Bioconjugate Chemistry

Editorial: What's New

The Chemistry of Targeting

This is the first of twelve issues of *Bioconjugate Chemistry* for 2008, a doubling of the print frequency. The change is mainly symbolic, but the underlying scientific progress is notable. One aspect of bioconjugate chemistry that has come into focus in recent years, which might be called the chemistry of targeting, has pervasively entered mainstream research in biology and medicine. Papers in this and recent issues of the journal give an idea of how it works in practice. Of course, the chemistry must come before the targeting, and there is plenty of chemistry. For example, synthetic peptides with target-binding properties, discovered by library screening, can be prepared with artificial components for conjugation to proteins (*1*). Synthetic reagents can be incorporated into natural proteins by ligation (*2*), and library-selected peptides with interesting new reactivity for conjugation to synthetic reagents can be cloned into proteins (*3*). Designing a nucleophilic affinity label to replace an electrophilic one can use an expressed protein to advantage and change the parameters of targeting (*4*), and a new fluorescent conjugate traces the intracellular targets of an electrophilic drug (*5*).

Then, the challenge of making new molecules that work *in vivo* begins. How can we add the properties of signal generation or therapeutic activity to a structure that provides affinity for particular cell types, and endow the product with the requisite biological behavior required for specific accumulation in the target? Here is an opportunity for creative thinking, especially when the goal is to deliver a payload to sites in the interior of a cell. The approach depends on the task. Cell-penetrating peptides are developing into reliable tools for intracellular targeting (*6*). Polymeric assemblies for nonviral gene delivery show promise (*7*), and quantum dots provide an interesting platform for siRNA (*8*). Delivery of proteins to cellular targets involves different strategies (*9*), as does protein-mediated delivery of small molecules (*10*).

Alongside this activity is new work related to vaccines (*11*), to highly sensitive RNA detection (*12*), and to the design of lipophilic prodrugs (*13*). And of course there are nanoparticle bioconjugates beyond those mentioned above, aimed at preparing ordered assemblies of biomolecules (*14*), liposomes guided by engineered proteins (*15*), and nanorod bioconjugates for intracellular Raman detection (*16*). Enzymatic biotinylation of DNA, followed by cross-linking with streptavidin, can lead to the stable formation of complex new synthetic nanostructures (*17*). These are only a few recent examples of bioconjugate chemistry published in the journal. Space restrictions do not allow a fuller account here; we invite you to see for yourself. As time goes forward, I believe we will see more emphasis on the construction of large, complex, multifunctional particles (*18*); clever chemistry and biology to specifically fuse biological molecules to nonbiological partners (*19*); better ways to target drugs and probes *in vivo* (*20*); and no doubt some unexpected developments in this always surprising field.

Thanks to Our Reviewers

It is a pleasure to acknowledge the contributions of the reviewers of manuscripts submitted in 2007 for publication in *Bioconjugate Chemistry*. Their unselfish service has been essential in the shaping of the 18th volume of the journal. The scientific community is fortunate that its members are willing to share their time and specialized knowledge in this way. The reviewers are listed on the following pages.

Porphyrinmaleimides: Towards Thiol Probes for Cysteine Residues in Proteins

Yihui Chen, Timothy Parr, Andrea E. Holmes,† and Koji Nakanishi*

Columbia University, Department of Chemistry, New York, New York 10027. Received July 17, 2007; Revised Manuscript Received September 21, 2007

Porphyrinmaleimides were synthesized and characterized. The thiol-containing amino acid L-cysteine reacted with 58% yield with these porphyrins to form bioconjugate adducts. The new thiol-active reagents were labeled cytoplasmic cysteine 140 and 316 in rhodopsin (Rh), a G protein coupled receptor (GPCR).

In order to gain further insight into conformational changes that occur upon light activation of the rhodopsin visual transduction cycle (*1, 2*), we needed a highly sensitive photoactive probe that absorbs in the visible light region. Thiol active–reactive dyes have been used for labeling biopolymers such as peptides, proteins, and oligonucleotides, and for demonstrating protein–nucleic acid interactions (*3–8*). Effective thiol labels include maleimides (*9*), halomethylketones, benzylic halides, and iodoacetamides (*10, 11*). Arrays of thiol-reactive agents are commercially available for studying conformational changes, topography, and interactions of proteins and membranes (*12*). Since thiol groups do not occur that frequently in proteins, these thiol-reactive agents can be introduced selectively and site-specifically.

In order to facilitate monitoring of the thiol probe reactions, sensitive assays using reagents that can be excited and absorb in the visible region are desirable. In the following, we describe the synthesis of a thiol-active porphyrin, a tetraphenylporphyrin maleimide (TPPM). Tetraarylporphyrins have high extinction coefficients, $\epsilon = 400\,000–500\,000$, and hence are highly sensitive. Their absorption in the visible region around $\lambda_{max} = 420$ nm, instead of in the UV region, results in favorable energy parameters in terms of stability of organic compounds, because visible radiation is lower in energy than UV radiation, thus expanding the scope to biological systems. Porphyrins have also been widely studied as sensitizers and are currently finding biomedical application in the treatment of malignant tumors (photodynamic therapy, PDT), plaque destruction, and psoriatic lesions, and more recently in the treatment of viral infections (*13–17*).

To our knowledge, there is no report of porphyrin containing thiol-reactive probes. Thus, we designed the porphyrin TPPM with a maleimide functional group to evaluate whether cysteine residues can be derivatized with these chromophores through thioether formation. Cysteine derivatization through thioether formation to the C-terminal can be utilized to attach fluorophores chemo- and regioselectively (*1, 2*). Of the ten Cys residues in Rh, only C140 and C316 can be derivatized, because the others are buried in the membrane, are present as disulfides, or are palmitoylated. C316 is more reactive than C140, and hence can be derivatized with high selectivity. A second porphyrin of different UV/fluorescent properties can then be linked to C140 with a large excess of the reagent. Modifications at these two positions are known not to interfere with formation of Rh photo intermediates or the interaction of Rh with the G protein.

TPPM 4 was synthesized by conventional condensation of benzaldehyde, pyrrole, and para-nitrobenzaldehyde, followed by reduction of the nitro group and subsequent derivatization of the amino moiety to the maleimide **TPPM 4** (Scheme 1). Compounds **1** and **2** were obtained according to literature procedures (*18, 19*). Porphyrin **2** was reacted with maleic anhydride to yield porphyrin **3** in 80% yield. Porphyrin **3** was converted to **TPPM 4** in 22% yield by reacting it with sodium acetate and acetic anhydride. We tested L-cysteine as an example to demonstrate that **TPPM 4** is reactive toward thiol bioconjugation. The cysteine bioconjugate **5** product was obtained by addition of L-cysteine to **TPPM 4** in DMSO (Scheme 1) at room temperature for 2 days.

TPPM 4 is soluble in nonpolar organic solvents. In order to attain water solubility under physiological conditions, we synthesized a 5,10,15,20-maleimido-tris-sulfonatophenyl porphyrin **TPPS 8** and its bioconjugate with cysteine **9** (Scheme 2).

Porphyrin **6** (Scheme 2) was obtained by treating porphyrin **2** with a large excess of concentrated sulfuric acid at 110 °C for 4 h followed by aqueous workup. The tris-sulfonated porphyrin was then converted to the ammonium salt by dissolution in excess concentrated ammonium hydroxide in 58% yield. **TPPS 8** and the L-cysteine bioconjugate **9** were obtained in 80% yield by procedures shown in Scheme 2.

Figure 1 summarizes porphyrins **4**, **8**, and **10** that were synthesized and reacted with L-cysteine. Metalloporphyrin **10** was synthesized because it is even more red-shifted than porphyrin **4** ($\lambda_{max} = 421$ nm in MeOH) and was obtained in quantitative yield by treatment of porphyrin **4** with zinc acetate. In order to determine the sensitivity of these porphyrins, we measured their extinction coefficients and fluorescence properties (Table 1). Porphyrin quantum yields are typically between 0.1% and 13% (*20, 21*). The data show that the porphyrins absorb in the visible region between 412 and 421 nm, with high extinction

coefficients, fluorescence emissions at ≥600 nm, and reasonable quantum yields.

The UV–vis profile of **TPPM 4** is shown in Figure 2. In phosphate buffer, **TPPM 4** only shows shallow absorbance (red), which shows that TPPM had poor solubility in phosphate buffer and will only aggregate in this buffer. In contrast, in DMSO (black) and CHAPS[1] buffer [0.75% CHAPS and 10 mM Tris-HCl (pH 7.4)], the solubility of TPPM increased, and aggregation is less apparent as seen by the sharp and intense Soret bands at 420 nm (pink, blue, green, and black), $\epsilon = 180\,000$ at pH = 6.6, which is a good pH for the active state of rhodopsin-meta II. Porphyrins **8** and **10** showed similar characteristics. We also obtained UV–vis spectra of the cysteine bioconjugates **5**, its Zn(II) derivative, and the rhodopsin bioconjugate before and after bleaching. As seen in Figure 3 (left), the bioconjugation did not affect the spectroscopic properties of the porphyrins, as there were no notable absorbance changes from the precursors. Conjugation to rhodopsin in the dark shows the porphyrin peak at 420 nm and the rhodopsin

[1]Abbreviations: CHAPS, 3-[(3-cholamidopropyl)dimethylammonio]-propanesulfonic acid; MOPS, 3-(*N*-morpholino)propanesulfonic acid; ROS, rod outer segments; SDS-PAGE, sodium dodecyl sulfate polyacrylamide gel electrophoresis.

Scheme 2. Synthesis of a Water-Soluble TPPS 8 and the L-Cysteine Bioconjugate 9

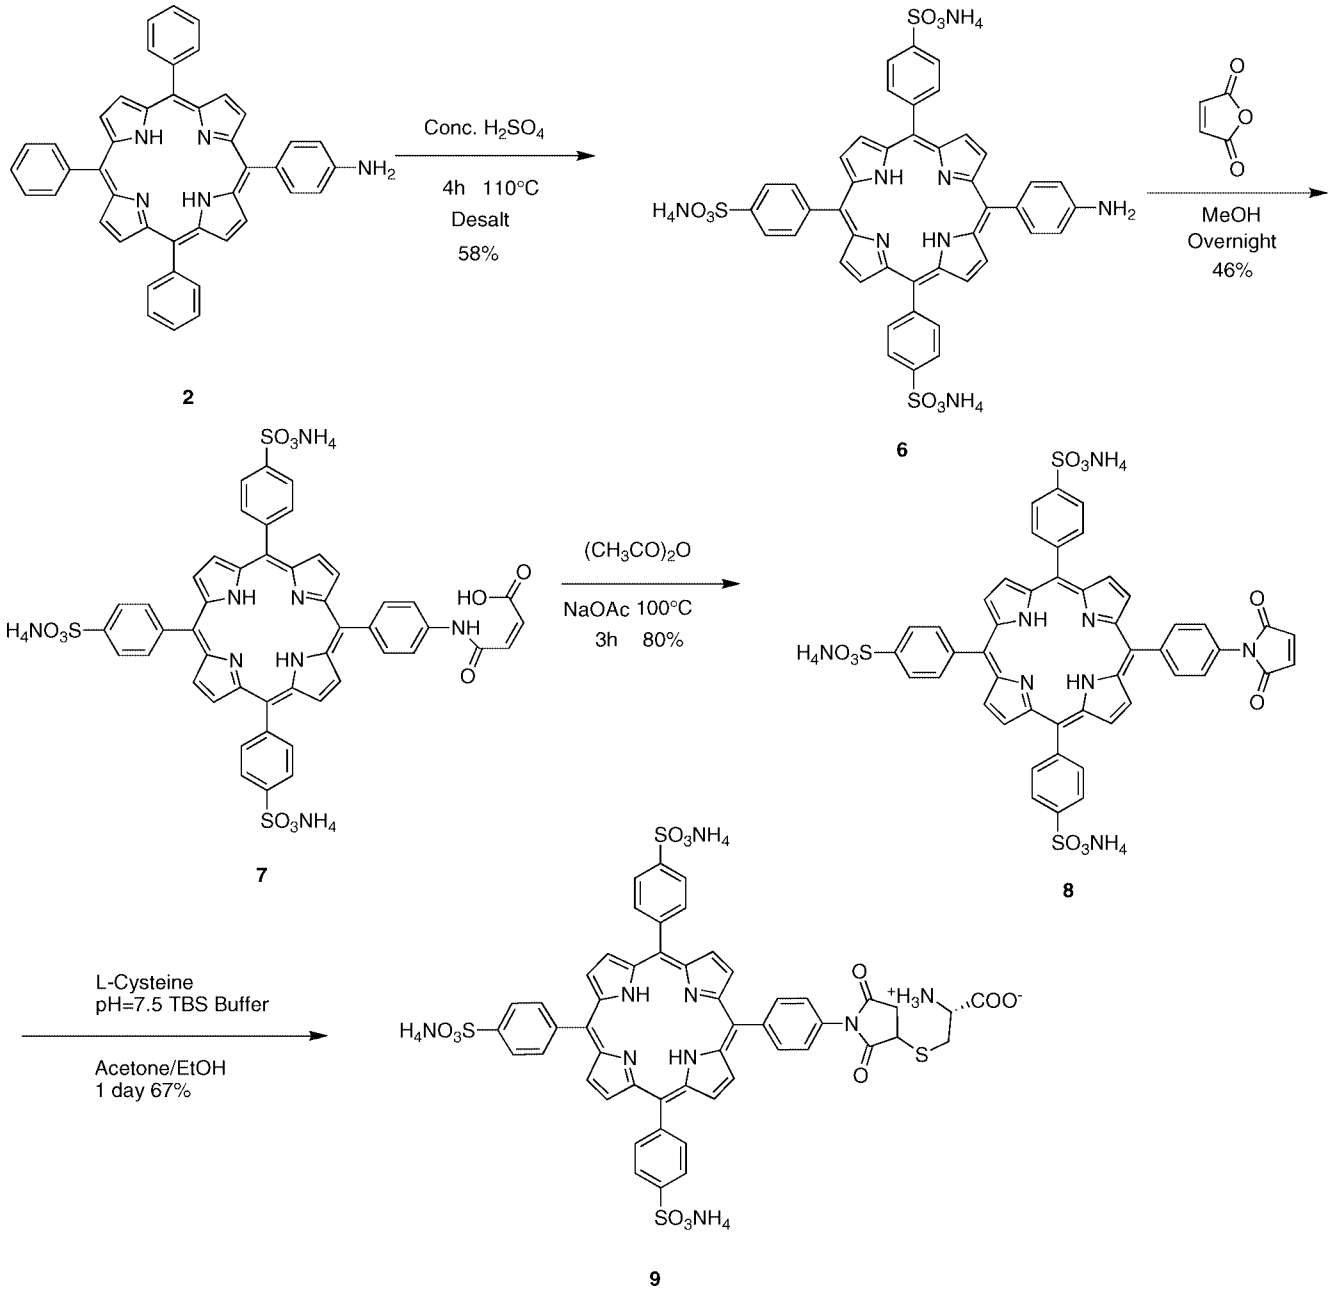

Table 1. UV Extinction Coefficient and Fluorescence Quantum Yields of the New Porphyrins

porphyrins	UV absorbance maximum (nm)	UV extinction coefficient (ϵ) cm^{-1}/M	fluorescence emission maximum (nm)	fluorescence quantum yield (φ) %
4 ($CHCl_3$)	418	532,000	647	5.8
8 (MeOH)	415	390,000	646	8.9
10 (MeOH)	421	329,000	601	6.0

peak at 495 nm. After bleaching with hydroxylamine, the rhodopsin transition disappears, and retinal oxime is produced at 365 nm. The porphyrin transition was not affected.

In order to demonstrate whether the new porphyrin probes can be used for the labeling of cysteine residues in rhodopsin, we cleaved rhodopsin after the porphyrin labeling into two fragments F1 and F2 with thermolysin. Fragment F1 contains cysteine residue 140 and F2 contains cysteine residue 316, both located on the cytoplasmic side of the protein. Using SDS-PAGE of 15% acrylamide gel, as shown in Figure 4, we monitored

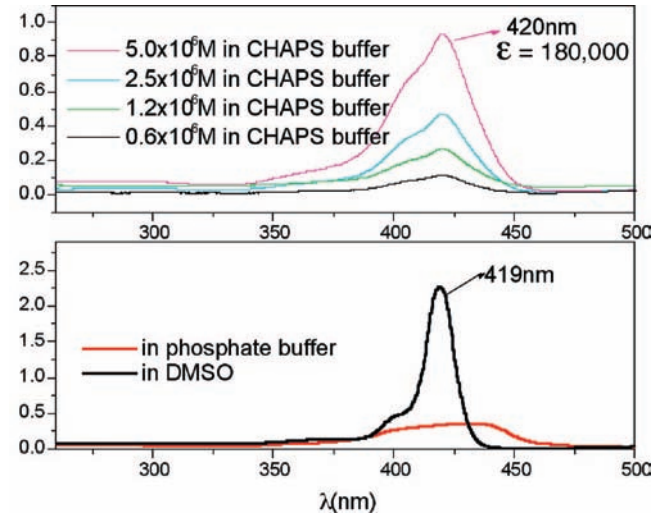

Figure 2. UV profile of **TPPM 4** in CHAPS, phosphate buffer, and DMSO.

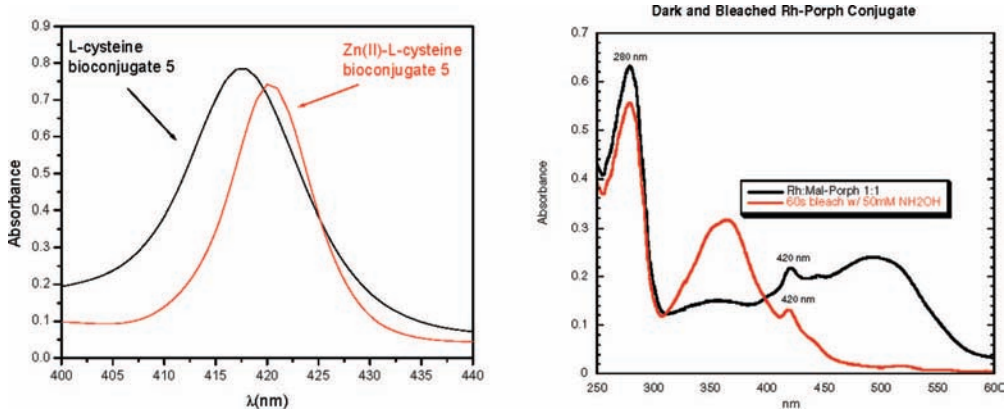

Figure 3. Left: UV–vis spectra of cysteine bioconjugate **5** and its Zn(II) derivative indicating a bathochromatic shift. Right: Dark and bleached Rh–porphyrin conjugate.

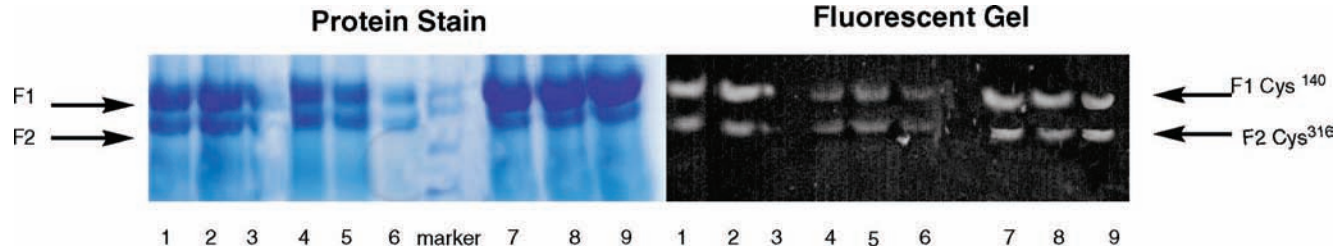

Figure 4. SDS-PAGE of the rhodopsin–porphyrin complexes with porphyrins **4**, **10**, and **8** in lanes 1–3, 4–6, and 7–10, respectively. The thermolytic F1 fragment shows labeling on Cys^{140}, whereas the F2 fragment shows labeling on Cys^{316}. The excitation wavelengths were 390–450 nm with a maximum at 435 nm. No bleaching of rhodopsin was observed in the conjugates.

the fluorescence emitted by the porphyrin-modified rhodopsin fragments. Since plain rhodopsin does not have porphyrin fluorescence, only the porphyrin-modified parts showed emission. Furthermore, SDS-PAGE determined whether both cysteine residues were labeled by the porphyrins, because both modified cysteine residue 140 and cysteine 316 will show fluorescence as labeled. Thus, rod outer segment (ROS) membranes containing about 3 mg of rhodopsin were suspended in 500 μL of 50 mM sodium phosphate buffer (pH 7.0). To the ROS suspension, 2.0 equiv of porphyrin solution (10 μM in DMSO) was added and reacted at room temperature for 2 days, then terminated with 30 μL of 55 mM glutathione. The reaction mixture was incubated in an ice bath for 30 min, then washed with 4 M urea once and twice with TRIS buffer [5 mM Tris–HCl and 0.5 mM $MgCl_2$ (pH 7.2)], and twice with ROS buffer [10 mM MOPS, 30 mM NaCl, 60 mM KCl, and 2 mM $MgCl_2$ 9 (pH 7.5)]. The porphyrin–rhodopsin complex was suspended in 10 mM Tris–HCl (pH 7.4) containing 5 mM $CaCl_2$ and 0.04 mg/mL thermolysin. The complexes were digested for 90 min at 37 °C, and then 5 μL of 50 mM EDTA was added. The SDS-PAGE in Figure 3 demonstrates successful labeling of both rhodopsin–cysteine residues with porphyrins **4**, **8**, and **10** as seen by the porphyrin fluorescence emissions of both F1 and F2.

We conclude that maleimide-containing porphryins **4**, **8**, and **10** have favorable spectroscopic parameters such as strong absorbances in the visible region, fluorescence emissions at long wavelengths, and high extinction coefficients. All the probes readily react with L-cysteine in quantitative yields. These characteristics could make these new porphyrins excellent candidates for protein labeling of specific cysteine residues, e.g., cysteines 140 and 316 on the cytoplasmic side of the visual pigment rhodopsin as seen by SDS-PAGE. Covalent attachment of prophyrins to rhodopsin would serve two purposes: 1. Porphyrins can be used as sensors to probe conformational changes of the high-energy intermediates, namely, photo, batho, lumi, meta-I, and meta-II rhodopsin by circular dichroism (CD). This technique would add an additional red-shifted spectroscopic region and could improve the sensitivity of the chiroptical signal due to the large extinction coefficients of porphyrins. 2. Rhodopsin is a prototypical example of a GPCR and has been well-characterized, especially in terms of the visual transduction pathway. Thus, rhodopsin could serve as a model for other GCPRs that yet have to be characterized and studied. Conformational studies of Rh–porphyrin conjugates are underway.

The assembly and proper alignment of two heterofluorescent proteins (sGFP and DsRed) in the mesoporous channels of ethanol-treated FSM6.2 (a folded-sheet mesoporous material with a pore diameter of 6.2 nm) was confirmed using a fluorescence resonance energy transfer (FRET) technique. The sGFP−DsRed−FSM6.2 conjugate showed a large decrease in the emission of donor (sGFP) fluorescence, indicating that the conjugate functions as an energy transfer system through the combination of the two heteroproteins, due to the successful encapsulation of the sGFP−DsRed pairs in the mesopores. Fluorescence spectral analysis demonstrated that the proteins were highly dispersed and homogeneously encapsulated in the mesopores of FSM6.2, even at high concentration, although they spontaneously aggregated and showed a red shift in solution at the concentration corresponding to that in the conjugate. Furthermore, an increase in the amount of sGFP and DsRed adsorbed to the pores of FSM6.2 led to a decrease in the distance between these proteins, resulting in enhancement of FRET efficiency.

Biomolecular assemblies such as protein subunits provide effective pathways for various chemical reactions in living bodies. Artificial assemblies of biomolecules have attracted much attention in the bioengineering field, due to potential applications to chemical processes such as catalytic reactions (*1–3*). One promising approach is the alignment of heteroproteins in the channels of mesoporous silicas. However, there have been no reports of a successful such assembly so far, the focus instead being on the incorporation of one kind of protein (*4–10*) mainly due to the difficulty in evaluating protein–protein interaction in the channels.

Here, we report the first ensemble of different proteins, which in combination function as a system for energy transfer similar to solar energy conversion (*11–16*) in the same silicate channel, i.e., the pores of folded-sheet mesoporous material (FSM) (*17, 18*). The presence of the artificial assembly of proteins in the pores was confirmed by detecting a fluorescence resonance energy transfer (FRET) between the proteins (*19, 20*). In other words, the interaction between the proteins in the pores or the assembly can be monitored by measuring FRET.

We chose sGFP and DsRed as the heteroproteins. They are fluorescent proteins having a donor–acceptor relationship in FRET, where they coexist within several nanometers (Förster radius is ∼5 nm) (*21*). The combination is also expected to be a good molecular probe to elucidate the effectiveness of mesoporous silicas as a scaffold for producing integrated proteins conjugated with FSM. In this study, two N-terminal hexa-histidine-tagged fluorescent proteins were overexpressed using BL21 Star *Escherichia coli* cells (cf. Supporting Information), after which the purified proteins were used for the FRET experiment. An engineered green fluorescent protein (GFP), sGFP (S65T) monomer, which is used for live-cell imaging in *Neurospora* (*22*) and plants (*23*), was employed as a donor. As an acceptor, a red fluorescent protein (RFP), the DsRed monomer from an IndoPacific sea anemone relative, *Discosoma* coral, was used (*24*). As the capsule for the proteins, we have developed an FSM6.2 (pore diameter of 6.2 nm) treated with hot ethanol (cf. Supporting Information) (*25*). The treatment enhances the structural stability of the framework, resulting in the successful incorporation of the proteins without damage to the framework. Thus, the heteroprotein−FSM6.2 conjugate enables us to construct an artificial biomolecular assembly. We can measure the FRET signal of the fluorescent proteins incorporated into FSM6.2 from the decrease of donor intensity (sGFP; ${\lambda_{ex}}^{max}/{\lambda_{em}}^{max}$ = 490 nm/511 nm, M_r 28 000), although the fluorescence from the acceptor (DsRed; ${\lambda_{ex}}^{max}/{\lambda_{em}}^{max}$ = 558 nm/580 nm, M_r 30 000) was very weak (*26*) compared with that of sGFP (the difference in intensity between sGFP and DsRed was a hundredfold). Donor quenching is the most convenient parameter for determining FRET efficiency, as has been reported elsewhere (*27*). The pore size of FSM6.2 is sufficient to immobilize the two fluorescent proteins, since both cylindrical proteins are 4–5 nm tall (Figures S1 and S2 in the Supporting Information). The proposed design of the FRET system in the sGFP–DsRed–FSM6.2 conjugate is shown schematically in Figure 1.

The fluorescent protein-incorporated FSM6.2 can be readily obtained (cf. Supporting Information), as shown in Figure 2. After incorporation of the proteins into FSM6.2, the conjugate was thoroughly rinsed with 20 mM Tris−HCl buffer (pH 8.0). At this point, little protein was detected in the supernatant and rinsed solution, suggesting that all proteins used for the incorporation were trapped within FSM6.2. In addition, the conjugate showed almost the same fluorescence as the original, even after several months at 4 °C. Thus, the proteins incorporated into FSM6.2 do not readily leach into the solution. On the other hand, most proteins were recovered from the supernatant when a noncalcined FSM6.2, whose mesopores were filled with surfactants, and a layered silicate, kanemite, which is the precursor before folding to give FSM (*17, 18*), were used

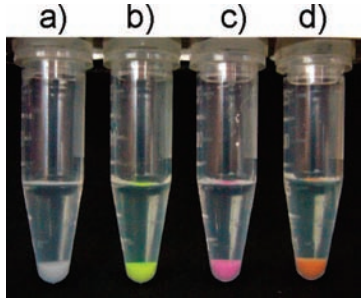

Figure 2. Picture taken without excitation of (a) FSM6.2, (b) sGFP–FSM6.2, (c) DsRed−FSM6.2, and (d) sGFP−DsRed−FSM6.2. Both sGFP and DsRed concentrations are 2 mg/mL. All samples were dispersed in 20 mM Tris−HCl buffer (pH 8.0).

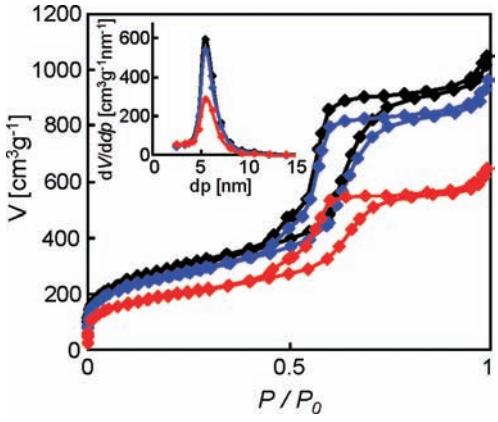

Figure 3. Changes in nitrogen adsorption–desorption isotherms and the corresponding pore size (dp) distribution curves obtained from the adsorption branch by the Barret-Joyner-Halenda (BJH) method (*28*) (inset) for sGFP−DsRed−FSM6.2 conjugates. Curves in black, blue, and red indicate the amounts of sGFP−DsRed adsorbed to the pores of FSM6.2 (50 mg): 0, 2, and 15 mg in total, respectively.

instead of FSM6.2 calcinated. This means that scarcely any proteins are adsorbed on the silica surface without mesopores.

The proportions of sGFP, DsRed, and their mixture adsorbed to the pores of FSM6.2 in 20 mM Tris−HCl buffer (pH 8.0) were approximately 40 wt % (Figure S5 in the Supporting Information). Figure 3 shows nitrogen adsorption–desorption isotherms and the corresponding pore size distribution curves for sGFP−DsRed−FSM6.2 conjugates. With an increasing amount of the proteins (0, 2, and 15 mg) confined in the pores of FSM6.2 (50 mg), the amount of nitrogen adsorbed by sGFP−DsRed−FSM6.2 progressively decreased. Simultaneously, the pore volumes decreased with an increase in the amount of the proteins (Figure 3, inset). The decline in porosity

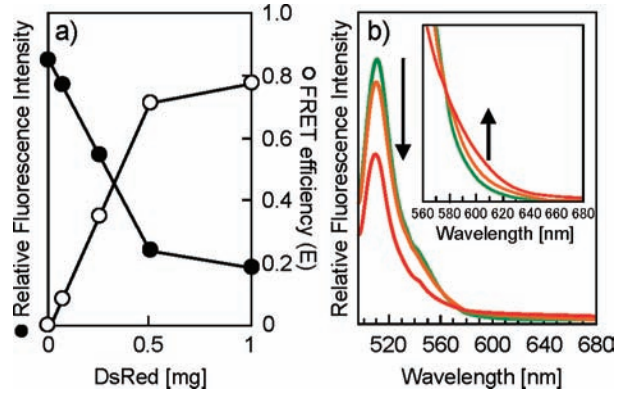

Figure 4. Effect of DsRed amount on sGFP-preimmobilized FSM6.2: (a) Fluorescence intensity of sGFP at 511 nm (filled circles) and FRET efficiency (E) (open circles). FRET efficiency; $E = 1 - (F_d'/F_d)$. Concentration of sGFP was constant (0.1 mg/mL; 50 μg sGFP/10 mg FSM6.2). (b) Fluorescence emission spectra of fluorescent proteins (λ_{ex} = 490 nm). The green, orange, and red curves indicate the fluorescence intensity in the sGFP:DsRed at quantitative ratios of 1:0, 1:1, and 1:5, respectively. Inset shows an extended figure of the emission spectra recorded at 560–680 nm. Buffer solution in all samples was 20 mM Tris−HCl (pH 8.0).

results from the incorporation of the two proteins into the mesopores of FSM6.2.

After preparing the fluorescent protein−FSM6.2 conjugate, an aliquot of 200 μL was transferred to a low-scattering microcell and the fluorescence intensity was measured using a fluorescence spectrophotometer (F-4500; HITACHI). The sample was excited at 490 nm, and the emission spectrum was recorded at 495–680 nm. To avoid any effect of the excitation light on the emission of sGFP, the slit width of the fluorescence spectrophotometer was set to 1 nm. The proteins retained their fluorescence activities after the treatment. However, the protein−FSM conjugates showed less intensity than the proteins in solution. There are two possible reasons for this. One explanation is a light-shielding effect of the silica component. The other is the low number of protein−FSM conjugates that exist within the excitation light transmissive window of the microcell in the fluorescence spectrophotometer, resulting from gravitational deposition of silica.[1]

We first examined whether energy is transferred between the proteins located in the pores of FSM6.2. Thus, we evaluated the effect of acceptor concentration on fluorescence intensity of the donor during a FRET reaction (Figure 4). Various amounts of DsRed were introduced into the mesopores after immobilization of a certain amount of sGFP (50 μg). The ratios of sGFP to DsRed in the protein−FSM6.2 conjugates obtained were 1:0, 1:1, 1:5, 1:10, and 1:20. At all ratios, proteins were completely captured into the mesopores. Figure 4a shows the fluorescence intensity of the donor at 511 nm and FRET efficiency (E). The FRET efficiency (E) from sGFP to DsRed was calculated approximately using the equation $E = 1 - (F_d'/F_d)$ (eq 1), where F_d and F_d' are the fluorescent intensities of the donor in the absence and presence of the acceptor, respectively. Fluorescence quenching of sGFP was observed when DsRed was introduced into the mesopores, with the fluorescence intensity decreasing gradually in inverse proportion to the amount of DsRed. The gradual, strong quenching indicates that energy transfer effectively occurred between sGFP and DsRed. At the same

[1] The sample was analyzed just after stirring. Although sluggish sedimentation of the conjugate started, it did not affect analysis of concentration-dependent emissions by sGFP and DsRed during measurement.

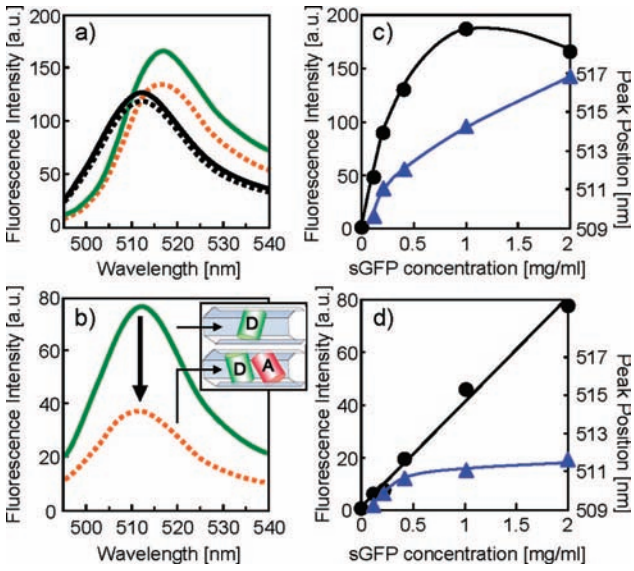

Figure 5. Fluorescence emission spectra of fluorescent proteins (λ_{ex} = 490 nm): (a) proteins only, (b) protein−FSM6.2 conjugate. Green curves and orange dashed curves indicate spectra for 2 mg/mL sGFP (D) only and the sGFP (D)−DsRed (A) mixture (2 mg/mL each), respectively. In (a), the black and black dashed curves indicate 0.4 mg/mL sGFP and the sGFP−DsRed mixture (0.4 mg/mL each). The green and orange dashed curves in (b) correspond to the samples shown in Figure 2b and d, respectively. The effect of the concentration of the sGFP solution on the maximum fluorescence intensity of sGFP (black circles) and peak position (blue triangles) is shown in (c) sGFP only and (d) sGFP−FSM6.2 conjugate. Measurement condition of fluorescence spectrophotometer slit width for both exciting light and fluorescence detection, 1 nm; voltage for photo multiplier tube, 700 V.

time, the FRET efficiency (*E*) was in proportion to the amount of DsRed. When the amount of DsRed exceeded the sGFP:DsRed quantitative ratio of 1:10, the FRET efficiency (*E*) remained at ∼0.8. This implies that DsRed cannot close with sGFP beyond a certain distance. In other words, all accessible sGFP molecules are already in contact with excess DsRed molecules. The notable FRET signal strongly indicates the possibility of high accessibility between sGFP and DsRed incorporated into the same channels of FSM6.2. Figure 4b shows the fluorescence emission spectra of the sGFP−DsRed−FSM6.2 conjugates recorded at 495–680 nm. When the fluorescence quenching of sGFP was observed with an increasing amount of DsRed, the fluorescence intensity increased in the wavelength range over the isosbestic point, resulting from the fluorescence enhancement of the acceptor. The appearance of the isosbestic point clearly indicates a transfer of energy from sGFP to DsRed, and DsRed functions effectively as a fluorescence quencher, although the acceptor emission is weak. In general, FRET can be evaluated by observing fluorescence enhancement of the acceptor, changes in the ratio of the fluorescence intensity of donor/acceptor, and fluorescence quenching of the donor (*27*). Among these indicators, the use of donor quenching is best suited to the FRET system using a sGFP−DsRed conjugate, as the FRET efficiency (*E*) from YFP (yellow fluorescent protein) to DsRed can be determined by donor quenching (*29*).

In order to demonstrate conclusively the efficacy of FSM6.2 as a capsule for energy transfer between sGFP and DsRed, we further measured the fluorescence spectra of sGFP and the same quantity of sGFP−DsRed mixture obtained at 490 nm excitation, with and without FSM6.2 (Figure 5a,b). The emission intensity of the sGFP−DsRed mixture was lower than that of sGFP, despite the concentration of sGFP being the same (Figure 5a). The lower intensity indicates a transfer of energy from sGFP to DsRed. A similar phenomenon was observed in the spectra of sGFP versus sGFP−DsRed−FSM6.2 conjugate (Figure 5b). This suggests that both proteins in the pores assume the correct conformation and interact with each other. This can be confirmed by carefully examining the intensity and peak position of the emission.

The decline in the intensity of sGFP−DsRed−FSM6.2 was considerably larger than that of the sGFP−DsRed mixture in solution. This characteristic decrease in sGFP intensity corresponds to the increase in the numbers of the FRET pair, probably due to the successful immobilization of the sGFP−DsRed pairs in the channels. Regarding the peak position of donor emission, it was found that the protein−FSM6.2 conjugate showed a distinct donor peak (511 nm, Figure 5b,d) even though 2 mg/mL of proteins without FSM6.2 showed a red shift of ∼6 nm from the peak for 0.4 mg/mL sGFP (Figure 5a,c), attributable to partial aggregation among the proteins. The retention of a suitable emission maximum can be rationalized as the uniform dispersion of monomeric proteins in channels of FSM6.2, as previously indicated by the dispersion of dye into SBA-15 (*30*) and the incorporation of chlorophyll into FSM (*31, 32*). Moreover, the intensity of the sGFP immobilized in FSM6.2 was linearly related to the sGFP concentration (Figure 5d; determination coefficient (R^2), 0.99), whereas nonimmobilized sGFP showed fluorescence quenching due to self-aggregation at a high concentration (Figure 5c). These results demonstrate that FSM6.2 provides a suitable platform for the immobilization and dispersion of proteins in mesopores with disintegration of the aggregate, even at a high concentration of proteins.

Table 1 shows the properties of the conjugates with different amounts of sGFP and DsRed adsorbed to the pores of FSM, the distance between these proteins, and FRET efficiency (*E*) from sGFP to DsRed, calculated using eq 1. As is clear from the table, the FRET efficiency (*E*) of the conjugate is considerably higher than that of the sGFP−DsRed mixture without FSM, the values for *E* in sGFP−DsRed−FSM6.2 and sGFP−DsRed (2 mg/mL each) mixture being 0.51 and 0.19, respectively. The reason for this is that the average distance between the donor and the acceptor is approximately 7 nm, which is enough for energy transfer, since the transfer of excited-state energy is inversely proportional to the sixth power of the distance between donor and acceptor dipoles, providing an effective range of no more than 10 nm (*33*). It is noteworthy that an increase in the amount of sGFP and DsRed adsorbed to the pores of FSM6.2 leads to the decrease in the distance between

Table 1. Effect of Protein Concentration with and without FSM6.2 on the Mean Distance of Proteins and FRET Efficiency

these proteins, accompanied by an enhancement of FRET efficiency (*E*).

In summary, we successfully prepared a heteroprotein−FSM conjugate and demonstrated protein–protein interaction in the mesopores of FSM by measuring intermolecular FRET. The conjugate showed a large decrease in the emission of sGFP fluorescence, which is caused by FRET, indicating that the conjugate functions as an energy transfer system through the combination of the two heteroproteins. The FRET signal indicated the possibility of high accessibility between sGFP and DsRed encapsulated in the same channels of FSM6.2. Furthermore, a fluorescence spectral analysis indicated that the proteins were highly dispersed and homogeneously encapsulated, even at high levels, in the mesoporous channels of FSM6.2, although they spontaneously aggregated with increasing content in the solution. The results reveal that mesoporous silicas are a good host for constructing protein assemblies.

Cysteinylated Protein as Reactive Disulfide: An Alternative Route to Affinity Labeling

Zheng Miao, Mark R. McCoy, Diment D. Singh, Brianda Barrios, Oliver L. Hsu, Sarah M. Cheal, and Claude F. Meares*

Department of Chemistry, University of California, Davis, California 95616. Received August 28, 2007; Revised Manuscript Received November 8, 2007

Engineering the permanent formation of a receptor−ligand complex has a number of promising applications in chemistry, biology, and medicine. Antibodies and other proteins can be excellent receptors for synthetic ligands such as probes or drugs. Because proteins possess an array of nucleophilic sites, the placement of an electrophile on the synthetic ligand to react with a nucleophile on the macromolecule is a standard practice. Previously, we have used the site-directed incorporation of cysteine nucleophiles at the periphery of an antibody's binding site, paired with the chemical design of weakly electrophilic ligands, to produce receptor–ligand pairs that conjugate specifically and permanently (Corneillie et al. (2004) *Bioconjugate Chem. 15,* 1392–1402 and references therein). After protein expression in Drosophila S2 cells, we found, as is frequently observed, that the engineered cysteine was reversibly blocked by disulfide linkage to a cysteine monomer (cysteinylated). Removal of the cysteine monomer requires some care because of the need to preserve other disulfide linkages in the protein. Here, we report that cysteinylation can be used to advantage by treating the cysteine monomer as a leaving group and the protein disulfide as an electrophile with special affinity for thiols. Two ligands bearing thiol side chains were synthesized and incubated with the cysteinylated antibody Fab fragment 2D12.5 G54C, with the finding that both ligands become covalently attached within a few minutes under physiological conditions. The attachment is robust even in the presence of excess thiol reagents. This rapid, specific conjugation is particularly interesting for biomedical applications.

According to Means and Feeney (*1*), site-specific derivatization of proteins (affinity labeling) began with the attachment of haloacetyl reagents to enzyme active sites, resulting in irreversible inhibition (e.g., *2, 3*) and the diazonium coupling of a hapten to an antibody's binding site (*4*). The derivatizing reagents were prepared by synthesizing a substrate or ligand for the macromolecular target and incorporating an electrophilic reactive group. The ligand's strong affinity for a particular site concentrates the reactive group there, where its reaction with a nearby amino acid side chain is promoted by mutual proximity. This approach has been widely employed in biomedical research, from protein structural studies to the development of new pharmaceuticals (e.g., (*5*)). Notably, even the antibiotic penicillin may be regarded as an affinity label (*6*).

Recently, an enhanced form of affinity labeling has been introduced which is aimed at the development of macromolecules that permanently capture small probe molecules (*7–12*). Here, the macromolecular target site is genetically modified to make a reactive partner for the affinity label, thus permitting rapid attachment by modestly reactive synthetic ligands that bind near the mutated residue. A related strategy, used for drug discovery screening, is tethering library ligands to a cysteine mutant receptor by disulfide formation (*13–15*). Here, the small molecules are in disulfide form, to react with free cysteine on the protein; a reducing buffer containing a thiol provides selective pressure so that only the ligands with highest affinity remain bound *in vitro*.

* Address correspondence to Claude F. Meares, Department of Chemistry, University of California, One Shields Avenue, Davis, California 95616, Phone (530) 752-0936, Fax (530) 752-8938, E-mail cfmeares@ucdavis.edu, http://www-chem.ucdavis.edu/people/meares.shtml.

Because proteins and other biological molecules commonly possess an array of nucleophilic sites but rarely contain electrophilic groups, the placement of an electrophile on the synthetic ligand to react with a nucleophile on the macromolecule seems to be a universal practice (e.g., *13–20*). A potential weakness of this strategy is that the electrophilic reagent may react with nucleophiles other than the target because there are so many. This is manifested by the occasional development of allergic reactions to drugs such as penicillin (*21*).

For the capture of probe molecules, it is attractive to use an antibody's binding site and engineer the antibody to display an appropriately located cysteine thiol side chain because of its distinctive nucleophilicity (*12*). However, in practice it is frequently observed that such Cys mutant proteins have their solvent-accessible cysteines reversibly blocked by disulfide linkage to a cysteine monomer, or sometimes another natural thiol such as glutathione or coenzyme A (*22, 23*).

Reductive removal of this naturally occurring protecting group without reducing the natural disulfide bonds of an antibody is difficult to achieve quantitatively (*10, 24*). While seeking improved strategies for this step, we conjectured that, rather than removing the cysteine monomer during purification of the protein, it might be possible to use protein cysteinylation as an advantage by thinking of the disulfide as a specialized electrophile and the cysteine monomer as a leaving group. An affinity label bearing a nucleophilic thiol group might bind and displace the cysteine, forming a new disulfide bond as illustrated in Figure 1. This hypothesis was plausible because we had engineered the antibody such that this cysteine would lie to the side of the antibody's binding site, not likely to interfere with normal binding of the synthetic ligand. Here, we describe experimental proof that this reaction does indeed take place, with a rate and efficiency that point to further development.

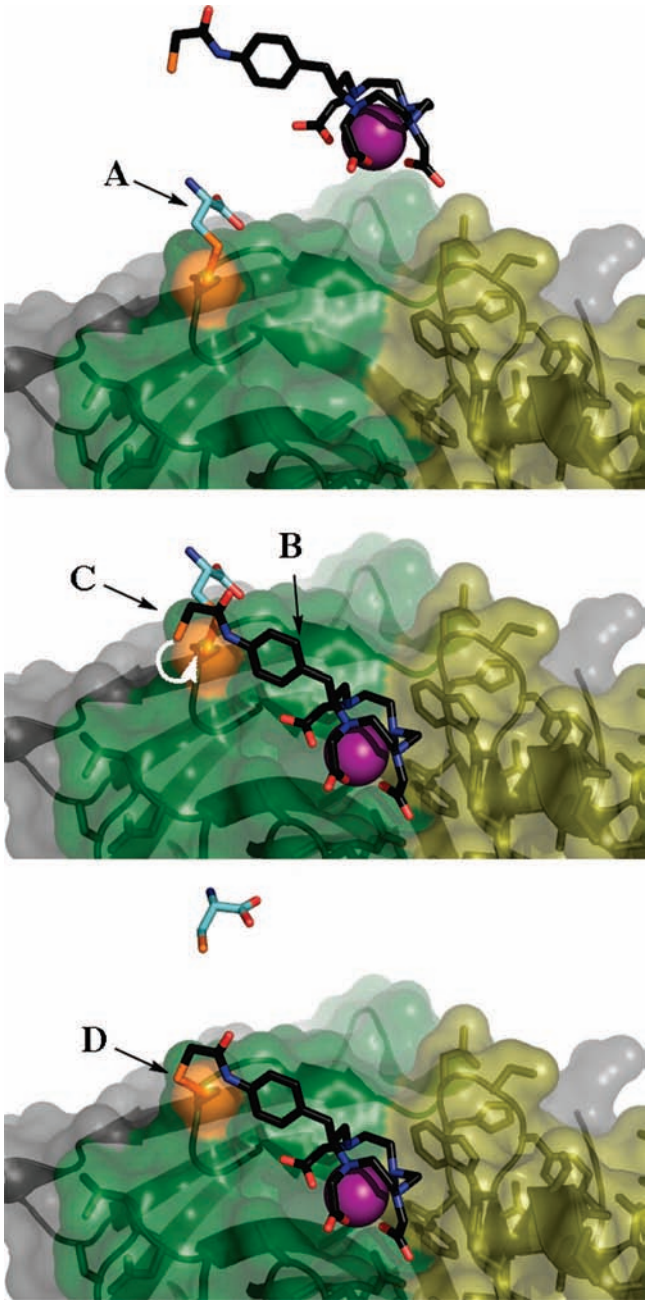

Figure 1. Infinite affinity binding of ligand **1** with cysteinylated 2D12.5 G54C Fab. Top: A cysteine monomer (A) is in disulfide linkage with the G54C when the protein is first expressed. The binding pocket of the 2D12.5 G54C Fab is pictured with CDR heavy chain regions shown in green, CDR light chain regions shown in yellow, and constant regions shown in gray. Ligand **1** is rendered in cpk colors, with the metal in purple. All sulfur atoms involved in the bond formation are colored orange. Middle: Association of chelate **1** with the binding pocket of the Fab (B) allows the free thiol group on the ligand to displace the cysteine monomer (C). Bottom: The disulfide bond (D) between the 2D12.5 G54C Fab and chelate **1** prevents dissociation of the ligand from the binding pocket.

We expressed the cysteinylated anti-DOTA[1] antibody Fab fragment 2D12.5 G54C in Drosophila S2 cells as described (*10*). After DTT reduction, we used amino acid analysis to confirm the release of cysteine monomer from the Fab.[2] As test affinity

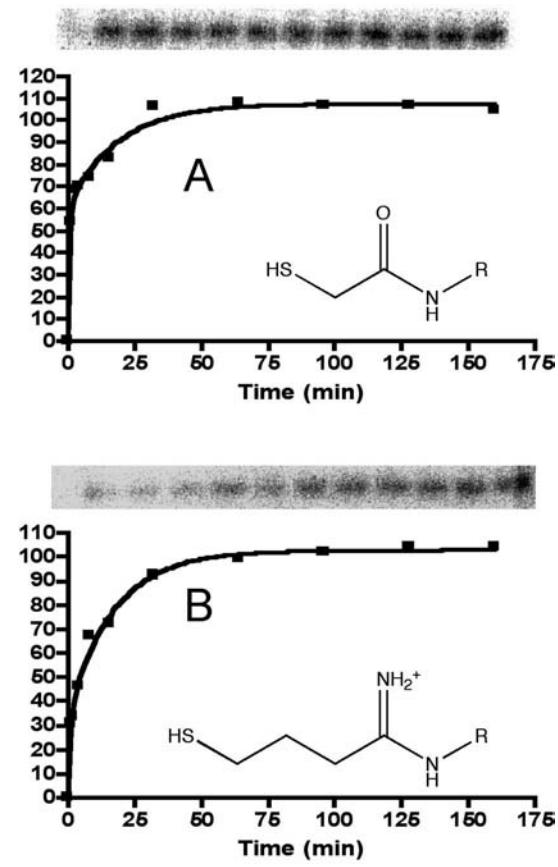

Figure 2. Panel A: covalent attachment of ^{90}Y-**1** to 2D12.5 G54C Fab as a function of time at 37 °C, pH 7.4, showing gel phosphorimages and plot of density. Panel B: covalent attachment of ^{90}Y-**2** to 2D12.5 G54C Fab.

Table 1. Covalent Attachment, As a Percentage of Total Bound Ligand, of ^{90}Y-1and ^{90}Y-3 to 2D12.5 G54C Fab with and without DTT Treatment[2]

	2D12.5 G54C	2D12.5 G54C w/DTT
^{90}Y-**1**[a]	83 ± 4%	77 ± 5%
^{90}Y-**3**	7.6 ± 0.1%	47 ± 1%

[a] ^{90}Y-**1** had a notably high efficiency of binding to DTT-treated G54C, which is only partially reduced to the sulfhydryl form, because the ^{90}Y-**1** sample contained both the free sulfhydryl (71%) and disulfide form (29%) of ^{90}Y-**1**.

labels, we synthesized nucleophilic compounds **1** and **2** to compare with previously reported electrophiles **3** and **4** (Chart 1). The method of Weiss (*25*) was used to prepare **1** from thiocyanate, bromoacetate, and aminobenzyl-DOTA; Traut's reagent was used to prepare **2**.[2]

Determination of Covalent Bond Formation between the Cysteinylated 2D12.5 G54C Fab Protein and ^{90}Y-1 or ^{90}Y-2. As suggested by Figure 1, each chelate was added to cysteinylated Fab to allow the formation of a new disulfide linkage. To ensure that the measured rates of covalent attachment would reflect the reaction in the binding site rather than the rate of association, the final concentration of the ^{90}Y-chelate was 10 μM and that of the protein was 1 μM in PBS buffer, pH 7.4. This solution was allowed to incubate at 37 °C for periods up to 160 min.[2]

In each case, the half-lives for covalent attachment were a few minutes at 37 °C, pH 7.4, and the attached ligands migrated with the protein during denaturing (nonreducing) gel electrophoresis. The results for ligands **1** and **2**, shown in Figure 2, are similar to the previous results for electrophiles **3** and **4** reacting with the free sulfhydryl form of this antibody (*10*).

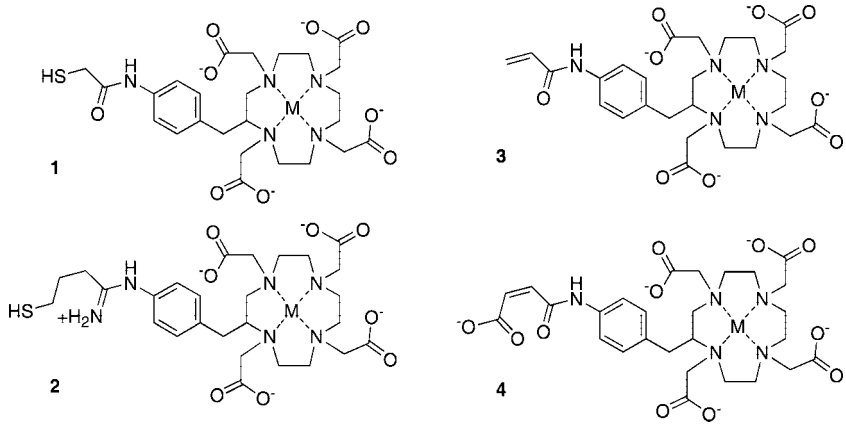
Chart 1. M = yttrium(III)



Quantitation of Covalent Bond Formation between the Cysteinylated 2D12.5 G54C Fab and ^{90}Y-1 or ^{90}Y-3 Before and After Mild Reduction. As will be shown below, the protein as expressed contains a small fraction of heavy chain cysteine-54 with a free thiol side chain (~7%), and a larger fraction of cysteinylated cysteine-54. Normally, before the 2D12.5 G54C Fab protein can react to a satisfactory degree with either **3** or **4** it must be reduced in order to increase the proportion of free thiol side chain at Cys-54, because the disulfide is nonreactive with electrophiles. This must be a mild treatment in order to avoid reduction of the structurally important disulfides, such as the interchain disulfide between the light and heavy chains of the Fab protein.

A sample of 2D12.5 G54C was treated with 25 μM DTT[1] followed by overnight incubation at 4 °C (*10*). Samples of 2D12.5 Fab G54C with or without DTT treatment were incubated with excess ^{90}Y-**1** or ^{90}Y-**3**, followed by gel filtration to remove excess chelate not associated with the Fab. The resulting samples of Fab contained both reversibly bound ligand and covalently bound ligand. To determine the percentage of chelate covalently bound to the protein, reversibly bound chelate was separated from the protein on a denaturing (nonreducing) polyacrylamide gel.[2]

The results for the four samples, reduced or nonreduced 2D12.5 G54C Fab reacting with either ^{90}Y-**1** or ^{90}Y-**3**, are shown in Table 1. For the naturally expressed protein without

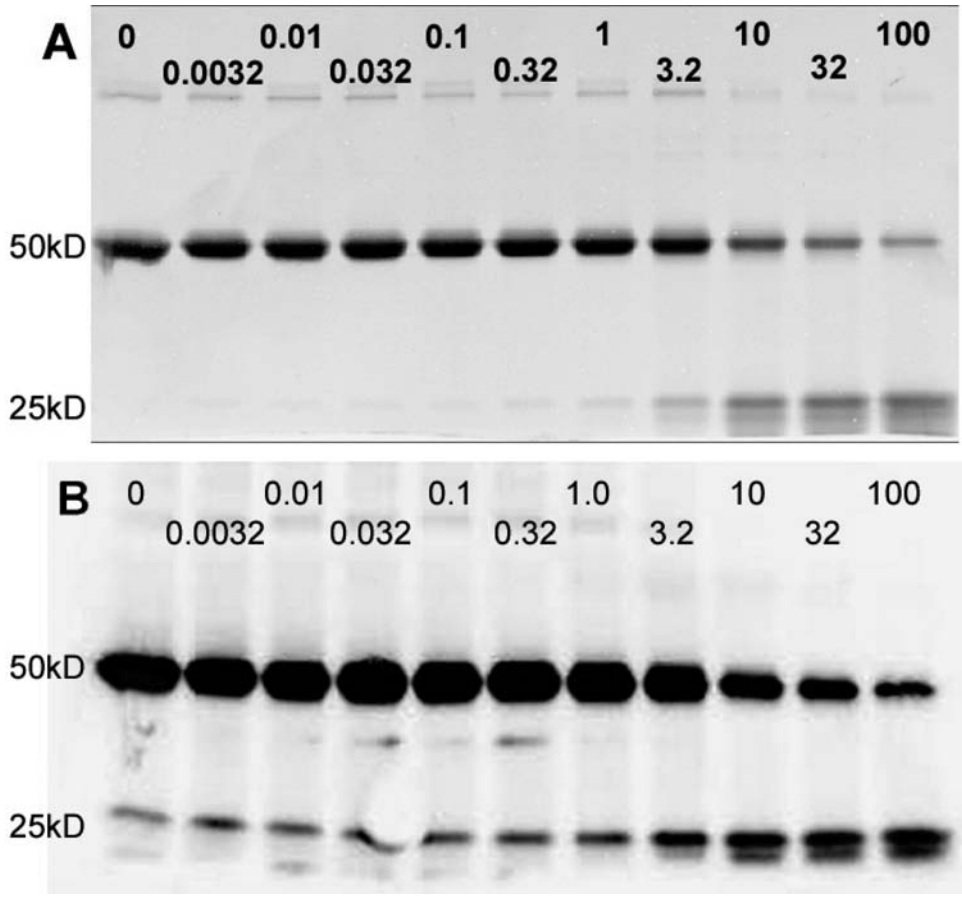


Figure 3. Sypro total protein stained gel (A) and anti-DOTA Western blot (B) analysis of samples of 2D12.5 G54C Fab conjugated to Y-**2** by disulfide bond formation. From left to right in each panel, the samples were treated with increasing concentrations of β-mercaptoethanol; numbers shown are BME concentration, mM.

DTT treatment, covalent bond formation with thiol ^{90}Y-**1** was approximately 11× more likely than reaction with acrylamide ^{90}Y-**3**. Mild reduction of the cysteinylated Fab increased covalent attachment of electrophile ^{90}Y-**3** approximately 6×, but had little effect on the covalent attachment of ^{90}Y-**1**. The reason for ^{90}Y-**1** having such a high efficiency here is that it becomes partially oxidized during metalation: for this experiment, 29% was in the disulfide form,[2] which can react with the reduced Cys-54.

Having formed the disulfide, we sought an indication of how stable the bond is. Because the binding site has high affinity for the DOTA chelate, the loss of the chelate after disulfide reduction should be disfavored. This may be envisioned as similar to the situation of the light and heavy chains of the Fab, which are held together by strong van der Waals interactions in addition to the interchain disulfide bond. We treated samples of the Y-**2**-Fab disulfide with increasing amounts of BME.[1] We analyzed the samples by denaturing, nonreducing gel electrophoresis immediately after removing the BME by a desalting column (Figure 3), finding that there is neither significant reduction of the Fab interchain disulfide nor loss of Y-**2** until the concentration of free BME exceeds 1 mM, where a small amount of interchain disulfide reduction becomes detectable. At 10 mM BME, the interchain disulfide is half-reduced, whereas the Y-**2**-Fab disulfide is only approximately 20% reduced.[2] It is also notable that a significant portion of the 25 kD disulfide-linked Y-**2**-heavy chain is produced at higher BME concentrations, confirming that the interchain disulfide is reduced while the Y-**2** disulfide remains intact. Since the Y-**2**-Fab disulfide bond is more stable than the interchain disulfide, Y-**2**-Fab should remain intact under physiological conditions.

While all four ligands in Chart 1 were designed to be unreactive in ordinary circumstances but to react quickly upon binding to the specific antibody, the thiol−disulfide reaction is particularly mild. The properties of the disulfide bond are of special interest for probe capture applications, because under physiological conditions, the only likely reaction is thiol−disulfide interchange. In the human circulatory system, thiol−disulfide interchange reactions are possible since both thiols and disulfides are present. Normally, there are micromolar concentrations of small thiol-containing molecules in human plasma. However, studies of the relative concentrations of cysteine (∼9 μM) and its oxidation partner cystine (∼47 μM), compared to glutathione (∼2 μM) and oxidized glutathione (∼0.05 μM), show that the partners are not in equilibrium (*26*). Thus, interchange reactions do not occur efficiently in the absence of a special circumstance such as proximity in a binding site.

Another interesting feature of this system is that it may be possible to displace the cysteine monomer *in vitro* with other thiols, either natural or synthetic, before use with the affinity label. In this way, we might adjust the reactivity of the disulfide, or perhaps attach a drug or probe molecule to be released upon ligand binding.

ACKNOWLEDGMENT

We thank other members of the Meares lab for their contributions and helpful discussions, and NIH Research Grants CA016861 and CA098207 (C.F.M.) for support.

Fluorometric Identification of 5-Methylcytosine Modification in DNA: Combination of Photosensitized Oxidation and Invasive Cleavage

Hisatsugu Yamada, Kazuhito Tanabe,* and Sei-ichi Nishimoto*

Department of Energy and Hydrocarbon Chemistry, Graduate School of Engineering, Kyoto University, Katsura Campus, Kyoto 615-8510, Japan. Received August 29, 2007; Revised Manuscript Received November 7, 2007

An efficient fluorometric detection system of DNA methylation has been developed by a combination of a photooxidative DNA cleavage reaction with 2-methyl-1,4-naphthoquinone (NQ) chromophore and an invasive cleavage reaction with human Flap endonuclease-1. Enzymatic treatment of a mixture of photochemically fragmented target oligodeoxynucleotides (ODNs) at 5-methylcytosine (^{m}C) and hairpin-like probe oligomer possessing a fluorophore (F) and a quencher (D) resulted in a dramatic enhancement of fluorescence. In contrast, fluorescence emission for the ODN containing cytosine but not ^{m}C at the target sequence was extremely weak. In addition, by monitoring the fluorescence change, this system allows for the detection of ^{m}C in DNA at subfemtomole amounts. This system would provide a highly sensitive protocol for determining the methylation status in DNA by fluorescence emission.

Fluorescence technology provides considerable potential for obtaining sequence information of genes in a fast and simple manner. Various fluorescence-labeled DNAs that give signals in a sequence-specific fashion have found wide-ranging applications to gene analysis (*1–3*); e.g., TaqMan probe, molecular beacon probe, base-discriminating fluorescent probe, and invader assays.

Methylated cytosine (^{m}C) at the 5-position is a physiologically modified nucleobase involved in the epigenetic repression of genetic information that can cause various human diseases including cancer (*4–6*). Establishment of a means of assessing the methylation status of specific cytosine (C) residues in DNA is important for elucidating the biological effects of C methylation. Several protocols have been developed to identify the methylation status of a gene, representative examples of which are the methylation-insensitive restriction enzyme assay, sequencing with a bisulfite modification, Maxam−Gilbert modification, and labeling of ^{m}C with an osmium complex (*7–15*). While individual methods have their own advantages, most of the conventional methods present practical drawbacks to some extent, such as complicated procedures, long reaction periods for chemical modification, limitations in the detectable base sequences, and low sensitivity. Therefore, much recent effort has been made to explore more simple and efficient detection methods with easy procedures, short reaction times, and sequence-independent reactions in association with an epigenetic analysis of human genome.

We present herein a fluorometric method by which the normal C and its modified ^{m}C in DNA can be sensitively discriminated. The proposed system consists of the 2-methyl-1,4-naphthoquinone (NQ)-photosensitized strand cleavage at ^{m}C of DNA and the subsequent invasive cleavage reaction that is one of the most successful methods for fluorometric detection of single-nucleotide polymorphisms (SNPs) without PCR amplification (*16–18*). In the previous study, we displayed an exclusive strand cleavage at ^{m}C in the partial sequence of the human p53 gene, which occurred in a sequence-specific manner by photosensitization of NQ-tethered complementary oligodeoxynucleotide (ODN) (*19, 20*). Although the present NQ-sensitized site-selective strand cleavage at ^{m}C is a promising detection system for cytosine methylation with high sequence selectivity (*20*), sensitivity and convenience of the system are limited because of the low yield of photochemical cleavage at ^{m}C and the requirement of time-consuming gel electrophoresis to determine the methylation status. To overcome these problems, we attemptted to incorporate the Invader assay (*16–18*) with a highly sensitive fluorometry into the ^{m}C-selective photochemical fragmentation of the target strand. We observed intense fluorescence emission from the sample solution containing ODN with the target ^{m}C upon photooxidation followed by the invasive cleavage, whereas only weak fluorescence was detected from a control solution containing the reference ODN with C at the corresponding target. In addition, we confirmed that the present system is capable of detecting ^{m}C in DNA at the subfemtomole level, presumably because of the large turnover number in the efficient enzymatic cleavage of the invasive substrate.

The protocol for fluorometric discrimination between C and ^{m}C by a combination of the NQ-photosensitized strand cleavage and the invasive cleavage assay is shown in Figure 1a. We designed a modified ODN containing an NQ chromophore in the interior of the strand so as to hybridize to target ODNs containing C or ^{m}C. Photooxidation and subsequent alkali treatment of the duplex with ^{m}C induced exclusive strand cleavage at ^{m}C to generate the characteristic ODN fragments. To the resulting solution was added a fluorescent hairpin oligomer probe (Probe ODN) containing fluorescein at the 5′-end and a dabcyl quencher in the interior of the strand to be hybridized with the photolyzed ODN fragment into a complex that could form an overlap structure as a recognition domain of human Flap endonuclease-1 (FEN-1) (*21, 22*). Thus, treatment of the complex by FEN-1 led to the strand cleavage of Probe ODN at the invasive site, releasing the fluorophore that showed intense fluorescence emission as a result of separation from the intramolecular quencher. In contrast to the intense emission observed for the DNA with target ^{m}C site, faint fluorescence emission was observed when the DNA sequence contained the normal C instead of the target ^{m}C, which was stable to

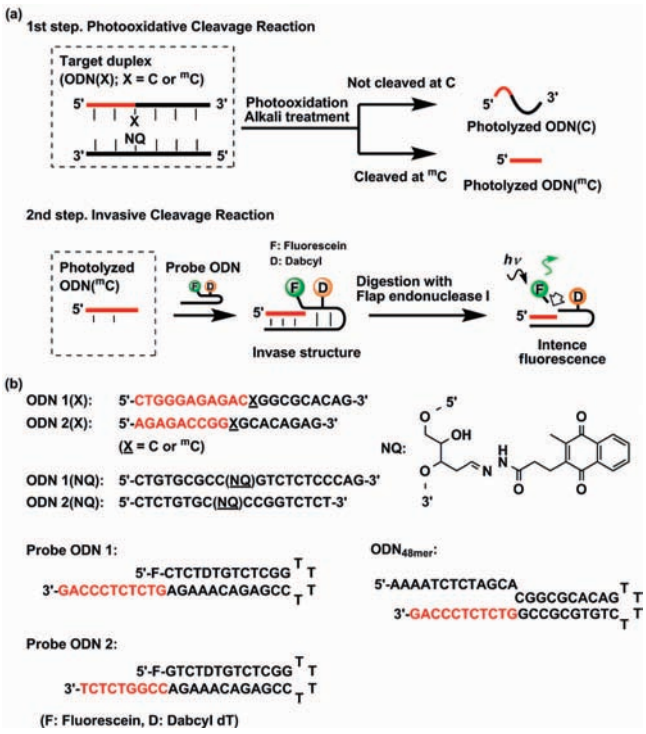

Figure 1. (a) Protocol for fluorometric discrimination between C and ^{m}C in DNA using the photooxidative-invasive dual cleavage system. "F" and "D" of Probe ODNs denote fluorescein and dabcyl groups, respectively. (b) Sequences and structures of ODNs used in this study.

photosensitized oxidation and alkali treatment, so that hybridization with the Probe ODN could not occur.

We performed discrimination analysis between C (ODN 1(C)) and ^{m}C (ODN 1(^{m}C)) in a partial sequence of the human p53 gene corresponding to codons 278–284 of exon 8, which has been identified as a methylation hot spot (*23*). The sequences of ODNs used in this study are summarized in Figure 1b. Duplex of ODN 1(NQ) with 500 fmol ODN 1(C) or ODN 1(^{m}C) was photoirradiated with 312 nm UV light at 0 °C in 2 mM sodium cacodylate buffer (pH 7.0) containing 20 mM NaCl and treated with hot piperidine to produce fragments with a specified base sequence. We estimated the cleavage efficiency of ODN 1(^{m}C) at ^{m}C to be 5.1% yield by densitometric anaylsis of the gel image (See Supporting Information Figure S1).[1] Probe ODN and FEN-1 were then added to the photolyzed ODNs and incubated at 30 °C. As shown in Figure 2a, intense fluorescence emission was observed for the sample derived from enzymatic digestion by FEN-1 of the photolyzed ODN 1(^{m}C), whereas fluorescence intensity for the similarly photolyzed and digested ODN 1(C) was at background level as in the digestion of Probe ODN 1 alone.[2] Fluorescent microscopic analysis of the digested mixture was also carried out in agarose gel. The highly viscous medium of agarose gel can effectively suppress dynamic fluorescence quenching by molecular oxygen, resulting in an enhanced visualization of the fluorescence emission (*24, 25*).[3] Intense green fluorescence was thus observed in the gel containing the photolyzed ODN 1(^{m}C), whereas only faint

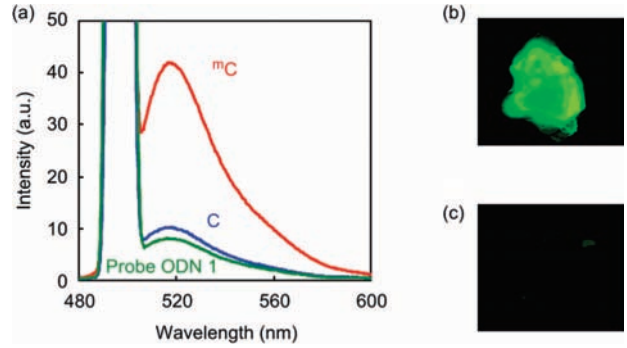

Figure 2. Fluorometric discrimination between C and ^{m}C in a partial sequence of the p53 gene using a combination of photosensitized oxidation and invasive cleavage. (a) Fluorescence spectra (excitation at 495 nm) of the reaction mixture after photoirradiation of the 500 fmol ODN 1(NQ)/ODN 1(X) duplexes, piperidine treatment, and enzymatic digestion by FEN-1: photolyzed ODN 1(^{m}C)/Probe ODN 1, red line; photolyzed ODN 1(C)/Probe ODN 1, blue line; Probe ODN 1 alone, green line. Fluorescence micrograph of the gel containing (b) photolyzed ODN 1(^{m}C) or (c) photolyzed ODN 1(C).

fluorescence could be detected in the gel containing the photolyzed reference ODN 1(C) (Figure 2b,c). Similar fluorometric identification of ^{m}C in a different site of exon 8 in the p53 gene (ODN 2(X)) was conducted, using the corresponding ODN 2(NQ) and Probe ODN 2. Consequently, we also confirmed intense fluorescence emission for the ODN containing ^{m}C at the target site (See Supporting Information Figure S3). These results strongly suggest that the methylation status of DNA can be quantified as a positive signal by fluorometry of the photolyzed target ODN(^{m}C) after hybridization with appropriate Probe ODNs and treatment with FEN-1.

An attempt was also made to determine the concentration limit of modified ^{m}C for discrimination from normal C in the same DNA with a partial sequence of the p53 gene, using the present combination protocol of NQ-sensitized photoreaction and invasive cleavage reaction. We evaluated the photoreaction of ODN 1(NQ) in the presence of 500 to 0.5 fmol ODN 1(C) or ODN 1(^{m}C), followed by the enzymatic digestion of an excess amount of Probe ODN 1 using FEN-1. As shown in Figure 3, the fluorescence intensity for photolyzed ODN 1(^{m}C)/Probe ODN 1 decreased with decreasing concentration of target ODN 1(^{m}C), in which we could detect a distinct emission even at 0.5 fmol target DNA. Thus, the present protocol provides a simple visualization procedure that is capable of detecting ^{m}C in target DNA at the subfemtomole level.

It is noteworthy that the fluorescence emission from the FEN-1-digested sample containing 0.5 fmol ODN 1(^{m}C) was similar to that from 5 fmol Probe ODN digested completely by calf intestinal alkaline phosphatase, nuclease P1, and phosphodiesterase I. This result indicates occurrence of a turnover process, in which a net amount of ca. 5 fmol free fluorescein was released from Probe ODN 1 by the proposed mechanism during the FEN-1 digestion for 5 min in the presence of only 0.5 fmol ODN 1(^{m}C). Since the enzymatic digestion reaction was performed near the melting temperature (T_m = ca. 33 °C) of the hybrid of Probe ODN 1 with a fragment derived from the target photolyzed ODN 1(^{m}C),[4] the Probe ODN 1 digested to release fluorescein could be readily replaced by an undigested probe into a fresh hybrid. This strand exchange may occur consecutively during the enzymatic reaction at around the T_m, resulting in significant enhancement of fluorescence due to the

[1] To characterize a photolyzed product, we performed MALDI-TOF mass analysis of photoirradiated and alkali-treated ODN 1(NQ)/ODN 1(^{m}C), which indicated the 5′-fragment of ODN 1(^{m}C) as a photolyzed ODN 1(^{m}C): 5′-d(CTGGGAGAGAC)-3′ *m/z* 3405.75 (calcd. for $[M - H]^{-}$ = 3405.24).

[2] We also confirmed that photoirradiation and alkali treatment are responsible for the fluorometric detection of ^{m}C (See Supporting Information Figure S2).

[3] The dynamic fluorescence quenching rate constant (k_q) of fluorescein with molecular oxygen decreases with increasing medium viscosity, thus resulting in the increased fluorescence quantum yields; see ref (*25*).

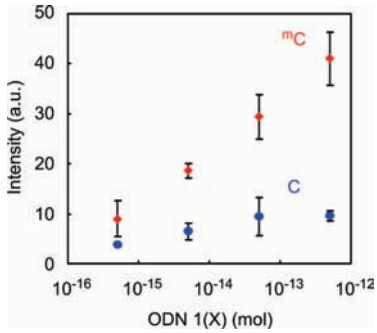

Figure 3. The detection limit of the present protocol for fluorometric identification of ^{m}C modification in a partial sequence of the p53 gene using the present combination protocol. The fluorescence intensity at 518 nm (excitation at 495 nm) of the reaction mixture upon varying the concentration of ODN 1(X): for photolyzed ODN 1(^{m}C)/Probe ODN 1, ♦ (red); photolyzed ODN 1(C)/Probe ODN 1, (blue).

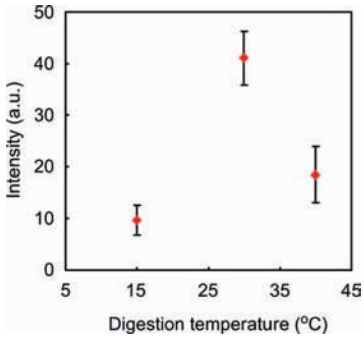

Figure 4. The influences of temperature on the FEN-1 digestion and the fluorescence intensity of the photolyzed ODN 1(^{m}C)/Probe ODN 1. Fluorescence intensity at 518 nm (excitation at 495 nm) of the reaction mixture was monitored after photoirradiation of 500 fmol ODN 1(NQ)/ODN 1(^{m}C) duplex, piperidine treatment, and enzymatic digestion by FEN-1 at given temperatures of 15, 30, and 40 °C.

accumulation of released fluorescein. Therefore, highly sensitive discrimination between C and ^{m}C in a subfemtomolar amount of DNA is accessible by the rational use of photochemical site-selective cleavage at ^{m}C in the target sequence and subsequent enzymatic digestion.

To confirm the influence of temperature on the enzymatic digestion with turnover process, we carried out the enzymatic reaction of Probe ODN 1 in the presence of photolyzed ODN 1(^{m}C) at various temperatures. As shown in Figure 4, the fluorescence intensity values for photolyzed ODN 1(^{m}C)/Probe ODN 1 digested at both 15 and 40 °C were much smaller than the corresponding intensities upon similar digestion at 30 °C. In view of the characteristic melting temperature of $T_m = 33.8$ °C corresponding to the dissociation of photolyzed ODN 1(^{m}C)/Probe ODN 1,[4] the apparent activity of the enzyme decreases due to dissociation of duplex DNA at the higher temperature of 40 °C, while the enzymatic digestion reaction is more accelerated with increasing temperature. At present, however, another possibility cannot be ruled out: FEN-1 may be less active for strand cleavage at 40 °C. In any event, there should be an appropriate temperature below T_m for the enzymatic digestion in order to obtain the maximum intensity of fluorescence emission.

To gain insight into a reaction mechanism by which Probe ODNs form hybrids with fragments derived from photolysis of ODNs to undergo enzymatic digestion, we performed a control enzymatic reaction by FEN-1, using ^{32}P-labeled ODN$_{48mer}$ instead of fluorescein-bearing Probe ODNs. To a solution of ODN 1(^{m}C) and ODN 1(NQ) after photosensitized oxidation and alkali treatment were added ^{32}P-labeled ODN$_{48mer}$ and FEN-1, and the resulting reaction mixture was analyzed by PAGE. As shown in Figure 5, the major cleavage band observed is consistent with a 13-mer ODN marker, demonstrating that enzymatic strand cleavage could occur at the invasive site of ODN$_{48mer}$. It is also evident that the strand cleavage releasing similar 13-mer ODN occurs in negligible amount comparable to the background level, when the hybrid of ^{32}P-labeled ODN$_{48mer}$ with photolyzed ODN 1(C) was digested by FEN-1. These results are a strong indication that the intense fluorescence emission is attributable to the efficient occurrence of the prescribed cleavage at the invasive site.

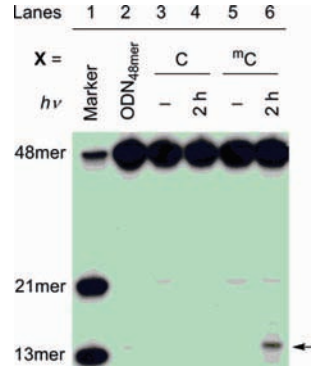

Figure 5. A representative autoradiogram of denaturing gel electrophoresis for ^{32}P-labeled ODN$_{48mer}$. Photoreaction of the duplexes containing NQ chromophore was carried out for 0 h (lanes 3 and 5) or 2 h (lanes 4 and 6), followed by a hot piperidine treatment. ^{32}P-labeled ODN$_{48mer}$ was added to the solution and incubated with FEN-1 at 30 °C for 7 h: lane 1, marker lane; lane 2, ODN$_{48mer}$; lanes 3 and 4, photolyzed ODN 1(C)/ODN$_{48mer}$; lanes 5 and 6, photolyzed ODN 1(^{m}C)/ODN$_{48mer}$.

It has been reported that the Invader assay requires absolute complementarity between the probe and the target sequence at the position of overlap for efficient enzymatic cleavage, by which a cleavage rate at least 300 times higher than that for a noncomplementary substrate can be achieved (*17*, *18*). In a control experiment, we also examined the enzymatic digestion of a mixture containing photolyzed ODN 1(^{m}C) and fluorescein-bearing ODN with a noncomplementary base sequence. As predicted, no fluorescence emission was observed using such a noncomplement Probe ODN, indicating that the present detection system requires accurate complementation as in the Invader assay to detect SNPs. It is also noted that this procedure allows site-specific discrimination of modified ^{m}C and normal C in a given DNA (See Supporting Information Figure S5).

In summary, we developed a simple and sensitive method for fluorometric discrimination between C and ^{m}C in DNA using the dual action of photosensitized oxidative cleavage and a modified Invader method. Distinct fluorescence emission was detected upon invasive digestion reaction of the hybrid of fluorescein-bearing Probe ODNs with the sequences-specific fragment released photochemically from the target DNA containing the ^{m}C site, by which the discrimination between ^{m}C and C in the target DNA is feasible even at the subfemtomole level. Because of such a high sensitivity, the present fluorometric system may be a promising protocol to determine the methylation status of DNA.

ACKNOWLEDGMENT

Comparison of a Tartaric Acid Derived Polymeric MRI Contrast Agent to a Small Molecule Model Chelate

Robie L. Lucas, Michael Benjamin, and Theresa M. Reineke*

Department of Chemistry, University of Cincinnati, Cincinnati, Ohio 45221-0172. Received October 6, 2007

Contrast agents with high relaxivity are needed to increase the sensitivity of magnetic resonance imaging (MRI) for novel clinical and research applications. For this reason, polymeric structures containing multiple Gd(III) chelates are of current interest. Described in this communication are the syntheses and characterization of a glycopolymer derived from L-tartaric acid, Gd**4**(H_2O), as well as a low molecular weight compound, Gd**10**(H_2O), that models the Gd(III) chelate structure in the repeat unit of polymer Gd**4**(H_2O). Luminescence lifetime measurements in H_2O and D_2O for Eu(III) analogues of Gd**4**(H_2O) and Gd**10**(H_2O) [named Eu**4**(H_2O) and Eu**10**(H_2O)] reveal that the lanthanide in both structures likely has one water ligand in the primary coordination sphere. The relaxivity of the model chelate Gd**10**(H_2O) at 400 MHz and 310 K was determined to be 4.7 $mmol^{-1}\cdot s^{-1}$, representing a nearly 50% increase over Magnevist (3.2 $mmol^{-1}\cdot s^{-1}$). Relaxivity values on a per Gd basis for the polymeric structure Gd**4**(H_2O) prepared at two degrees of polymerization, $n = 12$ and 19, are similar, but slightly lower than Gd**10**(H_2O) (4.4 $mmol^{-1}\cdot s^{-1}$ and 4.5 $mmol^{-1}\cdot s^{-1}$, respectively). However, their molecular relaxivities of 51 $mmol^{-1}\cdot s^{-1}$ and 80 $mmol^{-1}\cdot s^{-1}$, respectively, provide a substantial increase over that of Magnevist.

The utility of magnetic resonance imaging (MRI) is currently being expanded beyond its role as the leading imaging modality in diagnostic medicine (*1*). MRI is noninvasive and provides real-time images, which make it an ideal research tool for visualizing drug delivery (*2*, *3*), monitoring biological processes, and following functional changes in vivo (*4*). To reach the full potential of MRI for such advanced imaging applications requires that the inherently low sensitivity of MRI be modulated with contrast agents containing paramagnetic metal ions, such as Gd(III) (*5*, *6*). However, current clinically used contrast agents based on low molecular weight Gd(III) chelates, such as Magnevist, do not sufficiently enhance water proton relaxation rates enough to function for these purposes (*7*), and their image-enhancing properties dramatically diminish at the increasingly higher magnetic fields of modern MRI instruments (*8*). In fact, the advanced applications described above will likely require macromolecular systems with multiple Gd(III) centers (*6*), which may retain their high relaxivities at high magnetic field strengths. Several design strategies have been used to incorporate multiple Gd(III) chelates within macromolecular structures, including linear polymers (*9*–*12*), dendritic systems (*13*–*16*), carbon nanotubes (*17*), and self-assembled bimetallic complexes (*18, 19*). For example, Kiessling and co-workers recently reported a linear polymer prepared via ring-opening metathesis polymerization that contained hydroxypyridonate (HOPO)-based Gd(III) chelates (*12*). Incorporating the high relaxivity HOPO-Gd(III) chelates (*20*) into a polymeric structure provided a contrast agent with per Gd and molecular relaxivities substantially higher than those of clinical contrast agents at 60 MHz. This example clearly demonstrates the ability of multivalent systems to significantly enhance relaxation properties. However, the influence of specific features of molecular structure in polymeric systems on relaxation properties has not been clearly established, particularly at higher magnetic field strengths (*21*).

Our previous work has demonstrated that incorporating carbohydrate residues along a polymer backbone decreases the toxicity of gene delivery vectors (*22*). Here, we extend this strategy to create a system that contains repeated carbohydrates with Gd(III) chelates along the polymer backbone. Incorporating carbohydrate-based components within the repeat unit increases hydrophilicity and may serve to enhance biocompatibility. Herein, a linear polymer, Gd**4**(H_2O), has been prepared that contains a repeat unit consisting of a tartaric acid diamide moiety, an ethylenediamine-derived linker, and a Gd(III)-DTPA(bisamide) chelate (Figures 1 and 2). In addition, to assist our understanding of the coordination environment of this polymer, a low molecular weight chelate, Gd**10**(H_2O), intended to model the Gd(III) chelate within the polymer repeat unit has been synthesized. These structures are allowing us to investigate the influence of polymer and repeat unit structure on the relaxivity properties of glycopolymer contrast agents. The syntheses, characterization, relaxivities, and water coordination properties of these macromolecular systems are presented.

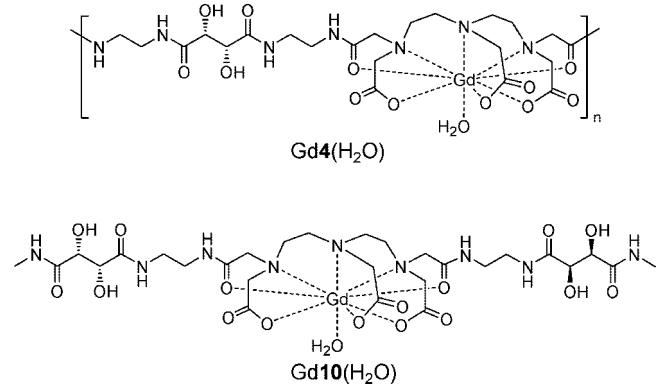

Figure 1. Target structures of the tartaramide-based polymer Gd**4**(H_2O) and model chelate Gd**10**(H_2O).

We have developed a methodology to prepare carbohydrate−diamine monomers that undergo step-growth polymerization with diethylenetriaminepentaacetic acid-bisanhydride (DTPA-BA) to yield novel glycopolymers that chelate Gd(III). To

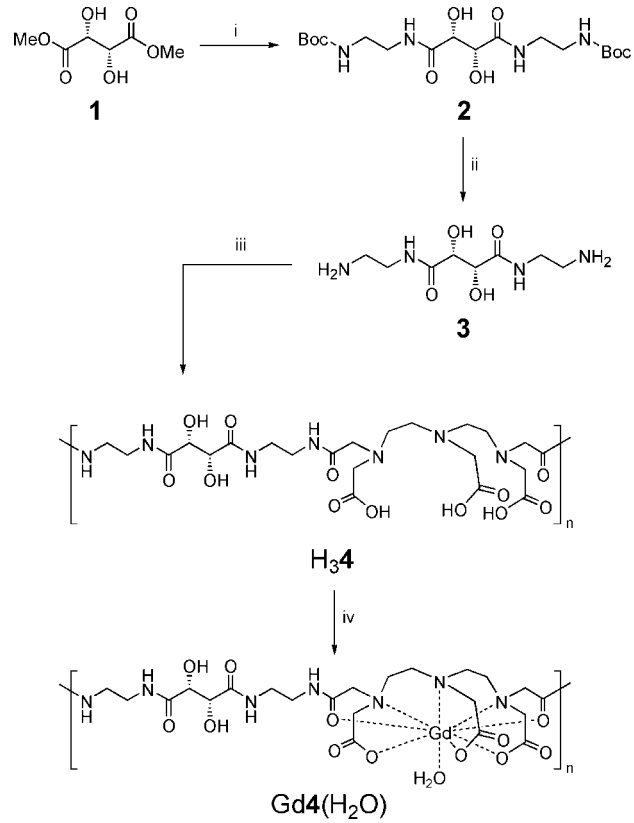
Scheme 1. Synthetic Protocol for the Polymer Gd4(H_2O)[a]



[a] (i) Mono-*N*-Boc-ethylenediamine, MeOH, Δ; (ii) 4.0 M HCl in 1,4-dioxane; (iii) DTPA-BA, DMSO, 24 or 72 h; (iv) $GdCl_3 \cdot 6H_2O$, NaOH, H_2O, pH 6−7.

prepare the carbohydrate−diamine monomer **3**, dimethyl L-tartrate **1** was refluxed with 2 equiv of mono-*N*-Boc-ethylenediamine in MeOH, which provided the Boc-protected tartaric acid diamide **2** in 67% yield (Scheme 1). Treatment of the diamide **2** with a solution of HCl in 1,4-dioxane to remove the Boc groups, followed by purification of the resulting diamine hydrochloride salt via ion exchange chromatography, yielded the pure monomer **3** in quantitative yield. The polymer precursors H_3**4** were synthesized by condensing **3** with DTPA-BA in DMSO at room temperature, and the molecular weight was varied by increasing the polymerization time. After the polymerizations were complete, the polymers were purified by exhaustive dialysis against ultrapure water using 3500 MWCO membranes and were then lyophilized to dryness. Formation of Gd**4**(H_2O) occurred by treatment of the polymers H_3**4** with $GdCl_3$ in aqueous solution, while maintaining a pH of 6–7 with aqueous NaOH. Following Gd(III) chelation, the polymers were again purified by exhaustive dialysis in 1000 MWCO membranes against ultrapure water to remove any unchelated Gd(III) ions and other salts. Characterization of Gd**4**(H_2O) was accomplished by gel permeation chromatography (GPC) using a triple detection system of refractive index, viscometry, and static light scattering. Two polymers were synthesized with weight-averaged molecular weights (M_w) of 8.9 kDa and 14.0 kDa, which correspond to degrees of polymerization of $n = 12$ and $n = 19$, respectively. The polymers revealed relatively low polydispersity indices for a step-growth mechanism (1.4 and 1.6, respectively), which is likely an artifact of the dialysis step. The Mark–Houwink−Sakurada α values (0.6–0.7) obtained from viscometry data demonstrated the formation of linear, randomly coiled polymers.

Synthesis of the small molecule chelate to model the polymer repeat unit required the preparation of an unsymmetrical tartaric acid diamide with only a single primary amine (compound **9** in Scheme 2). To prepare this compound, we made use of the known di-*O*-acetyl protected tartaric anhydride **6**, which was prepared from L-tartaric acid **5** in 81% yield by refluxing in acetic anhydride in the presence of sulfuric acid (*23*). The anhydride **6** was subsequently converted to the *N*-methyltartaramic acid **7** in 75% yield by treatment of the anhydride with a solution of methylamine in THF. This sequence was deemed more practical than attempting a selective monoamidation of L-tartaric acid directly. Standard coupling conditions using *N*,*N*′-dicyclohexylcarbodiimde (DCC) were used for amide bond formation between tartaramic acid **7** and mono-*N*-Boc-ethylenediamine to provide the diamide **8** in 47% yield. Simultaneous removal of the Boc (*24*) and acetyl (*25*) protecting groups was then achieved with 3 equiv of *p*-toluenesulfonic acid monohydrate in a CH_2Cl_2−MeOH solvent system. The crude product resulting from this reaction was purified and neutralized by ion exchange chromatography, giving the unsymmetrical tartaric acid diamide **9** in 91% yield. The ligand of the model chelate H_3**10** was then obtained in 65% yield by reacting 2 equiv of **9** with DTPA−BA in DMF at 65 °C. The ESI mass spectrum of H_3**10** showed only two significant peaks at $m/z = 768$ and $m/z = 385$, corresponding to the proton adduct $[H_3\mathbf{10} + H]^+$ of the desired product and its doubly charged derivative $[H_3\mathbf{10} + 2H]^{2+}$, respectively. The model chelate Gd**10**(H_2O) was prepared by treating an aqueous solution of the ligand H_3**10** with $GdCl_3$ at a pH of 6–7 and purifying by exhaustive dialysis in a 1000 MWCO membrane against ultrapure water. The major peak in the ESI mass spectrum corresponded to the proton adduct of the anhydrous chelated product {$[Gd\mathbf{10} + H]^+$, $m/z = 923$}. Complete loading of Gd(III) was also evidenced by the absence of a peak at $m/z = 768$ (the proton adduct of the unchelated ligand H_3**10**).

Knowledge of the structure of a Gd(III) chelate in aqueous solution is important for understanding the factors that dictate its capacity to enhance proton relaxation. Of particular importance is knowing the number of water molecules bound in the primary coordination sphere, *q*, of the Gd(III) center. The isostructural nature of Ln(III) complexes with a common chelating ligand is useful for probing the solution structure of Gd(III) chelates (*7*). Replacement of Gd(III) with Eu(III) makes it possible to determine *q* by using the proportionality of their corresponding luminescence decay rates in H_2O and D_2O (*26*). With this in mind, the Eu(III) analogues of the model chelate and the polymer were synthesized in a fashion similar to the related Gd(III) structures. Analysis of Eu**4**(H_2O) via GPC indicated a polymer with a M_w value of 18.6 kDa (25 repeat units). Luminescence lifetimes were measured for both Eu(III) structures in H_2O and D_2O, and *q* values were calculated using an equation developed by Horrocks et al., [$q = 1.11(k_{H_2O} - k_{D_2O} - 0.31 + 0.075n_{O=CNH})$] (*27*). These experiments revealed the same *q* values of 1.2 for both the Eu(III) model chelate, Eu**10**(H_2O), and for the Eu(III) polymer, Eu**4**(H_2O). It should be noted that these results (Table 1) are in good agreement with other Ln(III)-DTPA derivatives with a single water molecule in the primary coordination sphere (*27*).

Relaxivity values for the model chelate Gd**10**(H_2O) and the polymers Gd**4**(H_2O) were determined at 400 MHz (9.4 T) and 310 K. For comparison to a clinical contrast agent at this magnetic field, we measured the relaxivity, r_1, of Magnevist and obtained a value of 3.2 $mmol^{-1} \cdot s^{-1}$. The relaxivity value of the model chelate Gd**10**(H_2O) was found to be 4.7 $mmol^{-1} \cdot s^{-1}$, which represents an approximately 50% increase over Magnevist. The relaxivity values for the polymeric chelates Gd**4**(H_2O) on a per Gd basis are slightly lower than that obtained for the small molecule model chelate, with values of 4.4 $mmol^{-1} \cdot s^{-1}$ (for $n = 12$) and 4.5 $mmol^{-1} \cdot s^{-1}$ (for $n = 19$).

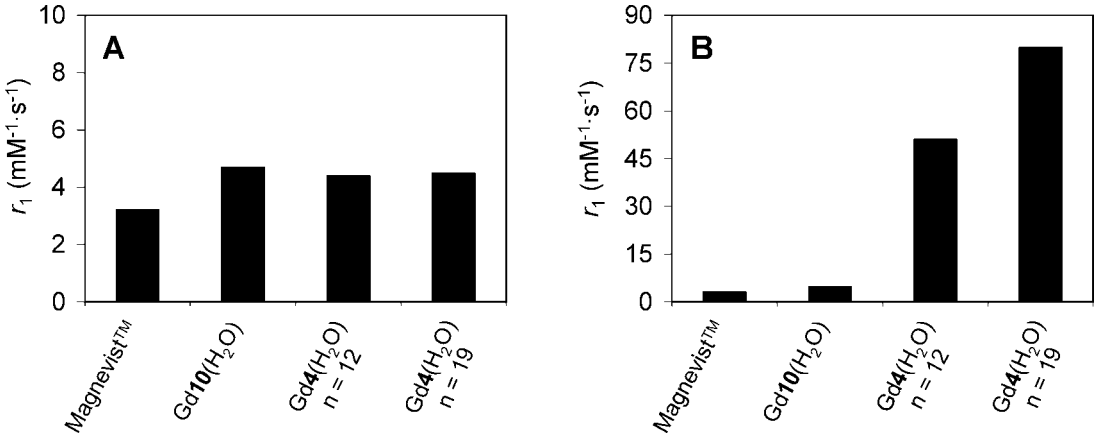


Figure 2. Per Gd(III) ion (A) and per molecule (B) relaxivities of Magnevist, the small molecule model chelate Gd**10**(H_2O), and the polymeric system Gd**4**(H_2O) with 12 and 19 repeat units.

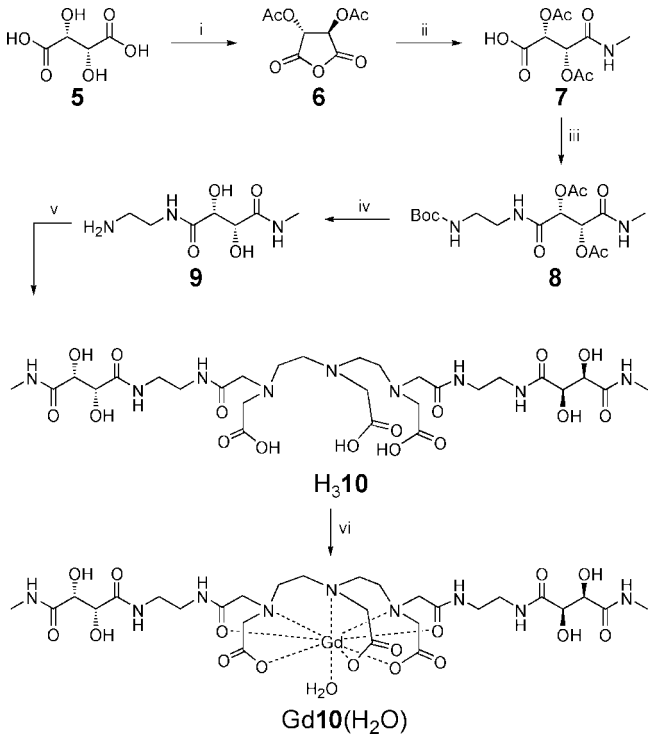
Scheme 2. Synthesis of the Model Chelate Gd10(H_2O)[a]



[a] (i) Acetic anhydride, H_2SO_4, Δ; (ii) 2.0 M methylamine in THF; (iii) *N,N′*-dicyclohexylcarbodiimide, CH_2Cl_2, 0 °C to rt; (iv) *p*-toluenesulfonic acid monohydrate, MeOH−CH_2Cl_2 (1:9); (v) DTPA−BA, DMF, 65 °C; (vi) $GdCl_3·6H_2O$, NaOH, H_2O, pH 6−7.

Table 1. Luminescence Lifetime Data for the Polymer Eu4(H_2O) and Model Chelate Eu10(H_2O)[a]

compound	τH_2O (ms)	τD_2O (ms)	q^a
Eu**4**(H_2O)	0.60	2.3	1.2
Eu**10**(H_2O)	0.62	2.5	1.2

[a] The polymer Eu**4**(H_2O) consists of 25 repeat units based on M_w from GPC analysis. Values of q were determined using the equation developed by Horrocks et al. (*27*).

These relaxivity values suggest that the relatively short polymers have considerable internal flexibility, despite incorporating the DTPA-based Gd(III) chelates directly into the polymer backbone. In addition, the lack of rigidity may facilitate electronic relaxation via Gd−Gd interactions and decrease relaxivity (*28*). Merbach et al. previously synthesized a series of related linear polymers prepared by polymerizing DTPA−BA with simple straight-chain alkyldiamines, where the number of methylenes between the amino groups was 4, 6, 10, or 12 (*9*). The high relaxivities exhibited by the polymers formed from diamines with 10 and 12 methylene groups was attributed to the formation of micelle structures with strong hydrophobic interactions, a consequence of using lipophilic alkyldiamine monomers. The polar diamine monomer **3** used in the present study is hydrophilic and would not form micelle-like structures in aqueous solution. Besides the influence of rotational properties, the limited relaxivity gains for Gd**4**(H_2O) and Gd**10**(H_2O) versus Magnevist may also be due to the well-established slow water exchange rate of Gd(III)-DTPA(bisamides) (*29*). Despite the fact that the per Gd relaxivity does not increase for the polymers of the present study versus the model chelate, the molecular relaxivities are very high for the polymers of $n = 12$ and $n = 19$, with values of 51 mmol^{-1}·s^{-1} and 80 mmol^{-1}·s^{-1}, which represent 16- and 25-fold increases, respectively, over the molecular relaxivity of Magnevist. Molecular relaxivities for polymeric systems are substantial, as they demonstrate the potential for higher Gd concentration to increase local proton relaxation in the vicinity of the contrast agent.

Advanced biomedical and molecular imaging applications using MRI contrast agents will likely require incorporating multiple Gd(III) chelates into macromolecular structures (*6, 21, 30*). We have presented the synthesis, characterization, and properties of two novel contrast agents, a small molecule model chelate, Gd**10**(H_2O), and a polymeric structure, Gd**4**(H_2O), which were formed by coupling tartaric acid derived amines with DTPA−BA. The relaxivity properties of the Gd(III) chelates within the polymeric structures are similar to that of their low molecular weight analogue Gd**10**(H_2O) on a per Gd basis; however on a molecular basis, the polymers clearly yielded substantially higher relaxivities. The generality of the synthetic protocol for these polymers is currently being utilized to generate a series of related polymeric materials using different carbohydrate-based monomers. The influence of carbohydrate structural variation within this series is currently under investigation.

Curing HIV-1 infection has remained elusive because of low and fluctuating drug levels arising from poor absorption, the development of viral reservoirs and sanctuary sites, toxicity, and patient nonadherence. The present study addresses the issue of insufficient drug exposure in macrophages. Viral reservoir sites such as macrophages are believed to be responsible for the viral rebound effect observed upon the discontinuation of anti-HIV drug therapy. In our proposed model, a drug can be covalently attached to a nanocarrier in order to facilitate the delivery of therapeutic agents to the site(s) of infection. As an initial step, we propose the covalent attachment of several copies of *N*-formyl-Met-Leu-Phe (fMLF), a known chemo-attractant for macrophages. In this article, one or more copies of fMLF were conjugated to multifunctional commercially available or novel, peptide-based PEG nanocarriers in which the structure was varied by appending PEGs with average molecular weights of 5, 20, and 40 kDa. U937 cell-specific binding and cellular uptake were analyzed. The results of uptake studies indicate that (i) uptake is energy dependent and mediated by a fMLF receptor, (ii) appending only 2 copies of the targeting ligand to the multifunctional nanocarrier appears sufficient for binding *in vitro*, and (iii) of the three configurations studied, the nanocarrier with a molecular weight of about 20 kDa, corresponding to a size of 20–60 nm, demonstrated the highest uptake. The results of the current studies demonstrate the feasibility of targeting macrophages and the suitability of using these synthetically versatile peptide−backbone PEG nanocarriers. The convenience, flexibility and possible limitations of this nanocarrier approach are discussed.

INTRODUCTION

Infection by human immunodeficiency virus type 1 (HIV-1) is the cause of acquired immunodeficiency syndrome (AIDS). AIDS is characterized by the severe impairment of immune system functions resulting in a profound decrease in the number of CD4+ T cells. The advent of highly active antiretroviral therapy (HAART), a multiple drug treatment regimen, has led to a dramatic decrease in both the morbidity and mortality of HIV patients (*1*). Despite this success, curing HIV infection has remained an elusive goal because of many challenges, including low and fluctuating drug concentrations due to poor drug absorption or patient nonadherence (*2*), the presence of viral reservoirs and sanctuary sites (*3*), and drug toxicity due to chronic therapy (*4*).

Macrophages are infected early during HIV infection and play an important role throughout the course of infection (*5*). Viral strains that establish infection in the new host are macrophage-tropic in over 95% of early asymptomatic individuals (*5*, *6*). HIV enters macrophages via interactions with surface receptor CD4 (cluster designation 4) and coreceptor CCR5 (chemokine C-C motif receptor 5). Individuals bearing a homozygous deletion of CCR5 (CCR5 △ 32) are highly resistant to HIV-1 infection despite multiple sexual exposures (*7*, *8*). HIV-1 infection of macrophages is productive but noncytopathic, permitting them to serve as a long-lived source of HIV production. Infected macrophages are found in all tissues including the brain, gut, liver, lungs, lymphoid tissues, and spleen. More significantly, they represent major viral reservoirs and are responsible for the relapse of infection and development of resistance upon the discontinuation of treatment. Taken together, macrophages represent a key target and an important HIV cellular reservoir for therapeutic approaches aimed at decreasing the replication of the residual virus that survives HAART (*9*).

Among the major causes of HIV treatment failure, insufficient drug exposure due to poor penetration into viral reservoirs is

one of the areas where little progress has been made, and efforts are generally lacking. Macrophage-specific drug delivery could significantly improve current anti-HIV therapy by improving therapeutic efficacy, minimizing systemic toxicity, and simplifying administration regimens. Targeting may possibly be achieved by covalently attaching a drug to a macrophage-specific ligand via a polymeric nanocarrier. A number of natural ligands for macrophage targeting have been explored. An example of such a ligand is IgG-derived immunomodulating peptide tuftsin (Thr-Lys-Pro-Arg), which has been conjugated to the HIV reverse transcriptase inhibitor 3′-azido-3′-deoxythymidine (AZT) (*10*). The AZT−tuftsin chimera possessed characteristics of both components, including inhibition of reverse transcriptase and HIV−antigen expression, stimulation of IL-1 release from mouse macrophages, and augmentation of the immunogenic function of the cell. Similarly, acetylated low-density lipoprotein (AcLDL), a ligand for macrophage scavenger receptors, has been conjugated to AZT (*11*). A 10-fold increase in the uptake of AcLDL−AZT was observed as compared to AZT in murine (J774) and human (U937) macrophage cell lines.

N-formyl peptides are cleavage products of bacterial and mitochondrial proteins and serve as potent chemoattractants for mammalian phagocytic leukocytes. The synthetic peptide *N*-formyl-methionyl-leucyl-phenylalanine (fMLF) is the first identified and most potent chemoattractant for human macrophages (*12*). fMLF binds to the formyl peptide receptor (FPR) with high affinity (10–30 nM) and to its variant FPRL1 with low affinity (*12*). When the free fMLF chemotactic peptide binds to a phagocytic cell, rapid receptor-mediated internalization takes place (*13*). After binding to the receptors, fMLF activates phagocytic leukocytes through a G-protein-mediated signaling cascade resulting in increased cell migration, calcium mobilization, and the heterologous down-regulation of the expression and function of the two chemokine receptors CCR5 and CXCR4, which are the key fusion coreceptors for HIV-1 (*12*). fMLF has been used for imaging of infection and inflammation (*14*).

Previous work by our group showed that increasing the number of fMLF residues (up to eight) attached to a single PEG polymer resulted in enhanced avidity (K_d = 0.18 nM) for neutrophil-like differentiated HL-60 cells relative to free fMLF (K_d = 28 nM) (*15*). A PEG polymer bearing four fMLF and four digoxigenin residues showed specific enhancement in binding to differentiated HL-60 cells and mouse peritoneal macrophages *in situ* relative to a polymeric carrier lacking fMLF. Furthermore, increasing copy numbers of fMLF increased avidity more potently than it increased cell activation, suggesting that toxicity due to excessive phagocyte activation might not be a problem. These early results provided conceptual feasibility. However, further studies are required in order to evaluate if biologically compatible polymer conjugates bearing multiple fMLF residues can be used as effective targeted drug delivery systems for phagocytic cells. In general, the successful development of a nanocarrier delivery system requires an understanding of (1) the relationship between cell uptake and the copy number, size, and shape of the constituent PEG chains, (2) the avidity and specificity of the interactions between the ligands appended to the nanocarriers and the cognate receptors on the target cell, and (3) the chemical reactions required for the synthesis of such macromolecules, including the stability of the conjugates prior to administration and disassembly and release of the active drug after reaching the target site.

In the present study, a series of PEG nanocarriers with different numbers of fMLF and various PEG structures were designed, synthesized, and evaluated *in vitro* for targeting to human U937 cells induced to differentiate into a macrophage phenotype. The relationship between the molecular features of PEG-fMLF nanocarriers (i.e., number of targeting peptide and PEG sizes) and cell uptake was elucidated. The current studies further demonstrate the feasibility of using macrophage-targeted nanocarriers, while also introducing a new nanocarrier that allows for the attachment of multiple drugs and targeting moieties resolving a potentially major limitation of commercially available PEGs.

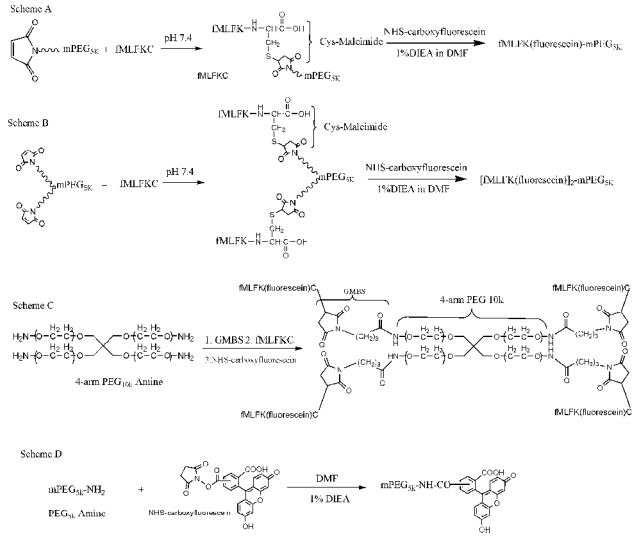
MATERIALS AND METHODS

Materials. *N*-formyl-Met-Leu-Phe-Lys-Cys-amide and the backbone peptides acetyl-Cys(thiopyridine)-(β-Ala-β-Ala-Lys)$_n$-amide (n = 2, 4) were synthesized via Fmoc Chemistry by the W.M. Keck Facility (New Haven, CT). *N*-hydroxysuccinimide (NHS)-PEG-vinyl sulfone (VS; NHS-PEG-VS) (MW ∼5 kDa), mPEG-MAL (MW ∼5.5 kDa), mPEG-(MAL)$_2$ (MW ∼5.5 kDa, 20 kDa, and 40 kDa), mPEG-NH$_2$ (MW ∼5 kDa), and 4-arm PEG-(NH$_2$)$_4$ (MW ∼10 kDa) were obtained from Nektar Therapeutics (Huntsville, AL). *N*-maleimidobutyryloxysuccinimide ester (GMBS) was obtained from Pierce Biotechnology (Rockford, IL). NHS-carboxyfluorescein was obtained from Sigma-Aldrich (St. Louis, MO). Fluo-4 AM (acetoxymethyl ester) was obtained from Molecular Probes (Eugene, OR). DMF **(**dimethylformamide), DIEA (diisopropylethylamine), acetonitrile (ACN), trifluoroacetic acid (TFA), ether, and other chemical reagents were purchased from Sigma-Aldrich (St. Louis, MO).

Synthesis and Characterization of PEG-fMLF Nanocarriers. *PEG$_{5k}$-fMLF(fMLFK(FLUORESCEIN)C-mPEG$_{5K}$) and PEG$_{5K,20K,40K}$-(fMLF)$_2$ ([fMLFK(FLUORESCEIN)C]$_2$-mPEG$_{5K,20K,40K}$).* mPEG$_{5K}$-maleimide (11.2 mg, 2 mmol) was dissolved in 1 mL of phosphate-buffered saline (PBS, pH 7.4) at room temperature. To this were added 3 equivalents of fMLFKC (4 mg, 6 mmol). The reaction was stirred overnight at room temperature. For the 2-copy forked conjugates (PEG$_{5K,20K,40K}$-(fMLF)$_2$ ([fMLFK(FLUORESCEIN)C]$_2$-mPEG$_{5K,\ 20K,\ 40K}$) a similar protocol was used (e.g., 3 equiv 8 mg, 12 mmol fMLFKC was utilized for PEG$_{5K}$-(fMLF)$_2$ ([fMLFK(FLUORESCEIN)C]$_2$-mPEG$_{5K}$)). The excess solvent was removed under reduced pressure. The solid PEGylated product was further reacted with 3 equiv of NHS−carboxyfluorescein (3 mg, 6 mmol) and 1% DIEA (5 μL) in 500 μL of DMF. The reaction was stirred for 3 h at room temperature. The final product was recrystallized from cold ether, washed three times to remove impurities, and lyophilized. The dried product was then dissolved in ∼5 mL of ddH_2O and subjected to dialysis against ddH_2O for 2 days in the dark in order to remove the excess unreacted reagents (NHS−carboxyfluorescein, fMLFKC) and salts, which might have not been removed during the ether precipitation step. The solution was then lyophilized to yield the purified product. [fMLFK(fluorescein)C]$_2$-mPEG$_{20K,40K}$ was synthesized using a similar approach (Scheme 1).

