Received June 25, 2008; Revised Manuscript Received August 14, 2008

New active particulate polymeric vectors based on branched polyester copolymers of hydroxy-acid and allyl glycidyl ether were developed to target drugs to the inflammatory endothelial cell surface. The hydroxyl and carboxyl derivatives of these polymers allow grafting of ligand molecules on the polyester backbones at different densities. A known potent nonselective selectin ligand was selected and synthesized using a new scheme. This synthesis allowed the grafting of the ligand to the polyester polymers, preserving its binding activity as assessed by docking simulations. Selectin expression on human umbilical cord vascular endothelial cells (HUVEC) was induced with the pro-inflammatory bacterial lipopolysaccharide (LPS) or with the nonselective inhibitor of nitric oxide synthase L-NAME. Strong adhesion of the ligand decorated nanoparticles was evidenced *in vitro* on activated HUVEC. Binding of nanoparticles bearing ligand molecules could be efficiently inhibited by prior incubation of cells with free ligand, demonstrating that adhesion of the nanoparticles is mediated by specific interaction between the ligand and the selectin receptors. These nanoparticles could be used for specific drug delivery to the activated vascular endothelium, suggesting their application in the treatment of diseases with an inflammatory component such as rheumatoid arthritis and cancer.

INTRODUCTION

Inflammation is a naturally occurring defense mechanism upon exposure to specific antigens, chemicals, infections, and physical stress. It is characterized by different events taking place at or near the injured area, including vascular endothelium cell (VEC) activation and leukocyte accumulation. VEC, upon activation by pro-inflammatory cytokines, increases the expression of cell adhesion molecules (CAMs) in a highly regulated and sequential process. This sequence involves expression of P-selectin followed by E-selectin, which promote rolling and tethering of leukocytes along the vessel wall (*1*). Exaggerated and/or prolonged inflammatory response is associated with a large number of acute and chronic disorders, including organ ischemia/reperfusion injury, allergic asthma, rheumatoid arthritis, inflammatory bowel disease, and atherosclerosis.

The selectin family has three members, namely, L-, E-, and P-Selectin. Their expression is restricted to circulating leukocytes (L-selectin) and VEC (P- and E-selectins). Upon inflammatory stimulation, P-selectin (CD62P) appears rapidly at the cell surface, owing to its intracellular storage in Weibel-Palade bodies. On the other hand, maximum levels of E-selectin (CD62E) are reached in 4−6 h after activation, due to *de novo* synthesis (*2*). Since E-selectin is expressed in both acute and chronic inflammation, it has been considered as a good candidate for drug targeting. In addition, the cytokines IL-1β and TNFα, as well as bacterial lipopolysaccharide (LPS), have been shown to stimulate the expression of E-selectin (*3*). Moreover, E-selectin is reported to exhibit a highly localized expression in neovasculature (*4*) and prostate cancer (*5*). The natural ligands of E- and P-selectin are either fucosylated glycoproteins (ESL-1, for E-selectin ligand) or sialomucin glycoproteins (PSGL-1 for P-selectin glycoprotein-1) presenting sialylated carbohydrate moieties (sialyl-Lewis x, sLe^x) epitopes. These selectin ligands are known to be present on circulating leukocytes plasmatic membrane (*6*, *7*). Synthetic analogues of the natural ligands have been investigated for their ability to block inflammation (*6*, *8*, *9*). Some of these analogues have been reported to have higher affinity to the target compared to the natural ligand, rendering them very attractive molecules for active drug targeting developments.

Among promising new therapeutic approaches, targeted drug carriers have received increasing interest during the past few decades (*10*). These carriers aim to release the drug close to the pathologic site, protecting the active substance from fast degradation and elimination leading to dose reduction and avoiding side effects. Several approaches such as drug immunoconjugation, bioconjugation, liposomes, dendrimers, micelles, or coated nanoparticles (NPs) have been proposed to achieve active or passive targeting of drug. However, compared to other delivery systems, polymeric NP drug carriers offer the possibility of encapsulating several types of molecules and protecting them from enzymatic degradation. The polymers forming the NP carriers are generally highly stable in physiological media and allow controlled release by matrix degradation.

A general approach to confer targeting capabilities to NPs is to functionalize their surface with a specific ligand. This approach is strongly limited by the stability of the link between the ligand and the NP surface. If this link is not stable enough in physiological media, release of the ligand (by hydrolysis, for example) from the NP surface could be rapid. To circumvent

this severe drawback and to improve the binding properties of the NPs, new coupling strategies must be investigated.

Specific drug delivery to activated VECs to modulate the inflammation response have been shown to be a valid therapeutic strategy (*11*). Drug immunoconjugation (*12*, *13*) and immunoliposomes directed against E-selectin (*14*−*16*), as well as liposomes incorporating sLe^x as ligands (*17*−*19*), are among the most described methods. They all present the strong disadvantage of using natural ligands (as sLe^x) which are in competition with the free homologue in the bloodstream.

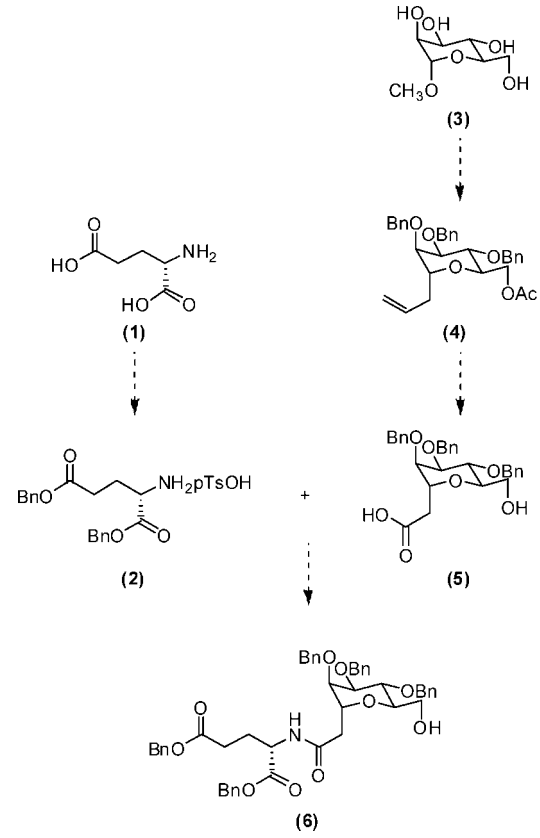
In this study, a ligand of E- and P-selectin was synthesized and conjugated to a poly-L,D-lactic acid polymer (PLA). The ligand is a nonselective selectin antagonist, which may be advantageous in pathological settings involving both P- and E-selectin activities. The conjugation was done using carboxylic acid functions introduced in the PLA backbone. This functionalized polymer was subsequently mixed with pure PLA to form the NPs. NPs formulated with ligand functionalized PLA (NP-L) present higher adhesive capabilities to HUVEC plasmatic membrane compared to nonfunctionalized PLA NPs. Inhibition of binding could be observed for NP-L when cells are incubated with free ligand prior to the NP introduction. This study provides strong evidence that NPs functionalized with the synthetic ligand can specifically bind to endothelial cells activated by pro-inflammatory molecules.

EXPERMENTAL PROCEDURES

Materials. Chemicals were purchased from Sigma-Aldrich (Oakville, ON, Canada). Solvents were from Laboratoire MAT (Québec, PQ, Canada). All media and reagents for cell culture were purchased from Gibco (Invitrogen, Burlington, ON, Canada). Human vascular endothelial cells (CRL 1730) were from ATCC; Raw 264.7 murine macrophage cell line was a gift from Pr. J. C. Leroux.

Ligand Docking Simulations. All simulations were performed with E-selectin receptor using GOLD (Genetic Optimisation for Ligand Docking) docking program (*20*) in order to identify the most probable conformation of the free and grafted ligand interacting with its receptor. The structure of the chosen ligand can be seen in Scheme 1. The protein data file was obtained from the structure published by Somers et al. (*21*). The protein was prepared as described by Jones et al. (*20*, *22*). The ligand and grafted ligand (Scheme 1 and compound (**9**)) were built using Material Studio software (Accelrys, San Diego, USA) and their structure was minimized using the Discover module assigning CFF force field to each atom. The grafted ligand consisted of a ligand molecule linked to a PLA chain (of 4 monomers) via a glycidyl linker. For the docking simulations, the binding pocket of E-selectin was defined using the conformation of the natural ligand sialyl Lewis acid X (sLe^x) given by Somers et al. The two equatorial hydroxyl groups of the mannose ring of the studied ligand were constrained to bind the calcium ion present in the binding pocket. In that way, the mannose ring of the ligand overlaid onto the L-fucose ring of the sLe^x and the glutamate side chain was free to bind to the protein amino acids. More than 30 genetic algorithm runs were performed in order to identify best fitting structures. The final optimized conformations were picked using GOLD scoring function.

Scheme 2. General Synthesis of the Selectin Ligand



Ligand Synthesis. A general scheme of the ligand synthesis is represented in Scheme 2.

*Synthesis of Fragment **2**.* 25.5 g of *p*-toluene sulfonic acid (*p*TsOH) were added to a solution of 10 g glutamic acid **1** in 100 g of benzylic alcohol under N_2 atm. The mixture was heated at 80 °C for 24 h under stirring and subsequently poured onto 1 L aqueous solution of 1 M NaOH and extracted three times with diethyl ether (Et_2O). The organic phases were pooled and dried on Na_2SO_4. A solution of 10 g (*p*TsOH) sulfonic acid (*p*TsOH) in 100 mL Et_2O was added to the organic phase, which was kept at 4 °C for 24 h. The crystals obtained were filtered and washed with ether to yield 12.3 g of product **2** (36% yield).

^{1}H NMR (400 MHz, DMSO-d_6) δ 2.00−2.17 (m, 2 H, -CH_2−CH_2−CH-), 2.28 (s, 3 H, CH_3- (*p*TsO^-)), 2.43−2.66 (m, 2 H, -CH_2−CO_2Bn), 4.17 (t, 6.60 Hz, 1 H, -CH(NH_3^+)-CO_2-), 5.05−5.12 (m, 2 H, -CH_2−Ph), 5.17−5.26 (m, 2 H, -CH_2−Ph), 7.12 (d, 8.0 Hz, 2 H, aromatic *p*TsO^-), 7.31−7.43 (m, 10 H, aromatic -Bn), 7.51 (d, 8.0 Hz, 2 H, aromatic *p*TsO^-), 8.28−8.64 (m, 3 H, -NH_3^+). SM (FAB) *m*/*e* 328.5 (M + H-*p*TsOH, 100%), 192.3 (10%), 154.2 (32%).

*Synthesis of Fragment **4**.* 3.8 g of tetrabutyl ammonium iodide (TBAI) and 54 mL of bromobenzyl (BnBr) were added to a 10% (w/w) solution of α-methylmannoside **3** in dimethyl formamide (DMF) under N_2 atmosphere. The mixture was cooled down to 0 °C and 18.2 g of NaH was slowly added to avoid a temperature rise. The mixture was stirred for 16 h and cooled down to 0 °C. 100 mL of isopropanol was slowly added, followed by 20 g of salicylic acid. The solution was evaporated and redissolved in 500 mL of ethyl acetate (EtAc). The organic phase was washed three times successively with 100 mL NaOH 10%, 100 mL 1 N HCl, and 100 mL NaCl saturated salt solutions. The organic phase was dried on Na_2SO_4, filtered, and evaporated. The residual product was purified by flash chromatography on silica with an eluent mix 10:90 to 20:80 Et_2O and hexane (HEX) to yield 27.3 g (43%) of intermediate product.

^{1}H NMR (400 MHz, $CDCl_3$) δ 3.35 (s, 3 H, -OCH_3), 3.74−3.84 (m, 4 H), 3.90−3.93 (m, 1 H), 3.97−4.04 (m, 1 H), 4.51−4.82 (m, 8 H), 4.91 (d, 11.0 Hz, 1 H), 7.17−7.42 (m, 20 H, aromatic). ^{13}C NMR (400 MHz, $CDCl_3$) δ 54.7, 69.2, 71.6, 72.0, 72.5, 73.3, 74.4, 74.8, 75.0, 80.2, 98.9, 127.4−128.4 (m, 20 C), 138.2−138.4 (m, 4 C). SM (FAB) *m/e* 553.4 (M − H, 7%), 271.4 (10%), 181.3 (100%). SMHR Calculated for $C_{35}H_{37}O_6$ (M − H) 553.2590, found 553.2600 (−1.8 ppm).

Allyltrimethylsilane (14.3 mL) and trimethylsilyl triflate (4.1 mL) were added to a solution of 25 g of intermediate product in acetonitrile (ACN) at 0 °C under N_2 atmosphere. The mixture was maintained at 4 °C for 16 h, and then 65 mL of anhydrous acetic acid was added. Under stirring at room temperature, 600 mL of dichloromethane (DCM) and 60 mL of aqueous solution of $NaHCO_3$ were added to the mixture. The pH was adjusted to 12 with 10% w/v NaOH. After phase separation, the aqueous phase was extracted with 300 mL of DCM. The obtained organic phases were pooled, dried on Na_2SO_4, and filtered. The solvents were eliminated by distillation under vacuum. The residual product was purified by flash chromatography on silica, using a mix of Et_2O and HEX in proportion ranging from 25:75 to 100:0 to yield 18.5 g (79%) of product **4**.

^{1}H NMR (400 MHz, $CDCl_3$) δ 2.05 (s, 3 H, Ac-), 2.24−2.40 (m, 2 H), 3.61−3.64 (m, 1 H), 3.75−3.83 (m, 3 H), 4.05−4.10 (m, 1 H), 4.23−4.27 (m, 1 H), 4.37−4.42 (m, 1 H), 4.53−4.63 (m, 5 H), 4.74−4.77 (m, 1 H), 4.99−5.04 (m, 2 H), 5.67−5.77 (m, 1 H), 7.27−7.37 (m, 15 H, aromatic).

*Synthesis of Fragment **5***. 90 mL water and 4.5 mL of an aqueous solution of 50% (w/w) of 4-methylmorpholine *N*-oxide (NMO) were added to a solution of 9.00 g of compound **4** in 90 mL distilled acetone, followed by an addition of 2.25 mL of a 2.5% (w/w) solution of osmium tetraoxide in *t*-butanol. The solution was stirred for 3 h; then, 2.25 mL of an aqueous solution of 10% (w/w) $Na_2S_2O_3$, 9 g of Florisil, and 180 mL of water were added. The pH was adjusted to 1 with 1 M HCl. The aqueous phase was extracted three times with 500 mL of EtAc. The organic phases were pooled, dried on Na_2SO_4, and filtered. The solvent was eliminated by distillation under vacuum. The diol intermediate product was used in the next step without purification. 4.5 g of sodium periodate and 90 mL of water were added to a solution of 17.4 mM of the intermediate diol in 90 mL THF. The solution was stirred for 1 h and then 450 mL of water was added. The aqueous phase was extracted three times with 450 mL of EtAc. The organic phases were pooled, dried on Na_2SO_4, filtered, and the solvent eliminated by distillation under vacuum. The residual aldehyde product was used in the next step without further purification. 20.9 mM of CrO_3 from the Jones reagent (CrO_3:H_2SO_4:H_2O, 1:1:3) were added to a solution of 17.4 mM of aldehyde product in 90 mL of distilled acetone at 0 °C. After 15 min, reagent in excess was neutralized by the addition of 10 mL of isopropanol. The solution was poured on 900 mL of 1 M HCl and extracted three times with 400 mL of EtAc. The organic phases were pooled, and the remnant solvent was eliminated by distillation under vacuum. The aldehyde product was used in the next step without further purification. A solution of 4.0 g potassium hydroxyde was prepared with 20 mL water and 20 mL of MeOH. This solution was added to a solution of 17.4 mM of intermediate aldehyde compound in 100 mL MeOH. 100 mL of potassium hydroxyde 10% (w/v) was further added and the mixture poured into 1 L of 1 N HCl; then, the aqueous phase was extracted three times with 500 mL EtAc. The organic phases were pooled, dried on Na_2SO_4, filtered, and the solvent eliminated by distillation under vacuum. The residual product was purified by flash chromatography on silica using Et_2O as the eluent to obtain 7.56 g of acid alcohol **5**. The yield of the synthesis was 88%.

^{1}H NMR (400 MHz, $CDCl_3$) δ 2.54 (dd, 9.9 and 16.7 Hz, 1 H), 2.82 (dd, 3.3 and 16.8 Hz, 1 H), 3.45 (dd, 3.7 and 12.1 Hz, 1 H), 3.55 (dd, 3.6 and 5.0 Hz, 1 H), 3.62 (dd, 2.8 and 7.6 Hz, 1 H), 3.81 (dd, 3.0 and 5.0 Hz, 1 H), 3.84−3.92 (m, 1 H), 4.21 (dd, 9.1 and 12.2 Hz, 1 H), 4.39−4.59 (m, 7 H), 7.22−7.38 (m, 15 H), -OH and -COOH absent. SM (FAB) *m/e* 515.2 (M + Na, 4%), 271.1 (8%), 181.1 (100%), 132.9 (51%). SMHR Calculated for $C_{29}H_{32}O_7Na$ (M + Na) 515.2046, found 515.2032 (+2.7 ppm).

*Coupling **2** and **5**: Protected Ligand **6***. 9.5 g of amine tosylate **2** was solubilized in 200 mL of EtAc and mixed three times with the same volume of 1 N NaOH. The amine compound corresponding to **2** was obtained after drying the organic phase on Na_2SO_4 and filtration and elimination of the solvent by evaporation under vacuum. A 10% (w/w) solution of the acid alcohol **5** in DCM was added with a canula to a solution containing 2.4 g of ethyl-3-(3-dimethylaminopropyl)-carbodiimide (EDC). 1.7 g of 1-hydroxybenzotriazole hydrate (HOBt) and compound **2** were mixed in 31 mL DCM under N_2 atmosphere. The solution was stirred for 16 h. Solvents were eliminated by distillation under vacuum. The residual product was purified by flash chromatography on silica using 1:1 EtAc/HEX to get 3.17 g of the protected ligand **6** (yield of 63%).

Polymer Synthesis and Subsequent Ligand Conjugation and Deprotection. Synthesis of PLA polymer bearing pendant carboxyl groups for ligand grafting has been described elsewhere (*23*). A solution of PLA 1 mg/mL with 1% (mol/mol) (relative to lactic monomer) acyl chloride pendant groups in chloroform was prepared (polymer **7**) and to this were added successively 1.5 equiv of **6** in chloroform at a concentration of 0.25 mM and a 10% (w/v) solution of dimethylamino propane (DMAP) in pyridine. The mixture was stirred for 3 h after which a 1 N HCl solution was added to neutralize the pyridine. Chloroform was evaporated and the aqueous phase was filtered to yield the protected ligand−PLA. Activated palladium (Pd−C 5%) was added to a solution of 0.8 mg/mL of protected ligand−polymer in glacial acetic acid at a ratio of 1 mg/mg. This mixture was placed under hydrogen (atmospheric pressure) for 16 h. Pd−C was eliminated by filtration on Celite (MeOH as eluent). Solvent was eliminated by evaporation, and the product dissolved in chloroform. Chloroform was eliminated by evaporation in the presence of an equivalent volume of water to yield the precipitated polymer in aqueous phase. This step was repeated twice to obtain PLA with 5 mol % of grafted selectin synthetic ligand (compound **9** or PLA-$SEL_{5\%}$) with a 70% yield for the two-step procedure after drying.

PLA polymer bearing hydroxyl groups was synthesized as described in Nadeau et al. (*23*). Rhodamine B was grafted to the PLA backbone using standard EDC/NHS coupling reaction. The obtained polymer (PLA-$Rhod_{5\%}$) was precipitated in water and dissolved in DCM after complete water removal. This

operation was repeated three times for complete elimination of remnant chemicals.

NP Preparation. NPs were prepared by the solvent evaporation method. Briefly, 500 mg of a 1:1 mixture of PLA-$Rhod_{5\%}$ and PLA (or PLA-$Sel_{5\%}$) were dissolved in 15 mL of DCM. The polymer solution was then gently injected into 100 mL of aqueous 15% (w/v) of sucrose solution containing a surfactant mixture (2.5% Tween 20, 0.5% PEG Laurate), while emulsification was being achieved by means of high-pressure homogenization (Emulsiflex C30, Avestin, Ottawa, ON, Canada) at 10 000 psi for 3 min in order to obtain the NP suspension. After collection of the NPs, the suspension was stirred for 5 h under reduced pressure to allow solvent evaporation and NP solidification. NP suspension was then lyophilized (Freeze-Dry System, Lyph.Lock 4.5, Labconco) and stored at 4 °C until further use.

NP Characterization. *Particle Size Distribution.* NP size distribution was measured by photon correlation spectroscopy (PCS) (N4 Plus, Coulter Electronics, Miami, FL) at 90° scattering angle for 180 s and at 25 °C. The mean particle diameter was calculated using differential size distribution processor (SDP) intensity analysis program.

Zeta Potential Measurements. NPs were suspended in 0.25% (w/v) saline solution filtered through 0.22 μm filter and zeta potential was measured at 25 °C on a Malvern ZetaSizer Nanoseries ZS (Malvern Instruments, Worcestershire, UK) in triplicate.

Time-of-Flight Secondary Ion Mass Spectrometry (TOF-SIMS). NP samples were analyzed using a TOF-SIMS IV (ION-TOF GmbH, Munster, Germany). The mass spectra were produced by irradiating the NPs with a 15 keV monoisotopic $^{69}Ga^+$ primary ion source with a target current of 1.02 pA in order to stay in static regime (ionic dose lower than 10^{13} ions/cm^2). Mass resolution was above 8200 μma for $^{29}Si^+$. The scanned surface area was 40 μm × 40 μm. Both positive and negative secondary ions were collected over a mass range 5−800 and analyzed.

Cytotoxicity Assay of NPs. Cytotoxicity assay was performed on two cell lines using MTT cell proliferation assays. RAW 264.7 murine macrophage cell line was cultured in Dulbecco's Modified Eagle Medium (DMEM) supplemented with 10% fetal bovine serum (FBS) and penicillin/streptomycin (Invitrogen Canada, Burlington, ON, Canada). Human vascular endothelium cells were cultivated in F12 Kaighn's modification medium, 10% FBS with penicillin/streptomycin supplemented with heparin, and endothelial growth supplement from neural bovine tissue (Sigma-Aldrich, Oakville, ON). Both cell lines were grown in tissue culture flasks and incubated at 37 °C in a 5% CO_2 atmosphere.

Raw 264.7 cells were diluted in complete medium at a final concentration of 5×10^5 cells/mL and plated (100 μL/well) on a 96 well flat-bottom microplate (Corning, NY). NPs suspended in 10 μL PBS sterile buffer were added in the wells in triplicate for each concentration. The plates were incubated for 24 h after which cellular proliferation was assessed by MTT assay. Cell medium was removed and cell monolayer washed with PBS. Complete medium was replaced and 10 μL of thiazolyl blue tetrazolium bromide (Sigma-Aldrich, Oakville, ON, Canada), dissolved in PBS (10 mM, pH 7.4) at a concentration of 5 mg/mL and filtered on 0.22 μm sterile filter (Millipore, Bedford, MA), was added to each well. After 3 h incubation time at 37 °C in 5% CO_2 atmosphere, 50 μL of solubilizing solution (Isopropanol, 10% Triton X100, 0.1 N HCl) was added to each well to dissolve the dark blue formazan crystals. Absorbance was read at a wavelength of 570 nm on a microplate reader (SAFIRE, Tecan, Austria). Procedures with HUVECs were similar, except for initial seeding densities of 2×10^4 cell/m were plated on 96 well flat-bottom microplate (treated with fibronectin) and extra incubation time of 6 h was used prior to addition of solubilizing solution.

***In Vitro* Binding Assays.** *Selectin Induction by Pro-Inflammatory Drugs.* HUVEC were plated on sterile round coverslips (Fisher Scientific, Ottawa, ON, Canada) treated with human fibronectin at a seeding density of 5×10^4 cells/wells and grow for 48 h prior to experiment in 24 well plates (Costar, Corning). Selectin expression on the cell surface was induced by LPS (5 μg/mL) or with L-NAME (3 mM) for 4 h. After repeated rinsing with cold PBS, the activated cells were fixed with a filtered 1% (w/w) formaldehyde PBS solution for 10 min. After addition of 250 μL of blocking solution (2% (w/v) BSA in PBS), cells were incubated overnight at 4 °C with mouse anti-E-Selectin (clone BBIG-E4 (5D11), R&D Systems, Minneapolis, MN) or P-Selectin (clone P8G8, Chemicon, Temecula, CA) antibodies. After washing with PBS, secondary goat antimouse Alexa546 antibody (Invitrogen) was added for 2 h. Cell nucleus staining was performed using Hoechst 33352. All micrographs were taken using an inverted Olympus IX71 microscope (Olympus Canada Inc., Markham, ON) and an Evolution VF camera (MediaCybernetics, Bethesda, MD) with the same 60× objective lens and exposure time to allow comparison of measurements. All images were processed with ImagePro software (MediaCybernetics, Bethesda, MD).

NP Binding Assays. HUVECs were activated as described above and cooled to 4 °C prior to incubation with cold NP suspension for 5 min (100 μg/wells) in serum-free medium. After repeated rinsing with cold PBS, cells were lysed for 2 h at 2 °C with a 0.2% (w/w) Triton X100 solution (1 N NaOH), and fluorescence intensity was read with a fluorescence plate reader (Ex., 550 nm; Em., 580 nm). A similar procedure was used for studies using the free ligand as an inhibitor. Activated HUVECs were incubated for 30 min at 37 °C with different concentrations of free ligand and cooled to 4 °C before incubation with NPs (50 μg/mL) in serum-free medium. After repeated rinsing with cold PBS, cells were lysed during 2 h and fluorescence was read at 25 °C.

Statistical Analysis. The data were calculated as means ± SE, where statistical significance was determined by Student's *t* test.

RESULTS

Ligand Docking Simulations. The synthetic ligand (see Scheme 1), an analogue of the sLe^x epitope, was selected in this study due to its high binding affinity for P- and E-selectin (*8*) compared to sLe^x (*9*). Ligand docking simulations were performed on E-selectin in order to confirm that grafted ligands still possess high binding affinity to receptors. The synthetic ligand is a mannose-based mimic of sLe^x, whose structure incorporates a carboxylate group which replaces the Gal residue. Interaction between sLe^x and E-selectin has been extensively described and is now well-understood. The binding site of E-selectin is known to be located on the lectin domain of the protein. The calcium ion present in this domain has two main functions: to maintain the structure of the binding site (the calcium ion interacts with 5 residues of the protein, namely, Glu80, Asn82, Asn83, Asn105, and Asp106) and to bind the two hydroxyl groups in the equatorial position of the l-fucose ring of the sLe^x ligand. This last function has been extensively used to develop ligands derived from mannose and having two hydroxyl functions in the equatorial position and another one in the radial position.

Results from docking simulations performed with the synthetic ligand showed that the mannose cycle fits in the binding site and interacts strongly with a large number of amino acids forming the binding pocket. One of the two equatorial hydroxyl functions of the mannose ring was able to bond strongly to the

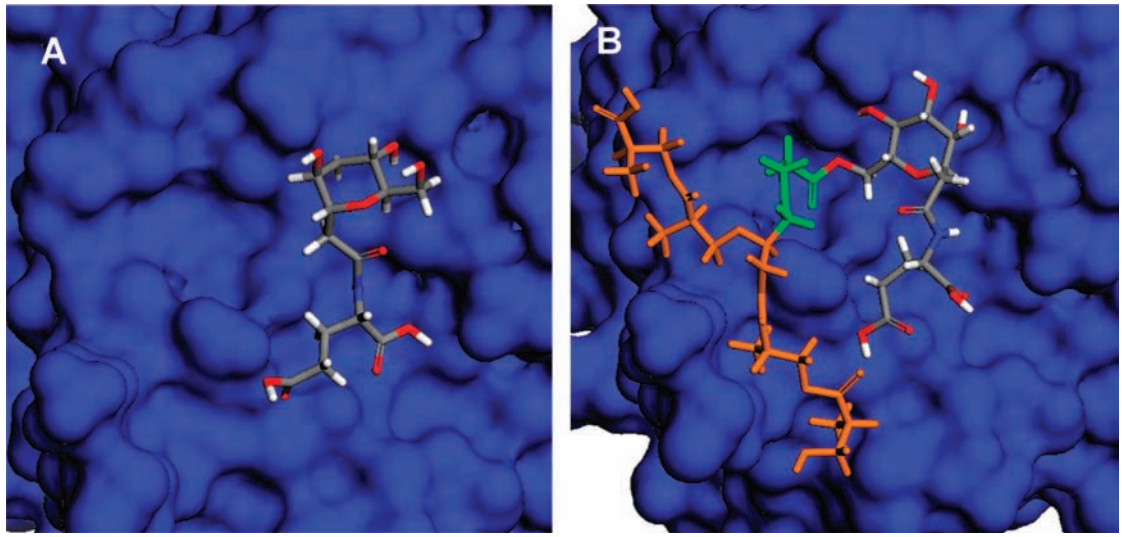

Figure 1. Conformation of the ligand in the bonded state obtained from docking experiments. (A,B) Top view of the binding pocket. Protein is represented by the Connelly surface in blue. The PLA is chain represented in orange. Linker monomer is represented in green.

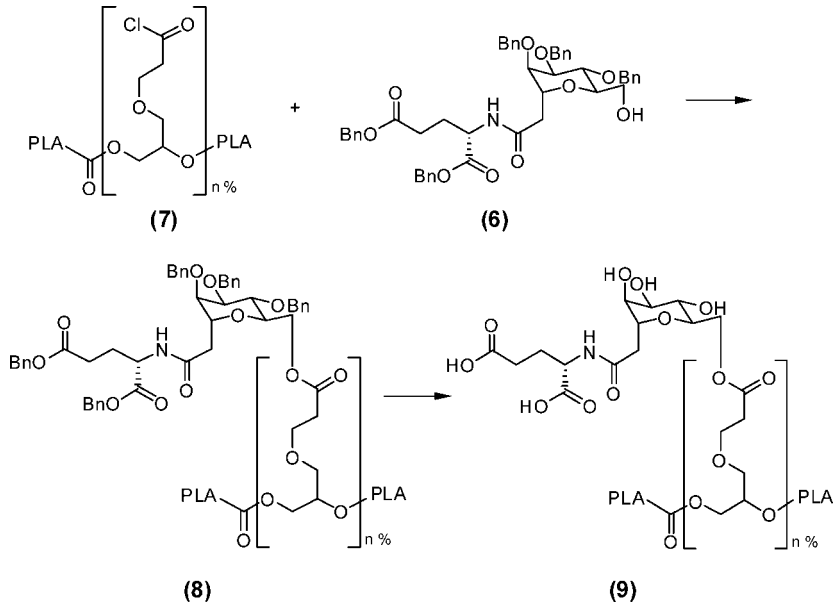
Scheme 3. Grafting Reaction of the Synthetic Ligand on a PLA Chain and Deprotection



calcium ion of the lectin domain, while the other one interacted with Asp106 and Asn83 side chains. Moreover, one carboxylate of the glutamate moiety of the ligand binds strongly to Arg97 and to Tyr48. These interactions allow the ligand to be positioned in a similar direction to sLe^x. It is interesting to note that the synthetic ligand interacts with the same amino acid as sLe^x but with almost no steric constraint, which is certainly the cause of its potent inhibition capacity. Moreover, these docking simulations showed that one hydroxyl group of the mannose ring is not involved in the binding pattern and could be used as a coupling function with a macromolecule.

We performed another series of docking simulations using the synthetic ligand grafted to a PLA chain of 5 monomers. The interaction pattern of the grafted ligand was very similar to the original nongrafted ligand. We observed that the fitness index of the best structure was much higher for the grafted ligand than for the nongrafted ligand, indicating that the presence of the polymer chain favored binding of the ligand. The conformations of the free and grafted ligands in the binding pocket are slightly different. One remarkable difference is the position of the mannose ring, which is flipped in the case of the grafted ligand (Figure 1). This conformational change allows the polymer chain to lie aside from the binding pocket. Surprisingly, this conformation does not affect the interaction pattern of the ligand. The hydrogen bond network between the receptor and the grafted ligand was identical to that of the free ligand. The same amino acids from the receptor were involved in the interaction pattern as well as the same hydroxyl groups from the mannose ring and the carboxylate groups from the glutamate moiety of the ligand. The main difference between the two interaction patterns is located in the two hydroxyl groups of the mannose ring, which are inverted in the case of the grafted ligand compared to the free ligand configuration.

Table 1. Particle Size and Zeta Potential Measurements of the Different NPs Used in This Study

tested nanoparticles	particle size (nm)	zeta potential (mV)

amino acid **2** and the acid **5** (Scheme 2). A challenging aspect of this reaction was to realize the coupling in the presence of free hydroxyl functions on **5**. The reaction sequence was important in order to prevent oxidation of the primary hydroxyl groups into carboxylic acid. We used acetyl functions to protect the primary alcohol during the reaction. As illustrated in Scheme 3, the coupling reaction yielded the amide ligand **6** ready to be grafted to PLA. The grafting of the synthetic ligand to PLA was mediated by an ester linkage on pendant groups of a new family of polyester polymers developed in our laboratory (*23*). For this purpose, the ligand must present only one reactive hydroxyl group, which does not belong to the active part of the ligand. The use of a benzyl group to protect the other hydroxyl and carboxyl functions was guided by the ease of removal by hydrogenation in one step after polymer grafting. The presence and removal of the benzyl group before and after deprotection of the grafted ligand was confirmed by NMR (data not shown). The ligand grafting reaction takes place between the unprotected hydroxyl group on the ligand **6** and the acyl chloride groups present on the polymer pendant groups **7** in the presence of DMAP and pyridine (Scheme 3). Molecular weights of the synthesized polymers, determined by GPC, were found to be M_n 23 103, M_w 41 623 for PLA and M_n 16 412, M_w 34 868 for PLA-SEL$_{5\%}$. A small decrease of the molecular weight of PLA-SEL$_{5\%}$ could be due to partial hydrolysis of the polymer, as some reaction steps of the ligand grafting reaction involve acidic or basic treatments. The free ligand was obtained by catalytic hydrogenation of **6**, which removed the benzyl protecting groups and gave the ligand described by Wong et al. (*8, 24*). The structure of the free ligand was confirmed by mass spectrometry as well as ^{1}H and ^{13}C NMR.

Preparation and Characterization of NPs. Particle size and zeta potential measurements performed on the NPs used in this study are summarized in Table 1. As expected, no significant differences in zeta potential between bare PLA and PLA-SEL$_{5\%}$ NPs were observed due to the low concentration of synthetic ligand in the NPs. The negative surface charge of the NPs is mostly due to the remnant carboxylic groups of PLA.

NP Surface Characterization. We used TOF-SIMS to detect the presence of the ligand directly on the surface of the NPs. For these experiments, no fluorescently labeled polymers were used. Excipients coming from NP preparation and polymers used did not contain any nitrogen atoms. TOF-SIMS is a very surface-specific technique and sensitive to the outermost 10 Å of the NP surface. In Figure 2, the 40−46 amu region of the mass

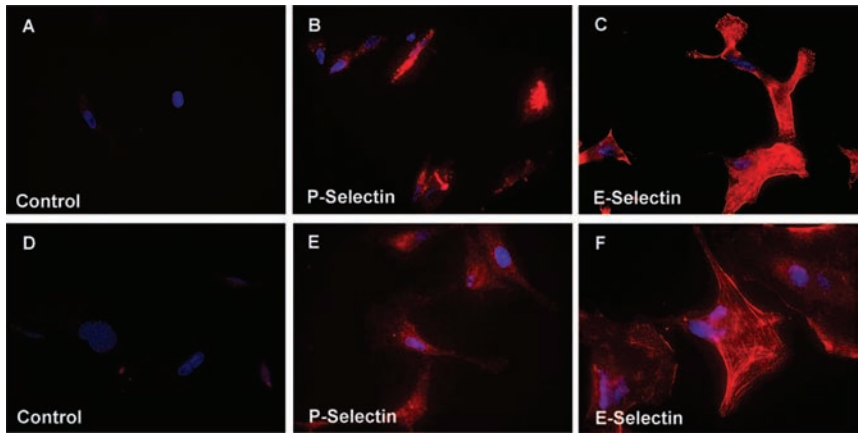

Figure 5. Fluorescent micrographs of HUVECs activated with LPS (B,C) and with L-NAME (E,F). Significant localization of fluorescence (red channel) was observed for E-selectin induced by L-NAME compared to LPS, while LPS-activated cells demonstrate higher levels of E- and P-selectin on their surfaces. Control experiments represent E-selectin (A) and P-selectin (D) expression under basal conditions. Blue channel represents nucleus staining.

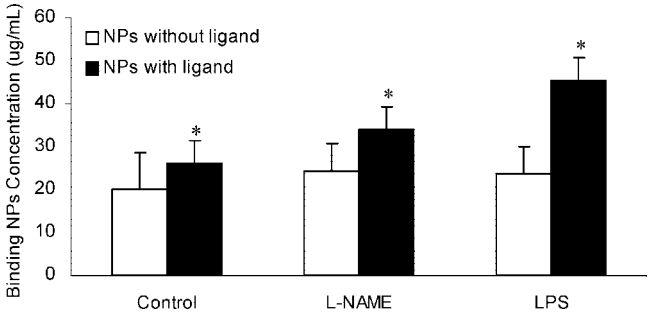

Figure 6. Fluorescence spectrophotometry demonstrates that binding of the NPs is regulated by receptor expression. The concentration of bound NPs on the cell surface was dependent on the activating molecule and was a maximum for LPS ($p < 0.01$, $n = 3$). NP binding time was 5 min at 4 °C, followed by extensive washing and cell lysis.

spectra is displayed, showing peak differences that can be attributed to nitrogen compounds found on ligand-functionalized NPs only.

NP Cytotoxicity Studies. Cytotoxicity of NPs made of PLA or PLA- $SEL_{5\%}$ was investigated *in vitro* on two different cell lines, namely, rat macrophages (Raw 264.7) and human vascular endothelial cells (Figure 3A,B). Blank experiments showed no significant polymer absorbance in the concentration range studied. Results of MTT assay demonstrated that the NPs are nontoxic in concentration lower than 100 μg/mL. Moreover, microscopic observations of the macrophage or human vascular endothelial monolayer during the study showed no changes in cell morphology or growing patterns (data not shown).

Binding Capacity of the NPs *in Vitro.* Selectin expression by HUVECs incubated with pro-inflammatory drugs was characterized by fluorescence microscopy. The relative concentration of E- and P-selectins on HUVEC surface was quantified using fluorescent anti-E-selectin and anti-P-selectins mAbs and normalized to basal concentrations on control cells (Figure 4). Upon incubation with LPS, E- and P-selectin concentrations could be enhanced 3- and 2-fold, respectively. Incubation of cells with the drug L-NAME leads to lower expression of the receptors but was still significantly higher than control cells. Fluorescence micrographs also evidenced differences in E-selectin distribution on the surface of activated cells dependently of the activating drug (Figure 5). P-selectin stained with anti-P-selectin mAbs appeared to be uniformly distributed around the cell nucleus independently of the activating drug (Figure 5B,E). E-Selectin exhibits a very different distribution pattern depending on the activating molecules. With LPS activation, a large fraction of the proteins are uniformly distributed on cell surfaces, (Figure 5C), while with L-NAME, a significant amount are clustered in filamentous structures (Figure 5F). Cytoskeletal staining with anti-F-actin mAbs was done to ensure that cell membrane permeability was not increased by formaldehyde treatment.

To determine the binding capacity of NPs to HUVECs expressing basal or high levels of selectin receptors, cells were treated with NPs for 5 min at 4 °C in order to decrease uptake by active endocytosis. After this short incubation, cells were abundantly washed and the concentration of bound NPs was quantified at 25 °C by fluorescence photospectrometry (Figure 6). For cells incubated with LPS, NPs formulated with PLA-$Sel_{5\%}$ present a 2-fold enhancement of bound concentration compared to nonactivated cells and a 30% enhancement for cells incubated with L-NAME. NPs formulated with PLA were not sensitive to expression levels of selectins and exhibit a constant but low bound NPs concentration independently of the experimental conditions. The level of NPs bearing the synthetic ligand corresponds well with the level of expression of E- and P-selectin induced by LPS and L-NAME, indicating that adhesion of these NPs is strongly dependent on selectin expression.

Fluorescent micrographs of cells activated with LPS confirmed this result. Strong fluorescence localized on the whole surface of the cell was observed after just 5 min of incubation with NPs bearing the synthetic ligand, while almost no fluorescence could be observed with the NPs formulated with PLA (Figure 7). Control experiments of F-actin staining on permeabilized and nonpermeabilized cells were also realized and confirmed that the observed fluorescence in micrographs came from cell surfaces and not from cytosol (data not shown).

Binding assay of NPs in the presence of free ligand was also realized. Free ligand was incubated for 30 min with HUVEC, which were activated with LPS or L-NAME. They were cooled to 4 °C prior to the introduction of the NPs. An increase of the free ligand concentration was followed by a decrease in the fluorescence intensity only for the NPs bearing the synthetic ligand (Figure 8). Fluorescence intensities similar to those of control cells, which were not activated or incubated with the free ligand, were obtained for free ligand concentrations higher

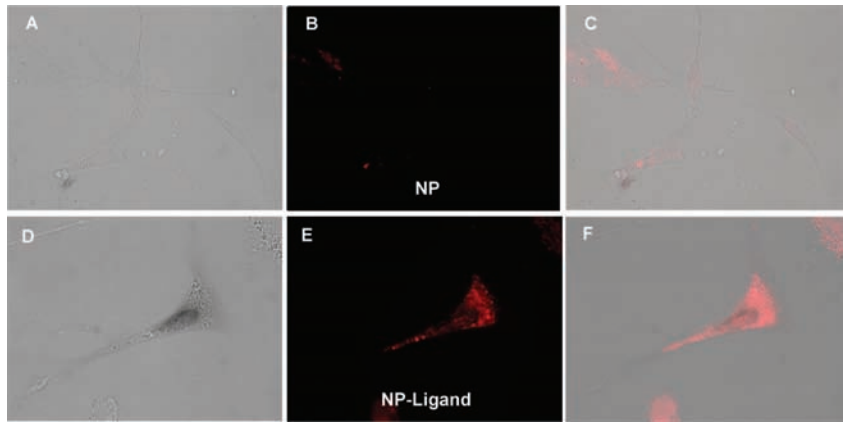

Figure 7. Fluorescent microscopy was used to assess localization of the NPs (red) on LPS activated cell surface. Images confirmed that NPs bearing ligand molecules rapidly adhere to the cell surface (E) compared to the bare NPs (B). NP binding time was 5 min at 4 °C and was followed by extensive washing and fixation of the cells. (A) and (D) are DIC images; (C) and (F) are merged images.

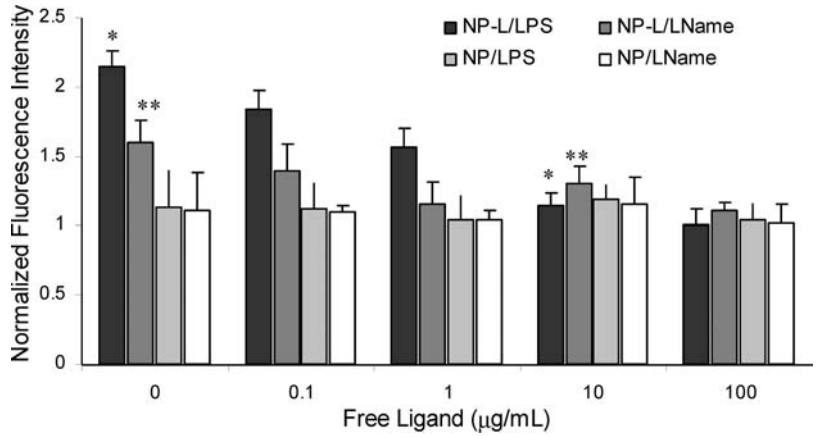

Figure 8. Fluorescence spectrophotometry demonstrated that free ligand can inhibit binding of NPs bearing ligand molecules ($p < 0.01$, $n = 3$). Binding of bare NPs was not affected. NP binding time was 5 min at 4 °C and was followed by extensive washing and cell lysis. Fluorescence intensities were normalized to control conditions (nonactivated cells treated with NPs).

than 10 μg/mL. NPs formulated with PLA were not sensitive to the presence of free ligand in the whole range of concentration studied.

DISCUSSION

The natural ligand of E- and P-selectin, the tetrasaccharide sialyl Lewis x (sLe^X), has a weak affinity (around 0.6 mM) for E-selectin as determined in cell-free assays (*25*). Development of synthetic carbohydrate ligands having higher affinities has been hindered by the fact that the synthesis of modified carbohydrate is complex and expensive. Moreover, most proteins bind carbohydrates with weak affinity. At a molecular level, X-ray diffraction analysis of E- and P-selectin (*21*) binding sites of natural ligand sLe^x had recently shown the essential chemical groups involved in the binding pocket. Consequently, several designs of antagonist ligands have been proposed (*8, 9*). Among them, carbohydrate mimetics of sLe^x based on a mannose ring have been extensively studied (*24, 26*). The advantage of these molecules is the relative ease of their synthesis and their high affinity toward E- and P-selectin. The binding pattern and conformation of the synthetic ligand grafted to a polymeric chain of PLA was evaluated and compared to the free synthetic ligand. Docking experiments performed on the free synthetic ligand showed that one of the anomeric hydroxyl functions present at the 6-O position of the α-D-mannopyranosyl ring is nonessential for the binding of the ligand. Thus, it could be possible to graft a polymeric chain at that position. The simulation results showed that grafting the synthetic ligand to a hydrophobic polymeric chain like PLA did not alter significantly the interaction pattern of the ligand with the protein. This is in agreement with previous experimental observations made by Wong et al. who showed that conjugation of hydrophobic groups like C_{16} alkyl chains on the nonessential hydroxyl group of the ligand strongly increased the affinity of the ligand to E- and P-selectin (*24*). The technique used to evaluate the NPs allows mixing of functionalized and nonfunctionalized PLA chains and offers the possibility of adjusting the concentration of ligand in the NPs. This versatility in the formulation has also allowed encapsulation of hydrophilic (*27*) or hydrophobic drugs (*28*) in PLA NPs and fine-tuning of the delivery kinetics of these drugs. An important advance of the present approach resides in the fact that, by mixing a ligand functionalized polymer with a nonfunctionalized homologue, a high concentration of ligand on the NP surface can be maintained during the whole lifetime of the NPs, contrary to NPs that are surface-functionalized only (*29*).

As already mentioned, the presence of the synthetic ligand on the NPs is a key factor to ensure strong affinity of the NPs to their target. TOF-SIMS results ensured that functionalized NPs really exposed the synthetic ligand on their surfaces. Cytotoxicity assays did not reveal any toxicity associated with NPs over a large range of NP concentrations, ensuring that binding of NPs was not affected by the chemical components of the polymers.

Under normal conditions, both E-selectin and P-selectin are present in low concentrations in vascular endothelial cells but can be induced by interleukins (IL), tumor necrosis factor-α

(TNF-α), lipopolysaccharides, endotoxins (*30*), and cytomegalovirus infection (*31*). Expression of E- and P-selectin by L-NAME has been used in model systems of ischemia or artherosclerosis, as it has been reported to inhibit the production of nitric oxide from endothelial cells. Our observation showed that the concentration and the distribution of E-selectin following L-NAME activation and LPS activation in HUVECs are very different. E- and P-selectin levels are higher on cells stimulated with LPS after 4 h of induction. Maximum expression of selectin on the cell surface has been reported to be at 4 h for both LPS and L-NAME activation (*32, 33*), suggesting that the differences observed in selectin concentration do not come from different expression kinetics. We observed marked differences in selectin distribution on endothelial cells activated by L-NAME or LPS. Scholz et al. reported a more diffuse pattern of E-selectin distribution on HUVEC cells activated by IL-β (*34*). This suggest that receptor distribution on the cell surface is strongly dependent on the stimulating molecule and therefore on the regulation process. More experiments are needed to truly characterize the effect of the protein distribution on the adhesive capacity of the NPs, but it can be advanced that this factor is expected to strongly affect the adhesive properties of the NPs as already suggested by other studies. Indeed, it has been reported that the location of the ligand−receptor bond relative to the endothelial or particle surface influences the adhesion of NPs to the endothelium (*35, 36*).

Results from *in vitro* adhesion tests demonstrated that the presence of the ligand was necessary to achieve strong adhesion between cells and NPs. Given that the NPs used in this study have the same particle size and similar zeta potentials, differences in binding properties of the NPs could be directly correlated with the presence of the ligand on NP surface. We observed that NP binding was modulated by selectin upregulation. Indeed, different levels of selectin expression could be achieved by incubating the cells with different pro-inflammatory drugs. These differences in receptor expression could be correlated with differences in binding concentrations for the NPs bearing the synthetic ligand.

In a nutshell, these results obtained *in vitro* confirm the adhesion capabilities of NPs functionalized with selectin ligand, which makes them good candidates for active targeting of the endothelium. Such findings provide important information regarding possible treatments of acute inflammation using drug delivery systems.

The gastrin releasing peptide receptor (GRP-R) is overexpressed on a number of tumors and cancer cell lines including pancreas, prostate, breast, gastrointestinal, and small cell lung cancer (SCLC). Radiolabeled bombesin (BBN) analogues have exhibited high binding affinity and specificity to the GRP-R. A bombesin analogue with an antagonist targeting vector at the C-terminus, DOTA-aminohexanoyl-[*D*-Phe^6, Leu-NHCH$_2$CH$_2$CH$_3$^{13}, des Met^{14}] BBN[6−14] (**1**, "Bomproamide"), has been synthesized and displays high binding affinity (IC_{50} = 1.36 ± 0.09 nM) against ^{125}I-Tyr^4-BBN in in vitro competitive assays using PC-3 cells. Maximum internalization of ^{111}In-**1** reached 14% in PC-3 cells after 45 min of incubation. Rapid (0.25 h PI) and high (12.21 ± 3.2%ID/g) pancreatic uptake of ^{111}In-**1** was observed in healthy CF-1 mice, and 90% of the activity was blocked by coinjection of 100 μg of BBN. Rapid (0.25 h PI) and high uptake (6.90 ± 1.06%ID/g) was observed in PC-3 prostate cancer xenografts in SCID mice, as well as visualized clearly in a SPECT/CT study. These results support the use of a bombesin construct with an antagonist C-terminal vector as a candidate of choice for specific in vivo imaging of tumors overexpressing GRP-receptors.

INTRODUCTION

Receptor-avid radiopharmaceuticals have attracted great attention as efficient biomarkers. Molecular selectivity is achieved with the appropriate choice of a biomolecule, whether it is a monoclonal antibody or fragment, small molecule, or peptide. For many imaging or radiotherapeutic applications, introduction of the radioactive nuclide is addressed through the bifunctional chelate approach. Regulatory peptides such as the bombesin (BBN), gastrin-releasing peptide (GRP), and neuromedin-B are a group of promising small biovectors. BBN contains 14 amino acid residues and is the amphibian analogue of the mammalian counterpart GRP which contains 27 amino acid residues (*1, 2*). BBN, originally isolated and purified from the skin of European frog *Bombina bombina*, shows marked binding affinity and specificity to the GRP receptor subtype BB2 (*3*). GRP receptors are normally expressed in the non-neurocrine tissues of the pancreas and breast as well as in neuroendocrine tissue of the prostate, lung, colon, and anterior pituitary cells, as well as central and peripheral nervous system (*4*−*6*). Overexpression of several regulatory peptide receptors, such as BB2, has been detected in various human neoplasia (*7*−*12*) and may act as a prognostic marker for prostate, breast, and lung carcinogenesis (*13*−*15*).

Agonist-based peptide constructs have been studied as receptor targeting agents (*16*−*21*) due to their ability to induce receptor-mediated internalization, most likely by endocytosis.

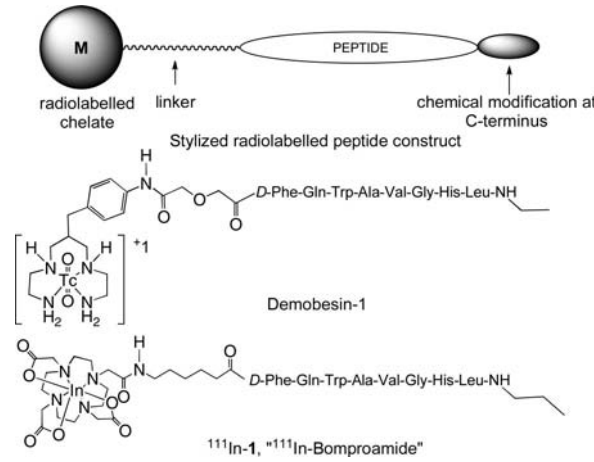

Figure 1. General structure for a radiolabeled peptide construct, structure of Demobesin-1 and ^{111}In-Bomproamide (^{111}In-**1**).

Accumulation of the radioconjugate within the targeted cells is a prerequisite to triggering efficient internalization. For therapeutic purposes, efficient internalization of the radioconjugate appears to be important in delivering the highest radioactivity dose to the targeted cells.

Structural modifications to these radiopharmaceuticals have included variation in the peptide sequence, the nature of the chelate and radiometal, and the length of the spacer attaching the two components (Figure 1). For example, an agonist BBN analogue, DO_3A-CH_2CO-G-4-aminobenzoyl-Q-W-A-V-G-H-L-M-NH_2 (AMBA), was synthesized and labeled with ^{177}Lu for prostate cancer targeting (*22*). ^{177}Lu-AMBA shows a high affinity for the GRP-R (IC_{50} = 2.50 ± 0.50 nM) and 76.8% internalization. The in vitro binding properties of ^{177}Lu-AMBA were subsequently investigated in human neoplastic and non-neoplastic tissues known for their expression of GRP-receptors

(*16*). Interestingly, in contrast to the labeling observed in GRP-positive mouse pancreas, the authors reported that the human pancreas shows no labeling with ^{177}Lu-AMBA unless chronic pancreatitis was present.

A novel series of DTPA coupled BBN analogues with a shortened peptide sequence also containing non-natural amino acid residues was recently reported (*19*). Among this series, DTPA-ACMpip-Tha^{6}-BAla^{11}-Tha^{13}-Nle^{14}-BBN[6-14] showed two to three times higher uptake for CA20948 pancreas tumor and 1.3 times for PC-3 prostate tumors when compared to DTPA-BBN[1−14]. The authors concluded that shortening the amino acid sequence and replacing specific amino acids in the BBN sequence can improve the receptor binding affinity (*19*).

A method of radiolabeling with technetium or rhenium via the metal precursor $[M(H_2O)_3(CO)_3]^+$ was tested with an agonist BBN analogue containing an appended 2,3-diaminopropanoyl moiety. The radiolabeled construct, (DPr)-Ser-Ser-Ser-Gln-Trp-Ala-Val-Gly-His-Leu-Met-(NH_2), exhibits excellent binding affinity to the GRP-receptors in the human PC-3 cell line (IC_{50} $\sim$ 0.86 nM). In addition, high uptake (16 $\pm$ 1.3%ID/g) in normal pancreas and extensive internalization 80% after 90 min incubation with PC-3 cells was reported (*23*). Studies on compounds reported by Nock et al. in 2005 utilized the open chain tetraamine-functionalized BBN analogue based on the agonist sequence [Pro^{1}, Tyr^{4}, Nle^{14}] BBN, Demobesin-4 (*15*). Demobesin-4 has binding affinity for the GRP-receptors in the PC-3 cells with (IC_{50} $\sim$ 0.15 nM) (*15*). The number of receptors to which an agonist or antagonist binds may differ. For example, ^{125}I-[Tyr^{0}]rat urocortin, an agonist, was shown to bind to less corticotropin-releasing factor type 1 receptor sites than ^{125}I-[DTyr^{1}]astressin, an antagonist (*24*).

Two chelation systems, CB-TE2A (1,4,8,11-tetraazabicyclo[6.6.2]hexadecane-4,11-diacetic acid) and NOTA (1,4,7-triazacyclononane-1,4,7-triacetic acid), have been compared to DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) for the stable incorporation of ^{64}Cu for PET imaging of prostate cancer using the construct BBN[7−14]NH_2 (*18, 25*). The authors reported that the lack of retention of NOTA complex radioactivity in collateral tissues such as liver at 4 and 24 h time points suggests a high degree of in vivo stability of NOTA complex as compared with peptide conjugates comprising similar polyaminocarboxylate chelators such as DOTA (*25*). The images of the ^{64}Cu-CB-TE2A radioconjugate demonstrate considerably reduced activity in the kidneys and gastrointestinal tract compared to ^{64}Cu-DOTA radioconjugate. The authors reported that the high stability of ^{64}Cu-CB-TE2A radioconjugate in vivo contributes to less retention of the radioactivity as opposed to the ^{64}Cu-DOTA radioconjugate (*18*). Kidney uptake and retention of ^{64}Cu-NOTA conjugate was lower than the ^{64}Cu-DOTA-conjugate and very similar to ^{64}Cu-CB-TE2A-Y3-TATE at 1 h postinjection (*25*).

The effect of the length of the hydrocarbon spacer [0-carbon, β-Ala, 5-Ava, 8-Aoc, and 11-Aun] between the agonist BBN [7−14]NH_2 moiety and the radiochelate on the in vitro binding affinity toward GRP-Receptors was studied (*26*).The results illustrated that analogues containing either no spacer or the 11 carbon spacer (11-Aun) exhibited GRP-receptor specificity, but the measured affinity was less than 1% of the eight-carbon spacer analogue. The authors concluded that the length of the hydrocarbon spacer could be varied from three to eight carbon atoms without adversely affecting the resultant binding affinity.

Structural modifications at the C-terminus of bombesin yield peptides that retain their superb binding affinity for GRP-receptors, but also confer antagonist properties (*27, 28*). The rationale of developing antagonist agents is their capability of binding the receptors regardless of their limited capability to trigger internalization. The superb binding characteristics of antagonist radioconjugates may be due to their ability to bind a higher number of receptor binding sites than agonists (*24, 29*). These antagonist-based peptide constructs are now gaining attention as efficient targeting agents for diagnostic applications (*30, 31*). The in vitro biological results (*32*) as well as the solid-phase synthesis (*33*) of some of these parent peptides have been reported. One BBN analogue, [*D*-Phe^{6}, Leu-NHEt^{13}, des Met^{14}] BBN[6−14], was derivatized with a benzylaminodiglycolic acid linker and the open-chain tetraamine chelate to incorporate technetium to yield Demobesin-1 (Figure 1) (*33*). Results show that Demobesin-1 has a high binding affinity (IC_{50} = 0.7 nM) in human prostate PC-3 cancer cells. Pancreatic uptake of 58.7%ID/g at 30 min postinjection was also reported. Demobesin-1 internalized within the cells to approximately 25%. During the course of our work, Demobesin-1 was tested for its internalization properties using the intercellular calcium mobilization-based signaling assay in PC-3 and HEK-GRPR cells and an ELISA-based internalization assay in HEK-GRPR cells. On the basis of these results, the authors confirm that their construct was acting as an antagonist. In addition, Demobesin-1 exhibited a much higher in vivo uptake than the aforementioned Demobesin-4, an agonist; thus, the authors concluded that GRP-receptor antagonists may be preferable agents to GRP-receptor agonists for tumor targeting (*30*).

In this study, we report the solid-phase synthesis of an antagonist bombesin analogue, DOTA-aminohexanoyl-[*D*-Phe^{6}, Leu-NHCH$_2$CH$_2$CH$_3^{13}$, des Met^{14}] BBN [6−14] (**1**, "Bomproamide"; Figure 1), as a targeting vector for radioimaging human prostate cancer (PC-3) overexpressing GRP-receptors. This peptide was chosen because the reported IC_{50} of [*D*-Phe^{6}, Leu-NHCH$_2$CH$_2$CH$_3^{13}$, des Met^{14}] BBN [6−14] to guinea pig acini was higher (1.6 nM) than that observed for [*D*-Phe^{6}, Leu-NHCH$_2$CH$_3^{13}$, des Met^{14}] BBN [6−14] (7.0 nM) (*27*). The peptide is first synthesized and then equipped with a six-carbon linker to a DOTA chelate for the efficient incorporation of ^{111}In. The initial in vitro and in vivo evaluation of this radioconjugate in CF1 mice and those containing PC-3 prostate cancer xenografts in SCID mice are described.

MATERIALS AND METHODS

All reagents used were of analytical reagent or HPLC grade. All syntheses were conducted in a manual solid-phase peptide synthesis (SPPS) reaction vessel. HPLC analysis and separations were performed with a C-18 Kromosil column (5 μm, 100 Å, 150 mm $\times$ 4.5 mm, Keystone Scientific Inc.). HPLC solvents consisted of 0.1% aqueous trifluoroacetic acid (TFA) (solvent A) and acetonitrile (ACN) containing 0.1% TFA (solvent B) at a 1.0 mL/min flow rate and UV detection at 214 and 280 nm.

A TSQ700 mass spectrometer (Thermo Finnigan) was coupled to an HPLC equipped with a NovaPak C18 column (3.9 $\times$ 300 mm, Waters) for LC-MS analyses.

HPLC analysis and isolation of the ^{111}In-radiolabeled constructs were performed with a C-18 Jupiter (RP-18) HPLC analytical column, (5 μm, pore size 300 Å, 4.6 $\times$ 250 mm, Phenomenex). HPLC solvents consisted of water (H_2O) containing 0.1% TFA (solvent A) and ACN containing 0.1% TFA (solvent B). Elution system of 25% to 40% ACN in 60 min was used for purification. The flow rate was maintained at 1.5 mL/min for all the analytical and separation runs at 280 nm.

$^{111}InCl_3$ in 0.05 M HCl (pH $\sim$1.48) was obtained from Mallinckrodt Inc., St. Louis, MO. Radioactivity was counted using a well counter equipped with a sodium iodide (thallium), NaI(Tl), scintillation detector. Gamma ray radioactivity of the in vitro binding affinity (IC_{50}) studies was counted using a gamma counter.

All biodistribution studies performed during the course of this research were conducted using protocols approved by the

Institutional Animal Care and in accordance with U.S. Public Health Service Guidelines.

The micro single photon emission tomography (microSPECT) imaging was performed using a microCAT II SPECT/CT (Siemens Medical Solutions) small animal system composed of dual SPECT system. Each microSPECT detector contains 10 000 NaI(Tl) crystals (1.25 × 1.25 × 5 mm elements) with a detector pitch of 1.45 mm and a field of view of 145 mm × 145 mm. The detectors are coupled to a 3 × 3 array of position sensitive photomultiplier tubes (Hamamatsu H8500), each of which has a 49 × 49 mm^2 nominal active area and housing dimensions of 52 × 52 mm^2. The crystal arrays are separated by approximately 0.20 mm with the region between the crystals filled with an opaque white reflective compound material. The imaging was performed using dual pinhole collimators with interchangeable pinhole apertures of 2 mm in diameter. The pinhole focal length or detector-to-aperture distance was 90 mm. The pinhole apertures were fabricated as knife-edge apertures to minimize photon penetration and are fabricated of tungsten.

The micro computed tomography (CT) images were performed using Micro CT unit (microCAT II MicroCT scanner, CTI). The system consists of a fully shielded cabinet X-ray system with a maximum voltage of 80 kV, maximum current of 500 μA, and a tungsten anode. The X-ray detector has a 4096 × 4096 pixel charge-coupled device (CCD) array that is couple to a phosphor screen via a fiber-optic device. The scanner is a third-generation "step and shoot" system in which the low-power X-ray source and CCD array detector rotate about the specimen. Computer algorithms were use for reconstructing images of <50 μm isotropic voxel dimension using the *Cobra 4.1* reconstruction engine.

The human immortalized prostate PC-3 cancer cell lines (American type Culture Collection) used in the course of this study were grown in custom PRMI medium 1640 (Invitrogen Corp.) with 10% fetal bovine serum (US Bio-Technologies Inc.) and gentamicin (American Pharmaceutical Partners, Inc.). The PC-3 cell lines were grown and maintained by the University of Missouri Cell and Immunology Core Facility.

DOTA-Aminohexanoyl-[*D*-Phe^6, Leu-NHCH$_2$CH$_2$CH$_3^{13}$, des Met^{14}] BBN[6−14] (1), "Bomproamide.". The *D*-Phe^6, Leu-NHCH$_2$CH$_2$CH$_3^{13}$, des Met^{14} BBN[6−14]-HMBA resin precursor, **2,** was synthesized as previously described (*34*). Three equivalents, relative to the resin loading, of Fmoc-6-aminohexanoic acid (0.520 mmol, 183 mg) was dissolved in 9 mL NMP. HBTU (466 μmol, 177 mg) and HOBt (518 μmol, 79.0 mg) were dissolved in 3 mL DMF. These two solutions were mixed, and 3 equiv (518 μmol, 89 μL) of DIPEA were added and vortexed thoroughly for 10−15 min and added directly to **2** in a manual SPPS reaction vessel and agitated gently for 30 min under N_2 at rt. The Fmoc group was removed by adding 3−4 mL of 25% (v/v) piperidine/DMF to yield 6-aminohexanoyl-[*D*-Phe^6, Leu-NHCH$_2$CH$_2$CH$_3^{13}$, des Met^{14}] BBN [6−14]-HMBA resin, **3**. Three equivalents, relative to the resin loading, of DOTA *tris* (*t*-Bu ester) (0.520 mmol, 296 mg) were dissolved in 9 mL of NMP. The carboxylic acid moiety was activated as above and was mixed with **3** and agitated gently for 30 min under N_2 at rt to yield **4**. The acid-sensitive side chain protecting groups of histidine, tryptophan, and glutamine, as well as the three BOC protecting groups on DOTA, were removed by adding a deprotection−scavenger cocktail (10−20 mL cocktail per 1 g peptidyl resin) consisting of 95%TFA/2.5%H_2O/2.5%TIS for 3−4 h at rt with gentle agitation using a stream of N_2. DOTA-aminohexanoyl-[*D*-Phe^6, Leu-NHCH$_2$CH$_2$CH$_3^{13}$, des Met^{14}] BBN [6−14]-HMBA resin was separated by filtration, washed twice with TFA, then five times with NMP, and dried. Subsequently, a sample was swelled with THF (12 mL/g) for 1 h and a cleavage solution of TEA/propylamine/THF (1:5:5 v/v), 50 mL of cleavage cocktail/g peptidyl resin, was added to the mixture and stirred overnight (∼18 h) at 50 °C. The solution containing **1** was filtered and reduced in volume to ∼1 mL of yellowish oil. **1** was precipitated by the addition of cold diethyl ether to yield 180 mg (87.4% crude recovery) as white granules in 76% purity; $k' = 8.11$. Crude **1** was dissolved in 4 mL DMSO and 7 mL of ACN/H_2O (50:50 v/v) and purified by semi-preparative HPLC using 10% ACN/H_2O at starting flow rate of 4 mL/min with a gradient from 30% to 50% ACN in 60 min at a flow rate of 10 mL/minute. Fractions containing **1** with the same purity were collected and lyophilized to yield 23 mg (39.5%) as a white powder: $k' = 8.07$, >90% purity. ESI-MS showed the molecular ions (*m*/*z*): theoretical $C_{72}H_{108}O_{17}N_{18}$ = 1496.81; actual $(M + H)^+ = 1497.7$ and $(M + 2H)^{2+}/2 = 749.7$. The conjugate was stored at 4 °C.

In Vitro Competitive Cell Binding Affinity Assay. The binding affinity of **1** to immortalized human prostate carcinoma PC-3 cells was examined by competitive displacement of ^{125}I-Tyr^4 BBN. In brief, 22 000 cpm of ^{125}I-Tyr^4-BBN and eight increasing concentrations (from 3.33×10^{-13} to 3.33×10^{-6} M) of **1** were incubated for 30 min at 37 °C in humidified air containing 5% CO_2 with 3×10^4 PC-3 cells suspended at pH 7.4 in Roswell Park Memorial Institute (RPMI) medium 1640, containing 4.8 mg/mL *N*-(2-hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid), HEPES, 0.1 μg/mL Bacitracin, and 2 mg/mL bovine serum albumin (BSA). At the end of the incubation period, the medium was aspirated and the cells were washed three times with fresh medium solution to remove any unbound radioactivity. The remaining cell-bound radioactivity was counted using a Packard Riastar gamma counter. The 50% inhibitory concentration (IC_{50}) value of was determined by plotting the percentage of the ^{125}I-Tyr^4-BBN radioactivity bound to the PC-3 cells surface receptors versus the concentration of **1**.

Labeling with ^{nat}In. A sample of **1** (1.5 mg, 1.0 μmol) was dissolved in NH_4OAc buffer (5 mg/mL, 65 mM, 200 μL) and mixed with a solution of $^{nat}InCl_3$ (2.2 mg, 10 μmol) in NH_4OAc buffer (200 μL). The pH of the NH_4OAc buffer solution was adjusted to ∼5.5−6.0 using 0.01 M aqueous HCl. The solution was incubated for 60 min at 80 °C. After cooling to rt, ^{nat}In-**1** was obtained as a white powder (1.3 mg, 81% crude recovery); $k' = 9.03$, 87.5% purity. ESI-MS showed the molecular ions (*m*/*z*): theoretical $C_{72}H_{105}InO_{17}N_{18}$ = 1608.69; actual $(M + H)^+$ = 1610.1, and $(M + 2H)^{2+}/2 = 805.5$.

Radiolabeling with ^{111}In. A sample of conjugate **1** (110 μg, 67.0 nmol) was dissolved in ammonium acetate (NH_4OAc) buffer (200 μL, 0.4 M, pH 7.0) and mixed with ascorbic acid (∼20 mg). $^{111}InCl_3$ (5.55 MBq, 150 μCi) as $^{111}InCl_3$ in 0.05 M HCl (pH ∼1.48) was added to the solution of **1** (resultant pH ∼5.5) and incubated for 60 min at 80 °C. Ammonium acetate buffer solution, pH 7.0, was used to adjust the pH of the radiolabeling mixture. EDTA (50 μL, 0.002 M) was added to chelate any remaining $^{111}In^{3+}$, and the reaction mixture was allowed cool to rt. A few crystals of $CuSO_4 \cdot 5H_2O$ were added to complex excess **1**. Aliquots (25 μL) of the radiolabeling mixture solution were subjected for HPLC analysis. The HPLC radiochromatogram indicates that 74% of the detected radioactivity was located at t_R = 18.86 min corresponding to ^{nat}In-**1**. The HPLC UV chromatogram indicates the absence of **1**, while the UV peak corresponding to ^{nat}Cu-DOTA−peptide conjugate retention time appeared (t_R = 20 min).

^{111}In-**1** was purified by RP-HPLC with a gradient consisting of 25% to 40% ACN in 60 min (1.0% ACN/4.0 min). The HPLC eluent containing pure ^{111}In-**1**, was diluted with 3 mL of water and concentrated on an Empore C18-High Performance Extraction Disk (C18-HD) Cartridge 4215. The retained radioactivity was eluted using a 400 μL of ethanol/saline (6:4 v/v)

mixture. A Capintec CRC-15W Dose Calibrator/well counter was used to measure the collected radioactivity of ^{111}In-**1** before and after concentration. Approximately 90−94% of the original radioactivity was recovered and the radiochemical purity of the formulated ^{111}In-DOTA−peptide conjugates was found to be ≥98% by HPLC.

For the in vitro internalization and efflux studies, as well as in vivo pharmacokinetic studies, ^{111}In-**1** was diluted with an adequate volume of sterile normal saline to achieve 0.148−0.185 MBq (4−5 μCi)/100 μL solution. For the SPECT/CT imaging studies, the ethanol concentration was reduced to <5% by evaporation under a stream of nitrogen. Quality control runs were performed using an HPLC separation gradient of 25% to 40% ACN in 60 min. Only samples with radiochemical purity of >99% were used for the subsequent in vivo and imaging studies.

In Vitro Internalization and Efflux Studies. The degree of residualization in the PC-3 human prostate cancer cells was tested by incubating ∼20 000 cpm of ^{111}In-**1** with 3×10^4 PC-3 cells at 37 °C in an environment of 5% CO_2 for various time periods. The PC-3 cells were suspended in an ice-cooled RPMI medium comprising 2.8 mg/mL HEPES and 2 mg/mL BSA (pH 7.4). After 15, 30, 45, 60, 90, and 120 min incubation periods, the interaction between ^{111}In-**1** and the PC-3 cells was stopped by aspiration of the incubation medium and washing the cells three times with fresh ice-cooled cell culture medium. The PC-3 cell-surface-bound radioactivity was removed by incubating the PC-3 cells with an acidic buffer solution (pH 2.5) comprising 0.2 M acetic acid and 0.5 M sodium chloride for 5 min. At the end of the incubation period, the PC-3 cells were precipitated from the buffer solution by centrifugation. The supernatant, containing the removed PC-3 cell-surface-bound radioactivity, was aspirated, and the precipitated PC-3 cells were washed two times with fresh pH 2.5 buffer solution. Both the supernatant and the PC-3 cells were counted for their associated radioactivity, and thereafter, the percentages of both the internalized and the cell-surface-bound radioactivity were calculated.

The efflux studies were performed using the PC-3 cells at the time identified above with the highest percentage of ^{111}In-**1** internalization. The PC-3 cells after 45 min incubation were allowed to efflux at 15, 30, 45, 60, and 90 min periods. The PC-3 cells were treated and counted for their associated radioactivity as described above. The percentages of both the cell-surface-bound and effluxed radioactivity were calculated.

Biodistribution Studies in Healthy CF-1 Mice. Twenty healthy CF-1 mice mice, with an average weight of 27 g (five mice per time point), were injected with 100 μL of 0.148 MBq (4 μCi) aliquots of ^{111}In-**1** via the tail vein. The mice were sacrificed by neck dislocation at 0.25, 1, 4, and 24 h postinjection. Blood and urine were collected immediately after the mice were sacrificed. The organs and tissues of interest were excised and weighed, and their associated radioactivity was counted using an NaI(Tl) well counter. The small and large intestines as well as the stomach were weighed and counted without evacuating their contents. The %ID of the whole blood weight and %ID/g blood were calculated assuming that the whole blood volume constituted 6.5% of the whole mouse body weight. The distribution of radioactivity was calculated as a percentage of the injected dose per organ (%ID/organ) and as a percentage of the injected dose per gram (%ID/g), using an in-house program.

Blocking Studies. Three mice were injected with ^{111}In-**1** (100 μL, 0.185 MBq, 5 μCi) aliquots via the tail vein. Three mice were injected with ^{111}In-**1** (100 μL, 0.185 MBq, 5 μCi) along with 100 μg BBN via the tail vein. The mice were sacrificed by neck dislocation 1 h postinjection. The organs and tissues of interest were excised and weighed, and their associated radioactivity was counted. Distribution of radioactivity was calculated as %ID/organ and %ID/g using an in-house program.

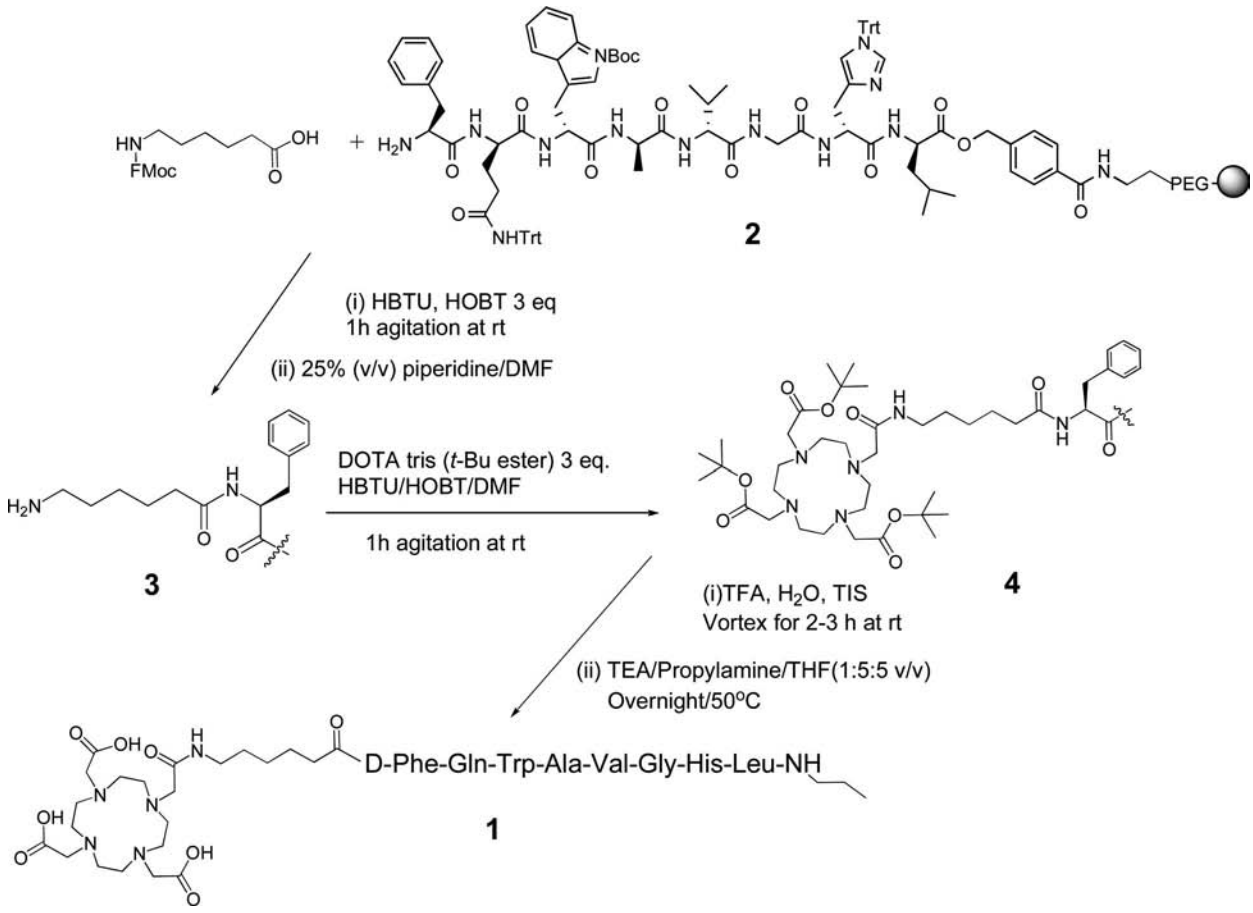
Pharmacokinetic Studies in PC-3 Tumor-Bearing SCID Mice. PC-3 cells were suspended in the culture media, centrifuged, and the culture media decanted. The resultant PC-3 cells pellets were suspended in Dulbecco's phosphate-buffered saline solution. The concentrations of the PC-3 cells were adjusted to approximately 5 million cells per 100 μL of Dulbecco's phosphate-buffered saline solution. Four-to-five-week-old ICR (Institute of Cancer Research) severely compromised immunodeficient (SCID) female mice were obtained from Taconic Farms. The mice were fed with the supplied irradiated rodent chow and water (Ralston Purina Corporation) ad libitum. Each group of five mice was housed in a sterile microisolator cage (Alternative Design) in temperature-and humidity-controlled rooms with alternating 12 h periods of light and darkness. The mice were anesthetized for PC-3 cells inoculation with a gas composed of ∼3.5% isoflurane (Baxter Healthcare Corp.) and ∼1 L/min oxygen. The gas anesthesia was administrated to SCID mice using a non-rebreathing multiterminal anesthesia vaporizer apparatus (Summit Medical Equipment Co.). Approximately five million PC-3 cells suspended in 100 μL of normal sterile saline were inoculated subcutaneously in the bilateral flank of each SCID mice under gas anesthesia. The tumors were allowed to grow (ranging from 0.2 to 1.0 g) in the flanks of the SCID mice for 3−4 weeks after inoculation. The biodistribution was studied by injecting twenty mice, of average weight of 23.4 g (five mice per time point), with 100 μL (0.185 MBq, 5 μCi) aliquots of ^{111}In-**1** via the tail vein. The mice were sacrificed by neck dislocation at 0.25, 0.5, 1, and 4 h postinjection. Blood and urine were collected immediately after the mice were sacrificed. The organs and tissues of interest were processed as described above.

MicroSPECT/MicroCT Imaging Studies. The microSPECT imaging was performed using a microCAT II SPECT/CT (Siemens Medical Solutions) small animal system composing of dual SPECT system. The microCT images performed using MicroCT unit (microCAT II MicroCT scanner, CTI, Knoxville, TN). The tomographic SPECT imaging of a PC-3 tumor-bearing SCID mouse was performed at 1 h postinjection with ^{111}In-**1** (11.1 MBq, 300 μCi). The mouse was sacrificed 1 h after administration of ^{111}In-**1**, and scanned for γ-ray acquisition. The mouse was aligned at the center of the scanner using a laser beam. The image was collected with the detectors fully calibrated and normalized for ^{111}In. The mouse was scanned for 60 projections (rotation steps) over 360°. Reconstructed SPECT mouse data generated with a 3D-OSEM algorithm with geometrical corrections. The reconstructed images were smoothed postreconstruction with a 3D Gaussian kernel. A concurrent microCT scan was performed on the same mouse for future anatomical coregistration of the SPECT data.

RESULTS AND DISCUSSION

Synthesis of Construct 1. Bombesin and GRP most likely exert their effects through binding to the membrane surface G-protein bound receptors characterized by their similar seven trans-membrane domains which cluster to form the peptide binding pocket (*2*). The bombesin analogue, [*D*-Phe^6, Leu-NHCH$_2$CH$_2$CH$_3$^{13}, des Met^{14}] BBN[6−14], was developed as a potential antagonist binding motif for targeting GRP receptors (*35, 36*). Placing *D*-Phe in position 6 was based on the reported results indicating that placing *D*- or an unnatural amino acid in the peptide increases the resistance to proteolysis (*35, 36*). The readily oxidized Met^{14} residue was removed so that leucine became the C-terminal residue in position 13. This terminus was derivatized upon cleavage from the resin with propylamine, resulting in a structural change that confers

Scheme 1



antagonist behavior on the peptide. DOTA was selected as a bifunctional chelating agent to confer high thermodynamic stability and kinetic inertness to the formed ^{111}In chelate. Since it is reported that the length of the hydrocarbon spacer could be varied from at least 3 to 8 carbon atoms without interrupting the binding affinity to the GRP receptors (*26*), we linked DOTA to the peptide through an aminohexanoyl moiety. The construct, DOTA-aminohexanoyl-[*D*-Phe^6, Leu-NHCH$_2$CH$_2$CH$_3$^{13}, des Met^{14}] BBN[6−14] (**1**), "Bomproamide", was synthesized on HMBA resin as shown in Scheme 1 using conventional solid-phase peptide synthesis strategies and our published protocols (*34*). Briefly, coupling of Fmoc-6-aminohexanoic acid and DOTA *tris*-(*t*-Bu ester) was performed sequentially by conventional in situ carboxy activation using HBTU and HOBT to afford **3** and **4**, respectively. Side chain deprotection using TFA yielded DOTA-hexanoyl-*D*-Phe^6-BBN [6−13]-HMBA resin. Treatment with TEA/propylamine/THF (1:5:5 v/v) overnight at 50 °C achieved cleavage of the peptide from the resin with concomitant formation of the C-terminal propylamide to afford **1**. After purification of **1** by RP-HPLC, 23 mg (∼13%) at >92% purity was recovered and characterized using ESI-MS.

In Vitro Competitive Cell Binding Affinity Assay. The in vitro competitive cell binding affinity experiments were performed with **1** against ^{125}I-Tyr^4-BBN as the GRP receptor radioligand. The experiments were performed with immortalized human androgen-insensitive prostate cancer PC-3 cells that are known to overexpress the GRP receptors predominantly. **1** retained high affinity (1.36 ± 0.09 nM) toward the GRP-receptor subtype.

Labeling with ^{nat}In and ^{111}In and Characterization. The metalation of **1** was performed under standard conditions and was analyzed by LC-MS. Results indicate that the HPLC peak at t_R = 23.5 min (k' = 8.7) corresponds to the ^{nat}In-DOTA−peptide, ^{nat}In-**1**, in 89% purity. The radiolabeling of **1** with ^{111}In was performed and the HPLC chromatograms show the coincidence of the major HPLC radio peak with the UV peak of ^{nat}In-**1**, offset only by the order of respective detectors of the HPLC. The isolation of pure ^{111}In-**1** was achieved by two modifications of a standard radiolabeling protocol prior to preparative HPLC. First, EDTA was added at the end of the radiolabeling period to chelate any remaining noncomplexed ("free") $^{111}In^{3+}$. In addition, a few crystals of $CuSO_4 \cdot 5H_2O$ were added to complex excess **1**. Aliquots (25 μL) of the radiolabeling mixture were analyzed by HPLC. The chromatogram depicts that most of the detected radioactivity was located at t_R = 18.86 min corresponding to ^{111}In-DOTA−peptide conjugate, ^{111}In-**1**, while the UV peak corresponding to the unlabeled DOTA−peptide conjugate, **1**, was absent. The UV peak at longer retention time (t_R = 20 min) is assigned as ^{nat}Cu-**1**. Pure ^{111}In-**1** was obtained through preparative HPLC in 75−80% radiochemical yield in high radiochemical purity. The corresponding UV chromatogram confirms the absence of **1** or ^{nat}Cu-**1**. This result is important, as the presence of excess **1** or ^{nat}Cu-**1** could saturate the receptors in vivo. Only samples with radiochemical purity of >99% were used for the subsequent in vivo studies. Concentration of the HPLC eluent containing ^{111}In-**1** was achieved through solid-phase extraction. Approximately 90−94% of the original radioactivity could be recovered after the formulation.

In Vitro Internalization and Efflux Studies. Internalization is the process of radioconjugate accumulation over time within the cells expressing the targeting receptors. The internalization behavior of ^{111}In-**1** in the human PC-3 prostate cancer cells was studied by incubation at 37 °C for 15, 30, 45, 60, 90, and 120

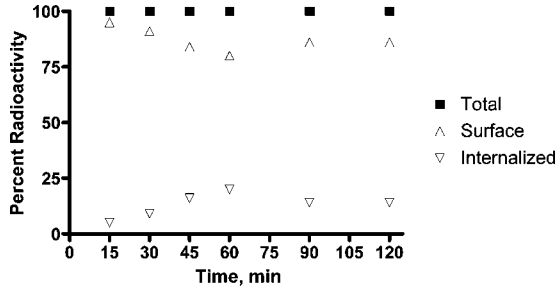


Figure 2. Internalization of ^{111}In-**1** in prostate cancer PC-3 cells as a function of time ($n = 2$; trials conducted in duplicate).

min. The percentage of ^{111}In-**1** trapping within the cells was characterized by a steady and gradually increasing rate of accumulation within the cells up to 45 min of incubation (Figure 2). Internalization reaches its maximum value, ~14%, after 45 min of incubation. The percentage of surface-bound radioactivity exceeded the percentage of the internalized activity over the entire investigated time points of incubation. The internalization does not increase by extending the incubation period beyond 45 min. The percentage of the internalized radioligand decreases to 12% at 60 min of incubation and then plateaus at 120 min of incubation. The level of internalization of ^{111}In-**1** is consistent with its antagonist-based structure.

Efflux, on the other hand, is the process of radioconjugate externalization over time from the cells expressing the targeted receptors. The externalization behavior of ^{111}In-**1** from the PC-3 cells was observed after a 45 min incubation, the time at which the highest internalization percentage (14%) had been noted. Efflux of radioactivity was studied over 15, 30, 45, 60, and 90 min. The internalized radioactivity remained almost constant over the investigated efflux time points (data not shown). This behavior is consistent with prior trapping of a small amount of ^{111}In-**1** within the cells, and a significantly slow washout.

In Vivo Biodistribution Studies. The usefulness of bombesin-based constructs for in vivo GRP receptor targeting has been primarily assessed using agonists. Very little is known about the potential of using antagonist-based constructs as suitable biomarkers for in vivo GRP receptor imaging (*33*). Thus, the in vivo targeting behavior of ^{111}In-**1** for GRP receptors was studied using healthy (CF-1) and tumor-bearing SCID mice.

Pharmacokinetic Studies in Healthy CF-1 Mice. The biodistribution behavior of ^{111}In-**1** in healthy CF-1 mice at 0.25, 1, 4, and 24 h postinjection is presented in Table 1. The pancreas is the primary nonmalignant tissue that normally expresses a high density of GRP cell-surface receptors (*37*). It is well-established that accumulation of the radioactivity in the pancreatic tissue in preference over other tissues is a direct reflection of the efficiency of the radioconjugate under evaluation for in vivo targeting of GRP cell surface receptors (*13, 26, 33*). The results indicate that ^{111}In-**1** demonstrates rapid (0.25 h PI) and high (12.21 ± 3.2% ID/g) uptake in the pancreatic tissue. This pancreatic uptake was reduced to 0.95 ± 0.26%ID/g at 1 h PI and diminished to 0.01 ± 0.01%ID/g at 4 h PI. The observed decrease of pancreatic uptake was consistent with the suspected uptake behavior of an antagonist-based construct that exhibits limited internalization. It has been reported that the pancreatic uptake of Demobesin-1 decreases from 33.13 ± 3.63%ID/g at 1 h PI to 4.59 ± 0.63%ID/g at 4 h PI (*33*). Marginal uptake was observed in the liver (1.33 ± 0.24%ID/g) and abdominal area at 0.25 h PI. The liver uptake diminishes significantly (0.18 ± 0.02%ID/g) at 1 h PI. Similarly, the abdominal uptake decreased markedly [small (0.35 ± 0.03%ID/g) and large (0.20 ± 0.05%ID/g) intestine] at 1 h PI. ^{111}In-**1** demonstrated rapid clearance from the blood (0.17 ± 0.05%ID/g at 1 h PI) mainly by renal extraction (1.74 ± 0.32%ID/g at 1 h PI) and urinary tract excretion (0.86 ± 0.46%ID/g at 1 h PI) into the urine (94.70 ± 0.62%ID/g at 1 h PI).

Blocking Studies. The effect of blocking the GRP receptors on the pancreatic uptake of ^{111}In-**1** was investigated in CF-1 mice (Table 2). More than 90% of the GRP receptor-mediated radioconjugate uptake in the pancreatic tissue was blocked by coinjection of 100 μg of BBN. The pancreatic uptake in the control mice was 2.04 ± 0.17%ID/g at 1 h postinjection and was significantly decreased by a factor of 10 to 0.20 ± 0.01%ID/g by blocking the binding sites with BBN. The remaining activity in the pancreas may be a reflection of GRP receptor subtype-mediated trapping of ^{111}In-**1**. Uptake studies in healthy CF-1 mice at 1 h PI showed pancreatic uptake of 0.95 ± 0.26%ID/g and lung uptake of 0.30 ± 0.09%ID/g (Table 1). However, the blocking studies in healthy CF-1 control mice at 1 h postinjection showed pancreatic uptake of 2.04 ± 0.17%ID/g and lung uptake of 1.37 ± 0.08%ID/g (Table 2). The observed difference in the pancreas and lung uptakes between these two studies might be due to the differences in the density of normal GRP receptor expression. This expectation is strongly confirmed by the substantial decrease, ~75% less, in uptake (0.35 ± 0.05%ID/g) of the blocked lung tissue.

Pharmacokinetic Studies in PC-3 Tumor-Bearing SCID Mice. The pharmacokinetic studies in healthy CF-1 mice reflect a significant decrease of ^{111}In-**1** in the tissues with time. At 24 h PI, the investigated tissues retained insignificant radioactiv-

excretion (% ID ± SD)	40.86 ± 4.60	68.70 ± 7.55	89.15 ± 7.11	96.16 ± 1.06
tumors	6.90 ± 1.06	5.76 ± 1.54	3.72 ± 0.60	2.15 ± 0.36

[a] All data, except excretion, are presented as an average %ID/g ± SD.

ity. Accordingly, 0.5 h PI was selected as a new time point for investigating the pharmacokinetic behavior of ^{111}In-**1** in PC-3 tumor-bearing SCID mice, and the 24 h time point was excluded. The biodistribution behavior of ^{111}In-**1** in immortalized prostate cancer PC-3 tumor-bearing mice at 0.25, 0.5, 1, and 4 h postinjection are presented in Table 3. Rapid (15 min postinjection) and significantly high uptake (6.90 ± 1.06%ID/g) as observed in the tumors. The tumor uptake decreased over time to a value at 4 h PI that was approximately 30% that found at 15 min (2.15 ± 0.36%ID/g). In contrast to the prolonged uptake of ^{111}In-**1** in the tumor tissue, fast clearance from the other tissues was observed. This behavior is consistent with the reported data of antagonist-based Demobesin 1 (*33*). In these animals, ^{111}In-**1** demonstrated rapid (0.25 h PI) and significantly high (14.88 ± 1.8%ID/g) uptake in the pancreatic tissue. This pancreatic uptake showed a steep reduction to 3.99 ± 0.49%ID/g at 0.5 h PI and 0.96 ± 0.18%ID/g at 1 h PI. The pancreatic uptake behavior in PC-3 tumor-bearing mice mirrored its behavior in healthy CF-1 mice. The pancreatic uptake of ^{111}In-**1** at 4 h PI decreased by ~57% of its uptake at 1 h PI. This behavior is comparable with the reported decrease (~65%) of Demobesin-1 (*33*). These results are consistent with the marked internalization behavior of the agonist-based constructs and the limited internalization capabilities of the antagonist-based constructs. The observed high retention of ^{111}In-**1** in the tumor tissue over the investigated time points may be due in part to the fact that the human tumor xenografts are supported by murine vasculature architecture (*26*). It is also reported that antagonists form slowly dissociating antagonist−receptor complexes that result in long-lasting in vivo receptor binding (*38*). On the other hand, the low retention of ^{111}In-**1** in the pancreatic tissue may be due to excessive enzymatic activity of the pancreatic tissue as well as the limited internalization capabilities of the antagonist-based constructs (*33*). The high uptake and retention in the tumors and pancreas cells over the entire investigated time points is a direct reflection of the efficiency of antagonist-based constructs for in vivo targeting of the GRP cell surface receptors. Therefore, antagonist-based constructs seem to be the candidates of choice for in vivo imaging purposes, while for in vivo therapy purposes, the agonist-based constructs (trigger the internalization process that confers the basis for an efficient accumulation of the radioconjugate within the cells over the time) seem to be the candidates of choice.

Table 4. Target-to-Nontumor Uptake Ratios of ^{111}In-1 in PC-3 Tumor-Bearing SCID Mice ($n = 5$)

tumor/nontumor tissue	0.25 h PI	0.5 h PI	1 h PI	4 h PI
tumor/blood	1.62	2.87	10.76	108.5
tumor/muscle	6.92	13.28	50.71	108.5
tumor/liver	3.23	6.03	13.15	18.08
tumor/kidneys	0.58	0.90	1.16	0.97
tumor/lung	1.56	1.49	1.99	1.47
tumor/bladder	0.49	0.76	2.13	8.35
tumor/spleen	7.06	9.00	23.67	36.17
tumor/stomach	3.62	4.54	10.44	43.4
tumor/l. intestine	4.33	9.00	6.57	2.47
tumor/s. intestine	2.03	3.64	5.73	12.06

Significant uptake of 4.45 ± 0.82%ID/g was observed in the lung tissue at 0.25 h PI and retained over the entire investigated time points. This lung uptake may be in part due to the normal expression of the GRP receptors in this tissue (*39*). Lung tissue is one of the gastro-entero-pancreatic-neuroendocrine tissues (GEP-NET) that is characterized by normal expression of GRP receptors in the interface between the endocrine hormonal cells and nervous cells (*37*). It is also reported that the three bombesin family receptors are expressed with various degrees in overlapping subsets of lung cancer cell lines (*40*, *41*). The committed lung uptake at the various investigated time points may act as a prognostic biomarker for early detection of small cell lung cancer (SCLC) and non-small lung cells (NSLC) carcinogenesis. More research would have to be conducted to explore this hypothesis further.

Low uptake of ^{111}In-**1** was observed in the liver (2.14 ± 0.14%ID/g) and abdominal area. The liver uptake decreased (0.88 ± 0.2%ID/g) at 0.5 h postinjection. Similarly, the abdominal uptake decreased markedly [small (1.46 ± 0.35%ID/g) and large (0.59 ± 0.07%ID/g) intestines] at 0.5 h PI. ^{111}In-**1** demonstrated rapid clearance from the blood (1.85 ± 0.47%ID/g at 0.5 h PI) mainly by renal extraction (5.88 ± 1.91%ID/g at 0.5 h PI) and urinary tract excretion (7.03 ± 8.68%ID/g at 0.5 h PI) into the urine (68.70 ± 7.55%ID at 0.5 h PI).

Tumor to Nontumor Uptake Ratios of ^{111}In-1. The main pharmacokinetic consideration in the development of peptide-based imaging agents is to achieve diagnostically useful tumor to nontumor uptake ratios (~5) with minimal time required to achieve them. Table 4 shows the tumor/nontumor uptake ratios of ^{111}In-**1** at 0.25, 0.5, 1, 4 h postinjection. At the same time, significantly high (>10) and diagnostically useful ratios were achieved in most of the tissues after 1 h postinjection. The tumor/nontumor uptake ratios in certain tissues (muscle, spleen) were significantly high, >20, at both 1 and 4 h PI. Comparable (difference less than five) target to nontarget uptake ratios were achieved at 1 and 4 h PI in certain tissues (liver and small intestine). Higher tumor/nontumor uptake ratios were achieved at 1 h PI, rather than 4 h, in certain tissues (kidneys, lung, and large intestine). For prostate cancer radioimaging, there is high demand for achieving minimal possible noise in the abdominal area (large intestine, small intestine, stomach, liver, kidneys, and bladder) in a minimal possible time. It is clear from the tumor/nontumor uptake ratios that diagnostically useful ratios in mice could be achieved in most of the abdominal tissues (except bladder) at 1 h PI. Accordingly, microSPECT imaging of PC-3 tumor xenografts in SCID mouse was performed at 1 h PI.

MicroSPECT/Micro CT Imaging Studies. MicroSPECT/CT images of immortalized prostate cancer-xenografts (Figure 3) were taken over 16 h after 1 h PI of 11.1 MBq (300 μCi) of ^{111}In-**1** in a PC-3 tumor-bearing SCID mouse. The camera head was positioned at multiple angles around the mouse body accumulating as many as 360° of views at specific angular intervals. The radioactivity associated with the images was acquired over time due to the rapid clearance properties of ^{111}In-

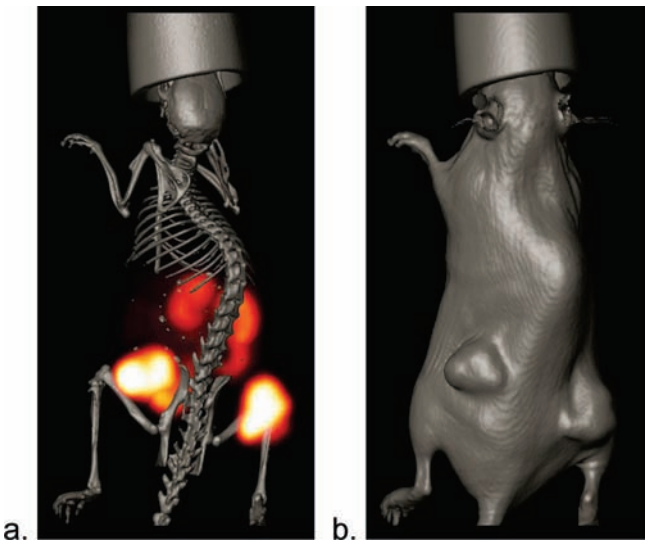

Figure 3. (a) Axial MicroSPECT/CT image of PC-3 xenografts in a SCID mouse after 1 h of ^{111}In-**1** administration. (b) Skin CT image. Details of acquisition are found in the Materials and Methods.

1. A reconstruction process was performed to retrieve the radiotracer spatial distribution from the projection data using a fully 3D OSEM algorithm. Regions where backprojection lines from different angles intersect represent areas that contain a higher concentration of radiopharmaceutical. The PC-3 tumor xenografts in the SCID mouse were visualized clearly in the images. Delineating the kidneys in the image is an indication of the radioconjugate clearance via renal excretion. The images revealed the absence of the liver's anatomical boundaries and delineated the insignificance of radioactivity uptake in the gastrointestinal tract. The radioactivity distribution and accumulation in the microSPECT/CT images are consistent with the biodistribution data obtained from the pharmacokinetic studies. The power of the presented diagnostic imaging lies in its external detection of the in vivo radioactivity delineating anatomical boundaries and having a clue to status of the organs being imaged.

CONCLUSION

The bombesin antagonist, [*D*-Phe^6, Leu-NHCH$_2$CH$_2$CH$_3$^{13}, des Met^{14}] BBN[6−14], was synthesized and developed into ^{111}In-DOTA-aminohexanoyl-[*D*-Phe^6, Leu-NHCH$_2$CH$_2$CH$_3$^{13}, des Met^{14}] BBN[6−14] (^{111}In-**1**), "Bomproamide", a high-affinity imaging agent targeting the GRP receptor. This study demonstrates the potential of using the bombesin analogues possessing antagonist C-terminal vectors as a diagnostic candidate of choice for specific in vivo targeting of the tumors overexpressing GRP receptors.

ACKNOWLEDGMENT

The authors acknowledge the National Cancer Institute (P50 CA 103130: Center for Single Photon-Emitting Cancer Imaging Agents, W.A. Volkert, PI) for partial support of this research. This work was supported with the resources and the use of facilities at the Chemistry Department, University of Missouri-Columbia and Harry S. Truman Memorial VA Hospital.

Cell-Permeable MR Contrast Agents with Increased Intracellular Retention

Paul J. Endres,[†] Keith W. MacRenaris,[†] Stefan Vogt,[‡] and Thomas J. Meade*[,†]

Departments of Chemistry, Biochemistry, and Molecular and Cell Biology, Neurobiology, and Physiology, and Radiology, Northwestern University, 2145 Sheridan Road, Evanston, Illinois 60208, and X-ray Science Division, Argonne National Laboratory, 9700 S. Cass Avenue, Argonne, Illinois 60439. Received July 11, 2008; Revised Manuscript Received August 26, 2008

Magnetic resonance imaging (MRI) is a technique used in both clinical and experimental settings to produce high-resolution images of opaque organisms without ionizing radiation. Currently, MR imaging is augmented by contrast agents, and the vast majority these small molecule Gd(III) chelates are confined to the extracellular regions. As a result, contrast agents are confined to vascular regions reducing their ability to provide information about cell physiology or molecular pathology. We have shown that polypeptides of arginine have the capacity to transport Gd(III) contrast agents across cell membranes. However, this transport is not unidirectional, and once inside the cell, the arginine-modified contrast agents efflux rapidly, decreasing the intracellular Gd(III) concentration and corresponding MR image intensity. By exploiting the inherent disulfide reducing environment of cells, thiol compounds, Gd(III)-DOTA-SS-Arg_8 and Gd(III)-DTPA-SS-Arg_8, are cleaved from their cell-penetrating peptide transduction domains upon cell internalization. This reaction prolongs the cell-associated lifetime of the chelated Gd(III) by cleaving it from the cell transduction domain.

INTRODUCTION

The advent of wide-bore, high-field instruments with improved coil designs and pulse sequences has made magnetic resonance imaging (MRI[1]) a powerful tool for observing developmental and physiological events (*1*−*4*). This versatile modality is noninvasive and allows 3D imaging of whole animals (*5*). This imaging technique is supplemented with an array of exogenous Gd(III) contrast agents conjugated to scaffolds (nanoparticles, antibodies, and proteins) that can detect physiological events (metal ion concentration, enzyme activation, and pH), and can be cell membrane permeable (via cell-penetrating peptides or receptor uptake) (*6*−*17*). The focus of this work is to develop cell-permeable contrast agents that can be trapped inside cells via a cleavable disulfide linkage between the agent and the transduction moiety.

The biological role of thiol-containing molecules has been actively explored, and a great deal is known about the active species and relative concentrations (*18*). The pseudotripeptide of glutathione (GSH) is recognized as the most abundant and subsequently most active thiol species in biological environments (*19, 20*). Previous work has shown that the intracellular GSH concentration of living cells (∼1−10 mM) is significantly higher than that of the surrounding extracellular plasma (∼2 μM). Therefore, thiols can be exploited as a selective chemical release switch for intracellular delivery of cargo (*21*−*23*). We have applied this strategy to our reported intracellular MR contrast agents in order to reduce cellular leaching (*24*). As a result, we have prepared a class of MR probes that are cell-permeable while displaying increased intracellular lifetimes. These probes provide a method to passively label and noninvasively track the fate of transplanted tissues and cells.

It has been shown that an octamer of arginine residues allows cell membrane transduction of various cargo molecules, including fluorophores and contrast agents (*25*−*27*). However, the ability of these probes to cross cell membranes is not unidirectional. Not surprisingly, arginine-modified agents are able to leach out of the cells displaying a concentration decay curve of intracellular contrast agent and consequently decreasing the observed MR signal over time (*28, 29*).

Therefore, contrast agents containing a disulfide bond between the Gd(III) chelate and the transduction moiety (e.g., an octamer of arginine residues) were synthesized to enhance cell-associated retention (Figure 1). Exploiting the inherent disulfide reducing environment of cells, these new agents are cleaved from the cellular transduction domains upon entrance into the cytoplasm. This cleavage of the arginine transport domain shows prolonged cellular lifetime of the MR probe by dissociation of the transport peptide.

EXPERIMENTAL PROCEDURES

All reagents and solvents were of the highest purity available from Sigma-Aldrich (Milwaukee, WI) and Fluka (Sigma-Aldrich Chemie; GmbH, Switzerland) unless otherwise noted. Modified Wang resin and amino acids were purchased from Novabiochem (San Diego, CA). DMEM (with 4 mM L-glutamine modified to contain 4.5 g/L glucose and 1.5 g/L sodium carbonate), EMEM

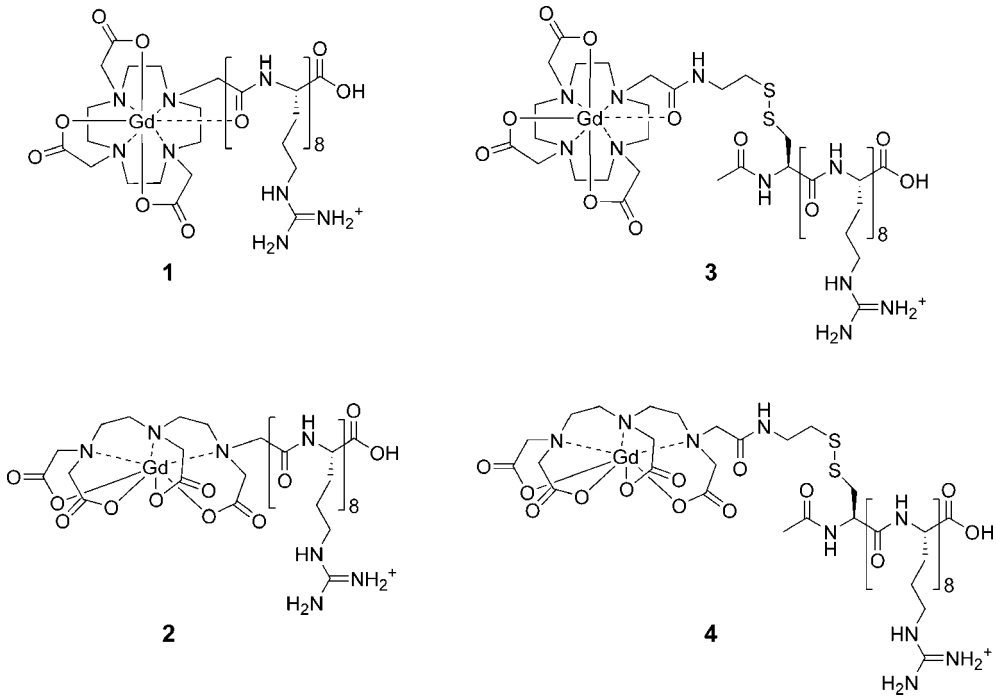

Figure 1. Structures of the arginine-modified (cell-permeable contrast agents) and disulfide-bridged (cell-permeable contrast agents), respectively. (**1**) Gd(III)-DOTA-Arg_8, (**2**) Gd(III)-DTPA-Arg_8, (**3**) Gd(III)-DOTA-SS-Arg_8, and (**4**) Gd(III)-DTPA-SS-Arg_8.

(with Earle's BSS and 2 mM L-glutamine modified to contain 1.0 mM sodium pyruvate, 0.1 mM nonessential amino acids, and 1.5 g/L sodium bicarbonate), NIH/3T3 cells, FBS, CBS, and 0.25% trypsin/EDTA solutions were purchased from the American Type Culture Collection (ATCC; Manassas, VA). Vent-cap flasks, multiwell plates, cell scrapers, and DPBS without calcium and magnesium were purchased from Fisher Scientific (Pittsburgh, PA).

^1H and ^{13}C NMR spectra were obtained on a Varian (Walnut Creek, CA) Inova spectrometer at 500 and 125 MHz, respectively. Compounds were dissolved in D_2O (4.80 ppm used as internal references for NMR spectra). Due to the minimal solubility associated with the peptide−chelate conjugates, ^{13}C NMR spectra were collected in D_2O, and the first carbon resonance was assigned a value of 24.42 ppm. Mass spectrometry samples were analyzed using ESI, single quadrupole mass spectrometry on a Varian 1200 L spectrometer, or MALDI-TOF mass spectrometry on an Applied Biosystems (Foster City, CA) Voyager-DE Pro. Results reported for *m*/*z* are for $[M + H^+]^+$ or $[M - H^+]^-$ unless stated otherwise. Elemental analyses were performed at Desert Analytics Laboratory (Tuscon, AZ).

ICP-MS was performed on a computer-controlled Thermo Elemental (Waltham, MA) PQ ExCell inductively coupled plasma mass spectrometer. All standards and samples contain 5 ng/mL of a multielement internal standard (Spex CertiPrep; Metuchen, NJ) consisting of Bi, Ho, In, Li, Sc, Tb, Y, and 3% nitric acid (v/v). Gadolinium standards were prepared in concentrations of 0.05, 0.10, 0.25, 0.50, 1.0, 5.0, 10, 25, and 50 ng/mL. Analysis was accomplished with 1 survey and 3 main scans (peak jumping, 100 sweeps per run) using ^{156}Gd and ^{157}Gd isotopes and interpolating through ^{209}Bi and ^{115}In internal standards.

HPLC-MS. Analytical reverse-phase HPLC-MS was performed on a computer-controlled Varian Prostar system consisting of a 410 autosampler equipped with a 100 μL sample loop, two 210 pumps with 5 mL/min heads, a 363 fluorescence detector, a 330 photodiode array (PDA) detector, and a 1200 L single quadrupole ESI-MS. All separations were executed with a 1.0 mL/min flow rate using a Waters 4.6 × 250 mm 5 μm Atlantis C18 column, with a 3.1:1 split directing one part to the MS and 3.1 parts to the series-connected light and fluorescence detectors. Mobile phases consisted of Millipore Synthesis grade water (solvent A) and HPLC-grade MeCN (solvent B). Preparative HPLC was accomplished using a Varian Prostar system. Two Prostar 210 pumps with 25 mL/min heads supplied a 5 mL manual inject sample loop. Detection was performed after a 20:1 split by a two-channel Prostar 325 UV−visible detector and, on the low-flow side, a HP 1046A fluorescence detector. The mobile phases were Millipore Synthesis grade water and HPLC-grade MeCN. Preparative runs were on a Waters 19 × 250 mm 10 μm Atlantis C18 column.

Relaxivity (r_1). A 2 mM stock solution of **1**−**4**, Gd(III)-DTPA, or Gd(III)-DOTA in 100 mM PBS buffer at pH 7.41 were serially diluted to give 500 μL of each of the five approximate concentrations for each compound: 0.15, 0.3, 0.5, 1.0, and 2.0 mM. The T_1 of each sample was determined at 60 MHz (1.5 T) and 37 °C using an inversion recovery pulse sequence on a Bruker mq60 minispec (Bruker Canada; Milton, Ontario, Canada) and at 600 MHz (14.1 T) and ambient temperature using a saturation recovery pulse sequence on a Bruker Omega 600WB spectrometer (Bruker BioSpin; Billerica, MA). Reproducibility of the T_1 data was ±0.3%. Ten microliters of each sample was analyzed for exact gadolinium concentration using ICP-MS. The inverse of the longitudinal relaxation time (T_1) was plotted against the concentration obtained from ICP-MS and fit to a straight line. Lines were fit with $R^2 > 0.998$, and each relaxivity was assessed in duplicate.

Determination of *q* by Luminescence Lifetime Measurements. Complexes (*10*−*13*) were dissolved in H_2O and D_2O. Emission was monitored at 544 nm with excitation at 229 nm on a Hitachi F4500 Fluorescence Spectrophotometer operating in phosphorescence lifetime mode. Twenty-five scans were averaged and fit to a monoexponential decay ($R^2 > 0.98$) to give the phosphorescent lifetimes which were entered into this equation (corrected for one amide oscillator, where k is given in ms^{-1}): $q = 5.0(k_{H2O} - k_{D2O} - 0.06)$ (*30*, *31*).

Determination of τ_m by ^{17}O Transverse Relaxation Rate Measurements. Samples of **1**−**4**were prepared at 15−20 mM concentrations in 1% ^{17}O enriched water (Medical Isotopes, Inc.; Pelham, NH) adjusted to pH 7.40. Lock was achieved by means of an external D_2O standard. ^{17}O spectra were obtained at 54 MHz (number of averaged transients was 160−320 and relaxation delay was 400 ms) at temperatures ranging from 1 to 86 °C in 5 °C increments. The ^{17}O transverse relaxation rate was determined by obtaining the line width (in Hz) at half of the peak height, $\Delta P_{1/2}$, of the ^{17}O water signal and later fitting the data (*32*−*34*). Using known sample concentrations and q values, the relaxation data were fit to these four parameters at 25 °C: τ_m (water exchange rate), $\Delta H^{\ddagger}$ (activation enthalpy), T_{1e} (electronic relaxation rate), and ΔE_{T1e} (activation energy of T_{1e}) (*35*).

Cell Culture Conditions. All cell lines, media, sera, buffers, and dissociation reagents were purchased from ATCC. NIH/3T3 cells (CRL-1658) were grown in DMEM (with 4 mM L-glutamine, 4.5 g/L glucose, 1.0 mM sodium pyruvate, 1.5 g/L sodium carbonate, and phenol red supplemented with 10% CBS). Cells were grown in a humidified incubator at 37 °C and 5% CO_2. Cells were washed with DPBS (without calcium and magnesium) and dissociated with a 0.25% trypsin−EDTA solution. All flasks and multiwell plates were Corning brand, tissue culture treated, and sterile. The studies for each contrast agent and time point were performed in triplicate.

Cells were counted and viability assessed using a Guava EasyCite Mini Personal Cell Analyzer (Guava Technologies; Hayward, CA). Cell samples were diluted 10-fold with Guava ViaCount reagent (total volume of 200 μL), allowed to stain at room temperature for at least 5 min (but no longer than 20 min), vortexed, and measured. Each sample was measured using the Guava ViaCount software module using 1000 trials per run doing 2 separate runs per sample. Instrument reproducibility was assessed daily following the manufacturer's suggested protocol using GuavaCheck reagent and the corresponding software module.

ICP-MS assessment of the cell-associated gadolinium was determined by collecting and processing all cell and media samples via this procedure: addition of 70% (v/v) nitric acid in water, vortexing (∼5 min), and digestion at 65 °C for at least 4 h. Samples were added to a 15 mL conical tube along with internal standard (5 ng/mL of indium and holmium) and water to give a final nitric acid concentration of 3% (v/v).

Synchrotron Radiation X-ray Fluorescence (SR-XRF) Analysis. NIH/3T3 cells were grown to 65% confluency on silicon nitride windows (membrane thickness of 500 nm and frame size of 5.0 mm × 5.0 mm, Silson Ltd.; Northampton, England) in Corning brand 24-well cell culture treated plates. Each well had two silicon nitride windows (one incubation sample and one leach sample). Cells were incubated with 3.0 mM of compounds **1**−**4** for 4 h. Samples were rinsed three times with DPBS and one window was removed for processing (time = 0, named *No leach* sample) while one window was allowed to incubate with fresh media for 4 more hours followed by processing (named *Leached* sample). Windows were processed by cell fixation in 3.7% formalin for 5 min at room temperature, rinsing with DPBS (1×), rinsing with Millipore water (1×), rinsing with 100% ethanol (1×), and drying overnight (18 h, room temperature). The silicon nitride windows were mounted onto a kinematic specimen holder for both visible light and X-ray fluorescence microscopy. The samples were examined on a light microscope (Leica DMXRE), and the cells to be scanned with SR-XRF were located on the window relative to a reference point (one of the four window corners) using a high spatial resolution motorized x/y stage (Ludl Bioprecision).

Scanning SR-XRF microscopy was carried out at the 2-ID-E beamline of the Advanced Photon Source at Argonne National Laboratory (IL, USA). Hard X-rays from an undulator source were monochromatized using a single bounce Si κ monochromator. The energy was selected to allow for efficient excitation of the Gd L-lines, and also to enable the detection of the P, S, Fe, and Zn K-lines. A Fresnel zone plate (320 μm diameter, focal length f = 250 mm, X-radia; Concord, CA) was used to focus the monochromatic X-ray beam to a spot size of∼0.4 × 0.3 μm^2 on the specimen. The sample was raster scanned through the beam at room temperature under a helium atmosphere. At each scan position, a full fluorescence spectrum was acquired using an energy-dispersive germanium detector (Ultra-LEGe detector, Canberra; Meriden, CT). Elemental content was determined by comparison of fitted sample spectra with NBS thin film standards 1832 and 1833 (NIST; Gaithersburg, MD) using MAPS software supplemented with fitting of fluorescence spectra at every pixel (*36*).

MR Imaging and T_1 Analysis. MR measurements were performed on a General Electric/Bruker Omega 600WB 14.1 T imaging spectrometer fitted with Accustar shielded gradient coils at ambient temperature (∼25 °C). Spin lattice relaxation times (T_1) were measured using a saturation recovery pulse sequence with static T_E (10.18 ms) and variable T_R (127.5, 165, 200, 300, 500, 1000, 2000, 5000, 7500, 10 000 ms) values. Two independent trials were run per sample and at least 5 slices were quantified per trial. Student's t-tests were calculated in Origin 7 SR2 (Origin Laboratory; Northampton, MA) at a 95% confidence level with 8 degrees of freedom and a null hypothesis value (minimum acceptable time difference) of 100 ms. Images were acquired using a T_1-weighted, spin−echo pulse sequence (T_E = 10.18, T_R = 750 ms) on freshly harvested cells that were spun down (at 250 g) within glass capillary tubes for 5 min prior to image acquisition. Total time from harvest to image acquisition was 1−2 h.

Synthesis. Complex Gd(III)-DOTA-Arg_8 (**1**), Gd(III)-DTPA-Arg_8 (**2**), and (*S*-(2-Aminoethylthio)-2-thiopyridine hydrochloride) (AETP) were synthesized following previously published procedures (*14*, *24*, *37*) and (1,4,7-tris(acetic acid-*tert*-butyl ester)-10-acetic acid-1,4,7,10-tetraazacyclododecane) (DOTA-tris-TB) was purchased from Macrocyclics (Dallas, TX).

Synthesis of End-Capped RRRRRRRRC (5). Polystyrene-based Wang resin containing an Fmoc-protected arginine residue (2.00 g, 0.580 mmol/g) was swelled in CH_2Cl_2 for 10 min (×3) and washed with peptide synthesis grade DMF (4 × 10 min). The resin was treated three times with a solution of 20% piperdine in DMF (10 min), and the deprotected resin was washed with DMF (4 × 10 min). In a separate vial, Fmoc-protected Pbf-arginine (1.51 g, 2.32 mmol), HATU (0.881 g, 2.32 mmol), and DIPEA (0.748 g, 5.80 mmol) were dissolved in approximately 3 mL of DMF. The resulting solution was added to the deprotected resin, and nitrogen was bubbled through the mixture for 6−8 h. The peptide solution was removed from the resin, which was subsequently rinsed with DMF (4 × 10 min). This procedure was repeated a total of seven times in order to achieve the synthesis of an eight-amino-acid polyarginine oligomer bound to the Wang resin (3.96 g).

The Arg_8 functionalized resin (2.00 g, 0.290 mmol/g, 0.580 mmol) was deprotected with the piperdine solution and washed with DMF as described above. In a separate vial, Fmoc-protected Trt-cysteine (0.725 g, 1.16 mmol) and 2,4,6-trimethylpyridine (0.154 g, 1.27 mmol) were dissolved in a minimal amount of DMF. The resulting solution was added to the deprotected resin, and nitrogen was bubbled through the mixture for 6−8 h. The peptide solution was removed, and the resin was washed with DMF (4 × 10 min each). The resin-bound Arg_8-Cys oligomer was deprotected with the piperdine solution and washed with

DMF. The resin was resuspended in a solution of acetic anhydride (0.118 g, 1.16 mmol), DIPEA (0.374 g, 2.90 mmol), and DMF (3 mL). Bubbling nitrogen through this mixture for 4 h effectively capped the peptide's N-terminus. Upon removal of the capping solution, the resin was washed with DMF, CH_2Cl_2, and MeOH (4 × 10 min each). Following the methanol washes, the resin was dried under vacuum. A solution of 95% TFA, 2.5% EDT, 1.5% H_2O, and 1.0% TIS (50 mL) was added to the resin, and nitrogen was bubbled through the mixture for 1 h. The resin was filtered, and to the filtrate was added MTBE (40 mL) to precipitate a white solid that was subsequently washed with MTBE (3×). The solid was dissolved in 30 mL of water and freeze−dried to yield white flaky crystals of the peptide, Arg_8-Cys (0.692 g, 84%). ^{1}H NMR spectrum (D_2O @ pH 1.0): δ = 1.22−1.40 (m, 16H), 1.50 (dd, J = 8.5, 5.5 Hz, 16H), 1.59−1.69 (m, 2H), 1.74 (d, J = 6.0 Hz, 3H), 2.89 (m, 16H), 3.95−4.10 (m, 8H). ^{13}C NMR (D_2O @ pH 1.0): δ = 24.42, 27.50, 28.03, 39.36, 40.52, 52.26, 53.25, 156.57, 172.61, 173.44, 174.84. With ESI-MS (*m*/*z*): 1413.58; calc. for $C_{53}H_{105}N_{33}O_{11}S + H^+$: 1413.68.

Synthesis of 1,4,7-Tris(carboxymethyl)-10-(*N*-[2-(pyridin-2-yldithio)ethyl]acetamide)-1,4,7,10-tetraazacyclododecane (6). DOTA-tris-TB (0.600 g, 1.05 mmol), HATU (1.20 g, 3.15 mmol), and anhydrous DIPEA (0.683 g, 5.25 mmol) were dissolved in 4.0 mL of anhydrous DMF and allowed to stir for 10 min under a nitrogen atmosphere while AETP (0.466 g, 2.10 mmol) was dissolved in 2.0 mL of anhydrous DMF. After a 10 min activation time, the AETP solution was added via syringe and the mixture was allowed to stir for 5 h while being monitored by TLC [KNO_3−H_2O−MeCN (1:9:90)]. Upon reaction completion, the solution was evaporated *in vacuo*. The resulting yellow residue was stirred overnight in 95% TFA, 2.5% TIS, and 2.5% H_2O (30 mL). The reaction mixture was concentrated to 10 mL by application of a steady stream of dry nitrogen across the top of the vessel. The crude product was precipitated by addition of MTBE (40 mL) and was subsequently washed with MTBE (3×). The yellow solid was dried *in vacuo* to yield 1.12 g of the crude product.

The crude mixture was submitted to preparatory HPLC using a Waters Atlantis column. The solid was brought up in H_2O and purified using the following method: begin at 0% B, ramp to 3% B over 1 min, hold at 3% B for 15 min, ramp to 20% B over 7 min, and hold for 8 min, followed by a wash to 100% B before returning to 0% B. The desired fractions (retention time: 32.20 min by UV spectroscopy at 235, 280 nm) were collected and freeze−dried to yield the product as a white solid (0.410 g, 68%). ^{1}H NMR spectrum (D_2O): δ = 2.96−3.10 (m, 11H), 3.41−3.51 (m, 13H), 3.79 (q, J = 16.5 Hz, 4H), 7.33 (t, J = 4.5 Hz, 1H), 7.88 (d, J = 3.5 Hz, 2H), 8.40 (d, J = 4.5 Hz, 1H). ^{13}C NMR spectrum (D_2O): δ = 37.05, 38.13, 48.22, 48.46, 50.94, 51.64, 53.73, 55.51, 56.59, 121.92, 122.26, 139.56, 148.50, 158.48, 170.02, 171.96, 175.07. ESI-MS (*m*/*z*): 573.26; calc. for $C_{23}H_{36}N_6O_7S_2 + H^+$: 573.70. with Anal. Calcd. for $C_{23}H_{36}N_6O_7S_2 \cdot Na \cdot 1.5\ H_2O$: C, 44.36; H, 6.31; N, 13.50; S, 10.30. Found: C, 44.20; H, 6.17; N, 13.38; S, 10.98.

Synthesis of [(2-{Carboxymethyl-[2-(carboxymethyl-{[2-(pyridin-2-yldisulfanyl)ethylcarbamoyl]methyl}amino)ethyl]-amino}ethyl)amino]acetic Acid (7). DTPA dianhydride (2.00 g, 5.60 mmol) was dissolved in 100 mL of anhydrous DMSO and allowed to stir under a nitrogen atmosphere, while AETP (0.672 g, 3.04 mmol) was dissolved in a stirring solution of anhydrous DMSO (25 mL) and anhydrous DIPEA (1.07 g, 8.21 mmol). The AETP solution was slowly added to the DTPA dianhydride solution via syringe pump over 5 h. Upon complete addition, the resulting solution was stirred for an additional hour before being quenched with H_2O (100 mL) and concentrated *in vacuo*. The resulting residue was brought up in H_2O and submitted to preparatory HPLC with the Waters Atlantis column using the following method: begin at 0% B, ramp to 100% B over 35 min, followed by a wash at 100% B for 5 min before returning to 0% B. The desired fractions (retention time: 10.28 min by UV at 235, 280 nm) were collected and freeze−dried to yield the product as a white solid (1.07 g, 63%). ^{1}H NMR (D_2O): δ = 3.04 (t, J = 5.5 Hz, 2H), 3.24−3.35 (m, 6H), 3.54 (t, J = 6.0 Hz, 2H), 3.59 (t, J = 6.0 Hz, 2H), 3.69 (s, 2H), 3.75−3.90 (m, 8H), 7.57 (t, J = 6.5 Hz, 1H), 8.05 (d, J = 8.5 Hz, 1H), 8.15 (t, J = 8.5 Hz, 1H), 8.53 (d, J = 5.5 Hz, 1H). ^{13}C NMR (D_2O): δ = 37.45, 37.94, 50.30, 51.24, 52.52, 52.09, 54.48, 56.52, 57.04, 57.21, 123.29, 123.95, 142.71, 145.62, 157.07, 168.74, 170.56, 172.17, 172.78. ESI-MS (*m*/*z*): 560.19; calc. for $C_{21}H_{31}N_5O_9S_2 - H^+$: 560.63. Anal. Calcd. for $C_{21}H_{31}N_5O_9S_2 \cdot Na$: C, 43.14; H, 5.34; N, 11.98; S, 10.97. Found: C, 42.70; H, 5.21; N, 12.02; S, 11.29.

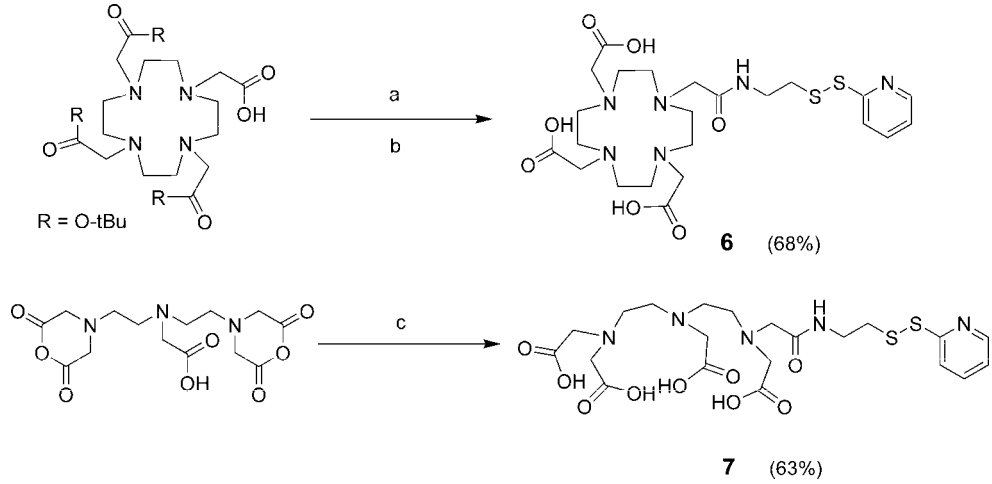
Synthesis of DO3A-SS-Arg_8 (8). Compound **6** (0.160 g, 0.306 mmol) was added to end-modified Arg_8-Cys (**5**) (0.432 g, 0.306 mmol) dissolved in 30 mL of degassed phosphate buffer (10 mM, pH 8.0). The solution was stirred under nitrogen atmosphere at room temperature. The reaction was monitored by analytical HPLC and found to be complete after 72 h. An aliquot (2.5 mL) of the solution was removed for characterization, while the remaining material (27.5 mL) was carried onto the synthesis of Gd(III)-DOTA-SS-Arg_8 (**3**). Dialysis (MW cutoff 1000) against Millipore H_2O (4 L × 4 days) yielded 3 mL of a translucent liquid that was 0.2 μm syringe-filtered and freeze−dried to yield a white solid (0.389 g, 74%). ^{1}H NMR spectrum (D_2O) shows the disappearance of all aromatic protons. ^{13}C NMR spectrum (D_2O): δ = 24.42, 28.16, 28.88, 37.11, 38.17, 40.65, 40.79, 48.44, 50.71, 51.90, 53.59, 54.91, 55.52, 56.66, 156.86, 170.04, 172.19, 172.80, 173.75, 175.41. ESI-MS (*m*/*z*): 1875.31; calc. for $C_{70}H_{136}N_{38}O_{18}S_2 + H^+$: 1875.21.

Synthesis of DTPA-SS-Arg_8 (9). Compound **7** (0.175 g, 0.312 mmol) was added to end-modified Arg_8-Cys (**3**) (0.440 g, 0.312 mmol) dissolved in 30 mL of degassed phosphate buffer (10 mM, pH 8.0). The solution was stirred under a nitrogen atmosphere at room temperature. The reaction was monitored by analytical HPLC and found to be complete after 72 h. An aliquot (2.5 mL) of the solution was removed for characterization, while the remaining material (27.5 mL) was carried onto the synthesis of Gd(III)-DTPA-SS-Arg_8 (**4**). Dialysis (MW cutoff 1000) against Millipore H_2O (4 L × 4 days) yielded 4 mL of a translucent liquid that was 0.2 μm syringe-filtered and freeze−dried to yield a white solid (0.351 g, 66%). ^{1}H NMR (D_2O) shows the disappearance of all aromatic protons. ^{13}C NMR (D_2O): δ = 24.42, 28.20, 38.79, 40.66, 50.53, 52.19, 53.44, 53.53, 54.94, 55.19, 57.88, 58.91, 156.84, 172.70, 172.97, 173.60, 174.32, 178.33. ESI-MS (*m*/*z*): 1864.21; calc. for $C_{69}H_{131}N_{37}O_{20}S_2 + H^+$: 1864.14.

Synthesis of Gd(III)-DOTA-SS-Arg_8 (3). To an aliquot of DO3A-SS-Arg_8 (**8**) (27.5 mL, 0.285 mmol) was added $Gd(OH)_3$ (0.064 g, 0.314 mmol). All metalations were performed with a 1.1:1.0 molar excess of metal salt to unmetalated complex to minimize unmetalated final product. The reaction mixture was brought to pH 6.0 with 1.0 M NaOH and allowed to stir for 7 d at room temperature under a nitrogen atmosphere. Dialysis (MW cutoff 1000) against Millipore H_2O (4 L × 4 days) yielded 30 mL of a translucent liquid that was brought to pH 11.0 with concentrated NH_4OH to precipitate excess free gadolinium. This suspension was 0.2 μm syringe-filtered and freeze−dried to yield a white powder which was found to be (**3**) (0.453 g, 78%) by ESI-MS (*m*/*z*): 2029.44 (*m*/1), 1014.70 (*m*/2), 677.43 (*m*/3), 508.26 (*m*/4) with Gd isotope pattern; calc. for $C_{71}H_{133}GdN_{38}O_{18}S_2 + H^+$: 2029.44.

Synthesis of Gd(III)-DTPA-SS-Arg_8 (4). To an aliquot of DTPA-SS-Arg_8 (**9**) (27.5 mL, 0.286 mmol) was added $Gd(OH)_3$

Scheme 1. Synthesis of the Pyridyl-Activated Gd(III) Chelators[a]



[a] Conditions: (a) AETP, HATU, DIPEA, DMF; (b) TFA/H_2O/TIS, followed by MTBE precipitation; (c) AETP, DMSO, and H_2O.

(0.064 g, 0.315 mmol). The reaction mixture was brought to pH 6.0 with 1.0 M NaOH and allowed to stir for 7 d at room temperature under a nitrogen atmosphere. Dialysis (MW cutoff 1000) against Millipore H_2O (4 L × 4 days), yielded 30 mL of a translucent liquid that was brought to pH 11.0 with concentrated NH_4OH to precipitate excess free gadolinium. This suspension was 0.2 μm syringe-filtered and freeze−dried to yield a white powder which was found to be (**4**) (0.484 g, 84%) by ESI-MS (*m*/*z*): 2017.30 (*m*/1), 1008.55 (*m*/2), 672.99 (*m*/3), 505.12 (*m*/4), 404.38 (*m*/5) with a Gd isotope pattern; calc. for $C_{69}H_{127}GdN_{37}O_{20}S_2 + H^+$: 2017.36.

Synthesis of Tb(III)-DOTA-Arg$_8$ (10). The Tb(III) analogue of **1** was synthesized using a previously outlined metalation procedure and substituting $Tb(OH)_3$ for $Gd(OH)_3$ (*14*). The resulting white solid was found to be **10** (45.7 mg, 42%) by ESI-MS (*m*/*z*): 1810.85 (*m*/1), 906.07 (*m*/2), 604.24 (*m*/3), 453.47 (*m*/4); calc. for $C_{64}H_{121}N_{36}O_{16}Tb + H^+$: 1810.80.

Synthesis of Tb(III)-DTPA-Arg$_8$ (11). The Tb(III) analogue of **2** was synthesized using a previously outlined metalation procedure and substituting $Tb(OH)_3$ for $Gd(OH)_3$ (*24*). The resulting white solid was found to be **11** (42.0 mg, 52%) by ESI-MS (*m*/*z*): 1798.63 (*m*/1), 899.91 (*m*/2), 600.26 (*m*/3), 450.47 (*m*/4); calc. for $C_{62}H_{115}N_{35}O_{18}Tb + H^+$: 1798.73.

Synthesis of Tb(III)-DOTA-SS-Arg$_8$ (12). The Tb(III) analogue of **3** was synthesized using compound **8** (10.0 mg, 0.005 mmol), $Tb(OH)_3$ (1.23 mg, 0.006 mmol), and the same metalation procedure previously described for **3** (6.0 mg, 60%). ESI-MS (*m*/*z*): 2031.01 (*m*/1), 1016.00 (*m*/2), 677.73 (*m*/3) 508.54 (*m*/4), 407.12 (*m*/5); calc. for $C_{71}H_{133}N_{38}O_{18}S_2Tb + H^+$: 2031.12.

Synthesis of Tb(III)-DTPA-SS-Arg$_8$ (13). The Tb(III) analogue of **4** was synthesized using compound **9** (10.0 mg, 0.005 mmol), $Tb(OH)_3$ (1.23 mg, 0.006 mmol), and the same metalation procedure described for **4** (5.9 mg, 55%). ESI-MS (*m*/*z*): 2019.02 (*m*/1), 1010.01 (*m*/2), 673.64 (*m*/3) 505.43 (*m*/4), 404.65 (*m*/5); calc. for $C_{69}H_{127}N_{37}O_{20}S_2Tb + H^+$: 2019.04.

RESULTS

Synthesis. The synthesis of the pyridyl-activated Gd(III) chelators was accomplished by coupling an amine-terminated AETP to an activated form of either the DTPA or DOTA chelate (Scheme 1). Commercially available DTPA-dianhydride is amidated forming amines, while the DOTA-tris-TB was activated *in situ* by the commonly used uranium salt, HATU. Both reactions required an excess of DIPEA in order to deprotonate the hydrochloride salt starting material (AETP) and to aid in amide bond formation (*24*). Upon purification via preparative RP-HPLC, compounds **4** and **5** were afforded with yields of 68% and 63%, respectively. The peptide RRRRRRRRC was synthesized without automation using standard Fmoc solid-phase synthesis methodology on preloaded Wang resin (*24*, *25*). After the addition of the cysteine residue, the resin was treated with acetic anhydride to end-cap the peptide's terminal amine. To prepare peptide sequences with minimal structural differences as compared to the previously published Arg$_8$-MR contrast agents (e.g., charge and no free terminal amine), this end-capping step was performed prior to cleavage and deprotection from the resin (*24*, *25*).

In order to optimize the thiol exchange reaction required to produce **8** and **9**, the pyridyl-activated chelates (**6** or **7**) were quickly added to stirring solutions of the end-capped Arg$_8$-Cys (**5**) oligomer under a nitrogen atmosphere in degassed phosphate buffer at pH 8.0 (Scheme 2). It was found that, when **6** and **7** were added in equimolar quantities to **5**, synthetic yields were maximized. We speculate that adding higher amounts of the free thiol (**5**) lowered the overall yield by increasing oxidation and disulfide exchange of the desired product. This effect has been observed in previous disulfide exchange reactions (*38*). Metalation of the cell-permeable contrast agents was achieved by adding $Gd(OH)_3$ to the phosphate buffered solutions of **8** and **9**. To ensure the complete insertion of Gd(III), the buffered solutions were lowered to pH 6.0 and allowed to stir for 7 days under a nitrogen atmosphere. The proposed structures of the peptide conjugates **5**, **8**, and **9** were confirmed by NMR spectroscopy, ESI-MS, and HPLC, while the unconjugated, small molecule chelates were characterized by NMR spectroscopy, ESI-MS, HPLC, and EA.

Relaxivity, q, and τ_M. The relaxivity measurements (r_1, $mM^{-1}\,s^{-1}$) provided in Table 1 show the relative enhancement of water proton relaxation rates per Gd(III) ion for complexes **1**−**4**. These rates were measured at 1.5 and 14.1 T in order to provide data at both clinical and research field strengths. As expected, the r_1 rates are strongly field dependent; however, **1**−**4** maintain higher relaxation rates than currently available contrast agents, Gd(III)-DOTA and Gd(III)-DTPA, at both 1.5 and 14.1 T. The relaxation rates of **1**−**4** were tested over a wide pH range (1.0−12.5) in order to determine the efficacy of these agents to relax water molecules at biologically relevant pH levels (Figure 3). At low pH (∼1−4), the relaxivity for **1**−**4** is consistent with Gd(III) diassociation from the chelating cage. Conversely, at high pH (∼9−13), the relaxivity shows a decrease that is most likely attributable to a structure that allows

carbonate ion binding or association of the metal center to the slowly exchanging hydroxyl ions (*23*, *39*, *40*). However, in the physiologically relevant range of pH 4−8, all four of the cell-permeable agents display constant relaxivity values.

The Tb(III) analogues of complexes **1**−**4** (complexes **10**−**13**) were subjected to fluorescence measurements so that the number of complex-associated water molecules could be determined. These measurements provided the following data (ms^{-1}): **10**, $k_{H2O} = 0.566$, $k_{D2O} = 0.315$; **11**, $k_{H2O} = 0.635$, $k_{D2O} = 0.331$; **12**, $k_{H2O} = 0.644$, $k_{D2O} = 0.397$; **13**, $k_{H2O} = 0.671$, $k_{D2O} = 0.390$. These values were inserted into the equation listed in the Experimental Procedures section, resulting in the q values shown in Table 1. Typical of most small molecule DOTA and DTPA-based contrast agents where one carboxylic acid arm has been replaced with an amide, these values reflect one bound water molecule within acceptable experimental error of ±0.5 (*41*, *42*).

To evaluate the mean residence lifetime (τ_m) of the water molecule coordinated to the metal center of complexes **1**−**4**, temperature-dependent ^{17}O NMR measurements were performed (*32*,*34*). Plotting the paramagnetic contribution of the observed ^{17}O NMR transverse relaxation rate of water gave the expected bell-shaped curves for each complex that were subjected to the fitting parameters outlined in the Experimental Procedures section

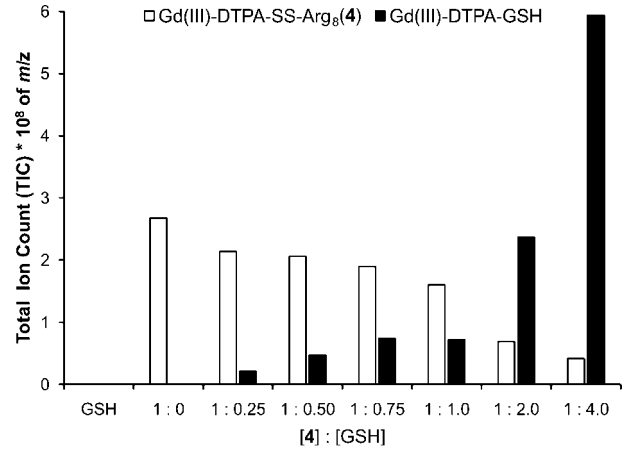

Figure 2. Quantification of *in vitro* cleavage of Gd(III)-DTPA-SS-Arg$_8$ (**4**) via disulfide exchange with GSH. **4** was incubated with increasing amounts of GSH for 4 h in 1.0 mM DPBS. The exchange was monitored by plotting the total ion count (TIC) of the desired product (Gd(III)-DTPA-GSH, $m/z = 912^+$amu, black bars) and the starting material (**4**, $m/z = 3, 673^+$ amu, white bars). The data represent the calculated total area under the curve of the integrated molecular ion chromatograms (912^+ and 673^+). **4** decreases with increasing amounts of GSH which corresponds to an increase in Gd(III)-DTPA-GSH representing*in vitro*disulfide exchange. GSH had no discernible peak to integrate.

(Supporting Information Figure S1) (*32*−*34*). The fitted ^{17}O vs temperature (T) profiles revealed the τ_m values displayed in Table 1.

The τ_m values for **1**−**4** are similar and decidedly higher than the previously reported optimal value of 10 ns for Gd(III) MR contrast agents (*41*). These bound-water lifetimes are substantially slower than those reported for DOTA and DTPA; however, this observation can be explained. Substitution of an acetate arm to an amide linkage (as in the case of **1**−**4**) decreases the steric crowding of the lanthanide and lowers the overall molecular charge of the metalated complexes (*1*, *43*). Both factors affect τ_m, and such values are similar to those obtained for other amidated DOTA and DTPA structures (*44*−*46*).

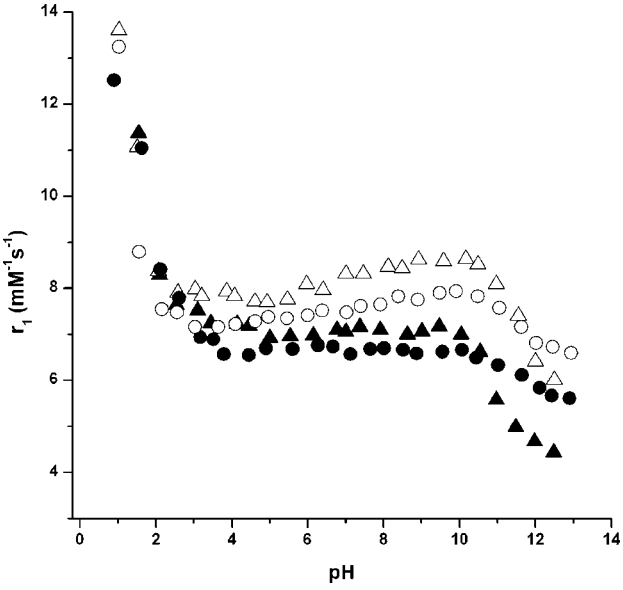

Figure 3. The millimolar relaxivities (r_1, mM^{-1} s^{-1}) of complexes **1**−**4** plotted against pH. Values were measured at 60 MHz and 37 °C. The contrast agents are represented as follows: **1** (closed triangles), **2** (open triangles), **3** (closed circles), and **4** (open circles). Comparison of the closed data points allows correlation of the two DOTA-based ligands. Comparison of the open data points allows correlation of the two DTPA-based ligands.

Typically, a structural modification that lengthens τ_m should be avoided, however, the relaxivity of these small molecule chelates at high fields (>20 MHz) is dominated by another parameter, the rotational correlation motion (τ_R) (*47*). Although the contrast agent is attached to the transport peptide via a flexible linker, τ_R for **1**−**4** must be substantially higher than Gd(III)-DOTA and Gd(III)-DTPA. **1**−**4** have the same q, T_{1e}, and less than optimal τ_m values compared to Gd(III)-DOTA and Gd(III)-DTPA, yet exhibit a 2.0−2.5-fold increase in overall relaxivity. Therefore, the increase is likely due to an increase in τ_R (through an increase in molecular weight). In summary, this system is highly dependent on τ_R, allowing relaxivity values to remain acceptable in spite of varying, less-than-optimal τ_m values (*1*).

In Vitro Cleavage. To assess thiol-mediated release of the chelated Gd(III) from the disulfide-linked arginine oligomer in solution, varying equivalents of GSH were added to a solution of **4** and the cleavage product was quantified via HPLC-MS. The samples were prepared by adding increasing amounts of GSH, from 0.25:1 to 4:1 (GSH/**4**), to a stock solution of **4** (1.0 mM in DPBS). These samples were combined with incrementally delayed starting times so that each could be incubated in a 37 °C water bath for 4 h prior to LC-MS analysis (this is consistent with the cell culture conditions). Separation was accomplished by a gradient ramp starting with 0% MeCN which reached 60% MeCN at 40 min before returning to 0% MeCN. The proposed cleavage reaction was followed by plotting the total ion count (TIC) of the desired product (Gd(III)-DTPA-GSH, $m/z = 912^+$ amu) and the starting material (**4**, $m/z = 3$, 673^+ amu), as their concentrations changed in response to GSH addition (Supporting Informatio Figure S2). The molecular ions chromatograms (912^+ and 673^+) were integrated so that the total area under the curve could be calculated (Figure 2).

Cellular Retention. To elucidate cellular uptake and retention of complexes **1**−**4**, 80% confluent cultures of NIH/3T3 cells were incubated with 0.10 mM of **1**−**4** for 4 h. After a 4 h incubation, the cells were washed three times with DPBS (time = 0, initial amount), placed in fresh media, and allowed to equilibrate for 1 h. Three cell samples and aliquots of the corresponding cell media were removed for analysis. This procedure was repeated 4 times for a total of 5 washes where the last wash was allowed to leach for 24 h.

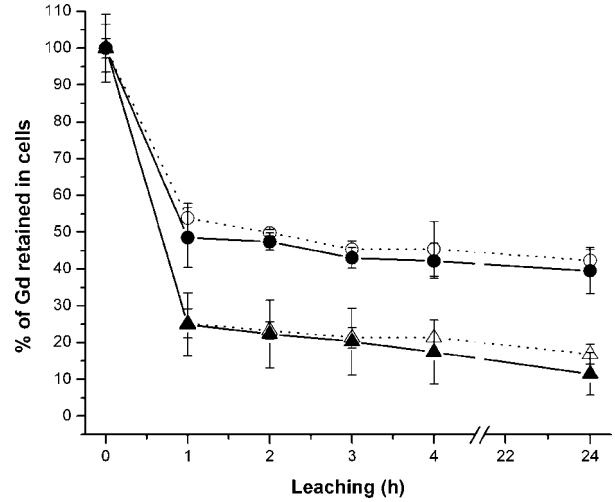

Figure 4. The percentage of Gd(III) associated with the NIH/3T3 cells as a function of the initial uptake concentration (data taken directly from Supporting Information Table S1). Cells were washed with DPBS at each time point displayed. The contrast agents are represented as follows: **1** (closed triangles), **2** (open triangles), **3** (closed circles), and **4** (open circles). Comparison of the closed data points allows correlation of the two DOTA-based ligands. Comparison of the open data points allows correlation of the two DTPA-based ligands.

Each cell culture well consists of two Gd(III)-containing phases: (i) the cells and (ii) the external media. ICP-MS provided absolute quantities of accumulated, retained, and leached Gd(III) for the cells at five time points. These data show that, prior to leaching of the agent, nondisulfide complexes **1** and **2** show increased uptake efficacy over **3** and **4** (Supporting Information Table S1). However, Figure 4 shows that, after washes, cells treated with **1** and **2** lose a more significant amount of the agent than those treated with **3** and **4**. The absolute quantities (Supporting Information Table S1) were divided by their respective initial concentrations (those collected at time = 0) in order to elucidate the relative amount of each agent retained within the cells. Incorporation of a disulfide linkage between the transduction moiety and Gd(III) chelate of these cell-permeable contrast agents drastically improves cellular retention (Figure 4; e.g., from 15% to 40% in the case of **1** vs **3** in the NIH/3T3 cell line).

SR-XRF Analysis. Synchrotron-based XRF analysis was performed to determine the cellular association of complexes **1**−**4**. For each sample, three to five randomly chosen areas were raster-scanned to acquire a multicell-containing image with high resolution (60 × 60 μm with 0.25 μm^2 pixel size). These high-resolution elemental maps provide pixel by pixel data sets that globally confirm, map, and quantify the Gd distribution within each sampled area (*24*). An example of these data is displayed in Figure 5 where the leaching and nonleaching data of **2** and **4** in the NIH/3T3 cell line is compared. Fluorescence maps of inherent biological elements (e.g., P and S) accompany each gadolinium image to prove cellular existence and provide boundaries. The overlay column combines the data from the three elemental maps (P, S, and Gd columns) to provide information on the areas of multielement overlap. Owing to the proximity of the Gd and Fe fluorescence energy levels, it is important to deconvolute potential peak overlap between Fe and Gd fluorescence. This was accomplished using modified Gaussian curves that were fitted at each scan position to the acquired X-ray fluorescence spectra (*36*). Supporting Information Figure S3 contains images of complexes **1** and **3**. The top two rows of images displayed in Figure 5 show the extent to which leaching

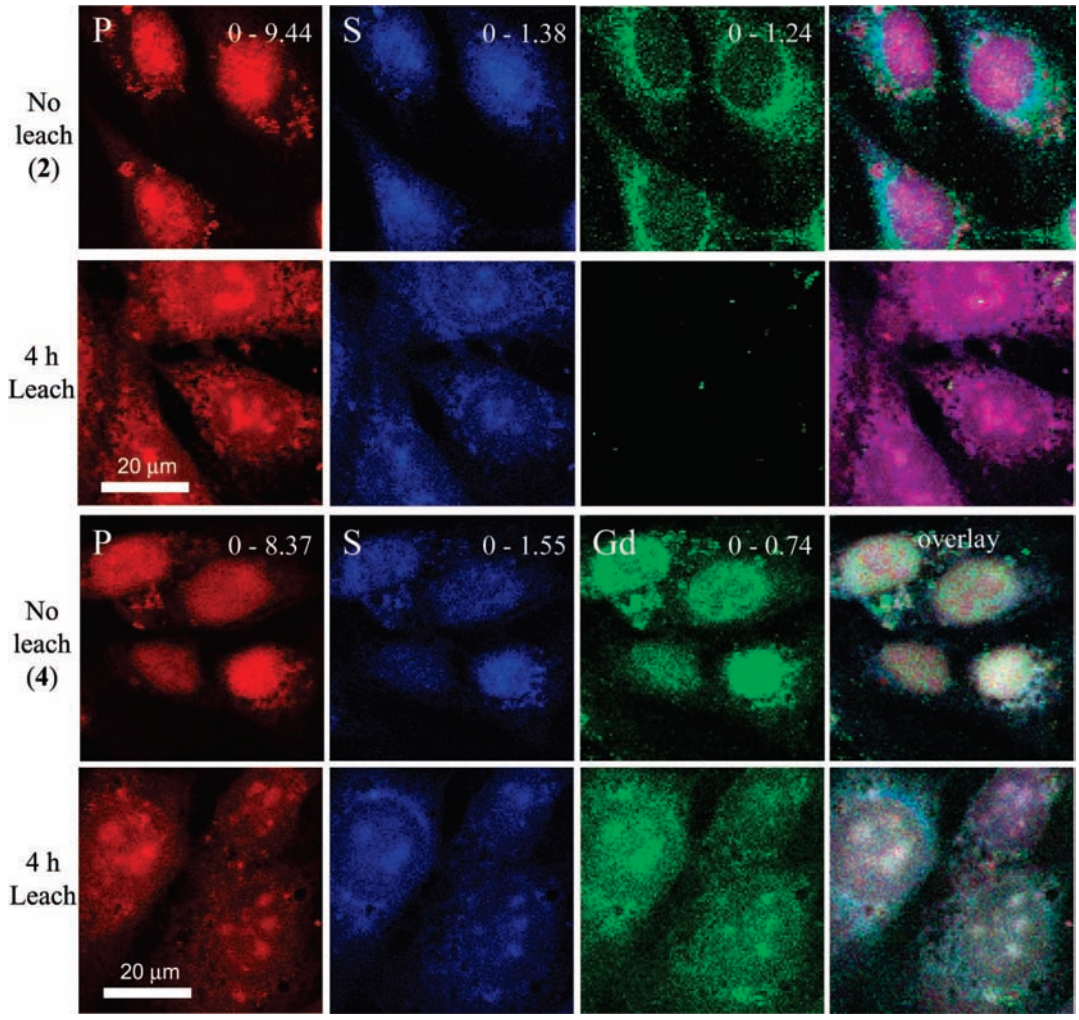

Figure 5. XRF images of NIH/3T3 cells treated with contrast agents **2** (top 8 images) and **4** (bottom 8 images) at time = 0 (No leach) and after 4 h (Leach). Phosphorus fluorescence is red, sulfur is blue, and gadolinium is green. Note that each column of images is scaled to its respective maximum value (displayed at the upper right corner and given in $\mu g/cm^2$).

has depleted the NIH/3T3 cells of associated gadolinium when treated with the nondisulfide contrast agent (**2**). Conversely, when the cells are treated with a disulfide linked contrast agent (**4**), they retain a large amount of gadolinium postleach (bottom 2 rows, Figure 5).

MR Imaging and T_1 Analysis. In order to assess the feasibility of the disulfide linkage to increase cell retention and maintain MR image contrast over an extended time period, NIH/3T3 cells were incubated with 1.0 mM of **1**−**4**. After the cells were harvested and placed in glass capillary tubes, MR images were acquired (Figure 6A). Cells incubated with complexes **1** and **2** exhibit a significantly brighter signal than control cells. However, after the washing procedure outlined for the SR-XRF and ICP-MS experiments (4 h, with washes at 1 h intervals), the cells incubated with **1** and **2** have a significantly lower intensity in the MR image. This loss of image contrast (due to leaching of the contrast agent) is much less in the case of the cells incubated with complexes **3** and **4** (Figure 6B). The signal intensities of the leached cells are similar to their respective nonleached samples, and show little loss of signal intensity (MR image intensity differences were mathematically confirmed via Student's *t*-tests of the corresponding T_1 values (Supporting Information Table S2).

DISCUSSION

Arginine-bound cell-permeable contrast agents **3** and **4** were prepared via thiol-activated pyridyl intermediates to create cell-permeable MR conjugates linked to cell transduction moieties via a disulfide bond. These agents (**3** and **4**), although structurally similar to **1** and **2**, must be coupled to their respective Gd(III) chelating moieties off-resin and under strict pH and equivalence control. Once conjugated to the end-capped Arg_8-Cys, compounds **8** and **9** are exposed to $Gd(OH)_3$ to provide cell-permeable MR contrast agents with antileaching properties (Scheme 2).

The structural changes made to **1** and **2** in order to incorporate the disulfide bond were tested to determine their affect on proton relaxation. As seen in Table 1, the coordination environment of the Gd(III) ion (expressed by the q, τ_m) and relaxivity measurements has not been significantly changed in spite of the structural differences between nondisulfide (**1** and **2**) and disulfide (**3** and **4**) agents. Even with varying pH, the observed relaxivities remain relatively constant (Figure 3). This structural stability and documented characterization make contrast agents **1**−**4** excellent choices for labeling cells cultured in a nonleaching environment (Supporting Information Table S1).

In order to quantify the efficiency of in vivo disulfide cleavage, we used a model disulfide exchange reaction in vitro. Disulfide-bridged complexes undergo exchange or reduction with endogenous thiols, especially GSH (*18*). As a result, the Gd(III) chelate will be cleaved from its cell-penetrating polyarginine oligomer and consequently prolong the intracellular lifetime of the chelated Gd(III). The lifetime of the disulfide linkage was assessed by incubating agent **4** at 37 °C in the

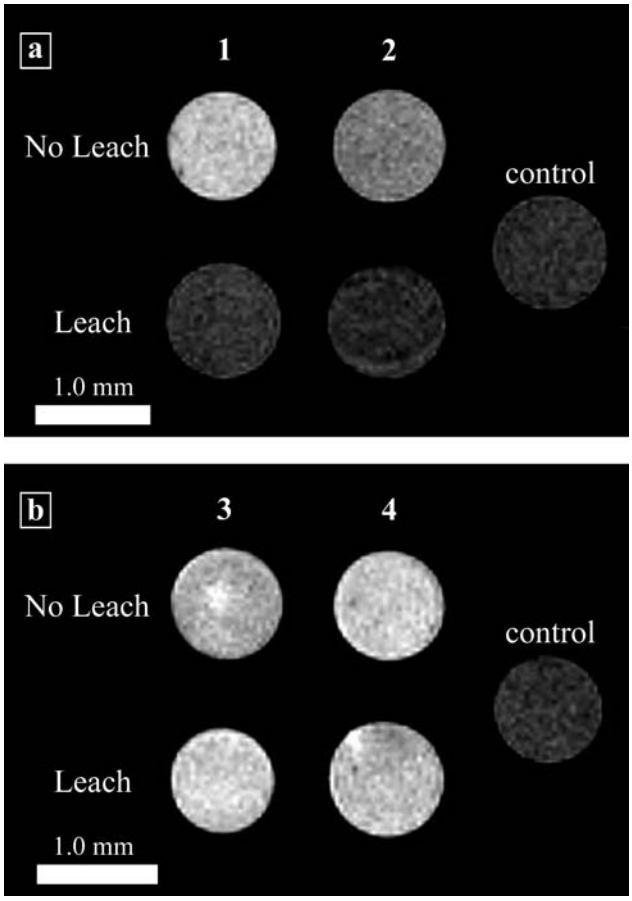

Figure 6. T_1-weighted MR images of NIH/3T3 cells incubated with complexes **1**−**4**. The No Leach rows are the cell populations that were not allowed to leach. The Leach rows are the cell populations that were allowed to leach for 4 h with washes of DPBS at the hours. The control cells were not incubated with contrast agent but were harvested and packed following the same procedure. (a) Cells incubated with Gd(III)-DOTA-Arg_8 or Gd(III)-DTPA-Arg_8 (**1** and **2**). (b) Cells incubated with Gd(III)-DOTA-SS-Arg_8 or Gd(III)-DTPA-SS-Arg_8 (**3** and **4**). Images were acquired at 14.1 T with a FOV of 10 × 10 mm^2 (matrix size 256 × 256) and a slice thickness of 1.0 mm. The scale bar represents 1.0 mm. T_1 values and Student's *t*-tests confirming statistically significant differences can be found in Supporting Information Table S2.

presence of increasing quantities of GSH (Figure 2). A qualitative depiction of these results is displayed in Supporting Information Figure S2. As the concentration of GSH is increased, the amount of desired product (Gd(III)DTPA-GSH) detected via quantitative HPLC-MS is increased. Conversely, as the concentration of GSH is increased, the amount of starting material (Gd(III)DTPA-SS-Arg_8, **4**) decreases. This trend continues through ratios of [GSH]:[**4**] that reach 4:1 and implies that, while disulfide cleavage begins at very low GSH concentrations (0.25 equiv), complete cleavage is not obtainable even at GSH concentrations that are 4 times that of the contrast agent.

When cells are incubated with the same initial concentration of agent, cell uptake of **1** and **2** is higher in NIH/3T3 cells than **3** and **4** (Initial Amount, Supporting Information Table S1). The initial uptake values of **1** and **2** show that NIH/3T3 cells prefer the negatively charged DTPA over the neutral DOTA chelate with the same transduction moiety. Conversely, with agents **3** and **4**, the neutral DOTA chelate is preferred over the charged DTPA. We have previously shown that small changes in structure or charge have significant effects on the uptake efficiency multiple contrast agents (*24*). In contrast to initial uptake, the percentage of Gd(III) retained in cells postleaching implies that incorporation of the disulfide bond into **3** and **4** has a positive effect on long-term contrast agent retention. Addition of the reactive disulfide linkage (**3** and **4**) increases cell retention of the Gd(III) chelate 3.5 and 2.5 more than their nondisulfide counterparts (**1** and **2**), respectively (Figure 4).

To covalidate ICP-MS measurements at the single cell level, cells incubated with **1**−**4** were evaluated by SR-XRF. SR-XRF microprobes alleviate the difficulties associated with visualizing intracellular lanthanides and allow direct gadolinium imaging without covalent attachment of organic fluorophores that alter cell transport properties. Additionally, SR-XRF offers submicrometer resolution and quantifiable elemental data of subcellular regions of interest that are displayed in two-dimensional, intensity-weighted images (*48*). As shown, cells labeled with **2** and **4** (fixed at time = 0) show a significant amount of associated gadolinium (No leach, rows 1 and 3, Figure 5). In contrast, rows 2 and 4 have significant differences in the amount of gadolinium (4 h Leach for **2** and **4**, respectively). The 4 h leach images for complex **2** show only trace amounts of gadolinium, while the corresponding images of cells treated with **4** display a relatively large amount of gadolinium comparable to nonleached cells. These results are in agreement with the ICP-MS measurements and can be attributed to the incorporation of the disulfide linkage between the Gd(III) chelate and the arginine transduction moiety.

The data from ICP-MS and SR-XRF images reveals that incorporation of the disulfide linkage increases the cell retention of contrast agents **3** and **4**. However, since ICP-MS and SR-XRF are highly sensitive toward gadolinium concentration, the utility of **1**−**4** to increase MR image intensity was examined (before and after the leaching). This assessment was accomplished by incubating **1**−**4** (1.0 mM) on 2 populations of NIH/3T3 cells, one subjected to the leaching protocol outlined in the Experimental Procedures section and one that was not. Visual comparison of the images in Figure 6A to those in B clearly show that cells incubated with **3** and **4** retain their image contrast enhancement to a greater extent than those incubated with **1** and **2** (e.g., 88% signal retention for complex **3** over the leaching period). These images show that the SR-XRF and ICP-MS data have translated to MRI whereby increased cell retention of the Gd(III)-based contrast agents prolongs image contrast. We performed T_1 analysis to validate that the image intensity changes are due to changes in T_1. As shown in Supporting Information Table S2, the shortest T_1 values correspond to the highest image intensities.

Complexes **1**−**4** undergo similar cell uptake; the disulfide exchange reactions possible for **3** and **4** must significantly alter their intracellular fate from **1** and **2**. If **1** and **2** are nonspecifically bound to the internal membrane or sequestered in lysosomes, the image intensity and resultant T_1 values will decrease due to reduced Gd(III) access to the bulk water. This explains the high T_1 values and reduced MR image intensity in Figure 6A (Leach) despite the Gd(III) measurements displayed in Supporting Information Table S1. Such encapsulation allows the contrast agent access to only a small number of rapidly exchanging inner sphere water molecules. This phenomenon has been observed within artificial systems such as those involving LIPOCEST contrast agents and, more importantly, within certain subcellular compartments (*49, 50*)

The SR-XRF images display a similar loss of gadolinium signal after the leaching process. We propose that **1** and **2** have been processed differently than **3** and **4**, leaving the Gd(III) chelate nonspecifically bound to the recycling membrane (either endosomal or lysosomal). Thus, nonspecific contrast agent binding was only removed when the cells were subjected to harsh conditions (i.e., the formaldehyde fixation and dehydration necessary for SR-XRF sample preparation). Therefore, the SR-XRF images supplement the MR images while supporting our current hypothesis of membrane internalization and nonspecific binding of complexes **1** and **2**.

In conclusion, we have synthesized Gd(III)-DOTA-SS-Arg_8 (**3**) and Gd(III)-DTPA-SS-Arg_8 (**4**), cell-permeable contrast agents that show increased cell retention via disulfide bond incorporation, which may be a result of intracellular thiol concentrations. The agents' relaxometric properties, pH stability, in vitro cleavage kinetics, and cell retention have been investigated. As expected, **3** and **4** show increased cell retention (ICP-MS), single cell association (SR-XRF), and viability as long-term MRI contrast agents (MR images). These agents could be used to ectopically label cell populations and provide long-term contrast enhancement for cell tracking and lineage analysis using MR imaging.

ACKNOWLEDGMENT

We thank Prof. Matthew J. Allen for helpful discussions. This research was supported by the National Institutes of Health under Grant Number 1 R01 EB005866-01, the Nanomaterials for Cancer Diagnostics and Therapeutics under 5 U54 CA1193 41-02, and the Center for Excellence in Transitional Human Stem Cell Research under 1 P50 NS0542 78-01. Determination of τ_m by ^{17}O Transverse Relaxation Rate Measurements. Samples of **1**-**4** were prepared at 15-20 mM concentrations in 1% ^{17}O enriched water (Medical Isotopes, Inc., Pelham, NH) adjusted to pH 7.40. Lock was achieved by means of an external D_2O standard. ^{17}O spectra were obtained at 54 MHz (number of averaged transients was 160 – 320 and relaxation delay was 400 ms) at temperatures ranging from 1 °C to 86 °C in 5 °C increments. The ^{17}O transverse relaxation rate was determined by obtaining the line width (in Hz) at half of the peak height, $\Delta\nu_{1/2}$, of the ^{17}O water signal and later fitting the data at 25 °C (references 22-24). This data and their respective fittings are shown below in Figure S1.

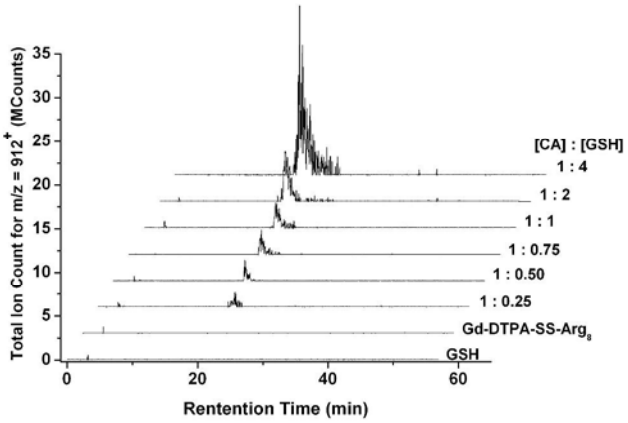
Supporting Figure S1. (A) Raw ^{17}O data and τ_m fitting of compound **1**. (B) Raw ^{17}O data and τ_m fitting of compound **2**. (C) Raw ^{17}O data and τ_m fitting of compound **3**. (D) Raw ^{17}O data and τ_m fitting of compound **4**. The relaxation data were fit to these four parameters: τ_m (water exchange rate), $\Delta H^{\ddagger}$ (activation enthalpy), T_{1e} (electronic relaxation rate), and ΔE_{T1e} (activation energy of T_{1e}).

In Vitro Cleavage. Determination of disulfide exchange using the total ion count (TIC) of **4** plus the addition of GSH with increasing amounts of GSH for 4 hours in PBS.



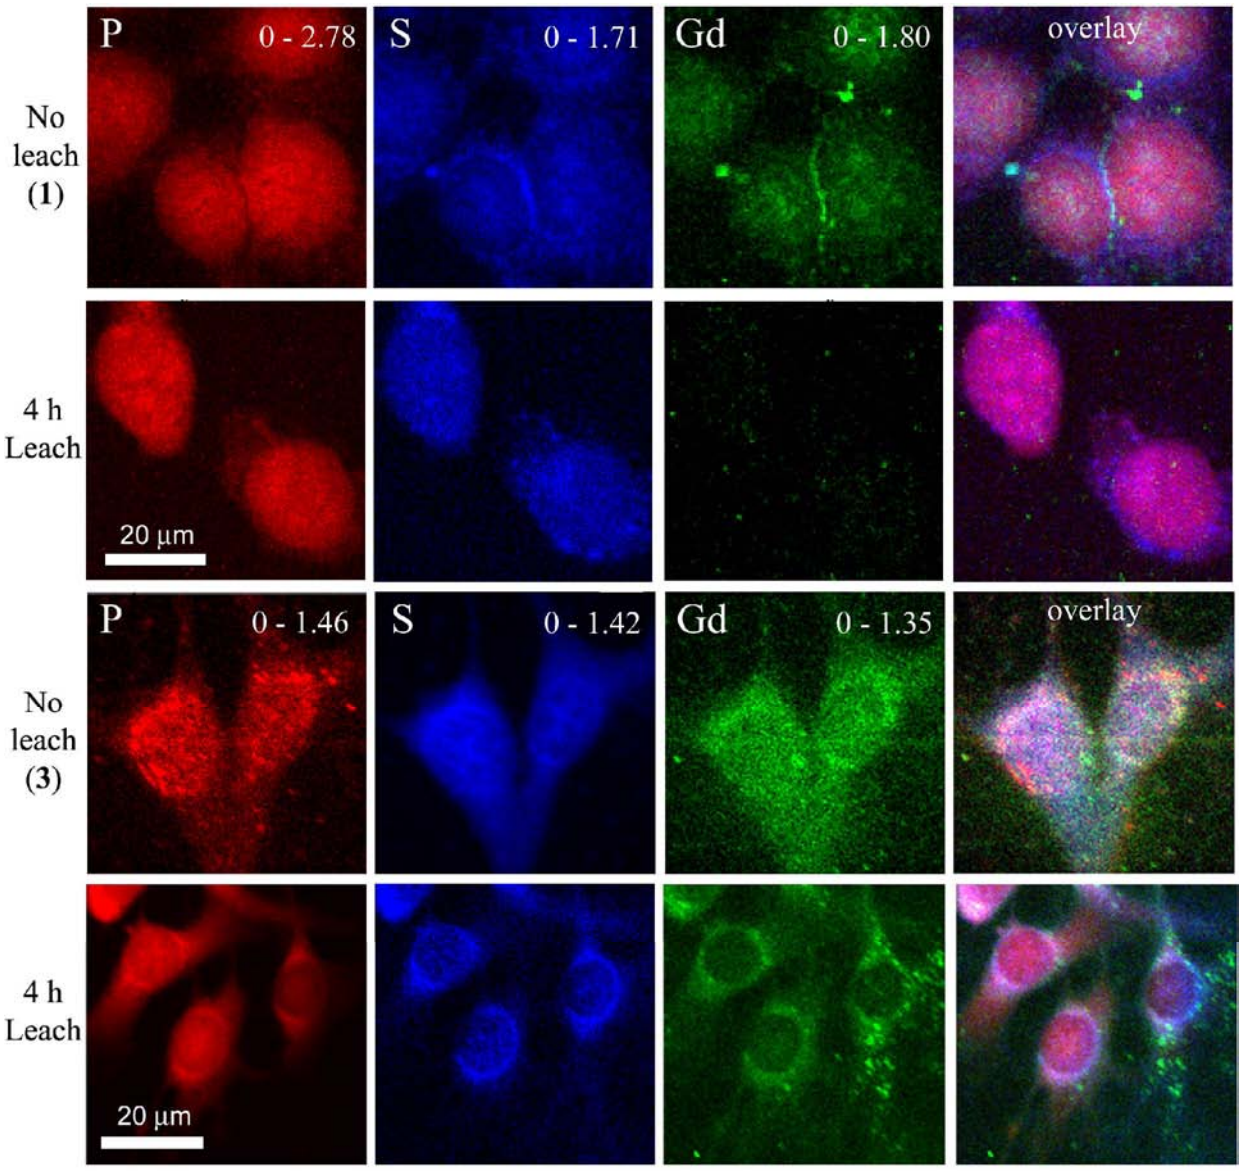
Supporting Figure S2. Treatment of **4** with increasing concentrations of GSH leads to disulfide exchange and subsequent product formation (Gd(III)-DTPA-GSH, $m/z = 912^{+}$).

Quantitation of Cell Uptake. Gadolinium ICP-MS data for complexes **1-4** associated with NIH/3T3 cells before (Initial Amt.) and after leaching. These data were used to produce Figure 3.

Complex	**1**	**2**	**3**	**4**
Initial Amt.(10^{-11} moles)	13.6 ±0.36[a]	15.3 ±1.0	2.45 ±0.22	2.23 ±0.04
Leach 1 (1 h)	3.39 ±0.03	3.87 ±0.15	1.18 ±0.09	1.12 ±0.16
Leach 2 (2 h)	3.04 ±0.21	3.58 ±0.03	1.16 ±0.02	1.06 ±0.02
Leach 3 (3 h)	2.77 ±0.26	3.27 ±0.10	1.05 ±0.02	0.97 ±0.07
Leach 4 (4 h)	3.56 ±0.22	3.26 ±0.24	1.03 ±0.05	0.94 ±0.04
Leach 5[b] (24 h)	2.35 ±0.08	2.59 ±0.06	0.97 ±0.06	0.92 ±0.03

Supporting Table S1. All values given in 10^{-11} moles. [a]Error is given as +/- one standard deviation of triplicate runs. [b]A single wash allowed to leach for 24 hours.

SR-XRF Analysis. Synchrotron XRF analysis was performed to determine the cellular association of complexes **1**-**4**. These images are representative of the NIH/3T3 cells following the image acquisition procedure reported in the Experimental Procedures section. From our previous report, these high-resolution elemental maps provide pixel by pixel data sets that globally confirm, map, and quantify the Gd distribution within each sampled area *(24)*.



Supporting Figure S3. XRF images of NIH/3T3 cells treated with contrast agents **1** (top 8 images) and **3** (bottom 8 images) at time = 0 (No leach) and after 4 h (Leach). Phosphorus fluorescence is red, sulfur is blue, and gadolinium is green. Note that each column of images is scaled to its respective maximum value (displayed at the upper right corner and given in $\mu g/cm^2$).

MR Imaging and T_1 Analysis. To assess the feasibility of the disulfide linkage to increase cell retention and increase MR image contrast over an extended time period, NIH/3T3 cells were incubated with 1.0 mM of **1**-**4**. After the cells were harvested and placed in glass capillary tubes, they were visualized via MRI.

Figure 6 (in text) and accompanying table, **Supporting Table S2**. T_1 values and student *t*-tests confirming statistically significant differences. Student's *t*-tests were calculated in Origin 7 SR2 (Origin Lab, Northampton, MA) at a 95% confidence level with 8 degrees of freedom, independent testing, and a null hypothesis value (minimum acceptable time difference) of 100 ms. At least 5 slices per sample were averaged.

Synthetic and Immunological Studies of *5′-N*-Phenylacetyl sTn to Develop Carbohydrate-Based Cancer Vaccines and to Explore the Impacts of Linkage between Carbohydrate Antigens and Carrier Proteins

Qianli Wang, Sandamali Amarasingha Ekanayaka, Jian Wu, Junping Zhang, and Zhongwu Guo*

Department of Chemistry, Wayne State University, 5101 Cass Avenue, Detroit, Michigan 48202. Received June 17, 2008; Revised Manuscript Received September 3, 2008

5′-N-Phenylacetyl sTn (sTnNPhAc), an unnatural derivative of sTn antigen expressed by many tumors, and its α-linked protein conjugates were prepared and investigated to explore glycoconjugate cancer vaccines. sTnNPhAcα-KLH elicited a robust T cell dependent immunity. The antiserum derived from sTnNPhAcα- or sTnNPhAc*β*-KLH-inoculated mice was similarly reactive to sTnNPhAcα and sTnNPhAc*β* but showed very little reactivity to sTn, NeuNPhAcα(2,3)GalNAc—a regioisomer of sTnNPhAc, isolated phenylacetyl group, and the linker employed to conjugate sTnNPhAc and carrier protein. It was concluded that the sTnNPhAc-elicited immunity was specific for the whole antigen rather than the phenylacetyl group or other partial structures of sTnNPhAc and that the reducing end configuration or linkage of sTnNPhAc did not affect its immunological identity. It was also concluded that a new linker designed to conjugate carbohydrates and proteins did not provoke any immune reaction and that the linker, as well as the associated new and convenient coupling strategy, can be safely used for the development of glycoconjugate vaccines.

INTRODUCTION

Tumor-associated carbohydrate antigens (TACAs) are useful targets in the development of cancer vaccines (*1*−*3*). To form functional cancer vaccines, TACAs must be covalently conjugated to carrier proteins, because free carbohydrates only induce T cell independent immune responses (*4*), which are not particularly useful in the treatment of cancer. Therefore, different linkers or spacers and coupling methods have been developed to facilitate the conjugation between carbohydrates and proteins (*2, 5*). However, many linkers contain functionalities that are not compatible with the chemical synthesis of oligosaccharides, while late-stage installation of a linker to synthesized oligosaccharides can be difficult and usually needs multistep transformations. To address these issues, our group developed a novel strategy for coupling synthetic oligosaccharides to proteins, which employs a simple linker as shown in Scheme 1 (*6*). The azido group utilized to attach the linker is a widely adopted protecting group in oligosaccharide synthesis; thus, it can be installed as a protection of the oligosaccharide reducing end during the TACA synthesis. After oligosaccharides are accomplished, the azido group can be readily reduced to give a free amino group for introducing an unsaturated acyl linker, which in turn can be selectively oxidized to form an aldehyde functionality, enabling the reliable and effective coupling of synthetic TACAs to carrier proteins via reductive amination. This coupling strategy has been used to construct some hopeful conjugate vaccines (*7, 8*).

Because all synthetic glycoconjugate vaccines contain unnatural linkers or spacers, it is natural to inquire how these linkers may affect the immunological properties of resultant vaccines. It has been reported that some linkers themselves may provoke a strong immune response (*9, 10*), which is not only unhelpful but rather detrimental, and that some linkers may even suppress the immune system and decrease its response to TACAs (*9, 11*). Immunological studies of the synthetic glycoconjugates containing this new linker suggest that it is probably immunologically inert (*7, 8*), which is a useful property and needs to be investigated in detail.

In nature, TACAs are directly α- or *β*-linked to membrane proteins or lipids on the cell surfaces, while most synthetic cancer vaccines have TACAs coupled to carrier proteins via unnatural linkers or anomeric linkages. Consequently, another question about these vaccines is whether this would affect the immunological identity of TACAs or whether the provoked immune system can recognize and target cancer cells that bear differently configured TACAs. For example, sialyl Tn (sTn, Figure 1) is a disaccharide TACA α-linked to the polypeptide backbone of mucins on cancer cells and is richly expressed by numerous tumors including breast, prostate, colorectal, ovarian, pancreatic, and gastric cancer (*12*−*15*). Due to its unique expression on cancer cells and its relevance to tumor metastasis (*16*), sTn has become an attractive target in cancer vaccine development (*17*−*22*). Recently, we have shown that sTn derivatives containing unnatural *N*-acyl sialic acids, for instance, *N*-phenylacetyl sialic acid (NeuNPhAc), were much more immunogenic than the natural counterpart and that the sTn derivatives could elicit robust T cell dependent immune responses (*7*). However, the glycoconjugates employed there, such as the keyhole limpet hemocyanin (KLH) conjugate of unnatural 5′-*N*-phenylacetyl sTn (sTnNPhAc) (**1**), had the sTn derivatives *β*-linked to carrier proteins. It is therefore natural to inquire whether the provoked immune system would interact with the α-linked antigens expressed on cancer cells following metabolic engineering (*23, 24*).

An even more interesting question about glycoconjugate vaccines is whether the elicited immune reactions were mainly against the whole carbohydrate antigens or they also directed at partial structures of the antigen, such as a segment of an oligosaccharide or the unnatural functionality of a conjugate vaccine consisting of an unnatural TACA derivative. An answer to this question should be helpful for understanding the functions and functional mechanisms of carbohydrate-based vaccines. It

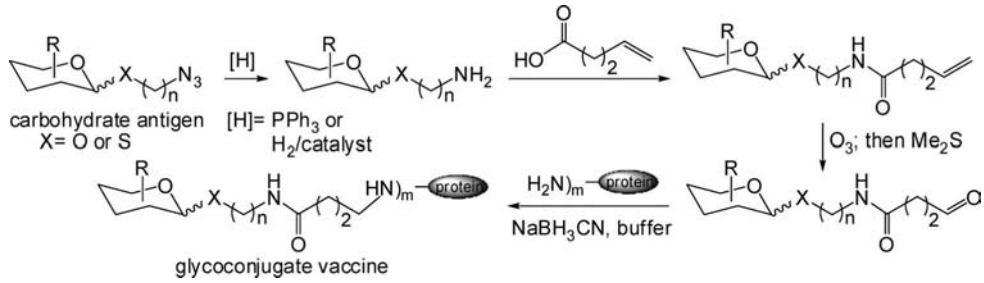
Scheme 1



can also assist in addressing issues concerning the specificity of a novel strategy for cancer immunotherapy developed by our laboratory, where synthetic glycoconjugate vaccines consisting of unnatural TACA derivatives are combined with metabolic engineering of cancer cells for their expression of the unnatural TACA derivative (*7*, *8*, *25*−*27*).

To explore the problems mentioned above, we prepared glycoconjugate **3**, which has sTnNPhAc α-linked to KLH, and compared its immunological properties with that of the *β*-linked glycoconjugate **1**. The α-linked human serum albumin (HSA) conjugate of sTnNPhAc **4** was prepared and employed in assaying the immunological properties of **3**. Meanwhile, HSA conjugates **2**, **5**, **6**, and **7** containing sTnNPhAc*β*, natural sTn, the phenylacetylated linker, and NeuNPhAcα(2,3)GalNAcα—a regioisomer of sTnNPhAcα, respectively, were also prepared to check the reactivity of **1** and **3** provoked antisera to sTn, *β*-linked sTnNPhAc, the linker, NeuNPhAc, the phenylacetyl functionality, and other partial structures of sTnNPhAc.

EXPERIMENTAL PROCEDURES

General Methods. NMR spectra were recorded on a 400 MHz spectrometer with chemical shifts reported in ppm (*δ*) in reference to $SiMe_4$ if not specified otherwise. Coupling constants (*J*) are reported in hertz (Hz). High-resolution (HR) ESI MS was performed on a Micromass Autospec Ultima magnetic sector mass spectrometer or on Waters GCT time-of-flight mass spectrometers. MALDI TOFMS was obtained on a Bruker Ultraflex mass spectrometer. Thin layer chromatography (TLC) was performed on silica gel GF_{254} plates detected by charring with phosphomolybdic acid in EtOH or with 1% H_2SO_4/EtOH solution. Molecular sieves were dried under high vacuum at 170−180 °C for 6−10 h just before use. Glycoconjugates **1**, **2**, and **5** were prepared and reported previously (*7*), and glycoconjugate **7** was prepared for a different project and will be reported separately. Commercial anhydrous solvents and other reagents were used without further purification.

2-Azidoethyl 2-Acetamido-2-deoxy-α-D-galactopyranoside (10). To a solution of *N*-acetyl-D-galactosamine (**8**, 1.2 g, 5.42 mmol) in 2-chloroethanol (15 mL) at 0 °C was added dropwise acetyl chloride (0.47 g, 5.97 mmol), and the reaction mixture was heated at 70 °C for 4 h. The solution was concentrated, and the residue was coevaporated with toluene and then purified by flash column chromatography (CH_2Cl_2/MeOH 10:1) to yield **9** as a white solid (0.66 g, 45%). ^{1}H NMR (D_2O, 400 MHz): *δ* 4.95 (d, $J = 3.2$ Hz, 1H, H-1), 4.14 (dd, $J = 11.6$ and 4.0 Hz, 1H, H-2), 4.02 (t, $J = 6.8$ Hz, 1H, H-4), 3.97−3.90 (m, 3H), 3.79−3.72 (m, 5H), 2.02 (s, 3H, NHAc); ^{13}C NMR (D_2O, 100 MHz): *δ* 174.9, 97.5, 71.4, 68.7, 68.5, 67.8, 61.5, 50.1, 43.8, 22.2. The mixture of **9** (0.51 g, 1.80 mmol), NaN_3 (1.17 g, 18.0 mmol), and monobenzo-15-crown-5 (48 *μ*g, 0.18 mmol) in anhydrous DMF (5 mL) was stirred at 80 °C overnight. After cooling to rt, inorganic salts were removed by filtration and washed with CH_3CN. The filtrate and washings were combined and concentrated. The residue was purified by flash column chromatography (CH_2Cl_2/MeOH 10:1) to give **10** as a white solid (0.52 g, quantitative). Its spectroscopic data were consistent with that reported in the literature (*28*).

2-Azidoethyl 2-Acetamido-2-deoxy-3,4-*O*-(1-methylethylidene)-α-D-galactopyranoside (11). To a solution of **10** (0.45 g, 1.55 mmol) in a mixture of DMF (4.5 mL) and 2,2-dimethoxypropane (9.0 mL) was added *p*-toluenesulfonic acid monohydrate (0.029 mg, 0.155 mmol) at 65 °C. After the solution was stirred at 65 °C for 5 h, it was cooled to rt, and Et_3N (0.5 mL) was added. The mixture was stirred for another 15 min, and it was concentrated and coevaporated twice with toluene to remove traces of Et_3N. The residue was dissolved in MeOH/H_2O (10:1) (15 mL) and heated under reflux for 30 min until TLC (CH_2Cl_2/MeOH 16:1) showed the complete disappearance of the reaction intermediate. The solution was then concentrated and coevaporated with toluene. The residue was purified by flash column chromatography (CH_2Cl_2/MeOH 20:1) to give **11** as light yellow oil (0.47 g, 92%). $R_f = 0.20$ (CH_2Cl_2/MeOH 16:1). ^{1}H NMR ($CDCl_3$, 400 MHz): *δ* 5.62 (d, $J = 10.0$ Hz, 1H, NHAc), 4.87 (d, $J = 3.2$ Hz, 1H, H-1), 4.31 (dt, $J = 9.2$ and 3.6 Hz, 1H, H-2), 4.21 (dd, $J = 4.8$ and 2.4 Hz, 1H, H-4), 4.12−4.04 (m, 2H), 4.01−3.90 (m, 2H), 3.85 (dd, $J = 11.6$ and 4.0 Hz, 1H, H-3), 3.66−3.60 (m, 1H), 3.49−3.42 (dq, 1H), 3.36−3.29 (m, 1H, H-5), 2.03 (s, 3H, NHAc), 1.57, 1.34 (s, 2 × 3H, CH_3). ^{13}C NMR ($CDCl_3$, 100 MHz): *δ* 170.5, 110.3, 98.3, 74.6, 73.6, 68.2, 67.8, 62.9, 50.6, 50.5, 28.1, 26.8, 23.6. HR ESI MS (*m*/*z*) calcd. for $C_{13}H_{22}N_4NaO_6$ $(M + Na)^+$ 353.1437, found 353.1442.

Methyl (Ethyl 4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-2-thio-5-phenylacetamido-D-glycer-D-galacto-non-2-ulopyranosid)onate (15). A solution of **13** (4.0 g, 7.47 mmol) (*7*, *8*) and methanesulfonic acid (1.9 mL, 29.88 mmol) in anhydrous methanol (60 mL) was refluxed overnight. After the reaction was completed, the reaction mixture was neutralized with Et_3N to pH 8 and then concentrated under reduced pressure. The residue was dissolved again in methanol (60 mL) and Et_3N was added to adjust pH to 9. After the mixture was cooled to 0 °C, phenylacetic anhydride (3.8 g, 14.94 mmol) was added slowly and the mixture was stirred at rt for 1 h. The reaction mixture was concentrated under vacuum and the residue was purified by flash column chromatography (toluene/AcOEt/CH_3OH 5:5:1) to give **14** (2.47 g, 75%), which was dissolved in pyridine (12 mL) at 0 °C, followed by addition of DMAP (42 mg) and acetic anhydride (6 mL). After the mixture was stirred at 0 °C for 30 min and at rt for 5 h, it was diluted with ethyl acetate (100 mL); washed with 1 N HCl, brine, saturated $NaHCO_3$ aqueous solution, and brine; dried over anhydrous Na_2SO_4; and concentrated under vacuum. The residue was purified by flash column chromatography (AcOEt/hexanes 1:1) to give an anomeric mixture of **15** as a white solid (3.14 g, 92%). ^{1}H NMR ($CDCl_3$, 400 MHz): *δ* 7.37−7.22 (m, 5 H, aromatic H), 5.36 (t, $J = 3.2$ Hz, 1H), 5.25 (m, 1H), 5.17−5.04 (m, 2H), 4.76 (dd, $J = 12.4$ and 2.4 Hz, 1H), 4.24 (dd, $J = 10.4$ and 2.4 Hz, 1H),

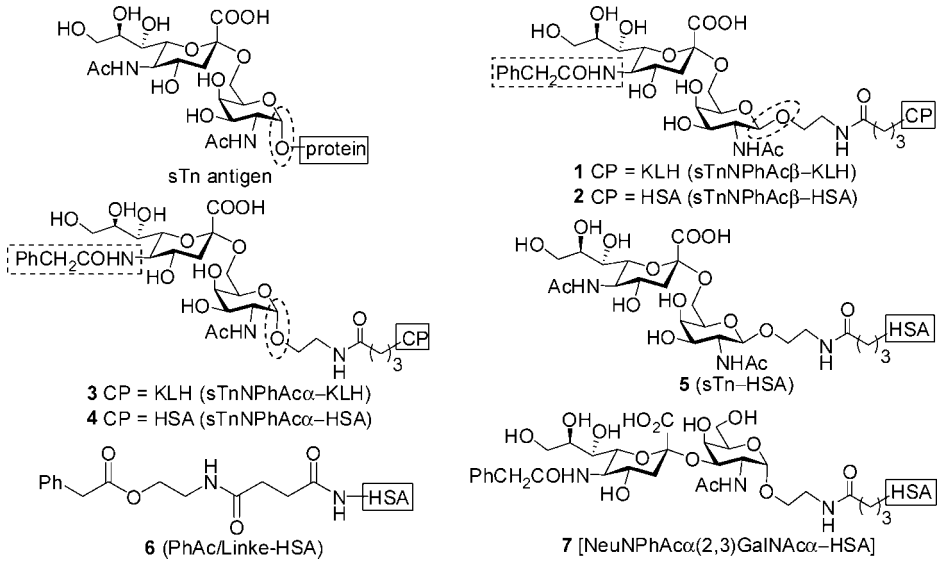


Figure 1. Structures of sTn antigen and the conjugates used in this research.

4.15 (dd, $J = 12.4$ and 8.0 Hz, 1H), 4.05 (d, $J = 10.4$ Hz, 1H), 3.78 (s, 3H, $COOCH_3$), 3.44 (d, $J = 2.4$ Hz, 1H), 2.58−2.44 (m, 2H), 2.14 (s, 3H), 2.07 (s, 3H), 2.03 (s, 3H), 1.81 (s, 3H), 1.16 (t, $J = 8.0$ Hz, 3H). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 171.3, 170.9, 170.8, 170.7, 170.5, 168.6, 134.5, 129.7, 129.2, 127.6, 85.1, 72.7, 72.3, 69.0, 68.7, 62.6, 53.0, 49.7, 44.0, 37.5, 22.9, 21.2, 21.1, 21.0, 20.8, 14.3. 2-Azidoethyl [Methyl 4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-5-phenylacetamido-D-glycero-α-D-galacto-2-nonulopyranosylonate]-(2→6)-*O*-2-acetamido-2-deoxy-α-D-galactopyranoside (16). A mixture of **15** (0.32 g, 0.52 mmol), **11** (0.16 g, 0.48 mmol), and activated MS 3Å (1.5 g) in anhydrous CH_3CN (5.0 mL) was stirred at rt for 2 h under an atmosphere of argon. After the mixture was cooled to −35 °C, NIS (0.44 g, 1.93 mmol) and TfOH (18 μL, 0.193 mmol) were added with stirring. The reaction was kept at −35 °C for 1 h and then quenched with the addition of Et_3N. The solid material was filtered off and washed with DCM. The combined filtrate and washings were washed with aqueous $Na_2S_2O_3$ and water, dried over anhydrous Na_2SO_4, and concentrated under vacuum. The residue was dissolved in 65% HOAc/H_2O (v/v, 5 mL) and heated at 65 °C for 1.5 h. The mixture was concentrated and the residue was purified by flash column chromatography (CH_2Cl_2/MeOH 30:1) to afford **16** as a white solid (212 mg, 52%), $R_f = 0.35$ (CH_2Cl_2/MeOH 15:1) and its β-anomer (64 mg, 15.7%), $R_f = 0.40$ (CH_2Cl_2/MeOH 15:1). **16**: ^{1}H NMR ($CDCl_3$, 400 MHz): δ 7.37−7.22 (m, 5 H, aromatic H), 5.98 (d, $J = 8.4$ Hz, 1H), 5.36−5.29 (m, 1H), 5.24 (dd, $J = 8.4$ and 2.0 Hz, 1H), 5.16 (d, $J = 9.2$ Hz, 1H), 4.89 (d, $J = 3.2$ Hz, 1H), 4.80−4.73 (m, 1H), 4.36−4.30 (m, 2 H), 4.09−3.99 (m, 3H), 3.98−3.92 (m, 2H), 3.89−3.82 (m, 2H), 3.78 (s, 3H, $COOCH_3$), 3.74 (dd, $J = 10.4$ and 3.2 Hz, 1H), 3.67−3.60 (m, 2H), 3.55−3.47 (m, 1H), 3.44 (d, $J = 3.2$ Hz, 2H), 3.37−3.30 (m, 1H), 2.61 (b, -OH), 2.54 (dd, $J = 12.8$ and 4.0 Hz, 1H, H-3′e), 2.15, 2.11, 2.05, 2.03 (4s, 4 × 3H, Ac), 1.90 (t, $J = 12.0$ Hz, 1H, H-3′a), 1.83 (s, 3H, Ac). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 172.6, 171.5, 171.1, 170.8, 170.5, 170.4, 168.3, 134.5, 129.7, 129.1, 127.6, 99.0, 98.0, 72.9, 70.6, 69.2, 69.1, 68.7, 68.4, 67.7, 67.5, 63.7, 62.7, 53.2, 50.8, 50.5, 49.5, 44.0, 37.8, 23.4, 21.3, 21.1, 21.0, 20.8. Procedure for the Coupling between 19 and KLH or HAS. A solution of **19** (10 mg), KLH or HSA (10 mg), and $NaBH_3CN$ (10 mg) in 0.1 M $NaHCO_3$ (0.3 mL, pH 7.5−8.0) was allowed to stand at rt in the dark for 4 days with occasional shaking. The reaction mixture was then purified by a Biogel A 0.5 column using 0.1 M phosphate buffered saline (PBS) (I = 0.1, pH =7.8) as the eluent. The fractions containing the glycoconjugates, positively characterized by both the bicinchoninic acid (BCA) assay for proteins and the Svennerholm method for sialic acid, were combined and dialyzed against distilled water for 2 d. It was then lyophilized to give the expected glycoconjugates **3** and **4** (ca. 10 mg) as white powders.

2-Pent-4-enamidoethyl 2-Phenylacetate (21). To a solution of *N*-(2-hydroxyethyl)-4-pentenamide (**20**, 0.3 g, 2.1 mmol) in pyridine (5 mL) were added phenylacetic anhydride (1.06 g, 4.2 mmol) and DMAP (25 mg, 0.21 mmol) at 0 °C. After stirring at rt overnight, the mixture was extracted with AcOEt, and the extract was washed with saturated $NaHCO_3$ aqueous solution and brine, dried over anhydrous Na_2SO_4, and concentrated under vacuum. The residue was purified by flash column chromatography (AcOEt/hexanes 1:2) to give **21** as oil (0.5 g, 92%). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 7.35−7.26 (m, 5 H, Ar), 5.81−5.73 (m, 1H, CH═), 5.62 (brs, 1 H, NH), 5.06−4.97 (m, 2H, ═CH_2), 4.16 (t, J = 6.0 Hz, 2H), 3.63 (s, 2H, PhCH_2), 3.47 (dd, J = 10.4 and 5.6 Hz, 2H), 2.29 (dd, J = 14.8 and 5.6 Hz, 2H), 2.16 (t, J = 7.2 Hz, 2H). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 172.5, 171.8, 137.1, 134.1, 129.4, 128.9, 127.5, 115.8, 63.8, 41.5, 38.8, 35.8, 29.6. Synthesis of Conjugate 6. To the stirred solution of **22** (10 mg, 0.036 mmol), *N*-hydroxysuccinimide (9.0 mg, 0.078 mmol), and DMAP (catalytic amount) in anhydrous CH_2Cl_2 (2 mL) was added DIC (9.9 mg, 0.078 mmol) at 0 °C. After the mixture was stirred at 0 °C for 2 h, it was concentrated under vacuum, and the residue was dissolved in anhydrous DMF (0.5 mL) and cooled to 0 °C. Then, a 0.1 mL solution of HSA (10 mg) in 50 mM carbonate buffer (pH 9.1) was added dropwise. After the mixture was stirred at 0 °C overnight, it was diluted with water and washed with AcOEt. The aqueous layer was dialyzed against H_2O and then lyophilized to give **6** as a white powder (9 mg).

Analysis of the Carbohydrate Loading Levels of Glycoconjugates 3 and 4 (*8*). The solution of an exactly weighed glycoconjugate (0.5 mg) in distilled water (1.0 mL) was mixed with the resorcinol reagent (2.0 mL). The mixture was heated in a boiling water for 30 min. It was cooled to rt, and to this mixture was added an extraction solution (1-butanol acetate and 1-butanol, 85:15 v/v, 3.0 mL). The mixture was shaken vigorously before it was allowed to stand still for ca. 10 min to allow the organic layer to separate well from the inorganic layer. The organic layer was transferred to a 1.0 cm cuvette, and its absorbance at 580 nm was determined by a UV−vis spectrometer, using a blank organic solution as the control. The sialic acid content of the glycoconjugate was determined against a calibration curve created with the standard NeuNPhAc solution analyzed under the same conditions. The carbohydrate loading of each glycoconjugate was calculated according to the following equation.

$$\text{sTnNPhAc loading (w/w \%)} = \frac{\text{sTnNPhAc content (mg) in sample}}{\text{weight of sample (mg)}} \times 100\% \quad (1)$$

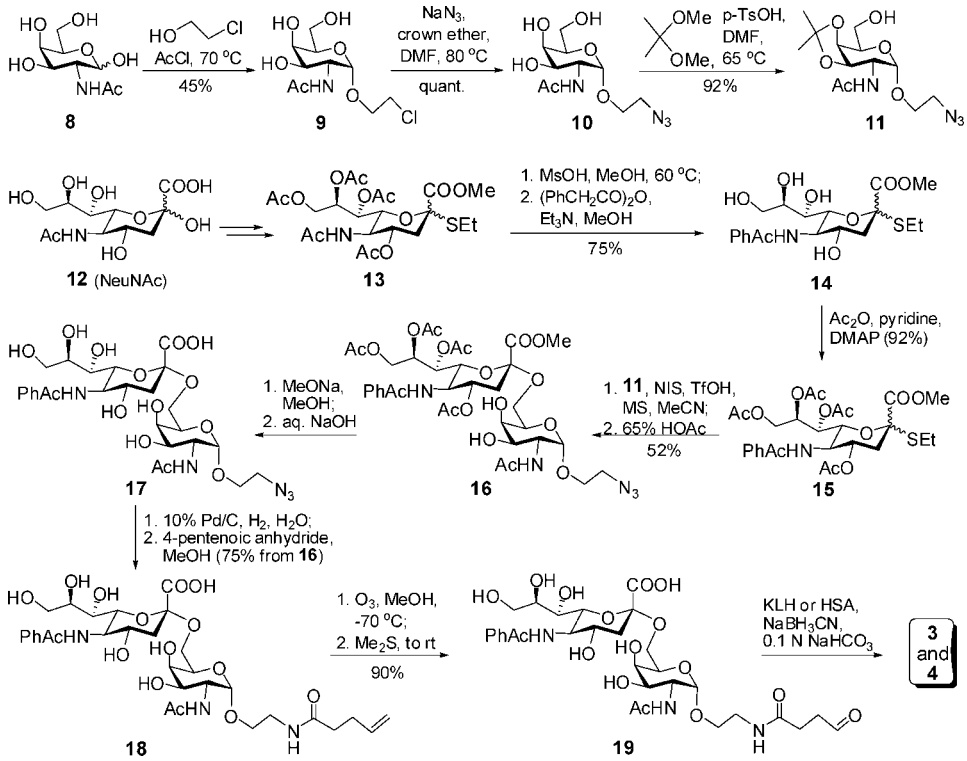
Immunization of Mouse. A total of 0.1 mL of an emulsion of sTnNPhAcα-KLH **3** containing 2 μg of sTnNPhAc and Titermax Gold adjuvant (Sigma) was intramuscularly injected to each of 5 female C57BL/6 mice at the age of 6−8 weeks (Jackson Laboratories, Bar Harbor, ME) on day 0, day 14, day 21, and day 28, respectively. The mice were bled on day −1 prior to the initial immunization and on day 27 and day 35 after immunization. Blood samples of 5 mice collected on each date were pooled and then clotted to obtain serum, which was stored at −80 °C before use.

ELISA. ELISA plates were incubated with a 100 μL solution of sTnNPhAcα-HSA (**4**, 2 μg/mL), or other HSA conjugates including **2**, **5**, **6**, and **7**, in the coating buffer (0.1 M bicarbonate, pH 9.6) at 4 °C overnight, which was followed by washing 3 times with PBS buffer containing 0.05% Tween-20. Pooled antisera diluted 1:300 to 1:72900 in serial half-log dilutions in PBS buffer containing 0.02% sodium azide (100 μL/well) were added in the coated ELISA plates, and the plates were incubated at 4 °C overnight. The plates were washed again with PBS buffer and then incubated with alkaline phosphatase linked goat antimouse kappa, IgM, or IgG2a antibody (1:1000 dilution) or with alkaline phosphatase linked antimouse IgG1 or IgG3 antibody (1:2000 dilution) for 1 h at rt. Finally, the plates were washed with PBS buffer and developed with 100 μL of PNPP solution (1.67 mg/mL in PNPP buffer) for 30 min at rt for colorimetric readout using a plate reader at 405 nm wavelength. For titer analysis, the OD values were plotted against dilution numbers, and a best-fit line was obtained. The equation of this line was used to calculate the dilution number at which an OD value of 0.5 was achieved, and this dilution number gives the antibody titer.

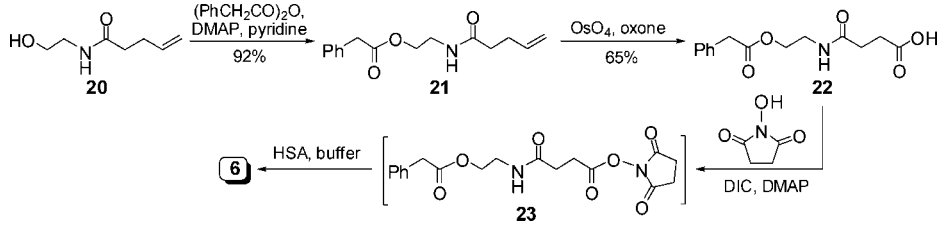
RESULTS AND DISCUSSION

The synthesis of sTnNPhAc, as well as its protein conjugates **3** and **4**, is shown in Scheme 2. First, a new and short route was developed to prepare glycosyl acceptor **11** from *N*-acetylgalactosamine **8**. Treating **8** with 2-chloroethanol in the presence of a catalytic amount of acetyl chloride produced 2-chloroethyl glycoside **9** (*28*), of which the anomeric α-configuration was affirmed by ^{1}H NMR ($J_{1,2}$ = 3.2 Hz). The chlorine atom in **9** was then substituted by an azido group after reacting with sodium azide at 80 °C in the presence of monobenzo-15-crown-5 to afford **10** in a quantitative yield. The reaction progress was monitored by ^{13}C NMR, since on TLC the R_f values of **9** and **10** were similar, but their ^{13}C NMR spectra were very different. The chemical shift of the carbon

Scheme 2



Scheme 3



linked to the azido group in **10** was 50.6, while the same carbon in **9** appeared at δ 43.8. Finally, the 3,4-hydroxyl groups in **10** were selectively protected as acetonide under acidic conditions to give a high yield (92%) of **11**.

For the synthesis of sTn antigen and related derivatives, the most difficult step is probably the sialylation reaction. In our previous synthesis of sTn derivatives (*7*), Boons method (*29*) was used to obtain good yields and stereoselectivity for α-sialosides. In the present work, we planned to directly use *N*-phenylacetylthiosialoside **15** as a glycosyl donor with the hope of saving a few synthetic steps. Thus, after *N*-acetyl sialic acid (NeuNAc, **12**) was transformed into **13** by an established procedure (*7*), its *N*-acetyl group was replaced with a phenylacetyl group in two steps including deacetylation under acidic conditions to remove both *O*- and *N*-acetyl groups and then selective phenylacetylation of the free amino group. Thereafter, the hydroxyl groups were protected again by acetyl groups to give **15** as a mixture of α- and β-anomers. Since both α and β anomers could act as glycosyl donors, the mixture was directly applied to the subsequent sialylation reaction.

The sialylation of **11** by **15** was performed in CH_3CN using *N*-iodosuccinamide (NIS) and triflic acid (TfOH) as promoters to give a clean reaction (judged by TLC). ^{1}H NMR of the product showed that it was a mixture of α- and β-anomers (3.3:1.0). The anomers were nearly inseparable by column chromatography. Fortunately, after the isopropylidene group was removed, the resultant diol products were readily separated to afford the desired α-disaccharide **16** (52%), as well as the β anomer (16%). The α-configuration of sialic acid in **16** was assigned on the basis of the unique downfield shift of the NMR signal of H-3′e (δ 2.54) compared to that of β-linked sialic acids (δ 2.42), which have been observed in all sialosides. Moreover, the strong correlation between C-1′ and H-3′a, but not between C-1′ and H-3′e, in the HMBC spectrum of **16** suggests that the dihedral angle between C-1′ and H-3′a is close to 180°, which further proves the α-configuration of the sialyl residue in **16**. Therefore, the sialylation reaction using **15** as a sialyl donor gave an excellent yield and good stereoselectivity. Finally, all protecting groups in **16** were removed after treatments first with a methanolic solution of NaOMe and then with a methanolic/aqueous solution of NaOH to afford **17**, which was directly used in the next step for conjugation to proteins.

The protein conjugates of **17** were prepared by an established procedure (*6*). First, the azido group in **17** was reduced to form a primary amine, which was regioselectively acylated for the introduction of a pentenoyl group. The product **18** was purified with a Biogel P2 column using distilled water as the eluent, and its identity and purity were confirmed by NMR and HR MS. Next, the C═C double bond in **18** was selectively oxidized by ozone in methanol to afford aldehyde **19** which was purified with a Biogel P2 column. The ^{1}H NMR spectra of **19** showed the hydrated aldehyde proton signals (δ 5.3−5.5) with the disappearance of signals of protons linked to C═C double bond. Finally, **19** was coupled to carrier proteins, KLH and HSA, by

reductive amination carried out in a 0.1 N $NaHCO_3$ buffer solution in the presence of $NaBH_3CN$. Aldehyde **19** was used in excess, and unreacted **19** was readily separated from the conjugate products on a Biogel A 0.5 column. Column fractions containing the desired glycoconjugates, which gave positive results in both sialic acid assays and protein assays, were combined and dialyzed against water. Lyophilization of the resultant aqueous solution afforded **3** and **4** as white fluffy solids. Glycoconjugate **7** used as a coating antigen in this study was prepared from the 2,3-linked disaccharide by a similar procedure.

The antigen loading levels of glycoconjugates **3**, **4**, and **7** were analyzed by measurements of their sialic acid contents as reported in the literature (*8*). It was found that they contained 4.0−5.3% (w/w) of sugars, respectively. These loading levels were similar to those obtained previously (*7*). The KLH conjugate **3** was used as a vaccine for immunization of animals, and the HSA conjugates **4** and **7** were employed as the coating antigen in immunological assays.

HSA conjugate **6**, which contains the linker and the phenylacetyl group as an ester, was prepared according to Scheme 3. Acylation of **20** by phenylacetic anhydride followed by oxidative cleavage of the C═C double bond in the resultant **21** using OsO_4 and oxone (*30*) afforded carboxylic acid **22**, which was then converted into an active ester **23** for conjugation with HSA. An attempt to purify **23** by silica gel column chromatography resulted in decomposition on the column; therefore, it was directly applied to the conjugation step without purification. Because **6** did not contain sialic acid, its hapten loading level was determined by MALDI TOF MS. The molecular weight of **6** was found to be 80 186. On the basis of the molecular weights of HSA (66 592) and **22** (262), we estimated that on average each HSA molecule was modified by 51 copies of the phenylacetylated linker in **6**.

The immunological property of **3** as a vaccine was examined in C57BL/6 mouse, and the animal immunizations and the enzyme-linked immunosorbent assays (ELISA) to evaluate antibody responses were performed according to the protocols described for the β-linked conjugate **1** (*7*). Thus, 0.1 mL of an emulsion of **3** (containing 2 μg of carbohydrate antigen) and Titermax Gold adjuvant were injected to each of a group of 5 mice intramuscularly on days 0, 14, 21, and 28, respectively. These mice were bled three times on day −1, day 27, and day 35, respectively, prior to and after immunization. Blood samples of all 5 mice collected on each date were pooled for the preparation of antisera, and each serum would give a mean antibody concentration. The titers of total antibody and individual antibody isotypes including IgM, IgG1, IgG2a, and IgG3 of the antisera were assessed by ELISA. The antibody titer is the serum dilution number at which the optical density (OD) of an ELISA experiment reaches 0.5. Consequently, the ELISA OD values of each serum were plotted against serum dilution numbers, and the best-fit line was obtained for the calculation of antibody titer. sTnNPhAcα-HSA **4** was used as the capture antigen to coat plates in ELISA for the detection of sTnNPhAc-reactive antibodies, and the plate-bound antibodies were analyzed by various antiantibodies (*7*). The use of HSA conjugate as the capture antigen in ELISA allowed us to eliminate any interference potentially caused by KLH and detect antibodies specific for sTnNPhAc or the linker. Similarly, HSA conjugates of other antigens were employed to detect antibodies reactive to the specific antigen.

Figure 2 shows the observed total antibody and IgM, IgG1, IgG2a, and IgG3 antibody titers of the obtained sera. Day −1 serum did not show any binding to **4**, while day 27 and day 35 antisera both displayed high total antibody titers, with the latter higher than the former, suggesting a progressive immune response to **3** produced in animals. Detailed analysis of the

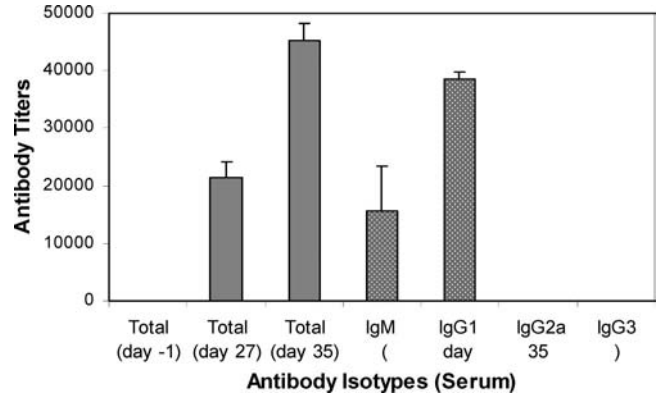


Figure 2. Total antibody titers of day −1, day 27, and day 35 sera and IgM, IgG1, IgG2a, and IgG3 antibody titers of day 35 serum determine by ELISA with **4** as the coating antigen. All antibody titers were obtained with pooled sera of five replicate animals.

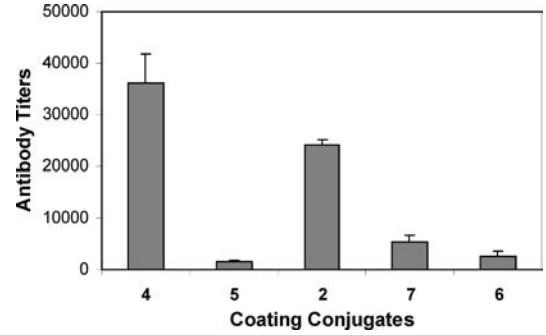

Figure 3. Titers of total antibody reactive to sTnNPhAcα, sTn, sTnNPhAcβ, NeuNPhAcα2,3GalNAc, and PhAc/linker, respectively, in the pooled day 35 serum derived from five replicate mice inoculated with sTnNPhAcα-KLH **3**. For ELISA, after the plates were coated with **4**, **5**, **2**, **7**, and **6**, respectively, they were treated with the antiserum, and the antibodies bound to the plates were then analyzed.

antibody isotypes revealed that **3** provoked mainly IgG1 antibody, which indicates a strong T cell dependent immune response. As usual, IgM antibody as the first line of antibody response to foreign antigens was also observed. These results were very similar to those derived from the β-linked conjugate vaccine **1** (*7*). It is apparent that the unnatural sTn derivative sTnNPhAc, whether it is α- or β-linked to a carrier protein, could form functional vaccines that elicited strong T cell dependent immunity useful for the treatment of cancer.

We also investigated the reactivity of the antiserum obtained with sTnNPhAcα-KLH **3** to natural sTn, sTnNPhAcβ, and NeuNPhAcα(2,3)GalNAcα, the linker between the antigen and protein, and isolated phenylacetyl functionality by means of ELISA, and the results are depicted in Figure 3. In these studies, ELISA plates were first coated with sTnNPhAcα-HSA **4**, sTn-HSA **5**, sTnNPhAcβ-HSA **2**, NeuNPhAcα(2,3)GalNAcα-HSA **7**, and PhAc/linker-HSA **6**, respectively, and then treated with the day 35 antiserum described above. It was demonstrated that the antiserum showed very strong binding to **2**, with a titer only slightly lower than that of **4**, indicating that the sTnNPhAcα-elicited antibodies could hardly differentiate the reducing end anomeric configurations of the capture antigens in ELISA. On the other hand, the antiserum produced a very low antibody titer with **7**-coated plate and did not exhibit major cross-reactivity with **5**- and **6**-coated plates. The significantly lower reactivity of the antiserum to **7** than to **4** suggest that the majority of antibodies raised by the glycoconjugate vaccine were specific to the whole antigen, sTnNPhAc, rather than to its partial structures such as NeuNPhAc and the phenylacetyl group or to the linker, as glycoconjugates **4** and **7** are only different in terms

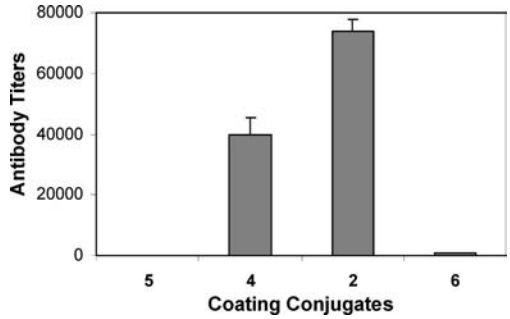

Figure 4. Titers of total antibody reactive to sTn, sTnNPhAcα, sTnNPhAcβ, and PhAc/linker, respectively, in the pooled serum derived from five replicate mice inoculated with sTnNPhAcβ -KLH **1**. For ELISA, after the plates were coated with **5**, **4**, **2**, and **6**, respectively, they were treated with the antiserum, and the antibodies bound to the plates were then analyzed.

of their inner glycosidic linkage, α(2,6)- vs α(2,3)-linkage, while they showed very different reactivity to the antiserum. The extremely low reactivity of the antiserum to sTn-HSA **5**, which differs from **4** only in the acyl group linked to the sialic acid 5-*N*-position, further proves that the **3**-induced immune response was specific to sTnNPhAc. Meanwhile, because **5** contains the same linker, its low reactivity to the antiserum further proves that no significant level of antibodies against the linker was induced. Moreover, the low reactivity of the antiserum to **6** also suggests that the antiserum did not contain a significant level of antibodies against the linker or the phenylacetyl group in a slightly different form, namely, as an ester.

We have also examined the reactivity of the antiserum obtained with sTnNPhAcβ-KLH **1** (*7*) to natural sTn, α-linked sTnNPhAc, the linker, and the isolated phenylacetyl functionality. For ELISA, again, the plates were first coated with sTn-HSA **5**, sTnNPhAcα-HSA **4**, sTnNPhAcβ-HSA **2**, and PhAc/linker-HSA **6**, respectively, and then treated with the anti-sTnNPhAcβ serum. As shown in Figure 4, the anti-sTnNPhAcβ serum had very strong binding to both **4**- and **2**-coated plates, but only a very low antibody titer was observed with **6**-coated plate and no cross-reactivity was detected with **5**-coated plate. These results further support the conclusions derived from the experiments described above.

