferred to microcentrifuge tubes, and a solution of the aldehyde tethered sugar ligand **1** (0.3 mol L^{-1} in 10% H_2O/MeCN) was added. The mixtures were shaken at ambient temperature for either 4 or 18 h [sequences containing one (**14**) or more (**15**−**17**) non-nucleosidic units (*2*), respectively]. The supports were filtered, washed with 10% H_2O in MeCN and MeCN, dried, and treated with concentrated ammonia (33% aqueous NH_3, 3 h at room temperature) to release and deprotect the resulting oligonucleotide glycoconjugates. The crude products (**18**−**21**) were analyzed by RP HPLC (protocol A), and the authenticity of the conjugates was verified by MS(ESI) spectroscopy (properties of **18**−**21**; see Table 1).

Phosphorothioate Oligodeoxyribonucleotide Synthesis. Phosphorothioate oligodeoxyribonucleotides were assembled as described for oligodeoxyribonucleotides except for replacement of oxidation with sulfurization (60 s), which was carried out prior to each capping step using 3-dimethylaminomethyleneamino-1,2,4-dithiazole-5-thione as the sulfurizing reagent. In

addition, a commercial 5′-fluorescein phosphoramidite label, 6-[(3′,6′-di-*O*-pivaloylfluorescein-6-yl)carboxamido]hexyl 2-cyanoethyl *N,N*-diisopropylphosphoramidite (6-FAM), was attached to the 5′-end of the sequences.

Synthesis of Phosphorothioate Oligonucleotide Glycoconjugate 28. Protected phosphorothioate oligonucleotide sequence 5′-(6-FAM)-d(TGG CGT CTT CCA TTT XT)-3′ (**22**), where X stands for the non-nucleosidic building block **2**, was assembled as described above. The support-bound oligonucleotide was treated with hydrazinium acetate for half an hour and then with sugar ligand **1**, as described for the preparation of oligothymidine conjugates **18**−**21.** No degradation of the oligonucleotide was observed. A prolonged reaction time of 6 h was used for the oximation with **1** to obtain **25**. The product was released and deprotected with concentrated ammonia (33% aqueous NH_3, 17 h at 55 °C). Evaporation, dissolution in water, RP HPLC purification (with a gradient elution from 12% to 37% MeCN in 0.1 mol L^{-1} Et_3NHOAc buffer over 18 min), and desalting gave conjugate **28** in 17% overall isolated yield (OD = 28.98). The authenticity of **28** was verified by MS(ESI): M requires 6854.8, found 6852.3.

Synthesis of Phosphorothioate Oligonucleotide Glycoconjugate 29. Conjugate **29** was prepared using sequence 5′-(6-FAM)-d(TGG CGT CTT CCA TTT XTX T)-3′ (**23**). The procedure described for **28** was followed except for a prolonged oximation step (18 h). A gradient elution from 15% to 37% MeCN in 0.1 mol L^{-1} Et_3NHOAc buffer over 16 min was applied to the RP HPLC purification followed by desalting. Conjugate **29** was isolated in 19% overall yield (OD = 33.48).

Synthesis of Phosphorothioate Oligonucleotide Glycoconjugate 30. Conjugate **30** was prepared using sequence 5′-(6-FAM)-d(TGG CGT CTT CCA TTT XTX TXT)-3′ (**24**). The procedure described for **29** was followed except that a steeper gradient elution from 12% to 45% MeCN in 0.1 mol L^{-1} Et_3NHOAc buffer over 16 min was applied to the purification followed by desalting. The isolated yield of **30** was 21% (OD = 40.68).

Synthesis of Reference Oligonucleotides 31 and 32. Two phosphorothioate oligonucleotides, labeled 5′-(6-FAM)-d(TGG CGT CTT CCA TTT)-3′ (**31**) and unlabeled 5′-d(TGG CGT CTT CCA TTT)-3′ (**32**) were synthesized to be used as reference material in the cellular studies. The procedure described above for phosphorothioate oligodeoxyribonucleotide synthesis was followed. Products were released and deprotected with concentrated ammonia (33% aqueous NH_3, 17 h at 55 °C). Evaporation, dissolution in water, RP HPLC purification [with a gradient elution from 25% to 85% MeCN in 0.1 mol L^{-1} Et_3NHOAc buffer over 20 min (**31**) or from 25% to 65% MeCN in 0.1 mol L^{-1} Et_3NHOAc buffer over 18 min (**32**)], and desalting gave the products; authenticity was verified by MS(ESI) spectroscopy. **31**: MS(ESI): M requires 5305.5, found 5302.5. **32**: MS(ESI): M requires 4749.9, found 4749.5.

Cellular Uptake Studies. Phosphorothioate oligonucleotide glycoconjugates **28**−**30** with 5′-fluorescein label were used in the cellular uptake studies. Fluorescein-labeled nonconjugated phosphorothioate oligonucleotide **31** and the corresponding unlabeled parent oligonucleotide **32** were used as negative controls. All freeze−dried oligonucleotides were dissolved in sterile water and diluted with phosphate buffered saline (PBS buffer, pH = 7.5).

Cell Culture. Immortalized human corneal epithelial cells (HCE cells) were grown at 37 °C in humidified air with 5% CO_2, in standard culture medium. Dividing HCE cells have been shown to express the CD44 receptor (*47*). Cells with passage numbers from 20 to 30 were used. All experiments were conducted with undifferentiated cells. The standard medium consisted of DMEM/Ham's F12 (1:1), 15% heat-inactivated fetal bovine serum (FBS), 0.3 mg mL^{-1} L-glutamine, 0.1 mg mL^{-1} streptomycin, 1000 IU mL^{-1} penicillin, 5 μg mL^{-1} insulin (human recombinant), 0.1 μg mL^{-1} cholera toxin, 10 ng mL^{-1} epidermal growth factor (EGF, human), and 0.5% dimethyl sulfoxide.

Cellular Uptake Studies with Flow Cytometric Analysis. HCE cells were seeded onto 24-well plates at a density of 200 000 cells/well 24 h prior to the uptake experiment. After washing and adding culture medium without serum to the cells, HCE cells were incubated in the presence of conjugates (0.2 or 2 nmol of conjugate/300 μL concentration). Labeled (*31*) and unlabeled (*32*) non-conjugated oligonucleotides were used as negative controls. After one hour, the cells were washed twice with PBS buffer, once with 1 mol L^{-1} NaCl solution (pH = 7.5), and again twice with PBS buffer to remove all conjugates attached to the cellular plasma membrane. The cells were then detached from the wells with trypsin−EDTA solution and fixed by incubation with 1% paraformaldehyde (PFA, pH = 7.5). Then, the cells were washed twice with 1% PFA and stored at 4 °C until analysis by flow cytometry (BD LSR II, BD Biosciences) with 10 000 events collected for each sample. Samples were excited with Coherent Sapphire blue laser (488 nm), and fluorescence of carboxyfluorescein was collected at 515−545 nm. All conjugates were tested in triplicate in two independent experiments. Dot plots and population hierarchy were generated with BD *FACSDiva* software (BD Biosciences).

RESULTS AND DISCUSSION

Synthesis of the Hyaluronan Disaccharide Ligand (1). 2-Acetamido-2-deoxyglycopyranosides are constituents of many naturally occurring oligosaccharides, being most frequently engaged in β-glycosidic linkages. Accordingly, the glycosylation reactions of 2-*N*-acetylated donors have been studied in considerable detail (*48*). While the 2-*O*-acetyl group is an excellent participating protective group, which steers the glycosyl acceptor in a *trans*-1,2-position, the 2-*N*-acetylated donors form cyclic 1,3-oxazolinium intermediates, which are too stable to be opened by the acceptor. To avoid this, highly electron-withdrawing acyl groups, which subsequently can be converted to an acetyl group, are used for the 2-*N*-protection of the glycosyl donor (*49*). We chose to compare the synthetic applicability of the trichloroacetyl (TCA, **7**) and 2,2,2-trichloroethoxycarbonyl (Troc, **8**) protected trichloroacetimidate donors, both of which had previously been reported to undergo β-glycosidic bond formation via a reactive *N*-acyloxazolinium intermediate in good yield. Both donors, **7** (*44*) and **8** (*45*), were synthesized as described in literature.

The glucuronic acid acceptor was introduced into the dimer as a 6-*O*-benzyl precursor (**6**), synthesized as outlined in Scheme 1. Accordingly, commercially available glucopyranose pentaacetate was first converted to fully acetylated allyl β-D-glucopyranoside (**3**) by $BF_3 \cdot OEt_2$ promoted glycosidation in CH_2Cl_2 (*42*), the acetyl groups were removed by methoxide ion catalyzed transesterification in MeOH, and a 4,6-*O*-benzylidene acetal protection was introduced by acid-catalyzed transacetalization with α,α-dimethoxytoluene to obtain **4**. The remaining 3-OH was acetylated, and the benzylidene acetal obtained (**5**) was selectively reduced to the corresponding 6-*O*-benzyl derivative **6** by treatment with trifluoroacetic acid and triethylsilane (*50*).

Glycosidation of donors **7** and **8** with acceptor **6** was performed in CH_2Cl_2 in the presence of a catalytic amount of trimethylsilyl trifluoromethanesulfonate (TMSOTf). The TCA protected disaccharide (**9**) was obtained in a good yield (95%), whereas the yield of the Troc protected disaccharide (**10**) was rather modest (58%). The latter reaction was hampered by the formation of an unidentified side product. The amino protecting

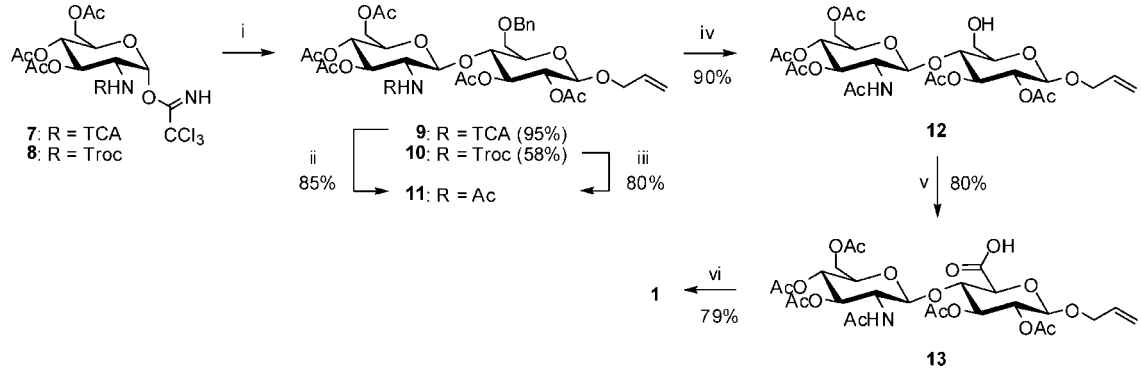
[a] Reagents and conditions: (i) NaOMe, MeOH; (ii) $PhCH(OMe)_2$, p-TsOH, MeCN; (iii) Ac_2O, Py; (iv) Et_3SiH, TFA, CH_2Cl_2

Scheme 2. Synthesis of the Hyaluronan Disaccharide 1[a]



[a] Reagents and conditions: (i) **6**, TMSOTf, CH_2Cl_2; (ii) Zn, AcOH, CH_2Cl_2 (Method A); (iii) Zn, Ac_2O (Method B); (iv) (1) DDQ, CH_2Cl_2, (2) H_2O; (v) H_5IO_6, CrO_3, aq MeCN; (vi) OsO_4, $NaIO_4$, dioxane, H_2O.

groups were transformed to *N*-acetyl group with zinc dust either in AcOH (for **9**, Method A) or in Ac_2O (for **10**, Method B). The reductive dehalogenation of the TCA group, although sluggish, proceeded cleanly and gave the 2-*N*-acetyl protected dimer **11** in 85% yield. Reduction of the Troc group gave only a slightly lower yield (80%), but was accompanied by formation of an intermediate which was difficult to detect by TLC. Oxidative debenzylation of **11** with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) (*51*) was then performed. Two days refluxing in dry CH_2Cl_2 in excess of DDQ (*52*) gave the 6-OH deprotected dimer **12** and a varying amount of a side product which, however, was converted to the desired product upon treatment of the reaction mixture with water. The ^1H NMR and mass spectra suggested the side product to be a dimer of **12** (data not shown). Attempts to perform the oxidation directly in wet dichloromethane failed. Finally, the primary hydroxyl function of **12** was oxidized to a carboxyl group (**13**) with periodic acid in the presence of a catalytic amount of chromium trioxide in wet acetonitrile (*53*). The anomeric aldehyde tether was generated by osmium tetroxide catalyzed periodate oxidation (*54*, *55*), which gave the protected hyaluronan disaccharide **1**.

Synthesis of the Oligothymidine Glycoconjugates (18−21). The previously developed solid-phase oximation (*40*, *56*) was applied to the attachment of the aldehyde-functionalized saccharides to oligonucleotides on a solid support. The method exploits a bis(hydroxymethyl)malondiamide-derived phosphoramidite (**2**), which is inserted in the oligonucleotide chain during normal chain assembly. The building block bears two masked aminooxy groups which, when exposed on support, allow conjugation of aldehyde ligands through stable oxime linkages. To test the applicability of the hyaluronic acid disaccharide **1** to the conjugate formation, four oligonucleotide glycoconjugates (**18**−**21**) were prepared. The non-nucleosidic phorphoramidite building block **2** was synthesized essentially as described previously (*40*) (for the modifications, see Experimental Procedures). Short oligothymidine sequences containing one (**14**), two (**15** and **16**), or three (**17**) intrachain non-nucleosidic units **2** were assembled by standard machine-assisted phosphoramidite chemistry. In addition, the influence of an extra thymidine residue between the adjacent building blocks was studied (**15** and **16**). After the assembly of the oligonucleotide sequences, the phthaloyl protections of the building block were removed by treatment with hydrazinium acetate. The exposed aminooxy groups of the support-bound oligonucleotide were then oximated with the aldehyde-tethered sugar ligand **1** in MeCN containing 10% water to ensure the solubility of the disaccharide. The reaction time was 4 h for conjugate **18**, while conjugates **19**−**21** containing several non-nucleosidic building blocks were obtained by an overnight reaction. The support-bound conjugates were released and deprotected by standard ammonolytic treatment and analyzed by RP HPLC. The RP HPLC profiles of the crude product mixtures are presented in Figure 2. In each case, the desired conjugate was the main product as verified by MS(ESI) spectroscopy (Table 1, entries 1−4). An additional thymidine residue between the adjacent branching units seemed to slightly enhance the coupling efficiency, as seen by comparison of the relative peak areas of conjugates **19** and **20** (Table 1, entries 2 and 3).

Synthesis of the Fluorescently Labeled Phosphorothioate Oligonucleotide Glycoconjugates (28−30). For the cellular uptake studies, three 5′-fluorescein-labeled (6-FAM) phosphorothioate oligonucleotide glycoconjugates (**28**−**30**) were prepared. These contained one, two, or three non-nucleosidic units, i.e., two, four, or six hyaluronan ligands, respectively. Except for the labeling and sulfurization steps, the protocol described above was followed (Scheme 3). For sulfurization, 3-dimethylaminomethyleneamino-1,2,4-dithiazole-5-thione was used. The RP HPLC profiles of the crude product mixtures are presented in Figure 3. Products were purified and desalted by RP HPLC and isolated in 17−21% yield. Additionally, a fluorescein-labeled non-conjugated phosphorothioate oligonucleotide 5′-(6-FAM)-d(TGG CGT CTT CCA TTT)-3′ (**31**) and the corresponding unlabeled parent oligonucleotide 5′-d(TGG CGT CTT CCA TTT)-3′ (**32**) were synthesized for reference materials to be used in the cellular studies. The 15-mer sequence used in these antisense oligonucleotides was targeted against the luciferase gene expression.

The authenticity of the glycoconjugate **28** was verified by MS(ESI) spectroscopy. For larger conjugates (**29** and **30**), the

presence of several acidic hyaluronan moieties hindered the ionization to the extent that no adequate signals could be detected. Acidic oligosaccharides are known to be difficult to analyze using MS due to their instability and inefficient ionization under general ionization and detection conditions (*57*). Susceptibility to fragmentation was also detected during the analysis of simpler oligothymidine glycoconjugates **18**−**21**. However, authenticity of **29** and **30** was convincing on the basis of successful synthesis of the corresponding oligothymidine glycoconjugates (**18**−**21**) and homogeneity of the purified product by HPLC. The conjugates were thus further subjected to cellular uptake studies.

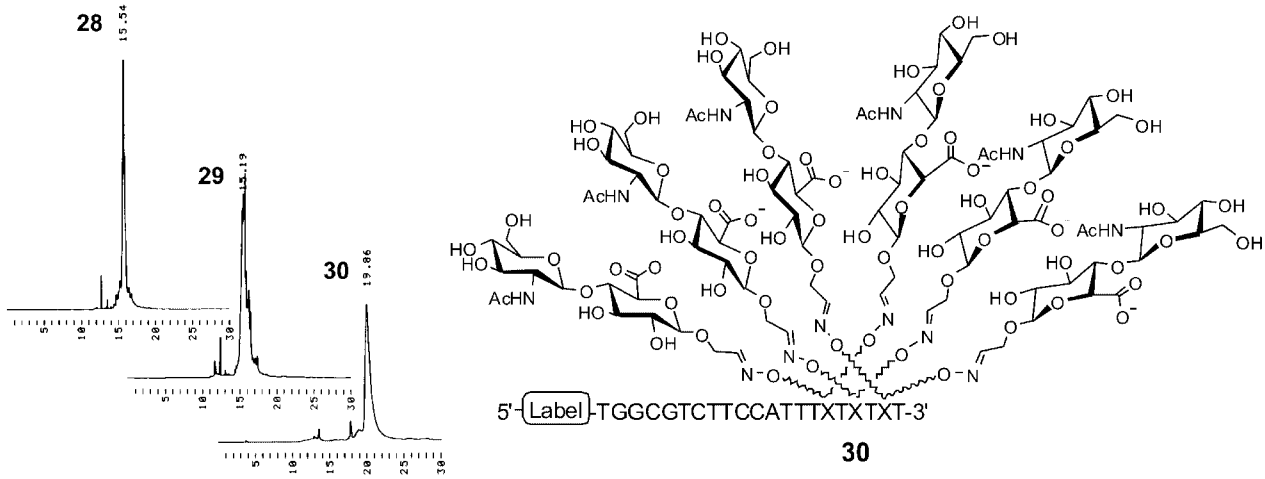

Figure 3. RP HPLC profiles of the crude glycoconjugates **28**−**30**. For the chromatographic conditions, see protocol B in Experimental Procedures. Structure of the conjugate **30** is only shown.

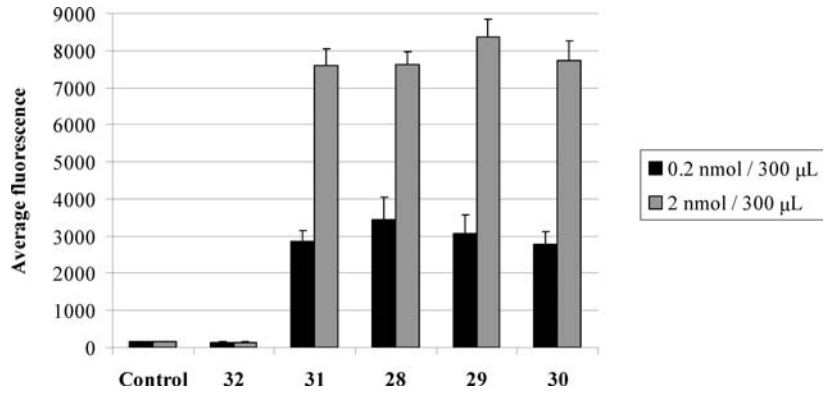

Figure 4. Cellular uptake of fluorescein-labeled conjugates determined by flow cytometry (at 515−545 nm, 488 nm excited). Oligonucleotide conjugates **28**−**30** and control oligonucleotides **31** and **32** were added for HCE cells at dose of 0.2 or 2 nmol/300 μL medium. Results are presented as mean fluorescence in cell. Each data point is a mean of six replicates from two independent experiments (means ± standard deviation, $n = 6$).

Cellular Uptake Studies with Flow Cytometric Analysis. CD44 is the primary cell surface receptor for hyaluronan and binds ligand via a lectin-like fold termed the Link module. The recognition appears to be dominated by hydrogen bonds and van der Waals forces rather than electrostatic or sugar-aromatic stacking interactions (*23*). The rationale in the conjugate design was that the carbohydrate part would bind to CD44, thereby leading to internalization of the conjugate via receptor-mediated endocytosis.

To determine the influence of hyaluronan ligands, the phosphorothioate oligonucleotide glycoconjugates labeled with carboxyfluorescein (**28**−**30**), and labeled (**31**) and unlabeled (**32**) control oligonucleotides were incubated with immortalized human corneal epithelial cell line (HCE) that expresses the cell surface hyaluronan receptor CD44. The incubation was performed under standard conditions (37 °C, 5% CO_2) for one hour in two different concentrations (0.2 or 2 nmol of test compound/300 μL medium). After washing procedures, the fluorescence intensity of the cells was determined by flow cytometry at 515−545 nm. Flow cytometry revealed that the number of fluorescent cells was high and similar both in the cell cultures treated with labeled control oligonucleotide **31** and with oligonucleotide conjugate bearing two (**28**), four (**29**), or six (**30**) hyaluronan ligands (data not shown). The mean fluorescence of the cell cultures treated with labeled control oligonucleotide or any oligonucleotide conjugate was comparable at both oligonucleotide doses (Figure 4).

It has been known for 30 years that hyaluronan fragments are capable of binding cell surface receptors and that the binding depends on the molecular weight of hyaluronan (*58*). The major hyaluronan receptor, CD44, is known to trigger internalization of small hyaluronan fragments, with the minimum size being a hexasaccharide (3 disaccharide units in length) (*59, 60*). Instead, another hyaluronan receptor, toll-like receptor 4 (TLR4), recognizes even shorter tetrasaccharide fragments (*61*), but TLR4 is not expressed on the surface of HCE cell lines (*62*). In the present study, the hyaluronan moieties attached to the oligonucleotide did not improve the cellular delivery of the oligonucleotide. On the contrary, previous study with hyaluronan (<10 kDa) coated DNA complexes demonstrated active CD44-mediated uptake in HCE cells (*47*). Most likely, the hyaluronan moieties attached to the oligonucleotide are too short for efficient recognition and two, four, or six disaccharides attached to the same oligonucleotide do not interact with the receptor similarly as a single hexasaccharide. We do not know the exact mechanism of cellular uptake for unconjugated and hyaluronan-conjugated oligonucleotides, but no benefit was seen by the hyaluronan conjugation. The surprisingly high basic level of oligonucleotide uptake is an interesting finding and may be a cell-specific feature. The cellular entrance may be based on unspecific affinity of phosphorothioate for the cell surface as phosphorothioates are known to have high nonspecific protein binding levels. On the other hand, a sodium chloride washing

procedure should remove the surface-bound and non-internalized oligonucleotides (*63*).

CONCLUSIONS

An efficient synthesis route for novel protected hyaluronic acid disaccharide has been developed. Disaccharides have been used to construct multivalent hyaluronic acid−oligonucleotide glycoconjugates on solid supports. The biological properties of the conjugates have been tested in cellular uptake studies with a cell line expressing the hyaluronan receptor. Series of hyaluronan repeating units attached to the oligonucleotide do not improve cellular delivery of the oligonucleotide. The detected uptake must be unspecific, since the unconjugated control oligonucleotide was taken into the cell on an equivalent basis with the conjugated ones. The hyaluronan moieties are most likely too short for efficient recognition, and perhaps, the same concept with longer hyaluronan chains would yield better delivery. Since the cellular binding and uptake is cell type-dependent, the conjugates could be tested with other cell lines known to express hyaluronan receptor CD44.