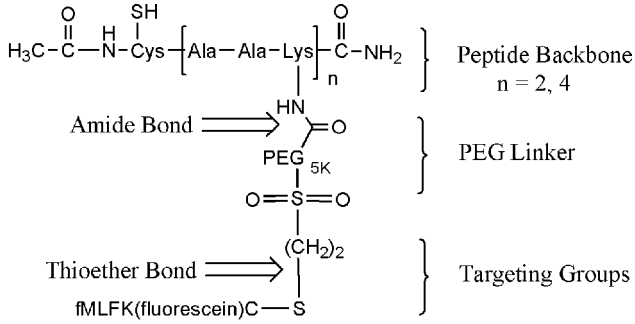
PEG$_{10k}$-(fMLF)$_4$ [fMLFK(FLUORESCEIN)C]$_4$. PEG$_{10K}$-(NH$_2$)$_4$ (20 mg, 2 mmol) was first activated with a 3-fold molar excess of the heterobifunctional cross-linker GMBS in DMF to form a maleimide-activated PEG. The reaction was stirred overnight at room temperature. The product was precipitated with cold ether and dried under vacuum to yield the solid PEGylated product. The GMBS linker essentially converts a primary amino group to a maleimide group that can react with a thiol group to form a stable thioether bond. This activated intermediate was reacted with 3 equiv of fMLFKC (16 mg, 24 mmol) in 1 mL of phosphate-buffered saline (PBS, pH 7.4) at room temperature. The reaction was stirred overnight at room temperature. The excess solvent was removed under reduced pressure. The reaction product was further reacted with 3 equiv of NHS−carboxyfluorescein (12 mg, 24 mmol) and 1% DIEA (5 μL) in 500 μL of DMF. The reaction was stirred for 3 h at room temperature. The final product was recrystallized from cold ether and washed three times to remove impurities. Then

Scheme 1. Synthesis of PEG-fMLF Nanocarriers with 1 Copy (PEG_{5k}-fMLF, Scheme A), 2 Copies (PEG_{5k}-$(fMLF)_2$,Scheme B), and 4 Copies (PEG_{10k}-$(fMLF)_4$, Scheme C) of fMLF, and the Fluorescein-Labeled Control PEG_{5k} without fMLF Peptides (Scheme D)[a]



[a] Note that PEG does not have any charge. It tends to give a weak signal in MALDI-TOF.

Scheme 2. Design of Peptide-Based PEG Nanocarriers with 2 and 4 Copies of fMLF Peptides[a]



[a] The peptide acetyl-Cys-(β-Ala-β-Ala-Lys)*n*-amide (n = 2, 4) is the backbone. NHS-PEG_{5k}-VS is the linker between the peptide backbone and targeting groups fMLFKC, which form an amide bond with amine group on acetyl-Cys-(β-Ala-β-Ala-Lys)*n*-amide and a thioether bond with the thiol group on fMLFKC.

the dried product was dissolved in ~5 mL of ddH_2O and was subject to dialysis against ddH_2O for 2 days in the dark. The solution was lypholyzed to yield the purified product.

PEG_{5k} ($mPEG_{5K}$-FLUORESCEIN). The amino groups of $mPEG_{5k}$-NH_2 (5 mg, 1 mmol) were reacted with 3 equiv of NHS−carboxyfluorescein (1.5 mg, 3 mmol) and 1% DIEA (5 μL) in 500 μL of DMF to yield $mPEG_{5k}$-fluorescein. The reaction was stirred for 3 h at room temperature. The final product was recrystallized from cold ether, washed three times to remove impurities, and dried under vacuum. Then the dried product was dissolved in ~5 mL of ddH_2O and was subject to dialysis against ddH_2O for 2 days in the dark. The solution was lyophilized to give the purified product.

Peptide−Backbone PEG-fMLF Nanocarriers. To achieve a branch shape and multiple coupling sites, peptide−backbone PEG nanocarriers were designed (Scheme 2). In order to synthesize fMLF PEG nanocarriers with two copies of fMLF (Scheme 2), the backbone peptide acetyl-Cys(thiopyridine)-β-Ala-β-Ala-Lys-β-Ala-β-Ala-Lys-amide (1.4 mg, 2 mmol) was reacted with 2 equiv of NHS-PEG_{5k}-VS (40 mg, 8 mmol) and 1% DIEA (5 μL) in 500 μL of DMF. The reaction was carried out at room temperature for 3 h. The PEGylated intermediate acetyl-Cys(thiopyridine)-[β-Ala-β-Ala-Lys(PEG_{5k}-VS)]$_2$-amide was purified by size-exclusion chromatography on a TSK Gel-3000pw column. The size of the product in eluted fraction volume was confirmed by MALDI-TOF mass spectrometry, and peak fractions were pooled and dried under vacuum. The PEGylated intermediate was dissolved in 1 mL of phosphate-buffered saline (PBS, pH 7.4) at room temperature. To this, 3 equiv of fMLFKC (8 mg, 12 mmol) was added. The reaction was stirred overnight at room temperature. The product was then treated with a 5 M excess of dithiothreitol (DTT) for another 2 h. The product was dialyzed against ddH_2O for 2 days. Then the excess solvent was removed under reduced pressure. The solid PEGylated product was further reacted with 3 equiv of NHS−carboxyfluorescein (6 mg, 12 mmol) and 1% DIEA (5 μL) in 500 μL of DMF. The reaction was stirred for 3 h at room temperature. The final product was recrystallized from cold ether, washed three times to remove impurities, and dried under vacuum. Then the dried product was dissolved in ~5 mL of ddH_2O and was subject to dialysis against ddH_2O for 2 days in the dark. The solution was dried under vacuum to give the purified product. The PEG nanocarrier with four copies of fMLF and fluorescein was synthesized by a similar scheme (Scheme 2).

Size-Exclusion Chromatography (SEC). Purified nanocarriers were dissolved in ddH_2O at a final concentration of ~1 mg/mL. The solution was loaded into a Waters HPLC equipped with a SEC TSK-GEL G3000PW HPLC column (Tosoh Corp., Japan). The mobile phase was 100% ddH_2O, and the flow rate was 1 mL/min. Eluents were monitored for absorbance at 220 nm with a Waters UV detector.

MALDI-TOF Mass Spectrometry. Mass spectrometry was performed using an Applied Biosystems Voyager DE Pro matrix-assisted laser desorption time-of-flight mass spectrometer (MALDI-TOF). The instrument was operated in the linear positive ion mode at 25.0 kV utilizing delayed extraction (100 ns). Data were collected over a mass range of 2000–10,000 M/z with 100 shots per spectrum. Samples were dissolved in 50:50 H_2O/ACN with 0.1% TFA at ~10 mg/mL. The matrix solution was (10 mg/mL) α-cyano-4-hydrocinnamic acid (10 mg/mL) in 50:50 H_2O/ACN with 0.1% TFA. A sample (4 μL) was combined with 1 μL of matrix solution. This mixture was then spotted onto the sample plate and allowed to dry. The instrument was externally calibrated by analysis of a three-component peptide mixture over a mass range of ~1000–10000 *m/z*. Data analysis consisted of baseline correction and noise reduction utilizing Data Explorer software, version 5.1 (Applied Biosystems). The difference in molecular weight between the final nanocarrier and the unreacted PEG corresponds to the molecular weight additions on the PEG skeleton. The relative intensity for unconjugated PEG is much lower than that of its peptidic core conjugated counterpart since the unconjugated PEG cannot be ionized to the same extent. (Figure 1).

Amino Acid Analysis. Amino acid analysis of the free fMLF, PEG_{5k}-fMLF, PEG_{5K}-$(fMLF)_2$, PEG_{10k}-$(fMLF)_4$, and peptide-based PEG_{10k}-$(fMLF)_2$ and PEG_{20k}-$(fMLF)_4$ nanocarriers was performed at the Protein Facility of the Iowa State University Office of Biotechnology (Ames, Iowa) to confirm the presence and concentration of fMLF on PEG nanocarriers. The sample was transferred to a hydrolysis tube and dried under vacuum. The tube was placed in a vial containing 6 N HCl and a small amount of phenol, and the samples were hydrolyzed by the HCl vapors under vacuum for 65 min at 150 °C. Following hydrolysis, each sample was dissolved in distilled water containing EDTA. An aliquot containing ~1 nmol of each amino acid was placed on a sample slide, and derivatization was done under basic conditions for 30 min with phenyliso-

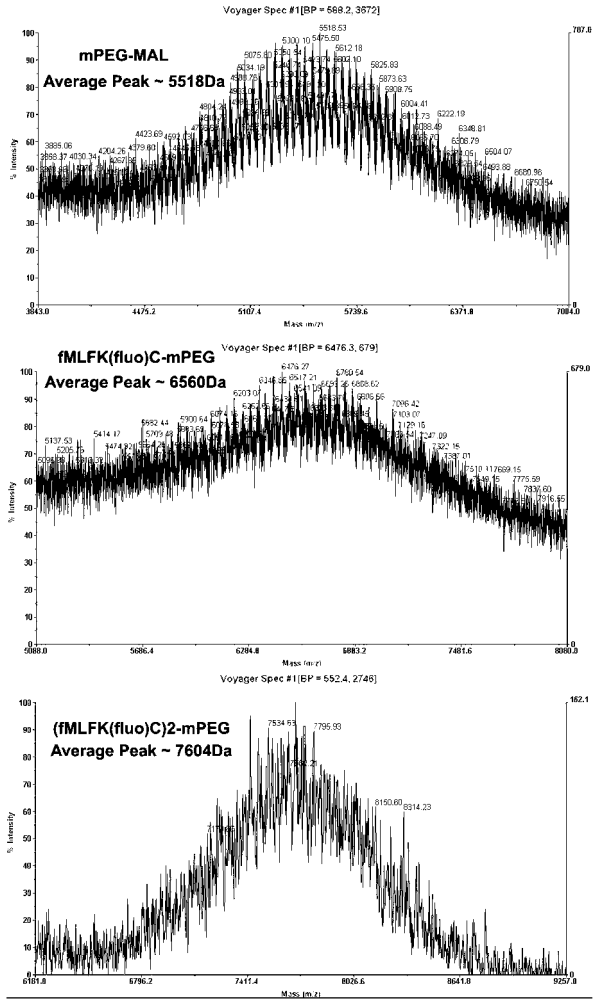


Figure 1. MALDI-TOF spectra of PEG-fMLF nanocarriers. The starting material mPEG-MAL showed the polydisperse peaks with average molecular weight at about 5518 Da. fMLFK(fluorescein)C-mPEG showed an average peak at 6560 Da, and [fMLFK(fluorescein)C]$_2$-mPEG showed an average peak at 7604 Da.

thocyanate (PITC). The resulting phenylthiocarbamyl (PTC) derivatives were separated by reverse-phase chromatography and quantitated by absorbance at 254 nm.

Stability in PBS and Rabbit Plasma. The stability of the fluorescein-labeled PEG-fMLF nanocarriers was tested in 10 mM PBS (pH 7.4) and rabbit plasma at 37 °C for 24 h. The nanocarrier solutions were incubated separately in 10 mM PBS (pH 7.4) or in spiked rabbit plasma at 37 °C. Aliquots were withdrawn at different time points and centrifuged at 14,000*g* for 90 min with a Microcon filter (molecular weight cutoff = 3,000 Da) (Amicon Inc., Beverly, MA). The free fMLF cleaved from the PEG nanocarrier during the incubation passes through the filter, whereas the fMLF that remains linked is retained. The eluents and retentates resulting from the different incubation time points were withdrawn and subjected to fluorescence detection. Each measurement was done in triplicate.

Cell Lines. The U937 cell line, which had been isolated from a patient suffering from histiocytic lymphoma, was later found capable of terminal differentiation upon induction into a macrophage phenotype. U937 cells were grown in RPMI 1640 DM medium supplemented with 10% FBS (fetal bovine serum) as suspended cells. They differentiated into macrophage-like cells after treatment with 1 mM dibutyryl-cAMP for 48 h, remaining suspended. The U937 cell line is potentially an excellent model system to study formyl peptide receptors because, in the undifferentiated state, these cells express low

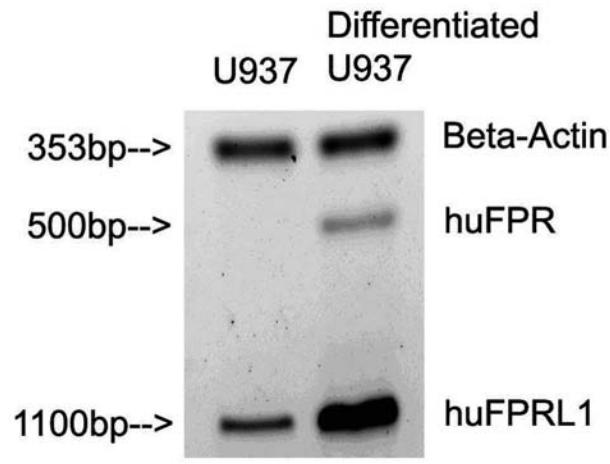

Figure 2. mRNA expression of formyl peptide receptor (FPR) and formyl peptide receptor-like 1 (FPRL1) in undifferentiated and differentiated U937 by RT-PCR determined using semiquantitative RT-PCR. Differentiated U937 cells expressed high levels of FPR mRNA (500 bp product) and FPRL1 mRNA (1100 bp product), while undifferentiated U937 cells only expressed a low level of FPRL1 mRNA and no FPR mRNA.

levels of formyl peptide receptors and showed no movement toward any stimuli (*16, 17*). A variety of differentiating agents induce U937 cells toward a more mature phenotype in which they express formyl peptide receptors and display migratory properties similar to those of peripheral blood monocytes or neutrophils.

Expression of Formyl Peptide Receptors. The expression of the two relevant human receptors for fMLF, FPR and FPRL1, was evaluated using semiquantitative RT-PCR. Total RNA was extracted from U937 and differentiated U937 cells. RNA (2 μg) was used as a template for RT-PCR. The sense oligonucleotide primer 52-CTGCTGGTGCTGCTGGCAAG-32 and antisense primer 52-AATATCCCTGACCCCATCCTCA-32 based on the sequences flanking the human FPRL1 coding region (1.1 kb) were designed to amplify FPRL1. The sense primer 52-CTCCAGTTGGACTAGCCACA-32 (nucleotide 1639–1658 in exon 2) and antisense primer 52-CCATCACCCAGGGC-CCAATG –32 (nucleotide 5341–5359 in the coding region of exon 3) were designed to amplify human FPR. The sense primer 5′-GCTCG TCGTC GACAA CGGCT C-3′ and the antisense primer 5′-CAAAC ATGAT CTGGG TCATC TTCTC-3′ for beta-Actin were used as controls.

A commercially available rabbit polyclonal antibody was used in a Western Blot analysis without success. The antibody should have been able to detect both receptors but produced bands that were not always reproducible or consistent with the expected sizes.

Time-Dependent Cellular Association of PEG-fMLF Nanocarriers in Differentiated U937 Cells. U937 cells in suspension were differentiated into macrophage-like cells after treatment with 1 mM dibutyryl-cAMP for 48 h. The suspended differentiated cells were washed by centrifugation twice with uptake buffer (Hanks Balanced Salt Solutions (HBSS) with 20 mM HEPES to adjust pH to neutral). The washed cells were added to wells of 24-well polycarbonate plates at a density of 1×10^5 cells/well in the presence of 50 nM fluorescein-labeled PEG-fMLF nanocarriers for 1, 2, 4, or 8 h at 37 °C. The concentrations of all fMLF-bearing nanocarriers were normalized based on the fMLF moiety concentration. That is, a nanocarrier bearing one copy of fMLF was used at 50 nM fMLF and 50 nM whole-molecule concentration, a nanocarrier bearing two copies of fMLF was used at 50 nM fMLF and 25 nM whole-molecule concentration, and so forth. At the end of an

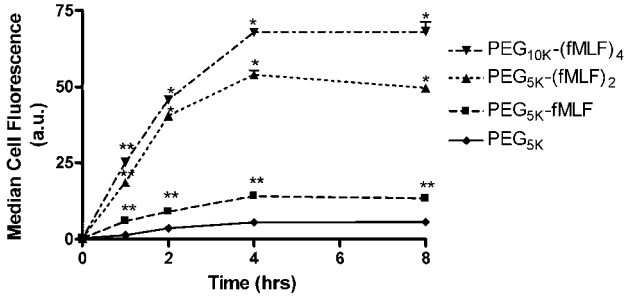

Figure 3. Time course of total cell-associated fluorescein-labeled PEG-fMLF nanocarriers in differentiated U937 cells at 37 °C. Differentiated U937 cells were incubated for the indicated time periods and plotted against the cell-associated nanocarrier amounts. The cell-associated fluorescence was measured by cell flowcytometry and reported as the medium value of intensity distribution. The means ± SD for three independent experiments are shown for each nanocarriers. PEG_{5K}-fMLF enhanced macrophage association about 15-fold ($p < 0.05$) after 4 h of incubation at 37 °C compared to the control PEG_{5k}. The values were about 45- and 60-fold higher for PEG_{5k}-$(fMLF)_2$ and PEG_{10k}-$(fMLF)_4$, respectively, than for the control PEG_{5k} ($p < 0.01$). (Statistically significant differences were observed between the PEG-fMLF nanocarriers and the control PEG_{5k}, * $p < 0.01$, ** $p < 0.05$.)

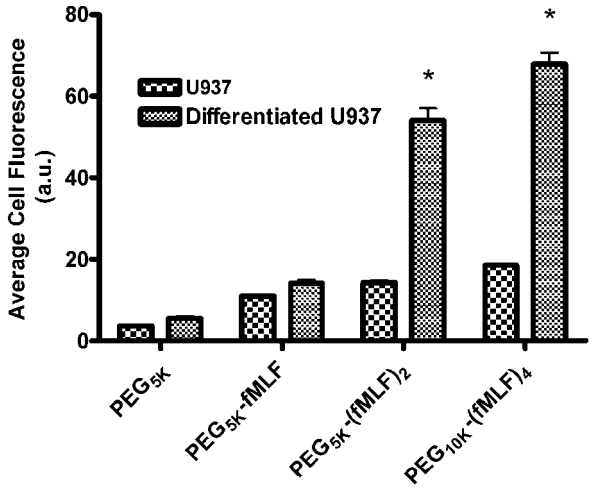

Figure 4. Total cellular association (uptake from now on) of fluorescein-labeled PEG-fMLF nanocarriers in the undifferentiated and the differentiated U937 cells at 37 °C after 4 h of incubation. The means ± SD for three independent experiments are shown for each value. (*, statistically significant difference between undifferentiated and differentiated U937 cells, $p < 0.01$.)

incubation period, washing the cells twice with ice-cold uptake buffer stopped the uptake. The cells were subsequently resuspended in uptake buffer. Cell-associated fluorescence was analyzed by flow cytometry using a Coulter EPICS PROFILE (Fullerton, CA) equipped with a 25 mW argon laser. For each analysis, 10,000 to 20,000 events were accumulated. The results are shown in Figure 3.

U937 Cell Uptake by Undifferentiated and Differentiated U937 Cells. To show that the cellular association of 50 nM PEG-fMLF nanocarriers was based on uptake, the uptake experiments were performed with both undifferentiated and differentiated U937 cells as described above for the time-dependent cellular association. The results are shown in Figure 4.

Temperature-Dependent Uptake of PEG-fMLF Nanocarriers. To further demonstrate that the cellular association of 50 nM PEG-fMLF nanocarriers was based on uptake, differentiated U937 cells were incubated with fluorescein-labeled PEG-fMLF nanocarriers for 4 h at 37 or 4 °C. At the end of an incubation period, the cells were washed, and resuspended, and cell-

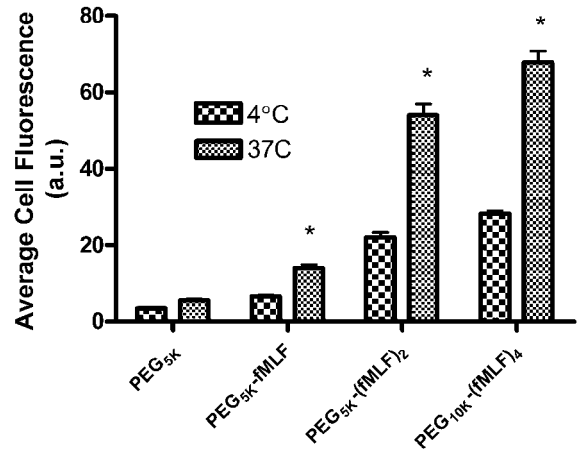

Figure 5. Uptake of fluorescein-labeled PEG-fMLF nanocarriers in differentiated U937 cells at 4 and 37 °C after 4 h of incubation. The means ± SD for three independent experiments are shown for each value. (*, statistically significant difference between 4 and 37 °C treatments, $p < 0.01$.)

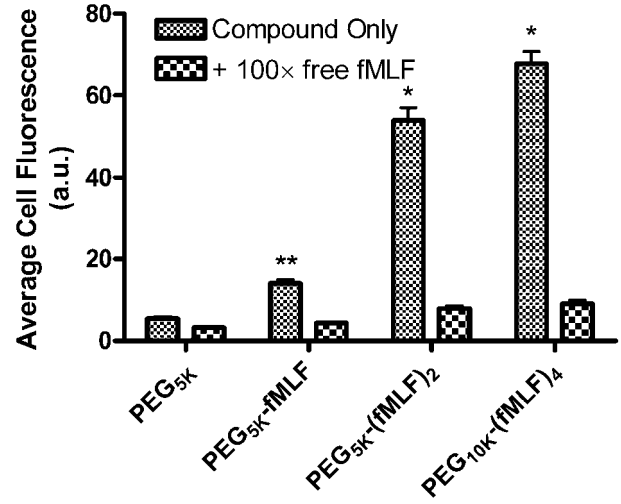

Figure 6. Uptake of fluorescein-labeled PEG-fMLF nanocarriers in differentiated U937 cells at 37 °C after 4 h of incubation in the absence and presence of 5 μM free fMLF (100× in excess to the concentration of the labeled nanocarriers). The means ± SD for three independent experiments are shown for each value. (Statistically significant difference between the differentiated U937 cells incubated with and without free fMLF * $p < 0.01$, ** $p < 0.05$.)

associated fluorescence was analyzed by flow cytometry as described above. The results are shown in Figure 5.

Uptake Inhibition by Free fMLF Peptide. The involvement of formyl peptide receptors in differentiated U937 cell uptake of PEG-fMLF nanocarriers was also investigated using inhibition studies. Free fMLF peptide (5 μM), a competitive substrate of formyl peptide receptor, was coincubated with 50 nM fluorescein-labeled PEG, mPEG-fMLF, mPEG-$(fMLF)_2$, or PEG-$(fMLF)_4$ nanocarriers. Uptake assays were performed as described above for the temperature-dependent uptake. The results are shown in Figure 6.

Uptake by Fluorescence Microscopy. Differentiated U937 cells were incubated in 24-well microplates with 50 nM fluorescein-labeled PEG, mPEG-fMLF, mPEG-$(fMLF)_2$, or PEG-$(fMLF)_4$ nanocarriers for 4 h. After incubation, the cells were washed twice using centrifugation and resuspended in Hanks Balanced Salt Solutions (HBSS). The stained cell suspension was placed on slides, covered, and observed under a Zeiss Axiostar Plus fluorescence microscope (Thornwood, NY) with an objective magnification of 63× and an Insight digital

Table 1. Results of Amino Acid Analysis of PEG-fMLF Nanocarriers[a]

sample name	amino acid ratio (normalized by phenylalanine) Met	Leu	Phe	Lys	concentration (nM) (expected 50 nM)
fMLF	0.90	1.20	1.00	1.00	36.00
PEG-(fMLF)	0.95	1.20	1.00	1.00	37.10
PEG-$(fMLF)_2$	0.97	1.23	1.00	0.95	37.87
PEG-$(fMLF)_4$	0.91	1.19	1.00	1.01	42.00
PB-PEG-$(fMLF)_2$	0.91	1.17	1.00	2.08	40.00
PB-PEG-$(fMLF)_4$	0.96	1.19	1.00	1.87	37.90

[a] The amino acids were normalized relative to phenylalanine. PB: peptide-based.

camera (Sterling, MI) with proper filter sets. Digital images were taken with the Insight digital camera and its companion Spot software.

Calcium Mobilization. Differentiated U937 cells were loaded with 4 μmol/L fluo-4 AM in HBSS for 30 min at 37 °C in the dark. The cells were washed and incubated for 30 min at room temperature to allow the Fluo-4 AM dye to completely de-esterify. The cells were washed, resuspended in HBSS, and treated with 1 μM PEG-fMLF nanocarriers at 37 °C. Fluorescence readings were obtained using a Tecan fluorescence plate reader for 400 at 2 s intervals.

Statistical Analysis. All statistical tests were performed using GraphPad Instat (GraphPad Software, Inc., San Diego, CA). A minimal *p*-value of 0.05 was used as the significance level for all tests. One-way analysis of variance and the Tukey test were performed on the uptake data. All data are reported as means ± SD of three observations, unless otherwise noted. The graphs were plotted using GraphPad Prism 4.01 (GraphPad Software, Inc., San Diego, CA).

RESULTS

Synthesis and Characterization of PEG-fMLF Nanocarriers. The PEG-fMLF nanocarriers $mPEG_{5K}$-fMLF, $mPEG_{5K}$-$(fMLF)_2$, and PEG_{10K}-$(fMLF)_4$ were prepared by coupling the fMLFKC to mPEG-MAL, mPEG-(MAL)2, and PEG-$(NH_2)_4$ according to the procedures described in Scheme 1. All nanocarriers were purified by the removal of low molecular weight contaminants using 3 kDa dialysis bags in ddH_2O for 2 days. The structures of purified products were confirmed by a combination of SEC, MALDI-TOF, and amino acid analysis. Amino acid analysis of the final nanocarrier showed the presence of methionine, leucine, phenylalanine, lysine, and cysteine in the proper ratios (Table 1). Matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry was used to accurately determine the molecular masses of polydisperse polymeric nanocarriers (Figure 1). A comparison of the MALDI-TOF spectra of unreacted mPEG-MAL (MW ~5518 Da) with that of the fMLFK(fluorescein)C-mPEG (~6560 Da) and $[fMLFK(fluorescein)C]_2$-mPEG (~7604 Da) revealed average mass peak shifts of ~1040 Da and ~2080 Da, respectively, confirming that the polymeric nanocarriers created were derivatized with either fMLFK(fluorescein)C (1042 Da) or $[fMLFK(fluorescein)C]_2$ (2084 Da). Thus, although the polymer is polydisperse because of variations in the number of ethylene glycol repeats, the fMLFK(fluorescein) content of each preparation is monodisperse.

Novel peptide−backbone nanocarriers were prepared by coupling the peptide backbone, acetyl-Cys(TP)-(β-Ala-β-Ala-Lys-)$_n$-amide (n = 2, 4) to a heterobifunctional PEG, NHS-PEG-VS (Scheme 2). The NHS moiety reacts specifically with the ε-amine group of the backbone peptide, and the VS group is used for the attachment of PEG to the sulfhydryl (SH) moiety of the fMLFKC peptide. The linkages formed amide (for NHS) and thioether (for VS) bonds between PEG and the fMLFKC and the peptide backbone, respectively. Both bonds are highly stable under physiological conditions. The thiol group of the cysteine moiety in the peptide backbone provides a suitable site for the attachment of a drug moiety. This moiety is protected by thiopyridine, which is an excellent leaving group that can be readily reacted with sulfhydryl-containing drugs or peptides. TP is replaced by fMLFKC during synthesis via a reversible thiol linkage. The product was further reacted with DTT in order to remove the reversibly linked fMLFKC peptide. Thus, the targeting moiety fMLFKC in the nanocarrier is attached via stable and nonreversible thioether linkage. The β-alanine moiety in the scaffold serves as a spacer, reducing steric hindrance during the PEGylation reaction. Scaffold (peptide-based PEG carrier) size was varied by using peptide backbones of different lengths, which could be conjugated with different (2 or 4) numbers of copies of NHS-PEG-VS in reactions proceeding to complete peptide derivatization. In Scheme 2, the Cys residue in the backbone peptide is shown with an −SH group. However, during the synthesis reactions, the thiol must be protected such as with a thiopyridine group, which may later be removed for other conjugation reactions, as shown in Scheme 2.

Stability in PBS and Plasma. The stability of the fluorescein-labeled PEG-fMLF nanocarriers was tested in 10 mM PBS (pH 7.4) and rabbit plasma at 37 °C for 24 h. For nonpeptide PEG-fMLF nanocarriers, the linkages formed a thioether bond between fMLFKC and PEG, and a urethane bond between the fMLFKC and the fluorescein. For peptide−backbone PEG nanocarriers, the linkages formed urethane (from NHS) bonds between PEG and the peptide backbone or a thioether (from VS) bond between PEG and fMLFKC. All bonds were highly stable under physiological conditions. Stability was analyzed by the release of the fluorescence tag. The released fluorescence tag was monitored after 24 h of incubation in PBS or plasma at 37 °C. The degraded product was quantitatively detected in the filtrate using ultrafiltration (5 kDa MWCO). The nanocarriers were found to be stable with less than 3% degradation in PBS or plasma during a 24 h incubation at 37 °C.

Expression of Formyl Peptide Receptors. The expression of the two relevant fMLF receptors, FPR and FPRL1, in the undifferentiated and differentiated U937 cells was confirmed using semiquantitative RT-PCR. Differentiated U937 cells expressed high levels of the formyl peptide receptor (FPR, 500 bp RT-PCR product) and formyl peptide receptor-like 1 (FPRL1, 1100 bp RT-PCR product) transcripts, while undifferentiated U937 cells only expressed low levels of FRPL1 and no detectable FPR (Figure 2). Even though an FPRL-1 antibody was available, we had limited success using it because of inconsistency in size and reproducibility. The RT-PCR result is in agreement with known U937 cell phenotype in the literature.

Time-Dependent Total Cellular Association of PEG-fMLF Nanocarriers in Differentiated U937 Cells. To understand how differentiated U937 cells would interact with PEG-fMLF nanocarriers, we first investigated the time course of total cellular association of 50 nM nanocarriers using flow cytometry. The association of PEG-fMLF nanocarriers with macrophage-like differentiated U937 cells at 37 °C showed a progressive increase from 0 h through 4 h, with steady-state apparently being reached at 4 h (Figure 3). The results are the average of three independent experiments performed on three separate days, and they showed that PEG_{5k} lacking fMLF had very low uptake at all time points during the incubation. In general, the attachment of 1, 2, or 4 copies of fMLF to PEG significantly increased the cellular association at all time points. Specifically, PEG_{5K}-fMLF enhanced macrophage cellular association about 15-fold (p < 0.05) after 4 h of incubation at 37 °C compared to the control

PEG_{5k}. PEG_{5k}-$(fMLF)_2$ and PEG_{10k}-$(fMLF)_4$ further increased uptake about 45- and 60-fold ($p < 0.01$), respectively, compared to the control PEG_{5k}. The correlation between fMLF copy numbers per nanocarrier with the amount of association suggests that the association is mainly mediated by fMLF receptors. Since data below further suggests fMLF receptor-mediated active uptake, from now on we will replace the term total cellular association with the term uptake.

U937 Cell Uptake by Undifferentiated and Differentiated U937 Cells. To show that the uptake of 50 nM PEG-fMLF nanocarriers was mediated by fMLF receptors, a comparison was made between the uptake in undifferentiated U937 cells expressing low levels of FPRL1/no FPR and differentiated U937 cells expressing high levels of FPR and FPRL1 (Figure 4). The results represent the average of three independent experiments performed on three separate days. The uptake of the control PEG_{5k} was low and showed no significant difference between undifferentiated and differentiated U937 cells. In contrast, the uptake of PEG-fMLF nanocarriers with 1, 2, or 4 copies of fMLF was significantly higher in differentiated as compared to undifferentiated U937 cells ($p < 0.01$). PEG_{5k}-fMLF uptake in differentiated U937 cells increased 1.52-fold as compared to undifferentiated U937 cells. Similarly, PEG_{5k}-$(fMLF)_2$ and PEG_{10k}-$(fMLF)_4$ increased 3.76-fold and 3.65-fold, respectively. Significantly higher uptake in differentiated U937 cells expressing FPR and FPRL1 is consistent with uptake being specifically mediated by formyl peptide receptors.

Temperature-Dependent Uptake of PEG-fMLF Nanocarriers. To confirm the expectation that uptake occurred mainly by an active cellular process, temperature-dependent uptake was investigated. The uptake of PEG-fMLF nanocarriers in differentiated U937 cells after 4 h of incubation at 4 °C showed significantly lower cell uptake than at 37 °C in three separate experiments (Figure 5). Nonderivatized PEG_{5k} showed similar low uptake levels at both temperatures. PEG_{5k}-fMLF uptake at 4 °C was only 46.2% of that at 37 °C, while the ratio of 4:37 °C for PEG_{5k}-$(fMLF)_2$ and PEG_{10k}-$(fMLF)_4$ was 40% and 41.6%, respectively. A substantial portion of cell-associated nanocarriers at low temperature are bound to the cell surface but are not internalized, representing both specific receptor binding as well as binding to other cell-surface components. Thus, the temperature-dependent portion at 37 °C is consistent with a receptor-mediated active uptake mechanism.

Uptake Inhibition by Free fMLF Peptide. The specificity of uptake was further investigated using differentiated U937cells incubated with 50 nM PEG-fMLF nanocarriers at 37 °C in the presence of 5 μM free fMLF, which was 100-fold greater than the 50 nM fMLF moiety nanocarrier concentration (Figure 6; the results are the average of three independent experiments performed on three separate days). The presence of 100-fold excess fMLF significantly inhibited the average uptake of PEG-fMLF nanocarriers in differentiated U937 cells. The inhibition led to a relative decrease in the uptake of PEG-fMLF nanocarriers with 1, 2, and 4 copies of fMLF to 31.5%, 14.8%, and 13.5%, respectively. Excess fMLF did not significantly affect the amount of cell-associated PEG_{5k}. Complete inhibition of uptake may not occur because of the fact that there is always some nonspecific binding that occurs, regardless of the concentration of free fMLF that is used (*15*). Taken together, these results further suggest that PEG-fMLF nanocarrier uptake was mediated by formyl peptide receptors.

In the presence of free f-MLF, all three f-MLF-bearing PEG nanocarriers still show statistically higher uptake into U937 cells than PEG_{5k} ($p < 0.05$). PEG-fMLF is higher than PEG_{5k} ($p = 0.011$), and PEG-(fMLF)2 and PEG-(fMLF)4 are higher than PEG-fMLF ($p = 0.018$), whereas there is no difference between PEG-(fMLF)2 and PEG-(fMLF)4 ($p = 0.254$). We roughly estimate that the receptors on the cells are saturated with the 5 μM free fMLF and largely occupied by the 50 nM fMLF-equivalents of fMLF-bearing PEG nanocarriers. Despite receptor saturation by free fMLF and high occupancy by all fMLF-bearing PEG nanocarriers, there is still some correlation between fMLF copy number and the amount of uptake. The reason for this is not clear but could have something to do with the PEG moiety of the fMLF-bearing nanocarriers.

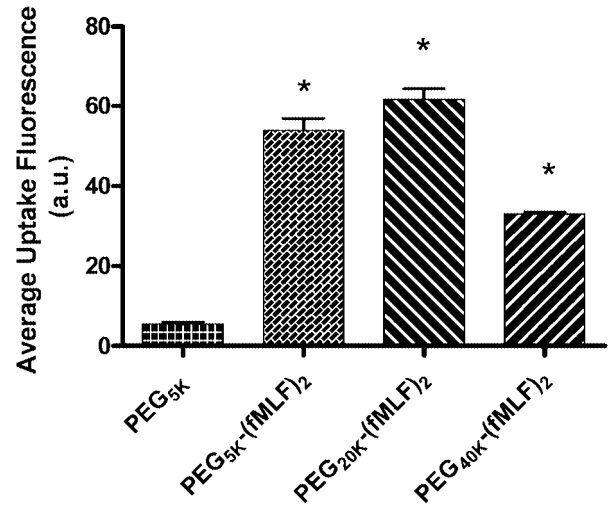

Figure 7. Uptake of fluorescein-labeled PEG-fMLF nanocarriers of different sizes in differentiated U937 cells after 4 h of incubation at 37 °C. The means ± SD for three independent experiments are shown for each value. (*, statistically significant difference between the PEG_{5k} and the derivatized nanocarriers, $p < 0.01$.)

Effect of PEG Sizes on PEG-fMLF Nanocarrier Uptake. To evaluate the effect of PEG size on macrophage uptake, PEG-$(fMLF)_2$ prepared using 5 K, 20 K, or 40 K PEGs were incubated with differentiated U937 cells for 4 h at 37 °C (Figure 7). Increasing PEG size from 5 kDa to 20 kDa slightly enhanced the uptake of PEG-$(fMLF)_2$ by about 14.4% ($p < 0.05$). However, when PEG size increased to 40 kDa, the uptake of PEG-$(fMLF)_2$ decreased by 38.6% ($p < 0.05$), suggesting that 20 kDa was the optimal size in this group and that 20–40 kDa should be further explored.

Peptide-Based PEG Nanocarriers. The PEG-fMLF nanocarriers synthesized from commercially available multifunctional PEGs showed enhanced macrophage uptake. However, the limited ability to produce PEGs with a defined number of cargo moieties, especially in high numbers, limits their use as nanocarriers when multiple targeting or therapeutic moieties are necessary. Thus, a novel peptide−backbone PEG nanocarrier was designed and synthesized to overcome this limitation. The peptide-PEG scaffold comprises the peptide backbone, acetyl-Cys(TP)-[β-Ala-β-Ala-Lys]$_{2,4}$-amide. PEG is attached to the scaffold via the ε-amine group of lysine. The heterobifunctional PEG (NHS-PEG-VS) is linked to the scaffold by a stable urethane linkage that is the result of the succinimidyl reaction with the ε-amino group of lysine. The targeting moieties are appended to the other end of the PEG. The peptide−backbone acetyl-C-[AAK(PEG_{5K}-(fMLFK(fluorescein)C]$_2$-amide and acetyl-C-[AAK(PEG_{5K}-(fMLFK(fluorescein)C]$_4$-amide demonstrated increased macrophage uptake after 4 h of incubation at 37 °C, about 4.2- and 5.7-fold more than PEG-fMLF (Figure 8), respectively. This is similar to but slightly higher than PEG-$(fMLF)_2$ and PEG-$(fMLF)_4$ derived from the commercially available PEGs. The results indicate that the number of attached targeting groups has much greater impact on the extent of macrophage uptake than other factors such as nanocarrier shape or the geometric distribution of attached groups. Previously, we

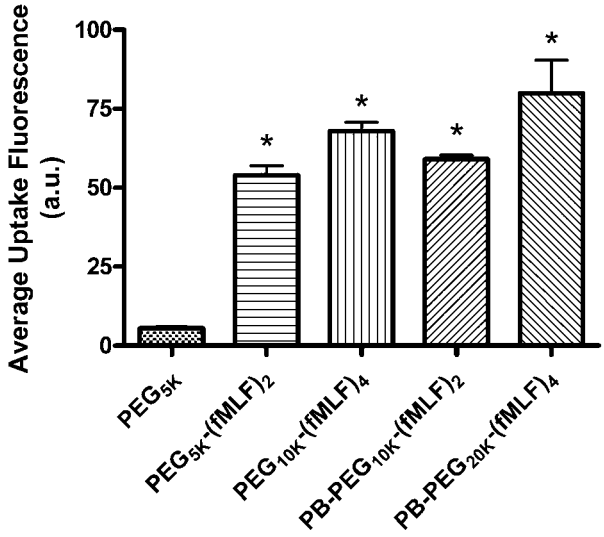

Figure 8. Uptake of fluorescein-labeled PEG-fMLF nanocarriers derived from Nektar PEGs or peptide−backbone (PB-)PEGs in differentiated U937 cells after 4 h of incubation at 37 °C. The means ± SD for three independent experiments are shown for each value. (*, statistically significant difference between the control PEG_{5k} and PEG-fMLF nanocarriers, $p < 0.01$.)

showed that a linear 30 kDa PEG with 4 conjugated fMLF moieties has a FPR binding constant that is practically indistinguishable from an 8-arm 20 kDa PEG with 4 appended fMLF.

Fluorescence Microscopy. Cells incubated with the control, fluorescein-labeled PEG_{5k}, lacking fMLF, showed no signal by fluorescence microscopy (Figure 9A). PEG_{5k}-fMLF showed faint fluorescence in cells, suggesting weak uptake (Figure 9B). The presence of punctate fluorescence suggested that the nanocarriers were internalized via endocytosis, which is typical of macromolecular uptake. PEG_{5k}-$(fMLF)_2$ and PEG_{10k}-$(fMLF)_4$ exhibited strong fluorescence throughout the cell, suggesting significantly higher binding/uptake to cells. A representative histogram of flow cytometry results for PEG_{5k} (PEG), PEG_{5k}-fMLF, PEG_{5k}-$(fMLF)_2$, and PEG_{10k}-$(fMLF)_4$ (Figure 9E) confirmed the microscopic observations. Since the same ratio of fluorescein moiety to fMLF moiety was maintained in each nanocarrier particle, and the local fluorescein environment in different particles were similar, the fluorescence intensity per nanocarrier particle was expected to be similar. Therefore, the binding/uptake results could be reasonably compared.

Calcium Mobilization. All PEG-fMLF nanocarriers showed decreased ability to activate macrophages cells, relative to free fMLF, as measured by transient stimulation of the release of calcium ions from intracellular stores into the cytoplasm. The change of cytoplasmic calcium concentration was monitored by the fluorescent calcium indicator Fluo-4 AM preloaded in the cell cytoplasm. The linkage to PEG decreased calcium release by about 40% in all PEG-fMLF nanocarriers compared to that in the free fMLF peptide (Figure 10). Interestingly, the linkage to PEG not only decreased macrophage activation of fMLF but also delayed the starting time of activation. This time delay and reduced activation by fMLF linked to PEG versus free fMLF was observed in our previous study in differentiated HL-60 cells (*15*) and may reflect a difference in the molecular pathways for macrophage activation and ligand internalization mediated by the same formyl peptide receptors.

DISCUSSION

The clinical potential of anti-HIV agents has been limited by a variety of factors, such as drug toxicity in uninfected cells, and the development of drug resistance, which leads to

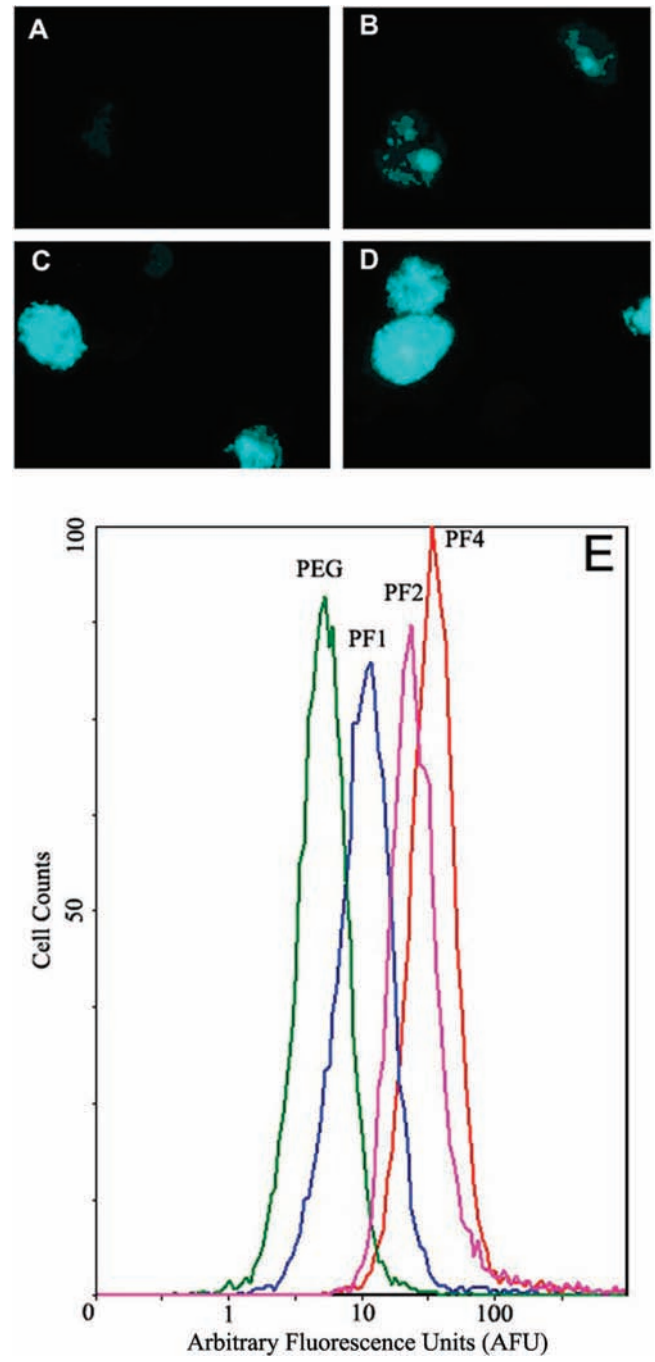

Figure 9. Fluorescence images of differentiated U937 cells incubated with fluorescein-labeled (A) PEG_{5k}, (B) PEG_{5k}-fMLF, (C) PEG_{5k}-$(fMLF)_2$, and (D) PEG_{10k}-$(fMLF)_4$, all at 50 nM concentrations. (E) Representative histogram of flow cytometry results for PEG_{5k} (PEG), PEG_{5k}-fMLF (PF1), PEG_{5k}-$(fMLF)_2$ (PF2), and PEG_{10k}-$(fMLF)_4$ (PF4).

subtherapeutic drug levels and the formation of viral reservoirs. Better drug delivery and targeting technologies are required to specifically increase target-cell exposure. Therefore, drug-delivery nanocarriers specifically targeted to macrophage cell-surface receptors could potentially improve therapeutic efficacy and minimize the systemic toxicity of anti-HIV drugs.

fMLF was chosen as the targeting moiety for the formyl peptide receptor on macrophages. fMLF resembles the amino terminus of unprocessed eubacterial proteins and binds avidly to the formyl peptide receptors on the surface of macrophages, where it serves as a chemoattractant, triggers cellular activation, and enters the cells to which it binds (*18*). The potential of using

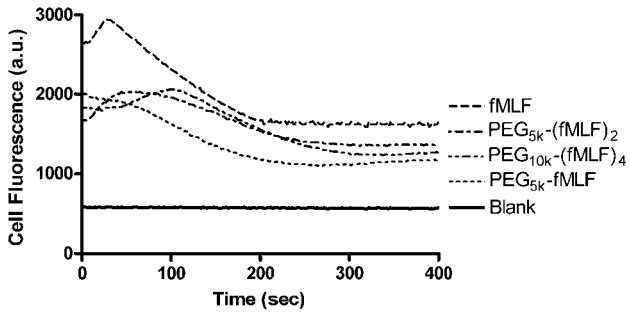

Figure 10. Calcium mobilization of U937 cells after exposure to fMLF and PEG-fMLF nanocarriers. One hundred nanomolars of each compound was tested in differentiated U937 cells preloaded with the calcium indicator Fluo-4 AM, and the calcium flux was monitored in cellular fluorescence at Ex485 nm and Em530 nm for up to 400 s.

fMLF as a targeting peptide to deliver PEG nanocarriers into macrophages was investigated in this study. The fMLF peptide was chosen as the targeting agent for several reasons. First, formyl peptide receptors are specifically expressed on phagocytic cells, such as macrophages, dendritic cells, and neutrophils. Second, fMLF specifically binds to formyl peptide receptors on macrophages with high affinity. Third, fMLF activates macrophages and down-regulates the coreceptors of HIV entry, CCR5 and CXCR4. The down-regulation of CCR5 coreceptor by fMLF could potentially inhibit viral entry in macrophages, which might potentiate the therapeutic effects of such targeted nanoparticles.

In the current study, multiple copies of fMLF were conjugated to various PEG nanocarriers and evaluated for targeting to human macrophage-like differentiated U937 cells. Since the formyl peptide retains its binding constant for FPR even with the covalent addition of several amino acids to its C-terminus, we were not concerned with a possible reduction in binding activity due to conjugation of the peptide (*15, 18*). The formyl, methionine and phenylalanine moieties are most crucial for receptor binding (*18*). Those moieties were specifically left unmodified, but we added a lysine (for fluorescence tagging) and a cysteine for PEG attachment to the C-terminus of the formyl peptide. The number of copies (1, 2, and 4) of fMLFKC conjugated to a single PEG nanocarrier was evaluated in order to determine the effects on avidity and macrophage uptake. Our previous work has shown that increasing the number of fMLF residues (up to eight) attached to a single PEG polymer results in enhanced avidity (K_d = 0.18 nM) for neutrophil-like differentiated HL-60 cells relative to free fMLF (K_d = 28 nM), with less enhancement of activation than of binding by increasing fMLF number (*15*). In the current study, we show that increasing the number of fMLF residues attached to a single PEG polymer from one to two resulted in significantly enhanced uptake (~4-fold, $p < 0.05$) in macrophage-like differentiated U937 cells, while further increasing this number from two to four only resulted in a modest increase in uptake. While the molecular basis of enhanced avidity by multivalency (i.e., multiple ligands attached to a single polymeric carrier molecule) is not proven, it is likely due to multimeric ligands interacting with multiple cellular receptors.

PEG was chosen as the pharmaceutical nanocarrier for the macrophage-targeted drug delivery system because of our long experience with this polymer class. PEGylation, the process of attaching polyethylene glycol (PEG) to drug molecules, has been a highly successful strategy for improving the pharmacokinetics and pharmacodynamics of pharmaceuticals, especially for protein and peptide therapeutics (*19–25*). In previous reports from our laboratory, we have shown that multicomponent macromolecular conjugates consisting of PEG, saquinavir, and R.I.CK-Tat retained antiviral activity *in vitro* and showed favorable therapeutic indices (*26, 27*). Studies of PEG in solution showed that each ethylene glycol subunit is tightly associated with two or three water molecules. The binding of water to PEG makes PEGylated compounds physically behave as though they are 3 to 9 times larger than a corresponding soluble protein of similar molecular weight (*28, 29*). In drug conjugates, PEG polymers with associated water molecules act like a shield to protect the attached drug from enzymatic degradation, inhibit interactions with cell-surface proteins, and provide increased size to prevent rapid renal filtration and clearance. These stealth properties of PEG have proven to be very valuable in prolonging drug persistence in the systemic circulation. However, the inability of PEG to interact with cell surfaces theoretically limits its use as a biomaterial for cell-surface or intracellular drug delivery and targeting. Therefore, the very property of PEGylation that has made it clinically useful and commercially successful is exactly the opposite of what is needed for promoting effective targeted drug therapy in diseases such as AIDS. In other words, currently used PEGylation approaches that have been enormously successful for treating certain diseases such as cancer may not be appropriate for treating HIV infection in viral reservoirs or sanctuary sites, such as macrophages, the central nervous system, and the testis. Our approach to functionalize PEG in order to shift the site of drug delivery from the blood to target cells is novel and counterintuitive given the current use of PEG. However, the general stealth properties of the PEG moiety may reduce toxicity by reducing nanocarrier binding to cells not expressing FPR and FPRL1.

Experimental studies on targeted drug delivery into cells have identified size as an important factor in the cellular uptake of nanomaterials. It has been shown that particles with radii <50 nm exhibit significantly greater uptake compared with particles >50 nm (*30, 31*). Aoyama and co-workers (*32, 33*) reported on the effect of size on receptor-mediated endocytosis in glycoviral gene delivery by excluding potential complications arising from charge effects. They concluded that receptor-mediated endocytosis is strongly size-dependent and that the optimal size is around 25 nm. In our study, increasing PEG size from 5 K to 20 K slightly enhanced nanocarrier uptake, but uptake decreased when the size was further increased to 40 K. The estimated molecular size of a 5 kDa PEG molecule is ~2 nm, while that of a 20 kDa PEG is 7 nm and 10 nm for 40 kDa (*34*). The effective or apparent size of PEG nanocarriers is significantly increased by the binding of water to PEG; the hydrodynamic radius of the hydrated PEG nanocarrier is 3 to 9 times higher than that predicted by their molecular weight (*34*). Therefore, a 20 kDa PEG-$(fMLF)_2$ has an effective molecular size of 20–60 nm. The optimal uptake of this nanocarrier and its size are consistent with the suggestions of Aoyama et al. However, 5 kDa and 40 kDa PEG-$(fMLF)_2$ showed less uptake because their effective sizes are either <25nm or >50 nm. Effective targeting to macrophages residing in tissues depends on multiple factors, including plasma clearance, tissue distribution, receptor binding, and cell uptake. The pharmacokinetics and biodistribution of nanocarriers relate to their size, charge, shape, and rigidity and are primarily controlled by renal glomerular filtration (*35*). The current results suggest that a delicate balance must be struck between maximizing the circulation half-life of nanocarriers in blood and their penetration into macrophage tissue compartments.

PEGylated systems made from commercially available multifunctional PEGs have a linear or forked shape. However, they have limited capacity to conjugate mulutiple copies of functional groups or drugs. These limitations have affected their potential as pharmaceutical drug carriers. Therefore, we designed and

synthesized a prototypical novel peptide-based PEG nanocarrier. The central component of the proposed nanocarriers is the peptide-based PEG scaffold that comprised the peptide backbone, Cys-(β-Ala-β-Ala-Lys-)$_n$-amide ($n = 2$, 4, or more), with 1 thiol group on the cysteine side chain and amino groups on lysine side chains. The flexibility of this peptide-based PEG nanocarrier is evident. For example, if a higher number of targeting agents is needed, a larger scaffold with more lysine moieties for PEG attachment can be utilized. Drugs can be attached by a disulfide (reversible) or thiosulfonyl (nonreversible) via a vinyl sulfone bond. The disulfide linkage can possibly be cleaved after the entry of the nanocarrier into the cell because of the high concentration of reduced glutathione within the cell. In this scenario, the drug is released from the nanocarrier. The scaffold consisting of a peptide backbone and PEG are the critical central feature of the nanocarrier drug conjugates since (1) it controls body and cellular disposition, and uptake/retention, (2) it allows us to add functional groups (i.e., effectors) to target specific cell types and cause surface binding or uptake, and (3) it allows us to attach exact numbers of multiple drugs or multiple targeting moieties using releasable or nonreleasable bonds. Furthermore, the molecular population of nanocarriers is monodisperse in its derivatization, a distinct advantage over other PEGylation carriers. Using these features, we could potentially precisely control how, when, and where anti-HIV drugs are able to exert their therapeutic effect.

CONCLUSIONS

The current results demonstrate that PEG nanocarriers with multiple copies of fMLF can specifically target human macrophage-like cells *in vitro* and that the number of fMLF copies attached determines the extent of uptake. The results suggest that two fMLF residues are sufficient for achieving targeting and improving uptake *in vitro*. We also demonstrated that 20 kDa (corresponding to 20–60 nm) may be the optimal PEG nanocarrier size for improved macrophage uptake. Since typical commercially available multifunctional PEGs limit the numbers of copies of drugs and targeting groups that may be attached to a nanocarrier, we designed an alternate carrier that retained the targeting and uptake properties of nonpeptide-based PEGs. However, the new nanocarrier allows for far greater flexibility in attaching multiple drugs, copies of drugs, and/or targeting moieties. These results indicate great promise for improving targeted drug delivery to HIV-infected macrophages, which may eventually allow for better therapeutic regimens by reducing dose and improving tolerability and patient compliance with complicated regimens.

Conjugated Platinum(IV)−Peptide Complexes for Targeting Angiogenic Tumor Vasculature

Sumitra Mukhopadhyay,[†,§] Carmen M. Barnés,*[,‡,§] Ariel Haskel,[†] Sarah M. Short,[‡] Katie R. Barnes,[†] and Stephen J. Lippard*[,†]

Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, and Vascular Biology Program, Children's Hospital and Harvard Medical School, Boston, Massachusetts 02115. Received January 29, 2007; Revised Manuscript Received June 14, 2007

The integrins $\alpha_v\beta_3$ and $\alpha_v\beta_5$ and the membrane-spanning surface protein aminopeptidase N (APN) are highly expressed in tumor-induced angiogenesis, making them attractive targets for therapeutic intervention. Both integrins and APN recognize a broad range of peptides containing RGD (Arg-Gly-Asp) and NGR (Asn-Gly-Arg) motifs, respectively. Here, we describe the design, synthesis, and characterization of a series of mono- and difunctionalized platinum(IV) complexes in which a conjugated peptide motif, containing RGD, (CRGDC)c, (RGDfK)c, or NGR, is appended as a "tumor-homing device" to target tumor endothelial cells selectively over healthy cells. Platinum(IV)−peptide complexes with nonspecific amino acids or peptide moieties were prepared as controls. Concentration–response curves of these compounds were evaluated against primary proliferating endothelial cells and tumor cell lines and compared to those of cisplatin, a well-described platinum-based chemotherapeutic agent. The Pt(IV)−RGD conjugates were highly and specifically cytotoxic to cell lines containing $\alpha_v\beta_3$ and $\alpha_v\beta_5$, approaching the activity of cisplatin. The Pt(IV)−NGR complexes were less active than Pt(IV)−RGD-containing compounds but more active than nonspecific Pt−peptide controls. Integrin $\alpha_v\beta_3$ mediated, at least in part, the anti-proliferative effect of a Pt(IV)−RGD conjugate, as demonstrated by a decreased inhibitory response when endothelial cells were either (1) incubated with an excess of $\alpha_v\beta_3/\alpha_v\beta_5$-specific RGD pentapeptides or (2) transfected with RNAi for β_3, but not β_1, integrins. These results suggest a rational approach to improved chemotherapy with Pt(IV)−peptide conjugates by selective drug delivery to the tumor compartment.

INTRODUCTION

Cisplatin, *cis*-diamminedichloroplatinum(II), is standard chemotherapy for testicular, ovarian, cervical, head, neck, esophageal, and non-small-cell lung cancer (*1–6*). Cisplatin displays limited activity toward the more common colon and breast cancers, however, and toxic side effects are associated with its intake (*1*). A key objective of our current research program is to synthesize novel Pt-based drugs with equal potency but reduced toxicity derived from their ability to target tumor tissue. Targeted platinum therapy has the potential to increase the net amount of platinum that reaches the tumor environment, thereby decreasing the amount of platinum required and consequently reducing side effects on healthy, noncancerous tissues.

Tumor cell survival, growth, and metastasis are driven by angiogenesis, the process by which new blood vessels are formed (*7–9*). Tumor blood vessels are permeable and morphologically distinct from normal blood vessels. Because the tumor endothelial cell can be selectively recognized, it has become a major target for treating cancer (*10*).

Among the cell surface proteins upregulated in endothelial cells and on certain tumor cells during tumor growth and metastasis are the $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins (*11–13*) and aminopeptidase N (APN or CD13) (*14*), which are absent or barely detectable in resting endothelial cells. Integrins are transmembrane-spanning receptors that participate in cell−cell and cell−matrix interactions in all normal and malignant cell types (*15, 16*). The integrin $\alpha_v\beta_3$ plays a critical role in the adhesion and migration of endothelial cells to extracellular matrix components. Integrins $\alpha_v\beta_3$ and $\alpha_v\beta_5$ and APN recognize the peptide motifs RGD (Arg-Gly-Asp) (*17, 18*) and NGR (Asn-Gly-Arg) (*14*), respectively, with high affinity. The $\alpha_v\beta_3$ integrin can also bind NGR but with lower affinity (*19*). RGD- and NGR-containing peptide motifs and peptidomimetics specifically target the tumor vasculature (*10, 14, 20*) and have been evaluated as antagonists of $\alpha_v\beta_3$ and APN. RGD-containing peptides compete in the binding of ECM proteins to cell surface $\alpha_v\beta_3$ and $\alpha_v\beta_5$, preventing cellular adhesion to the extracellular matrix, thwarting cell metastasis, and inducing apoptosis (*21, 22*). Linear and cyclic RGD peptide motifs have been employed as delivery agents for small molecular weight drugs, peptides, and proteins to the tumor endothelial cells, as recently reviewed (*23*).

On the basis of these findings, we have developed a strategy to prepare new platinum(IV) anticancer drug candidates in which the conjugated peptide motif, containing either RGD or NGR, would serve as a "tumor-targeting device"and selectively kill angiogenic tumor endothelial cells. Here, we describe the design, synthesis, and characterization of the first such conjugates, mono- and difunctionalized Pt(IV)−peptide complexes. As previously reported for platinum(IV) analogues containing a tethered steroid hormone moiety, reduction in the cell releases the axially appended ligand to unmask cisplatin (*24*).

As targeting moieties, we have used the RGD and NGR linear tripeptides; an RGD-containing disulfide-bridged cyclic pentapeptide, (CRGDC)c; and the cyclic pentapeptide, (RGDfK)c. (CRGDC)c and (RGDfK)c were chosen because cyclic peptides target angiogenic endothelial cells more efficiently compared to their linear counterparts (*12, 21, 25, 26*). The two cysteine

residues in CRGDC form a disulfide bond which gives the RGD portion a constrained bent structure that facilitates specific recognition by the integrins on the cell surface (*20*, *21*, *25*, *26*). (RGDfK)c is an antiangiogenic peptide derived from the $\alpha_v\beta_3$ and $\alpha_v\beta_5$ inhibitor (RGDfV)c. (RGDfK)c preserves the biological activity of its parent compound (*27*) but can be readily attached to different moieties through the lysine ϵ-amino group without losing its selectivity properties (*28*). In addition, several other Pt(IV) compounds linked to a nonspecific amino acid or a tripeptide have been prepared as controls.

All peptides or amino acid residues were attached by means of an amide bond to the terminal carboxylate group of the axially coordinated succinato ligands in *cis*,*cis*,*trans*-diamminedichlorodisuccinatoplatinum(IV) complex, *cis*,*cis*,*trans*-[$Pt(NH_3)_2Cl_2$(succinate)$_2$] (**1**) (*24*). Numerical designations and abbreviations of these complexes and their charges at pH 7 are given in Chart 1 (*29*). Concentration−response curves of these Pt(IV)−peptide complexes along with that of cisplatin and **1** were assessed against different primary endothelial cells and tumor cell lines, which include bovine capillary endothelial (BCE) cells, human umbilical vein endothelial cells (HUVEC), human dermal microvascular endothelial cells (HMVEC), human glioblastoma (U87), human pancreatic carcinoma (ASPC1), human uterine sarcoma (MES-SA), and human cervical carcinoma (HeLa) cells. We found that both endothelial cells and the tumor lines tested were positive either for both $\alpha_v\beta_3$ and $\alpha_v\beta_5$ or for $\alpha_v\beta_5$ integrins. The activity profiles of all the platinum complexes against these cells are described herein.

EXPERIMENTAL PROCEDURES

Materials. Potassium tetrachloroplatinate(II) was a gift from Englehard. Cisplatin, *cis*,*cis*,*trans*-diamminedichlorodihydroxyplatinum(IV), and *cis*,*cis*,*trans*-diamminedichlorodisuccinatoplatinum(IV) were synthesized according to literature procedures (*24*, *30*, *31*). (RGDfK)c was prepared as reported (*32*, *33*). Chemicals and solvents were of reagent-grade quality and used as received from commercial suppliers. Abbreviations are listed in reference 29.

Instrumentation and Analytical Measurements. An Advanced ChemTech automated instrument (model ACT 348Ω) was used for peptide synthesis. HPLC purifications using C18 analytical (VYDAC, 4 mm × 250 mm) and C18 semipreparative (VYDAC, 40 mm × 250 mm) columns were performed with Waters instrumentation comprising a 600S system controller coupled with an absorption detector (Waters 2487) and pump (Waters 616). Purifications with a C18 preparative (VYDAC, 100 mm × 250 mm) column used a Waters 600E system controller coupled with an absorption detector (Waters 486) and pump (Waters 600). LC-MS analyses were performed on an Agilent 1100 series instrument using a ZORBAX extended SB-C18 column of dimensions 4.6 mm × 150 mm and a ZORBAX 80A extended C18 column of dimensions 2.1 mm × 100 mm. High-resolution mass spectral analyses were performed at the MIT Department of Chemistry Instrument Facility (DCIF).

Synthesis of Peptides and Platinum Complexes RGD, NGR, AGR, (CRGDC)c. The linear peptides were prepared by using the standard Fmoc protocol on an automated peptide synthesizer. The rink amide resin with a loading capacity of 0.61 mmol/g was used as the solid support. In a typical 16-well synthesis, a total of 1.2 g (0.74 mmol) of the resin and a 10-fold excess of each amino acid (7.36 mmol) in 24 mL of *N*-methyl-2-pyrrolidinone (NMP) solution were used in the presence of 1,3-diisopropylcarbodiimide (DIC), acetic anhydride, 1-hydroxybenzotriazole (HOBt), and diisopropylethylamine (DIPEA) (0.5 M solution of each in DMF). Fmoc-Asn(Trt)-OH, Fmoc-Asp(OtBu)-OH, Fmoc-Arg(Pbf)-OH, and Fmoc-Cys(Trt)-OH provided sources of Asn, Asp, Arg, and Cys, respectively. The Fmoc protecting group was removed with a 20% piperidine solution in DMF. After the synthesis, the peptides were cleaved from the resin with a solution of 95% TFA, 2.5% triisopropylsilane (TIPS), and 2.5% water to obtain amide functionalization at the C-terminus. The resulting peptides were precipitated by cold ether. The aqueous solution of linear CRGDC was air-oxidized overnight to form the S−S bridged (CRGDC)c. The purification of these peptides was carried out by reverse-phase HPLC by using a C18 preparative column (VYDAC, 100 mm × 250 mm) in greater than 90% yield. Their purity was verified by LC-MS and mass spectrometry. ESI-MS: for RGD: calcd $[M + H]^+$ 346.36 amu; found 346.3 amu; for NGR: calcd $[M + H]^+$ 345.38 amu, found 345.51 amu; for AGR: calcd $[M + H]^+$ 302.35 amu, found 302.29 amu; and for (CRGDC)c: calcd $[M + H]^+$ 550.2 amu, found 550.4 amu.

RGD-Conjugated Diamminedichloroplatinum(IV) Complexes (2a and 2b). To a solution of **1** (0.025 g, 0.043 mmol) in 200 μL of water was added a 100 μL solution of EDC (0.082 g, 0.43 mmol), followed by a 100 μL solution of NHS (0.050 g, 0.43 mmol) with vigorous stirring. This solution was then added to an aqueous solution (200 μL) of RGD tripeptide (0.075 g, 0.22 mmol) in a dropwise manner. The reaction mixture was stirred for ∼24 h in the dark. The products were purified by reverse-phase HPLC (C18 semipreparative column, 40 mm × 250 mm, linear gradient from 100% H_2O to 15% acetonitrile over 30 min). The mono- (**2a**) and diconjugated (**2b**) products were collected separately and lyophilized to yield ∼4.3 mg of **2a** (11.6% with respect to the starting complex, **1**) and ∼2.4 mg of **2b** (5% with respect to **1**). The purity of these complexes was confirmed by LC-MS and mass spectrometry. ESI-MS: for **2a**, calcd $[M + H]^+$ 861.1665 amu, found 861.1646; for **2b**, calcd $[M + H]^+$ 1188.332 amu, found 1188.3235 amu; and calcd $[(M + 2H)/2]^{2+}$ 594.6699 amu, found 594.6680 amu.

NGR-Conjugated Diamminedichloroplatinum(IV) Complexes (3a and 3b). These complexes were prepared and purified following the same procedure described above for **2a** and **2b** except that the linear NGR tripeptide was used instead of RGD, and a shorter linear gradient was used in the HPLC purification (25 min). The mono- (**3a**) and diconjugated (**3b**) products were collected separately and lyophilized to afford 14% of **3a** and 8% of **3b**. The purity of these complexes was confirmed by LC-MS and mass spectrometry. ESI-MS: for **3a**, calcd $[M + H]^+$ 860.1825 amu, found 860.1618; for **3b**, calcd $[M + H]^+$ 1186.3639 amu, found 1186.3735 amu; and calcd $[(M + 2H)/2]^{2+}$ 593.6859 amu, found 593.6715 amu.

AGR-Conjugated Diamminedichloroplatinum(IV) Complexes (4a and 4b). These complexes were prepared and purified by following the same procedure as described above for **2a** and **2b** but with the linear AGR tripeptide instead of RGD. The mono- (**4a**) and diconjugated (**4b**) products were collected separately and lyophilized to afford 16% of **4a** and 7% of **4b**. The purity of these complexes was confirmed by LC-MS and mass spectrometry. ESI-MS: for **4a**, calcd $[M + H]^+$ 817.1766 amu, found 817.1735 amu; for **4b**, calcd $[M + H]^+$ 1100.3523 amu, found 1100.372 amu; and calcd $[(M + 2H)/2]^{2+}$ 550.68 amu, found 550.50 amu.

Glycinamide-Conjugated Diamminedichloroplatinum (IV) Complexes (5a and 5b). These complexes were prepared by following a procedure similar to that for the other platinum(IV)−peptide conjugates except that glycinamide was used instead of a tripeptide. The complexes were purified as described for **3a** and **3b**. The mono (**5a**) and diconjugated (**5b**) products were collected separately and lyophilized to afford ∼50% of **5a** and ∼44% of **5b**. The purity of these complexes was confirmed by LC-MS and mass spectrometry. ESI-MS: for **5a**, calcd $[M + H]^+$ 590.0384 amu, found 590.0389 amu; for **5b**, calcd $[M + H]^+$ 646.0759 amu, found 646.0757 amu.

(CRGDC)c-Conjugated Diamminedichloroplatinum(IV) Complex (6). This complex was prepared by following the same procedure as described above for the Pt(IV)−RGD complexes using (CRGDC)c peptide. A white precipitate, observed in the reaction mixture upon stirring overnight, was discarded by filtration. In this case, however, the diconjugated complex was not detected by LC-MS or HPLC. The monoconjugated product, **6**, was purified by reverse-phase HPLC as described above for **2a** and lyophilized to afford the product in ∼10% yield. The purity of this complex was confirmed by LC-MS and mass spectrometry. ESI-MS: for **6**, calcd $[M + H]^+$ 1066.17 amu, found 1066.2 amu.

(RGDfK)c-Conjugated Diamminedichloroplatinum(IV) Complexes (7a and 7b). These complexes were prepared by following a procedure similar to that described for the other platinum(IV)−peptide conjugates except that the cyclic pentapeptide, (RGDfK)c, was used instead of a tripeptide, and the lysine ϵ-amino group of (RGDfK)c was activated with DIPEA prior to reaction with **1**. The products were purified by reverse-phase HPLC as described above for **3a** and **3b**. The mono- (**7a**) and diconjugated (**7b**) products were collected separately and lyophilized to afford ∼12% of **7a** and ∼8% of **7b**. The purity of these complexes was confirmed by LC-MS and mass spectrometry. ESI-MS: for **7a** calcd $[M + H]^+$ 1120.30 amu, found 1120.20 amu; for **7b** calcd $[M + H]^+$ 1705.61 amu, found 1705.3 amu; and calcd $[(M + 2H)/2]^{2+}$ 853.81 amu, found 853.80 amu.

Cell Culture. Endothelial and tumor cells were all grown at 37 °C under a 5% CO_2 atmosphere, except for bovine capillary endothelial (BCE) cells, which were grown at 10% CO_2. BCEs were isolated from bovine adrenal cortex and cultured in pregelatinized tissue culture plates in Dulbecco's modified Eagle's medium (DMEM; Invitrogen/GIBCO) containing 10% bovine calf serum (Hyclone Laboratories, Logan, UT) and 3 ng/mL basic fibroblast growth factor (bFGF), and 1% GPS, as previously described (*34*). Human dermal microvascular endothelial cells (HMVEC-d; Lonza Inc. and Cascade Biologics, Portland, OR) and human umbilical vein endothelial cells (HUVEC; Lonza Inc.) were maintained according to supplier's directions. HMVEC-d were cultured in microvascular endothelial growth medium (EGM-MV; Cambrex Bio Science); human umbilical vein endothelial cells (HUVEC; Cambrex Bio Science) were cultured in endothelial growth medium-2 (EGM-2; Cambrex Bio Science). All endothelial cells were plated on pre-gelatinized tissue culture plates (1.5% gelatin in PBS). Human glioblastoma cell line U87, purchased from the American type Culture Collection (ATCC, Rockville, MD), and HeLa cells were grown in DMEM supplemented with 10% heat-inactivated (56 °C for 40 min) fetal calf serum (hi-FCS) (Invitrogen/GIBCO, Grand Island, NY), 2 mM L-glutamine, and 1% penicillin−streptomycin (GPS, glutamine/penicillin/streptomycin; Invitrogen/GIBCO). Human uterine sarcoma MES-SA cells (ATCC) were cultured in modified McCoy's 5a medium (ATCC) supplemented with 10% hi-FCS and 1% GPS. Human pancreatic adenocarcinoma cell line ASPC-1 (ATCC) was cultured in RPMI 1640 (ATCC) containing 10% hi-FBS and 1% GPS.

Concentration−Response Curves of Platinum Complexes. BCE cells were plated at 7.5×10^3 cells per well in DMEM containing 10% bovine calf serum. After overnight incubation at 37 °C (in 10% CO_2), the medium was replaced with DMEM containing 5% BCS, 2.0 ng/mL, and various concentrations of the Pt compound (stock solutions prepared in PBS) to a final concentration range of 10 nM to 1 mM. Wells with and without bFGF in the absence of platinum complex were kept as positive and negative controls, respectively. All concentrations were tested in triplicate. After 72 h, viable cells were trypsinized (Trypsin-EDTA; Invitrogen/GIBCO BRL), resuspended in isotonic diluent (Fisher Scientific, Pittsburgh, PA), and counted using a particle counter. Data were analyzed as described below.

HMVEC-d (passages 2–5) were seeded at 7.5×10^3 cells per well in pre-gelatinized 48-well plates in endothelial basal medium (EBM-2; Cambrex Bio Science) supplemented with 5% FBS and incubated at 37 °C (in 5% CO_2). After 24 h, the medium was replaced with microvascular endothelial growth medium (EGM-MV) and the Pt compound dissolved in PBS (10% volume) or PBS alone (positive control). For the negative control, the medium was replaced with EBM-2 supplemented with 5% FBS instead. Cells were incubated for 72 h, trypsinized, and counted on a particle counter. HUVEC were performed as described for HMVEC-d with the following changes. Cells were plated in EBM-2 supplemented with 2% FBS, challenged with EGM-2, and EBM-2 containing 2% FBS was used as a negative control.

To investigate the effect of Pt(IV) complexes in tumor lines, tumor cells were seeded at a density of 5.0×10^3 cells per well. For plating and challenging, the corresponding cultivation medium supplemented with 5% hi-FBS and 1% GPS were used (DMEM in the case of U87 and HeLa cells; modified McCoy's 5a medium was employed in the case of MES-SA and MES-SA/Dx; RPMI-1640 for ASPC-1). After 24 h, the medium was replaced with fresh medium containing 5% FCS and the Pt compound dissolved in PBS (10% volume). Cells were incubated for 72 h, trypsinized, counted on a particle counter, and analyzed as described below.

Analysis of Concentration−Response Curves and Determination of IC_{50} Values. Cell numbers determined from the concentration−response curves were converted to percent cell number. For each cell line and each compound tested, the data for all independent experiments (*2–9*) were combined and analyzed by nonlinear regression to a hyperbolic decay equation. The data were fit by using *SigmaPlot 8.0* to a two-parameter hyperbolic decay model $y = a \times b/(b + x)$, where $y =$ % cell number and $x =$ concentration of platinum compound. A three-parameter hyperbolic decay model ($y = y_0 + a \times b/(b + x)$, tested both in the absence and presence of constraints ($a = 95$, $y_0 = 5$), yielded larger P values and was therefore not used. The IC_{50} values were determined on the basis of the fitted data, and standard error and P values were derived from the b parameter.

Competition Studies in BCE with Free Peptides. BCE cells were plated as described for the concentration-dependent curves. After 24 h, the medium was replaced with DMEM containing 5% BCS, 2.0 ng/mL basic fibroblast growth factor, with or without **2a** (2 μM), and with or without various concentrations of RGD peptides (0.1–1 mM). The effects of the RGD tripeptide and the cyclic pentapeptides, (CRGDC)c and (RGDfK)c, in **2a**-treated cell proliferation were assessed. Wells with and without bFGF in the absence of platinum complex were kept as positive and negative controls, respectively. All concentrations were tested in triplicate. After 72 h, viable cells were trypsinized and counted using a particle counter. Data were analyzed as described above.

siRNA Transfection. The β_1, β_3, and α_v integrins and control siRNAs were purchased as four oligonucleotide SmartPools (Dharmacon Research, Inc.), containing an approximate 50% guanidine−cytosine content (Dharmacon Research, Inc.). Subconfluent HMVEC-d were washed with HBSS and transfected with 10 nM siRNAs using SiLentFect (Biorad) following the manufacturer's protocol. The medium was changed after a 4 h transfection period. Cells were trypsinized 24 h post-transfection and plated onto gelatin-coated 48-well plates at a density of 7500 cells/well, in EBM-2 supplemented with 5% FBS. After overnight incubation at 37 °C, cells were challenged with either **2a** or cisplatin. Cells were counted after 72 h, and results were analyzed as described above.

Western Analysis. Downregulation of protein expression following RNAi interference was confirmed by Western analysis of cell lysates harvested 120 h post-transfection, at the same time that proliferation plates were counted. Lysate preparation and Western analysis were performed as described previously (*35*). mAbs against integrin subunits included: anti-β_1 (clone B3B11, Chemicon International), anti-β_3 (R&D Systems), anti-α_v (Chemicon). mAb against α-actin (Abcam) was used as a control for equal protein loading. Immunoreactivity was detected on Hyperfilm using ECL (Amersham Biosciences). Films were scanned and band intensities were quantitated with *Image J 1.37* software. Band intensities were normalized to actin and shown as percent protein levels.

Fluorescence-Activated Cell Sorting. The expression of integrins $\alpha_v\beta_3$ and $\alpha_v\beta_5$ was detected by immunofluorescence in unfixed cells. Cells were briefly trypsinized, washed in PBS containing 2% FBS, and incubated on ice for 1 h with Cy5-conjugated anti-human $\alpha_v\beta_3$ (MAB1976S) or $\alpha_v\beta_5$ (MAB1961S) monoclonal antibodies in PBS containing 2% FBS (10 μg/mL; Chemicon, Temecula, CA). Unlabeled cells were used as negative controls. BCE and HMVEC cells were analyzed for APN expression using mouse anti-human CD13 IgG (10 μg/mL; BD Biosciences Pharmingen, San Jose, CA). Mouse IgG was used as a negative control. After incubation on ice for 1 h, the cells were washed three times in PBS containing 2% FBS, incubated with FITC-labeled horse anti-mouse IgG (1:100) (Vector Laboratories, Burlingame, CA) for an additional hour, and then washed again. Cells were analyzed on a fluorescence-activated cell sorting (FACS) VantageSE flow cytometer using the *Cell Quest* software (Beckton Dickinson, San Jose, CA). For each cell type, the fluorescence emitted by negative control cells was used to set a threshold gate. FITC or Cy5-labeled cells emitting higher fluorescence than the threshold value were considered positive and were used to determine the percentage of positively labeled cells. Each experiment was performed twice. FACS images were overlaid in *Adobe Photoshop 7.0*.

RESULTS AND DISCUSSION

Synthesis and Characterization of Pt(IV)−Peptide Conjugates. Cisplatin and other platinum(II) drugs are generally administered to patients intravenously, whereas platinum(IV) agents can be taken orally because of their greater stability in the gastrointestinal (G.I.) tract (*31, 36*). One such compound, *cis,trans,cis*-amine(cyclohexylamine)diacetatodichloroplatinum(IV), or satraplatin, is currently in a phase III clinical trial for hormone-refractory prostate cancer (*37*). Whereas the half-life of satraplatin in tissue culture medium and human plasma is long (22 and 5.3 h, respectively), the Pt(IV) compound undergoes rapid biotransformation in blood to a Pt(II) species, with a half-life of only 6.3 min (*38*). The Pt(II) metabolite of satraplatin, *cis*-amine(cyclohexylamine)dichloroplatinum(II), forms DNA cross-links that are structurally very similar to those of cisplatin (*39*).

A targeting Pt(IV) complex requires a sufficiently long half-life to reach the tumor environment. Because the average cardiac output in an adult resting human is 5 L per minute, and the average total circulating volume in an adult male is 5 L, it takes approximately 1 min for the blood to circulate once through the body. On the basis of the satraplatin half-life in blood, we estimate that an intravenous administration of a targeting Pt(IV) compound should have sufficient time to reach the tumor site before its conversion to Pt(II).

By exploiting integrin- and APN-specific peptide recognition as the guiding strategy, we have designed new Pt(IV) anticancer drug candidates for targeting angiogenic tumor endothelial cells and tumor cells expressing such integrins. The RGD and NGR containing tri- and pentapeptide sequences in these molecules are tethered as axial ligands to the Pt(IV) center. Following selective binding to the tumor cell surfaces, these Pt(IV) species have the potential to enter the cells where they will be readily reduced by glutathione or other intracellular reductants to afford cisplatin (*40–42*). If successful, the level of toxicity of these complexes toward normal cells should be greatly diminished.

cis,trans,cis-Diamminedisuccinatodichloroplatinum(IV), *cis-cis-trans*-[Pt-$(NH_3)_2$(succinate)$_2Cl_2$] (**1**), was employed as the precursor in the synthesis of all Pt−peptide conjugates. Compound **1**, prepared as reported elsewhere (*24*), is suitable for additional derivatization at its axial positions by appropriate coupling with the terminal carboxylate groups of the succinato moieties. A similar strategy was employed successfully in our laboratory to obtain a series of estrogen-tethered platinum(IV) compounds, which are capable of inducing the overexpression of HMGB1 (high mobility group binding protein 1) in MCF-7 cells and thus sensitizing them to the conjugates (*24*).

Three different tripeptide sequences, RGD, NGR, and AGR, and the disulfide-bridged pentapeptide, (CRGDC)c, were prepared by solid-phase synthesis. The –SH groups of cysteine residues in linear CRGDC peptide were oxidized in air to form intrapeptide S−S bridged (CRGDC)c. The peptides were purified by reverse-phase HPLC on a C18 column and characterized by LC-MS, MALDI, and ESI-MS. The cyclopentapeptide, (RGDfK)c, was prepared by following the literature procedure (*32, 33*).

Five monofunctionalized $Pt^{IV}(NH_3)_2Cl_2$−peptide conjugates, denoted as Pt-RGD-mono (**2a**), Pt-NGR-mono (**3a**), Pt-AGR-mono (**4a**), Pt-(CRGDC)c-mono (**6**), and Pt-(RGDfK)c-mono (**7a**), and four difunctionalized analogues designated Pt-RGD-bis (**2b**), Pt-NGR-bis (**3b**), Pt-AGR-bis (**4b**), and Pt-(RGDfK)c-bis (**7b**), were synthesized (Scheme 1). These complexes form upon treatment of **1** with peptide molecules in aqueous solution in the presence of 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide (EDC) and *N*-hydroxysuccinimide (NHS) as activators and coupling reagents. In the case of (RGDfK)c, the ϵ-amino group of the lysine side chain was activated with a base, DIPEA, before it was allowed to react with **1**. Except for the (CRGDC)c peptide, these reactions afforded both mono- and diconjugated Pt−peptide species, which were separated and purified by reverse-phase HPLC. An HPLC chromatogram for the purifica-

tion of linear RGD conjugated Pt(IV) complexes, **2a** and **2b**, is shown in Figure S1 (Supporting Information). For the (CRGDC)c peptide, no difunctionalized complex was detected in the reaction mixture. In addition to the aforementioned complexes, a single amino acid residue, glycinamide, was tethered to the succinato group(s) in a similar fashion to obtain mono- and difunctionalized Pt(IV) conjugates, **5a** and **5b**. These complexes were characterized by LC-MS and high-resolution ESI-MS. The experimental mass spectral data are in excellent agreement with the calculated values and display the proper isotopic mass distribution patterns (see Figure S2, Supporting Information, for representative mass spectra). Lower yields were obtained for the platinum−peptide conjugates in comparison to the glycinamide−platinum conjugates. The decreased yield is most likely the consequence of steric effects generated by the longer amino acid side chains of tri- and pentapeptides. In contrast, glycinamide is a single amino acid containing hydrogen as a side chain; therefore, the coupling reaction is facilitated.

Concentration−Response Curves of the Pt(IV)−Peptide Conjugates on Proliferating Cells. In vitro activity studies of the monofunctionalized (**2a**−**5a**, **6**, and **7a**) and difunctionalized (**2b**−**5b** and **7b**) platinum(IV) complexes, as well as cisplatin and **1**, were performed on proliferating endothelial and tumor cells that express APN and/or the integrins $\alpha_v\beta_3/\alpha_v\beta_5$, discussed above. Cisplatin was used as positive control; compounds **4a**, **4b**, **5a**, and **5b**, and complex **1** were investigated as negative controls. We used primary cultures of endothelial cells, including bovine capillary endothelial (BCE) cells, human microvascular endothelial cells (HMVEC), and human umbilical vein endothelial cells (HUVEC). The tumor cell lines glioblastoma (U87), pancreatic carcinoma (ASPC1), uterine sarcoma (MES-SA and MES-SA/Dx-5), and cervical (HeLa) were also tested on the basis of their expression of at least one of the two $\alpha_v\beta_3$ or $\alpha_v\beta_5$ integrins (*43–47*), which we determined by fluorescence-activated cell sorting (Supporting Information, Figure S3). The expression of aminopeptidase N (CD13) was also confirmed in BCE and HMVEC cells. As shown in Table 1. and Figure S3, only endothelial cells and the tumor lines U87 and ASPC1 expressed $\alpha_v\beta_3$; all cells expressed $\alpha_v\beta_5$.

Cell growth was evaluated in subconfluent, serum- and growth factor-stimulated endothelial cells or serum-stimulated tumor cells in the presence or absence of Pt compounds. BCE cells were stimulated with basic fibroblast growth factor (bFGF); HMVEC and HUVEC were stimulated with endothelial growth media containing bFGF, insulin-like growth factor 1 (IGF-1), hepatocyte growth factor (HGF), and vascular endothelial growth factor (VEGF). The activities of the platinum complexes were determined after 72 h by comparing the number of viable cells as a function of platinum concentration in treated versus untreated cells. Short preincubation times (2 or 6 h) of cisplatin and **1** with BCE and HMVEC cells afforded limited decrease in cell viability, indicating the rates of internalization or activation of platinum complexes to be relatively slow. The activities of these complexes were independent of serum concentration, tested at 5% and 10% (data not shown).

Table 1. Expression Level of $\alpha_v\beta_3$ and $\alpha_v\beta_5$ Integrins in Different Cell Lines

	% labeling		
cell line	$\alpha_v\beta_3$	$\alpha_v\beta_5$	APN
BCE	77 ± 12	44 ± 23	25 ± 5
HMVEC	45 ± 3	98 ± 5	96 ± 1
HUVEC	90 ± 5	96 ± 5	n. d.
U87	82 ± 7	94± 7	n. d.
ASPC1	12 ± 6	46 ± 5	n. d.
MES-SA	1 ± 1	59 ± 26	n. d.
HeLa	1 ± 0.02	83 ± 13	n. d.

Concentration−response curves of the platinum−peptide complexes in all the cells were compared to those with cisplatin and **1**. To ensure unbiased data, two additional independent double-blinded experiments with all the complexes were performed in BCE cells, with reproducible results.

Inhibition of BCE and HMVEC Proliferation by Pt(IV) Conjugates. The IC_{50} values of these complexes, defined as the concentration at which 50% of the cells are viable, were determined for BCE and HMVEC and are summarized in Table 2.

The concentration−response curves of the monoconjugated and diconjugated platinum(IV) complexes, together with that of cisplatin and **1**, toward the BCE cells are plotted in Figure 1A,B, respectively. Among all these complexes, cisplatin was most efficient at inhibiting cell growth ($IC_{50} \approx 1.1$ μM). All Pt(IV) compounds containing conjugated targeting moieties were significantly more inhibitory than **1**, with difunctionalized and monofunctionalized compounds being equally effective. Targeted complexes **2a**, **2b**, containing the linear RGD tripeptide, and **7a**, **7b**, containing the (RGDfK)c pentapeptide, were the

Table 2. IC_{50} (μM) Values of Platinum Complexes for BCE and HMVEC Cells[a]

complex	BCE IC_{50}	*P*-value	HMVEC IC_{50}	*P*-value
Cisplatin	1.1 ± 0.11	****	1.2 ±0.22	****
1	21 ± 3.0	****	33 ± 3.7	****
2a	3.1 ± 0.33	****	5.5 ±0.74	****
2b	2.1 ± 0.31	****	4.5 ± 1.4	**
3a	5.1 ± 0.61	****	5.9 ±0.66	****
3b	7.1 ± 0.86	****	5.1 ±0.45	****
4a	18 ± 2.2	****	n.d.	
4b	28 ± 3.9	****	n.d.	
5a	19 ± 2.6	****	55 ± 11	***

7a/cisplatin	2.5		2.8	
5a/cisplatin	17		45	

[a] *P*-value = $P < 0.01$ (**), $P < 0.001$ (***), and $P < 0.0001$ (****); n.d. = not determined.

most active ($IC_{50} \approx 2.1$–3.4 μM), followed by **3a** and **3b** consisting of NGR tripeptide. In contrast, all platinum(IV) conjugates containing nontargeting peptides or amino acid residues were equal to or less active than **1**. The monofunctionalized compounds **4a** and **5a** are comparable in activity to **1** ($IC_{50} \approx 18.5$ μM), whereas their difunctionalized counterparts are less active (**4b**, **5b**) ($IC_{50} \approx 29$ μM).

A similar inhibitory trend was observed when the complexes were tested on HMVEC (Figure 2). The Pt(IV)−RGD conjugates, mainly **6**, **7a**, and **7b**, were most potent at inhibiting proliferation ($IC_{50} \approx 2.7$–3.4 μM) and comparable to cisplatin ($IC_{50} \approx 1.2$ μM), followed by **2a**, **2b**, and the Pt−NGR conjugates, **3a** and **3b** ($IC_{50} \approx 4.5$–5.9 μM). Nontargeting platinum(IV) complexes, **1**, **4a**, **4b**, **5a**, and **5b** were approximately an order of magnitude less potent ($IC_{50} \approx 33$–55 μM) (see Table 2).

The enhanced activity of RGD-containing Pt(IV) compounds was not caused by the targeting peptide moiety, as shown in Figure 1C. None of the free peptides, RGD, (CRGDC)c, or (RGDfK)c, inhibited BCE growth, even at very high concentrations. In addition, nonconjugated 1:1 and 2:1 mixtures of free RGD and **1** did not improve the concentration−response of **1** ($IC_{50} \approx 36$ μM) (data not shown). These results are consistent with the inhibitory properties of RGD peptides in vitro. RGD peptides interfere with cellular adhesion and migration by antagonizing the interaction between integrins and the extracellular matrix, but do not affect cellular proliferation when administered to subconfluent preadherent cells, as is the case in our study.

Competition Studies of 2a with Free RGD-Containing Peptides in BCE Cells. To determine whether the increased inhibitory response of RGD-containing platinum compounds could be blocked with an excess of RGD-containing peptides, we performed competition studies in BCE cells using **2a** as the RGD−platinum compound, and RGD, (RGDfK)c, and (CRGDC)c as the free peptides. As shown in Figure 3, the more constrained cyclic pentapeptides (CRGDC)c (purple) and (RGDfK)c (light green) could partially decrease the inhibitory effect of **2a** in BCE cells treated with 2 μM of the Pt−RGD compound, and this effect was statistically significant. In contrast, the RGD tripeptide had no effect, even at millimolar concentrations (light blue). By themselves, none of the free peptides affected BCE proliferation ((CRGDC)c in gray, (RGDfK)c in dark green, and RGD in dark blue), consistent with our previous findings (Figure 1C). The fact that the integrin-specific $\alpha_v\beta_3$ and $\alpha_v\beta_5$ ligand (RGDfK)c could reduce the inhibitory effect of the monofunctionalized RGD−Pt(IV) compound suggests that these integrins are playing a role in the recognition of RGD-containing Pt(IV) compounds.

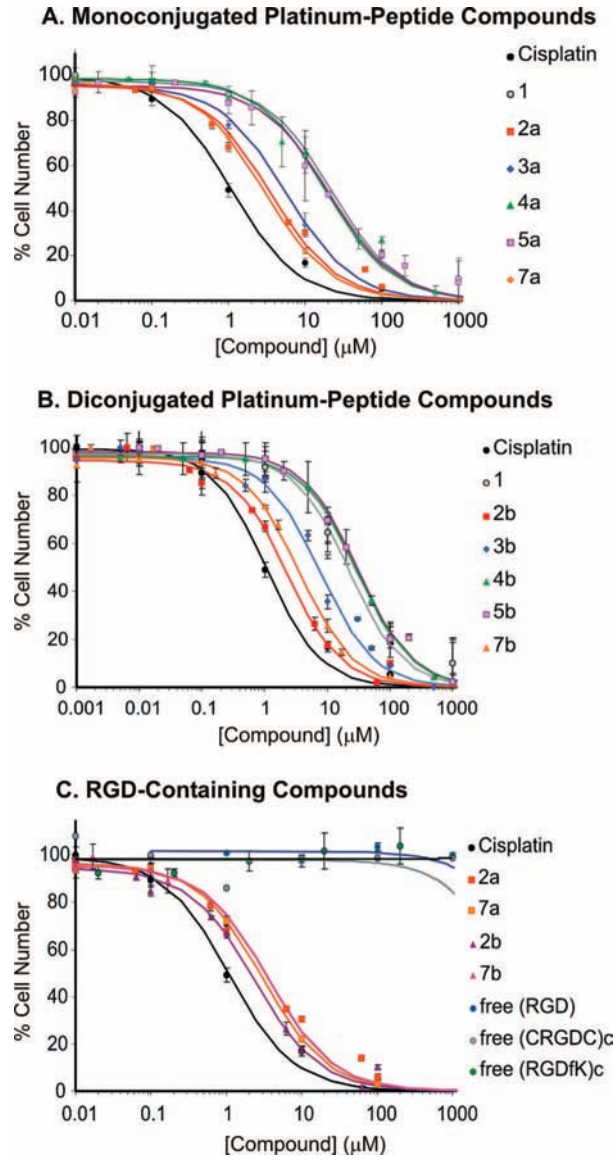

Figure 1. Concentration−response curves of the platinum complexes on BCE cells. (A) Monofunctionalized platinum(IV) complexes along with cisplatin and **1**. (B) Difunctionalized platinum(IV) complexes along with cisplatin and **1**. (C) Pt-RGD complexes and the RGD-containing tri- and pentapeptides. The cells were treated for 72 h with each complex and counted by using a Coulter Counter.

Concentration−Response Curves in HMVEC-d Lacking α_v, β_1, and β_3 integrins. Although the RGD tripeptide can bind to 8 of the 24 known integrin heterodimers of the integrin family, only 3 of these, $\alpha_5\beta_1$, $\alpha_v\beta_3$, and $\alpha_v\beta_5$, have been reported to be expressed in endothelial cells (reviewed in ref *48*). Integrin levels $\alpha_5\beta_1$, $\alpha_V\beta_5$, and $\alpha_V\beta_3$ are increased, mobilized, or induced during angiogenesis, and they can promote apoptosis of angiogenic endothelial cells in vitro and in vivo (*48*). To determine whether some or all of these integrins are responsible for the increased sensitivity of cells toward RGD-containing platinum compounds, we performed RNAi interference studies on HMVEC-d cells. HMVEC-d cells were transfected with β_1, β_3, α_v, or control RNAi, and loss of the integrins was confirmed by Western analysis at the end of the experiment (120 h post-transfection). Complete knockdown of the integrins was obtained for β_1 and β_3 but not for α_v, for which a significant

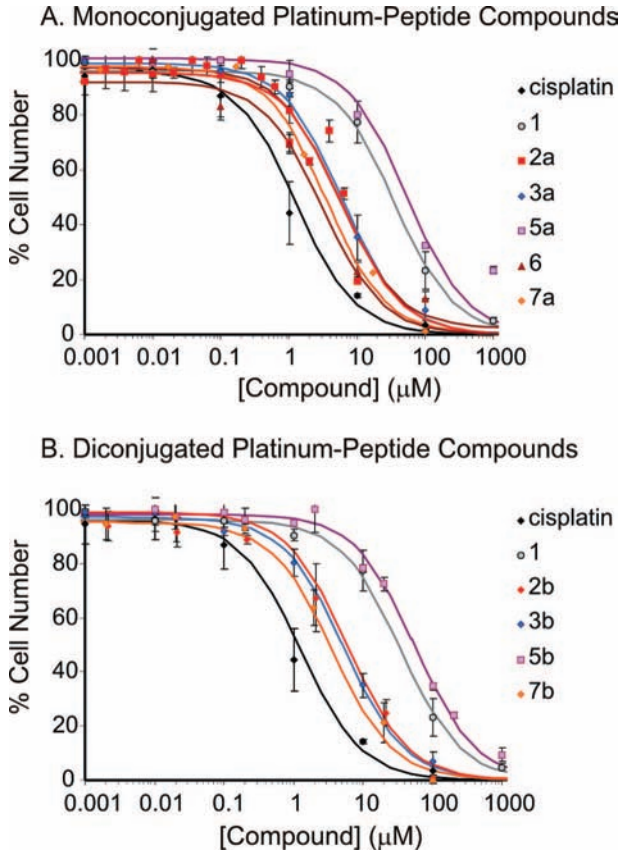

Figure 2. Concentration−response curves of platinum complexes on HMVEC cells. (A) Monofunctionalized platinum(IV) complexes along with cisplatin and **1**. (B) Difunctionalized platinum(IV) complexes along with cisplatin and **1**. The cells were treated for 72 h with each complex and counted using Coulter counter.

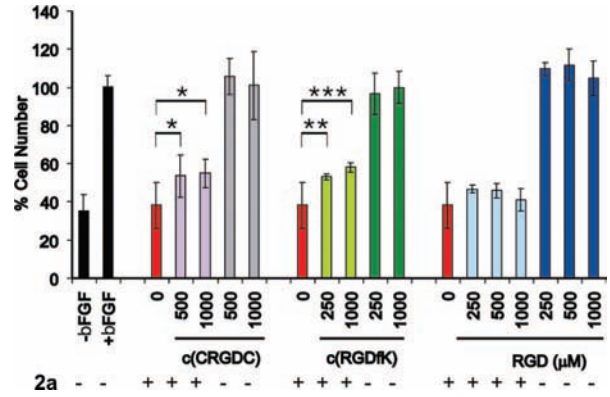

Figure 3. Competition of **2a** with RGD peptides in BCE cells. bFGF-stimulated BCE cells treated with **2a** (2 μM) either alone (red) or in the presence of a large excess of RGD-containing peptides: (CRGDC)c (purple), (RGDfK)c (light green), RGD (light blue). Controls: BCE proliferation with and without bFGF (black), and with bFGF and free RGD-peptides ((CRGDC)c in gray, (RGDfK)c in dark green, and RGD in dark blue). Asterisks indicate statistical significance, as measured with one-way analysis of variance (ANOVA), using the Tukey-Kramer multiple comparison test ($P < 0.05$ (*); $P < 0.01$ (**); $P < 0.001$ (***)). Samples run in triplicate; experiments performed in duplicate.

decrease in protein expression was achieved (Figure 4E,F). An increase in β_3 and β_1 protein expression was observed in cells transfected with β_1 and α_v, respectively, suggesting compensation by other integrin pairs. This was not the case of β_3-transfected cells, for which a decrease in α_v integrin was also observed.

Cells were plated 24 h after RNAi transfection, treated with either cisplatin or **2a**, and counted 3 days after treatment. We found poor cell growth in HMVEC-d transfected with β_3 RNAi. The cell numbers in β_3 knockdown cells 72 h post-treatment were nearly identical to the number of plated cells, demonstrating the critical role of β_3 integrin in endothelial cell proliferation (see Figure 4A,B). In contrast, HMVEC-d transfected with control RNAi, α_v, and β_1 integrins proliferated and had comparable cell numbers at the end of the experiment.

Despite differences in cell growth between the integrin knockdown HMVEC cells, cisplatin treatment afforded identical concentration−response curves (Figure 4C). In contrast, a shift in IC-50 was obtained with **2a** (Figure 4D), particularly with β_3 knockdown (5 to 13 μM), demonstrating that this integrin is involved in **2a**-mediated inhibition of cell growth (see also Table 3). Integrin β_5 could be compensating for the remaining targeting in the β_3 knockdown cells. Although α_v RNAi transfections were intended to remove the contribution from $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins, it was not possible to knock down α_v entirely (Figure 4E,F), possibly due to the importance of integrin $\alpha_v\beta_3$ in endothelial cell proliferation. The low levels of α_v found in α_v-transfected HMVEC-d may be sufficient to mediate an inhibitory effect by RGD−Pt(IV). Given the differences in β_1 expression in β_1 and α_v-transfected cells (Figure 4E,F) and their similarities in IC_{50} values (Table 3), β_1 is most likely not involved in the inhibition of cell proliferation by **2a**.

Because the (RGDfK)c pentapeptide specifically binds to $\alpha_v\beta_3$ and $\alpha_v\beta_5$, and our results with RGD− and (RGDfK)c−Pt(IV) conjugates are comparable, recognition of the Pt(IV) complex by the cells most likely occurs, at least in part, through either the $\alpha_v\beta_3$ or $\alpha_v\beta_5$ integrin. This conclusion is supported by our RNAi knockdown studies. Incorporation of NGR-containing Pt(IV) conjugates **3a/3b** may also be mediated in part by integrin $\alpha_v\beta_3$, because this integrin binds NGR peptides, albeit with lower affinity than their RGD analogues (*19*). APN does not appear to be solely responsible for recognition of **3a/3b** given that the IC_{50} values were comparable in BCE and HMVEC despite differences in their APN/CD13 expression levels (Table 1).

Inhibition of Cell Proliferation by RGD-Containing Pt(IV) Conjugates in $\alpha_v\beta_3$ Positive and $\alpha_v\beta_3$ Negative Cells. To determine whether $\alpha_v\beta_5$ could mediate delivery of the RGD-containing complexes in the absence of $\alpha_v\beta_3$, we compared the inhibition of Pt(IV) conjugates in endothelial cells or tumor lines that were positive (HUVEC, U87) and negative (MES-SA, MES-SA/DX-5, HeLa) for $\alpha_v\beta_3$. The concentration−response curves of the Pt−RGD conjugates were comparable on HUVEC, U87, ASPC1, MES-SA, and HeLa cell lines. The IC_{50} values of these complexes and cisplatin are summarized in Table 4 (See Figure S4, Supporting Information, for U87). Because each cell type had a different sensitivity to cisplatin, the IC_{50} ratio between **2a**/cisplatin and **7a**/cisplatin was used to compare the RGD and (RGDfK)c conjugates (see Tables 2 and 4). The best inhibitory effect was obtained in BCE, U87, ASPC1, and HeLa; because the last two cell lines are negative for $\alpha_v\beta_3$, our results suggest that $\alpha_v\beta_5$ is equally efficient at delivering Pt(IV) into the cell.

Targeting Efficiency: Linear vs Cyclic Peptides. According to literature reports, the cyclic RGD and NGR peptides containing cysteine residues that form disulfide bonds mark angiogenic endothelial cells with more efficiency compared to their linear counterparts (*20*, *21*, *25*, *26*). It is believed that the presence of disulfide linkage in the cyclic peptides provides the RGD and NGR motifs a constrained conformational arrangement resulting in stronger interactions with the integrins expressed on the cell surfaces. In some cases, the cyclic peptides

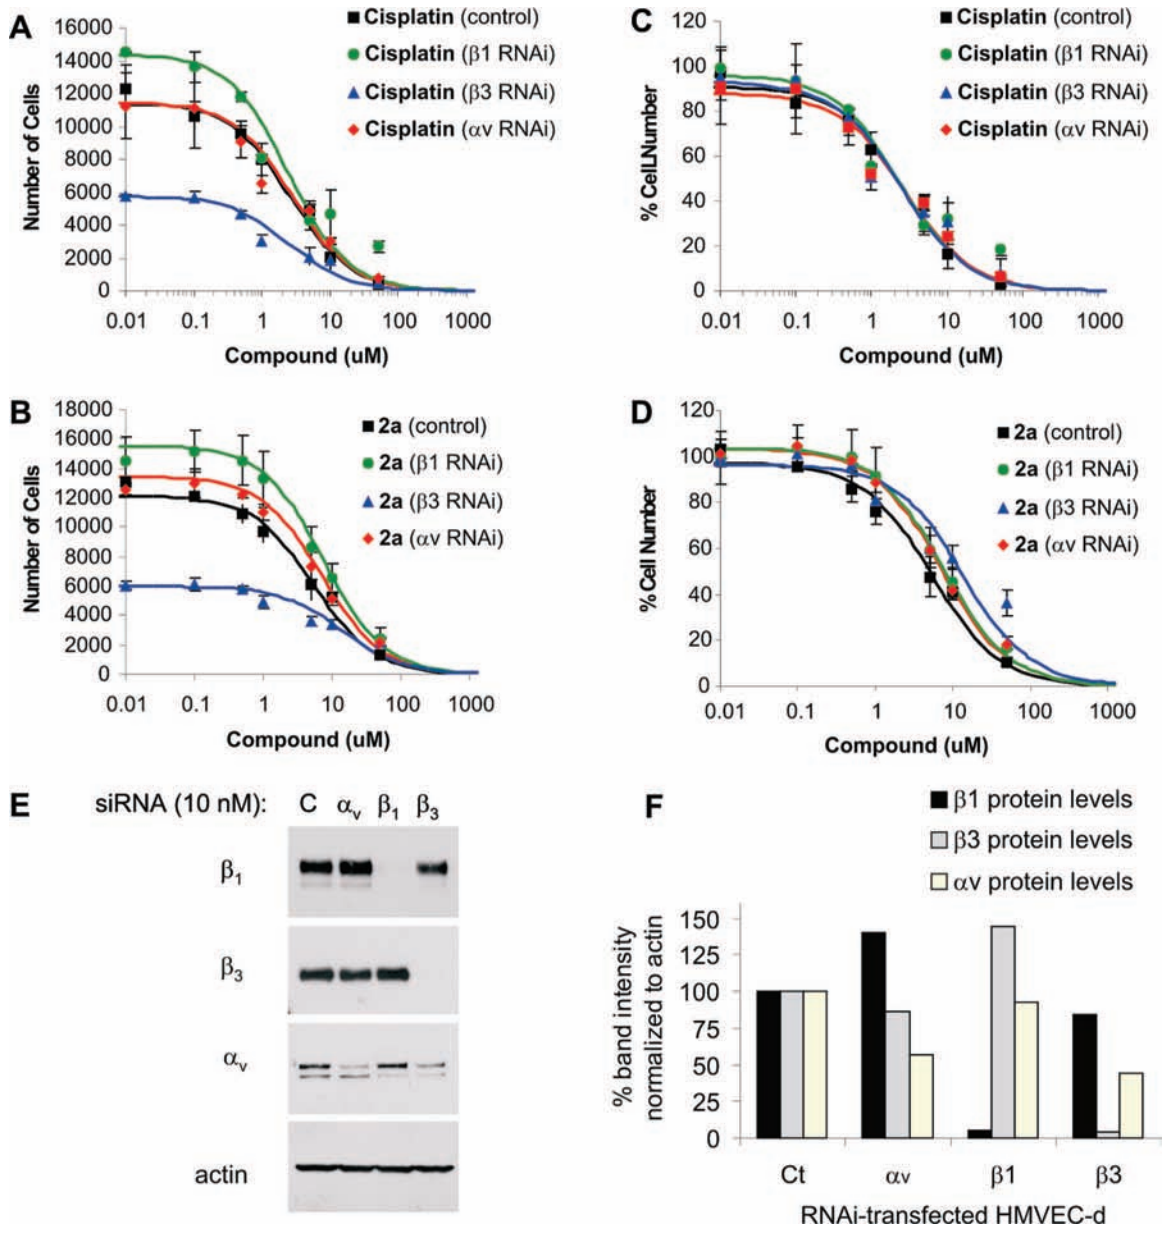

Figure 4. Integrin $\beta 3$ partially mediates Pt(IV)−RGD inhibition of proliferation in HMVEC-d cells. Concentration−response curves in HMVEC-d cells after RNAi knockdown of integrins β_1, β_3, or α_v displayed as total cell number (A,B) or percent cell number (C,D) 72 h after treatment. Poor cell growth was observed in HMVEC-d cells lacking integrin β_3, but not α_v or β_1 (A,B). Despite differences in cell growth between control, β_1 and β_3 knockdown cells, identical concentration–response curves were obtained with cisplatin (C). In contrast, a shift in IC-50 was obtained with **2a** (D), particularly with β_3 knockdown. (E) Western Blot of lysates from transfected HMVEC 120 h post-transfection. In lanes: control, α_v, β_1, and β_3 RNAi transfected HMVEC; in rows: lysates probed with mAb against integrins β_1, β_3, α_v, and Actin. (F) Gel quantitation and normalization to Actin, demonstrating nearly complete knockdown of β_1 and β_3, increased β_1 levels in α_v-transfected cells, and increased β_3 levels in β_1-transfected cells. Integrin α_v was significantly decreased (>45%) in both α_v- and β_3-transfected cells.

Table 3[a]

IC_{50} on HMVEC-d	Cisplatin (μM)	*P*-value	**2a** (μM)	*P*-value
control RNAi	2.2 ± 0.4	**	5.1 ± 0.8	**
α-v RNAi	2.2 ± 0.6	*	7.5 ± 0.7	****
β-1 RNAi	2.2 ± 0.8	*	8.0 ± 0.7	***
β-3 RNAi	2.2 ± 0.7	*	13 ± 4.3	*

[a] *P*-value = $P < 0.05$ (*), $P < 0.01$ (**), $P < 0.001$ (***), and $P < 0.0001$ (****); n.d. = not determined.

containing the RGD and NGR motifs were 10- to 200-fold more effective over the corresponding linear peptides in recognizing the receptors (*21*, *25*, *26*). In the present study, we examined both linear RGD and cyclic (CRGDC)c peptides to serve as the marker to transport the attached platinum complexes to the tumor cells. We also included the cyclic pentapeptide, (RGDfK)c, which is a potent inhibitor of $\alpha_v\beta_3/\alpha_v\beta_5$ (*27*, *49*).

The differential recognition of linear vs cyclic RGD peptides to integrins was indirectly confirmed in our competition studies, because both cyclic pentapeptides, (CRGDC)c and (RGDfK)c, could partially compete the inhibitory effect of **2a** in BCE cells, whereas the linear tripeptide RGD was ineffective. Although we have not yet determined the binding affinities of the linear RGD-containing Pt(IV) compounds and the cyclic RGD-containing Pt(IV) complexes, our results indicate that the linear RGD tripeptide containing Pt(IV) complexes are equally effective in inhibiting cell proliferation and cell killing, Only for about half of the cells tested did we find that the mono- and diconjugated (RGDfK)c compounds were slightly superior to

the mono- and bis-conjugated RGD compounds (HMVEC, U87, MES-SA). As supported by the values listed in Table 4, the IC_{50} ratios of the monoconjugated RGD containing Pt(IV) complexes, **2a** and **7a**, with respect to cisplatin are quite comparable for a given cell type. We have also demonstrated that at least some of the antiproliferative effect of **2a** is mediated by the $\alpha_v\beta_3/\alpha_v\beta_5$ integrins, because (1) the $\alpha_v\beta_3/\alpha_v\beta_5$ integrin-specific ligand, (RGDfK)c, and (CRGDC)c could partially compete off **2a** in BCE cells, and (2) loss of β_3 in HMVEC increased the IC_{50} of **2a** but not of cisplatin. It is possible that, upon conjugation to the succinate group in Pt(IV), the RGD linear tripeptide and the cyclic RGD pentapeptide targeting moieties become comparable at recognizing $\alpha_v\beta_3/\alpha_v\beta_5$ integrins. The Pt(IV) center could sterically hinder binding of the cyclic pentapeptides, decreasing their enhanced binding, or the Pt(IV) center may impose a more rigid conformation to the RGD linear targeting moiety enhancing its binding potential to the $\alpha_v\beta_3/\alpha_v\beta_5$ integrins. A high degree of targeting ability with a linear RGD tripeptide attached to glycosylated porphyrins was also observed in photodynamic cancer therapy against K562 leukemia cell lines (*50*).

Cell Internalization of Pt−Peptide Conjugates. The platinum complexes can enter the cells selectively, through internalization by a surface marker such as $\alpha_v\beta_3$ integrin, or nonselectively, by diffusion across the cell membrane or via other transporters or carriers. Cisplatin, a small neutral molecule, enters cells by passive diffusion (*4*) and, to a degree not yet quantified, by other transporters (*51, 52*). Differences in the size and overall charge on the complex will affect passive diffusion of the complexes through the cell membrane, with smaller, planar, and neutral complexes being more readily incorporated than large, nonplanar, and charged ones. Some of our platinum–peptide complexes are neutral at pH 7 in aqueous solution, whereas a few of the complexes are positively charged and several of them are negative (Chart 1). All of the Pt(IV) complexes have an octahedral geometry which, together with their variable overall charges, makes it unlikely that they would be internalized by passive diffusion. Except for cisplatin, the nontargeted Pt complexes should therefore enter cells by selective uptake. The toxicity profiles of the negatively charged monoglycinamide-tethered complex (**5a**), the neutral mono-AGR (**4a**) and bis-glycinamide complexes (**5b**), and the positively charged bis-AGR complexes (**4b**) are quite similar to that of **1**, which is smaller and negatively charged in aqueous solution. Although the monoconjugated RGD complexes are negatively charged, and the diconjugated complexes are neutral in water, they have a very similar inhibitory effect and are significantly more potent than the nontargeting Pt(IV) complexes. No significant differences in antiproliferative effect were observed between the targeting mono- and diconjugated complexes, suggesting that only one ligand is sufficient for cell surface recognition. These results indicate that the cellular uptake of the targeting platinum(IV) complexes is most likely mediated by internalization by surface markers, $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins, which would account for their greater potency compared to the nontargeting analogues.

From the perspective of evaluating compounds for further study in animal models and, eventually, human cancer treatment, it would have been valuable to test them against cells that were $\alpha_v\beta_5$ negative. The cell lines that we tested were all positive for this integrin (Table 1), however. Nevertheless, the significantly improved effectiveness of the targeting RGD, (RGDfK)c, and (CRGDC)c conjugates compared to the nontargeting AGR, Gly, and disuccinate precursor clearly establishes the value of targeting receptors involved in tumor vasculature as a strategy for improving the efficacy and selectivity of platinum-based drugs.