In summary, a new and highly efficient method was developed for the synthesis of sTnNPhAc antigen and its α-linked protein conjugates. Immunological studies of sTnNPhAcα-KLH in mice have shown that it could provoke a strong and robust T cell dependent immune response, and the results were very similar to those previously obtained with sTnNPhAcβ-KLH (*7*). Moreover, the antisera derived from sTnNPhAcα- and sTnNPhAcβ-KLH-inoculated mice showed very little difference in reacting with sTnNPhAcα- and sTnNPhAcβ-coated plates in ELISA experiments, while the antisera did not show significant binding to natural sTn, NeuNPhAcα(2,3)GalNAc—an α(2,3)-linked analogue of sTnNPhAc, or to the free phenylacetyl functionality and the linker. These results, together with the results from our previous studies (*7*, *8*), led us to conclude that sTnNPhAc can indeed elicit a specific immune response and the elicited immune response recognize the whole antigen instead of merely the unnatural functionality or other partial structures of sTnNPhAc. More interestingly, it seems that the reducing end configuration of sTnNPhAc or its unnatural linkage to conjugate proteins had very little or no influence on its immunological identity or on the recognition of sTnNPhAc by the provoked antibodies. These results have proven the designing principles of glycoconjugate vaccines that have carbohydrate antigens coupled to carrier proteins via artificial linkages, which is very important for the understanding of the functions of carbohydrate-based vaccines and for future design of novel glycoconjugate vaccines. They can also help to explain why an unnatural GM3 analogue-provoked antibody was specifically cytotoxic to cancer cells that were metabolically engineered to express the same GM3 analogue (*26*), but not to normal cells, though normal cells could also use the engineering precursor to express unnatural sialic acids or even a low level of the unnatural GM3 analogue. The results have further demonstrated that the new linker does not have any obvious influence on the immunological properties of the resultant glycoconjugates and that the linker does not provoke any immune response. Therefore, this linker and the associated coupling strategy can be safely employed in the development of glycoconjugate cancer vaccines. The conclusions of this work should be of general significance in the field of conjugate vaccine research.

ACKNOWLEDGMENT

This work was financially supported by an NIH/NCI grant (R01 CA95142). Ms. Admira Bosnjakovic provided the disaccharide used in the synthesis of **7**. We thank Dr. B. Shay and Dr. L. Hryhorczuk for MS measurements, and Dr. B. Ksebati for some NMR measurements.

Received April 15, 2008; Revised Manuscript Received August 11, 2008

Nitroxide-based electron paramagnetic resonance (EPR) imaging agents are useful quantitative probes of O_2 concentration in vivo in real time. Lipophilic, labile alkanoyloxymethyl esters of nitroxides can cross the blood−brain barrier, and after hydrolysis, the corresponding anionic nitroxide is intracellularly entrapped at levels sufficient to permit O_2 measurements. The utility of nitroxides as EPR imaging agents depends critically on their ability to accumulate in the brain to high levels. In this study, we systematically investigated the relationship between the structure of the alkanoyl moiety and the ability of the corresponding labile ester to deliver nitroxide intracellularly. We demonstrate, in a cultured cell model, that for nitroxide labile esters with unbranched alkanoyl chains, increasing the chain length improves intracellular loading. Moreover, by studying an isomeric series of labile esters, we conclude that branching of the alkanoyl chain drastically reduces intracellular loading. These structural insights improve our general ability to use labile esters to deliver carboxylates intracellularly, and suggest a strategy for enhancing delivery of nitroxide imaging agents across the blood−brain barrier in a living animal.

INTRODUCTION

Molecular oxygen is fundamental to many aspects of brain physiology. For example, in neurons, it is essential for the synthesis and catabolism of neurotransmitters such as dopamine, norepinephrine, and serotonin. Importantly, diverse pathophysiologies, including stroke, drug abuse, and neurodegenerative disorders such as Alzheimer's and Parkinson's diseases, are associated with acute or chronic alterations in brain O_2 concentration. In vivo measurement of O_2 in the brain in real time is not a trivial task. Blood oxygen level dependent (BOLD) MR imaging is only capable of qualitative O_2 measurements in vivo (*1*−*3*). Therefore, an alternative, minimally invasive imaging method for *quantitation* of O_2 in the living brain is highly desirable for pathophysiological studies.

Molecular oxygen, being paramagnetic, broadens the electron paramagnetic resonance (EPR) spectral lines of other paramagnetic species, such as nitroxides or trityl radicals. Changes in EPR spectral line width for these compounds have been used to measure O_2 concentrations in homogeneous solutions (*2*, *4*). The development of very-low-frequency EPR spectroscopy and imaging (*2*) along with suitable imaging probes makes it feasible to quantitate local O_2 concentrations in animals in real time. The concentration of O_2 in the vasculature of tumors has been successfully measured by EPR imaging using trityl radicals (*2*). Because of their large size and ionic charge, trityls cannot cross the blood−brain barrier or be intracellularly localized. Therefore, trityl radicals are unsuitable for O_2 measurements in the brain. Like trityls, suitably designed nitroxides are relatively resistant to bioreduction, but have the advantages of chemical flexibility and ease of chemical synthesis. Moreover, nitroxides are attractive probes for O_2 imaging in the brain because they can be prepared as small labile esters that can cross the blood−brain barrier to enter brain tissue.

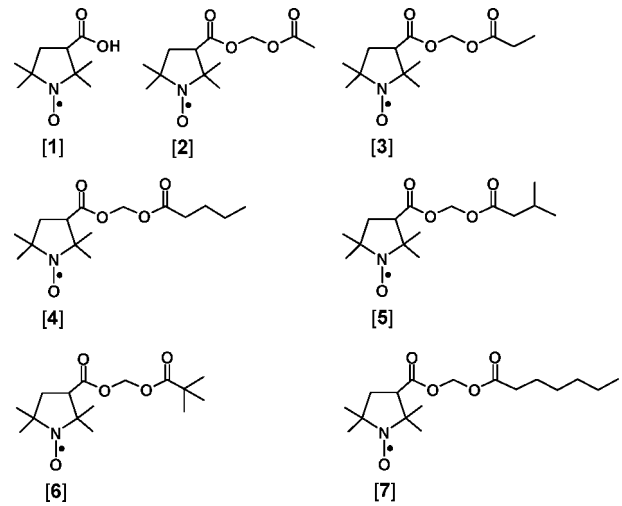

Figure 1. 3-Carboxy-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl [**1**] and its labile ester derivatives characterized in this study.

Previously, we demonstrated that the lipophilic labile ester, 3-acetoxymethoxycarbonyl-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl [**2**] (Figure 1), can cross the cell membrane and enter the cytosol, where it is hydrolyzed by intracellular esterases to yield membrane-impermeant 3-carboxy-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl [**1**], which, being anionic at physiologic pH, becomes trapped intracellularly (*5*, *6*) (Scheme 1). In vivo, **2** is also able cross the blood−brain barrier to enter brain tissue, where it is hydrolyzed to **1**, making local O_2 measurements possible (*4*).

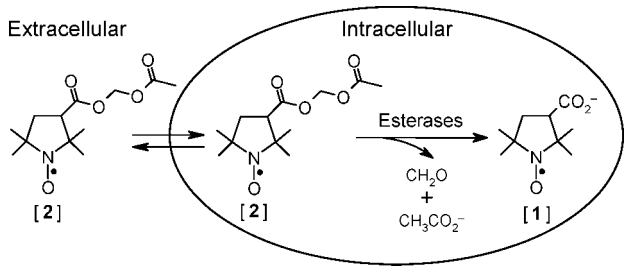
Scheme 1. Esterase-Assisted Intracellular Accumulation of Nitroxide 1



Although we have shown that nitroxide **2** is a usable pro-imaging agent (*4*−*6*), the potential utility of nitroxides as EPR imaging agents can be maximized by entrapping the highest concentrations of nitroxide **1** in the brain. We reasoned that increasing the lipophilicity of the labile ester pro-imaging agents would enhance their ability to cross biological membranes, and thus result in higher levels of trapped nitroxide **1**. In the present study, we synthesized a family of labile 3-alkanoyloxymethoxycarbonyl nitroxide esters that can be hydrolyzed to nitroxide **1** (Figure 1). Using our previous in vitro cell model (*5, 6*), we examined the ability of cells to accumulate nitroxide **1** when incubated with the different labile ester pro-imaging agents.

EXPERIMENTAL PROCEDURES

General Materials and Methods. Reagents and solvents from commercial vendors were used without further purification. Reagents were obtained from Aldrich Chemical Co. (Milwaukee, WI), and solvents were from VWR (West Chester, PA). Silica gel (230−400 mesh) and TLC plates (Silica Gel 60 F254) were from EMD Chemicals Inc. (Gibbstown, NJ). Cell culture media and biochemicals were from Invitrogen Corp. (Carlsbad, CA). 3-Carboxy-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl [**1**] was prepared as described by Rozantsev (*7*). 3-Acetoxymethoxycarbonyl-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl [**2**] was prepared as previously described (*6*). IR spectra were recorded on an FT-IR spectrometer (model 1600, Perkin-Elmer, Norwalk, CT) in $CHCl_3$. Mass spectrometric analysis was performed by the Mass Spectrometry Facility in the Department of Chemistry and Biochemistry at the University of Maryland, College Park. Elemental analyses were performed by Atlantic Microlab, Inc. (Norcross, GA). *Origin 8.0* software (OriginLab Corp., Northampton, MA) was used for data analysis. Unless otherwise indicated, standard deviations are reported for measurements.

Synthesis of 3-(2,2-Dimethylpropanoyl)oxycarbonyl-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl [6]. To a solution of nitroxide [**1**] (0.25 g, 1.3 mmol) in DMSO (2 mL) was added K_2CO_3 (0.37 g, 2.7 mmol). After the reaction mixture was stirred at room temperature for 5 min, chloromethyl pivalate (0.2 g, 0.19 mL, 1.4 mmol) was added. Stirring was continued at room temperature for 3 h before the mixture was diluted with CH_2Cl_2 (50 mL) and brine (100 mL). The organic layer was dried over anhydrous $MgSO_4$ and evaporated under high vacuum to remove traces of DMSO. The resulting crude product was purified by chromatography on silica gel; elution with 1% (v/v) acetone in $CHCl_3$ afforded compound [**6**] (0.29 g, 75% yield). IR ($CHCl_3$): 1753 cm^{-1} (broad ester peak). Anal. Calcd for $C_{15}H_{26}NO_5$: C, 59.98; H, 8.73; N, 4.66 Found: C, 59.90; H, 8.84; N, 4.53.

Synthesis of 3-Chloromethoxycarbonyl-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl [8]. This compound was prepared following the general procedure of Harada et al. (*8*). A mixture of CH_2Cl_2 (20 mL) and 20 mL of aqueous solution containing 3-carboxy-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl [**1**] (0.5 g, 2.7 mmol), $NaHCO_3$ (0.9 g, 10.8 mmol), and tetrabutylammonium bisulfate (91 mg, 0.27 mmol) was stirred for 10 min at room temperature before addition of chloromethyl chlorosulfate (0.54 g, 0.33 mL, 3.3 mmol). The reaction mixture was vigorously stirred at room temperature for 2 h, during which the yellow color of the nitroxide moved from the aqueous phase into the organic phase. The CH_2Cl_2 phase was separated, washed with brine (100 mL), dried over anhydrous Na_2SO_4, filtered, and evaporated under reduced pressure to yield compound [**8**] (0.54 g, 85% yield). TLC (silica gel, 2:1 (v/v) hexane/EtOAc) showed only one spot. The product was used in subsequent reactions without further purification.

Synthesis of 3-Pentanoylmethoxycarbonyl-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl [4]. A mixture of chloromethyl ester [**8**] (0.75 g, 3.2 mmol), K_2CO_3 (0.88 g, 6.4 mmol), and DMSO (2 mL) was stirred at room temperature for 5 min before addition of pentanoic acid (0.33 g, 0.34 mL, 3.2 mmol) and a few crystals of NaI. The reaction mixture was stirred at room temperature overnight and then diluted with CH_2Cl_2 (50 mL) and brine (100 mL). The organic phase was dried over anhydrous $MgSO_4$, filtered, and evaporated under high vacuum to remove traces of DMSO. The resulting crude product was purified on silica gel (7:3 (v/v) hexane/EtOAc) to give compound [**4**] (0.76 g, 80% yield). IR ($CHCl_3$): 1753 cm^{-1} (broad ester peak). Anal. Calcd for $C_{15}H_{26}NO_5$: C, 59.98; H, 8.73; N, 4.66. Found: C, 59.94; H, 8.83; N, 4.72.

Synthesis of 3-Propanoylmethyloxycarbonyl-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl [3]. This nitroxide was synthesized using propionic acid in the procedure for nitroxide [**4**]; the yield was 85%. IR ($CHCl_3$): 1752 cm^{-1} (broad ester peak). HR FAB MS (*m/z*): calculated for $C_{13}H_{22}NO_5$ (M^+) 272.1498; found, 272.1498. Anal. Calcd for $C_{13}H_{22}NO_5$: C, 57.33; H, 8.14; N, 5.14. Found: C, 57.46; H, 8.00; N, 5.10.

Synthesis of 3-(3-Methylbutanoyl)methoxycarbonyl-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl [5]. This nitroxide was synthesized using isovaleric acid in the procedure for nitroxide [**4**]; the yield was 74%. IR ($CHCl_3$): 1753 cm^{-1} (broad ester peak). Anal. Calcd for $C_{15}H_{26}NO_5$: C, 59.98; H, 8.73; N, 4.66. Found: C, 59.86; H, 8.81; N, 4.71.

Synthesis of 3-Heptanoylmethoxycarbonyl-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl [7]. This nitroxide was synthesized using heptanoic acid in the procedure for nitroxide [**4**]; the yield was 84%. IR ($CHCl_3$): 1753 cm^{-1} (broad ester peak). Anal. Calcd for $C_{15}H_{26}NO_5$: C, 62.17; H, 9.21; N, 4.26. Found: C, 62.33; H, 9.40; N, 4.22.

Determination of log *P* Values of Labile Esters. For each of the labile esters, the $\log_{10}$ of the octanol−water partition coefficient (log *P*) was determined. The log *P* values of ester **2**−**7** were evaluated from their capacity factors (k') as determined by HPLC on a reverse-phase column (Kromasil 100 RP-C8; Higgins Analytical, Mountain View, CA), with a mobile phase consisting of methanol and 0.02 M sodium phosphate buffer (pH 6.0) in a volume ratio of 7:3 (*9, 10*). The measurements were performed using isocratic elution (1 mL/min) on a Waters HPLC equipped with a diode-array detector (model 600; Milford, MA); the absorbance at 222 nm was used to construct the chromatograms. The capacity factor is defined as $k' = (t_R - t_0)/t_0$, where t_R and t_0 are, respectively, the elution times of the compound of interest and the void marker (thiourea). To generate a log *P* vs log k' calibration line, we used nine compounds with known log *P* values (in parentheses): caffeine (−0.07), 2-butanone (0.29), cycloheximide (0.55), benzyl alcohol (1.10), hydrocortisone (1.53), acetophenone (1.58), nitrobenzene (1.85), anisole (2.11), and naphthalene (3.37) (*11, 12*). The calibration line (Supporting Information Figure S1) was used to convert the log k' values of esters **2**−**7** into the corresponding log *P* values. Two to four replicates of each measurement were made.

Kinetics of Nitroxide Reduction by Ascorbate. The background buffer used for all kinetic measurements was a 9:1 (v/v) mixture of Dulbecco's phosphate buffered saline (Ca^{2+}- and Mg^{2+}-free) and absolute ethanol (final pH 7.3). Diethylenetriamine-*N*,*N*,*N*′,*N*′,*N*″-pentaacetic acid (DTPA; 0.5 mM) was added to the background buffer to sequester trace heavy metal ions. Nitroxide esters **2**−**7** were each dissolved in absolute ethanol to make a 20 mM stock solution. A 200 mM stock solution of crystalline L-ascorbic acid (Sigma Ultra grade) was prepared in deionized water (18.3 MΩ·cm resistivity) that had been sparged with argon gas for 30 min; the solution was maintained at 0 °C under N_2 atmosphere. Each experimental sample contained 50 μM nitroxide in background buffer. At time zero, 2 mM ascorbate was added to the sample, which was immediately transferred into a quartz flat cell and placed in the EPR spectrometer for spectroscopic measurement (details below). The amplitude of the downfield peak in the nitroxide EPR spectrum was monitored over 20−25 min. In all cases, peak amplitude as a function of time was fitted well by a single-exponential decay characterized by an apparent first-order rate constant, k_{red} (see Figure S2 in Supporting Information for typical data set and nonlinear curve fit). All experiments were conducted at 23 °C. Duplicate measurements were performed for each nitroxide labile ester; the sequence of measurements was randomized.

Cellular Loading of Nitroxides. Jurkat lymphocytes were cultured and loaded with nitroxides as previously described (*5*, *6*). Briefly, a suspension of 1.8×10^7 cells, at a density of 2×10^7 mL^{-1}, was incubated for 70 min at room temperature in serum-free RPMI 1640 medium containing the indicated concentration of the appropriate nitroxide labile ester and 0.0015% (w/v) of the surfactant Pluronic F-127 (BASF Corp, Florham Park, NJ). After incubation, cells were washed 3 times in Hanks' Balanced Salt Solution (HBSS), and resuspended in 400 μL HBSS. To lyse cells, 120 μM digitonin was added to each cell suspension, which was then sonicated for 1 min in a bath sonicator (model G112SPIG, Laboratory Supplies Company, Inc., Hicksville, NY). The lysate was assayed for nitroxide content by EPR spectroscopy. Each loading experiment was repeated two to four times.

EPR Spectroscopy. EPR spectra were recorded on an X-band spectrometer (model E-109, Varian Inc., Palo Alto, CA) at the following settings: microwave power, 20 mW; microwave frequency, 9.55 GHz; field set, 3335 G; modulation frequency, 1 kHz; modulation amplitude, 0.5 G; field sweep, 80 at 26.7 G min^{-1}. Where the amplitude of only the center spectral line was required, the sweep width was 8 G. EWWIN software (Scientific Software Solutions, Northville, MI) was used for spectrometer control and data acquisition. The nitroxide signal was measured as the peak-to-trough amplitude of the center line of the three-line spectrum.

RESULTS AND DISCUSSION

To adjust the lipophilicity of EPR pro-imaging agents systematically, we synthesized a series of alkanoyloxymethyl esters of **1** in which the hydrophobicity and steric bulk of the alkanoyl moiety was varied (Figure 1). Compound **6** was synthesized through the procedure developed for **2** (*6*), with commercially available chloromethyl pivalate used instead of bromomethyl acetate as the alkylating agent to esterify nitroxide **1** (Scheme 2A). However, for compounds **3**, **4**, **5**, and **7**, it was simpler to prepare the chloromethyl ester **8**, which could undergo reaction with a series of inexpensive carboxylic acids to yield the corresponding labile esters (Scheme 2B).

Previously, we had shown that compound **2** is relatively resistant to bioreduction (*5*, *6*). The new compounds **3**−**7**, bearing different alkanoyloxymethyl ester functions but the identical nitroxide moiety as **2**, are expected to be similar to compound **2** in their resistance to reduction. We assessed the susceptibility of all seven compounds used in this study to reduction by 2 mM ascorbate. The apparent first-order rate constants for reduction (k_{red}) of compounds **2**−**7** are given in Table 1. The differences in the values are not statistically significant. When all measurements were pooled, the mean value for compounds **2**−**7** is $k_{red} = 7.7\ (\pm 0.7) \times 10^{-2}\ min^{-1}$ ($n = 12$).

Scheme 2. Synthesis of Nitroxide Labile Esters

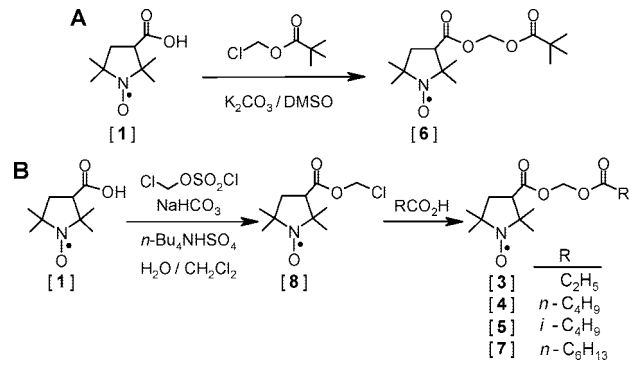


Table 1. Log *P* Values and Reduction Kinetics of Nitroxide Labile Esters 2−7

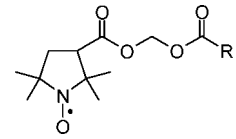

ester	R	log *P*	k_{red}[a] ($\times 10^{-2}$ min^{-1})
2	$-CH_3$	1.12	7.2
3	$-CH_2CH_3$	1.33	7.4
4	$-(CH_2)_3CH_3$	2.67	8.1
5	$-CH_2CH(CH_3)_2$	2.62	8.0
6	$-C(CH_3)_3$	2.60	8.0
7	$-(CH_2)_5CH_3$	3.54	7.6

[a] Apparent first-order rate constant for reduction by 2 mM ascorbate at pH 7.3, 23 °C. Each value is the average from two experiments.

To investigate the effectiveness of the various labile esters to deliver nitroxide **1** intracellularly, we incubated Jurkat lymphocytes with the esters over a range of concentrations and assayed the intracellular content of nitroxide **1**. We first compared the intracellular loading after incubation with esters **2**, **3**, **4**, and **7**—a family in which the length of the alkanoyl chain was systematically increased. The results are presented in Figure 2. It can be seen that, while increasing the alkanoyl chain length from 2 to 3 had a negligible effect on intracellular loading (compare results for esters **2** and **3**), increasing the chain length to 5 (ester **4**) resulted in a substantial enhancement of intracellular loading. A further increase of the chain length to 7 (ester **7**), however, brought no additional improvement in loading.

We next investigated the effect of branching in the alkanoyl chain in the labile ester on intracellular loading of nitroxide **1** by incubating the cells with the isomeric esters **4**, **5**, and **6**. The results in Figure 2 show that, while ester **4**, with an *n*-pentanoyl moiety, gave high intracellular levels of nitroxide **1**, esters **5** and **6**, with 3-methylbutanoyl (isovaleryl) and 2,2-dimethylpropanoyl (pivaloyl) moieties, respectively, gave very poor intracellular loading of nitroxide **1**. These findings indicate that increased branching in the alkanoyl chain drastically diminished the ability of the labile ester to deliver nitroxide **1** intracellularly.

Besides changing the steric bulk of the labile ester, increased branching in the alkanoyl chain is also expected to decrease the lipophilicity of the molecule. A commonly used measure

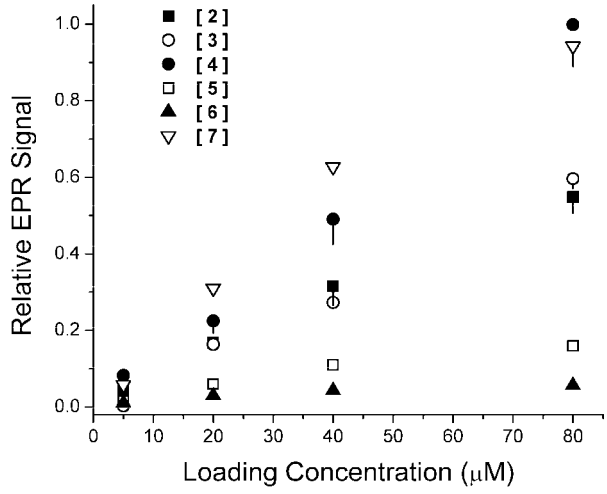

Figure 2. Intracellular loading of nitroxide **1** after Jurkat lymphocytes were incubated with various concentrations of the labile esters **2**−**7**. Error bars represent standard deviations; where not shown, the error bar is smaller than the symbol. For visual clarity, only down error bars are shown.

of lipophilicity is the $\log_{10}$ of the octanol−water partition coefficient, log *P*. The experimentally determined log *P* values for esters **2**−**7** (Table 1) show that lipophilicity does decrease with increased alkanoyl chain branching, but the effect is very slight. Thus, the isomeric esters **4**, **5**, and **6**, with primary, secondary, and tertiary alkanoyl chains, respectively, have log *P* values that decrease systematically but slightly, from 2.67 down to 2.60. Moreover, intracellular loading of the branched-chain esters **5** and **6** is much worse than that of straight-chain esters that are either less lipophilic (**2** and **3**) or more lipophilic (**7**). Therefore, the differences in lipophilicity cannot be invoked to explain differential intracellular loading. A reasonable inference is that intracellular esterases that hydrolyze alkanoyloxymethyl esters have a strong preference for straight over branched alkanoyl chains.

Having investigated the relationship between labile ester structure and the levels of intracellularly entrapped nitroxide **1**, we must investigate this relationship in vivo. Our cellular incubation model provided extremely promising data regarding the ability to load cells with nitroxides, but ultimate application of these compounds will depend on the ability of the lipophilic nitroxide esters to cross the blood−brain barrier. In anticipation of using the labile esters for EPR imaging of O_2 in living brain, studies are under way to determined the pharmacokinetics and pharmacodynamics of esters **3**, **4**, **5**, and **7**.

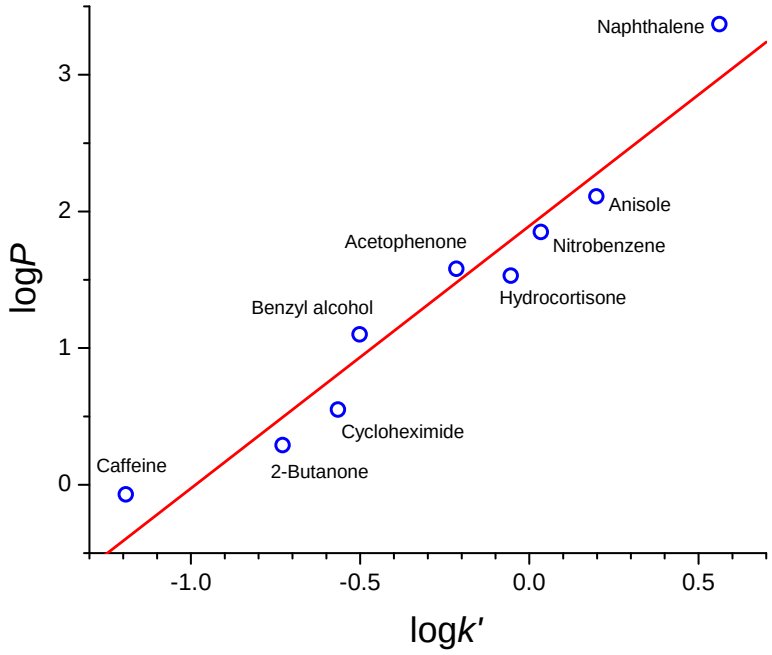

Figure S1. Standard calibration line of log*P* vs. log*k'*.

For each of nine standard compounds, the known log*P* value was plotted against the log*k'* value determined by the capacity factor method through HPLC on a C8 reverse-phase column (see Experimental Procedures for details). The red line is a linear least-squares fit to the data:

$$\log P = b + m \cdot \log k'$$

where $b = 1.89 \pm 0.10$ and $m = 1.92 \pm 0.18$.

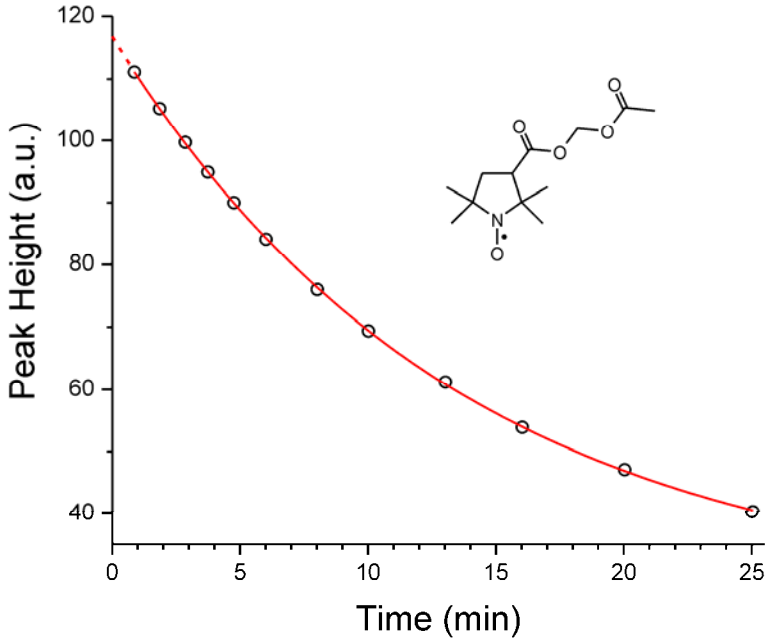

Figure S2. Kinetics of reduction of nitroxide labile ester [**2**] **by ascorbate.**

At time zero, 2 mM ascorbate was added to a solution of 50 μM nitroxide labile ester [**2**] and 0.5 mM DTPA in a 9:1 (v/v) mixture of Dulbecco's Phosphate Buffered Saline (Ca^{2+}- and Mg^{2+}-free) and absolute ethanol (final pH 7.3). The reaction mixture was transferred immediately to a flat quartz cell, and the amplitude of the downfield peak of the nitroxide spectrum was monitored over 25 min in an X-band EPR spectrometer (model E-109, Varian Associates, Palo Alto, CA). The amplitude of the downfield peak is plotted against time (circles). The data are well-fit by a single exponential decay (red curve) with an apparent first-order rate constant of $k_{red} = 7.4 \times 10^{-2}$ min^{-1}. Data from a replicate experiment performed ~1 hr later yielded an essentially identical result ($k_{app} = 7.1 \times 10^{-2}$ min^{-1}). All six compounds tested ([**2**] - [**7**]) showed similar kinetics of reduction by ascorbate—mean from all measurements: $k_{red} = 7.7 (\pm 0.7) \times 10^{-2}$ min^{-1} ($n = 12$).

Multifunctional Inorganic-Binding Beads Self-Assembled Inside Engineered Bacteria

Anika C. Jahns,[†] Richard G. Haverkamp,[‡] and Bernd H. A. Rehm*[,†]

Institute of Molecular Biosciences and Institute of Technology and Engineering, Massey University, Private Bag 11222, Palmerston North, New Zealand. Received May 16, 2008; Revised Manuscript Received July 23, 2008

Multifunctional shell−core nano/microbeads with a hydrophobic biopolymer core and a designed protein coat for selective binding of an inorganic substance and antibodies were self-assembled inside engineered bacteria. Hybrid genes were constructed to produce tailormade bead-coating proteins in the bacterium *Escherichia coli*. These fusion proteins contained a binding peptide for an inorganic material, the antibody binding ZZ domain, and a self-assembly promoting as well as biopolymer synthesizing enzyme. Production of these multidomain fusion proteins inside *E. coli* resulted in self-assembly of beads comprising a biopolyester core and displaying covalently bound binding sites for specific and selective binding of an inorganic substance and any antibody belonging to the immunoglobulin G class. Engineered beads were isolated and purified from the respective *E. coli* cells by standard cell disruption procedures. Bead morphology and the binding functionalities displayed at the bead surface were assessed by the enzyme-linked immunosorbent assay, transmission electron microscopy, elemental analysis, backscattering electron density, analytical density ultracentrifugation, and atomic force microscopy. These analyses showed that bacteria can be engineered to produce fusion proteins mediating self-assembly of spherical biopolymer beads with binding affinity to gold and/or silica and antibodies. Spherical structures of this type could conceivably serve as nano/microdevices for bioimaging in medical approaches where an antibody mediated targeted delivery of an inorganic contrast agent would be desired.

INTRODUCTION

Biological structures that specifically bind inorganics exert numerous potential biomedical applications. Therefore, the exploration of nature's structures for this purpose and the establishment of novel production methods is of great interest. In particular, beads (nano or microbeads) made of biological and inorganic materials are suitable for a variety of applications such as, e.g., diagnostics (*1, 2*), imaging (*3*), and drug delivery (*4*). In binding assays, it was demonstrated that nanobeads displaying an antibody at high density show a higher binding affinity than the antibody itself enhancing the sensitivity of a diagnostic assay (*5*). Molecular biomimetic approaches have been used to specifically coat biological nanostructures, such as, e.g., self-assembling virus beads, with various inorganics for applications in imaging, biosensing, laboratory methods, and electronics (*6, 7*). Genetically engineered proteins for inorganics (GEPI) have been obtained using combinatorial approaches including phage display or cell surface display in order to select peptides binding inorganics (*8*). Peptides were isolated specifically binding (noble) metals, semiconducting oxides, and other technological compounds (*7*−*11*). This ultimately enabled the use of biological structures with protein components as templates for the defined nanoscale deposition of inorganics as well as control of geometrical shapes and sizes of inorganic nanobeads. This was achieved by engineering of proteins contributing to these structures enabling display of GEPIs for binding of inorganics (*7*−*11*). This resembles the morphogenesis in hard tissues (such as bones, dental tissues, mollusk shells, spicules) which is controlled by inorganic-binding proteins.

In this study, microbial polymer inclusions (50−300 nm) were conceived as biological template structures (*12*−*14*). These spherical inclusions are self-assembled inside the bacterial cell mediated by a single protein, the polyester synthase (PhaC) (*15, 16*). The polymer inclusions serve as reserve materials and comprise a hydrophobic polyester core surrounded by at least the PhaC protein (*17*). This natural polyester is composed of (*R*)-3-hydroxy fatty acids. Interestingly, PhaC catalyzes the core polymer synthesis as well as is required for the self-assembly. Moreover, PhaC has been found to remain covalently attached to the polymer core (*18, 19*). Further structural proteins (e.g., PhaP) have been found to specifically hydrophobically interact with the polymer core, but are not required for self-assembly (*15, 20*−*22*). Protein engineering of the synthase or structural proteins demonstrated that various functional proteins can be displayed at the polymer inclusions surface and that these inclusions can be stably maintained outside the cell as beads (*18, 23*−*28*). Here, it was demonstrated that genetic fusions of GEPIs to PhaC or previously engineered PhaC enabled production of beads that bind inorganic and biological molecules simultaneously. In this study, the antibody binding domain of protein A from *Staphylococcus aureus* was used as an additional binding functionality, which ultimately enabled the production of spherical nano/microbeads that could specifically bind not only any specific antibody but also an inorganic as suitable contrast agent applicable for, e.g., bioimaging approaches (*29*) (Figure 1). Moreover, the use of engineered *E. coli* as a cell factory to produce functionalized beads in one step provides an efficient and economic production strategy.

EXPERIMENTAL PROCEDURES

Bacterial Strains, Plasmids, Oligonucleotides, and DNA Constructs. Bacterial strains, plasmids, and oligonucleotides used in this study are listed in Table 1. *E. coli* XL1-Blue was grown at 37 °C, BL21(DE3) at 25 °C. When required, ampicillin

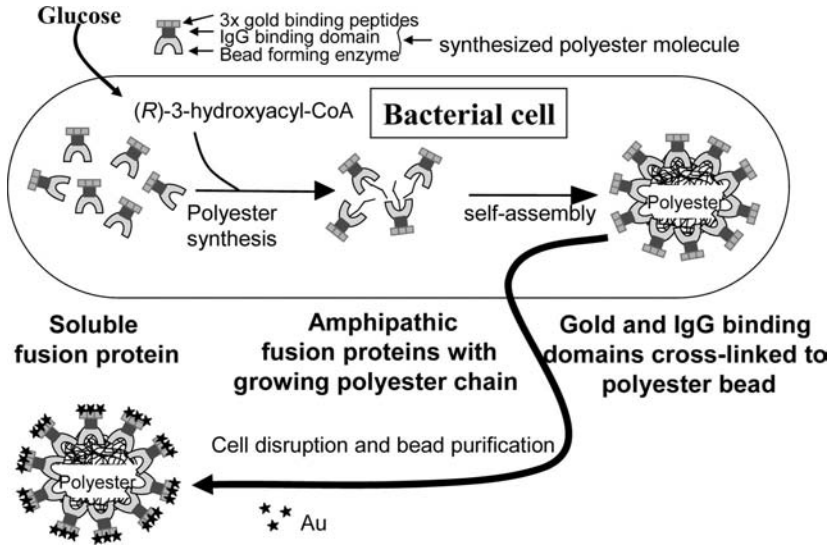

Figure 1. Schematic overview of polymer bead assembly.

75 μg/mL, tetracycline 12.5 μg/mL, or chloramphenicol 50 μg/mL were added. All chemicals were purchased from Sigma-Aldrich (St. Louis, MO).

General cloning procedures and isolation of DNA were performed as described elsewhere (*30*). DNA primers, deoxynucleoside triphosphate, T4 DNA ligase, and Taq polymerase were purchased from Invitrogen (CA, USA). DNA sequences of new plasmid constructs were confirmed by DNA sequencing according to the chain termination method using an automatic sequencer (Applied Biosystems, 3730 DNA Analyzer).

Gold-Binding Beads. To enable production of fusion proteins mediating production of polymer beads selectively binding gold, the GBP1 (*31*) encoding DNA sequence was inserted as a DNA fragment, composed of hybridized oligonucleotides GNI and GNII (Table 2), into the restriction enzyme sites *Xba*I/*Nde*I of plasmid pCWE. The resulting pCWE-GN-phaC contained the respective hybrid gene and was transformed into *E. coli* XL1-Blue harboring the plasmid pMCS69, which mediates synthesis of the polymer precursor required for bead production.A DNA sequence showing three repeats of the gold-binding peptide (*32*) was synthesized (DNA 2.0, Inc., CA, USA). The corresponding *Xba*I/*Sun*I fragment was inserted into plasmid pCWE, which was previously engineered to encode a pentaglycine linker and the ZZ domain of protein A both fused to the N terminus PhaC. The resulting plasmid pCWE-3xGN-G_5-ZZ-phaC was used to transform *E. coli* XL1Blue (pMCS69). To enable overproduction of the respective fusion protein, the corresponding hybrid gene was overexpressed under the control of the strong T7 promoter. Therefore, the hybrid genes were inserted into the *Xba*I/*Bam*HI site of vector pET-14b. The resulting plasmid pET-14b-3xGN-G_5-ZZ-phaC was used to transform *E. coli* BL21(DE3) harboring plasmid pMCS69.

Bead formation was assessed by analyzing the polyester constituting the bead core using gas chromatography−mass spectrometry as previously described (*16*). Moreover, beads formed inside the bacterial cell were stained with Nile red and observed using fluorescence microscopy as well as subjected to electron microscopy (*16*).

Silica-Binding Beads. To produce polymer beads with silica/antibody binding properties, the DNA sequence encoding the silica-binding peptide (*33*) encoding *Xba*I/*Nde*I DNA fragment, which was generated by hybridization of oligonucleotides SNI and SNII (Table 2), was ligated to the 5′ end of *phaC* in plasmid pCWE. Together with pMCS69, this construct led to bead formation in *E. coli* XL1Blue. To achieve overproduction of the respective fusion proteins at the bead surface and thereby enhance the binding density, hybrid genes encoding fusion proteins were expressed under control of the strong T7 promoter. Therefore, the 1838 bp *Xba*I/*Bam*HI fragment was inserted into the respective sites of plasmid pET-14b and then transformed into *E. coli* BL21(DE3) cells harboring the plasmid pMCS69. A hybrid gene similar to the hybrid gene encoding the extended gold-binding fusion protein was also constructed by using the oligonucleotides SN+I and SN+II (Table 2). This hybrid gene was inserted into plasmid pCWE which resulted in plasmid pCWE-SN-G_5-ZZ-phaC. The hybrid gene comprising the 2261 bp *Xba*I/*Bam*HI fragment was then subcloned into the respective sites of pET-14b to enable overexpression under T7 promoter control.

Multifunctional Beads. To synthesize polymer beads with gold, silica, and antibody binding capability, the SN-G_5-ZZ(−)phaC sequence was amplified by PCR using oligonucleotides 3′PhaC-*Blp*I and *Bam*HI-SN+ (Table 2). The PCR product was confirmed by DNA sequencing and ligated into *Bam*HI/*Blp*I site of plasmid pET-14b-3xGN-G_5-ZZ(−)phaC which resulted in plasmid pET-14b-3xGN-G_5-ZZ(−)phaC/SN-G_5-ZZ(−)phaC. This new plasmid was used to transform competent *E. coli* BL21(DE3) cells harboring pMCS69 and to mediate production of multifunctional beads.

Isolation of Polymer Beads. The polymer beads were isolated by harvesting respective cells using centrifugation for 20 min at 6000 × *g* and 4 °C. The sediment was washed and suspended in 3 volumes of 50 mM phosphate buffer (pH 7.5). Cells were passed through a French Press two times at 16 kpsi. The cell lysate (0.75 mL) was loaded onto a glycerol gradient (88% and 44% (v/v) glycerol in phosphate buffer). After ultracentrifugation for 2.5 h at 100 000 × *g* and 10 °C, beads could be isolated from a white layer above the 88% glycerol layer. The PHA beads were washed with 10 volumes phosphate buffer (50 mM, pH 7.5) and centrifuged at 100 000 × *g* for 60 min at 10 °C. The sediment containing the PHA beads was suspended in phosphate buffer and stored at 4 °C.

Gold-Binding Assay. The gold-binding was carried out at 20 °C in PKT buffer (10 mM KPO_4 (pH 7), 0.1 M KCl, 1% Triton X-100) with 250 μM $HAuCl_4$ and 200 μM sodium ascorbate according to Brown (*31*). For a 10 mL assay, a 1 mg/mL bead protein solution was used. The whole assay was incubated on a shaker until a pink color appeared, indicating the formation of colloidal gold. To let the gold bind to the peptides, the solution was further incubated. To wash the

unbound gold out of the sample, the assay was centrifuged at 4000 × *g* for 15 min. The resulting sediment was suspended in 1 mL PKT buffer and loaded on a sucrose gradient (2.25 M − 0 M, 0.25 M increments, sucrose in PKT buffer). This gradient was undergoing ultracentrifugation for approximately 16 h at 100 000 × *g*. The resulting layer at 2 or 2.25 M sucrose, consisting of beads and gold, was washed with PKT buffer and centrifuged in an ultracentrifuge for 1 h at 100 000 × *g*. The sediment was used for TEM analysis and AFM measurements.

Silica-Binding Assays. The silica-binding assay was performed at room temperature according to Dickerson et al. (*34*). 1 mg/mL bead protein was dissolved in 50 mM potassium phosphate buffer, pH 7.5. The silica solution was freshly prepared by dissolving tetramethyl orthosilicate (TMOS, Sigma-Aldrich, St. Louis, MO) in 1 mM HCl to a final concentration of 1 M. The silica solution was then added to the protein solution so that the final concentration of TMOS in the silica-binding assay was 0.1 M. This mixture was then incubated on a shaker for 10 min and centrifuged for 5 min at 13 000 rpm. The sediment was washed three times with 50 mM potassium

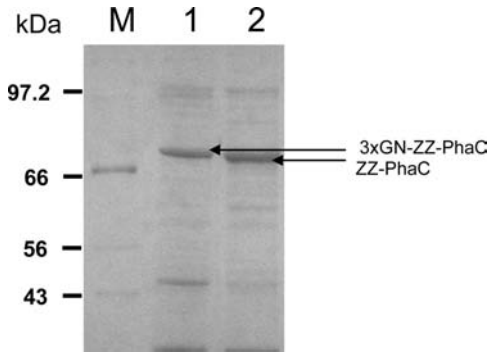

Figure 2. Protein profile of polymer beads displaying gold binding peptides. M, molecular mass standard (New England Biolabs, United Kingdom); Lane 1, polymer beads from *E. coli* BL21(DE3) (pET-14b-3xGN-G_5-ZZ(−)phaC); lane 2, polymer beads from *E. coli* BL21(DE3) (pET-14b-ZZ(−)phaC).

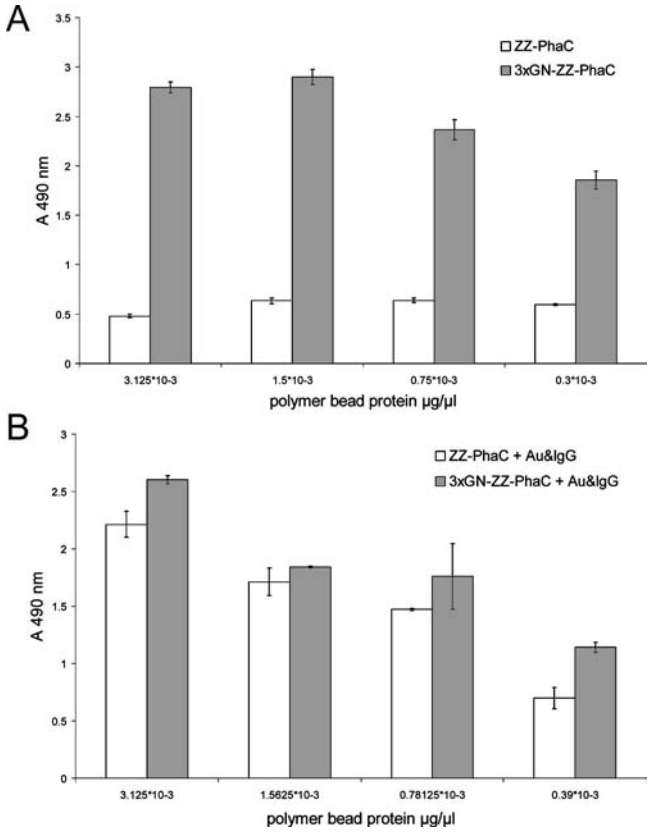

Figure 3. (A) Gold binding of various polymer beads assessed by ELISA. Polymer beads were isolated from *E. coli* BL21(DE3) harboring pET-14b-3xGN-G_5-ZZ(−)phaC (black columns) or pET-14b-ZZ(−)phaC (white columns). Streptavidin−HRP conjugate was used to detect bound 10 nm biotin−gold. Measurements were conducted in triplicates, the standard deviation is indicated. (B) Impact of gold binding on IgG binding of various polymer beads assessed by ELISA. Polymer beads were isolated from *E. coli* BL21(DE3) harboring pET-14b-3xGN-G_5-ZZ(−)phaC and incubated with gold followed by an incubation with human IgG (3xGN-ZZ-PhaC + Au&IgG, black columns). As controls, beads isolated from *E. coli* BL21(DE3) harboring pET-14b-ZZ(−)phaC were used and treated in the same way (gold incubation followed by human IgG incubation as ZZ-PhaC + Au&IgG, white columns). Goat polyclonal antihuman IgG-horseradish peroxidase conjugate was used for detection of bound human IgG. All measurements were conducted in triplicate; standard deviations are indicated.

phosphate buffer, pH 7.5, to remove unbound silica. To investigate the bead density changes due to silica binding, the washed sediments were suspended in 50 mM potassium phosphate buffer, pH 7.5, and separated using a sucrose gradient

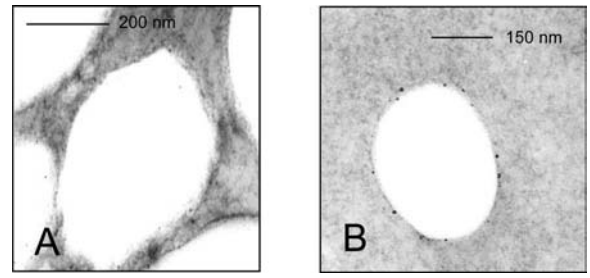

Figure 4. TEM images of polymer beads after incubation with colloidal gold. (A) Polymer beads displaying ZZ(−)phaC protein at the surface. (B) Polymer beads coated with the engineered protein 3xGN-G_5-ZZ(−)phaC mediating display of the gold-binding peptide.The pictures show slices through polymer beads embedded in BSA.

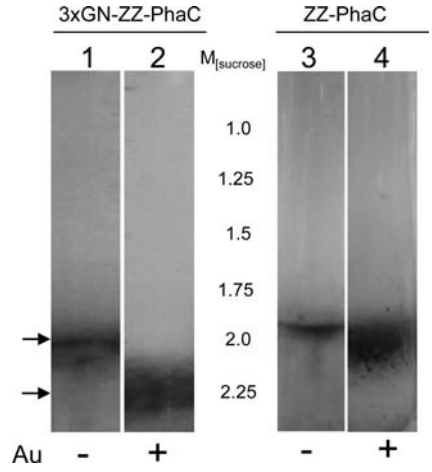

Figure 5. Gold binding to polymer beads demonstrated by density-dependent migration in a sucrose gradient using ultracentrifugation. Arrows indicate where the beads accumulated in the sucrose gradient after ultracentrifugation after incubation with 250 μM colloidal gold (+) and without (−). Lanes 1,2, polymer beads from *E. coli* BL21(DE3) (pET-14b-3xGN-G_5-ZZ(−)phaC); lanes 3,4, polymer beads from *E. coli* BL21(DE3) (pET-14b-ZZ(−)phaC.

(0−2.25 M sucrose in 0.25 M increments, sucrose in 50 mM potassium phosphate buffer, pH 7.5). These gradients underwent ultracentrifugation at 100 000 × *g* for 16 h at 10 °C. The resulting layers or sediments were washed in 50 mM potassium phosphate buffer, pH 7.5, and used for further investigations. In another silica binding assay, 0.5 mg/mL bead protein suspension was mixed with 0.003 g/mL SiO_2 (silica beads with a size range 1−5 μm) in potassium phosphate buffer and incubated on a shaker at room temperature for 4 h. The mixture was separated by sucrose gradient ultracentrifugation. The protein concentration of resulting layers and sediments was determined by Bradford (*35*). To qualitatively assess the binding of the engineered polymer beads to silica beads, fluorescence microscopy was used. For this purpose, the polymer beads were selectively stained with the hydrophobic fluorescent dye Nile red.

ELISA. For the enzyme-linked immunosorbent assay (ELISA), the wells of microtiter plates were coated with 100 μL of a polymer bead suspension (normalized to protein concentration, in a range from 0.05 μg/μL to 0.4 × 10^{-3} μg/μL) and incubated overnight at 4 °C. After being blocked with 3% (w/v) bovine serum albumin for 2 h, each well was incubated with 10 nm gold−biotin (Nanocs Inc., New York, USA) for 2 h followed by 1 h incubation with streptavidin−horseradish peroxidase conjugate (streptavidin-HRP; Sigma-Aldrich, St. Louis, MO). After each step, the wells were washed several times with phosphate-buffered saline containing 0.05% Tween 20. As substrate, 100 μL of an *o*-phenylenediamine solution (Abbott

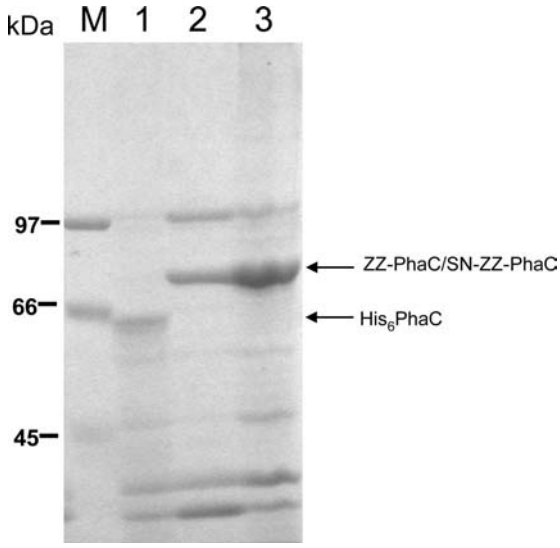

Figure 7. Protein profile of polymer beads displaying silica binding peptides. M, molecular mass standard (Amersham Biosciences, USA); lane 1, polymer beads from *E. coli* BL21(DE3) (pHAS); lane 2, polymer beads from *E. coli* BL21(DE3) (pET-14b-ZZ(−)phaC); lane 3, polymer beads from *E. coli* BL21(DE3) (pET-14b-SN-G_5-ZZ(−)phaC).

Diagnostics, IL, USA) was added to each well, and after 15 min, the reaction was stopped by adding 100 μL of 1 N H_2SO_4. The amount of substrate conversion was measured at a wavelength of 490 nm using a microtiter plate reader.

Protein Analysis. Bead protein profiles were routinely analyzed by sodium dodecyl sulfate (SDS)−polyacrylamide gel electrophoresis (PAGE) as described elsewhere (*36*). The gels were stained with Coomassie brilliant blue G250.

In order to identify proteins linked to the polymer beads, the bead proteins were separated by SDS-PAGE and protein bands of interest were cut off the gel. Proteins were subjected to MALDI-TOF mass spectrometry. Identification of tryptic peptides was performed by collision-induced dissociation tandem mass spectrometry and enabled identification of fusion proteins.

To identify N-terminally fused GEPIs, fusion proteins were subjected to N terminal sequencing using Edman degradation.

Microscopic Analysis. Atomic force microscopy imaging was performed on an Asylum Research MFP-3D instrument (Asylum Research, Santa Barbara, CA) in ac mode. All images were recorded in potassium phosphate buffer solution at a concentration of beads corresponding to 1−10 μg protein/mL.

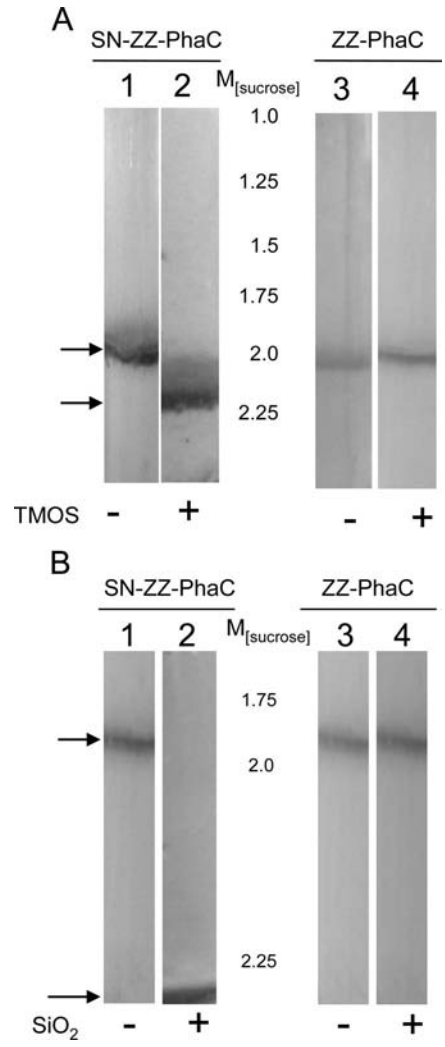

Figure 8. Silica binding to polymer beads demonstrated by density-dependent migration in a sucrose gradient using ultracentrifugation. (A) Images of tubes used for density assessment. Arrows indicate where the beads accumulated in the sucrose gradient after (+) and without (−) TMOS incubation. Lanes 1,2, polymer beads from *E. coli* BL21(DE3) (pET-14b-SN-G_5-ZZ(−)phaC); lanes 3,4, polymer beads from *E. coli* BL21(DE3) (pET-14b-ZZ(−)phaC). (B) Images of tubes used for density assessment. Arrows indicate the areas where the main part of the beads accumulated after SiO_2 binding (+) and without (−). Lanes 1,2, polymer beads from *E. coli* BL21(DE3) (pET-14b-SN-G_5-ZZ(−)phaC); lanes 3,4, polymer beads from *E. coli* BL21(DE3) (pET-14b-ZZ(−)phaC).

Higher bead concentrations were not used, as they resulted in scattering of the laser, which obscured the signal reflected from the cantilever and inhibited AFM operation. Approximately 100 μL of bead suspension was placed on a gold-coated mica substrate shortly before imaging. AFM cantilevers were either silicon Ultrasharp NSG11 (NT-MDT Co, Moscow, Russia) with force constants in the range 5−25 N/m and a tip radius around 10 nm, or silicon nitride TR400PSA (Olympus Corporation, Japan) with a force constant around 0.08 N/m and a tip radius <20 nm. Images of 512 × 512 points were collected at line scan frequencies of 1−8 Hz.

For transmission electron microscopy (TEM) analysis, cells or beads were prepared as described previously (*26*). Sections were stained and assessed using a Philips CM10 TEM. To visualize the gold binding, the beads were incubated with colloidal gold as described above in the gold-binding assay. Beads with bound colloidal gold or control beads not binding colloidal gold were then subjected to TEM sample preparation.

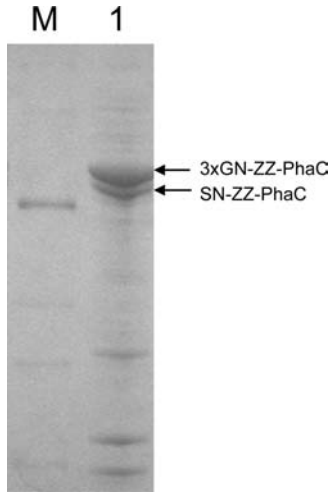

Figure 9. Protein profile of polymer beads displaying both binding activities (gold and silica). Lane M, molecular mass standard (New England Biolabs, U.K.); lane 1, polymer beads from *E. coli* BL21 (DE3) (pET-14b-3xGN-G_5-ZZ(−)phaC/SN-G_5-ZZ(−)phaC).

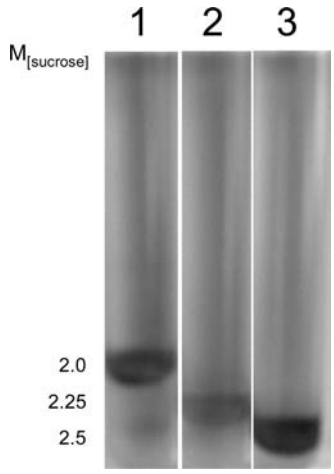

Figure 10. Different polymer beads were incubated with gold and silica and purified via ultracentrifugation of a sucrose gradient. Lane 1, pET-14b-ZZ(−)phaC; lane 2, pET-14b-3xGN-G_5-ZZ(−)phaC; lane 3, pET-14b-3xGN-G_5-ZZ(−)phaC/SN-G5-ZZ(−)phaC.

For elemental analysis, freeze-dried bead samples were mounted, using double-sided tape, on an aluminum specimen stub and then carbon-coated for EDS (energy dispersive spectrometry). Analysis was done using EDAX EDS system (EDAX, Mahwah, USA) in a FEI Quanta 200 SEM (scanning electron microscope; FEI, Eindhoven, The Netherlands). For imaging the gold in the samples, the BSED (back-scattered electron detection) mode was used.

RESULTS

Design and Production of Bifunctional Gold/Antibody Binding Beads. The capability of bacteria to produce intracellular granules with a hydrophobic biopolymer core and proteins attached to its surface from various cheap carbon and energy sources, such as, e.g., glucose, was utilized in this study to produced tailormade nano/microbeads suitable for molecular biomimetics.

The bead-forming and coating protein PhaC was engineered to enable simultaneous bead surface display of the gold-binding peptide GBP1 (*31*) and the antibody (IgG) binding ZZ domain (*37*). This strategy harnesses nature's capability to covalently cross-link the PhaC protein to polymer inclusions, which can be isolated and maintained as spherical beads with defined surface binding functionality (*26*). In order to produce the various multifunctional fusion proteins in the bacterium *E. coli* that mediate production of gold-binding polymer beads, the respective hybrid genes were constructed and inserted into an overexpression vector under control of the strong T7 promoter. In general, bead formation was monitored by polyester accumulation analysis, fluorescence microscopy of Nile red stained cells, and TEM. A fusion protein with only one gold-binding peptide did not mediate production of beads showing gold-binding affinity (data not shown). However, the use of three gold-binding peptide repeats, a pentaglycine spacer region followed by the IgG-binding domain fused to PhaC, mediated formation of beads with specific gold and antibody binding properties. This fusion protein 3xGN-G_5-ZZ-PhaC at the bead surface was demonstrated by SDS-PAGE and confirmed by MALDI-TOF/MS and N-terminal sequencing (Figure 2, Table 2). The SDS-PAGE analysis also showed an additional but less abundant 97 kDa protein, which was identified as copurified ATPase (Accession No. P0ABB9*)* derived from the production host *E. coli*.

To quantitatively assess the gold-binding activity of these novel polymer beads, an enzyme-linked immunosorbent assay was established employing the binding of biotinylated gold particles. Biotinylated gold particles bound to the beads were detected using streptavidin−HRP conjugate. The absorbance at 490 nm was increased at least 10-fold using the gold-binding peptide displaying beads when compared to the control beads not displaying the peptide (Figure 3A). Furthermore, elemental analysis and back-scattered electron density analysis was applied to confirm the presence of gold bound to the engineered beads (data not shown). The bead shape and size distribution was assessed by atomic force microscopy (data not shown).

The triple gold-binding peptide-ZZ-PhaC fusion protein additionally showed IgG binding activity due to a functional ZZ domain between the gold-binding peptides and PhaC. This activity was assessed by ELISA as previously described (*28*) (Figure 3B). The gold binding was visualized by transmission electron microscopy (TEM) (Figure 4). To further study gold binding and its impact on bead density, sucrose density gradients using ultracentrifugation were applied. The incubated samples as well as control samples were analyzed by sucrose gradient ultracentrifugation. Samples that were not incubated with colloidal gold formed a layer located at a density corresponding to <2 M sucrose ($d = 1.33$ g/mL). Control beads, PhaC(−)ZZ beads only displaying the IgG binding domain, when incubated with gold did not show a shift in density. In contrast, beads displaying the gold-binding peptides migrated further in the density gradient and formed a layer corresponding to a density of <2.25 M sucrose ($d = 1.4$ g/mL) when incubated with gold (Figure 5). Overall, these data suggested that the engineered beads displayed both binding functionalities (Figure 6).

Design and Production of Bifunctional Silica/Antibody Binding Beads. As described above for the design of the gold/antibody-binding peptide displaying beads, hybrid genes were constructed to enable production of multifunctional fusion proteins mediating formation of silica/antibody-binding polymer beads. Hybrid genes were overexpressed in *E. coli* and the resulting beads were isolated and characterized (Figure 7). The fusion protein SN-G_5-ZZ-PhaC was confirmed by MALDI-TOF/MS and N terminal sequencing (Table 2). The SDS-PAGE analysis also showed an additional but less abundant 97 kDa protein, which was identified as copurified ATPase (accession no. P0ABB9*)* derived from the production host *E. coli*.

The ability of the respective beads displaying silica-binding peptides to bind silica was shown using two different methods assessing either binding of silica to the bead surface or binding

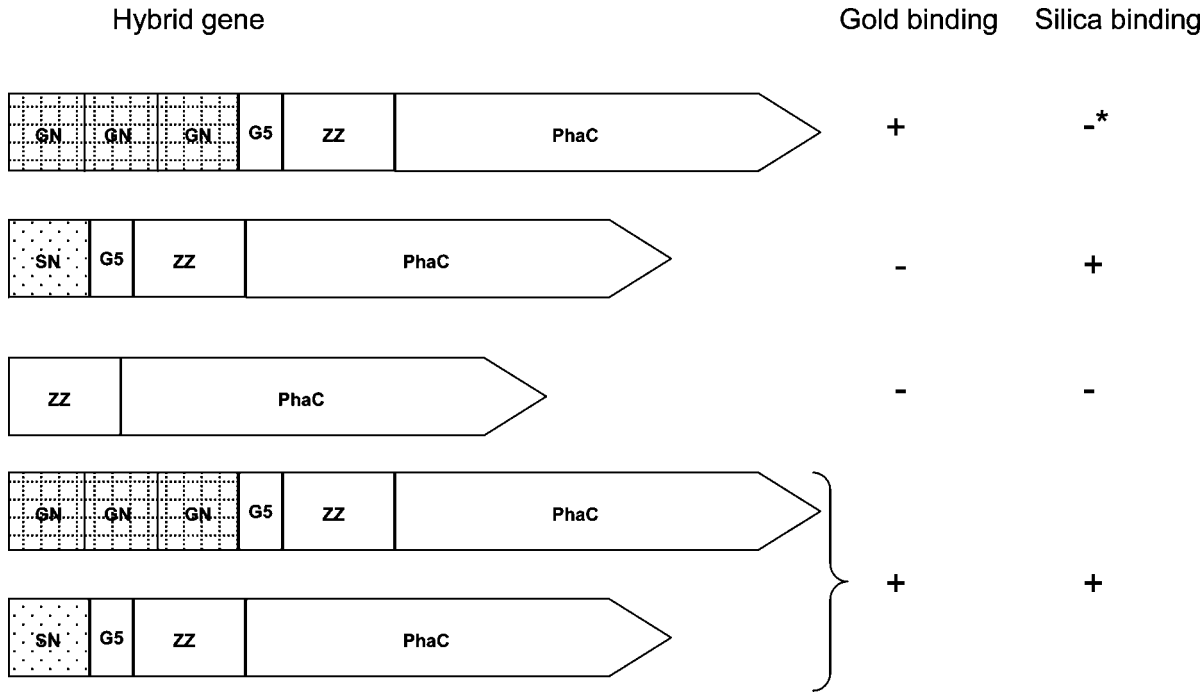

Figure 11. Schematic overview of hybrid genes used in this study. The bracket combining the last two constructs illustrates that both genes are located on the same plasmid. Gold binding ability was assessed as described above, and the silica binding ability was assessed using TMOS precipitation as described above. Binding is indicated by +, nonbinding by -; -* indicates a slightly increased unspecific silica binding compared to the control.

of the engineered polymer beads to commercially available silica beads. Beads displaying silica-binding peptides and control beads were incubated with TMOS dissolved in HCl and then separated by sucrose density ultracentrifugation as described in the Experimental Procedures. Different migration behavior of the engineered and control beads was observed representing a change in bead density (Figure 8A). PhaC(−)ZZ beads formed a layer at the 2 M sucrose (d = 1.33 g/mL) independent of treatment with TMOS. The respective beads self-assembled using fusion protein SN-G_5-ZZ-PhaC showed a density greater than the control beads and assembled at 2.25 M sucrose (d = 1.4 g/mL) after treatment with TMOS. These findings were additionally confirmed by elemental analysis showing silica only present in the engineered bead samples (data not shown). The direct fusion of the silica-binding peptide to the N terminus of PhaC resulting in SN-PhaC did not result in an increased density. These beads always behaved like the control beads without binding peptide.

Commercially available silica beads (silicon dioxide, 1−5 μm; Sigma-Aldrich, St. Louis, MO) were used as a second method to qualitatively assess silica binding by the engineered beads. Fusion and control beads were incubated with silica beads and separated using sucrose density ultracentrifugation as described in the Experimental Procedures. Protein determination by Bradford (*35*) was used to quantify binding. The respective control beads PhaC(−)ZZ showed about 85% of the protein content at a density corresponding to the polymer beads not bound to the commercial silica beads, and about 15% was found at much greater density in the sediment colocalizing with the commercial silica beads. In contrast, about 70% of beads displaying the silica-binding peptide employing fusion protein SN-G_5-ZZ-PhaC colocalized with the commercial silica beads when separated in sucrose density ultracentrifugation (Figure 8B).

Design and Production of Multifunctional Gold/Silica/Antibody Binding Beads. As described for the design of the bifunctional beads, hybrid genes mediating production of multifunctional gold/silica/antibody-binding polymer beads were constructed and overexpressed in *E. coli*. Two different hybrid genes each encoding a fusion protein comprising bead forming and inorganic binding domain were coexpressed to mediate production of multifunctional beads (Figure 9). The fusion proteins were confirmed by MALDI-TOF/MS (data not shown).

The gold and IgG binding ability of the respective beads was confirmed using ELISA as described above (data not shown). The silica-binding ability of the respective engineered beads was confirmed as described above (data not shown). To assess the multifunctionality, the respective engineered beads were incubated subsequently with colloidal gold and TMOS, and vice versa. After each incubation step, the samples were purified via sucrose density ultracentrifugation as described in the Experimental Procedures. As controls, the respective bifunctional polymer beads were incubated the same way as beads displaying the ZZ domain only. After incubation with colloidal gold followed by TMOS incubation, PhaC(−)ZZ beads accumulated in an area corresponding to 2 M sucrose (d = 1.33 g/mL), whereas bifunctional gold/antibody binding beads formed a layer located at a density of 2.25 M sucrose (d = 1.4 g/mL). Multifunctional gold/silica/antibody binding beads treated the same way migrated even further and formed a layer corresponding to a density of 2.5 M sucrose (d = 1.45 g/mL; Figure 10).

DISCUSSION

In this study, it was shown that microorganisms can be genetically modified to produce polymer inclusions that perform as beads displaying binding sites for antibodies and various inorganics at the same time. Thus, the bioengineering of polymer inclusions provides a valid molecular tool to generate novel hybrid materials that combine biological and inorganic agents suitable for numerous potential biomedical applications (*2*−*5*). Different hybrid genes were constructed (Figure 11) and successfully overexpressed, and the engineered protein functions could be displayed at the respective bead surfaces (Figures 2, 7, and 9). The gold/antibody binding polymer beads displaying the triple gold-binding peptide GBP1 (*38, 39*) showed strong gold binding in ELISA, which was established as a tool to quantitatively assess the gold binding. Control beads that did

not display this special binding peptide showed no significant gold binding (Figure 3A). These findings were confirmed by density-based migration behavior of the different beads in a sucrose gradient. Only beads displaying the gold-binding peptide showed an increased density after incubation with colloidal gold. TEM assessment of the polymer beads indicated specific gold binding to respectively engineered beads (Figure 4). However, the density of bound colloidal gold was rather low, which could be due to the isolation procedure applied to beads after binding the colloidal gold as well as the TEM sample preparation method. Additionally, no interference of both displayed binding domains—gold-binding and IgG-binding—was found. Moreover, it could be demonstrated that polymer beads engineered to bind gold and antibodies bind as much IgG as polymer beads displaying only the antibody binding domain (Figure 3B).

To test the possibility that the polymer beads in general can be designed to bind any inorganic, the protein bead surface was designed to bind silica. The binding of silica, obtained as precipitate from an aqueous TMOS solution, increased the density of the respective engineered beads, whereas the control beads without engineered binding sites showed no increased density (Figure 8A,B). Further confirmation of the successful functional displaying of the silica-binding peptide was obtained by assessing the binding of engineered SN-G_5-ZZ-PhaC and PhaC(−)ZZ control beads to commercial silica particles. Control beads showed only a minor background reaction compared to the binding ability of the engineered beads (Figure 8 C,D). A direct fusion of the silica-binding peptide to the N terminus of PhaC did not result in functional silica-binding polymer beads. Therefore, the exposure of the binding peptide—gained by employing the IgG binding ZZ domain as spacer—seems to be required for functionality. Elemental analysis using energy dispersive spectrometry proved the existence of silica in samples that were expected to precipitate silica out of TMOS, e.g., silica-binding peptide displaying beads. Silica could not be detected in control samples treated the same way. Due to the displayed ZZ domain, the engineered beads were additionally able to bind IgG as well as the control beads only displaying the ZZ domain. In contrast to the gold binding, it was not possible to obtain clear evidence that IgG binding and silica binding do not interfere with each other. This is due to the lack of an ELISA protocol for silica binding to the beads.

The multifunctional beads designed in this study were not only able to bind IgG antibodies plus gold and/or silica, but were also able to specifically bind all three compounds. However, it was shown that a deposition of silica at the bead surface impaired binding of gold, whereas beads with gold attached to their surface showed no weaker silica deposition as in the absence of gold. These data suggested that the silica deposition could block the binding sites for gold at the bead surface. Additionally, multifunctional beads incubated with gold and silica showed a higher density in sucrose gradients than observed for bifunctional beads. This indicates a possible binding of the silica to the already bound gold particles. Overall, this study clearly demonstrated that bacterial polymeric inclusions can be engineered as biomimetic tools to specifically and simultaneously bind biological and inorganic compounds, which could enable applications of these beads in diagnostic medicine as well as biotechnology. Numerous particles composed of various materials such as organic polymers, semiconductors, lipids, carbon or silica material have been produced and proposed for various biomedical applications (*40*−*46*). In contrast to the one-step manufacturing process described in this study for the production of new polymer beads, all other particles requiring functionalization were obtained by a process comprising at least two steps such as, e.g., bead production and chemical cross-linking of a functionality.

This biomimetic approach offers a tool to produce beads with covalently cross-linked functionalities in one step. These shell−core biobeads with specific binding properties could, for example, be applicable in medical bioimaging procedures in which antibody-based targeting of contrast agents is of special interest. In a previous study, it was demonstrated that a scFv immobilized at the surface of these beads showed a 75-fold increase in binding affinity when compared with the respective soluble scFv (*26*). Thus, the engineered beads could provide a very sensitive diagnostic tool. Moreover, the module like composition of these small biobeads offers versatile targeting of different tissues by simply incubating the beads with the relevant targeting antibody. Due to the displayed antibody binding functionality, an antibody of choice or even a combination of antibodies could be easily combined with bound gold to generate a contrast agent for bioimaging applications.

ACKNOWLEDGMENT

This work was supported by the New Zealand Foundation for Research Science and Technology and the Massey University Research fund. Ms. Anika Jahns received a Technology for Industry doctoral fellowship. This research has been facilitated by access to the Australian Proteome Analysis Facility established under the Australian Government's Major National Research Facilities program.

Synthetic peptides are valuable tools in fundamental and applied biomedical research. On one hand, these molecules provide highly efficient access to competitive inhibitors of molecular interactions and enzyme substrates by rational design. On the other hand, peptides may serve as powerful vectors to mediate cellular uptake of molecules that otherwise enter cells only poorly. The coupling of both such functionalities provides access to molecules interfering with molecular processes inside the cell. However, the combination of several functionalities on one synthetic peptide may be compromised by problems associated with the synthesis of long peptides. Native chemical ligation enables the chemoselective coupling of fully deprotected functional building blocks. However, peptide thioesters are still not accessible by standard solid-phase peptide synthesis. Here, we demonstrate the cofunctionalization of a thioester-activated *N*-hydroxypropyl methacrylamide (HPMA) copolymer (28 500 Da) with the cell-penetrating peptide (CPP) nonaarginine and a bioactive peptide as independent building blocks by native chemical ligation. Nonaarginine was employed as a cell-penetrating peptide (CPP), a fluorescein-labeled analogue of a pro-apoptotic peptide as a biofunctional cargo. Incorporation of the fluorescein label enabled the highly sensitive quantification of the coupling stoichiometry by fluorescence correlation spectroscopy (FCS) using 0.4 pmol/12 ng of labeled construct. A construct only bearing the functional cargo peptide required cellular import by electroporation in order to show activity. In contrast, a construct combining all functionalities was active upon incubation of cells, validating the modular nature of the approach.

INTRODUCTION

Peptides provide a rich source of bioactive molecules, and numerous peptides and analogues are now used as drugs (*1*−*3*). In fundamental biological and biomedical research, peptides have become a highly valuable tool for defining the principles of molecular recognition (*4*).

However, given the poor capacity of peptides to enter cells, most applications of bioactive peptides have focused on extracellular targets, recombinant proteins, or cell lysates. In order to mediate cellular entry, over the past years, conjugation with cell-penetrating peptides has received increasing attention. Cell-penetrating peptides are a diverse class of peptides of 8 to 30 amino acids in length that promote the cellular uptake of the cargo molecules they are connected to (*5*). In our hands, nonaarginine has proven to be a CPP of choice (*6*). This CPP is very well tolerated by cells, has high import efficiency, and moreover, truncated sequences also show high activity as a CPP, rendering purification less problematic (*7*).

For the cellular import of peptides, in most cases, the conjugation with the CPP occurs by N-terminal elongation during solid-phase peptide synthesis. However, especially for longer peptides, purity and postsynthesis workup may become limiting factors. Moreover, in order to streamline the process from in vitro to intracellular testing, one may want to render a peptide that has shown activity in an in vitro assay competent for cell entry without the need for de novo synthesis of a cell-penetrating analogue.

Native chemical ligation (NCL) has proven to be a potent technique for the efficient and chemoselective coupling of fully deprotected peptides (*8*, *9*). In its original form, a peptide bearing an N-terminal cysteine residue forms an amide bond with another peptide, carrying a C-terminal thioester-activated amino acid. In spites of its success in the synthesis of longer polypeptides, the lack of protocols to generate the required C-terminal thioesters by standard solid-phase Fmoc peptide chemistry is still a limiting factor for its broader application.

As an alternative approach to overcome these limitations, we describe here the modular coupling of cysteine-bearing unprotected peptides to thioester-activated hydroxypropyl methacrylamide copolymer (HPMA). The HPMA serves as a linear scaffold to which the functional peptides are linked. HPMA has been demonstrated to be biocompatible and has therefore been used as a drug carrier in numerous applications (*10*−*12*). Furthermore, conjugation with the Tat-derived CPP (*13*) has

been shown to facilitate the uptake of HPMA−doxorubicin conjugates (*14*).

The pro-apoptotic peptide AVPIAQK (*15, 16*) served as a bioactive cargo. This peptide corresponds to the seven N-terminal amino acids of the Smac (second mitochondria-derived activator of caspase) protein (*17*). Smac is a pro-apoptotic protein, that, following an apoptotic stimulus, is released from mitochondria and inhibits the antiapoptotic action of IAPs (inhibitor of apoptosis proteins) (*18*). Introduction of this peptide into cells specifically enhances the controlled cell death, i.e. apoptosis, in cells exposed to ligands of death receptors such as the tumor necrosis factor receptor or Fas (*16*). This peptide exerts this activity only when introduced into the cytoplasm. We had shown for this peptide previously that measurement of cell viability provides a reliable readout for comparing import efficiencies of different delivery strategies (*15*).

With respect to the quantification of coupled peptides per polymer, three options were considered. The first option had been the implementation into the synthesis protocol by photometric determination of a leaving group that is released upon coupling of a bioactive moiety (*19*). The second option is based on the degradation of an aliquot of the conjugate postsynthesis and quantification of a suitable degradation product of the bioactive moiety (*20*). Finally, the third option is based on the spectroscopic quantification of a functional group per unit weight of polymer. Using a fluorescently labeled conjugate of the bioactive moiety, we chose options 2 and 3. Confocal fluorescence-correlation spectroscopy (FCS) was employed as the analytical method to follow the release of a degradation product according to option 3 (*21*). This technique provides information on the average number and size of fluorescently labeled molecules diffusing through a confocal detection volume. FCS works at concentrations of probe molecules in the lower nanomolar to subnanomolar range and in microliter volumes, therefore reducing sample consumption to a minimum.

Our results show that the functionalization of HPMA via NCL occurs with uniform yields. By addressing the activity and cellular uptake of HMPA conjugated to the AVPIAQK peptide or R9 alone or to a combination of both peptides, it is established that all three molecular entities act as functionally independent building blocks.

EXPERIMENTAL PROCEDURES

Reagents. The preactivated hydroxypropyl methacrylamide copolymer *N*-methacrylateglycylglycine *p*-nitrophenyl ester (poly(HPMA-*co*-methacrylate-Gly-Gly-*p*-nitrophenyl ester)) was supplied by Polymer Laboratories (Shropshire, Great Britain). It has a linear structure, an average molecular weight (MW) of 28.5 kDa (M_w/M_n: 1.32) and a total nitrophenol content of 8.28 mol %. On the basis of the specifications provided by the manufacturer, we estimated 12.5 reactive groups per molecule. Rink amide resin was from Rapp Polymers (Tübingen, Germany). Fmoc amino acids were purchased from Novabiochem (Läufelingen, Switzerland) and Senn Chemicals (Dielsdorf, Switzerland). The other chemicals for synthesis were supplied by Fluka (Deisenhofen, Germany), PD-10 columns by GE Healthcare (Uppsala, Sweden), and Sephacryl S-200 HR gel from Pharmacia Biotech (Uppsala, Sweden). Cell culture media were purchased from PAN biotech (Aidenbach, Germany). The agonistic anti-Fas-antibody was supplied by Biomol (Hamburg, Germany), cycloheximide by SIGMA (Steinheim, Germany), and Alexa647-labeled Annexin V by Invitrogen (Karlsruhe, Germany).

Peptide Synthesis. Peptides were synthesized by automated solid-phase peptide synthesis using Fmoc/tBu chemistry. Fluorescein-labeled peptides were synthesized on Nα-carboxyfluorescein-labeled lysyl-Rink amide resin ((Fluo(Trt))-Lys-Rink), unlabeled peptides on Rink amide resin (*22*). Purity was determined by analytical RP-HPLC (Nucleosil 100, 250 × 2 mm, C18 column, 5 μm particle diameter; Grom, Herrenberg, Germany), identity was validated via MALDI-TOF-mass spectrometry. For the R9-amide analogue CYRRRRRRRRR, the tyrosine residue was included to enable detection at 280 nm. Concentrations were determined by UV/vis spectroscopy of peptides and conjugates diluted 1000-fold in Tris/HCl buffer pH 8.8 assuming an extinction coefficient for fluorescein E_{492} = 78 000 L/(mol × cm).

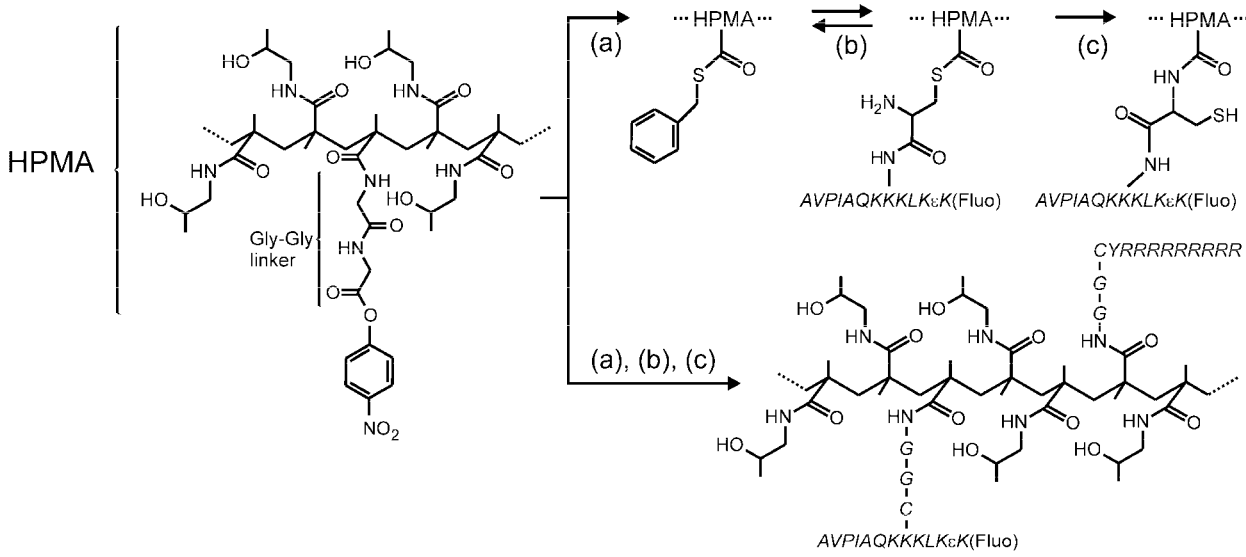
Synthesis of the Peptide with a Lysine-Coupled Cysteine Residue. Ala-Val-Pro-Ile-Ala-Gln(Trt)-Lys(Boc)-Lys(Dde)-Lys(Boc)-Leu-Lys(Boc)-εLys(Fluo) (15 μmol) was synthesized on (Fluo(Trt))-Lys-Rink amide resin. The peptide was N-terminally protected by reaction with boc-anhydride (32.7 mg, 150 μmol) in dimethylformamide (DMF) (1 mL) containing *N*,*N*-diisopropylethylamine (DIPEA) (29.8 μL, 180 μmol) for 24 h at 20 °C. After cleavage of the Dde-protecting group by hydrazine hydrate (2% v/v in DMF, 2 × 1 mL, 5 min, 20 °C), the ε-amino group was conjugated with Fmoc-Cys(Trt)-OH (87.9 mg, 150 μmol) using 1-hydroxybenzotriazole (20.3 mg, 150 μmol) and diisopropylcarbodiimide (23.5 μL, 150 μmol) in DMF (1 mL, 24 h, 20 °C). Following removal of the Fmoc-protecting group by piperidine (20% v/v in DMF), the peptide was cleaved off the resin and side chains deprotected using a mixture of 92.5% TFA, 2.5% triisopropylsilane, 2.5% 1,2-ethanedithiole, and 2.5% H_2O (v/v/v), precipitated in cold diethyl ether (4 °C) and spun down (4000 rpm, 5 min). The precipitate was washed with cold diethyl ether twice. Then, the precipitate was dissolved in a mixture of acetonitrile/water (4 mL, 1:1, v/v) and lyophilized.

Synthesis of HPMA−Peptide Conjugates. Poly(HPMA-*co*-methacrylate-Gly-Gly-*p*-nitrophenylester) (4 mg) was dissolved in anhydrous DMSO (200 μL), and benzylmercaptan (50 μL) was added. After 15 min, peptide was dissolved in this solution (4.4 to 11.2 mM corresponding to an 8- to 20-fold excess over polymer and 0.64 to 1.60 excess over reactive groups, respectively) and incubated for 30 min at 20 °C. After addition of thiophenol (50 μL) and incubation for 16 h at 20 °C, phosphate buffer (100 mM) and guanidinium chloride (6 M), pH 7.5 (200 μL), were added and the mixture incubated for 72 h at 20 °C. Finally, the reaction mixture was diluted with PBS (700 μL) and purified twice with a PD-10 column followed by lyophilization. The formation of a conjugate was validated using analytical gel filtration chromatography (ÄKTA-explorer fast protein liquid chromatography (FPLC) station; flow, 0.25 mL/min; 4 °C; Sephacryl S-200 HR-column, 150 × 10 mm). Absorption was detected at 215 nm (peptide bonds), 280 nm (aromatics), and 492 nm (fluorescein).

Microscopy. HeLa cells were incubated with HPMA-$(H_2N\text{-AVPIAQKK(C)KLK}\epsilon\text{K(Fluo)-NH}_2)_n(\text{CYR}_9\text{-NH}_2)_m$ denoted as AVPIAQK-HPMA-R9 and HPMA-$(H_2N\text{-AVPIAQKK(C)KLK}\epsilon\text{K(Fluo)-NH}_2)_n$ denoted as AVPIAQK-HPMA (each 20 μM with respect to the AVPIAQK peptide) in RPMI medium (45 min, 37 °C) and afterward analyzed by confocal laser scanning microscopy using an LSM 510 confocal microscope (Carl Zeiss, Göttingen) equipped with a Plan-Apochromat 63× N.A. 1.4 Oil DIC objective.

Determination of Stoichiometry by FCS. Autocorrelation measurements were performed in a 384-well plate (175 μm, low-base design, MMI, Eching, Germany) using a ConfoCor 2 fluorescence correlation spectroscope equipped with a C-Apochromat 40× N.A. 1.2 water immersion lens (Carl Zeiss, Jena, Germany) and a TCS SP5 fluorescence correlation spectroscope equipped with an HCX PL APO 63× N.A. 1.2 water immersion lens (Leica Microsystems, Mannheim, Germany). A solution of 25 nM peptide−HPMA was incubated in

Scheme 1. Coupling of the AVPIAQK Analogue to a Preactivated HPMA (Poly(hydroxypropyl Methacrylamide)-*co*-(Methacrylate-Gly-Gly-Nitrophenyl Ester))[a]



[a] (a) DMSO (anhydrous), benzylmercaptane; (b) DMSO (anhydrous), thiophenol; (c) DMSO, thiophenol, phosphate buffer (100 mM), guanidiniumchloride (6 M, pH 7.5). Amino acids represented in single letter code are printed in italics.

PBS-buffer containing 30 U/mL proteinase K for 1.5 h at RT. During this incubation, autocorrelation measurements were performed in regular intervals until the diffusional autocorrelation time and the amplitude of the autocorrelation function had reached a minimum. After digestion, the number of particles and the fpm of intact and completely digested samples were compared. The ratio of the number of particles after and before digestions represents the stoichiometry of peptides per polymer.

Bioactivity of Electroporated Conjugates. HeLa cells were detached by trypsination. Cells (4×10^5 cells in 200 μL serum-containing medium) were electroporated with the indicated peptides or conjugates in a 4 mm cuvette (peqlab Biotechnologie GmbH, Germany) using a 12.5 ms, 350 mV, 1700 μF pulse (Fischer, Germany). After incubation for 10 min on ice, the cells were washed by centrifugation, transferred to a 96-well microtiter plate (2×10^4 cells per well), and incubated in 200 μL serum-containing RPMI medium with anti-Fas antibody (100 ng/mL, human activating mouse IgM, clone CH11) and CHX (2 μg/mL) for 20 h at 37 °C and 5% CO_2. Dead cells were removed by washing twice with PBS, whereas the attached cells were stained with crystal violet (100 μL, 0.5% w/v crystal violet, 20% methanol v/v, 80% PBS) (15 min, 20 °C). After removal of excess dye by washing with cold water, the intracellular dye was resolved in 100 μL methanol and the absorption at 550 nm was determined.

Caspase-3 Activity Assay. HeLa cells were incubated with medium containing constructs for 30 min at 37 °C. After one washing step, cells were treated as indicated with agonistic Fas antibody (100 ng/mL) and CHX (2 μg/mL) for the induction of apoptosis followed by incubation for a further 3 h. Cells were harvested by scraping, washed with ice−cold PBS, and lysed in lysis buffer (1% Triton, 150 mM NaCl, pH 7.7, supplemented with protease inhibitor cocktail tablets (Roche Diagnostics, Mannheim, Germany) for 30 min on ice. The protein content in lysates was determined using a commercially available Bradford protein assay kit (Bio Rad Laboratories, München, Germany). Equivalents of 30 μg protein for each sample were diluted in caspase activity buffer (20 mM HEPES, 10 mM dithiothreitrol, 10% glycerol, 100 mM NaCl, pH 7.5). Fluorogenic caspase-3 substrate (Ac-DEVD-AMC, Calbiochem, Bad Soden, Germany) was added to the samples to a final concentration of 2 μM. The efficiency of the substrate cleavage by active caspase-3 was analyzed immediately after substrate addition and after 3 h incubation at 37 °C using a luminescence spectrometer LS50B (PerkinElmer, Norwalk, CT).

RESULTS AND DISCUSSION

Synthesis and Analytical Characterization of HPMA Conjugates. In order to ensure broad applicability of a polymer-based approach, robust synthesis procedures as well as reliable analytical methods to determine coupling efficiencies are required. To validate our protocol, a series of coupling reactions with structurally different peptides was performed and, for selected peptides, also repeated several times. As a bioactive peptide, the pro-apoptotic AVPIAQK peptide was selected. This peptide requires a free N-terminus for biological activity. Therefore, in this case, the cysteine residue required for NCL was introduced via coupling to a lysine side chain (Supporting Information Scheme 1). A protease-releasable fluorescent reporter group was introduced by C-terminal elongation with the tripeptide Lys-Leu-Lys, followed by a fluorescein-labeled lysine residue (*22*). The HPMA was obtained as a preactivated hydroxypropyl methacrylamide copolymer poly(HPMA-*co*-methacrylate-Gly-Gly-*p*-nitrophenyl ester) (linear structure, average MW 28.5 kDa, total nitrophenol content 8.28 mol %) with about 12.5 reactive groups per molecule. The active ester was first transesterified to a benzylmercaptyl-thiol ester in water-free DMSO, as we were concerned that due to its high reactivity the nitrophenyl ester moiety would engage in reactions with nucleophilic functional groups other than the sulfhydryl group of the N-terminal cysteine residue. Next, the polymer was incubated with peptide in water-free DMSO. After 16 h, aqueous buffer was added. The products were purified by gel filtration chromatography (Figure 1). The chemoselectivity of this modified one-pot ligation protocol was validated in an independent experiment using control peptides with and without an N-terminal cysteine residue (Supporting Information Figure 1).

For the determination of loading efficiency, two independent approaches were evaluated. First, the absorption per weight was measured for a defined amount of polymer. Second, the number of fluorescent particles before and after digestion of peptide-coupled HPMA with 30 U/mL proteinase K (Figure 2) was determined by fluorescence correlation spectroscopy. Due to the nanomolar sensitivity and microliter measurement volumes of

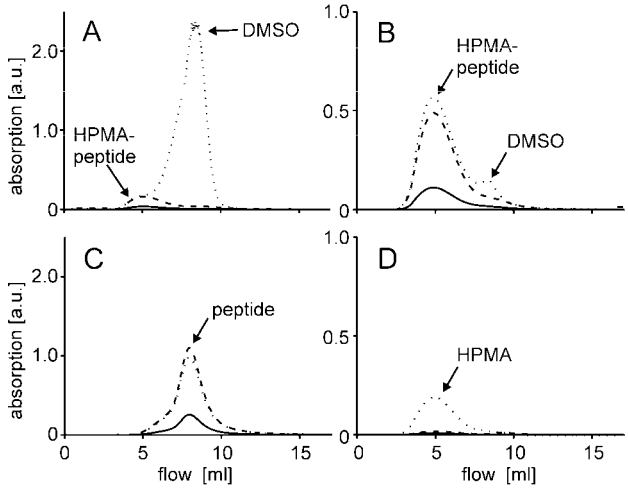


Figure 1. Analytical gel filtration chromatography of the HPMA(H_2N-AVPIAQKK(C)KLKεK(Fluo)-NH_2) conjugate: (A) crude reaction mixture, (B) after purification with a desalting column, (C) unbound peptide H_2N-AVPIAQKK(C)KLKεK(Fluo)-NH_2, and (D) free HPMA. Chromatograms were recorded at 215 nm (dotted lines), 280 nm (solid lines), and 492 nm (dashed lines).

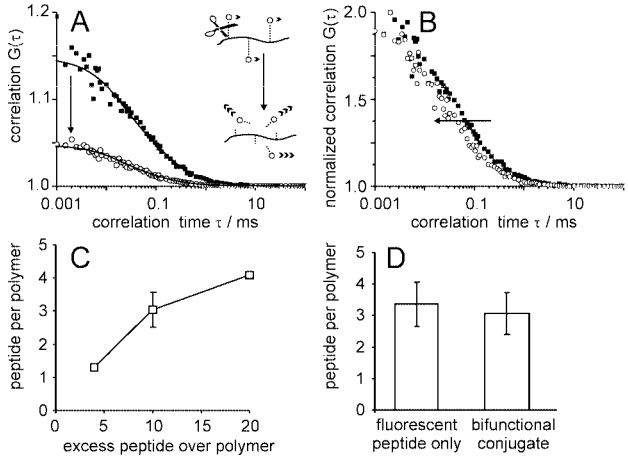

Figure 2. Quantification of peptide loading per polymer by fluorescence correlation spectroscopy (FCS). One aliquot of the HPMA−peptide conjugate AVPIAQK-HPMA-R9 was digested by addition of proteinase K (30 U/mL) to the polymer conjugate solution (10 μM). After incubation for 1.5 h at 37 °C, the solution was diluted in PBS (500-fold) and transferred to a 384-well plate. A reference aliquot was prepared in the same way in the absence of proteinase K. (A) Autocorrelation functions for the digested sample (open circles) and the undigested control (filled squares). (B) Superposition of the autocorrelation functions normalized to an amplitude of 1 to better visualize the shift toward shorter diffusional autocorrelation times. (C) Positive correlation of peptides coupled per polymer and the excess of peptide over polymer in the coupling reaction. Values were taken from Table 1. The excess relates to the excess of the fluorescently labeled analogue. (D) The coupling efficiency was independent from the presence of a second peptide. The conjugates for which the coupling efficiency was only determined by absorption-per-weight are not included in this graph.

FCS, only 0.4 pmol, corresponding to 12 ng of the labeled construct, was required for one measurement. Digestion led to a decrease of the amplitude of the autocorrelation function (Figure 2A), corresponding to an increase in the number of fluorescent particles. The completeness of the reaction was confirmed by following the reaction over time. The stoichiometry of peptide loading was derived by calculating the number of particles before and after digestion (Table 1). The release of the fluorescent reporter group from the scaffold was also reflected by the shift in the diffusional autocorrelation time from approximately 100 to 35 μs (Figure 2B).

The results obtained by FCS corresponded very well to those obtained by the absorption-per-weight-based methods. A slightly lower loading efficiency was obtained by the latter. This may be due to the presence of counterions in the polymer preparation, leading to an overestimate of the amount of material. Due to the fact that the FCS-based method is not affected by salt that compromises a correct determination of weight and requires much smaller amounts, we judge this method to be superior.

For the coupling efficiency, there was a positive correlation between the ratio of peptide in the coupling reaction over reactive groups (Figure 2C). Typically, with a molar excess of 10 with respect to the polymer, corresponding to 0.8 peptides per reactive group, about 3 peptides were coupled per polymer. Interestingly, in the tested concentration ranges, addition of a nonfluorescent peptide did not affect the coupling efficiency of the fluorescently labeled peptide (Figure 2D). This observation indicates that, at these concentrations, peptides did not compete for reactive groups. Also, for R9, the AVPIAQK peptide and a fluorescein-labeled cysteinyl-ε-lysyl moiety, similar coupling yields were obtained. This result indicates the suitability of the coupling protocol for the testing of larger collections of structurally diverse peptides, without the need for the optimization of coupling conditions for each individual case.

Moreover, by dividing the total fluorescence through the average number of molecules, information on the average fluorescence per molecule (fpm) was obtained. In principle, for polymers carrying several fluorescently labeled particles, the fpm should be a function of the stoichiometry of loading. However, due to self-quenching, the fpm can also be lower than expected (*23*). The fpm for the HPMA conjugates relative to the value of the free peptide was around 1, independent of the coupling efficiency. This result confirms the presence of fluorescence quenching. The molecular brightness of the polymers therefore does not provide information on the coupling efficiency.

We relate to quenching as a reduction of fluorescence per particle due to the spatial proximity of several fluorophores, not to the complete extinction of fluorescence for those polymers carrying more than one fluorophore. One could argue that, for particles carrying several fluorophores, fluorescence is quenched completely and these conjugates could not be detected. Then, for the undigested sample, only those conjugates carrying one fluorophore could be detected. Upon digestion, fluorescent groups would be cleaved off polymers carrying several fluorophores, resulting in their dequenching. As a consequence, the number of particles per polymer would be overestimated.

However, in our view, the very good agreement of the determination of coupling efficiency based on absorbance-per-weight and the FCS-based method argue against a total quenching of fluorescence for polymers carrying several fluorescein moieties. Assuming a Poissonian distribution of coupling efficiency, then at an average coupling ratio of 3 about 15% of the conjugates carry only 1 fluorophore. 80% of the peptides would be coupled to polymers carrying two or more fluorophores. If all these moieties would only become visible after release from the polymer, then a coupling efficiency of 6−7 would be derived.

Coupling to HPMA Preserves the Activity of the AVPIAQK Peptide. Next, we intended to establish that conjugation of the peptide to the polymer does not compromise its biological activity. Previously, for the AVPIAQK-peptide we had employed electroporation as a means for CPP-independent cytoplasmic delivery (*15*). The free and the HPMA-coupled peptide as well as their counterparts with the reverse sequence were loaded into HeLa cells by electroporation. The

Table 1. Summary of Coupling Reactions[a]

conjugate	fold excess	excess over reactive group	fluo-analogue per polymer	reactive groups coupled to fluo-analogue	rfpm[b]	used in figure
AVPIAQK(Fluo) -HPMA-YR9[d]	4:4:1	0.64	1.3	10%	1.1

[a] For the bifunctional conjugates, information on coupling efficiency was obtained for the fluorescein-labeled analogue only. [b] The relative fluorescence per molecule (rfpm) was determined by dividing the fluorescence per molecule for the conjugate as determined by FCS through the one of the released peptide. [c] Loading efficiency determined by measuring the absorption per unit weight of peptide-coupled polymer. [d] AVPIAQK(Fluo) relates to Ala-Val-Pro-Ile-Ala-Gln-Lys-Lys(Cys)-Lys-Leu-Lys-εLys(Fluo) (see experimental procedures). [e] KQAIPVA(Fluo) relates to Lys-Gln-Ala-Ile-Pro-Val-Ala-Lys(Cys)-Lys-Leu-Lys-εLys(Fluo) (see experimental procedures). [f] R9(Fluo) relates to Cys-Arg_9-εLys(Fluo).

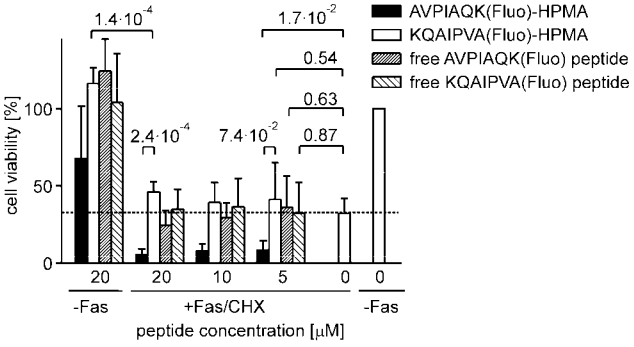

Figure 3. Enhancement of apoptosis induction by electroporated HPMA−conjugates. The concentration was adjusted with respect to the fluorescent moiety. In this case, peptide loading was determined by absorption per weight (Table 1). Cell viability was determined by crystal violet staining. AVPIAQK(Fluo) relates to Ala-Val-Pro-Ile-Ala-Gln-Lys-Lys(Cys)-Lys-Leu-Lys-εLys(Fluo) (see Experimental Procedures); KQAIPVA(Fluo) relates to Lys-Gln-Ala-Ile-Pro-Val-Ala-Lys(Cys)-Lys-Leu-Lys-εLys(Fluo) (see Experimental Procedures). The statistical significance was determined by a two-tailed unpaired Student's *t* test.

AVPIAQK-peptide does not induce apoptosis by itself. Instead, it increases cell death in the presence of an apoptosis-inducing stimulus, as for example an agonistic anti-Fas antibody. Stimulation with anti-Fas alone reduced cell viability by 64% (Figure 3). With the AVPIAQK peptide at a concentration of 20 μM, cell viability was reduced by a further 8%. In comparison, the HPMA-conjugated AVPIAQK peptide at a concentration of 20 μM (related to the fluorescein moiety, i.e., AVPIAQK peptide) reduced the viability by a further 29%. This difference in activity indicates that conjugation to the HPMA strongly promotes the activity of the peptide, possibly by protection from proteolytic degradation. The reverse sequences had no effect on cell viability. For the HPMA constructs, electroporated in the absence of an apoptotic stimulus viability was also fully maintained, demonstrating the biocompatibility of the HPMA scaffold.

Cellular Uptake and Bioactivity of Bifunctional Conjugates. Having established that the HPMA is inert with respect to cell entry and that the HPMA-conjugated AVPIAQK−peptide fully maintains activity, we next cofunctionalized the HPMA with the AVPIAQK−peptide and nonaarginine to obtain conjugates competent for cell entry. Both the HPMA conjugate functionalized with R9 only as well as the one cofunctionalized with R9 and the AVPIAQK peptide efficiently entered cells (Figure 4). In contrast to what we typically observe for free R9, a large part of the fluorescence was localized close to the plasma membrane. In addition, there was homogeneous intracellular fluorescence. Inside the nucleus, the nucleoli were

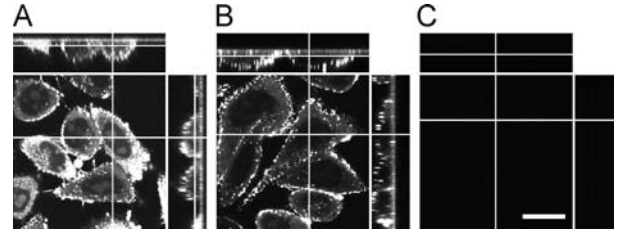

Figure 4. Cellular uptake and subcellular distribution of HPMA−peptide conjugates. Confocal microscopy of cells incubated (A) with HPMA-R9, (B) the bifunctional AVPIAQK-HPMA-R9 conjugate, and (C) a conjugate bearing the functional peptide only (AVPIAQK-HPMA) (20 μM). One confocal slice as well as orthogonal sections along the indicated lines are shown. Cells were incubated with the respective conjugate at a concentration of 20 μM with respect to the fluorescent moiety for 45 min at 37 °C. The bar denotes 20 μm.

visible, an observation that we and others have made for cell-penetrating conjugates before (*24*). For the bifunctional HPMA construct, only the AVPIAQK moiety was fluorescently labeled. The intracellular fluorescence therefore provided direct evidence for the cofunctionalization of the HPMA scaffold with the nonaarginine.

Finally, we assessed whether the bifunctional HPMA conjugate would also combine both biological functions, namely, cell entry and apoptosis enhancement. To fully establish that the conjugates acted by enhancement of apoptosis and to exclude the possibility that a reduction of cell viability was due to general cell toxic effects, we determined the activity of the executioner caspase 3 in cell lysates as an apoptosis-specific readout.

Neither of the constructs led to an increase of caspase 3 activity beyond the approximate 2-fold increase in activity observed for control cells incubated in the absence of stimulus and conjugate (Figure 5). The apoptotic stimulus increased the caspase 3 activity 3.5-fold. For the conjugate bearing the AVPIAQK moiety alone, no further increase was observed, consistent with the inability of this molecule to enter the cells. In contrast, the bifunctional conjugate increased the caspase 3 activity by up to 8-fold in a concentration-dependent manner. Some increase in activity to 5.3-fold was also observed for the conjugate bearing the nonaarginine moiety only. This activity may be due to a higher sensitivity of the apoptosis-induced cells to the import of a polycation (*25*). In the absence of the proapoptotic stimulus, there was no cytotoxic activity for either of the constructs. This result, in conjunction with the absence of activity for the electroporated reverse KQAIPVA(Fluo)-HPMA conjugate, validates the biocompatibility of the conjugates.

At present, the molecular basis for the different subcellular localization of the HPMA conjugates in comparison to free CPPs is not understood. To this point, we have not resolved whether this distribution is a consequence of a poor induction of

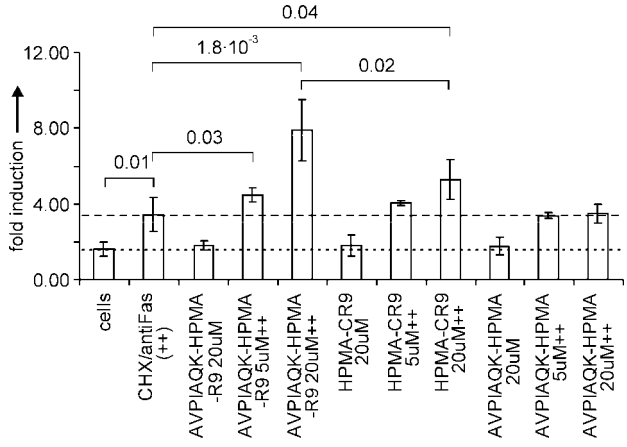

Figure 5. Bioactivity of HPMA conjugates. HeLa cells were incubated with different concentrations of the counjugates for 30 min at 37 °C. Afterward, the cells were washed and apoptosis was induced by stimulation with an agonistic anti-Fas antibody (100 ng/mL) and cycloheximide (CHX, 2 μg/mL).For measurements of the caspase-3 activity, cells were harvested 3 h after induction of apoptosis. The figure shows averages and standard deviations of two independent cell stimulations that were analyzed twice/three times by a colorimetric caspase assay. The biological activity is expressed as fold-induction of caspase 3 activity in relation to lysates of untreated cells obtained at $t = 0$. The results of the individual assays were normalized on the basis of the accumulated absorbance of all samples. The pointed line indicates the increase of caspase 3 activity during the 3 h incubation period of the assay in the absence of an apoptotic stimulus. The dashed line indicates the Fas stimulus-dependent increase in caspase activity, ++ the presence of the apoptotic stimulus. Concentrations were derived from the absorption of fluorescein. The statistical significance was determined by a two-tailed unpaired Student's *t* test.

endocytosis and therefore increased association with the plasma membrane or of differential vesicular trafficking of HPMA-loaded vesicles. For free cell-penetrating peptides, sequestration within the endolysosomal compartment is also a major limitation for bioactivity (*15*). Typically, these vesicles are distributed throughout the cell (*24*). More importantly with respect to their application, the localization close to the plasma membrane is not associated with the induction of membrane damage as validated by the biocompatibility of the conjugates in the absence of an apoptotic stimulus.

CONCLUSIONS

In summary, our results show that the HPMA-based strategy provides a convenient access to cell-penetrating bioactive peptides. Peptides mediating cell entry and bioactivity are coupled as fully unprotected building blocks to the preactivated HPMA polymers by native chemical ligation. Due to the modular nature of the approach, shorter peptides may be employed, which facilitates the synthesis of cell-penetrating conjugates especially for longer bioactive peptides. Therefore, the modular nature of the approach represents a considerable shortcut for testing the activity of peptides inside a cell. The assessment of bioactivity and uptake for the individual conjugates confirmed that the functionality of the three molecular elements, i.e., scaffold, bioactive peptide, and CPP, combine independently in a modular fashion.

The coupling reaction proceeded with little day-to-day variation. Our results indicate that the coupling efficiency correlates positively with the excess of peptide over functional groups. In further studies, it will therefore be highly interesting to systematically assess the effect of variations of either the number of bioactive peptides or the CPP with respect to bioactivity, uptake, and trafficking. Also, the incorporation of peptides known to promote endosomal release as a further element will be a promising option to explore for increasing bioactivity (*26*). These advancements will strongly promote the development and application of functional peptides in fundamental and applied biomedical research (*27*).

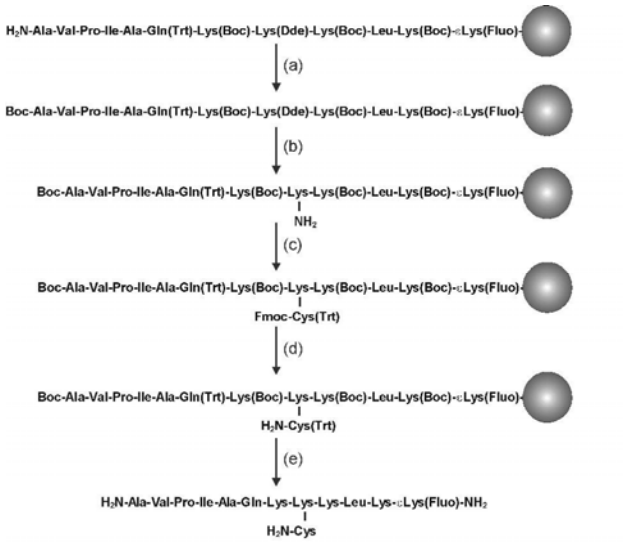
Supplemental material – contents

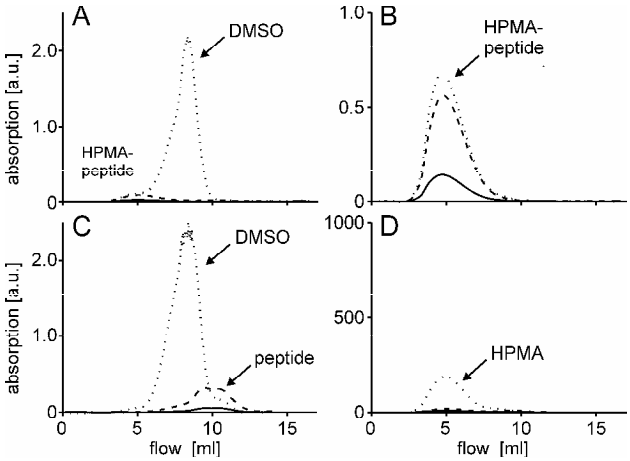
1. Supplemental scheme 1 - Synthesis of the proapoptotic peptide with a cysteine residue coupled to a lysine side chain
2. Validation of the chemoselectivity of the modified native chemical ligation protocol
3. Further evidence for self-quenching of the polymer-coupled fluorophores using fluorescence spectroscopy

1) Supplemental Scheme 1 – Synthesis of the proapoptotic peptide with a cysteine residue coupled to a lysine side chain



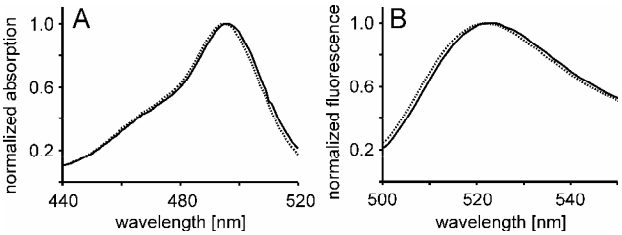
Synthesis of a proapoptotic peptide with a cysteine residue coupled to a lysine side chain for native chemical ligation to a thioester-preactivated HPMA polymer. (a) Boc-anhydride (78.6 mg, 360 μmol), DIPEA (29.8 μL, 180 μmol), DMF; (b) hydrazine hydrate (2 % v/v), DMF, 2 x 5 min; (c) Fmoc-Cys(Trt)-OH (87.9 mg, 150 μmol), 1-hydroxybenzotriazole (20.3 mg, 150 μmol), diisopropylcarbodiimide (23.5 μL, 150 μmol), DMF, 24 h; (d) piperidine (20 % v/v), DMF, 2 x 5 min; (e) triisopropylsilane (2.5 % v/v), 1,2-ethanedithiole (2.5 % v/v), H_2O (2.5 % v/v), trifluoracetic acid, 3 h; boc = tert-butyloxycarbonyl; Fmoc = 9-fluorenylmethoxycarbonyl.

2) Validation of the chemoselectivity of coupling using a modified native chemical ligation (NCL) protocol. Conversion of the highly reactive HPMA-nitrophenyl ester into a benzyl thioester and incubation with peptide in water-free DMSO are modifications of the standard NCL protocol. In order to validate the chemoselectivity of this modified NCL protocol, after incubation of the HPMA-co-methacrylate-Gly-Gly-p-nitrophenylester with a benzylmercaptan-thiol ester, the polymer was incubated either with a peptide containing an N-terminal cysteine residue (H_2N-CKLKεK(Fluo)-NH_2) or an analog in which this residue was replaced by an alanine residue (H_2N-AKLKεK(Fluo)-NH_2). Only the cysteine-containing peptide was ligated to the polymer (Suppl. Figure 1). For the control peptide, gel filtration retarded the DMSO as well as the free peptide.



Suppl. Figure 1. Chemoselectivity of the modified NCL protocol. (A,B) Analytical gel filtration chromatography of the HPMA thioester after reaction with the peptide H_2N-CKLKεK(Fluo)-NH_2 before (A) and after (B) removal of DMSO with a desalting column. (C, D) Analytical gel filtration chromatography after incubation of the HPMA thioester with the peptide H_2N-AKLKεK(Fluo)-NH_2 before (C) and after (D) purification with a desalting column (dotted line: absorption at 215 nm, solid line: absorption at 280 nm, dashed line: absorption at 492 nm)

3) Characterization of polymer-coupled peptides by fluorescence spectroscopy. Further evidence for self quenching was obtained by comparison of adsorption and emission spectra of both the free peptide and the peptide-loaded polymer (Suppl. Figure 2). Recording of absorption and fluorescence emission spectra confirmed that conjugation of the peptide to the polymer affected the spectral characteristics of fluorescein. Spectroscopically determined absorbance and fluorescence spectra indicate bathochrome shifts of few nanometres. The shift in the absorption spectrum could even be observed with the naked eye as solutions of the polymer conjugates appeared more orange, whereas unconjugated peptides appeared more yellow.



Suppl. Figure 2. Characterization of photophysical shifts occurring upon HPMA conjugation of peptides. (A) Normalized absorbance and (B) fluorescence emission spectra of the free, fluorescein-labeled AVPIAQK analog (dashed line) and the HPMA-AVPIAQK conjugate (solid line). The conjugate and the free peptide were dissolved in Tris/HCl pH 8.8 to a concentration of 2.0 μM with respect to the fluorescein moiety.

The Inhibitory Potencies of Monoclonal Antibodies to the Macrophage Adhesion Molecule Sialoadhesin Are Greatly Increased Following PEGylation

PEGylation of antibodies is known to increase their half-life in systemic circulation, but nothing is known regarding whether PEGylation can improve the inhibitory potency of antibodies against target receptors. In this paper, we have examined this question using antibodies directed to Sialoadhesin (Sn), a macrophage-restricted adhesion molecule that mediates sialic acid dependent binding to different cells. Anti-Sn monoclonal antibodies (mAbs), SER-4 and 3D6, were conjugated to PEG 5 kDa or and PEG 20 kDa, resulting in the incorporation of up to 3 molecules of PEG per mAb molecule. Following purification of PEGylated mAbs by anion exchange chromatography, it was shown that PEGylation had little or no effect on antigen binding activity but led to a dramatic increase in inhibitory potency that was proportional to both the size of the PEG and the degree of derivatization. Thus, PEGylation of antibodies directed to cell surface receptors could be a powerful approach to improve the therapeutic efficacy of antibodies, not only by increasing their half-life in vivo, but also by increasing their inhibitory potency for blocking receptor−ligand interactions.

INTRODUCTION

The modification of proteins with poly(ethylene glycol) (PEG) is now a well-established technique. At a therapeutic level, a number of benefits of PEGylation have been found, including the prolongation of protein half-life in the body, reduced degradation by metabolic enzymes, and elimination of its immunogenicity (for reviews, see *refs 1, 2*). PEG is a highly motile polymer which, when conjugated to a protein, can mask antigenic sites and sterically hinder access of proteolytic enzymes. Given the flexibility and large hydrated volume of PEG chains, another potential advantage of coupling PEG to proteins such as antibodies is an enhancement in their inhibitory potency via steric effects. This could be particularly useful for antibodies directed to cell surface proteins designed to disrupt receptor−ligand interactions. For example, blocking antibodies directed to endothelial cell adhesion molecules like VCAM and ICAM are potentially useful for treatment of inflammatory diseases due to their key roles in leukocyte recruitment and activation (*3, 4*).

Sialoadhesin (Sn, Siglec-1, CD169) is a macrophage-restricted adhesion molecule and a member of the Siglec family of sialic acid binding immunoglobulin (Ig)-like lectins (*5*). It contains 17 Ig-like domains and mediates sialic acid dependent adhesion to a range of cell types including lymphoid and myeloid cells (*6*). The sialic acid binding site of Sn is located on the surface of domain 1 and has been characterized at the atomic level by X-ray crystallography (*7*). Sn was originally characterized in the mouse as a non-phagocytic sialic acid dependent sheep erythrocyte receptor expressed on macrophage subsets (*8*), especially those in secondary lymphoid organs (*9*). Sn can be upregulated on monocytes and macrophages during inflammatory responses, including autoimmune diseases such as rheumatoid arthritis (*10*) and experimental autoimmune encephalomyelitis (*11*), and on macrophages that infiltrate human breast tumors (*12*). Studies on Sn-deficient mice have shown that Sn is able to exacerbate T cell dependent inflammatory responses in a model of autoimmune uveoretinitis (*13*) and in genetically determined demyelination neuropathies of the central and peripheral nervous systems (*14*). These results suggest an important role for Sn during inflammatory and immune responses (*15*).

SER-4 and 3D6 are monoclonal rat IgG2a anti-Sn antibodies directed to two distinct epitopes of mouse Sn, domains 2 and/or 3 for SER-4, and domain 1 for 3D6 (*6, 16, 17*). When used separately, each antibody can partially inhibit Sn-dependent adhesion, and when mixed together, a synergistic effect on inhibition was observed (*5, 18*). These antibodies therefore provide a useful model system to explore the potential of PEGylation in increasing inhibitory potency of antibodies directed close to the ligand binding site of Sn. The present study describes the preparation and characterization of PEG-mAbs directed to Sn and demonstrates that PEGylation can lead to a dramatic increase in the inhibitory potency of anti-Sn mAbs. This approach could lead to improved therapeutic efficacy for a range of immune and inflammatory disorders, not only for Sn, but also for other adhesion molecules important in cell-to-cell interactions in inflammatory and immune responses and potentially more broadly for other membrane receptors.

EXPERIMENTAL PROCEDURES

PEG. PEG reagents were purchased from Nektar Therapeutics (Huntsville, AL). Two succinimidyl α-methylbutanoate-PEG (abbreviated SMB-PEG) reagents were used: a 5 kDa linear PEG chain and a 20 kDa linear PEG chain. Modification of mAb with PEG molecules is abbreviated as, for example, SER-4−2PEG 5 kDa and denotes a modification of SER-4 mAb with 2 linear PEG chains of 5 kDa.

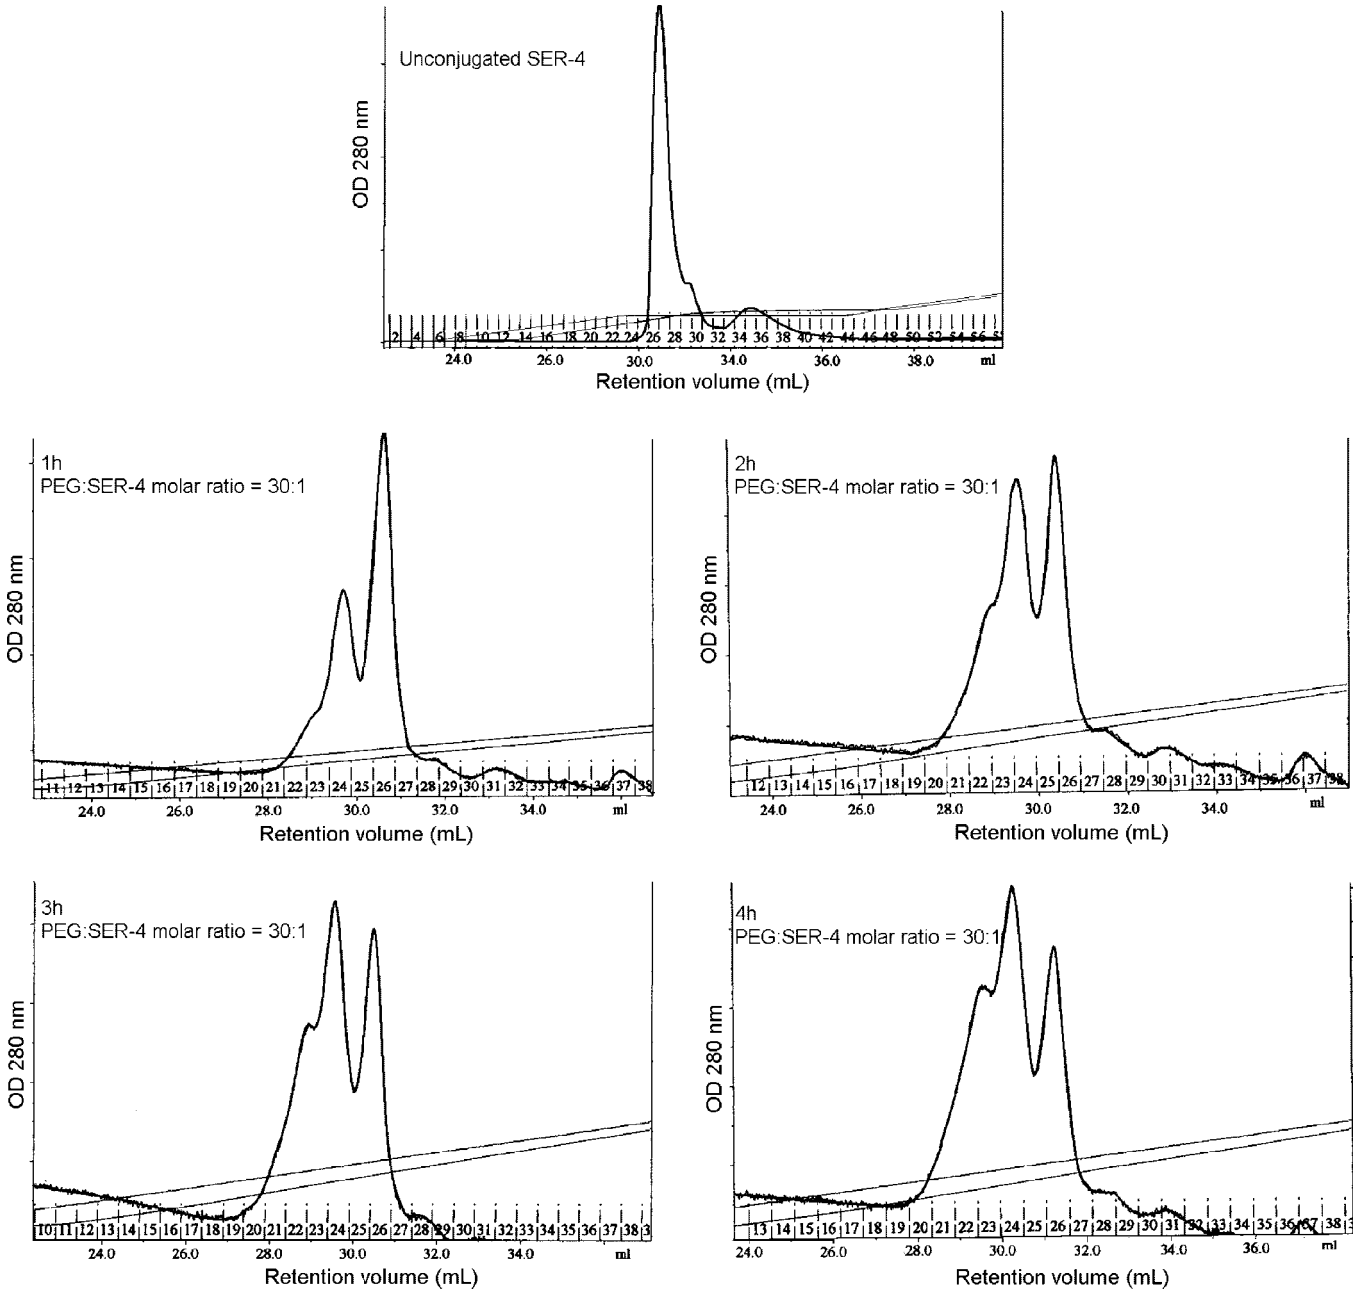

Figure 1. Anion exchange chromatograms of unconjugated SER-4 mAb (top) and modified SER-4 mAb following PEGylation in PBS pH 7.4 with initial PEG 5 kDa/SER-4 molar ratio of 30:1 and incubation for the different times indicated.

Purification of SER-4 and 3D6 Monoclonal Antibodies. Hybridomas producing SER-4 and 3D6 mAbs were expanded in IMDM + L-glutamine + 25 mM HEPES medium (Gibco, Invitrogen Corporation) supplemented with 10% hybridoma serum (FBS Gold from PAA Laboratories GmbH) and 1% penicillin/streptomycin. The conditioned supernatant was passed through a 0.2 μm filter to remove protein aggregates and cell debris and the SER-4 and 3D6 IgGs were purified from supernatants by affinity chromatography using a Protein-G Sepharose column. Bound IgGs were eluted with 0.1 M glycine (pH 3), and fractions containing protein were neutralized by the addition of 0.1 volume 1 M Tris (pH 8) and dialyzed into PBS. SER-4 and 3D6 mAbs were further purified by anion exchange Mono Q HR 5/5 high-performance liquid chromatography (HPLC) column (Amersham, Biosciences, UK). The flow rate was 0.5 mL/min, and the column was maintained at 4 °C. A salt gradient was used for elution: Buffer A was 25 mM Tris (pH 8); buffer B was 25 mM Tris, 1 M NaCl (pH 8).

Preparation of mAb-PEG Conjugates. SMB-PEG was allowed to react with free amino groups of SER-4 or 3D6 mAbs (2 mg/mL) at a SMB-PEG:antibody ratio 30:1 in PBS, pH 7.4, for 3 h at room temperature. The reaction was stopped by addition of 0.1 M glycine, and the mixture was then desalted with a PD-10 column (Amersham, Biosciences, UK) equilibrated with 25 mM Tris, pH 8. Anion exchange Mono Q HR 5/5 HPLC column chromatography was used to separate and purify PEG conjugates. Fractions were analyzed by SDS-PAGE using 7.5% and 12% acrylamide gels for nonreducing and reducing conditions, respectively (*19*), and stained in Brilliant Blue G-Colloidal suspension (Sigma). MALDI TOF-mass spectrometry analysis was also performed on fractions in order to confirm the size and the degree of

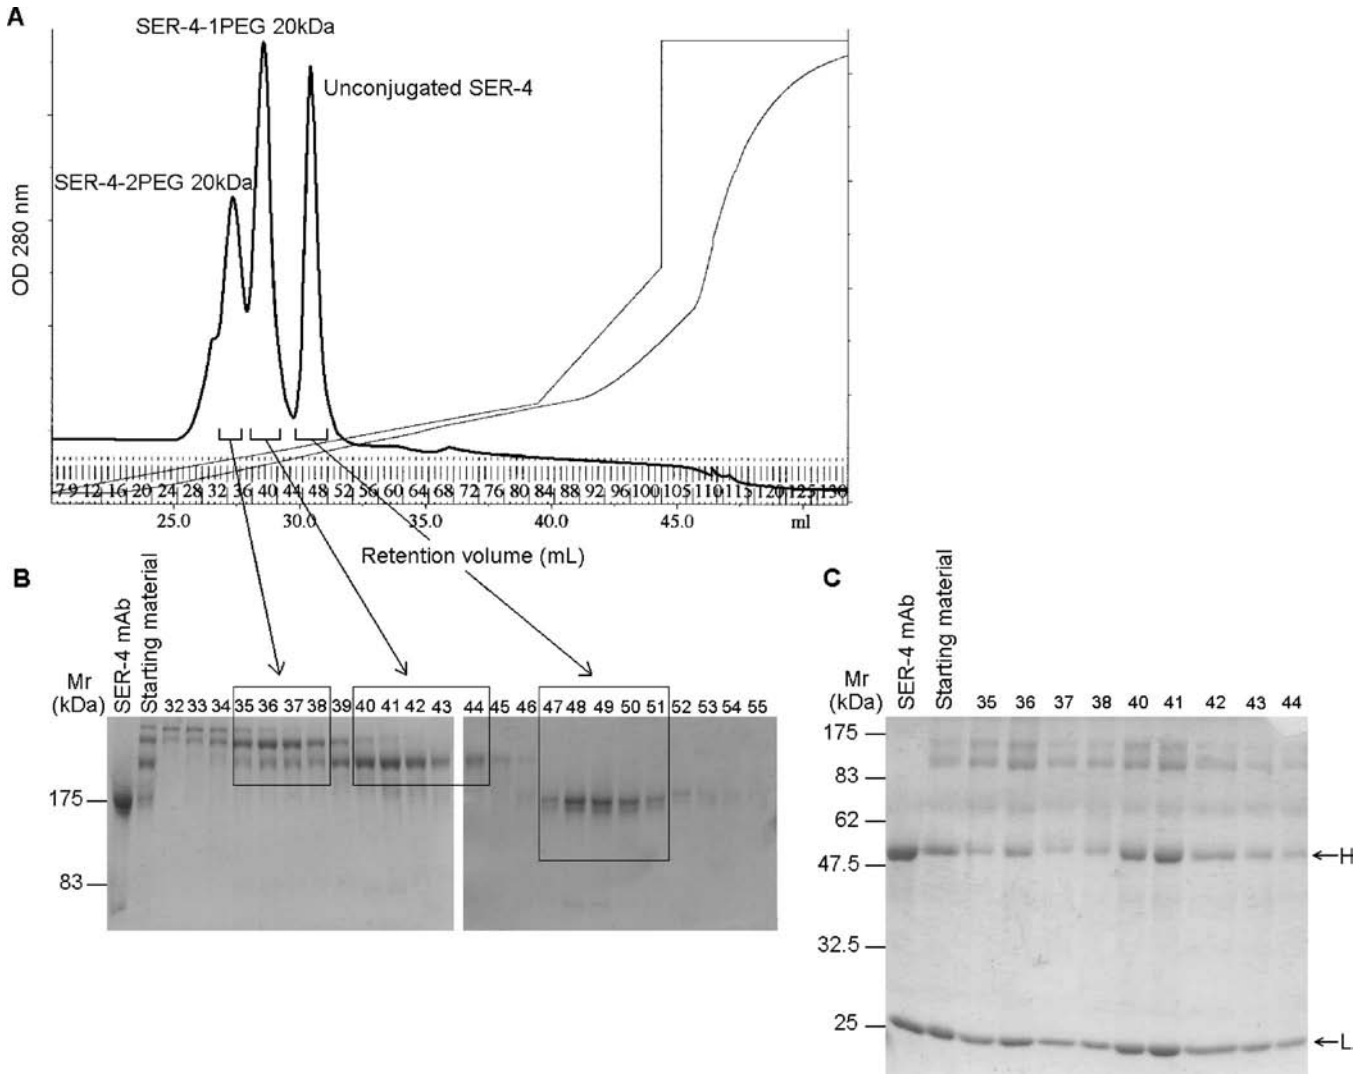

Figure 2. SER-4 mAb was conjugated to PEG 20 kDa (3 h in PBS pH 7.4 at room temperature) and PEG conjugates were purified by anion exchange chromatography (A). Fractions were analyzed by SDS-PAGE under nonreducing and reducing conditions to determine the degree of attachment and location of PEG on heavy and light chains. Sizes of molecular markers are shown. Under nonreducing conditions (B), SDS-PAGE stained with Coomassie blue shows 3 different degree of PEGylation. Under reducing conditions (C), arrows show heavy (H) chains of SER-4 at ~50 kDa and light (L) chains of SER-4 at 25 kDa. The band running between the 62 and 83 kDa markers in all tracks is a contaminant protein that was also present in the buffer-only lane (not shown).

modification of the different PEGylated products (Applied Biosystems 4700 Proteomics Analyzer).

Biotin Labeling of mAbs. Biotin labeling of SER-4 and 3D6 mAbs was performed using EZ-Link NHS-LC-Biotin reagent (Pierce, Rockford, IL) according to the manufacturer's procedure. Briefly, SER-4 or 3D6 mAbs (2 mg/mL) were mixed with 20-fold molar excess of *N*-hydroxysuccinimide (NHS)-activated biotin in PBS, pH 7.4, for 1 h at room temperature. Unreacted NHS-biotin was removed from the reaction mixture using PD-10 columns (Amersham, Biosciences, UK). Concentrations of biotin-labeled SER-4 or 3D6 were measured using a BCA protein assay kit (Pierce, Rockford, IL).

Antibody Binding Activity of PEG-mAb Conjugates. The antibody binding activities of each PEGylated product were determined by a competitive immunoassay using human Fc-chimera Sn (domains 1 to 3) immobilized on microtiter plate. 96 well Immulon-4 plates (Thermo, Milford, MA) were coated with 10 μg/mL antihuman IgG (Fc specific) mAb (Sigma) diluted in 0.1 M bicarbonate coating buffer (pH 9.6) and blocked with PBS + 5% skimmed milk. After washing, human Fc-chimera Sn was adsorbed to wells at a concentration of 2 μg/mL in PBS + 0.1% BSA. The wells were washed and incubated with biotin-labeled SER-4 or 3D6 anti-Sn mAb (0.1 μg/mL) mixed with serial dilutions of either unlabeled mAbs or mAb-PEG conjugates in PBS + 0.1% BSA. After washing, horseradish peroxidase conjugated streptavidin was added (Caltag). The wells were washed and the peroxidase activity was measured using 0.4 mg/mL *O*-phenylenediamine dihydrochloride (OPD) in 0.05 M phosphate-citrate buffer containing 0.014% H_2O_2 (Sigma) as substrate, and the absorbance at 450 nm was measured. The inhibition of biotin-labeled mAbs binding to Sn by PEG conjugates was compared to the inhibition seen with unlabeled mAbs. The percentage of biotin-labeled mAbs binding was determined by the following formula:

$$Abs_{\text{with competitor}} \times 100/Abs_{\text{without competitor}}$$

where $Abs_{\text{with competitor}}$ = absorbance when biotin-labeled mAbs are in competition with PEG conjugates or parent mAbs.

$Abs_{\text{without competitor}}$ = absorbance when biotin-labeled mAbs are used alone (100% of binding).

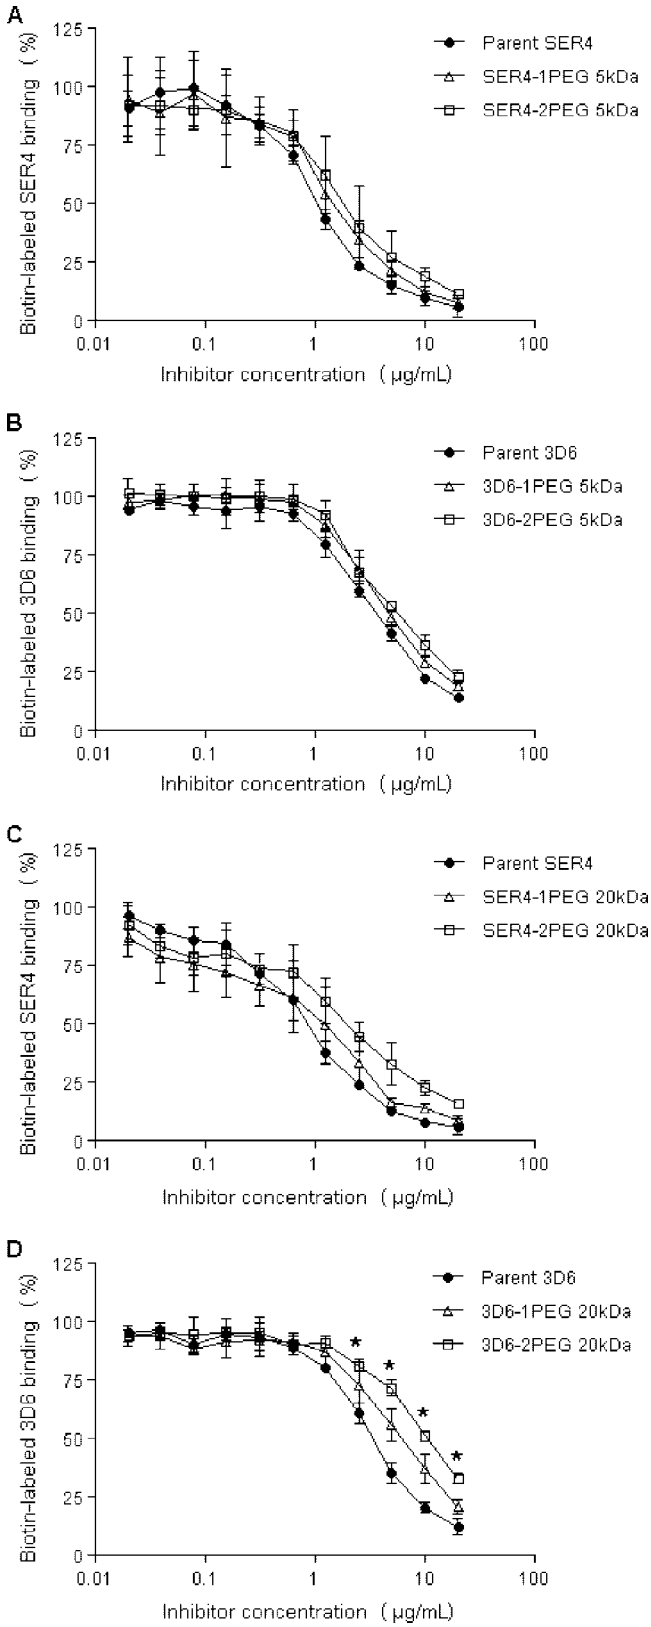

Figure 3. Binding activity of PEGylated mAbs. Conjugates of SER-4 (A,C) and of 3D6 (B,D) were tested at several concentrations for their ability to competitively inhibit the binding of biotin-labeled SER-4 and 3D6, respectively, to Sn-coated microtiter plates. Panels A and B: PEGylation of both mAbs with 1 (open triangles) or 2 (open squares) molecules of PEG 5 kDa does not affect the binding activity of mAbs. Panels C and D: Both SER-4 and 3D6 modified with 2 (open squares) molecules of PEG 20 kDa show a slight reduction of binding activity when compared to unconjugated mAbs (solid circles). * indicates a statistically significant difference in binding inhibition compared to unconjugated mAbs (Tukey test, $P < 0.001$). Each data point represents the mean ± SD ($n = 3$ in duplicate wells).

Solid-Phase Red Blood Cell (RBC) Binding Assay. To assess the inhibitory potency of PEGylated mAbs, RBC binding assays were carried out. Briefly, 96 well Immulon-4 plates were coated with antihuman IgG (Fc specific) mAb (Sigma) followed by incubation with human Fc-chimera Sn (domains 1 to 3). After washing, the wells were incubated for 1 h with 50 μL PBS + 0.1% BSA containing serially diluted unconjugated mAbs or PEG conjugates, used alone or in combination. One hundred microliters of freshly prepared human RBC at 0.5% volume/volume were then added directly to the wells, mixed, and incubated for 30 min at room temperature (*18*). The wells were gently washed with PBS + 0.1% BSA several times. To determine RBC binding quantitatively, the plate was dried, fixed with methanol for 5−10 min, and dried again, and the bound RBC were measured using 0.4 mg/mL *O*-phenylenediamine dihydrochloride (OPD) in 0.05 M phosphate−citrate buffer containing 0.014% H_2O_2 (Sigma). The absorbance at 450 nm was taken using a 96 well plate reader (Roses and Anthos 2001).

The percentage of inhibition of RBC binding was determined by the following formula:

$Abs_{with\ mAbs} \times 100/Abs_{without\ mAbs}$

where $Abs_{with\ mAbs}$ = absorbance when PEG conjugates or parent mAbs were previously incubated with Sn.

$Abs_{without\ mAbs}$ = absorbance when Sn is only incubated with RBC (100% of RBC binding).

Statistics. All results are expressed as mean ± standard deviation (SD). The one-way analysis of variance (ANOVA) test and Tukey test were performed to demonstrate statistical differences ($P < 0.05$), using the software *GraphPad Prism 5* for Windows.

RESULTS AND DISCUSSION

PEGylation of Anti-mouse Sn mAbs. Following purification by protein G-Sepharose and anion-exchange chromatography, both antibodies were PEGylated using either 5 kDa or 20 kDa SMB-PEG, a succinimidyl-α-methylbutanonate derivative of NHS-PEG with a significantly longer half-life in solution (*20, 21*). PEGylation was carried out at pH 7.4, a condition that favors selective coupling to the N-terminal residues over surface-exposed lysine residues. Since IgG molecules are composed of 2 identical light chains (25 kDa) and 2 identical heavy chains (50−70 kDa), between 1 and 4 PEG molecules can, in principle, be attached per IgG molecule. PEGylation was monitored by anion-exchange chromatography (Figure 1). Under the conditions used, the more strongly PEGylated antibodies eluted first in the increasing salt gradient (Figure 2A), presumably as a result of a charge-shielding effect of PEG that weakens their binding to the anion exchange resin (*2*). Initial experiments using 5 kDa SMB-PEG showed that a molar ratio of 30:1 PEG/mAb resulted in ∼33% of antibody molecules incorporating PEG after 1 h at room temperature (Figure 1). When the time of incubation was increased to 3 h, up to ∼70% of antibody molecules were labeled with PEG (Figure 1), but longer incubations did not lead to improved yields. Similar findings were made using SMB-PEG 20 kDa (not shown).

Anion exchange chromatography showed 3 peaks following PEGylation with SMB-PEG 5 kDa (Figure 1, 3 h time) and up to 4 peaks following PEGylation with SMB-PEG 20 kDa (Figure 2A). The 20 kDa-PEGylated mAbs were eluted with a lower salt concentration than 5 kDa-PEGylated mAbs. This may be due to a greater shielding effect of 20 kDa-PEG chains resulting from their increased length and mobility.

Characterization of SER-4-PEG and 3D6-PEG. *PEGylation Analysis.* SDS-PAGE was used under nonreducing and reducing conditions to investigate the attachment and location of PEG to mAbs. With 20 kDa-PEG, the starting material

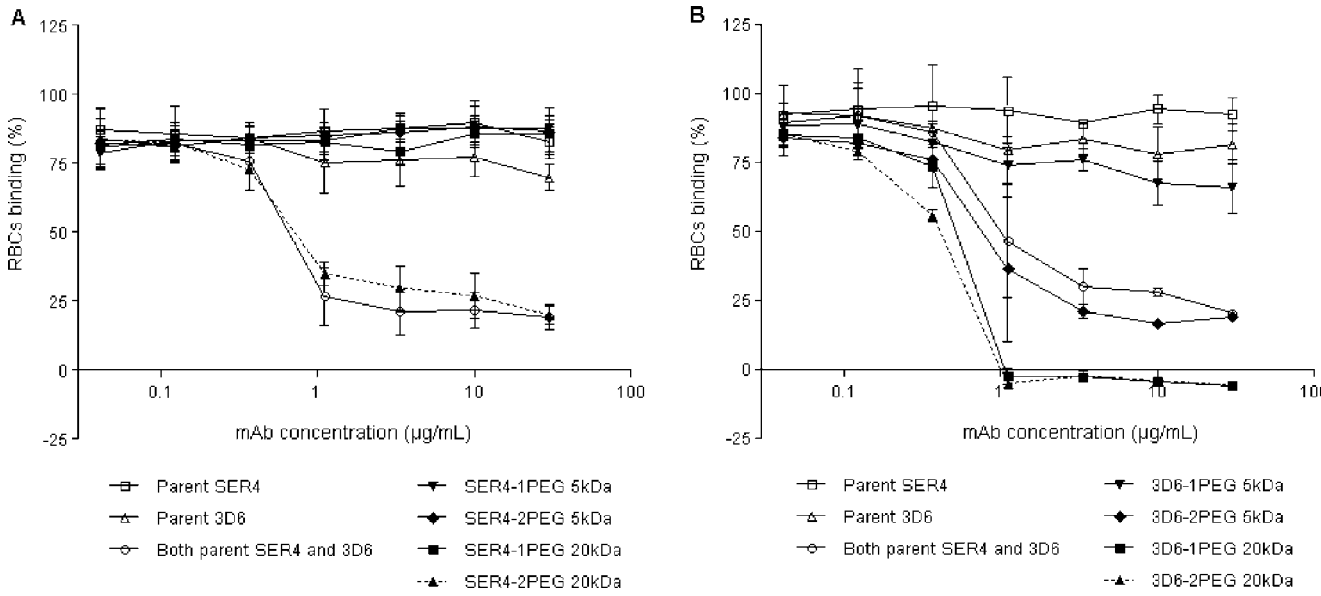

Figure 4. Inhibitory potency of PEGylated SER4 and 3D6 mAbs. A truncated form of Sn (domains 1 to 3) fused to the Fc region of human IgG1 was coated on wells at a concentration of 2 μg/mL. Wells were then preincubated with serially diluted unconjugated mAbs or PEG conjugates prior to the addition of human RBC. A preincubation of wells with SER-4 carrying 2 molecules of PEG 20 kDa reduced binding by about 75% (A). In the case of 3D6, a preincubation of wells with 3D6−2PEG 5 kDa resulted in ∼75% inhibition, and a complete inhibition of RBC binding was seen with 3D6 carrying either 1 or 2 molecules of PEG 20 kDa (B). Each data point represents the mean ± SD ($n = 3$ in duplicate wells).

showed the presence of four bands under nonreducing conditions, which corresponded to parent IgG (lower band) and 3 different degrees of PEGylation (Figure 2B). Similar findings were made with both SER-4 and 3D6, and only the data for SER-4 are shown. Following anion-exchange chromatography, the first peak (fractions 32−34) contained doubly and triply derivatized mAbs, the second peak (fractions 35−38) was strongly enriched in doubly derivatized mAb, and the third peak (fractions 40−44) was strongly enriched with singly derivatized mAb (Figure 2B). The fourth peak (fractions 47−51) contained underivatized mAb. These interpretations were supported by analysis of selected fractions by MALDI-TOF mass spectrometry (data not shown).

When these fractions were analyzed under reducing conditions, introduction of PEG was only observed with the heavy chains, suggesting that the N-terminal residues of the light chains were not readily conjugated under the conditions used (Figure 2C). Interestingly, heavy chains contained both one and two PEG molecules per heavy chain, suggesting that both the N-terminal residue and an internal lysine residue were modified on the same chain. These findings indicate that each mAb pool is heterogeneous with respect to the PEG modification, with each heavy chain containing 0, 1, or 2 PEG molecules, although the total number of PEG molecules per antibody molecule rarely exceeded 2.

Binding Activity of PEGylated mAbs. To investigate whether SMB-PEG modification affected the antigen-binding activity, derivatized SER-4 and 3D6 mAbs were tested in a competitive inhibition enzyme-linked assay (Figure 3). For this purpose, SER-4 and 3D6 mAbs were labeled with biotin and the abilities of parent mAbs and PEGylated mAbs (with 1 or 2 molecules of PEG 5 kDa and 20 kDa) to inhibit the binding of biotin-labeled mAb to antigen were compared. We showed that PEGylation of both mAbs with 1 or 2 molecules of PEG 5 kDa did not affect the inhibitory activity of mAbs (Figure 3A,B). However, both the SER-4 and 3D6 mAbs containing 2 molecules of PEG 20 kDa showed a slight reduction in inhibitory activity when compared with unlabeled mAbs (Figure 3C,D). This difference was statistically significant only in the case of 3D6 mAb ($P < 0.001$). These results showed that PEGylation of N-terminal residues of anti-Sn mAbs had little or no effect on their antigen binding strength.

Effect of PEGylation on Inhibitory Potency of SER-4 and 3D6. Human RBC bind strongly to Sn in a sialic acid dependent manner, and this provides a useful model system to study adhesion mediated by the receptor (*17*). To investigate whether PEGylation of anti-Sn mAbs could enhance their inhibitory potency, we used a well-defined solid-phase RBC binding assay in which recombinant Sn is coated on a plate and allowed to bind RBC in the presence and absence of anti-Sn mAbs (*5*). As shown previously (*5*), we found that neither SER-4 nor 3D6 mAb was able to inhibit binding when added alone, but in combination, they reduced binding by about 75% (Figure 4). When the inhibitory activities of PEGylated mAbs were analyzed, SER-4 carrying 2 molecules of PEG 20 kDa resulted in about 75% inhibition, but incorporation of 1 or 2 molecules of PEG 5 kDa or 1 molecule of PEG 20 kDa had no effect (Figure 4A). As SER-4 is directed to domains 2/3 of Sn, it is likely that the steric effects of 2 molecules of PEG 20 kDa are sufficient to mask the sialic acid binding pocket on domain 1 of Sn and inhibit the binding of RBC.

In the case of 3D6, no increased inhibition was seen with 1 molecule of PEG 5 kDa, but 2 molecules of PEG 5 kDa resulted in ∼75% inhibition. Strikingly, complete inhibition of RBC binding was seen with 3D6 carrying either 1 or 2 molecules of PEG 20 kDa with an IC_{50} values of 0.5 and 0.35 μg/mL, respectively (Figure 4B).

Finally, we compared inhibitory potency of antibodies when used in combination. A total of sixteen combinations of SER-4-PEG and 3D6-PEG were compared to the parent SER-4 and 3D6 combination in solid-phase RBC binding assays, and the IC_{50} values were calculated (Figure 5). All combinations of PEGylated antibodies were better inhibitors than the mixture of unlabeled SER-4 and 3D6. As expected,

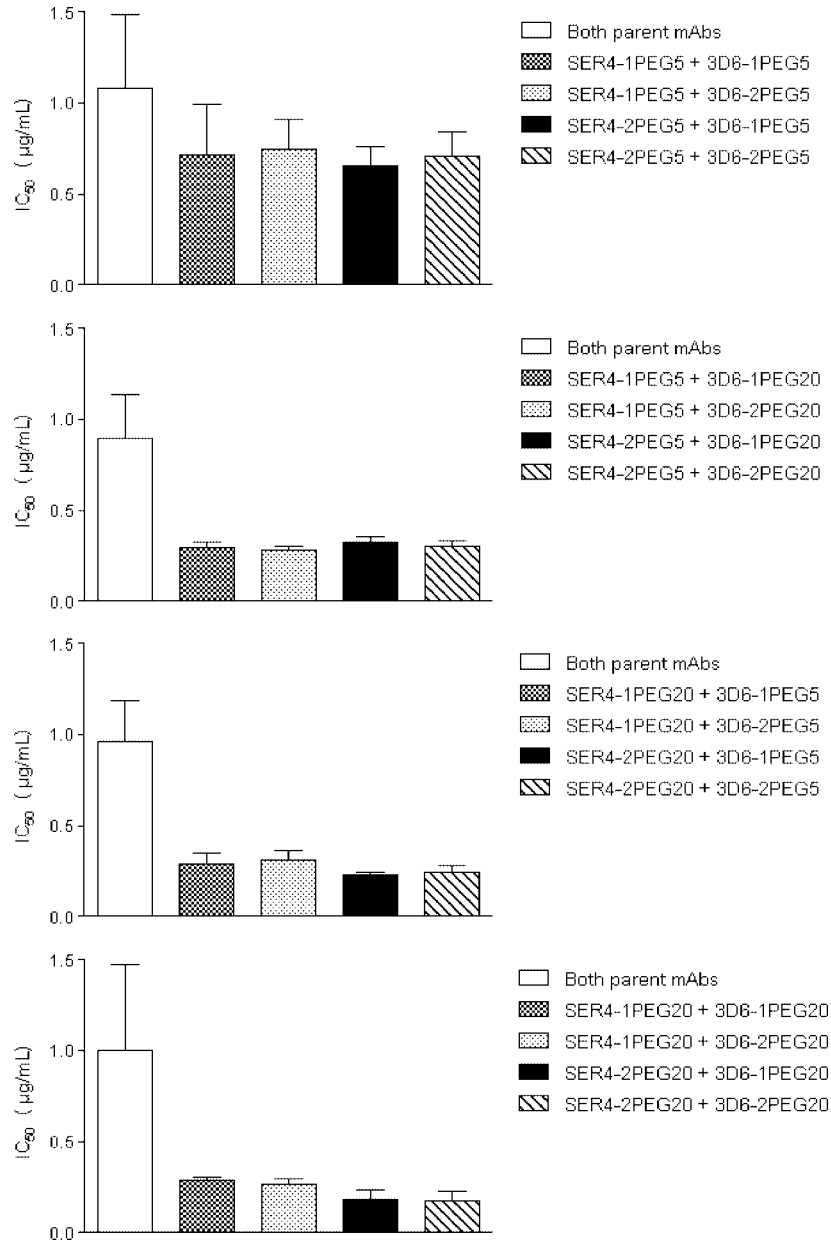

Figure 5. Inhibitory potency of PEGylated SER4 and 3D6 mAbs used in combination. A truncated form of Sn (domains 1 to 3) was coated on wells at a concentration of 2 μg/mL. Wells were then preincubated with serially diluted unconjugated mAbs or PEG conjugates in combination prior to the addition of human RBC. A total of sixteen combinations of SER-4-PEG and 3D6-PEG were compared to the parent SER-4 and 3D6 combination in RBC binding assays and concentrations inhibiting 50% of RBC binding (IC_{50}) were compared. All combinations of PEGylated antibodies were better inhibitors than the mixture of unlabeled SER-4 and 3D6. Bar represents the mean values of $IC_{50} \pm$ SD ($n = 3$ in duplicate wells).

the inhibitory potency further increased in line with the degree of PEGylation, with the most potent combination containing SER-4 and 3D6, each with 2 molecules of PEG 20 kDa, resulting in an IC_{50} of 0.3 μg/mL compared to an IC_{50} of $\sim$1.0 μg/mL using the mixture of non-PEGylated SER-4 and 3D6 mAbs (Figure 5).

In conclusion, this study shows that PEGylation of antibodies directed to the macrophage adhesion molecule, Sn, can have a dramatic effect on the inhibitory potency with minimal impact on binding strength. The pattern of results seen using the two antibodies directed to different epitopes, two sizes of PEG and different extents of derivatization fits very well with the concept of PEG-dependent steric hindrance. Thus, PEGylation of antibodies directed to cell surface receptors leads not only to increased circulating half-life, but also increased inhibitory potency that could be potentially exploited in a therapeutic setting such as in autoimmune or inflammatory diseases.

ACKNOWLEDGMENT

We would like to thank Sharon Shepherd for assistance with the FPLC analysis and purifications and the 'FingerPrints' proteomics facility (University of Dundee, Scotland) for providing the mass-spectrometry analysis of PEGylated conjugates. This research was funded by a "FIRST EUROPE" grant (Walloon Region, Belgium and European social fund) and a Wellcome Trust Senior Fellowship awarded to PRC. Rita Vanbever is a Chercheur Qualifié of the Fonds National de la Recherche Scientifique (FNRS, Belgium).

REVIEWS

A Semiempirical Model of Tumor Pretargeting

Guozheng Liu* and Donald J. Hnatowich

Division of Nuclear Medicine, Department of Radiology, University of Massachusetts Medical School, Worcester, Massachusetts 01655. Received July 3, 2008; Revised Manuscript Received September 4, 2008

This article provides an overview of a semiempirical pretargeting model now under development. After a brief review of the pretargeting concept, the strategies available, and the complexities of optimizing the dosage and timing, a semiempirical model is described that is not only capable of optimizing dosage and timing but also capable of predicting the results of pretargeting as a function of most pretargeting variables. The model requires knowledge of the pharmacokinetics of both the pretargeting agent (usually an antibody) and the effector, the accessibility of the pretargeting antibody for the effector, and their quantitative relationships in vivo. Several misconceptions that often surround pretargeting are also clarified.

INTRODUCTION

Conventional targeting of solid tumor with radiolabeled antibodies has vastly improved recently with the development of high-affinity antibodies and small antibody-like constructs. Similar improvements have also been made in parallel in the pretargeting of solid tumors for both imaging and therapy (*1*−*10*) such that encouraging results are now increasingly being reported in clinical trials of pretargeting (*11*). Pretargeting is popularly considered as a means of separating tumor targeting and radionuclide delivery and thus differs from conventional targeting in which the two are bound and administered together (*2, 3, 12*−*18*). The concept, strategies, applications, and prospects of pretargeting have been frequently reviewed (*1, 2, 9, 14, 16*−*29*), but the description of the pretargeting process therein remains largely qualitative, and pretargeting investigations are generally performed with dosages and timing selected largely by trial and error. Recently, we have made efforts to understand the pretargeting process quantitatively (*30*−*33*).

The justification for these efforts is the promise of greatly improved tumor-to-nontumor (T/NT) radioactivity ratios achieved shortly after administration of the radiolabeled effector compared to the conventional targeting with radiolabeled antibodies (*34*−*39*). By attaching the radionuclide to a small effector designed for rapid pharmacokinetics, the nuclide not only reaches the tumor rapidly but also clears rapidly from most normal tissues. The rapidly improving T/NT ratios of the radionuclide permit early imaging and reduce unwanted radiation exposure to normal tissues. The T/NT ratios in some tissues reached in hours by pretargeting are often equivalent to those achievable in days by conventional targeting, and more favorably, the T/NT ratios by pretargeting in some other tissues such as liver and spleen may actually exceed those by conventional targeting. This latter favorable outcome will result if the antibody becomes sequestered in these tissues (but not the tumor) and thereby becomes "invisible" to the radiolabeled effector. However, suggestions that pretargeting will provide a higher percent tumor accumulation of the radiolabeled effector may not be correct

(*15*, *22*, *27*−*29*), since the rapid pharmacokinetics of the effector will limit the efficiency of its delivery into tumor and thus limit the percent accumulation (*40*).

Since the concept, approaches, applications, and prospects of pretargeting have been adequately reviewed (*1*, *2*, *9*, *14*, *16*−*29*), there is little need for another comprehensive coverage of past studies. Instead, this contribution focuses on the difficulty of optimization in pretargeting and describes a semiempirical model under development in this laboratory that not only is capable of optimizing dosage and timing but also is capable of predicting the results of pretargeting as a function of most pretargeting variables. We begin with an introduction briefly summarizing the different pretargeting systems and conclude with a discussion of the utility of the semiempirical model. Because pretargeting has been exclusively applied to tumor as the target, this report will refer throughout to pretargeting in this context, with the understanding that in the future normal tissues as targets may benefit from pretargeting as well.

PRETARGETING SYSTEMS

At least three systems have now been used for pretargeting: bispecific antibody/hapten (*41*, *42*), (strept)avidin/biotin (*43*), and oligomer/complementary oligomer (*44*−*46*), each with several distinct strategies. The simplest strategy includes two injections, and more complicated strategies may add one or more intermediate injections to clear the pretargeting antibody in the circulation, to amplify the number of the targeting sites on the cell surface, to block the binding sites of the pretargeting antibody still in blood and normal tissues, or, in the case of (strept)avidin/biotin pretargeting, to avoid the interference of endogenous biotin.

Concerning first the bispecific antibody/hapten system, the usual strategies involve two injections, although a blocking or clearing agent may be administered intermediately between the antibody and effector (*47*−*50*). Three types of hapten effectors have been reported: monovalent of moderate affinity, bivalent of moderate affinity, and monovalent of infinitive affinity. Figure 1 schematically illustrates the binding patterns of the three haptens. A monovalent hapten of moderate affinity (a) was reported to provide insufficient tumor retention (*51*−*54*). As a result, bivalent haptens (b) are usually used. The rationale for the use of bivalent hapten is that bivalency has been reported to provide enhanced binding affinity to the tethered antibody on tumor compared to the untethered antibody in circulation (*25*). The most recent effort to enhance binding affinity (*1*) involves a covalent bond formed automatically following the binding of the hapten to the antibody (c). Since this covalent bond will presumably form in circulation as well, whether this strategy provides lower T/NT ratios compared to the affinity enhancement remains to be seen.

Figure 2 illustrates three streptavidin/biotin strategies. In contrast to the bispecific antibody/hapten system, the streptavidin/biotin system is more flexible, since both (strept)avidin

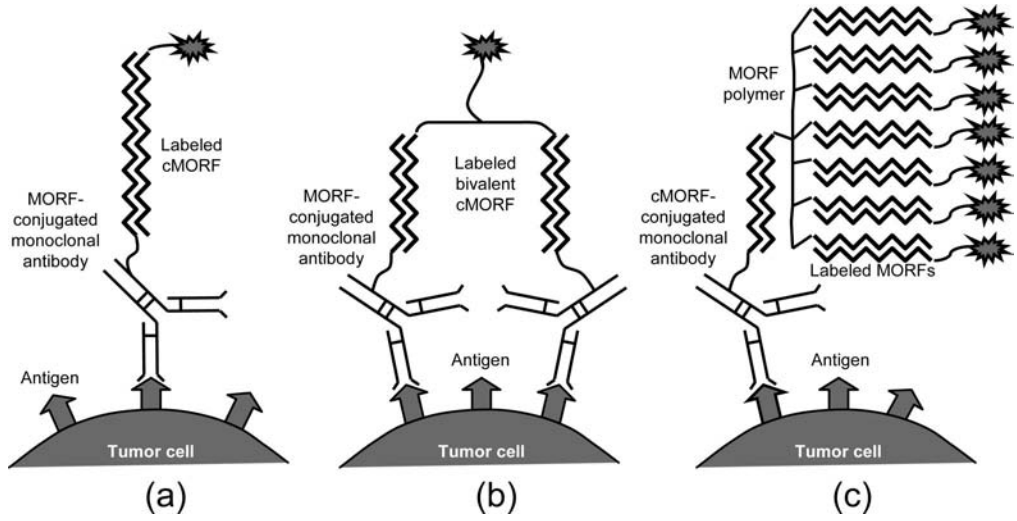

Figure 3. Three MORF/cMORF pretargeting strategies under development: (a) traditional two-step pretargeting, (b) affinity enhancement pretargeting, and (c) amplification pretargeting.

and biotin can be used as effectors. However, using radiolabeled (strept)avidin as effector and a biotinylated antibody (biotin is a small molecule also known as vitamin H) as pretargeting agent (a) is no longer being pursued (*43, 55−59*), because the slow pharmacokinetics of the radiolabeled (strept)avidin (*60, 61*) violates the principle of pretargeting whereby the radiolabel is to be attached to an effector with rapid pharmacokinetics. Therefore, the radiolabel is now attached to biotin and the (strept)avidin to the antibody (b). A potential complication of this strategy is the interference by endogenous biotin (*62, 63*) and the immunogenicity of streptavidin (*64*). Avidin may be a less immunogenic substitute for streptavidin (*65*) possibly only because its glycosylation encourages rapid accumulation into the liver (*66*). While a simple two-step strategy was used initially to show proof-of-concept (*67−70*), most studies now include a clearing step prior to effector administration. Increasing the pretargeting interval, i.e., the time between injections, would accomplish the same goal of clearing the pretargeting antibody but perhaps at the expense of reduced antibody expression in tumor due to internalization. Evidence has been presented that certain antibodies internalize more rapidly after conjugation with streptavidin (*71, 72*).

Another pretargeting strategy (c) of the same system involves three steps, the stepwise administration of biotin-antibody, avidin, and radiolabeled biotin (*43, 56, 73, 74*). The avidin serves multiple purposes: it clears the biotinylated antibody into the liver, helps clear endogenous biotin, and may modestly amplify the signal on the tumor sites by as much as a factor of 3 (*75*).

Within the oligomer/complementary oligomer system, the most extensively studied strategy thus far is to use phosphorodiamidate morpholino oligomers (MORFs). Other DNA analogues have been little used for a variety of reasons including instability of the native phosphodiester DNAs to nucleases (*44, 76*), the high binding affinity of phosphorothioate DNAs to serum and tissue proteins (*77*), and the aqueous insolubility of peptide nucleic acids (PNA) depending upon base sequence (*78*). MORFs exhibit high hybridization affinities to their complements (cMORFs), good hydrophilicity, and fast renal clearance (*79*). The different MORF/cMORF pretargeting strategies now under development are shown in Figure 3, including (a) the traditional two-step pretargeting, (b) affinity enhancement pretargeting, and (c) amplification pretargeting. While investigations of the latter two strategies continue (*80, 81, 78, 82, 83*), emphasis thus far has been on the first (*30−33, 46, 84−87*) because of its relative simplicity.

Although not described in this article, several miscellaneous studies could be considered pretargeting such as the use of enzyme/substrate interactions as a recognition system (*88*) and the use of MORF/cMORF binding to quantitate the internalization of antibodies (*89*).

FUNDAMENTAL DIFFICULTIES IN OPTIMIZING DOSAGE AND TIMING IN PRETARGETING

Although pretargeting has improved radionuclide delivery over conventional targeting, the improvement comes with a degree of complexity not shared by conventional targeting. Compared to the two variables of conventional targeting (dosage of radiolabeled antibody and detection time), there are four dosage-and-timing-associated variables in two-step pretargeting strategies (dosage of the pretargeting antitumor antibody, the pretargeting interval, the dosage of labeled effector, and the detection time) and considerably more in three-step strategies. The relationship between the two variables in conventional targeting is relatively simple. Provided that antigenic sites are not saturated, the percent of radioactivity accumulating in tumor does not vary greatly with the dosage of radiolabeled antibody but varies only with time. By contrast, in pretargeting, the accumulation in tumor of the radiolabel, now on the effector, will be influenced by changes in any of the pretargeting variables. Furthermore, there are at least three more system-associated variables (the pretargeting antibody, the radiolabeled effector, and the tumor model) compared to only two in conventional targeting (the radiolabeled antibody and the tumor model). Therefore, optimization of pretargeting is comparatively difficult especially in clinical trials (*40*).

In practice, optimization in pretargeting is almost always achieved experimentally. Theoretically, mathematical modeling could provide a method of simplifying the optimization. Several reports on purely mathematical modeling have appeared. For example, one report simulated an antibody/hapten pretargeting system (*90*), but the quantitatively predictive accuracy may have been compromised by the use of an oversimplified pharmacokinetic model and assumed parameters. A similar attempt at mathematical modeling compared a biotin/streptavidin two-step pretargeting strategy to a conventional targeting, but once again assumed parameters were used in the model (*91*). Similar observations may apply to additional reports (*92, 93*). In general, thus far pure mathematical modeling has not been able to predict optimal pretargeting conditions. In referring to those attempts, it has been stated that "some of the apparent anomalies between

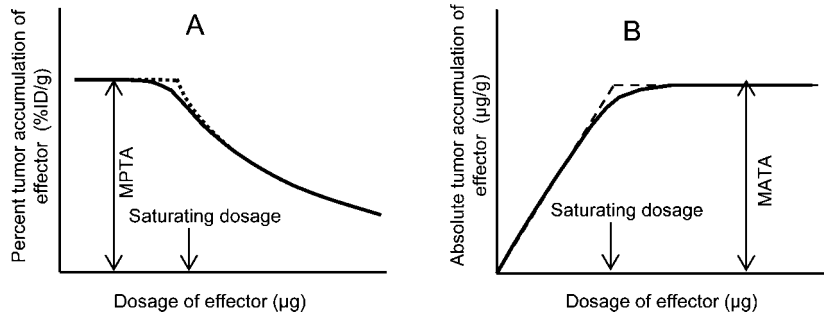

Figure 4. Schematic illustration of the relationship between the percent (A) and the absolute (B) tumor accumulation of effector and its dosage in pretargeting. The dotted lines represent theoretical curves (*30*).

the model and experience may be the result of using assumed parameters in the model which are not truly representative" (*29*).

While previous reports on experimental optimization do not describe a generalized approach, two reports, both concerning the bispecific antibody/hapten two-step strategy, deserve mention. One study optimized the pretargeting interval, antibody dosage, effector dosage, and detection time (*54*) by considering each variable separately while holding the others fixed at arbitrary values. In the second study (*94*), the influence of antibody dosage on the pharmacokinetics of a bispecific antibody was first determined, and an antibody dosage below antigen saturation was selected for the optimization of the pretargeting interval. Thereafter, optimization of the dosages of effector and antibody was achieved by increasing the effector dosage at fixed antibody dosage and vice versa. The pretargeting interval was arbitrarily set and, as the authors stated, "this interval might require further adjustment if either the bsMAb or peptide dosage changes".

More difficulties have been encountered in the optimization of the streptavidin/biotin pretargeting system, since most of these strategies involve three-steps. Among these three-step studies, those of Sharkey et al. (*63*) and Axworthy et al. (*95*) did not rely solely on trial and error. In the latter study, the dosage of antibody−streptavidin was first optimized by measuring antigen saturation. Then, the streptavidin accessibility was measured by histochemical examinations of tumor at two time points. Subsequently, at a fixed antibody dosage and a fixed pretargeting interval, a dosage of the clearing agent capable of removing more than 90% of the circulating antibody−streptavidin was selected along with an optimal dosage range of the radiolabeled biotin. However, optimization is always conditional on the selection of antibody dosage and pretargeting interval. Any change in these or other variables such as different antibodies will require a corresponding change in dosage of the clearing agent and dosage of the effector. Thus, these optimization studies provide limited general guidance (*36, 96*−*100*).

Similar optimization studies based purely on experimental observations of the MORF/cMORF pretargeting system have encountered similar difficulties even for the simplest two-step strategy. In one example (*85*), the influence of pretargeting interval on the pretargeting results was first examined, followed by the influence of the pretargeting antibody dosage. It subsequently became apparent that this optimization is incomplete, resulting in incorrect conclusions about the accessibility of antibody and antigen saturation (*30*).

In principle, any pretargeting strategy can be fully optimized experimentally provided that sufficient studies with variations in these variables have been performed, but besides being impractical in most cases, the optimization conditions of one system established in this manner will not apply to another. Furthermore, optimization in this manner would be extremely difficult in the clinic (*101*−*105*).

QUANTITATIVE UNDERSTANDING OF PRETARGETING − A SIMIEMPIRICAL MODEL

Recently, we have made efforts to understand pretargeting quantitatively beginning with the relatively simple two-step strategy of the MORF/cMORF pretargeting system (*30*−*33*). A semiempirical model capable of estimating the optimal tumor accumulation and optimal T/NT ratios for any combination of pretargeting variables was designed that will hopefully lead to an understanding of how each variable influences the pretargeting outcome. The influences of different pretargeting variables on both percent and absolute tumor accumulations (%ID/g and μg/g) of the effector and its radioactivity levels in normal organs were first examined so that several quantitative relationships could be established. These relationships are summarized below.

1. Maximum Percent and Maximum Absolute Tumor Accumulations (MPTA and MATA) of Effector. The tumor accumulation of radiolabeled effector has been expressed quantitatively by the following equation:

$$\text{Tumor accumulation of effector (\%ID/g)} = F \times f \times W^{-1} \times \int_{t=0}^{t=\infty} E \times C(\%\text{ID/g})_{\text{blood}} \times \mathrm{d}t \quad (1)$$

where F is the cardiac output; f is the fraction of the cardiac output reaching tumor; W is the tumor weight; E is the tumor trapping fraction of effector (defined as the retained fraction of effector molecules reaching the tumor); and C_{blood} is the blood level of free effector (i.e., effector in circulation not bound to circulating antibody) (*33*). This equation may be used to describe how the radiolabeled effector, tumor model, and pretargeting antibody influence the tumor accumulations of effector.

When the effector dosage is above that required to saturate the antibody in tumor, E will become zero, since additional effector arriving cannot be retained. However, at effector dosages below that required to saturate the antibody in tumor, E will be a constant of effector dosage, since during the entire delivery process (from $t = 0$ to infinity), the same fraction of effector reaching tumor will be trapped. Therefore, under these conditions E can be placed outside the integral sign in eq 1. Furthermore, under these conditions the tumor accumulation will be a maximum in percent, i.e., the maximum percent tumor accumulation (MPTA) as shown in eq 2:

$$\text{MPTA of effector (\%ID/g)} = F \times f \times W^{-1} \times E \times \int_{t=0}^{t=\infty} C(\%\text{ID/g})_{\text{blood}} \times \mathrm{d}t \quad (2)$$

By eq 2, the MPTA will vary with the tumor host (via F), tumor type and size (via f, W, and E), and the effector (via E and the integral of C) (*33*). The MPTA will not change with different antibodies provided that each antibody is not entirely inaccessible.

The influence of effector dosage on percent tumor accumulation is demonstrated schematically in Figure 4A. As shown, the percent tumor accumulation of the effector is a constant at its maximum value (MPTA) below the saturating dosage. Beyond this saturating dosage, the percent tumor accumulation gradually declines.

As shown in Figure 4B, the absolute tumor accumulation of radiolabeled effector (μg/g = %ID/g × dosage of effector (μg)/100%) increases linearly with the increasing dosage of effector until the saturating dosage is reached. Thereafter, the absolute tumor accumulation of the effector becomes constant at its maximum value (MATA), as further effector cannot bind to the saturated antibody localized in tumor.

2. Tumor Saturating Dosage of Effector and Accessibility of Antibody in Tumor. The number of moles of a monovalent effector accumulated in tumor at the point of saturation will equal the number of moles of antibody in tumor after corrected for groups per molecule and accessibility (*30, 31*). Thus, the tumor saturating dosage of effector ($SD_{effector}$) is related to the administered antibody dosage by eq 3:

$$\frac{SD_{effector}}{MW_{effector}} \times MPTA = \frac{D_{antibody}}{MW_{antibody}} \times \%ID/g_{antibody} \times gpm \times accessibility \quad (3)$$

where $MW_{effector}$ is the molecular weight of the effector; $D_{antibody}$ and $MW_{antibody}$ are, respectively, the dosage and the molecular weight of the antibody; the $\%ID/g_{antibody}$ is the tumor accumulation of antibody; gpm is the number of the effector-binding sites on each antibody; and the accessibility is the fraction of the effector-binding antibody in tumor still accessible to the effector at the time of effector administration. Since the MATA in μg is equal to the product of the number of micromoles of effector in tumor and its molecular weight, it is related to administered antibody dosage by eq 4:

$$\text{MATA of effector} = \frac{MW_{effector}}{MW_{antibody}} \times D_{antibody} \times \%ID/g_{antibody} \times gpm \times accessibility \quad (4)$$

Unless a pretargeting antibody is radiolabeled, its tumor accumulation ($\%ID/g_{antibody}$) is difficult to measure. It is commonly assumed that the pharmacokinetics of an antibody may be accurately traced by its radioactivity if radiolabeled with a limited gpm and with care leading to preserved integrity and immunoreactivity. Although this assumption is valid in at least one case of an antibody (*30*), we recently found that the biodistribution of antibodies can differ significantly when labeled with the same chelator but with different linker between the antibody and the chelator (*32*). We therefore believe that, for the purposes of prediction, measuring the biodistribution of radiolabeled antibody should be assumed to provide only an approximate measure of the pharmacokinetics of the unlabeled antibody. Fortunately, it is not the concentration of the antibody but the concentration of the accessible antibody, i.e., the product of $\%ID/g_{antibody}$ × accessibility, that is important. This concentration of accessible antibody can be measured by observing how the tumor accumulation of the radiolabeled effector changes with increasing effector dosage as in Figure 4. In a recent study, we measured the accessible level of a pretargeting antibody using this effector dosage escalation approach (see below).

3. Quantitative Presentation of Effector Levels in organs. Simple considerations will illustrate how the effector levels in tumor and normal tissues may be predicted (*31*). As mentioned above, before saturation of the antibody, the percent tumor accumulation of the effector is the MPTA. After saturation, the percent accumulation of effector in tumor will be the bound effector in tumor and the free effector present in blood within the tumor as in eq 5:

$$\text{Tumor accumulation of effector} = \%ID/g_{total\ effector\ in\ tumor} = \frac{D_{antibody} \times \%ID/g_{antibody} \times gpm \times accessibility}{MW_{antibody}} \times \frac{MW_{effector}}{D_{effector}} + \%ID/g_{free\ effector\ in\ tumor} \quad (5)$$

At the time of effector administration, the level of antibody in circulation is usually sufficiently low such that the antibody in blood becomes saturated with the effector. Thus, the total effector level in blood is the sum of both antibody-bound and free, as expressed in eq 6:

$$\%ID/g_{total\ effector\ in\ blood} = \frac{D_{antibody} \times \%ID/g_{antibody\ in\ blood} \times gpm}{MW_{antibody}} \times \frac{MW_{effector}}{D_{effector}} + \%ID/g_{free\ effector\ in\ blood} \quad (6)$$

In the same manner, the level of effector in an organ equals the level of effector bound to antibody plus the level of free effector in that organ. However, we have found experimentally that the effector-bound antibody in any organ other than kidney (see below) is in equilibrium with the effector-bound antibody in blood (*31*). Therefore, these organ levels can be obtained from the antibody-bound effector in blood, the organ to blood ratios of bound effector ($R_{O/B}$), and the free effector in that organ:

$$\%ID/g_{total\ effector\ in\ organ} = (\%ID/g_{total\ effector\ in\ blood} - \%ID/g_{free\ effector\ in\ blood}) \times R_{O/B} + \%ID/g_{free\ effector\ in\ organ} \quad (7)$$

Since the effector clears through kidney, the sole exception to eq 7 is this organ. The radioactivity level of effector in this organ is a function of the effector itself and is approximately independent of the accumulation of antibody.

If the pharmacokinetics of the pretargeting antibody and effector and the accessibility of the antibody are known, the biodistribution of the labeled effector under any conditions can be calculated using the above quantitative relationships (*31*). Since the application of these relationships requires experimental data, this model is semiempirical.

UTILITY OF THE SEMIEMPIRICAL MODEL

Besides helping to optimize dosage and timing, the semiempirical model may provide useful guidance in the selection of a pretargeting strategy including the selection of antibody and effector (pretargeting pair), their evaluation in preclinical studies, and, if encouraging, their use in clinical trials. Even though empirical measurement will continue to play an important role in each step, we believe that quantitative understanding may be helpful in reducing the number of empirical measurements needed.

Observations Useful in the Optimization of Timing and Dosages. The following observations resulting from studies on a two-step MORF/cMORF pretargeting strategy in a given mouse tumor model will be of general guidance for the optimization of T/NT ratios and tumor accumulations in the two-step strategies of other pretargeting systems (*33*).

a. Any dosage of pretargeting antibody is acceptable that is below that required to saturate the tumor antigenic sites. Higher antibody dosages may benefit diffusion into tumor against a binding site barrier or pressure gradient but will result in increased blood levels and therefore lower T/NT ratios.

b. Any pretargeting interval is acceptable that provide a set of acceptable T/NT ratios of antibody in all normal organs of interest. The T/NT ratios of the antibody usually improve steadily with increasing pretargeting interval over at least several days. If desired or necessary, acceptable T/NT ratios may be achieved at an earlier pretargeting interval through the use of an antibody clearance agent.

c. The optimal dosage of radiolabeled effector is the dosage just sufficient to saturate the accessible antibody in tumor.

d. Any detection time is acceptable that provides an acceptably low level of free radiolabeled effector in circulation and tissues (except kidney) compared to the level of effector bound to pretargeting antibody.

As an example of the application of these guidelines, in the case of the two-step MORF/cMORF strategy, optimization of the dosage and timing began by separately measuring the pharmacokinetics of both the labeled pretargeting antibody and the ^{99m}Tc-labeled cMORF effector and by measuring dosage saturation of tumor by antibody. The antibody results provided an estimate of the MORF-antibody concentration in tumor and provided a means of selecting the pretargeting interval. In this case, a time was chosen when the antibody reached 1−2%ID/g in blood. Knowledge of the pharmacokinetics of the labeled effector provided a means of selecting an acceptable detection time when the labeled effector was essentially cleared from circulation, in this case a blood level of 0.04%ID/g at about 3 h. The accessible level of the pretargeting antibody was then accurately measured by dosage escalation of the labeled effector so that the optimal dosage of the effector could be predicted.

Selection of Pretargeting Pairs. Any comparison of different pretargeting pairs should be under optimal conditions of dosage and timing for each. Fortunately, because of the quantitative relationships provided by the semiempirical model, the experiments required to obtain the optimal conditions may not all be necessary. Using the two-step pretargeting strategy again as the example, one prediction from eq 2 is that the nature of the pretargeting antibody normally does not influence the MPTA. It has been reported correctly that the pretargeting antibody affects percent tumor accumulation of effector (*36, 106*−*109*), but these percent tumor accumulations were not at the MPTA defined by eq 2. Thus, two pretargeting antibodies may differ in their level of tumor accumulation but still provide the same MPTA of the effector (*33*).

Selection of the antibody should therefore be dictated by the desired effector T/NT ratios rather than a desired effector MPTA. The effector T/NT ratios by pretargeting can be roughly estimated from the T/NT ratios of the radiolabeled antibody, but an accurate prediction of effector T/NT ratios requires the T/NT ratios of the accessible antibody. The tumor accessible level of antibody can be measured accurately by effector dosage escalation. Antibodies in blood may be assumed to be completely accessible to the effector. Since effector-bound antibody in any organ (other than kidney) is in equilibrium with the effector-bound antibody in blood, it becomes relatively easy to estimate the accessible levels of the antibody in these organs using the empirical organ/blood ratios of the accessible antibody. In this way, the effector T/NT ratios achievable with that antibody can be predicted with reasonable accuracy.

Another observation useful in the selection of the pretargeting antibody is its influence on the MATA. Higher absolute concentration of effector binding sites will lead to higher MATA, which can be achieved by increasing the dosage of the pretargeting antibody (*30*), increasing the gpm of pretargeting antibody (*110*), choosing a pretargeting antibody with better tumor accumulation (*33*), or, perhaps more effectively, using an amplification mechanism (*78, 82, 83*).

Concerning the selection of the effector, although any effector will be suitable, provided it is not trapped in any normal organs, the semiempirical model shows that the MPTA of different effectors can be different and usually the effectors providing higher MPTA will be preferred. The selection among effectors can be accomplished by measuring their MPTA values by effector dosage escalation. No further studies are required. As such, judgment can be reached on which effector is superior in tumor accumulation with no need of a pretargeting study under optimal pretargeting conditions.

The Semiempirical Model and the Clinic. The ultimate objective of pretargeting optimization studies is to improve tumor targeting in the clinic. In principle, the above observations obtained from the model MORF/cMORF pretargeting studies in animals should apply equally well in patients.

The main complication in clinical translation is tumor variation. Tumors originating from the same organ may differ in antigenic expression from patient to patient, and the antigenic expression of metastases may vary from its primary tumor. Experimentally, tumor type can greatly influence tumor accumulation of both antibody and effector. For example, tumor accumulation of a labeled cMORF in the LS174T tumor model (*31*) was 2−4 times higher than that in the CWR22 model (*32*). Similarly, the tumor accumulation of another labeled effector in one tumor model (*111*) was 10 times that in another (*112*). It can be easily understood from eq 2 that the MPTA of an effector may be different for different tumor models.

A better understanding of how tumor properties influence tumor accumulation of both antibody and effector would certainly be helpful both in selecting a pretargeting antibody dosage that does not saturate tumor antigenic sites and in selecting the saturating dosage of effector. Because experiences thus far on the use of different tumor models for pretargeting are limited, our understanding of the tumor influence on the pretargeting results is also limited. For example, whereas tumor size was found to correlate inversely with the effector accumulation in tumor in one tumor model (*31*), it was found to have no influence on the effector accumulation in another (*32*).

Planning a pretargeting study in a cancer patient might proceed by administering the radiolabeled pretargeting antibody at a tracer dosage that is expected to be below the antigen saturation dosage. By both noninvasive imaging and blood sampling, knowledge of the pharmacokinetics of the antibody can be obtained that will help to select an acceptable pretargeting interval. Thereafter, a dosage of labeled effector that is expected to just saturate the antibody in tumor may be selected on the basis of the assumption of an accessibility in tumor comparable to that in blood. In this way, an estimate of the MPTA and the T/NT ratios can be made. Presumably, a strategy of this complexity may have more relevance to tumor radiotherapy than imaging.

General Applicability to Other Pretargeting Systems and Strategies. Thus far, the development and applications of the semiempirical model have been limited to the two-step MORF/cMORF model pretargeting system. However, the semiempirical model should apply equally well to other two-step pretargeting systems and strategies, provided that the pharmacokinetic parameters are available, possibly after minor modifications. For example, a valency correction will be required in the application of eqs 1−6 to the streptavidin/biotin system if multiple biotin binding sites are present. Furthermore, for any system or strategy, it will be necessary to confirm in connection with eq 7 that the accessible levels of effector binding sites in blood and normal organs are in equilibrium. Otherwise, all quantitative relationships should remain valid.

CONCLUDING REMARKS

A semiempirical model of pretargeting is under continuous development and has been applied thus far to the two-step MORF/cMORF pretargeting strategy in mouse tumor models. The resulting observations may be used as a guide for the optimization of dosage and timing, leading to a set of optimal conditions with much less effort than required by trial and error. Even though the application of this model to the clinic has yet to be attempted, its utility is readily apparent, since the

pretargeting mechanism and the quantitative relationships should be identical for patients as subjects. Nevertheless, despite these pretargeting observations, the ability to select an optimal pretargeting procedure for a patient by semiempirical analysis must await further studies on how tumor variance influences tumor accumulations of both the pretargeting antibody and the effector.

Covalently conjugated sialyl Lewis X (SLeX) on the mesenchymal stem cell (MSC) surface through a biotin−streptavidin bridge imparts leukocyte-like rolling characteristics without altering the cell phenotype and the multilineage differentiation potential. We demonstrate that the conjugation of SLeX on the MSC surface is stable, versatile, and induces a robust rolling response on P-selectin coated substrates. These results indicate the potential to increase the targeting efficiency of any cell type to specific tissue.

Cell therapy including platelet transfusions, bone marrow cell infusion, and islet cell transplantation have had a profound impact on improving patient quality of life and extending patient survival overall, and have demonstrated an impressive safety record (*1*). Culture expanded mesenchymal stem cells (MSCs), also referred to as connective tissue progenitor cells, have been approved for a limited number of applications (*2*) and have recently entered preclinical and clinical trials for treatment of numerous ailments including heart disease (*3*−*5*), brain and spinal cord injury (*6*), cartilage and bone injury (*7*, *8*), Crohn's disease (*9*), and graft versus host disease during bone marrow transplantation (*10*). The significant interest in MSC based therapies is due to their convenient isolation, lack of significant immunogenicity (*10*−*12*), lack of ethical controversy, and potential to differentiate into tissue specific cell types. However, a significant barrier to the effective implementation of all cell therapies is the inability to deliver these cells under minimally invasive conditions with high efficiency of engraftment within tissues of interest. Systemic infusion is thus a desired mode of cell delivery; however, systemically administered culture expanded MSCs home at low efficiencies (*13*−*16*).

The white blood cells (i.e., leukocytes) and hematapoetic stem cells have evolved mechanisms for effective and specific tissue targeting (i.e., "homing" or "trafficking") that have been dissected at the cellular, molecular, and biophysical level. This includes a multistep adhesion and activation cascade that allows leukocytes to adhere to the luminal surface of the vascular endothelium and subsequently migrate into the underling tissues. It is well-established that transient rolling-type interactions (mediated by selectins) and transition to firm adhesion (mediated by integrins) are absolutely essential and limiting components of leukocyte and hematopoetic cell trafficking (*17*−*20*). The blood vessels in each tissue are known to exhibit particular surface properties that can direct the trafficking of circulating cells. In addition, upon an active stimulus such as inflammation, specific homing receptors or ligands are expressed on the surface of the endothelium within the inflamed tissue.

Current MSC transfusion experiments have shown that only subsets of MSCs have the capacity to home to specific tissues (*21*) and that MSCs may lose their capacity to home after cell culture (*22*). This is complicated by the heterogeneity in receptor expression on MSCs and the changes in receptor expression observed during culture (*23*−*25*). The limited homing efficiency of MSCs is likely due to a lack of relevant cell surface adhesion molecules.

The central hypothesis for this work is that surfaces of cells that exhibit poor homing capabilities such as culture expanded MSCs (*26*−*29*) can be engineered to possess leukocyte-like adhesion properties, without otherwise altering function, in order to promote more effective rolling, adhesion, and ultimately *in vivo* homing. The proof of principle for this hypothesis is provided by recent work by Sackstein et al., which showed enhanced bone marrow engraftment of systemically administered MSCs (*30*). Strategies for modification of cell surfaces to promote adhesion are typically elaborate and include genetic modifications, insertion of glycosylphosphatidylinositol-modified proteins into the membrane, and metabolic delivery of specific moieties to the cell surface (*31*). While it has been shown that cells modified using *N*-hydroxy-succinimide ester coupling to cell surface amine groups retain viability and the ability to be cultured (*32*, *33*), this simple strategy has not been explored for promoting stem cell homing. Here, we demonstrate that it is possible to use this simple strategy to covalently couple the sialyl Lewis X (SLeX) moiety onto the surface of mesenchymal stem cells (MSCs) through biotin−streptavidin chemical modifications (Scheme 1) without compromising MSC viability, adhesion, proliferation, and multidifferentiation potential. We further show that this modification of SLeX homing receptors onto the surface of MSCs can promote a cell rolling response *in vitro* on substrates coated with P-selectin. A simple coupling scheme that is minimally invasive on the cell makes this

approach a simple method to potentially target any cell type to specific tissues via the circulation.

The free amine groups present on the surface of cells are available to react with the *N*-hydroxy-succinimide group of biotinyl-*N*-hydroxy-succinimide to biotinylate the cell surface. To improve the biotinylation efficiency, sulfonated biotinyl-*N*-hydroxy-succinimide (sulfo-NHS-Biotin, BNHS) was used. BNHS is water-soluble, which limits its transport through the cell membrane and thus facilitates maximal interaction of the NHS group with the cell membrane. After biotinylating the MSC surface, cells were incubated with streptavidin to form biotin−streptavidin complexes. The strong interaction between biotin and streptavidin stabilized the streptavidin on the cell surface. The streptavidin was then complexed with biotinylated-SLeX (sialyl-Lewis^X-PAA-Biotin, BSLeX; see Supporting Information) to introduce SLeX on the cell surface. It is believed that the absence of targeting agents such as SLeX on the surface of MSCs is responsible for their poor homing characteristics (*30*). Thus, we anticipated that synthetic immobilization of SLeX on the cell surface would induce a homing response through promoting cell rolling as shown in Scheme 1.

To assess the cell modification by BNHS and streptavidin, rhodamine-conjugated streptavidin (S) was added to biotinylated cells (BNHS+S), and incubated for 20 min. Subsequently, excess unbound S was removed by multiple washes with buffer, and the fluorescence intensity of the cells was measured. The controls used for this experiment were cells treated with only S (a control to assess the nonspecific adsorption of S), cells treated with both biotin (B) and S (B+S) to examine the need for covalent conjugation of biotin to the cell surface, and cells treated with only PBS to probe the impact of cell modifications on cell function and phenotype. The total fluorescence intensity was normalized to the group treated with PBS. All experiments were performed on ~80−90% confluent monolayers on tissue culture polystyrene, and fluorescence was only observed in regions with cells. Cells functionalized with BNHS (covalent attachment) had considerably higher fluorescence intensity compared to cells treated with B+S, indicating that cells that were covalently functionalized using the NHS moiety had greater amounts of streptavidin immobilized on their surfaces. After 7 days, the fluorescence intensity of BNHS+S treated cells was much higher compared to B+S and S controls (noncovalent

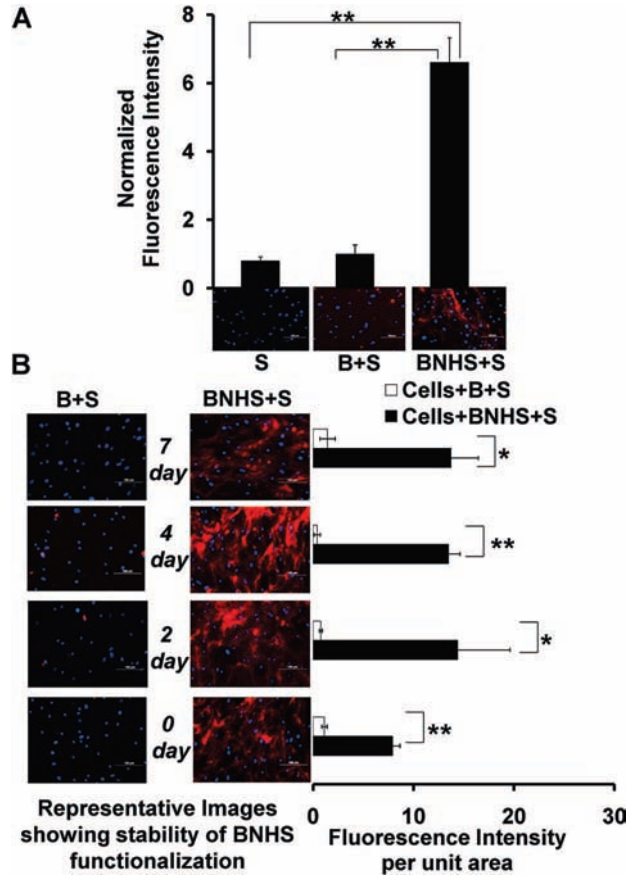

Figure 1. (A) Modification of the MSCs measured as a function of fluorescent signal 7 days after addition of S. (B) Accessibility (and stability) of covalently conjugated or adsorbed biotin on the MSC surface measured by addition of S at each time point.

and nonspecifically adsorbed, respectively), indicating that the conjugation of streptavidin to the biotinylated cells was efficient and stable (Figure 1A). By enumerating the number of DAPI stained nuclei with surrounding rhodamine fluorescence, after 7 days of the modification, the percentage of cells modified by BNHS+S was found to be 97 ± 1%, which was significantly higher than the controls B+S (10.5 ± 1.7%, $P = 0.004$) and S (2.3 ± 0.4%, $P = 0.008$). To assess the temporal accessibility of biotin on the cell surface, rhodamine−streptavidin was added at each time point to the biotinylated cells, and following multiple washes, the fluorescence intensity was measured (Figure 1B).

Specifically, MSCs were covalently functionalized with BNHS or functionalized via adsorption with native biotin (B) as a negative control. In both cases, experiments were conducted for 3 separate samples per group (triplicate) per time point. Each sample was processed and imaged. S was added on days 0, 2, 4, and 7, and after removing excess S by buffer washes, the fluorescence intensity was assessed (Figure 1B). An increase in the fluorescence intensity at day 2 compared with day 0 was observed, which may indicate the rearrangement and reorientation of the biotin moiety on the cell surface. The fluorescence intensity was stabilized and retained thereafter for up to 7 days and was significantly higher than the negative control at all time points ($P < 0.05$). This indicates the stability and accessibility of biotin on the cell surface via covalent immobilization chemistry. Presumably, streptavidin−biotin conjugated moieties, such as SLeX, would remain stably conjugated to the cell surface, accessible to interact with host biology. These results indicate the versatility and stability of the present approach.

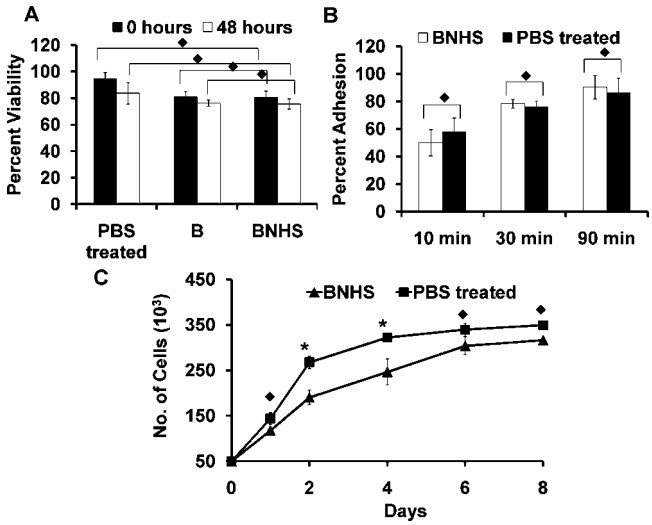

Figure 2. (A) Viability of the BNHS modified cells immediately after modification (0 h) and after 48 h. (B) Adherence of BNHS modified cells measured at 10, 30, and 90 min compared to the PBS treated cells. (C) Proliferation of the BNHS modified cells over an 8 day period compared to PBS treated cells. Error bars denote standard deviation from three separate experiments.

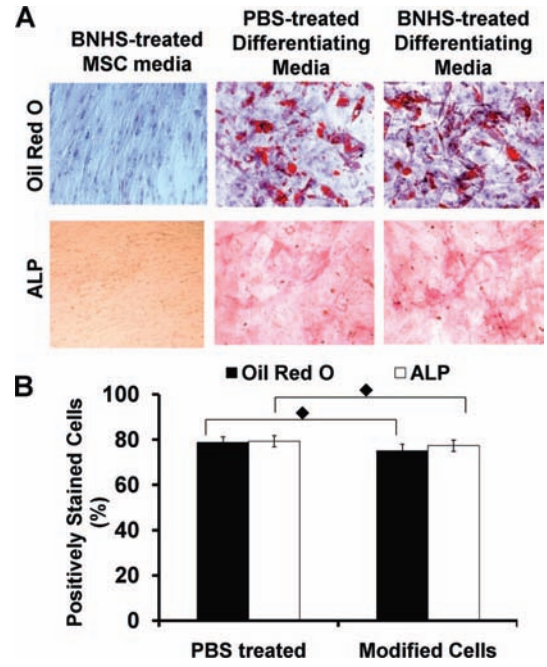

Figure 3. (A) Alkaline phosphatase (ALP) and oil red O (ORO) staining, 23 days after addition of osteogenic and adipogenic differentiation media, respectively. Negative controls (BNHS modified cells cultured in expansion media) showed no ORO or ALP staining. Positive controls (PBS treated cells in differentiating media) showed positive ORO and ALP staining. Experimental group (BNHS modified cells cultured in respective differentiating media) showed positive staining for both ORO and ALP. (B) Percentage of positively stained cells for ORO and ALP staining for PBS treated and BNHS modified cells. Error bars represent standard deviation from three separate treatments.

To gain insight into the effect of covalent modification on cell characteristics such as viability, proliferation, adhesion, and ability to differentiate into multiple lineages, a series of experiments were performed. The cell viability was not considerably affected up to 48 h after BNHS+S modification compared to the control groups (Figure 2A). Specifically, 95% and 85% of PBS treated cells were viable after 0 and 48 h, respectively, whereas cells treated with B (noncovalent) were 81% and 76% viable and cells treated with BNHS (covalent) were 79% and 75% viable. This indicates that the BNHS+S modification did not induce substantial cell toxicity. Cell adhesion characteristics were also not affected, as shown by the adhesion dynamics to tissue culture plastic of BNHS modified and PBS treated cells after 10, 30, and 90 min. This clearly indicates that the covalent modification of the cell surface did not compromise the ability of cells to interact with their extracellular environment (Figure 2B). On the contrary, BNHS modification inhibited the proliferation compared to the unmodified PBS treated cells on day 2 ($P = 0.01$, $n = 3$) and day 4 ($P = 0.02$, $n = 3$) (Figure 2C); however, both groups attained a confluent monolayer. This indicates that the covalent modification of the cell surface by biotin−streptavidin conjugation may have short-term negative impacts on proliferation but does not alter the normal substrate colonization characteristics of the MSCs.

Positive staining for oil red O (ORO) and alkaline phosphatase (ALP), indicators for adipogenic and osteogenic differentiation, respectively, was retained after BNHS modification (Figure 3; see Figure S1 in Supporting Information for higher magnification images). No differences in ORO or ALP staining were observed between BNHS modified cells and those treated with PBS after induction of osteogenic and adipogenic differentiation. Covalently modified MSCs cultured in nondifferentiating conditions (i.e., in MSC expansion medium) did not stain positively for osteogenic and adipogenic markers and the modification did not affect the number of positively stained cells compared to positive controls as shown in Figure 3B ($P > 0.05$, $n = 3$).

Taken together, the results suggest that BNHS modification of MSCs does not impair the potential for multilineage differentiation. However, it is important in future work to examine if other lineages are affected by the modification and if the trophic and immunomodulatory properties of MSCs are compromised. This work focused on examining the impact of cell surface modification with BNHS and S on cell function and phenotype. Although it is anticipated that the specific ligand attached through the streptavidin bridge would have a limited effect on these cell properties, each application would require extensive characterization for the candidate targeting ligand.

Since all experiments were performed with MSCs between passage 4 and 6, cell surface markers of passage 6 MSCs were examined by flow cytometry and immunofluorescence (data not shown). MSCs did not express hematopoetic markers CD34 or CD45 (0% of cells) but were shown to express high levels of MSC markers including CD90 and CD146 (100% of cells) as evidenced by flow cytometry. Immunofluorescence showed 0% expression of CXCR4 and 100% expression of MSC markers CD146, CD90, and CD271.

After examining the characteristic properties of MSCs with BNHS+S, BSLeX was introduced on cell surface as shown in Scheme 1, and its ability to impart a homing response was investigated via cell rolling within a standard parallel plate flow chamber system. Typically, culture expanded MSCs do not express ligands on their surface to enable cell rolling on selectin coated surfaces (*30*). MSCs modified with BNHS+S and biotinylated SLeX showed considerably lower velocities on immobilized P-selectin substrates compared to PBS treated cells ($P = 0.003$, $n = 3$) and cells treated with physically adsorbed BSLeX ($P = 0.04$, $n = 3$) (Figure 4A). Specifically, the interaction between SLeX and P-selectin reduced the velocity from ~65 μm/s to ~2 μm/s at a wall shear stress 0.366 dyne/cm^2. This clearly indicates that covalent modification of MSCs by biotin−streptavidin followed by SLeX−biotin induces a cell rolling response for culture expanded MSCs that is not typically observed.

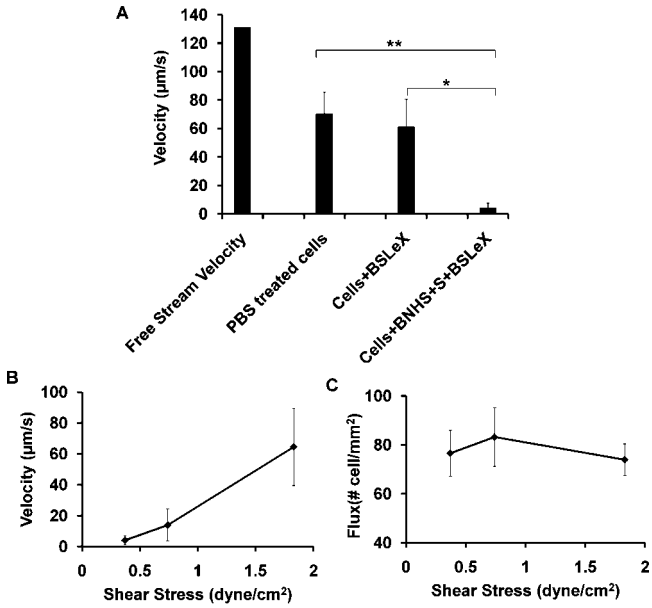

Figure 4. (A) Velocity of SLeX modified cells and controls on P-selectin treated surfaces at the shear stress of 0.366 dyne/cm^2. (B) Effect of shear stress on the rolling velocity. (C) Effect of shear stress on the number of interacting cells per unit area for the cells modified with SLeX.

The effect of flow rate and thus different shear stresses on the rolling characteristics is shown in Figure 4B,C. As shear stress is increased from 0.366 to 1.89 dyne/cm^2, the velocity of the modified cells increased whereas the number of cells interacting with P-selectin substrate remained relatively constant at ~75 cells/mm^2 (for 1 mM BNHS concentration) whereas the PBS treated cells displayed a near constant flux of ~20 cells/mm^2. This indicates that cells modified with SLeX interact with P-selectin substrates via recognized cell rolling based adhesion phenomena. The sharp increase in rolling velocity with increase in shear stress (Figure 4B), yet unchanged flux, may indicate that the SLeX is not uniformly distributed on the cell surface, or perhaps that the distribution of SLeX is unlike the clustering that typically appears on microvilli. Future work is thus required to characterize and optimize these parameters prior to *in vivo* homing studies. Together, this work demonstrates the potential to induce a leukocyte-like cell rolling response that may be useful to increase concentrations of MSCs and other cell types within specific tissues after systemic administration.

In conclusion, we have shown a novel, platform method for imparting a rolling response through functionalization of primary human MSCs with SLeX through combined covalent and biotin−streptavidin chemistries. Contrary to enzymatic modifications and retroviral transduction methods, the present approach is a simple, yet versatile method to engineer the cell membrane to induce a homing response. Importantly, covalently modified cells showed similar viability, proliferation, adhesion, and differentiation potential (as judged by ORO and ALP staining for adipogenic and osteogenic differentiation, respectively) compared to PBS treated cells. Apart from the specific interactions between SLeX and P-selectin to induce a rolling response, there are several other important cellular and molecular features that are crucial to induce and sustain cell trafficking behavior including cell deformability and cell−substrate contact area that is typically dictated by microvillus extensions (*33*), firm adhesion, and transmigration. Future work will involve characterizing the impact of the covalent immobilization methodology on these parameters and investigating coimmobilization of other adhesion molecules to further enhance the potential for an effective *in vivo* homing response. It would also be important to characterize the impact of engineered MSCs on the latter stages of cell homing that involve transendothelial migration and chemotaxis in response to soluble cues. We anticipate that the present approach to covalently modify the cell surface and immobilize required ligands is not limited to MSCs or the SLeX ligand. Hence, this technology should have broad implications on cellular therapies that utilize systemic administration and require targeting of cells to specific tissues.

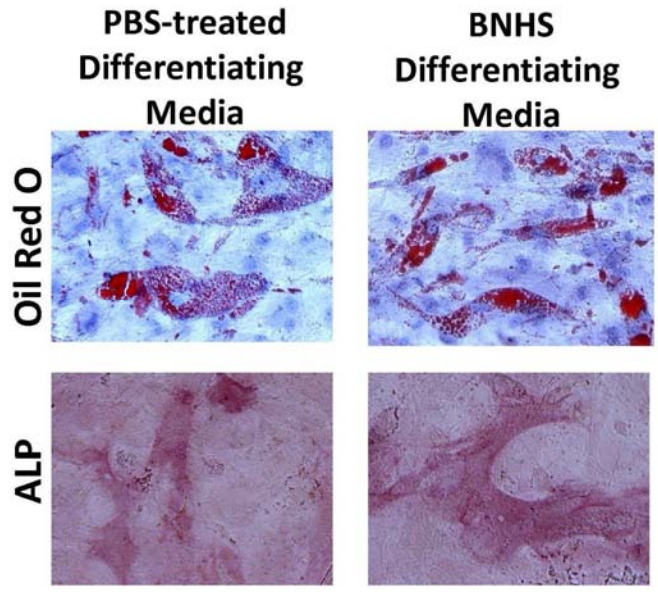

Figure S1. Alkaline phosphatase (ALP) and Oil Red O (ORO) staining, 23 days after addition of osteogenic and adipogenic differentiation media, respectively. Negative controls (BNHS modified cells cultured in expansion media) showed no ORO or ALP staining. Positive controls (PBS treated cells in differentiating media) showed positive ORO and ALP staining. Experimental group (BNHS modified cells cultured in respective differentiating media) showed similar positive staining for both ORO and ALP compared to the unmodified cells. 20X magnification.

Experimental Section:

Materials

P-selectin was purchased from R&D systems (Minneapolis, MN) and biotinylated sialyl Lewis(x)-poly(acrylamide) (sialyl-Lewis^X-PAA-Biotin) was purchased from Glycotech (Gaithersburg, MD). Primary human MSCs were obtained from the Center for Gene Therapy at Tulane University which has a grant from NCRR of the NIH, Grant # P40RR017447. α-MEM, Fetal Bovine Serum, L-Glutamine and Penn-Strep were purchased from Invitrogen. All other

chemicals and reagents were purchased from Sigma Aldrich (St. Louis, MO) and were used without further modification unless specified.

Mesenchymal Stem Cell Culture and Characterization

Primary human MSCs obtained from the Center for Gene Therapy at Tulane University were isolated from human marrow of healthy consenting donors and thoroughly characterized as previously described (Sekiya, I., Larson, B. L., Smith, J. R., Pochampally, R., Cui, J.-G., Prockop, D. J. (2002) Expansion of human adult stem cells from bone marrow stroma: Conditions that maximize the yields of early progenitors and evaluate their quality. *Stem Cells 20*, 530-41.). MSCs were maintained in expansion medium that consisted of 15% Fetal Bovine Serum (selected for its ability to expand MSCs), 1% (v/v) L-Glutamine, 1% (v/v) Penn-Strep, and α-MEM. All experiments were performed using MSCs at passage number 4-6. For MSC characterization, passage 6 cells were incubated for 10 minutes in non-enzymatic cell dissociation solution (Sigma). After washing with PBS containing 1% FBS and 0.05% NaN3 (FACS buffer), cells were filtered using a 40 μm cell strainer and incubated for 30 minutes using the following mouse IgG1, k antibodies: 1.) CD34 fluorescein isothiocyanate (FITC) conjugated antibody (diluted at 1:800 with FACS buffer), 2.) CD45 FITC-conjugated antibody (diluted at 1:800), 3.) CD90 FITC-conjugated antibody (diluted at 1:400), 4.) and CD146 R phycoerythrin (R-PE) conjugated antibody (diluted at 1:400). After staining, cells were washed again with FACS buffer and fluorescence levels were determined using a BD FACS Calibur flow cytometer and analyzed using the Cell Quest software.

Covalent Conjugation of Biotin (and Streptavidin) to the MSC surface

5000 cells in 200 µL MSC cell expansion media were added to the wells of a 96 well plate for a period of 24-48 hours to reach ~80-90 % confluency. To chemically modify the cells, media was aspirated from the wells and the cells were gently washed with 200 µL of phosphate buffer saline (PBS, pH 7.4 without Ca/Mg) at room temperature in each well. 100 µL of 1 mM BNHS solution in PBS, pH 7.4 without Ca/Mg was added to each well for 20-25 minutes at room temperature. After designated times, the cells in each well were washed twice with 200 µL of phosphate buffer saline (PBS, pH 7.4 without Ca/Mg). Then to each well, 50 µL of streptavidin solution (50 µg/mL in PBS, pH 7.4 without Ca/Mg) was added for 20 minutes at room temperature.

Stability of Covalently Conjugated Biotin (and Streptavidin) on the MSC surface

To characterize the stability of streptavidin bound to covalently conjugated biotin, 200 µL of S (rhodamine-conjugated streptavidin) solution made from 50 µg/mL in PBS, pH 7.4 without Ca/Mg was added for 20 minutes at room temperature on PBS, Biotin, and BNHS treated cells. After the addition of S, the cells were thoroughly washed with PBS and the fluorescence intensity of microscopic images was measured (day 0). Cells in separate wells were incubated for 7 days at 37 °C and 5% CO_2 with media changes every 2 days followed by examination of the fluorescence intensity.

Accessibility of Biotin on the MSC surface

To characterize the accessibility of the biotin on the cell surface after BNHS modification, 200 µL of S solution (50 µg/mL in PBS, pH 7.4 without Ca/Mg) was added for 20 minutes at room

temperature on either Biotin or BNHS treated cells after 0, 2, 4 and 7 days. After addition of S, the cells were fixed with 4% formaldehyde solution and stained with 100 µL of DAPI solution (1 µg/mL in PBS) after treatment with 100 µL of 0.1% TRITON X solution in PBS. The fluorescence intensity of microscopic images from BNHS and Biotin treated cells were analyzed using Nikon quantitative software (NIS-Elements version 3).

Viability, Adhesion and Proliferation Characteristics

The viability of the cells was examined using trypan blue exclusion. Briefly, cells were plated into 12 well plates, left to adhere over night and the cells were treated with BNHS solution as described above. The cells were incubated for 48 hours at 37 °C and 5% CO_2. The media was then aspirated (similar quantities of floating cells were observed between the groups – typically 1-5 per well) and the cells were detached with 200 µL of cell dissociation solution. 300 µL of media was added and the total 500 µL of the cell dispersion was collected in an eppendorf tubes. From this 10 µL of cell dispersion was diluted to 1:1 with 4% trypan blue solution and cells were counted in a hemocytometer to determine the number of viable (non-blue) and nonviable (blue) cells. The controls for this experiment included PBS treated cells and the cells treated with biotin and S without NHS (non covalent). Cell adhesion was quantified by measuring the number of adherent cells on tissue culture surfaces in 96 well plates after BNHS treatment. Briefly, 80-90% confluent cells in a T25 flask were biotinylated with BNHS as described above. 5000 cells were added to each well of a 96 well plate in 200 µL of MSC cell expansion media followed by incubation at 37°C. The non-adhered cells were removed by washing with PBS. Proliferation was quantified by manually tabulating the number of cells within a T25 flask at multiple time points with light microscopy at 10X.

Differentiation of cells

Multi-lineage differentiation potential of the BNHS modified and PBS treated cells was examined by treating cells with osteogenic and adipogenic induction media followed by respective colorimetric histological staining.

Osteogenic Differentiation

MSCs seeded in the wells of 24 well plates were cultured in MSC expansion media until reaching 90% confluence. For cell modification, cells were biotinylated with 1mM BNHS followed by conjugation with streptavidin (50 µg/mL) in PBS at room temperature. Osteogenic differentiation was induced by culturing the cells for 23 days in osteogenic induction media (from Lonza –MSCs Osteogenic Single Quote kit) containing dexamethasone, β-glycerophosphate, L-ascorbic acid-2-phosphate, and α-MEM. For a positive control, PBS-treated (un-modified) cells were maintained in osteogenic induction medium and for a negative control, BNHS modified cells were maintained in MSC expansion media. The media in both groups was changed every 3 days. Osteogenesis was evaluated by cell membrane associated alkaline phosphatase activity. Alkaline phosphatase activity was examined after 23 days by carefully aspirating the medium and washing the cells with distilled water. The cells were fixed with 3.7% formaldehyde solution for 15 min at room temperature followed by rinsing with distilled water. 0.06% Red Violet LB salt solution in Tris HCl was added with distilled water containing DMF and Naphthol AS MX-PO_4. The plates were incubated for 45 minutes and then the wells were rinsed 3 times with distilled water and visualized with light microscopy.

Adipogenic Differentiation

MSCs seeded in 4 wells of a 24 well plate were cultured in cell expansion media until reaching 100% confluence. Typically cells were biotinylated with 1mM BNHS followed by conjugation

with streptavidin (50 µg/mL) in PBS at room temperature. Adipogenic differentiation was induced by culturing the cells for 23 days in adipogenic induction media (from Lonza –MSCs Adipogenic Single Quote kit containing h-Insulin (recombinant), L-Glutamine, Dexamethasone, Indomethacin, IBMX (3-isobuty-l-methyl-xanthine), Pen/Strep) and adipogenic maintenance media (from Lonza –MSCs Adipogenic Single Quote kit containing h-Insulin (recombinant), L-Glutamine, Pen/Strep). As a positive control, PBS-treated (un-modified) cells were maintained in adipogenic induction medium, and as a negative control the BNHS modified cells were maintained in normal MSC expansion media. The media in both groups were changed every 3 days in a periodic exposure of induction and maintenance media as suggested by the supplier (Lonza). Adipogenesis was evaluated by Oil Red O staining. Following aspiration of the media, cells were washed once with PBS, and fixed in PBS with 3.7 % formaldehyde for 30 min at room temperature. Following fixation cells were rinsed with distilled water for a few minutes, and incubated with isopropanol containing an Oil Red O working solution (prepared by diluting 30 mL of 0.5% isopropanol / Oil Red O solution with 20 mL of distilled water). After 45 minutes culture well were rinsed twice with distilled water and 1 mL of hematoxylin was added to each well for 1 minute followed by aspiration and washing with distilled water. The wells were viewed using an inverted phase contrast microscope. Lipid droplets appeared red and nuclei appeared blue.

The percentage of cells that positively stained for alkaline phosphatase (an indicator of osteogenic differentiation) and for Oil Red O (an indicator of adipogenic differentiation) was calculated by enumerating the number of stained and unstained cells in 3 wells per group (3 fields per well)

Preparation of P-selectin Surfaces

Glass surfaces used for the preparation of P-selectin surface was cleaned by Piranha solution and subsequently washed with double distilled water three times. The cleaned surfaces were dried overnight under vacuum. P-selectin (700 μL of a 5 μg/mL solution) was placed on top of the glass surface and incubated on a plate shaker for 18 hours at room temperature. All the P-selectin surfaces were prepared fresh before the flow chamber assay.