Received September 29, 2008; Revised Manuscript Received November 12, 2008

With the increasing demand for confocal and two-photon fluorescence imaging, the availability of reactive probes that possess high two-photon absorptivity, high fluorescence quantum yield, and high photostability is of paramount importance. To address the demand for better-performing probes, we prepared two-photon absorbing amine-reactive fluorenyl-based probes 2-(9,9-bis(2-(2-methoxyethoxy)ethyl)-2-isothiocyanato-9*H*-fluoren-7-yl)benzothiazole (**1**) and 2-(4-(2-(9,9-bis(2-(2-ethoxyethoxy)ethyl)-2-isothiocyanato-9*H*-fluoren-7-yl)vinyl)phenyl)benzothiazole (**2**), incorporating the isothiocyanate as a reactive linker. Probe design was augmented by integrating high optical nonlinearities, increased hydrophilicity, and coupling with reactive functional groups for specific targeting of biomolecules, assuring a better impact on two-photon fluorescence microscopy (2PFM) imaging. The isothiocyanate (NCS) derivatives were conjugated with cyclic peptide RGDfK and Reelin protein. The study of the chemical and photophysical properties of the new labeling reagents, as well as the conjugates, is described. The conjugates displayed high chemical stability and photostability. The NCS derivatives had low fluorescence quantum yields, while their bioconjugates exhibited high fluorescence quantum yields, essentially "lighting up" after conjugation. Conventional and 2PFM imaging and fluorescence lifetime imaging (FLIM) of HeLa, NT2, and H1299 cells, incubated with two-photon absorbing amine-reactive probe (**1**), RGDfK-dye conjugate (**7**), and Reelin-dye conjugate (**6**), was demonstrated.

INTRODUCTION

In the past decade, two-photon fluorescence microscopy (2PFM) has provided several advantages in biological research, including high three-dimensional (3D) spatial resolution as a result of the inherent nonlinear dependence of two-photon fluorescence (2PF) on the illumination intensity (*1*−*4*). In this technique, the excitation volume is limited to the focal plane, minimizing out-of-focus excitation, fluorescence, photobleaching, and photodamage. Near-IR excitation used in 2PFM (*1*) enables deeper imaging into optically thick tissue (*5*) and improves tissue viability (*6*). The inherently low 2PF signal in contrast to one-photon fluorescence (1PF) is due to the small two-photon absorption (2PA) cross sections ($\sim 10^{-50}$ cm^4·s) of the fluorescent probes. This is the motivating factor in the continuing efforts to synthesize fluorescent markers with large 2PA cross sections. A steady increase in the biomedical applications of 2PFM has uncovered the lack of efficient two-photon absorbing fluorescence probes with high specificity. In order to be truly useful for such applications, it is necessary to have not only an imaging component which undergoes strong two-photon absorption (2PA) at wavelengths greater than 700 nm, but also a targeting component which binds the fluorescent probe selectively to the target tissue or organelle.

Currently, only a limited number of 2PA fluorophores, specifically tailored for direct labeling of biomolecules for two-photon induced fluorescence imaging studies, have been reported (*7*−*11*). The most common of these are fluorophores designed for the labeling of lysine residues on proteins with amine-reactive compounds bearing functional groups capable of forming a stable linkage with these biomolecules. Representative labeling functionalities include isothiocyanates and succinimidyl esters for coupling with primary and secondary amines.

Our previous success with fluorene dyes in the field of 2PA (*13*−*19*) encouraged us to further investigate this class of chromophores as two-photon excitable fluorescent labels. Here, we present the synthesis of novel two-photon excitable fluorescent labeling reagents, along with their peptide and bioconjugate analogues. Our strategy consists of building 2PA chromophores containing the isothiocyanate functionality, −N═C═S, capable of forming a stable linkage with biomolecules containing $-NH_2$ amino groups. The chromophores are based on fluorene derivatives containing the benzothiazole motif as an electron-acceptor group. The π-electron conjugation length was increased via the incorporation of a styryl group directly connected to the fluorenyl π-bridge construct.

EXPERIMENTAL SECTION

Materials and Methods. The cyclic peptide (Ar-Gly-Asp-D-Phe-Lys) c(RGDfK) was purchased from Peptides International, Inc. All other chemicals and reagents were purchased from Aldrich or Acros Organics and used as received unless otherwise specified. 2-(7-Nitrofluoren-2-yl)benzothiazole (**A**), 2-iodo-7-nitrofluorene (**D**), and 2-(4-vinylphenyl)benzothiazole **(F)** were prepared as described previously (*13*, *14*, *19*).

^{1}H and ^{13}C NMR spectra were recorded in $CDCl_3$ on a Varian 300 NMR spectrometer (300 MHz for ^{1}H, referenced to TMS at $\delta = 0.0$ ppm and 75 MHz for ^{13}C, referenced to $CDCl_3$ at $\delta = 77.0$ ppm). FT-IR spectra were recorded on a Perkin-Elmer spectrophotometer model PE-1300 F0241. Elemental analyses

were performed at Atlantic Microlab, Inc., Norcross, GA. High-resolution mass spectrometry (HR-MS) analysis was performed in the Department of Chemistry, University of Florida, Gainesville, FL.

*General Synthetic Procedure for Preparation of 2-(9,9-Di(2-(2-methoxyethoxy)ethyl)-7-nitrofluoren-2-yl)benzothiazole (**B**) via Alkylation.* 2-(7-Nitrofluoren-2-yl)-benzothiazole (**A**) (2.18 g, 6.33 mmol), 1-bromo-2-(2-methoxyethoxy)ethane (2.77 g, 15.13 mmol), and KI (0.1 g, 0.65 mmol) were placed into anhydrous DMSO at room temperature. To the stirred solution, freshly powdered KOH (1.43 g, 25.49 mmol) was slowly added, turning the yellow reaction mixture dark green. Reaction progress was monitored by TLC hexanes/EtOAc (65:35). The reaction mixture was poured into distilled water and its organic components extracted with CH_2Cl_2 and dried over $MgSO_4$. Removal of solvent provided a dark orange oil, which was purified via silica gel column chromatography using the eluent system above. Compound B was obtained as a yellow solid (2.5 g, 51% yield, mp 78−79 °C). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.33 (s, 1H), 8.30 (d, 1H), 8.22 (s, 1H), 8.15 (d, 1H), 8.11 (d, 1H), 7.94, (d, 1H), 7.88 (d, 1H), 7.86 (d, 1H), 7.52 (t, 1H), 7.41 (t, 1H), 3.22 (m, 4H, OCH_2), 3.21 (m, 6H, OCH_3), 3.15, (m, 4H, OCH_2), 2.90 and 2.82 (m, 4H, OCH_2), 2.55, (t, 4H, CH_2). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 167.37 (Ar−C═N), 154.17, 151.70, 151.37, 147.67 (CNO_2), 145.78, 140.89, 135.18, 134.59, 127.81, 126.71, 125.66, 123.76, 123.47, 122.60, 121.90, 121.85, 120.60, 119.37, 71.94, 70.25, 67.16, 59.29 (OCH_3), 52.77 (C9), 39.67 (CH_2). Anal. Calcd. for $C_{30}H_{32}N_2O_6S$: C, 65.67; H, 5.88; N 5.11. Found: C, 65.73; H, 5.98; N, 4.96.

*Synthesis of 7-(Benzothiazol-2-yl)-9,9-di(2-(2-methoxyethoxy)-ethyl)fluoren-2-amine (**C**).* 2-{9,9-Di-[2-(2-methoxyethoxy)-ethyl]-7-nitrofluoren-2-yl}-benzothiazole, **B**, (0.218 g, 0.4 mmol) was dissolved into a mixture of EtOH/THF (1:1) mixture at room temperature. To this was added 0.019 g of 10% Pd/C, and the reaction was heated to 70 °C under N_2. Hydrazine monohydrate (0.124 g, 2.48 mmol) was added dropwise and the reaction mixture stirred for 12 h. Upon completion, the reaction was passed through a silica gel plug washed with diethyl ether/MeOH (1:1), concentrated, and purified via silica gel column chromatography using diethyl ether/MeOH (9.5:0.5) as eluent. A bright yellow solid was isolated (0.192 g, 93% yield, mp 137−139 °C) that was used directly in the next step. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.08 (s, 1H, ArH), 8.06 (d, 1H, ArH), 8.02 (d, 1H, ArH), 7.91 (d, 1H, ArH), 7.60 (d, 1H, ArH), 7.50 (d, 1H, ArH), 7.45, (t, 1H, ArH), 7.36 (t, 1H, ArH), 6.74 (s, 1H, ArH), 6.68, (d, 1H, ArH), 3.87 (s, 2H, NH_2), 3.29 (m, 4H, OCH_2), 3.25, (s, 6H, OCH_3), 3.21 (m, 4H, OCH_2), 2.79 (m, 4H, CH_2), 2.49 and 2.38 (m, 4H, OCH_2). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 168.59 (Ar−C═N), 154.27, 151.75, 148.70, 147.34 (CNH_2), 144.15, 135.0, 131.02, 130.49, 127.51, 126.39, 125.05, 123.01, 121.89, 121.70, 121.61, 118.92, 114.67, 109.88, 72.02, 70.22, 67.30, 59.31 (OCH_3), 51.41 (C9), 40.27 (CH_2). Anal. Calcd. for $C_{30}H_{34}N_2O_4S$: C, 69.47; H, 6.61; N 5.40. Found: C, 69.29; H, 6.60; N, 5.57.

Synthesis of Amine-Reactive Fluorene Probe (1). Compound C, (0.6 g, 1.15 mmol) was dissolved in $CHCl_3$ to which aq $CaCO_3$ (0.26 g, 2.11 mmol) was added at 0 °C. Thiophosgene (0.12 mL, 1.5 mmol) was then added dropwise with vigorous stirring (*20*). After 1 h, the starting material was completely consumed, as determined by TLC (9:1 diethyl ether/MeOH), achieving near-quantitative conversion. After an additional 30 min, 10% HCl was added until no gas generation was observed. The reaction mixture was poured into H_2O, extracted with CH_2Cl_2, dried over $MgSO_4$, and, upon filtration and concentration, resulted in an orange oil. The crude product was purified by column chromatography on silica gel eluting with diethyl ether/MeOH, (90:10), followed by hexane/EtOAc (60:40), affording 0.65 g of a yellow solid (94% yield, mp 70−71 °C). The FT-IR spectrum revealed a characteristically strong −NCS stretch at 2111 cm^{-1}, while no signal from the $-NH_2$ group (ca. 3600 cm^{-1}) was observed. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.15 (s, 1H), 8.09 (dd, 2H), 7.93 (d, 1H), 7.75 (q, 2H), 7.50 (t, 1H), 7.42 (m, 2H), 7.24 (d, 1H), 3.21 (m, 10H, OCH_3, OCH_2), 3.13 (m, 4H, OCH_2), 2.85 (m, 4H, OCH_2), 2.48 (m, 4H, CH_2). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 167.82 (Ar−C═N), 154.18, 151.58, 150.13, 142.07, 138.72, 135.75 (N═C═S), 135.10, 133.23, 130.89, 127.69, 126.61, 125.45, 125.40, 123.32, 122.30, 121.82, 121.36, 120.74, 71.99, 70.28, 67.16, 59.36 (OCH_3), 52.26 (C9), 39.91 (CH_2). Anal. Calcd. for $C_{31}H_{32}N_2O_4S_2$: C, 66.40; H, 5.75; N 5.00. Found: C, 66.63; H, 5.80; N, 4.95.

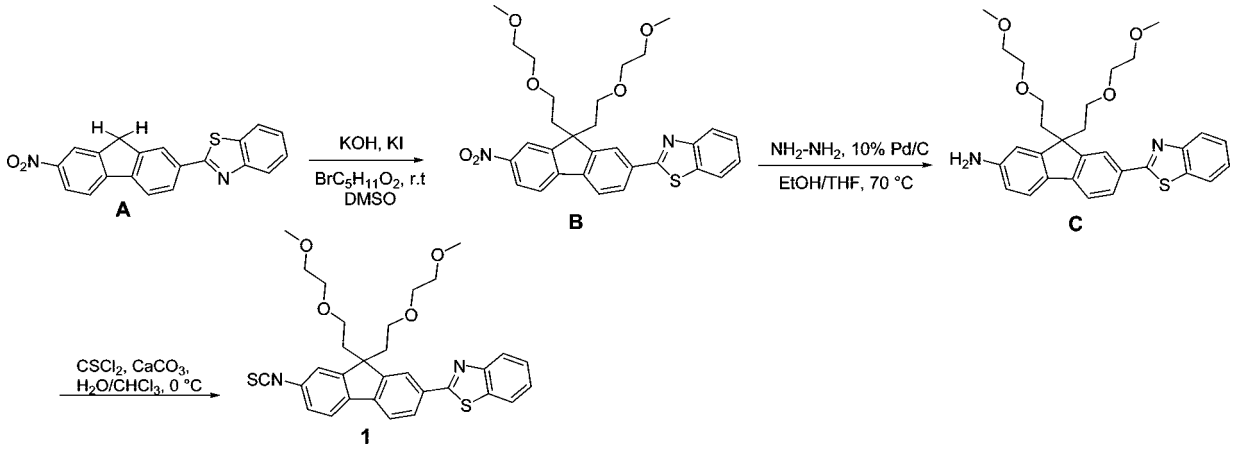
*Synthesis of 2-Iodo-9,9-di-[2-(2-ethoxyethoxy)-ethyl]-7-nitrofluorene (**E**) via the General Alkylation Procedure (above).* Compound **E** was obtained as a yellow oil, which solidified into a waxy solid (0.88 g, 42% yield). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.26 (s, 1H), 8.24 (d, 1H), 7.82 (s, 1H), 7.76 (d, 1 H), 7.73 (1H), 7.51 (d, 1H), 3.37 (q, 4H, OCH_2), 3.29 (t, 4H, OCH_2), 3.15 (t, 4H, OCH_2), 2.85 (m, 4H, OCH_2), 2.47 (m, 4H, CH_2), 1.13 (t, 6H, CH_3). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 152.90, 150.12, 147.50 (CNO_2), 145.85, 137.74, 136.99, 133.12, 123.65, 122.69, 120.05, 119.0, 95.52, 70.14, 69.60, 66.75, 66.62 (OCH_2), 52.24 (C9), 39.20 (CH_2), 15.07 (CH_3). Anal. Calcd. for $C_{23}H_{28}INO_6$: C, 52.73; H, 5.66; N, 2.46. Found: C, 52.36; H, 5.60; N, 2.47.

*Synthesis of 2-(4-(2-(9,9-Bis(2-(2-ethoxyethoxy)ethyl)-2-nitrofluoren-7-yl)vinyl)phenyl)benzothiazole (**G**).* 9,9-Bis(2-(2-ethoxyethoxy)ethyl)-2-iodo-7-nitro-fluorene **E** (0.5 g, 0.88 mmol), 2-(4-vinylphenyl)benzothiazole **F** (0.25 g, 1.04 mmol), $Pd(OAc)_2$ (90 mg, 0.40 mmol), tri-*o*-tolylphosphine (0.21 g, 0.69 mmol), and DMF/Et_3N (9.5 mL) were combined in a screwcap vial and heated at reflux for 40 h The mixture was cooled to room temperature and filtered. All volatiles were removed under reduced pressure, and the resulting residue was then dissolved in CH_2Cl_2, washed with distilled water, dried over $MgSO_4$, filtered, and concentrated. The crude product was purified by column chromatography on silica gel, eluting with hexane/EtOAc (3.5:1.5), followed by hexane/EtOAc/THF (3.5:1:0.5), affording 0.40 g of an orange solid (68% yield, mp 131−132 °C). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.31, (m, 2H), 8.12 (q, 3H), 7.94 (d, 1H), 7.77 (d, 2H), 7.67 (d, 3H), 7.61 (d, 1H), 7.52 (t, 1H), 7.40 (t, 1H), 7.26 (m, 2H), 3.34 (m, 12H, OCH_2), 2.88 (m, 4H, OCH_2), 2.51 (m, 4H, CH_2), and 1.12 (t, 6H, CH_3). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 167.22 (Ar−C═N), 153.91, 151.11, 150.51, 146.80 (CNO_2), 146.16, 139.38, 138.06, 137.80, 134.77, 132. 68, 129. 63, 128. 65, 127.76, 126.91, 126.71, 126.18, 125.02, 123.46, 122.96, 121.41, 121.20, 119.65, 118.70, 70.01, 69.47, 66.72, 66.47 (OCH_2), 51.83 (C9), 39.36 (CH_2), 15.01 (CH_3). Anal. Calcd for $C_{40}H_{42}N_2O_6S$: C, 70.77%; H, 6.24%; N, 4.13%. Found: C, 70.46%; H, 6.33%; N, 4.03%.

*Synthesis of 9,9-Bis(2-(2-ethoxyethoxy)ethyl)-7-(4-(benzothiazol-2-yl)styryl)-fluoren-2-amine (**H**).* Nitro compound **G** (0.32 g, 0.48 mmol) was dissolved in a 8 mL of 1:1 (v/v) EtOH/THF at room temperature. To this was added 0.02 g of 10% Pd/C. The reaction mixture was then heated to 70 °C under Ar to which hydrazine hydrate (0.09 g, 2.97 mmol) was added dropwise via syringe over 20 min. The reaction mixture was stirred for 18 h at 70 °C, cooled to room temperature, and concentrated, affording a yellow oil. Purification was accomplished by column chromatography using hexane/THF/MeOH (3:1:1), resulting in 0.27 g of yellow solid (90% yield). This intermediate was not further characterized and used directly in the next step due to oxidative lability.

*Synthesis of Amine-Reactive Fluorene Probe (**2**).* 9,9-Bis(2-(2-ethoxyethoxy)ethyl)-7-(4-(benzothiazol-2-yl)styryl)-fluoren-2-amine **H** (0.21 g, 0.33 mmol) was dissolved in $CHCl_3$ (8 mL)

Scheme 1. Preparation of the Isothiocyanate Amine-Reactive Tag 1



to which aq $CaCO_3$ (0.11 g, 2.11 mmol) was added. Thiophosgene (0.04 mL, 0.56 mmol) was added dropwise at 0 °C with vigorous stirring. After 2.5 h, the starting material was completely consumed, as determined by TLC (silica, 1:1 hexane/THF). 10% HCl (5 mL) was added until no gas generation was observed. The reaction mixture was poured into H_2O, extracted with CH_2Cl_2, dried over $MgSO_4$, and, upon filtration and concentration, resulted in an orange oil. The crude product was purified by column chromatography on silica gel eluting with hexane/THF (1:1), followed by hexane/THF (3.5:1.5), affording 0.15 g of a yellow solid (64% yield, mp 73−74 °C). FT-IR analysis revealed a characteristically strong −NCS stretch at 2111 cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$) δ: 8.08, (t, 3H), 7.89 (d, 1H), 7.62 (q, 4H), 7.51 (t, 2H), 7,40 (t, 2H), 7.28 (m, 4H), 3.39 (m, 8H, OCH_2), 3.21, (d, 4H, OCH_2), 2.80 (m, 4H, OCH_2), 2.43 (bs, 4H, CH_2), and 1.13 (t, 6H, CH_3). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 167.11 (Ar−C═N), 153.72, 150.56, 149.31, 139.47, 138.85, 138.77, 136.36 (N═C═S), 134.78, 134.58, 132.26, 129.80, 129.55, 127.56, 126.63, 126.41, 125.99, 124.81, 122.77, 121.25, 120.72, 120.58, 120.27, 120.05, 69.91, 69.42, 66.66, 66.40 (OCH_2), 51.32 (C9), 39.55 (CH_2), 15.02 (CH_3). Anal. Calcd. for $C_{41}H_{42}N_2O_4S_2$: C, 71.27%; H, 6.13%; N, 4.05%. Found: C, 71.06%; H, 6.28%; N, 4.01%.

*General Synthetic Procedure for Reactive Probe Adduct via Addition Reaction (**3**).* A mixture of amine-reactive probe **2** (0.12 g, 0.214 mmol) and *n*-butylamine (0.23 mL) was stirred at room temperature for 2 h. The excess *n*-butylamine was removed in vacuo and the residue purified by column chromatography on silica gel eluting first, with EtOAc/THF (95:5), followed by diethyl ether/EtOAc (80:20), affording 0.082 g of pale yellow solid (63% yield, mp 128−129 °C). ^1H NMR (300 MHz, $CDCl_3$) δ: 8.11 (s, 1H), 8.10 (t, 2H), 8.04 (d, 1H), 7.92 (q, 2H), 7.79 (t, 2H), 7.72 (t, 1H), 7.50 (d, 1H), 6.8 (s, 1H, NH), 3.67 (m, 16H, OCH_3, OCH_2, CH_2), 2.10 (m, 4H, OCH_2), 1.54 (m, 4H, CH_2), 1.36 (m, 2H, CH_2), 1.15 (m, 2H, CH_2), 0.91 (t, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 180.72, 168.37 (Ar−C═N), 155.84, 154.22, 150.91, 149.35, 143.52, 140.05, 135.03, 134.21, 131.88, 127.62, 126.50, 125.24, 123.15, 121.99, 121.77, 121.33, 119.85, 119.15, 114.29, 72.00, 70.13, 67.33 (OCH_2), 59.22, 51.7(C9), 40.42, 40.03 (CH_2), 32.71, 20.57, 14.33 (CH_3). Anal. Calcd. for $C_{35}H_{43}N_3O_4S_2$: C, 76.11; H, 8.94; N, 5.92. Found: C, 76.28; H, 9.19; N, 5.90.

*General Preparation of Reelin−Fluorene Bioconjugate (**6**).* A stock solution of Reelin (2 mg/mL) in freshly prepared $NaHCO_3$ (0.1 M, pH 9) solution was used. A stock solution of the amine-reactive probe dissolved in anhydrous DMSO (5.23×10^{-3} M) was freshly prepared and aliquots added dropwise into the Reelin solution (1 mL of stock) with gentle stirring. The concentration of the probe solution was varied such that a 1:10 and a 1:5 mol ratio of protein to probe were prepared to establish a degree of labeling (DOL) for the probe. The reaction was kept in the dark and allowed to stir at room temperature for 3 h, after which the mixture was passed through a gel chromatography column (12 cm length, Bio-Rad Econo-Pac 10DG) equilibrated in and eluted with phosphate buffered saline (PBS, pH 7.2; Fisher). Fractions containing the bioconjugate were identified spectrophotometrically by monitoring both the protein fraction at 280 nm and the dye at 355 nm. The molar absorptivity (ε_{278}) of Reelin in PBS (pH 7.2) was determined to be 39.4×10^3 L mol^{-1} cm^{-1}.

*Preparation of Cyclic Peptide Conjugate (**7**).* Cyclic peptide RGDfK (10 mg, 0.016 mmol) was dissolved in DMSO (0.75 mL), and then amine-reactive dye **1** (9.6 mg, 0.017 mmol) was added slowly to the solution. The clear solution was stirred at room temperature that gradually changed to a fluorescent yellow coloration. After 5 h, the starting material was completely consumed as determined by TLC (silica gel, diethyl ether). DMSO was removed by washing with diethyl ether several times, producing 16 mg of yellow solid (90% yield, mp 265−266 °C). ^1H NMR (300 MHz, $CDCl_3$) δ: 9.85 (s, 1H, COOH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 180.78, 174.52, 172.47, 171.52, 171.23, 170.91, 168.19 (Ar−C═N), 157.19, 154.13, 150.59, 143.62, 140.75, 138.74, 134.96, 131.63, 129.54, 128.59, 127.24, 126.60, 125.98, 123.26, 122.89, 122.21, 120.83, 71.78, 69.84, 67.14 (OCH_3), 58.70, 55.71, 52.00 (C9), 49.55, 44.02, 32.33, 28.47, 25.60, 23.81. HRMS-ESI theoretical *m*/*z* $[M + H]^+ = 1164.49$, found 1164.49; theoretical *m*/*z* $[M + Na]^+ = 1186.38$, found 1186.48.

NT2 Cell Culture. The NT-2/D1 cells were plated at a density of 5×10^6 per 75 cm^2 in a tissue culture treated flask (Corning). Cell culture media was Dulbecco's modified Eagle's medium with F-12 (DMEM/F12, Invitrogen), supplemented with 10% heat-inactivated fetal bovine serum (Atlanta Biologics). An incubation chamber was used to maintain a humidified atmosphere of 5% CO_2 and 37 °C. NT2 cells were passed twice a week with trypsin/EDTA (Invitrogen) treatment.

*HeLa Cells Incubated with Amine-Reactive Probe (**1**).* HeLa cells were plated onto 4-well glass chamber slides. Stock solutions of fluorophore **1** dissolved into DMSO were prepared as either 10 or 5 μM solutions. Diluted solutions in complete growth medium were then freshly prepared and placed over the cells for either a 1 or 5 h period. All cells were washed with PBS (3−5×) and fixed in a 3.7% formaldehyde solution for 5 min at room temperature.

*NT2 Cells Incubated with Reelin Conjugate (**6**).* Reelin conjugate **6** diluted in NT2 cell media was added to NT2 cells and incubated for 3 h. After incubation, cells were washed once

with PBS followed by addition of fresh media. Cells were fixed prior to viewing using 4% paraformaldehyde.