CONCLUSION

Targeted drug delivery is currently an active area of research in cancer therapy. It offers two major advantages over traditional chemotherapy: (1) it avoids damage to the normal tissue, and (2) it can limit drug resistance, which is a real concern for the current palette of platinum anticancer drugs. In the present investigation, several Pt(IV)−peptide conjugates were designed and synthesized for the purpose of targeted drug delivery to tumor endothelial cells and tumor cells expressing $\alpha_v\beta_3/\alpha_v\beta_5$ integrins. The tri- and pentapeptides, containing either an RGD or an NGR motif, attached by an amide linkage to the platinum(IV) center through a succinato group, serve as tumor-targeting units. The concentration–response curves of these complexes were examined against different endothelial and human cancer cells *in vitro*. RGD-tethered Pt(IV) complexes are potent inhibitors of cellular proliferation when compared to both nontargeting platinum(IV) compounds and to the unconjugated targeting RGD tri- and pentapeptide moieties. NGR conjugates were less inhibitory than RGD counterparts but were still more active than nonspecific Pt(IV)−peptide analogues, suggesting greater affinity of RGD units to the transmembrane receptors over NGR-containing peptides. These results introduce the possibility of selective transport of platinum anticancer agents into tumor endothelial cells.

ACKNOWLEDGMENT

This research was supported by grant CA34992 from the National Cancer Institute. CMB was supported by Postdoctoral Fellowship Grant #PF-03-111-01-CSM from the American Cancer Society and by the Eleanor and Miles Shore Faculty Career Development Award from Children's Hospital, Boston, MA. AH thanks the Pew Latin American Fellows Program in the Biomedical Sciences sponsored by the Pew Charitable Trusts. The MIT Department of Chemistry Instrument Facility is funded by the National Science Foundation (CHE-9808061, CHE-9808063, and DBI-9729592). We thank Prof. Judah Folkman and Catherine Butterfield at the Vascular Biology Program, Children's Hospital for helpful suggestions and for generously providing BCE cells used in this study. We thank Dr. Deborah Freedman, Children's Hospital, Boston, for providing the basic fibroblast growth factor, and Ryan Todd (Massachusetts Institute of Technology), and Arshiya Ahuja (Children's Hospital) for their experimental assistance.

Use of Multiple Carboxylates to Increase Intracellular Retention of Fluorescent Probes Following Release From Cell Penetrating Fluorogenic Conjugates

Xiaoxu Li,[†,§] Ryuji Higashikubo,[‡] and John-Stephen Taylor*[,†]

Chemistry Department, Washington University, St. Louis, Missouri 63130, and Department of Radiation Oncology, Washington University School of Medicine, St. Louis, Missouri 63108. Received March 8, 2007; Revised Manuscript Received September 18, 2007

Fluorogenic reporter systems for use inside cells require that the fluorophore be retained inside the cell following activation to ensure accumulation of an observable signal. In the process of developing ester-based nucleic acid-triggered probe activation systems for use in cells, we found that simple O-alkylated fluorescein esters coupled to cell-penetrating peptides led to very poor signals, presumably because the released fluorophore was too membrane permeable and rapidly exited the cell. To circumvent this problem, we have examined the effect of adding one or two carboxylates to the fluorescein to reduce its membrane permeability. *N*-maleimido D-valine and α-methyl-*β*-L-alanine esters of fluorescein, in which the second phenolic hydroxyl group was derivatized with a carboxymethyl group and then further conjugated with glutamate, were linked to the cell-penetrating peptide Arg_9Cys through conjugate addition of the thiol group to the maleimido group. HeLa cells were incubated with these conjugates, washed, and then further incubated for various times prior to analysis by flow cytometry. Quantitative analysis of the data by a simplified kinetic scheme showed that the fluorescein with two appended carboxylic acid groups effluxed with a rate constant of about 0.00113 min^{-1}, corresponding to a half-life of 8.8 h. The dicarboxylated fluorescein effluxed about 6.1 times more slowly than the fluorescein with a single carboxylic acid group and led to a fairly stable signal. The analysis also showed that the D-Val ester was hydrolyzed about 4.6 times more slowly than the *β*-alanine ester and had a half-life of about 31 min. These data indicate that the fluorescein with two appended carboxylates may be a useful membrane-impermeant fluorophore for fluorogenic probe applications inside living cells.

INTRODUCTION

Fluorogenic compounds have found extensive use as probes for a wide range of intracellular biomolecules and processes by becoming fluorescent only after activation by a specific chemical or enzymatic event (*1–7*). Fluorogenic compounds can also be used to assist the development and optimization of prodrugs by enabling the lability of the prodrug-activating reaction to be monitored in target and nontarget cells (*8–10*). Recently, we have proposed a new approach to chemotherapy and diagnostics called NATPA for nucleic acid-triggered prodrug and probe release (*11–15*). This new approach depends on a disease-specific mRNA sequence to template the association of a complementary prodrug or probe with a catalytic component that then catalyzes the release of the prodrug or probe. For this system to work efficiently, the prodrug or probe must be both stable to the diverse biological environments it will encounter and labile to the catalyst.

Selecting an optimal prodrug or probe for NATPA requires screening a large number of candidates in serum and inside cells. An ideal fluorogenic probe would be one that enters the cell faster than it is activated and one for which the fluorescent product effluxes from the cell more slowly than it is produced (Figure 1). Recently, we developed a general fluorogenic system **1** (Figure 2) that could be used for monitoring the stability of ester-based prodrugs and probes inside cells that consists of a fluorogenic ester of a monoalkylated fluorescein attached to a cell-penetrating Arg_9 peptide (*16*).

The advantage of using the cell-penetrating peptide, Arg_9, to deliver a fluorogenic substrate is that this short peptide has been shown to rapidly deliver attached cargo into cells, irrespective of their inherent membrane permeability or size. The Arg_9 peptide, which has charge and amino acid composition similar to that of HIV Tat peptide 46–57, promotes rapid cellular uptake of diverse types of molecules, such as drugs, peptides, and enzymes into cells, in many different cell lines (*17–20*). A strategy based on using a cell-penetrating peptide for delivering fluorogenic substrates is therefore much more flexible and general than one that requires that the fluorogenic agent itself be membrane permeable and that relies on the activation reaction to render the fluorophore less membrane permeable (*21*). This latter strategy is severely limited by how permeable the fluorogenic substrate can be made as well as how much less permeable the fluorescent probe can be made by the activating reaction. However, attachment of a cell-penetrating carrier such as Arg_9 makes it possible to transport a variety of different fluorogenic probes into cells rapidly so that the activation rates of various probes can be easily compared and quantified. This method of cellular delivery has recently been applied to the design of a number of fluorogenic reagents (*22*).

Esters of mono-O-alkylated fluoresceins were chosen as the fluorogenic ester component because monoalkylated fluoresceins have fluorescence properties similar to those of fluorescein and are easy to prepare, thereby making it easy to tailor the efflux properties of the fluorescein (*16*). When the remaining phenolic oxygen of a monoalkylated fluorescein is esterified, the fluorescein derivative becomes trapped in its nonfluorescent lactone

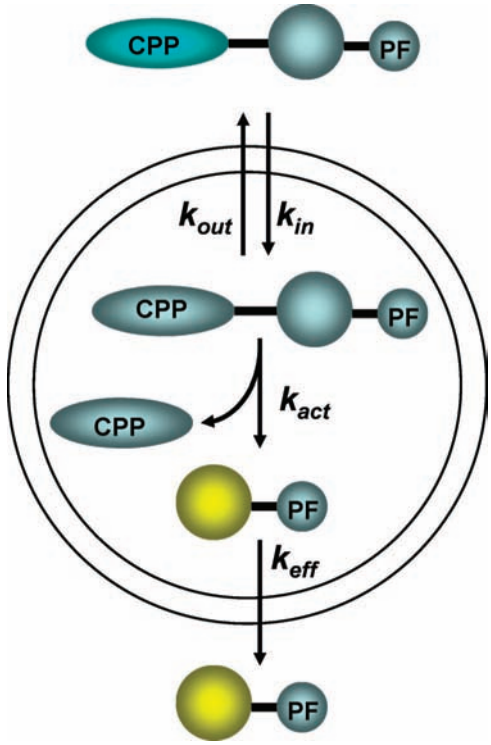

Figure 1. General mechanistic scheme for the entry and activation of a fluorogenic ester conjugate of a cell-penetrating peptide. In the first step, the conjugate enters the cell with rate constant k_{in}, presumably by an endocytotic mechanism mediated by the cell-penetrating peptide (CPP), and exits by a slower, more complex mechanism. In the second step, the ester linkage is cleaved by endogenous enzymes, thereby activating the fluorophore with rate constant k_{act}. Depending on the nature of the permeability factor (PF), the fluorophore will efflux the cell with rate constant k_{eff}.

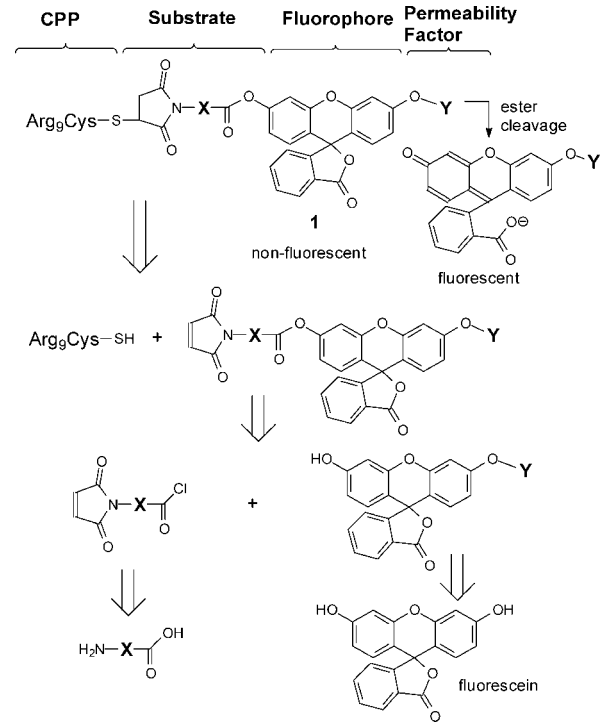

Figure 2. Design and retrosynthesis of the fluorogenic ester conjugate **1**. Cleavage of the ester linkage results in the formation of a fluorescent monoalkylated fluorescein derivative whose efflux rate depends on the properties of the attached permeability factor. Linkage of the cell-penetrating peptide Arg_9Cys is carried out through conjugate addition of the thiol group on the peptide to the maleimido group on the fluorogenic ester. The fluorogenic ester is prepared by reacting the acid chloride of an *N*-maleoyl amino acid with a monoalkylated fluorescein that is prepared from fluorescein.

form. As a result, di-O-substituted fluoresceins have been widely used as fluorogenic substrates for *in vitro* enzyme activity studies. For example, mono-O-alkylated fluorescein phosphate has been used as a fluorogenic substrate for the continuous assay of phosphoinositide-specific phospholipase C, (*23, 24*) and *N*-acetyl-β-D-glucosaminides of 6-O′-alkylated fluorescein derivatives have been used as substrates for a kinetic assay of *N*-acetyl-β-D-glucosaminidase (*25*). In these studies, enzyme activities were quantified by analysis of the fluorescence resulting from enzymatic formation of the fluorescent monoalkylated fluorescein.

As part of our program to develop fluorogenic probes for *in vivo* gene expression, we wanted to examine fluorescent activation of the *N*-maleimido α-D,L-methyl-β-alanine and D-valine esters of monoalkylated fluoresceins. We have previously shown that nitrophenyl and fluorescein esters tethered to an oligodeoxynucleotide (ODN) or peptide nucleic acid (PNA) that is complementary to a target nucleic acid sequence can be hydrolyzed by imidazole tethered to another ODN or PNA that is complementary to the adjacent site on that sequence (*11–13, 15*). For our system to work *in vivo*, however, requires that the background spontaneous or enzyme-catalyzed hydrolysis of the fluorescein esters occurs much more slowly than the mRNA templated hydrolysis of the esters by imidazole. We had already shown that increasing substitution of the ester slows down the background hydrolysis in human serum (*12*) but did not know what the effect would be inside human cells.

In our previous study, we synthesized conjugates of *N*-maleimido β-L-alanine and D-valine esters of a series of monoalkylated fluoresceins with Arg_9Cys for the purpose of studying the stability of these ester linkages in cells (*16*). To render the monoalkylated fluorescein component more water soluble and less membrane permeable, we had replaced the hydrophobic butyl substituent of a reported fluorescein derivative with methoxyethoxymethyl (MEM) and ethylmethylethene (EME) groups. Unfortunately, in subsequent studies, we found that these conjugates showed very little fluorescence inside cells in spite of other data indicating that these esters should have hydrolyzed rapidly. This suggested to us that the released fluorescein derivatives were effluxing faster than they were being produced. This is consistent with previous findings that fluorescein and some of its derivatives quickly exit numerous types of cell lines either via passive cell membrane permeation or via multidrug resistance protein 1(MRP1)-mediated transport (*26–28*). However, carboxylate-derivatized forms of fluorescein are not substrates for export by MRP1, and the presence of additional charges lowers their membrane permeability (*28–30*).

In this article, we report the synthesis of Arg_9 conjugates of fluorogenic esters of monoalkylated fluoresceins bearing one or two carboxylic groups. We also show that the fluorescein with two carboxylates effluxes much more slowly than the one with one carboxylate and that both lead to intracellular fluorescence signals in HeLa cells that can be quantified by flow cytometry. By using these conjugates, we were able to estimate the rates of background hydrolysis of the *N*-maleimido α-D,L-methyl-β-alanine and D-valine ester linkages and the efflux rates of the two fluorophore derivatives.

EXPERIMENTAL PROCEDURES

General Procedures. Dichloromethane (DCM) and triethylamine (TEA) were dried by refluxing with CaH_2 overnight followed by distillation. Fluorescein, *t*-butyl-bromoacetate, ethyl-bromoacetate, thionyl chloride, D-valine, D,L-3-amino-2-methylpropionic acid, DCC, DIPEA, and TFA were purchased from

Aldrich. Fmoc amino acids, *t*-butyl glutamic acid diester, resin, and ByPOP for solid phase peptide synthesis were purchased from NovaBiochem. *N*-maleoyl-D,L-α-methyl-*β*-alanine and *N*-maleoyl-D-valine were prepared as previously described (*12*). ^{1}H NMR spectra were obtained on a 300 MHz Varian UnityPlus-300 or Varian Mercury-300 spectrometer. Proton chemical shifts are expressed in ppm from tetramethylsilane. Flash chromatography was performed on Selecto Scientific silica gel. TLC and preparative TLC were run on precoated 254-nm fluorescent silica gel sheets manufactured by Alltech Associates. Fluorescence spectra were recorded on a SPEX Fluoromax instrument. UV spectral data were acquired on a Bausch and Lomb Spectronic 1001 spectrophotometer or Varian Cary 100 Bio UV–visible Spectrophotometer. Matrix-assisted laser desorption–ionization (MALDI) mass spectra of peptide conjugates were measured on a PerSeptive Voyager RP MALDI-time of flight (TOF) mass spectrometer. HR-FAB mass spectra were obtained on a MS-50TA (Ion Spec B126). HPLC purifications were carried out on Beckman Coulter System Gold 126 with RP C18 semi preparative columns.

Compound 3a. *t*-Butyl-bromoacetate (1.07 g, 1.57 mL, 10.6 mmol) was added dropwise with stirring to a suspension of the disodium salt of fluorescein **2** (*12*) (1 g, 2.65 mmol) in DMF (30 mL) containing catalytic NaI at RT and then heated to 90 °C with stirring for 5 h. The DMF was removed from the mixture by evaporation under reduced pressure. The residue was redissolved in 50 mL of CH_2Cl_2 and washed with H_2O (2 × 40 mL), then dried over Na_2SO_4, and evaporated to give the crude product. Further purification by chromatography on silica gel using hexane/ethyl acetate (2:1) gave 0.325 g (27.5% yield) of **3a** as a yellow powder. ^{1}H NMR (CD_3COCD_3): δ 1.47 (s, 9H), 4.71 (s, 2H), 6.64–6.66 (m, 2H), 6.69–6.77 (m, 3H), 6.84 (d, *J*=2.1 Hz 1H), 7.30 (d, $J = 7.5$ Hz, 1H), 7.74 (td, $J = 7.2$, 1.2 Hz, 1H), 7.81 (td, $J = 7.5$, 1.2 Hz, 1H), 7.98 (d, $J = 7.5$ Hz, 1H), 9.02 (s, 1H); HR FAB MS (*m/z*), calculated for $C_{26}H_{23}O_7$ ($M + H^+$) 447.1444; found, 447.1442.

Compound 3b. Compound **5** (50 mg, 0.128 mmol) and *t*-butyl glutamic acid diester (free base) (35 mg, 0.134 mmol) were dissolved in 10 mL of DCM/DMF (50/50), and DCC (52 mg, 0.252 mmol) was added. The reaction mixture was stirred at RT for 1 h, after which 20 mL of DCM was added. After removal of the precipitate, the organic phase was washed with 1% $KHSO_4$ aqueous solution (2 × 20 mL) and H_2O (1 × 20 mL), dried over Na_2SO_4, and evaporated. The residue was purified by Flash silica gel chromatography using ethyl acetate/hexane (1:1.3) to give 70 mg of compound **3b** as a yellow syrup (87% yield). ^{1}H NMR (CD_3COCD_3): δ 1.41 (s, 9H), 1.44 (s, 9H), 1.69–1.79 (m, 2H), 2.32 (t, $J = 7.5$ Hz, 2H), 4.44–4.49 (m, 1H), 4.65 (d, $J = 2.7$ Hz, 2H), 6.61–6.67 (m, 2H), 6.69–6.83 (m, 3H), 6.95 (d, $J = 2.1$ Hz, 1H), 7.29 (d, $J = 7.5$ Hz, 1H), 7.74 (t, $J = 7.2$ Hz, 1H), 7.82 (t, $J = 7.2$ Hz, 1H), 7.98 (d, $J = 7.5$ Hz, 1H); HR FAB MS (*m/z*), calculated for $C_{35}H_{38}O_{10}N$ ($M + H^+$) 632.2496; found, 632.2500.

Compound 5. Ethyl-bromoacetate (1.18 mL, 1.77 g, 10.6 mmol) was added dropwise with stirring to a suspension of the disodium salt of fluorescein **2** (1.00 g, 2.65 mmol) in DMF (30 mL) at RT and then heated at 90–100 °C with stirring for 5 h. The DMF was removed from the mixture by evaporation under reduced pressure and the residue treated with 25 mL of 4% NaOH in MeOH/water (3:1, v/v) and stirred for 2 h. After the removal of MeOH in vacuum with a rotatory evaporator, the solution was then acidified by the dropwise addition of 1 M aqueous HCl until a pH of about 2.0. The aqueous solution was extracted with ethyl acetate (3 × 20 mL), and the combined ethyl acetate fractions were dried over Na_2SO_4, and evaporated to give the crude product. Further purification by flash chromatography on silica gel using ethyl acetate/hexane (3:1) then ethyl acetate/methanol (10:1) gave 0.53 g (51% yield) of **5** as a yellow powder. ^{1}H NMR (CD_3OD): δ 4.73 (s, 2H), 6.55–6.58 (m, 2H), 6.68–6.73 (m, 3H), 6.85–6.86 (m, 1H), 7.20 (d, $J = 7.2$ Hz, 1H), 7.70 (td, $J = 7.5$ Hz, 1.2 Hz, 1H), 7.78 (td, $J = 7.2$, 1.2 Hz, 1H), 8.01 (d, $J = 7.5$ Hz, 1H); HR FAB MS (*m/z*), calculated for $C_{22}H_{15}O_7$ ($M + H^+$) 391.0818; found, 391.0818.

Compound 8a. This compound was prepared as described for compound **9a**. *N*-maleoyl-D,L-3-amino-2-methylpropionic acid (36 mg, 0.18 mmol) was treated with 5 mL of thionyl chloride, and the resulting mixture was slowly added to a stirred mixture of **3a** (40 mg, 0.090 mmol) and triethylamine (TEA) (25 μL, 18 mg, 0.18 mmol) in 10 mL of CH_2Cl_2 at 0 °C and allowed to warm to room temperature for 3 h. Following workup, the residue was purified by preparative silica gel TLC (1:2 ethyl acetate–hexane) to give 42 mg (77% yield) of compound **8a** as a white powder. ^{1}H NMR (CD_3OCD_3): δ 1.26 (d, $J = 7.2$ Hz, 3H), 1.47 (s, 9H), 3.08–3.16 (m, 1H), 3.76 (dd, $J = 14.1$, 6 Hz, 1H), 3.92 (dd, $J = 14.1$, 7.5 Hz, 1H), 4.73 (s, 2H), 6.74–6.83 (m, 2H), 6.88–6.97 (m, 5H), 7.23–7.25 (m, 1H), 7.36 (d, $J = 7.2$ Hz, 1H), 7.77 (td, $J = 7.5$ Hz, 1.2 Hz, 1H), 7.84 (td, $J = 7.5$, 1.2 Hz, 1H), 8.03 (d, $J = 7.2$ Hz, 1H); HR FAB MS (*m/z*), calculated for $C_{34}H_{30}NO_{10}$ ($M + H^+$) 612.1869; found, 612.1871.

Compound 8b. Compound **8b** was prepared from *N*-maleoyl-D,L-α-methyl-*β*-alanine (22 mg, 0.11 mmol) and **3b** (34 mg, 0.054 mmol) following the same procedure described for the preparation of **8a**. Preparative silica gel TLC (1:2 ethyl acetate–hexane) gave 24 mg (56% yield) of **8b** as a white powder. ^{1}H NMR (CD_3COCD_3): δ 1.26 (d, $J = 7.2$ Hz, 3H), 1.41 (s, 9H), 1.44 (s, 9H), 1.70–1.80 (m, 2H), 2.32 (t, $J = 7.5$ Hz, 2H), 3.08–3.17(m, 1H), 3.76 (dd, $J = 14.1$, 6 Hz, 1H), 3.92 (dd, $J = 13.5$, 7.5 Hz, 1H), 4.43–4.51 (m, 1H), 4.67 (d, $J = 2.1$ Hz, 2H), 6.72–6.86 (m, 2H), 6.87–7.02 (m, 5H), 7.23–7.25 (m, 1H), 7.35 (d, $J = 7.2$ Hz, 1H), 7.77 (t, $J = 7.5$ Hz, 1H), 7.84 (t, $J = 7.5$, 1H), 8.03 (d, $J = 7.5$ Hz, 1H); HR FAB MS (*m/z*), calculated for $C_{43}H_{45}O_{13}N_2$ ($M + H^+$) 797.2921; found, 797.2922.

Compound 9a. *N*-Maleoyl-D-valine (29 mg, 0.14 mmol) (*11*) was dissolved in 5 mL of thionyl chloride and heated at reflux until gas evolution had ceased; at which point, the excess thionyl chloride was removed under reduced pressure. The residual thionyl chloride was removed by dissolving the residue in carbon tetrachloride and then removing the solvent under reduced pressure. The crude acid chloride **7** was dissolved in 5 mL of CH_2Cl_2 and was slowly added to a stirred mixture of 3′-*O*-butyloxycarbonylmethyl-fluorescein (**3a**) (30 mg, 0.067 mmol) and triethylamine (19 μL, 14 mg, 0.14 mmol) in 10 mL of CH_2Cl_2 at 0 °C. The reaction mixture was allowed to warm to RT. After stirring for 3 h, the reaction mixture was diluted with 20 mL of CH_2Cl_2, washed with brine and water (2 × 25 mL), dried over Na_2SO_4, and concentrated in vacuo. The residue was purified by silica gel TLC (1:2 ethyl acetate–hexane) to afford 22.3 mg (53% yield) of **9a** as a white powder. ^{1}H NMR (CD_3OCD_3): δ 0.94 (d, $J = 6.9$ Hz, 3H), 1.14 (d, $J = 6.9$ Hz, 3H), 1.47 (s, 9H), 2.58–2.70 (m, 1H), 4.73 (s, 2H), 4.83 (d, $J = 7.2$ Hz, 1H), 6.74–6.83 (m, 2H), 6.87–6.95 (m, 3H), 7.05–7.14 (m, 1H), 7.34 (d, $J = 7.2$ Hz, 1H), 7.76 (t, $J = 7.2$ Hz, 1H), 7.83 (t, $J = 7.5$, 1H), 8.02 (d, $J = 7.2$ Hz, 1H); HR FAB MS (*m/z*), calculated for $C_{35}H_{32}NO_{10}$ ($M + H^+$) 626.2026; found, 626.2010.

Compound 9b. Compound **9b** was prepared from *N*-maleoyl-D-valine (23 mg, 0.11 mmol) and **3b** (34 mg, 0.054 mmol) following the same procedure described for the preparation of **9a**. Preparative silica gel TLC (1:2 ethyl acetate–hexane) gave 15 mg (34% yield) of **9b** as a white powder. ^{1}H NMR (CD_3COCD_3): δ 0.94 (d, $J = 6.9$ Hz, 3H), 1.12 (d, $J = 6.9$ Hz,

3H), 1.41 (s, 9H), 1.44 (s, 9H), 1.69–1.79 (m, 2H), 2.32 (t, J = 7.5 Hz, 2H), 2.58–2.69 (m, 1H), 4.43–4.49 (m, 1H), 4.67 (d, J = 2.1 Hz, 2H), 4.78 (d, J = 7.2 Hz, 1H), 6.71–7.00 (m, 5H), 7.04–7.14 (m, 3H), 7.34 (d, J = 7.5 Hz, 1H), 7.76 (t, d, J = 7.5, 1.2 Hz, 1H), 7.83 (t, d, J = 7.2, 1.2 Hz, 1H), 8.02(d, J = 7.2 Hz, 1H). HR FAB MS (*m/z*), calculated for $C_{44}H_{47}O_{13}N_2$ ($M + H^+$) 811.3078; found, 811.3072.

General Procedure for the Preparation of Compounds 10a,b and 11a,b. Compounds **8a**,**b** and **9a**,**b** were dissolved in TFA-DCM (50/50, v/v) and stirred under N_2 at RT for 4 h. Complete removal of TFA and DCM under reduced pressure afforded the corresponding deprotected compounds **10a**,**b** and **11a**,**b** as white solids.

Compound 10a. ^{1}H NMR (CD_3OCD_3): δ 1.25 (d, J = 7.2 Hz, 3H), 3.06–3.17 (m, 1H), 3.76 (dd, J = 14.1, 5.7 Hz, 1H), 3.92 (dd, J = 14.1 Hz, 7.8 Hz, 1H), 4.83 (s, 2H), 6.76–6.82 (m, 2H), 6.89–6.96 (m, 5H), 7.23–7.25 (m, 1H), 7.35 (d, J = 7.5 Hz, 1H), 7.76 (t, J = 7.5 Hz, 1H), 7.83 (t, J = 7.2 Hz, 1H), 8.02 (d, J = 7.2 Hz, 1H); HR FAB MS (*m/z*), calculated for $C_{30}H_{22}NO_{10}$ ($M + H^+$) 556.1243; found, 556.1223.

Compound 10b. ^{1}H NMR (CD_3COCD_3): δ 1.26 (d, J = 7.2 Hz, 3H), 1.70–1.80 (m, 2H), 2.45 (t, J = 7.5 Hz, 2H), 3.08–3.18 (m, 1H), 3.76 (dd, J = 14.1, 6 Hz, 1H), 3.92 (dd, J = 13.8, 7.5 Hz, 1H), 4.58–4.65 (m, 1H), 4.67 (s, 1H), 4.91 (s, 1H), 6.72–6.85 (m, 2H), 6.87–7.02 (m, 5H), 7.23–7.25 (m, 1H), 7.35 (d, J = 7.2 Hz, 1H), 7.77 (t, J = 7.2 Hz, 1H), 7.84 (t, J = 7.5, 1H), 8.03 (d, J = 7.2 Hz, 1H); HR ESI MS (*m/z*), calculated for $C_{35}H_{28}O_{13}N_2Na$ ($M+Na^+$) 707.1513; found, 707.1498.

Compound 11b. ^{1}H NMR (CD_3COCD_3): δ 0.93 (d, J = 6.9 Hz, 3H), 1.12 (d, J = 6.9 Hz, 3H), 1.69–1.81 (m, 2H), 2.42 (t, J = 7.5 Hz, 2H), 2.58–2.69 (m, 1H), 4.47–4.54 (m, 1H), 4.65 (s, 1H), 4.78 (d, J = 7.2 Hz, 1H), 4.91 (s, 1H), 6.71–7.00 (m, 5H), 7.04–7.14 (m, 3H), 7.34 (d, J = 7.2 Hz, 1H), 7.76 (t,d J = 7.5, 1.2 Hz, 1H), 7.83 (t,d J = 7.5, 1.2 Hz, 1H), 8.02 (d, J = 7.5 Hz, 1H). HR FAB MS (*m/z*), calculated for $C_{36}H_{31}O_{13}N_2$ ($M + H^+$) 699.1826; found, 699.1829.

Synthesis of TyrArg$_9$Cys. The oligopeptide H_2N-Tyr-(Arg)$_9$-Cys-$CONH_2$ was synthesized by standard solid phase Fmoc peptide synthesis methodology as described previously (*16*). The oligopeptide was purified by semipreparative RP-HPLC with a 30 min 0–40% gradient of A (acetonitrile containing 0.1% TFA) in B (water containing 0.1% TFA) at a flow rate of 1.0 mL/min and detection at 270 nm. MALDI-TOF MS (*m/z*), calculated ($M + 1$) 1689; found, ($M + 1$): 1689.8.

General Method for the Preparation of Arg$_9$Cys Fluorogenic Ester Conjugates. Compounds **10a**,**b** and **11a**,**b** (4 equiv) were each dissolved in 50 μL of acetonitrile, added separately to TyrArg$_9$Cys in 0.5 mL of deoxygenated MeOH, and then shaken under N_2 for 2–4 h at RT. Ethyl ether (10-fold excess) was then added to precipitate the products. Purification was carried out by semipreparative RP-HPLC with a 1.0 mL/min 30 min 0–40% gradient of B (acetonitrile containing 0.1% TFA) in A (water containing 0.1% TFA) with detection at 270 nm. MALDI-TOF MS (*m/z*), calculated ($M + 1$); observed, **12a**, 2244, 2245.73; **12b**, 2373, 2374.37; **13a**, 2258, 2259.51; **13b**, 2387, 2389.41.

Flow Cytometry. Exponentially growing HeLa cells were subcultured 48 h before the studies at a concentration that would ensure the exponential growth of cells at the time of experimentation. The cells were monodispersed by trypsinization and washed twice with 5 mL of Hanks' balanced salt solution containing 10 mM Hepes (pH 7.3), 1 mM MgCl, 1 mM CaCl, and 0.1% bovine serum albumin (HBSS buffer). An aliquant of the samples were examined by flow cytometry to establish the background fluorescence intensity level. To 1 mL of cell suspension containing approximately 0.75×10^6 cells, an appropriate volume of a probe was added, and flow cytometric observation was conducted at 1 min after the addition. Cells were incubated for 5 min with 40 μM probe, washed twice with 5 mL of HBSS, and resuspended in 1 mL of HBSS. Cells were kept at room temperature in the dark and analyzed by flow cytometry at the times indicated. Flow cytometry was carried out on a Becton Dickinson FACS 440 (San Jose, CA). The cells were excited with 300 mW of 488 nm argon ion laser, and fluorescence was detected through a 525 nm band-pass filter. A minimum of 20,000 events, gated by forward and side-scatter intensities, were recorded for each time point in list mode in a CYTOMATION CICERO/CYCLOPS data acquisition/analysis system (Ft. Collins, CO). The mean intensity of green fluorescence for intact cells was calculated and normalized to the background fluorescence intensity of unlabeled cells. Three independent experiments were conducted for each of the probes, and their means are presented in the data (except for **12a**, for which only two of the data sets were used because of a data collection problem). Following flow cytometric examination, samples containing fluorescent cells were examined by fluorescence microscopy (Olympus BX40, Olympus, Center Valley, PA).

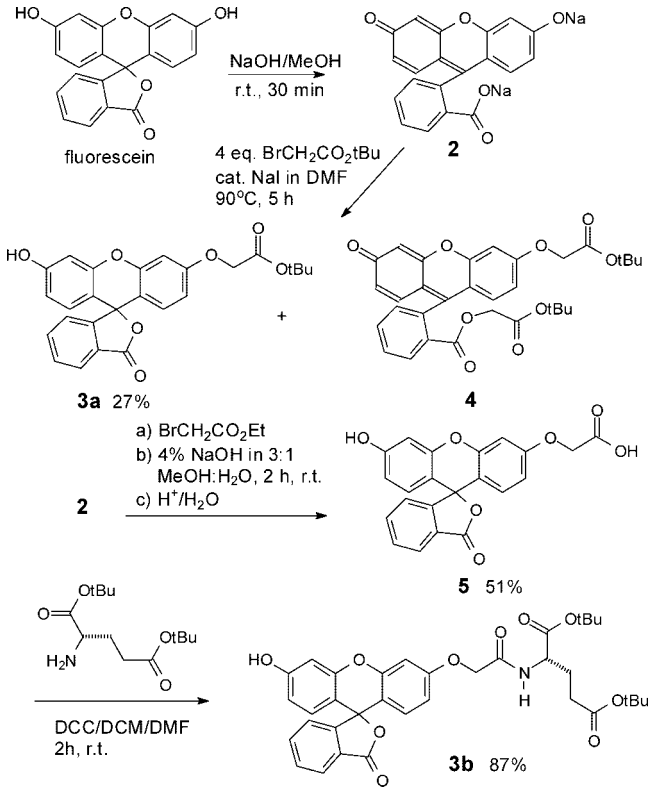
RESULTS AND DISCUSSION

Design. The fluorogenic esters were designed so that it would be easy to systematically vary the cell-penetrating peptide, ester substrate, and the permeability and other properties of the fluorophore (Figure 2). The peptide component can be synthesized by solid phase Fmoc synthesis, while ester linkage can be made directly from a variety of natural and unnatural amino acids through a simple two-step procedure. The permeability properties of fluorescein can be tailored through a side chain attached to one of the phenolic oxygens. Though the fluorogenic esters prepared in this article were made by solution-phase synthesis, it would be quite easy to adapt the synthetic scheme to a solid supported route, as we have previously found that the phenyl esters are stable to the deprotection conditions for the peptide and carboxylate groups.

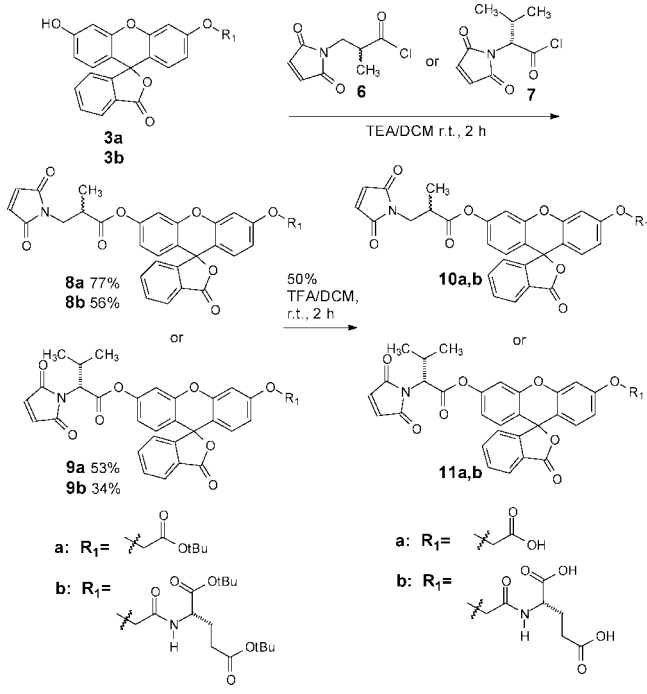
Synthesis of the Monoalkylated Fluoresceins. Fluorescein was monoalkylated as illustrated in Scheme 1 by a method we previously reported for the synthesis of other monoalkylated derivatives (*16*). The disodium salt of fluorescein **2** was prepared by treatment of fluorescein **1** with 2 equiv of NaOH and then alkylated with *t*-butyl α-bromoacetate to afford *t*-butylcarboxymethyl fluorescein (**3a**) and dialkylated product **4.** The dialkylated product could be converted back to **3a** by hydrolysis with NaOH followed by acidification but was never carried out in practice. Removal of the *t*-butyl group with TFA then provided carboxylic acid **5**, which is a more versatile intermediate than fluorescein for adding functionality, as it can be easily coupled to a wide variety of functionalized amines and amino acids by amide bond formation. Compound **5** could be obtained in a better overall yield of 52%, however, by basic hydrolysis of the mixture of monoalkylated and dialkylated fluoresceins that is produced by treatment of the disodium salt of fluorescein **2** with ethylbromoacetate instead of *t*-butylbromoacetate. To prepare an acid labile precursor to a dicarboxylate, compound **5** was coupled to the amino group of the di-*t*-butyl ester of L-glutamic acid with DCC to produce compound **3b** in 53% yield.

Synthesis of *N*-Maleoyl Amino Acid Esters of the Monoalkylated Fluoresceins. The monoalkylated fluoresceins **3a** and **3b** were then converted to the *N*-maleoyl-α-methyl-β-

Scheme 1. Synthesis of the Monoalkylated Fluorescein Building Blocks 3a and 3b

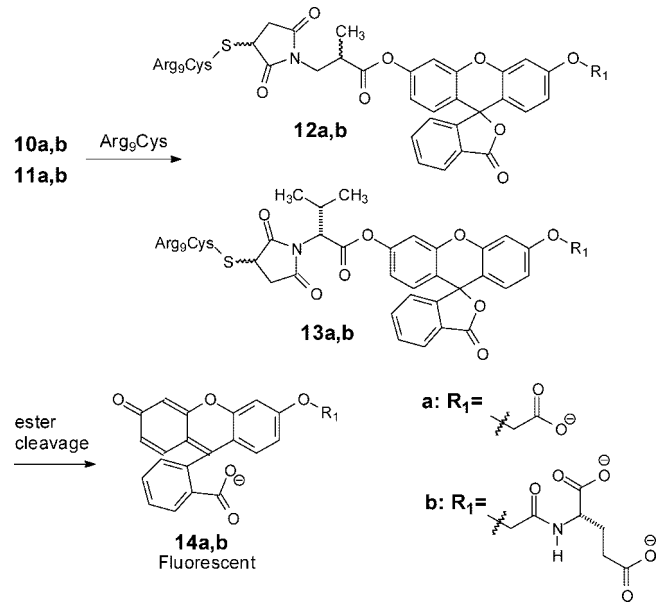


Scheme 2. Synthesis of the *N*-Maleoyl Amino Acid Esters of the Monoalkylated Fluoresceins, 10a,b and 11a,b



amino butyric acid and *N*-maleoyl-D-Val esters **8a**,**b** and **9a**,**b** via acid chlorides **6** and **7** in the presence of triethylamine (Scheme 2). These acids chlorides are readily prepared in two steps from the corresponding amino acids (*11*). The *t*-butyl groups were then removed by TFA to afford the maleimido fluorogenic esters **10a**,**b** and **11a**,**b** bearing one and two carboxylates.

Scheme 3. Synthesis of the Arg_9Cys Conjugates of the Fluorogenic Esters, 12a,b and 13a,b



Conjugation of the *N*-Maleimido Amino Acid Esters of the Monoalkylated Fluoresceins to Arg_9Cys. The cell-penetrating peptide Arg_9 with a cysteine at the carboxy terminus was synthesized by standard Fmoc solid phase synthesis. The cysteine was introduced to provide a thiol group at the carboxy terminus of the peptide for conjugating to the maleimide group of the *N*-maleoyl amino acid esters **10a**,**b**, and **11a**,**b**. The resulting fluorogenic ester conjugates **12a**,**b** and **13a**,**b** were obtained by incubating the peptide with the maleimido esters in a 1:4 ratio for 2 h (Scheme 3). Methanol was preferred as a solvent because of its ability to dissolve both reactants and from which the conjugated products could be easily isolated by ether precipitation. All of the conjugates were purified by RP-HPLC and characterized by MALDI-TOF MS.

Flow Cytometry. To determine the stability of the esters inside living cells, the Arg_9 peptide fluorescein ester conjugates **12a**,**b** and **13a**,**b** were incubated with Hela cells (one million/mL) in media for 5 min at a concentration of 40 μM, after which

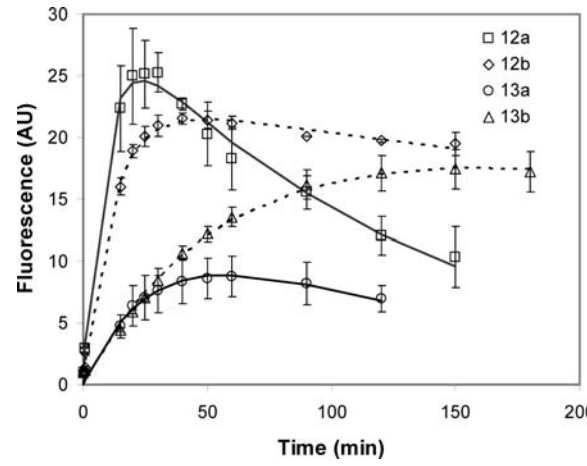


Figure 3. Fluorescence activation of the fluorogenic ester conjugates **12a**,**b** and **13a**,**b** in HeLa cells. A plot of the average fluorescence observed in HeLa cells as a function of time and fitted to an analytical expression for two sequential irreversible first order steps is shown. The error bars represent the standard deviation for three separate experiments (except for **12b**, which is for two experiments). All values for the plot are given in Table 1.

Table 1. Kinetic Parameters for the Fluorescence Activation of the Ar_9 Fluorogenic Ester Conjugates 12a,b and 13a,b by Fitting Each Curve Individually To an Expression for Two Sequential Irreversible Steps

cmpd	amino acid	no. of carboxylates	Ao	k_{act} (min^{-1})	k_{eff} (min^{-1})
12a	α-methyl-β-Ala	1	29.7 ± 1.0	0.12 ± 0.016	0.008 ± 0.0006
12b	α-methyl-β-Ala	2	22.9 ± 0.6	0.087 ± 0.007	0.0013 ± 0.0003
13a	D-Val	1	14.1 ± 0.9[a]	0.032 ± 0.005[a]	0.008[a]
13b	D-Val	2	21.7 ± 0.5[b]	0.017 ± 0.0008[b]	0.0013[b]

[a] Values from fitting when k_{eff} is fixed at 0.008 min^{-1}. [b] Values from fitting when k_{eff} is fixed at 0.0013 min^{-1}.

the cells were washed twice to remove agents that had not penetrated the cells. The cells were then incubated under standard conditions (37 °C, 5% CO_2), for various times, after which the average fluorescence intensity of the cells was determined by flow cytometry for three separate experiments and then averaged except for **12b** for which two data sets were averaged (Figure 3). Fluorescence from the α-methyl-β-alanine ester conjugate bearing a single carboxylate, **12a**, increased more rapidly than that from D-valine conjugate **13a**, but both lost fluorescence at longer incubation times. This behavior is what would be expected for a fluorescent probe that is able to escape from the cell. Fluorescence from the α-methyl-β-alanine ester conjugate bearing two carboxylates, **12b**, also increased more rapidly than for D-valine conjugate **13b**, but unlike the conjugates bearing a single carboxylate, **12a** and **13a**, the fluorescence did not appreciably decrease at longer incubation times. Thus, it would appear that having two additional negative charges on the fluorophore was sufficient to render it practically membrane impermeable. Attempts to visualize the location of the released probes by fluorescence microscopy 30 and 120 min after treatment revealed only faint images, possibly due to low concentration and diffuse, nonlocalized distribution of the probes.

Semi-Quantitative Analysis of the Flow Cytometry Data. Because of the limited data, it was not possible to reliably fit all the rate constants in Scheme 1 for the four different probes. Therefore, we decided to carry out a semiquantitative assessment of the rates of fluorescent probe activation and efflux from the cells by fitting the fluorescence data to an analytical expression (*31*) for two sequential irreversible first order steps, $A_{in} \rightarrow B_{in} \rightarrow B_{out}$, with rate constants k_{act} and k_{eff} as follows: $[B_{in}] = [A_{in}]_o * (\tau^{\kappa} - \tau)/(1 - \kappa)$, where $\tau = \exp(-k_{act}t)$ and $\kappa = k_{eff}/k_{act}$.

In this expression, k_{act} corresponds to the rate constant for activating the fluorogenic probe A inside the cell, and k_{eff} corresponds to the rate constant for efflux of the resulting fluorophore B from inside the cell as diagrammed in Figure 1. This simplified analysis is based on the assumption that there is no external fluorogenic probe that can enter the cell (k_{in}) following washing of the cells and that efflux of the fluorogenic probe from the cell (k_{out}) is negligible compared to k_{act}. This would appear to be a reasonable set of assumptions given the results of many studies indicating that cationically charged cell-penetrating peptides enter cells rapidly through macropinocytosis and become trapped in endosomes (*32–34*). Furthermore, any activation of the fluorogenic probe bound to the surface would not contribute to the signal observed by flow cytometry, as it would be released into the medium.

Fits of the fluorescence data for the two α-methyl-β-alanine conjugates to the two-step model gave a rate constant of 0.12 min^{-1} for fluorescence activation of the conjugate with one negative charge (**12a**), which was very similar to that of 0.087 min^{-1} for the conjugate with two negative charges (**12b**). The average half-life for the activation of these two conjugates was about 6.8 min. The efflux rates of the released fluoresceins, however, differ by a factor of about 6.1, with the fluorescein bearing two carboxylates (**14b**, Scheme 3) effluxing with a rate constant of about 0.0013 min^{-1}, corresponding to a half-life of 8.8 h. The fluorescein bearing one carboxylate (**14a**), however, effluxes much more rapidly with a rate constant of 0.008 min^{-1} corresponding to a half-life of 87 min. The amplitudes, $[A_{in}]_o$ for the fits to **12a** and **12b** differed slightly (29.7 vs 22.9) and might have been due to differing amounts of material absorbed by the cells and/or to differing experimental conditions.

Attempts to fit the data for the two D-valine ester conjugates **13a** and **13b** in a similar fashion resulted in rate constants and amplitudes with large standard deviations, indicating that the fit for these curves was underdetermined. To reduce the number of variables to be fit, we fixed the efflux rate constants for the activated probes **14a** and **14b** to be the same as those obtained from fitting the data for **12a** and **12b**, which release the same probes. Fixing the efflux rates in this manner led to good fits with small standard deviations. The activation rate constants and amplitudes differed by almost a factor of two, however, suggesting that the kinetic scheme may be more complicated for this set of probes and warrants further study. The average of the activation rate constants for the D-valine ester (0.025 min^{-1}) determined in this fashion is about 4.6 times less than the average for the alanine esters of 0.11 min^{-1}, indicating that the D-valine ester is more stable than the alanine ester inside HeLa cells. This is consistent with previous studies on the stability of D-valine esters compared to glycine esters in human serum (*12*). The calculated half-life of about 31 min for the D-valine ester, though much longer than that of about 7 min for the alanine ester, is probably too short to be useful for NATPA *in vivo*. We propose, however, to use this assay system to screen for a more stable ester.

CONCLUSIONS

In our studies, we found that the Arg_9 peptide can rapidly transport a sufficient amount of fluorogenic ester into cells to lead to quantifiable signals in flow cytometry that can be analyzed by a simple two-step kinetic scheme involving fluorescence activation followed by efflux. These conjugates would therefore appear to be useful for evaluating libraries of fluorogenic esters in which the structure and properties of the ester and the permeability factor are systematically varied. In this way, we should be able to identify fluorogenic esters suitable for NATPA and possibly fluorogenic esters capable of distinguishing between various cell types and conditions. The ability to tune the hydrolysis and efflux rates could be very useful for optimizing fluorogenic compounds for particular assays.

We offer a novel methodology for formulating liposomes by incorporating sequence-specific collagen-mimetic peptides such that they are specifically "uncorked" by a matrix metalloproteinase, MMP-9. By encapsulating carboxyfluorescein (as a self-quenching fluorescent dye), we demonstrate that the time-dependent release of the dye from liposomes is due to the specific enzymatic cleavage of the surface-exposed collagen-mimetic peptides. The specificity of such cleavage is attested by the fact that the liposomal "uncorking" and their content release occur only by MMP-9 and not by a general proteolytic enzyme, trypsin, despite the fact that the collagen mimetic peptides contain the trypsin cleavage site. The mechanistic details underlying the formulations of liposomes and their enzyme-selective "uncorking" and content release are discussed. Arguments are presented that such liposomes can be fine-tuned to serve as the drug delivery vehicles for the detection and treatment of various human diseases, which occur due to the overexpression of a variety of pathogenic matrix metalloproteinases.

INTRODUCTION

Of the four major classes of extracellular matrix degrading enzymes (viz., cysteine proteases, aspartic proteases, serine proteases, and metalloproteases,), matrix metalloproteases (MMPs) have been implicated in several diseases (*1, 2*). On the basis of the structural features (including the amino acid sequences, domain organizations, etc.), 26 different types of MMPs have been recognized in human tissues, which fall into six major classes: (i) collagenases, (ii) gelatinases, (iii) stromelysins and stromelysin-like MMPs, (iv) matrilysins, (v) membrane-type MMPs, and (vi) other MMPs (viz., MMP-20, MMP-23, and MMP-28) (*3*). Although many of these MMPs have been implicated in different types of human diseases, MMP-2 and MMP-9 have been widely recognized to be involved in the progression and metastasis of most of the human tumors. They have been found to be overexpressed in breast tumors (*4*), colorectal tumors (*5*), lung tumors (*6*), prostate tumors (*7*), pancreatic tumors (*8*), and ovarian tumors (*9*). In view of their involvement in different human diseases, there have been major efforts to design MMP-selective inhibitors as therapeutic agents and develop strategies for delivering them to their target sites (*10*).

Of the different approaches of delivering drugs (e.g., via liposomes, polymers, microspheres, antibody−drug conjugates etc.), the liposome-assisted drug delivery systems offer several advantages. Presently, there are about 13 liposome-mediated drug delivery systems approved for treating a variety of human diseases (e.g., breast cancer, ovarian cancer, meningitis, fungal infections, leukemia, etc.), and about 30 additional systems for delivering small molecule drugs, DNA fragments, diagnostic compounds, and so forth, are currently at different stages of clinical trials (*11, 12*). Hence, the selective targeting of liposomes is of significant importance to ensure the delivery of therapeutic "loads" to the diseased tissue sites. This feature has been considerably optimized by attaching cell surface-specific antibodies (*13*), peptides (*14*), and small molecule agonists/antagonists of the cell surface receptors (*15*) to differently formulated liposomes.

Usually, liposomes slowly deliver their contents via fusion with the cell membranes, micropinocytosis, endocytosis, or simply by slow dissociation and passive diffusion of drugs from the liposomal lumen to the interior of the affected cells (*11, 12*). In order to accelerate the drug delivery process, liposomes are often "armed" with triggering devices. Some of the "triggering" agents include change in pH (*16*), mechanical stress (*17*), metal ions (*18*), temperature (*19*), light (*20*), enzymes (*21*), and so forth. Hence, both recognition of the diseased tissues and triggered release of the contents are the desirable features of the liposome-assisted drug delivery system. As will be noted in the following sections, both of these features are intrinsically built in our uniquely formulated liposomes. In addition, these liposomes can be "uncorked" in the vicinity of the cancerous tissues, which express high amounts of MMP-9.

Out of about 25 000 papers (listed in PubMed) and 600 patents (listed at the USPTO site) on liposomes, there are only a handful of papers (less than 15) on the triggered release of liposomal contents by enzymes. Some of the enzymes utilized for cleaving liposomes and releasing their contents include elastase, alkaline phosphatase, trypsin, and phospholipase A_2 (*21*). Herein, we report the design of triple helical peptides and their lipopeptide derivatives, incorporation of those lipopeptides into liposomes (such that the triple helical peptides protrude from the surface of the liposomes for facile cleavage), and MMP-9-assisted "uncorking" of the liposomes and release of their contents. We believe the overall strategy can be fine-tuned to diagnose and treat human diseases which occur due to overexpression of pathogenic matrix metalloproteinases, such as MMP-9 (*22*).

EXPERIMENTAL PROCEDURES

Synthesis of the Peptides. The peptides were synthesized on a Rainin Symphony Quartet automatic peptide synthesizer,

using standard Fmoc-protected amino acids and HBTU−HOBT as the coupling reagents. The commercially available CLEAR acid resin was used as the solid support. Each coupling step took 3 h and was repeated twice with 5-fold excess of reagents. Cleavage was performed for 3 h using a cocktail of CF_3CO_2H, anisole, and water (95%/2.5%/2.5%). The crude peptides were precipitated in ice-cold ether and purified by a semipreparatory RP-HPLC, using a linear gradient of 0–70% acetonitrile in water over 40 min. Each solvent contained 0.1% trifluoroacetic acid. The purified peptides were characterized by the CD and mass spectroscopy (MALDI-TOF).

Conditions for Analytical HPLC. Vydac C_{18} analytical HPLC column (238TP5415); eluant, linear gradient of 0–70% acetonitrile in water over 40 min; both solvents contained 0.1% CF_3CO_2H; flow rate, 1.5 mL/min.

Conditions for Semipreparatory HPLC. Vydac C_{18} HPLC column (238TP152022); eluant, linear gradient of 0–70% acetonitrile in water over 40 min; both solvents contained 0.1% CF_3CO_2H; flow rate, 5 mL/min.

Synthesis of the Lipopeptides. After the completion of the peptide synthesis, the N-terminal Fmoc group was removed from the peptide. Conjugation with stearic acid was performed using the same procedure as the amino acid coupling with 5-fold excess of reagents. A shaker was used for better mixing of reagents. Cleavage conditions were the same as that for the peptides. The crude lipopeptides were purified by RP-HPLC, employing a Vydac semipreparatory diphenyl column (RP 219TP510).

Analytical HPLC Conditions. Vydac analytical HPLC column (219TP5415); eluant, linear gradient of 0–70% acetonitrile in water over 40 min; both solvents contained 0.1% CF_3CO_2H; flow rate, 1.5 mL/min.

Semipreparatory HPLC Conditions. Vydac HPLC column (219TP510); eluant, linear gradient of 0–70% acetonitrile in water over 40 min; both solvents contained 0.1% CF_3CO_2H; flow rate, 5 mL/min.

The mass spectral data for the reported peptides and the lipopeptides are provided in Supporting Information.

Circular Dichroism Spectroscopy. CD spectra were recorded on a Jasco J-815 instrument using a cell of 0.2 mm path length. The concentration of the peptides or lipopeptides was 1 mg/mL in 10 mM phosphate buffer, pH = 4.0. The solutions were stored for 12 h at 4 °C before recording the spectra. For temperature-dependent CD spectra, the sample was equilibrated for 15 min at each temperature before recording the spectra.

Cloning, Expression, and Purification of MMP-9. The catalytic and fibronectin domains (truncating the hemopexin domains from the full-length enzymes) of human MMP-9 were cloned in pET20b vector (Novagen), and the enzyme was overexpressed in BL21(DE3) *Escherichia coli* cells. The expressed proteins were primarily recovered from the inclusion bodies. The purified MMP-9 showed a single band on SDS gel electrophoresis. The yield from 1 L of bacterial culture was in the range 30–80 mg. The experimental details of the cloning, expression, and purification of MMP-9 will be published elsewhere.

Peptide and Lipopeptide Cleavage Studies with MMP-9 and Trypsin. For the cleavage studies, the conditions are: [peptide] or [lipopeptide] = 1 mg/mL in 25 mM HEPES buffer, pH = 8.0, containing 10 mM $CaCl_2$; [MMP-9] = 5 nM, 25 °C. At different time intervals, 50 μL samples were withdrawn and 2 μL of CF_3COOH was added to stop the reaction. The products were analyzed by RP-HPLC, using the same elution condition as employed for the analysis of the peptides and lipopeptides.

Liposomal Formulation. MMPP_4HFA (30 mol %) and POPC (1-palmitoyl-2-oleoyl-*sn*-glycero-3 phosphocholime, 70 mol %, total lipid concentration of 1 mg/mL) were dissolved in $CHCl_3$. A thin film was prepared by evaporating the solvent using a rotary evaporator. The film was placed under high vacuum for 12 h. The film was then hydrated with 100 mM 5-carboxyfluorescein solution (prepared in 25 mM in HEPES buffer, 10 mM $CaCl_2$ at pH = 8.0) for 1 h at 60 °C followed by sonication for another hour at 60 °C. Nonencapsulated dye was separated from liposomes via gel filtration chromatography with a Sephadex G75 column. Before loading the crude liposomal preparation on the column, the osmolarity of the elution buffer (with same composition) was adjusted by the addition of solid NaCl.

Kinetics of Release of Carboxyfluorescein from Liposomes. MMP-9 (10 μL of 200 μM solution) was added to a 2 mL solution of liposome in 25 mM HEPES buffer, pH 8.0, containing 10 mM $CaCl_2$ at 25 °C. The emission spectra of the control and liposomes with MMP-9 were measured. The emission intensity at 518 nm (excitation: 480 nm) was monitored as a function of time for 5 h. The experimental condition for the leakage studies with trypsin was the same as that for MMP-9.

RESULTS

It is known that incorporation of Gly Pro-Hyp repeats in polypeptide chains tend to form the triple-helical collagen-mimetic peptides (*23*). The magnitude of such helicity increases with either attachment of alkyl groups at the N-terminus (*24*) or introduction of cysteine knots (*25*), or metal ions (*26*). To incorporate collagen-mimetic triple helical peptides on the surface of liposomes for their recognition by MMP-9 and subsequent cleavage, we synthesized a few such peptides and conjugated them with stearic acid via their N-terminal NH_2 groups. Four criteria were taken into consideration for syntheses of such lipopeptides: (i) the peptides should exhibit the triple helical conformations, (ii) the peptides should contain the cleavage site for MMP-9, (iii) the peptides should be resistant to the cleavage by general proteases, (iv) the triple helical peptides must exhibit propensity to undergo facile unwinding to be effectively cleaved by MMP-9. With these criteria in mind, we synthesized a series of lipopeptide conjugates and investigated their physicochemical properties.

Although the natural substrate for MMP-9 is the type IV collagen (which is cleaved between Gly^{439}−Val^{440} bond), the enzyme exhibits overlapping substrate specificity for a variety of synthetic (collagen mimetic) peptide substrates (*27, 28*). Usually, the enzyme cleaves between **G** and **X** (where **X** = Leu, Ile, or Val) of a peptide sequence GPQ**GX**AGQR. In view of the amino acid sequence around Gly^{904} of type I collagen, as well as GPO or GPP repeats (responsible for forming the triple helical units), we synthesized the following peptides:

MMPP3_H: H_2N-G^{904}PQ**GL**A**GQ**RGIVGLOG^{919}-COOH
MMPP4_H: H_2N-G^{904}PQ**GI**A**GQ**R$(GPO)_4$GG-COOH
MMPP4_GPP: H_2N-G^{904}PQ**GL**A**GQ**R$(GPP)_4$GG-COOH
MMPP5_H: H_2N-G^{904}PQ**GL**A**GQ**R$(GPO)_4$GG-COOH
MMPP7_H: H_2N-G$(GPO)_4$**GL**A**GQ**R$(GPO)_4$GG-COOH
MMPP8 (control): H_2N-G^{904}PQ**GA**A**GQ**RGIVGLOG^{919}-COOH.

Whereas these peptides are known to be efficiently cleaved by collagenases (MMP-1, -8, and -13), they are also cleaved (albeit somewhat sluggishly) by gelatinases (MMP-2 and -9) (*28, 29*), and thus they are ideally suited for investigating the MMP-9-assisted cleavage reaction on longer time scales. We undertook the standard Fmoc-based, solid-phase synthetic protocol for synthesizing the above peptides, and subsequently purified those by the HPLC method. Of these, **MMPP8** was neither expected to be cleaved by MMP-9 (due to the lack of the cleavage site) nor had the potential to form the triple helix (due to the lack of the GPO or GPP repeats). On the other hand, although **MMPP3_H** could not form the triple helical structure (due to the lack of the GPO or GPP repeats), it contained the

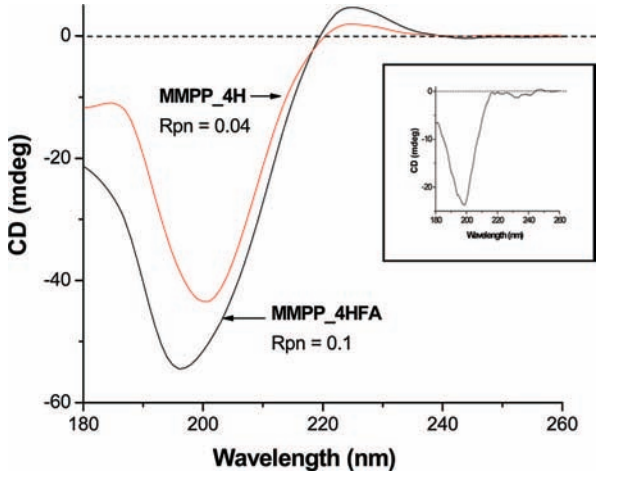

Figure 1. Circular dichroic spectra of **MMPP3_H** (inset), **MMPP4_H** and **MMPP4_HFA** in 10 mM phosphate buffer, pH = 4.0 at 4 °C. The concentration of each peptide/lipopeptide was 1 mg/mL. The solutions were stored at 4 °C for 12 h before recording the spectra.

cleavage site for MMP-9. The GPP repeats in **MMPP4_GPP** and the presence of the GPO repeats on both sides of the cleavable sequence in **MMPP7_H** were utilized to ascertain their potentials to form the triple helices, as well as the feasibility of unwinding during the MMP-9-dependent cleavage reaction. The N-termini of all these peptides were conjugated with stearic acids using the HBTU/HOBt coupling agents. The corresponding lipopeptides (identified by the suffix "**FA**", to denote the fatty acid conjugation, after the name of the parent peptides) were subjected to final purification by HPLC, followed by their characterizations by CD and mass spectroscopy.

Figure 1 shows the representative CD spectra of **MMPP3_H, MMPP4_H** and its fatty acid conjugate **MMPP4_HFA**. Note that all these peptides are characterized by negative elliptical bands at 196–200 nm and positive elliptical bands at 220–223 nm regions. However, the latter band is miniscule (or nonexistent) in the case of **MMPP3_H** (Figure 1, inset), suggesting the lack of the triple helical structure in its sequence. This was not unexpected, since it contained neither the GPO nor GPP repeat units. In contrast, both **MMPP4_H** and **MMPP4_HFA** exhibited pronounced ellipticities in the 220–223 nm regions, suggesting their ordered helical structures (Figure 1). The ratio of θ_{198} to θ_{225} (referred to as the Rpn value) (*29*) for **MMPP4_H** and **MMPP4_HFA** was found to be equal to 0.04 and 0.1, respectively. Given that the Rpn value of naturally occurring "collagen" is equal to 0.13 (*30*), it appears evident that the addition of a fatty acid chain to **MMPP4_H** (forming **MMPP4_HFA**) considerably enhances the magnitude of the triple helicity in the above peptide.

We recorded the spectra of all the synthetic peptides and their fatty acid conjugates (Supporting Information) and calculated their Rpn values (Table 1). The data of Table 1 reveal that the magnitude of the triple helicity of all peptides containing GPO (and to a lesser extent containing GPP) repeats increases upon converting them to their fatty acid derivatives. As expected, the control peptide **MMPP8** did not show any evidence of the triple helical structure. These data are consistent with the previous studies of Fields and his collaborators on the alkyl group assisted formation of the triple helical structures in collagen-mimetic peptides (*24*).

To determine the stability of our synthetic collagen-mimetic peptides, we subjected them to thermal denaturation. We incubated each peptide at different temperatures for 15 min and then recorded their CD spectra. Figure 2 shows a representative set of CD spectra of **MMPP4_H** (Figure 2A) and **MMPP4_HFA** (Figure 2B) as a function of temperature. The

Table 1. Rpn Values and Melting Temperatures (T_m) of Synthetic Peptides and Lipopeptides

peptides/ lipopeptides	Rpn	T_m (°C)
MMPP3_H	-	-
MMPP3_HFA	-	-

MMPP7_HFA	0.08	55
MMPP8	-	-
MMPP8_FA	-	-

temperature-dependent spectral data of both these peptides exhibit a decrease in the magnitude of the negative and positive elliptical peaks, with isosbestic points at 210 and 213 nm, respectively. This feature is consistent with a one-step transition between triple helices and their monomeric forms. The insets of Figure 2 show the positive elliptical peaks at 225 nm as a function of temperature.

The solid lines are the best fits of the data according to the conventional equation (*24*) for determining the T_m value from the temperature-dependent spectral changes. As apparent from the data of Figure 2A (inset), the T_m value of **MMPP4_H** is not easily resolvable, and its magnitude appears to be smaller than 57 °C for **MMPP4_HFA** peptide (Figure 2B, inset). Hence, besides enhancing the extent of triple helicity, the fatty acid conjugation with **MMPP4_H** increases its stability. Identical experiments were performed with other synthetic collagen-mimetic peptides and their fatty acid conjugates (Supporting Information). It should be mentioned that, although the thermal transition of most of the peptides/lipopeptides conformed to the single isosbestic point, **MMPP4_GPPFA** exhibited at least two isosbestic points (Supporting Information). The origin of the latter features is not clear at this point. A cumulative account of the spectral and thermal transition data of Figures 1 and 2 for all peptides and lipopeptides is presented in Table 1. An inspection of spectral and thermodynamic parameters of different peptides/lipopeptides revealed that **MMPP4_HFA** would be the best-suited lipopeptide for formulating liposomes and investigating their uncorking by MMP-9. Hence, all subsequent experiments were performed with **MMPP4_H** and **MMPP4_HFA** pair. Since the cleavage and the liposomal leakage studies are performed at pH = 8.0, we recorded the CD spectrum of the lipopeptide **MMPP4_HFA** at that pH. The CD spectrum indicated that **MMPP4_HFA** retains its triple helical conformation at pH = 8.0 (Rpn = 0.12) with a melting temperature of 42 °C (Figure S3, Supporting Information).

To determine whether or not **MMPP4_H** and **MMPP4_HFA** would be efficiently cleaved by MMP-9, we incubated individual peptides (5 μM) with 5 nM MMP-9 in 25 mM HEPES buffer, pH = 8.0. At different time intervals, 50 μL aliquots were withdrawn and transferred to a vial containing 2 μL of trifluoroacetic acid (TFA). The latter was used to denature the enzyme and stop further cleavage of the peptides. The aliquots collected at different time intervals were subjected to the HPLC analysis using a C_{18} Vydac analytical column and monitoring the elution profile at 214 nm. Figure 3A,B shows the time course of the HPLC profiles for the cleavage of **MMPP4_H** and **MMPP4_HFA**, respectively, by MMP-9. From the HPLC profiles of Figure 3A, it is evident that, at zero time, **MMPP4_H** elutes as a single (nearly symmetrical) peak at 15 min. Upon cleavage for 5 min, the above peak diminishes, and a new peak emerges (due to the formation of one of the cleaved products exhibiting high absorption at 214 nm) at 13 min. The absence

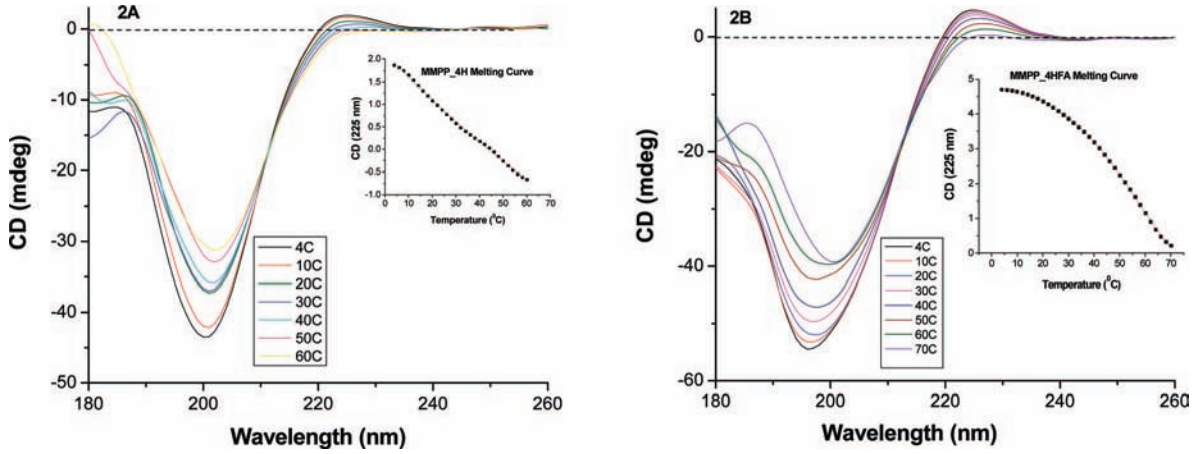

Figure 2. Temperature-dependent CD spectra for **MMPP4_H** (A) and **MMPP4_HFA** (B) are shown. The insets show the melting curves obtained by plotting the peak intensities at 225 nm as a function of temperature. The solid lines in the insets are the fitted curves. The experimental conditions are the same as those of Figure 1.

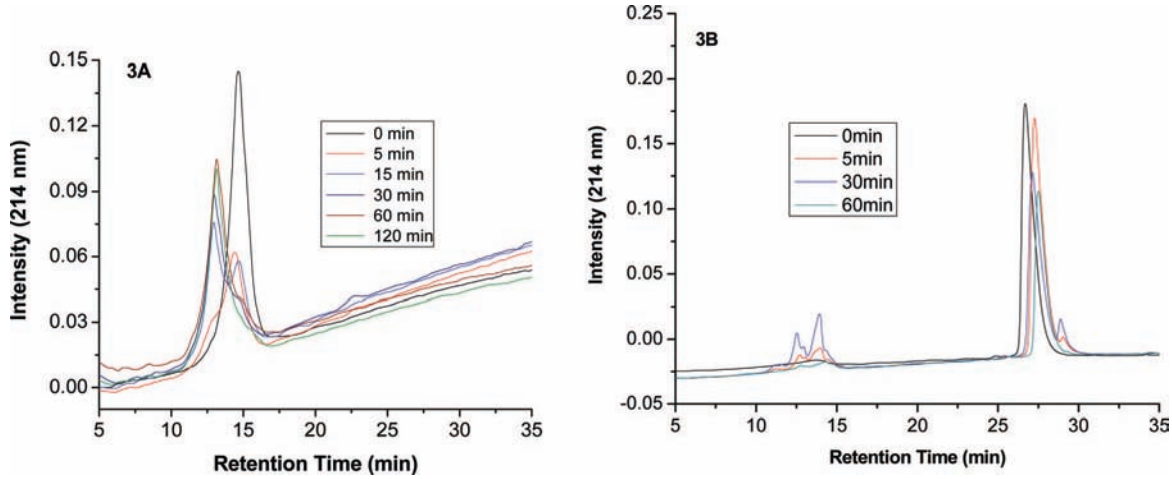

Figure 3. HPLC elution profiles for the cleavage of **MMPP4_H** (A) and **MMPP4_HFA** (B). The cleavage reactions were performed using 5 μM peptide/lipopeptide and 5 nM MMP-9 in 25 mM HEPES buffer, pH = 8.0, 25 °C.

of the second peak (expected to be formed upon treatment with MMP-9) on the HPLC profile is presumably due to its shorter chain length, showing low absorption at 214 nm. As the time of cleavage reaction progresses, the peak at 15 min decreases in magnitude and the peak at 13 min increases. This pattern is suggestive of the MMP-9-assisted cleavage of the peptides. Due to the presence of fatty acid chain in **MMPP4_HFA**, the HPLC cleavage peaks were significantly separated, with reactant and products eluting at 27 and 14 min, respectively.

As observed for the cleavage of **MMPP4_H**, the diminution of the reactant HPLC peak at 27 min proceeded concomitant with the increase in the product peak at 14 min. Qualitatively, it appeared that the **MMPP4_H** was being cleaved about 4-fold more efficiently than its fatty acid conjugate, **MMPP4_HFA**, by the same amount of MMP-9. Given that the magnitude of triple helicity is more pronounced with **MMPP4_HFA** (Rpn = 0.1) compared to **MMPP4_H** (0.04), it is tempting to speculate that the MMP-9-assisted cleavage of the collagen-mimetic peptide requires unwinding of the triple helix. Such a mechanistic feature was also envisaged by Fields (*31*).

As a hindsight control, we probed whether or not a general proteolytic enzyme, such as trypsin, can cleave either **MMPP4_H** or **MMPP4_HFA** or both. Trypsin was chosen because the above peptides contained the Arg-Gly peptide bond, which is recognized and cleaved by the enzyme. We observed that, whereas trypsin could efficiently cleave the above bond in the case of **MMPP4_H** peptide, it failed to cleave the same bond in **MMPP4_HFA** lipopeptide (at least up to 2 h of incubation; data not shown). Clearly, the trypsin cleavable bond is not accessible to the enzyme in the triple helical conformation of the lipopeptide.

Having established the cleavage of the collagen-mimetic triple helical **MMPP4_HFA** by MMP-9, we proceeded to formulate liposomes using the above lipopeptide as minor components (30 mol %) and 1-palmotoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) as the major component (70 mol %). While preparing liposomes, a self-quenching fluorescent dye (carboxyfluorescein) was encapsulated (*32*). The free dye was separated from the liposome-encapsulated by the Sephadex G-75 gel filtration column chromatography. The dye-encapsulated liposomes thus prepared showed a fairly uniform distribution of their size on TEM, and their average diameter can be determined as being equal to 50 nm (Supporting Information).

The fluorescence emission intensity of liposome encapsulated carboxyfluorescein (λ_{ex} = 480 nm, λ_{em} = 518 nm) remains quenched (due to the local concentration effect) until it is released to the surrounding medium (*32*). This feature serves as a prototype for monitoring the release of the liposomal content under different experimental conditions. We determined the influence of MMP-9 on cleavage of the **MMPP4_HFA** lipopeptide incorporated in the liposomes, and their subsequent destabilization and release of the entrapped carboxyfluorescein. During these experiments, we incubated 2 mL solution of liposomes (100 μg lipids) with 1 μM MMP-9 in 25 mM HEPES

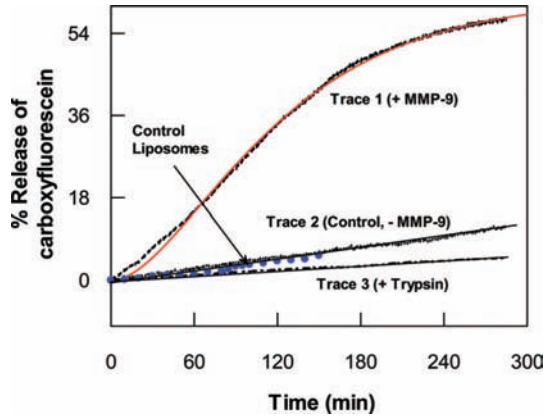

Figure 4. Time courses of release of carboxyfluorescein from liposomes under different conditions. Trace 1: in the presence of 1 μM MMP-9; the solid smooth red line is the best fit of the data according to eq 2 with k_1 and k_2 values of 0.018 and 0.014 min^{-1}, respectively. Trace 2: in the absence of MMP-9 (control). Trace 3: in the presence of 1 μM trypsin. The blue circles indicate the release profile from control liposomes (formulated without **MMPP4_HFA**) in the presence of 1 μM MMP-9. The solid lines of traces 2 and 3 are linear regression analyses of the data.

buffer, pH = 8.0, containing 10 mM $CaCl_2$, and monitored the time course of the increase in the fluorescence emission intensity at 518 nm (λ_{ex} = 480). Figure 4, trace 1, shows the time-dependent profile for the release of carboxyfluorescein under the above experimental condition. To ensure that the release of carboxyfluorescein from liposome was due to the cleavage of the collagen-mimetic lipopeptide, we performed a control experiment exactly under the above condition, but without MMP-9 (Figure 4, trace 2). Note that the time-dependent release of the dye in the absence of MMP-9 (trace 2) is far less pronounced than that observed in the presence of the enzyme (trace 1). To calculate the percent release of the dye during the above experiments, the liposomes were completely disrupted with a 5% aqueous solution of a detergent, Triton-X, and the total increase in fluorescence was determined (taken as a measure of 100% release of the dye from the liposomes). Given these data, we propose that, due to cleavage of the surface-exposed collagen-mimetic triple helical peptide by MMP-9, the lipid domains of the liposomes are destabilized, resulting in the release of the encapsulated fluorescent dye. The overall process is cumulatively referred to as the liposomal "uncorking". If the liposomes do not contain any **MMPP4_HFA**, the enzyme MMP-9 does not release the dye to any significant extent (Figure 4, blue circles).

We already demonstrated that, despite the presence of the trypsin cleavage site in **MMPP4_HFA**, the enzyme does not cleave the latter lipopeptide. If this property remained unchanged upon incorporation of **MMPP4_HFA** into liposomes, trypsin would not be able to "uncork" the liposomes. This expectation was clearly substantiated when we incubated the **MMPP4_HFA**-containing liposomes with 1 μM trypsin, precisely under the experimental conditions of trace 1 of Figure 4. As shown by trace 3 of Figure 4, the time course of leakage of the fluorescent dye matches that of the control experiment (performed in the absence of any enzyme), and it is significantly slower than that observed in the presence of MMP-9 (trace 1, Figure 4). As an additional control, we prepared the liposomes incorporating the stearic acid conjugate of the peptide **MMPP8** (i.e., **MMPP8_FA**) encapsulating carboxyfluorescein. In the presence of MMP-9 (1 μM), these liposomes showed a release profile very similar to trace 3 in Figure 4 (data not shown). The lipopeptide **MMPP8_FA** does not contain the cleavage site for the enzyme MMP-9; hence, it is not surprising that MMP-9 does not release the encapsulated dye from the liposomes incorporating the lipopeptide **MMPP8_FA**.

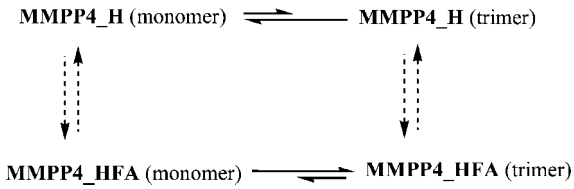
One apparent feature of the MMP-9-assisted uncorking of liposomes is the presence of a lag phase. A simple mechanistic explanation for the prevalence of such a lag phase is the involvement of at least one intermediary step during the overall uncorking process. However, even if one or multiple intermediary steps predominate during the course of liposome uncorking, the observed signal is given only by the carboxyfluorescein release step. For example, if the above liposome is cleaved by MMP-9, but its content is not released until the lipid domains are reorganized, the overall kinetic profile would involve a finite lag phase similar to that observed in Figure 4. Assuming that the MMP-9-assisted uncorking adhered to a two-step process, we analyzed the kinetic profile of Figure 4 (trace 1) by a two-step mechanism (see Discussion). The solid smooth (red) line is the best fit of the data for the k_1 and k_2 values of 0.018 $\pm$ 0.0034 and 0.014 $\pm$ 0.0016 min^{-1}, respectively. However, it should be noted that the fitted line does not precisely correspond to the experimental data (broken black line, trace 1). Clearly, the overall uncorking process is more complex than that explainable in light of the two-step mechanism (see Discussion).

DISCUSSION

The formulation of MMP-9-cleavable liposomes required synthesis of collagen-mimetic peptides, which could provide the cleavage sites for the enzyme. Of the different lipopeptides (synthesized on the basis of the amino acid sequences present around the cleavable site of type I collagen), **MMPP4_HFA** was found to be the best-suited for formulating such liposomes. The other lipopeptides either did not form adequate triple helical structures, comparable to those found in the natural collagen (e.g., **MMPP3_HFA**, **MMPP4_GPPFA**, **MMPP8_HFA**), or they formed triple helices that were too compact as evidenced by their high T_m values (e.g., **MMPP5_HFA)**, cleaved somewhat sluggishly by MMP-9 (**MMPP7_HFA)**, or cleaved non-specifically, such as by trypsin (**MMPP7_HFA**). It should be mentioned that, although **MMPP4_H** contained the trypsin-cleavage site (and it was cleaved by the enzyme in its native/unconjugated state), its stearic acid derivative (i.e., **MMPP4_HFA**) was not cleaved by trypsin. Clearly, the trypsin cleavage site of the original (monomeric) peptide (**MMPP4_H**) is masked upon formation of the triple helical structure in **MMPP4_HFA**. Whether or not the oligomerization of polypeptide units in triple helical peptides incorporates selectivity for matrix metalloproteinases, and obviates their cleavage by general proteases (e.g., trypsin, chymotrypsin, etc.), remains to be investigated. However, our experimental data provide clues as to why cellular matrices are constituted of fibrillar proteins, and they are specifically cleaved by matrix metalloproteinases.

The fact that a small segment of collagen-mimetic peptide (e.g., **MMPP3_H**) is devoid of the triple helical structure, whereas the native collagen is predominantly triple helical in nature, implies that the origin of the triple helicity lies in the cooperative interaction among the extended polypeptide chains. The latter feature is augmented by the presence of the GPO and GPP repeats in the polypeptide chains. The cooperative interaction among "shorter" chain containing peptides appears to be significantly enhanced upon attachment of C_{18} hydrophobic tail at the N-terminal end (*24*). This is apparent from the data of Figure 1; the Rpn value of **MMPP4_H** is increased from 0.04 to 0.1 upon conjugation with stearic acid. The question arises whether the Rpn value of 0.04 in **MMPP4_H** is simply due to its preponderance in the form of polyproline II helix (*33*) or its ability to form a partial triple helical structure. In attempting to answer this question, we realized that the peptide containing the GPP (instead of GPO) repeats (viz.,

Scheme 1. Proposed Thermodynamic Model of the Monomer−Trimer Equilibria of MMPP4_HFA Lipopeptide



MMPP4_HGPP) does not contain any discernible positive elliptical peak at 225 nm. Since the presence of the GPO repeats in the peptide sequence facilitates the formation of the triple helical structure, it follows that **MMPP4_H** exists in an equilibrium mixture of the monomeric and trimeric (i.e., triple helical) forms. This equilibrium is favored toward the trimeric form upon conjugation with the stearic acid as depicted by the model of Scheme 1.

Consistent with the model of Scheme 1, the temperature-dependent CD spectra of **MMPP4_H** and **MMPP4_HFA** (Figure 2) conform to single isosbestic points. As the temperature increases, the magnitude of elipticity at both 195 and 225 nm decreases, albeit by different amounts. This feature results in a continuous diminution in the Rpn value as a function of increasing temperature, presumably because of the conversion of the triple helical form (trimer) form of **MMPP4_HFA** to the monomeric form.

The observation that **MMPP4_H** appears to be more efficiently cleaved by MMP-9 than **MMPP4_HFA** implies that the conjugation of stearic acid impairs the catalytic activity of the enzyme. We believe the origin of the above disparity lies in the preference of MMP-9 to cleave the monomeric rather than triple helical peptides. This is consistent with the postulate that MMP-9 unwinds the triple helical peptides prior to cleaving them (*31*). Given this, we surmise that the sluggish rate of cleavage of **MMPP4_HFA** (*vis a vis* **MMPP4_H**) by MMP-9 is due to the rate-limiting unwinding of the triple helical peptide to its monomeric form. The question arises as to why the triple helical form of the peptide is not unwound to produce the monomeric unit prior to their cleavage by trypsin. The most plausible answer to this question is that the unwinding of the triple helix requires assistance from specialized proteases, such as MMP-9 (which contain noncatalytic fibronectin domain), and such functions are not accomplished by general proteases such as trypsin.

A marked success in our overall endeavor has been the demonstration that the lipopeptide, **MMPP4_HFA**, could be easily incorporated in the liposomes, and the latter are selectively "uncorked" by MMP-9 but not by trypsin. On the basis of the literature (*32*), it is expected that the C_{16}-hydrocarbon moiety of the lipopeptide **MMPP4_HFA** will be embedded in the lipid bilayer of the liposomes. The triple helical peptide portion of the molecules will protrude outside the lipid bilayer. The amino acids GPQ may act as a spacer, making the MMP-9 cleavage site of the peptide accessible to the enzyme. Since the cleavage of the triple helical peptides destabilizes the lipid domains, their contents are released.

Due to ease in performing the liposomal uncorking experiments, we chose a self-quenching fluorescent dye, carboxyfluorescein. As long as the dye remains confined inside the liposomal lumen, its fluorescence remains quenched (*33*). As soon as the dye leaks out from the liposomes, its fluorescence starts increasing. The time course of the increase in fluorescence emission intensity at 518 (Figure 4) is the sum of a sequence of microscopic events associated with the overall uncorking process. Hence, it is not surprising that the overall kinetic profile is complex (Figure 4, trace 1). However, since the kinetics of increase in the fluorescence intensity involved a finite lag phase, and the signal of measurement came from the release of carboxyfluorescein to the exterior environment, a minimal two-step model of uncorking was envisaged (eq 1).

$$\mathrm{L-F} \xrightarrow{k_1} \mathrm{L*F} \xrightarrow{k_2} \mathrm{L*} + \mathrm{F} \qquad (1)$$

Where L and F represent liposomes and carboxyfluorescein, respectively. The first step involves the cleavage and destabilization of the liposomes. The intermediary species L*−F is representative of the cleaved liposomes, but fluorescence dye still remains confined in the liposomal lumen. The second step is release of the fluorescence dye with concomitant increase in the fluorescence emission intensity at 518 nm. For this two irreversible step model, the time course of formation of F can be given by eq 2 (*34*).

$$\mathrm{F} = [\mathrm{L-F}]\left[1 + \left(\frac{1}{k_1 - k_2}\right)\left(k_2 e^{-kt} - k_2 e^{-kt}\right)\right] \qquad (2)$$

The solid, smooth line of trace 1 (Figure 4) is the best fit of the data according to eq 2, with k_1 and k_2 being equal to 0.018 ± 0.0034 min^{-1} and 0.014 ± 0.0016 min^{-1}, respectively. However, since the fitted line (red) somewhat deviates from the experimental data (broken black lines), it appears that the sequence of events of the MMP-9-assisted uncorking is more complex than that conceivable in light of the two-step model. This is not unexpected, since even after the cleavage of the triple helical peptides, a series of microscopic steps may intervene prior to the onset of the final step of the dye release. The lipopeptide **MMPP4_HFA** contains one fatty acid, and this may not form tight domain boundaries with the major lipid of the liposomes, POPC (*35*). The 10% release of the dye in the absence of MMP-9 (Figure 4, trace 2) may arise from these domain boundaries.

We have observed that, in buffer solutions (pH = 8.0), the recombinant MMP-9 self-hydrolyzes and inactivates itself within 3 h. This self-hydrolysis is one of the possible reasons for not releasing all of the liposomal contents. In order to test this hypothesis, we repeated the liposomal release experiments under the conditions as described previously. We observed that the rate of release of the encapsulated carboxyfluorescein decreases considerably after 130 min (54% release, as indicated in Figure 4). However, the addition of a second aliquot of MMP-9 (10 μL of 200 μM solution) restarted the release of carboxyfluorescein from the liposomes. Cumulatively, 94% of the encapsulated dye was released in 6 h (Figure 5). We are currently in the process of fine-tuning the molecular mechanism of liposomal uncorking and its content release, and we will report on these findings subsequently.

In conclusion, we have provided the first detailed studies on the formulation of liposomes, which harbor the MMP-9-cleavable collagen-mimetic peptides on their surface. The cleavage of the above peptides by MMP-9 results in destabilization of the lipid domains of the liposomes, leading to the release of their encapsulated contents (referred to as "uncorking"). Since MMP-9 is invariably expressed in most of the cancerous tissues, our liposomal formulation will find unique application as a drug delivery vehicle not only for inhibiting MMP-9, but for all other pathogenic enzymes/proteins which are expressed at the target sites. When liposomes will be encapsulated with an MMP-9-specific inhibitor, the triple helical peptides will serve as the "bait" for the enzyme, and the enzyme will essentially "commit suicide" once it "uncorks" the liposomes and releases its own inhibitor. Once the enzyme is inhibited, it will lose its potency to further uncork the liposomes. In this way, our overall approach has the potential to serve as a "self-adjusting" drug delivery system, where the amount of drug released will be

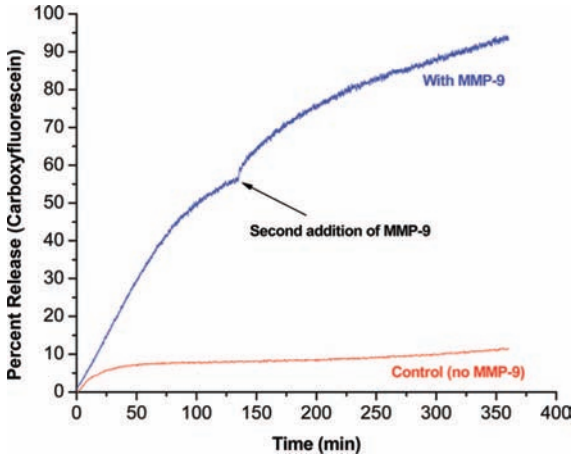


Figure 5. The increase in the fluorescence intensity due to the release of the liposome-encapsulated dye (carboxyfluorescein) is shown (λ_{ex} = 480 nm, λ_{em} = 518 nm) in the presence of the recombinant human MMP-9 (blue trace, 1 μM enzyme, 25 mM HEPES buffer, pH = 8.0, 20 °C) and in the absence of the enzyme (red trace). A second aliquot of MMP-9 was added after 150 min. In the presence of MMP-9, 94% encapsulated carboxyfluorescein was released in 6 h.

dictated by the amount of the catalytically active enzyme present in its resident environment. On the other hand, if the liposomes are encapsulated with fluorescent or magnetic resonance contrast agents, the triggered release of their contents will find usage in imaging the diseased tissues (expressing MMP-9). Both these features of our uniquely designed liposomes are of prime importance in diagnosis and treatment of a wide variety of cancers in human patients.

2′-Anthraquinone-Conjugated Oligonucleotide as an Electrochemical Probe for DNA Mismatch

Satoshi Kumamoto, Mariko Watanabe, Naoko Kawakami, Mitsunobu Nakamura, and Kazushige Yamana*

Department of Materials Science and Chemistry, Graduate School of Engineering, University of Hyogo, 2167 Shosha, Himeji, Hyogo 671-2201, Japan. Received March 19, 2007; Revised Manuscript Received September 26, 2007

We previously prepared the oligonucleotides (ODNs) conjugated to an anthraquinone (AQ) group via one carbon linker at the 2′-sugar position. When these modified ODNs bind to cDNA sequences, the AQ moiety can be intercalated into the predetermined base-pair pocket of a duplex DNA. In this paper, 2′-AQ-modified ODNs are shown to be an excellent electrochemical probe to clarify the effect of a mismatch base on the charge transfer (CT) though DNA. Two types of DNA-modified electrodes were constructed by assembly of disulfide-terminated 2′-AQ-ODN duplexes onto gold electrodes. One type of electrodes (system I) contains fully matched base pairs or a single-base mismatch in duplex DNA between the redox center and the electrode. The other (system II) consists of the mismatch but at the outside of the redox center. The modified electrodes were analyzed by cyclic voltammetry to estimate the CT rate through duplex DNA. In system I, the CT rate was found to be $\sim 50\ s^{-1}$ for the fully matched AQ-ODN duplexes, while the CT rates of the mismatched DNA were considerably slower than that of the fully matched DNA. In system II, the AQ-ODN duplexes showed almost similar CT rates ($\sim 50\ s^{-1}$) for the fully matched DNA and for the mismatched DNAs. The detection of a single-base mismatch was then performed by chronocoulometry (CC). All the DNA duplexes containing a mismatch base in system I gave the reduced electrochemical responses when compared to the fully matched DNA. In particular, the mismatched DNAs including G−A mismatch can be differentiated from fully matched DNA without using any electrochemical catalyst. We further tested the usefulness of single-stranded (ss) AQ-ODN immobilized on a gold electrode in the electrochemical detection of a single-base mismatch through hybridization assay. The ss-AQ-ODN electrodes were immersed in target-containing buffer at room temperature, and the CC measurements were carried out to see the changes in the integrated charge. Within 60 min, the mismatched DNA was clearly distinguishable by the CC differences from the fully matched target. Thus, the electrochemical hybridization assay provides an easy and convenient detection for DNA mutation that does not require any extra reagents, catalyst, target labeling, and washing steps.

INTRODUCTION

The DNA sequence variation among individuals is of interest because it provides the basis of heritable variation in disease susceptibility (*1*). The most common type of human genetic variation is the single-nucleotide polymorphisms (SNPs), which can serve as genetic markers for identification of disease genes. Ongoing challenges are being directed toward the discovery of functional SNPs that are associated with susceptibility of certain disease (*2–4*). SNP genotyping will thus play an important role in future diagnostics. The development of simple and accurate methods for SNP assay is the current subject of intense research.

Electrochemical methods for SNP genotyping are attractive because of their rapid electrochemical transduction, sensitive detection, and ease of fabrication of microdevices. Several methods for electrochemical detection of DNA mutation have been reported, each of which has specific advantages. One approach is based on the electrochemical transduction of the hybridization event using exogenous redox-active reporters having preferential affinity for duplex DNA (*5*). The other approach is the so-called sandwich assay by the use of redox-labeled oligonucleotide probes that bind to target DNA sequence (*6–8*). Although these approaches are straightforward, they usually suffers from several problems such as background signal due to nonspecific binding of redox reporters, hybridization error, and difficulties in the design of probe sequences. Another possible approach, first reported by Barton et al., is the method that relied on long-range charge transport (CT) though DNA (*9–14*). The efficiency of CT though DNA is significantly decreased when any perturbation of base-pair stacking such as due to a mismatched base occurs within DNA. The presence of a single-base mismatch in DNA can be determined from the reduced charge transferability compared with fully matched DNA. While the CT-based assays do not require any stringent washing steps, they need a densely packed DNA array, a specific redox-active intercalator, and an electrocatalyst.

The design of oligonucleotide probes covalently attached to a redox reporter has been an important subject to develop a practical electrochemical method for mutation detection based on a CT-based approach (*12–14*). As a part of our research efforts to develop an electrochemical assay of SNPs, we focused on an anthraquinone derivative that is site-specifically incorporated into DNA oligonucleotides. We previously prepared the oligonucleotides conjugated to an anthraquinone group via one carbon linker at the 2′-sugar position (*15, 16*). When these modified oligonucleotides bind to cDNA sequences, the anthraquinone moiety can be intercalated into the predetermined base-pair pocket of a duplex DNA (*16–20*). In this paper, we demonstrate that 2′-anthraquinone-modified oligonucleotides are indeed an excellent probe to measure long-range charge transfer through duplex DNA. With this measurement, mismatch-containing DNA can be distinguished by the reduced charge transferability from fully matched DNA. Unlike other mismatch

detections based on CT through DNA (*9–11*), our method does not require any exogeneous reagents and catalyst. When compared to the method using ferrocene-modified oligonucleotide probes (*13*), the design and fabrication of our anthraquinone-modified DNA bound electrodes are relatively simple and easy. The assay format solely involves conventional electrochemical measurements, which is in contrast to the photoelectrochemical assay (*14*). Our approach therefore provides easy and convenient detection of DNA mutation.

EXPERIMENTAL PROCEDURES

Materials. Deoxyribonucleoside phosphoramidites and 1-*O*-dimethoxytritylpropyl disulfide-modified CPG were purchased from Transgenomics and Glen Research Inc., respectively. 2′-Anthraquinone-modified uridine phopshoramidite was prepared according to a reported procedure (*16*). 2′-Anthraquinone-modified oligonucleotides containing a disulfide anchor at the 3′-teminus and other oligonucleotides were synthesized on an ABI 394 DNA/RNA synthesizer, purified using reversed-phase HPLC, and characterized as described (*16*). Au[111] surfaces on glass slides were prepared by Osaka Vacuum Chemical (Osaka, Japan) by the vapor deposition method.

Double-Stranded DNA Bound Electrodes. Before DNA modification, the Au surface was soaked at room temperature in piranha solution (H_2O_2/H_2SO_4 = 1:3, v/v) for 15 min × 2, washed with deionized water, and dried with a blow of nitrogen gas. The clean Au−glass was attached to a window (geometrical area: 0.36 cm^2) of a glassware cell that is designed for electrochemical measurements. 2′-Anthraquinone-modified oligonucleotide containing a disulfide anchor at the 3′-teminus was mixed with cDNA to form a duplex and then used for DNA modification. The modification was performed by immersion of the Au electrode (0.36 cm^2) in 0.1 mM DNA (50 μL) in 0.1 M NaCl, 0.01 M sodium phosphate, and 0.01 M $MgCl_2$ (pH 7) at room temperature for 12 h. The modified surface was then exposed to 100 μL of 2.5 mM mercaptopropanol in the same buffer for 2 h.

Electrochemical Measurements. Electrochemical measurements were carried out in the cell consisting of the modified Au electrode (0.36 cm^2), a Pt wire auxiliary electrode, and a Ag/AgCl reference electrode, using an electrochemical analyzer (ALS/H CHI model 612B or 630C). All cyclic voltammetry and chronocoulometry measurements were performed at room temperature in a pH 7 buffer (2 mL) containing 0.1 M NaCl and 0.01 M sodium phosphate. The buffer was thoroughly degassed with nitrogen before measurements.

Mismatch Detection via Hybridization Assays. The single-stranded (ss) 2′-anthraquinone-modified oligonucleotide containing a disulfide anchor at the 3′-teminus was assembled on the Au electrode, and the remaining Au surface was covered with mercaptopropanol in a similar way as described for double-stranded DNA modification. The charge (I_{ss}) required for the reduction of the ss anthraquinone−DNA probe during the integration time (5 s) was first recorded in the phosphate buffer by chronocoulometry (CC). Target DNA (4 nM) was then poured into the buffer, and the same CC measurements were performed at the defined time intervals to obtain the charge after hybridization (I_{hb}). The % changes in charge responses are defined as $[(I_{hb} - I_{ss})/I_{ss}] \times 100$. All CC measurements started at an applied voltage of −100 mV vs Ag/AgCl, and then the potential was changed to −600 mV vs Ag/AgCl and held at the defined time period.

RESULTS AND DISCUSSION

Double-Stranded 2′-Anthraquinone-Modified DNA Bound Electrodes. In our electrochemical study of charge transfer (CT) through DNA, 2′-anthraquinone-modified oligonucleotides containing a disulfide anchor at the 3′-teminus were prepared using an anthraquinone-modified nucleoside phosphoramidite (*16*) and a solid support linked to a hydroxypropyl disulfide. The duplexes of disulfide-containing anthraquinone−oligomers with appropriate DNA sequences were assembled on gold electrode surfaces by a usual method (*20*). To clarify the effect of a mismatch base on the CT through DNA, two types of DNA-modified electrodes were constructed as shown in Figure 1. One type of electrode contains fully matched base pairs or a single-base mismatch in duplex DNA between the redox center and the electrode (system I, AQ-ODN Duplex 1–3). The other consists of the mismatch but at the outside of the redox center (system II, AQ-ODN Duplex 4).

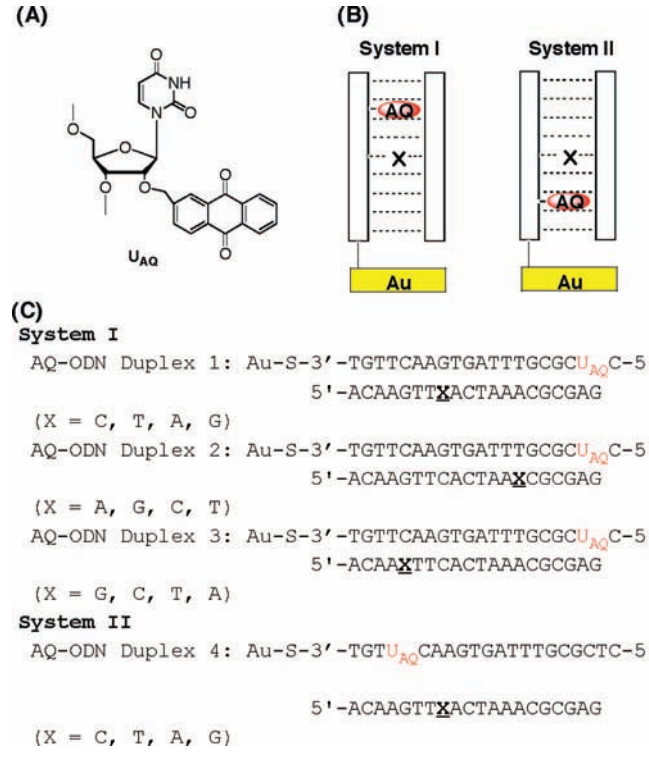

Figure 1. (A) 2′-Anthraquinone-modified uridine (U_{AQ}). (B) Double-stranded anthraquinone-modified oligonucleotide bound electrodes. Electrodes of system I contain fully matched base pairs or a single-base mismatch in duplex DNA between the redox center and the electrode. The others (system II) consist of the same mismatch but at the outside of the redox center. (C) Sequences of anthraquinone-modified oligonucleotides and their target DNAs in systems I and II.

Electrochemical Characterization of DNA-Modified Electrodes. The modified electrodes were characterized by cyclic voltammetry (CV). The typical CV curves (AQ-ODN Duplex 1; X = C; and AQ-ODN Duplex 4; X = C) are shown in Figure 2. Reversible waves associated with the reduction and oxidation of the pendant anthraquinone group were obtained with $E_{1/2}$ of −0.44 ∼ −0.42 V vs Ag/AgCl and are very similar to that of an unmodified anthraquinone molecule in the shape of the CV responses. As the CV scan rates were increased, both the anodic and cathodic peak currents were intensified. The plots of the peak current vs CV scan rate (Figure 2, inset) are linear, confirming that the observed CVs are derived from the surface-confined redox molecule. Similarly, the mismatch-containing DNAs showed the scan rate dependence of the CV peak current (Supporting Information). The CV responses of the DNA-modified electrodes against $Fe(CN)_6^{3-}$ were decreased when compared with the bare Au electrode, being consistent with the DNA monolayer on the gold surface. The surface coverage of the anthraquinone−DNA duplexes were determined by the

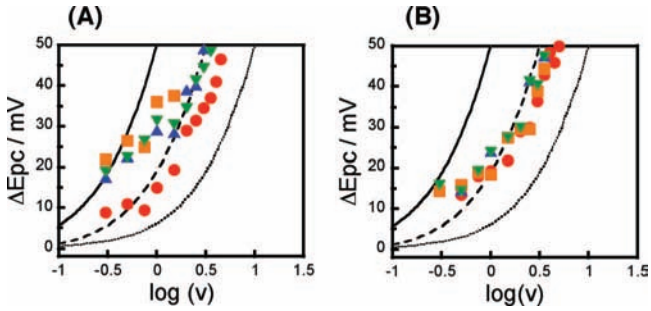

Figure 3. Plots of the peak splitting ΔE_{pc} ($=E_{pc} - E^0$) vs log(υ), where υ = scan rate. Panel A: red, AQ-ODN Duplex 1, X = C; green, AQ-ODN Duplex 1, X = T; blue, AQ-ODN Duplex 1, X = A; orange, AQ-ODN Duplex 1, X = G. Panel B: red, AQ-ODN Duplex 4, X = G; green, AQ-ODN Duplex 4, X = C; blue, AQ-ODN Duplex 4, X = T; orange, AQ-ODN Duplex 4, X = A. Simulation curves for electron transfer rates of 10 s^{-1} (solid lines), 50 s^{-1} (broken line), and 100 s^{-1} (dotted line) are indicated for comparison.

ruthenium hexamine assay (*21*) to be 2 ∼ 3 pmol/cm^2, which indicates that the duplex DNAs were not densely packed. It is noted that the DNA duplexes should adopt upright orientation along the electrode surface at the applied CV potentials (−100 ∼ −800 mV vs Ag/AgCl) because of the electrostatic repulsion of the DNA polyanion (*22*).

Effect of Mismatch Bases on Charge-Transfer Rate through DNA. The CV data were analyzed to estimate the electron transfer (CT) rate through DNA (*9, 23*). Figure 3 shows the plots of the peak splitting ΔE_{pc} ($=E_{pc} - E^0$) versus log(υ) (where υ = scan rate). Comparison of the experimental data with the simulated curves gave a CT rate that is estimated to be ∼50 s^{-1} for the fully matched AQ-ODN Duplex 1 of system I. The ΔE_{pc} for the mismatched DNA duplexes (AQ-ODN Duplex 1; X = T, A, G) became wider at the CV scan rates <1 V/s than those for the fully matched DNA and significantly deviated from the simulated curves. These observations indicate that the CT rates of the mismatched DNA are considerably slower than that of the fully matched DNA. In contrast, the AQ-ODN duplexes (AQ-ODN Duplex 4 of system II) containing a mismatched base at the site out of the redox center showed almost similar CT rates (∼50 s^{-1}) for the fully matched DNA and for the mismatched DNAs. It is thus clearly shown that the anthraquinone intercalator appended onto the 2′-sugar residue of DNA can be used for probing the slower CT rates through mismatch-containing DNA than fully matched DNA. Interestingly, the CT rates through the perfectly matched DNA

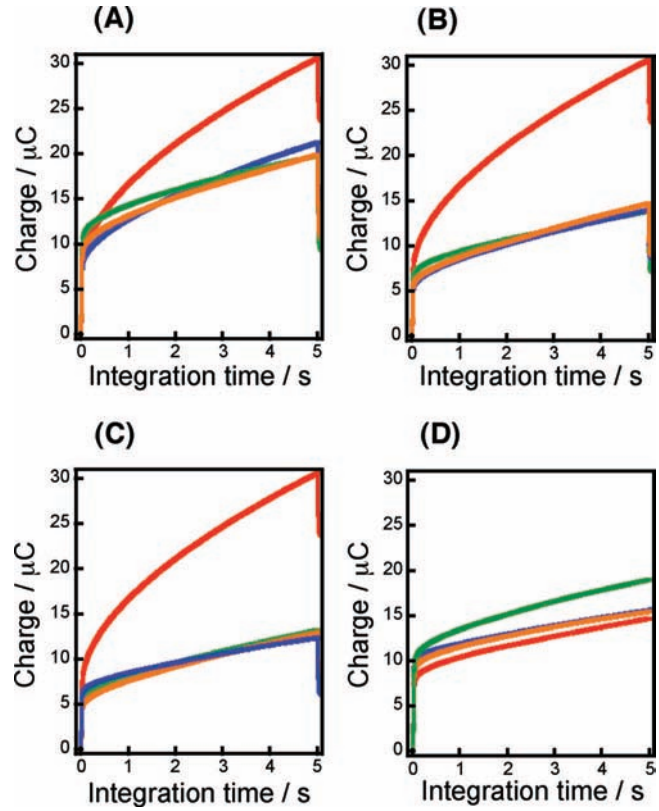

Figure 4. Charge responses for double-stranded anthraquinone-modified oligonucleoitde bound electrodes obtained from chronocoulometry. Panel A: red line, AQ-ODN Duplex 1, X = C; green line, AQ-ODN Duplex 1, X = T; blue line, AQ-ODN Duplex 1, X = A; orange line, AQ-ODN Duplex 1, X = G. Panel B: red line, AQ-ODN Duplex 2, X = A; green line, AQ-ODN Duplex 2, X = G; blue line, AQ-ODN Duplex 2, X = C; orange line, AQ-ODN Duplex 2, X = T. Panel C: red line, AQ-ODN Duplex 3, X = G; green line, AQ-ODN Duplex 3, X = C; blue line, AQ-ODN Duplex 3, X = T; orange line, AQ-ODN Duplex 3, X = A. Panel D: red line, AQ-ODN Duplex 4, X = C; green line, AQ-ODN Duplex 4, X = T; blue line, AQ-ODN Duplex 4, X = A; orange line, AQ-ODN Duplex 4, X = G. The measurements started at the initial potential of −100 mV vs Ag/AgCl. The applied potential was then changed to −600 mV vs Ag/AgCl and held at that potential for the defined time period.

duplexes (AQ-ODN Duplex 1 and AQ-ODN Duplex 4) are not dependent on the intervening DNA length between the redox center and the electrode, which is in agreement with the earlier study (*24, 25*).

DNA Mutation Detection by Chronocoulometry. The detection of a single-base mismatch was performed by chronocoulometry involving the measurements of charge as a function of time. The measurements started at the initial potential of −100 mV vs Ag/AgCl at which there is no electrolysis. The applied potential was then changed to −600 mV vs Ag/AgCl that leads to reduction of the pendant anthraquinone group and was held at that potential for the defined time period. The results are shown in Figure 4. In system I, regardless of the kinds and positions of the base mismatches, all the DNA duplexes containing a base mismatch in studies here gave reduced electrochemical responses when compared to the fully matched DNA. In particular, the mismatched DNAs including a G−A mismatch can be differentiated from fully matched DNA without using an electrochemical catalyst. As expected, in system II, the DNA with the same mismatch that is placed out of the site from the redox center did not show any significant differences in the electrochemical response from the fully matched DNA.

DNA Mutation Detection via Hybridization Assay. As outlined in Figure 5, the usefulness of single-stranded (ss) AQ-

ODN (2 pmol/cm^2) immobilized on a gold electrode was tested in the electrochemical detection of a single-base mismatch through hybridization assay. The charge required for the reduction of the anthraquinone moiety of ss-AQ-ODN Chips (AQ-ODN Chip 1 and 2) was first recorded in the absence of target DNA using chronocoulometry (CC). Then, the chips were immersed in target-containing buffer (4 nM target DNA) at room temperature, and the CC measurements were carried out at an appropriate time interval to measure the changes in the integrated charge. The results are shown in Figure 6. It should be noted that the present assay for DNA mutation does not involve any washing steps. We confirmed by the ruthenium hexamine assay (*20*) that, after 1 h of the assay conditions, ca. 65% of ss-AQ-ODNs on the chip were hybridized with both fully matched and mismatch-containing DNAs. AQ-ODN Chip 1 showed the relatively large chronocoulometrical response after hybridization with fully matched DNA, while the hybrids with oligonucleotides containing a single-base mismatch did not show significant changes in the charge responses. We also investigated the performance of AQ-ODN Chip 2 that was designed for the detection of SNP associated with susceptibility to myocardial infarction (*4*). In this case, the mismatched DNA gave the reduced charge responses compared to ss-AQ-ODN Chip 2, which is clearly distinguishable from the fully matched target that yield larger charges than ss-AQ-ODN.

CONCLUSION

In summary, we have demonstrated that an anthraquinone-modified oligonucleotide is a useful probe to measure the charge transfer (CT) through a π-stack of DNA at the metal surface. The significant differences between mismatch-containing DNA and fully matched DNA were observed in electrochemical responses due to the reduced CT from a single-base mismatch. Owing to the simplicity of the analysis format and ease of making the redox-DNA bound chip, our method provides a promising way for sensitive detection of single-base mismatches in DNA.

ACKNOWLEDGMENT

This paper is dedicated to Prof. Dr. Isao Saito on the occasion of his 65th birthday. This research was supported by a Grant-in-Aid for Scientific Research from JSPS (K.Y.) and in part by SORST of JST. We would like to express sincere gratitude to Prof. Dr. Isao Saito for his encouragements.

Received April 3, 2007; Revised Manuscript Received October 9, 2007

Chemotherapy is often limited by toxicity to normal cells. Therefore, an ideal anticancer drug should discriminate between normal tissue and tumors. This would require a target receptor molecule mostly present in tumors. The cyclic peptide cCPGPEGAGC (PEGA) is a homing peptide that has previously been shown to accumulate in breast tumor tissue in mice. PEGA peptide does not cross the plasma membrane *per se*; however, when attached to the cell-penetrating peptide *p*VEC, the conjugate is taken up by different breast cancer cells *in vitro*. Additionally, the homing capacity of the PEGA-*p*VEC is conserved *in vivo*, where the conjugate mainly accumulates in blood vessels in breast tumor tissue and, consequently is taken up. Furthermore, we show that the efficacy of the anticancer drug, chlorambucil, is increased more than 4 times when the drug is conjugated to the PEGA-*p*VEC chimeric peptide. These data demonstrate that combining a homing sequence with a cell-penetrating sequence yields a peptide that combines the desirable properties of the parent peptides. Such peptides may be useful in diagnostics and delivery of therapeutic agents to an intracellular location in a specific tumor target tissue.

INTRODUCTION

Breast cancer is one of the major causes of death in developed countries, and there is a 1 in 7 risk of developing cancer during a woman's lifetime. Today, there are several choices available for treating breast cancer, including hormone therapy, aromatase inhibitors, and cytotoxins (for review, see ref (*1*)). Still, there is a need for improvement, i.e., to target the cytotoxic agents to the cancer cells in order to reduce side effects and toxicity in noncancer cells.

Blood vessels in normal individual tissues and different tumor tissues express different molecular markers (*2, 3*). In tumors, both blood and lymphatic vessels differ from their normal counterparts (*4*). Furthermore, lymphatic and blood vessels are distinguishable in different tumor types and various stages of tumor development (*5*). Numerous peptides that detect such differences have been isolated by combining *ex vivo* and *in vivo* screening of phage display libraries for tumor homing (*6–9*). One of these vascular homing peptides is a cyclic nonapeptide, cCPGPEGAGC, henceforth referred to as PEGA peptide, with a disulfide bridge between the two cysteines in the sequence (*8*). The PEGA peptide accumulates in breast vasculature as well as in premalignant breast tissue and primary breast tumors, and is thought to bind to the membrane-bound aminopeptidase P which is expressed at high levels in mouse breast tissue (*8, 10*).