Flow Chamber Assay

For flow chamber experimentation, the cells were biotinlyated with BNHS as described above in a T25 flask. 200 µL of S solution (50 µg/mL in PBS, pH 7.4 without Ca/Mg) was added for 20 minutes at room temperature to BNHS treated cells. Cells were washed twice with 1 mL of phosphate buffer saline (PBS, pH 7.4 without Ca/Mg) at room temperature in each well followed by addition of 1 mL of 4µg/mL biotinylated SLeX (Biotin-PAA-SLeX in PBS, pH 7.4 without Ca/Mg) at room temperature. The cells were detached from the flask by using 1 mL of cell dissociation solution and then resuspended in MSC expansion media (~10^5 cells/mL) for analysis of cell velocities within a parallel plate flow chamber.

The rolling characteristics of the cells were assessed using a rectangular parallel plate flow chamber (Glycotech, Gaithersburgh, MD) with 127 µm gasket thickness and a length of 6 cm. For the majority of experiments, a flow rate of 20 µL/min corresponding to a wall shear stress of 0.366 dyne/cm^2 was used. To monitor cell rolling, phase contrast microscopy (TE2000-U Inverted Nikon Microscope with a DS-Qi1 Monochrome Cooled Digital Camera) was utilized and images were recorded in a 10X field at 10 second intervals. The velocity of the cells was calculated by measuring the distance cells travelled within a 10 second interval. A cell was

classified as rolling if it rolled for 10 seconds while remaining in the field of view and if it translated at an average velocity less than 50% of the calculated free stream velocity of a non-interacting cell. The number of interacting cells was calculated manually based on number of cells remaining adhered in the field view for 10 seconds. To assess the effect of shear rate and the concentration of BNHS added to the cells, the rolling velocity and the flux of the cells were measured at flow rates of 20, 40 and 100 µL/min corresponding to 0.366, 0.73 and 1.89 dyne/cm^2, respectively.

Statistical Analysis:

For multiple pairwise comparisons, a two-tailed Student's t test was used with the Bonferroni correction. Error bars in bar graphs represent standard deviations, and statistical significance is denoted by ◆ $P > 0.05$, * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$.

Redmond Red as a Redox Probe for the DNA-Mediated Detection of Abasic Sites

Marisa C. Buzzeo and Jacqueline K. Barton*

Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, California 91125. Received August 6, 2008; Revised Manuscript Received September 9, 2008

Redmond Red, a fluoropore containing a redox-active phenoxazine core, has been explored as a new electrochemical probe for the detection of abasic sites in double-stranded DNA. The electrochemical behavior of Redmond Red-modified DNA at gold surfaces exhibits stable, quasi-reversible voltammetry with a midpoint potential centered around −50 mV versus NHE. Importantly, with Redmond Red positioned opposite an abasic site within the DNA duplex, the electrochemical response is significantly enhanced compared to Redmond Red positioned across from a base. Redmond Red, reporting only if well-stacked in the duplex, represents a sensitive probe to detect abasic sites electrochemically in a DNA-mediated reaction.

Since its discovery, the ability of DNA to conduct charge has been exploited in a variety of arenas, including time-resolved spectroscopy (*1*−*3*), conductivity measurements (*4*−*7*), and the development of biosensors (*8*). Our group, in particular, has explored the versatility of this intrinsic property of DNA by performing extensive electrochemical studies on surfaces modified with DNA duplexes (*9*−*15*). Typically in such systems, thiol-modified oligonucleotides are tethered to a gold electrode at the 5′ terminus by a Au−S bond and further modified at the opposite end with a redox probe, thus allowing the duplexes to act as an extension of the conducting medium. The reduction of the attached probe, as observed voltammetrically, serves as an indicator of the transport of charge via the DNA duplex. Importantly, it has been shown that DNA-mediated charge transport is remarkably sensitive to the integrity of the base stack; upon introduction of a single base mismatch located between the electrode and the redox probe, measured currents are dramatically diminished (*9, 10*). This behavior not only provides conclusive evidence that the observed electrochemical reactions are indeed DNA-mediated, but also allows naturally occurring perturbations, which may only subtly interrupt π-stack overlap, to be detected (*11*−*15*).

Among these possibly destabilizing defects are abasic sites, which appear naturally and frequently among DNA sequences as the result of hydrolytic cleavage of the glycosidic bond (*16*−*23*). Specific enzymes are responsible for correcting these damaged sites prior to transcription and replication. When this repair pathway is delinquent, however, the persistence of these defects can impart deleterious effects on genetic encoding, leading to the development of cancer, among other diseases (*24*−*26*). Because they represent a potential threat, the reliable and specific detection of abasic sites is critical, although still very much under exploration. Development of an electrochemical system to detect these unwanted sites specifically could contribute to the understanding of their occurrence and repair. Here, we employ Redmond Red (RR), obtained as a commercially available phosphoramidite and used commonly as a fluorophore, as a new redox probe for the detection of abasic sites. We find that the width of the covalently tethered phenoxazine derivative is particularly well accommodated when positioned opposite an abasic site within a DNA duplex, thus facilitating efficient DNA-mediated reduction as a "turn on" probe for their presence (Figure 1).

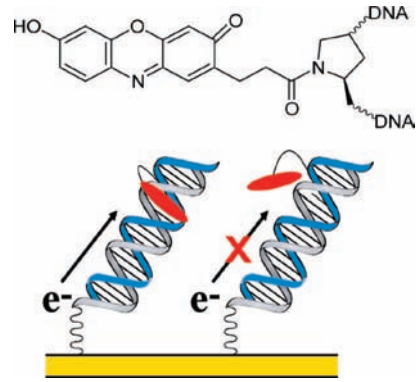

Figure 1. Structure of Redmond Red (RR), an electroactive phenoxazine derivative covalently tethered to DNA, along with a schematic representation of the basis of the abasic site probe. With Redmond Red placed opposite an abasic residue (left), DNA-mediated reduction can proceed, but if opposite a base (right), RR is excluded from the duplex and DNA-mediated reduction cannot proceed. Note that the three-ring phenoxazine core is comparable in size to a base pair.

Alkane thiol-modified DNA strands were synthesized as described previously (*14, 15*) with Redmond Red internal to the sequence and hybridized to a complement containing an abasic site in the opposite position. All syntheses were performed using standard phosphoramidite chemistry. Redmond Red-modified strands were cleaved from the solid support resin using 0.05 M K_2CO_3 in MeOH at ambient temperature for 12−17 h. Complementary strands were cleaved using concentrated NH_4OH at 60 °C for 8−12 h. Samples were purified twice by reversed-phase HPLC and characterized by MALDI-TOF mass spectrometry and UV−visible spectroscopy (see Supporting Information). For those oligonucleotides containing an abasic site, the commercially available tetrahydrofuranyl analogue was used (*27*); the naturally occurring, hemiacetal abasic residue is unstable and reactive on the time scale of DNA synthesis.

Freshly etched gold macroelectrodes were incubated with 50 μM modified duplex DNA overnight at 5 °C in the presence of 100 mM $MgCl_2$ to encourage formation of densely packed films. Electrochemical measurements were performed at ambient

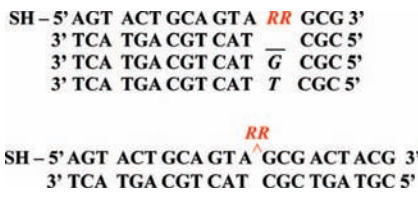

Figure 2. Sequences employed to determine the sensitivity of the DNA-mediated reduction of Redmond Red to the presence of the opposing base. Shown are the thiol-modified strands, along with the variable complementary strands, where "*RR*" indicates a Redmond Red moiety, and "__" an abasic site.

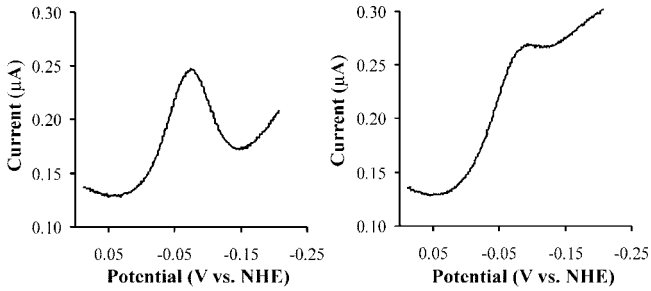

Figure 3. Electrochemical reduction at a ^{RR}DNA-modified electrode, observed by square wave voltammetry, when RR is positioned opposite an abasic site (left) or a guanine residue (right); the reductive signal is significantly attenuated in the latter case. Peak areas were determined by integrating above the baseline of the voltammograms, thus accounting for differences in the background responses.

temperature in phosphate buffer (5 mM sodium phosphate, 50 mM NaCl, pH 7) using a CH Instruments 760B potentiostat. A saturated calomel electrode served as a reference electrode, and a platinum wire as a counter. Square wave voltammograms were recorded at a frequency of 15 Hz and an amplitude of 0.025 V. Under such conditions, Redmond Red-modified DNA (^{RR}DNA) displays stable, quasi-reversible voltammetry with a midpoint potential centered around −50 mV versus NHE. The measured peak currents scale linearly with scan rate, indicating that RR behaves as a surface-bound species, as anticipated, and is not under diffusional control.

To test if the observed voltammetric response is in fact dependent on the presence of an abasic site, the same thiolated ^{RR}DNA was then hybridized to complementary sequences containing a guanine (G) or thymine (T) opposite the probe, and the resulting voltammetry recorded (see Figure 2 for sequences). The observed reductive signal is severely affected. Figure 3 shows a comparison of typical square wave voltammograms obtained for both assemblies, and Figure 4 presents a comparison of the average peak areas measured for the different sequences. More than a 2-fold increase is consistently observed when RR is situated opposite an abasic site versus an intact DNA strand. It therefore becomes apparent that inclusion of an opposing base precludes well-stacked insertion of RR into the duplex, thus preventing efficient reduction through the π-stack. Conversely, when an abasic residue is located on the complementary strand, the phenoxazine derivative, itself having a similar dimension to a base pair, is now able to insert into the duplex and become available for DNA-mediated reduction. The enhancement of signal seen for the well-stacked Redmond Red is consistent with earlier results that have shown the redox signal to reflect how well the probe is coupled into the base stack (*14*, *28*). This discrimination of abasic sites indicates that the DNA-mediated reduction of RR can provide a convenient means by which to detect the abasic defect.

We also investigated whether or not RR would respond voltammetrically to a base deletion. A complementary strand was synthesized in which the position opposite the RR was

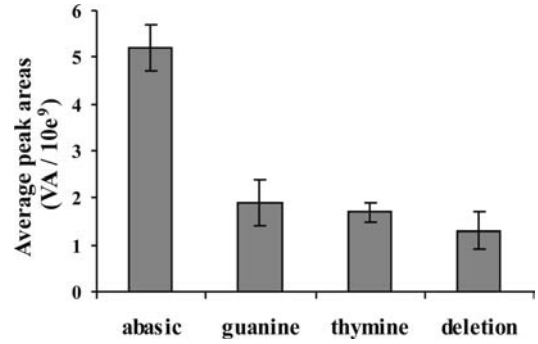

Figure 4. Bar chart representation of the differences observed in peak areas for the reduction of Redmond Red when positioned opposite an abasic residue, a base, or a deletion site within a DNA duplex. Peak areas, determined from square wave voltammetry, have all been normalized to the area of the gold surface as determined by sulfuric acid etches performed immediately prior to measurement. Error bars shown represent one standard deviation of the measurement.

occupied not by an abasic site, but instead by the base that corresponds to the next position on the RR strand; in short, no complementary base was assigned to RR (Figure 2). Under these conditions, we considered that the RR may be pinched out of the sequence, allowing the bases above the probe to fully hybridize and thus inhibiting reduction of the phenoxazine moiety. For these experiments, the length of the oligonucleotide was extended by six bases in order to prevent fraying above the probe site while keeping the position of Redmond Red relative to the electrode surface constant. As observed by both cyclic and square wave voltammetry, duplexes containing the deleted site do indeed consistently yield diminished currents, and the magnitude of the effect (300% increase for an abasic site) is in line with those results observed when a G or T is situated opposite RR (Figure 4). This indicates that the probe is, in fact, excluded from the base stack in order to allow for the remaining bases to hybridize and is therefore not available for reduction in a DNA-mediated fashion.

Early work first demonstrated the sensitivity of electrochemical techniques to the presence of abasic sites resulting from depurination in chromosomal DNA: differential poloragraphic responses were observed for nondenatured DNA versus the apurinic form (*29*−*31*). More recently, studies have reported the detection of these damaged sites specifically in synthetic oligonucleotides using chronopotentiometric and square wave voltammetric techniques (*32*−*35*). These systems, however, possess intrinsic limitations that prevent them from serving as practical diagnostics. In the first example, the target DNA must be consumed via acid-induced oligonucleotide digestion (*32*), while the other detection schemes are specific to thymine-related mutations (*33*−*35*). Here, the redox probe is covalently attached to the DNA, the target oligonucleotide remains intact, and the electrochemical measurement is fast, simple, and selective. Moreover, electrocatalytic coupling may provide enhanced signal discrimination, thus affording the increased sensitivity needed on the genomic scale (*11*, *12*).

The studies presented here once again highlight how sensitive DNA-mediated charge transport chemistry can be in reporting on DNA structure. Earlier we used DNA-mediated electrochemistry to characterize perturbations in the *intervening* DNA structures using a well-stacked probe, but here how well the probe is itself stacked serves as a specific reporter of local conformation. The selective enhancement found with RR opposing an abasic residue confirms that, to detect efficient reduction of the probe at a distance from the electrode, the reduction must be DNA-mediated. The dependence of probe detection on the spatial constraints of the duplex underscores

the general sensitivity of DNA-mediated charge transport chemistry to local DNA conformation.

ACKNOWLEDGMENT

1. Synthesis of modified DNA

All syntheses were performed using standard phosphoramidite chemistry. Thiol-modified DNA strands were synthesized as previously described using a C_6-disulfide phosphoramidite, available from Glen Research. Treatment with excess dithiothreitol in 10 mM Tris buffer (pH 8) for 30 min at ambient temperature resulted in cleavage of the disulfide bond and concomitant removal of the dimethoxytrityl (DMT) protecting group. Nap-5 Sephadex columns (GE Healthcare) were used to isolate the thiolated strands, and reversed-phase HPLC was used to purify the DNA before and after disulfide cleavage (see Figure S1). Redmond Red was incorporated into the DNA sequence at the desired position as a phosphoramidite (also available from Glen Research). Given the sensitivity of Redmond Red to typical cleavage and deprotection conditions (NH_4OH at 60 ºC), less harsh conditions were employed (K_2CO_3/MeOH at ambient temperature for 12 – 17 h) for strands containing this modification. Accordingly, phosphoramidites containing more labile protecting groups than standard reagents were required for synthesis (Glen Research). All synthesized DNA strands were purified by reversed-phase HPLC before and after removal of DMT protecting groups using a Varian DYNAMAX C18 semi-preparative column. Isolated products were characterized by MALDI-TOF mass spectrometry, UV-visible spectroscopy, and melting temperature analysis of hybridized duplexes. Representative purification and characterization data are shown below

2. Electrochemical experimental conditions

Prior to self-assembly, gold macroelectrodes (1.6 mm nominal diameter, BAS) were polished on a clean, damp microcloth (Buehler) with alumina slurries of decreasing particle size (1.0 μm, 0.05 μm, Buehler). Electrodes were then etched in H_2SO_4 to expose a fresh, clean surface as well as determine the working area, and rinsed copiously with deionized H_2O. Immediately following, a 20 μl droplet of 50 μM duplex DNA was immobilized on the gold surface and monolayers were allowed to self-assemble overnight at 5 ºC. Duplexes were incubated in the presence of 100 mM $MgCl_2$ in order to encourage the formation of densely packed films. Electrodes were rinsed thoroughly in phosphate buffer (5 mM sodium phosphate, 50 mM NaCl, pH 7) prior to electrochemical measurement.

3. Characterization data

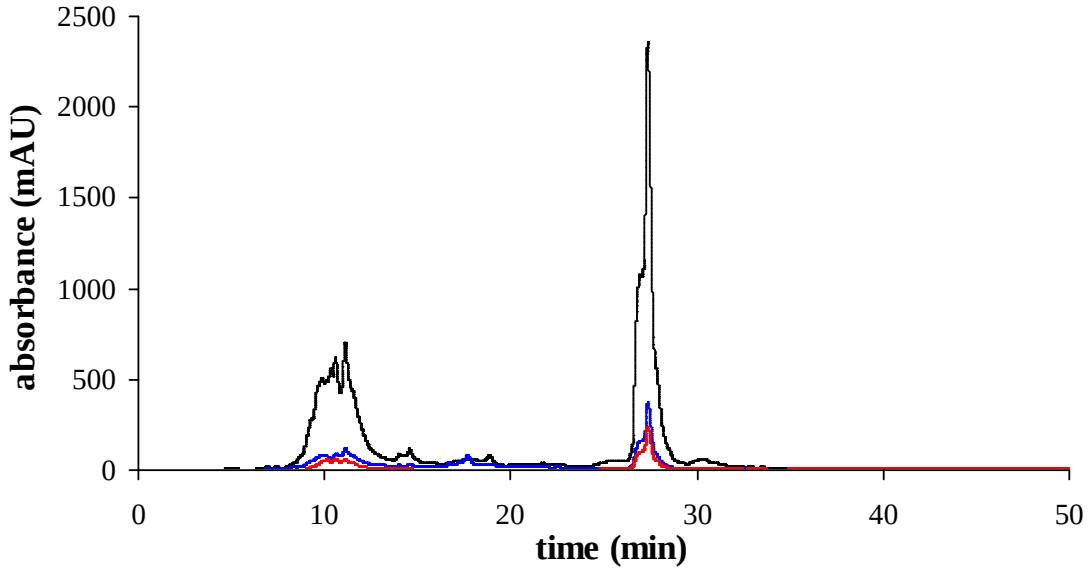

Figure S1a. HPLC chromatogram for Redmond Red-modified DNA (SH- 5' AGT ACT GCA GTA *RR* GCG 3'), prior to disulfide cleavage and DMT deprotection (black: 260nm, blue: 295 nm, red: 580 nm). Failed oligonucleotide syntheses appear around 10 min, while the product elutes around 28 min. Gradient: 100% 50mM NH_4OAc / 0% MeCN to 50% 50 mM NH_4OAc / 50% MeCN in 50 min (1% / min), at 3.5 ml / min.

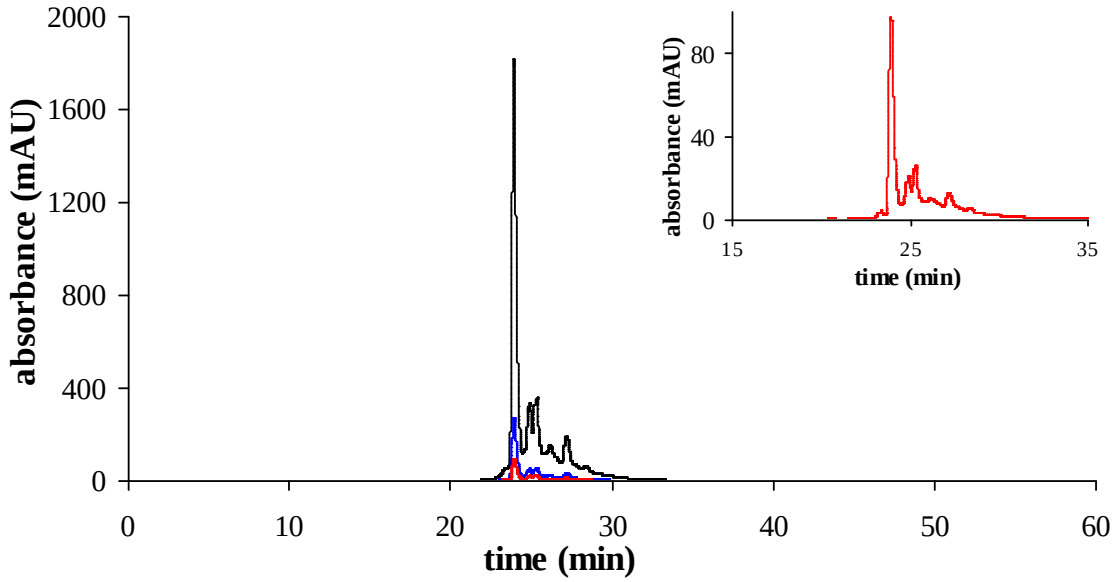

Figure S1b. HPLC chromatogram for Redmond Red-modified DNA, following disulfide cleavage achieved by treatment with DTT (black: 260nm, blue: 295 nm, red: 580 nm). The first main peak, centered around 24 min, corresponds to the product. Mass spectrometry confirmed that the side peaks that follow are not the desired product. Gradient: 100% 50mM NH_4OAc / 0% MeCN to 40% 50 mM NH_4OAc / 60% MeCN in 80 min (0.5% / min), at 3.5 ml / min. Inset: magnified view of the spectrum recorded at 580 nm.

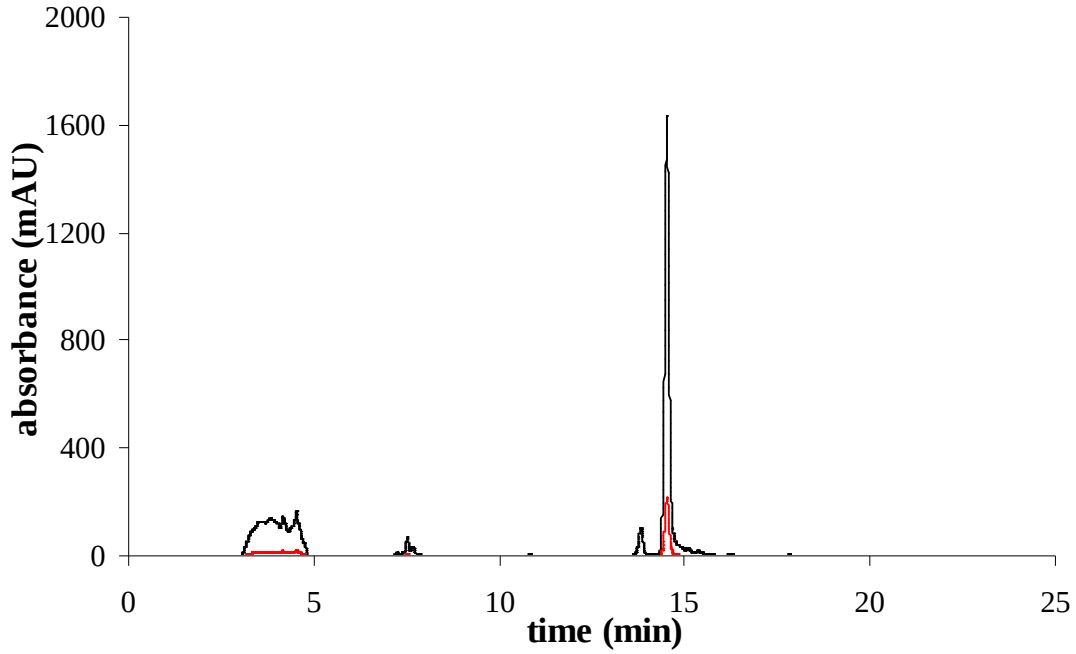

Figure S2a. HPLC chromatogram for DNA strand containing an abasic site (5' CGC __ TAC TGC AGT ACT 3' where "__" indicates the abasic site), prior to removal of DMT protecting group (black: 260nm, red: 294 nm). Product peak appears around 14 min. Gradient: 95% 50mM NH_4OAc / 5% MeCN to 35% 50 mM NH_4OAc / 65% MeCN in 40 min (2% / min), at 3.5 ml / min.

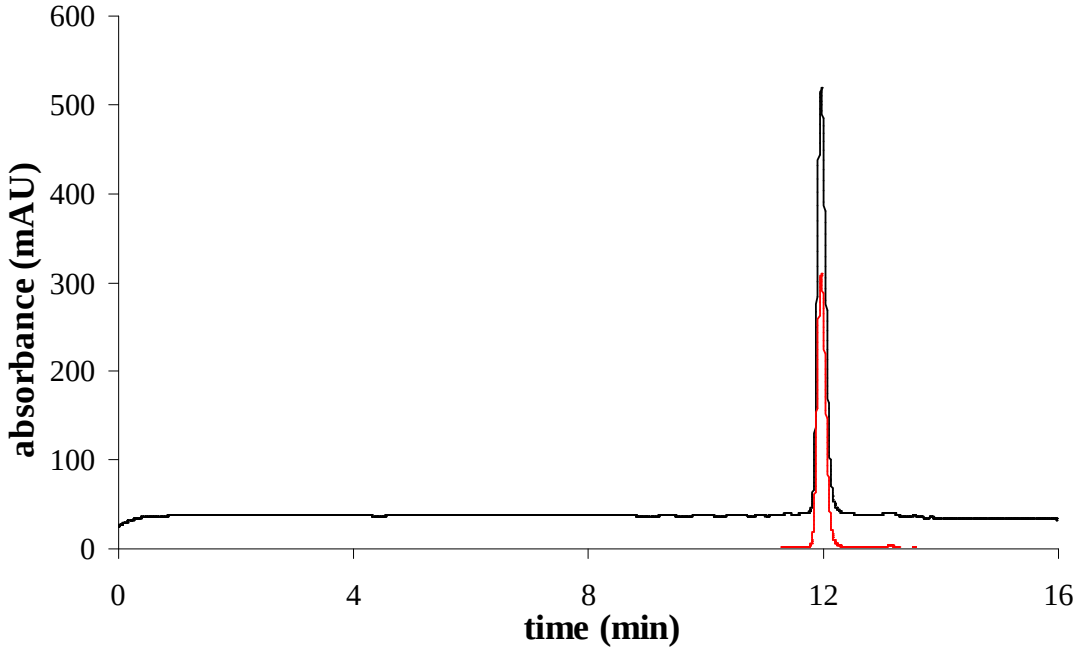

Figure S2b. HPLC chromatogram for DNA strand containing an abasic site, (5' CGC __ TAC TGC AGT ACT 3') following deprotection (black: 260nm, red: 294 nm). Deprotection is achieved by incubating DNA in 80% CH_3HOOH for 30 min and then precipitating with cold EtOH. Gradient: 95% 50mM NH_4OAc / 5% MeCN to 75% 50 mM NH_4OAc / 25% MeCN in 40 min (0.5% / min), at 3.5 ml / min. Product confirmed by mass spectrometry.

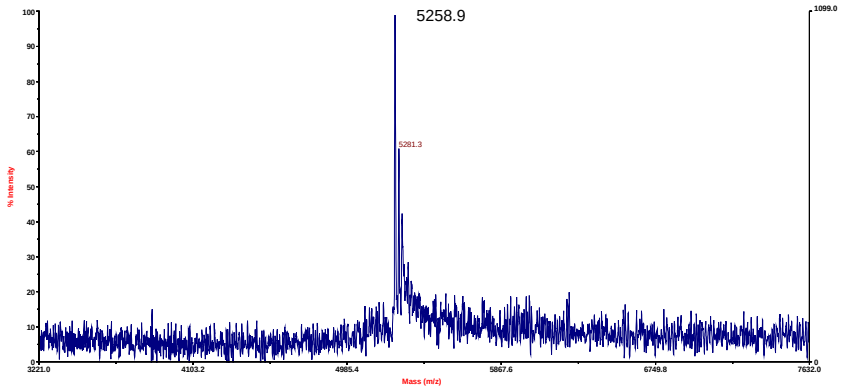

Figure S3a. Mass spectrum of thiolated, Redmond Red modified DNA (^{RR}DNA): SH- 5' AGT ACT GCA GTA *RR* GCG 3'; m/z = 5259 (expected 5254).

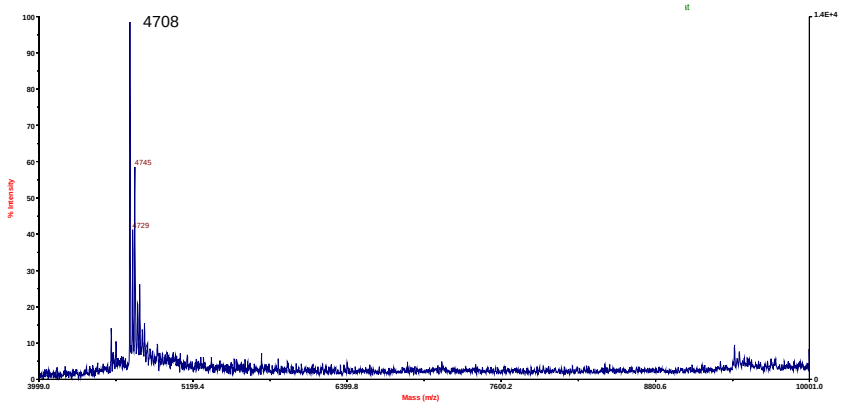

Figure S3b. Mass spectrum of complementary strand containing an abasic site opposite RR: 5' CGC __ TAC TGC AGT ACT 3', where "__" indicates an abasic site; m/z = 4708 (expected 4706).

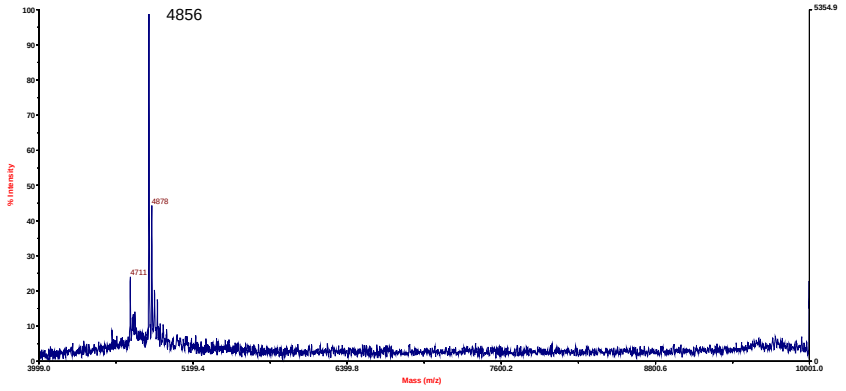

Figure S3c. Mass spectrum of complementary strand containing G opposite RR: 5' CGC *G* TAC TGC AGT ACT 3'; m/z = 4856 (expected 4854).

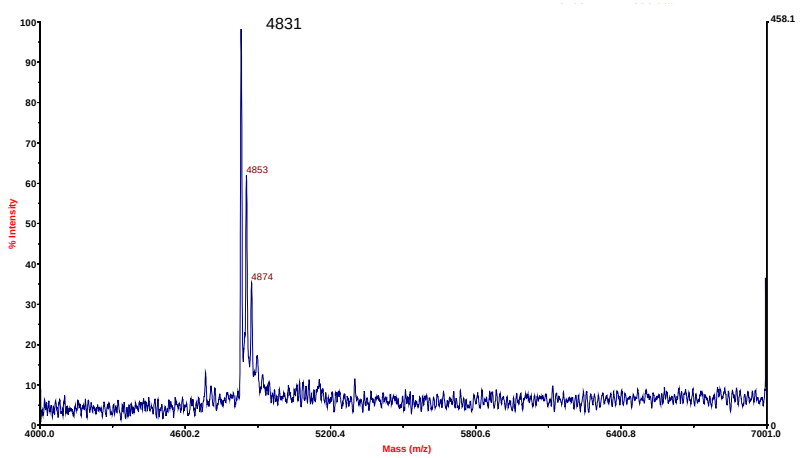

Figure S3d. Mass spectrum of complementary strand containing G opposite RR: 5' CGC *G* TAC TGC AGT ACT 3'; m/z = 4831 (expected 4830).

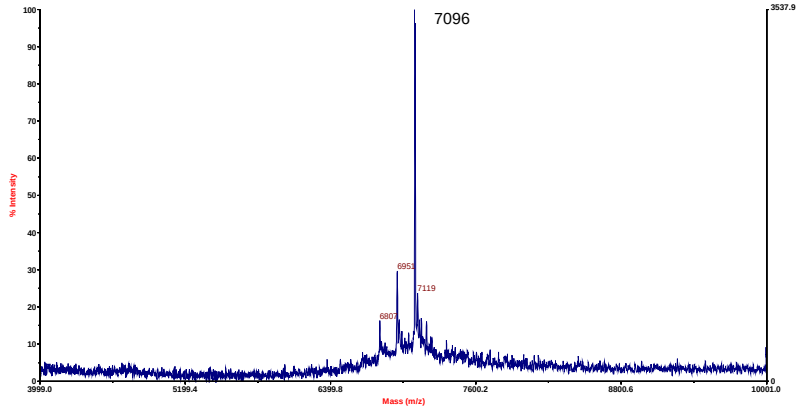

Figure S3e. Mass spectrum of thiolated, Redmond Red modified DNA (^{RR}DNA): SH- 5' AGT ACT GCA GTA *RR* GCG ACT ACG 3'; m/z = 7096 (expected 7091).

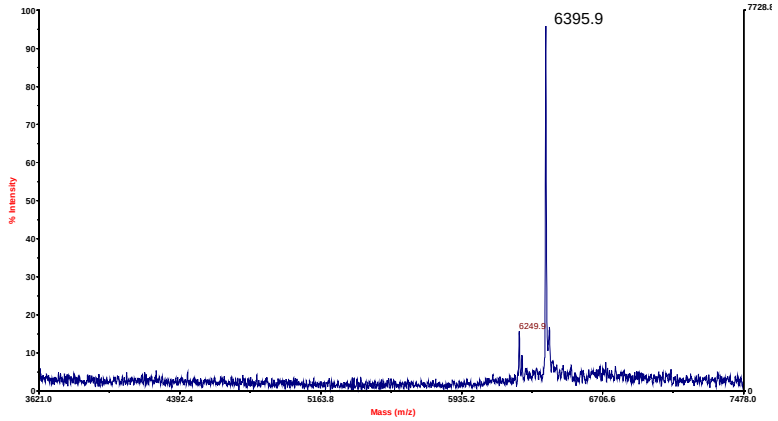

Figure S3f. Mass spectrum of complementary strand containing a 'deletion site' opposite RR: 5' CGT AGT CGC TAC TGC AGT ACT 3'; m/z = 6396 (expected 6393).

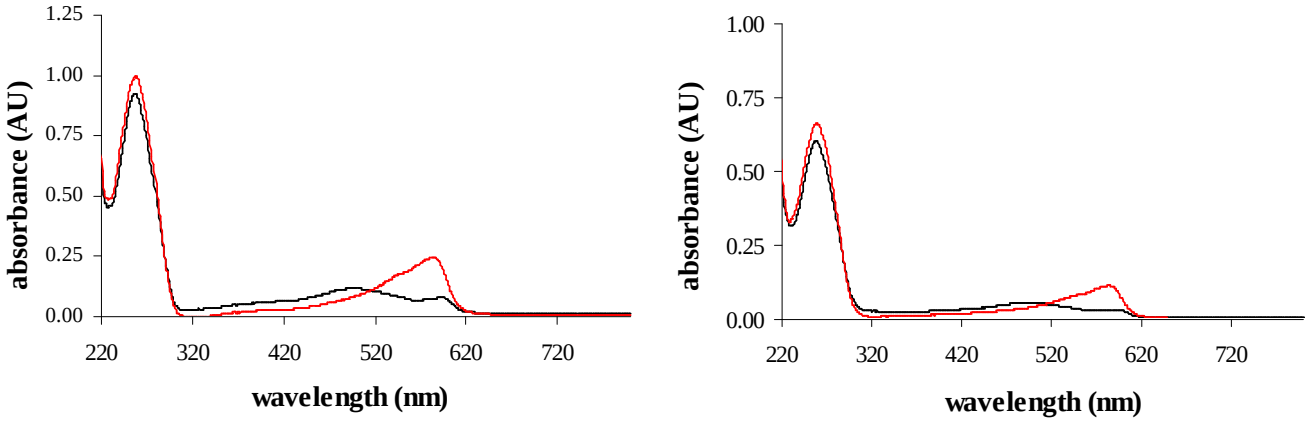

Figure S4. UV-vis spectra of Redmond Red-modified DNA at room temperature (black) and at 80 ºC (red), with characteristic maxima at 260 nm (DNA) and 580 nm (RR). At elevated temperatures, the interactions between Redmond Red and the DNA bases are discouraged, thus increasing the absorbance observed at 580 nm. Left: SH – 5' AGT ACT GCA GTA *RR* GCG 3' (15mer); right: SH – 5' AGT ACT GCA GTA *RR* GCG ACT ACG 3' (21mer).

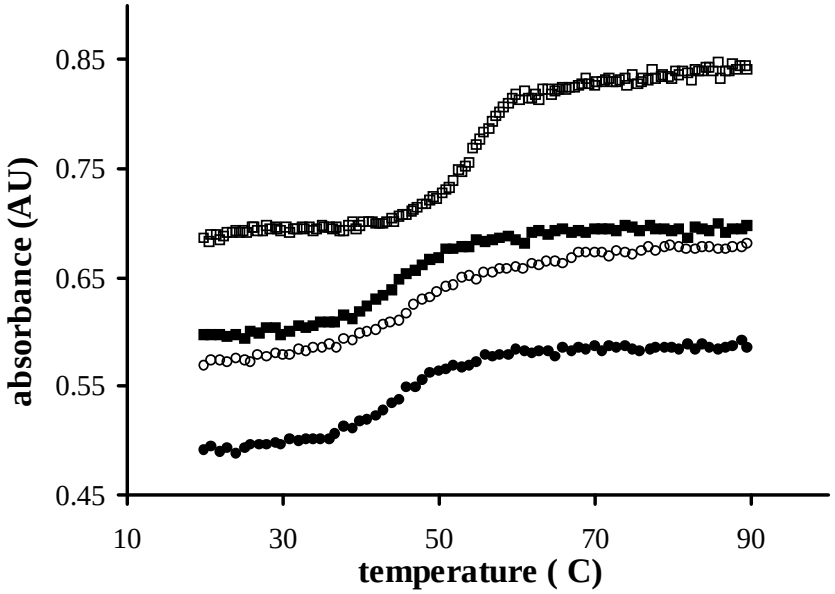

Figure S5. Melting temperature analysis for the four different duplexes employed: Redmond Red opposite a spacer site (closed circles, T_m = 45 ºC), guanine (open circles, T_m = 47 ºC), thymine (closed squares, T_m = 45 ºC) and a deleted site (open squares, T_m = 54 ºC). For these measurements, duplexes were heated to 90 ºC and then cooled back down to 15 ºC, at a typical rate of 0.5 ºC/min. Absorbance values at 260 nm were recorded at every degree interval.

Dual Function Labeling of Biomolecules Based on DsRed-Monomer

A. M. Goulding,[#] Y. Rahimi,[#] S. Shrestha, and S. K. Deo*

Department of Chemistry and Chemical Biology, Indiana University Purdue University Indianapolis, Indianapolis, Indiana 46202. Received April 9, 2008; Revised Manuscript Received September 17, 2008

Unavailability of fusion tags that possess both affinity and visualization properties is a hurdle for biomolecular research. Typically, either a choice is made between an affinity tag and a reporter tag or both are employed in tandem if a fusion can be made at both termini of the target biomolecule. In this work, we have developed a site-specific genetic fusion approach employing DsRed-Monomer, a red fluorescent protein, that provides for both affinity and reporter functionality in a single tag. As a proof-of-concept, two fusion proteins, bradykinin-DsRed-Monomer and calmodulin-DsRed-Monomer, were prepared for the study. These fusion proteins were purified using a copper-immobilized column based on the inherent copper-binding property of DsRed-Monomer. Spectroscopic characterization of fusion proteins and comparison with native DsRed-Monomer showed no effect of fusion on the properties of DsRed-Monomer. Further, bradykinin-DsRed-Monomer was employed in the development of a competitive fluorescence immunoassay for the peptide bradykinin. Calmodulin-DsRed-Monomer was used to detect binding of the calmodulin ligand chlorpromazine, based on a change in the fluorescence of DsRed-Monomer upon binding of chlorpromazine to calmodulin. The studies performed demonstrate the application of DsRed-Monomer as a dual function tag indicating the potential usefulness of DsRed-monomer in proteomics and biomolecular research.

INTRODUCTION

Protein purification and its detection/localization are both essential components of proteomics and biomolecular research (*1*−*3*). Proteins are routinely purified utilizing affinity purification strategies with either chemical or biological tags (*4*−*8*). For efficient purification, either peptides or proteins are used as affinity tags (*9*−*11*). A single affinity tag is now seldom used because of its limitations on purification effectiveness, but is rather used in tandem to achieve better results (*12*−*14*). For protein detection or localization, fluorescent probes such as fluorescent proteins, quantum dots, or fluorophores have to be fused to the protein as reporter tags (*15*−*20*). This requires two separate tags to be fused to the protein to accomplish protein purification and detection, which limits the flexibility in terms of available termini for protein fusions. Hence, the availability of a single tag that will aid in both purification and detection/visualization of the protein will prove significant in today's biomolecular research. However, there are only a few reports published on methods that demonstrate dual functionality of tags used. In one of the reports, a six-histidine tag was engineered within the loop of green fluorescent protein (GFP), which was utilized for affinity purification and optical detection of a target protein (*21*). Although six-histidine tag insertion resulted in a 40% loss of the fluorescence activity of GFP, the remaining GFP fluorescence was sufficient for the detection of the fused target protein. In another report, a carrier protein fused to the target protein was labeled with a stilbene reporter using the phosphopantetheinyltransferase (PPTase) (*22*). When the stilbene reporter binds to the anti-stilbene antibody, the fluorescence of the stilbene reporter group is turned on. The stilbene-labeled fusion protein can then be purified using the antibody-bound column. Dye and antidye−antibody combinations have also been used as dual function tags (*23*). The major problem with the aforementioned antibody-based purification is the high cost and low stability of the immobilized antibody.

This manuscript describes site-specific tagging of peptides/proteins of interest with a red fluorescent protein, specifically DsRed-Monomer. Here, we demonstrate that DsRed-Monomer serves as a dual function tag based on its inherent fluorescence and copper-binding properties. Recently, we have established that DsRed-Monomer can bind copper ions and this property can be utilized in a single step affinity-based purification method (*24*). Using a copper-immobilized column, we were able to isolate more than 95% of the DsRed-Monomer from a crude *E. coli* extract with higher than 95% purity. In the work presented here, we demonstrate that the DsRed-Monomer can be used as an affinity tag for purification of fused peptides/proteins, and that the fluorescence of DsRed can be utilized as a reporter to perform bioassays. The advantages of a DsRed-Monomer-based tagging system include flexibility to attach target protein to either termini, the ability to perform site-specific genetic encoding, and achievement of efficient detection over low cellular autofluorescence due to its excitation−emission in the red region of the spectrum. In addition, protein-based affinity tags have been shown to aid in proper folding of the fused target protein, thereby enhancing the solubility of the fusion protein compared to peptide-based tags (*9*). Furthermore, the copper-immobilized columns needed for the purification are cheaper and more stable compared to the antibody-immobilized columns.

DsRed-Monomer is a monomeric variant of native tetrameric DsRed (*25, 26*). It is a 28 kDa autofluorescent protein that shows broad excitation and emission bands with wavelength maxima at 584 and 591 nm, respectively. It matures faster than the native DsRed, and is pH- and temperature- (up to 37 °C) stable (*26*−*28*). The excellent physical properties and far-red fluorescence of DsRed allow for its use as a reporter in a variety of applications. To demonstrate the ability of DsRed-Monomer to function as a dual-function tag and to show its flexibility in genetic fusions of peptides/proteins, we constructed two fusion proteins. As a proof-of-concept, a fusion protein between a peptide, bradykinin, and DsRed-Monomer was constructed through the N-terminus of DsRed-Monomer. Bradykinin is a vasodilator peptide consisting of Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg residues (*29*). Another fusion protein between DsRed-Monomer and a model protein calmodulin (CaM) was constructed through the N-terminus of DsRed-Monomer. CaM is a Ca^{2+}-binding protein that is involved in the regulation of several cellular responses through its interaction with other proteins (*30, 31*). In the absence of Ca^{2+}, the CaM has a collapsed conformation (*32, 33*). In the presence of Ca^{2+}, CaM changes its conformation from a collapsed to a "dumbbell" configuration exposing its hydrophobic region that acts as a docking area for target peptides, proteins, and the tricyclic phenothiazene class of compounds (*32, 34*−*37*). The bradykinin-DsRed-Monomer fusion protein was expressed in *E. coli*, purified using a copper-immobilized column, and employed in the development of an immunoassay for bradykinin. The calmodulin-DsRed-Monomer (CaM-DsRed-Monomer) fusion protein was also expressed in *E. coli* and purified using a copper-immobilized column. This fusion protein was further employed to evaluate binding of a known CaM ligand, chlorpromazine to the fusion protein (*35, 37*).

EXPERIMENTAL SECTION

Reagents. The pDsRed-Monomer was purchased from Clonetech (Palo Alto, CA). Plasmid pVCU-1 containing the gene for calmodulin was kindly supplied by Prof. Sylvia Daunert from the University of Kentucky. Luria−Bertani (LB) broth and agar were purchased from DIFCO Laboratories (Detroit, MI). Bradykinin peptide, chlorpromazine hydrochloride, ampicillin, bovine serum albumin (BSA), and Coomassie brilliant blue R250 stain were obtained from Sigma Laboratories (St. Louis, MO). The chelex column and 96-well neutravidin-coated white microtiter plates were purchased from Pierce Technology (Rockford, IL). The Hi-Trap chelating column was from Amersham Bioscience. Rabbit antibradykinin antibody was purchased from Fitzgerald (Concord, MA). Goat antirabbit Fc specific biotinylated secondary antibody was obtained from ICN Biomedicals (Aurora, OH). ProTEV protease was obtained from Promega (Madison, WI).

Apparatus. Cell cultures were grown in a Fisher Scientific orbital shaker, and centrifuged using a Beckman J2-MI centrifuge (Palo Alto, CA). The fractions were lyophilized using a Fisher Bench Top freeze-dryer. Fluorescence measurements were performed on the Varian Cary Eclipse fluorescence spectrophotometer (Palo Alto, CA). All fluorescence intensities reported are the average of three replicates and have been corrected for the contribution of the background.

Plasmid Construction and Protein Expression. *Construction of Bradykinin-DsRed-Monomer Fusion.* The plasmid pDsRed-Monomer was used as a template for the PCR reaction. Primers were designed that encoded the DNA sequence for the bradykinin peptide, Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg. Using two consecutive PCRs, the DNA sequence for the peptide was inserted at the N-terminus of the DsRed-Monomer sequence present in the plasmid pDsRed-Monomer. Primer 1 coded for the three amino acid linker, Gly-Ser-Gly and the Arg-Pro-Pro part of bradykinin; Primer 2 encoded the remaining part of bradykinin, Gly-Phe-Ser-Pro-Phe-Arg and the linker Gly-Ser. Briefly, the steps involved include two PCRs using primer designed to encode for the bradykinin sequence and a three amino acid linker between the bradykinin and the DsRed-Monomer sequence (Forward Primer PCR1-GTCGACTCTAGAGGATGGTAGTGGTAGACCACCAGG CCCCCGGGTACCGGTC, Reverse Primer PCR1-GACCGGTACCCGGGGGCCTGG TGGTCTACCACTACCATCCTCTAGAGTCGAC, Forward Primer PCR2-GGTAGA CCACCAGGCTTCAGTCCATTTAGAGGTAGTCCCCGGGTACCGGT, Reverse Primer PCR2-GACCGGTACCCGGGGACTACCTCTAAATGGACTGAAGCCTGGT GGTCTAC). After each PCR step, digestion was performed with Dpn I to digest the original plasmid, leaving the plasmid with the inserted bradykinin DNA intact. This plasmid was then transformed into *E. coli* ER2566 strain. The colonies were picked, and miniprep was performed. DNA sequencing was performed to confirm the insertion of the bradykinin DNA sequence. The plasmid (pSKD103) with the entire bradykinin sequence and the linker sequence at the N-terminus of the DsRed-Monomer gene was obtained after the second step of PCR and employed for the expression of the fusion protein.

Construction of Calmodulin-DsRed-Monomer Fusion. The PCR primers were designed to introduce the sequences for the restriction enzymes, *Sph*I and *Xma*I on the CaM gene (Forward Primer-ATATATGCATGCGATGGCTGATCAGCTGACTGACGAGCAG, Reverse Primer- ATATATCCCGGGCCTTAGCCATCATAACCTGAACGAACTC). The plasmid PVUC-1 was used as a template (*36*). The CaM gene obtained after PCR and the pDsRed-Monomer were digested with *Sph*I and *Xma*I followed by ligation of the CaM gene into pDsRed-monomer plasmid to obtain pSKD104. The plasmid pSKD104 was transformed into *E. coli* ER2566 strain. The colonies were picked, and miniprep was performed. DNA sequencing was utilized to determine the sequence of the fusion protein.

Construction of CaM-DsRed-Monomer Fusion with TEV Protease Cleavage Site between CaM and DsRed-Monomer. To construct this fusion gene, the same primers, restriction enzymes, and molecular biology techniques were used as above for the CaM-DsRed-Monomer fusion. However, a new reverse primer was designed (new CaM Reverse Primer-CCCGGG*CCCCTGGAAGTACAGGTTTTCC*TTAGC-CATCATAACCTGAACG) which incorporated the TEV cleavage site, Glu-Asn-Leu-Tyr-Phe-Gln-Gly, before the *Xma*I restriction site. The DNA coding for TEV cleavage site is in italics and the DNA coding for *Xma*I is underlined. The PCR product was ligated into pDsRed-Monomer plasmid to obtain the plasmid pSKD105. This plasmid was transformed into *E. coli* JM107 strain.

Fusion Protein Expression. The cells containing the plasmid (pSKD103, pSKD104, and pSKD105) that encodes for fusion proteins were grown in Luria−Bertani (LB) broth containing ampicillin with shaking at 250 rpm at 37 °C to an optical density of 0.5 measured at 600 nm. Protein expression was induced using IPTG (1 mM) and the cells expressing bradykinin-DsRed-Monomer were allowed to grow further at 37 °C for an additional 3 h. The cells expressing calmodulin-DsRed-Monomer were allowed to grow at 37 °C overnight after induction with IPTG. The cells expressing CaM-TEV recognition site-DsRed-Monomer fusion protein were allowed to grow a further 16 h at 30 °C. The cells were harvested by centrifugation at 4 °C, 4000 × *g*, for 15 min and were sonicated using 20s on and 20 s off for 5 min. The crude fusion proteins were obtained by centrifugation at room temperature, 4000 × *g* for 30 min. Subsequently, the fusion proteins were purified as described below.

Fusion Protein Purification. The fusion proteins were purified on a Hi-Trap Chelating column (GE Healthcare). These columns are packed with Chelating Sepharose High Performance, a highly cross-linked agarose bead. These agarose beads have iminodiacetic acid coupled by stable ether groups, through a spacer arm of seven atoms. The column was prepared by washing with 5 mL of distilled water to remove ethanol used to store the column. Copper was immobilized on the column by passing through the column a volume of 0.5 mL of 0.1 M $CuSO_4$. The column was washed with an additional 5 mL of distilled water. Any non-immobilized copper was removed by passing 5 mL of acidic buffer (0.02 M sodium acetate containing 1.0 M NaCl, pH 4.0) through the column. The column was next equilibrated with 5 mL of binding buffer (50 mM sodium phosphate buffer containing 300 mM NaCl, pH 8.0). Crude fusion proteins in binding buffer were loaded onto the copper-immobilized column and incubated for 30 min at 37 °C. The column was then washed with 20 mL of binding buffer followed by 20 mL of wash buffer (50 mM sodium phosphate buffer containing 2 mM imidazole and 300 mM NaCl, pH 8.0). Purified fusion proteins were eluted with 5 mL of elution buffer (50 mM sodium phosphate containing 300 mM NaCl and 10 mM imidazole, pH 8.0). For the entire purification procedure, a flow rate of about 6 mL/min was used. Eluted fractions which displayed fluorescence emission characteristics of DsRed-Monomer were collected, and the purity was determined by SDS-PAGE using Coomassie staining solution. A dialysis step was performed using the buffer, 50 mM sodium phosphate containing 100 mM NaCl, pH 7.4, for bradykinin-DsRed-Monomer and buffer, 30 mM Tris containing 10 mM calcium, pH 7.2 for the CaM-DsRed-Monomer protein. Protein concentration was determined by using the Bradford assay.

Determination of Protein Recovery after Purification. To determine the recovery of protein, 180 mg of purified bradykinin-DsRed-Monomer/Calmodulin-DsRed-Monomer fusion protein was loaded onto the copper column. Purification steps outlined in the earlier section were followed, and the concentrations of eluted proteins were determined.

Protease Cleavage of CaM from CaM-DsRed-Monomer. Promega ProTEV protease was used according to the manufacturer's recommendations with the supplied buffer to cleave the CaM from the purified CaM-DsRed-Monomer fusion. The reaction was allowed to continue for 24 h at 37 °C. Complete cleavage of CaM was verified by running an SDS-PAGE gel with Coomassie staining.

Fluorescence Spectra. A volume of 200 μL of 1.0 μM DsRed-Monomer-bradykinin fusion protein and 1.0 μM of Calmodulin-DsRed-Monomer was placed into different wells of a microtiter plate, and excitation and emission scans of the protein were obtained at room temperature using a Cary Eclipse fluorescence spectrophotometer.

UV−visible Spectra. A volume of 1 mL of 1.0 μM DsRed-Monomer-bradykinin and 1.0 μM of Calmodulin-DsRed-Monomer fusion proteins were placed in a cuvette, and the absorption spectra of the proteins were recorded at room temperature using an Agilent 8453 UV/vis Spectrometer from Agilent Technologies (Santa Clara, CA).

Bradykinin Assay Development. *Dilution Study.* Standard solutions of bradykinin-DsRed-Monomer fusion protein were prepared by serially diluting the stock solution of the protein in assay buffer 1 (50 mM sodium phosphate containing 100 mM NaCl, pH 7.4). A volume of 100 μL of these solutions was mixed with 100 μL of assay buffer 1 and placed in a microtiter plate, and the fluorescence intensity was measured using an excitation maximum wavelength of 558 nm and an emission wavelength maximum of 591 nm. All fluorescence intensities were obtained in triplicate.

Binder Dilution Study Using Bradykinin-DsRed-Monomer. A volume of 100 μL of biotinylated goat antirabbit secondary antibody (10 μg/mL) in assay buffer 1 was added to the neutravidin-coated 96-well white microtiter plate and incubated for 2 h at room temperature with shaking at 250 rpm. The wells of the plate were washed 3 times with the wash buffer (50 mM sodium phosphate containing 150 mM NaCl, pH 7.4). Next, 100 μL of different concentrations of antibradykinin antibody in assay buffer 1 were added to the wells coated with secondary antibody. An incubation step was performed for 2 h at room temperature with shaking at 250 rpm followed by a wash step to remove unbound antibody. A volume of 50 μL of 0.1 μM concentration of the bradykinin-DsRed-Monomer fusion protein mixed with 50 μL of assay buffer 1 was added to the well plate, and incubation was performed for 2 h at room temperature. After a wash step, 200 μL of assay buffer 1 was added to the plate, and fluorescence emission readings were monitored at 591 nm.

Dose−Response Curve for Bradykinin. The primary (1:100 dilution) and secondary antibody (10 μg/μL) were immobilized on the wells of a microtiter plate as described earlier. A dose−response curve was generated for bradykinin by simultaneously incubating different concentrations of 50 μL of bradykinin peptide and 50 μL of 0.1 μM bradykinin-DsRed-Monomer fusion protein with immobilized antibradykinin antibody on a microtiter plate. The plate was incubated at room temperature for 2 h with shaking at 250 rpm. The plate was washed three times with the wash buffer to remove any unbound components. The fluorescence intensity was measured as described before.

Calmodulin Ligand-Binding Study. *Dilution Study.* Standard solutions of calmodulin-DsRed-Monomer fusion protein were prepared by serially diluting the stock solution of the protein in assay buffer 2 (30 mM Tris containing 10 mM calcium, pH 7.2). A volume of 100 μL of these solutions was mixed with 100 μL of assay buffer 2 and placed in a microtiter plate, and the fluorescence intensity was measured using an excitation maximum wavelength of 558 nm and the emission wavelength maximum of 591 nm. All fluorescence intensities were obtained in triplicate.

Dose−Response Curve for Chlorpromazine. Different concentrations of chlorpromazine were prepared by diluting in assay buffer 2. A volume of 100 μL of 1 μM calmodulin-DsRed-Monomer was mixed with different concentrations of 100 μL of chlorpromazine. The fluorescence intensity was monitored corresponding to DsRed-Monomer excitation/emission wavelength. A control study was performed using DsRed-Monomer and chlorpromazine. In another control study, solutions of varying concentrations of chlorpromazine (1×10^{-3} to 1×10^{-6} M) were excited at 556 nm and the fluorescence emission was monitored at 591 nm.

RESULTS AND DISCUSSION

The results described in this study demonstrate dual application of DsRed-Monomer. Reporter proteins, such as DsRed-Monomer, are commonly fused to the target protein for fluorescent-based bioassay development. However, if the same reporter protein can also function as an affinity purification tag, then this will reduce the assay development time and will simplify the assay development process. To demonstrate the versatility of DsRed-Monomer as a dual-function tag, we selected a peptide, bradykinin, and a protein, calmodulin, as fusion partners in this proof-of-concept study.

The DNA encoding for the bradykinin peptide and the gene for calmodulin were fused to the gene coding for the DsRed-Monomer using genetic engineering tools to construct two gene fusions. Plasmids pSKD103 and pSKD104 containing the fusion genes were transformed into *E. coli* cells and the fusion proteins

were expressed. The fusion proteins were purified using a copper-immobilized column utilizing DsRed-Monomer as an affinity tag. Briefly, copper was first immobilized on an iminodiacetic acid containing chelating column and crude fusion proteins were passed through the column. Purified fusion protein fractions were collected after a wash step by passing through an elution buffer containing imidazole. The elution of the purified fusion proteins were monitored by the pink coloration of the protein and by measuring its fluorescence. Purity of fusion proteins was verified by SDS-PAGE using Coomassie staining (Figure 1). Single bands corresponding to the molecular weight of the bradykinin-DsRed-Monomer fusion protein (27 kDa, Figure 1A) and calmodulin-DsRed-Monomer (41.5 kDa, Figure 1B) were observed (Figure 1). We have also performed an expression study to compare the effect of fusion of calmodulin to DsRed-monomer on the expression yield. For this study, we expressed wild-type calmodulin and calmodulin-DsRed-Monomer proteins under identical conditions. The conditions followed were the same as that used for the expression of the protein described in Experimental Section. An SDS-PAGE was performed (Figure 1C) that showed similar expression yield for calmodulin and calmodulin-DsRed-Monomer protein. Additionally, the total protein yields for the two proteins were similar. These observations indicate that fusion of the target protein to DsRed-Monomer does not affect the expression of the target protein. Concentrations of the purified fusion proteins were determined using the Bradford assay. Percent recovery of the purified protein was estimated by passing a known quantity of purified fusion proteins through the copper-immobilized column. The purification procedure was followed, and the concentration of eluted protein was determined. The amount of eluted protein was compared to the amount of protein initially loaded on the column, and recoveries were calculated to be 95% and 96% for bradykinin-DsRed-Monomer and calmodulin-DsRed-Monomer fusion proteins, respectively.

Table 1. Characteristics of DsRed Fusion Proteins

	DsRed-Monomer	Bradykinin-DsRed-Monomer	Calmodulin-DsRed-Monomer
$\lambda_{excitation}$, nm	556	556	556
$\lambda_{emission}$, nm	597	597	597
absorbance maxima, nm	480, 556	480, 556	480, 556
ε, M^{-1} cm^{-1}	34 715	40 427	59 000

To demonstrate that the target protein can be separated after purification from DsRed-Monomer if desired, we incorporated a TEV protease cleavage site between CaM- and DsRed-Monomer. The fusion protein was purified using a copper-bound column employing DsRed-Monomer as an affinity tag. The DsRed-Monomer was cleaved off easily and completely from the CaM-TEV recognition site-DsRed-Monomer fusion protein within 24 h time period. This was verified by running the reaction mixture on an SDS-PAGE gel. Figure 1 D shows two bands corresponding to CaM and DsRed-Monomer. Therefore, we can say that although DsRed-Monomer is a large affinity tag it can be efficiently separated from the target protein if desired.

Although variants of DsRed have been employed as fusion tags in other studies, there are no published reports on fusions of DsRed-Monomer. Therefore, spectral characteristics of the fusion proteins were first evaluated to determine any effect of peptide/protein fusion on the DsRed-Monomer protein structure and fluorescence emission (Table 1). Fluorescence excitation−emission scans were performed for both fusion proteins. An excitation wavelength maximum of 556 nm and an emission wavelength maximum of 591 nm were obtained for both fusion proteins, which is characteristic of the DsRed-Monomer (*24*).

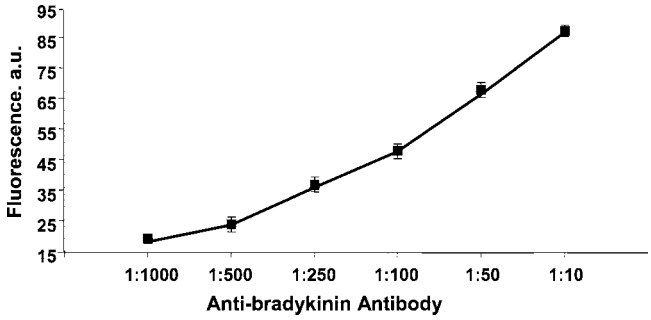

Figure 2. Binder dilution curve obtained by incubating a volume of 100 μL of varying dilutions of antibradykinin antibody immobilized on a microtiter well plate with 50 μL of 0.1 μM bradykinin-DsRed-Monomer fusion protein and 50 μL of assay buffer 1.

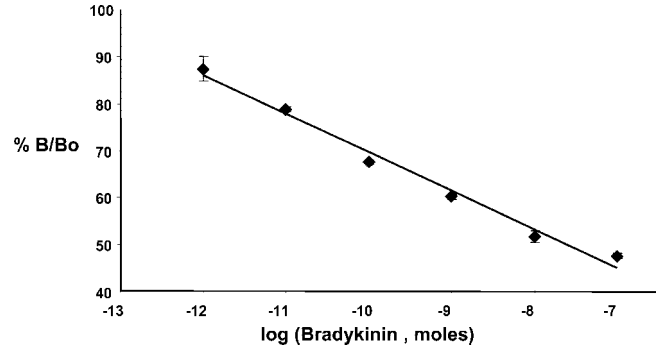

Figure 3. Dose−response curve for bradykinin peptide obtained by incubating 50 μL of 0.1 μM bradykinin-DsRed-Monomer protein and 50 μL of different concentrations of free bradykinin peptide with immobilized antibradykinin antibody. B corresponds to light intensity obtained from the sample containing free bradykinin and B_0 corresponds to light intensity obtained from the sample without the free bradykinin.

UV−visible absorbance spectra of both fusion proteins showed two peaks at 480 and 556 nm, which are similar to that observed in the case of DsRed-Monomer protein (*28*). A comparison of spectral properties of fusion proteins with the DsRed-Monomer protein showed no effect of peptide/protein fusion on the DsRed-Monomer fluorescence activity. These studies indicated that the fusion of a peptide/protein to DsRed-Monomer does not affect the fluorescence activity of the protein.

Next, to demonstrate the function of DsRed-Monomer as an optical tag, we performed studies that utilized DsRed-Monomer in assay development based on its inherent fluorescence. In that respect, a solid-phase competitive fluorescence immunoassay for the detection of bradykinin was developed using antibradykinin antibody and bradykinin-DsRed-Monomer fusion protein. A dilution study for the bradykinin-DsRed-Monomer fusion protein was performed to determine the concentration of the fusion protein that can be used in the development of the assay. On the basis of the dilution curve, a concentration of 0.1 μM was employed for the peptide immunoassay study. The next step in the assay was to study the binding between the bradykinin-DsRed-Monomer fusion protein and the antibradykinin antibody. For this study, biotinylated secondary antibody was immobilized on neutravidin-coated well plates. Varying dilutions of antibradykinin antibody were then immobilized on the plate through the secondary antibody. The fluorescence signal was measured after incubation of the bradykinin-DsRed-Monomer fusion protein on the plate. As expected, with increasing amounts of antibradykinin antibody a higher fluorescence signal was observed, because higher amounts of bradykinin-DsRed-Monomer fusion protein could bind to the antibody (Figure 2). From this curve, a 1:100 dilution of the antibradykinin antibody was selected for generating a dose−response curve for the bradykinin peptide.

A dose−response curve for bradykinin was generated by employing a competitive assay design (Figure 3). For this assay design, the antibradykinin antibody was immobilized on a neutravidin-coated plate through a biotinylated secondary antibody using biotin−neutravidin interaction. The free bradykinin peptide and the bradykinin-DsRed-Monomer fusion protein were added simultaneously to the antibradykinin antibody immobilized on a plate, and were allowed to compete to bind to the same antibody. The amount of antibradykinin antibody and the bradykinin-DsRed-Monomer fusion protein is kept fixed. With increasing amount of free bradykinin, less of the fusion protein could bind to the antibody, yielding a reduction in the fluorescence signal compared to the signal obtained in the absence of the free peptide. Therefore, the plot of the ratio of fluorescence intensity in the presence of free bradykinin upon the fluorescence signal in the absence of free bradykinin against the log units of the moles of free bradykinin showed a linear response with a negative slope (Figure 3). The dose−response curve was linear over 5 orders of magnitude, extending from 1×10^{-12} to 1×10^{-7} mol of bradykinin. A detection limit of 1 pmol for bradykinin peptide was calculated using a S/N ratio of 3. A detection limit of 1 pmol of bradykinin peptide was calculated using a signal-to-noise (S/N) ratio of 3. In normal plasma samples, approximately 2.1×10^{-11} mol of bradykinin are found; however, under diseased conditions the level of bradykinin increases (*38, 39*). Therefore, a higher bradykinin level will fall well within the working range of our assay. These results indicate that the assay developed in this study can be used in clinical diagnostics to test levels of bradykinin and is comparable to existing assays for bradykinin detection (*29, 40−42*). The effect of matrix on the fluorescence activity of DsRed-Monomer was evaluated by incubating bradykinin-DsRed-Monomer protein in plasma samples. Comparison of the fluorescence of DsRed-Monomer in clear plasma samples and in buffer samples showed an insignificant effect of matrix on the activity of the protein. This indicates that our assay could be employed in plasma screening of bradykinin if desired.

Spectroscopic and purification analysis of calmodulin-DsRed-Monomer fusion protein showed that proteins of interest could be fused to the DsRed-Monomer without affecting its copper-binding affinity and fluorescence. This should prove useful in visualization of fusion proteins followed by their isolation. Furthermore, we wanted to demonstrate that fusion with DsRed-Monomer can also be utilized in the optical detection of the interactions of fused target protein with its ligands. In that respect, calmodulin is a well-studied protein with known ligands that are commercially available; therefore, we decided to study binding of CaM ligands to calmodulin-DsRed-Monomer fusion protein. This can be performed in two ways. The calmodulin-DsRed-Monomer fusion protein can be genetically encoded to study calmodulin interacting proteins/ligands *in vivo*, or the isolated fusion protein can be used to study calmodulin interacting molecules *in vitro*. It has been reported by other groups that the fusion protein between green fluorescent protein (GFP) and calmodulin can be utilized in screening ligands that bind calmodulin (*35, 43, 44*) in solution-phase assay. On the basis of this, we performed a solution-based study by mixing calmodulin-DsRed-Monomer and a known representative CaM ligand, chlorpromazine. Addition of chlorpromazine resulted in a quenching of CaM-DsRed-Monomer fluorescence. This change in fluorescence can be attributed to the conformational change that occurs in CaM upon binding its ligand. It has been hypothesized previously that the conformational change in CaM may lead to a change in the microenvironment of fused fluorescent proteins affecting the fluorescence output of these proteins. A dose−response curve was generated by varying the

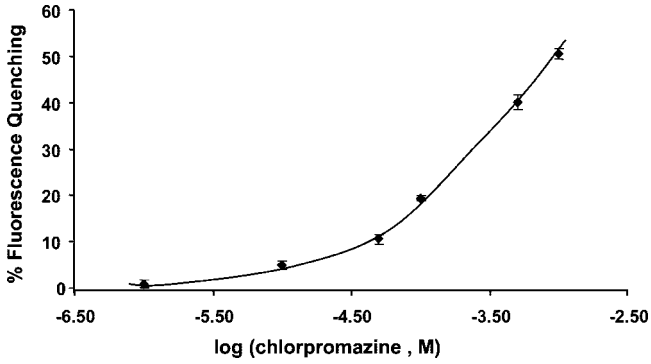

Figure 4. Dose−response curve for chlorpromazine generated by monitoring fluorescence change upon addition of different concentrations of chlorpromazine to calmodulin-DsRed-Monomer fusion protein. Fluorescence was measured using a 556 nm excitation wavelength maximum and a 591 nm emission wavelength maximum.

amount of chlorpromazine and relating it to the change in fluorescence intensity (Figure 4). A detection limit of 5×10^{-6} M was obtained for chlorpromazine, which is comparable to that achieved with other reported fluorescence-based assays for chlorpromazine (*34*, *35*). A control study was performed by adding chlorpromazine to DsRed-Monomer protein, which did not result in fluorescence quenching (data not shown). In another control study, we evaluated the effect of fluorescence excitation at 556 nm on chlorpromazine, which is inherently fluorescent. For this study, solutions of varying concentrations of chlorpromazine were excited at 556 nm, and the emission was monitored at 591 nm. The fluorescence intensity obtained from these samples was same as the buffer blank, demonstrating no effect of fluorescence excitation on chlorpromazine. Overall, the study performed shows that the binding between CaM and its ligand can be monitored using the fluorescence of DsRed-Monomer and the observed fluorescence quenching is due to the specific binding of chlorpromazine to CaM. We hypothesize that binding of other phenothiazene-based CaM ligands would yield similar results and could be evaluated if desired. It should be noted that the fluorescence change observed upon binding of ligands to CaM may not be universally applicable to other target protein−ligand pairs. Nevertheless, the fluorescence of DsRed-Monomer could still be used in the evaluation of target-protein ligand pair using a solid-phase assay technique.

In summary, through this study we have demonstrated a dual function of DsRed-Monomer as an affinity and a reporter tag. The combination of fluorescence and affinity properties of DsRed-Monomer makes it a unique reporter for *in vivo* and *in vitro* protein analysis. We believe that in the future new vectors based on DsRed-Monomer could be designed that allow the insertion of any protein. The recombinant proteins produced could then be expressed in different organisms, monitored optically, purified, and employed in assay development. Further, if desired, protease cleavage sites could be incorporated into fusion protein designs to isolate the target protein following purification. We do not anticipate any problems with the protease cleavage between DsRed-Monomer and the target protein, because this technique is well-developed and has been performed with DsRed previously (*45*−*49*). In one of these studies, the substrate of the hepatitis C virus protease fused to the DsRed-Express was cleaved about 54% by the membrane protease within 24 h. In another report, the 6-histidine tag fused to DsRed-Monomer incorporating the cleavage site for tobacco etch virus (TEV) protease was cleaved completely within 24 h (*46*). Additionally, the DsRed-tetramer/GFP pair has been employed to design fluorescence resonance energy transfer assays for the detection of protease activity by inserting substrate for the protease between the genes of the two fluorescent proteins (*47*−*49*). This is the first report on the fusion of a peptide/protein to DsRed-Monomer and its use as a label in a peptide detection assay as well as in the detection of protein−ligand binding. We envision that the DsRed-Monomer can be employed as a tag to visualize and isolate protein−protein interactions directly from cells expanding its utility in fundamental biomolecular research.

ACKNOWLEDGMENT

We would like to thank the National Institutes of Health and the National Science Foundation for their support. We would like to thank Prof. Sylvia Daunert from the University of Kentucky for providing the pVUC-1 plasmid. We appreciate funding from IUPUI Research Support Funds Grant. We would like to thank Christopher Konz for supplying plasma samples.

We recently reported that the ferrocene-containing cationic lipid BFDMA [bis(11-ferrocenylundecyl)dimethylammonium bromide] can be used to mediate cell transfection, and that levels of transfection depend critically upon the oxidation state of the ferrocenyl groups of the lipid. Here, we report that the redox activity of BFDMA can be exploited to transform lipoplexes formed from oxidized BFDMA (which do not transfect cells) to lipoplexes that are "active" (and thus mediate high levels of transgene expression) by treatment with the chemical reducing agent glutathione (GSH). We demonstrate that GSH can be used to reduce the ferrocenium groups of oxidized BFDMA rapidly both (i) in solution and (ii) in lipoplexes formed by mixing oxidized BFDMA and DNA. Lipoplexes transformed in this manner mediate levels of cell transfection *in vitro* that are comparable to levels of transfection mediated by lipoplexes prepared by mixing DNA and reduced BFDMA. We demonstrate further that the chemical reduction of oxidized BFDMA leads to changes in the zeta potentials of these lipoplexes (e.g., from negative to positive). Characterization of lipoplex internalization using confocal microscopy demonstrated that these changes in zeta potential correlate to differences in the extents to which these lipoplexes are internalized by cells. These results provide a framework from which to interpret differences in cell transfection mediated by reduced and oxidized BFDMA. When combined, the results of this study suggest the basis of an approach that could be used to transform lipoplexes actively or "on-demand" and provide spatial and/or temporal control over the transfection of cells in a range of different fundamental and applied contexts.

INTRODUCTION

Cationic lipids are used widely as agents for the delivery of DNA to cells because they can interact with DNA to form nanoscale aggregates (or "lipoplexes") with sizes, charges, and other properties that can be used to address several critical barriers to cell transfection (*1*−*6*). Numerous past studies have identified a wide range of structural features and physical properties of cationic lipids that are important for the transfer of DNA into cells (*1*−*12*). This past work has contributed broadly to the development of cationic lipids and lipid-based formulations that can be used to promote high levels of cell transfection *in vitro* and *in vivo*.

Past studies on the development of cationic lipids for DNA delivery have focused, in large measure, on the design of lipids and lipoplex formulations that are (i) stable in extracellular environments (*13*−*15*) and/or (ii) unstable in (or designed to be responsive to) conditions found in intracellular environments (*16*−*27*). The former goal is often accomplished by the conjugation or incorporation of chemical functionality that resists protein adsorption or prevents the premature disruption of lipid/DNA interactions (*13*−*15*). The second goal has been addressed generally by the design of lipids containing functional groups that respond to changes in pH (*16*−*19, 26*), redox-potentials (*19*−*23*), or enzyme concentrations (*19, 24, 25*) present in intracellular environments. The broad motivations for the design of lipoplexes having this combination of properties are clear, as effective lipoplex-mediated transfer of DNA into cells will ultimately require lipoplexes that address effectively both extracellular barriers and intracellular barriers to the transport, internalization, and processing of DNA by cells.

In contrast to the work described above, less work has been focused on the development of lipoplexes or other nonviral DNA delivery systems that are designed to be transformed chemically or physically in extracellular environments (*27*). Lipoplexes that could be transformed in extracellular environments (for example, from states that may be "inactive", and, thus, unable to transfect cells, to states that are "active" and, thus, able to transfect cells efficiently) could be useful in a broad range of fundamental and applied contexts. For example, the ability to exert spatial and/or temporal control over the "activation" of inactive lipoplexes *in vitro* could lead to new methods for the patterning of cell transfection or the delivery of DNA to defined subpopulations of cells, and could thus contribute broadly to the development of new tools for both basic and applied biomedical research. The ability to exert such control could also prove useful for the localization of DNA delivery *in vivo*.

The work reported here builds upon the results of several past studies by our groups (*28*−*42*) and others (*43*−*50*) demonstrating that redox-active amphiphiles containing ferrocenyl groups can be used to exert spatial and/or temporal control over a broad range of properties of aqueous systems (*28*−*36, 43*−*50*) and interactions with macromolecular species (*37*), including DNA (*38*−*42*). Of particular relevance to the study described here, we reported recently that a two-tailed, ferrocene-containing cationic lipid [bis-(11-ferrocenylundecyl)dimethylammonium bromide (BFDMA; Figure 1)] (*44, 45, 47*) can be used to transfect cells (*38, 39*). One important outcome of these past studies was the observation that the oxidation state of the ferrocenyl groups of the BFDMA used to form lipoplexes with DNA plays a critical role in determining the ability of lipoplexes to promote transgene expression (*38, 39*). Lipoplexes formed

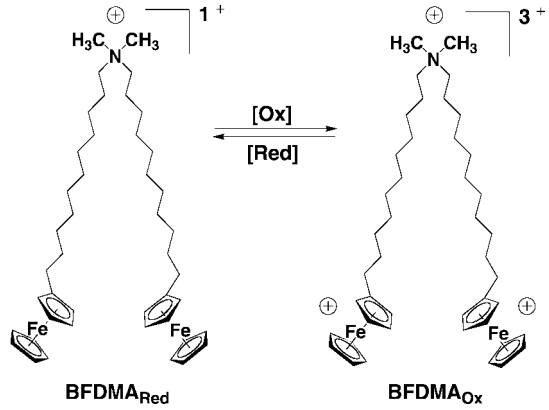

Figure 1. Structure of BFDMA, a redox-active cationic lipid. The charge of BFDMA can be cycled between +1 (reduced) and +3 (oxidized) by oxidation or reduction of the ferrocenyl groups at the end of each hydrophobic tail.

from DNA and reduced BFDMA (which has an overall net charge of +1) can be used to mediate high levels of cell transfection. However, lipoplexes formed using DNA and oxidized BFDMA (which has an overall net charge of +3) generally promote very low levels of cell transfection (*38, 39*). In subsequent studies aimed at characterizing the physical properties of lipoplexes formed from reduced and oxidized BFDMA, we identified differences in lipoplex sizes (*38, 39, 41*), internal dynamics (*41*), zeta potentials (*41*), and nanostructures (*42*) that correlated to these large differences in cell transfection. The results of these past studies, when combined, suggest that changes in the physical properties (and thus the transfection behaviors) of lipoplexes formed from reduced and oxidized BFDMA can be understood broadly in terms of changes in the amphiphilicity of BFDMA that occur upon the oxidation or reduction of ferrocene (*38, 39, 41, 42*). Because the redox state of ferrocenyl surfactants can, in general, be transformed rapidly and reversibly in aqueous environments (e.g., using either chemical or electrochemical methods) (*28*−*50*), these past results also suggest a basis for the development of methods that could permit active or reversible control over the ability (or the inability) of lipoplexes formed from BFDMA to transfect cells.

This current investigation sought to determine whether it was possible to exploit the redox activity of ferrocene to transform "inactive" lipoplexes formed from oxidized BFDMA to lipoplexes that are "active" and, thus, able to transfect cells. We report here that it is possible to transform or "activate" lipoplexes formed from DNA and oxidized BFDMA to lipoplexes that mediate high levels of transfection by treatment with a chemical reducing agent (glutathione, GSH). We demonstrate that GSH can be used to reduce the ferrocenium groups of oxidized BFDMA rapidly both (i) in solution and (ii) in lipoplexes formed by mixing oxidized BFDMA and DNA, and that lipoplexes transformed in this manner mediate levels of cell transfection *in vitro* that are comparable to levels of transfection mediated by lipoplexes prepared by the direct mixing of DNA and reduced BFDMA. We demonstrate further that the chemical reduction of the oxidized BFDMA in these lipoplexes leads to changes in zeta potentials (e.g., from negative values to positive values) and that these changes in zeta potential correlate to significant differences in the extents to which these lipoplexes are internalized by cells.

Our results demonstrate that it is possible to transform both the physicochemical properties and the biological behaviors of nanoscale aggregates of DNA and a redox-active cationic lipid. The results of this study, in combination with the results of our past studies (*38, 39, 41, 42*), suggest a basis for the development of methods for the transformation of cationic lipids and/or lipoplexes actively or "on-demand" in ways that could be used to provide spatial and/or temporal control over the transfection of cells *in vitro* or *in vivo*.

MATERIALS AND METHODS

Materials. Bis-(11-ferrocenylundecyl)dimethylammonium bromide (BFDMA) was synthesized as previously described (*45*). Glutathione (GSH) and lithium sulfate monohydrate were purchased from Sigma Aldrich (St. Louis, MO). Dodecyltrimethylammonium bromide (DTAB) was purchased from Acros Organics (Morris Plains, NJ). Plasmid DNA encoding enhanced green fluorescent protein [pEGFP-N1 (4.7 kb), >95% supercoiled] was purchased from the Waisman Clinical Biomanufacturing Facility at the University of Wisconsin - Madison. Plasmid DNA encoding firefly luciferase [pCMV-Luc, >95% supercoiled] was purchased from Elim Biopharmaceuticals, Inc. (San Francisco, CA). Deionized water (18 MΩ) was used to prepare all buffers and salt solutions. Dulbecco's modified Eagle's medium (DMEM), OptiMEM cell culture medium, phosphate-buffered saline (PBS), fetal bovine serum (FBS), Lipofectamine 2000, live/dead viability/cytotoxicity assay kits, calcein AM, and Lysotracker Red were purchased from Invitrogen (Carlsbad, CA). Bicinchoninic acid (BCA) protein assay kits were purchased from Pierce (Rockford, IL). Glo Lysis Buffer and Steady-Glo Luciferase Assay kits were purchased from Promega Corporation (Madison, WI). Cy5 Label-IT nucleic acid labeling kits were purchased from Mirus Bio (Madison, WI). Glass inset dishes used for laser scanning confocal microscopy (LSCM) were purchased from MatTek (Ashland, MA). All commercial materials were used as received without further purification unless otherwise noted.

General Considerations. Oxidation of BFDMA was conducted at 75 °C using a bipotentiostat (Pine Instruments, Grove City, PA) and a three-electrode cell to maintain a constant potential of 500 mV between the working electrode and a Ag/AgCl reference electrode. Platinum mesh (1.0 in^2) was used as the working and counter electrodes. The progress of oxidation was followed by monitoring current passed at the working electrode and by UV/visible spectrophotometry, as described previously (*38, 39*). All UV/visible absorbance values were recorded using a Beckman Coulter DU520 UV/vis spectrophotometer (Fullerton, CA). All zeta potential measurements were performed using a Zetasizer 2000HS instrument (Malvern Instruments, Worcestershire, UK). Fluorescence microscopy images used to evaluate the expression of enhanced green fluorescent protein (EGFP) in cell transfection experiments were recorded using an Olympus IX70 microscope and were analyzed using the *Metavue* version 7.1.2.0 software package (Molecular Devices; Toronto, Canada). Fluorescence, luminescence, and absorbance measurements used to characterize cytotoxicity, luciferase expression, and total cell protein were made using a PerkinElmer EnVision multilabel plate reader (Calcein AM: Ex, 492 nm; Em, 535 nm. Ethidium homodimer-1: Ex, 535 nm; Em, 620 nm. Luciferase: Em, 700 nm cutoff. BCA: Abs 560 nm). For DNA used in LSCM experiments, DNA was labeled using a Label-IT nucleic acid labeling kit according to the manufacturer's protocol (labeling density ~100 labels per plasmid). Labeled DNA was purified by ethanol precipitation, and labeling densities were determined using a UV/vis spectrophotometer, as described by the manufacturer of the labeling kit. LSCM was performed using a Bio-Rad Radiance 2100 MP Rainbow laser scanning confocal microscope equipped with a multiphoton laser. LSCM images were processed using the LaserSharp 2000 processing kit (Bio-Rad; Hercules, CA), *ImageJ* 1.38× (National Institutes of Health, Washington, DC; and Photoshop CS2 (Adobe Systems; San Jose, CA).

Preparation of Reduced and Oxidized BFDMA Solutions. Solutions of reduced BFDMA were prepared by dissolving a desired mass of reduced BFDMA in aqueous Li_2SO_4 (1.0 mM) followed by serial dilution with water over the desired concentration range (see text). Solutions of oxidized BFDMA were prepared by electrochemical oxidation of a 1.0 mM Li_2SO_4 solution containing reduced BFDMA, followed by serial dilution to desired concentrations, as described previously (*38*, *39*).

Preparation of Lipoplexes. Lipoplexes prepared from oxidized and reduced BFDMA were prepared in the following general manner. A solution of plasmid DNA (24 μg/mL in water) was added to a vortexing solution of aqueous Li_2SO_4 containing an amount of reduced or oxidized BFDMA sufficient to give the final lipid concentrations reported in the text. Total sample volumes for UV/vis absorbance experiments and zeta potential experiments were 1.0 mL. Sample volumes for LSCM and cell transfection experiments were 500 and 50 μL, respectively. Lipoplexes were allowed to stand at room temperature for at least 30 min before characterization or use in cell transfection experiments. Lipoplexes prepared to characterize the kinetics of reduction of BFDMA upon addition of GSH were used immediately after preparation.

Characterization of Transformation of Lipoplexes upon Addition of GSH. Experiments involving the addition of GSH to lipoplexes were performed by adding a negligible volume (0.5−5 μL) of a concentrated solution of GSH (0.5 M) to solutions of lipoplexes in an amount sufficient to yield the GSH/lipid molar ratios described in the text. Time-dependent changes in the oxidation state of BFDMA upon the addition of GSH to lipoplexes were characterized by measuring UV/vis absorbance spectra at wavelengths ranging from 400 to 800 nm. For these experiments, lipoplexes were prepared at higher lipid concentrations (but at equivalent lipid/DNA charge ratios) compared with lipoplexes prepared for use in transfection experiments to allow characterization of absorbance spectra. Following the acquisition of an initial wavelength scan, a kinetic scan was initiated by monitoring the absorbance of the solution at 5 s intervals at a wavelength of 630 nm (a wavelength characteristic of the absorbance of oxidized BFDMA). GSH was then added to the lipoplex solution, and the absorbance at 630 nm was monitored until a plateau in the measured value was observed. A second wavelength scan was performed over the range 400−800 nm at the conclusion of the kinetic experiment. For experiments involving measurements made on solutions of reduced BFDMA, DTAB was added immediately prior to measurement of absorbance to eliminate clouding observed in BFDMA solutions at concentrations greater than 100 μM. Note that DTAB does not absorb light in the visible region of interest of 400−800 nm. For experiments for which GSH was added to transform lipoplexes formed using oxidized BFDMA (described above), DTAB was added at the conclusion of each experiment before making a final absorbance measurement.

Characterization of Zeta Potential. Experiments designed to characterize the zeta potentials of lipoplexes after preparation or after exposure to GSH were conducted in the following general manner. For each sample prepared as described above, 1 mL of lipoplex solution was injected into the inlet of a Zetasizer 2000HS instrument, and measurements were made at ambient temperature using an electrical potential of 150 V. A minimum of four measurements were recorded for each sample, and the Henry equation was used to calculate zeta potentials from measurements of electrophoretic mobility (*51*). For this calculation, we assumed the viscosity of the solution to be the same as that of water.

General Protocols for Transfection and Characterization of Gene Expression. COS-7 cells used in transfection experiments were grown in clear or opaque polystyrene 96-well culture plates (for experiments using pEGFP-N1 and pCMV-Luc, respectively) at initial seeding densities of 15 000 cells/well in 200 μL of growth medium (90% Dulbecco's modified Eagle's medium, 10% fetal bovine serum, penicillin 100 units/mL, streptomycin 100 μg/mL). After plating, all cells were incubated at 37 °C for 24 h. At approximately 80% confluence, culture medium was aspirated and replaced with 200 μL of serum-free media (OptiMEM), followed by addition of 50 μL of lipoplex samples. Lipoplexes prepared as described above were added to assigned wells via pipet in replicates of three, and the cells were incubated for 4 h at 37 °C, at which point lipoplex-containing media was aspirated from all wells and replaced with 200 μL of serum-containing medium. Samples were incubated for an additional 48 h prior to characterization of transgene expression. For experiments conducted using lipoplexes formed using pEGFP-N1, cell morphology and relative levels of EGFP expression were characterized using phase contrast and fluorescence microscopy. For experiments conducted using lipoplexes formed using pCMV-Luc, quantitative cytotoxicity measurements were conducted using a commercially available fluorescence live/dead assay kit according to the manufacturer's instructions. Luciferase protein expression was determined using a commercially available luminescence-based luciferease assay kit using the manufacturer's specified protocol. Samples were compared with signals from control wells and/or normalized against total cell protein in each respective well using a commercially available BCA assay kit (Pierce). Lipoplexes formed using Lipofectamine 2000 were used as a positive control and prepared according to the manufacturer's instructions.

Characterization of Internalization of Lipoplexes Using LSCM. COS-7 cells were grown in glass inset confocal microscopy dishes at initial seeding densities of 2.4×10^5 cells in 2.0 mL of growth medium [90% (v/v) Dulbecco's modified Eagle's medium, 10% (v/v) fetal bovine serum, 100 units/mL penicillin, 100 μg/mL streptomycin]. Cells were allowed to grow overnight to approximately 90% confluence. Growth medium was then replaced with 2.0 mL of serum-free culture medium (OptiMEM), and 500 μL of lipoplex solutions (prepared using Cy5-labeled plasmid DNA) were added to sample dishes to achieve the final concentrations described in the text. Cells were incubated for 4 h at 37 °C, and media was aspirated and replaced with 2 mL of PBS buffer. Immediately prior to imaging, cells were incubated with solutions of calcein AM (live cell stain) and Lysotracker Red (endosome/lysosome stain) according to the manufacturer's protocols. Extents of internalization of fluorescently labeled DNA were then evaluated using LSCM. LSCM images were acquired using a 60×/1.40 NA oil immersion objective. Calcein AM, Lysotracker Red, and Cy5-labeled DNA were excited sequentially using laser lines at 488, 543, and 637 nm, respectively. Fluorescence emission signals were collected for three individual channels using direct scanning mode ($N = 1$, scan speed = 50 lps) and merged to create three-color images.

RESULTS AND DISCUSSION

The results of our past studies demonstrate that the oxidation state of the ferrocene groups in BFDMA influences significantly both the physical properties of BFDMA/DNA aggregates and the ability of these aggregates to transfect cells *in vitro* (*38*, *39*, *41*, *42*). Because the oxidation state of ferrocenyl surfactants can be transformed readily using a variety of chemical or electrochemical methods (for example, using electrochemical potentials applied to electrodes or a range of different chemical oxidizing or reducing agents) (*28*−*50*), BFDMA offers the potential to formulate lipoplexes with physical properties or behaviors that can be transformed

actively or reversibly. This investigation sought to determine (i) whether it was possible to use chemical reducing agents to reduce the ferrocenium groups in lipoplexes formed using DNA and oxidized BFDMA and (ii) whether the reduction of oxidized BFDMA could cause changes in the physical properties of lipoplexes sufficient to alter the ability of these aggregates to transfect cells. In the sections below, we describe the treatment and transformation of lipoplexes formed from oxidized BFDMA using GSH, a naturally occurring chemical reducing agent found in both extracellular and intracellular environments and involved in numerous biochemical processes and synthetic pathways (*52*).

Chemical Reduction of Oxidized BFDMA and Oxidized BFDMA/DNA Lipoplexes Using GSH. GSH has been demonstrated in previous studies to mediate the chemical reduction of ferrocenium species to ferrocenyl species (*53, 54*). It was not clear at the outset of this study, however, whether GSH could be used to promote the reduction of oxidized BFDMA or whether the reduction of oxidized BFDMA within lipoplexes could be made to occur at rates, or to extents, that would be useful in the context of cell transfection. We thus conducted a series of initial experiments to characterize the ability of GSH to mediate the reduction of oxidized BFDMA in solution (i.e., in the absence of DNA). Characterization of solutions of oxidized BFDMA in aqueous Li_2SO_4 using UV/vis spectrophotometry demonstrated that the addition of GSH (at molar excesses ranging from 10-fold to 50-fold) could be used to cause the quantitative reduction of oxidized BFDMA to reduced BFDMA (see Figure S1, Supporting Information). Additional experiments demonstrated that reduction occurred rapidly at high concentrations of GSH (e.g., within seconds to minutes in the presence of a 50-fold excess of GSH; reduction occurred more slowly (e.g., over ~90 min) in the presence of a 10-fold excess of GSH). The results of these initial experiments demonstrated the feasibility of reducing oxidized BFDMA using GSH and provided a baseline for characterization of the reduction of oxidized BFDMA in lipoplexes using UV/vis spectrophotometry.

We next conducted a series of experiments to determine whether it was possible to use GSH to reduce the oxidized BFDMA present in lipoplexes formed by mixing plasmid DNA and oxidized BFDMA. For these experiments, we used lipoplexes formed using oxidized BFDMA and plasmid DNA at a lipid/DNA charge ratio (CR) of 4.1:1. This charge ratio was chosen for these initial experiments on the basis of our past transfection results demonstrating that lipoplexes formed from oxidized BFDMA at a CR of 4.1:1 do not transfect cells, but that lipoplexes formed using reduced BFDMA at a CR of 1.4:1 mediate high levels of cell transfection (*39*). [We note here, in this context, that lipoplexes formed from DNA and oxidized BFDMA (which has a net charge of +3) at a CR of 4.1:1 contain the same molar ratio of BFDMA and DNA as lipoplexes formed from DNA and reduced BFDMA (which has a net charge of +1) at a CR of 1.4:1 (*39*).]

Figure 2 shows the UV/vis absorbance spectrum (over wavelengths ranging from 400 to 800 nm) of a solution of lipoplexes formed using oxidized BFDMA (dotted curve). Inspection of these data reveals an overall shape similar to that of solutions of oxidized BFDMA, and an absorbance peak at 630 nm that is diagnostic of oxidized BFDMA (as reported in past studies (*38, 39*); see also Figure S1, Supporting Information). Figure 2 also shows the UV/vis absorbance spectrum of a solution of lipoplexes of oxidized BFDMA after the addition of a 50-fold molar excess of GSH. Inspection of these data (solid gray curve) reveals large changes in the absorbance spectrum. In particular, we note the loss of the absorbance peak at 630 nm and the appearance of a new maximum in absorbance at

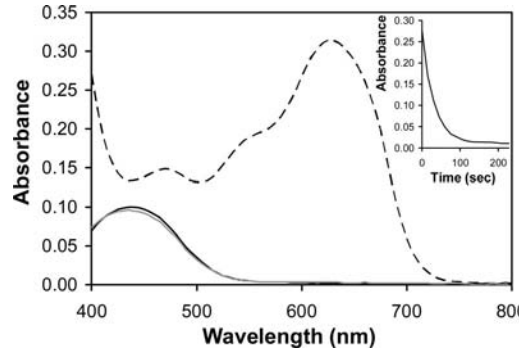

Figure 2. UV/visible absorbance spectra for solutions of lipoplexes formed from DNA and reduced (dark solid line) or oxidized (dark dashed line) BFDMA. The light solid line corresponds to lipoplexes formed from DNA and oxidized BFDMA and treated with a 50-fold excess of GSH. Inset: Decrease in absorbance vs time for lipoplexes formed from DNA and oxidized BFDMA upon treatment with a 50-fold excess of GSH. Absorbance was monitored at the absorbance maximum for oxidized BFDMA (630 nm).

445 nm. The maximum in absorbance at 445 nm indicates the presence of reduced BFDMA (*38, 39*), and the overall shape of this new absorbance spectrum is identical to that of the absorbance spectrum of lipoplexes formed using reduced BFDMA (at a CR of 1.4:1; see Figure 2, dark solid curve) (*38, 39*). These observations, when combined, demonstrate that (i) GSH is able to reduce the BFDMA in aggregates formed by the mixing of DNA and oxidized BFDMA and (ii) that the reduction of oxidized BFDMA occurs quantitatively under these conditions (e.g., as evidenced by the complete disappearance of the peak in absorbance at 630 nm). Subsequent investigation of the time dependence of the decrease in absorbance at 630 nm also demonstrated that the reduction of oxidized BFDMA occurred rapidly at higher concentrations of GSH (e.g., over a period of ~100 s in the presence of 50-fold excess GSH; see Figure 2, inset). Further characterization revealed this transformation to occur more slowly at lower concentrations of GSH (e.g., treatment of lipoplexes with a 10-fold molar excess of GSH resulted in the complete reduction of oxidized BFDMA, but this transformation occurred over a period of ~90 min; data not shown).

Characterization of Levels of Cell Transfection Mediated by Transformed Lipoplexes. The results above demonstrate that GSH can be used to chemically reduce BFDMA in lipoplexes formed from oxidized BFDMA and plasmid DNA. We next performed a series of experiments to determine whether transformation of the redox state of BFDMA in these lipoplexes could change the ability of these lipoplexes to mediate cell transfection *in vitro*. These experiments were conducted using the COS-7 cell line, a plasmid DNA construct encoding enhanced green fluorescent protein (EGFP), and transfection protocols similar to those used in our past studies (*38, 39*). To evaluate the general feasibility of this approach, we conducted a series of transfection experiments using lipoplexes at CRs identical to those used for the experiments described above (but at a lower overall concentration of BFDMA of 10 μM). As noted above, lipoplexes prepared using oxidized BFDMA at a CR of 4.1:1 were found to be "inactive" and did not mediate high levels of cell transfection in our past studies, but lipoplexes prepared using reduced BFDMA at a CR of 1.4:1 did mediate high levels of transgene expression (*38, 39*). This series of initial experiments was thus designed to determine whether the addition of GSH to solutions of lipoplexes formed from oxidized BFDMA could be used to produce solutions of lipoplexes that promote high levels of cell transfection.

Figure 3 shows representative fluorescence microscopy images of cells 48 h after treatment with lipoplexes prepared using

Figure 3. Representative fluorescence micrographs (100× magnification; 1186 μm × 899 μm) of EGFP expression in COS-7 cells treated with lipoplexes formed from (A) pEGFP-N1 and 10 μM reduced BFDMA, (B) pEGFP-N1 and oxidized BFDMA, and (C) pEGFP-N1 and oxidized BFDMA and treated with a 20-fold excess of GSH following lipoplex formation. Images were acquired at 48 h after exposure of cells to lipoplexes in serum-free medium (see text).

(A) reduced BFDMA, (B) oxidized BFDMA, or (C) lipoplexes prepared using oxidized BFDMA and treated with a 20-fold excess of GSH prior to addition to cells (see Materials and Methods section for additional details of transfection protocols). Inspection of the images in Figure 3A,B reveals that lipoplexes prepared using reduced BFDMA mediated high levels of EGFP expression and that lipoplexes prepared using oxidized BFDMA did not. These results are consistent with the results of our past studies (*38, 39*) and illustrate the significant influence of the oxidation state of BFDMA on levels of cell transfection. Inspection of the image in Figure 3C, however, reveals levels of EGFP expression that are (i) significantly higher than those shown in Figure 3B and (ii) qualitatively similar to the high levels of EGFP expression shown in Figure 3A. We conclude on the basis of these results that the addition of GSH to lipoplexes formed using oxidized BFDMA can be used to "activate" or transform solutions of these "inactive" lipoplexes to lipoplexes that mediate levels of transgene expression that are qualitatively similar to those formed using reduced BFDMA.

To characterize the ability of GSH-treated lipoplexes to mediate cell transfection more quantitatively, and across a greater range of lipid/DNA charge ratios, we conducted a second set of transfection experiments using lipoplexes formed from BFDMA and a plasmid DNA construct encoding firefly luciferase (pCMV-Luc). These transfection experiments were performed in a manner identical to our past experiments used to quantify the ability of reduced and oxidized BFDMA to mediate cell transfection (*38, 39*). These experiments were conducted using lipoplexes prepared at molar concentrations of BFDMA ranging from 2 to 60 μM. These molar concentrations correspond to lipid/DNA CRs ranging from 0.3:1 to 8.3:1 (for lipoplexes prepared using reduced BFDMA) and from 0.8:1 to 24.8:1 (for lipoplexes prepared using oxidized BFDMA). A table comparing lipid/DNA CRs to the molar concentrations of BFDMA used in the experiments described below can be found in a past publication (*39*).

Figure 4 shows quantitative luciferase expression results (expressed as relative light units normalized to total cell protein) for cells treated with lipoplexes prepared using concentrations of reduced BFDMA (white bars) or oxidized BFDMA (gray bars) ranging from 2 to 60 μM. Figure 4 also shows levels of luciferase expression for experiments using GSH-treated lipoplexes over this same range of BFDMA concentrations (black bars). The results of experiments using lipoplexes prepared using reduced and oxidized BFDMA (white bars and gray bars) are in general agreement with the results of our past studies (*38, 39*), and confirm that reduced BFDMA mediates high levels of cell transfection over a broad range of lipid concentrations, while oxidized BFDMA, in general, does not. Inspection of the data corresponding to levels of transfection mediated by GSH-treated lipoplexes reveals that these aggregates are also able to mediate

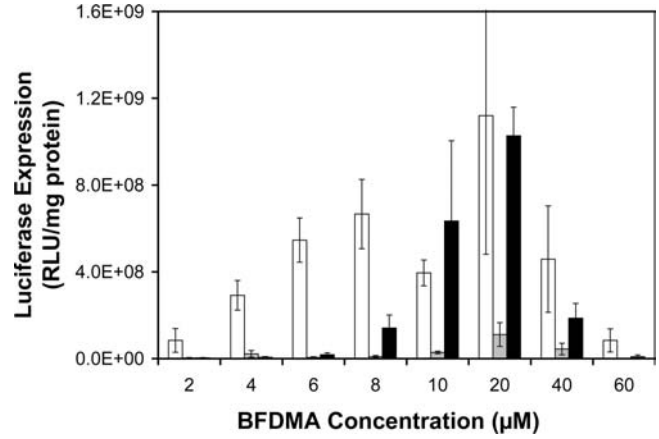

Figure 4. Normalized luciferase expression in COS-7 cells mediated by lipoplexes formed from reduced BFDMA (white bars), oxidized BFDMA (gray bars), and oxidized lipoplexes treated with a 20-fold excess of GSH prior to addition to cells (black bars). Experiments were performed in Opti-MEM with an exposure time of 4 h.

transgene expression at lipid concentrations ranging from 8 to 40 μM at levels that are, in several cases, comparable to the levels of expression mediated by lipoplexes formed from reduced BFDMA. The levels of transfection mediated in control experiments using lipoplexes formed from reduced BFDMA and treated with 20 μM GSH prior to addition to cells were identical (within error) to the levels of luciferase expression mediated by lipoplexes formed from reduced BFDMA alone (data not shown). These results, when combined, provide support for the view that the levels of gene expression mediated by the GSH-treated lipoplexes formed from oxidized BFDMA shown in Figure 4 result from the chemical reduction of oxidized BFDMA and not from any potential general influence of added GSH on cell transfection.

Inspection of the data in Figure 4 also demonstrates that levels of luciferase expression mediated by reduced BFDMA are a function of lipid concentration: levels of luciferase expression increase up to concentrations of 20 μM and decrease at concentrations higher than 40 μM (at which levels of lipid cytotoxicity become high) (*38, 39*). Further inspection of the results using GSH-treated lipoplexes of oxidized BFDMA reveals a similar concentration dependence (black bars), but over a more narrow range of concentrations (e.g., from 8 to 40 μM). We note that the decrease in luciferase expression at higher lipid concentrations (e.g., from 40 to 60 μM) again results, at least in part, from significant increases in the cytotoxicity of BFDMA at these concentrations (as described above; see also Figure S2 in the Supporting Information for results showing levels of cytotoxicity corresponding to transfection experiments in Figure

Table 1. Zeta Potentials of BFDMA Lipoplexes[a]

sample	500 μM BFDMA	10 μM BFDMA
Red BFDMA	26.5 ± 2.3 mV	27.6 ± 5.5 mV
Red BFDMA + GSH	26.9 ± 6.3 mV	26.3 ± 1.9 mV
Ox BFDMA	−16.0 ± 0.5 mV	−18.9 ± 3.1 mV
Ox BFDMA + GSH	30.3 ± 1.0 mV	17.6 ± 0.9 mV

[a] Concentrations given correspond to concentrations of BFDMA used in UV/vis spectrophotometry (500 μM; second column) and cell transfection and DNA internalization (10 μM; third column) experiments. Note that, in all cases, lipid/DNA charge ratios were fixed at 1.4:1 for reduced lipoplexes and 4.1:1 for oxidized lipoplexes (see text).

4). The specific reasons for the much lower levels of luciferase transfection at lower lipid concentrations (e.g., from 2 to 8 μM) are not yet completely understood. However, the results shown in Figures 3 and 4, when combined, do demonstrate that the treatment of lipoplexes formed from oxidized BFDMA (at concentrations ranging from 10 to 20 μM) with GSH can be transformed or activated in a manner that leads to lipoplexes that transfect cells at levels similar to those mediated by lipoplexes formed from reduced BFDMA. In the sections below, we demonstrate that these large changes in transfection behavior may result, at least in part, from large changes in the zeta potentials of lipoplexes upon treatment with GSH.

Characterization of the Zeta Potentials of Lipoplexes upon Treatment with GSH. We reported previously that the zeta potentials of lipoplexes formed from DNA and reduced BFDMA are negative at low lipid concentrations and positive at the lipid concentrations that promote the highest levels of transfection (e.g., 20 μM) (*41*). In contrast, lipoplexes formed using oxidized BFDMA were measured to remain negative or nearly neutral over the broad range of lipid concentrations used in the transfection experiments described above (as measured both in aqueous Li_2SO_4 and in serum-free cell culture media). Because particles with positive zeta potentials are generally internalized by cells more readily than particles with negative zeta potentials (e.g., by nonspecific endocytosis) (*55*, *56*), these results provided a framework from which to interpret and evaluate the large differences in cell transfection mediated by reduced and oxidized BFDMA (e.g., Figure 4) (*42*). The results shown in Figures 3 and 4 demonstrate clearly that the treatment of lipoplexes of oxidized BFDMA with GSH leads to large changes in EGFP and luciferase expression. We sought to understand whether these large increases in the transfection behavior of these lipoplexes could also be understood in terms of changes in zeta potentials that occur upon treatment with GSH.

Table 1 shows zeta potentials measured for lipoplexes formed from reduced or oxidized BFDMA either (i) before or (ii) after the addition of GSH. For these experiments, lipoplexes were formed at lipid/DNA CRs of 4.1:1 at total lipid concentrations of either 500 or 10 μM. These conditions were evaluated to permit comparison to the results of both UV/vis spectrophotometry experiments shown in Figure 2 ([BFDMA] = 500 μM) and the results of cell transfection experiments shown in Figures 3−5 ([BFDMA] = 10 μM).

The results shown in Table 1 demonstrate that the zeta potentials of lipoplexes formed from reduced BFDMA were positive (approximately +27 mV) and that the zeta potentials of lipoplexes formed from oxidized BFDMA were negative (from approximately −16 mV to −18 mV) at both lipid concentrations. These results are in general agreement with the results of our past study (*41*). The data in Table 1 also demonstrate that the addition of a 20-fold molar excess of GSH to lipoplexes of reduced BFDMA results in no significant changes in zeta potential. We note, however, that the addition of a 20-fold molar excess of GSH to lipoplexes of oxidized BFDMA results in large changes in zeta potential. In particular, the zeta potentials of these lipoplexes were found to change from negative to positive upon treatment with GSH (e.g., values of approximately +30 mV and +18 mV for lipoplexes prepared at 500 μM and 10 μM lipid, respectively). These results, when combined with those shown in Figure 2, provide additional support for the view that the treatment of lipoplexes of oxidized BFDMA with GSH results in chemical reduction of the ferrocenium groups of BFDMA. These results also suggest that these GSH-treated lipoplexes are able to reorganize physically over periods of ∼30 min in a manner that results in lipoplexes with positive zeta potentials. Additional experiments will be required to characterize changes in the nanostructures of these GSH-transformed lipoplexes and understand the dynamics of this physical transformation more completely. We demonstrate below, however, that these changes in zeta potential are consistent with large differences in the extents to which these lipoplexes are internalized by cells.

Characterization of the Internalization of Lipoplexes Using Confocal Microscopy. The data described above, and the results of our past studies (*41*), suggest that the redox state of the ferrocenyl groups of BFDMA could influence transfection, at least in part, by its influence on the zeta potentials of lipoplexes (which could, in turn, result in differences in the rates at which, or the extents to which, lipoplexes are internalized by cells). To characterize the internalization of lipoplexes by cells directly, we conducted a series of experiments using laser scanning confocal microscopy (LSCM) and lipoplexes formed using plasmid DNA labeled with a fluorescent probe (Cy5). Figure 5 shows representative LSCM images corresponding to cells incubated with (A,B) lipoplexes formed from reduced BFDMA, (C) lipoplexes formed from oxidized BFDMA, or (D) lipoplexes formed from oxidized BFDMA and then treated with a 20-fold excess of GSH prior to addition to cells. In these images, Cy5-labeled DNA is false-colored blue; the green and red fluorescence signals in these images correspond to calcein AM (a whole-cell stain) and Lysotracker Red (an endosome/lysosome stain), respectively. These experiments were conducted using lipoplexes prepared at charge ratios and lipid concentrations identical to those used in the transfection experiments shown in Figure 3. Lipoplexes were added to cells and incubated for 4 h before acquisition of the fluorescence microscopy images shown in Figure 5 (see Materials and Methods for additional details).

Figure 5A shows a representative image of cells treated with lipoplexes of reduced BFDMA at a magnification of 600×. The image in Figure 5B shows an enlarged view of a portion of the image shown in Figure 5A. Inspection of these two images reveals DNA to be present in three different locations: (i) in large aggregates that appear to be associated with (but not internalized by) cells, (ii) in endosomes and/or lysosomes (e.g., as identified by plain white arrows in Figure 5B), and (iii) in small, punctate blue fluorescent spots in the cytosol that are not colocalized with endosomes or lysosomes (e.g., as identified by starred white arrows in Figure 5B). (We note here for clarity that the endosome/lysosome stain used in this experiment is red, but that the vesicles in these images, in general, appear as yellow or orange/yellow in cases where calcein is also colocalized; stained vesicles that also contain Cy-5 labeled DNA appear as punctate magenta-colored spots in these images).

The images in Figure 5A,B demonstrate that lipoplexes formed from reduced BFDMA are internalized readily during the 4 h period over which they were exposed to cells. These results contrast to the results shown in the image in Figure 5C, which corresponds to cells treated with lipoplexes of oxidized BFDMA. Inspection of this image reveals that these cells do contain areas of faint punctate blue fluorescence (e.g., as

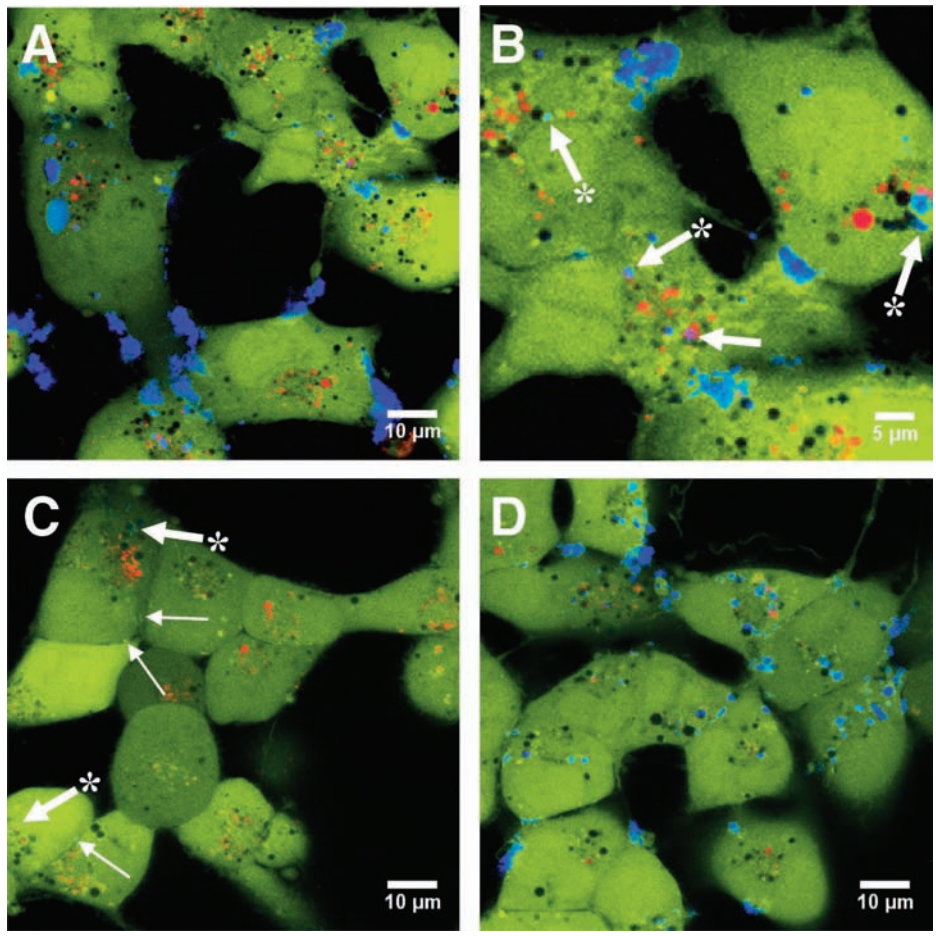

Figure 5. Representative confocal fluorescence micrographs showing DNA internalization in COS-7 cells treated with lipoplexes formed from (A,B) fluorescently labeled pEGFP-N1 and 10 μM reduced BFDMA, (C) fluorescently labeled pEGFP-N1 and 10 μM oxidized BFDMA, and (D) fluorescently labeled pEGFP-N1 and 10 μM oxidized BFDMA and treated with a 20-fold excess of GSH following lipoplex formation. Images were acquired 4 h after addition of lipoplexes (see Materials and Methods). Fluorescence signals correspond to Cy5 (fluorescently labeled DNA; blue signal), calcein AM (live cell stain; green signal), and Lysotracker Red (endosome/lysosome stain; red signal). See text for explanation of arrows. See Figure S3 of the Supporting Information for a high resolution reproduction of this image.

identified by starred white arrows), but that these punctate structures are both smaller in size and less numerous than those observed in Figure 5B. Inspection of this image also reveals small areas of faint blue fluorescence that are associated with, but apparently not internalized by, these cells (e.g., as identified by thin plain white arrows). The results shown in Figure 5C are representative of the sizes and numbers of punctate structures observed within cells treated with lipoplexes of oxidized BFDMA. We note, however, that considerable variability existed in the amounts of DNA that were associated with cell membranes. A comparison of the results in Figure 5C to those in Figure 5A,B suggests that the redox state of BFDMA influences significantly the internalization of lipoplexes by cells over the 4 h incubation period investigated in this study. We note that these apparent differences in extents of internalization correlate with the results of zeta potential measurements discussed above (Table 1) and provide a basis for interpreting the large differences in cell transfection mediated by reduced and oxidized BFDMA (e.g., Figures 3 and 4). Figure 5D shows images of cells that were incubated in the presence of GSH-treated lipoplexes for 4 h and reveals small, punctate blue fluorescent spots in nearly all cells. These results also correlate with our measurements of changes in zeta potential and cell transfection described above, and provide additional support for the view that chemical reduction of oxidized BFDMA by GSH can be used to activate lipoplexes of oxidized BFDMA that are otherwise inactive and do not transfect cells efficiently.

The observation of lipoplexes in Figure 5A,B,D that are colocalized with intracellular vesicles is consistent with the internalization of lipoplexes by endocytosis and, in general, with the results of past studies investigating the internalization of polyplexes formed using a range of other lipids (*1*−*6*). In this context, the observation of lipoplexes that are not colocalized with endosomes or lysosomes is an interesting result and suggests that lipoplexes formed from reduced BFDMA (or GSH-treated lipoplexes of oxidized BFDMA) may be able to mediate escape from these intracellular vesicles (or, alternatively, that they could potentially enter cells through a mechanism that does not involve endocytosis). Additional experiments will be required to characterize mechanisms of lipoplex internalization and trafficking quantitatively and determine the ultimate fates of lipoplexes of BFDMA more completely. In the context of this present study, however, we do observe that differences in transfection measured using reduced and oxidized BFDMA appear to correlate with a limited ability of oxidized BFDMA to mediate the transport of DNA into cells as compared to reduced BFDMA.

SUMMARY AND CONCLUSIONS

We have demonstrated that it is possible to exploit the redox properties of ferrocene to chemically activate or transform "inactive" lipoplexes formed from oxidized BFDMA and DNA to lipoplexes that mediate high levels of cell transfection by treatment with the chemical reducing agent glutathione (GSH).

Our results demonstrate that GSH can be used to reduce the ferrocenium groups of oxidized BFDMA rapidly and quantitatively both (i) in solution and (ii) when it is present as a component of a lipoplex. The results of our cell transfection experiments demonstrate that lipoplexes of oxidized BFDMA treated with GSH mediate levels of transgene expression that are, in several cases, comparable to those mediated by lipoplexes prepared by mixing DNA and reduced BFDMA.

We suggested in a previous report (*41*) that the dependence of cell transfection on the oxidation state of BFDMA could arise from differences in the zeta potentials of lipoplexes formed from either reduced or oxidized BFDMA. Characterization of the zeta potentials of lipoplexes in this present study revealed that the surface charges of lipoplexes of oxidized BFDMA undergo large changes in zeta potential (e.g., from negative to positive) upon treatment with GSH. In addition, the results of our confocal microscopy experiments using lipoplexes formulated using fluorescently labeled DNA suggested that differences exist in the levels at which lipoplexes of reduced BFDMA and lipoplexes of oxidized BFDMA were internalized by cells. These experimental results, when combined, provide experimental support for the proposition that the oxidation state of BFDMA influences cell transfection, at least in part, through its influence on the zeta potentials of lipoplexes formed from reduced and oxidized BFDMA.

In summary, we have demonstrated that it is possible to transform both the physicochemical properties and the biological behaviors of nanoscale aggregates of DNA and a redox-active cationic lipid by treatment with a chemical reducing agent. These results suggest the basis of a general approach that could, with further development, lead to methods for the transformation of cationic lipids and/or lipoplexes actively or "on-demand" in ways that could be used to provide spatial and/or temporal control over the transfection of cells *in vitro* or *in vivo*.

ACKNOWLEDGMENT

Financial support was provided by the National Institutes of Health (1 R21 EB006168) and the National Science Foundation (CTS-0754921). We are grateful to Lance Rodenkirch, Michael Hendrickson, and the W. M. Keck Center for Biological Imaging at the UW for access to and assistance with confocal microscopy facilities. We thank Selin Aytar and John Muller for many helpful discussions. D.M.L. is a Research Fellow of the Alfred P. Sloan Foundation.

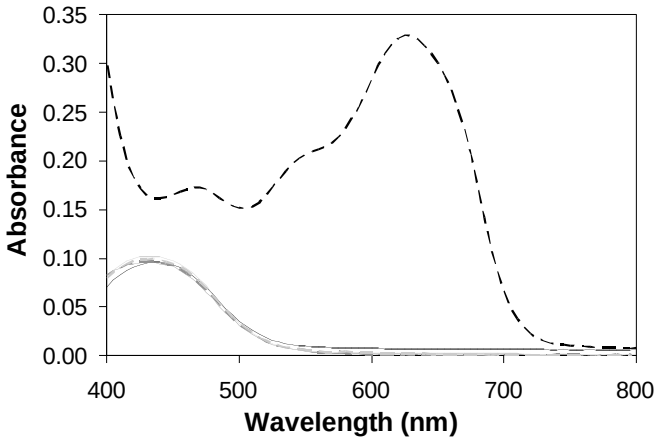

Figure S1: UV/visible absorbance spectra for solutions of reduced BFDMA (dark solid line) or oxidized BFDMA (dark dashed line). Also shown are spectra corresponding to solutions of oxidized BFDMA treated with GSH at a 50-fold excess (dark grey solid line), 30-fold excess (dark grey dashed line), 20-fold excess (light grey solid line), and 10-fold excess (light grey dashed line). See Experimental Section of main text for experimental details.

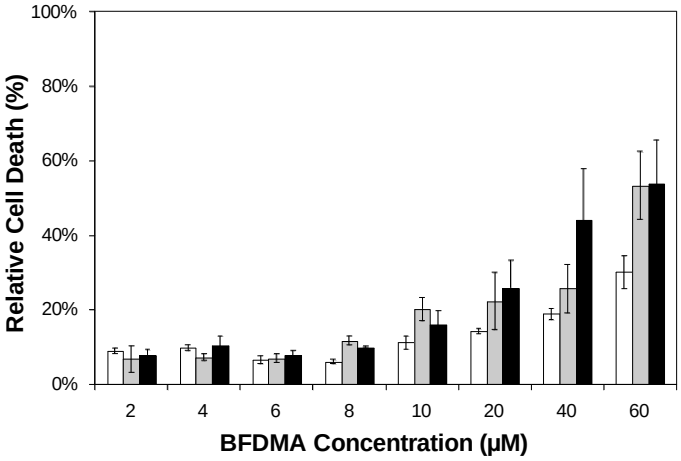

Figure S2: Relative cell death in COS-7 cells resulting from exposure to lipoplexes formed from reduced BFDMA (white bars), oxidized BFDMA (grey bars), and oxidized lipoplexes treated with a 20-fold excess of GSH prior to addition to cells (black bars). Experiments were performed in Opti-MEM with an exposure time of 4 h, and data correspond to luciferase expression data shown in Figure 4. See experimental section of main text for experimental details.

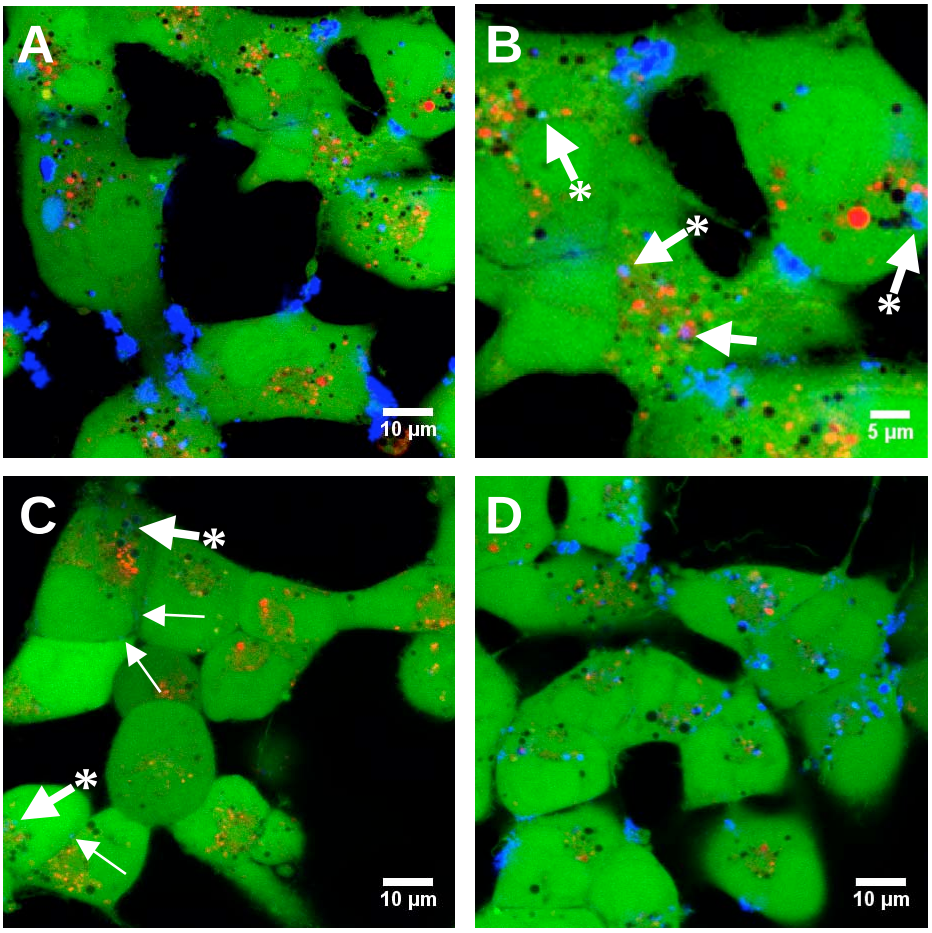

Figure S3: High-resolution reproduction of the images in Figure 5 of the main text showing representative confocal fluorescence micrographs of DNA internalization in COS-7 cells treated with lipoplexes formed from A-B) fluorescently-labeled pEGFP-N1 and 10 µM reduced BFDMA, C) fluorescently-labeled pEGFP-N1 and 10 µM oxidized BFDMA, and D) fluorescently-labeled pEGFP-N1 and 10 µM oxidized BFDMA and treated with a 20-fold excess of GSH following lipoplex formation. Images were acquired 4 h after addition of lipoplexes (see Materials and Methods). Fluorescence signals correspond to Cy5 (fluorescently-labeled DNA; blue signal), calcein AM (live cell stain; green signal), and Lysotracker Red (endosome/lysosome stain; red signal). See main text for explanation of arrows.

Peptide-Mediated Cellular Uptake of Cryptophane

Garry K. Seward, Qian Wei, and Ivan J. Dmochowski*

Department of Chemistry, University of Pennsylvania, 231 South 34th Street, Philadelphia, Pennsylvania 19104-6323. Received June 1, 2008; Revised Manuscript Received August 24, 2008

Cryptophane-A has generated considerable interest based on its high affinity for xenon and potential for creating biosensors for ^{129}Xe nuclear magnetic resonance (NMR) spectroscopy. Here, we report the cellular delivery of three peptide-functionalized cryptophane biosensors. Cryptophanes were delivered using two cationic cell penetrating peptides into several human cancer and normal cell lines. An RGD peptide targeting $\alpha_v\beta_3$ integrin receptor was shown to increase specificity of cryptophane cell uptake. Labeling the peptides with Cy3 made it possible to monitor cellular delivery using confocal laser scanning microscopy. The peptido-cryptophanes were determined to be relatively nontoxic by MTT assay at the micromolar cryptophane concentrations that are required for ^{129}Xe NMR biosensing experiments.

INTRODUCTION

Magnetic resonance imaging (MRI) identifies molecules at high spatial resolution within deep tissue and can facilitate the diagnosis of many diseases. However, MRI suffers from low sensitivity and high background signals due to intrinsic ^{1}H signals from water and fat. In MRI procedures involving human subjects, signals are typically enhanced using gadolinium- or iron-oxide-based agents at approximately 0.1 mmol/kg. However, it has been challenging using these contrast agents to identify biomolecular targets, such as proteins, which are typically present in cells at low concentrations (*1, 2*). Moreover, U.S. and European agencies recently issued advisories regarding the risks posed by gadolinium agents in patients with impaired renal function. These findings motivate studies of non-proton-based, hyperpolarized MRI agents such as ^{129}Xe, ^{13}C, and ^{3}He, which enable physiological assays, and provide potentially more sensitive methods for studying proteins and metabolites (*3*−*5*). ^{129}Xe is particularly attractive due to its large chemical shift window and laser polarization of nuclear spins, which enhances ^{129}Xe NMR signals by more than 10 000-fold. Importantly, the environmental sensitivity of the xenon chemical shift allows the simultaneous detection of multiple species in solution. ^{129}Xe NMR biosensing has been elegantly demonstrated using a cryptophane organic host molecule that binds xenon and can be targeted to specific analytes in solution (*6*).

Cryptophanes are versatile host molecules whose size can be tuned to bind xenon and a variety of organic solvents and cationic species (*7*). In cryptophane-A, two cyclotriveratrylenes are joined by three ethylene linkers to form a 1-nm-diameter pseudospherical cage with internal volume of ∼95 Å^3. Hill et al. showed that a tricarboxylate-modified cryptophane-A binds xenon with comparable affinity in buffer (K_A = 30 000 M^{-1}) and human plasma (K_A = 22 000 M^{-1}) at 310 K (*8*). This avidity for xenon has motivated the design of cryptophane-A biosensors for detecting protein binding (*9*) or enzyme-related activity (*10*) by laser-polarized ^{129}Xe nuclear magnetic resonance (NMR) spectroscopy. Biotin-functionalized cryptophanes produced a 1−4 ppm change in ^{129}Xe NMR chemical shift upon streptavidin binding (*11*−*14*). Similarly, peptide-decorated cryptophane-A reported cleavage by matrix metalloproteinase-7 (MMP-7), which is secreted from many human tumors (*10*). Importantly, the cryptophane did little to affect MMP-7 activity, with peptide cleavage producing a 0.5 ppm change in ^{129}Xe NMR chemical shift. These results motivate the development of cryptophane biosensors for in vivo ^{129}Xe NMR studies. However, very few water-soluble cryptophanes (*15*) have been synthesized, and little is known about their biological activity. We are not aware of any cell or animal studies involving cryptophanes that have been reported up to this time. In the current study, we investigated the uptake of peptide-modified cryptophane-A in human cancer, fibroblasts, and red blood cells.

Cryptophane-A has poor (low micromolar) water solubility and a molecular weight of 895 g/mol, which limits spontaneous intracellular diffusion, as can occur with smaller drug-like compounds. Thus, in order to test cryptophane cellular compatibility, one possible delivery method involves the use of polycationic peptides that help to solubilize the cryptophane and are rich in the basic amino acids arginine and lysine. These peptides, known generally as cell penetrating peptides (CPPs), can transport through cell membranes covalently attached cargo such as therapeutics, nucleic acids, and imaging agents (*16*−*19*). In one example, porphyrins useful for photodynamic therapy were delivered to cellular compartments by conjugating a segment of the human immunodeficiency transcriptional activator (HIV-1 TAT) or short peptides containing 6−9 consecutive arginines (*20*). Buckminsterfullerene, which is similar to cryptophane-A in molecular weight and chemical formula, was delivered to HEK-293 cells by attaching oligomers of lysine (*21*). These studies highlight the utility of CPPs for improving cellular uptake and bioavailability of large organic molecules.

Another cell delivery method involves the specific targeting of cell surface receptors, such as integrins (*22*−*24*), somatostatin (*25*−*27*), or folate (*28*). Integrin receptors are overexpressed in a variety of cancer cells and linked to tumor metastasis and invasion (*29, 30*). It is found that the $\alpha_v\beta_3$ integrin receptor in particular is substantially up-regulated in fast-growing tumor cells, compared to minimum expression in most normal tissues (*31, 32*). A cyclic tripeptide RGD sequence is known to target the $\alpha_v\beta_3$ integrin receptor (ABIR) (*33*−*36*). More recently, it was demonstrated that linear multimeric $(RGD)_n$ sequences also target the ABIR and promote the uptake of near-infrared-emitting cypate in A549 nonsmall cell carcinoma cells (*37*).

This strategy of selectively delivering biologically active molecules is particularly useful for imaging tumors, which overexpress a large number of cell surface receptors.

In the present study, we report the synthesis of cryptophane-A conjugated to HIV-1 TAT (residues 48−60), a nonamer of D-arginine, or the $(RGD)_4$ dodecamer. Cell penetrating peptides were chosen to examine initially whether cryptophanes could be delivered to cells and to measure the effects of nonspecific delivery on cell viability. The $(RGD)_4$ peptide was chosen for its ability to target cells overexpressing ABIR (*37*). Cysteine incorporation within these peptides provided a route for subsequent labeling with Cy3. Cell uptake and cytotoxicity were measured for AsPC-1 and CAPAN-2 pancreatic cancer cells, HFL-1 human lung fibroblasts, and human red blood cells.

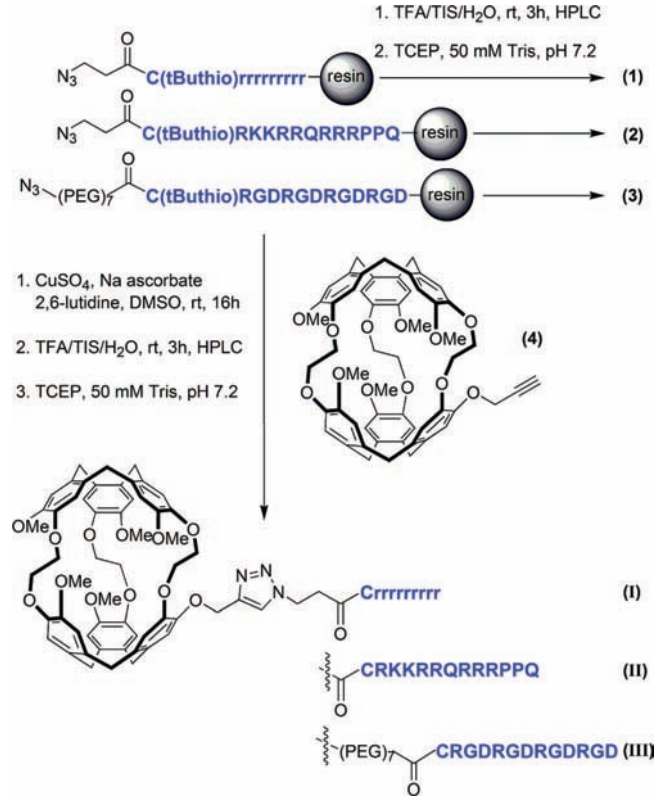
EXPERIMENTAL PROCEDURES

Reagents. Organic reagents and solvents were used as purchased from the following commercial sources: Sigma-Aldrich: dimethyl sulfoxide (DMSO), dimethylformamide (DMF), methanol, triisopropylsilane (TIS), 2,6-lutidine, piperidine, 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT); Fisher: sodium chloride, copper(II) sulfate, trifluoroacetic acid (TFA), diethyl ether (Et_2O), glutathione; Alfa Aesar: cesium carbonate, L-glutathione; Novabiochem: 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), *N*-methylmorpholine (0.4 M), O-(2-azidoethyl)-O′-(*N*-diglycolyl-2-aminoethyl)heptaethyleneglycol ($(PEG)_7$ linker), Rink amide resin, Fmoc-protected amino acids including Fmoc-L-Lys(Boc)-OH, Fmoc-Gly-OH, Fmoc-L-Arg(Pbf)-OH, Fmoc-Gln(Trt)-OH, Fmoc-Cys(tButhio)-OH, Fmoc-L-Pro-OH); GE Healthcare*:* Cy3 monoreactive dye pack, Sephadex G-25 size exclusion column; Calbiochem: tris(2-carboxyethyl)phosphine hydrochloride (TCEP-HCl), cyclo-Arg-Gly-Asp-D-Phe-Val (cyclo-RGDfV); Invitrogen: RPMI medium 1640, Dulbecco's phosphate buffered saline (DPBS), anti-CD51 mouse antibody; Pierce: Ellman's reagent. For biological assays, all solutions were prepared using deionized water purified by Mar Cor Premium grade Mixed Bed Service Deionization. The standard buffer is defined herein as 50 mM Tris, 5 mM $CaCl_2$, 300 mM NaCl, pH 7.2.

General Methods. All air- and moisture-sensitive reactions were performed under dinitrogen with glassware oven-dried and then flamed under partial vacuum. Peptides were generated using a Protein Technologies PS3 Peptide Synthesizer. HPLC analysis was performed on an Agilent 1100 system equipped with a quaternary pump and diode array detector using a Zorbax Rx-C8 semipreparative (9.4 × 250 mm, 5 μm) or analytical column (4.6 × 150 mm, 5 μm). The gradient eluent was composed of two solvents: 0.1% aqueous TFA (solvent A) and a 0.1% solution of TFA in CH_3CN (solvent B). Mass identification of all peptide-containing compounds was performed by the Wistar Institute Proteomics Facility using an Applied Biosystems Voyager 6030 MALDI-TOF mass spectrometer. UV−visible spectra for peptides and peptide-cryptophane-A conjugates were measured using an Agilent 89090A spectrophotometer. Fluorescence spectra were collected for Cy3-labeled peptides dissolved in standard buffer (λ_{ex} = 552 nm) using a Varian Cary Eclipse fluorescence spectrophotometer in small volume, 1-cm path length quartz cuvettes at rt (1 nm steps, 5 nm excitation and emission slits). The 96 well fluorescence measurements were made using a Labsystems Fluoroskan II microplate reader.

Peptide Synthesis and Purification. Peptides **1**−**3** (Scheme 1) were prepared by solid-phase synthesis using standard Fmoc amino acid protection chemistry on Rink Amide resin (0.1 mmol scale). Couplings of Fmoc-protected amino acids to the resin were carried out with HBTU and *N*-methylmorpholine to generate the activated ester. The resin was swelled in DMF (10 min) prior to synthesis. Amino acids were then added sequentially until 3-azidoproponic acid was attached at the N-terminus as the final step. All residues were coupled onto resin by the following procedure: removal of Fmoc group (20% piperidine solution in DMF, 2 × 5 min), wash (DMF, 6 × 30 s), activation (amino acid/HBTU/*N*-methylmorpholine, 1 × 30 s) coupling (amino acid/HBTU/*N*-methylmorpholine, 1 × 20 min), rinse (DMF, 3 × 30 s). Cleavage from the resin was accomplished with a mixture of TFA, TIS, and water (90/5/5) at rt for 3 h. The cleavage cocktail removed side chain protecting groups from all amino acids except for cysteine, which was protected by *t*-butylthiol. Semipreparative HPLC purification of all Cys-protected peptides was accomplished with a gradient: time 0, A/B = 100/0; 0−25 min, linear increase to A/B = 75/25; 25−27 min, linear change to A/B = 20/80; 27−37 min, A/B = 20/80. Selective cysteine deprotection was later performed by treating with TCEP (1 equiv) for 30 min, and running the reaction mixture through a NAP-10 gel filtration to remove TCEP.

Scheme 1. Synthesis of Peptides 1−3 and Peptide−Cryptophane Conjugates I−III[a]



[a] Azidopeptide on solid support was reacted with monopropargyl-cryptophane-A via a Cu(I)-mediated [3 + 2] cycloaddition reaction. $(PEG)_7$ = -$(CH_2)_2$-O-$(CH_2CH_2O)_7$-$CH_2CH_2NHCOCH_2OCH_2$.

The peptide sequences prepared were as follows: N_3−CH_2CH_2−CONH−Crrrrrrrrr (D-Arg_9, **1**), N_3−CH_2CH_2−CONH−CGRKKRRQRRRPPQ (TAT, **2**), and N_3−$CH_2CH_2O(PEG)_7$−CONH−CRGDRGDRGDRGD (RGD_4, **3**). MALDI MS calculated for D-Arg_9 peptide, $C_{60}H_{119}N_{40}O_{12}S_1$ ($M + H^+$) 1623.97; found 1624.09. MALDI MS calculated for TAT peptide, $C_{76}H_{139}N_{39}O_{18}S_1$ ($M + H^+$) 1918.09; found 1919.15. MALDI MS calculated for RGD_4 peptide $C_{73}H_{128}N_{29}O_{33}S_1$ ($M + H^+$) 1970.90; found 1971.07. Pure peptides **1**−**3** were studied as-is, or subsequently conjugated with Cy3.

Synthesis of Peptide−Cryptophane Conjugates, I−III. [3 + 2] Cycloaddition reactions between azide-terminated peptides (still attached to solid support) and monopropargylated cryptophane-A **4** were performed to generate the peptide−cryptophane-A conjugates (Scheme 1) following established protocols

(*10*). Briefly, an aqueous solution of copper (II) sulfate (0.006 mmol, 0.5 equiv) was added to the resin containing azidopeptide (20 mg, maximum 0.0124 mmol azidopeptide, 1 equiv) followed by 2,6-lutidine (2.78 mL, 0.024 mmol, 2 equiv), sodium ascorbate (0.018 mmol, 1.5 equiv), and **4** (21 mg, 0.024, 2 equiv). Monopropargylated cryptophane-A was synthesized as previously described (*10*). The suspension was degassed with N_2 and stirred at rt for 16 h. The resin was then transferred to a fritted reaction vessel and washed sequentially with CH_2Cl_2, MeOH, water, and 1:1 MeOH/CH_2Cl_2 before drying under vacuum.

Cleavage from the resin was accomplished with a mixture of TFA, TIS, and water (90/5/5) at rt for 3 h. The Cys-protected peptide−cryptophane conjugates were precipitated and washed with anhydrous Et_2O before drying under vacuum. Analytical HPLC was performed using a gradient: time 0, A/B = 75/25; 0−25 min, linear increase to A/B = 50/50; time 25−27 min, linear change to A/B = 20/80; 27−37 min, A/B = 20/80. HPLC traces and retention times are provided in the Supporting Information. The cysteine was subsequently deprotected with TCEP in order to generate conjugates **I**−**III** (Scheme 1). MALDI MS calculated for $C_{116}H_{173}N_{40}O_{24}S_1$ (D-Arg_9-cryptophane, **I**) ($M + H^+$) 2542.33; found 2542.08. MALDI MS calculated for $C_{132}H_{193}N_{39}O_{30}S_1$ (TAT-cryptophane, **II**) ($M + H^+$) 2836.45; found 2836.96. MALDI MS calculated for $C_{129}H_{182}N_{29}O_{45}S_1$ ($(RGD)_4$-cryptophane, **III**) ($M + H^+$) 2889.26; found 2889.07. An extinction coefficient for **I**−**III**, 9300 M^{-1} cm^{-1} at 280 nm in water, was determined from solutions containing a weighed sample, as described previously (*10*).

Cysteine Labeling with Cy3. The pure Cys-protected peptides and Cys-protected peptide−cryptophane-A conjugates were dissolved in Tris buffer (50 mM, pH 7.2) at a concentration of 60 μM. Cysteine labeling with the Cy3-maleimide construct was performed according to the manufacturer's protocol. As described previously, cysteine was deprotected with TCEP, which was then removed by NAP-10 column. Cy3 dye was added dropwise and reacted for 3 h. The reaction was quenched by addition of glutathione (1 equiv). The reaction mixture was run through a NAP-10 gel filtration column before analytical HPLC purification.

For Cy3-labeled **I**−**III**, HPLC elution was achieved with the following gradient: time 0, A/B = 75/25; 0−25 min, linear increase to A/B = 50/50; 25−27 min, linear change to A/B = 20/80; 27−37 min, A/B = 20/80. MALDI MS calculated for $C_{153}H_{215}N_{44}O_{33}S_3$ (Cy3-**I**) ($M + H^+$) 3304.57; found 3304.82. MALDI MS calculated for $C_{170}H_{235}N_{43}O_{39}S_3$ (Cy3-**II**) ($M + H^+$) 3586.69; found 3587.84. MALDI MS calculated for $C_{167}H_{224}N_{33}O_{54}S_3$ (Cy3-**III**) ($M + H^+$) 3639.50; found 3640.07. Extinction coefficients used to determine solution concentrations of Cy3-labeled **I**−**III** were ε_{280} = 12 300 M^{-1} cm^{-1} and ε_{552} = 150 000 M^{-1} cm^{-1} in water.

For Cy3-labeled **1**−**3**, HPLC elution was achieved with the following gradient: time 0, A/B = 100/0; 0−25 min, linear increase to A/B = 75/25; 25−27 min, linear change to A/B = 20/80; 27−37 min, A/B = 20/80. HPLC traces and retention times are provided in the Supporting Information. MALDI MS calculated for $C_{97}H_{161}N_{44}O_{21}S_3$ (Cy3-**1**) ($M + H^+ - H_2O$) 2356.30; found 2357.68. MALDI MS calculated for $C_{113}H_{181}N_{43}O_{27}S_3$ (Cy3-**2**) ($M + H^+ - 2H_2O$) 2632.29; found 2632.12. MALDI MS calculated for $C_{110}H_{170}N_{33}O_{42}S_3$ (Cy3-**3**) ($M + H^+ - N_2$) 2697.12; found 2696.37. The concentration of Cy3-labeled peptides **1**−**3** in solution was determined using ε_{552} = 150 000 M^{-1} cm^{-1}, and accounting for the fraction labeled. Cy3 labeling efficiency was determined using Ellman's reagent according to manufacturer's protocol.

Cell Culture. HFL-1 human diploid lung fibroblasts and AsPC-1 and CAPAN-2 human pancreatic carcinoma cell lines were obtained from the Cell Culture Core of the Center for Molecular Studies in Liver and Digestive Diseases (University of Pennsylvania Medical School, Philadelphia, PA). NCI-H1975 cells were from Dr. Intae Lee and red blood cells were from Dr. Don Siegel (University of Pennsylvania Medical School, Philadelphia, PA). All cells were grown in 25 cm^2 tissue culture flasks in RPMI-1640 with 25 mM HEPES supplemented with 2 mM L-glutamine, 15% fetal calf serum, 100 units of penicillin, and 100 units of streptomycin. Cells were subcultured weekly, or more frequently, as needed.

Cytotoxicity Assays. In 96 well plates, 25 000 cells were plated per well and allowed to grow overnight. Nonfluorescently labeled peptide−cryptophane conjugates **I**−**III** were added from a stock solution in DPBS to wells in triplicate at final concentrations of 2, 10, 25, 50, 80, and 100 μM and incubated for 24 h in the dark. The medium was removed and the cells were washed thrice with DPBS before being treated with 20 μL of MTT for 3 h. The medium was removed once more and the resulting crystals were solubilized in DMSO. Absorbance at 540 nm was recorded in each well using the plate reader. Absorbance readings were subtracted from the value of wells containing untreated cells, and the reduction in cell growth was calculated as a percentage of control absorbance in the absence of any treatment. Data show the mean of at least three independent experiments ± SD.

Cell Uptake Studies. Cells were grown to confluence on LabTek 8-well microscope slides with glass coverslip bottoms. For uptake studies, cells were incubated with 2 μM solutions of Cy3-labeled **I**, **II**, or **III** for 15 min. For blocking studies, cells were pretreated for 45 min with an 100 μM solution of a cyclic RGDfV peptide containing D-phenylalanine that was previously identified to bind tightly to the integrin $\alpha_v\beta_3$ receptor (*37, 38*). In the antibody blocking studies, cells were pretreated for 30 min with 10 μM blocking anti-α antibody. For visualizing the results of both the uptake and blocking studies, the medium was removed and the cells were washed three times with DPBS. Cells were visualized using an Olympus FV1000 confocal laser scanning microscope with 543 nm (HeNe) laser excitation and Cy3 emission filter under 40× magnification (Olympus UApo/340 40×, 1.15 W).

Time-Dependent Cellular Uptake. Cells were plated at 10 000 cells per well in a CoStar 96-well plate and allowed to grow overnight. Cy3-labeled **I**, **II**, or **III** was added to the wells at a concentration of 10 μM and incubated for 0, 1, 2, 4, 8, and 24 h at 37 °C. At the end of the incubation time, the loading medium was removed, and the cells were washed thrice with DPBS. The cells were solubilized by the addition of 100 μL of 0.25% Triton X-100 in DPBS. To determine conjugate concentration, samples were excited at 544 nm and fluorescence at 590 nm was recorded using a plate reader. The cell numbers were then quantified using the CyQuant reagent (Molecular Probes) according to manufacturer protocol.

RESULTS AND DISCUSSION

Synthesis and Characterization of Peptide−Cryptophane Conjugates. Monopropargylated cryptophane-A **4** was synthesized in 12 nonlinear steps and 3% overall yield (*10*). The yields of purified peptides (**1**−**3**) were 80−85% for all peptide coupling and cleavage steps, based on the maximum possible yield from starting resin. Azidopeptides, while still attached to the solid support, were reacted with **4** by a copper (I)-catalyzed [3 + 2] cycloaddition in 80−89% yield (*39*−*41*). Peptide−cryptophane conjugates (with Cys still protected) were cleaved from the resin, and purified by reverse-phase HPLC (Supporting Information Figures S1−S3). The cysteine was deprotected before use with TCEP to yield **I**−**III**. The deprotected cysteines showed no evidence of disulfide formation leading to cryptophane dimer-

ization on the time scale of hours when purified by HPLC. The free thiols, however, may interact with endogenous sulfhydryls when introduced into cells.

The $(RGD)_4$ linear peptide was chosen to target ABIR, because it was readily synthesized and attached to cryptophane using established protocols (*10*). Furthermore, polypeptides of similar length were found to confer excellent cryptophane water solubility. In constrast, the cryptophane−$(RGD)_4$ conjugate presented solubility problems, most likely due to charge interactions between the repeating sequence of arginine and glutamic acid residues. A prior version of conjugate **III** was synthesized without the PEG_7 linker separating the cryptophane from the RGD tetramer. This prototype exhibited poor water solubility, which prevented its usefulness for *in vitro* cell studies. Addition of the PEG_7 linker increased water solubility, allowing concentrations up to 120 μM when DMSO (10% final concentration) was added to the buffer solutions.

The cysteine sulfhydryl group on the peptides and peptide−cryptophane conjugates was deprotected and reacted with maleimide-functionalized Cy3 to generate Cy3-labeled **1**−**3** and **I**−**III**. Mixtures of fluorescently labeled and unlabeled conjugates were obtained after reverse-phase HPLC purification (Supporting Information Figures S4−S6). For the cryptophane−peptide conjugates **I**−**III**, Cy3 labeling efficiencies of 50−69% were determined from the ratio of dye absorbance at 552 nm to the cryptophane absorbance at 280 nm. Cy3 labeling efficiencies were initially lower than expected. To improve yields, the reducing agent TCEP was removed from the solution by gel filtration chromatography before the addition of the Cy3 monoreactive dye pack. Removal of TCEP improved Cy3 conjugation yields by about 10%.

Ellman's reagent was used to determine the Cy3 labeling efficiencies for **1**−**3**, and confirmed the previous measurements determined for Cy3-labeled **I**−**III**. The 5,5′-dithiobis(2-nitrobenzoic acid) reacted with any free (previously unreacted) sulfhydryl groups to yield 2-nitro-5-thiobenzoic acid, which was quantified by measuring absorbance at 412 nm (ε_{412} = 14 150 M^{-1} cm^{-1}) (*42*). This assay found slightly higher Cy3 labeling efficiencies for **1**−**3** (60−72%) than for **I**−**III** (47−70%), which was in good agreement with the previously described ratiometric (A_{552}/A_{280}) UV−vis measurements for Cy3-labeled **I**−**III**.

Cell Toxcity Assays. The cytotoxicity of the cryptophane conjugates was evaluated in AsPC-1, CAPAN-2, and HFL-1 cell lines by exposing cells to increasing concentrations of **I**, **II**, or **III** as shown in Figure 1. The $(RGD)_4$−cryptophane conjugate **III** showed 25−30% proliferation inhibition of the various cell lines at the highest concentration studied (100 μM). Slightly higher amounts of cytotoxicity were also found for the D-Arg_9- and TAT-cryptophane conjugates, **I** and **II**, in both the AsPC-1 and CAPAN-2 cell lines. In general, the three conjugates appeared to be more toxic to HFL-1 fibroblast cells than either AsPC-1 or CAPAN-2 cancer cells. The toxicity profile is comparable to that of the similarly sized fullerene C_{60} molecule, which decreased viability of HEK cells by 10−50% over a similar range of concentrations (*43*). For compound **III**, 50% inhibition of proliferation was not reached in any of the cell lines at the concentrations tested. Compounds **I** and **II** showed 50% inhibition at 60 and 75 μM in HFL-1 fibroblasts. **I** also showed IC_{50} of 75 μM in AsPC-1 cells and more than 100 μM in CAPAN-2. **II** had IC_{50} values of 100 μM in AsPC-1 cells, while 50% inhibition was not reached in CAPAN-2 cells at 100 μM. Increased toxicity for compounds **I** and **II** as compared to **III** is thought to be a result of cryptophane delivery to the cell nucleus by TAT or D-Arg_9 nuclear localization peptides. For compound **III**, 10% DMSO was required to work at the higher concentrations. Cell viability assays for this compound were performed using 10% DMSO at all sample concentrations, and these viability data were normalized to cells treated with 10% DMSO without cryptophane. In absolute terms, 10% DMSO alone reduced cell counts by 2000−3500, corresponding to a 8−14% decrease compared to untreated cells.

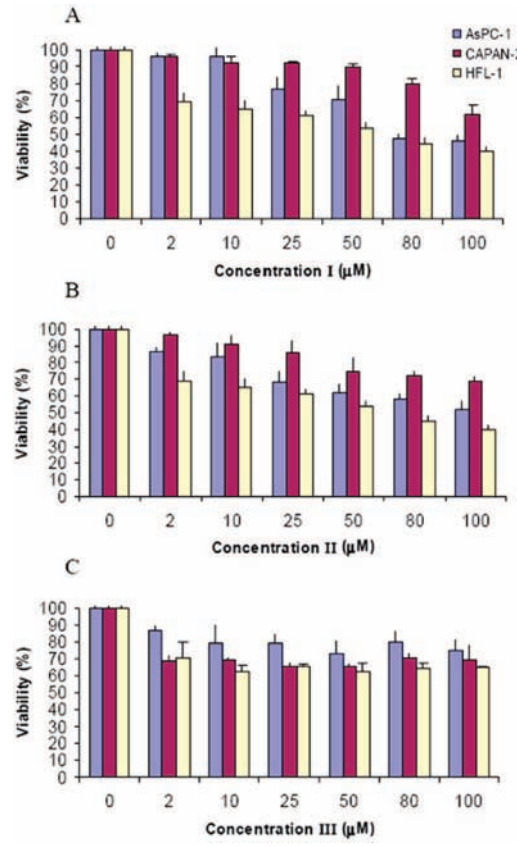


Figure 1. Cytotoxicity assay for conjugates **I** (A), **II** (B), and **III** (C) in AsPC-1 (blue), CAPAN-2 (maroon), and HFL-1 (off-white) cells. %Viability was determined via MTT assay after 24 h incubation with increasing concentrations of each conjugate, as compared to untreated cells.

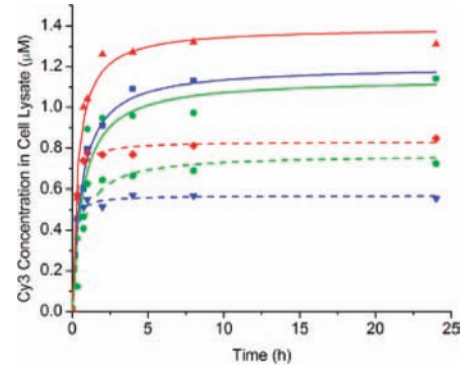

Figure 2. Uptake of peptides (solid lines) was measured for **1** (blue squares), **2** (red triangles), and **3** (green circles) and peptide−cryptophane conjugates (dashed lines) for **I** (blue inverted triangles), **II** (red diamonds), and **III** (green pentagons) by CAPAN-2 cells over 24 h.

Cell Uptake Studies. The time-dependent uptake of Cy3-labeled peptide−cryptophane conjugates **I**−**III** and peptides **1**−**3** at 10 μM was investigated in CAPAN-2 cells (Figure 2). All conjugates showed similar uptake kinetics with a rapid accumulation of compounds within the first hour. Maximum uptake was achieved by 4 h, and a plateau was observed for the remaining 20 h. In order to quantify cell uptake for each time point, 10 000 cells containing each fluorescent compound were placed in 100 μL lysis buffer. The concentrations of

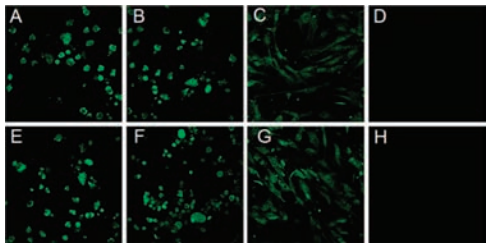

Figure 3. Cellular uptake of 2 μM Cy3-labeled **I** (top row) and **II** (bottom row) in AsPC-1 (A,E), CAPAN-2 (B,F), and HFL-1 cells (C,G) after 1 h incubation at 37 °C. Uptake of **I** and **II** was inhibited after 1 h incubation at 4 °C (D,H).

fluorescent peptides and conjugates were quantified by fluorometry after generating a fluorescence standard curve for Cy3 in the same lysis buffer, and correcting for the Cy3-labeling efficiency of each compound. Fluorescent peptides **1**−**3** were measured in the cell lysate solution at concentrations of 1.0−1.4 μM, whereas fluorescent cryptophane conjugates **I**−**III** were determined to be 500−800 nM. Within the error of the measurements, we cannot draw distinctions regarding the uptake efficiency of the three peptide motifs.

A procedure was developed to estimate the intracellular concentration of each compound from the lysate data. When detached from the surface, the CAPAN-2 cells were spherical and measured with a microscope to be ~35 μm in diameter. The average cell volume was calculated, and the fraction of the 100 μL cell lysate originally occupied by the cells was determined to be 0.0050. Thus, the measured cell lysate concentrations of 500−800 nM gave an approximate range of intracellular concentrations of 100−160 μM for **I**−**III** after the 24-h incubation period. This corresponds to 10−16-fold enrichment of **I**−**III** inside the cell (originally present in the media at 10 μM). Support for this finding comes from ratiometric measurements (Supporting Information Figures S7−S9) showing a range of fluorescence intensities that is 4−20 times greater inside the CAPAN-2 cells than the surrounding cell media. Importantly, these intracellular concentrations are within the limits of detection for laser-polarized ^{129}Xe NMR experiments (*43*).

Confocal laser scanning microscopy (CLSM) confirmed cellular delivery of cryptophane with the D-Arg$_9$− and TAT−cryptophane conjugates, **I** and **II** (Figure 3). After 1-h exposure to Cy3-labeled **I** and **II**, fluorescence was seen evenly distributed throughout most AsPC-1, CAPAN-2, and HFL-1 cells. Cy3-labeled **I** and **II** translocated into the cell nucleus, as was expected for conjugates of these peptides (*45*−*47*). After 1-h incubation at 4 °C with Cy3-labeled **I** and **II**, no fluorescence was observed (Figure 3D,H) by CLSM, which confirmed that uptake occurred via an energy-dependent endocytic pathway.

Cell uptake of Cy3-labeled **III** was also confirmed by CLSM. After 30-min incubation and rigorous cell washing, fluorescence was observed in NCI-H1975, CAPAN-2, and AsPC-1 cells (Figure 4A−C). Translocation of Cy3-labeled **III** was not observed in red blood cells, as expected, as these cells do not express $\alpha_v\beta_3$ integrin receptor (Figure 4D). In contrast to Cy3-labeled **I** and **II**, Cy3-labeled **III** was not observed to cross the nuclear membrane. In general, nuclear internalization of imaging agents is undesirable because of potential mutagenic effects on healthy cells. To determine whether uptake of **III** was mediated by ABIR, cells were preincubated with 100 μM cyclic RGDfV peptide, which is known to bind $\alpha_v\beta_3$ integrin receptor with high affinity (*48*). Figure 4D shows that the cyclic RGDfV peptide inhibited uptake of (RGD)$_4$−cryptophane as indicated by reduction in fluorescence. Internalization was also inhibited by coincubation with 10 μM anti-α_v mouse antibody (Figure 4F). Cyclic RGDfV and anti-α_v mouse antibody blocking groups also inhibited uptake in HFL-1 and CAPAN-2 cells (data not shown). These blocking data suggest that the (RGD)$_4$-labeled conjugate was specifically recognized by the $\alpha_v\beta_3$ integrin receptor and the α_v subunit is critical for cellular uptake of **III**.

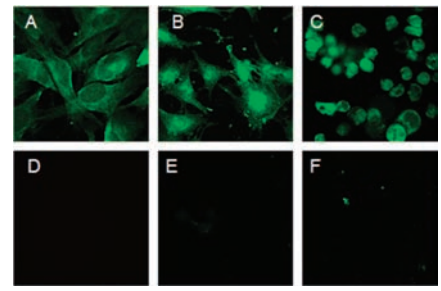

Figure 4. Uptake of 2 μM Cy3-labeled **III** targeting $\alpha_v\beta_3$ integrin in NCI-H1975 (A), HFL-1 (B), and CAPAN-2 (C) cells after 30 min incubation at 37 °C. Red blood cells (D) did not uptake this compound. Targeting in NCI-H1975 was successfully blocked with 100 μM cyclic RGDfV peptide (E) and 10 μM anti-α_v antibody (F).

Attempts at performing hyperpolarized ^{129}Xe NMR spectroscopy were made with compound **III** in isolated cells in culture. However, these experiments were unsuccessful due to the limited solubility of **III** and inability to achieve sufficient cell density within the detection volume. The requirement for incorporating DMSO in the buffers used to solubilize **III** further complicated the NMR data collection, as ^{129}Xe NMR chemical shift is very sensitive to solvent composition. The requirement for DMSO also made it difficult to achieve the high density of viable cells required for these NMR experiments.

Conjugates **I**−**III** have molecular weights of 2500–3500 Da and their transport and clearance properties in vivo are not yet known. Fullerenes, which are similar in size and chemical composition, have been found to localize to a variety of tissues in rats with large accumulations in the liver, spleen, and kidneys, suggesting that these compounds are cleared rapidly (*49*, *50*). PEG coatings may be used to improve bioavailability if the biodistribution of cryptophane is found to be similar to that of fullerene (*51*).

CONCLUSION

Cryptophane-A was conjugated to (D-Arg)$_9$, TAT, and (RGD)$_4$ peptides using a modified [3 + 2] cycloaddition reaction. This reaction provides a facile route for synthesizing chemically stable peptide−cryptophane conjugates (*40*, *52*). All compounds were examined for cell toxicity, and fluorescently labeled with Cy3 to facilitate cellular imaging studies by CLSM.

Conjugates **I** and **II** were delivered nonspecifically to all cell types tested and showed little cytotoxicity in concentration ranges that are relevant for solution-based hyperpolarized ^{129}Xe NMR experiments. Conjugate **III**, which contained an (RGD)$_4$ $\alpha_v\beta_3$ integrin receptor binding motif, was selectively delivered to cells expressing this receptor and excluded from human red blood cells. **III** was similarly nontoxic as **I** and **II**. Importantly for laser-polarized ^{129}Xe NMR studies, cryptophane concentrations in excess of 100 μM were achieved in CAPAN-2 cells using the three peptides.

An important goal of these studies is to identify cell delivery motifs that can be attached to cryptophane and effectively discriminate between cancer and normal cells. The results of this initial study are very promising, and motivate the search for peptides and small molecules that promote the cellular delivery of even higher concentrations of cryptophanes, with reduced toxicity, in order to facilitate in vivo NMR studies. As examples, the transportan and penetratin CPP sequences were shown previously to deliver higher concentrations of attached cargo than TAT and (D-Arg)$_9$ peptides (*53*, *54*). Additional cell

targeting motifs will be explored for use with other cancer biomarkers. Finally, protocols must be developed to perform ^{129}Xe MRI experiments using xenon biosensors in tissue samples, where higher cellular density (and associated cryptophane per unit volume) will improve ^{129}Xe MR signals. This work demonstrates that, due to their limited cytotoxicity and ready delivery to cells expressing specific cell surface receptors, cryptophanes offer considerable promise for in vivo xenon biosensing experiments.

ACKNOWLEDGMENT

We thank Intae Lee for providing cells and helpful discussions; Jeffery Saven, Ronen Marmorstein, and Scott Diamond for access to instrumentation; the Cell Culture Core of the University of Pennsylvania Center for Molecular Studies in Liver and Digestive Diseases for cells; Tobias Baumgart and Eric Meggers for access to cell culture facilities. Region of Interest (ROI) intensity analysis (red lines) shows fluorescence that is 10-15 times more intense inside cells than in the surrounding solution.

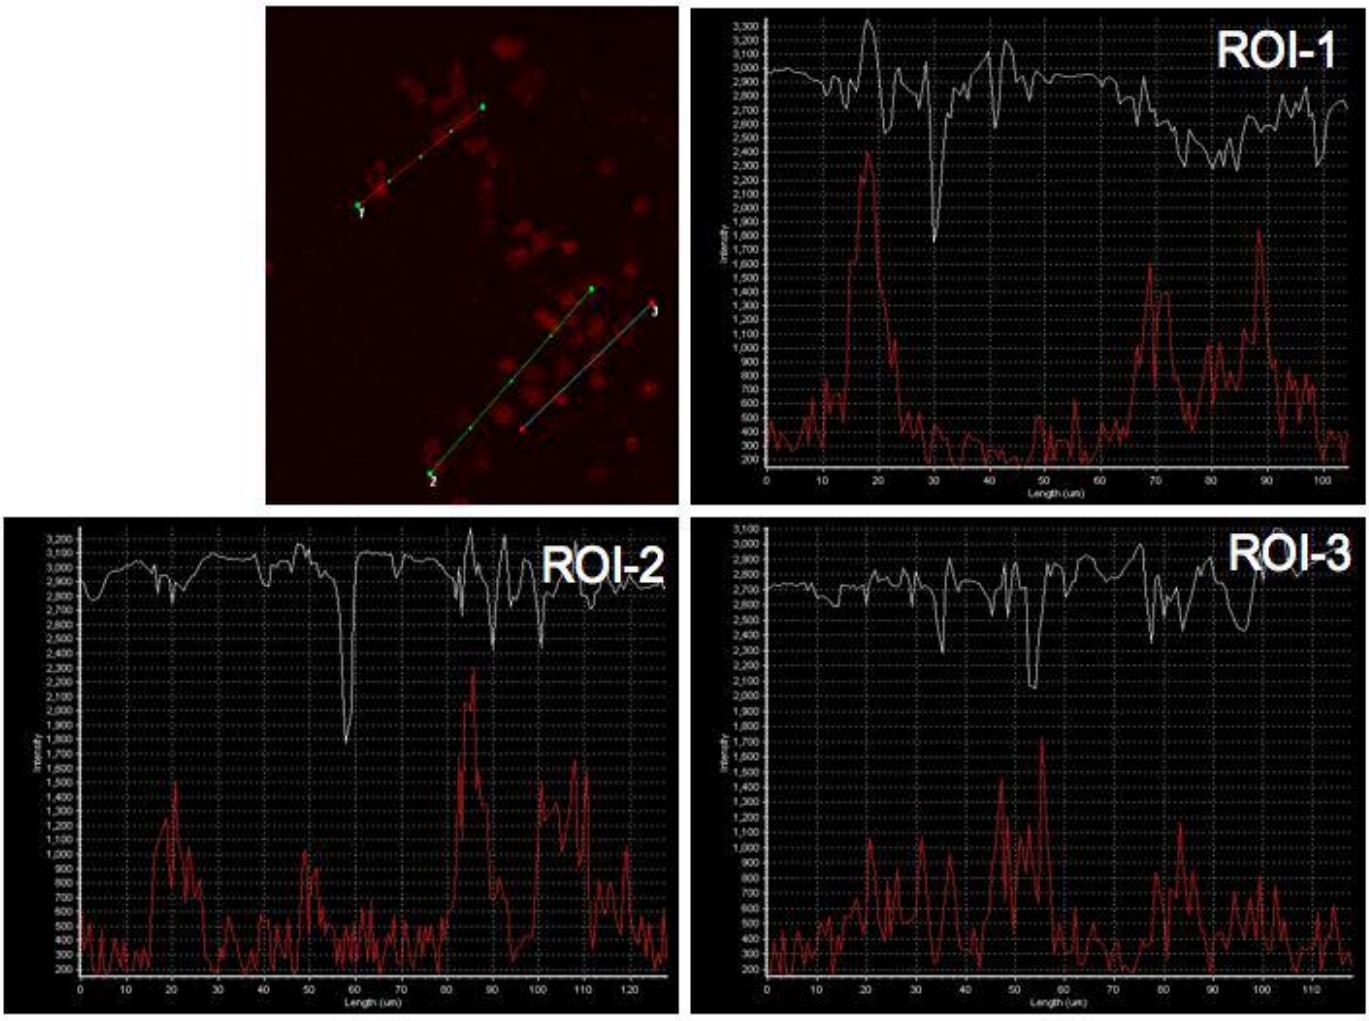

Figure S9. Sample Confocal Data Set 3. Confocal image of CAPAN-2 cells incubated with 10μM Cy3-**3** for 1 h. Cells were not washed and media was not changed before imaging. Images were taken using an Olympus FV1000 confocal laser scanning microscope with 543 nm (HeNe) laser excitation and Cy3 emission filter under 40x magnification (Olympus UApo/340 40x, 1.15 W). Region of Interest (ROI) intensity analysis (red lines) shows fluorescence intensity that is 4-8 times more intense inside cells than in the surrounding solution.

A Facile Method for the Construction of Oligonucleotide Microarrays

Dalip Sethi, A. Kumar, K. C. Gupta,* and P. Kumar*

Institute of Genomics and Integrative Biology (CSIR), Delhi University Campus, Mall Road, Delhi-110007, India. Received June 14, 2008; Revised Manuscript Received September 17, 2008

In recent years, the oligonucleotide-based microarray technique has emerged as a powerful and promising tool for various molecular biological studies. Here, a facile protocol for the construction of an oligonucleotide microarray is demonstrated that involves immobilization of oligonucleotide−trimethoxysilyl conjugates onto virgin glass microslides. The projected immobilization strategy reflects high immobilization efficiency (∼36−40%) and signal-to-noise ratio (∼98), and hybridization efficiency (∼32−35%). Using the proposed protocol, aminoalkyl, mercaptoalkyl, and phosphorylated oligonucleotides were immobilized onto virgin glass microslides. Briefly, modified oligonucleotides were reacted first with 3-glycidyloxypropyltriethoxysilane (GOPTS), and subsequently, the resultant conjugates were directly immobilized onto the virgin glass surface by making use of silanization chemistry. The constructed microarrays were then used for discrimination of base mismatches. On subjecting to different pH and thermal conditions, the microarray showed sufficient stability. Application of this chemistry to manufacture oligonucleotide probe-based microarrays for detection of bacterial meningitis is demonstrated. Single-step reaction for the formation of conjugates with the commercially available reagent (GOPTS), omission of capping step and surface modification, and efficient immobilization of oligonucleotides onto the virgin glass surface are the key features of the proposed strategy.

INTRODUCTION

Oligonucleotide arrays have emerged as a powerful and convenient tool for parallel and high-throughput experimentation in molecular biological research (*1*−*6*). Array technology has considerably simplified the process involved in disease diagnosis and gene mapping, as it offers advantages of using a very small amount of biological probes (nanomoles and picomoles), along with the capability of analyzing thousands of analytes in parallel (*7*).

Direct syntheses (in situ) of oligonucleotides on the chip surface following conventional or photolithographic methods and immobilization of presynthesized oligonucleotides on the selected substrates are the two predominant methods for construction of oligonucleotide microarrays. The in situ synthesis protocol allows the preparation of high-density oligonucleotide microarrays; however, it suffers from certain drawbacks (*8*−*12*). The deposition method, on the other hand, offers flexibility in the sense that a variety of biomolecules can be immobilized on the surface of choice but limited to generation of low to medium density arrays (*14*−*19*). Therefore, the deposition method has become a method of choice for routine applications in research and commercial laboratories. The choice of surface and the chemistry employed for attachment of oligonucleotides are the key factors that govern the quality of constructed microarray. Out of various surfaces used, glass is a substrate of choice owing to its widespread availability, low cost, well-characterized silane chemistry for functionalization, and favorable optical properties, which permits highly sensitive laser-induced fluorescence imaging.

For the attachment of oligonucleotides, various covalent and noncovalent oligonucleotide immobilization techniques have been documented. The simplest of them is the immobilization of probes via electrostatic adsorption onto a charged priming layer like aminopropyl or polylysine-coated glass slides; however, it results in poor hybridization efficiency (*13*). Covalent attachment of probes onto the solid support is a preferred approach, as it results in higher stability and hybridization efficiency as compared to noncovalent immobilization. Some commonly used attachment chemistries (surface-probe) are semicarbazide-aldehyde (*14*), epoxide-amine (*15*), aldehyde-amine (*16*), gold-thiol (*17*, *18*), and thiol-thiol (*19*) interactions. Various hetero- and homobifunctional reagents have also been reported for tethering oligonucleotides to polymeric surfaces (*20*−*24*). In addition to the covalent chemistries employed for the fabrication of arrays, some "organic−inorganic" interactions have also been utilized to realize immobilization of oligonucleotides. Attachment of thiol-modified probes to metallic gold via sulfur−gold linkage and phosphorylated oligonucleotides on zirconylated surface are the representative examples of this approach (*18*, *25*).

Here, we describe a simple two-step method that involves attachment of modified oligonucleotides (aminoalkyl, mercaptoalkyl, and phosphorylated oligomers) onto a virgin glass surface. The first step involves the reaction between a modified probe and a commercially available reagent, 3-glycidyloxypropyltriethoxysilane (GOPTS), to form a silylated conjugate, which, in turn, reacts with silanol functionalities of the glass slide to result in surface-bound oligonucleotides. The proposed strategy not only resulted in signal reproducibility but also showed superior spot morphology and homogeneity. The study undertaken herein includes investigation of optimal time required for the formation of oligomer−trimethoxysilyl conjugate followed by their immobilization on a virgin glass surface and determination of the threshold concentration of conjugate required for visualization. The thermal and pH stability of constructed microarrays was evaluated. The constructed microarrays were compared with the standard method to clearly

highlight the advantages of the projected strategy in terms of immobilization and hybridization efficiency.

EXPERIMENTAL PROCEDURES

Chemicals and Reagents. Virgin glass microslides (75 × 22 mm^2), *N*-methylimidazole (NMI), and 3-glycidyloxypropyltrimethoxysilane (GOPTS) were obtained from Sigma-Aldrich Chemical Co., St. Louis, MO. Absolute ethanol was procured from Tedia Company Inc., Fairfield, U.S. 4,5,6,7-Tetrachlorofluorescein (TET) phosphoramidite was obtained from Applied Biosystems Inc., Foster City, CA. All other reagents used were of analytical grade and used as received from the commercial source, unless specified.

Instrumentation. Scan Array Lite Scanner (GSI Lumonics), Speed Vac concentrator (Hetovac VR-1), Lambda Bio 20 UV−vis spectrophotometer (Perkin-Elmer, USA), and *Quant Array* software for quantification of fluorescence intensity of the spots (Packard Biosciences, USA) were used.

Cleaning of Glass Slides. The glass slides were treated with 1 M NaOH for 1 h followed by washing with MilliQ water (3 × 150 mL). Then, the slides were treated with 1.5 M HCl for 1 h followed by extensive washings with MilliQ water (3 × 150 mL). Finally, the slides were immersed in absolute ethanol (2 × 150 mL, for 15 min each), dried, and stored under inert atmosphere.

Reagents and Buffers. (i) GOPTS solution (0.0136 M): Prepared by dissolving 30 μL GOPTS in 10 mL of dimethylformamide (DMF)/tetrahydofuran (THF)/acetonitrile (ACN). (ii) Reaction buffer (0.1 M NMI): Prepared by dissolving 80 μL in 10 mL of MilliQ water. (iii) Washing buffer: 125 mM SSC buffer containing 750 mM sodium chloride, pH 7.0. (iv) Hybridization buffer: 125 mM SSC buffer containing 1 M sodium chloride, pH 7.0.

Oligonucleotide Synthesis and Purification. Oligonucleotides, used in this study, were synthesized on 0.2 μmol scale on a Pharmacia LKB Gene Assembler Plus using the standard phosphoramidite approach following the manufacturer's protocol (*26*). Labeled oligonucleotides were prepared by performing the last coupling with TET-phosphoramidite in an analogous manner to that of normal nucleoside−phosphoramidites, except that an extended coupling time (5 min) was employed. A list of oligonucleotide sequences assembled along with their deprotection conditions and yields are given in Table 1. The ammoniacal solutions in all the cases were concentrated in a speed vac; the residue obtained was dissolved in water (200 μL) and applied onto a desalting column (reverse-phase ODS-silica gel column). The oligonucleotides were eluted with 30% acetonitrile in water, concentrated, purified, and stored at 4 °C.

Determination of Optimal Conditions Required for Immobilization of Modified Oligonucleotides on a Virgin Glass Microslide. *Preparation of Oligonucleotide−Trimethoxysilyl Conjugate.* Oligonucleotide sequence, TET-d(CTT CTT TTT CCT GTT ACC GT)-OPO_3^{2-} (0.6 nmol), dissolved in the reaction buffer (100 μL), was allowed to react with a GOPTS solution (100 μL) prepared in DMF for 8 h on an Eppendorf mixer. The reaction mixture was then concentrated, and the viscous material obtained was suspended in MilliQ water (40 μL) and centrifuged. The supernatant was collected and concentrated. The residue was finally dissolved in 10% DMSO in water to fix the concentration of the probe solution to 5 μM and then spotted (0.5 μL) manually using a 2 μL pipetteman onto a virgin glass microslide. After spotting, the microslide was kept at 45 °C for 35 min. The slide was washed with 1× SSC buffer (2 × 50 mL for 15 min each), followed by MilliQ water (2 × 50 mL), and dried under vacuum. Subsequently, the spots on the microslide were visualized under a laser scanner and quantified.

Likewise, the experiment was performed in other solvent systems, viz., THF/water (1:1, v/v) and ACN/water (1:1, v/v).

Time Kinetics for the Synthesis of Conjugate. To determine the optimum time required for the formation of conjugates, a kinetic study was performed. Twelve Eppendorfs were equally charged with GOPTS solution (100 μL) in DMF and TET-labeled oligonucleotide, TET-d(CTT CTT TTT CCT GTT ACC GT)-OPO_3^{2-} (0.6 nmol in 100 μL reaction buffer). The Eppendorfs were kept at 45 °C and withdrawn at different time intervals. Subsequently, the reaction mixture was worked up and microarray constructed, as described above. After usual washings and drying, the spots on the microslides were scanned under a laser scanner and quantified. The extent of reaction was evaluated by plotting fluorescence intensity of the spots against time. A similar study was carried out with aminoalkyl and mercaptoalkylated oligonucleotides.

Threshold Concentration of the Conjugate Required for Visualization. In order to determine the threshold concentration of conjugate required for visualization under a laser scanner, oligomer−trimethoxysilyl conjugate, TET-d(CTT CTT TTT CCT GTT ACC GT)-OPO_3^--$CH_2CH(OH)CH_2O(CH_2)_3$-Si-$(OMe)_3$, was dissolved in 10% DMSO in MilliQ water and spotted manually in duplicate in different concentrations (0.5, 1, 2.5, 5, 10, and 20 μM) on a glass microslide. The spotted slide was kept in a humidity chamber at 45 °C for 35 min, followed by washings with the washing buffer (2 × 50 mL for 15 min each) and MilliQ water (2 × 50 mL). The slide was dried under vacuum and scanned under a laser scanner.

Likewise, the conjugates of aminoalkyl and mercaptoalkylated probes were studied.

Evaluation of Glass Surface for Immobilization. In order to evaluate the homogeneity of glass surface, an experiment was performed. An oligomer−trimethoxysilyl conjugate, TET-d(CTT CTT TTT CCT GTT ACC GT)-OPO_3^--$CH_2CH(OH)CH_2O(CH_2)_3$-Si-$(OMe)_3$ (5 μM), was spotted manually on virgin glass microslides at different locations and kept at 45 °C for 35 min. After washing and drying, as described above, the slide was scanned.

Hybridization Studies. Oligonucleotide sequence, d-(ACG GTA ACA GGA AAA AGA AG)-OPO_3^- (0.6 nmol), dissolved in 100 μL of reaction buffer, was mixed with 100 μL solution of GOPTS in DMF. The reaction mixture was agitated for 270 min at 45 °C. Then, the solution was concentrated under vacuum to obtain a syrupy residue of oligonucleotide−trimethoxysilyl conjugate, which was resuspended in MilliQ water (40 μL). The mixture was centrifuged to get rid of excess GOPTS as undissolved material. The supernatant was concentrated under vacuum to obtain a residue, which was reconstituted in MilliQ water containing 10% DMSO (v/v) to make an oligonucleotide conjugate concentration to 5 μM. The conjugate was then spotted manually in duplicate on a glass slide. The spotted microslide was incubated at 45 °C in a humidity chamber for 35 min, followed by washings with washing buffer (3 × 50 mL for 15 min each) and then subjected to hybridization experiment. The microslide was kept in a hybridization chamber and treated with a solution of the complementary fluorescent oligonucleotide, TET-d(CTT CTT TTT CCT GTT ACC GT) (40 μL, 40 μM), prepared in hybridization buffer, under a coverslip at 45 °C for 1 h and then at 25 °C for 12 h. After removal of coverslip, the glass microslide was then washed with hybridization buffer (3 × 50 mL for 15 min each) to get rid of excess complementary oligomer. Subsequently, the microslide was dried, examined under a laser scanner, and quantified.

Similarly, the aminoalkyl and mercaptoalkylated oligonucleotide conjugates were immobilized on a microslide and hybridization assay was performed.

Detection of Base Mismatches. The specificity of the system was demonstrated by immobilizing oligomer−trimethoxysilyl conjugates on virgin glass microslides. Four oligonucleotide conjugates, viz., d(ACG GTA ACA GGA AAA AGA AG)-OPO_3^--$CH_2CH(OH)CH_2O(CH_2)_3$-$Si(OMe)_3$, d(ACG GTA ACA GGA AAA AGC AG)-OPO_3^--$CH_2CH(OH)CH_2O(CH_2)_3$-$Si(OMe)_3$, d(ACG GTA ACA CGA AAA AGC AG)-OPO_3^--$CH_2CH(OH)CH_2O(CH_2)_3$-$Si(OMe)_3$, and d(TTT TTT TTT TTT TTT TTT TT)-OPO_3^--$CH_2CH(OH)CH_2O(CH_2)_3$-$Si(OMe)_3$ (5 μM), having zero, one, and two mismatches and noncomplementary probe, were spotted on a virgin glass slide and processed as described above. Subsequently, the spots on the microslide were hybridized with a complementary labeled TET-d(CTT CTT TTT CCT GTT ACC GT) and kept at 45 °C for 1 h and then at room temperature for 12 h. After washings with hybridization buffer (3 × 50 mL for 15 min each), the microslide was subjected to laser scanning followed by quantification. Under identical conditions, conjugates of aminoalkyl and mercaptoalkylated oligomers were immobilized, hybridized, and quantified.

In order to demonstrate that the epoxy group of GOPTS specifically reacts with terminal functional groups of end-modified oligonucleotides, a comparative study was performed. Conjugates of two oligonucleotide sequences, viz., TET-d(CTT CTT TTT CCT GTT ACC GT) and TET-d(CTT CTT TTT CCT GTT ACC GT)-OPO_3^{2-}, were prepared, as described above and after usual workup, the conjugates (5 μM) were spotted manually on virgin glass slide. After usual washings, the spots were visualized under a laser scanner and quantified.

Quantification of Immobilized Oligonucleotides. To quantify the density of immobilized oligonucleotides, an oligomer sequence, TET-d(CTT CTT TTT CCT GTT ACC GT)-OPO_3^{2-}, diluted to different concentrations (0.05, 0.10, 0.25, 0.50, 0.75, 1.0, 2.0 μM), was spotted on a glass microslide in duplicates. After drying the spots under vacuum, the microslide was visualized under a laser scanner and the fluorescence signal intensity corresponding to each spot was measured. Using these values, a standard curve was plotted between fluorescence intensity (A.U.) and concentration (μM) of the spot.

Thermal and pH Stability. To evaluate the thermal stability of probe immobilization, a microarray was constructed by spotting oligonucleotide−trimethoxysilyl conjugates at a concentration of 5 μM. The fabricated microarrays were treated under PCR-like conditions for 0, 5, and 10 cycles in 1× SSC buffer (pH 7). PCR parameters were as follows: 94 °C for 30 s (denaturing step), 54 °C for 30 s (annealing step), and 72 °C for 30 s (extension step). After thermocycling, the slide was washed, dried, and visualized under a laser scanner.

The pH stability was evaluated by preparing microarrays in a similar way and then subjecting them to washings with 1× SSC buffer of different pH (7, 8, and 9) (3 × 50 mL for 15 min each). The microslides, after usual washings and drying, were visualized under a laser scanner.

Detection of Bacterial Meningitis. *PCR-Amplification.* The PCR reaction was performed in 25 μL PCR Eppendorf containing 0.25 mM dNTPs (of each dATP, dCTP, dGTP, and dTTP), forward primer TET-d(GCT GCG GTA GGT GGT TCA A), and reverse primer TET-d(TTG TCG CGG ATT TGC AAC TA) (0.4 μM of each), genomic DNA (50 ng/reaction), Taq-polymerase (0.75 units), and MilliQ water. All PCR reactions were performed on an MJ Research thermocycler using the following profile: (1) 5 min at 95 °C (initial denaturation step); (2) 35 cycles of 50 s at 95 °C (denaturation step), 40 s at 58 °C (annealing step), 1 min at 72 °C (extension step); (3) 7 min at 72 °C (final extension step); hold temperature: 4 °C. The labeled PCR-amplifications, 111bp fragment of *ctrA* gene (*Neisseria meningitidis*; serogroup A), were analyzed by agarose gel electrophoresis, and detection was performed by ethidium bromide (10 μg/mL) in standard TAE buffer, pH 8.

PCR Amplicon Capture. Two oligonucleotide−trimethoxysilyl conjugates, d(ACG TGT CAG CTG CAC ATT CGT)-OPO_3^--$CH_2CH(OH)CH_2O(CH_2)_3$-$Si(OMe)_3$ (complementary) and d(CGT CGA GTC GGG CAT CTT TTT)-OPO_3^--$CH_2CH(OH)CH_2O(CH_2)_3$-$Si(OMe)_3$ (control, noncomplementary) were immobilized on the glass slide as described above. Amplicons were hot-denatured (5 min, 95 °C), cooled on ice (10 min), and used for the hybridization assay. After usual washings, the slide was visualized under a laser scanner.

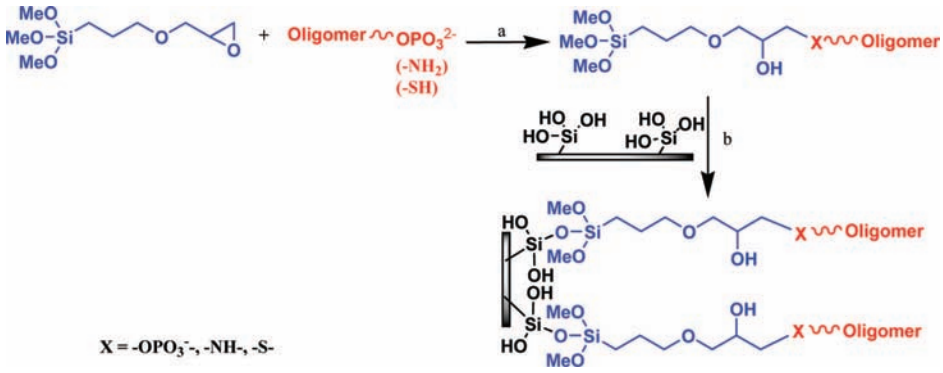
Signal Evaluation and Quantification. Microarrays were scanned on a Scan Array Lite Scanner (GSI Lumonics) fitted with a Cy3 optical filter with 30 μm resolution; laser power and PMT were set to 85% and 80%, respectively. Spot intensities were quantified using *Quant Array* software (Packard Bioscience) and graphs were plotted in Microsoft *Excel*.

For each experimental condition tested on the microarrays, the experiments were repeated 2−3 times. The immobilization and hybridization data presented are the average of these repetitions, and the error bars represent the percentage error (∼3−5%) observed on this average.

RESULTS AND DISCUSSION

Homo- and heterobifunctional cross-linkers have been finding extensive use for various applications, such as preparation of affinity matrices, modification and stabilization of diverse structures, identification of ligand and receptor binding sites,

Scheme 1. Immobilization of Oligonucleotides on Virgin Glass via Oligonucleotide−Trimethoxysilyl Conjugates[a]



[a] Conditions: (a) 45 °C, 4.5 h (phosphoryl-oligomer); 45 °C, 3 h (aminoalkyl-oligomer); 45 °C, 2 h (mercaptoalkyl-oligomer); and (b) 45 °C, 35 min.

structural studies, and so forth. Of these, heterobifunctional reagents, which contain two different functional groups, have proven to be more advantageous, as cross-linking can be controlled both selectively and sequentially. By taking advantage of the differential reactivity of the two reactive groups, these reagents are finding extensive use in DNA microarray technology for tethering oligonucleotides to solid surfaces (*20*−*24*). Recently, immobilization of biomolecules on glass/silicon wafers has gained importance, as these are being used in constructing microarrays of biomolecules (e.g., oligonucleotide, peptide, protein, polysaccharides, and so forth). The primary aim of the present investigation was to design a facile and economical protocol for immobilization of aminoalkyl, mercaptoalkyl, and phosphorylated oligonucleotides, as they can easily be synthesized using commercially available reagents and chemicals, onto the virgin glass surface. While designing such a protocol, the following points were kept in mind: (i) the methodology should not require modified surfaces, (ii) the reagents should be commercially available and inexpensive, and (iii) the protocol should not involve complex chemistry and stringent reaction conditions. Guided by these considerations, we could find out three reagents, viz., 3-glycidyloxypropyltrimethoxy silane (GOPTS), 3-isocyanatopropyltriethoxysilane (IPTS), and 3-mercaptopropyltriethoxysilane (MPTS), for this purpose. Among these reagents, IPTS can be used for immobilization of amino- and mercaptoalkylated oligonucleotide, however, due to highly moisture-sensitive nature, the results are not reproducible. MPTS results in immobilization of mercaptoalkylated oligomers via disulfide linkage, which is quite a labile linkage. Only GOPTS, which fulfills all the requirements, was considered to be the reagent of choice for immobilization of modified oligonucleotides ($-NH_2$, -SH, and $-OPO_3^{2-}$). The epoxy function present at one of the ends can react efficiently with a vast variety of nucleophiles as well as electrophiles under mild conditions, and the trimethoxysilyl functions at the other end of the reagent can specifically react with silanol functionalities on the virgin glass surface following silanization chemistry (Scheme 1). By taking advantage of these points, a rapid and clean protocol has been developed for immobilization of oligonucleotides bearing different functional groups.

Optimization of Reaction Conditions. In order to find an appropriate solvent system for the preparation of oligonucleotide−trimethoxysilyl conjugates, we surveyed the literature and observed that trialkoxysilane groups get hydrolyzed in aqueous solution in the presence of either strong ionizable acids or bases (*27*−*29*). However, the rate of hydrolysis is very dependent on the presence of an organic solvent in the reaction mixture (*30*, *31*). Among the various solvent systems reported, viz., acetone−water, methanol−water, dioxane−water, ethanol−water, and DMF−water, the slowest rate of hydrolysis of

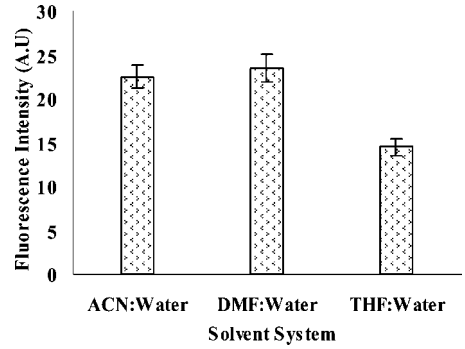


Figure 1. Effect of solvent systems on the reaction of end-modified oligonucleotides with GOPTS.

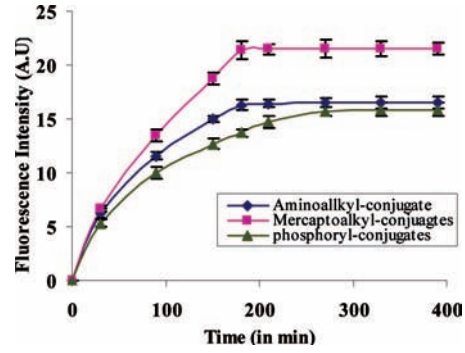

Figure 2. Kinetic study of the reaction between fluorescent-labeled end-modified oligonucleotides with GOPTS.

trialkoxysilanes was observed in DMF−water system, where DMF is believed to inhibit the hydrolysis of alkoxysilanes. Keeping these observations in mind, we carried out the conjugate formation (reaction between modified oligonucleotide and GOPTS) in DMF−water (1:1, v/v) using 0.1 M NMI, a nonionizable base, as reaction buffer. Even if, under such conditions, some of the trialkoxysilyl groups may get hydrolyzed, the use of a large excess of the conjugate for the immobilization reaction would hardly affect the efficacy of the system. Therefore, in order to evaluate the formation of oligonucleotide−trimethoxysilyl conjugates, three solvent systems, viz., ACN/water (1:1, v/v); DMF/water (1:1, v/v), and THF/water (1:1, v/v), were assessed. After carrying out the reaction for 8 h, the conjugate was spotted manually on a virgin glass microslide and incubated at 45 °C for 30 min. The results revealed that maximum fluorescence intensity (A.U.) of the spots was observed in case of DMF/water (1:1, v/v) containing 0.1 M NMI, indicating that the conjugation reaction proceeded efficiently in this solvent system (Figure 1). Therefore, in the

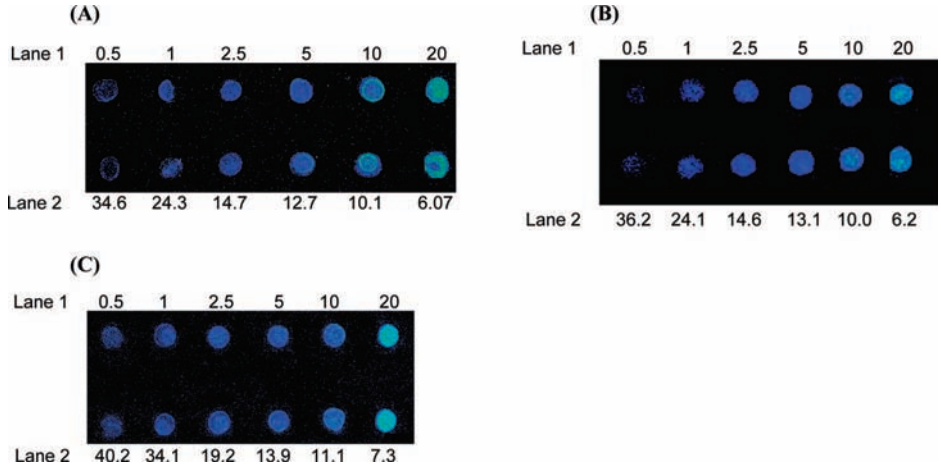

Figure 3. Pictorial representation of immobilization efficiency (%, lane 2) vs concentration (μM, lane 1) of (A) phosphoryl−trimethoxysilyl conjugate, (B) aminoalkyl−trimethoxysilyl conjugate, and (C) mercaptoalkyl−trimethoxysilyl conjugate.

rest of the experiments, oligonucleotide−trimethoxysilyl conjugates were prepared in DMF/water solvent system (1:1, v/v).

With the aim of determining the time required for the completion of reaction between aminoalkyl, mercaptoalkyl, and phosphorylated oligonucleotides and epoxy groups of GOPTS, kinetic studies were undertaken at 45 °C. Phosphorylated oligonucleotide, TET-d(CTT CTT TTT CCT GTT ACC GT)-OPO_3^{2-}, taken in twelve Eppendorf tubes, was allowed to react with GOPTS, and the tubes were withdrawn at different time intervals. After the usual workup, a microarray was constructed, as mentioned in the Experimental Section. The slide was visualized under a laser scanner, and fluorescence intensity (A.U.) of the spots was determined, which was subsequently plotted against time (min), as shown in Figure 2. The results indicate that the formation of the conjugate essentially completes in 180 min (3 h) in the case of aminoalkyl, 120 min (2 h) for mercaptoalkyl, and 270 min (4.5 h) for phosphorylated oligomers. In the subsequent experiments, a respective time period was employed for the preparation of conjugates between modified probes and GOPTS.

To determine the threshold concentration of the conjugate required for visualization under a laser scanner, an oligonucleotide−trimethoxysilyl conjugate, TET-d(CTT CTT TTT CCT GTT ACC GT)-OPO_3^--$CH_2CH(OH)CH_2O(CH_2)_3$-$Si(OMe)_3$, serially diluted from 20 μM to 0.5 μM, was spotted manually on a virgin glass slide and incubated at 45 °C. After the usual workup, the slide was scanned under a laser scanner and the spots were quantified. The pictorial view of the slide is depicted in Figure 3A. Similar experiments were carried out for aminoalkyl and mercaptoalkylated oligonucleotide conjugates (Figure 3B,C). The immobilization efficiency against each concentration was determined with the help of a standard curve (Figure 4). The results revealed that immobilization efficiency followed an inverse relation with concentration of spotted conjugates. The spots corresponding to 0.5−2.5 μM concentration were visible; however, to construct a good quality biochip, a concentration of 5 μM was selected and used for immobilization purposes.

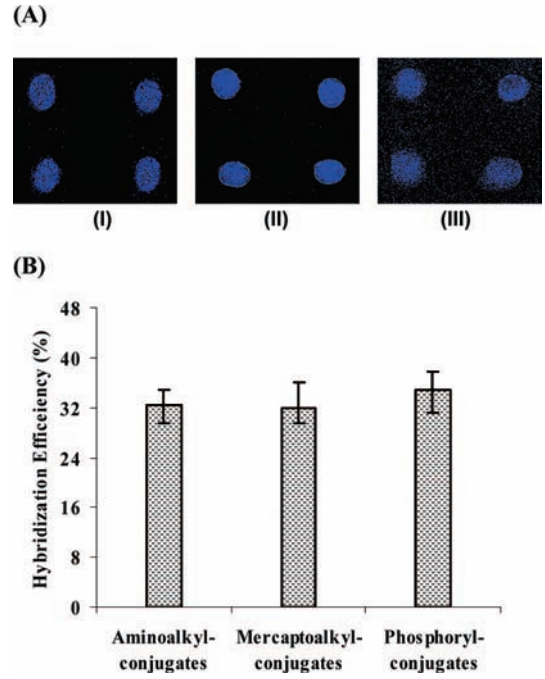

Figure 5. (A) Immobilization of (I) d(AGC GTA ACA GGA AGA AGC TG)OPO_3-$(CH_2)_6$NH- $CH_2CH(OH)CH_2O(CH_2)_3$-$Si(OMe)_3$, (II) d(AGC GTA ACA GGA AGA AGC TG)OPO_3-$(CH_2)_6$S-$CH_2CH(OH)CH_2O(CH_2)_3$-$Si(OMe)_3$, and (III) d(AGC GTA ACA GGA AGA AGC TG)OPO_3^--$CH_2CH(OH)CH_2O(CH_2)_3$-$Si(OMe)_3$ on a virgin glass surface followed by hybridization with labeled oligomer, TET-d(CAG CTT CTT CCT GTT ACG CT). (B) Quantitative hybridization efficiency.

Homogeneity of virgin glass microslides procured from Sigma Chemical Co., USA, was evaluated by manually spotting the TET-labeled conjugate at different positions on the glass microslides. The fluorescence intensity of spots was found to be in the range ~25.3−27.2 A.U., which showed that the density of silanol functionalities on the glass surface was present almost uniformly throughout the glass surface. The stability of the

oligomer−trimethoxysilyl was also checked on storage at 4 °C for up to 30 days, and it was found to be stable.

Hybridization Assay. The applicability of the projected strategy was evaluated by performing hybridization assay of slides fabricated via immobilization of the trimethoxysilyl conjugates of aminoalkyl, mercaptoalkyl, and phosphorylated oligomers onto the glass slides at 5 μM concentration. The microarrays constructed were visualized by hybridizing them with the corresponding complementary TET-labeled oligonucleotides. After thorough washings and drying, the microslides were screened under a laser scanner and the fluorescent spots were visualized, as depicted in Figure 5A. The fluorescent spots on the microslides were quantified using *QuantArray* software. The quantification data is shown in Figure 5B. The proposed strategy resulted in high hybridization efficiency (∼32−35%). Furthermore, the spot morphology was also found to be almost identical.

Specificity of Chemistry and Base Mismatch Detection. To demonstrate the specificity of the proposed chemistry and the extent of involvement of internucleotidic phosphodiester groups in the formation of conjugates, a study was performed using TET-labeled phosphorylated oligomer and its nonphosphorylated labeled analogue, as described in the Materials and Methods section. Fluorescence intensity of spots of nonphosphorylated oligomer was only ∼10% as compared to that of phosphorylated oligonucleotides.

In order to demonstrate the specificity of the microarrays, four oligonucleotide−trimethoxysilyl conjugates having zero (d(AGC GTA ACA GGA AGA AGC TG)OPO_3^{2-}), one (d(AGC GTA ACA GGA AGA TGC TG)OPO_3^{2-}), and two (d(AGC GTA CCA GGA AGA TGC TG)OPO_3^{2-}) mismatches and a non-complementary sequence, d(TTT TTT TTT TTT TTT TT)OPO_3^{2-}, to the TET-d(CAG CTT CTT CCT GTT ACG CT) were immobilized onto a virgin glass slide. After the usual washings with SSC buffer and MilliQ water, the microarrays were subjected to a hybridization step with a labeled oligomer (complementary to zero mismatch sequence). Figure 6A(I) clearly shows the base mismatches. The results revealed that the fluorescence intensity of spots decreased for single-mismatch and was reduced to minimal for double-mismatch as compared to that of the perfect complementary oligomer.

Hybridization of the non-complementary oligonucleotide did not result in significant signal after hybridization, implying the specificity of the hybridization. Similarly, specificity of other microarrays constructed using amino- and mercaptoalkylated oligonucleotide−trimethoxysilyl conjugates was evaluated as depicted in Figure 6A(II and III). The quantification data are shown in Figure 6B.

Thermal and pH Stability. The thermal stability of constructed microarray was evaluated by subjecting it to 0, 5, and 10 cycles of PCR-like conditions. The percentage reduction in fluorescence intensity was observed to be ∼8.2% for phosphorylated oligomer conjugates, ∼5.8% for aminoalkylated oligomer, and ∼4.9% for mercaptoalkylated oligomer conjugates (Figure 7A), indicating that constructed microarrays are sufficiently stable to be used in biological research. The stability of constructed microarrays was also analyzed at different pHs (7, 8, and 9). The results indicated that the constructed microarrays are sufficiently stable in SSC buffers of different pH. The decrease in fluorescence intensity was ∼5% at pH 8 and ∼10% at pH 9 as compared to fluorescence intensity at pH 7 for the oligomer conjugates (Figure 7B).

Comparison of the Projected Strategy with Standard NTMTA Method. The efficacy of the proposed method was demonstrated by comparing with the NTMTA method (*20*). For comparison purposes, an equal concentration of an oligonucleotide (each at 5 μM) was used in all three methods. However, different reaction conditions as well as time were employed, as reported. After immobilization and hybridization with labeled complementary target, the slides were subjected to usual washings and drying. The slides were then subjected to scanning under a laser scanner for quantification, and the hybridization efficiency for each method was calculated. The hybridization efficiency of the proposed method (∼32−35%) was found to be significantly higher than the standard method, NTMTA (∼10.2%), as shown in Figure 8.

Detection of Bacterial Meningitis. In order to devise a biochip for the diagnosis of the bacterial infection, a microarray was constructed on a glass microslide using a unique probe sequence of the *CtrA* gene and a non-complementary probe sequence as control, as described in the Materials and Methods section. Subsequently, the spots on the glass surface were subjected to hybridization with the labeled PCR amplicons. After washings and drying, the slide was visualized under a laser scanner. Figure 9 shows the pictorial view of the slide. Spots of probe sequence specific to *ctrA* gene of bacteria (*N. Meningitidis*) showed fluorescence, while the spots pertaining to the control did not fluoresce at all, signifying the specificity of the system to prepare biochips for the detection of bacterial meningitis in humans.

CONCLUSIONS

An efficient and facile method for fabricating oligonucleotide microarrays has been developed employing conjugates of oligonucleotides. The method permits attachment of modified probes, which can be synthesized easily on the machine itself using commercially available reagents, onto virgin glass slides with high immobilization and hybridization efficiency and signal-to-noise ratio (∼98). The protocol offers an added advantage that it bypasses the capping step. The method involves commonly used reagents, chemicals, and simple chemistry; it is hoped that this will provide individuals, particularly the end users or nonchemists, an easy access to an oligonucleotide microarray for various applications including diagnosis of genetic as well as infectious diseases.

ACKNOWLEDGMENT

Financial support from the Department of Biotechnology, New Delhi, India, is gratefully acknowledged. One of the authors, D.S., acknowledges the University Grants Commission (UGC), New Delhi, India, for the award of Research Fellowship to carry out his work. Authors are thankful to Dr. Sunil Gupta and Dr. Shashi Khare, National Institute of Communicable Diseases (NICD), Delhi, India, for providing meningitis sample and facilities.

Poly(2-methacryloyloxyethyl phosphorylcholine) for Protein Conjugation

Andrew Lewis,*,† Yiqing Tang,† Steve Brocchini,‡,§ Ji-won Choi,‡ and Antony Godwin*,‡

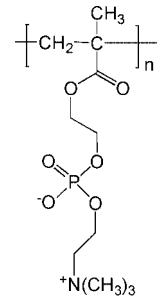
Biocompatibles UK Ltd, Weydon Lane, Farnham, Surrey GU9 8QL, PolyTherics Ltd, 2 Royal College Street, London NW1 0TU, and The School of Pharmacy, University of London, 29 Brunswick Square, London WC1N 1AX, United Kingdom. Received June 17, 2008; Revised Manuscript Received September 19, 2008

The water-soluble, biocompatible polymer poly(2-methacryloyloxyethyl phosphorylcholine) (PMPC) was evaluated for protein conjugation. PMPC is a zwitterionic polymer that is able to form a more compact conformation in aqueous solution than poly(ethylene glycol) (PEG). While a terminally functionalized N-hydroxysuccinimide derivative of PMPC was not efficient for conjugation to an amine moiety on interferon-α2a (IFN), we found that a bis-thiol specific derivative of PMPC could be conjugated after reduction of the disulfide bonds in IFN. Utilizing PMPC that displayed a similar hydrodynamic volume to 20 kDa PEG, we evaluated the *in vitro* antiviral and antiproliferative activity and pharmacokinetics of a PMPC-IFN conjugate. As a hygroscopic zwitterionic polymer, PMPC is able to form a compact conformation in aqueous solution, which was found to be more compact than PEG. This suggests that PMPC protein conjugates may display different plasma elimination characteristics than PEG protein conjugates. PMPC-IFN displayed marked resistance to antibody binding in Western blot analysis with a polyclonal anti-IFN antibody while displaying comparable *in vitro* antiviral and antiproliferative activity to PEG-IFN. During an *in vivo* pharmacokinetic study, the absorption $t_{1/2}$ for PMPC-IFN was considerably extended compared to the native IFN and 20 kDa PEG analogue. This is also consistent with the SDS-PAGE result where an apparent reduction in mobility through a hydrated medium was observed. The elimination $t_{1/2}$ was also vastly extended over the native IFN and twice the value of 20 kDa PEG-IFN. This suggests that tissue migration of PMPC-IFN occurs more slowly than the 20 kDa PEG-IFN despite their similarity in hydrodynamic volume, leading to an an improved depot effect, which could explain the longer elimination $t_{1/2}$. In this study, we demonstrate a potential use of PMPCylation as a novel tool for enhancing the pharmacokinetic profile of therapeutic proteins in ways that complement PEGylation.

INTRODUCTION

Medicines that are derived from proteins form a significant proportion of new medicines that are being approved for clinical use. As is well-known, protein-based medicines are burdened by several limitations that increasingly have to be overcome in order for the medicine to gain regulatory approval. Many limitations can be addressed by the covalent conjugation of poly(ethylene glycol) (PEG) to a protein. Protein PEGylation is clinically proven to favorably alter the protein's pharmacokinetics by prolonging its circulation time and to decrease the protein's toxicity profile, especially with respect to the reduction of immunogenicity (*1*−*4*). Prolonging the circulation time is critical for reducing the frequency of administration, thus further lowering the propensity for immunological side effects.

Additional advantages of PEGylation include the potential to increase water solubility and the storage stability of a protein. PEGylation can also decrease the propensity for protein aggregation. Such formulation advantages are critical in preventing the protein from losing activity or from becoming immunogenic. Although existing conjugation technologies often result in significantly less biological activity of the PEG−protein conjugate *in vitro*, the improved bioavailability and reduced immunogenicity *in vivo* leads to a safer and more efficacious medicine. While PEGylation is clinically proven, it is not without limitation, and there are a variety of obstacles and pitfalls to overcome in the continued development of a novel PEGylated biopharmaceutical (*5*). To further improve the properties of polymer−protein conjugates, there is considerable ongoing effort on many different strategies. One strategy is to conjugate other biocompatible, water-soluble macromolecules to proteins. The water-soluble polymers derived from 2-methacryloyloxyethyl phosphorylcholine (MPC) **1** are well-known to be biocompatible.



1

Since its earliest reported synthesis in the late 1970s (*6*), the methacrylate-functional monomer, 2-methacryloyloxyethyl phosphorylcholine (MPC), has been the mainstay component used in the synthesis of phosphorylcholine-bearing polymers. These materials have been periodically reviewed with respect to their highly biocompatible nature and consequent application in the medical device field (*7*−*14*). They have found widespread commercialization as bulk materials for contact lenses (*15*, *16*), as coatings on a number of devices including coronary stents (*17*), extracorporeal circuits (*18*, *19*), guidewires (*20*), ureteric

stents and nephrostomy drains (*21*), and tympanostomy tubes (*22*), and as additives in contact lens solutions and cosmetic creams (*23*).

It was the use of MPC polymer (PMPC) coatings on coronary stents to deliver antirestenosis therapies in the bloodstream that demonstrated the potential of PMPC materials in the field of drug delivery (*24*−*36*). In recent years, there have been reports of the use of water-soluble copolymers of MPC for solubilization of drugs such as paclitaxel and amphotericin B (*37*−*39*). A variety of different nanocarrier systems based on PMPC have been described, including blended systems with other polymers such as PLA (*40*, *41*) and DNA complexing systems for gene delivery (*42*−*46*). Some systems have the ability to self-assemble into micelles (*47*, *48*) and polymersomes (*45*, *49*) with drug-carrying properties. Often, these polymers have been made by employing specialized methods of polymerization such as atom transfer radical polymerization (ATRP) (*50*−*53*) and reversible addition−fragmentation chain transfer (RAFT) (*54*) in order to afford more controlled polymer molecular weight distributions and architectures such as diblock copolymers, with low polydispersities.

Miyamoto *et al.* first reported the use of carboxyl-terminated PMPC and PEO polymers that were covalently conjugated to the enzyme papain and demonstrated that the polymers maintained the activity of the enzyme when stored for four weeks compared to native enzyme, the activity of which diminished within one week (*55*). In this case, the PMPC conjugate was more stable than the PEO analogue, with studies suggesting that PMPC induced a small change in the tertiary structure of the papain and inhibited self-digestion of the enzyme. Chiba *et al.* have made terpolymers containing PMPC, cationic DMAEA, and *p*-nitrophenylcarbonyloxyethyl methacrylate to conjugate to hepatitis B surface antigen for specific delivery of DNA to human hepatocytes (*56*). Similar terpolymers with BMA instead of DMAEA have been conjugated to interleukin-2 (IL-2) to target anticancer drugs to tumor cells expressing IL-2 receptors (*57*). Although there has been a very recent report on the use of end-functionalized PMPC for protein conjugation (*58*), there remains no reports on the conjugation of PMPC polymers to therapeutically relevant proteins in an effort to increase the plasma half-life *in vivo*. Since PMPC polymers have a long history of being biocompatible while also being structurally fundamentally different from PEG, it is appropriate to evaluate water-soluble PMPC polymers for therapeutic protein conjugation. Here, we describe the first such example, in which well-defined PMPC made *via* ATRP has been conjugated to interferon-α2a using a novel disulfide bridging linker, and its effects were evaluated in both *in vitro* bioassays and *in vivo* pharmacokinetic study.

MATERIALS AND METHODS

Materials. Reagents and solvents were purchased from either Sigma-Aldrich or Acros and used as received unless otherwise stated. Interferon-α2a (IFN) was purchased from Peprotech (cat. no. 300-02A). The HiLoad Superdex 200 prep grade (cat. no. 17-1069-01), PD-10 (Sephadex G-25 desalting, cat. no. 52-1308-00), HiTrap SP FF cation-exchange (cat no. 17-5054-01), and HiTrap Q FF anion-exchange (cat. no. 17-5053-01) columns were purchased from GE Healthcare. Phosphate buffered saline (PBS) for SEC analysis was prepared from tablets (Oxoid, cat. no. BR0014G). The water used for buffer preparation was deionized and of ultrapure grade I standard.

Instrumentation. Proton NMR experiments were performed on a 400 MHz Bruker NMR spectrometer at 298 K. Samples were prepared by dissolving approximately 10−20 mg of each sample in 0.75 mL of deuterated methanol, chloroform, or water.

The SEC system comprised a guard column and two Viscotek 7.8 mm × 30 cm $GMPW_{xl}$ columns connected to a Viscotek model 270 series dual detector (right-angle laser light scattering (RALLS) and viscometer) and a Viscotek VE 3580 RI detector. The three detectors together comprised the triple detection SEC system referred to herein. The equipment was calibrated using a PEG standard of Mw 21 450 (Polymer Laboratories). The SEC eluent that was used was either 0.2 M $NaNO_3$ with 10% acetonitrile or PBS at pH 7.3 using a flow rate of 0.7 mL/min. The triple detection SEC system was controlled using Viscotek *OmnicSEC 3.1* software. Samples were prepared at a concentration between 3 and 5 mg/mL in the eluent and filtered through 0.2 μm Anotop 10 filters (Whatman cat. no. 6809-1022). All samples were run in triplicate and the results averaged.

The d*n*/d*c* value used (0.142) for the MPC polymers was obtained from a sample of the polymer run at concentrations of 5, 4, 3, 2, and 1 mg/mL (from a stock solution of 80 mg PMPC in 4 mL buffer) on the triple detection SEC system. Conventional calibration was obtained using a set of PEG standards (Polymer Laboratories and Fluka) with Mp values of 167.7, 126.5, 82.3, 40.0, 19.2, and 12.3 kDa on the same SEC system.

The field flow fractionation system comprised a Wyatt Eclipse F separation system (350 μm thick channel; 10 000 MWCO regenerated cellulose membrane) and an Agilent 100 series autosampler running water (with 0.02% w/v azide) at 1 mL/min channel flow and 3 mL/min cross-flow. The analysis system comprised Wyatt DAWN EOS enhanced optical system and Wyatt Optilab DSP Interferometric refractometer. The system was controlled and data analyzed using Wyatt *ASTRA* software v 4.90.04. DAWN calibration was performed with toluene and normalization with BSA monomer.

General ATRP of PMPC Homopolymer Synthesis. The typical protocols of ATRP synthesis of PMPC homopolymers using ethyl 2-bromoisobutyrate, *N*-succinimidyl 2-bromo-2-methylpropionate **3**, Fmoc-protected 2-(2-aminoethoxy)ethyl 2-bromoisobutyrate, and bis-sulfide linker initiator **8** are given below.

Ethyl 2-bromoisobutyrate (0.25 g, 0.127 mmol, 1 equiv) was mixed with 10 mL methanol, and the mixture was subsequently purged with nitrogen over 30 min. Catalysts Cu(I)Br (18.2 mg, 0.127 mmol, 1 equiv) and 2,2′-bipyridine (39.7 mg, 0.254 mmol, 2 equiv) were added to the mixture under nitrogen, and the solution became dark brown immediately under stirring. Solid MPC (6.35 g, 2.16 mmol) was then added to the reaction mixture under nitrogen atmosphere, which followed a temperature increase of 2 to 3 °C due to exothermal polymerization. After 3 h, the reaction was stopped by exposure to air in order to oxidize Cu(I) to Cu(II), and with the addition of 50 mL methanol, the dark brown color of the solution became blue quickly. The blue solution was passed through a silica column to remove the copper catalyst, and the polymer was eluted by adding 150 mL of methanol. The collected solution was evaporated by rotary evaporation to remove methanol, and the colorless solid was further dried under vacuum for 20 h; mass = 6.00 g.

PMPC Bis-Sulfone 10 Synthesis. *(i) Synthesis of ATRP Initiator* **8.** A 50 mL round-bottom flask was charged with the succinimidyl ester bis-sulfide **6** prepared using the procedures already described (*59*) (1 g, 1.88 mmol, 1 equiv) . The flask was sealed with a septum and purged with argon for approximately 1 min. Anhydrous dichloromethane (100 mL) was then added and a solution allowed to form. To the stirred solution, neat 2-(2-aminoethoxy)ethanol (207 μL, 2.13 mmol, 1.13 equiv) was added dropwise and the resulting solution allowed to stir at RT overnight. Volatiles were then removed under vacuum to leave a sticky residue, which was immediately dissolved in ethyl acetate (50 mL). The resulting organic phase was washed with 3 × 30 mL of deionized water (the last 30

mL was acidified with several drops of 0.1 N HCl) and with a saturated brine solution (30 mL). The organic phase was then dried with magnesium sulfate, filtered under gravity, and the solvent removed under vacuum in a 100 mL round-bottom flask. The sticky residue afforded **7**, which was further dried in a vacuum oven at RT overnight and used without further purification. Accurate weighing of the material **7** in the drying flask was not possible, but it appeared to be of high yield and so was taken to be quantitative for the next step. The residue contained in the 100 mL round-bottom flask was sealed with a septum and placed in an argon atmosphere. Anhydrous dichloromethane (10 mL) was then added and a homogeneous solution allowed to form by stirring. Neat 2-bromoisobutyryl bromide (225 μL, 2.06 mmol, 1.1 equiv) was then added. Next, 4-dimethylaminopyridine (11 mg, 0.05 equiv) in dichloromethane (1 mL) was added and the resulting solution allowed to stir at RT overnight. The reaction solution was diluted with ethyl acetate (50 mL), transferred to a separating funnel, and washed in succession with deionized water (50 mL), 0.1 M sodium bicarbonate (15 mL), deionized water (15 mL), and finally with saturated brine (20 mL). The organic phase was dried with magnesium sulfate, filtered under gravity, and the volatiles removed under vacuum to leave a sticky product that was allowed to further dry in a vacuum oven at RT (0.7 g, 56% yield). Final purification was performed using dry flash chromatography. A no. 2 sintered glass funnel (4 cm diameter) was filled with approximately 3 cm depth of silica (BDH, code 153325P). A portion of the product (0.3 g) was dissolved in a small volume of dichloromethane and added to the silica. The column was then eluted with 25 mL portions of dichloromethane, ethyl acetate/hexane (1:2 v/v), ethyl acetate/hexane (1:1.5 v/v), and ethyl acetate/hexane (1:1 v/v). The elution of compounds was followed by TLC analysis (ethyl acetate/hexane 1:1 v/v, UV lamp detection) of the fractions obtained. The ethyl acetate/hexane (1:1.5 v/v) fractions were shown to contain the major product (Rf ~0.4), and these fractions were combined and the volatiles removed under vacuum to leave the desired product **8** (0.13 g). ^{1}H NMR: ($CDCl_3$) δ 1.89 (s, 6H, Ar-CH_3); 2.35 (s, 6H, $(CH3)_2CBr$); 3.19 (A2B2X, 4H, CH_2S); 3.69 (br m, 4H, OCH_2CH_2O); 3.76 (t, 2H, NCH_2CH_2O); 3.79 (m, 1H, COCH); 4.37 (t, 2H, CH_2N); (br s, 1H, NH); 7.06, 7.14 (AB q, 8H, SO_2Ar); 7.60, 7.74 (AB q, 4H, COAr). High resolution mass spectrometry analysis for $C_{33}H_{38}BrNO_5S_2$: theoretical masses should be to 2 sig figs at most (672.14).