Spectroscopic Measurements. Steady-state absorption and fluorescence emission spectra of compounds **1**−**3** were investigated in DMSO in concentrations on the order of 10^{-6} M at room temperature in 1 × 1 cm quartz cuvettes using an Agilent 8453 spectrophotometer and PTI Quantamaster spectrofluorimeter, respectively. All solvents and solutions used in these experiments were checked for spurious emission in the region of interest. Fluorescence quantum yields, *Q*, were measured for

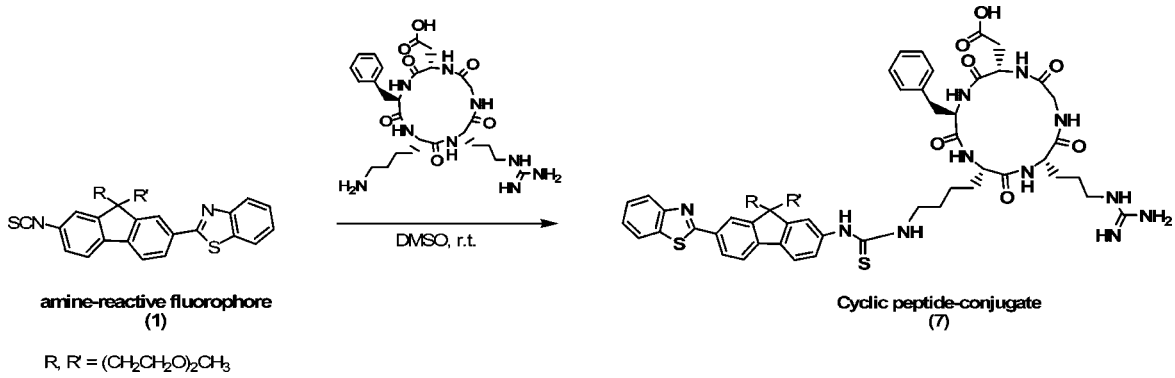
Scheme 4. Preparation of the Bioconjugate 7 with the Amine-Reactive Tag 1



all compounds by a standard method (*21*), relative to Rhodamine 6G in ethanol (Q = 0.94) (*22*).

Two-Photon Absorption Properties. The two-photon fluorescence (2PF) spectra and two-photon absorption (2PA) cross sections of all molecules studied were determined by employing a two-photon induced fluorescence method (*23*, *24*), using a tunable femtosecond Ti:sapphire laser (Mira 900-F, 220 fs pulse width, 76 MHz repetition rate, Coherent, USA) as the excitation source. After passing through a round, continuously variable neutral density filter that was used to control the laser irradiance, the femtosecond NIR laser beam was focused into a 1 × 1 cm quartz cuvette containing sample solutions by a plano-convex lens (f = 50 mm, Thorlabs, USA). The excitation laser was adjusted to be as close to the wall as possible in order to reduce reabsorption effects. The upconverted fluorescence was first collected by an objective lens (20×, NA = 0.50, Newport, USA) at a direction perpendicular to the pump beam, then focused by a large beam collimator (F810SMA-543, Thorlabs, USA) into a multimode fiber (400 μm core, Ocean Optics, USA), and, finally, delivered to a fiber optic spectrometer (SD2000, Ocean Optics, USA), which was used to record the upconverted fluorescence spectra. The two-photon fluorescence spectra recorded by the spectrometer were used without further linearity correction. This technique was confirmed by measuring the 2PA cross section of a well-characterized fluorene-based 2PA fluorophore (*13*, *25*).

One-Photon Fluorescence Imaging. An inverted microscope (Olympus IX70) equipped with a QImaging cooled CCD (Model Retiga EXi) was used for conventional fluorescence imaging, where the output of a filtered 100 W mercury lamp was used as the excitation source. A customized filter cube (Ex 377/50, DM 409, Em 460/50) was used for fluorescence imaging.

Two-Photon Fluorescence Microscopic Imaging and Two-Photon Fluorescence Lifetime Imaging. Two-photon fluorescence microscopic imaging (2PFM) and two-photon fluorescence lifetime imaging (2P-FLIM) were performed on a modified Olympus Fluoview FV300 microscope system coupled with the tunable Coherent Mira 900F Ti:sapphire laser and a compact FLIM system from PicoQuant, Germany. Output from the femtosecond NIR laser (tuned to 760 nm, 220 fs pulse width, 76 MHz repetition rate) was used as the two-photon excitation source for both 2PM and 2P-FLIM experiment. The fluorescence collected by a 40× microscopic objective (UPLANAPO 40×, NA = 0.85, Olympus) was reflected by a dichroic beam splitter

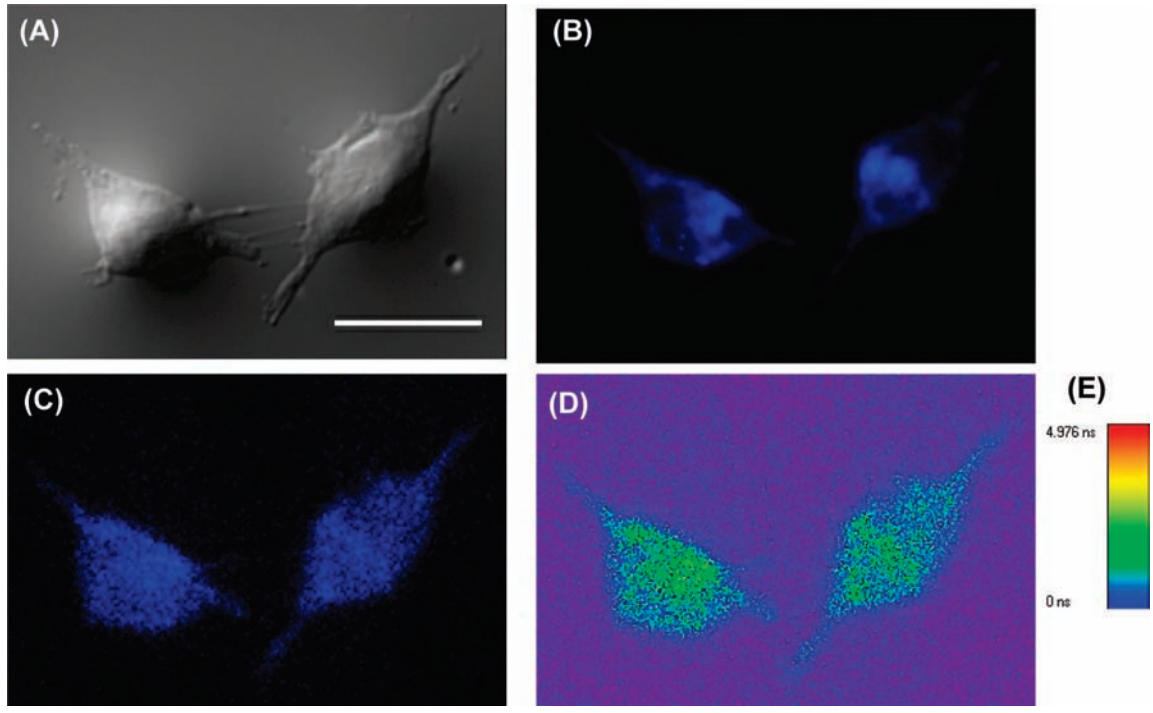


Figure 4. NT2 cells labeled with Reelin conjugate **6** (DOL= 3.4): (A) DIC, (B) 1PM, (C) 2PM, (D) 2P-FLIM. Scale bar in (A) corresponds to 20 μm. (E) Lifetime scale bar for (D). Pseudo color is used for (B), (C), and (D).

(FF665-Di01−25 × 36, Semrock Inc.), and then focused into a multimode fiber by a microscope objective (20×, NA = 0.4, Newport). A beam reducer, consisting of a plano-convex lens and a plano-concave lens, was used to reduce the fluorescence beam diameter in front of the objective. The output fluorescence was delivered to an avalanche photodiode (APD) detector (PicoQuant, Germany). A broad band-pass filter (D500/200m, Chroma) was placed in front of the APD detector. Data acquisition and analysis were done with a combination of a stand-alone time-correlated single photon counting (TCSPC) module TimeHarp 300 and software package *SymPhoTime*, both from PicoQuant, Germany.

RESULTS AND DISCUSSION

Synthesis and Characterization of the Amine-Reactive Fluorenyl Dyes 1 and 2. The reactivity of the isothiocyanate group −N=C=S is well-documented, yielding thioureas upon reaction with amines. The molecular structures of the target isothiocyanate fluorophores share some similarity with our previously described two-photon fluorescent chromophores (*13*). In the 9-position of these fluorophores, two identical oligo(ethylene glycol) chains were used to impart hydrophilicity and provide better solubility. In the 7-position, we opted for the benzothiazole moiety as an electron-withdrawing group (Schemes 1 and 2).

A key intermediate in the synthesis of the isothiocyanate derivative **1** was amine **C**. This was achieved via the quantitative reduction of nitro derivative **B** using hydrazine hydrate and 10% Pd/C in a 1:1 mixture of EtOH/THF at 70 °C. The isothiocyanate reactive group was then obtained by reaction of amine **C** with thiophosgene. The target functionalized chromophore **1** was obtained in 94% yield.

For isothiocyanate derivative **2**, the conjugation length was increased via the addition of a polarizable π-system (styryl) between the fluorenyl moiety and the benzothiazole acceptor group. The route began with the synthesis of 2-(4-(2-(9,9-bis(2-(2-ethoxyethoxy)ethyl)-2-nitro-fluoren-7-yl)vinyl)phenyl)benzothiazole (**G**) via an efficient Pd-catalyzed Heck coupling reaction between 9,9-bis(2-(2-ethoxyethoxy)ethyl)-2-iodo-7-nitrofluorene (**E**) and 2-(4-vinylphenyl)benzothiazole (**F**), fol-

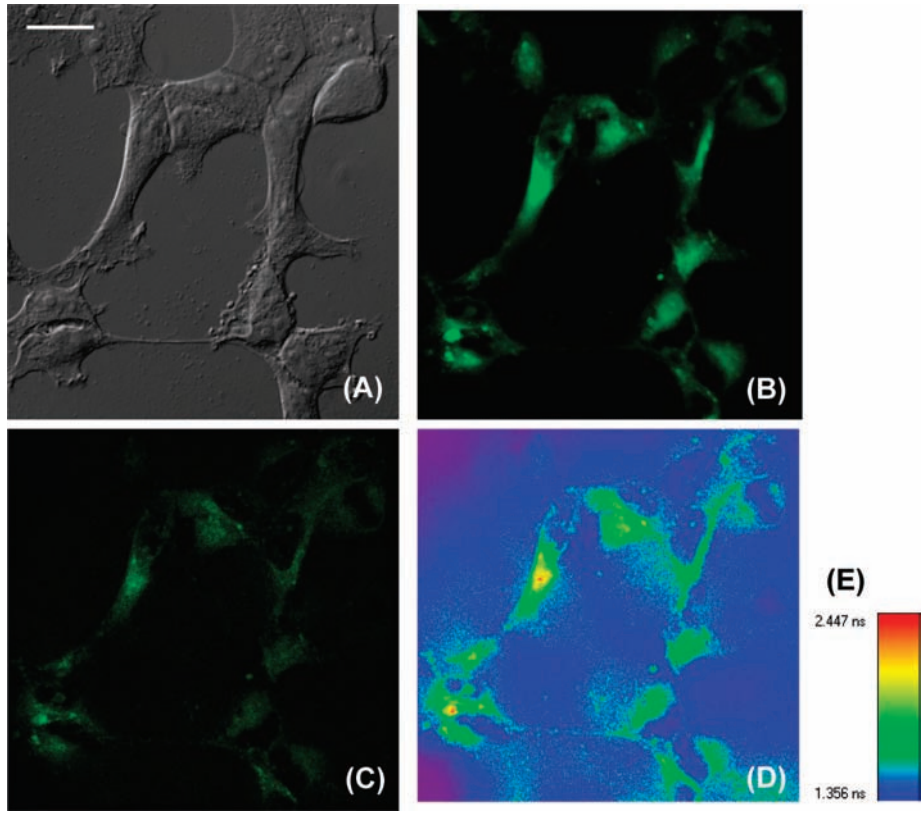

Figure 6. H1299 cells labeled with cyclic peptide bioconjugate **7**: (A) DIC, (B) 1PM, (C) 2PM, (D) 2P-FLIM. Scale bar in (A) corresponds to 20 μm. (E) lifetime scale bar for (D). Pseudo color is used for (B), (C), and (D).

lowing the synthetic pathway shown in Scheme 2. The FT-IR spectra of the isolated compounds revealed characteristically strong $-$NCS stretching at 2111 cm^{-1}, whereas no signal at ca. 3600 cm^{-1} from the $-NH_2$ group was observed. Structures of all new compounds have been confirmed by ^1H and ^{13}C NMR and C, H, N analysis, with the exception of oxidatively labile amine **H**, which was used immediately after being formed.

Conjugation with *n*-Butylamine and Reelin, and Their Optical Properties. To test the feasibility of the conjugation of fluorene isothiocyanate with biopolymers, we first used a simple reaction of *n*-butylamine with the amine-reactive probes **1** and **2** as model reactions (Scheme 3). Furthermore, preparation of the model adducts (**3** and **4**) allowed for facile single- and two-photon spectroscopic characterization, which more closely resembles the bioconjugate than that of the amine-reactive probe (conjugate precursor). The reaction of the amine-reactive dye with *n*-butylamine was fast, with completion in ~40 min at room temperature. The expected thiourea group was evident in the ^1H NMR spectrum.

To show the potency of the isothiocyanate-functionalized chromophore in two-photon-based biological applications, the protein Reelin was conjugated with amine-reactive probes **1** and **2** (Scheme 3). Reelin is a large extracellular matrix glycoprotein, important in guiding neural steam cells in the central nervous system in normal development (*26*, *27*). While much attention is focused on Reelin's role during corticogenesis, the existence of Reelin expression in several neural population in the adult brain may point to other important functions for this protein. Consequently, attaching a 2PA fluorophore to Reelin enhances the possibility of visualizing cellular events that involve Reelin by using 2PFM.

Conjugation of Reelin with **1** and **2** was performed according to standard methods (*27*) in PBS buffer by dissolving the fluorenyl isothiocyanate in DMSO immediately prior to addition into a stirred Reelin carbonate buffer solution (pH 9.5). The reaction mixture was stirred for 3 h at ambient temperature. The bioconjugate was then separated from the unbound fluorophore by filtration through a gel chromatography column, enabling the separation of the bioconjugate in PBS solution (pH 7.2). The bioconjugate was collected in several fractions that were then identified and characterized spectrophotometrically. The concentration of the reactive dye solution was varied such that a 1:10 and a 1:5 mol ratio of protein to reactive dye were prepared to establish a degree of labeling (DOL) for the probe. Hence, a 1:10 and a 1:5 mol ratio of protein to probe allowed for an estimated DOL ranging from 2.2 to 3.4.

The normalized UV$-$visible absorption and steady-state fluorescence emission spectra of amine-reactive probe **1**, dye adduct **3** in DMSO, and Reelin bioconjugate **5** in PBS (buffer pH 7.2) are shown in Figure 1. For reference, the absorption spectrum of the free Reelin protein in PBS solution is also shown. The Reelin bioconjugate exhibited absorption peaks corresponding to that of the Reelin protein in the shorter wavelength range (λ_{max} = 280 nm), as well as that of the fluorescent dye in the longer absorption range (λ_{max} = 357 and 375 nm), and exhibited an emission maximum at 455 nm. We observe that the absorption spectrum of the Reelin bioconjugate **5** showed only some broadening compared to the absorption spectrum of the unbound fluorophore **1**. The fluorescence quantum yield of the NCS-containing amine-reactive probe in DMSO was 0.02, nearly nonfluorescent, while that of the dye adduct **3** in DMSO increased significantly to 0.72, indicating that the fluorescence of the reactive tag is restored (turns on) upon conjugation. The increase in conjugation of the π-system from compound **1** to compound **2** is reflected in an increase of its fluorescence quantum yield (0.85).

RGD Conjugation and Spectroscopic Characteristics of the Cyclic Peptide Conjugate (7). Integrins are a family of heterodimeric transmembrane glycoproteins that play an important role in mediating cell$-$cell and cell$-$matrix interactions

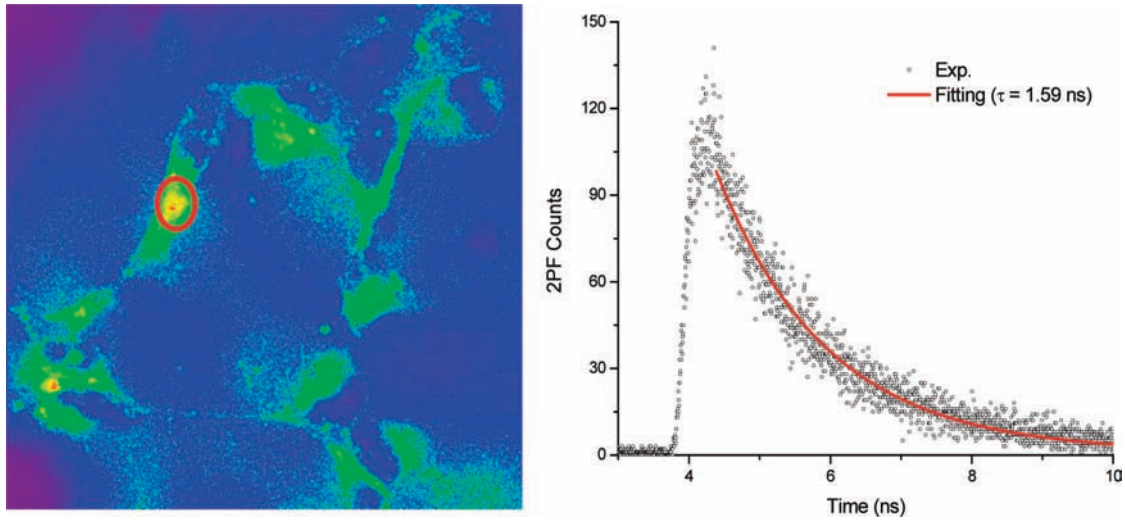

Figure 7. Fluorescence lifetime FLIM of H1299 cells labeled with cyclic peptide bioconjugate **7**. The decay curve corresponds to the circled area in the left image.

(*29, 30*). Integrins recognize short peptide sequences found in the extracellular matrix and on the cell surface. Particularly, the sequence Arg-Gly-Asp (RGD) is recognized by a number of integrins (*29*). Numerous studies have assessed the potential of $\alpha_v\beta_3$ as a target for tumor imaging agents (*30*). Along with the derivatives of the RGD-series, c(RGDfK) is often used for the delivery of therapeutics, because the lysine residue (K) makes it an ideal building block for further chemical conjugation reactions. To show the efficacy of the amine-reactive probe to be used as a two-photon fluorescence marker for optical tumor imaging, the RGDfK peptide was conjugated with amine-reactive probe **1** in DMSO at room temperature (Scheme 4). High-resolution mass spectrometric analysis confirmed the molecular structure of oligopeptide conjugate **7**.

The linear absorption and emission spectra of cyclic peptide-conjugate **7** in DMSO are shown in Figure 2. Conjugate **7** displayed absorption peak at 352 nm, while the emission maximum shifted from 400 nm for **1** to 460 nm for **7**. In addition, the fluorescence quantum yield of **7** increased to 0.9 after conjugation.

Two-Photon Absorption Properties. 2PA cross sections were obtained by the upconversion fluorescence method using a femtosecond Ti:sapphire laser as the excitation source. The 2PF measurements of the amine-reactive probe **2**, model adduct **4**, and cyclic peptide bioconjugate **7** were performed in DMSO (1.6×10^{-3} M) and exhibited a 2PA cross section of ~30 GM at 740 nm. With its fluorescence quantum yield of ~0.7−0.9, the two-photon action cross section for the model adduct is ~20 GM, reasonable enough to be used for bioimaging. These values are higher than those for common commercial dyes (0.16 GM for DAPI, 1 GM for cascade blue) used currently as blue fluorescence dyes in 2PFM (*23*).

Single- and Two-Photon Fluorescence and FLIM Cell Imaging. The utility of amine-reactive tag **1** as a 2PA biological marker was demonstrated by incubation with HeLa cells. Cells were incubated with a solution of 10^{-6} mol L^{-1} of chromophore, and after 1 and 5 h incubation times, images were taken with a modified Olympus Fluoview FV300 microscope system. Strong fluorescence was observed after 5 h of incubation, with a homogeneous coloration of the cytoplasm region. Differential interference contrast (DIC) and epifluorescence microscopic images of the stained cells are shown in Figure 3a,b. The low quantum yield of this probe (0.02) was an important characteristic, because after incubation, it appeared to have reacted spontaneously with a protein in HeLa cells, generating a bioconjugate with significantly enhanced fluorescence (Qy = 0.7), improving detection by single- and two-photon fluorescence microscopy imaging (Figure 3b). 2PFM images of the same amine-reactive fluorene **1** stained cells were collected on a modified Olympus Fluoview FV300 microscope system combined with a tunable Coherent Mira 900F Ti:sapphire laser. Two-photon induced fluorescence was observed predominantly from the cytoplasmic region, consistent with the images collected from epifluorescence imaging (Figure 3c).

DIC and epifluorescence microscope images of NT2 neuron fixed cells incubated with Reelin conjugate **6** (DOL = 3.4) were collected on a modified Olympus Fluoview FV300 microscope (Figure 4a,b). The resulting optical images clearly showed that successful uptake was achieved. 2FPM images and fluorescence lifetime imaging microscopy (FLIM) were performed on the same cells. Though select areas of the cells were chosen for lifetime analysis, the area selected was representative of the dye distribution within the cytoplasm, resulting in a homogeneous monoexponential fluorescence decay (Figure 4c and 5). The average lifetime was on the order of 1.5 ns.

The efficacy of cyclic peptide-conjugate **7** was evaluated by incubation with H1299 lung tumor line cells (Figures 6 and 7). Additionally, fluorescence was observed predominantly from the cytoplasmic region of the cells, with the nucleus clearly outlined. Two-photon induced fluorescence was observed predominantly from the cytoplasmic region, consistent with the images collected from single fluorescence images (Figure 6c). Some differences were observed in the probe lifetime. This is a subject of further investigation.

CONCLUSIONS

The data presented in this paper confirm that our strategy of introducing the −NCS functionality into the aromatic skeleton of suitably derivatized fluorenes, by means of commercial thiophosgene, proven both useful and versatile, facilitating the preparation of a variety of fluorescent fluorene isothiocyanates (amine-reactive probes). The fluorene isothiocyanate derivatives, whose synthesis and conjugation to a protein and oligopeptide are reported in this paper, represent an improvement over commercial isothiocyanate probes. Our results demonstrate the potential of these fluorene-based amine-reactive probes as fluorescent markers, owing to their good optical properties, chemical and optical stability, ease of color tunability, and reactive functionality for biomolecule conjugation. Demonstration of 2PM images of HeLa cells incubated with a well-

characterized 2PA fluorophore lends credence to our efforts to further refine fluorene-based derivatives for bioimaging applications. Performance of second-generation fluorene-based fluorophores for aqueous compatibility and integrated with additional specific biomolecule-reactive functionalities and vectors is currently being investigated.

TECHNICAL NOTES

Effects of Lysine-Containing Mercaptoacetyl-Based Chelators on the Biodistribution of ^{99m}Tc-Labeled Anti-HER2 Affibody Molecules

Thuy A. Tran,*[,†] Torun Ekblad,[‡] Anna Orlova,[†,§] Mattias Sandström,[||] Joachim Feldwisch,[§] Anders Wennborg,[§] Lars Abrahmsén,[§] Vladimir Tolmachev,[†,§,⊥] and Amelie Eriksson Karlström[‡]

Unit of Biomedical Radiation Sciences, Rudbeck Laboratory, Medical Radiation Physics, Uppsala University Hospital, and Department of Medical Sciences, Uppsala University, Uppsala, Sweden, School of Biotechnology, Division of Molecular Biotechnology, Royal Institute of Technology, Stockholm, Sweden, and Affibody AB, Bromma, Sweden. Received June 18, 2008; Revised Manuscript Received November 4, 2008

The effects of polar (mercaptoacetyl-triseryl) and negatively charged (mercaptoacetyl-triglumatyl) chelators on the biodistribution of ^{99m}Tc-labeled anti-HER2 Affibody molecules were previously investigated. With glycine, serine, and glutamate, we demonstrated that substitution with a single amino acid in the chelator can significantly influence the biodistribution properties and the excretion pathways. Here, we have taken this investigation further, by analyzing the effects of introduction of a positive amino acid residue on the in vivo properties of the ^{99m}Tc-labeled Affibody molecule. The Affibody molecules with mercaptoacetyl-seryl-lysyl-seryl (maSKS) and mercaptoacetyl-trilysyl (maKKK) extensions were produced by peptide synthesis and labeled with ^{99m}Tc in alkaline conditions. A comparative biodistribution was performed in normal mice to evaluate the excretion pathway. A shift toward renal excretion was obtained when serine was substituted with lysine in the chelating sequence. The radioactivity in the gastrointestinal tract was reduced 3-fold for the ^{99m}Tc-maSKS-$Z_{HER2:342}$ and ^{99m}Tc-maKKK-$Z_{HER2:342}$ in comparison with the ^{99m}Tc-maSSS- $Z_{HER2:342}$ conjugate 4 h post injection (p.i.). The radioactivity in the liver was elevated when a triple substitution of positively charged lysine was used. The tumor targeting properties of ^{99m}Tc-maSKS-$Z_{HER2:342}$ were further investigated in SKOV-3 xenografts. The tumor uptake of ^{99m}Tc-maSKS-$Z_{HER2:342}$ was 17 ± 7% IA/g 4 h p.i. Tumor xenografts were well-visualized by gamma scintigraphy. In conclusion, the substitution with one single lysine in the chelator results in better tumor imaging properties of the Affibody molecule $Z_{HER2:342}$ and is favorable for imaging of tumors and metastases in the abdominal area. Multiple lysine residues in the chelator are, however, undesirable due to elevated uptake both in the liver and kidneys.