Cell-penetrating peptides (CPPs)[1] are peptides which translocate the cell membrane and have the ability to transport different cargos such as oligonucleotides (*11*), plasmids (*12*), and proteins (*13*) across the cell membrane. CPPs can be divided into different classes depending on their origin (for review, see ref (*14*)); a common trait is that the CPPs are rich in basic amino acid residues. The translocation mechanism for CPPs is still not clear and might vary between the different classes of CPPs, as well as depending on cargo, and so forth; however, there is increasing evidence that endocytosis plays a significant role in the CPP uptake at least in cases where cargo molecules are attached (*15, 16*). A major drawback with most CPPs is that they are not cell-type specific.

The nitrogen mustard, chlorambucil (Cbl), is a well-known cytotoxic agent, which acts by alkylating and cross-linking the DNA, concomitantly inhibiting further cell proliferation. The effect is mediated through alkylation of guanine N7 in the major groove of DNA and subsequent interstrand cross-linking (*17, 18*). Moreover, this interstrand cross-link may induce apoptosis (*18, 19*). Cancer chemotherapy is often limited by toxicity to normal cells and tissues (for review, see ref (*20*)). Whether a drug such as chlorambucil can be administered at a dose that eliminates a tumor generally depends on the toxicity of the same dose to normal cells. An ideal anticancer drug is targeted toward cancer cells that are subsequently killed, but it has little or no effect on normal cells.

In the present study, we have designed and synthesized a breast tumor homing cell-penetrating peptide in order to provide a more effective and specific vector for anticancer drug delivery. We combined a tumor-specific vascular homing peptide cCPGPEGAGC (PEGA) sequence (*8*) with a well-studied CPP, *p*VEC (*21*), and demonstrated that the resultant PEGA-*p*VEC peptide colocalizes with the tumor vasculature marker and furthermore accumulates in tumor cells *in vivo*. We also showed *in vitro* that the efficacy of chlorambucil toward breast cancer cells is several fold higher when conjugated to PEGA-*p*VEC as compared to treatment with chlorambucil alone.

EXPERIMENTAL PROCEDURES

Peptide Synthesis. Peptides (Table 1) were synthesized on an Applied Biosystems model 433A by solid-phase method using a small-scale (0.1 mmol) *t*-Boc strategy on *p*-methylbenzhydrylamine resin (Neosystem) generating C-terminally ami-

Table 1. Sequences of the Studied Peptides

name	sequence
PEGA	cCPGPEGAGC-NH_2[a,b]
PEGA-*p*VEC	cCPGPEGAGC-LLIILRRRIRKQAHAHSK-NH_2[a,b,c]
*p*VEC	LLIILRRRIRKQAHAHSK-NH_2[b,c]
TP10	AGYLLGKINLKALAALAKKIL-NH_2

[a] PEGA, PEGA-*p*VEC are cyclic peptides, cyclized between the two cysteins. [b] For uptake studies, PEGA, PEGA-*p*VEC, and *p*VEC were fluoresceinyl-labeled at the N-terminus of the peptide. [c] For toxicity studies, PEGA-*p*VEC and *p*VEC were conjugated to chlorambucil at the N-terminus of the peptide.

dated peptides as reported previously (*22*). Stepwise coupling reactions were performed with *t*-Boc-protected amino acids (Neosystem), 1-hydroxybenzotriazole, *N,N′*-dicyclohexylcarbodiimide (4:4:4 equiv, 35 min, RT), followed by N-terminal deprotection of the *t*-Boc group with TFA/dichloromethane (1:1) (14 min, RT). For fluorophore labeling, the peptides were coupled N-terminally with 5(6)-carboxyfluorescein succinimidyl ester (Molecular Probes) (2 equiv) and diisopropylethylamine (2 equiv) in dimethyl sulfoxide/dimethylformamide (1:1) in the dark overnight. For chlorambucil coupling, chlorambucil (4 equiv) was coupled to the N-terminal amino group of the peptide with activation by 1-hydroxybenzotriazole and diisopropylethylamine (4:4 equiv, 30 min, RT) in dimethyl sulfoxide/dimethylformamide (1:1). After deprotection and cleavage of peptides, the disulfide bond formation between the two cysteines in the PEGA and PEGA-*p*VEC sequences was carried out by oxidation in excess of dimethyl sulfoxide overnight (*23*). Deprotection of the dinitrophenyl group was performed by treating the peptide (*p*VEC and PEGA-*p*VEC) with thiophenol:dimethylformamide (1:5) (1 h, RT), and the formyl group was removed by treating the peptide (TP10) with piperidin/dimethylformamide (1:5) (30 min, RT). Final cleavage of the peptides from the resin was performed in liquid hydrofluoric acid (1 h, 0 °C) in the presence of *p*-cresol and *p*-thiocresol. All peptides were purified by RP-HPLC (Discovery C-18 HPLC column, 25 cm, 21.2 mm, 5 μM) using a gradient of acetonitrile/water containing 0.1% TFA (50 min, 8 mL/min). The identity of the purified products was verified by matrix-assisted laser desorption–ionization time-of-flight mass spectrometer (Voyager-DE STR, Applied Biosystems). The mass spectra were acquired in positive ion reflector mode using α-cyano-4-hydroxycinnamic acid as a matrix (Sigma-Aldrich) (10 mg/ml, 7:3 acetonitrile/water, 0.1% TFA).

Cell Culture. The human breast cancer cell lines MDA-MB-231 and MCF-7 (ATCC) were cultured in RPMI-1640 supplemented with 10% fetal bovine serum (FBS), sodium pyruvate (1 mM), penicillin (100 U/mL), streptomycin (100 μg/mL), and 1% nonessential amino acids (further denoted as complete medium) (Invitrogen). The human breast cancer cell line MDA-MB-435 was maintained in DMEM supplemented with 10% fetal calf serum, penicillin (100 U/mL), and streptomycin (100 μg/mL). All cells were incubated at 37 °C in 5% CO_2.

Quantitative Cellular Uptake Studies. 150 000 cells/well were seeded two days before the experiment on a 12 well plate to get cells at 80% confluence. On the day of the experiment, the cells were washed with phosphate buffered saline (PBS) (1000 μL) and incubated with fluoresceinyl peptides (500 μL, 5 μM) in complete medium for 30 min at 37 °C. Cells were washed with PBS (2 × 1000 μL), whereafter trypsin (200 μL) was added and incubated for 5 min at 37 °C. PBS was added (1000 μL), and cells were transferred to Eppendorf tubes and centrifuged (10 min, 1000 *g*). Cells were lysed in sodium hydroxide solution (0.1 M, 300 μL) for 1 h and centrifuged (10 min, 10 000 *g*). The fluorescence (494/518 nm) was measured with SPECTRAmax GEMINI XS spectrofluorometric plate reader (Molecular Devices). The amount of internalized peptide was normalized against the amount of protein (Lowry, BioRad).

Microscopic Analysis of Cellular Peptide Uptake. MCF-7, MDA-MB-231, and MDA-MB-435 cells (20 000 cells/well) were seeded two days before the experiment on a Laboratory-Tek 8-well chamber slide (NUNC). The cells were washed with PBS (400 μL) and exposed to fluoresceinyl peptides (400 μL, 5 μM) in complete medium for 30 min at 37 °C. The cells were washed with PBS (3 × 400 μL) and visualized with an UltraView ERS Confocal Live Cell Imager microscope (Perkin-Elmer).

Toxicity Studies. Cell viability was measured using the Promega CellTiter-Glo assay according to the manufacturer's instructions. MCF-7 and MDA-MB-231 cells (20 000 cells/well) were seeded in a 48 well plate two days before the experiment. The cells were exposed to chlorambucil-conjugated peptide solution or free chlorambucil solution at different concentrations in complete media containing 1% FBS. After 3 h, complete media containing 10% FBS was added to achieve 5% FBS and then incubated for another 45 h at 37 °C. After reaching RT, CellTiter-Glo Reagent was added, the plate was incubated for 10 min at RT, and then the luminescence was measured. In the CellTiter-Glo assay, luciferin and luciferase are used to measure ATP content in the cells after incubation with peptides in different concentrations for 48 h. The ATP content is proportional to the amount of viable, metabolically active cells.

***In Vivo* Tumor Homing Analysis of Chimeric Peptides.** To produce tumors, nude BALB/c mice were orthotopically injected with 1 × 10^6 MDA-MB-435 tumor cells into the mammary fat pad. The tumor-bearing mice were used for homing analysis of peptides when the tumor diameter reached about 10 mm. Tissue distribution of fluoresceinyl-labeled peptides was studied by intravenously injecting the peptides (100 μM in 200 μL PBS) into tumor-bearing mice. The injected peptides were allowed to circulate 2 h, and the mice were perfused with 4% paraformaldehyde through the left ventricle of the heart. Tumors and various control tissues were dissected and frozen in OCT embedding medium (Tissue-Tek, Elkhart, IN). Frozen sections were prepared for immunohistological analysis and were observed under a Radiance MP confocal microscope to determine the internalization of peptides into cells *in vivo*. The immunohistochemical staining of tumor blood vessels was performed as previously described (*5, 9*). Briefly, frozen tissue sections were air-dried, fixed with cold acetone for 1 min, and washed with PBS three times. The slides were incubated with blocking buffers (PBS with 5% normal goat serum and 1% BSA) for 30 min at RT and then incubated with rat antimouse MECA-32 antibody (BD PharMingen) (1:50) overnight at 4 °C. After washing, the corresponding secondary antibody AlexaFluor-594 goat antirat or rabbit IgG (1:1000; Molecular Probes) was added and incubated for 1 h at RT. The slides were washed three times with PBS and mounted in Vectashield mounting medium with 4′,6-diamidino-2-phenylindole (DAPI; Vector Laboratories).

RESULTS

Selection of CPP. We tested the toxicity of two well-known CPPs, *p*VEC (*21*) and TP10 (*24*), in MCF-7 cells using a luciferase-based assay (Figure 1). TP10 shows considerable toxicity already at a concentration of 10 μM resulting in 48% of viable cells. *p*VEC exhibited toxicity first at 50 μM, where the amount of viable cells was reduced to 60%. Since *p*VEC was less toxic among the two studied CPPs, it was selected for coupling to a homing peptide sequence.

Cellular Uptake of Homing CPP *in Vitro*. The uptake of fluoresceinyl-labeled PEGA, PEGA-*p*VEC, and *p*VEC was studied by fluorescence microscopy in MDA-MB-231, MCF-7, and MDA-MB-435 cells. As expected, fluoresceinyl-*p*VEC was internalized into the tested cells. The homing peptide,

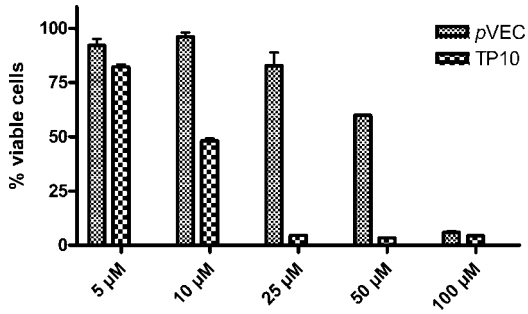

Figure 1. Effects of CPPs *p*VEC and TP10 on MCF-7 cell viability. The cells were exposed to different concentrations of peptides in media for 48 h followed by measurement of the amount of ATP (i.e., viable cells). Cells in untreated cultures were set to 100% viable. Mean ± SEM is presented.

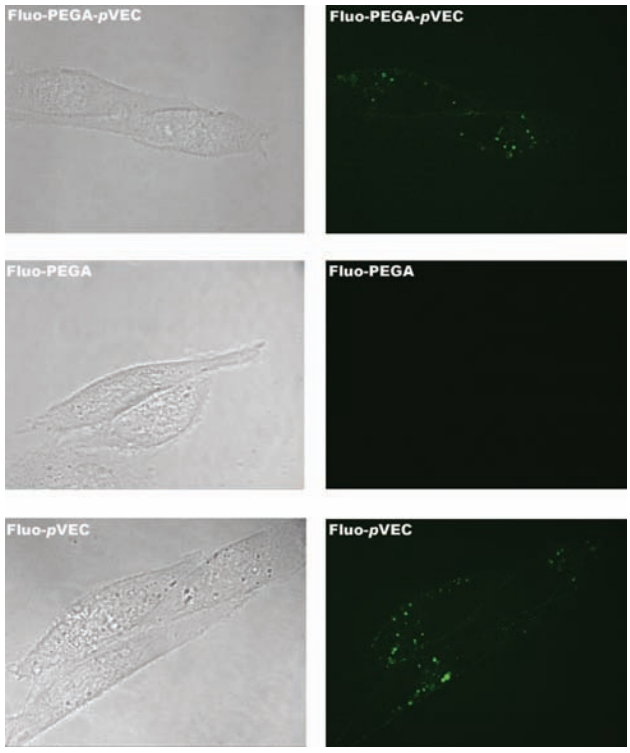

Figure 2. Detection of fluoresceinyl peptides in MDA-MB-231 cells by confocal laser scanning microscopy. Cells were incubated with 5 μM fluoresceinyl peptide, as indicated in the figure, for 30 min followed by imaging in bright field (left column) and corresponding image in fluorescence mode (green; right column).

fluoresceinyl-PEGA, alone did not enter the cells, while the conjugate, fluoresceinyl-PEGA-*p*VEC, was internalized in MDA-MB-231 (Figure 2), MCF-7, and MDA-MB-435 cells (data not shown).

Cellular uptake of the peptides was quantified by the detection of the intracellular amount of fluoresceinyl-labeled PEGA, PEGA-*p*VEC, and *p*VEC in MCF-7 and MDA-MB-231 cells. The results are presented in Figure 3 where the amount of the internalized peptide is normalized against the amount of total cellular protein in the culture well. The pattern of uptake was similar in both MDA-MB-231 cells and MCF-7 cells but slightly higher in MDA-MB-231 cells. As shown in Figure 3 for MDA-MB-231 cells, we confirmed that the homing peptide fluoresceinyl-PEGA alone did not display cell-penetrating properties; its uptake was 1 pmol/mg protein, whereas when conjugated to *p*VEC, the uptake increased to 630 pmol/mg protein. Fluoresceinyl-*p*VEC showed the highest uptake at 2400 pmol/mg protein.

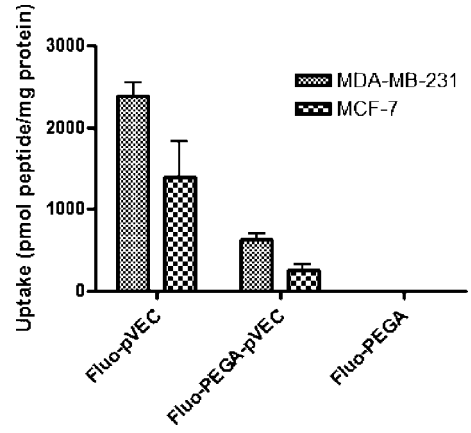

Figure 3. Uptake of fluoresceinyl peptides into MDA-MB-231 and MCF-7 cells. Cells were exposed to 5 μM fluoresceinyl peptide solution for 30 min, followed by removal of extracellular peptide by washing and trypsination of the cells. The cells were lysed in 0.1 M sodium hydroxide, and fluorescence at 494/518 nm was measured. The amount of internalized peptide was calculated on the basis of linear relation between fluorescence and concentration and normalized to the amount of protein. Mean ± SEM is presented.

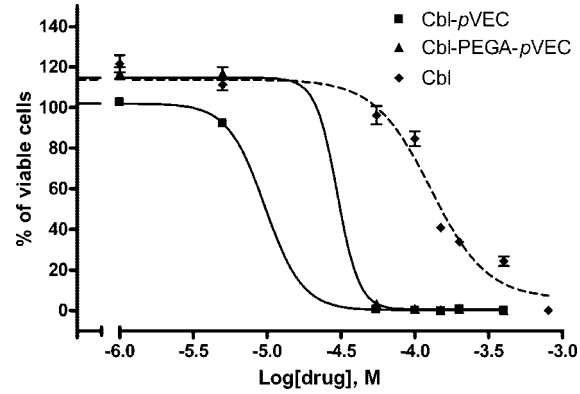

Figure 4. Cytotoxicity of chlorambucil (Cbl), Cbl-*p*VEC, and Cbl-PEGA-*p*VEC to MCF-7 cells. Cells were exposed to different concentrations of the chlorambucil-conjugated peptide solution or free chlorambucil in media for 48 h. Cells in untreated cultures were set to 100% viable. The results are presented as mean ± SEM. Data are analyzed using nonlinear regressions, *GraphPad Prism* software.

***In Vitro* Drug Activity.** In order to evaluate whether the activity of chlorambucil is improved when conjugated to PEGA-*p*VEC, we exposed chlorambucil or chlorambucil-conjugated peptides at different concentrations to MCF-7 and MDA-MB-231 breast cancer cells for 48 h. After incubation, the ATP content was measured. The IC_{50} was similar in both MCF-7 (Figure 4) and MDA-MB-231 cells (data not shown). The calculated IC_{50} for chlorambucil alone in MCF-7 cells was 128 μM, while the IC_{50} for chlorambucil conjugated to *p*VEC was 9.6 μM. When chlorambucil was conjugated to the PEGA-*p*VEC, the IC_{50} value was 30 μM. The toxicity appears to be due to the chlorambucil moiety of the conjugate, since *p*VEC alone displayed little toxicity at concentrations below 50 μM (Figure 1).

Homing Specificity of PEGA-pVEC Peptide *in Vivo*. To evaluate the homing specificity of the PEGA-*p*VEC, MDA-MB-435 tumor-bearing mice were intravenously injected with 100 μM of fluoresceinyl-PEGA-*p*VEC chimeric peptide or fluoresceinyl-PEGA or fluoresceinyl-*p*VEC as controls in 200 μL PBS. Each of the peptides was detected in tumor tissue (Figure 5), where they partially colocalized with a blood vessel specific marker MECA-32 that stained with anti-MECA-32 antibody; the colocalization was particularly prominent with fluoresceinyl-

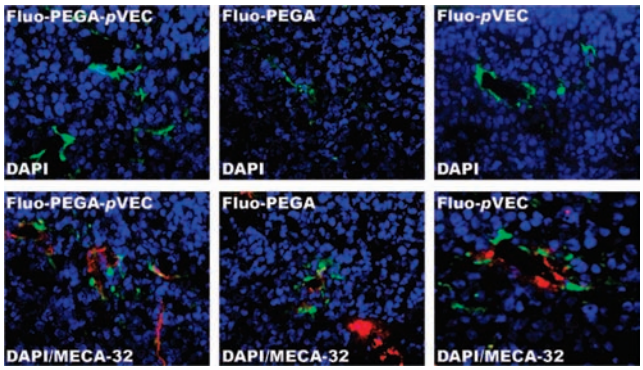

Figure 5. Localization of fluoresceinyl peptides in MDA-MB-435 tumors. The mice were injected i.v. with fluoresceinyl peptides as indicated in the figure, and tissue sections were examined for fluorescence. Fluoresceinyl peptides (green) and blood vessels stained with anti-MECA-32 antibody (red; bottom row) in tumor tissue. Anti-MECA-32 antibody is specific for vascular endothelial cells. Nuclei were detected by DAPI staining (blue).

PEGA-*p*VEC (Figure 5). At some parts, fluoresceinyl-PEGA-*p*VEC and fluoresceinyl-*p*VEC appeared to be in nuclei in the tumor cells. Apparently, the amount of fluoresceinyl-PEGA-*p*VEC in nontumor tissues was much lower than that of fluoresceinyl-*p*VEC (Figure 6). These data show that the peptide chimera combines the main desirable properties of the component peptides, specific homing to tumors and internalization into target cells.

DISCUSSION

In this report, we show, for the first time, that by combining homing and cell-penetrating peptide sequences a new effective tumor-specific peptide with the capability to translocate cargo inside target cells is obtained. Moreover, this new peptide shows considerable improvement in anticancer drug cytotoxicity.

Here, we used a cyclic homing peptide cCPGPEGAGC (PEGA) that has been previously isolated by *in vivo* phage display library screening (*8*). The PEGA peptide is not cell-penetrating *per se*; however, by conjugation it to the well-studied CPP, *p*VEC (*21*), both the cell-penetrating property of *p*VEC and the homing property of PEGA are achieved in a chimeric peptide. The quantitative and qualitative *in vitro* uptake studies in MCF-7, MDA-MB-231, and MDA-MB-435 cells (data not shown) confirmed that PEGA-*p*VEC is a CPP. There are studies of homing peptides with cell-penetrating abilities (*7, 9, 25*), but they are not extensively characterized so far.

There are different classes of CPPs depending on their origin (for review, see ref (*14*)); common for all classes is that CPPs are rich in basic amino acids. The PEGA peptide withholds no basic amino acids but a negatively charged glutamic acid, and as expected, the PEGA peptide has no CPP properties (Figures 2 and 3). However, when conjugated to the well-characterized CPP, *p*VEC, the lack of basic amino acids in the PEGA sequence is compensated with the basic residues in *p*VEC. The reduced uptake of the PEGA-*p*VEC peptide compared to *p*VEC might be a result of the reduced net positive charge of the PEGA-*p*VEC peptide in relation to *p*VEC. These results are in accordance to a CPP prediction method outlined by Hällbrink et al. (*26*) suggesting differential cell-penetrating properties of these two peptides.

The PEGA-peptide has previously been shown to accumulate in breast vasculature as well as in premalignant breast tissue and to primary breast tumors *in vivo* (*8*). We confirmed with our study that the fluoresceinyl-PEGA-*p*VEC translocates breast cancer cells and also human aortic endothelial cells *in vitro* (unpublished data).

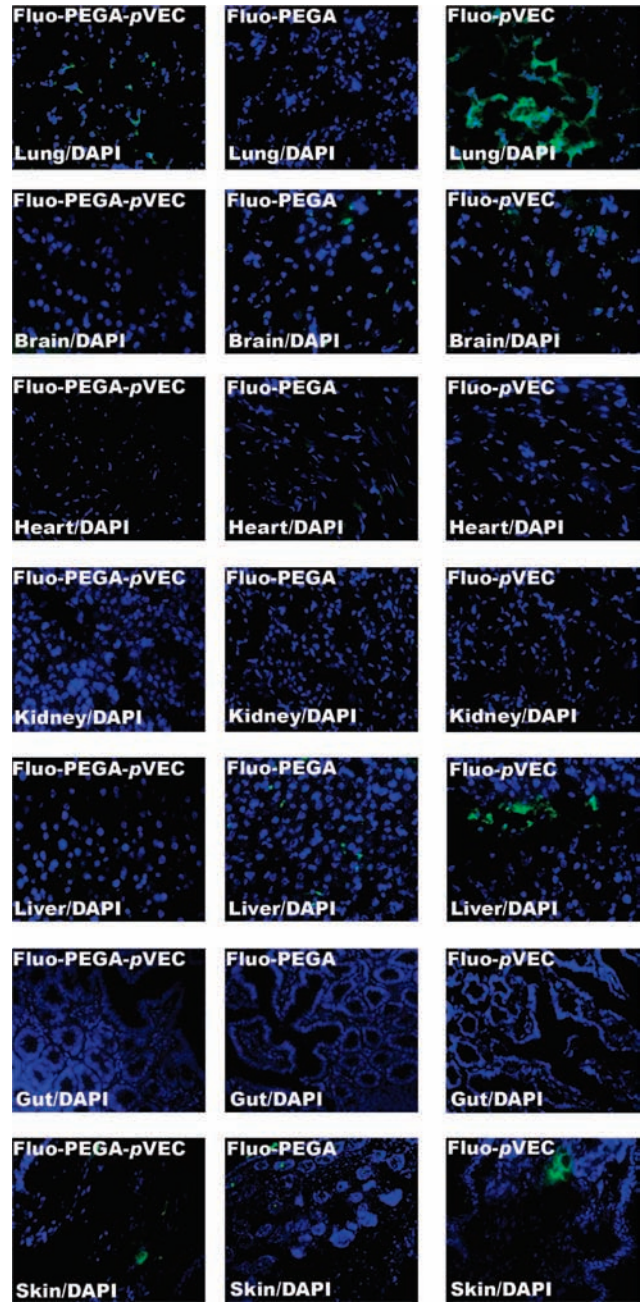

Figure 6. Distribution of fluoresceinyl peptides (green) in nontumor tissues of mice bearing MDA-MB-435 tumors. The mice were injected i.v. with fluoresceinyl-PEGA-*p*VEC (left column), fluoresceinyl-PEGA (middle column), and fluoresceinyl-*p*VEC (right column).The tissue sections, as indicated in the figure, were examined for fluorescence. Nuclei were detected by DAPI staining (blue).

The major obstacle in cancer treatment is the lack of specificity of therapeutic agents to cancer cells. It has been shown that drug therapy can be improved if the drug is targeted to tumor cells (*27, 28*). *In vivo* accumulation of fluoresceinyl-labeled PEGA-*p*VEC into the MDA-MB-435 tumor vasculature as well as tumor cells and not into control tissues suggested that our chimeric peptide could also be used for this purpose. In order to test this idea, we conjugated the DNA alkylating anticancer drug chlorambucil (*17, 18*) to PEGA-*p*VEC and studied the cytotoxicity of the conjugate in breast cancer cells. The efficacy of cytotoxicity measured as IC_{50} value of chlorambucil is lowered by more than 4-fold when the drug is conjugated to PEGA-*p*VEC (Figure 4). Chlorambucil is believed to be taken up by passive diffusion (*29*); however, that mechanism is less

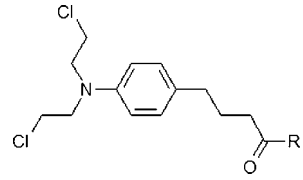

Figure 7. Chlorambucil coupled to the N-terminus of the *p*VEC and PEGA-*p*VEC (R), via an amide bond.

efficient as compared to conjugation to a CPP. *p*VEC contributes to transport of chlorambucil over the cell membrane, enhancing the efficiency of the drug. Chlorambucil is conjugated to the N-terminus of the peptides via an amide bond (Figure 7) leaving the alkylating moiety of chlorambucil available for the reaction to be able to exert its effect.

The uptake mechanism of CPPs is not yet clear and might vary among different CPPs; endocytosis seems to be one route for cellular import of CPPs (for review, see ref (*30*)). The uptake mechanism for PEGA-*p*VEC will be a subject for further studies. Preliminary experiments show that the fluoresceinyl-PEGA-*p*VEC is not colocalized with lysosomal marker (LysoTracker Red DND-99, Molecular Probes) (data not shown). In the *in vivo* studies, the fluoresceinyl peptides are injected intravenously in the mice; already after 2 h, it is possible to detect the accumulation of the peptides in the tumor cells (Figure 5). The colocalization of fluoresceinyl-PEGA-*p*VEC with the blood vessel marker, MECA-32, and the translocation of the fluoresceinyl-PEGA-*p*VEC in the breast cancer cells in the tumor, indicates that chlorambucil-PEGA-*p*VEC could be used for *in vivo* targeting of breast cancer cells as well as tumor microvascular endothelial cells.

Another possible approach for fluoresceinyl-labeled PEGA-*p*VEC is to use the peptide for imaging of tumors. This application could be useful in detection of tumors in early as well as progressed stages and for studying the response to therapy, i.e., imaging of tumor growth. Imaging of tumors and cancer cells has successfully been carried out by other homing peptides, i.e., fluoresceinyl-labeled Lyp-1 peptide *in vivo* in mice (*31*).

In summary, we have characterized a breast tumor-homing peptide, PEGA-*p*VEC, which translocates the cell membrane *in vitro* and homes to breast tumor tissue *in vivo*. We have also shown that by conjugating chlorambucil to PEGA-*p*VEC the efficacy of chlorambucil to tumor cells was increased more than 4-fold *in vitro*.

ACKNOWLEDGMENT

Peptide-Functionalized Poly(ethylene glycol) Star Polymers: DNA Delivery Vehicles with Multivalent Molecular Architecture

Katye M. Fichter,[†] Le Zhang,[‡] Kristi L. Kiick,*[,‡] and Theresa M. Reineke*[,†]

Department of Chemistry, University of Cincinnati, Cincinnati, Ohio 45221-0172, and Department of Materials Science and Engineering, University of Delaware, and Delaware Biotechnology Institute, Newark, Delaware 19716-3106. Received April 4, 2007; Revised Manuscript Received July 3, 2007

Exploring the development of nonviral nucleic acid delivery vectors with progressive, specific, and novel designs in molecular architecture is a fundamental way to investigate how aspects of chemical and physical structure impact the transfection process. In this study, macromolecules comprised of a four-arm star poly(ethylene glycol) and termini modified with one of five different heparin binding peptides have been investigated for their ability to bind, compact, and deliver DNA to mammalian cells *in vitro*. These new delivery vectors combine a PEG-derived stabilizing moiety with peptides that exhibit unique cell-surface binding ability in a molecular architecture that permits multivalent presentation of the cationic peptides. Five peptide sequences of varying heparin binding affinity were studied; each was found to sufficiently bind heparin for biological application. Additionally, the macromolecules were able to bind and compact DNA into particles of proper size for endocytosis. In biological studies, the PEG-star peptides displayed a range of toxicity and transfection efficiency dependent on the peptide identity. The vectors equipped with peptides of highest heparin binding affinity were found to bind DNA tightly, increase levels of cellular internalization, and display the most promising transfection qualities. Our results suggest heparin binding peptides with specific sequences hold more potential than nonspecific cationic polymers to optimize transfection efficiency while maintaining cell viability. Furthermore, the built-in multivalency of these macromolecules may allow simultaneous binding of both DNA at the core of the polyplex and heparan sulfate on the surface of the cell. This scheme may facilitate a bridging transport mechanism, tethering DNA to the surface of the cell and subsequently ushering therapeutic nucleic acids into the cell. This multivalent star shape is therefore a promising architectural feature that may be exploited in the design of future polycationic gene delivery vectors.

INTRODUCTION

The delivery of nucleic acids by nonviral vectors is an intense area of research due to the promise of synthetic materials to be tailored for specific drug targets (*1, 2*). It has been found that even moderate chemical modifications of the vector architecture may significantly affect the ability of the molecule to transfect cells efficiently (*3–8*). Under many conditions of polycation—DNA complex (polyplex) formation, the surface charge on positively charged polyplexes is neutralized, which allows polyplex—polyplex aggregation to occur, and even in the absence of complete charge neutralization, cationic polyplexes can bind and flocculate with oppositely charged serum proteins. By preventing this aggregation, polyplexes can remain in circulation for extended time periods, avoid clearance by macrophages, and maintain a small, uniform size for vascular penetration and cellular endocytosis under *in vivo* conditions (*9–12*). The addition of poly(ethylene glycol) chains to polycationic vectors has previously been shown to favorably stabilize polycation/DNA complexes, known as polyplexes, against flocculation in conditions containing salt and serum, which has improved their potential for *in vivo* gene delivery (*13*).

Nitrogen-dense polycations such as Poly(ethyleneimine) (PEI) have been shown to have high transfection efficiency; however, the cytotoxicity of this and many similar vectors are high in many cell lines (*14*). To retain high transfection efficiency and minimize toxicity, modified polycationic systems have been created. For instance, the modification of PEI with PEG has been developed either as a copolymer or with a grafted architecture (*15–17*). In addition, PEGylated poly(L-lysine) vectors have recently been shown to have very low cytotoxicity as well as notable stability *in vivo*, although increasing the transfection efficiency of these vectors is still a current research goal (*18–20*). To understand the architectural impact of these vectors, a wide variety of novel methods for the incorporation of hydrophilic moieties are being examined. For example, supramolecular vectors utilizing a PEG moiety grafted onto preformed DNA/polycationic vectors (*21*) or even rotaxane-type vectors utilizing cyclodextrin molecules threaded around hydrophilic polymers (*22–24*) have been developed. Additionally, low molecular weight branched PEI conjugated onto the end of star-shaped PEG molecules has been found to have promising transfection potential (*25*). In our work reported here, we have incorporated cationic peptide chains derived from the binding portion of heparin binding proteins (HBPs) onto the termini of star-shaped PEG macromolecules to create multivalent DNA vectors that can both efficiently complex DNA and target heparan sulfate-containing endocytic receptors.

There have been numerous reports implicating the role of proteoglycans in the uptake of polyplexes into cells (*26, 27*). We hypothesize that polyplexes containing heparin binding peptides may increase cell-surface adhesion and subsequent uptake, more so than classical nonspecific polycationic vectors. This may occur through specific interaction with ubiquitous heparan sulfate moieties on cell surfaces, which are similar to heparin in structure. Specific HBP−proteoglycan binding may enhance cellular uptake via sequence-specific association. This could eliminate the need to design highly charge-dense vectors

sHIP	CKAAKRPKAAKDKQTK	scrambled HIP sequence
ATIII	CK(βA)FAKLAARLYRKA	antithrombin III (*35, 37*)

that nonspecifically bind heparan sulfate (*5, 28*), and negatively impact cell viability (*14*). Such approaches employing PEG-HBPs for complexation of nucleic acids therefore offer unique opportunities for controlling and improving DNA delivery.

The specificity and affinity of protein interactions with heparin are governed by the specific placement of cationic amino acid residues relative to the sulfation pattern of heparin. This pattern may provide a strategy for manipulating heparin binding affinity and DNA delivery. Literature. reports suggest that heparin-interacting protein (HIP) and antithrombin III (ATIII) bind to similar pentasaccharide sequences found in heparin (*29*). Four tetrasaccharides are thought to be required for efficient heparin binding of human platelet factor 4 (PF4) (*30*), thus providing higher affinity binding for PF4 over that of HIP and ATIII. Furthermore, peptides that contain multiple arginine residues have been suggested to have high heparin binding affinity, since similar structures are found in heparin binding proteins (*31, 32*).

The reported PEG-star peptide bioconjugates have been previously exploited to assemble noncovalently cross-linked hydrogels (*33–37*) via the interactions of the heparin binding termini (peptide mimics of the heparin binding domains of ATIII (*38*), HIP (*39*), PF4 *30, 40*)) with PEG-star molecules modified with heparin. The mechanical and biological properties of such hydrogels can be engineered on the basis of the heparin−BP interactions and applied in the controlled delivery of proteins *35, 40*). Electrostatic interactions are a key component in HBP−heparin associations (*41*); therefore, it is likely that these PEG star HBP conjugates will also be capable of mediating the binding, condensation, and delivery of other polyanions such as DNA. Furthermore, the multivalent nature of these molecular stars may permit the simultaneous interaction of the bioconjugate with both DNA at the core of the polyplex and glycosaminoglycan at the cell surface through the interaction of both DNA-bound peptide arms and unbound arms on the surface of the nanoparticle. This simultaneous interaction may tether the DNA complexes to the cell surface, which may subsequently act to usher nucleic acid–based therapeutics into cells.

To this end, we have measured the heparin binding affinities and kinetics for the HBPs, examined their complexation with DNA, and correlated this information with the transfection efficiencies of the resulting polyplexes. Polyplexes formed with two of the structures described here, PEG-star $PF4_{ZIP}$ and PEG-star RRP, inhibit serum-mediated aggregation and exhibit promising transfection in the presence of serum. In addition, physical characterization of polyplexes created with these novel vectors as well *in vitro* biological activity profiles are presented. Figure 1and Table 1 show details of the PEG-star peptide structure, the proposed transfection scheme, and the amino acid sequences used to create these unique bioconjugates.

EXPERIMENTAL PROCEDURES

I. Materials. For the synthesis of the PEG-HBPs, low molecular weight heparin sodium salt (LMWH) from porcine intestinal mucosa (average molecular weight 3000 g/mol) was obtained from Sigma (St. Louis, MO), and heparin from porcine intestinal mucosa (average molecular weight 6000 g/mol) was purchased from Celsus Laboratory., Inc. (Cincinnati, OH). Hydroxy-terminated four-arm PEG (M_n = 10 300; M_w = 11 300 g/mol; M_w/M_n = 1.1) and thiol-terminated, four-arm PEGs (M_n = 10 000; M_w = 10 800 g/mol; M_w/M_n = 1.1) were purchased from Polymer Source (Dorval, Quebec, Canada). Deionized water (18 MΩ) was applied in all the experiments (Barnstead NANOpure Diamond Ultrapure water Systems, Barnstead Inc., Dubuque, IA). Amino acids, rink amide MBHA (4-methylbenzhydrylamine) resin, and HBTU were purchased from Novabiochem Corp. (San Diego, CA). DMF and acetonitrile (HPLC grade) were obtained from Fisher Scientific (Fairlawn, NJ). General chemicals were all purchased from Sigma-Aldrich unless otherwise specified. Triethylamine (TEA) was distilled from CaH_2. All other reagents were used as received.

Branched polyethylenimine (PEI), a positive control used in some experiments, was obtained from Aldrich. For the execution of biological studies, pCMVβ plasmid DNA and gWiz-Luc were acquired from PlasmidFactory (Bielefeld, Germany) and Aldevron (Fargo, ND), respectively. Nuclease-free water, Opti-MEM, and DMEM (supplemented with 10% fetal bovine serum (FBS), 100 units/mL penicillin, 100 μg/mL streptomycin, 0.25 μg/mL amphortericin), and PBS were all purchased from Invitrogen (Carlsbad, CA). For the luciferase assay, cell culture lysis buffer and the luciferase substrate assay reagent were purchased from Promega (Madison, WI). For the viability assay, a Bio-RAD DC protein assay kit was purchased from Bio-Rad (Hercules, CA), and bovine albumin (98%) was purchased from Sigma (St. Louis, MO).

II. Synthesis and Characterization of the PEG-HBPs. The synthesis of the PEG-star HBP conjugates was conducted via addition reactions between vinyl sulfone-terminated four-arm star-PEG and cysteine-terminated HBPs. The synthetic protocols for preparing the peptides and bioconjugates for the PEG-ATIII, PEG-HIP, and PEG-$PF4_{ZIP}$ have been described previously (*35, 36, 40*).

Synthesis of RRP and sHIP. The RRP peptide RRRRRRRGGG and the sHIP peptide CKAAKRPKAAKDKQTK were prepared on Rink Amide MBHA resin via solid-phase peptide synthesis with Fmoc protection using a PTI PS3 peptide synthesizer (Protein Technologies, Inc., AZ). A preparative-scale Delta 600 HPLC (Waters) equipped with a Waters Symmetry 300 C18 column (5 μm particle size, 19 × 150 mm) was applied for the crude RRP peptide purification. Solvent A (water/0.1% TFA) and solvent B (acetonitrile/0.1% TFA) were employed as HPLC solvents in programmed gradients. Peptides isolated as single fractions via HPLC were characterized via ESI mass spectrometry. The mass of the purified RRP was confirmed via ESI mass spectrometry, m/z = 641.9[$(M^+2H)^{2+}$, calcd 642.2] and m/z = 428.0[$(M^+3H)^{3+}$, calcd 428.5]. The mass of the purified sHIP was similarly confirmed, m/z = 886.2[$(M^+2H)^{2+}$, calcd 887.5], m/z = 591.3[$(M^+3H)^{3+}$, calcd 591.7], and m/z = 443.8[$(M^+4H)^{3+}$, calcd 444.0] (see Supporting Information). These peptides were used in heparin affinity measurements and circular dichroic spectroscopy, while peptides with an N-terminal cysteine were used in the synthesis of the PEG conjugates. Because of the virtually identical synthesis and purification, it is assumed that this slight modification in sequence does not significantly alter the peptide for our purposes.

Synthesis of PEG-RRP and PEG-sHIP Conjugates. The synthesis of PEG-RRP and PEG-sHIP conjugates was accomplished using a similar method applied previously for the synthesis of other PEG-HBP conjugates (*36*). Characterization

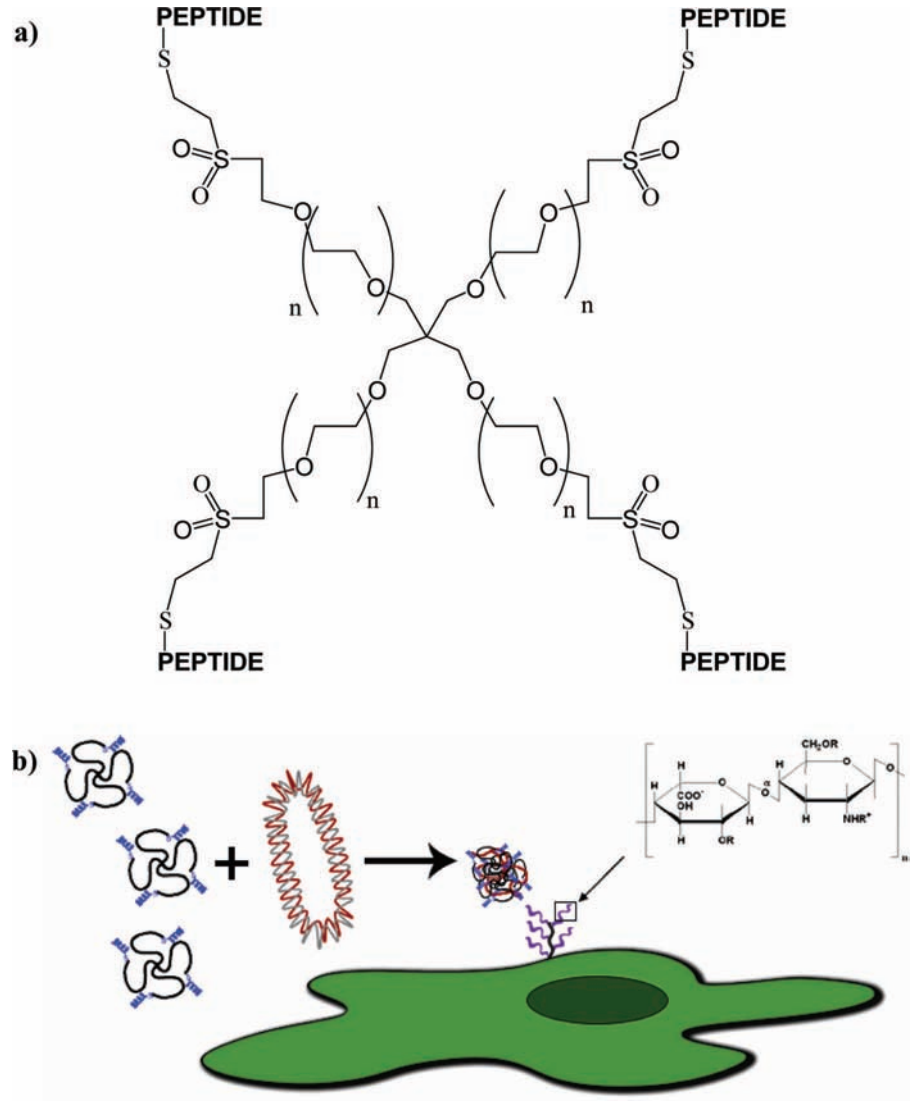

Figure 1. (a) Chemical structure of PEG-star peptides depicting their molecular architecture. "PEPTIDE"refers to one of 5 different peptides listed in Table 1. $n = 60$. (b) Proposed scheme for the transfection of mammalian cells with pDNA using PEG-star HBP vectors. The star polymers are multivalent and peptides functionalized on the termini of the PEG-star should be competent to bind both DNA in the core of the polyplex and heparan sulfate on the surface of cells simultaneously.

data for these macromolecules via size exclusion chromatography and NMR are given in the Supporting Information.

III. Heparin Affinity Measurements. *Affinity Liquid Chromatography.* The heparin affinities of the HBPs and PEG-HBPs were first determined via heparin-sepharose affinity liquid chromatography on an ÄKTA Explorer FPLC equipped with a HiTrap Heparin HP column (5 mL, ~10 mg heparin/mL gel, Amersham Biosciences Corp, Piscataway, NJ), using previously described procedures in which peptides bound to a heparin-modified affinity column are eluted with buffer of varying concentrations of sodium chloride (*35*).

Surface Plasmon Resonance (SPR). SPR characterization of the binding of HBPs to LMWH was performed on a Biacore 3000 instrument (Biacore Inc., Piscataway, NJ), employing a high-capacity LMWH surface created on a commercially available streptavidin-coated SA chip via treatment with biotinylated LMWH, as previously described (*35*). Equilibrium dissociation constants (K_D) were calculated from experimentally determined association and dissociation rate constants, via standard fitting protocols previously described (*35*) and described in the Supporting Information.

IV. DNA Binding Assay. To determine whether these materials bind and complex pDNA, a series of gel shift assays were performed with polyplexes formulated at a range of charge ratios. This charge ratio represents the number of positive charges on the peptide side chain to the number of phosphate groups along the DNA backbone. A more thorough treatment of this calculation for the PEG-star peptides can be found in the Supporting Information.

Polyplexes were formed by adding a solution of the PEG-HBP (150 μL) dissolved in nuclease-free water to an equal volume of solution of plasmid DNA (15 μg) at various charge ratios. After a 30 min incubation period, 1 μL of running buffer (Blue Juice, Invitrogen, Carlsbad, CA) was added to each sample. Ten microliters of each polyplex sample was then loaded into the wells of a 0.6% agarose gel prepared in TAE buffer containing 0.06 μg/mL ethidium bromide. The samples were subsequently electrophoresed in an electric field of 60 V.

V. Circular Dichroic Spectroscopy (CD). Circular dichroic spectroscopy was used to characterize the structures of select peptides while bound to pDNA. Characterization was conducted on $PF4_{ZIP}$ and HIP peptides in solution with pDNA (rather than on PEG-HBPs) in order to preserve the optical clarity of the solutions for CD measurements. CD spectra were acquired at 25 °C on a Jasco J-810 spectropolarimeter (Jasco Inc., Easton, MD) equipped with a Jasco PTC-424S temperature controller.

Polyplexes consisting of heparin binding peptides and pDNA were formulated at a charge ratio of 5, and the final DNA concentration of the polyplex formulation was chosen to be 1 μg/100 μL in PBS to match that used in DNA transfection experiments. To form the polyplexes, either $PF4_{ZIP}$ or HIP was added to the pDNA solution to reach a final peptide concentration of 15.2 μM or 21.6 μM, respectively. Polyplexes at a charge ratio of 1 were formed at the same concentration (21.6 μM) of HIP, but with 1 μg/20 μL pDNA.

Samples were equilibrated at 25 °C for 30 min prior to data collection. The equilibration of the samples was indicated by the absence of further changes in the CD signal at longer equilibration times. All CD spectra were taken in a 1 mm path length quartz cuvette, at wavelengths from 200 to 250 nm. Data points were recorded at every nanometer with a 4.0 s response time. (Refer to Supporting Information for spectra.)

VI. Polyplex Size and Zeta Potential Measurements. In order to characterize polyplex stability, the size and zeta potential of polyplexes formulated by complexing pDNA with the PEG-HBPs were measured via dynamic light scattering using a Zetasizer Nano ZS[Malvern Instruments (Malvern, UK) equipped with a 633 nm laser]. Ultrapure water, Opti-MEM, and DMEM were filtered with a 0.2 μm filter before any polyplexes were formed to remove particulates and dust from the initial solutions. The solutions were not filtered after polyplex formation. Polyplexes were formed in a similar manner as described above for the gel shift assays, except 3 μg pDNA was used and the polyplexes were created at a charge ratio of 5. Measurements were performed at 25 °C. After initial incubation for 1 h, the polyplex solutions were diluted to 900 μL with Millipore water, Opti-MEM (serum-free media), or DMEM containing 10% fetal bovine serum. Solutions were then immediately transferred to a cuvette and measured. Polyplex size measurements were taken consecutively at 0, 20, 40, 60, and 120 min. Zeta potential measurements were taken consecutively at 0 and 20 min.

VII. Cell Viability and Transfection Efficiency. BHK-21 cells were cultured under the conditions recommended by the ATCC. Twenty-four hours before transfection, cells were seeded in 24 well plates at 50000 cells per well and incubated in supplemented DMEM at 37 °C and 5% CO_2. Immediately before transfection, the polyplexes were created with pDNA (gWiz-Luc) as described above for the previous experiments (gel-shift and particle size assays). For the delivery experiments, the polyplexes were created at a range of charge ratios as well as a charge ratio of 0, which represents the delivery of naked pDNA. One hour after polyplex formation, 600 μL of Opti-MEM or DMEM was added to each polyplex solution. Prior to the transfections, the media in each well was aspirated off, the cells were washed with PBS, and 300 μL of the polyplex solution was added. This volume was used to normalize the delivery of DNA to each well to 1 μg. Controls of both untransfected cells and cells transfected with pDNA only were also performed. Transfections at all charge ratios and the controls were performed in triplicate. Four hours after transfection, 800 μL of DMEM supplemented with 10% FBS was added to each well. Twenty-four hours after transfection, the media was removed from each well, and 1000 μL of fresh DMEM was added. Forty-eight hours after transfection, the media was removed from each well, the cells were washed with PBS, and 100 μL of lysis buffer was added to each well. The cell lysates were then assayed for luciferase expression using the protocol provided by Promega and protein content using the protocol provided with the Bio-Rad DC protein assay kit. The results of the protein assay were analyzed using a standard curve of bovine serum albumin and normalized against the untransfected control to obtain the fraction of cell survival.

VIII. Cellular Internalization. BHK-21 cells were cultured under conditions recommended by the ATCC. Twenty-four hours before transfection, cells were seeded in 6 well plates at 250 000 cells/well and incubated in DMEM supplemented with 10% FBS at 37 °C and 5% CO_2. Formulation of polyplexes proceeded in the manner described above except 250 μL of each PEG-Star HBP was added to 5 μg Cy5-labeled DNA (250 μL total DNA solution volume) to formulate polyplexes at an N/P ratio of 5. After incubation for 1 h, 1 mL of Opti-MEM was added to each polyplex solution. The cells were washed with PBS and each well was transfected with a corresponding polyplex solution in Opti-MEM and subsequently incubated for 4 h. Afterward, the transfection media was aspirated and each well was washed twice, with 2 mL and then 1 mL PBS, to remove bound polyplexes from the cell surface. The cells were subsequently incubated for two more hours in DMEM with 10% FBS to allow further trafficking of DNA. After this final incubation period, the media was removed and cells were again washed with 1 mL PBS and subsequently trypsinized at 37 °C for 10–15 min. Next, 1 mL DMEM was added to each well and the cells were transferred to Falcon tubes and spun at 1000 rpm for 10 min. The supernatant was then removed, 1 mL PBS was used to wash the pellet, and the cells were spun again in the same conditions. Again, the supernatant was removed and the pellet was resuspended in PBS supplemented with 2% FBS. The cell suspensions were analyzed with a FACS Calibur flow cytometer, using appropriate forward and side scatter gates, and the Cy5 fluorescence intensity of 50 000 cells in each sample was measured. A control of untransfected cells was used to create a gate less than 1% of cells exhibiting Cy5 fluorescence. This gate was used for subsequent samples transfected with the PEG-HBPs to determine the percent of cells transfected.

RESULTS AND DISCUSSION

I. PEG-HBP Synthesis and Characterization. Polysaccharides, such as heparan sulfate, are widely distributed on a broad range of cell types. Many cell-surface receptors involve the binding of an external molecule to heparan sulfate to initiate internalization via receptor-mediated endocytosis. By improving the polyplex-cell surface interaction involving these anionic polysaccharides, the cellular internalization, and thus transfection efficiency, may also be improved. For example, adeno and adeno-associated viral vectors with heparan sulfate and heparin binding domains have been previously constructed as gene delivery vectors (*42*, *43*), to enhance cellular internalization via heparan-sulfate-associated receptors. Additionally, adenoviral vectors with modified fiber coat proteins containing cationic poly(lysine) have been shown to increase the transduction of macrophages, as well as endothelial, smooth muscle, glioblastoma, and T cells (*44*). However, to the best of our knowledge, polymeric DNA delivery agents comprising heparin binding domains attached to star-shaped PEG molecules have not yet been applied for pDNA delivery and may offer advantages in both reduced aggregation and improved transfection efficiency.

In this study, we chose to examine the PEG-HBP macromolecules for their ability to complex pDNA and deliver it into a mammalian cell line. As displayed in Figure 1, five different heparin binding peptides (HIP, sHIP, ATIII, $PF4_{ZIP}$, and RRP) were selected for attachment to the PEG-star macromolecules. All five peptides are positively charged at physiological pH and should therefore be capable of electrostatically complexing DNA. The peptide sequences were each selected for their high affinity for heparin. The HIP and ATIII peptides are derived from the heparin binding domains of heparin-interacting protein and antithrombin III, respectively (*38, 39*). The peptide denoted sHIP represents a motif generated by scrambling the HIP sequence, which was synthesized to confirm the role of sequence

Table 2. Heparin Binding Affinity Data (at 25 °C) for Heparin Binding Peptides Determined via Affinity Chromatography and SPR at pH = 7.4

HBP	salt required for elution from heparin column (mM)	k_a ($M^{-1}s^{-1}$)	k_d (s^{-1})	K_D (M)	PEG-HBP	salt required for elution from heparin column (mM)
$PF4_{ZIP}$[a]	882 ± 3	$2.24 \pm 0.05 \times 10^5$	$2.56 \pm 0.10 \times 10^{-3}$	$1.14 \pm 0.03 \times 10^{-8}$	PEG-$PF4_{ZIP}$	798 ± 13
RRP	1160 ± 10	$2.64 \pm 0.08 \times 10^5$	$1.18 \pm 0.12 \times 10^{-3}$	$4.47 \pm 0.34 \times 10^{-9}$	PEG-RRP	1271 ± 1
HIP[b]	695 ± 14	$1.10 \pm 0.08 \times 10^3$	$4.64 \pm 0.02 \times 10^{-3}$	$4.21 \pm 0.3 \times 10^{-6}$	PEG-HIP	628 ± 7
sHIP	929 ± 4	$9.29 \pm 0.17 \times 10^4$	$5.62 \pm 0.13 \times 10^{-3}$	$6.05 \pm 0.03 \times 10^{-8}$	PEG-sHIP	763 ± 4
ATIII[b]	594 ± 2	$1.56 \pm 0.06 \times 10^2$	$2.00 \pm 0.3 \times 10^{-3}$	$1.28 \pm 0.13 \times 10^{-5}$	PEG-ATIII	558 ± 1

specificity in heparin binding (*45*) and to test the hypothesis that heparin binding alone, outside of changes in peptide composition and charge density, plays a role in controlling DNA delivery. The $PF4_{ZIP}$ sequence is a dimeric coiled-coil, heparin binding peptide modeled after the heparin binding domain of human platelet factor 4 (*40*). The RRP sequence (Table 1) was chosen on the basis of the fact that arginine is a commonly identified residue in randomly synthesized 7-mer peptides that have been shown to efficiently bind to and immobilize heparin (*31, 32*). Additionally, polyarginine peptides have been shown to have promising transfection properties (*46*). The glycine residues were included in the RRP sequence to provide flexible linkers between the short oligo-arginine sequence and the PEG backbone.

The previously unreported PEG-RRP and PEG-sHIP conjugates have been successfully synthesized via Michael addition reactions between vinyl sulfone-terminated four-arm PEG (*47*) and cysteine-terminated HBPs, using a similar method applied previously for the synthesis of other PEG-HBP conjugates (*36*). Functionalization of the PEG-star termini with the HBPs has yielded values of 77% (*35*), 63% (*36*), and 59% (*37*) for the PEG-HBP modified with the heparin binding proteins HIP, ATIII, and $PF4_{ZIP}$, respectively. Similarly, in these investigations, the compositions of the PEG-RRP and the PEG-sHIP were determined from their ^1H NMR spectrum (see Supporting Information). Functionalization of the PEG-RRP was found to be 119%. This may result from association of the RRP peptides during synthesis and purification. Significant aggregation is not suggested to occur between the PEG-RRP conjugates, as solutions of the PEG-RRP remain clear and nonviscous. Functionalization of the PEG-sHIP was found to be 100%. It has been previously demonstrated that the PEG-HBPs readily associate with multivalent heparin moieties to form noncovalently associated hydrogels (*35–37*). Therefore, although the precise number of termini modified with RRP cannot be determined, we anticipated that a sufficient number of PEG termini were modified with the RRP to support network, and therefore polyplex, formation (functionalization ≥2). The functionalization values of 77% (PEG-HIP), 100% (PEG-sHIP), 63% (PEG-ATIII), 59% (PEG-$PF4_{ZIP}$), and 119% (PEG-RRP) were used in all charge ratio calculations for PEG-HBP/pDNA polyplexes.

II. Heparin Binding Affinity of HBPs. Previous reports have demonstrated that targeting ligands, such as monoclonal antibodies, peptides, and sugars, can be conjugated to DNA carriers to promote receptor-mediated endocytosis (*48, 49*). Additionally, a limited number of reports suggest that modification of viral vectors via the use of heparin and heparan-binding peptides enhance binding with heparan sulfate-associated endocytic receptors on a broad range of cell types, thus increasing internalization (*42, 43*). Heparin-sepharose affinity chromatography and surface plasmon resonance (SPR) experiments were therefore performed to compare the heparin binding affinity of different HBPs to confirm the potential difference in cellular uptake between PEG-HBP/pDNA complexes. Results of these experiments are summarized in Table 2. For heparin affinity chromatography experiments, the concentration of NaCl required for HBP elution from a heparin-sepharose column is used as an indication of the affinity of the peptide for heparin. Elution from the heparin-sepharose column required a salt concentration of 1160 ± 10 mM for RRP and 929 ± 4 mM for sHIP (Table 2). Comparison of these values to those obtained with the previously synthesized peptides (HIP: 695 ± 14 mM, ATIII: 594 ± 2 mM, $PF4_{ZIP}$: 882 ± 3 mM) indicates that RRP has the highest heparin binding affinity. The enhanced heparin binding of the nonspecific RRP sequence is likely due to the high cationic charge density of this peptide and suggests the potential for the PEG-RRP to elicit the highest cellular uptake of the PEG-HBPs.

The sHIP peptide, which is composed of a scrambled HIP sequence, was actually found to have higher binding affinity for heparin than the natural HIP sequence. Although this result was not anticipated, the sHIP sequence serves as an excellent comparison for assessing the role of heparin binding affinity in DNA transfection efficiency because it removes the complications of differences in composition and charge density. In order to support this initial finding, further SPR binding experiments were conducted.

The interaction of the five HBPs with a low molecular weight heparin-modified SA chip surface was investigated and results are reported in Table 2. No mass transport limitations, linked reactions, or nonspecific binding of HBP to SA chips were observed in any of the SPR measurements, as assessed via manufacturer-recommended standard control experiments (see Supporting Information). Analysis of the association and dissociation regions of the binding curves provided relative association and dissociation rates for comparison to previous studies conducted on the same chip surface (*35, 37*). The measured association of the RRP with LMWH proceeds with a rate constant of $2.64 \pm 0.08 \times 10^5$ M^{-1} s^{-1} based on the analysis of the association regions of the binding curves, while the dissociation proceeds with a rate constant of $1.18 \pm 0.12 \times 10^{-3}$ s^{-1}, yielding a K_D of $4.47 \pm 0.34 \times 10^{-9}$ M. Similar calculations resulted in a K_D value of $6.05 \pm 0.03 \times 10^{-8}$ M for the sHIP peptide (Table 2). Comparison of these results to our previous studies indicates that faster association kinetics for RRP, sHIP, and $PF4_{ZIP}$, relative to those reported for the ATIII and HIP (*35*), are the primary cause of the lower calculated K_D values, and the trend of the dissociation constants is consistent with the chromatography results. Furthermore, relative to the reported value for HIP, the K_D value of the sHIP peptide is lower and agrees with our chromatography results. This confirms the higher heparin affinity of the sHIP sequence versus the natural HIP sequence. Overall, the more rapid association rate, coupled with the similar dissociation rate of RRP, sHIP, and $PF4_{ZIP}$ versus the other HBPs, suggest the strong binding of anionic heparin by these peptides, which suggests their strong interaction with cell surfaces.

Heparin affinity of the PEG-HBP conjugates was also investigated using column chromatography. As shown in Table 2, the trend in heparin binding affinity of the PEG conjugates correlate well with the free peptides, with PEG-RRP, $PF4_{ZIP}$,

Table 3. Heparin Binding Affinity Data (at 25 °C) for $PF4_{ZIP}$ (peptide) at Various pH Values, as Determined via SPR

pH	k_a (M^{-1} s^{-1})	k_d (s^{-1})	K_D (M)
6	$1.11 \pm 0.03 \times 10^4$	$7.05 \pm 0.03 \times 10^{-4}$	$6.35 \pm 0.20 \times 10^{-8}$
7.4	$2.24 \pm 0.05 \times 10^5$	$2.56 \pm 0.10 \times 10^{-3}$	$1.14 \pm 0.03 \times 10^{-8}$
8	$1.97 \pm 0.08 \times 10^4$	$8.70 \pm 0.49 \times 10^{-3}$	$4.42 \pm 0.63 \times 10^{-7}$

Table 4. Heparin Binding Affinity Data (at 25 °C) for RRP (peptide) at Different pH Values, as Determined via SPR

pH	k_a (M^{-1} s^{-1})	k_d (s^{-1})	K_D (M)
6	$1.35 \pm 0.13 \times 10^4$	$1.00 \pm 0.01 \times 10^{-3}$	$7.41 \pm 0.82 \times 10^{-8}$
7.4	$2.64 \pm 0.08 \times 10^5$	$1.18 \pm 0.12 \times 10^{-3}$	$4.47 \pm 0.34 \times 10^{-9}$
8	$9.94 \pm 0.26 \times 10^3$	$5.33 \pm 0.15 \times 10^{-3}$	$5.36 \pm 0.01 \times 10^{-7}$

Table 5. Heparin Binding Affinity Data (at 25 °C) for sHIP (peptide) at Various pH Values, as Determined via SPR

pH	k_a (M^{-1} s^{-1})	k_d (s^{-1})	K_D (M)
6	$2.73 \pm 0.08 \times 10^4$	$1.36 \pm 0.01 \times 10^{-2}$	$4.98 \pm 0.12 \times 10^{-7}$
7.4	$9.29 \pm 0.17 \times 10^4$	$5.62 \pm 0.13 \times 10^{-3}$	$6.05 \pm 0.03 \times 10^{-8}$
8	$2.26 \pm 0.22 \times 10^4$	$1.82 \pm 0.04 \times 10^{-2}$	$8.05 \pm 0.86 \times 10^{-7}$

and sHIP displaying highest binding affinity. In general, the PEG-HBP conjugates required slightly lower salt concentration for elution from the heparin-modified column. This seemed surprising, since multivalent presentation of binding epitopes often results in binding enhancements due to statistical and multivalent effects. However, the PEG-HBP conjugates are of low molecular weight and low valency (3–4 peptides per conjugate), and such polymers often do not show significant multivalent enhancement (*50*). In any case, the focus of these studies was to determine the heparin binding affinity of the PEG-HBPs for correlation to DNA delivery efficiency, and our results demonstrate that the heparin binding affinities of the HBPs have similar trends regardless of their conjugation to PEG.

As a control, we performed chromatography experiments on PEI, which is a commonly used transfection reagent. It was found that PEI eluted at 1980 ± 0.002 mM NaCl, which indicates that this incredibly charge-dense polycation binds heparin with very high affinity. However, the PEI−heparin binding mechanism likely involves a great deal of cooperativity, which may cause the dissociation of pDNA at the cell surface and decreased cellular uptake. We propose that the multivalent cationic nature of the PEG-HBPs holds the most promise for simultaneous binding of DNA and cell-surface heparan via electrostatic interactions.

Cellular uptake and release of PEG-HBP/pDNA complexes via endocytosis may be directly affected by the progressive acidification from the physiological pH (7.4) of the extracellular medium to pH 6.5–6.0 in endosomes (*51*). The heparin binding kinetics between low molecular weight heparin and the peptides of highest heparin affinity (RRP, sHIP, and $PF4_{ZIP}$) were monitored via SPR at pH values between 6 and 8, to determine potential changes in binding kinetics that might alter the process of cellular uptake or release of pDNA from the PEG-HBP/pDNA complex. An increase in the K_D value signifies a decrease in the affinity of the peptide for heparin. As shown in Tables 3, 4, and 5, K_D values for PEG-RRP, sHIP, and $PF4_{ZIP}$ generally increase slightly as the pH is lowered below 7.4, which suggests that the PEG-HBP/pDNA bound to the cell-surface heparan sulfates will likely remain associated with these proteoglycans during internalization, but may begin to dissociate from heparan sulfate as the polyplex/heparan sulfate complexes begin to traffic through the progressively acidifying vesicles of the endocytic pathway. Such dissociation of the vectors from internalized heparan sulfate in the endosomes may enhance the intracellular motility of the complexes out of these vesicles.

III. DNA Binding. For use as potential nucleic acid delivery vectors, the conjugates must be able to package DNA into small particles capable of being endocytosed. The PEG-HBP/pDNA complexes are described by their charge ratio, which is a ratio that indicates the number of positively charged residues in the peptide sequence to the number of anionic phosphate residues in the DNA backbone. The amount of material needed to completely complex the DNA is established by this assay, with results shown in Figure 2. The lane in which pDNA no longer migrates through the gel is regarded as the charge ratio at which the PEG-HBPs completely complex pDNA (see Figure 2a, lanes 2–50). This assay indicates that the PEG-HBPs are able to complex pDNA at a charge ratio of 2 or lower. Similar values have been reported for PEGylated poly(L-lysine) vectors which have previously shown promising transfection characteristics (*19, 20, 52*).

At higher charge ratios, the bands produced by polyplexes created with PEG-RRP and PEG-ATIII appeared to fade and disappear (*i.e.*, Figure 2b,e, lanes 5–50), which may indicate that these star polymers were able to bind pDNA sufficiently tightly to exclude the intercalating agent ethidium bromide used to visualize the bands. Moreover, the ATIII peptide has two aromatic residues that may be capable of intercalating pDNA; this may displace ethidium bromide as well and contribute to the low charge ratio needed to complex pDNA. It is worth noting that both PEG-RRP and PEG-ATIII demonstrate similar qualitative pDNA binding in these gel experiments, despite the significant differences in their heparin binding affinity, suggesting that the strength of heparin binding does not correlate to the ability of the polymer to complex pDNA, as might be expected since the associations involve different binding motifs.

CD characterization of peptide conformation at charge ratios of 5 (sufficient to completely complex DNA in all cases) and 1 (to increase the relative amount of bound peptide in the sample) indicated that the HBPs showed no significant change in conformation upon binding DNA (see Supporting Information), although changes in peptide conformation upon the binding of DNA have been previously observed for select peptides (*53*). Therefore, it is expected that observed differences in DNA binding and transfection efficiency result from the physicochemical properties of the peptide and not from additional conformational changes upon complexation.

IV. Polyplex Size. The salt and serum stability of polyplexes is critical for their application *in vivo*; if the particles are unstable at high ionic strength and in the presence of serum proteins, they may aggregate to form large particles which would be detrimental to their efficacy. Dynamic light scattering was therefore employed to measure the size of the PEG-HBP/pDNA polyplexes in various dispersants over time.

The size of the polyplexes formed between the star macromolecules and pDNA, shown in Figure 3, again displayed a dependence on the cationic peptide moiety of the vector. The polyplex solutions created with PEG-HIP in Opti-MEM and PEG-ATIII created in DMEM revealed bimodal peaks in size measurements. The large difference in size between the two populations likely indicates that the shapes of the polyplexes created with these vectors are too complex to fit to the simple algorithm supplied by the manufacturer, which assumes spherical particles. Furthermore, inspection of the size distribution fit depicts three slopes, which likely indicate more than one mode of motion over time and also suggest the lack of spherical shape of the particles. Previous work has shown that the morphology of DNA/polycation complexes varies with the chemical structure of the cationic vector (*54*). Particularly, AFM microscopy studies have shown that polyplexes created with PEGylated poly(amidoamines) exhibit both torodial and rodlike morphologies (*55*). These studies also have reported the visualization of a dynamic

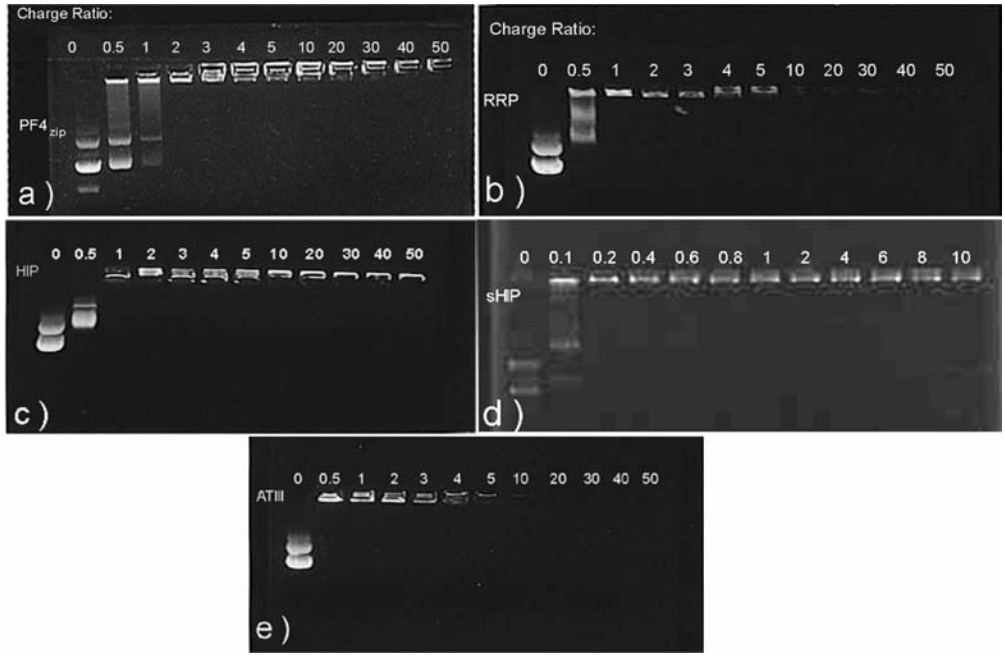

Figure 2. Results of the gel shift assays. (a) PEG-$PF4_{ZIP}$. (b) PEG-RRP. (c) PEG-HIP. (d) PEG-sHIP. (e) PEG-ATIII. Polyplexes were created at the indicated charge ratios in water. Samples were electrophoresed in an agarose gel under a 60 V electric field.

equilibrium in the spatial conformations of the polyplexes (*55*). Our experiments are consistent with the potential existence of varied structures in polyplexes created with PEG-HIP in Opti-MEM and PEG-ATIII in DMEM, so an accurate assessment of particle size under these conditions cannot be made. No other polyplex/condition exhibited such bimodality. Further investigations of the size and morphology of these polyplexes via TEM studies are in progress.

In water, the polyplex size varies between about 90 and 200 nm, which is consistent with the sizes of polyplexes created with un-PEGylated polycations (*54*, *56–58*). Upon the addition of Opti-MEM, PEG-$PF4_{ZIP}$ and PEG-ATIII polyplexes did not aggregate and showed a small and uniform polyplex size over 120 min. In the presence of DMEM (containing 10% serum), all of the PEG-HBP polyplexes showed some increase in size. PEG-HIP polyplexes rapidly aggregated to almost 5 μm after 20 min. In contrast, PEG-$PF4_{ZIP}$, PEG-sHIP, and PEG-RRP polyplexes yielded particles of roughly 500 nm upon initial DMEM addition that did not change significantly in size (relative to the other systems) over the course of 120 min. PEG-sHIP appears to be particularly stable in serum-containing media relative to the other PEG-HBP vectors. The utility of particles in this size range is suggested by previous studies. For example, particles as large as 200 nm can enter the endocytic pathway through clathrin- and caveolae-mediated endocytosis, and particles as large as 2 μm can enter the cell through macropinocytosis (*59*, *60*). Additionally, it has been shown that polyplexes can enter the cell through multiple uptake pathways (*61*). The ability of the polyplexes to be trafficked in the nucleus may be less clear, as recent research has shown that the nuclear pore complex is capable of importing particles up to 39 nm in size (*62*). While this topic is still being actively investigated in *in vivo* systems utilizing slowly dividing cells, the scope of our current research focuses on *in vitro* procedures that likely allow polyplex diffusion into the nucleus during the rapid mitosis of cell lines in culture. Although the sizes of PEG-$PF4_{ZIP}$, PEG-sHIP, and PEG-RRP polyplexes are somewhat larger than ideal, the size stability of these vectors over the course of 2 h evidence their promise for future studies, particularly given the low molecular weight of the PEG employed (~2700 Da per arm). The use of PEG star polymers of higher molecular weight may result in particles that are completely stable from aggregation in the presence of serum; previous studies have shown that PEG_{5000} is typically required to stabilize the size of polyplexes formed from PEG-PEI polymers (*63*).

V. Cell Viability Studies. To examine how well the PEG-HBPs perform under biological conditions, *in vitro* transfection studies were conducted with BHK-21 (golden Syrian hamster kidney) cells. A commonly used transfection polymer, PEI, was used as a positive control to compare the relative toxicity of the novel experimental vectors. The toxicity of polyplexes was measured via a protein assay of the cell lysates, normalized against a nontransfected control, to obtain the fraction of cell survival. This assay was performed on cells transfected both without serum (Opti-MEM) and in culture media containing 10% FBS (DMEM) to help draw conclusions about the serum stability of the complexes and their efficacy.

Figure 4a reveals the viability of BHK-21 cells transfected in Opti-MEM over a variety of charge ratios. The results show that the cell survival in the presence of PEG-$PF4_{ZIP}$, PEG-HIP, and PEG-sHIP polyplexes remains high (>90%) up to a charge ratio of 15, and greater than 50% survival was found at a charge ratio of 30. PEG-sHIP shows particularly low toxicity, even at high charge ratio doses. In contrast, the polyplexes formed with PEI, PEG-RRP, and PEG-ATIII were found to be quite toxic. Notably, PEG-ATIII is extremely toxic—even more toxic than PEI, which is well-known to exhibit high cytotoxicity in many cell lines. PEG-RRP appears to have low cytotoxicity at a low charge ratio of 5, but the toxicity rapidly increases at higher doses. All three of these vectors, PEG-ATIII, PEG-RRP, and PEI, show less than 50% viability at an N/P ratio of 15 or above. Figure 4b depicts the viability of BHK-21 cells transfected in the presence of 10% serum; the data indicate the reduced toxicity of all of the vectors under these experimental conditions, which is likely to result from a simple reduction in cellular uptake of the polyplexes as a result of their larger size in serum, consistent with previous reports of decreasing cellular uptake of polycationic vectors in the presence of serum (*6*).

The trend of toxicity among PEG-HBPs generally correlates with the cationic charge density of the peptide, with the PEG-RRP displaying greater cytotoxicity than the PEG-$PF4_{ZIP}$ or PEG-HIP. Other studies have also shown that the cytotoxicity

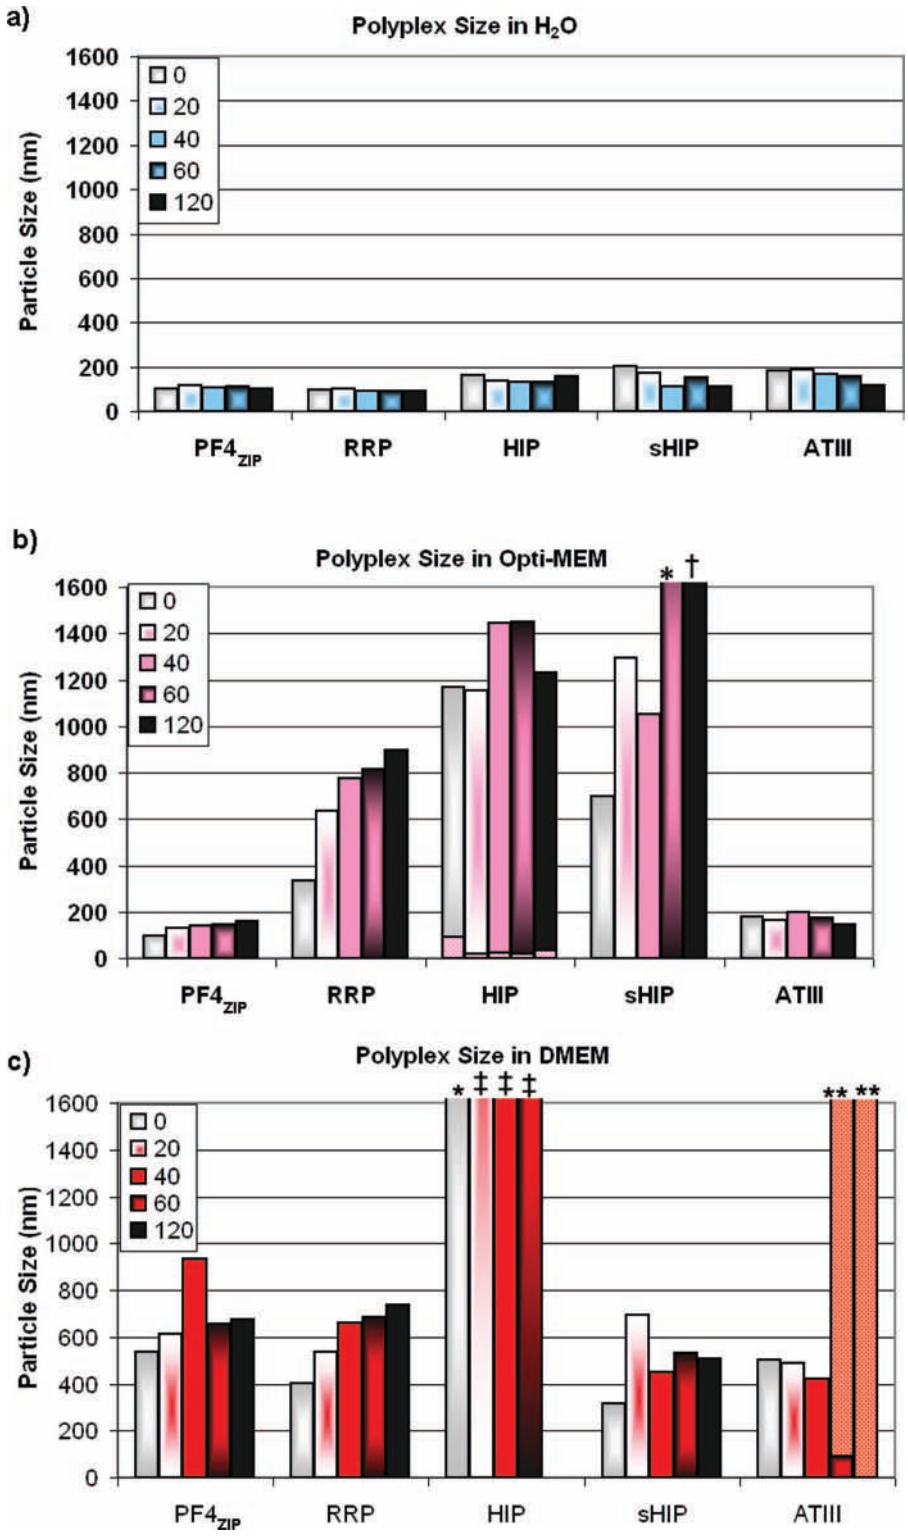

Figure 3. Particle sizes of PEG-HBP/pDNA polyplexes in various dispersants. Polyplexes were formed by adding an equal volume of PEG-HBP solution to pDNA at a charge ratio of 5 in water. Dynamic light scattering was used to measure the hydrodynamic diameter of the polyplexes at time 0 (immediately after addition of dispersant) and thereafter consecutively at 20, 40, 60, and 120 min. (a) Sizes of the polyplexes dispersed in water. (b) Sizes of the polyplexes dispersed in serum-free Opti-MEM. (c) Sizes of the polyplexes dispersed in DMEM containing 10% FBS. Overlaid bars are indicative of bimodal data. * denotes ~2 μm, ** denotes ~3 μm, † denotes ~4 μm, ‡ denotes 4.5–5 μm.

of PEG-RRP is high even compared with other cationic peptides, such as antennapedia, TAT, and transportan (*64*), likely as a result of this high charge density (*14*). The RRP peptide employed in these studies has a charge density of 0.58 (7 arginines out of 12 total amino acids), while the ATIII, HIP, and $PF4_{ZIP}$ peptides have charge densities of 0.33, 0.31, and 0.18, respectively. The PEG-sHIP vector deviates slightly from this trend. However, the toxicity is very low and similar to PEG-HIP, which is expected given their identical composition. The unusually high toxicity of the PEG-ATIII polyplexes, despite the lower cationic charge density, most likely results from the higher hydrophobicity of the peptide (which contains two aromatic residues). This is consistent with the previously reported toxicity of positively charged and hydrophobic peptides

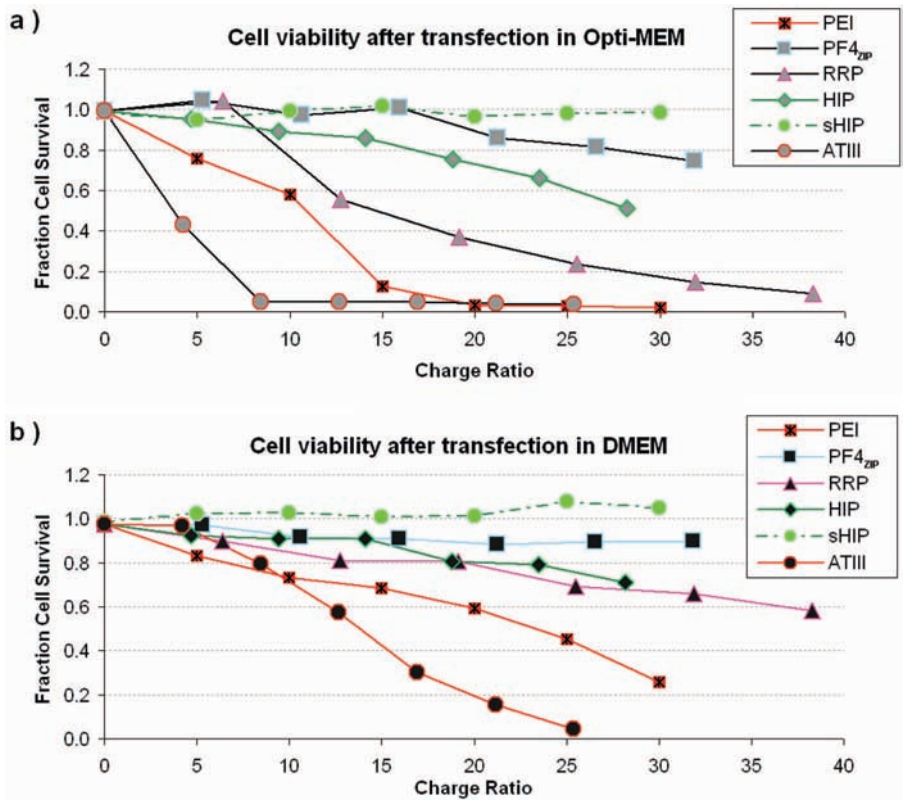

Figure 4. Viability of BHK-21 cells after transfection with polyplexes created with PEG-HBPs in both (a) nonserum and (b) 10% serum conditions at the indicated charge ratios for 48 h. Cells were lysed after 48 h, and protein content was assayed and normalized against a nontransfected control to obtain the fraction of cell survival. Data are reported as a mean ± standard of deviation of three replicates.

of similar cationic charge (of about 5–7 positive charges per peptide) (*65*, *66*). Importantly, the cell viability profiles of transfections performed with PEG-sHIP, PEG-$PF4_{ZIP}$, and PEG-HIP are very promising in comparison to the unmodified PEI control and are also significantly improved relative to that reported for PEGylated PEI polymers (in which cells reveal less than 50% cell viability in transfection experiments performed above a charge ratio of 20) (*17*). PEG-$PF4_{ZIP}$ and PEG-sHIP, in particular, show extremely promising cell viability data, with at least 80% cell viability at a high charge ratio of 30, even under serum-free conditions.

VI. Transfection Efficiency Studies. To determine the overall transfection efficiency of the vectors, the PEG-HBPs were complexed with plasmids encoding the luciferase reporter gene for transfection of BHK-21 cells. A luciferase reporter gene assay was performed in both serum-free conditions (Opti-MEM) and conditions containing serum (DMEM with 10% FBS) to study the transfection efficiency of these vectors. Again, the widely used polymer, PEI, was included as a positive control, as this vector has shown high transfection efficiency despite its increased toxicity. Figure 5 depicts the results of these reporter gene assays.

The results of transfection efficiency in Opti-MEM shows that PEG-$PF4_{ZIP}$, PEG-sHIP, and PEG-RRP polyplexes demonstrated significantly higher transfection efficiencies ($\sim 1 \times 10^8$ RLU/mg protein) than PEG-HIP and PEG-ATIII polyplexes ($<1 \times 10^7$ RLU/mg protein), as shown in Figure 5a. Although transfection efficiency for the PEI positive control is initially high, it was only measurable up to an N/P ratio of 10 in Opti-MEM due to the high toxicity of this vector at elevated doses, which detracts from its utility as a delivery vector. Similarly, delivery data for PEG-ATIII polyplexes in Opti-MEM and DMEM could only be obtained at maximum charge ratios of 5 and 25, respectively. Despite the apparent high transfection efficiency of PEG-ATIII, the toxicity profile is unsuitable for delivery applications, and this vector will not be discussed further.

The data in Figure 5a also indicate the similar transfection efficiencies of PEG-$PF4_{ZIP}$, PEG-sHIP, and PEG-RRP polyplexes, despite the large difference in their aggregation behavior (Figure 3b), indicating that other steps in the transfection pathway such as endosomal escape and subsequent intracellular mobility play a large role in the overall transfection efficiency. It is well-documented that the intracellular travel of polyplexes likely involves acidic vesicles of the endosomal trafficking pathway (*61*). The K_D of the HBPs with heparin measured at acidic pH values (Tables 3–5) suggests the potential for increased dissociation of the peptides from heparan sulfate (bound to the internal membrane of endosomal vesicles) during intracellular travel. A positive effect on the transfection efficiency pathway could result and may be due to the increase in the mobility of the pDNA once inside the cell.

In addition, these vectors showed maximum transfection efficiencies at a charge ratio of 5, suggesting the utility of these and similar vectors owing to the low toxicity (Figure 4a) and vector concentration needed to promote efficient delivery. The transfection efficiencies of PEG-RRP and PEG-$PF4_{ZIP}$ are nearly identical up to a charge ratio of 25, although the PEG-RRP vectors were highly toxic, and the $PF4_{ZIP}$ vectors showed little toxicity at the same transfection level. The PEG-sHIP exhibits similar transfection efficiency as that of PEG-$PF4_{ZIP}$, with no toxicity, and a greater efficiency than PEG-HIP, consistent with the heparin binding data. Overall, the transfection assays in Opti-MEM strongly indicate the potential and enhanced utility of HBPs of specific sequences, relative to other nonspecific, high charge density polymers such as polyarginine and PEI, via the optimization of transfection efficiency per unit of cationic charge.

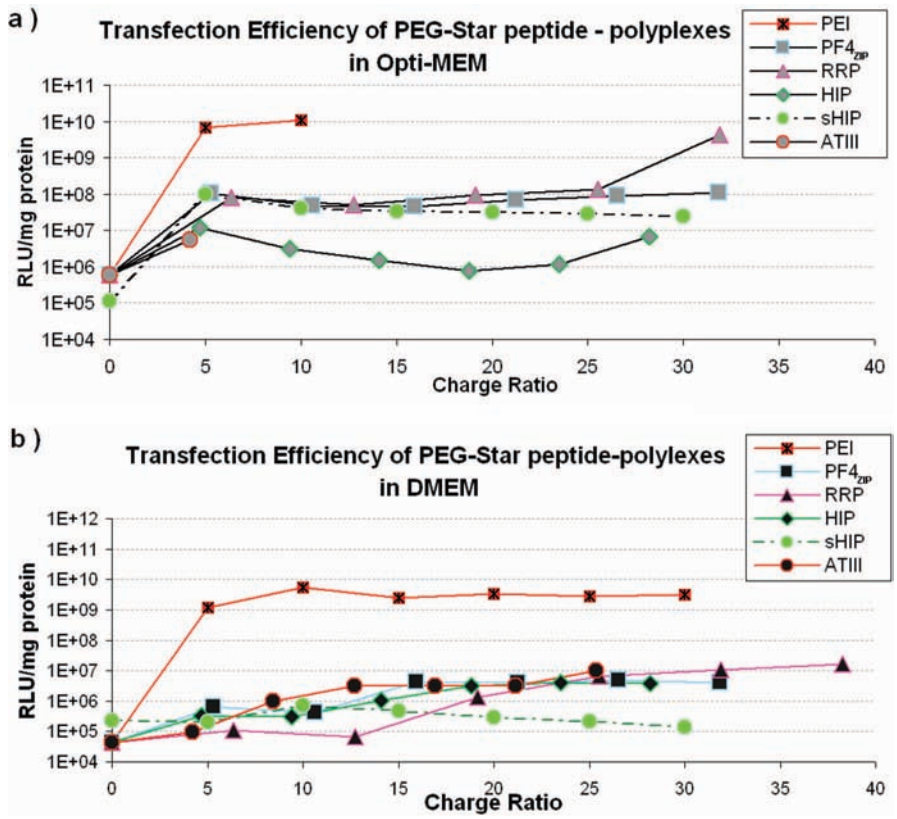

Figure 5. The transfection efficiency of PEG-HBP/pDNA polyplexes in (a) nonserum- and (b) serum-containing conditions. BHK-21 cells were transfected with polyplexes containing the reporter gene for luciferase and incubated for 48 h. A luciferase assay was performed on the cell lysates and data is displayed as RLU/mg protein. Data are reported as a mean ± standard of deviation of three replicates.

Comparison of the data in Figure 5a and b reveals that transfections with most of the PEG-HBPs in DMEM (Figure 5b) displayed a 10- to 100-fold reduction in efficiency when compared to transfections performed in Opti-MEM (Figure 5a). Such a decrease was not observed for PEI in these experiments. When coupled with the decrease in viability of cells transfected with PEI at increasing N/P ratios (80% at N/P 5, 40% at N/P 25), these results may suggest differences in endosomal escape, DNA protection from nucleases, and nuclear trafficking for the PEI relative to the PEG-HBPs. Engineering such responses in the PEG-HBPs could significantly improve their transfection performance in serum-containing media. In addition, the plateau in transfection efficiency of the polyplexes in DMEM did not occur until a charge ratio of approximately 20–25, which may reflect the increased amount of polymer required to sufficiently stabilize the pDNA polyplexes in medium containing serum. Indeed, the transfection efficiency of the PEG-sHIP vector, which appears to be more serum stable than the rest of the PEG-HBP vectors, plateaus at a lower charge ratio of 10, in agreement with this observation.

Taken altogether, the data from these investigations show a general correlation between the heparin binding affinity of the peptide and the transfection efficiency of the PEG-HBP conjugate. The heparin affinity chromatography and SPR experiments (Table 2) indicated heparin binding affinity in the order RRP > $PF4_{ZIP}$ ≈ sHIP > HIP > ATIII, which is very similar to the trend in transfection efficiency in Opti-MEM. That is, PEG-RRP, PEG-sHIP, and PEG-$PF4_{ZIP}$ show significantly increased transfection efficiencies over the PEG-HIP and PEG-ATIII vectors. This correlation suggests the importance of cell-surface association with glycosaminoglycans in the trafficking of these vectors, promoting enhanced cellular uptake by increasing polyplex—glycosaminoglycan affinity. To further examine specific events involving cellular binding and internalization, we investigated the cellular uptake of DNA via flow cytometry.

VII. Cellular Internalization Studies. To more specifically concentrate on the effect of cell-surface binding and internalization of the PEG-HBPs, flow cytometry was used to measure the amount of DNA internalized by transfected cells. BHK-21 cells were transfected with Cy5-labeled pDNA and subjected to analysis via flow cytometry. An N/P ratio of 5 was chosen, as it showed maximum transfection efficiency for the vectors in serum-free media. In all samples, greater than 80% of cells exhibited Cy5 fluorescence (data not shown). Figure 6 depicts the results of these internalization studies.

The trend in cellular internalization of Cy5-labeled pDNA among PEG-HBPs (PEG-RRP > PEG-$PF4_{ZIP}$ >PEG-sHIP > PEG-HIP ≈ PEG-ATIII) is almost identical to the observed trend in heparin affinity (RRP > $PF4_{ZIP}$ ≈ sHIP > HIP > ATIII). Furthermore, the increased heparin binding affinity of sHIP versus HIP is reflected in the internalization experiments. Interestingly, PEG-ATIII, which has been shown to give stable polyplexes in nonserum-containing media (Figure 3b), shows very low cellular uptake. This result is likely due to the lowered affinity of this peptide for heparin (Table 2) and further illustrates the utility of cell-surface binding peptides for controlling internalization.

These cellular uptake results also corroborate the trend in luciferase gene expression and further substantiate our hypothesis that enhanced cell binding increases cellular delivery. Furthermore, the trend in the magnitude of internalization generally correlates with gene expression; for example, the internalization and transfection efficiency of PEG-RRP and PEG-$PF4_{ZIP}$ are about 1 order of magnitude higher than those of PEG-HIP. This may be due to the combined effect of the

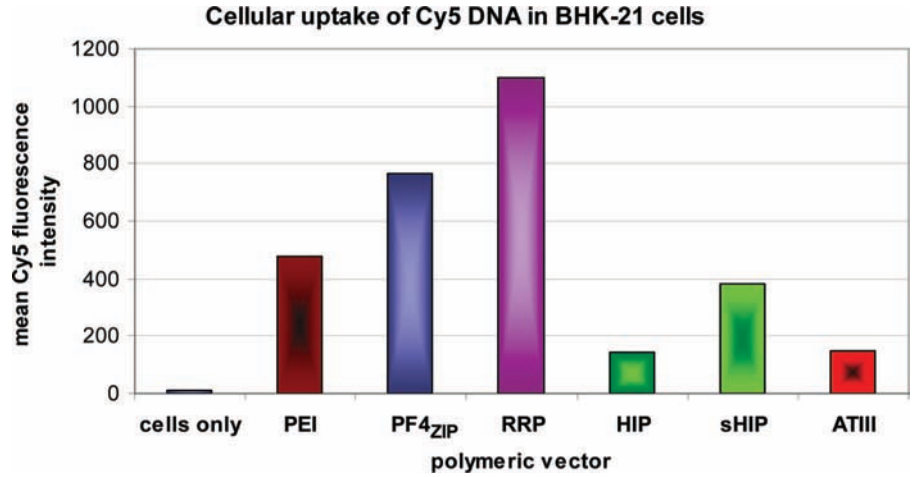

Figure 6. The cellular uptake of Cy5-labeled DNA via polyplexes in nonserum-containing media. BHK-21 cells were transfected with polyplexes formulated with Cy5-labled DNA. Four hours after transfection, the cells were washed well with PBS and allowed to traffic for 2 more hours. The cells were then trypsinzed and analyzed via flow cytometry. Each sample represents the mean fluorescence in 50 000 cells.

decreased polyplex stability (Figure 3b) and heparin binding affinity (Table 2) of the HIP peptide.

The two strongest binding PEG-HBPs, PF_{4ZIP} and RRP, were internalized to a larger degree than the positive control, PEI, despite the higher heparin binding affinity of PEI. These data lend further confidence to our proposal that the multivalent star architecture of the PEG-star HBPs allows simultaneous binding of DNA at the core of the polyplex and heparan sulfate at the surface of the cell. Conversely, the PEI-DNA polyplex, dependent on cooperative interactions between the polymers to remain intact, may be more susceptible to competition with extracellular polyanions such as heparan sulfate. PEI from the surface of the polyplex may bind with heparan sulfate at the surface of the cell in a cooperative manner, leading to extracellular unpackaging of DNA. Clearly, the molecular architecture of the polymeric ligand, as well as the heparin binding affinity of the cationic moiety plays a large role in the cell-surface kinetics and internalization pathways of the polyplexes. It should be noted that although the cellular uptake of PEG-RRP and PEG-$PF4_{ZIP}$ was higher than that of PEI (Figure 6) their gene expression profiles were still lower than observed with PEI (Figure 5). This suggests that endosomal escape could be a barrier for the PEG-HBP vectors.

CONCLUSIONS

Five PEG-HBPs, capable of multivalent interactions with polyanionic biological molecules, have been shown to bind both heparin and plasmid DNA sufficiently well to make them useful for a variety of applications. Examination of dynamic light scattering data revealed that three polyplexes, produced with PEG-RRP, PEG-sHIP, and PEG-$PF4_{ZIP}$, had notable stability against aggregation in cell culture media containing 10% serum. Transfection studies complemented these results and showed that these vectors also appear to have significant transfection efficiency in BHK-21 cells under both conditions. With the exception of the PEG-ATIII polyplex (which is very cytotoxic), increased heparin affinity correlated with increased transfection efficiency. This correlation was further indicated in the relationship between heparin affinity and cellular uptake. Most clearly, this is evidenced by the increased cellular uptake of PEG-sHIP polyplexes relative to those prepared with PEG-HIP; these are compositionally identical peptides which differ only in that the sHIP sequence demonstrated higher heparin affinity than the nonscrambled HIP sequence. These results suggest that cell-surface binding and uptake, mediated by heparan sulfate, play a large role in the overall transfection pathway of these vectors.

Comparison of polyplexes created with PEG-$PF4_{ZIP}$ and charge-dense polyplexes (PEG-RRP and PEI) demonstrates that an increase in heparin affinity alone can confer improved transfection efficiency without requiring an increase in the charge density and resulting toxicity. Furthermore, the PEG-HBPs which bind heparin mostly strongly, PEG-RRP and PEG-$PF4_{ZIP}$, have enhanced cellular uptake compared to PEI, whose charge density is much higher than any of the PEG conjugates. These data corroborate our proposal that the multivalent presentation of peptides permit simultaneous interaction between DNA at the core of the polyplex and heparan sulfate at the surface of the cell without disruption of the polyplex, enhancing cellular uptake. Given the flexibility of synthetic strategies for producing PEG-HBPs with varying architectures and peptide identity, these results suggest that the star PEG-HBPs are promising and versatile candidates as gene delivery vectors.

ACKNOWLEDGMENT

We gratefully acknowledge the National Institutes of Health (1-R01-EB003172-1) and the Arnold and Mabel Beckman Foundation for partial funding of the synthetic aspects of this project (KLK and LZ). TMR and KMF thank the Arnold and Mabel Beckman Foundation and the Department of Chemistry at the University of Cincinnati for partial funding of the biological studies performed herein. Additionally, we recognize and thank Nori Yamaguchi for assistance with the synthesis of some PEG−peptide conjugates and Yemin Liu for performing some of the gel-shift assays.

Received May 3, 2007; Revised Manuscript Received September 3, 2007

Radiolabeled anti-carcinoembryonic antigen (CEA) antibodies have the potential to give excellent images of a wide variety of human tumors, including tumors of the colon, breast, lung, and medullar thyroid. In order to realize the goals of routine and repetitive clinical imaging with anti-CEA antibodies, it is necessary that the antibodies have a high affinity for CEA, low cross reactivity and uptake in normal tissues, and low immunogenicity. The humanized anti-CEA antibody hT84.66-M5A (M5A) fulfills these criteria with an affinity constant of $>10^{10}$ M^{-1}, no reactivity with CEA cross-reacting antigens found in normal tissues, and >90% human protein sequence. A further requirement for routine clinical use of radiolabeled antibodies is a versatile method of radiolabeling that allows the use of multiple radionuclides that differ in their radioemissions and half-lives. We describe a versatile bifunctional chelator, DO3A-VS (1,4,7-tris(carboxymethyl)-10-(vinylsulfone)-1,4,7,10-tetraazacyclododecane) that binds a range of radiometals including ^{111}In for gamma-ray imaging and ^{64}Cu for positron emission tomography (PET), and which can be conjugated with negligible loss of immunoreactivity either to sulfhydryls (SH) in the hinge region of lightly reduced immunoglobulins or surface lysines (NH) of immunoglobulins. Based on our correlative studies comparing the kinetics of radiolabeled anti-CEA antibodies in murine models with those in man, we predict that ^{64}Cu-labeled intact, humanized antibodies can be used to image CEA positive tumors in the clinic.

INTRODUCTION

In order to be effective tumor imaging agents, radiolabeled antitumor antibodies must demonstrate both high tumor uptake and high tumor to normal tissue ratios (*1*). Monoclonal antibodies (150 kDa) have a relatively slow blood clearance (second phase half-life $t_{1/2\,\beta} = 48$–72 h), allowing ample time for high accumulation in tumor, but suffer from low tumor to normal tissue contrast due to slow clearance from the vasculature. In order to improve the dynamic biodistribution, researchers have focused their attention on engineering recombinant antibody fragments. For example, single-chain (sc) Fv recombinant antibodies (25 kDa) are rapidly cleared from the blood ($t_{1/2\,\beta} = 0.5$–2.0 h), resulting in very high tumor to blood ratios, but suffer from low accumulation of radioactivity in tumor. For this reason, intermediate-sized antibody fragments have been engineered and studied intensively (*2*). We have shown that, in order to predict optimal tumor imaging, one must account for both tumor uptake and tumor to normal tissue contrast using pharmacokinetic analytic indicators such as the Imaging Figure of Merit (*1*). In spite of the advancement of engineered antibody fragments, the fact remains that most new antibodies with clinical potential originate as intact immunoglobulins. Conversion of IgGs to optimized recombinant fragments is time-consuming and fraught with many problems, including the potential loss of immunoreactivity, loss of the original high affinity for target antigen, and difficulty in obtaining high production yields in culture. Therefore, we have investigated the development of methods that allow the direct imaging of tumors using intact immunoglobulins.

Another major consideration in developing a versatile radioimmunoimaging agent is the choice of radionuclide. While most intact antibodies can be easily and inexpensively radioiodinated, a potential drawback to radioiodinated antibodies is that they may be rapidly metabolized and dehalogenated in tissues, including the tumor, especially if the antigen undergoes internalization after binding to cells. Even in the case of anti-CEA antibodies that undergo negligible internalization, we and others have observed higher tumor uptake and persistence at the tumor site for radiometal, compared to radioiodine-labeled antibodies (*3*). For this reason, we have favored the use of radiometals for labeling antibodies, but there are still drawbacks including high normal tissue accumulation in the kidney and liver (*4*). Furthermore, to take advantage of the wide range of radiometals available, the antibody must be conjugated to a bifunctional chelator. Although much progress has been made in this area (*5*–*8*), the search for a truly versatile bifunctional chelator continues. In this report, we describe such a bifunctional chelator (DO3A-VS), based on the stable metal ion binding properties of the tetraazamacrocyle ring with pendent carboxymethy groups and the chemically reactive linker (vinylsulfone, VS) that can be conjugated to either the easily reduced disulfides in the immunoglobulin hinge region or surface lysines of intact antibodies. We demonstrate the versatility of DO3A-

VS in labeling a humanized anti-CEA antibody hT84.66-M5A and imaging tumors in a murine xenograft model using both ^{111}In for gamma-ray imaging and ^{64}Cu for PET imaging. The PET images obtained for ^{64}Cu-labeled M5A show excellent tumor to normal tissue ratios as early as 24 h postinjection, suggesting that intact antibodies radiolabeled with ^{64}Cu can be useful for imaging CEA-positive tumors in man.

PET imaging with the glucose analogue [^{18}F]fluorodeoxyglucose (FDG) has, in recent years, become the modality of choice for assessing extent of disease in many types of cancer, including those in which CEA expression is common. PET/FDG is also increasingly used for assessment of residual tumor viability and recurrence following treatment. Nonetheless, there remains a potential role for tumor-targeted PET imaging agents (immuno-PET, (*9*)) such as ^{64}Cu anti-CEA MAbs both due to the limitations of FDG (including uptake in regions of inflammation, high accumulation in bladder, and a tendency for low to moderate uptake in less aggressive tumors) and the need to assess tumor targeting and biodistribution in radioimmunotherapy with these antibodies. The use of radiometal positron emitters for immuno-PET is especially attractive, since they can be chelated to antibody–chelate conjugates in a kit form. Among the current choices are ^{86}Y with a half-life of 14.7 h (*10*), ^{89}Zr with a 3.3 d half-life (*11*), and ^{64}Cu with a 12.7 h half-life (*12*). Although ^{86}Y has the potential advantage of being coupled to ^{90}Y β particle therapy, its availability and prompt γ-emissions make its use limited. ^{86}Zr is attractive in terms of its long half-life and good spatial imaging, but has a potential problem with a 909 keV γ-emission. Appropriate BFCs for this metal ion have only recently been described (*11*). ^{64}Cu was chosen for the studies reported here based on its wide availability, good spatial resolution, and relatively short half-life, limiting its potential imaging dose to patients.

MATERIALS AND METHODS

Materials, Cell Culture, Antibody, Immunoreactivity, and Mass Spectrometry. DO3A tri-*t*-butyl ester and NHS-DOTA were obtained from Macrocyclics, Inc. (Dallas TX) The synthesis of DO3A-VS was previously described (*13*). SATA (*N*-succinimidyl-*S*-acetylthioacetate) was purchased from Pierce Biotechnology (Rockford, IL). All other reagents were obtained from Aldrich-Sigma (St. Louis, MO). LS-174T cells were purchased from ATCC and maintained in sterile growth media consisting of Eagle's Minimal Essential Media 1X (EMEM) (Cellgro, Herndon, VA) supplemented with 10% heat inactivated fetal bovine serum (FBS) (Omega Scientific, Tarzana, CA), and 1% L-glutamine, 10 mM sodium pyruvate, 0.1 mM non-essential AA. The production and purification of anti-CEA hT84.66-M5A has been previously described (*14*). Chelate conjugated antibodies were radiolabeled either with ^{111}In (Mallinckrodt, St. Louis. MO, 74–259 MBq/mg of protein) or with ^{64}Cu (Washington University, St. Louis, MO, 148–351 MBq/mg of protein). Percent labeling was measured by ITLC or by size exclusion chromatography (SEC) on a TSK column (1 × 30 cm, 1 mL/min, TOSOH Bioscience) or a Superdex 75 column (1 × 30 cm, 0.5 mL/min, Pharmacia Biotech). Radiolabeled antibody was purified by SEC on the same columns (in saline, fraction sizes of 1.0 and 0.5 mL, respectively). Immunoreactivity was determined by incubating the purified radiolabeled sample with a 20-fold excess by mass of CEA or a two-domain recombinant version of CEA, NA3 (*15*), at 37 °C for 15 min and then running the sample over a Superose 6HR10/30 column (GE Healthcare). Immunoreactivity was calculated as percentage total radioactivity that shifted to complexes of higher molecular weight. MALDI-MS was performed on a Perkin-Elmer-Sciex prOTOF 2000 using sinapinic acid [10 mg/mL in TFA/water/acetonitrile (0.1/50/50 v/v/v)] as a matrix. Prior to mixing with matrix, the sample was desalted on a Sephadex G25 spin column (100–200 mg in a 250 μL pipet tip) that was equilibrated in water.

Conjugation and Radiolabeling.*SH-DO3A-VS-M5A.* For conjugation of DO3A-VS to reduced cysteine hinge residues, M5A antibody (2 mg of 6.5 mg/mL, 13 nmol in PBS pH 7.5) was mixed with 144 μL of PBS and 2 μL of TCEP (tris-carboxyethyl phosphine, 200 mM, 400 nmol) and reduced for 2 h at 37 °C under argon on a rotator. Excess TCEP was removed on a Sephadex G25 spin column (1 mL, in PBS, 1200 rpm, 2 min), reacted with 3.6 μL of DO3A-VS (100 mg/mL in water, 774 nmol) under argon for 2 h at RT on a rotator, and dialyzed vs pH 7.0 0.25 M ammonium acetate containing 1 g/L Chelex for 5 d with five changes of buffer. Aliquots were removed to confirm (a) complete reduction by SDS gel electrophoresis and (b) reaction with DO3A-VS by MALDI-TOF-MS and IEF gel electrophoresis.

NH-DO3A-VS-M5A. For conjugation of DO3A-VS to surface lysine residues, 2 mg (13 nmol) of M5A (6.5 mg/mL in PBS) was mixed with 100 μL of PBS plus 6.2 μL of DO3A-VS (100 mg/mL in water, 1.3 μmol), the pH was adjusted to 9.0 with 0.1 NaOH, and the mixture was reacted for 18 h at RT on a rotator. The sample was dialyzed vs 0.25 M ammonium acetate as described above.

SATA-DO3A-VS-M5A. For conjugation of DO3A-VS to SATA generated surface sulfhydryls, 2 mg (13 nmol) of M5A (6.5 mg/mL in PBS) was mixed with 100 μL of PBS plus 2 μL of SATA (0.2 M in DMF, 400 nmol), reacted for 2 h at RT on a rotator, and then treated with 6 μL of hydroxylamine hydrochloride (0.2 M, 1200 nmol) to remove the acetyl protecting groups. The product was purified on a Superdex 200 column (Amersham, 1 × 30 cm, in PBS, 0.5 mL/min) and the antibody peak fraction (at 25 min) collected, concentrated to 0.4 mL on a Amicon Ultra-4, and reacted with 3.6 μL of DO3A-VS (100 mg/mL, 0.77 μmol) for 2 h at RT on a rotator. The sample was dialyzed vs 0.25 M ammonium actetate as above.

NHS-DOTA-M5A. For conjugation of DOTA to surface lysine residues, M5A was conjugated at a molar ratio of 20:1 chelate/antibody with DOTA-NHS-ester. Briefly, 10.5 mg (70 nmol) of M5A (7 mg/mL) was dialyzed against PBS + chelex, pH 7.2, and 0.1 M $NaHCO_3$ + chelex, pH 8.5, in a Slide-A-Lyzer cassette (Pierce, Rockford, IL). 150 μL of DOTA-NHS-ester (7.6 mg/mL in water, 1.4 μmol) was added and reacted for 2 h at RT on a rotator. The sample was dialyzed vs 0.25 M ammonium acetate as described above.

Conjugates were concentrated to 3–5 mg/mL in a Amicon Ultra-4 10 000 cutoff (Millipore, Billerica, MA) and sterile-filtered. Conjugates were characterized by both SDS and IEF gel electrophoresis (see Results section). The antibody conjugates were buffered with 0.25 M ammonium acetate, pH 7, except for M5A-NHS-DOTA that was buffered with 0.25 M sodium acetate, pH 7.2. Also, M5A-NHS-DOTA was more concentrated (7.7 mg/mL) than the other conjugates (3–5 mg/mL).

For labeling with ^{111}In no additional buffer was added to the reaction mixture except for NHS-DOTA-M5A, where 0.25 M sodium acetate, pH 6.5, was added. This mixture was incubated for 45–60 min at 43 °C, and the reaction was terminated by the addition of one-ninth the reaction volume of 10 mM DTPA to achieve a final concentration of 1 mM. The radiolabeled product was then purified on a size exclusion column. For labeling with ^{64}Cu, 0.1 M ammonium citrate, pH 5.5, was added to the reaction mixture. This mixture was incubated for 45 min at 43 °C, and the reaction was terminated by the addition of one-ninth the reaction volume of 10 mM DTPA to achieve a final concentration of 1 mM. The radiolabeled product was then purified on a size exclusion column.

Serum Stability Studies. The DO3A-VS NH and SH M5A antibody conjugates were radiolabeled with ^{64}Cu at a specific activity of 11 μC/μg (80 μg of antibody) using 0.87 mC of $^{64}CuCl_2$ for 45 min at 43 °C in ammonium citrate (0.1 M, pH 5.5). The radiolabeled samples were purified on a TSK G2000 SW size exclusion column (7.5 mm × 30 cm) and the peak IgG fractions pooled and counted. One aliquot (ca. 10 000 000 cpm) was incubated with human serum (15 μL sample plus 150 μL human serum) at 37 °C and aliquots (200 000 cpm uncorrected for decay) removed at various times for analysis by SEC (Pharmacia Superose 6, 1 × 30 cm). A second aliquot (10 μC, 1–2 μg) was injected into a nude mouse, blood removed at various times, and the serum fraction analyzed by SEC as above.

Xenograft Model, Biodistributions, and PET imaging. Female, athymic nu/nu mice (Charles River), 10–12 weeks old, were injected with LS-174T human colon cancer cells (5×10^6) s.c. in the flank. Tumors were established within 7–10 days postinjection. Athymic mice bearing LS-174T xenografts were injected via a tail vein with 200 μL of 133–148 kBq/1.7–2.2 μg ^{111}In or 333–370 kBq/2–2.4 μg of ^{64}Cu labeled DO3AVS-conjugates. Five mice were sacrificed at various time points (see Results section) and dissected for biodistribution measurements. Samples (blood, liver, spleen, kidneys, lungs, tumor, and carcass) were weighed with an analytical balance and assayed for radioactivity using a calibrated gamma counter. Measured activities were corrected for radiodecay after injection, and percentage of injected activity dose per gram of tissue (%ID/g) was calculated for each specimen.

Tumor-bearing mice (22–26 g) were injected i.v. with ^{64}Cu-labeled antibody and imaged beginning at 1.0–1.7 h, 4.5–5.5 h, 21–26 h, and 45–48 h with a small-animal PET scanner (microPET model R4; Siemens/CTIMI, Knoxvillle, TN). Injected activity and protein load ranged from 42 to 127 kBq/g and from 0.3 to 0.6 μg/g, respectively. Shortly before scanning, mice were anesthetized with isoflurane, secured in a prone position on a thin cardboard platform attached across the scanner bed, and centered in the instrument's field of view. Scan duration was 20 min for the two earliest time points and 60 min for the two later time points. The microPET's laser alignment tool was used to position the base of the tail approximately 4.0 cm from the axial center of the 8.0-cm-long field of view in each scan; mice were placed in approximately the same orientation for each scan by aligning them with body outlines traced on the cardboard platforms prior to the scans at 1 h.

Immediately after completion of the final scan, a blood sample (0.2 cc) was obtained by cardiac puncture, the mouse was sacrificed, and the tumor and various major organs were excised, weighed, and counted. Measured activities were corrected for radiodecay after injection, and percentage of injected activity dose per gram of tissue (%ID/g) was calculated for each specimen. Tumor weights at time of sacrifice ranged from 126 to 227 mg.