(ii) Polymerization Using ATRP Initiator **8.** The bis-sulfide linker initiator **8** (120 mg, 0.18 mmol, 1 equiv) was dissolved in 7 mL methanol, and the mixture was purged with nitrogen over 30 min. After adding Cu(I)Br catalyst (25.8 mg, 0.18 mmol, 1 equiv) and bipyridine (56.2 mg, 0.36 mmol, 2 equiv), solid MPC monomer (3.68 g, 12.6 mmol) was added to the reaction mixture under nitrogen and the solution stirred for 16 h. The reaction was stopped by exposure to air and adding methanol (50 mL). The solution was then eluted through a silica plug (SiO_2 = 30 g) to remove catalyst, and 200 mL methanol was used to further elute the polymer. After solvent evaporation in a rotary evaporator in a 40 °C water bath, the polymer was further dried under vacuum overnight; mass = 3.50 g.

(iii) Fractionation of PMPC Bis-Sulfide **9** *and Oxidation to PMPC Bis-Sulfone* **10.** A solution of the crude PMPC bis-sulfide polymer in deionized water (150 mg/mL) was loaded (2.0 mL) onto a Superdex 200 column running with a pH 4.0, 20 mM sodium acetate mobile phase at 1 mL/min, and with UV detection at 280 nm. Fractions of elute were collected every 1 min during peak elution. Typically, three runs were performed and fractions 60−61, 61−62, and 62−63 min were combined since this was equivalent to the peak of 20 kDa PEG when run under the same conditions. The 9 mL obtained was then concentrated to approximately 2 mL using a 7 mL ICON centrifugal concentrator (MWCO 7000; Pierce). The sample was diluted to 6 mL using deionized water and then reconcentrated to about 1 mL. This step was then repeated.

The 1 mL of concentrated PMPC bis-sulfide in water was diluted with methanol (1 mL) and under stirring Oxone was added (7 mg). The 2 mL solution was then allowed to stir at RT overnight. The solution was then diluted to 2.5 mL with deionized water (0.5 mL) and loaded onto a PD-10 desalting column (pre-equilibrated with deionized water) to remove Oxone. After discarding the 2.5 mL of flowthrough, the column was eluted with a further 3.5 mL of deionized water and the eluent allowed to drip into 35 mL of ice-chilled acetone. The solid that precipitated was isolated by centrifugation (4000 rpm, 20 min) with the liquid phase decanted away and the solid dried under vacuum; mass = 27 mg.

Conjugation of PMPC-NHS 4 to IFN. Representative Procedure. To a 1 mL solution of IFN (1 mg/mL, PBS pH 7.7) was added PMPC-NHS ester **4** (192 mg) at RT. The mixture was vortexed for several seconds until homogeneous and then placed at 4 °C for 2 h. The reaction solution was then diluted with 3.2 mL of 25 mM sodium acetate buffer pH 4.0 (no NaCl) and loaded onto a pre-equilibrated 1 mL HiTrap SP FF column (collecting 1 mL load fractions L1 to L4; 0.2 mL for L5). Unreacted polymer was removed by washing the column with 10 mL of fresh buffer (collecting 1 mL wash fractions, W1 to W10). Protein species were then eluted with 10 mL of pH 4.0 acetate buffer containing 1 M NaCl (collecting 1 mL elution fractions E1 to E10). Two fractions containing the highest concentration of protein species (E1 and E2; A280 nm = 0.182 and 0.360, respectively) were combined and purified by SEC, collecting fractions every 1 min. Fractions were analyzed by SDS-PAGE for conjugation.

Conjugation of MPC Bis-Sulfone 10 to IFN; *in vivo* Sample Preparation Described. IFN (1 mg) was reconstituted with deionized water (1 mL) and reduced with the addition of dithiothreitol (DTT, 10 μL of a 0.4 M stock solution, 4 mM DTT final concentration) at RT for 30 min. The DTT was then removed and the buffer exchanged to PBS pH 8.2, 5 mM EDTA, using a PD-10 column pre-equilibrated with PBS pH 8.2, 5 mM EDTA. After loading the 1 mL of protein solution, the column was eluted with 5 mL of fresh buffer (collecting 1 mL elution fractions E1 to E5). Fractions E3 and E4 were identified as containing reduced protein by their A280 nm readings (typically 0.700 and 0.250, respectively) and were combined to give a 2 mL solution.

Five milligrams of the PMPC-bis-sulfone **10** was then added to the reduced IFN and the polymer allowed to dissolve with gentle shaking. The solution was then placed at 4 °C overnight. An oxidizing glutathione solution (50 μL; 1.5 mg reduced glutathione and 3.0 mg oxidized glutathione in 1 mL of PBS, pH 8.2) was then added and the solution incubated at 4 °C for further 48 h. The solution was then diluted to 2.5 mL with fresh buffer (0.5 mL) and buffer exchanged to 10 mM Tris, pH 8.0 (no NaCl), using a PD-10 column (3.5 mL solution resulting). A second batch of IFN was also PMPCylated as described (0.6 mg IFN, 2.5 mg PMPC-bis-sulfone). The two PMPCylated IFN solutions in 10 mM Tris were combined, and the polymer−protein conjugate was isolated by ion exchange chromatography followed by size-exclusion chromatography as described below.

For ion exchange, a 1 mL HiTrap Q FF anion-exchange column was equilibrated with 10 mM Tris buffer, pH 8.0 (no NaCl). The protein solution was loaded onto the column using a peristaltic pump and the filtrate collected as the load fraction. The column was then washed with 10 mL of fresh 10 mM Tris buffer to remove any unreacted PMPC polymer (collecting 1 mL wash fractions W1 to W10). The column was then eluted

with 5 mL of 10 mM Tris buffer containing 0.7 M NaCl to elute all protein species (collecting 1 mL elution fractions E1 to E5). The two fractions containing the highest concentration of protein species (E2 and E3; A280 nm = 0.799 and 0.166, respectively) were subsequently combined and purified by SEC in a single run (PBS pH 7.3). Fractions were collected every 1 min during the peak elution and stored immediately at 4 °C. Fractions 68−69, 69−70, 70−71, and 71−72 min were pooled to give the sample for *in vivo* evaluation.

SDS-PAGE. SDS-PAGE was carried out using either NuPAGE 4−12% or 12% Bis-Tris gels (1 mm, 10 or 12 wells, Invitrogen cat. nos. NP0321BOX and NP0342BOX, respectively). SeeBlue prestained molecular weight marker proteins (5 μL, Invitrogen cat. no. SEE50225) with an apparent mass range from 3 to 191 kDa were used for calibration. Aqueous solutions of polymers were prepared between 1 and 4 mg/mL. To a 20 μL sample of each polymer was added 5 μL of LDS running buffer (Invitrogen cat. no. 1191942). The resulting mixtures were vortexed, and between 10 and 25 μL of each was added to the appropriate well. The running conditions were 200 V for approximately 50 min in MOPS SDS running buffer (Invitrogen cat. no. 124555). After running, the gels were placed in a protein fixing solution of methanol/water/acetic acid 50: 40:10 v/v/v and stained using a colloidal blue stain (Invitrogen cat. no. 46-7015).

Quantification of Protein in PMPC Conjugates. The concentration of IFN in a pooled conjugate solution was determined by Micro BCA assay according to the manufacturer's instructions (Micro BCA assay kit, Pierce cat. no. 23235). Briefly, 150 μL of reagent was mixed with 150 μL of sample and incubated for 3 h at 37 °C. Absorbance was then measured at 570 nm. The concentration was determined after obtaining a standard curve from different concentrations of unconjugated IFN standard (see Supporting Information). The PMPC polymer on its own did not interfere with the Micro BCA assay.

Hemolysis. A 2-fold dilution series was made for each of the PMPC and PEG polymers (100 mg/mL stock in PBS) in RPMI 1640 media (with L-glutamine; Invitrogen cat. no. 21875-034) to give a range from 4 mg/mL to 31.25 μg/mL. To 96-well V-bottom tissue culture plates were added 100 μL of each dilution in duplicates. Triton-X (1%) was used as positive control. Red blood cells (RBCs) were prepared by layering 20 mL of single donor blood on 10 mL of Ficoll-Paque PLUS (GE Healthcare cat. no. 17-1440-02). After a 15 min centrifugation at 600 *g*, RBCs could be isolated as sediment. A 2% solution was prepared by diluting the RBC solution in RPMI 1640 media, then aliquoted into the sample plate (100 μL/well). After the desired incubation period at 37 °C (up to 3 h), the plates were centrifuged at 600 *g* for 10 min to sediment the RBCs. Following this, 100 μL of the supernatant fraction was carefully transferred to a new 96-well flat-bottom tissue culture plate, and the absorbance was measured at 490 nm using a spectrophotometer.

Western Blot Analysis. For the Western blot analysis, the SDS-PAGE gel following an electrophoresis step was assembled for a wet electroblotting and the resolved proteins transferred onto nitrocellulose membrane (Hybond ECL; GE Healthcare cat. no. RPN2020D). The condition used was 100 V for 1 h in transfer buffer (25 mM Tris, 192 mM glycine, 20% methanol). Cold packs and magnetic stirrer were used to dissipate heat generated during the transfer. After the transfer was complete, the membrane was blocked in 5% skimmed milk/TBST (10 mM Tris, 150 mM NaCl, 1% Tween 20) for 1 h at RT on a rocking platform, then briefly washed 5 times with TBST by agitation. Primary polyclonal anti-IFN-α rabbit antibody (R&D Systems cat. no. 31130-1) was then added at a dilution of 1:10 000 and was allowed to bind from overnight to 72 h at 4 °C on a rocking platform. Membrane was then washed for 15 min twice with TBST by agitation on a shaker. Secondary anti-rabbit HRP-conjugated antibody (GE Healthcare cat. no. NA934-1 ML) was added at a dilution of 1:10 000 and incubated for 1 h at RT on a rocking platform, and the membrane was subsequently washed by agitation with TBST twice at 15 min per wash. Bands containing IFN were identified and visualized by chemiluminescence using ECL reagent as per manufacturer's instruction (GE Healthcare cat. no. RPN2209) and by exposing the membrane onto an autoradiography film (Hyperfilm ECL; GE Healthcare cat. no. RPN1674K) in a dark room.

Antiviral Activity of PMPC-IFN. Antiviral activity of PMPC-IFN was analyzed using lung fibroblast cells, A549 (ECACC, cat. no. 86012804). A549 cells were cultured in DMEM media (high glucose with D-glucose; Invitrogen cat. no. 10938-025) supplemented with 10% fetal calf serum (FCS, EU approved, heat-inactivated; Invitrogen cat. no. 10108-165) and antibiotics (penicillin−streptomycin solution; Invitrogen cat. no. 15070-063). Before plating, cells were trypsinized and suspended at a concentration of 0.2×10^6 cells/mL. Cells were then plated at 50 μL/well on 96-well flat-bottom tissue culture plates and were allowed to adhere at 37 °C. On the following day, PMPC-IFN samples were diluted in DMEM/10% FCS at twice the desired concentration and added to wells (50 μL/well) in quadruplicate. After 24 h, media were removed and a working dilution of encephalomyocarditis virus (EMCV; LGC Promochem cat. no. VR-129B) was added to each well (50 μg/mL). The plates were then cultured until virus-induced cell death was observed. Media containing the virus was removed and the cells washed with PBS (300 μL/well) to remove cellular debris. Cells were then stained with 4% formaldehyde/0.1% methyl violet 2B (50 μL/well; Sigma-Aldrich cat. no. 19809-9) for 30 min. Stain was then removed by aspiration and the plates washed twice in PBS (300 μL/well). Solubilization of the stain was achieved by agitation with 10% SDS (50 μL/well) and the absorbance was measured at 570 nm using a spectrophotometer. If the absorbance exceeded the upper limit of detection, the stain was diluted by adding 150 μL of water into each well and subsequently removing 100 μL of solution. The optical densities were plotted against the IFN concentration and a curve fit was drawn using a nonlinear regression to determine the 50% effective dose (ED_{50}).

Antiproliferative Activity of PMPC-IFN. Antiproliferation activity of PMPC-IFN was measured in lymphoblast cells, Daudi (ECACC cat. no. 85011437). Daudi cells were cultured in RPMI 1640 supplemented with 10% FCS and antibiotics. For seeding, cells were suspended in 0.2×10^6 cells/mL and plated into 96-well U-bottom tissue culture plates at 20 000 cells/well (100 μL/well). PMPC-IFN samples were diluted in RPMI 1640/10% FCS at twice the desired concentration and 100 μL added to each well in quadruplicates. After 72 h, 20 μL of MTT (Sigma-Aldrich cat. no. M5655-1G; 5 mg/mL in RPMI 1640; filtered) was added to each well and incubated for 5 h at 37 °C. The plates were then centrifuged at 500 g for 10 min and the supernatant carefully removed. To each well was added 50 μL of DMSO (Sigma-Aldrich cat. no. 154938-2 L) and the solution agitated until the purple formazan crystals were completely dissolved. The solution was then transferred to a 96-well flat-bottom tissue culture plate for better optical uniformity, and the absorbance was measured at 570 nm using a spectrophotometer.

Pharmacokinetic Study of PMPC-IFN in Mice. The pharmacokinetic properties of PMPC-IFN were investigated in a mouse model using C57BL/6 mice. IFN (Roferon-A, Roche) and 40 kDa PEG-IFN (Pegasys, Roche) were also tested in parallel as references. The time courses were determined according to the published half-lives of IFN and PEGylated IFNs. Time points selected for IFN were 0.5, 1, 2, 4, 6, and

12 h post-injection and for PMPC-IFN and PEG-IFN the time points were 1, 2, 6, 12, 24, 48, and 72 h post-injection. For each time point, 5 mice were injected subcutaneously. At selected time points, mice were sacrificed and the serum collected by incubating the blood for 30 min at RT followed by centrifugation at 600 g for 10 min at 15 °C to sediment the blood cells. Serum samples were then stored at −80 °C until use. A fixed amount of two sets of pooled serum from 5 mice was assayed using an antiviral assay.

Data Analysis and Statistics. Data analyses were performed using GraphPad *Prism 5.0* software. All statistical values shown are expressed as mean ± SEM.

RESULTS AND DISCUSSION

PMPC Synthesis. It was first necessary to evaluate the properties of PMPC in comparison to PEG. We prepared a series of PMPC polymers with different molecular weights by ATRP using ethyl 2-bromoisobutyrate as the initiator and methanol as the solvent at RT. The ATRP of PMPC in methanolic medium is well-controlled, affording narrow molecular weight distributions (*51, 52*). The polydispersity (M_w/M_n) from conventional SEC and triple detection SEC in Table 1 suggest a controlled polymerization especially at low target DP, and the molecular weight of PMPC measured by conventional GPC was close to target molecular weight. However, with high target molecular weights (entries 4 and 5), the polymerization lost some control, which led to higher polydispersities, attributable to the fast conversion at increased monomer concentration (*51, 52*). The molecular weight from conventional GPC using PEG calibrant was significantly lower than the target at higher molecular weight (sample PMPC-3 and PMPC-4), a trend observed in the literature (*52*). The yield of PMPC polymers made by ATRP was high, above 90% within the period of 10 to 24 h.

The molecular weight characteristics of five PMPC polymers (batches PMPC-1 to PMPC-5; Table 1) were obtained by conventional SEC (using PEG calibrants) and by triple detection SEC for absolute molecular weight determination. All these PMPC polymers were soluble to at least 10 mg/mL in aqueous buffers between pH values of 4.0 to 7.3. The triple detection system comprised refractive index, light scattering (90°), and viscometry detectors, and the molecular weight characteristics were obtained using a d*n*/d*c* value of 0.142 (the value is almost the same as that reported in the literature (*39*), 0.142 for $PMPC_{96}-BMA_{76}$ at 632.8 nm). The molecular weight characteristics of PMPC-2 and PMPC-3 were also determined by field flow fractionation where M_n (M_w/M_n) values of 27.1 kDa (1.16) and 63.3 kDa (1.17) were obtained, respectively. Four commercial PEG samples (from 12 to 40 kDa) were used for comparison (Table 1).

As expected, the zwitterionic character of the PMPC polymers afforded a more compact conformation in aqueous solution compared to the more open solution conformation of PEG (*60, 61*). This can be seen by comparing the hydrodynamic radii between PMPC and PEG polymers of different absolute molecular weights (Table 1). The molecular weights (M_n) that were obtained by light scattering and by conventional SEC using PEG calibrants also illustrate the difference in PMPC and PEG solution conformations. Little change in PMPC hydrodynamic radii occurred when measured at 37 °C, suggesting that the more dense structure of PMPC could be maintained *in vivo*. More compact PMPC−protein conjugates might be expected to display different tissue uptake characteristics than that observed for their analogous PEG−protein conjugates. Ultimately, the maintenance of a smaller solution conformation of the conjugated polymer could be important to minimize the potential for accumulation of the polymer within the body. For example, the more dense structure of PMPC may result in different extravasation properties into malignant tissue when compared to PEG. Since the denser conformation of PMPC results in a lower viscosity than PEG of comparable solution size, this lower relative viscosity may have advantages in terms of dosing and avoiding safety issues of blood viscosity changes.

Initial Evaluation of PMPC for Protein Conjugation. Before examining PMPC conjugation to IFN, hemolysis assays were conducted with PMPC alone. No hemolysis was observed with any of the PMPC or control PEG polymers at concentrations up to 4 mg/mL for up to 3 h using blood from human donors. This is not surprising, given that PMPC polymers have been primarily developed for use within the body, particularly in applications where blood contact is required such as guidewires (*20*), stents (*17*), extracorporeal circuits (*18*), and blood filtration applications (*62, 63*).

PMPC polymers were compared to PEG using SDS-PAGE in conditions suitable for the analysis of PEG and IFN. Notably, there was no evidence of PMPC staining with the standard protein stains of colloidal blue and silver after background destaining. An increase in molecular weight of the protein bands after conjugation in SDS-PAGE would therefore be indicative of PMPC conjugation. When PEG is used for protein conjugation, the PEG is stained strongly with barium iodide and is slightly stained by colloidal blue and silver.

It was also necessary to determine the properties of PMPC elution over an ion-exchange column suitable for protein purification. Often, non-conjugated polymeric species that are uncharged such as unreacted PEG can be removed by ion-exchange chromatography during the purification of the charged protein−polymer conjugate. Since PMPC is zwitterionic, we were concerned that any unconjugated PMPC might be difficult to remove by ion-exchange chromatography in the presence of protein species. The loading of a 2.5 mg/mL solution of PMPC-2 (1 mL) in 20 mM sodium acetate at pH 4.0 to a cation-exchange column (SP FF) was followed by a 5 mL wash with the same buffer, and then 3 mL of acetate buffer, pH 4.0, with 1 M NaCl added was used to elute any remaining species bound to the

column. These conditions are often used to remove unreacted PEG, while the protein species are retained on the column until the application of the high salt elution buffer. By spotting the fractions collected on a TLC plate and staining with phosphomolybdic acid for detection, PMPC polymer was found to pass straight through the column in the loading fraction and low salt wash in the same manner as PEG, confirming that PMPC−protein conjugates would be suitable for purification by ion-exchange chromatography.

Preparation of Functional PMPC Polymers for Protein Conjugation. Many PEGylation reactions have been conducted by acylation of protein amines with PEG reagents that are functionalized at one terminus with an *N*-hydroxysuccinimide (NHS) active ester. Using the initiator **3** (*64*), we prepared the NHS-functionalized PMPC polymer **4** (Scheme 1). A linear relationship of the evolution of M_n *vs* conversion demonstrated that the polymerization had a living characteristic (unpublished data), and the relatively low polydispersities (PD 1.2−1.3) showed a controlled polymerization. However, the NHS functional group on the PMPC polymer was sensitive to hydrolysis due to the hygroscopicity of MPC monomer and polymer. Monitoring proton NMR spectra of the polymer indicated that the ratio of NHS and methyl group on PMPC backbone gradually decreased with storage, meaning a loss of the NHS functional group over time. The data in Table 2 shows that only half of the PMPC sample remained functionalized with the NHS groups at the time of conjugation.

A series of experiments were performed under different conditions, varying pH (6.5 to 8.0), NHS ester to protein equivalence (20 to 840), and reaction time (2 to 18 h). Although many different conditions were tried for the MPCylation of IFN using an PMPC-NHS ester, no evidence of conjugation was found by SDS-PAGE analysis. One reaction sample (pH 7.7) was purified by ion-exchange and then size-exclusion chromatography, but only non-conjugated IFN was observed after analyzing the chromatographic fractions by SDS-PAGE, which confirmed that the PMPC-NHS ester had not undergone reaction with IFN. Since proton NMR analysis of PMPC-NHS indicated that a significant proportion of the polymer was functionalized (49%), some conjugation was expected to be observed, given the sufficient excess that was used. The PMPC-NHS **4** was however shown to be reactive toward the small molecule benzylamine in methanol by the disappearance in the NMR spectrum of the diagnostic NHS ester methylene signals at 2.9 ppm. This suggests that the accessibility of the linker group on the relatively large PMPC polymer may be low toward large protein molecules in an aqueous environment. We also wanted to prepare a functional PMPC polymer capable of thiol-selective conjugation. Amine conjugation is less efficient and selective than thiol-based conjugation in mild conditions (i.e., pH 6.5 to 7.5) that are appropriate for maintaining the activity of most therapeutic proteins. Many therapeutically relevant proteins do not have accessible cysteines that can be used for conjugation, so amine conjugations have predominated. Since cysteines are found paired as disulfides in many therapeutically relevant proteins, we have recently prepared PEG reagents that are capable of site-specific conjugation to both sulfur atoms that derived from a disulfide bond (*59*−*67*). Such reagents are capable of exploiting the increased efficiency and selectivity of native thiols in proteins.

Our PEGylation reagents **5** have a substituted propenyl conjugating moiety that comprises an electron-withdrawing group (e.g., carbonyl), an α,β-unsaturated double bond, and α β′-sulfonyl group that is prone to elimination as sulfinic acid (Scheme 2). The electron-withdrawing group promotes thiol addition, and the conjugated double bond in the PEG monosulfone **5** is required to initiate a sequence of interactive and sequential addition−elimination reactions (Scheme 2). The addition of the first thiolate anion allows the elimination of a sulfinic acid derivative. This generates another conjugated double bond at the α,β′-position for the addition of a second thiolate. If the two thiols are derived from a disulfide bond, a three-carbon bridge is formed between the two cysteine sulfur atoms. This juxtaposition of chemical functionality leads to a latently cross-conjugated moiety capable of thermodynamically driven bis-alkylation with the two sulfur atoms that are liberated by the mild reduction of an accessible disulfide within a protein. This results in PEG conjugation *via* a three-carbon bridge that links the two original sulfur atoms (Scheme 2).

To avoid conducting a post-polymerization reaction that involved an acylation or alkylation reaction at the PMPC terminus, we elected to prepare an ATRP initiator that would provide the terminal bis-sulfone moiety (Scheme 3). Since the bis-sulfone end group can undergo *in situ* elimination of one sulfinyl moieties to give alkenyl monosulfones such as **5** (Scheme 2), the bis-sulfide initiator **8** (Scheme 3) was chosen, as it was more likely to be stable during the polymerization. The functionalized ATRP initiator **8** was prepared in two steps from the NHS activated bis-sulfide **6** with an overall crude yield of 55%. After purification, the initiator **8** was used in the ATRP conditions to give the PMPC bis-sulfide **9**. The bis-sulfide initiator is soluble in methanol and stable under the condition of ATRP and purification. The polymerization of MPC initiated by **8** followed the general protocol; copper(I) catalyst was mixed with nitrogen-purged methanol solution of initiator **8** first, followed by the addition of MPC powder. It is observed that the bis-sulfide functional group on α-bromoester has no remarkable effect on the initiation of ATRP of MPC, which was fast and showed controlled polymerization (PD 1.2−1.4), compared to other initiators used in this study, such as ethyl 2-bromoisobutyrate, *N*-succinimidyl 2-bromo-2-methylpropionate **3** (*64*), and Fmoc-protected 2-(2-aminoethoxyl)ethyl 2-bromoisobutyrate (*68*). The PMPC bis-sulfide terminated polymers **9** were prepared with number average molecular weights ranging from approximately 20 to 50 kDa as determined by triple detection SEC (Table 3).

The bis-sulfide polymers **9** displayed narrow molecular weight distributions with polydispersities (M_w/M_n) that ranged from 1.2 to 1.4. These are the expected values for polymers that are prepared from a controlled radical polymerization reaction. PEG, however, has been prepared over many decades and is routinely

available at polydispersities of less than 1.1 for molecular weights less than 40 kDa.

To improve homogeneity during conjugate preparation and characterization, it was decided to fractionate the PMPC bis-sulfide polymer **9** to reduce the polydispersity. Our initial experiments were conducted by running PMPC bis-sulfide batches **9c** and **9d** (2 mL of 85 to 150 mg/mL solutions loaded) separately over a Superdex 200 size-exclusion column with HPLC-grade water as the mobile phase (1 mL/min). The UV absorbance at 280 nm was used to detect the polymer, and 1 mL fractions were collected separately every minute during peak elution. Some of the fractions from both the **9c** and **9d** fractionations were then pooled into three batches (fractions 60−67 min, 68−75 min, and 82−85 min) and their molecular weight characteristics determined by triple detection SEC analysis (Table 4). The polydispersities of all three pooled samples were between 1.13 and 1.17, compared to 1.19 to 1.24

before fractionation. Combining a select fraction (**4** from **8**) from **11c** fractionation only did not lead to a reduction in polydispersity (Table 4). Later fractionations of PMPC were performed using a mobile phase of 20 mM sodium acetate at pH 4.0 to minimize any pH-related conformational changes in the polymer and to minimize the resulting polydispersities. We found that the retention times of the fractionated samples when rerun on the SEC column were reproducible under these conditions after oxidation of the end group to the bis-sulfone **12** form (Table

Table 5. Reproducible Retention Times of PMPC Bis-Sulfone 10 That Was Fractionated as PMPC Bis-Sulfone 10 Using a Superdex 200 Column at pH 4.0 with Sodium Acetate Buffer and Comparison with 20 kDa and 30 kDa PEG

5). In a further fractionation, the retention times of 20 and 30 kDa PEG polymers ($M_w/M_n = 1.12$) were used (Table 5) to decide which PMPC fractions to pool so that a comparison with PEG could be made after protein conjugation. To prepare PMPC for the conjugation to IFN for the *in vivo* study, the fractions from 60−61, 61−62, and 62−63 min were combined. This is equivalent to the peak elution when 20 kDa PEG is run under the same condition, which indicates an equivalence of hydrodynamic volume of PMPC to that of a 20 kDa PEG. It should be noted that we were further able to fractionate the resulting PMPC-IFN conjugates using the same method during conjugate purification (i.e., by SEC on the Superdex 200 column).

Treatment of the PMPC bis-sulfide **9** overnight with the mild oxidant Oxone gave the desired PMPC bis-sulfone **10** with no trace of the starting bis-sulfide of **9** when analyzed by proton NMR (see Supporting Information). The MPC pendant group signals in the NMR spectrum were consistent with the starting compound and were therefore thought to be unaffected by the oxidation.

PMPC Bis-Sulfone 10 Conjugation to IFN. To utilize the PMPC bis-sulfone **10** for protein conjugation first requires that an accessible disulfide bond in the protein is reduced to give the two free sulfhydrals. Initial conjugations to IFN were thus performed after reducing both of the disulfide bonds of IFN using 4 mM DTT. Following the removal of DTT using a pre-equilibrated PD-10 column, PMPC was added in increasing amounts (4.6 to 12.8:1 PMPC/IFN by mass) to the reduced IFN. Conjugation was performed at pH 8.2 for *in situ* generation of the protein thiol reactive monosulfone from the bis-sulfone **10** added to the conjugation. The reaction solutions were analyzed by SDS-PAGE (Figure 1), which showed two tight bands at high molecular weight. These were attributable to the mono- and di-PMPCylated IFN. Unreacted IFN was also observed in these gels. The relative intensities of the conjugated proteins indicated that the reaction was moderately efficient. Also, increasing the amount of PMPC afforded greater yields of mono- and di-PMPCylated protein.

Mono-PMPC-IFN could be isolated from the reaction mixture using anion-exchange chromatography followed by size-exclusion chromatography (Figures 2 and 3, respectively). The PMPC-IFN bound to the HiTrap Q FF anion-exchange column (elution with 0.05 M NaCl) but less well than the non-conjugated protein (elution with 0.15 to 0.7 M NaCl) due to changes in surface charge density post-polymer conjugation. Similarly to

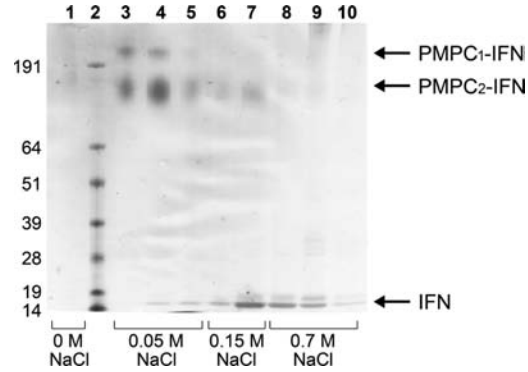

Figure 2. SDS-PAGE gel of anion-exchange chromatography fractions showing a typical purification of a PMPC-IFN reaction.

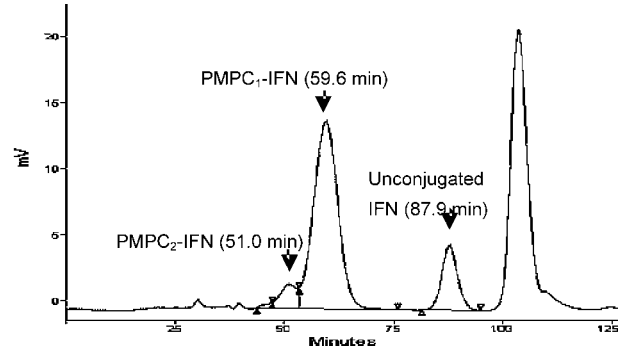

Figure 3. Representative size-exclusion chromatogram showing isolation the mono-PMPC-IFN. Column, HiLoad 16/60 Superdex 200 prep grade; mobile phase, PBS pH 7.3, 250 mM NaCl, 1.0 mL per min; A280 nm detection.

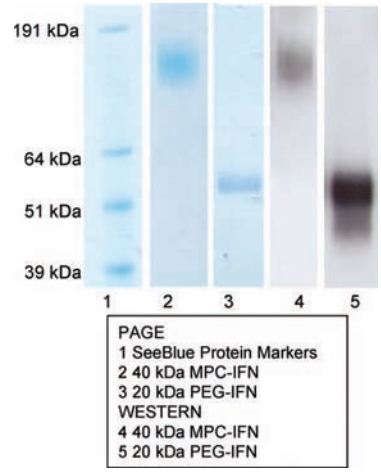

Figure 4. SDS-PAGE and Anti-IFN Western blot for *in vivo* PMPC-IFN candidate (lanes 2 and 3) and comparison with the 20 kDa disulfide bond PEG-IFN (lanes 4 and 5).

PEGylation, this difference was exploited for an effective separation of the two protein species as well as unreacted PMPC for the chromatography step. To ensure that all of the unreacted IFN was removed from the product, a second purification step was performed using size-exclusion chromatography. Fractions were collected every minute (Figure 3), and those fractions forming the peak for mono-PMPC-IFN were then pooled for further study.

SDS-PAGE and Western blot analysis using a polyclonal anti-IFN-α antibody was performed on the purified PMPC-IFN and compared to the 20 kDa PEG-IFN prepared by the same disulfide bond conjugation method (Figure 4). In both methods,

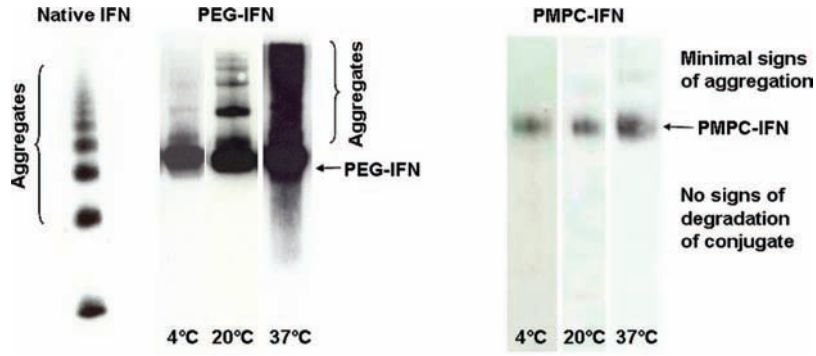

Figure 5. Stability of PEG-IFN (left) and PMPC-IFN (right) after 7 days at 4, 20, and 37 °C. PMPC-IFN shows high resistance toward self-aggregation. Of note, PMPC-IFN required longer incubation with anti-IFN antibody than PEG-IFN.

Table 6. Antiviral and Antiproliferative Activity of 20 kDa PEG-IFN, 20 kDa PEG equivalent PMPC-IFN, and 40 kDa PEG-IFN (Pegasys)

conjugates	ED_{50} (pg/mL)	IFN activity (%)
	Antiviral Activity	
IFN	12 ± 1	100

Pegasys[c]	7.4 ± 0.2	>50	16 ± 4

[a] No data point before 0.5 h. [b] Literature value (*2*). [c] In agreement with literature.

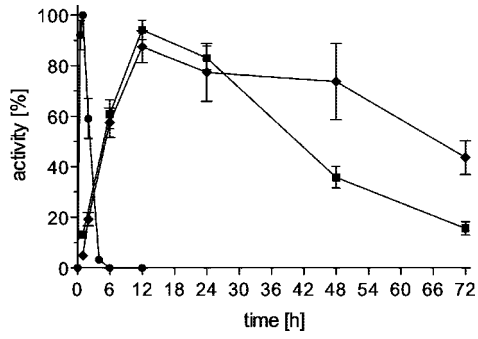

Figure 6. Pharmacokinetic profiles of IFN (●), 40 kDa PEG-IFN (◆), and 20 kDa PEG equivalent PMPC-IFN (■). Percentage activity of IFN, PEG-IFN, and PMPC-IFN was measured from their respective maximal activity.

purified PMPC-IFN was shown as a single high molecular weight band with no detectable free unconjugated IFN present. Of note, optimal detection of PMPC-IFN by Western blot required an incubation time with primary antibody of at least 72 h compared to that of PEG-IFN, which required 24 h. Furthermore, the migration distance of PMPC-IFN was less than that of the PEG-IFN conjugate of equivalent hydrodynamic volume. Given the property of the PMPC polymer to form a much more compact structure than the PEG of equivalent size in aqueous condition, the greater retention seen with the PMPC-IFN is likely due to the much greater size of the unravelled PMPC polymer in the presence of SDS.

Native IFN is known to aggregate over time if not stored correctly. Both the PEG and PMPC-IFN conjugates were stored at 4, 20, and 37 °C for one week and Western blot analysis performed (Figure 5). The PEG-IFN showed minimal aggregation at 4 °C, but severe aggregation at 20 and 37 °C. Notwithstanding the lower intensity of staining for the PMPC-IFN due to the increased resistance toward antibody binding, there was little suggestion of aggregation and no signs of degradation across all storage temperatures. This is indicative of an increased stability of the PMPC-IFN conjugate relative to the PEG-IFN and native protein.

Antiviral and Antiproliferative Activity of PMPC-IFN. We evaluated the *in vitro* antiviral and antiproliferative activities of the 20 kDa PEG equivalent PMPC-IFN and compared them against native IFN and 20 kDa PEG-IFN. EMCV and A549 cells for the antiviral assay and Daudi cells for proliferative assay were used (*69*). The ED_{50} values for the assays are shown in Table 6. The results for PMPC-IFN and PEG-IFN show a significant reduction in both activities compared to the native IFN. This is due to steric shielding by PEG or PMPC that is also seen with commercially available PEGylated IFNs and many other PEGylated proteins (*1*) as well as contribution by the linker that is inserted at the disulfide (*66*). Notably, the PMPC-IFN conjugate showed similar activities to the 20 kDa PEG-IFN, which shares the same hydrodynamic volume, in both assays (18.1% and 16.1% for antiviral, respectively; 3.2% and 3.9% for antiproliferative, respectively). Contrary to the Western blot results where IFN-specific antibody showed a markedly reduced detection of PMPC-IFN compared to PEG-IFN, the two *in vitro* assays both suggest that the degree of steric hindrance imposed by PMPC and PEG on protein−receptor interaction are similar at least in terms of their ability to trigger downstream immunological responses.

Pharmacokinetic Study of PMPC-IFN. The pharmacokinetic properties of a 20 kDa PEG equivalent PMPC-IFN were evaluated and compared to those of commercially available IFN-α2a (Roferon-A) and 40 kDa PEG-IFN-α2a (Pegasys) and the absorption and elimination half-life ($t_{1/2}$) determined in a mouse model. The representative absorption and elimination half-lives of IFN, 20 kDa PEG equivalent PMPC-IFN, and 40 kDa PEG-IFN are shown in Figure 6, and the average values presented in Table 7. A commercial formulation of IFN (Roferon-A) showed a mean elimination half-life of 0.8 h. An accurate absorption half-life could not be measured, as no ascending trend was seen within the time points tested indicating its entry into bloodstream within 30 min of subcutaneous injection. The commercial formulation of 40 kDa PEG-IFN (Pegasys) showed a mean absorption half-life of 7.4 h. Elimination half-life was measured as >50 h, as two out of three $t_{1/2}$ values exceeded the range of

time course tested in this study (>60 h). Similarly, the mean absorption and elimination half-lives of 20 kDa PEG equivalent PMPC-IFN showed a substantial extension of blood retention time over that of unconjugated IFN (7.3 and 24 h, respectively). This compares favorably to both IFN (<1 h) and the published value of 12 h for 20 kDa disulfide bond PEGylated IFN (*66*). Alternatively, similar $t_{1/2}$ values were also obtained when the data points from individual data sets were pooled to obtain a combined pharmacokinetic profile.

Taken together, these results clearly indicate that the conjugation of PMPC to IFN leads to a substantial extension in the elimination half-life of IFN. Surprisingly, despite their equivalent solution size, the extension of half-life observed for a 20 kDa PEG equivalent PMPC-IFN was greater than that reported for a 20 kDa disulfide PEGylated IFN. Together with the indication that the PMPCylated IFN is able to retain similar biological activity to its PEGylated equivalent while providing improved protein shielding from IFN-specific antibodies over PEG, these results demonstrate potentially novel properties of PMPC polymer in addition and complementary to the pharmacokinetic improvements to conjugated therapeutic agents.

CONCLUSIONS

IFN can be successfully conjugated with high efficiency to the biocompatible PMPC polymer. Compared to PEG of an equivalent mass, PMPC forms a more compact conformation in aqueous solution. At equivalent hydrodynamic size (20 kDa), this has enabled us to conjugate a dense polymer to IFN, which presented different properties to IFN conjugated with a more flexible PEG. The PMPC-IFN showed remarkable resilience to IFN-specific antibody in the Western blot analysis using a polyclonal anti-IFN antibody compared to PEG-IFN and IFN. While this is not a definitive endeavor to assess the effect of PMPC on immunogenicity, it is a crude indication of how effective PMPC may be on shielding immunogenic epitopes. Considering the dense nature of PMPC compared to PEG, it is also interesting that in the antiviral and antiproliferative assays PMPC-IFN demonstrated a similar potency to PEG-IFN of an equivalent hydrodynamic size. This strongly indicates that the physiological differences between the two biocompatible polymers do not affect their ability to trigger the two immune responses. In the *in vivo* pharmacokinetic study, the absorption half-life for PMPC-IFN was considerably extended compared to the native IFN and also to its disulfide-conjugated PEG analogue reported by Shaunak et al. (*66*), and similar to that of the reference 40 kDa PEG-IFN formulation. This is also consistent with the SDS-PAGE result where an apparent reduction in mobility through a hydrated medium (tissue or gel) was observed. There was also a marked increase in the elimination half-life for PMPC-IFN compared to the native IFN. The $t_{1/2}$ value placed the PMPC-IFN between 20 kDa PEG-IFN and the reference 40 kDa PEG-IFN in its ability to remain in the bloodstream. These results suggest that the tissue migration of the PMPC-IFN occurs more slowly than the 20 kDa PEG-IFN despite their similarity in hydrodynamic volume, leading to an improved depot effect in the tissue and a subsequent longer elimination half-life. Taken together, this work demonstrates a potential for PMPCylation of therapeutic proteins as a novel tool for modifying their *in vivo* characteristics in ways that are similar to PEGylation while offering improved pharmacokinetic enhancement and epitope masking.

ACKNOWLEDGMENT

The authors would like to thank Dr. Christine Wallrapp of CellMed AG for her help in the preclinical study.

Polyelectrolyte complex (PEC) micelles modified with cancer cell targeting moieties were prepared for intracellular delivery of vascular endothelial growth factor (VEGF) small interfering RNA (siRNA). A luteinizing hormone-releasing hormone (LHRH) peptide analogue was coupled as a cancer targeting ligand to the distal end of the poly(ethylene glycol) (PEG)−siRNA conjugate. The siRNA-PEG-LHRH conjugate self-assembled to form nanosized PEC micelles upon mixing with poly(ethylenimine) (PEI) via ionic interactions. The PEC micelles showed spherical morphology with a hydrodynamic diameter of ca. 150 nm. For LHRH receptor overexpressing ovarian cancer cells (A2780), the PEC micelles with LHRH exhibited enhanced cellular uptake compared to those without LHRH, resulting in increased VEGF gene silencing efficiency via receptor-mediated endocytosis. This study showed that PEC micelles decorated with specific cell-recognizable targeting ligands could be used for targeted delivery of siRNA.

INTRODUCTION

RNA interference (RNAi) induced by small interfering RNA (siRNA) has recently been recognized as a potential therapeutic tool for silencing genes linked to human diseases (*1*, *2*). High sequence specificity and relatively small dose requirement of siRNA make it even more attractive to use RNAi technology for treatment of various diseases including cancer (*3*, *4*). Despite high therapeutic potentials of siRNAs, critical delivery problems remain to be solved for clinical applications (*5*). The most challenging hurdles in siRNA delivery are serum instability of siRNA during circulation in the bloodstream, poor cellular uptake, and limitation in targeted delivery to specific tissues or cells. To address such problems, various delivery systems, including cationic lipids (*6*, *7*), cationic polymers and peptides (*8*−*10*), viral vectors (*11*), and varied modified siRNA (*12*), have been introduced.

In our previous studies, we showed the possibility of using a polyelectrolyte complex (PEC) micelle-based siRNA delivery system in a systemic cancer therapy (*13*). The PEC micelles are composed of two essential components, PEG-conjugated siRNA (siRNA-PEG) and a polycation, polyethylenimine (PEI). The siRNA−PEG conjugate was covalently coupled via a disulfide linkage, which can be reduced to release intact siRNA in the reductive cytosolic condition. The PEC micelles can be self-assembled to form a core−shell structure via electrostatic interactions between the two oppositely charged polyelectrolytes of siRNA and PEI, resulting in the formation of an insoluble core. At the same time, the siRNA/PEI inner core can be stabilized by the PEG chains exposed on the surface. The distinctive core−shell structure confers stability on PEC micelles in the bloodstream, possibly leading to prolonged circulation. The PEG shell layer could sterically shield the polyelectrolyte complex core from accessibility of serum proteins, thereby protecting the PEC micelles from aggregation and enzymatic degradation of siRNA. In addition, owing to their small size (<150 nm), the PEC micelles can be passively localized to tumor sites through loosened tight junctions of endothelium in the vicinity of highly proliferative cancer cells (*13*). Extended retention of the micelles is also expected due to lack of lymphatic drainage in solid tumors (enhanced permeation and retention effect, EPR). The delivery systems based on VEGF siRNA-PEG/PEI PEC micelles showed dramatic target gene silencing and retardation of tumor growth in cancer xenografted animal models, when administered locally and systemically.

Cell-specific ligands, including antibodies, sugar molecules, vitamins, and hormones, have been popularly employed to confer tissue- or cell-specificity on gene carriers (*14*, *15*). Specific interaction between a targeting ligand and its cellular receptor generally enhances the cellular uptake of gene carriers by a mechanism called receptor-mediated endocytosis. Therefore, increasing specific cellular uptake by targeted gene delivery can significantly improve therapeutic efficacy with a much lower dose (*5*, *16*, *17*). In this study, cell-specific targeting property was added to the PEC micellar delivery system by employing luteinizing hormone releasing hormone (LHRH) as a cancer targeting moiety (Figure 1). The PEC micelle-based cancer targeting system for VEGF siRNA was demonstrated.

EXPERIMENTAL PROCEDURES

Materials. A peptide analogue of LHRH was synthesized and purified by Peptron Inc. (Daejeon, South Korea). The modified sequence of LHRH peptide was Gln-His-Trp-Ser-Tyr-DLys-Leu-Arg-Pro (MW 1196) with N-terminal pyroglutamation and C-terminal amidation, often referred to as Leuprolide Acetate in the literature (*18*−*20*). A heterofunctional poly(eth-

ylene glycol) (NH_2-PEG-COOH, MW 3400) derivative and methoxy-PEG with a sulfhydryl group (mPEG-SH, MW 3400) were obtained from Nektar (Huntsville, AL). *N*-Succinimidyl-3-(2-pyridyldithio)propionate (SPDP) was purchased from Pierce (Rockford, IL). Branched poly(ethylenimine) (PEI, MW 25 000), 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC), and dithiothreitol (DTT) were obtained from Sigma-Aldrich (St. Louis, MO). A human VEGF siRNA was supplied from Qiagen Inc. (Valencia, CA). A synthetic VEGF siRNA has a sense strand (5′-GAGUACCCUGAUGAGAUCdTdT-3′) modified with or without 3′-hexylamine and an antisense strand (5′-GAUCUCAUCAGGGUACUCCdTdT-3′). For FACS analysis and confocal microscopy, the 5′-end of the sense strand of VEGF siRNA was further modified with indocarbocyanine dye (Cy3) (Dharmacon Research, Lafayette, CO). Fetal bovine serum (FBS) and Roswell Park Memorial Institute 1640 medium (RPMI 1640) were obtained from Gibco BRL (Grand Island, NY). All other chemicals and reagents were of analytical grade and used without further purification.

Preparation of siRNA-PEG-LHRH Conjugate. siRNA−PEG conjugate with a disulfide bond (siRNA-s-s-PEG) was prepared according to the previous methods (*9, 13*). siRNA-PEG-LHRH conjugate was synthesized with the modified procedure (Figure 2A). To synthesize sulfhydryl-PEG-LHRH, the α-amino group of NH_2-PEG-COOH (17 mg, 5 μmol) in PBS solution (1 mL, pH 7.5) was first activated with SPDP (15.6 mg, 50 μmol) dissolved in DMSO (50 μL) at room temperature. After 1 h reaction, unreacted SPDP was removed during dialysis against deionized water (MWCO 2000). The terminal carboxyl group of 2-pyridyl disulfide-PEG-COOH derivative was then conjugated to the ε-amino group of a lysine residue in LHRH peptide (12 mg, 10 μmol) with EDC (9.6 mg, 50 μmol) in a final volume of 5 mL PBS solution at room temperature overnight. The medium pH was maintained in the range of 5−6 by adding HCl. Four hundred micrograms of DTT (50 mM) was then added to the reaction solution and incubated for 3 h, followed by dialysis (MWCO 2000) against deionized water and then lyophilized. To conjugate the sulfhydryl-PEG-LHRH segment to siRNA via a disulfide bond, the siRNA−2-pyridyl disulfide conjugate was first prepared on the basis of the previous studies (*7, 12*). The 2-pyridyl disulfide activated siRNA (300 μg, 20 nmol) was reacted with sulfhydryl-PEG-LHRH conjugate (1 mg, 200 nmol) in PBS solution (pH 7.5) at room temperature for 24 h. Unreacted siRNA or PEG molecules were removed by extensive dialysis against deionized and distilled water (MWCO 10 000). The siRNA-PEG-LHRH conjugate was concentrated using a speed vacuum pump and adjusted to a concentration of 0.5 mg/mL in deionized water.

Characterization of siRNA-PEG-LHRH Conjugate and siRNA-PEG-LHRH/PEI PEC Micelles. Each reaction step was evaluated with various analytical methods including mass and size analysis. PEG-LHRH conjugate, PEG (NH_2-$PEG_{3,400}$-COOH), and sulfhydryl-$PEG_{3,400}$-LHRH were analyzed by MALDI-TOF (Kratos AXIMA-LNR) mass spectrometry. 3-Hydroxypicolinic acid (HPA) used as a matrix was dissolved in deionized water at a concentration of 0.05 M. Ammonium citrate (0.05 M) was added to the matrix solution (HPA/ammonium citrate = 8:1). The sample was dissolved in water at a concentration of 0.5 mM. The sample (50 μL) and the matrix solution (50 μL) were mixed and the resulting mixture (1 μL) was placed on the MALDI plate. The sample crystallization was carried out by a rapid solvent evaporation method. The siRNA-PEG-LHRH conjugate and other substrates (naked siRNA, sulfhydryl-PEG-LHRH, and LHRH) were analyzed by high-performance size-exclusion chromatography (HPLC-SEC, Waters 510 HPLC pump system) with UV detection at 280 nm. Samples were loaded into Shodex protein KW-800 column (Showa Denko, Japan). The mobile phase was composed of 50 mM NaCl and 50 mM Tris-HCl (pH 8.0) and the flow rate was fixed at 1.0 mL/min.

Gel mobility retardation assay was performed to analyze and isolate the synthesized siRNA-PEG-LHRH conjugate. To confirm the cleavage of the disulfide bond between siRNA and PEG segment in a simulated intracellular environment, 1 μg of siRNA-PEG-LHRH or siRNA-PEG was incubated in 50 μL RPMI 1640 media with or without 10 mM glutathione (GSH) for 2 h at 37 °C. The cleaved siRNA and siRNA conjugate (siRNA-PEG and siRNA-PEG-LHRH) were run on 2% agarose gel and visualized with ethidium bromide staining. The siRNA-PEG-LHRH/PEI PEC micelles were formed by mixing the siRNA-PEG-LHRH conjugate with PEI in PBS solution (pH 7.2) at an N/P ratio of 12 and stabilizing the mixing solution for 15 min at room temperature (Figure 1). The particle size and morphology of siRNA-PEG-LHRH/PEI PEC micelles were observed by atomic force microscope (PSIA XE-100 AFM system, separated $x-y$ and z scanner, scan size 50 × 50 μm^2). The sample solution was loaded on a freshly cleaved mica surface and dried in a vacuum oven at room temperature. AFM image was taken from a 2.5 × 2.5 μm^2 area. The particle size distribution of siRNA-PEG-LHRH/PEI PEC micelles was evaluated by using a dynamic light scattering (DLS) instrument (Zeta-Plus, Brookhaven, New York).

Cells and Cell Culture. Human ovarian carcinoma A2780 cells (LHRH receptor positive cancer cell line) were obtained from American type Culture Collection (ATCC). Human ovarian cancer SK-OV-3 cells (LHRH receptor negative cancer cell line) were purchased from the Korean Cell Line Bank (KCLB, Seoul, Korea). Cells were cultured in RPMI 1640 medium supplemented with 10% fetal bovine serum at 37 °C in a humidified atmosphere of 5% of CO_2. Cells were reseeded 24 h before cell transfection experiments.

Cellular Uptake of siRNA-PEG-LHRH/PEI PEC Micelles. To visualize the LHRH receptor-mediated cellular uptake of siRNA-PEG-LHRH/PEI PEC micelles by confocal microscopy and FACS analysis, red fluorophore Cy3-labeled siRNA and siRNA conjugates (siRNA-PEG and siRNA-PEG-LHRH)

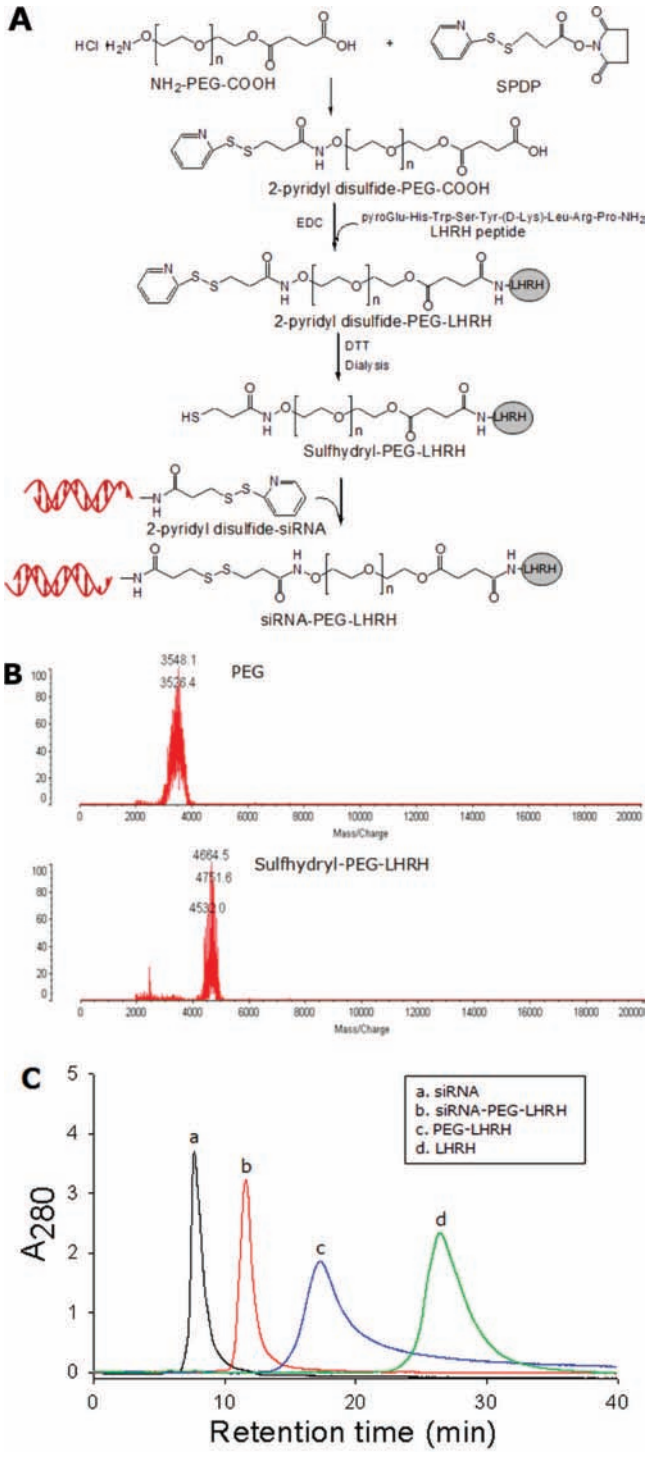

Figure 2. (A) Synthetic scheme of siRNA-PEG-LHRH conjugate containing a disulfide linkage between siRNA and PEG. (B) MALDI-TOF MS spectra for $PEG_{3,400}$ (upper panel) and sulfhydryl-$PEG_{3,400}$-LHRH (lower panel). (C) HPLC-SEC analysis of naked siRNA, siRNA-PEG-LHRH, sulfhydryl-PEG-LHRH, and LHRH peptide.

were utilized. For confocal microscopy, A2780 cells were incubated in a cell culture chamber slide at a density of 1×10^4 cells per well in 10% FBS containing RPMI 1640 medium for 24 h at 37 °C. After replacement of the culture medium, the cells were transfected with PEI complexes of siRNA, siRNA-PEG, and siRNA-PEG-LHRH at an N/P ratio of 16, which has been already optimized in our previous work (*6*, *7*). Thirty picomoles of various siRNA formulations was loaded into the medium per well. The cells were incubated for 1 h, washed three times with cold PBS solution, and fixed with 1% (w/v) *p*-formaldehyde solution. The slides were covered with a mounting solution (SuperMount, InnoGenex, San Ramon, CA). The cells were imaged by confocal laser scanning microscope (LSM 510, Carl-Zeiss Inc., USA) with a 543 nm helium−neon laser. To investigate LHRH receptor-targeted delivery of siRNA using FACS, the cells cultured in a 6-well plate (3.0×10^5 cells/well) were transfected with 30 nM siRNA and siRNA conjugates (siRNA-PEG and siRNA-PEG-LHRH), which were complexed with PEI (0.93 μg) at an N/P ratio of 16. For the LHRH ligand competition assay, free LHRH agonist (1 μM) was added to the transfection medium 30 min before the treatment of siRNA-PEG-LHRH/PEI PEC micelles. The harvested cells were fixed in 0.5% (w/v) *p*-formaldehyde solution. The extents of intracellular uptake of various siRNA formulations were monitored by flow cytometry (FACScan, Becton Dickinson) using *CELLQUEST* software (PharMingen).

RT-PCR Analysis. Reverse transcriptase-polymerase chain reaction (RT-PCR) analysis was performed to estimate the expression level of LHRH receptor in human ovarian cancer A2780 and SK-OV-3 cells. Total RNA was extracted from the cells (5×10^6) using RNeasy Mini Kit (Qiagen, Valencia, CA) according to the protocol supplied by the manufacturer, and the treatment with the RNase-Free DNase Set (Qiagen, Valencia, CA) was subsequently performed. One microgram of total RNA harvested from the cells was subjected to RT-PCR using SuperScript III One-Step RT-PCR System with Platinum Taq DNA Polymerase (Invitrogen, Carlsbad, CA). The primer sequences used were as follows: LHRH primer sequences (forward, 5′-GACCTTGTCTGGAAAGATCC-3′; reverse, 5′-CAGGCTGATCACCACCATCA-3′) and human $\beta\beta_2$-microglobulin (internal standard) primer sequences (forward, 5′-ACCCCCACTGAAAAAGATGA-3′; reverse, 5′-A TCTTC-AAACCTCCATGATG-3′). The PCR primers were supplied from Bioneer Co. (Daejeon, South Korea). Reverse transcription was performed at 45 °C for 60 min for the synthesis of cDNA followed by 5 min of incubation at 95 °C for the denaturation of DNA−RNA heteroduplexes. The following condition of thermal cycling was used for amplification: PCR amplification, 28 cycles at 94 °C for 1 min, at 55 °C for 50 s, and at 72 °C for 1 min; final extension, 1 cycle at 60 °C for 10 min. The PCR products were analyzed by 0.8% agarose gel electrophoresis and visualized by staining with ethidium bromide. The PCR products for LHRH receptor and human β_2-microglobulin were 319 bp and 114 bp in length, respectively.

LHRH Receptor-Mediated VEGF Gene Suppression by siRNA-PEG-LHRH/PEI PEC Micelles. Two types of human ovarian carcinoma cell lines were used to investigate LHRH receptor-mediated VEGF gene silencing. A2780 (LHRH receptor-overexpressing cell line) and SK-OV-3 (LHRH receptor-deficient cell line) were seeded in a 6-well plate at a density of 3.0×10^5 cells per well and incubated for 24 h prior to transfection experiment. The medium was replaced with a fresh one containing 50 nM siRNA formulations (siRNA-PEG/PEI and siRNA-PEG-LHRH/PEI) and incubated for 4 h at 37 °C. After exchanging the transfection medium with fresh medium containing 10% FBS, the cells were further incubated at 37 °C for 6 h. The medium was removed and supplemented with fresh medium containing 10% FBS and 20 μg/mL of heparin. The amount of VEGF released from the cells for 18 h was analyzed by using enzyme-linked immunosorbent assay (Quantikine human VEGF immuno-detection kit, R&D Systems, Minneapolis, MN) according to the manufacturer's instruction. The data were given as mean ± standard deviation (SD) of three independent measurements. Statistical analysis was performed

with a student's *t* test. Statistical significance was assigned for *P* value of <0.01.

RESULTS AND DISCUSSION

Systemic siRNA delivery based on nonviral vectors has been scarcely reported mainly due to lack of non-cytotoxic cationic lipid and polymer carriers that can effectively deliver nucleic acid drugs to a target tumor site. In addition to maintaining superior colloidal stability during systemic circulation, nanosized siRNA/carrier complexes should be efficiently transported from blood vessels to a cancerous tissue and finally taken up by the target cells. Our previous studies showed that the PEC micelle-based delivery system can be potentially exploited as an efficient and non-cytotoxic systemic siRNA delivery vehicle, which can partially overcome the challenging delivery barriers. The systemic administration of VEGF siRNA-PEG/PEI PEC micelles demonstrated significant accumulation of the PEC micelles in a tumor region presumably via an EPR effect, leading to dramatic retardation of tumor growth in an animal tumor model (*13*). These results suggest that the therapeutic effect of siRNA can be further enhanced by adding cancer cell specificity to the PEC micelles.

An LHRH analogue, (pyroE)-H-W-S-Y-(dK)-L-R-P(amide), was selected as a cancer targeting ligand, since the LHRH receptor is known to be overexpressed especially in prostate, breast, and ovarian cancer cells, but barely expressed in healthy human tissues (*18*, *19*). In addition, the LHRH analogue is resistant to *in vivo* degradation and has a high binding affinity toward LHRH receptor. Several LHRH agonists have been successfully used as a targeting moiety for cancer-targeted drug delivery (*20*). A conjugate of siRNA-PEG-LHRH containing a disulfide linkage between siRNA and PEG was synthesized as shown in Figure 2A. Prior to the conjugation of the LHRH peptide to PEG, the primary amine group of a heterofunctional PEG derivative (NH_2-PEG-COOH) was reacted with an active NHS group of a heterofunctional cross-linking reagent, *N*-succinimidyl-3-(2-pyridyldithio)propionate (SPDP). The terminal carboxylic group of the PEG derivative was then activated by EDC chemistry and used for the conjugation of an LHRH peptide. Since the N-terminal α-amino group of the peptide was blocked, the ε-amine group of a lysine residue in the LHRH peptide was the only one that participated in the coupling reaction. The 2-pyridyl disulfide-PEG-LHRH conjugate was then treated with 50 mM DTT to generate a free sulfhydryl group (-SH). The synthesis of SH-PEG-LHRH was confirmed by MALDI-TOF mass spectrometry (Figure 2B). An siRNA derivatized with primary amine at the 3′-end of a sense strand was separately activated using SPDP to produce 2-pydridyl disulfide-modified siRNA. The 2-pyridyl disulfide-activated siRNA was coupled to SH-PEG-LHRH via a sulfhydryl exchange reaction. The resulting siRNA-PEG-LHRH containing a disulfide linkage between siRNA and PEG (siRNA-ss-PEG-LHRH) was further purified by a gel elution method. The conjugation was monitored by size exclusion chromatography (SEC). Figure 2C exhibits chromatography profiles for naked siRNA (MW 15 000, line a), siRNA-PEG-LHRH (MW 19 596, line b), sulfhydryl-PEG-LHRH (MW 4596, line c), and LHRH peptide (MW 1196, line d). The four conjugates were well-separated depending on their molecular weights. However, it should be noticed that the siRNA-PEG-LHRH was eluted later than naked siRNA. The LHRH analogue has a slightly positive charge of +1 under basic pH regime between 7 and 12. Thus, the siRNA-PEG-LHRH conjugate might have a hairpin structure with the formation of a PEG loop due to the ionic interaction between the negatively charged siRNA and the slightly positively charged LHRH peptide. The self-folded structure of siRNA-PEG-LHRH may have a smaller hydrodynamic size than

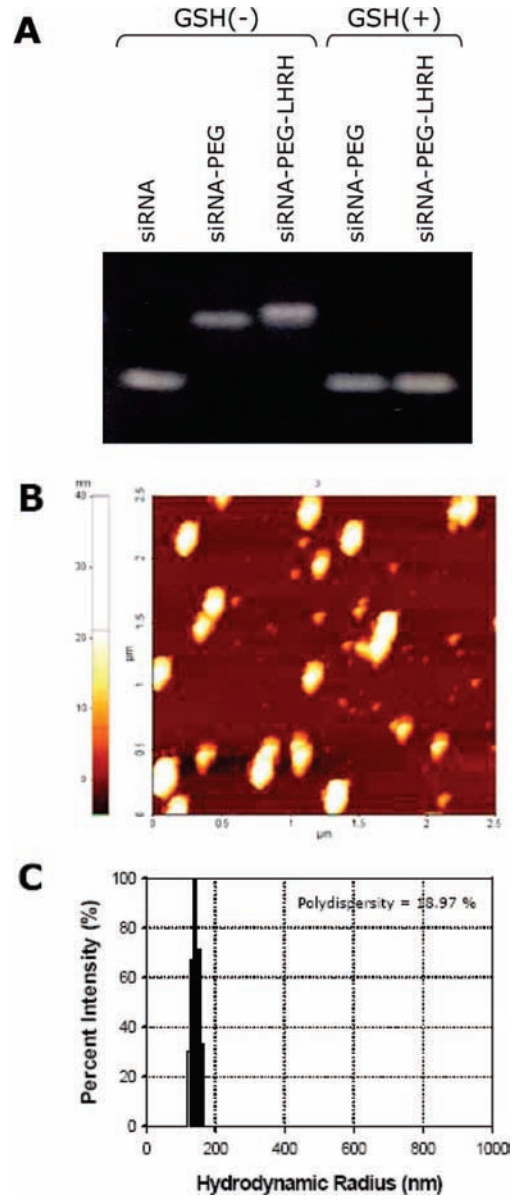

Figure 3. (A) Electrophoretic mobility shift assay for the analysis of siRNA-PEG-LHRH conjugation and disulfide bond cleavage under reducing conditions. GSH (+) and GSH (−) represent the treatment with and without 10 mM glutathione (GSH). (B) Representative AFM image of siRNA-PEG-LHRH/PEI PEC micelles at N/P ratio of 16. (C) Particle size distribution of siRNA-PEG-LHRH/PEI PEC micelles at N/P ratio of 16. Percent polydispersity = (polydispersity index)$^{1/2}$ × 100.

linear naked siRNA, resulting in the delayed elution. However, since electrostatic interactions between LHRH and siRNA were weak, the folded structure of siRNA-PEG-LHRH conjugate was likely to be readily dissociated upon interaction with highly charged PEI. The inner core part of the siRNA-PEG-LHRH/PEI PEC micelles could be formed by preferential electrostatic interactions between siRNA and PEI with releasing LHRH moieties on the shell surface.

The synthesis of the siRNA-PEG-LHRH conjugate was further verified by an electrophoretic mobility shift assay. The migration of the purified siRNA-PEG-LHRH in an electrophoretic field was significantly retarded, compared to that of unmodified siRNA (Figure 3A). This result directly shows the successful conjugation of SH-PEG-LHRH with siRNA. The incubation of siRNA-PEG-LHRH with GSH caused the complete reduction of the disulfide linkage between siRNA and PEG, leading to the generation of an intact form of siRNA (Figure

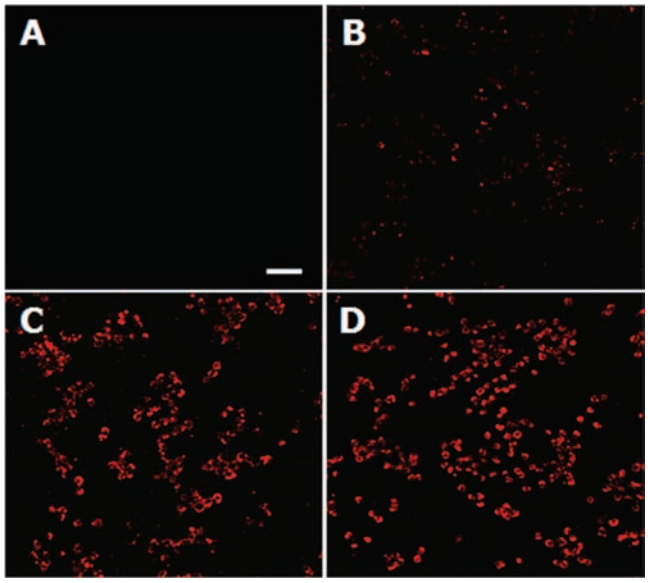

Figure 4. Confocal microscopy images of human ovarian cancer A2780 cells after no treatment (A) and treatment with (B) siRNA/PEI, (C) siRNA-PEG/PEI, and (D) siRNA-PEG-LHRH/PEI. Red signal represents Cy3 dye-labeled siRNA. Scale bar: 50 μm.

3A, lane 5). Considering that the concentration of GSH (10 mM) is similar to that of cytosolic GSH ranging between 0.5 and 10 mM (*21*), it can be deduced that free siRNA could be successfully rescued from the conjugates in a highly reductive environment of the cytoplasm. Since the presence of PEG in siRNA-PEG-LHRH may limit the access of the cytoplasmic RNA-induced silencing complex (RISC) due to the steric hindrance effect, we hypothesized that the reducible release of intact siRNA from the PEG chain in the cytoplasm may facilitate the incorporation of siRNA into RISC, which may lead to the enhanced silencing of a target gene.

The electrostatic interaction of siRNA-PEG-LHRH with PEI in an aqueous medium led to the spontaneous formation of PEC micelles. The resulting PEC micelles exhibit a spherical shape, as visualized by atomic force microscopy (Figure 3B). The spherical morphology could also be observed with ODN-PEG/PEI and siRNA-PEG/PEI PEC micellar formulations (*9*, *22*). The hydrodynamic diameter of the PEC micelles determined by a light scattering method was 142 nm with a narrow size distribution (polydispersity = 18.9%) (Figure 3C).

LHRH receptor-targeted delivery of siRNA-PEG-LHRH/PEI PEC micelles was studied in human ovarian carcinoma cells (A2780) using Cy3-conjugated siRNA. A2780 cells are known to overexpress LHRH receptor (*20*). Confocal microscopy observation demonstrated that the introduction of LHRH considerably increased the cellular uptake extent of siRNA-PEG-LHRH/PEI PEC micelles, as compared to the PEC micelles without LHRH ligand, siRNA-PEG/PEI (Figure 4). The enhanced cellular uptake of siRNA-PEG-LHRH/PEI PEC micelles can be attributed to a receptor-mediated endocytosis process. Enhanced intracellular delivery of LHRH−drug conjugate in ovarian cancer cells was also reported in previous studies (*18*, *19*). In the serum containing medium, the siRNA-PEG/PEI PEC micelles either with or without targeting ligands showed much higher intracellular siRNA delivery efficiencies than non-PEGylated siRNA/PEI polyelectrolyte complexes. The enhanced cellular uptake was primarily due to the improved stability of the PEC micelles in the presence of serum proteins. The surface-exposed PEG segments could stabilize the PEC micelles by forming a thermodynamically favorable core−shell structure and minimizing nonspecific binding of serum components to the PEC micelles, which can effectively prevent serum protein-mediated interparticulate aggregation (*22*, *23*). Receptor-mediated cellular uptake of siRNA-PEG-LHRH/PEI PEC micelles was further studied using flow cytometry. The extent of cellular uptake of LHRH-modified PEC micelles was increased by about 50% in an arbitrarily gated region (M1), compared to that of siRNA-PEG/PEI without LHRH (Figure 5). The presence of excess free LHRH peptide (1 μM) in the transfection medium significantly reduced the cellular uptake of siRNA-PEG-LHRH/PEI PEC micelles, suggesting that free LHRH peptides could

LHRH receptor (upper panel) and human β_2-microglobulin (B2M, lower panel) used as an internal standard have 319 and 114 bp, respectively. (B) LHRH receptor-mediated VEGF gene silencing in A2780 and SK-OV-3 cells. Cells were transfected with VEGF siRNA-PEG/PEI and VEGF siRNA-PEG-LHRH/PEI PEC micelles. Data were expressed as mean ± standard deviation ($n = 3$). * = $P < 0.01$.

compete with LHRH-modified PEC micelles for binding to LHRH receptors on the cell surface. In conjunction with the result from confocal microscopy, the flow cytometry result clearly demonstrates that the enhanced cellular uptake of siRNA-PEG-LHRH/PEI PEC micelles was mainly due to the specific interaction between LHRH moiety of PEC micelles and its cellular receptor, resulting from receptor-mediated endocytosis.

The potential therapeutic use of the siRNA-PEG-LHRH/PEI PEC micellar system was evaluated using VEGF-silencing siRNA. Two types of human ovarian cancer cells, A2780 and SK-OV-3, were used for comparatively analyzing gene silencing efficiency. Prior to the test of LHRH receptor-mediated gene silencing, the expression of LHRH receptor for the two cells was estimated by RT-PCR analysis as depicted in Figure 6A. Semiquantitative RT-PCR showed that a high level of LHRH receptor expression was detected in A2780 cells, while LHRH receptor expression in SK-OV-3 cells was negligible, in good agreement with previous reports (*22, 23*). For further *in vitro* transfection studies, the level of cellular toxicity of each formulation was evaluated using a cell viability assay (*24*). No detectable cytotoxicity was observed with all the formulations used in this experiment, suggesting that gene silencing was directly related to siRNA-induced RNAi (data not shown). For A2780 cells, the PEC micelles tethered with LHRH showed a higher inhibition extent of VEGF expression (139.4 ± 15.2 pg/mL) than those without LHRH (214.1 ± 25.4 pg/mL). In contrast, for SK-OV-3 cells, the LHRH targeting moiety did not affect the VEGF gene silencing efficiency, in which the PEC micelles with and without LHRH exhibited almost the same level of VEGF expression, 245.0 ± 77.8 pg/mL and 231.8 ± 56.3 pg/mL, respectively. Since various cancer cell lines exhibit a wide range of VEGF expression level depending on the cell type, SK-OV-3 cells secreted about a 2-fold higher amount of VEGF (832.2 ± 77.5 pg/mL) than A2780 cells (379.0 ± 56.9 pg/mL) prior to transfection. After transfecting siRNA-PEG-LHRH/PEI PEC micelles, SK-OV-3 cells apparently showed greater gene silencing percent (70.4 ± 9.4%) than A2780 cells (63.2 ± 4.0%). This was likely because the two cells have inherently different cellular uptake extents of PEC micelles and intracellular RNAi activities, resulting in different gene silencing efficiencies even when using the same transfection agent (*22, 23*). Although LHRH receptor-positive A2780 cells had lower VEGF silencing efficiency than LHRH receptor-deficient SK-OV-3 cells, they showed significantly improved gene silencing efficiency only when transfected with the LHRH-modified PEC micelles. The results suggest that the enhanced VEGF gene silencing by VEGF siRNA-PEG-LHRH/PEI PEC micelles was

mainly attributable to improved cellular uptake via an LHRH receptor-mediated endocytosis mechanism.

CONCLUSIONS

Here, we demonstrated that siRNA-PEG-LHRH/PEI PEC micelles could be used for cancer-targeted delivery of therapeutic siRNA. We have successfully synthesized and purified siRNA-PEG-LHRH conjugate, and prepared siRNA-PEG-LHRH/PEI PEC micelles in a nanometer size range. An LHRH receptor-targeted siRNA formulation (siRNA-PEG-LHRH/PEI PEC micelle) enhanced the intracellular delivery of siRNA for A2780 cells, due to LHRH-specific receptor−ligand interaction. VEGF siRNA-PEG-LHRH/PEI PEC micelles specifically inhibited VEGF expression in cancer cells in an LHRH receptor-specific manner. On the basis of the current formulation strategy, many different cancer targeting ligands such as folic acid, transferrin, peptides, antibodies, and growth factors could be similarly tethered to the distal end of the PEG chain in the siRNA-PEG/PEI micellar formulation for cancer-targeted delivery of siRNA therapeutics.

Hemospan is an acellular hemoglobin-based oxygen therapeutic in clinical trials in Europe and the United States. The product is prepared by site-specific conjugation of maleimide-activated poly(ethylene) glycol (PEG, MW ~5500) to human oxyhemoglobin through maleimidation reactions either (1) directly to reactive Cys thiols or (2) at surface Lys groups following thiolation using 2-iminothiolane. The thiolation/maleimidation reactions lead to the addition of ~8 PEGs per hemoglobin tetramer. Identification of PEG modified globins by SDS-PAGE and MALDI-TOF reveals a small percentage of protein migrating at the position for unmodified globin chains and the remaining as separate bands representing globin chains conjugated with 1 to 4 PEGs per chain. Identification of PEG modification sites on individual α and *β* globins was made using reverse-phase HPLC, showing a series of α globins conjugated with 0 to 3 PEGs and a series of *β* globins conjugated with 0 to 4 PEGs per globin. Mass analysis of tryptic peptides from hemoglobin thiolated and maleimidated with *N*-ethyl maleimide showed the same potential sites of modification regardless of thiolation reaction ratio, with seven sites identified on *β* globins at *β*8, *β*17, *β*59, *β*66, *β*93, *β*95, and *β*132 and three sites identified on α globins at α7, α16, and α40.

INTRODUCTION

Hemospan is a new class of hemoglobin-based oxygen therapeutic, designed using site-specific, maleimide poly(ethylene glycol) (PEG) conjugation chemistry with oxyhemoglobin (Hb) (*1, 2*). Hemospan, also referred to as MP4 or MalPEG-Hb in the literature, has been the subject of extensive biochemical (*2*−*6*) and physiologic studies (*7*−*10*). The product has completed phase I (*11*) and phase II clinical trials in Sweden (*12*) and the U.S., with phase III trials just finished in Europe.

Several general benefits have been attributed to PEG conjugation to proteins, including decreased immunogenicity, prolonged intravascular retention time, and increased colloidal osmotic pressure as a function of PEG mass and protein concentration (*3*). A recent study using small-angle X-ray scattering to obtain the three-dimensional structure of Hemospan in solution (P5K6 in that study) showed that PEGylation increases the macromolecular dimensions of hemoglobin from a maximum particle dimension of 70 Å for Hb to 130 Å for P5K6; in addition, PEGylation introduces an intermolecular repulsive effect that increases with PEG mass (*6*). Even though this PEGylated Hb molecule is not cross-linked intramolecularly and, therefore, remains capable of tetramer−dimer dissociation upon dilution (*13*), the PEG surface shielding and intermolecular repulsion prolong the circulatory half-life of Hemospan to approximately 20 h in surgical patients (*12*).

In the present study, we describe the number and distribution of PEG polymers on the individual α and *β* globin subunits in Hemospan. Because the maleimide−PEG raw material has a relatively wide mass distribution (~5500 ± 750 Da), sites of modification, under reaction conditions specified for Hemospan, were identified by mass analysis using a small molecular weight model, i.e., *N*-ethyl maleimide (NEM) in the place of maleimide−PEG. NEM as a model compound was validated recently in a study of modification sites in a similar product made using thiolation/maleimidation reactions with deoxyHb (*14*). Thiolation/maleimidation under Hemospan reaction conditions with oxyHb shows both similar and dissimilar sites compared to the same reaction conditions carried out on deoxyHb reported by Iafelice (*14*). A primary difference is that the *β*93Cys is modified in Hemospan, leading to higher O_2 affinity (*2, 4*).

EXPERIMENTAL SECTION

Hemospan Production. Hemospan was prepared using the process described earlier (*2*), with a small increase in processing temperature from 6° ± 2 to 10 °C, which does not affect the final reaction product. Briefly, stroma-free Hb was purified from human red blood cells and diluted to 1 mM (in tetramer) in phosphate-buffered saline (PBS), pH 7.4. Hb thiolation was carried out using a 10-fold molar excess (over Hb tetramer) of 2-iminothiolane (2-IT, Sigma Aldrich, St. Louis, MO) for 4 h at 10 °C. This was followed by PEG conjugation using a 20-fold molar excess (over Hb tetramer) of maleimide-activated PEG (MW ~5500 Da) (NOF Corp., Tokyo, Japan) for 2 h at 10 °C. The PEG-modified hemoglobin was diafiltered against lactated Ringer's solution using 70 kD tangential flow filtration to remove both unreacted Hb and maleimide-activated PEG. The final product was concentrated to a final Hb concentration of 4.2 g/dL.

NEM-Hb Production. NEM-Hb was prepared using the same reaction conditions described above for PEG conjugation. Hb was first reacted with a 10-fold molar excess of 2-IT for 4 h at 10 °C, followed by reaction with 20-fold molar excess of *N*-ethyl maleimide (NEM) (in the place of maleimide-activated PEG) for 2 h at 10 °C. NEM-modified Hb was dialyzed against lactated Ringer's solution to remove unreacted NEM.

Degree of Hemoglobin Modification. The degree of thiolation and maleimidation (or PEGylation) was evaluated from the number of reactive thiols on Hb after the thiolation and

maleimidation reactions. Free thiols were measured by disulfide exchange with the 4,4′-dipyridinedisulfide to produce the corresponding 4-thiopyridone (4-TP), measured at 324 nm ($\varepsilon = 1.98 \times 10^4$ M^{-1} cm^{-1}) (*15*). The difference between the number of free thiols immediately following thiolation versus post-maleimidation corresponds to the number of PEG or NEM molecules conjugated to the hemoglobin tetramer.

Two additional test methods were used to evaluate the degree of PEGylation: (1) ^{1}H NMR spectroscopy (Varian 400 MHz; Inova; performed at Spectral Data Services, Inc., Champaign, IL), using D_2O as the solvent, (trimethylsilyl)propionic acid-D4 as internal standard, and comparing spectra of Hemospan with samples of pure PEG (10 mg) dissolved in D_2O following the method of Jackson (*16*). The NMR signal at 3.5−3.9 ppm represents the chemical shift for the oxyethylene groups in PEG, and the integrated signal for pure PEG was used to calculate the amount of PEG in the hemoglobin conjugate. (2) A dry weight method was performed using Hb and Hemospan at equal concentrations in heme by subtracting the dry weight of Hb from the dry weight of PEG-conjugated Hb to calculate the number of ∼5 kD PEGs conjugated per Hb molecule. Dry weights were made following lyophilization (Virtis, Gardiner, NY) and oven-drying at 130 °C until weights no longer changed.

[a] ND = not detected.

Degree of PEGylation by SDS-PAGE and MALDI-TOF Mass Spectrometry (MS). Hemospan was analyzed by sodium dodecylsulfate/polyacrylamide gel electrophoresis (SDS-

PAGE) on Bis-Tris precast gels (Invitrogen), with a 4−12% gradient. Experiments were carried out under conditions to avoid removing conjugated PEG from the globins, and so heating and β-mercaptoethanol treatments were not employed in the SDS process. To confirm dissociation of globins, control experiments were performed on Hb both with and without heating and β-mercaptoethanol treatment in which no differences in band separation were observed. Gels were stained differentially using Coomassie blue for protein and iodine for PEG (*17*, *18*), and bands were analyzed by densitometry (Image Scanner, PowerLook 1120). Protein and PEG-conjugated globin bands were electroeluted for MALDI-TOF analysis by mixing samples with sinapinic acid in 50% acetonitrile/0.1% formic acid. An intact Hemospan solution sample was submitted independently for MALDI-TOF mass analysis. Samples were air-dried on the MALDI sample plate and analyzed on an Applied Biosystems Voyager DE mass spectrophotometer.

Degree of PEGylation by Reverse-Phase HPLC. Reverse-phase high-performance chromatography (RP HPLC) was used for analysis of modified globins. The modified hemoglobin solution was eluted on a C_3 column (4.6 × 50 mm) (Agilent 1100 series) at a flow rate of 2 mL/min at 50 °C in 35−40% acetonitrile with 0.1% trifluoroacetic acid (TFA) over 1 min, followed by 40−51% acetonitrile with 0.1% TFA over 11 min.

Mass Analysis by Electrospray Mass Spectrometry (ESI-TOF MS). Hb and NEM-Hb were desalted on a PD-10 column containing Sephadex G-25 medium (GE) and submitted for ESI-TOF analysis on an Agilent ESI-TOF mass spectrometer. Samples were electrosprayed into the TOF reflectron analyzer at an ESI voltage of 4000 V and a flow rate of 200 μL/min (50:50 acetonitrile/water/0.1% formic acid v/v) using flow injection with an Agilent microwell autosampler. The averaged mass spectrum was converted to a neutral charge state spectrum using a maximum entropy deconvolution algorithm (MaxEnt) as part of the *Analyst* data analysis software (Agilent).

Sites of Hemoglobin Maleimidation. Sites of thiolation/maleimidation in Hemospan were identified using NEM-Hb as a model compound. To evaluate potential preferences of Hb residues to react with 2-IT, Hb was subjected to thiolation under identical reaction conditions at four different ratios of Hb to 2-IT (1:3, 1:5, 1:7, and 1:10). NEM was added subsequently at a Hb/NEM molar ratio of 1:20 in each case. NEM-Hb samples prepared at the molar reaction ratio of 1:10:20 were run in triplicate. The same sites were found to be modified for all ratios tested, and samples prepared at the lower reaction ratios were run only once. NEM-Hb samples were subjected to SDS-PAGE on Bis-Tris precast gels, with a 4−12% gradient. Gels were stained with Coomassie blue. After staining, NEM-Hb bands were excised and pretreated prior to in-gel trypsin digestion. Reduction of disulfide linkages was performed using 10 mM dithiothreitol, followed by alkylation with 55 mM iodoacetamide (Sigma-Aldrich, St. Louis, MO). In-gel digestion with trypsin (Promega) was performed overnight at 37 °C at an estimated (1:30) enzyme to substrate ratio in 50 mM ammonium bicarbonate. Tryptic peptides were extracted from the gel using acetonitrile and formic acid and subjected to analysis by LC/MS/MS (Scripps Research Institute, MS Lab, San Diego, CA). Separation was performed on a laser-pulled, 100 μm ID C_{18} column with a tip of <5 μm that was also used as the nanoelectrospray emitter. Gradient elution was used with 0.1% formic acid/acetonitrile as the mobile phases, from 5% to 60% acetonitrile over 90 min, and then maintained for an additional 20 min with flow rates of ~200 nL/min. MS/MS analysis was performed on a LTQ-DECA (Thermoelectron Corp.) and Agilent LC/MSD Trap ion trap mass spectrometer. Data-dependent scanning was used to maximize the number of peptides sequenced in the highly complex mixture. This mode of operation uses preset criteria to select unique peptides on-the-fly for undergoing MS/MS. Sequences were searched by MASCOT (Matrix Science, Limited), with Sequest search engine software (University of Washington, WA) using either NCBInr (nonredundant) or SwissProt 55.1 databases. To improve searching efficiency, taxonomic categories were limited to mammalian proteins. Only peptides producing good quality fragmentation spectra and scoring higher than the threshold required for the 95% confidence level for MASCOT were used for protein identification.

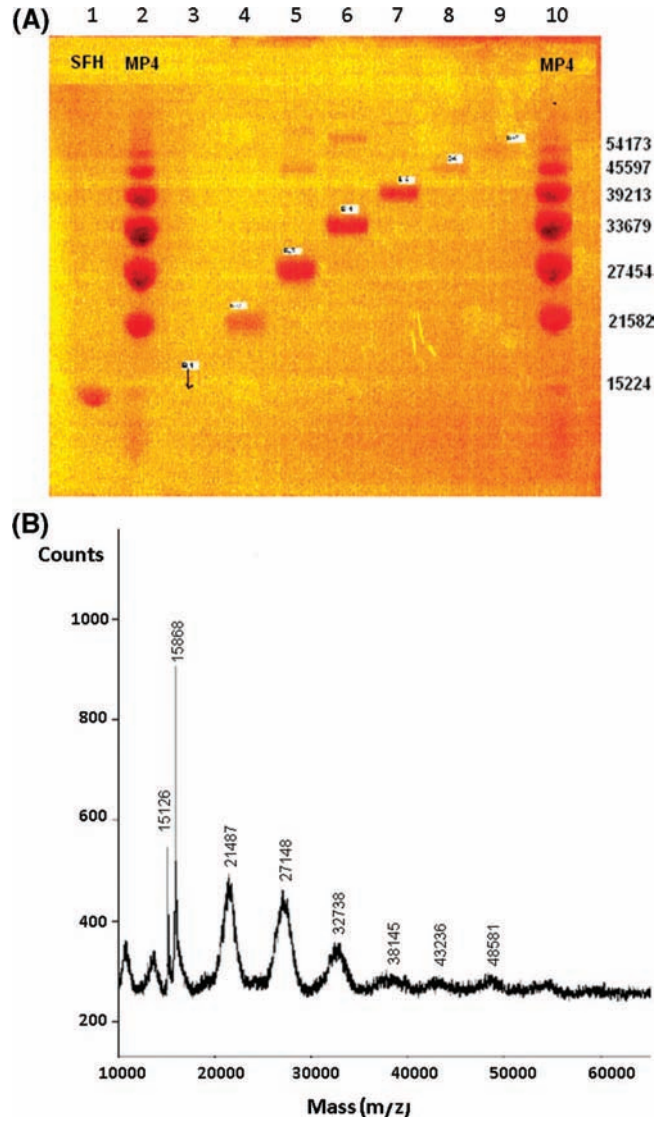

Figure 2. (A) SDS-PAGE of Hb (SFH) is shown in lane 1; Hemospan (MP4) is shown in lanes 2 and 10. Each Hemospan (MP4) band from lane 1 was extracted from the gel and rerun on SDS-PAGE (lanes 3−9). These bands were subjected to MALDI-TOF for mass determination, and the masses for each band are shown on the right-hand side of the gel. (B) Intact Hemospan was subjected to MALDI-TOF, showing peaks for unmodified globins (α = 15 126; β = 15 868) and additional peaks, increasing in mass by a factor of ~5.5 kDa, corresponding to the number of conjugated PEGs.

RESULTS

Degree of PEG Modification. The primary method used to measure the degree of PEGylation in Hemospan was the colorimetric technique (*15*). Unmodified Hb was used as a standard for this method, because human oxyHb contains two reactive thiols at the βCys93 residues. For 12 separate Hemospan lots prepared at Sangart's manufacturing facility, the oxyHb standard prepared prior to thiolation and PEGylation showed

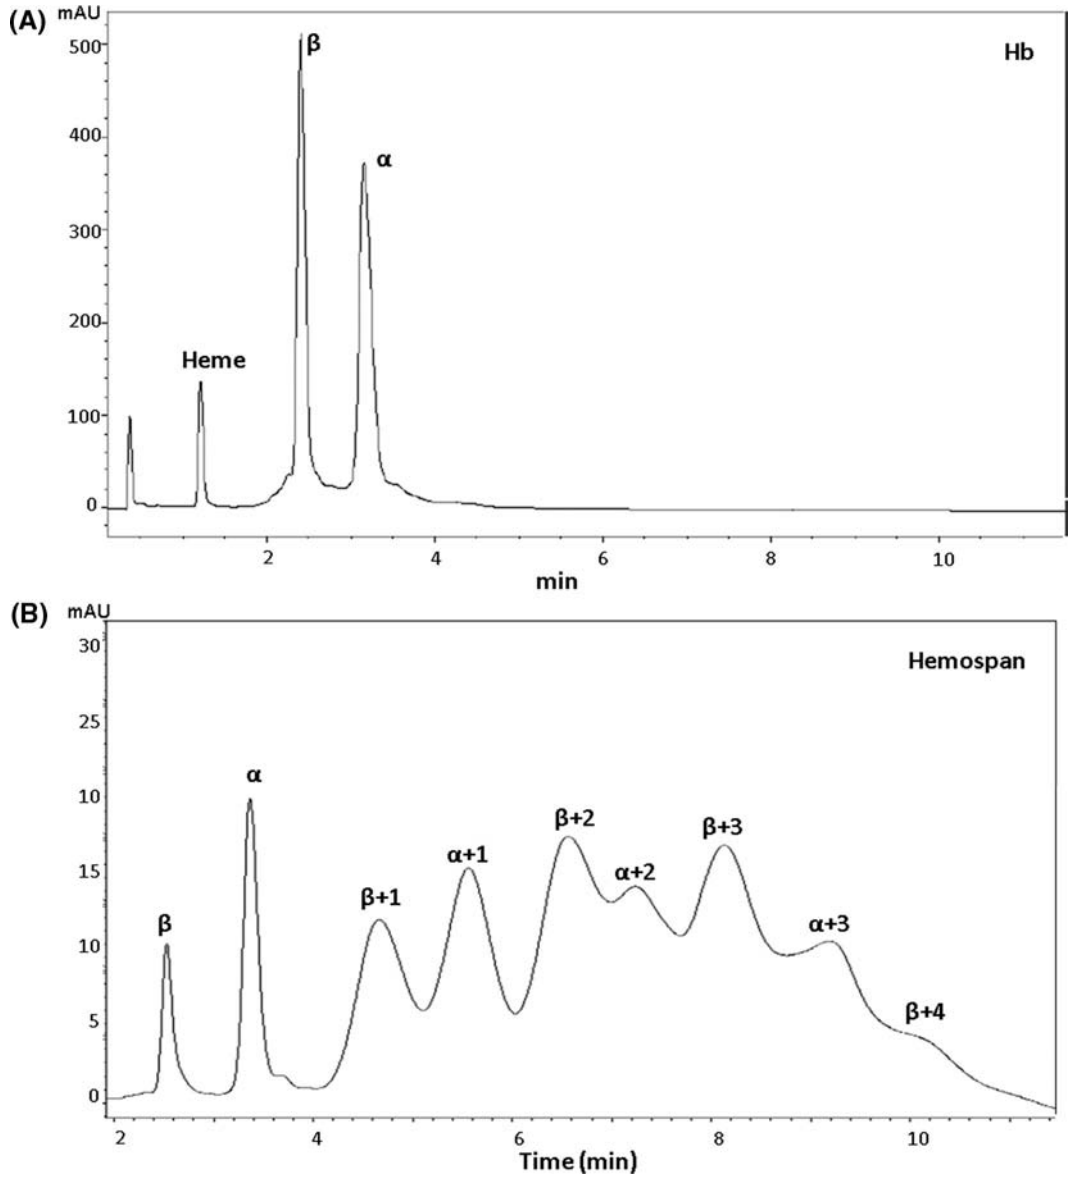

Figure 3. C_3 RP HPLC of Hb (A) and Hemospan (B); UV detection at 210 nm. Free heme and unmodified β and α globin peaks are assigned in (A). Unmodified β and α globin peaks and globin chains with increasing numbers of attached PEGs are assigned in (B). Note expanded scale in (B).

2.1 ± 0.03 (average ± standard deviation) free thiols. Following thiolation and PEGylation, the number of PEGs per Hb tetramer was 7.9 ± 0.2, with 0.4 ± 0.1 residual free thiols remaining. Degree of PEGylation measurements were also performed on single lots of Hemospan by ^{1}H NMR or dry weight analysis, giving values of 7.2 and 7.6, respectively. Therefore, on the basis of three independent measures, the average number of conjugated PEGs per Hb tetramer in Hemospan is 7−8. Thus, in addition to the two residing, reactive thiols on the β chains, the thiolation reaction with 2-IT at a 10-fold molar excess to Hb tetramer provides, on average, an additional 5−6 sites of PEG conjugation on the Hb tetramer, with <1 free thiol remaining.

Globin Analysis by SDS-PAGE. Representative SDS-PAGE of Hb and Hemospan are shown in Figure 1, with Coomassie blue staining for proteins (Figure 1A) and iodine staining for PEG (Figure 1B). In Figure 1A, Hb (lane 1) shows a major band migrating at ~15 kDa, corresponding to α and β globins migrating at the same position. A higher molecular weight protein band can also be seen in lane 1, migrating near the protein MW marker at ~31 kDa. To determine if the Hb solution contained any non-Hb, red cell protein, this band was treated with trypsin, and the tryptic peptides were extracted from the gel and subjected to LC/MS/MS analysis. The primary protein hit was identified as human hemoglobin β chain, with 95% sequence coverage and a mass of 16 102. A secondary protein was also present and was identified as carbonic anhydrase, with 57% sequence coverage and a mass of 28 909. Hemospan (lane 3) shows multiple bands by protein staining, with increasing molecular weights. Densitometry maps for Hb and Hemospan from the protein-stained gels are displayed in Figure 1C,D, with peaks ranked from the top to the bottom of the gel; percentages of total for the peaks are shown in Table 1.

Differential staining with iodine in Figure 1B, which is specific for PEG, shows no detectable band for either Hb or the protein MW markers (lanes 1 and 2, respectively). For Hemospan (lane 3), all bands stained for both protein and PEG, with the exception of one band seen by protein staining alone that migrated at ~15 kDa. To assess lot-to-lot consistency, densitometry of the ~15 kDa band from the 12 Hemospan lots tested showed $6.2 \pm 2.1\%$ (average ± standard deviation) of combined non-PEGylated globins. Each Hemospan band was

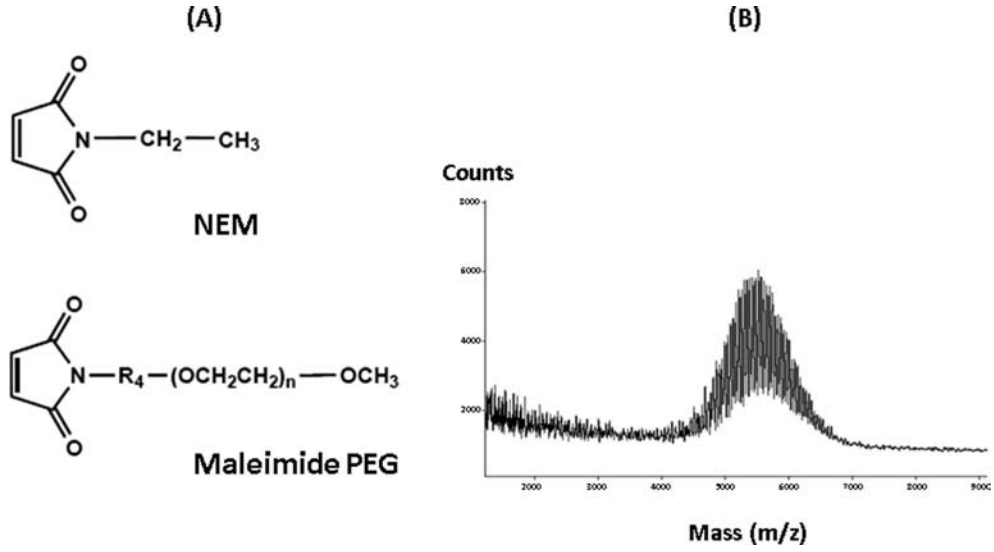

Figure 4. (A) Chemical structures of NEM and maleimide PEG, where R_4 is an alkyl linker between the maleimide functional group and the oxyethylene backbone in PEG. The number of repeating oxyethylene units in PEG (*n*) is approximately 114 for a ~5.5 kDa polymer. (B) MALDI-TOF analysis of the free maleimide−PEG.

extracted from the gel and rerun on SDS-PAGE (Figure 2A, lanes 3−9). The individual bands were also subjected to MALDI-TOF for mass determinations, with the measured masses reported on the right side of Figure 2A, aligned with their respective bands. The SDS-PAGE bands showed masses for globins with an increasing number of attached PEGs (~5.5 kDa for each PEG): lane 3, 0 PEGs (MW = 15 224); lane 4, 1 PEG (MW = 21 582); lane 5, 2 PEGs (MW = 27 454); lane 6, 3 PEGs (MW = 33 679); lane 7, 4 PEGs (MW = 39 213). Lighter bands were observed at positions with masses = 45 597 and 54 173, making up <10% of the total.

The MALDI-TOF spectrum for intact Hemospan is shown in Figure 2B as a series of mass peaks corresponding to unmodified α and β chains at 15 126 and 15 868, respectively, and additional peaks following, increasing in mass by a factor of ~5.5 kDa, again corresponding to the number of attached PEG units per globin in close agreement with the mass of the extracted SDS-PAGE bands in Figure 2A.

Globin Analysis by Reverse-Phase (RP) HPLC. RP HPLC (C_3) provides a protein separation method based on hydrophobicity and size. Using this method, the heme groups are stripped from the hemoglobin tetramers, and the subunit globins dissociate. Since human hemoglobin β chains are more hydrophilic compared to α chains, the individual chains can be resolved (*19*). Representative C_3 chromatograms of Hb and Hemospan are shown in Figure 3A and B, respectively. The heme peak and unmodified α and β globin peaks from Hb are identified in Figure 3A. The chromatographic profile for Hemospan is shown on an expanded scale in Figure 3B, with unmodified α and β globin peaks and seven additional, less well resolved modified globin peaks. Each peak was fractionated and run separately on the C_3 column, showing that they are made up of individual components (data not shown). Lot-to-lot consistency was assessed for the 12 Hemospan lots by integration of the well-resolved peaks for the unmodified β and α globins, showing 1.2 ± 0.2% and 4.8 ± 0.2% (average ± standard deviation), respectively, thus reflecting a high degree of consistency between manufacturing lots. This consistency was also observed in the PEGylated peaks that were not subject to integration. Tentative assignments for the peaks of the modified globins were defined based on globin chain hydrophobicity and degree of PEGylation and independently from PEG conjugation to individual α and β chains identified by MALDI-TOF (data not shown).

ESI-TOF Mass Spectrometry. To increase the resolution for determining the number of sites of maleimidation, ESI-TOF mass spectra were run on unmodified Hb and NEM-Hb. NEM has the same functionally reactive group as maleimide-activated PEG but with a lower, well-defined mass (126 Da) (Figure 4A, top), in marked contrast to the large mass and size distribution of free PEG (~5500 ± 750 Da) (Figure 4A, bottom), as demonstrated by its MALDI-TOF spectrum shown in Figure 4B. The NEM-Hb reaction was carried out using the same thiolation molar ratio of 2-IT to Hb used in the manufacturing process for the 12 lots of Hemospan, and the thiolated-Hb product was then reacted with NEM at the same molar ratio as used in the manufacturing process with PEG. The degree of maleimidation for NEM-Hb was 8.2. ESI-TOF spectra for Hb and NEM-Hb are shown in Figure 5A and B, respectively. For Hb, the $[M + H]^+$ ions at m/z = 15 127 and 15 867 correspond to unmodified α and β globins, respectively. For NEM-Hb, thiolated-NEM attachments by mass units are as follows: NEM alone = 126 mu; thiolated + NEM (Th + NEM) = 227 mu. The ESI-TOF results in Figure 5B show clearly defined peaks for α globin, with 0, 1, 2, or 3 Th + NEM modified sites, and β globin with 1 NEM-only modified site plus 1, 2, 3, or 4 Th + NEM modified sites. Free β globin could not be clearly resolved. These findings are in good agreement with the number of PEGylated sites found for Hemospan using either SDS-PAGE (Figure 2) or RP HPLC (Figure 3B).

Sites of Hemoglobin Modification. The simplified model system for maleimide PEGylation by using NEM as a substitute for PEG was used to evaluate the sites of Hb modification at ratios of Hb/2-IT/NEM of 1:3:20, 1:5:20, 1:7:20, and 1:10:20. At these ratios, the degree of maleimidation was determined to be 4.1, 5.3, 6.3, and 8.2 conjugated NEM sites per Hb tetramer, respectively. Each NEM-modified Hb sample was subjected to SDS-PAGE and trypsin digestion, followed by LC/MS/MS to identify modified-hemoglobin tryptic peptides by the increase in the atomic mass unit of modified peptides (amu), such that the addition of NEM alone is equal to +126 amu compared to addition of 2-IT + NEM = +227 amu. Regardless of the ratio of Hb/2-IT/NEM used, the same 10 modified residues were identified (Table 2). Tryptic peptides with 2-IT + NEM modified terminal Lys residues showed a mass increase of approximately 227 amu. The tryptic peptide in the β chain with NEM-modified

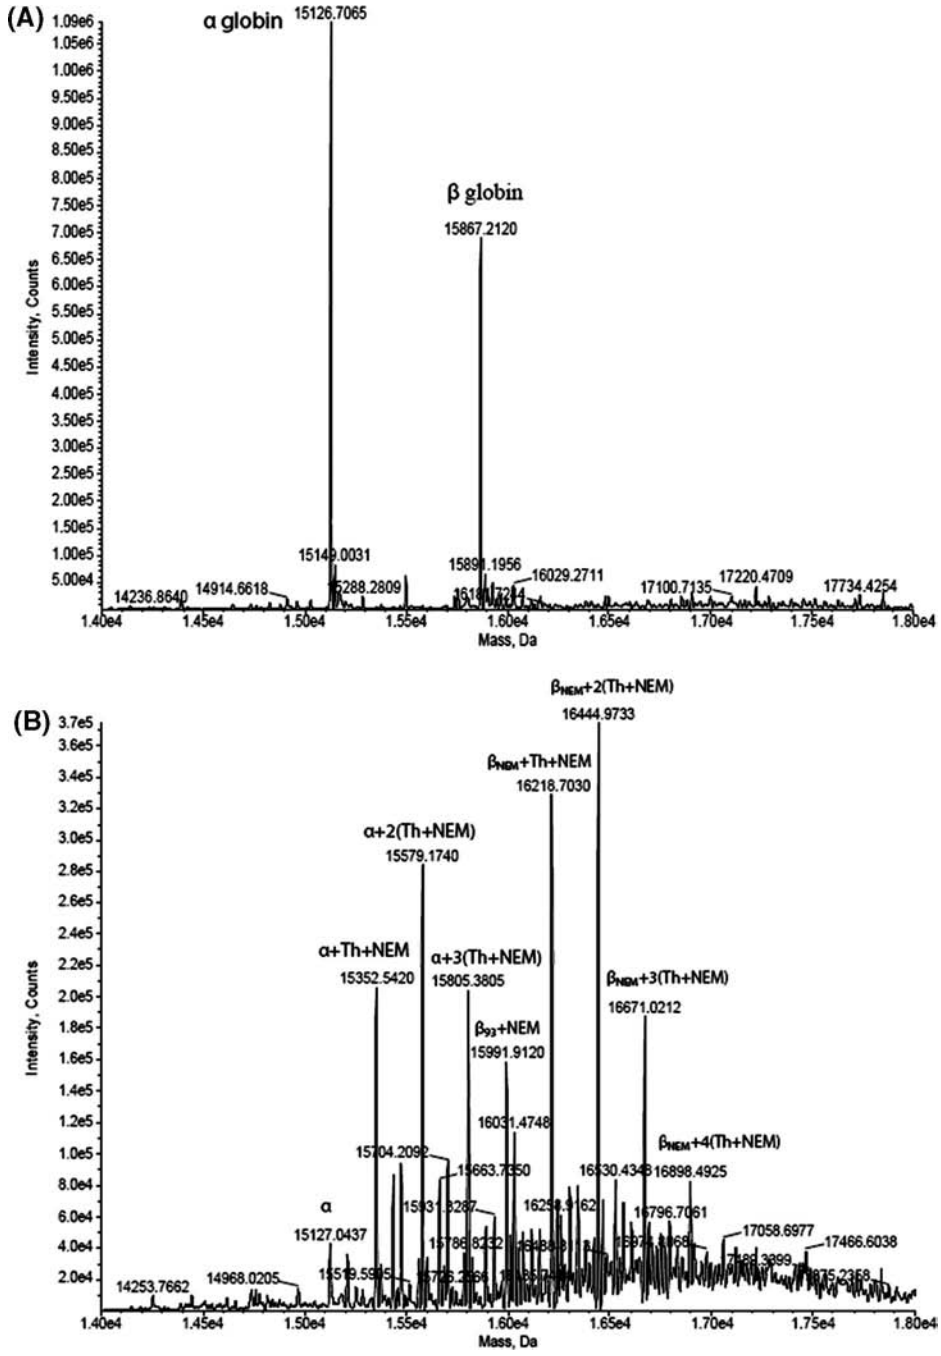

Figure 5. (A) ESI-TOF mass spectrum of Hb, showing α chain with a mass of 15 127 Da and β chain with a mass of 15 867 Da. (B) ESI-MS of NEM-Hb; peaks are identified as unmodified α globin, α globin plus the number of thiolated + NEM (Th + NEM) groups, β globin + NEM (i.e., β93Cys), and β globin plus the number of thiolated + NEM groups (Th + NEM). Little or no unmodified β globin could be resolved.

Cys at position 93 and with 2-IT + NEM modified terminal Lys at position 95 showed a mass increase of approximately 353 amu.

Considering a tetrameric hemoglobin molecule, a total of 20 potentially modifiable residues have been identified. Three thiolated-maleimidated sites were identified on the α globin: αLys7, αLys16, and αLys40. Six thiolated-maleimidated sites were identified on β globin: βLys8, βLys17, βLys59; βLys66, βLys95, βLys132, and one NEM-modified only site at βCys93. The globin distribution shows a preference for reactivity at β chains. These sites are depicted on a molecular diagram of human oxyhemoglobin in Figure 6 (PDB entry 2DN1) (*20*).

DISCUSSION

Hemospan has been the subject of many studies, including structural (*6*), functional (*7*−*10*), and clinical (*11, 12*), but the sites of chemical modification have not been defined until now. In this study, we present chemical analysis of the Hemospan product, including average degree of PEGylation, number of PEGs per globin, and sites of maleimidation.

Hemospan is human oxyHb modified using monofunctional maleimide PEG (∼5.5 kDa), with an average of 7−8 linear PEG polymers conjugated on the surface of the protein and <0.5 free thiol. An earlier publication on the reaction process used in the development of MP4 reported the degree of PEGylation to be 6.1 ± 0.2 (*2*). The higher number reported in the present study for Hemospan is most likely due to improvements in processing efficiency and controls at the manufacturing scale.

According to SDS-PAGE (Figures 1), the starting Hb product shows ∼90% α and β globins migrating at the same elution position at ∼16 kDa. However, a larger protein component making up ∼10% of the total by densitometry migrates at ∼31

[a] The same modified peptides were identified at all ratios of Hb/2-IT/NEM studied (see text for details). Lys (K) residues hit by trypsin are identified by their chain sequence number. The β Cys (C) residue is also identified by its chain sequence number. Helical assignments for the terminal Lys residues in each peptide are shown to the right in parentheses. Identified modified peptides and helices are shown in bold. Modified residues are underlined.

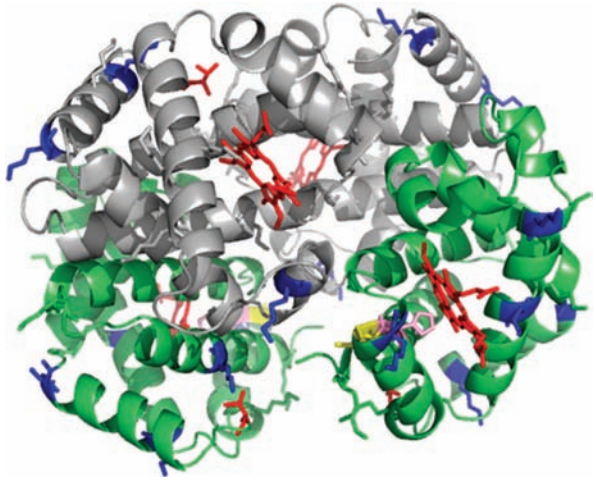

Figure 6. Three-dimensional structural model of tetrameric oxyHb (PDB entry 2DN1 (*20*)). α chains are shown in silver, β chains in green, and hemes in red. All Lys residue side chains are depicted. Modified Lys residues identified in this study are shown in blue, and the modified β93Cys is shown in yellow next to the proximal β92His residue (shown in pink) in contact with the β hemes.

kDa. This band was sequenced by tryptic digestion, matched against known protein sequences, and found to be primarily human β globin but with a lower score also identifying residual carbonic anhydrase. These data suggest that this band may be a mixture of nondissociated αβ dimer, a fraction of ββ dimer, which was identified by mass analysis by LC/MS/MS, that could arise through disulfide bridge formation between β globins since β-mercaptoethanol was not used, and possibly a small fraction of the red cell enzyme, carbonic anhydrase.

By SDS-PAGE, the Hemospan product comprises ∼5% unmodified α and β chains, ∼85% α and β chains conjugated to 1−4 PEGs, and ∼10% globin chains with >4 PEGs. Globins with >4 PEGs were also seen as minor peaks in the MALDI-TOF spectrum (Figure 2B), RP HPLC analysis of Hemospan (Figure 3B), and with NEM-globin modifications by ESI-TOF experiments (Figure 5B). Hemospan, which is not cross-linked intramolecularly, is dissociable at dilute concentrations, but even under fully dissociating conditions in high salt, <1% of the product exists as free, nonPEGylated αβ dimer (*13*), and haptoglobin has been reported to disappear transiently in human trials (*11*).

NEM was used as a simple model system in place of PEG (see Figure 4A) for the maleimidation reaction to evaluate the sites of hemoglobin modification by mass analysis. Reaction with NEM stabilizes the thiolated sites from forming disulfide bonds and provides a small molecular weight marker for mass analysis. Thus, any site found that reacted with NEM can react with PEG in the PEGylation reaction. Regardless of the Hb/2-IT reaction ratio used, the same Lys residues were identified, showing an equal propensity for thiolation, without kinetic preference. At the reaction ratio of 1:10:20 used to produce Hemospan, ∼8 maleimidated sites per Hb tetramer were measured for either NEM or PEG reactions, showing that PEGylation over a distribution of sites is not different from the reaction with the small maleimide model.

Out of 20 potential sites of modification identified by the NEM/tryptic peptide analysis on the Hb tetramer (see Table 2), less than half are modified on average under the conditions of the Hemospan reaction, and the product can best be described as Hb modified with PEG over a distribution of surface sites. Heterogeneity in sites of PEGylation does not necessarily extrapolate to functional heterogeneity. We have reported previously on the kinetics of CO binding (*13*) and heme loss (*5*), in which intramolecular (i.e., differences between subunits) showed a higher signal compared to intermolecular heterogeneities. The primary reason for this appears to be the modified β93Cys residues immediately adjacent to the β-subunit proximal histidines (β92His) directly bound to β hemes. There appears to be a preference for thiolation of Lys residues within β subunits, with six modified β Lys residues identified by tryptic digestion compared to only three sites on the α chains. Another preference may be reaction at the A helices on both α and β chains, with 8 out of 20 modified sites in this region of the molecule. On the three-dimensional structure showing these sites in Figure 6, there is a tendency to identify these sites at the outer corners of the A helical structures. No clear relation of modified sites to relative solvent accessibilities were found in the PDB entry 2DN1 (*21*), particularly considering that the β93Cys shows zero relative solvent accessibility in either oxy- or deoxyHb conformations by this method.

A similar method has been used to identify sites of thiolation and maleimidation to deoxygenated human Hb with 5−8 PEG chains conjugated per Hb tetramer (*14*). In that study, they showed (1) that NEM modification does not interfere with tryptic proteolysis at sites flanking the modified site, (2) that terminal Val residues were not modified, and, as we also have found here, (3) that the sites of modification do not depend on the kinetics of the reaction. A comparison between their study on human Hb bound to PEG under deoxygenated conditions and ours with Hemospan shows the same sites modified on α chains at Lys7 and Lys16 and on the β chains at Lys8, Lys17, Lsy59, and Lys66. Otherwise, they reported more modifications to α chains but not to βLys132, as we report here. A notable distinction is that the β93Cys was modified less so or not at all in the deoxyHb reaction but is clearly modified in Hemospan,

likely contributing to Hemospan's ligand binding effects reported for O_2 and CO (*4, 13*).

CONCLUSION

The two-step method of oxyHb thiolation and PEG maleimidation offers a simple, reliable method to produce a modified hemoglobin-based oxygen carrier that is being tested clinically to impart hemodynamic stability in surgery patients. In addition to the intrinsic β93Cys thiols that are PEGylated, the thiolation reaction is specific for 18 out of a total of 44 surface Lys residues. For the reaction under our process conditions, the β93Cys residue and 9 Lys residues are modified per $\alpha\beta$ dimer, distributed over the surface of hemoglobin, with a preponderance on the β subunits and a tendency for a higher proportion of modification on the A helical corners of either α or β chains. At this time, the reason for specificity of the thiolation reaction of the Lys residues identified here has not been determined.

N-Substituted porphyrins are well-known for the distortion they exhibit of the porphyrin plane through the sp^3 hybridization of one of the pyrrolenic units. They have served as model compounds in investigations of many biochemical processes. In this paper, we developed an efficient route to *N*-substituted porphyrins, and report the synthesis of a series of new *N*-substituted cobaltacarborane−porphyrins containing one or two cobaltabisdicarbollide anions linked by $(CH_2CH_2O)_2$ chains to either the core porphyrin nitrogens or to a *meso*-aminophenyl group. These conjugates show different degrees of distortion of the porphyrin macrocycle, which affect their spectroscopic and electrochemical properties. In particular, the core *N*-substituted conjugates show significant fluorescence quenching in comparison with the noncore substituted macrocycles. The X-ray structures of two targeted core *N*-cobaltacarborane porphyrin conjugates are presented. The electrochemical and spectroelectrochemical properties of these porphyrin conjugates were investigated; while the peripheral *N*-substituted cobaltacarboranylporphyrins undergo three reversible reductions and three reversible oxidations (two attributed to the porphyrin and one to the Co^{III} cluster), the core *N*-substituted porphyrins exhibit complicated electrochemical behavior with coupled chemical reactions.

INTRODUCTION

In the past few decades, porphyrin and related compounds have assumed broad importance in diverse areas of medicine, catalysis, and molecular electronics (*1*). Structural modification and conformational distortion of porphyrin macrocycles are widely studied because they may have the potential to control the properties and functions of tetrapyrroles in biological systems. In particular, porphyrins with substituents at a pyrrolenic nitrogen atom, i.e., *N*-substituted porphyrins, are of biochemical significance and have served as model compounds in investigations of biochemical processes (*2*−*8*). These compounds are well-known for the distortion of the porphyrin plane through the sp^3 hybridization of one of the pyrrolenic units. They are also powerful inhibitors of the enzyme ferrochelatase, which is essential for the formation of heme for hemoglobin, myoglobin, and cytochromes, and have been shown to be produced in a biochemical monooxygenation process catalyzed by cytochrome P-450 enzymes (*2*−*8*). The unique structures of synthetic *N*-substituted porphyrin derivatives has led to their investigation for potential applications in the fields of catalysts (*9*), molecular recognition (*10, 11*), medicine (*12*), and energy transfer (*13*). In addition, interesting new macrocycles have been reported from the ring expansion or reduction of *N*-substituted porphyrins and analogues (*14*−*17*). Despite the potential wide range of applications of these compounds and the important role they have played in understanding biological processes, the synthetic routes currently available to obtain *N*-substituted porphyrins are limited and most employ harsh conditions that result in low yields of the target molecules.

Recently, porphyrins bearing boron clusters have been identified as useful agents in boron neutron capture therapy (BNCT) of cancer because of their abilities to localize in tumors and their high boron content (*18, 19*). Among the boron clusters, the metallacarboranes and in particular the cobaltabisdicarbollide anion $[Co(C_2B_9H_{11})_2]^-$ and its adducts have attracted much attention because of their remarkable chemical, thermal, and photostabilities (*20*). As part of our studies of the development of new boron-containing porphyrins and derivatives, we recently reported the synthesis of porphyrin−cobaltacarborane conjugates, via an efficient nucleophilic ring-opening reaction of [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)] by porphyrins containing phenol or pyridinum groups at the peripheral *meso*-positions (*21*). Herein, we report that the core porphyrin nitrogen atoms can also function as the nucleophilic species in the ring-opening reaction of [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)], and this methodology allows the efficient synthesis of *N*-cobaltacarboranyl−porphyrins in high yields. Using as the starting porphyrins, free-base *meso*-tetraphenylporphyrin (H_2TPP) and octaethylporphyrin (H_2OEP), both mono- and di-*N*-substituted derivatives were obtained in high yields by slight modification of the reaction conditions. These compounds show unique and characteristic optical spectra and strong fluorescence quenching. We also report the synthesis of two new *N*-cobaltacarboranyl−porphyrins from the reaction of mono-(*p*-aminophenyl)triphenylporphyrin with [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)]. The electrochemical and spectroelectrochemical properties for both types of compounds are reported, and comparisons are made to the individual monomeric units under the same experimental conditions.

EXPERIMENTAL PROCEDURES

Electrochemical and Spectroelectrochemical Measurements. Cyclic voltammetry (CV) measurements were performed at 298 K on an EG&G model 173 potentiostat coupled with an EG&G model 175 universal programmer in deaerated PhCN solution containing 0.1 M TBAP as a supporting electrolyte. A three-electrode system was utilized and consisted of a glassy carbon working electrode, a platinum wire counter electrode,

and a saturated calomel reference electrode (SCE). The reference electrode was separated from the bulk of the solution by a fritted-glass bridge filled with the solvent/supporting electrolyte mixture. UV−visible spectroelectrochemical experiments were performed with a home-built thin-layer cell (*22*) that had a light transparent platinum net working electrode. Potentials were applied and monitored with an EG&G PAR model 173 potentiostat. Time evolution of the UV−visible spectra was recorded with a Hewlett-Packard model 8453 diode array spectrophotometer.

Syntheses. All reactions were monitored by TLC using 0.25 mm silica gel plates with or without UV indicator (60F−254). Silica gel Sorbent Technologies 32−63 μm was used for flash column chromatography. ^{1}H and ^{13}C NMR were obtained on either a DPX-250 or a ARX-300 Bruker spectrometer. Chemical shifts (δ) are given in ppm relative to actone-d_6 (2.05 ppm, ^{1}H; 206.0 ppm, ^{13}C) unless otherwise indicated. Electronic absorption spectra were measured on a Perkin-Elmer Lambda 35 UV−vis spectrophotometer, and fluorescence spectra were measured on a Perkin-Elmer LS55 spectrometer. Mass spectra were obtained on an Applied Biosystems QSTAR XL. All solvents were obtained from Fisher Scientific (HPLC grade) without further purification. Cs[Co($C_2B_9H_{11}$)$_2$] was obtained from Katchem, Ltd, Czech Republic, *meso*-tetraphenylporphyrin (H_2TPP, **1**), and octaethylporphyrin (H_2OEP, **2**) were obtained from Frontier Scientific, Logan, Utah. 5-(4-Aminophenyl)-10,15,20-triphenylporphyrin and its zinc complex were synthesized according to a literature method (*23*). Intensity data were collected for the μ-EtO-cobaltacarborane, porphyrin **3** (as the monohydrate, bis pyridine solvate), and porphyrin **4** at $T = 110$ K using graphite monochromated Mo Kα radiation (λ = 0.710 73 Å) on a Nonius KappaCCD diffractometer fitted with an Oxford Cryostream cooler. Data reduction included absorption corrections by the multiscan method, using HKL SCALEPACK (*24*). Structures were solved by direct methods and refined by full-matrix least-squares, using SHELXL97 (*25*). Crystallographic data (excluding structure factors) for the structures in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 704151-704153. Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, (fax: +44- (0)1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

***N*-Cobaltacarborane Tetraphenylporphyrin (3).** H_2TPP (**1**) (61.4 mg, 0.10 mmol) and [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$(1′,2′-$C_2B_9H_{10}$)] (65.4 mg, 0.16 mmol) were dissolved in ODCB (25 mL). The reaction solution was heated at 140 °C, and the color changed to green in about 15 min. Two hours later, TLC indicated no starting H_2TPP left, and the reaction was stopped by cooling. The reaction mixture was directly loaded on silica gel column using toluene to elute ODCB and trace H_2TPP. Then, the title porphyrin was eluted using dichloromethane and recrystallized from chloroform/hexane. After drying under vacuum, porphyrin **3** was obtained in 81% yield (82.8 mg), along with 4.7% (6.8 mg) of porphyrin **5**. For the title porphyrin, HRMS (MALDI-TOF) for $C_{52}H_{59}N_4O_2B_{18}Co$: *m*/*z* calcd, 1025.5788, found 1025.5717. ^{1}H NMR ($CDCl_3$): 9.32 (d, 2H, $J = 5.0$ Hz, β-H), 9.08 (d, 2H, $J = 5.0$ Hz, β-H), 8.85 (s, 2H, β-H), 8.54 (b, 4H, o-phenyl-H), 8.32 (d, 2H, $J = 7.75$, o-phenyl-H), 8.23 (d, 2H, $J = 7.75$, o-phenyl-H), 8.15 (s, 2H, β-H), 8.00 (m, 6H, m, p-phenyl-H), 7.87 (m, 6H, m, p-phenyl-H), 3.91 (s, 2H, car-H), 3.30 (s, 2H, car-H), 3.07 (t, 2H, OCH_2), 2.71 (t, 2H, OCH_2), 0.71 (t, 2H, OCH_2), 0.1−4.0 (br, 17H, BH), −4.83 (t, 2H, NCH_2). UV−vis (CH_2Cl_2) λ_{max} (nm) 450 (ε 320, 500), 613 (13 800), 669 (38 300).

Crystal data for **3**: $C_{52}H_{59}B_{18}CoN_4O_2 \cdot 2C_5H_5N \cdot H_2O$, dark blue, FW = 1201.76, triclinic, space group $P\bar{1}$, $a = 14.488(2)$, $b = 15.269(2)$, $c = 15.850(3)$ Å, $\alpha = 66.662(7)$, $\beta = 76.501(6)$, $\gamma = 83.995(7)°$, $V = 3130.2(8)$ Å^3, $Z = 2$, $D_{calc} = 1.275$ g cm^{-3}, $\mu = 0.326$ mm^{-1}, $T = 110$ K, $\theta_{max} = 32.6°$, 73 501 measured reflections, 22 598 independent ($R_{int} = 0.118$), 10 070 with $I > 2\sigma(I)$, $R_1 = 0.094$, w$R(F^2) = 0.163$, $S = 1.030$, 813 refined parameters, $\Delta\rho_{max} = 0.98$ eÅ^{-3}, $\Delta\rho_{min} = -1.06$ eÅ^{-3}.

***N*-Cobaltacarborane Octaethylporphyrin (4).** H_2OEP (**2**) (53.5 mg, 0.10 mmol) and [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$(1′,2′-$C_2B_9H_{10}$)] (43.3 mg, 0.11 mmol) were dissolved in 10 mL of ODCB. The reaction solution was stirred at 140 °C for 2 h until TLC indicated no H_2OEP left. The reaction mixture was purified on a silica gel column using dichloromethane/hexane for elution. The first purple fraction was collected, recrystallized from chloroform/hexane, and dried under vacuum to yield the title porphyrin (86.1 mg, 89%). HRMALDI-TOF-MS for $C_{44}H_{75}N_4O_2B_{18}CoNa$: *m*/*z* calcd, 968.6934 [M + Na]$^+$, found 968.6957. ^{1}H NMR ($CDCl_3$): 10.67 (s, 2H, meso-H), 10.41 (d, 2H, meso-H), 4.28−4.42 (m, 8H, CH_2), 4.18−4.22 (m, 2H, car-H), 4.04−4.15 (m, 8H, CH_2), 3.59 (brs, 2H, car-H), 3.02−3.05 (m, 2H, OCH_2), 2.27−2.30 (m, 2H, OCH_2), 1.96−2.01 (t, 12H, CH_3), 1.47−1.53 (t, 12H, CH_3), 0.09−0.22 (m, 2H, OCH_2), 0.1−4.0 (br, 17H, BH), −5.60−5.57 (m, 2H, NCH_2). UV−vis (acetone) λ_{max} (nm) 400 (ε 145, 500), 539 (9, 200), 562 (12, 400), 581 (10, 200).

Crystal data for **4**: $C_{44}H_{75}B_{18}CoN_4O_2$, FW = 945.59, garnet red, triclinic, space group $P\bar{1}$, $a = 11.140(7)$, $b = 15.492(8)$, $c = 16.413(11)$ Å, $\alpha = 64.83(3)$, $\beta = 87.51(3)$, $\gamma = 84.12(4)°$, $V = 2550(3)$ Å^3, $Z = 2$, $D_{calc} = 1.231$ g cm^{-3}, $\mu = 0.378$ mm^{-1}, $T = 110$ K, $\theta_{max} = 22.9°$, 21 636 measured reflections, 6832 independent ($R_{int} = 0.074$), 4358 with $I > 2\sigma(I)$, $R_1 = 0.070$, w$R(F^2) = 0.126$, $S = 1.086$, 628 refined parameters, $\Delta\rho_{max} = 0.25$ eÅ^{-3}, $\Delta\rho_{min} = -0.35$ eÅ^{-3}.

***N,N*-Dicobaltacarborane Tetraphenylporphyrin (5).** Monosubstituted porphyrin **3** (26.0 mg, 0.025 mmol), [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$(1′,2′-$C_2B_9H_{10}$)] (20.1 mg, 0.05 mmol), and K_2CO_3 (35 mg, 0.25 mmol) were stirred in ODCB (10 mL) and then the reaction mixture was heated to 140 °C until the disappearance of starting porphyrin **3** (monitored by TLC). The reaction mixture was purified on a silica gel column using dichloromethane/ethyl acetate for elution. The main green fraction was collected, recrystallized from chloroform/hexane, and dried under vacuum to yield the title porphyrin (26.6 mg, 73%). HRMALDI-TOF-MS for $C_{60}H_{87}N_4O_4B_{36}Co_2Na$: *m*/*z* calcd, 1458.8903, found 1458.8850; *m*/*z* calcd, 1481.8801 [M + Na]$^+$, found 1481.8874; *m*/*z* calcd, 1435.9006 [M − Na]$^-$, found 1435.9014. ^{1}H NMR (acetone-d_6): 8.97 (d, 2H, $J = 4.9$ Hz, β-H), 8.79 (m, 4H, β-H), 8.53 (b, 2H, o-phenyl-H), 8.33 (m, 4H, o-phenyl-H), 8.17 (t, 2H, o-phenyl-H), 8.01 (m, 9H, m, p-phenyl-H), 7.91 (m, 3H, m, p-phenyl-H), 7.77 (d, 2H, $J = 4.7$, β-H), 4.24 (brs, 4H, car-H), 3.48 (br s, 4H, car-H), 2.93 (brs, 4H, OCH_2), 2.49 (brs, 2H, OCH_2), 2.43 (brs, 2H, OCH_2), 0.69 (brs, 4H, OCH_2), 0.1−4.0 (br, 34H, BH), −2.64 (s, 1H, NH), −4.30 (m, 2H, NCH_2), −5.83 (m, 2H, NCH_2). RESULTS

Synthesis. The synthesis of zwitterionic cobaltacarborane [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$(1′,2′-$C_2B_9H_{10}$)] was first reported in 1997 (*26*) and then modified by Teixidor et al. (*27*). Upon refluxing the cobaltabisdicarbollide anion $[Co(C_2B_9H_{11})_2]^-$ in 1,4-dioxane in the presence of BF_3•Et_2O, [3,3′-Co(8-$C_4H_8O_2$-

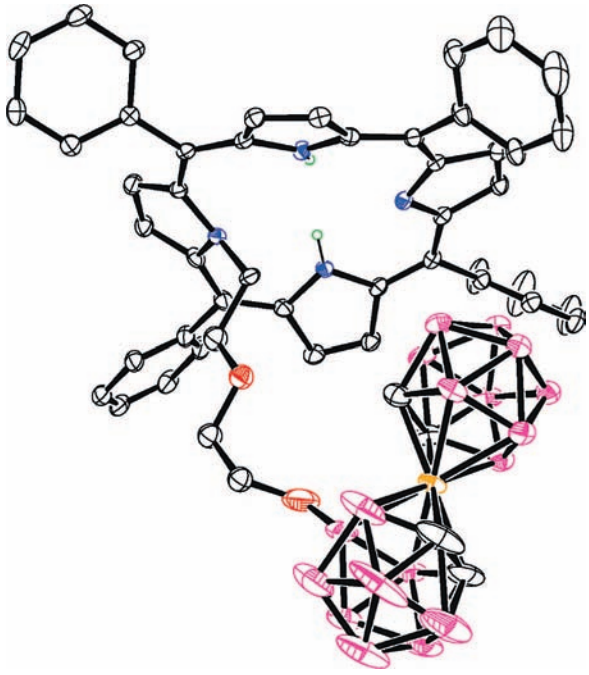

Figure 1. Molecular structure of *N*-cobaltacarborane porphyrin **3**. The C-H and B-H hydrogen atoms, and the hydrogen-bonded pyridine and water molecules are not shown for clarity.

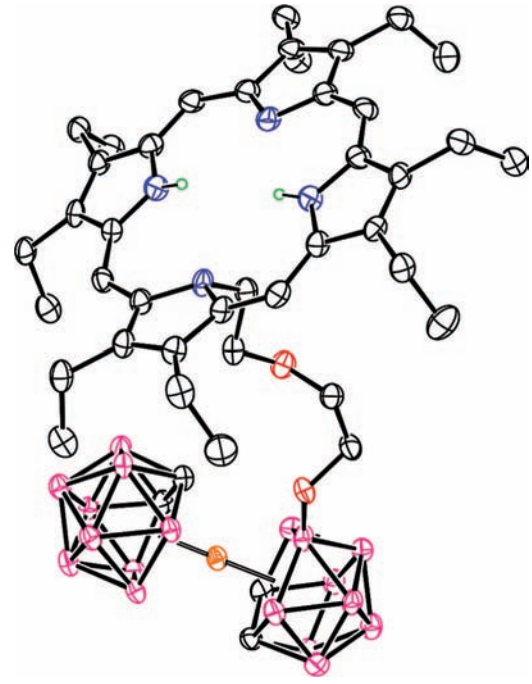

Figure 2. Molecular structure of *N*-cobaltacarborane porphyrin **4**. The C-H and B-H hydrogen atoms are not shown for clarity.

1,2-$C_2B_9H_{10}$(1′,2′-$C_2B_9H_{10}$)] was isolated in 80% yield, along with a slightly less polar minor fraction of [8,8′-μ-(C_2H_5O)-3,3′-Co(1,2-$C_2B_9H_{10}$)$_2$] in 4% yield. The structure of this minor fraction was confirmed by X-ray crystallography (see Supporting Information, Figure S1). The cobaltacarborane [8,8′-μ-(C_2H_5O)-3,3′-Co(1,2-$C_2B_9H_{10}$)$_2$] has been previously synthesized in low yield (5%) from [Co($C_2B_9H_{11}$)$_2$]$^-$, by refluxing in acetic anhydride in the presence of sulfuric acid (*28*). The structure of [8,8′-μ-(C_2H_5O)-3,3′-Co(1,2-$C_2B_9H_{10}$)$_2$] is similar to the known methyloxonium derivative [8,8′-μ-(CH_3O)-3,3′-Co(1,2-$C_2B_9H_{10}$)$_2$] (*29*) in that the C_2B_3 pentagonal planes bound to the cobalt atom are nonparallel due to the short oxygen bridge (mean B−O = 1.517(2) Å, B−O−B = 95.41(11)°), forming a dihedral angle of 26.48(10)°.

The reaction of metal-free H_2TPP (**1**) or H_2OEP (**2**) with [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$(1′,2′-$C_2B_9H_{10}$)] in refluxing ODCB yielded the corresponding monosubstituted *N*-cobaltacarborane porphyrins **3** and **4**, in 81% and 89% yield, respectively (Scheme 1). Similar yields were obtained using chloroform as the solvent in the presence of $NaHCO_3$, but the reaction took 10 days for completion, instead of 2 h in ODCB. Small amounts of the disubstituted derivatives **5** or **6** (1−5%) were also isolated under the above reaction conditions. Higher yields (73−83%) of the *N*,*N*-dicobaltacarborane porphyrins were obtained upon reaction of the monosubstituted derivatives **3** or **4** with [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$(1′,2′-$C_2B_9H_{10}$)] in refluxing ODCB and in the presence of a base ($NaHCO_3$). Porphyrins **3**−**6** are highly basic and were isolated in their core-protonated forms. On the other hand, monoaminoporphyrin **7** (*23*) reacted with [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$(1′,2′-$C_2B_9H_{10}$)] in a mixture of chloform and acetonitrile (v/v = 1/2) to produce the *N*-substituted derivatives **8** and **9** in 46% and 26% yields, respectively (Scheme 2).

The structures of porphyrins **3**−**6**, **8**, and **9** were confirmed by HRMS, NMR, and, in the case of **3** and **4**, by single-crystal X-ray crystallography (Figures 1−6). The molecular structures of porphyrins **3** and **4**, shown in Figures 1 and 2, respectively, are rare examples of singly protonated *N*-substituted porphyrins. The crystal of porphyrin **3** was grown from pyridine/cyclohexane and the two inner porphyrin NHs form hydrogen bonds with one water molecule, which also forms two additional hydrogen bonds with two solvent pyridine molecules, as seen in Figure S2 of the Supporting Information. On the other hand, the crystal of porphyrin **4** was grown from dichloromethane/methanol, and this molecule is less distorted from planarity than **3**, as shown in Figure 2. The NMR spectra confirmed the proposed structures for porphyrins **3**−**6**, **8**, and **9**, and confirmed the remarkable regioselective in the formation of di-*N*,*N*-substituted porphyrins **5** and **6**. The UV−vis and fluorescence spectra are also consistent with the assigned structures.

Electrochemistry and Spectroelectrochemistry. Two types of electrochemical behavior are obtained, one for conjugates

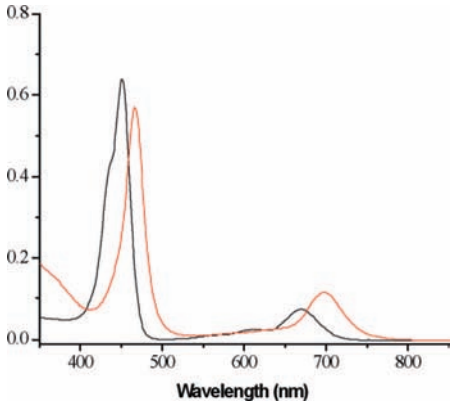

Figure 4. UV−visible spectra of porphyrins **3** (black) and **5** (red) in acetone at 2×10^{-6} M.

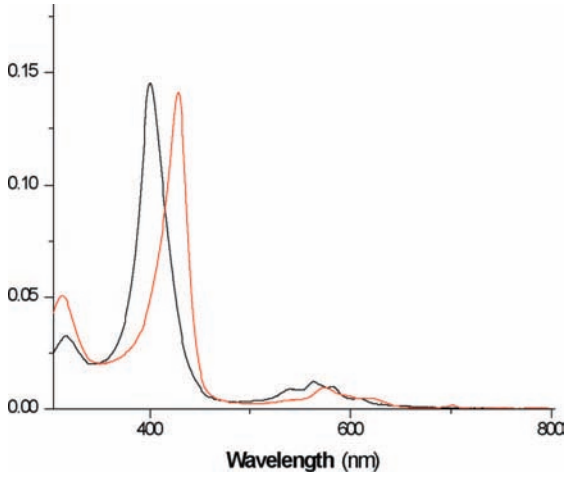

Figure 5. UV−visible spectra of porphyrins **4** (black) and **6** (red) in acetone at 1×10^{-6} M.

3−**6** where the porphyrin−cobaltabisdicarbollide linkage is at one or two of the four central porphyrin nitrogens (Scheme 1) and the other for conjugates **8** and **9**, which are linked at a single *meso* position of the macrocycle as seen in Scheme 2. Cyclic voltammograms for reduction and oxidation of the six conjugates are shown in Figures 7 and 8, but are well-defined only in the case of compounds **8** and **9** (Figure 7); compounds **3**−**6** exhibit irreversible processes due to coupled chemical reactions which occur during or after electron transfer, and this leads to the more complicated cyclic voltammograms (Figure 8). A summary of peak potentials for all of the investigated compounds in PhCN is given in Table 1.

In order to investigate the site of electron transfer, the reduced and oxidized forms of the conjugates were monitored by thin-layer spectroelectrochemistry. Examples of the spectral changes

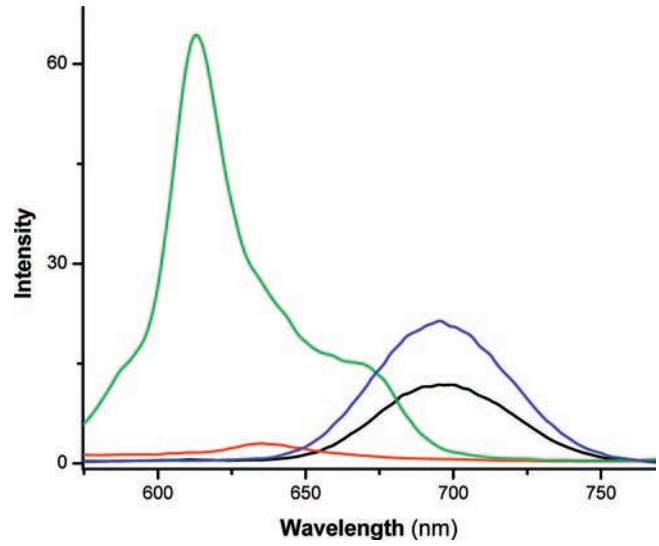

Figure 6. Fluorescence spectra of porphyrins **3** (blue), **5** (black), **4** (green), and **6** (red) in acetone at 1×10^{-6} M.

during the oxidation and reduction are shown in Figures 9−12 and a summary of the UV−visible data is given in Table 2 which includes H_2TPP for comparison.

DISCUSSION

In the absence of a nucleophilic group at the macrocycle periphery, metal-free porphyrins H_2TPP (**1**) and H_2OEP (**2**) reacted with zwitterionic [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{10}$)] to give the corresponding mono-*N*- (**3** and **4**) and di-adjacent (**5** and **6**) *N*,*N*-cobaltacarboranyl porphyrins, in their core-protonated forms, in high yields. On the other hand, in agreement with our previous reports showing that free-base porphyrins containing one or multiple nucleophilic groups (hydroxyl, pyridyl, phenol) at the macrocycle periphery react with [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{10}$)] preferentially at these sites (*21*), monoaminoporphyrin **7** produced the *N*-substituted derivatives **8** and **9** in low to moderate yields, probably due to steric hindrance and the low nucleophilicity of the amino group.

The spectroscopic properties of the new *N*-cobaltacarborane porphyrin conjugates were investigated, and two X-ray structures of the mono-*N*-cobaltacarborane porphyrins **3** and **4** were obtained, which show the different degrees of distortion from planarity in these molecules. In the molecular structure of porphyrin **3** (Figure 1), the two protonated pyrrolenic rings are located adjacent to the alkylated ring and are rotated in the opposite sense. Since there is a negative charge on the cobaltacarborane moiety, this molecule is zwitterionic. On the other hand, the structure of porphyrin **4** (Figure 2) is less distorted from planarity than the corresponding H_2TPP derivative

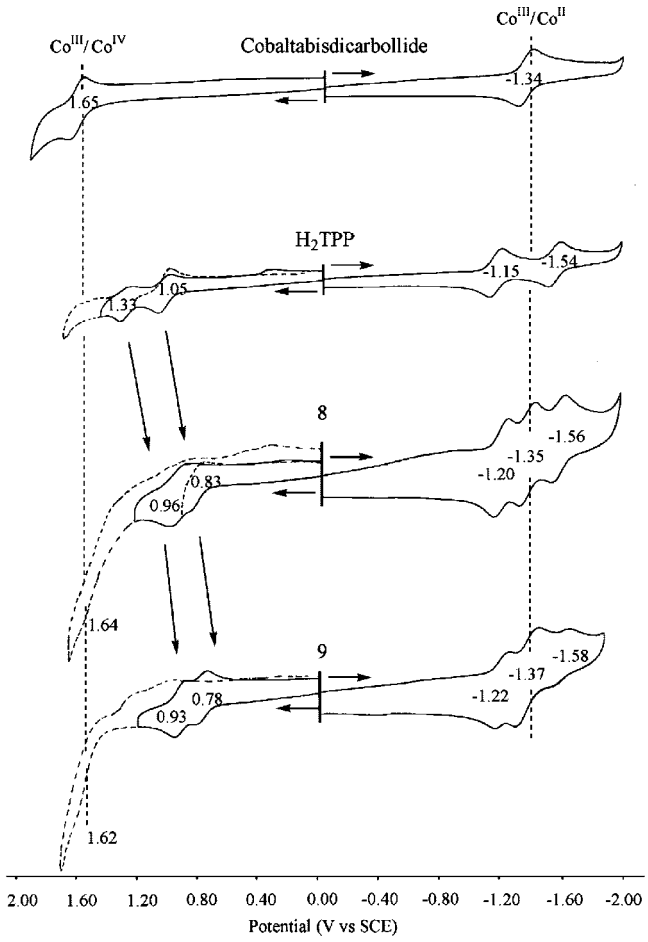

Figure 7. Cyclic voltammograms of cobaltabisdicarbollide, H_2TPP, and *meso*-substituted conjugates **8** and **9** in PhCN containing 0.1 M TBAP.

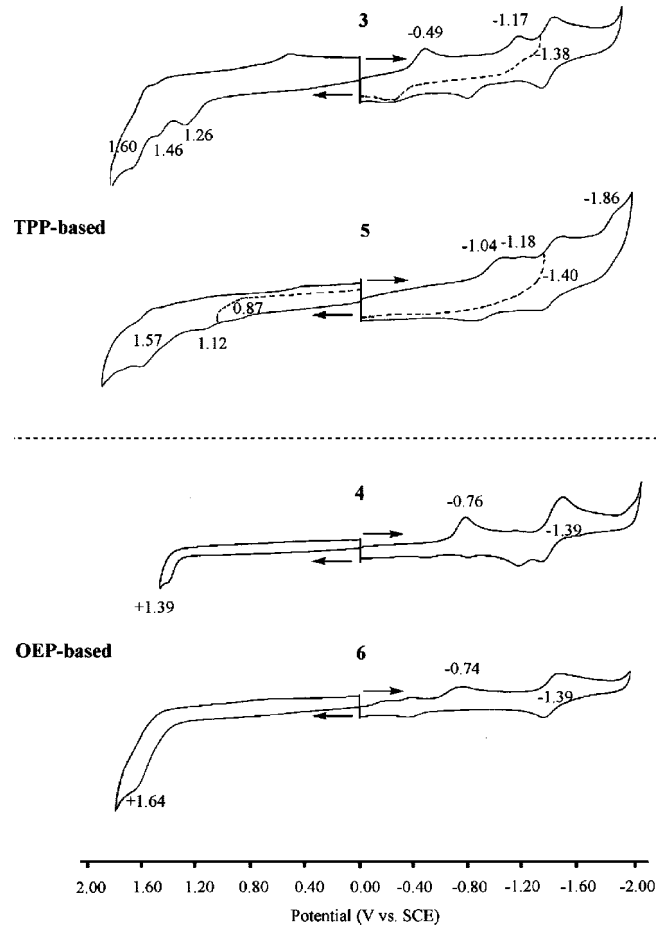

Figure 8. Cyclic voltammograms of *N*-substituted conjugates **3**−**6** in PhCN containing 0.1 M TBAP.

3, most likely because of the lack of hydrogen bonding to a water molecule, as exists in **3**, (see Supporting Information Figure S2) and perhaps lower steric hindrance of the pyrrolic ethyl groups of H_2OEP compared with the *meso*-phenyl groups of H_2TPP (*30*). In **4**, the porphyrin N atom carrying the cobaltacarborane substituent lies 0.371(4) Å out of the plane of the other three N atoms, and the cobaltacarborane-carrying pyrrole ring forms a dihedral angle of 17.2(5)° with the plane of the other 19 atoms in the porphyrin ring. This is quite similar to the conformation found in the analogous compound in which the substituted N atom carries an ethoxycarbonylmethyl group (*2*), where the dihedral angle is 19.1° and the substituted N atom lies 0.28 Å out of the N_3 plane. In that structure, there is also a lack of intermolecular hydrogen bonding involving the porphyrin N atoms.

The ^{1}H NMR of porphyrin **3** shows the NCH_2 signals at −4.83 ppm, in agreement with data reported for *N*-methyl-TPP (*12*), while the NCH_2 signals for porphyrin **4** appear at −5.57 ppm. The ^{1}H NMR spectrum of porphyrin **4** also shows two singlet resonances for the four *meso*-protons at 10.67 and 10.61 ppm, which are split into two signals of the same intensity (1:1). In contrast, the ^{1}H NMR spectrum of the disubstituted porphyrin **5** gave two different NCH_2 peaks at −5.80 ppm and −4.25 ppm, and one NH peak at −2.64 ppm. The ^{1}H−^{1}H COSY NMR spectrum for porphyrin **5** shows that the two hydrogen atoms of the NCH_2 are in different environments and therefore generate the two observed peaks at −5.80 ppm and −4.25 ppm. The symmetry observed in the ^{1}H and ^{13}C NMR spectra of porphyrin **5** indicates that the two alkylated nitrogen atoms are adjacent to each other (Figure 3a). The eight β-protons are split into 2:4:2, suggesting adjacent *N*-substitution. Similarly, the ^{1}H NMR spectrum of porphyrin **6** shows three resonances for the *meso*-protons, split into 1:2:1 (Figure 3b), which further indicates that the two substituents are on adjacent nitrogen atoms. Porphyrins **5** and **6** were isolated as the monocations due to the strong basicity of the corresponding free bases. Their remarkable regioselective formation has been previously observed in

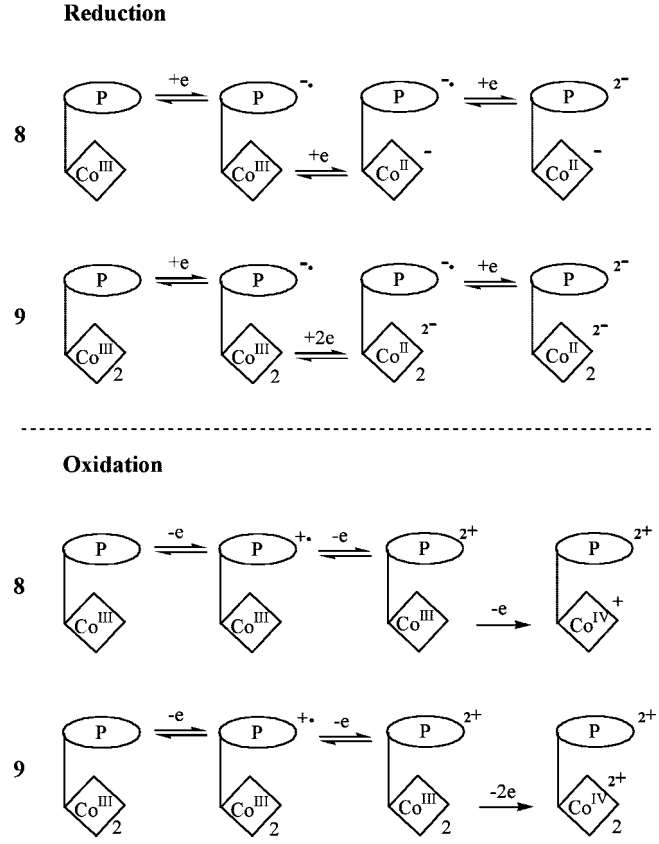
N-alkylation reactions (*30*−*36*). The *N*-methylations of H_2TPP and H_2OEP using a variety of methylation reagents are reported to give adjacent *N*,*N*-dimethyl derivatives due to attack from the less sterically hindered side of the mono-*N*-methylated derivative. The regioselectivity of this reaction has been confirmed by X-ray structures in both cases (*30*, *34*).

N-Substitution is known to increase the degree of nonplanarity of the porphyrin macrocycle, and as a consequence, bathochromic shifts are usually observed in the optical spectra of *N*-substituted porphyrins, which correlate with the degree of conformation distortion (*5*). Significant red-shifts (15−32 nm) in the Soret bands of porphyrins **3**−**6** were observed (Figures 4 and 5), in comparison with the starting porphyrins H_2TPP (**1**) and H_2OEP (**2**) as well as with the *meso*-substituted porphyrins

Scheme 3[a]



[a] Site of electron transfer at the porphyrin or cobaltabisdicarbollide part of conjugates **8** and **9**.

8 and **9** (see Supporting Information, Figures S3 and S4), which result from the distortion of the porphyrin macrocycle upon *N*-substitution. The fluorescence emission spectra of porphyrins **3**−**6** (Figure 6) show nearly complete fluorescence quenching for all *N*-substituted porphyrins (more than 90% as compared with starting porphyrins **1** and **2**), and this is due to strong distortions of the porphyrin planar conformation by the cobaltocarboranes attached to the central nitrogen atom(s). On the other hand, *N*-substituted porphyrins **8** and **9** showed similar spectroscopic data to the starting aminoporphyrin, since in these compounds, there is no significant distortion of the porphyrin macrocycle.

Electrochemistry. The unlinked cobaltbisdicarbollide undergoes two reversible metal-centered reactions (*37*) at $E_{1/2} = -1.34$ V ($Co^{III/II}$) and 1.65 V ($Co^{III/IV}$), while the unlinked free base porphyrin H_2TPP, **1**, displays four reversible reactions, two oxidations and two reductions (*38*). Conjugates **8** and **9** are characterized by six electron transfer processes, four of which are assigned to the porphyrin part of the molecule and two to the cobalt center of the cobaltabisdicarbollide. The cobalt-centered reactions of **8** and **9** occur at $E_{1/2} = -1.35$ to -1.37 V for reduction and $E_p = 1.62$ to 1.64 V for oxidation at a scan rate of 0.1 V/s, and are at virtually identical potentials as for reduction and oxidation of unlinked cabaltabisdicarbollide under the same solution conditions (see dashed lines in Figure 7).

As indicated above, H_2TPP undergoes two reversible one-electron oxidations (at $E_{1/2} = 1.05$ and 1.33 V), and two one-electron oxidations are also seen for conjugates **8** (0.83 and 0.96 V) and **9** (0.78 and 0.93 V). The easier oxidations of **8** and **9** as compared to H_2TPP result from the electron-donating substituent $PhNR_2$ at one *meso*-position of the porphyrin macrocycle. Easier oxidations have also been reported for porphyrins containing $PhNR_2$ substituents at all four *meso* positions of a porphyrin

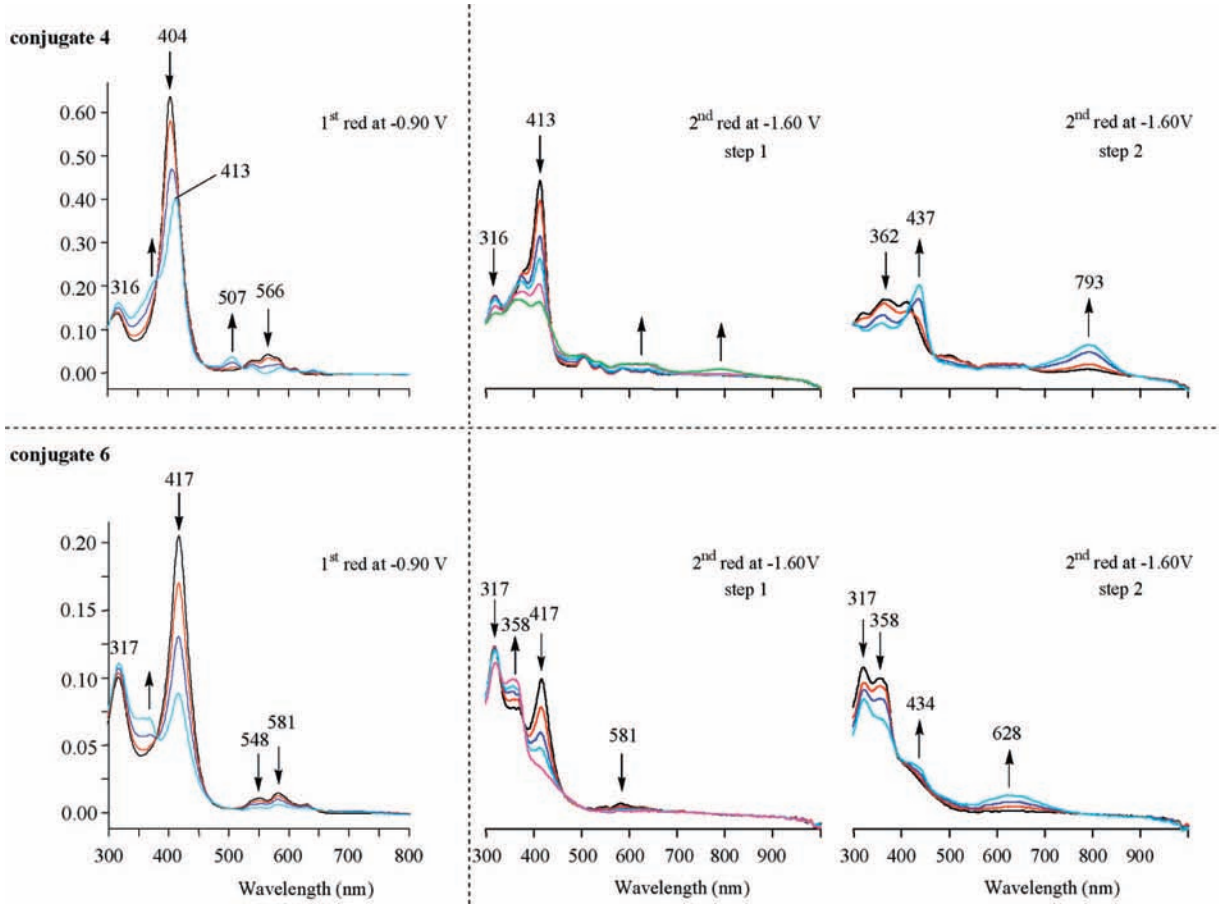


Figure 11. Spectral changes of the *N*-substituted conjugates **4** (top) and **6** (bottom) during reduction processes in PhCN containing 0.1 M TBAP.

macrocycle (*41*−*43*). The difference in potential between the first oxidation of H_2TPP and the first oxidation of conjugate **8** is 220 mV, while the difference in the $E_{1/2}$ value between the second oxidation of the two compounds is 370 mV. A further negative shift in $E_{1/2}$ of 30−50 mV is then seen upon going from conjugate **8** to conjugate **9** in PhCN, 0.1 M TBAP.

The two reversible reductions of H_2TPP at $E_{1/2} = -1.15$ and −1.54 V can be compared to similar electroreduction potentials for conjugate **8** at −1.20 and −1.56 V and conjugate **9** at −1.22 and −1.58 V (Figure 7). Here, the two conjugates are only 10−20 mV harder to reduce than H_2TPP. This lack of a substantial substituent effect on reductions is consistent with what has been observed in the literature for porphyrins with four $PhNR_2$ as *meso* substituents (*41*−*43*).

The reversible reduction potentials of porphyrin **8** at −1.35 V and porphyrin **9** at −1.37 V are unambiguously assigned to the Co^{III}/Co^{II} processes of the linked cobaltabisdicarbollide. The peak currents for reduction of the unlinked cobaltabisdicabollide and **8** are about equal in PhCN, consistent with one electron being transferred in each case. These contrast with what is seen for reduction of **9** where the peak current of the $Co^{III/II}$ process is approximately double that of **8**, consistent with the addition of two electrons, one to each electroactive cobaltabisdicarbollide group on the compound. Changing the number of cobaltabisdicarbollide groups from one to two does not affect the values of $E_{1/2}$, suggesting that no interaction occurs between these two redox centers in conjugate **9**.

A summary of peak potentials for all of the investigated compounds in PhCN is given in Table 1. The reduction of **8** and **9** first proceeds via a one-electron addition to the porphyrin macrocycle giving a π-anion radical, after which one electron is added to each cobaltabisdicarbollide unit at a more negative potential of −1.35 to −1.37 V. Further reduction at the porphyrin macrocycle then occurs at $E_{1/2} = -1.56$ to −1.58 V as shown in Figure 7. This reduction mechanism is shown graphically in Scheme 3 which also includes data for the oxidations. In this case, the first two one-electron abstractions from **8** or **9** ($E_{1/2} = 0.78$ to 0.96 V) involve the porphyrin part of the molecule, and the third electron abstraction involves the cobalt center of the cobaltabisdicarbollide. Additional proof for these assignments is given by spectroelectrochemical data described on the following pages.

Because irreversible chemical reactions are coupled to the electron transfers of **3**−**6**, attempts to assign a mechanism of electron transfer are tenuous at best, and this is made more difficult by the fact that compounds **3** to **6** not only have different core porphyrin structures (H_2TPP vs H_2OEP) but also differ in the number of linked cobaltabisdicarbollide groups (1 or 2) on the central nitrogen atoms. Nonetheless, several comparisons can be made from the current−voltage curves in Figure 8. The first is that **3** and **4**, which have a single linked *N*-substituted cobaltabisdicarbollide group, both show current−voltage curves characteristic of a chemical reaction following electron transfer (an electrochemical EC mechanism). The peak potential for the first reduction of **3** is located at $E_p = -0.49$ V for a scan rate of 0.1 V/s, while the E_p of **4** is located at −0.76 V under the same experimental conditions. This 270 mV difference in peak potential between E_p for reduction of **3** and **4** is similar in magnitude to potential separations for reductions of many metalloporphyrins with OEP and TPP core structures where the TPP derivatives are always easier to reduce (*38*−*40*). In fact, the 280 mV difference in $E_{1/2}$ between the first reduction of H_2TPP (−1.15 V vs SCE) and H_2OEP (−1.43 V) in PhCN,

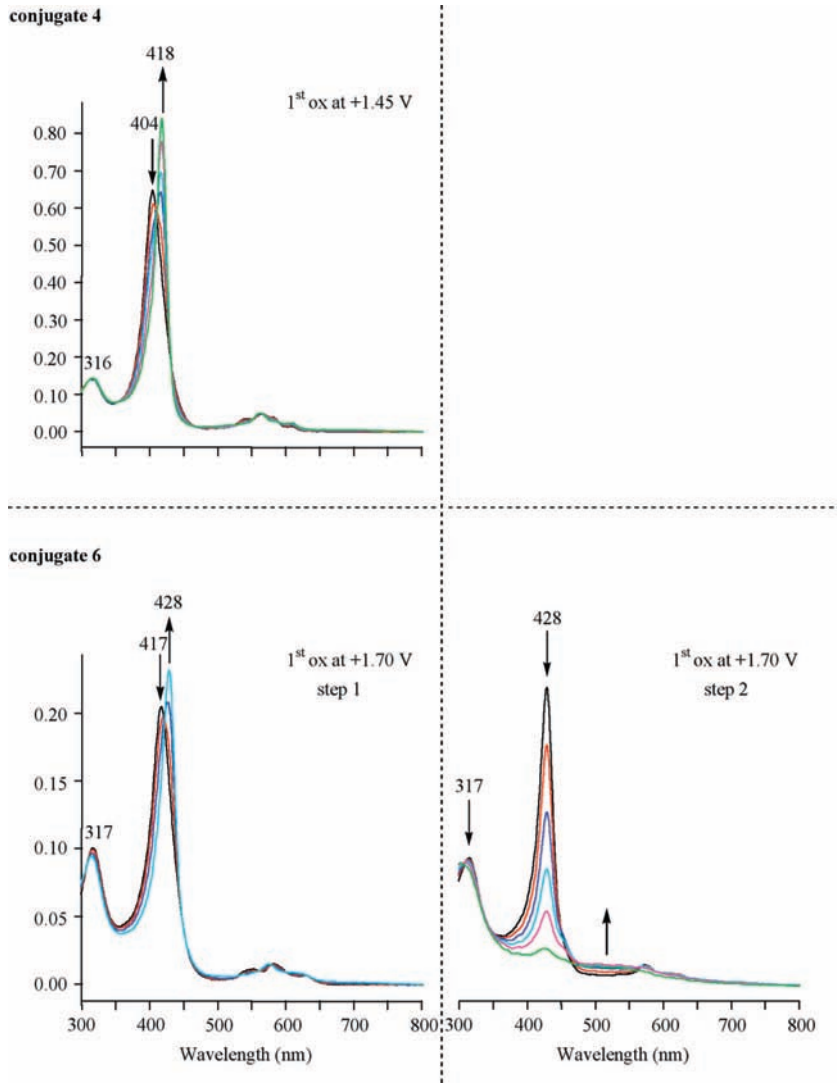

Figure 12. Spectral evolutions of the *N*-substituted conjugates **4** (top) and **6** (bottom) during oxidation processes in PhCN containing 0.1 M TBAP.

0.1 M TBAP, is experimentally the same as the ΔE_p value between the first reduction of **3** and **4** under the same solution conditions.

One can also compare the E_p values for reduction of **3** and **4** to $E_{1/2}$ values for reduction of H_2TPP or H_2OEP (see *refs 38–40* and voltammograms of free-base porphyrins in Supporting Information Figure S5). Conjugate **3** ($E_p = -0.49$ V) is 660 mV easier to reduce than H_2TPP ($E_{1/2} = -1.15$ V), while conjugate **4** (−0.76 V) is 670 mV easier to reduce than H_2OEP (−1.43 V).

Altogether, three reductions are seen for conjugate **3** in PhCN containing 0.1 M TBAP. As mentioned above, the first is irreversible and occurs at $E_p = -0.49$ V. The next two reductions are located at $E_p = -1.17$ V and $E_{1/2} = -1.38$ V and are similar to processes also seen for conjugate **5**. This might suggest that the cobaltabisdicarbollide group dissociates from the porphyrin after the first electron transfer in **5**. The measured redox potentials observed for reaction of the cobalt groups in the H_2TPP-based conjugates (−1.38 and 1.60 V for **3** and −1.40 and 1.57 V for **5**) are similar to $E_{1/2}$ values for the unlinked comparison compound (−1.34 and 1.65 V), and this suggests that in the ground state there are only weak electronic interactions between the porphyrin and cobaltabisdicarbollide groups within the conjugate.

Irreversible oxidation processes are observed at 1.39 and 1.64 V for conjugates **4** and **6**, respectively. Two reduction processes are observed at $E_p = -0.76$ and $E_{1/2} = -1.39$ V in conjugate **4**, while conjugate **6** undergoes several irreversible reduction processes and one reversible reduction at $E_{1/2} = -1.39$ V. Comparison of these values with redox potentials of H_2OEP leads to the conclusion that the reduction at $E_{1/2} = -1.39$ V occurs at the Co(III) center of the cobaltabisdicarbollide group and the oxidation at $E_p = 1.39$ V occurs at the porphyrin macrocycle.

The *N*-cobaltacarboranyl porphyrins **8** and **9** undergo three reversible reductions, two of which are assigned to porphyrin macrocycle reactions and one is characterized by Co^{III} to Co^{II}. They also have two reversible porphyrin ring-centered oxidations and one irreversible Co^{III}/Co^{IV} oxidation.

The core *N*-substituted porphyrins exhibit complicated electrochemical behavior with coupled chemical reactions. However, the cobalt-centered reaction site could be assigned by comparison with the $E_{1/2}$ of the unlinked cobaltabisdicarbollide.

Spectroelectrochemistry. When the intensity of a porphyrin Soret band significantly decreases after a reduction or oxidation, the electron transfer site is generally porphyrin ring-centered, leading to the formation of a π-anion or π-cation radical (*38, 40*). However, when the Soret band is only slightly shifted in wavelength and undergoes little or no change in molar absorptivity upon reduction or oxidation, the electron transfer site can often be assigned as the metal-centered. Thus, comparisons

between the observed spectral changes during oxidation or reduction of the conjugates with spectral changes obtained during oxidation or reduction of H_2TPP and H_2OEP may shed light on the probable site of electron transfer in the investigated compounds.

The changes in spectra during oxidations of conjugate **8** are shown in Figure 9. As the oxidation proceeds, the original Soret band at 424 nm decreases in intensity and shifts to 433 nm and a new band grows at 716 nm. These changes are consistent with formation of a porphyrin π-cation radical during the first electron abstraction. In the second oxidation process, a new intense Soret band grows in 444 nm and a well-defined visible band at 666 nm is also observed. Similar spectral changes are observed during the two oxidations of H_2TPP in PhCN, 0.2 M TBAP (Supporting Information, Figure S6).

The UV−visible spectral evolution upon the first one-electron reduction of **8** or **9** is also similar to spectral changes upon reduction of H_2TPP (Table 2) and is assigned to reactions occurring at the conjugated π-ring system of the porphyrin. During reductions of conjugates **8** and **9**, the Soret band decreases in intensity and a new Soret band is seen at 455−488 nm together with a broad band between 600 and 900 nm, which can be interpreted as formation of a porphyrin π-anion radical. The second reduction of **8** and **9** occurs at the linked cobaltabisdicarbollide. As Co^{II} is formed, there is a decreased intensity of the band at about 314 nm (characteristic of Co^{III}) and an increased intensity of the absorption at the 348 nm band which is assigned to Co^{II}.

In the case of the *N*-substituted conjugates, an assignment of the electron transfer site is less clear. As seen in Figure 10, the spectral evolution of **3** during the first reduction shows a blue shift of the Soret band from 441 nm (Soret band of H_2TPP) to 436 nm. The UV−visible spectrum of the singly reduced conjugate looks similar to that of neutral H_2TPP, thus suggesting loss of the cobaltabisdicarbollide group after the first reduction.

In the case of conjugates **4** and **6**, comparisons may be made with spectral changes during the reduction or oxidation of H_2OEP. When a potential of −0.90 V is applied to a solution of **4** or **6**, a similar evolution of the spectra is seen (Figure 11) and the final spectra can be interpreted in terms of porphyrin π anion radical formation. The second reduction involves two steps for these two conjugates, and here the electron transfer occurs at both the porphyrin π-ring system and the metal center of the cobaltabisdicarbollide group.

For conjugate **6** (Figure 12), a two-step electron transfer occurs during the first oxidation. The intensity of the Soret band at 417 nm decreases and a new band grows at 428 nm. No spectral changes are observed at 317 nm, suggesting that the electron transfer in this step occurs at the porphyrin π-ring system. The Soret band at 428 nm disappears during the second step electron transfer, as the intensity of the band at 317 nm decreases. This band is characteristic for Co(III), and the second electron transfer is therefore proposed to occur at the cobalt center. However, for conjugate **4**, only a one-step electron transfer is observed during the first oxidation, and the spectral changes are similar to the initial oxidation step of conjugate **6**. The results indicate that, for conjugate **4**, the electron transfer occurs at only the porphyrin π-ring system in the first oxidation, while for conjugate **6**, a two-step electron transfer occurs during the first oxidation process, one electron being abstracted from the porphyrin π-ring system and another from the cobaltabisdicarbollide group.

Cellular Delivery and Biological Activity of Antisense Oligonucleotides Conjugated to a Targeted Protein Carrier

Hyunmin Kang, Md. Rowshon Alam, Vidula Dixit, Michael Fisher, and Rudy L. Juliano*

Division of Molecular Pharmaceutics, School of Pharmacy, CB 7360, University of North Carolina, Chapel Hill, North Carolina 27599. Received July 1, 2008; Revised Manuscript Received September 5, 2008

Targeted delivery can potentially improve the pharmacological effects of antisense and siRNA oligonucleotides. Here, we describe a novel bioconjugation approach to the delivery of splice-shifting antisense oligonucleotides (SSOs). The SSOs are linked to albumin via reversible S−S bonds. The albumin is also conjugated with poly(ethylene glycol) (PEG) chains that terminate in an RGD ligand that selectively binds the $\alpha v\beta 3$ integrin. As a test system, we utilized human melanoma cells that express the $\alpha v\beta 3$ integrin and that also contain a luciferase reporter gene that can be induced by delivery of SSOs to the cell nucleus. The RGD-PEG-SSO-albumin conjugates were endocytosed by the cells in an RGD-dependent manner; using confocal fluorescence microscopy, evidence was obtained that the SSOs accumulate in the nucleus. The conjugates were able to robustly induce luciferase expression at concentrations in the 25−200 nM range. At these levels, little short-term or long-term toxicity was observed. Thus, the RGD-PEG-albumin conjugates may provide an effective tool for targeted delivery of oligonucleotides to certain cells and tissues.

INTRODUCTION

Antisense and siRNA oligonucleotides exhibit considerable promise as therapeutic agents (*1, 2*). While there are numerous examples of *in vivo* biological effects of oligonucleotides administered in free form, that is without use of a delivery system (*3, 4*), some investigators have suggested that oligonucleotide-based therapeutics could be enhanced via effective delivery strategies (*5, 6*). In this context, a variety of approaches have been pursued that generally fall into two broad categories. First, there are many reports dealing with the use of various types of nanoparticles for oligonucleotide delivery, including liposomes, lipoplexes, micelles, polymeric nanocarriers, and metallic particles, as discussed in several recent reviews and articles (*7*−*12*). A second strategy has been to synthesize conjugates of oligonucleotides with various peptides including so-called cell-penetrating peptides (*13, 14*), or peptides able to bind to specific cell surface receptors, and thus promote targeting of the conjugate (*15, 16*).

Both of these general approaches have advantages and liabilities. Even relatively small nanoparticles (∼100 nm diameter) are quite large in molecular terms, with masses in the millions of daltons. Nanoparticles cannot readily pass across the capillary endothelium in most normal tissues, and thus their biodistribution is limited to tissues that have extensive fenestrations in the endothelium such as liver, spleen, and some types of tumors (*17*−*19*). Nanoparticles are also scavenged by the phagocytes of the reticuloendothelial system (*20*), thus reducing their delivery to desired sites in the body, although this can be partially attenuated by surface modifications such as conjugation with poly(ethylene glycol) (PEG) (*21*). In contrast, oligonucleotides themselves, being relatively small with masses of several thousand daltons, are rapidly cleared from the bloodstream via renal excretion but nonetheless have broad distribution in many tissues (*22*−*24*). The pharmacokinetics and biodistribution of peptide−oligonucleotide conjugates has only been studied to a limited degree; however, a recent analysis of a peptide−morpholino oligonucleotide conjugate indicated broad distribution to various tissues (*25*).

With these considerations in mind, it seemed desirable to develop intermediate-sized delivery agents for oligonucleotides that might avoid renal clearance and thus have a longer circulation time than free oligonucleotides, but not have the same size constraints on biodistribution as typical nanoparticles. As an initial step in that direction, we report on the synthesis and characterization of macromolecular-scale oligonucleotide carriers based on human serum albumin (HSA). Some of the surface amino groups of albumin are conjugated with PEG chains that terminate in a targeting ligand, namely, a cyclic RGD (Arg-Gly-Asp) peptide. This ligand provides high-affinity binding to the $\alpha v\beta 3$ integrin, which is strongly expressed in angiogenic endothelia and in some tumor cells (*26*). Additional surface amino groups are used to link antisense oligonucleotides to the albumin via bioreversible S−S bridges. In this study, the antisense molecule used was a 2′-*O*-Me-phosphorothioate splice switching oligonucleotide (SSO) (*27*) that was designed to correct splicing of an aberrant luciferase reporter gene. Effective delivery of the SSO to the cell nucleus results in increased luciferase activity and thus provides an easily monitored positive readout.

Albumin has been extensively studied as a nontoxic carrier for conventional drugs (*28, 29*), and thus, we felt that it might have merit as a macromolecular carrier for oligonucleotides as well. The RGD-albumin-SSO conjugates we developed were tested in a cell culture model and were found to provide highly effective receptor-specific delivery. The endocytotic pathway of the conjugates involved trafficking via smooth vesicles rather than clathin-coated pits, and ultimately led to substantial nuclear accumulation of the splice switching oligonucleotide. This resulted in a marked increase in luciferase activity, an effect that was fully inhibited by excess RGD peptide, indicating receptor-dependent delivery. Thus, at the cell culture level, this approach has led to a highly

specific and effective delivery system in the macromolecular or subnanoscale size range.

EXPERIMENTAL PROCEDURES

Materials. Human serum albumin (HSA) was purchased from Sigma-Aldrich (St. Louis, MO, USA). Alexa Fluor 488 C5 maleimide and a CBQCA amino assay kit were obtained from Invitrogen (Carlsbad, CA, USA). Dual-functionalized poly-(ethylene glycol), Malhex-NH-PEG-O-C_3H_6-CONHS (MW 5000), was from Rapp Polymere (Tubingen, Germany). Cyclo-[RGDfK(Ac-SCH_2CO)] peptide was purchased from Peptide International (Louisville, KY, USA). Sulfosuccinimidyl 6-(3′-[2-pyridyldithio]-propionamido) hexanoate (Sulfo-LC-SPDP) was from Thermo Fisher Scientific (Rockford, IL, USA). Glass-bottom tissue culture plates were obtained from MatTek (Ashland, MA, USA). Splice shifting oligonucleotide 623, or a mismatched version, was synthesized by an oligonucleotide core facility at University of North Carolina at Chapel Hill. These oligonucleotides were 2′-*O*-Me phosphorothioates functionalized with thiol groups at the 5′ position; in some cases, a Tamra fluorophore was included at the 3′ position (*15*).

Cells. A375SM melanoma cells that express the $\alpha v\beta 3$ integrin were stably transfected with a plasmid, pLuc/705, containing an aberrant intron inserted into the firefly luciferase coding sequence (*15*). The resulting A375SM-Luc705-B cells were grown in Dulbecco's Modified Eagle's Medium (DMEM) (Gibco/Invitrogen, Carlsbad, CA, USA) supplemented with 10% feta bovine serum (FBS).

Preparation of Albumin Conjugates with Cyclic RGD PEG or Cysteine PEG. Human serum albumin (denoted as A) (5 mg, 7.4×10^{-8} mol) was reacted with either L-cysteine (0.05 mg, 3.67×10^{-7} mol) or Alexa Fluor 488 C5 maleimide (0.27 mg, 3.67×10^{-7} mol) in phosphate buffered saline (PBS) supplemented with 1 mM EDTA (pH 7.4) for 4 h at room temperature to conjugate the single surface thiol group on albumin; this was followed by dialysis (MW cutoff 3500). The amino groups of the albumin were then reacted with Malhex-NH-PEG-O-C_3H_6-CONHS (11 mg, 2.21×10^{-6} mol) in PBS/1 mM EDTA (pH 7.4) for 4 h at room temperature. The product, a human albumin derivative with PEG-maleimide groups on the surface (termed PA), was purified from unincorporated PEG materials by dialysis (MW cutoff 100 000). The average number of PEG groups conjugated to albumin was determined by using the CBQCA assay, according to the manufacturer's instruction, to measure residual free amino groups. The thiol group on cyclic RGDfK needed for conjugation with the maleimide group on albumin was freshly generated by 1 h incubation of cyclo-[RGDfK(Ac-SCH_2CO)] (5 mg, 7.35×10^{-6} mol) in pH 7.0 deprotection buffer (HEPES (50 mM), NH_2OH (50 mM) and EDTA (30 mM)) at room temperature. The maleimide groups on the albumin derivative were then reacted with the thiol group of cyclic RGDfK (or cysteine as a control) in PBS with 1 mM EDTA (pH 7.4) overnight at room temperature and purified by dialysis (MW cutoff 100 000).

Conjugation of RGD-PEG-Albumin with Oligonucleotides. PEG−albumin conjugates, derivatized with either cyclo RGD (termed RPA, 9.2 mg, 7.35×10^{-8} mol) or cysteine (termed CPA, 8.7 mg, 7.35×10^{-8} mol), were reacted with dual functional sulfosuccinimidyl 6-(3′-[2-pyridyldithio]propionamido)hexanoate (1.2 mg, 2.21×10^{-6} mol) linker in PBS with 1 mM EDTA (pH 7.4) for 4 h at room temperature, and purified by dialysis (MW cutoff 100 000). Thiol-derivatized 623 oligonucleotide (or a mismatch version) (see Table 1) was then added to the intermediate in PBS with 1 mM EDTA (pH 7.4), and the reaction was maintained at room temperature for 24 h and purified by dialysis (MW cutoff 100 000). The average number of oligonucleotides linked to albumin was determined as 9.8 by observing the release of pyridine-2-thione (λ_{max} = 343 nm) from the reaction intermediate. This was also confirmed by monitoring the increase in OD260 subsequent to the oligonucleotide conjugation.

[a] All oligonucleotides consist of 2′-OMe ribose residues with a phosphorothioate backbone.

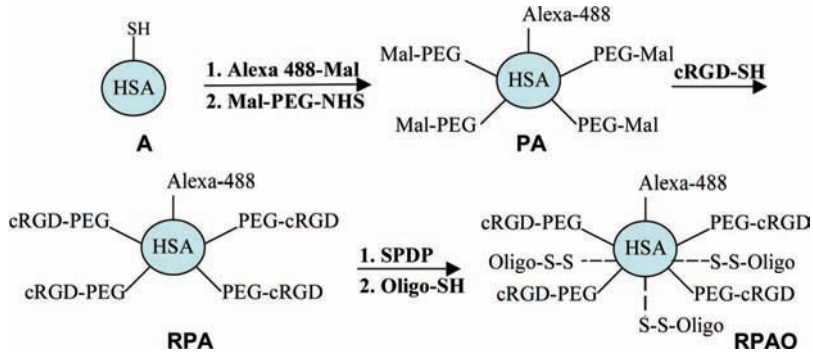
Physical Characterization of the RGD-PEG-Albumin-Oligonucleotide Conjugates. The cyclic RGD derivatized albumin conjugate of oligonucleotide (termed RPAO) was analyzed by gel filtration fast protein chromatography (FPLC) (GE Healthcare) using a Superose 6 10/300 size exclusion column. The size and polydispersity of the conjugates were determined by a quasi-elastic dynamic light scattering (QELS) method as they eluted from the column (Wyatt, Santa Barbara, CA, USA).

Oligonucleotide Treatment of Cells and Luciferase Assay. A375SM-Luc705-B cells were seeded onto 12 well plates at 1×10^5 cells per well in medium containing 10% FBS. After 24 h, cells were rinsed, placed in OPTI-MEM (Gibco/Invitrogen, Carlsbad, CA, USA), and treated with free 623 oligonucleotide, various versions of the PEG-albumin-623 oligonucleotide conjugates, or 623 oligonucleotide complexed with Lipofectamine 2000 per manufacturer's instruction. After 4 h of treatment, FBS was added to each well to 1%. After 24 h, cells were washed with DMEM medium containing 10% FBS and incubated in DMEM supplemented with 1% FBS for 48 h prior to harvest. Activation of luciferase gene expression due to correction of splicing by oligonucleotide 623 was determined using a Luciferase assay kit (Promega, Madison, WI, USA) on a Monolight 2010 instrument (Analytical Luminescence Laboratory, San Diego, CA, USA).

Cellular Uptake and Confocal Microscopy. Cells were seeded onto either 12 well plates at 1×10^5 cells per well for cellular uptake measurements or in 12 well glass-bottom plates at 2×10^4 cells per well for live cell analysis by confocal microscopy. After treatment of cells with Tamra labeled oligonucleotide derivatives for 24 h, the cells were either lysed for measurement of Tamra fluorescence using a Nanodrop microfluorimeter (Nanodrop Technologies, Wilmington, DE, USA) or washed with DMEM containing 10% FBS and then placed in DMEM without phenol red, supplemented with 1% FBS, for confocal microscopy analysis. Colocalization of Tamra-labeled oligonucleotides with Alexa 488 labeled Transferrin or Dextran (Molecular Probes, Beaverton, OR, USA) in live cells was also examined by confocal microscopy. An Olympus confocal microscope with a 60× objective lens was used, and the data were processed using Fluoview software (Olympus, Center valley, PA, USA) as described previously (*15*).

Toxicity Studies. Cells were treated with various concentrations of oligonucleotides or conjugates as described above. After 48 h of treatment, cells were trypsinized and viable cells were counted using a Cellzone electric particle counter (Elmhurst, IL, USA) for short-term toxicity studies or replated at low density in 6 well plates containing a mixture of 1% low gelling temperature agarose (SeaKem, Rockland, ME, USA) supplemented with DMEM-H/10% FBS for 14 day studies of colony forming ability as described previously (*15*).

Scheme 1. Preparation of RGD Targeted HSA Oligonucleotide Conjugates[a]



[a] Alexa 488-Mal = Alexa Fluor 488 C5 maleimde; Mal-PEG-NHS = Malhex-NH-PEG-O-C_3H_6-CONHS; cRGD-SH = cyclo[RGDfK-$COCH_2SH$]; SPDP = Sulfo-LC-SPDP; Oligo-SH = 623-SH, Tamra-623-SH, MM-SH, or Tamra-MM-SH (see Table 1).

Table 2. Measurement of Available Amino Groups on HSA by CBQCA

	CBQCA fluorescence (%)	number of estimated surface amino groups
HSA	100.00 ± 2.2	59
HSA-PEG	81.3 ± 3.3	48

Nuclease Stability. Micrococcal nuclease (400 gel units) was added to solutions of 623-Tamra or RPA-623-Tamra and the samples were incubated for various periods of time at 37 °C. The reactions were then stopped by the addition of EDTA (50 mM), and the fluorescent samples were analyzed on 10% polyacrylamide gels and examined under long-wavelength ultraviolet illumination to detect possible nucleolytic cleavage of the Tamra-labeled oligonucleotides.

RESULTS

Synthesis and Characterization of PEG-Albumin-Antisense Conjugates. The overall strategy for preparation of the various conjugates is outlined in Scheme 1. First, the single sulfhydryl group on human serum albumin was labeled with the green fluorophore Alexa 488 (in some cases, the sulfhydryl was simply blocked by forming an S−S bridge with cysteine). Subsequently, several surface amino groups were reacted with Mal-PEG-NHS to form a pegylated albumin (PA). The number of PEG chains conjugated to PA was determined by using a CBQCA assay to quantitate the number of exposed amino groups on albumin before and after the reaction with PEG; this indicated that approximately 10 PEG chains were conjugated per albumin molecule (Table 2). After purification of the PA conjugate, excess thiol-containing cyclic RGD peptide was reacted with the terminal maleimide groups on PA to form RGD-PEG-albumin (RPA). As a control, cysteine was used instead of RGD to react with the PA; this product was termed CPA. After purification, additional exposed amino groups were reacted with the bifunctional reagent Sulfo-LC-SPDP, and then, the 623 oligonucleotide (or mismatch version) was conjugated to form RPA-Oligonucleotide (RPAO) (also termed RPA-623). In some cases, the 623 oligonucleotide included a 3′ Tamra (red) fluorophore (with the resulting product termed RPA-623-Tamra). The number of oligonucleotides linked to the conjugate was determined in two ways (Figure 1). First, formation of the colored product pyridine-2-thione (λ_{max} = 343 nm) was monitored as the 5′-thiol oligonucleotide reacted with the SPDP-conjugated albumin. Second, the OD260 was determined before and after the conjugation reaction. Both of these methods led to close agreement with 8−11 oligonucleotides linked per albumin in various preparations.

The polyacrylamide gel migration behavior of the starting materials and the conjugates is illustrated in Figure 2A. The

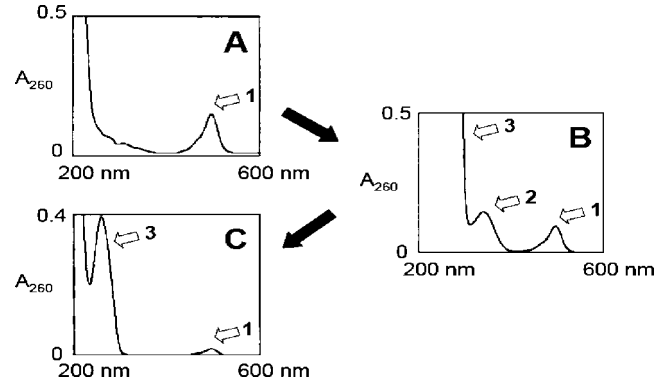


Figure 1. Cleavable disulfide formation between RPA and oligonucleotide. UV spectra of (A) RPA, (B) reaction mixture of RPA-SPDP and 623-SH, and (C) RPA-623. Peak 1: Alexa 488. Peak 2: Pyridine-2-thione. Peak 3: 623. Spectra of diluted samples are shown to include peak 2 and peak 3.

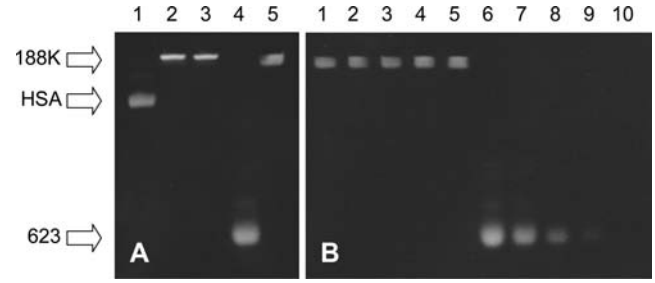

Figure 2. Polyacrylamide gel (10%) electrophoresis analysis of conjugates (A) and nuclease resistance (B). Panel (A): (1) HSA-Alexa 488, (2) PA-Alexa 488, (3) RPA-Alexa 488, (4) 623-Tamra, (5) RPA-623-Tamra. Panel B: RPA-623-Tamra (1−5) and 623-Tamra (6−10) were digested with Micrococcal nuclease (400 gel units) for 0 h (1,6), 1 h (2,7), 2 h (3,8), 4 h (4,9), and 12 h (5,10).

623-Tamra and RPA-623-Tamra are detected by their red fluoresence, while the RPA is detected by its green (Alexa 488) fluorescence. As seen, Alexa 488-modified human serum albumin migrated well into the gel, consistent with its molecular weight of 68 kDa, while the unconjugated 623-Tamra oligonucleotide migrated near the dye front. Both RPA and RPA-623-Tamra failed to significantly enter the gel, indicating molecular size greater than the largest molecular weight marker used (188 kDa). We also used gel analysis to evaluate the relative nuclease stability of 623-Tamra versus that of RPA-623-Tamra. As seen in Figure 2B, although 623-Tamra is a rather stable 2′-*O*-Me-phophorothioate oligonucleotide, incubation with micrococcal nuclease caused a gradual degradation of this material. In contrast, there was no loss of Tamra-labeled

	Polydispersity Mw/Mn	Hydrodynamic radius Rh(z)
HSA	1.000 ± 0.003	2.2 nm
RPA-623	1.092 ± 0.013	6.0 nm

Figure 3. FPLC/QELS analysis. Starting materials (HSA and 623 oligonucleotide) and the final RPA-623 product were analyzed for relative molecular size using FPLC/QELS as described in experimental procedures. The faster migrating shoulder peaks seen in the HSA and 623-SH samples likely represent S−S bridged dimers.

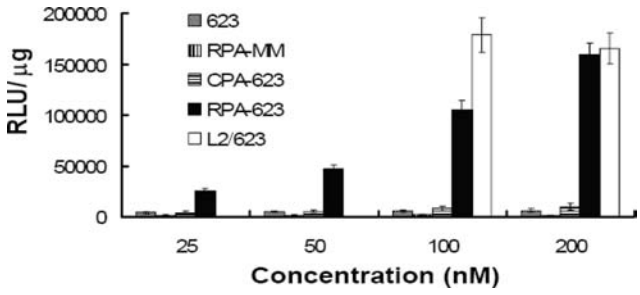

Figure 4. Dose response and specificity studies. Cells were treated with free 623, RPA-MM, CPA-623 (prepared by conjugating cysteine with the maleimide on PEG), RPA-623 at 25 to 200 nM, or 623 complexed with Lipofectamine 2000 (1.5 ug/mL) at 100 and 200 nM (L2/623) as described in experimental procedures. Luciferase activity was determined after 72 h from the cell lysates and expressed as relative luminescence units (RLUs) per ug of protein. Results are means and standard errors of three determinations.

oligonucleotide from the RPA-623-Tamra conjugate. This suggests that the oligonucleotides linked to PEG−albumin are partially protected against nuclease degradation.

The molecular size of the RPA-623 conjugate was estimated using size-exclusion chromatography and quasi-elastic laser light scattering. As indicated in Figure 3, the RPA-623 conjugate is heterodisperse, migrating as a broad peak while albumin has a sharper migration profile. The hydrodynamic radius of the RPA-623 conjugate was estimated at approximately 6 nm, while that of albumin was estimated at 2.2 nm. Thus, the average radius of the conjugate is about 2.7 times that of the ummodified albumin carrier. The albumin−oligonucleotide conjugates were stable during several weeks' storage in buffer at 4 °C, with no indication of aggregation.

Pharmacological Effect of the PEG-Albumin-Antisense Oligonucleotide Conjugates. In order to evaluate the pharmacological effectiveness of the conjugates, A375SM-Luc705-B cells were incubated with various concentrations of "free" 623 oligonucleotide, 623 complexed with Lipofectamine 2000, or several versions of the conjugates, and the increase in luciferase activity was quantitated. As indicated in Figure 4, treatment with the RPA-623 conjugate resulted in a concentration-dependent increase in luciferase activity over the range 25−200 nM, while use of a mismatched oligonucleotide version (RPA-MM), or a version where the PEG chains were terminated with cysteine (CPA-623), failed to achieve an effect. Free 623 also did not cause a significant increase in luciferase activity, while 623 complexed with Lipofectamine 2000 had a strong effect. It is interesting to note that the magnitude of the effect achieved

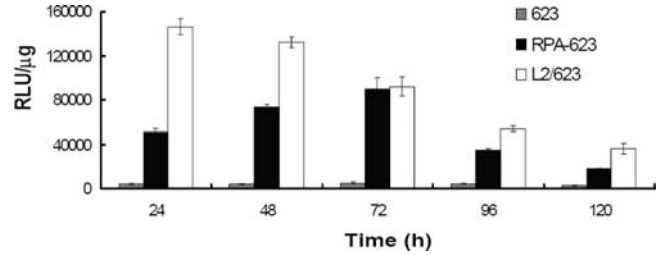

Figure 5. Time response studies. Cells were treated with 200 nM of free 623, RPA-623, or 623 complexed with Lipofectamine 2000 (1.5 ug/mL) (L2/623). After 24 h, cells were washed and placed in DMEM/1% FBS. Luciferase activity was determined from cell lysates collected at various times and expressed as relative luminescence units (RLUs) per microgram of cell protein as described in experimental procedures. Results are means and standard errors of three determinations.

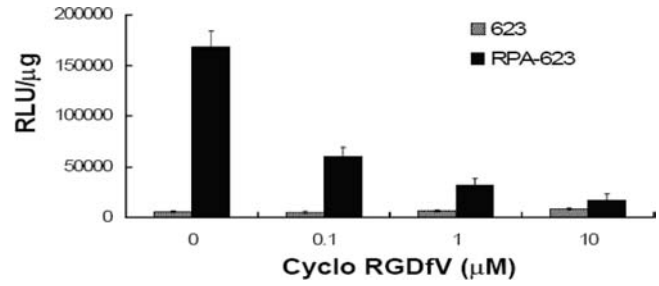

Figure 6. Inhibition of 623 antisense effect by excess cRGD peptide. Free cyclo RGDfV peptide at the indicated concentrations was added to the cells 30 min prior to treatment with either free 623 (100 nM) or RPA-623 (100 nM). Luciferase activity was determined after 48 h from cell lysates and expressed as relative luminescence units (RLUs) per microgram of cell protein. Results are means and standard errors of three determinations.

by the RPA-623 conjugate almost equaled that of the Lipofectamine complex; the latter is often considered the "gold standard" for delivery of oligonucleotides to cells in culture. The time course of luciferase activation differed markedly between RPA-623 and the 623-Lipofectamine complex. Thus, as seen in Figure 5, treatment with RPA-623 resulted in activity that rose gradually, attained a maximum at 72 h post-treatment, and then gradually declined. In contrast, use of the 623-Lipofectamine complex resulted in a rapid rise of activity within 24 h of treatment followed by a monotonic decline. This pattern suggests that the Lipofectamine complex rapidly delivers olgonucleotide to the cytosol and nucleus, while delivery of oligonucleotide from the RPA-623 conjugate involves a more complex and protracted trafficking within the cell. The intracellular delivery mediated by the RPA-623 conjugate clearly involves the $\alpha v\beta 3$ integrin since, as seen in Figure 6, incubation with excess cyclic RGD peptide completely blocks the ability of the conjugate to activate luciferase. At the concentrations used, the RGD peptide does not cause cell detachment or other obvious toxicity.

Uptake and Subcellular Distribution of the Conjugates. We examined the total cellular accumulation of the various materials using a Nanodrop fluorimeter assay, as seen in Figure 7. Total uptake was approximately linear with time in all cases. The highest uptake was observed with 623-Tamra complexed with Lipofectamine 2000, followed by RPAO (either 623 or mismatched), followed by CPA-623 and free 623-Tamra.

We also examined the subcellular distribution of the 623-Tamra labled oligonucelotide after delivery by the conjugates or via complexation with Lipofectamine. As seen in Figure 8, live cells treated with either RPA-623-Tamra or a Lipofectamine 2000/623-Tamra complex displayed substantial intracellular Tamra fluorescence at 24 h, including material present in

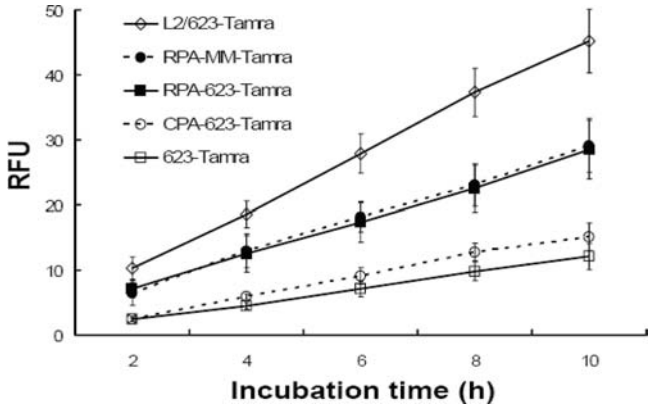

Figure 7. Cellular accumulation. Cells were treated with 100 nM of free 623-Tamra, 623-Tamra complexed with Lipofectamine 2000 (1.5 ug/ml) (L2/623), RPA-MM-Tamra, RPA-623-Tamra, or CPA-623-Tamra. After each incubation period, cells were washed and lysates were analyzed using a Nanodrop fluorimeter for uptake measurements. Results are means and standard errors of three determinations.

cytoplasmic vesicles as well as in the nucleus. By contrast, cells treated with free 623-Tamra or with CPA-623-Tamra exhibited less intracellular fluorescence with no evidence of nuclear accumulation. These observations suggest that the RGD-PEG-albumin conjugate can provide effective delivery of the pendant oligonucleotides to the cell nucleus.

To further understand the cellular uptake and trafficking of the conjugates, we coincubated them with well-known markers for different endocytotic pathways and then compared their subcellular distributions. In these studies, we used transferrin as a marker for clathrin-coated vesicle-mediated uptake and dextran as a marker for smooth vesicle endocytosis (*30*). These molecules were labeled with Alexa 488, a green fluorophore, while the RPA-623-Tamra conjugate displays a red fluorescence. As seen in Figure 9, at early time points (2 h) there was little overlap of the RPA-623-Tamra fluorescence with that of transferrin, but there was substantial overlap with the dextran fluorescence. At later time points, there was fluorescence overlap in both cases, although it was most pronounced for dextran. Nuclear accumulation of Tamra fluorescence was observed at the later time points, similar to that seen in Figure 8. These observations suggest that the RGD-PEG-albumin-oligonucleotide conjugate (RPAO) is initially taken up via smooth vesicle endocytosis, but later the material enters endomembrane compartments that are accessible via both the coated vesicle and smooth vesicle pathways. Inhibitor studies were consistent with this interpretation. Thus, as seen in Figure 10, cellular accumulation of the RPA-623-Tamra was inhibited by nontoxic concentrations of β-cyclodextrin and by cytochalasin D (as well as by excess RGD peptide). This indicates that the RPA-623-Tamra is taken up by an actin-dependent pathway that involves smooth vesicles rich in lipid-raft components (*30*).

Lack of Cytotoxicity of the Conjugates. We examined the cytotoxicity of the RPA-623 conjugate using both short-term and long-term assays. A375MLuc705 cells were treated with RPA-623, free 623, or 623 complexed with Lipofectamine. For the short-term assay, cell number was determined immediately after the incubation period. The long-term assay involved colony formation in soft agar over a 14 day period. As seen in Figure 11, there was little acute or long-term toxicity of RPA-623 even when used at concentrations needed to obtain a strong pharmacological effect.

DISCUSSION

Albumin has a long history as a biodegradable, nontoxic carrier for conventional low molecular weight drugs (*28, 29*). Here, we have employed human serum albumin as a targetable carrier for antisense oligonucleotides. The splice-switching oligonucleotide (SSO) termed 623 was conjugated to albumin via reversible S−S linkages. RGD-PEG chains were also conjugated in order to provide stabilization and the ability to target a specific cell surface receptor, the $\alpha v\beta 3$ integrin. This approach has provided a highly efficient carrier system that could be exploited in a variety of ways. The overall strategy is very flexible, and one could easily visualize using many other high-affinity ligands in addition to RGD peptides, thus offering the possibility of "targeting" to many types of cell surface receptors. The "payload" of the conjugates is quite high, with an average of 10 oligonucleotides of approximately 7000 MW conjugated per albumin; this means that the molecular mass of the payload is similar to the total mass of the albumin. PEGylation seems necessary, since in preliminary studies (not shown), we found that conjugation of the oligonucleotides to albumin in the absence of PEG led to nonspecific binding to cells. Interestingly, the PEG moieties also seemed to provide some protection against oligonucleotide degradation mediated by an endonuclease.

The RGD-PEG-albumin-oligonucleotide conjugate (RPA-623-Tamra) was taken up by cells in an RGD-dependent

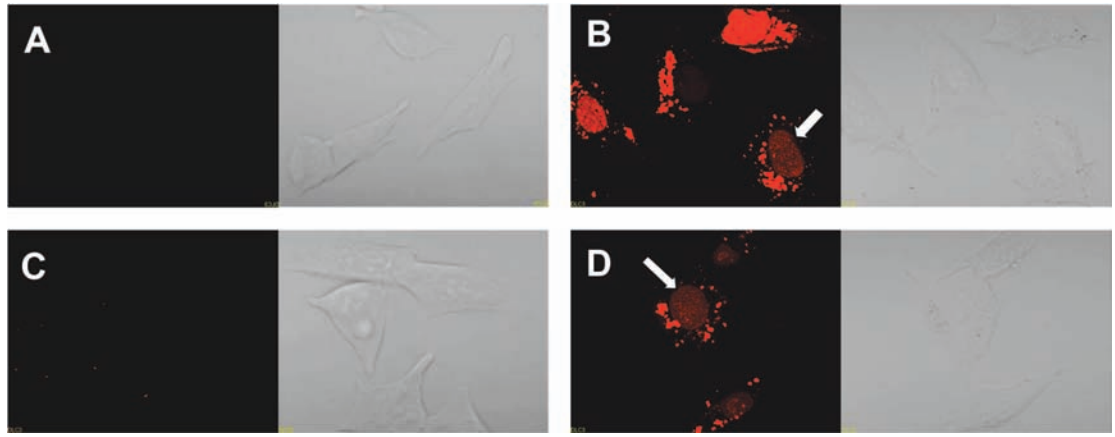

Figure 8. Confocal microscopy analysis of 623 uptake. Cells were treated with 100 nM of either (A) free 623-Tamra, (B) 623-Tamra complexed with Lipofectamine 2000 (1.5 ug/mL), (C) CPA-623-Tamra, or (D) RPA-623-Tamra as described in experimental procedures. After 24 h, cells were washed with DMEM containing 10% FBS and placed in DMEM supplemented with 1% FBS without phenol red for analysis on an Olympus confocal fluorescence microscope as described in experimental procedures. Arrows indicate Tamra fluorophore accumulated in nuclei.

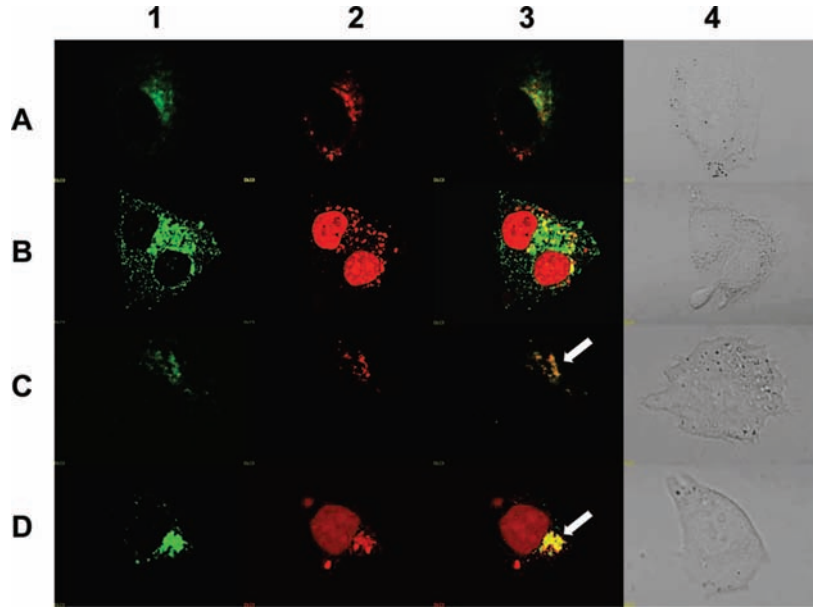

Figure 9. Colocalization of 623 with endosomal pathway markers. RPA-623-Tamra (100 nM) prepared by conjugating an HSA surface thiol group to a cysteine instead of Alexa 488 was coincubated with (A) Transferrin-Alexa 488 (200 nM) for 2 h, (B) Transferrin-Alexa 488 (100 nM) for 24 h, (C) Dextran-Alexa-488 (2 uM) for 2 h, and (D) Dextran-Alexa-488 (2 uM) for 24 h. Live cells were observed for (1) Alexa-488, (2) Tamra, (3) merged images of Alexa-488 and Tamra, and (4) differential interference contrast (DIC) image using an Olympus confocal fluorescence microscope as described in experimental procedures. Arrows represent colocalization of Alexa 488 and Tamra fluorophores.

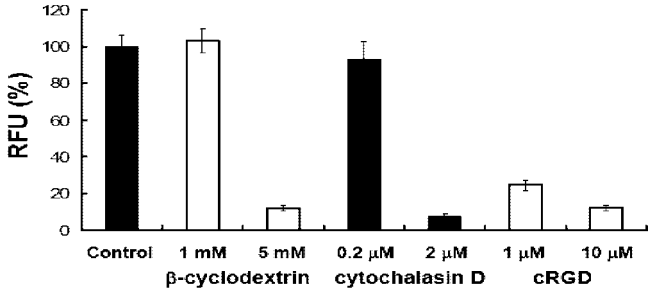

Figure 10. Cellular uptake inhibition. Cells were treated with β-cyclodextrin, cytochalasin D, or cyclo RGDfV (cRGD) for 30 min prior to treatment with either free 623-Tamra (100 nM) control or RPA-623-Tamra (100 nM). After 4 h, cells were washed and lysates were analyzed using a Nanodrop fluorimeter for uptake measurements. Results (RFU) are expressed as percentages relative to RFU of control (no inhibition) and are means and standard errors of three determinations.

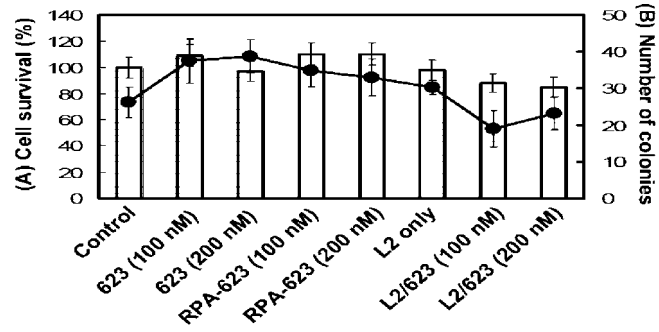

Figure 11. Toxicity studies. Cells were treated with free 623, 623 complexed with Lipofectamine 2000 (1.5 ug/ml) (L2/623), or RPA-623 under the same conditions as used for luciferase induction experiments. After 48 h, cells were trypsinized and viable cells were counted for short-term studies (A, shown as bars). Alternatively cells were replated in 6 well plates containing a mixture of 1% low gelling temperature agarose and complete DMEM medium with 10% FBS for long-term toxicity studies (B, shown as circles and a line). After 14 days, surviving colonies larger than 25 cells were counted. Survival is expressed as colonies per 100 cells plated.

fashion and was initially delivered to smooth-walled endosomes rich in lipid rafts and then trafficked to additional endomembrane compartments. Thus, the initial path of entry of the RGD conjugates seems similar to that of integrins themselves, which utilize smooth-walled vesicles, including caveolae, for internalization (*31*, *32*). Eventually, 623 oligonucleotide was delivered to the nucleus where it exerted a strong effect in terms of correcting splicing of the aberrant luciferase reporter gene. This effect was attained when the conjugate was used at oligonucleotide concentrations in the 25−200 nM range.

It is interesting to note that the degree of nuclear delivery and the subsequent effect on luciferase were very similar using the RPA conjugate and utilizing a Lipofectamine 2000 complex. However, given the long history of therapeutic use of albumin and of various PEGylated proteins (*33*), it seems likely that delivery using the albumin conjugates will be far less toxic *in vivo* than delivery obtained with cationic lipid complexes (*34*). It will also be of interest to see if the current albumin carrier technology can be adapted to the delivery of duplex siRNAs, as well as single-stranded antisense compounds.

The RPA-623 complex is polydisperse with an average hydrodynamic radius of about 6 nm. This is substantially smaller than the size of most nanoparticles currently being used to carry therapeutic agents (*35*); however, it is large by molecular standards. Thus, egress of the RPA-623 conjugates from the bloodstream in many normal tissues will be limited to some degree. It seems likely that RPA-623 will be able to exit capillaries via the so-called "large pore" system that allows egress of proteins as large as pentavalent IgM, but will have restricted access to the more abundant small pore system that largely excludes molecules >4.5 nm (*18*). In some tumors, as well as inflamed tissues, gaps in the endothelium allow egress of larger molecules, possible including the RPA conjugates (*36*). In contrast, an unconjugated oligonucleotide (5−15 000 da) is likely to have a much broader tissue distribution. In the current case, it may be possible to devise PEG-albumin-oligonucleotide conjugates that utilize smaller or fewer PEG molecules, thus reducing hydrodynamic radius and allowing more extensive

tissue distribution; this issue remains to be explored. In any case, further development of this intermediated-sized delivery system for oligonucleotides will entail substantial *in vivo* experimentation. Here, we have simply explored the basic aspects of the system at the cellular level.

Delivery of imaging agents to the brain is highly important for the diagnosis and treatment of central nervous system (CNS) diseases, as well as the elucidation of their pathophysiology. Quantum dots (QDs) provide a novel probe with unique physical, chemical, and optical properties, and become a promising tool for *in vivo* molecular and cellular imaging. However, their poor stability and low blood−brain barrier permeability severely limit their ability to enter into and act on their target sites in the CNS following parenteral administration. Here, we developed a QDs-based imaging platform for brain imaging by incorporating QDs into the core of poly(ethylene glycol)−poly(lactic acid) nanoparticles, which was then functionalized with wheat germ agglutinin and delivered into the brain via nasal application. The resulting nanoparticles, with high payload capacity, are water-soluble, stable, and showed excellent and safe brain targeting and imaging properties. With PEG functional terminal groups available on the nanoparticles surface, this nanoprobe allows for conjugation of various biological ligands, holding considerable potential for the development of specific imaging agents for various CNS diseases.

INTRODUCTION

Delivery of imaging agents to the brain is highly important for the diagnosis and treatment of central nervous system (CNS) diseases (*1*−*3*), which also offers the opportunity to examine the structural, functional, and biochemical changes in the brain that will lead to new insights regarding the pathophysiology of these disorders. However, brain delivery of agents is often restricted by the blood−brain barrier (BBB), which is formed by tight junctions within the capillary endothelium, preserving brain homeostasis as well as preventing active agents against doing their jobs in the brain (*4*).

Quantum dots (QDs), semiconductor nanocrystals with unique physical, chemical, and optical properties, are now emerging as a revolutionary means for imaging and optical detection (*5*−*7*) and achieving more and more attention in neuroscience (*8*, *9*). Functionalized QDs obtained by attaching to ligands such as antibodies (*10*), peptides (*11*), and carbohydrates (*12*) have been used for *in vivo* molecular and cellular imaging. TAT-conjugated quantum dots have been described for brain imaging following intra-arterial administration (*13*). A recent report suggested that transferrin-conjugated quantum rods as probes were efficient for transmigration across an *in vitro* BBB (*14*). However, the major drawbacks of these previous QDs-based imaging techniques are their poor stability in aqueous media and in the biological systems (*15*−*17*). Encapsulations of QDs with amphiphilic copolymers (*10*) and phospholipids (*18*) have been previously presented to increase the solubility and stability of QDs but limited by their low payload capacity and lack of brain delivery ability. In general, the poor stability and lack of BBB permeability severely limit the ability of QDs to enter into and act on the target sites in the CNS following parenteral administration.

Previous studies in our laboratory and others have demonstrated that intranasal administration offers a practical, noninvasive, alternative route for drug delivery to the brain (*19*−*21*). Our recent work suggested that it is possible to deliver agents carried by certain lectin-functionalized nanoparticles into the brain via intranasal administration (*22*−*24*). Continuing these efforts, here we developed a quantum dots-based nanoplatform for brain imaging by encapsulating QDs into the core of poly(ethylene glycol)−poly(lactic acid) (PEG-PLA) nanoparticles and conjugating the nanoparticles with wheat germ agglutinin (WGA) to improve their brain delivery. This innovative approach raises new possibilities for the development of QDs-based specific imaging agents for various CNS diseases. To address the feasibility of this nanoplatform, we evaluate the particle size, zeta potential, internal structure, biobinding activity, and stability under *in vitro* settings, as well as biodistribution, brain delivery, and imaging property of the resulting nanoparticles in animals following intranasal administration.

EXPERIMENTAL PROCEDURES

Preparation of WGA-Functionalized Quantum Dots-Loaded Nanoparticles (WGA-QDs-NP). WGA-QDs-NP were prepared by incorporating tri-*n*-octylphosphine oxide-coated CdSe/ZnS QDs (TOPO-QDs) into PEG-PLA nanoparticles followed by conjugating the resulting nanoparticles with Traut's reagent-thiolated WGA via maleimide groups at the ends of the PEG spacers (Scheme 1). TOPO-QDs, high-quality, hydrophobic QDs (size: 7.2 nm, emission wavelength: 607 nm), were synthesized as described previously (*25*) and kindly provided by Dr. Yang Yue (National Laboratory for Infrared Physics, Shanghai Institute of Technical Physics, Chinese Academy of Sciences). Methoxy-PEG-PLA and maleimide-PEG-PLA were synthesized by ring-opening polymerization of D,L-lactide (99.5% pure, PURAC) initiated by methyl-PEG and maleimide-

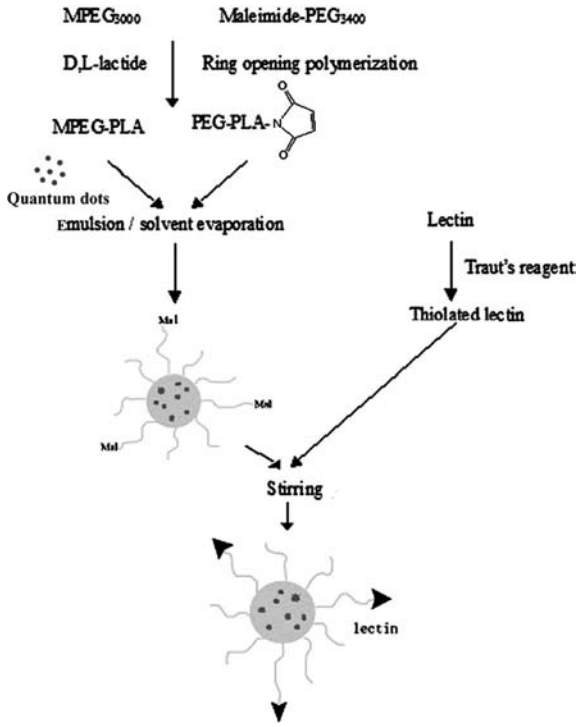
Scheme 1. Preparation of Lectin-Functionalized Quantum Dots-Loaded Nanoparticles 80 × 99 mm² (600 × 600 DPI)



PEG, respectively, using stannous octoate as catalyst (*26*). QDs-loaded PEG-PLA nanoparticles were prepared with a blend of maleimide-PEG_{3400}-PLA_{54000} and methyl-PEG_{3000}-PLA_{49000} using an emulsion/solvent evaporation technique. Briefly, 1 mg maleimide-PEG-PLA and 9 mg methyl-PEG-PLA were dissolved in 0.5 mL of dichloromethane containing 3.2×10^{-5} mol/L QDs. The solution was then emulsified by sonication (220 w, 30 s) on ice in 2 mL of a 1% aqueous sodium cholate solution. The emulsion obtained was diluted into 8 mL of a 0.5% aqueous sodium cholate solution under moderate magnetic stirring. Five minutes later, dichloromethane was evaporated at low pressure at 30 °C using Büchi rotavapor R-200 (Büchi, Germany). Then, the nanoparticles were centrifuged at 21 000 *g* for 45 min using TJ-25 centrifuge (Beckman Counter, USA) equipped with an A-14 rotor. The supernatant was discarded, and the obtained nanoparticles were subjected to a 1.5 × 20 cm sepharose CL-4B column and eluted with 0.05 M HEPES buffer (pH 7.0) containing 0.15 M NaCl to remove the QDs un-entrapped or absorbed to the exterior of the nanoparticles. Then, the QDs-loaded nanoparticles were incubated with 2-iminothiolane-thiolated WGA at the ratio of thiolated lectin to maleimide 1:3 for 9 h for WGA conjugation. After that, the resulting WGA-QDs-NP were purified with a 1.5 × 20 cm Sepharose CL-4B column.

Morphology, Particle Size, and Zeta Potential of WGA-QDs-NP. Morphological examination of the nanoparticles was performed by transmission electron microscopy following negative staining with sodium phosphotungstate solution. The mean diameter and zeta potential of the nanoparticles were determined by dynamic light scattering analysis using Zeta Potential/Particle Sizer NICOMPTM 380 ZLS, respectively.