INTRODUCTION

The overexpression or gene amplification of the human epidermal growth factor type 2, HER2 receptor (also known as ErbB2), is found in about 20% of all breast cancers (*1, 2*). HER2 expression also occurs in a number of other cancer types such as lung, colorectal, urothelial, ovary, and pancreas cancer (*3, 4*). The first therapeutic agent that targets HER2-positive breast cancer, approved for clinical use, was the humanized antibody trastuzumab (Herceptin, Genentech Inc.). Pertuzumab (Omnitarg, Genentech) is currently in phase III studies for treatment of HER2-positive breast cancer. Another type of targeting agent that is entering the clinics is the tyrosine kinase inhibitor, lapatinib (Tykerb, GlaxoSmithKline), that blocks several downstream signaling pathways of EGFR and HER2 receptors, involved in cell proliferation, invasion, and apoptosis (*5*).

Determination of HER2 status in breast cancer diagnostics is critically important for therapeutic decision making. The accuracy, precision, and reproducibility of a diagnostic method are highly essential in order to identify patients who would most likely benefit from anti-HER2 treatment. At present, immunohistochemical staining (IHC) and fluorescence in situ hybridization (FISH) of biopsy samples are clinically used for evaluating HER2 status (*6*). However, some limitations (*6, 7*) associated with these tests might cause false-negative results. Recently, the American Society of Clinical Oncology and the College of American Pathologist expert panel (*8*) reported that approximately 20% of current HER2 testing may be inaccurate. As an alternative, radionuclide imaging may be applied to visualize HER2 expression in both whole primary tumors and metastatic lesions, including sites where biopsies may be difficult to obtain.

HER2 has no known natural ligands, and HER2-targeted diagnostic imaging has been investigated using panels of radiolabeled agents, including the intact antibodies trastuzumab and pertuzumab, Fab and $F(ab')_2$ fragment of trastuzumab, minibody and scFv-Fc of trastuzumab, and ICR 12 (an anti-HER2 monoclonal antibody) (*9*). Recently, a new class of targeting agents, Affibody molecules, has been extensively studied for radionuclide therapy and imaging (*10*−*12*). Affibody

Table 1. Biophysical Characterization Data

protein	synthetic yield (%)	theoretical MW (Da)	experimental MW (Da)	K_D (pM)	T_m (°C)
$Z_{HER2:342}$	21	6718	6718	80	64
maSSS-$Z_{HER2:342}$	14	7054	7053	400	65
maKKK-$Z_{HER2:342}$	12	7177	7177	270	68
maSKS-$Z_{HER2:342}$	14	7095	7094	310	65

molecules are small (7 kDa) and cysteine-free three-helix bundle proteins, based on the 58 amino acid B-domain of staphylococcal protein A. By randomization of 13 solvent-exposed residues, a library of 3×10^9 variants has been generated and used for selection of affinity ligands to a variety of proteins (*13*).

The 7 kDa Affibody molecules are much smaller than antibodies and well-suited for in vivo imaging purposes. For HER2 targeting, the Affibody molecule $Z_{HER2:342}$ with an affinity of 22 pM (*14*) has been developed and labeled with a number of radioisotopes, ^{125}I (*14*), ^{111}In (*15, 16*), ^{90}Y (*17*), ^{68}Ga, ^{177}Lu (*10*), and ^{18}F (*18, 19*). All conjugates demonstrated good targeting of HER2-expressing SKOV-3 xenografts in mice (*14, 16*). The radionuclide ^{99m}Tc with a photon energy of 140 keV and a half-life of 6 h has also been investigated as a label for $Z_{HER2:342}$ because it is a readily available and cost-effective radionuclide for diagnostics. Earlier, the synthetic Affibody molecule $Z_{HER2:342}$ with the chelator maGGG (mercaptoacetyltriglycyl) site-specifically introduced at the N-terminus has been labeled with technetium-99m (*20*). Even though imaging of HER2 expression in tumors in mice was feasible with ^{99m}Tc-maGGG-$Z_{HER2:342}$, a high hepatobiliary clearance leading to high accumulation in the intestine was seen in the biodistribution studies. The hepatobiliary excretion can be reduced by reducing the lipophilicity of a peptide tracer (*21, 22*). Substitution of the chelator sequences with more hydrophilic amino acids in Affibody molecules, such as maSSS (mercaptoacetyl-triseryl) (*20*) or maEEE (mercaptoacetyl-triglutamyl) (*23*), results in suppressed hepatobiliary excretion, enabling abdominal detection. The use of negatively charged side chains, mercaptoacetyl-triglutamyl (maEEE), has proven to be efficient in reducing the hepatobiliary excretion (*23*). The combination of two serine and one glutamate in the chelator, as in mercaptoacetyl-glutamyl-seryl-glutamyl (maESE), shows favorable properties for imaging (*24*). In this study, we aimed to investigate the influence of the positively charged hydrophilic amino acid lysine on the biodistribution properties. For this purpose, the two novel Affibody molecules maSKS-$Z_{HER2:342}$ (mercaptoacetyl-seryl-lysyl-seryl) and maKKK-$Z_{HER2:342}$ (mercaptoacetyl-trilysyl) have been synthesized and labeled with ^{99m}Tc. The chelating sequences maSKS and maKKK were incorporated in the N-terminus during the peptide synthesis. These two conjugates were compared with each other and with maSSS-$Z_{HER2:342}$ (mercaptoacetyl-triseryl) with respect to the HER2-binding, cellular processing, and biodistribution properties. The labeled conjugates were not analyzed for their isomeric identities. They were used as a racemic mixture in all experiments.

EXPERIMENTAL PROCEDURES

Peptide Synthesis. The $Z_{HER2:342}$ sequence was assembled using Fmoc/*t*Bu solid-phase peptide synthesis on a Fmoc-amide resin with a substitution of 0.67 mmol/g (Applied Biosystems) as previously described (*20*). 1-Hydroxybenzotriazole (HOBt) and 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) (Advanced ChemTech, Louisville, KY) were used to activate equal molar equivalents of Fmoc-protected amino acid.

After synthesis of the full-length Affibody, the Tc-chelating peptide sequences Ser-Lys-Ser (SKS) and Lys-Lys-Lys (KKK) were introduced to the N-terminus of the $Z_{HER2:342}$-sequence by coupling the corresponding protected amino acids (Fmoc-Ser(tBu)-OH and/or Fmoc-Lys(Boc)-OH) one residue at the time in a stepwise manner. In the manual coupling reactions, 5 mol equiv (Eq) of Fmoc-protected amino acid were coupled with 5 Eq HBTU, 5 Eq HOBt, and 10 Eq *N*-ethyldiisopropylamine (DIEA, from Lancaster Synthesis, Morecambe, England). Ninhydrin tests were performed to evaluate the efficiency of the coupling reactions. Fmoc-deprotection was achieved by 20 min incubation in 20% piperidine-*N*-methylpyrrolidone (NMP, from VWR). Finally, the mercaptoacetyl moiety of the chelator was introduced by coupling *S*-trityl-protected mercaptoacetic acid (AnaSpec Inc., San Jose, CA) to the N-terminal amino group of the resin-bound peptide. The protecting groups were then deprotected and the full-length peptides with appended maSKS and maKKK chelators were released from the solid support by incubation in trifluoroacetic acid (TFA, Merck International)/H_2O/ethanedithiol (EDT, Aldrich chemical company Inc.)/triisopropylsilane (TIS, Merck International) (94:2.5:2.5:1) for 2 h. The proteins were extracted in *tert*-butyl methyl ether (Merck International)/H_2O (50:50).

Analytical RP-HPLC was run on the crude synthetic product using a 4.5×150 mm polystyrene/divinylbenzene matrix column with 5 μm particles (Amersham Biosciences, Sweden) and a 20 min elution gradient 20−60% B (B: 0.1% TFA-acetonitrile (CH_3CN; Merck International), A: 0.1% TFA-H_2O). The molecular weights of the modified Affibody molecules were confirmed by mass spectrometry and the proteins were purified on the same column in a 20 min gradient 25−45% B.

Biosensor Analysis. A Biacore 2000 instrument (Biacore AB, Uppsala, Sweden) was used for real-time biospecific interaction analysis. The extracellular domain of HER2 (Fox Chase Cancer Center, Philadelphia, USA) and human serum albumin, HSA (KabiVitrum, Sweden) were immobilized on a CM5 sensor chip by EDC/NHS coupling. HER2 and HSA were diluted to 20 μg/mL in 20 mM NaOAc pH 4.5 and the immobilization levels reached 500 and 900 response units (RU), respectively. The different Affibody molecules were diluted to concentrations varying from 0.5 to 10 nM in HBS (10 mM HEPES, 150 mM NaCl, 3.4 mM EDTA, 0.005% Surfactant P20, pH 7.4), and the binding kinetics were studied at a flow rate of 50 μL/min in HBS as running buffer in a 5 min association phase and a 10 min dissociation phase. After each injection of analyte, the sensor surface was regenerated by injection with 20 mM HCl in HBS. The specific response was obtained by subtracting the signal from the control surface (HSA) from the signal from binding to the HER2 surface. Mass transfer limitations were avoided by keeping a high flow rate and a low immobilization level of HER2 protein on the sensor surface.

Melting Point Analysis. Variable temperature measurements were performed using a JASCO J-810 spectropolarimeter (JASCO, Tokyo, Japan). Samples were diluted to a concentration of 50 μM in PBS pH 7.4. A cell with an optical path length of 1 mm was used. CD spectra from 250 to 195 nm were obtained at 20 °C before and after melting tests. For melting point measurements, the absorbance was measured at 221 nm and the temperature was increased by 5 °C/min from 20 to 90 °C.

^{99m}Tc-Labeling. For labeling, 20 μL of maSKS-$Z_{HER2:342}$ or maKKK-$Z_{HER2:342}$ (1 mg/mL in deionized, degassed water) was mixed with 20 μL 0.15 M NaOH to obtain a final pH of about 11. Stannous chloride (10 μL, 1 mg of $SnCl_2 \cdot 2H_2O$ in 1 mL 0.01 M HCl) was added to the mixture, followed by 100−200 μL (about 50 MBq) of freshly eluted pertechnetate solution. The mixture was slightly vortexed and incubated at room temperature for 60 min. After labeling, ^{99m}Tc-maSKS-$Z_{HER2:342}$ and ^{99m}Tc-maKKK-$Z_{HER2:342}$ were isolated from unreacted technetium and other low-molecular-weight components using size-exclusion chromatography on disposable NAP-5 columns

Table 2. Characterization Data of ^{99m}Tc-Labeled Conjugates

conjugate	^{99m}Tc-maSSS-$Z_{HER2:342}$	^{99m}Tc-maKKK-$Z_{HER2:342}$	^{99m}Tc-maSKS-$Z_{HER2:342}$

(Amersham Pharmacia Biotech AB, Uppsala, Sweden) pre-equilibrated with PBS. The purity was assessed by analysis with ITLC strips (Pall Life Sciences, Ann Arbor, USA), eluted in PBS. Validation experiments demonstrated that, in this system, pertechnetate and cysteine complexes of ^{99m}Tc migrate with the eluent front, while labeled Affibody molecules under these conditions remain at the origin. The labeling yield and the stability were determined using ITLC strips, eluted with PBS and analyzed with a Cyclone Storage Phosphor System (http://www.perkinelmer.com/) (Perkin-Elmer, Wellesley, MA). To determine the presence of reduced hydrolyzed technetium, ITLC was eluted with pyridine/acetic acid/water (5:3:1.5). In this eluent, the technetium colloids remained at the origin, while the radiolabeled Affibody molecules, pertechnetate, and other complexes of ^{99m}Tc migrated with the solvent front. To validate the radiochemical purity obtained with ITLC, an analysis was performed on an ÄKTAprime LC system (GE Healthcare, Uppsala Sweden) with the UV detector set to 280 nm. The analysis was run on a prepacked Superdex Peptide 10/300 GL column (GE Healthcare, Uppsala Sweden), with a flow rate of 0.5 mL/min using a 50 mM phosphate buffer with 150 mM NaCl (pH 7.0) as running buffer. Fractions were collected and radioactivity was measured on a gamma counter.

Stability Studies. *Cysteine Challenge.* The stability of labeled Affibody conjugates was tested in 300 molar excess of cysteine. A fresh solution of cysteine was prepared (1 mg/mL in PBS, pH 7.0). The radiolabeled conjugates were added to a final molar ratio of cysteine to peptide of 300:1. The test tubes were incubated for 2 h at 37 °C and the radiochemical purity was analyzed using ITLC, eluted in PBS.

Plasma Stability Test. Serum samples were prepared as described in ref *20*. Shortly, a serum sample (240 μL) was mixed with freshly labeled $Z_{HER2:342}$ (10 μL) to obtain an Affibody molecule concentration similar to the concentration in blood at the moment of injection. The sample was incubated for 1 h at 37 °C. After incubation, the sample was analyzed on NuPAGE 4−12% Bis-Tris Gel (Invitrogen) in MES buffer (200 V constant). A sample of pertechnetate, not treated in blood serum, was used as reference and run in parallel with the test sample on the same gel. After electrophoresis, the radioactivity distribution along the gel was evaluated using a Cyclone Storage Phosphor System.

In Vitro Cell Studies. The HER2-expressing ovarian carcinoma cell line SKOV-3, displaying approximately 1.2×10^6 HER2 receptors per cell (*25*), was used in this study. The cell line was cultured in McCoy's medium (Flow Irvine, UK). The medium was supplemented with 10% fetal calf serum (Sigma, USA), 2 mM L-glutamine, and PEST (penicillin 100 IU/mL and 100 μg/mL streptomycin), all from Biokrom Kg, Germany. The cells were cultured at 37 °C in a humidified incubator with 5% CO_2 and trypsinized using trypsin−EDTA solution (0.25% trypsin, 0.02% EDTA) from Biokrom Kg, Germany. SKOV-3 cells were cultivated on Petri dishes with a diameter of 3.5 cm to a cell density of $(2-5) \times 10^5$ cells per dish.

Binding Specificity Study. To test the binding specificity of the labeled conjugates, one set of SKOV-3 cells was presaturated with a 100-fold excess of nonlabeled Affibody molecules 10 min before the labeled conjugate was added and measured according to Engfeldt et al. (*26*).

Internalization and Retention Study. The internalization rates of the labeled conjugates on SKOV-3 cells were determined as described in Ahlgren et al. (*27*). Shortly, cultured SKOV-3 cells were incubated for 3 h at 4 °C using a 5:1 molar ratio of ^{99m}Tc-labeled conjugates to HER2 receptors. All procedures were performed on ice. Thereafter, the incubation medium was discarded, and the cells were washed three times using ice-cold serum-free medium. After addition of 1 mL complete medium, the cells were incubated further at 37 °C. At designated time points, up to 24 h, one group of three dishes was analyzed for cell-associated radioactivity. Medium was collected; cells were washed three times with ice-cold serum-free medium (these two steps were omitted for the time point 0 h) and treated with 0.5 mL of 4 M urea solution in 0.2 M glycine buffer, pH 2.5, for 5 min on ice. The acid fraction was collected, and cells were washed with additional 0.5 mL acid solution. The radioactivity in the acid wash fraction was considered membrane-bound radioactivity. After addition of 0.5 mL of 1 M NaOH, the cells were incubated at 37 °C for at 30 min, and the basic solution was collected. The cell dishes were washed with additional 0.5 mL of basic solution. The radioactivity in the alkaline fractions was considered internalized radioactivity. The radioactivity content of the samples was measured as mentioned above.

Antigen Binding Capacity Study. Assessment of antigen binding capacity of ^{99m}Tc-labeled conjugates was performed using SKOV-3 cells according to Engfeldt et al. (*26*).

In Vivo Animal Studies. The animal study was approved by the Local Ethics Committee for Animal Research. In comparative biodistribution studies, non-tumor-bearing NMRI mice were used. In tumor targeting and imaging experiments with ^{99m}Tc-maSKS-$Z_{HER2:342}$, female BALB/c *nu/nu* nude mice were used. The animals were acclimatized for one week at the Rudbeck laboratory animal facility before tumor implantation. The tumors were grafted by subcutaneous injection of $\sim 10^7$ SKOV-3 cells in the right hind leg. Xenografts were allowed to develop during 6 weeks. In all biodistribution studies, the mice were euthanized at predetermined time points with an intraperitoneal injection of Ketalar−Rompun solution (20 μL of solution per gram of body weight: Ketalar [ketamine], 10 mg/mL; Rompun [xylazin], 1 mg/mL). The mice were heart-punctured with a 1 mL syringe rinsed with diluted heparin (5000 IE/mL, Leo Pharma, Copenhagen, Denmark). Blood and organ samples were taken and weighed, and their radioactivity was measured using an automatic gamma counter. The organ uptake values were calculated as percent injected activity per gram tissue (% IA/g).

Biodistribution in NMRI Mice. Twelve mice were randomly divided into 3 groups with 4 animals each. The three groups were subcutaneously injected with ^{99m}Tc-maSSS-$Z_{HER2:342}$, ^{99m}Tc-maSKS-$Z_{HER2:342}$, and ^{99m}Tc-maKKK-$Z_{HER2:342}$, respectively (1 μg Affibody ligand, ∼100 kBq in 100 μL of PBS). The mice were euthanized at 4 h p.i.; organ samples were collected and measured. In previous studies, we have validated that the biodistribution of radiolabeled Affibody molecules 4 h p.i. is the same for both i.v. and s.c. injection and independent of the label (*28*, *29*). Subcutaneous injections were mainly chosen since they are more reproducible (smaller errors) when injecting into a large number of animals (*24*).

Biodistribution in Mice with SKOV-3 Xenografts. The tumor targeting properties of ^{99m}Tc-maSKS-$Z_{HER2:342}$, which demonstrated the best biodistribution properties in normal mice, were evaluated in female BALB/c *nu/nu* nude mice bearing SKOV-3 xenografts. The mice were intravenously injected with ^{99m}Tc-

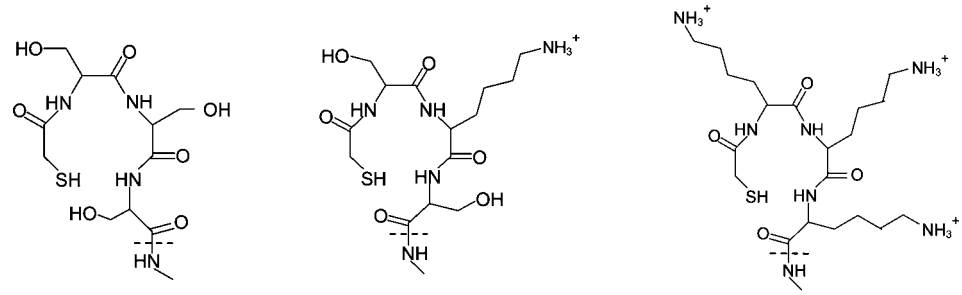

Figure 1. Chelator structures. Dashed lines indicate the border to the Affibody molecule $Z_{HER2:342}$.

maSKS-$Z_{HER2:342}$ (1 μg Affibody ligand, ~ 100 kBq in 100 μL of PBS). After 0.5, 1, 4, 8, and 24 h p.i., the mice were euthanized as described earlier. In the binding specificity study, one group of mice was preinjected with a 1000-fold molar excess of nonlabeled Affibody molecules prior to injection of ^{99m}Tc-maSKS-$Z_{HER2:342}$. At 4 h p.i., the mice were euthanized and organ samples were collected and measured.

Gamma Camera Imaging with ^{99m}Tc-maSKS-$Z_{HER2:342}$. Two mice were intravenously injected through the tail vein with 3 MBq of ^{99m}Tc-maSKS-$Z_{HER2:342}$ (10 μg in 100 μL of PBS) and imaged at 4 h p.i. Imaging was performed using a Siemens e.Cam gamma camera equipped with a LEHR collimator at the Department of Nuclear Medicine of Uppsala University Hospital. Static images were collected during 10 min and evaluation of the images was performed with *Osiris* v 4.19 software (Digital Imaging Unit, University Hospital of Geneva, Switzerland).

Data Treatment. In vitro and in vivo data were processed with Microsoft *Excel 2003* (Microsoft, Redmond, WA) and all graphs were drawn with GraphPad *Prism* v 4 (GraphPad Software, San Diego; CA). Statistical analysis was performed using Student's *t* test.

RESULTS

Peptide Synthesis and Characterization. The Fmoc solid-phase synthesis of $Z_{HER2:342}$ resulted in a yield of 21% of the full-length peptide, as determined by analytical RP-HPLC. The ^{99m}Tc-chelating sequences maSKS or maKKK were introduced N-terminally by manual synthesis, resulting in total synthetic yields of 14% and 12%, respectively (Table 1). The HPLC retention times were 13.9, 14.3, and 14.4 min for maKKK-$Z_{HER2:342}$, maSKS-$Z_{HER2:342}$, and maSSS-$Z_{HER2:342}$, respectively. Following purification by RP-HPLC, the purity was higher than 90%. Data of maSSS-$Z_{HER2:342}$ (*20*) are included for comparison. The molecular weights of the different conjugates were determined by mass spectrometry and correlated well with the theoretically calculated masses, as shown in Table 1.

The binding kinetics of the different Tc-chelating peptides were compared in a biospecific interaction analysis on a Biacore 2000 instrument. As indicated in Table 1, both conjugates showed similar subnanomolar affinities to surface-immobilized HER2 receptors: the dissociation constants (K_D) were 310 pM for maSKS-$Z_{HER2:342}$ and 270 pM for maKKK-$Z_{HER2:342}$ (Figure 2A).

The melting points were 64−68 °C for the conjugates, which are close to the previously reported values of $Z_{HER2:342}$ (see Table 1). The CD spectra of the proteins showed that the structures of the Affibody molecules were similar and refolded after heating to 90 °C (Figure 2B,C).

^{99m}Tc-Labeling and Stability Studies. The radiolabeling yields were above 90% for both ^{99m}Tc-maSKS-$Z_{HER2:342}$ and ^{99m}Tc-maKKK-$Z_{HER2:342}$, as shown in Table 2. The isolated yield after size-exclusion chromatography using NAP-5 columns was about 80%, and the radiochemical purity of the purified products

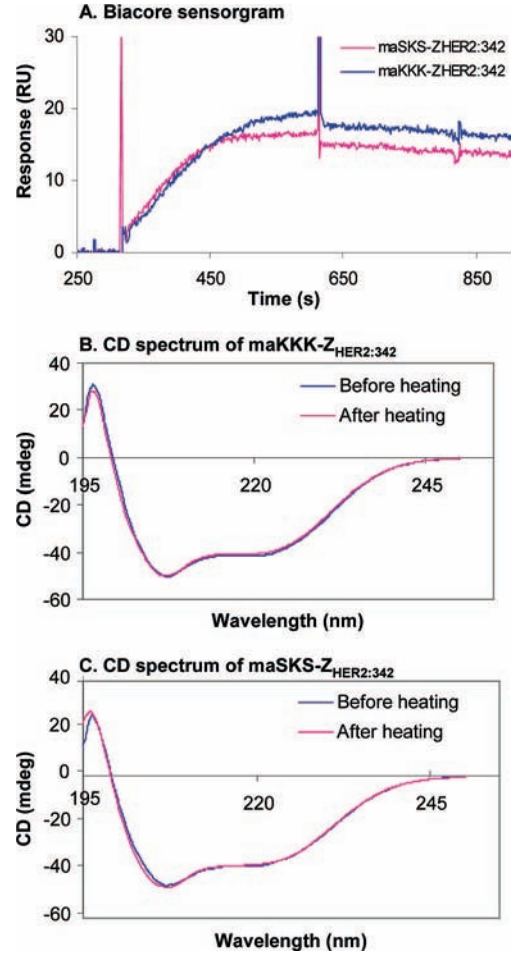

Figure 2. Illustrative Biacore sensorgram of maKKK-$Z_{HER2:342}$ and maSKS-$Z_{HER2:342}$, both at 5 nM (A) and CD spectra before and after heating to 90 °C of maKKK-$Z_{HER2:342}$ (B) and maSKS-$Z_{HER2:342}$ (C), respectively.

was typically over 97% for both lysine-containing conjugates. Size-exclusion chromatography confirmed that the retention volume of radiolabeled conjugates corresponded to the retention volume of monomeric form of Affibody molecules (see Figure 3). A typical specific activity of 18 GBq/μmol was obtained for both ^{99m}Tc-labeled Affibody molecules. The presence of reduced hydrolyzed technetium was less than 2% in all experiments.