Image processing and analysis were performed with the standard microPET software. Scan data were sorted into two-dimensional sinograms using the Fourier rebinning method and corrected for intrascan radiodecay, detector nonuniformity, and random coincidence noise. Images were reconstructed by the iterative ordered subsets expectation maximization (OSEM) method (4 iterations, 16 subsets). Volumetric regions of interest (VOIs) were defined to include the hottest 10–15% of voxels in the images of heart and the hottest 40–50% of voxels in the images of tumor. For liver, VOIs were drawn to lie well within the organ boundaries while excluding the region containing the large central blood vessels. Image activity densities were decay-corrected to time of injection to obtain relative time–activity curves (TACs). Absolute TACs for tumor, liver, and blood (in units of %ID/g) were obtained by normalizing the final time points of the PET-derived TACs to the direct tissue assays. Blood TACs were equated with heart TACs normalized to the blood samples taken just before sacrifice.

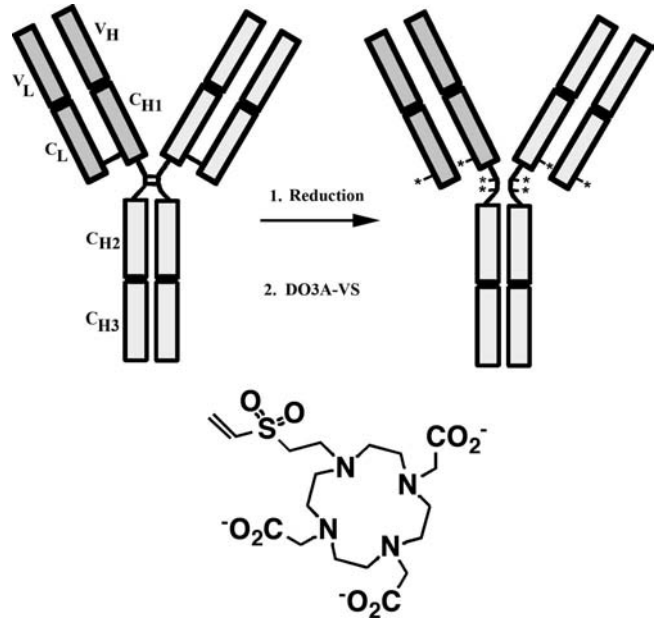

Figure 1. Schematic model of an immunoglobulin (IgG1) showing reduction of hinge sulfhydryls (*). In the second step, the sulfhydryls are reacted with DO3A-VS.

RESULTS AND DISCUSSION

DO3AVS-M5A Conjugates. In developing a bifunctional chelator for conjugation to intact immunoglobulins, our criteria were rapid synthesis, high and stable metal ion binding to a variety of radiometals, and an ability to conjugate to either sulfhydryl or amino groups present on the immunoglobulin molecule. Indeed, we had such a bifunctional chelator (DO3A-VS) in hand that previously had been shown to have high metal binding stability when conjugated to an antibody (*13*). Our interest in the use of vinyl sulfone as a bifunctional linker stems from its ability to react with primary surface amines at pH 9, as well as with thiols at acidic to neutral pH (*13*). In addition, we found that the thiol conjugates were chemically more stable than the often-used maleimide–thiol conjugates (*8*). The most accessible and/or reactive disulfides of immunoglobulins are located in the hinge region away from the antigen combining sites, and require only mild reduction of the antibody for generation of free sulfhydryls, and they can be targeted by DO3A-VS under very specific reaction conditions (pH 5.0–7.0 after mild reduction). Many studies have shown that modification of the hinge sulfhydryl groups has little or no effect on the antigen binding properties of an antibody (*16–19*), making this an ideal approach for site-specific conjugation (Figure 1). Nonetheless, the insertion of any derivative into the hinge region requires careful documentation of retention of antigen-binding activity. In addition, we have shown that vinyl sulfone-Cys-DOTA conjugates can react with surface lysine residues on antibodies at pH 9.0 (*13*). Thus, by control of pH and/or prior reduction of the antibody, one can conjugate DO3A-VS either to hinge region sulfhydryls or surface lysine residues.

Based on the concepts outlined above, the bifunctional reagent DO3A-VS was reacted either with the hinge region sulfhydryls (SH) or the surface lysines (NH) of hT84.66-M5A (M5A), and immunoreactivity and specific isotope incorporation were measured (Table 1). From these studies, we determined that both SH- and NH-DO3A-VS-M5A retained high immunoreac-

Table 1. Radiolabeling of DO3AVS-M5A Conjugates.[a]

conjugate	labeling buffer	ratio (μCi/ug)	% labeling	S.A. (μCi/ug)	% IR
SH-DO3AVS, In-111	none	2.1	99.8	2.1	100
SH-DO3AVS, Cu-64	0.1 M ammonium citrate, pH 5.55	4.2	100	4.2	100

NH-DO3AVS, Cu-64	0.1 M ammonium citrate, pH 5.5	9.5	50	4.8	100
SATA-DO3AVS, In-111	none	2.9	97	2.8	100
NH-NHS-DOTA, In-111	0.25 M sodium acetate, pH 6.5	7.1	99.3	7.1	100
NH-NHS-DOTA, Cu-64	0.1 M ammonium citrate, pH 5.5	8.3	99	8.2	100

[a] Reaction conditions include radiolabeling buffer with pH. Ratio refers to the μCi of isotope to μg of protein. Percent labeling efficiency was determined by HPLC purification. Specific activity (S.A.) was calculated by multiplying the labeling ratio with percent labeling. Percent immunoreactivity (%IR) was determined by in vitro incubation with 20 times mass excess of CEA (except for SH-DO3AVS, In-111, which was tested against 20× mass excess of NA3).

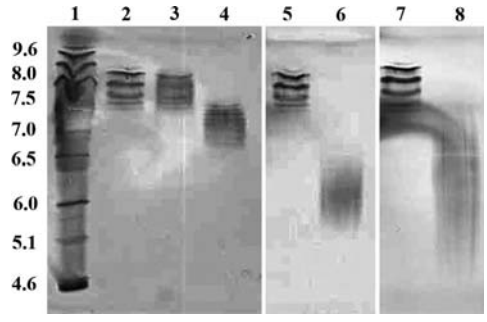

Figure 2. Characterization of DO3A-VS-M5A conjugates by IEF gel electrophoresis. 1. IEF standards (see pI values to the left). 2, 5, and 7. Unconjugated M5A. 3. M5A after reduction with TCEP. 4. SH-DO3A-VS-M5A. 6. NH-DO3A-VS-M5A. 8. SATA-DO3A-VS-M5A.

tivity and had isotope incorporation activities comparable to those published for other DOTA–antibody conjugates (*13*). We determined the relative degree of conjugation of DO3A-VS to M5A by IEF (Figure 2), an analysis that showed a shift to more acidic pI (pH) with increasing amounts of chelate substitution. Based on this analysis, conjugation of DO3A-VS to surface lysines was more extensive than to reduced sulfhydryls in the hinge region. To further characterize the degree of modification of the antibody with DO3A-VS, MALDI-TOF analysis was performed on the SH-modified sample. The results shown in Figure 3 reveal that both the light chain and heavy chain have been extensively modified (0.7 DO3A-VS per light chain and 3.3 DO3A-VS per heavy chain). Thus, the total number of chelates per 150 kDa immunoglobulin was 8.

In order to compare these conjugates to a more traditional DOTA conjugate, M5A was also reacted with a commercially available bifunctional chelator, DOTA-NHS. This DOTA conjugate could also be labeled well with ^{111}In and ^{64}Cu and retained high immunoreactivity (Table 1). MALDI-TOF analysis of this conjugate also revealed an average of eight chelates/immunoglobulin (data not shown). Other methods for conjugating DOTA to antibodies include that developed by Meares and co-workers, where lysines on the antibody were first reacted with iminothiolane and then conjugated to the bifunctional chelator BAT (*20*). To approximate this approach, we first reacted surface lysines with SATA, then with hydroxylamine to deprotect the lysine-coupled protected thiol groups, followed with DO3A-VS. This conjugate also gave high levels of isotope

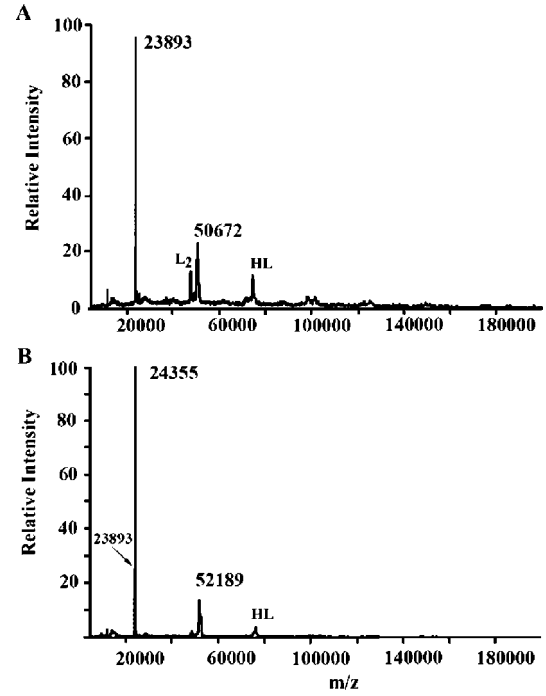

Figure 3. MALDI-TOF-MS analysis of SH-DO3A-VS-M5A. (A) Reduced M5A. The peak at 23 893 is the light chain, the peak at 50 672 is the heavy chain, and the peaks labeled L2 and HL are light chain and heavy–light chain dimers, respectively. (B) SH-DO3A-VS-M5A. The light chain has two peaks, one unmodified at *m*/*z* 23 893, and one increased by 462 mass units corresponding to the addition of one DO3A-VS. Based on peak heights, the degree of modification for the light chain is 0.67. The heavy chain has increased by 1517 mass units corresponding to the addition of an average 3.3 DO3A-VS. Note: The light chain has one "hinge" cysteine and the heavy chain three hinge cysteine residues in an IgG1 molecule.

incorporation and retained its high immunoreactivity (Table 1), but contained up to 10% dimers due to sulfhydryl cross-linking (Figure 4).

Prior to proceeding to biodistibution studies, we analyzed each of the radiolabeled conjugates by SEC before and after the addition of CEA to determine if the sample was homogeneous (single peak of the correct size) and if it was fully immunoreactive (shifted to higher molecular weight by the addition of a two-domain recombinant form of CEA, NA3, or human CEA). The results shown in Figure 4 demonstrate that the SH- and NH-DO3A-VS-M5A as well as the DOTA-NHS-M5A conjugates were free of aggregates, while the SATA-DO3A-VS-M5A conjugate contained up to 10% aggregates, but importantly, all four conjugates were 100% immunoreactive. For three of the conjugates tested, the results were equivalent whether labeled with ^{111}In or ^{64}Cu.

Since the serum stability of ^{64}Cu-labeled DOTA-based BFCs has been questioned (*21*, *22*), it was necessary to test both their in vitro and in vivo serum stabilities. When either SH or NH conjugated ^{64}Cu-labeled DO3A-VS-M5A was incubated with human serum at 37 °C and analyzed by SEC, 100% of the radioactivity remained in the IgG peak over a time course of 70 h, after which too few remaining counts remained for analysis (Figure 5A,B). In addition, when both radiolabeled conjugates were injected into mice, blood removed, and the serum fractions analyzed by SEC, 100% of the radioactivity was found in the IgG fraction over the time course of the analysis (Figure 5C,D). These analyses demonstrate that no significant transchelation of ^{64}Cu occurs in serum either in vitro or in vivo for both conjugates. These data are similar to that reported by Lewis et al. (*23*) who showed that both ^{64}Cu-labeled biotin DOTA and a ^{64}Cu-labeled DOTA–antibody conjugate were 100% stable

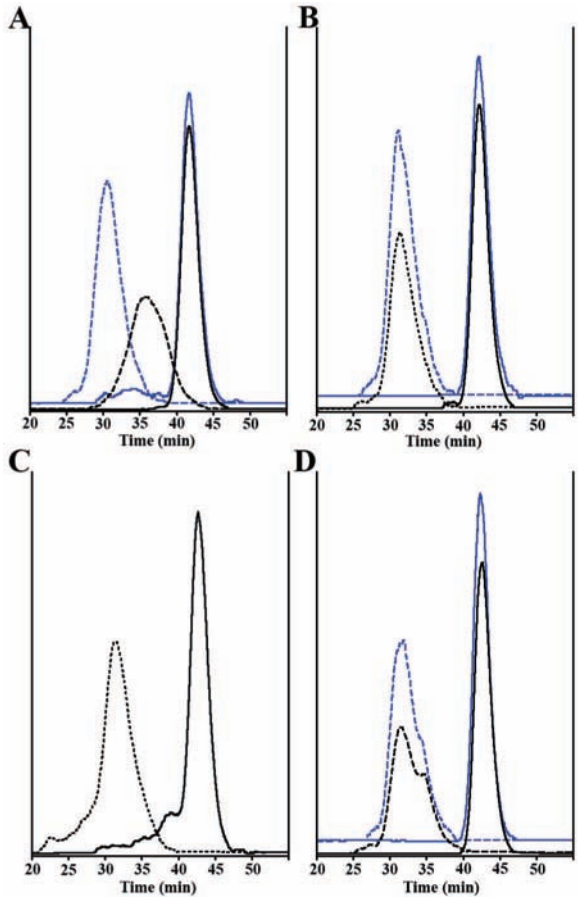

Figure 4. SEC analysis of radiolabeled M5A conjugates. (A) SH-DO3A-VS-M5A radiolabeled with ^{111}In (black) or ^{64}Cu (blue) before and after the addition of NA3 (black dotted) or CEA (blue dotted). (B) NH-DO3A-VS-M5A radiolabeled with ^{111}In (black) or ^{64}Cu (blue) before and after the addition of CEA (black or blue dotted). (C) SATA-DO3A-VS-M5A radiolabeled with ^{111}In (black) before and after the addition of CEA (black dotted). (D) DOTA-NHS-M5A radiolabeled with ^{111}In (black) or ^{64}Cu (blue) before and after the addition of CEA (back or blue dotted). Radioactivity (arbitrary units) shown on the *y*-axis.

in serum for up to 48 h. We conclude that the so-called instability of ^{64}Cu DOTA or TETA based conjugates refers to metabolism of the radiolabeled chelates or their conjugates in the liver where uptake of the radiolabel into SOD has been documented (*24*, *25*). The redistribution of radiolabels into other proteins after metabolism is a well-recognized phenomenon as illustrated by the metabolic redistribution of radioiodine from radioiodinated proteins into thyroglobulin.

Biodistributions of Radiolabeled M5A Conjugates. SH- and NH-conjugated DO3A-VS-M5A were radiolabeled with ^{111}In or ^{64}Cu, and biodistibutions were performed in nude mice bearing CEA positive LS-174T xenografts. The results shown in Figure 6 demonstrate high tumor uptake, reaching a maximum of 40–50% ID/g at 48–96 h. It is noteworthy that, overall, the dynamic biodistributions are similar between SH and NH conjugates whether radiolabeled with ^{111}In or ^{64}Cu in terms of both kinetics of tumor and normal tissue uptake and the ratios of tumor to normal tissue uptake. The one exception may be higher tumor uptake for ^{64}Cu-labeled NH-DO3A-VS-M5A, but in this experiment, higher blood levels track with the higher tumor uptake, leading to similar tumor to blood ratios compared to the other radiolabeled conjugates. We conclude from this study that SH- and NH-DO3A-VS conjugates give equivalent biodistributions whether radiolabeled with ^{111}In or ^{64}Cu.

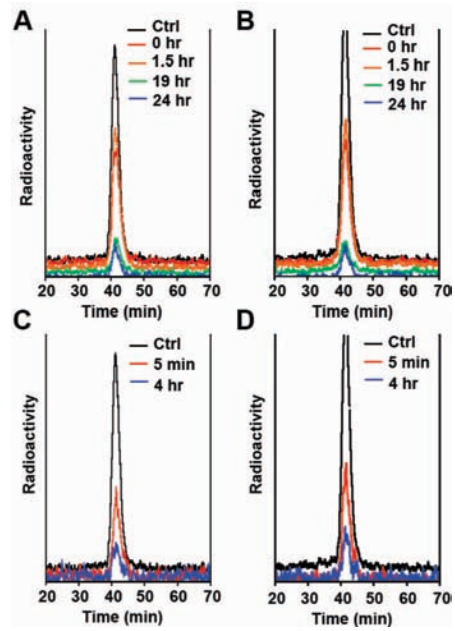

Figure 5. Serum stability analysis of ^{64}Cu-labeled M5A conjugates. ^{64}Cu labeled DO3A-VS-M5A was incubated with human serum and analyzed over time by SEC. The major peak at 42 min corresponds to the elution time for IgG. (A) SH-DO3A-VS-M5A. (B) NH-DO3A-VS-M5A. The sample was also injected into nude mice, blood removed over time, and the serum fraction analyzed by SEC. (C) SH-DO3A-VS-M5A. (D) NH-DO3A-VS-M5A.

As mentioned above, we were interested in comparing the SH- and NH-DO3A-VS-M5A conjugates with (a) DO3A-VS conjugated to surface sulfhydryls introduced into M5A by reaction of surface lysines with SATA and (b) the more conventional DOTA-NHS conjugated antibody. The results shown in Figure 7 demonstrate roughly equivalent tumor uptakes for both conjugates compared to each other and to those shown in Figure 6, but have interesting differences in the liver clearances. Over the period 0–96 h, the SATA conjugate had almost twice the liver uptake of the SH- and NH-DO3A-VS-M5A conjugates, while the DOTA-NHS conjugate had about a 25–50% increase in liver uptake compared to SH- and NH-DO3A-VS-M5A. The higher liver uptake for the SATA conjugate is likely due to the presence of aggregates that are absent in the other three conjugates (see Figure 4). However, the increase in liver uptake observed for the DOTA-NHS conjugate is harder to explain and implies that the SH- and NH-DO3A-VS conjugates may have improved imaging properties over those of the conventional DOTA-NHS conjugate.

^{64}Cu PET Imaging of SH- and NH-DO3A-VS-M5A. Based on the above biodistribution results, we predicted that tumors would be visualized as early as 24 h with ^{64}Cu-labeled conjugates for whole antibody, since tumor to blood ratios were >1.0 by that time. [Due to the constraint on injected activity because of radiation dose considerations, 24 h is a practical upper time limit on ^{64}Cu ($t_{½} = 13$ h) imaging in humans.] The dynamic biodistributions of radiolabel in the LS174T tumor/nude mouse model following injection of ^{64}Cu SH- and NH-DO3A-VS-M5A are illustrated via serial microPET images in Figure 8. The kinetics of the radiolabel were very similar for both forms of ^{64}Cu M5A antibody. At 1 and 5 h, the activity remained primarily intravascular, with tumor beginning to appear at the second time point. Tumor was the primary site of localization by 22 h, and tumor to normal tissue contrast was further increased by 45 h. Time–activity curves (TACs) derived from the microPET experiments (Figure 9) are quantitatively

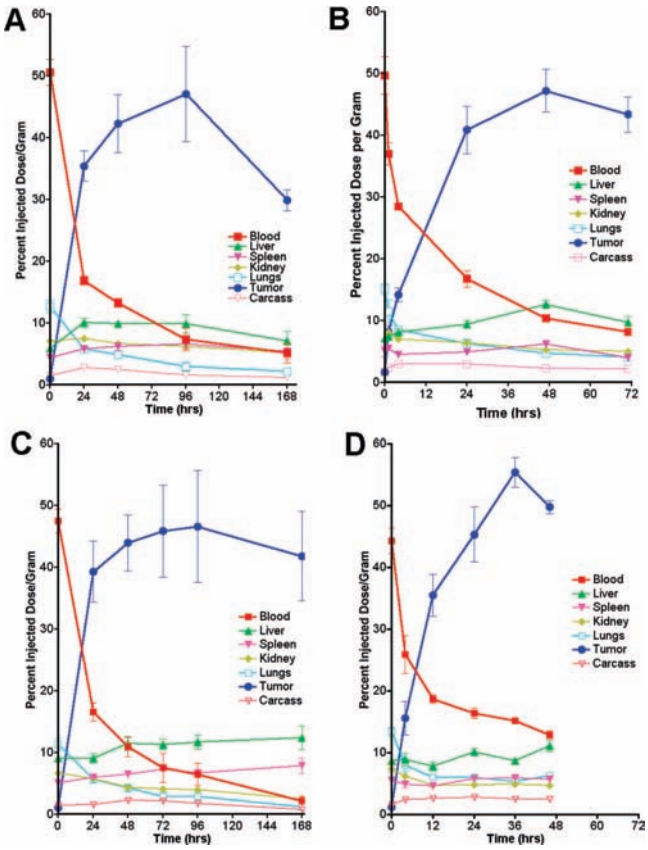

Figure 6. Biodistributions of ^{111}In- and ^{64}Cu-SH- and NH-DO3A-VS-M5A in nude mice bearing LS174T xenografts. The average %ID/g (±sem.) of five animals per time point is shown. (A) ^{111}In-labeled SH-DO3A-VS-M5A. (B) ^{64}Cu-labeled SH-DO3A-VS-M5A. (C) ^{111}In-labeled NH-DO3A-VS-M5A. (D) ^{64}Cu-labeled NH-DO3A-VS-M5A.

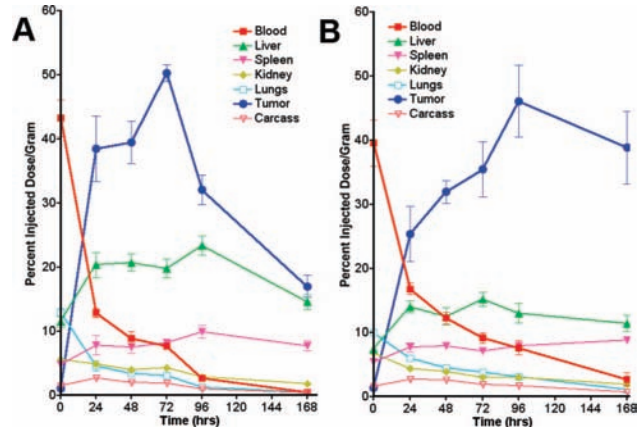

Figure 7. Biodistributions of ^{111}In- SATA-DO3A-VS-M5A and DOTA-NHS-M5A in nude mice bearing LS174T xenografts. The average %ID/g (±sem) of five animals per time point is shown. (A) ^{111}In-labeled SATA-DO3A-VS-M5A. (B) ^{111}In-labeled DOTA-NHS-M5A.

similar to those obtained in the direct-assay biodistribution experiments for ^{64}Cu SH- and NH-DO3A-VS-M5A (Figure 6C,D).

Note that, in spite of the very small sample sizes ($n = 2$ or 3 per data point), the standard deviations of the microPET time–activity curves (Figure 9) are similar to those of the standard biodistribution experiments, where $n = 5$ per data point (Figure 6). This illustrates a major advantage of serial quantitative imaging over the standard biodistribution approach, since it allows the determination of an entire TAC for a single mouse.

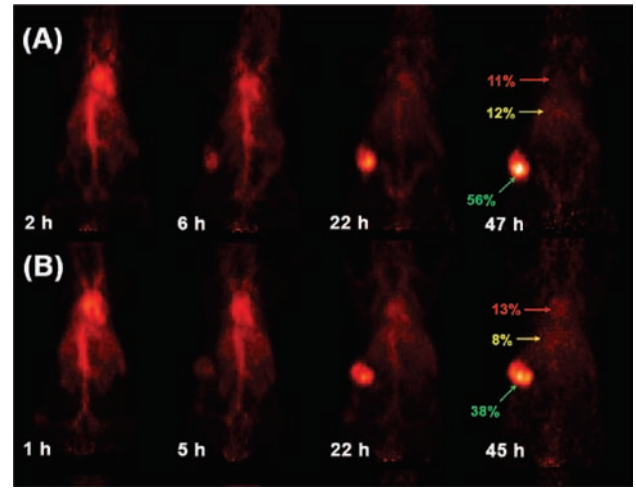

Figure 8. Dynamic biodistribution of ^{64}Cu-labeled hT84.66-M5A MAbs in athymic mice peripherally xenografted with CEA-positive LS-174T colon tumors. (A) SH-DO3A-VS-M5A; (B) NH-DO3A-VS-M5A. Images are PET anterior-view maximum intensity projections (MIPs) normalized to reflect radiodecay-corrected relative image intensity per unit injected activity. Labels in red, yellow, and green show directly measured %ID/g in blood (heart), liver, and tumor, respectively. Tumor weights at time of sacrifice were 126 and 155 mg in (A) and (B), respectively.

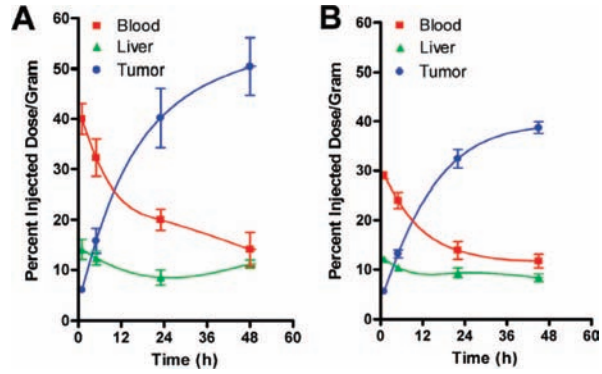

Figure 9. Time–activity curves derived from serial microPET studies. Data are average %ID/g (±sem.) for three (first three time points for SH-DO3A-VS-M5A) or two (NH-DO3A-VS-M5A and final time point for SH-DO3A-VS-M5A) mice.

CONCLUSIONS

Although much progress has been made in engineering radiolabeled antibodies for tumor imaging, many challenges still exist. In this study, we have returned to the use of intact antibodies because they arise at the earliest stage of clinical antibody development and can be produced in large quantities. Since recombinant engineering of antibodies is a time-consuming process and fraught with many obstacles, it is important to determine at the earliest point possible if the antibody of interest can indeed provide high targeting of tumor relative to normal tissue. If it can, then one could potentially use it at this stage of development as an in vivo diagnostic agent.

Until recently, radioimaging with antibodies was limited to the use of planar or SPECT imaging modalities, which have relatively poor spatial resolution and are not quantitative. Although PET has the potential to solve this problem, the need to match the isotope half-life with the blood clearance time of the antibody has limited most immuno-PET studies to antibody fragments labeled with short half-life radionuclides such as ^{18}F.

The newly available, 12.7 h half-life positron emitter ^{64}Cu offers a potential solution to this problem because it can be used to radiolabel whole antibody–chelate conjugates in a kit format. Based on the animal studies shown here, intact anti-CEA MAbs may deliver sufficient radiolabel to tumor to allow PET imaging as early as 22 h after injection. The improvement in PET images over those obtained with planar or SPECT imaging of ^{123}I- or ^{111}In-labeled antibodies is obvious; however, the ability to image tumors with low normal tissue background with whole ^{64}Cu-labeled antibodies in the mouse model came as a surprise, because most of our experience has been with planar gamma images. We attribute the majority of this improvement not only to the 3D nature and relatively high resolution of the microPET images, but also to the change in chelates, where DO3A-VS conjugates show less liver uptake that the more conventional DOTA-NHS conjugates. The ability to measure dynamic biodistributions in individual mice with micro-PET/^{64}Cu-labeled-mAb, as illustrated here, confers greater precision for a given sample size or, alternatively, permits substantial reduction in the number of mice required.

The practical advantages of using DO3A-VS-whole antibody conjugates include a versatile chemistry allowing conjugation at thiols in the mildly reduced hinge region or to surface amino groups in immunoglobulins, as well as maintaining the inherent metal ion binding and stability of the macrocyclic ring. Although reaction of DO3A-VS at the hinge region requires mild reduction of the antibody and removal of excess reducing agent, this is easily accomplished by the use of a spin column, and the resulting hinge thiols remain in the reduced state for up to 72 h before reoxidation occurs. Reaction of DO3A-VS at lysine residues requires brief exposure of the antibody to pH 9, conditions which, in our hands, have not compromised antigen-binding activity of several antibodies. Thus, DO3A-VS may be conjugated to antibodies under several conditions offering the researcher alternatives to the conventional NHS-active ester derivatives of DOTA that are inherently unstable and therefore less predictable in batch-to-batch conjugations. In addition, the quality of the PET images obtained within 24 h after injection indicates that PET/^{64}Cu-DO3A-VS-M5A should be evaluated for clinical use.

Modified "4 + 1" Mixed Ligand Technetium-Labeled Fatty Acids for Myocardial Imaging: Evaluation of Myocardial Uptake and Biodistribution

Received May 7, 2007; Revised Manuscript Received September 3, 2007

Our group previously synthesized ^{99m}Tc-labeled fatty acids suitable for myocardial metabolism and flow imaging. In this set of experiments, 29 new analogues were synthesized according to the "4 + 1" mixed ligand approach with some specific differences. Conventional "4 + 1" ^{99m}Tc-fatty acids are built in the sequence: Tc-chelate, alkyl chain, and carboxylic group. We developed compounds following a new design with the sequence: carboxylic group, alkyl chain, Tc-chelate, and lipophilic tail. Therefore, the ^{99m}Tc-chelate was transferred to a more central position of the compound, aiming toward an improved myocardial profile and an accelerated liver clearance. In this context, several functional groups incorporated in the lipophilic tail section were tested to evaluate their influence on the compound's character. In addition to biodistribution studies *in vivo*, the myocardial first-pass extraction of the compounds was tested in an isolated Langendorff rat heart model. A satisfactory myocardial uptake of up to 20% of the injected dose (% ID) in the perfused heart and a fast liver clearance *in vivo* with only 0.29% ID/g at 60 min postinjection demonstrate that the induced molecular modifications affect the kinetics of ^{99m}Tc-radiolabeled fatty acid compounds favorably. From the data set, rules for estimating the biodistribution of fatty acids tracers are deduced.

INTRODUCTION

The development of ^{99m}Tc-labeled fatty acids (FA) suitable for evaluation of myocardial function and metabolism has been studied by various research groups since 1975 (*1*). The greatest challenge has been proven to be the design of ligands, which offer a stable binding between the FA and the metal core. Simultaneously, these ligands should not interfere with the biological properties of the FA, allowing an unimpeded recognition by membranous and intracellular proteins. Of the broad variety of neutral and small-sized mixed ligand chelate types, square-pyramidal Tc(V) oxocomplexes of tetradentate ligands are most commonly used (*2–9*). Because of disappointing results in biodistribution studies, a strong interference with the metal oxo-unit was assumed, influencing the molecular properties and the *in vivo* behavior of FA. Besides these types, lipophilic Tc(I) species were evaluated (*10, 11*).

After gaining experiences in FA labeling with oxotechnetium(V) complexes (*12, 13*), we focused on the development of "4 + 1" mixed ligand Tc(III) FA derivatives (*13, 14*). The presently available evidence suggests that in the "4 + 1" donor atom arrangement the radiometal is well-shielded by both a tripodal tetradentate ligand and a monodentate ligand bearing the FA moiety (*15*).

+ Deceased on March 25, 2007.

In experiments using the isolated guinea pig heart, the evaluated compounds clearly outmatched the extraction results of the "3 + 1" oxotechnetium(V) FA analogues. Furthermore, no *in vitro* transchelation reaction with glutathione was observed, indicating a high stability toward those challenging agents (*15*).

Although promising uptake results were achieved with the isolated heart model, no "4 + 1" FA compound synthesized so far had similarly advantageous biodistribution parameters to those of established iodinated FA tracers (e.g., iodine-labeled 15-(*p*-iodophenyl)pentadecanoic acid, ^{123}I-IPPA, and 15-(*p*-iodophenyl)-3-(*R,S*)-methylpentadecanoic acid, ^{123}I-BMIPP). Therefore, the main problems, namely, the high liver uptake, as observed for many other ^{99m}Tc-labeled FA compounds, and a decelerated liver clearance, remained.

In an attempt to synthesize ^{99m}Tc-labeled FA based on the promising "4 + 1" mixed ligand approach with an improved myocardial profile and a faster liver washout, some innovative structural modifications were introduced. While the conventional "4 + 1" ^{99m}Tc-FA are built in the sequence Tc-chelate, alkyl chain, and carboxylic group, modified compounds were designed according to the sequence carboxylic group, alkyl chain, Tc-chelate, and lipophilic tail. Therefore, the ^{99m}Tc-chelate was transferred to a more central position, to avoid nonrecognition by membranous and intracellular enzymes because of a terminally positioned artificial ^{99m}Tc-chelate.

In the following, we describe the chemistry of modified "4 + 1" ^{99m}Tc-FA as well as some improvements and adaptation of the recently published labeling procedure (*14*). Moreover, we correlate changes in molecular structure of the synthesized ^{99m}Tc compounds with biological behavior, namely, uptake and biodistribution. For better clarity, Tc complexes and their corresponding Re compounds were organized into groups (denoted by **I-VII** and **ReI-ReVII** or rather **ReMeI-ReMeVII**

EXPERIMENTAL PROCEDURES

Materials and Instrumental Techniques. EDTA was purchased from Riedel-deHaen. $PhPMe_2$ (M0), PPh_3 (M1), Ph_2P-*p*-C_6H_4COOH (M2), $P(PropCN)_3$ (M3), P(*o*-Tol)$_3$ (M4), Ph_2POEt (M5), and trifluoroacetic acid (TFA) were purchased from Aldrich. 2-Isocyano-2-methylpropane (or TBI *t*-butyl isonitril) (M7) were purchased from Alfa products and a commercial Cardiolite kit with 1-isocyano-2-methoxy-2-methylpropane (or MIBI 2-methoxyisobutyl isonitril) (M8) from Bristol-Myers-Squibb. All commercial reagents were used without further purification. 2,3,5,6-Tetrafluorophenyl 4-isocyanobutanoate and 2,3,5,6-tetrafluorophenyl 4-(isocyanomethyl) benzoate, serving as precursors for the monodentate isocyano ligand, and 3-(benzylthio)-2-{bis-[2-(benzylthio)ethyl]amino} propanoic acid ($BzNS_3COOH$) were prepared as described (*16*). The alkyl (isocyano) alkanoates ethyl 8-isocyanooctanoate (M12), ethyl 4-isocyanobutyrate (M13), ethyl 2-isocyanoacetate (M14), methyl 15-isocyanopentadecanoate (M15-Me), methyl 5-[(7-isocyanoheptyl)thio]pentanoate (M16-Me) and methyl 12-isocyanododecanoate (M19-Me) were prepared according the procedure that was used before (*14*) (see Figure 1 in Supporting Information for detail).

Proton nuclear resonance (^{1}H NMR) spectra were recorded on a 400 MHz Varian Inova 400 spectrometer (^{1}H 400 MHz, ^{13}C 100 MHz, ^{31}P 162 MHz). The ^{1}H and ^{13}C chemical shifts are reported in parts per million (ppm) relative to residual solvent signals or TMS as reference. ^{31}P chemical shifts are reported relative to H_3PO_4 as an external reference. Mass spectrometric measurements were performed with a Micromass Tandem Quadropole Mass Spectrometer (Quadro LC) operating in the MS mode. Mass spectral data were recorded in the positive or negative ESI mode. About 10^{-4} M of the sample dissolved in 1.0 mL of methanol or acetonitrile was injected at a flow rate of 5 mL/min. Elemental analyses were performed on a LECO Elemental Analyzer CHNS-932. UV/vis spectra were recorded on a Varian Cary 50 Bio spectrometer. HPLC analysis and purification of ^{99m}Tc-complexes were performed using a Perkin-Elmer instrument consisting of a Turbo LC System with a quaternary pump (series 200 LC pump) and a programmable absorbance detector model 785A. Infrared spectra were recorded on a FTIR-Spectrophotometer Spectrum 2000 (Perkin-Elmer). Determination of melting points was carried out with the help of a BÜCHI Melting Point B-540 machine. Analytical thin layer chromatography was performed on POLYGRAM SIL G/UV_{254} foils (Machery-Nagel). Nonradioactive rhenium complexes were monitored by their UV absorption at 254 nm, and ^{99m}Tc-complexes by gamma-ray detection (Bohrloch, NaI(Tl) crystal).

Synthesis of Tetradentate NS_3-Ligands (T3-T5). *General Coupling to FA.* DCC (433 mg, 2.1 mM), dissolved in 5 mL dichloromethane, was added dropwise at 0 °C to a solution of 3-(benzylthio)-2-{bis-[2-(benzylthio)-ethyl]-amino}-propanoic acid [($BzNS_3COOH$) 1074 mg, 2.1 mM] in 10 mL dichloromethane. After stirring for 15 min, 1-hydroxybenzotriazole (284 mg, 2.1 mM) was added. Subsequently, the alkyl-ω-aminoalkanoate (2.5 mM) dissolved in 10 mL dichloromethane was added, after the deliverance of the amine in the organic phase via extraction with a saturated solution of potassium carbonate from the corresponding hydrochloride. The reaction mixture was stirred first for 2 h at 0 °C, then 12 h at room temperature. After filtering off the precipitated byproduct, *N*,*N*′-dicyclohexylurea, the solvent was removed in vacuo. The purification of the yellow, oily crude product was performed chromatographically (*n*-hexane/ethyl acetate = 1/1, R_f = 0.6–0.85 depending on chain length) and yielded a slightly yellow, viscous oil (selected NMR data are shown in Supporting Information). To the alkyl ($BzNS_3CONH$-) alkanoate (0.25 mM) dissolved in 10 mL dioxane was added 4 mL 1 N aqueous sodium hydroxide for the saponification of the ester function. After stirring overnight, the reaction mixture was acidified with 1 N aqueous hydrochloric acid. This step was necessary, because the reducing conditions in the following deprotection step led to alkanoles in the case of esters. After acidification with TFA to pH 3–4 and evaporation of the solvent, a 3-fold extraction with chloroform/water followed. The united organic phases were dried with $MgSO_4$, and the solvent was evaporated under reduced pressure. The residue was purified by column chromatography (*n*-hexane/ethyl acetate = 1/1, R_f = 0.55–0.65) (selected NMR data are shown in Supporting Information).

Deprotection of the Tris-Thiolate Ligand. The FA containing $BzNS_3CONH$R-ligand (0.49 mM) was dissolved in 3 mL waterfree THF and added dropwise to liquid ammonia at −50 °C. Under gentle stirring, pieces of sodium were added. The termination of the reaction was seen in the excess of sodium, giving the reaction mixture a deep blue color. Subsequently, the evaporation of the solvent followed in a nitrogen gas stream. The remaining solid was carefully dissolved in 10 mL water,

acidified with 1 N hydrochloric acid (to pH 3–4), and extracted 5 times, each with 7 mL ethyl acetate. The product was obtained by concentration of the organic phases in vacuo and precipitation of the product with hexane. Because of the product instability, no more purification steps were performed.

The syntheses of the unsubstituted tetradentate ligands (TX), the oxalic acid salt of tris(2-mercaptoethyl)amine (T1), and 1-carboxy-3-mercapto-*N*,*N*-bis(2-mercaptoethyl)-1-oxopropan-2-aminium chloride (T2) have been described recently (*16*, *17*).

1-[(7-carboxyheptyl)amino]-3-mercapto-*N*,*N*-bis(2-mercaptoethyl)-1-oxopropan-2-aminium chloride (T3). ^{1}H NMR (CD_3CN): 1.31 (m, 6H, CH_2), 1.46–1.57 (m, 4H, CH_2), 2.28 (t, 2H, CH_2COO, ^3J = 8.0 Hz), 2.63 (t, 2H, CONHCH_2, ^3J = 8.0 Hz), 3.14–3.21 (m, 10H, 2 × NCH_2CH_2SH, NCH_2), 3.35–3.37 (m, 1H, C*H*CONH). ^{13}C NMR (CD_3CN): 22.1, 23.0, 23.5, 24.8, 26.7, 28.9, 29.4 (2C), 33.5, 39.0, 54.2, 54.8, 72.3, 169.2, 175.1. IR (KBr): 3410 (COOH, CONH), 2928, 2853 (CH_2), 1715 (COOH), 1648 (CONH). ESI-MS (MeOH): *m*/*z* (%) = 383 (90) for $[C_{15}H_{31}N_2O_3S_3]^+$.

1-[(11-carboxyundecyl)amino]-3-mercapto-*N*,*N*-bis(2-mercaptoethyl)-1-oxopropan-2-aminium chloride (T4). ^{1}H NMR ($CDCl_3$): 1.21–1.27 (m, 14H, CH_2), 1.49–1.54 (m, 4H, CH_2), 2.28 (t, 2H, CH_2COO, ^3J = 7.8 Hz), 2.60 (t, 2H, CONHCH_2, ^3J = 7.9 Hz), 3.00–3.28 (m, 10H, 2 × NCH_2CH_2SH, NCH_2). 3.33–3.36 (m, 1H, C*H*CON). ^{13}C NMR ($CDCl_3$): 22.3, 23.9, 25.9, 27.2, 29.2, 29.3, 29.4 (2C), 29.5 (2C), 29.6, 29.7 (2C), 32.9, 39.9, 54.5, 67.1, 72.9, 169.5, 176.8. IR (KBr): 3426 (COOH, CONH), 2926, 2853 (CH_2), 1710 (COOH), 1645 (CONH). ESI-MS (MeOH): *m*/*z* (%) = 439 (35) for $[C_{19}H_{39}N_2O_3S_3]^+$.

1-[(14-carboxytetradecyl)amino]-3-mercapto-*N*,*N*-bis(2-mercaptoethyl)-1-oxopropan-2-aminium chloride (T5). ^{1}H NMR ($CDCl_3$): 1.20–1.27 (m, 20H, CH_2), 1.50 (m, 4H, CH_2), 2.28 (t, 2H, CH_2COO, ^3J = 8.0 Hz), 2.62 (t, 2H, CONHCH_2, ^3J = 7.9 Hz), 3.00–3.30 (m, 10H, 2 × NCH_2CH_2SH, NCH_2). 3.36 (m, 1H, C*H*CON). ^{13}C NMR ($CDCl_3$): 22.0, 22.9, 25.5, 26.0, 26.9, 28.9, 29.2, 29.4 (2C), 29.5 (4C), 29.6, 29.7 (2C), 33.5, 39.9, 54.5, 54.6, 72.7, 169.5, 177.2. ESI-MS (MeOH): *m*/*z* (%) = 481 (90) for $[C_{22}H_{45}N_2O_3S_3]^+$.

Syntheses of Monodentate Ligands MY (M6, M9–M11, and M17–M18).*Phosphorus(III) Ligands*. The phosphorus(III) ligands M0–M5 were commercial reagents and were used without further purification.

12-{[(Diphenylphosphino)acetyl]amino}dodecanoic acid (M6). The coupling of 12-aminododecanoic acid with diphenyl phosphine acetate was carried out with DCC as described above for $BzNS_3CONHR$, the precursors for T3–T5. DCC (43 mg, 0.21 mM), dissolved in 1 mL dichloromethane, was added dropwise at 0 °C to a solution of diphenyl phosphine acetate (49 mg, 0.2 mM) in 2 mL dichloromethane. After stirring for 15 min, 1-hydroxybenzotriazole (27 mg, 0.2 mM) was added first, followed by the 12-amino-dodecanoic acid (43 mg, 0.2 mM) suspended in 5 mL dichloromethane. The reaction mixture was stirred for 2 h at 0 °C, then for 12 h at room temperature. After filtering off the precipitated byproduct *N*,*N*′-dicyclohexylurea and unreacted amino acid, the solvent was removed in vacuo. Because of the product instability toward oxygen, no more purification steps were performed. Yield: 67 mg (76%); colorless waxy solid. ^{1}H NMR ($CDCl_3$): broad signals, because of an equilibrium of tautomeric species, 1.12–1.37 (m, 14H), 1.56 (m, 2H), 1.60 (m, 2H), 2.18 (m, 2H), 3.10 (m, 2H), 3.53 (m, 2H, PC H_2CONH), 6.6 (s, 1H, N*H*), 7.30 (m, 2H, phenyl), 7.38 (m, 4H, phenyl), 7.80 (m, 4H, phenyl). ^{13}C NMR ($CDCl_3$): 25.2, 25.9, 26.3, 26.9, 29.5 (3C), 34.2, 39.9, 49.1, 63.5, 129.0 (4C), 130.9 (2C), 132.6 (2C), 169.3 (*C*ONH), 179.8 (*C*OO). ^{31}P NMR ($CDCl_3$): −16.3. ESI-MS (MeOH): *m*/*z* (%) = 465 (100) for $[C_{26}H_{36}NNaO_3P]^+$.

Isocyano Ligands M9–M11 and M17–M18.*Isocyano Alkylamide Ligands M9–M11.General Procedures.* 0.10 mM of the amine, dissolved in 1 mL THF, was added dropwise to 2,3,5,6-tetrafluorophenyl 4-isocyanobutanoate (0.10 mM) and 2,3,5,6-tetrafluorophenyl 4-(isocyanomethyl)-benzoate (0.10 mM) dissolved in 1 mL THF. The reaction mixture was stirred for 2.5 h at room temperature. Then, separation of the solvent in vacuo and purification by column chromatography followed.

4-Isocyano-*N*-octylbutanamide (M9). After removal of the solvent, the crude product was purified by column chromatography (silica gel 60, *tert*-butyl methyl ether/*n*-hexane = 2/1, R_f = 0.10). Yield from 12.9 mg (0.10 mM) 1-aminooctane: 14.5 mg (65%) colorless oil. ^{1}H NMR ($CDCl_3$): 0.86 (t, 3H, CH_3, ^3J = 7.0 Hz), 1.25–1.28 (m, 10H, CH_2), 1.48 (m, 2H, CH_2), 1.95–2.03 (m, 2H, CH_2), 2.33 (t, 2H, CH_2CONH, ^3J = 7.0 Hz), 3.22 (m, 2H, NHCH_2), 3.47 (tt, 2H, CNCH_2, $^3J_{HH}$ = 6.2 Hz, $^2J_{HN}$ = 1.7 Hz), 5.56 (s, 1H, CON*H*). ^{13}C NMR ($CDCl_3$): 14.3, 22.8, 24.9, 27.1, 29.4, 29.5, 29.8, 32.0, 32.5, 39.8 (NH*C*H_2), 41.2 (t, CN*C*H_2, $^2J_{CN}$ = 6.5 Hz), 156.5 (t, *C*N, $^1J_{CN}$ = 5.8 Hz), 171.0. IR (KBr): 3313, 2957, 2927, 2856 (CH_2, CH_3), 2148 (CN), 1642, 1554. ESI-MS (MeOH): *m*/*z* (%) = 225 (100) for $[C_{13}H_{25}N_2O]^+$.

***N*-butyl-4-isocyano-*N*-methylbutanamide (M10).** Column chromatography (silica gel 60; *tert*-butyl methyl ether/*n*-hexane = 4/1, R_f = 0.40. Yield: (70%) colorless oil. ^{1}H NMR ($CDCl_3$): particular doubling of signals because of the mixture of cis/trans isomers, 0.90 (t, 3H, CH_3, ^3J = 7.2 Hz), 0.93 (t, 3H, CH_3, ^3J = 7.0 Hz), 1.21–1.36 (m, 4H, CH_2), 1.42–1.57 (m, 4H, 2 × CH_2), 1.92–2.03 (m, 4H, CH_2), 2.44 (t, 2H, CH_2CONH, ^3J = 6.8 Hz), 2.47 (t, 2H, CH_2CONH, ^3J = 6.8 Hz), 2.89 (s, 3H, NCH_3), 2.96 (s, 3H, NCH_3), 3.25 (t, 2H, NCH_2, ^3J = 7.6 Hz), 3.33 (t, 2H, NCH_2, ^3J = 7.6 Hz), 3.50 (tt, 4H, CNCH_2, $^3J_{HH}$ = 6.2 Hz, $^2J_{NH}$ = 1.9 Hz). ^{13}C NMR ($CDCl_3$): 14.0, 14.1, 20.2, 20.3, 24.5, 24.7, 28.7, 29.4, 29.6, 30.7, 33.6 (N *C*H_3), 35.3 (N *C*H_3), 41.4 (t, CN*C*H_2, $^2J_{CN}$ = 6.2 Hz), 41.5 (t, CN*C*H_2, $^2J_{CN}$ = 6.1 Hz), 47.8, 49.8, 156.2 (broad, *C*N), 170.8. ESI-MS (MeOH): *m*/*z* (%) = 183 (95) for $[C_{10}H_{19}N_2O]^+$.

4-(Isocyanomethyl)-*N*-octylbenzamide (M11). Column chromatography (silica gel 60, *tert*-butyl methyl ether/*n*-hexane = 2/1, R_f = 0.34). Yield: (91%) colorless solid. Mp 82 °C. ^{1}H NMR ($CDCl_3$): 0.86 (t, 3H, CH_3, ^3J = 6.6 Hz), 1.24–1.37 (m, 10H, CH_2), 1.60 (m, 2H, CH_2), 3.43 (t, 2H, NHCH_2, ^3J = 7.1 Hz), 4.68 (s, 2H, CNCH_2Ph), 6.23 (s, 1H, CON*H*), 7.38 (d, 2H, phenyl, ^3J = 8.4 Hz), 7.78 (d, 2H, phenyl, ^3J = 6.4 Hz). ^{13}C NMR ($CDCl_3$): 14.3, 22.9, 29.4, 29.5, 29.9, 31.8, 32.0, 40.4, 45.5 (t, CN*C*H_2Ph, $^2J_{CN}$ = 6.9 Hz), 126.9 (2C), 127.8 (2C), 135.3, 135.6, 156.8 (t, *C*N, $^1J_{CN}$ = 5.6 Hz), 166.9. IR (KBr): 3348, 3063 (CH-phenyl), 2954, 2921, 2851 (CH_2, CH_3), 2158 (CN), 1632. ESI-MS (MeOH): *m*/*z* (%) = 273 (100) for $[C_{17}H_{25}N_2O]^+$.

Alkyl isocyanoalkanoate. Preparation according the other described alkyl-(isocyano)alkanoates (*14*).

Octyl isocyanoacetate (M17). Yield: (86%) viscous colorless oil. ^{1}H NMR ($CDCl_3$): 0.86 (t, 3H, CH_3, ^3J = 6.0 Hz), 1.25–1.35 (m, 10H, CH_2), 1.61–1.69 (m, 2H, CH_2), 4.18–4.20 (m, 4H, CNCH_2+ OCH_2). ^{13}C NMR ($CDCl_3$): 14.3, 22.8, 25.9, 26.0, 28.6, 29.3, 31.9, 43.7, 67.1, 157.4 (broad), 164.2. ESI-MS (MeOH): *m*/*z* (%) = 198 (100) for $[C_{11}H_{20}NO_2]^+$.

Dodecyl Isocyanoacetate (M18). Yield: (89%) viscous colorless oil. ^{1}H NMR ($CDCl_3$): 0.84 (t, 3H, CH_3, ^3J = 6.2 Hz), 1.20–1.36 (m, 18H, CH_2), 1.60–1.68 (m, 2H, CH_2), 4.16–4.19 (m, 4H, CNCH_2+ OCH_2).^{13}C NMR ($CDCl_3$): 14.2, 22.6, 25.8, 26.1, 28.5, 29.1 (2C), 29.3 (2C), 29.6, 31.8, 43.5, 67.0, 156.8 (broad), 166.4. ESI-MS (MeOH): *m*/*z* (%) = 254 (100) for $[C_{15}H_{28}NO_2]^+$.

Preparation of Selected $^{185/187}$Rhenium and ^{99g}Technetium Complexes as Reference Compounds. "4 + 1" FA-NS_3 Re-dimethylphenylphosphine derivatives (TX-Re-M0) were used in ligand exchange reactions as ideal FA precursor complexes for the preparation of the corresponding isocyano-substituted compounds.

[Methyl 12-({*N*,*N*-bis[2-(mercapto-κS)ethyl]cysteinyl-κ^2N^2,S^3}amino)dodecanoate](dimethylphenylphosphine)rhenium (III) (MeT4-Re-M0). The tripodal ligand 1-[(11-carboxyundecyl)amino]-3-mercapto-*N*,*N*-bis(2-mercaptoethyl)-1-oxopropan-2-aminium chloride (T4) (100 mg, 0.21 mM) and the monodentate ligand dimethyl phenyl phosphine (M0) (58 mg, 0.42 mM) were refluxed for 3 h in methanol with the hexathiourea Re(III) complex $\{Re[SC(NH_2)_2]_6\}Cl_3 \times 1H_2O$ (161.5 mg, 0.21 mM) as an appropriate Re(III) precursor. The hydrochloric acid formed during the reaction in the methanol leads to esterification of the carboxyl group (MeT4). (This esterification does not happen with the no carrier added (nca) preparation of the appropriate ^{99m}Tc compounds in predominantly aqueous medium.) After removal of the solvent, the crude product was purified by column chromatography (silica gel 60, chloroform/ethyl acetate, 4/1, $R_f = 0.50$). Yield: 75 mg (46%) green solid. ^{1}H NMR ($CDCl_3$): 1.22–1.31 (m, 14H, CH_2), 1.50 (m, 2H, CH_2), 1.59 (m, 2H, CH_2), 2.07 (d, 6H, PCH_3, $^3J = 3.2$ Hz), 2.28 (t, 2H, CH_2COO, $^3J = 7.4$ Hz), 2.33–2.41 (m, 1H, NCH_2), 2.68–2.83 (m, 6H), 3.03–3.30 (m, 7H), 3.35–3.38 (m, 1H, NCH_2), 3.63 (s, 3H, OCH_3), 3.65–3.73 (m, 1H, C*H*CONH), 5.98 (t, 1H, CON*H*, $^3J = 5.6$ Hz), 7.25–7.29 (m, 1H, phenyl), 7.37–7.41 (m, 2H, phenyl), 7.70–7.75 (m, 2H, phenyl). ^{13}C NMR ($CDCl_3$): 25.1, 27.1, 28.9, 29.1 (2C), 29.3, 29.4 (2C), 29.5, 29.6 (2C), 34.3 (*C*H_2COO), 40.1 (CONH*C*H_2), 47.3, 47.4, 50.1, 51.4, 51.7 (O *C*H_3), 73.0 (*C*HCONH), 128.2 (2C), 128.9, 130.5 (2C), 130.6, 169.1 (*C*ONH), 174.7 (CH_2*C*OOR). ^{31}P NMR ($CDCl_3$): –13.4. IR (KBr): 3070, 3052 (phenyl), 2925, 2853 (CH_2, CH_3), 1737 (COOR), 1676 (CO). UV/vis ($CHCl_3$): λ_{max} (nm): 335.6, 465.4.

[12-({*N*,*N*-Bis[2-(mercapto-κS)ethyl]cysteinyl-κ^2N^2,S^3}amino) dodecanoato][2-(isocyano-κC)-2-methylpropane]rhenium(III) (ReIb). The Re-dimethylphenylphosphino precursor complex (MeT4-Re-M0) (10 mg, 0.0129 mM) was stirred with 2-isocyano-2-methylpropane (M7) (2 mg, 0.026 mM) for 2 h at room temperature in 2 mL chloroform. After an additional step for ester saponification and removal of the solvent, the crude product was purified by column chromatography (silica gel 60; chloroform/ethyl acetate = 4/1, $R_f = 0.65$). Yield: 8.6 mg (95%) green solid. ^{1}H NMR ($CDCl_3$): 1.21–1.36 (m, 14H, CH_2), 1.44 (s, 9H, CCH_3), 1.48–1.80 (m, 4H, CH_2), 3.44 (m, 1H, CH_2), 3.64 (m, 1H, CH_2), 3.78 (m, 1H), 3.94 (m, 1H, C*H*CON), 6.82 (s, broad, 1H, CON*H*). ^{13}C NMR ($CDCl_3$): 24.8, 25.5, 25.7, 26.6, 26.9, 28.4, 29.3, 29.4 (2C), 29.7, 31.0, 31.5, 32.9, 36.2, 40.1, 47.1, 49.7, 56.2, 71.2, (N*C*HCO), 164.9 (*C*NC(CH)$_3$), 169.5 (*C*ONH), 179.2 (*C*OOH). ESI-MS (MeOH): *m*/*z* (%) = 705 (100) for $[C_{24}H_{45}N_3O_3ReS_3]^+$.

[8-({*N*,*N*-Bis[2-(mercapto-κS)ethyl]cysteinyl-κ^2N^2,S^3}amino)-octanoic acid](triphenylphosphine)rhenium(III) (ReIIa). Prepared according the procedure for MeT4-Re-M0 under the use of T3 (19 mg, 0.05 mM), the hexathiourea Re(III) complex (38 mg, 0.05 mM) and M1 (26 mg, 0.1 mM) and an additional step for ester saponification. Column chromatography (silica gel 60, chloroform/ethyl acetate = 2/1, $R_f = 0.3$). Yield: 28 mg (69%) green solid. ^{1}H NMR (CD_3CN): 1.27–1.37 (m, 6H, CH_2), 1.55 (m, 4H, CH_2), 2.27 (t, 2H, CH_2CO, $^3J = 8.0$ Hz), 2.60–2.72 (m, 3H, CH_2), 2.96–3.11 (m, 3H, CONHCH_2 and CH_2), 3.14–3.28 (m, 2H), 3.37 (m, 1H, CH_2), 3.75 (m, 2H, C*H*CON), 6.84 (s, broad, 1H, CON*H*), 7.35 (m, 9H, phenyl), 7.46 (m, 6H, phenyl). ^{13}C NMR (CD_3CN): 24.7, 26.6, 28.7, 28.9, 29.1, 31.3, 33.4, 35.7, 39.2, 46.4, 49.8, 50.7, 56.3, 56.8, 72.4 (N*C*H), 127.8 (d, $^2J_{CP} = 8.0$ Hz), 129.2, 134.1 (d, $^3J_{CP} = 10.0$ Hz), 144.6 (d, $^1J_{CP} = 45.0$ Hz), 168.3 (*C*ONH), 174.4 (*C*OOH). ^{31}P NMR ($CDCl_3$): 28.5 (Re*P*Ph$_3$). ESI-MS (MeOH): *m*/*z* (%) = 827 (100) for $[C_{33}H_{42}N_2O_3PReS_3]^+$.

[12-({*N*,*N*-Bis[2-(mercapto-κS)ethyl]cysteinyl-κ^2N^2,S^3}amino) dodecanoato](triphenylphosphine)rhenium(III) (ReIIb). Prepared according to the procedure for MeT4-Re-M0 under the use of T4 (48 mg, 0.1 mM), the hexathiourea Re(III) complex (77 mg, 0.1 mM) and M1 (52 mg, 0.2 mM) and an additional step for ester saponification. Column chromatography (silica gel 60, chloroform/ethyl acetate = 2/1, $R_f = 0.45$). Yield: 53 mg (60%) green solid. ^{1}H NMR ($CDCl_3$): 1.23–1.36 (m, 14H, CH_2), 1.52–1.82 (m, 4H, CH_2), 1.91 (m, 2H), 2.38 (t, 2H, CH_2COOH, $^3J = 6.0$ Hz), 2.50 (m, 1H, CH_2), 2.75–2.89 (m, 4H, CH_2), 3.06–3.32 (m, 4H, CONHCH_2 and CH_2), 3.42 (m, 1H, CH_2), 3.64 (m, 1H, CH_2), 3.75 (m, 1H), 3.88 (m, 1H, C*H*CON), 5.89 (s, broad, 1H, CON*H*), 7.26–7.32 (m, 9H, phenyl), 7.47 (m, 6H, phenyl). ^{13}C NMR ($CDCl_3$): 25.0, 25.6, 25.7, 26.6, 27.0, 29.3, 29.4, 29.5, 29.7, 31.2, 32.9, 36.1, 40.1, 46.9, 49.7, 50.0, 51.0, 56.3, 73.1 (N*C*HCO), 127.9 (d, $^2J_{CP} = 9.0$ Hz), 129.1, 134.3 (d, $^3J_{CP} = 11.0$ Hz), 143.7 (d, $^1J_{CP} = 46.0$ Hz), 168.9 (*C*ONH), 179.8 (*C*OOH). ^{31}P NMR ($CDCl_3$): 28.1 (Re*P*Ph$_3$). ESI-MS (MeOH): *m*/*z* (%) = 883 (95) for $[C_{37}H_{50}N_2O_3PReS_3]^+$.

[Methyl15-({*N*,*N*-Bis[2-(mercapto-κS)ethyl]cysteinyl-κ^2N^2,S^3}-amino)pentadecanoate](triphenylphosphine)rhenium(III) (ReMeIIc). Prepared according to the procedure for MeT4-Re-M0 under the use of T5 (26 mg, 0.05 mM), the hexathiourea Re(III) complex (38 mg, 0.05 mM) and M1 (26 mg, 0.1 mM). Column chromatography (silica gel 60, chloroform/ethyl acetate = 5/4, $R_f = 0.45$). Yield: 30 mg (65%) green solid. Crystals are available from acetonitrile solution at 4 °C. ^{1}H NMR ($CDCl_3$): 1.20–1.29 (m, 20H, CH_2), 1.49–1.61 (m, 4H, CH_2), 2.28 (t, 2H, CH_2CO, $^3J = 8.0$ Hz), 2.49 (m, 1H, CH_2), 2.76–2.91 (m, 4H, CH_2), 3.08–3.31 (m, 4H, CONHCH_2 and CH_2), 3.41 (m, 1H, CH_2), 3.64 (s, 3H, OCH_3), 3.75 (m, 1H, C*H*CON), 5.83 (s, broad, 1H, CON*H*), 7.27–7.34 (m, 9H, phenyl), 7.47 (m, 6H, phenyl). ^{13}C NMR ($CDCl_3$): 25.2, 27.7, 29.3, 29.4 (2C), 29.6, 29.7 (5C), 29.9, 34.5, 40.0, 46.9, 47.0, 49.8, 50.9, 51.7, 56.3, 73.1 (N*C*H), 127.9 (d, $^2J_{CP} = 10.1$ Hz), 129.8, 134.4 (d, $^3J_{CP} = 11.1$ Hz), 143.7 (d, $^1J_{CP} = 46.3$ Hz), 168.9 (*C*ONH), 174.7 (*C*OOMe). ^{31}P NMR ($CDCl_3$): 28.2 (Re*P*Ph$_3$). ESI-MS (MeOH): *m*/*z* (%) = 940 (90) for $[C_{41}H_{59}N_2O_3PReS_3]^+$.

[15-({*N*,*N*-Bis[2-(mercapto-κS)ethyl]cysteinyl-κ^2N^2,S^3}amino)pentadecanoic acid](triphenylphosphine)rhenium(III) (ReIIc). The ester function was saponified by addition of 0.5 mL 1 N sodium hydroxide to a solution of 1 mg of (**ReMeIIc**) in 2 mL dioxane kept at 75 °C for 10 min After acidification with 1 N hydrochloric acid to pH 3–4, the FA complex (**ReIIc**) was purified by semipreparative HPLC (Hypersil RP-18; eluent, acetonitrile/water/0.1% TFA; gradient, in 10 min from 50 → 100% acetonitrile; flow rate, 2 mL/min; retention time, 16.2 min ESI-MS (MeOH), *m*/*z* (%) = 926 (80) for $[C_{40}H_{57}N_2O_3PReS_3]^+$.

[12-({*N*,*N*-Bis[2-(mercapto-κS)ethyl]cysteinyl-κ^2N^2,S^3}amino)dodecanoic acid](ethyldiphenylphosphinite-κP)rhenium (III) (ReIIIb). Prepared according to the procedure for MeT4-Re-M0 by use of T4 (24 mg, 0.05 mM), the hexathiourea Re(III) complex (38 mg, 0.05 mM) and M5 (23 mg, 0.1 mM). Column chromatography (silica gel 60, *tert*-butyl methyl ether/hexane = 3/1, $R_f = 0.75$). Yield: 8 mg 19% of a dark green solid. ^{31}P NMR ($CDCl_3$): 16.5 (Re*P*Ph$_2$OEt). UV/vis ($CHCl_3$): λ_{max} (nm) 444.5. ESI-MS (MeOH): *m*/*z* (%) = 875 (100) for $[C_{33}H_{50}NaN_2O_4PReS_3]^+$. ESI-MS negative mode (MeOH): *m*/*z* (%) = 851 (100) for $[C_{33}H_{50}N_2O_4PReS_3]^-$.

[12-({*N*,*N*-Bis[2-(mercapto-κ*S*)ethyl]cysteinyl-κ^2*N*^{2},*S*^{3}}amino)-dodecanoic acid][4-(isocyano-κ*C*)-*N*-octylbutanamide]rhenium(III) (ReIVa). The precursor Re-dimethylphenylphosphine complex (MeT4-Re-M0) (12 mg, 0.0155 mM) was stirred with 4-isocyano -*N*-octylbutanamide (M9) (7 mg, 0.031 mM) for 2 h at room temperature in chloroform. After an additional step for ester saponification and removal of the solvent, the crude product was purified by column chromatography (silica gel 60, chloroform/ethyl acetate = 5/4, +0.1% TFA, $R_f = 0.35$). Yield: 12 mg (93%) green solid. ^{1}H NMR ($CDCl_3$): 0.85 (t, 3H, C*H*$_3$, ^3J = 6.8 Hz), 1.19–1.35 (m, 24H, C*H*$_2$), 1.46 (m, 2H, C*H*$_2$), 1.55 (m, 4H, C*H*$_2$), 2.09 (m, 2H, C*H*$_2$), 2.27 (t, 2H, C*H*$_2$CO, ^3J = 7.4 Hz), 2.39–2.45 (m, 1H, C*H*$_2$), 2.51 (t, 2H, C*H*$_2$CO, ^3J = 7.0 Hz), 2.78–2.91 (m, 2H, C*H*$_2$), 2.98 (m, 1H, C*H*$_2$), 3.09–3.42 (m, 9H), 3.49 (m, 1H, C*H*$_2$), 3.88 (m, 1H, NC*H*), 4.70 (t, 2H, CNC*H*$_2$, ^3J = 5.8 Hz), 6.02 (t, 1H, CONH, ^3J = 5.6 Hz), 6.41 (t, 1H, CONH, ^3J = 5.3 Hz). ^{13}C NMR ($CDCl_3$): 14.3, 22.9, 24.9, 27.1, 27.2, 29.0, 29.2, 29.3, 29.4 (2C), 29.5 (3C), 29.6, 29.7, 32.0, 32.1, 33.8, 34.1, 39.9, 40.2, 44.2, 44.8, 46.7, 48.0, 55.4, 71.7 (N*C*H), 166.4 (*C*N), 168.5 (CONH), 172.6 (*C*ONH), 178.3 (*C*OOH). ESI-MS (MeOH): *m*/*z* (%) = 868 (80) for $[C_{32}H_{59}N_4NaO_4ReS_3]^+$.

^{99g}Tc [12-({*N*,*N*-bis[2-(mercapto-κ*S*)ethyl]cysteinyl-κ^2*N*^{2},*S*^{3}}amino)-dodecanoato][octyl(isocyano-κ*C*)acetate]technetium(III) (Vc). The "carrier added" ^{99g}Tc reference complex was prepared according to the ^{99m}Tc complex synthesis by addition of 20 μL of a 10^{-6} M $Na^{99g}TcO_4$ solution to the 0.5 mL generator eluate. The complex was purified via semipreparative HPLC (Hypersil RP-18; eluent, acetonitrile/water/0.1% TFA; gradient, in 10 min from 50 → 100% acetonitrile; flow rate, 2 mL/min; retention time, 15.4 min). ESI-MS (MeOH): *m*/*z* (%) = 732 (100) for $[C_{30}H_{55}N_3O_5S_3Tc]^+$.

{*N*,*N*-Bis[2-(mercapto-κ*S*)ethyl]cysteinato(3-)-κ^2*N*,*S*^{3}}[methyl 15-(isocyano-κ*C*)pentadecanoate]rhenium(III) (ReMeVIb). A further "4 + 1" NS_3-Re-triphenylphosphine derivative (T2-Re-M1) described in ref (*18*) (13 mg, 0.019 mM) was used as precursor in ligand exchange reactions with methyl 5-{[6-(isocyano-κ*C*)hexyl]thio} pentanoate (M16-Me) (8 mg, 0.03 mM). Column chromatography (silica gel 60, chloroform/ethyl acetate = 1/1, $R_f = 0.65$). Yield: 6.7 mg (59%) green solid. ^{1}H NMR ($CDCl_3$): 1.20–1.35 (m, 20H, C*H*$_2$), 1.51–1.61 (m, 2H, C*H*$_2$), 1.73–1.80 (m, 2H, C*H*$_2$), 2.28 (t, 2H, C*H*$_2$COO, ^3J = 7.6 Hz), 2.41–2.48 (m, 1H, C*H*$_2$), 2.63–2.70 (m, 1H, C*H*$_2$), 2.84–2.98 (m, 3H, CONHC*H*$_2$ and C*H*$_2$), 3.14–3.20 (m, 1H), 3.25–3.29 (m, 1H), 3.35–3.40 (m, 1H), 3.45–3.49 (m, 1H, C*H*$_2$), 3.53–5.58 (m, 1H), 3.66 (s, 3H, OC*H*$_3$), 3.73–3.77 (m, 1H, NC*H*CON), 4.75 (t, 2H, ^3J = 6.4 Hz, CNC*H*$_2$). ^{13}C NMR ($CDCl_3$): 25.1, 26.9, 29.2, 29.4, 29.5, 29.7 (2C), 29.8 (2C), 29.9, 33.3, 34.4, 44.4, 45.3, 46.6, 48.2, 51.9, 55.1, 56.4, 69.3 (N*C*H), 163.8 (*C*NCH$_2$), 175.2 (*C*OOMe). ESI-MS (MeOH): *m*/*z* (%) = 705 (90) for $[C_{24}H_{43}N_2O_4ReS_3]^+$.

{*N*,*N*-bis[2-(mercapto-κ*S*)ethyl]cysteinato(3-)-κ^2*N*,*S*^{3}}[15-(isocyanoκ*C*)pentadecanoic acid] rhenium(III) (ReVIb). The ester function was saponified by the addition of 0.5 mL 1 N sodium hydroxide to a solution of 1 mg of **ReMeVIb** in 2 mL dioxane kept at 75 °C for 10 min After acidification with 1 N hydrochloric acid to pH 3–4, the FA was purified by semipreparative HPLC (Hypersil RP-18; eluent, acetonitrile/water/0.1% TFA; gradient, in 10 min from 50 → 100% acetonitrile; flow rate, 2 mL/min; retention time, 13.0 min). ESI-MS (MeOH): *m*/*z* (%) = 691 (90) for $[C_{23}H_{41}N_2O_4ReS_3]^+$.

{*N*,*N*-Bis[2-(mercapto-κ*S*)ethyl]cysteinato(3-)-κ^2*N*,*S*^{3}}[methyl 5-{[6-(isocyano-κ*C*)hexyl]thio} pentanoate]rhenium(III) (ReMeVIc). The "4 + 1" NS_3-Re-triphenylphosphine derivative (T2-Re-M1) described in ref (*18*) (15 mg, 0.022 mM) was used as the precursor in a ligand exchange reactions with methyl 15-isocyanopentadecanoate (M16-Me) (11 mg, 0.04 mM). Column chromatography (silica gel 60, chloroform/ethyl acetate = 1/1, $R_f = 0.55$). Yield: 10 mg (65%) green solid. ^{1}H NMR ($CDCl_3$): 1.18–1.27 (m, 2H, C*H*$_2$), 1.41–1.47 (m, 2H, C*H*$_2$), 1.57–1.81 (m, 8H, C*H*$_2$), 2.32 (t, 2H, C*H*$_2$COO, ^3J = 7.6 Hz), 2.45 (m, 1H, C*H*$_2$), 2.48–2.52 (m, 4H, C*H*$_2$SC*H*$_2$), 2.63–2.70 (m, 1H, C*H*$_2$), 2.82–2.98 (m, 2H), 3.14–3.20 (m, 1H), 3.25–3.29 (m, 1H), 3.35–3.42 (m, 1H), 3.45–3.49 (m, 1H, C*H*$_2$), 3.54–5.57 (m, 1H), 3.65 (s, 3H, OC*H*$_3$), 3.73–3.77 (m, 2H, NC*H*CON + C*H*$_2$), 4.76 (t, 2H, CNC*H*$_2$, ^3J = 8.0 Hz). ^{13}C NMR ($CDCl_3$): 24.4, 26.5, 28.5, 29.3, 29.8, 29.9, 31.9, 32.3, 33.1, 33.9, 44.4, 45.2, 46.5, 48.2, 51.8, 55.1, 56.4, 69.6 (N*C*H), 161.6 (*C*NCH$_2$), 174.3 (*C*OOMe). ESI-MS (MeOH): *m*/*z* (%) = 594 (90) for $[C_{20}H_{35}N_2O_4ReS_4]^+$.

{*N*,*N*-Bis[2-(mercapto-κ*S*)ethyl]cysteinato(3-)-κ^2*N*,*S*^{3}}[5-{[6-(isocyano-κ*C*)hexyl]thio}pentanoic acid]rhenium(III) (ReVIc). The ester function was saponified by addition of 0.5 mL 1 N sodium hydroxide to a solution of 1 mg of (**ReMeVIc**) in 2 mL dioxane kept at 75 °C for 10 min After acidification with 1 N hydrochloric acid to pH 3–4, the FA was purified per semipreparative HPLC (Hypersil RP-18; eluent, acetonitrile/water/0.1% TFA; gradient, in 10 min from 50 → 100% acetonitrile; flow rate, 2 mL/min; retention time, 11.8 min). ESI-MS (MeOH): *m*/*z* (%) = 580 (90) for $[C_{19}H_{33}N_2O_4ReS_4]^+$.

(12-{[(Diphenylphosphino-κ*P*)acetyl]amino}dodecanoic acid)[2,2′,2″-(nitrilo-κ*N*)triethane thiolato-(3-)-κ*S*]rhenium(III) (T1-Re-M6 = ReVIIa). 28 mg (0.97 mM) of the oxalic acid salt of tris(2-mercaptoethyl)amine (T1) and 100 mg (1.9 mM) of the crude monodentate 12-{[(diphenylphosphino)acetyl]-amino}dodecanoic acid (**M6**) were refluxed for 3 h in methanol with 35 mg (0.046 mM) hexathiourea Re(III) complex $\{Re[SC(NH_2)_2]_6\}Cl_3 \times 1H_2O$ as an appropriate Re(III) precursor. After removal of the solvent, the crude product was purified by column chromatography (silica gel 60, chloroform/ethyl acetate = 4/1, $R_f = 0.50$). The acidic reaction conditions in methanol lead to the corresponding methyl dodecanoato FA complex. (NMR data of the methyl ester Re complex are shown in Supporting Information.) For the saponification of the ester function, 1 mL 1 N aqueous sodium hydroxide was added to the dissolved methyl ester complex in 5 mL dioxane and stirred for 24 h. After acidification with TFA to pH 3–4 and evaporation of the solvent, a 3-fold extraction with chloroform/water followed. The united organic phases were dried with $MgSO_4$, and the solvent was evaporated under reduced pressure. The residue was purified by column chromatography (silica gel 60, chloroform/ethyl acetate = 9/1, $R_f = 0.5$). Yield: 23 mg (58%). Mp > 220 °C (decomp.). ^{1}H NMR ($CDCl_3$): 1.05–1.30 (m, 16H), 1.58–1.63 (m, 2H), 2.33 (t, 2H, ^3J = 7.4 Hz), 2.60–3.20 (m, 12H), 3.0 (q, 2H, ^3J = 6.5 Hz), 3.75 (d, 2H, PC*H*$_2$CONH, $^2J_{HP}$ = 3.4 Hz), 6.2 (s, broad, 1H, CONH), 7.28 (t, 2H, phenyl, ^3J = 7.1 Hz), 7.36 (t, 4H, phenyl, ^3J = 7.4 Hz), 7.67 (dd, 4H, $^3J_{HH}$ = 7.6 Hz, $^3J_{HP}$ = 9.0 Hz). ^{13}C NMR ($CDCl_3$): 24.9, 27.0, 29.0, 29.1, 29.2, 29.4, 29.4, 29.4, 29.5, 33.9, 40.1 (*C*H$_2$NHCO), 47.0, 48.0 (d, P*C*H$_2$CONH, $^1J_{CP}$ = 19.7 Hz), 60.4, 128.1 (d, $^3J_{CP}$ = 9.5 Hz), 129.4, 133.0 (d, $^2J_{CP}$ = 11.4 Hz), 144.4 (d, $^1J_{CP}$ = 44.8 Hz), 168.5 (*C*ONH), 177.2 (*C*OO). ^{31}P NMR ($CDCl_3$): 17.0. ESI-MS (MeOH): *m*/*z* (%) = 845 (70) $[C_{32}H_{48}N_2NaO_3PReS_3]^+$.

X-ray Data Collection and Processing. The X-ray data were collected at room temperature (293 or 273 K) on a SMART-CCD diffractometer (Siemens), using graphite monochromatized Mo Kα radiation (λ = 0.710 73 Å). A summary of the crystallographic data of **ReMeIIc** is given in Table 2. The structures were solved by direct methods. After anisotropic refinement of the nonhydrogen atoms, the hydrogen positions were calculated according to ideal geometries. Empirical absorption corrections were made. Most of the calculations were carried out in the SHELXTL system with some local modifications. Selected bond lengths and angles are reported in figure

legends of the crystal structures. CCDC 638660 (**ReMeIIc**) contains the supplementary crystallographic data for this paper. These files can be obtained free of charge via http://www.ccdc.cam.ac.uk/data_request/cif, by e-mailing data_request@ccdc.cam.ac.uk, or by contacting The Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033.

Synthesis Procedure for the Modified "4 + 1" ^{99m}Tc Complexes. ^{99m}Tc-[12-({*N*,*N*-bis[2-(mercapto-κS)ethyl]cysteinyl-κ^2N^2,S^3}amino)dodecanoic Acid][4-(isocyano-κC)-*N*-octylbutanamide]technetium(III) (IVa). Before usage, all isocyano ligands were transferred to their corresponding Cu(I) complexes by addition of 0.25 equiv of Cu(I) chloride. 0.5 mL pertechnetate solution (100–500 MBq generator eluate) were added to a prepared EDTA kit containing EDTA (1 mg) and stannous (II) chloride (0.08 mg), as well as mannitol (5 mg). After 20 min tempering at 37 °C, a purity control was followed by radio TLC (silicagel/acetone). The ^{99m}Tc(III)–EDTA complex resulted with over 99% radiochemical purity.

The aqueous EDTA-complex solution was added to a solution of the tetradentate ligand TX (0.5 mg) in 0.1 mL *t*-butyl alcohol {exemplary: 1-[(11-carboxyundecyl)amino]-3-mercapto-*N*,*N*-bis(2-mercaptoethyl)-1-oxopropan-2-aminium chloride (T4)}, and the monodentate phosphine or isocyano ligand MY (0.05 mg) in 0.2 mL *n*-propyl alcohol (exemplary: Cu(I) complex of 4-isocyano-*N*-octylbutanamide M9), and heated 30 min at 65 °C. After cooling to room temperature, the ^{99m}Tc–FA complex was purified via semipreparative HPLC (Hypersil RP-18; eluent, acetonitrile/water/0.1% TFA; gradient, in 10 min from 50 → 100% acetonitrile; flow rate, 2 mL/min (retention time for **IVa**, 14.6 min). For each compound group, at least one representative was identified as the expected ^{99m}Tc-FA by comparison of retention times with the nonradioactive Re reference FA complex. After the removal of acetonitrile by vacuum evaporation, 200 μL propylene glycol was added. The radiochemical yield of **I**–**VII** was 50–80%.

Animals. All experiments were carried out on Wistar rats of both gender (body weight 200–250 g) purchased by Charles River (Sulzfeld, Germany). The investigations conformed to the Guide for the Care and Use of Laboratory Animals issued by the U.S. National Institutes of Health and were approved by the local government authority (AZ 24-9168.24-1-2002-14, AZ 24-9168.21-4/2004-1). Animals were kept under a 12 h light–dark cycle and fed with commercial animal diet and water ad libitum.

Isolated Heart Preparation. Anesthesia was performed in two steps: After resting in a diethyl ether chamber for a short time, deep anesthesia was achieved by an intraperitoneal (i.p.) injection of 2–3 mL urethane (15%). In addition, 1000 U/kg i.p. heparin was injected. Hearts were rapidly removed during continuous cooling (Krebs-Henseleit buffer (KHB) 4 °C) and mounted within 1 min via the aorta vertically on a perfusion cannula. Perfusion was immediately started according to the Langendorff technique with a modified KHB containing (mM/L): NaCl 116, KCl 4.6, $MgSO_4$ 1.2, KH_2PO_4 1.2, $NaHCO_3$ 25, $CaCl_2$ 2.5, glucose 11, and pyruvate 2. The buffer was equilibrated with a 95% O_2/5% CO_2 gas mixture (resulting pH 7.38), FA free bovine albumin (BSA) (0.1%/14.9 μM/L), and maintained at 37 °C. The pulmonary artery was catheterized to permit anaerobic collection of the coronary venous effluent perfusate. Total coronary flow was measured using an ultrasonic transit-time flowmeter (T206 Transonic Systems Inc., Ithaca, NY) inserted in the arterial perfusion line and kept constant at 10 mL/min. Coronary perfusion pressure (CPP) was measured through a pressure transducer (Gould Statham, USA) connected to the perfusion cannula. Heart rate was calculated manually from a CPP printout. "Arterial" and "venous" perfusate samples collected anaerobically were analyzed for pO_2, pCO_2, pH, HCO_3^- × (AVL 990S, AVL Scientific Corporation, Roswell, GA) before each intervention.

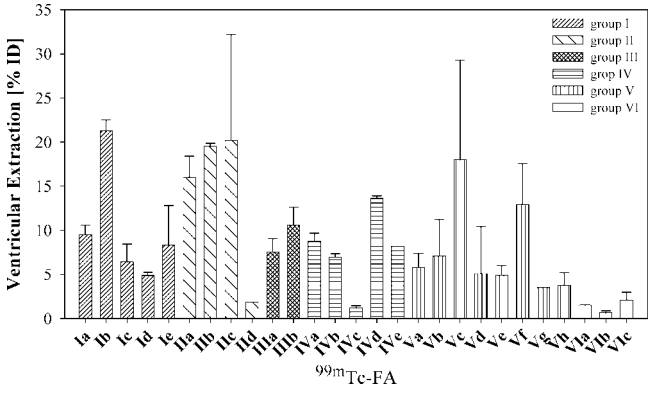

Figure 3. Ventricular extraction (in % of infused activity) of modified ^{99m}Tc-labeled FA evaluated with the Langendorff model.

Experimental Procedure. ^{99m}Tc-labeled FA were diluted in a ratio of 1:2 with KHB enriched with 6% BSA and left to equilibrate at room temperature for 30 min. After a period of 30 min to achieve hemodynamic stabilization of the beating heart, the ^{99m}Tc-labeled FA were infused proximal to the perfusion cannula in a ratio of 1:1000.

Starting with the FA infusion, the complete venous effluent perfusate was collected in 12 consecutive samples of 15 s each (samples 1–12). Following the stop of radioactivity infusion, another four samples during sole KHB perfusion were collected (rinse out of possible coronary radiolabeled substances; samples 13–16). Released radioactivity (A_{eff}) was taken to equal the sum of the radioactivity recovered from these 16 effluent perfusate samples corrected for background activity. Then, perfusion was stopped, and hearts were quickly removed and separated into atria and right and left ventricles. For input calculation (A_{in}), 5 15 s perfusate samples were collected under identical radioactivity infusion and flow settings directly from the perfusion cannula in the absence of a heart. All perfusate and heart samples were measured with a gamma counter (Wallac 1470 Wizard, PerkinElmer Freiburg, Germany).

Only experiments were used in which the calculated input (A_{in}) was in a range of ±20% of the measured total radioactivity of perfusate plus heart tissue samples ($A_{eff} + A_{tiss}$). Ventricular extraction (E_v) was calculated by dividing ventricular tissue radioactivity by the summed radioactivity of perfusate samples (A_{eff}) plus heart tissue samples (A_{tiss}).

Biodistribution Studies in Rats. Anesthesia was performed with an intraperitoneal injection (i.p.) of urethane (1.5 g/kg). A tail vein was surgically exposed, and a 200 μL (0.5 MBq) bolus of a solution containing the "4 + 1" ^{99m}Tc-FA compound and HSA (6%) in a 1:2 ratio were injected. The animals were sacrified by decapitation at 60 min after injection. The blood was immediately withdrawn by cardiac puncture with a heparinized syringe and the activity was counted. Organs were excised and weighed, and the radioactivity was determined (Wallac 1480 WizardTM gamma counter, PerkinElmer, Shelton, CT). The accumulated ^{99m}Tc activity in organs and tissues was calculated as percentage of the injected dose per organ (% ID/organ) or per gram tissue (% ID/g tissue). Data are given as mean ± standard deviation (SD) of four animals each.

RESULTS

Syntheses of FA Derivatives. With respect to the synthesis procedures, three important aspects deserve particular attention. First, the possibility to introduce the FA moiety to the tetradentate NS_3 ligand results in more influentual capabilities for the Tc–FA complex properties by variation of the monodentate ligand. Functionalized isocyano ligands can be used as well as different commercially available phosphines or phosphites with varying chemical and sterical characteristics. Second, the design of isocyano-substituted active esters provides easy access to various isocyano compounds by multifarious functionalization reactions at the active ester group. Third, the application of the isocyanide compounds as Cu(I) complexes is a very important fact regarding enhancement of reactivity toward ligand exchange at the [Tc(FA-NS_3)] core and concurrent stability of the isocyano group in the reaction medium. The advantages of this method are most obvious in all preparations in which the free FA appeared. As a consequence, the last saponification step, necessary when the isocyano FA is applied in the form of its ester, is redundant now, and thus, the synthesis proceeds more rapidly [50 min instead of 60 min; when

comparing the reaction conditions for the nca procedure given in ref (*14*)]. A further positive aspect is the decreased reaction temperature (from 90 to 65 °C), which causes no drop in the yields (in some cases, the yields are even higher) and diminishes the risk of forming the corresponding Tc(I) hexaisocyanide derivatives as byproducts.

The reaction route for the synthesis of "4 + 1" ^{99m}Tc/Re FA complexes with monodentate ligands bearing different metabolically stable functional groups is demonstrated in Figure 1.

Experiments on the Isolated Perfused Rat Heart. Figure 3 shows the extraction results of all synthesized and investigated compounds (the complex composition of each FA derivative in addition to uptake values is presented in Table 2 in the Supporting Information). The length of the FA chain in the tetradentate ligand varied among 1, 8, 12, and 15 carbon atoms. The highest value of ventricular extraction in the isolated perfused Langendorff rat heart was achieved with the dodecanoic FA derivative **Ib** with 21.25 ± 1.28% ID. Four other compounds (**IIa**, **IIb**, **IIc**, and **Vc**) also exceeded the extraction value of ^{123}I-IPPA, for which a ventricular extraction of 15.51% ID was measured (*14*). The lowest extraction (0.6–2.09% ID) showed the "4 + 1" ^{99m}Tc-FA with a tetradentate ligand bearing only a carboxylic group (**VIa–c**).

Biodistribution Studies in Rats. Table 3 shows the biodistribution of modified ^{99m}Tc "4 + 1" labeled FA in Wistar rats. Rapid clearance from blood was observed for all investigated compounds. The highest uptake in heart was achieved for **IIa** (2.88 ± 0.19% ID/g) with a remarkably high heart/blood ratio of 5.65 at 5 min postinjection (p.i.). **Vc** showed the most rapid washout from liver. Here, the initial liver uptake of 4.96 ± 0.31% ID/g was reduced down to 0.29 ± 0.08% ID/g at 60 min p.i.

The elimination of compounds from group **I–V** proceeded predominantly via the hepatobiliary system, whereas **VIc** and **VId** were excreted via the kidneys into the urine. The brain and the thyroid gland were almost free from radioactive species.

DISCUSSION

The development of ^{99m}Tc-labeled FA, suitable for myocardial metabolism imaging is a challenging task. In an effort to synthesize ^{99m}Tc-"4 + 1" FA compounds with an improved liver clearance and high myocardial uptake rate, the concept of simple linear molecules with an end-positioned chelate was abandoned for more complex molecules with the chelate unit within the chain. This structure modification is enabled by a carboxylic group at the chelate backbone that allows binding of the FA moiety by an ω-amino group via the carboxylic acid amide bound.

Thus, the remaining free coordination site on the tripodal metal core can additionally be functionalized by isocyanides or phosphorus(III) donors. The molecular structure of the triphenylphosphine complex **ReMeIIc**, the corresponding methyl ester of **ReIIc**, is presented as an example for the modified "4 + 1" FA species, bearing the FA unit bound to the tetradentate NS_3 ligand. The compound crystallizes as a racemic structure in the monoclinic spacegroup $P2(1)/n$ (see crystallographic data in Table 2). The centrosymmetry of the structure converts the 24(R) configuration into a 24(S) configuration. The structure of the chelate unit shows a large agreement with the basic structure of the unsubstituted "4 + 1" NS_3-triphenylphosphine complex (*19*). The complex unit adopted a trigonal bipyramidal geometry where the three NS_3 thiolate sulfurs form the trigonal plane and the amine nitrogen of the tetradentate FA ligand and the phosphorus atom of PPh_3 occupy the apical positions (Figure 4). Figure 5 shows the linkage of the molecules via hydrogen bonds between the nitrogen of the amide and one oxygen of the carboxyl group, resulting in a head-to-tail arrangement. This interaction leads to the formation of chains running parallel to the *b*-axis.

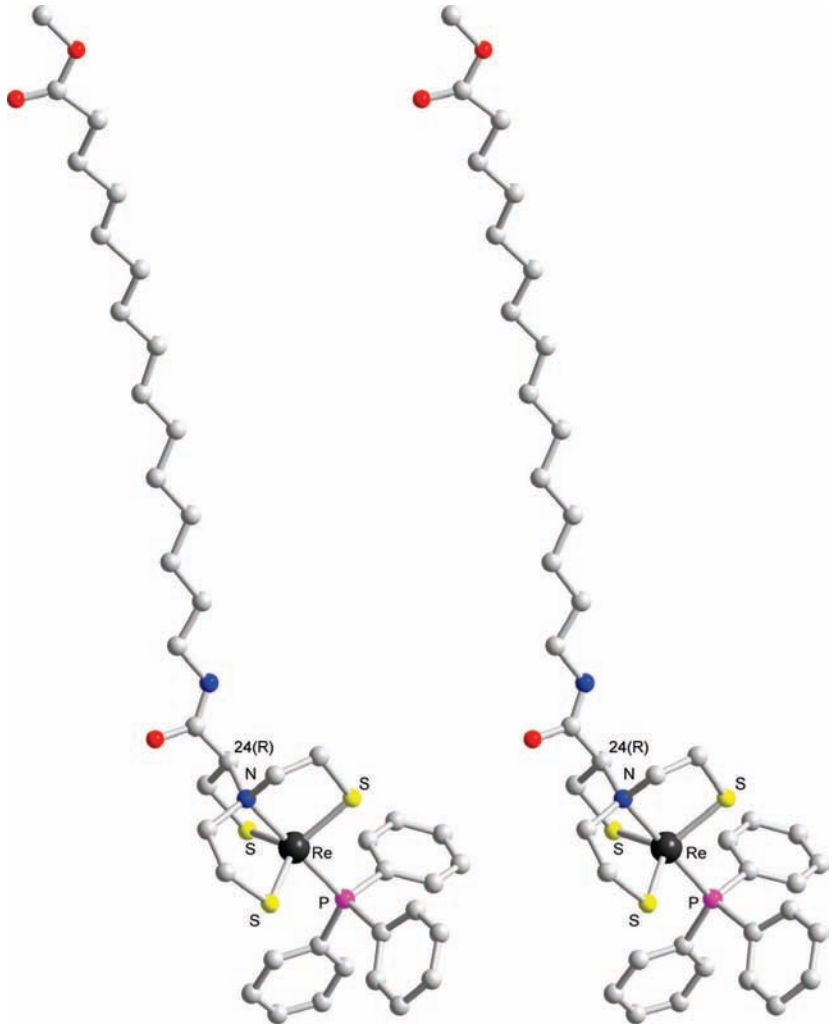

Figure 4. Stereo drawing of the "4 + 1" FA-Re-triphenylphosphine complex with selected bond lengths (pm) and angels (deg) Re-P 230.0(5), Re-N1 221.7(17), Re-S1 222.5(6), Re-S2 222.2(6), Re-S3 221.9(6), and N1-Re-P 178.0(5).

These structures allow variations on both parts of the chain by introducing metabolically active groups (e.g., ester or amide) and, thus, the tuning of the breakdown properties to vary the clearance characteristics, especially from the liver. The potentially improved recognition by membranous and cellular FA transport and degradation enzymes would be an additional advantage of the modified "4 + 1" compounds. The chelate is positioned relatively far away from both the lipophilic tail section and the polar acid section, and on both endings of the FA compound, only inartificial groups were found.

The configuration of natural FA was approximated by transferring the chelate from the end into the interior of the compound combined with a structural variation of the lipophilic tail composition. With the end-positioned carboxyl group, the synthesized derivates have a polar head serving as an important recognition feature. This polar section is so firmly connected with the chelate unit that decomposition is exclusively possible via β-oxidation. A lipophilic tail was constructed at the monodentate ligand, which represents a crucial characteristic of FA. Due to the included functional groups being cleaved in liver with a rate sequence of ester > ether > amide, the rapid formation of polar metabolites allows a fast washout from the liver (Figure 7).

Within this structure, the position of the chelate was varied and moved from the carboxyl group to the lipophilic tail. Therefore, the influence on heart uptake and biodistribution of the total length of the resulting molecule and the relation of the polar section to the lipophilic section were studied.

Regarding the results obtained from the isolated heart model, some of the newly synthesized compounds achieved extraction results of about 20% ID. The common characteristics of these well-extracted compounds are the high level of lipophilicity and a FA chain length between 12 and 15 carbon atoms. Thus, functional groups with particular lipophilic properties incorporated in the tail section are an important feature to increase the myocardial uptake. However, the length of the tail section and the chelate position have a minor influence. In contrast, a shortening of the alkyl chain down to the carboxylic group as done in **Vg** or **Vh** clearly decreases the myocardial uptake in the Langendorff heart model from 18.01% ID as achieved with **Vc** down to 3.51% and 3.77% ID, respectively. The room-filling "4 + 1" ^{99m}Tc-chelate reflecting a dodecanoic FA derivative with respect to elongation, comparable with palmitic acid, may explain the preference for the mentioned FA chain length.

Regarding the monodentate ligands used, isocyanides are preferred in consideration of the structural simplicity. However, one should keep in mind that the encumbering phosphine moiety is a part of many myocardium affine Tc tracers such as ^{99m}Tc-tetrofosmin or ^{99m}Tc-bis(diphosphines). Thus, it is not only permissive to involve phosphorus donor ligands in the intended tracer design, but rather reasonable profit may result from the binding properties of the phosphorus to technetium and the structural variability given by the three substituents. It involves the chance to locate positions at the phosphorus ligand that can be metabolized (as the phosphinite in complex **Vb**). Also worth mentioning is the prolonged myocardial retention time as

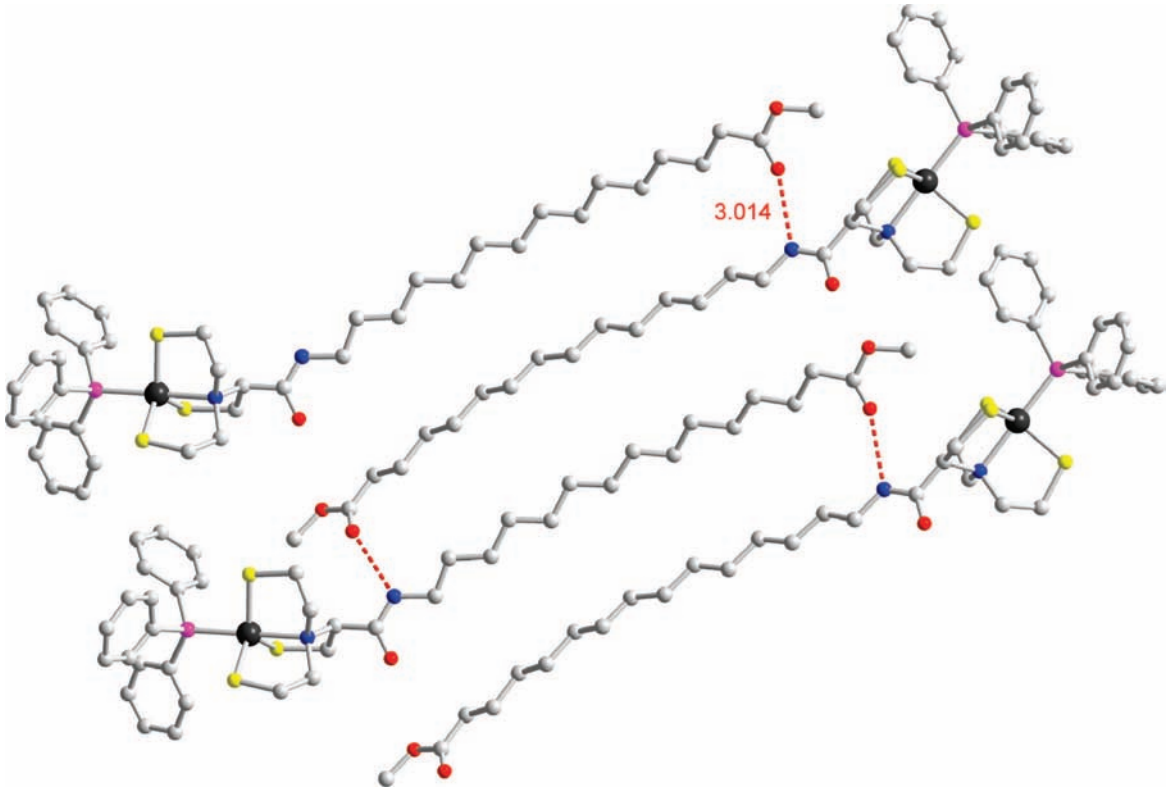

Figure 5. Molecules of the "4 + 1" FA-Re-triphenylphosphine complex building chains in the crystal structure. Dotted red lines indicate hydrogen bonds.

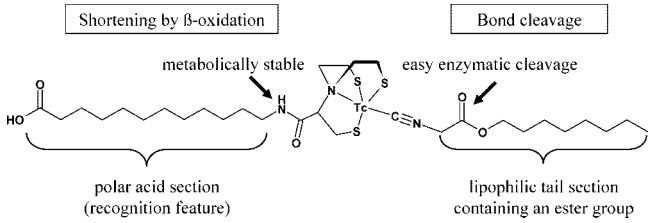

Figure 6. Lead structure (**V**) of the modified "4 + 1" ^{99m}Tc-FA concept for combining high myocardial uptake and fast liver clearance.

observed in biodistribution studies of **VII**, a "conventional" "4 + 1" FA derivative with an FA-bearing phosphine, and the triphenylphosphine containing compounds **IIa** and **IIb.** This fact is particularly obvious in comparison with "conventional" "4 + 1" FA with isocyano ligands (*14*). Initially, concerning in vivo stability of the presented ^{99m}Tc-FA compounds, metabolically stable ("inert") monodentate ligands (e.g., phosphines and amides [groups **II**–**IV**]) were synthesized. In further course, better metabolizable ligands (e.g., ester [group **V**]) were developed. In this context, group **IV** compounds with an NH-amide group incorporated into the tail can be regarded as precursors for derivatives developed later. At those compounds, the lipophilic tail is easily enzymatically cleaved by the introduction of an ester group (group **V**) (Figure 6).

A good example of how structural changes in the monodentate ligand are reflected in biodistribution patterns is given by comparison of FA derivatives with the phosphino monodentate (group **II**) vs isocyanide/ester compounds (group **V**) (Figure 7). **IIa** fulfills the demand for high lipophilicity resulting in promising uptake values in the isolated perfused rat heart and in biodistribution (Table 2 and Figure 7). Furthermore, convenient heart/blood and heart/lung ratios at 5 min p.i. were found. Unfortunately, data on liver clearance were disappointing. Compared with the value after 5 min p.i., the measured concentration of radioactive species in the liver at 60 min p.i.

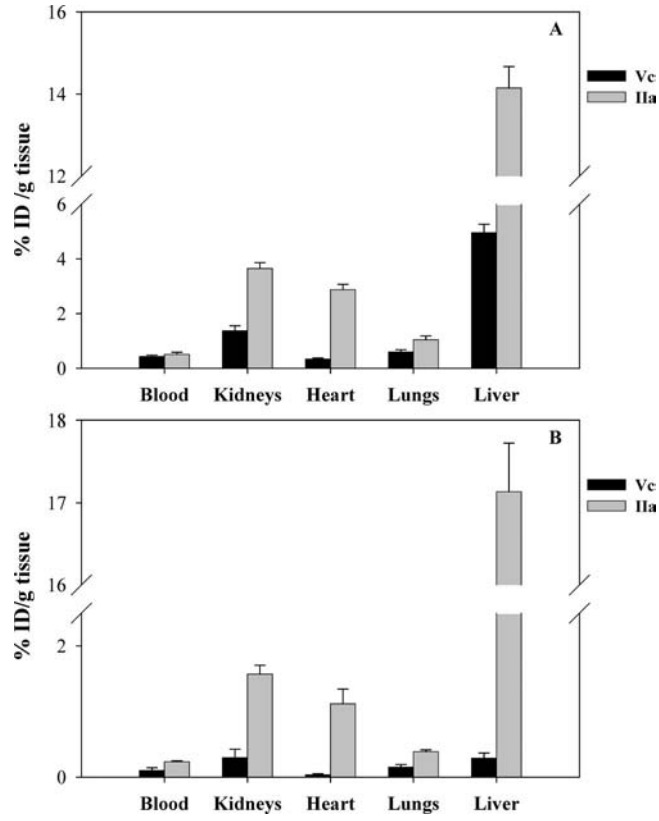

Figure 7. Biodistribution of ^{99m}Tc radioactivity concentration (% ID/g tissue) in male Wistar rats ($n = 4$) at 5 min (A) and 60 min (B) after intravenous injection of ^{99m}Tc-labeled FA.

was even higher, indicating the formation of lipophilic metabolites. A similar high accumulation in the liver is described for unsubstituted "4 + 1" $TcNS_3$–phosphine complexes (*16*).

In contrast, **Vc** exhibited accelerated liver clearance. Unfortunately, the myocardial uptake in biodistribution studies was rather low (Table 3). A possible reason for this shortcoming could be the untimely hydrolysis by plasma esterases. This is confirmed by the finding that the biodistribution of the dicarboxylic acid complexes **VIb** and **VId** shows a similar characteristic (low heart uptake and fast liver clearance). However, it should be considered that a more rapid rate of enzymatic hydrolysis in blood of rats (and mouse) is well-known. In addition, in case of the cationic technetium(I) hexakis (2-carbomethoxy-2-isocyano propane)$_6^+$ (^{99m}Tc-CPI), metabolic products are less lipophilic and of negative charge, leading to a disabled myocardial uptake. In contrast, in species with decreased plasma hydrolysis activity such as guinea pigs, rabbits, and chickens, myocardial accumulation was clearly increased (*20*). Therefore, it is likely that ester hydrolysis in **Vc** by blood plasma enzymes may be slow enough for a high initial heart uptake in other animal species and in humans. In addition, evidence for a satisfactory heart uptake of **Vc** in the absence of rat plasma esterases is given in experiments with the isolated perfused rat heart model, where a ventricular extraction of 18.01% ID was obtained. For a better evaluation of this result, one should bear in mind that the myocardial extraction of ^{123}I-IPPA in the same experimental setup was 15.51% ID (*14*).

A further attempt in the case of compounds **VIa–VId** was the combination of a tetradentate ligand containing the carboxyl group with a monodentate ligand bearing a free carboxyl group. It is well-known that the introduction of a carboxyl group in the NS_3 ligand results in a distinct decrease of lipophilicity (*16*). Therefore, the extraction obtained in the isolated heart was low, no matter whether a carboxyl group containing isocyano ligand as in **VIb** or a phosphine as in **VIa** was used as a monodentate ligand. However, the renal excretion of the dicarboxylic acid derivatives **VIb** and **VId** was increased and the clearance from liver was accelerated. These results are in good agreement with the fast liver clearance of the ester containing compound **Vc**, which was metabolized by esterases to the corresponding dicarboxylic acid. As expected, the heart uptake obviously decreased in the isolated heart and to a lesser extent in biodistribution studies compared to the more promising results of the recently presented "conventional" "4 + 1" ^{99m}Tc-FA with unsubstituted tetradentate NS_3 and isocyano FA ligands (*14*).

In comparison with the recently presented ^{99m}Tc-cyclopentadienyltricarbonyltechnetium-pentadecanoic acid, [^{99m}Tc] CpTT-PA (*21*), only **IIa** showed a similar myocardial uptake (2.88% ID/g). However, the heart/blood ratio at 5 min p.i. was clearly more promising for **IIa** (5.65 vs 2.93). Advantageous for the [^{99m}Tc] CpTT-PA is the combination of a satisfying uptake in heart and a rather low liver uptake.

In conclusion, 29 modified ^{99m}Tc-"4 + 1" FA dedicated in groups **I–VII** according to their physicochemical properties were synthesized and evaluated using the isolated heart model and in vivo biodistributution studies. Differences in heart uptake and biodistribution were induced by varying the position of the Tc chelate, the FA chain length, the incorporation of various functional groups (amide, ether, ester) into the lipophilic tail, the insertion of blocking groups (thiol, phenylene, and alkine) in both the alkyl chain and the tail section, and the usage of two different kinds of monodentate ligands (isocyanides vs phosphines). Whereas some compounds show a high myocardial uptake, others are characterized by an accelerated washout from the liver. However, to date no compound has been found in which both properties are combined properly. Thus, the heart/liver ratio could not be improved by the accomplished alterations of the binding mode between the "4 + 1" ^{99m}Tc chelate and the FA and the variations of the chelate position within the FA chain. Although a clear structure/biobehavior relationship is still missing, nevertheless some important rules were objectified.

ACKNOWLEDGMENT

This study was supported by an intramural grant (MedDrive programme 2003) funded by the Medical Faculty Carl Gustav Carus, by the DFG (Deutsche Forschungsgemeinschaft) grant SP 401, and by Nihon Medi-Physics Co., Inc., 9-8 Rokutanjicho, Nishinomiya-shi, Hyogo, 662-0918, Japan. The authors would like to thank Bianca Müller, Birgit Zatschler, and Regina Herrlich for excellent technical assistance.

Received May 8, 2007; Revised Manuscript Received November 12, 2007

Nonionic amphiphilic copolypeptides, which were composed of hydrophilic poly(sarcosine) and hydrophobic poly(γ-methyl L-glutamate) blocks, were synthesized with varying chain lengths of the blocks. The polypeptides having a suitable hydrophilic and hydrophobic balance were found to form vesicular assemblies of 100 nm size in buffer, which was evidenced by the TEM observation, the DLS analysis, and the encapsulation experiment. The genuine peptide vesicles, peptosomes, were labeled with a near-infrared fluorescence (NIRF) probe. *In vivo* retention in blood experiment showed long circulation of the peptosome in rat blood as stable as the PEGylated liposome. NIRF imaging of a small cancer on mouse by using the peptosome as a nanocarrier was successful due to the EPR effect of the peptosome. Peptosome is shown here as a novel excellent nanocarrier for molecular imaging.

INTRODUCITON

Molecular imaging has attracted more and more attention in the past decades (*1–3*) to target biological molecules (*4, 5*) and tumor tissues (*6, 7*) and so on. To image the biological objects, various modalities using positron-emission tomography (PET), magnetic resonance (MR), and fluorescence have been popular. Fluorescence imaging, particularly near-infrared fluorescence (NIRF) imaging (*8*), has an advantage for living body imaging, because the near-infrared and far-red light (650–900 nm) can avoid strong absorption by red blood cells and water to allow the light to permeate a biological body in the depth of several centimeters (optical window). The NIRF imaging has several benefits: cost efficiency in preparation of the probes and hardware for detection, high sensitivity, and low risk for the living body (*9, 10*). However, NIRF probes should be carried on a vehicle for selective accumulation of the imaging probes into the tumor tissue on a minute scale for early therapy.

There have been several targeting techniques using vehicles as the imaging probes (*11–14*). Using polymers or nanocarriers to support the probes is one of the most popular techniques to provide probes with targeting functionality (*15, 16*). In tumor tissues, submicron-sized defects exist on the vascular wall because of the rapid angiogenesis, enabling permeation of macromolecules through the wall. Further, the lymph system around tumor tissue grows too slowly to exclude foreign compounds from the tumor tissue (the enhanced permeability and retention (EPR) effect) (*17, 18*). Nanocarriers the size of 100 nm are considered to target passively and therefore to accumulate into tumor tissue by the EPR effect (*19, 20*).

Nanocarriers the size of 100 nm, which will exert the EPR effect, can be constructed via self-assembly of the amphiphilic molecules. Recently, spherical molecular assemblies of micelles (*21–23*) or vesicles (*24–26*) have been reported for applications to the drug delivery system (DDS) because of their capability to carry hydrophilic, lipophilic, or conjugated drugs (*27–30*). When molecular assembly is employed as a nanocarrier for *in vivo* use, such as molecular imaging and DDS, it is required to be biocompatible and/or biodegradable. The liposome, which is a vesicular assembly of lipids and therefore is considered to be excellent in terms of biocompatibility and biodegradability, has attracted continuous attention as the nanocarrier in DDS. For *in vivo* use, the liposomes have been PEGylated (modified with poly(ethylene glycol) (PEG) on their surfaces) in order to improve their retention in blood and to suppress the clearance by the reticuloendothelial system (RES) of the liver and spleen (*31, 32*). The PEGylated liposome containing anticancer drug has already been allowed for clinical application in Europe and the United States (*33, 34*). However, several risks of the PEGylated liposome in clinical use have been also reported: the conjugated PEG chains are artificial and nondegradable, and the PEGylated liposome has several side effects on the human body, including complement activation (*35, 36*). An alternative hydrophilic nonionic polymer for the nanocarrier is therefore expected to be developed.

Polypeptides are considered to be excellent in terms of biocompatibility and biodegradability (*37*). In addition, functionalization of polypeptides is rather facile by using their side chains (*38*). Our group has already reported that amphiphilic polypeptides formed vesicular assemblies in the sizes of ca. 100 nm in the aqueous medium, and named them "peptosome" (*39–41*). As in the case of liposome, peptosome can encapsulate water-soluble compounds suitably to DDS. Further, peptosome is a polymer vesicle, which has a more robust membrane via hydrophobic interaction among hydrophobic polymer chains than a liposome of small lipids (*24*).

In the present study, we designed and synthesized AB-type amphiphilic block copolypeptides composed of poly(sarcosine) (PSar) and poly(γ-methyl-L-glutamate) (PMLG) as a hydrophilic and hydrophobic block, respectively (Figure 1). The PSar block

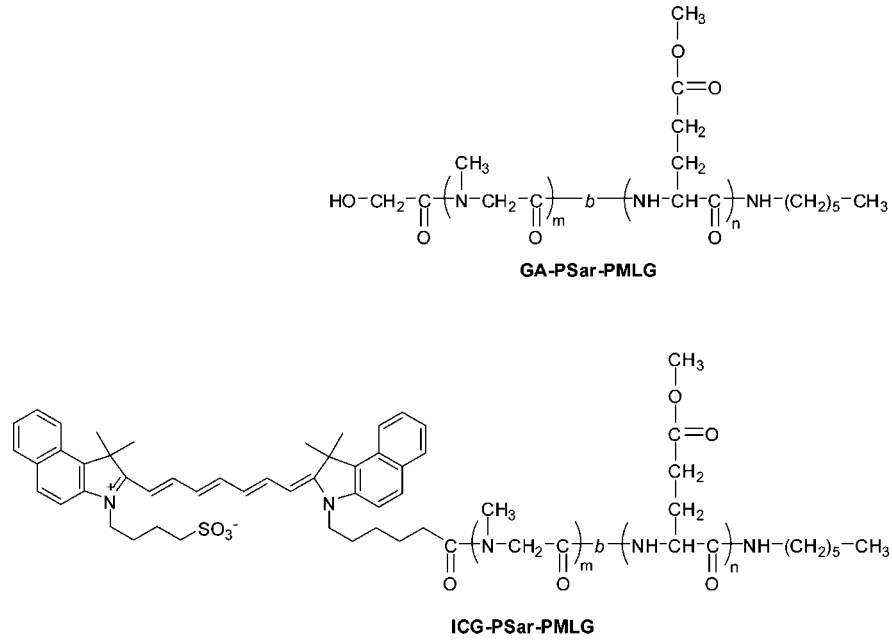

Figure 1. Chemical structures of amphiphilic block polypeptides, PSar-PMLGs. GA-PSar-PMLGs were used to prepare peptide assemblies, whereas ICG-PSar-PMLG was used for NIRF-labeling of peptosome.

is nonionic and hydrophilic like PEG, which will suppress the capture of the peptide assemblies by the RES due to the formation of a hydration layer on their surface (*42*, *43*). Further, sarcosine is a naturally occurring amino acid, and the structure is a part of creatine which helps to supply energy to muscle cells. Sarcosine is degraded endogenously by sarcosine dehydrogenase. No side effect of sarcosine was reported except the cases of sarcosinaemia, and so forth (*44*). PSar is therefore expected to be biocompatible. PSar-PMLGs of a variety of compositions were synthesized via a sequential *N*-carboxyanhydride (NCA) polymerization method (*45*). NIRF-labeled peptosomes were successfully prepared with using PSar-PMLGs. *In vivo* experiments about retention in rat blood and NIRF imaging of cancer on mouse by using the peptosomes as nanocarrier are discussed.