Internal Structure and Payload Capacity of WGA-QDs-NP. In order to determine the internal structure of WGA-QDs-NP, the nanoparticles were diluted to appropriate concentration and observed under a freeze−fracture electron microscope (JEOL 2010, JEOL, Japan) as described below. First, the samples were suspended in a microperforated grid under controlled temperature (25 °C) and humidity conditions (95−99%) and blotted gently to form a 100−250 nm thick liquid film with a filter paper. The liquid film was then immediately plunged into liquid ethane at its freezing point (−183 °C), producing a vitrified specimen, and kept under liquid nitrogen until loaded onto a cryogenic sample holder. Vitrified samples were observed under the freeze−fracture electron microscope at 200 kV using a magnification of 40 000. Images were recorded using a Gatan 832 multiscan CCD camera.

Haemagglutination Test. The retention of the bioactivity of WGA following covalent coupling to the surface of nanoparticles was confirmed by a haemagglutination test. Unmodified QDs-loaded NP and WGA-QDs-NP were incubated with 20% (v/v) suspension of fresh rat blood in 0.9% NaCl at 37 °C for 30 min, respectively. After that, the mixtures were observed under a fluorescence microscope (Olympus IX71), and the images were taken and colored with Image-Pro Plus.

Stability of WGA-QDs-NP in Aqueous Solution and in Serum. WGA-QDs-NP were prepared as 5 mg/mL solution in water and stored at 4 °C for one week and in serum for 24 h, respectively. After that, the solutions were diluted to appropriate concentration with the morphology and internal structure of the nanoparticles observed under freeze−fracture electron microscopy as described above.

Optical Properties of WGA-QDs-NP. The optical properties of WGA-QDs-NP were characterized by a luminescence spectrometer and compared with those of QDs at the excitation wavelength of 400 nm and emission wavelength between 550 and 650 nm. The excitation slit was 10.0 nm, E_m slit 2.5 nm, scan speed 30 nm/min, and the scan times 10 with a delay of 120 s.

Biodistribution of WGA-QDs-NP Following Intranasal Administration. Biodistribution of WGA-QDs-NP following intranasal administration in BALB/c nude mice was investigated by a NightOWL II LB983 NC320 *in vivo* optical imaging system (Berthold Technologies, Oak Ridge, TN) consisting of a highly sensitive Peltier cooled backlit CCD camera (2184 × 1472 pixels). The animal experiments were performed according to the protocols evaluated and approved by the ethical committee of Fudan University. First, nude mice (25−30 g) were anesthetized with sodium pentobarbital (50 mg/kg, i.p.) and imaged for the signal of autofluorescence. After that, the animals were given intranasally with WGA-QDs-NP at the dose of about 40 mg/kg (QDs 3.2×10^{-8} mol/kg) in 10 μL (5 μL each nostril) and imaged at 2 min and 1, 2, 3, 4, and 8 h postadministration, respectively ($n = 6$ for the time points of 2 min and 1, 2, and 3 h; $n = 3$ for the time points of 4 and 8 h). For imaging, mice were placed in the light-tight chamber, the filters for excitation and emission were set at 530 and 600 nm, respectively, and the photon emission was integrated over a period of 5 s. After that, a gray scale reference image was collected under white light. For localization of the photon emission, gray scale and pseudocolor images were merged using *WinLight* (*32*) software. From the luminescent images, regions of interest (ROIs) were drawn, and the peak and integrated bioluminescence flux (photons/s) were calculated utilizing the software.

To determine the biodistribution of WGA-QDs-NP in various organs, three hours following administration, three mice were euthanized and fixed by heart perfusion with their brains, hearts, livers, spleens, lungs, and kidneys collected for imaging under the NightOWL II LB 983 imaging system. After that, the brain tissues were immersed in 4% paraformaldehyde for 24 h, dehydrated in sucrose solution, embedded in Tissue-Tek O.C.T compound (Sakura Finetek, USA) and stored at −70 °C until frozen sectioning. Finally, the sections were transferred to microscope slides, counterstained with 4′,6-diamidino-2-phenylindole (DAPI), and observed under a fluorescence micro-

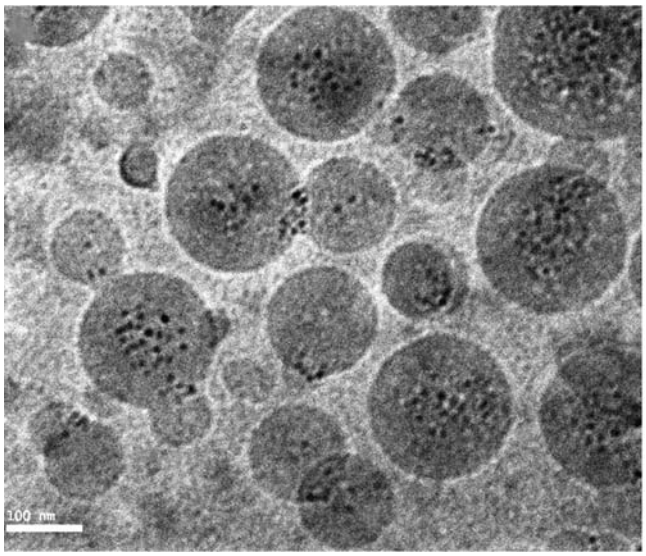

Figure 2. Internal structure of WGA-conjugated quantum dots-loaded nanoparticles (WGA-QDs-NP) exhibited by freeze−fracture electron microscopy. Bar, 100 nm. 80 × 68 mm (600 × 600 DPI).

scope (Olympus IX71) to determine the distribution of WGA-QDs-NP in the CNS.

RESULTS

Characterization of WGA-QDs-NP. The resulting nanoparticles exhibited a spherical shape under the examination of a transmission electron microscope (Figure 1B) with a number-based average diameter (95.3 ± 41.0 nm) comparable to that of the QDs-free WGA-functionalized nanoparticles (Figure 1A, 92.0 ± 33.7 nm). The zeta potential of WGA-QDs-NP was −22.67 ± 1.21 mV, which was also similar to that of QDs-free WGA-functionalized nanoparticles (−18.9 ± 2.4 mV). We examined the internal structure of WGA-QDs-NP with freeze−fracture electron microscopy, finding out that numerous QDs were encapsulated into each nanoparticle and most of them located at the center of the particles (Figure 2). We believe this phenomenon is mainly resulted from the strong hydrophobic interaction between TOPO and PLA fragment of the polymer, which composes the core of the resulting PEG-PLA nanoparticles (*27*).

The retention of WGA's bioactivity following covalent coupling to the surface of the QDs-loaded nanoparticles was confirmed by haemagglutination test. It was exhibited that the erythrocytes agglutinated following their incubation with WGA-QDs-NP and all the red fluorescence of QDs specifically stuck to the surface of the erythrocytes (Figure 3A). But in the case of the unmodified QDs-loaded nanoparticles, the fluorescent signals dispersed at random and did not show any specific affinity to erythrocytes (Figure 3B). This evidence clearly suggested that WGA, treated through the covalent coupling procedure, still retained the carbohydrate binding bioactivity and the incorporation of QDs into the nanoparticles did not alter the biobinding activity of the lectin-functionalized nanoparticles.

Stability of WGA-QDs-NP in aqueous solution and in serum was evaluated under freeze−fracture electron microscopy, respectively. The photos showed that WGA-QDs-NP dispersed well in water without significant changes in particle size even after one week storage (Figure 4A). Furthermore, they retained their structures and loadings after 24 h incubation in serum (Figure 4B). Such telling results strongly suggested the excellent solubility and stability of the present nanoplatform, indicating its potential to serve as a probe for imaging in the biological systems.

Optical properties of WGA-QDs-NP were characterized by a luminescence spectrometer and compared with those of QDs. The spectral curves of QDs reduced in intensity with increased light exposure, while those of WGA-QDs-NP showed a slightly blue shift but remained unchanged under the same scan condition (Figure 5), suggesting that the incorporation of QDs in the core of PEG-PLA nanoparticles also significantly improved their photostability.

Biodistribution of WGA-QDs-NP Following Intranasal Administration. Biodistribution of WGA-QDs-NP following intranasal administration was investigated in BALB/c nude mice by a dedicated imaging system. It was shown that, under the present imaging settings, autofluorescence of nude mice is negligible (Figure 6A, the first photo named "Blank") and fluorescent signals of WGA-QDs-NP in brain increased with exposure time, reaching peak at 3−4 h following administration, but almost disappeared at 8 h (Figure 6A,B). We also found that, 8 h following administration, certain amounts of fluorescent signals were detected near the urethra (photo taken when the animal was in supine position; Figure 6A, the last photo). Therefore, we deduced that at least part of WGA-QDs-NP were eliminated by filtration and excretion through the kidney.

To better understand the distribution of WGA-QDs-NP in different areas of the brain, 3 h following administration, three mice were euthanized with their brain collected, frozen-sectioned, and observed under a fluorescence microscope following nuclear staining with DAPI. It was shown that, 3 h after intranasal administration, fluorescence signals of WGA-QDs-NP were detected in the olfactory bulb, olfactory tract, cortex, caudate-putamen, hippocampus, third ventricle, dorsal third ventricle, and lateral ventricle (Figure 7), suggesting that the imaging agents distributed quickly and extensively into the CNS.

In addition, we found that the imaging agents described herein presented excellent brain targeting property following intranasal administration. Three hours following the administration, three mice were euthanized and fixed by heart perfusion with their brains, hearts, livers, spleens, lungs, and kidneys collected for imaging. The data showed that the relative average fluorescent intensities of WGA-QDs-NP in the tissues at this time point followed the order of brain ≥ lung > liver > kidney > heart > spleen (Figure 8A,B). These results clearly suggested the efficient brain targeting property of the present nanoplatform, which is very important for its safe and efficient *in vivo* imaging.

DISCUSSION

In the present study, we first developed a QDs-based imaging platform for brain imaging by incorporating QDs into the core

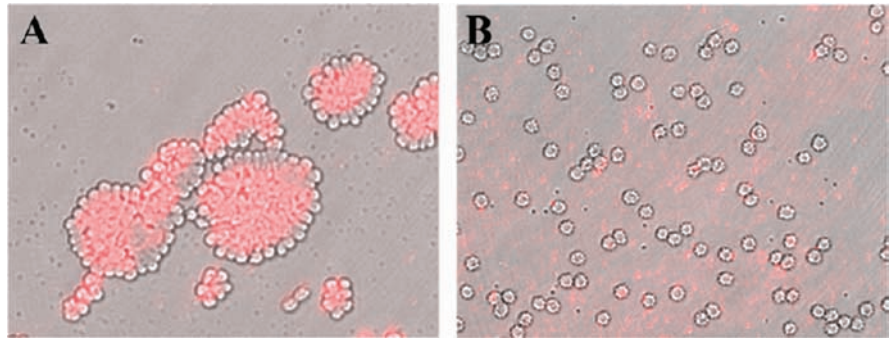

Figure 3. Interactions between erythrocytes and (A) WGA-conjugated quantum dots-loaded nanoparticles (WGA-QDs-NP) or (B) unmodified quantum dots-loaded nanoparticles (QDs-NP): erythrocytes suspension (4%, 200 mL) incubated with WGA-QDs-NP (10 mg/mL, 50 mL) and QDs-NP (10 mg/mL, 50 mL) at 37 °C for 30 min, respectively. 80 × 31 mm (300 × 300 DPI).

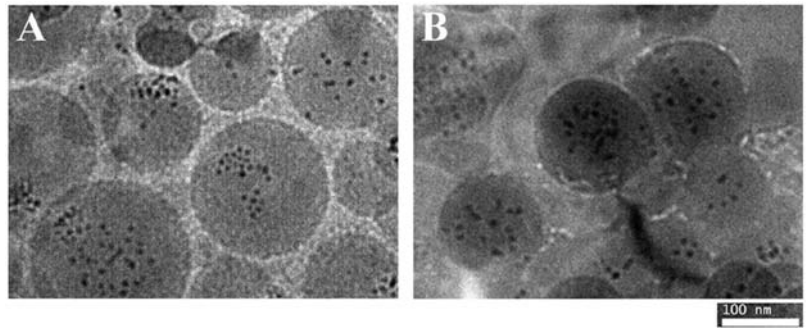

Figure 4. Freeze−fracture electron micrograph of WGA-conjugated quantum dots-loaded nanoparticles (WGA-QDs-NP) after (A) one week storage in aqueous solution and (B) 24 h incubation in serum. 80 × 33 mm (600 × 600 DPI).

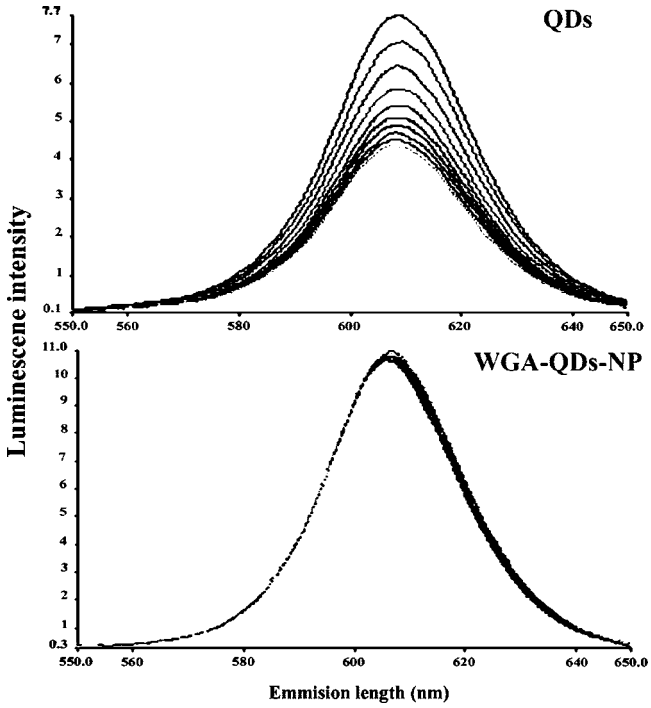

Figure 5. Luminescence emission spectra of quantum dots (QDs) (upper) and WGA-QDs-NP (lower) at the excited wavelength of 400 nm, respectively. The spectral curves of QDs reduced in intensity sequentially with the increase of light exposure, while those of WGA-QDs-NP showed a slightly blue shift but remained unchanged under the same scan condition (Ex: 400 nm, Em scan range: 550−650 nm; Ex slit: 10.0 nm; Em slit: 2.5 nm; Scan speed: 30 nm/min; Scan times: 10; Delayed: 120 s). 80 × 83 mm (600 × 600 DPI).

of PEG-PLA nanoparticles, which was then functionalized with WGA and delivered into the brain via nasal application. The resulting nanoparticles, with high payload capacity, are water-soluble, stable, and showed excellent and safe brain targeting and imaging properties. With the flexibility of having PEG functional terminal groups on the nanoparticles surface, this nanoprobe allows for conjugation of various biological ligands (e.g., sugars, peptides, proteins, and antibodies) as "smart nanoparticles" for targeting and imaging in various brain disorders.

Brain delivery properties of nanoparticles are essential for effective brain imaging *in vivo*. Our newly developed QDs-based nanoplatform showed the following advantages for *in vivo* brain imaging: First, WGA-QDs-NP stayed in the brain for more than 4 h (Figure 6), offering enough time for the recognition and binding of the imaging agents with the disorder regions in the CNS. Second, the imaging agents were almost cleared 8 h after administration (Figure 6), therefore supplying a safe technique for *in vivo* imaging. Third, the imaging agents distributed quickly and extensively into the CNS (Figure 7), which might provide a good opportunity for the recognition and binding of imaging agents with their targets. Furthermore, the excellent brain targeting property of WGA-QDs-NP following intranasal administration could thereby reduce potential toxicity to the peripheral organs (Figure 8).

The mechanism of brain delivery of WGA-QDs-NP is not clear yet. However, our previous work demonstrated that the enhancement of brain delivery of agents carried by WGA-functionalized nanoparticles was mediated by the substrates of WGA — *N*-acetyl-D-glucosamine and sialic acid, which were abundantly observed in the nasal cavity (*28*, *29*). It is well-documented that nasal mucosa was composed of the respiratory region, which had the highest degree of vascularization and was mainly responsible for drug absorption into the circulation, and olfactory mucosa, which played a vital role in the transport of drugs into the brain and cerebrospinal fluid (*30*). WGA, specifically binding to *N*-acetyl-D-glucosamine and sialic acid, presented a great affinity to the olfactory epithelium while a

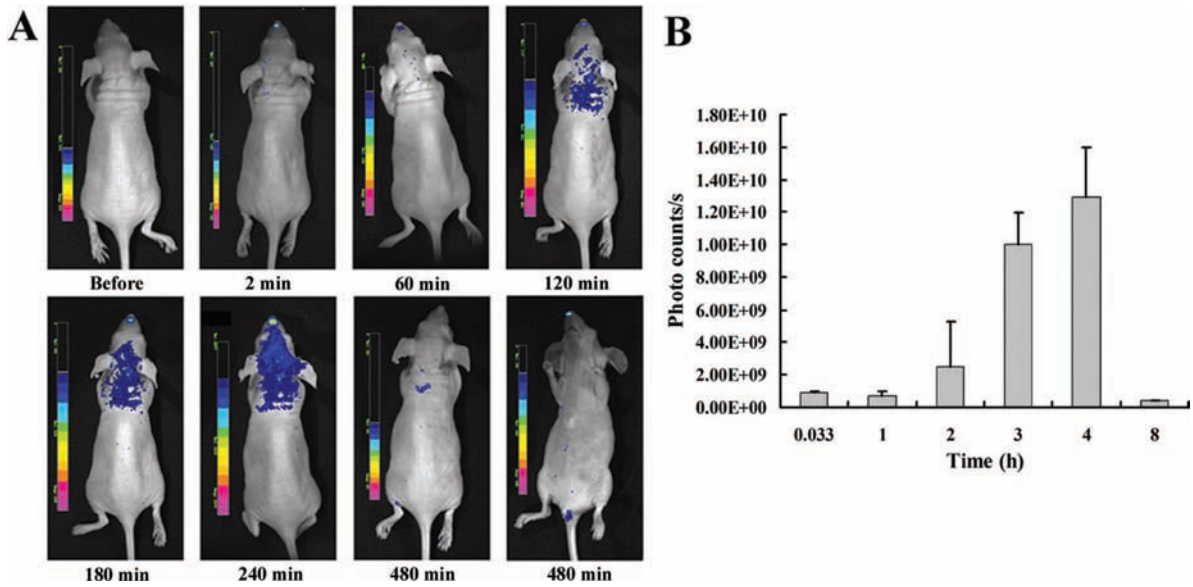

Figure 6. Distribution and retention of WGA-conjugated quantum dots-loaded nanoparticles (WGA-QDs-NP) in the brain following intranasal administration. (A) Representative optical images taken before, 2 min, and 1, 2, 3, 4, and 8 h after dose under a dedicated imaging system designed for small animals imaging. (B) Quantification of the luminescence signal from WGA-QDs-NP in the brain over time following intranasal administration ($n = 6$ for the time points of 2 min and 1, 2, 3 h; $n = 3$ for the time points of 4 and 8 h). 176 × 85 mm (300 × 300 DPI).

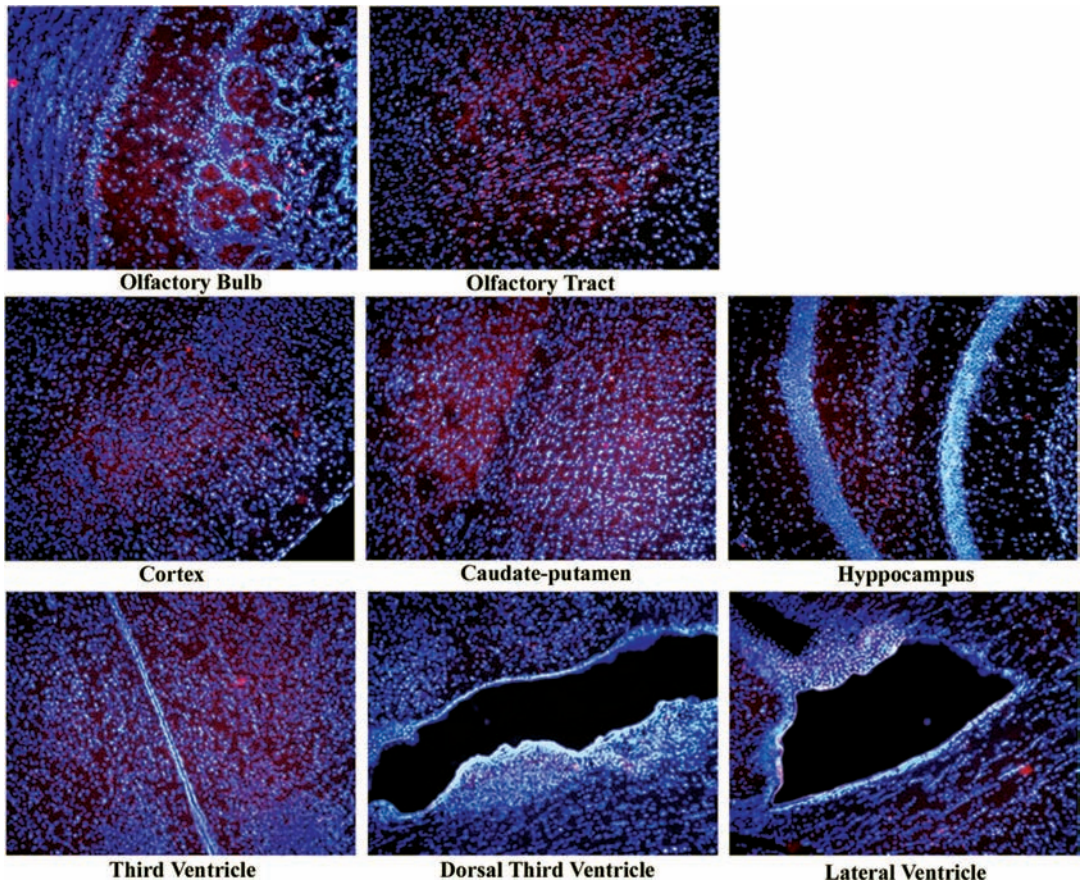

Figure 7. Distribution of WGA-conjugated quantum dots-loaded nanoparticles (WGA-QDs-NP, red) in the olfactory bulb, olfactory tract, cortex, caudate-putamen, hippocampus, third ventricle, dorsal third ventricle, and lateral ventricle of nude mice 3 h after intranasal application. 176 × 145 mm (300 × 300 DPI).

moderate degree to the respiratory epithelium (*29*, *31*). Accordingly, our previous data also showed that the affinity of WGA-NP to the olfactory mucosa was higher than that to the respiratory one (*24*). It has been well-presented that, following an intranasal administration to rats, wheat germ agglutinin−horseradish peroxidase (WGA-HRP) concentrated in the olfactory bulb, while a negligible amount of label was detected in the same location after intravenous administration of WGA-HRP or intranasal administration of unconjugated HRP (*32*). Therefore, we deduced that at least part of WGA-NP enter the brain via olfactory mucosa. If this is true, it would become much easier to understand why WGA-QDs-NP achieved such good

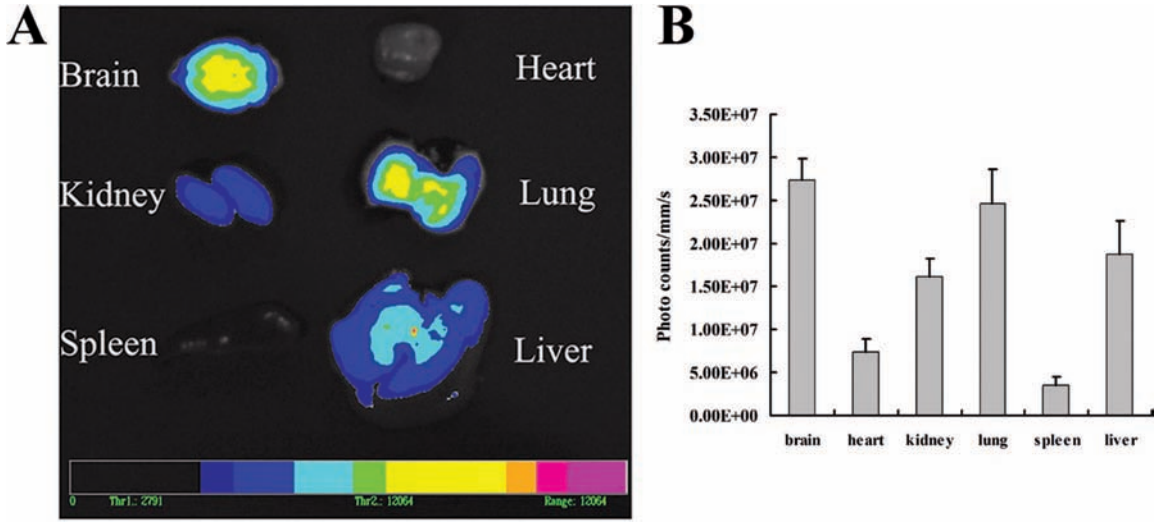

Figure 8. Distribution of WGA-conjugated quantum dots-loaded nanoparticles (WGA-QDs-NP) in various organs following intranasal administration in nude mice. (A) Representative optical image taken 3 h after dosing under a dedicated imaging system designed for small animal imaging. (B) Quantification of the luminescence signal from WGA-QDs-NP in various organs 3 h following intranasal application ($n = 3$). 176 × 81 mm (300 × 300 DPI).

brain targeting property. Previous research also strongly suggested that WGA-HRP can pass BBB following intravenous administration by absorptive-mediated mechanism (*33*). So, it is also possible WGA-NP achieve brain delivery via the systemic pathway.

The safety of QDs is now one of the major concerns for *in vivo* QDs-based imaging techniques. A recent paper suggested that cytotoxicity of QDs, which is mainly induced by the release of Cd^{2+} ions into the cellular environment, was greatly reduced by coating the bare QDs with polymers (*34*). In the present paper, QDs were entrapped into the core of nanoparticle and did not show any leakage after 24 h incubation in serum (Figure 4B). Therefore, the toxicity of QDs was considered to be low. The coating polymer PEG-PLA is a well-developed copolymer, and its safety has been well-acknowledged (*35*). In addition, the amount of WGA in the systemic circulation is far less than that required for the development of blood clots (*36*). Therefore, the application of WGA-QDs-NP is believed to be safe. Actually, no obvious side effects were observed in our experiments (data not shown). However, since the safety of the probe is now one of the major concerns for *in vivo* imaging, the long-term side effects of WGA-QDs-NP still need to be considered very carefully and deserve further research before their further application.

The emerging nanostructure QDs offer numerous potential applications in bioimaging *in vitro* and *in vivo*. However, conventional QDs-based imaging often encounters their poor stability in aqueous solution and in the biological systems, which was mainly caused by photocatalytic destruction of the mercaptoacetic acid coating and precipitation of the nanocrystals (*15*−*17*). Here, the use of TOPO-QDs encapsulation into PEG-PLA nanoparticles enables their potential application in imaging *in vivo*. Our data clearly suggested that QDs were encapsulated into the core of PEG-PLA nanoparticles with high loading efficiency (Figure 2) without changing the morphology, size, zeta potential, or biobinding activity of the lectin-functionalized nanoparticles (Figure 1, Figure 3). We believe that this phenomenon is mainly contributed by the strong hydrophobic interaction between TOPO and PLA fragment of the polymer, which composed the core of the resulting PEG-PLA nanoparticles (*27*). In the course of primary emulsification, TOPO-QDs coating with PLA remained inside the oil droplets while the hydrophilic group PEG migrated to the water surface. Upon solvent evaporation, the nanoparticles core solidified, forming solid nanoparticles with higher stability compared with both micelles and liposomes. The advantages of this preparation procedure were obvious. By using it, we obtained nanoparticles with high payload capacity and improved stability in both water and serum (Figure 4). In addition, the photostability of the encapsulated QDs was significantly improved compared with that of free QDs. In contrast, previous works in which QDs were encapsulated in the chloroform/ethanol solvent mixture to obtain QDs-loaded micelles had several drawbacks such as low payload (one QD per micelle) and easy aggregation (*10*).

Taking advantage of the thiolated-protein conjugating ability of maileimide group at the end of PEG, we successfully conjugated WGA to the surface of the QDs-loaded nanoparticles under mild condition without changing the biobinding ability of WGA. By incorporating PEG-PLA with other functional terminal groups such as biotin, amino (*11*), and carboxyl groups at the end of PEG, we can also further modify the nanoparticles with various biological ligands for specific molecular and cellular imaging (*17*). Therefore, WGA-QDs-NP described herein provided the following advantages to serve as a nanoplatform for bioimaging: (1) high payload capacity; (2) improved stability in aqueous solution and in biological system; (3) increased optical stability; (4) biobinding activity; and (5) flexibility of having PEG functional terminal groups available on the surface of nanoparticles, which allows conjugation of various biological ligands for specific molecular imaging. Further study is needed to fully optimize WGA-QDs-NP and to address the potential application of this nanoplatform in specific CNS disorders such as Alzheimer's disease and brain tumors.

ACKNOWLEDGMENT

The study was supported by National Key Basic Research Program (2007CB935800), National Natural Science Foundation of China (No. 30801442), and Grants from Shanghai Education Committee and Institute of Medical Sciences, Shanghai Jiaotong University School of Medicine. The authors also acknowledged Dr. Kunpeng Li and Prof. Ming Yao for their technical assistances in freeze−fracture electron microscopy and *in vivo* optical imaging, respectively.

Synthesis of Peptide Nucleic Acid FRET Probes via an Orthogonally Protected Building Block for Post-Synthetic Labeling of Peptide Nucleic Acids at the 5-Position of Uracil

Bereket Y. Oquare and John-Stephen Taylor*

Department of Chemistry, Washington University in St. Louis, One Brookings Drive, St. Louis, Missouri 63130. Received July 9, 2008; Revised Manuscript Received August 27, 2008

We report the design and synthesis of an orthogonally protected peptide nucleic acid (PNA) building block, Fmoc-PNA-U′-(Dde)-OH, and its use in the construction of PNA FRET probes. This building block allows for the post-synthetic attachment of reporter groups to the amino group attached to the 5-position of uracil (U) following selective deprotection of the Dde group. We illustrate the use of this building block for the synthesis of a series of FAM Cy5 donor acceptor pairs and their ability to detect a target DNA sequence.

The ability to directly detect and image gene expression inside living cells and organisms would greatly aid biological and biomedical research. One approach to image gene expression is to use antisense probes targeted to the mRNA of interest. Because endogenous mRNA transcripts are of very low copy number (1−10 000 copies/cell), it is critical that the signal from an antisense probe is greater than the background signal from the unbound agent in the cell. To accomplish this, various types of fluorogenic antisense probes have been developed that are designed to become fluorescent only upon binding to the target mRNA, most notably molecular beacons and binary FRET[1] probes.

Molecular beacons consist of a single antisense agent that bears a fluorescent donor on one end and a quencher on the other (*1, 2*). In the absence of the target, the molecular beacon folds in such a way to bring the donor in close proximity to the quencher, which quenches the fluorescence of the donor. In the presence of a target, the beacon unfolds to form a duplex, thereby distancing the quencher from the donor, which results in a strong fluorescence signal. In principle, molecular beacons should show high specificity and signal-to-noise, but in practice, nonspecific interactions with other biomolecules in a cell can open the beacon and activate fluorescence, as can cleavage of the backbone or linkers, which diminish the signal-to-noise.

Binary FRET probes consist of a pair of antisense agents, one bearing a donor fluorophore, and the other, an acceptor fluorophore. When present in low concentrations, energy transfer from the donor to the acceptor can only take place efficiently in the presence of a complementary template sequence which brings the two components together. As a result, binary FRET probes cannot be activated by nonspecific binding or degradation as can molecular beacons, and should possess much higher specificity and signal-to-noise. The first report of using binary FRET probes to detect a nucleic acid sequence in vitro came in 1988 (*3*), but it was not until 2000 that detection of an mRNA by a binary FRET probe in living cells was reported. Tsuji and co-workers showed that a pair of FRET probes could detect about 10 000 copies of c-fos mRNA produced from an over-expression vector by fluorescence microscopy (*4*). Later, they showed that they could detect about 900 copies by using time-resolved fluorescence imaging (*5*). They have also been able to detect about 10 000 copies of IL-2 mRNA by flow cytometry (*6*). To improve signal-to-noise, Bao and co-workers have developed dual FRET molecular beacons, in which the donor and acceptor probes are made into molecular beacons, which only become fluorescent when bound to the target mRNA. More recently, Kool and co-workers demonstrated the ability to detect mRNA in vivo by flow cytometry with a new class of quenched autoligating FRET probes (*7*).

Though the initial results in detecting mRNA in living cells by the binary FRET probes are promising, obtaining adequate signal-to-noise has been a problem. The FRET probes used in the previous cellular studies were all constructed from DNA, which can be degraded in vivo and thereby reduce the signal. Also, the RNA of DNA−RNA hybrids can be cleaved by RNaseH, which would further reduce the signal. Another disadvantage of DNA is that it is negatively charged, making it difficult to penetrate regions of folded RNA that would have high negative electrostatic potential. Peptide nucleic acids (PNAs) are a synthetic mimic of DNA with an electrically neutral amide backbone that recognize DNA or mRNA in a sequence-specific manner by Watson−Crick base pairing rules (*8*). PNA has become a particularly attractive nucleic acid analogue for the development of therapeutics and diagnostics because of its ability to form more stable duplexes with RNA than DNA, its stability to proteases and nucleases, and its ability to invade regions of secondary structure in RNA and not activate RNase H (*9, 10*).

PNA has recently been used for the construction of binary FRET probes in which the donor and acceptor fluorophores were attached to the ends of two PNAs (*11*). To maximize the FRET signal, however, the two PNAs had to bind to sites separated by about 7 bases. In designing FRET probes for folded mRNA in vivo, it would be easier if one only had to target a single

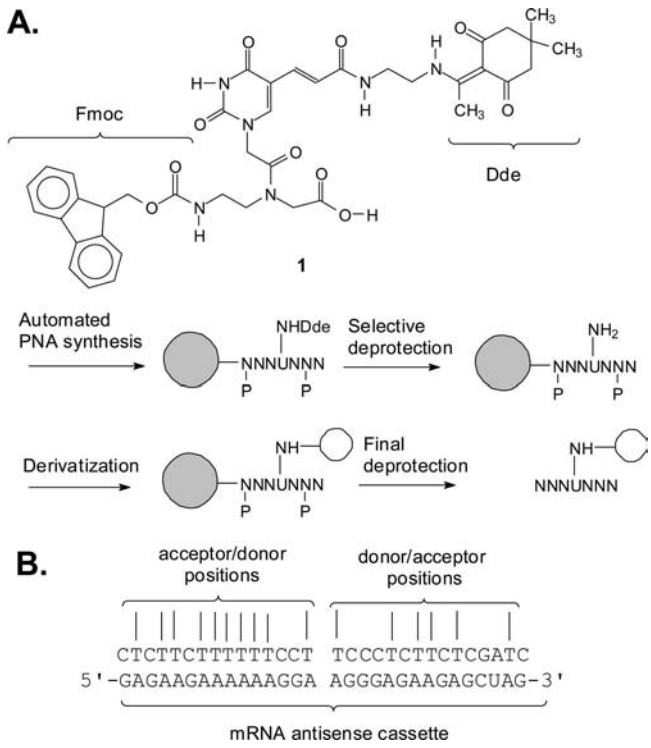

Figure 1. (A) Structure of the orthogonally protected Fmoc-PNA-U′-(Dde)-OH building block and its use for selectively derivatizing T's of PNAs. (B) Antisense cassette sequence and the possible complementary binary FRET PNA probes that could be prepared.

accessible site, rather than two accessible sites that are within 5−10 nt of each other, which would be much rarer. When targeting a single site, however, one of the fluorophores would have to be attached to an internal position of the PNA to maximize the FRET signal. More recently, PNAs internally labeled at C's with donor and acceptor fluorophores were used to create ligatible FRET probes (*12*).

Unlike endogenous genes, trans-genes can be genetically engineered to produce a high number of transcripts and to have any desired sequence. To take advantage of these features for the development of binary PNA FRET probes, we have undertaken the design and synthesis of mRNA cassettes that can be appended to a transgene to tag the mRNA with a repeating antisense site. Such a multimeric antisense tag would allow for the simultaneous binding of multiple binary FRET probes and could thereby greatly amplify the signal from such probes. To obtain an optimal signal output from a binary FRET probe requires that the distance between donor and acceptor can be varied, and the optimal placement of the donor and acceptor may ultimately depend on the number of cassettes and the conformation of the mRNA in vivo. Our initial design of an antisense cassette sequence is one that is devoid of secondary structure and is purine-rich. The sequence contains numerous A's and A-tracts, making it possible to easily vary the position of donor or acceptor fluorophores in a pair of adjacent PNAs through the use of a derivatizable T (Figure 1). Runs of purines in the mRNA sequence would also make it possible to further increase the affinity of a probe by triplex clamp formation. The purine-rich nature of the antisense cassette is also optimal for the complementary PNA sequence, as empirical rules dictate that optimal PNAs have <60% purine content and no more than four purines or three guanines in a row (http://www.appliedbiosystems.com/support/seqguide.cfm) (*13*).

PNAs have been derivatized with fluorophores directly through the amino group at the amino terminus, or at both amino or carboxy termini via addition of amino acids such as lysine or cysteine. Internally labeled PNAs have been prepared by Fmoc or Boc synthesis via derivatization of alkylamino derivative of the amino groups of A, C, and G (*14*) or at C or T by Boc synthesis through an aminoalkyl-modified backbone (*15*). For detecting our antisense cassette, however, we required an Fmoc PNA building block for derivatizing at T. We have previously developed a building block for introducing C5-thiomethyl uracil (U) into PNA by Fmoc synthesis, which can be post-synthetically derivatized via maleimide-linked reagents, though we found that a large excess of the maleimide is required to obtain a good yield of product (*16*). For our purposes, we decided to develop a new Fmoc building block for introducing a donor or acceptor fluorophore to a T through an amine linker. Furthermore, we wished that the linker have a well-defined orientation so that it might also be used to better report on the relative orientation between donor and acceptor groups. To this end, we designed two routes to a C5-derivative of U, compound **1**, containing a Dde-protected alkylamino group, which we show can be selectively deprotected and derivatized prior to complete deprotection of the PNA (Figure 1). We chose the Dde group because it has been previously shown to be compatible with Fmoc PNA synthesis and orthogonal to the other protecting groups (*17*). We also demonstrate the application of our building block to the synthesis of a binary FRET probe for the detection of the DNA sequence corresponding to our antisense mRNA cassette.

EXPERIMENTAL SECION

General Procedures. All reactions were performed under an argon or nitrogen atmosphere unless otherwise specified. All commercially available materials were used without further purification unless otherwise noted. Anhydrous solvents for reactions, such as DMF, DCM, and THF, were either used as obtained from Sigma-Aldrich or distilled from an appropriate drying agent, or dried with 4 Å molecular sieves. Analytical thin-layer chromatography (TLC) was performed using either Sigma-Aldrich's precoated silica gel plastic sheets 60 F_{254} (layer thickness of 250 μm) or general-purpose precoated silica gel glass sheets 60 F_{254} (250 μm) for compounds that are difficult to resolve on the plastic TLC plates. Molecules were visualized using UV light unless otherwise stated. Flash column chromatography was carried out on E. Merck (Bodman Industries, Aston, PA) silica gel 60 (40−63 μm) using the stated solvent system. ^{1}H NMR and ^{13}C NMR spectra were obtained on a Varian Mercury 300, Varian Oxford 300, and VarianUnityPlus 300 (all 300 MHz for ^{1}H NMR and 75 MHz for ^{13}C NMR spectrometers). The chemical shifts are expressed in parts per million (ppm) using deuterated NMR solvents in reference to TMS at 0 ppm.

Synthesis of *tert*-Butyl 2-(5-iodo-2,4-dioxo-3,4-dihydropyrimidin-1(2*H*)-yl) Acetate (3). To a suspension of iodouracil **2** (11.9 g, 50 mmol) and anhydrous K_2CO_3 (7.6 g, 55 mmol) in anhydrous DMF (175 mL) at 0 °C, *tert*-butylbromoacetate (9.75 g, 50 mmol) in anhydrous DMF (25 mL) was slowly added via syringe under a nitrogen atmosphere. After addition, the resulting reaction mixture was warmed to rt and vigorously stirred for 24 h. The byproduct precipitate of KBr salt was filtered under vacuum and washed with 10 mL of DMF. The solvent was evaporated in vacuo, and diluted with EtOAc (200 mL) and washed with water (3 × 100 mL). The aqueous phase was back-extracted with EtOAc (3 × 100 mL). The organic layers were combined, dried over Na_2SO_4, and evaporated to dryness in vacuo to yield the crude product. The product was then precipitated by adding cold water, collected in a sintered glass filter, and dried in vacuum overnight to give compound **3** as a white solid, 16.5 g, 94% yield. ^{1}H NMR (300 MHz, DMSO-d_6) δ (ppm): 11.8 (s, 1 H), 8.2 (s, 1 H), 4.4 (s, 2 H), 1.4 (s, 9

H). ^{13}C NMR (75 MHz, DMSO-d_6) δ (ppm): 177.5, 166.9, 161.0, 150.5, 150.1, 81.9, 67.9, 49.0, 27.6. ESI-MS (positive ion mode) calcd for $C_{10}H_{14}IN_2O_4$ $[M + H]^+$ 352.99; found 353.00.

Synthesis of (*E*)-3-(1-(2-*tert*-Butoxy-2-oxoethyl)-2,4-dioxo-1,2,3,4-tetrahydropyrimidin-5-yl)acrylic Acid (4). To a clean, dry 250 mL round-bottom flask was added *tert*-butyl-2-(5-iodo-2,4-dioxo-3,4-dihydropyrimidin-1(2*H*)-yl) acetate (**3**) (5.28 g, 15 mmol) and *N*-tetrabutylammonium bromide (5.80 g, 18 mmol), and dissolved in anhydrous DMF (70 mL). Then, acrylic acid (2.16 g, 30 mmol) in dry DMF (10 mL) was slowly added to the reaction mixture via a stainless steel syringe under nitrogen. A mixture of DMF/water/DIEA (10:10:10 mL) was added via syringe, and the reaction was evacuated (freed of any oxygen gas) and kept with stirring at rt under nitrogen. The catalyst, $Pd(OAc)_2$ (3% mol, 1.01 g, 4.5 mmol), was added under nitrogen. The flask was again evacuated and kept under nitrogen atmosphere. The reaction mixture was then heated to 80−90 °C in an oil bath for 16 h. The reaction mixture turned black for the first few hours, and then palladium particles precipitated while the solution turned yellow. The black particles were filtered under vacuum, and the DMF was evaporated in vacuo at an elevated temperature. The reaction mixture was then washed with water (25 mL) and diethyl ether (5 × 50 mL). The organics were combined, dried over Na_2SO_4, and evaporated to give the crude product as yellow oil. The product (**4**) was then precipitated by adding DCM/Et_2O mixture and a few drops of hexane in an ice bath. The product was collected by vacuum filtration in a sintered glass funnel and dried in vacuum overnight to give compound **4** as a yellow powder, 2.4 g, 54% yield. ^{1}H NMR (300 MHz, DMSO-d_6) δ (ppm): 12.3 (br, 1 H), 11.8 (s, 1 H), 8.3 (s, 1 H), 7.2 (d, J = 16 Hz, 1 H), 6.8 (d, J = 16 Hz, 1 H), 4.4 (s, 2 H), 1.4 (s, 9 H). ^{13}C NMR (75 MHz, DMSO-d_6) δ (ppm): 168.5, 167.4, 162.9, 150.4, 149.3, 137.3, 118.5, 108.4, 82.8, 50.4, 28.3. LR ESI-MS (positive mode) calcd for $C_{13}H_{17}IN_2O_6$ $[M + H]^+$ 297.11; found 297.11.

Synthesis of (*E*)-2,5-Dioxopyrrolidin-1-yl-3-(1-(2-*tert*-butoxy-2-oxoethyl)-2,4-dioxo-1,2,3,4-tetrahydropyrimidin-5-yl)acrylate (5). To (*E*)-3-(1-(2-*tert*-butoxy-2-oxoethyl)-2,4-dioxo-1,2,3,4-tetrahydropyrimidin-5-yl)acrylic acid (**4**) (0.59 g, 2.0 mmol) and NHS (0.46 g, 4 mmol) and DIEA (1.1 mL, 0.83 g, 6.4 mmol) in anhydrous DMF (20 mL) at 0 °C was added EDC·HCl (0.81 g, 4.2 mmol) in dry DMF (10 mL) dropwise via syringe under nitrogen. The reaction mixture was then warmed to rt and stirred for 12 h. The reaction was judged over by TLC, and the solvent was evaporated in vacuo. The crude product was purified by flash chromatography on a silica gel with 5% MeOH in DCM. The solvents were evaporated, and the product was dried in vacuum overnight to give 0.59 g **5** as a white solid in 75% yield. The product was immediately used for the next step owing to its instability. ^{1}H NMR (300 MHz, DMSO-d_6) δ (ppm): 8.1 (s, 1 H), 7.6 (d, J = 16 Hz, 1 H), 7.2 (d, J = 16 Hz, 1 H), 4.5 (s, 2 H), 2.8 (s, 4 H), 1.5 (s, 9 H); ^{13}C NMR (75 MHz, DMSO-d_6) δ (ppm): 177.5, 170.3, 166.4, 162.6, 161.9, 151.6, 149.4, 142.9, 109.2, 107.1, 82.2, 50.0, 27.5, 25.4.

Synthesis of the TFA Salt of 2-(1-(2-Aminoethylamino)-ethylidene)-5,5-dimethyl-1,3-cyclohexanedione (6). *tert*-Butyl 2-(1-(4,4-dimethyl-2,6-dioxocyclohexylidene)ethylamino) ethylcarbamate (*18*), (0.84 g, 2.6 mmol) was suspended in dry DCM (11.25 mL) and cooled to 0 °C. TFA (3.75 mL, 25%) was added dropwise via a syringe under atmospheric pressure. The reaction was allowed to occur at 0 °C for 30 min, and then warmed to rt and stirred for another 30 min. After 1 h, the reaction was judged complete by TLC analysis in 5% MeOH/DCM (R_f = 0). The solvent was evaporated in vacuo, and the residual TFA was removed by repeatedly evaporating from chloroform in small portions to give the product **6** as a yellow oil in quantitative yield (0.58 g). The product was immediately used for the next step without further purification, owing to its high instability. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 3.9 (t, J = 16 Hz, 2 H), 3.3 (t, J = 16 Hz, 2 H), 2.7 (s, 3 H), 2.5 (s, 4 H), 1.1 (s, 6 H).

Synthesis of (*E*)-*tert*-Butyl 2-(5-(3-(2-(1-(4,4-dimethyl-2,6-dioxocyclohexylidene)ethylamino)ethylamino)-3-oxoprop-1-enyl)-2,4-dioxo-3,4-dihydropyrimidin-1(2*H*)-yl)acetate (7). The basic form of compound **6** (0.17 g, 0.77 mmol) was freshly prepared by addition of DIEA until about pH 7−7.5 as judged by pH paper, and dissolved in dry DMF (5 mL). The solution was then slowly added via syringe under nitrogen to a reaction flask containing the NHS ester **5** (0.250 g, 0.64 mmol) in dry DMF (5 mL) at 0 °C and then warmed to rt and stirred for 4−6 h under nitrogen. The solvent was evaporated in vacuo, and the crude reaction mixture was dissolved in 70 mL of DCM and was extracted with 1 M aq HCl (3 × 30 mL). The aqueous phase was back-extracted with DCM, and the organic layers were combined and concentrated in vacuo to give the crude product, which was chromatographed on silica gel with 5% MeOH in DCM to give 0.27 g compound **7** as a pure white solid in 85% yield. TLC in 5% MeOH/DCM, R_f = 0.25. ^{1}H NMR (300 MHz, CD_3OD) δ (ppm): 7.9 (s, 1 H), 7.2 (d, J = 16 Hz, 1 H), 7.1 (d, J = 16 Hz, 1 H), 4.5 (s, 2 H), 3.7 (t, J = 6 Hz, 2 H), 3.5 (t, J = 6 Hz, 2 H), 2.6 (s, 3 H), 2.4 (s, 4 H),1.5 (s, 9 H) 1.0 (s, 6 H). ^{13}C NMR (75 MHz, CD_3OD) δ (ppm): 200.0, 176.1, 169.7, 168.4, 164.0, 151.8, 149.3, 134.5, 122.0, 110.7, 109.0, 84.1, 53.5, 51.0, 49.9, 43.5, 39.9, 31.0, 28.4, 18.4. LR ESI-MS (positive ion mode) calcd for $C_{25}H_{35}N_4O_7$ $[M + H]^+$ 503.25; found 503.24.

Synthesis of (*E*)-2-(5-(3-(2-(1-(4,4-Dimethyl-2,6-dioxocyclohexylidene)ethylamino)ethylamino)-3-oxoprop-1-enyl)-2,4-dioxo-3,4-dihydropyrimidin-1(2*H*)-yl) Acetic Acid (8). Compound **7** (2.5 g, 5.0 mmol) was dissolved in CH_2Cl_2 (15 mL), and TFA (15 mL) was slowly added dropwise via syringe at 0 °C. The reaction mixture was then warmed to rt after addition of the reagents and stirred for 4 h. The reaction was monitored by TLC (5% MeOH in DCM) until the disappearance of the starting material and appearance of a new spot near the baseline. After the reaction was complete, the solvent was evaporated in vacuo, and the residual TFA was coevaporated several times with chloroform, and the resulting solid was triturated with methanol. The solid product was dried in vacuo and isolated by filtering through a sintered glass funnel under vacuum to afford 2.2 g of compound **8** as a white solid (quantitative yield). ^{1}H NMR (300 MHz, DMSO-d_6) δ (ppm): 13.2 (t, J = 6 Hz, 1 H), 11.7 (s, 1 H), 8.4 (t, J = 6 Hz, 1 H), 8.1 (s, 1 H), 7.1 (d, J = 16 Hz, 1 H), 7.0 (d, J = 16 Hz, 1 H), 4.5 (s, 2 H), 3.6 (m, 2 H), 3.4 (m, 2 H), 2.5 (s, 3 H), 2.3 (s, 4 H), 0.9 (s, 6 H). ^{13}C NMR (75 MHz, DMSO-d_6) δ (ppm): 196.4, 173.2, 169.3, 166.1, 162.3, 149.8, 148.4, 132.1, 120.9, 108.2, 52.4, 49.0, 42.0, 40.3, 38.7, 38.4, 29.8, 27.9, 17.3. LR ESI-MS (positive ion mode): calcd for $C_{21}H_{27}N_4O7$ $[M + H]^+$ 447.19; found 447.18.

Synthesis of (*E*)-*tert*-Butyl 2-(*N*-(2-(((9*H*-fluoren-9-yl)methoxy) carbonylamino)ethyl)-2-(5-(3-(2-(1-(4,4-dimethyl-2,6-dioxocyclohexylidene)ethylamino)ethylamino)-3-oxoprop-1-enyl)-2,4-dioxo-3,4-dihydropyrimidin-1(2*H*)-yl)acetamido) Acetate (10). To a solution of carboxylic acid **8** (2.2 g, 5.1 mmol) and amine **9** (19) (1 equiv, 2.2 g, 5.1 mmol) in dry DMF (30 mL) was added redistilled DIEA (2.1 mL, 1.5 g, 11.7 mmol) via syringe under nitrogen, and the temperature was lowered to 0 °C. In a separate round-bottom flask, HATU (1.2 equiv, 2.3 g, 6.1 mmol) was dissolved in anhydrous DMF (10 mL) and transferred to the reaction mixture via syringe under a nitrogen, at 0 °C. The reaction was kept at 0 °C for 1 h and then warmed to rt and

stirred for 8 h. The reaction was monitored by TLC (5% MeOH in DCM). The reaction mixture was worked up by pouring into 100 mL of DCM and washed with water (8 × 50 mL). The aqueous and DCM layers did not separate completely, and both the clear organic layer and emulsion layer were collected, dried over Na_2SO_4, and evaporated in vacuo. The crude product was purified by flash chromatography with 5% MeOH in DCM to give 3.9 g of compound **10** as a white solid in 93% yield. TLC: 5% MeOH/DCM ($R_f = 0.20$). ^{1}H NMR (300 MHz, acetone-d_6) δ (ppm): 13.5 (t, $J = 6$ Hz, 1 H), 10.4 (s, 1 H), 7.9 (d, $J = 16$ Hz, 2 H), 7.8 (s, 1 H), 7.7 (d, $J = 16$ Hz, 2 H), 7.4 (t, $J = 16$ Hz, 2 H), 7.3 (t, $J = 16$ Hz, 2 H), 7.2 (d, $J = 16$ Hz, 1 H), 7.1 (d, $J = 16$ Hz, 1 H), 4.8 (s, 2 H), 4.4−4.2 (m, 3 H), 4.0 (s, 2 H), 3.7−3.3 (m, 8 H), 2.6 (s, 3 H), 2.3 (s, 4 H), 1.5 (s, 9 H), 1.0 (s, 6 H). ^{13}C NMR (75 MHz, acetone-d_6) δ (ppm): 205.7, 162.8, 162.3, 161.1, 158.9, 148.6, 144.5, 141.5, 132.9, 127.9, 127.4, 125.5, 121.4, 120.2, 109.3, 109.2, 80.3, 66.5, 66.3, 49.2, 48.7, 47.4, 42.6, 39.2, 39.0, 27.8, 27.6, 17.2. LR MS-ESI (positive ion mode) calcd for $C_{44}H_{532}N_6O_{10}$ $[M + H]^+$ 825.38; found 825.36.

Synthesis of (*E*)-2-(*N*-(2-(((9*H*-Fluoren-9-yl)methoxy)carbonylamino)ethyl)-2-(5-(3-(2-(1-(4,4-dimethyl-2,6-dioxocyclohexylidene)ethylamino)ethylamino)-3-oxoprop-1-enyl)-2,4-dioxo-3,4-dihydropyrimidin-1(2*H*)-yl)acetamido)acetic Acid; Fmoc-U′ (Dde)-OH (1). TFA (7 mL) was slowly added via syringe at 0 °C to a solution of compound **10** (0.825 g, 1.0 mmol) in DCM (7 mL). The reaction mixture was then warmed to rt and stirred for 4−5 h. The reaction was monitored by TLC (DCM/MeOH, 5:1) and judged complete in 4−5 h after which the solvents were evaporated in vacuo and the residual TFA coevaporated with CCl_4 several times, and then evaporated from methanol to give 0.77 g of Fmoc-U′(Dde)-OH (**1**) as a white solid in quantitative yield. ^{1}H NMR (300 MHz, DMSO-d_6) δ (ppm): 13.3 (t, $J = 6$ Hz, 1 H), 11.7 (s, 1 H), 8.4 (t, $J = 6$ Hz, 1 H), 8.0 (s, 1 H), 7.9 (d, $J = 16$ Hz, 2 H), 7.7 (d, $J = 16$ Hz, 2 H), 7.4 (t, $J = 16$ Hz, 2 H), 7.3 (t, $J = 16$ Hz, 2 H), 7.1 (d, $J = 16$ Hz, 1 H), 7.0 (d, $J = 16$ Hz, 1 H), 4.8 (s, 2 H), 4.3−4.2 (m, 3 H), 4.0 (s, 2 H), 3.6−3.2 (m, 8 H), 2.5 (s, 3 H), 2.3 (s, 4 H), 0.9 (s, 6 H). ^{13}C NMR (75 MHz, DMSO-d_6) δ (ppm): 196.3, 173.0, 170.3, 166.1, 162.3, 149.7, 148.6, 143.8, 140.7, 132.1, 127.5, 127.0, 125.1, 120.6, 120.0, 108.0, 65.4, 52.3, 48.2, 47.7, 46.7, 41.9, 38.3, 29.7, 27.8, 17.2. LR ESI-MS (positive ion mode) calcd for for $C_{40}H_{45}N_6O_{10}$ $[M + H]^+$ 769.32; found 769.28.

Synthesis of (*E*)-*tert*-Butyl 2-(3-(2,4-dioxo-1,2,3,4-tetrahydropyrimidin-5-yl)acrylamido)ethylcarbamate (13). To the (*E*)-3-(2,4-dioxo-1,2,3,4-tetrahydropyrimidin-5-yl)acrylic acid (**11**) (*20*) (0.55 g, 3.0 mmol) and *N*-hydroxysuccinimide, NHS, (0.38 g, 3.3 mmol) was added anhydrous DMF (10 mL) under nitrogen. Then, mono-Boc ethylenediamine (**12**) (0.72 g, 4.5 mmol) (Alfa Aesar) and diisopropylamine (0.85 g, 1.2 mL, 6.6 mmol) in DMF (5 mL) were added dropwise via syringe to the reaction mixture. The reaction mixture was cooled to 0 °C with stirring under nitrogen. Then, EDC·HCl (0.632 g, 3.3 mmol) dissolved in anhydrous DMF (10 mL) was slowly added to the reaction mixture at 0 °C. After addition, the reaction mixture was allowed to warm to rt and stirred overnight. The DMF was evaporated at elevated temperature (100−110 °C) in vacuo. The crude product was purified by flash chromatography by using 5% MeOH in DCM to afford 0.83 g of compound **13** as an off-white solid in 85% yield. Analytically pure compound was obtained by recrystallization from ethanol/ether. ^{1}H NMR (300 MHz, DMSO-d_6) δ (ppm): 11.3 (s, 1 H), 8.1 (t, $J = 7$ Hz, 1 H),7.9 (s, 1 H), 7.1 (d, $J = 16$ Hz, 1 H), 7.0 (d, $J = 16$ Hz, 1 H), 6.8 (t, $J = 6$ Hz, 1 H), 3.2 (m, 2 H), 3.0 (m, 2 H), 1.4 (s, 9 H). ^{13}C NMR (75 MHz, DMSO-d_6) δ (ppm): 165.9, 162.8, 155.5, 150.2, 144.7, 132.4, 120.5, 107.8, 77.5, 40.2, 38.5, 28.1. ESI-MS (positive ion mode) calcd for $C_{14}H_{21}N_4O_5$ $[M + H]^+$ 325.1512; found 325.1512.

Synthesis of (*E*)-*N*-(2-Aminoethyl)-3-(2,4-dioxo-1,2,3,4-tetrahydropyrimidin-5-yl)acrylamide (14). Compound **13** (0.70 g, 2.2 mmol) was dissolved in DCM (12 mL), and TFA (4 mL) was slowly added via syringe at 0 °C. The reaction mixture was warmed to rt and stirred for 2 h. The reaction was monitored by TLC in 10% MeOH/DCM until the disappearance of the starting material and appearance of a new spot (product) near the baseline. When the reaction was complete, the solvent was evaporated in vacuo, and the remaining solvent was evaporated with small portions of carbon tetrachloride. The product was precipitated by adding a small amount of methanol to give a brownish white solid (0.49 g, 99%). ^{1}H NMR (300 MHz, DMSO-d_6) δ (ppm): 9.2 (br, 3 H), 8.3 (t, $J = 6$ Hz, 1 H),7.9 (s, 1 H), 7.2−7.1 (d, $J = 16$ Hz, 1 H), 7.0−6.9 (d, $J = 16$ Hz, 1 H), 3.4−3.3 (m, 2 H), 2.9 (t, $J = 6$ Hz, 1 H). ^{13}C NMR (75 MHz, DMSO-d_6) δ (ppm): 166.5, 162.8, 150.3, 145.0, 132.9, 120.0, 107.6, 38.7, 36.7. LR ESI-MS (positive ion mode) calcd for $C_9H_{13}N_4O_3$ $[M + H]^+$ 225.10; found 225.09.

Synthesis of (*E*)-*N*-(2-(1-(4,4-Dimethyl-2,6-dioxocyclohexylidene)ethylamino)ethyl)-3-(2,4-dioxo-1,2,3,4-tetrahydropyrimidin-5-yl)acrylamide (16). Compound **14** (0.45 g, 2.2 mmol) was freshly prepared as described above and dissolved in dry DMF, and DIEA was slowly added at 0 °C until the pH of the solution was slightly basic. Dde-OH (**15**) (available from Aldrich) (0.48 g, 2.6 mmol) in DMF was then slowly added via syringe. The reaction mixture was refluxed under nitrogen for 24 h. The solvent was evaporated at elevated temperature and then coevaporated with EtOH to almost complete dryness. The product was then precipitated out of ethanol in an ice bath to give 0.72 g of compound **16** as a pale brown solid in 84% yield. TLC: in 5% MeOH/DCM ($R_f = 0.25$). ^{1}H NMR (300 MHz, DMSO-d_6) δ (ppm): 13.2 (t, $J = 6$ Hz, 1 H), 11.3 (s, 2 H), 8.3 (t, $J = 6$ Hz, 1 H), 7.9 (s, 1 H), 7.1 (d, $J = 16$, 1 H), 7.0 (d, $J = 16$, 1 H), 3.6 (m, 2 H) 3.4 (m, 2 H), 2.5 (s, 3 H), 2.3 (s, 4 H), 0.9 (s, 6 H). ^{13}C NMR (75 MHz, DMSO-d_6) δ (ppm): 196.3, 173.0, 166.3, 162.8, 150.2, 145.0, 132.9, 119.9, 107.6, 107.0, 52.2, 41.9, 40.2, 38.6, 38.3, 29.6, 27.8, 17.2. ESI-MS (positive ion mode) calcd for $C_{19}H_{25}N_4O_3$ $[M + H]^+$ 389.1825; found 389.1822.

Synthesis of (*E*)-*tert*-Butyl 2-(5-(3-(2-(1-(4,4-dimethyl-2,6-dioxocyclohexylidene)ethylamino)ethylamino)-3-oxoprop-1-enyl)-2,4-dioxo-3,4-dihydropyrimidin-1(2*H*)-yl)acetate (7) from 16. A solution of compound **16** (0.6 g, 1.5 mmol) and anhydrous K_2CO_3 (0.24 g, 1.7 mmol) were dissolved in anhydrous DMF (8 mL). A solution of *t*-butylbromoacetate (0.30 g, 1.5 mmol) in anhydrous DMF (4 mL) was slowly added via syringe at 0 °C. The reaction mixture was warmed up to rt and stirred under nitrogen overnight. The precipitate of KBr was filtered and washed several times with methanol (3 × 10 mL). The filtrates were combined, evaporated in vacuo at an elevated temperature, and coevaporated with EtOH to almost complete dryness. The crude product was dissolved in 100 mL DCM and extracted with water (5 × 30 mL), 1 M HCl (2 × 20 mL), and finally with brine (1 × 20 mL). The aqueous phases were back-extracted with DCM (1 × 100 mL), and the organics were combined, dried over Na_2SO_4, and evaporated in vacuo. The product was purified by flash chromatography by using 5% MeOH in DCM to give 0.69 g of compound **7** as a crystalline white solid in 92% yield with identical spectra as described for **7** prepared from **5**.

General PNA Synthesis, Purification, and Characterization Procedures. Anhydrous diethyl ether, DIEA, TFA, *meta*-cresol, hydrazine, and hydroxylamine hydrochloride were purchased from Sigma (St. Louis, MO). High-purity anhydrous DMF and NMP solvents for the synthesis and dilution of the

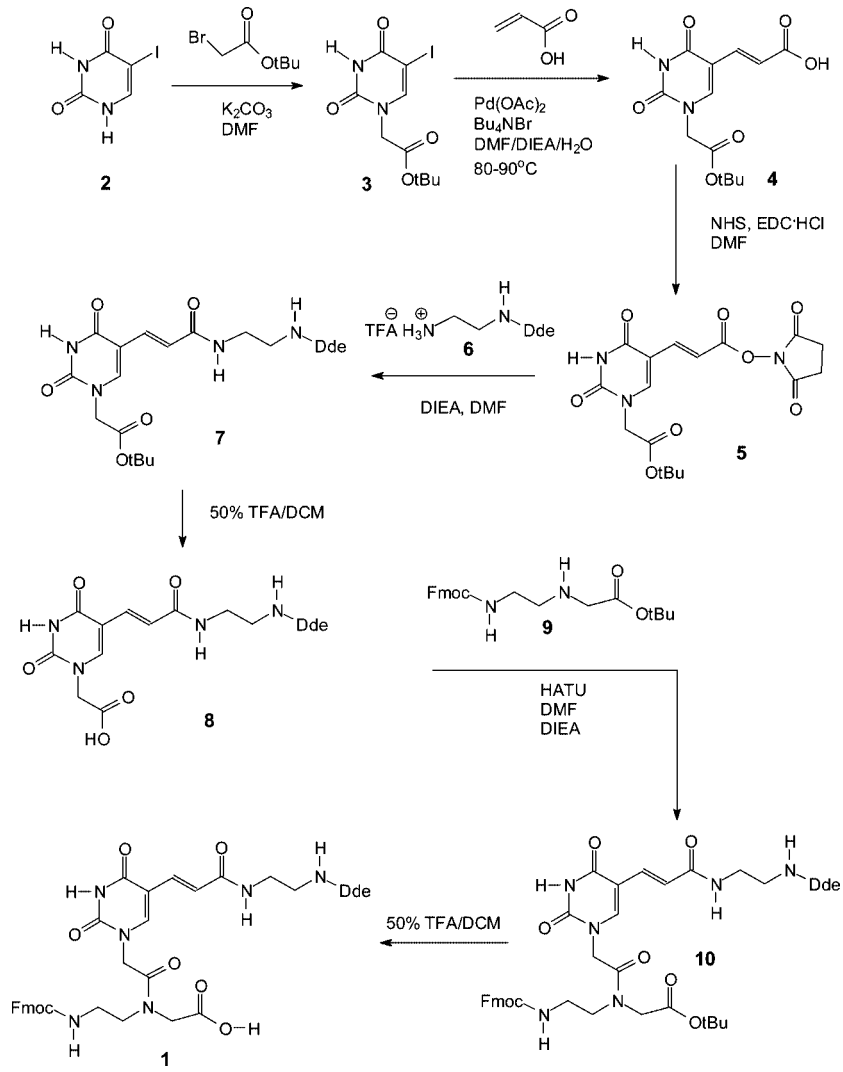
PNA monomers were used as obtained from either Applied-Biosystems (Foster City, CA) or Sigma-Aldrich (St. Louis, MO), HATU was purchased either from Applied Biosystems or GenScript Corp. (Piscataway, NJ). The Fmoc PNA monomers A, C, G, T, and reagents for peptide nucleic acid (PNA) synthesis were from Applied Biosystems or ASM-Research Chemicals (Hannover, Germany). ε-Boc-α-Boc-Lys and ε-Mtt-α-Fmoc-Lys were from EMD Chemicals (Gibbstown, NJ). Cy5-NHS was from Amersham Biosciences Inc. (Piscataway, NJ). FAM-NHS was from Molecular Probes (Eugene, Oregon). Ultrafree-MC 0.2 μM filtered microcentrifuge tubes were used for cleavage of the PNA from the resin (Millipore Inc., Bedford, MA). Labeling of PNAs with fluorophore groups was carried out in anhydrous solvents unless otherwise specified. The synthesis of the PNAs was carried out by solid-phase Fmoc PNA synthesis on Fmoc-XAL-PEG-PS resin on an Expedite 8909 DNA/PNA synthesizer (Applied Biosystems) on a 2 μmol scale. DNA (ODNs) templates for fluorescence solution studies were purchased from Integrated DNA Technologies Inc. (Coralville, IA). Crude PNA FRET donor and acceptor probes were analyzed and purified by reversed-phase high-performance liquid chromatography (RP-HPLC) on a Beckman instrument equipped with a UV array detector. PNAs were eluted with a 65 min, 1 mL/min, 0−70% linear gradient of acetonitrile in 0.1% aqueous TFA on Varian Microsorb-MV column (C-18, 5 μm, 300 Å pore size, 4.6 × 250 mm). The PNAs were characterized by UV−vis on a Bausch and Lomb Spectronic1001 spectrophotometer or on a Varian Cary 100 Bio UV−visible spectrophotometer and by fluorescence spectroscopy on a Varian Cary Eclipse fluorescence spectrophotometer in phosphate buffered saline (PBS, pH 7.0, 100 mM). MALDI-TOF mass spectrometry was carried out on a PerSeptive Voyager MALDI-TOF instrument using a sinapinic acid matrix (10 mg in 1 mL of 0.1% TFA in 2:1 H_2O-CH_3CN, mixed 1:1 with PNA). For PNAs with fluorescent tags, we were unable to obtain good MALDI spectra and instead relied on UV to identify the fractions containing the desired PNA by the ratio of the PNA and fluorophore absorbance at 260 nm to the fluorophore absorbance maximum in PBS. Estimated molar extinction coefficients at 260 nm were obtained from available data for PNA (*21*) and the fluorophores (http://www.basic.northwestern.edu/biotools/OligoCalcModifications.html) and also used to determine PNA concentration.

Incorporation of Fmoc-U′(Dde)-OH into PNA and Selective Dde Deprotection. PNAs were synthesized using Fmoc-protected monomers and Fmoc-XAL-PEG-PS universal support on an 8909 Expedite PNA synthesizer using Bhoc-protected Fmoc PNA monomers and the PNA building block, Fmoc-U′-(Dde)-OH **1**. The resin was divided into three microcentrifuge reaction tubes. One tube was treated twice with 2% hydrazine in DMF for 30 min to remove the Dde group (*22*) (1 mL/2 μmol of the protected PNA resin). Another tube was treated with 1 mL of $NH_2OH·HCl$/imidazole deprotection cocktail mixture (1 volume of DMF plus 5 volumes of 1.25 g of $NH_2OH·HCl$ and 0.918 g of imidazole in 5 mL of NMP) (*17*) for 3 h to remove the Dde group. The third reaction tube was not treated. Following completion of the reactions, the Fmoc was removed with 1 mL 20% piperidine/DMF for 20 min, and repeated. Then the resin was washed 5 × 1 mL of 1:1 DCM/DMF. The resins were then treated with 200 μL of TFA/*m*-cresol (4:1) for 90 min at rt to remove the Bhoc protecting groups and cleave the PNA from the resin. The solution was removed and the remaining resin treated a second time. The solutions were combined, and the PNA was precipitated by treatment with cold anhydrous diethyl ether (1 mL). The PNAs were then recovered as white pellets by spinning them down in a centrifuge at 2000 rpm (3 × 5 min) and removing the ether. The crude PNAs were purified by reversed-phase HPLC as described in the experimental section by monitoring the UV absorbance at 260 nm. The desired fractions were collected and concentrated to dryness on a centrifugal evaporator overnight. The PNAs were redissolved in pure water and analyzed and characterized by UV, and further characterized by MALDI-TOF mass spectrometry using sinapinic acid matrix. PNA **18**: MALDI $(M + H)^+$ Calcd 4327.7, found 4326.9; PNA **20** $(M + H)^+$ Calcd 4163.6, via hydrazine deprotection: found 4161.7; via hydroxylamine/imidazole deprotection 4162.7.

Solid-Phase Synthesis of the PNA-FAM 22 Donor Probes. The donor probes were synthesized on the Expedite 8909 PNA synthesizer using Fmoc-protected monomers and the universal support Fmoc-XAL-PEG-PS in which one of the monomers was the PNA building block, Fmoc-U′-(Dde)-OH, and with ε-Boc-α-Boc-Lys at the N-terminus. The resin was treated with 1 mL of the deprotection mixture ($NH_2OH·HCl$/imidazole in NMP/DMF) for 3 h and washed thoroughly with DCM/DMF (1:1) mixture (5 × 1 mL). The resin was then swelled with DMF (250 μL) and DIEA (11 μL) for 5 min, and a 10-fold molar excess of FAM-NHS (10 equiv, 10 mg) was dissolved in a separate tube with 100 μL of anhydrous DMF, vortexed for a few seconds to completely dissolve the activated FAM-NHS, and immediately added to the resin all at once and stirred for 4−6 h at rt. The resin was washed with DCM/DMF (1:1) mixture (5 × 1 mL) to remove excess reagents and thoroughly dried by purging with nitrogen gas for several minutes. The PNAs were then cleaved from the resin and deprotected with 200 μL of TFA/*m*-cresol (4:1) cocktail mixture as described above. The crude PNA-FAM conjugates **22** were then recovered as yellow-colored pellets by precipitation from cold anhydrous diethyl ether (3 × 1 mL). The crude PNAs were dissolved in 500 μL of water containing 0.1% TFA filtered using an Xpertek syringe filters (13 mm, 0.45 μm) before HPLC injection. The crude PNA-FAM donors **22** were purified by reversed-phase HPLC with conditions described in the General Procedures section. The HPLC fractions containing the PNAs were collected, concentrated to dryness on a centrifugal evaporator overnight and redissolved in freshly distilled deionized water, and characterized by UV in pH 7 PBS buffer. The expected ratio of 500/267 nm absorbances for PNA **22** was 0.60 based on an estimated absorbance of 70 000 M^{-1} cm^{-1} for FAM at 500 nm and 116 200 M^{-1} cm^{-1} at 260 nm (119 000 M^{-1} cm^{-1} minus 20% hypochromicity for the PNA plus 20 000 M^{-1} cm^{-1} for FAM); found: 0.52 for PNA **22-0**, 0.51 for **22-7**, and 0.61 for **22-13.**

Solid-Phase Synthesis of the PNA-Cy5 FRET Acceptor Probe 24 via ε-Mtt-α-Fmoc-Lys. The PNA was synthesized on the Expedite 8909 PNA synthesizer as described above and ε-Mtt-α-Fmoc-Lys was added to the C-terminus. After the PNA synthesis was completed, the Mtt group was selectively deprotected by treating the resin with 1% TFA in DCM (5 × 1 mL) for 5 min (*23, 24*). After 3 cycles of the reaction, the yellow color of the deprotection mixture (an indication of trityl group deprotection) started to fade away and finally cleared, indicating the completion of the reaction. The resin was then thoroughly washed with DCM/DMF (1:1) mixture (5 × 1 mL) to remove the deprotected Mtt group and excess reagents. Then, it was swelled with DMF (250 μL) and DIEA (11 μL) for 5 min, and Cy5-NHS ester (1 mg) in 100 μL of anhydrous DMF was immediately added to the resin and stirred for 4 h. The excess reagents were washed away with 5 × 1 mL DCM/DMF (1:1). Fmoc was removed with two treatments of 1 mL of 20% piperidine/DMF for 20 min and then washed 5 × 1 mL of DCM/DMF (1:1). The PNA was cleaved from the resin with 200 μL of TFA/*m*-cresol (4:1) for 90 min, followed by filtration to remove the crude PNA. The cleavage step was repeated one

Scheme 1. Synthesis of Fmoc-U′-(Dde)-OH 1 from Iodouracil via Intermediate 7



more time, and the filtrates were combined in one tube. The PNA-Cy5 FRET acceptor probe **24** was recovered by precipitation with cold anhydrous diethyl ether (1 mL). The crude PNA-Cy5 conjugate was purified by reversed-phase HPLC and characterized by UV in pH 7 PBS buffer. The expected ratio of the absorbances at 650 and 260 nm for PNA **24** was 2.3, based on an estimated absorbance of 250 000 M^{-1} cm^{-1} for Cy5 at 650 nm, and 108 600 M^{-1} cm^{-1} at 260 nm (123 200 M^{-1} cm^{-1} minus 20% hypochromicity for the PNA plus 10 000 M^{-1} cm^{-1} for Cy5): found 2.0.

Fluorescence Resonance Energy Transfer (FRET) Studies. The acceptor probe (PNA-Cy5 **24**) was added to the FRET donor probe (PNA-FAM **22**) with or without a DNA template and allowed to equilibrate at the concentration and time indicated in the Figure 2 legend. The emission spectrum was then recorded from 450 to 800 nm with excitation at 490 nm with 5 nm excitation and emission slit windows. The emission maximum for the PNA-Cy5 **24** probe was at 667 nm.

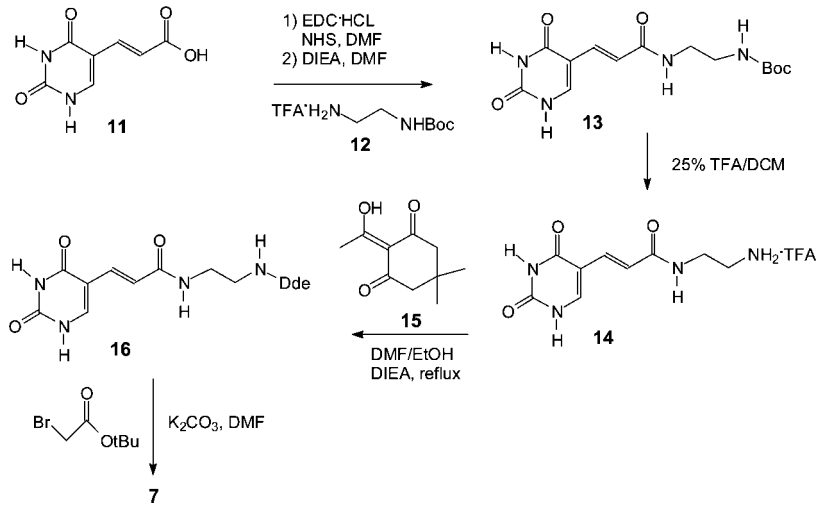
RESULTS AND DISCUSSION

Building Block Synthesis. Two synthetic routes were developed to the building block **1**. In route I (Scheme 1), commercially available iodouracil **2** was alkylated at N1 with *tert*-butyl bromoacetate in the presence of potassium carbonate in anhydrous DMF under nitrogen at room temperature for 24 h to give the *tert*-butyl ester **3** in 94% yield. The iodo group of **3** was replaced with an acryloyl group via Heck reaction with acrylic acid to give the carboxylic acid **4** in 54% yield. The carboxylic acid **4** was converted into an NHS ester **5** with *N*-hydroxysuccinamide and EDC in anhydrous DMF overnight in 75% yield. The NHS ester was coupled with the TFA salt of mono-Dde-protected ethylenediamine **6** (*18*) to give compound **7** in about 85% yield.

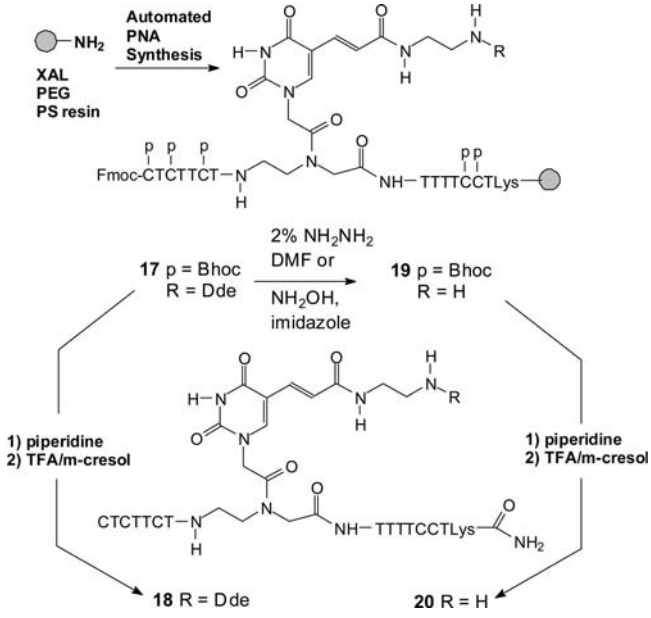
Compound **7** was converted to the Fmoc building block **1** in three additional steps. In the first step, compound **7** was treated with 50% TFA/DCM from 0 °C to rt for 4 h to give the carboxylic acid **8** in a quantitative yield without disturbing the Dde group. The carboxylic acid **8** was then coupled with *tert*-butyl-*N*-Fmoc-aminoethyl-glycinate **9** (*19*) by activation with HATU in the presence of DIEA in anhydrous DMF to give compound **10** in 93% yield. Finally, deprotection of the *tert*-butyl ester group of **10** with 50% TFA in dichloromethane afforded the desired PNA building block **1** in quantitative yield and in 30% overall yield from iodouracil.

We also investigated a second route to **7** that, though two steps longer, may be preferable for large-scale synthesis due to the ease of synthesis and purification of the intermediates and the better overall yield (Scheme 2). Acrylic acid **11** was first prepared in two steps in 85% yield from commercially available 5′-hydroxymethyluracil (*20*). We initially planned to couple **11** with mono-Dde protected ethylenediamine **6** as we had done in the first route, but due to the instability of **6**, we decided to

Scheme 2. Synthesis of Intermediate 7 from Uracil Acrylic Acid 11



Scheme 3. Synthesis of the PNA-U′-(Dde) 18 and PNA-U′-(NH_2) 20



couple the more stable mono-Boc-protected ethylenediamine **12** and convert the Boc group to a Dde group. Thus, acrylic acid **11** was converted to the NHS ester in 87% yield by first forming the NHS ester with EDC and then adding commercially available mono-Boc ethylenediamine **12** in the presence of DIEA in dry DMF. The *tert*-butyl protecting group was then deprotected with 25% TFA/DCM for 3 h to give the TFA salt **14** in quantitative yield. The TFA salt was refluxed with Dde-OH **15** in the presence of DIEA in anhydrous DMF to give compound **16** in 84% yield. Compound **16** was alkylated with *tert*-butyl bromoacetate in the presence of potassium carbonate in anhydrous DMF under nitrogen at rt for 12 h to afford compound **7** in 90% yield. Compound **7** was converted to the PNA building block **1** as previously described in 43% overall yield for nine steps from hydroxymethyluracil.

Incorporation of Dde-U into PNA. To demonstrate that the Dde-U building block **1** was compatible with automated PNA synthesis and that the Dde group can be selectively removed, we synthesized CTCTTCTU(Dde)TTTTCCTK, **18**, and CTCTTCTU(NH_2)TTTTCCTK, **20**, according to Scheme 3. First, Dde-U was incorporated into PNA by solid-phase automated Fmoc PNA synthesis with standard Bhoc monomers on a XAL-PEG-PS resin to give the solid-phase intermediate **17**, followed by treatment with TFA/*m*-cresol to give the Dde-protected PNA **18** as confirmed by HPLC and MALDI analysis. The ability of the Dde group to survive strongly acidic deprotection conditions demonstrates its orthogonality to acid-labile amine protecting groups such as Mtt that would therefore allow selective derivatization of other sites on the PNA.

We then examined 2% hydrazine/DMF (*22*) and NH_2OH/imidazole (*17*) as methods for removing the Dde group from the solid-supported PNA **19** to give **20** (Scheme 3). Following either treatment, the PNA was first treated with piperidine to remove the Fmoc group and then cleaved from the support and completely deprotected with TFA/*m*-cresol. HPLC and MALDI analysis of the major product from both deprotection methods showed the same peak corresponding to the Dde deprotected PNA **20**. In practice, the hydroxylamine reagent is preferable, as it is compatible with the Fmoc group, which undergoes a significant amount of deprotection with hydrazine (*17*).

Synthesis of FAM/Cy5 FRET Probes. We selected a FAM/Cy5 FRET system to maximize detection sensitivity. Cy5 has a red-shifted absorption maxima which minimizes background signal due to direct excitation of Cy5 upon irradiation of fluorescein. Because the Cy5 emission is also red-shifted, there is less background signal due to fluorescein emission at the Cy5 emission maximum. In spite of its red-shifted absorption spectrum, Cy5 still has sufficient overlap between its absorption spectrum and that of fluorescein to give a good FRET signal (*7*, *25*). To determine the optimal positioning of the donor relative to the acceptor for maximum FRET, we synthesized PNAs with the fluorescein attached to three different sites (PNA-FAM **22-0**, **22-7**, and **22-13**), and Cy5 to a single site on the ε-amino end of a carboxy-terminal lysine group on the acceptor PNA-Cy5 **24** (Scheme 3).

The FRET donor PNA-FAMs were prepared by removing the Dde group from the corresponding PNAs **21-0**, **21-7**, **21-13** with NH_2OH/imidazole, followed by coupling with the NHS ester of 5/6-carboxyfluorescein (FAM) in the presence of DIEA for 2 h. To help drive the coupling to completion, the support was additionally treated with 100 μL of HATU (0.2 M) in DMF an additional 2 h at room temperature. The support was then washed several times with DCM/DMF, followed by cleavage and deprotection with TFA/*m*-cresol to afford the crude PNA as a colored pellet. The PNAs were then purified by reverse phase HPLC in 0.1% aqueous TFA. When dissolved at pH 7, the fluorescein adopts the open fluorescent form as shown in Scheme 4. The FRET acceptor PNA-Cy5 **24** was prepared by selectively deprotecting a carboxy-terminal ε-Mtt-α-Fmoc-Lys PNA **23** with 1% TFA/DCM and coupling with the NHS ester

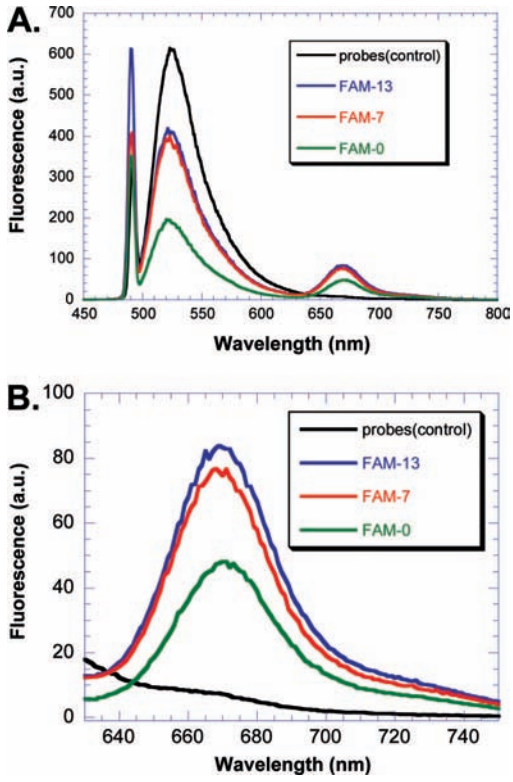


Figure 2. DNA-templated FRET system. PNA-FAM donor **22-0**, **7**, or **13** (2 μM), and PNA-Cy5 **24** (4 μM) were incubated with template DNA (2 μM) or without (control), in 100 mM PBS buffer pH 7.4 at 37 °C for 3 h. (A) The emission spectrum was then recorded from 450−800 nm with excitation at 491 nm, with 5 nm emission and excitation slit windows. (B) Expansion of the 630−750 nm region of the FRET signal.

of Cy5. The PNA was then treated with piperidine to remove the Fmoc group and then cleaved from the column and completely deprotected with TFA/*m*-cresol to give PNA-Cy5 **24**.

FRET Experiments. The donor and acceptor PNAs were then examined for their ability to detect a cDNA sequence by FRET. Fluorescence spectra were obtained with excitation at 491 nm in the presence of 2 μM PNA-FAM and 2 μM DNA and 4 μM PNA-Cy5. Fluorescence emission from fluorescein appears at 525 nm and that from Cy5 at 667 nm (Figure 2). The results clearly show a decrease in fluorescein emission and an increase in Cy5 emission for all the donor acceptor pairs. Maximal FRET was observed for fluorescein donors in positions 7 and 13. The similar FRET efficiencies for such two different spacings can be explained by similar donor acceptor distances resulting from the helical nature of the PNA·DNA duplex (*26*). Given the helical repeat of a PNA·DNA duplex as between 13 Å (*27*) and 15.6 Å (*28*), the fluorescein at position 7 will be out of phase with the Cy5, while the fluorescein at position 13 will be in-phase with the Cy5. The donor with fluorescein in position 0 showed more quenching but less Cy5 emission, indicating other quenching pathways were operating, presumably due to the formation of fluorescein-Cy5 complexes (*29*).

CONCLUSION

In conclusion, we have developed a new Fmoc-PNA building block **1** containing an orthogonally Dde protected alkyl amino group linked to C5 of uracil. We demonstrated that this building block could be incorporated into PNAs site-specifically and then selectively deprotected and derivatized with donor and acceptor fluorophores. Several fluorescein/Cy5 binary PNA probes were shown to detect the DNA sequence corresponding to the antisense mRNA cassette, but the optimal positioning for detecting a single or multimeric mRNA cassette remains to be determined. Further modification of the PNAs will also be required to render them membrane-permeable before they can be used to detect single and multiple mRNA cassettes in living cells.

NLS Peptide Conjugated Molecular Beacons for Visualizing Nuclear RNA in Living Cells

Nitin Nitin and Gang Bao*

Department of Biomedical Engineering, Georgia Institute of Technology and Emory University, Atlanta, Georgia 30332.
Received July 27, 2008; Revised Manuscript Received September 23, 2008

Imaging the expression and localization of RNAs in live-cell nucleus can provide important information on RNA synthesis, processing, and transport. Here, we report the development of a bifunctional molecular beacon (NLS-MB) composed of a single nuclear localization sequence (NLS) peptide conjugated to a molecular beacon for efficient delivery and imaging of endogenous RNAs in the nuclei of living cells. We characterized the NLS-MBs by comparing their signal-to-noise ratios with unmodified molecular beacons and determined their efficiency of nuclear import. We demonstrated the specificity and sensitivity of the method by observing in living cells the localization and colocalization of small nuclear RNAs (snRNA) U1 and U2 at discrete foci in the nucleoplasm, and the localization of small nucleolar RNA U3 in the nucleolus. These snRNAs were chosen because of their essential roles in RNA biogenesis. The results were validated using *in situ* hybridization as positive control and random beacons as negative control. This novel approach may be applied to imaging other nuclear RNAs and pre-mRNAs in living cells.

INTRODUCTION

Imaging RNA molecules in the nuclei of living cells can provide important spatial and temporal information on the dynamics of RNA synthesis, processing, and transport. Specifically, in eukaryotic cells, RNA molecules especially mRNAs (mRNA) are processed post-transcriptionally in the nucleus, including splicing, capping, polyadenylation, and methylation. These processing steps are carried out by multiple protein nanomachines and ribonucleoprotein (RNP) complexes (*1, 2*). The mature RNA molecules (including mRNA and rRNA) are then exported to the cytoplasm. Further, many viral genes are processed in the cell nucleus, including transcription and replication of viral RNAs. Therefore, the ability to detect and localize RNA molecules (including small nuclear RNAs) in live-cell nuclei may provide a powerful tool not only for studies of basic biology but also for disease detection and diagnosis. This ability will also complement the approaches of imaging RNA in the cytoplasm of living cells (*3, 4*) so that an integrated picture of RNA transport, distribution, and localization in the cell cytoplasm and nucleus can emerge.

Extensive efforts are being made to develop new approaches to image RNA in living cells. One novel approach uses a fusion protein, GFP-MS2, to track the localization and dynamics of RNA in living cells with single molecule sensitivity (*5*). Although a very powerful technique in tracking RNA dynamics, this method relies on transfecting cells to express GFP-MS2 as a reporter and add to the target RNA multiple (20−25) MS2 binding sequences. Therefore, this technique lacks the ability to image endogenous RNAs, which is important for diagnostic applications especially in vivo and may not be ideal for imaging small RNAs, since binding multiple MS2-GFPs may significantly perturb their structure and dynamics. Further, imaging assays have been performed by introducing fluorescently labeled linear oligonucleotide (ODN) probes into living cells for RNA expression, tracking, and localization studies (*6*−*8*). This approach, however, lacks the ability to distinguish background from true signal. In addition, although 2′-*O*-methyl backbone chemistry has been used to improve the affinity of linear ODN probes for binding to the target sequence (*7, 8*), in many cases the (*9*) increased affinity is associated with decreased specificity of the probe (*9*). To enhance detection specificity and increase signal-to-background ratio, two linear probes with a fluorescence resonance energy transfer (FRET) pair of (donor and acceptor) fluorophores have been used (*6*). This approach, however, may still have a high background signal due to direct excitation of the acceptor and emission detection of the donor fluorescence. Further, this dual-probe approach may be difficult to be used in targeting small nuclear RNAs.

Molecular beacon based approaches have been developed to image endogenous RNA in live cells. Molecular beacons are dual-labeled antisense oligonucleotide (ODN) probes with a fluorophore at one end and a quencher at the other end. In contrast to fluorescently labeled linear ODN probes, molecular beacons are designed to form a stem-loop (hairpin) structure in the absence of a complementary target so that fluorescence of the fluorophore is quenched (*10*). Hybridization with target RNA opens the hairpin and physically separates the reporter from the quencher, allowing a fluorescence signal to be emitted upon excitation. Molecular beacons have been used to image endogenous RNA localization in the cytoplasm of living cells as well as in live embryos during development (*3, 4, 7, 10*−*14*). However, most of the studies on live-cell RNA detection used microinjection to introduce linear or hairpin probes into cells. This delivery approach is labor-intensive when used for studying a large number of cells. Further, probes delivered using microinjection tend to nonspecifically accumulate in the nuclei of cells and thus have a high background signal. In some cases, no localized signal was observed (*12, 14*).

Here, we report the development of a bifunctional probe (NLS-MB) composed of a single nuclear localization sequence (NLS) peptide (*15*−*18*) conjugated to a molecular beacon (MB) for efficient delivery and imaging of endogenous snRNA and snoRNA in living cells. Using a combination of reversible membrane permeabilization and peptide-based delivery, we demonstrated the high specificity and sensitivity of the method

Negative Control Molecular Beacon 5′-Cy3-CGACGCGACAAGCGCACCGATACG(dT-C6-NH_2)CG-BHQ2−3′

by observing in living cells the localization and colocalization of snRNA U1 and U2 at discrete foci in the nucleoplasm and the localization of snoRNA U3 in the nucleolus. These small RNAs were chosen because U1 and U2 snRNAs are the key members of the spliceosome responsible for splicing of nuclear pre-mRNA (*15, 19*−*21*), and U3 snoRNA is one of the best characterized small nucleolar RNAs involved in the endonucleolytic cleavage of various pre-rRNAs (*22*). Our results clearly demonstrated the ability of the NLS-MBs in detecting snRNAs and snoRNAs in cell nucleus, which can be used to image other nuclear RNAs and pre-mRNAs in studying transcriptional and post-transcriptional processing of RNAs in living cells.

EXPERIMENTAL PROCEDURES

Molecular Beacon Design and Synthesis. Probes (as shown in Table 1) with modification in the stem region (dT-NH_2 on the quencher side) were synthesized by MWG Biotech, NC, and Biosearch Corp, CA. The molecular beacons were designed with regular DNA chemistry (deoxyribonucleotide backbone). The probes were purified using double HPLC. Probes for U1 and U2 snRNPs and U3 snoRNPs were designed with the Cy3 (fluorophore) and BHQ-II (quencher) pair. U2 snRNP probes were also designed to have Cy5 fluorophore and BHQ-III quencher. In all cases, the quencher was conjugated to the 3′-end, while the fluorophore was on the 5-end (Table 1).

Peptide Conjugation and Synthesis. In the conjugation scheme as shown in Figure 1, a nucleotide on the quencher-arm of a molecular beacon was modified with the dT-amine group and a 6-carbon spacer. To generate a stable linkage between a peptide and the modified molecular beacon, the NLS peptide was modified with a cysteine group at its N terminus. Amine-modified molecular beacons were reacted with a heterofunctional cross-linker sulfo-SMCC (Pierce Biotech) for 3 h at room temperature with intermediate shaking. The reaction was carried out with 1× (2 μm) molecular beacons and 20× (40 μm) sulfo-SMCC in PBS buffer. After 3 h, the excess of sulfo-SMCC was removed from the reaction mixture using centrifugal filter (YM-10) with a cutoff of 10 kDa. The resultant solution was brought to the same initial volume by adding PBS and reacted with 2× (4 μm) concentration of Cys-modified NLS peptide overnight at room temperature. Following this reaction, the peptide-linked molecular beacon complex was dialyzed overnight using Slide-A-Lyzer Dialysis Unit, 10K MWCO (Pierce Biotech Inc., Rockford, IL) to remove unconjugated peptide. The NLS peptide (99% purity) as shown in Table 1 was synthesized at SynPep Inc. The NLS peptide sequence was modified at its N terminus to introduce a cysteine residue. The aminohexanoic acid spacer (Ahx) equivalent to a length of ∼2 amino acids was introduced between the N terminus residue of NLS sequence and the cysteine residue to improve conjugation efficiency. Reaction between the thiol group (Cys) on an NLS peptide with the maleimide group introduced on a molecular beacon resulted in the formation of a thiol−maleimide bond, which is stable under physiological conditions, including the reducing intracellular environment.

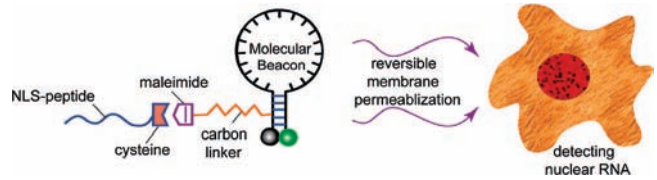

Figure 1. A schematic illustration of the design of a peptide-linked molecular beacon and its delivery into cell nucleus. The NLS peptide is covalently linked to the molecular beacon using a modified nucleotide (dT-C6-NH_2) in its quencher arm. The NLS-linked molecular beacons are delivered into the cytoplasm first using a reversible membrane permeabilization agent Streptolysin O (SLO), and the NLS peptide actively transports the probes into the nucleus of a living cell.

Cell Lines. All experiments in this study were carried out using HeLa cells. This cell line has been used in several nuclear transport studies and also in study of various snRNPs in fixed cells. HeLa cells were cultured using Dulbecco's modified Eagle's medium + fetal calf serum (10%) + horse serum (2.5%). HeLa cells were plated in T-25 (cell culture flask) using 1:10 dilution after each splitting cycle. A batch of HeLa was cultured only for about 10 splitting cycles. For imaging experiments, cells were plated on 4 well or 8 well Nalgene-Nunc chamber cover slides 24 h prior to the experiment.

Solution Assay for S/N of Modified and Unmodified Molecular Beacons. Measurements of signal-to-background ratio of peptide-linked molecular beacons and unmodified beacons were carried out using a SAFIRE microplate monochromator reader (TECAN, Austria). To determine the signal-to-background ratios, 200 nM conventional and peptide-linked molecular beacons were mixed with 200 nM of complementary target, respectively, in the microplate reader, and the fluorescence intensity at equilibrium (10 min incubation time) was recorded. The fluorescence signal of each molecular beacon type (conventional and peptide-linked) in the absence of target was recorded as background signal.

Cellular Delivery and Confocal Imaging. For cellular delivery of peptide-linked molecular beacons, experiments were carried out using HeLa cells (ATCC, VA). For imaging experiments, cells were cultured in a 4 well or 8 well Nalge Nunc culture plate with a glass coverslip bottom in their respective cell culture media (as described above) for 24 h before the experiment. For delivery, peptide-linked molecular beacons were mixed with activated streptolysin O (SLO) in serum-free media and incubated with the specific cells at 37 °C for 10 min. After incubation, the medium was changed to regular serum-rich media, and the cells were incubated for 1 h after changing the medium. We also conducted a control study in which NLS-conjugated, unquenched beacon probes were incubated with cells without streptolysin-O treatment. Our results indicate that there was essentially no uptake of unquenched beacons after 1 h of incubation without SLO (data not shown). Cells were then imaged alive using a confocal microscope (Axiovert LSM-100, Zeiss). For detection and imaging of localization of U1, U2 snRNPs, and U3 snoRNP, we used laser excitation at 543 nm with emission detection using a band-pass filter from 560−610 nm. For imaging colocalization of U1 and U2 snRNPs, we used both 543 and 640 nm laser excitation. The signal was detected using band-pass filter from 560−610 nm for Cy3 signal detection and long-pass filter from 660 nm for Cy5 signal detection.

RESULTS

Design of Peptide-Linked Molecular Beacons. In this study, we have designed and synthesized the peptide-linked molecular beacons targeting U1, U2 snRNAs, and U3 snoRNAs, as well as molecular beacons with a "random" probe sequence. The

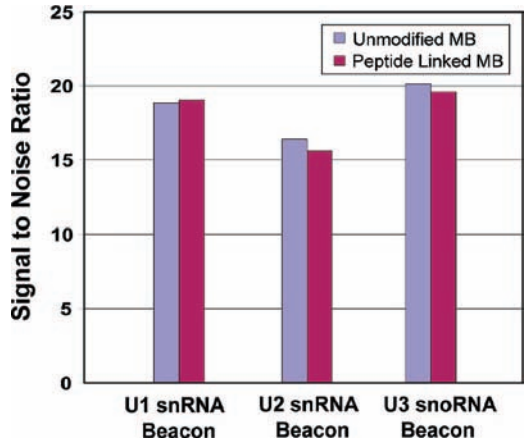

Figure 2. Signal-to-noise ratios of the NLS-linked and unmodified molecular beacons. For molecular beacons designed to target U1, U2 snRNAs, and U3 snoRNA, with and without the NLS peptide there is no significant difference in the signal-to-noise ratios.

specific oligonucleotide sequences of these MBs and the sequence of the NLS peptide are shown in Table 1, with the stem domain of a molecular beacon underlined. The design of these probes to target specific segments of small RNAs in the nuclei of living cells was based on previous fluorescence *in situ* hybridization (FISH) studies in fixed cells with linear oligonucleotide probes, which were shown to be able to access the target (*15, 16, 23*−*27*). The "random" beacon was designed as a negative control, with a 17-base probe sequence that does not have any exact match in the mammalian genome (*3, 4*). The probes used in this study are with deoxyribonucleotide backbone; the dye and quencher pairs (Cy3-BHQ-II and Cy5-BHQ-III) were selected to ensure effective quenching of the probes in their unhybridized state (stem-loop hairpin).

Signal-to-Noise Ratio of Peptide-Linked Molecular Beacons. To determine the possible effect of peptide conjugation on the molecular beacon function, in-solution hybridization assays were carried out to compare the signal-to-noise (S/N) ratios of the peptide-linked molecular beacons and unmodified beacons. When the positively charged NLS peptide is conjugated to a molecular beacon, the electrostatic interactions of the peptide with the negatively charged oligonucleotide hairpin may interfere with the probe-target (RNA) binding. As shown by the results in Figure 2, there were no significant changes in the S/N for each of the molecular beacons after modification with NLS peptide. This result is in agreement with our earlier results with Tat peptide-linked MBs for cytoplasmic delivery and mRNA detection (*4*).

Efficiency of Nuclear Delivery Using Peptide-Linked Molecular Beacons. To provide an estimate for the total concentration of NLS-MBs delivered into nucleus, we synthesized *unquenched*, U3-targeting hairpin probes with and without NLS peptide, respectively, and delivered them into the cytoplasm of living cells using SLO. Since U3 snoRNA does not have any target in the cytoplasm, there should be no specific signal in the cytoplasm; thus, this approach gives a good measure of probe distribution in the cytoplasm due to delivery but not probe−target hybridization. The total fluorescence signal was quantified in the cytoplasm and nucleus of approximately 40 cells. The average ratio of fluorescence intensity in the nucleus to total fluorescence in each cell was determined. A representative image of nuclear and cytoplasmic distribution of probes with and without NLS is shown in Figure 3A. There was a significant increase (∼3.3-fold increase) in the nuclear localization of NLS-conjugated probes compared to probes without the NLS peptides, as demonstrated in Figure 3B. Specifically, about 40% of the NLS-conjugated probes were

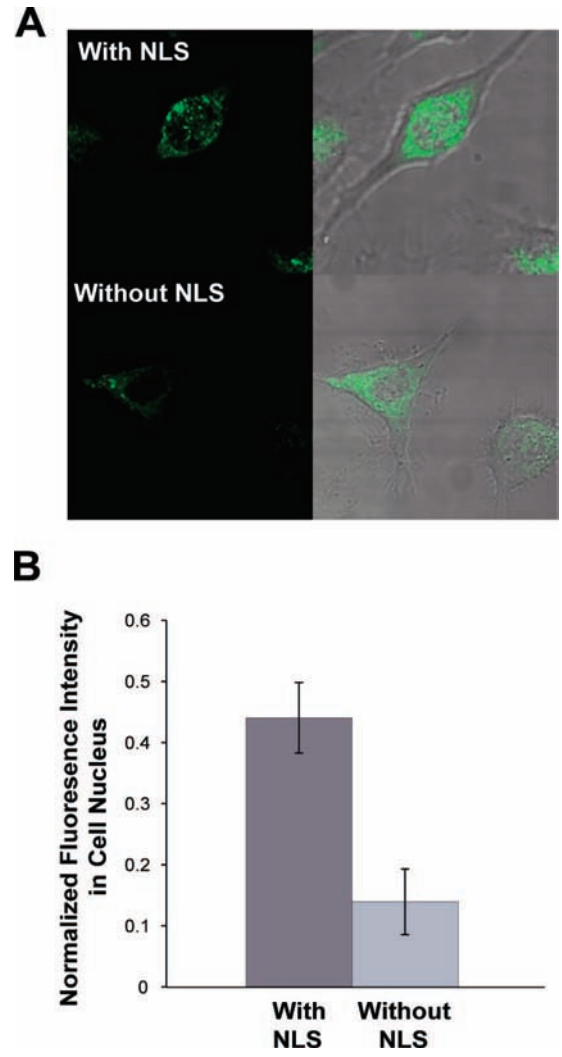

Figure 3. Efficiency of nuclear delivery of NLS-linked MB probes in living cells. (a) Fluorescence images of unquenched probes delivered to the cytoplasm of living cells using SLO. The NLS-conjugated probes show a much higher signal level in cell nucleus as compared with probes without the NLS peptide. (b) Quantification of nuclear delivery efficiency of probes with and without NLS peptide. The average fluorescence signal from NLS-conjugated probes in cell nucleus has a ∼3.3-fold increase compared with probes without NLS peptide.

delivered into the cell nucleus as compared to only about ∼10% of the probes without NLS peptide. This result is in agreement with a recent study using NLS-linked PNA probes (*28*).

Imaging of U3 snoRNP, U1, and U2 snRNPs in the Nuclei of Living Cells. To demonstrate the delivery of NLS-MBs into cell nuclei, and specific detection and imaging of an endogenous small RNA in the nuclei of living cells, we have performed detection assays to target U3 snoRNA and U1 and U2 snRNAs in the nucleus. The NLS-linked MBs targeting the respective small RNAs were introduced into the cell cytoplasm using a reversible cell membrane permeabilization method with Streptolysin O (SLO). The results for the detection of U3 snoRNP in the nucleus of a living cell are shown in Figure 4a. We observed very discrete localization of signal in the nucleolus and discrete peri-nucleolar foci in living cells with no detectable signal in the cytoplasm, consistent with the results obtained in previous studies (*24, 26, 27, 29*), indicating that U3 snoRNA is localized in the nucleolus and in certain cases associated with the cajal bodies. It is known that U3 snoRNA is processed in the cajal bodies prior to its transport and localization to the nucleolus. Furthermore, we observed heterogeneous localization (punctate pattern) of the U3 snoRNA in some nucleoli and a

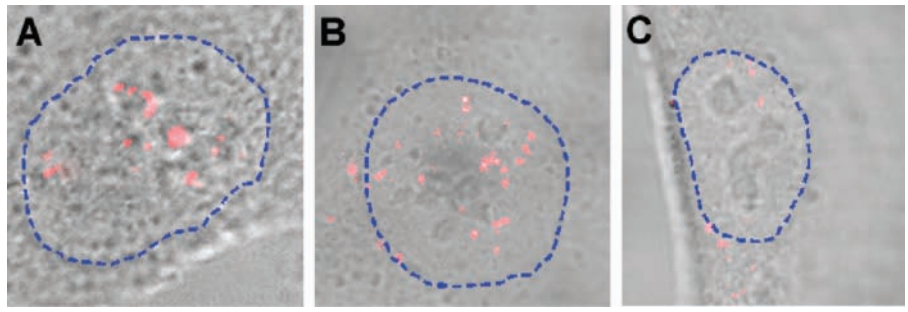

Figure 4. Imaging of U3 snoRNA, U1, and U2 snRNAs in the nucleus of living cells using NLS-linked molecular beacons. (a) Fluorescence signal of molecular beacons targeting U3 snoRNA in the nucleus of a living cell. Note that most of the localized signal was in the nucleolars, with no signal in the cytoplasm. (b) Imaging of U1 snRNA showing localized fluorescence signal in the nucleoplasm of a living cell excluding the nucleolus. Note that the discrete foci of U1 snRNPs are widely distributed in the nucleoplasm, with a few foci in the peri-nucleolar region. Note also the localized signal of U1 snRNPs in the peri-nuclear region of the cytoplasm, indicating the population of the U1 snRNAs exported to the cytoplasm for processing of its 5′ cap. (c) The fluorescence signal suggests that the localization of U2 snRNAs in the nucleus is similar to that of U1 snRNAs but with a much lower abundance.

uniform fluorescence pattern in others, also consistent with previous observations (*24*).

Shown in Figure 4b are the results of detection and imaging of U1 snRNPs using NLS peptide-linked MBs, clearly indicating the discrete localization of the U1 snRNPs in the nucleoplasm of HeLa cells but not in the nucleolus. The localized foci of U1 snRNPs are widely distributed in the nucleoplasm, with a few foci at discrete peri-nucleolar regions (marked with an arrow). This observation of widespread U1 snRNP localization in the nucleoplasm is in agreement with the results of the previous studies (*16, 23, 25, 30*). These studies have shown in fixed cells that U1 snRNPs are associated with both cajal bodies (processing of U1 snRNP after its import from cytoplasm) and speckles (site of assembly of splicing complex). In addition to widespread nucleoplasmic localization, we also observed some localized signal at discrete spots in the cytoplasmic, peri-nuclear region. This signal indicates a fraction of the U1 snRNPs exported to the cytoplasm. It has been suggested that U1 and some other snRNPs (excluding U6) are exported from the nucleus to the cytoplasm for assembly of the snRNP complexes and the processing of their cap (*31*−*33*). They are then imported back into the nucleus and further processed in the cajal bodies before transported to the speckle sites. This export process has been directly observed in *Xenopus* oocytes using labeled RNAs as well as EM-based high-resolution imaging (*17, 32*). These studies have also reported a rapid import of the snRNPs from the cytoplasm to nucleus after processing (*32*). The detection of both the cytoplasmic and nuclear portions of U1 snRNPs in live cells demonstrated clearly the high sensitivity of the molecular beacon based method.

Molecular beacon based imaging assays were performed to detect U2 snRNPs in live cells, and the results, displayed in Figure 4c, showed clear U2 localization at discrete foci in the nucleoplasm, excluding the nucleoli. In contrast to widespread localization of the U1 snRNPs in the nucleoplasm, the fluorescence signal of U2 snRNPs appeared at only a few discrete foci. This observation is in agreement with the results of the localization pattern obtained in previous studies (*16, 23*). We also observed the discrete signal of U2 snRNAs in the peri-nuclear region in the cytoplasm of living cells, confirming that U2 snRNPs, similar to U1 snRNPs, are exported to the cytoplasm for processing.

Taken together, the results in Figure 4 demonstrated that single NLS−peptide linked molecular beacons could be transported from the cytoplasm to the nucleus. To highlight the high specificity of the multifunctional probes in the nucleus, we have imaged RNA at discrete localizations (nucleoplasm vs nucleolus) with high signal to background ratio in the nuclei of living cells. However, it is unclear whether U1 and U2 snRNPs are restricted to the cajal bodies or the pattern observed in this study represents both the cajal bodies and the speckle sites. Answering this question through live-cell imaging studies would require the simultaneous labeling of some of the proteins in the speckle domains such as SF2/ASF (*34, 35*) as well as snRNAs. The combination of fusion proteins such as GFP with an exogenous probe for snRNA can provide valuable insight into the dynamics and function of RNAs in living cells. This will be pursued in a subsequent study.

Co-Localization of U1 and U2 snRNAs in Living Cells. U1, U2, and other members of the snRNP family, together with some non-snRNP proteins, form a splicing complex responsible for the trans-splicing of pre-mRNA transcripts. The assembly of this complex requires various snRNPs to come together to form a defined structure. Although in vitro characterization of the complex has been performed, there are still many unknowns concerning the assembly and inner workings of the spliceosome complex. For example, it is important to know the dynamics of U1 and U2 snRNPs, as they form a complex. As an initial effort, we have studied the colocalization of U1−U2 snRNAs in the cell nucleus to demonstrate the ability to simultaneously detect multiple RNAs in the nuclei of living cells. As shown in Figure 5a,c, some U1 and U2 snRNAs are colocalized at discrete foci in the nucleoplasm, with a more widespread distribution of U1 snRNPs, consistent with the results obtained using FISH with fixed cells (*15, 16*). This U1−U2 colocalization may be the first step toward the formation of the splicesosome. To our knowledge, this is the first direct observation of the colocalization of U1−U2 snRNAs in living cells.

In Situ Hybridization Studies with Fixed Cells. To confirm the observations in live cell studies, as a positive control we carried out fluorescence in situ hybridization (FISH) studies in fixed cells. The cells were fixed and permeablized according to the protocol described in the Experimental Section. The result of detecting U3 snoRNAs in fixed cells, shown in Figure 6a, clearly demonstrated the localization of U3 snoRNAs in the nucleoli, similar to what was observed in live cells. To validate our observations of the localization and colocalization of U1 and U2 snRNAs in living cells, we performed fluorescence in situ hybridization in fixed cells using probes targeted to U1 and U2 snRNAs. The results of the FISH studies are displayed in Figure 6b−d, which clearly show the discrete foci of colocalized U1 and U2 snRNAs. We also observed more widespread localization of the U1 snRNAs in the nucleoplasm of fixed cells. These observations are in good agreement with the results obtained from the live cell studies. In addition, we also observed few discrete foci of U1 and U2 snRNAs in the peri-nuclear region of cytoplasm in agreement with our live cell assay.

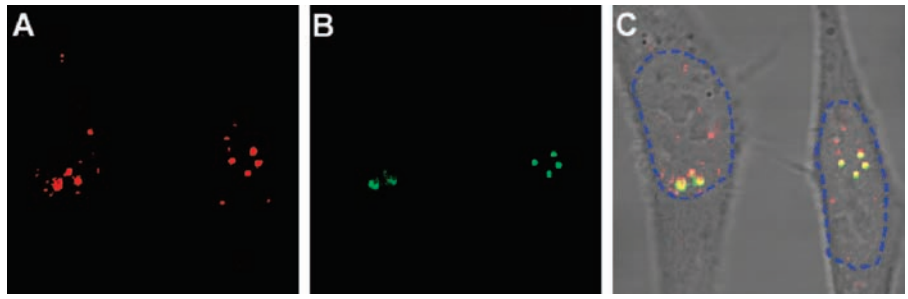

Figure 5. Co-localization of U1 and U2 snRNAs in the nucleoplasm of living cells imaged using peptide-linked molecular beacons. Shown in (a) and (b), respectively, are images of fluorescence signal from U1 and U2 snRNAs in the same living cell. (c) The overlay of the images in (a) and (b) indicating the co-localization of U1 and U2 snRNAs at discrete foci in nucleoplasm. In addition to the U1−U2 co-localized foci, U1 snRNAs can be observed at other foci in the nucleoplasm.

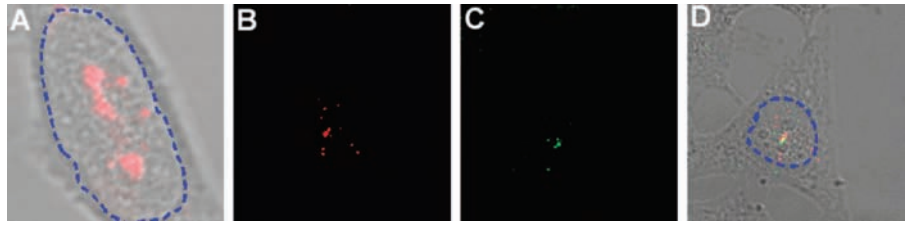

Figure 6. Fluorescence in situ hybridization (FISH) images of the U3 localization and U1−U2 co-localization in the nuclei of fixed cells. (a) FISH image of the U3 snoRNA in a fixed cell indicating that most of the signal was in the nucleolus, consistent with the live-cell results. Shown in (b) and (c), respectively, are FISH images of the U1 and U2 snRNAs localized at discrete foci in the nucleoplasm of the same fixed cell, in good agreement with that observed in live cells. (d) Overlay of the images in (b) and (c) shows the colocalization of U1 and U2 snRNAs in the nucleus of a fixed cell, confirming that observed in live cells.

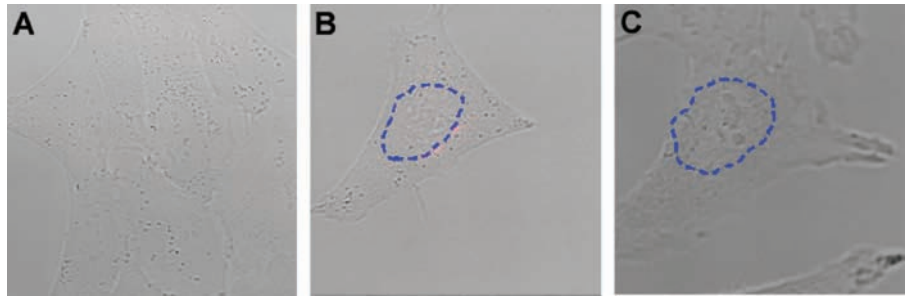

Figure 7. The results of negative control studies. (a) The low background signal from "random" beacons in the nuclei of living cells. These negative-control molecular beacons have no target in the mammalian genome thus indicating nonspecific opening of probes during delivery to and diffusion in the nucleus. (b) Fluorescence signal obtained by delivering U1-targeting molecular beacons without the NLS peptide. Only a few discrete foci in the peri-nuclear region in the cytoplasm could be observed but no significant signal in the nucleus of the living cell. (c) Fluorescence signal as a result of delivering unmodified molecular beacons targeting U3 snoRNA, indicating that without the NLS peptide attached to the U3-targeting beacons no significant signal could be detected in the nucleus or cytoplasm of a living cell.

Negative Control Studies. In order to determine the level of nonspecific interaction of NLS-MB in living cells, we carried out control studies with "random" molecular beacons, which have a specific sequence generated using "random walk", with no exact match in the mammalian genome. Figure 7a shows the signal from the NLS peptide-linked "random" beacons. Evidently, there was very low signal under the same imaging conditions as compared to the results shown in Figure 4. This clearly indicates that peptide-linked molecular beacons delivered to cells maintained their functionality during the course (∼1−1.5 h) of the study.

To further demonstrate that active transport of probes from the cytoplasm to nucleus is necessary for detecting nuclear RNAs (or RNAs in cell nuclei), we did a control study in which the molecular beacons designed to target U1 snRNAs and U3 snoRNA without any NLS peptide conjugated to them were delivered into the cytoplasm using SLO. Shown in Figure 7b and c are, respectively, the resulting images of U1- and U3-targeting molecular beacons. The image in Figure 7b shows discrete foci of U1 snRNA in the peri-nuclear region of the cytoplasm without any detectable signal in the nucleus, while no signal could be detected in the cytoplasm or in the nucleus from U3-targeting beacons (Figure 7c). This clearly indicates that, without conjugation of NLS peptides, molecular beacons cannot be actively transported to the nuclei of living cells. Since U1 snRNAs are exported from the nucleus for processing before being reimported back to the nucleus, their detection in the cytoplasm is in good agreement with our earlier results. Since U3 snoRNAs are being processed in the nucleus only, not exported to the cytoplasm, they should not be detected in the cytoplasm.

DISCUSSION

To detect specific RNAs in the nuclei of living cells, we have developed a peptide-linked molecular beacon, a bifunctional oligonucleotide probe that has both RNA targeting and nuclear delivery functions. Specifically, a single peptide with an NLS sequence was conjugated to a molecular beacon that targets an snRNA or snoRNA. To internalize the peptide-linked molecular beacons into the cytoplasm of living cells, we adopted a reversible permeabilization approach using streptolysin O (SLO). In some previous studies (*6*, *8*, *11*, *12*, *14*), probes (including

molecular beacons) were introduced into the cytoplasm of living cells by microinjection; however, upon microinjection most probes were nonspecifically sequestered in the nucleus, and molecular beacons had nonspecific opening in both the cytoplasm and the nucleus (*7*, *12*).

Unlike previous molecular beacon based studies in which high background signal was present in detecting RNAs in the nuclei of cells, the results presented in this study show highly specific targeting of nuclear RNAs with very low background levels (based on "random" beacon images and other negative controls). The significant difference between our results and that reported previously is believed to be a consequence of the delivery approach in introducing molecular beacons into living cells. The approach developed in this study allows for delivery of probes into the nucleus with high efficiency while maintaining the normal function of molecular beacons. Our results of detecting U1, U2 snRNAs, and U3 snoRNA, together with the control studies, provide strong evidence that the peptide-linked molecular beacons can be used not only to study fundamental RNA biology but also as a diagnostic imaging tool (*36*, *37*). In combination with our previous approaches (*4*), this method has the potential to image transcriptional and post-transcriptional processing of RNAs in living cells and provide an integrated picture of RNA distribution in the cell nucleus and cytoplasm. Although the delivery method presented in this study was used in cell culture assays, the NLS peptide can be combined with Tat and other cell penetrating peptides (CPPs) for in vivo delivery of probes. With molecular beacons designed to have near-infrared (NIR) reporter dyes, this approach can be further used to image RNAs in the cell nucleus of tissue samples.

In summary, in this study we have developed a novel method that allows for direct imaging of endogenous RNAs in the nuclei of living cells. This approach combines the high specificity and signal-to-noise ratio of molecular beacons with the ability of NLS peptide to effectively deliver oligonucleotide probes into the cell nucleus. This approach can be further combined with various protein tags to develop a comprehensive understanding of RNA biogenesis, transport, translation, and metabolism. This understanding will potentially lead to novel targets for therapeutic interventions in various diseases as well as significantly enhance our understanding of cell biology.

A strategy for quantification of multiple protein isoforms from a complex sample background is demonstrated, combining isotopomeric rhodamine 6G (R6G) labels and surface-enhanced Raman in polyacrylamide matrix. The procedure involves isotope-encoding by lysine-labeling with (R6G) active ester reagents, isoform separation by 2-DGE, fluorescence quantification using internal standardization to water, and silver nanoparticle deposition followed by surface-enhanced Raman detection. R6G sample encoding and standardization enabled the determination of total protein concentration and the distribution of specific isoforms using the combined detection approach of water-referenced fluorescence spectral imaging and ratiometric quantification. A detection limit of approximately 13.5 picomolar R6G-labeled protein was determined for the surface-enhanced Raman in a gel matrix (15-fold lower than fluorescence). High quantification accuracies for small differences in protein populations at low nanogram abundance were demonstrated for human GMP synthetase (hGMPS) either as purified protein samples in a single-point determination mode (3% relative standard deviation, RSD%) or as HCT116 human cancer cellular lysate in an imaging application (with 16% RSD%). These results represent a prototype for future applications of isotopic surface-enhanced resonance Raman scatter to quantification of protein distributions.

INTRODUCTION

Despite major advances in protein analysis, accurate and precise methodologies capable of assessing changes in protein distribution in biological systems represent a target for development. Specifically, post-translational modifications of proteins on the biological response time scale requires simultaneous monitoring of multiple protein isoforms to understand signaling. Examples include signal transduction pathways controlled by phosphorylation, such as activation of MAPK cascades, which are carefully tuned in terms of magnitude (*1, 2*), timing (*3*), duration (*4, 5*), and spatial regulation in response to specific stimuli (*6*). The relative changes in ERK1/2 isoforms can vary from 5% to 50% on the 10 min time scale in Ras activation (*3*) to 80−90% in response to amphetamine stimulation (*7*), and multiple isoforms are known for signaling proteins such as src kinase (*8*). Small changes in protein isoform content can translate into biologically meaningful distinctions due to downstream signal amplification. A different example is enzyme isoform diversity through post-translational modifications, such as those in GAPDH, which lead to variations of protein function aside from the catalytic activity (*9*−*11*).

Quantification of protein "isoforms" has been demonstrated using quantitative mass spectrometry (*12*) and differential gel electrophoresis (DIGE) (*13*). Bioconjugate chemistry combined with mass spectrometric methods have enabled a "bottom up" peptide analysis approach using stable isotope labeling of peptides, e.g., ICAT, iTRAQ, AQUA, or GIST (*12*). Label-free quantification methods are based on the abundance of specific ions sampled over a chromatographic peak (*12, 14*). This method requires careful selection of survey and fragment spectra (MS and MS/MS) sampling times relative to the chromatographic peak width. Recently, a targeted approach involving the use of multiple-reaction monitoring (MRM) to track a selected precursor ion, diagnostic of a specific molecular entity, has demonstrated an improved dynamic range 10^4-10^5 for phosphopeptide monitoring (*12, 15*). However, MRM has limitations in terms of reproducibility of proteome coverage, and the relative phosphorylation status for specific protein species is not readily accessible.

Comparative proteomic strategies using 2-DGE provide an avenue for potential quantification of changes in thousands of protein isoforms provided appropriate resolution of the targeted proteins in the sample (*16*). In practice, only the most abundant proteins in a proteome can be recovered in reasonable amounts for further analyses, and proteins with low levels of expression remain difficult to detect, quantify, and identify. This is a particularly important problem, because even in typical mammalian cells, the protein copy number can vary over a 10^6 range (*17*), and the expected number of unique protein entities can be as high as 10^5. This scenario is more challenging for serum proteomes (*18*), where the dynamic range has been estimated at up to 10^{12}.

Our efforts recently assessed the capacity of bioconjugation chemistry combined with silver-enhanced Raman detection based upon isotope ratio standardization in gel matrices to provide accurate quantification of proteins (*19*). Several limitations of fluorescence-based quantification may be addressed using surface-enhanced resonance Raman scattering (SERRS) spectroscopy. While internal standardization of single fluorophore content in gels has been demonstrated using Raman water signals (*20*), the capacity to multiplex with fluorescence requires the use of multiple dye classes. These distinct chemical modifications create higher-order separation problems for labeled

proteins in mixtures (*21*). Previous applications of surface-enhanced Raman-based detection for quantification have been limited due to variations in surface chemistry leading to large fluctuations in enhancement efficiency (*22, 23*). Isotopically encoded Raman active dyes such as Rhodamine 6-G (R6G) provided highly reproducible and quantitative SERRS-based concentration measurements (*24*). While Raman spectra of R6G isotopic variants are distinct, their physiochemical properties are virtually identical, thus making them ideal labels for internally standardized proteomic separations and quantification applications (*19, 24*).

Here, we present a new protein-encoding strategy that makes use of isotopic pairs of R6G-NHS ester labeling reagents for internally standardized ratiometric quantification analysis in silver-stained 2D gels (*19*). The ratiometric quantification accuracy, gel to gel reproducibility, and detection limit were assessed with a purified recombinant protein of interest, human GMP synthetase. The lower limit of detection for the SERRS measurement enabled a reduction in labeling and minimized separation artifacts. Three endogenous protein isoforms were quantified in cell lysates using internalized sample spiking with known quantities of recombinant hGMPS protein isoforms. The precision and accuracy in the resulting Raman-based quantifications justifies future development of the isotope edited internal standardized SERRS biomolecular quantification approach to protein isoform quantification methods.

MATERIALS AND METHODS

Materials. Isotope encoded d_0- or d_4-R6G NHS ester reagents were prepared by S. K. Deb as reported (*19*). All 2-DGE materials were from Biorad. Recombinant human GMP synthetase (hGMPS) was a gift from Justin C. Oliver, produced as described to >95% purity (*25*). All other reagents were purchased from Sigma.

Soluble Cell Lysate Preparation. HCT116 colon cancer cells (ATCC) were cultured using standard cell culture conditions in DMEM-F12 medium containing 10% FBS. Cells were harvested by trypsin release, then rinsed three times with PBS, and pelleted for storage at −80 °C. For lysis, thawed cell pellets were suspended in chilled lysis buffer containing 20 mM HEPES, pH 7.5, 0.25 M sucrose, 3 mM $MgCl_2$, 0.5% NP40, 2 mM DTT, and 1× Halt protease inhibitor cocktail (EDTA-free, Pierce). The cells (2×10^7 cells/mL) were homogenized with fifteen strokes of a 2 mL Dounce homogenizer and pestle B, and then cellular debris was pelleted at 12 000 *g* for 20 min at 4 °C. The supernatant was concentrated and buffer exchanged into 50 mM borate buffer pH 8.5 using 5 kDa MW cutoff ultrafree spin filters (Millipore), and the protein concentration was determined using the Biorad protein assay with BSA calibration. Prepared lysates were used immediately for labeling and 2-DGE analysis.

Protein Labeling. For lysate or recombinant protein sample labeling, 100−150 μg of protein was dissolved in 50 mM borate buffer pH 8.5 to a final volume of 200−1200 μL, to which was added 1 nmol (1 μL) of d_0- or d_4-R6G-NHS reagent stock dissolved in ethanol. After 1 h incubation in the dark at room temperature, the protein reaction was desalted on a PD-10 column (GE Healthsciences) into 50 mM Tris pH 7.5 buffer. The total protein eluate was concentrated then buffer exchanged with 8 M urea, 10 mM Tris pH 7.5, and 0.5% CHAPS on a 5k MW cutoff microspin filter, to remove any remaining unreacted dye. Protein concentration was determined using the Biorad protein assay, and dye content was assessed by UV−vis absorbance using $\varepsilon = 116\,000\ M^{-1}\ cm^{-1}$ at λ_{max} of 540 nm for R6G. These reaction conditions produce a low molar labeling efficiency (~0.1%), and were optimized using controlled mixtures of proteins with known pI and Mw and various dye/protein reaction stoichiometry, selecting for conditions that produced unaltered 2DGE images between labeled vs unlabeled samples (*20*). This method minimized the appearance of charge-shifts in the IEF dimension, due to potential side-reactions with Tyr, Thr, or Ser residues (*26*).

2D-PAGE. For isoelectric focusing, protein in a volume of less than 20 μL was diluted into sample rehydration buffer containing 8 M urea, 2% CHAPS, 50 mM DTT, 0.2% Bio-Lyte 3/10 ampholyte, and 0.001% bromophenol blue for rehydration of 11 cm, 3−10 nonlinear IPG strips. The IEF strips were focused under optimized conditions for mammalian cell lysates (*27*) over 16−20 h for a total of ~60 000 Vh using a shallow gradient over five voltage steps, reaching a maximum of 8000 V on a Biorad Protean IEF Cell apparatus. After focusing, the strips were reduced and alkylated in equilibration buffer containing 6 M urea, 0.375 M Tris pH 8.8, 4% SDS, 20% glycerol containing 2% DTT for 10 min, then 2.5% iodoacetamide for 10 min. For the second dimension, the strips were run on single well, precast, Criterion 12.5% acrylamide Tris-HCl gels. The gels were fixed in 50% methanol, 5% acetic acid for 1−2 h, followed by 50% methanol 1 h, then stored in water at 4 °C. Gels of non-R6G-labeled control protein samples were stained with SyproRuby according to the manufacturer protocol (Biorad).

Fluorescence Scanner Gel Documentation. Fluorescence images of 2D gels were recorded using a Typhoon fluorescence scanner (GE Life Sciences), with the following settings for R6G: 532 nm excitation, 580 (±30) nm bandpass emission filter, and 100 μm pixel size; and the photomultiplier voltage was adjusted for maximum dynamic range of signal, typically 650 V. For SyproRuby detection, 532 nm excitation and the 610 (±30) nm bandpass emission filters were used.

Silver Staining. Polyacrylamide gels were silver stained according to the Schevchenko method with modifications to minimize background staining (*28, 29*). Due to the importance of silver substrates for SERRS detection, details of the silver staining procedure are given here. The gels were reduced for 2 min in freshly prepared 2 mM sodium thiosulfate ($Na_2S_2O_3$). Then, the gels were rinsed twice in water over 5 min before incubation in chilled (4 °C) 0.1% silver nitrate solution for 20 min. The gels were then rinsed with two exchanges of water over 4 min, and then incubated in 10% sodium carbonate containing 0.04% formaldehyde until the protein spots had developed sufficient brown staining for visualization. Development was quenched before the appearance of excessive mirroring with a 2 min wash in 5% acetic acid. Where indicated, gels were preserved by soaking in 10% glycerol and drying between sheets of cellophane at room temperature.

***d_0/d_4*-R6G Ratiometric Accuracy.** The practical limits of the ratiometric quantification strategy were assessed using mixtures of separately labeled d_0- or d_4-R6G-recombinant hGMPS. Gel-to-gel reproducibility and precision were assessed for a 43% d_4-R6G composition sample, representing a 1.3-fold difference between d_0- and d_4-R6G concentrations. Three replicate gels containing 3 μg total of the mixed protein sample were separated by 2-DGE, silver stained, and then dried as described above. A practical detection limit was determined by sampling a series of 2-DGE samples containing 3 μg, 300 ng, 30 ng, or 3 ng total hGMPS protein. Here, the sample composition was selected to be 64.2% d_0-R6G, representing a 1.8-fold difference between d_0- and d_4-R6G samples, a value selected to be significant at picomolar R6G concentrations. For these samples, a single-point determination procedure was followed using a Senterra confocal Raman microscope (Bruker Optics) operated with *Opus* v 6 software.

The Senterra was equipped with a 532 nm laser and Olympus MPlan 20× (0.4 NA) or 50× (0.75 NA) objectives, with

collection spot size dimensions of 50 × 1000 μm, and 3−5 cm^{-1} resolution grating settings. The following settings were used to acquire spectra for 0.1−1 μg protein: 2 mW power, 2−5 scans, 30 s integration time; and for 1−10 ng protein: 5−10 mW, 5 scans, and 60 s integration. Data were fit using a manual curve fitting operation within *Opus* software around the signature 610 and 600 cm^{-1} peaks, using baseline subtraction between 619 and 587 cm^{-1}, and a Gaussian peak shape model. The ratio of areas of the 610 to 600 cm^{-1} peaks directly provided values of d_0/d_4 composition.

***d*$_0$/*d*$_4$-R6G-Labeled Spiked Lysate.** *Preparation.* To produce spiked lysate samples, HCT116 cell lysate was divided equally into three vials containing 750 μg lysate, to which was added 0, 1.5, or 3 μg of recombinant hGMPS. These samples were labeled in separate reactions to give two d_0-lysates containing w/w 0% or 0.2% spiked recombinant hGMPS and a single d_4-lysate containing 0.4% spiked recombinant hGMPS. Mixed composition d_0/d_4 samples were combined as follows: Sample A: 100 μg each of the d_0-labeled, 0% spiked, and d_4-labeled, 0.4% recombinant hGMPS-spiked lysates. Sample B: 100 μg each of the d_0-labeled, 0.2% spiked, and d_4-labeled, 0.4% spiked lysates. The d_0-R6G labeled, nonspiked lysate sample was also used as a control (Sample C).

Theoretical Percent d_4-R6G Composition in Spiked Lysates. The theoretical percent d_4-R6G composition in a given hGMPS protein spot was calculated as a function of the composition of endogenous hGMPS and the recombinant protein that was added to it. For each protein spot, endogenous (E) protein was defined as the mass (ng) of hGMPS present in 200 μg of cell-free lysate. The mass of recombinant (R) protein (ng) in a protein spot was calculated per 200 ng recombinant protein (or 0.1% w/w addition of recombinant protein to 200 μg of lysate). The theoretical composition of d_4-R6G (%) in samples A and B was then given by eqs 1 and 2.

$$\%d_4(\text{sample A}) = \frac{\left(\frac{E}{2} + 2R\right)}{(E + 2R)} \quad (1)$$

$$\%d_4(\text{sample B}) = \frac{\left(\frac{E}{2} + 2R\right)}{(E + 3R)} \quad (2)$$

Multispectral Fluorescence and Raman Imaging. Full spectral imaging was performed using a custom-built micro-Raman system (*30*), equipped with an air-cooled 514.5 nm Ar^+ laser (Melles-Griot) and an Olympus BX41 microscope. Raman scatter was collected using a 20× objective (Olympus ULWD MSPlan, 0.4 NA) and focused onto a circular-to-linear fiber bundle for detection using an imaging spectrograph (Acton Research, SpectraPro 300i) and a 1024 × 256 LN-cooled CCD (Princeton Instruments). Gel imaging was performed using a custom-written LabVIEW (National Instruments) program to raster scan the gel through the laser focus while collecting spectra from an array of points in the gel. The laser focal spot size was 10 μm in diameter and 100 μm in depth, effectively 10 pL focal volume, and the $x-y$ step size in fluorescence or Raman scatter images was 200 or 250 μm. Gels were placed on a low-fluorescence glass plate (Bio-Rad) under a small pool of Milli-Q water to prevent drying over the duration of the scan. Fluorescence imaging parameters were as follows: laser power, 1 mW at the sample; spectrograph grating, 300BLZ at 670 nm; exposure time, 5 ms; image size, ∼70 × 40 pixels = 17.5 × 10 mm; scan time = 10 min. SERRS imaging parameters were as follows: laser power, 14 mW at sample; spectrograph grating, 1200BLZ at 554 nm; exposure time, 1 s; image size, ∼48 × 48 pixels = 12 × 12 mm; scan time = 1 h.

Analysis of Multispectral Fluorescence and Raman Imaging. *Absolute Dye Quantification by Fluorescence.* For absolute R6G quantification in protein spots, the water-Raman subtraction method (WIS) of Loethen et al. (*20*) was applied to a small region of the gel containing the spiked sample. Calibration of dye concentration in solution was performed using d_0-R6G (calibration plot shown in Supporting Information Figure 1), and an additional region was imaged from the gel margin (protein-free) for calculating an average spectrum to be used as background. Savitzky-Golay second derivative solvent subtraction analysis of all spectra yielded the normalized value of R6G fluorescence to the water Raman band (*31*, *32*). Dye concentration was calculated over the volume of a protein spot using the protein-free R6G calibration and the normalized fluorescence spectral integration obtained from each image pixel. Using this method, a user-defined protein spot was selected as an internal standard for which the absolute molar amount of dye was quantified. Thus, the relative fluorescence in this spot could be used to normalize signal across replicate fluorescence gel images.

Automated SERRS Spectral Processing. To remove the fluorescence background from SERRS spectra, an automated method of polynomial fitting was used to model a composite fluorescence spectrum that could be subtracted (*33*). This procedure involved pixel by pixel comparison of the original spectra with a fourth-order polynomial fit and generating a composite spectrum by inputting the lesser of the original spectrum pixel value or the polynomial pixel value. Five or more iterations were performed to arrive at a composite spectrum that contained few or no Raman bands, smoothed using a second-order Savitsky-Golay width of 25 pixels (*32*), and subtracted from the original spectrum yielding a nearly null baseline SERRS spectrum.

Partial least-squares (PLS) modeling was used to quantify d_0- and d_4-R6G composition, using full-range, baseline-subtracted, second-derivative SERRS spectra. To generate the PLS model, a training set was collected with 200 spectra obtained for each of the following % d_4-R6G compositions: 100%, 75%, 50%, 25%, or 0% of a standard, d_0- or d_4-R6G-labeled purified protein (ferritin) (*19*). These spectra were weighted by standard deviation over the 200 spectra for each set, but otherwise were not manipulated for this analysis. The final calibration plots for PLS modeled training set data with observed versus expected % d_4-R6G composition had a linear R^2 correlation coefficient of 0.999 (Supporting Information Figure 2).

RESULTS

Quantitative Fluorescence and Raman Imaging. An analysis of cellular lysates as typical complex proteomic samples were used to establish the working protein and R6G concentrations for the overall quantitative fluorescence and Raman imaging strategy. Sample labeling used either 1A or 1B (Figure 1) (*19*) followed by 2-DGE separation, fluorescence spectral imaging, silver nanoparticle deposition, and Raman spectral imaging (Figure 2). In Figure 3 is shown the 2-DGE analysis of 30 μg soluble lysate sample prepared from HCT116 human colon cancer cells. This sample was labeled using R6G-NHS ester lysine labeling reagent 1A (Figure 1), at a ratio of 6.6 pmol dye per microgram protein to yield on average ∼0.1% labeling efficiency. Throughout this study, lower labeling levels were selected to minimize potential electrophoretic mobility shift effects (*34*). This reaction stoichiometry is reduced relative to typical sample labeling protocols (*35*), which yield approximately 1−2% protein labeling efficiency (*21*).

The absolute dye content in a single protein spot on the 2D gel was established using a water internal standardization method that compares the fluorescence of R6G to the water Raman signal (*20*). The corrected spectra for the R6G fluorescence intensity image is shown in Figure 3B, with sample

spectra from the designated protein spot shown in Figure 3C. The concentration of R6G in this protein spot was determined to be 3.1 nM, averaged over the gel volume with dimensions as drawn in Figure 3B. The detection limit was defined as 3× noise and routinely set at 0.2 nM. The Raman intensity image for this gel region (Figure 3D) accurately represented the fluorescence image (Figure 3B), and the Raman spectrum shown in Figure 3E was obtained from the selected protein spot containing 3.1 nM R6G.

Highlighted in these results is the use of a standard silver stain for acrylamide protein gels to generate a viable SERRS substrate formed *in situ*. Cryo EM imaging has shown that the sizes of brown, yellow, or blue−gray silver nanoparticles obtained in gels using silver deposition are typically 20−100 nm in size; these nanoparticles are within the range expected for surface-enhanced Raman substrates (*36, 37*). These sizes correlate well with data from size-controlled preparations of silver aggregates often used for surface-enhanced Raman (*38, 39*). Raman enhancement factors or efficacy were not analyzed, and no attempts to optimize the nanoparticle preparations (in terms of nanoparticle sizes, geometries, and roughness) were pursued.

GMP Synthetase Isoforms. For purposes of testing the feasibility of isotope edited internal standardization SERRS for protein isoform quantification, recombinant human GMP synthetase (hGMPS) posed a useful model protein. Human GMPS is encoded by a single gene (on the 3q chromosome), and only a single mRNA form has been reported; yet, it has been described in at least two distinct isoforms with different isoelectric points, as isolated from the T-lymphoma A3.01 cell line or produced in a recombinant baculovirus expression system (*40, 41*). A differential phosphopeptide analysis of the human tumor-derived cell line A431 indicated that Thr330 of hGMPS undergoes a phosphorylation event (*42*). Understanding which isoform is linked to a particular hGMPS function is an emerging question, with an example being the elevated expression in tamoxifen-resistant xenograft breast tumor 3366 cell line (*43*). The recombinant protein is purified as multiple species termed here as "isoforms", which resembled those found in endogenous HCT116 cell lysate as shown after 2-DGE separation (Figure 4). By fluorescence densitometry quantification using SyproRuby staining, the hGMPS protein species identified as E1−E4 in Figure 4B (MS/MS data in Supporting Information Table 1) comprised 0.1−0.2% of the total 200 μg protein lysate, or 200−400 ng, in the gel. Four species were also identified in recombinant hGMPS purified from an *E. coli* expression system (labeled R1−R4 in Figure 4C, MS/MS data in Supporting Information Table 2), suggesting that the modification of these putative hGMPS isoforms could originate from a similar chemical or biochemical process in both samples.

Gel-to-Gel Reproducibility of Ratiometric Quantification. An experiment was conducted to assess gel-to-gel reproducibility of the Raman spectral analyses using d_0- and d_4-R6G-labeled recombinant hGMPS at a fixed % d_4-R6G composition of 43%. Three replicate silver stained gels were prepared containing approximately 3 μg of total recombinant protein (or approximately 1 μg per protein species), and six Raman spectra were recorded for the most abundant hGMPS species (Figure 5). These spectra were submitted to Gaussian curve fitting analysis of the signature 611 and 600 cm^{-1} peaks to obtain d_0- and d_4-R6G composition directly; % d_4-R6G composition in each of the three gels (averaged over six spectra) was as follows: 43.3 ± 1.8%, 42.6 ± 0.6%, and 42.9 ± 1.3%. Percent relative standard deviation (RSD%) was used to summarize overall variance for the % d_4-R6G compositions, as described recently by Schröder et al. (*44*). Using single gel measurements (with $n = 6$ spectra), the RSD% for the three individual gels were 4.3%, 1.8%, and 3.1%. The value gained in recording data from three gels versus one gel was assessed by combining all eighteen spectra from the three gels, resulting in an RSD% of 3.0% overall. Therefore, there was no great advantage gained from recording SERRS spectra from multiple gels in this analysis, avoiding various sources of reproducibility error in 2-DGE (*44*). The result highlights the inherent accuracy in the ability of Raman to simultaneously detect isotopomeric dye populations in the same spectra.

Detection Limit of Ratiometric Quantification. To assess the practical detection limit of the ratiometric measurement, recombinant hGMPS samples were prepared in a 10-fold dilution series and developed on 2-DGE. In these samples, 64.2% d_4-R6G composition (or 1.8-fold difference between d_0- and d_4-R6G) was chosen to allow for absolute quantification errors over the range of nM to pM concentrations. The expected concentration of dye in the ~1 ng protein per spot sample was estimated as 75 pM based on 0.1% labeling efficiency, 76 kDa molecular weight, and approximate spot size of 0.5 × 0.5 mm^2. The most abundant protein species were quantified in each of these gels and found to contain % d_4-R6G of 63.9 ± 1.0%, 64.5 ± 1.2%, and 64.3 ± 2.5% for the 1 μg, 100 ng, and 10 ng per spot gels, respectively. Signal to noise ($S/N = 2$), acquisition

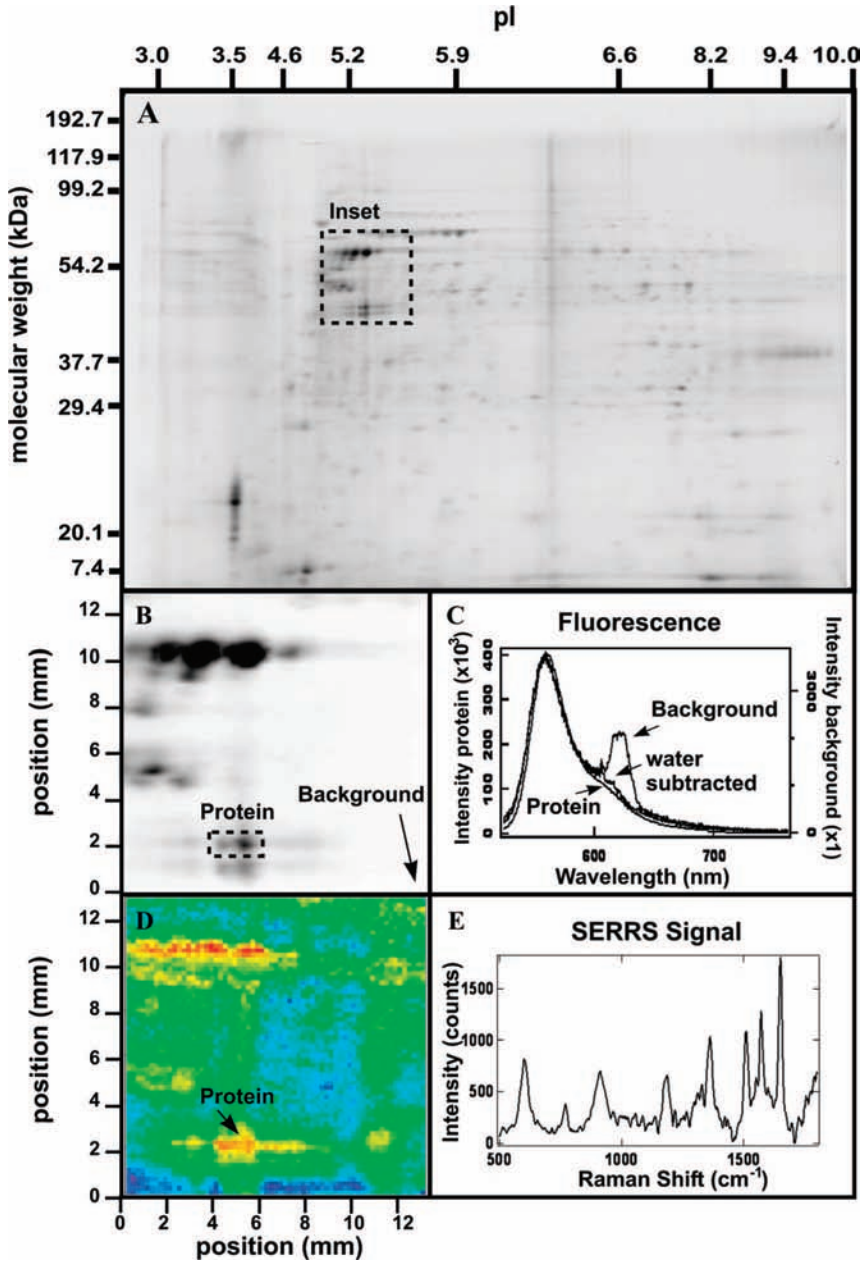

Figure 3. Shown here is a 2-DGE analysis of 30 μg of R6G-labeled lysate. (A) The full-sized fluorescence image was recorded with a Typhoon fluorescence scanner. (B) The 13 × 13 mm^2 inset region was further imaged using our confocal system by fluorescence (200 μm step size). (C) Representative fluorescence spectra are shown for protein (on the × 10^3 scale), background (on the 1× scale), and water-subtracted background (1× scale). (D) The gel was silver stained, then imaged by Raman in the same inset region, color coded for intensity at 1650 cm^{-1} from red (high) to blue (low). (E) A representative background-subtracted SERRS spectrum from the marked protein spot is shown.

time (~30 min), and background became limiting in the 1 ng gel for this simple Gaussian peak fitting method, and only three spectra could be manually fit for this sample. If, however, the peak-shaped model from the 1 μg−10 ng samples was applied to the 1 ng sample spectra, a % d_4-R6G of 64.9 ± 6.1% could be obtained (over $n = 3$ spectra). Thus, the practical protein detection limit was approximately 1 ng per spot for a simple single-point measurement method, comparable to silver stain (0.3−10 ng/spot), Sypro Ruby dye (1−2 ng), and Cyanine dye covalent labeling (0.25−0.95 ng) protein detection limits in gels (*45*, *46*). Using the metric of 3-fold variance in the 75 pM sample, the SERRS detection limit in terms of dye concentration was on the order of 13.5 pM.

Ratiometric Quantification of hGMPS Isoforms in Lysate. To evaluate the ratiometric quantification strategy in typical proteomic samples, an imaging-based internally standardized analysis was designed to quantify small-fold changes in hGMPS isoform distribution with a constant protein background in a complex cell lysate. In this experiment, two pairwise ratiometric analyses were performed with recombinant hGMPS spiked lysates. The tasks were to determine both the accuracy in % d_4-R6G composition for multiple hGMPS species and the composition of endogenous hGMPS in the lysate.

SERRS imaging was used for direct quantification of d_4-R6G composition in mixed lysate samples containing 0%, 0.2%, or 0.4% mass-spiked hGMPS, analyzed as samples A and B. The results reported in Table 1 were based upon single gel analyses for samples A and B (Figure 6), as justified by the gel-to-gel reproducibility experiment. Each pixel in Figure 6 represents a full R6G Raman (SERRS) spectrum. Representative SERRS spectra that compose the image maps of samples A and B are shown in Figure 6, and the complete data set is provided in Supporting Information Figure 3. These spectra (48 × 48 = 2304 per image) were fitted using a partial least-squares analysis

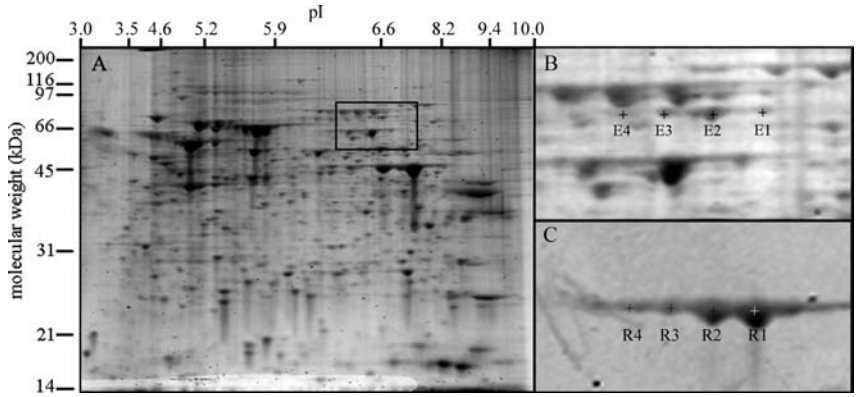

Figure 4. Shown here is a comparison between endogenous and recombinant hGMPS protein species in unlabeled, SyproRuby stained 2-D gels. (A) The full-scale fluorescence image of 200 μg of HCT116 lysate was recorded using a Typhoon scanner. (B) The inset region of panel A was enlarged and contrasted to show putative endogenous species of hGMPS, labeled E1-E4. (C) The 2-DGE image of 1 μg of recombinant hGMPS is shown on the same scale as panel B and contained four distinct species of hGMPS (R1−R4).

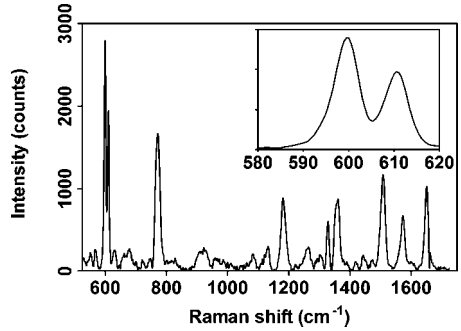

Figure 5. Baseline-corrected SERRS spectrum of d_0/d_4-R6G-labeled recombinant hGMPS in a 2-D gel. The inset spectrum shows an expanded view of the 600 cm^{-1} spectral region containing the well-resolved d_0 (right) and d_4 (left) peaks.

Table 1. Percent d_4-R6G Composition in hGMPS and Background Protein Species in Samples A and B, Determined by Full-Spectral Raman Analysis

protein species	% d_4 (sample A)	% d_4 (sample B)
1	86 ± 4	66 ± 5
2	76 ± 8	60 ± 5
3	70 ± 2	56 ± 9
4	50 ± 9	49 ± 9
b1	46 ± 8	45 ± 3
b2	43 ± 8	52 ± 8
b3	40 ± 13	46 ± 15
b4	46 ± 1	57 ± 5

that had been modeled using a training set of 1000 spectra recorded at controlled % d_4-R6G compositions (described in the Materials and Methods section). The % d_4-R6G compositions in each of the hGMPS and background species (Table 1) were calculated by PLS analysis and averaged over three spectra per protein spot.

As a measure of overall variance for this ratiometric quantification imaging method, the total RSD% were determined separately for samples A and B, using the average and standard deviations of replicate readings for the eight identified protein species reported in Table 1. For both samples A and B, the total RSD% are 16%. Using the high scan rate, low signal-to-noise Raman spectra, the quantification strategy had a total RSD% that was at least comparable with fluorescence-based methods evaluated at similar protein concentrations. For example, the total RSD% from native protein fluorescence detection was reported to be 12−16% (*44*), and data reported in a benchmarking study for the DIGE method had a total RSD% of ∼31% for four standard proteins analyzed with pooled sample internal standardization. By way of comparison, a recent

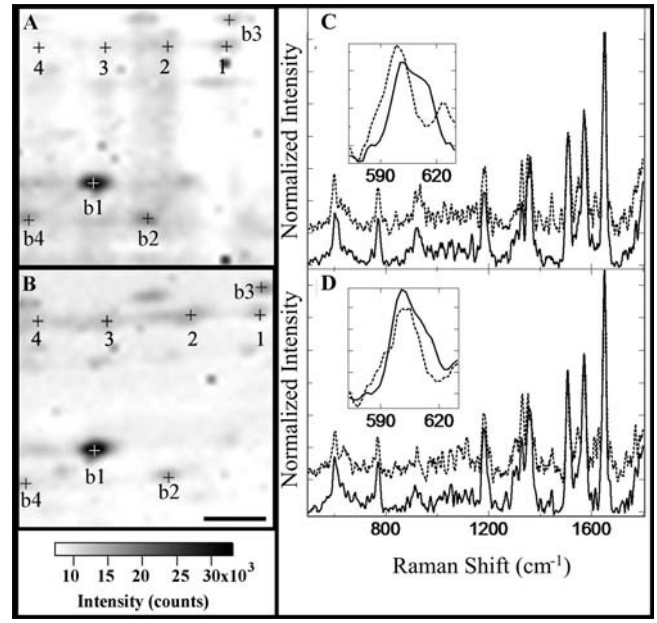

Figure 6. Raman mapping images are shown for samples A and B, in panels A and B respectively. Protein species labeled 1−4 in samples A and B were confirmed to be hGMPS by in gel trypsin digestion and MS/MS peptide sequencing (Supporting Information Table 3). Also shown are the background lysate proteins, labeled b1−b4, selected for % d_4-R6G composition calculations. Scale bar represents 2.5 mm. Representative baseline-corrected SERRS spectra from samples A and B are shown in panels C and D, respectively. Signal from the background protein species b1 (solid trace) is compared with signal from the hGMPS species 1 (dashed trace). The inset shows the signature d_0-R6G (611 cm^{-1}) and d_4-R6G (600 cm^{-1}) peaks, with d_4-R6G signal enrichment in the dashed hGMPS species traces as expected in these spiked samples. The full set of SERRS spectra from hGMPS and background species in samples A and B is provided in Supporting Information Figure 3.

report using the SILAC quantitative MS method, which also employs isotope encoding (*47*), had an overall RSD% of 11% within a narrow 3-fold difference range. The Raman spectra used here were acquired using settings optimized for speed in an imaging application, but which resulted in relatively high noise levels, and are the primary source of variance in these measurements.

hGMPS Isoform Quantification in HCT116 Lysate. The mass composition of endogenous hGMPS could be determined in the four putative isoforms of hGMPS (species 1−4) by defining the recombinant hGMPS sample as the internal standard. Recombinant hGMPS (*R*) was quantified indepen-

dently by fluorescence densitometry analysis of the 2-DGE analysis shown in Figure 4C and with knowledge of the protein concentration. Given the Raman measured % d_4-R6G compositions reported in Table 1, it was possible to solve for the endogenous hGMPS (*E*) values reported in Table 2 using eqs 1 and 2. The % d_4-R6G compositions in samples A and B were determined from independent silver-enhanced Raman experiments; therefore, it is significant that the calculated endogenous protein values were consistent for these two experiments. For the least abundant hGMPS species (species 4), the endogenous amount could not be determined due to the low abundance in the recombinant internal standard. It was apparent that the mass distribution among endogenous isoforms of hGMPS, with the most abundant species E2 (Figure 4B) was pI-shifted to a more acidic form relative to the major recombinant species (R1 in Figure 4C). One interpretation would be that the most basic recombinant hGMPS species (R1) was an unmodified or native parent species, while the remaining putative hGMPS isoforms (2−4) were likely to be modified versions of this protein found in the endogenous sample.

DISCUSSION

The potential for application of isotope encoded internally standardized SERRS detection to quantification of multiple protein isoforms within a complex biological sample background is now apparent. R6G-protein encoding has enabled the absolute quantification of sample in hydrated gels using water-internal standardized fluorescence spectral imaging. The particular combination of chemical features in d_0- and d_4-R6G labeling reagents and in situ silver nanoparticle formation around protein in a gel matrix has enabled highly accurate relative quantification using SERRS detection with an established protein separation workflow. SERRS occurs when a molecular species occupies specific "hot spots" on metal surfaces such as silver, gold, or copper, with curvature features that are smaller than the wavelength of the incident light (*48*). Local electric field enhancement by metal surface plasmons lead to enhanced Raman scattering from adsorbed molecular species, by a factor of 10^6 or more. Furthermore, under electronic resonance (SERRS) conditions, enhancements on the order of 10^{14} can be obtained, thus allowing single molecule detection (*49, 50*). Isotope editing provides for the first time a solution to a recurring problem with variations in SERRS efficiencies (*51, 52*), enabling application of Raman features to quantitative biomolecular detection.

The inherent accuracy of isotope encoded internally standardized SERRS ratiometric quantification was demonstrated in analyses of gel-to-gel reproducibility and practical detection limits for the method. Sample to sample variations in gel efficiency (*44*) are eliminated through the use of internal standardization, as was demonstrated by comparison of error between single and multiple gel analyses. Furthermore, the ability to simultaneously monitor two isotopomeric species of R6G in a single SERRS spectral measurement allows for significant reduction of Poisson noise in the measurement due to variations in SERRS efficiency, therefore expanding the practical detection limit into the low picomolar dye concentration realm. For example, in the 10 ng per spot samples, the d_0 and d_4 peak area results obtained from five replicate measurements were 427 ± 260 and 746 ± 377 counts, respectively. If the variances in the peak areas were uncorrelated (Poisson noise), then it would not be possible to determine the value of the area ratio with an accuracy of better than about $\pm 50\%$. The fact that the experimentally measured standard deviation of the isotopic area ratios obtained from these same samples was $\pm 2.5\%$ indicates that most of the variance in the peak areas is highly correlated. In other words, because the d_0- and d_4-R6G chromophores are virtually chemically identical, the areas of the resulting SERRS peaks vary in unison, in spite of the large batch to batch variations in the SERRS activity of the sample.

On the basis of throughput and protein identification, mass spectrometry is often preferred over optical detection methods for quantitative proteomic analysis. However, it is arguable that the identity of a protein spot on a 2-D gel only needs to be determined once when studying the dynamics of the species in a known system. We have shown that it is possible to accurately determine relative compositions of isotopically labeled protein samples at low nanogram protein levels with the caveat that species identification and 2-D gel position must be proven at higher concentrations, since the SERRS detection limit is effectively 15-fold lower than fluorescence.

In this work, we have demonstrated accurate and precise quantification of three major species of human GMP synthetase through internal standardization. In a single-point determination mode, purified recombinant hGMPS species could be quantified in single gels with a 1−6% error over a 1 μg to 1 ng protein mass range. In an imaging application using automated spectral analysis, an RSD% of 16% could be obtained. Future applications will likely combine imaging and single-point determinations for high-accuracy quantification. This level of detection, accuracy, and precision in protein isoform quantification represents a new benchmark for isoform quantification (*13, 44, 47*) and sets the stage for future applications of isotopic surface-enhanced Raman to quantitative analysis of biomolecules.

CONCLUSION

In this study, we have demonstrated a new application of SERRS detection to the quantification of protein distributions, through the use of isotopically paired R6G lysine labeling reagents for sample encoding. By virtue of the inherent accuracy of Raman-based spectral quantification of isotopic dye populations, this strategy is uniquely positioned to overcome both the challenges of 2-DGE due to the reproducibility as well as variations in SERRS efficiency through ratiometric analyses. Furthermore, there is a strong implication in the matching of the detection capacity of SERRS limit of detection and dynamic range to the scale of protein abundances found in proteomic samples. In particular, an approach to accurately assess the graded variance in individual protein species has been established. This work has shown that the ratiometric comparisons that can be made by using isotopic variants of SERRS-active dyes as internal references results in highly accurate and precise quantification of protein distributions, and justifies the future development of SERRS-based biomolecular quantification using isotope encoded internal standardization.

ACKNOWLEDGMENT

We thank the Davisson and Ben-Amotz groups for critical reading of this manuscript. The authors were funded by NCI 1F32-CA123662 (G.M.K.), GM067195-04 and GM053155-10

Supplementary Table 1. MS/MS identification of hGMPS protein in 2DGE of HCT116 lysate. Putative hGMPS protein spots were selected for in-gel tryptic digestion using a protocol from the UCSF mass spectrometry facility (http://donatello.ucsf.edu/ingel.html), with zip tip treatment and using α-cyano-4-hydroxycinnamic acid matrix for MALDI preparation. MS/MS analysis was performed using a 4800 MALDI TOF/TOF analyzer from Applied Biosystems, and analyzed using ProteinPilot software v. 2.0, searching the Uniprot+Swissprot databases (2007.01.23) with the following settings: trypsin digestion, urea denaturation, iodoacetamide Cys alkylation, species *H. sapiens*, with special factors: phosphorylation emphasis, gel-based ID, and ID focus biological modifications. The search included 15652 proteins, and found only one protein with a score >1.30 (95%): SwissProt# P49915, human GMPS. The number of matched peptides and sequence coverage are listed below. These samples were analyzed through a service provided by the Purdue Proteomics Facility.

Sample	Unused[§]	Total	Peptides	%Coverage
E2□	24.48	24.48	13	28
E3	12.36	12.36	9	19
E4	2.07	2.07	2	3

□ Protein spot names are labeled in Figure 4B. Although E1 was also analyzed, no significant proteins could be identified from this species.

[§]Unused and Total refer to protein scoring used in ProteinPilot software to indicate a summed score for unique peptides that have been unused by other protein hits in the identification, out of the total available.

Supplementary Table 2. MS+MS/MS analysis of recombinant hGMPS species in 2DGE. Samples were selected and digested as described above for MALDI-MS/MS analysis, using an Applied Biosystems MALDI 4700 Protein Analyzer. The 4000 Series Explorer software was used for mass list export into GPS explorer software, searching the NCBInr database (2007.06.18) using the Mascot search engine software (v. 2.1) (www.matrixscience.com). Search settings were: combined MS+MS/MS scoring, species *H. sapiens*, 1 allowed missed cleavage, iodoacetamide modification of Cys, and variable modifications: phospho S,T, Y, Met-ox, Pyro-Glu. The number of matched peptides and sequence coverage are listed for the top hit in all cases: identification of gi|4504035, human GMPS.

Sample	Protein Score[§]	Peptides	%C.I.	Total Ion Score	Best Ion Score	%C.I. best ion
R1□	1,450	40	100	1,013	112	100

Site-Selective Glycosylation of Hemoglobin on Cys β93

Yalong Zhang,[†] Veer S. Bhatt,[‡] Guoyong Sun,[§] Peng G. Wang,[†,‡] and Andre F. Palmer*[,§]

Department of Chemistry, Biophysics Program and Department of Biochemistry, and Department of Chemical and Biomolecular Engineering, The Ohio State University, Columbus, Ohio 43210. Received July 29, 2008; Revised Manuscript Received September 17, 2008

In this work, we describe the synthesis and characterization of a novel glycosylated hemoglobin (Hb) with high oxygen affinity as a potential Hb-based oxygen carrier. Site-selective glycosylation of bovine Hb was achieved by conjugating a lactose derivative to Cys 93 on the β subunit of Hb. LC-MS analysis indicates that the reaction was quantitative, with no unmodified Hb present in the reaction product. The glycosylation site was identified by chymotrypsin digestion of the glycosylated bovine Hb followed with LC-MS/MS and from the X-ray crystal structure of the glycosylated Hb. The chemical conjugation of the lactose derivative at Cys β93 yields an oxygen carrier with a high oxygen affinity (P_{50} of 4.94 mmHg) and low cooperativity coefficient (n) of 1.20. Asymmetric flow field-flow fractionation (AFFFF) coupled with multiangle static light scattering (MASLS) was used to measure the absolute molecular weight of the glycosylated Hb. AFFFF-MASLS analysis indicates that glycosylation of Hb significantly altered the $\alpha_2\beta_2-\alpha\beta$ equilibrium compared to native Hb. Subsequent X-ray analysis of the glycosylated Hb crystal showed that the covalently linked lactose derivative is sandwiched between the β_1 and α_2 (and hence by symmetry the β_2 and α_1) subunits of the tetramer, and the interaction between the saccharide and amino acid residues located at the interface is apparently stabilized by hydrogen bonding interactions. The resultant structural analysis of the glycosylated Hb helps to explain the shift in the $\alpha_2\beta_2-\alpha\beta$ equilibrium in terms of the hydrogen bonding interactions at the $\beta_1\alpha_2/\beta_2\alpha_1$ interface. Taken together, all of these results indicate that it is feasible to site-specifically glycosylate Hb. This work has great potential in developing an oxygen carrier with defined chemistry that can target oxygen delivery to low pO_2 tissues and organs.

INTRODUCTION

Hemorrhagic shock is a well-documented clinical condition in which 50% of the blood volume is lost due to some trauma. The loss of oxygen carrying capacity results in the development of low pO_2 levels in key organs like the brain, liver, and heart. Therefore, it is imperative that resuscitation strategies first target oxygen delivery to these low pO_2 tissues and organs in order to preserve their function, before transporting oxygen to well-oxygenated sites in the body (*1*). Since hemoglobin (Hb) is responsible for oxygen transport and storage in red blood cells (RBC), it is not surprising that much effort has been spent to develop hemoglobin-based oxygen carriers (HBOCs) for treatment of hemorrhagic shock. The initial development of RBC substitutes was driven by the needs of the military (*2*). Early attempts toward developing a RBC substitute using acellular Hb in human recipients met with failure due to hypertension, short intravascular half-life, and nephrotoxicity (*3*). These problems have been attributed in large part to the affinity of Hb for nitric oxide (*4*) and dissociation of the $\alpha_2\beta_2$ tetramer into $\alpha\beta$ dimers that can further unfold to release cytotoxic heme that is eventually filtered through the renal glomeruli (*2, 5*−*7*).

In order to overcome the disadvantages associated with transfusing acellular Hb, several types of HBOCs have been developed over the past 20 years, such as cross-linked Hb (*8, 9*) polymerized Hb (*6, 10*−*15*), surface-conjugated Hb (*16*−*19*), liposome (*20*−*24*), and nanoparticle encapsulated Hb (*25*−*27*), and recombinant Hb (*7, 28, 29*).

In nature, glycoproteins possess a large hydration shield afforded by relatively small oligosaccharides (*30*), which will protect a protein from proteolysis and stabilize the protein by forming hydrogen bonds with amino acid residues on the protein surface. Glycosylation of Hb at Lys or N-terminal amines in the systemic circulation by glucose is a well-characterized non-enzymatic reaction (*31, 32*). Previously, oxidized dextran (*10, 33*) and oxidized raffinose (Hemolink, Hemosol Inc., Toronto, Canada) (*34*−*35*) were used to cross-link and polymerize Hb in order to increase its molecular radius and to prevent its extravasation through blood vessels. However, those early attempts at cross-linking and polymerizing Hb with oxidized saccharides yielded highly heterogeneous products with the resultant chemical modification of key amino acid residues that regulate oxygen affinity and the structural stability of the tetramer. In the case of Hemolink, Boykins et al. (*36*) confirmed that *O*-raffinose cross-linked and polymerized Hb was constrained in a locked T-state conformation that promotes heme instability. In addition, *in vivo* experiments also showed that Hemolink induced microvascular damage and increased the permeability of the microvasculature when compared to other HBOCs (*37*). In light of these results, recent advances in glycochemistry indicate that it is important and necessary to prepare homogeneous glycoproteins with specific glycosylation sites (*38*).

In the present study, the feasibility of site-selective glycosylation of bovine Hb (Figure 1) was investigated by conjugating a reactive lactose derivative to Cys β93. Bovine Hb was chosen as the source of Hb, since it has two cysteine residues per tetramer, each located at the Cys 93 position on the β subunit. Conversely, human Hb has 6 cysteine residues. Cys β93 is located in a conformationally plastic domain, which contains amino acid residues that regulate the allosteric properties of the Hb tetramer (*39*). Previous modification of Cys β93 with maleimide resulted in an increase in oxygen affinity and the

loss of some hydrogen bonds within the $\alpha_1\beta_2/\alpha_2\beta_1$ interface of Hb (*39*−*41*). In this study, the modified lactoside derivative could compensate for the lost hydrogen bonds by forming additional hydrogen bonds with amino acid residues within the $\alpha_1\beta_2/\alpha_2\beta_1$ interface in order to stabilize the tetrameric structure of Hb as well as to increase the molecular radius of Hb, therefore preventing its extravasation through the lumen of blood vessels and subsequent NO scavenging.

EXPERIMENTAL PROCEDURES

Materials. β-D-Lactose, 2-[2-(2-chloroethoxy)ethoxy]ethanol, and 6-maleimidohexanoic acid *N*-hydroxysuccinimide ester were purchased from Sigma-Aldrich (Milwaukee, WI) and used without further purification. HEMOX-solution, additive-A, and antifoaming agent were purchased from TCS Scientific Corp. (New Hope, PA). Bovine RBCs were purchased from QUAD 5 (Ryegate, MT). All other reagents, unless specified, were obtained from commercial sources and used without further purification. Solvents were distilled from the appropriate drying agents before use. Unless stated otherwise, all reactions were carried out at room temperature under a positive pressure of argon or nitrogen and were monitored by TLC on silica gel 60 F254 (0.25 mm, E. Merck, Gibbstown, NJ). Spots were detected under UV light or by anisole anhydride/H_2SO_4/MeOH (5/15/80). Column chromatography was performed on silica gel 60 (230−400 mesh) purchased from EMD Chemicals Inc. (Darmstadt, Germany). The ratio between silica gel and crude product ranged from 20 to 30:1 (w/w). For the characterization of reaction products, ^{1}H NMR spectra were recorded at 500 MHz, and chemical shifts referenced to $CDCl_3$ (7.26, $CDCl_3$). ^{13}C NMR spectra were recorded at 125 MHz, and ^{13}C chemical shifts referenced to $CDCl_3$ (77.00, $CDCl_3$).

Synthesis of *N*-3′,6′-Dioxa-9′-octyl-*O*-(β-D-glucopyranolsyl)-(1→4)-β-D-galactoside-6-maleimidohexanamide (maleimide−lactoside). The method of preparing maleimide−lactoside is shown in Scheme 1. First, the peracetyl-protected lactoside **1** was treated with 2-[2-(2-chloroethoxy)ethoxy]ethanol catalyzed by boron trifluoride and then reacted with sodium azide to yield 1-azido-4,6-dioxa-9-octyl-peracetyl-lactoside **2**. Second, the acetyl groups were removed by treating with sodium methoxide to yield compound **3**. Finally, the azido group of **3** was hydrogenated to an amine and reacted with 6-maleimidohexanoic acid *N*-hydroxysuccinimide ester to yield maleimide−lactoside **4**.

Hb Purification (*42, 43*). Hb was extracted from bovine RBCs suspended in 3.8% sodium citrate solution. RBCs were washed 3 times with 3 volumes of isotonic saline solution (0.9%) at 4 °C. Cells were then lysed with 2 volumes of hypotonic, 15 mOsM phosphate buffer (PB), pH 7.4, on ice for 1 h. Lysed cells were then filtered 3 times through glass wool and a filter paper to remove cell debris. The crude solution of Hb was dialyzed against 20 mM Tris-HCl buffer (pH = 8.2). This buffer was the starting buffer for the chromatographic purification of Hb. Hb purification was performed using an ÄKTA Explorer 100 system controlled by *Unicorn 5.1* software (GE Healthcare, Piscataway, NJ). Dialyzed Hb lysate was loaded onto a XK 26/40 (400 mm in length and 26 mm I.D., GE Healthcare, Piscataway, NJ) column packed with 120 mL Q-Sepharose XL resin (GE Healthcare, Piscataway, NJ) and eluted with a linear salt gradient (0 to 0.15 M NaCl in 5 column volumes). The eluted Hb was collected with a fraction collector (Frac 900, GE healthcare, Piscataway, NJ). The purity of Hb was assessed by SDS-PAGE. Pure Hb fractions were pooled for measurement of Hb concentration and methemoglobin (metHb) level. The concentrations of Hb and metHb in solution were determined using an adaptation of the cyanomethemoglobin (cyanometHb) method (*20, 44*). Hb solution was placed in a 1.5 mL cuvette and diluted with buffer (20 mM PB, pH 7.2) with a total volume of 1.0 mL (dilution factor: D_1) in order to yield an absorbance less than 1 at 630 nm (oxyHb + deoxyHb + metHb). Potassium cyanide (KCN) solution (50 μL, 10% KCN in 50 mM PB, pH 7.6) was added to the solution to convert metHb into cya-

nometHb, and the absorbance was measured at 630 nm to yield L_2 (since cyanometHb does not absorb at 630 nm), L_2 refers to the absorbance of oxyHb + deoxyHb. Thus, the concentration of metHb can be obtained from this equation: [metHb] = $D_1(L_1 - L_2)$/3.7 mM. To measure the concentration of Hb, potassium ferricyanide ($K_3Fe(CN)_6$) (50 μL, 20% $K_3Fe(CN)_6$ in 50 mM PB, pH 7.6) was mixed with diluted Hb solution (dilution factor: D_2), which converts oxyHb and deoxyHb into metHb. The solution was incubated for 5 min, and then KCN (50 μL, 10% KCN in 50 mM PB, pH 7.6) was added to the mixture to convert metHb to cyanometHb. The absorbance was measured at 540 nm (L_3). Thus, [Hb] = D_2L_3/11 mM.

Site-Selective Glycosylation of Hb. To a solution of Hb (60 mg, 9.34×10^{-4} mmol) in Tris-HCl buffer (20 mM, pH 8.2, 2.0 mL) was added maleimide−lactoside **4** (4.4 mg, 6.56×10^{-3} mmol) which was stirred at r.t. for 24 h. Sodium cyanoborohydride (12 mg, 9.34×10^{-2} mmol) was added to the reaction mixture, and the solution was stirred for another 24 h. The modified Hb was transferred to a Millipore centrifugal filter device (10 000 MW cutoff) and washed 4 times with Tris-HCl buffer (20 mM, pH 8.2, 2.0 mL) in a centrifuge at 5000 rpm to remove unreacted maleimide−lactoside **4** and sodium cyanoborohydride.

Analysis of Glycosylated Hb by LC-MS. LC-MS analysis of purified Hb and glycosylated Hb was performed on a Waters Alliance 2690 high-performance liquid chromatography (HPLC) system (Waters, Milford, MA) connected in series to a Waters LCT (Waters, Milford, MA) mass detector. Samples were analyzed using a Vydac C18 column (5 μm particle size, 1.0 × 250 mm) at a flow rate of 50 μL/min and injection volume of 10 μL. The mobile phase consisted of the following: phase A, 0.1% trifluoroacetic acid, and phase B, acetonitrile/0.1% trifluoroacetic acid. The percentage of phase B was increased according to a linear gradient from 0% to 65% in 45 min and then increased from 65% to 100% in 15 min. The amino acid sequence and molecular weight of bovine Hb was obtained from ProteinProspector at UCSF (http://prospector.ucsf.edu/).

Chymotrypsin Digestion of the β Chain of Glycosylated Hb. The β chain of glycosylated bovine Hb was purified via a Shimadzu HPLC LC-20AT (Columbia, MD) equipped with a Supelco bio wide pore C18 column (5 μm in particle size, 15 × 150 mm, and 300 Å in pore size, Sigma-Aldrich, Milwaukee, WI). The mobile phase and gradient were the same as those utilized in the LC-MS analysis. Twenty microliters of glycosylated bovine Hb (15 mg/mL) was injected into the RP-HPLC column, and the second peak was collected (22.67 min). The molecular weight of the collected fraction was confirmed by LC-MS 2010A (Shimadzu, Columbia, MD). The lyophilized protein was digested using a protocol similar to the reference (*45*) at the Campus Chemical Instrument Center (CCIC) at The Ohio State University by Dr. Liwen Zhang. Proteins were desalted using manual syringe protein traps from Michrom BioResources (Auburn, CA) and resuspended in 10 μL of water. Five microliteres of DTT (5 mg/mL) in 100 mM ammonium bicarbonate was incubated with the sample at 50 °C for 15 min to reduce all cysteine residues. Five microliters of iodoacetamide (15 mg/mL) in 100 mM ammonium bicarbonate was then added and incubated with the mixture in the dark for 15 min to alkylate the cysteine residues. Sequencing grade chymotrypsin from Roche was prepared as 25 ng/μL in 50 mM ammonium bicarbonate. The final buffer conditions for digestion were 25 mM ammonium bicarbonate and 5% acetonitrile. The digestion was carried out at 37 °C overnight and terminated by acidification. The digest was concentrated in a speed vac to ~30 μL for subsequent LC-MS/MS analysis.

LC-MS/MS Analysis of the β Chain of Glycosylated Hb. Capillary−liquid chromatography−nanospray tandem mass spectrometry (LC-MS/MS) was performed on a Thermo Finnigan LTQ mass spectrometer equipped with a nanospray source operated in positive ion mode at CCIC by Dr. Liwen Zhang. The LC system was an UltiMate Plus system from LC-Packings (Sunnyvale, CA) with a Famos autosampler and a Switchos column switcher. Five microliters of each sample was first injected into the trapping column (LC-Packings), and washed with 50 mM acetic acid. The injector port was switched to inject, and the peptides were eluted off the trap onto a 5 cm, 75 μm (inner diameter) ProteoPep II C18 reverse-phase column (New Objective, Inc. Woburn, MA) packed directly in the nanospray tip. Solvent A was composed of 50 mM acetic acid in water, and solvent B was composed of acetonitrile. Peptides were eluted directly off the column into the LTQ system at a flow rate of 300 nL/min. The gradient was initiated and maintained at 2% B for the first 3 min, then B was increased to 50% in 27 min, and further increased to 80% in 15 min. B was kept at 80% for another 5 min, then returned to 2% in 0.1 min. The total run time was ~65 min.

The MS/MS was acquired according to the standard conditions established at the CCIC. Briefly, a nanospray source operating at a spray voltage of 3 KV and a capillary temperature of 200 °C was used. The scan sequence of the mass spectrometer was based on the TopTen method; briefly, the analysis was programmed for a full scan to be recorded between 350 and 2000 Da, and a MS/MS scan was used to generate product ion spectra to determine the amino acid sequence in consecutive instrument scans of the ten most abundant peaks in the spectrum. The CID fragmentation energy was set to 35%. Dynamic exclusion was enabled with a repeat count of 30 s, exclusion duration of 350 s, and a low mass width of 0.5 and high mass width of 1.5 Da. Sequence information from the MS/MS data was processed using the *Mascot 2.0* active Perl script with standard data processing parameters. The data was later searched by *Mascot 2.0* (Matrix Science, Boston, MA) for protein identification and MassMatrix for the identification of cysteine glycosylation (*46*). Methionine oxidation and carbamidomethylation of cysteines were also considered as possible modifications.

Crystallization of Glycosylated Hb. Purified glycosylated Hb was used for all crystallization experiments. The protein was concentrated to 30 mg/mL in Tris-HCl Buffer (20 mM, pH 7.4), and a microbatch experiment was set up (*47*) under mineral oil (Sigma-Aldrich) at 25 °C. To find initial crystallization hits, sample drops were set up against commercial (Hampton Research, CA) as well as homemade screens in a ratio of 1:2. Crystalline forms could be observed in several different precipitants in the pH range 7.5−8.5. These conditions were optimized further by varying the concentration and pH of the corresponding crystallization reagent for each hit. Eventually, crystals grown in reagent droplets containing 25% w/v PEG MME 2000, 0.2 M trimethylamine *N*-oxide dehydrate, and 0.1 M Tris pH 8.25 were used to collect full data sets. These crystals grew as clustered thin plates with the longest dimension measuring 100 μm. They were flash-frozen after cryoprotection using 38% PEG MME 2000 and stored in liquid nitrogen until further use.

Data Collection and Processing. The X-ray intensity data to 3.5 Å resolution was collected at −160 °C using a R-AXIS IV++ imaging plate area detector and Cu K radiation generated from a rotating-anode X-ray generator (Rigaku-MSC, TX) operating at 46 kV and 90 mA. The temperature was maintained during data collection using an X-STREAM cryogenic device (Rigaku-MSC, TX). Although crystals diffracted to 3.3 Å, the completeness beyond 3.5 Å was lower than 20%. Therefore, the final data set was collected to 3.5 Å resolution. The data

were processed using the *CrystalClear* software, which is based on the d*TREK package (*48*). The crystals belong to the orthorhombic space group $P2_12_12_1$ with one molecule in the asymmetric unit. The unit-cell parameters are $a = 62.6$, $b = 74.0$, and $c = 129.8$ Å. Solvent analysis suggested only one molecule to be present in the asymmetric unit. Assuming that one protein molecule in the asymmetric unit has a molecular weight of 64 kDa, V_M was calculated to be 2.35 Å^3 Da^{-1}. The details of the crystallographic data are summarized in Table 1 in Supporting Information.

Structure Determination and Refinement. The structure of bovine Hb is already well-known (*46*). However, the protein can exist in different quaternary states depending on whether it is liganded (R-state) or not (T-state). Furthermore, several intermediate quaternary forms have been found to exist and are apparently governed by pH (*49*). Thus, structure determination could be pursued by molecular replacement (*49*, *50*) only when the correct quaternary model was provided. In doing so, three starting models of carbonmonoxy-bound Hb (*48*) with pdb 1g0a, 1g08, and 1g09 were evaluated. 1g0a clearly gave the best solution among all the models (*R*-factor, 37.0%; and correlation coefficient, 70.5%). Crystals of model (1g0a) were also grown at a pH (8.5) similar to that of our sample protein (8.25) further corroborating its validity as the correct model.

The model obtained from molecular replacement was refined using the program *REFMAC* (*51*). The initial steps of manual model building with the program coot (*52*) using $|2F_o - F_c|$ and $|F_o - F_c|$ Fourier maps yielded R and R_{free} factors of 0.322 and 0.357, respectively. Densities of the lactose and its succinimide linker were clearly evident (Figure 5) in the vicinity of Cys93 of the β subunit of the protein. Densities for all four bound heme groups and Fe^{3+} were clearly observed at this stage. The model thus obtained including the sugar and cofactors was subjected to several cycles of refinement alternating with several rounds of manual model building. Although the positions of water molecules were not sought at this resolution, there were good densities in $|2F_o - F_c|$ and $|F_o - F_c|$ for 8 water molecules, which seemed to hydrogen bond with various protein atoms. These were therefore included in the further refinement, to which they responded well. The R and R_{free} factors finally converged to 0.268 and 0.332, respectively. The refinement statistics are given in Table 2 (available in Supporting Information) (*53*, *54*). The program PROCHECK was used to validate the quality of the final structure (*54*). 91.1% of the residues were found in the most favored regions of the Ramachandran plot (*55*) and the remaining residues were in the additionally allowed regions.

Quality of the Model. The final coordinate set consists of 4582 non-hydrogen atoms from a total of 574 amino acid residues, one sugar-moiety covalently bound to Cys93 (on the β_1 subunit) via a succinimide linkage, four heme groups each with Fe^{3+} coordinated in the center, and two water molecules. The electron density map of the second sugar molecule was not as discernible, given the highly flexible nature of the linker. Thus, only one sugar molecule was incorporated into the final coordinate set. The protein structure exhibited a geometry close to ideal values, with root-mean-square (rms) deviations of 0.006 Å and 1.01 Å from standard values of bond lengths and bond angles, respectively. The overall mean B factor was found to be 91.2 Å^2. The high value of the B factors suggests that the quality of glycosylated Hb crystals is not good. Despite this, the electron density was very well defined for almost all of the main chain of the protein, all the heme groups, and even one of the covalently bound lactoses.

Oxygen Equilibria of Glycosylated Hb. Oxygen equilibrium curves of native Hb/glycosylated Hb were measured on a Hemox analyzer (TCS Scientific, New Hope, PA). This instrument simultaneously measures the Hb saturation via dual-wavelength spectrophotometry, while measuring the dissolved oxygen concentration with a Clark oxygen electrode. The temperature was maintained at 37 °C for all measurements. Samples were prepared by thoroughly mixing 500 μL of native Hb or glycoslylated Hb with 5 mL of the Hemox buffer (pH 7.4, TCS Instruments, Southampton, PA), 20 μL of Additive-A, 10 μL Additive-B, and 10 μL of antifoaming agent. The sample was saturated with compressed air at a pO_2 of 145 ± 2 mmHg. Then, the gas stream was switched to pure N_2 to deoxygenate the sample. The absorbance of oxy- and deoxy-Hb in solution was recorded as a function of pO_2 via dual-wavelength spectroscopy. Oxygen equilibrium curves were fit to a four-parameter (A_0, A_∞, P_{50}, n) Hill model (eq 1). In this model, the P_{50} represents the pO_2 at which Hb is half-saturated with O_2, and n is the Hill coefficient, while A_0 and A_∞ represent the absorbance at 0 mmHg and full saturation, respectively.

$$Y = \frac{\mathrm{Abs} - A_0}{A_\infty - A_0} = \frac{pO_2^n}{pO_2^n + P_{50}^n} \tag{1}$$

Molecular Weight Distribution Analysis of Glycosylated Hb. An asymmetric flow field-flow fractionator (AFFFF) (Wyatt Technology Corp., Santa Barbara, CA) coupled in series with a multiangle static light-scattering (MASLS) photometer (Wyatt Technology Corp.) and a differential interferometric refractometer (DIR) (Wyatt Technology Corp) was used to measure the absolute molecular weight distribution of native Hb and glycosylated Hb. During a typical experiment, the sample is injected into the AFFFF channel, where it is separated. The resultant eluent is then sent through the flow cell of the MASLS photometer, which continuously measures the macromolecule's Raleigh ratio (scattered light intensity) at 16 angles. The eluent is then sent through the flow cell of the DIR, which measures the macromolecule's concentration. Using a formulation of the angular distribution of scattered light derived by Zimm, it is possible to extract the molecular weight of each eluting monodisperse slice of the fraction (*56*). Hence, we can measure the absolute molecular weight of native and glycosylated Hb to evaluate whether glycosylation still favors the tetrameric structure of native Hb. All measurements were conducted at 25 °C. In preparation for AFFFF-MASLS-DIR experiments, all glassware was carefully cleaned, and all solutions were thoroughly filtered through 0.2 μm filters.

AFFFF-MASLS-DIR measures the weight average molecular weight (M_w) of native and glycosylated Hb in solution. M_w is defined as

$$M_w = \frac{\sum_i (c_i M_i)}{\sum_i c_i} \tag{2}$$

where c_i is the mass concentration of component i in solution and M_i is the molecular weight of component i in solution. In solution, the Hb tetramer will exist in equilibrium with $\alpha\beta$ dimers. Therefore, if C_T is the total mass concentration of Hb in the tetrameric and dimeric forms, then we can write expressions for the mass concentration of tetramer ($C_{\alpha_2\beta_2}$) and dimer ($C_{\alpha\beta}$) in solution if $x_{\alpha\beta}$ represents the mass fraction of $\alpha\beta$ dimers in solution.

$$C_{\alpha\beta} = C_T x_{\alpha\beta} \tag{3}$$

$$C_{\alpha_2\beta_2} = C_T(1 - x_{\alpha\beta}) \tag{4}$$

Substituting eqs 3 and 4 into eq 2 yields an expression for $x_{\alpha\beta}$ (eq 5).

$$x_{\alpha\beta} = \frac{M_w - M_{\alpha_2\beta_2}}{M_{\alpha\beta} - M_{\alpha_2\beta_2}} \tag{5}$$

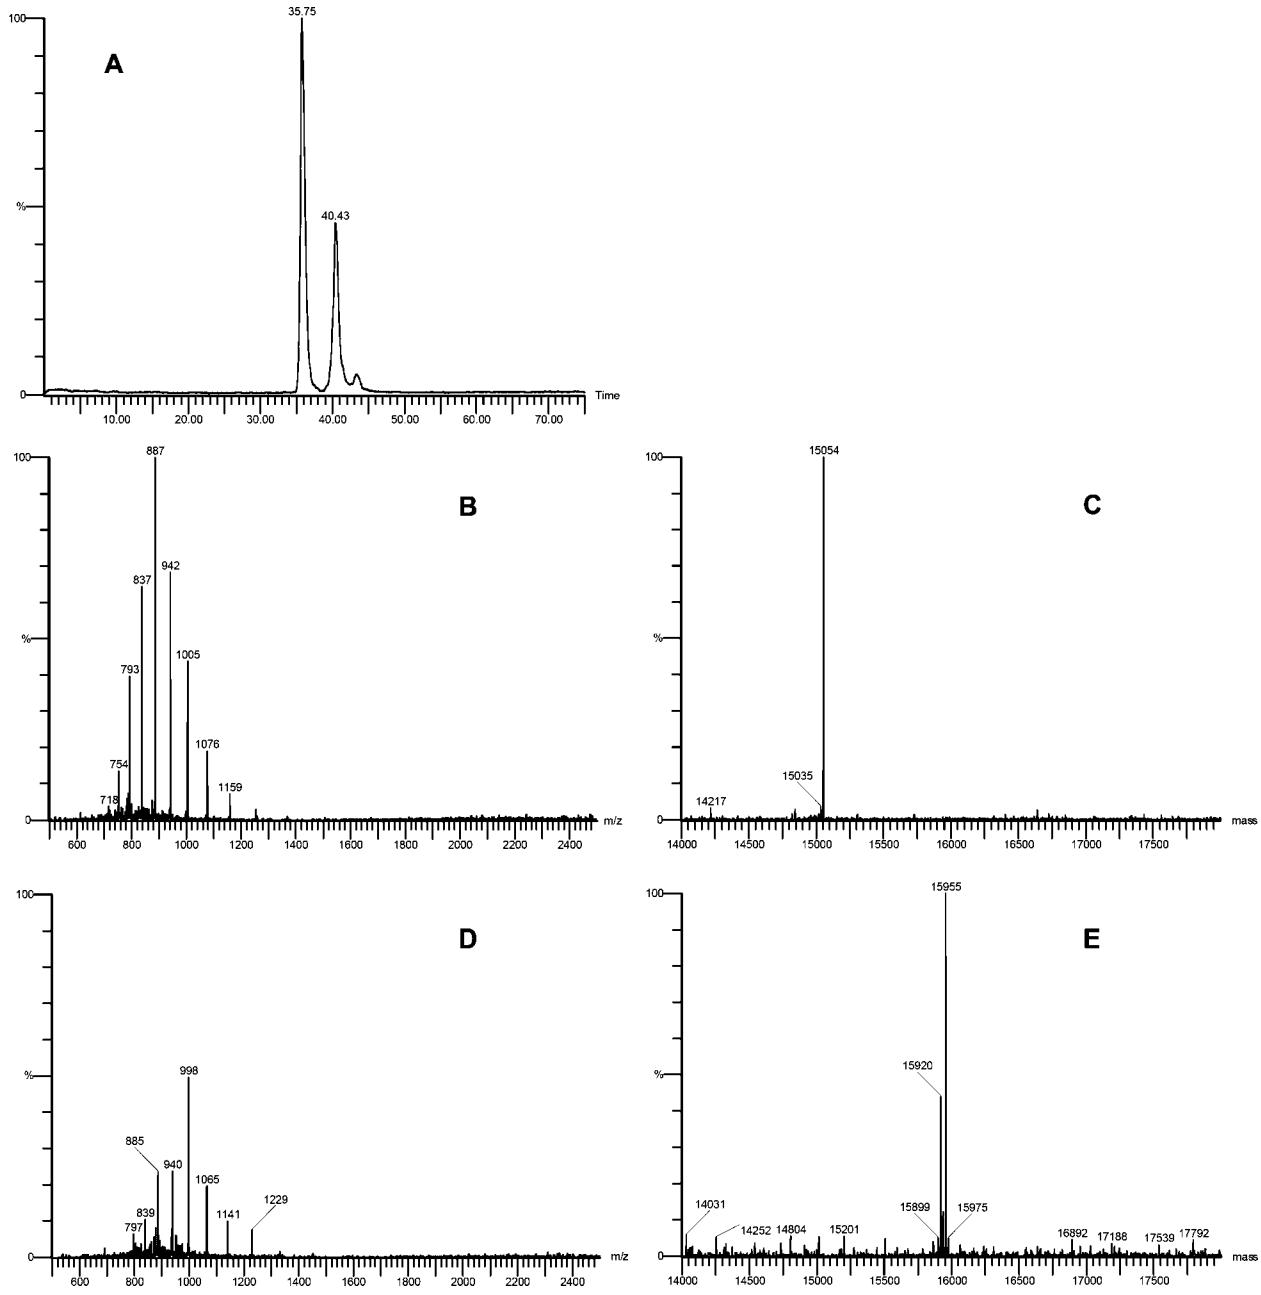

Figure 2. Analysis of bovine Hb by LC-MS. **A** represents the RP-HPLC chromatogram of bovine Hb. **B** represents the ESI-TOF mass spectra of the peak eluting at 35.75 min. **C** represents the deconvoluted molecular ion of the peak eluting at 35.75 min. **D** represents the ESI-TOF mass spectra of the peak eluting at 40.43 min. **E** represents the deconvoluted molecular ion of the peak eluting at 40.43 min.

Hence, substituting M_w (measured with AFFFF-MASLS-DIR), $M_{\alpha_2\beta_2}$(theoretical mass of tetrameric Hb), and $M_{\alpha\beta}$(theoretical mass of dimeric Hb) into eq 5 allows us to calculate $x_{\alpha\beta}$ and thus the mass fraction of tetrameric Hb ($x_{\alpha_2\beta_2} = 1 - x_{\alpha\beta}$).

RESULTS AND DISCUSSION

Preparation of Glycosylated Bovine Hb. Bovine Hb is a tetramer, which consists of two identical α chains and two identical β chains. The amino acid sequence of bovine Hb shows that only one cysteine, Cys-93, is located on the β chain. The molecular weight of the α chain and β chain are 15 053 and 15 955 Da, respectively. Since maleimide−lactoside **4** (M_w = 666 Da) can selectively react with thiol groups on cysteine residues, the reactive disaccharides can be selectively conjugated to Cys-93 on the β chain. As a result, the molecular weight of the β chain increases to 16 621 Da. In order to verify the glycosylation of bovine Hb by maleimide−lactoside **4**, the mass spectra of native bovine Hb and glycosylated Hb was measured by LC-MS (Figures 2 and 3, respectively).

In Figure 2, only two peaks were present in the RP-HPLC chromatogram (graph A). The ESI mass spectrum of the first peak (graph B) was deconvoluted to yield the mass of the molecular ion, 15 054 Da (graph C), which indicates that the first peak was due to the α chain of bovine Hb. The ESI mass spectrum of the second peak (graph D) was deconvoluted to yield the mass of the molecular ion, 15 955 Da (graph E), which indicates that the second peak was due to the β chain of bovine Hb. Comparing native bovine Hb (Figure 2) and glycosylated Hb (Figure 3), there was no significant difference in the retention time for both peaks in the LC chromatograms. Since it is the polarity of the molecule that determines the retention time in reverse-phase chromatography, this result indicates that the polarity of glycosylated Hb was not changed. The molecular

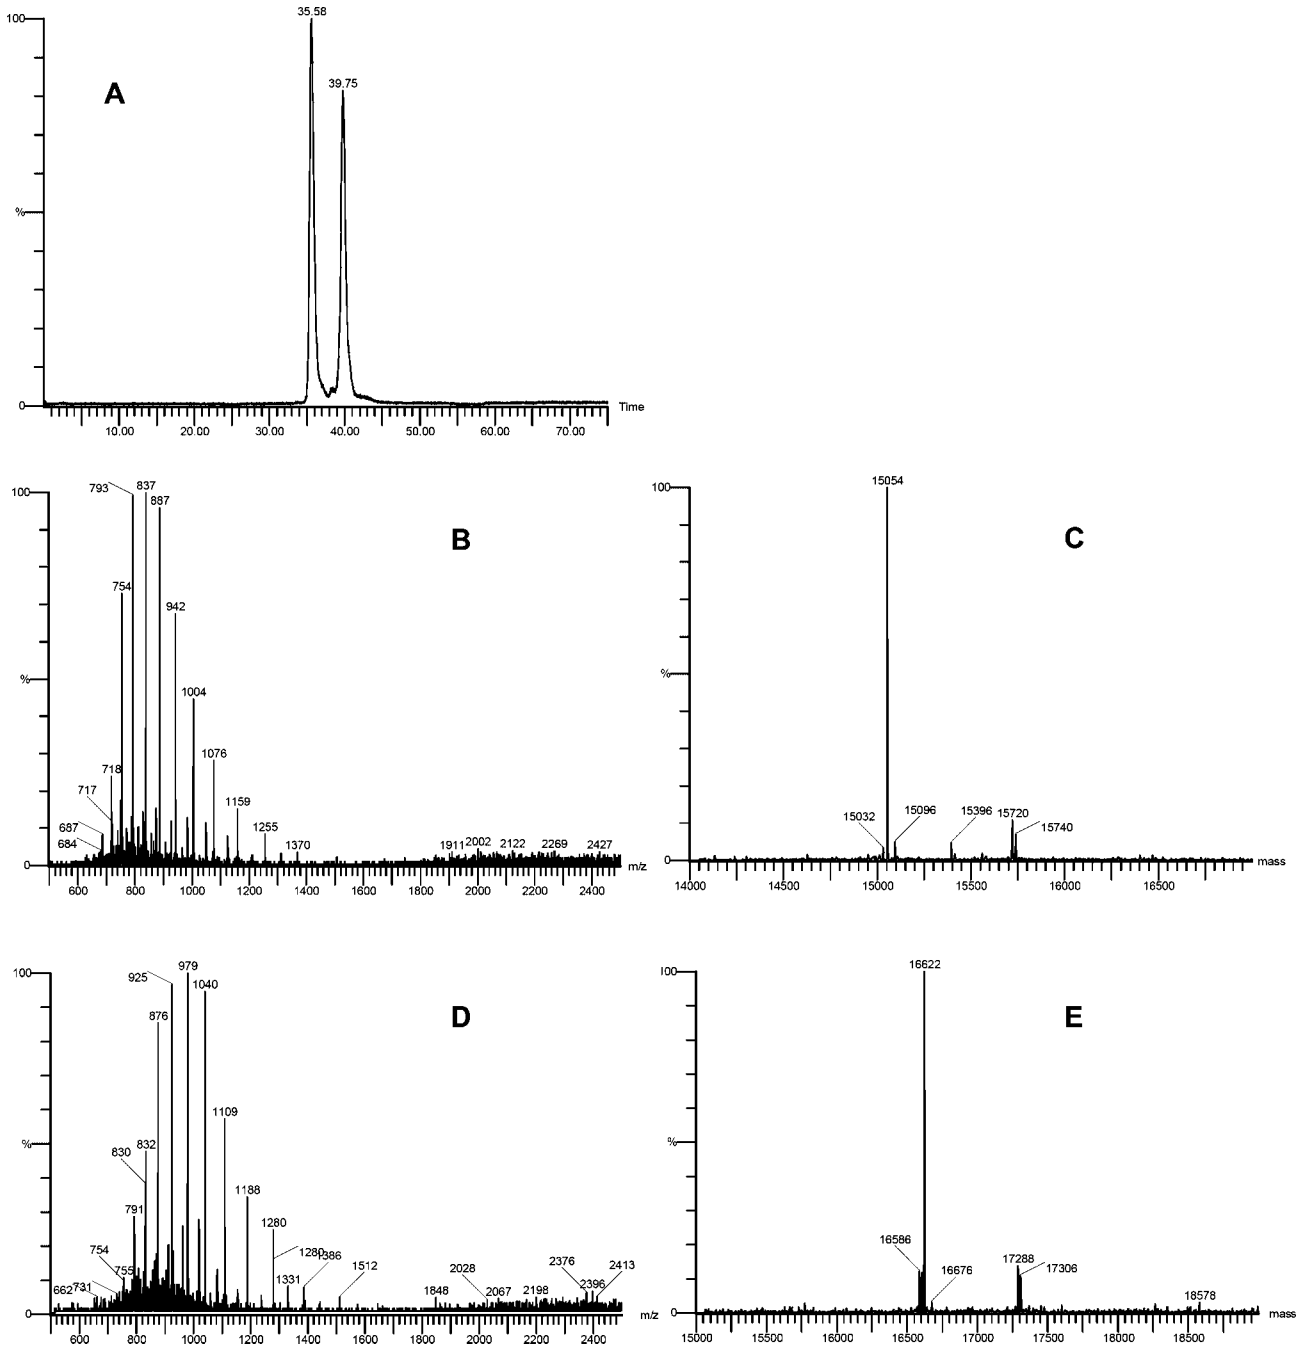

Figure 3. Analysis of glycosylated bovine Hb by LC-MS. **A** represents the RP-HPLC chromatogram of glycosylated bovine Hb. **B** represents the ESI-TOF mass spectrum of the peak eluting at 35.58 min. **C** represents the deconvoluted molecular ion of the peak eluting at 35.58 min. **D** represents the ESI-TOF mass spectrum of the peak eluting at 39.75 min. **E** represents the deconvoluted molecular ion of the peak eluting at 39.75 min.

weight of the α chain of the glycosylated Hb was 15 054 Da (Figure 3C), which was calculated by deconvolution of the ESI mass spectrum (Figure 3B). This result indicates that no lactoside derivative was conjugated to the α chain. However, the ESI mass spectrum of the second peak of Figure 3 (graph D) when deconvoluted (graph E) showed that the molecular weight of the β chain of glycosylated Hb increased to 16 622 Da. Therefore, the molecular weight difference between the β chain of natural Hb and glycosylated Hb is 667 Da, which is consistent with the molecular weight of maleimide−lactoside **4** (M_w = 666.3 Da). Therefore, LC-MS analysis of glycosylated Hb indicates that maleimide−lactoside is conjugated only to the β chain of Hb. Furthermore, the absence of a mass peak at 15 955 Da in graph E implies the absence of any unmodified β chains. This result shows that the conjugation reaction was quantitative and required no separation of unreacted protein products.

Determination of the Glycosylation Site on Bovine Hb. Tandem mass spectrometry was performed on the peptide fragments derived from the β chain of glycosylated bovine Hb digested by chymotrypsin, which will cleave the protein at Phe, Tyr, and Trp (*57*). The resulting data permit us to identify the conjugated latoside derivative, the chemotryptic peptides (AALSELHC*DKLHVDPENF) ($T_{\beta 85-102}$), and the glycosylation site in Figure 4 (The proteolytic MS-MS data are available in the Supporting Information). The calculated molecular weight for the glycosylated $T_{\beta 85-102}$ was 2704.3 Da. Peaks at 1271.56 (2+) and 848.08 (3+) were observed, which translate into

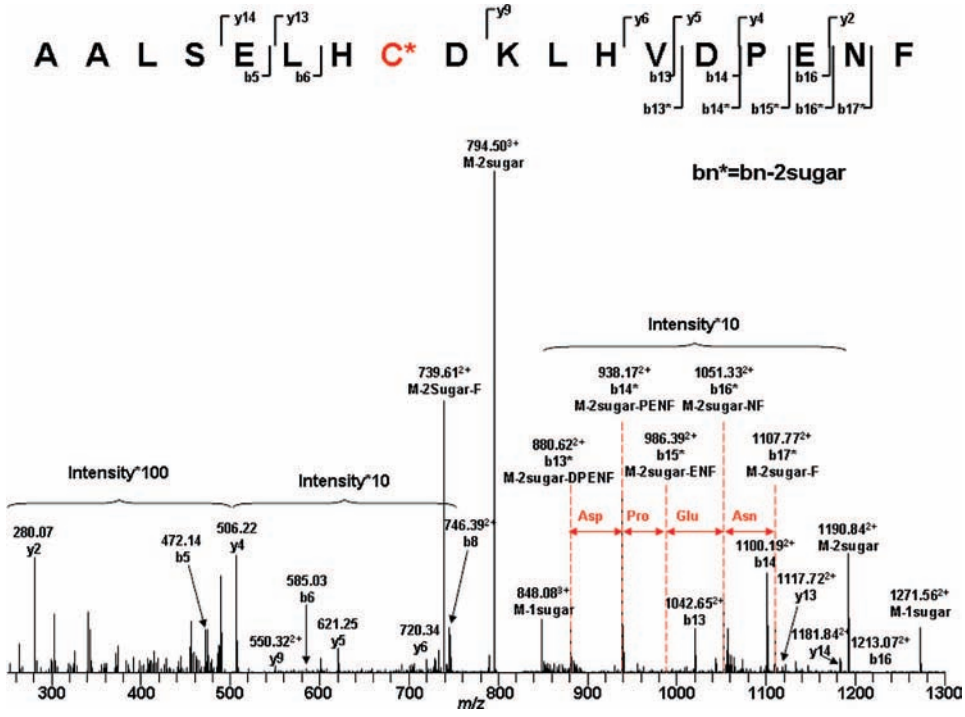

Figure 4. ESI-MS/MS spectra of the glycosylated β-globin chymotryptic peptides 85−102. *Represents the fragment containing the lactoside derivative.

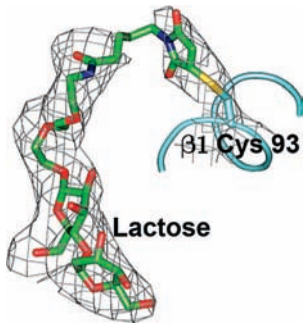

Figure 5. Succinimide linked lactose sandwiched between the β_1 and α_2 subunits of bovine Hb.

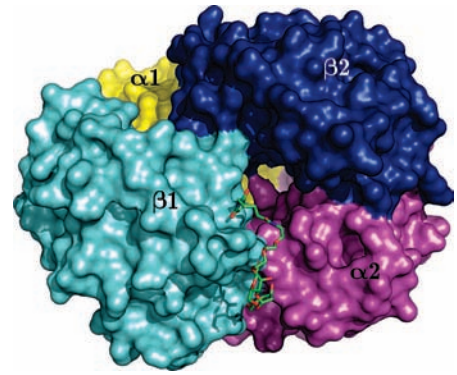

Figure 6. Final electron density map ($2F_o - F_c$) at 0.7σ showing β_1-Cys 93 covalently bound to the succinimide linked lactose.

molecular weights of 2542.12 and 2542.24 Da, respectively. The difference between the calculated molecular weight and the observed data was 162, which corresponds to the loss of one hexose. Peaks at 1190.84 (2+) and 794.50 (3+) were also observed, which correspond to a molecular weight 324 Da less than the calculated data (two hexoses lost). These observations confirm the conjugation of the lactoside derivative (a disaccharide) on this peptide fragment. Second, the peptide sequence were confirmed by observation of the ion series from b13 to b17, showing the loss of the DPENF sequence from the peptide fragment. Finally, the observation of y13 (1117.72^{2+}), y9 (550.32^{2+}), and b6 (585.03) indicate that the modified amino acid was located on the three peptide sequence HCD.

X-ray Structure of Glycosylated Hb. The complete amino acid sequence of bovine Hb shows that both α subunits consist of 141 and both β subunits consist of 145 amino acid residues. A sequence comparison with human Hb performed using CLUSTALW (*58*) shows 88% sequence identity in the α and 84% sequence identity in the β subunits. Thus, it is apparent that bovine Hb can serve as a good functional and structural mimic of human Hb.

It was found that the homogeneous lactoside glycosylated Hb can be crystallized and the crystal was analyzed to verify the site of modification and to access any structural changes associated with the glycosylation reaction. The crystal structure could provide definitive evidence that the Hb is glycosylated (Figures 5 and 6). The electron density of one succinimide-linked lactose could be found with slight discontinuity close to Cys β93 at 0.7σ cutoff in these maps. This result confirms the covalent glycosylation of the lactoside derivative at Cys β93. Since a significant deviation from native quaternary structure could strongly indicate a loss in function, this possibility had to be investigated. It was found that the structure of glycosylated bovine Hb was very similar to native bovine Hb (Figure 7). The overall rms deviation between the two structures was found to be as low as 0.40 Å. The overall quaternary fold is essentially identical to the native protein (pdb 1g0a) in most parts of the superimposition as seen in Figure 7. The only parts where there are discernible albeit minor differences in the fold are the two surface loops and the two glycosylation sites (red) compared with that of native Hb (blue). Since the Cys β93 residue forming the glycosylation site is part of a helix, this imposes severe geometrical constraints on it and, thus, probably prevents it from distorting the overall tertiary fold. The disturbance in the tertiary structure by chemical modification results in the breakage of the β94-β146 and β146-α40 hydrogen bonds (*39*−*41*). This loss

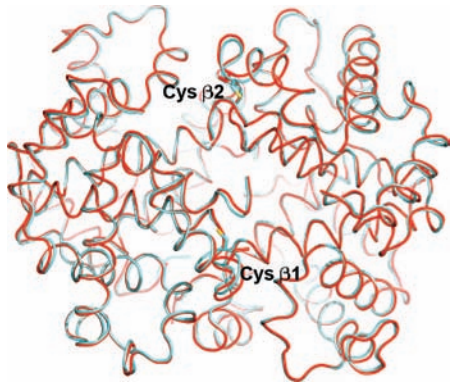

Figure 7. Superimposition of glycosylated bovine Hb (red) and native bovine Hb (blue).

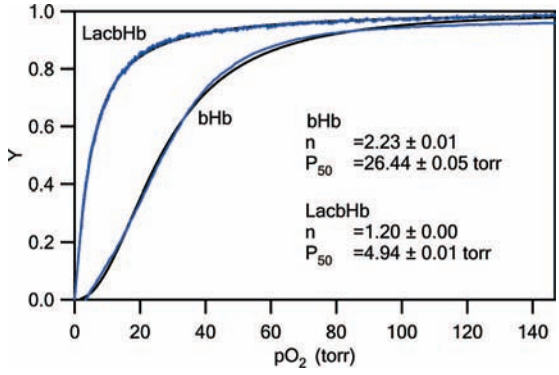

Figure 8. Oxygen dissociation curves of bovine Hb and glycosylated bovine Hb.

of hydrogen bonds will help to destabilize the T-state (*40*) and increase the oxygen binding affinity as well as decrease the cooperativity.

Oxygen Equilibria of Glycosylated Hb. The oxygen dissociation curves are shown in Figure 8 for native and glycosylated Hb. For native Hb, the P_{50} is 26.44 torr, while for glycosylated Hb, it is only 4.94 Torr. The P_{50} is an indicator of oxygen affinity and refers to the partial pressure of oxygen at which half of the HBOC is saturated with oxygen. The low P_{50} of the glycosylated Hb indicates that it has a higher affinity for oxygen versus native Hb. Furthermore, it was found that the cooperativity coefficient of glycosylated Hb is 1.2, which is almost half compared with that of native Hb (2.23). The cooperativity of hemoglobin is associated with the allosteric transition from T-state (tense) to R-State (relaxed) upon oxygenation (*39*). One reason for the decrease in cooperativity can be explained by the disturbance of the tertiary structure of Hb by maleimide modification of Cys β93. Another reason may be structural changes imposed by the glycosylation reaction. On the basis of the crystal structure (Figure 6), it was found that the lactose derivative is located within the $\alpha_1\beta_2/\alpha_2\beta_1$ interface. As a result, the additional hydrogen bonds between the disaccharide and various amino acid residues within the interface will hinder the transition from T-state to R-state and thus leads to a decrease in cooperativity. On the other hand, the additional hydrogen bonding interactions between the disaccharide and various amino acid residues at the interface could stabilize the overall tetrameric structure of Hb. This would be a novel feature of the glycosylated Hb and indicates that it should be more stable (not dissociate into $\alpha\beta$ dimers) in the bloodstream versus native Hb when transfused into patients. In addition, the high oxygen affinity of the glycosylated Hb indicates that it can be used to treat hemorrhagic shock by

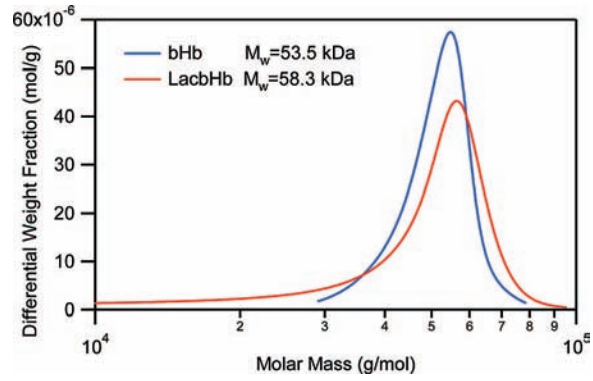

Figure 9. Differential molar mass distribution of bovine Hb (bHb, blue) and lactoside derivative conjugated to bovine Hb (LacbHb, red).

delivering oxygen to regions of the body with low oxygen levels instead of systemically.

AFFFF-MASLS-DIR of Glycosylated Hb. In order to prove our hypothesis that glycosylation of Hb will stabilize the tetrameric structure of Hb, an asymmetric flow field-flow fractionator (AFFFF) coupled in series with a multiangle static light-scattering (MASLS) photometer was used to measure the absolute molecular weight distribution of native Hb and glycosylated Hb. In aqueous solution, the Hb tetramer ($\alpha_2\beta_2$) exists in equilibrium with $\alpha\beta$ dimers. Because of this equilibrium, the measured molar mass of Hb in solution will be between that of the intact $\alpha_2\beta_2$ tetramer (64 kDa) and the $\alpha\beta$ dimer (32 kDa). In Figure 9, we observe this behavior. The average M_w for native Hb was calculated to be 53.5 kDa, and it was 58.3 kDa for glycosylated Hb. The molecular weights of the native Hb tetramer and dimer are 64 kDa and 32 kDa, respectively. If two lactose derivatives are conjugated to the native Hb tetramer, the resultant molecular weights of the glycosylated Hb tetramer and dimer are 65.334 kDa and 32.667 kDa, respectively. Therefore, substituting these values into eq 5 reveals that the mass fraction of $\alpha_2\beta_2$ is 0.67 for native Hb in solution and 0.78 for glycosylated Hb, respectively. Hence, the increase in the mass fraction of $\alpha_2\beta_2$ tetramer for glycosylated Hb indicates that the $\alpha_1\beta_2/\alpha_2\beta_1$ interface between adjacent $\alpha\beta$ dimers is more "sticky" for glycosylated Hb versus native Hb. The origin of this "stickyness" can be elucidated by recognizing that the sugar is sandwiched between the β_1 and α_2 subunits of the protein (Figure 6). Interestingly, hydrogen bonds are formed between the sugar molecule and amino acid residues within the $\alpha_2\beta_1$ interface, and it is this hydrogen bonding interaction that leads to the "stickyness" of the $\alpha\beta$ interface by stabilizing the overall tetrameric structure of Hb. This observation further explains why the equilibrium of glycosylated Hb favors the tetrameric structure when compared to native Hb. Therefore, an added benefit of the glycosylation reaction is that it can stabilize the tetrameric structure of Hb. As mentioned earlier, this feature will reduce the formation of $\alpha\beta$ dimers and therefore reduce the amount of Hb extravasation through the lumen of blood vessels and subsequent NO scavenging.