As presented in Table 2, the stability of the labeled conjugates was evaluated in a cysteine challenge test and the results showed high stability of the labeled conjugates, with over 90% radioactivity still attached to the conjugates. After incubation in mouse serum, the stability of ^{99m}Tc-maSKS-$Z_{HER2:342}$ and ^{99m}Tc-maKKK-$Z_{HER2:342}$ was good. No release of free pertech-

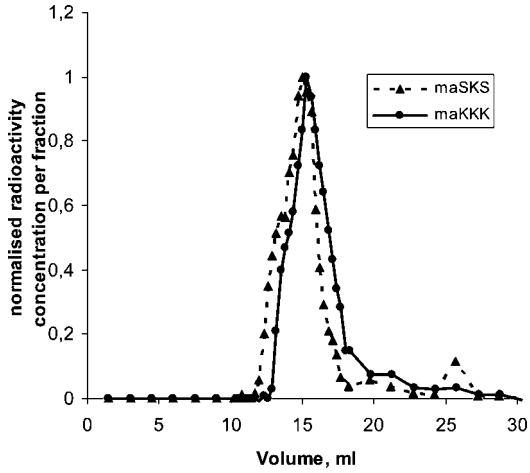

Figure 3. Size-exclusion chromatography analysis of radiolabeled conjugates was performed using a Superdex Peptide 10/300 GL column as described in the Experimental Procedures section. Radioactivity of the fractions was measured off-line.

netate could be detected (data not shown). However, there is a peak, corresponding to a higher molecular weight, of approximately 19% of the radioactivity. This could indicate some binding of the labeled conjugate to blood proteins.

In Vitro Cell Studies. *Binding Specificity and Antigen Binding Capacity.* The in vitro binding specificity of ^{99m}Tc-maKKK-$Z_{HER2:342}$ and ^{99m}Tc-maSKS-$Z_{HER2:342}$ to SKOV-3 cells showed specific binding to HER2 receptors, since it could be blocked with receptor saturation by 100-fold excess of unlabeled $Z_{HER2:342}$. The cell-binding radioactivity was reduced from 33 ± 2% to 5.1 ± 0.3% ($p < 0.0005$) between the nonsaturated and saturated groups for ^{99m}Tc-maSKS-$Z_{HER2:342}$ and from 35 ± 5% to 5.4 ± 0.04% ($p < 0.0005$) for ^{99m}Tc-maKKK-$Z_{HER2:342}$. The antigen binding capacity was estimated to be around 60% for the ^{99m}Tc-labeled $Z_{HER2:342}$, indicating that the labeling procedure had a minor effect on the conjugates.

Cellular Retention and Internalization. The cellular processing of ^{99m}Tc-labeled $Z_{HER2:342}$ Affibody molecules is illustrated in Figure 4. The conjugates displayed a high retention of radioactivity on SKOV-3 cells, with a slow decrease over time. After 24 h, the cell-associated radioactivity retained by the SKOV-3 cells was about 60−70%. The internalization of the labeled conjugates was slow over time, with about 12% of radioactivity internalized 4 h after interrupted incubation. Both conjugates showed a similar internalization pattern within the error of the experiment.

In Vivo Animal Studies.

Biodistribution in Normal Mice. The comparative biodistribution in NMRI mice (Figure 5) showed that, by replacing one serine with one lysine in the chelator (maSSS vs maSKS), the kidney uptake was doubled from 18 ± 4% to 33 ± 2% IA/g ($p = 0.001$), while the accumulation in intestines with content was significantly reduced from 11 ± 2% to 4.3 ± 0.5% IA/whole sample ($p = 0.0006$). Substitution of all serines with lysines (maSSS to maKKK) significantly increased the kidney uptake 7-fold ($p = 5.7 \times 10^{-7}$) while the intestine uptake was decreased 2-fold ($p = 0.0004$), reaching the same level as for maSKS. On the other hand, the radioactivity of ^{99m}Tc-maKKK-$Z_{HER2:342}$ was found to be significantly higher in other organs such as blood, spleen, stomach and salivary glands, thyroid, muscle, and liver ($p < 0.05$). The liver uptake was estimated to be about 5 times higher for ^{99m}Tc-maKKK-$Z_{HER2:342}$ than for ^{99m}Tc-maSKS-$Z_{HER2:342}$ (6.8 ± 2.5% vs 0.49 ± 0.28% IA/g, $p = 0.002$).

Biodistribution in Mice Bearing SKOV-3 Xenografts. Data from the comparative biodistribution suggested that ^{99m}Tc-maSKS-$Z_{HER2:342}$ was the most suitable conjugate of the two new tested variants, with low radioactivity accumulated in the intestines and an intermediate level of kidney uptake. Thus, this conjugate was further evaluated in HER2-expressing SKOV-3 xenografts. The distribution of ^{99m}Tc-maSKS-$Z_{HER2:342}$ was examined at 0.5, 1, 2, 4, 8, and 24 h p.i. as presented in Figure 6. The tumor accumulation was high, reaching 17 ± 8% IA/g at 4 h p.i., and the radioactivity was cleared rapidly from the blood circulation, with 0.35 ± 0.13% IA/g at 4 h after administration. The tumor-to-blood ratio was 47 at this time point. Other organs showed low uptake, and the clearance from these organs was rapid over time. A blocking experiment demonstrates that ^{99m}Tc-maSKS-$Z_{HER2:342}$ bound specifically to HER2 receptors in SKOV-3 xenografts (Table 4). The tumor uptake in the blocked group with excess of nonlabeled Affibody molecules was significantly lower ($p < 0.001$). Much smaller but significant ($p < 0.05$) reduction of uptake was found also in blood, lung, liver, and spleen and in intestines of animals in the blocking group. A possible explanation is that some part of radiolabeled ^{99m}Tc-maSKS-$Z_{HER2:342}$ should dissociate continuously from the receptors in the xenografts, drain from the tumors, and re-enter the blood circulation. Such a depot is much smaller when HER2 receptors are blocked by a nonradioactive Affibody molecule.

Gamma Camera Imaging with ^{99m}Tc-maSKS-$Z_{HER2:342}$. The gamma camera image of SKOV-3 xenografts 4 h after administration of ^{99m}Tc-maSKS-$Z_{HER2:342}$ is shown in Figure 7. The tumors located on the right hind legs accumulated a large amount of radioactivity and were clearly visualized. A high accumulation of radioactivity was also seen in the kidneys, while no or very little uptake was seen in other organs. The ROI

[a] The blocked group ($n = 3$) was intravenously pre-injected with an excess amount of nonlabeled $Z_{HER2:342}$. Results are presented as percentage of injected activity per gram of tissue (% IA/g). * Statistical significance according to Student's t test gave $p < 0.001$. ** Statistical significance according to Student's t test gave $p < 0.05$.

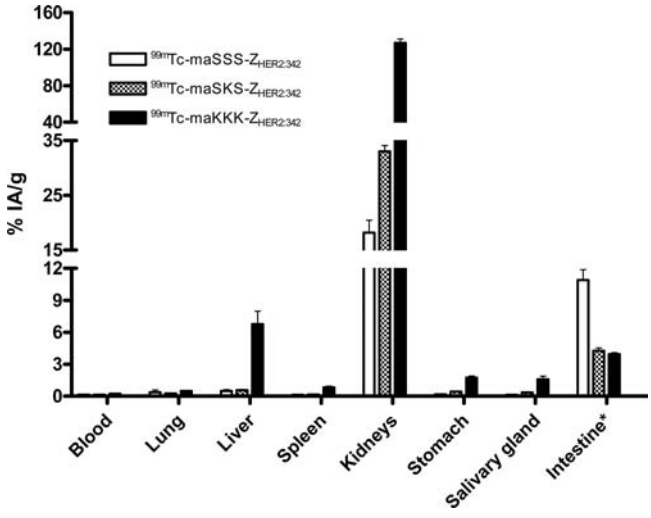

Figure 5. Comparative biodistribution of $Z_{HER2:342}$ labeled with ^{99m}Tc using maSSS, maSK,S and maKKK chelators in NMRI normal mice, 4 h p.i. Data are presented as an average % IA/g of four animals ± SD. *Data for intestine are presented as % IA per whole sample. Historical data of ^{99m}Tc-maSSS-$Z_{HER2:342}$ was taken from ref *20*.

analysis showed that the ratio of the tumor to the contralateral thigh was (average ± standard deviation) 43 ± 2.

DISCUSSION

In this study, the HER2-targeting Affibody molecule, $Z_{HER2:342}$, with the chelators mercaptoacetyl-seryl-lysyl-seryl (maSKS) and mercaptoacetyl-trilysyl (maKKK) attached to the N-terminus were synthesized in order to investigate how the incorporation of the hydrophilic positively charged amino acid lysine in the chelator sequence would affect the biodistribution properties in mice for imaging of HER2 expression in vivo. These two conjugates, maSKS-$Z_{HER2:342}$ and maKKK-$Z_{HER2:342}$, were labeled with technetium-99m and were compared with a formerly studied conjugate, ^{99m}Tc-maSSS-$Z_{HER2:342}$. The radioisotope ^{99m}Tc was chosen because of its advantages of low cost and availability, a reasonably long half-life ($T_{1/2} = 6$ h), and suitable photon energy for SPECT cameras.

The ^{99m}Tc-labeling of maSKS-$Z_{HER2:342}$ and maKKK-$Z_{HER2:342}$ were efficient and resulted in yields of more than 94%. Preserved HER2 binding capacity on SKOV-3 cells was demonstrated for all conjugates. In vitro, both ^{99m}Tc-maSKS-$Z_{HER2:342}$ and ^{99m}Tc-maKKK-$Z_{HER2:342}$ were found to be quite stable after 2 h incubation in mouse serum. Approximately 80% of the conjugates remained intact, and the rest seemed to bind to serum proteins (data not shown). In comparison to ^{99m}Tc-maSSS-$Z_{HER2:342}$, which did not demonstrate such binding under the same conditions, this level of protein binding (20% of the radioactivity) does not seem to affect clearance from the blood and other organs (see Table 3).

The in vitro cell studies showed that the labeled Affibody molecules had a slow internalization rate in SKOV-3 cells over time, which is consistent with previous results obtained for ^{111}In-labeled Affibody molecules (*27*). Other investigations have indicated that slow internalization of antibodies is advantageous for tumor targeting due to better penetration and retention in tumors (*30*). The retention of ^{99m}Tc-maSKS-$Z_{HER2:342}$ and ^{99m}Tc-maKKK-$Z_{HER2:342}$ was high, with about 60−70% of radioactivity retained in the cells 24 h following incubation. This level of retention is similar to what was previously determined for other ^{99m}Tc-labeled synthetic conjugates (*20, 23*).

The in vivo results showed that a single substitution of one serine with one lysine in the chelator (maSSS to maSKS) decreased the hepatobiliary excretion 2-fold and that the kidney uptake was increased. This shift might be explained by the overall higher hydrophilicity of the lysine in the chelator. However, substitution of all three serines with lysines (maSSS to maKKK) did not improve the hepatobiliary excretion further (intestine uptake 4 ± 0.3% IA/sample for labeled maKKK-$Z_{HER2:342}$ compared to 4.3 ± 0.5% IA/sample for maSKS-$Z_{HER2:342}$, $p = 0.34$), while the kidney accumulation was significantly higher. The radioactivity of ^{99m}Tc-maKKK-$Z_{HER2:342}$ was also found to be higher in other organs including the liver, spleen, stomach, and salivary glands, compared with what was seen with labeled maSSS-$Z_{HER2:342}$ or maSKS-$Z_{HER2:342}$.

An interesting finding from the biodistribution study was the elevated liver uptake for the maKKK conjugate compared with the maSKS or maSSS conjugates. It has previously been reported that positively charged substances preferentially accumulate in liver (*31*), and it has been suggested that cationization of proteins by chemical modification could be a way to achieve liver-specific targeting of a protein drug (*32*). Furthermore, the accumulation of radioactivity in the liver was higher for an antibody radioiodinated via a strongly positively charged D-amino acid tag (KRYRR) than for the same antibody radioiodinated through an *N*-succinimidyl 5-iodo-3-pyridinecarboxylate (SIPC) reagent (*33*), demonstrating a dramatic influence by a minor modification of the protein. Similarly, a previous study of Affibody molecules demonstrated that the use of multiple copies of the amino acid histidine (as in His-tagged Affibody molecules) also caused a high accumulation of radioactivity in the liver (*27*). In the present study, it was therefore not completely unexpected that using multiple lysine residues for ^{99m}Tc-labeling could promote elevated liver ac-

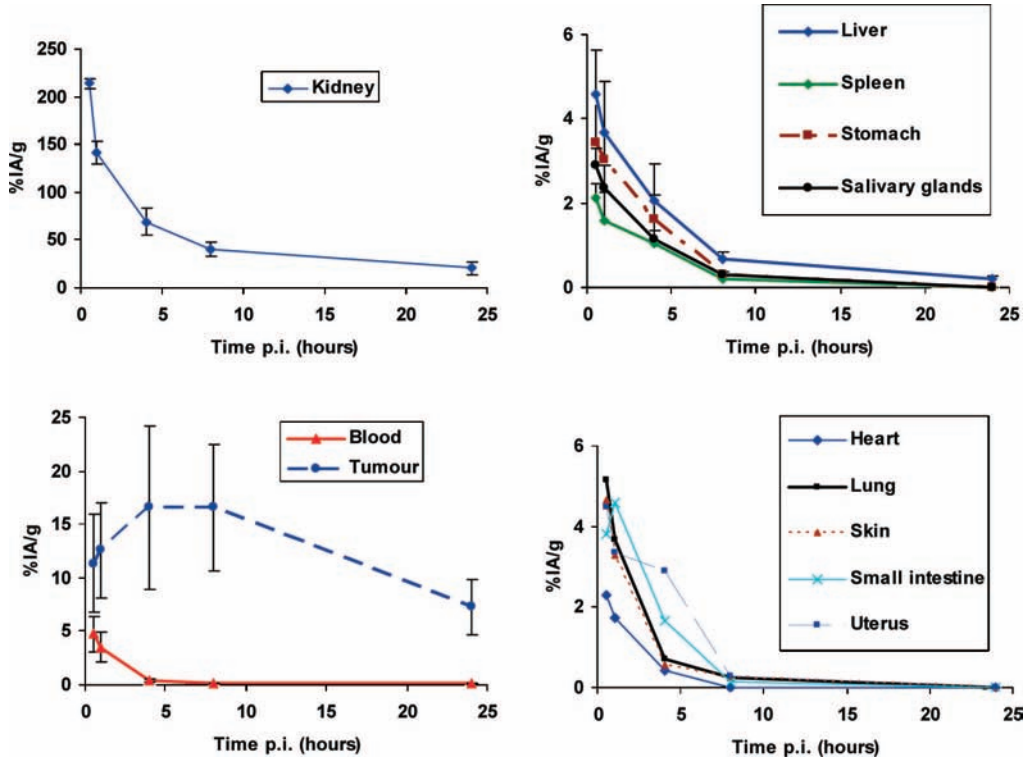

Figure 6. Biodistribution of ^{99m}Tc-maSKS-$Z_{HER2:342}$ in BALB/c *nu*/*nu* mice bearing SKOV-3 xenografts at 0.5, 1, 4, 8, and 24 h p.i. Data are presented as an average % IA/g of four animals ± SD.

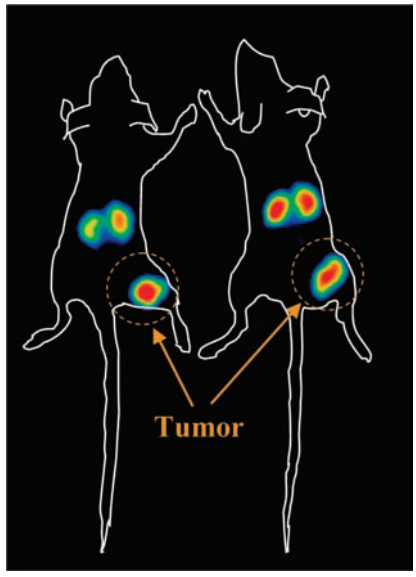

Figure 7. Gamma camera imaging of Balb/c *nu*/*nu* mice, bearing SKOV-3 xenografts on the right hind legs. The mice were imaged 4 h after administration of ^{99m}Tc-maSKS-$Z_{HER2:342}$. The tumors are indicated by arrows, while the hot spots visualized in the images are the kidneys.

cumulation. However, the detailed mechanism behind this phenomenon is still unclear.

Out of the three conjugates, ^{99m}Tc-maSKS-$Z_{HER2:342}$ showed the most promising biodistribution properties, with intermediate accumulation of radioactivity in the kidney and low accumulation in the liver. This conjugate was therefore further evaluated in mice with SKOV-3 xenografts. The in vivo evaluation in mice bearing tumors showed that ^{99m}Tc-maSKS-$Z_{HER2:3}$ led to specific and efficient accumulation in the SKOV-3 tumors (Table 4 and Figure 6). Four hours after injection, 17% IA/g was detected in the tumors, while the blood clearance was rapid; resulting in good tumor-to-blood and tumor-to-nontumor ratios for the gamma scintigraphy.

The images acquired in gamma camera after an i.v. injection of ^{99m}Tc-maSKS-$Z_{HER2:3}$ clearly visualized the tumors on the right hind legs of nude mice (Figure 7). Since small-sized (Mw < 60 kDa) substances are rapidly cleared through renal filtration, a high amount of radioactivity was also seen in the kidneys.

Our previous results showed that an increase of the chelator hydrophilicity improves the excretion properties of $Z_{HER2:342}$ (*20*, *23*). It is therefore interesting to compare the biodistribution properties of the new positively charged chelators with those of previously studied neutral and negatively charged chelators. As illustrated in Table 3, ^{99m}Tc-maSSS-$Z_{HER2:342}$ was used as the starting conjugate for the development of a suitable HER2 imaging agent. ^{99m}Tc-maSSS-$Z_{HER2:342}$ provided good tumor-to-organ ratios for imaging (*20*), but an elevated hepatobiliary excretion was seen (intestine uptake of 11 ± 2% of injected activity per whole sample), which would complicate detection of metastases in the abdominal area. The use of multiple negatively charged glutamic acids (^{99m}Tc-maEEE-$Z_{HER2:342}$) successfully switched the hepatobiliary to renal excretion (*23*), but the substitution of serine with multiple positively charged lysine (^{99m}Tc-maKKK-$Z_{HER2:342}$) remarkably increased the liver uptake (0.21% IA/g for maEEE vs 7% IA/g for maKKK). This excludes ^{99m}Tc-maKKK-$Z_{HER2:342}$ from further evaluation in tumor-bearing mice, since its clinical application would be restricted for detection of tumors in the extrahepatic sites. On the other hand, the substitution with one single lysine, as in ^{99m}Tc-maSKS-$Z_{HER2:342}$, seemed superior to ^{99m}Tc-maEEE-$Z_{HER2:342}$ in terms of renal uptake (see Table 3). Along these lines, the substitution with two glutamic acids instead of three in the chelator sequence has been evaluated. The resulting combination of serine and glutamic acid (^{99m}Tc-maESE-$Z_{HER2:342}$) was shown to provide imaging properties as good as for ^{99m}Tc-maSKS-$Z_{HER2:342}$ in terms of reduced renal uptake and

low blood, liver, and intestine accumulation, while maintaining the tumor localization capacity for imaging (*24*).

In conclusion, we have shown that substitution with serine for lysine in the chelators has a clear effect on the biodistribution of radioactivity. The introduction of multiple lysines gives rise to a high liver accumulation. However, substitution of one serine with one single lysine in the mercaptoacetyl-based chelator of Affibody molecules reduced the hepatobiliary excretion 2-fold, and the ^{99m}Tc-maSKS-$Z_{HER2:342}$ conjugate is thus favorable for imaging. We believe that our observation on the influence of different amino acid residues in the mercaptoacetyl-based chelators would be useful for design of; not only Affibody molecules, but also other small-sized peptide or scaffold-protein based tracers.

A Novel Method to Label Preformed Liposomes with ^{64}Cu for Positron Emission Tomography (PET) Imaging

Jai Woong Seo,[†] Hua Zhang,[†] David L. Kukis,[‡] Claude F. Meares,[§] and Katherine W. Ferrara*[,†]

Department of Biomedical Engineering, University of California, Davis, California 95616, Center for Molecular and Genomic Imaging, Department of Biomedical Engineering, University of California, Davis, California 95616, and Department of Chemistry, University of California, Davis, California 95616. Received July 12, 2008; Revised Manuscript Received October 10, 2008

Radiolabeling of liposomes with ^{64}Cu ($t_{1/2}$ = 12.7 h) is attractive for molecular imaging and monitoring drug delivery. A simple chelation procedure, performed at a low temperature and under mild conditions, is required to radiolabel preloaded liposomes without lipid hydrolysis or the release of the encapsulated contents. Here, we report a ^{64}Cu postlabeling method for liposomes. A ^{64}Cu-specific chelator, 6-[*p*-(bromoacetamido)benzyl]-1,4,8,11-tetraazacyclotetradecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (BAT), was conjugated with an artificial lipid to form a BAT−PEG−lipid. After incorporation of 0.5% (mol/mol) BAT−PEG−lipid during liposome formulation, liposomes were successfully labeled with ^{64}Cu in 0.1 M NH_4OAc pH 5 buffer at 35 °C for 30−40 min with an incorporation yield as high as 95%. After 48 h of incubation of ^{64}Cu-liposomes in 50/50 serum/PBS solution, more than 88% of the ^{64}Cu label was still associated with liposomes. After injection of liposomal ^{64}Cu in a mouse model, 44 ± 6.9, 21 ± 2.7, 15 ± 2.5, and 7.4 ± 1.1 (n = 4) % of the injected dose per cubic centimeter remained within the blood pool at 30 min, 18, 28, and 48 h, respectively. The biodistribution at 48 h after injection verified that 7.0 ± 0.47 (n = 4) and 1.4 ± 0.58 (n = 3) % of the injected dose per gram of liposomal ^{64}Cu and free ^{64}Cu remained in the blood pool, respectively. Our results suggest that this fast and easy ^{64}Cu labeling of liposomes could be exploited in tracking liposomes *in vivo* for medical imaging and targeted delivery.

INTRODUCTION

Liposomes are widely used in preclinical and clinical applications as carriers of drugs, genes, or contrast agents (*1, 2*). The incorporation of hydrophilic polyethylene glycol (PEG[1]) on the surface of liposomes further improves their properties (*3*). To obtain the biodistribution of long-circulating liposomes and to obtain noninvasive images in animals and humans, past studies have utilized liposomes loaded or labeled with radionuclides such as indium-111 (*4*), technetium-99m (*5*−*7*), and gallium-67 (*8*) for single photon emission computed tomography (SPECT). Labeling with fluorine-18 (*9, 10*) has been used for positron emission tomography (PET).