EXPERIMENTAL PROCEDURES

Materials. All reagents and solvents were purchased commercially and were used as received unless otherwise noted. Solvents used for NCA preparation and polymerization and *n*-hexylamine used as an initiator were purified just before usage according to the ordinary procedures. ICG (indocyanine green)-Sulfo-OSu, DY-675, and m-dPEG12 amine were purchased from Dojin Laboratory Ltd., Dyomics GmbH, and Quanta BioDesign, Ltd., respectively, and was used as received.

Synthesis. Amphiphilic block polypeptides, PSar-PMLGs, were synthesized by the NCA polymerization method. PMLG block was obtained from γ-methyl-L-glutamate-*N*-carboxyanhydride (Glu(OMe)-NCA) using *n*-hexylamine as an initiator, followed by polymerization of sarcosine-*N*-carboxyanhydride (Sar-NCA). The number-average molecular weight of the polymers prepared in the present study was in the range 2800−8300. The *N*-terminal of the polypeptides was successively capped by glycolic acid using HATU as a coupling reagent to afford GA-PSar-PMLG, or by ICG-Sulfo-OSu to afford ICG-PSar-PMLG (Figure 1). Crude polypeptides were purified by a Sephadex LH20 column with *N*,*N*-dimethylformamide (DMF) as eluent. The compositions of the polypeptides were determined by ^{1}H NMR spectrum analysis using trifluoroacetic acid-*d* as deuterated solvent. Degrees of polymerization (DP) of PMLG and PSar blocks were determined from methyl ester protons and *N*-methyl protons, respectively, in comparison with signals from the initiator. The capping reaction of the *N*-terminal was also confirmed by ^{1}H NMR. The detail of the synthesis is as follows.

Sar-NCA. Benzyloxycarbonyl sarcosine (10.0 g, 44.8 mmol) was dissolved in $SOCl_2$ (10 mL), and the solution was shaken vigorously for 8 min at 50 °C. The solution was poured into petroleum ether (200 mL) to afford Sar-NCA as a white solid. The crude Sar-NCA was purified three times by recrystallization from ethyl acetate/petroleum ether. FT-IR: 1850, 1780 cm^{-1}. Melting point: 95–96 °C.

Glu(OMe)-NCA. To a suspension of H-Glu(OMe)-OH (7.11 g, 44.1 mmol) in tetrahydrofuran (THF, 70 mL) at 50 °C was added triphosgene (4.36 g, 14.7 mmol). After 1 h stirring, another triphosgene (0.86 g, 2.91 mmol) was added, and the mixture was stirred for 2 h. The reaction mixture was poured into hexane (210 mL), and the suspension was cooled at −20 °C to complete crystallization. The crude Glu(OMe)-NCA was purified two times by recrystallization from THF/hexane. FT-IR: 1850, 1780, 1710 cm^{-1}. Melting point: 95–97 °C.

GA-PSar-PMLG. To a solution of Glu(OMe)-NCA (0.1 M) in dry DMF under Ar atmosphere was added *n*-hexylamine with the amount of the specified monomer/initiator ratio in feed, and the solution was stirred for 3 h at room temperature. After confirmation of the disappearance of NCA signals from the solution by FT-IR measurement, Sar-NCA in DMF was added with the amount of the specified ratio of Sar block (PSar) and Glu(OMe) (PMLG) block in the copolymer. The solution was kept stirring until the NCA was fully consumed. To the solution were added glycolic acid (5 equiv), *O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU) (5 equiv), and *N*,*N*-diisopropylethylamine (DIEA) (7.5 equiv) at 0 °C, and the solution was stirred at room temperature for 12 h under N_2 atmosphere. Additional portions of HATU (3 equiv) and DIEA (4 equiv) were added further to the solution at 0 °C, and the solution was kept stirring at room temperature for another 12 h under N_2 atmosphere. The solution was concentrated and purified by a Sephadex LH 20 column with DMF as eluent. The fraction of the copolymer was collected, and the product was precipitated from DMF/diethyl ether, followed by washing with acetone. The composition of PSar/PMLG in the

product was determined by ^{1}H NMR (trifluoroacetic acid (TFA)-*d*) with comparing the signal strengths of *N*-CH_3 of PSar, methyl ester of PMLG, and the terminal methyl of the initiator.

ICG-PSar-PMLG. Instead of glycol acid at the capping reaction in the preparation of GA-PSar-PMLG, ICG-sulfo-OSu (5 equiv of the terminal amino group) was added to the polymerization solution. The product was purified similarly to the case of GA-PSar-PMLG. The capping with ICG at the *N*-terminal of the copolymer was confirmed by ^{1}H NMR using 2,2,2-trifluoroethanol-d_3 as solvent.

DY-PEG. To a solution of DY-675 (5.0 mg, 7.1 μmol) and CH_3O-PEG_{12}-NH_2 (4.3 mg, 7.8 μmol, m-dPEG12 amine) in DMF were added HATU (3.0 mg, 7.8 μmol) and DIEA (2.0 μL, 12 μmol) at 0 °C, and the solution was stirred at room temperature for 6 h under N_2 atmosphere. HATU (0.55 mg, 1.4 μmol) and DIEA (0.37 μL, 2.6 μmol) were added further to the solution, and the solution was kept stirring at room temperature for another 16 h under N_2 atmosphere. The solution was concentrated under reduced pressure, and the residue was purified by a Sephadex LH 20 column with using DMF as eluent to afford the product. Mass analysis (FAB, matrix; nitrobenzylalcohol): *m*/*z* 1248.6 (calcd for $C_{67}H_{98}N_3O_{17}S$ [$(M + H)^+$] *m*/*z* 1248.66).

Preparation of Aqueous Dispersion. Polypeptides were dispersed in a Tris-buffered saline (TBS) (10 mM Tris−HCl, 100 mM NaCl, pH 7.4) by the injection method using 2,2,2-trifluoroethanol (TFE) as solvent. GA-PSar-PMLG (4.5 mg) was dissolved in 75 μL of TFE, and the solution was rapidly injected into 1.5 mL of TBS, which was stirred and cooled on ice. The aqueous dispersion was applied on a Sephacryl S-100 column (1.5 × 30 cm, GE healthcare Bio-Sciences) using TBS as eluent to remove TFE and others. The peptide concentration was in the range 0.5–0.8 mg/mL. Labeling of the polypeptide assembly with NIRF was achieved by adding a few wt % of ICG-PSar-PMLG to GA-PSar-PMLG in a TFE solution before injection.

Dynamic Light Scattering Analysis. The size of the molecular assemblies formed in aqueous dispersion was analyzed by dynamic light scattering (DLS) on a Photal DLS-8000 (Otsuka Electronics Co., Japan) using a cylindrical optical cell of 1 cm diameter. Vertically polarized light of either wavelength 632.8 nm from a He−Ne laser or 488 nm from an Ar laser was used as the incident beam from a scattering angle of 90°. All measurements were performed at 25 °C. In order to avoid contamination of dust, all aqueous dispersions were prepared in a clean room and filtered through a 0.80 μm cellulose acetate membrane filter. The autocorrelation function was analyzed by the time interval method of photon correlation. The light scattering data were analyzed by the program of Contin (*46, 47*).

TEM Observation. TEM images were taken using a JEOL JEM-2000EXII at an accelerating voltage of 100 kV. For the observation of molecular assembly, a dispersion of GA-PSar56-PMLG12 in 10 mM Tris−HCl buffer (pH 7.4) was applied on a carbon-coated Cu grid, and the sample was stained negatively with 2% uranyl acetate, followed by suction of the excess fluid with a filter paper.

Encapsulation of Water-Soluble Drug Model. A solution of a mixture of GA-PSar43-PMLG18 and GA-PSar65-PMLG18 (3:1) and 1 wt % ICG-PSar63-PMLG20 in TFE was injected rapidly into 1.5 mL TBS containing 4 mg/mL FITC−dextran (MW: 4000). The mixture of ICG-labeled molecular assembly and FITC−dextran was applied on a Sephacryl S-100 column (1.5 × 30 cm) with using TBS as eluent, and the elution profile was monitored by absorbance at 780 and 490 nm of ICG and FITC, respectively. Encapsulation of DY-PEG was also done similarly to the method of encapsulation of FITC−dextran.

Circular Dichroism. To analyze the conformation of polypeptides in their aqueous dispersion, circular dichroism (CD) spectroscopy was carried out on a JASCO J600 spectropolarimeter with an optical cell of 0.1 cm optical path length at room temperature.

***In Vivo* Retention in Blood Measurement.** *In vivo* retention in blood of peptosome was evaluated by using rats as the experimental animals. Seven-week-old Crl:CD(SD) male rats were used. Peptosomes prepared from GA-PSar56-PMLG12 ($n = 2$) and a mixture of GA-PSar43-PMLG18 and GA-PSar65-PMLG18 (1:1) ($n = 3$) were NIRF-labeled with the addition of 5 wt % ICG-PSar63-PMLG20. The dispersions were administered at 0.8 mg/mL/kg to rats via tail vein. After administration of the peptosome, blood samples of 0.5 mL were taken temporally from rats and were centrifuged to collect the blood plasma samples. The amount of the ICG-labeled peptosome in the sample was estimated by fluorescence assay (Ex, 768 nm; Em, 807 nm). *In vivo* retention in the blood of the peptide micelle from GA-PSar93-PMLG12 and 5 wt % ICG-PSar63-PMLG20 was also evaluated by the same procedure ($n = 2$).

Cell Culture and Hypoxic Treatment *in Vitro*. SUIT-2 human pancreatic cancer cell line was purchased from the American type Culture Collection. SUIT-2/EF-Luc cells that carry the luciferase reporter gene under control of pEF constitutive promoter were isolated by the same method as described elsewhere. SUIT2/EF-Luc cells were maintained at 37 °C with 5% FBS-Dulbecco's modified Eagle medium (Nacalai Tesque, Kyoto, Japan).

Tumor Model. SUIT-2/pEF-luciferase cells were subcutaneously inoculated at 1×10^6 cells/mL of phosphate-buffered saline (PBS) into front legs, hind legs, or back of 8-week-old female nude mice (BALB/c nu/nu; Japan SLC Inc., Hamamatsu, Japan).

***In Vivo* Cancer Imaging.** For taking images of bioluminescence from the SUIT2/EF-luc xenografts, tumor-bearing mice were intraperitoneally injected with 100 μL D-luciferin solution (10 mg/mL in PBS; Promega Corp., Madison, WI). In 20 min, the mice were set in an IVIS-200 *in vivo* photon-counting device (Xenogen Corp., Alameda, CA). For taking fluorescence images from the NIRF-labeled peptosome, tumor-bearing mice were set in the IVIS-200 at the indicated time following intravenous injection of the peptosome dispersion (ca. 0.5 mg/mL, 200 μL). During imaging process, the mice were kept on the imaging stage under anesthetized condition with 2.5% of isoflurane gas in oxygen flow (1.5 L/min).

The fluorescence images from ICG were taken with the accessory ICG filter set, and those from DY-675 were taken with the Cy5.5/Cy5.5 Bkg filter sets. The pseudo images from the photon counts were constructed by *Living Image 2.50 - Igor Pro 4.09A* software (Xenogen Corp.).

RESULTS AND DISCUSSION

Synthesis of Polypeptides and Their Dispersibility in TBS. Amphiphilic block copolypeptides, GA-PSar-PMLGs and ICG-PSar-PMLG (Figure 1), were newly designed and synthesized by the conventional NCA method with the capping reaction using HATU as a coupling reagent or using active ester. Compositions of PSar-PMLGs were estimated by ^{1}H NMR analysis and found to be close to the monomer/initiator ratios in the feed (Table 1). GA-PSar-PMLGs having more than 43 sarcosine residues (entries 3–8) were dispersed stably in TBS by the TFE injection method (*48*), whereas those with shorter PSar chains yielded precipitates (entries 1, 2). Moderately long PSar chains are therefore necessary for PMLG chains of 12–18 residues to be dispersed stably in buffer.

Morphology of Molecular Assembly. Size and shape of molecular assembly of GA-PSar-PMLGs formed in buffer were analyzed by the DLS measurement and the TEM observation. Size distribution analysis by the DLS measurements suggested

[a] GA, capped *N*-terminal with glycolic acid, ICG, capped *N*-terminal with ICG-Sulfo-OSu. [b] P, peptosome, M, micelle, the former capital letter of P, M or M, P represents the predominant morphology of the mixed molecular assemblies. The block polypeptides are categorized into three groups, group PRE (precipitate), group PEP (peptosome), and group MIC (micelle), according to the predominant morphology in buffer (shown in the parentheses). [c] A mixture of GA-PSar43-PMLG18 and GA-PSar65-PMLG18 at the molar ratio of 1:1. [d] A mixture of GA-PSar43-PMLG18 and GA-PSar65-PMLG18 at the molar ratio of 3:1. [e] A solution of DMF and chloroform (3/1 v/v) was used for polymerization of entries 3 and 5. In other cases, DMF was used.

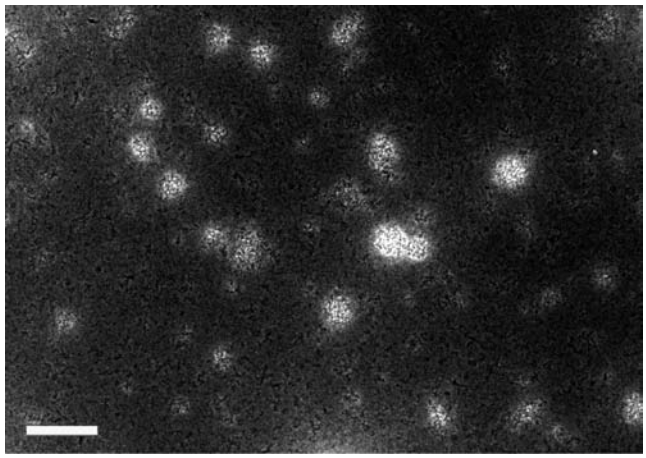

Figure 2. TEM image of peptosome in the aqueous dispersion of GA-PSar56-PMLG12. The sample was stained negatively with uranyl acetate. Scale bar represents 0.5 μm.

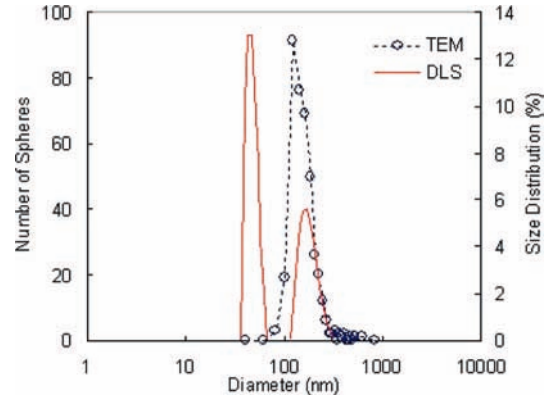

Figure 3. Comparison of size distributions determined by DLS measurement and TEM image (histogram). In both measurements, GA-PSar56-PMLG12 was used for preparation of the peptide assembly.

a bimodal distribution for some polypeptides (Table 1, entries 4, 5, 7, 8) due to formation of two types of molecular assemblies. However, the regularization procedure such as Contin used here may overfit the data to produce apparently two peaks. Indeed, upon changing the scattering angles in the DLS measurements, the bimodal distribution could become a smooth monomodal distribution in some cases. Table 1 shows two values as the molecular assembly size in some cases, but the sizes of the minor components are not thus fully convincing. In addition to the DLS measurements, we therefore analyzed the elution profiles of the molecular assemblies through gel permeation chromatography using Sephacryl S-100 or Sephadex 4B. The elution profiles were agreeable with the results of the DLS measurements summarized in Table 1. So, the sizes of the minor components of the molecular assemblies are shown in Table 1 despite their inaccuracy.

The fraction ratio of the two assemblies differs depending on the length of the PSar block in the copolypeptides. Diameter of the smaller assembly is in the range from 30 to 40 nm, and that of the larger one from 100 to 200 nm. Since the molecular length of GA-PSar-PMLGs is estimated to be about 20 nm with an extended form of the PSar block and α-helical conformation of the PMLG block, the smaller molecular assembly is assigned to a spherical micelle having a hydrophobic core and a hydrophilic shell.

An aqueous dispersion of GA-PSar56-PMLG12 was observed by TEM with negative staining (Figure 2). Spheres in the size range from 100 to 200 nm were present in the TEM image, and the size distribution of these large spheres is in agreement with that of the larger assemblies detected by DLS (Figure 3). Even though the detail analysis of the smaller assemblies detected by DLS was not possible by TEM due to the poor resolution, the peptide micelle should be formed with GA-PSar56-PMLG12 from the elution profile through gel permeation chromatography. On the other hand, GA-PSar43-PMLG18, a block polypeptide with a shorter PSar segment and a longer PMLG segment, formed the large spheres of ca. 150 nm from the DLS analysis (Table 1). These observations of amphiphilic polypeptides are consistent with previous reports that the morphology of molecular assemblies is related generally with the hydrophilic and hydrophobic balance of amphiphiles (*49*, *50*); with increasing the hydrophobic property of amphiphiles, the major morphology shifts from a small micelle to cylinder and a large vesicle in water. When this relationship is applied to the present polypeptides, the large assembly of GA-PSar43-PMLG18 in buffer should be a vesicle. This structural point is discussed later with the encapsulation experiment.

Adjustment of the assembly size by mixing two kinds of polypeptides was examined (Table 1, entries 7, 8). Interestingly, the size of molecular assembly of GA-PSar43-PMLG18 was reduced from 150 to 100 nm by incorporation of GA-PSar65-PMLG18 at the molar ratios of 1:1 and 3:1 (GA-PSar43-PMLG18: GA-PSar65-PMLG18). The longer PSar block of GA-PSar65-PMLG18 in the mixture should favor staying at the outer surface of the spherical assembly to reduce the steric congestion compared with staying at the inner surface, resulting in a large curvature of the smaller spherical assembly. GA-PSar65-PMLG18 is thus considered to be inserted into the outer surface to increase the curvature of the vesicle due to the bulky PSar

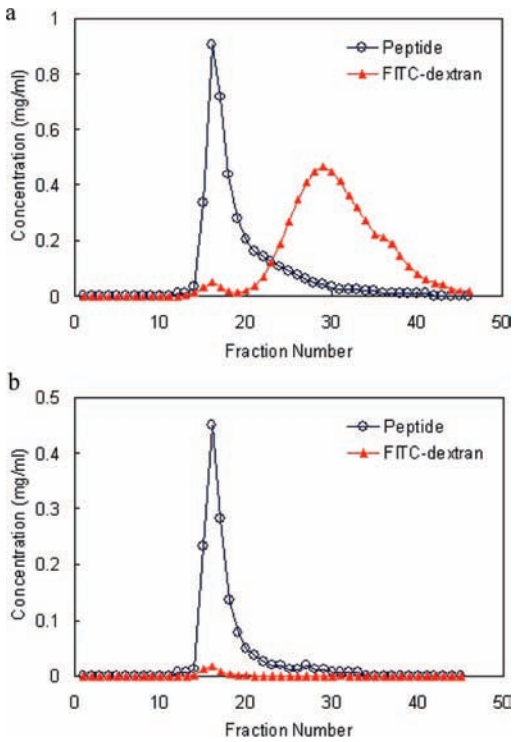

Figure 4. Encapsulation experiment of FITC−dextran in ICG-labeled molecular assembly prepared from a mixture of GA-PSar43-PMLG18 and GA-PSar65-PMLG18 (3:1). Elution profiles of size exclusion chromatography by a Sephacryl S-100 column were monitored by absorption of ICG (○) and fluorescein (▲). Figure 5. CD spectra of (a) GA-PSar43-PMLG18, (b) GA-PSar65-PMLG18, and (c) a mixture of GA-PSar43-PMLG18 and GAPSar65-PMLG18 (1:1) in 10 mM Tris buffer containing 0.1 M NaCl and 5% TFE. The residue concentration of Glu(OMe) was set at 5×10^{-4} M for all the samples.

block at the outer surface. The mixing effect on the assembly size, however, was not so sensitive in the mixing ratios of 1:1 and 3:1.

To obtain information on the molecular assembly of 100 nm, the encapsulation experiment was carried out with using the peptide assembly of a mixture of GA-PSar43-PMLG18 and GA-PSar65-PMLG18 (3:1) labeled with 1 wt % ICG-PSar63-PMLG20. The elution profile through a SEC column of the peptide assembly prepared in the presence of FITC-dextran (Mw: 4000) in buffer shows coelution of FITC−dextran with the peptide assembly (Figure 4a). The amount of the encapsulated dextran in the peptide assembly looks small, but the ratio of the encapsulated dextran against the total amount of dextran in buffer is consistent with the ratio of the total inner volume of the vesicles against the total solution

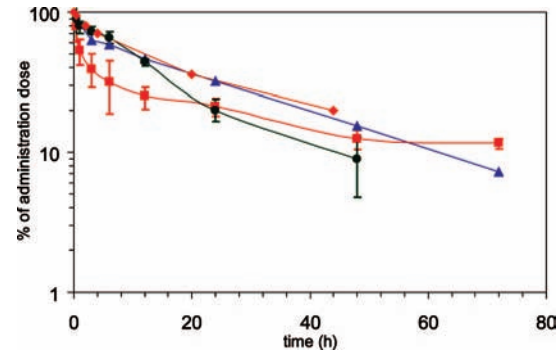

Figure 6. *In vivo* blood clearance curves of ICG-labeled peptosome (blue ▲, GA-PSar56-PMLG12; red ■, a mixture of GA-PSar43-PMLG18 and GA-PSar65-PMLG18 (1:1)) and ICG-labeled peptide micelle (green ●, GA-PSar93-PMLG12), in comparison with that of PEGylated liposomal doxorubicin, Doxil, in the literature (*53*) (orange ♦).

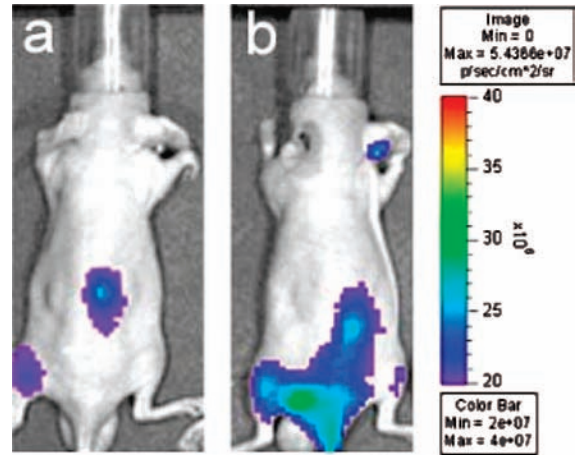

Figure 7. *In vivo* cancer imaging using NIRF-labeled peptosome. ICG-labeled peptosome prepared from a mixture of GA-PSar43-PMLG18 and GA-PSar65-PMLG18 (1:1) labeled with 3 wt % ICG-PSar63-PMLG20 was used. (b) Image of fluorescence from ICG, 1 day after the administration of ICG-labeled peptosome.

volume at the preparation, which was calculated under the following assumptions: the vesicular assembly of 100 nm diameter, the diameter of 2 nm for one peptide molecule occupying at the membrane, and interdigitation structure of the membrane. Further, the repeated column chromatography of the peptide fraction did not reduce the relative intensity of FITC−dextran, suggesting that FITC−dextran was encapsulated firmly in the vesicle (Figure 4b). Consequently, the peptide assembly of 100 nm has an inner aqueous phase to encapsulate a water-soluble compound, indicating the peptide assembly of vesicle, so-called “peptosome”.

After our previous reports on preparation of peptosome in the size range of 100 nm (*39–41*), Deming et al. have also reported preparation of micrometer-sized vesicular assembly from ionic polypeptides (*51*). They reduced the size of assembly into about 100 nm by using the extruder method. In our case, a 100 nm sized peptosome was spontaneously formed only by injection of the peptide solution into buffer, and the size remained stable for weeks.

Conformation of polypeptides in the molecular assemblies was studied by CD spectroscopy. The aqueous dispersion of GA-PSar43-PMLG18 (group PEP; Table 1) showed negative Cotton effects at 222 and 208 nm (Figure 5), indicating α-helical conformation of the hydrophobic PMLG block (*52*). Since the signal at 222 nm was more intensive than that at 208 nm, α

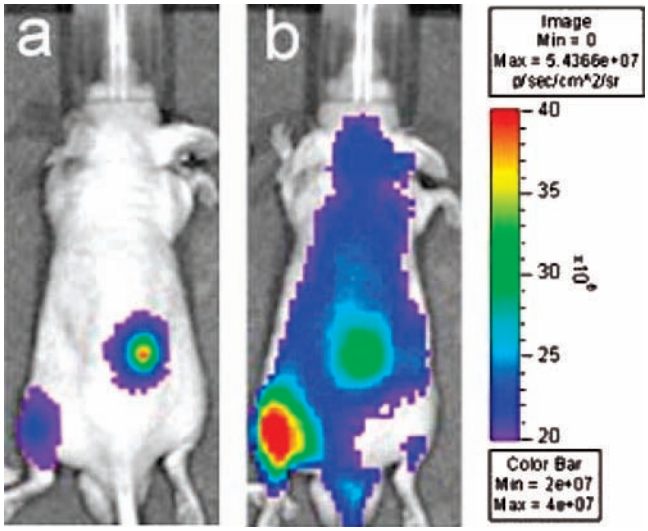

Figure 8. *In vivo* cancer imaging using NIRF-labeled peptide micelle. ICG-labeled peptide micelle prepared from GA-PSar93-PMLG12 labeled with 3 wt % ICG-PSar63-PMLG20 was used. (a) Bioluminescence image of SUIT2/EF-luc xenografts on the tumor-bearing mouse after administration of D-luciferin. (b) Image of fluorescence from ICG, 1 day after the administration of ICG-labeled peptide micelle.

helices should form a bundle structure in the peptide membrane. Similar results were obtained with GA-PSar65-PMLG18 (group MIC; Table 1) and a mixture of GA-PSar43-PMLG18 and GA-PSar65-PMLG18 (1:1) (group PEP). The α-helical structure in the peptide assembly makes a contrast to our previous report on amphiphilic poly(sarcosine)-*b*-poly(alanine), in which the hydrophobic poly(alanine) block took β-sheet structure in peptide micelle or aggregates (*27*). The conformation difference between these two types of block polypeptides in the molecular assemblies may be attributed to the difference of the side chains between alanine and Glu(OMe). The large hydrophobic side chain of Glu(OMe) may prevent the PMLG block from taking β-sheet structure of the tight molecular packing.

***In Vivo* Retention in Blood Measurement.** GA-PSar56-PMLG12 (group PEP) and a mixture of GA-PSar43-PMLG18 and GA-PSar65-PMLG18 (1:1) (group PEP) were chosen for preparation of about 100 nm sized peptosomes, and were subjected to *in vivo* retention in blood assay. The ICG-labeled peptosomes were administered to rats via a tail vein. Residual amounts of ICG-labeled peptosomes in blood plasma at different times were determined by fluorescence photometry (Figure 6). A small fraction of the peptosomes was cleared at the beginning stage, but the greatest part showed long retention circulating in the rat blood. When the two-compartment model was applied to the clearance curve, the half-lives at the β phase of the clearance curves were estimated to be about 20–40 h for these peptosomes. The relatively long half-life of the peptosomes is comparable to PEGylated liposome under the same experimental conditions (*54*).

ICG-labeled peptide micelle prepared from GA-PSar93-PMLG12 (group MIC) also showed a long retention circulation (Figure 6). However, the peptide micelle disappeared completely in 48 h, whereas a part of peptosome remained in blood even after 72 h from the injection. This result may be ascribed to the smaller size of the peptide micelle, which should promote its accumulation in liver (*55, 56*).

***In Vivo* Cancer Imaging.** *In vivo* NIRF imaging of cancer on mouse was carried out with using ICG-labeled peptosome prepared from a mixture of GA-PSar43-PMLG18 and GA-PSar65-PMLG18 (1:1) (group PEP). At 1 day after the administration, intensive fluorescence from ICG was observed at the two transplanted cancer sites (Figure 7b), which was confirmed by the bioluminescence from luciferin (Figure 7a). The peptosome is therefore considered to accumulate in the tumor tissue by the EPR effect.

ICG-labeled peptide micelle prepared from GA-PSar93-PMLG12 (group MIC) was also administered to the tumor-bearing mouse, and NIRF imaging was carried out. The intensive fluorescence from ICG was observed similarly at the tumor tissue (Figure 8). However, the fluorescence level at the background was moderately high. The peptide micelle may be

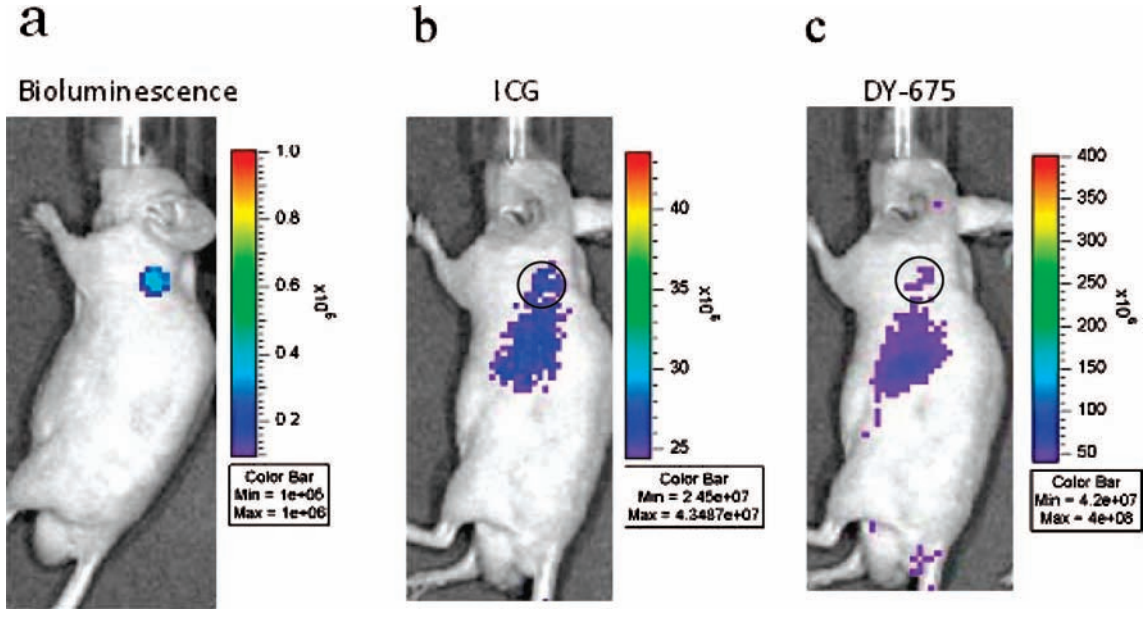

Figure 9. *In vivo* cancer imaging using NIRF-labeled peptosome encapsulating water-soluble far-red fluorophore. ICG-labeled peptosome prepared from a mixture of GA-PSar43-PMLG18 and GA-PSar65-PMLG18 (3:1) labeled with 3 wt % ICG-PSar63-PMLG20 and encapsulating DY-PEG in the inner aqueous phase (the concentration of DY-PEG was set at 4 mg/mL at the preparation). (a) Bioluminescence image of SUIT2/EF-luc xenografts on the tumor-bearing mouse after administration of D-luciferin. (b) Image of fluorescence from ICG, 2 days after the administration of peptosome. (c) Image of fluorescence from DY-675, 2 days after the administration of peptosome. Black circles in b and c represent the tumor site.

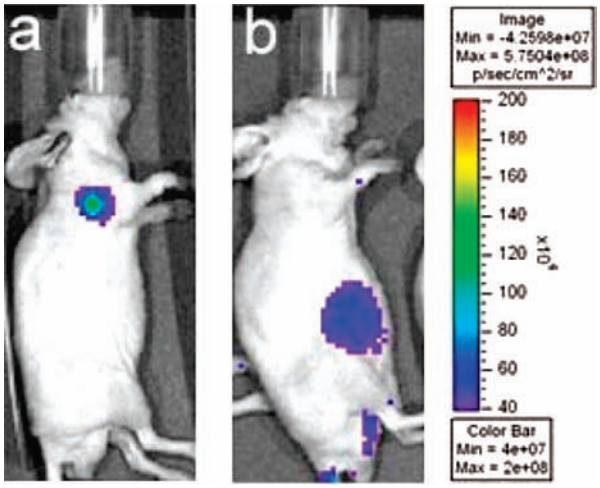

Figure 10. Control imaging experiment using water-soluble far-red fluorophore, DY-PEG. The amount of DY-PEG was adjusted to that used in the doubly labeled peptosome shown in Figure 9. (a) Bioluminescence image of SUIT2/EF-luc xenografts on the tumor-bearing mouse after administration of D-luciferin. (b) Image of fluorescence from DY-675, 2 days after the administration of DY-PEG.

partly incorporated into normal tissues probably due to the small size or physical instability.

Doubly labeled peptosome, in which the peptide membrane was labeled with ICG peptide and the inner aqueous phase encapsulated DY-675 labeled PEG (DY-PEG), was prepared and administered to the tumor-bearing mouse. These two kinds of fluorophores can be detected separately by choosing proper optical filters of the imaging apparatus, because ICG and DY-675 fluoresce at far-red and near-infrared region, respectively. ICG-labeled peptosome was prepared from a mixture of GA-PSar43-PMLG18 and GA-PSar65-PMLG18 (3:1) (group PEP) in a buffer containing DY-PEG. At 2 days after the intravenous administration to the tumor-bearing mouse, fluorescence from ICG was detected at the cancer site (Figure 9b), and at the same site, fluorescence from DY-675 was also observed (Figure 9c). In these images, accumulation of the peptosome in liver was also detected by both probes. On the other hand, when DY-PEG alone was administered to the tumor-bearing mouse, fluorescence at the cancer site was not observed at all even though accumulation in bladder was detected (Figure 10). Taken together, the peptosome was confirmed to be accumulated in the tumor tissue while maintaining its vesicular structure and preserving the water-soluble compound inside. The selective accumulation is therefore due to the EPR effect.

PSar chains around the peptosome are expected to take a role of suppressing the capture of peptosome by the RES, and *in vivo* retention in blood of peptosome was actually proven to be extremely long. In the case of PEGylated liposomes, the retention time in blood was improved by optimization of the mixing ratio of long and short PEG chains (*51*). Therefore, peptosome coated by optimized PSar layer may show further retention in blood, which is currently under investigation. Further, poly(ethylene glycol) (PEG), which is a common artificial water-soluble polymer and is used frequently for biocompatible materials, may be replaced with PSar in many cases.

In conclusion, we have succeeded in preparation of 100 nm sized peptosome, which is a vesicular assembly of genuine amphiphilic polypeptide, using PSar as a hydrophilic block and PMLG as a hydrophobic block. NIRF-labeled peptosome was prepared by adding ICG-conjugated polypeptide. Diameter of the peptosome prepared from GA-PSar-PMLGs was in the range from 100 to 200 nm, which is the appropriate size for the passive targeting into the solid tumor by the EPR effect. *In vivo* retention in blood of ICG-labeled peptosome was assayed by using rats as experimental animals, and the retention time was proven to be as long as the PEGylated liposome. ICG-labeled peptosome was also administered to the tumor-bearing mouse and successfully detected the tumor tissue due to the EPR effect.

ACKNOWLEDGMENT

This study is a part of joint research, which is focusing on the development of the basis of technology for establishing COE for nanomedicine, carried out through Kyoto City Collaboration of Regional Entities for Advancing Technology Excellence (CREATE) assigned by Japan Science and Technology Agency (JST). *In vivo* retention in blood studies were carried out with help of Termo Co. Japan.

Received May 12, 2007; Revised Manuscript Received September 14, 2007

A novel bimodal fluorescent and paramagnetic liposome is described for cellular labeling. In this study, we show the synthesis of a novel gadolinium lipid, Gd.DOTA.DSA, designed for liposomal cell labeling and tumor imaging. Liposome formulations consisting of this lipid were optimized in order to allow for maximum cellular entry, and the optimized formulation was used to label HeLa cells *in vitro*. The efficiency of this novel bimodal Gd-liposome formulation for cell labeling was demonstrated using both fluorescence microscopy and magnetic resonance imaging (MRI). The uptake of Gd-liposomes into cells induced a marked reduction in their MRI T_1 relaxation times. Fluorescence microscopy provided concomitant proof of uptake and revealed liposome internalization into the cell cytosol. The optimized formulation was also found to exhibit minimal cytotoxicity and was shown to have capacity for plasmid DNA (pDNA) transfection. A further second novel neutral bimodal Gd-liposome is described for the labeling of xenograft tumors *in vivo* utilizing the enhanced permeation and retention effect (EPR). Balb/c nude mice were inoculated with IGROV-1 cells, and the resulting tumor was imaged by MRI using these *in vivo* Gd-liposomes formulated with low charge and a poly(ethylene glycol) (PEG) calyx for long systemic circulation. These Gd-liposomes which were less than 100 nm in size were shown to accumulate in tumor tissue by MRI, and this was also verified by fluorescence microscopy of histology samples. Our *in vivo* tumor imaging results demonstrate the effectiveness of MRI to observe passive targeting of long-term circulating liposomes to tumors in real time, and allow for MRI directed therapy, wherein the delivery of therapeutic genes and drugs to tumor sites can be monitored while therapeutic effects on tumor mass and/or size may be simultaneously observed, quantitated, and correlated.

INTRODUCTION

As an established noninvasive clinical imaging modality, magnetic resonance imaging (MRI) has recently received much interest within the field of molecular imaging (*1, 2*). MRI is capable of producing three-dimensional images of tissues containing water with a high degree of spatial resolution. In MRI, contrast agents are used to further improve the quality of an image. These agents consist of molecules which incorporate a paramagnetic metal ion, most commonly gadolinium (Gd) or iron (Fe). Image improvement arises due to the effect of the enhancement of longitudinal (T_1) or transverse (T_2) relaxation rates of the surrounding bulk water protons by the coordinated metal ion under an applied magnetic field. Contrast agents incorporating Gd increase both $1/T_1$ and $1/T_2$ but are generally used in T_1-weighted imaging where their $1/T_1$ effect is greater in tissue than their $1/T_2$ enhancement. In contrast, Fe containing agents lead to more substantial increases in $1/T_2$ and are therefore visualized with T_2-weighted images (*3*).

As a result of the successful coupling of the main Gd-chelating ligands 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) and diethylenetriamine pentaacetic acid (DTPA), which are also clinical contrast agents, to various biologically relevant molecules, a large number of specific second generation contrast agents have been developed to further enhance the clinical potential of MRI. Specific Gd-chelating contrast agents have been designed for a whole host of biological MRI applications; ranging among gene expression (*4*), tumor imaging (*5*), angiogenesis (*6*), atherosclerosis (*7*), and neurological diseases (*8*), However, a limitation encountered when using Gd-based agents is local concentration; the tissue concentration necessary to image with T_1 contrast agents is often high, and therefore method development is needed to increase the number of Gd moieties bound per contrast agent molecule. As such, there have been a number of reports concerning the conjugation of Gd chelates to macromolecules such as dendrimers, linear polymers, and proteins, as well as the use of liposomes as Gd-chelate carriers (*9–11*).

Liposomes are versatile tools used traditionally in drug and gene delivery and are easily adapted for use *in vitro*, *ex vivo*, or *in vivo*. The overall liposome property can be adjusted using parameters such as lipid composition, head group charge, and lipid tail size. It is known that cationic liposomes are effective at mediating cell entry *in vitro* and that their circulation time *in vivo* is greatly enhanced with the use of neutral PEG polymers (*12–14*). Here, we report the utility of liposomes as bimodal paramagnetic and fluorescent imaging systems both for *in vitro* cell labeling and *in vivo* tumor imaging. In addition, the synthesis of the novel Gd-lipid Gd.DOTA.DSA **1** is shown. Based on the structural paradigm described by Miller et al. (*15*), *in vitro* Gd-**B** liposomes and *in vivo* stealth Gd-**BC** liposomes were prepared, whereby **B** represents the lipidic layer and **C** represents the PEG polymer masking layer designed to allow

for tumor Gd and fluorescence labeling. The cell labeling efficiency *in vitro* was achieved by the inclusion of a cationic lipid in the formulation and tumor imaging was made possible *in vivo* by formulating neutral Gd-liposomes for prolonged blood circulation and consequent extravasations through leaky tumor vasculature due to angiogenic blood vessels (*16*). This study demonstrates that Gd-liposomal systems are useful multifunctional platforms or tools for understanding the underlying problems associated with drug or nucleic acid delivery and for elucidating potential solutions. Further modification of these Gd-**BC** liposomes would involve the condensation of nucleic acids (**A** layer) within their aqueous core producing Gd-**ABC** liposomal therapeutic nanoparticles which can also be bestowed with specificity by adding a targeting **D** layer in the form of a suitable ligand (hence Gd-**ABCD** liposomal nanoparticles).

EXPERIMENTAL PROCEDURES

Materials. N^1-cholesteryloxycarbonyl-3,7-diaza-1,9-diaminonane (CDAN), 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE), phosphatidylethaolamine Lissamine rhodamine B (DOPE-Rhodamine), cholesterol, 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPC), and 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*n*-methoxy(poly(ethylene glycol))-2000 (DSPE-PEG_{2000}) were purchased from Avanti Polar Lipids Inc. (Alabaster, AL). Organic compounds were purchased from Sigma-Aldrich, Lancaster, or Merck Biosciences. ^{1}H and ^{13}C NMR spectra were recorded on a 400 MHz Bruker Advance 400 spectrometer. Infrared (IR) spectra were recorded on a JASCO FT/IR-620 infrared spectrophotometer. Analytical HPLC was conducted on a Hitachi-LaChrom L-7150 pump system equipped with a Polymer laboratories PL-ELS 1000 evaporative light-scattering detector. Flash column chromatography was performed using Merck 0.040 to 0.063 mm, 230 to 400 mesh silica gel. MRI experiments were conducted on a 4.7 T Magnex magnet (Oxford, UK) Varian Unity Inova console (Palo Alto, CA). All procedures on animals were conducted in accordance with UK Home Office regulations and the Guidance for the Operation of Animals (Scientific Procedures) Act (1986).

2-(4,7,10-Tris(2-*tert*-butyloxycarbonylmethyl)-1,4,7,10-tetraazacyclododecan-1yl)acetic Acid (2). 2-Chlorotrityl chloride resin (916.7 mg, 1.265 mmol) was added to a solid-phase synthesis vessel and swelled by the addition of CH_2Cl_2 (40 mL) and the vessel agitated for 30 min (0.8 mmol.g^{-1} loading). Bromoacetic acid (1.758 g, 12.65 mmol, 10 equiv) and *i*Pr_2NEt (1.107 mL, 6.325 mmol, 5 equiv) were added to the resin, and the vessel was agitated on a motor shaker overnight at room temperature. MeOH (1000 equiv) was added as a capping reagent and the reaction agitated for a further 10 min; the solution was filtered, and the resin was washed by alternating between CH_2Cl_2 and *i*PrOH (3×) and MeOH (2×) and finally dried. Cyclen (2.179 g, 12.65 mmol, 10 equiv) was dissolved in CH_2Cl_2 (40 mL) and added to the vessel containing the bromoacetyl resin; the reaction mixture was agitated for 4 h at room temperature. The solvent was filtered and the resin washed alternating among CH_2Cl_2 and *i*PrOH (3×), CH_2Cl_2 and MeOH (3×), distilled H_2O (2×), and finally CH_2Cl_2 and *i*PrOH (3×). The chloroanil test was positive. The resin was then washed with DMF (2×) and dried. *tert*-Butyl bromoacetate (3.064 mL, 18.975 mmol, 5 equiv per free amine), NEt_3 (1.587 mL, 11.389 mmol, 3 equiv per free amine) were dissolved in DMF (40 mL) and added to the cyclen-functionalized resin. The reaction was left shaking for a further 12 h at room temperature. The solvent was removed by filtration, and the resin was washed with *i*PrOH and distilled H_2O (3×), CH_2Cl_2 and *i*PrOH (3×), MeOH (2×), toluene (2×), and finally diethyl ether (2×). The chloroanil test was negative. The resin was transferred to a round-bottomed flask, stirred into a solution of CH_2Cl_2/trifluroethanol 2:1 (v/v) for a further 2 h at room temperature, and subsequently filtered and washed with CH_2Cl_2 (3×), and the filtrate was collected and reduced *in vacuo* to give a yellow oil. The compound was purified by flash column chromatography ((eluted with CH_2Cl_2/MeOH/H_2O 34.5:9:1): CH_2Cl_2 3:7 v/v) to yield a crystalline pale yellow solid (361.79 mg, 51%, mp = 88–93 °C), R_f [CH_2Cl_2/MeOH/H_2O 34.5:9:1 v/v] 0.48. ^{1}H NMR (400 MHz, d_6-DMSO, 400 K): δ (ppm) 3.14 (s, br, 8H, 4× $CH_2COOC(CH_3)_3$), 2.58 (s, br, 16H, 4× NCH_2CH_2N), 1.46 (s, 27H, $C(CH_3)_3$ 3×). ^{13}C NMR (400 MHz, $CDCl_3$): δ (ppm) 174.9 (*C*OOH), 172.3 (*C*OO*t*-Bu), 82.3 ($C(CH_3)_3$ 2×), 82.0 ($C(CH_3)_3$), 56.7 (CH_2COOH), 56.1 (CH_2COO*t*-Bu), 55.7 (CH_2COO*t*-Bu), 50.9 (CH_2 2×), 50.2 (CH_2 2×), 28.1 ($C(CH_3)_3$). FTIR: (cm^{-1}) 3735, 3397, 2925, 2853, 2726, 2366, 1731, 1458, 1377, 1310, 1262, 1227, 1160. HPLC t_R = 16.0 min, column C-4 peptide: gradient mix A = MeCN/0.1% TFA; mix B = H_2O/TFA; mix C = MeOH/$CHCl_3$ mix D = MeOH, 0.0 min [100% B], 15–25.0 min [100% A], 25.1–45.0 min [100% D], 45.1–55.0 min [100% C]; flow 1 mL/min. HRMS (FAB^+) calcd for $C_{28}H_{52}N_4O_8$ *m/z* 573.3785, found 573.386 (M–H).

***N,N*-Distearylamidomethylcarbamic Acid *tert*-Butyl Ester (8).** Boc-glycine (310 mg, 1.77 mmol) and dioctadecylamine (923.96 mg, 1.77 mmol) were dissolved in dry chloroform (30 mL). HBTU (804.12 mg, 2.12 mmol) and DMAP (648.72 mg, 5.31 mmol) were added to the solution, and the reaction was stirred at room temperature under N_2 for 12 h. The solvents were removed *in vacuo*. The mixture was dissolved in CH_2Cl_2 (50 mL) and extracted with H_2O (3 × 50 mL). The combined aqueous extracts were back-extracted with CH_2Cl_2/MeOH (2 × 50 mL), the solvents reduced and redissolved in diethyl ether, and a subsequent extraction with 7% citric acid and H_2O was performed; the organic layer was washed with brine, collected, and filtered through celite and finally dried over $MgSO_4$. The diethyl ether was evaporated *in vacuo* to yield a pure white solid (1.164 g, 97% yield, mp = 82–85 °C). R_f [CH_2Cl_2/MeOH/H_2O, 34.5:9:1 v/v] 0.56. ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) 5.50 (br, s, 1H, amide N*H*), 3.99 (s, br, 2H, $NHCH_2$), 3.35–3.25 (d, br, 2H, $OCNCH_2$), 3.17–3.07 (d, br, 2H, $OCNCH_2$), 1.44 (s, 9H, $C(CH_3)_3$), 1.61–1.44 (m, 13H, $C(CH_3)_3$ and $OCN(CH_2CH_2)$), 1.25 (s, 60H, CH_2's alkyl chain), 0.872 (s, br, 6H, CH_3 2×). ^{13}C NMR (400 MHz, $CDCl_3$): δ (ppm) 167.6 ($CON(CH_2)_{17}$), 156.0 ($C(CH_3)_3COCO$), 79.0 ($C(CH_3)_3$), 46.9 ($N(CH_2CH_2)_9$), 46.1 ($N(CH_2CH_2)_9$), 42.2 ($NHCH_2CO$), 31.9–26.9 (CH_2 30×), 22.7 ($N(CH_2CH_2)_9$), 14.1 ($C(CH_3)_3$). FTIR: (cm^{-1}) 2953, 2923, 2853, 2360, 1723, 1650, 1610, 1460, 1160, 1580, 1377, 837, 721. HPLC: t_R= 36.08 min, column C-4 peptide: gradient mix A = MeCN/0.1% TFA; mix B = H_2O/TFA; mix C = MeOH/$CHCl_3$; mix D = MeOH, 0.0 min [100% B], 15–25.0 min [100% A], 25.1–45.0 min [100% D], 45.1–55.0 min [100% C]; flow 1 mL/min. HRMS: (FAB+) calcd for $C_{43}H_{86}N_2O_3$ *m/z* 678.660, found 679.6953 $(M + H)^+$.

***N,N*-Distearylamidomethylamine (DSA) (3).** The protected amine was dissolved in anhydrous CH_2Cl_2 (5 mL), to which was added trifluoroacetic acid (3 mL). The reaction was stirred under an atmosphere of N_2 for 2 h. The solvents were removed *in vacuo* and the product dried under vacuum to obtain a white powder (158 m, 94% yield, mp = 59–64 °C). R_f [hexane/ethyl acetate 9:1 v/v] 0.44.^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) 3.85 (s, 2H, $OCCH_2NH_2$), 3.32 (t, J = 7.2 Hz, 2H, $OCNCH_2CH_2$), 3.13 (t, J = 7.2 Hz, 2H, $OCNCH_2CH_2$), 2.39 (s, very br, 2H, NH_2), 1.61–1.55 (m, 4H, $OCNCH_2CH_2$), 1.26 (s, 60H, chain CH_2's), 0.86 (t, 6H, J = 6.8, CH_3 2×). ^{13}C NMR (400 MHz, $CDCl_3$): δ (ppm) 168.8 (*C*O), 43.7 ($OCNCH_2$), 41.9 ($OCNCH_2$), 35.6 ($CH_3CH_2CH_2$), 33.4 (alkyl chain CH_2's), 32.3, 31.1 ($NCH_2CH_2CH_2$), 22.7–14.1 (alkyl chain CH_2's). Gd(III) [*N*,*N*-Bis-stearylamidomethyl-*N*′-amidomethyl]diethylenetriamine Tetraacetic Acid (Gd.DTPA.BSA). A stoichiometric amount of $Gd.Cl_3.6H_2O$ (45 mg, 0.0502 mmol) was added to BSA.DTPA (18.67 mg, 0.0502 mmol), and the reaction was stirred in distilled H_2O (20 mL) at 90 °C for 3 h (pH dropped to 3.5). The water was freeze-dried to yield a white powder (48 mg, 91% yield, decomp 350 °C). R_f [CH_2Cl_2/MeOH/H_2O 34.5:9:1 v/v]. The Xylenol orange test indicated no detectable free Gd^{3+} ions. FTIR: (cm^{-1}) 3947.57, 3882.97, 3779.8, 3674.69, 3595.63, 3481.85, 3357.46, 2921.63, 2271.73, 1991.14, 1868.68, 1771.3, 1683.55, 1652.7, 1575.56, 1497, 1396.21, 1317.14, 1068.37, 1044.26, 668.214. HPLC: t_R= 34.60 min, column C-4 peptide: gradient mix A = MeCN/0.1% TFA; mix B = H_2O/TFA; mix C = MeOH/$CHCl_3$; mix D = MeOH, 0.0 min [100% B], 15–25.0 min [100% A], 25.1–45.0 min [100% D], 45.1–55.0 min [100% C]; flow 1 mL/min. HRMS: (FAB+) calcd. for $C_{50}H_{94}GdN_5O_8$ *m/z* 1050.56, found 1051.10 $(M + H)^+$.

Xylenol Orange Test. The presence of free gadolinium ions in Gd-incorporated compounds was determined by measuring the absorbance at 573 nm of a mixture of Xylenol orange solution (990 μL, 0.5 mM in sodium acetate buffer (0.1 M, pH 5.2) and test solution (in an appropriate solvent) containing the

Gd compound (10 μL). Extinction coefficient ε = 20, 700 L mol^{-1} cm^{-1}, whereby [Free Gd] = A573/ε.

Chloroanil Test. To 1–5 mg of resin was added one drop of 2% acetaldehyde in DMF (v/v) followed by one drop of 2% *p*-chloranil in DMF (w/v). The sample was allowed to stand at room temperature for 5 min. Blue-stained beads indicate the presence of secondary amines.

Liposome Preparations. All lipids were stored as stock solutions in anhydrous organic solvents ($CHCl_3$, MeOH, or a mixture of both), at −20 °C under argon. Liposomes were made with a range of defined molar ratios of individual lipids to give a predetermined total lipid concentration of 1.2 mg mL^{-1} in water for *in vitro* and 30 mg mL^{-1} in HEPES (20 mM, NaCl 135 mM, pH 6.5) for *in vivo* experiments. Fluorescent liposomes always contained 0.5 mol % and 1 mol % DOPE–Rhodamine (Avanti Polar Lipids Inc., USA) for *in vitro* and *in vivo* experiments, respectively. Appropriate volumes of each lipid stock were placed in a round-bottom flask (typically 5 mL) containing distilled CH_2Cl_2 (500 μL) and stirred to ensure thorough mixing of the lipids. The solvent was slowly removed *in vacuo* to ensure production of an even lipid film. The film was rehydrated with water or buffer at a defined volume. The resulting solution was sonicated for 5–8 min for *in vitro* formulations and 30 min (at 30 °C) for *in vivo* formulations in order to form liposomes of appropriate size. The pH of the liposomal suspension was checked by pH Boy (Camlab Ltd., Over, Cambridgeshire, UK) and if appropriate adjusted to neutral by addition of aqueous solutions of NaOH (0.99 M) and HCl (0.99 M). For each preparation, the size of the liposomes was measured by photon correlation spectroscopy (PCS) to ensure a size distribution of below 250 nm for *in vitro* experiments and 100 nm for *in vivo* experiments.

MRI Analysis of Gd.DOTA.DSA and Gd.DTPA.BSA. For T_1 analysis, Gd.DOTA.DSA **1**, Gd.DTPA.BSA, and controls of the metal-free compounds and Magnevist (Schering AG, Germany) were added to water to give a final concentration of 0.5 mM. The solutions (200 μL) were placed in Eppendorf tubes and T_1 relaxation values measured on a 4.7T Varian MR scanner at ambient temperature. For relaxivity measurements; Gd liposome formulations were prepared in order to obtain five different Gd concentrations between 0.55 and 1.85 mM in 200 μL of distilled water, and the molar relaxivity r_1 (m M^{-1} s^{-1}) determined. T_1 values were obtained using saturation recovery experiments performed with a standard spin–echo sequence and a 2 mm single slice acquisition (TR = 50, 100, 200, 300, 500, 700, 1200, 3000, 5000, 7000 ms; TE = 15 ms), the number of signal averages was 2, FOV; 70 × 70 mm^2, collected into a matrix of 256 × 128.

***In Vitro* Fluorescent Cell Uptake Assay.** At 24 h prior to Gd-liposome uptake experiments, adherent HeLa cells were grown in Dulbecco's Modified Eagle culture medium (DMEM) with 10% fetal calf serum and 1% penicillin–streptomycin (Sigma), in a 48-well plate (80 000 cells per well, 250 μL of complete medium) and in a wet (37 °C) 10% CO_2/90% air atmosphere. The cells were grown until 80% confluence was reached. The media was then removed and replaced with fresh media (same volume as previous). Bimodal Gd liposomes (see Table 2) containing 0.5 mol % DOPE–Rhodamine were then added at three different doses to the wells, swirled to ensure even dispersion, and then incubated in a wet (37 °C) 10% CO_2/90% air atmosphere for 4, 6, 8, or 10 h. The amount of Gd per liposome sample added to each well was as follows: For the 6 μg Gd liposome dose, liposomes 1 and 2 contained 0.358 μg; liposomes 3 and 4, 0.449 μg; liposomes 5 and 6, 0.554 μg; and liposomes 7 and 8 contained 610.32 μg of Gd. For the 12 μg Gd liposome dose, liposomes 1 and 2 contained 0.716 μg; liposomes 3 and 4, 0.898 μg; liposomes 5 and 6, 1.108 mg; liposomes 7 and 8, 1.220 mg of Gd. Finally, for the 18 μg Gd liposome dose, liposomes 1 and 2 contained 1.074 mg; liposomes 3 and 4, 1.347 mg; liposomes 5 and 6, 1.662 mg; and liposomes 7 and 8, 1.831 mg of Gd. After liposome uptake, the cells were washed with PBS (2 × 200 μL) and then treated with lysis buffer (100 μL per well). Cell lysate (80 μL) was diluted with MeOH (50 μL) and $CHCl_3$ (300 μL). The resulting solution was vigorously vortexed and then allowed to separate into two phases (organic and aqueous). The organic layer was isolated, and its fluorescence was recorded on a RF-5301PC Shimadzu spectrofluorophotometer (λ_{ex} 545 nm, λ_{em} 585 nm). As a positive control, control Gd liposomes (6, 12, or 18 μg) were added to the lysate of untreated cells, to provide a 100% liposome uptake result. The amount of cellular protein was quantified with a BCA assay (Pierce, Rockford, IL).

Lactate Dehydrogenase Toxicity Assay. Twenty-four hours prior to the assay, adherent HeLa cells were grown in Dulbecco's Modified Eagle culture medium (DMEM) with 10% fetal calf serum and 1% penicillin–streptomycin (Sigma), in 48-well (4×10^4 cells per well, 250 μL of complete medium) plates and in a wet (37 °C) 10% CO_2/90% air atmosphere. The cells were grown until 80% confluent, and the media was then removed and replaced with fresh media (same volume as previous). The same Gd liposomes used in the *in vitro* fluorescence cell uptake assay (see Table 2) were added to each well at the previously stated three doses and the cells incubated in a wet (37 °C) 10% CO_2/90% air atmosphere for 4, 6, 8, or 10 h. In addition, this experiment was repeated; however, at the end of each incubation period the cells were washed and then incubated for a further 24 h period. The LDH assay was carried out using the CytoTox 96 non-radioactive cytotoxicity assay (Promega, USA).

MRI Analysis of Cells. Twenty-four hours prior to liposome uptake, adherent HeLa cells were grown in Dulbecco's Modified Eagle culture medium (DMEM) with 10% fetal calf serum and 1% penicillin–streptomycin (Sigma), in a 25 cm^3 culture flask (5×10^5 cells per well, 5 mL of growth medium) and in a wet (37 °C) 10% CO_2/90% air atmosphere. The cells were grown until 80% confluent, and the media was then removed and replaced with fresh media. Gd liposomes (144 μL of 1.2 mg mL^{-1} liposome solution containing 4.49 μg Gd (the optimal dose was scaled up from the *in vitro* fluorescence assay to label 5×10^5 cells) were then added to each flask, swirled to ensure even dispersion, and then incubated in a wet (37 °C) 10% CO_2/90% air atmosphere for 8 h. After liposome uptake, the cells were washed with PBS (2 × 2 mL) and then treated with trypsin–EDTA (500 μL trypsin, 1 mM EDTA) for 2 min at 37 °C. DMEM (complete, 3 mL) was added to neutralize the trypsin. The cells were washed with PBS and then centrifuged in PBS buffer (1 mL), the solution was decanted, and the cells reconstituted in PBS by vortexing and spun (1500 rpm for 5 min) into pellets in Eppendorf tubes filled with 200 μL PBS. The tubes were imaged and T_1 values were measured on a 4.7T Varian MR Scanner. T_1 values were obtained from saturation recovery experiments performed with a standard spin–echo sequence and a 10 mm single slice acquisition (TR = 50, 100, 200, 300, 500, 700, 1200, 3000, 5000, 7000 ms; TE = 15 ms), four signal averages, FOV; 100 × 100 mm^2, collected into a matrix of 256 × 128. As negative controls; cells treated with liposomes containing no Gd lipid (substituted for by using the Gd free lipid DOTA.DSA); untreated cells and an Eppendorf containing PBS buffer were also imaged.

Fluorescence Microscopy. Twenty-four hours prior to Gd liposome uptake, adherent HeLa cells were grown in Dulbecco's Modified Eagle culture medium (DMEM) with 10% fetal calf serum (FCS, sigma) and 1% penicillin–streptomycin (Sigma), in a 6-well (1.25×10^5 cells per well, 3 mL of complete

medium) plate fitted with plastic microscopy slides, in a wet (37 °C) 10% CO_2/90% air atmosphere. The cells were grown until 80% confluent, and the media was then removed and replaced with fresh media (same volume as previous). Fluorescent Gd liposomes, 37.5 μg per well (31.25 μL of 1.2 mg mL^{-1} liposomes containing 5.26 μg of Gd, based on scaling up of optimal dose from *in vitro* fluorescence assay) were then added to appropriate wells, swirled to ensure even dispersion, and then incubated in a wet (37 °C) 10% CO_2/90% air atmosphere for 8 h. After liposome uptake, the media was removed, and the cells were washed with PBS (2×), heparin (1× (20 mg mL) in order to remove unbound liposomes from cell surface), PBS (2×), paraformaldehyde (PFA) (1× (20 min at 37 °C)), PBS (2×), glycine (1× (20 mM, 20 min at 37 °C)), PBS (2×). The slides were removed from the wells and fixed. Microscopy images were obtained on an Olympus 251 scope.

Gd-AB Liposomes (Gd-Lipoplexes) for Transfection. Gd-lipoplexes (Gd-LD's) were prepared as per the Trojene transfection protocol (Avanti Polar Lipids Inc., USA). At 24 h prior to transfection, adherent HeLa cells were grown in OptiMEM media with 10% fetal calf serum (FCS, Sigma) and 1% penicillin–streptomycin (Sigma), in 24-well (6×10^4 cells per well, 300 μL of complete medium) plates and in a wet (37 °C) 10% CO_2/90% air atmosphere. The cells were grown until 80% confluence was reached. The media was then removed and replaced with fresh media. Gd-LD mixtures were added to each well, swirled to ensure even distribution, and then incubated in a wet (37 °C) 10% CO_2/90% air atmosphere for 4 h. The media was removed, and the cells washed with PBS and then replaced with fresh media (300 μL). The cells were then incubated for a further 24 h. Before the luciferase assay was carried out, the cells were washed with PBS and harvested with lysis buffer (100 μL).

Luciferase Reporter Assay. Luciferase gene expression was measured with the Luciferase Assay System purchased from Promega. Light output readings were done on a Berthold Lumal LB 9507 luminometer. Transfection efficiency, measured in relative light units (RLU), was normalized to the total mass of cellular protein using the Bio-Rad Protein Assay Dye Reagent (Bio-Rad).

ICP–AES Analysis. 150 μL of sample was pipetted and diluted to 3.75 mL with 2% nitric acid to give a total dilution of 1 in 25. All data were corrected for these dilutions, and the values from a blank 2% nitric acid sample were also analyzed. Samples were run on a Varian VISTA PRO instrument.

Tumor Model. 5×10^6 IGROV-1 cells were implanted into the flanks of 6–8 week old Balb/c nude mice for generation of subcutaneous tumors. After ~2 weeks (estimated tumor weights 40–50 mg), the mice were anaesthetized with an isoflurane/O_2 mix and placed into a quadrature ^{1}H volume coil and positioned into the magnet. Baseline scans were obtained, and then the mice were injected intravenously via lateral tail vein with a 200 μL liposome solution (HEPES (20 mM, NaCl 135 mM, pH 6.5)) and imaged at 3, 16, and 24 h postinjection at 4.7T (spin–echo sequence, TR = 400–2800 ms, TE = 10 ms, FOV = 45 × 45 cm^2; averages, 1; matrix size, 256 × 128 thickness; 2.0 mm, and 20 slices). The injected volume contained 9.87 μmol of Gd.

Histology Experiments. Following MRI, the animals were sacrificed and tumors excised, frozen in liquid nitrogen, embedded in OCT (VWR) embedding fluid, and 10 μm thick sections cut, mounted on slides, and studied by fluorescence microscopy.

RESULTS

Our previous work has shown the novel Gd-lipid Gd.DOTA-.Chol to be an effective MR signal enhancer and MAGfect, a liposome formulation containing this Gd-lipid, an efficient cellular dual labeling and transfection vehicle (*17*). The need to provide a more robust membrane anchor designed ultimately for *in vivo* applications led us to investigate an alternative saturated long-chain alkyl moiety in place of the cholesteryl functionality. For this purpose, a novel paramagnetic lipid Gd.DOTA.DSA **1** was synthesized using a combination of solution- and solid-phase chemistries. The DOTA chelate was conjugated to the lipid via a stable yet biodegradable amide functional group. Gd-lipid **1** was also designed with a five-atom spacer between the Gd chelator and lipidic alkyl chain moieties. This spacing between the Gd chelator and lipidic alkyl chain moieties was selected to be optimal to ensure maximum exposure of the Gd-chelate to water on the hydrophilic surface of a liposome particle. Furthermore, Gd-lipid **1** was also designed with the DOTA chelate rather than DTPA, since the former macrocyclic ligand is considered to be a more effective chelator of Gd, able to retain the metal ion even in the acidic environment of the endosome (*18*).

The synthetic approach toward the protected precursor DOTA macrocycle **2** utilized a similar route as carried out by Peterson et al. (*19*). Solid-phase synthesis offers a cleaner and more selective option for the synthesis of compounds such as **2**, allowing for the functionalization of three sites on the azamacrocycle while the fourth position is attached to the resin and hence temporarily protected (Scheme 1). Initially, MeOH partial capping was used to prevent molecular overcrowding in the chlorotrityl resin (Scheme 1). Thereafter, the resin was then functionalized with bromoacetic acid to yield an acyl bromide. An excess of cyclen was then added, leading to resin-bound cyclen wherein each cyclen was associated with resin via combination with a single acyl bromide site, leaving three uncombined secondary amine sites per bound cyclen. These remaining free amine sites were then further modified with the introduction of three *tert*-butyloxycarbonyl (Boc) protecting groups, and the reaction was then judged to have reached completion using the chloroanil test. A facile resin cleavage in mildly acidic conditions yielded macrocycle **2**, in reasonable purity (60–70% yield depending upon the freshness of resin used). Macrocycle **2** was then reacted with lipid amine **3** under typical peptide bond synthesis conditions to yield **4**, employing 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) and dimethylamino pyridine (DMAP) as carboxylic acid activators. Initially, amide bond formation appeared to be hindered significantly by steric crowding imposed by the bulky Boc groups on DOTA, leading to poor yields of coupled product **4**. However, this problem was overcome by making use of highly pure reagents, dry chloroform, and elevated reaction temperatures, leading to improved yields (ranging from 60% to 88%) and product quality. The DOTA cyclic ring is a highly conformationally strained system and can therefore adopt a more flexible conformation upon heating, rendering better access to the preactivated carboxylate site for conjugation with lipid amine **3**.

A simple deprotection of **4** using HCl/dioxane 1:1 v/v ratio gave DOTA.DSA **5** in good yield and purity. With **5** in hand, Gd complexation was carried out by simple stoichiometric addition of $GdCl_3.6H_2O$ to **5** in water at 90 °C for optimum solubility of the starting materials, thereby generating Gd-DOTA.DSA **1**. No significant free Gd^{3+} ions were detectable post-complexation according to the xylenol orange assay, and the pH was observed to have dropped to 3.5 (Scheme 1). Potentiometric studies of Moreau et al. have shown that the complexation of lanthanide cations to DOTA involves the instantaneous formation of metal ion complexes as soon as metal ions are combined with ligand, leading to proton expulsion and

a dramatic reduction in reaction pH (*20*). Synthesis of precursor lipid amine **3** was accomplished in two steps as shown (Scheme 2). Amide coupling of Boc–glycine **6** with distearylamine **7** resulted in protected lipid amine **8**. A facile deprotection afforded lipid amine **3** [*N*,*N*-distearylamidomethylamine (DSA)] in good yield and purity.

Gd-DTPA-bis(stearylamide) (Gd.DTPA.BSA) was also synthesized for control MRI relaxivity studies. Since the use of

Table 1. T_1 Values and Images of Gd.DOTA.DSA 1 and Gd.DTPA.BSA with Relative Controls

Sample		T_1 (ms)
1	0.5 mM Gd.DOTA.DSA	400.1 ± 15.92
2	0.5 mM DOTA.DSA	2356 ± 112.588
3	Magnevist® *	371.0 ± 4.321
4	H_2O	2750 ± 121.8
5	0.5 mM Gd.DTPA.BSA	687.5 ± 26.03
6	0.5 mM DTPA.BSA	3760 ± 211.7

* Dose calculated to ensure an equivalent Gd atom content relative to sample **1**. The T_1 values for controls of the compound without Gd complexed are also shown for completeness.

this compound in liposome formulations has had precedence in recent literature, the method of Nepveu et al. was adapted for the synthesis of this molecule (*21*).

MRI Studies of Aqueous Solutions of Gd.DOTA.DSA 1. In order to establish the relaxation properties of Gd.DOTA.DSA **1**, MRI studies of the lipid in aqueous solution were performed and T_1 values and relaxivity parameters generated in milliseconds. The efficacy of Gd-lipid **1** was compared to the clinical contrast agent Magnevist (Schering AG) and Gd.DTPA.BSA (see Table 1), and was found to compare favorably at the clinically relevant dose. These data also showed **1** to have a comparable, if slightly better, T_1 relaxation than the widely used Gd.DTPA.BSA lipid. A standard T_1 saturation recovery method was used to determine T_1 values (according to eq 1), where x is TR (time to repeat), and S_i is the measured signal for a given TR.

$$S_i = S_0(1 - e^{(-x/T_1)}) \quad (1)$$

Liposomes were also formulated with Gd.DOTA.DSA **1** and relaxivities measured. Relaxivity can be defined as the capability of a contrast agent to increase the relaxation rate ($mM^{-1}\ s^{-1}$) of surrounding water proton spins. The relaxivity for Gd.DOTA.DSA **1** in liposome formations was found to be 4.10 ± 0.34 $mM^{-1}\ s^{-1}$ according to calculations made using eq 2 where R_1 is the relaxivity and $1/T_1[C]$ is the measured solvent relaxation rate in the presence of Gd.DOTA.DSA **1** liposomes, with α_1 and [C] being the T_1 relaxation and Gd concentration values, respectively.

$$R_1[C] = 1/T_1[C] + \alpha_1 \times C \quad (2)$$

Optimization of Liposome Formulations. In order to establish the cellular labeling efficiency of liposomes prepared with Gd.DOTA.DSA **1**, a series of eight liposome formulations were tested on HeLa cells so that an ideal nontoxic cell labeling liposome formulation could be determined able to deliver a maximal amount of Gd to the cells. HeLa (human ovarian carcinoma) cells were chosen, since they require minimum handling, are a robust cell line, and are therefore adequate for our proof of concept study of cellular labeling prior to progressing to more challenging and specialized cells. A simple method to quantify the uptake of liposomes into cells is the inclusion of a small mole percent of a fluorescent component in the liposome formulation, in this case, the fluorescent lipid DOPE–Rhodamine. Here, the measured fluorescence intensity of the cell lysate can be used to estimate the amount of liposome and hence Gd-lipid that is internalized by the cells. Additionally, incorporation of a fluorescent lipid can be used to examine the process of cellular uptake by means of fluorescence microscopy studies. The liposome formulations studied were prepared using Gd.DOTA.DSA **1**, N^1-cholesteryloxycarbonyl-3,7-diazanonane-1,9-diamine (CDAN), dioleoyl-L-α-phosphatidylethanolamine (DOPE), and DOPE-Rhodamine lipids in various mole percentages relative to each other. Other parameters investigated were incubation time and dose. Our objective was to determine a formulation, dose, and incubation period that resulted in the most ample liposome uptake into cells without the appearance of cellular toxicity. Gd-liposomes **1**–**4** (Table 2) displayed a high percentage uptake consistent with the presence of both CDAN and DOPE at high mole percentages. Gd-liposomes **5** and **6** were less effective, consistent with the absence of either DOPE or CDAN, supporting the hypothesis that both the cationic charge and fusogenic properties of CDAN and DOPE lipids, respectively, are necessary for effective cellular entry and cytosolic delivery. Gd-liposomes **8** were similarly less effective owing to formulation toxicity and lack of effective cationic charge for cell surface adhesion. Given the superior performances of Gd-liposomes **1**–**4** and **7**, cell toxicity studies were then performed with Gd-liposomes **1**, **2**, and **7**. Gd-liposome **4** showed the highest fluorescence uptake; however, it was not carried forward for toxicity studies due to the presence of an excess of cationic charge.

Table 2. Gd-Liposome Formulations Assessed for Their Cell Labeling Efficiency with Their Associated Mean Sizes[a]

liposome	Gd.DOTA.DSA (%)	CDAN (%)	DOPE (%)	DOPE–Rhoda (%)	liposome size (nm)	fluorescence uptake (%)

[a] Stock solutions of lipids were mixed in relevant mol % ratios.

Lactate Dehydrogenase Cytotoxicity Assay. In order to assess the toxic effects of the three selected Gd-liposome formulations (**1**, **2**, and **7**) chosen from the fluorescence uptake studies on cells, a lactate dehydrogenase assay (LDH) assay was carried out. The toxic effects of the liposomes were all found to be minimal over a 24 h period (Figure 1). Indeed, there was little difference in toxicity between all Gd-liposome formulations studied (Table 2) irrespective of incubation times (4, 6, 8, 10, and 24 h) and total lipid doses (6, 12, and 18 μg/well.). After initial incubation periods (4, 6, 8, and 10 h), the cells were allowed to grow for 24 h; LDH release from these cells was minimal in all cases, suggesting that normal cell growth and proliferation were taking place in spite of the presence of Gd-liposomes. From the liposome fluorescence uptake assay and LDH toxicity assay data, it was concluded that the optimal formulation for cellular uptake and Gd cell labeling could be Gd-liposome formulation **1**, administered at a total lipid dose of 12 μg/well (48-well, containing 0.716 μg/well of Gd) and incubated for 8 h.

ICP–AES and MRI of Cells Labeled with Gd-Liposomes. Once favorable *in vitro* conditions for Gd-liposome cellular uptake were determined, inductively coupled plasma atomic emission spectroscopy (ICP–AES) studies were carried out using cell lyzate postincubation with Gd-liposome formulation **1** to assess the amount of Gd internalized into the cells more precisely. From this, we determined that 21% of the

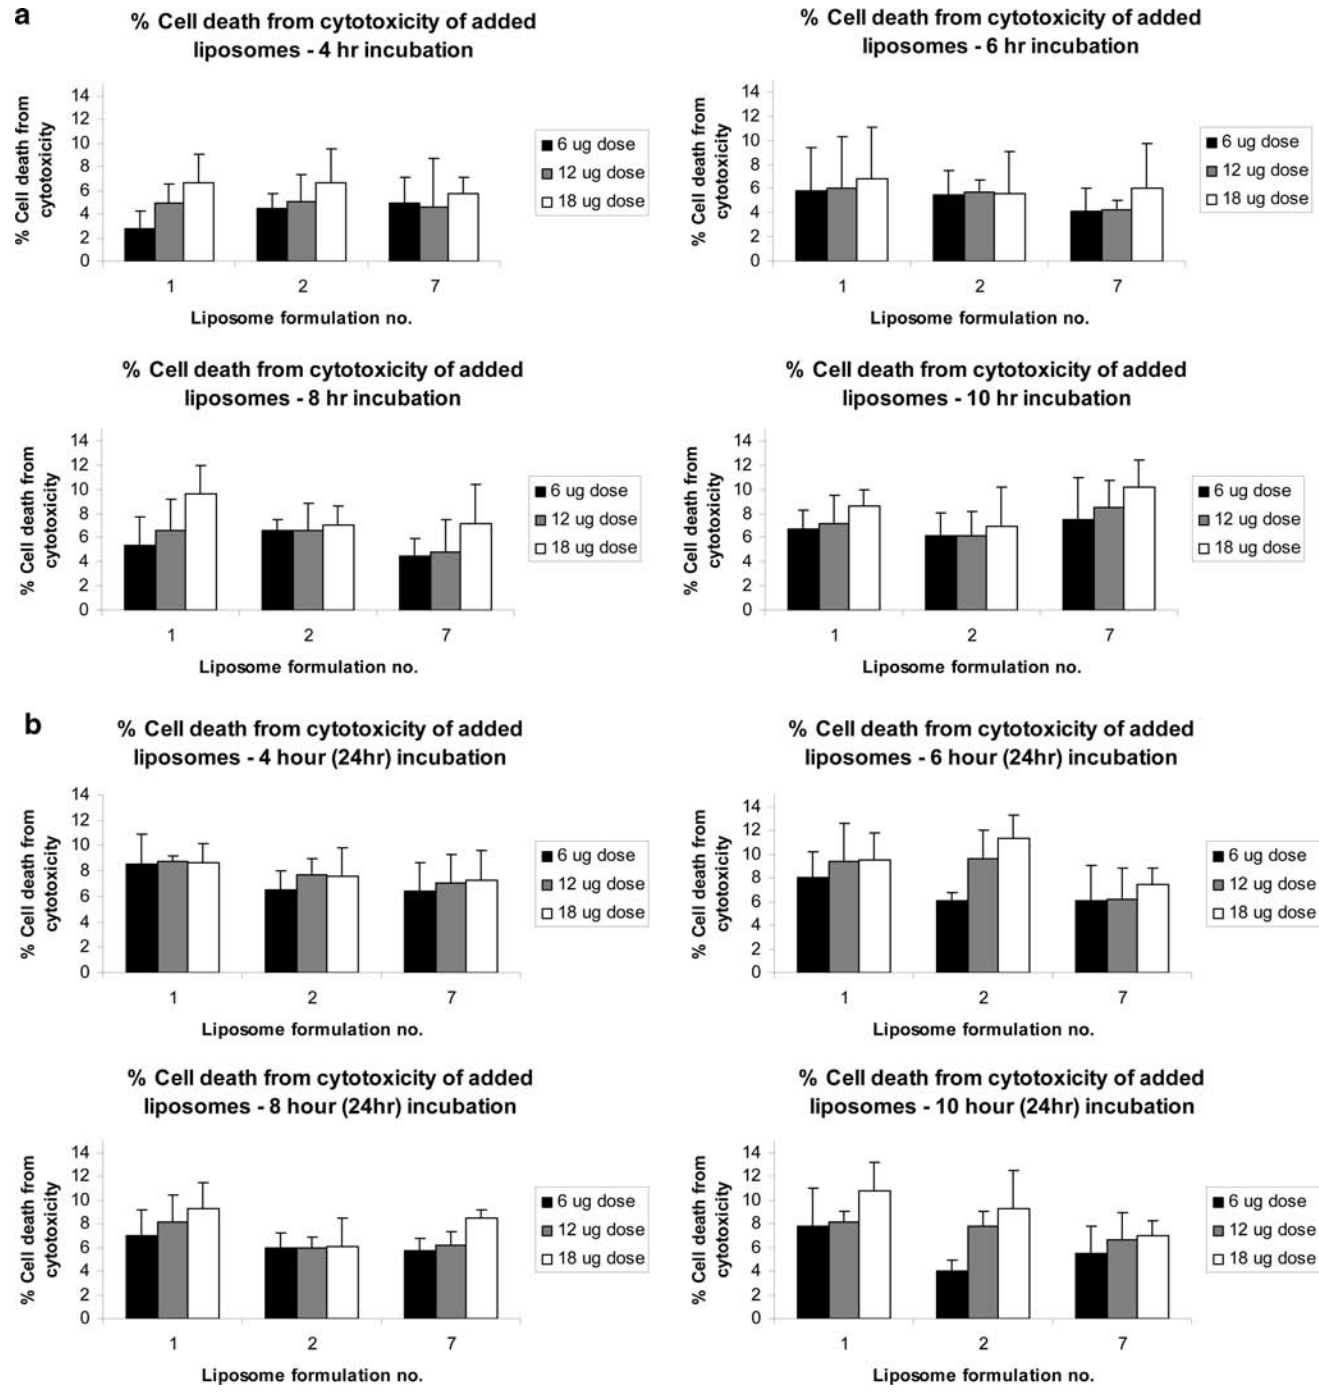

Figure 1. (a) Lactate dehydrogenase (LDH) assay results calculated to show % cytotoxicity as a result of added Gd-liposome formulations **1**, **2**, and **7** at three liposome doses (6, 12, and 18 μg) and 4 incubation periods (4, 6, 8, and 10 h). (b) LDH assay calculated to show % cytotoxicity as a result of added Gd-liposomes as per (a); in addition, cells being washed after the initial incubation periods and then allowed to grow for up to 24 h. These results show cytotoxicity induced by the added Gd-liposomes to be in general <10% of total cell death.

administered Gd was retained within the cells. This result is within 10% error in comparison to the fluorescence uptake assay (see Table 2), and validates this fluorescence method as a quick and simple method for screening large numbers of differing formulations prior to more accurate ICP-MS analysis of Gd content. The ability of Gd-liposome formulation **1** to produce *in vitro* contrast enhancement postadministration to cells was assessed with the labeling of approximately 1×10^6 HeLa cells. After 8 h incubation with Gd-liposome formulation **1**, cells were spun into pellets and imaged by MRI at 4.7 T using a spin–echo T_1 weighted sequence. The results of cell labeling are described in terms of T_1-weighted images and resulting T_1 values, relative to controls (Table 3). The MRI analysis of HeLa cell pellets labeled with Gd-liposome **1** produced a brightly visible mass of cells, and the T_1 value in cells was measured at 65% the level measured in control cells (Table 3). This promising result demonstrated the cell labeling efficiency of the novel Gd-liposome formulation **1** *in vitro*.

Cellular Uptake of Gd-Liposomes and Transfection. In order to examine the intracellular uptake of Gd-liposome formulation **1** into HeLa cells, we chose to take advantage of the imaging bimodality of this liposome, in that a fluorescent lipid was included with the paramagnetic liposome (DOPE-Rhodamine, Avanti Polar Inc.). In this instance, the cell labeling conditions were set up for the labeling of 1.25×10^5 HeLa cells/well, and any noninternalized Gd-liposomes not taken up

[a] T_1 values for Gd-liposome formulation **1** incubated with HeLa cells (control liposome: CDAN/DOPE/DOTA.DSA: 40/30/30 mol %).

were washed away after the conclusion of the uptake period of 8 h. Fluorescence microscopy revealed that the cellular uptake of these bimodal Gd-liposomes led to intracellular, cytosolic accumulation of the fluorescent label, which is in accordance with endocytosis-mediated uptake followed by endosomolysis (Figure 2). This result is consistent with successful Gd-labeling implied by reduction of T_1 values, relative to controls (Table 3).

Gd-liposome formulation **1** mediated transfection of HeLa cells was investigated with plasmid DNA (pDNA) expressing the luciferase gene. Here, the level of luciferase enzyme activity in cells post pDNA delivery represents a quantitative measure of transfection efficiency. Gd-liposome formulation **1** was combined with pDNA (12:1 w/w) to form Gd-liposome-plasmid DNA complex (Gd-lipoplex: Gd-LD) particles. Gd-LD transfection data are shown (Figure 3). Gd-liposome formulation **1** mediated transfection appears to be equivalent to CDAN/DOPE (50:50 mol %) (Trojene) mediated transfection, demonstrating that the Gd incorporation does not interfere with liposome-mediated transfection of HeLa cells to any perceptible degree. Furthermore, successful Gd-liposome mediated transfection of HeLa cells provides functional proof for Gd-liposome cellular entry by endocytosis followed by endosomolysis and cytosolic accumulation, as observed by fluorescence microscopy, since transfection is contingent on successful endocytosis and endosomolysis. Gd-LD particles prepared with Gd-liposome formulation **1** were also shown not to be toxic according to LDH assay data as well (data not shown).

***In Vivo* Tumor MRI.** Having demonstrated successful bimodal cellular MRI and fluorescence imaging of HeLa cells by means of Gd-liposome formulation **1**, as well as bifunctional labeling and transfection, we wanted to demonstrate the efficacy of our Gd-lipid, Gd.DOTA.DSA, toward imaging of xenograft tumors *in vivo*. Tumors were established by induction of IGROV-1 (human ovarian cancer cells) xenografts in nude mice. In this instance, we replaced the *in vitro* suited Gd-liposome formulation **1** with charge-neutral Gd-liposome formulation **9**, Gd.DOTA.DSA/DOPC/Cholesterol/DSPE-PEG_{2000}: 30/32/30/7 mol % (also containing 1 mol % DOPE-Rhodamine). This formulation was rendered stable to biological fluids by the incorporation of a stealth/biocompatibility polymer outer-coat calyx comprising poly(ethylene glycol) (PEG). In terms of our synthetic self-assembly **ABCD** nanoparticle concept, this can be described as a Gd-**BC** liposome nanoparticle system (*15*). Post i.v. injection of Gd-liposome **9**, xenograft tumors ($n = 3$) were monitored by MRI over a 24 h period. Over this period, we observed a substantial 60% reduction in tumor T_1 values compared to the situation with control liposomes (without Gd) and visibly enhanced tumor image brightness (Figure 4). This outcome suggested that the neutral Gd-liposome **9** was in fact a liposome system with a substantial systemic half-life ($t_{1/2} >$ 4 h) capable of long-term circulation in the blood and passive targeting to the xenograft tumor by an enhanced permeation and retention (EPR) mechanism due to the porous nature of the endothelial cell layer (*22*). This finding was supported by fluorescence imaging of tumor tissue slices (postmortem) taking advantage of the bimodal imaging capacity of our Gd-liposome **9** for MRI and fluorescence microscopy. The fluorescence images obtained demonstrate liposome accumulation in intravascular spaces and in surrounding viable tumor tissue (Figure 5).

DISCUSSION

The synthesis of a new Gd-lipid contrast agent (Gd.DOTA.DSA **1**) was carried out, and this lipid was shown to have similar T_1 relaxation behavior to the common clinical contrast agent Magnevist at the clinically relevant dose of 0.5 mM (see Table 1). This can be attributed to the mixed micellar structures of the Gd.DOTA.DSA lipid in water whereby the rotational tumbling rate is reduced as a result. Also, Gd.DOTA.DSA was shown to be 10% more effective than the commonly used Gd.DTPA.BSA lipid at reducing bulk water T_1. The relaxivity for Gd.DOTA.DSA in liposome form was established, and further liposomes were formulated (Table 2). The *in vitro* Gd-liposome formulation **1** was shown to effect bimodal labeling of HeLa cells for MRI and fluorescent imaging (Figure 2; Table 3) which was made possible by mediating the delivery of chelated Gd to cells and subsequent shortening of T_1 relaxation times. This formulation was found to be nontoxic to HeLa cells by the LDH assay (Figure 1) and to be capable of bifunctional labeling with transfection (Figure 3) consistent with a cell labeling mechanism in which Gd liposomes enter by endocytosis followed by endosomolysis leading to cytoplasmic accumulation of the label (Figure 2). The neutral Gd-liposome **9** was shown to assist the visualization of xenograft tumors *in vivo* by means of MRI (Figure 4), apparently by concentrating Gd in viable tumor tissue by the widely reported passive targeting and EPR effect originally described by Maeda et al., whereby as a result of slow venous return and poor lymphatic clearance in tumor tissue liposomal particles can become trapped, leading to their accumulated concentration in solid tumors (*23*). It also appears that the colloidal Gd liposomes extravasate in areas of vascular hyperpermeability within the tumor mass, which can shed light on the more intense and heterogeneous fluorescence pattern observed throughout the tumor tissue (Figure 5). Here, the potential extent of Gd labeling is demonstrated by making use of the bimodal imaging capacity of our neutral Gd-liposome **9** for MRI and fluorescence imaging.

The traditional method of encapsulating contrast agents, mainly clinically used Gd chelates, has the disadvantage of entrapped agents easily "leaking" out of liposome cavities prior to reaching the target site. This can be avoided by chelation of Gd with lipid-chelate molecules such as **5** (Scheme 1) that readily insert their dialkyl chains into the bilayer of a liposome, thereby anchoring Gd to a liposome surface instead. Also, the potential downfall of an encapsulation approach is reduced water flux in the vicinity of Gd, leading to reduced paramagnetic relaxation of water and weaker T_1 reductions in contrast to the situation observed with free Gd-chelates. However, our data suggest that liposome presented lipidic Gd-chelates remain useful paramagnetic relaxation agents both *in vitro* and *in vivo*. The bifunctional capacity of Gd-liposome formulation **1** to simultaneously label and transfect HeLa cells relies on the dual capacities of CDAN and DOPE which are known to be

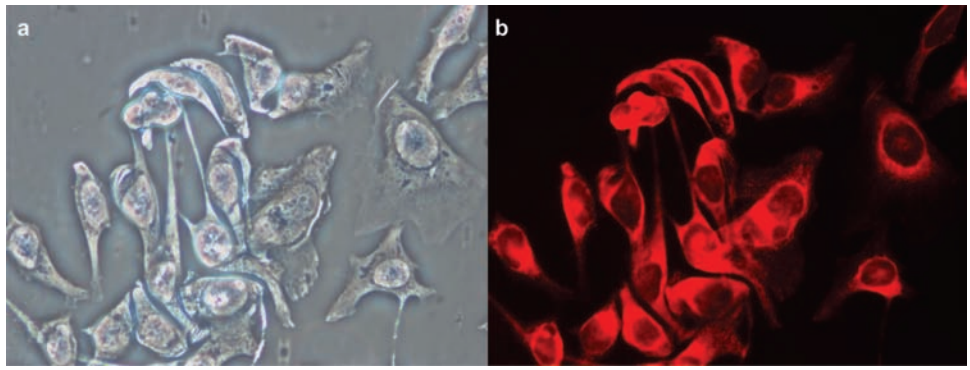

Figure 2. (a) Bright field image of HeLa cells labeled with Gd-liposome formulation **1**. (b) Red fluorescence image of HeLa cells labeled with Gd-liposome formulation **1**, at 40× magnification.

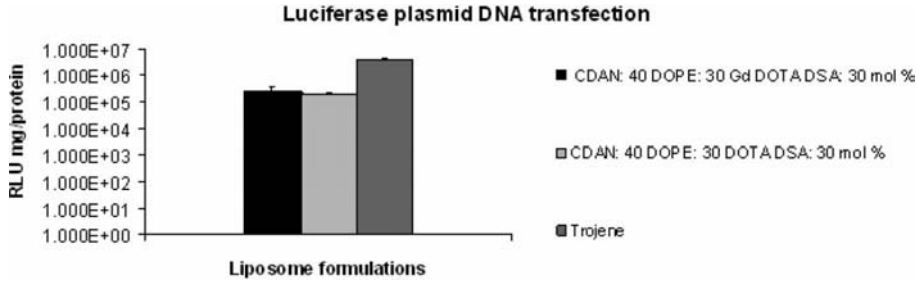

Figure 3. Gd-lipoplex (Gd-liposome **1** plus DNA) transfection of HeLa cells compared with control Gd-free lipoplex transfection and CDAN/DOPE (50:50 mol %) (Trojene mediated transfection). Transfection is comparable in both DMEM and OptiMEM media in the presence of 10% fetal calf serum (data not shown.).

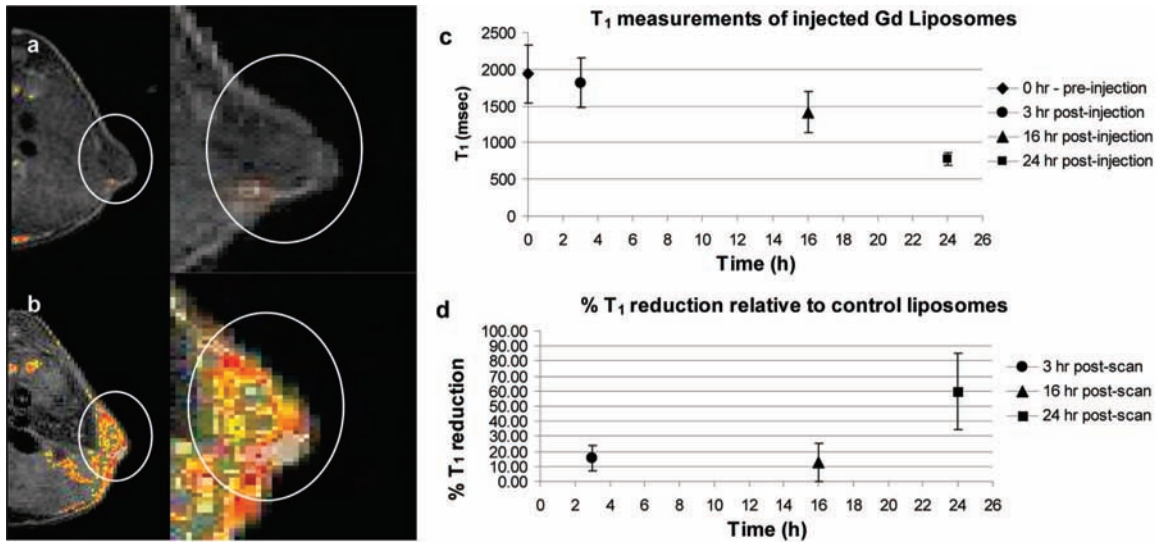

Figure 4. (a) Preinjection MR images of induced IGROV-1 tumors under the right flanks of nude Balb/c mice: large white circle represents zoomed image of tumor area marked with small circle. (b) MR images 24 h post i.v. injection of Gd-liposomes **9**; the color map shows enhancement of tumor area: large white circle is zoomed image of tumor area marked with small circle. (c) T_1 measurements were obtained from tumor slices. (d) Image enhancement is supported by a 60% measured reduction in tumor T_1 values 24 h post i.v. injection relative to control liposomes (no Gd complexed; Gd.DOTA.DSA replaced with DOTA.DSA).

nontoxic (*24, 25*). In addition, CDAN comprises a head-group that possesses amine functional groups with notably perturbed pK_a values. It is known that higher pK_a amine groups function to neutralize, condense, and assist nucleic acid encapsulation, not to mention assist cell binding and endocytosis, while lower pK_a amine functional groups provide the means for endosome buffering post cell entry leading to potential endosomolysis by osmotic shock (*12*). The inclusion of DOPE is widely believed to assist endosomolysis owing to the fusogenic character of DOPE *in vitro* (*26*). These characteristics are most likely helpful to ensure Gd access to the cellular cytosol for optimal cellular Gd labeling at a level appropriate for cellular MRI.

The success of the neutral Gd-liposome **9** with respect to tumor Gd and fluorescence labeling almost certainly relies on a different assembly of liposomal properties. Excessive cationic charge and size are a detriment to effective long-term circulation *in vivo*, and therefore the control of both is essential (*15*). Minimal charge tending to neutrality and sizes of 100 nm and below are clear requirements here. Alternatively, elements of stability can be introduced into the **B**-layer lipid structure (*27*)

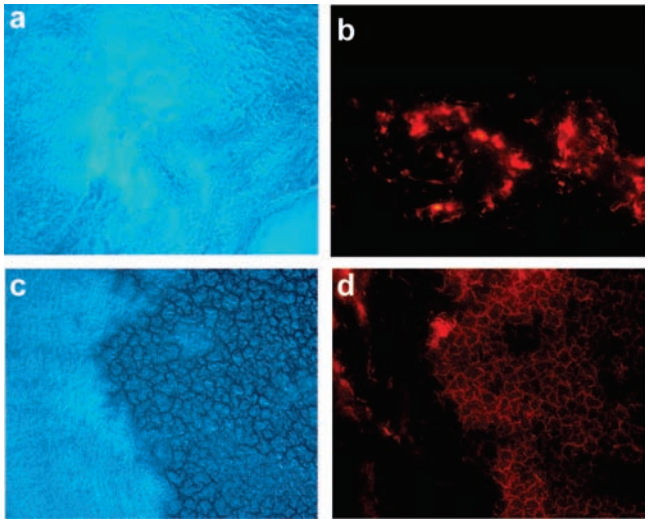

Figure 5. Histology images of the tumor in Figure 4 are shown: (a) and c) are bright field images of sectioned IGROV-1 tumors 24 h postadministration of Gd-liposome formulation **9**, where **a** represents a middle and **b** a surface slice of the excised tumor. (b) and (d) are corresponding fluorescent images at 20× magnification.

such that lipids used tend to favor the presence of lamellar phases over inverted hexagonal lyotropic mesophases under physiologically relevant conditions of temperature and pH (*28*). The neutral Gd-liposome **9** was designed to comply with all these requirements. Furthermore, a PEG stealth/biocompatibility outer layer was introduced. This is essential to reduce the uptake of liposomes in general by the reticulo-endothelial system (RES) in the spleen and liver (*29*). PEG also renders a liposome surface substantially hydrophilic in character, thereby decreasing the adsorption of serum proteins and opsonins to the surface of the liposome bilayer, and in this manner, the nonspecific recognition of liposomes by macrophages is also curtailed (*16*). Overall, our combined imaging data appear to suggest that the neutral Gd-liposome formulation **9** is a useful indication of formulations appropriate for long-term circulation and tumor delivery of an associated payload.

CONCLUSION

We have demonstrated the utility of novel bimodal fluorescent and paramagnetic liposomes for *in vitro* cellular labeling and *in vivo* tumor imaging, and covalidated our observed results by both MR and fluorescence imaging. The ability of liposomes to become "trapped" both inside and in vicinal tumor areas can be exploited further for drug and nucleic acid delivery. There is ample evidence of the effectiveness of actively targeted liposomes functionalized with targeting agents such as antibodies and ligands (*30–37*); however, we have demonstrated both *in vitro* and *in vivo* the effectiveness of the more facile passive targeting of Gd liposomes for the labeling of cancer cells and the detection of solid tumors by MRI and fluorescence microscopy.

ACKNOWLEDGMENT

We thank Dr. Ian McNeish (CRUK) for the kind gift of IGROV-1 cells, the Natural History Museum (London) for ICP-AES analysis, and Ms. Lorraine Lawrence (Imperial College London) for assistance with histology experiments. Funding for Nazila Kamaly was provided by the GTC and MRC.

Received June 19, 2007; Revised Manuscript Received September 13, 2007

Here, we report on NBD-Wm, a fluorescent wortmannin (Wm) probe that maintains the bioactivity of Wm as an inhibitor of PI3 kinase and as an antiproliferative agent. The attachment of the NBD fluorochrome permits NBD-Wm in cells to be monitored by NBD fluorescence-based methods such as FACS or fluorescence microscopy or with an anti-NBD antibody. The fluorescence of NBD-Wm treated cells reached a peak at 1.5 h and then decreased because of the extrusion of a fluorescent compound into the culture media. Cells accumulated NBD-Wm to levels about 30-fold higher than those in the media. NBD-Wm modified five major proteins, with the modification of the catalytic subunit of PI3 kinase being a minor band. The bioactivity of NBD-Wm, coupled with a variety of techniques available for determining its disposition, suggest that NBD-Wm can be a useful tool in understanding the mechanism of action of viridins.

INTRODUCTION

Wm is a fungal product that covalently reacts with a lysine residue in the active site of the p110 catalytic subunit of PI3K and is a nonisotype specific inhibitor of these enzymes, which are important regulators of a wide variety of biological processes. Wm has been widely used to define the PI3 kinase dependence of biological phenomena, with some 4700 Medline citations (1995–2007) after the 1994 observation (*1*) that it was an inhibitor of this enzyme. The central role played by PI3 kinase suggests that compounds inhibiting its activity might be useful in diverse conditions including the treatment of cancer (*2, 3*) or as anti-inflammatory/immune suppressive agents (*4–6*). Efforts to develop Wm derivatives as drugs involve the antiproliferative and anticancer activities (*7, 8*) of these compounds.

However, using Wm to define the PI3 kinase dependence of biological processes, or as a scaffold for drug development, is complicated since both the fate of Wm in biological systems and mechanism of interaction with molecular targets are so unlike those of man-made kinase inhibitors. Wm has a short half-life in various culture media (*9*) and reacts with amino acids such as lysine or proline in PBS (*10*). These observations, as well as others, led us to propose that Wm's instability in culture media was due to its reaction with amino acids at the C20 position but that the resulting WmC20 amino acid derivatives maintain biological activity because of their ability to regenerate Wm (*11*). The unusual properties of Wm suggest that understanding its fate in biological systems will be essential to understanding its mechanism of action.

Our objectives were to demonstrate the antiproliferative bioactivity of a fluorescent wortmannin conjugate (NBD-Wm) and to describe the fate of NBD-Wm in cultured cells at the micromolar concentrations needed for the antiproliferative effects of Wm or Wm derivatives (see below). By fate we mean both the chemical reactions Wm undergoes when added to a biological fluid and its disposition, which includes its time course, concentration, and intracellular location. Our studies employed 10 μM NBD-Wm, a concentration that is modest in relation to its antiproliferative effects but which is several orders of magnitude higher than the concentrations needed for many actions of Wm. The IC50 values for the inhibition of cell proliferation by Wm or Wm derivatives are in the micromolar range with all cell lines (see Table 1 or refs *7*, *12*, and *13*. At concentrations below 100 nM, Wm antagonizes insulin-stimulated glucose transport (*14–16*), histamine release (*17, 18*), or respiratory burst (*19–21*). Earlier studies examining Wm-modified proteins using fluorescent (*22, 23*) and radioactive (*24*) forms of Wm employed lower concentrations than that employed here. In addition, others have employed low concentrations of Wm to demonstrate its reaction with a lysine in the ATP site of PI3 kinase (*25*), with polo-like kinase (*23*) and DNA-PK (*22, 23*). The antiproliferative actions of Wm are typically measured by exposing cells to relatively high micromolar concentrations and for long

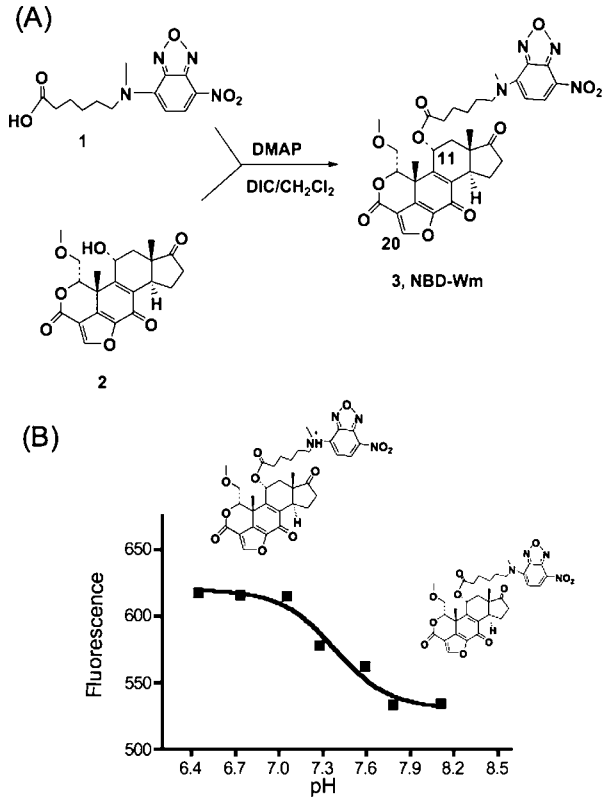

Figure 1. Synthesis and ionic forms of NBD-Wm. (A) Synthesis of NBD-Wm. (B) Fluorescence of compound 1 as a function of pH. An apparent pK_a of 7.5 was obtained. NBD-Wm exists as a neutral (pH >> 7.5) or positively charged species (pH << 7.5).

periods of time, 24–72 h; such long exposure times are necessary to allow cell proliferation and measure its inhibition. The antiproliferative effects of Wm and Wm derivatives are of interest because of recent efforts to develop anticancer drugs using these materials (*7*, *8*, *26*, *27*).

Using the fluorescence of NBD-Wm, we determined the time course of the compound's uptake by cells (by FACS), its intracellular distribution (by fluorescence microscopy), and its cellular concentration (by lysate fluorescence). Using an antibody to NBD, we determined the time course and molecular weights of Wm-modified proteins with the usual Western blot method. NBD-Wm can be a useful compound to further our understanding of the mechanism of action of the viridin class of antibiotics of which Wm is the best studied member.

MATERIALS AND METHODS

The scheme and nomenclature for the synthesis of molecules used in this study are shown in Figure 1. Wortmannin was a gift of the natural products branch of the NCI. All reagents and solvents were of standard quality. Compound 1 was prepared by reacting *N*-methyl-6-aminohexanoicacid and 4-chloro-7-nitrobenz-2-oxa-1,3-diazole (NBD-Cl) as previously described (*28*), while compound 2 was prepared according to earlier procedures (*29*, *30*). NMR was performed on a Varian 400 MHz instrument (Varian Instruments, Palo, Alto, CA) with $CDCl_3$ as the solvent, while mass spectra were obtained on a Micromass LCT instrument with a time-of-flight ESI technique (Waters, Milford, MA). HPLC (Varian Prostar 210 with a variable wavelength PDA 330 detector) employed reverse phase C18 columns (VYDAC, Cat.#: 218TP1022) with water containing 0.1% trifloroacetic acid (buffer A) and acetonitrile (containing 20% buffer A) (buffer B) as elution buffer.

Preparation of NBD-Wm, 3. To a mixture of compound **1** (19.3 mg, 0.05mmol) and compound **2** (37 mg, 0.12mmol) in anhydrous dichloromethane (4 mL) were added DIC (diisopropylcarbodiimide) (40 μL) and DMAP (2 mg). The color of the reaction turned from red to blue. The reaction could be completed in a few minutes. Water (5 mL) was added, and the aqueous layer was extracted with dichloromethane (3 × 5 mL). After drying over Na_2SO_4, the organic layers were concentrated, and the residue was further purified by preparative TLC with dichloromethane and methanol. A red powder **3** was obtained. Yield, 91%. MS: calcd $C_{34}H_{36}N_4O_{11}$, 677.2459 ($M + H^+$), found 677.2455; ^{1}H NMR: 0.97 (3H, s, CH_3-13), 1.23 (2H, b), 1.42–1.52 (2H, m), 1.52–1.60 (1H, m), 1.73 (3H, s, CH_3-10), 1.76–1.86 (2H, m), 1.99–2.16 (1H, m), 2.20–2.32 (1H, m), 2.34–2.50 (2H, m), 2.54–2.64 (2H, m), 2.84–2.92 (1H, m), 2.92–3.00(1H, m), 3.12–3.22 (4H, m), 3.40–3.56 (4H, m, CH_3N, CH_3OCH_2), 4.06–4.16 (2H, b, CH_2N), 4.69–4.74 (1H, m, H-1), 6.11 (1H, d, $J = 9$ Hz, Ar-H), 6.14–6.22 (1H, m, H-11), 8.25 (1H, s, H-20), 8.45 (1H, d, $J = 9$ Hz, Ar-H). ^{13}C NMR: 14.75, 23.16, 24.43, 26.25, 26.69, 27.67, 34.02, 35.91, 36.38, 40.93, 41.52, 44.33, 49.39, 55.89, 59.68, 70.36, 73.09, 88.77, 101.31, 114.39, 122.64, 135.63, 140.60, 142.92, 144.72, 145.04, 145.09, 145.50, 149.59, 150.29, 157.68, 172.21, 172.76, 216.42. Proton and 13C NMR spectra are provided in Supporting Information.

Cell Culture. Human cervical cancer HeLa, lung cancer A549, breast cancer MCF-7 and BT20, colon cancer HT29, and ovarian cancer SKOV3 cells were purchased from the American Type Culture Collection (Manassas, VA). HeLa, BT20, and MCF-7 cells were grown in MEM supplemented with 10% FBS, 1 mM sodium pyruvate, 0.1 mM nonessential amino acids, 2 mM L-glutamine, 100 units/mL penicillin, and 100 μg/mL streptomycin. A549 cells were grown in RPMI supplemented with 10% FBS, 2 mM L-glutamine, 100 units/mL penicillin, and 100 μg/mL streptomycin. HT29 and SKOV3 cells were grown in McCoy's medium supplemented with 10% FBS, 2 mM L-glutamine, 100 units/mL penicillin, and 100 μg/mL streptomycin. All cells were incubated at 37 °C under a 5% CO_2 atmosphere. A549 cells were used for all experiments, with additional cell lines used in Table 1.

PI3 Kinase and Antiproliferative Assays. The PI3 kinase assay was the fluorescent energy transfer method (*31*). The assay has higher IC50 values for Wm (12 nM) than the radioactive lipid phosphorylation assays (1–4 nM) because it uses a higher ATP concentration (100 μM). IC50 values for both assays were determined by curve fitting performed using Prism 4.0a software. The antiproliferative activity was evaluated by the sulforhodamine-B (SRB) method (*32*). Briefly, cells were seeded in 96-well plates at a density of 5000 cells/well in 100 μL media and allowed to incubate overnight at 37 °C. Cells were incubated with 0–100 μM Wm or Wm derivative added once, at the start of the 48 h incubation at 37 °C. Following incubation with Wm or NBD-Wm, cells were fixed by the addition of 50% cold TCA and subsequent incubation at 4 °C for 1 h. The cells were then washed with tap water, allowed to air-dry O/N, and stained with 100 μL of 0.4% SRB in 1% acetic acid for 10 min at RT. Unbound SRB was removed by washing plates with 1% acetic acid. Bound SRB was solubilized in 200 μL of 10 mM Tris buffer, after which the absorbance of each well was measured at 490 nm using an E_{max} precision microplate reader (Molecular Devices, Sunnyvale, CA). Percent cell survival was calculated using Prism 4 software (GraphPad Software, San Diego, CA) for each concentration as the ratio of the measured absorbance to that of the untreated wells. Statistical tests were done using Graph Prism and analyzed by two-way ANOVA.

NBD-Wm Uptake. A549 cells were incubated with 10 μM NBD-Wm for the indicated time, washed three times with HBSS, and detached with trypsin. Cell fluorescence was measured using a FACS Calibur flow cytometer (Becton-Dickinson, Franklin Lakes, NJ) of the live cell population

identified using forward and side light scattering measurements. Cell-associated NBD was measured in the FL1 channel. Fluorescence was calculated as the geometric mean of labeled cells divided by the geometric mean of unlabeled cells, termed relative cell fluorescence or RCF.

Cell-Associated NBD-Wm Concentration. A549 cells were seeded in 96-well plates at a density of 10^4 cells/well in 100 μL media. Cells were treated with 10 μM NBD-Wm at 37 °C for varying times. After treatment, the media was removed from each well, and the cells were washed 3 times with 300 μL of HBSS. Cells were then lysed in 100 μL of lysis buffer (150 mM NaCl, 1% NP-40, and 50 mM Tris at pH 8.0) for 1 h at RT and the fluorescence measured (ex 485 nm, em 535 nm) by a SpectraMax Gemini XS plate reader (Molecular Devices, Sunnyvale, CA). Protein content was determined using the BCA assay (Pierce, Rockford, IL) and used to determine the number of cells, where the amount of protein per cell was determined for cells counted by a hemocytometer. Cell volume was then the number of cells times 2.4 pL/cell for A549 cells from (*33*).

Visualizing Wortmannylated Proteins by Western Blots and in Immunoprecipitates. A549 cells were seeded in 12-well plates and grown to 70–80% confluence. Cells were treated with 10 μM NBD-Wm continuously for the times indicated. After treatment, the culture medium was removed, and the cells were washed 2× in ice-cold PBS. Whole-cell protein extracts were prepared from adherent cells by adding 250 μL of ice-cold radioimmune precipitation assay (RIPA) buffer (20 mM Tris at pH 7.4, 100 mM NaCl, 1% sodium deoxycholate, 1% Nonidet NP-40, and 1% SDS). On the day of use, the lysis buffer was supplemented with the following: 1 mM Na_3VO_4, 1 mM NaF, 1 mM PMSF, 50 mM β-glycerophospate, and 50 μL/mL protease inhibitor cocktail (Sigma-Aldrich, St. Louis, MO) to each well of the 12-well tissue culture plate. The cells were lysed for 15 min on ice and the lysate cleared by centrifugation at 16,000 rpm at 4 °C for 15 min.

Alternatively, for the immunoprecipitation of PI3 kinase, cells were grown to confluence in 10 cm plates ($\sim 10^6$ cells/well). Cell were treated with 2 mL of culture medium or 2 mL of medium with NBD-Wm (10 μM) and incubated for 2 h. Cultures were then washed twice with ice-cold HBSS and incubated with 1 mL of NP40 lysis buffer (1% Nonidet NP-40, 100 mM NaCl, and 20 mM Tris at pH 7.4), which was supplemented with the inhibitors used in RIPA the day of use, for 15 min at 4 °C with rocking. Plates were scraped and debris and lysate collected and cleared as described before. Lysates were pooled and 750 μL aliquoted for immediate use or brief storage at −20 °C. Lysates were then incubated with 5 μg of either anti-NBD, anti-p85α, anti-p110α, or an equivalent nonimmune isotype control overnight with rotation at 4 °C. Protein A/G agarose beads (Santa Cruz Biotechnology, Santa Cruz, CA) were slurried and washed five times with lysis buffer. Washed beads were then aliquoted, combined with lysates, and incubated for 4 h at 4 °C with rotation. Immune complexed beads were pelleted for 1 min at 1500 rpm at 4 °C. Supernatants were transferred to new tubes, and immune complexed beads were washed five times with cold lysis buffer.