CONCLUSION

We describe in this work an approach for the site-selective chemical glycosylation of Hb as a potential HBOC. A lactoside derivative with a terminal maleimide moiety was synthesized and conjugated to Cys 93 on the β chain of bovine Hb. The glycosylation reaction was quantitative and required no special purification steps, which was confirmed by LC-MS. Chymotryptic digestion of the glycosylated β-globin chain followed by tandem mass spectroscopy and X-ray crystallography of the glycosylated Hb identified the glycosylation site at Cys β93.

The glycosylation of Cys β93 on Hb results in an oxygen carrier with a high oxygen affinity (P_{50} = 4.94 mmHg) and low cooperativity coefficient (1.20). The stability of the glycosylated Hb was evaluated by AFFFF-MASLS-DIR analysis. AFFFF-MASLS-DIR analysis showed that the tetrameric structure of glycosylated Hb was more stable compared to native Hb. Subsequent X-ray analysis of the glycosylated Hb crystal revealed that the lactose derivative is sandwiched between the β_1 and α_2 subunits of the protein. This indicates that the glycosylated Hb is stabilized by hydrogen bonding interactions between the disaccharide and amino acids within the interface. These hydrogen bonding interactions explain the stability of the glycosylated Hb versus native Hb. In conclusion, glycosylated Hb exhibits high oxygen affinity and improved tetrameric stability, which shows great potential as an artificial blood substitute.

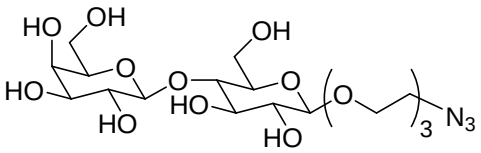
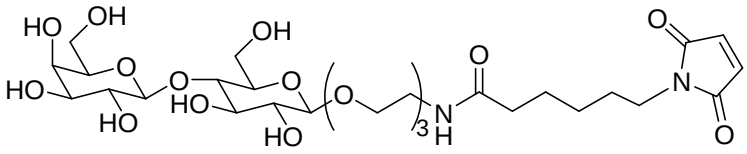
1-azido-3,6-dioxa-9-octyl-*O*-(2,3,6-tri-*O*-acetyl-β-D-glucopyranolsyl)-(1→4)-2,3,4,6-tetra-*O*-acetyl -β-D-galactoside (2). To a solution of peracetyl lactoside **1** (10.0 g, 14.7 mmol) in acetonitrile (150 mL) was added 2-[2-(2-chloroethoxy)ethoxy]ethanol (4.6 mL, 44.2 mmol) and 4 Å MS (Molecular Sieve) (2 g). The mixture was stirred at r.t. for 0.5 h and then cooled to 0 ºC. After that, boron trifluoride ether solution (3.9 mL, 29.4 mmol) was injected into the solution. The solution was slowly warmed to room temperature and stirred overnight. The solution was neutralized with saturated $NaHCO_3$ aqueous solution and extracted with ethyl acetate. The organic phase was dried with Na_2SO_4, filtered and concentrated. The crude product was purified by flash column chromatography with Hexanes/ EtOAc (1:1, v/v). The product (5.0 g, 6.35 mmol) in DMF (50 mL) was reacted with sodium azide (1.24 g, 19.1 mmol) and stirred at 80 ^{o}C overnight. The DMF was removed under reduced pressure and the crude product was purified by flash column chromatography with Hexanes/ EtOAc (1:1, v/v) to yield **2** (3.2 g) in an overall yield of 30% (two steps) as a colorless oil. ^{1}H NMR (500 MHz, $CDCl_3$) δ 1.97 (s, 3H), 2.05-2.06 (m, 9H), 2.07 (s, 3H), 2.13 (s, 3H), 2.16 (s, 3H), 3.41 (dd, *J* = 9.5, 4.3 Hz, 2H), 3.63-3.71 (m, 9H), 3.71-3.75 (m, 1H), 3.80 (t, *J* = 9.6 Hz, 1H), 3.86-3.93 (m, 2H), 4.07-4.16 (m, 3H), 4.48-4.51 (m, 2H), 4.58 (d, *J* = 8.0 Hz, 1H), 4.90 (dd, *J* = 9.5, 8.0 Hz, 1H), 4.96 (dd, *J* = 10.4, 3.5 Hz, 1H), 5.11 (dd, *J* = 10.5, 8.0 Hz, 1H), 5.20 (t, *J* = 9.4 Hz, 1H), 5.35-5.36

(m, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ 20.49, 20.61, 20.69, 20.80, 20.85, 50.69, 60.81, 62.02, 66.63, 69.05, 69.14, 70.05, 70.40, 71.00, 71.69, 72.65, 72.84, 76.29, 100.64, 101.08, 169.07, 169.65, 169.76, 170.05, 170.14, 170.34, 170.36.



1-azido-3,6-dioxa-9-octyl-*O*-(β-D-glucopyranolsyl)-(1→4)-β-D-galactoside (3). To a solution of compound **2** (3.3 g, 4.16 mmol) in MeOH (20 ml) was added sodium methoxide (22.5 mg, 0.416 mmol). The mixture was stirred at r.t. for 5 h, and neutralized with Dowex 50WX2-100 (H^+) resin. The resultant solution was then concentrated under reduced pressure to yield **3** (1.7 g, 82%) as a white solid. ^{1}H NMR (500 MHz, D_2O) δ 3.23-3.26 (m, 1H), 3.41 (t, *J* = 5.2 Hz, 2H), 3.44-3.46 (m, 1H), 3.48-3.51 (m, 1H), 3.55-3.57 (m, 3H), 3.61-3.63 (m, 7H), 3.65-3.67 (m, 4H), 3.69-3.77 (m, 2H), 3.82 (d, *J* = 3.3 Hz, 1H), 3.87-3.89 (m, 1H), 3.94-3.99 (m, 1H), 4.34 (d, *J* = 7.9 Hz, 1H), 4.42 (d, *J* = 8.0 Hz, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ 50.09, 60.03, 60.98, 68.71, 69.17, 69.45, 69.55, 69.65, 70.91, 72.48, 72.78, 74.26, 74.73, 75.31, 78.31, 102.04, 102.90.



***N*-3',6'-dioxa-9'-octyl-*O*-(β-D-glucopyranolsyl)-(1→4)-β-D-galactoside-6-maleimido-hexanamide (maleimide-lactoside) (4).** To a solution of compound **3** (0.20 g, 0.40 mmol) in MeOH (10 mL) was added a catalytic amount of Pd/C. The mixture was stirred under hydrogen atmosphere at r.t. for 24 h. Consequently, the Pd/C was removed by filtration and the solution was concentrated under reduced pressure to yield the amine compound. The amine compound (50 mg, 0.106 mmol) in DMF (5.0 mL) was reacted with 6-maleimidohexanoic acid *N*-hydroxysuccinimide ester (34.0 mg, 0.111 mmol) and Et_3N (21 μL, 0.148 mmol). The solution was stirred at 40 ^{o}C overnight. The solvent was removed under reduced pressure and the residue was purified by flash chromatography with EtOAc:IPA:H_2O (6:3:1) to yield the

product as a colorless oil (26.1 mg) with an overall total yield of 37% (two steps). ^{1}H NMR (500 MHz, MeOD) δ 1.30-1.34 (m, 2H), 1.59-1.66 (m, 4H), 2.21 (t, *J* = 7.4 Hz, 2H), 3.29 (t, *J* = 8.3 Hz, 1H), 3.32-3.34 (m, 4H), 3.36-3.38 (m, 2H), 3.43-3.46 (m, 1H), 3.50-3.53 (m, 3H), 3.54-3.57 (m, 4H), 3.59-3.64 (m, 4H), 3.68-3.74 (m, 5H), 3.75-3.82 (m, 2H), 3.84-3.87 (m, 2H), 3.92 (dd, *J* = 12.2, 2.6 Hz, 1H), 4.01-4.05 (m, 1H), 4.38 (d, *J* = 7.6, 5.6 Hz, 2H), 6.83 (s, 2H). ^{13}C NMR (125 MHz, MeOD) δ 25.05, 25.92, 27.88, 35.41, 37.04, 38.92, 60.58, 61.09, 68.30, 68.90, 69.24, 69.80, 70.08, 70.14, 71.16, 73.34, 73.44, 74.90, 75.12, 75.69, 79.31, 102.90, 103.73, 133.98, 171.23, 174.73. HRMS: Calculated for $C_{28}H_{46}N_2O_{16}Na$ ($M+Na^+$) 689.2745; found 689.2744.

Unimolecular Micelles based on Hydrophobically Derivatized Hyperbranched Polyglycerols: Biodistribution Studies

Rajesh Kumar Kainthan[†] and Donald E. Brooks*[,†,‡]

Department of Pathology and Laboratory Medicine, Centre for Blood Research, and Department of Chemistry, University of British Columbia, Vancouver, British Columbia, Canada V6T 2B5. Received March 6, 2008; Revised Manuscript Received September 9, 2008

We recently reported the synthesis and testing of a new class of unimolecular micelles based on hyperbranched polyglycerols as second generation synthetic plasma expanders and as general drug delivery vehicles. A detailed biodistribution study of two derivatized hyperbranched polyglycerols of different molecular weights derivatized with hydrophobic groups and short poly(ethylene glycol) chains is reported in this article. In mice, these materials are nontoxic with circulation half-lives as high as 31 h, controllable by manipulating the molecular weight and the degree of PEG derivatization. Organ accumulation is low, presumably due to the "pegylation" effect. Thermal degradation and hydrolysis data suggest that these polymers are highly stable with a long shelf life, a major advantage for a pharmaceutical product. Degradation under acidic conditions has been observed for these polymers.

INTRODUCTION

There is a huge clinical demand for human serum albumin (HSA), with the world market being in the ~$1.5B/yr range (*1*). Because of supply and contamination problems with the human material, a number of alternatives have been developed as plasma expanders, but they all suffer from significant failings compared to the native protein (*2, 3*). While they can reproduce the osmotic function of HSA, none provide one of the most significant physiological functions of HSA, namely, the binding and transport in the circulation of a wide variety of small molecules including fatty acids, steroids, metal ions, and bilirubin, as well as hydrophobic drugs. Moreover, since most are linear polysaccharides, they increase plasma viscosity significantly, typically cause deleterious red cell aggregation, and exhibit a variety of complex physiological effects (*4*−*7*).

Our overall goal is to develop a second-generation synthetic substitute for HSA consisting of a dendritic biocompatible polymer that not only has superior volume replacement properties compared to other plasma expanders, due to its low intrinsic viscosity, but also will closely mimic the compatibility, binding, and transport properties of the natural material. Toward this end, we recently reported the synthesis and preliminary testing of several derivatized hyperbranched polyglycerols (dHPGs) functionalized with octadecyl chains and monomethyl poly(ethylene glycol) (MPEG-400) oligomers (*8*). A simple one-pot synthetic strategy has been developed with the aim of reducing the cost of synthesis in an industrial setting. These dHPGs were shown to be highly biocompatible using various *in vitro* hemocompatibility studies owing to the presence of PEG oligomers which protect the alkyl chains from interacting with cell membranes and plasma proteins. Being highly branched, these polymers have low intrinsic viscosity values and therefore are expected to increase blood viscosity only slightly. Moreover, they behave as unimolecular micelles and have been shown to bind fatty acids and model hydrophobic drugs, implying that these polymers can also be applied as general drug carriers (*8, 9*). Due to the presence of functionalizable hydroxyl groups, they can also be decorated with targeting groups for directed drug therapy or bioactive materials that could be active intracellularly.

An ideal synthetic plasma expander should have a reasonably long plasma circulation half-life compared to that of HSA (~15 days) and should be metabolized or excreted as soon as it leaves the blood compartment. The circulation half-life of a polymer generally increases with increase in molecular weight and size; however, organ accumulation and uptake by the reticuloendothelial system (RES) also increases. Therefore, a balance is often sought for optimum performance. Long-term tissue deposits are a potential problem and still remain one of the drawbacks of the currently used plasma expanders (*10*). A detailed study of the biodistribution of two dHPGs therefore was carried out in mice, the results of which are the subject of the current manuscript.

EXPERIMENTAL PROCEDURES

Materials. All chemicals were purchased from Sigma-Aldrich Canada Ltd. (Oakville, ON) and used without further purification except as noted. Glycidol (96%) was purified by vacuum distillation and stored over molecular sieves in a refrigerator (2−4 °C). 1,2-epoxyoctadecane was synthesized by the peroxidation of octadecene with *m*-chloroperbenzoic acid. α-epoxy,ω-methoxy poly(ethylene glycol) 350 (MPEG epoxide) was synthesized from a reaction of MPEG 350, sodium hydroxide, and epichlorohydrin. Two dHPGs of molecular weight 40 kDa (dHPG-40) and 83 kDa (dHPG-83) were prepared as previously reported (*8*).

Polymer Characterization. NMR spectra were recorded on a Bruker Avance 400 MHz NMR spectrometer using deuterated solvents (Cambridge Isotope Laboratories, 99.8% D) with the solvent peak as a reference. Molecular weights and polydispersities of the polymers were determined by gel permeation chromatography (GPC) connected to a multiangle laser light scattering (MALLS) detector (GPC-MALLS). The GPC system used consists of a Waters 2690 separation module fitted with a DAWN EOS MALLS detector from Wyatt Technology Corp.

with 18 detectors placed at different angles (laser wavelength = 690 nm) and a refractive index detector (Optilab DSP from Wyatt Technology Corp.). An Ultrahydrogel linear column with bead size 6−13 μm (elution range 10^3 to 5×10^6 Da) and an Ultrahydrogel 120 with bead size 6 μm (elution range 150 to 5×10^3 Da) from Waters were used. An aqueous 0.1 N $NaNO_3$ solution was used as the mobile phase at a flow rate of 0.8 mL/min. The dn/dc value for polyglycerol was determined to be 0.12 mL/g in aqueous 0.1 N $NaNO_3$ solutions and was used for molecular weight calculations. The data were processed using Astra software provided by Wyatt Technology Corp.

All thermogravimetric analyses, to study the thermal stability of the polymers, were performed on a TGA Q500 (TA Instruments, USA). A constant ramping temperature program (20.0 °C/min to 800 °C) was used in the experiments with a balance gas flow of 40 mL/min (Nitrogen) and a sample gas flow of 60 mL/min (Nitrogen). The real-time weight percentage and TGA chamber temperature were recorded. Analysis of the data was performed using TA Universal Analysis 2000 software (version 4.2E, TA Instruments, USA) to find the onset points.

***In Vitro* Aqueous Degradability.** The polymer dHPG-83 was dissolved in buffer solutions of pH 5 (30 mM acetate buffer with 70 mM $NaNO_3$) and 7.4 (30 mM phosphate buffer with 70 mM $NaNO_3$) at a concentration of 10 mg/mL and incubated at 37 °C. Samples were withdrawn at 1, 2, and 4 week intervals and analyzed by size exclusion chromatography for molecular weight characteristics.

Radiolabeling of dHPGs. Radiolabeling was done by partial conversion of hydroxyl groups to methoxides using tritiated methyl iodide. Briefly, 1 g of polymer was dissolved in 10 mL dimethylsulfoxide (DMSO) and approximately 5% of the hydroxyl groups were converted to potassium alkoxides by reaction with potassium hydride (35 mg). To this, 20 μL of tritiated methyl iodide (toluene solution) dissolved in 1 mL DMSO was added and the reaction mixture stirred at room temperature for 15 h; then, 5 mL water was added and the reaction mixture was acidified with dilute HCl. The polymer was purified by dialysis against water using a dialysis membrane of MWCO 1000 until the dialyzate contained low amounts of radioactivity; this normally took 24 h. The polymer solutions were then filtered through a syringe filter (0.2 μm) and the total polymer weight was determined from the total volume and the dry weight of a known volume (100 μL) of solution after freeze−drying (measured in duplicate). The polymer solution was then concentrated by evaporating off the water in a fume hood, and the final concentration of 100 mg/mL in 150 mM

saline solution was made by appropriate dilution with an aqueous NaCl solution. This allowed the specific activity to be determined by counting an aliquot of solution.

Animal Studies. All animal experiment protocols were reviewed and approved by the Institutional Animal Care Committee (IACC) at UBC prior to conducting the studies. The care, housing, and use of animals were performed in accordance with the Canadian Council on Animal Care Guidelines. The studies were conducted at the British Columbia Cancer

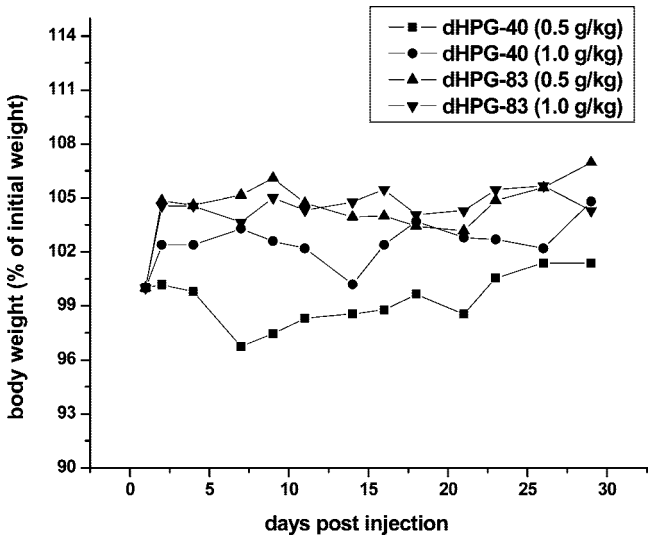

Figure 5. Change in body weight after administration of the dHPG polymers.

Research Centre under the supervision of Dr. Dawn Waterhouse and Prof. Marcel Bally.

Female Balb/C mice (7−11 weeks) were heated under a lamp for 1−2 min to increase blood circulation, and gently placed into a mouse restrainer for injection. The tail was wiped down with 70% isopropanol to clean the injection site and to aid in increasing circulation. Mice were injected intravenously (bolus) via lateral tail vein with a polymer solution of concentration 100 mg/mL (four mice per group) to a prescribed dose of 1 g/Kg. The injected volume was 200 μL/20 g mouse. Mice were then returned to their cages.

All animals were observed post-administration, at least once a day, and more if deemed necessary, during the pretreatment and treatment periods for mortality and morbidity. In particular, signs of clinical ill health were based on body weight loss, change in food consumption, and behavioral changes such as altered gait, lethargy, and gross manifestations of stress.

Blood was collected at various time intervals (30 min, 2, 4, 8, 24, and 48 h, and 7, 14, and 30 days) by cardiac puncture after termination by CO_2 inhalation. Plasma was separated by centrifuging samples at 2500 rpm for 15 min. Aliquots of plasma were placed in scintillation vials and analyzed with a Packard 1900 scintillation counter after adding 5 mL scintillation cocktail.

Mice in one group (time point 48 h) were housed in a metabolic cage. Urine and stools were collected as pooled samples at 1, 4, 8, 24, and 48 h post-injection. Aliquots of urine were analyzed by scintillation counting. Stool samples were pooled and made into a 30% homogenate in a known amount of water prior to obtaining aliquots for scintillation counting.

Upon termination, liver, spleen, kidney, lungs, and heart were removed from all the mice, weighed, and processed for scintillation counting. Livers (one lobe) were made into a 30% homogenate in a known amount of water using a polytron tissue homogenizer. Aliquots (in triplicate) of 200 μL homogenate were transferred to scintillation vials. All other organs were dissolved in 500 μL SOLVABLE. Vials were incubated at 50 °C overnight, then cooled prior to addition of 50 μL 200 mM EDTA, 25 μL 10 M HCl, and 200 μL 30% H_2O_2. This mixture was incubated at room temperature for 1 h prior to addition of 5 mL scintillation cocktail. Samples were analyzed by scintillation counting.

Evaluation of Antibody Mediated Clearance. Female Balb/c mice (total of 16) were individually weighed and divided into groups of 4. Mice in groups 3 and 4 received injections of dHPG- 83 every 2 weeks for 8 weeks. One week following the final injection, all mice received an i.v. injection of the radiolabeled dHPG-83, and blood was collected at different time points. Plasma was collected and assessed for polymer levels by scintillation counting.

RESULTS AND DISCUSSION

Synthesis and Characterization. The synthetic method we have employed for the dHPGs is a simple and efficient one-pot approach based on anionic ring-opening polymerization of epoxides. The structure of the polymer is given in Figure 1; the details of the synthesis have been described in an earlier manuscript (*8*). Briefly, an HPG of molecular weight 7000 g/mol was prepared by anionic ring-opening multibranching polymerization of glycidol from partially deprotonated trimethylolpropane using potassium methylate (*11*). HPG has numerous hydroxyl end groups, with the number per molecule being roughly equal to the degree of polymerization. Some of these were modified with C18 alkyl chains (2−5%) and MPEG-350 chains (mol wt 350) (20−40%) by sequential addition of 1,2-epoxyoctadecane and MPEG-epoxide. The unreacted alkyl epoxide was removed from the methanolic polymer solution by extraction with hexane. The final polymer product was purified by dialysis against water to remove any unreacted PEG chains and then freeze−dried. Two dHPGs of molecular weight 40 kDa and 83 kDa were prepared for biodistribution studies; their molecular characteristics are given in Table 1. The polymers were purified by dialysis. The molecular weight distributions of the polymer are narrow, in the range 1.5−1.8.

***In Vitro* Aqueous Degradability.** The dHPG polymer backbones contain −C−C− and −C−O−C− bonds only. Since these are not substrates for common enzymes in the circulation, no rapid enzymatic breakdown in blood is anticipated. We tested the stability of dHPG-83 in buffer solutions of pH 5 (lysosomal pH) and 7.4 (physiological pH) incubated at 37 °C by monitoring its molecular weight distribution profile over time by GPC. The chromatograms are shown in Figure 2. The RI traces indicated only a small decrease in peak molecular weight and the appearance of material in the 20 000−40 000 range after 14 and 30 days when the polymers were incubated at pH 7.4 (Figure 2A,B). However, the polymers degraded more noticeably at pH 5.0 and a much more prevalent lower molecular weight fraction, in the range 10 000−40 000, could be seen in the RI traces for the 15 and 30 day samples with an obvious reduction in the peak molecular weight (Figure 2C,D). The average molecular weight decreased from 83 to 20 K. Since the HPG core was reported earlier to be stable under similar conditions (*12*), the decrease observed might be due to degradation of the PEG chains, with the degradation of PEG under acidic conditions having been reported (*13*). However, the occurrence of relatively high molecular weight PEG chains would be expected to be relatively rare at the monomer concentrations used in the synthesis, so this is unlikely to be the whole explanation. A more detailed study of the degradation reaction is under way.

Thermal Degradation. A desirable property of dHPGs would be sufficient thermal stability to allow them to be autoclaved for sterilization. The core HPGs are thermally quite stable with onset of thermal decomposition in the range 360−390 °C (*14, 15*). The thermograms obtained for dHPG-40 and dHPG-83 are shown in Figure 3. It is evident from the figure that the derivatized HPGs are also highly stable up to a temperature of 300 °C with no indication of thermal decomposition. The onset of decomposition is around 350 °C. Aqueous solutions of dHPG at two different concentrations (50 mg/mL and 100 mg/mL) were autoclaved under standard conditions for sterilization, and the GPC chromatograms before and after the sterilization

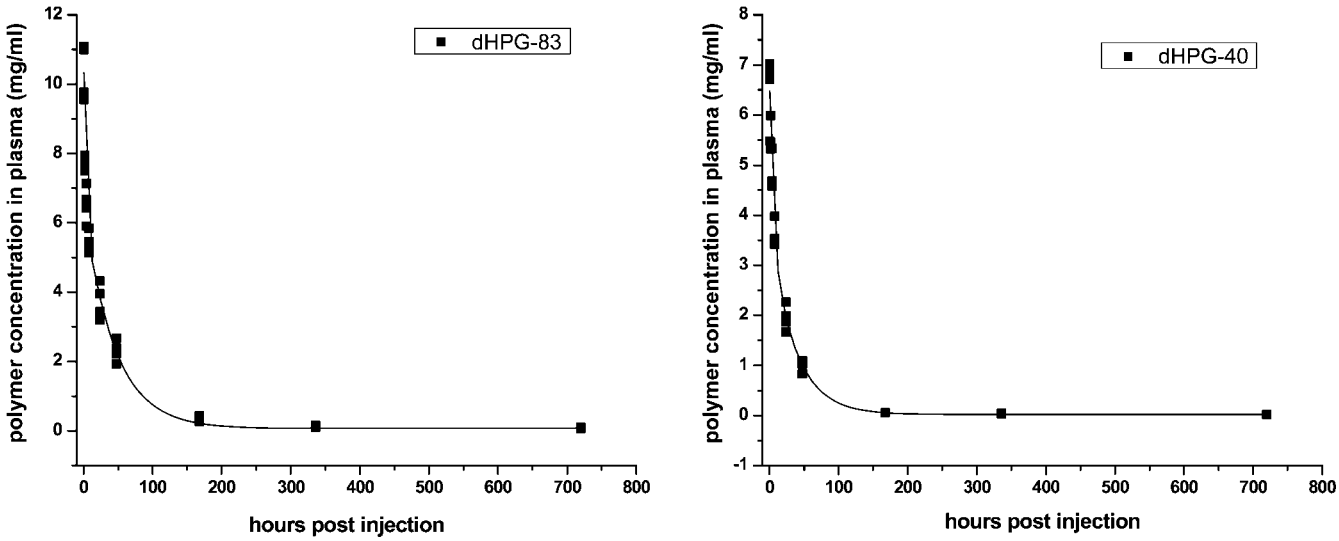

Figure 6. Plot of polymer concentration of dHPG polymers in plasma with respect to time.

Table 2. Rate Constants Determined from Pharmacokinetic Analysis of Polymer Concentrations in Plasma over Time[a]

polymer	P_0 (mg/mL plasma)	V_c (mL plasma)	α (h^{-1})	β (h^{-1})	$t_{1/2}$ (h)	k_{12} (h^{-1})	k_{21} (h^{-1})	k_2 (h^{-1})	$AUC_{0-\infty}$mg.mL^{-1}.h
dHPG-40	6.8 ± 1.4	2.94 ± 0.62	0.028 ± 0.007	0.20 ± 0.07	24.9 ± 6.2	0.060 ± 0.089	0.12 ± 0.05	0.046 ± 0.027	148.4 ± 44.9
dHPG-83	11.7 ± 0.4	1.7 ± 0.06	0.022 ± 0.002	0.61 ± 0.11	31.0 ± 2.9	0.249 ± 0.130	0.34 ± 0.06	0.040 ± 0.011	295.4 ± 29.9

[a] k_{12} and k_{21} represent the rate constants for transfer between the plasma and tissue compartments; k_2 is the rate constant for elimination.

procedure are shown in Figure 4. The chromatograms are indistinguishable with no change in molecular weight. These results demonstrate that aqueous solutions of dHPG polymers are sufficiently stable to allow them to be autoclaved.

Animal Studies. *Mouse Toxicity.* The derivatized HPGs dissolved in isotonic saline were injected i.v. into Balb/c mice at 0.5 g/Kg and 1 g/Kg, two mice per concentration per compound, and followed for 30 days for signs of toxicity and body weight loss. No untoward indicators were found, and all the animals grew normally with no signs of distress, as was found for underivatized HPGs (*16*). No signs of toxicity (e.g., lethargy, dry eyes, change in food consumption, altered gait, or scruffy coats) were observed. The animals were followed for 30 days for weight changes, and no weight loss was observed during this period (Figure 5). On autopsy, liver, gall bladder, spleen, lung, kidney, heart, intestine, lymph nodes, and bladder were examined macroscopically for gross pathology; all the organs appeared normal with no unusual finding observed.

Biodistribution. The circulating levels of both polymers are shown in Figure 6 as a function of time, expressed as milligrams polymer per milliliter of plasma. The data were analyzed by a standard two-compartment open pharmacokinetic model (*12, 17*). The rate constants (k_{12} - plasma to tissue, k_{21} - tissue back to plasma, and k_2 - elimination) calculated from the graphs are given in Table 2.

The plasma half-life for dHPG-40 was ~25 h, while that of dHPG-83 was ~31 h. The value for the area under the plasma concentration curve ($AUC_{0-\infty}$) was ~2 times that for the higher molecular weight polymer, implying that this polymer's tissue exposure was twice that of the lower molecular weight material. The results show that it is possible to adjust the retention time in blood and tissue exposure by manipulating the molecular weight through changes in the PEG content of the polymer, since both the dHPGs had similar HPG contents (16 000 and 24 000 for the low and high molecular weights, respectively, whereas the PEG contents were around 22 500 and 56 000). The core HPG molecular weight can also be varied with related effects as we have shown recently with higher molecular weight non-pegylated material (*12*). The plasma half-lives obtained for these polymers are consistent with the periods required for postoperative support in many cases (*18*). Lower molecular weight polymers, which would be excreted faster, can be made by reducing the molecular weight of HPG or degree of substitution with PEG; in some surgical settings, faster excretion is preferred. Even though the molecular weight of the dHPG-83 is double that of dHPG-40, the plasma half-life did not change dramatically. This might be due to the plasma half-life's dependence on many factors, one of which is the molecular size, which increases only weakly with molecular weight for hyperbranched polymers.

The plasma half-lives observed for these polymers are higher than those for linear polymers of similar molecular weights, presumably due to their globular shape and relative rigidity. For example, poly-*N*-(2-hydroxylpropyl)methacrylamide (HPMA), which has been extensively studied for anticancer drug delivery, has a circulation half-life of only 25 h for a molecular weight of 556 000 (*19*). The hydrodynamic radii of dHPG polymers are well above the glomerular filtration threshold, which is about 3.7−6.0 nm pore radius (*20*). Perhaps more relevant is the inability of dHPGs to pass through pores via reptation, an option available for linear polymers (*21, 22*). A related observation is that longer circulation times have been reported for pegylated polyester bow-tie dendrimers, which likewise cannot reptate (*13*).

The values for the distribution rate constants were calculated from the graphs and are summarized in Table 2. While the two polymers were eliminated from the system at essentially the same rate, the transfer of the higher molecular weight polymer dHPG-83 from blood to tissue (k_{12}) was about 4 times faster and the reverse process (k_{21}) almost 3 times faster than the rates for dHPG-40, consistent with the higher tissue accumulation observed for the higher molecular weight polymer as discussed below.

At termination, liver, spleen, lungs, and heart were collected and processed for scintillation counting. Levels of polymer in the organs were analyzed. The data was not corrected for the

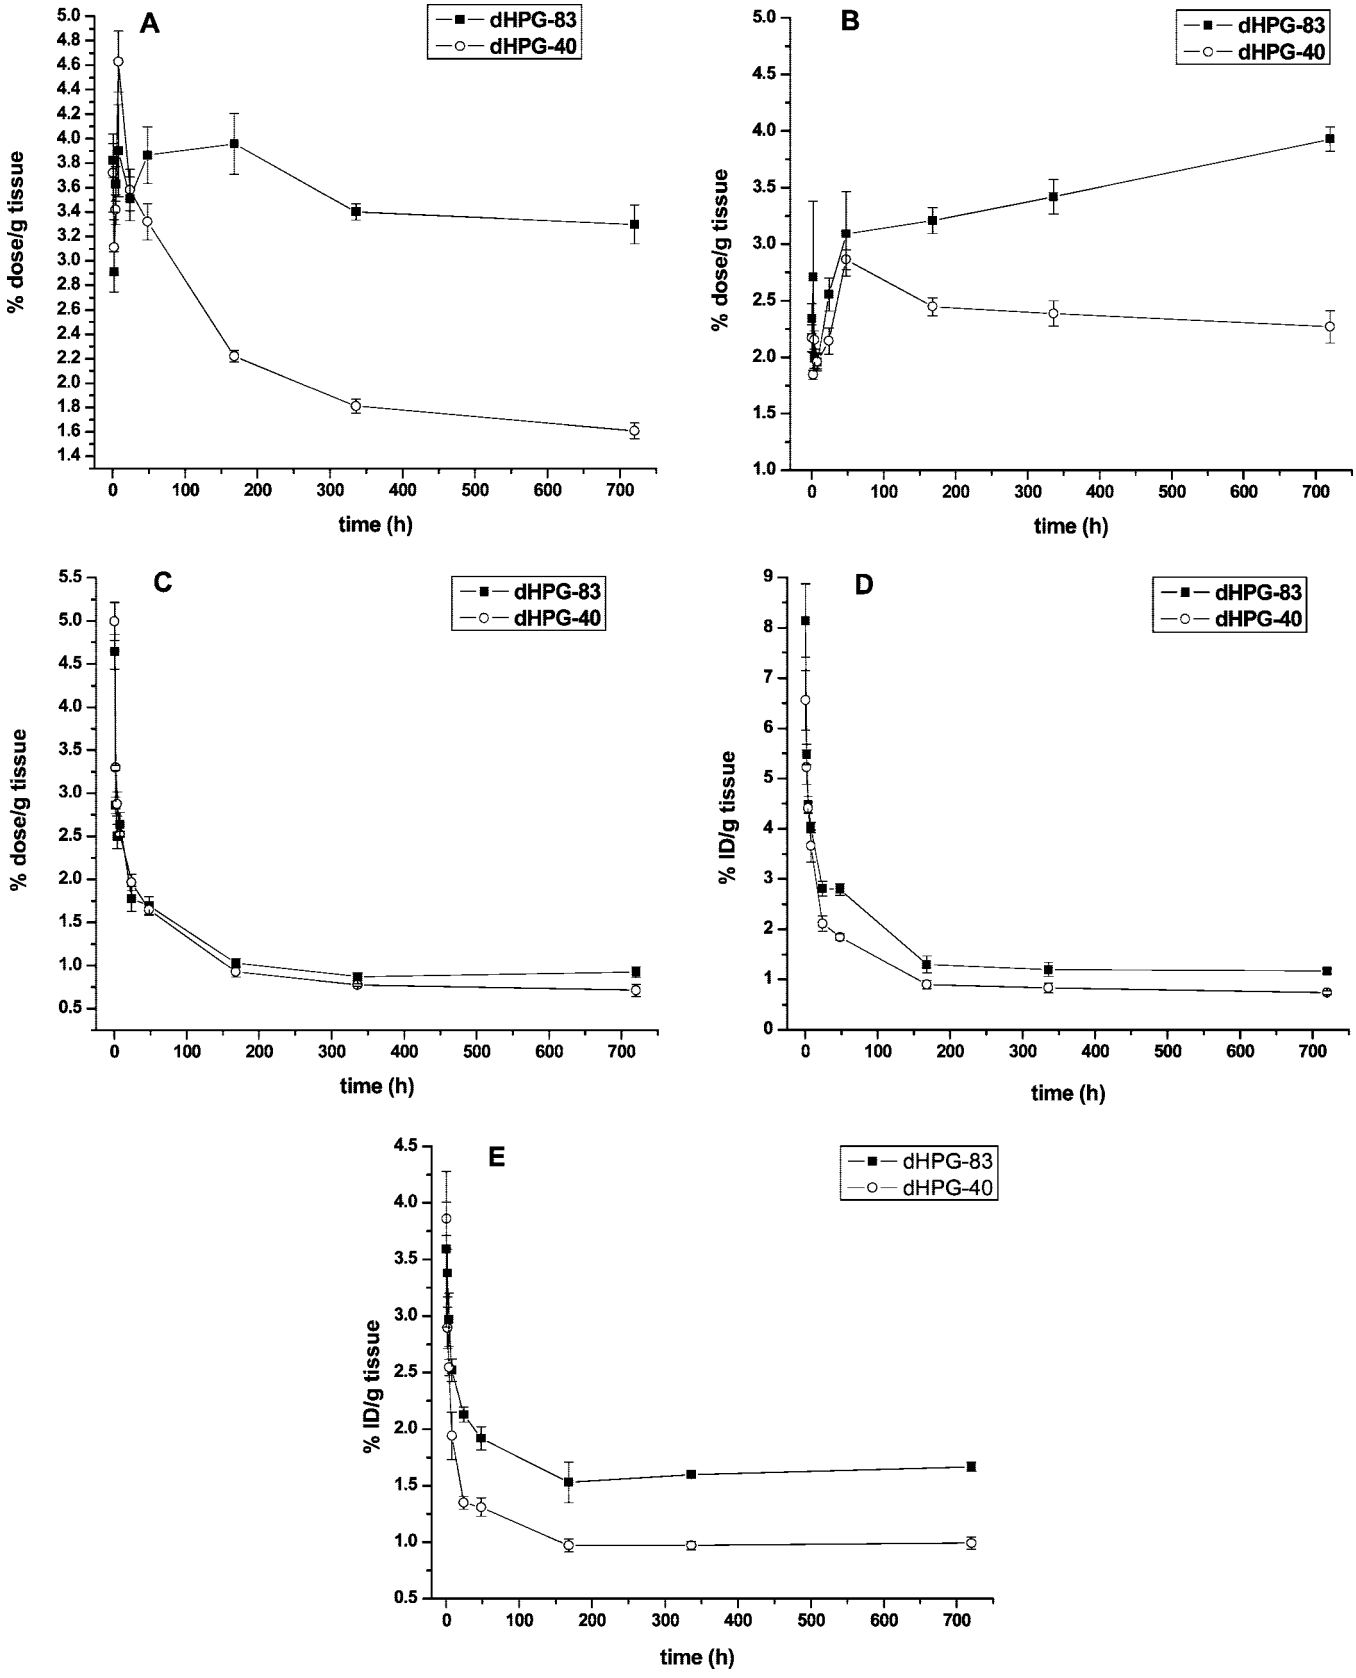

Figure 7. Levels of polymer accumulated over time in liver (A), spleen (B), kidney (C), lungs (D), and heart (E).

plasma present in these organs, so the high levels of radioactivity up to 48 h are largely due to the plasma present in them. Both polymers accumulate in liver and spleen to a small extent with values below 5% ID/g tissue (ID = initial dose) over the 30 day study period (Figure 7A,B). The low levels observed for these polymers compared to HPGs and other polymers reported in the literature evidently are due to the presence of PEG chains, supporting the concept that PEG grafting reduces uptake by the RES (*23, 24*). The levels in the organs were higher for the higher molecular weight polymer, which remained almost constant in liver and increased in spleen during the study period. A similar dependence of tissue accumulation on molecular weight has

Table 3. Polymer Levels in Urine and Feces at the Times Indicated[a]

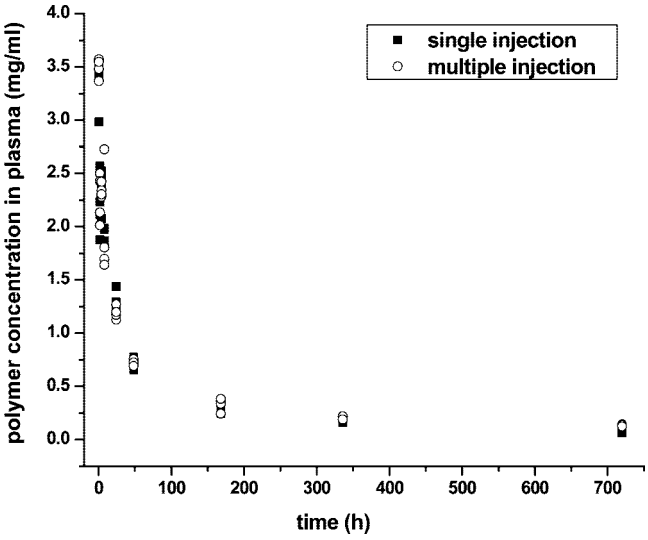

Figure 8. Plot of polymer concentration of dHPG-83 in plasma of animals preinjected with the polymer with respect to time.

been reported for other polymers, likely because the total tissue exposure was higher as indicated by the greater $AUC_{0-\infty}$value for dHPG-83 (Table 2) (*25*, *26*).

The levels of the lower molecular weight polymer in kidney, lungs, and heart were below 1% ID/g tissue (Figures 7C,D,E). The levels of the higher molecular weight polymer were around 1% in kidney and lungs and ~2% in heart. Similar organ accumulations have been reported for hetastarch, which is widely used clinically (*25*, *27*). These levels of apparent accumulation were accompanied by no gross effects on organ histology, however; the animals remained healthy throughout the observation period. The fate of the residual polymer in these organs after 30 days is unknown, and long-term toxicity studies are needed to assess the effect. However, the *in vitro* degradation data suggest that the polymer might degrade in the acidic compartments of the cells following uptake, resulting eventually in slow excretion from the body. Enzymatic degradation of polyethers has been reported earlier (*28*−*30*).

A metabolic study with a group of mice ($n = 4$) injected with the polymers was performed by collecting urine and feces as pooled samples at 1, 4, 8, 24, and 48 h. The values of polymer clearance into urine and feces are given in Table 3. Approximately 50% of dHPG-40 was excreted from the body within 24 h, with 27% through urine and 22% through feces. The dHPG-83 is mostly eliminated through urine with 17% eliminated within 24 h. Even though the amount of polymer present per unit mass of feces was similar for each, the total amount of dGHPG-83 excreted was only ~1% due to significantly lower amounts of feces excreted within 48 h for this group of animals. Most urinary excretion was over within 24 h for both polymers.

Evaluation of Antibody Mediated Clearance. We have not developed an enzyme-linked immunosorbent assay (ELISA) for the anti-dHPG polymer family due to the lack of a positive control. However, we have tested for evidence of antibody mediated clearance by attempting to sensitize mice with a sequence of prior injections before measuring the plasma depletion curve. If these dHPG polymers are immunogenic, the plasma half-lives of the polymer injected subsequently should be reduced due to the antibody mediated clearance mechanism (*31*−*33*). In order to study this, 16 mice were divided into groups of 4. Mice in groups 3 and 4 were injected with non-radiolabeled dHPG-83 every 2 weeks for 8 weeks at dose of 1 g/kg. One week following the final injection, all mice received an i.v. injection of the radiolabeled dHPG-83 at a dose of 1 g/kg, and blood was collected at different time points. Plasma was collected and assessed for polymer levels by scintillation counting. All the animals grew normally during the study period, and no signs of toxicity or weight loss were observed (data not shown). On autopsy, all organs appeared normal with no gross pathology.

The levels of dHPG-83 in the plasma for both the groups of animals, determined by scintillation counting, are shown as a function of time in Figure 8. It can be seen that the polymer levels are very similar with no significant change in plasma half-life, indicating that there is no significant antibody mediated clearance of the polymer.

The dHPG polymers, with potential applications as an albumin substitute or a general drug delivery vehicle, are highly biocompatible as evidenced by the *in vivo* results described above. The results also suggest that these polymers are non-immunogenic, as they can be administered in repeated doses without change in plasma half-lives. The polymers were well-tolerated by mice at doses as high as 1 g/kg. The plasma half-lives exceeded 24 h and can be controlled by varying the molecular weight through changing the polyglycerol core or the PEG content, as in the present case. The tested polymers are of sufficient size to not pass out immediately into the urine. The overall data considering the plasma half-life and the organ accumulation suggests that a derivatized HPG polymer with a number-average molecular weight of 40 000 is well-suited to an application as a plasma expander. The presence of radioactivity over relatively long periods of time suggests that these structures do not break down appreciably in the circulation over the time courses utilized. However, the *in vitro* degradation studies suggest that these PEG-containing polymers could degrade slowly, particularly under the acidic conditions of an intracellular environment.

ACKNOWLEDGMENT

Folate and Folate−PEG−PAMAM Dendrimers: Synthesis, Characterization, and Targeted Anticancer Drug Delivery Potential in Tumor Bearing Mice

Prateek Singh, Umesh Gupta, Abhay Asthana, and Narendra K. Jain*

Pharmaceutics Research Laboratory, Department of Pharmaceutical Sciences, Dr. H. S. Gour University Sagar (M.P.) 470003 India. Received March 25, 2008; Revised Manuscript Received August 8, 2008

Ligand-mediated targeting of drugs especially in anticancer drug delivery is an effective approach. Dendrimers, due to unique surface topologies, can be a choice in this context. In the present study, PAMAM (polyamidoamine) dendrimers up to fourth generation were synthesized and characterized through infrared (IR), nuclear magnetic resonance (NMR), electrospray ionization (ESI) mass spectrometric, and transmission electron microscopic (TEM) techniques. Primary amines present on the dendritic surface were conjugated through folic acid and folic acid−PEG (poly(ethylene glycol))−NHS (*N*-hydroxysuccinimide) conjugates. Tumor in mice was induced through the use of KB cell culture. Prepared dendritic conjugates were evaluated for the anticancer drug delivery potential using 5-FU (5-fluorouracil) in tumor-bearing mice. Approximately 31% of 5-FU was loaded in folate−PEG−dendritic conjugates. Results indicated that folate−PEG−dendrimer conjugate was significantly safe and effective in tumor targeting compared to a non-PEGylated formulation. Tailoring of dendrimers via PEG−folic acid reduced hemolytic toxicity, which led to a sustained drug release pattern as well as highest accumulation in the tumor area.

INTRODUCTION

Nanoparticulate drug delivery systems containing anticancer agents have received much attention recently due to their unique accumulation behavior at the tumor site. Targeted anticancer drug delivery includes drug delivery by avoiding reticuloendothelial system (RES), utilizing the enhanced permeability and retention (EPR) effect and tumor specific targeting (*1*−*3*). Polymers have been used as drug carriers in the last 2−3 decades due to their ability to control drug release, to sustain circulation times, and to increase drug solubility. These drug carriers demonstrated higher affinity for preferential accumulation in tumor tissue as a result of EPR effect (*4*, *5*). Polymeric drug carriers encapsulate, complex, or conjugate drug molecules to deliver them to the desired site. In this context, applicability of dendrimers to deliver anticancer drugs and other bioactives is well-reported in the literature (*6*−*13*). These are a relatively new type of polymer known for their three-dimensional, monodispersed, highly branched, macromolecular nanoscopic (1−100 nm) architecture with a number of reactive end groups (*14*). Apart from drug delivery, dendrimers have recently been used successfully in the field of biomedicine and targeting (DNA and gene delivery, cancer diagonosis), catalysis, as light-harvesting devices, optical sensors, and so forth. Dendrimers have been reported to host both hydrophilic and hydrophobic drugs with high drug payload (*15*−*22*). Earlier dendrimers have successfully been delivered via transdermal, intravenous, and opthalamic routes, proving their transfection capabilities (*23*−*25*). The solubilization property of dendrimer makes them a promising carrier for insoluble drug delivery (*26*). However, toxicity problems with the surface cationic charge of dendrimers like polyamidoamine (PAMAM) and polypropyleneimine (PPI) pose a hurdle in their biomedical potential (*25*−*28*). Recently, surface-engineered/conjugated dendrimers, with drug molecules or targeting ligands or both, are receiving much attention as an alternative to the toxicity problems (*25*−*29*). In some reports, dendrimer−poly(ethylene glycol) (PEG) grafts were designed as a drug carrier that possesses an increased interior and biocompatible surface for the encapsulation of drugs like 5-fluorouracil, chloroquine phosphate, and so forth (*6*, *30*, *31*). In another study, PEGylated dendrimers encapsulating anticancer drugs adriamycin and methotrexate were prepared by extraction with chloroform from the mixtures of the PEGylated dendrimers and varying amounts of drug. Among the PEGylated dendrimers synthesized, the highest ability was achieved by the fourth-generation dendrimer having the PEG graft with average molecular weight of 2000 Da that could retain 6.5 adriamycin molecules or 26 methotrexate molecules per dendrimer molecule. The methotrexate-loaded PEG attached dendrimers slowly released the drug in an aqueous solution of low ionic strength (*32*).

The major drawback with the anticancer drug delivery is that these indiscriminately attack healthy cells as well as cancerous cells. The harmful side effects due to such therapy, however, can be reduced by developing a drug delivery system that is specific to tumor cells. To overcome this, a strategy called active targeting can be followed, wherein functionalities that respond to overexpressed receptors (e.g., folate conjugation on dendrimer surfaces) on tumor cells are attached to the drug carrier. Folate receptors (FR), which are 38 kDa glycosylphosphotidylinositol-anchored proteins, exist in three major forms, namely, FR-α, FR-β, and FR-γ. The FR-α form is overexpressed in many types of tumors including ovarian, endometrial, breast, renal cell carcinomas, and so forth. The fact that high-affinity FR binding is retained when folate is covalently linked via its γ-carboxyl group to a foreign molecule, combined with the prevalence of FR overexpression among tumors, makes it a good choice for targeted drug delivery to tumors (*33*, *34*). Tailored folic acid conjugated PAMAM dendrimers via EDC [1-ethyl-l-3-(3 methylaminopropyl carbodiimide)] linkage were more efficient in delivery of methotrexate (*9*, *35*). In another approach, PEGylation and folate conjugation were combined and a folate−PEG conjugate, capable of covalent coupling to primary amines present at the surface of polyplexes, was developed (*36*).

In the present study, a similar approach was designed in which PAMAM dendrimers up to fourth generation were synthesized, characterized, and conjugated to folic acid directly or indirectly through PEG4000 as spacer. 5-Fluorouracil, an anticancer drug, was encapsulated in both types of dendrimer−folic acid conjugates and assessed for their *in vitro* as well as *in vivo* anticancer potential in tumor-bearing mice.

EXPERIMENTAL PROCEDURES

Materials. Methyl acrylate, triethylamine, toluene, folic acid, PEG-4000, and ethylenediamine were purchased from Central Drug House, India. Thionyl chloride was obtained from Spectrochem, Mumbai (India). DMF (Dimethylformamide) was purchased from Merck, India. NHS (*N*-hydroxysuccinimide), and DSS (disuccinimidyl suberate) were purchased from Sigma Aldrich, Germany. DCC (*N*,*N*-dicyclohexyl carbodiimide) and culture medium RPMI 1640 were obtained from Hi Media, Mumbai (India). All the other common chemicals used were of analytical grade and were identified by respective chemical tests before their use in the study. The drug 5-fluorouracil was obtained as a generous gift from Cadila Pharmaceuticals Pvt. Ltd. India.

Synthesis and Characterization of 4.0 G PAMAM Dendrimers. Synthesis of PAMAM dendrimers was carried out following a two-step process, involving Michael addition of a suitable amine initiator core with methyl acrylate, and exhaustive amidation of the resulting esters with large excess of ethylenediamine, reported elsewhere (*14*).

Briefly, ethylenediamine (EDA) was used as an initiator core for the synthesis of dendrimers by attaching four acrylate moieties on each amino group of EDA (Scheme 1). Table 1 holds the molar equivalents of the reagents used in the synthesis of PAMAM dendrimers. The resulting compound was referred to as "generation −0.5G PAMAM tetra ester" (Scheme 1). This led to branching in the dendritic structure. The second step was used for amidation of the terminal carbomethoxy ($COCH_3$) groups of methylacrylate with EDA. This tetra ester with excess EDA gave "generation 0.0 PAMAM tetra amine". Similar steps were repeated for the synthesis of higher-generation PAMAM dendrimers, subsequently. The reaction sequence was followed by the removal of excess reagents by rotary vacuum evaporation (Superfit, India; 55−60 °C) at every step. Synthesis was carried out in the dark at room temperature (25 °C), using amber-colored round-bottom flask corked tightly. The reaction was carried out as per the quantities given in Table 1 and Scheme 1.

Dendrimers were subjected to physical and chemical characterization. Half- and full-generation dendrimers were distinguished by IR spectroscopy and chemical reaction of copper sulfate aqueous solution (1% w/v) with dendrimer (0.1% w/v in methanol). A synthesized 4.0 G dendritic system was characterized by IR, NMR, ESI mass spectroscopy, and transmission electron microscopy. In IR analysis, dendrimer samples were analyzed by the KBr pellet method in a Perkin-Elmer 783 IR spectrophotometer and displayed characteristic peaks at 3350.2 cm^{-1} (N−H stretch of primary amines); 3245 cm^{-1} (quarternary ammonium ion peak); 3190.0 cm^{-1} (antisymmetric N−H stretch of substituted primary amine); 1641.3 cm^{-1} (−C═O stretch); 2890 cm^{-1} (aliphatic C−H stretch); 1566.0, 1471.7, 1327.9 cm^{-1} (N−H bending of N substituted amide); 1118.4 cm^{-1} (CC bending). NMR spectroscopy (Bruker Advance DRX 300, Germany) was performed using D_2O as solvent and methanol as cosolvent at 300 MHz; δ 2.418, 2.436 ($-CH_2C$═O); δ 2.5−2.9 (amide-NH); δ 3.1−3.4 (-CH_2NH_2 terminal group); δ 4.762 (methanolic -OH) (Scheme 1).

ESI mass spectra were recorded on a Micromass Quattro II Triple Quadrupole mass spectrometer. The samples (dissolved in suitable solvents such as methanol/acetonitrile/water) were introduced into ESI source through a syringe pump at the rate of 5 μL/min. The ESI capillary was set at 3.5 KV and the cone voltage was 40 V. Spectra were collected in 6S scans, and the printouts were averaged spectra of 6−8 scans. Spectra recorded at high mass units were computerized decovoluted.

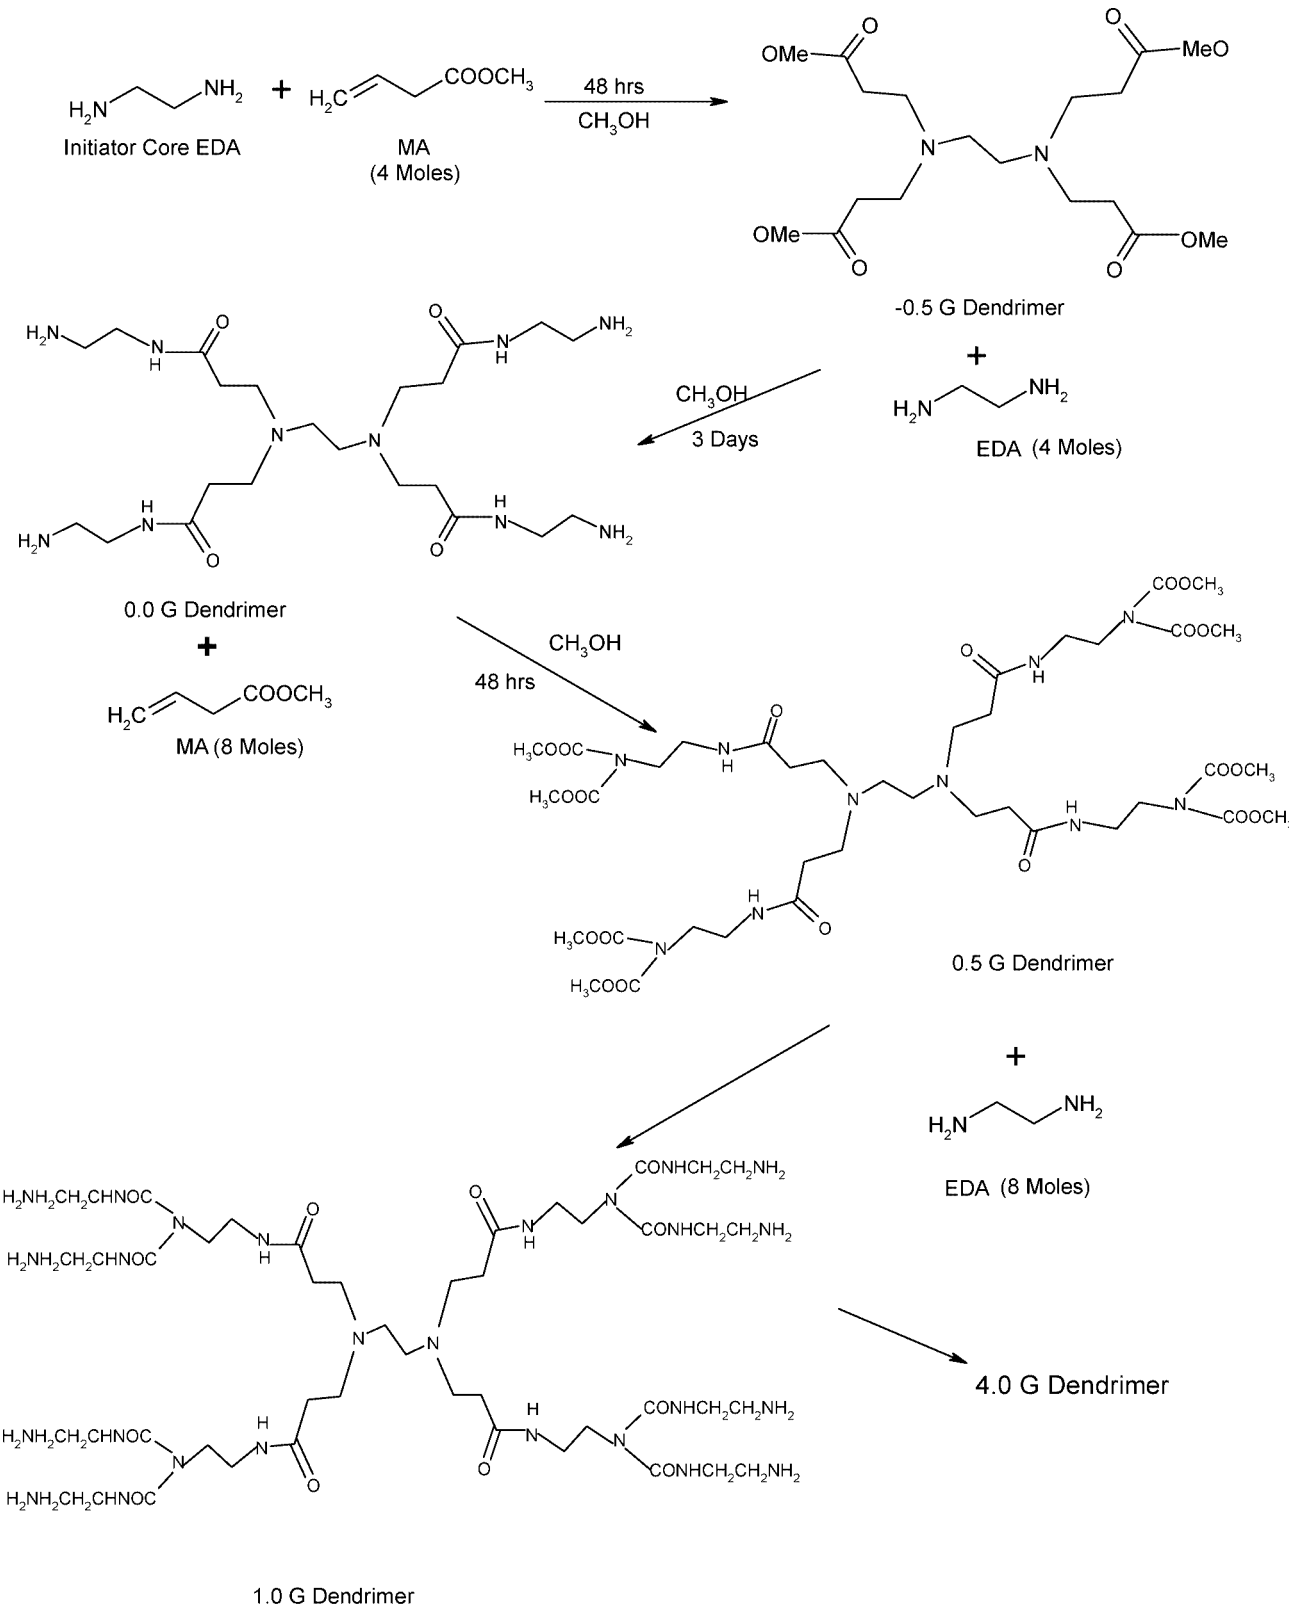
Transmission electron microscopy (TEM) of the prepared 4G PAMAM dendrimer was carried out after drying on 3 mm forman (0.5% plastic powder in amyl acetate) coated copper grid (300 mesh) at 60 KV (Philips Morgani, 268D trasmission electron microscope; Holland) after staining negatively, using uranyl acetate (4%). Photomicrographs (Figure 1A) were taken at suitable magnifications from the Electron Microscopy Section of Anatomy Division of All India Institute of Medical Sciences, New Delhi, India.

Synthesis and Characterization of PEG-4000 Bis Amine. PEG-4000 bis amine (H_2N-PEG4000-NH_2) was synthesized in three steps following a modified method reported by Zalipsky et al. (*37*). In the first step, PEG-4000 (19 g, 0.004 mol) was dissolved in toluene (100 mL) and dried by distillation. Dry pyridine (1.6 mL, 0.019 mol) was mixed to the above solution, and then thionyl chloride (4.36 mL, 0.059 mol) was added dropwise in a period of 30 min under reflux to the mixture. The mixture was heated for 4 h, cooled to room temperature (25 °C), filtered from pyridine hydrochloride, and toluene was evaporated in vacuum. The residue was dissolved in about 20 mL of dichloromethane (DCM), dried over anhydrous K_2CO_3, and filtered. The filtrate was treated with alumina (30 g, activated by heating at 120 °C for 2 h). Alumina was separated by filtration, and the filtrate was precipitated by cold ether. The polymer was recrystallized from dichloromethane (DCM) yielding 15 g (79%) of Cl-PEG-4000-Cl. In the second step, sodium azide (16 mmol, 1 g) was added to the solution of Cl-PEG-4000-Cl (3.6 g) in DMF (20 mL), and the mixture was placed in an oil bath maintained at 120 °C for 1 h; thereafter, DMF (20 mL) was added, and the mixture was stirred at 80 °C for 4 h, cooled, and filtered, and DMF was evaporated in vacuum. The residue was taken in DCM, filtered, and precipitated with cold ether. Yield was 3 g (83%) and N_3-PEG 4000-N_3 was formed. In the third and the final steps, N_3-PEG 4000-N_3 (1.6 g) was dissolved in absolute ethanol (40 mL), 10% Pd/C (0.1 g) was added, and the mixture was hydrogenated in a catalytic hydrogenation apparatus (Low-Pressure model PCHS 500, India) overnight. The catalyst was removed by filtration, and the polymer conjugate was precipitated using dry ether and was vaccuum-dried. A yield of 1.2 g (75%) NH_2-PEG 4000-NH_2 was obtained. PEG-4000 bis amine synthesis was characterized by IR spectroscopy, at every step.

Conjugation of Folic Acid to 4.0 G PAMAM Dendrimers. Folic acid was conjugated to 4.0 G PAMAM dendrimers surface through two approaches, i.e., direct conjugation and conjugation through PEG spacer (indirect).

Direct Conjugation. Preparation of NHS Ester of Folic Acid. The active ester of folic acid was prepared by a reported method (*38*). Briefly, folic acid (0.30 g, 0.68 mM) and triethylamine (0.15 mL, 1.0 mmol) were dissolved in DMSO (10 mL), and DCC (0.14 g, 0.68 mmol) was added to it. The solution was stirred for 1 h at room temperature in the dark, and NHS (0.12 g, 1.0 mmol) was added. The mixture was stirred overnight in the dark at room temperature, filtered via glass wool to remove the insoluble byproduct, dicyclohexylurea, and was precipitated using diethyl ether. The active ester of folic acid was collected by filtration, washed with dry tetrahydrofuran (THF) and dried under vacuum (Scheme 2). The NHS ester of folic acid was characterized through IR spectroscopy. Important peaks obtained for the folic acid were at 3545.0, 3415.3 cm^{-1} (N−H stretch of primary amine and amide); 3324.8 cm^{-1} (alkyl C−H and C═C stretch); 1694.8 cm^{-1} (aromatic C═C bending

Scheme 1. Synthesis of PAMAM Dendrimers up to Fourth Generation



G- Generation, EDA- Ethylene Diamine, MA- Methylacrylate

and stretching); 1484.2 cm^{-1} (CH−NH−C=O amides bending); 837.8 cm^{-1} (aromatic C−H bending and benzene 1,4-disubstitution); and for the NHS conjugated folic acid 3691.6 cm^{-1} (amide N−H and C=O stretching); 3444.2 cm^{-1} (primary aliphatic amine N−H stretching); 2997.0 cm^{-1} (carboxylic acid C=O and O−H stretching unconjugated); 1712.7 cm^{-1} (ketones C=O unconjugated stretch), which confirmed the synthesis of NHS ester of folic acid.

Conjugation of Active Ester of Folic Acid to 4.0G PAMAM Dendrimers. The active ester of folic acid in DMSO (25 mg/mL) and that of amine-terminated 4.0 G PAMAM dendrimers in DMSO (10 mg/mL) were mixed and stirred for

Table 1. Details of the Reactants and Products in the Synthesis of PAMAM Dendrimers

generation	moles of reactant[a]	moles of reactant in excess	product mol. wt.	number of surface functional groups
−0.5G	4 moles (400 g) MA	5% excess of 4 moles	404	4

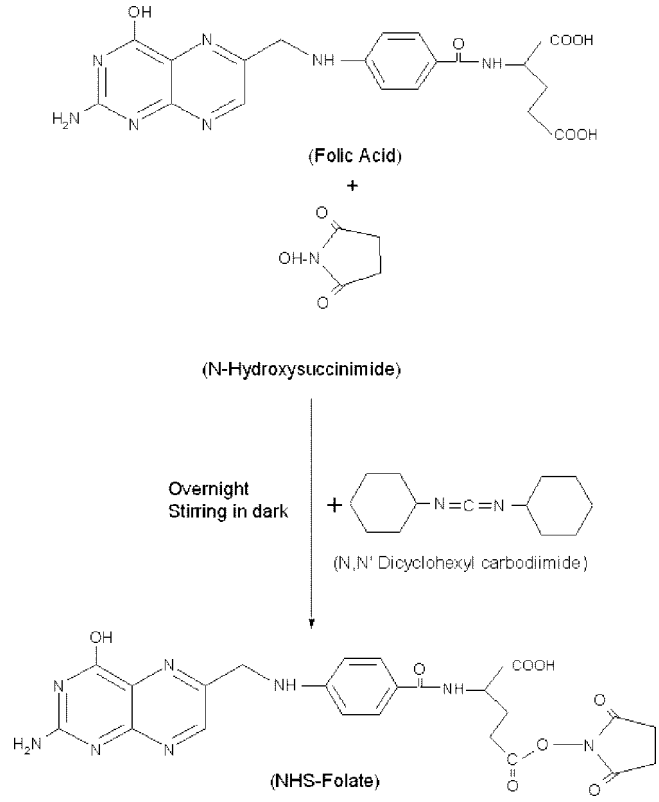
5 days at room temperature (25 °C) using a metabolic shaker. Acetone was added to the reaction mixture, and a yellow precipitate thus formed was collected by filtration and dried under vacuum. The crude product was dissolved in deionized water, and the pH was adjusted to 9.0 using 1 N NaOH solution. The solution was loaded to a Sephadex G-25 column using deionized water as effluent. Fractions containing the conjugate were collected, and the pH of the solution was adjusted to 3

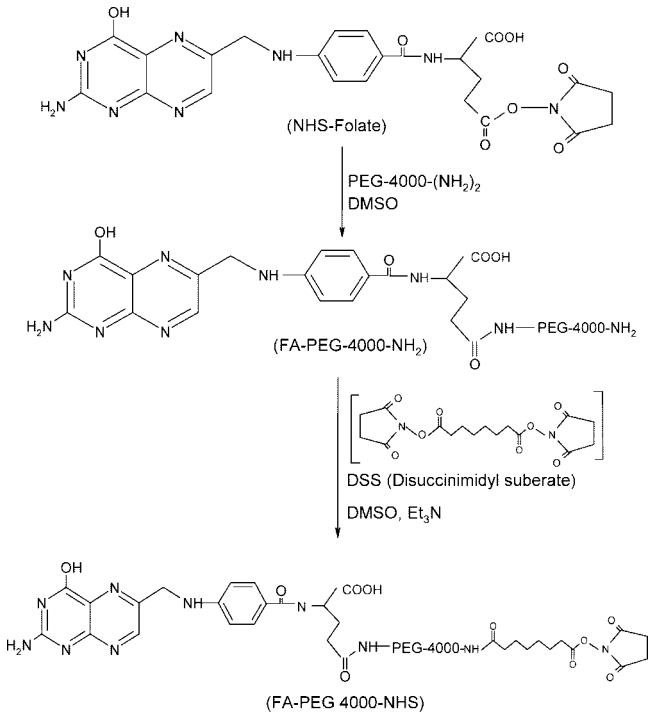
Scheme 2. Preparation of NHS Ester of Folic Acid



using 1 N HCl (*8*). The product was precipitated out, collected by filtration, and dried under vacuum.

Indirect Folic Acid Conjugation through PEG Spacer. Preparation of NHS-Activated Folate-Conjugated PEG. A similar method to that given in an earlier step was followed to obtain the NHS ester of folic acid. 65 mg (148 μmol) of FA-NHS (folic acid-*N*-hydroxy succinimide) ester was added to PEG-4000 bis-amine (900 mg, 225 μmol) in DMSO (5.0 mL) in the presence of triethylamine (4.0 μL). The mixture was stirred overnight, and the product was purified by filtration over a Sephadex G-25 column equilibrated with 0.1 M $NaHCO_3$ to remove unconjugated folic acid and unreacted PEG-bis amine fragments. Folate-containing product was detected by UV−visible spectrophotometer (Shimadzu 1601, Japan; absorbance at λ_{max} = 363 nm). The filtrate obtained was precipitated with acetone and dried under vacuum, yielding folate−PEG conjugate (NH_2-PEG-FA) as a pale yellow solid. Thereafter, 50 mg of the product was dissolved in DMSO (5.0 mL) containing triethylamine (4.0 μL) as a base, and a 10-fold excess of DSS (12.5 mg) was added. After stirring overnight, the PEG was precipitated by addition of acetone. The product was redissolved in DCM and filtered, and solvents were removed under reduced pressure. The product was then dissolved in DMSO and purified

Scheme 3. Synthesis of NHS-PEG4000-Folic Acid Conjugate from NHS-Folic Acid Conjugate



over a Sephadex G-25 column, using DMSO as an eluent (based on modified method) (*36*). The product was finally precipitated using acetone. NHS-PEG 4000-FA, so obtained (Scheme 3), was characterized at each step by IR spectroscopy. Important peaks in IR spectra were 3690.5 cm^{-1} (amide N−H and C═O stretching); 3400 cm^{-1} (primary aliphatic amine N−H stretching); 2911.5 cm^{-1} (alkyl C−H stretching); 112.5 cm^{-1} (strong peak of C−O of ether linkage); 1710.0 cm^{-1} (unconjugated C═O stretch); and 701.4 cm^{-1} (aromatic C−H bending), which confirmed the synthesis of NHS-PEG-FA.

Conjugation of NHS-PEG 4000-FA to 4.0 G PAMAM Dendrimers. The active ester NHS-PEG 4000-FA in DMSO (25 mg/mL) was conjugated to the amine-terminated 4.0 G PAMAM dendrimer in a similar manner to conjugation of FA-NHS in an earlier step (*8*).

Characterization of Folate Conjugated Systems. Synthesized folate conjugates were characterized by IR spectroscopy using the KBr pellet method. For NMR spectroscopy (Bruker Advance DRX 300, Country, Germany), folate conjugated 4.0 G PAMAM dendrimers were solubilized in D_2O using methanol as cosolvent and analyzed at 300.1299987 MHz. The electrospray mass spectra of folate conjugates were recorded on a Micromass Quattro II Triple Quadrupole mass spectrometer, similar to the PAMAM dendrimers. Similarly, TEM photomicrographs (Figure 1B,C) were taken at suitable magnifications using Philips Morgani, 268D; transmission electron microscope (Holland).

Drug Loading. 5-FU was loaded in PAMAM dendrimers and dendritic conjugates following the equilibrium dialysis method reported earlier (*39, 25*). Briefly, 1 mL of aqueous solution of 5-FU (1000 μg/mL) was mixed with 100 mg of 4.0 G PAMAM dendrimer, and the volume was increased to 10 mL with double-distilled water. The mixed solutions were incubated with slow magnetic stirring (50 rpm) using Teflon beads for 24 h. Percent drug encapsulation was confirmed indirectly through UV−visible spectrophotometry. The formulations having final drug concentrations were scanned against similar concentrations of dendritic solution without drug loading, as control (*40*). Similarly, drug was loaded in folic acid conjugated 4.0 G PAMAM (FA-PAMAM) and FA-PEG conjugated 4.0 G PAMAM (FA-PEG-PAMAM) dendrimers. The three different drug-loaded formulations so formed were drug-loaded 4.0 G PAMAM dendrimers (DF), drug-loaded folic acid conjugated 4.0 G PAMAM dendrimers (FA-DF), and drug-loaded FA-PEG conjugated 4.0 G PAMAM dendrimers (FA-PEG-DF).

***In Vitro* Studies.** *Entrapment Efficiency.* Ten milliliters each of three formulations (i.e., DF, FA-DF, and FA-PEG-DF) were taken separately in a cellophane bag (MWCO 12 000−14 000, Sigma, Germany). The contents were dialyzed under strict sink conditions against two portions of 50 mL water, and the unentrapped drug was allowed to pass out of the bag against perfect sink conditions for 10 min. The released drug was analyzed by UV−visible scanning after appropriate dilutions, indirectly. Similarly, dialyzed and diluted dendrimer solution without drug was taken as control. The percent entrapment of drug (% w/w in dendrimer solution) was determined indirectly.

In Vitro Release. For *in vitro* release studies, 5 mL of formulations (after complete removal of unentrapped drug) were taken in a dialysis bag and dialyzed against 100 mL of water as reservoir under sink conditions, separately. Aliquots of these formulations (i.e., DF, FA-DF, and FA-PEG-DF) were collected at hourly intervals for 24 h, and drug content was estimated by UV−visible spectrophotometer using water as control (*40*).

Hemolytic Toxicity. RBC suspension was obtained as per the well-known and reported procedure for hemolytic studies (*41*). Briefly, whole human blood was collected using heparin as anticoagulant in HiAnticlot blood collecting vials (Hi media, India) and centrifuged at 3000 rpm for 15 min. RBCs collected from the bottom were washed with normal saline (0.9% w/v) in double-distilled water until a clear, colorless supernatant was obtained above the cell mass. Cells were resuspended in normal saline. The RBC suspension so obtained was used further for hemolytic studies. To 1 mL of RBC suspension, 5 mL distilled water was added, which was considered to be 100% hemolytic. Similarly, 5 mL of normal saline was added to 1 mL of RBC suspension in another tube assumed to produce no hemolysis, hence acting as control. A half milliliter of formulation was added to 4.5 mL of normal saline and 1 mL of RBC suspension. Similarly, 0.5 mL of drug solution and 0.5 mL of dendrimer solution were taken in separate tubes and mixed with 4.5 mL of normal saline and 1 mL of RBC. Drug (i.e., 5-FU) and dendrimer in separate tubes were taken in such an amount that the resultant final concentrations of drug and dendrimer were equivalent in all the cases. The tubes were allowed to stand for half an hour with gentle intermittent shaking and were centrifuged for 15 min at 3000 rpm. The supernatants were taken and diluted with an equal volume of normal saline, and absorbance was taken at $\lambda_{max} = 540$ nm, against supernatant of normal saline diluted similarly, as control. The percent hemolysis was calculated for each sample by taking the absorbance of water as 100% hemolytic sample, using the following equation

$$\% \text{ hemolysis} = \left[\frac{AB_S}{AB_{100}}\right] \times 100$$

AB_S = Absorbance for the sample

AB_{100} = Absorbance for control

Similar procedure was followed for all the three formulations.

Stability Study. Formulations (i.e., DF, FA-DF, and FA-PEG-DF) were stored in tightly closed glass vials in dark (in amber colored vials) and light (in colorless vials) at 0 °C, room temperature (25−30 °C), and 50 °C (in controlled oven) for a period of seven weeks. Samples were analyzed weekly for up to seven weeks for any precipitation, turbidity, crystallization, change in color, consistency, and drug leakage. Data obtained

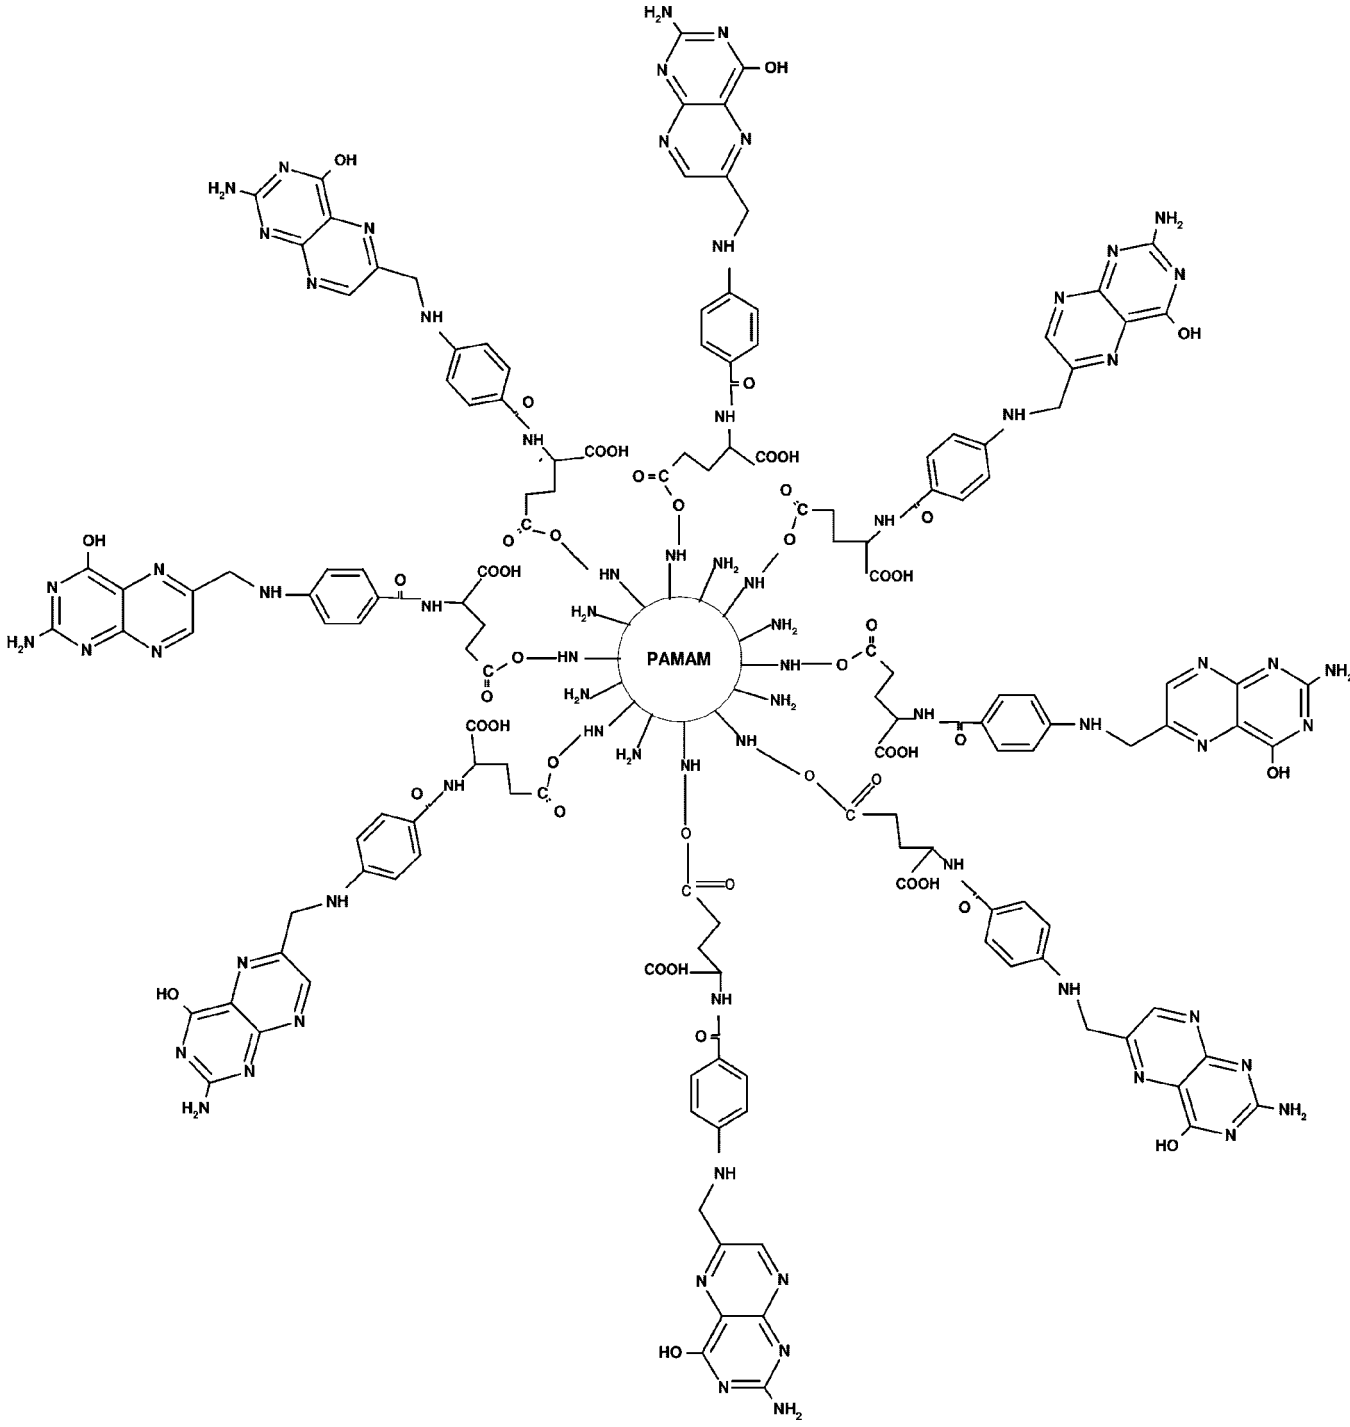


Figure 2. Chemical model structure of folic acid conjugated 4.0G PAMAM dendrimers.

were used for the analysis of any physical or chemical degradation, the required storage conditions, and the precautions required for storage. Leakage studies were performed for any increase in the release of drug from the formulations after storage at accelerated conditions. Formulations (2 mL) were kept in cellulose tubing (1200−1400 MWCO, Sigma, Germany) and dialyzed. The external medium (50 mL) was analyzed for content of the drug, spectrophotometrically. The procedure was repeated every week for up to seven weeks. The percentage increases in drug leakage from the formulations were used to analyze the effect of accelerated conditions of storage on the formulations (*6*).

***In Vivo* Studies.** *Tumor Induction in Mice.* Eight- to-nine-week-old female BALB/c mice (avg. body weight 25.0 ± 2.0 g) were used for the *in vivo* studies. The *in vivo* experimental protocol was duly approved by the Institutional Animal Ethical Committee of Dr. H.S. Gour University, Sagar, (M. P.) India. The KB cell line, which is human epidermoid carcinoma that overexpresses folate receptors, was purchased from the National Centre for Cell Science (NCCS, Pune; India), and grown continuously as a monolayer at 37 °C and 5% CO_2 in RPMI 1640 medium supplemented with penicillin (100 units/mL), streptomycin (100 μg/mL), and 10% heat inactivated fetal bovine serum (FBS). The culture was maintained *in vitro* for more than two months. KB cells were prepared for the injection in the female BALB/c mice. 1.5 mL 0.25% trypsin/1 mM EDTA solution was added and swirled to cover the plate and incubated at room temperature for 2 min, followed by addition of 5−7 mL serum-free media to harvest trypsinized cells from the plate and transfer to conical tube. These cells were centrifuged for 4

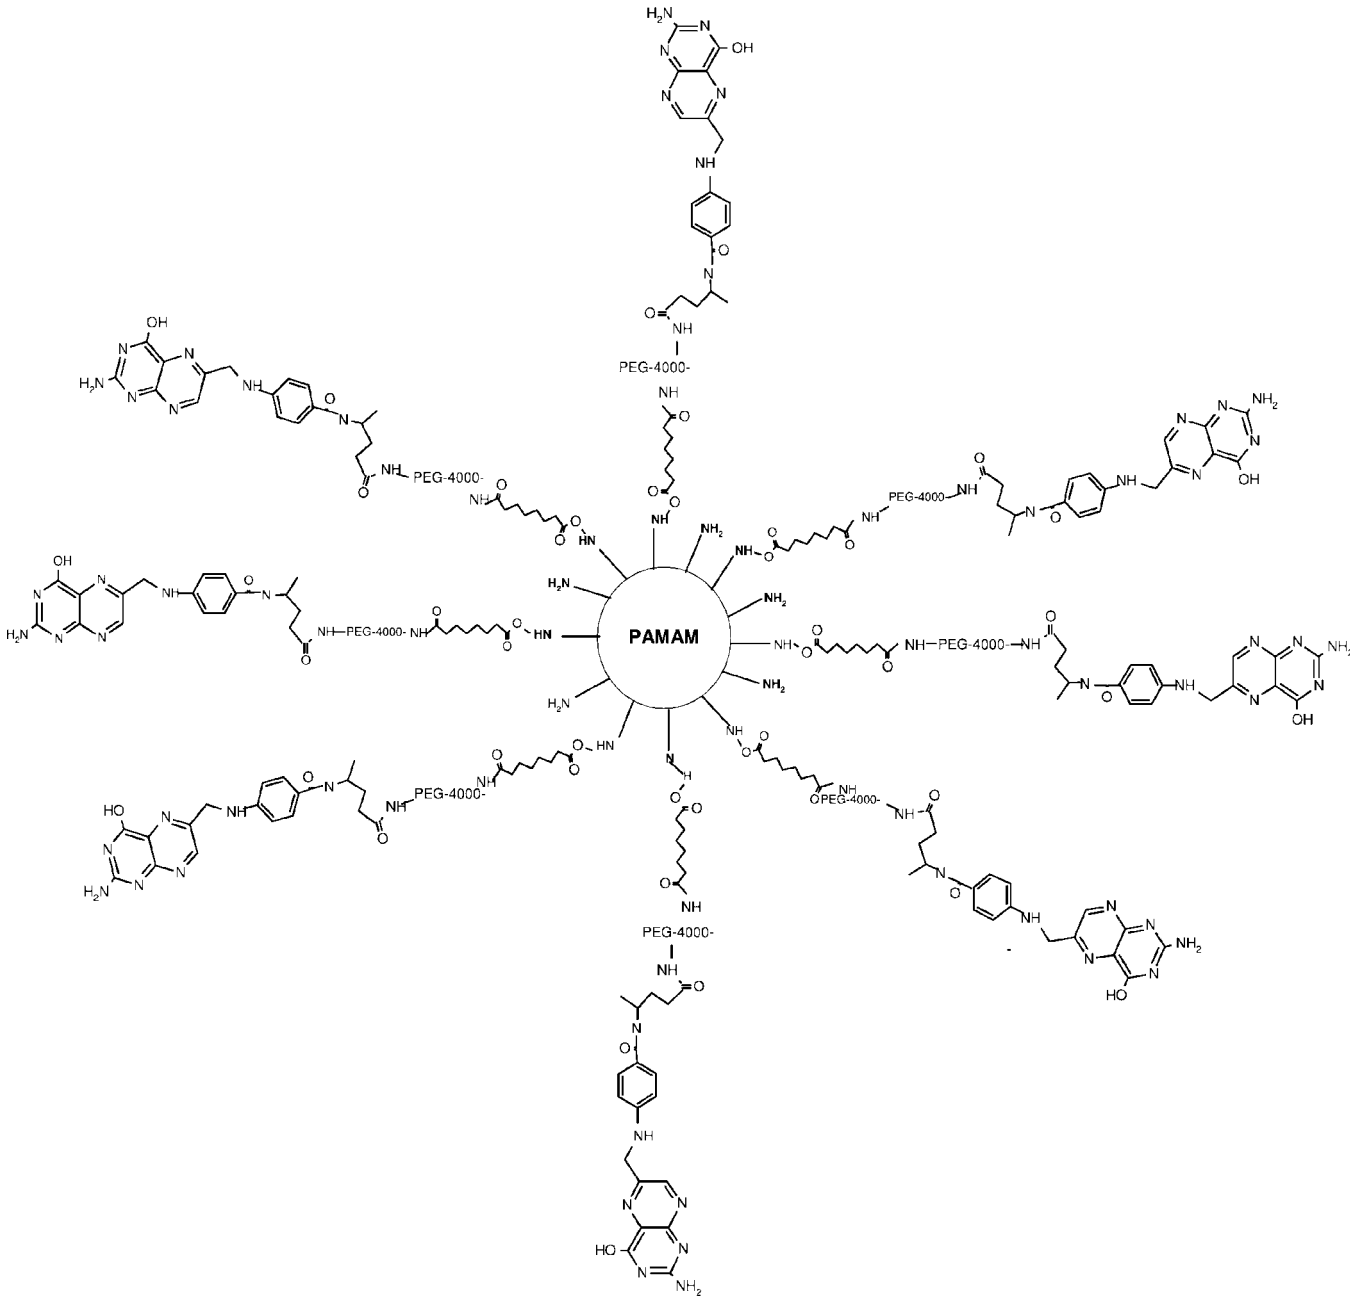

Figure 3. Chemical model structure of folic acid−PEG4000−4.0G PAMAM dendrimers.

min at 1200 rpm (25 °C); the supernatant was discarded and the pellet resuspended in serum-free medium. Cells were diluted with serum-free medium to the desired concentration (2×10^6 cells/0.2 mL) and placed on ice and injected cells immediately to maintain viability of cells. A tuberculin syringe (1 mL) was loaded with cells (KB tumor cells 2×10^6 cells/ 0.2 mL) using an 18-gauge hypodermic needle. Eight-week-old female BALB/c mice were maintained in hygienic and ventilated cages and fed a special low-folate diet (casein 100 g/kg, soya protein 100 g/kg, soyabean 70 g/kg, cellulose 47.5 g/kg, cornstarch 170 g/kg, sucrose 450 g/kg, mineral mix 45, folate-free vitamin mix 12.68 g/kg, choline 1.5 g/kg, BHT 0.014 g/kg, L-cystine 3.3 L-cystine) from one week prior to tumor inoculation until mice were sacrificed for *in vivo* performance (*42*). These KB tumor cells in serum-free medium suspension were inoculated in the subcutaneous space in the right flank of the mice. The mice were monitored daily for tumor onset by palpating the injection area with the index finger and thumb for the presence of the

tumor. Two to three weeks past inoculation, the mice injected with KB cells developed palpable solid tumors.

Pharmacodynamic Studies. Female BALB/c mice (avg. body weight 25.0 ± 2.0 g) were subcutaneously implanted with human epidermal carcinoma KB cells. Following the implantation, tumor cells were allowed to grow for another 21 days until well-established, at which time dosing with DF, FA-DF, FA-PEG-DF, and free drug solution (equivalent dose of 5-FU = 12 mg/kg) suspended in PBS was injected through tail vein of animals at day 0 and day 7. At a predetermined time, a major and minor axis of the tumor were measured using calipers. The formula used to compute tumor volume was as for the standard volume of an ellipsoid, where $V = 4/3\pi$ (1/2 length × 1/2 width × 1/2 depth) with an assumption that width equals depth and π equals 3; the formula (*43*) used was $V = 1/2 \times \text{length} \times \text{width}^2$.

Pharmacokinetic Studies. Calibration curves of 5-FU in serum and tissues of various organs were prepared using a reported HPLC method (*44*) with slight modifications. Briefly, a heparin-rinsed 1 mL tuberculin syringe was loaded with 0.1 mL heparin solution, and the anaesthetized female BALB/c mice, bearing appropriately sized primary tumors, was selected for the preparation of the standard curve. The chest cavity was opened with dissecting equipment to expose the heart. While the heart was pumping, the 27-gauge needle penetrated and blood was drawn into the 1 mL tuberculin syringe containing 0.1 mL heparin solution. Using scissors and forceps, organs and tumor were removed and weighed accurately. Later, they were placed in a separate well of a tissue culture plate containing HBSS in the freezer for further studies.

The blood sample was centrifuged at 3000 rpm for 10 min to separate RBCs and serum. The upper supernatant (serum) was collected separately with the help of a micropipette. The 100 μg/mL stock solution of 5-FU prepared in deionized distilled water was used, and aliquots of concentrations of 0.1, 0.3, 0.5, 1.0, 5.0, and 10.0 μg/mL in 10 mL volumetric flasks were prepared. From each of these concentrations, 100 μL (0.1 mL) volumes were withdrawn and transferred to labeled microcentifuged tubes. To each of these tubes, 100 μL of serum was added, and the tubes were vortexed at high speed for 10 min. After vortexing, the volume in each tube was increased to 1000 μL by adding 800 μL deionized water to get a concentration range 100−10 000 ng/mL. The prepared stocks were vortexed for another 10 min and then centrifuged at 3000 rpm at 15 °C (Beckman GS-15R microcentrifuge, USA). A control was also prepared in a similar fashion after adding 900 μL of deionized water to 100 μL of serum by vortexing and centrifuging at 3000 rpm at 15 °C. From each of these preparations, clear supernatant was removed and filtered through a 0.22 μm membrane filter (Gelman filter, Mumbai, India) using a syringe filtration assembly to a microcentrifuge tube. The drug sample in serum was in this way ready for preparation of the calibration curve. The retention time of drug was found to be 3.7 min.

Similarly, the drug samples in tissue of various organs like liver, spleen, kidney, and tumor were prepared. To each organ, the required amount of deionized water was added and homogenized for few minutes, followed by centrifugation at 4000 rpm, and the supernatant of each organ tissue was collected separately. The proper dilutions of tissue supernatant and drug concentration were made using deionized water to get a suitable concentration range. A set of concentrations were prepared for each organ.

The calibration curve data was obtained in the range 100−10 000 ng/mL. The HPLC column (Shimadzu, C_{18}, Japan) was cleaned thoroughly with deionized water and then with the mobile phase [water/methanol (85:15)]. The samples starting from blank to increasing concentration were injected and run through an HPLC column. The flow rate was kept at 1.0 mL/min at pressure of 102/101 bar, and the run time was adjusted to 10 min. The observations were taken at 260 nm wavelength in consideration of its retention time (RT) and area.

Biodistribution Studies. On the basis of the results observed in pharmacodynamic studies, FA-PEG-DF was found to be the most suitable in terms of efficacy and potential to carry 5-FU. This formulation (FA-PEG-DF) along with FA-DF was selected for further pharmacokinetic and tissue distribution studies in BALB/c mice (avg. wt. 25.0 ± 2.0 g) with KB cell induced tumor on their right flank as described earlier. Constant temperature conditions were maintained in the laboratory, avoiding any kind of stress on mice.

Mice were divided into three groups with each group comprising 12 tumor-induced mice and marked properly. Formulations (FA-PEG-DF and FA-DF) and plain drug (D) solubilized in saline at dosage of 12 mg/kg body weight were administered through the intravenous route in mice, separately. Following administration, blood samples were collected from

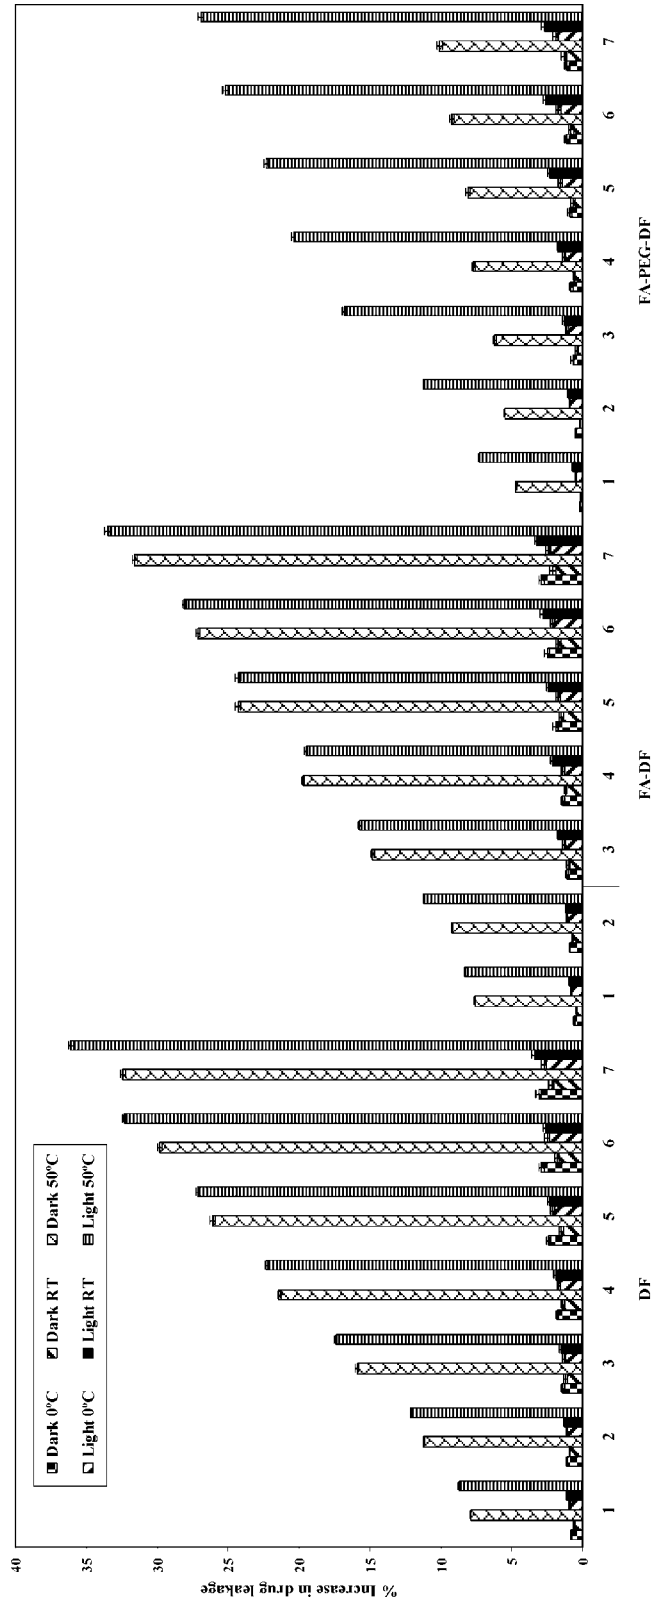

Figure 6. Percent increase in drug leakage from DF, FA-DF, and FA-PEG-DF formulations at accelerated conditions. Values represent means ± SD ($n = 4$).

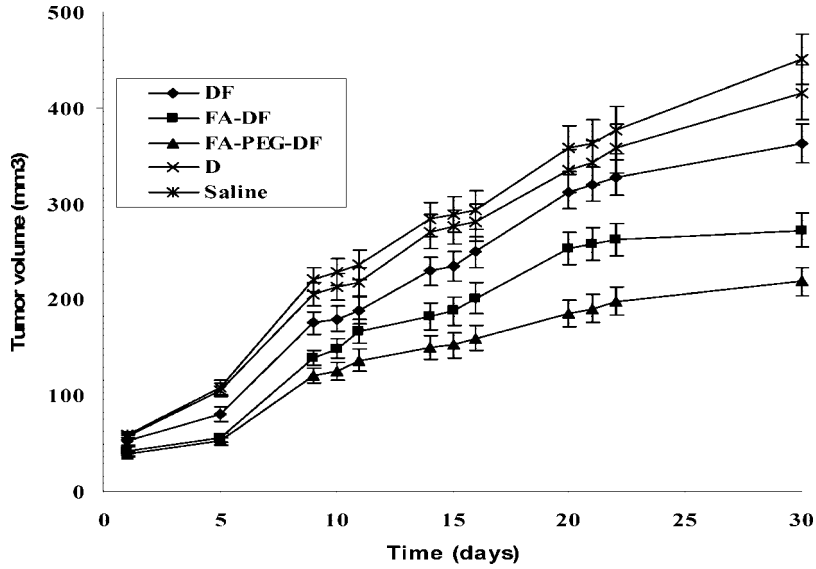

Figure 7. Screening data for tumor growth.

Table 3. Pharmacokinetic Parameters of DF, FA-DF, and 5-FU in Serum of BALB/c Mice[a]

formulation	AUC (0→t) (μg/mL/h)	MRT (h)	C_{max} (μg/mL)	t_{max} (h)
5-FU	19.96	0.09	31.8	0.1
FA-DF	19.78	0.58	4.2	1−2.5
FA-PEG-DF	14.16	1.21	1.28	2.5−5.0

[a] AUC = area under the curve, MRT =mean residence time, C_{max} = maximum drug concentration, t_{max} = time of peak concentration.

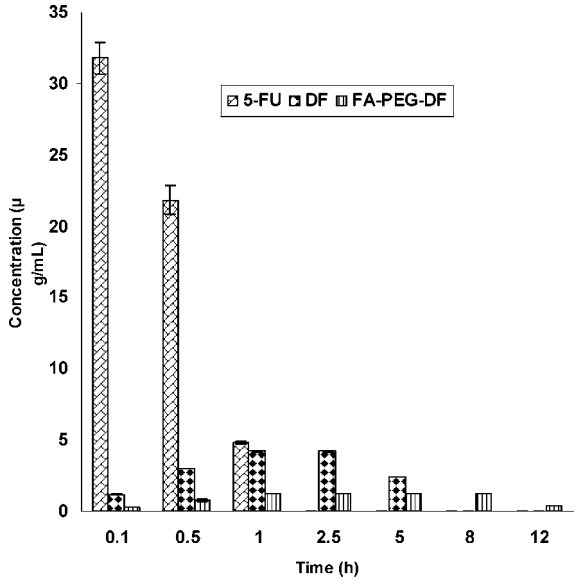

Figure 8. Plasma concentration vs time studies with the formulations DF and FA-PEG-DF.

tail vein at 0.1, 0.5, 1.0, 2.5, 5, 8, 12, and 24 h intervals. Not more then 0.3 mL withdrawals from each mouse were taken. In each case, blood was centrifuged at 3000 rpm for 10 min to separate RBCs and serum. The upper supernatant (serum) was collected separately with the help of a micropipette, mixed with 2 mL of ethyl acetate, and subsequently centrifuged to remove the organic layer, evaporated to dryness, and resuspended in the mobile phase for analysis of the presence of drug.

For biodistribution studies, mice were again divided into three groups with twelve mice in each. Each group received the same intravenous dose of different formulations and 5-FU similar to pharmacokinetic studies. Four mice from each group were sacrificed at 2, 8, and 24 h. Immediately after sacrificing the mice, organs, viz., spleen, kidney, liver, and tumor were carefully removed and weighed. Each of these specimens was stored under deep-freeze condition (−70 °C). Weighed tissue samples were suspended in 2 mL ethyl acetate and homogenized for 5 min. The homogenate was transferred to Eppendroff tube and centrifuged at 3000 rpm for 10 min at 4 °C. The organic layer was subsequently transferred into a second tube and evaporated to dryness under vacuum. The compound was resuspended in 1 mL of the mobile phase, vortexed, and then stored at deep-freeze condition (−70 °C) and analyzed for 5-FU by HPLC. In addition, one separate group of mice was injected with 181 mmol folic acid. This group was administered an equivalent dose of FA-PEG-DF, similar to the previous group through intravenous route, 15 min after administration of free folic acid. The pharmacokinetic and biodistribution parameters were calculated. The plasma concentration vs time were fitted to a biexponential equation

$$C_{(t)} = A_1 \times e^{-k_1 \times t} + A_2 \times e^{-k_2 \times t}$$

where $C_{(t)}$ is the drug concentration (*y*-axis) at time *t* (*x*-axis), A_1 and A_2 are the *y*-intercepts, and k_1 and k_2 are the slopes of apparent first-order elimination rate constants.

RESULTS AND DISCUSSION

Synthesis and Characterization of 4.0G PAMAM Dendrimers. Synthesis was carried out, taking increasing amounts of reactants in every progressive step (Table 1). Preliminary completion of synthesis was confirmed by copper sulfate color reaction, which results in a purple/blue color on reaction with primary amines. Full generations of the PAMAM dendrimers (e.g., 1.0G, 2.0G, 3.0G, etc.) gave purple color, whereas half-generations gave deep blue color, due to copper chelation at the terminal groups of dendrimers (*27*). Dendrimers were found to be oily liquids, and the intrinsic viscosity was higher in the case of full generation than half-generations, on complete removal of excess solvents and reagents. The color as seen was yellowish/ deep yellow to honey-like, and higher generations were found to be glassy masses.

IR, NMR, and ESI mass spectroscopy confirmed dendritic synthesis. In IR spectrum, the N−H stretch of surface primary amines was obtained at 3350.2 cm^{-1}, and the peak at 1641.3 cm^{-1} indicated the presence of −C═O groups in dendrimers. In NMR spectroscopic studies, chemical shifts of -CH_2NH_2

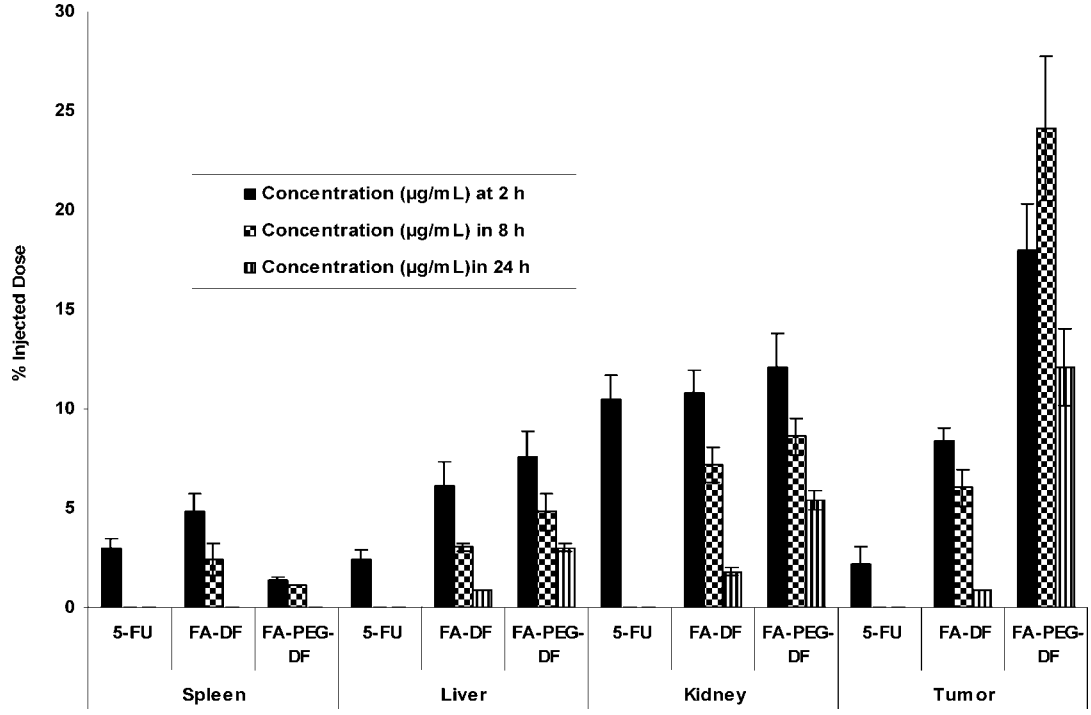

Figure 9. Tissue distribution data of plain drug (5-FU) and different formulations at different time intervals. Values represents means ± SD (n = 6).

terminal groups were obtained between δ 3.1 and 3.4 ppm, while peaks between δ 2.5 and 2.9 indicated the presence of amide NH in the structure. The NMR and IR spectra were found to be in accordance with the structure of PAMAM dendrimers (Scheme 1). The theoretical mass of the 4.0 G PAMAM dendrimers is about 14 196, and the report of the ESI mass study was 14 210; which is very close to the theoretically calculated mass (Table 1). TEM photographs of prepared 4.0 G PAMAM dendrimers revealed (Figure 1A) the size range of around 100 nm (*25, 27*).

Folic Acid Conjugation to 4.0 G PAMAM Dendrimers. The conjugation of folic acid on 4.0 G PAMAM dendrimer was accomplished using two methods by direct conjugation on the periphery and through the PEG spacer (Figures 2 and 3).

Direct Conjugation of Folic Acid. In the direct conjugation, NHS ester of folic acid (Scheme 2) was synthesized using DCC, NHS, and triethylamine (TEA) following a reported method (*38*). This NHS activated folic acid was conjugated to PAMAM dendrimers (*8*), and the synthesized folate conjugates were characterized using IR, NMR, and mass spectroscopy, which will be discussed in further sections.

Folic Acid Conjugation through PEG (Indirect Conjugation). In the second method, attachment of folic acid was accomplished through use of a PEG spacer, i.e., PEG bis amine (H_2N-PEG-4000-NH_2). PEG bis amine (NH_2-PEG 4000-NH_2) was synthesized in three successive steps (*37*), in which PEG-4000 was converted to Cl-PEG-4000-Cl using thionyl chloride and dry pyridine, then Cl-PEG-4000-Cl was converted to N_3-PEG-4000-N_3 using sodium azide, and thereafter N_3-PEG-4000-N_3 was used to get NH_2-PEG-4000-NH_2 (PEG bis amine) by a simple hydrogenation step (Catalytic Hydrogenator, Superfit, India) using Raney Nickel as catalyst. PEG bis amine synthesis was confirmed by IR spectroscopy at each step. The IR spectrum of PEG 4000 revealed peaks at 3430.7 cm^{-1} (O−H stretch); 1282.6 cm^{-1} (O−H deflection); 2886 cm^{-1} (C−H stretch); 1244 cm^{-1} (C−O deflection); 1112.5 cm^{-1} (strong peak of C−O stretch of ether), and so forth. Cl-PEG-4000-Cl displayed peaks at 670.2 cm^{-1} (strong, C−Cl stretch) and absence of O−H stretch peak at 3430.7 cm^{-1}, which was evident in PEG 4000. In the next step, conversion of Cl-PEG4000-Cl to N_3-PEG-4000-N_3 was confirmed through a peak at 2108 cm^{-1} (presence of N_3 groups). The last step in the synthesis of PEG bis amine was conversion of N_3-PEG-N_3 to H_2N-PEG-NH_2, which was again confirmed through the presence of N−H stretch of primary amines at 3350.2 cm^{-1}. Other important peaks obtained were at 3190.0 cm^{-1} (N−H stretch antisymmetric of substituted primary amine); 1566.0, 1471.7, 1327.9 cm^{-1} (N−H bending of N substituted amide); 3245.0 cm^{-1} (quaternary ammonium ion peak), and so forth.

NHS-activated folate-conjugated PEG was obtained through a series of aforementioned reaction sequences and was conjugated to amine-terminated 4.0 G PAMAM dendrimers similar to NHS-FA conjugation, as explained earlier (Scheme 3).

Characterization of Folic Acid-PAMAM and Folic Acid-PEG-PAMAM Conjugates. Conjugation of folic acid through both strategies (Figures 2 and 3) was again confirmed through IR, NMR, and ESI mass spectroscopic techniques. IR spectrum of FA-4.0 G PAMAM dendrimers revealed aromatic C−H bending at 826.6 cm^{-1}; ester unconjugated C═O stretching at 1262.5 cm^{-1}; and aromatic C═C bending and stretching at 1655.9 cm^{-1} due to attachment of folic acid, which contained aromatic rings. The IR spectrum of FA-PEG-4.0 G PAMAM dendrimers showed a strong and sharp peak of the C−O stretch ether linkage at 1117.8 cm^{-1}, which was due to the polyether b*a*ckbone of PEG, while other important peaks, which confirmed the conjugation, were at 2922.5 cm^{-1} (carboxylic acid C═O and O−H stretch unconjugated); 1626.4 cm^{-1} [aromatic C═C bending and stretching); 1461.4 cm^{-1}1 (CH−NH−C(═O) amides bending], and so forth. NMR spectral chemical shifts of folate-conjugated 4.0 G PAMAM dendrimers further confirmed conjugation. In FA-4.0 G PAMAM, a newer peak of R−(C═O)−NH−CH_2−CH_3 of folic acid linkage appeared at δ 1.0−2.0 ppm. Similarly, in FA-PEG 4.0 G PAMAM conjugate, a newer peak of the ether group of PEG appeared at δ 3.665 ppm, which was in contrast to its total absence in the 4.0 G NMR spectrum. The ESI mass of FA-4.0 G PAMAM

was 17 295, and for FA-PEG-4.0 G PAMAM, it was 49 730. The increase in mass after conjugation suggested that at least seven molecules of folic acid were attached by direct conjugation and eight molecules through PEG spacer. The electron microscopic analysis of dendrimers proves them to be nanometric, which was evident from TEM photographs (Figure 1B,C). The photographs revealed an increase in particle size on folate conjugation directly as well as through PEG spacer (*25*).

***In Vitro* Studies.** *Drug Loading, Formulation Development, and Entrapment Efficiency.* The drug, 5-FU, was encapsulated in all the conjugates, i.e., 4.0 G PAMAM dendrimer, folic acid−PAMAM dendrimer conjugates, and folic acid−PEG−PAMAM dendrimer conjugates. Drug loading was accomplished by the equilibrium dialysis method, i.e., excess drug interaction for prolonged duration with the dendrimeric systems. The loading of drug in PAMAM dendrimers as well as conjugates (FA-PAMAM, FA-PEG-PAMAM) was confirmed through UV−visible spectroscopy. Modified values of λ_{max} were observed and compared to the values of λ_{max} of 5-FU. Drug encapsulation was determined indirectly through dialysis using cellulose membrane (MWCO 12 000−14 000) and measuring the amount of unentrapped drug in the external sink. The data depict that there was less drug entrapment and retention inside the PAMAM (6.84% w/w) and FA-PAMAM (11.47% w/w) dendrimeric systems compared to the FA-PEG-PAMAM (31.45% w/w) dendrimeric system. Drug encapsulation was accomplished in both conjugates and PAMAM dendrimers through the equilibrium dialysis method. Encapsulation might be facilitated by hydrophilicity and aqueous partitioning of the drug molecules within the dendritic structures of folate conjugated and nonconjugated species. The formation of dendrimer−drug complex was confirmed indirectly, spectrophotometrically (*40*). Drug encapsulation was highest in the case of folic acid−PEG−PAMAM conjugates, which might be due to increased internal architecture of these conjugates leading to increased loading of the drug.

In Vitro Release and Hemolytic Toxicity. In vitro release studies were performed in the water under perfect sink conditions. The rate of drug release from FA-PEG-DF (49.6 ± 2.12% in 24 h) was observed to be lower compared to DF (92.3 ± 4.09% in 24 h) and FA-DF (71.4 ± 3.12% in 24 h) formulations (Figure 4). The rate of drug release of FA-PEG-DF was observed to be slowest, which could possibly be due to more dense and bulky (FA-PEG) surface-attached molecules providing a closed structure. The release pattern also indicated sustained release behavior of the drug for this formulation.

The hemolytic toxicity of the dendrimers imposes a constraint on its use as a drug delivery system. The toxicity is attributed to the polycationic nature of the PAMAM dendrimers. The percent hemolysis of RBC's with DF (18.67 ± 0.92%; $n = 6$) was comparatively higher, which may be a constraint on its use as a drug delivery system. However, FA-PEG-DF drastically reduced the hemolysis of RBC compared to FA-DF (Figure 5) from 15.47 ± 0.71% to 5.74 ± 0.28% ($n = 6$), which might be due to surface conjugation of the terminal -NH_2 groups by PEG resulting into increased biocompatible surface.

Stability Studies. The formulations were found to be most stable in the dark at room temperature. Formulation FA-PEG-DF displayed the best stability among all formulations (Table 2). Drug leakage was a minimum at room temperature compared to 0 and 50 °C for seven weeks, possibly due to the conformational change of the dendritic structure leading to a decrease in drug enclosing cavity (Figure 6). A drug leakage study again revealed that the FA-PEG-DF formulation was more stable than FA-DF and DF formulations. Finally, the FA-PEG-DF formulation was selected for further *in vivo* studies.

***In Vivo* Studies.** *Tumor Induction.* Female BALB/c mice were used for the tumor induction through KB cell lines. The mice were monitored daily for tumor onset by palpating up to three weeks.

Pharmacodynamic Studies. Pharmacodynamic studies were carried out to evaluate therapeutic efficacy of various dendritic formulations and plain drug solution (5-FU in PBS 7.4). The data obtained for each group were divided on the basis of different dendritic formulations, i.e., DF, FA-DF, FA-PEG-DF, plain 5-FU solution, and saline, as presented in Figure 7. As compared to drug (5-FU) entrapped in plain dendrimer (DF), folate conjugated PEG-4.0 G PAMAM (FA-DF) displayed a significant difference ($p < 0.05$) of the tumor growth with time. It was observed that after 20 days tumor volumes for mice treated with FA-PEG-DF and FA-DF were about 40% and 19% of those treated with DF. Also, from the tenth day onward (Figure 7) a significant difference in tumor growth was observed among the two formulations FA-DF and FA-PEG-DF. This may be attributed to the fact that the PEGylated system might be affecting 5-FU release, as observed previously in the *in vitro* data, justifying a relatively slow release compared to FA-DF and DF. Further, the FA-PEG-DF formulation, possibly due to prolonged systemic circulation, might have increased the chances of extracellular drug concentration at the tumorous site, which reflected better therapeutic potential at all time intervals in the pharmacodynamic study.

Pharamacokinetic Studies. Pharamacokinetic studies were carried out following intravenous administration to study the effect of PEGylation on the release profile and retention of dendritic formulations in systemic circulation. Serum concentrations of FA-PEG-DF were found to possess lower C_{max} compared to DF (Table 3 and Figure 8). However, the duration of C_{max} in the case of FA-PEG-DF was prolonged, i.e., from 2.5 to 8 h. This behavior was similar to the *in vitro* release profile, where drug release was lower in the case of FA-PEG-DF than that of DF (Figure 4). Also, FA-PEG-DF retarded the release of drug compared to the plain drug. Plasma drug concentration with DF was detected until the fifth hour, and thereafter no drug was detected. MRT of FA-PEG-DF was found to be near 12- and 3-fold that of free drug (5-FU) and DF, respectively. This indicated slow release of the drug from PEGylated dendritic systems compared to non-PEGylated and plain drug. Also, plasma concentration vs time studies revealed prolonged retention of PEGylated dendritic formulation (t_{max}, 2.5−5.0 h) in systemic circulation (Figure 8), although the blood level of the drug was observed to be lower at all time intervals as compared to DF and the plain drug solution (Table 3).

Biodistribution Studies. Biodistribution studies were conducted to evaluate drug delivery at various sites of interest, especially tumor. Plain drug, DF, and FA-PEG-DF formulations were found to have greater access to kidney (Figure 9). In the case of DF, drug concentration decreased rapidly, compared to FA-PEG-DF. The plain drug was not detected at the 8th and 24th hours of sampling. This observation suggests that kidney is the major clearance organ for dendritic systems and the bioactivity accounts for the higher concentration there. The kidney is known to express high levels of the folate receptors (*45*) and probably retained FA-PEG-DF for a longer duration compared to DF.

DF and FA-PEG-DF concentrations in liver were found to be considerably higher. However, DF concentration declined more rapidly compared to FA-PEG-DF. The liver, like the kidney, expresses high levels of folate receptors (*46*), thus supporting the larger uptake of FA-PEG-DF; whereas DF, although achieving higher concentration, was not retained for a long time. The drug levels observed in organs with both dendritic formulations, viz., DF and FA-PEG-DF, were higher as compared to plain drug. However, FA-PEG-DF was found to have scored much better against DF (Figure 9).

The drug levels observed in tumor tissues with both dendritic formulations, viz., DF and FA-PEG-DF, were higher compared to plain drug. However, FA-PEG-DF was found to have scored much better against DF (Figure 9). As folate receptors are expressed on solid tumors created by KB cells, the FA-conjugated dendritic formulation, FA-PEG-DF, displayed up to 15.5%, 20.1%, and 10% of ID (injected dose) at the 2nd, 8th, and 24th hour, respectively, at the tumor sites; whereas with DF, the scores were much lower, i.e., 7%, 5%, and 1.0% at 2nd, 8th, and 24th hour, respectively. In the case of plain drug, no active ingredient was detected at the 8th and 24th hour sampling. This indicated the localized action and higher retention potential of FA-PEG-DF at the tumorous site, thereby enhancing therapeutic efficacy. This above effect can be attributed to a synergistic effect of the modified vasculature at the tumor site as well as to the overexpression of folate receptors.

The specificity of targeted drug delivery was further addressed in a group of mice receiving 181 mmol folic acid 15 min before injection with FA-PEG-DF. At the eighth hour after injection, less than $0.5 \pm 0.01\%$ accumulation was observed in the tumor tissue. However, in the case of FA-PEG-DF administered to the group without prior dosing of free folic acid, up to $15.0 \pm 2.3\%$ drug uptake was noticed. This reduction in specificity may be attributed to blocking of the folate receptors with free folic acid at the tumorous tissue. This suggests that the difference in targeted and nontargeted dendritic conjugates is possibly due to specific uptake of these molecules through folate receptors overexpressed in the tumor.

The major drawback associated with anticancer drugs is their cytotoxicity and reduced availability of the appropriate dose at the tumor. The treatment of cancer requires the development of a "safe" and "effective" dosage form. The conventional mode of administration of such bioactives leads to their interaction with cancerous as well as normal cells. This not only precipitates toxicity but also adds to a considerable loss of dose before reaching the desired site. Any attempt to slightly modify the chemical structure of the drug to achieve results may reduce its efficacy. At the same time, the carrier systems need to be so designed that they bind to target cells as a result of their intrinsic affinity. An attractive approach may be the use of "ligands" that facilitate homing of therapeutic moieties at specific epitopes. The specific and selective binding of a ligand to its receptor site determines the biodistribution of anticancer drugs and hence exerts control over the pharmacokinetic properties of the drug (*47*, *48*). Dendrimers today are among the efficient carriers for drug delivery purposes. However, recently, emphasis of today's dendrimer research for drug delivery is mostly on surface-engineered dendrimers (*29*) pertaining to biocompatibility and toxicity (*28*) associated with the parent dendrimers like PAMAM (*49*) and PPI (polypropylene imine) dendrimers. To avoid the possible hazards in cancer chemotherapy, folate-based PAMAM dendritic systems having PEG residues were selected as drug carriers. The system was hypothesized to have the drug (i.e., 5-FU) within its internal cavities, which are shielded by exterior groups linked to folic acid and folate−PEG ligands. Earlier, this approach was proven to be efficient in anticancer drug targeting (*9*, *35*). The present study suggests that the PEGylation of dendrimers can extend the circulation time, and folate-conjugated systems may support the site-specific delivery of the bioactives. The developed formulation might be acting through the EPR effect as well as receptor-mediated endocytosis (RME), providing synergistic action thereby enhancing the therapeutic potential.

Conclusively, engineering of the dendritic surface with a targeting ligand such as folic acid can enhance the site-specific anticancer drug delivery. PEGylation of dendrimers can improve the circulation time of dendrimers in the body. In the present study, combination of both of these approaches displayed promising results in terms of efficacy and longer circulation time in the body. The present study was aimed at designing PAMAM dendrimers with more biocompatibility and less toxicity, but at the same time the ability to deliver drug at the desired site of action. The reduced toxicity and enhanced efficacy with FA-PEG-DF can be used most suitably as a controlled and targeted drug delivery system for the delivery of anticancer drugs like 5-FU. The formulation can be given through the intravenous route as a long-term circulatory nanoparticulate system.

ACKNOWLEDGMENT

The authors would like to acknowledge University Grants Commission (UGC) New Delhi, India, for the financial support to conduct this study.

Lactoferrin (LF) is an iron-binding glycoprotein that possesses multifunctional biological activities. Recent reports from clinical trials suggest that LF is potentially effective as a therapeutic protein against cancer and gangrene. However, pharmaceutical proteins such as LF are unstable in vivo. Therefore, to improve stability, we developed mono-PEGylated bovine LF (20k-PEG-bLf) with branched 20 kDa (2 × 10 kDa) poly(ethylene glycol) (PEG). We examined in vitro activities such as iron binding, IL-6 cell based assay, and resistance to a proteolytic enzyme in artificial gastric fluid. The 20k-PEG-bLf protein was fully active in iron binding and exhibited 69.6 ± 2.9% (mean ± S.E., $n = 6$) of the original anti-inflammatory activity. The proteolytic half-life increased 2-fold over that of unmodified LF. In vivo pharmacokinetic analyses were performed to examine absorption from the intestinal epithelium and serum clearance. Direct administration of 20k-PEG-bLf (30 mg/kg) into rat stomachs demonstrated that the amount of absorption from the intestinal tract increased approximately 10-fold relative to unmodified LF. Intravenous injection of the protein (1 mg/kg) revealed that 20k-PEG-bLf prolongs serum half-life by approximately 5.4-fold, and that the area under the curve (AUC) was increased approximately 9.2-fold compared to that of unmodified LF. PEGylation improved the physical and pharmacokinetic properties of bovine LF. This is the first report on the use of bioconjugation of LF for the development of a promising oral pharmaceutical agent.

INTRODUCTION

Lactoferrin (LF)[1] is an 80-kDa member of the transferrin family of iron-binding glycoproteins that is found in biological fluids such as milk, blood, cervical mucus, seminal fluids, saliva, and tears, and within the specific granules of polymorphonuclear leukocytes (*1*). It is a multifunctional protein that exhibits antimicrobial (*2*−*4*), antiviral (*5*), immunomodulation (*6*), antioxidation (*7*), anti-inflammation (*8*, *9*), antistress (*10*), and analgesic (*11*) effects, as well as enhancement of lipid metabolism (*12*). At present, LF is a commercially available fortified dairy product, but this multitude of biological activities has created great interest in the use of LF in drug discovery.

Agennix, Inc. (USA) has reported that orally administered Talactoferrin, an immunomodulatory recombinant human lactoferrin preparation, was effective in the treatment of patients with diabetic neuropathic foot ulcers (*13*) and in non-small-cell lung cancer (NSCLC) therapy in combination with cisplatin treatment in a phase I/II clinical trial (*14*). Talactoferrin has also been used in a recent renal cell carcinoma clinical trial (*15*). These findings suggest not only that LF is beneficial as a food supplement, but that it might also serve as a protein-based drug. In addition, LF reportedly inhibits hepatitis C viral entry into cells, suggestive of a use as a hepatitis C therapeutic agent (*16*−*18*).

Food proteins are generally absorbed from the intestine and transferred to the portal system, but the protein absorption dynamics of bovine LF (bLF) is extremely unique (*19*−*21*). Intact bLF goes directly to the intestine and is absorbed from intestinal epithelial cells by two possible pathways, specific receptor-mediated transcytosis and nonselective transcytosis. The incorporated bLF is then shifted to the lymphatic system, not the portal system, and transferred to the thoracic duct lymph. Thereafter, bLF enters systemic circulation. Accordingly, it is absolutely necessary that intact bLF reach and be absorbed from the intestine for it to exert its biological activities.

Native bLF has the drawback that it is susceptible to digestive juices. This phenomenon results in only a small amount of delivery to the intestinal tract. Therefore, enteric-coated (*22*) and liposomal formulations (*23*) have been developed to increase absorption efficiency of intact bLF.

Attempts have been made to alter biological therapeutic proteins, such as cytokines and antibodies, by covalent modification with a macromolecular substance, such as poly(ethylene glycol) (PEG). This technique, known as PEGylation, is used in drug delivery systems to improve the physical and pharmacokinetic properties of the native proteins (*24*). PEGylation imparts diminished immunogenicity and improved pharmacokinetic behavior (e.g., proteolytic resistance due to steric hindrance, inhibition of renal clearance due to the increased molecular mass after PEGylation), culminating in better pharmacological effects. Many proteins have been successfully PEGylated, including interferon-α (*25*, *26*), asparaginase (*27*), G-CSF (*28*), adenosine deaminase (*29*), and growth hormone receptor antagonist (*30*), and are now marketed drugs. To date,

most pharmaceutical proteins (including cytokines, antibody preparation, and PEGylated proteins) must be administered by subcutaneous, intramuscular, or intravenous injection in a hospital. Parenteral administration, however, places a burden on patients due to frequent hospital visits, increased costs, and difficulty and discomfort in self-injection. This has stimulated interest in the investigation of orally administered pharmaceutical proteins to improve the patients' quality of life; however, the progress to date in developing orally administered protein drugs has been inadequate (*31, 32*). The goal of this study was to develop a bLF amenable to oral administration by conjugating the protein to a branched PEG with a molecular mass of 20 kDa. We synthesized PEGylated bLF (20k-PEG-bLf) and characterized the in vitro biological activities and in vivo pharmacokinetics.

MATERIALS AND METHODS

Materials. Bovine lactoferrin (bLF) was acquired from MG Nutritionals (Melbourne, Australia). A 20-kDa (2 × 10 kDa) branched PEG of *N*-hydroxysuccinimidyl derivative (PEG-NHS, SUNBRIGHT GL2−200GS2) was purchased from the NOF Corp. (Tokyo, Japan). Heparin Sepharose 6 Fast Flow and PD-10 desalting columns were supplied by GE Healthcare (Uppsta, Sweden). Centriplus was supplied by Millipore (Billerica, MA). Titrisol, a concentrated iodine solution, was purchased from Merck KGaA (Darmstadt, Germany). Recombinant human IFN-γ was acquired from R&D systems (Minneapolis, MN). Calcitriol was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). LPS from *E. coli* O127:B8 was purchased from Sigma (St. Louis. MO). The Cell Counting Kit-8 was purchased from Dojindo laboratories (Kumamoto, Japan). The Human IL-6 ELISA Kit was purchased from Kamakura Techno-Science (Kanagawa, Japan).

Experimental Animals. Wistar male rats (Institute for Animal Reproduction, Ibaragi, Japan) weighing 220−228 g were used in this study. The animals were maintained at a controlled temperature of 22 ± 2 °C with 12 h light/12 h dark cycles (light cycle 7:00−19:00), and were given standard chow (CE-2, Nihon Clea, Tokyo, Japan). All procedures were approved by the Animal Research Committee at Tottori University.

Preparation and Purification of 20 k-PEG-bLf. The PEGylated reaction mixture consisted of bLF and branched 20-kDa PEG-NHS reagent at a 1:10 molar ratio in phosphate buffered saline (PBS) pH 7.4. The final protein concentration was 0.5 mg/mL. The reaction was carried out for 1 h at 25 °C, and stopped by cooling (0−4 °C). The reaction mixture was applied to a column packed with Heparin Sepharose 6 Fast Flow resin, previously equilibrated with 10 mM sodium phosphate, pH 7.6. The column was washed with five column volumes of equilibration buffer to remove excess PEG reagent and byproduct. 20k-PEG-bLf was eluted with 300 mM sodium chloride, and unmodified bLF was eluted with 1 M sodium chloride at a flow rate of 2 mL/min. The 20k-PEG-bLf eluates were desalted using a PD-10 column and concentrated with Centriplus. Protein concentration was determined by the Bradford protein assay procedure with BSA as a standard.

SDS-PAGE Analysis. The reaction mixture and purified 20k-PEG-bLf were analyzed by sodium dodecyl sulfate (SDS)−polyacrylamide (7.5%) gel electrophoresis according to the methods of Laemmli (*33*) under nonreducing conditions and were stained with Coomassie Brilliant Blue (CBB). PEG-bLf and excess PEG reagents were specifically stained with Titrisol iodine solution according to the procedure of Kurfürst with some modifications (*34*). The SDS-PAGE gel was then rinsed with distilled water and placed in a 5% barium chloride solution for 10 min. The gel was washed with distilled water and transferred to 0.1 N Titrisol iodine reagent for 15 min. Excess Titrisol iodine was washed off with distilled water, and the PEG-conjugated proteins and excess PEG reagent were detected as brown bands.

N-Terminal Amino Acid Sequence. Unmodified bLF and purified 20k-PEG-bLf (600 μg/mL each) were digested with pepsin at a concentration of 60 ng/mL for 1 h at 37 °C. Digested proteins were subjected to SDS-PAGE and electroblotted to a PVDF membrane (Bio-Rad, Hercules, CA). Protein bands were visualized with CBB and excised from the membrane. Determination of the N-terminal amino acid sequence was carried out by automated Edman degradation on an Applied Biosystems model 470A sequencer.

Iron-Binding Assay. Starting with the native LF, apo- and iron-rebinding forms of bLF and 20k-PEG-bLf were prepared according to the method of Shimazaki et al. (*35*). The apo-LF was prepared in the presence of citrate. The reconstituted form of LF containing the ferric ions was prepared in the presence of bicarbonate. Iron concentration of each LF was determined using the method of Kirkpatrick et al. (*36*) with the Fe−C Test Kit (Wako Pure Chemicals, Osaka, Japan).

In Vitro Anti-Inflammation. A cell stimulation assay was carried out using the methods of Mattsby-Balzer et al. (*8*) and Håversen L et al. (*9*) with minor modifications. THP-1 (human monocyte leukemia cell line, JCRB0112) cells were obtained from the Health Science Research Resource Bank (Osaka, Japan) and grown in RPMI 1640 medium supplemented with 10% heat-inactivated fetal bovine serum (FBS) and 2 mM Glutamax (Invitrogen, Carlsbad, CA) in a CO_2 incubator at 37 °C. Logarithmic growth phase cells were treated with 20 ng/mL IFN-γ and 40 ng/mL calcitriol for 48 h to increase sensitivity against LPS. Following incubation, the cells were collected and suspended in cell assay medium (RPMI 1640 containing 10% FBS and 2 mM Glutamax) at a concentration of 1×10^6 cells/mL. The cells (400 μL) were then added to a 24-well plate. The cells were stimulated with LPS alone at a concentration of 100 ng/mL, with 100 ng/mL LPS plus 100 μg/mL test sample or with 100 μg/mL of the test sample alone at 37 °C for 24 h in a 5% CO_2 atmosphere. After incubation, culture supernatants were collected and IL-6 concentration was measured by ELISA.

Cytotoxicity of 20k-PEG-bLf. THP-1 cell suspension (100 μL of 1×10^6 cells/mL) was dispensed to each well of a 96-well plate in triplicate. Ten micrograms of unmodified bLF or 20k-PEG-bLf was added to each well and incubated at 37 °C for 24 h in an atmosphere of 5% CO_2. Cell Counting Kit-8 Solution (10 μL) was then added to each well, and the plate was incubated at 37 °C for 1 h in 5% CO_2. Cell viability was determined by measuring the absorbance at 450 nm (reference absorbance at 655 nm) using a microplate reader.

Proteolytic Digestion. Unmodified bLF or 20k-PEG-bLf was dissolved in 10 mM HCl at a concentration of 0.5 mg/mL and adjusted to pH 3.2. Pepsin was added to the protein solution at a final concentration of 20 ng/mL and incubated at 37 °C. Reaction mixture was collected at 0, 5, 10, 15, 20, 40, 60, and 100 min and terminated by the addition of SDS-PAGE loading buffer. Samples were heated at 95 °C for 5 min and analyzed by SDS-PAGE. The gel was stained with CBB, and the intensity of staining in each band was analyzed by *Image J* software.

Lymphatic bLF Transport from the Intestine. The experimental procedure was conducted according to the method of Takeuchi et al. (*19*) with some modifications. Eight-week-old Wistar rats ($n = 4-5$) were anesthetized with urethane (4 g/kg, s.c.) and sodium pentobarbital (0.1 mL, s.c.) before unmodified bLF (30 mg/kg or 300 mg/kg) or 20k-PEG-bLf (30 mg/kg) was injected intragastrically, over 1 min, using a 27-gauge needle. Thoracic lymph fluid was harvested and collected in heparinized tubes throughout the sampling period (at time zero and hourly after the injection for 4 h). The samples were centrifuged, and

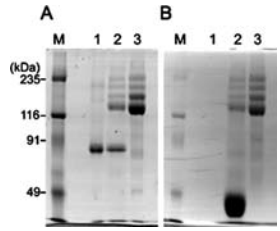

Figure 1. SDS-PAGE analysis of unmodified and PEGylated bLf. (A) Protein staining with Coomassie Brilliant Blue. Lanes: M, molecular weight marker; 1, unmodified bLF (2 μg); 2, PEGylation reaction mixture; 3, purified 20k-PEG-bLf (2 μg). (B) PEG-specific staining with iodine. Lanes: M and 1−3, same as in part A.

bLF concentration in the supernatant was determined by polyclonal antibody-based ELISA.

Pharmacokinetic Study. The experimental procedure was conducted according to the methods of Takeuchi et al. (*19*) with some modifications. Eight-week-old Wistar rats ($n = 6-10$) were anesthetized with sodium pentobarbital (60 mg/kg, i.p.), and a cannula for blood collection was inserted into the external jugular vein. Unmodified bLF (1 mg/kg or 10 mg/kg) or 20k-PEG-bLf (1 mg/kg) was injected into the femoral vein. The blood was collected from the external jugular vein through a cannula. Blood was collected at 0, 1, 5, 10, 15, 30, 60, 120, 180, and 240 min after sample administration. bLF blood concentration was determined quantitatively by polyclonal antibody-based ELISA.

Statistical Analysis. The Mann−Whitney test was used to determine statistical significance in the lymphatic transport study. The Student's unpaired *t* test was used to evaluate the area under the curve (AUC) in the pharmacokinetic study. *P* values of <0.05 were considered significantly different.

RESULTS

Preparation of 20 kDa-PEG Conjugate bLF. PEGylated bLF was generated as a result of the reaction between *N*-hydroxysuccinimide (NHS) ester derivatives of a 20 kDa branched PEG molecule and the free amino groups (ε- and α-amino groups) of bLF. Figure 1 shows the SDS-PAGE profile of unmodified bLF, the reaction mixture, and purified PEGylated bLF (PEG-bLf) detected by CBB (Figure 1A) and PEG-specific staining (Figure 1B). The reaction mixture contained various molecular weights of PEG-bLfs, unmodified bLF, and an excess of PEG reagent. CBB and PEG-specific staining showed that 20k-PEG-bLf was successfully purified by Heparin affinity chromatography from the PEGylation mixture. The proportions of mono, di, tri, and tetra PEGylated bLF were 81.7%, 12.2%, 3.2%, and 2.8%, respectively, as judged by the intensity of each stained band in the gel.

Iron-Binding Assay. LF has two domains, the N-lobe and the C-lobe. Each lobe contains an iron site where the ferric ion (Fe^{3+}) is tightly bound in the presence of HCO_3^{2-} (*37*). The iron-scavenging properties of LF are reportedly involved in antioxidative effects and antimicrobial activities. We measured the iron content of 20k-PEG-bLf and compared it to that of unmodified bLF. Representative data obtained from five independent experiments are shown in Table 1. 20k-PEG-bLf and unmodified bLF bound iron at the concentration of 1021 ng and 833.7 ng Fe^{3+} per mg of protein, respectively, revealing 122.5% relative binding activity of 20k-PEG-bLf to that of unmodified bLF. This result suggested that PEG modification did not affect the iron-binding ability of bLF.

In Vitro Anti-Inflammation. As an anti-inflammatory agent, bLF down-regulates LPS-induced IL-6 secretion in human monocytic cells (*8, 9*). The effect of 20k-PEG-bLf on this response was analyzed in the monocytic cell line THP-1.

Table 1. Iron-Binding Activities of 20k-PEG-bLf

protein	Fe concentration (ng/mg protein) apo-form	holo-form	relative binding ratio (% of unmodified bLF)
Unmodified bLF	79.7	913.4	100.0
20k-PEG-bLf	125.6	1146.6	122.5
BSA[a]	67.0	119.6	6.3

[a] BSA was used as a negative control.

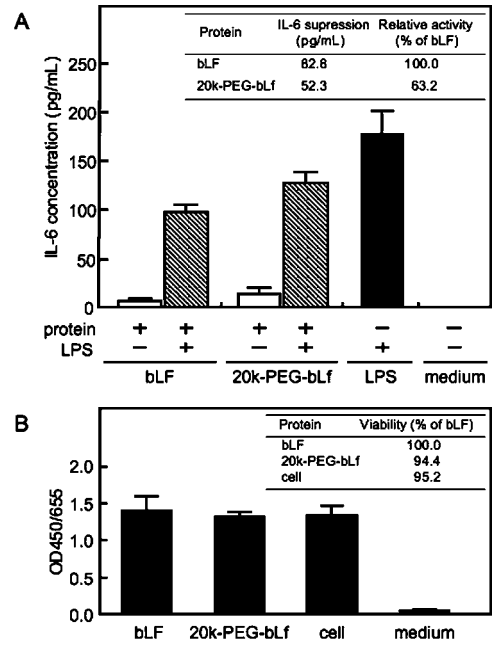

Figure 2. Inhibition of the LPS-induced IL-6 response in THP-1 cells by 20k-PEG-bLf. (A) ELISA comparison of IL-6 levels in supernatants from LPS stimulated THP-1 cells. Bovine LF (bLF) or 20k-PEG-bLf, at a dose of 100 μg/mL, was added after LPS (100 ng/mL) stimulation. All data represent means ± SD from triplicate wells. The inset shows the mean relative anti-inflammatory activity of 20k-PEG-bLf compared to that of bLF. The suppressed IL-6 concentrations were calculated by subtracting the values of "bLF + LPS" or "20k-PEG-bLf + LPS" from "cells treated with LPS only". (B) Viability of THP-1 cells treated with 20k-PEG-bLf. bLF or 20k-PEG-bLf (100 μg/mL) was added to THP-1 cells. All data represent means ± SD from triplicate wells. The inset shows the mean relative cell viability compared to that of bLF.

Representative data obtained from six independent experiments are shown in Figure 2A. No IL-6 was detected in the culture fluid of LPS-untreated cells, whereas IL-6 was slightly detected in the supernatants of cells treated with only 20k-PEG-bLf or unmodified bLF. Both 20k-PEG-bLf and unmodified bLF inhibited the LPS-induced IL-6 secretion, with mean reductions of 52.3 pg/mL and 82.8 pg/mL IL-6, respectively. Thus, the relative inhibitory activity of 20k-PEG-bLf was approximately 63.2% that of unmodified bLF. Six independent experiments revealed that the residual anti-inflammatory activity of 20k-PEG-bLf was 69.6 ± 2.9% (means ± S.E.) of the original. In order to rule out possible cell toxicity of the added samples, which could account for the observed inhibitory effect, we evaluated the effect of 20k-PEG-bLf on THP-1 cell viability. Neither 20k-PEG-bLf nor bLF affected cell viability, suggesting no cytotoxic effect from the added samples (Figure 2B).

Stability of 20k-PEG-bLf (Proteolytic Characterization). Artificial gastric fluid was used to compare the in vitro peptic susceptibility of unmodified bLF and 20k-PEG-bLf. Unmodified bLF (80 kDa) was degraded within 40 min, whereas 20k-PEG-bLf (predominantly mono PEG-bLf of 140 kDa) was still detectable at 100 min (Figure 3A). The PEGylation of bLF induced a 2-fold increase in the half-life of peptic digestion

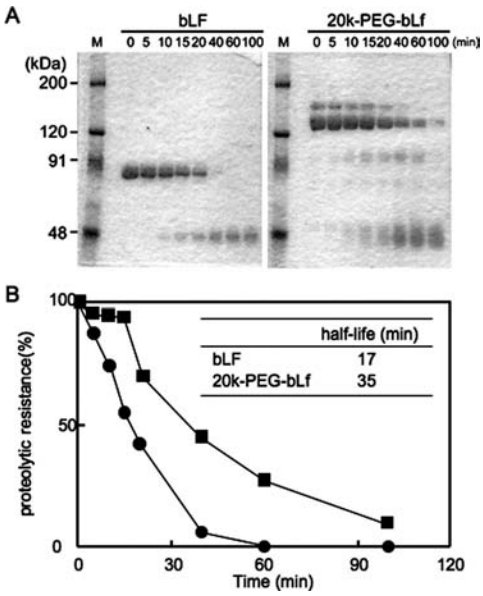

Figure 3. In vitro susceptibility of unmodified bLF and 20k-PEG-bLf to pepsin hydrolysis. (A) SDS-PAGE profile of pepsin-digested proteins. (B) Degradation rates of pepsin-digested unmodified bLF and 20k-PEG-bLf. Proteins were visualized with Coomassie Brilliant Blue, and residual protein bands were quantified using *Image J* software by reference to untreated bLF and 20k-PEG-bLf, which were arbitrarily set at 100%. Each data point was derived from one experiment, and all the time points were from the same incubation. The inset shows the half-life of resistance against pepsin digestion.

(Figure 3B), suggesting high stability of 20k-PEG-bLf in the gastrointestinal tract.

N-Terminal Amino Acid Sequence of Pepsin-Digested 20k-PEG-bLf. N-terminal amino acid sequences of pepsin-digested fragments from 20k-PEG-bLf were determined to estimate PEG conjugation sites on the 20k-PEG-bLf protein. Digestion of 20k-PEG-bLf with pepsin gave rise to four digestive fragments (Figure 4A, lane 2). Of these four, the three indicated by arrows specifically stained with iodine (data not shown), suggesting the presence of PEG-attached fragments. The following N-terminal amino acid sequences were obtained for the three PEG-attached fragments: Subfragment 1 (~105 kDa) - APRKNVRWXTIXQ (X stands for an uncertain residue); subfragment 2 (~80 kDa) - VVKLTVKFQL; and subfragment 3 (~60 kDa) - VKETYVFENL. These N-terminal amino acid sequences correspond to 1−13, 97−106, and 209−218, respectively, of mature bLF (689 amino acids length) (Figure 4B). These sequences are all in the N-terminal half of bLF. These results permit us to speculate that the N-terminal half of bLF is not a main target site of PEG modification.

Lymphatic Transport Study. Intact bLF is incorporated via the intestinal tract and transported into the thoracic duct lymph (*19*−*21*). To examine the absorption and transport of 20k-PEG-bLf in rats, 20k-PEG-bLf (30 mg/kg body weight) or unmodified bLF (30 or 300 mg/kg body weight) was administered intragastrically. bLF transport to the thoracic duct lymph was detected by ELISA (Figure 5). No bLF was detected before administration in either group. Unmodified bLF and 20k-PEG-bLf were detected 1 h after administration. The concentration of 20k-PEG-bLf continued to increase up to 4 h after administration, while the concentration of unmodified bLF (30 and 300 mg/kg body weight) remained constant. Consequently, the concentration of absorbed 20k-PEG-bLf (30 mg/kg body weight) at 4 h after administration was approximately 10-fold higher than that of absorbed unmodified bLF (30 mg/kg body weight), although no statistical difference was observed because of the large individual differences in absorbed 20k-PEG-bLf (Mann−Whitney test).

Pharmacokinetic Study. Pharmacokinetic parameters were determined by the intravascular administration of unmodified bLF and 20k-PEG-bLf in Wistar male rats. The mean serum concentrations of bLF versus time curves of 20k-PEG-bLf (1 mg/kg) and unmodified bLF (1 mg/kg, 10 mg/kg) are shown in Figure 6. No bLF was detected in the serum before injection. The concentration of bLF rapidly decreased and became undetectable by 60 and 120 min after administration of an unmodified bLF (1 mg/kg and 10 mg/kg), respectively. In contrast, 20k-PEG-bLf continued to be detected up to 240 min after intravenous administration. The area under the curve (AUC) of 20k-PEG-bLf was approximately 9.2-fold higher than that of unmodified bLF (1 mg/kg treatment group). 20k-PEG-bLf had a half-life of 42.4 min, whereas unmodified bLF (1 mg/kg) had a half-life of 7.8 min. Therefore, PEGylation of bLF led to a 5.4-fold prolongation of the half-life compared to unmodified bLF (1 mg/kg).

DISCUSSION

PEGylation is an established method for improving the pharmacokinetic properties and pharmacodynamic effects of therapeutic proteins (*24*). In most cases, PEGylated pharmaceutical proteins are administered parenterally. Few studies have reported on the oral administration of PEGylated proteins. Bioconjugation of PEG to granulocyte colony stimulating factor (G-CSF) enhanced oral delivery (*32*), suggesting that PEGylation could be a successful approach to not only parenteral formulation but oral formulation. Thus, this report encouraged us to attempt the PEGylation of oral bLF to achieve greater efficacy than that of unmodified bLF.

Lysine amino groups are most frequently used as PEGylation conjugation sites. This PEGylation, however, is nonspecific and may result in a high number of PEGylated mixtures. In cases where bLF was modified with the linear and small molecular mass of the PEG-NHS derivative (5 kDa), hyper-modified PEGylated bLF was formed, as judged by a smear pattern on SDS-PAGE gels (data not shown). This phenomenon may occur due to 54 internal lysine residues that act as potential conjugation sites in bLF. For example, analysis of several reactions with varying pH, temperature, and PEG-to-bLF ratios showed that the 20 kDa (this study) and 40 kDa PEG-NHS (data not shown) in the branched shape gave rise to a discrete band on SDS-PAGE.

The amino groups of proteins are considered to be suitable conjugation sites for PEGylation because they are the most represented groups and are highly reactive. This approach, however, frequently leads to reduction or loss of bioactivity, mainly because protein active sites are in or near conjugation sites, or are hindered by long polymer strands (so-called steric hindrance). In fact, PEGylated interferons (IFNs) (*25, 26*), which are now marketed for treatment of hepatitis B and C, show markedly reduced in vitro antiviral activity (e.g., PEG-IFN α2a (PEGASYS), 7%; PEG-IFN α2b (Intron), 28%). This reduced biological activity was largely compensated for by an extended in vivo half-life, eventually accounting for improved therapeutic efficacy. In contrast, our PEGylated bLF (20k-PEG-bLf) showed high residual in vitro activities. The iron binding activity was equivalent to that observed in native bLF, and the anti-inflammatory activity retained 69.6% of the action of native bLF. Thus, 20k-PEG-bLf would be a promising drug candidate for in vivo pharmacological study.

The proteolytic profiles showed that 20k-PEG-bLf displayed a significantly higher resistance to pepsin treatment compared to unmodified LF. Resistance to pepsin treatment of 20k-PEG-bLf revealed biphasic curves, high resistance (0−15 min) and

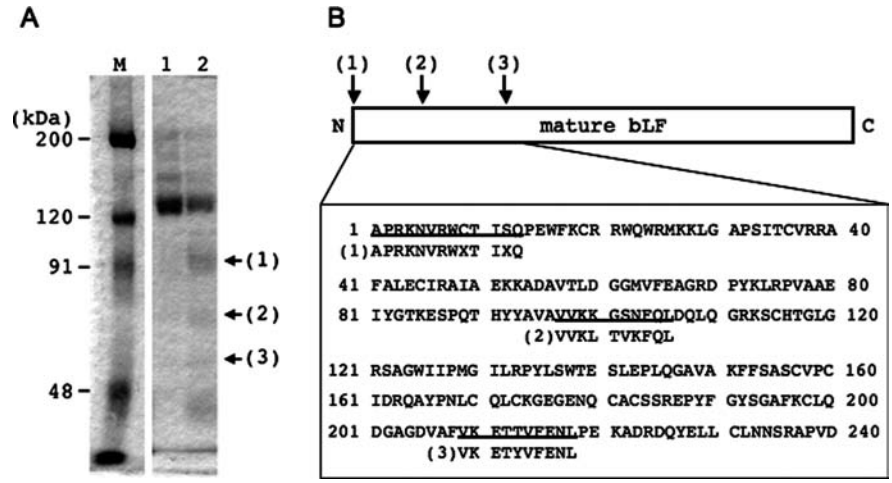

Figure 4. Deduced N-terminal amino acid sequences of pepsin-digested 20k-PEG-bLf fragments. (A) 20k-PEG-bLf was treated with pepsin at a concentration of 60 ng/mL for 60 min at 37 °C. Lanes: M, molecular weight markers; 1, undigested 20k-PEG-bLf; 2, 20k-PEG-bLf digested with pepsin. (B) Schematic diagram showing the location of the N-terminal amino acid sequences from pepsin-digested 20k-PEG-bLf.

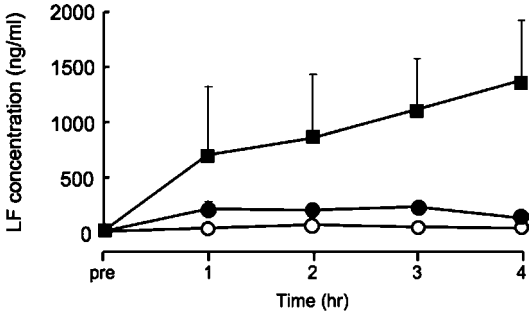

Figure 5. Changes in LF concentration in thoracic lymph over a 4 h time course. Open circles, closed circles, and closed squares show the data from bLF and 20k-PEG-bLf infusion into Wistar rats at a dosage of 30 mg/kg (bLF), 300 mg/kg (bLF), and 30 mg/kg (20k-PEG-bLf), respectively. Lymphatic fluid was collected every hour for 4 h, and LF concentration in thoracic lymph was measured by ELISA. Data represent means ± SE from 4−5 rats. The concentration of absorbed 20k-PEG-bLf (30 mg/kg body weight) at 4 h after administration was approximately 10-fold higher than that of absorbed unmodified bLF (30 mg/kg body weight).

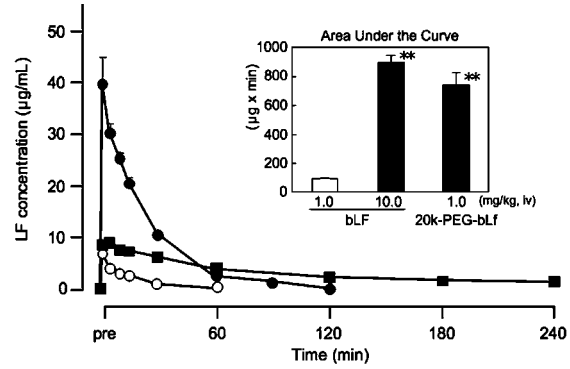

Figure 6. Pharmacokinetic profiles of unmodified bLF and 20k-PEG-bLf after intravenous injection. Open circles, closed circles, and closed squares show the data from rats injected at a dosage of 1 mg/kg (unmodified bLF), 10 mg/kg (unmodified bLF), and 1 mg/kg (20k-PEG-bLf), respectively. The inset shows the data from the area under the curve (AUC). Blood was collected at the indicated time points and assayed for bLF serum levels by ELISA. Data represent means ± SE from 5−7 rats. **Significant difference from unmodified bLF (1 mg/kg) administration ($P < 0.01$).

low resistance (15−100 min). The second curve slope apparently corresponds to fully released LF digestion.

The N-terminal region of LF contains unique clusters of basic amino acid residues that are involved in various biological functions such as antimicrobial and antiviral activities and affinity to heparin and LPS (*38*−*42*). The N-terminal amino acid sequences of pepsin-digested fragments from 20k-PEG-bLf indicate that the N-terminal portion of bLF was not modified with PEG. The high residual activities of 20k-PEG-bLf could be explained by this fact.

It has been reported that bLF taken up from the intestinal lumen is transported into the blood via the lymphatic, not portal, pathway in adult rats. The present study demonstrated enhanced uptake of PEGylated bLF from the rat intestine. PEGylated bLF might transfer across the small intestinal mucosal membranes by two possible pathways, specific receptor-mediated transcytosis and nonselective transcytosis. Considering that the ligand−receptor interaction could be reduced due to PEGylation, enhanced uptake of PEGylated bLF from the rat intestine could not be explained by specific receptor-mediated transcytosis. We, therefore, consider that this phenomenon may be mainly associated with nonselective transcytosis. The permeability of the epithelial membranes may be altered by PEGylation of bLF.

The area under the curve (AUC) of 20k-PEG-bLf was approximately 9.2-fold higher than that of unmodified bLF (1 mg/kg treatment group), and was similar to that of unmodified bLF (10 mg/kg treatment group). Approximately 4-fold higher serum concentration of unmodified bLF (10 mg/kg) than 20k-PEG-bLf (1 mg/kg) was detected 10 min postadministration, then decreased rapidly, and was undetectable 120 min postadministration. In contrast, the serum concentration of 20k-PEG-bLf (1 mg/kg) was detected 10 min postadministration, then decreased very slowly, and continued to be detected up to 240 min after intravenous administration, consequently giving rise to a similar AUC value to that of unmodified bLF (10 mg/kg).

Various attempts to deliver an intact molecule of bLF to the intestine have been made. Enteric-coated bLF resisted gastric digestion and was more efficiently absorbed than nonenteric-coated bLF (*20*, *22*). Liposomalization of bLF (bLF in enteric-formulated capsules protected in liposomes) reportedly enhances its anti-inflammatory activity, although liposomalization did not enhance the absorption of bLF from the intestine (*23*). These formulations, however, have the drawback that noncoated bLF is released from the capsules when they reach the intestine, resulting in degradation and inactivation of bLF in systemic circulation. In contrast, PEGylated bLF has the potential ability

not only of resistance to degradation in the stomach but also of stabilization in blood circulation.

In conclusion, PEGylated bLF with high biological activities and enhanced pharmacokinetic properties has been developed. PEGylation of bLF is a promising strategy for the improved oral delivery of bLF, and shows that the PEGylation technique may be a breakthrough in converting functional food proteins into pharmaceutical proteins.

ACKNOWLEDGMENT

We thank Professor H. Nyunoya and Associate Professor Y. Matsushita (Tokyo University of Agriculture and Technology, Tokyo, Japan) for determination of the N-terminal amino acid sequence. We also thank Kamakura Techno-Science Inc. (Kamakura, Japan) for large-scale preparation of purified 20k-PEG-bLf. This work was supported by grants from the New Energy and Industrial Technology Development Organization (NEDO).

Received March 20, 2008; Revised Manuscript Received September 22, 2008

During the past decade, biodegradable polymers or oligopeptides recognized by cell-surface receptors have been shown to increase drug specificity, lowering systemic drug toxicity in contrast to small-size fast-acting drugs. The goal of the present study was to develop anticancer bioconjugates based on chemotactic drug targeting (CDT). These constructs are composed of methotrexate (Mtx) attached to a tuftsin-like peptide carrier through an enzyme-labile pentapeptide spacer (GFLGC) and several copies of a chemotactic targeting moiety (H-TKPR, For-TKPR, H-TKPKG, and Ac-TKPKG). Carriers with targeting moieties in the branches were prepared by solid-phase synthesis using mixed Boc and Fmoc strategies. The drug molecule connected to an enzyme-labile spacer was attached to the branched oligopeptide in solution. *In vitro* chemotaxis, cellular uptake, and cytotoxicity assays were carried out on the MonoMac6 cell line. The most effective conjugates with H-TKPR or Ac-TKPKG targeting moieties in the branches, which have the most advantageous chemotactic properties, can be internalized rapidly, and these conjugates trigger higher toxic effect than the free drug (Mtx). The results suggest that our tuftsin-based drug delivery systems might be potential candidates for targeting cancer chemotherapy.

INTRODUCTION

Numerous drug delivery systems (DDS) have been developed over the years to establish novel antitumor therapeutics. The main goal of these developments is the investigation of various approaches toward targeting toxic drugs to tumor cells using their conjugated forms with carriers and/or targeting moieties. In this way, a controlled location and higher concentration of toxic drugs can be reached at the site of action; furthermore, side effects and therapeutical doses can be reduced. The application of drug delivery systems for targeting chemotherapy might result in increased selectivity and efficiency in the cancer treatment (*1, 2*).

Peptide-based biodegradable conjugates represent one group of DDS. These conjugates consist of a drug molecule, an enzyme-labile or pH-sensitive spacer sequence, a biodegradable peptide carrier, and targeting moieties (e.g., peptide hormones, lectins, sugars, or antibodies) (*3*), which have been shown to bind to cell-surface receptors and can be internalized by receptor-mediated endocytosis. Chemotactic drug targeting (CDT), a special form of drug targeting, was investigated in our laboratory (*4*). Previously, we reported on the synthesis of chemotactic drug delivery systems for drug targeting. We used the well-known chemotactic peptides (For-Met-Leu-Phe and For-Nle-Leu-Phe) as targeting moieties, capable to bind to specific chemotactic receptors on phagocytic cells (*5*). In this study, we have further developed this system by modifying the chemotactic targeting moieties. Conjugates composed of chemotactically active ligands (chemotactic peptides), drug, and carrier induce chemotactic activity of target cells. In this way, responder cells accumulate in the high-concentration region of tissues, and internalization of the drug is also increased. To achieve conjugates suitable for CDT, chemotactic peptides as targeting moieties were built up as branches in the carrier.

In this study, a sequential oligopeptide, a tetratuftsin derivative, was applied as carrier. Human tuftsin, a naturally occurring tetrapeptide (H-TKPR-OH) was described by Najjar and Nishioka in 1970 (*6*). Tuftsin is the 289−292 sequence in the CH2 domain of the Fc fragment of the heavy chain of IgG (*7*). It is an immunopotentiating peptide, which stimulates phagocytosis and cell migration (*8*) and possesses antitumor activity (*9, 10*). In our present study, a tuftsin analogue (H-TKPK-OH) derived from canin and having human tuftsin-like activities, elongated with Gly at the *C*-terminal (H-TKPKG-OH), was used. The carrier in multifunctional conjugates was the H-$[TKPKG]_4$-NH_2 tetramer (OT20) (*11*). Inasmuch as the human tuftsin and its analogue have a chemotactic effect on monocytes (*12, 13*), these peptides and their formylated or acetylated derivatives at the *N*-terminal were attached to the carrier and applied as targeting moieties (H-TKPR, For-TKPR, H-TKPKG, Ac-TKPKG) in the branches.

Methotrexate, (*S*)-2-(4-(((2,4-diaminopteridin-6-yl)methyl)-methylamino)benzamido)pentanedioic acid (Mtx), an antimetabolite and antifolate molecule was incorporated as an anticancer drug. Mtx is used for chemotherapy in cancers and autoimmune diseases (*14*−*16*). It is mainly applied for the treatment of acute lymphoblastic leukemia (*17*), but it is also used against leishmania (*18, 19*) or in the treatment of rheumatoid arthritis (RA) (*20*). However, methotrexate could cause severe toxicity; the most frequent reactions include low white blood cell counts and toxicity of the liver and bone marrow resulting in immunosuppression.

To decrease the toxic side effects, the release of free drug molecules in target cells is important. The release of the Mtx from the conjugates can be influenced by the type of linkage applied between the drug and the carrier. The use of specific

oligopeptide sequences recognized by intracellular enzymes is a promising approach for increasing the site-specific release of the drug; therefore, Mtx was coupled to the carrier *via* a cathepsin B-cleavable tetrapeptide spacer sequence (GFLG). This linker is frequently used in drug conjugates and could be cleaved in the lysosomes (*21*, *22*). For the present study, the spacer sequence was elongated at the *C*-terminal with a cysteine to introduce a thiol group for conjugation through the thioether bond to the carrier.

In this paper, the synthesis and characterization as well as the chemotactic and cytotoxic properties of the new bioconjugates and their components (carrier, carrier with targeting moieties in the branches, Mtx, and Mtx-spacer) are reported. To ensure the release of the drug from the conjugates, enzymatic digestions were investigated using Cathepsin B. The chemotaxis, cellular uptake, and apoptosis assays were carried out on human MonoMac6 cell line, representing monocytic cells with a closely related pattern of surface receptors, and they display phenotypic and functional features of mature human monocytes and macrophages (*23*). Inasmuch as monocytes and macrophages express tuftsin receptors (*24*, *25*), MonoMac6 cells might express these receptors as well. In this way, we can ensure that our conjugates might be internalized by receptor-mediated endocytosis.

Chemotaxis assays were carried out with the Mtx-conjugates and with their components. Each of the conjugates could elicit significant chemotactic effect on MonoMac6 cells. Cellular uptake of the CF-labeled analogues of the conjugates was studied by flow cytometry. Rapid internalization of each CF-labeled conjugate was observed. We investigated the cytotoxicity of Mtx-conjugates and Mtx *via* apoptosis assay on the MonoMac6 cell line. Mtx-conjugates and the Mtx itself induced significant cell death at 1 μM concentration after 24 or 48 h. Our data show that MonoMac6 cells are highly susceptible to the toxic effects of the conjugates through enhanced cell death by necrosis.

Our results indicated that these kind of drug delivery systems are rather effective on the MonoMac6 cell line. Some of our conjugates were attractants for the cells, could be taken up considerably, and could elicit a toxic effect inside the cells.

EXPERIMENTAL PROCEDURES

Materials. Amino acid derivatives were purchased from Reanal (Budapest, Hungary) or NovaBiochem (Läufelfingen, Switzerland), MBHA and Rink-Amide MBHA resins were NovaBiochem products. Reagents for synthesis [*N*,*N*′-dicyclohexylcabodiimide (DCC), *N*,*N*′-diisopropylcarbodiimide (DIC), *N*-diisopropyl-ethylamine (DIEA), 1-hydroxybenzotriazole (HOBt), 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU), piperidine, trifluoroacetic acid (TFA), hydrogen fluoride (HF), *p*-cresol, *p*-thiocresol, thioanisole, phenol, 1,2-ethanedithiol (EDT), 1,4-DL-dithiothreitol (DTT), and 5(6)-carboxyfluorescein (CF) were purchased from Fluka (Buchs, Switzerland). Acetic anhydride (Ac_2O), dimethylsulfoxide (DMSO), and solvents for the synthesis were obtained from Reanal. HPLC-grade acetonitrile and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were ordered from Sigma-Aldrich Kft. (Budapest, Hungary). Methotrexate was purchased from Lederle Laboratories (Gosport, UK). Chloroacetic acid pentachlorophenyl ester (ClAc-OPcp) and formic acid trichlorophenyl ester (For-OTcp) were prepared in our laboratory from the appropriate acids and phenol derivatives (Fluka products) with DCC according to the method described by Martinezet al. (*26*).

Synthesis of the Components: H-TKPR-NH_2 (1), H-TKPKG-NH_2 (2), Ac-[TKPKG]$_4$-NH_2 (OT20) (3). The peptides were built up on MBHA resin (1.04 mmol/g capacity) by stepwise synthesis using standard Boc chemistry. The synthetic protocol was as follows: (i) washing of the resin with DCM (3 × 0.5 min), (ii) removal of Boc protecting groups with 33% TFA in DCM (2 + 20 min), (iii) DCM washing (5 × 0.5 min), (iv) neutralization with 10% DIEA in DCM (4 × 1 min), (v) DCM washing (4 × 0.5 min), (vi) coupling of 3 equiv Boc-amino acid derivative-DCC-HOBt (60 min), (vii) DMF washing (3 × 1 min), (viii) DCM washing (2 × 0.5 min), and (ix) ninhydrin or isatin assay (*27*, *28*). The following amino acid derivatives were applied: Boc-Thr(Bzl)-OH, Boc-Lys(ClZ)-OH, Boc-Pro-OH, Boc-Gly-OH, and Boc-Arg(Tos)-OH. After the synthesis, the components, which were used as control peptides in the bioassays, were cleaved from the resin simultaneously with the removal of the protecting groups in the presence of *p*-cresol, using HF (10 mL HF/1 g *p*-cresol). The cleavage was carried out at 0 °C for 90 min. The crude peptides were purified by reverse-phase high-performance liquid chomatography (RP-HPLC), and the purified components were characterized by analytical RP-HPLC and electrospray ionization mass spectrometry (ESI-MS) (Table 1).

[a] RP-HPLC column: Phenomenex Synergy C_{12} (4 μm, 80 Å, 250 × 4.6 mm); eluents: 0.1% TFA/water (A eluent), 0.1% TFA/acetonitrile-water 80:20 v/v (B eluent); flow rate 1 mL/min; gradient: 0 min 0% B, 5 min 0% B, 50 min 90% B. [b] ESI-MS was performed on a Bruker Esquire 3000+ ion trap mass spectrometer. Standard resolution mode resolving 2+ ions @ 13 000 u/s. Maximum resolution mode resolving 3+ and 4+ ions @ 1650 u/s. Extended mass range 200−6 000 *m*/*z* @ 27 000 u/s. Unsurpassed sensitivity in the low pg range.

Synthesis of the Branched Chain Oligopeptides: Ac-[TKPK(H-TKPR)G]$_4$-NH_2 (4), Ac-[TKPK(For-TKPR)G]$_4$-NH_2 (5), Ac-[TKPK(H-TKPKG)G]$_4$-NH_2 (6), Ac-[TKPK-(Ac-TKPKG)G]$_4$-NH_2 (7). The carrier backbone was built up on MBHA resin using the Boc strategy as described earlier (*29*). The following amino acid derivatives were applied: Boc-Thr(Bzl)-OH, Boc-Pro-OH, Boc-Gly-OH, Boc-Lys(ClZ)-OH in position 2, and Boc-Lys(Fmoc)-OH in position 4 in the repeat units. Prior to the synthesis of the branches, the *N*-terminus of the backbone was acetylated. Fmoc groups of the lysine side chains were removed selectively and the appropriate branches were built up in every second lysine residue using the mixed Fmoc/Bzl strategy. For this, the following amino acid derivatives were used: Fmoc-Arg(Pbf)-OH, Fmoc-Gly-OH, Fmoc-Lys(ClZ)-OH, Fmoc-Pro-OH, Fmoc-Thr(Bzl)-OH, and Z-Thr-OH.

In the case of peptides H-TKPR and H-TKPKG in the branches (peptides **4** and **6**), Z-Thr-OH was used for the incorporation of the *N*-terminal amino acid. In this way, a free amino terminus was formed in the branches after removal of the protecting groups with HF. In the case of For-TKPR and

Ac-TKPKG in the branches (branched peptides **5** and **7**), Fmoc-Thr(Bzl)-OH was applied. After the removal of the last Fmoc group from the *N*-terminus of the branches, a formyl (compound **5**) or acetyl group (compound **7**) was attached to the free α-amino groups using either For-OTcp (20 equiv in DMF for 3 h) or Ac_2O (Ac_2O/DIEA/DMF = 1:1:3 mL for 0.5 h).

The branched peptides were cleaved with HF, were purified and characterized in the same way as described above. Characteristics of the purified compounds are listed in Table 1.

Synthesis of the Branched Peptides with Chloroacetylated *N*-Terminal Lysine in the Backbone: ClAc-K(ClAc)-[TKPK(H-TKPR)G]$_4$-NH$_2$ (8), ClAc-K(ClAc)-[TKPK(For-TKPR)G]$_4$-NH$_2$ (9), ClAc-K(ClAc)-[TKPK(H-TKPKG)G]$_4$-NH$_2$(10),ClAc-K(ClAc)-[TKPK(Ac-TKPKG)-G]$_4$-NH$_2$ (11). The carrier backbone was built up on MBHA resin using the Boc strategy as described above, and a Boc-Lys(Boc)-OH was attached to the *N*-terminus using DIC/HOBt activation. Fmoc groups were removed and the branches were built up to form the chemotactic targeting sequences similarly to peptide **4**−**7**. Boc groups from *N*-terminal Lys were removed, and chloroacetylation was performed using 10 equiv of ClAc-OPcp in DMF. The chloroacetylated peptides were cleaved and worked up similarly to the previously described derivatives, but 10 mL HF/0.5 g *p*-cresol and 0.5 g *p*-thiocresol was used as the cleavage mixture that is suggested to haloacetylated peptides (*30*). The reaction time was 90 min at 0 °C. The crude peptides were purified by semipreparative RP-HPLC, and the purified components were characterized by analytical RP-HPLC and ESI-MS. Analytical data of chloroacetylated peptides are presented in Table 1.

Synthesis of Mtx$^{\gamma}$-GFLGC-NH$_2$ (12) and CF-GFLGC-NH$_2$ (17). The synthesis and isomer separation of Mtx-GFLGC-NH_2 peptide were published earlier (*4*). The Mtx-containing GFLGC peptide was built up on Rink-Amide MBHA resin using standard Fmoc chemistry. The synthetic protocol was as follows: (i) washing of the resin with DMF (3 × 1 min), (ii) removal of Fmoc protecting groups with 2% piperidine and 2% DBU in DMF (2 + 2 + 5 + 20 min), (iii) DMF washing (8 × 1 min), (iv) coupling of 3 equiv Fmoc-amino acid derivative-DIC-HOBt (60 min), (v) DMF washing (3 × 1 min), (vi) DCM washing (2 × 0.5 min), and (vii) ninhydrin or isatin assay (*27*, *28*). A trityl group was used for the side chain protection of Cys. The peptide was cleaved from the resin with 10 mL TFA using scavengers (phenol/thioanisole/EDT/water = 0.75 g/0.5 mL/0.25 mL/0.5 mL). The crude products were purified, and the isomers were separated by semipreparative RP-HPLC. CF-GFLGC-NH_2 was prepared in the same way, but the isomers of 5(6)-carboxyfluoresceine were not separated. The pure compounds were characterized by analytical HPLC and ESI-MS (Table 1).

Conjugation of the Chloroacetylated Peptides with Mtx$^{\gamma}$-GFLGC-NH$_2$ or CF-GFLGC-NH$_2$ (13−16 and 18−21). The chloroacetylated peptides were dissolved in 0.1 M Tris buffer (pH 8.2) at 10 mg/mL peptide concentration and Mtx$^{\gamma}$-GFLGC-NH_2 or CF-GFLGC-NH_2 was added to the solution in solid form at regular intervals. Under these conditions, thioether bonds can be formed between the chloroacetyl group of the branched peptides and the thiol group of the Cys in the spacer sequence resulting in compounds **13**−**16** and **18**−**21**. The conjugation reaction was monitored by analytical HPLC. At the end of the reaction, the mixtures were acidified and purified by RP-HPLC directly. The yields of the conjugations were 50−60% calculated for the carrier. The pure compounds were characterized by analytical RP-HPLC and ESI-MS (Table 1).

Reverse-Phase High-Performance Liquid Chomatography (RP-HPLC). Analytical RP-HPLC was performed on a Knauer (H. Knauer, Bad Homburg, Germany) HPLC system using a Phenomenex Synergy C_{12} column (4 μm, 80 Å, 250 × 4.6 mm I.D.) (Torrance, CA) as the stationary phase. Linear gradient elution (0 min 0% B, 5 min 0% B, 50 min 90% B) was used with the following eluents: 0.1% TFA/water (A eluent), 0.1% TFA/acetonitrile−water 80:20 v/v (B eluent). The flow rate was 1 mL/min at ambient temperature, and the peaks were detected at λ = 220 nm.

The crude peptides and conjugates were purified on a semipreparative Phenomenex Jupiter C_{18} column (10 μm, 300 Å, 250 × 10 mm I.D.) (Torrance, CA). The applied flow rate was 4 mL/min at ambient temperature, and the peaks were detected at λ = 220 nm. The same eluents as described above with an appropriate linear gradient were applied.

Electrosray Ionization Mass Spectromerty (ESI-MS). ESI-MS was performed on a Bruker Esquire 3000+ Ion trap mass spectrometer (Bremen, Germany), operating in continuous sample injection mode at 4 μL/min flow rate. Samples were dissolved in 50% acetonitrile/50% water containing 0.01% acetic acid. Mass spectra were recorded in positive ion mode in the *m*/*z* 200−1500 range.

Enzymatic Digestion by Cathepsin B. Conditions for digestion (enzyme concentration, pH, temperature) were chosen to approximate the lysosomal medium as a model for intracellular drug release. Compounds **12** and **15** were dissolved in a solution of 5 mM cysteine/2 mM EDTA (pH = 5). For the digestions, 200 μL aliquots of the solutions were used, and 0.1 unit of human liver cathepsin B (Merck Kft., Budapest, Hungary) was added to the solutions. The mixtures—giving the following initial concentrations: [cathepsin B]:[substrate] = 1:50—were incubated at 37 °C for 15 min and 1 h. Stabilities of the compounds were also measured without cathepsin B at pH 5 under the same conditions. After the incubation, the enzyme-containing solutions as well as the control samples were measured using tandem mass spectrometry, and the fragments were identified.

Cell Culture. Human monocytic MonoMac6 cells were grown in suspension in RPMI-1640 (Sigma Ltd. St. Louis, MO) supplemented with 10% heat-inactivated fetal calf serum (FCS; Gibco, Cergy-Pontoise, France) L-glutamine (2 mM) and gentamicin (35 μM). Cells were routinely maintained on plastic tissue culture dishes at 37 °C in an incubator with a humidified atmosphere containing 5% CO_2/95% air.

Chemotaxis Assay. The chemotactic ability of MonoMac6 cells was evaluated using a 96-well modified Boyden chamber (NeuroProbe, Gaithersburg, MD) (*31*). Polycarbonate filters with a pore size of 8 μm were used. Due to the requirements of cell-physiological experiments, the peptides were dissolved in an identical substance to culturing free of the ligand to be studied. For this purpose, RPMI-1640 supplemented with 10% heat-inactivated FCS, L-glutamine (2 mM/mL), and gentamicin (35 μM) was used. The concentration dependence of the chemotactic response was determined to be in the 0.0001−1 μM range. The 96-well plate was placed into the chamber, 395 μL of peptide solution was added to the bottom wells for each experiment, and the chamber was locked. The cells in medium (100 μL) at density of 10^5 cell/mL were applied to each of the top wells. The incubation time was 3 h at 37 °C in a humidified atmosphere containing 5% CO_2/95% air, allowing migration across the membrane. After the incubation, nonmigrated cells were removed from the upper surface of the membrane, and the number of cells, which were migrated into the 96-well plate through a filter, was determined by the 3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyl-tetrazolium bromide (MTT) assay (*32*, *33*). For this, 20 μL of 12 μM MTT solution was added to wells. Cells were incubated with MTT at 37 °C for 24 h, then the plates were centrifuged at 2000 rpm for 5 min. Sample supernatants were removed, formazan crystals were solubilized in DMSO,

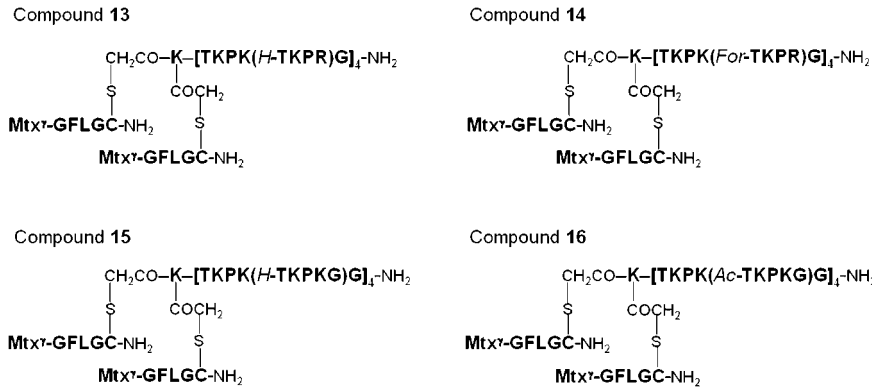

Figure 1. Schematic structure of the Mtx conjugates.

and the colorimetric measurement was carried out by an ELISA reader (Labsystems Multiscan MS-Reader, Helsinki, Finland) at $\lambda = 540$ and $\lambda = 620$ nm. Each data point represents the average of fifteen parallel measurements.

Cellular Uptake. MonoMac6 cells were cultured in RPMI-1640 supplemented with 10% FCS, L-glutamine (2 mM), and gentamicin (35 μM). Cell culture was maintained at 37 °C in a humidified atmosphere with 5% CO_2. To study the cellular uptake of fluorescent-labeled analogues of the conjugates, 10^5 cells per well were plated on 24-well plates. After 24 h incubation at 37 °C, cells were treated with the conjugates dissolved in serum-free RPMI-1640 for 1.5 h. The compounds were used in the 0.1−100 μM concentration range. Cells treated with serum-free medium for 1.5 h were used as control. After incubation, cells were washed with HPMI (glucose, $NaHCO_3$, NaCl, HEPES, KCl, $MgCl_2$, $CaCl_2$, $Na_2HPO_4 \times 2H_2O$) and were treated with trypsin for 10 min. The trypsinization was stopped by HPMI supplemented with 10% fetal calf serum, and cells were moved from the plate to FACS tubes. After washing, cells were resuspended in HPMI. The increase of the fluorescence of MonoMac6 cells after this preparation was monitored by flow cytometry (BD LSR II, BD Bioscience, San Jose, CA). Data were analyzed with *FACSDiVa* software. Fluorescence mean values of the untreated control were subtracted from the mean fluorescence of treated samples. Statistical analysis of data was performed using the Student's *t* test at the 95% confidence level.

Annexin V Apoptosis Assay. Mtx and Mtx-conjugates were dissolved in RPMI-1640 supplemented with 10% heat-inactivated FCS, L-glutamine (2 mM), and gentamicin (35 μM). Flow cytometry and cell staining was applied with fluorescein isothiocyanate- (FITC) labeled annexin-V (green fluorescence) (*34*−*37*), simultaneously with propidium iodide (PI) stain (red fluorescence) (*38*), to discriminate intact cells from apoptotic cells and necrotic cells after treatment with the conjugates and Mtx. The apoptotic/necrotic effect of Mtx and of conjugates was determined in the 0.01−1 μM range. Briefly, after cultured cells were pretreated with Mtx or conjugates for 3, 24, and 48 h at 37 °C in a humidified atmosphere containing 5% CO_2, cells were harvested and washed with phosphate-buffered saline (PBS). Cells were then resuspended in 100 μL of Annexin-V binding buffer (10 mM HEPES, 140 mM NaCl, and 2.5 mM $CaCl_2$, pH 7.4), incubated with 5 μL of Annexin-V-FITC at room temperature in the dark for 15 min followed by adding 400 μL of Annexin-V binding buffer to the cells. The cell suspensions were vortexed and analyzed immediately by flow cytometry using a Becton Dickinson FACS-Calibur flow cytometer with *Cell Quest* software (Becton Dickinson, Mountain View, CA). Finally, 5 μL PI was added to each tube, and the tubes were vortexed and analyzed again by flow cytometry. Untreated cells displayed 0% annexin+/PI− (early apoptosis) and 0% annexin−/PI+ (necrosis) after 3, 24, and 48 h incubation.

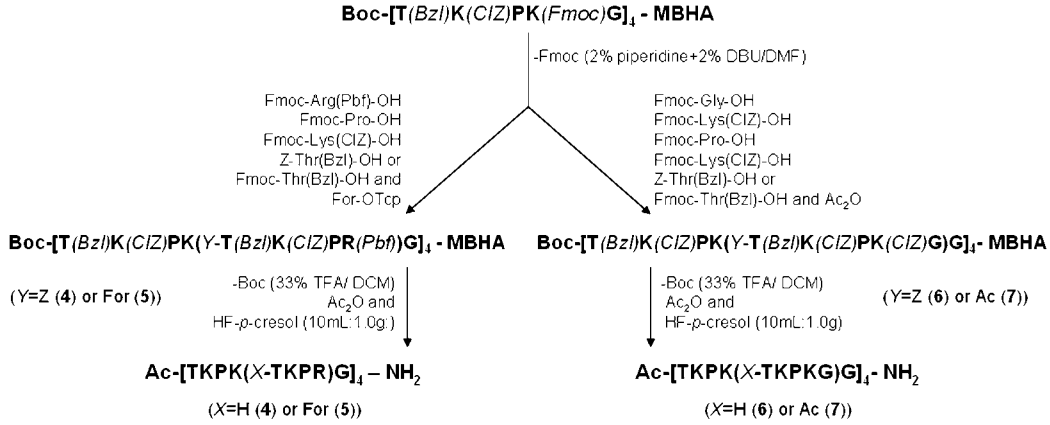
Statistical Evaluation of Data. Data shown in the figures demonstrate the averages ± SE values. The statistical analysis was done by the application of the *t* test of *Origin 7.0*.

RESULTS AND DISCUSSION

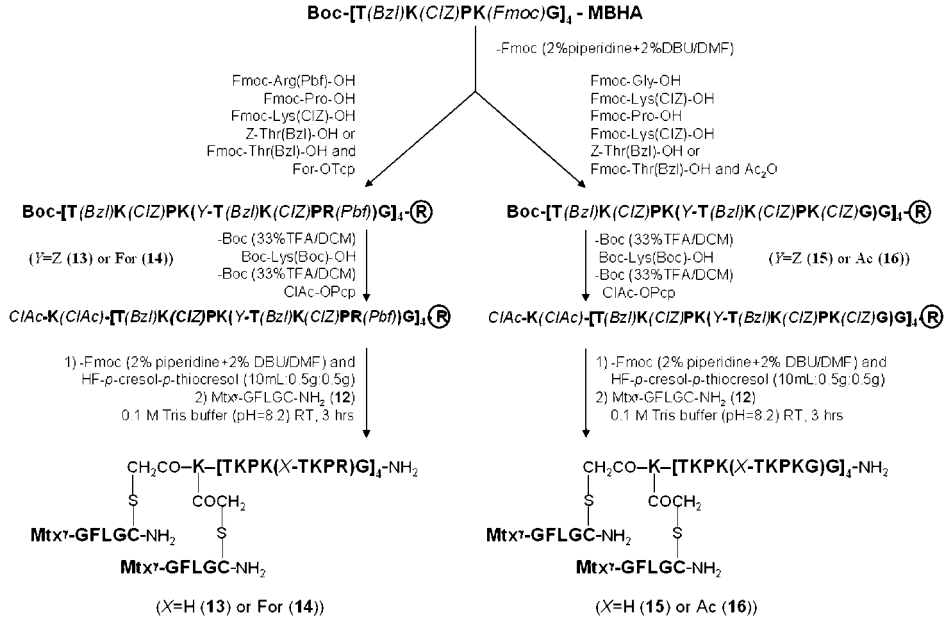
New anticancer drug delivery systems based on chemotactic drug targeting (CDT) were developed consisting of Mtx as the anticancer drug attached to an immunomodulatory carrier molecule through an enzyme-labile peptide spacer and targeting sequences with chemotactic activities. Four novel Mtx-conjugates (Figure 1), their Mtx-CF exchanged analogues, and their components were synthesized, purified, and characterized. These peptide conjugates were tested in various relevant biological assays: chemotaxis, cellular uptake, and cytotoxicity on the MonoMac6 cell line.

Synthesis. Linear peptides representing the components of the designed chemotactic branched oligopeptides and the carrier backbone (tetratuftsin derivative) were synthesized by standard Boc chemistry. The branches on carrier backbone were built up using Fmoc/Bzl strategy. In the case of the branched peptides without Mtx, the *N*-terminus of the backbone was acetylated (**4**−**7**), as outlined in Scheme 1. In the case of the drug or CF-labeled oligopeptide conjugates, an additional Lys residue was coupled to the *N*-terminus of the carrier backbone, and then both α- and ε-amino groups were chloroacetylated to form two conjugation sites (Scheme 2). Peptides were cleaved from the resin with liquid HF in the presence of appropriate scavengers. In addition, Mtx or CF containing spacer peptides (GFLG) elongated with a Cys residue at the *C*-terminus (Mtx$^{\gamma}$-GFLGC-NH_2 (**12**), CF-GFLGC-NH_2 (**17**)) were synthesized by Fmoc chemistry. The peptides were purified by RP-HPLC. The isomers (α, α-D, and γ) of Mtx containing peptide could be separated (*4*), but in case of the 5- and 6-carboxyfluoresceine derivatives, the separation was not successful. In order to form conjugates, the purified chloroacetylated branched oligopeptides were dissolved in 0.1 M Tris buffer (pH 8.2), and Mtx$^{\gamma}$-GFLGC-NH_2 or CF-GFLGC-NH_2 was added to the solution in solid form at regular intervals over 3 h at RT. Under these conditions, a thioether bond was formed between the chloroacetyl group of the branched oligopeptides and the thiol group of the cysteine in the spacer peptide resulting in compounds **13**−**16** (Scheme 2) and **18**−**21**. All compounds were purified by RP-HPLC and characterized by analytical HPLC and ESI-MS (Table 1). The chemoselective ligation followed by RP-HLPC purification resulted in conjugates (Figure 1) with 50−60% yields and 93−97% purity in all cases. While the two isomers of CF-

Scheme 1. Synthesis of Acetylated Branched Peptides



Scheme 2. Synthesis of Mtx-Conjugates



GFLGC-NH_2 were separated on the applied analytical HPLC column, the CF labeled conjugates (**18**−**21**) gave only single peaks.

Enzymatic Digestion by Cathepsin B. To determine the intracellular drug release enzymatic digestions with cathepsin B, a lysosomal enzyme, were carried out with the drug-spacer Mtx^{γ}-GFLGC-NH_2 (**12**) and conjugate **15** (Figure 1). In both cases, the main fragment split by cathepsin B was Mtx^{γ}-Gly-OH ($[M + H^+] = 512.3$), but Mtx^{γ}-Gly-Phe-OH ($[M + H^+] = 659.4$) and Mtx^{γ}-Gly-Phe-Leu-Gly-OH ($[M + H^+] = 829.5$) fragments were also identified by mass spectrometry. However, no significant enzymatic cleavage between Leu and Gly was observed (Figure 2). In the case of the conjugate (compound **15**), the multiple charged peaks of $[M + H^+] = 4560.0$ fragment (381.4 (12+); 415.4 (11+); 457.0 (10+); 506.3 (9+); 570.9 (8+); 652.5 (7+)) were also detected, which do not include the two Mtx^{γ}-GFLG sequences on the carrier backbone (Figure 3). No significant split in the oligotuftsin backbone could be detected, and the cleavage pattern did not change when the incubation time was increased from 15 min to 1 h. Our results suggested that the main cleavage site is between the Gly and Phe amino acid residues in the spacer sequence; thus, the drug can be released from the conjugates in the lysosomes. It is worth noting that the cleavage of the Ala-Cys bond in the lysosomal preparations was observed in the case of a conjugate of H-LLEDPVGTVAC-NH_2 (HSV epitope peptide) attached to the OT20 carrier through a thioether bond (*39*). On the basis of this similarity, we can hypothesize that peptides with Cys-amide at the *C*-terminus might provide a cleavage site for cathepsin B, which cannot be prevented by conjugation of Cys through thioether bond. This type of conjugation with an appropriate spacer sequence might provide some benefits to an effective drug release from drug delivery systems.

Chemotactic Activity of Compounds 1, 2, and 3. Chemotactic activity of H-TKPR-NH_2 (**1**), H-TKPKG-NH_2 (**2**), and Ac-[TKPKG]$_4$-NH_2 (OT20) (**3**) was examined. Compound **1** triggered a significant chemoattractant effect at 1 μM (337.9 ± 7.6%) and 10^{-3} μM (203.0 ± 5.0%), but at 10^{-1} μM, it was repellent (68.8 ± 18.2%), and at the other concentrations, it was neutral. In contrast, compound **2** was significantly repellent at 10^{-1} μM (55.6 ± 18.2%) and 10^{-4} μM (75.0 ± 7.8%), and neutral at the other concentrations. The tetratuftsin derivative carrier (**3**) also had chemorepellent behavior at 1 μM (56.5 ± 20.3%). However, no significant chemoattractant or chemorepellent effect was observed at the other concentrations on MonoMac6. These data indicated that the oligomerization of H-TKPKG-NH_2 (**2**) produced a carrier molecule (**3**) without a significant change of chemotactic activity (Supporting Information S2).

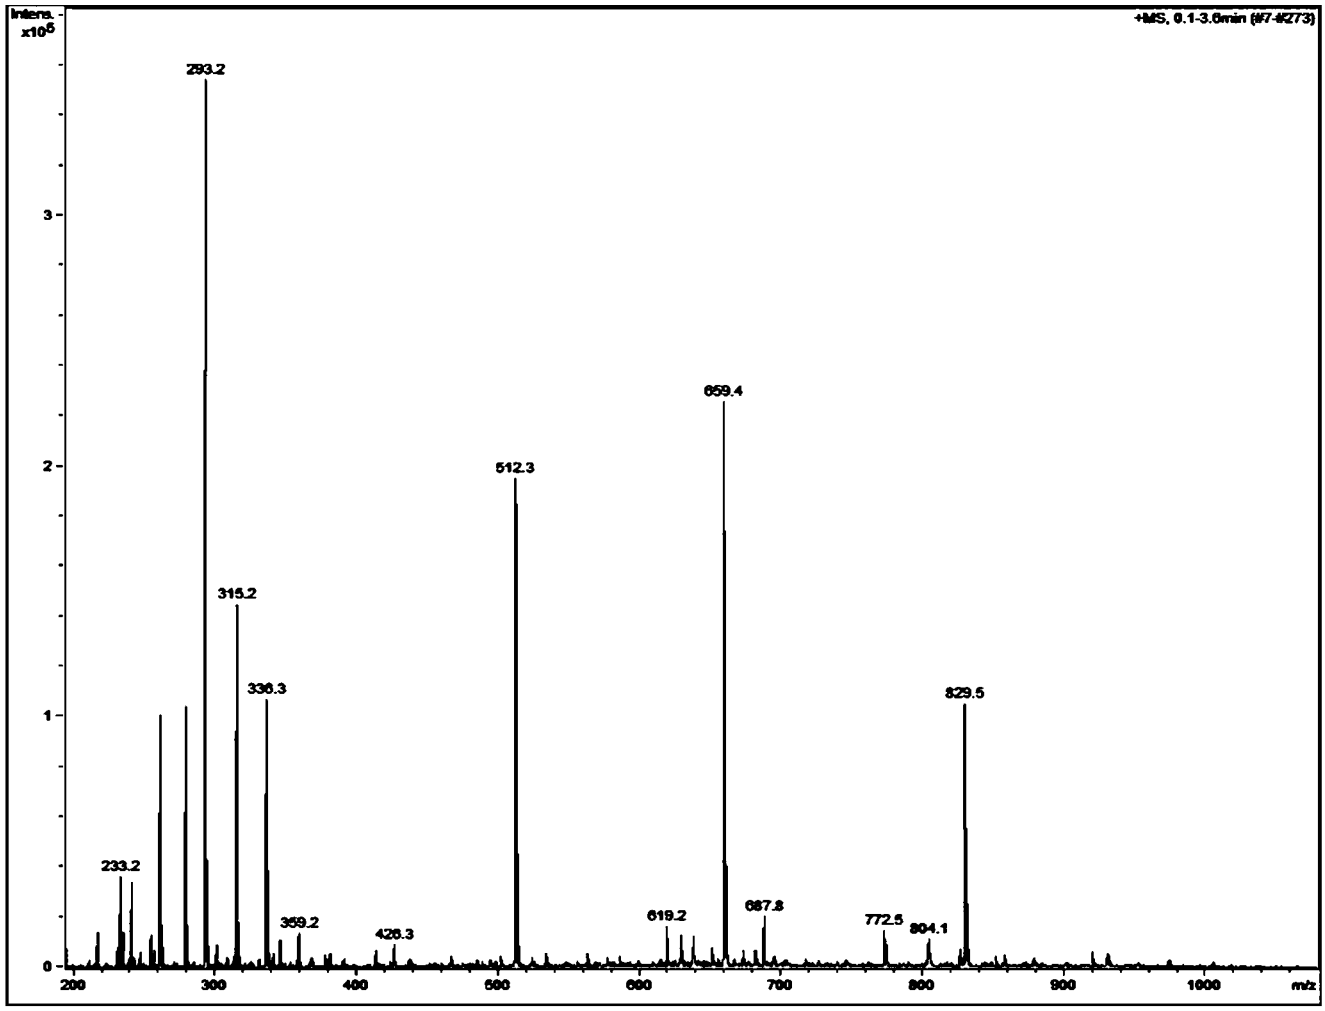


Figure 2. Mass spectrum of Mtx$^{\gamma}$-GFLGC-NH_2 (**12**) after digestion with cathepsin B.

Chemotactic Activity of Mtx and Mtx$^{\gamma}$-GFLGC-NH_2. Chemotactic activity of Mtx and Mtx$^{\gamma}$-GFLGC-NH_2 (**12**) molecules was also tested on MonoMac6. The Mtx itself was significantly repellent at the lower concentration range (10^{-2} μM, 47.3 ± 14.6%, 10^{-3} μM, 78.6 ± 19.6%; 10^{-4} μM, 66.9 ± 20.7%) and neutral at the higher concentrations. In contrast to Mtx, compound **12**, the drug containing enzyme sensible spacer sequence of the total CDT bioconjugate, was found to be significantly attractant at the lower concentration range (10^{-2} μM: 145.5 ± 4.8%, 10^{-3} μM: 153.5 ± 4.6%, 10^{-4} μM: 138.5 ± 6.5%), but it was repellent at the highest concentration (1 μM: 63.5 ± 16.1%). The effect of GFLGC on the repellent moiety of Mtx seems to be very advantageous with respect to the biological/clinical activity of the CDT bioconjugate (Supporting Information S3).

Chemotactic Activity of the Branched Peptides and the Mtx-Containing Bioconjugates. Four different targeting moieties in branches (H-TKPR, For-TKPR, H-TKPKG, Ac-TKPKG) were built up on the tetratuftsin carrier, resulting in the *N*-terminal acetylated branched peptides (**4**, **5**, **6**, **7**). In the case of the Mtx conjugates, chloroacetylation of both amino groups of Lys inserted in the *N*-terminus of the carrier was performed and these chloroacetylated branched peptides were conjugated with the Mtx$^{\gamma}$-GFLGC-NH_2 in solution (Scheme 2). This reaction resulted in four Mtx-containing conjugates (**13**, **14**, **15**, **16**). The four drug−oligopeptide conjugates as well as the corresponding branched oligopeptides were tested in chemotaxis assay on MonoMac6 cells. In the case of H-TKPR branches, the branched peptide (**4**) had a chemoattractant effect at 1 μM (115.1 ± 3.5%), and it was slightly repellent at the lower concentration range (10^{-2} μM, 82.6 ± 6.9%; 10^{-3} μM, 85.0 ± 6.1%) (Supporting Information S4). When Mtx$^{\gamma}$-GFLGC-NH_2 was coupled to the peptide resulting in compound **13**, significant chemoattractant behavior appeared over the whole concentration range (10^{-1} μM, 174.7 ± 4.3%; 10^{-2} μM, 306.9 ± 2.3%; 10^{-3} μM, 321.8 ± 2.3%; 10^{-4} μM, 289.6 ± 3.2%) (Figure 4A). In this case, the coupling of the Mtx$^{\gamma}$-GFLGC-NH_2 considerably amended the biological properties of the branched peptide.

In the case of the formylated branches, the branched peptide (**5**) had a chemoattractant effect at 1 μM (135.2 ± 7.4%), but it was repellent at the lower concentration range (10^{-2} μM, 57.5 ± 17.6%; 10^{-4} μM, 68.0 ± 16.7%) (Supporting Information S4). The conjugation with Mtx$^{\gamma}$-GFLGC-NH_2 does not modulate the chemotactic behavior of the molecule (**14**), the conjugate was still significantly attractant at 1 μM (157.6 ± 7.6%), and in the lower concentration range, it could elicit a chemorepellent effect (10^{-2} μM, 70.5 ± 14.1%; 10^{-4} μM, 73.9 ± 12.3%) (Figure 4B).

In case of H-TKPKG branches, the acetylated branched peptide (**6**) showed a biphasic effect; it could trigger a chemorepellent effect at the higher concentration range (1 μM, 53.3 ± 16.2%; 10^{-1} μM, 30.9 ± 20.3%), but it exhibited significant attractant chemotactic activity at the lower concentration range (10^{-2} μM, 388.9 ± 1.9%; 10^{-3} μM, 396.0 ± 2.1%; 10^{-4} μM, 251.4 ± 4.0%) (Supporting Information S4). The coupling of the Mtx$^{\gamma}$-GFLGC-NH_2 to the branched peptide resulted in adverse and less significant effects; the conjugate (**15**) was attractant at 10^{-1} μM (160.0 ± 1.9%), but it could

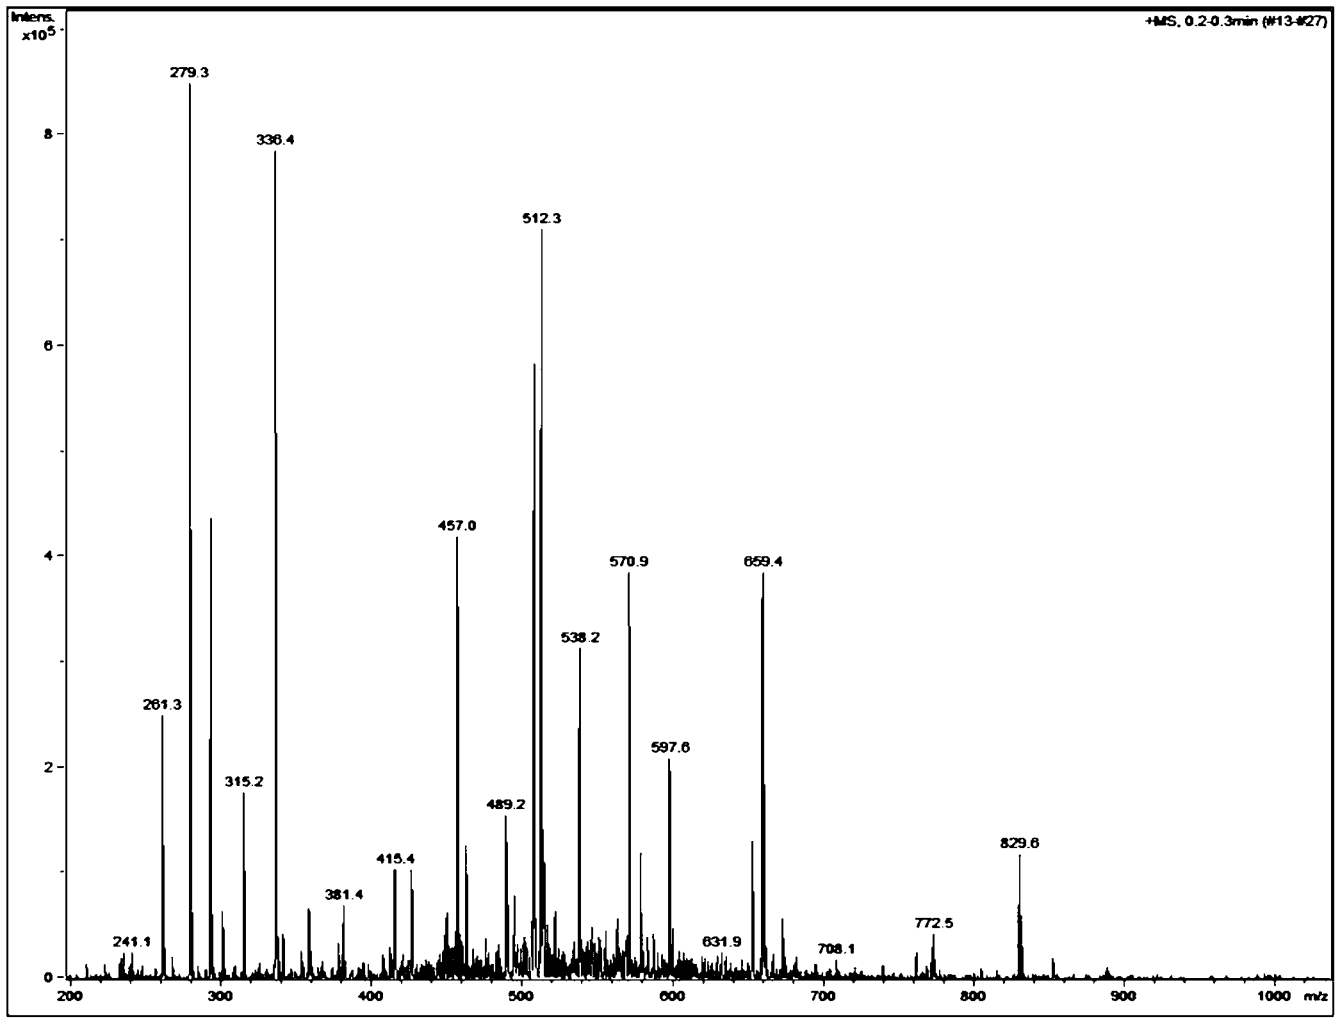

Figure 3. Mass spectrum of conjugate **15** after digestion with cathepsin B.

elicit a repellent effect in the lower concentration range (10^{-2} μM, 59.5 ± 19.3%; 10^{-3} μM, 71.9 ± 17.5%) (Figure 4C).

When the Ac-TKPKG branched peptide was studied, a significant attractant behavior was detected at 10^{-1} μM (139.6 ± 3.9%), which was retained, but shifted to the lower concentration range (10^{-2} μM: 146.1 ± 5.2%) after conjugation with Mtx$^{\gamma}$-GFLGC-NH_2 resulting in compound **16** (Supporting Information S4; Figure 4D).

Cellular Uptake of the CF-Labeled Conjugates. For the cellular uptake studies, the synthesis of CF-labeled conjugates was carried out. For this, CF-GFLGC-NH_2 was synthesized—similarly to Mtx$^{\gamma}$-GFLGC-NH_2—and coupled to the branched peptide *via* a thioether bond. Four CF-labeled conjugates (**18**, **19**, **20**, **21**) were studied. The mean fluorescence intensity of cells was quantitated by flow cytometry. After treatment for 90 min, cells were analyzed. We observed the concentration-dependent accumulation of fluorescence signal within the cells (Figure 5), indicating rapid internalization of each CF-labeled conjugate. A high level of internalization of the CF-labeled conjugates with For-TKPR branches was observed, while the internalization of the CF-labeled conjugates with H-TKPR branches was less pronounced (Figure 5A,B). Consequently, the formylation of the branches increased the cellular uptake of the conjugates. In the case of H-TKPKG branches, a relatively high internalization was observed, whereas the CF-labeled conjugates with Ac-TKPKG branches were internalized considerably within 90 min. In fact, the CF-labeled conjugates with Ac-TKPKG branches showed higher levels of internalization at all studied concentrations (Figure 5C,D). Consequently, the acetylation of the branches also increased the cellular uptake of the conjugates. The cellular uptake of the conjugates with H-TKPR branches was higher compared to the H-TKPKG branches. By the same token, the internalization of the conjugates with For-TKPR branches was compared to the conjugates with Ac-TKPKG branches: the rate of the cellular uptake was almost the same. A very high increase of fluorescence intensity in the cells was observed when the concentration of the conjugates was elevated from 4 μM to 20 μM. We believe that at lower concentration the conjugates are taken up in a receptor-mediated way, while at a higher concentration, they enter into the cells by fluidic endocytosis or the conjugates behave as cell penetrating peptides because of their strong positively charged character. The mechanism of the cellular uptake of these conjugates requires further study.

Apoptosis Assay. Phosphatidylserine (PS) is asymmetrically located in the lipid bilayer of the plasma membrane in mammalian cells. In cells undergoing apoptosis, PS is transferred from the cytoplasmic surface of the cell membrane to the outer surface of the plasma membrane and therefore serves as an early marker for apoptosis. By simultaneous staining with Annexin-V-FITC and PI, we could distinguish among intact cells, early apoptosis, late apoptosis, and cell death. Assessment of MonoMac6 cells exposed to 10^{-2}, 10^{-1}, and 1 μM Mtx and Mtx conjugates for different periods of time (3, 24, and 48 h) showed that 2−12% cells were undergoing necrosis (Figure 6; Supporting Information S5−6). MonoMac6 cells showed an an-

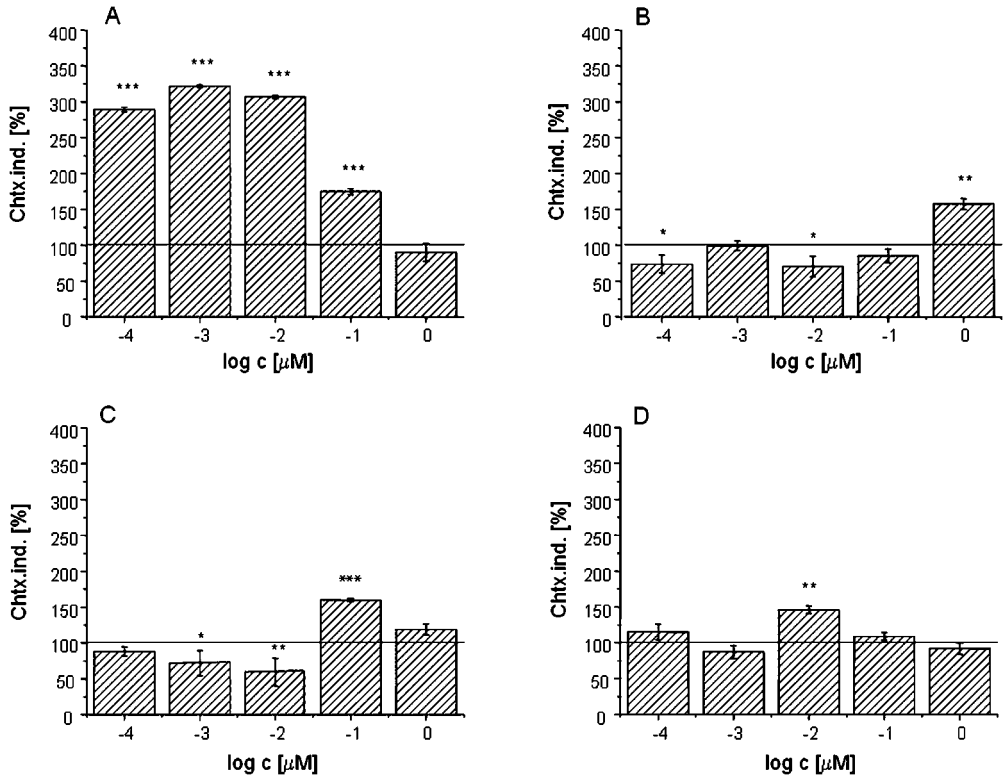

Figure 4. Chemotactic activity of Mtx conjugates with **A**, H-TKPR (**13**); **B**, For-TKPR (**14**); **C**, H-TKPKG (**15**); **D**: Ac-TKPKG (**16**) peptides in the branches. (* $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$).

nexin-/PI+ (indicating cell necrosis) pattern after 3, 24, and 48 h treatment with Mtx and Mtx conjugates in all concentrations. Only a few annexin+/PI− cells (indicating cell apoptosis) and annexin+/PI+ (indicating later stage of apoptotic cells) were observed. As it is shown in Figure 6 and Supporting Information S5−6, detection of MonoMac6 necrotic cells was dose- and

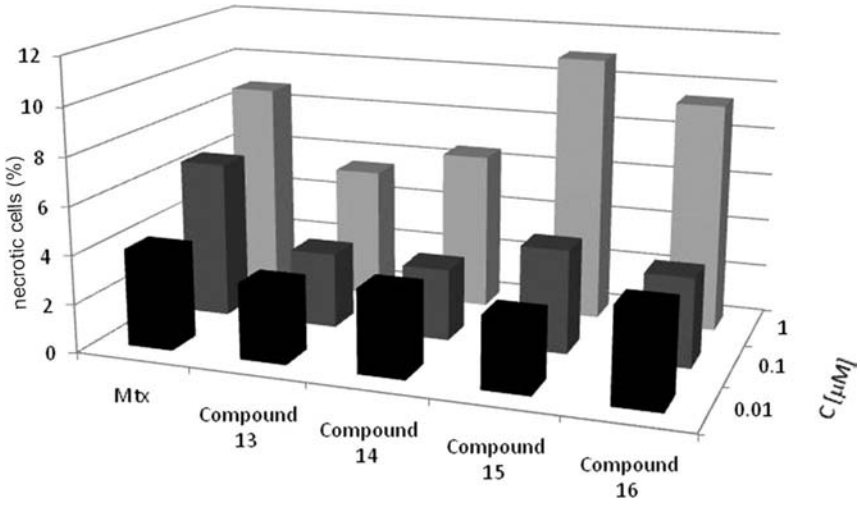

Figure 6. Effect of Mtx and Mtx-conjugates with H-TKPR (**13**), For-TKPR (**14**), H-TKPKG (**15**), and Ac-TKPKG (**16**) peptides in the branches in apoptotic assay on the MonoMac6 cell line after 24 h incubation.

time-dependent (maximum at 24 h, Figure 6). Mtx was more active than the conjugates at the concentrations of 0.01 and 0.1 μM, but at 1 μM dose, conjugates **15** and **16** showed higher toxity on MonoMac6 cells during the whole experiment.

CONCLUSION

In summary, new targeted peptide-based drug delivery systems were synthesized and biochemically characterized. These biodegradable conjugates consist of Mtx as the drug, an enzyme labile peptide spacer (GFLGC), a biodegradable peptide carrier (OT20), and four types of targeting peptide moieties (H-TKPR, For-TKPR, H-TKPKG, and Ac-TKPKG), which have been shown to bind to tuftsin receptors, and the conjugates can be internalized by receptor-mediated endocytosis. Inside the cells, in the lysosomes, the drug molecules could be released from the conjugates after enzymatic (cathepsin B) cleavage; therefore, our conjugates could elicit the proper anticancer effect. *In vitro* biological assays were performed with the prepared conjugates. Chemotaxis assays were carried out with the compounds and the branched peptides, as well as with the drug-conjugates. Each of the branched peptides and the drug conjugates could trigger a significant chemotactic effect on MonoMac6 cells, but the most effective conjugate was compound **13**, which was significantly attractant in a wide concentration range ($10^{-1}-10^{-4}$ μM). Rapid internalization of the CF-labeled conjugates was observed. Apoptosis assay was performed using simultaneous staining with Annexin-V-FITC and PI. MonoMac6 cells were undergoing necrosis after treatment with Mtx or with compunds **13**−**16**. Compounds **15** and **16** were the most effective ones; these conjugates triggered a higher toxic effect than the free drug (Mtx). Compound **13** induced necrosis in MonoMac6 cells. The effectiveness of compound **13** is comparable to that of the free drug at 3 or 48 h incubation (Supporting Information S5, S6). First and last, if we draw a parallel between Mtx and Mtx-conjugates (**13**, **14**, **15**, and **16**) we can conclude that the conjugates have many advantages in comparison with Mtx. The conjugates can attract the MonoMac6 cells in certain concentrations, especially compound **13**, which has the most advatageous chemotactic properties. Its significant chemoattractant behavior appears at a wide concentration range. Beside the chemotaxis, the conjugates can be internalized rapidly and at the same level as the Mtx, but the mechanism of internalization is different. Mtx can simply diffuse through the membrane without any specificity in contrast to the conjugates, which can be taken up by the cells through receptor-mediated endocytosis. By the same token, the conjugates are at least as cytotoxic as Mtx. To conclude the results of the biological assays, the most promising compounds are **13** and **16**. The results of the biological tests confirmed the feasibility of this new chemotactic drug targeting strategy for increasing the efficacy and specificity of chemotherapy especially in tumor treatments.

Received January 25, 2008; Revised Manuscript Received August 19, 2008

A series of camptothecin open-ring lactone tripartate conjugates were synthesized, in which polyamine side chains with different architecture (ethane-1,2-diamine, spermidine, homospermidine, spermine, and 4,8,13,17-tetrazaicosane-1,20-diamine) are linked to the 21-carboxylic function through an amidic bond, while the 17-CH_2OH is acetylated. The rationale for the synthesis of these compounds was to explore the influence of the polyamine architecture on the activity of these CPT conjugates into cells, since the positively charged ammonium cations would favor interaction through electrostatic binding to the negatively charged DNA backbone. Topoisomerase I-mediated DNA cleavage assay was used to investigate the ability of these compounds to stimulate the DNA damage. The cleavage pattern was found to be similar to that of SN38 for all the new CPTs. The CPT tripartates were tested for growth inhibition ability against the human non-small-cell lung cancer carcinoma NCI-H460 cell line. Although these compounds were less potent than topotecan, SN38, and CPT after 1 h of treatment, the antiproliferative effects greatly increased after 72 h of exposure. The growth inhibition potency during long-term exposure is correlated with the number of charges of the 21-amide substituent. Both cleavage assay and *in vitro* effects support the interpretation that the compounds may have inhibitory activity also in the open-ring form. The architecture of the polyamine moiety is important for antiproliferative activity, and a balance between the hydrophilic and lipophilic properties of the polyamine is critical for CPT potency.

INTRODUCTION

Camptothecins (CPT, **1**, Figure 1) are an effective class of antitumor drugs, used in the treatment of a wide spectrum of human cancers. The molecular target of the CPTs family is the enzyme DNA topoisomerase I (topo I), a ubiquitous enzyme which is overexpressed in a variety of tumor cell lines and involved in the regulation of DNA topology during replication, recombination, and transcription (*1*−*4*). The drug stabilizes a reversible enzyme−DNA complex, which is termed the cleavable complex, thus preventing the ligation step of the enzyme action. These biochemical observations, integrated by crystallographic (*5*−*7*), UV−vis (*8, 9*), and NMR (*9*) spectroscopic information and quantum mechanic calculations (*9*−*14*), allowed the design of binding models for CPT with the covalent binary complex (*5, 11, 12, 15*).

Therapeutic applications of CPT have been limited by its low water solubility and by the high *in vivo* reactivity of the α-hydroxy-δ-lactone pharmacophore, which, under physiological conditions, reversibly hydrolyzes to the "ring-opened" carboxylate form (**1a**, Figure 1) (*16*). The latter is very toxic (*17*) and far less active with respect to inhibition of topo I (*18, 19*). In addition, the carboxylate form (**1a**) readily binds to human serum albumin, making it less accessible for cellular uptake (*20, 21*). This behavior gives rise to a drop in therapeutic efficacy, along with formulation difficulties (*21*). For these reasons, all the elements controlling the structure and lactone−carboxylate equilibrium are key factors in determine their potency. To avoid this inconvenience, a number of CPT analogues have been synthesized to improve lactone stability and aqueous solubility. These efforts have produced the two water-soluble semisynthetic analogues: topotecan (Hycamptin, **2**) (*22*) and irinotecan (Camptostar, **3**) (*23*), which received FDA approval for the clinical treatment of the ovarian, small-cell lung, and refractory colorectal cancers, while several other analogues are currently under development. Although **2** and **3** showed activity against a wide range of tumors, both of them have a relatively low therapeutic index and considerable toxic effects (*24*−*26*). In this regard, several prodrug strategies (*27*−*29*) have rapidly emerged to achieve site-specific delivery of

cytotoxic CPTs. Most of these strategies are based on the use of conjugates that maintain CPT in the closed-lactone form into the plasma compartment. To this end, it is known that the free 20-hydroxyl group favors the lactone ring-opening through intramolecular hydrogen bonding (*30*). Therefore, acylation of the 20-hydroxyl group would render the lactone moiety more stable toward ring opening (*31*). Accordingly, 20(*S*)-*O*-acyl esters (*32, 33*), 20(*S*)-*O*-carbonated linked tripeptide conjugates (*34*), and 20(*S*)-*O*-linked glycoconjugates (*35*) were synthesized and showed excellent *in vitro* cytotoxicity. Alternatively, reactive functional groups, such as amino, hydroxyl, and carboxylic acid substituents, were introduced in the quinoline (A/B) ring system as linkers for ligand conjugation (*36*−*41*).