Three distinct approaches have been developed for the labeling or loading of liposomes with radioisotopes: (a) entrapping a soluble radiotracer inside the aqueous liposomal core, e.g., via chelating the preloaded polar ligand with ^{111}In (*11*), ^{67}Ga (*12*), or ^{99m}Tc-complex (*5, 7*), or via extrusion with 2-[^{18}F]fluorodeoxyglucose (2-[^{18}F]FDG) (*13*); (b) inserting radiolabeled lipid into the liposome bilayer (*9, 10*); and (c) attaching ^{99m}Tc onto the surface of liposomes via the chelation between ^{99m}Tc and a chelator-lipid conjugate (*14, 15*). In contrast to the extensive studies using SPECT to track liposomes in vivo, reports of PET imaging of liposomes are limited, although PET has many potential advantages (*16*). Previous reports have focused on the use of fluorine-18 to label liposomes (*9, 10*), but its short 110-min half-life makes extended studies difficult. In the treatment of diseases such as cancer, it is desirable to create stable particles that can circulate and accumulate in tumors over days to weeks (*17, 18*). Because of the temperature dependence of liposome structures (*19*), these particles may not withstand exposure to high temperatures after formulation. Here, we report a gentle postlabeling method using ^{64}Cu (half-life 12.7 h) and its application to track liposomes over 48 h. For the surface chelation method, the incorporation of a lipid−PEG−chelate conjugate (Scheme 1) in the liposome bilayer (Figure 1) was chosen, as used in previous nuclear medicine studies (*14, 20*). Previous surface chelation methods used lipid−chelate conjugates such as octadecylamine diethylenetriaminepentaacetic acid (DTPA) (*15*), dipalmitoylphosphatidylethanolamine-diethylenetriaminetetraacetic acid (DPPE-DTTA) (*20, 21*), and hydrazino nicotinamide (HYNIC) conjugated-DSPE (*14*). However, none of those reagents have been shown to bind copper stably under physiological conditions, nor would they be expected to, due to the kinetic properties of the copper ion. Among several effective copper(II) macrocyclic

[a] Reagents: (a) Fmoc-cysteine (2 eq.), HBTU (*O*-benzotriazole-*N*,*N*,*N*′,*N*′-tetramethyl-uronium-hexafluoro-phosphate) (2 eq.), DIPEA (4 eq.), 60 min; (b) 20% piperidine in DMF, 2 × 10 min, 10 min; (c) Fmoc-NH-(PEG)27-COOH (1.1 eq.), HBTU (1.1 eq.), DIPEA (2.2 eq.), 60 min; (d) Fmoc-Lys(Fmoc)-OH (2 eq.), HBTU (2 eq.), DIPEA (4 eq.), 60 min; (e) stearic acid (4 eq.), HBTU(4 eq.), DIEA(8 eq.), 60 min; (f) 1% TFA/DCM, 5 × 3 min; (g) BAT(1.5 eq.), DIPEA (10 eq.), 4 h; (h) TFA/TIPS/H_2O (95/2.5/2.5), 3 h.

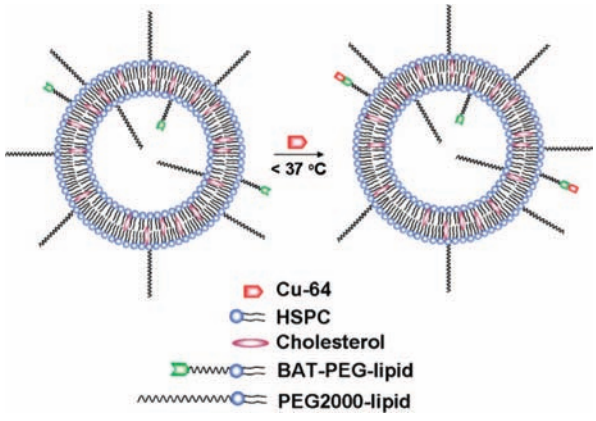

Figure 1. Surface chelation model of ^{64}Cu-labeled long circulating liposomes, where labeling was performed under mild conditions (<37 °C) to preserve liposome stability and loading during labeling.

chelators, such as DOTA, NOTA, TETA and TE2A (*22*, *23*), we chose 6-[*p*-(bromoacetamido)benzyl]-1,4,8,11-tetraazacyclotetradecane- *N*,*N*′,*N*″,*N*‴-tetraacetic acid, BAT (*24*), as the chelating ligand. BAT, a derivative of 6-benzyl-TETA (Scheme 1), has been found to form stable (*25*, *26*) and highly selective complexes with copper(II) (*27*) and has been utilized for antibody labeling (*28*, *29*) for preclinical and clinical trials. Although the cross-bridged ligand TE2A has been shown to be very stable for radiolabeling small molecules (*30*), the heating step (>70 °C) required for the incorporation of ^{64}Cu into TE2A exceeds the transition temperature of many liposomal formulations (thus releasing the contents) and could also alter lipid structure in other ways, such as hydrolysis.

EXPERIMENTAL PROCEDURES

Materials. Fmoc-Cys(Mmt)-OH, Fmoc-NH-(PEG)27-COOH, Fmoc-Lys(Fmoc)-OH, and coupling agent (HBTU, 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethylaminium hexafluorophosphate) were purchased from EMD Biosciences (La Jolla, CA) and stearic acid from Sigma-Aldrich. Fmoc-PAL-PEG-PS resin (0.16−0.21 mmol/g) was from Applied Biosystems (Foster City, CA). Solvents and other agents were all of analytical purity and from Sigma-Aldrich (Milwaukee, WI) and VWR (Brisbane, CA). All lipids and a mini-extruder were purchased from Avanti Polar Lipids (Alabaster, AL). $^{64}CuCl_2$ was purchased from Trace

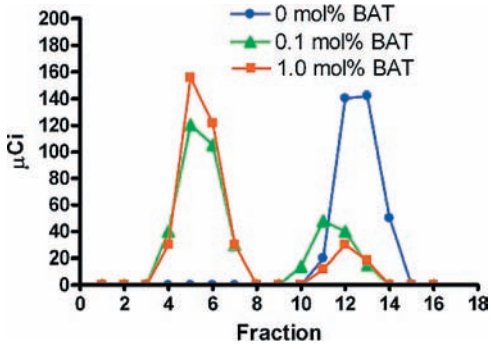

Figure 3. Elution profiles of ^{64}Cu-labeled liposomes after incubation with $^{64}CuCl_2$ for 1 h and EDTA for 20 min at room temperature in 0.1 M ammonium acetate buffer (pH 5.0). The molar ratios of lipid-PEG-BAT are 0 mol% (circle), 0.1 mol% (triangle), and 1.0 mol% (square), and are combined with 90% DPPC and 10% DSPE-PEG2000 (mol/mol).

life Science (Denton, TX, specific activity >80,000 Ci/g for *in vitro* and *in vivo* studies) or Nordion (Ontario, Canada, specific activity >5000 Ci/g for the feasibility study) under a protocol controlled by the University of California, Davis. High purity ammonium acetate (≥99.995%) was purchased from Sigma-Aldrich (St. Louis, MO). PBS was purchased from Invitrogen Corporation (Carlsbad, CA). Mouse serum was purchased from Innovative research (Novi, MI). All eppendorf tubes and glassware for labeling were prewashed with absolute ethanol and acetone, and dried in an oven before use.

Synthesis of the BAT-PEG-Lipid Conjugate (7). As shown in Scheme 1, **7** was synthesized by Fmoc solid phase synthesis. Briefly, Fmoc-Cys(Mmt)-OH, Fmoc-NH-(PEG)27-COOH, Fmoc-Lys(Fmoc)-OH, and stearic acid were sequentially coupled to the PAL-PEG-PS resin to obtain **5**. After the protecting group, Mmt, was removed with 1% TFA/DCM, BAT (*24*) was coupled onto the resin in the solvent (DMF/DMSO/H_2O = 1:1:1, v/v/v), at pH 8.0 ± 0.5, adjusted with DIPEA. The reaction was monitored with DTNP solution. The final product (**7** in Scheme 1) was cleaved from the resin by the TFA/TIPS/H_2O mixture (TFA/TIPS/H_2O = 95:2.5:2.5, v/v/v) and purified by reversed-phase high performance liquid chromatography (HPLC), with the mass confirmed by MALDI-TOF ($M + H^+$, measured, 2662; calculated, 2663). Reversed-phase HPLC was performed using a Phenomenex Jupiter 4 μm Proteo 90A (250 × 4.6 mm, analytical) and a Phenomenex Jupiter 10 μm Proteo 90A (250 × 10.0 mm, semipreparative) with a gradient from 10−90% B in 30 min (solvent A, 0.05% TFA; solvent B, acetonitrile) and a flow rate of 1.5 or 3.0 mL/min for the analytical/semipreparative column. The retention time of the BAT−PEG−lipid conjugate was 35.5 min. MALDI was measured with ABI-4700 TOF−TOF (Applied Biosystems) using matrix sinapinnic acid with a 3-layer sample preparation method (*31*). The MALDI spectral results are shown in Figure 2.

BAT-Liposome Preparation. Lipids in chloroform were mixed in a test tube and dried by gently blowing nitrogen gas with vortexing to create a thin film, which was further dried under vacuum overnight to completely remove chloroform. The dried lipid thin film was resuspended by adding 0.1 M ammonium acetate buffer (pH 5) and incubated for 5−10 min at 60 °C. After 1 min of sonication, this lipid mixture was extruded by 21 passes through a 100 nm membrane filter (Whatman, NJ) at 60−62 °C on a heating block, to form 100 nm liposomes. The liposome solution was stored at 4 °C until needed for radiolabeling.

^{64}Cu Labeling of BAT−PEG−lipids. BAT−PEG−lipids (20 μg, 7.5 nmol) in chloroform (20 μL) were added into a glass test tube, and chloroform was evaporated by gently blowing nitrogen gas with vortexing. After overnight storage under high vacuum, citrate buffer (0.1 M, 0.4 mL, pH 5.5) was added to the glass test tube containing BAT−PET−lipids. Buffered $^{64}CuCl_2$ (5.31 mCi, 196.47 MBq) in ammonium citrate (pH 5.5, 0.1 M) was added to the lipid solution, which was transferred to a plastic tube. The mixture was incubated at 37 °C and monitored by radio TLC (chloroform/ethanol/H_2O = 50:40:6, v/v/v), which showed 97% labeling yield after 40 min of incubation. After cooling to room temperature, the solution was passed through an activated C-18 sep-pak cartridge and washed with deionized water (5 mL) and anhydrous acetonitrile (8 mL). Radioactivity remaining in the cartridge was extracted by mixed ethanol and chloroform solution (1 mL, 1:1, v/v). After the solution was removed under a nitrogen stream, the activity was resuspended with 7% ethanol/PBS for the *in vivo* study. Radiochemical yield at the end of synthesis (EOS) was 59%, and specific activity was greater than 575 Ci/mmol. Radiochemical purity on both radio TLC and reversed-phase HPLC was 99% (C4 column, 250 × 4.6 mm, analytical; solvent A, 0.05 volume% trifluoroacetic acid in deionized water; solvent B, acetonitrile; flow rate, 1.5 mL/min; gradient from 10−90% B in 30 min and 90−10% B in 30−60 min; retention time, 29.6 min).

^{64}Cu Labeling of Liposomes. *For the Feasibility Study.* $^{64}CuCl_2$ (8.31 mCi, 307.47 MBq) in a volume of 35 μL (pH 1−2) was received, and NH_4OAc solution (4 μL, 1 M, pH 5.0) was added to adjust the pH. This solution (5.08 mCi, 187.96 MBq, 25 μL) was added to 475 μL of 0.1 M NH_4OAc solution (pH 5.0), and the final concentration of ^{64}Cu was 10 mCi/mL. This ^{64}Cu solution (50 μL) was added to the liposome solutions (12 mg/300 μL, total lipid mol = 12.7 μmol, DPPC/DSPE−PEG2000/BAT−PEG−lipid = 90-*x*:10.0:*x*, mol/mol/mol, *x* = 0, 0.1, and 1.0). The concentration of BAT−PEG−lipids in 12 mg of lipids was 0, 12.7, and 127 nmol, respectively. After vortexing, the mixture was incubated for 1 h at room temperature. Then, EDTA solution (0.1 M, 35 μL) was added (final EDTA concentration 10 mM), and the mixture was incubated for 20 min at room temperature. Liposomes were separated by a G-75 column (GE Healthcare, NJ) in PBS, and fractions were collected in 250 μL tubes. The radioactivity was measured with a calibrated Cu-64 mode of CRC-15 DualPET (Capintec, NJ) with noncorrection of Cu-67, and the incorporation yield was determined by eq 1 as decay corrected yield (*Fl*, radioactivity in liposome fractions; *Fa*, the sum of all radioactive fractions).

$$\text{Incorporation yield} = \frac{Fl}{Fa} \quad (1)$$

For the in Vitro Study. Liposomes (10 mg) containing 0.5 mol% of BAT−PEG−lipid (HSPC/cholesterol/DSPE-PEG2000/BAT−PEG−lipid = 55.5:39:5.0:0.5, mol/mol/mol/mol, the number of BAT−PEG−lipids, 68.7 nmol) and without BAT−PEG−lipid (HSPC/cholesterol/DSPE-PEG2000 = 56:39:5.0, mol/mol/mol) were prepared by the procedure described above. Both liposome formulations were incubated with $^{64}CuCl_2$ (2.15 mCi, 79.55 MBq) at 35 °C for 40 min. The purification

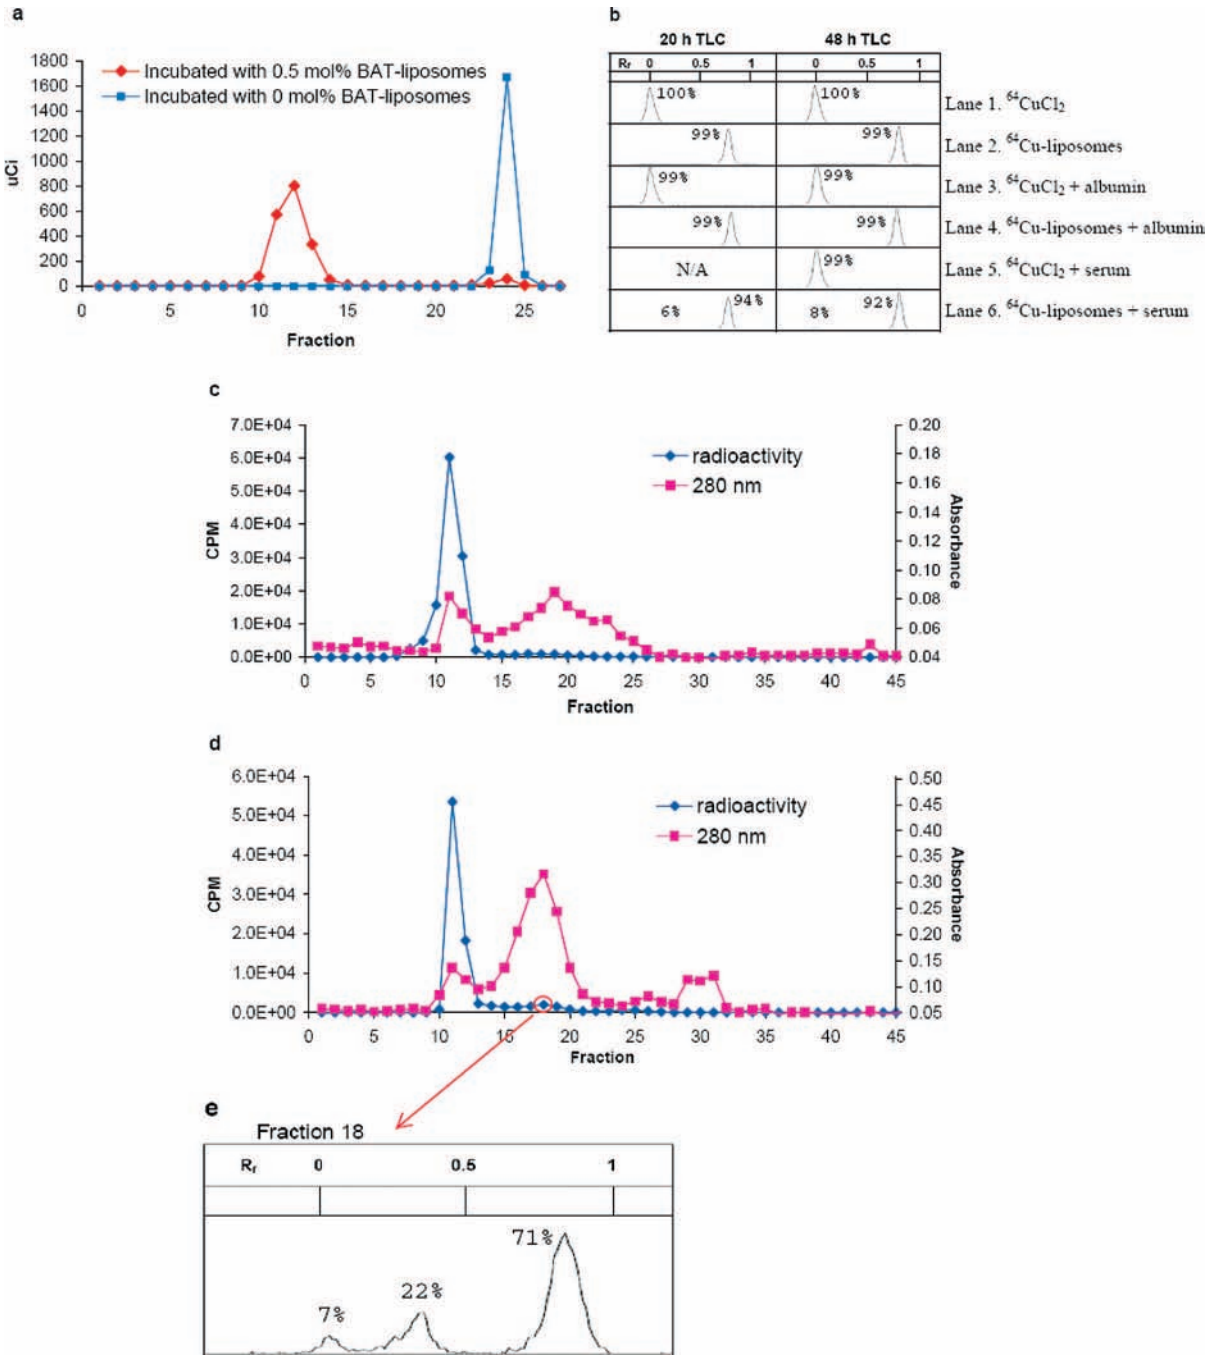

Figure 4. In vitro assay of ^{64}Cu-labeled liposomes: (a) Elution profiles of liposomes with 0.5 mol% BAT−PEG−lipid (HSPC/cholesterol/DSPE-PEG2000/BAT−PEG−lipid = 55.5:39:5.0:0.5, mol/mol/mol/mol, red diamond) and 0 mol% BAT−PEG−lipid (HSPC/cholesterol/DSPE-PEG2000 = 56:39:5.0:0.5, mol/mol/mol, blue square) after incubation with $^{64}CuCl_2$ for 40 min and EDTA for 15 min at 35 °C in 0.1 M ammonium acetate buffer (pH 5.0). Liposomes were separated by a size exclusion column. With 0.5 mol% BAT−PEG−lipid, ^{64}Cu was associated with liposomes; without BAT−PEG−lipid, ^{64}Cu was not detected in the liposomal fraction. (b) Radio TLC on silica plate was developed with eluant (chloroform/methanol/H_2O = 50:40:6, vol/vol/vol). Retention factor (R_f) of ^{64}Cu-BAT−PEG−lipid was 0.8 and that of $^{64}CuCl_2$ was 0. Lanes 1−6 were measured at 20 and 48 h as indicated in b. (c) Chromatogram of the mixture of ^{64}Cu-liposomes and albumin (8 mg/mL) in PBS after 48 h of incubation at 37 °C. The mixture was separated by a size exclusion column. Elution of liposomes and serum proteins was measured by gamma-counter (diamonds) and UV absorbance at 280 nm (squares). (d) Chromatogram of the mixture of ^{64}Cu-liposomes and serum in PBS (PBS/serum = 1:1, vol/vol) after 48 h of incubation at 37 °C. (e) Radio TLC of fraction 18 performed as described in b. The peak (R_f 0.8) represents ^{64}Cu-BAT−PEG−lipid. The small peak near 0 indicates free ^{64}Cu, and the middle peak has not been characterized.

continued as described above, and the labeling yield was determined by eq 1.

For the in Vivo Study. Liposomes (1 mg, HSPC/cholesterol/DSPE-PEG2000/BAT−PEG−lipid = 55.5:39:5.0:0.5, mol/mol/mol/mol, the number of BAT−PEG−lipid, 6.85 nmol) were prepared by the procedure above. $^{64}CuCl_2$ (2.75 mCi, 101.75 MBq) solution was added to 300 μL (0.1 M NH_4OAc, pH 5) of BAT−liposome solution and incubated at 37 °C for 40 min. Purification continued as described above. After the radioactivity decayed, size and zeta potential were measured with a NICOMP 380 ZLS (Particle Sizing Systems, CA).

***In Vitro* Stability Test.** Separated ^{64}Cu-labeled liposomes (~1.0 mg lipids) in PBS buffer (pH 7.4, 0.5 mL) were added to 0.5 mL of mouse serum and albumin solution (final concentration, 8 mg/mL). The mixture was kept in a shaker (300 rpm) at 37 °C, and a sample of 100 μL was taken from the

Table 1. Size (nm) and Zeta Potential (mV) of 0.5 mol% BAT-Liposomes ($n = 2$)

	size (nm)		zeta potential (mV)	
liposome	before	after	before	after

solution at 48 h and hand-loaded onto a sephachryl-300HR (GE Healthcare, NJ) packed column (15 mm I.D, 250 mm height), which was eluted with PBS under a pressure of 2 psi. Fractions (1.5 mL per fraction) were collected into test tubes, and radioactivity was measured with the 1470 Automatic Gamma Counter (Perkin-Elmer Life Sciences, MA). After the radioactive decay, the absorbance of all fractions was measured at 280 nm.

Radio TLC assay. Each aliquot (10 μL) of six solutions described below was dissolved into 50% ethanol solution (100 μL) after 20 and 48 h incubation at room temperature: $^{64}CuCl_2$ in 0.1 M NH_4OAc solution, $^{64}CuCl_2$ in serum solution (PBS/serum = 1:1, v/v), $^{64}CuCl_2$ in albumin solution, ^{64}Cu-labeled liposomes in PBS buffer, ^{64}Cu-labeled liposomes in albumin solution, and ^{64}Cu-labeled liposomes in serum solution (PBS/serum = 1:1, v/v). TLC was run on aluminum-backed silica gel sheets (silica gel 60 F_{254}, EMD, NJ), developed with chloroform/methanol/H_2O (50:40:6, v/v/v). The radio TLC was recorded by a radio-TLC Imaging Scanner (Bioscan, NW).

Biodistribution Study. All animal studies were conducted under a protocol approved by the University of California, Davis Animal Use and Care Committee. A total of 10 animals (male FVB mice, 8−13 weeks, 25−30 g, Charles River, MA) were examined over the course of this study. For each image, four or three mice per group were anesthetized with 3.5% isofluorane and maintained at 2.0−2.5%, and catheterized to ensure proper tail vein injection, after which bolus injections of ^{64}Cu-BAT−PEG−lipids (0.263 ± 0.013 mCi, 9.73 ± 0.48 MBq per animal), ^{64}Cu-labeled liposomes (4.6−18 μmol/kg, 0.17−0.21 mCi, 6.29−7.77 MBq per animal), and $^{64}CuCl_2$ (carrier free, 0.15−0.4 mCi, 5.55−14.7 MBq per animal) in PBS (pH 7.2) were administered as PET scans were initiated, using a manually controlled injection that was timed for uniform administration over 15 s. After the 48-h PET scans, the mice were euthanized by cervical dislocation, and organs of interest were harvested and weighed. Radioactivity was measured using a 1470 Automatic Gamma Counter.

PET Scans and Time-Activity Curves (TAC). PET scans were conducted with the microPET Focus (Concorde Microsystems, Inc., TN) over 60 min. Maximum a posteriori (MAP) files were created with ASIPro software (CTI Molecular Imaging) and used to obtain quantitative activity levels in each organ of interest as a function of time. TACs were obtained with region-of-interest (ROI) analysis using ASIPro software and expressed as percentage of injected dose per cubic centimeter (%ID/cc).