Cell lysates were analyzed for total protein concentrations as determined by BCA protein assay (Pierce, Rockland, IL). Typically, 10 μg of total protein was added to 2× SDS sample buffer (100 mM Tris at pH 6.8, 20% glycerol, 4% SDS, and 0.15 mM bromophenol blue) made by 1% β-mercaptoethanol and boiled for 5 min. Immune complexes were eluted from agarose beads with 35 μL of 2× SDS sample buffer, boiled for 5 min, and cleared by centrifugation at 16K rpm for 10 min. Samples were then resolved by SDS–PAGE on a 7.5% Tris·HCl Ready Gel (BioRad, Hercules, CA) run at 50 V for 3 h and then transferred to a PVDF membrane (BioRad) overnight at 35 V. Membranes were blocked for 1 h at room temperature in 5% nonfat milk in Tris buffered saline with Tween (TBST) and probed with a 1:3000 dilution of anti-NBD rabbit polyclonal antibody (Biogenesis, Munich, Germany), anti-p85α mouse monoclonal (Upstate, Temecula, CA), anti-p110α rabbit polyclonal (Cell Signaling, Danvers, MA), or anti-HSP90 mouse monoclonal (Stressgen, Ann Arbor, MI) in TBST for 3 h at RT or overnight at 4 °C. The PVDF membrane was washed 3× at RT with TBST and subsequently incubated with a 1:5000 dilution of goat antirabbit-HRP or goat antimouse-HRP secondary antibody (Chemicon, Temecula, CA and Santa Cruz, respectively) for 1 h at RT. The PVDF membrane was washed 3× with TBST and incubated with ECL detection reagent (Amersham Biosciences, Piscataway, NJ) for 90 s. Proteins were detected by exposing the PVDF membrane to BioMax MR autoradiography film (Eastman Kodak, Rochester, NY). Immunoblots were stripped with restore buffer (Pierce) and reprobed with anti-HSP90 to visualize equal loading of protein. Films, where indicated, were evaluated for relative band intensity using ImageJ version 1.38n software. Total protein was also evaluated by Imperial protein stain (Pierce) according to the manufacturer's protocol.

Fluorescent Microscopy. A549 cells were seeded in 24-well plates and grown to 60–70% confluence, and treated with 10 μM NBD-Wm at 37 °C. For nuclear staining, cells were incubated with 1 μg/mL Hoechst 33342 (Molecular Probes, Eugene, OR) for 30 min at 37 °C. For plasma membrane staining, cells were incubated with 5 μg/mL of FM 4-64 (Molecular Probes, Eugene, OR) for 1 min at RT. Images were acquired on either a Nikon Eclipse TE2000S fluorescent microscope equipped with a Spot Insight QE CCD camera (Diagnostic Instruments, Sterling Heights, MI) or a Nikon Eclipse 80i fluorescent microscope equipped with a Photometrics (Tucson, AZ) Cascade 512B CCD camera. Images obtained on the Nikon Eclipse TE2000S microscope were processed using Spot Software (Diagnostic Instruments). Images obtained on the Nikon Eclispe 80i microscope were processed using IPLab (Scanalytics, Inc., Rockville, MD) software.

Fluorescence Titration of Compound 1. The pH of a solution of sodium citrate (0.1 M) and sodium phosphate (0.1 M) was adjusted with 6 M HCl to give a series of buffers whose pH values differed by 0.25 pH units. Compound 1, dissolved in DMSO, was added to 200 μL of buffer to give a final concentration of 10 μM and a fluorescence read (466 nm excitation, 536 nm emission) using a Spectromax gemini XS plate reader (Molecular Devices, Sunnyvale, CA).

RESULTS

The synthesis of NBD-Wm was accomplished by reacting compound 1 with compound 2 as shown in Figure 1A. The ester bond of NBD-Wm was highly stable in PBS, pH 6.8, with a half-life of greater than 700 h when assessed by the times dependence of HPLC peak area (*10*). To assess the ionic forms of NBD-Wm, which might contribute to an understanding of its membrane permeability, compound 1 was titrated by fluorescence (Figure 1B). The titration of NBD-Wm was not attempted because the lactone group of Wm hydrolyzes above pH 8, complicating titration data (Yuan and Josephson, unpublished observations). At physiological pH values close to the pK_a of 7.5, NBD-Wm exists both as a singly protonated and neutral species. Implications of the charged species of NBD-Wm are discussed below.

We first compared Wm and NBD-Wm for their ability to inhibit PI3 kinase activity as shown in Table 1. The IC50 of NBD-Wm was 1.84-fold higher than Wm, consistent with other studies that lipophilic modifications of Wm at C11 can have little effect on the ability of Wm derivatives to inhibit PI3

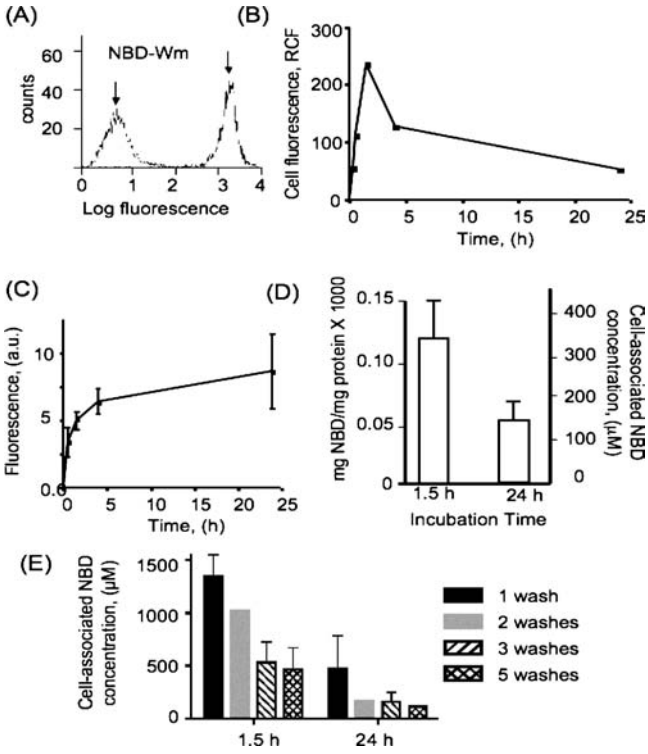

Figure 2. Cellular fate of NBD-Wm in A549 cells. The uptake (B), extrusion(C), and cellular concentrations of NBD-Wm (D) are shown. (A) Cell fluorescence by FACS after exposure to NBD-Wm is also shown (1.5 h, 10 μM). The arrows indicate the median fluorescences of NBD-Wm exposed or unexposed cells that were used to calculate relative cell fluorescence (RCF). Cells were uniformly labeled by NBD-Wm. (B) Time course as the RCF for cells exposed to 10 μM NBD-Wm. RCF is the median fluorescence of labeled cells divided by the median of cells not exposed to NBD-Wm. Even though NBD-Wm is present in the media for 24 h, a peak of fluorescence at 1.5 h is obtained. (C) Time course of culture media fluorescence for cells exposed to NBD-Wm (10 μM, 1.5 h). NBD-Wm-containing media were replaced at 1.5 h with fresh media at $t = 0$. (D) Cellular concentrations of NBD-Wm. Cells were exposed to 10 μM NBD-Wm for 1.5 or 24 h, washed, lysed, and cell-associated NBD determined. (E) Effect of wash number on the concentration of cell-associated NBD-Wm. A549 cells were incubated with 10 μM NBD-Wm for 1.5 or 24 h, washed 1–6 times with HBSS, and lysed. The concentration of cell-associated NBD-Wm was determined as described in 2D.

kinase (*29*, *34*). We next compared the antiproliferative effect of NBD-Wm and Wm on various cell lines as shown in Table 1. The IC50 of NBD-Wm was the same as that of Wm in two cell lines (A549, MCF-7) or lower than that of Wm in four others (SKOV-3 HeLa, HT-29, and BT-20). Therefore, the addition of the NBD-NMeHA adduct to the C11 of Wm did not impair the ability of Wm to enter cells with the six cell lines tested. NBD-Wm is therefore a Wm probe with a bioactivity similar to or better than that of Wm in both the cell-free PI3 kinase assay and cell-based antiproliferative activity and was therefore used to obtain data on the kinetics of Wm uptake, the target proteins it modified, and its intracellular concentration and disposition.

We examined the uptake of NBD-Wm by exposing cells to 10 μM NBD-Wm, detaching cells with trypsin, and analyzing cell fluorescence by FACS. As shown in Figure 2A, cells were uniformly labeled, with arrows showing the geometric means of labeled or unlabeled cell populations. These geometric means were used to obtain the relative cellular fluorescence or RCF (geometric mean labeled cells/geometric mean unlabeled cells), which was used to quantify the amount of fluorescence of a labeled cell population.

We next determined the time course of cellular uptake as the RCF versus incubation time with a 10 μM NBD-Wm; see Figure 2B. Cell fluorescence reached a peak at 1.5 h and then fell precipitously, even though NBD-Wm had not been removed from the media. To determine whether the decrease in cellular fluorescence between 1.5 and 24 h of exposure to NBD-Wm was due to cells transporting a fluorescent material to the media, cells were incubated with NBD-Wm (10 μM, 1.5 h), and the media containing NBD-Wm was removed and replaced with fresh, non NBD-Wm-containing media. As shown in Figure 2C, media fluorescence rapidly increased during the first 5 h, corresponding to the rapid decrease in cell fluorescence seen with FACS during this time period.

To obtain values for the amounts NBD-Wm cells internalized and to further verify the unusual drop in fluorescence between 1.5 and 24 h (Figure 2C), cells were incubated with 10 μM NBD-Wm for 1.5 or 24 h and the amount of cell-associated NBD-Wm determined from lysate fluorescence and NBD-Wm standards. Cell-associated NBD was significantly higher at 1.5 than 24 h ($p < 0.001$; see Figure 2D) and paralleled the time dependence of cell fluorescence seen with FACS (Figure 2B). The amount of cell-associated NBD was expressed as both per mg of cell protein in the lysate, a value that does not reflect cell volume, and as the average cellular concentration using literature values for the volume of an A549 cell. The fluorescence-based average cellular concentrations were 360 $\pm$ 20 μM and 110 $\pm$ 20 μM at 1.5 and 24 h, respectively, compared to the media concentration of 10 μM. (The means have at least four data points.) Thus, exposure of A549 cells to NBD-Wm had two unusual features: a transient peak at 1.5 h and an accumulation to cellular concentrations at least 10-fold higher than that of the media. These observations with NBD-Wm were not unique to A549 cells but were also seen with HeLa cells (data not shown) and are further discussed below. The concentration of cell-associated NBD obtained was independent of the number of cell washes once three washes were employed ($p > 0.05$ for 3 or 5 washes; see Figure 2E).

We next examined the time course with which NBD-Wm modified cellular protein as shown in Figure 3A. Cells were incubated with 10 μM NBD-Wm for the indicated times and lysed, and the cell protein was analyzed by the Western blot method using anti-NBD. Six bands at 35, 50, 75 85, 95, and 130 kDa were seen. The time course of the six wortmannylated species was determined by quantitative analysis of band intensity as shown in Figure 3B, with the total amount of wortmannylated protein (sum of the intensities of six bands) shown in Figure 3C. Total wortmannylated protein reached a peak at 1.5 h and declined slowly thereafter.

Proteins modified by reaction with NBD-Wm were next examined in greater detail as shown Figure 4. Wortmannylated proteins, visualized by reaction with anti-NBD, and total cell protein were compared as shown in Figure 4A. Wortmannylated proteins occurred with molecular weights and with band intensities that differed markedly from the pattern seen with the total protein, indicating that NBD-Wm-modified proteins were a distinct subset of total cell proteins. To demonstrate that the catalytic subunit of PI3 kinase, p110, was modified by NBD-Wm, we employed an immunoprecipitation (IP) with anti-p85, the regulatory subunit of the enzyme. As shown in Figure 4B, the clarified lysate (CL) from the anti-p85 IP did not appear to be missing a band in the vicinity of 110 kDa. However, when the IP pellet was then electrophoresed and stained with anti-NBD (Figure 4C), a wortmannylated band at 110 kDa was present in NBD-Wm-treated cells and not in control cells. However, the amount of total cellular p110 was sufficient to enable visualization by anti-p110 without IP purification (Figure 4D). We conclude that NBD-Wm reacts with the catalytic subunit of PI3

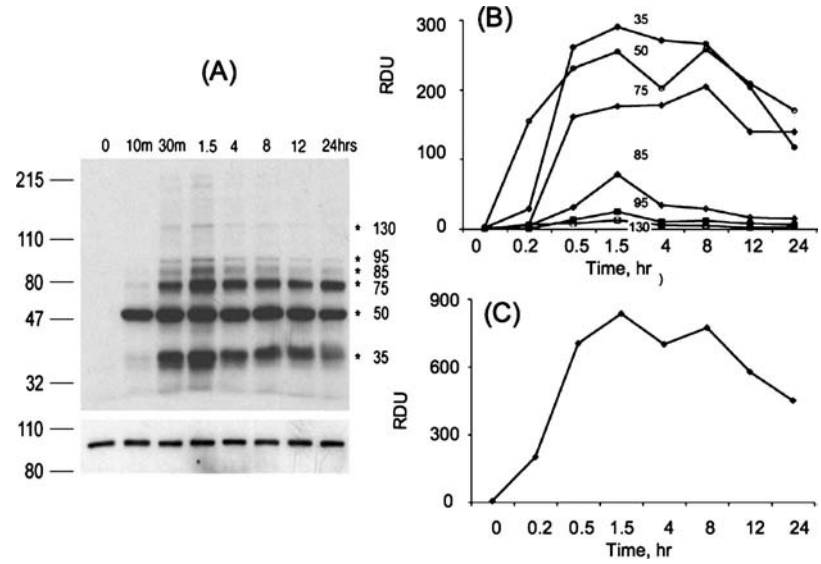

Figure 3. Time course for the wortmanylation of proteins by NBD-Wm. (A) Cells were exposed NBD-Wm (10 μM) for the indicated time, lysed, and stained for modification by NBD-Wm with anti-NBD. Molecular weights of prominent wortmanylated proteins (asterisks) are given on the right. (B) Densitometric scan for the time course wortmannylated protein from A. The numbers refer to the molecular weights from A. RDU = relative density units. (C) Time course for the total amount of wortmannylated protein. The values are the sum of the six wortmannylated proteins shown in B.

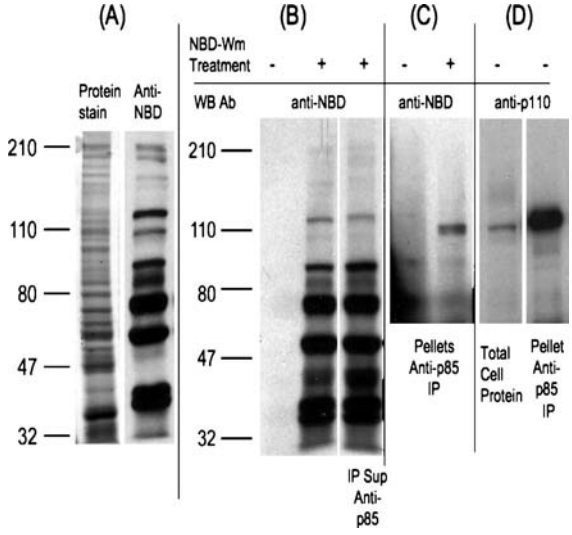

Figure 4. Comparison of total cell protein, wortmannylated protein, and wortmannylated p110 from cells. (A) Cells were exposed to NBD-Wm (4 h, 10 μM) and then stained for total protein. Wortmannylated proteins were visualized by Western blot (WB) with anti-NBD. Wortmannylated proteins were a distinct subset of total cell proteins. (B) Cells were treated with NBD-Wm as indicated and immunoprecipated (IP'ed) with anti-p85 to remove p110 from cell lysates. The IP supernatant (IP Sup, Anti-p85) was not missing a band at 110 kDa. WB Ab indicates the use of the Western blot method with the indicated antibody. (C) IP pellets from NBD-Wm were treated and control cells reacted with anti-NBD. A band at 110 kDa was visible. (D) WB with anti-p110 for total cell protein or the IP Pellet. p110 was visible in total cell protein and prominent in IP Pellet.

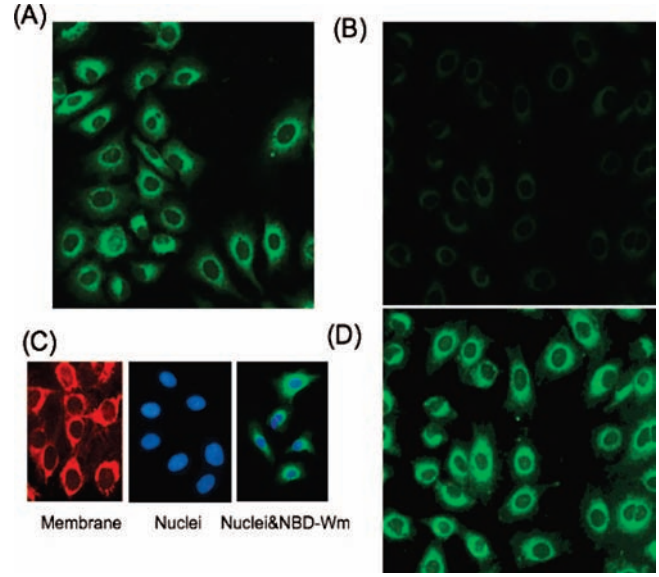

Figure 5. Fluorescent microscopy with NBD-Wm. Cells were incubated with 10 μM NBD-Wm for 1.5 (A) or 24 h (B). Cells incubated for 24 h have far less fluorescence. (C) Cells stained for membranes, nuclei, or nuclei and NBD-Wm. (D) The intensity of the cells shown in (B) was increased to permit the comparison of intracellular distribution of cells shown in A and B.

kinase (p110), but the amount of NBD-Wm-modified p110 is extremely small compared to the other proteins it modifies.

The intracellular distribution of NBD-Wm was monitored by fluorescence microscopy as shown in Figure 5. Fluorescence at 1.5 h (Figure 5A) was distinctly higher than that at 24 h (Figure 5B), paralleling cell fluorescence data obtained from FACS analysis (Figure 3B). The fluorescence intensity from Figure 5B was increased through image processing (Figure 5D) to permit comparison of the intracellular fluorescence (Figure 5A and B). Fluorescence intensity by microscopy (compare Figure 5A at 1.5 h to Figure 5B at 24 h) closely paralleled the time course of fluorescence seen with FACS (Figure 2B). To shed light on the subcellular localization of NBD fluorescence, cells were stained for nuclei and membranes and NBD fluorescence viewed against those stains (Figure 5C). At both 1.5 h (Figure 5A) and 24 h (Figure 5D), cells treated with NBD-Wm showed a distinct pattern of perinuclear fluorescence that colocalized with a membrane stain (red stain, Figure 5C). The colocalization of NBD fluorescence with membrane structures, high cellular concentrations of NBD-Wm (Figure 2D), and the hydrophobic nature of NBD-Wm suggest that a large pool of NBD-Wm is solubilized in membranes.

Our results on the fate of NBD-Wm in A549 cells are summarized in Figure 6. The model describes the major

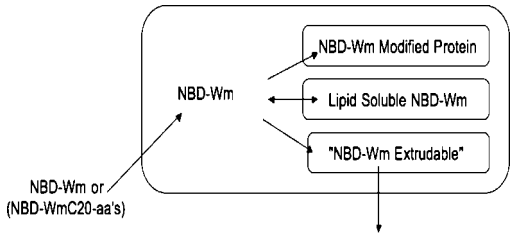

Figure 6. Pools of NBD-Wm in cells. NBD-Wm (or NBD-WmC20 amino acid derivatives) enters cells. NBD-Wm is found in two pools, an intramembrane pool and as modified proteins. Once in cells, NBD-Wm is converted to a second chemical entity termed NBD-Wm extrudable, whose efflux from cells causes the drop in cell fluorescence (1.5–24 h; see Figure 2B).

intracellular pools of NBD, the form that enters cells, and the formation of a fluorescent form that is extruded by cells.

Form of NBD-Wm Entering Cells. The model proposes that either NBD-Wm or NBD-WmC20 amino acid derivatives enter the cells. The possibility that NBD-WmC20 derivatives may enter cells is based on (i) the fact that C20 of Wm reacts rapidly with amino acids (half-life of 0.99 min in culture media (*11*)) and (ii) the fact that with antiproliferation assays many Wm amino derivatives, which bear negative, positive, or zwitter ion charges, are more active than Wm (*7, 11, 35*). Since NBD-Wm reacts with amino acids under physiological conditions, it is difficult to determine which species enters the cells.

Major Intracellular Pools of NBD-Wm. Two major pools of NBD-Wm proposed by the model are a membrane-localized pool, based on the colocalization of NBD fluorescence and a stain for membranes shown in Figure 5, and as covalently reacted with protein, based on the NBDylated protein (see in Figure 3). Other minor pools or forms of NBD-Wm may exist, and the model does not propose that any specific form gives rise to biological or pharmacological effects of Wm. For example, a minor cytoplasmic form of NBD-Wm might not appear on fluorescence microscopy and yet react with kinases and cause important physiological effects. Using an HPLC method (*11*), the ester bond in NBD-Wm was found to be highly stable in PBS, with a half-life longer than 700 h at 37 °C in PBS (data not shown). Nonenzymatic hydrolyzis of the ester bond of NBD-Wm is therefore unlikely. As mentioned with respect to Figure 2D, NBD-Wm was added to cell culture media, lysis buffer, or lysis buffer with cell protein, and each time yielded a time independent, stable fluorescence. For these reasons, the fluorescence from NBD is assumed to be from NBD-Wm in Figure 6, a simplifying assumption.

Formation of an Extrudable Form of NBD. The characteristic peak accumulation of cell fluorescence at 1.5 h and the decrease thereafter was seen when A549 cells were incubated with NBD-Wm with multiple techniques. These included (i) FACS (Figure 2B), (ii) lysate fluorescence (Figure 2D), and (iii) fluorescence microscopy (compare Figure 5A at 1.5 h vs Figure 5B at 24 h)). This transient peak of cell-associated NBD was inconsistent with a model where a single fluorescent entity (or single class of fluorescent molecules) equilibrated between two compartments (media and cells), a mechanism through which the cell-associated NBD-Wm would asymptotically approach a maximum value. Since cells extrude fluorescence into the culture media (Figure 2C), we propose that NBD-Wm must be converted to a second form, which undergoes rapid cell extrusion.

DISCUSSION

Here, we describe the bioactivity of a fluorescent Wm probe, NBD-Wm, and its fate in a cell-based system. Our experiments differ from those of others who have used Bodipy or tetramethylrhodamine-based Wm probes to label cell protein (*22, 23*). First, we have demonstrated that NBD-Wm is similar to or better than Wm in a quantitative bioassay using intact cells, the antiproliferation assay. The physical basis of the similar bioactivity of NBD-Wm and Wm is further discussed below. Second, we employed the fluorescence of NBD-Wm to determine its uptake and visualize its intracellular disposition in cells by FACS and fluorescence microscopy. Third, we employed NBD-Wm to determine the average cellular concentrations of NBD, demonstrating the ability of cells to concentrate this compound above the concentrations found in media. Using a linker different from our own linker, Giner et al. conjugated NBD to Wm and showed that the conjugate was an effective inhibitor of PI3 kinase (*34*).

The similar or superior bioactivity of NBD-Wm relative to Wm may reflect the relatively small increase in size that results from NBD attachment. The nominal molecular weights of Wm and NBD-Wm were 428 and 677 Da, respectively. Support for the view that the size of the fluorochrome attached at the C11 of Wm can be an important determinant of the bioactivity of the resulting conjugate can be obtained from our earlier studies. Attachment of fluorescein to Wm, a fluorochrome far larger than NBD, resulted in a conjugate that was a poor inhibitor of PI3 kinase. (See compound 7c of Table 1 from ref *30*.) The charge of NBD-Wm may also contribute to its bioactivity since it exists with a single positively charged species below pH 7.5 and as a neutral species above pH 7.5 (Figure 1B). Although our biotinylated-Wm inhibited PI3 kinase (compound 7a of Table 1 from *30*), its antiproliferative IC50 (A549 cells) was 63.0 $\pm$ 2.2 μM, compared to the IC50 of 11.4 $\pm$ 0.5 μM for Wm and 12.2 $\pm$ 0.8 μM for NBD-Wm (see Table 1). Similar poor results with the biotinylated-Wm were obtained in other cell lines examined (HeLa, MCF-7, and HT-29; data not shown). For these reasons, NBD-Wm was superior to the fluorescent and biotinylated Wm probes we have synthesized earlier.

At a concentration of 10 μM, NBD-Wm initially labeled a 50 kDa protein (10 min exposure) followed by a labeling of four additional proteins, a distinct subset of the total cell protein. The p110 catalytic subunit of PI3 kinase was a minor band; however, when p110 was concentrated by immunoprecipitation, labeling of this band was apparent. The time course for the formation of wortmannylated protein exhibited a broad plateau between 1 and 24 h, with substantial levels present 24 h after NBD-Wm was added to cells (Figure 3). Using 20 nM tritiated Wm, Thelen et al. showed that a single protein (110 kDa) was labeled in human neutrophils (*24*). However, when Bodipy-Wm was used to label YZ5 cells, multiple labeled bands were obtained (see Figure 6 of ref *22*), as was the case with a tetramethyrhodamine-Wm (50 nM) and Jurkat T cell lysates (see Figure 2 of ref *23*). In both studies, the reaction of fluorescent Wm probes was specific for proteins of certain molecular weights (Wm displaceable) and nonspecific for others (non-Wm displaceable). Given the very high levels of NBD-Wm achieved in cells (Figure 2D) and the ability of Wm to react with the epsilon amino groups of lysine in PBS (*11*), NBD-Wm may react with the epsilon amino groups of a select subset of cellular proteins (Figure 4A), whose function remains unknown, in addition to labeling the lysines in the ATP sites of kinases.

Though we considered it surprising that A549 cells accumulated NBD-Wm at far higher concentrations than those of the culture media of 10 μM (see Figure 2D), a variety of factors indicate that this observation is correct. First, our method of determining the concentration of cell-associated NBD-Wm employed a high detergent lysis buffer, one containing 1% w/v of the nonionic detergent NP-40, which disrupts cell structure

and completely solubilizes cell membranes and organelles. To obtain cell-associated NBD concentrations, fluorescent standards were employed; these standards were obtained by diluting known amounts of NBD-Wm into lysate buffer containing protein from lysed cells. Our method of determining cell-associated NBD concentrations destroyed cell structure and read the fluorescence of standards and unknowns in precisely the same media so that possible environmental effects on NBD fluorescence would not yield incorrect values. Second, the fluorescence of NBD-Wm when added to culture media, lysis buffer, or lysis buffer plus cell protein was stable for at least 24 h, indicating a lack of enzymatic or nonenzymatic mechanisms for altering fluorescence (data not shown). Third, the use of our standard three wash protocol reduced cell-associated fluorescence to a value that was independent of the number of washes employed. At both 1.5 and 24 h of incubation, cell-associated fluorescence reached a plateau after three washes that was not affected by additional washes (Figure 2E). Fourth, we considered that the high cellular concentrations of NBD-Wm that we obtained might be secondary to toxic effects of the NBD-Wm. However, cells exposed to the nonfluorescent Wm (10 μM, 23 h) then internalized 10 μM NBD-Wm in a manner identical to that of non-Wm exposed cells. Finally, key observations made with A549 cells (Figure 2B, time course of cell fluorescence, and Figure 2D, average cellular concentration) were also made with HeLa cells as well, indicating that our observations were not cell line specific. On the basis of these experiments, A549 cells apparently accumulate NBD-Wm to far higher levels than that present in the media, reaching average cell-associated concentrations as high as 300 μM when incubated with 10 μM NBD-Wm (1.5 h exposure).

An interesting issue is the implication of these findings for the molecular targets of Wm and Wm derivatives. Literature values for the IC50 values of Wm for kinases are 1–4 nM (PI3 kinase *1, 29*), 24 nM (polo-like kinase (*23*)), 200 nM (mTOR (*36*)), and 200 nM (DNA-dependent protein kinase (*37*)). The micromolar concentrations of NBD-Wm needed to inhibit cell proliferation, coupled to the observation that cells concentrate NBD-Wm to values far above that in culture media (Figure 2D), means that the average cellular concentrations of NBD-Wm far exceeds the IC50 values of all known kinases for Wm. For example, if a selective PI3 kinase inhibition were the basis of NBD-Wm's antiproliferative effects, on the basis of known IC50 values, a cytoplasmic concentration on the order of 10 nM NBD-Wm would be required. This concentration is some 30,000-fold lower than the 300 μM concentration of cell-associated NBD-Wm we obtained. While it is technically difficult to determine the concentration of NBD-Wm in the environment of an enzyme, we regard such a massive reduction in concentration unlikely and instead propose that the antiproliferative effects of NBD-Wm result from the inhibition of a variety of targets, one of which is PI3 kinase. Consistent with the proposed lack of selectivity of NBD-Wm as a specific PI3 kinase inhibitor in vivo was its ability to modify many proteins, of which the p110 catalytic subunit of PI3 kinase was an extremely minor band.

Others have determined Wm-modified proteins using radioactive (*24*) or fluorescent Wm probes at lower concentrations than those employed here (*22, 23*). A different pattern of Wm-modified proteins maybe obtained at these low Wm concentrations, which are adequate to produce many important effects on cells. Our goal, however, was to describe the fate of NBD-Wm in cells at concentrations associated with its antiproliferative effects.

Our objectives were to demonstrate that the bioactivity of NBD-Wm was similar to (or better than) Wm and to describe the fate of NBD-Wm in cultured cells associated with its antiproliferative effects using a variety of techniques (microscopy, FACS, and Western blot). Immunochemical methods of detecting of NBD can in principle be extended from Wm to other NBD-based probes or drugs that covalently modify proteins in cell-based systems. Antibody-based methods are not subject to interference from background fluorescence and amenable to enzyme amplification to increase sensitivity. On the basis of the variety of fluorescence-based and immunochemical methods for detecting NBD, we envision NBD-Wm as a powerful tool for future investigations concerning the mechanism of action of viridins.

Layered Inorganic/Enzyme Nanohybrids with Selectivity and Structural Stability upon Interacting with Biomolecules

Guo-Jing Chen, Ming-Cheng Yen, Jen-Ming Wang, Jiang-Jen Lin,† and Hsin-Cheng Chiu*

Department of Chemical Engineering, National Chung Hsing University, Taichung 402, Taiwan. Received June 20, 2007; Revised Manuscript Received November 1, 2007

Effective intercalation of protein molecules within the galleries of montmorillonites can be achieved via simple space enlarging and exchange processes while retaining the native conformation of the guest protein and the multilayered structure of the bioinert host plates. The capacity of accommodating protein molecules in the galleries can be markedly larger than that governed by the Langmuir-type adsorption of protein molecules on the external surfaces of particles. The basal spacing in the multilayered structure of clay is abruptly enlarged when the extent of protein intercalation increases to a critical point. Beyond this critical point, the nanohybrids show well-preserved catalytic activity in hydrolyzing small substrates while establishing a barrier to interactions with large biomacromolecules. Furthermore, the structural stability of the inorganic/organic nanohybrids is enhanced such that neither exchange of biomolecules nor exfoliation of layered clay particles occurs when exposed to other proteins. The results indicate that, through the benign accommodation of protein species between the inorganic platelets, this nanoscaled manipulation of protein functions can be highly useful in developing new inorganic/enzyme nanohybrids for protein therapeutics and tissue engineering.

INTRODUCTION

Inorganic/organic nanohybrids formed via accommodating bioactive macromolecules inside the galleries of inorganic materials with layered structure have found a variety of potential applications in biomedical and biochemical fields. For example, inorganic layered double hydroxide (LDH)/DNA hybrids can facilitate the endocytic uptake of DNA fragments and their intracellular release from the hybrids by complete dissolution of LDH in the acidic environment of endosomes (*1, 2*). Biologically active proteins such as enzymes incorporated in synthetic layered α-zirconium phosphate, while retaining their conformation and activity, have been found capable of acting as nanoscale biocatalytic systems (*3–9*). Mutual interactions between guest biomolecules and inorganic host plates occur mainly by electrostatic attraction (*10, 11*). Small DNA fragments and antisense oligonucleotides can be readily embedded within the galleries of cationic LDH layered structures by either direct anionic exchange or coprecipitation in the in situ formation of LDH layers (*1, 2*). The hybrids prepared from the latter approach can accommodate double-stranded DNAs over a wide range of molecular sizes (*2*). Similarly, owing to the three-dimensional size, large globular proteins can be successfully embedded within inorganic layered hosts only by self-assembly with synthetic exfoliated plates in aqueous phase into hybrids of double- or triple-layered structure (*3–8*). Hybrids with elevated stacking in the layered structure that act as highly efficient bioreactors have not been attainable due to the instability problem encountered. On the other hand, montmorillonite (MMT), one of the most abundant smectite clays, consists of aluminosilicate plates with dimensions of ca. $100 \times 100 \times 1$ nm^3 in each plate piling in a primary stack of ca. 8−10 layers through intensive charge attraction (*12*). Therefore, it is easily realized that, by taking the advantage of the high aspect ratio surface area of each layer within a multilayered structure, MMT may serve as a benign host to provide spacious sites for protein accommodation. Unfortunately, the basal spacing in multilayers of MMT homoionic, for example, to Na^+ (Na^+-MMT) is 1.2 nm. With the thickness of each layer equal to 1 nm, the interlayer free space is 0.2 nm. Interactions of the multilayered particles with such narrow galleries and most large globular proteins are inevitably restricted to their external bulk surfaces. The incorporation of guest biomolecules in the clay galleries is therefore severely limited in variety and adsorption/intercalation capacity.

In this study, inorganic/enzyme hybrids were obtained by a simple exchange process of the protein molecules with an originally intercalated linear synthetic polymer within the spatially enlarged galleries of MMT. Taking advantages of its globular structure and catalytic activity in hydrolyzing both low molecular weight and macromolecular substrates, α-chymotrypsin (CHT) was employed as a model protein intercalant. In addition to detailed characterization of morphology and structure of the hybrids, the selectivity and stability of the hybrids regarding interactions with biomolecules of varying sizes was studied.

EXPERIMENTAL SECTION

Materials. CHT (EC 3.4.21.2, type II, from bovine pancreas), bovine serum albumin (BSA), catalase (from bovine liver), *N*-benzoyl-L-tyrosine *p*-nitroanilide (Bz-Tyr-NAp), and *N*-succinyl-L-phenylalanine *p*-nitroanilide (Su-Phe-NAp) were purchased from Sigma. α,ω-Diaminopoly(oxypropylene) (POP, Mw 2000 g/mol) was obtained from Aldrich. Na^+-MMT with a cationic exchange capacity (CEC) of 1.15 mequiv/g was obtained from Kunimine. Deionized water used in the protein intercalation, and buffer preparation was prepared from Milli-Q Synthesis (Millipore). All other chemicals were reagent grade and used as received.

Inorganic/Enzyme Hybrid Preparation. Preparation of the inorganic/enzyme hybrids was carried out first by spatial enlargement of the galleries of MMT via cationic exchange of

POP with sodium counterions within the galleries of MMT, followed by exchange of POP with the CHT molecules. The POP intercalation was performed as described previously (*13*). In brief, to a Na^+-MMT slurry in deionized water was added the aqueous solution of POP/HCl (1:1 in mole ratio) to a stoichimetric ratio of POP/CEC at 1.0 with stirring at 80 °C for 24 h. The inorganic/organic weight ratio of the MMT/POP hybrids was determined to be 31/69 by thermal gravimetric analysis. The mechanism of the POP intercalation and structure of MMT/POP hybrids have been studied in detail previously (*13–15*). The intercalation/adsorption of CHT on MMT/POP and Na^+-MMT particles, respectively, was performed by the addition of a prescribed amount of CHT in the aqueous clay suspension solutions (4.7 mg of Na^+-MMT in 15 mL phosphate buffer (pH 7.0, I 0.01 M) or 15.0 mg/15 mL of MMT/POP, equivalent to 4.7 mg of clay in 15 mL of the aqueous solution) at 4 °C for 12 h with stirring. The inorganic/enzyme composite particles were subjected repeatedly to centrifugation (10 000 g at 4 °C for 30 min) and resuspension with phosphate buffer and deionized water until protein in the supernatant was no longer detected. The products were then collected by lyophilization and stored at −20 °C for further characterization of their structure and enzymatic activity. The extent of the protein intercalation/adsorption was determined by measuring the protein concentration in the combined supernatants via the Bradford protein assay (Bio-Rad protein assay reagent) at 596 nm. The intercalation/adsorption isotherms were established by plotting the amount of CHT intercalated/adsorbed per gram of clay (μmol/g clay) versus the equilibrium CHT concentration (μM) in aqueous solution, i.e., the protein concentration in the supernatant after the equilibrium adsorption. The released amount of POP from the MMT/POP composite particles in protein intercalation was estimated by gel permeation chromatography (GPC) measurements (Superose 12, FPLC, GE-Pharmacia, the eluent: Tris buffer, 0.4 mL/min, RI detection) of the POP concentration in the supernatant of the first centrifugation.

Structural and Morphologic Characterization. The X-ray powder diffraction measurements of the MMT/CHT hybrids were performed using a powder diffractometer (Mac Science MXP-18) with a Cu target at 30 kV and 20 mA. The basal spacing was determined from their reflections (00l, $l = 1, 2, 3$, etc.) using the Bragg's law ($l\lambda = 2d \sin\theta$). For the atomic force microscopic (AFM) image analyses, the sample was suspended in deionized water (10^{-6} mg/mL) and spin-coated on the surfaces of glass substrate. The measurement was performed with scanning probe microscopy (SPM, dynamic force mode, Seiko, SPI 3800N) using rectangular Si cantilevers with 129 kHz resonant frequency and 12 N/m spring constant (Seiko, SI-DF20).

Enzymatic Activity Characterization. The hybrids were first tested for activity in catalytic hydrolysis of two small substrates, namely, Bz-Tyr-NAp and Su-Phe-NAp. The substrate stock solutions were prepared in DMSO at a concentration of 5.0×10^{-3} M. The reaction was performed in Tris buffer (0.08 M Tris + 0.01 M $CaCl_2$, pH 8.0) at 37 °C with a DMSO content less than 5.0% (v/v) of the incubation mixtures. The enzyme concentration in the reaction solution was 2.0×10^{-7} M, unless stated otherwise. The release of *p*-nitroaniline was monitored at 410 nm, and its molar absorptivity of 8800 M^{-1} cm^{-1} at this wavelength was employed to calculate its concentration over time (*16*). The kinetic parameters were obtained according to the Michaelis–Menten kinetic model, and each set of kinetic measurements was performed in duplicate with eight different substrate concentrations.

For the activity of the hybrids toward biomacromolecules, reactions were carried out with the concentrations of substrates (BSA and catalase, respectively) of 5 mg/mL and of CHT 2×10^{-5} M in Tris buffer at 37 °C. The MMT/CHT hybrids with a degree of CHT intercalation of 176 μmol/g clay were used. The extents of cleavage at different time intervals were evaluated in terms of the reduction (%) of the molecular peak of the substrates with respect to that at $t = 0$ in the GPC measurements under UV detection at 280 nm (*16*).

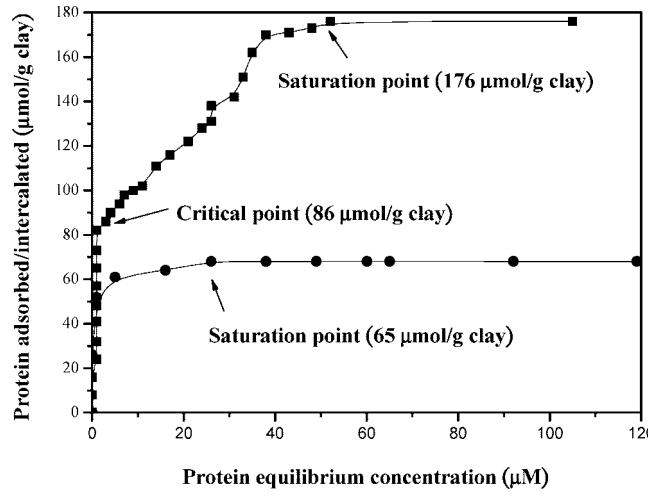

Figure 1. Adsorption/intercalation isotherms of CHT on the native Na^+-MMT particles (●) and MMT/POP hybrids (■) at 4 °C.

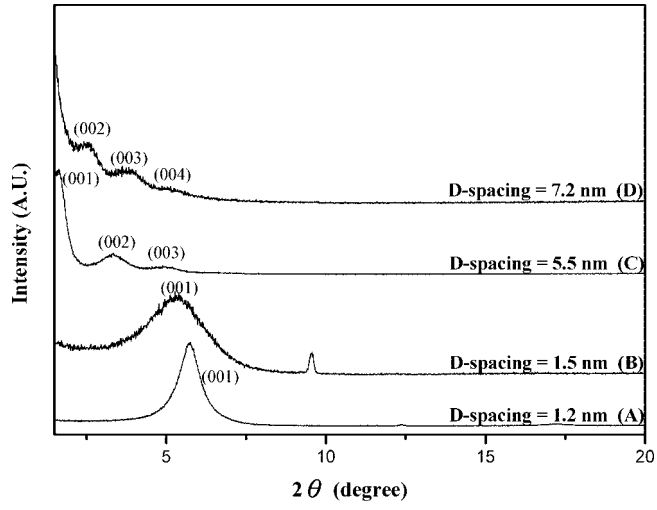

Figure 2. Powder XRD patterns of the native Na^+-MMT particles before (A) and after (B) CHT adsorption (65 μmol/g clay) and of the MMT/POP hybrids before (C) and after (D) the CHT intercalation/adsorption (MMT/CHT; 176 μmol/g clay).

RESULTS AND DISCUSSION

The intercalation/adsorption of CHT on MMT/POP particles significantly enhances the amount of CHT incorporated into the particles to 176 μmol/g clay (the saturation point) in comparison with that of only 65 μmol/g clay on native Na^+-MMT particles, as evidenced by two different adsorption isotherms in Figure 1. The adsorption behavior of CHT on Na^+-MMT particles is described well by the ideal Langmuir adsorption model as shown in the Supporting Information. In addition, after the CHT adsorption, the basal spacing of the clay particles was only slightly enlarged from 1.2 to ca. 1.5−2.2 nm by X-ray diffraction characterization (Figure 2). Apparently, the narrow interlayer space of Na^+-MMT particles (0.2 nm) fails to accommodate the globular CHT molecules with an original dimension of ca. $5 \times 6 \times 6$ nm^3, and the adsorption of protein species occurs to

a significant extent through the electrostatic interactions with the external particle surfaces (*10, 11, 17*). On the other hand, owing to the enlarged basal spacing of the clay layered particles by POP intercalation from 1.2 to ca. 5.5 nm (Figure 2), the complex isotherm of interacting CHT with the MMT/POP nanohybrids exhibits two different phases with respect to the simple Langmuir-type adsorption of CHT on Na^+-MMT. In the first phase, where the adsorption/intercalation amount is less than 86 μmol/g, the protein molecules are significantly adsorbed on the external surfaces of the multilayered particles. With only few CHT molecules being intercalated into each interlayer gallery, the basal spacing originally expanded by POP was slightly reduced (Supporting Information) due to the significant release of POP without sufficient incorporation of CHT. At an adsorption/intercalation extent of 80 μmol/g clay, it was observed that more than 40% of the POP molecules originally intercalated were released and the basal spacing was decreased from the initial 5.5 to 5.2 nm. Further expansion of the basal spacing to 7.2 nm was accomplished (Figure 2) by the enzyme entrapment amounting to 86 μmol/g (referred to as the critical point signifying the onset of the second phase) with the initial enzyme concentration in slurry at 440 μM. The basal spacing thereafter remained at ca. 7.2 nm, while the protein intercalation continued to proceed until equilibrium saturation was reached (Supporting Information). The expanded interlayer space of MMT/CHT at 6.2 nm is consistent with the molecular dimension of CHT, but significantly larger than those (with the basal spacing enlarged to a range of only 1.5−3.0 nm) by external surface adsorption and partial intercalation of various large protein molecules in previous reports (*18–21*). Herein, the extents of CHT (65 μmol/g clay at the saturation point) adsorbed on the surfaces of external plates of the Na^+-MMT particles and partially intercalated within their galleries were estimated based upon the saturation adsorption/intercalation of CHT at 176 μmol/g clay via MMT/POP. Assuming that each clay particle consists of 10 aluminosilicate plates and the CHT molecules are adsorbed/intercalated evenly on each of the external plate surfaces (×2) and within each of galleries (×9) of individual particles via MMT/POP, the enzyme adsorption on the external plate surfaces of particles amounts to ca. 32 μmol/g clay. With the same amount (32 μmol/g) of CHT adsorbed on the external plate surfaces, the extent of the protein intercalation within the Na^+-MMT galleries is only 33 μmol/g with respect to that of 144 μmol/g via MMT/POP. It has been reported that partial intercalation of large protein molecules takes place primarily in the outer regions of the interlayer spaces of native MMT particles, which, in agreement with our findings, results in only a small shift to higher basal spacing and a broadening of the d_{001} peak in the XRD measurements (*21*). Since the protein intercalation within Na^+-MMT occurs only in the outer regions of the galleries, herein it is referred to as a portion of the external particle surface adsorption for convenience. It is noteworthy that the MMT/POP particles originally in an extensively aggregated state at ambient temperature due to the inherent lower critical solution temperature (ca. 16−19 °C) of POP in water became well-dispersed at 4 °C, at which the clay structure became accessible to the protein intercalation and the biological functions of the protein were well-preserved. After the intercalation of the protein and release of POP, the new nanohybrids became easily dispersed in aqueous phase at ambient temperature. The SPM characterization of the MMT/CHT nanohybrids beyond the critical point shows that the hybrids were expanded to ca. 62−68 nm in height (Figure 3), as compared to only ca. 15−22 nm of Na^+-MMT particles with the maximum external surface adsorption of CHT (Supporting Information). With the basal spacing of 7.2 nm and the protein adsorption on the particle external surfaces taken into account,

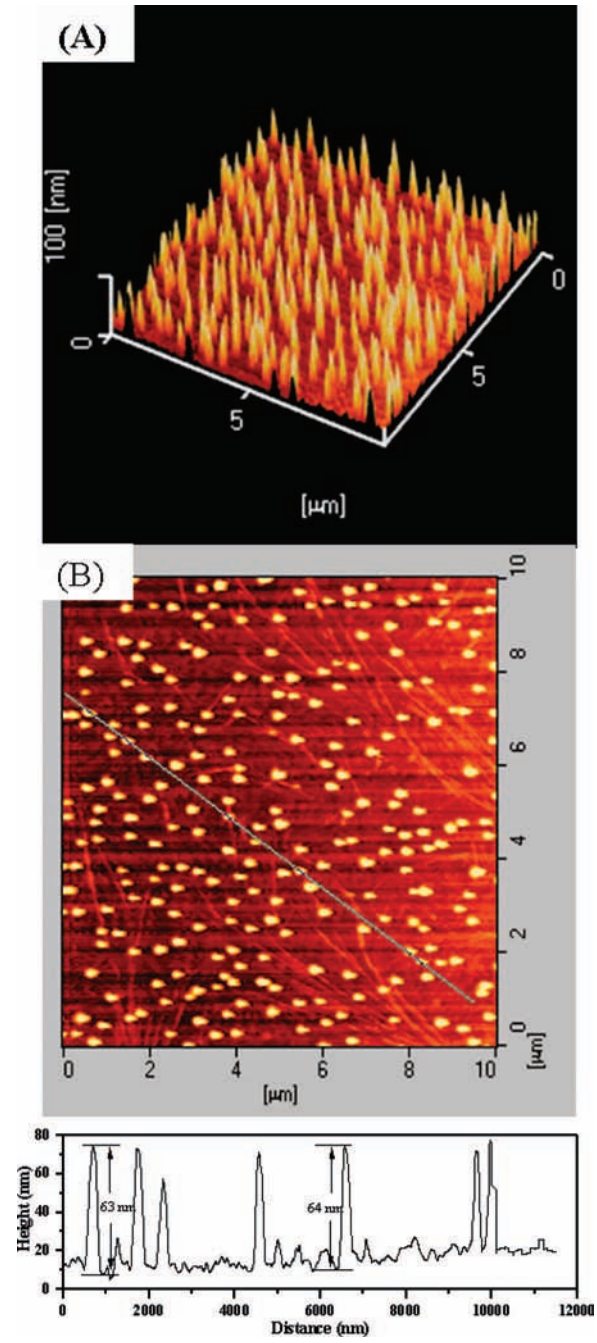

Figure 3. (A) Three dimensional AFM image and (B) the SPM topographical image of the MMT/CHT hybrids (176 μmol CHT/g clay) with lateral heights of ca. 62−68 nm.

the MMT/CHT nanohybrids are piling into ca. 8–10 platelets in a stack per particle. With further examination of the native Na^+-MMT and composite MMT/POP particles by SPM, the observations of the particle heights (ca. 11−13 and 40−45 nm, respectively, as shown in the Supporting Information) is in good agreement with the structure of 8−10 layers in a stack. Obviously, neither the intercalation of POP in Na^+-MMT nor exchange of the enzyme from the MMT/POP complexes leads to exfoliation of the clay multilayered structure.

Figure 4 illustrates the dependence of the enzyme activity in cleaving a small substrate, Bz-Tyr-NAp, on the extents of CHT intercalated and adsorbed on MMT particles (via MMT/POP and Na^+-MMT), respectively, at constant enzyme (2×10^{-7} M) and substrate (1.67×10^{-4} M) concentrations at 37 °C for 1 h. For comparison, free CHT has shown the capability of catalyzing the hydrolysis of the substrate to 78% under identical

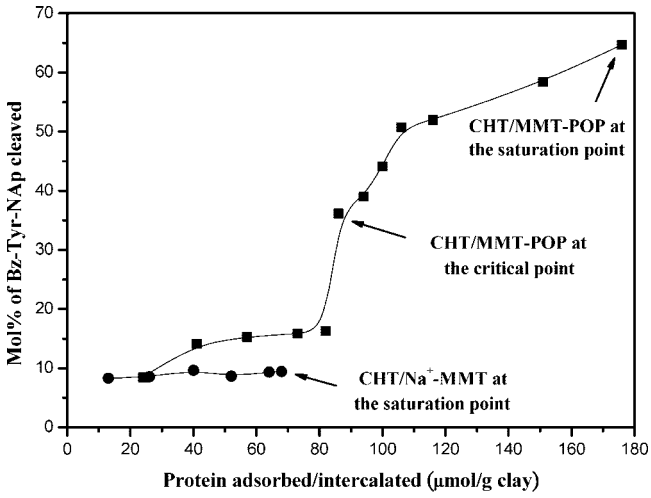

Figure 4. Dependence of the catalytic activity of CHT in hydrolyzing Bz-Tyr-NAp (mol %) on the extents of CHT adsorbed on Na^+-MMT particles (●) and intercalated within MMT/CHT hybrids (■). The reactions were carried out with a substrate concentration of 1.67×10^{-4} M at 37 °C for 1 h.

Table 1. Kinetic Parameters of the Cleavage of Two Small Substrates by Free CHT and MMT/CHT Hybrids[a]

Bz-Tyr-NAp	k_{cat} (s^{-1})	K_M (M) × 10^4	k_{cat}/K_M (s^{-1} M^{-1})
free CHT	0.437 ± 5.3%	1.60 ± 11.0%	2731 ± 10.0%
CHT/MMT-POP	0.422 ± 4.9%	3.15 ± 4.5%	1340 ± 2.3%
CHT/Na^+-MMT	0.288 ± 6.9%	3.70 ± 5.0%	778 ± 7.7%
Su-Phe-NAp	k_{cat} (s^{-1})	K_M (M) × 10^4	k_{cat}/K_M (s^{-1} M^{-1})
free CHT	0.182 ± 1.1%	7.00 ± 2.9%	257 ± 1.0%
CHT/MMT-POP	0.185 ± 3.2%	15.20 ± 5.8%	120 ± 4.3%
CHT/Na^+-MMT	0.084 ± 6.3%	17.20 ± 8.0%	49 ± 7.2%

[a] The extents of CHT intercalated in the MMT/CHT hybrids were 176 μmol/g clay and of adsorbed on external Na^+-MMT surfaces 65 μmol/g clay.

conditions. Independent of the extent of CHT adsorbed on the Na^+-MMT external particle surfaces, the enzyme shows reduced but constant activity. On the other hand, the MMT/CHT hybrids first show relatively low activity at the extents of the CHT intercalation below the critical point (86 μmol/g clay), where most CHT molecules reside on the external particle surfaces, and then abruptly enhanced activity beyond the critical point. Apparently, the spatially enlarged host galleries are essential for the enzyme to preserve its conformation and activity. The enzymatic activity continued to increase thereafter with increasing ratio of CHT embedded in the galleries to that adsorbed on the external particle surfaces until saturation of the CHT intercalation was achieved. Based upon the Michaelis–Menten kinetic theory, the kinetic parameters of the MMT/CHT hybrids in hydrolyzing two small substrates are listed in Table 1. The intercalated enzyme exhibits essentially identical catalytic activity (k_{cat}) to its free counterpart. However, the Michaelis constants (K_M) in interaction of both substrates increase significantly compared to the free enzyme. This can be ascribed to the reduced rate constant (k_1) in forming the enzyme/substrate complexes due to more retarded diffusion of the nonpolar substrates within the hybrids than that in bulk aqueous phase. In contrast, the enzyme suffers a dramatic reduction in activity (as signified by both the decreased k_{cat} and the increased K_M) when they are immobilized on the external particle surfaces of Na^+-MMT. The fully preserved activity of the intercalated CHT molecules within the clay galleries can be accounted for by the salt-bridge effect resulting from the electrostatic interactions of the enzyme molecules with negatively charged platelets of both top and bottom sides on stabilizing the native conformation of the protein in a manner similar to that of the engineered proteins (*4, 22*). Confinement of the enzyme molecules within the rigid clay galleries may additionally protect the protein from unfolding by steric hindrance (*23*). The protein conformation can also be partially stabilized by reducing the activity of water molecules in the galleries and therefore reducing the extents of hydration of the nonpolar groups of the intercalated proteins and of dehydration of their polar groups, which is suggested to be essential for protein unfolding (*4, 24*). On the other hand, owing to the absence of the electrostatic interactions with both the top and bottom platelet surfaces, the enzyme molecules, when being adsorbed on the Na^+-MMT external plate surfaces, can be more easily denatured. In addition, it is expected that the conformation of the CHT molecules intercalated in the outer regions of the Na^+-MMT galleries be largely perturbed due to the compressive effects of the inorganic platelets with the narrow basal spacing of 1.5−2.2 nm. Similar results on the reduction of catalytic activity of the enzymes upon immobilization on MMT surfaces have been observed and ascribed to the perturbation of protein conformation and modification of their active centers, mostly using the FTIR measurements (*10, 19–21, 25, 26*).

Taking advantage of CHT as a protease, the clay/enzyme nanohybrids were tested for their residual activity toward Bz-Tyr-NAp after preincubating the clay/enzyme suspensions alone for 1 h at varying temperatures. Figure 5A shows the relative activity of CHT in varying forms (the free, externally adsorbed, and intercalated, respectively) after preincubation at different temperatures to that preincubated at 5 °C as a function of the extent of intercalation (via MMT/POP) or external particle surface adsorption (via Na^+-MMT) at a constant enzyme concentration (2.0×10^{-7} M) in solutions. Figure 5B emphasizes the effects of the enzyme concentrations (1.0×10^{-6} and 2.0×10^{-7} M) in solutions, while the extent of CHT intercalated (100 μmol/g) or adsorbed (41 μmol/g) was kept unchanged. With increasing enzyme concentration and preincubation temperature (up to 55 °C, the temperature for the optimal activity of CHT, both the free and intercalated), the degree of reduction in the relative activity of the free CHT increases primarily as a result of the proteolytic action on CHT molecules themselves (self-digestion). In contrast, for the CHT adsorbed on the external surfaces of Na^+-MMT particles, the activity profile upon preincubation was independent of both the enzyme concentration and the adsorption extent, strongly indicative of the lack of significant self-interactions and -digestion of the enzyme molecules. The observed temperature effect on the reduction in the activity of CHT adsorbed on the external particle surfaces is attributed to thermally facilitated protein denaturation on the external surfaces of inorganic particles. On the other hand, the residual activity of the intercalated CHT is influenced markedly by both the preincubation temperature and the intercalation extent at a constant enzyme concentration, but is insensitive to change in the enzyme concentration in solutions for the MMT/CHT nanohybrids of a certain extent of enzyme intercalation. Similar to free CHT, the change of the relative activity is caused significantly by self-digestion, but occurs within the nanohybrids exclusively. Strong dependence of self-cleavage on the intrinsic concentration of enzyme within the nanohybrids was hence observed. However, one of the prerequisites for the protease molecules to self-digest so extensively in their medium relies more likely on their ability to migrate freely to interact with each other. Owing to negative charges evenly distributed throughout the plate interior surfaces, enzyme molecules residing in the galleries retain not only the native structure but also the mobility in sliding in a two-dimensional manner within the confinement without deterioration of the electrostatic attractions. The difference in the concentrations between the intercalated CHT within the nanohybrids and the

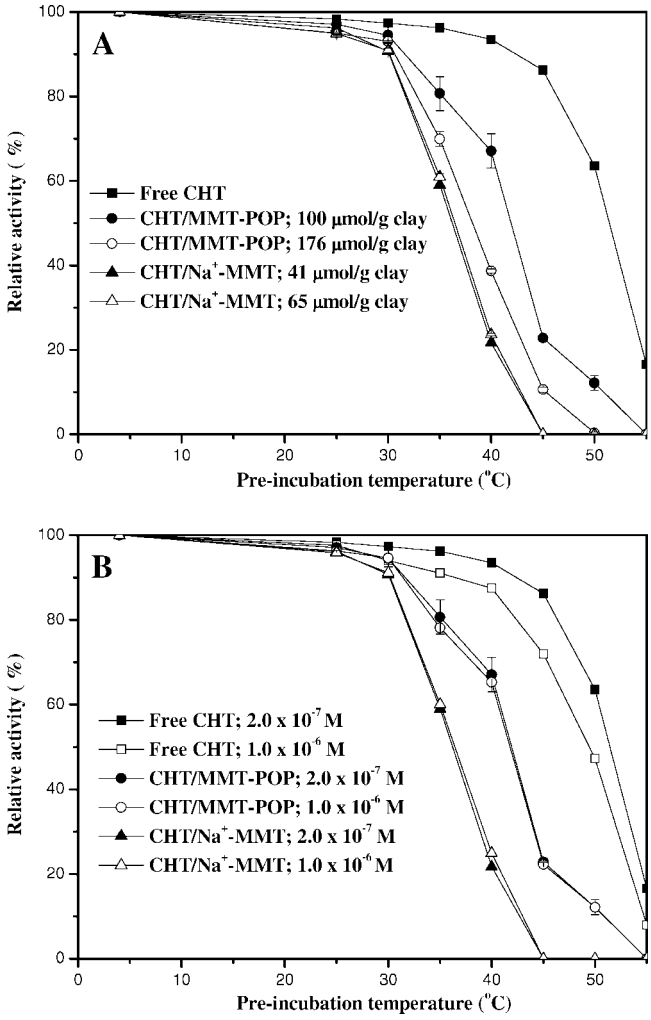

Figure 5. Effects of the preincubation of the aqueous solution of CHT in the free, intercalated (via MMT/POP hybrids), and adsorbed (on Na^+-MMT particles) forms at varying temperatures on relative residual activity in hydrolyzing Bz-Tyr-NAp to that of the preincubation at 5 °C as functions of (A) the extents of CHT intercalated and adsorbed at a constant enzyme concentration (2.0×10^{-7} M) and (B) of the enzyme concentration with the constant extents of intercalation at 100 μmol/g clay (via MMT/POP) and of external adsorption at 41 μmol/g clay (Na^+-MMT), respectively.

free counterpart in aqueous solution also leads to varying degrees of self-digestion and therefore the residual activity. It should be noted that the self-digestion occurs usually by proteases only and is not observed from nonproteolytic enzymes, including those employed for protein therapeutics and biomedical applications.

The interaction of CHT within the hybrids with biomacromolecules was characterized in terms of the extent of proteolytic cleavage of protein–substrates (BSA and catalase, respectively) by incubating with the MMT/CHT particles in aqueous solutions. The degradation was evaluated by monitoring the change in the molecular peaks of protein–substrates from the GPC measurements with time. Figure 6 shows that catalase was only degraded slightly (<18% in the molecular cleavage) by the MMT/CHT nanohybrids within an incubation time interval of 72 h while extensive proteolysis (>92%) occurred by the free CHT. Similarly, BSA, being employed as the other macromolecular substrate, was severely restricted to interacting with the CHT molecules embedded within the galleries of the MMT particles in comparison with its rapid digestion by the free enzyme (Supporting Information). The restriction of interacting the intercalated CHT molecules with biomacromolecular substrates is caused primarily by both the steric hindrance of the inorganic host plates in the layered structure and the limited free space remaining within the host galleries in addition to the CHT occupation. The observed proteolytic action of the MMT/CHT hybrids on both catalase and BSA is most probably due to the accessibility of the CHT molecules that reside on the external particle surfaces (including the outer regions of the clay galleries) to interaction with the substrates. Morphologic examination of the MMT/CHT nanohybrids after incubating with catalase by SPM demonstrates that the lateral heights of

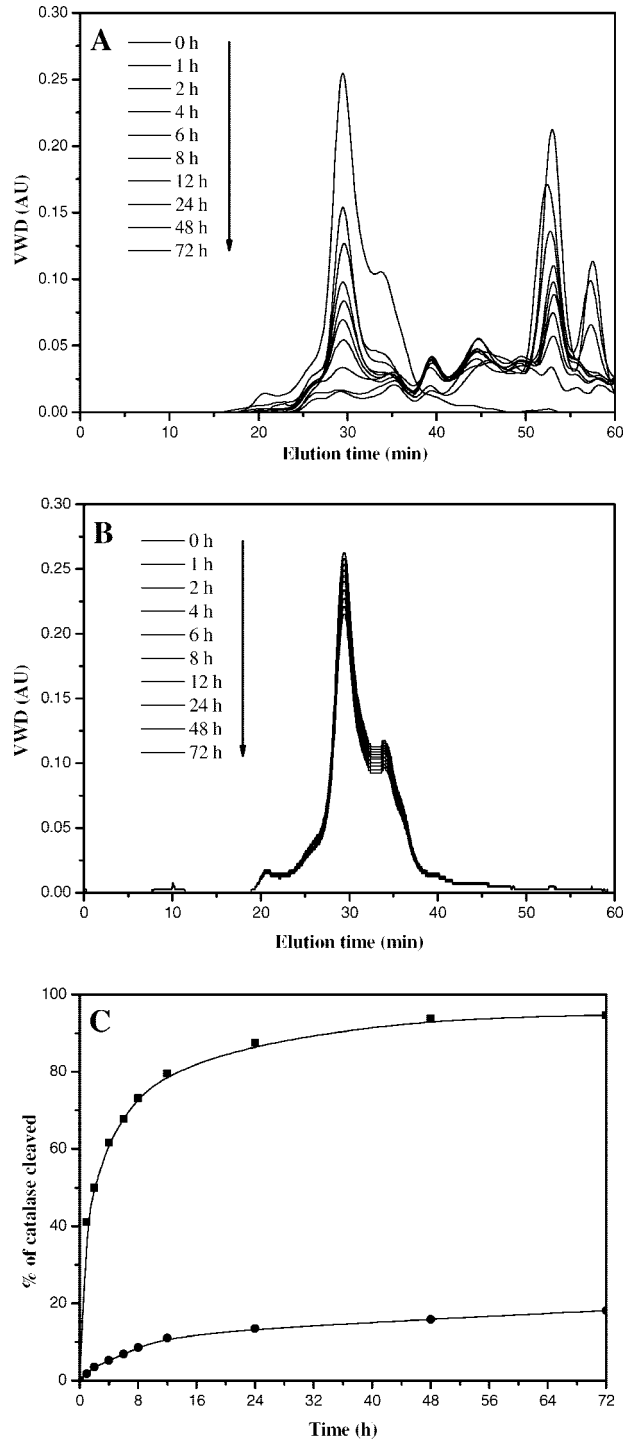

Figure 6. GPC spectra of catalase as a function of the incubation time with (A) the free CHT and (B) MMT/CHT hybrids (176 μmol/g clay), respectively. (C) Cleavage extents of catalase in terms of the decreases (%) of the molecular peak height of catalase by proteolytic action of the free CHT (■) and MMT/CHT hybrids (●) with time.

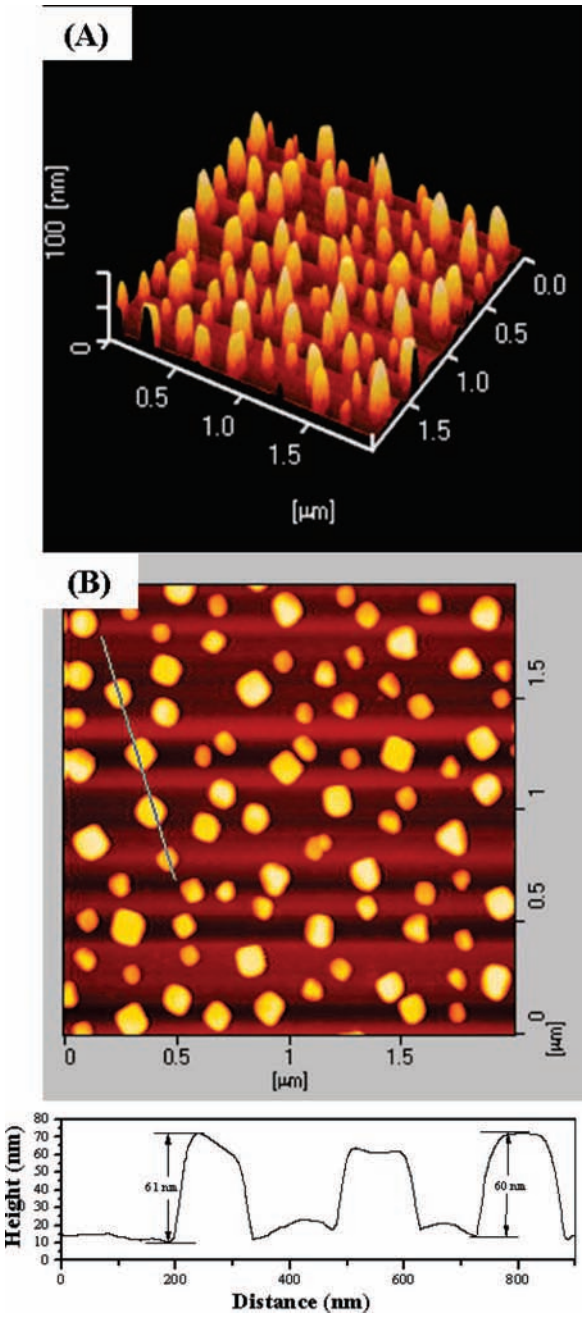

Figure 7. (A) Three-dimensional AFM image and (B) the SPM topographical image of the MMT/CHT hybrids (176 μmol/g clay) with lateral heights of ca. 60∼70 nm after incubation with catalase for 72 h.

the nanohybrids in the range 60−70 nm were essentially the same as those prior to the incubation reactions (Figure 7). Similar observation was obtained from the incubation of the hybrids with BSA (Supporting Information). The results further suggest that neither exfoliation of the clay multilayered structure nor exchange with the originally intercalated CHT occur by catalase and BSA in approaching the MMT/CHT hybrids, although the latter has been found capable of being intercalated in the galleries of MMT/POP via cationic exchange with POP (*27*). It has been confirmed that the expansion of the basal spacing from 1.2 to 5.5 nm with the POP intercalation to a critical extent is supported mainly by significant hydrophobic segregation of the polymer strains in aqueous medium within the gallery (*15*). The different fates of BSA while in contact with MMT/POP and MMT/CHT hybrids suggest that the stability of the inorganic layered structure becomes enhanced by accommodating protein molecules within the galleries due to the more extensive electrostatic attractions with negatively charged platelets on both top and bottom sides and the more compact hydrophobic association of the protein globular structure in nature. Therefore, it is not surprising that the CHT molecules originally intercalated within the clay multilayered structure underwent conformational change by placing the lyophilized hybrids in organic solvents, such as DMSO, leading to inactivation of the enzyme molecules and exfoliation of the clay layered structure (data not shown).

The MMT/CHT nanohybrids reported herein have shown similarity in several aspects to PEG−enzyme adducts. The enzyme molecules residing within the galleries of the MMT particles most likely retain their structure in the native conformation. However, the enzyme functions are tailored such that the enzymatic activity toward small substrates can be fully preserved and interactions with the approaching biomacromolecules effectively inhibited. On the other hand, the hybrids in nanoscale render themselves particularly useful when fixation or immobilization is strongly preferred. This nanoscaled manipulation of enzyme functions through a clay accommodation and immobilization can be a valuable approach whereby hybrids of therapeutically active enzymes with preference for activity only in small substrates can possibly be developed as new therapeutics or bioreactors in tissue engineering, taking advantage of their easy fixation and reduced interactions with biomacromolecules, including those responsible for proteolytic action and immune response.

CONCLUSIONS

The MMT/enzyme nanohybrids obtained by a facile exchange process of the enzyme molecules with POP in space-enlarged galleries of MMT/POP have shown the capability of retaining the layered structure of the inorganic host and enzymatic activity of the guest molecules in hydrolyzing small substrates while rejecting interactions with large biomacromolecules. The capacity in accommodating protein within clay galleries is much larger than that by only adsorption on the external surfaces of Na^+-MMT particles. In addition, the stability of the layered structure of MMT/CHT nanohybrids can be further enhanced as compared to MMT/POP, leading to the observation that neither exchange nor exfoliation occurred when the hybrids were in contact with other proteins. This study indicates that, through the accommodation capability of clay, the simple nanoscaled manipulation of protein functions can be highly useful in developing new clay/enzyme nanohybrids for protein therapeutics and tissue engineering.

PLGA Nanoparticle−Peptide Conjugate Effectively Targets Intercellular Cell-Adhesion Molecule-1

Na Zhang,[†,§] Chuda Chittasupho,[†] Chadarat Duangrat,[†,||] Teruna J. Siahaan,[†] and Cory Berkland*[,†,‡]

Departments of Pharmaceutical Chemistry, and Chemical and Petroleum Engineering, University of Kansas, Lawrence, Kansas 66047. Received June 20, 2007; Revised Manuscript Received July 23, 2007

Targeted delivery of therapeutics possesses the potential to localize therapeutic agents to a specific tissue as a mechanism to enhance treatment efficacy and abrogate side effects. Antibodies have been used clinically as therapeutic agents and are currently being explored for targeting drug-loaded nanoparticles. Peptides such as RGD peptides are also being developed as an inexpensive and stable alternative to antibodies. In this study, cyclo(1,12)PenITDGEATDSGC (cLABL) peptide was used to target nanoparticles to human umbilical cord vascular endothelial cell (HUVEC) monolayers that have upregulated intercellular cell-adhesion molecule-1 (ICAM-1) expression. The cLABL peptide has been previously demonstrated to possess high avidity for ICAM-1 receptors on the cell surface. Poly(DL-lactic-coglycolic acid) nanoparticles conjugated with polyethylene glycol and cLABL demonstrated rapid binding to HUVEC with upregulated ICAM-1, which was induced by treating cells with the proinflammatory cytokine, interferon-γ. Binding of the nanoparticles could be efficiently blocked by preincubating cells with free peptide suggesting that the binding of the nanoparticles is specifically mediated by surface peptide binding to ICAM-1 on HUVEC. The targeted nanoparticles were rapidly endocytosed and trafficked to lysosomes to a greater extent than the untargeted PLGA-PEG nanoparticles. Verification of peptide-mediated nanoparticle targeting to ICAM-1 may ultimately lead to targeting therapeutic agents to inflammatory sites expressing upregulated ICAM-1.

INTRODUCTION

A variety of drug treatments have been investigated in recent decades outlining the potential of targeting specific cytokines or cell adhesion molecules that facilitate leukocyte recruitment in inflammatory diseases (*1–4*). In particular, monoclonal antibodies (mAbs) have been developed to target and bind molecules to disrupt the inflammatory pathway. However, the application of mAbs may be limited by immunogenicity, production cost, low physicochemical stability, and short *in vivo* half-life. As an alternative, nanoparticles may be targeted to a specific tissue with up-regulated cell adhesion molecules such as intercellular cell-adhesion molecule-1 (ICAM-1), which is dramatically up-regulated (~10-fold or more) on the vascular endothelium in response to the increased production of proinflammatory cytokines, such as interleukin-1-β, interferon-γ, and tumor necrosis factor-α (*5*). Recent studies have indicated that coupling anti-ICAM-1 mAbs to the surface of nanoparticles facilitated binding and internalization on the vascular endothelium (*6, 7*). In light of these findings, drugs encapsulated into nanoparticles and targeted to ICAM-1 may have the potential to pool to sites of ICAM-1 upregulation for a localized therapeutic effect (*7*).

Inhibition of ICAM-1 binding to leukocytes using mAbs has been shown to suppress T-cell activation (*8, 9*). In addition, therapies combining drugs such as methotrexate with mAbs against proinflammatory cytokines (e.g., TNF-α) have shown great promise in halting the progression of joint deterioration (*10, 11*). A variety of therapeutic strategies utilizing mAbs against CD4, CD5, CD7, CD25, and CD52 have also been investigated in an effort to interfere with the activation of CD4+T cells, thus, blocking inflammation (*1, 12, 13*). Previously, Siahaan and others found linear and cyclic peptides derived from the α- and β-subunits of LFA-1 that can inhibit homotypic and heterotypic T-cell adhesion as well as mixed lymphocyte reaction (*14*). The peptide cyclo(1,12)PenITDGEATDSGC (cLABL) demonstrated the highest avidity for domain-1 (D1) of ICAM-1 and could block ICAM-1-mediated T-cell adhesion. In addition, this peptide was internalized by ICAM-1 and entered into the cytoplasmic domain of activated T cells and endothelial cells (*14*). cLABL, has also been shown to provide therapeutic benefit by mitigating T-cell adhesion in the pancreatic microvasculature (*15*). Further enhancement of the demonstrated therapeutic efficacy may be afforded by multivalent peptide/receptor interactions (e.g., on a nanoparticle surface) coupled with sustained, localized release of appropriate therapeutics.

Nanoparticles have garnered attention for use as delivery vehicles for therapeutic drugs since they can be designed to slip between intercellular spaces, enter cells, or transport directly through biological barriers to access disease sites (*16–18*). Nanoparticles also encapsulate therapeutic agents offering potential protection from enzymatic degradation, metabolism, and filtration. Choosing the proper particle-forming materials allows the controlled release of drug over time or in response to a biological cue (*19, 20*). Delivering drugs in this manner also allows functionalization of the nanoparticle surface without compromising the activity of the drug itself, often a problem when covalently bonding targeting ligands to therapeutics as a prodrug strategy.

Surface modification of nanoparticles is a key requisite for extending circulation half-life and promoting localization. For example, nanoparticles coated with a highly cationic

[a] PLGA nanoparticles fabricated using PEMA surfactant.

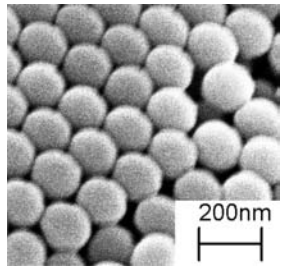

Figure 1. Scanning electron micrograph of PEMA-coated PLGA nanoparticles.

polymer have been used to enhance cellular uptake or open intercellular tight junctions (*16*, *21*). Recently, folate receptors overexpressed on the surface of malignant human cells were targeted by grafting folate on the surface of nanoparticles (*22*). Studies revealed that the nanoparticles attained a 10-fold higher affinity for the surface folate binding protein than free folate (*23*). Researchers reasoned that the multivalent form of folate on the nanoparticle surface interacted strongly with folate receptors, which often cluster on the surface of cancer cells, similar to the clustering of ICAM-1 during T-cell adhesion. Finally, research efforts are ongoing to improve nanoparticle performance *in vivo* by extending nanoparticle circulation and limiting interaction with blood constituents (*17*, *24*–*26*).

In this article, cLABL was conjugated to the surface of biodegradable PLGA nanoparticles to target ICAM-1 on the surface of human umbilical cord vascular endothelial cells (HUVEC). The amino terminus of modified polyethylene glycol was conjugated to carboxylic acid groups on PLGA nanoparticles via a peptide bond. The density of carboxyl groups on the nanoparticle surface was augmented using poly(ethylene-maleic acid) (PEMA) as a surfactant on the basis of methods recently described by Saltzman and others (*27*). Particles were further modified by conjugating the N-terminus of cLABL to the carboxylic acid group of PEG on the nanoparticle surface. The cLABL nanoparticles demonstrated rapid binding to HUVEC in comparison to PLGA-PEG particles. The binding of cLABL nanoparticles was enhanced upon upregulation of ICAM-1 receptors by interferon-γ and was interrupted by incubating HUVEC with free cLABL peptide prior to nanoparticle introduction. Labeling lysosomes revealed that cLABL nanoparticles trafficked to lysosomes and accumulated to a much greater extent than PLGA-PEG nanoparticles. This research provides evidence that cLABL nanoparticles can rapidly and specifically targeted to cells with upregulated ICAM-1, thus offering the potential for site-specific drug delivery.

EXPERIMENTAL PROCEDURES

Materials. Poly(DL-lactic-coglycolic acid) (50:50) (PLGA, inherent viscosity 0.89, Mw ∼150 kDa) was purchased from Absorbable Polymers. Poly(ethylene-maleic anhydride) (PEMA), was purchased from Polysciences, Inc. Fmoc-PEG_{3400}-COOH was purchased from Nektar. Alexa Fluor 488, LysoTracker Red, and Texas Red (10,000 kDa, lysine fixable) were purchased from Molecular Probes. Human interferon-γ (hIFN-γ, 100,000 U) was purchased from Roche Applied Science. Six-well glass bottom microwell dishes were purchased from MatTek corporation and 8-well BD Falcon* Culture Slides and 4% paraformaldehyde were purchased from Fisher Scientific. Acrodisc Syringe Filters with Supor PES Membrane were acquired from VWR international, Inc. Dulbecco's modified Eagle's medium and Triton X-100 were purchased from Sigma Aldrich. Penicillin−streptomycin, nonessential amino acids, and fetal bovine serum (FBS) were purchased from Invitrogen. Float-A-Lyzers (MWCO 500) were purchased from Spectrum laboratories. Micro BCA protein assay kit was purchased from Pierce Chemical Company.

Preparation of PLGA Nanoparticles. PLGA nanoparticles were prepared by a solvent diffusion method. Briefly, 50 mg of PLGA was dissolved in 3.0 mL of acetone, and the PLGA solution was added to 0.2% PEMA (30 mL) through a syringe pump (20 mL/h) under stirring at 200 rpm in a hood to evaporate acetone. PEMA was utilized as a surfactant to increase the number of carboxyl groups on the particle surface. Saltzman and others have previously reported this method to form stable antibody conjugates on PLGA particles (*27*). The nanoparticles produced were collected by centrifugation (15,000 rpm, 45 min). The nanoparticles were washed three times using double-distilled water. The sizes and zeta potentials of the PLGA nanoparticles were determined using a ZetaPALS dynamic light scattering system (Brookhaven, ZetaPALS).

Synthesis of PEGylated-PLGA Nanoparticles and cLABL Conjugation. Deprotection of the amine of Fmoc-PEG_{3400}-COOH was accomplished by stirring Fmoc-PEG_{3400}-COOH in 1.5 mL of 20% piperidine in DMF for 2 h at room temperature. The solution was transferred to polypropylene centrifuge tubes, and water was added. Centrifugation and filtration (MWCO 5,000) essentially resulted in the complete removal of Fmoc. The solution was further subjected to extensive dialysis in 500 MWCO Float-A-Lyzers before being lyophilized to dryness.

Five milligrams of PLGA nanoparticles in suspension (∼0.2 mg/mL in double-distilled water) were incubated with 23 mg of *N*-hydroxysuccinimide (NHS, 0.2 mmol), the pH was adjusted to 5.80, and then 153 mg of 1-(3-dimethylaminopropyl)-3-ethylcarbodimide hydrochloride (EDC, 0.8 mmol) was added and incubated for 2 h at room temperature with gentle stirring. The resulting NHS-activated particles were covalently linked to 10 mg of NH_2-PEG-COOH. The resulting PLGA-PEG-COOH nanoparticles were again washed, resuspended, and preserved in suspension form in double-distilled water. PLGA-PEG-COOH nanoparticles were activated by NHS as described above. The resulting NHS-activated particles were covalently linked to 5 mg of cLABL peptide or 0.2 mg of Alexa 488. PLGA-PEG-Alexa 488 particles served as control particles for all studies. The resulting PLGA-PEG-peptide-COOH nanoparticles were again activated by NHS as described above. The resulting NHS-activated particles were covalently linked to 0.2 mg of Alexa 488.

Quantification of PEG and cLABL Peptide on the Surface of Nanoparticles. The unreacted PEG or the unreacted cLABL peptide was separated from nanoparticles after the corresponding reaction step by centrifugation at 15,000 rpm for 45 min The amount of free PEG or cLABL peptide in the supernatant was determined using 2,4,6-trinitro-benzenesulphonic acid (TNBS) as a colorimetric assay (*28*). Seven hundred microliters of aqueous solution containing free PEG or cLABL peptide was added to 700 μL of 0.1 M sodium borate buffer (pH 9.2). Three hundred and fifty microliters of TNBS aqueous

Table 2. Density of Conjugated Molecules

	size (nm)	total surface area (m^2/mg)	surface PEG (pmol/cm^2)	surface peptide (pmol/cm^2)	surface Alexa 488 (pmol/cm^2)
PLGA-PEG	202	22.14	4.0 ± 0.8		
PLGA-PEG-Alexa 488	224	20.05			0.011 ± 0.002
PLGA-PEG-cLABL	244	18.36		2.3 ± 0.9	
PLGA-PEG-cLABL-Alexa 488	269	16.7			0.012 ± 0.002

solution (1.65 mg/mL) was added, and the solution was rapidly mixed. After incubation at 40 °C for 45 min, the reaction was stopped by adding 350 μL of 0.1 M NaH_2PO_4 containing 1.5 mM Na_2SO_3, and absorption at 420 nm was determined on a UV/vis spectrometer (Agilent 8453). The amounts of PEG and cLABL peptide on the surface of nanoparticles were calculated by subtracting the free amount from the total amount added into the reaction system.

The amount of Alexa 488 on the surface of nanoparticles was analyzed by the fluorescence intensity of nanoparticles using a fluorescence plate reader (SpectraMax M5; Ex., 490 nm; Em., 520 nm). Standard curves were obtained by diluting the free Alexa 488 with blank PLGA-PEMA nanoparticles (size = 266 nm) over a concentration range from 0.01 to 0.1 μg/mL (r = 0.9991).

Binding and Uptake of Nanoparticles in HUVEC Culture. Pooled HUVEC were grown in DMEM medium supplemented with 10% FBS, 0.1% nonessential amino acids, and 0.1% penicillin−streptomycin and were maintained at a density of 1×10^5 to 1×10^6 cells/mL at 37 °C in a humidified 5% CO_2 atmosphere. HUVEC were plated in 8-well BD Falcon* Culture Slides at a density of 1.0×10^5 cells/mL and used for uptake studies on day 2. Freshly prepared nanoparticles were diluted with serum-free medium to give a concentration of 0.3 mg/mL. Two hundred microliters of the nanoparticle suspension was added to each well. The cells were incubated with nanoparticles for different time periods to allow surface binding, washed three times with serum-free medium, incubated at 37 or 4 °C for different time periods, washed three times with ice-cold PBS, and fixed with 3.7% paraformaldehyde at room temperature.

For studies using free peptide as an inhibitor, HUVEC monolayers were preincubated for 30 min at 37 °C in the presence of different concentrations of free cLABL peptide, washed three times with serum-free media, and incubated with nanoparticles as described above. At varying periods of time, the cell monolayers were fixed, lysed, and the fluorescence determined. For ICAM-1 upregulation studies, HUVEC were activated with hIFNγ for 16–18 h, then washed three times with serum-free media, and incubated with nanoparticles as described above for uptake studies.

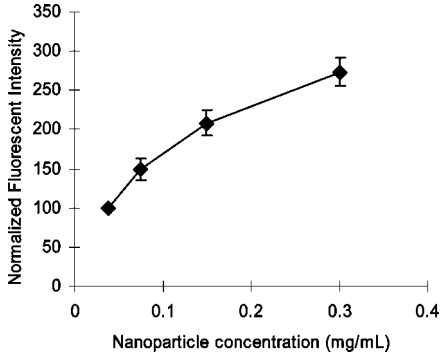

Figure 2. Fluorescent intensity increased in HUVEC as nanoparticle concentration increased. cLABL peptide-modified PLGA nanoparticle binding time was 1 h, followed by washing and incubation for 2 h prior to cell lysis.

Quantification of Nanoparticle Interaction with HUVEC. The experiments above were terminated by washing the cells three times with ice-cold phosphate-buffered saline (PBS; 8 g/L NaCl, 0.2 g/L KCl, 1.44 g/L Na_2HPO_4, and 0.24 g/L KH_2PO_4 in water at pH 7.4) and solubilizing the cells with 1 mL of 0.5% Triton X-100 in 0.2 M NaOH. Nanoparticle content was quantified by analyzing the cell lysate using a fluorescence plate reader (SpectraMax M5; Ex., 490 nm; Em., 520 nm). Uptake was normalized to the amount of cellular protein. The protein content of the cell lysate was determined using the Micro BCA protein assay kit. The plate reader was calibrated with standard preparations of nanoparticles, which were diluted with a cell lysate solution prepared by solubilizing 2×10^5 HUVEC in 1 mL of 0.5% Triton X-100/0.2 N NaOH solution. Linear calibration curves (r = 0.9991) over the nanoparticle concentration range of 6 to 48 μg/mL were obtained.

Intracellular Trafficking of Nanoparticles. To follow intracellular trafficking of nanoparticles, HUVEC were incubated for 2 h at 37 °C with Lysotracker to label lysosomes, washed three times with serum-free medium, and incubated with nanoparticles as described above for uptake studies. Briefly, freshly prepared nanoparticles were diluted to 0.3 mg/mL with serum-free medium. Two hundred microliters of the nanoparticle suspension was added into each well. The cells were incubated with nanoparticles for 10 min to allow surface binding, washed three times with serum-free medium, and incubated at 37 °C. At varying periods of time after internalization, the cells were washed three times with ice-cold PBS, and fixed with 3.7% paraformaldehyde at room temperature. Then, the colocalization of nanoparticles within Lysotracker-labeled cellular compartments was determined. The results were confirmed by labeling lysosomes with Texas Red dextran (10,000 kDa) following a similar protocol (*7*, *29*).

RESULTS

Preparation of Nanoparticles. As previously described by Saltzman and others (*27*), multiple molecules were conjugated to PLGA nanoparticles in the presence of PEMA surfactant by

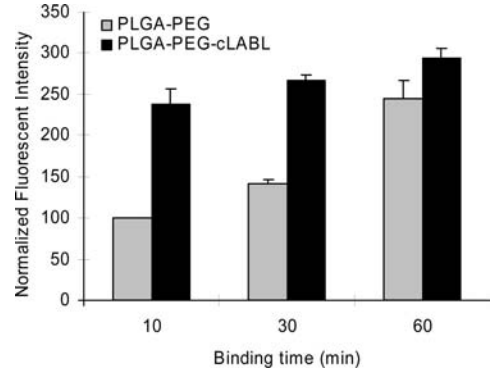

Figure 3. Fluorescent intensity of nanoparticles associated with HUVEC was significantly higher for targeted cLABL nanoparticles for short binding times ($p < 0.001$ for 10 and 30 min). Nanoparticle binding time was followed by washing and incubation for 2 h prior to cell lysis.

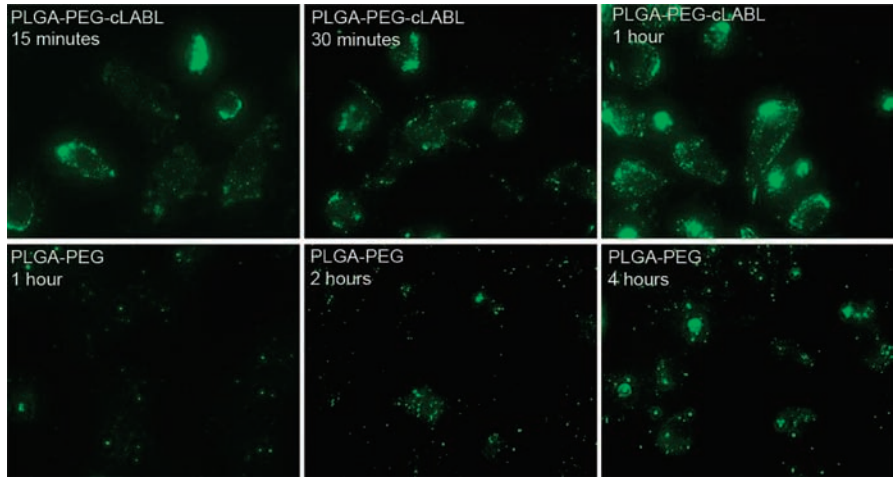

Figure 4. Fluorescent micrographs demonstrate that the binding of PLGA nanoparticles mediated by cLABL occurred rapidly. Significant localized fluorescence was noted at 15 min for cLABL nanoparticles; however, PLGA-PEG nanoparticles required >2 h to demonstrate similar localization to cells. No significant differences in fluorescence were observable after 4 h. Nanoparticle binding time was 10 min, followed by washing and incubation for 2 h prior to cell lysis or imaging.

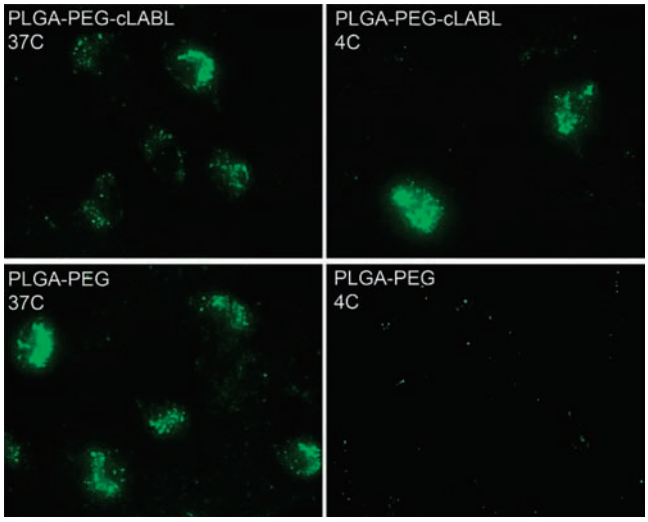

Figure 5. Nanoparticle binding was studied at 4 °C to mitigate energy dependent endocytic pathways. Binding of cLABL nanoparticles was still apparent at low temperature. Nanoparticle binding time was 1 h, followed by washing and incubation for 2 h prior to cell imaging.

sequentially activating and conjugating the available terminal carboxyl groups. Original PLGA particles coated with PEMA were ~175 nm in size with a relatively low polydispersity (Table 1). Dynamic light scattering results were confirmed by scanning electron microscopy, which verified the narrow particle size distribution and revealed a relatively smooth surface morphology (Figure 1). Reacting the terminal amine of PEG to PEMA carboxyl groups resulted in a slight increase in the average particle size and polydispersity. Further addition of the fluorescent dye, Alexa 488, or cLABL produced a further increase in average particle size and polydispersity. This trend continued when linking Alexa 488 to free carboxyl terminus of cLABL. Increasing particle size, presumably due to particle agglomeration, was suspected to result from the addition of NHS when conjugating molecules since NHS presents a relatively hydrophobic intermediate on the particle surface. Sequential conjugations also demonstrated a systematic increase in nanoparticle zeta potential, presumably a result of the occupation of carboxyl sites and increasing particle size.

The density of molecules on the nanoparticle surface was estimated after each reaction step. The total particle surface area was calculated assuming a normal Gaussian particle size distribution. The concentration of molecules was determined indirectly by quantifying the amount of molecules left in solution. Appropriate controls were utilized to ensure that this method was accurate (i.e., no loss of molecules through nonspecific adsorption to the vial, etc.) The density of PEG on the surface of PLGA particles corresponded well with other reports (Table 2) (*30, 31*). In addition, the density of peptide was sufficient to facilitate particle interactions *in vitro*. Alexa 488 surface concentration provided a significant signal for detection by fluorescent microscopy and spectroscopy.

To effectively determine nanoparticle interactions with cells, colloidal stability is a key requisite. PEGylated nanoparticles with and without peptide possessed good colloidal stability in both water and serum-free cell culture media. A slight increase in particle size, polydispersity, and zeta potential was evident in media. Large precipitates were not obvious in either water or media, although larger, ~1 μm, agglomerates were visible by fluorescence microscopy on rare occasions. Preincubation of nanoparticles with cell culture media in an ultrasound bath prior to dispersing into wells helped to mitigate the agglomeration of nanoparticles.

The cLABL peptide has been previously shown to bind to the D1 domain of ICAM-1 (*32*). ICAM-1 is expressed at a basal concentration of 5–10 $\times$ 10^4 sites/cell, although the expression may be increased to 3.5 $\times$ 10^6 sites/cell upon treatment of HUVEC with TNF-α (*33*). To determine the binding avidity to HUVEC expressing basal levels of ICAM-1, nanoparticles were incubated with HUVEC for 1 h and washed, and fluorescence was quantified after 2 h. Increasing the concentration of peptide-labeled nanoparticles resulted in a corresponding increase in the fluorescence intensity (Figure 2). The decreasing effect of increasing particle concentration may be indicative of the saturation of ICAM-1 receptors or the removal of ICAM-1 from the surface via endocytosis at high nanoparticle concentrations.

HUVEC were incubated with PLGA nanoparticles grafted with PEG or PEG-cLABL at 300 μg/mL to assess the specificity of binding mediated by cLABL. The presence of cLABL on nanoparticles resulted in an ~2.5-fold enhancement of the fluorescent intensity in HUVEC (Figure 3). Increasing the binding time decreased the differential between cLABL and nonspecific nanoparticle interactions with HUVEC. Fluorescent micrographs were also collected over time to observe the kinetic interaction of nanoparticles with HUVEC. Rapid localization of cLABL nanoparticles to the cell periphery was observed (Figure 4). This observation was consistent with the short

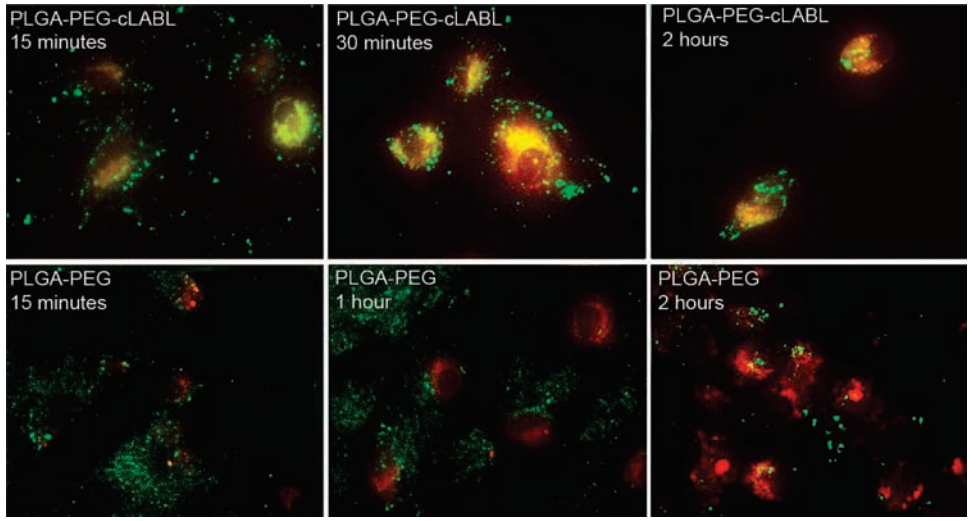

Figure 6. Fluorescent microscopy was utilized to assess the colocalization of nanoparticles (green) with lysosomes using Lysotracker (red). Images confirm the rapid binding of cLABL nanoparticles. In addition, cLABL nanoparticles rapidly trafficked to the lysosome with colocalization visible within 15 min. PLGA-PEG nanoparticles began to appear in lysosomes after 2 h. Nanoparticle binding time was 10 min, followed by washing and incubation for different times prior to cell imaging.

nanoparticle binding times determined spectroscopically. Punctate fluorescent patterns developed very quickly (∼15 min), which suggested rapid internalization of cLABL nanoparticles as well. Focusing on the cell midline and deconvoluting these images, that is, removing of out of focus fluoresent light, provided additional evidence that fluorescent foci were indeed inside the cells. In contrast, fluorescence in PLGA-PEG nanoparticle incubations remained relatively disperse over more than 2 h, and a similar localization of fluorescence was not noted until later times, providing circumstantial evidence that these particles did not enter cells to as great an extent.

Since studies revealed that the binding of cLABL nanoparticles occurred rapidly, experiments were designed to further determine if nanoparticles were indeed entering cells. Reports from Muro and others have verified that ICAM-1 mediates endocytosis along a novel pathway (*34*) and prior work by Labhasetwar and others demonstrated the endocytosis and exocytosis of PLGA nanoparticles in multiple cell lines (*35*, *36*). HUVEC were incubated at 4 °C to minimize energy dependent endocytic pathways. Uptake of nanoparticles was effectively mitigated at low temperature. For cLABL nanoparticles, association with cells was still apparent at 4 °C, confirming that the binding of these nanoparticles was not substantially reduced at low temperature (Figure 5).

Lysotracker was utilized to determine the rate at which nanoparticles were transported to lysosomes in HUVEC. This dye accumulates in lysosomes, staining them with red fluorescence; therefore, nanoparticles (green) accumulating in these organelles produced a yellow color. Some punctate yellow color was noted after only 15 min of incubation with cLABL nanoparticles subsequent to the 10 min binding time (Figure 6). PLGA-PEG nanoparticles remained dispersed for longer periods and did not appear in lysosomes until a minimum of 2 h had passed. Also, PLGA-PEG nanoparticles were much more dispersed in the cell culture. These studies were confirmed using a pulse−chase approach to label lysosomes with texas red dextran as reported by colleagues (*7, 29*). This method provided additional evidence of the rapid binding and internalization of cLABL nanoparticles. In addition, the green fluorescence of nanoparticles separated from lysosomes at later time points (Figure 7; ∼6 h.) Colocalization of nanoparticles with lysosomes was assessed semiquantitatively by summing the number of yellow pixels from images and dividing by the number of cells in a particular field of view at selected time

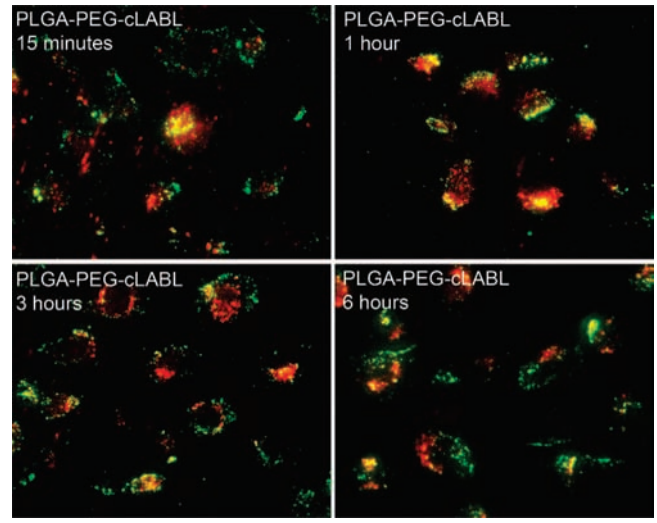

Figure 7. Lysosomes were labeled with fluorescent dextran (red) to confirm results obtained with Lysotracker using cLABL nanoparticles. Again, nanoparticles (green) rapidly colocalized with lysosomes and remained for about 4–6 h. For times >4–6 h, colocalization was no longer as apparent. Nanoparticle binding time was 10 min, followed by washing and incubation for different times prior to cell imaging.

points. Kinetic data derived from images showed that cLABL nanoparticles appeared in lysosomes to a much greater extent than PLGA-PEG nanoparticles (Figure 8). In addition, cLABL nanoparticles steadily disappeared from lysosomes after 4 h, while PLGA-PEG nanoparticle accumulation continued to steadily increase. This result suggested that cLABL nanoparticles, cleaved peptide with dye, or cleaved dye may have entered a recycling endosome, a process that is known to return ICAM-1 to the cell surface (*7*). Alternatively, cLABL nanoparticles, cleaved peptide with dye, or cleaved dye may have escaped the endolysosomal pathway and entered the cytosol; however, this hypothesis was not confirmed.

HUVEC were grown as monolayers to determine the effect of receptor upregulation on nanoparticle binding. For this study, the surface of HUVEC was incubated for ∼16–18 h with different concentrations of human IFN-γ. The relative ICAM-1 concentration on the surface of HUVEC was determined using fluorescent anti-ICAM-1 mAbs and normalized to basal concentrations of ICAM-1 on control cells (Figure 9A). ICAM-1

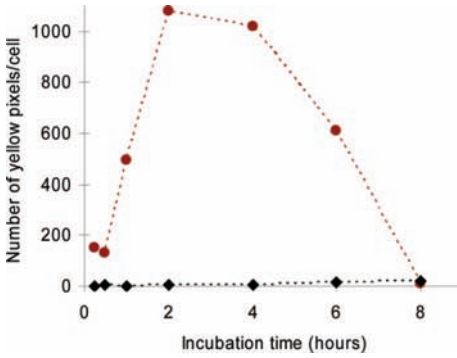

Figure 8. Yellow pixels signifying colocalization of nanoparticles (green) with lysosomes (red) were quantified over time demonstrating the rapid and transient localization of cLABL nanoparticles (circles) with lysosomes. Relatively fewer PLGA-PEG nanoparticles transitioned to lysosomes at later times (>2–4 h).

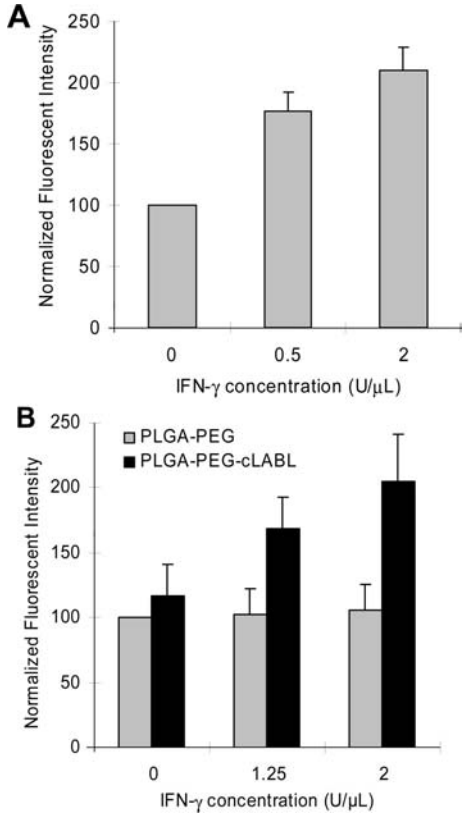

Figure 9. (A) Fluorescence spectrophotometry was used to quantify ICAM-1 expression in response to IFN-γ and normalized to basal ICAM-1 expression (blank). (B) Fluorescent spectrophotometry demonstrated that fluorescent intensity increased in HUVEC as IFN-γ concentration increased ($p < 0.001$ for 1.25 U/μL and 2 U/μL). Nanoparticle binding time was 1 h, followed by washing and incubation for 2 h prior to cell lysis or imaging.

concentration on the surface of HUVEC could be enhanced more than 2-fold. Upregulated ICAM-1 significantly enhanced the binding of cLABL nanoparticles (Figure 9B). The level of enhancement of nanoparticle interaction with HUVEC corresponded well to the relative enhancement of ICAM-1 expression induced by INF-γ. In contrast, PLGA-PEG nanoparticles showed no sensitivity to ICAM-1 expression levels. Studies were conducted using a long nanoparticle binding time (~1 h) to achieve similar fluorescence levels of targeted and untargeted nanoparticles at basal ICAM-1 expression levels (see Figure 2). Binding studies using upregulated ICAM-1 receptors were also verified by fluorescence microscopy; in this case, the overall

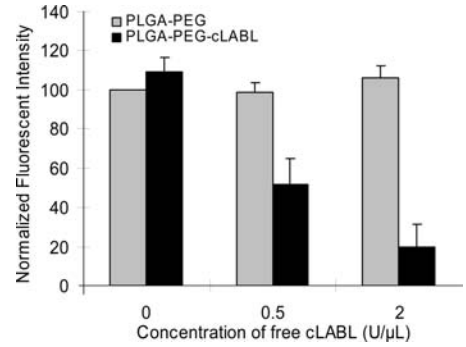

Figure 10. Fluorescent spectrophotometry demonstrates that binding of cLABL nanoparticles was inhibited by preincubating HUVEC with free peptide ($p < 0.001$ for 0.5 U/μL and 2 U/μL). PLGA-PEG nanoparticle binding was unaffected. Nanoparticle binding time was 1 h, followed by washing and incubation for 2 h prior to cell lysis or imaging.

fluorescence for cLABL formulations was enhanced as ICAM-1 expression increased on the cell surface (data not shown).

Free cLABL peptide was utilized as a competitive inhibitor of cLABL-modifed nanoparticle binding to HUVEC. The free peptide was incubated at various concentrations with cells prior to the introduction of nanoparticles to the media. The extended nanoparticle binding time (1 h) was again selected to minimize differentials between particle types attributable to binding kinetics (see Figure 3). Increasing free peptide concentration resulted in a corresponding decrease in fluoresence intensity; thus, even for long binding times, inhibition of nanoparticle-cell interactions was evident (Figure 10). The dramatic inhibition of the uptake of cLABL nanoparticles suggests a reduced role for other endocytic pathways in the uptake of these drug delivery vehicles. In a separate experiment, fluorescent micrographs confirmed the trend of free peptide inhibition of cLABL nanoparticle binding (data not shown). No inhibition was evident in PLGA-PEG nanoparticles via spectroscopic measurement of cell lysate fluorescence or in fluorescent micrographs.

DISCUSSION

Therapeutic interventions stand to benefit greatly from site-specific drug targeting. Substantial research efforts have focused on targeting molecular markers in cancer, infectious disease, and other diseases. The vascular endothelium remains a prime target for localizing drug delivery, and ICAM-1 is an attractive receptor for therapeutic interventions (*37*) and for targeting therapeutic drug carriers to vascular endothelium because it has shown to be upregulated during a variety of disease states, including infections, injuries, ischemia, autoimmune diseases, and certain cancers (*38–40*). In addition, localized upregulation of ICAM-1 facilitates the recruitment of leukocytes, suggesting that circulating drug carriers may selectively pool at these regions.

The cLABL peptide was derived from the I-domain of the α-subunit of LFA-1. This peptide has been shown to inhibit ICAM-1/LFA-1-mediated homotypic (*41*) and heterotypic (*42*) T-cell adhesion. Interestingly, the peptide blocked adhesion of T cells but not monocytes to pancreatic islet microvascular endothelium, thus demonstrating specificity (*43*). Recently, the cLABL peptide was shown to block the formation of microtubule-organizing center at the cell−cell contact region of human T-lyphotropic virus (HTLV-1)-infected T cells, suggesting that cLABL can be used to inhibit the spread of HLTV-1 from infected to noninfected human T cells (*44*). The mechanism of activity of this peptide is partly due to its binding to ICAM-1 at the LFA-1 binding site. Using monoclonal antibodies, it has been shown that the cLABL peptide binds to the D1 domain of

Table 3. Nanoparticle Colloidal Stability

	sizes (nm)	polydispersity	zeta potential (mV)
PLGA-PEG-cLABL- Alexa 488 in water	269 ± 19	0.181	−8.3 ± 0.9
PLGA-PEG-Alexa 488 in water	224 ± 14	0.116	−15.4 ± 1.2
PLGA-PEG-cLABL- Alexa 488 in media	292 ± 8.9	0.219	−13.4 ± 1.7
PLGA-PEG-Alexa 488 in media	272 ± 13	0.141	−21.3 ± 2.2

ICAM-1 (*32*). The peptide has been specifically designed with a stable conformation including a β-II′ turn at Asp4-Gly5-Glu6-Ala7 and a β-I turn at Pen1-Ile2-Thr3-Asp4 as determined by NMR spectroscopy (*45*). Molecular docking experiments suggest that this peptide binds to ICAM-1 at the F and C strands of D1 domain (*45*). By itself, the fluorescent-labeled cLABL peptide was internalized into activated Molt-3 T cells, presumably by ICAM-1 receptors (*32*). Recently, we have shown that the Ile2, Asp4, and Glu6 residues in cLABL and the β-turn structure at Asp4-Gly5-Glu6-Ala7 are important for peptide activity. In addition, a cyclic hexapeptide, cyclo(1,6)ITDGEA, derived from cLABL has been shown to have activity comparable with that of the parent cLABL; this cyclic peptide is currently being optimized by mutating some of its residues. In the future, this smaller cyclic peptide may also be used to target drugs or nanoparticles to cells with high expression of ICAM-1 as shown here.

Multiple groups have validated the potential of utilizing ICAM-1 as a molecular marker for targeting therapeutic particles. Eniola and others have reported the importance of multiple ligand–receptor interactions in achieving firm adhesion of particles in flow fields (*3, 46*). Elegant work by Muro and others has also established ICAM-1 as a valid target for delivering therapeutic nanoparticles. They demonstrated that nanoparticles conjugated with anti-ICAM-1 mAbs were rapidly bound and endocytosed by HUVEC via a novel endocytic pathway (*6*). Targeting the same receptor, cLABL nanoparticles reported here were also observed to bind rapidly and traffic to lysosomes in ∼1–2 h. Any minor differences in the trafficking kinetics of these two nanoparticle types may be due to the surface concentration of ligand on nanoparticles and/or the relative avidity of targeting molecules (mAbs vs peptides). Perhaps, the lower density and lower binding strength of cLABL to ICAM-1 may lead to easier disruption of binding events and a slightly more rapid transit to lysosomal compartments. It is also possible that cluster formation of ICAM-1 receptors on the cell surface during binding to cLABL-modified nanoparticles is different from that of anti-ICAM-1-modified particles.

In this work, we have successfully modified the surface of nanoparticles with cLABL peptide to target the vascular endothelium with upregulated ICAM-1. The cLABL peptide effectively mediated rapid nanoparticle binding and internalization. Binding was enhanced upon upregulation of ICAM-1 on HUVEC, and this binding could be specifically inhibited by blocking ICAM-1 receptor sites with free cLABL peptide. These results suggest that the cLABL-nanoparticle conjugates may have dual therapeutic applications, namely, inhibition of the infiltration of immune cells via blockage or internalization of ICAM-1 receptors coupled with the ability to localize drug delivery to regions of ICAM-1 upregulation.

ACKNOWLEDGMENT

These studies were funded by grants from the Juvenile Diabetes Research Foundation, the American Heart Association, and the NIH (1R03 AR054035-01A1, P20 RR016443, and P20 RR015563). We are sincerely grateful to the China Scholarship Council in the People's Republic of China for the partial support of Na Zhang as a postdoctoral researcher. Special thanks to Russ Middaugh and to Jeff Krise for the use of laboratory equipment.

Attachment of Peptide Building Blocks to Proteins Through Tyrosine Bioconjugation

Dante W. Romanini[†] and Matthew B. Francis*[,‡]

Department of Chemistry, University of California, Berkeley, California 94720-1460, and Materials Sciences Division, Lawrence Berkeley National Labs, Berkeley, California 94720-1460. Received June 21, 2007; Revised Manuscript Received October 4, 2007

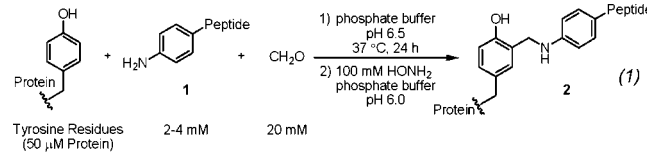
Recent efforts have yielded a number of short peptide sequences with useful binding, sensing, and cellular uptake properties. In order to attach these sequences to tyrosine residues on intact proteins, a three-component Mannich-type strategy is reported. Two solid phase synthetic routes were developed to access peptides up to 20 residues in length with anilines at either the N- or C-termini. In the presence of 20 mM formaldehyde, these functional groups were coupled to tyrosine residues on proteins under mild reaction conditions. The identities of the resulting bioconjugates were confirmed using mass spectrometry and immunoblot analysis. Screening experiments have demonstrated that the method is compatible with substrates containing all of the amino acids, including lysine and cysteine residues. Importantly, tyrosine residues on proteins exhibit much faster reaction rates, allowing short peptides containing this residue to be coupled without cross reactions.

INTRODUCTION

Structural studies on naturally occurring proteins have identified a number of short peptide sequences with functions ranging from ion sensing to cellular uptake enhancement (*1–4*). In terms of *de novo* strategies, techniques such as phage display (*5*) and combinatorial synthesis (*6*) have yielded numerous peptides with specific target binding capabilities. These building blocks allow new functions to be added to virtually any protein of interest, provided that a convenient strategy is available for their incorporation into the full sequence. While genetic methods often suffice for the introduction of desired sequences at the N- and C-termini or in flexible loops, such additions are limited to proteins that are expressed in exogenous hosts and are difficult to use for the introduction of peptides containing unnatural amino acids.

To expand the available options, several chemical strategies have been developed to incorporate synthetic peptides into full-sized proteins. In particular, the native chemical ligation has emerged as a powerful tool for the total or semisynthesis of proteins through the coupling of C-terminal thioesters to N-terminal cysteine residues (*7, 8*). To introduce peptides at locations other than the termini, a chemoselective Staudinger ligation has been used to attach peptide−phosphine conjugates to azides displayed on carbohydrate moieties (*9, 10*) and unnatural amino acids (*11–13*). More recently, a Cu(I)-catalyzed cycloaddition reaction has been reported for the attachment of peptides to azides and alkynes previously introduced using NHS−ester coupling reactions (*14*).

To add to these methods, we have applied a one-step Mannich-type coupling reaction for the conjugation of synthetic aniline-containing peptides (**1**) to native tyrosine residues on proteins (eq 1) (*15*). We have performed this reaction with peptides containing all the amino acids without cross reactivity, including the target side chain of tyrosine, in contrast to methods such as cysteine alkylation or lysine acylation. Furthermore, we have devised a simple synthetic route toward the reagents to allow the attachment of peptides via their N- or C-termini.