A scarcely explored family of CPT conjugates is the tripartate prodrugs, which are characterized by an E-ring open form, where the C-21 position is linked to a *carrier* by an amidic bond, while the 17-hydroxy group is acetylated. The synthesis of these conjugates relies on the fact that the 17-OH-21-amide CPT derivatives (dipartates) are sufficiently stable to allow the 17-OH acylation, yielding more stable ester−amide tripartates (*42*). These 17-*O*-acylated 21-amides, which are stable under physiological conditions for several hours, are supposed to act through a two-step mechanism: the acyl moiety undergoes enzymatic hydrolysis, affording the corresponding dipartate 17-CH_2OH-21-amides (*43*−*45*), subsequently, the free 17-OH group anchimerically assists the spontaneous amide hydrolysis, which generates the lactone species through cyclization. Although only a few examples have been reported in the literature, their biological data showed that their action strongly depends on the structure of both the ester and the amide moieties. For example, the inhibitory activity of CPT tripartates bearing an acyl ester, a carbonate, or a carbamate moiety at the 17 position and a N^1,N^1-dimethylaminoethylamide group at the 21 position (compound **I**, Figure 2) showed higher *in vivo* activity than the 7-ethylcamptothecinic sodium salt (*43, 44*). Instead, the 17-*O*-acyl esters of CPT tripartates bearing an isopropylamide substituent at the 21 position (compound **II**, Figure 2) showed lower *in vitro* and *in vivo* activity than camptothecinic sodium salt (*42, 43*). This behavior is due to the different hydrolytic profile of the amide group of their corresponding 17-CH_2OH dipartates. Actually, the amidic bond of compound **I** hydrolyzes very rapidly at physiological pH, while the isopropyl amide group (compound **II**) hydrolyzed very slowly, being the rate-determining step in the generation of the lactone species.

Besides compounds of types **I** and **II**, two very efficient CPT PEGylate tripartates were reported (**4** and **5**, Figure 3), which show little *in vitro* efficacy in tissue cultures (*45*).

According to the authors, an initial rapid hydrolysis of the ester (or carbonate) affords the corresponding relatively stable and nonactive dipartates. Therefore, cyclization to the active lactone species, which occurs only within the tumor environment, is the rate-determining step (*46*).

The tripartate reactivity scenario is further complicated when considering the possibility that these compounds may exhibit intrinsic antitumor activity. Our recent results regarding the water-soluble CPT tripartate **6** (Figure 4) showed that this compound and its analogues maintain the same order of potency of their reference CPTs, despite the E ring opened form (*47*).

These results cannot be ascribed to the derivative lactonization, since no free CPT was recovered at the end of DNA cleavage assays, and the low amount of CPT detectable in plasma and tumor did not account for the observed efficacy. Thus, these 17-acetate-21 spermidine derivatives could represent the first example of an effective CPT drug with opened lactone ring.

To provide novel insights into this class of open-lactone conjugates, we have synthesized a family of 17-O-acyl protected tripartates of CPT bearing polyamines at the C21-carboxyl group. The ubiquitous polyamines, such as cadaverine, putrescine, spermidine, and spermine, are biosynthesized in humans and play an essential role as regulators of cell growth and differentiation (*48*−*50*). Many tumor types contain high levels of polyamines and an activated exogenous polyamines transporter (PAT) (*51*). Polyamines are organic cations, since the primary and secondary amino groups are protonated at physiological pH. The unique feature of polyamine structure is the presence of methylene groups, which favor hydrophobic interactions, and the presence of positive charges at defined distances, which can electrostatically interact with negatively charged DNA (*52*). In addition to this charge neutralization, polyamines interact with nucleic acid bases, dock into the major or minor grooves, and enter into multisite interactions depending on the ionic environment (*53, 54*). However, the mechanism of polyamine entry into mammalian cells remains poorly defined (*55*−*57*), and more data are needed on the transporters that are believed to facilitate specific delivery to tumor cells, in order to design proper prodrugs. Nevertheless, several attempts to design a polyamine vector have been reported, which are based on structure−activity studies aimed at explaining which polyamine sequence would be the most suitable to access the transporter (*58*−*62*). These studies suggest that small structural changes in the polyamine skeleton give rise to strong differences in their transport behavior and that linear polyamines are superior vectors to the branched ones (*54, 63*−*69*).

MATERIALS AND METHODS

General. All reactions were performed under an atmosphere of dry nitrogen using oven-dried glassware. Tetrahydrofuran, toluene, and ethyl ether were distilled from sodium benzophenone ketal. Dichloromethane and DMF were distilled from calcium hydride. All other solvents were HPLC grade. Reactions were magnetically stirred and monitored by thin-layer chromatography (TLC) with E. Merck silica gel 60-F254 plates. Flash column chromatography was performed with Merck silica gel (0.04−0.63 μm, 240−400 mesh) under high pressure. NMR spectra were recorded on a 400 MHz spectrometer. Unless otherwise stated, all NMR spectra were measured in $CDCl_3$ solutions and referenced to the $CHCl_3$ signal. All ^{1}H and ^{13}C shifts are given in ppm (s = singlet; d = doublet; t = triplet; dd = quadruplet; dt = doublet of triplets, m = multiplet; br s = broad signal). Coupling constants *J* are given in Hz. Assignments of proton resonances were confirmed, when possible, by selective homonuclear decoupling experiments or by correlated spectroscopy. IR spectra were recorded on a FT-IR ESP spectrometer as thin films on NaCl plates. Mass spectra were recorded on an ion trap spectrometer with an ionization

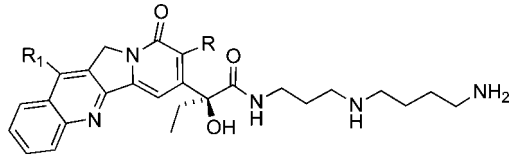

Figure 4. Compounds **6** and **7**.

potential of 70 eV. High-resolution mass spectra (HRMS) were performed with a resolution of 10 000 against a suitable mass standard. The commercially available reagents were used as received without further purification.

General Procedure. For the synthesis of tripartate conjugates **18**, **7**, and **19** from CPT **1** and *N*-^{t}BOC polyamines **13**, **14**, and **16**, respectively, CPT **1** (1.0 equiv), was suspended in 5.0 mL of dry pyridine, and the *N*-*t*BOC-polyamines **13**, **14**, and **16** (4.0 equiv) were added. The reaction was heated at 80 °C for 70 h, and than the solvent was removed under reduced pressure. Flash chromatography, CH_2Cl_2−MeOH (30:1), of the crude material afforded the derivatives 17-hydroxy-21-Boc-amides in 88%, 55%, and 10% yields, respectively, as yellow solids. These compounds (1.0 equiv) were dissolved in dry pyridine (5.0 mL), and acetic anhydride (20.0 equiv) was added. The reaction mixture was magnetically stirred for 2 h at 20 °C, and then the excess of solvent and reagent were removed under vacuum. The resulting solid residue was purified by silica gel flash chromatography, CH_2Cl_2−MeOH (30:1), affording the corresponding 17-*O*-acyl-21-*N*-^{t}Boc-amides in quantitative yield. To a cooled solution (0 °C) of these conjugates (1.0 equiv) in dry DCM (8.0 mL), TFA (15.7 equiv) was added dropwise with stirring over a period of 30 min. The reaction was stirred for 60 h at 0−4 °C, and then the solvent was removed under reduce pressure to obtain the tripartates **18**, **6**, and **19**, respectively, as pale yellow solids.

Compound 18. (88%); pale yellow solid. HRMS *m*/*z* calcd for $C_{26}H_{27}F_3N_4O_7$ $[M]^+$ 564,1832; *m*/*z* found 564,1841. ^{1}H NMR (400 MHz, DMSO-d_6/D_2O) δ 8.58 (s, 1 H, Ar), 8.08 (d, 1 H, J = 8.4 Hz, Ar), 8.01 (d, 1 H, J = 8.4 Hz, Ar), 7.81 (t, 1 H, J = 8.4 Hz, Ar), 7.64 (t, 1 H, J = 8.4 Hz, Ar), 7.53 (s, 1 H, Ar), 5.29 (d, 1 H, J = 11.2 Hz), 5.20 (d, 1 H, J = 11.2 Hz), 5.15 (s, 2 H, H-5), 3.38 (m, 1 H), 3.22 (m, 1 H), 2.86 (bt, 2 H), 2.22 (m, 1 H), 2.13 (m, 1 H), 1.95 (s, 3 H), 0.87 (t, 3 H, J = 7.8 Hz). ^{13}C NMR (100 MHz, DMSO-d_6) δ 174.1, 171.0, 161.3, 156.2, 153.4, 148.6, 144.9, 132.3, 131.1, 130.7, 129.7, 129.2, 128.7, 128.3, 123.9, 99.4, 79.3, 59.4, 51.0, 38.9, 37.3, 32.4, 21.4, 8.5.

Compound 6. (55%); pale yellow solid. HRMS *m*/*z* calcd for $C_{33}H_{39}F_6N_5O_9$ $[M]^+$ 763,2652; *m*/*z* found 763,2644. ^{1}H NMR (400 MHz, DMSO-d_6/D_2O) δ 8.63 (s, 1 H, Ar), 8.12 (d, 1 H, J = 8.4 Hz, Ar), 8.05 (d, 1 H, J = 8.4 Hz, Ar), 7.86−7.81 (m, 1 H, Ar), 7.70−7.65 (m, 1 H, Ar), 7.50 (s, 1 H, Ar), 5.29 (d, 1 H, J = 11.2 Hz, H-17), 5.24 (d, 1 H, J = 11.2 Hz, H-17), 5.21 (s, 2 H, H-5), 3.20−3.00 (m, 2 H), 2.88−2.80 (m, 4 H), 2.80−2.72 (m, 2 H), 2.18−2.28 (m, 1 H), 2.06−2.18 (m, 1 H), 1.95 (s, 3 H), 1.76−1.66 (m, 2 H), 1.60−1.48 (m, 4 H), 0.88 (t, 3 H, J = 7.8 Hz). ^{13}C NMR (100 MHz, DMSO-d_6) δ 173.9, 171.0, 161.3, 158.0 (q, CO_2H of TFA), 156.5, 153.4, 148.7, 144.9, 132.3, 131.1, 130.6, 129.7, 1292, 128.7, 128.3, 124.0, 99.5, 79.4, 59.5, 51.0, 46.8, 45.3, 38.9, 36.7, 32.3, 26.5, 24.8, 23.3, 21.4, 8.6.

Compound 19. (10%); pale yellow solid. HRMS *m*/*z* calcd for $C_{38}H_{47}F_9N_6O_{11}$ $[M]^+$ 934,3159; *m*/*z* found 934,3168. ^{1}H NMR (400 MHz, CD_3OD) δ 8.65 (s, 1 H, Ar), 8.18 (d, 1 H, J = 8.4 Hz, Ar), 8.07 (d, 1 H, J = 8.4 Hz, Ar), 7.88 (t, 1 H, J = 8.4 Hz, Ar), 7.83 (s, 1 H, H-14), 7.72 (t, 1 H, J = 8.4 Hz, Ar), 5.46 (d, 1 H, J = 11.2 Hz, H-17), 5.40 (d, 1 H, J = 11.2 Hz, H-17), 5.33 (s, 2 H, H-5), 3.18−3.00 (m, 12 H), 2.48−2.40 (m, 1 H, H-19), 2.34−2.26 (m, 1 H, H-19), 2.12−2.08 (m, 4 H), 2.06 (s, 3 H), 1.90−1.76 (m, 4 H), 1.06 (t, 3 H, J = 7.6 Hz). ^{13}C NMR (100 MHz, CD_3OD) δ 176.4, 173.2, 163.3, 158.5, 153.8, 149.7, 146.2, 133.4, 132.0, 131.0, 130.0, 129.8, 129.7, 129.1, 125.5, 102.2, 80.0, 60.5, 51.8, 46.7, 46.3, 45.9, 37.8, 37.1, 36.8, 33.2, 27.7, 27.5, 25.4, 24.3, 22.4, 8.3.

17-Acetylcamptothecin-21-benzylamide (*21*). CPT **1** (350 mg, 1.01 mmol), was suspended in dry benzyl amine (2.5 mL). The reaction mixture was heated at 45−50 °C for 2.5 h, and then the solvent was removed under reduced pressure. Water was then added, and the aqueous layer was extracted with CH_2Cl_2 (15 mL × 3). The combined organic extracts were dried over anhydrous Na_2SO_4, filtered, and concentrated under vacuum to afford 17-hydroxy-21-benzylamide as a yellow solid (440 mg, 96%). The crude material was used for the next step without further purification.

17-hydroxy-21-benzylamide (440 mg, 0.97 mmol) was dissolved in dry pyridine (10 mL), and acetic anhydride (1.8 mL, 19.4 mmol) was added. The reaction was stirred at room temperature until TLC analysis [CH_2Cl_2−MeOH (30:1)] showed complete consumption of the starting material (2.5 h). The solvent and the excess of reagent were then removed under vacuum, and water was added. The aqueous layer was extracted with CH_2Cl_2 (20 mL × 3). The organic layer was further washed with 5% HCl and dried over anhydrous Na_2SO_4, filtered, and concentrated in vacuo to afford **21** (480 mg, ∼100%) in quantitative yield as a pale yellow solid. HRMS *m*/*z* calcd for $C_{29}H_{27}N_3O_5$ $[M]^+$ 497,1951; *m*/*z* found 497,1964. ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.19 (s, 1 H, Ar), 8.11 (d, 1 H, J = 8.4 Hz, Ar), 7.74 (t, 1 H, J = 8.4 Hz, Ar), 7.69 (d, 1 H, J = 8.4 Hz, Ar), 7.63 (s, 1 H, H-14), 7.51 (t, 1 H, J = 8.4 Hz, Ar), 7.35−7.20 (m, 5 H, Ar), 5.56 (d, 1 H, J = 12.0 Hz), 5.44 (d, 1 H, J = 12.0 Hz), 5.19 (d, 1 H, J = 16.4 Hz), 5.13 (d, 1 H, J = 16.4 Hz), 5.13 (s, 1 H, O*H*), 4.53 (dd, 1 H, J_1 = 4.8 Hz, J_1 = 6.4 Hz), 4.39 (dd, 1 H, J_1 = 14.8 Hz, J_1 = 6.4 Hz), 2.56−2.46 (m,

1 H, H-19), 2.38−2.28 (m, 1 H, H-19), 2.04 (s, 3 H), 1.08 (t, 3 H, $J = 7.6$ Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ 172.1, 171.1, 161.5, 157.0, 151.3, 148.0, 144.1, 137.7, 130.5, 130.1, 128.9, 128.6, 128.5, 128.0, 127.8, 127.7, 127.5, 127.2, 124.9, 100.7, 78.5, 58.7, 50.3, 43.5, 33.1, 20.9, 7.9.

17-Acetylcamptothecin-21-benzyl Ester (*23*). To a solution of **21** (480 mg, 0.97 mmol) in a 2:1 mixture of Ac_2O (12 mL) and AcOH (6 mL) was added granular $NaNO_2$ (1.34 g, 19.4mmol) in portions over 2 h at 0−4 °C. Evolution of brown gas occurred. The flask was kept in the ice bath for 2 h and allowed to warm to room temperature and further reacted for 24 h. The mixture was then poured into ice/water and extracted with CH_2Cl_2 (3×). The combined organic layers were washed with 5% Na_2CO_3 followed by H_2O and dried over Na_2SO_4. Evaporation of solvent afforded compound **22** as yellowish solid, which was immediately dissolved with anhydrous 1,4-dioxane (16 mL) and refluxed for 5 h. The reaction mixture was cooled to room temperature, and the solvent was removed under vacuum to give **23** (483 mg, ≈100%). The crude product was sufficiently pure for the following step. However, an analytical sample of **23** was purified by silica gel flash chromatography CH_2Cl_2−MeOH (30:1). **23**: HRMS *m*/*z* calcd for $C_{29}H_{26}N_2O_6$ $[M]^+$ 498,1791; *m*/*z* found 498,1798. ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.33 (s, 1 H, Ar), 8.20 (d, 1 H, $J = 8.4$ Hz, Ar), 7.89 (d, 1 H, $J = 8.4$ Hz, Ar), 7.80 (t, 1 H, $J = 8.4$ Hz, Ar), 7.63 (t, 1 H, $J = 8.4$ Hz, Ar), 7.52 (s, 1 H, H-14), 7.33−7.24 (m, 5 H, Ar), 5.50 (d, 1 H, $J = 11.6$ Hz), 5.47 (d, 1 H, $J = 11.6$ Hz), 5.29 (d, 1 H, $J = 12.0$ Hz), 5.23 (s, 2 H), 5.16 (d, 1 H, $J = 12.0$ Hz), 4.32 (s, 1 H, O*H*), 2.41−2.24 (m, 2 H, H-19), 2.03 (s, 3 H), 0.95 (t, 3 H, $J = 7.6$ Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ 173.5, 171.0, 161.4, 153.4, 152.5, 148.7, 144.7, 134.7, 131.0, 130.5, 129.5, 128.8, 128.6, 128.6, 128.3, 128.1, 128.1, 127.8, 124.9, 99.8, 79.4, 68.2, 58.7, 50.2, 32.2, 20.9, 7.6.

17-Acetylcamptothecinic Acid (*20*). Crude **23** (226 mg, 0.45 mmol) was dissolved in THF−EtOH (1:1). Dry 10% Pd/C (48 mg) was carefully added to the reaction mixture, and the dissolved oxygen was removed under vacuum. Then, a balloon of hydrogen was mounted, and the mixture was stirred for 10 h at room temperature. The catalyst was removed by filtration through a celite pad, and the filtrate was concentrated under vacuum. The crude material was purified by silica gel flash chromatography CH_2Cl_2−MeOH (step gradient elution 20:1, 10:1) to afford **20**. HRMS *m*/*z* calcd for $C_{22}H_{20}N_2O_6$ $[M]^+$ 408,1321; *m*/*z* found 408,1330. ^{1}H NMR (400 MHz, DMSO-d_6) δ 8.64 (s, 1 H, Ar), 8.18 (d, 1 H, $J = 8.4$ Hz, Ar), 8.08 (d, 1 H, $J = 8.4$ Hz, Ar), 7.85−7.81 (m, 2 H, Ar), 7.68 (t, 1 H, $J = 8.4$ Hz, Ar), 5.90 (s, 1 H, O*H*), 5.61 (d, 1 H, $J = 10.4$ Hz), 5.39 (d, 1 H, $J = 10.4$ Hz), 5.20 (s, 2 H), 1.98−1.82 (m, 5 H, H-19 + Me), 0.82 (t, 3 H, $J = 7.6$ Hz). ^{13}C NMR (100 MHz, DMSO-d_6) δ 171.0, 161.8, 160.0, 153.9, 148.7, 143.5, 132.0, 130.9, 130.6, 129.7, 129.1, 128.5, 128.1, 123.6, 101.3, 80.6, 60.2, 50.6, 33.8, 21.5, 9.6.

General Procedure. For the preparation of tripartate conjugates **24**, **19**, and **25** from the addition reaction of **20** to N-^{t}BOC polyamines **15**, **16**, and **17**, respectively, to a solution of **20** (1 equiv) in dry DMF (2 mL) the polyamine (2 equiv) and Et_3N (3 equiv) were sequentially added. The reaction mixture was cooled at 0 °C and 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (EDCI.HCl, 2.2 equiv) and *N*-hydroxybenzotriazole (HOBt, 2.1 equiv) were added. The mixture was stirred at 0 °C for 2 h, then warmed at 20 °C and reacted further for 40−50 h. The solvent was removed under reduced pressure, and the crude material was purified by silica gel flash chromatography in CH_2Cl_2−MeOH (step gradient elution 40:1, 30:1, and 15:1), to afford the corresponding 17-acetyl-21-*N*-^{t}BOC protected amides in 62%, 50%, and 27% yields, respectively. To a solution of these conjugates (1 equiv), in DCM (8 mL) TFA (15.7 equiv) was added dropwise at 0 °C. The solution was stirred for 60 h at 0−4 °C, and then solvents were removed under reduced pressure to afford the desire products **24**, **19**, and **25**, as pale yellow solids.

19: (50%); pale yellow solid.

Compound 24. (62%); pale yellow solid. HRMS *m*/*z* calcd for $C_{34}H_{43}F_6N_5O_9$ $[M]^+$ 779,2965; *m*/*z* found 779,2972. ^{1}H NMR (400 MHz, CD_3OD) δ 8.59 (s, 1 H, Ar), 8.13 (d, 1 H, $J = 8.4$ Hz, Ar), 8.02 (d, 1 H, $J = 8.4$ Hz, Ar), 7.83 (t, 1 H, $J = 8.4$ Hz, Ar), 7.78 (s, 1 H, H-14), 7.68 (t, 1 H, $J = 8.4$ Hz, Ar), 5.46 (d, 1 H, $J = 11.2$ Hz, H-17), 5.39 (d, 1 H, $J = 11.2$ Hz, H-17), 5.25 (s, 2 H, H-5), 3.10−2.90 (m, 8 H), 2.54−2.44 (m, 1 H, H-19), 2.33−2.24 (m, 1 H, H-19), 2.06 (s, 3 H), 1.82−1.66 (m, 8 H), 1.07 (t, 3 H, $J = 7.6$ Hz). ^{13}C NMR (100 MHz, CD_3OD) δ 174.5, 172.1, 162.2, 157.6, 152.5, 148.4, 144.8, 132.1, 130.7, 129.7, 128.7, 128.6, 128.5, 127.9, 124.5, 101.1, 78.7, 59.3, 50.5, 47.3, 46.9, 38.8, 38.4, 32.1, 26.3, 24.4, 23.5, 23.1, 21.4, 7.1.

Compound 25. (27%); pale yellow solid. HRMS *m*/*z* calcd for $C_{47}H_{63}F_{15}N_8O_{15}$ $[M]^+$ 1264,4173; *m*/*z* found 1264,4165. ^{1}H NMR (400 MHz, CD_3OD) δ 8.60 (s, 1 H, Ar), 8.14 (d, 1 H, $J = 8.4$ Hz, Ar), 8.03 (d, 1 H, $J = 8.4$ Hz, Ar), 7.85 (t, 1 H, $J = 8.4$ Hz, Ar), 7.80 (s, 1 H, H-14), 7.69 (t, 1 H, $J = 8.4$ Hz, Ar), 5.46 (d, 1 H, $J = 11.2$ Hz, H-17), 5.40 (d, 1 H, $J = 11.2$ Hz, H-17), 5.27 (s, 2 H, H-5), 3.18−3.00 (m, 20 H), 2.48−2.40 (m, 1 H, H-19), 2.34−2.26 (m, 1 H, H-19), 2.18−2.07 (m, 8 H), 2.06 (s, 3 H), 1.90−1.76 (m, 4 H), 1.06 (t, 3 H, $J = 7.6$ Hz). ^{13}C NMR (100 MHz, CD_3OD) δ 176.4, 173.2, 163.4, 158.4, 153.7, 149.6, 146.1, 133.3, 131.9, 131.0, 130.9, 129.9, 129.8, 129.7, 129.1, 125.5, 102.2, 80.0, 60.4, 51.7, 48.2, 46.8, 46.4, 45.9, 45.8, 45.8, 37.8, 37.1, 33.3, 30.9, 27.7, 27.5, 25.3, 24.1(2 C), 21.0, 8.3.

Growth Inhibition Assays. Human non-small-cell lung cancer NCI-H460 cells were cultured in RPMI 1640 containing 10% FCS. Cell sensitivity was assessed by growth inhibition assay after 1 or 72 h of drug exposure. Cells in the logarithmic phase of growth were seeded in duplicates into six-well plates. Twenty-four hours later, cells were exposed to the drug and counted with a Coulter counter 72 h after the beginning of drug exposure for 1 h of treatment and at the end of drug exposure in the case of 72 h of treatment. IC_{50} is defined as the inhibitory drug concentration causing a 50% decrease of cell growth over that of the untreated control.

Topoisomerase I-Dependent DNA Cleavage Assays. A gel-purified 751-bp *Bam*HI-*EcoRI* fragment of SV40 DNA was used for the cleavage assay (*1*). DNA fragments were uniquely 3′-end-labeled. Topoisomerase I-DNA cleavage reactions (20 000 cpm per sample) were done in 20 μL of 10 mM Tris-HCl (pH 7.6), 150 mM KCl, 5 mM $MgCl_2$, 15 μg/mL bovine serum albumin, 0.1 mM DTT, and the human recombinant enzyme (full-length topoisomerase I) for 30 min at 37 °C. Reactions were stopped using 0.5% SDS and 0.3 mg/mL of proteinase K for 45 min at 42 °C. Persistence of DNA cleavage at different time points was examined by adding 0.6 M NaCl after 30 min of incubation with 10 μM drug. After precipitation, DNA was resuspended in denaturing buffer (80% formamide, 10 mM NaOH, 0.01 mM EDTA, and 1 mg/mL dyes) before loading on a denaturing 8% polyacrylamide gel in Tris-borate EDTA buffer. Overall, DNA cleavage levels were measured with a PhosphoImager 425 mode (*2*).

Stability of Compound 18 in Cell Culture Medium and DNA Cleavage Buffer. The stability study was performed by using high-performance liquid chromatography (HPLC) coupled with mass spectrometry (LC-MS). In order to optimize the method, MS analyses in direct infusion mode were carried on a LCQ-Duo mass spectrometer (ThermoFinnigan, San Jose, CA), equipped with an electrospray ionization source (ESI),

operating in positive polarity under the following condition: spray voltage 4.5 kV, capillary temperature 200 °C. The mass spectra were recorded in total ion current (TIC) within 150 and 2000 *m/z* and in tandem mass modality (MS/MS). Quantitative LC-MS analyses of the cell culture media diluted 1:10 with 0.1% formic acid/acetonitrile 85:15 (v/v) were conducted on a Cap-LC liquid chromatograph interfaced with a Q-TOF hybrid mass analyzer (Micromass, Manchester, UK). Q-TOF micro was employed with a Z-spray ion source (source condition: capillary voltage 3.0 kV, source temperature 90 °C, desolvation temperature 250 °C). Chromatograms were acquired in the *m/z* range 100−600 (TIC modality). Reverse-phase chromatographic separations were obtained on a C18 Waters symmetry column (150 × 0.3 mm I.D., 3.5 μm), assembled with a security guard column (Waters Symmetry 300, C18 5 μm, NanoEase), using a gradient elution from A [water/acetonitrile/formic acid 95:5:0.1 (v/v/v)]/B [acetonitrile/water/formic acid 95:5:0.1 (v/v/v)] 80:20 (v/v), for 10 min, to A/B 10:90 (v/v), within 15 min, up to 25 min, to A/B 80:20 (v/v) within 25.10 min. Equilibration time at A/B 80:20 (v/v) was 15 min. The flow rate was 4.0 μL/min, and the injection volume was 0.3 μL.

Cell culture media (RPMI 1640 plus 10% FCS) containing 50 μM of compound **18**, after 1 and 72 h of incubation at 37 °C, and cleavage buffer (10 mM Tris-HCl (pH 7.6), 150 mM KCl, 5 mM $MgCl_2$, 15 μg/mL bovine serum albumin, 0.1 mM DTT) containing 50 μM of **18** after 1 h of incubation at 37 °C, were diluted 1: 10 with a mixture of 0.1% formic acid/acetonitrile 85:15 and analyzed by LC-Q-TOF system. To test whether the cell metabolism influences the E-ring closure of **18**, NCI-H460 cells (6×10^5) were seeded in cell culture flask (75 cm^2) and treated 24 h later with compound **18** for 1 h at the concentration corresponding to the IC_{80} value (about 60 μM). After 1 h exposure, cells and culture medium were immediately recovered and analyzed.

The analyses of standard compound **18** performed on the LCQ-Duo (see Supporting Information, Figure 8) showed the in-source fragmentation of its parent ion $[M + H]^+$ at 451.25 *m/z* to the main daughter ion at *m/z* 391.07. This fragmentation was confirmed by MS/MS analysis on the ion at *m/z* 451.25. The analyses on the LC-Q-TOF system (see Supporting Information, Figure 9) gave a more extensive in-source fragmentation, leading to the complete disappearance of compound **18** parent ion and the formation of the main fragment at 391.1938 *m/z* (exact mass) and other minor fragment at *m/z* 374.1770, 356.1726. CPT, a possible degradation product of **18**, was also analyzed by LC-MS ($[M + H]^+$ at 349.1090 *m/z*), and it was revealed in compound **18** standard solution as an impurity (3.66%). For calibration, five solutions of **18** (1.142 × 57.10 μM) were analyzed [equation curve: $y = 3.130 \pm 0.02112)x + 0.3937(\pm 0.5535)$; $r^2 = 0.9999$]; the limit of quantitation (LOQ) was measured at the concentration of 0.571 μM.

CHEMISTRY

To optimize the efficiency of this novel family of open-lactone ring CPTs, we explored the influence of the polyamine architecture on the activity of these CPT conjugates into cells. Since the molecular recognition events involved in polyamine transport are sensitive to the number of nitrogens present in the molecule and to the distance between them (*64*, *65*), the following polyamine scaffolds were selected for our investigation: ethane-1,2-diamine **8**, spermidine **9**, homospermidine **10**, spermine **11**, and 4,8,13,17-tetraza-icosane-1,20-diamine **12** (Figure 5).

Direct amidation of CPT **1** with N-protected polyamines **13**, **14** (*70*), **16** (*71*) was performed in pyridine at 80 °C according to a modified Adamovics's protocol (*42*) (Scheme 1). Sequential

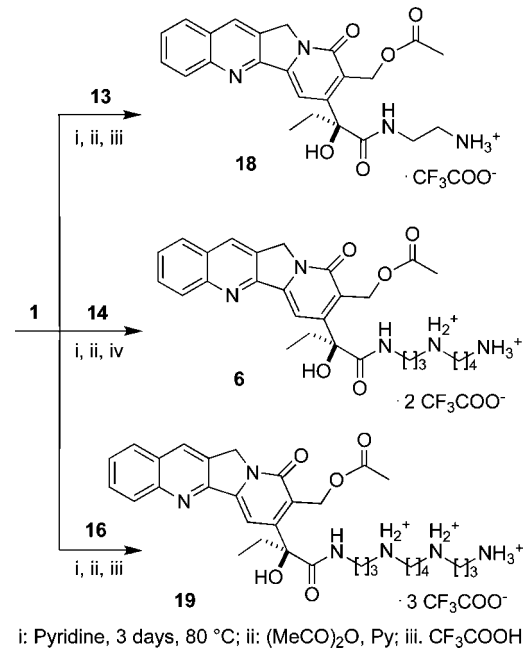
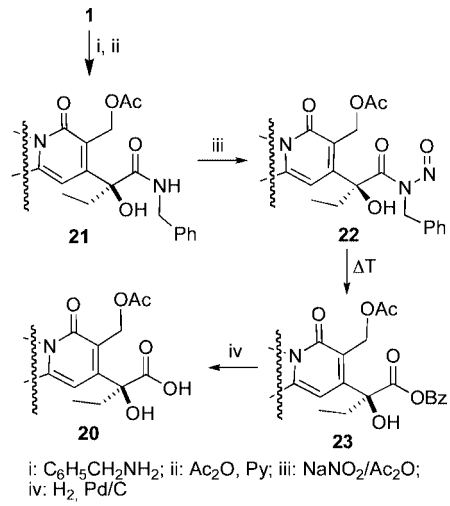


Scheme 2. Synthesis of 17-*O*-Acyl Protected Camptothecinic Acid 20



17-OH esterification of the resulting amides with Ac_2O followed by deprotection of the polyamine with trifluoroacetic acid afforded the tripartate conjugates **18**, **6**, and **19** as ammonium trifluoroacetates. Chemical yields of CPT amidation decreased with the enhancement of the polyamine length. For instance,

Table 1. Antiproliferative Activity of Camptothecin Derivatives on H460 Cells.[a]

	1 h exposure	72 h exposure	F.I.[b]
Topotecan	1.18 ± 0.24	0.015 ± 0.0027	79
SN38	0.22 ± 0.013	0.012 ± 0.001	18
CPT	0.18 ± 0.01	0.0059 ± 0.0024	30
18	6.04 ± 1.97	0.0023 ± 0.0004	2600
6	3.66 ± 0.34	0.048 ± 0.0075	76
19	2.1 ± 1.85	0.077 ± 0.019	28
24	7.7 ± 3.6	0.12 ± 0.03	64
25	1.44 ± 0.38	0.17 ± 0.027	8.5

[a] Sensitivity was assessed by growth inhibition assay after 1 or 72 h of drug exposure. Cells were counted 72 h after drug exposure for 1 h of treatment and at the end of drug exposure in the case of 72 h of treatment. The reported values are the mean ± SD of three independent experiments. [b] Fold increase: ratio between IC_{50} (μM) at 1 h and IC_{50} at 72 h.

chemical yields for the amidation of **1** were 88% and 55%, with the *N*-BOC derivatives **13** and **14**, respectively, but dropped to 10% when the spermine derivative **16** was used, while the coupling of CPT with polyamine **17** failed.

Such failure, along with the poor yields in the formation of compound **19**, prompted us to explore a more efficient protocol for the amidation reaction. We reasoned that 17-O-acyl camptothecinic acid **20** could be a suitable precursor for the synthesis of our tripartates. It has been reported that this naturally occurring compound can be either isolated from *Nothapodytes fetida* or obtained by acetylation of the corresponding sodium salt of **1** with Ac_2O in DMF (*72*). In our hands, this semisynthetic route was not reproducible, affording compound **20** in very low yield (<10%). Thus, we developed a new high-yielding and reproducible four-step synthesis, which afforded **20** in 80% starting from CPT. This methodology involves the one-pot sequential amidation of **1** with benzylamine, followed by acetylation of the free 17-OH group with acetic anhydride which provides the amide derivative **21** (Scheme 2).

Nitrosation of **21** with $NaNO_2$, in the presence of a mixture of Ac_2O and AcOH, afforded the corresponding *N*-nitroso amide **22**, which thermally rearranged to the benzylic ester **23**. Reductive debenzylation with H_2/Pd produced the target compound **20** in more than 80% overall yield. Amidation of **20** with **15**, **16**, and **17** (*73*) was performed according to a standard coupling procedure, using 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride, in the presence of 1-hydroxybenzotriazole (Scheme 3). TFA removal of the *tert*-butoxy carbonyl protecting groups afforded the target conjugates **24**, **19**, and **25** as the trifluoroacetate salts.

BIOCHEMICAL ADN BIOLOGICAL EVALUATION

The CPT analogues were tested for growth inhibition ability against the human non-small-cell lung cancer carcinoma NCI-H460 cell line (Table 1) (*74*). The reduced potency of polyamine CPT derivatives with respect to topotecan, SN38, and CPT is likely related to the limited drug uptake, caused by their water-soluble salt formulation.

Although CPT derivatives were less potent than topotecan, SN38, and CPT after 1 h treatment, their antiproliferative effects increased after 72 h exposure. During long-term exposure, growth inhibition potency of **18** was higher than that of the reference drugs. Topoisomerase I-mediated DNA cleavage assay was carried out to investigate the ability of the compounds to stimulate DNA damage. Purified human topo I was used with SN38 as a reference compound (Figure 6A). Compound **18** exhibited DNA damage similar to that of SN38, and derivatives **6** and **19** revealed an intensity of DNA cleavage only slightly inferior to SN38, whereas **24** and **25** were substantially less efficient.

The cleavage pattern was found similar to that of SN38 for all the new CPTs. The stabilization of the ternary cleavable complex was also evaluated after the addition of a high salt concentration (0.6 M NaCl), which favors the drug−enzyme−DNA complex dissociation. As shown in Figure 6B, the compounds revealed DNA damage persistence similar to that of SN38. The best activity was achieved with compound **6**. The introduction of the homospermidine produced a reduction in the persistence of DNA damage with respect to spermidine (**24** vs **6**). A reduced persistence was also observed in the presence of a spermine instead of a spermidine (compound **19** vs **6**). Compound **18** was the least effective in stabilizing the DNA damage.

Compounds **18**, **6**, and **24**, which bear different polyamines in position C21, were tested for their capability to bind the DNA by evaluating the reduced migration in agarose gel of SV40 DNA plasmid (Figure 7). In comparison to compound **18**, compounds **6** and **24** revealed the most dose-dependent reduced migration of DNA plasmid. This feature was dependent on the number of positive charges carried by the polyamine residue (one for compound **18** and two for compounds **6** and **24**). Of note, the DNA binding affinity was also influenced by the architecture of the polyamine chain (compare **24** vs **6**), since homospermidine introduction at the C21 position, instead of spermidine, increased the capability to interact with DNA.

Stability studies of compound **18** in cell culture medium and cleavage buffer solutions were conducted on the ESI generated ion 391.1938, in single ion monitoring (SIM) modality (see Materials and Methods for details and Figure 10 in the Supporting Information section for representative sample TIC and SIM chromatograms).

As shown in Table 2, compound **18** was stable after 1 h of incubation at 37 °C both in cell culture medium and in cleavage buffer, because a marginal content of CPT (about 3%) was observed in both conditions. Appreciable degradation of **18** was observed when the compound was incubated in cell culture medium for 72 h, with the appearance of a significant amount of CPT. When the experiments were performed in the presence of cells, after 1 h of treatment at the IC_{80} value, no CPT was

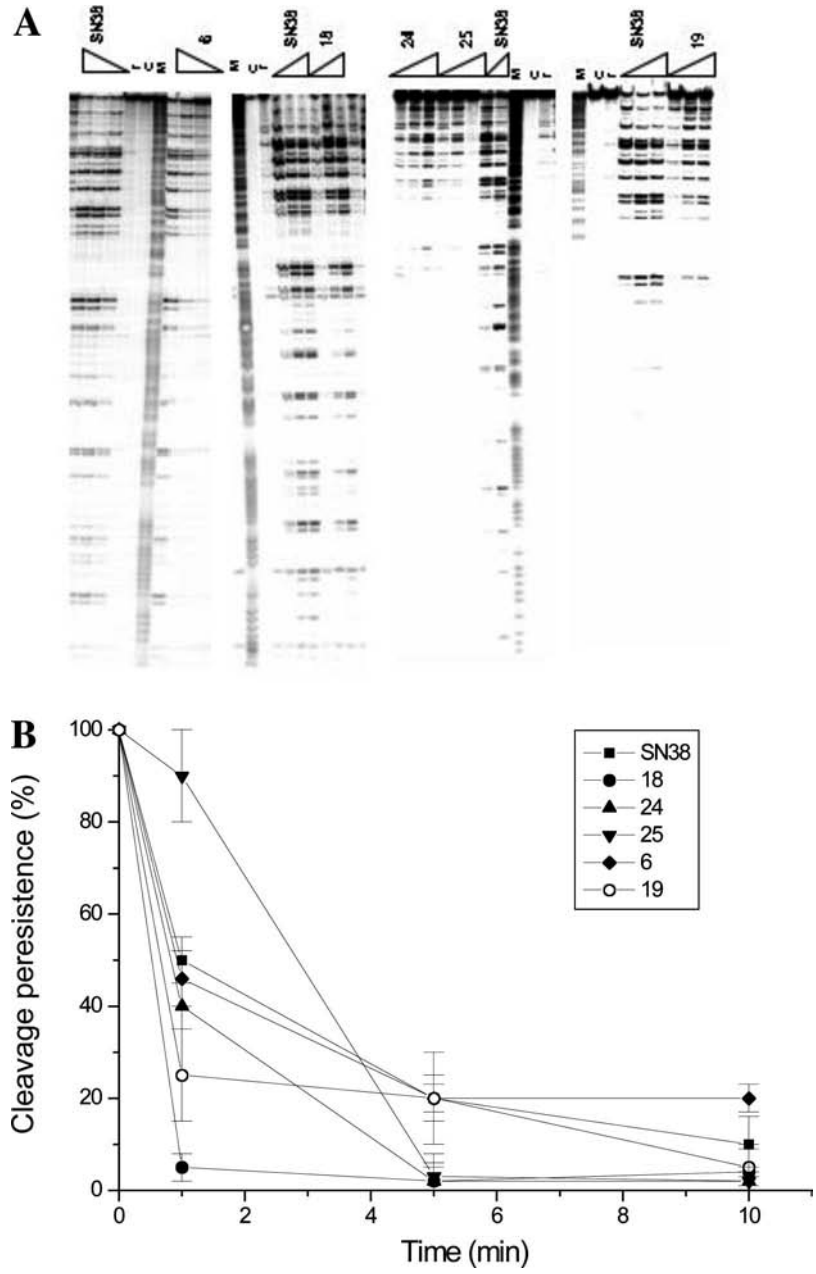

Figure 6. (A) Topoisomerase I-mediated DNA cleavage by SN38 and different camptothecin derivatives. Samples were reacted with 1, 10, and 50 μM drug at 37 °C for 30 min. Reaction was then stopped by adding 0.5% SDS and 0.3 mg/mL proteinase K and incubating for 45 min at 42 °C before loading on a denaturing 8% polyacrylamide gel. C, control DNA; T, reaction without drug; M, purine markers. (B) Persistence of topoisomerase I-mediated DNA cleavage in the presence of different compounds. The samples were reacted for 30 min with 10 μM drug in presence of top I. After this time, DNA damage was reversed by adding 0.6 M NaCl and incubating at 37 °C for 1, 5, and 10 min. The 100% value is referred to the extent of DNA cleavage at 30 min of incubation with top I. The experiment was repeated 3 times and the results of a representative value are reported.

found in the cell pellet; whereas a slight amount of CPT (3.7%) was recognized in cell culture medium (Table 2).

DISCUSSION AND CONCLUSION

The results reported in this study provide further evidence (*42*) that CPT polyamine conjugates with the open E-ring may be effective as cytotoxic agents and topo I inhibitors. Their activity was markedly dependent on the polyamine substituent. The introduction of suitable substituents in the open carboxylate form results in derivatives able to stabilize the cleavable complex. These CPT derivatives exhibited growth inhibition potency similar to or higher than that of topotecan, SN38, and CPT after long-term exposure. It is likely that the nature of the substituent is critical in promoting rapid intracellular drug accumulation and in achieving an optimal cytotoxic effect. Indeed, it is well-known that pharmacokinetic behavior at the cellular level is a critical determinant of the antitumor efficacy of CPTs, because as a consequence of the potential reversibility of the cleavable complex, adequate intracellular concentrations and exposure are required to produce a lethal extent of DNA damage. The growth inhibition potency during long-term exposure is correlated with the number of the charges of the substituent. Indeed, **18** was found the most active compound, while **25**, **24**, **19**, and **6**, which are the most charged derivatives, were the less active of the series. Interestingly, this pattern of activity was not observed after 1 h exposure for which, on the

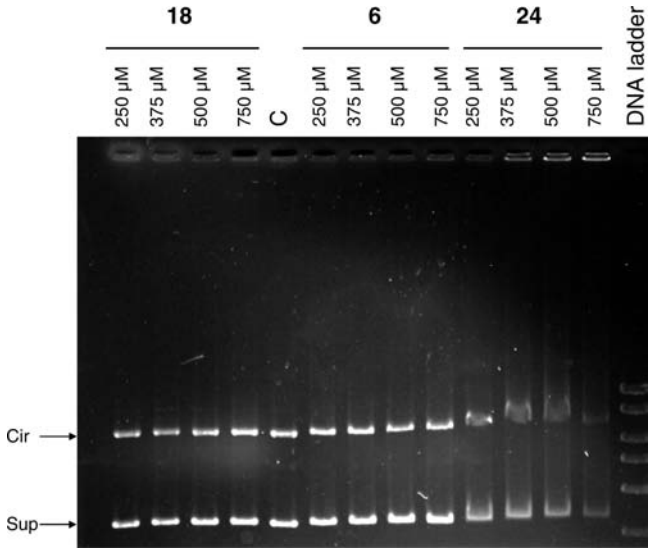

Figure 7. DNA binding of compounds **18**, **6**, and **24**. DNA and CPT analogues were incubated in 20 μL of phosphate buffered saline for 1 h at 37 °C in the presence of 100 ng of SV40 DNA plasmid at the indicated concentrations of compounds. Samples were analyzed on 0.7% agarose gel, followed by ethidium bromide staining. The arrows indicate the migration of the circular (Cir) and supercoiled (Sup) DNA plasmid.

Table 2. Stability of Compound 18[a]

experimental conditions		concentration (%)	
		18 (%)	CPT (%)
cell free conditions	medium (1 h)	96.4	3.6
	medium (72)	82.7	17.3
	cleavage buffer (1 h)	97.7	2.3
in presence of cells	medium (1 h)	96.3	3.7

[a] The amount of camptothecin produced by incubating compound **18** in different conditions was determined using LC/MS. The concentration of **18** added to cell culture medium or cleavage buffer was 50 μM. The experiments in presence of cells were performed by treating the cell culture at the IC_{80} value (about 60 μM) of **18** for 1 h and immediately harvesting both cell pellet and culture medium. The values are the means of three independent measures.

contrary, the most active derivative was **25**, which contains the longest polyamine side chain. The high antiproliferative activity observed for **18** after long-term exposure could suggest a major capability of this compound in promoting the E-ring closure, thus producing the structure of natural CPT. This feature is supported by an antiproliferative potency of **18** similar to that of CPT and by the formation of CPT (about 17%) after long-term incubation (72 h) in cell culture medium (Table 2). Thus, it is likely that, for this derivative, long-term exposure is required to produce E-ring closure. However, the cleavage assay and *in vitro* effects support the interpretation that the compounds may have inhibitory activity also in the open ring form. This feature is corroborated by the low amount of CPT (3.7%) observed incubating **18** for short-term exposure (1 h) in culture medium and by the absence of CPT recovered in the cells after this time exposure (Table 2). The architecture of the polyamine moiety is important for antiproliferative activity, and a balance between the hydrophilic and lipophilic properties of the polyamine is critical for CPT potency. The introduction of homospermidine instead of a spermidine in C21 reduced the antiproliferative effect after both short- and long-term exposure (compound **24** vs **6**). In addition, during short-term exposure, the potency seems to be correlated with the length of the polyamine, e.g., **25** versus topotecan; while during long-term exposure, a reduced potency was found for those compounds bearing long polyamine side chain. This observation supports a crucial role of the polyamine in the cellular pharmacokinetics.

The capability to stabilize the cleavable complex was found to be markedly dependent on the nature/length of the substituent linked to the 21-position of the CPT. Indeed, **24** and **25**, which carry a long polyamine moiety, displayed a low potency; on the contrary, **18** was very active in producing DNA damage. This feature appears independent from the capability of compound **18** to interact with the DNA in the absence of topo I (Figure 7) indicating that the ethyl-diamine moiety is more proficient than other substituents in fitting the CPT into the enzyme−DNA and thus producing more potent inhibition. Interestingly, reduced DNA damage was observed after exposure to a high concentration (50 μM) of **25** (Figure 6A). It is likely that this behavior is the result of the interaction between the long polyamine chain and the DNA substrate that, in so doing, inhibits the access of the enzyme into DNA sequences, thus reducing the cleavage efficacy of the compound. This hypothesis is also supported by the major capability of compounds **6** and **24** to interact with the DNA in the absence of topo I (Figure 7). Although of slight magnitude, compound **6** produced the more stable DNA damage, indicating that spermidine presents the best architecture for the interaction with the DNA in the presence of topo I. Our results support the efficacy per se of CPT with an open lactone ring in poisoning the topo I. Nevertheless, the antiproliferative activity and time-dependent effects probably reflect not only the inhibitory potency at target level but also the pharmacological behavior, which is determined by multiple and complex interactions, e.g., drug uptake, DNA interaction, and E-ring closure. The latter event could correlate with the properties of the polyamine moiety linked to the C21. Indeed, among the tested compounds, the most evident increase in cytotoxic potency found comparing short- and long-term exposure was observed for compound **18** (2600- vs 30-fold compared to CPT) that could indicate that the presence of an ethyl-diamine moiety may favor an efficient E-ring closure as a consequence of its easy release.

At concentrations of **18** required for cytotoxic effects during long-term exposure, the presence of free CPT was not measurable in cell culture medium. The expected amount on the basis of stability experiments (17%, Table 2) does not account for the activity reported in Table 1. Indeed, the potency of **18** is higher than that of CPT itself. In conclusion, although a contribution of CPT itself could not be ruled out, the available evidence supports that the CPT polyamine conjugates with the open E-ring may be active "per se".

(46) This suggestion seems to be in contrast with literature results (*43*), claiming that the 17-OH-21-N^1,N^1-dimethylaminoethyl amide dipartates are not stable enough to survive cell tissue culture experiments, undergoing rapid cyclization to the lactone form at physiological pH. Hence, compound **4** should be *in vitro* active.

TECHNICAL NOTES

Aqueous Solubilization of Fullerenes Using Poly(amidoamine) Dendrimers Bearing Cyclodextrin and Poly(ethylene Glycol)

Chie Kojima, Yoko Toi, Atsushi Harada, and Kenji Kono*

Graduate School of Engineering, Osaka Prefecture University, Osaka, Japan. Received April 11, 2008; Revised Manuscript Received September 8, 2008

Fullerene has a unique structure and notable chemical and physical properties, which have been studied in diverse fields including biological applications. The extremely poor solubility of fullerenes in water limits their usage for biomedical applications. In this study, we synthesized polyamidoamine dendrimers having both β-cyclodextrin (CD) and poly(ethylene glycol) (PEG) and characterized the resulting dendrimers by ^{1}H NMR, IR, and gel permeation chromatography. We prepared 2.8 μM of aqueous fullerene solutions using these dendrimers. The clustering effect of CD and PEG at the surface of the dendrimer might be crucial for the solubilization of fullerene.

INTRODUCTION

Fullerene, C_{60}, has a unique structure and notable chemical and physical properties, which have been studied in diverse fields including biological applications. Fullerene has been reported to act as an antioxidant, a neuroprotective agent, and as anti-HIV and antimicrobial agents. In addition, fullerenes have photochemical properties, by which reactive oxygen species are generated in high quantum yields after irradiation to affect abnormal cells (*1*−*3*). However, extremely poor solubility in water limits their usage for biomedical applications. There are two strategies to improve the solubility. One is the chemical modification of C_{60}. Many researchers have designed a wide variety of fullerene derivatives as water-soluble fullerenes, such as fullerenes bearing carboxyl, hydroxyl, and amino groups, and water-soluble polymers, such as polyvinyl alcohol, poly(ethylene glycol) (PEG), and water-soluble dendrimers (*1*−*3*). However, modification is thought to lose and/or reduce the function of C_{60}. Alternatively, the addition of solubilizers has been shown to improve the solubility of C_{60} (*1*, *2*, *4*−*7*). Generally, this kind of molecular assembly may be unstable because of its dynamic properties. Further, without dispersing C_{60} at the molecular level, it may also cause loss and/or reduction of the function of C_{60} due to quenching.

Dendrimers are attractive polymers with unique structures, which have a monodispersed molecular weight, well-defined morphology, and an inner space capable of holding drug molecules, which is quite different from classical polymers (*8*). In addition, one of the major advantages of dendritic polymers is the modification and dense packing of functional moieties at the periphery (*8*−*11*). We previously modified dendrimers with PEG, as PEG is known to enhance water solubility and biocompatibility (*12*). We reported that these dendrimers could encapsulate anticancer drugs and photosensitizers (*12*, *13*). In the present study, we designed a solubilizer/carrier of C_{60} based on our PEG-modified dendrimers bearing cyclodextrin (CD) with dense packing. It has been reported that two CDs are complexed with one fullerene (*14*, *15*). The ability to complex with fullerene may be enhanced by accumulating CD at the periphery of the dendrimer. Therefore, we synthesized poly(amidoamine) (PAMAM) dendrimers modified with both CD and PEG, which may provide the benefit of clustering of CDs at the dendrimer periphery to improve the complex formation and also the exposure of the biocompatible and water-soluble surface for nanomedical applications. Previously, Arima et al. synthesized dendrimers modified with CDs for applications directed to gene delivery (*16*). They showed that the α-CD-modified PAMAM dendrimers exhibited the most effective transfection activity and were much improved over the dendrimers modified with mannose (*16*, *17*). In this study, we used β-CD for the binding CD because it does not tend to interact with PEG (*18*). We synthesized and characterized the PEG and CD-modified dendrimer and prepared a highly concentrated C_{60} aqueous solution using the dendrimer.

MATERIALS AND METHODS

Synthesis of PEG/CD-Modified Dendrimer. Monotosylated β-CD was synthesized according to the previous report (*19*). Briefly, to a 1% NaOH solution containing β-CD (20 g) was added CH_3CN solution containing *p*-toluenesulfonyl chloride (3.4 g) dropwise at room temperature. After 2 h, 1 M HCl was added to the reaction mixture to adjust the pH to 2.5. After the solution was stored at 4 °C overnight, the precipitation was harvested. The crude product was recrystallized from water. The yield was 2.3 g (7.8%). ^{1}H NMR (400 MHz, dimethylsulfoxide (DMSO)-d_6) δ 2.4 (s), 3.3−3.7 (m), 4.2−4.5 (m), 4.8 (m), 5.7 (m), 7.4 (d), 7.8 (d).

A generation 4 (G4) PAMAM dendrimer with ethylenediamine core was obtained from Sigma-Aldrich Corp. (St. Louis, MO). The G4 PAMAM dendrimer was reacted with monotosylated β-CD according to a previous report, with some modification (*16*). Briefly, the G4 PAMAM dendrimer (200 mg) and monotosylated β-CD (1.74 g) were dissolved in 4 mL of distilled DMSO. The mixture was stirred for 5 days at 60 °C under nitrogen gas. The product was purified using a Sephadex

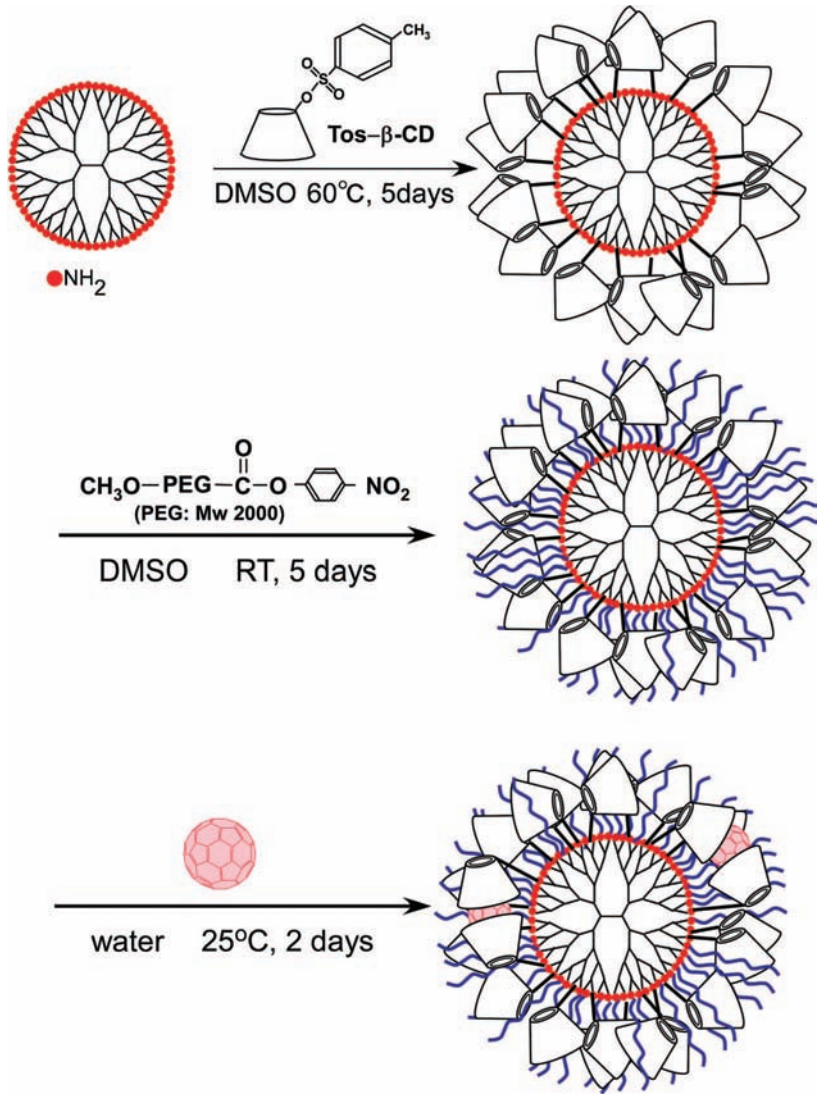
Scheme 1. Preparation Method of the PEG/CD-Modified Dendrimer Including C_{60}



G-75 column with 0.1 M Na_2SO_4 aqueous solution as the eluent. The yield was 581 mg. Next, monomethoxy PEG (molecular weight: 2000) 4-nitrophenyl carbonate was bound to the CD-modified dendrimer according to our previous report (*12*). The CD-modified dendrimer (250 mg) and monomethoxy PEG 4-nitrophenyl carbonate (609 mg) were dissolved in 5 mL of distilled DMSO, and triethylamine (39 μL) was added. After stirring for 5 days at room temperature, the mixture was purified according to our previous report (*12*). The yield was 405 mg. PEG/CD-modified dendrimers at different ratios were also synthesized. The G4 PAMAM dendrimer (60 mg) and monotosylated β-CD (522 mg) dissolved in 1.6 mL of distilled DMSO were reacted and purified, as mentioned before. The yield was 145 mg. Next, pegylation was performed as mentioned before. The yield was 257 mg. Thin-layer chromatography of these compounds showed that free β-CD and PEG were free from contamination.

Characterization of the PEG/CD-Attached Dendrimer. The products were characterized by ^{1}H NMR, FTIR, fluorescamine assay, and gel permeation chromatography (GPC). ^{1}H NMR and FTIR were measured using a JNM-LA-400 instrument (JEOL, Japan) and FTIR-8400 (Shimadzu Corp., Japan), respectively. A fluorescamine assay was performed according to previous reports (*20, 21*). Fluorescamine reacted with primary amine was measured using an FP-6500 instrument (JASCO, Inc., Japan; $\lambda_{ex} = 390$ nm, $\lambda_{em} = 480$ nm). The GPC system (TSK-gel G3000PW and G4000PW; Toso Co., Ltd., Japan) had two detectors, a differential refractive index detector (RI-930; Jasco Inc., Japan) and a UV−vis detector ($\lambda = 220$ nm; UV-970; Jasco Inc., Japan). These dendrimers and the complexes with C_{60} were dissolved in water, and the sample solutions of 10−20 μL were injected. These dendrimers were eluted with 10 mM phosphate buffer containing 0.2 M sodium sulfate (pH 7.4) at 0.5 mL/min at 30 °C.

Preparation of C_{60} Aqueous Solutions with the PEG/CD-Modified Dendrimer. C_{60} aqueous solutions were prepared by mixing the solubilizers (free CD, 116 nmol, or dendrimers, 4 nmol) with C_{60} (0.25 mg) and stirring vigorously at 25 °C for 2 days. The suspension was centrifuged at 13 000 *g* for 20 min to remove the free C_{60} (*22*). The UV−vis spectra of the supernatant were measured using a V-560 instrument (JASCO, Inc., Japan). Those of the solubilizers themselves were also measured. Then, after water was removed, the residues were dissolved in toluene. The absorbance at 336 nm was measured ($\varepsilon = 5.7 \times 10^4$ M^{-1} cm^{-1}).

RESULTS AND DISCUSSION

Synthesis of the PEG/CD-Modified Dendrimer. Both PEG- and CD-modified dendrimers were synthesized according to Scheme 1. PAMAM dendrimer was reacted with monotosylated β-CD according to a previous report, with some modification,

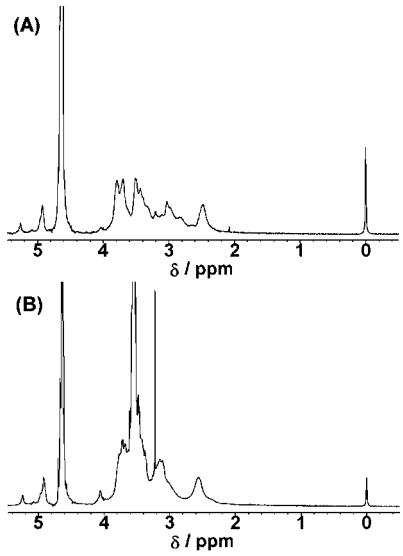


Figure 1. ^{1}H NMR spectra of the CD_{29}-modified dendrimer (A) and the PEG_{35}/CD_{29}-modified dendrimer (B) in D_2O.

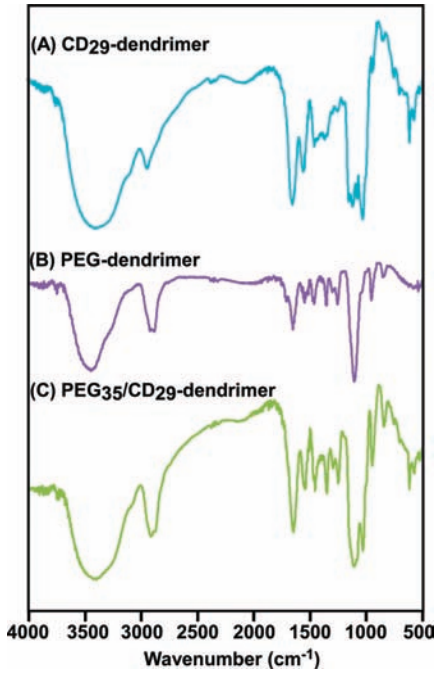

Figure 2. FTIR spectra of the CD_{29}-modified dendrimer (A), the PEG- modified dendrimer (B), and the PEG_{35}/CD_{29}-modified dendrimer (C).

to obtain the CD-modified dendrimer (*16*). Next, monomethoxy PEG 4-nitrophenyl carbonate was bound to the CD-modified dendrimer via urethane bonds, according to our previous report (*12*). These products were identified by ^{1}H NMR, as shown in Figure 1. The ^{1}H NMR spectrum of the CD-modified dendrimer had peaks which were derived from CD and the PAMAM dendrimer. From the ratio of the typical signal of CD (4.9−5.3 ppm) to the other signals except the solvent peak, the estimated number of CD molecules bound to the PAMAM dendrimer was 29. In the ^{1}H NMR spectrum of the PEG/CD-modified dendrimer, in contrast, the signals derived from CD, PEG, and the dendrimer were largely overlapped. It was difficult to estimate the number of PEG molecules bound to the CD-modified dendrimer from the ^{1}H NMR spectrum. Therefore, we analyzed the residual primary amino groups of the PEG/CD-modified dendrimer using fluorescamine assays. Fluorescamine fluoresces

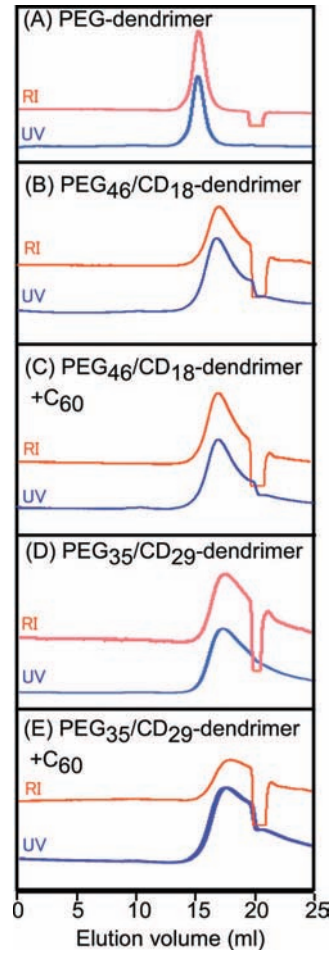

Figure 3. GPC profiles of the PEG-modified dendrimer (A), the PEG_{46}/CD_{18}-modified dendrimer (B,C), and the PEG_{35}/CD_{29}-modified dendrimer (D,E) before (B,D) and after (C,E) the addition of C_{60}. PEGs of 1, 2, 5, 10, 20, 50, and 140 kDa used as a standard were eluted at 20.6, 19.6, 18.6, 17.4, 16.4, 15.8, and 13.5 mL.

by reacting with a primary amino group (*20*, *21*). The fluorescamine assay of the PEG/CD-modified dendrimer indicates that the number of residual primary amino groups of the PEG/CD-modified dendrimers was 0.3 per dendrimer, suggesting that essentially every terminal amino group was attached to either a CD or PEG chain. Because the CD-modified dendrimer possessed 29 CD molecules in 64 terminal amino groups of the dendrimer, the PEG/CD-modified dendrimer may have 35 PEG chains and 29 CD molecules. We also synthesized the dendrimer with different contents of PEG and CD. This dendrimer was characterized as the PEG_{46}/CD_{18}-modified dendrimer by ^{1}H NMR and the fluorescamine assay.

Characterization of the PEG/CD-Modified Dendrimer. The CD-modified dendrimer and PEG/CD-modified dendrimer were characterized by FTIR spectrometry, as shown in Figure 2. The dendrimer modified with PEG chains at every terminal (PEG-dendrimer) was also analyzed as a control. The signals of both PEG and CD were observed in the PEG/CD-modified dendrimer, which is also consistent with the ^{1}H NMR results. It was reported that the FTIR spectra of the complex of PEG and CD have typical bands at 2800−3100 cm^{-1} and 3407 cm^{-1} (*23*). However, the PEG/CD-modified dendrimers did not exhibit these bands. This suggests that β-CD did not interact intra- or intermolecularly with PEG in these dendrimers. The PEG/CD-modified dendrimers were also characterized by GPC. The dendrimer modified with PEG chains at every terminal (PEG-dendrimer) was also analyzed as a control. The GPC profiles

Table 1. Summary of C_{60} Aqueous Solutions with Various Solubilizers

solubilizer	$[C_{60}]$	[solubilizer]	$[C_{60}]$/1 mM solubilizer	ref
PEG/CD-modified dendrimer	2.8 μM	2.0 μM	1.4 mM	this work
tetradecyl trimethylammonium hydroxide lauric acid	1.64 mM	100 mM	16.4 μM	*5*
humic acid (Mw = 10^3−10^5)	5.41 μM	1−100 mM (100 mg/mL)	54.1 nM−5.41 μM	*6*
fluoroalkyl end-capped acryloyl-morpholine oligomers (Mw = 4360)	29 μM	0.459 mM (2 g/L)	63 μM	*7*

are shown in Figure 3, in which the single peaks were observed. This suggests that the PEG/CD-modified dendrimer did not aggregate via the interaction between PEG and CD. As mentioned before, our IR analysis indicates that there were no interactions between CD and PEG in the PEG/CD-modified dendrimer. These data are also supported by a previous report demonstrating that the affinity of β-CD for PEG is much less than the affinity of α- and γ-CD for PEG (*18*). The peak tops of the dendrimers having both PEG and CD were shifted to a larger elution volume, as the ratios of CD in the dendrimer increased. The calculated molecular weights of the PEG-dendrimer, the PEG_{46}/CD_{18}-modified dendrimer, and the PEG_{35}/CD_{29}-modified dendrimer were 1.44×10^5 Da, 1.28×10^5 Da, and 1.18×10^5 Da, respectively, which is consistent with these chromatograms. In addition, the broader peaks of the PEG/CD-modified dendrimers were observed and compared with the PEG-dendrimer. This may be caused by the affinity of CD with the column gel. It is likely that the PEG/CD-modified dendrimers in our synthetic procedure are not obtained as a single molecule; different amounts of CD and PEG were attached to the dendrimer, although 29 or 18 molecules of CD and 35 or 46 molecules of PEG were attached on average. The broad peak may reflect the molecular distribution of the dendrimers. The large negative reflective indexes and the discontinuous UV peaks may come from the solvent of the sample, because the background RI and UV of the eluent (phosphate buffer containing Na_2SO_4) were affected by the injected sample solvent.

We then prepared C_{60} aqueous solutions with both PEG- and CD-modified dendrimers, according to the report of the preparation of the complexes between β-CD and C_{60} (*22*). Since free C_{60} could be removed by centrifugation due to aggregation, aqueous solutions of C_{60} were obtained as a supernatant. GPC analysis of the PEG/CD-modified dendrimer after the incubation with C_{60} was performed. Because the elution volume of the dendrimer in the absence and presence of C_{60} was almost the same, the complexes were formed in the dendrimer but did not form aggregates (Figure 3C,E).

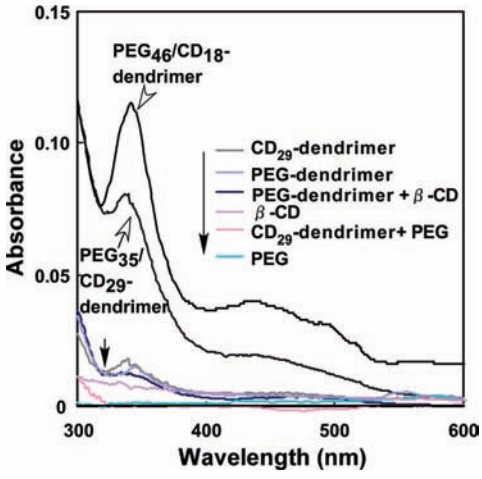

Figure 4. UV−vis spectra of C_{60} aqueous solutions containing the PEG_{46}/CD_{18}-modified dendrimer (2.0 μM), the PEG_{35}/CD_{29}-modified dendrimer (2.0 μM), the CD_{29}-modified dendrimer (2.0 μM), and the PEG_{64}-modfied dendrimer (2.0 μM), free CD (58 μM), free PEG (70 μM), or the mixtures. These spectra were obtained by subtracting the spectra of these compounds without C_{60} from those of the complex.

Solubilization of C_{60} by the PEG/CD-Modified Dendrimer. We prepared C_{60} aqueous solutions of the PEG/CD-modified dendrimers, the CD-modified dendrimer, the PEG-dendrimer, free CD, and free PEG. The corresponding UV−vis spectra are shown in Figure 4. We found that a more highly concentrated C_{60} aqueous solution was prepared using the CD-modified dendrimers than free CD, suggesting that the clustering of CD enhanced the ability to complex with C_{60}. Although it was previously reported that PEG interacts with C_{60} (*24*), under our conditions the PEG-modified dendrimer and free PEG did not dissolve C_{60} efficiently due to their low affinity. In the present study, the much stronger absorption derived from C_{60} was observed in the solution containing both PEG- and CD-modified dendrimers. This suggests that both PEG and CD of the dendrimer were crucial for the efficient complex formation with C_{60}. In other words, these data suggest that PEG was also involved in the interaction with C_{60} in the dendrimer. It is possible that C_{60} is complexed with CD and PEG, and that C_{60} is dispersed by surrounding it with PEG to enhance the interaction between C_{60} and the two CDs. Here, C_{60} was not rendered highly soluble by mixing the CD-modified dendrimer and free PEG or by mixing the PEG-modified dendrimer and free CD. Therefore, the effect of CD and PEG likely resulted from clustering at the surface of the dendrimer. Among the PEG/CD-modified dendrimers, the PEG_{46}/CD_{18}-modified dendrimer could solubilize slightly greater amounts of C_{60} than the PEG_{24}/CD_{29}-modified dendrimer. The attached CD molecules of the PEG_{24}/CD_{29}-modified dendrimer might be too crowded to interact with C_{60} at the surface of the dendrimer. It is also possible that the sufficient number of PEG chains at the surface of the dendrimer need to disperse the complex with C_{60}. Since the absorbance of C_{60} at 336 nm in toluene obeys the Beer−Lambert law, the amount of C_{60} was estimated from the absorbance of toluene solutions of the dendrimers. The numbers of complexed C_{60} molecules per PEG_{35}/CD_{29}-modified dendrimer and per PEG_{46}/CD_{18}-modified dendrimer were determined as 1.1 and 1.6, respectively. Figure 3 shows that the complex was not formed by the aggregation of C_{60} and the dendrimers, which is useful for the usage of C_{60} with their own function. The complex formed between C_{60} and both the PEG- and CD-modified dendrimers remains to be elucidated in detail. In addition, optimization of the bound ratios of CD and PEG to the dendrimer can improve the water solubility of C_{60}.

CONCLUSION

We synthesized and characterized PEG/CD-modified dendrimers. Highly concentrated C_{60} aqueous solutions with the dendrimer were prepared. We estimated the C_{60} concentration in the aqueous solution of the PEG_{46}/CD_{18}-modified dendrimer (2.0 μM) as 2.8 μM, although the solubility of C_{60} in pure water is reported as 2×10^{-24} M (*3*). Table 1 summarizes the previously reported C_{60} aqueous solutions by the simple mixing of C_{60} with various solubilizers in aqueous solution. Our C_{60}

aqueous solution has the highest observed concentration compared with the other methods involving the simple mixing of C_{60} with small amounts of the solubilizers in aqueous solution (*5*−*7*).

ACKNOWLEDGMENT

We are grateful to Akihiro Nomoto and Akiya Ogawa (Osaka Prefecture University) for their generous support in FTIR analysis. We also thank Sayako Tsumura for her kind support in fluorescamine assay. This work was supported by Grants from the Saneyoshi Scholarship Foundation, and in part by Grants-in-aid from the Ministry of Education, Culture, Sports, Science, and Technology of Japan (MEXT).

REVIEWS

DNA-Mediated Electrochemistry

Alon A. Gorodetsky, Marisa C. Buzzeo, and Jacqueline K. Barton*

Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, California 91125. Received July 22, 2008; Revised Manuscript Received September 2, 2008

The base pair stack of DNA has been demonstrated as a medium for long-range charge transport chemistry both in solution and at DNA-modified surfaces. This chemistry is exquisitely sensitive to structural perturbations in the base pair stack as occur with lesions, single base mismatches, and protein binding. We have exploited this sensitivity for the development of reliable electrochemical assays based on DNA charge transport at self-assembled DNA monolayers. Here, we discuss the characteristic features, applications, and advantages of DNA-mediated electrochemistry.

1. INTRODUCTION

Since the elucidation of the double helical structure of DNA, scientists have been fascinated by the possibility that the stacked aromatic base pairs of the duplex may promote charge transport (CT) over significant distances (*1, 2*). Consequently, the nature of the conductive properties of duplex DNA has attracted substantial interest (*3*−*7*). Over the past two decades, a wide-ranging collection of experiments has both revealed the fundamental details of DNA-mediated CT and illustrated its potential for sensing applications.

Initial solution experiments featured photoinduced DNA-mediated CT between well-defined donor and acceptor sites (*8, 9*). While long-range CT has been shown to yield oxidative damage in DNA up to 200 Å away from the bound oxidant (*10, 11*), DNA CT has also been found to be exquisitely sensitive to the integrity of the base pair stack (*9, 12*) and to the coupling of the donors and acceptors with the DNA (*13*). Indeed, this sensitivity has prompted both the consideration of biological roles for DNA CT (*14*) and the construction of electrochemical DNA-based sensors for mutations, base lesions, and protein-binding (*15*).

Electrochemical techniques provide a particularly convenient means for the study of heterogeneous electron transfer at solid surfaces (*16*). Typically, redox-active molecules are modified with thiol-terminated alkyl chains and self-assembled as well-ordered monolayers on metal surfaces (*17*). Under an applied potential, electrons or holes are then transferred to pendant, redox-active head groups with the rates and yield of charge transfer (as measured electrochemically) providing information on the structure of the thiol terminated linker. In our laboratory, we have extended this methodology to the study and application of DNA-modified surfaces where charge transfer is *mediated* by the DNA monolayers, which are self-assembled onto conductive substrates.

Before embarking on a general discussion of the application of this methodology, it is important to have a clear understanding of the architecture of DNA-modified surfaces. Independent of the material employed, duplex DNA is modified at the 5′-end of a single strand with a linker, which allows it to interact with the electrode surface (Figure 1). In the case of gold, this tether is an alkane thiol; for graphitic surfaces, it is pyrene. Electrodes are then incubated with modified duplexes and an organized

monolayer is allowed to self-assemble. A redox-active molecule is introduced either by exposure to a solution or through covalent attachment to the 5′-terminus of the single strand lacking the linker. Subsequent addition of an inert backfilling agent, such as mercaptohexanol, promotes the removal of nonspecifically adsorbed duplexes and single strands.

We have extensively characterized these DNA monolayers on both gold and graphite via electrochemical and physical techniques (*15*). Structural characterization has confirmed that the DNA duplexes within a DNA monolayer adopt an upright orientation, at an angle relative to the surface. The uniformity and reliability of this structure enables the duplexes to serve as an extension of the active electrode surface, thus allowing DNA-bound, redox-active molecules to be reduced via the π-stack. Importantly, fabrication of the surface with rigid, structurally defined DNA duplexes, rather than with single-stranded DNAs that can stick to the surface in ill-defined conformations, provides an enormous level of control and reliability in the construction of the monolayers. Moreover, since the electrochemistry of the DNA probe is remarkably sensitive to the integrity of the base pair stack, single base mismatches and lesions, located between the surface and the probe, dramatically attenuate the electrochemical yield of CT. These findings have been extended to general assays for the study of DNA/RNA hybrids and RNA transcripts. Furthermore, we have been able to detect a wide variety of DNA-binding proteins based on their association and electronic communication with the base pair stack. These data have underscored the strength and versatility of this methodology.

It is noteworthy that the CT properties of DNA monolayers are not simply of utility in the context of electrochemistry. The base pair stack of each individual duplex serves as a conduit for charge transfer, as recently confirmed by single molecule experiments within our laboratory (*18*). In fact, when considered in the context of an electrical circuit, the DNA duplexes and bound redox-active probes act as transducer elements with extraordinary gain; biochemical binding events such as hybridization are sensitively transduced into electrical signals. This emphasizes the role of DNA as a remarkably unique medium that provides unprecedented opportunities for studies and applications of long-range CT.

Finally, this review is by no means exhaustive but rather seeks to provide an overview of DNA-mediated electrochemical studies undertaken within our group. Here, we present our explorations of features characteristic of DNA-mediated CT that have been critical for applications of DNA monolayers as biosensors. In fact, several other reviews have detailed the use of electrochemical DNA sensors (*19*−*21*), and where appropriate, examples from other authors are presented.

2. SURFACE CHARACTERIZATION

For proper interpretation of experimental observations, extensive physical characterization of these self-assembled DNA monolayers is crucial. A gamut of experimental techniques can be utilized for investigating the structure and characteristics of DNA monolayers including (but not limited to) radioactive labeling (*22*−*25*), fluorescence self-interference (*26*−*28*), scanning tunneling microscopy (*29*−*31*), atomic force microscopy (*23*, *25*, *32*−*36*), scanning electrochemical microscopy (*37*−*39*), and surface plasmon resonance (*40*, *41*). When dense DNA monolayers are desired, the monolayers are assembled in the presence of Mg^{2+} to allow for close packing of the duplexes (schematically illustrated in Figure 1). Our group, in particular, has focused on surface characterization via radioactive labeling and scanning probe techniques. These investigations have indicated that DNA monolayers adopt an upright orientation and have predictable surface coverages, thereby allowing us to develop a detailed picture of DNA monolayer morphology.

Quantification of Surface Coverage via Radioactive Labeling. Radioactive labeling of the duplexes provides a reliable measure of surface coverage for DNA monolayers. In a typical radioactive labeling experiment, the 5′-end of the DNA complementary to the thiolated strand is labeled with polynucleotide kinase, and the amount of DNA is quantified directly via scintillation counting after self-assembly. On gold and graphite, these measurements indicated surface coverages of ∼40 pmol/cm^2 for well-packed DNA monolayers self-assembled in the presence of Mg^{2+} (*22*, *25*) and coverages of ∼12 pmol/cm^2 for loosely packed DNA monolayers in the absence of Mg^{2+} (*23*). Interestingly, the well-packed monolayer coverages obtained via radioactive labeling correspond to only ∼75−85% of the theoretical coverages of ∼60 pmol/cm^2 with DNA helices packed perpendicular to the surface. This fact strongly hinted that the DNA is oriented at an angle with respect to the surface.

The reliability and sensitivity of radioactive labeling relative to electrochemical assays cannot be understated. For example, monolayer formation can be *qualitatively* monitored via attenuation of an anionic probe such as ferri/ferrocyanide, $Fe(CN)_6^{3-/4-}$ (*22*). In addition, a cationic probe such as ruthenium hexammine can be utilized to quantify DNA coverages semiquantitatively (*42*, *43*), but this common electrochemical assay of surface coverage can lead to errors of up to 65% within each experiment (*44*). Accordingly, in our laboratory, radioactive labeling studies have proven to be particularly illuminating.

Scanning Tunneling Microscopy of DNA Monolayers. While radioactive labeling affords a quantitative measurement of the overall surface coverage, the electronic structure of local areas of a DNA monolayer can be probed via scanning tunneling microscopy (STM), providing atomic level information (*29*). Indeed, STM allows for the investigation of the electronic properties of DNA as a function of duplex orientation. Therefore, the images obtained yield information on not only the morphology but also the local density of states of the sample. At negative potentials, where the DNA adopts an upright orientation, agglomerates of duplexes are visible because the tip can electronically access the oriented DNA in an effective metal−molecule−metal junction. However, at positive potentials, the DNA is encouraged to lie down and the DNA film is effectively not visible to the STM tip. These data indicated that the DNA duplexes comprising a DNA monolayer aggregate in small hexagonal groups of ∼10 nm diameter. Furthermore, the inclusion of a mismatch within the monolayer dramatically attenuates communication between the tip and the surface, demonstrating that the STM is accessing the local density of states of the DNA π-stack.

Atomic Force Microscopy of DNA Monolayers. The morphology of self-assembled DNA monolayers can be further explored at the nanometer scale with atomic force microscopy (AFM). These investigations have indicated that 5′-tethered films are essentially smooth and featureless within the resolution of the AFM tip with the DNA dispersed in a uniform manner (*32*). AFM measurements also provide important information about the morphology and depth of the DNA monolayer at various substrate biases. By applying a large downward force to the

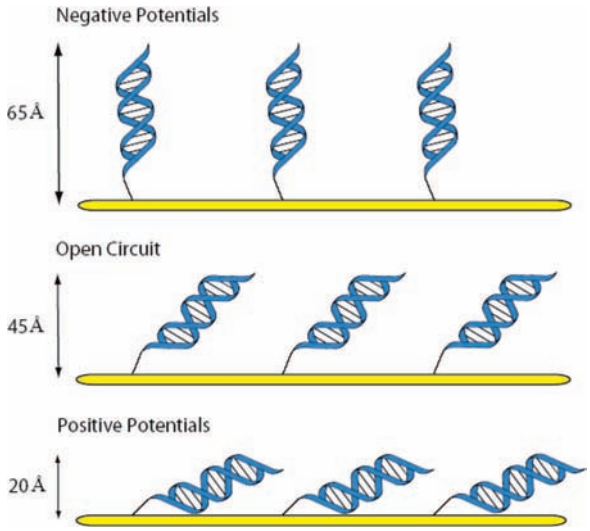

Figure 2. Schematic illustration of the modulation of the height of a DNA monolayer at different substrate potentials. At open circuit, imaging studies have shown that duplexes are oriented upright and at a ~45° angle relative to the surface. At positive potentials, the polyanionic DNA duplexes are attracted to the surface, while at negative potentials (used for most electrochemistry experiments described here), the duplexes are in an upright orientation with the helix axes perpendicular to the electrode surface.

monolayer with the AFM tip, a bare spot can be uncovered on the DNA-modified surface. Height contrast measurements between this bare spot and the surrounding DNA monolayer indicate a film depth which ranges from 4.2 to 4.6 nm for 15mer duplexes at open circuit on both gold and graphite. In fact, the height of these films can be reversibly modulated from 2 nm (the diameter of the duplex) at positive potentials to 5.5 nm (the full length of the duplex when normal to the surface) at negative potentials (Figure 2). These data, in conjunction with the above experiments, indicate that the duplexes adopt an upright orientation at negative potentials and are oriented at a ~45 ° angle with respect to the surface in the absence of an applied bias (*25, 32*).

In a complementary study, we also investigated alternative linkages of the thiol to the DNA. Interestingly, 3′- rather than 5′-grafted DNA monolayers did not adopt an upright orientation relative to the gold surface, as confirmed by their corresponding film depth of only ~2 nm. Since vertical orientation of the monolayer is absolutely essential for studies based on DNA-mediated CT, this work underscored the importance of considering linker placement when designing self-assembled DNA monolayers (*33*).

Several other AFM investigations of DNA monolayers are particularly noteworthy, especially when considering the electrochemical monitoring of DNA with larger macromolecules, such as proteins. Loosely packed DNA monolayers assembled in the absence of Mg^{2+} are necessary for improved accessibility of proteins, but such monolayers have a distinct "island" morphology since the DNA has room to lie flat on the gold surface in the absence of an applied potential (*23*). However, monolayers back-filled with a short-chain alkanethiol such as mercaptohexanol were demonstrated to adopt an upright orientation relative to the gold surface even at open circuit (*35, 36*). Furthermore, these studies showed that even loosely packed films formed from longer 24mer and 30mer duplexes adopt an upright orientation. This well-defined morphology of "deeper" monolayers is a crucial design point to consider in the sequence-specific detection of DNA binding proteins with extensive binding footprints.

3. DNA-MEDIATED ELECTROCHEMISTRY OF SMALL MOLECULES BOUND TO DNA

We have explored numerous redox-active probes in our investigations of DNA CT, and at first glance, many molecules appear adequate for these studies. The large collection of experiments conducted in our laboratory over the past decade, however, has taught us essential lessons regarding the selection of an appropriate redox probe. Three criteria are paramount: the species must (i) be electronically well-coupled to the base pair stack, (ii) be reliably linked to the duplex, and (iii) undergo stable reduction or oxidation within a potential window that does not compromise the integrity of the DNA monolayer. Furthermore, in addition to affording insight into the optimum probe design, our systematic studies clearly indicate that no one probe is ideally suited for every experiment. Instead, different markers offer distinct advantages and must be individually evaluated for specific applications.

The behavior of the redox probes employed in our studies do, however, display some common features when monitored electrochemically. When bound to DNA, small molecules appear to act as surface-bound species as indicated by a linear relationship between the peak current and scan rate. This relationship is not strictly linear for DNA-bound redox proteins, where the proteins are not situated in one fixed position or conformation and thus exhibit a slight diffusive component. Nonetheless, covalent probes bound to DNA typically do not display a square-root-dependence of the peak current on the scan rate that is indicative of free diffusion. In addition, DNA binding typically shifts the redox potential of the probe by 20−50 mV from direct reduction at the bare surface, and the voltammetry adopts a skewed shape relative to a classically adsorbed couple; the reductive and oxidative peaks are separated slightly due to the intervening DNA/alkanethiol spacer. Electrochemical reversibility and stability are also specific to each probe, but they can be investigated simply by repetitive cycling over the potential window of interest. Taken together, all of these features allow us to distinguish DNA-mediated processes from ones involving direct electrochemistry.

Early work in our laboratory employed probes that were not covalently attached to DNA but instead interacted with the base pair stack electrostatically or via intercalation (*22*). Although the majority of our studies have involved the intercalator methylene blue, we have also studied the interaction between DNA and anionic ferricyanide, cationic ruthenium hexammine, the tris-heteroleptic intercalator $Ir(bpy)(phen)(phi)^{3+}$, and the antitumor agent daunomycin (Figure 3). While these noncovalent markers have afforded a significant foundation for the study of DNA-mediated CT, they are intrinsically limited in the mechanistic detail and experimental control they can provide. As a result, more recent efforts have largely focused on developing covalently bound probes, specifically those that are electronically well-coupled to the base pair stack. This latter family began with investigations of cross-linked daunomycin and has been more recently expanded to include other covalently attached molecules such as anthraquinone and phenoxazine derivatives (Figure 3).

Electrochemistry of Small Molecules Non-Covalently Bound to DNA. In our earliest electrochemical experiments, methylene blue (MB), a well-studied aromatic intercalator that undergoes a $2e^-/1H^+$ reduction in aqueous systems, was employed as a reporter of DNA-mediated processes (*22*). Figure 4 shows a schematic illustration of the reduction of MB at a DNA monolayer; a reversible redox couple is seen with a midpoint potential centered at −10 to −50 mV vs NHE, shifted by ~30 mV from bare gold. The measured peak currents scale linearly with scan rate, indicating that the redox molecule is surface-bound, and a combination of electrochemical and

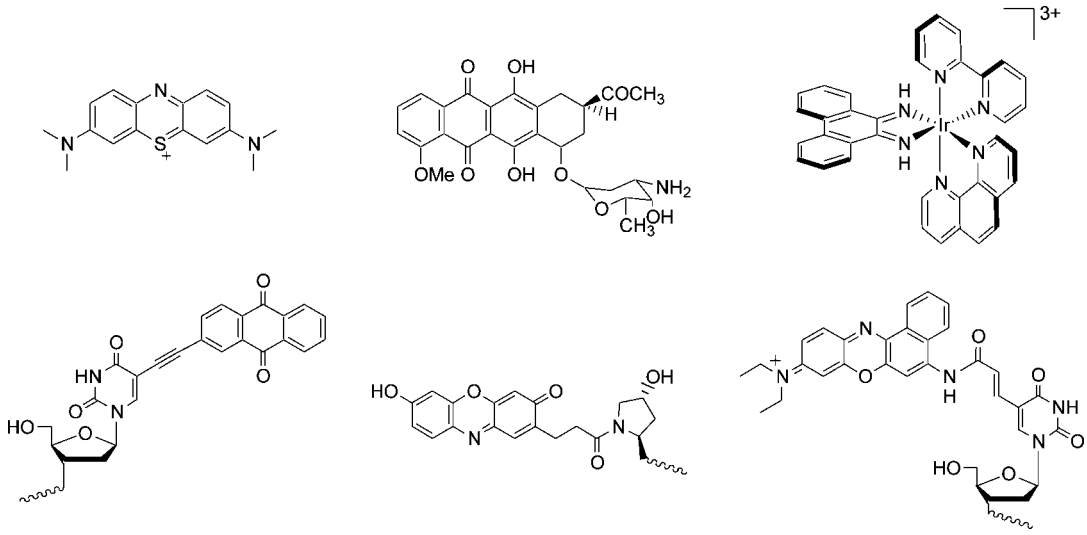

Figure 3. Chemical structures of redox-active probes which have been utilized to explore DNA-mediated CT. Noncovalent probes are on the top row (from left to right): methylene blue, daunomycin, and Ir(bpy)(phen)(phi)$^{3+}$. Covalent probes are on the bottom row (from left to right): anthraquinone, Redmond Red, and Nile Blue.

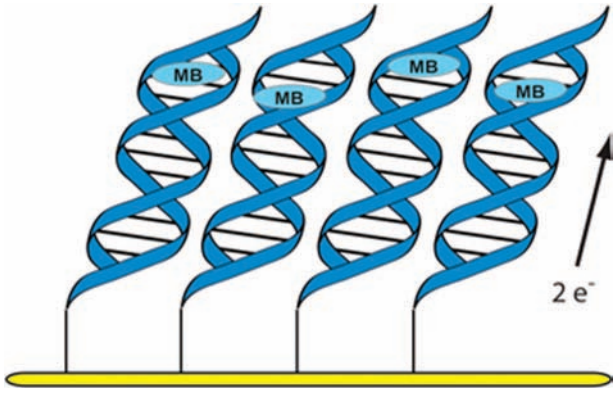

Figure 4. Schematic illustration of the reduction of methylene blue (blue) via DNA-mediated CT at a DNA monolayer. The probe is constrained to intercalate near the top of the monolayer.

spectroscopic measurements give a saturation value of 1.4 ± 0.2 molecules per duplex at high MB concentrations. This latter finding suggests that, for well-packed monolayers, MB is constrained to the top of the film. Any observed reduction, therefore, can be attributed to a DNA-mediated process, as the surface is inaccessible to the molecule.

To characterize this redox process in greater detail, a number of systematic studies were conducted (*44*−*49*). Initially, the behavior of the intercalator MB was compared to the groove-binder ruthenium hexammine (*47*). At high salt concentrations, where interaction with the charged duplex is inhibited, fewer molecules are reduced, thus illustrating the importance of efficient and tight binding to the monolayer for charge transfer. The reduction of these two probes was also monitored on surfaces that had been passivated with electropolymerized 2-naphthol. If the DNA were truly serving as a medium for charge transport, passivation would not affect the process being measured electrochemically. The reduction of ruthenium hexammine, which is thought to proceed via facilitated diffusion along the duplex, decreased by 70%, while reduction of MB was relatively unaffected. Although this study does not elucidate the mechanism of MB reduction, it supports the notion of a DNA-mediated process.

To further prove that the reduction of distally bound probes proceeds in a DNA-mediated fashion, we explored the electrochemistry of small molecules at DNA monolayers containing single base mismatches positioned between the electrode surface and the probe (*45*). It was theorized that, if the DNA base pairs combined to form a continuous, π-stacked conduit for charge transfer, the disruption of a single base pair, as in a mismatch, could interrupt the CT pathway. The presence of a single base mismatch causes no global change in the duplex structure, and yet, the inclusion of an intervening CA mismatch proved to have a dramatic effect on the efficiency of charge transfer to DM. These results are in excellent agreement with STM studies of matched and mismatched duplexes and with studies of photoinduced DNA CT in solution (*9*) (*vide supra*). Interestingly, not only could several mismatches be detected, but the DNA-mediated chemistry was also found to be independent of sequence context. Furthermore, this exquisite sensitivity to base pair stacking has since been observed for numerous intercalating probes including MB and Ir(bpy)(phen)(phi)$^{3+}$ but not for the groove-binding ruthenium hexammine. Thus, the observed electrochemistry is DNA-mediated and a general characteristic of the DNA, independent of the redox probe.

To increase the sensitivity of mismatch detection and further improve discrimination, MB was coupled to freely diffusing $Fe(CN)_6^{3-}$ in an electrocatalytic cycle (Figure 5). In this catalytic process, MB undergoes a $2e^-$ reduction via the base pair stack and, upon reduction to leucomethylene blue, loses some affinity for DNA, thus dissociating from the duplex (*45*, *46*). In turn, the cycle continues when leucomethylene blue is reoxidized by $Fe(CN)_6^{3-}$ in solution and binds again to DNA for another cycle of DNA-mediated reduction. It should be noted that $Fe(CN)_6^{3-}$ cannot be reduced directly at the negatively charged monolayer owing to repulsion from the polyanionic DNA monolayer. The entire process is effectively governed by the on/off kinetics of the methylene blue/leucomethylene blue redox couple, as confirmed by rotating disk electrode experiments (*48*). In fact, during the course of a single voltammogram, the DNA is repeatedly sampled, amplifying the absolute signal of MB and increasing the signal attenuation associated with a mismatch.

The detection of all naturally occurring mismatches and nearly all common lesions was achieved with the MB/$Fe(CN)_6^{3-}$ electrocatalytic couple via cyclic voltammetry and chronocoulometry (Figure 6). In addition, low detection limits were achieved in a chip-based format, with mismatch discrimination possible at electrodes as small as 30 μm in diameter (*46*). It should also be noted that the relatively stable GA mismatch could *not* be detected without the aid of the described catalytic

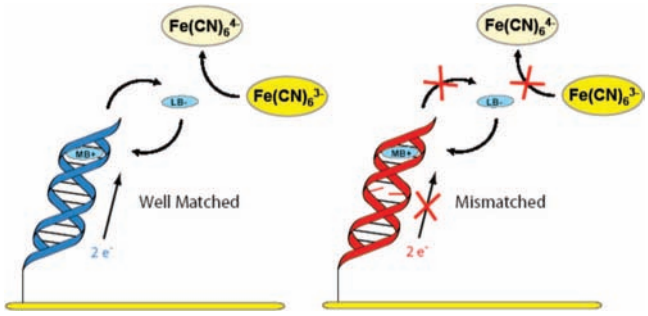

Figure 5. Schematic illustration of the methylene blue/ferricyanide electrocatalytic cycle on the DNA monolayer. DNA-bound methylene blue is reduced in a DNA-mediated reaction to leucomethylene blue (LB), which dissociates from the monolayer and is reoxidized by ferricyanide in solution; the reoxidized methylene blue returns to the DNA for another round of DNA-mediated electrochemistry. This electrochemical amplification leads to enhanced discrimination of all single base mismatches in DNA, since the intervening mismatch shuts down the DNA-mediated reaction and thus the electrocatalytic cycle.

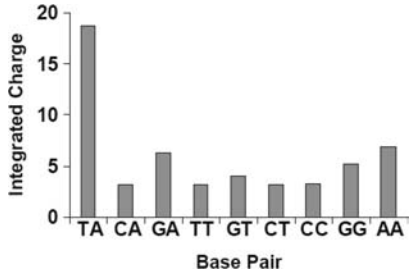

Figure 6. A comparison of the relative integrated charge obtained from chronocoulometry of 2 mM $Fe(CN)_6^{3-}$ and 0.5 μM MB at well-matched DNA monolayers (TA) and in the presence of various mismatches (adapted from ref *46*).

cycle, emphasizing the utility of electrocatalysis as an electrochemical tool. Furthermore, even base lesions that cause minor thermodynamic destabilization to the duplex could be detected with electrocatalysis: a systematic investigation revealed that the efficiency of CT was dramatically decreased even by subtle base modifications that altered base structure, steric bulk, or hydrogen bonding (*49*). Perhaps not surprisingly, modifications with methyl groups that do not participate in hydrogen bonding had little to no effect on the DNA-mediated electrochemistry. The sensitive detection of all single base mismatches independent of sequence context is remarkable and has proven to be valuable in the application of DNA electrochemistry for the diagnosis of single nucleotide polymorphisms.

MB electrochemistry was also extensively explored through self-assembled DNA monolayers on highly ordered pyrolytic graphite (HOPG), onto which the DNA is anchored to the surface via a pyrene moiety (*25*). As a surface, HOPG provides an attractive alternative since its accessible potential window is no longer limited by the oxidative reduction or desorption of thiols. The behavior of MB on graphite is quite similar to that on gold. Evidence that the charge transfer is DNA-mediated is provided by the facile detection of the CA and GT mismatches. The wider potential window afforded by HOPG allowed for the study of the voltammetry of $Ru(bpy)_2dppz^{2+}$ and $Os(phen)_2dppz^{2+}$. As expected, the electrochemistry of both intercalators was found to be DNA-mediated.

Electrochemistry of Small Molecules Covalently Bound to DNA. To facilitate the systematic investigation of charge transduction of DNA, it became necessary to employ redox-active probes that are covalently conjugated to the base pair stack. Our initial efforts focused on covalently attached daunomycin (DM), which can be site-specifically cross-linked to the exocyclic amine of guanine, forming a covalent bond, as shown in Figure 7 (*50*−*52*). Most importantly, this allows for controlled placement of the probe within the sequence. Since functionalization with DM occurs after the synthesis of the DNA, it does, however, necessitate that all guanines other than the one to be linked are replaced by inosine, a close base analogue. For the purpose of electrochemical measurements, this substitution has no influence on the results, but this requirement does have to be considered when developing sensing applications. Importantly, covalent attachment of this probe for DNA electrochemistry has made possible several seminal conclusions about DNA-mediated CT involving *ground-state* reactants.

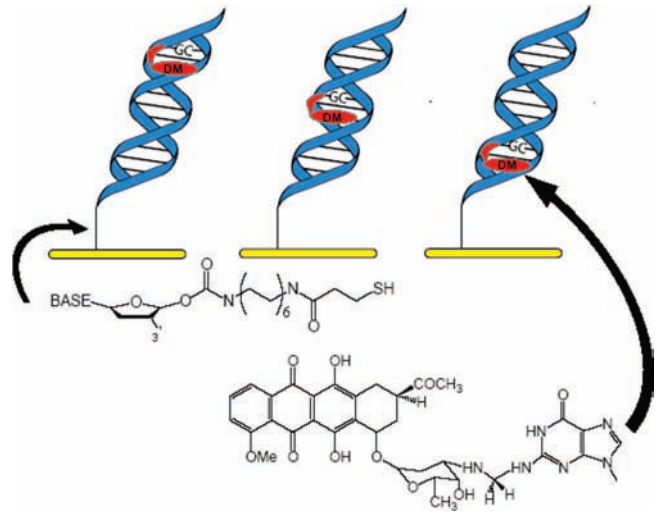

Figure 7. A schematic illustration of DNA duplexes with daunomycin covalently cross-linked at various separations from the electrode surface. Also depicted are the DM-guanine cross-link (right) and the thiol-terminated tether which connects the duplex to the electrode surface (left). This tether provides 16 σ bonds between the electrode and the base stack.

In initial experiments, the separation between the gold surface and the DM adduct was varied from 15 Å to 45 Å, and no effect on the yield or rate of electron transfer was observed (*50*). The inclusion of a mismatch in the intervening DNA, however, completely shuts off the electrochemistry of DM, conclusively demonstrating that CT is DNA-mediated. Subsequently, with DM held in a fixed position in the duplex, the length of the thiolated alkyl tether was varied to probe the effect of tether length on the rate of charge transfer (*51*). While the yield of CT remained the same regardless of chain length (the number of intervening methylene units was increased from 4 to 9), significantly, the rate of electron transfer decreased with increased tether length with a β_n of 1.0 per $-CH_2-$ unit, as expected for the variation in coupling with σ-bonded systems. Therefore, CT through the alkyl tether, not through 30 Å of π-stacked DNA, was the rate-limiting step of the DNA-mediated reduction. Taken together, these findings illustrate that the DNA−DM construct behaves as a single redox-active entity with dramatically different rates of CT through the stacked DNA and the σ-bonded alkyl chain.

In a later study, DM was employed to prove that DNA-mediated electrochemistry occurs via the base pair stack and not the sugar−phosphate backbone (*52*). With two DM moieties cross-linked to guanine residues, voltammograms of duplexes containing a nick in the backbone, a nick and a mismatch, a nick on both strands, and no modifications were compared. Nicks in the phosphate backbone do not attenuate CT, but, consistent with previous results, mismatches significantly attenuate the electrochemistry of DM. Interestingly, a later study

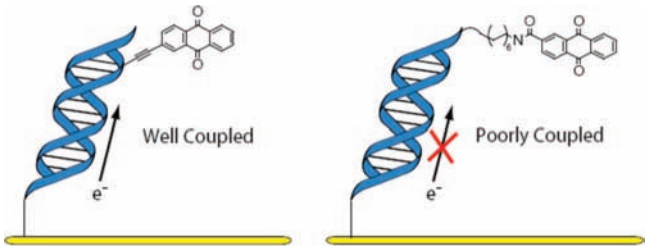

Figure 8. A schematic representation of the electrochemistry of anthraquinone derivatives that are well-coupled (left) and poorly coupled (right) to the base pair stack.

on HOPG showed that the electrochemistry of thiols incorporated within the sugar−phosphate backbone was DNA-mediated but proceeded at low yield (*53*). Therefore, while DNA electrochemistry proceeds through the base pair stack rather than through the sugar−phosphate backbone, it can promote reactions on the DNA backbone.

While DM afforded several key findings for our applications, it does possess some inherent limitations. As mentioned above, all guanine residues, other than the one to be linked, must be replaced by inosines, limiting its applicability in biosensors. Moreover, the stability of the linkage between DM and DNA is heat-sensitive. As a result, we have been focused on developing a new generation of probes that can be covalently attached to DNA with synthetic flexibility, are stable, and are electronically well-coupled to the base pair stack.

Through a variety of experiments conducted in both our laboratory and others, it has become apparent that efficient coupling of the probe to the base stack is critical for efficient DNA CT. Recently, the groups of Saito and Gooding introduced thymines modified with anthraquinone as effective, covalently attached probes of charge transfer at DNA-modified surfaces (*54*−*57*). Using this technology, Gooding and co-workers demonstrated the application of these modified probes to the detection of primer extension reactions (*54*, *55*), and Saito and co-workers demonstrated the photostimulated detection of mismatches with applications to genotyping of single nucleotide polymorphisms (*56*, *57*). However, the low current densities obtained in these studies led us to conduct a comparative study of anthraquinone linked to DNA through conjugated and saturated tethers (*58*). Importantly, we found efficient redox chemistry and mismatch sensitivity for anthraquinone only when linked through an alkyne and not when tethered by an alkyl chain (Figure 8). Thus, not only the choice of probe but also how the probe is coupled to the base pair stack are key to effective DNA-mediated CT.

More recently, we have investigated two phenoxazine-based probes, Redmond Red and Nile Blue, as covalent reporters of DNA CT (Figure 3). Redmond Red is commercially available, affording facile incorporation into DNA with no sequence restrictions (*59*), and Nile Blue can be attached in high yield to DNA by reacting its exocylic amine with a carboxy-NHS-ester-thymine (*60*). These probes can be incorporated via standard phosphoramidite chemistry, have virtually no sequence restrictions, are stable to light/heat, and support DNA-mediated electrochemistry. Accordingly, they are preferable to DM for routine use and high-throughput experiments; both of these probes have already been applied for electrochemical monitoring of protein/DNA interactions (*vide infra)*. Furthermore, Nile Blue has proven effective for detection of hybridization and has displayed electrocatalytic activity (unpublished results). Redmond Red, moreover, has proven to be a particularly sensitive reporter of abasic sites in DNA. The development of these probes holds great promise for future experiments.

4. ELECTROCHEMICAL DETECTION OF HYBRIDIZATION AND TRANSCRIPTION PRODUCTS

The studies described thus far report findings achieved with prehybridized duplexes on gold or graphite; the monolayers were formed exclusively via self-assembly of duplex DNA prior to electrochemical investigation. It is of tremendous importance, from both a fundamental and an applications perspective, to demonstrate similar behavior of DNA-mediated electrochemistry when duplexes are instead formed *in situ*. This approach allows for repeated, internally normalized investigations of a single surface, thereby laying the groundwork for the detection of lesions, mutations, and mismatches in chip-based genetic analysis.

Initial promising results have led current efforts to focus on the design and development of an electrochemical assay for the products of transcription. Consequently, we first explored DNA-mediated CT in DNA/RNA hybrids. Given the known correlation between several RNA sequences and the development of disease, the ability to simply and quantitatively detect the concentration of particular RNA sequences could ultimately be exploited for both disease diagnosis and chemotherapeutic design.

Electrochemical Detection of Mismatches *in Situ.* A comparative *in situ* experiment on modified gold surfaces allowed for a CA mismatch to be reversibly detected via DNA-mediated CT (*45*). DNA was immobilized on two separate electrodes, one bearing duplexes with well-matched complements, the second containing duplexes with a single base mismatch. Following exposure to a solution of DM, the electrodes exhibited the behavior expected for their respective complements, namely, the signals were much larger for the well-matched duplex. The duplexes were then dehybridized by heat denaturation and reincubated with the opposite complement; the resulting well-matched duplex exhibited an increased signal, while the response from the mismatched duplex displayed significant attenuation. Importantly, the signals observed for single-stranded DNA were qualitatively different from those observed for either mismatched or well-matched DNA, confirming duplex formation.

By utilizing the MB/$Fe(CN)_6^{3-}$ electrocatalytic couple, highly sensitive detection limits for hybridization have been achieved (*46*). Monolayers containing well-matched DNA were first self-assembled at gold microelectrodes manufactured in a chip-based format and investigated with chronocoulometry. The DNA was subsequently rehybridized with 100 pM mismatched complement before chronocoulometry was performed again (Figure 9). Dramatic signal attenuation was observed *in situ* in the presence of even a single mismatch. Controls performed with single-stranded DNA again yielded voltammetry which was broad, weak, irreproducible, and qualitatively different, again confirming duplex formation.

In addition to cyclic voltammetry and chronocoloumetry, an alternative electrochemical technique, electrochemical impedance spectroscopy, can also report on duplex formation *in situ*. Differences in the surface coverage are reflected in the electron-transfer resistance, (R_{ET}), as determined by this measurement. Using $Fe(CN)_6^{3-}$ as an electrochemical reporter, electrode surfaces were taken through several dehybridization/rehybridization cycles (using simple heat denaturation and room-temperature annealing), where the impedance at the surface was monitored at each step. The sensitivity of this technique allowed for excellent discrimination between dehybridized and rehybridized surfaces, allowing for label-free detection of duplex formation (*44*).

Electrochemistry through DNA/RNA Hybrids. As a complement to the hybridization studies described above, our laboratory has also investigated DNA-mediated charge transport through

Figure 9. A schematic representation of the protocol used for DNA electrochemistry before heat denaturation of DNA monolayers (left), after denaturation to yield single-stranded DNA (center), and after rehybridization with mismatched DNA (right). A dramatic attenuation in DNA-mediated CT is observed with hybridization of the mismatched strand compared to the well-matched DNA. Electrochemistry of the single-stranded monolayer gives a broad, weak, and irreproducible signal.

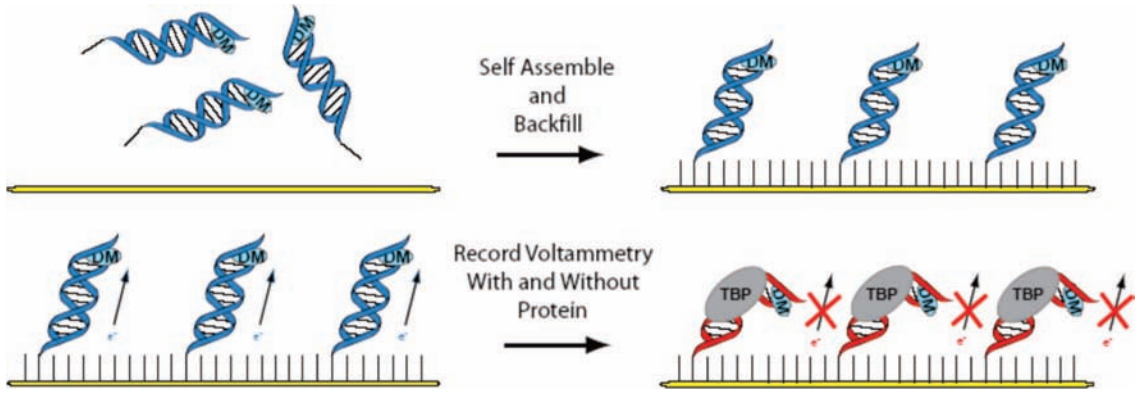

Figure 10. Illustration of the fabrication of DNA-modified gold electrodes for electrochemical analysis of protein binding and reaction. First, loosely packed DNA monolayers are formed and the surface is back-filled with mercaptohexanol for passivation. In the absence of protein, DNA-mediated redox chemistry to the DNA-bound probe is observed. Binding a protein that interrupts the base pair stack also interrupts the DNA-mediated redox chemistry, leading to an attenuation in the redox signal.

DNA/RNA hybrids directly. It is known that these naturally occurring intermediates adopt a conformation that more closely resembles A-form DNA, whereby the helix is significantly wider and more compact than canonical B-form. While these structural differences could potentially interfere with a charge transport pathway down the helix, electrochemical studies within our laboratory have demonstrated that DNA/RNA hybrids are indeed capable of conducting charge in a manner similar to DNA/DNA duplexes (*61*, *62*). Noncovalent MB reduced via a DNA/RNA hybrid exhibits nearly identical voltammetric behavior to that observed with DNA. Moreover, electrocatalytically coupling MB with $Fe(CN)_6^{3-}$ affords discrimination of all possible mismatches in DNA/RNA hybrids, as was monitored by chronocoulometry. These studies reveal that DNA-mediated CT can serve as an effective methodology for the detection of transcription products. Current efforts are now focused on the development of a sensitive and quantitative electrochemical hybridization assay for mRNA using covalently attached anthraquinone.

5. ELECTROCHEMICAL MONITORING OF PROTEIN/DNA INTERACTIONS

Self-assembled DNA monolayers also provide particularly convenient platforms for electrical monitoring of protein/DNA interactions. These interactions play crucial roles in many cellular processes such as transcription, repair, and replication. In particular, the association of transcription factors with DNA is an important area for exploration in proteomics and genomics; it is these interactions that control the developmental and regulatory responses of the cell, often in a complicated fashion. Therefore, the development of convenient and inexpensive methodologies for monitoring protein−DNA interactions remains of critical importance.

In a typical experiment, a loosely packed DNA monolayer is self-assembled with or without a covalently appended probe, and the surface is back-filled (Figure 10). Subsequently, voltammetry of the DNA-modified electrode is recorded before and after addition of protein. Detection of protein binding can be achieved in two ways: (1) proteins that perturb the base pair stack will attenuate the yield of DNA CT to a distally bound electroactive probe and (2) proteins featuring a redox-active cofactor such as an iron−sulfur cluster will cause the appearance of a new DNA-dependent electrochemical signal. These experiments have particularly benefited from the development of covalently attached probes which have allowed for conclusive quantification of the yield of DNA CT before and after protein binding. Furthermore, such electrochemical assays are general and based on exquisitely sensitive DNA-mediated electrochemistry, so a wide range of protein/DNA interactions and binding motifs can be sequence-specifically investigated in real time.

Detection of Transcription Factors. Our early studies at DNA−DM monolayers demonstrated that we could easily detect TATA-binding protein (TBP), a ubiquitous transcription factor that bends duplex DNA by ~90° (*23*). The addition of TBP to a DNA-modified surface results in distortion of the DNA and lowers the yield of DNA CT (Figure 10). Later, we extended this methodology to the detection of TBP at DNA-modified microelectrodes (*60*). At DNA monolayers modified with Nile Blue, TBP could be readily detected at either the macro- or microscale. However, microelectrodes allowed for the rapid detection of nanomolar concentrations of this transcription factor: 300 nM TBP could be reversibly detected with total signal loss in less than 30 s. Furthermore, 30 nM concentrations of TBP were detected even in the presence of micromolar amounts of bovine serum albumin, EndonucleaseIII, or *Bam*HI methyltransferase. These data hinted at the potential of assays based on DNA CT for the high-throughput, multiplexed electrical monitoring of numerous DNA binding proteins on a single chip.

Detection of Base-Flipping Enzymes. Methyltransferases are base-flipping enzymes that catalyze the transfer of a methyl group from *S*-adenosyl-methionine to adenine or cytosine within a DNA duplex. Establishing base flipping by a protein was historically quite difficult, usually requiring a crystal structure, but the electrical detection of base flipping using DNA electrochemistry has been found to be a sensitive, rapid, and attractive method for this characterization.

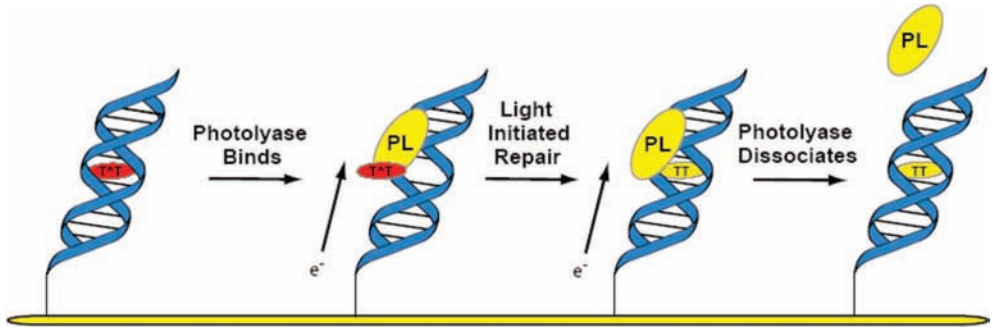

Figure 11. Schematic illustration using DNA electrochemistry to monitor the repair of thymine dimers in a DNA monolayer by photolyase. In the absence of photolyase, no signal is observed, but when the protein is added, a weak signal is observed due to binding of the T^T dimer. Control studies show that the signal corresponds to the flavin bound within the photolyase. Upon irradiation, the thymine dimer is repaired, the integrity of the base pair stack is restored, and the signal grows in intensity as more effective coupling of the protein-bound flavin to the DNA base pair stack is restored. Last, because the protein has a lower affinity for the undamaged DNA, it dissociates, leading to the slow loss of the protein redox signal.

While methyl substitution does not appreciably perturb the base pair stack, methyltransferases, in carrying out the base flip, significantly attenuate DNA-mediated CT. Upon the basis of this attenuation, we have detected base flipping in binding both uracil DNA glycosylase and *Hha*I methyltransferase to their cognate sequences (*23*). At a surface featuring a DNA−DM monolayer, for example, the addition of M.*Hha*I disrupts the integrity of the base pair stack with the concomitant decrease in the DM redox signal. Upon the basis of the crystal structure of the protein/DNA complex, it is apparent that, upon base flipping the internal cytosine of the recognition sequence 5′-GCGC-3′, M.*Hha*I also intercalates Gln 237, a nonaromatic residue into the base pair stack, filling the space occupied by the flipped-out cytosine, and interrupting the π-stacking within the duplex. Accordingly, electrochemistry experiments were conducted with a Q237W mutant enzyme. In this case, we expected that the mutant protein would insert the aromatic tryptophan residue into the π-stack upon base flipping, so little signal loss would be found; indeed, little attenuation in DM signal upon binding the mutant protein was observed. Moreover, to establish that the lack of attenuation was the result of restoration of the π-stack and not simply poor DNA binding by the mutant, we also examined binding of both wild-type and mutant M.*Hha*I to a DNA−DM monolayer containing an abasic site at the position of what would be the flipped-out cytosine. On this DNA−DM monolayer, the DM redox signal is only weakly detected both in the absence of protein and in the presence of wild-type M.*Hha*I, owing to the poor stacking of the duplex with an intervening abasic site. Nonetheless, in the presence of the Q237W mutant, the DM redox signal is restored. This enhanced signal for DM on binding the mutant reflects insertion of the tryptophan from the mutant protein within the base pair stack, so as to restore proper stacking in the DNA−DM duplex. Hence, DNA-binding proteins are seen to modulate DNA CT both positively and negatively, depending upon how they affect the conformation of the DNA.

Electrical Monitoring of Proteins in Real Time. Another advantage of monitoring protein binding to DNA electrically comes from the fact that this technique allows the sensitive detection of events in real time. This was illustrated first by showing double-stranded cleavage on a DNA−DM monolayer using the *Pvu*II restriction enzyme (*23*). In the presence of magnesium ion, *Pvu*II cleaves DNA sequence-specifically. Addition of *Pvu*II to a DNA monolayer containing the *Pvu*II recognition sequence with DM attached to the top of the film but without magnesium causes little perturbation in the DM redox signal. However, the addition of magnesium ion is seen to trigger loss of the DM signal; as the protein cleaves the DNA, the fragment containing the redox probe is released into solution. Interestingly, the kinetics of this signal loss parallels closely that seen for the protein restricting DNA in solution followed by DNA cleavage analysis using gel electrophoresis. The advantage of the electrochemistry technique, however, is clear: the restriction reaction can be monitored in real time.

Monitoring the repair of thymine dimers in DNA by photolyase provides another illustration of how protein/DNA reactions may be monitored sensitively and in real time using DNA electrochemistry (*63*). Photolyase is a repair enzyme from *E. coli* containing a flavin cofactor that binds pyrimidine dimers in duplex DNA and repairs them, upon photoactivation, in a reaction involving electron transfer from the reduced flavin cofactor to the dimer flipped out of the DNA duplex and bound in the pocket of the enzyme near the cofactor. Importantly, in monitoring photolyase reactions electrochemically on DNA monolayers, we did not utilize an externally bound DM redox probe; instead we depended upon the redox signal of the flavin, intimately bound in the protein pocket against the DNA. In binding the photolyase to a DNA monolayer containing the thymine dimer, we found first a weak redox signal arising at 40 mV versus NHE. Through control studies with apoprotein and a mutant, we assigned this redox signal to the flavin and attributed the weak signal to poor electrochemical coupling owing to the intervening destacked thymine dimer. We then carried out the repair reaction by illuminating the electrode surface. With irradiation, we observed an increase of almost an order of magnitude in the integrated flavin signal, and we confirmed repair of the thymine dimer using HPLC analysis. Thus, we could monitor *in real time*, as a function of irradiation, the repair of the thymine dimer by photolyase; as the photolyase repairs the thymine dimer, the base pair stack is restored, the photolyase becomes well-coupled into the base stack, and the flavin signal is enhanced (Figure 11) Subsequently, we found that, once the DNA is repaired, the protein dissociates from the monolayer and the signal intensity is lost.

The ability to monitor, in real time, the binding and chemical reaction of photolyase on DNA highlights the potential of DNA-mediated CT more generally in the analysis of DNA-binding proteins. DNA electrochemistry is unique in its sensitive reporting on DNA conformational changes that may be associated with protein reactions.

Electrochemistry of Base Excision Repair Enzymes Containing Iron Sulfur Clusters. Our DNA electrochemistry experiments with photolyase provide illustrations not only of how DNA electrochemistry can be used to assess DNA conformational changes associated with protein binding, but also how DNA electrochemistry may be utilized to measure the redox potentials of DNA-binding proteins in their active, DNA-bound form. For these experiments, no external redox probe, such as

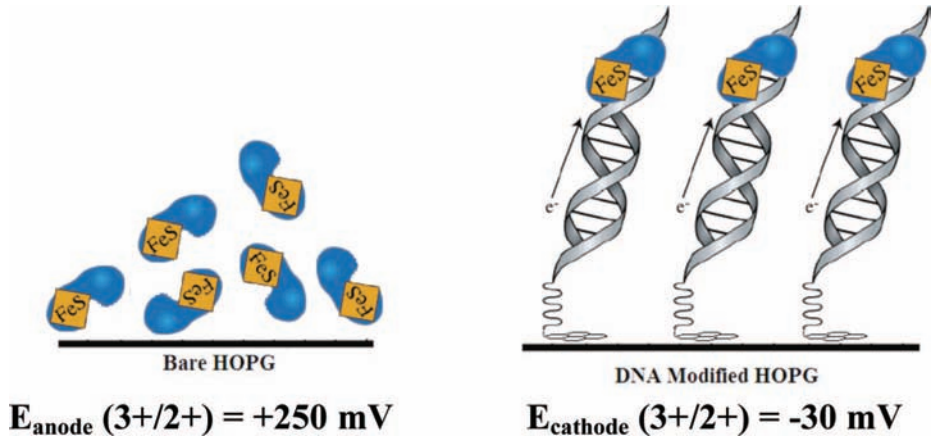

Figure 12. Schematic illustration of the electrochemistry of Endonuclease III in the presence and absence of DNA on graphite. DNA binding causes a potential shift negative of more than 200 mV.

MB or DM, was utilized. Importantly, we could determine the potential of the internally bound flavin cofactor and under conditions where the protein was bound to DNA to carry out its chemistry.

DNA electrochemistry has now been more generally applied in assessing the redox characteristics of DNA-binding proteins in their *active, DNA-bound* form. An illustrative example is found in the characterization of the redox chemistry associated with two base excision repair (BER) enzymes: MutY, a glycosylase that excises adenine from 8-oxoguanine:adenine mispairs, and Endonuclease III (EndoIII), a glycosylase that targets oxidized pyrimidines (*64*−*71*). Crystal structures of these enzymes indicated that they both contain an iron−sulfur cluster with the C-X_6-C-X_2-C-X_5-C motif in close proximity to the DNA backbone (*65*−*68*). This Fe_4S_4 motif, moreover, is conserved in base excision repair proteins from bacteria to man. Interestingly, in MutY, this cluster is not necessary for protein folding or stability but is crucial for DNA binding and *in vivo* activity (*69*). EPR experiments have demonstrated that the cluster is in its $[4Fe\text{-}4S]^{2+}$ form when isolated from the cell, but the protein cannot be reduced within a physiologically relevant window nor oxidized by ferricyanide without degradation (*70*, *71*). These studies, suggesting that redox activity was not associated with reaction by the repair proteins, were, however, conducted in the absence of DNA. Significantly, we found that EndoIII and MutY display stable, quasi-reversible signals with potentials of ∼90 mV versus NHE (*72*, *73*); at DNA-modified, surfaces, back-filled with mercaptohexanol for passivation; this potential is appropriate for a physiologically relevant redox switch. Importantly, these signals are not observed at surfaces back-filled with mercaptohexanol but lacking DNA. Furthermore, weak signals for the proteins on a surface containing a DNA duplex with an abasic site demonstrate that the observed redox processes for the proteins are DNA-mediated.

Experiments performed on DNA-modified, HOPG allowed for the direct comparison of the electrochemistry of EndoIII in the presence and absence of DNA (*74*). Qualitatively similar results were obtained in the presence of DNA on Au and HOPG. Due to its extended potential window, however, HOPG allows for the study of the electrochemistry of EndoIII also in the absence of DNA, a measurement made impossible by the potential window limit on gold. Oxidation of the $[4Fe\text{-}4S]^{2+/3+}$ form of the cluster without DNA led to an anodic signal at 250 mV versus NHE, which was followed by rapid decomposition, in confirmation of solution studies; reductive scans revealed a cathodic peak assigned to the $[4Fe\text{-}4S]^{2+/1+}$ couple of EndoIII. The ability to measure the redox potential of both free and bound EndoIII on the same surface thus allowed for the convincing demonstration that binding to DNA shifts the redox potential of the cluster by −200 mV and stabilizes its $[4Fe\text{-}4S]^{3+}$ state (Figure 12). The cluster therefore is redox-active at ambient temperature in its physiologically relevant, DNA-bound form.

These data underscore the importance of characterizing the redox chemistry of DNA-binding proteins in their biologically relevant, DNA-bound forms. Base excision repair enzymes represented an interesting target for us to study, given the ubiquity of the iron−sulfur clusters in these enzymes with no apparent function. In our laboratory, the finding that these repair proteins become activated to redox chemistry upon binding DNA presents an attractive context for possible DNA-mediated CT *in vivo*. Importantly, this is but one example, and other DNA-binding enzymes that contain a potential redox cofactor may also take advantage of this chemistry. DNA electrochemistry thus provides a first assay to characterize the redox chemistry of DNA-binding and, significantly, to begin to determine whether these proteins may utilize DNA-mediated redox chemistry within the cell.

Electrochemistry of a Transcription Factor Bound to DNA. SoxR is a 17 kDa transcription factor that binds DNA as a dimer with a [2Fe-2S] cluster in each monomer (*59*, *75*, *76*). The loss of the cluster does not affect protein folding, DNA binding, or promoter affinity, but oxidation of the cluster triggers the transcription of SoxS and the subsequent expression of over 100 other genes responsible for the oxidative stress response in bacteria. Interestingly, the redox potential of this cluster in the absence of DNA was determined as −290 mV vs NHE. Importantly, this measurement of the potential of SoxR led to a conundrum: given the reducing environment of the cell, the cluster would always be in its oxidized form, thereby making SoxR essentially constituitively activated *in vivo*. How does the cell keep this protein reduced and transcriptionally silent unless required? Since DNA-modified surfaces allow us to determine the redox potential of proteins in their DNA-bound forms, we explored the electrochemistry of the SoxR transcription factor on DNA-modified HOPG to ask what is the redox potential of SoxR in its physiologically relevant DNA-bound form.

To facilitate these experiments, self-assembled DNA monolayers were prepared on graphite with an appended redox-active probe, Redmond Red (*59*). Redmond Red provided a convenient internal reference for the voltammetry of the SoxR [2Fe-2S] cluster (Figure 13). With this extra probe for calibration, we could conclusively determine that binding to DNA shifts the redox potential of the [2Fe-2S] cluster of SoxR by 490 mV, to +200 mV in its DNA-bound form. Importantly, this potential shift provided a direct rationale for how SoxR stays transcriptionally silent *in vivo* until activated under oxidative conditions: the DNA-bound and physiologically relevant form is always

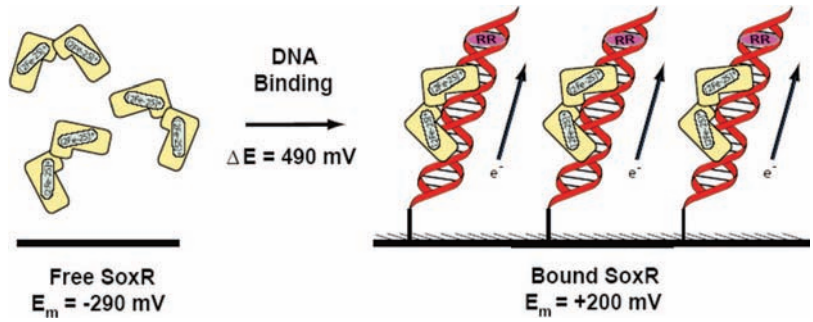

Figure 13. Schematic representation of the electrochemistry of SoxR on DNA-modified graphite with Redmond Red as an internal standard. Binding to DNA shifts the redox potential of SoxR by approximately 500 mV, and this shift likely reflects a substantial change in conformation on binding.

reduced and only conditions of extreme oxidative stress serve to oxidize and thereby activate this transcription factor. We are examining currently whether this activation occurs from a distance, by DNA-mediated CT.

It is interesting to note that the shift seen here on binding to DNA was opposite that seen for the base excision repair proteins and of a significantly larger magnitude. Thus, this large potential shift also provided insight into changes in the structure of SoxR on binding to DNA. Because the binding affinities for DNA of the oxidized and reduced protein are comparable, a significant structural difference between the free (low energy) and DNA-bound (high energy) forms of SoxR was postulated on the basis of electrochemical data. Later, crystal structures of SoxR with and without DNA (*77*) validated our proposal on the basis of these electrochemical data. These experiments once again underscore the importance of investigating the redox chemistry of DNA-binding proteins in their biologically relevant forms, bound to DNA.

6. CONCLUSION

The intrinsic ability of DNA to conduct charge along its base pair stack and the remarkable sensitivity of this chemistry to the integrity of the DNA duplex has intrigued us for over two decades. A combination of detailed structural characterization and careful experimental design has allowed the investigation of this chemistry on DNA-modified surfaces to explore the range and applications of DNA-mediated CT. Through a host of electrochemical studies, we have not only uncovered several fundamental properties of this chemistry but have also demonstrated its potential use in a variety of biosensing and biochemical applications.

DNA-modified surfaces offer an ideal platform on which to investigate CT. Structural studies have provided information on the morphology of these self-assembled monolayers, which are found to orient themselves upright and away from the surface, thereby creating an accessible conduit for the transport of charge. We have employed several different redox-active, DNA-bound molecules to serve as sensitive reporters of this process. While earlier work largely involved noncovalent intercalating moieties, subsequent studies have taken advantage of the precise control and improved electronic coupling afforded by covalent attachment.

In all cases, DNA-mediated CT displays an exquisite sensitivity to the stacking of the base pairs that intervene between the electrode surface and the pendant probe, allowing for the electrochemical discrimination of single base mismatches, lesions, and conformational perturbations. Our investigations are now being extended to DNA/RNA systems, with particular focus on the ability to detect products of transcription. Initial findings illustrated that DNA/RNA hybrids behave similarly to homologous DNA/DNA duplexes, allowing us the utilize DNA-mediated CT for development of a sensitive and quantitative hybridization assay. Finally, due to the possible DNA conformational changes associated with protein binding, we have also been able to demonstrate the sensitive detection of protein/DNA interactions and redox chemistry in real time and under their active, DNA-bound conditions.

This review is intended to survey the structural and electrochemical studies performed in our research group that have elucidated several key features of DNA-mediated charge transport. Much remains to be discovered with regard to the scope and fundamentals of this process. Can we harness this chemistry in the construction of highly sensitive nanoscale devices to detect proteins and RNA in real time in a multiplexed chip format? Are we, in fact, simply mimicking what Nature already exploits for long-range signaling among proteins in the cell that utilize DNA CT? Many more questions remain to be addressed, yet it is abundantly clear that DNA electrochemistry and, more generally, DNA CT, represent a remarkably rich field for study.

ACKNOWLEDGMENT

We gratefully acknowledge the NIH (GM61077) for their financial support. We are also very grateful to our many coworkers who have helped in elucidating this chemistry. We thank in particular Prof. M. G. Hill, without whom this chemistry could not have been discovered and described.

Received October 15, 2008; Revised Manuscript Received October 21, 2008

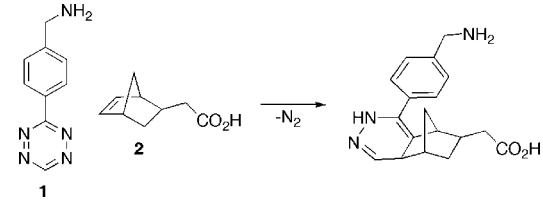
Bioorthogonal tetrazine cycloadditions have been applied to live cell labeling. Tetrazines react irreversibly with the strained dienophile norbornene forming dihydropyrazine products and dinitrogen. The reaction is high yielding, selective, and fast in aqueous media. Her2/neu receptors on live human breast cancer cells were targeted with a monoclonal antibody modified with a norbornene. Tetrazines conjugated to a near-infrared fluorochrome selectively and rapidly label the pretargeted antibody in the presence of serum. These findings indicate that this chemistry is suitable for in vitro labeling experiments, and suggests that it may prove a useful strategy for in vivo pretargeted imaging under numerous modalities.

Bioorthogonal reactions for coupling materials in the presence of complex biological milieu are of great interest in biology and medicine. Such reactions have become key components in a variety of applications including protein engineering (*1*, *2*), immunoassay development (*3*), and cell surface modification (*4*, *5*). To date, only a few bioorthogonal reactions have been reported, the most popular being the Staudinger ligation and the [3 + 2] cycloaddition "click" reaction between azides and alkynes (*6*, *7*). Here, we report on the use of [4 + 2] Diels−Alder cycloadditions between a tetrazine and olefin as an alternative bioorthogonal reaction. The reaction is extremely selective, high yielding, and proceeds rapidly in aqueous media. The reaction partners show excellent stability in biological media and are simple to synthesize. The utility of this reaction is demonstrated by the specific labeling of Her2/neu receptors on breast cancer cells.

Recently, there has been tremendous interest in the use of the click reaction for biological labeling. The typical click reaction involves copper(I)-catalyzed coupling of an azide and terminal alkyne to generate a stable triazole (*7*). Until recently, the necessity of the copper catalyst precluded the use of this reaction in biological systems due to concerns regarding toxicity. Bertozzi and others have elegantly solved this problem by developing several new ring-strained cyclooctyne derivatives that do not require a catalyst (*4*, *8*, *9*). However, many of these derivatives have poor water solubility or require complex multistep synthesis and are not readily obtainable in large quantities. Despite these shortcomings, the cycloaddition reaction between azides and ring-strained cyclooctynes has been employed for imaging of cells (*4*) and zebra fish embryos (*10*).

Our search for alternative rapid, selective, and chemically accessible coupling reactions that do not require a catalyst led us to investigate the [4 + 2] Diels−Alder cycloaddition. Not only is the Diels−Alder reaction compatible with aqueous environments, but the second-order rate constants for this reaction are known to be enhanced up to several hundred-fold in aqueous media in comparison to organic solvents (*11*, *12*). Many Diels−Alder reactions are reversible (*13*) and therefore may not be suitable for biological labeling. The inverse electron demand Diels−Alder cycloaddition of olefins with tetrazines, however, results in irreversible coupling, giving dihydropyridazine products (Scheme 1). During this reaction, dinitrogen is released in a retro Diels−Alder step (*14*). A variety of tetrazines (*15*) and dienophiles including cyclic and linear alkenes or alkynes (*16*) have been studied in this reaction. Selection of the appropriate reaction partners allows for tuning of the coupling rate by several orders of magnitude (*15*, *16*).

Scheme 1



To probe the feasibility of the tetrazine−dienophile reaction as a tool for biological labeling, a modified norbornene (**2**) was selected as a model dienophile. Norbornenes offer an excellent balance between facile strain-promoted reactivity with tetrazines and overall chemical stability. Furthermore, a selection of norbornenes with additional conjugation handles are commercially available. In contrast, few tetrazines containing additional reactive groups have been reported. One potential starting point, dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate, has been investigated extensively, but is not stable in aqueous or protic media (*17*). Other amine-modified tetrazines such as 1,2,4,5-tetrazine-3,6-diamine (*18*) or 3,6-bis-(4-aminophenyl)-1,2,4,5-tetrazine (*19*) have been described, but have poor reactivity with dienophiles. In this communication, we detail

the synthesis of a stable benzylamine-modified tetrazine with excellent dienophile reactivity and investigate its use in the bioorthogonal pretargeting of live cells.

The tetrazine, 3-(4-benzylamino)-1,2,4,5-tetrazine (**1**), is prepared by reaction of 4-(aminomethyl)benzonitrile with formamidine acetate and anhydrous hydrazine in the presence of elemental sulfur. The initial dihydrotetrazine product is oxidized to the tetrazine by treatment with sodium nitrite in acetic acid in 20% overall yield. The primary amine can be modified via standard amide-coupling procedures to prepare the near-infrared (NIR) fluorophore-modified conjugate, tetrazine-VT680 (**3**).

Tetrazine **1**, shows excellent stability in PBS buffer with little or no observed decomposition after prolonged standing at room temperature (data not shown). The stability of **1** in biological media is also very good, with only 15% decomposition observed after 15 h in fetal bovine serum (FBS) at 20.0 °C. Since both tetrazine **1** and norbornene **2** are asymmetric compounds, the Diels−Alder cycloaddition of these two components generates multiple isomeric dihydropyridazine products (Scheme S1 and Figure S5, Supporting Information) Analysis of the reaction products by LCMS indicates a clean reaction with >93% conversion to the dihydropyridazines. Tetrazine **1** reacts smoothly and rapidly with norbornene **2** in aqueous buffer and FBS with second-order rate constants of 1.9 and 1.6 M^{-1} s^{-1}, respectively. The use of more reactive tetrazines and highly strained dienophiles such as cyclooctynes will likely increase coupling rate constants by several orders of magnitude, and we are currently exploring these strategies (*20*).

Labeling of specific functional groups on live cells has emerged as a powerful application of bioorthogonal couplings. To demonstrate this, the tetrazine-based cycloaddition reaction was used to label antibodies bound to Her2/neu receptors on live SKBR3 cancer cells. Such strategies are of interest, because although antibodies show great specificity for antigens, their long blood half-lives result in high background signals when directly labeled with imaging agents or cytotoxins. Pretargeting offers the opportunity for un- or nonspecifically bound antibody to clear before chasing with a smaller, readily excreted molecule that selectively couples to the remaining antibody, drastically reducing background (*21*). Previous pretargeting strategies primarily have relied on the interaction between biotin and avidins to achieve specificity (*22*). Although these approaches have shown promise in the clinic, they suffer from problems such as immunogenicity and steric crowding resulting from the >50 kDa size of the avidins. A small molecule based pretargeting strategy may circumvent these problems.

To demonstrate the utility of the tetrazine−dienophile reaction for live-cell labeling, we used the FDA-approved monoclonal antibody trastuzumab (Herceptin) which binds to Her2/neu growth factor receptors (Figure 1) (*23*). Trastuzimab was simultaneously labeled with norbornene and tetramethyl rhodamine using standard coupling conditions. Human breast cancer SKBR3 cells, which overexpress Her2/neu, were incubated with 200 nM antibody, and then treated with 50 μM **3** in 10% FBS/HBSS solution for 30 min at 37 °C. After washing, the cells were imaged using both rhodamine and NIR fluorescence channels (Figure 2A,B). Significant labeling, which colocalizes, was observed (Figure 2C). Cells incubated with a control antibody, which contained rhodamine but not norbornene, showed no NIR labeling after exposure to **3** (Figure 2D and E). These experiments demonstrate the specificity of the tetrazine imaging agent for norbornene-modified antibody in the presence of live cells and serum. The reaction is rapid even with micromolar concentrations of the labeling agent and importantly in the presence of serum. These findings clearly indicate that this chemistry is suitable for in vitro experiments and suggests that it may prove a useful strategy for in vivo imaging under numerous modalities.

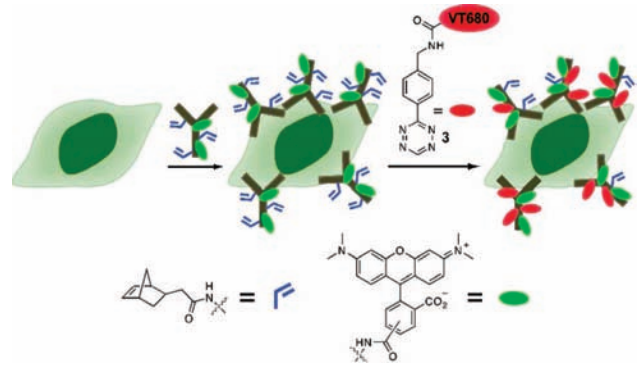

Figure 1. Pretargeting of SKBR3 cells with norbornene and tetramethylrhodamine co-labeled trastuzumab, followed by tagging the live cells with tetrazine-VT680 (**3**) via an inverse electron demand Diels−Alder coupling.

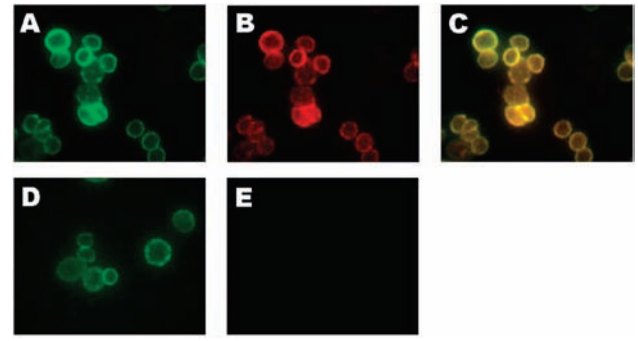

Figure 2. Fluorescent microscope images of SKBR3 human breast cancer cells after pretargeting trastuzumab antibodies modified with rhodamine and norbornene and subsequent labeling with **3**. (A) Rhodamine channel. (B) Near-IR channel (tetrazine-VT680). (C) Merged image of A and B. Images were also taken of cell surfaces targeted with a control antibody modified with only rhodamine and exposed subsequently to **3**. (D) Rhodamine channel. (E) Near-IR channel.

ACKNOWLEDGMENT

The authors would like to thank Drs. Fangwei Shao and Jered Haun for their assistance in the preparation of this manuscript. This research was supported in part by NIH grants U01-HL080731 and T32 − CA 79443.

Supporting Information Available: Detailed synthetic and cell labeling procedures, kinetic data, and full characterization for all compounds. This material is available free of charge via the Internet at http://pubs.acs.org.

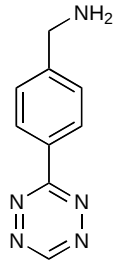
Supporting Information:

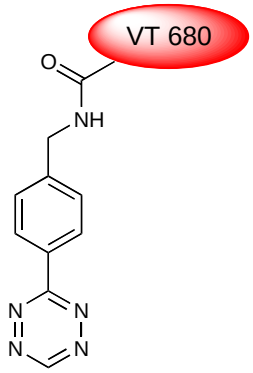
General materials and methods. All chemicals were purchased from Sigma Aldrich unless noted and were used as received. The norbornene, (1S,2S,4S)-bicyclo[2.2.1]hept-5-en-2-yl acetic acid, was purchased from ChemBridge. All solvents were of reagent grade or higher and were used without further purification. Analytical HPLC and LC/MS were performed on a Waters 2695 HPLC equipped with a 2996 diode array detector, a Micromass ZQ4000 ESI-MS module, and a Grace-Vydac RPC18 column (model 218TP5210) at a flow rate of 0.3 mL/min. Preparative HPLC was performed on a Varian ProStar model 210 instrument equipped with a model 335 diode array detector, a model 701 fraction collector, and a Varian RPC18 column (model A6002250X212) at a flow rate of 21 mL/min. For all HPLC runs, solvent A consists of water with 0.1% TFA and solvent B is composed of acetonitrile with 10% water and 0.1% TFA. All UV/vis spectra and kinetics experiments were recorded on an Agilent 8453 diode array UV/vis spectrophotometer. Pseudo first order rate constants from all kinetics experiments were calculated using the Agilent UV/vis Chemstation software package Rev. A.10.01. Fluorescence measurements were obtained using a Varian Cary Eclipse fluorescence spectrophotometer. ^{1}H (400 MHz) and ^{13}C NMR (100 MHz) spectra were collected on a Bruker Advance-400 NMR spectrometer at ambient temperature in D_2O with 3-(trimethylsilyl)-propionic-2,2,3,3-D_4 acid sodium salt (TSP) as an internal standard. High-resolution electrospray ionization (ESI) mass spectra were obtained on a Bruker Daltonics APEXIV 4.7 Tesla Fourier transform mass spectrometer (FT-ICR-MS) in the Department of Chemistry Instrumentation Facility at the Massachusetts Institute of Technology.

Synthetic Procedures:



3-(*p*-Benzylamino)-1,2,4,5-tetrazine (**1**): To a thoroughly blended mixture of 4-(aminomethyl)benzonitrile hydrochloride (25 mmol, 4.21 g), formamidine acetate salt (100 mmol, 10.41 g) and sulfur (25 mmol, 801 mg) was added anhydrous hydrazine (7.84 mL, 250 mmol). After addition of the hydrazine, the reaction mixture becomes a thick clear slurry with gas evolution. After stirring vigorously for 20 h, the now yellow slurry is added to acetic acid (50 mL) and filtered through a glass frit. Sodium nitrite (125 mmol, 8.63 g) in 15 mL of water is then added to the acetic acid solution, cooled in an ice/water bath, over 15 min (**Caution**: the sodium nitrite addition generates a large amount of toxic nitrogen oxide gasses and should be performed in a well ventilated fume hood). During the sodium nitrite addition, the solution turns bright pink in color. The residue remaining after removal of the acetic acid by rotary evaporation at 60 °C and 5 torr is then washed with acetonitrile (3x20 mL) and filtered. After removal of the acetonitrile by rotary evaporation, the remaining viscous pink oil (~20 g) is dissolved in 250 mL of buffer A and partially purified in 5 portions by loading onto 70 g Varian Mega Bond Elute RPC18 flash chromatography cartridges eluting with buffer A containing 25% MeOH. The resulting pink fractions were combined, concentrated, and purified by preparative HPLC using a gradient from 0 to 25% buffer B over 30 min, giving **1** (0.92 g,

20%) as a pink crystalline solid after solvent removal. The purity of **1** was verified by analytical HPLC (Figure S1). ^{1}H NMR (400 MHz, D_2O): δ 10.41 (1H, s), 8.52 (2H, d, J = 8.4 Hz), 7.73 (2H, d, J = 8.4 Hz), 4.34 (2H, s). ^{13}C NMR (400 MHz, DMSO-d_6): δ 169.23, 160.49, 140.57, 135.05, 132.74, 131.91, 45.69. HRMS-ESI $[M+H]^+$ m/z calcd. for $[C_9H_{10}N_5]^+$ 188.0931, found 188.0935.



3-(*p*-Benzylamino)-tetrazine-VT680 conjugate (**3**): To a solution of **1** (15.0 mg, 0.08 mmol) in 2.5 mL of 0.1 M PBS, pH 8.3, was added VT680 NHS ester (12.4 mg, 0.01 mmol). The dark blue solution was allowed to stir overnight in the dark. Pure **3** (5.2 mg) was obtained following preparative HPLC of the reaction solution using a gradient from 0 to 25% buffer B over 30 min. Product purity was assessed by analytical LC/MS (Figure S9). The synthesis of **3** was confirmed by low resolution ESI mass spectrometry. The expected molecular weight of **3** was calculated to be approximately 1309 for $[M+H]^+$ from the molecular weight of **1** and the vendor supplied molecular weight of 1238 for the NHS ester of VT680. The experimentally observed molecular weight of **3** for $[M+H]^+$ is 1309.7.

Antibody labeling

Norbornene carboxylic acid ((1S,2S,4S)-bicyclo[2.2.1]hept-5-en-2-yl acetic acid) was stirred for three hours with 1.1 equivalents of disuccinimidyl carbonate in acetontrile using 1 equivalent of pyridine as base. After reaction, solvent and base were removed by rotary evaporation and the crude norbornene succinimidyl ester with N-hydroxysuccinimide side product was recovered. Commercially purchased humanized anti-HER2/neu antibody trastuzumab (Genentech, San Francisco, CA) in 0.1M sodium bicarbonate buffer (pH 8.2) was incubated for three hours at room temperature with a 5 molar excess of 5-(and-6)-carboxytetramethylrhodamine, succinimidyl ester (Invitrogen) and a 30 molar excess of crude norbornene succinimidyl ester. The antibody was then isolated and washed by centrifuge purification and stored in PBS buffer. Control antibody was modified in an identical manner but excluding the norbornene NHS.

Cell labeling and imaging

SKBR-3 human mammary carcinoma cell lines were maintained in complete McCoy's medium. Cells were incubated at 37 ^{o}C with 200 nM modified trastuzumab for 30 minutes and then washed twice with 10% fetal bovine serum (FBS) in Hanks balanced salt solution (HBSS). Tetrazine labeling was performed by incubating the cells for 30 minutes at 37 ^{o}C in 10% FBS/HBSS containing 50 μM of tetrazine-VT680. Cells were then washed twice with 10% FBS/HBSS and imaged with by fluorescence microscopy.

A Peptide Targeted Contrast Agent Specific to Fibrin-Fibronectin Complexes for Cancer Molecular Imaging with MRI

Furong Ye,[†] Eun-Kee Jeong,[‡] Zhanjun Jia,[§] Tianxin Yang,[§] Denis Parker,[‡] and Zheng-Rong Lu[†,*]

Department of Pharmaceutics and Pharmaceutical Chemistry, Department of Radiology, and Department of Internal Medicine, University of Utah, Salt Lake City, and Veterans Affairs Medical Center, Salt Lake City, Utah. Received May 21, 2008; Revised Manuscript Received September 19, 2008

A peptide targeted contrast agent, CLT1-(Gd-DTPA), was synthesized for molecular imaging of fibronectin−fibrin complexes in tumor tissue with magnetic resonance imaging (MRI). The T_1 and T_2 relaxivities of CLT1-(Gd-DTPA) were 4.22 and 4.45 mM^{-1} s^{-1} at 3 T, respectively. The targeted contrast agent specifically bound to tumor tissue and resulted in significant tumor contrast enhancement at a dose of 0.1 mmol Gd/kg for at least 60 min in mice bearing HT-29 human colon carcinoma xenografts as shown in dynamic MR images. In contrast, a control nontargeted contrast agent, Gd(DTPA-BMA), was cleared rapidly with little tumor enhancement 60 min postinjection. Tumor enhancement with CLT1-(Gd-DTPA) was significantly reduced after coinjection with a 3-fold excess of free CLT1 peptide. The preliminary study has shown that CLT1-(Gd-DTPA) can specifically bind to the fibrin−fibronectin complexes in tumor tissues, resulting in significant tumor enhancement. The targeted contrast agent has a potential for cancer molecular imaging with MRI.

Magnetic resonance imaging (MRI) is a powerful imaging modality for morphological and functional imaging. MRI provides anatomical images of soft tissues with high spatial resolution and is effective for noninvasive imaging of physiological properties, e.g., diffusion, perfusion, and vascularity, of the tissues of interest (*1*). However, MRI has not been effectively used for molecular imaging because of its low sensitivity. The direct conjugation of targeting agents, e.g., peptides, antibodies, and proteins, to clinical MRI contrast agents, e.g., Gd(III) chelates, could not deliver a sufficient amount of contrast agents for MRI to effectively detect the molecular targets expressed on the surface of cells of interest (*2, 3*). Consequently, a large number of Gd(III) chelates have been incorporated into various targeted nanoparticles for MR molecular imaging to increase local concentration of contrast agents (*4*−*8*). Unfortunately, the size of these nanoparticles is much larger than the renal filtration threshold (ca. 4.5 nm), and they cannot be readily excreted from the body. Long-term tissue retention of high-dose Gd(III) based contrast agents may also cause toxic side effects such as systemic nephrogenic fibrosis (*9, 10*).

The limitations of MRI for molecular imaging can be overcome by proper selection of molecular biomarkers and using agents that can be readily excreted (*11*). Stable Gd(III) chelates have been proven safe in patients except those with intermediate and late-stage renal diseases. Since the amount of biomarkers expressed on the cell surface may not be sufficient for molecular imaging with MRI, other biomarkers with high local expression can be used for MR molecular imaging. It has been reported that tumor stroma have a unique meshwork of clotted plasma proteins that are not present in normal tissues (*12, 13*). The presence of the fibrin in tumor meshwork is known to associate with increased microvessel permeability in neoplastic tissues (*12*), and fibronectin in tumor stroma is also associated with tumor angiogenesis (*13*). The clotted plasma proteins might be attractive targets for molecular imaging with MRI. Recently, Ruoslahti and colleagues have identified peptides, including CLT1 and CLT2 peptides, which can specifically bind to the fibronectin−fibrin clots in various tumor tissues with little nonspecific binding to normal tissues (*14*). The incorporation of such peptides to Gd(III) chelates may result in targeted contrast agents for specific tumor imaging with MRI. As compared to nanoparticulate targeted contrast agents, the small molecular targeted contrast agents can rapidly diffuse into tumor tissue and bind to tumor meshwork. The unbound contrast agents can be rapidly excreted from the body via renal filtration. Consequently, significant signal enhancement of molecular targets can be visualized by MRI with minimal nonspecific background enhancement.

Here, we report a targeted contrast agent, a conjugate of a cyclic decapeptide CGLIIQKNEC (CLT1) and Gd-DTPA, for MR molecular imaging of fibrin−fibronectin complexes in tumor tissues. The peptide CLT1 was first synthesized using standard solid-phase peptide synthesis from Fmoc-protected amino acids (*15*) on a 2-chlorotrityl chloride resin. At the end of the peptide synthesis, an excess of DTPA dianhydride in DMSO was reacted with the peptide on the beads at room temperature for 4 h to conjugate DTPA at the N-terminal of the peptide. The resin was completely washed with water, DMF, dichloromethane, and methanol three times each. The CLT1−DTPA was then removed from the resin using TFA solution (TFA 94%, 1,2-ethanedithiol 2.5%, triisobutylsilane 2.5%, water 1%). The product was exposed to air for about 2 h to allow the formation of disulfide bonds for the cyclic peptide and then purified using preparative HPLC with a C18 column. CLT1−(Gd-DTPA) was finally prepared by complexation of CLT1−DTPA with $Gd(OAc)_3$ at pH 6. Excess $Gd(OAc)_3$ was removed by precipitation at pH 11. The final product was purified by preparative HPLC. The mass (m/z, $M + H^+$) of CLT1−(Gd-DTPA) was 1650.75 (calcd 1650.2) as determined by MALDI-

structure of CLT1−(Gd-DTPA) and the plots of the T_1 and T_2 water proton relaxation rates at various concentrations of the contrast agent at 3 T.

In vivo molecular imaging of fibrin−fibronectin complexes in tumor with the targeted contrast agent and MRI was evaluated in female athymic nu/nu mice bearing HT-29 human colon carcinoma xenografts with a T_1-weighted 2D spin−echo sequence. A clinical contrast agent, Gd(DTPA-BMA), was used as a control. Competitive targeting of free CLT1 peptide to CLT1−(Gd-DTPA) was also studied with coinjection of CLT1−(Gd-DTPA) and a 3-fold excess of free CLT1 peptide. A group of 3 mice was used for each contrast agent. The mice were anesthetized by intramuscular administration of a mixture of ketamine (45 mg/kg) and xylazine (6 mg/kg) for MRI. The CLT1−(Gd-DTPA) and Gd(DTPA-BMA) was intravenously injected at a dose of 0.1 mmol/kg. Contrast-enhanced MR images were acquired before and after injection at 1, 10, 30, and 60 min on a Siemens Trio 3T scanner using a human wrist coil. High-resolution 3D images were acquired with a 3D FLASH sequence with 25° flip angle, TR/TE = 7.8/2.7 ms, slice thickness 0.5 mm, field of view (FOV) 120 mm, voxel size 0.5 × 0.5 × 0.5 mm^3. T_1-weighted 2D axial tumor images were acquired with a 2D spin−echo sequence with TR 400 ms, TE 10 ms, 90° tip angle, and FOV 50 mm. Mice were sacrificed 24 h postinjection, and tumor tissues were removed and fixed with 3% paraformaldehyde and embedded in paraffin. Tissue sections (4 μm thickness) were incubated in 3% H_2O_2 for 10 min to block endogenous peroxidase activity and boiled in antigen retrieval solution for 15 min in microwave. The sections were then incubated with primary antibody overnight and secondary antibody the next day for visualization using the ABC kit (Santa Cruz Biotechnology).

Figure 2 shows the representative axial T_1-weighted 2D spin−echo images of the tumor tissues of the mice bearing HT-29 tumor xenografts before and after injection of the contrast agents. Significant enhancement was observed in tumor tissues for CLT1-(Gd-DTPA) 10 min postinjection, and strong en-

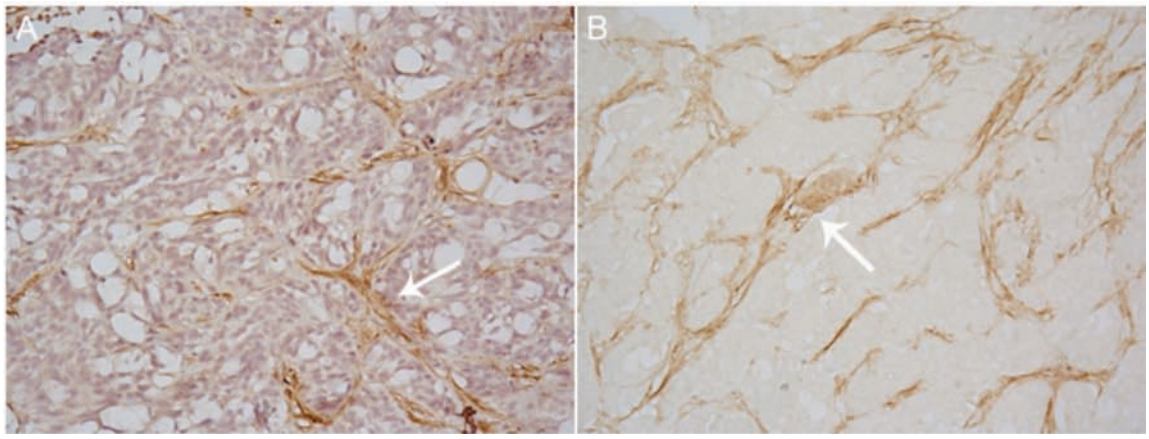

Figure 4. Staining of fibronectin in HT-29 tumor tissues with hemoxylin (A) or without hemoxylin (B) (40× magnification). Arrows point to the stained fibronectin (brown color) in the EES space, and blue in A indicates nuclus stained with hemoxylin.

hancement was visible in the tumor tissues at 60 min after injection. For the competitive study, the tumor enhancement with CLT1−(Gd-DTPA) was reduced after the coinjection of free peptide, which indicates that the free peptide recognizes the same binding site within tumor tissue as CLT1−(Gd-DTPA). The control agent Gd(DTPA-BMA) did not show a strong tumor enhancement as compared to CLT1−(Gd-DTPA).

MR signal intensity was also measured, and the contrast to noise ratio (CNR) in the tumor tissues was calculated as CNR $= (SI_{tissue} - SI_{muscle})/SD_{noise}$. Statistical analysis was perform using two-way ANOVA. Figure 3 shows the CNR of the tumor tissue in tumor periphery and inner areas before and at various time points after injecting the contrast agents. CLT1−(Gd-DTPA) showed higher CNR at 10 min after injection in the tumor periphery area and decreased gradually. At the same time, CNR in tumor inner area increased gradually during the period of 60 min postinjection. The CNR in both tumor periphery and inner tissue with Gd(DTPA-BMA) decreased rapidly after it reached the maximum values at 1 min postinjection. The CLT1−(Gd-DTPA) showed significantly higher CNR than the control Gd(DTPA-BMA) in tumor periphery since 10 min postinjection ($p < 0.05$) and in the tumor inner area since 30 min postinjection ($p < 0.05$). The results indicate binding and retention of the targeted contrast agent to tumor tissue. The presence of free peptide resulted in significant reduction of CNR in both tumor periphery and inner tumor tissue ($p < 0.05$) except at the point of 30 min postinjection. The result indicated that the presence of free peptide inhibited the binding of the targeted contrast agent to its target, resulting in decreased contrast enhancement in tumor tissue.

The plasma proteins fibrin(ogen) and fibronectin play a prominent role in hemostasis and wound healing. Fibrinogen is activated to form an insoluble fibrin clot following vascular injury. The clot also serves as a provisional matrix for adhesion and migration of cells or proteins including fibronectin, which is incorporated into the fibrin clot upon fibrin polymerization. The presence of the fibrin and fibronectin in tumor meshwork has also been reported in the literature due to the leakiness of tumor vasculature (*16*, *17*). CLT1 peptide was reported to specifically bind the fibrin−fibronectin complexes in tumor tissues (*14*). We further carried out immunohistochemical study to verify the presence of fibronectin in the HT-29 tumor tissues after MR imaging. Figure 4 shows the immunostaining of fibronectin in HT-29 tumor tissues with (Figure 4A) or without (Figure 4B) nucleus staining. The histochemical staining clearly indicated the existence of fibronectin in the extracellular spaces of tumor tissues.

It is a challenge for MRI to detect in vivo molecular targets with molecular imaging because of its low sensitivity. We have shown here that MRI can be effective for molecular imaging if suitable molecular targets are identified. The targeted contrast agent CLT1-(Gd-DTPA) had little nonspecific binding and accumulation in the normal tissue despite that the peptide was hydrophobic. It bound to its molecular target in tumor tissue, resulting in significant and prolonged tumor enhancement. The result was consistent to what was originally reported by Ruoslahti et al. in other tumor models, which further confirmed that CLT1 peptide had a high specificity to fibrin−fibronectin complexes in tumor stroma (*14*). Because of the high content of the fibrin−fibronectin complexes in the tumor stroma, the peptide was able to deliver a sufficient amount of Gd-DTPA chelates to the molecular targets to generate detectable signal enhancement for MRI. Since the contrast agent was a low molecular weight chelate with a small size, it was able to be cleared rapidly from the blood circulation and normal tissues, resulting in strong CNR in the tumor tissue.

MR molecular imaging of fibrin−fibronectin complexes in tumor tissue with CLT1−(Gd-DTPA) also has the potential to characterize tumor angiogenesis. It has been reported that the presence of fibrin in the tumor meshwork is associated with increased microvessel permeability in neoplastic tissues (*12*), and fibronectin in tumor stroma is also associated with tumor angiogenesis (*13*). The result suggested that CLT1−(Gd-DTPA) was able to detect the presence of fibrin−fibronectin complexes in the angiogenic tumor tissues. The correlation of fibrin−fibronectin complexes to tumor angiogenesis may provide an effective method for tumor angiogenesis imaging with MRI and CLT1−(Gd-DTPA). Accurate assessment of tumor angiogenesis is critical for tumor grading, assessment of tumor response to anticancer therapies, particularly antiangiogenesis therapies, and patient management.

Fibrin−fibronectin complexes are also present in the plasma clots of wounds and other pathologic tissues with leaky blood vessels such as atherosclerotic plaques. Ruoslahti and colleagues showed that fluorescein-labeled CLT peptides specifically bound to the injured blood vessel wall, not the intact arteries and tissues (*14*). It suggests that MRI with CLT1−(Gd-DTPA) may have broad applications, including molecular imaging of cancer, angiogenesis, vascular integrity, and assessment of wound healing, anthrosclerosis, and tumor response to antiangiogenesis therapies. As compared to other targeting moieties, including proteins, antibodies, and their fragments, the peptide targeted Gd(III) chelate is advantageous for MR molecular imaging due to its excellent tissue permeability and rapid clearance from nonspecific tissue or organs.

In summary, a targeted contrast agent CLT1−(Gd-DTPA) specific to fibrin−fibronectin complexes was prepared and preliminarily evaluated in an animal tumor model for effective

cancer MR molecular imaging. The targeted contrast agent had minimal nonspecific binding and accumulation in normal tissues. CLT1 peptide was able to deliver a sufficient amount of Gd-DTPA chelates to its molecular target for effective molecular imaging with MRI in tumor. CLT1−(Gd-DTPA) is a promising targeted contrast agent for MR molecular imaging of fibrin−fibronectin complexes. It has a great potential for cancer detection and diagnosis, characterization of tumor angiogenesis, and imaging wounds and atherosclerosis.

ACKNOWLEDGMENT

Design of DNA-Conjugated Polypeptide-Based Capture Probes for the Anchoring of Proteins to DNA Matrices

Ryan M. Schweller, Pamela E. Constantinou, Nicholas W. Frankel, Priyanka Narayan, and Michael R. Diehl*

Department of Chemistry, and Department of Bioengineering, Rice University, 6100 Main Street, MS 142 Houston, Texas 77005. Received August 22, 2008; Revised Manuscript Received November 11, 2008

A new method for protein surface functionalization was developed that utilizes DNA-conjugated artificial polypeptides to capture recombinant target proteins from the solution phase and direct their deposition onto DNA-functionalized matrices. Protein capture is accomplished through the coiled-coil association of an engineered pair of heterodimeric leucine zippers. Incorporating half of the zipper complex directly into the polypeptides and labeling these polymers with ssDNA enables the polypeptide conjugates to form intermediate linkages that connect the target proteins securely to DNA-functionalized supports. This synthetic route provides an important alternative to conventional DNA-conjugation techniques by allowing proteins to be outfitted site-specifically with ssDNA while minimizing the need for postexpression processing. We demonstrate these attributes by (i) using the capture probes to prepare protein microarrays, (ii) demonstrating control over enzyme activity via deposition of DNA, and, (iii) synthesizing finite-sized, multiprotein complexes that are templated on designed DNA scaffolds in near quantitative yield.

Protein coupling and immobilization strategies remain central to the investigation of protein interactions and constitute an important design element for a wide variety of protein detection technologies (*1*−*3*). To meet these needs, an array of polypeptide-based affinity tags has been implemented that can mediate the surface anchoring of proteins (*4, 5*). In addition to being expressed as small protein fusions, these functionalities offer significant advantages over physical adsorption as well as most direct covalent attachment schemes, since they provide control over the orientations of proteins on their supports and, in many circumstances, help preserve the native folded state of proteins (*6*).

Alternatively, DNA−protein conjugate molecules have been developed to facilitate protein immobilization onto DNA-coated matrices such as DNA microarrays (*7*−*9*) and organized molecular scaffolds formed from DNA (*10*). DNA-directed immobilization of proteins allows oligonucleotide sequences to encode the spatial positioning and composition of multiple proteins on solid supports via the controlled deposition of DNA (*7*). This approach can simplify the preparation of solid supports for protein immobilization and provide sensitive control over protein deposition, since DNA-surface chemistries are more established and robust than most protein immobilization techniques. DNA-directed protein deposition can also provide routes to tune the quantitative activities of enzymes in ways that can be difficult to achieve using protein affinity tags alone and offer new opportunities to build artificial systems of interacting proteins with complex kinetic properties. Such control has been demonstrated by recent work to "program" the stoichiometric ratios of multiple enzymes immobilized on the surfaces of DNA-coated 96-well plates (*11*). Similarly, multienzyme complexes have been created using DNA as a molecular scaffold and used to explore how proximity effects influence their coupled-enzyme reaction dynamics (*11, 12*).

Despite the advantages of using DNA hybridization to direct protein deposition, various technical obstacles still limit the utility of this approach for a variety of applications. Particularly, the production of large numbers of DNA−protein conjugates remains challenging. Although commercially available cross-linking agents can be used to couple amine- or thiol-functionalized DNA strands to surface cysteine and lysine residues of proteins (*13, 14*), the efficiency of these reactions tends to be low, and postlabeling purification is generally required to isolate the conjugates. Furthermore, site-specific DNA conjugation through this route requires that the majority of surface cysteines and lysines are mutated to nonreacting residues. Even if these or alternative modifications are possible, the direct labeling of proteins with DNA may interfere with protein function (*14*). These issues can be avoided by coupling DNA to proteins indirectly through protein affinity tags. Protocols that employ intein tags along with expressed protein ligation (*15, 16*), DNA−streptavidin conjugates and biotin labeling (*7*), reactions of chemically modified DNA molecules with SNAP-tag fusion (*17*), and protein farnesyltransferase labeling coupled with click chemistry (*18*) have all been adopted for this purpose. However, most of these methods still require purification steps to isolate the DNA−protein conjugates. Consequently, a host of technological applications stand to benefit from the development of new synthetic routes to prepare DNA−protein conjugates that emulate the simple and robust processing afforded by commonly used protein affinity tags alone.

In this report, we describe a new synthetic strategy to couple proteins to DNA matrices that involves the production of DNA-conjugated polypeptide polymers **1** that function as capture probes by associating with recombinant affinity-tagged proteins in solution and then directing their deposition onto DNA-coated supports. These polymers are based on artificial proteins that some of us have previously used to control the surface immobilization of proteins (*19*) and to build finite-sized multiprotein complexes (*20*). With this system, protein capture is achieved through the coiled-coil association of an engineered parallel pair of heterodimeric leucine zippers, designated Z_E and Z_R. The zipper sequences are derived from polypeptides

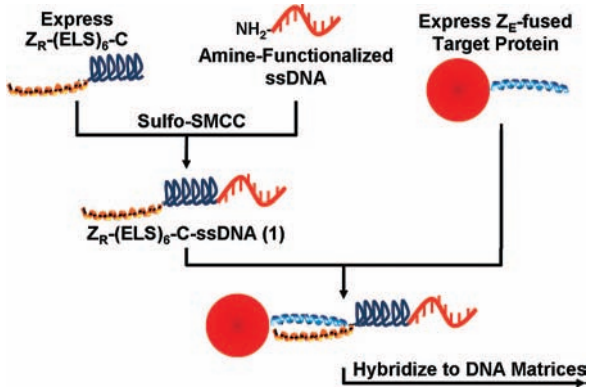
Scheme 1. Synthetic Route to Employ Artificial Protein−DNA Conjugates for Recombinant Protein Capture



developed by Vinson et al. (*21*) and form exceptionally strong heterodimeric complexes ($K_D \sim 10^{-15}$ M) with much weaker homodimeric complexes ($K_D \sim 10^{-3}$ to 10^{-6} M). Half of the zipper complex is fused to a target protein as an affinity tag, while the other component is incorporated into the polymer as a genetic fusion. The polymers also contain a mechanically flexible and repetitive domain based on the elastomeric poly(VPGV$_\alpha$G) structural motif of the protein elastin (EL). Substitution of amino acids at the V$_\alpha$ position of this domain provides control over the hydrophilicity of the polymer and can be used to either direct or minimize physical adhesion of the polymers to functionalized surfaces (*19*). Here, we demonstrate that a DNA-conjugated version of these artificial proteins can be used to direct the self-assembly of target proteins onto DNA supports by forming a monovalent and stable intermediate linkage between immobilized ssDNA and the target proteins (Scheme 1).

The polypeptide polymers employed here contain the basic portion of the zipper complex (Z_R), a polymerized elastic "midblock domain" or ELS fragment (VPGVG VPG**S**G VPGVG VPG**S**G VPGVG), and a C-terminal cysteine, yielding Z_R-(ELS)$_6$-C. After the *in vivo* expression and purification of these polymers, sulfosuccinimidyl 4-[*N*-maleimidomethyl]cyclohexane-1-carboxylate (sulfo-SMCC) was used as a heterobifunctional cross-linker to couple an amine-functionalized oligonucleotide to the C-terminal cysteine of the polymers (*13*). The large shift in the isoelectric point of the polymers after DNA labeling allowed the conjugates to be purified to homogeneity using fast protein liquid chromatography (FPLC). Since the artificial proteins can sustain, without loss of function, lyophilization, resuspension in denaturing buffers, and extended dialysis, the labeling reactions can be scaled up, and this route allows concentrated stock solutions of Z_R-(ELS)$_6$-C-ssDNA to be prepared despite the intrinsic inefficiency of the sulfo-SMCC cross-linking reaction.

To test the ability of **1** to control the deposition of protein on DNA matrices, we labeled two samples of Z_R-(ELS)$_6$-C with different oligonucleotides containing non-complementary sequences. These polymers were then used as solution-phase capture probes that encode the spatial deposition of recombinant proteins onto DNA-printed microarrays (Figure 1). In this procedure, green fluorescent protein (GFP) and glutathione-*S*-transferase (GST) were chosen as target proteins and were expressed *in vivo* with C-terminal Z_E fusions. Protein capture was achieved by mixing samples of either Ni^{2+}-NTA purified target proteins (~1 mg/mL) or expressed proteins in unpurified cell lysates with a single conjugated version of **1** at a 3:1 molar ratio of target protein to polymer. After a brief incubation period (<30 min), these solutions were incubated for ~12 h over a custom-fabricated DNA microarray. Each array was washed and

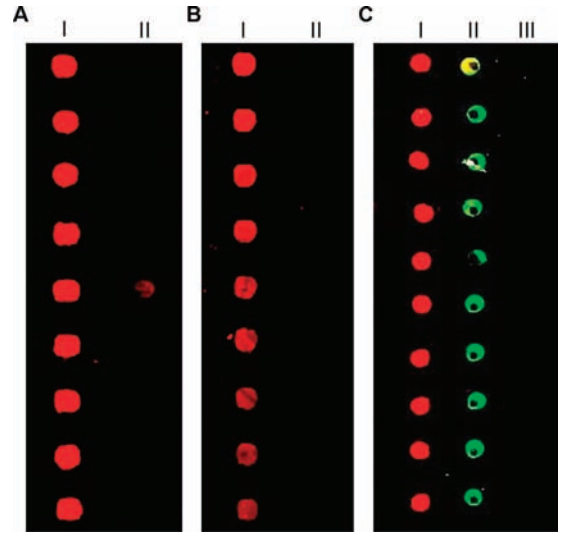


Figure 1. The use of artificial polypeptide conjugates to create protein microarrays encoded by DNA. Arrays probed with Alexa647-anti-GFP were prepared using purified GFP-Z_E (A) and cell lysates containing expressed GFP-Z_E (B). In both cases, column I denotes spots containing the complementary sequence for GFP-Z_E/polymer complex while a non-complementary control strand was spotted in column II. Images in A and B were cropped and placed together for clarity. The pitch between spots is 250 μm. (C) Two-component arrays were fabricated through a single incubation of precaptured GFP-Z_E and GST-Z_E proteins. Column I contains a complementary strand for GFP-Z_E/polymer complex, column II contains a complementary sequence for a second GST-Z_E /polymer complex, and column III contains spots of a non-complementary control strand. Multiprotein arrays were probed simultaneously with a mixture of Alexa647-anti-GFP and Cy3-anti-GST. The pitch between spots is 500 μm.

probed with fluorescently labeled antibodies (either Alexa647-anti-GFP or both Alexa647-anti-GFP and Cy3-anti-GST at 1 μg/mL) and scanned using a GenePix 4000B microarray scanner (Molecular Devices). DNA-directed self-assembly of both GFP-Z_E and GST-Z_E was found to be highly selective. As expected, arrays formed using either purified proteins or cell lysates demonstrated the oligonucleotide sequence-specific targeting of the proteins. Microarray spots containing the appropriate complementary ssDNA sequence possessed average signal-to-noise ratios (SNR) with a range of 20 to 60. Proteins appearing in the Cy3 channel tended toward the higher end of this range. On the other hand, average SNR values were significantly lower for spots containing non-complementary strands, an SNR range of 1.6 to 5. Furthermore, when precaptured protein solutions were combined for 1, 2, 4, or 8 h prior to their incubation on the microarray, we did not observe evidence of exchange between proteins displaying the zipper fusion.

We also examined the effect our DNA-directed immobilization strategy had on enzymatic activity. As a test case, we immobilized a β-lactamase enzyme (PSE-4) onto the surface of 96-well plates that were functionalized with streptavidin and then biotin-labeled oligonucleotides. DNA-directed deposition was performed using a similar procedure to that developed for the microarrays except that the PSE-4-Z_E fusion protein was prepared using standard periplasmic expression and lysis methods. Nitrocefin was used as a substrate for PSE-4, since the enzymatic opening of its β-lactam bond produced a detectable change in absorption at 485 nm using a Tecan Infinite 200 microplate reader. Measurements of nitrocefin hydrolysis rates again verified ability of **1** to selectively control enzyme deposition of target proteins (Figure 2B). Wells containing 5 μg of a complementary oligonucleotide to **1** showed a 4-fold increase in activity over wells that contained non-complementary sequences or where the ssDNA was omitted (Figure 2).

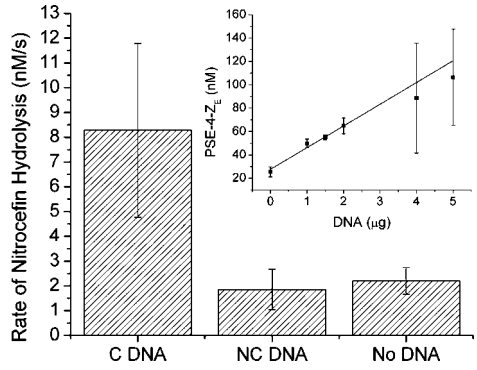

Figure 2. DNA-directed control over immobilized enzyme activity. A 4-fold increase in PSE-4-Z_E activity over background nitrocefin hydrolysis is seen in wells that were incubated with 5 μg of cDNA strands (C DNA) when compared to wells containing the same amount of a non-cDNA strand (NC DNA). Control wells where the DNA-functionalization step was omitted (No DNA) are also shown for comparison. The inset shows the linear dependence of PSE-4-Z_E activity on the amount of cDNA deposited in the wells.

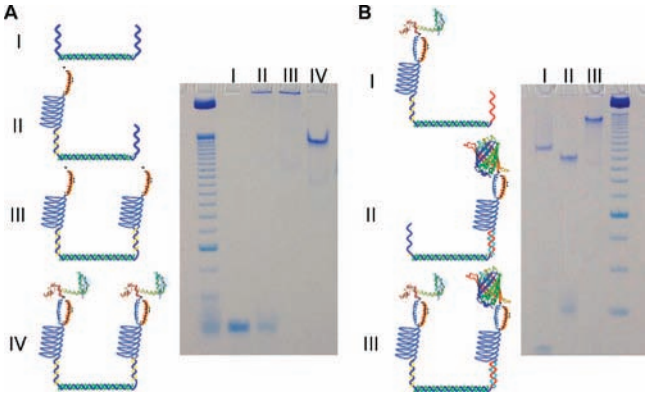

Figure 3. Non-denaturing PAGE-gels confirming the synthesis of multiprotein complexes. (A) Native PAGE-gel showing the successful formation of the complex containing two CaM-Z_E proteins assembled on a single DNA double helix. The dominant species observed in the individual lanes of the gel are indicated by Roman numerals. The labeling scheme is as follows: I. DNA scaffold alone; II. assemblies prepared at a 1 to 0.5 ratio of ssDNA scaffold to conjugates; III. a "half" complex composed of the DNA scaffolds and two artificial polypeptides; IV. complete assemblies formed at a 1:1:1 ratio of all assembly components. (B) Gel demonstrating the assembly of multiprotein complexes containing both a GFP-Z_E and a CaM-Z_E (III), templated on a DNA scaffold possessing two different "overhang" sequences. Partial complexes formed using only one type of protein and corresponding to either CaM-Z_E (I), or GFP-Z_E (II) are also shown.

Consistent with previous reports that utilize DNA-directed immobilization of enzymes (*11*), levels of PSE-4 activity were found to be linearly dependent on the amount of DNA that is immobilized in the wells (Figure 2 inset). Using soluble PSE-4-Z_E as a calibration standard, the hydrolysis rate was converted to PSE-4-Z_E concentration, yielding a slope of 18.6 nM PSE-4-Z_E per microgram of DNA.

Finally, the two different conjugated versions of **1** were synthesized and used to facilitate the self-assembly of multiprotein complexes onto molecular-scale scaffolds formed from DNA. Complexes containing either two GFP-Z_E proteins or a GFP-Z_E and a calmodulin protein (CaM-Z_E) were prepared (Figure 3). The DNA scaffold consisted of a 10-nm-long double helix (34 bases) flanked by unique single-strand "overhangs" comprising 20 bases on either end. The "overhangs" possessed either the same or orthogonal oligonucleotide sequences depending on whether single or multicomponent complexes were being synthesized. Multiprotein assemblies were synthesized by preincubating **1** with GFP-Z_E or CaM-Z_E, and then adding the DNA scaffold. In each case, the protein, polymer, and "overhang" concentrations were held at a 1:1:1 stoichiometry. Complex formation was examined using non-denaturing polyacrylamide gel electorphoresis (PAGE) and by staining for DNA and protein using Stains-All (Sigma). Clear separation between the scaffold and both partially and fully formed assemblies was observed. For each complex, gel intensity analysis indicated that the multiprotein complexes formed in high yield (>95%) using these conditions, proving that the association of the zipper complex and DNA-hybridization provided stable and selective linkages to drive the assembly process near quantitative yield, and that this process does not require the addition of large excesses of individual assembly components to form complete complexes.

In summary, we have demonstrated that DNA-conjugated artificial polypeptides can be used as protein capture probes that facilitate the oligonucleotide sequence-dependent deposition onto DNA-functionalized matrices. Furthermore, we have shown that these polymers allow the stoichiometries of enzymes to be deterministically controlled by forming a stable intermediate linkage between DNA-coated supports and target proteins. Importantly, our modular strategy separates the production of recombinant target proteins from DNA-conjugation procedures. Here, the synthesis of a single set of polymer allows diverse combinations of Z_E-tagged proteins to be immobilized for different applications. Furthermore, the selectivity and stability of the heterodimeric association of the leucine zipper system employed here permits target protein capture and pull down from unpurified cellular lysates and is compatible with a variety of protein expression systems and techniques. In this way, our strategy presents a flexible and versatile alternative to existing DNA-conjugation methods that is advantageous for applications where the ability to conjugate proteins with DNA is limiting, and in circumstances that require minimal postexpression processing of target proteins.

MATERIALS AND METHODS

General. All reagents were purchased from Sigma-Aldrich unless otherwise noted. All oligonucleotides were purchased from IDT DNA. The Alexa647-anti-green fluorescent protein (GFP) was purchased from Molecular Probes. Anti-GST antibodies were purchased from GE Healthcare and labeled in house using a Cy3 mono-reactive dye pack (GE Healthcare) and the resulting dye to antibody ratio (6 to 1) was determined according to the manufacturer's protocols.

All cloning procedures were carried out in the *E. coli* strain XL1-Blue (Stratagene). Expression was performed using BL21 (DE3) strains (Novagen). The sequences of the plasmids produced from each cloning step were verified using restriction mapping and DNA sequence analysis.

Primers sequences used to construct synthetic genes were designed using a web-based software tool (DNAWorks) (*1*). DNA sequences used for conjugation, surface-functionalization, and to form molecular scaffolds based on single DNA duplicies were designed using a program called SEQUIN (*2*). This software was used to minimize sequence repeats in the different strands used for conjugation and spotting, as well as those incorporated into the DNA scaffolds. All oligonucleotides were individually purified using denaturing PAGE protocols.

Plasmid Construction. Genes encoding for each domain of the artificial proteins including the basic portion of the zipper complex (Z_R) and the elastic 'mid-block domain' or ELS fragment (VPGVG VPG**S**G VPGVG VPG**S**G VPGVG) were constructed from synthetic oligonucleotides through PCR. During this process a C-terminal cysteine and a stop codon was introduced into the gene. The resulting fragments were directionally ligated into a pQE60 vector (Qiagen). This gene was then polymerized stepwise into larger Z_R-$(ELS)_2$-C, Z_R-$(ELS)_4$-C and Z_R-$(ELS)_6$-C constructs using the recursive directional ligation (RDL) procedure described in reference (*3*) with slight modifications. At each intermediate cloning step, two gene fragments were isolated from each vector by digestion with *Nco*I and *Bgl*I or *PflM*I and *Hind*III restriction endonucleases. These two fragments were then simultaneously inserted directionally into the *Nco*I and *Hind*III sites of a new pQE60 vector.

The recombinant target proteins containing Z_E fusions GST-Z_E, GFP-Z_E, calmodulin-Z_E (CAM-Z_E), and PSE-4-Z_E were all prepared using standard cloning procedures. Each of these genes contained a C-terminal Z_E and 6xHistidine (6xHis) for purification.

Protein Expression and Purification. To avoid proteolytic degradation of the Z_R fragment of the artificial proteins, and to facilitate Ni^{2+}-NTA purification, Z_R-$(ELS)_6$-C was co-expressed with a Z_E-6xHis gene that was created in pQE60 and then inserted into the *Nhe*I sites of a pREP4 vector (Qiagen). Both vectors contained the inducible, bacteriophage T5 promoter of the pQE plasmid. For expression, cells were grown in terrific broth (TB; 24 g of casein hydrolysate, 12 g of yeast extract, 4 mL glycerol, 17 mM KH_2PO_4, 72 mM K_2HPO_4), and antibiotics (50 mg/L ampicillin and 35 mg/L kanamycin). The cells were cultured at 37 ˚C until an OD_{600} of 1 was reached. Afterwards, expression was induced for 5 hours by adding 1 mM IPTG. Cells were then pelleted (5,000 RPM and 4 ˚C) an resuspended in lysis buffer (8 M urea, 10 mM Tris-HCl, 100 mM NaH_2PO_4, pH 8.0) and allowed to lyse overnight at 4 ˚C with vigorous stirring. The cell lysate was clarified by centrifugation and the supernatant was applied to a column containing Ni^{2+}-NTA resin. After washing with lysis buffer, the artificial protein was eluted using a buffer containing 6 M guanidine-HCl, 100 mM NaH_2PO_4, 10 mM Tris-HCl, pH 8.0. This buffer disassociates the Z_E/Z_R complex, allowing the Z_R-$(ELS)_6$-C to be eluted while the majority of the Z_E-6xHis proteins remain on the column. To remove excess Z_E-6xHis, the eluent was run through a second Ni^{2+}-NTA column. The flow through of this column was dialyzed with frequent water exchanges for 3 days and lyophilized. The protein purity was verified using SDS-PAGE and matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectroscopy. The MALDI-TOF of the polymers gave peaks at 18652 m/z and 9323 m/z corresponding to the M^+ and M^{+2} polymer species, respectively. The Z_E-6xHis polypeptide was not present at detectable levels using either SDS-PAGE or MALDI-TOF analyses.

Cells expressing the target proteins were cultured similarly to those used for artificial protein production. However, expression was induced overnight at 23 ˚C. Purification of the

target proteins were carried out using standard native lysis and Ni^{2+}-NTA purification protocols with the exception of the PSE-4-Z_E. Cells containing these proteins lysed using an osmotic shock procedure that allows the outer membrane of cells to be broken using an osmotic shock buffer (30% sucrose, 1 mM EDTA, 30 mM Tris, pH 8.0). Protein expression and purification was verified using SDS-PAGE analysis while protein concentrations were determined using the Bradford method. For some experiments, clarified lysates were saved, aliquoted, and stored at -80 ˚C for experiments with unpurified proteins.

Artificial Protein-DNA conjugation. Artificial proteins were labeled with DNA as described in reference (*4*) with slight modifications. Briefly, concentrated stock solutions of Z_R-$(ELS)_6$-C (10 mg/mL) were prepared by dissolving the lyophilized polymers in 8 M Urea, 100 mM NaH_2PO_4, 10 mM Tris, pH 7.2. Disulfide bonds between polymers were then reduced by adding 400 mM tris(2-carboxyethyl)phosphine (TCEP) and incubated at 37 ˚C for 1.5 hours. Simultaneously, amine-labeled oligonucleotides, 20 bp in length, were reacted for one hour at 37 ˚C with the heterobifunctional crosslinker, sulfosuccinimidyl 4-[*N*-maleimidomethyl]cyclohexane-1-carboxylate (sulfo-SMCC). Afterwards, the reduced artificial protein and the DNA solutions were passed through two separate NAP-5 desalting columns, combined, and incubated for 2 hours at room temperatures and then overnight at 4 ˚C. The following day, the Z_R-$(ELS)_6$-C-ssDNA conjugates were isolated using a HiTrapQ ion-exchange column and fast protein liquid chromatography (FPLC). The peak fractions containing the conjugate were pooled and dialyzed with frequent water exchanges for 3 days and lyophilized. The polymers were then redissolved in Tris-EDTA (TE) buffer (pH 7.4) at a concentration of approximately 35 μM. The actual conjugate stock concentrations were determined from the OD_{260} using an extinction coefficient

from the appended ssDNA's extinction coefficient (ε_{260} = 185,000 M^{-1} cm^{-1}). Conjugate stock solutions were aliquoted and stored at -20 ˚C until needed.

DNA-Templated Protein Microarray Fabrication. DNA microarrays were fabricated by printing 5'-amine modified oligonucleotides on silyated (amine-aldehyde) functionalized slides (CEL Associates Inc). Oligonucleotide stocks were diluted appropriately with spotting buffer (40% glycerol in PBS, pH 6.6). For the single protein arrays, the arrays were printed in 90, 50, and 10 μM concentrations and a control strand was printed at 90 μM. The multi-protein arrays were all printed at 50 μM. A custom built microarrayer outfitted with SMP3 pins (Telechem Int.) was used for all printing. After printing, the slides were placed in a humid chamber for 45 minutes, and then allowed to dry outside the chamber for 10 minutes. The remaining free aldehyde groups were quenched in a solution of 25% ethanol and 0.25% $NaBH_4$ in PBS for 5 minutes. The slides were then thoroughly rinsed with milli-Q water (Millipore) and blocked using pre-hybridization buffer (20 mM Tris-HCl pH 7.4, 150 mM NaCl, 5 mM EDTA, 1% Tween 20, 0.1 mg/mL denatured herring sperm DNA, 0.1 mg/mL BSA, 3% dry milk) with gentle agitation for 2 hours. The arrays were then washed 3 times for 10 minutes each in wash buffer (20 mM Tris-HCl pH 7.4, 150 mM NaCl, 5 mM EDTA, 0.01% Tween 20), thoroughly rinsed with milli-Q water and dried under a nitrogen stream.

Artificial protein-DNA conjugates were used to direct the assembly of target proteins onto the DNA-spotted microarrays by first pre-incubating the target Z_E-fusion proteins individually with the artificial protein conjugates. A three-fold molar excess of target protein was typically maintained during these incubations. A reaction chamber was prepared by affixing a Gene Frame (AB Gene) to the microarrays. Mixtures of artificial proteins and target proteins

were brought to a final volume of 100 μL with hybridization buffer (20 mM Tris-HCl pH 7.4, 150 mM NaCl, 5 mM EDTA, 0.01% Tween 20, 0.1 mg/mL denatured herring sperm DNA, 0.5% dry milk) and perfused into the reaction chamber. For multi-protein array fabrication, two solutions of polymer-target protein complexes were prepared separately, combined into one solution, and introduced to the reaction chamber. The slides were left at room temperature to incubate overnight. Afterwards, the Gene Frames were removed and the slides were washed three times with wash buffer, rinsed with milli-Q water, and dried under nitrogen stream. New Gene Frames were applied to each array and a solution containing Alexa647-anti-GFP antibodies or both Alexa647-anti-GFP and Cy3-anti-GST antibodies were added at concentrations of 1 μg/mL for two hours. The slides were then washed 3 times for 10 minutes in wash buffer, rinsed briefly with milli-Q water and dried. The slides were immediately imaged on a GenePix 4000B microarray scanner (Molecular Devices) using a gain of 450.

The possibility of zipper exchange was also examined through a time-series study. Here, we prepared two leucine-zipper complexes: (1) a GFP-Z_E protein captured using a DNA-polypeptide conjugate and (2) an unconjugated Z_R-$(ELS)_6$-C polypeptide complexed to a GST-Z_E protein. The two captured proteins were mixed and incubated for periods of 1, 2, 4, or 8 hours before being applied to a printed microarray. Arrays were washed probed and scanned as in the two-channel experiments described above.

Surface-Immobilized β-Lactamase Assays. All reagents used to prepare substrates for these assays were dissolved in TE buffer (pH 7.4). 96-well plates were incubated with biotin-BSA (1 mg/mL) for 10 minutes. The plates were then blocked with casein (1 mg/mL) followed by BSA (1 mg/mL) for 1 minute each, and washed twice with TE buffer. Next, streptavidin (0.5 mg/mL)

was added to each well and incubated for 10 minutes. Afterwards, the streptavidin solutions were aspirated off and the plates were rinsed briefly with the casein solution and then twice with TE buffer. Biotin functionalized DNA was added to the appropriate wells to a final volume of 50 μL and incubated for 30 minutes. Certain wells were designated for controls that either omitted the DNA deposition or contained a non-complementary DNA strand. Excess DNA that did not bind the surface was removed by washing with casein and BSA as before. To immobilize enzymes, PSE-4-Z_E was pre-incubated in 3 fold excess of the Z_R-$(ELS)_6$-C-ssDNA conjugate for 30 minutes. The PSE-4-Z_E and conjugate solution were applied to the appropriate wells. The plate was left to incubate for 2 hours and then protein solutions were aspirated from the wells. After washing 4 times with TE buffer, each well was brought to a final volume of 100 μL by adding TE buffer. Subsequently, nitrocefin was added to each well, bringing the wells to a final volume of 200 μL and a final substrate concentration to 150 μM. The plates were scanned using a Tecan Infinite 200 microplate reader. Absorbance readings at 485 nm were monitored every 50 seconds for 3 hours at 25 ˚C. The steady-state reaction rates of the immobilized β-Lactamase enzymes were determined via linear regression analysis.

Synthesis and Characterization of Multi-Protein Assemblies. The DNA scaffold consisted of a single duplex of DNA (34 bases; 10 nm in length) flanked by unique single-strand 'overhangs' comprised of 20 bases on either end. To create scaffolds, strands were mixed stoichiometrically as estimated by A_{260}, and annealed from 95 ˚C to RT, over 1.5 hrs in TAE/Mg^{2+} buffer (40 mM Tris, 40 mM Acetic Acid, 2 mM EDTA, 12.5 mM Mg^{2+} Acetate, pH 8) for a final concentration of 1.8 μM. Target protein (either CaM-Z_E or GFP-Z_E) and its respective Z_R-$(ELS)_6$-C-ssDNA conjugate were mixed in a 1:1 ratio and incubated at 4 ˚C for at least 1 hr. DNA scaffold was

added in a 1:2 or 1:1 ratio with the protein mixture (depending on whether it was the single or two protein system) and incubated at RT for 1.5 hrs, then 4 ˚C for 30 min. A 7% non-denaturing PAGE gel was run at 200 V at 4 ˚C (SE 600 Ruby, GE Healthcare) in TAE/Mg^{2+} buffer. The DNA/protein complexes were visualized by staining with Stains-All (Sigma).

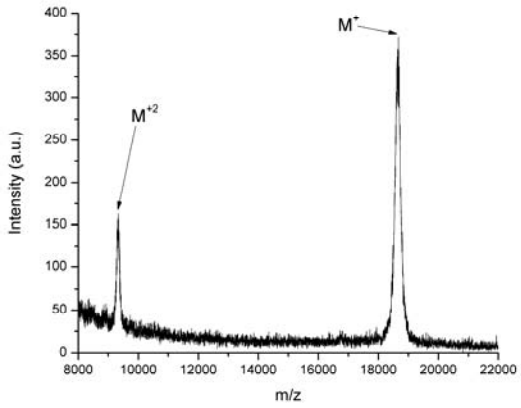

Figure S1. MALDI-TOF spectrum for the Z_R-$(ELS)_6$-C protein. The spectrum shows peaks at 9323 m/z and 18652 m/z, corresponding to the M^{+2} and M^{+} peaks, respectively. The calculated theoretical mass of the full-length polymers is 18793.5 Da, and 18662.3 Da if the N-terminal methionine is cleaved.

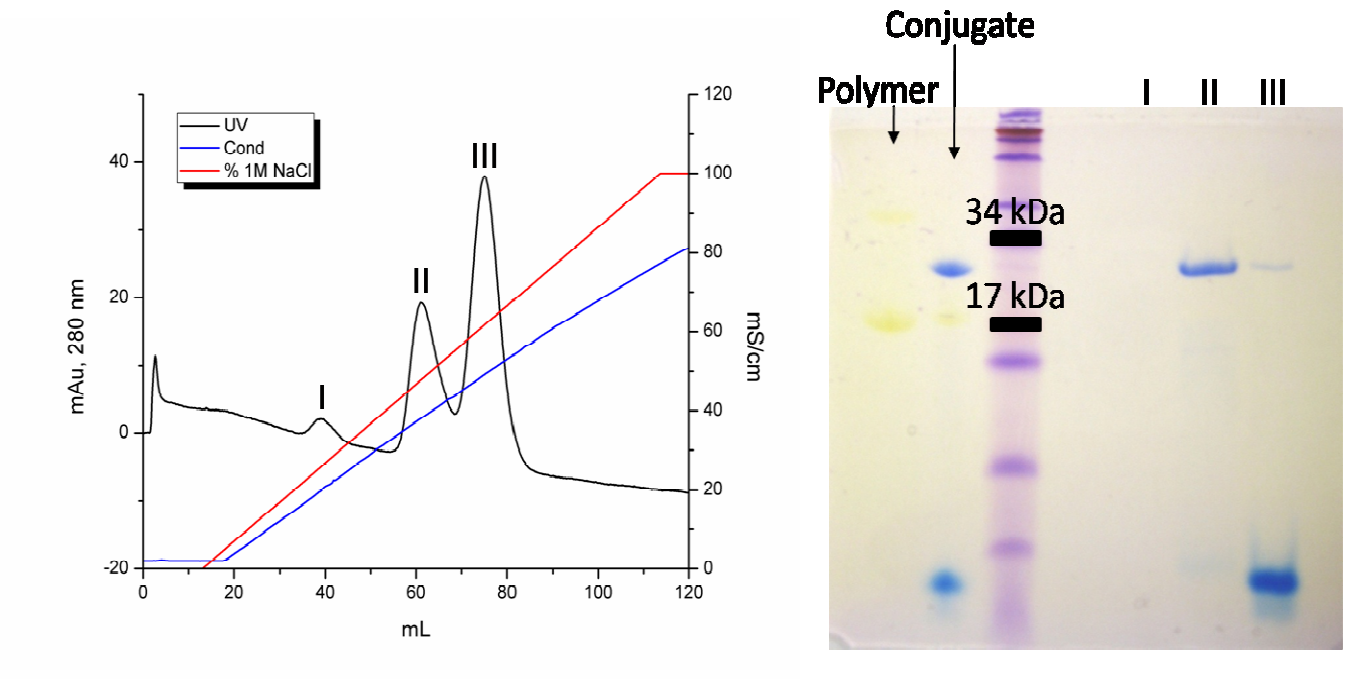

Figure S2. FPLC chromatogram and SDS-PAGE gel for conjugate synthesis and purification, indicating the absorption measured at 280 nm, gradient implemented, and measured conductivity. The chromatogram shows the characteristic 3 peaks from the crosslinking reaction: I. Unconjugated polymer; II. Conjugate; III. Unconjugated DNA. The corresponding gel shows purified polymer, the crosslinking reaction products (Conjugate), and a sample of each of the 3 peaks. The Stains-All stains DNA blue and protein yellow. The shift in the DNA band shows the presence of the conjugate in peak II.

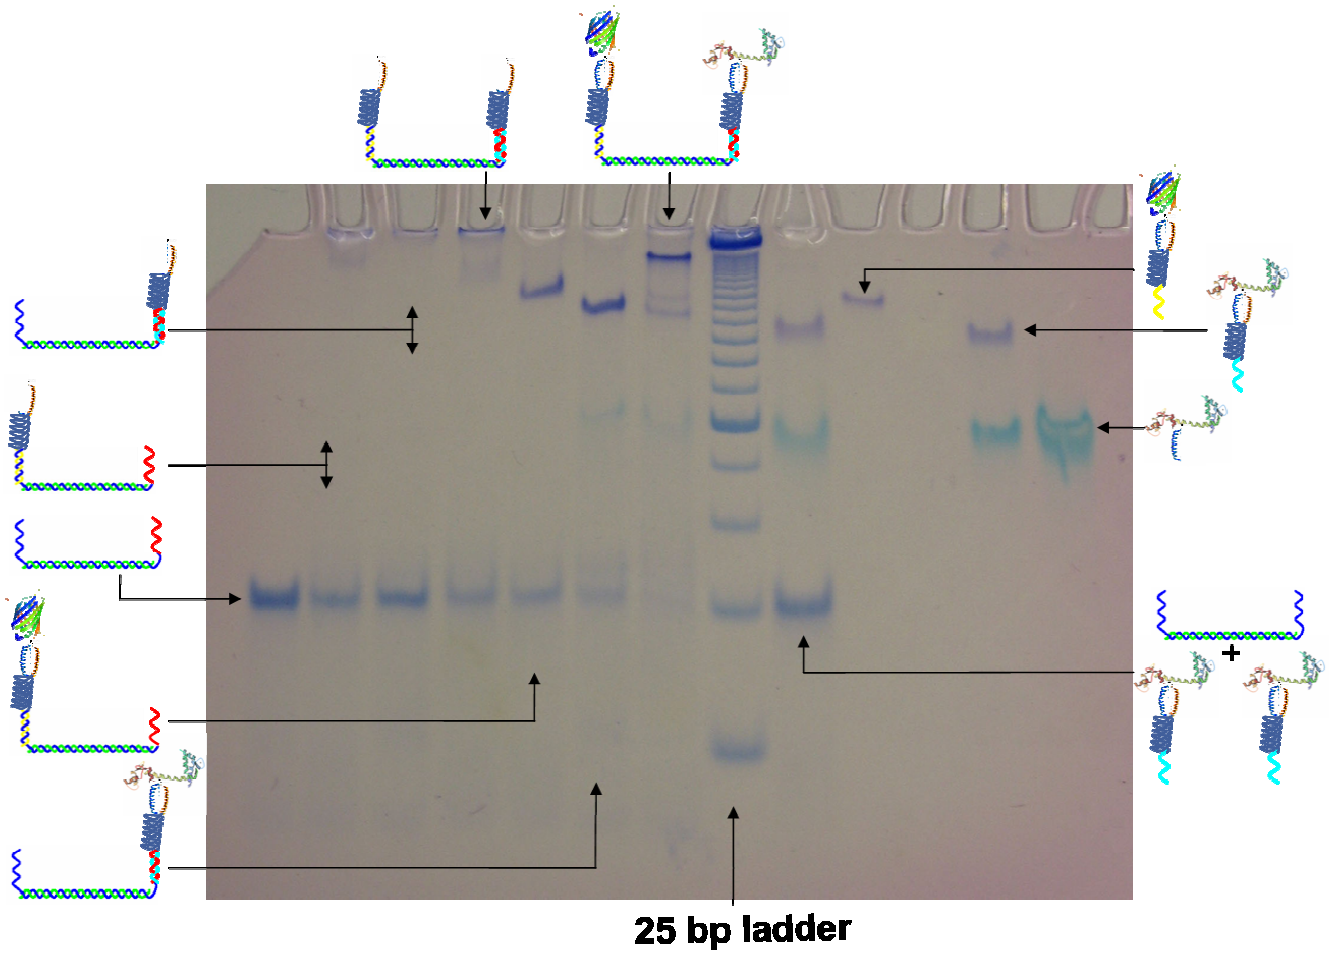

Figure S3. A non-denaturing PAGE gel displaying each of the components of the assembly individually as well as intermediate structures. The corresponding components of each lane are depicted at the periphery of the gel. From this analysis, we are able to adjust the volumes of individual protein stocks to compensate for errors in protein concentration measurements, in order to drive assembly formation more quantitatively.

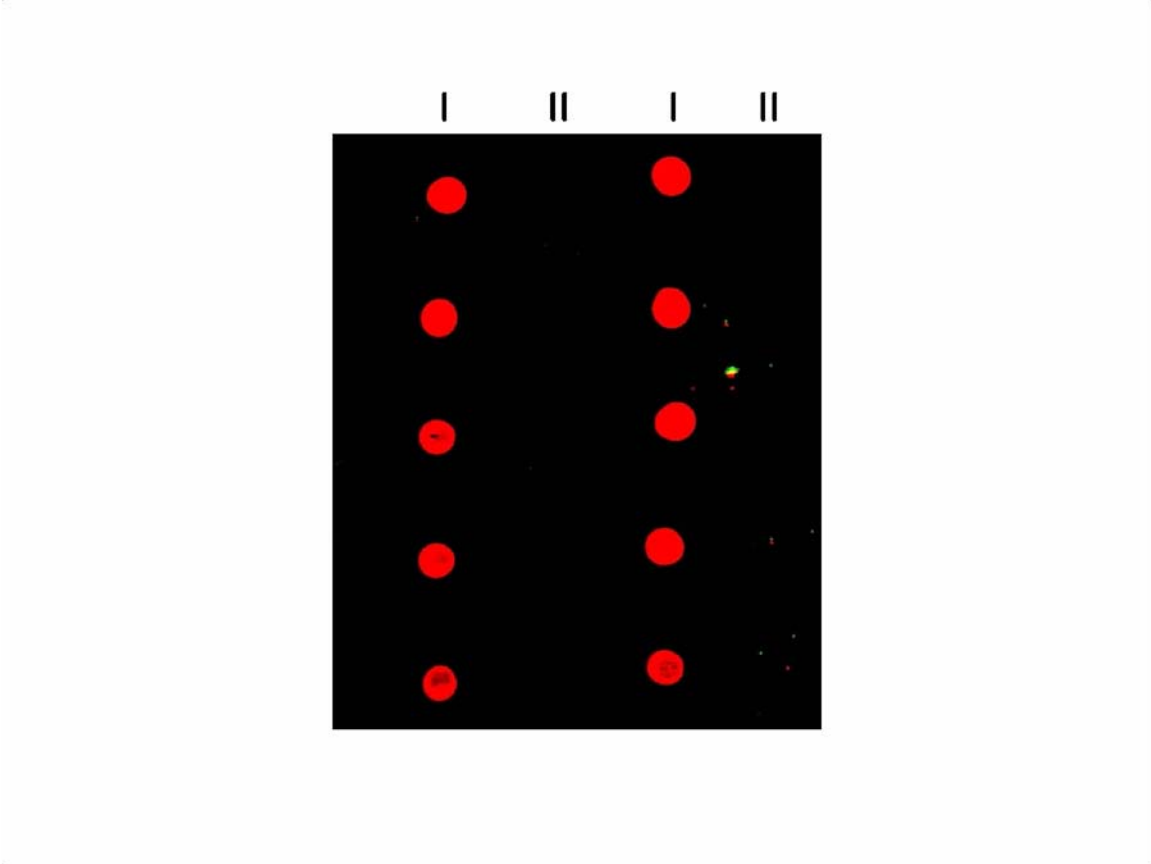

Figure S4. Microarray experiment showing the leucine zippers do not exchange between target proteins. Two protein complexes: (1) a GFP-Z_E protein captured using a DNA-polypeptide conjugate, and (2) a GST-Z_E complexed with an unconjugated Z_R-$(ELS)_6$-C polypeptide were mixed together for periods of 1-8 hours to test exchange. Afterwards, this solution was incubated for 16 hours over DNA-spotted array. Without exchange, the GST-Z_E protein should not immobilize on our arrays, and any exchange should result in the appearance of a GST-positive signal. All of the arrays show selective capture of the GFP-Z_E. We did not observe evidence of exchange in any experiments. The 8 hour time point is shown in the figure. The positive control strand was printed in lane I (the GFP positive lane), while a non-complementary strand is was printed in lane II : The GST signal (green) was lower than background in all spots in the array.

Fluorescently Labeled Risedronate and Related Analogues: "Magic Linker" Synthesis

Boris A. Kashemirov,[†] Joy Lynn F. Bala,[†] Xiaolan Chen,[†] F. H. Ebetino,[‡] Zhidao Xia,[§] R. Graham G. Russell,[§] Fraser P. Coxon,[||] Anke J. Roelofs,[||] Michael J. Rogers,[||] and Charles E. McKenna*[,†]

Received August 29, 2008; Revised Manuscript Received October 31, 2008

We report synthesis of the first fluorescently labeled conjugates of risedronate (**1**), using an epoxide linker strategy enabling conjugation of **1** via its pyridyl nitrogen with the label (carboxyfluorescein). Unlike prior approaches to create fluorescent bisphosphonate probes, the new linking chemistry did not abolish the ability to inhibit protein prenylation in vitro, while significantly retaining hydroxyapatite affinity. The utility of a fluorescent **1** conjugate in visualizing osteoclast resorption in vitro was demonstrated.

Nitrogen-containing bisphosphonates (N-BPs) are therapeutic agents for the treatment of diseases associated with increased bone resorption, such as osteoporosis and Paget's disease (*1, 2*). N-BPs inhibit farnesyl diphosphate synthase (FPPS), preventing the prenylation of small GTPase proteins that are crucial for the function and survival of bone-resorbing osteoclasts (*3*−*6*). Phosphonocarboxylate (PC) analogues of BPs are also able to inhibit bone resorption, but inhibit Rab geranylgeranyl transferase (RGGT), thereby selectively preventing the prenylation of Rab proteins (*7*).

Some N-BPs and PC analogues also demonstrate antitumor effects in vitro and in vivo (*1, 2*). However, it is unknown whether the antitumor effects of these drugs result from direct effects on tumor cells or derive chiefly from inhibition of bone resorption (*1, 2, 8*). Therefore, specific imaging probes to elucidate the skeletal distribution and cellular uptake of these drugs in bone and other tissues are highly desirable.

Fluorescent analogues of bisphosphonates are of increasing interest as biological probes exploiting the high bone affinity of these compounds. Recently, the primary aminoalkyl N-BP alendronate was coupled to Alexa Fluor 488 via the drug's γ-amino functionality; however, the conjugated labeled drug was obtained in only 7% purity (*9*). In a separate study, ε-amino N-BP pamidronate conjugated to IRDye78 or IRDye800CW was observed to bind to hydroxyapatite (HA) (*10, 11*). In all these cases, the imaging dyes were attached via an amide linkage at the terminal amino group of the drug (*9*−*12*), resulting in a large decrease in nitrogen basicity expected to lower greatly the inhibitory potency of the resulting conjugate. Also, this approach is not applicable to heterocyclic N-BPs such as risedronate (RIS, **1**), which lack a primary amine susceptible to facile acylation by activated esters of fluorescent labels. Thus, no successes in fluorescent labeling of any member of this class of drugs have yet been reported (*9*−*13*).

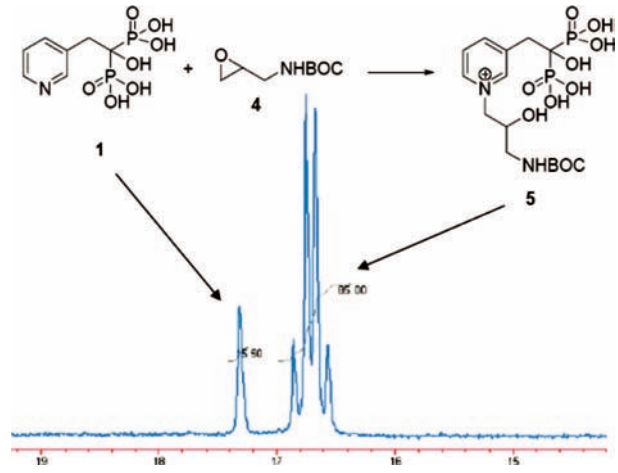

Figure 1. ^{31}P NMR spectrum of reaction mixture of **1** and **4** after 18 h at 40 °C.

We began our work with the concept of designing a universal linker, which, once attached to the drug, would permit conjugation with any fluorophore activated ester while, ideally, not adversely influencing bone affinity and retaining some ability to inhibit protein prenylation. On this basis, the phosphonate/carboxylate moieties (or the α-hydroxyl group) of the drug were considered to be unsuitable sites for attachment of a linker moiety. If a linker group could be connected via the pyridine nitrogen, a positively charged quaternary nitrogen atom would be generated, perhaps simulating a putative carbocation-like transition state analogue in the active site (*6*), thereby offering the possibility that the fluorescent conjugate could retain activity. Finally, this linking chemistry would need to be compatible with an incorporated primary amine group to allow subsequent conjugation of the drug−linker complex to an imaging molecule, and should address the low solubility of the drug in nonaqueous media.

In search of such a "magic" linker, we investigated the reaction of heterocyclic N-BPs with the epoxide **4** to generate N-alkylated analogues of the parent drugs **1**−**3** (Scheme 1). We find that epoxide **4** couples to the pyridine nitrogen of **1**−**3** under

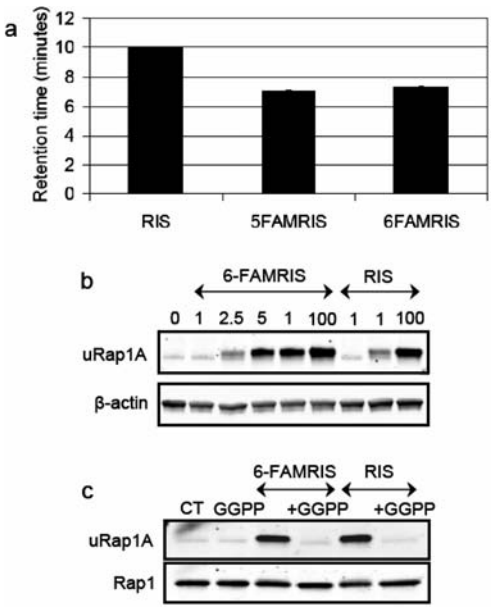

Figure 2. (a) Comparison of RIS (**1**) (**12**) and 6-FAMRIS (**13**) on hydroxyapatite column. (b, c) Western blot assays for unprenylated Rap1A (uRap1A). J774.2 macrophages were treated for 24 h with (b) 0−100 μM **13** or **1**; or (c) vehicle, 20 μM **13**, or 20 μM **1** in the presence or absence of 100 μM GGPP. Detection of β-actin (b) or total Rap1 (c) served as loading control.

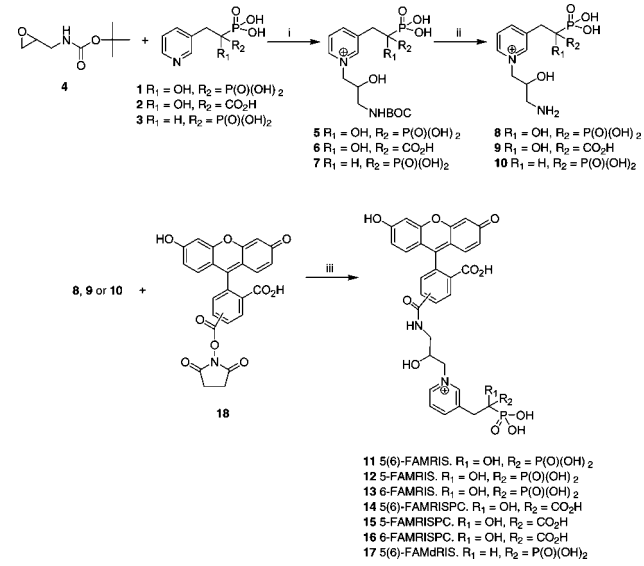
Scheme 1[a]



[a] Reagents: (i) ~5% MeOH/H_2O, 40−50 °C. (ii) 1:1 TFA/H_2O, room temperature; (iii) $NaHCO_3$/DMF, pH 8.3, room temperature, in darkness.

mild (pH nearly neutral, 40−50 °C) aqueous conditions, with high yields and regioselectivity (*14*). This linker affords the key functionalities referred to above: (1) a primary amine (after suitable deprotection) for facile conjugation to activated esters of fluorescent or other labels; (2) a permanent positive charge on the pyridinium nitrogen; and (3) a hydroxyl group (from the epoxide ring-opening) to balance the hydrophobic alkyl chain.

At 40 °C, nearly quantitative yields are achieved, affording intermediates **5**−**7** with less than 1% O-alkylation according to ^{31}P NMR (Figure 1). Aminohydroxypropane esters of 1-hydroxyethylidene-1,1-bisphosphonic acids were previously synthesized in aqueous conditions near neutral pH at 60−70 °C (*15*). Since we aimed to avoid forming ester linkages between the phosphonate group and the linker, the regioselectivity of our reaction was a welcome discovery. This linking strategy may be applicable to N-alkylation of other nitrogen-containing heterocycles (*16*).

Treatment of the N-*t*BOC-protected linker−drug intermediates **5**−**7** with TFA yielded the corresponding free amino forms **8**−**10**, which were then readily coupled to 5(6)-carboxyfluorescein via its succinimidyl ester (5(6)-FAM, SE, **18**). Individual isomers (5- and 6-FAM) of the labeled products may be isolated by semipreparative HPLC, although compounds **12**, **15**, and **16** were also synthesized directly from their respective isomerically pure FAM, SE starting materials. All labeled products were characterized by high-resolution mass, ^{1}H and ^{31}P NMR, UV absorption, and fluorescence emission spectra (see Supporting Information). FAM-labeled compound **11** showed no decomposition by analytical TLC after 1 week at room temperature in phosphate buffer (pH 7.2), demonstrating the stability of the labeled product.

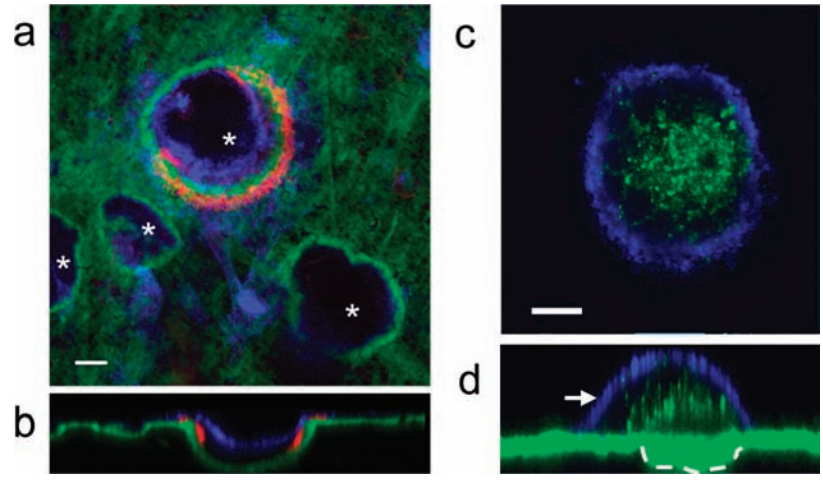


Figure 3. Binding and "recycling" of 5(6)-FAMRIS **11** to the surface of dentine (a, b) and uptake of **11** by rabbit osteoclast in vitro (c, d); bar = 10 μM. Rabbit osteoclasts were seeded onto dentine discs that had been precoated with **11** (green); osteoclasts were immunostained for VNR (blue), and actin rings of osteoclasts were visualized using TRITC-phalloidin (red; a, b only). (a) 1 μm *xy* image at the surface of the dentine; resorption pits identified by asterisks; (b) *zx* image of the same field-of-view. (c) 1 μm *xy* image 8 μm above the surface of the dentine and (d) *zx* image of the same osteoclast. *Z* position of (c) is denoted by arrow in (d). Dashed line in (d) shows the outline of the resorption pit. Note that detector gain in (c, d) was optimized to detect **11** intracellularly resulting in saturated signal from **11** at the dentine surface.