RESULTS AND DISCUSSION

Fmoc solid phase synthesis was used to create the lipid−PEG−chelate conjugate to minimize hydrolysis of the ester group in the lipid conjugate and maximize purity of the final conjugate (**7** in Scheme 1) (*32*). A short PEG spacer (28 repeat units, MW ~1232) was introduced to facilitate accessibility of ^{64}Cu to the chelator by minimizing the steric effect of neighboring lipid head groups, while burying the chelator within the longer PEG brush (45 repeat units, MW ~1980) of the surrounding lipid molecules. Briefly, Fmoc-Cys(Mmt)-OH, Fmoc-NH-(PEG)27-COOH, Fmoc-Lys(Fmoc)-OH, and stearic acid were sequentially coupled to the PAL-PEG-PS resin, to obtain **5** in Scheme 1. After the protecting group, Mmt, was removed with 1% TFA/DCM, BAT was coupled to the resin in the mixture solvent (DMF/DMSO/H_2O = 1:1:1, v/v/v), at pH 8.0 ± 0.5, adjusted with DIPEA. The reaction was monitored with DTNP solution. The final product (**7** in Scheme 1) was cleaved from the resin by a TFA/TIPS/H_2O mixture (TFA/TIPS/H_2O = 95:2.5:2.5, v/v/v) and purified by HPLC, with the mass confirmed by MALDI ($M + H^+$, measured, 2662; calculated, 2663; Figure 2).

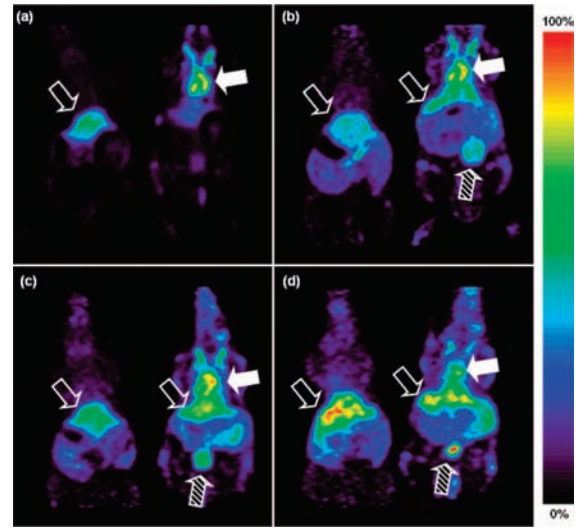

Figure 5. Coronal view of a microPET image with two mice (left, $^{64}CuCl_2$ injected; right, ^{64}Cu-liposomes) at four time points ((a) 0, (b) 18, (c) 28, and (d) 48 h after i.v. injection). A relative scale (the brightest spot is maximum) was applied for images. The filled arrow indicates the blood pool, the striped arrow indicates the bladder, and the unfilled arrow indicates the liver.

To check the feasibility of chelating ^{64}Cu onto BAT liposomes, the chelation yields were compared for three temperature sensitive liposome formulations (*33*, *34*), with 0, 0.1, and 1.0 mol% BAT−PEG−lipid, respectively (Figure 3). Similar to the labeling protocol developed for antibodies (*25*), chelation of ^{64}Cu onto liposomes was performed in 0.1 M NH_4OAc pH 5 buffer at room temperature for 60 min. Unchelated ^{64}Cu was removed by mixing the liposome solution with 1/10 (v/v) 0.1 M EDTA solution for 20 min. ^{64}Cu-labeled liposomes and ^{64}Cu-EDTA complexes were separated with a Sephadex-G75 column with the normalized radioactivity of each fraction shown in Figure 3. The ^{64}Cu chelation yields for 0, 0.1, and 1.0 mol% BAT liposomes were 0%, 83%, and 89%, respectively. Specific activity of the chelator was determined as 29.1 μCi (0.1 mol%) and 31.3 μCi (1.0 mol%) per 1 mg of total lipids and as 27.5 and 2.96 Ci per 1 mmol BAT−PEG−lipids. The number of BAT−PEG−lipid molecules in the 0.1 mol% BAT liposomes was 11 times more than the molecules of added $^{64}CuCl_2$ (0.42 mCi).

To demonstrate that this technique can successfully label multiple liposomal formulations and to demonstrate stability over 48 h, *in vitro* and *in vivo* assays were performed with long circulating liposomes (*35*). The *in vitro* stability of ^{64}Cu-labeled liposomes was also tested with 0.5 mol% BAT−PEG−lipids in a nontemperature sensitive formulation. Incubation of both liposomes with $^{64}CuCl_2$ at 35 °C for 45 min, followed by treatment with EDTA solution for 15 min, gave an estimated 95% labeling yield with 0.5 mol% BAT liposomes (Figure 4a). Specific activity was measured as 0.194 mCi per 1 mg of total lipids or 28.2 Ci per 1 mmol BAT−PEG−lipids.

^{64}Cu was not detected on liposomes lacking the BAT-lipid. Labeled liposomes in PBS (pH 7.4) were mixed with albumin (10 mg/mL) and mouse serum (PBS/serum = 1:1, v:v). Mixtures were allowed to stand at 37 °C, and the stability was monitored by radio TLC (Figure 4b) and chromatography with a size exclusion column (Figure 4c,d). As shown in the TLC study

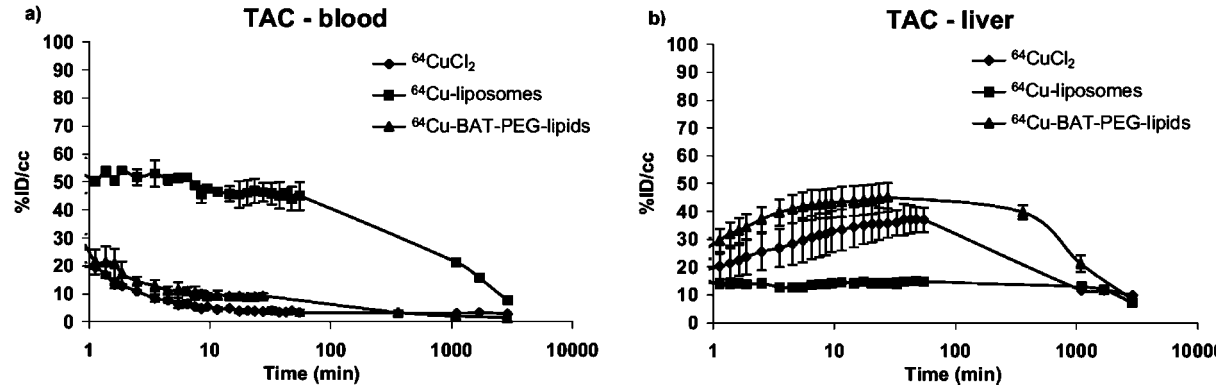

Figure 6. Time activity curves in blood and liver of mice ($n = 3-4$ per group) after bolus injections of $^{64}CuCl_2$, ^{64}Cu-BAT−PEG−lipid, and ^{64}Cu-labeled liposomes. TACs for heart and liver (a and b) were obtained from microPET in each organ of interest as a function of time by drawing regions of interest (ROI).

(Figure 4b), radioactivity in the form of $^{64}CuCl_2$ (lane 1), $^{64}CuCl_2$ associated with albumin (lane 3), and $^{64}CuCl_2$ associated with serum (lane 5) were retained at the origin. However, the relatively lipophilic ^{64}Cu-liposomes (lane 2) (^{64}Cu−BAT−PEG−lipid on silica plate), shifted to R_f 0.8, including 99% of the radioactivity. ^{64}Cu-liposomes incubated with albumin (lane 4) for 48 h also showed 99% of the radioactivity in the R_f 0.8 region. This suggests that ^{64}Cu-liposomes are inert to albumin. With ^{64}Cu-liposomes incubated with mouse serum, 6% and 8% of the activity was found in R_f 0.0 after 20 and 48 h of incubation, respectively. The chemical form of the copper was not investigated further.

To further characterize the effect of serum on chelation stability, an analysis was performed using size exclusion chromatography, with aliquots of solution loaded into the size exclusion column after incubation with albumin and serum for 1 and 48 h. The radioactivity was measured with a gamma-counter and absorbance of the serum component read at 280 nm. The size exclusion chromatogram of radioactivity from the albumin mixture (Figure 4c) showed that fractions (f1−30) contain more than 99% of the total radioactivity. Liposome fractions in the main peak (f7−15) and minor broad peak (f16−22) contained 95% and 4.1% of the total radioactivity, respectively. Thus, the labeled liposomes (radioactivity) and albumin (280 nm) could be separated, and albumin, the major component of serum, did not affect the stability of the labeled liposomes.

Size exclusion chromatography (Figure 4d) following serum incubation also showed that fractions (f1−30) contain more than 99% of the total radioactivity. As shown in Figure 4d, three peaks, with fractions f9−15, f16−22, and f23−30 were found to have 88%, 9.1%, and 2.7% of the radioactivity, respectively. To elucidate whether the second peak (f16−22) contains ^{64}Cu−BAT−PEG−lipid or dissociated ^{64}Cu, radio TLC of one fraction was performed. TLC showed three peaks (Figure 4e) corresponding to R_f equal to 0 (7%), 0.35 (22%), and 0.8 (71%). If the result is compared with lane 2 in Figure 4b, the major peak (R_f of 0.8) corresponds with the ^{64}Cu-liposomes. Radioactivity after the 14th fraction in Figure 4d is assumed to represent ^{64}Cu−BAT−PEG−lipids, which associated with serum during incubation. Therefore, we estimate that more than 88% of the ^{64}Cu remained associated with the liposomes after 48 h in serum. Prior work with ^{67}Cu-antibodies labeled using BAT showed a dissociation of copper from the chelator of approximately 1% per day under physiological conditions in serum (*25*). The properties of liposomes, including possible exchange of lipids with other serum components, make it difficult to specifically measure the rate of copper dissociation for the system studied here.

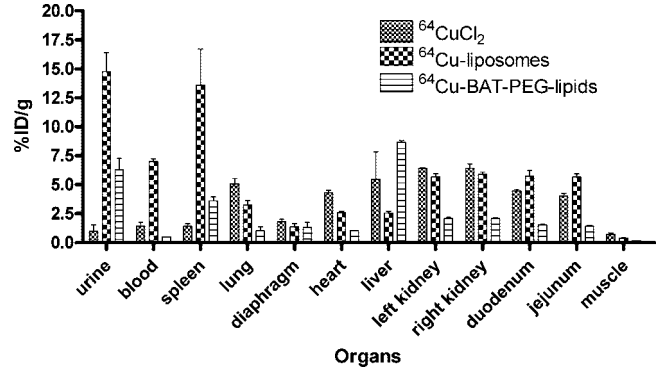

Figure 7. Biodistribution of liposomal ^{64}Cu ($n = 4$), ^{64}Cu-BAT−PEG−lipid ($n = 3$), and free ^{64}Cu ($n = 3$) in mice at 48 h after injection.

The *in vivo* performance of ^{64}Cu-labeled liposomes was studied, with the *in vivo* results compared with previously reported ^{99m}Tc-labeled liposome studies (*14*, *36*). Liposomes with 0.5 mol% BAT−PEG−lipid were labeled with $^{64}CuCl_2$ (3.0−4.0 mCi/mg lipids) at 37 °C for 40 min. The labeling yield was 62 ± 13% ($n = 2$), and the specific activity was 1.65 ± 0.29 ($n = 2$) mCi per 1 mg of total lipids or 242 ± 42 ($n = 2$) Ci per 1 mmol BAT−PEG−lipids. The size and zeta potential of liposomes before and after labeling are listed in Table 1. The liposomes were reduced in size by about 10 nm after labeling, likely due to a difference in osmolarity before (0.1 M ammonium acetate buffer, ∼240 mOsm, pH 5.0) and after labeling (10 mM PBS buffer, ∼300 mOsm, pH 7.4). Zeta potential was not significantly changed before (−40.8 mV) and after (−41.2 mV) labeling.

In vivo imaging with ^{64}Cu-labeled liposomes was then performed in FVB mice with microPET and compared with free ^{64}Cu ($^{64}CuCl_2$). Figure 5 shows four images from 30-min scans at 0, 18, 28, 48 h after i.v. injection, for both a free ^{64}Cu injection (left) and a liposomal ^{64}Cu injection (right). Free ^{64}Cu rapidly accumulated in the liver (Figure 5a−d), and accumulation was highest in the liver throughout the scan as in ref *37*. In contrast, liposomal ^{64}Cu remained in the blood pool (Figure 5a−d) through 18, 28, and 48 h. Uptake of the liposomes by the reticulo-endothelial system is expected with previous SPECT studies showing accumulation similar to that observed here (*14*). The accumulation of ^{64}Cu in the liver and other organs can result from intracellular processes via the metabolism of liposomes (*38*) and transchelation of ^{64}Cu to ceruloplasmin (*26*), superoxide dismutase (SOD) (*38*, *39*), or copper chaperone for SOD (*40*);

however, comparing our results with previous liposomal SPECT studies using Tc-99m, these effects do not appear to be substantial.

Time activity curves (TAC) corresponding to blood and liver are shown in Figure 6. For the ^{64}Cu-liposomes, decay-corrected radioactivity in the blood pool decreased to 44 ± 6.9, 21 ± 2.7, 15 ± 2.5, and 7.4 ± 1.1 ($n = 4$) %ID/cc at 30 min, 18, 28, and 48 h, respectively (Figure 6). To compare our TAC data with (*14*), the maximum %ID/cc (50 ± 8.9) at 2 min was fixed as the initial blood pool activity, and the TAC estimates at 30 min, 18, 28, and 48 h were converted to 88%, 42%, 30%, and 15%, repectively, of the original radioactivity in the blood pool. These values are similar to those observed by Laverman in a study of rats with ^{99m}Tc-HYNIC liposomes, which showed 40% of the initial blood-pool radioactivity remaining at 24 h (*14*). Similarly, 38% of initial activity was retained in the blood pool at 20 h following injection of labeled liposomes into rats in (*36*). A solution of ^{64}Cu−BAT−PET−lipid (specific activity, 575 Ci/mmol) was also injected into the mouse tail vein ($n = 3$). As a result, radioactivity accumulated in the liver within 30 min and cleared in a manner similar to that of the injected $^{64}CuCl_2$ (Figure 6).

The biodistribution at 48 h shows that activity in the urine, blood, and spleen of liposomal ^{64}Cu was significantly higher than that of free ^{64}Cu or ^{64}Cu-BAT-PET-lipid (Figure 7). Subsequent studies have indicated that the activity within the spleen is dependent on the lipid dose injected, decreasing with larger amounts of lipid (data not shown).

CONCLUSIONS

We describe a novel ^{64}Cu labeling method for liposomes. By solid phase synthesis, a BAT−PEG−lipid conjugate was prepared, and by incorporating BAT−PEG−lipid into liposomes and incubating the resulting liposomes with $^{64}CuCl_2$, ^{64}Cu liposomes were obtained with a labeling yield as high as 95%. The liposomal ^{64}Cu was stable in mouse serum *in vitro* and was long-circulating *in vivo*. These results suggest that this novel labeling method (^{64}Cu-BAT-liposomes) can be further exploited for tracking liposomes with PET *in vivo*.

ACKNOWLEDGMENT

The staff in the CMGI (Center for Molecular and Genomic Imaging, UC Davis) for handling ^{64}Cu and imaging studies are gratefully acknowledged. The support of NIH CA 103828 is appreciated.

A generally applicable strategy of chemically labeling (-)-morphine (**1**) is described. The synthesis starts from commercially available starting materials and can be completed in two steps with an overall yield of 23%. In silico simulation and NMR results show that the binding of (-)-morphine to one of its molecular targets, toll-like receptor **4** (TLR4), was not affected by the modification. Secreted embryonic alkaline phosphatase (SEAP) reporter assay results demonstrate that C_3 biotinylated and unmodified (-)-morphine show similar biological activities in live cells. To our knowledge, these studies provide the first practical and concise method to label various opioid derivatives, a group of important therapeutics in pain management, for biochemical/pharmacological studies.

INTRODUCTION

(-)-Morphine is a naturally occurring substance extracted from the unripe seedpods of the opium poppy, *Papaver somniferum*, and is widely used as a narcotic analgesic in the control of severe pain. (-)-Morphine activates opioid receptors expressed on neurons in the central and peripheral nervous system (*1, 2*). Activation of the receptor leads to the release of opioid peptides which prompt a diverse array of biological responses including pain suppression. Aside from its clinical application, (-)-morphine has firmly established itself as a model for the studies of opiate pharmacokinetics and pharmacodynamics. However, investigations of precisely how (-)-morphine binds to its molecular target and regulates the signaling cascade are underrepresented due to the lack of a straightforward labeling method (*3*). To the best of our knowledge, no chemical labeling has been previously reported, partly because of the challenge posed by the complex structure of (-)-morphine (**1**) and the difficulty to retain its drug activity upon modification. Herein, we report the first practical and concise synthesis of biotinylated (-)-morphine (**2**) as a novel probe for the molecular target toll-like receptor **4** (TLR4), which has been recently discovered to play an essential role in microglial activation (*4, 5*). In particular, TLR4 signaling mediates the production of a variety of proinflammatory cytokines and pain mediators. These mediators sensitize neurons and activate other microglia as part of a positive feedback loop (*6*). This method provides a potentially generally applicable strategy to label various opioid derivatives, a group of important therapeutics in pain management, for biochemical/pharmacological studies.

Our design strategy was to attach a biotin probe while minimally affecting the binding activity of (-)-morphine (**1**) to TLR4. Previous structure−activity relationship studies of (-)-morphine (**1**) and other related opioid derivatives showed that the phenolic C_3 position as well as the alcoholic C_6 position (Figure 1) in (-)-morphine can be potential sites to introduce chemical labels (*4, 5*). In fact, the human body's own metabolism of morphine in the liver and small intestine involves attaching a pyranose ring to either the C_3 or the C_6 position, producing morphine-3-glucuronide (**3**) (M3G) or morphine-6-glucuronide (**4**) (M6G) with M3G as the major metabolite (*7*).

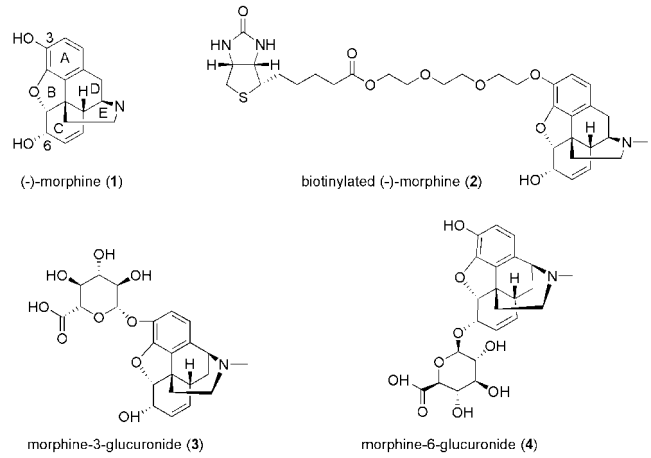

Figure 1. Chemical structures of (-)-morphine (**1**), biotinylated (-)-morphine (**2**), M3G (**3**), and M6G (**4**).

The rationale for introducing a chemical label at the C_3 position was to mimic the M3G, the major metabolite and the active form for the TLR4-activating functions of (-)-morphine in vivo. Further, the C_3- phenol is a conserved functional group found in many clinically relevant opiate alkaloids (e.g., naloxone, naltrexone, nalmefene), which makes this labeling strategy generally applicable. Biotinylated (-)-morphine (**2**) is predicted to have similar receptor-binding properties to unmodified (-)-morphine (**1**), allowing various biochemical/biophysical measurements and thereby establishing a novel tool for the study of opioid pharmacology (*4, 5*). Cellular assays performed using biotinylated (-)-morphine (**2**) and (-)-morphine (**1**) indicated that both show similar interactions to TLR4. This observation in conjunction with in silico binding studies solidifies biotinylated (-)-morphine's potential as a novel probe for more extensive studies of morphine/TLR4 interactions.

EXPERIMENTAL METHODS

General Methods and Materials. Unless otherwise mentioned, solvents and reagent were purchased from commercial sources and used as received. NMR spectra were recorded on Varian 400/500 NMR spectrometers. High-resolution mass data

were recorded on a high-resolution mass spectrometer in the ESI or MALDI mode.

Synthesis of Compound 7. Under N_2 atmosphere, into a 15-mL Schlenk flask containing biotin (**5**) (244 mg, 1.0 mmol) in 5 mL anhydrous DMSO at 25 °C, was added NaH (44 mg, 1.1 mmol, 60% dispersion in mineral oil). The reaction mixture was stirred at this temperature for 10 min. Then, 1,2-bis(2-iodoethoxy) ethane (**6**) (555 mg, 1.5 mmol) was added dropwise, and the reaction mixture was stirred for another 14 h, followed by adding a half-saturated NH_4Cl-H_2O solution (10 mL) at this temperature. The solution mixture was extracted with EtOAc (25 mL × 3), and the combined organic phase was dried over $MgSO_4$. After the removal of volatile solvents under vacuum, the crude product was further purified by silica gel column chromatography with ethyl acetate/petroleum ether (1:3) to give product **7** as a white solid, yield 65% (318 mg). Characterization for compound **7**: $[\alpha]^{25}_D = +31.0$ ($c = 1.0$, $CHCl_3$). ^1H NMR ($CDCl_3$, 500 MHz) δ 5.81 (s, 1H); 5.23 (s, 1H); 4.52−4.54 (m, 1H); 4.32−4.35 (m, 1H); 4.23−4.28 (m, 2H); 3.78 (t, $J = 7.0$ Hz, 2H); 3.73 (t, $J = 4.5$ Hz, 2H); 3.69 (s, 4H); 3.29 (dd, $J = 7.0$, 6.0 Hz, 2H); 3.16−3.19 (m, 1H); 2.93 (dd, $J = 12.5$, 5.5 Hz, 1H); 2.76 (d, $J = 12.5$ Hz, 1H); 2.40 (t, $J = 7.0$ Hz, 2H); 1.67−1.76 (m, 4H); 1.45−1.50 (m, 2H). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 173.9, 164.0, 72.1, 70.7, 70.4, 69.4, 63.6, 62.1, 60.3, 55.8, 40.8, 34.0, 28.5, 28.4, 24.9, 3.2. HRMS (MALDI) calcd. For $C_{16}H_{28}N_2O_5S$ ($M + H^+$): 487.0758, Found 487.0754.

Synthesis of Biotinylated (-)-Morphine (2). Under N_2 atmosphere, into a 15-mL Schlenk flask containing (-)-morphine (**1**) (29 mg, 0.1 mmol) in 2.0 mL anhydrous DMSO at 25 °C, NaH was added (4.4 mg, 0.11 mmol). The reaction mixture was stirred at this temperature for 10 min. Then, compound **7** (49 mg, 0.1 mmol) dissolved in 0.5 mL anhydrous DMSO was added dropwise, and the reaction mixture was stirred for another 12 h. Silica gel column chromatography with methanol/dichloromethane (10:1) afforded biotinylated (-)-morphine (**2**) as an oil, yield 35% (20 mg). Characterization for compound **2**: $[\alpha]^{25}_D = -24.5$ ($c = 1.25$, $CHCl_3$). ^1H NMR (CD_3OD, 400 MHz) δ 6.69 (d, $J = 8.2$ Hz, 1H); 6.53 (d, $J = 8.2$ Hz, 1H); 5.62−5.66 (m, 1H); 5.32−5.36 (m, 1H), 4.83 (dd, $J = 6.2$, 1.2 Hz, 1H); 4.45−4.49 (m, 1H), 4.07−4.30 (m, 7H); 3.78−3.81 (m, 2H), 3.64−3.71 (m, 6H), 3.38−3.41 (m, 1H), 3.16−3.20 (m, 1H), 3.07 (d, $J = 19.4$ Hz, 1H), 2.91 (dd, $J = 12.0$, 4.0 Hz, 1H); 2.69 (d, $J = 12.0$ Hz, 1H), 2.66−2.67 (m, 1H), 2.59−2.63 (m, 1H), 2.44 (s, 3H); 2.39−2.43 (m, 1H), 2.34−2.38 (m, 3H); 2.09 (td, $J = 7.5$, 4.8 Hz, 1H), 1.80−1.83 (m, 1H), 1.53−1.75 (m, 4H), 1.40−1.48 (m, 2H). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 173.9, 163.6, 147.2, 141.2, 133.6, 131.6, 128.5, 128.1, 119.7, 115.3, 91.7, 70.8, 70.7, 70.1, 69.4, 69.2, 66.7, 63.6, 62.0, 60.2, 59.0, 55.6, 46.6, 43.4, 43.1, 41.0, 40.7, 36.0, 33.9, 28.4, 28.3, 24.9, 20.5. (-)-Morphine (1) Conformational Analysis. Conformational analysis of biotinylated (-)-morphine **2** was performed using *Spartan 06* software from Wave function Inc. MMFF94 force field was used in the conformational scan simulation. Following a geometric optimization of the molecule using AM1 semiempirical methods, the Spartan program carried out a scan for the lowest energy conformer. The twelve conformers with the lowest respective energies were selected and their structures superimposed to validate the energy minimization. The final structure visualization is the lowest energy of these conformers compared to the (-)-morphine (**1**).

Ligand Docking. Using *AutoDock 4.0* (*8*), in silico docking experiments were carried out to search for potential binding sites on TLR4 (*9*). Lamarckian generic algorithm (LGA) and the torsion angles of the ligand were varied using AUTOTORS. First, the high-resolution structure of TLR4 was used as the target receptor after modification of Gasteiger charges and surface solvation. The full length of TLR4 is split into two parts to which the opioid molecules were docked in order to carry out more accurate calculation. Both receptor and ligand were allowed flexibility when running morphine against TLR4. Energy-minimized biotinylated (-)-morphine (**2**) was used in the docking and allowed to have seventeen of its bonds able to rotate within its structure to simulate realistic binding of this ligand to TLR4. A total of 100 runs were carried out and the results were grouped into clusters using an rmsd-tolerance of 2.0 Å. Finally, the resultant clusters were ranked using a force field scoring function (*10*). The credibility of the docking results was evaluated by estimating binding energy and the distribution of the independent runs in clusters (fewer binding modes predicted is preferred). Among those, the highest-ranked docked structure was used for molecular visualization.

SEAP Assay Methods. All materials were obtained commercially from sources (Invitrogen and Invivogen). Materials for the SEAP assay were obtained from Applied Biosystems and utilized according to the manufacturer's specifications (*11*). Cell Culture: Human embryonic kidney 293 (HEK293) stably transfected with TLR4 and a secreted alkaline phosphatase (SEAP) reporter gene were obtained from Invivogen. Cells were cultured in DMEM medium supplemented with 10% fetal bovine serum, 10× penicillin/streptomycin, 10× L-glutamine, 1× Normocin (ant-nr-1), and 1× HEK Blue (hb-sel). Cells were implanted in 96 well plates 48 h at 37 °C prior to drug treatment. On the day of treatment, media was removed from the 96-well plate replaced with cerebrospinal fluid (CSF) buffer (124 mM NaCl, 5 mM KCl, 0.1 mM $CaCl_2$, 3.2 mM $MgCl_2$, 26 mM $NaHCO_3$, and 10 mM glucose, pH 7.4) containing 0.25−4.0 mM biotinylated morphine.

A sample of CSF buffer (15 μL) from each well was collected and transferred to an opaque white 96 well plate (Microfluor 2, Thermo Scientific). Each well was treated with 45 μL of 1× dilution buffer, covered with microseal (MSB1001, Bio-Rad), and incubated for 30 min at 65 °C. After 30 min, plates were cooled to room temperature on ice and 50 μL of SEAP assay buffer was added to each well. After a 5 min incubation, 50 μL of disodium 3-(4-methoxyspiro{1,2-dioxetane-3,2-(5-chloro)-tricyclo[3.3.1.13,7]decan}-4-yl) phenyl phosphate (CSPD) diluted 1:20 with reaction buffer was added to each well. After 20 min, the luminescence of each well was measured using a Beckman Coulter, DTX 880 plate reader with multimode analysis software. Regression analyses were carried out using KaleidaGraph. Experimental data were fitted to one-site-saturation ligand binding mode. Raw luminescence scores were expressed as a percentage of luminescence against a control.

RESULTS AND DISCUSSION

Our straightforward synthesis of biotinylated (-)-morphine (**2**) is outlined in Scheme 1. The intermediate **7** can be readily obtained in good yield (65%) by the classical substitution reaction between deprotonated biotin (**5**) and commercially available 1,2-bis-(2-iodoethoxy)-ethane (**6**). It is observed that the choice of base is pivotal for this reaction, since compound **6** is unstable under strong basic conditions. Compound **7** was then subject to react with (-)-morphine (**1**). We found that the conditions had to be carefully tuned to selectively alkylate the C_3 phenolic hydroxyl group. It is also important to prevent elimination of HI from compound **7**. Several bases (NEt_3, KOH, or NaH) and solvents (Et_2O, DMF, $CHCl_3$, or DMSO) were tested (Table 1), each of which had different effects in promoting the reaction. Using weaker bases, such as K_2CO_3 and NEt_3, and less polar solvents, no reaction occurred and the reactants could be recovered completely. When the reaction was subjected to the strong inorganic base KOH, compound **7** partly degraded

Scheme 1. Synthesis of Biotinylated (-)-Morphine (2)

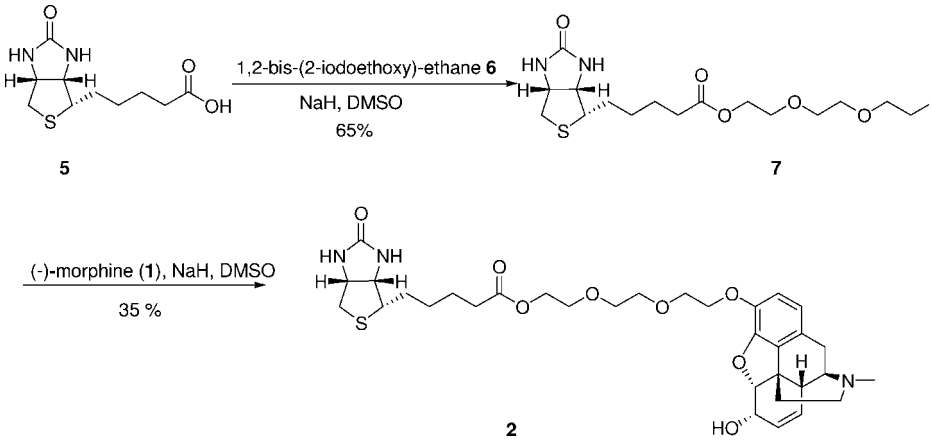

Table 1. Optimization of the Coupling Reaction between Compound 7 and (-)-Morphine (1)

entry	reaction conditions	yield (%)
1	K_2CO_3, Et_2O, rt.	0
2	NEt_3, DMSO, rt.	0
3	KOH, DMSO, rt.	0
4	NaH, DMSO, rt.	35
5	NaH, DMF, rt.	30
6	NaH, 18-crown-6, $CHCl_3$, rt.	0
7	NaH, 18-crown-6, DMSO, rt.	10[a]

[a] Based on the ^{1}H NMR of the mixture of compound **2** and 18-crown-6.

due to the fragile nature of compound **7** under strong basic conditions. Finally, optimal conditions were obtained by using NaH to deprotonate the phenol of (-)-morphine (**1**) in DMSO, which subsequently reacted with compound **7** to provide biotinylated (-)-morphine (**2**) in 35% yield.

Further optimization using phase transfer catalyst, 18-crown-6, to improve the yield did not prove successful. Given the concise synthetic route (only two steps with an overall yield of 23%) and commercially available starting materials, our synthesis represents a very streamlined approach to obtaining C_3 labeled morphine.

The fact that the chemical modification did not significantly alter the binding mode of (-)-morphine (**1**) to its receptor TLR4 is supported by the in silico simulation, NMR spectroscopy, and whole cell assays. Using a molecular mechanics (MM) simulation model with a Merck molecular force field (MMFF), a total of 2704 conformers of biotinylated (-)-morphine (**2**) were scanned to search for the most favorable structure (Figure 2). Energy minimization of the (-)-morphine (**1**) and biotinylated (-)-morphine (**2**) suggests that the morphine substructure in compound **2** retains much of its rigidity after the addition of biotin (Figure 2), with a root-mean-square-deviation (rmsd) of less than 0.7 Å.

In silico binding assays were performed using AutoDock with biotinylated (-)-morphine (**2**) and unlabeled (-)-morphine (**1**) on the model protein, murine TLR4, whose high-resolution structure was recently solved using X-ray crystallography analysis (*9*). We searched the entire surface of TLR4 and ranked the docking results in the order of favorable binding energy. Statistical analysis of 100 independent searches indicate that the biotinylated (-)-morphine (**2**) found the same pocket to which unlabeled (-)-morphine (**1**) binds with a slightly improved binding energy (−7.3 kcal/mol vs −6.6 kcal/mol). These results supported that both species recognize the same region of this protein (compare Figure 3A and B), suggesting that the biotin label and the linker did not affect the target recognition ability of (-)-morphine. Attaching the biotin label in the C_3 position appears to be most conducive to retaining the integrity of (-)-morphine's active sites in binding to TLR4. Previous data have shown that the C_6−OH group plays an essential role in TLR4-binding (*4, 5*), which agrees well with the predictions made by the docking simulation that both unlabeled (Figure 3C) and labeled (Figure 3D) (-)-morphines use the C_6−OH to recognize the target pocket on the TLR4 surface.

AutoDock results also showed that the flexibility of the PEG-linker is important in receptor recognition. The PEG-linker was allowed to rotate freely during the docking process, facilitating the morphine substructure of **2** in retaining its 3-D presentation upon binding to the TLR4 receptor. It was also suggested that the partial flexibility of the C-ring region may be essential to the functionality of biotinylated (-)-morphine (**2**), while both the A- and D-ring remain relatively rigid and partially involved in binding. Close examination of Figure 3 reveals that the flip of the C-ring is variable in TLR4-bound (-)-morphine (**1**) and biotinylated (-)-morphine (**2**), pointing again to its importance.

The C-ring conformation changes were further probed by a ^{1}H NMR spectroscopy comparison of biotinylated (-)-morphine (**2**) and (-)-morphine (**1**) at the same concentration in deuterated methanol solvent. Deuterated methanol (CD_3OD) was chosen as the solvent for the NMR studies to more closely mimic the polarity of an aqueous environment in the body. As shown in Figure 4, several protons on the C-ring experience small changes in chemical shift. Ha, Hb, and Hc undergo insignificant chemical

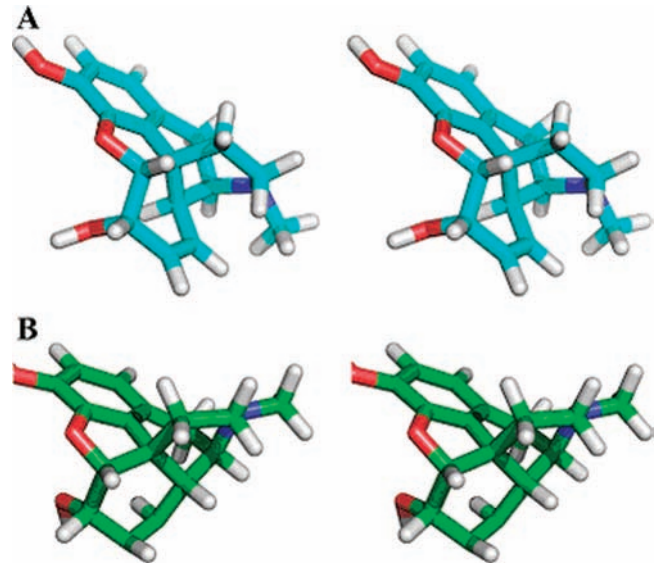

Figure 2. Stereoviews (cross-eyed) of energy-minimized (A) (-)-morphine (**1**) and (B) the morphinyl substructure of **2**.

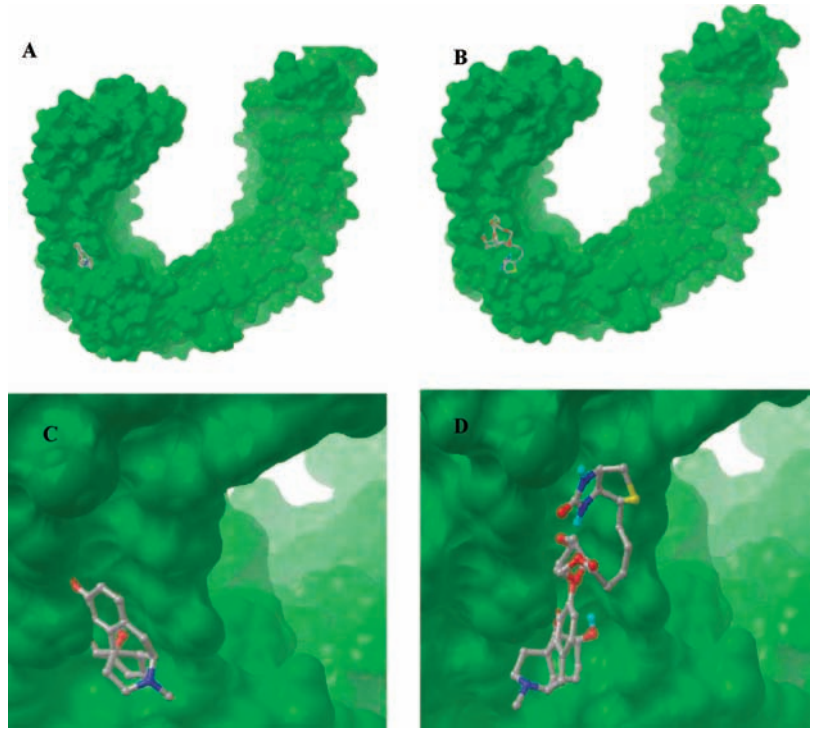

Figure 3. Docking results indicate that (A) (-)-morphine (**1**) and (B) biotinylated (-)-morphine (**2**) recognize the same pocket on the surface of TLR4 (shown with green surface). Close-up views of (C) (-)-morphine (**1**) and (D) biotinylated (-)-morphine (**2**) at the TLR4 binding site.

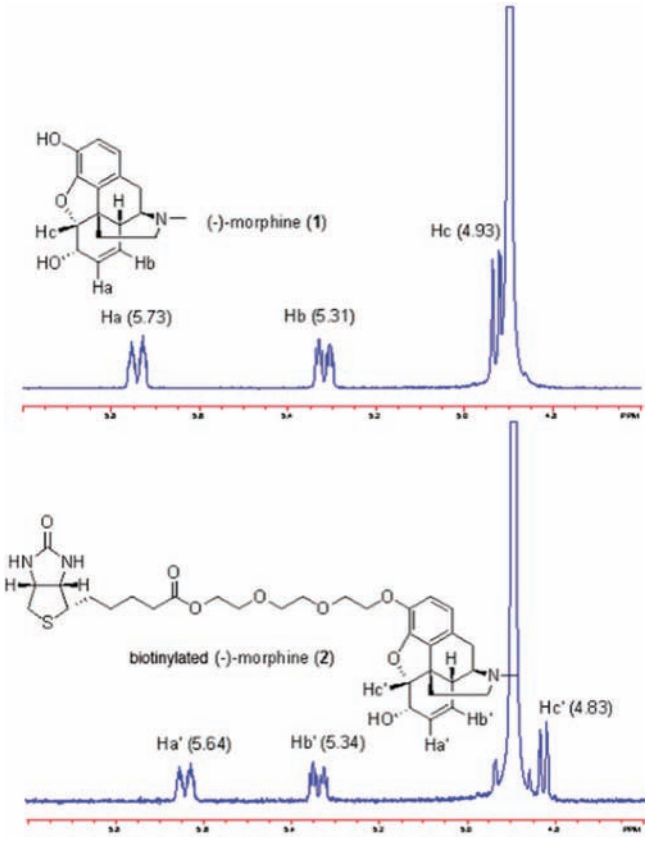

Figure 4. Corresponding regions (4.6−6.0 ppm) of the NMR spectra of (-)-morphine (**1**) (top) and biotinylated (-)-morphine (**2**) (bottom).

shift changes (0.09, 0.03, and 0.10 ppm, respectively) (*12, 13*), suggesting that the C-ring in (-)-morphine (**1**) experiences minimal conformational changes after (-)-morphine (**1**) is labeled with biotin. The ^{1}H NMR analysis was consistent with the MM simulation and the docking results, both of which point to a C-ring flip in biotinylated (-)-morphine (**2**).

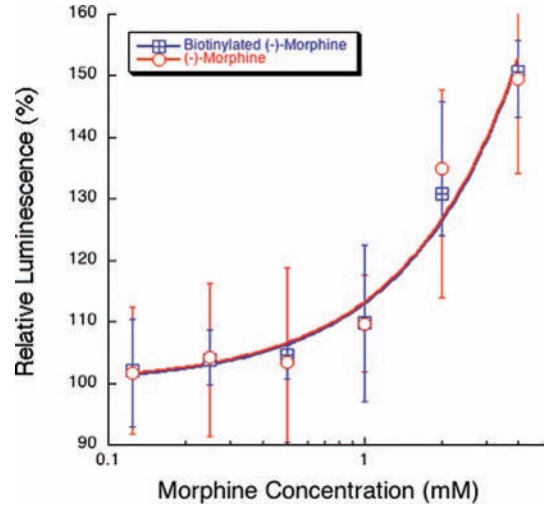

Figure 5. SEAP assay data showing a close correlation of activities between compound **2** (blue) and (-)-morphine (**1**) (red).

Further evidence of the comparative activity of biotinylated (-)-morphine (**2**) and (-)-morphine (**1**) on TLR4 is presented by cellular data obtained using a secreted embryonic alkaline phosphatase (SEAP) assay that measures TLR4 activation by monitoring downstream SEAP activities (*11*). SEAP utilizes stably transfected HEK 293 cells that overexpress TLR4 and secrete an alkaline phosphatase reporter gene in response to TLR4 activation via the NF-κB transcription factor. SEAP data (Figure 5) demonstrate that biotinylated (-)-morphine (**2**) activates TLR4 in a manner that closely resembles that of native (-)-morphine (**1**) over a concentration gradient of 0.1−4.0 mM, confirming their similar biological activities. By contrast, M6G **4** did not induce TLR4 activation under the same assay conditions (data not shown), supporting the hypothesis that C-3

modification provides the most conducive labeling strategy for (-)-morphine (**1**).

CONCLUSION

In summary, a practical and concise approach to the synthesis of biotinylated (-)-morphine (**2**) was developed. The sequence involves two synthetic steps with an overall yield of 23%. As the C_3 hydroxy group is a conserved functional group, this method could potentially be generalized to other opioid derivatives. Also, in silico simulation, NMR, and cellular assays were performed, showing that biotinylated (-)-morphine (**2**) binds to the same region of TLR4 as (-)-morphine (**1**) and that biotinylated morphine (**2**) acts on TLR4 with similar biological activities.

ACKNOWLEDGMENT

We thank the Council on Research & Creative Work at the University of Colorado at Boulder for financial support of the work. Y.L. thanks the University of Colorado Cancer Center (UCCC) for a postdoctoral fellowship. A.R.C. is grateful for a Bioscience Undergraduate Research Skills and Training (BURST) summer research award. C.T.B. thanks the NIH/HHMI Scholars Program for Diversity in the Biosciences for financial support. T.X.Z. is grateful for an HHMI undergraduate grant for biomedical research provided by the Undergraduate Research Opportunities Program at the University of Colorado at Boulder.

General:

Unless otherwise mentioned, solvents and reagent were purchased from commercial sources and used as received. ^{1}H NMR spectra were recorded with Me_4Si as internal standard. ^{13}C NMR spectra were recorded on Varian INOVA 400 NMR spectrometers. High-resolution mass data were recorded on a high-resolution mass spectrometer in the ESI or MALDI mode.

Procedure for the substitution reaction of biotin (**5**) with 1,2-bis(2-iodoethoxy) ethane (**6**).

Under N_2 atmosphere, into a 15-mL Schlenk flask containing biotin (**5**) (244 mg, 1.0 mmol) in 5mL DMSO at 25°C, was added NaH (44 mg, 1.1 mmol, 60 % dispersion in mineral oil). The reaction mixture was stirred at this temperature for 10 min. Then 1,2-bis(2-iodoethoxy) ethane (**6**) (555 mg, 1.5 mmol) was added dropwise and the reaction mixture was stirred for another 14 h, followed by adding a half-saturated NH_4Cl-H_2O solution (10 mL) at this temperature. The solution mixture was extracted with EtOAc (25 mL x 3), and the combined organic phase was dried over $MgSO_4$. After the removal of volatile solvents under vacuum, the crude product was further purified by silica gel column chromatography with ethyl acetate/petroleum ether (1: 3) to give product **7** as a white solid, yield 65 % (318 mg). Characterization for compound **7**: $[\alpha]^{25}_D$ = +31.0 (c = 1.0, $CHCl_3$); ^{1}H NMR ($CDCl_3$, 500 MHz) δ 5.81 (s, 1H); 5.23 (s, 1H); 4.52-4.54 (m, 1H); 4.32-4.35 (m, 1H); 4.23-4.28 (m, 2H); 3.78 (t, J = 7.0 Hz, 2H); 3.73 (t, J = 4.5 Hz, 2H); 3.69 (s, 4H); 3.29 (dd, J = 7.0, 6.0 Hz, 2H); 3.16-3.19 (m, 1H); 2.93 (dd, J = 12.5, 5.5 Hz, 1H); 2.76 (d, J = 12.5 Hz, 1H); 2.40 (t, J = 7.0 Hz, 2H); 1.67-1.76 (m, 4H); 1.45-1.50 (m, 2H). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 173.9, 164.0, 72.1, 70.7, 70.4, 69.4, 63.6, 62.1, 60.3, 55.8, 40.8, 34.0, 28.5, 28.4, 24.9, 3.2; HRMS (MALDI) calcd. For $C_{16}H_{28}N_2O_5S$ ($M + H^+$): 487.0758, Found 487.0754.

Preparation of biotinylated (-)-morphine (**2**).

Under N_2 atmosphere, into a 15-mL Schlenk flask containing (-)-morphine (**1**) (29 mg, 0.1 mmol) in 2.0 mL DMSO at 25 ^oC, NaH was added (4.4 mg, 0.11 mmol). The reaction mixture was stirred at this temperature for 10 min. Then compound **7** (49 mg, 0.1 mmol) dissolved in 0.5 mL DMSO was added dropwise and the reaction mixture was stirred for another 12 h. Silica gel column chromatography with methanol/dichloromethane (10 : 1) afforded biotinalyted (-)-morphine (**2**) as an oil, yield 35 % (20 mg). Characterization for compound **2**: $[\alpha]^{25}_D$ = –24.5 (c = 1.25, $CHCl_3$); ^1H NMR (CD_3OD, 400 MHz) δ 6.69 (d, J = 8.2 Hz, 1H); 6.53 (d, J = 8.2 Hz, 1H); 5.62-5.66 (m, 1H); 5.32-5.36 (m, 1H), 4.83 (dd, J = 6.2, 1.2 Hz, 1H); 4.45-4.49 (m, 1H), 4.07-4.30 (m, 7H); 3.78-3.81 (m, 2H), 3.64-3.71 (m, 6H), 3.38-3.41 (m, 1H), 3.16-3.20 (m, 1H), 3.07 (d, J = 19.4 Hz, 1H), 2.91 (dd, J = 12.0, 4.0 Hz, 1H); 2.69 (d, J = 12.0 Hz, 1H), 2.66-2.67 (m, 1H), 2.59-2.63 (m, 1H), 2.44 (s, 3H); 2.39-2.43 (m, 1H), 2.34-2.38 (m, 3H); 2.09 (td, J = 7.5, 4.8 Hz, 1H), 1.80-1.83 (m, 1H), 1.53-1.75 (m, 4H), 1.40-1.48 (m, 2H). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 173.9, 163.6, 147.2, 141.2, 133.6, 131.6, 128.5, 128.1, 119.7, 115.3, 91.7, 70.8, 70.7, 70.1, 69.4, 69.2, 66.7, 63.6, 62.0, 60.2, 59.0, 55.6, 46.6, 43.4, 43.1, 41.0, 40.7, 36.0, 33.9, 28.4, 28.3, 24.9, 20.5. ESI (m/z) 644.2 ($M + H^+$); HRMS (ESI) calc. For $C_{33}H_{46}N_3O_8S^+$ ($M + H^+$): 644.3000, Found 644.2970.

Procedure for AutoDock4 *in silico* docking

The TLR4 pdb file was obtained from RCSB database (ID 2z64) with binding partner MD-2, which was removed as were all ligands via Molegro Molecular Viewer. The modified pdb file was input into AutoDock 4.0, hydrogens added and resaved in pdbqt format. Morphine was obtained using PubChem isomeric SMILES then converted to pdb using a structure file generator (http://cactus.nci.nih.gov/services/translate/). The biotinylated morphine structure was drawn with ChemDraw Ultra 9.0, then converted into pdb format and bond angles optimized with Chem3D Ultra 9.0. In AutoDock, ligand torsion tree roots were generated automatically by choosing 'detect root', and number torsions set at zero for morphine; biotinylated morphine was allowed its natural rotations. Figures shown cover lowest energy results from left portion of receptor only, AutoGrid center set at (-44.725, 4.064, -0.446) with 126 grid points expanding each direction on TLR4, which was kept in its rigid form. The search parameters employed a genetic algorithm set for #GA 100, Max Evals $5x10^6$ and 0.375 Å spacing. All dockings executed with Lamarkian genetic algorithms on Apple desktop computers running OS X 10.4.