To investigate whether structural differences between **1** and labeled **12** and **13** could interfere with their role as imaging probes, a hydroxyapatite column was utilized as a model for their binding affinity to bone (*17*). The labeled compounds showed only a moderate decrease in retention time ($R_t = 7$ min) compared to **1** ($R_t = 10$ min) (Figure 2a). Probe **13** also inhibits the prenylation of the small GTPase Rap1A (at similar concentrations to RIS) (Figure 2b), an effect that could be reversed by the addition of exogenous GGPP (the isoprenoid required for prenylation of Rap1A; Figure 2c), indicating that the compound retains this activity of the parent N-BP. Fluorescent alendronate (F-ALN), where the primary amino nitrogen was converted to a neutral amide by the dye attachment chemistry, was inactive in this assay (*18*).

11, intensely labeled the surface of dentine, demonstrating its high affinity for a physiological mineralized substrate. Furthermore, following the culture of rabbit osteoclasts for 18 h on dentine discs precoated with **11** prior to seeding of the cells, **11** also labeled the newly exposed surface of resorption pits beneath actively resorbing osteoclasts (Figure 3a,b), indicating that **11** binds to newly exposed mineral surfaces after being released from the dentine surface during resorption (*18*). Other fluorescent bone-labeling agents with low bone affinity, such as calcein and xylenol orange, do not exhibit this recycling to resorption pits (*18*). In these cultures, **11** could also be detected within intracellular vesicles in resorbing osteoclasts (Figure 3c,d), in accordance with our previous studies demonstrating endocytic uptake of F-ALN by both macrophages and resorbing osteoclasts (*9, 18*).

In summary, we report the first synthesis of fluorescently labeled conjugates of drugs **1**−**3**, using a novel linking strategy. Advantages of the approach described include the exceptionally mild reaction conditions used to attach the linker to the drug (aqueous solution, pH near neutral, ∼room temperature), high yields, and regioselectivity. This approach has provided, for the first time, a fluorescent conjugate of an N-BP that inhibits protein prenylation.

ACKNOWLEDGMENT

Funding and compounds **1**−**3** were provided by Procter & Gamble Pharmaceuticals. Mass spectra were obtained by Dr. Ron New at the University of California Riverside. C.E. McKenna has been a consultant for P & G Pharmaceuticals.

SUPPLEMENTARY METHODS

Reagents and Spectral Measurements. 5(6)-, 5-, and 6-carboxyfluorescein, succinimidyl ester (FAM, SE) were purchased from Sigma Aldrich. Compounds **1**, **2**, and **3** were kind gifts from Procter & Gamble Pharmaceuticals. All other compounds were purchased from Aldrich or Alfa Aesar. Triethylamine (TEA) was distilled from KOH; CH_2Cl_2 was distilled from P_2O_5; and allylamine was distilled under N_2. All other compounds were used as supplied by the manufacturer. Thin layer chromatography was performed on Merck Silica Gel 60 F_{254} plates, and the developed plates were visualized under a UV lamp at 354 nm. HPLC separations were performed on a Rainan Dynamax Model SD-200 system with a Rainan Dynamax absorbance detector Model UV-DII. NMR spectra were recorded on either 400 MHz Varian or 500 MHz Bruker spectrometers. UV spectra were recorded on a DU 800 spectrometer, and fluorescence emission spectra were taken on a Jobin Yvon Horiba FluoroMax-3 fluorimeter equipped with a DataMax Software version 2.20 (Jobin Yvon Inc). High resolution mass spectra were performed by Dr. Ron New at UC Riverside High Resolution Mass Spectrometry Facility on a PE Biosystems DE-STR MALDI TOF spectrometer with a WinNT (2000) Data System.

Chemical Synthesis.

Synthesis of tert-butyl (oxiran-2-ylmethyl)carbamate (**4**) from allylamine: Freshly distilled allylamine (2.3 mL, 30 mmol, 1.0 eq) in 10 mL dry CH_2Cl_2 was cooled in an ice bath (0 °C). To this cold solution, 6.54 g di-*tert*-butyl dicarbonate (30.0 mmol, 1.00 eq) in 20 mL dry CH_2Cl_2 was added. The solution was brought to rt and stirred for 4 h. The reaction mixture was then diluted with additional CH_2Cl_2 and washed with 5% citric acid solution, followed by brine. The organic layer was dried over Na_2SO_4 and concentrated in vacuo, yielding 3.3 g (68%) of the *tert*-butyl allylcarbamate. The ^{1}H NMR spectral data matched previously reported values for this compound (*1*).

^{1}H NMR ($CDCl_3$): δ 1.38 (s, 9H), 3.68 (br, 2H), 4.53 (brs, 1H), 5.02-5.16 (m, 2H), 5.72-5.84 (m, 1H).

The *tert*-butyl allylcarbamate (1.0 g, 6.4 mmol, 1.0 eq) was dissolved in 50 mL dry CH_2Cl_2. The solution was cooled to 0 °C and kept cold during addition of 2.8 g of 3-chlorobenzenecarboperoxoic acid ((MCPBA), (commercially available as 77% pure), 12 mmol, 1.9 eq). The solution was then brought to rt and stirred overnight. The reaction mixture was then diluted with additional CH_2Cl_2. The solution was washed with 10% Na_2SO_3, followed by washing with saturated $NaHCO_3$ 3x, and finally by washing with water. The organic layer was dried over Na_2SO_4 and concentrated in vacuo, yielding crude epoxide **4**. According to the ^{1}H NMR spectrum (*1*), the yield was 85%.

^{1}H NMR ($CDCl_3$): δ 1.44 (s, 9H), 2.59-2.78 (m, 2H), 3.04-3.54 (m, 3H), 4.75 (brs, 1H).

General synthesis of N-alkylated drug intermediates 8, 9 and 10. The parent drug is dissolved in water and the pH adjusted to 5.7-6.0 with 1 N NaOH. Epoxide **4** is dissolved in minimal methanol (MeOH) and added to the water solution, causing a slight precipitation to occur. The precipitate disappears on heating (40-50 °C) and as the reaction progresses. The reaction is monitored by ^{31}P NMR or by analytical reverse-phase HPLC. After 90-95% of the desired product is obtained (^{31}P NMR), the solvent is removed in vacuo, and the resulting white powder is washed with diethyl ether, filtered, and dried in a dessicator. Standard deprotection is performed with 1:1 trifluoroacetic acid (TFA): H_2O. After the reaction mixture is stirred for 3-4 h at rt, the solvent is removed in vacuo, and the resulting crystals are washed with diethyl ether and MeOH to yield the drug-linker conjugate for labeling reactions.

Synthesis of 1-(3-amino-2-hydroxypropyl)-3-(2-hydroxy-2,2-diphosphonoethyl)pyridinium (**8**):

The monosodium salt of (1-hydroxy-2-pyridin-3-ylethane-1,1-diyl)bis(phosphonic acid), **1** (287 mg, 0.94 mmol, 1.00 eq), was dissolved in 4 mL water, and the pH adjusted to 6.2 with 1 N NaOH. To this solution, 163 mg of **4** (0.94 mmol, 1.00 eq) in minimal MeOH was added. The reaction mixture was stirred at 40 °C for 18.5 h, yielding 90% of **5** by ^{31}P NMR. The solvent was removed in vacuo, and the residue was washed with diethyl ether, filtered, and dried in a dessicator. **5**, a white solid, was then used without further purification.

^{1}H NMR (D_2O): δ 1.27 (s, 9H), 3.07-3.30 (m, 4H), 3.95-4.03 (m, 1H), 4.18-4.27 (dd**,** *J* = 13.7 Hz, 3.7 Hz, 1H), 4.58-4.65 (part. obscured by HDO, about 1H), 7.75 (t, *J* = 6.8 Hz, 1H), 8.39 (d, *J* = 7.8 Hz, 1H), 8.43 (d, *J* = 6.5 Hz, 1H), 8.65 (s, 1H). ^{31}P{^{1}H} NMR (D_2O): δ 16.33 (d, *J* = 21.1 Hz, 1P), 16.55 (d, *J* = 21.1 Hz, 1P).

The entire sample of **5** was dissolved in 3 mL water. 3 mL TFA was slowly added, and the solution was stirred at rt for 3 h. According to ^{1}H NMR, a 100% yield of **8** was achieved. The solvent was then removed in vacuo, and the resulting solids were washed with ether, filtered, and dried, yielding **8** as white crystals, which were used without further purification.

^{1}H NMR (D_2O): 3.01 (t, *J* = 11 Hz, 1H), 3.31 (d, *J* = 12.6 Hz, 1H), 3.39 (t, *J* = 11.6 Hz, 2H), 4.25-4.33 (m, 1H), 4.36-4.44 (br, 1H), 7.88 (t, *J* = 6.6 Hz, 1H), 8.48 (d, *J* = 8.0 Hz, 1H), 8.58 (d, *J* = 5.5 Hz, 1H), 8.77 (s, 1H). ^{31}P{^{1}H} NMR (D_2O): δ 16.04 (d, *J* = 27.5 Hz, 1P), 16.40 (d, *J* = 27.5 Hz, 1P).

Synthesis of 1-(3-amino-2-hydroxypropyl)-3-(2-carboxy-2-hydroxy-2-phosphonoethyl)pyridinium (**9**):

Compound **2** (0.52 g, 2.10 mmol, 1.00 eq), 2-hydroxy-2-phosphono-3-pyridin-3-ylpropanoic acid, was dissolved in 10 mL water, and the pH adjusted to 5.9 with 1 N NaOH. To this solution, 0.45 g of **4** (2.57 mmol, 1.22 eq) in minimal MeOH was added. The reaction mixture was stirred at 50 °C for 6 h and then stirred at rt overnight, yielding 90% of **6** (^{31}P NMR). The solvent was removed in vacuo, and the residue was washed

with diethyl ether, filtered, and dried in a dessicator, leaving **6** (diastereoisomeric mixture), which was then used without further purification.

^{1}H NMR (D_2O): δ 1.27 (s, 9H), 3.00-3.23 (m, 3H), 3.45 (dd, *J* = 14.2 Hz, 3.6 Hz, 1H), 3.91-4.00 (m,1H), 4.19-4.27 (m, 1H), 4.58-4.64 (br, 1H), 7.78 (dd, *J* = 8.3 Hz, 6.2 Hz, 1H), 8.24-8.29 (m, 2H), 8.47 (d, *J* = 6.0 Hz, 1H), 8.49-8.53 (brd, 1H). ^{31}P{^{1}H} NMR (D_2O): δ 14.96 (s, 1P), 14.98 (s, 1P).

The entire sample of **6** was dissolved in 50:50 water:TFA (v/v). After stirring at rt for 4 h, a 100% yield of **9** was obtained (^{1}H NMR). The solvent was then removed in vacuo, and the residue was washed with diethyl ether, filtered, and dried, yielding **9** (a diastereoisomeric mixture) as white crystals, used without further purification.

^{1}H NMR (D_2O): δ 2.90 (m, 1H), 3.18-3.28 (m, 2H), 3.50 (m, 1H), 4.14-4.22 (m, 1H), 4.31-4.40 (m, 1H), 4.71-4.74 (m, 1H), 7.87 (dd, *J* = 8.3 Hz, 6.1 Hz, 1H), 8.34-8.39 (brd, 1H), 8.56-8.68 (m, 2H). ^{31}P{^{1}H} NMR (D_2O): δ 12.53 (s, 1P), 12.62 (s, 1P).

Synthesis of 1-(3-amino-2-hydroxypropyl)-3-(2,2-diphosphonoethyl)pyridinium (**10**):

Compound **3** (38.0 mg, 0.14 mmol, 1.00 eq), (2-pyridin-3-ylethane-1,1-diyl)bis(phosphonic acid), was dissolved in 1 mL water and the pH brought to 5.4 with 1 N NaOH. To this solution was added 25.5 mg of **4** (0.15 mmol, 1.07 eq) in minimal MeOH. The reaction mixture was stirred at 40 °C overnight, and the reaction was monitored by ^{31}P NMR. After 19 h, 20% of starting material **3** remained. Thus, an additional 5.30 mg (0.03 mmol, 0.21 eq) of **4** in MeOH was added to the reaction mixture. After 42 h, 90% of the desired product was obtained. The solvent was removed

in vacuo, and the resulting white powder was washed with diethyl ether, filtered, and dried, giving **7**, which was used without further purification.

^{1}H NMR (D_2O): δ 1.26 (s, 9H), 2.12 (tt, *J* = 21.2 Hz, 7.1 Hz, 1H), 3.09-3.24 (m, 4H), 3.94-4.00 (m, 1H), 4.22 (dd, *J* = 13.7 Hz, 9.6 Hz, 1H), 4.57-4.64 (m. 1H), 7.84 (dd, *J* = 8.6 Hz, 6.1 Hz, 1H), 8.40 (d, *J* = 8.1 Hz, 1H), 8.50 (d, *J* = 6.1 Hz, 1H), 8.69 (s, 1H). ^{31}P{^{1}H} NMR (D_2O): δ 17.20-17.28 (m, 2P).

The entire sample of **7** was dissolved in water. An equal volume of TFA was slowly added, and the solution was stirred at rt for 3 h, giving a 100% yield of **10** (^{1}H NMR). The solvent was removed in vacuo, and the residue was washed with diethyl ether and methanol, filtered, and dried, yielding **10** as white crystals, which was then used without further purification.

^{1}H NMR (D_2O): δ 2.18-2.36 (brt, 1H), 2.92 (brt, 1H), 3.14-3.28 (m, 3H), 4.16-4.24 (m, 1H), 4.60 (dd, *J* = 13.5 Hz, 9.5 Hz, 1H), 7.79 (dd, *J* = 8.7 Hz, 6.1 Hz, 1H), 8.37 (d, *J* = 8.2 Hz, 1H), 8.44 (d, *J* = 6.1 Hz, 1H), 8.64 (s, 1H). ^{31}P{^{1}H} NMR (D_2O): δ 17.2-18.0 (br, 2P).

General synthesis of FAM-labeled compounds 11-17. 8, 9, or **10** (3 eq) is dissolved in 0.1 N $NaHCO_3$. The pH is adjusted to 8.3 with solid Na_2CO_3. 5(6)-Carboxyfluorescein, *N*-hydroxysuccinimide ester (a mixture of 5-{[(2,5-dioxopyrrolidin-1-yl)oxy]carbonyl}-2-(6-hydroxy-3-oxo-3*H*-xanthen-9-yl)benzoic acid and 4-{[(2,5-dioxopyrrolidin-1-

yl)oxy]carbonyl}-2-(6-hydroxy-3-oxo-3*H*-xanthen-9-yl)benzoic acid*, 5(6)-FAM, SE, **18,** 1 eq), is dissolved in anhydrous DMF (~50 mg per 200 µL) and combined with the water solution, forming a dark red-orange solution with a small amount of precipitate. The pH is again adjusted to 8.9 with Na_2CO_3, dissolving all the precipitate, and the reaction mixture is stirred at rt overnight. The reaction mixture is purified by TLC with 100% MeOH as the eluant. The FAM label moves quickly with the solvent, giving a yellow upper band, while the phosphonate-containing compounds remain at the origin, and are extracted with water. The combined aqueous extracts are treated with Chelex (sodium form) to remove metals extracted from the silica, centrifuged, and concentrated in vacuo to yield a dark red-orange solid, which is dissolved in either water, 20% MeOH in 0.1 N triethylammonium acetate (TEAAc), or triethylammonium carbonate (TEAC) buffer (pH 7) and filtered through Nanosep 30K Omega filter. The product is purified by semi-preparative reverse-phase HPLC: Dynamax C18 (21.4 mm x 25 cm, 5 µm, 100 Å pore size) column, flow rate 8.0 mL/min, UV detection at 260 nm, gradient as follows: (Method A, used for **11**-**13**) 10% MeOH 0.1 N TEAAc or TEAC (pH 7) to 40% of 75% MeOH 0.1 N TEAAc or TEAC (pH 7) in 12 min, increasing to 70% of Buffer B in 100 min or (Method B, used for **14**-**17**) isocratic elution with 20% MeOH 0.1 N TEAC (pH 7) for 12 min, linearly increasing to 100% of 70% MeOH 0.1 N TEAC (pH 7) in 22 min (Supplementary Figures 2-3). The final amount of labeled product is calculated from the

* Systematic names obtained from IUPAC Nomenclature of Organic Chemistry generated by ACD/IUPAC Name Web Service™ (http://ilab.acdlabs.com/); note that numbering differs from trivial fluorescein numbering scheme.

UV absorption spectrum taking $\varepsilon = 73000\ M^{-1}cm^{-1}$ in 0.1 N phosphate buffer at pH 7.2(*2*, *3*), and the isolated eluate is lyophilized, yielding a red-orange solid.

Synthesis of 5(6)-FAMRIS (5-FAMRIS: 1-(3-{[3-carboxy-4-(6-hydroxy-3-oxo-3*H*-xanthen-9-yl)benzoyl]amino}-2-hydroxypropyl)-3-(2-hydroxy-2,2-diphosphonoethyl)pyridinium; 6-FAMRIS: 1-(3-{[4-carboxy-3-(6-hydroxy-3-oxo-3*H*-xanthen-9-yl)benzoyl]amino}-2-hydroxypropyl)-3-(2-hydroxy-2,2-diphosphonoethyl)pyridinium (**11**):

The following synthesis and purification steps were performed under minimal lighting. Intermediate **6** (177 mg, 0.36 mmol, 4.50 eq) was dissolved in 2 mL of 0.1 N $NaHCO_3$. The pH of the solution was adjusted to 8.3 with Na_2CO_3. To this solution was added 41.0 mg of **18** (0.08 mmol, 1.00 eq) in 200 μL anhydrous DMF, forming a dark red-orange solution with a small amount of precipitate. The pH was again adjusted to 8.1 with Na_2CO_3, causing the precipitate to dissolve. The reaction mixture was then stirred at rt for 3 h.

The reaction mixture was applied to TLC plates which were eluted with 100% MeOH. The dark orange band remaining at the origin was extracted with HPLC water, and the solution was treated with Chelex (sodium form) to remove metals extracted from the silica, then centrifuged and concentrated in vacuo to yield a dark red-orange solid, which was dissolved in HPLC water and filtered through Nanosep 30K Omega filters. The product was then purified by HPLC according to Method A with TEAAc buffers (Supplementary Figure 2). Peaks eluting from 25-75 min were collected. During evaporation of the buffer solution, product precipitated from the solution. Consequently,

a second HPLC purification was performed according to Method A but eluting with TEAC buffers (pH 7.5) (Supplementary Figure 2). This maintained basic conditions when the buffer was removed in vacuo. The final amount of labeled product was calculated from the UV absorption spectrum, and the solution was lyophilized to yield a bright reddish-orange solid (26 mg, 42%).

5(6)-FAMRIS, **11** (as a triethylammonium carbonate salt): ^{1}H NMR (D_2O): δ 3.33-3.39 (m, 2H), 3.43-3.66 (m, 2H), 4.08-4.42 (m, 3H), 4.72-4.80 (brd, 1H), 6.36-6.48 (m, 4H), 6.93 (d, 2H), 7.09 (s, 1H), 7.43 (s, 0.4 H), 7.68-7.87 (m, 2H), 8.06 (s, 0.6 H), 8.37-8.56 (m, 2H), 8.69-8.78 (2 s, 1H). ^{31}P{^{1}H} NMR (D_2O): δ 16.26 (d, J = 23 Hz, 1P), 16.50 (d, J = 23 Hz, 2P).

Synthesis and HPLC Separation of 5- and 6-FAMRIS (**12** and **13**): Intermediate **8** (149 mg, 0.30 mmol, 1.4 eq) was dissolved in 1 mL H_2O and 1.5 mL 0.1 N $NaHCO_3$. The pH was adjusted to 8.4 with additional Na_2CO_3. To this solution was added 100 mg of **18** (0.21 mmol, 1 eq) in ~700 μL anhydrous DMF in darkness. After the addition of the label, the pH was again adjusted to 8.4 to increase solubility of the label. The reaction mixture was stirred at rt in darkness for 3 h.

The solvent was then removed in vacuo, yielding a bright reddish-orange solid. The unpurified product was redissolved in water and purified by size exclusion chromatography (Sephadex G10 column eluted with 50 mM TEAAc). The bright orange compound can easily be seen traveling through the column. The first ~20 mL of compound eluted were analyzed by TLC (eluent, 100% MeOH) and showed no traces of

free 5(6)-FAM.

The solvent of this fraction was then removed in vacuo and redissolved in a 10% MeOH 0.1 N TEAAc buffer (pH 7). The product compounds were then purified by semi-preparative reverse-phase HPLC according to Method A (Supplementary Figure 2). 6-FAMRIS and 5-FAMRIS eluted at very different retention times, 27 and 44 min, respectively; each isomer was collected separately. Each fraction collected was analyzed by TLC (eluant, 100% MeOH) to ensure no traces of 5(6)-FAM was present. Each isomer was then concentrated in vacuo to remove buffer.

Compound **12** was also directly synthesized from 5-FAM, SE according to the method described above. The ^{1}H and ^{31}P NMR spectra and HPLC retention time corresponded to the peak eluting at 44 min, thus confirming our isomer assignments given to compounds **12** and **13** that were separated by HPLC (Supporting Figs. 3, 6-9). A slight difference can be seen, however, in the ^{1}H NMR spectra. Compound **12** synthesized from 5(6)-FAM, SE contains a minor singlet at δ 7.56, indicating a trace of the 6-isomer, which is absent from the product directly synthesized from the pure 5-isomer starting material. Detailed NMR descriptions given below correspond to the HPLC-separated products.

Compound **12** samples obtained from 5(6)-FAM, SE and from 5-FAM, SE were combined; the final amount was calculated from the UV absorption spectrum as described above, and the product obtained after lyophilization as a bright reddish-orange solid (11.9 mg, 8%).

The final amount of compound **13** was calculated from the UV absorption spectrum

as described above, and the product obtained after lyophilization as a bright reddish-orange solid (5.5 mg, 4%).

5-FAMRIS, **12** (retention time 44 min, as a triethylammonium acetate salt): ^{1}H NMR (D_2O): δ 3.37 (brt, 2H), 3.57 (dd, *J* = 14.1 Hz, 6.7 Hz, 1H), 3.61-3.69 (m, 1H), 4.22-4.31 (m, 1H), 4.36-4.45 (m, 1H), 4.79 (d, 1H), 6.61-6.71 (m, 4H), 7.11 (d, *J* = 9.2 Hz, 2H), 7.33 (d, *J* = 8.0 Hz, 1H), 7.56 (s, 0.14H), 7.83 (t, *J* = 7.2 Hz, 1H), 7.91 (d, *J* = 8.1 Hz, 1H), 8.15 (s, 1H), 8.44 (d, *J* = 8.3 Hz, 1H), 8.56 (d, *J* = 5.9 Hz, 1H), 8.74 (s, 1H). ^{31}P{^{1}H} NMR (D_2O): δ 16.47 (brs).

HRMS (positive ion MALDI, M^+): calcd 715.1089 m/z; found 715.1055 m/z; MS (negative ion MALDI, M^-): found 713.

6-FAMRIS, **13** (retention time of 27 min, as a triethylammonium acetate salt): ^{1}H NMR (D_2O): δ 3.27-3.37 (m, 2H), 3.44 (dd, *J* = 14 Hz, 6.9 Hz,1H), 3.58 (dd, *J* = 14 Hz, 4.9 Hz, 1H), 4.19 (brs, 1H), 4.35 (dd, *J* = 14 Hz, *J* = 9.3 Hz, 1H), 6.60-6.73 (m, 4H), 7.04 (d, *J* = 9.4 Hz, 2H), 7.53 (s, 1H), 7.81 (dd, *J* = 8.2 Hz, 6.4 Hz, 1H), 7.88 (d, *J* = 8.1 Hz, 1H), 7.95 (dd, *J* = 8.0 Hz, 1.6 Hz, 1H), 8.43 (d, *J* = 8.1 Hz, 1H), 8.53 (d, *J* = 6.5 Hz, 1H), 8.70 (s, 1H). ^{31}P{^{1}H} NMR (D_2O): δ 16.51 (brs).

HRMS (positive ion MALDI, M^+): calcd 715.1089 m/z; found 715.1082 m/z.

Synthesis of 5(6)-FAMRISPC (5-FAMRISPC: 1-(3-{[3-carboxy-4-(6-hydroxy-3-oxo-3*H*-xanthen-9-yl)benzoyl]amino}-2-hydroxypropyl)-3-(2-carboxy-2-hydroxy-2-phosphonoethyl)pyridinium; 6-FAMRISPC: 1-(3-{[4-carboxy-3-(6-hydroxy-3-oxo-3*H*-xanthen-9-yl)benzoyl]amino}-2-hydroxypropyl)-3-(2-carboxy-2-hydroxy-2-

phosphonoethyl)pyridinium (**14**): The following synthesis and purification steps were performed under minimal lighting. Intermediate **9** (158 mg, 0.36 mmol, 3.60 eq) was dissolved in 1 mL of water. The pH of the solution was adjusted to 8.3 with Na_2CO_3. To this solution was added 53 mg of **18** (0.1 mmol, 1.0 eq) in 200 μL anhydrous DMF, forming a dark red-orange solution with small amount of precipitate. The pH was again adjusted to 8.1 with Na_2CO_3, causing the precipitate to dissolve, and the reaction mixture was stirred at rt overnight.

The reaction mixture was directly placed on TLC plates with 100% MeOH as eluant. Free label moves quickly with the solvent, resulting in a yellow upper band, while phosphonate-containing compounds remain at the origin. The band with $R_f = 0$ was extracted from the silica with HPLC water. The solution was treated with Chelex (sodium form) to remove metals extracted from the silica, then centrifuged and concentrated in vacuo to yield a dark red-orange solid, which was dissolved in HPLC water and filtered through Nanosep 30K Omega filters. The solution was then purified by HPLC according to Method B. Peaks eluting at 25-40 min were collected together as **14**. The final amount was calculated from the UV absorption spectrum, and the product obtained after lyophilization as a bright reddish-orange solid (9.6 mg, 13%).

5(6)-FAMRISPC **14** (as a triethylammonium carbonate salt): ^{1}H NMR (D_2O): δ 3.27-3.62 (m, 3H), 4.03-4.40 (m, 2H), 6.42 (m, 4H), 6.92 (dd, *J* = 9.5 Hz, 3.5 Hz, 2H), 7.10 (d, *J* = 8.1 Hz, 1H), 7.42 (s, 0.4H), 7.70-7.86 (m, 2H), 8.06 (s, 0.6H), 8.27 (brs, 1H), 8.46-8.63 (m, 2H). $^{31}P\{^1H\}$ NMR (D_2O): δ 15.28 (brs, 1P).

HRMS (positive ion MALDI, M^+): calcd 679.1335 m/z; found 679.1321 m/z.

Single isomers of FAMRISPC were synthesized directly from isomerically pure starting materials (5-FAM, SE or 6-FAM, SE) according to the method above used for isomeric mixtures.

5-FAMRISPC, **15** (retention time 28 min, as a triethylammonium carbonate salt, 2 mg, 29%): ^{1}H NMR (D_2O): δ 3.39-3.52 (m, 2H), 3.55-3.63 (m, 1H), 4.14-4.23 (m, 1H), 4.30-4.40 (m, 1H), 6.43-6.60 (m, 4H), 7.04 (d, *J* = 9.0 Hz, 2H), 7.25 (d, *J* = 8.2 Hz, 1H), 7.77-7.86 (m, 2H), 8.08 (s, 1H), 8.23-8.33 (brs, 1H), 8.45-8.62 (m, 2H).

HRMS (positive ion MALDI, M^+): calcd 679.1324 m/z; found 679.1356 m/z.

6-FAMRISPC, **16** (retention time 25 min, as triethylammonium carbonate salt. 2.5 mg, 36%): ^{1}H NMR (D_2O): δ 3.31-3.45 (m, 2H), 3.47-3.55 (m, 1H), 4.05-4.15 (m, 1H), 4.24-4.34 (m, 1H), 6.45-6.59 (m, 4H), 7.00 (d, *J* = 9.0 Hz, 2H), 7.48 (s, 1H), 7.71-7.80 (m, 2H), 7.85 (dd, *J* = 8.1 Hz, *J* = 1.7 Hz, 1H), 8.21-8.27 (m, 1H), 8.47-8.55 (m, 2H).

HRMS (positive ion MALDI, M^+): calcd 679.1324 m/z; found 679.1321 m/z.

Synthesis of 5(6)-FAMdRIS (5-FAMdRIS: 1-(3-{[3-carboxy-4-(6-hydroxy-3-oxo-3*H*-xanthen-9-yl)benzoyl]amino}-2-hydroxypropyl)-3-(2,2-diphosphonoethyl)pyridinium; 6-FAMdRIS: 1-(3-{[4-carboxy-3-(6-hydroxy-3-oxo-3*H*-xanthen-9-yl)benzoyl]amino}-2-hydroxypropyl)-3-(2,2-diphosphonoethyl)pyridinium (**17**):

Intermediate **10** (53 mg, 0.1 mmol, 2.5 eq) was dissolved in 0.5 mL HPLC water and 0.5 mL of 0.1 N $NaHCO_3$. The pH was adjusted to 8.3 with Na_2CO_3. To this solution was added 18.0 mg of **18** (0.04 mmol, 1.00 eq) in 100 μL anhydrous DMF, forming a dark red-orange solution with a small amount of precipitate. The pH was again adjusted to 8.9

with Na_2CO_3, causing the precipitate to dissolve, and the reaction mixture was stirred at rt overnight.

The reaction mixture was purified by TLC with 100% MeOH as the eluant. The dark orange band at the origin was extracted from silica with water. The solution was treated with Chelex (sodium form) to remove metals extracted from the silica, then centrifuged and concentrated in vacuo to yield a dark red-orange solid, which were dissolved in 20% MeOH in 0.1 N TEAAc buffer (pH 7) and filtered through Nanosep 30K Omega filters. The solution was then purified by HPLC according to Method B. Peaks eluting from 27-45 min were collected as **17**. The final amount was calculated from the UV absorption spectrum, and the product obtained lyophilization as a bright reddish-orange solid (9.4 mg, 36%).

5(6)-FAMdRIS **17** (as triethylammonium acetate salt): ^{1}H NMR (D_2O): δ 2.07-2.27 (m, 1H), 3.10-3.27 (m, 2H), 3.35 (dd, *J* = 14.2 Hz, 6.8 Hz, 0.4H), 3.44-3.53 (m, 1H), 3.60 (dd, *J* = 14.2 Hz, 4.7 Hz, 0.6H), 4.08-4.16 (m, 0.4H), 4.18-4.25 (m, 0.6H), 4.25-4.40 (m, 1H), 4.71-4.77 (m, 1H), 6.40-6.52 (m, 4H), 6.96 (dd, *J* = 8.1 Hz, 4.1 Hz, 2H), 7.17 (d, *J* = 8.1 Hz, 0.6H), 7.44 (s, 0.4H), 7.72 (d, *J* = 8.1 Hz, 0.4H), 7.76-7.86 (m, 2H), 8.07 (d, *J* = 1.7 Hz, 0.6 H), 8.38 (t, *J* = 8.7 Hz, 1H), 8.47 (d, *J* = 5.9 Hz, 1H), 8.53 (d, *J* = 6.1 Hz, 1H), 8.67-8.71 (2 s, 1H). ^{31}P{^{1}H} NMR (D_2O): δ 16.51 (brs).

HRMS (positive ion MALDI, M^+): calcd 699.1139 m/z; found 699.1137 m/z.

UV absorption and fluorescence emission spectra. All samples were dissolved in water and diluted with 0.1 N phosphate buffer, pH 7.2. The final concentration is calculated

from the UV absorption spectrum at λ = 493 nm (ε = 73000 $M^{-1}cm^{-1}$ at pH 7.2) (*2*, *3*), assuming the labeled products have the same ε as 5(6)-FAM. Emission spectra were recorded using an excitation wavelength of 490 nm; the excitation and emission slits were set at a 1 nm spectral bandwidth. Integration time and increment were set to 0.5 s and 1 nm, respectively.

HA binding affinity. Column chromatography with hydroxyapatite ceramic spheres (20 μm, BioRad) was utilized to study the structural determinants of binding affinity (*4*). BPs were eluted by Fast Performance Liquid Chromatography (FPLC) in phosphate buffered (pH 7.0) solution with a gradient between 1 mM and 1 M over 50 min at a flow rate of 2 mLs/min and detected by UV absorbance.

Inhibition of protein prenylation. J774.2 macrophages were treated with 0-100 μM **13**, **1**, or vehicle and 20 μM **13** or 20 μM **1** in the presence or absence of 100 μM GGPP. Cells were lysed, and unprenylated Rap1A was detected by sodium dodecyl sulphate-polyacrylamide gel electrophoresis and immunoblotting using an antibody that preferentially binds to the unprenylated form of Rap1A *(5)*. Detection of β–actin or total Rap1 served as loading control.

Rabbit osteoclast cultures on dentine discs labeled with 5(6)-FAMRIS (11). Dentine discs in 96-well plates were pre-incubated with 100 μM **11** for 1 h, then washed 3 times in PBS prior to seeding with rabbit osteoclasts, isolated as described previously (*5*). After

24 h, cells were fixed using 4% paraformaldehyde and osteoclast membranes were stained using an antibody to the vitronectin receptor. F-actin was also visualized by counterstaining with 0.5 μg/ml of TRITC-phalloidin in PBS for 30 min (*5*). Samples were then analyzed by laser scanning confocal microscopy using a Zeiss LSM510 META system.

Received February 22, 2008; Revised Manuscript Received September 18, 2008

In this study, we investigated whether a cyclodextrin polymer (polyβCD) complexed with cationic adamantyl derivatives (Ada) could be used as a vector for gene delivery. DNA compaction as a function of adamantyl/DNA phosphate ratio (A/P) by this new class of vector was demonstrated using surface enhanced Raman spectroscopy, ζ potential measurements, and DNA retardation assays. Transfection data highlight the relationship between *in vitro* gene delivery efficiency and the combination of several physical properties of the polyβCD/Ada/DNA polyplexes, including cationic polar headgroup valency and chemical structure of the spacer arm of Ada connectors, the adamantyl/DNA phosphate ratio (A/P) of the polyβCD/Ada/DNA polyplexes, and the ionic strength of the medium. Finally, when associating the best formulation with a fusogenic peptide, we reached transfection levels which were of the same order as those obtained with DOTAP.

1. INTRODUCTION

The delivery of DNA and other nucleic acid-based drugs such as siRNAs has a great potential in a wide variety of applications, including basic research and therapies for genetic and acquired diseases. However, the success of gene and siRNA therapies is largely dependent on the development of efficient delivery systems. One approach exploits the properties and tropisms of viruses. This is currently the most widely studied system, including in clinical trials (67% of the trials were done with viral vectors; for more details refer to the Web site http://www.wiley.co.uk/genetherapy/clinical/). All other approaches, collectively termed "nonviral gene delivery systems" try to mimick the efficiency of viral vectors by artificial means (*1*). The most studied nonviral approach consists of using structurally well-defined synthetic compounds, among which a majority is cationic, such as polymers (*2*−*4*), lipids (*5*−*7*), and peptides (*8*−*10*). These molecules share several functions that are essential for transfection: besides condensing the DNA, they usually form positively charged particles which efficiently enter the cell after binding to negatively charged proteoglycans on the outer face of the membrane (*11*). Depending on the carrier, these cationic vectors can also facilitate the escape into the cytosol of the DNA complexes from the lumen of intracellular endolysosomal compartments.

Despite the development of many compounds and a better understanding of the mechanism of transfection, the challenge of producing a nonviral vector with low toxicity and high transfection efficiency still remains. Indeed, polyethylenimines and cationic lipids, which are the most used cationic transfection agents, were shown to have measurable cytotoxicity *in vitro* and *in vivo* (*12*−*14*). Only a few attempts have been made to correlate the influence of the physicochemical properties of DNA complexes on transfection efficiency. The first studies were done with cationic lipid−DNA complexes (*15*−*18*). Structures of DNA complexes based on cationic polymers have also been studied (*19*−*21*), but without correlating the physicochemical characteristics of the DNA complexes with their capacity to deliver DNA (*22*, *23*). In this context, our work aims at both developing a versatile delivery system on the one hand and identifying the physicochemical properties required for an efficient gene transfer on the other hand.

We are developing an innovative system resulting from the association between a cyclodextrin polymer (polyβCD) which has found interest in the field of gene therapy (*24*−*26*) and amphiphilic cationic connectors (Figure 1A). This association is obtained through the formation of inclusion complexes. Cyclodextrins (CD) are cyclic water-soluble molecules of 6 (αCD), 7 (βCD), or 8 (γCD) α-D-glucose units with a cone-shaped architecture describing a cavity with an apolar interior which can induce an inclusion complex with a hydrophobic moiety (*27*, *28*). The hydrophobic group of the amphiphilic cationic connector forms an inclusion complex with the CD cavity of the polyβCD, and this results in a "polycation". The ternary complex, which is being called a "polyplex", is achieved via cooperative electrostatic interactions between the cationic charge of the connector and the negatively charged phosphate groups of DNA. This system should present several advantages: (i) the charge density of the vector is easily controlled by a simple addition of a connector to the vector (polyβCD/connector), (ii) it has been shown that CD can lower the cell

toxicity in transfection experiments (*29*) and increase transfection efficiency (*30, 31*), (iii) this vector can also be used for cell targeting using adamantane derivatives coupled to a specific compound recognized by cell receptors (*32*−*34*), and (iv) the polyplex characteristics and thus the transfection properties can be modified by changing the connectors.

In the present study, we have synthesized three different amphiphilic connectors (Figure 1B), which have in common the adamantyl hydrophobic group, which is well-known to make strong inclusion complexes, especially with βCD cavities. Several methods were then used to obtain information about DNA compaction and complexation. DNA mobility shift assays and ζ potential measurements allow the determination of the adamantyl/DNA phosphate ratio required for DNA complexation and the surface charge of the polyplexes. We have earlier elaborated a useful tool to study DNA compaction using surface enhanced Raman spectroscopy (SERS) (*35*). We can follow DNA compaction by monitoring the SERS signal of adenyl residues because the SERS signal of a nucleic acid mainly corresponds to the interaction of adenyl residues with silver colloid $(Ag)_n^+$. DNA compaction involves electrostatic interactions between the phosphate groups of DNA and the ammonium group of the vector. These intermolecular interactions will compete with silver adsorption of adenyl. In this study we also focused on the role of ionic strength in DNA complexation by using DNA retardation assays and small angle neutron scattering. Indeed, in cell culture media the ionic strength is about 170 mM (*36*), which probably influences DNA complexation. Finally, the *in vitro* transfection efficiency of these new DNA vectors was evaluated.

2. MATERIALS AND METHODS

2.1. Synthesis of the Cyclodextrin Polymer. The poly-β-cyclodextrin polymer (polyβCD) was synthesized by polycondensation of βCD (a gift from Roquette Company, France) and epichlorohydrin under strong alkaline conditions (*37*). A full description of the polyβCD synthesis and the polyβCD characterization has been published (*37, 38*). The polyβCD sample used in this study has an average molecular weight of M_w = 160 000 g mol^{-1} with a βCD content of 59% w/w, and its polydispersity index is M_w/M_n = 1.9.

2.2. Synthesis of Adamantanyl Connectors. Ada2 (2-(1-adamantyl)ethyltrimethylammonium bromide) was synthesized according to the previously published procedure (*35*).

The synthesis scheme of Ada3 and Ada4 connectors is described in Figure 2, and the experimental procedure was as follows:

Ada3 (2-(1-Carbamoylmethyladamantane)ethyltrimethylammonium Chloride). 1-Adamantane acetic acid (7 g, 36 mmol, Aldrich, Saint-Quentin-Fallavier, France) dissolved in 20 mL of thionyl chloride (Aldrich, Saint-Quentin-Fallavier, France) was placed in a distilled apparatus. After 1 h of reflux, thionyl chloride was removed by distillation and the apparatus was kept under vacuum. 5.8 g of 2-(1-adamantyl)ethanoyl chloride (**1**) as a pale pink liquid was obtained by distillation (75% yield). Compound **1** was characterized by ^{1}H NMR ($CDCl_3$, 300 MHz) δ (ppm): 1.8 − 1.7 (m, 12H; Ada), 2.1 (s, 3H; Ada), 2.7 (s, 2H; $-CH_2-CO$).

2-(1-Adamantyl)ethanoyl chloride (**1**) (2.12 g, 10 mM) was added dropwise to a solution of *N*,*N*′-dimethylethylenediamine (0.8 mL, 7 mmol, Aldrich, Saint-Quentin-Fallavier, France) in 15 mL of pyridine previously placed under argon at 0 °C. Then, the mixture was stirred overnight and protected from the light. The product was evaporated three times with acetone to remove pyridine. The obtained solid was dissolved in a solution of H_2SO_4 (10%, pH = 2.3) and then extracted with ether. Sodium hydroxide was added to the aqueous layer at 0 °C until pH = 10 and then extracted with ether. Before being dried over anhydrous $MgSO_4$, 2 g of product (**2**) was obtained as a beige solid (75% yield). Compound **2** was characterized by ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm): 1.6 (m, 12H; Ada), 1.9 (m, 5H; Ada and Ada-CH_2-), 2.2 (s, 6H; -N(CH_3)$_2$), 2.4 (t, 2H; -N-CH_2), 3.3 (q, 2H; $-CH_2-NH$).

Compound **2** (2 g, 76 mmol) was dissolved in 5 mL of anhydrous dichloromethane, and then 1 mL of iodomethane (Aldrich, Saint-Quentin-Fallavier, France) was added drop by drop. The mixture was kept under reflux for 7 h and the solution was cooled to room temperature. Ether was added before filtration to obtain 2.6 g of Ada3 (80% yield) as a white solid. Iodide counterion was exchanged by chloride counterion with Dowex (2 × 8−100) anion exchange resin (Aldrich, Saint-Quentin-Fallavier, France).

Ada3 was characterized by ^{1}H NMR ($CDCl_3$, 300 MHz) δ (ppm): 1.6−1.7 (m, 12H; Ada), 1.9 (m, 3H; Ada), 2.0 (s, 2H; Ada-CH_2-), 2.4 (t, 2H; -N-CH_2), 3.5 (s, 9H; -CH_3), 3.8−3.9 (m, 2H; $-CH_2-CH_2-N$).

Ada4 (2-(1-Carbamoylmethyladamantane)di(ethyl(diethylmethylammonium)) dichloride). A solution of 2-(1-adamantyl)ethanoyl chloride (**1**) (1 g, 4.7 mmol, Aldrich, Saint-Quentin-Fallavier, France) in 10 mL of anhydrous ether was added drop by drop under argon to a solution of *N*,*N*,*N*′,*N*′-tetraethyldiethylenetriamine (1.33 mL, 5.1 mmol, Aldrich, Saint-Quentin-Fallavier, France) in a mixture of 30 mL of anhydrous ether and 0.65 mL of triethylamine. After 2 h of reflux, the white solid formed was filtered to eliminate triethylammonium chloride. The solution was evaporated to give 1.85 g (80% yield) of compound **3** as a yellow oil. Compound **3** was characterized by ^{1}H NMR ($CDCl_3$, 300 MHz) δ (ppm): 1.1 (m, 12H; -CH_3), 1.7 (m, 12H; Ada), 1.9 (m, 3H; Ada), 2.1 (s, 2H; Ada-CH_2-), 2.6 (m, 12H; $-N-C\underline{H}_2-CH_3$ and -CO-N-$CH_2-C\underline{H}_2$-), 3.4 (m, 4H, -CO−N−$C\underline{H}_2$-CH_2-).

To a solution of 1.5 g (3.8 mmol) of compound **3** in 50 mL of anhydrous dichloromethane was added drop by drop 1 mL of iodomethane. The mixture was kept under reflux for 2 h, and the solution was cooled to room temperature. The solution was filtered, and the solid product was washed with ether to give 1.8 g (70% yield) of Ada4 as a white solid. Iodide counterions were exchanged by chloride counterions with Dowex (2 × 8−100) anion exchange resin. Ada4 was characterized by ^{1}H NMR (DMSO, 300 MHz) δ (ppm): 1.2 (m, 12H; -CH_3), 1.6 (m, 12H; Ada), 1.9 (m, 3H; Ada), 2.1 (s, 2H; Ada-CH_2-), 3.0 (m, 6H; $^+N-CH_3$), 3.4 (m, 12H, $-CO-N-C\underline{H}_2-CH_2-$ and $-CH_2-CH_3$), 3.6 and 3.8 (m, 4H; $-CH_2-N^+$).

2.3. Polyplex Preparation. The vector composed of the polyβCD and the connector was generated by mixing a fixed amount of CD cavities of polyβCD [120 μmol·L^{-1} (10 equiv)] with various amounts of adamantyl connector ranging from 12 μmol·L^{-1} (1 equiv) to 120 μmol·L^{-1} (10 equiv). Polyplex formation was achieved by adding DNA plasmid solution in order to have a fixed 12 μmol·L^{-1} (1 equiv) of phosphate groups. All complexes were prepared in ultrapure water. PolyβCD/Ada/DNA polyplexes were prepared at various adamantyl/DNA phosphate ratios (A/P), which corresponds to the ratio between the number of adamantyl connectors and the DNA phosphate group number.

2.4. Physicochemical Characterization. *2.4.1. Fluorescence Measurements.* The association constants (determined with a standard deviation of 10%) between the cyclodextrin derivatives and the connectors were measured with a SLM Aminco 8100 fluorimeter (Bioritech, Chamarande, France). A complete description of the method was published previously (*39*). A fluorescent probe, 4-amino-*N*-*tert*-butylphthalimide, able to make inclusion complexes with CDs, was used as a competitor (*40*) for Ada2, Ada3, and Ada4. The cyclodextrin derivatives used in these experiments are βCD, (2-hydroxypropyl)-β-CD (HPβCD) (Aldrich, Saint-Quentin-Fallavier, France), and the synthesized polyβCD.

2.4.2. DNA Retardation Assays. The polymeric vector binding to the DNA at different adamantyl/DNA phosphate ratios (A/P) was determined by using a 1% agarose gel electrophoresis (w/v) containing ethidium bromide in a TBE buffer (89 mM Tris/89 mM boric acid/2 mM EDTA, pH = 8.3). Gels were run for 15 min at 100 V, and DNA was visualized using an UV illuminator.

2.4.3. ζ Potential. The ζ potential of the polyplexes were analyzed using a Zetasizer nano ZS (Malvern Instruments) at 25 °C. The measurements were performed in folded capillary cell (DTS 1060C, Malvern Instruments) with a 4 mW He−Ne laser at a wavelength of 633 nm. The ζ potential was automatically calculated from the electrophoretic mobility based on the Hemholtz−Smoluchowski relationship (*41*) for the polyplex polyβCD/Ada/DNA and based on the Hückel approximation for the vector polyβCD/Ada.

2.4.4. Surface Enhanced Raman Spectroscopy (SERS). The SERS experiments were carried out at 488 nm excitation of an argon ion laser on a Dilor XY Raman spectrophotometer (Horiba Jobin Yvon SAS, Longjumeau, France) equipped with a liquid-nitrogen-cooled CCD camera. Silver colloids for SERS measurements were prepared according to the Creighton method (*42*) and display an absorption band centered at 398 nm measured on a Cary 3 UV−visible spectrometer (Varian, Les Ulis, France). Polyplex samples were obtained by mixing 90 μL of colloid with 10 μL of polyplex aqueous solution and 10 μL of a 1 mM aqueous solution of $MgCl_2$. All SERS spectra were recorded after an incubation time of 20 min. The laser power was fixed at 40 mW at the sample, and the accumulation time was fixed at 180 s.

2.4.5. Small-Angle Neutron Scattering (SANS). The SANS experiments were carried out with the PACE spectrometer at the Laboratoire Léon Brillouin (LLB), Saclay, France. The experimental scattering vector **q** (**q** = $(4\pi/\lambda)\sin(\theta/2)$) range was $0.0032 < \mathbf{q}$ (Å^{-1}) < 0.12 and was covered by two sample-to-detector distances (3 m at the neutron wavelength of 6 Å^{-1} and 4.6 m at 13 Å^{-1}). The wavelength dispersion $\Delta\lambda/\lambda$ of the

velocity selector was 10%. The samples were kept in quartz cells (Hellma) with a path length of 2 mm for samples in D_2O. The collected data were normalized for the detector efficiency using the isotropic scattering of a 1 mm thick calibration sample of H_2O. The raw data were corrected for background from the solvent and sample cells. All the samples were prepared in D_2O to maximize the contrast between the β-cyclodextrin polymer (ρpolyβCD $= 2.29 \times 10^{10}$ cm^{-2}) and the solvent ($\rho D_2O = 6.41 \times 10^{10}$ cm^{-2}). The scattering length densities of Ada2, Ada3, and Ada4 are 0.22×10^{10} cm^{-2}, 0.46×10^{10} cm^{-2}, and 0.23×10^{10} cm^{-2}, respectively (without the counterions). In the SANS experiments, the DNA samples used are extracted from herring sperm (Sigma). Due to a lack of information regarding the relative composition in adenine, guanine, cytosine, and thymine, the scattering length density of the DNA sample could not been calculated (a theoretical value of 4.11×10^{10} cm^{-2} has been reported in the literature for the scattering length density of chicken erythrocyte nucleosomal DNA) (*43*).

The concentration of each compound in the polyplex formulation is as follows: $C_{poly\beta CD} = 10^{-2}$ M (corresponding to 10 equiv of βCD cavities), $C_{DNA} = 10^{-3}$ M (1 equiv of phosphate groups), $C_{Ada2} = 5 \times 10^{-3}$ M (5 equiv of adamantyl groups), and $C_{Ada3} = 5 \times 10^{-3}$ M (5 equiv of adamantyl groups). Because the scattered intensities of polyplex used under the concentration conditions of the other techniques are too weak to be detected, all sample concentrations are 10-fold higher in the SANS experiments.

2.5. Cell Culture and Transfection. In vitro cell transfection experiments have been performed using a plasmid DNA SMD2-LucΔITR (7.6 kb) encoding a luciferase gene on the human hepatocarcinoma cell line HepG2 (American type Culture Collection, Rockville, MD) and the human transformed embryonal kidney cells HEK293 (American type Culture Collection, Rockville, MD). Cells were plated 24 h before transfection in 24-well plates at 37 °C in a 5% CO_2/95% air incubator in a complete medium DMEM (Dulbecco's modified Eagle's medium) supplemented with 1% (v/v) of the penicillin−streptomycin antibacterial solution (Invitrogen) and 10% (v/v) fetal bovine serum (Invitrogen). For transfection, cells were used at 50−80% confluency and all the tests were performed in triplicate. Culture media was removed and replaced by a mixture of 400 μL of serum free DMEM and 100 μL of polyplex aqueous solution at the desired adamantyl/DNA phosphate ratio (A/P) containing 2 μg of plasmid DNA per well. After 3 h, the transfection medium was removed and replaced with 1 mL of complete medium. Luciferase activity was measured 24−48 h post-transfection. The luciferase assay was performed as described (*44*). Luciferase background was subtracted from each value, and the transfection efficiency was expressed as total light units/10 s/well and is the means of the triplicates. The protein content of the transfected cells was measured by using the BioRad protein assay.

Where indicated, the transfection experiments were done in the presence of the fusogenic peptide JTS-1 (Genepep), which has the following sequence: GLFEALLELLESLWELLLEA. The commercialized transfection agents PEI of 25 kDa (*2*) and the cationic lipid DOTAP (*7*) (*N*-(1-(2,3-dioleoyloxy)propyl)-*N*,*N*,*N*-trimethylammonium chloride) were used without peptide. DOTAP was used at a ± charge ratio of 4 whereas, for B-PEI, we used an amine to phosphate ratio of 13. Notably, in preliminary experiments, we found that these ratios were optimal for the transfection of HepG2 and HEK293 cells.

2.6. Cell Viability Assay. Cytotoxicity was evaluated by performing the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT; Sigma) assay (*45*). Briefly, one day after transfection, the cell culture medium was removed and replaced by serum-free DMEM containing 0.5 mg/mL MTT. After incubation at 37 °C for 3 h, the medium was removed and 200 μL of DMSO was added to each well to dissolve the formazan crystals produced from the reduction of MTT by viable cells. Absorbance was then measured at 570 nm. Untreated cells were used as control.

Table 1. Logarithm of the Binding Constants (Determined with a SD of 10%) for Different Cyclodextrin Derivatives (βCD, HPβCD, and polyβCD) to the Adamantyl Connectors (Ada2, Ada3, and Ada4) and Their Variation with the Addition of NaCl

$\log(K_{HP\beta CD})$	3.95	3.98	3.18
+ NaCl 150 mM	*4.04*		*3.11*
$\log(K^{app}{}_{poly\beta CD})$	3.04	2.85	2.18
+ NaCl 150 mM	*3.72*		

3. RESULTS AND DISCUSSION

3.1. Chemical Structure of the Connectors. The adamantyl connectors described in Figure 1B have been synthesized in order to evaluate the influence of the chemical structure on the transfection efficiency, in terms of the spacer and the charge valency of the polar headgroup. The three connectors have in common a hydrophobic adamantyl group, which is well-known to form inclusion complexes with CDs. The Ada2 connector has a spacer formed by an alkyl chain, and the polar headgroup is monocationic. On the other hand, Ada3 and Ada4 have a spacer composed by an amide function which is able to form hydrogen bonds with DNA (*46*−*48*). Furthermore, Ada3 has a monocationic polar headgroup whereas Ada4 is bicationic.

3.2. Fluorescence Measurements. Table 1 shows the logarithm of the binding constants, obtained by fluorescence measurements, of the three adamantyl connectors (Ada2, Ada3, and Ada4) for the cyclodextrin derivatives βCD, HPβCD, and polyβCD. These three cyclodextrin derivatives have different cavity accessibilities with an encumbering which ranks as follows: βCD < HPβCD < polyβCD.

Adamantane derivatives show good affinities for βCD, as described in the literature (*49*). The logarithms of the binding constants are of the order of 5. HPβCDs have a higher steric hindrance than βCD due to their hydroxypropyl groups. This hindrance results in a decrease of the logarithm of the binding constants by one unit for Ada2 and by about 1.6−1.7 for Ada3 and Ada4 connectors. This corresponds to decreases from 20 to 30% of the binding energies. The measurements performed in a salt-rich medium in order to reduce the electrostatic repulsions of charges did not alter the binding efficiencies. Thus, the decrease of the binding constants is mainly due to a steric hindrance phenomenon. The lowest binding constants are obtained for polyβCD with Ada2, Ada3, and Ada4, as shown in Table 1. This is due to two complementary effects. On the one hand, the steric hindrance of the polyβCD, which is a branched cyclodextrin polymer, causes limited cavity accessibility. On the other hand, the polyelectrolyte behavior of the vector polyβCD/Ada generates unfavorable electrostatic repulsions between the connectors in solution and those which are already complexed in the CD cavity of the polyβCD. These electrostatic repulsions hinder complete complexation of free connectors. The Ada4 connector, with its two positive charges, is particularly sensitive to this effect, as shown by the low value of the logarithm of the binding constant ($\log(K^{app}{}_{poly\beta CD/Ada4}) = 2.18$). This value is lower by one unity than the one obtained for the complexation of polyβCD with Ada2 ($\log(K^{app}{}_{poly\beta CD/Ada2}) = 3.04$). The increase of this later value with NaCl salt addition ($\log(K^{app}{}_{poly\beta CD/Ada2}NaCl) = 3.72$) supports the explanation of unfavorable electrostatic repulsions (Table 1).

3.3. DNA Complexation and Compaction. *3.3.1. DNA Retardation Assay.* We determined, in a first set of experiments,

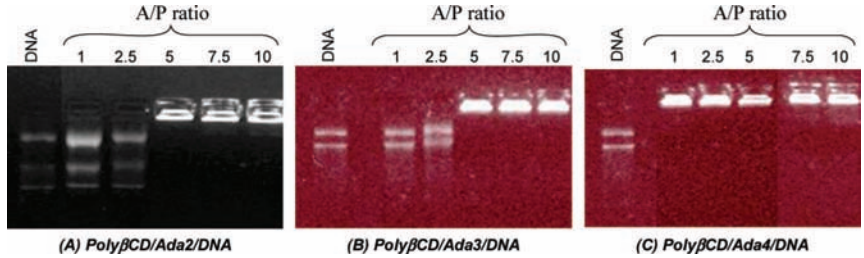

Figure 3. DNA retardation assay performed with the following DNA complexes: (A) Ada2 polyplexes, (B) Ada3 polyplexes, and (C) Ada4 polyplexes prepared at different adamantyl/DNA phosphate ratios (A/P).

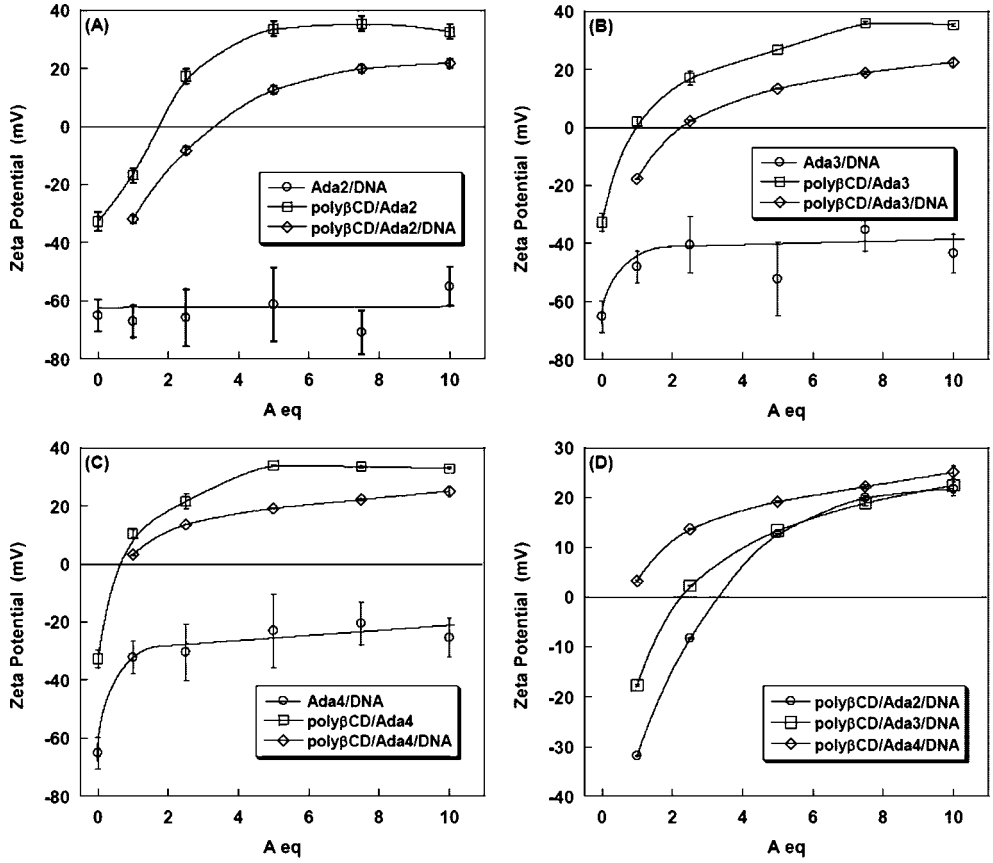

Figure 4. ζ potential of the three systems Ada/DNA vector, poly*β*CD/Ada vector, and poly*β*CD/Ada/DNA polyplex, at different adamantyl equivalents (A eq) (1 A eq = 12 μmol·L^{-1}), as a function of the connector: (A) Ada2, (B) Ada3, and (C) Ada4. (D) Comparison of the polyplex behavior according to the type of Ada connector.

the ability of the different vectors to interact with plasmid DNA by performing a gel shift mobility assay which allows us to identify the amount of cationic vector required to inhibit the migration of the plasmid DNA during gel electrophoresis. Figure 3 shows the results of the DNA retardation assay using Ada2, Ada3, and Ada4 polyplexes prepared at an adamantyl/DNA phosphate ratio (A/P) ranging from 1 to 10. The first lane of each gel corresponds to noncomplexed plasmid DNA. Notably, the different bands represent three forms of the plasmid DNA. It is also important to mention that the connectors Ada2, Ada3, and Ada4 alone, used in the absence of poly*β*CD, are not able to compact DNA (data not shown). The resulting gels show that the different vectors altered the DNA migration, which underscores that poly*β*CD is an essential component of the vector system. For Ada2 and Ada3 polyplexes, full retardation occurs at about the same charge ratio (i.e., A/P between 2.5 and 5). Ada4 polyplexes inhibit DNA retardation slightly more efficiently than the two other systems, since an A/P = 1 (equivalent to a ± ratio of 2) is sufficient due to its bicationic headgroup.

3.3.2. ζ Potential. In order to study more accurately the interactions of poly*β*CD/Ada with DNA, we performed ζ potential measurements of the polyplexes. Figure 4 reports the ζ potential as a function of the adamantyl equivalents (A eq) for the following different systems: connector/DNA, poly*β*CD/connector, and poly*β*CD/connector/DNA. We observed the same behaviors for the three connectors Ada2 (Figure 4A), Ada3 (Figure 4B), and Ada4 (Figure 4C). First, a connector/DNA mixture generates a negative ζ potential, proving the inability of the connector alone to mediate DNA complexation. The addition of poly*β*CD permits us to obtain a positive ζ potential value, indicating a DNA complexation which is consistent with the gel electrophoresis results. Notably, the DNA association with poly*β*CD/connector induces lower ζ potentials than the poly*β*CD/connector alone. This surface charge decrease, which is expected, is due to the neutralization of cationic charges by the anionic charges of the DNA. Figure 4D compares the ζ potential variation of the three polyplexes as a function of the adamantyl equivalents (A eq). At low A eq, Ada2 and Ada3 polyplexes have negative ζ potential values, indicating the

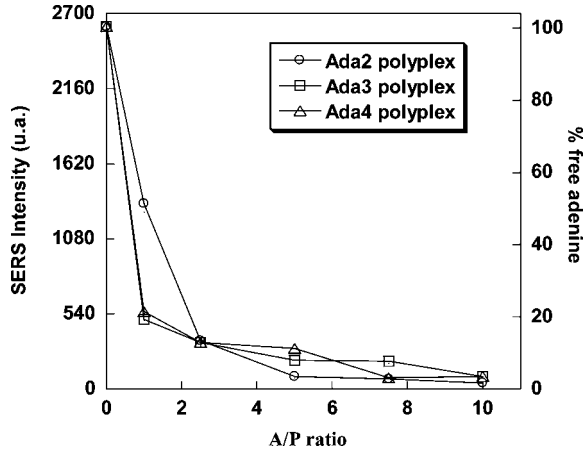

Figure 5. Influence of the nature of the connector on the SERS intensity of the polyplexes and on the percentage of free adenyl residues within the polyplexes.

presence of free DNA phosphate groups. Interestingly, a neutral surface charge of the polyplexes is obtained at an adamantyl equivalent of A/P ~ 3.3 for Ada2, A/P = 2.2 for Ada3, and of A/P = 1 for Ada4 polyplexes. These results underline that the ability of Ada4 to complex DNA depends on the chemical structure of the connectors. Of note, the Ada3 vector offers better DNA complexation properties than Ada2, probably due to the amide function of its spacer, which can create hydrogen bonds with the DNA bases. Finally, the even more efficient DNA complexation properties of Ada4 may be based on the combination of two effects: hydrogen bonding as with Ada3 and the multivalency of the polar headgroup.

3.3.3. Surface Enhanced Raman Spectroscopy (SERS). The Raman signal intensity of an adsorbed molecule on or near special metal surfaces such as silver colloids can be enhanced by factors of up to 10^8 relative to the signal obtained for the same compound at the same concentration by classical Raman spectroscopy. This enhancement of diffusion permits the detection of molecules at very low concentration (10^{-6} M to 10^{-10} M) and then is particularly attractive for DNA studies. The SERS advantage is its ability to analyze the adenyl bases availability in nucleic acids. In fact, it has been proven that adenine is a very good SERS active molecule because free adenine has a specific affinity for silver colloids. Thus, the SERS signal of nucleic acids is mainly due to the interaction of these residues with the silver colloid. The spectral intensity of the observed SERS signal is a function of the availability of these residues. We have shown that the SERS method can be used to study the DNA compaction (*35*). The DNA compaction was analyzed in terms of the SERS signal decrease of adenyl residues by monitoring the intensity of the band at 1046 cm^{-1}. This band is assigned to the vibrational motion of the $C(6)NH_2$ site (*35*) and acts as a probe of the amount of adenyl adsorbed onto the silver colloids.

Figure 5 shows the influence of the vector adamantyl/DNA phosphate ratio (A/P) on the adenyl residues accessibility of DNA at 1046 cm^{-1}. The first point at the origin corresponds to the reference SERS signal intensity of DNA alone at 1046 cm^{-1}. At low adamantyl/DNA phosphate ratio (A/P), the SERS intensity decreases strongly due to the formation of cooperative interactions between the cationic polar head of the connector and the anionic phosphate groups of DNA. Because of these interactions, which induce DNA reorganization, adenyl residues become more and more inaccessible to the silver colloids. The SERS intensity variation reveals an equivalent pattern for both polyβCD/Ada3 and polyβCD/Ada4 vectors whereas the polyβCD/Ada2 vector shows a milder variation. This indicates again that the polyβCD/Ada2 vector has less efficient DNA compaction properties. The formation of efficiently compacted polyplexes occurs at the adamantyl/DNA phosphate ratio 2.5 < A/P < 5 for the Ada2 polyplexes and at 1 < A/P < 2.5 for both Ada3 and Ada4 polyplexes. The free adenine percentage within the

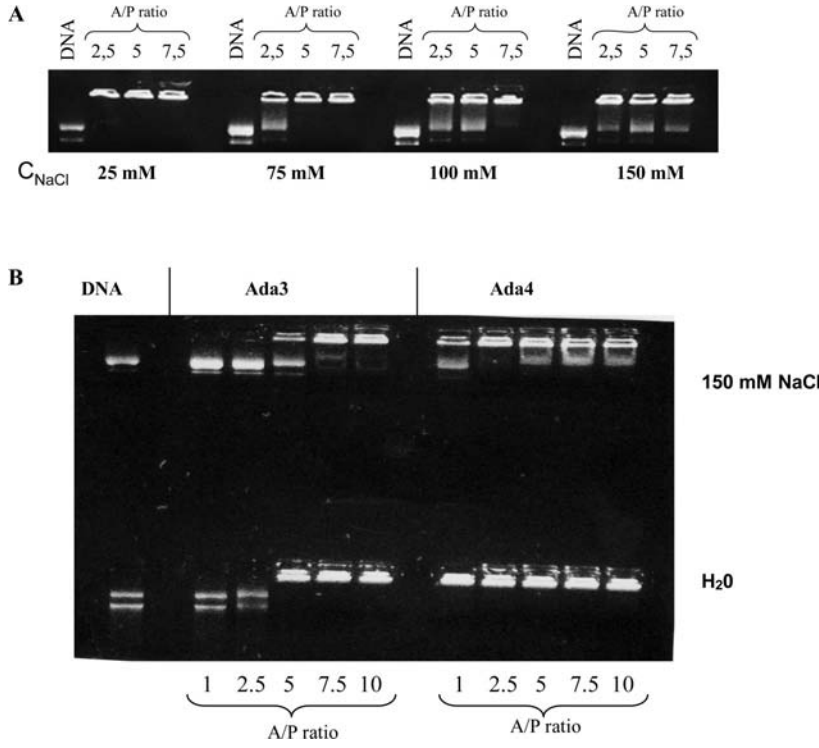

Figure 6. (A) Stability study of polyβCD/Ada2/DNA polyplexes at different adamantyl/DNA phosphate ratios (A/P = 2.5, 5, 7.5) in the presence of various NaCl concentrations (C_{NaCl} = 25, 75, 100, and 150 mM). (B) Stability of polyβCD/Ada3 and Ada4/DNA polyplexes at different adamantyl/DNA phosphate ratios (A/P = 1, 2.5, 5, 7.5, 10) in water or in the presence of 150 mM of NaCl.

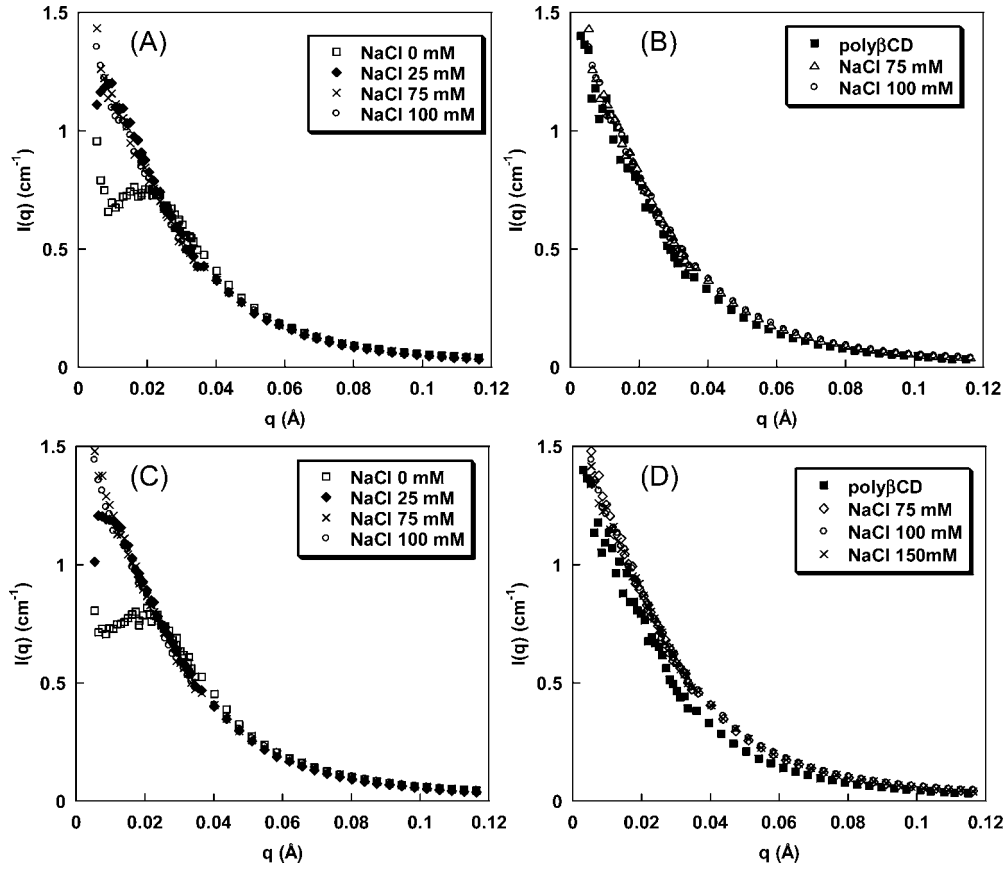

Figure 7. (A) Ionic strength influence on the scattered intensities of polyβCD/Ada2/DNA (10/5/1) polyplexes and (B) comparison of the scattering behavior of the polyβCD alone in solution with the scattering behavior of polyβCD/Ada2/DNA (10/5/1) polyplexes in 75 mM and 100 mM salt concentration. (C) Ionic strength influence on the scattered intensities of polyβCD/Ada3/DNA (10/5/1) polyplexes and (D) comparison of the scattering behavior of the polyβCD alone in solution with the scattering behavior of polyβCD/Ada3/DNA (10/5/1) polyplexes in 75, 100, and 150 mM salt concentration.

polyplex was estimated at different adamantyl/DNA phosphate ratios (A/P) by the probe band at 1046 cm^{-1} and corresponds to the intensity ratio $(I_{polyplex}/I_{DNA})_{1046cm}{}^{-1}$, where I_{DNA} is the reference SERS intensity of DNA and $I_{polyplex}$ is the SERS intensity of the polyplex at the adamantyl/DNA phosphate ratio (A/P). Under the preparation conditions of the neutral polyplex (from the ζ potential data), Ada2 polyplexes have nearly 10% (A/P = 3.3) of free adenyl residues, the Ada3 polyplex has 14% (A/P = 2.2), and the Ada4 polyplex has 21% (A/P = 1). The percentage of free adenyl residues decreases with an increase of the adamantyl/DNA phosphate ratio, which is an indication of the strength of DNA compaction. The Ada4 vector shows the highest free adenine percentage because the neutral polyplex was obtained at the lowest A/P ratio due to its bivalency. At highest adamantyl/DNA phosphate ratio, <5% of adenyl residues are free, suggesting a strong DNA compaction. These results clearly demonstrate that DNA compaction by the presented new vectors is efficient and depends on the nature of the connector.

3.4. Salt Effect on Polyplex Stability. Figure 6 shows the influence of ionic strength on the Ada2 polyplex stability. The Ada2 polyplexes have been prepared at three different adamantyl/DNA phosphate ratios, A/P = 2.5, 5, and 7.5, and at four different NaCl concentrations, C_{NaCl} = 25, 75, 100, and 150 mM (physiological salt conditions). At weak salt concentration (i.e., 25 mM), all DNA was retarded onto the gel, showing that Ada2 polyplex stability was unaffected. When the salt concentration was increased, the DNA retardation assays show a dissociation of the Ada2 polyplexes. This phenomenon depends on the adamantyl/DNA phosphate ratio and is demonstrated by the presence of the plasmid DNA which migrates toward the cathode in a similar manner as naked DNA. At C_{NaCl} = 75 mM, only the Ada2 polyplex with a A/P = 2.5 is partially dissociated. A concentration of C_{NaCl} = 100 mM induces dissociation of Ada2 polyplexes prepared at an adamantyl/DNA phosphate ratio of 2.5 and 5. Finally, under physiological salt conditions (C_{NaCl} = 150 mM), the Ada2 polyplexes are subject to a partial dissociation even at the highest adamantyl/DNA phosphate ratio tested. These results show that an increase of the ionic strength induces a partial dissociation of the Ada2 polyplexes which is probably due to a shielding of the electrostatic interactions. Notably, the polyβCD/Ada complex remains assembled because it has been demonstrated that an increase of the ionic strength reinforces hydrophobic interactions. A partial dissociation of the DNA complexes in the presence of 150 mM of NaCl was also observed with Ada3 and Ada4 (Figure 6B).

These results were complemented with small angle neutron scattering measurements. The ionic strength effect on Ada2 polyplex and Ada3 polyplex prepared at an adamantyl/DNA phosphate ratio A/P = 5, with different NaCl concentrations, C_{NaCl} = 0 (salt-free), 25, 75, 100, and 150 mM (physiological salt conditions), is shown in Figure 7A and 7C. These results express the influence of the salt addition on the conformation of the polyβCD chains and on their interactions with the polyplex and the surrounding medium. Under salt-free conditions, the scattering behaviors of both Ada2 polyplex (Figure 7A) and Ada3 polyplex (Figure 7C) show a clear diffusion peak which is characteristic of a polyelectrolyte (PEL) behavior. Indeed, these peaks indicate that, in the presence of connector Ada2 or Ada3, the polyplexes repulse each other by electrostatic interactions due to the global positive charge carried by the polyplexes. At weak ionic strength (C_{NaCl} = 25 mM), the

scattering behavior describes a poorly defined PEL peak, which indicates that the critical salt concentration which allows entire charge shielding is almost reached. The increase of the ionic strength at $C_{NaCl} = 75$ mM is sufficient to induce the disappearence of the PEL peaks obtained in salt-free conditions. The PEL peak is replaced by a monotonous intensity decrease as a function of **q**, which indicates a shielding of Coulombic repulsive interactions of polycationic chains. The same behavior is also observed at higher salt concentrations. Parts B and D of Figure 7 compare the diffusion behavior of Ada2 and Ada3 polyplexes, respectively, prepared at $C_{NaCl} = 75$ mM and above, with the scattering behavior of polyβCD alone in salt-free solution. In the case of Ada2 polyplexes (Figure 7B), their diffusion curves were superimposed with the one of polyβCD alone. This result shows that Ada2 polyplexes are dissociated for $C_{NaCl} \geq 75$ mM. From these data, it may be concluded that the weak charge density of the polyβCD/Ada2 vector does not permit the DNA complexation in the presence of salt.

In comparison, the diffusion curves of Ada3 polyplexes (Figure 7D), prepared at NaCl concentrations ranging from 75 to 150 mM, were not superimposed to the scattering behavior of polyβCD alone even under physiological salt conditions ($C_{NaCl} = 150$ mM). This result suggests that Ada3 polyplexes are less sensitive to the effect of salt than the Ada2 complexes, which is probably due to the hydrogen bond involved between the amide function of its spacer and the DNA bases.

3.5. In Vitro Transfection. After having studied the influence of the connector's chemical structure on polyβCD/Ada/DNA interaction properties, we evaluated the ability of the vectors to transfect DNA into cells. *In vitro* cell transfection experiments have been performed using a plasmid DNA encoding a *luciferase* gene on HepG2 and HEK293 cells. The addition of the JTS-1 peptide to polyplexes such as polylysine/DNA was previously shown to significantly increase the transfection efficiency, probably by improving the escape of the complexes from the endosomes (*50*). The adamantyl/DNA phosphate ratio (A/P) of the polyplexes used in the transfection studies was increased to increase the fraction of complexed connector, due to the poor apparent binding constant ($K^{app}_{poly\beta CD/Ada} < 10^3\ M^{-1}$) of Ada3 and Ada4 (Table 1). It should be specified that these constants are probably much lower than the ones in the ternary systems (not determined) where additional cooperative effects of coupled inclusion complex and electrostatic interactions might increase the affinity constants.

The transfection studies first revealed that the Ada2 polyplexes have only marginal DNA delivery efficiencies (data not shown). This was expected, since the ionic strength of the culture medium DMEM (i.e., 170 mM) probably induces polyplex dissociation before they can enter into the cells. Complexes generated with Ada3 were then evaluated on HepG2 cells by using increasing amounts of JTS-1 (Figure 8A). The results show that the addition of the fusogenic peptide is unable to increase the transfection activity above the control (i.e., without JTS-1). The same experiments were repeated using HEK293 cells, which are known to be more permissive to transfection than HepG2 cells. This time, the polyplexes generated with the highest dose of polyβCD/Ada3/JTS-1 allowed for a significantly higher transgene expression than polyplexes without JTS-1. However, the expression levels still remained several orders of magnitude lower than those obtained with B-PEI or DOTAP (Figure 8B).

Finally, we evaluated the transfection activity of the Ada4 vector on both cell lines. As shown in Figure 9, this formulation had a transfection efficiency which was of the same order as that of DOTAP on both cell lines. Notably, the efficiency of the Ada4 based complexes was dependent on the amount of added JTS-1 peptide (the difference between 10 and 40 μg of JTS-1 is significant on both cell lines). The best transfection results were obtained with the highest amount of peptide that was tested (i.e., 40 μg). Noteworthy also is the fact that the

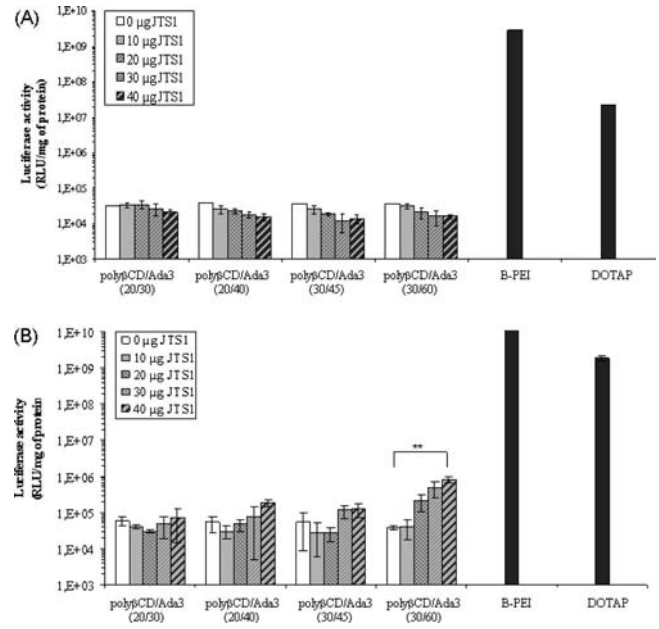

Figure 8. Transfection efficiency of Ada3-based polyplexes on (A) HepG2 cells and (B) HEK293 cells. Differences between formulations were determined using the Student's paired *t* test: $^{**}p < 0.01$.

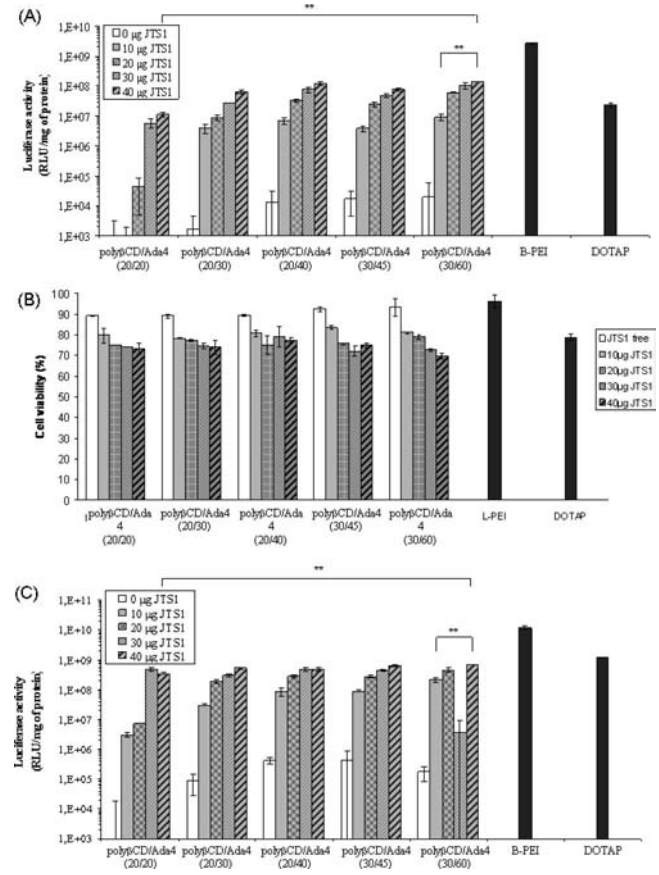

Figure 9. Transfection efficiency of Ada4 polyplexes on (A) HepG2 and (C) HEK293 cells. Differences between formulations were determined using the Student's paired *t* test: $^{**}p < 0.01$. (B) Evaluation of the cytotoxicity of the formulations. After 24 h of transfection of HepG2 cells, cell viability ($n = 2$) was measured. The results are given for the same formulations as those shown in part A.

transfection efficiency on HEK293 cells was not strongly modified when changing the polyβCD/Ada ratio (Figure 9C). However, the highest dose of polymer/Ada/JTS-1 led on both cell lines to the best transfection. From this study, it appears that the amide function of the Ada4 connector spacer associated with the double cationic charge of the polar head is the key parameter in the connector composition for DNA delivery. The toxicity of the polyβCD/Ada4/DNA $\pm$ JTS1 complexes on HepG2 cells following transfection was estimated by performing the MTT colorimetric assay (Figure 9B). The results indicate that the cytotoxicity of the complexes in the absence of the fusogenic peptide is very low. In fact, the cell viability decreases with the addition of JTS1. However, even with the highest amount of peptide, the cell viability remains of the same order as that observed with DOTAP.

4. CONCLUSION

We have presently demonstrated that cyclodextrin polymers (polyβCD) complexed with adamantyl cationic derivatives (Ada) constitute novel and efficient nonviral vectors for gene delivery. The design of the vector involves supramolecular inclusion complex interactions between polyβCD cavities and the hydrophobic part of the Ada connectors whereas, in the vector−DNA polyplex, additional supramolecular electrostatic interactions take part between the positive charges of Ada and the negative charges of DNA. The tailoring of the system was shown to be strongly dependent upon the chemical structure of the Ada connector: the nature of the spacer arm between the adamantyl moiety, and the charge valency of the connector. The physicochemical properties using three different Ada connectors have been extensively studied by different techniques testing the following properties: (i) the affinity between Ada connectors and polyβCD using fluorimetry, (ii) the DNA complexation and compaction using complementary experiments of gel electrophoresis, ζ potential, and SERS, and (iii) the structure of the polyplexes by SANS. The optimal properties were obtained with the Ada4 connector bearing a bivalent cationic charge and an amide function along its arm. This amide function proved to be important in the system, since the possible hydrogen bond interactions with DNA should have stabilized the polyplexes against dissociation under physiological conditions. *In vitro* transfection experiments performed on two cell lines (HepG2 and HEK293) correlated perfectly the results of the physicochemical study. The Ada4 vector, when associated with the fusogenic peptide JTS1, had a transfection efficiency similar to that of DOTAP.

Taken together, we would like to underscore that the improved reversibility of our system as compared to classical vectors makes the Ada4 formulation a very promising reagent for gene transfer. Further improvements of this vector should involve cell targeting. This can be easily realized by adding another adamantane derivative bearing a specific ligand recognized by cell receptors.

Received February 25, 2008; Revised Manuscript Received September 23, 2008

Specific targeting of tumor cells to achieve higher drug levels in tumor tissue and to overcome cardiotoxic and other secondary effects is the major goal in cancer therapy. With trastuzumab as a humanized monoclonal antibody binding, the HER2 receptor specific targeting is possible. In the present study, target-oriented nanoparticles based on biodegradable human serum albumin (HSA) loaded with cytostatic drug doxorubicin were developed. The surface of the nanoparticles was modified by covalent attachment of trastuzumab. HER2 overexpressing breast cancer cells showed a good cellular binding and uptake of these nanoparticles. The specific transport of the cytostatic drug doxorubicin with this nanoparticulate formulation into the HER2 overexpressing breast cancer cells, their release, and biological activity was demonstrated. The results indicate that these cell-type specific drug-loaded nanoparticles could achieve an improvement in cancer therapy. To our knowledge, this is the first study demonstrating a specific trastuzumab-based targeting of HER2 overexpressing breast cancer cells with doxorubicin-loaded nanoparticles.

INTRODUCTION

Cytostatic drugs are very useful substances in the fight of tumor diseases. However, the main disadvantages of conventional chemotherapy are modest tumor response and dose limiting side effects because of nonspecific action of drugs to all fast proliferating tissues (*1*). One possibility to avoid these disadvantages is the development of colloidal drug carrier systems (*2*). In this regard, nanoparticles show a high drug loading efficiency with minor drug leakage as well as the ability to circumvent multidrug resistance paired with good storage stability. Using human serum albumin (HSA) as particle forming polymer has the following advantages (*3*): human serum albumin is a physiological starting material and particles made of HSA are biodegradable. Additionally, the production of these particles is easy and reproducible (*4*). Functional groups are located on the surface of the prepared particles. Consequently, covalent linkage, for example, with drug targeting ligands is possible.

Depending on the carrier system, a differentiation between passive and active drug targeting can be made (*5*). Malignant tumors induce an increased angiogenesis with the consequence of hypervascularization consisting of leaky vasculature in combination with poor lymphatic drainage (*6*). The pore size in the vasculature ranges from 200 to 600 nm in diameter. These characteristics lead to an enhanced extravasation and accumulation of carrier systems such as liposomes and nanoparticles. This phenomenon is called "enhanced permeability and retention (EPR) effect". Consequently, long-circulating nanoparticles with poly(ethylene glycol) modifications on their surface are able to conduct passive tumor targeting (*7*). A further approach is the covalent linkage of drug targeting ligands such as monoclonal antibodies on the surface of the drug carrier systems to specifically target malignant cells (*8*−*10*). Thus, an active targeting with the advantage of an efficient accumulation of drugs in tumor tissue with higher drug levels in target cells can be achieved.

Concerning drug targeting ligands, the focus of many groups is mainly on monoclonal antibodies (mAb) (*11*). Trastuzumab (Herceptin), a humanized monoclonal antibody targeting the HER2 receptor, was approved by the FDA in 1998. HER2 is a member of a family of four transmembrane epidermal growth factor receptor (EGFR) tyrosine kinases and is overexpressed in a variety of human cancer cells such as breast, lung, and ovarian carcinomas (*12*). HER2 overexpression is an adverse prognostic factor in women with breast cancer (*13*). Trastuzumab administered as single agent leads to response rates ranging from 15% to 30% (*13*). Increased response rates can be achieved by using the antibody in combination with conventional chemotherapy. In this context, some clinical trials showed that an anthracycline-containing regimen leads to a greater benefit in women whose tumors overexpress HER2 than regimes without anthracyclines (*14*). The main drawback of the combination of trastuzumab and anthracyclines is that both trastuzumab and anthracyclines show cardiotoxic effects. That is the reason why this antibody−drug combination is only used in clinical trials where physicians have the possibility to monitor the heart function of the patients. On the other hand, it could be expected that trastuzumab-modified nanoparticles as drug carrier system for anthracyclines could reduce these side effects due to the ability of the particles to transport the embedded drug specifically to the tumor cells (*15*). Furthermore, the antibody concentration of the drug carrier system is far below the concentrations used in a therapeutic trastuzumab regime and a therapeutic antibody effect is not intended. The antibody only has a ligand function within such a nanoparticulate system. Upon arrival at the tumor tissue, trastuzumab molecules which are covalently attached to the particle surface by poly(ethylene

glycol) cross-linker chains will lead to the entry of the drug-loaded particles into the tumor cells (*9, 16*). Due to the biodegradability of human serum albumin, the particles are degraded within the cells. Thereupon, the released cytostatic drug specifically kills the tumor cells without acting in nontarget cells such as heart tissue. Therefore, this approach could be an answer to the crucial combination of trastuzumab and doxorubicin with the possibility to offer this effective therapy to women with HER2 overexpressing cancer cells.

EXPERIMENTAL PROCEDURES

Human serum albumin (HSA, fraction V, purity 96−99%), glutaraldehyde 8% aqueous solution, and human IgG antibody were obtained from Sigma (Steinheim, Germany). Doxorubicin was obtained from Sicor (Milan, Italy). 2-Iminothiolane (Traut's reagent) and D-Salt Dextran desalting columns were purchased from Pierce (Rockford, USA). Trastuzumab (Herceptin) was obtained from Roche (Mannheim, Germany). The succinimidyl ester of methoxy poly(ethylene glycol) propionic acid with an average molecular weight of 5.0 kDa (mPEG5000-SPA) and the cross-linker poly(ethylene glycol)-α-maleimide-ω-NHS ester with an average molecular weight of 5.0 kDa (NHS-PEG5000-Mal) were purchased from Nektar (Huntsville, USA). All reagents were of analytical grade and used as received.

Preparation of Doxorubicin-Loaded Nanoparticles. An amount of 160 mg HSA was dissolved in 4 mL purified water and the solution was filtered through a 0.22 μm cellulose acetate membrane filter (Schleicher & Schuell, Dassel, Germany). An aliquot (500 μL) of this solution was added to 200 μL of a 0.5% (w/v) aqueous stock solution of doxorubicin. To this mixture, 300 μL of purified water was added. For lower drug loading of the particles, the 0.5% (w/v) doxorubicin stock solution was diluted to 0.05% (w/v) or 0.025% (w/v), respectively, before mixing with the aqueous HSA solution. In order to adsorb doxorubicin to human serum albumin in solution, the mixture was incubated under stirring (550 rpm) for 2 h at room temperature (*17*). For the preparation of nanoparticles by desolvation, 3 mL ethanol (96%, v/v) was added continuously (1 mL/min) with a tubing pump (Ismatec IPN, Glattbrugg, Switzerland). After protein desolvation, an aliquot of 4.7 or 11.75 μL 8% glutaraldehyde solution, respectively, was added to induce particle cross-linking (corresponding to 40% or 100% stoichiometric protein cross-linking, respectively). The cross-linking was performed for 24 h under constant stirring at ambient temperature. Aliquots (2.0 mL) of the resulting nanoparticles were purified by two cycles of differential centrifugation (16 100 *g*, 12 min) and redispersion. Within the first cycle, redispersion was performed with 2.0 mL purified water, whereas in the second cycle, nanoparticles were redispersed with phosphate buffer (pH 8.0) to a volume of 500 μL using a vortexer and ultrasonication. The polymer content of the doxorubicin-loaded nanoparticles was determined by gravimetry.

The collected supernatants were used to determine the non-entrapped doxorubicin by HPLC. The content of entrapped doxorubicin was calculated from the difference between total doxorubicin and unbound drug. For the quantification of doxorubicin, a Merck Hitachi D7000 HPLC system equipped with a LiChroCART 250−4 LiChrospher-100 RP-18 column (Merck, Darmstadt, Germany) was used. Separation was obtained using a mobile phase of water and acetonitrile (70:30) containing 0.1% trifluoroacetic acid at a flow rate of 0.8 mL/min. Doxorubicin was quantified by UV (250 nm) and fluorescence detection (excitation 560 nm, emission 650 nm).

Surface Modification of Drug-Loaded Nanoparticles. Drug-loaded HSA nanoparticles were prepared as described above and were modified as follows: One milliliter of HSA nanoparticle suspension dispersed in phosphate buffer (pH 8.0) was incubated with 250 μL of mPEG5000-SPA solution (60 mg/mL in phosphate buffer pH 8.0) or poly(ethylene glycol)-α-maleimide-ω-NHS ester, respectively, for 1 h at 20 °C under constant shaking (Eppendorf thermomixer, 600 rpm). The nanoparticles were purified by centrifugation and redispersion as described above. The content of the nanoparticles was determined by gravimetry.

For the thiolation step of the antibodies, trastuzumab and IgG were dissolved in phosphate buffer pH 8.0 at a concentration of 1.0 mg/mL. For the introduction of thiol groups, trastuzumab or IgG, respectively, were incubated with a 50-fold molar excess of 2-iminothiolane solution ($c = 1.14$ mg/mL; 40.2 μL) for 2 h as previously described by Steinhauser et al. (*16*). The antibodies were purified by size exclusion chromatography (SEC, D-Salt Dextran desalting column). The resulting solution contained thiolated antibody (trastuzumab or IgG, respectively) at a concentration of about 500 μg/mL. For the coupling reaction, 1.0 mL of the sulfhydryl-reactive nanoparticle suspension was incubated with 1.0 mL of the thiolated trastuzumab or IgG, respectively, to achieve a covalent linkage between antibody and the nanoparticle system. For the preparation of samples with adsorptively attached antibody, 1.0 mL of the mPEG5000-SPA modified nanoparticles were incubated with 1.0 mL of thiolated trastuzumab or IgG, respectively. The incubation of all samples was performed for 12 h at 20 °C under constant shaking (600 rpm). The samples were purified from unreacted antibody by centrifugation and redispersion as described earlier. To determine unbound antibody, the resulting supernatants were collected and analyzed by size exclusion chromatography (SEC) on a SW_{XL} column (7.8 mm × 30 cm) in combination with a TSKgel SW_{XL} guard column (6 mm × 4 cm) (Tosoh Bioscience, Stuttgart, Germany) using phosphate buffer (pH 6.6) as eluent at a flow rate of 1.0 mL/min. Aliquots of 20.0 μL were injected, and the eluent fraction was monitored by detection at 280 nm. In order to calibrate the SEC system for molecular weight, globular protein standards were used. The amount of antibody bound to the nanoparticle surface was calculated as difference between the amount of antibody obtained after thiolation and purification and the amount of antibody determined in the supernatant obtained after the conjugation step.

Nanoparticle Characterization. Nanoparticles were analyzed with regard to particle diameter and polydispersity by photon correlation spectroscopy (PCS) using a Malvern Zetasizer $3000HS_A$ (Malvern Instruments Ltd., Malvern, UK). The zeta potential was measured with the same instrument by Laser Doppler microelectrophoresis. Prior to both measurements, the samples were diluted with purified water. Particle content was determined by gravimetry. For this purpose, 50.0 μL of the nanoparticle suspension was pipetted into an aluminum weighing dish and dried for 2 h at 80 °C. After 30 min of storage in an exsiccator, the samples were weighed on a microbalance (Sartorius, Germany).

Cell Culture. For all experiments, HER2 overexpressing breast cancer cells SK-Br-3 (ATCC, LGC Promochem, Wesel) were used. The cells were cultured at 37 °C and 7.5% CO_2 in McCoy's 5A medium (PromoCell, Heidelberg) supplemented with 10% fetal calf serum (Invitrogen, Karlsruhe) and antibiotics (50 U/mL penicillin and 50 μg/mL streptomycin; Invitrogen, Karlsruhe).

As a control cell line, HER2 weakly expressing MCF7 cells were used. The cells were cultured at 37 °C and 7.5% CO_2 in RPMI 1640 medium (Invitrogen, Karlsruhe) supplemented with 10% fetal calf serum (Invitrogen, Karlsruhe) and antibiotics (50 U/mL penicillin and 50 μg/mL streptomycin; Invitrogen, Karlsruhe).

Cellular Binding of Nanoparticles. HER2 overexpressing SK-Br-3 cells were cultured in 24 well plates (Greiner,

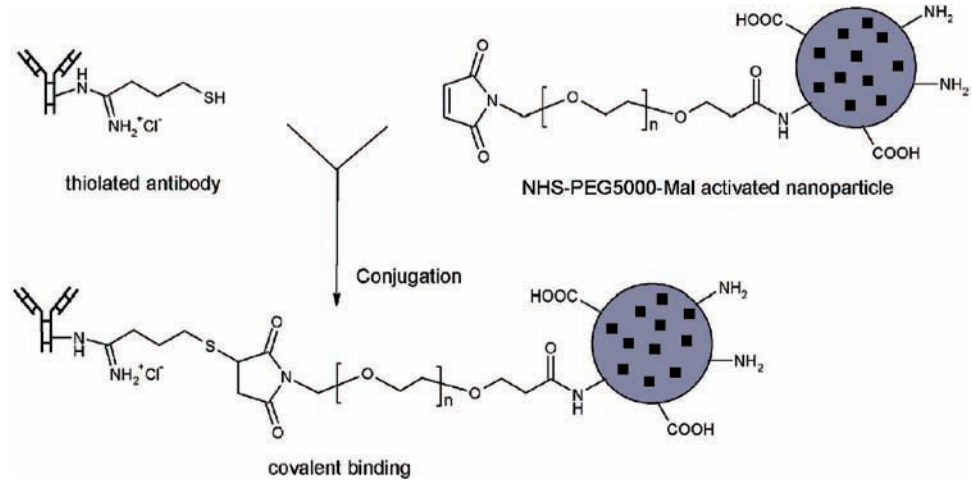

Figure 1. Covalent linkage of thiolated antibody to cross-linker-activated drug-loaded nanoparticle (black square = doxorubicin).

Frickenhausen) and treated with the different nanoparticle formulations for 4 h at 37 °C. After this incubation, the cells were washed twice with PBS (Invitrogen, Karlsruhe), then trypsinized and harvested. After washing with PBS and fixing with FACS-Fix (10 g/L PFA and 8.5 g/L NaCl in PBS, pH 7.4), flow cytometry (FACS) analysis was performed with 10 000 cells/sample, using *FACSCalibur* and *CellQuest Pro* software (Becton Dickinson, Heidelberg). Due to a green autofluorescence of these nanoparticles at 488/520 nm, this FACS analysis was possible.

For control experiment, HER2 weakly expressing MCF7 cells were cultured in 24 well plates (Greiner, Frickenhausen) and treated with the different nanoparticle formulations for 4 h at 37 °C. The sample preparation for flow cytometry analysis was performed as described before.

Cellular Uptake and Intracellular Distribution. Cellular uptake and intracellular distribution of the nanoparticles were studied by confocal laser scanning microscopy. SK-Br-3 cells were cultured on glass slides and treated with the different nanoparticle formulations for 4 h at 37 °C. After that incubation time, the cells were washed twice with PBS and the cell membranes were stained with 50 ng/μL Concanavalin A AlexaFluor 594 (Invitrogen, Karlsruhe) for 2 min. Cells were fixed with cold ethanol for 30 min. After fixation, the cells were washed and then embedded in Vectashield HardSet Mounting Medium (Axxora, Grünberg). The confocal microscopy study was performed with an Axiovert 200 M microscope with a 510 NLO Meta device (Zeiss, Jena), MaiTai femtosecond or an argon ion laser and the LSM Image Examiner software. The green autofluorescence of the nanoparticles was also used here.

Cellular Doxorubicin Recovery. Doxorubicin recovery was performed with flow cytometry (FACS) analysis. SK-Br-3 cells were cultured in 24 well plates (Greiner, Frickenhausen) and treated with the different nanoparticle formulations or free doxorubicin for 4 h at 37 °C. After this incubation, the cells were washed and incubated with fresh medium for different periods of time, and afterward trypsinized and harvested. Flow cytometry (FACS) analysis was performed after fixation with FACS-Fix (10 g/L PFA and 8.5 g/L NaCl in PBS, pH 7.4) with 10 000 cells/sample, using *FACSCalibur* and *CellQuest Pro* software (Becton Dickinson, Heidelberg). The red fluorescence of doxorubicin at 488/590 nm was used.

Biological Activity. Cell viability was determined in SK-Br-3 cells using WST-1 assay (Cell Proliferation Reagent; Roche Diagnostics) based upon the absorption measurement of formazan formation. Briefly, cells were cultured in 6 well plates and incubated with the different nanoparticulate formulations in PBS or PBS containing 100 μM chloroquine for 4 h at 37 °C. An amount of 10 000 cells/well were seeded in 96 well plates and further incubated for 7 d at 37 °C. The determination of cell viability was carried out after addition of WST-1 reagent and formazan measurement as described in the manufacturer's instruction manual.

For control experiment, HER2 weakly expressing MCF7 cells were used. The cell viability assay was performed as described before.

Statistical Analysis. Statistical analysis was made using the two-tailed Mann−Whitney U Test, which is equivalent to the Wilcoxon rank sum test (*18*−*20*). Statistical significance was defined at $P < 0.01$ values.

RESULTS AND DISCUSSION

Particle Preparation and Characterization. In the first step of the study, doxorubicin-loaded nanoparticles (Dox-NP) were prepared by using a well-established desolvation method (*17*). The nanoparticles were stabilized by two different amounts of glutaraldehyde. Therefore, nanoparticles were achieved with 40% (Dox-NP 40%) or 100% (Dox-NP 100%) stochiometric cross-linking of the particle matrix. Using 2-iminothiolane, thiol groups were introduced into the monoclonal antibody trastuzumab and the control antibody IgG. Finally, the drug-loaded particles were activated with a heterobifunctional poly(ethylene glycol)-α-maleimide-ω-NHS ester (NHS-PEG5000-Mal) or a monofunctional succinimidyl ester of methoxy poly(ethylene glycol) propionic acid (mPEG5000-SPA), respectively. In the first case, the heterobifunctional cross-linker leads to a covalent linkage between antibody and nanoparticle (Dox-NP-mAb) (Figure 1). In the second case, only an adsorptive binding between antibody and nanoparticle was expected because of the nonreactive methoxy group at the end of the poly(ethylene) glycol chain (Dox-NP + thiol mAb).

The results of the physicochemical characterization are presented in Tables 1 and 2 for 40% or 100% cross-linked nanoparticles, respectively. The resulting particles were characterized by particle diameters of 391.3 ± 14.0 nm and 385.2 ± 30.8 nm for 40% or 100% cross-linked nanoparticles, respectively. The polydispersity ranged between 0.053 ± 0.036 and 0.094 ± 0.057 indicating a monodisperse particle size distribution. Depending on the cross-linking degree, the doxorubicin loading was 51.39 ± 1.29 μg/mg for 40% cross-linked nanoparticles and 57.90 ± 0.44 μg/mg for 100% nanoparticles. Independent of whether the surface of the particles was modified or not, the particles showed a zeta potential between −40.1 ± 2.3 mV and −46.4 ± 3.4 mV.

Covalent linkage of trastuzumab to the particle surface was achieved with 14.92 ± 1.34 μg antibody/mg nanoparticle (40%

polydispersity		0.094 ± 0.057	0.080 ± 0.043	0.052 ± 0.034	0.055 ± 0.044	0.041 ± 0.048
zeta potential	[mV]	−42.6 ± 1.5	−46.4 ± 3.4	−43.7 ± 2.9	−41.2 ± 3.4	−43.8 ± 2.0
particle content	[mg/mL]	15.37 ± 0.34	14.24 ± 0.96	14.35 ± 1.13	14.30 ± 1.29	14.16 ± 1.57
antibody binding efficiency	[%]		90.6 ± 14.0	82.7 ± 15.5	39.2 ± 18.1	14.2 ± 5.0
	[μg/mg]		16.09 ± 3.71	15.39 ± 3.60	7.52 ± 5.29	2.73 ± 1.26
drug loading	[μg/mg]	57.90 ± 0.44	57.90 ± 0.44	57.90 ± 0.44	57.90 ± 0.44	57.90 ± 0.44

cross-linked nanoparticles) and 16.09 ± 3.71 μg trastuzumab/mg nanoparticle for the 100% cross-linked particles. With the control antibody IgG, similar results were obtained: Particles with a cross-linking degree of 40% showed a surface modification of 13.80 ± 2.30 μg antibody/mg nanoparticle, whereas more highly cross-linked particles resulted in a binding of 15.39 ± 3.60 μg IgG/mg nanoparticle on their surface.

In the case of preparations with antibodies bound by adsorption, a larger difference between the 40% and 100% cross-linked nanoparticles was observed: With a higher degree of cross-linking, the amount of adsorptively attached antibody increased from 3.50 ± 1.13 μg/mg (40%) to 7.52 ± 5.29 μg/mg (100%) for trastuzumab and from 0.93 ± 1.14 μg/mg (40%) to 2.73 ± 1.26 μg/mg (100%) for IgG. This may be due to a certain amount of covalent antibody binding by residues of monovalent bound glutaraldehyde. Under all preparation conditions, in the case of trastuzumab a more pronounced tendency to unspecific binding to particle surfaces was observed.

When comparing the results of nanoparticles with a covalent linkage to samples with only an adsorptive antibody attachment to the particle surface, it becomes obvious that the majority of the antibody molecules were covalently attached to the particle surface by the heterobifunctional PEG spacer. Only a minor part of the ligands were adsorbed to the nanoparticles or bound by monovalent glutaraldehyde.

Cellular Binding. HER2 overexpressing breast cancer cells SK-Br-3 were incubated with the same concentration (0.1 mg/mL referred to nanoparticles concentration) of nanoparticles with a covalent linkage of trastuzumab (Dox-NP-trastuzumab) as well as with samples with only an adsorptive attachment of trastuzumab on the particle surface (Dox-NP + thiol trastuzumab). Both nanoparticulate formulations showed good cellular binding. There was no difference in binding efficiency between the Dox-NP-trastuzumab and the Dox-NP + thiol trastuzumab (data not shown). Under the chemical point of view, covalent bonding is much stronger than adsorptive bonding. Particularly, this is true when the nanoparticles are administered into the bloodstream. The adsorptively bound antibodies are subjected to desorption processes. This phenomenon can be avoided by applying a covalent linkage between nanoparticle and antibody. Therefore, due to a supposed better stability of the covalent coupling, only the nanoparticle preparations with antibodies covalently linked by heterobifunctional PEG spacers were used for further cell culture experiments.

The SK-Br-3 cells were incubated with Dox-NP-trastuzumab nanoparticles (nanoparticle concentration corresponding to 2 μg/mL trastuzumab modification) with either 40% or 100% cross-linking. Just as the modality of mAb coupling, the degree of cross-linking had no influence on cellular binding efficiency (Figure 2a). Both nanoparticulate formulations, the 100% cross-linked as well as the 40% cross-linked Dox-NP-trastuzumab, displayed good cellular binding. Because there was no difference in cellular uptake between the 100% and 40% cross-linked nanoparticulate formulation (recognized on the same histogram shift, the same Y Mean fluorescence and the same percentage of positive cells, Figure 2a), further experiments were performed only with 100% cross-linked nanoparticles.

Specific targeting of tumor cells to achieve higher drug levels in tumor tissue and to overcome cardiotoxic and other secondary effects is the major goal in cancer therapy. With trastuzumab as a humanized monoclonal antibody, binding the HER2 receptor specific targeting is possible. HER2 overexpressing breast cancer cells SK-Br-3 were incubated with either nanoparticles modified with specific trastuzumab on surface (nanoparticle concentration corresponding to 2 μg/mL trastuzumab modification) or nanoparticles with unspecific control mAb IgG on the surface (concentration referred to specific nanoparticle concentration). As shown in Figure 2a, there was a specific targeting with Dox-NP-trastuzumab (73.80% positive cells for the 100% cross-linked nanoparticles and 73.07% positive cells for 40% cross-linked nanoparticles), whereas Dox-NP-IgG nanoparticles had a marginal cellular binding (5.57% positive cells). When the cells were incubated with increasing amounts of Dox-NP-trastuzumab, cellular binding increased in a concentration-dependent manner (see histograms and table in Figure 2b). Therefore, a highly specific targeting of HER2 overexpressing cancer cells could be shown with this trastuzumab-modified Dox-NP.

As a control experiment, we did flow cytometry binding studies with the trastuzumab-modified nanoparticles on the HER2 weakly expressing MCF7 breast cancer cell line. The MCF7 cells were incubated with either nanoparticles modified with specific trastuzumab on surface or control nanoparticles with IgG modification. As seen in Figure 3, trastuzumab-modified nanoparticles showed a marginal cellular binding, due to the low expression of HER2. Therefore, these MCF7 cells represented an optimal commonly used negative control. The comparison of the cellular binding of trastuzumab-modified

	Y Mean fluorescence	% positive cells
Dox-NP-trastuzumab (100%)	6.61	73.80
Dox-NP-trastuzumab (40%)	6.91	73.07

Figure 3. Control of cellular binding on HER2 weakly expressing MCF7 cells. HER2 weakly expressing MCF7 cells were treated with Dox-NP-trastuzumab or Dox-NP-IgG for 4 h at 37 °C. Flow cytometry (FACS) analysis was performed to quantify their cellular binding. The data are shown as histograms of the FL1-H-channel (autofluorescence of the nanoparticles) as well as a table with Y Mean fluorescence data. Green: Dox-NP-trastuzumab. Red: Dox-NP-IgG. Blue: untreated control.

nanoparticles on HER2 overexpressing SK-Br-3 breast cancer cells, showing a really specific cellular binding (Figure 2a), and HER2 weakly expressing MCF7 breast cancer cells, showing a marginal cellular binding (Figure 3), demonstrated the specificity of our nanoparticulate drug targeting system.

Cellular Uptake and Intracellular Distribution. The cellular uptake and intracellular distribution of these nanoparticulate formulations were shown by confocal laser scanning microscopy (CLSM). HER2 overexpressing breast cancer cells were incubated with nanoparticles with covalent coupled trastuzumab on particle surface (Dox-NP-trastuzumab) as well as with control nanoparticles (Dox-NP-mPEG) (Figure 4). Green fluorescence of specifically uptaken Dox-NP-trastuzumab was visible within the inner part of the red-stained cell membrane (Figure 4f), whereas only some unspecific Dox-NP-mPEG stuck onto the outer part of the cell membrane (Figure 4c). Dox-NP-trastuzumab incubated cells were optically sliced in a stack of 0.75 μm thickness each by confocal laser scanning microscopy to prove the intracellular uptake. The picture series is displayed as a gallery (Supporting Information supplement 1). An animation of such a picture stack is shown in Supporting Information supplement 2 as well as the 3D projection of cells with internalized Dox-NP-trastuzumab in Supporting Information supplement 3. These movies demonstrate the intracellular uptake of the Dox-NP-trastuzumab.

In summary, this flow cytometry and CLSM data clarify the specific targeting and intracellular uptake of Dox-NP-trastuzumab.

Cellular Doxorubicin Recovery. In a next step, the specific transport of the cytostatic drug doxorubicin with this nanoparticulate formulation into the cancer cells, their release, and biological activity was proven. A first recovery experiment was

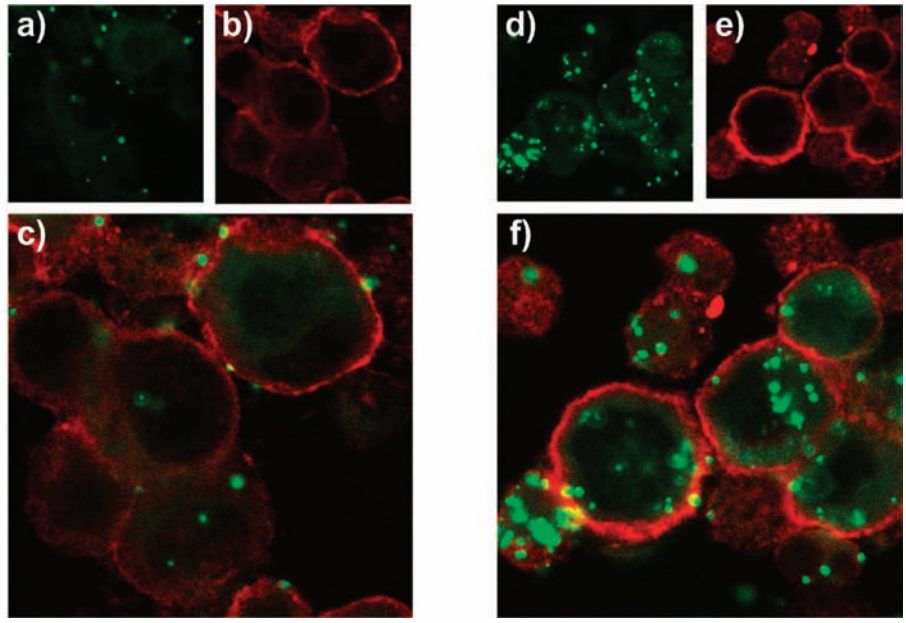

Figure 4. Cellular uptake and intracellular distribution of the nanoparticles studied by confocal laser scanning microscopy. SK-Br-3 cells were cultured on glass slides and treated with the different nanoparticle formulations for 4 h at 37 °C. The green autofluorescence of the nanoparticles was used, and the cell membranes were stained with Concanavalin A AlexaFluor 594 (red). Pictures were taken within inner sections of the cells. (a−c) Incubation of the cells with control nanoparticles without mAb modification. (d−f) Incubation of the cells with the specific Dox-NP-trastuzumab. (a) and (d) display the green nanoparticles channel; (b) and (e) display the red cell membrane; (c) and (f) overlay of the both fluorescence channels.

Dox- NP- IgG (2.78 µ g Dox /mg NP)	2.29	0.45

Figure 6. Doxorubicin recovery studied by flow cytometry. HER2 overexpressing SK-Br-3 cells were treated with different nanoparticulate formulations with different intraparticular doxorubicin concentrations for 4 h at 37 °C. Flow cytometry (FACS) analysis was performed to quantify their cellular binding. (a) The data are shown as histograms of the FL1-H-channel (autofluorescence of the nanoparticles) as well as a table with Y Mean fluorescence data and percentage of positive cells. (b) The data are shown as histograms of the FL2-H-channel (fluorescence of the doxorubicin) as well as a table with Y Mean fluorescence data and percentage of positive cells. Deep green: Dox-NP-trastuzumab nanoparticles with an intraparticular doxorubicin concentration of 5.96 μg doxorubicin/mg nanoparticle. Light green: Dox-NP-trastuzumab with an intraparticular doxorubicin concentration of 2.78 μg doxorubicin/mg nanoparticle. Red: control Dox-NP-IgG with an intraparticular doxorubicin concentration of 5.96 μg doxorubicin/mg nanoparticle. Orange: Dox-NP-IgG with an intraparticular doxorubicin concentration of 2.78 μg doxorubicin/mg nanoparticle.

incubated with different doxorubicin concentrations for 4 h at 37 °C. The results of flow cytometry analysis are shown in Figure 5a. A clear distinction between the different doxorubicin concentrations is possible with flow cytometry and *CellQuest Pro* software.

When the cells were incubated with doxorubicin-loaded nanoparticles with specific trastuzumab on particle surface (NP concentration corresponding to 15 μM doxorubicin concentration) or with doxorubicin-loaded nanoparticles with unspecific IgG (NP concentration corresponding to 15 μM doxorubicin) or with the same concentration of free doxorubicin (15 μM), different histograms were detected on the FL2-H channel (Figure 5b). Free doxorubicin showed the highest level of fluorescence intensity, followed by Dox-NP-trastuzumab and then Dox-NP-IgG (see table of Y Mean fluorescence Figure 5b). This effect demonstrated that different amounts of doxorubicin were transported to the cells by the different nanoparticulate formulations or free doxorubicin. Due to its specific cellular uptake, Dox-NP-trastuzumab transported more doxorubicin to the cells than the unspecific Dox-NP-IgG. The better uptake of free doxorubicin is a known phenomenon, but this is an unspecific transport to all kinds of cells responsible for all adverse secondary effects during a doxorubicin-based cancer therapy.

However, it was possible to influence the transported doxorubicin concentration by nanoparticles different in doxorubicin loading. HER2 overexpressing SK-Br-3 cells were treated with the specific Dox-NP-trastuzumab nanoparticles with an intraparticular doxorubicin concentration of 5.96 μg or 2.78 μg doxorubicin/mg nanoparticle or with the unspecific control Dox-NP-IgG nanoparticles with the same intraparticular doxorubicin concentration for 4 h at 37 °C. The flow cytometry data showed a better nanoparticulate cellular binding in the FL1-H-channel (Figure 6a) for the specific nanoparticulate formulations (over 90% positive cells) than the unspecific nanoparticulate formulations (approximately 1.3% positive cells), as already known. However, there was no difference in binding among the Dox-NP-trastuzumab nanoparticulate formulations with the different intraparticular doxorubicin concentrations, as well as among Dox-NP-IgG, meaning that the intraparticular doxorubicin concentration does not influence the cellular binding. However, there was a better transport of doxorubicin to the cells by higher loaded Dox-NP-trastuzumab than by lower loaded (see histogram and table in Figure 6b). This effect was also seen for unspecific nanoparticulate formulations. Thus, there was a possibility to influence the doxorubicin concentration transported to the cell. This could also be done by a higher amount of incubated nanoparticles, but a certain relation between the number of cells and the quantity of incubated nanoparticles should be maintained. Indeed, it is important for a nanoparticulate cancer therapy to administer highly loaded formulations in order to achieve a small drug infusion volume.

In a further recovery experiment, HER2 overexpressing SK-Br-3 cells were treated with Dox-NP-trastuzumab (NP concentration corresponding to 7 μM doxorubicin concentration), Dox-NP-IgG (0.1 mg/mL NP concentration corresponding to 7 μM doxorubicin concentration), or free doxorubicin (7 μM) for 4 h at 37 °C and were analyzed directly or further incubated with fresh medium for 20 or 44 h. Flow cytometry (FACS) analysis was performed to quantify their cellular binding and to investigate the doxorubicin processing. The data are shown as histograms of the FL2-H-channel for 4 h nanoparticle incubation only (Figure 7a), 4 h nanoparticle incubation and 20 h incubation time with medium (Figure 7b), and 4 h nanoparticle incubation and 44 h incubation time with medium (Figure 7c). For a better understanding of the results, we drew two lines in Figure 7a−c. The first goes through the histogram maximum of the histogram

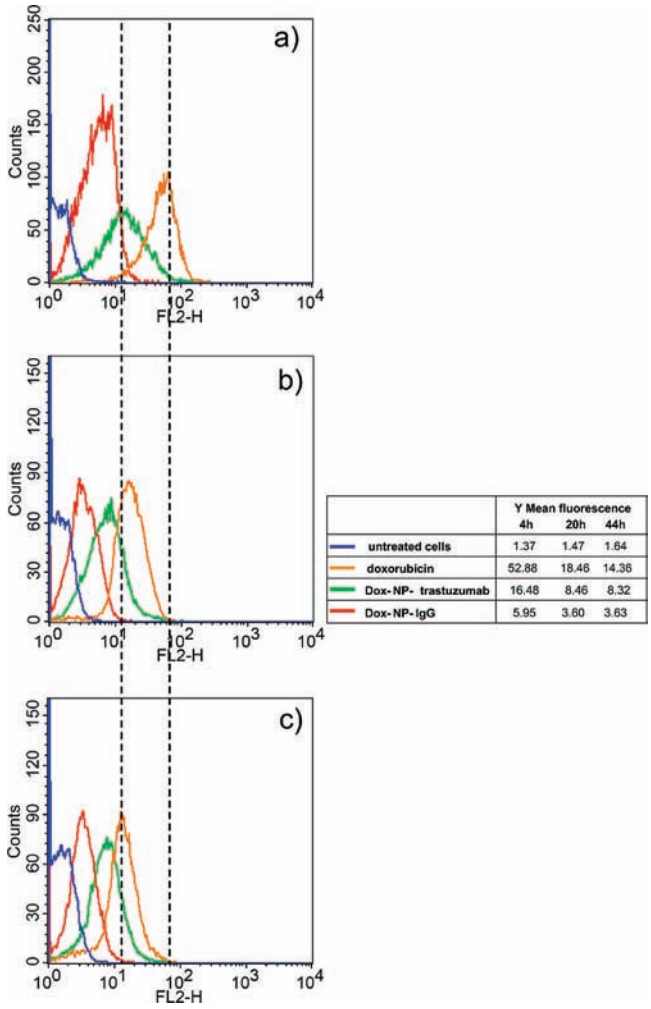

Figure 7. Doxorubicin recovery by flow cytometry: intracellular doxorubicin processing. HER2 overexpressing SK-Br-3 cells were treated with different nanoparticulate formulations or free doxorubicin for 4 h at 37 °C and incubated with fresh medium for different periods of time at 37 °C. Flow cytometry (FACS) analysis was performed to quantify their cellular binding. The data are shown as histograms of the FL2-H-channel (fluorescence of the doxorubicin) as well as a table with Y Mean fluorescence data. Orange: free doxorubicin. Green: Dox-NP-trastuzumab. Red: Dox-NP-IgG. Blue: untreated control. (a) 4 h nanoparticle incubation only. (b) 4 h nanoparticle incubation and 20 h incubation time with medium. (c) Four h nanoparticle incubation and 44 h incubation time with medium. (One representative experiment out of four independent experiments is shown.)

of free doxorubicin incubation analyzed after 4 h, and the second goes through the histogram maximum of the histogram of Dox-NP-trastuzumab after 4 h incubation. Both lines were elongated and cross the histograms after further 20 h and 44 h incubation. First of all, the already known histogram formation of doxorubicin transport to the cells was recognized: free doxorubicin was the best, followed by Dox-NP-trastuzumab and Dox-NP-IgG. However, if the cells were incubated with fresh medium and analyzed after 20 or 44 h a faster regression of the doxorubicin signal of free doxorubicin was recognized than of Dox-NP-trastuzumab. For the regression of the doxorubicin signal of free doxorubicin, we can read off values from approximately 65 (4 h incubation) to 13 (further 44 h incubation), which is a regression by a factor of 5. For the regression of the doxorubicin signal of Dox-NP-trastuzumab, we can read off values from approximately 13 (4 h incubation) to 8 (further 44 h incubation), which is a regression by a factor of 1.6. A reason for this observation could be the known drug efflux pumps of the cells. Free doxorubicin is transported out of the cells by these pumps, but nanoparticulate wrapped doxorubicin is saved. This sustained release effect could help to minimize the needed doxorubicin quantity for the cancer therapy in the future and to reduce secondary effects.

Biological Activity. In addition to the cellular uptake of the nanoparticulate doxorubicin, the therapeutic effect of these formulations was determined. HER2 overexpressing SK-Br-3 cells were incubated with the specific Dox-NP-trastuzumab or the unspecific Dox-NP-IgG in PBS for 4 h at 37 °C at a concentration of 15 μM referred to doxorubicin concentration, and a further incubation time of 7 d followed. Cell viability was determined using WST-1 assay based on the absorbance measurement of formazan formation. The formazan formation is only possible in the mitochondria of healthy cells; therefore, untreated cells set the 100% standard. After the incubation of Dox-NP-trastuzumab, the cells showed only a viability of 20.1% compared to cells incubated with Dox-NP-IgG reaching a viability of 56.5% (Figure 8a). Therefore, the Dox-NP-trastuzumab offered a better specific cellular uptake as well as a better cytotoxic activity.

To test whether the nanoparticles are entrapped within the endosomes or lysosomes and could not release their loaded cytostatic drug, chloroquine was used. Chloroquine is a weak basic reagent, which rapidly diffuses into the cells and accumulates in acidic compartments. This accumulation leads to an inhibition of lysosomal enzymes because of the pH increase. Lysosomal enzymes only work at acidic pH. Furthermore, chloroquine inhibits the fusion of endosome and lysosome, so entrapped agents are no longer degraded. The accumulation of chloroquine in endosomal vesicles induces an osmotic swelling of them, and therefore, the endosomes are destabilized and release the entrapped agents. However, there was no significant difference between the viability of the cells incubated with nanoparticulate formulations in either PBS (Figure 8a) or PBS containing chloroquine (Figure 8b). After incubation with Dox-NP-trastuzumab, there were 20.1% of healthy cells in the case of PBS incubations and 19.6% in the case of chloroquine use. The findings after incubation with Dox-NP-IgG were similar. There are 56.5% of healthy cells after incubation in PBS and 51.7% after incubation in PBS containing chloroquine. These results indicate that the nanoparticulate formulations are not entrapped in the endosomes or lysosomes, and the release of the cytostatic drug is not prohibited respectively.

In order to exclude whether or not these biological effects result from the trastuzumab surface modification of the nanoparticles and are mainly induced by the biological effect of trastuzumab itself, we compared doxorubicin-loaded trastuzumab-modified nanoparticles and unloaded trastuzumab-modified nanoparticles. As shown in Figure 9, the doxorubicin-loaded trastuzumab-modified nanoparticles had, as already known, a cytotoxic effect on cells, but the unloaded trastuzumab-modified nanoparticles did not alter the cell viability. Therefore, we can conclude that the trastuzumab modification of the particles had no influence on cell viability and the doxorubicin component of the particulate system must have caused the biological activity of our nanoparticulate system.

To demonstrate the specificity of our nanoparticulate system, we incubated the HER2 weakly expressing control cell line MCF7 with either the specific trastuzumab-modified nanoparticles or the unspecific IgG-modified nanoparticles (NP concentration corresponding to 1 μM doxorubicin). Both nanoparticulate formulations showed the same cytotoxicity due to an unspecific nanoparticle uptake of both nanoparticle formulations (Figure 10). These results verify the specificity and the biological activity of our newly designed ligand targeted nanoparticulate formulation based on human serum albumin with doxorubicin loading.

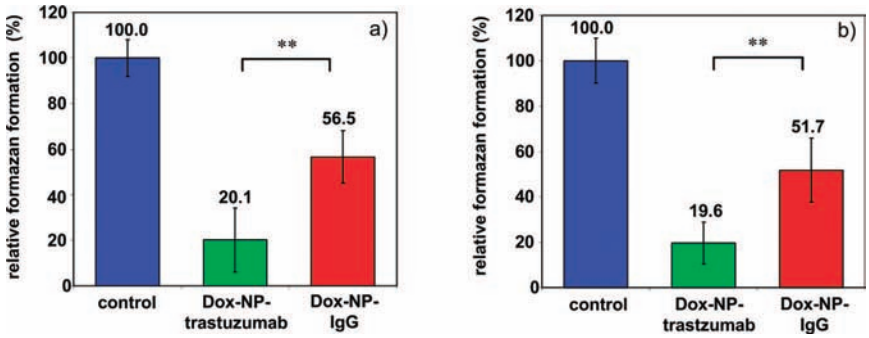

Figure 8. Cell viability assay: comparison between Dox-NP-trastuzumab and Dox-NP-IgG. HER2 overexpressing SK-Br-3 cells were incubated with the Dox-NP-trastuzumab or Dox-NP-IgG at the same concentration in (a) PBS or (b) PBS containing chloroquine for 4 h at 37 °C. After washing, the cells were further incubated for 7 d at 37 °C. The cell viability was determined after addition of WST-1 reagent and measurement of formazan formation, as described in the manufacturer's instructions manual. Untreated cells set the 100% standard. (internal control of each experiment $n = 9$, one representative experiment out of three independent experiments is shown for experiment (a))* *: The two samples are significantly different ($P < 0.01$, two-tailed Mann−Whitney U Test equivalent to the Wilcoxon rank sum test).

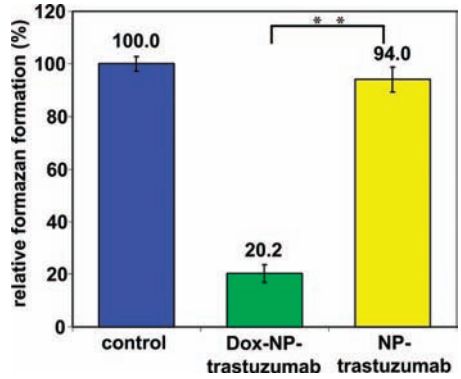

Figure 9. Cell viability assay: comparison between Dox-NP-trastuzumab and NP-trastuzumab. HER2 overexpressing SK-Br-3 cells were incubated with the Dox-NP-trastuzumab or NP-trastuzumab at the same concentration for 4 h at 37 °C. After washing, the cells were further incubated for 7 d at 37 °C. The cell viability was determined after addition of WST-1 reagent and measurement of formazan formation, as described in the manufacturer's instructions manual. Untreated cells set the 100% standard. (internal control of each experiment $n = 9$)* *: The two samples are significantly different ($P < 0.01$, two-tailed Mann−Whitney U Test equivalent to the Wilcoxon rank sum test).

HER2 weakly expressing MCF7 cells were incubated with the Dox-NP-trastuzumab or Dox-NP-IgG at the same concentration for 4 h at 37 °C. After washing, the cells were further incubated for 7 d at 37 °C. The cell viability was determined after addition of WST-1 reagent and measurement of formazan formation, as described in the manufacturer's instructions manual. Untreated cells set the 100% standard. (Internal control of each experiment $n = 9$)* *: The two samples are significantly different ($P < 0.01$, two-tailed Mann−Whitney U Test equivalent to the Wilcoxon rank sum test).

In the future, nanoparticle development for cancer chemotherapy will be a significant and expanding part of nanobiotechnology. The search for new tumor targets, novel ligands, new strategies for targeting, and particle stabilization will occupy science in the future to improve drug delivery at the tumor site while decreasing toxicity to normal tissues.

There already exist a lot of nanostructured formulations in order to reach this goal (for review, see Haley et al. (*21*)). For example, there are FDA-approved liposomal doxorubicin encapsulations (Doxil/Caelyx and Myocet) where the anthracycline pharmacokinetics are changed and cardiac risk is decreased but not eliminated (*22*−*25*). Anthracycline toxicity to normal tissue is reduced by liposomal encapsulation. After extravasation through tumor endothelium, liposomes disintegrate and deliver doxorubicin. Drug concentration has been measured 10 times higher in tumor tissue treated with Doxil compared to conventional free drug administration (*26*).

A further example is the first HSA-based nanoparticle formulation, Abraxane, approved by the FDA in 2005 and by the EMEA in 2008. The 130 nm large nanoparticles contain the cytostatic drug paclitaxel. Due to the bad solubility of paclitaxel in water, the conventional drug preparation (Taxol) contains polyethylated castor oil (Cremophor EL) and ethanol as vehicles. The drug incorporation in nanoparticles follows a new concept to improve drug solubility, with a variety of advantages compared to the standard paclitaxel therapy. Therefore, a nanoparticulate-bound paclitaxel infusion leads to a 33% increase in intratumoral concentrations and a 50% higher dose of delivered paclitaxel in comparison to a conventional paclitaxel infusion. Additionally, since nanoparticulate-bound paclitaxel is solvent-free, the infusion time is 30 min in contrast to the 3 h infusion for conventional taxol, and no premedication is required (*27, 28*).

In earlier studies, we have optimized and established a desolvation process to prepare human serum albumin nanoparticles (*4*). Previous studies have demonstrated that nanoparticles based on HSA were rapidly degraded after cellular uptake and led to a significant cellular accumulation of the entrapped drug (*29*). Therefore, we advanced this process to load human serum albumin based nanoparticles with the antineoplastic agent doxorubicin (*17*).

As already discussed, the specific targeting of cancer cells will be a breakthrough in cancer therapy. The treatment with monoclonal antibodies recognizing tumor-associated markers is a common strategy in cancer therapy. One of the most promising targets is the human epidermal growth factor receptor-2 (HER2), whose overexpression is strongly associated with poor prognosis. HER2 is a transmembrane tyrosine kinase

growth factor receptor, which is only marginally expressed in adult tissue (*30*), but is overexpressed in approximately 30% of human gastric, lung, and breast carcinoma. Trastuzumab (Herceptin), a humanized monoclonal antibody directed against the extracellular domain of HER2, is the only HER2-targeted therapy approved by the FDA for treatment of breast cancer (*31*). However, the best results in therapy were achieved when trastuzumab was given in combination with other cytotoxic agents. Because of its enhanced expression on tumor cells, its extracellular accessibility and its ability to internalize after antibody binding, HER2 represents a suitable target for tumor therapy with cell-specific nanoparticles. In a former study, we demonstrated an improvement of the specific uptake into HER2 overexpressing cells with trastuzumab surface-modified human serum albumin based nanoparticles (*9, 16*).

In the present study, we combined the specific trastuzumab-based nanoparticles with the cytostatic drug loading efficiency, to achieve a specific drug delivery system. Thus, we can conclude that we have developed a novel specific drug carrier system, which allowed us a specific transport of doxorubicin to HER2 overexpressing breast cancer cells. The duration of the uptaken doxorubicin within these cells was elongated and the drug was better saved against efflux, a known effect of nanoparticulate incorporated cytostatic drugs. Therefore, a minimization of needed doxorubicin volume in cancer therapy is presumed. Concerning the specificity and the minimized drug infusion volume, a reduction of the secondary side effects can be estimated. Due to the mAb directed specificity of the nanoparticles, our novel drug carrier system should be more efficient compared to the already known PEGylated liposomal doxorubicin carrier (Doxil or Caelyx). Additionally, nanoparticles show a higher loading capacity with a lower tendency of drug leakage than liposomes. Furthermore, a better stability of nanoparticles compared to liposomal formulations is known.

These trastuzumab-modified nanoparticles efficiently bind to and are specifically internalized in HER2 overexpressing breast cancer cells. They release the incorporated drug effectively. The combination of specific targeting with drug loading in these nanoparticulate formulations should lead to an improvement in cancer therapy.

Supplement 1

Cellular uptake and intracellular distribution of the nanoparticles studied by confocal laser scanning microscopy: optical stack.

SK-Br-3 cells were cultured on glass slides and treated with Dox-NP-trastuzumab for 24 h at 37°C. The green autofluorescence of the nanoparticles was used and the cell membranes were stained with Concanavalin A AlexaFluor 594 (red). Cells were optically sliced in a stack of 0.75 µm thickness each and the picture series is displayed as a gallery.

Supplement 2

Cellular uptake and intracellular distribution of the nanoparticles studied by confocal laser scanning microscopy: animation of an optical stack.

SK-Br-3 cells were cultured on glass slides and treated with Dox-NP-trastuzumab for 4 h. The green autofluorescence of the nanoparticles was used and the cell membranes were stained with Concanavalin A AlexaFluor 594 (red). Cells were optically sliced in a stack of 0.67 µm thickness each. The picture series was animated to demonstrate the intracellular uptake of the nanoparticles. The animation was done by the image processing program Image J.

Supplement 3

Cellular uptake and intracellular distribution of the nanoparticles studied by confocal laser scanning microscopy: 3D projection.

SK-Br-3 cells were cultured on glass slides and treated with Dox-NP-trastuzumab for 4 h. The green autofluorescence of the nanoparticles was used and the cell membranes were stained with Concanavalin A AlexaFluor 594 (red). Cells were optically sliced in a stack of 0.67 µm thickness each. A picture series of cells with internalized nanoparticles were semitransparently animated as a 3D projection to demonstrate the intracellular uptake of the nanoparticles. The animation was done by the image processing program Image J.

Design, Synthesis, and DNA Binding Properties of Photoisomerizable Azobenzene−Distamycin Conjugates: An Experimental and Computational Study

Sumana Ghosh,[‡] Dandamudi Usharani,[§] Ananya Paul,[‡] Susmita De,[§] Eluvathingal D. Jemmis,[†,§] and Santanu Bhattacharya*[,‡,||]

Department of Organic Chemistry and Department of Inorganic and Physical Chemistry, Indian Institute of Science, and Chemical Biology Unit, Jawaharlal Nehru Centre of Advanced Scientific Research, Bangalore 560 012, India. Received March 30, 2008; Revised Manuscript Received August 26, 2008

Here, we present the synthesis, photochemical, and DNA binding properties of three photoisomerizable azobenzene−distamycin conjugates in which two distamycin units were linked via electron-rich alkoxy or electron-withdrawing carboxamido moieties with the azobenzene core. Like parent distamycin A, these molecules also demonstrated AT-specific DNA binding. Duplex DNA binding abilities of these conjugates were found to depend upon the nature and length of the spacer, the location of protonatable residues, and the isomeric state of the conjugate. The changes in the duplex DNA binding efficiency of the individual conjugates in the dark and with their respective photoirradiated forms were examined by circular dichroism, thermal denaturation of DNA, and Hoechst displacement assay with poly[d(A-T).d(T-A)] DNA in 150 mM NaCl buffer. Computational structural analyses of the uncomplexed ligands using ab initio HF and MP2 theory and molecular docking studies involving the conjugates with duplex $d[(GC(AT)_{10}CG)]_2$ DNA were performed to rationalize the nature of binding of these conjugates.

INTRODUCTION

The distamycin and netropsin are well-known naturally occurring DNA minor groove binders (*1, 2*). These are known to selectively recognize A/T-rich base pairs via hydrogen bonding with base pairs together with van der Waals and electrostatic interactions with DNA (*3, 4*). Consequently, there is a continuing effort to modify natural distamycin A to enhance its sequence recognition and binding affinity with double-stranded (ds) DNA. In the past few years, various synthetic strategies have been developed to modify the distamycin scaffold to enhance the recognition efficiency together with mixed base-pair reading capacity. Thus, various new types of DNA binding molecules were designed to enhance and alter sequence specificity of distamycin to any desired target stretch of ds-DNA (*5, 6*). Another strategy to achieve improved DNA binding involved dimerization of DNA minor groove binders (MGB) (*7*−*9*). Although the gain in binding constant is often not as much as expected from dimerization, these modified ligands were found to recognize an extended stretch of 15−16 consecutive AT/GC base pairs with higher binding constant values (*10*−*12*).

We have been working on different DNA binding/cleaving molecules (*13*−*18*) and, in particular, with the distamycin analogues including its tail-to-tail dimers for improving their DNA recognition properties (*19*−*21*). We also reported the thermal stabilization of DNA upon conjugation of distamycin with oligodeoxynucleotides (*22*). In another effort, we have described the differences in their photochemical and DNA binding abilities of distamycin dimers connected through isomeric 2,2′ and 4,4′-dialkoxyazobenzene units (*23*). Herein we introduce the conjugates possessing an azobenzene moiety to which two distamycin arms has been connected via different types of linkages. The reason for choosing the azobenzene is due to its nearly reversible photoisomerization property (*24*). The light-induced isomerization of azobenzene is accompanied by significant changes in geometry and polarity of the chromophore (*25*). This unique property has already been widely exploited in various side chains and backbones of peptides, oligonucleotides, sugar scaffolds, and phospholipids to modify and regulate various biological processes (*26*−*30*). Indeed, an azobenzene group was also tethered into many transcription factors and at various positions of the T7-promoter site to modulate the transcription machinery in the presence of light (*31, 32*).

Here, we present the syntheses of three distamycin−azobenzene conjugates that vary in terms of the electronic nature of the linkage and in the length and the type of the spacer that connects them. The dimeric distamycin−azobenzene conjugates, **1**, **2**, and **3**, were synthesized using two different distamycin analogues, **Dist-1** and **Dist-2**. These distamycin analogues have an identical number of amide bonds for interaction with DNA bases, but they differ in terms of the number of N-methyl pyrrole rings and with respect to the position of partial charge developed along the distamycin backbone at physiological pH. So in the case of **1a**, **Dist-1** analogue is covalently connected to the 4,4′ (para) position of the electron-donating alkoxy substituted azobenzene moiety. On the other hand for ligands **2a** and **3a**, **Dist-1** and **Dist-2** units are covalently conjugated to the 4,4- position of the azobenzene core with *electron-withdrawing* carboxamido substituents, respectively, to furnish azobenzene−distamycin conjugates with a long or short spacer (Figure 1). We have examined the influence of the azobenzene moiety on the

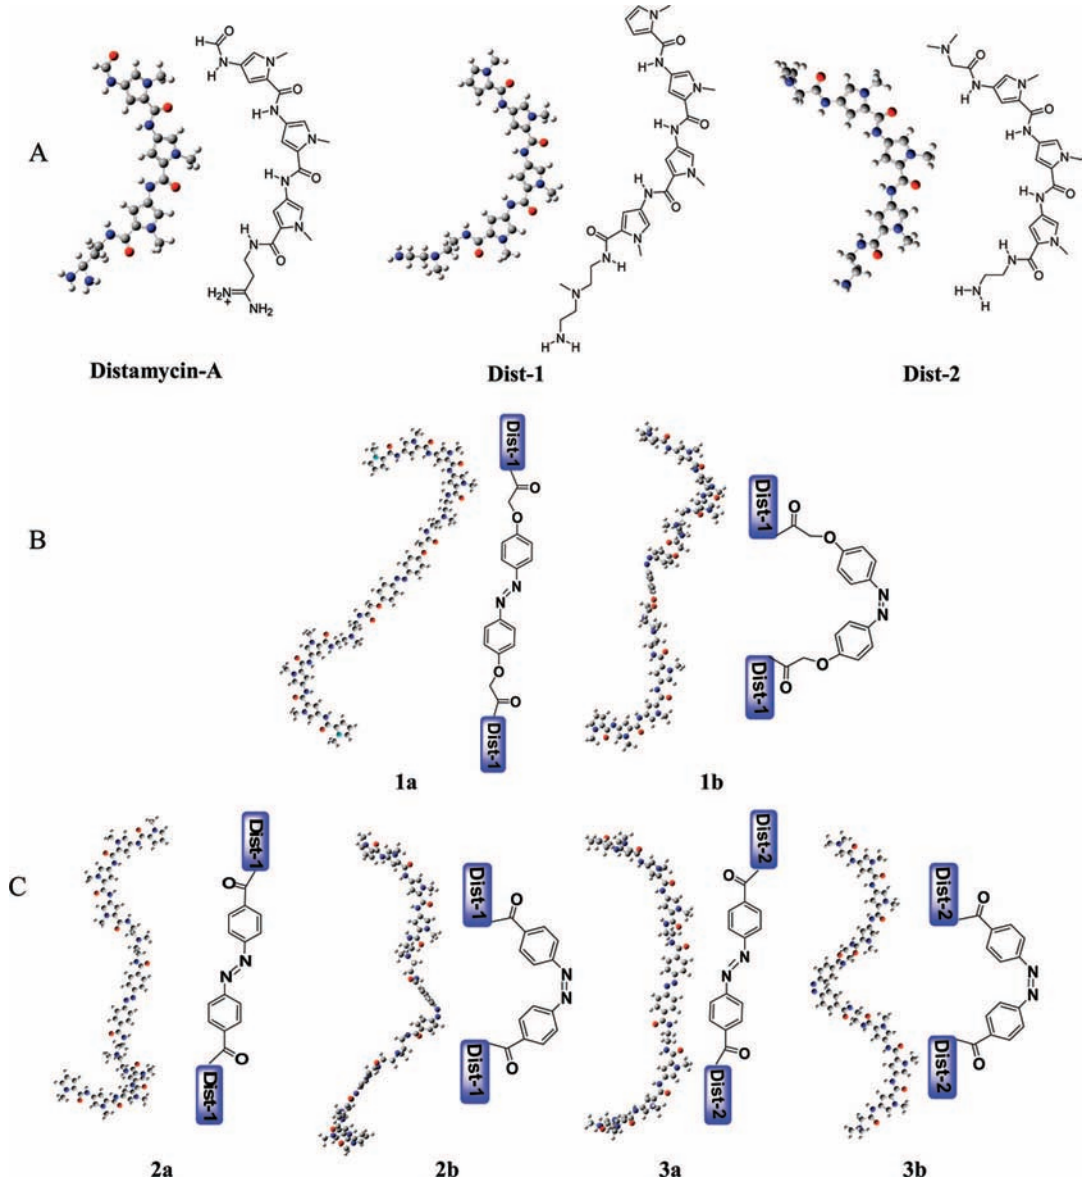

Figure 1. Chemical and optimized structures at the HF/3−21G level of theory of natural distamycin A, distamycin analogues, **Dist-1** and **Dist-2** (A), 4,4′-bis-alkoxyazobenzene containing **Dist-1** in **1a** (trans) and **1b** (cis) (B), 4,4′-bis-carboxamidoazobenzene containing **Dist-1** in **2a** (trans) and **2b** (cis); and (C) **Dist-2** in **3a** (trans) and **3b** (cis) linked via short spacer.

distamycin binding of the DNA minor groove and the changes in ds-DNA binding upon photoisomerization of the conjugate.

By examining the binding properties of these azobenzene−distamycin compounds (**1**, **2**, and **3**) with duplex DNA before and after photoillumination, we sought to address the following questions. Does the incorporation of azobenzene moiety in conjugates **1**, **2**, and **3** interfere with distamycin binding on DNA minor grooves in the ground state? How do the binding of distamycin arms vary upon changing the electronic nature of substituent (alkoxy vs carboxamido) on the azobenzene, e.g., between ligands **1** and **2**? How do ds-DNA binding characteristics vary with linker lengths between the long spacer based **2** and the short spacer based **3** for carboxamido-substituted azobenzene−distamycin conjugates? Finally, how much influence does the photoisomerization impart on the DNA binding properties of such azobenzene−distamycin conjugates?

We first illuminated ligand **1** at ∼360 nm and ligands **2** and **3** at ∼330 nm in solution to produce the corresponding photoisomeric forms. DNA binding properties and the changes in DNA binding efficiencies of individual conjugates in both their ground and photoisomerized states were studied by circular dichroism spectroscopy, thermal denaturation studies, and Hoechst displacement assay. We have also compared with **Dist-1** the DNA binding affinity of different photoirradiated forms of **1**, **2**, and **3** (in their photostationary state) designated as **1***, **2***, and **3***, respectively, to evaluate the effect of incorporation of azobenzene on DNA binding. The experimental results were then analyzed by ligand docking studies using duplex $d[(GC(AT)_{10}CG)]_2$ DNA scaffold. Both experimental and theoretical studies indicate that the duplex DNA binding is highly dependent on the linker length between the azobenzene and the distamycin. The linker length also influences the hydrogen bonding contacts between the pyrrole amide with DNA bases and helps to achieve proper shape complimentarity with the double helical DNA axis.

EXPERIMENTAL PROCEDURES

Synthesis. All reagents used in this study were of the highest purity available and were used without purification. Distamycin analogue, **Dist-1**, is a tetra *N*-methylpyrrole based oligopeptide, which has been synthesized and shown to interact with ds-DNA

along the minor groove surface as reported earlier (*33*). Compounds **4**, **8**, and **10** were prepared as described earlier (*33*−*36*).

4,4′-Dihydroxyazobenzene (*4*). A mixture of KOH (50 g, 760 mmol), *p*-nitrophenol (10 g, 72 mmol), and water (10 mL) was first heated to 120 °C and left to stand in a heating bath for 1 h. When the temperature slowly rose to 195−200 °C, the reaction vigorously started with the formation of large number of bubbles to give a brown viscous liquid. After the reaction was completed, the mixture was cooled and the products were dissolved in water. This afforded a dark red solution, which was acidified to pH 3 with concentrated HCl and extracted with ethyl acetate. Combined ethyl acetate extracts were dried over anhydrous Na_2SO_4 and removed to dryness under reduced pressure. Residue was recrystallized several times with distilled ethanol to give yellow crystals of **4** (*35*). The isolated yield was 4.0 g (43%). IR (cm^{-1}): 1600. ^1H NMR (300 MHz, DMSO-d_6) δ (ppm): 6.9 (d, $J = 9$ Hz, 4H), 8.2 (d, $J = 9$ Hz, 4H). ESI MS (positive ions): *m*/*z* calcd. 215.2 $[M + H]^+$, found 215.2 $[M + H]^+$.

4,4′-Bis(1-(carbomethoxy)methoxy)azobenzene (*5*). Methyl bromoacetate (1.2 mL, 13.0 mmol) was added to a mixture of 4,4′-dihydroxyazobenzene (0.8 g, 3.8 mmol), K_2CO_3 (5.4 g, 26.0 mmol), and 18-crown-6 (0.12 g, 0.46 mmol) in dry acetone (20 mL), and the mixture was refluxed for 15 h. The reaction mixture was then cooled to room temperature, filtered, and evaporated. The residue was dissolved in ethyl acetate, washed with water, and dried over anhydrous $MgSO_4$. The solvent was removed to dryness, and the crude product was purified by column chromatography over silica gel using EtOAc/hexane eluent (20:80) followed by EtOAc/hexane (30:70). This furnished 1.0 g of **5** as a yellow-colored solid (75%). IR (cm^{-1}): 1756.8, 1598.7. ^1H NMR (300 MHz, $CDCl_3$) δ (ppm): 3.83 (s, 6H), 4.7 (s, 4H), 7.01 (d, $J = 8.7$ Hz, 4H), 7.88 (d, $J = 9.0$ Hz, 4H). ESI MS (positive ions): *m*/*z* calcd. 359.4 $[M + H]^+$, found 359.4 $[M + H]^+$.

4,4′-Bis(1-(carboxylic acid)methoxy)azobenzene (*6*). Compound **5** (1.0 g, 2.8 mmol) was dissolved in 20 mL THF. A solution of 2.2 g (56 mmol) of NaOH in 50 mL water was added into the above solution and the mixture was heated under reflux for 2 h. Then, THF was removed under reduced pressure, and the remaining solution was cooled and acidified with 0.5 N HCl. The yellow solid that precipitated was filtered and dried over anhydrous P_2O_5. This furnished 0.74 g of acid, **6** (80% yield). IR (cm^{-1}): 3438.5, 1734.6, 1707.6, and 1600.6. ^1H NMR (300 MHz, DMSO-d_6) δ (ppm): 4.8 (s, 4H), 7.08 (d, $J = 9$ Hz, 4H), 7.82 (d, $J = 9.3$ Hz, 4H). ESI MS (positive ions): *m*/*z* calcd. 330.27 $[M]^+$, found 330.2 $[M]^+$.

4,4′-Bis(1-(chlorocarbonyl)methoxy)azobenzene (*7*). Compound **6** (150 mg, 0.5 mmol) was dissolved in 5.0 mL dry THF and into that 15 mL of distilled $SOCl_2$ was added under ice−cold condition. The reaction mixture was refluxed for 3 h. After that, both solvent and $SOCl_2$ were evaporated under vacuum. This resulted in the formation of a gummy acid chloride in ∼70% isolated yield. The acid chloride was directly used in the next step. IR (cm^{-1}): 1758.8, 1599.6.

4,4′-Bis[(1-carboxamide-*N*-2-2-[(2-aminoethyl)(methyl)amino[(1-methyl-4[(1-methyl-4[(1-methyl-4 [(1-methyl-1*H*-pyrrol-2-yl)carbonyl]amino-1*H*-pyrrol-2-yl)carbonyl]amino-1*H*-pyrrol-2-yl)carbon-yl]amino-1*H*-2-pyrrolecarboxamide]methoxy)azobenzene (*1*). The distamycin derivative, **Dist-1**, (0.6 g, 1.1 mmol) was dissolved in 15 mL of dry THF, and into it, 150 μL of *N*,*N*′-diisopropyl-*N*-ethylamine (DIEA) (0.9 mmol) was added. Acid chloride, **7**, (100 mg, 0.3 mmol) was dissolved in dry THF and added slowly into the above solution. The reaction mixture was stirred at room temperature for 4 h. The solvent was evaporated and the reaction mixture was adsorbed in neutral Al_2O_3 and eluted with $CHCl_3$ followed by MeOH/$CHCl_3$ (2:98) mixture. This furnished **1** as a yellow solid (0.2 g) in 53% isolated yield. ^1H NMR (300 MHz, DMSO-d_6) δ (ppm): 2.23 (s, 6H), 2.49 (s, 8H), 3.78, 3.83, 3.84, 3.87 (s, 12H), 4.56 (s, 4H), 6.04 (dd, $J_1 = 2.4$ Hz, $J_2 = 4.0$ Hz, 1H), 6.86 (m, 1H), 6.9−6.94 (m, 2H), 7.03 (bs, 2H), 7.07−7.1 (dd, 4H, $J_1 = 8.7$ Hz), 7.163 (bs, 1H), 7.22 (bs, 2H), 7.77−7.8 (dd, 4H, $J_1 = 8.7$ Hz), 9.8, 9.86, 9.9 (bs, 8H). ^{13}C NMR (125 MHz, DMSO-d_6) δ (ppm): 36.1, 42.0, 55.96, 72.52, 104.2, 104.73, 106.68, 108.16, 112.66, 115.3, 117.9, 118.45, 121.25, 122.2, 122.8, 124.1, 125.45, 126.32, 128.16, 145.56, 161.3, 163.2, 164.6, 167.22, 168.7, 169.88; ESI MS (positive ions): *m*/*z* calcd. 1475.58 $[M]^+$, 738.3 $[(M + H)/2]^+$, found 1475.6 $[M]^+$ (20%), 738.6 $[(M + H)/2]^+$, (100%). Anal. Calcd. for $C_{74}H_{86}N_{22}O_{12}.H_2O$: C, 59.5; H, 5.94; N, 20.63. Found: C, 59.1; H, 6.3; N, 20.3.

Azobenzene 4,4′-Dicarboxylic Acid (*8*). *p*-Nitrobenzoic acid (15 g, 67.5 mmol) and NaOH (50 g, 1.25 mmol) were mixed in water (225 mL), and the solution was heated on a water bath until the solid dissolved; hot aqueous glucose (100 g in 150 mL of water) was then added slowly into the above mixture at 50 °C whereupon a yellow precipitate was obtained, which immediately changed to a brown solution upon further addition of glucose. This reaction was highly exothermic. Then, a stream of air was passed into the mixture for 3 h and a light brown precipitate was obtained. This was filtered, dissolved in water, and acidified with acetic acid (25 mL) whereupon a light pink precipitate was obtained. This was filtered, washed with plenty of water (300 mL), and dried in a desiccator to obtain **8** (yield 9 g, 80%) as a brownish orange powder (*36*). ^1H NMR (300 MHz, DMSO-d_6) δ (ppm): 8.15 (d, 4H, $J = 8.7$ Hz), 7.99 (d, 4H, $J = 8.7$ Hz).

Azobenzene 4,4′-Dicarbonyl Chloride (*9*). To a suspension of **8** (1 g, 3.7 mmol) in 20 mL of 1,2-dichloromethane was added 2.0 g PCl_5 at 0 °C and then refluxed for 2 h. This afforded bright red crystals, which were filtered and recrystallized repeatedly from toluene to afford **9** (*36*) (0.84 g, 75%). IR (ν, cm^{-1}): 1776.12 (CO) and 1600 (N═N); ^1H NMR (300 MHz, $CDCl_3$) δ (ppm): 8.1 (d, $J = 8.7$ Hz, 4H), 8.32 (d, $J = 8.4$ Hz, 4H).

***N*-Methyldiethylenetriamine-Based Bis-Carboxamido Azobenzene−Distamycin Conjugate (*2*). Dist-1** (0.14 g, 0.30 mmol) was dissolved in 3.0 mL dry THF and into it DIEA (54 μL, 0.18 mmol) was added. Acid chloride, **9**, (18 mg, 0.06 mmol) dissolved in 4 mL dry THF was added slowly into the above solution. The reaction mixture was then stirred at room temperature for 12 h. The solvent was evaporated, and the reaction mixture was adsorbed in neutral alumina and first eluted with $CHCl_3$ followed by a mixture of MeOH/$CHCl_3$ (2:98) mixture. This furnished 0.04 g of **2** as an orange solid in overall 50% yield. ^1H NMR (300 MHz, $CDCl_3$) δ (ppm): 2.4 (bs, 6H), 2.7 (bs, 8H), 3.4−3.45, 3.55 (m, 8H), 3.71, 3.73, 3.86, 3.97 (s, 12H), 6.1 (dd, $J_1 = 2.4$ Hz, $J_2 = 3.6$ Hz, 1H), 6.64 (bs, 2H), 6.71, (bs, 1H), 6.76 (bs, 1H), 6.92 (bs, 2H), 7.1 (bs, 1H), 7.26 (bs, 1H), 7.58 (d, $J = 7.8$ Hz, 4H), 7.7 (d, $J = 8.4$ Hz, 4H). ^{13}C NMR (125 MHz, DMSO-d_6) δ (ppm): 36.5, 56.7, 105.2, 113.1, 118.3, 118.9, 122.6, 123.0, 123.3, 125.9, 126.8, 128.6, 128.9, 152.0, 153.5, 159.2, 162.0, 166.0, 167.22, 168.7, 169.88. ESI MS (positive ions): *m*/*z* calcd. 1415.53 $[M]^+$, found 1415.8 $[M]^+$. Anal. Calcd. for $C_{72}H_{82}N_{22}O_{10}.H_2O$: C, 60.32; H, 5.91; N, 21.49. Found: C, 59.9; H, 6.27; N, 21.1.

Azasuccinimidyl-1-methyl-4-[(1-methyl-4-nitro-1*H*-2-pyrrolyl)carbonyl]amino-1*H*-2-pyrrolecarboxylate (*11*). 1-Methyl-4-[(1-methyl-4-nitro-1*H*-2-pyrrolyl)carbonyl]amino-1*H*-2-pyrrole carboxylic acid **10** (0.15 g, 0.36 mmol) was dissolved in DMF (1 mL) and cooled in an ice bath. *N*-Hydroxysuccinimide (54 mg, 0.47 mmol) was added into the solution followed by dicyclohexyl carbodiimide (100 mg, 0.47 mmol). The

resulting solution was stirred for 1 h, first at 0 °C and then at room temperature for another 6 h. The precipitated dicyclohexyl urea was filtered off, and the filtrate was diluted with EtOAc. The EtOAc and DMF were evaporated under vacuum to obtain the succinimide ester of pyrrole carboxylic acid derivative **11** as a pure solid. The isolated yield was 0.15 g (80%). However, the product was found to be hydrolytically very unstable, and due to this, the product **11** was directly used for the next step without further purification.

2-*tert*-Butoxycarbonylamino-1-aminoethane (*12*). Ethylene diamine (3.35 mL, 50 mmol) was dissolved in dry THF and cooled in an ice bath. Triethyl amine (1.74 mL, 12.5 mmol) was added into it followed by dropwise addition of di *t*-butyl dicarbonate (2.7 g, 12.5 mmol). The reaction mixture was stirred for 12 h at room temperature. After that, the solvent was removed by rotary evaporation and the resultant mass was dissolved in ethyl acetate. The EtOAc layer was washed successively with 5 mL water and 5 mL brine and dried over anhydrous Na_2SO_4. The resultant solution was evaporated and adsorbed in neutral alumina column. It was first eluted with $CHCl_3$, followed by (1:99) MeOH/$CHCl_3$ mixture to obtain **12** as a pure solid. The isolated yield was 1.5 g (75%). ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 1.45 (s, 9H), 1.98 (bs, 2H), 3.16−3.21 (q, $J_1 = 5.4$ Hz, $J_2 = 5.1$ Hz, 2H), 5.03 (bs, 2H).

***N*-2[*tert*-Butoxycarbonylamino-1-aminoethane[1-methyl-4-[(1-methyl-4-nitro-1*H*-pyrrol-2-yl) carbonyl]amino-1*H*-2-pyrrole carboxamide (*13*).** A solution of **11** (0.2 g, 0.4 mmol) in dry THF was added dropwise into a solution of 12 (0.072 g, 0.45 mmol) in THF at room temperature. A catalytic amount of triethylamine was added and the resulting mixture was stirred at room temperature for 4 h. At the end of 4 h, the solvent was evaporated and directly adsorbed on silica. The resulting mixture was purified by eluting column with $CHCl_3$ followed by MeOH/$CHCl_3$ (3:97) mixture. This yielded 0.13 g of **13** (60%). ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 1.44 (s, 9H), 3.35−3.5 (m, 4H), 3.71, 3.82, 3.91 (s, 9H), 6.54 (s, 1H), 6.7 (s, 1H), 7.22 (bs, 2H), 7.6 (s, 2H), 7.74, 7.77, 8.12, 8.2 (bs, 4H). ESI MS (positive ions): *m*/*z* calcd. 556.7 $[M]^+$, found 557 $[M]^+$.

***N*-2[*tert*-Butoxycarbonylamino-1-aminoethane[1-methyl-4-[(1-methyl-4-[bromoethanamido]-1*H*-pyrrol-2-yl)carbonyl]amino-1*H*-2-pyrrolecaroboxamide (*14*).** 200 mg (0.36 mmol) of **13** was dissolved in 1.5 mL of dry DMF and hydrogenated over 90 mg of Pd/C (5%) for 20 h at room temperature. The catalyst, Pd/C, was filtered off and the residue was washed twice with 1 mL each of dry DMF. The combined filtrate and washings were collected together and mixed with 0.3 mL (1.7 mmol) of DIEA and was cooled to 0 °C. To this solution, 0.1 mL (1.0 mmol) of bromoacetyl bromide was added, and the resultant solution was stirred for 2 h at 0 °C and then at room temperature for 8 h. At the end of this period, the reaction mixture was washed with water and extracted with ethyl acetate. The crude reaction mixture obtained upon evaporation of ethyl acetate was adsorbed on silica gel and purified by column chromatography upon elution with $CHCl_3$ followed by MeOH/$CHCl_3$ (4:96) mixture. The product was isolated as a yellow solid. The isolated yield was 93 mg (40%). ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 1.4 (s, 9H), 3.3−3.45 (m, 4H), 3.83, 3.85, 3.87 (s, 9H), 3.96 (s, 2H), 6.54 (bs, 2H), 6.7 (s, 1H), 7.1 (s, 1H), 7.21 (bs, 2H), 8.2, 8.5, 8.63 (bs, 4H). ESI MS (positive ions): *m*/*z* calcd. 669.0 $[M + Na]^+$, 671.0 $[M + Na]^+$; found 669.2 $[M + Na]^+$, 671.2 $[M + Na]^+$.

***N*-2[*tert*-Butoxycarbonylamino-1-aminoethane[1-methyl-4-[(1-methyl-4-[dimethylaminoethanamido]-1*H*-2-pyrrolyl) carbonyl]amino-1*H*-2-pyrrolecarboxamide (*15*).** Compound **14** (0.05 g, 0.08 mmol) was dissolved in dry MeOH, the solution was cooled in an ice−water bath, and excess dimethylamine gas was passed into it in a screw-top pressure tube. The resultant mixture was then heated at 70 °C for 12 h. Excess dimethylamine was evaporated, and the residual mass was dissolved in ethyl acetate, washed with saturated $NaHCO_3$ solution, water and brine, and finally dried over anhydrous Na_2SO_4. The gummy mass obtained upon evaporation of solvents was purified by column chromatography on alumina using $CHCl_3$ followed by MeOH/$CHCl_3$ (2:98) mixture as eluent. This afforded **15** as a gum (35 mg, 75%). ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 1.4 (s, 9H), 2.3 (s, 6H), 3.05 (s, 2H), 3.3 (m, 2H), 3.45 (m, 2H), 3.84, 3.87, 3.9 (three s, 9H), 6.56 (s, 1H), 6.6 (s, 1H), 6.9 (s, 1H), 7.0 (s, 1H), 7.16 (s, 1H), 7.22 (s, 1H), 5.3, 6.8, 8.03, 8.16, 8.94 (bs, 5H). Photoisomerization and UV−vis Analysis. Photoillumination of ligand **1** was carried out using a xenon lamp 450 with light intensity of ca. 40 W, which transmitted light around 360 nm. On the other hand for carboxamido substituted ligands **2** and **3**, photoillumination was done using a water-cooled high-pressure 250 W Hg lamp that transmitted light between 320 and 380 nm after passing through a set of bandpass chemical filters (*37*). The rate of isomerization was measured spectrophotometrically for each ligand (**1**, **2**, and **3**) in DMSO at a given concentration on a UV−vis spectrophotometer at 25 °C. Such spectral analysis as a function of time gave the approximate time required for reaching the photostationary state from each of the azobenzene−distamycin conjugates.

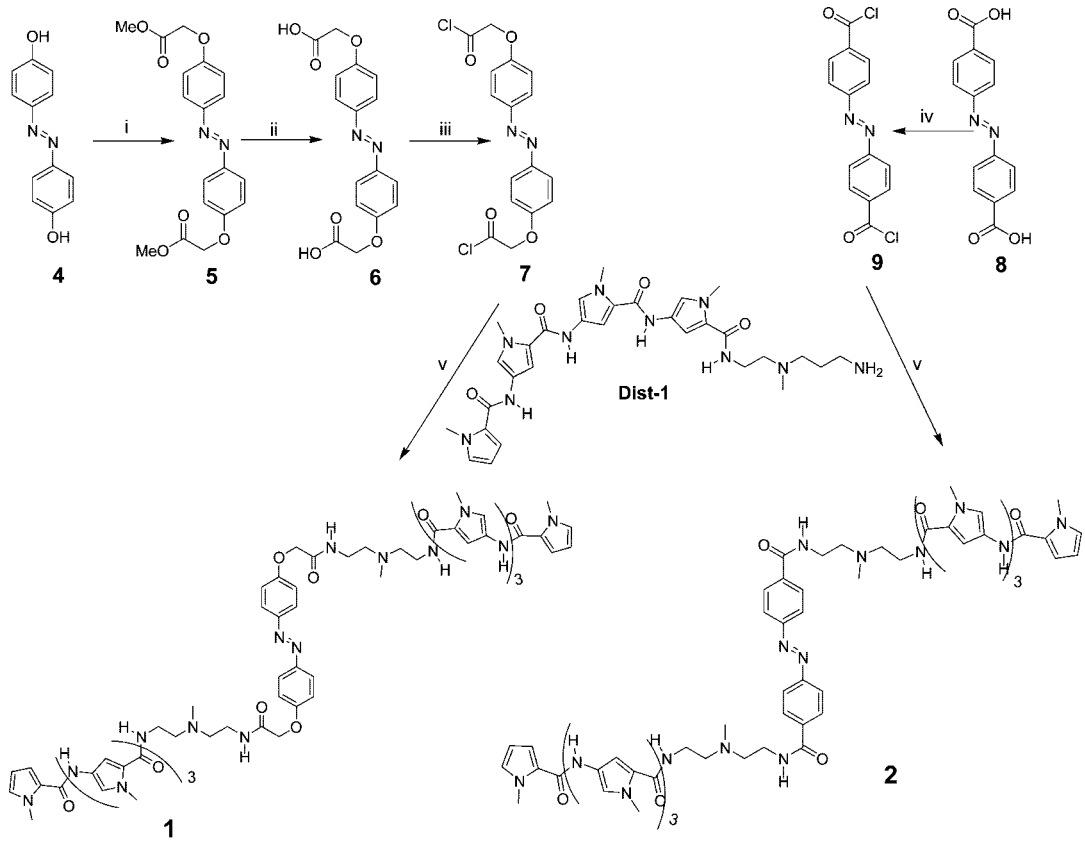
^{1}H NMR Spectroscopy. ^{1}H NMR experiments with each ligand for configurational analysis were carried out at 25 °C using a 300 MHz spectrometer. Individual samples of around 1 mM concentration were taken in d_6-DMSO, and the corresponding changes in the molecular configuration after photoillumination were determined by recording ^{1}H NMR spectros-

Scheme 1[a]



[a] Reagents, conditions, and yields. (i) Methyl bromoacetate, K_2CO_3, 18-crown-6, acetone, reflux, 14 h, 75%; (ii) 0.5 N NaOH, THF, reflux, 2 h, followed by acidification with 0.5 N HCl, 90%; (iii) $SOCl_2$, THF, reflux, 3 h, 90%; (iv) PCl_5, $ClCH_2CH_2Cl$, reflux 2 h, 75%; (v) DIEA, THF, RT, 4 h, 50%.

copy. Integration of the respective azobenzene protons allowed quantitative determination of the percentage of trans and cis forms of each sample in their photostationary states.

Circular Dichroism Spectroscopy. CD spectra were recorded on a spectropolarimeter equipped with a temperature controller. The experiments were performed in NaCl buffer (150 mM NaCl, 0.01 M Tris-HCl, 0.1 mM EDTA buffer at pH 7.4) using 20 μM duplex poly[d(A-T).d(T-A)] with or without the azobenzene−distamycin conjugates at 25 °C. All CD titrations were averaged over two acquisitions and the scan rate was maintained at 50 nm/min with optical cells of path length of 1 cm. Titration was performed under dark and utmost care was taken to minimize the isomerization of azobenzene−distamycin hybrids. The CD values were expressed in millidegree. The changes in ICD intensity at 336 nm were plotted against [ligand]/[DNA] ratio to obtain the concentration of conjugate required to saturate the ds-DNA binding.

Melting Temperature Measurements. The thermal stability of each ligand/ds-DNA complex was assessed from thermal denaturation studies. Using a UV−vis spectrophotometer equipped with a temperature-programmable cell block, the changes in absorbance at 260 nm were followed as a function of temperature. The samples were heated at 0.5 °C/min, and the absorbance values were recorded for every 0.5 °C rise in temperature. All T_m experiments were carried out in NaCl buffer at saturated [ligand]/[DNA] ratios.

Minor Groove-Bound Hoechst Displacement Assay. First, 0.25 μM Hoechst was taken in NaCl buffer and various aliquots of concentrated poly[d(A-T).d(T-A)] solutions were added progressively to saturate Hoechst binding on duplex DNA surface. The fluorescence intensity of Hoechst 33258 increased on binding with duplex poly[d(A-T).d(T-A)]. Each azobenzene−distamycin conjugate was then added individually into saturated solution of the Hoechst−DNA complex, and the displacement of Hoechst from ds-DNA was measured from a decrease in the fluorescence emission intensity at 464 nm (λ_{ex} = 355 nm) at 25 °C. Titration was performed under dark and care was taken to minimize the isomerization of azobenzene−distamycin conjugates. The apparent binding constant (K_{app}) has been calculated as $K_a = K_{app}[L_{50}]$, where K_a indicates the binding constant of Hoechst, which was found to be 1.5×10^7 M^{-1} by Scatchard analysis (*38*) with poly[d(A-T).d(T-A)] in NaCl buffer, and $[L_{50}]$ is the concentration of individual ligand achieving 50% quenching of DNA-bound Hoechst fluorescence.

Computational Details. All the bis-alkoxy and bis-carboxamido substituted azobenzene−distamycin conjugates (**1**−**3**) and **Dist-1** and **Dist-2** analogues were optimized at the HF/3−21G level of theory using *Gaussian 03* (*39*). Single point energies are obtained for the model azobenzenes **17** and **18** at the MP2/6−31+G* level of theory. The Mülliken atomic charges of the optimized ligands (**1**−**3**) obtained from the calculation at the HF/3−21G level of theory are used for docking studies. A nucleotide sequence of $d[GC(AT)_{10}CG]_2$ was generated from the nucgen program of *AMBER 8* (*40*) instead of poly[d(A-T).d(T-A)] DNA. The B-form of DNA built by this procedure is assigned with AMBERff03 force field (*41*) and minimized for 250 steps by steepest decent algorithm and a further 250 steps by the conjugate gradient method to remove the bad strains in the DNA. The modeled ds-DNA was then docked with the optimized ligand structures using AUTODOCK 3.05 version (*42*, *43*). The center of the macromolecule is the grid center with grid size of 80 × 80 × 126 and grid spacing of 0.4186 Å. Docking runs were performed using the Lamarckian genetic algorithm (LGA) with some modifications of the docking

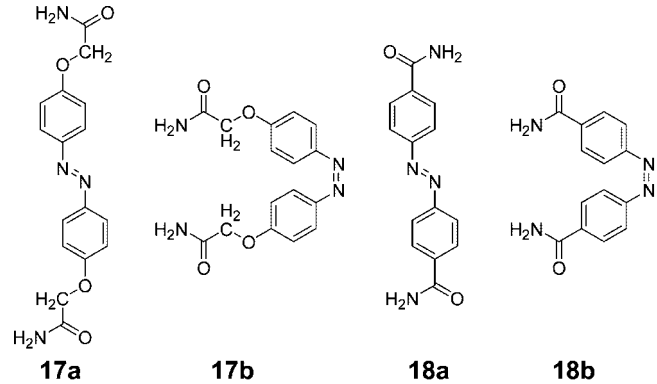
parameters. LGA was used because of the existence of 32−48 rotable bonds in these conjugates and to evaluate the right conjugate−DNA conformation, as it is known to reproduce various experimental ligand−DNA complex structures (*44*−*46*). Docking began with rigid docking of the initial Gaussian optimized structures. Docking of each ligand was derived from 20 different runs that were set to be obtained after a maximum of 500 000 energy evaluations or 25 000 000 generations, to give 20 conformations. The probability that docking solution in the population would undergo a local search was set to 0.06 and the constraint was set to a maximum of 300 iterations per search. The size of local search space (rho) was set to 1.0−0.01. A pseudo-Solis and Wets local search was then used to minimize

Scheme 3. Structures of the Trans and Cis Isomers of Model Azobenzenes 17 (Alkoxy Substituent) and 18 (Carboxamido Substituent)



energy of the population where the population size was set to 50. The elitism number and the rates of gene mutation and gene crossover were 1, 0.02, and 0.08, respectively. The flexible docking procedure was repeated until substantial interactions of the extended binding mode of ligand with DNA were

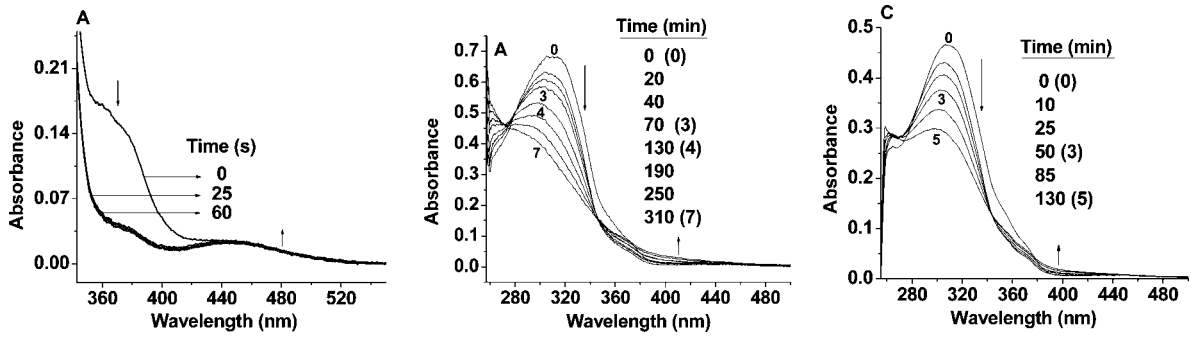


Figure 2. Changes in the absorption spectra of a solution of **1** in DMSO (12 μM, A), **2** (10 μM, B), and **3** (10 μM, C) upon photoillumination at appropriate λ values. Arrows indicate the nature of changes in the observed absorption region of $\pi-\pi^*$ and $n-\pi^*$ transitions of the azobenzene units, respectively.

obtained. Further, the lowest dock conformation obtained from the flexible docking was again submitted for rigid docking to remove the internal energy of ligand (steric clashes) and retain the hydrogen bonding interaction with ds-DNA bases.

RESULTS AND DISCUSSION

Synthesis. The key starting material **Dist-1** for the synthesis of **1** has been obtained following a procedure described earlier (*19*, *33*). The synthesis of **1** began with the alkylation of 4,4′-dihydroxy azobenzene, **4**, with 3.5 equiv of methyl bromoacetate in acetone under reflux conditions as summarized in Scheme 1. The dimethyl ester, **5**, was saponified and then converted to the corresponding acid chloride, **7**. This was then directly used for coupling with 4 equiv of **Dist-1** in dry THF in the presence of Hünig's base at room temperature to furnish **1** as a yellow solid in 50% isolated yield (Scheme 1).

The other starting material azobenzene 4,4′-dicarboxylic acid, **8**, and the corresponding azobenzene 4,4′-dicarbonyl chloride, **9**, were prepared according to the reported procedures (*35*). The synthesis of **2** was accomplished by amide bond formation between the amine tethered distamycin derivative, **Dist-1** (~4 equiv) and **9** in THF at room temperature (Scheme 1). The reaction mixture was chromatographically purified to furnish **2** as an orange solid in 50% isolated yield.

The synthesis of **3** began with tri-*N*-methylpyrrole based nitro acid, **10**, which was synthesized according to a reported procedure (*34*) The acid functionality was activated as NHS ester, **11**, and then directly coupled with **12** in dry THF at room temperature to furnish **13** in ~60% isolated yield. The nitro group present at the N-terminus of the oligopeptide derivative was hydrogenated over Pd/C (5%) in dry DMF followed by capping of the amine functionality by bromoacetyl bromide. The reactive bromide at the N-terminus of the oligopeptide derivative was coupled with dimethyl amine under reflux condition for 12 h to obtain **15**. The *tert*-butoxycarbonyl group present at the C-terminus of oligopeptide was deprotected using TFA to furnish primary amine, **16** (**Dist-2**). Then, ~4 equiv of **16** was directly used for coupling with **9** in dry THF at room temperature to afford **3** in 40% isolated yield (Scheme 2).

Optimized Ligand Structures. The conjugates (*1*−*3*) can give rise to many conformations, which arise due to the change in the dihedral angle around the central C−N═N−C bond of azobenzene. Among various possible conformational isomers, we have calculated the two most significant conformations, cis and trans, at the HF/3−21G level of theory using the *Gaussian 03* program package (*39*). The optimized structures of these ligands are shown in Figure 1. The letters "a" and "b" after structure number indicate trans and cis isomer, respectively. The trans isomers are found to be more stable compared to their respective cis isomers for all the ligands (Table 1). The order of relative stability of the trans isomers with respect to the corresponding cis isomers is **1** (−13.1 kcal/mol) < **3** (−15.4

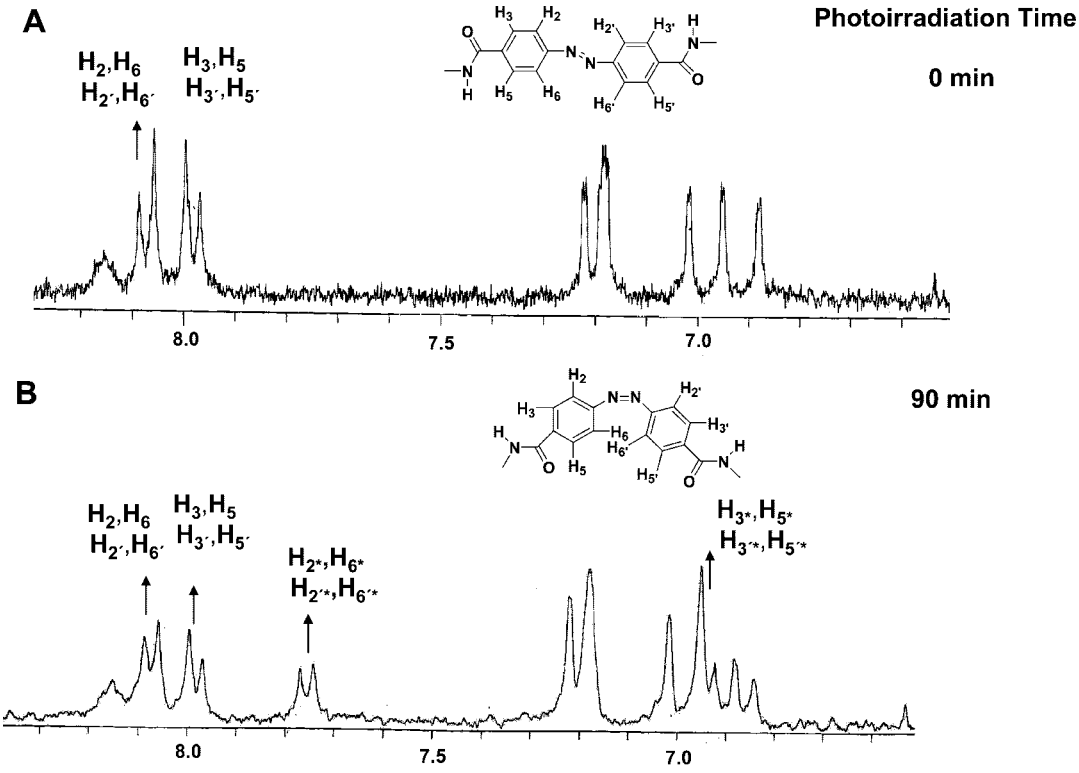

Figure 4. ^{1}H NMR spectra of a d_6-DMSO solution of **3** (1 mM) before (A) and after (B) 90 min of photoillumination at ∼330 nm. Chemical shifts of the respective azobenzene protons before and after irradiation are indicated with respect to TMS as standard. The symbol * refers to the sample after irradiation.

kcal/mol) < **2** (−18.6 kcal/mol). The ligands **1** and **2** feature long linker based **Dist-1**, and ligand **3** has short linker based **Dist-2** (Table 1). It shows that, for a constant linker length, trans isomers are relatively more stable for the electron-withdrawing bis-carboxamido-substituted azobenzenes **2** and **3** as compared to the electron-donating bis-alkoxy-substituted azobenzenes, **1** (Table 1).

In order to understand the electronic effect of the bis-carboxamido versus bis-alkoxy substituents, model azobenzenes **17** and **18** are studied. Structure **17** has OCH_2CONH_2 and structure **18** has $CONH_2$ substituents at the para position to mimic ligands **1** and **2** (or **3**), respectively, (Scheme 3). The trans isomers **17a** and **18a** are more stable in comparison to their respective cis isomers **17b** and **18b** by 11.0 and 12.3 kcal/mol, respectively, at the MP2/6−31+G* level of theory (Table 1). Thus, the trend in the relative energies for ligand **1** is also retained in the model azobenzenes **17** and **18**. This indicates that the bis-carboxamido substituents can stabilize the trans isomer more than the bis-alkoxy substituents.

The azobenzene moiety in the trans isomer is planar, but deviation from planarity is ∼50° in the cis isomer. As a result, the stabilization of the azobenzene π-orbital due to the delocalization in the substituents can only be observed in the trans isomer. The carboxamido group stabilizes the π-molecular orbital of the azobenzene in the trans isomer **18a** by 0.87 eV as compared to the trans isomer **17a** having an alkoxy group. This supports the greater stability of the trans isomers (**2a**, **3a**) of the carboxamido-substituted ligands over the trans isomer (**1a**) of alkoxy-substituted ligands.

Photoisomerization of the Ligands in Solution. As anticipated, the distamycin−azobenzene conjugates photoisomerize upon light illumination. Detailed investigation of the isomerization of azobenzene is important in order to know the composition of the trans and cis isomeric forms at the photostationary state. Accordingly, we followed this for each conjugate by UV−visible and ^{1}H NMR spectroscopy.

UV−vis Analysis. The isomerization process was assessed by irradiation of the distamycin−azobenzene conjugate **1** (12 μM) in DMSO solution at 360 nm (Figure 2A). Upon photoillumination, the absorption band intensity at ∼365 nm due to $\pi-\pi^*$ transition decreased with a considerable blue shift, while the band due to n−π^* transition at ∼450 nm increased. According to previous studies (*35*), the absorption band around 360 nm is due to the trans form of the azobenzene moiety, while that around 450 nm is ascribed to the *c*is form. Therefore, the irradiation indicates transformation of the trans azobenzene to the cis azobenzene moiety. This process continued over a period up to 60 s until the photostationary state was reached. Similarly, photoisomerization studies were individually conducted on 10 μM solution of compounds **2** and **3** in DMSO by UV−vis spectroscopy upon photoillumination at ∼330 nm. In both cases, the distamycin band appeared at ∼306 nm overlapped with the 330 nm $\pi-\pi^*$ absorption band of the −N═N− group, and a less intense n−π^* band appeared at around 370 nm (Figure 2B,C). During photoisomerization, the $\pi-\pi^*$ absorption bands for both ligands at 330 nm decreased along with the distamycin absorption band at ∼306 nm. For compound **2**, all curves passed through common points at 280 and 346 nm during 1 h irradiation (Figure 2B). Irradiation for a period longer than 1 h shifted the common point at 280 to 274 nm. Importantly, throughout the isomerization process, each sample maintained an apparent isosbestic point at ∼346 nm, and monotonous absorption enhancement was observed for the n−π^* transition at ∼380 nm. Photoillumination beyond 5 h, however, resulted in a loss of isosbestic point at 346 nm. So, photoisomerization might have led to different isomerized products that remain in an apparent equilibrium. Similarly, photoillumination of a 10 μM DMSO solution of conjugate **3** up to ∼130 min resulted in both a decrease and blue shift of the $\pi-\pi^*$ absorption intensity at ∼308 nm and enhancement of the n−π^* absorption band intensity at ∼370 nm via an apparent isosbestic point at ∼343 nm as shown

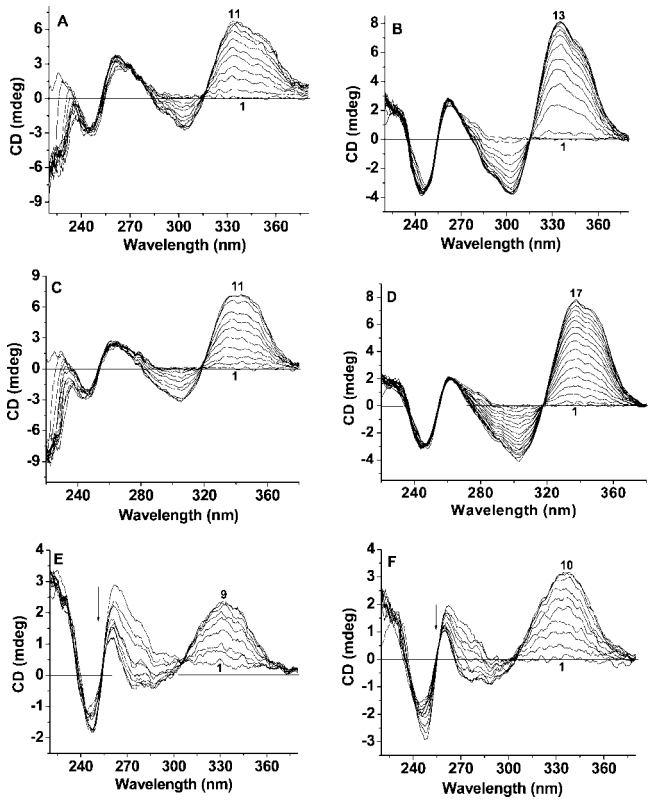

Figure 5. CD titration curves due to **1** in trans form (A), **1*** in cis form (B), **2** in trans form (C), **2*** in ~8/2 (trans/cis) isomeric form (D), **3** in trans form (E), **3*** in ~8/2 (trans/cis) isomeric form (F) carried out with 20 μM poly[d(A-T).d(T-A)] in 10 mM Tris-HCl, 150 mM NaCl, 0.1 mM EDTA at pH 7.4 at 25 °C. For all the panels, trace 1 corresponds to the CD spectrum of poly[d(A-T).d(T-A)] DNA alone. Addition of DNA enhances the ICD band at ~334 nm. Traces 9−11, 13, and 17 signify the corresponding saturation at a given [ligand]/poly[d(A-T).d(T-A)] ratios. No significant change in DNA band was observed for panels A to D upon ligand addition into a given DNA solution. In panels E and F, the down arrow indicates the decrease in DNA band with increasing ligand concentration.

in Figure 2C. Overall, the ligand **3** required ~2 h to reach the photostationary state.

Photoisomerization followed by ^{1}H NMR Spectroscopy. ^{1}H NMR spectroscopy is a very useful technique to determine the cis and trans composition of the ligands in the photostationary state. The changes in ^{1}H NMR spectra of 1 mM solution of **1**, **2**, and **3** in d_6-DMSO upon photoillumination at the respective wavelengths, after periodic time intervals of irradiation, are shown in Supporting Information Figure S4 and Figures 3 and 4. Irradiation of **1** for ~10 min completely shifts 3,3′,5,5′-*H*s (meta protons of azobenzene at ~7.1 ppm) and 2,2′,6,6′-*H*s (ortho protons of azobenzene at ~7.8 ppm) upfield at ~6.8 and ~6.86 ppm, respectively (Supporting Information Figure S4) as verified from reported observations (*35*). Compound **1** required ~10 min to reach the photostationary state with ~100% cis isomeric form. Similarly, upon photoillumination for ~1 h for symmetrical carboxamido-substituted azobenzene derivative, **2** the downfield protons of the azobenzene unit at ~7.9 ppm and ~8.0 ppm shifted upfield as doublets at ~7.7 ppm and ~6.9 ppm, respectively (Figure 3). Analysis of the integration after 3.5−4 h of irradiation revealed that only ~20% of the trans form has been converted into the cis form in the photostationary state. Similar characteristic features were also seen with the carboxamido ligand, **3** (Figure 4). However, unlike in **2** here the photostationary state was reached after 1.5 h, with a composition of ~8:2 (trans/cis) form.

The electronic character of the azobenzene in **1** is different from that in **2** and **3**. In **1**, the substituent is electron-donating, whereas in **2** and **3**, the substituent is electron-withdrawing. It is known both experimentally (*47, 48*) and theoretically (*49, 50*) that the electron-donating substituents render azobenzene susceptible to ready photoisomerization. The nature of spacer that connects distamycin with the azobenzene nucleus is also important. Thus, in **2**, the spacer is protonated, while in **3**, the sites of protonation are at the termini of the oligopeptide chains and not at the spacer unit. This explains why the isomerization is slower in **2** compared to **3**.

DNA Binding Properties. In order to assess the duplex DNA binding properties of each of these conjugates, circular dichroism spectroscopy, thermal melting, and Hoechst displacement assay were employed. For CD experiments, we carried out titration by adding different photoisomeric forms of each conjugates into the fixed (20 μM) poly[d(A-T).d(T-A)] solution in NaCl buffer, and the respective results are shown in Figure 5. The DNA binding properties of these conjugates were investigated starting with 4,4′-substituted bis-alkoxy derivative, **1** and **1***, to the bis-carboxamido-substituted long spacer based **2** and **2*** and short spacer based **3** and **3*** azobenzene−distamycin conjugates (where * indicates the photoirradiated form of the ligands at their respective photostationary states). To understand the mode of binding of azobenzene−distamycin conjugates with duplex DNA, the strength of ligand−DNA interactions were also assessed using molecular docking studies.

A. Circular Dichroism Spectral Titrations. We used circular dichroism spectroscopy to characterize the binding of azobenzene−distamycin conjugates both in their ground state and photoirradiated form to the duplex poly[d(A-T).d(T-A)]. Figure 5A−F shows the circular dichroism spectra from 220 to 380 nm obtained by incremental addition of individual conjugates into the fixed poly[d(A-T).d(T-A)] solution. CD measurements of each ligand with poly[d(A-T).d(T-A)] yielded a set of curves showing two pairs of bands. The intense negative and positive bands observed at 245 and 260 nm arise from the DNA molecule (intrinsic CD). The negative and positive CD bands centered at 303 and 336 nm arise solely from the induction of optical activity of the DNA-bound nonchiral azobenzene−distamycin hybrid molecule (extrinsic or induced CD) (*50*). The induced CD (ICD) values at 336 nm were plotted with the increase [ligand]/[DNA] ([D]/[P]) ratio to evaluate the extent of ligand−DNA interaction and saturation [D]/[P] ratio.

The parent distamycin derivative, **Dist-1**, required a [D]/[P] ratio of 0.2 to "saturate" DNA binding on its minor grooves. This corresponds to 2:1 binding mode, where two **Dist-1** ligands occupy five base pairs along the DNA minor groove (*21*).

During CD titration, there exists an equilibrium between the free ligand in solution and ligand bound to duplex DNA. With increasing DNA affinity of the ligand, the concentration of "free ligand" in solution will be lower. On comparing the binding affinity between trans and cis forms of ligand **1** (Figure 5A vs B), we see from the CD titration that the cis form of the ligand requires a lower concentration (saturation point or maximum ICD intensity at [D]/[P] ratio of 0.2) to cover most of the AT-base pairs along the duplex DNA minor groove than the corresponding trans form (saturation point or maximum ICD intensity at [D]/[P] ratio of 0.3) (Figure 6A). This indicates that at a comparable ligand concentration more trans form of ligand **1** remains free in solution as compared to the cis form in the presence of a fixed DNA concentration. This shows that binding of the cis form of ligand **1** is higher than that of the trans form.

An ICD enhancement at 336 nm was also observed with the ~8/2 (trans/cis) isomeric form of **2*** compared to the 100% trans form of **2** (Figure 5C vs D). The CD titration of **2** required ~0.47 [D]/[P] ratio, while ~8/2 (trans/cis) isomeric mixture of

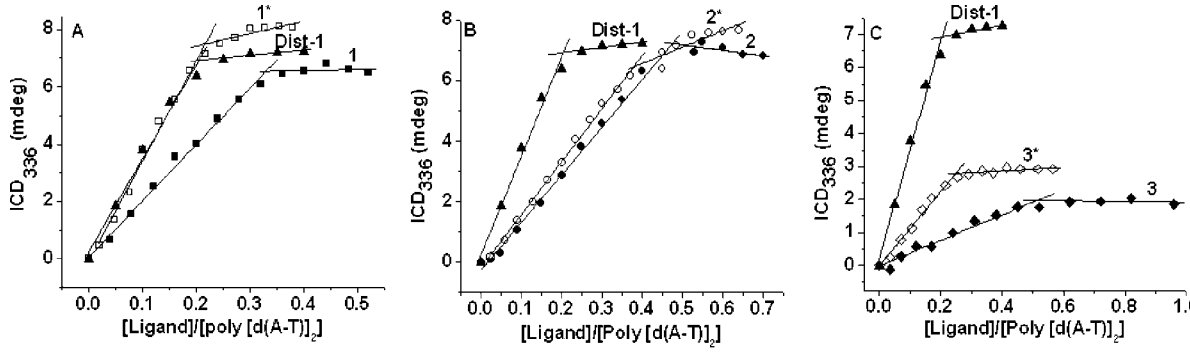

Figure 6. Changes in ICD intensities at 336 nm due to photoisomeric forms of ligands **1** (A), **2** (B), and **3** (C) during titration with 20 μM poly[d(A-T).d(T-A)] in 10 mM Tris-HCl, 150 mM NaCl, 0.1 mM EDTA buffer at pH 7.4 at 25 °C in dark condition. Different isomeric compositions of the ligands are as follows: **1** (∼100% trans), **1*** (∼100% cis), **2** (∼100% trans), **2*** (∼8/2 (trans/cis)), **3** (∼100% trans), and **3*** (∼8/2 (trans/cis)). Distamycin analogue, **Dist-1**, has also been included for comparison.

Table 2. Melting Temperatures (T_m), Apparent Binding Constants (K_{app}), and Saturation [D]/[P] Ratios Obtained from Binding of Dist-1 and Different Forms of 1, 2, and 3 with Poly[d(A-T).d(T-A)]

DNA + ligands	T_m (°C)[a]	ΔT_m (°C)[b]	$K_{app} \times 10^{-5}$ (M^{-1})[c]	[D]/[P]
Poly[d(A-T).d(T-A)] alone	64.7	−		
+ **Dist-1**	67.4	2.7	6.5	0.2
+ **1**	74.0	9.3	7.2	0.3
+ **1***	75.0	10.3	7.4	0.2
+ **2**	81.0	16.3	6.4	0.47
+ **2***	81.9	17.2	7.0	0.37
+ **3**	85.7	21.0	6.8	0.5
+ **3***	86.7	22.0	10.4	0.25

[a] T_m indicates the average melting temperature value of two independent melting experiments that has been done with the complexes of poly[d(A-T).d(T-A)] in the presence of different ligands in 150 mM NaCl, 10 mM Na_2HPO_4, 0.1 mM EDTA, pH = 7.4, at the saturated [D]/[P] ratio. The error is within ±0.2 °C. [b] ΔT_m corresponds to the difference in T_m between DNA alone and DNA−ligand complexes. [c] K_{app} = apparent binding constant obtained from Hoechst displacement assay.

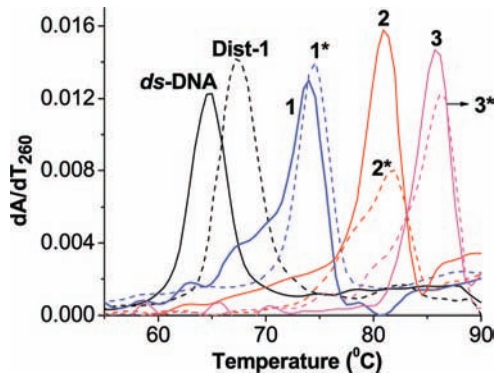

Figure 7. Thermal melting of 20 μM poly[d(A-T).d(T-A)] complexed with various azobenzene−distamycin ligands in NaCl buffer at saturating [D]/[P] ratios. The label of each curve corresponds to DNA: 20 μM poly[d(A-T).d(T-A)]. **Dist-1**: Distamycin analogue, at [D]/[P] = 0.2; **1** and **1*** at [D]/[P] = 0.3 and 0.2; **2** and **2*** at [D]/[P] = 0.47 and 0.37; **3** and **3*** at [D]/[P] = 0.5 and 0.25, respectively.

2* required 0.37 [D]/[P] ratio to saturate ligand binding on DNA minor grooves (Figure 6B). This improvement in ICD intensity and [D]/[P] ratio suggests higher binding of **2*** compared to **2**. A more significant improvement in ICD intensity at 336 nm was observed with the ∼8/2 (trans/cis) isomeric form of **3*** compared to **3** (Figure 5E vs F). The CD titration of 100% trans form of **3** required ∼0.50 [D]/[P] ratio, while ∼8/2 (trans/cis) isomeric mixture of **3*** required only 0.25 [D]/[P] ratio to saturate ligand binding on the DNA minor groove (Figure 6C).

B. Competition for DNA Minor Groove. The apparent binding constants of each ligand toward ds-DNA were evaluated by estimating their efficiency in replacing fully bound Hoechst 33258 from minor grooves of ds-DNA in NaCl buffer. In contrast to CD results, a subtle difference in apparent binding constant values between **1** and **1*** was not apparent from Hoechst displacement assay (Table 2). This is, however, not too surprising, as the binding constant of Hoechst 33258 to the minor groove of ds-DNA is considerably greater than that of distamycin. Interestingly, however, both isomeric forms of **1** rapidly quenched Hoechst fluorescence preferably when 50% of Hoechst was displaced from the duplex DNA minor groove (Supporting Information Figure S5). On the other hand, **2** and **2*** possessed comparable binding constants and manifested a similar type of Hoechst displacement curves (Supporting Information Figure S5). However, a significant difference in ICD intensity observed with **3** and **3*** correlates well with the lower concentration required by **3*** to remove Hoechst from the DNA minor grooves than that of **3**. This fact explains the significant difference in their apparent binding constant values ($K_{app} = 6.8 \times 10^{-5}$ M^{-1} and 10.4×10^{-5} M^{-1}) between the ground and photoisomerized forms of **3** (Supporting Information Figure S5 and Table 2).

C. Influence on DNA Melting. The thermal DNA melting experiment is an important method for the determination of the stability of ligand−ds-DNA complexes. It is known that minor groove binders like distamycin enhance the helix-to-coil transition temperature via recognition of AT-specific bases of ds-DNA (*19*). Here, the thermal denaturation experiments with all ligand−DNA complexes were performed at saturating [D]/[P] ratio in NaCl buffer by following the absorbance change at 260 nm with increase in temperature (Figure 7, Table 2). Importantly, the DNA melting experiment at the saturated [D]/[P] value for each ligand allows us to compare the duplex stability imposed by various alkoxy- and carboxamido-substituted azobenzene distamycin analogues.

The ligand-saturated DNA complexes of both irradiated and non-irradiated solutions of ligand **1** were found to stabilize ds-DNA almost to the same extent. The photoirradiated forms of **1** stabilize ds-DNA by ∼1 °C from that of its ground state. However, they were found to stabilize duplex DNA by ∼7.1 °C more compared to the distamycin analogue, **Dist-1** (Figure 7, Table 2). Such higher T_m for conjugate **1** indicates that a greater number of hydrogen bonding interactions together with other noncovalent interactions (hydrophobic, electrostatic, van der Waals) are responsible for the stabilization of such ligand−DNA complexes. Similarly, the ligand **2** and photoisomerized **2*** stabilized the duplex poly[d(A-T)]$_2$ to 81 and 81.9 °C, respectively, (i.e., by ∼14.5 °C more compared to distamycin analogue, **Dist-1**). The photoisomeric forms of **3** stabi-

Table 3. Free Binding Energies (Δ*G*), Docked Energies, and the Close Contact Distances of Amide Bond of Ligand with DNA Bases Obtained From *Autodock* Calculations of Dist-1, Dist-2, Hoechst, 1, 2, and 3 Ligands with Modeled Duplex [d(GC(AT)$_{10}$CG)]$_2$ DNA[a]

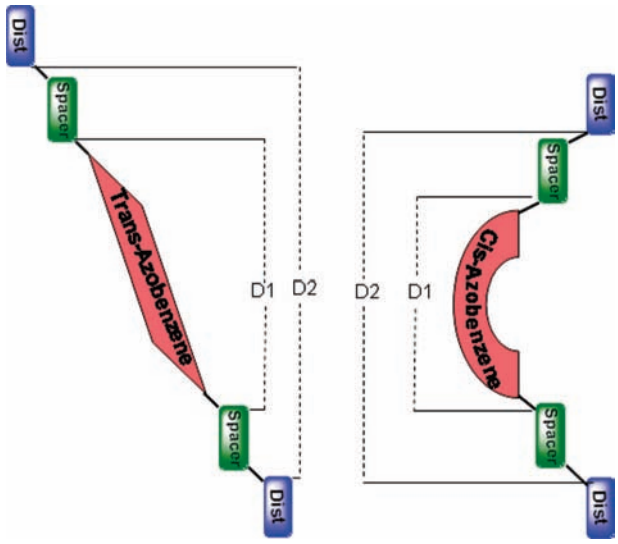
[a] The D1 and D2 are the distances in Å between azobenzene and linker containing azobenzene moiety of the ligands as shown in Scheme 4. [b] The values obtained by rigid docking of the lowest docked conformation of the ligands initially obtained from the flexible docking studies.

Scheme 4. Schematic Representation of D1 and D2 Distances in the trans and cis Azobenzene−Distamycin Conjugates[a]



[a] Here, D1 represents the length of azobenzene, and D2 represents the length of azobenzene along with the spacer.

lized duplex poly[d(A-T).d(T-A)] to 85.7 and 86.7 °C, respectively, and ∼18−19 °C more compared to distamycin analogue, **Dist-1** (Figure 7, Table 2). It may be noted that in all cases the ΔT_m and the apparent binding constants (K_{app}) were higher for the photoirradiated forms of the conjugates even if they were small. Importantly, however, the ΔT_m was always achieved with photoirradiated forms of the conjugates at lower [D]/[P] ratio than the respective trans form.

We have also carried out the melting experiment with duplex poly[d(A-T).d(T-A)] in the presence of each ligand including their photoilluminated forms at a fixed [D]/[P] ratio of 0.5, which bring out the differences between trans and cis isomeric forms more clearly. Thus, at this [D]/[P] ratio of 0.5, while **1** stabilized poly[d(A-T).d(T-A)] by 11.5 °C, **1*** afforded a stabilization of 13.3 °C (Supporting Information Table SI-2). Similarly, under the same conditions, photoisomerized **2***and **3***, respectively, brought about 2.4 °C and >1 °C higher stabilization of poly[d(A-T).d(T-A)] than **2** and **3**. These results demonstrate greater stabilization of DNA by the photoisomerized forms of the distamycin−azobenzene conjugates. Hence, the cis form of the conjugates possess higher affinity toward duplex DNA.

D. Molecular Docking on DNA Duplex. To rationalize the experimental trends quantitatively using molecular modeling, initially a rigid docking of the optimized ligand structures with modeled duplex d[GC(AT)$_{10}$CG]$_2$ DNA were performed by *AUTODOCK* v 3.05 (*42*) However, favorable hydrogen bonding interactions between ligand and DNA bases obtained at this level did not adequately explain the experimental results. So, either one side or both sides of the linker atoms were chosen as rotable units for flexible docking of ligands. Finally, a rigid docking was performed with the lowest docked conformation obtained from the flexible docking studies. Such lowest docked conformations of different ligand−DNA complexes were considered for discussion below. The corresponding docking energies and free binding energies (Δ*G*) of all types of rigid and flexible dock conformations of ligand−DNA complexes are shown in Table 3 and Supporting Information Table SI-1. The docked energies and binding energies obtained from the molecular docking studies correlated well with the thermal melting values, as the stabilization of the overall ligand−DNA complexes is influenced by hydrogen bonding and other noncovalent interactions. The binding energies obtained from PreDICCTA (*52*) by supplying the experimental ΔT_m values were similar to these results.

A rigid docking of the **Dist-1** gave a binding free energy of −7.0 kcal/mol (Table 3). There are four hydrogen bonding contacts between the pyrrole amide bond of **Dist-1** and A/T base pairs of DNA in addition to the other noncovalent interactions with the oxo group of the ribose sugar moiety (Figure 8). The DNA base-pair recognition efficiency of **Dist-1** as obtained from the saturation [D]/[P] ratio is supported by the number of hydrogen bonding contacts.

The docking of **1**, **2**, and **3** showed that the azobenzene moiety allows both the distamycin arms to satisfy the extended mode of binding (*11*) unlike the hairpin conformation as observed with γ-amino butyric acid linker based distamycin derivatives (*53*). The isomer **1b** has more pyrrole amide bonds available for hydrogen bonding with the AT base pairs than **1a**. This was supported by higher ICD intensity and low [D]/[P] ratio of **1*** than **1** (Figure 6A, Table 2). One or both benzene moieties of the planar azobenzene group in the trans form (**1a**) approach the ds-DNA to be involved in hydrophobic interactions with the DNA bases. In addition, with long spacer (∼11 Å), the number of pyrrole amides that are able to form hydrogen bonds with the DNA bases decreases, while the nonplanar azobenzene moiety in the cis form prefers to remain out of the DNA helical surface and thus allow more pyrrole amide bonds to satisfy hydrogen bonding interactions with DNA bases (not shown).

The better hydrogen bonding contacts of the para-substituted **1b** over **1a** can also be explained by the difference in D1 and D2 distances. D1 corresponds to the length of azobenzene and D2 represents D1 and spacer length (Scheme 4). The D2 distance varies in the ligands due to variation of electron-donating vs electron-withdrawing substituent of the azobenzene moiety (**1, 2**) and also due to the existing spacer in **Dist-1** and **Dist-2** (Figure 1). In the case of trans to cis photoisomerization of **1**, the lowest-energy docked conformation has D1 = ∼3.5 Å and an overall decrease of D2 from 21.53 Å to 14.06 Å leading to an increase in hydrogen bonds (Table 3). The docked (−21.9 and −21.6 kcal/mol) and free binding energies (−8.2 and −7.9 kcal/mol) are in tune with the melting temperature values (Table 3). The subtle differences in docked and free

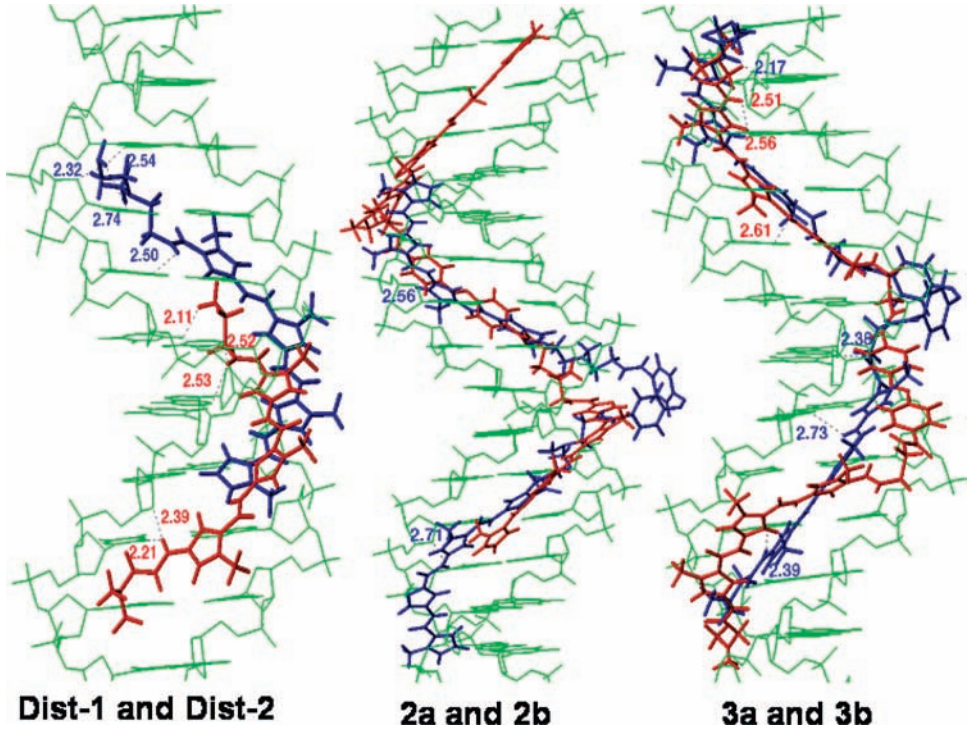


Figure 8. The docked conformations of **Dist-1**, **Dist-2**, and both isomeric forms of the ligands **2** and **3** with duplex d[GC(AT)$_{10}$CG]$_2$ DNA scaffold are shown. Ligand, **Dist-1**, and cis form of ligands **2b** and **3b** are shown in blue-colored capped sticks, whereas **Dist-2** and trans forms of ligand **2a** and **3a** are shown in red-colored capped sticks. The image is from *Sybyl 7.0* (*54*).

binding energies between **1a** and **1b** support the low variation in melting temperature at saturating [D[/[P] ratio and apparent binding constant (K_{app}) values. This explains the DNA binding features of the dialkoxy azobenzene−distamycin dimers **1a** and **1b**.

In the case of dicarboxy azobenzene−distamycin conjugatees also, the docked conformations of **2b** with ds-DNA show greater availability of the hydrogen bond contacts between pyrrole amide bonds and AT base pairs over **2a** (Figure 8, Table 3) as observed from the CD spectral titrations. As seen in **1a** and **1b**, a similar large variation of D1 = ∼3.7 Å around the azobenzene moiety and contraction of D2 from 19.4 Å to 11.91 Å, where D2 = [-(CH$_2$)$_2$NMe(CH$_2$)$_2$NHOCPhN═NPhCONH(CH$_2$)$_2$NMe-(CH$_2$)$_2$-], are observed during trans to cis photoisomerization (Table 3). This might cause a subtle improvement in [D]/[P] ratio of **2*** than that of **2**. The comparative binding constant values are proportional to that of **Dist-1**, as possible hydrogen bonding contacts seem to be similar for both cases (Table 3). The improved T_m values compared to **1** and **1**** can again be correlated with the higher docking (−22.7 and −22.3 kcal/mol) and free binding energies (−10.3 and −9.8 kcal/mol), as hydrogen bonding interactions together with other noncovalent interactions contribute to stabilizing the ligand−DNA complexes. Smaller differences in docking and free binding energies between both photoisomeric forms of **2** again quantify their small variation in both melting temperature and K_{app} values.

The docked conformation of **3b** has shown a larger number of hydrogen bonding contacts with DNA bases compared to **3a** (Figure 8). The trans to cis isomerization of **3** has shown a decrease in the length of D1= ∼4.4 Å around the azobenzene moiety and simultaneous contraction of D2 from 17.05 Å to 8.3 Å along the linker length containing the azobenzene moiety (Scheme 4, Table 3). This helps both distamycin arms in **3b** to align along the isohelical pitch of the DNA helical axis, which achieves a maximum number of hydrogen bonding contacts and favorable electrostatic interactions with DNA in comparison to **3a** (Table 3). These observations support higher ICD intensity, lower [D]/[P] ratio, and higher K_{app} value for **3*** than **3**. A higher apparent binding constant value of the photoirradiated form of **3** may be a consequence of its higher free binding energy of −14.1 kcal/mol compared to free binding energy of Hoechst 33258 (−12.1 kcal/mol). This implies that a greater difference in DNA binding affinity and apparent DNA binding constant between the ∼8/2 (trans/cis) isomeric form and the trans form can be achieved with short linker based conjugate, **3**, compared to the flexible, long linker based ligand **2**. Photoisomerization of azobenzene induced a greater change of D2 in **3** compared to the docked conformations of **1** and **2** (Table 3). This eventually caused a greater difference in DNA binding affinity between **3** and **3**** compared to both isomeric forms of **1** and **2**. Further, the shape of **3b** was found to be more appropriately matched with the DNA helical axis (Figure 8). Even the positive charge at the N-terminal position is relatively more freely available for electrostatic interaction with the phosphates of DNA. This in fact contributed to enhancing the ligand−DNA interaction of **3** compared to other ligands (**1**, **2**).

CONCLUSIONS

The combined experimental data established how distamycin binding on DNA minor grooves was influenced by the presence of an azobenzene core. From ^{1}H NMR and UV−vis spectroscopy, it has been found that the nature of the substituent with respect to the core azobenzene unit (**1** vs **2**) and the linker lengths between distamycin and azobenzene unit (**2** vs **3**) influence the rate and the extent of azobenzene isomerization. Thus, the DNA binding properties of such conjugates were found to directly depend on the orientation of the distamycin with respect to the azobenzene core linker length between azobenzene and distamycin moiety and on the position of positive charge along the oligopeptide backbone. The azobenzene core influenced the conformational freedom of the oligopeptide largely, thereby preventing favorable isohelical orientation of the distamycin units along the ds-DNA minor grooves. Thus, at room temperature, geometrical features of the

azobenzene core prevent simultaneous participation of both distamycin arms in an optimal DNA recognition process. This was manifested by a less intense ICD band and the requirement of high [ligand]/[DNA] ratio to saturate minor groove binding by azobenzene−distamycin hybrids compared to the distamycin alone. According to the results obtained from CD spectroscopy, the photoirradiated forms **1***, **2***, and **3*** favored DNA binding affinity compared to the corresponding trans form as evidenced from high ICD_{336} intensity and low [D]/[P] values for the cis form of the ligands.

Molecular docking studies indicate that during photoisomerization the difference in planarity of the azobenzene moiety together with the change in the length either around the azobenzene moiety (D1) or along the linker containing the azobenzene moiety (D2) determines the orientation of both distamycin arms along the DNA minor groove surface. This eventually causes a greater number of hydrogen bonding contacts between the pyrrole amide and the DNA bases in their cis geometry compared to that in the trans configuration. For example, a greater difference in D2 during photoisomerization for the short spacer based azobenzene−distamycin conjugates explains the relatively larger difference in the ICD intensity and the DNA binding constant values between **3** and **3***. CD spectra allowed measurements of the differences in the DNA binding affinity between trans and photoirradiated form of all the ligands. This was not, however, possible with the Hoechst displacement assay. Except for ligand **3**, there was very little difference in the apparent binding constant values between the isomeric forms of other ligands. This could be due to lower binding free energies of these ligands (**1a**, **1b**, **2a**, and **2b**) compared to Hoechst 33258 as a MGB. As expected, all the dimeric distamycin−azobenzene conjugates were able to stabilize polymeric alternating A/T-rich duplex DNA more effectively compared to the monomeric distamycin analogue, **Dist-1**. There is a gradual increase in the overall stability of DNA−ligand complexes as we move from **1a** to **3a**. Although no major differences in T_m values were observed between the conjugates before and after photoillumination at "saturating" [D]/[P] ratio based on ICD titration data, there was a perceptible increase in T_m values when DNA melting was performed at a constant [D]/[P] ratio of 0.5 with each ligand. This indicates that the cis isomeric forms of such conjugates stabilize ds-DNA more than their trans counterparts at a fixed ligand/DNA ratio.

Experimental and theoretical studies of DNA binding with ligands (**1**, **2**, and **3**) demonstrate the role of linker length between azobenzene and distamycin conjugates for achieving favorable DNA binding affinity and a perceptible difference in duplex DNA binding affinity during photoisomerization. Thus, it was possible to regulate distamycin binding on ds-DNA to some extent by properly anchoring a photoactive disubstituted azobenzene unit to the oligopeptide backbone using a short and rigid spacer.

In summary, the present study describes how specific alterations in a set of azobenzene−distamycin conjugates alter their molecular structure and geometry, which in turn influences their DNA binding affinity on the floor of the minor groove. This also gives significant leads for the design of MGBs, with structural prerequisites to selectively control DNA recognition in the presence of external stimulus. Such an approach reveals a way to control certain biological events where one can regulate the binding specificity and efficiency of small molecules on duplex DNA with light.