EXPERIMENTAL PROCEDURES

General Procedures and Materials. Unless otherwise noted, all chemicals and reagents were obtained from commercial sources and used without further purification. Protected amino acids were obtained from Novabiochem (San Diego, CA, USA). Water used in biological procedures or as a reaction or chromatography solvent was deionized using a NANOpure purification system (Barnstead, USA). Acetonitrile was HPLC-grade and was used without purification. Dry dimethylformamide was obtained from Acros Organics (USA). Chymotrypsinogen A, Hen Egg White Lysozyme, and RNase A were obtained from Sigma (USA) and used without purification. Enhanced Green Fluorescent Protein was obtained from Aaron Esser-Kahn (*16*).

Instrumentation and Sample Analysis Preparations. UV–vis spectroscopic measurements were conducted on a Tidas-II benchtop spectrophotometer (J & M, Germany). Centrifugations were conducted with the following: (1) Allegra 64R Tabletop Centrifuge (Beckman Coulter, Inc., USA); (2) Sorvall RC5C refrigerated high-speed centrifuge (Sorvall, USA); or (3) 5415D Benchtop Centrifuge (Eppendorf, Germany).

Desalting and removal of other small molecules of protein samples was achieved using Microcon YM-10 (10,000 MWCO) centrifugal concentrators (Millipore, USA).

^{1}H and ^{13}C spectra were measured with either a Bruker AVB-400 (400 MHz) or DRX-500 (500 MHz) spectrometer, as indicated. Proton chemical shifts are reported as δ in units of parts per million (ppm) relative to chloroform-*d* (δ 7.26, s) or deuterium oxide (δ 4.79, s). Multiplicities are reported as follows: s (singlet), d (doublet), t (triplet), q (quartet), dd (doublet of doublets), m (multiplet), and br (broadened). Coupling constants are reported as a *J* value in Hertz (Hz). The number

of protons (*n*) for a given resonance is indicated as nH and is based on spectral integration values. ^{13}C NMR spectra are reported as δ in units of parts per million (ppm) relative to chloroform-*d* (δ 77.23, t).

HPLC was performed on an Agilent 1100 series HPLC system (Agilent Technologies, USA). The mobile phases used were (A) ddH_2O + 0.1% TFA; (B) MeCN + 0.1% TFA. Sample analysis for all HPLC experiments was achieved with an inline diode array detector (DAD) and an inline fluorescence detector (FLD). Analytical chromatography was performed using a Jupiter 5 μm C18 300 Å reversed phase column (2.0 mm × 150 mm) (Phenomenex, USA). Preparative HPLC was performed on a Zorbax 300SB-C18 300 Å reversed phase column (9.4 mm × 250 mm) (Agilent).

Fast atom bombardment (FAB) mass spectra were obtained at the UC Berkeley Mass Spectrometry facility. Matrix assisted laser desoprtion-ionization time of flight (MALDI-TOF) mass spectra were obtained on Voyager DE-PRO (Applied Biosystems, USA). MALDI matrices were prepared daily as solutions (generally 10 mg/mL). For protein and peptide analysis, α-cyano-4-hydroxycinnamic acid (CHCA) or sinapinic acid in 3:2 MeCN/H_2O (0.1% TFA) were used. Electrospray ionization (ESI) mass spectra were obtained on a Bruker Apex II FT-ICR mass spectrometer (Bruker, Germany) or an API 150EX system (Applied Biosystems, USA) equipped with a Turbospray ion source and an Agilent 1100 series LC pump. Peptide chromatography was performed using a Jupiter 5 μm C18 300 Å reversed phase column (2.0 mm × 150 mm) (Phenomenex, USA). Protein chromatography was performed using a Jupiter 5 μm C5 300 Å reversed phase column (2.0 mm × 150 mm) (Phenomenex). A MeCN/ddH_2O gradient mobile phase containing 0.1% formic acid (250 μL/min) was used for all LC/MS. Protein mass reconstruction was performed on the charge ladder with Analyst software (version 1.3.1, Applied Biosystems).

For protein analysis, sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) was accomplished on a Mini-Protean apparatus (Bio-Rad, USA). Commercially available markers (Bio-Rad, USA) were applied to one lane of each gel for the calculation of apparent molecular weights. Visualization of protein bands was accomplished by staining with Coomassie Brilliant Blue R-250 (Fisher, USA). Gel imaging was performed on an EpiChem3 Darkroom system (UVP, USA). Relative protein amounts were determined from densitometry of gel bands with ImageJ software (NIH, USA).

3-(4-Azidophenyl)propionic Acid (9). To a solution of 3-(4-aminophenyl)propionic acid (200 mg, 1.21 mmol) in 20% sulfuric acid (20 mL) at 0 °C was added sodium nitrite (92 mg, 1.3 mmol) dissolved in ddH_2O (3 mL). After stirring for 15 min, a solution of sodium azide (157 mg, 2.42 mmol) in ddH_2O (3 mL) was added. Following continued stirring at 0 °C for 1 h, a white precipitate formed. The precipitate was collected by filtration, and the filtrate was placed at 4 °C for 2 h. Following this, a new crop of precipitate was collected. The combined white solids, 146 mg (64%), were used without further purification. ^1H NMR (500 MHz, $CDCl_3$): δ 7.20 (d, 2H, J = 8.5 Hz), 6.96 (d, 2H, J = 8 Hz), 2.94 (t, 2H, J = 7.5 Hz), 2.67 (t, 2H, J = 7.5 Hz). ^{13}C NMR (125 MHz, $CDCl_3$): δ 178.1, 138.1, 136.8, 129.6, 119.1, 35.4, 29.9. HRMS (FAB) calcd for $C_9H_9N_3O_2$ (M^+) 191.0695, found 191.0692.

2-(4-Azidophenyl)ethylamine, Tosylate Salt (10). To a stirring solution of 2-(4-aminophenyl)ethylamine (800 mg, 5.87 mmol) and *p*-toluenesulfonic acid monohydrate (3.91 g, 20.5 mmol) in ddH_2O (60 mL) at 0 °C was added sodium nitrite (425 mg, 6.16 mmol) dissolved in ddH_2O (3 mL). Upon the addition of sodium nitrite, the solution turned a slight orange−brown color. After stirring for 15 min, a solution of sodium azide (954 mg, 14.7 mmol) in ddH_2O (3 mL) was added. A thick white precipitate immediately formed. The precipitate was collected by filtration, and the filtrate was placed at 4 °C for 2 h. Following this, a new crop of precipitate was collected. The combined off-white solids, 1453 mg (74%), were used without further purification. ^1H NMR (500 MHz, D_2O): δ 7.64 (d, 2H, J = 8), 7.23 (d, 2H, J = 8 Hz), 7.28 (d, 2H, J = 8 Hz), 7.06 (d, 2H, J = 8 Hz), 3.21 (t, 2H, J = 7.5 Hz), 2.93 (t, 2H, J = 7.5 Hz), 2.35 (s, 3H). ^{13}C NMR (125 MHz, D_2O): δ 142.3, 139.2, 138.6, 133.1, 130.2, 129.3, 125.2, 119.2, 40.4, 32.1, 20.3. HRMS (FAB) calcd for $C_8H_{11}N_4$ (M^+) 163.0984, found 163.0982.

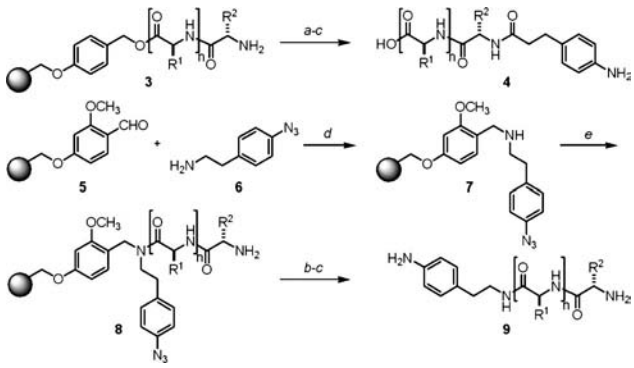
General Procedures for Peptide Synthesis. Peptides were synthesized using standard Fmoc-based chemistry. The side chain protecting groups used were as follows: Asn(Trt), Asp(tBu), Arg(Pbf), Cys(Trt), Gln(Trt), Glu(tBu), His(Trt), Lys(Boc), Ser(tBu), Thr(tBu), Trp(Boc), and Tyr(tBu). Synthesis was accomplished through one of the following methods: (1) manually, using 5 equiv of amino acid in dimethylformamide with *O*-(benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HBTU) (5 equiv) as the coupling reagent with 1-hydroxybenzotriazole (HOBT) (5 equiv) and *N*,*N*-diisopropylethylamine (DIPEA) (10 equiv) as additives; (2) on an Apex 396 Peptide Synthesizer (AAPPTech, USA) using 10 equiv of amino acid in *N*-methylpyrrolidone with diisopropylcarbodiimide (10 equiv) as the coupling reagent with HOBT (10 equiv) as an additive; and (3) by the Howard Hughes Mass Spectrometry and Peptide Synthesis facility at the University of California, Berkeley, on a model 433 peptide synthesizer (Applied Biosystems, USA).

All peptides were cleaved from resin using a cocktail of 94% trifluoroacetic acid, 5% H_2O, and 1% triisopropylsilane and precipitated in cold *tert*-butylmethylether. In the cases of peptides containing cysteine, ethanedithiol was added at 1% v/v to the cleavage cocktail. Crude peptides were purified using preparative reversed-phase HPLC and subsequently lyophilized before use.

Synthesis of C-terminal Anilines though Backbone Amide Linker: Reductive Amination to Form 7. To a 50 mL round-bottom flask equipped with a Teflon stirbar was added (4-formyl-3-methoxyphenoxy)butyryl AM resin (200 mg, 0.18 mmol aldehyde) (Novabiochem, USA) and dimethylformamide (5 mL). The resin was stirred and allowed to swell for 30 min. *N*,*N*-Diisopropylethylamine (219 mg, 1.69 mmol) was added, followed by a solution of **10** (595 mg, 1.78 mmol) in 99:1 DMF/AcOH (5 mL). Sodium cyanoborohydride (112 mg, 1.78 mmol) was added as a solid, and any residual solids were washed into the suspension with DMF. The mixture was stirred at room temperature overnight. The resin was then transferred to a fritted peptide synthesis tube (Econopak tubes, BioRad, USA) and washed with CH_2Cl_2 (5 mL), DMF (5 mL), 9:1 DMF/DIPEA (5 mL), DMF (2 × 5 mL), and CH_2Cl_2 (3 × 5 mL).

Acylation of 7. The resin was swelled in dry DMF (3 mL) for 15 min with gentle end-over-end agitation and then filtered. In a separate vessel were combined *N*-Fmoc-glycine (265 mg, 0.89 mmol), *O*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HATU, 312 mg, 0.89 mmol), and dry DMF (3 mL). After the addition of DIPEA (230 mg, 1.78 mmol), this solution was immediately added to the resin, and agitation was continued at room temperature for 6 h. The resin was then filtered and washed with DMF (3 × 5 mL), CH_2Cl_2 (3 × 5 mL), and MeOH (1 × 5 mL). UV quantitation of dibenzofulvene released during Fmoc removal generally showed between 60 and 90% yield over two steps. Following these steps, peptides were synthesized according to standard methods.

Scheme 1. Synthesis of Peptides with N- and C-Terminal Anilines[a]



[a] Reagents: (a) 3-(4-Azidophenyl)propionic acid, HBTU, HOBT, DIPEA, and DMF. (b) $(NH_4)_2S$, H_2O/DMF. (c) TFA, H_2O, TIPS. (d) $NaCNBH_3$, DMF. (e) *N*-Fmoc-AA, HATU, DIPEA, DMF, then Fmoc SPPS.

General Procedure for the Reduction of Aryl Azides on Solid Support. Dry resin containing the protected peptide was placed in a disposable peptide synthesis tube. Dimethylformamide (1800 uL) was added, and the resin was incubated with gentle end-over-end agitation for 15 min. Ammonium sulfide (aqueous solution, 21.2% w/v, 200 μL) was added to the resin suspension, which immediately turned green. Agitation was continued for 2 h at room temperature. The resin was then filtered and washed with DMF (4 × 5 mL), CH_2Cl_2 (3 × 5 mL), MeOH (5 mL), CH_2Cl_2 (5 mL), and MeOH (2 × 5 mL), and dried.

General Procedure for Protein Labeling Reactions. In a 0.6 mL conical centrifuge tube were combined solutions of protein (1 μL of 1 mM in pH 6.5 phosphate buffer), peptide (8 μL of 10 mM in pH 6.5 phosphate buffer), formaldehyde (3.3 μL of 150 mM in pH 6.5 phosphate buffer), and 100 mM phosphate buffer (pH 6.5) to a final volume of 20 μL. Final concentrations were 50 μM in protein, 4 mM in peptide, and 25 mM in formaldehyde. For peptides with reduced cysteines, tris(carboxyethyl)phosphine (TCEP) was added to a final concentration of 10 mM. Reactions were incubated at 37 °C in a heated incubator for 20–24 h. This procedure was preferable to incubation in a water bath, which led to solvent evaporation and condensation on the caps of the tubes and concomitant precipitation of protein. Reactions were quenched with the addition of a 1 M solution of hydroxylamine HCl (pH adjusted to 6 with 5 N NaOH) to a final concentration of 100 mM. Samples were purified using centrifugal dialysis or size-exclusion chromatography.

General Procedure for Immunoblots. Protein samples were separated by SDS−PAGE according to the procedure developed by Laemmli. Proteins were then transferred to nitrocellulose using a Mini Trans-Blot assembly (BioRad) in 13 mM $NaHCO_3$ buffer at pH 9.9 (with 20% MeOH) at 350 mA for 1 h. The nitrocellulose membrane was blocked with 5% dry milk in TBS-Tween20 at room temperature overnight. Primary antibody (mouse α-FLAG conjugated to horseradish peroxidase, Sigma, USA) was added at 1:1000 to 1:5000 dilution in 5% milk/TBS-T and was incubated at RT for 1–2 h. Membrane was washed 4 × 5 min in TBS-T and visualized by treatment with an ECL detection kit (Amersham Biosciences, UK) and exposing BioMax MR Film (Kodak, USA).

RESULTS AND DISCUSSION

To access aniline-bearing peptides, two similar solid-phase strategies were developed (Scheme 1). In the first, a peptide containing the Myc epitope (*17*) (EQKLISEEDL) was synthesized on acid-cleavable Wang resin (*18*) to yield **3**. The terminal amino group was then acylated with 3-(4-azidophenyl)propionic acid using HBTU as a coupling agent. Reduction of the aryl azide with ammonium sulfide in DMF/H_2O proved to be the most effective method for unmasking the aniline group, affording quantitative conversion in less than 2 h. Peptide−aniline **4** was obtained following resin cleavage and protecting group removal using trifluoroacetic acid (TFA).

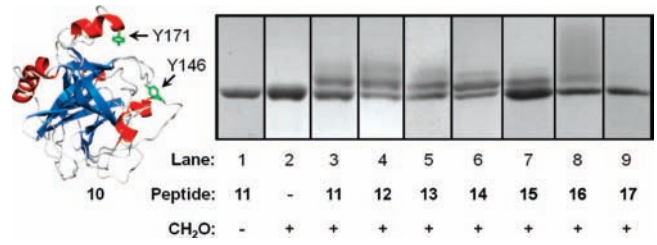


Figure 1. Chymotrypsinogen A (**10**) after incubation with 4 mM peptide aniline and 20 mM formaldehyde at 37 °C for 20 h. Higher molecular-weight bands indicate Mannich products. In the absence of formaldehyde (lane 1) or peptide (lane 2), no addition was observed.

A second synthetic route was developed to prepare peptides bearing an aniline at the C-terminus. Following the attachment of amine **6** to 4-formyl-3-methoxyphenoxybutyryl AM resin (*19*) (**5**) via reductive amination with $NaCNBH_3$, the resulting secondary amine (**7**) was acylated with N-Fmoc-glycine and HATU. Standard Fmoc solid-phase peptide synthesis was then carried out to produce a resin-bound protected peptide of the desired sequence (**8**). After the reduction of the azide with ammonium sulfide, peptide **9** was cleaved from the resin and deprotected using TFA. The peptides prepared using both methods were purified using HPLC and characterized via ESI-MS (Table 1).

Following the synthesis and purification of the peptides, tyrosine modification was achieved by exposing a 50 μM solution of α-chymotrypsinogen A (**10**) to 2–4 mM peptide−aniline and 20 mM formaldehyde in phosphate buffer (pH 6.5) at 37 °C for 24 h. The reactions were then treated with a solution of hydroxylamine (previously adjusted to pH 6.0), a step we have found to be necessary to cleave any remaining formaldehyde imines. This quenching step was found to be less effective at pH values below 6. Following the removal of the small molecules using ultrafiltration, protein modification could be observed through the appearance of a new higher molecular weight band in a Coomassie-stained SDS−PAGE gel (Figure 1, Lanes 3–8). Mass spectral analysis of these samples indicated an increase in mass corresponding to the peptide plus 1 equiv of formaldehyde (Figure 2a). No new bands were observed when either formaldehyde (lane 1) or the peptide (lane 2) was withheld from the reaction mixture. We have found that this amount of formaldehyde does not lead to protein cross-linking (protocols for this purpose typically use concentrations at least 10 times higher). It is notable that these concentrations of reactants are lower than our previously reported amounts necessary for adequate labeling using this method (*15*). In the case of these anilines, we have successfully performed the reaction with concentrations up to an order of magnitude lower.

In addition to the Myc tag, several other useful peptide anilines were synthesized and coupled to **10** (Table 1). This set included the FLAG epitope (**13**) (*20*), an HIV-Tat derived peptide (**14**) (*2*), a sequence that nucleates gallium arsenide nanocrystals (**15**) (*21*), and a sequence that binds terbium(III) ions (**16**) (*22*). In each case, 34% to 84% conversion was achieved, as determined using densitometry measurements after Coomassie staining (Table 1). In general, an increase in the number of flexible glycine residues between the aniline and the α-branched amino acids led to an increase in reactivity,

Table 1. Peptide Anilines Screened in the Mannich Reaction[a]

[a] An indicates the site of the aniline, either 3-(4-aminophenyl)propionic acid (N-terminal anilines, i.e., 4) or 2-(4-aminophenyl)ethylamine (C-terminal anilines, i.e., 9). Coupling yields (expressed as percents, $+n$ where n is the number of modifications) were determined through densitometry analysis of the Coomassie-stained gel in Figure 1. [b] Calculated peptide masses are monoisotopic. Spectra for multiply charged species were deconvoluted to the parent mass. [c] Peptide 17 was oxidized to form a cyclic disulfide.

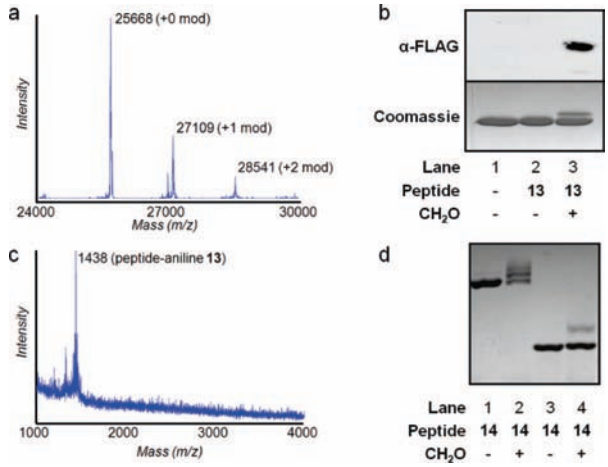

Figure 2. (a) Typical ESI-MS spectrum of chymotrypsinogen (**10**) modified with peptide-aniline **13**. (b) Immunoblot and Coomassie stained gel of **10** modified with **13**. Antibody binding was observed only when both peptide-aniline and formaldehyde are present. (c) MALDI-TOF MS of **13** after incubation with formaldehyde for 20 h at 37 °C. (d) Coomassie-stained gels of proteins following reaction with **11**. Proteins are eGFP (Lanes 1 and 2) and Myoglobin (Lanes 3 and 4).

suggesting that the steric environment around the aniline was crucial to its ability to undergo the Mannich reaction. Both N- and C-terminal peptide−anilines provided similar coupling results. Notably, a peptide containing free cysteine residues (**16**) participated in the reaction, but upon oxidation to form disulfide **17**, reactivity was abrogated.

To confirm that the new species observed in the gels contained desired peptide, a sample of chymotrypsinogen A modified with FLAG sequence **13** was transferred to nitrocellulose and probed with HRP-conjugated anti-FLAG antibodies. The presence of the FLAG epitope was only detected in reactions containing both peptide−aniline and formaldehyde (Figure 2b).

Trypsin digests of Chymotrypsinogen labeled with **14** indicated the modification of a peptide fragment containing Y171. The small amount of double labeling is presumed to occur at Y146, which has been observed to participate in other coupling reactions (*15*, *23*); however, neither this nor other modified fragments could be identified in the digested samples.

In previous studies (*15*), we have observed that this coupling reaction proceeds much more rapidly on proteins than on peptide and small molecule substrates. Presumably, this is due to hydrophobic interactions between the reactive partners that serve to increase the effective concentration. This reactivity difference suggested that tyrosine-containing peptides could also be used as substrates in the reaction. To examine this possiblity, peptides **13**, **16**, and **17** were incubated with formaldehyde under reaction conditions in the presence and absence of protein. No peptide cross-linking was observed with MALDI-TOF mass spectrometry (Figure 2c). These experiments demonstrate the compatibility of tyrosine-containing peptides with the Mannich-type reaction, which is a potential advantage of this method compared to lysine- and cysteine-targeting strategies. While it is likely that cross-reactivity could occur in some situations, these results suggest that a wide range of sequences may be compatible with the Mannich-type coupling. Consistent with previous observations of this reaction, eGFP (*24*) (which has several exposed tyrosines on its surface when viewed as a crystal structure) participates readily, while myoglobin demonstrates poor levels of reactivity (Figure 2d). Clearly, the local environments of tyrosine residues have a significant impact on their reactivity, a feature that is anticipated to yield significant advantages for site selectivity as these effects are elucidated.

CONCLUSIONS

We have demonstrated the utility of a previously reported three-component tyrosine bioconjugation reaction for the coupling of peptides to preexisting proteins. Such ligations are challenging propositions for which few methods exist. This method should find use in cellular uptake and trafficking studies, protein purification, and materials applications. It also provides a simple way to add peptides containing unnatural amino acids to full-size proteins. We are currently investigating these peptides for use in other bioconjugation reactions involving anilines (*25*), and we are continuing to examine the mechanisms of bioconjugation reactions to improve and expand the options available to protein chemists and biochemists.

ACKNOWLEDGMENT

We gratefully acknowledge the NIH (GM072700-01) and the DOE Nanoscale Science, Engineering, and Technology Program (NSET) for funding. We also thank David King and Jason Rush for lending their peptide synthesis knowledge and Arnold Falick for his mass spectrometry expertise.

Streptavidin in Antibody Pretargeting. 5. Chemical Modification of Recombinant Streptavidin for Labeling with the α-Particle-Emitting Radionuclides ^{213}Bi and ^{211}At

D. Scott Wilbur,*,† Donald K. Hamlin,† Ming-Kuan Chyan,† and Martin W. Brechbiel‡

Department of Radiation Oncology, University of Washington, Seattle, Washington, and National Cancer Institute, National Institutes of Health, Bethesda, Maryland. Received June 30, 2007; Revised Manuscript Received September 29, 2007

We are investigating the use of recombinant streptavidin (rSAv) as a carrier molecule for the short-lived α-particle-emitting radionuclides ^{213}Bi ($t_{1/2}$ = 45.6 min) and ^{211}At ($t_{1/2}$ = 7.21 h) in cancer therapy. To utilize rSAv as a carrier, it must be modified in a manner that permits rapid chelation or bonding with these short-lived radionuclides and also modified in a manner that diminishes its natural propensity for localization in the kidney. Modification for labeling with ^{213}Bi was accomplished by conjugation of rSAv with the DTPA derivative *p*-isothiocyanatobenzyl-CHX-A″ (CHX-A″), **3a**. Modification for *direct labeling* with ^{211}At was accomplished by conjugation of rSAv with an isothiocyanatophenyl derivative of a *nido*-carborane (nCB), **3b**, or an isothiocyanatophenyl-dPEG/decaborate(2-) derivative, **3c**. After conjugation of the chelating or bonding moiety, rSAv was further modified by reaction with an excess (50–100 equivalents) of succinic anhydride. Succinylation of the lysine amines has previously been shown to greatly diminish kidney localization. rSAv modified by conjugation with **3a** and succinylated rapidly radiolabeled with ^{213}Bi (<5 min), providing a 72% isolated yield. ^{211}At labeling of modified rSAv was accomplished in aqueous solution using chloramine-T as the oxidant. Astatination of rSAv conjugated with **3b** and succinylated occurred very rapidly (<1 min), providing a 50% isolated radiochemical yield. Astatination of rSAv conjugated with **3c** and succinylated was also very rapid (<1 min) providing 66–71% isolated radiochemical yields. Astatination of succinylated rSAv, **2a**, which did not have conjugated borane cage moieties, resulted in a much lower radiolabeling yield (18%). The ^{213}Bi or ^{211}At-labeled modified rSAv preparations were mixed with the corresponding ^{125}I-labeled rSAv, and dual-label in vivo distributions were obtained in athymic mice. The in vivo data show that ^{213}Bi-labeled succinylated rSAv [^{213}Bi]**6a** has tissue concentrations similar to those of ^{125}I-labeled modified rSAv [^{125}I]**6b**, suggesting that ^{213}Bi is quite stable toward release from the chelate in vivo. In vivo data also indicate that the ^{211}At-labeled rSAv conjugated with **3b** or **3c** and succinylated are stable to in vivo deastatination, whereas succinylated rSAv lacking a boron cage moiety is subject to some deastatination. The modified rSAv conjugated with *nido*-carborane derivative **3b** has a higher retention in many tissues than rSAv without the carborane conjugated. Interestingly, the rSAv conjugated with **3c**, which also contains an m-dPEG$_{12}$ moiety, has significantly decreased concentrations in blood and other tissues when compared with those of direct-labeled rSAv, suggesting that it may be a good candidate for further study. In conclusion, rSAv that has been modified with CHX-A″ and succinylated (i.e., **5a**) may be useful as a carrier of ^{213}Bi. The encouraging results obtained with the PEGylated decaborate(2-) derivative **3c** and succinylated (i.e., **5c**) suggests that its further study as a carrier of ^{211}At in pretargeting protocols is warranted.

INTRODUCTION

α-Emitting radionuclides are of high interest for targeted radionuclide therapy (TRT[1]) of disseminated (micro)metastatic cancer (*1–4*). The short path length of the α-particle results in the deposition of a large amount of energy in a few cell diameters, providing very effective cell killing for single cells or small clumps of cells without affecting the surrounding normal tissues. Two of the most promising α-particle-emitting radionuclides for use in TRT are ^{213}Bi and ^{211}At (*5*). Unfortunately, both of these radionuclides have relatively short half-lives (45.6 min and 7.21 h, respectively), making it imperative that rapid and efficient radiolabeling chemistry be available or developed. The short half-lives of these radionuclides also makes it imperative that the cancer-targeting carrier molecule be able to localize rapidly to the cancer cells in the body. Furthermore, the high cytotoxicity of these radionuclides requires that they remain attached to the carrier molecule during the period they are present in the body.

The cancer-targeting agent is a critical component in TRT. While there are a large number of biological agents to choose from, making the choice of an appropriate cancer-targeting agent to carry highly cytotoxic, short half-lived, α-emitting radionuclides is not easy. For systemic delivery, intact monoclonal antibodies (mAbs) and their F(ab′)$_2$ fragments are questionable for carrying ^{213}Bi or ^{211}At because of their inherent properties (*6–8*) and unfavorable tumor-targeting pharmacokinetics. Smaller mAb fragments, engineered proteins, and peptides are also unfavorable because of their propensity to localize in the kidney, although a number

In the structures of the borane cage moieties, the open circles represent boron or B-H atoms and solid (black) circles represent carbon atoms.

of studies to decrease localization have been published (*9–13*). As an alternative, we have been investigating the use of two different two-step approaches[2] for targeting ^{213}Bi and ^{211}At to cancer cells in vivo termed pretargeting. In one form of the two-step pretargeting approach (*14, 15*), monoclonal antibodies (mAbs) are conjugated with a biotin derivative, and that conjugate is injected to target the cancer cells. At some time later (i.e., 24 h post injection of the mAb-biotin), a radiolabeled recombinant streptavidin (rSAv) is injected to bind with the tumor cell-surface-associated mAb-biotin.

Proteins, such as rSAv, cannot be labeled with ^{213}Bi or ^{211}At without conjugation of a binding or bonding moiety (BM) first. Furthermore, proteins such as rSAv, which have molecular weights of ~50 kDa, can localize rapidly to the kidney (*16*), posing the same serious limitations of mAb fragments and peptides. Fortunately, prior studies have reported several methods to decrease the kidney localization of rSAv without significantly affecting the biotin-binding affinity (*17–19*). Of these options, succinylation of the amines on rSAv is perhaps the most readily achieved and provides low kidney concentrations. Thus, the use of rSAv as a carrier of radionuclides requires two modification steps: the first is to conjugate a binding or bonding moiety, and the second is to react all (or most) of the remaining surface lysine amines with a molecule that neutralizes the lysine's positive charge, such as a succinic anhydride moiety.

A cyclohexyl-DTPA derivative, isothiocyanato-benzyl-CHX-A″, was chosen for conjugation with rSAv for ^{213}Bi labeling. This choice was based on our prior studies (*20, 21*) and those of other investigators (*22–26*) that have demonstrated that proteins conjugated with the CHX-A″ moiety are rapidly labeled with ^{213}Bi in high radiochemical yields. The choice for the modification of rSAv to attain efficient ^{211}At labeling was not as readily apparent. Unlike radioiodination, direct astatination of proteins can result in an unstable label when injected in vivo (*27, 28*). The application of *p*- or *m*-astatobenzoate NHS esters often used in protein astatinations (*29, 30*) was considered for labeling rSAv. However, the use of such astatinated benzoate derivatives appeared problematic because of the requirement of modification of rSAv to eliminate kidney localization following the radiolabeling step. Additionally, it was desirable to obtain a simpler and perhaps higher yielding approach for astatination of rSAv. In other studies, we have shown that astatination of a mAb Fab′ can be accomplished rapidly in high yield using borane cage moieties (*31*). Because of the differences noted previously for *nido*-carborane conjugates and decaborate(2-) conjugates, we felt that it was important to evaluate both options in this investigation. The protein-reactive α-emitting radionuclide's binding (chelating) or bonding moieties used to modify rSAv are shown in Figure 1.

The primary goals of this investigation were to determine whether modifications made to rSAv for ^{213}Bi and ^{211}At labeling altered its in vivo properties and whether the rSAv conjugates prepared for study were stable to in vivo release of the radionuclides. A secondary goal was to evaluate the efficiency of radiolabeling with these expensive radionuclides, as that may impact on whether these radionuclides can be successfully applied to cancer therapy. The results obtained in the investigation are reported herein.

EXPERIMENTAL PROCEDURES

General Procedures. All chemicals purchased from commercial sources were of analytical grade or better and were used without further purification. Succinic anhydride and most other chemicals were obtained from Aldrich (Sigma-Aldrich Corp., Milwaukee, WI). The m-dPEG$^{TM}_{12}$ amine was obtained from Quanta BioDesign, Ltd. (Powell, OH). Chloramine-T (ChT) and phosphate-buffered saline (PBS) were obtained from Sigma (St. Louis, MO). Avidin was obtained from Pierce (Rockford, IL). Bismuth metal used as the target for the preparation of ^{211}At was obtained from Alpha Aesar (Ward Hill, MA) as Puratronic 99.999%. Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μm) prior to use. Recombinant streptavidin (rSAv) was obtained from Boehringer Mannheim (Indianapolis, IN). Silica gel chromatography was conducted with 70–230 mesh 60 Å silica gel (Aldrich Chemical Co.). Sephadex G-25 desalting columns (PD-10 and NAP-10) were obtained from Amersham Biosciences (Piscataway, NJ). Centricon-30 centrifugation concentrators were obtained from Amicon (Beverly, MA).

Radioactivity. All radioactive materials were handled according to approved protocols at the University of Washington. Na[^{125}I]I was purchased from Perkin-Elmer Life and Analytical Services as high concentration/high specific activity radioiodide in 0.1 N NaOH. [^{225}Ac]Actinium nitrate was purchased from the Department of Energy (Oak Ridge, TN) on a column (actinide resin, 100–200 mesh, EiChrom Technology Inc., Darien, IL) ready for elution of ^{213}Bi in the radiolabeling experiments. ^{211}At was produced by an α-particle irradiation (28 MeV) of natural bismuth, ^{209}Bi(α, 2n)^{211}At, on a Scandatronix MC-50 cyclotron. The ^{211}At activity was distilled from the bismuth target at 650–700 °C into a cooled trap as previously described (*32*). The dry distillation of ^{211}At was conducted in a charcoal filtered glovebox (Innovative Technologies, radioisotope glovebox). The distilled ^{211}At was trapped in a cooled

[2]The term two-step is often not accurate because a clearing step may be used to rid the blood of remaining mAb-biotin or mAb-SAv conjugates, in effect making it a three-step approach.

(−78 °C) vial or peek tubing (1 mm ID × 35 cm length) (*33*) and was rinsed from the vial with $CHCl_3$ or 0.05 N NaOH for use in the labeling experiments.

Radiohalogenation reactions were conducted in a charcoal-filtered Plexiglas enclosure (Biodex Medical Systems Inc., Shirley, NY) housed within a radiochemical fume hood. The radiohalogenation reactions (^{125}I or ^{211}At) were conducted in vials capped with Teflon-coated septa. Reaction vials were vented through a 10 mL charcoal-filled syringe. Additions of reagents and radionuclides to, or removal of materials from, radiohalogenation vials were conducted by passing a syringe needle through the septa.

Measurement of ^{213}Bi, ^{211}At, and ^{125}I was accomplished on a Capintec CRC-15R. The calibration numbers provided by Capintec Technical Services were used for measurement of ^{213}Bi and ^{211}At on these instruments. Tissue samples containing these radionuclides were counted in a Wallac Wizard gamma counter (PerkinElmer Life and Analytical Sciences, Wellesley, MA). The tissue samples had either ^{213}Bi or ^{211}At, along with ^{125}I. Total radioactivity counts (cpm) for the samples were obtained by counting in all channels of the detector. To determine the counts from each radionuclide in tissues, the tissue samples were allowed to decay for 1–2 days, resulting in <0.01% ^{213}Bi being present (<0.01%) or 3–5 days resulting in <0.1% ^{211}At being present. Re-counting tissue samples after the decay period provided the ^{125}I counts. The total counts and ^{125}I counts for tissues were transferred to an Excel (Microsoft Corp., Redmond, WA) spreadsheet. The counts for ^{213}Bi or ^{211}At radioactivity were calculated by subtracting the ^{125}I counts from the total cpm for each tissue sample, and the ^{213}Bi and ^{211}At counts were corrected for the decay of each sample during the counting process.

Spectral Analyses. ^1H and ^{11}B NMR spectra for compounds were obtained on either a Bruker AV 300 (300 MHz) or Bruker AV 500 (500 MHz) instrument. ^1H chemical shifts are expressed as ppm using tetramethylsilane as an internal standard (δ = 0.0 ppm). ^{11}B chemical shifts were referenced to BF_3OEt_2 as an external standard. High-resolution mass spectra (HRMS) and low-resolution mass spectra (LRMS) were obtained on a Bruker APEX III 47e Fourier Transform Mass Spectrometer using electrospray ionization. For analysis, the samples were dissolved in 50/50 MeOH/H_2O and were introduced by an integral syringe infusion pump (Cole Parmer Series 74900).

Analytical Chromatography. All synthetic reactions were monitored by HPLC. Samples were assessed on a system that contained a Hewlett-Packard quaternary 1050 gradient pump, a variable wavelength UV detector (254 nm), and a Varex ELSD MKIII evaporative light-scattering detector. Analyses of HPLC data were conducted using Hewlett-Packard HPLC ChemStation software. Reversed-phase HPLC chromatography was carried out on an Alltech Altima C-18 column (5 μm, 250 × 4.5 mm) using a gradient solvent system at a flow rate of 1 mL/min. A gradient of MeOH and H_2O/0.1% HOAc was used. Starting with 40% MeOH, the initial solvent mixture was held for 2 min, then the gradient was increased to 100% MeOH over the next 10 min, then held at 100% MeOH for 8 min. Retention times (t_R) under these conditions for new compounds are provided with the compound experimental data.

HPLC separations of the (nonradioactive) modified rSAv were conducted on a Hewlett-Packard isocratic system consisting of a Model 1050 pumping system and a Model 1050 Multiple Wavelength Detector (280 nm). The proteins were evaluated on a Protein Pak 300 SW glass size-exclusion column (10 μm, 8 mm × 30 cm, Waters Corporation, Milford, MA) run at 1.0 mL/min, eluting with 50 mM sodium phosphate buffer (pH 6.8), which contained 300 mM NaCl, 1 mM EDTA, and 1 mM sodium azide. Analyses of the HPLC data were conducted on Hewlett-Packard HPLC ChemStation software. Retention time (t_R) for the succinylated r-SAv was 9.8 min and that for boron cage-modified rSAv was ~10.5 min using these conditions.

Radiolabeled rSAv. Size-exclusion chromatography was also used to evaluate radiolabeled modified rSAv. HPLC separations of radioiodinated proteins were conducted on a system consisting of a Model 1050 pumping system, a Waters Lambda-Max 481 UV detector, and a Beckman model 170 radioisotope detector. The detectors were connected to a computer through a Hewlett-Packard Model 35900 interface, and data from the chromatograms was obtained on a computer running Hewlett-Packard ChemStation Software. The same size-exclusion column and elution conditions were used for the radiolabeled proteins as unlabeled proteins.

Isoelectric Focusing. IEF was obtained on a Novex PowerEase 500 instrument with the XCell II chamber using Invitrogen (Novex) precast gels, pH 3–10 (1.0 mm, 12 well), running under the standard IEF Program. The protein was stained with GelCode Blue Stain (Pierce). IEF standards were from Serva Electrophoresis GmbH: (pI) 10.7, cytochrome C; 9.5, ribonuclease A; 8.3, 8.0, 7.8, lectin; 7.4, 6.9, myoglobin; 6.0, carbonic anhydrase; 5.3, 5.2, δ-lactoglobulin; 4.5, trypsin inhibitor; 4.2, glucose oxidase; 3.5, amyloglucosidase.

Syntheses. The following compounds were prepared as previously described: isothiocyanatobenzyl-CHX-A″ DTPA[3], **3a** (*34*) ; 3-(3′-(*nido*-carboranyl)propionyl)amino-1-isothiocyanatobenzene, **3b** (*35*); 5-*N*-(*tert*-butyloxycarbonyl)-aminoisophthalate bis-tetrafluorophenyl ester, **7** (*36*); $[Et_3NH]B_{10}H_9$-CO-trioxatridecanediamine, **10** (*31*).

5-(*N*-*tert*-Butyloxycarbonylamido)-3-(m-dPEG$_{12}$-amido)-isophthalamic Acid 2,3,5,6-Tetra-fluorophenyl Ester, 9. A solution of m-dPEG$_{12}$-amine, **8**, (100 mg, 0.18 mmol) in anhydrous DMF (2 mL) was added dropwise over 30 min to a solution of **7** (207 mg, 0.36 mmol) and Et_3N (30 μL, 0.36 mmol) in anhydrous DMF (5 mL) at room temperature. After the addition was complete, the reaction mixture was stirred at room temperature for an additional 10 min, then the volatile materials were removed under vacuum. The crude residue was purified by silica gel chromatography, eluting with 10% MeOH/EtOAc to give 138 mg (80%) of **9** as a colorless oil. ^1H NMR (CD_3OD, 300 MHz): δ 1.59 (s, 9H), 3.35 (s, 3H), 3.51–3.71 (m, 48H), 7.46–7.58 (m, 1H), 8.23 (t, J = 2.0 Hz, 1H), 8.28 (t, J = 1.6 Hz, 1H), 8.51 (t, J = 1.9 Hz, 1H), 8.72 (t, J = 5.2 Hz, 1H). HRMS (ES+) $C_{44}H_{66}N_2O_{17}F_4Na$ $(M + Na)^+$; calcd, 993.4195; found, 993.4193. HPLC: t_R = 14.2 min.

5-(*N*-*tert*-Butyloxycarbonylamido)-3-(m-dPEG$_{12}$-amido)-1-((13′-nonahydro-*closo*-decaborate(2-))-4,7,10-trioxatridecanediamine)-aminoisophthalate, 11. A solution containing $[Et_3NH]$**10** (53 mg, 0.113 mmol), **9** (110 mg, 113 μmol), Et_3N (32 μL, 0.227 mmol), and anhydrous DMF (5 mL) was stirred at room temperature for 2 h. EtOAc (20 mL) was added, and the mixture was stirred for an additional 10 min. The liquid was decanted from the residue. The crude product was redissolved in MeOH/water (1/1) and purified by flash chromatography (Biotage C18 FLASH 25+M column), eluting with a gradient mixture composed of MeOH and 0.1% aqueous HOAc (pH 3.25). The starting gradient mixture of 25% MeOH was held for 2 min, increased to 100% MeOH over the next 10 min, then held at 100% MeOH for 8 min. Isolation yielded 112 mg (78%) of **11** as a light-brown tacky solid. ^1H NMR (DMSO-d_6, 500 MHz): δ 1.17 (t, J = 7.3 Hz, 9H), 1.46 (s, 9H), 1.71–1.81 (m, 4H), 3.04–3.09 (m, 6H), 3.21 (s, 3H), 3.29 (dd, J = 6.6, 12.4 Hz, 2H), 3.39–3.72 (m, 71H), 7.72 (bs, 1H), 7.82 (s, 1H), 7.98 (d, J = 8.0 Hz, 2H), 8.43 (t, J = 5.5 Hz, 1H), 8.47 (t, J =

[3]This reagent is available commercially from Macrocyclics, Dallas, TX (www.macrocyclics.com).

5.5 Hz, 1H), 9.28 (bs, 1H), 9.58 (s, 1H). ^{11}B NMR (DMSO-d_6, 96.29 MHz): δ −5.03 (2B), −15.90 (2B), −24.66 (6B). LRMS (MALDI$^-$) $C_{49}H_{95}B_{10}N_4O_{20}K$ $(M + K)^-$; calcd, 1208.7; found, 1208.8. HPLC: t_R = 11.0 min.

5-(Isothiocyanato)-3-(m-dPEG$_{12}$-amido)-1-((13′-nonahydro-*closo*-decaborate(2-))-4,7,10-trioxatridecanediamine)-aminoisophthalate, 3c. A quantity of **11** (100 mg, 0.079 mmol) was dissolved in neat TFA (1 mL), and that solution was stirred at room temperature for 10 min. The excess TFA was removed under a stream of Argon, then the residue was dissolved in a solution of MeOH (3 mL) and Et_3N (0.2 mL). After solvents were evaporated on a rotoevaporator, the deprotected compound was dried under vacuum for 2 h, then dissolved in anhydrous DMF (1 mL).

To the DMF solution was added thiocarbonyldiimidazole (28 mg, 0.157 mmol). That solution was stirred at room temperature for 1 h. Et_2O was added, and the solution was stirred for an additional 30 min. The solvents were decanted, and the residue was washed with EtOAc (3 × 15 mL) to afford 91 mg (95%) of **3c**. ^{1}H NMR (DMSO-d_6, 500 MHz): δ 1.16 (t, J = 7.2 Hz, 9H), 1.71–1.77 (m, 4H), 3.06 (q, J = 7.3 Hz, 6H), 3.16 (s, 1H), 3.21 (s, 2H), 3.30 (dd, J = 6.6, 12.3 Hz, 2H), 3.39–3.74 (m, 71H), 7.40 (s, 2H), 7.93 (d, J = 8.1 Hz, 2H), 8.24 (s, 1H), 8.51 (s, 1H), 8.66 (t, J = 5.2 Hz, 1H), 8.75 (t, J = 5.1 Hz, 1H). ^{11}B NMR (DMSO-d_6, 96.29 MHz): δ −5.25 (2B), −16.67 (2B), −25.99 (6B). HPLC: t_R = 13.1 min.

Succinylation of rSAv, 2a. Succinylation of rSAv was accomplished as previously described (*17*). Briefly, a 200 μL aliquot of a 5 mg/mL solution of rSAv (1 mg, 1.9×10^{-2} μmol) was added to 370 μL of 50 mM $NaHCO_3$ buffer (pH 8.5). To this solution was added 100 equivalents (188 μg; 1.88 μmol) of succinic anhydride in 20 μL of DMSO. After 30 min at room temperature, the contents were transferred to a Centricon-10 and concentrated to approximately 50 μL. PBS (500 μL) was added, and the solution was again concentrated to 50 μL. This wash step was repeated 5 times.

Preparation of Succinylated rSAv-CHX-A″, 5a. Three steps were taken to prepare the rSAv conjugate, **5a**, such that it could be radiolabeled with ^{213}Bi. The first step involved demetalation of rSAv. The second step involved conjugation of the CHX-A″ chelate, **3a**, then succinylation of that conjugate. The third step was purification of the modified rSAv under demetalation conditions. The conditions used in each step are described below.

Demetalation of rSAv. The rSAv (5 mg) was dialyzed against 2 L of metal-free HEPES buffer with a minimum of 5 buffer changes over 3 days at 4 °C using a Slide-A-Lyzer 10K cassette (Pierce, Rockford, IL). All buffers used were prepared with metal-free (18 mega-ohm) water passed over a column of Chelex-100 resin (250 g/12 L). Chelex-100 resin (10 g) was added to each buffer change. The demetallated mAbs were removed from dialysis and placed in acid-washed 15 mL conical vials, and care was taken to ensure that no metals were introduced.

Conjugation of 3a and Succinylation. To the demetallated rSAv (4.5 mg, 85 nmol) in 1 mL of demetallated HEPES buffer at pH 8.5 at room temperature was added 44 μL (1.7 μM) of an isothiocyanatobenzyl-CHX-A″, **3a**, solution (22.4 mg/mL in DMSO). The reaction mixture was stirred at room temperature for 18 h to yield **4a**. After that time, 0.43 mg (4.24 μmol) of succinic anhydride was added, and the mixture was stirred for another 1 h at room temperature to give **5a** (80%, 4.5 mg/mL, 0.8 mL).

Purification and Second Dialysis. After the conjugation reaction was complete, the reaction mixture was placed in a dialysis cassette and dialyzed against 3 × 2 L of metal-free citrate buffer (50 mM sodium citrate, 150 mM NaCl, 0.05% NaN_3 adjusted to pH 5.5) over 2 days and against 4 × 2 L of 150 mM NaCl for 2 days. The number of CHX-A″ chelates per rSAv molecule in **5a** was assessed using the yttrium−arsenazo III complex spectrophotometric assay (*37*). The modified rSAv was stored at 4 °C until used.

Preparation of Succinylated rSAv-nCB, 5b. To 2.5 mg (500 μL at 5 mg/mL in PBS at pH 7.2) of rSAv was added 1 mL of 50 mM sodium bicarbonate buffer at pH 8.5, followed by 40 μL of a solution of **3b** (4.85 mg/mL in DMSO). This was allowed to react overnight at room temperature. The solution was then passed over a PD-10 column (Pharmacia, Uppsala, Sweden) eluting 1 mL fractions with 0.9% saline. The protein fractions were combined and concentrated using Centricon-30 (Millipore, Bedford, MA) to give 2.4 mg (400 μL of 6 mg/mL; 96%) of rSAv-nCB, **4b**.

To 1.0 mg of rSAv-nCB (167 μL of 6 mg/mL in 0.9% saline solution) was added 334 μL of 50 mM sodium bicarbonate buffer at pH 8.5, followed by 20 μL of a solution of 4.7 mg/mL succinic anhydride in DMSO. After 30 min at room temperature, the solution was passed over a PD-10 column and collected in 0.9% saline. The protein fractions were combined and concentrated in a Centricon-30 to give 0.94 mg (260 μL of 3.6 mg/mL solution; 94%) of succinylated rSAv-*nido*-carborane, **5b**.

Preparation of Succinylated rSAv-B$_{10}$H$_9$-m-dPEG$_{12}$, 5c. To 11 mg (207 nmol) of rSAv in 1 mL of 500 mM sodium borate buffer at pH 8.0 was added 137 μL (2.08 μmol) of a solution of **3c** (20 mg/mL in DMF). This was allowed to react overnight at room temperature. The solution was then passed over a PD-10 column and collected in PBS at pH 7.2. The protein-containing fractions were combined and concentrated in Centricon-30 to give 790 μL of a 12.7 mg/mL solution (91%). To 700 μL of this solution (8.9 mg) was added 700 μL of 100 mM sodium bicarbonate at pH 8.5, followed by 1.68 mg of succinic anhydride in 30 μL of DMF. After 30 min at room temperature, the solution was concentrated in Centricon-30 and washed with 4 × 1 mL of PBS at pH 7.2. This yielded 7.9 mg (1.1 mL at 7.2 mg/mL; 88%) of succinylated rSAv-B10/dPEG, **5c**.

Preparation of [^{213}Bi]6a. ^{213}Bi was obtained from ^{225}Ac ($t_{1/2}$ = 10 days) by elution of the generator column with 1 M HCl using a dual syringe pump (*38*). As the elution proceeded, the ^{213}Bi/HCl solution was mixed with water (in a plastic chamber) and run across an MP-50 cation-exchange column. ^{213}Bi was trapped on the ion-exchange column, and the column was removed from the generator system. The column was then eluted with freshly prepared 0.1 N HI, then the pH of the eluant was adjusted to 4.2–4.5 using 3 M NH_3OAc (Ultrex grade).

A 200 μg quantity of demetallated and succinylated rSAv with approximately 1.5 CHX-A″ chelates/molecule in 120 μL of PBS was diluted with 100 μL of 1 M NaOAc (pH 4), then 300 μL of ^{213}Bi eluant (95 MBq; 2.56 mCi) was added. After 5 min at room temperature, the reaction mixture was passed over a PD-10 column, and 68 MBq (72%) of [^{213}Bi]**6a** was obtained. The radiochemical purity of the [^{213}Bi]**6a** was analyzed using instant thin-layer chromatography (ITLC) on an ITLC-SG strip (Gelman, Ann Arbor, MI). After spotting, the ITLC strips were allowed to air-dry, then were placed in a development chamber containing 80% methanol/20% 10 mM DTPA in water as eluant. When the solvent had nearly reached the top of the strip, it was air-dried, cut in sections, and counted in a gamma counter. The percent bound activity was obtained by dividing the activity in the first half of the strip (from point of spotting) divided by the total activity on the ITLC strip (×100).

^{211}At/^{125}I Labeling and Preparation of [^{211}At]2b, [^{125}I]2b, [^{125}I]6b, [^{211}At]6c, [^{125}I]6c, [^{211}At]6d, and [^{125}I]6d. The following general procedures were used to obtain the ^{211}At- and ^{125}I-labeled rSAv conjugates.

[^{125}I]6b. To a solution of **5a** (100 μL of 4.5 mg/mL in PBS) was added 25 μL of sodium phosphate (500 mM, pH 7.4), then 1 μL of Na[^{125}I]I (195 μCi in 0.1 N NaOH). That addition was followed by 12 μL of a 1 mg/mL solution of ChT in water. After 5 min at room temperature, the reaction was quenched with 1.2 μL of a 10 mg/mL solution of sodium metabisulfite in water. The reaction mixture was then placed on a NAP-10 column (Amersham Pharmacia Biotech) and eluted with PBS. The protein fractions were combined to yield 166 μCi (85%) of [^{125}I]**6b**.

[^{125}I]2b and [^{125}I]6c. To 600 μg of succinylated rSAv-nCB, **5b** (1.7 mg/mL in PBS), or succinylated rSAv, **2a** (12.6 mg/mL in PBS), was added 25 μL of sodium phosphate 500 mM at pH 7.4. This was followed by 1.5 μL (310 μCi) of Na[^{125}I]I in 0.1 N NaOH and 38 μL of a solution of 1 mg/mL ChT in water. After 30 s at room temperature, 3.8 μL of a solution of 10 mg/mL sodium metabisulfite in water was added to quench the reaction. The mixture was then passed over a NAP-10 column and collected in 0.9% saline. The protein fractions were combined. This procedure gave radiochemical yields of 54% for [^{125}I]**2b** and 68% for [^{125}I]**6c**.

[^{211}At]2b and [^{211}At]6c. To 600 μg of succinylated rSAv-*nido*-carborane, **5b** (1.7 mg/mL in PBS) or succinylated rSAv, **2a** (12.6 mg/mL in PBS) was added 100 μL of 500 mM sodium phosphate at pH 7.4. This was followed by 40 μL (360–410 μCi) of Na[^{211}At]At solution at pH 7 and 38 μL of a solution of 1 mg/mL ChT in water. After 30 s at room temperature, 3.8 μL of a solution of 10 mg/mL sodium metabisulfite in water was added to quench the reaction. The mixture was then passed over a NAP-10 column (Pharmacia, Uppsala, Sweden) and collected in 0.9% saline. The protein fractions were combined. This procedure gave radiochemical yields of 18% for [^{211}At]**2b** and 50% for [^{211}At]**6c**.

[^{211}At]rSAv-B$_{10}$, [^{211}At]6d. To 750 μg of **5c** (2.9–7.2 mg/mL in PBS) was added 100 μL of 500 mM sodium phosphate at pH 7.4. This was followed by the addition of 400–500 μL (600–660 μCi) of Na[^{211}At]At solution in 0.05 N NaOH. To this solution was added 75 μL of a solution of 1 mg/mL ChT in water. After 1 min at room temperature, the reaction was quenched with 75 μL of 1 mg/mL sodium metabisulfite in water. The mixture was then passed over a NAP-10 column and collected in 0.9% saline. The protein fractions were combined to give radiochemical yields of 66 and 71% (2 radiolabeling reactions) for [^{211}At]**6d**.

[^{125}I]rSAv-B$_{10}$, [^{125}I]6d. To 750 μg of **5c**, (7.2 mg/mL in PBS) was added 25 μL 500 mM sodium phosphate at pH 7.4. This was followed by the addition of 2 μL (800–980 μCi) of Na[^{125}I]I solution in 0.1 N NaOH. To this solution was added 20 μL of a solution of 1 mg/mL ChT in water. After 30 s at room temperature, the reaction was quenched with 20 μL of 1 mg/mL sodium metabisulfite in water. The mixture was then passed over a NAP-10 column and collected in 0.9% saline. The protein fractions were combined to give radiochemical yields of 81 and 86% (two radiolabeling reactions) for [^{125}I]**6d**.

Biodistribution Studies. The animal studies were approved by the University of Washington's Institutional Animal Care and Use Committee prior to being conducted. Male athymic mice (BALB/c *nu/nu*), 4–5 weeks of age, were obtained from Simonsen Laboratories (Gilroy, CA). The mice were housed for a minimum of 1 week in the animal facility prior to the study. In dual-label experiments, the ^{213}Bi or ^{211}At-labeled modified rSAv was mixed with the appropriate (matched) ^{125}I-labeled modified rSAv. That mixture was diluted in phosphate-buffered saline (PBS) to prepare quantities of ~100 μL for administration. In each set of experiments, the dual-labeled succinylated rSAv was injected into 15 athymic mice via the lateral tail vein. The actual amount of injectant each animal received was determined by weighing the administering syringe before and after injection. Groups of five mice were sacrificed by cervical dislocation at 45, 90, and 180 min for samples containing ^{213}Bi, or 1, 4, and 24 h post injection for samples containing ^{211}At. Blood samples were obtained by cardiac puncture immediately before sacrifice. Urine samples were obtained by syringe bladder tap at the time the tissues were excised. The tissues were excised, blotted free of blood, weighed, and counted. Excised tissues are listed in Tables S1−S4 (Supporting Information). The amount of radioactivity and quantity of rSAv, as well as the average animal weights in the biodistributions, are provided in the legends for Tables S1−S4. Calculation of the percent injected dose (%ID) and percent injected dose per gram (%ID/g) in the tissues was obtained by measuring standards containing 10 μL of the injected dose. The ^{213}Bi and ^{211}At counts were adjusted for decay from the time of counting standards. Total blood volume was estimated to be 6.0% of body weight (*39*) for the calculations. Statistical analysis of the data was conducted using the paired Student's *t*-test. Differences were considered statistically significant when $p < 0.05$.

RESULTS

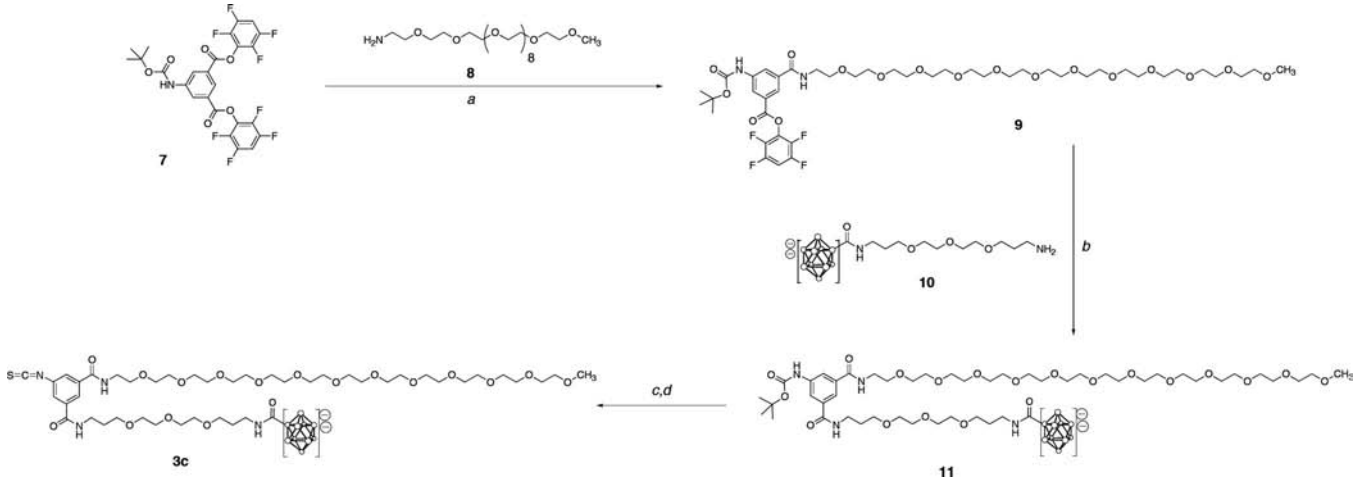
Reagents for Conjugation. Reagents containing bonding or chelating moieties that were used for the modification of rSAv were synthesized. The protein-reactive isothiocyanatobenzyl-CHX-A″ DTPA derivative, **3a**, was obtained in a multistep synthesis as previously reported (*34*). The isothiocyanatophenyl-*nido*-carborane derivative, **3b**, was also obtained in a multistep synthesis as previously described (*31*). The protein-reactive decaborate(2-) derivative, **3c**, was obtained as shown in Scheme 1. In that synthesis, the reaction of an excess of 5-*N*-(t-Boc)-aminoisophthalate-bis-tetrafluorophenyl (TFP) ester, **7**, (*36*) with m-dPEG$_{12}$ amine, **8**, and Et$_3$N in DMF for 40 min at room temperature provided 5-*N*-(t-Boc)-1-(m-dPEG^{12} amino)-aminoisophthalate TFP ester, **9**, in 80% yield after purification. Reaction of **9** with 2-(4,7,10-trioxatridecane-13-amine-1-amido)-undecahydro-*closo*-decaborate (2-), **10**, and Et$_3$N in DMF for 2 h at room temperature gave a 78% yield of **11**. Deprotection of the aniline in neat TFA for 10 min at room temperature yielded the free amine, which was converted to the isothiocyanate derivative **3c** in 95% yield by reaction with thiocarbonyldiimidazole in DMF for 1 h at room temperature.

Modification of rSAv. The reactions used to modify rSAv are shown in Scheme 2. In all examples studied, rSAv was modified by succinylation of surface amines to decrease kidney localization. For comparison, succinylated rSAv, **2a**, was prepared without a binding or bonding moiety (BM). That preparation was accomplished by reaction of rSAv with 50–100[4] molar equivalents of succinic anhydride in $NaHCO_3$ buffer at pH 8.5 at room temperature for 30 min. Good protein recovery yields (e.g., 85–95%) are generally obtained in this reaction. In the preparation of the other modified rSAv, succinylation was conducted after conjugation of **3a**, **3b**, or **3c**.

Modification of rSAv for binding (chelating) ^{213}Bi or bonding ^{211}At was conducted by reaction with 10 mol equiv of the protein-reactive reagents **3a**, **3b**, and **3c** (Figure 2) in HEPES buffer at pH 8.5, at room temperature for 18 h to provide **4a**, **4b**, and **4c**. After that time, the modified rSAv species were

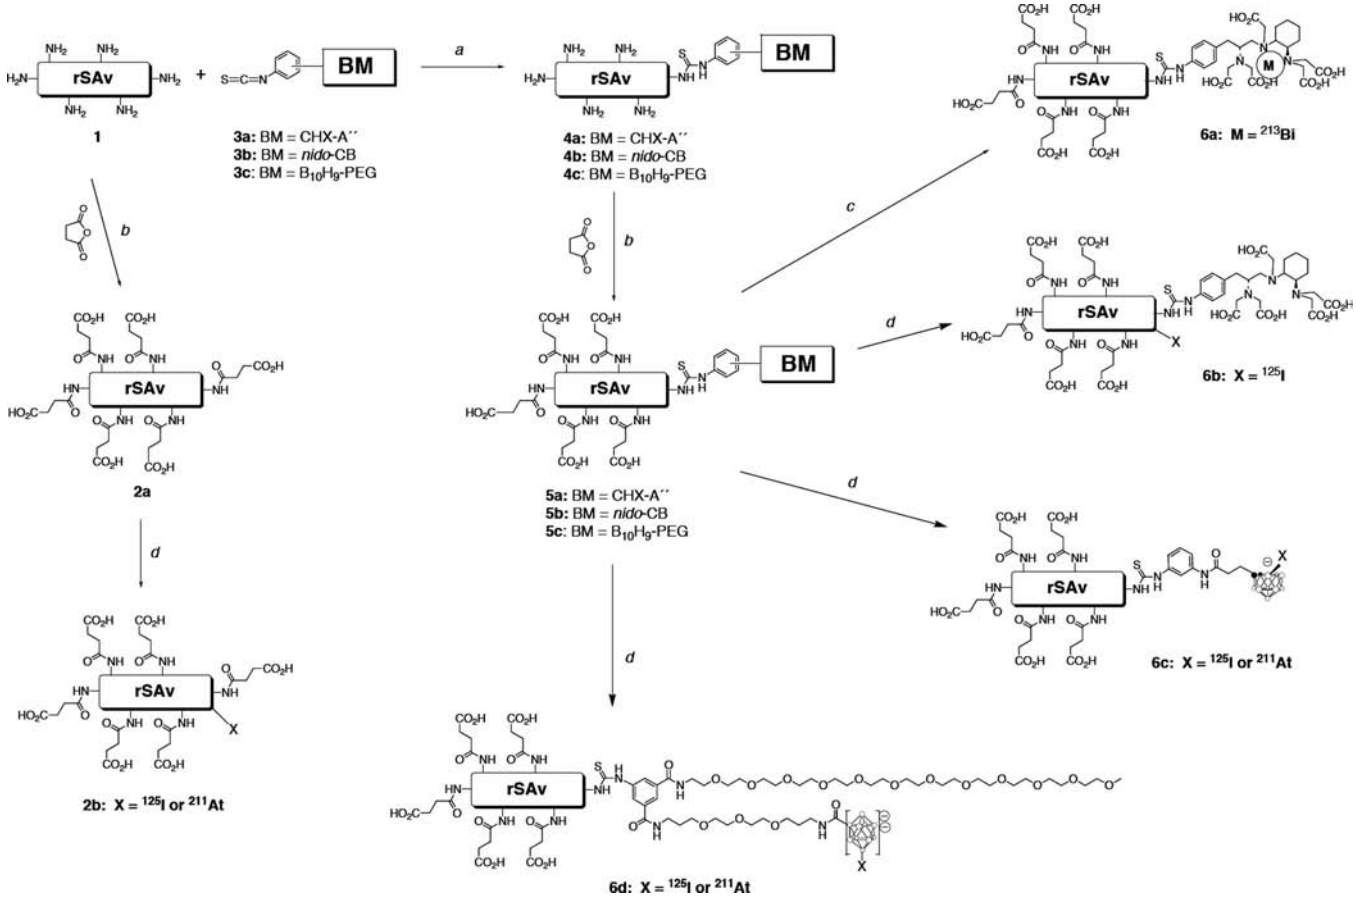
[4]The initial studies were conducted with 50 equivalents of succinic anhydride, but later studies used 100 equivalents to be certain that as many amines are capped as possible.

Scheme 1. Synthetic Pathway for the Preparation of Protein-Reactive Phenylisothiocyanato-undecahydro-decaborate(2-) Derivative, 3c[a]



[a] In the structures of the decaborate(2-) moiety, the open circles represent boron or B-H atoms. (a) **8**, DMF, Et_3N, rt, 40 min, 80%; (b) **10**, Et_3N, rt, 2 h, 78%; (c) TFA, rt, 10 min; (d) TCDI, rt, 1 h, 95%.

Scheme 2. Chemical Steps for the Modification of rSAv and Radiolabeling with ^{213}Bi, ^{211}At, or ^{125}I[a]



[a] (a) **3a**, **3b** or **3c**, HEPES, pH 8.6, rt, 18 h; (b) succinic anhydride, DMSO, $NaHCO_3$, pH 8.5, 30 min, rt; (c) $BiCl_3$, pH 4–5, NaOAc, HOAc; (d) Na[^{211}At]At or Na[^{125}I]I, ChT, H_2O, HOAc, rt, 30 s.

not isolated, but rather 50–100[4] equivalents of succinic anhydride were added, and the reaction was allowed to proceed for an additional 30 min. Prior to and after conjugation of the modified DTPA derivative, **3a**, the rSAv was demetallated using Chelex-100 resin. The recovery of modified rSAv species, **5a**, **5b**, and **5c** varied with the protein-reactive reagent used. Size-exclusion HPLC of the modified rSAv showed very little change from unmodified rSAv. For rSAv modified with **3a** (CHX-A″), the number of CHX-A″ moieties conjugated was determined by the spectrophotometric assay using the yttrium−arsenazo III complex (*37*). Using this method, it was determined that there were ~1.5 chelates/rSAv in the preparation used for the animal study (i.e., Table S1, Supporting Information). Quantification of the number of **3b** (*nido*-CB moieties) and **3c** (dPEG[a]/B_{10} moieties) conjugated with rSAv was not readily accomplished. However, changes in isoelectric points (pI) brought about by conjugation were evaluated by IEF analyses. An example of an IEF gel is shown in Figure 2. IEF gels showed that rSAv had protein bands in the range of pH 7.4–7.8. The protein bands (pI) shifted to pH 7.0–5.2 when conjugated with monoanion

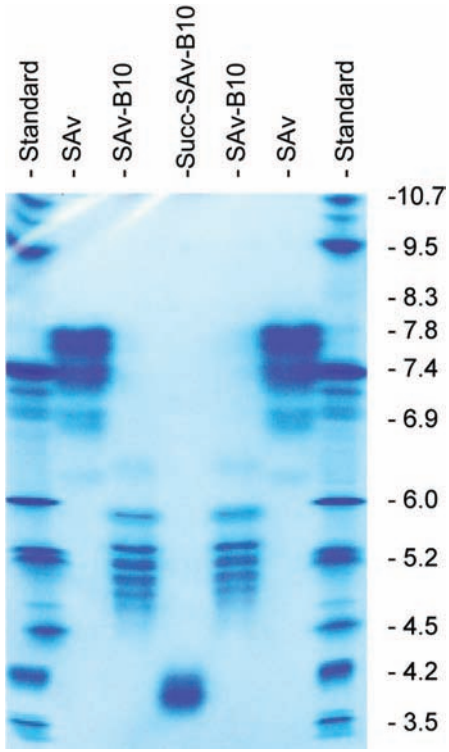


Figure 2. Digitized image of an IEF gel showing changes in pI when rSAv is modified with the decaborate(2-) derivative **3c** to prepare conjugate **4c** and after further modification with succinic anhydride to give **5c**. Lanes 1 and 7: IEF standards (Serva electrophoresis GmbH, broad pI; 3–10) run in the direction of application (bottom to top) and in the direction opposite to the application of sample (e.g., top to bottom). Lanes 2 and 6: unmodified rSAv. Lane 3 and 5: r-SAv conjugated with **3c**. Lane 4: r-SAv conjugated with **3c** and further modified by reaction with an excess succinic anhydride.

3b. The protein bands (pI) shifted further to pH 5.2–4.3 when rSAv-**3b** (**4b**) was succinylated. Greater shifts in the pI were noted (5.9–4.7) when rSAv was conjugated with dianionic **3c**. Succinylation of rSAv-**3c** (**4c**) shifted the pI even further (4.1–3.7). The fact that none of the unmodified rSAv is present after conjugation of **3b** or **3c** indicates that all rSAv tetramers have at least one of these moieties conjugated. In fact, it is likely that each tetramer has more than two conjugates, or some of the unmodified rSAv would be present.

Radiolabeled Modified rSAv: Preparation of 2b, 6a, 6b, 6c. The modified rSAv was radiolabeled with either ^{213}Bi or ^{211}At to assess radiochemical yields and in vivo stability. rSAv conjugates **2a**, **5a**, **5b**, and **5c** were also radioiodinated with ^{125}I. Radioiodination of rSAv was conducted to provide a comparison with the astatination yields and to provide an internal control for comparisons in vivo. The ^{225}Ac/^{213}Bi generator system previously described (*38*) was used to obtain ^{213}Bi for labeling. The succinylated rSAv-CHX-A″, **5a**, was reacted in 1 M NaOAc buffer at pH 4 for 5 min. Purification was accomplished by size-exclusion chromatography (NAP-10 column) to give a 72% isolated yield of [^{213}Bi]**6a**. Dry distillation of an irradiated bismuth target provided ^{211}At for labeling. Astatination was very rapid (<1 min) using chloramine-T in phosphate-buffered saline (PBS) at pH 7.4. After purification by size-exclusion chromatography (NAP-10), isolated yields of 18% for [^{211}At] **2b** and 50%–88% for [^{211}At]**6c** and [^{211}At]**6d** were obtained.

Biodistribution Studies. Four biodistribution studies were conducted in athymic mice. In each study, the ^{213}Bi- or ^{211}At-labeled rSAv was mixed with a radioiodinated version of the same modified rSAv and injected into three sets of 5 mice each. Because rSAv is very resistant to protease degradation, direct radioiodination can be used to provide a standard that closely reflects the distribution of the modified rSAv (*16*). In the first biodistribution study, [^{213}Bi]**6a** and [^{125}I]**6b** were coinjected, and tissue samples were obtained at 45 min and 90 and 180 min (~1, 2, and 4 half-lives) post injection (pi). The data obtained at 90 and 180 min are plotted in Figure 3, panel A, and the data obtained at all three time points are provide in Table S1 (Supporting Information). The plotted data show that the tissue concentrations of the two radionuclides are very similar at the two time points. Analysis of the concentrations of radionuclides in mice by the paired Student's *t*-test indicated that the only tissue with a significant difference in concentrations of ^{213}Bi and ^{125}I was kidney at the 180 min time point.

In a second biodistribution, ^{211}At-labeled succinylated rSAv, [^{211}At]**2b**, and ^{125}I-labeled succinylated rSAv, [^{125}I]**2b**, were coinjected, and tissue samples were obtained at 1, 4, and 24 h (~0.14, 0.6, and 3.3 half-lives) pi. The data obtained at 4 and 24 are plotted in Figure 3, panel B, and the data obtained at all three time points are provided in Table S2 (Supporting Information). The plotted data show differences in concentrations of radionuclides in blood, kidney, spleen, neck, and stomach. When analyzed by the Student's *t*-test, several differences were found to be significant. At the 1 and 4 h time points, the concentration of radionuclides in blood, spleen, neck, and stomach were significantly different. The differences in concentrations of ^{211}At and radioiodine in lung, spleen, neck, and stomach are an indication that there was free [^{211}At]astatide in vivo (*40*). It is interesting to note that at 24 h pi, there is no difference between the radionuclide concentrations in any tissue except muscle (Table S2, Supporting Information).

In the third biodistribution, [^{211}At]**6c** and [^{125}I]**6c** were coinjected, and tissue samples were obtained at 1, 4, and 24 h pi. The data obtained at 4 and 24 are plotted in Figure 3, panel C, and the data obtained at all three time points are provided in Table S3 (Supporting Information). By inspection of Figure 3C, it can be seen that with the exception of concentrations of radionuclides in blood at the 1 h time point, the concentrations of the two radionuclides in tissues are quite similar at the two time points plotted. A small but significant difference in the radionuclide concentrations was found in the stomach at 1 h pi, but the lack of significant differences in concentrations in other tissues makes it likely that very little free [^{211}At]astatide was present. At the 4 h time point, significant differences in radionuclide concentrations were seen in the blood, muscle, kidney, and spleen. Again, lack of significant differences in the lung, stomach, and neck makes it unlikely that the differences were reflective of astatide release from the rSAv conjugates.

In a fourth biodistribution, [^{211}At]**6d** and [^{125}I]**6d** were coinjected, and tissue samples were obtained at 1, 4, and 24 h pi. The data obtained at 4 and 24 are plotted in Figure 3, panel D, and the data obtained at all three time points are provided in Table S4 (Supporting Information). From the plotted data, it is apparent that concentrations of ^{211}At and ^{125}I are essentially the same in all tissues, indicating a high degree of stability toward deastatination. When subjected to the paired Student's *t*-test, a small but significant difference was noted for the radionuclide concentration in only one tissue (spleen) examined and that only at 4 h pi. Because there were no differences observed in the lung, stomach, or neck, it seems unlikely that the observed difference was due to free astatide. Interestingly, the concentration of both radionuclides (^{125}I and ^{211}At) was considerably lower in the blood and other tissues than that observed with the other radiolabeled rSAv conjugates. Indeed, the blood and tissue concentrations of [^{125}I]**6d** are less than half-that obtained with the other labeling methods. While that is the case, the liver concentrations were found to be similar to that

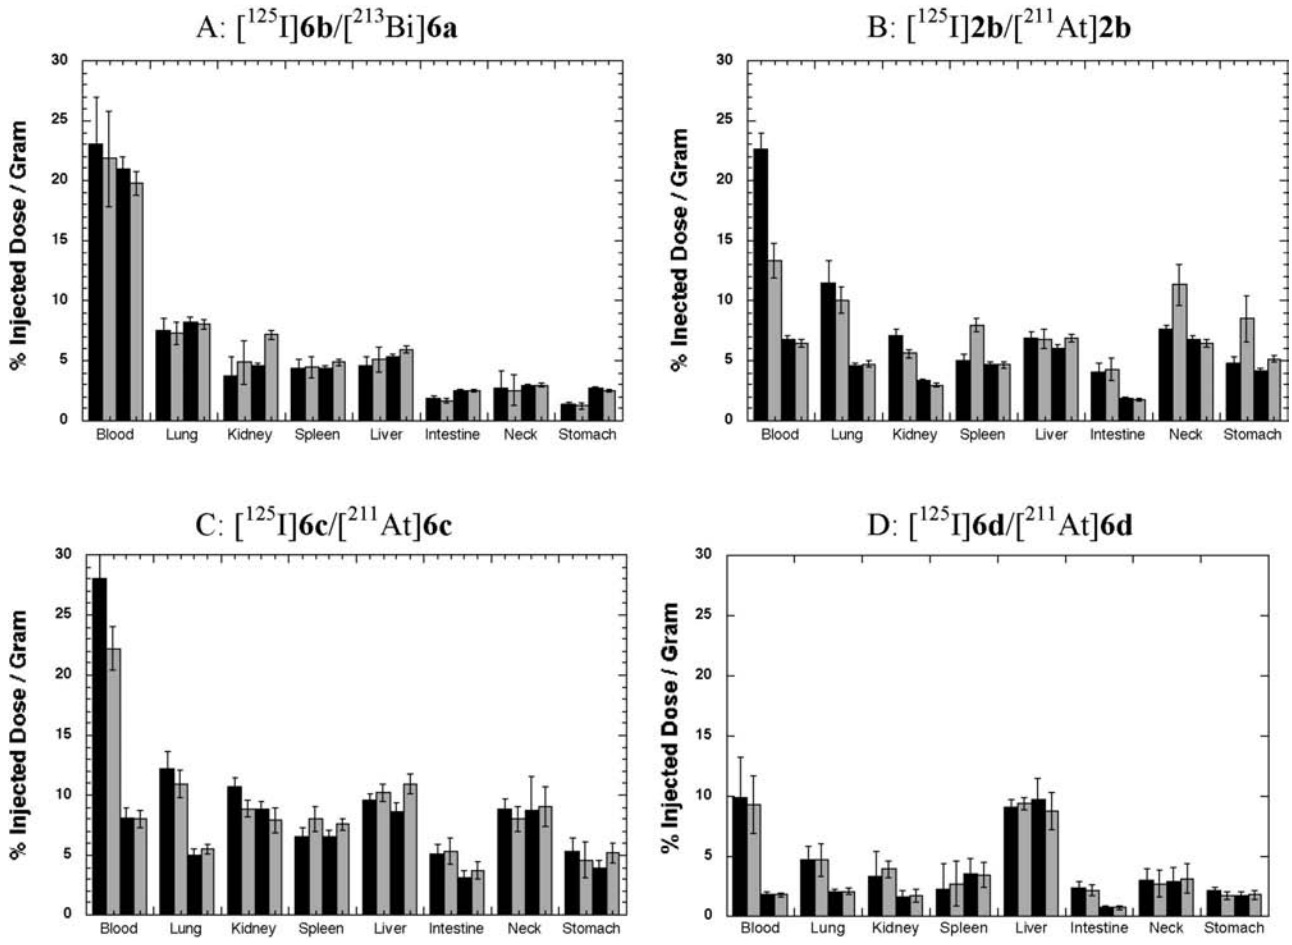

Figure 3. Bar graphs of selected biodistribution data obtained from coinjections (^{125}I- and α-emitter ^{213}Bi or ^{211}At-labeled) modified rSAv. ^{125}I-labeled modified rSAv data are plotted as black bars in each panel. ^{213}Bi or ^{211}At biodistribution data are plotted as gray bars. Panel A shows tissue distributions of ^{213}Bi-labeled succinylated rSAv-CHX-A″, [^{213}Bi]**6a**, in comparison with ^{125}I-labeled succinylated rSAv-CHX-A″, [^{125}I]**6b**, at 1.5 h (1st pair of bars) and 3 h (2nd pair of bars) pi. Panel B shows tissue distributions of ^{211}At- and ^{125}I-labeled succinylated rSAv that had no boron cage conjugated, [^{211}At]**2b** and [^{125}I]**2b**, at 4 (1st pair of bars) and 24 h (2nd pair of bars) pi. Panel C shows tissue distributions of ^{211}At- and ^{125}I-labeled succinylated rSAv that had *nido*-carborane cages conjugated, [^{211}At]**6c** and [^{125}I]**6c**, at 4 and 24 h pi. Panel D shows tissue distributions of ^{211}At- and ^{125}I-labeled succinylated rSAv that had decaborate(2-) cages conjugated, [^{211}At]**6d** and [^{125}I]**6d**, at 4 and 24 h post injection. Tables (S1−S4) of biodistribution data are provided in Supporting Information.

observed for the *nido*-carborane conjugate, [^{125}I]**6c**. Those concentrations were 3–5%ID/g higher than that found for the rSAv conjugated with CHX-A″, [^{125}I]**6b**, or when there was no bonding/binding moiety conjugated, [^{125}I]**2b**.

DISCUSSION

There are only a few α-emitting radionuclides that are considered reasonable candidates for TRT applications. Of those, ^{213}Bi and ^{211}At are particularly attractive because of the fact that they do not decay to α-particle-emitting daughter radionuclides. While they are very different in many aspects, choosing between ^{213}Bi and ^{211}At for TRT is difficult because each radionuclide has its own strengths and weaknesses. For example, ^{213}Bi is available from a generator system, ^{225}Ac/^{213}Bi (*41*), which could potentially allow widespread use in clinics and treatment centers. Furthermore, the short half-life of ^{213}Bi may allow repeated (fractionated) treatments in an outpatient setting while posing minimal danger to the patients' family and health care providers. However, the half-life of ^{213}Bi may be problematic, as targeting approaches may not be rapid enough in some tissues to adequately target cancer cells before decay occurs. The longer half-life of ^{211}At (∼9.4×) may circumvent this shortcoming of ^{213}Bi. Additionally, at present, it is difficult to obtain clinical quantities of ^{225}Ac (for ^{213}Bi production), whereas ^{211}At can be prepared in quantities sufficient for clinical studies (*42*). However, treatment with an ^{211}At-labeled molecule may require being within a short distance from the cyclotron used for its production. Rather than argue the merits of either ^{213}Bi or ^{211}At, our approach has been to investigate both. The strengths and weaknesses of each radionuclide will likely dictate usefulness for a specific therapeutic application.

A key issue with the use of the short half-lived α-emitting radionuclides ^{213}Bi and ^{211}At is employing an appropriate cancer-targeting approach. Several preclinical therapy studies using intact monoclonal antibodies or their fragments have shown promising results with ^{213}Bi (*43–46*) and ^{211}At (*47*, *48*). However, we believe that another antibody-based approach, termed pretargeting (*49*), may be the most promising for the short half-lived α-emitting radionuclides. That belief is based primarily on results from studies using antibody−rSAv chemical conjugates or fusion proteins in conjunction with biotin labeled with β-emitting radionuclides (*50–53*). The belief is also supported by results obtained in a study using ^{213}Bi in a pretargeting protocol for the therapy of adult T-cell leukemia in a murine model (*54*). In that study, pretargeted ^{213}Bi provided effective therapy, whereas ^{90}Y did not.

In the majority of pretargeting studies, including those cited above, the radionuclide is carried by biotin. But there is an alternative approach where a biotinylated mAb is administered first (pretargeted), and radiolabeled rSAv is administered

later (*49, 55–58*). In this investigation, initial steps of rSAv toward evaluating the potential for this alternate pretargeting approach to target short half-lived α-emitting radionuclides have been taken. We hypothesize that using streptavidin as a carrier for treating minimal residual disease with α-emitting radionuclides may have advantages. Its longer serum half-life should allow higher concentrations in blood and tissues, perhaps allowing a lower quantity of expensive radionuclides to be administered. While recombinant streptavidin, a ∼53 kDa protein, will not penetrate solid tumors as rapidly as radiolabeled biotin, with minimal residual disease such as micrometastatic lesions, tissue penetration may not be a problem. Furthermore, in contrast to significant normal tissue irradiation from β-emitting radionuclides such as ^{90}Y, the short path length of the α-particle should cause minimal normal tissue damage and toxicity when decaying in blood. Data from bone marrow conditioning studies have provided some evidence that supports this hypothesis (*20*). Although the use of succinylated rSAv as a carrier of radionuclide in pretargeting protocols may limit the second administration of the radioactive material because of its immunogenicity, we believe that the potential for efficient targeting of α-emitting radionuclides to metastatic disease warrants investigation.

The primary goals of this investigation were to evaluate methods for modifying radiolabeling rSAv with ^{213}Bi and ^{211}At and determine the effect that modification had on tissue distribution and pharmacokinetics in the mouse model. An important factor in the studies was normal tissue localization of the radiolabeled rSAv. Fortunately, prior investigations (*17, 18*) had shown that the natural propensity for kidney localization of rSAv (i.e., 20+ % ID/g (*16*)) could be dramatically decreased by succinylation. The results of these studies demonstrate that even in the case where succinylation of rSAv is conducted after modifying with binding or bonding moieties, this modification greatly diminishes sequestration in the kidney.

Another important aspect of the studies was to determine whether the α-emitting radionuclides remained stably attached to the rSAv in vivo. While quantification of released bismuth is not readily achieved, a reasonable assessment of the stability of ^{213}Bi-labeled rSAv can be obtained by comparing coinjected ^{213}Bi- and ^{125}I-labeled succinylated rSAv localized in the kidney. Free bismuth localizes to kidney (*59, 60*), thus, if *excess* ^{213}Bi activity is found in the kidney, it is a good indicator that ^{213}Bi has been released from the labeled rSAv. The DTPA derivative isothiocyanatobenzyl-CHX-A″, **3a**, was chosen for conjugation with rSAv for the chelation of ^{213}Bi. Studies have shown that ^{111}In and ^{90}Y can be chelated rapidly on bioconjugates containing this group, and the resultant labeled molecules have been shown to be stable to in vivo demetalation (*61–63*). In our prior studies, **3a** was conjugated with mAbs against antigens on canine hematopoietic cells, then radiolabeled with ^{213}Bi, and evaluated in dogs (*20, 21, 38*). In these studies, kidney enzymes were monitored for several months, and no damage to that tissue was noted, likely indicating that ^{213}Bi was not released in vivo.

In this investigation, rSAv was modified with CHX-A″, succinylated and radiolabeled with ^{213}Bi. The data plotted in Figure 3, panel A (Table S1 in Supporting Information) show that the distributions of the radionuclides are very similar. Indeed, the only significant difference between the ^{213}Bi and ^{125}I concentrations (by Student's *t*-test) is in the kidney at 3 h pi. From the data, it appears that there is a small amount of ^{213}Bi released in vivo. However, the important consideration is that release is relatively slow, and the magnitude of difference is quite small. At the 3 h time point, 4 half-lives of ^{213}Bi have passed; therefore, ∼94% of the radioactivity has decayed. An alternative labeling method is to conjugate the DOTA-chelation group to rSAv for binding ^{213}Bi (*64*). This may result in essentially no release of ^{213}Bi in vivo, but it is much more difficult to obtain the radiolabeled rSAv, as elevated temperatures (e.g., 37–45 °C) are required for up to an hour to achieve reasonable labeling yields. Thus, it appears that the CHX-A″ is the appropriate chelation group for executing ^{213}Bi-labeled rSAv studies.

Instability of ^{211}At-labeled proteins and small molecules has presented a serious problem with its application to cancer therapy. We considered using *m*-[^{211}At]astatobenzoate NHS ester (*29*) and *p*-[^{211}At]astatobenzoate NHS ester (*32*) for labeling rSAv with ^{211}At. Either of these derivatives would be expected to be stable to in vivo deastatination because rSAv is very resistant to protease degradation. However, in our experience, 40–60% labeling yields in the two-step labeling procedure are the best that can be (consistently) obtained with those reagents. Obtaining a high efficiency of radionuclide labeling is very important with ^{211}At as well. Rather than use the benzoate-labeling reagents, we chose to evaluate anionic borane cage pendent groups already under investigation in this laboratory (*31*). With conjugates of boron cage moieties, *direct astatination* yields of up to 81% had been obtained. Unfortunately, studies of ^{211}At-labeled benzoate and *nido*-carborane derivatives (*35*) did not provide encouraging results regarding in vivo stability. However, because of the protease resistance of rSAv, we chose to investigate a *nido*-carborane conjugate **3b** as a pendent group for direct astatination. The *nido*-carborane derivative **3b** had been previously evaluated in conjugates of a mAb Fab′ fragment. We chose to investigate a decaborate(2-) derivative as well since its use with Fab′ gave higher ^{211}At-labeling yields and appeared to impart less perturbation of the in vivo properties of the protein.

For this investigation, we could not readily adapt either of the two decaborate (2-) derivatives previously prepared for use with ^{211}At (*31*). One decaborate (2-) derivative was conjugated by reaction with sulfhydryl groups, while the other contained a biotin moiety. Since rSAv does not have disulfide bonds to reduce for reaction with maleimide derivatives (and we did not want to use reagents to produce sulfhydryl groups on rSAv), the sulfhydryl-reactive reagent did not appear to be a good candidate. Similarly, the use of a biotin-containing decaborate (2-) was not appropriate for conjugation with rSAv. Therefore, a new reagent containing a decaborate (2-) moiety and a methoxyl-terminated discrete-length (dPEG) polyethylene glycol moiety was prepared. The rationale for the use of dPEG moiety was that such a group might keep the dianionic decaborate moiety from interacting with serum proteins. Furthermore, other investigators have shown that PEGylation of avidin (Av) (albeit with larger PEG moieties) can improve their in vivo properties for pretargeting applications (*65, 66*).

Before labeling the rSAv conjugated with **3b** or **3c**, direct labeling of succinylated rSAv, **2a**, was evaluated. Astatination studies of an mAb Fab′ fragment resulted in none (<1%) of the astatinated protein being recovered after labeling using ChT and reducing with sodium metabisulfite (*31*). Other investigators obtained similar results (e.g., <5% bound) when ChT was used as oxidant (*67–69*). Therefore, it was interesting that an 18% isolated radiochemical yield was obtained with directly labeled succinylated rSAv in this investigation. The reason for the difference in radiolabeling yields is not known. However, it may be due to the presence of disulfides in the Fab′ molecule or a lack of them in the rSAv molecule. Investigators have shown that electrochemical oxidation and oxidation with H_2O_2 can provide higher yields of astatinated proteins (*68*); however, studies indicate that ^{211}At is bound with sulfhydryl groups rather than tyrosine moieties (*69, 70*). An important point is that rSAv has no disulfides or cysteine or methionine residues (*71*); therefore, the labeling can not be associated with sulfhydryl or

thioether groups. Streptavidin has six tyrosine residues per subunit. Although one tyrosine residue is buried in the biotin-binding pocket, five are on each subunit, giving a total of 20 tyrosine residues per molecule that might be astatinated. In related studies, ^{211}At-labeling of succinylated avidin, which has only one tyrosine per subunit (in biotin binding pocket), gave low radiochemical yields (unreported results)[5]. The combined results are suggestive that electrophilic ^{211}At can react with tyrosine residues in proteins when no disulfides are present. Early astatine-labeling studies demonstrated that direct labeling of tyrosine was possible (*72*).

The three ^{211}At-labeled rSAv preparations ([^{211}At]**2b**, [^{211}At]**6c**, [^{211}At]**6d**) have noticeably different distributions. The tissue distribution of radioiodinated succinylated rSAv, [^{125}I]**2b**, correlates well with data obtained in a previous study (*16*). If that iodinated derivative is compared with directly labeled [^{211}At]**2b**, it is apparent that there is some instability of the astatinated rSAv. However, when the boron cage moieties **3b** and **3c** are conjugated to rSAv, in vivo deastatination is not detected. A noticeable difference in tissue (e.g., kidney, spleen, and liver) accumulation and retention is observed for the *nido*-carborane conjugated rSAv relative to succinylated [^{125}I]rSAv. In contrast to this, the astatinated decaborate(2-)−rSAv conjugate [^{211}At]**6d** appears to be cleared from the blood much more rapidly than the succinylated native protein. It is not known why this conjugate has such a rapid blood clearance. Clearance is more rapid from all tissues except the liver, which has concentrations similar to that of native protein at the times studied. One possible explanation for the rapid clearance is that the m-dPEG$_{12}$ moiety destabilizes the rSAv tetramer by inserting between the rSAv monomers. Higher molecular weight fusion proteins made of antibody single chain constructs and rSAv have also been noted to have much more rapid clearance than rSAv or chemical conjugates of rSAv and antibodies (*51*). A plausible explanation for the observed fast clearance in that case is that the fused four scFv destabilize the rSAv tetramer.

Summary. This investigation has demonstrated that after appropriate modification, rSAv can be labeled with either ^{213}Bi or ^{211}At in good radiochemical yield. Most importantly, the data obtained from biodistributions conducted in athymic mice have shown that the ^{213}Bi-labeled succinylated rSAv has nearly the same distribution and pharmacokinetics as the nonmetallated rSAv conjugate. While there is slight (but significant) difference in the distributions after 4 half-lives (3 h) of ^{213}Bi, at that time there is less than 10% of the activity remaining, and the magnitude of specific kidney localization appears small. From the data, we conclude that the ^{213}Bi-labeled succinylated CHX-A″-rSAv has adequate stability to be used in pretargeting protocols. The biodistribution data obtained for succinylated rSAv directly labeled with ^{211}At, that is, [^{211}At]**2b**, indicate that this labeling approach is not adequate for pretargeting studies because of low radiochemical yields and low in vivo stability. Higher in vivo stability was obtained with the *nido*-carborane conjugated rSAv, [^{211}At]**6c**, but that functional moiety appears to increase blood and tissue retention such that it is not an ideal conjugate either. The data obtained from the in vivo studies with the PEGylated decaborate(2-)-conjugated rSAv, [^{211}At]**6d**, suggests that this method of labeling not only provides a stable label but also provides very good radiochemical yields and modifies the in vivo pharmacokinetics in what appears to be a favorable manner. Therefore, additional studies with the PEGylated decaborate(2-) conjugate are planned to evaluate its use in pretargeting protocols.

[5]Astatination of succinylated avidin and succinylated avidin conjugated with the *nido*-carborane moiety, **3b**, was also conducted to show the difference in yields. Avidin has only 1 tyrosine residue per subunit, making it less likely to be astatinated. Astatination of succinylated avidin gave a radiochemical yield of 5%, whereas astatination of succinylated avidin conjugated with **3b** gave a 52% radiochemical yield.

ACKNOWLEDGMENT

We thank Kent Buhler, Janna Quinn, Nicole Lavoie, Holly Nguyen, and Dr. Robert Vessella for assistance with the animal studies conducted in this investigation, and Dr. Ruedi Risler for assistance with the production of ^{211}At. We are particularly grateful to the Department of Defense (DAMD 17-98-1-8258) and National Cancer Institute, NIH (5 RO1 CA113431) for financial support of the studies. This research was supported in part by the Intramural Research Program of the NIH, National Cancer Institute, Center for Cancer Research. We thank Quanta BioDesign (http://www.quantabiodesign.com) for the gift of m-dPEG$^{TM}_{12}$ amine used in the studies.

Supporting Information Available: Numerical data for the four biodistributions conducted in this investigation. This information is available free of charge via the Internet at http://pubs.acs.org.

Oligothiophene-5-Labeled Deoxyuridines for the Detection of Single Nucleotide Polymorphisms

Massimo L. Capobianco,* Antonella Cazzato,† Silvia Alesi, and Giovanna Barbarella

Istituto per la Sintesi Organica e la Fotoreattività del Consiglio Nazionale delle Ricerche (ISOF-CNR).
Via P. Gobetti 101, 40129 Bologna, Italy. Received July 10, 2007; Revised Manuscript Received September 13, 2007

We report the synthesis of four oligothiophene-5-labeled deoxyuridines. These modified fluorescent nucleosides have been incorporated into oligodeoxynucleotides designed to be used as probes to discriminate, through changes in fluorescence emission, between hybridization with a perfectly complementary strand and that with a single nucleotide mismatch facing the modified uridines. Upon hybridization, remarkable differences (up to 47%) of the emitted light, depending on the uridine facing base, were observed.

INTRODUCTION

Single mutations of nucleosides inside DNA, even in the absence of mutagens, can be randomly produced during DNA replication with an esteemed frequency in the range 10^{-7}–10^{-11} per replication. Such mutations can be inherited and are known as single nucleotide polymorphism (SNP) (*1*). Most of the time, SNPs occur in untranscribed DNA or into introns, but occasionally, they can affect an exon and alter the gene translation, leading to a truncated or a mutated protein. Detection of SNPs is thus of great importance in medicine and biology, and a great effort has been devoted to finding suitable methods of analysis. Among a plethora of methodologies (*2*–*6*), based on sequencing, selective hybridization (*7*), amplification (*8*, *9*), colorimetric methods (*10*), mass spectrometry, (*2*–*4*) and so forth, those based on variation of the emitted light of modified nucleosides, inserted into a probe in front of the mutation spot of the oligonucleotide to be analyzed, are perhaps the most straightforward (*11*, *12*). The methods rely on the fact that the electronic distribution of a nucleobase is modified by the presence (or absence) of the Watson–Crick hydrogen bonds formed with the facing nucleoside in a duplex. If a suitable fluorophore is conjugated on the nucleobase opposite the presumed mutated base, it can be affected from that variation, and fluoresce in a different way whether correctly paired or mispaired.

Our group is studying the fluorescence properties of oligothiophenes as markers for proteins and oligonucleotides (*13*, *14*) and exploring their use as diagnostic tools in biotechnologies (*15*). As part of this study, we have synthesized four deoxyuridine derivatives (Figure 1) in which bi- or terthiophene moieties have been conjugated to the 5-position of a 2′-deoxyuridine with or without an ethynyl spacer. We have used phosporamidite chemistry to insert each of these labeled compounds at the center of an oligonucleotide, designed to hybridize with model oligonucleotides corresponding to a region known to contain an SNP (A to G transition), that occurs in some patients that present a mutated form of hemoglobin. For this work, the probes

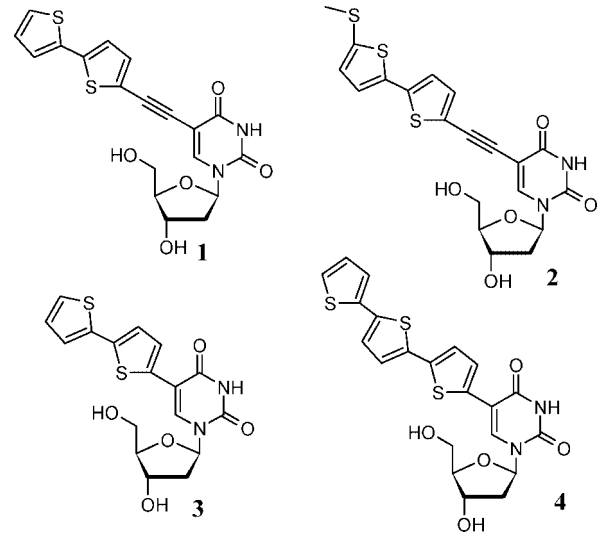

Figure 1. The 5-labelled uridines used in the work.

(**P1**–**4**), the normal (**A**), and the three mutated targets (**G**, **C**, and **T**) containing mismatches (Table 1) were prepared and purified.

MATERIALS AND METHODS

Materials and Instrumentation. All chemicals were of commercial grade unless otherwise stated. Microwave reactions were performed with a Prolabo synthwave 402 oven. The synthesis of the oligonucleotides was achieved with a Pharmacia Gene Assembler 2. NMR analysis were carried out with a Varian VXR-200 or a Varian Mercury 400 spectrophotometer. UV–vis and melting temperature were recorded with a Perkin Elmer lambda 20 spectrophotometer. Fluorescence measurements were performed with a Perkin Elmer LS-50B spectrofluorimeter. Mass analysis were performed with a Finningan Mat GCQ or in ESI[1] mode with a Bruker Esquire 3000+. HPLC analysis and purifications were done with a Waters 600 E, using a Waters UV detector and a Varian Pro Star 363 spectrofluorimeter.

[a] ***U*** = modified uridine (compounds **1**–**4** as in Figure 1). Triplets correspond to reading codons.

5-Iodo-[2,2′]bithiophene (5). The synthesis and characterization of this compound have already been reported (*16*, *17*).

[2,2′]Bithiophenyl-5-ethynyltrimethylsilane (6). The microwave oven reactor was charged with 5-iodo-[2,2′]bithiophene (**5**) (500 mg, 1.7 mmol), ethynyltrimethylsilane (380 μL, 2.7 mmol), tetrakis(triphenylphosphine)palladium (100 mg, 0.085 mmol), CuI (98 mg 0.51 mmol), and TEA (10 mL). After 20 min of irradiation at 150 °C, TLC on silica gel with *n*-hexane as eluent showed the absence of **5**. The mixture was diluted with Et_2O (20 mL) and washed with 4 M aq HCl (15 mL) and water (15 mL), and then the organic phase was dried over Na_2SO_4 and the solvent removed. After chromatography, a brown solid was isolated (355 mg, 79% yield).

MS (*m/z*): 262 [$M^{\cdot+}$] (calcd for $C_{13}H_{14}S_2Si$ 262), 247 [M – CH_3]$^+$. ^{1}H NMR ($CDCl_3$ 200 MHz) δ 7.24 (d, 2.7 Hz, 1H), 7.18 (d, 1.8 Hz, 1H), 7.14 (d, 1.8 Hz 1H), 7.03–7.01 (dd, 2 Hz, 2H), 0.29 (s, 9H). ^{13}C NMR ($CDCl_3$ 50 MHz) δ 138.84, 136.65, 133.42, 127.9, 125.03, 124.23, 123.24, 121.73, 99.90, 97.36, −0.164.

5-Ethynyl-[2,2′]bithiophene (7). The 5-trimethylsilyl protecting group was removed from [2,2′]bithiophenyl-5-ethynyltrimethylsilane (**6**) (355 mg, 1.35 mmol) by reacting it with K_2CO_3 (560 mg 4.05 mmol, 3 equiv) in of *n*-hexane/MeOH (8:2) (15 mL) at rt for 2 h. The reaction was quenched by adding water (1 mL), diluted with Et_2O (20 mL), and washed with water (2 × 15 mL). The organic layer was dried over Na_2SO_4 and evaporated. The desilylated compound was isolated as a yellow oil (190 mg, 74% yield) and used in the following step without further purification.

MS (*m/z*): 190 [$M^{\cdot+}$] (calcd for $C_{10}H_6S_2$ 190). ^{1}H NMR ($CDCl_3$ 400 MHz) δ 7.25 (d, 5.2 Hz, 1H), 7.19 (d, 3.6 Hz, 1H), 7.17 (d, 3.6 Hz, 1H), 7.03–7.01 (m, 2H), 3.4 (s, 1H).

5-(5-Ethynyl-[2,2′]bithiophenyl)-2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)uridine (8). 5-Ethynyl-[2,2′]bithiophene (**7**) (200 mg, 2 equiv, 1.05 mmol), 5′-*O*-(4,4′)-dimethoxytrityl)-5-iodo-2′-deoxyuridine (*1819*) (346 mg, 1 equiv, 0.527 mmol), $Pd(PPh_3)_4$ (30 mg, 0.026 mmol, 0.05 equiv), CuI (7 mg, 0.037 mmol, 0.07 equiv), and TEA (368 μL, 2.635 mmol, 5 equiv) were dissolved in DMF (7 mL). The solution was stirred under nitrogen for 3 h at 25 °C. The reaction mixture was concentrated in vacuo, then diluted with CH_2Cl_2 (15 mL), washed with water (2 × 10 mL), and purified by flash chromatography eluting with CH_2Cl_2/MeOH (95:5) to achieve the desired product (227 mg, 60% yield) as a yellow solid.

ESI-MS (*m/z*): 740.8 [M + Na]$^+$ (calcd for $C_{40}H_{34}N_2O_7S_2$ + Na 741), 303 [DMT]$^+$. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 9.60 (bs, 1H), 8.11 (s, 1H), 7.36–7.08 (m, 11H), 7.01 (d, 3.2 Hz, 1H), 6.895 (dd, 3.6 Hz, 1H), 6.808 (d, 4 Hz, 1H), 6.77–6.66 (m, 4H), 6.28 (t, 6.6 Hz, 1H), 4.51 (t, 2.4 Hz, 1H), 4.09 (d, 2.4 Hz 1H), 3.61 (s, 6H), 3.34–3.24 (m, 2H), 2.54–2.50 (m, 1H), 2.28–2.23 (m, 1H). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 161.42, 158.5, 149.37, 144.26, 142.38, 138.99, 136.61, 135.50, 135.31, 133.35,129.94, 129.84, 127.98, 127.86, 126.96, 124.87, 124.06, 123.09, 120.96, 113.27, 100. 20, 87.01, 86.84, 86.07, 84.59, 72.42, 55.15, 63.53, 35.4.

5-(5-Ethynyl-[2,2′]bithiophenyl]-2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)uridine-3′-*O*-(2-cyanoethyl-*N*,*N*-diisopropyl)phosphoramidite (9). 5-(5-Ethynyl-[2,2′]bithiophenyl)-2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)uridine (**8**) (200 mg, 0.279 mmol, 1 equiv) and ethyl-*N*,*N*-diisopropylamine (238 μL, 1.4 mmol, 5 equiv) were stirred in dichloromethane (2 mL) and treated with 2-cyanoethyl-*N*,*N*-diisopropylchlorophosphoramidite (93 μL, 0.42 mmol, 1.5 equiv) under nitrogen. After 30 min at rt, the reaction mixture was diluted with dichloromethane (5 mL) and washed with sat aq $NaHCO_3$ (5 mL). The aqueous phase was re-extracted twice with dichloromethane (2 × 5 mL), and the combined organic phases were dried over Na_2SO_4. After solvent evaporation, the crude residue was purified by flash chromatography (silica gel, column prepared with CH_2Cl_2/TEA 9:1 and eluted with CH_2Cl_2/TEA/MeOH 98:1:1) to yield **9** (191 mg, 76% yield) as a yellow solid mixture of diasteroisomers.

^{31}P NMR (80 MHz, $CDCl_3$): δ 149.07 R_L, 148.65 R_{Hr}. ^{1}H NMR ($CDCl_3$, 400 MHz): δ 9.60 (bs, 2H, R_H + R_L), 8.22 (s, 1H, R_H), 8.17 (s, 1H, R_L), 7.44–7.15 (m, 22H, R_H + R_L), 7.10 (d, 4 Hz, 1H, R_L), 7.09 (d, 3.6 Hz, 1H, R_H), 6.99 (dd, 4 Hz, 3.6 Hz, 2H, R_H + R_L), 6.90 (d, 4 Hz, 1H, R_L), 6.88 (d, 4 Hz, 1H, R_H), 6.817–6.775 (m, 6H, R_H + R_L), 6.72 (d, 3.6 Hz, 1H, R_L), 6.68 (d, 3.6 Hz, 1H, R_H), 6.34 (t, 6 Hz, 1H, R_L), 6.32 (t, 6 Hz, 1H, R_H), 4.6 (m, 2H, R_H + R_L), 4.2 (m, 4H, R_H + R_L), 3.88–3.80 (m, 2H, R_H + R_L), 3.72 (s, 6H, R_L), 3.71 (s, 6H, R_H), 3.67–3.50 (m, 4H, R_H + R_L), 3.50–3.26 (m, 4H, R_H + R_L), 2.63 (m, 4H, R_H + R_L), 2.44 (t, 6.4 Hz, 2H, R_H + R_L), 2.35 (m, 2H, R_H + R_L), 1.18 (d, 6.5 Hz, 12H, R_L), 1.16 (d, 6.0 Hz, 12H, R_H).

2-Bromo-5-thiomethylthiophene (10). To a solution of 2-thiomethylthiophene (500 mg, 3.8 mmol, 1 equiv) in CH_2Cl_2/CH_3COOH (1:1) (33 mL) under nitrogen was added NBS (547 mg, 3.07 mmol, 0.8 equiv) at −15 °C in 30 min. After 2 h, the reaction mixture was diluted with CH_2Cl_2 (20 mL) and washed with 10% aq KOH (40 mL), sat aq $NaHCO_3$ (40 mL), and water (40 mL). The organic layer was dried over Na_2SO_4 and evaporated. The crude product was isolated as a colorless oil (583 mg, 73% yield) and used in the following step without further purification.

MS (*m/z*): 208, 210 [$M^{\cdot+}$] (calcd for $C_5H_5BrS_2$ 208, 210), 193, 195, [M – Me]$^+$. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 6.90 (d, 4.0 Hz, 1H), 6.87 (d, 4.0 Hz, 1H), 2.46 (s, 3H).

5-Thiomethyl-[2,2′]bithiophene (11). The microwave oven reactor was charged with 2-bromo-5-thiomethylthiophene (**10**) (583 mg, 2.79 mmol, 1 equiv), 2-(tributylstannyl)thiophene (886 μL 2.8 mmol, 1 equiv), $Pd(PPh_3)_4$ (322 mg, 0.28 mmol, 0.1 equiv) in toluene (10 mL). After 45 min of irradiation at 120 °C, TLC on silica gel with *n*-hexane as eluent showed the absence of **10**. The solvent was removed in vacuo, and the crude mixture was directly charged on a chromatography column. After chromatography eluting with *n*-hexane, the title compound was isolated (414 mg 70% yield).

MS (*m/z*): 212 [$M^{\cdot+}$] (calcd for $C_9H_8S_3$ 212), 197 [M – Me]$^+$. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 7.21 (d, 4.2 Hz, 1H), 7.13 (d, 3.4 Hz, 1H), 7.03–6.97 (m, 3H), 2.5 (s, 3H). ^{13}C NMR ($CDCl_3$, 50 MHz) δ 139.95, 137.10, 136.70, 131.79, 127.79, 124.53, 123.82, 123.76, 22.11.

5-Iodo-5′-thiomethyl-[2,2′]bithiophene (12). To a solution of 5-thiomethyl-[2,2′]bithiophene (414 mg, 1.95 mmol, 1 equiv) in CH_2Cl_2/CH_3COOH (1:1) (33 mL) under nitrogen was added NIS (395 mg, 1.76 mmol, 0.9 equiv) at –15 °C over 30 min After 2 h, the reaction mixture was diluted with CH_2Cl_2 (30 mL) and washed with 10% aq KOH (40 mL), sat aq $NaHCO_3$ (40 mL), and distilled water (40 mL). The organic layer was dried over Na_2SO_4 and evaporated. After chromatography eluting with *n*-hexane, the target product (488 mg, 74% yield) was isolated as a colorless oil.

MS (*m/z*): 338 [$M^{\cdot+}$] (calcd for $C_9H_{12}IS_3$ 338), 323 [M – Me]$^+$, 196 [M – Me – I]$^+$. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 7.14 (d, 4.0 Hz, 1H), 6.96 (d, 3.6 Hz, 1H), 6.95 (d, 3.6 Hz, 1H),

6.79 (d, 4.0 Hz, 1H), 2.5 (s, 3H). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 142.87, 138.08, 137.62, 137.12, 131.48, 124.98, 124.20, 22.92.

5-(Ethynyl)-2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)uridine (13). The synthesis and characterization of 5-(ethynyl)-2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)uridine (**13**) have been reported elsewere (*20*).

5-(5-Ethynyl-5′-tiomethyl-[2,2′]bithiophenyl)-2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)uridine (14). To a solution of 5-iodo-5′-thiomethyl-[2,2′]bithiophene (68 mg, 0.2 mmol) in anhydrous DMF (2 mL) under nitrogen was added CuI (8 mg, 0.04 mmol, 0.2 equiv), TEA (140 μl, 5 equiv), 5-(ethynyl)-2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)uridine (**13**) (111 mg, 0.2 mmol) and $Pd(PPh_3)_4$ (23 mg, 0.1 equiv, 0.02 mmol). The mixture was stirred 3 h at rt. The reaction mixture was concentrated in vacuo, then diluted with CH_2Cl_2 (20 mL), and washed with sat aq citric acid (15 mL), sat aq $NaHCO_3$ (15 mL), and water (15 mL). The organic phase was dried over Na_2SO_4, the solvent removed, and the crude mixture purified by flash chromatography eluting with 5% MeOH in CH_2Cl_2. The desired product was obtained as brown oil (110 mg, 66% yield).

ESI-MS (*m/z*): 786.9 $[M + Na]^+$ (calcd for $C_{41}H_{36}N_2O_7S_3$ + Na 787). ^{1}H NMR ($CDCl_3$, 200 MHz) δ 8.11 (s, 1H), 7.80 (bs, 1H), 7.90 (dd, 3.6 Hz, 1H), 7.58–7.50 (m, 1H), 7.44–7.38 (m, 2H), 7.36–7.14 (m, 9H), 6.84–6.70 (m, 4H), 6.33 (t, 6.6 Hz, 1H), 4.60 (m, 1H), 4.08 (d, 2.4 Hz 1H), 3.65 (s, 6H), 3.40–3.20 (m, 2H), 2.54–2.50 (m, 1H), 2.50 (s, 3H), 2.28–2.23 (m, 1H).

5-(5-Ethynyl-5′-tiomethyl-[2,2′]bithiophene)-2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)uridine-3′-*O*-(2-cyanoethyl-*N*,*N*-diisopropyl)phosphoramidite (15). A 0.45 M solution of tetrazole (0.104 mmol, 0.232 mL, 1 equiv) in anhydrous CH_3CN was added, with stirring under a flow of nitrogen, to a solution of 5-(5-ethynyl-5′-thiomethyl-[2,2′]bithiophenyl)-2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)uridine (**14**) (80 mg, 0.104 mmol, 1 equiv) in anhydrous CH_3CN (222 μL), followed by a solution of 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite (32 μL, 0.0708 mmol, in 40 μL of anhydrous CH_3CN). TLC analysis showed that the reaction was completed within 45 min with the formation of two diastereoisomers. The precipitated diisopropylammonium tetrazolide was removed by filtration and the solution diluted with anhydrous CH_3CN (1 mL) to give a 0.1 M solution of **15**. The solution was immediately used in the phosphitlylation step on the automated synthesizer, without further purification or analysis except for a check of the presence of the correct phosphoroamidite specie by phosphorous NMR analysis, on a small aliquot of the solution.

^{31}P NMR($CDCl_3$, 80 MHz) δ 149.46, 149.75.

5-(5-[2,2′]Bithiophenyl)-2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)uridine (17a). A mixture of 5′-*O*-(4,4'dimethoxytrityl)-5-iodo-2′-deoxyuridine (100 mg, 0.152 mmol 1 equiv), 5-tributylstannyl-[2,2′]-bithiophene (**16a**) (*21*) (277 mg, 0.610 mmol 4 eq) and $Pd(PPh_3)_2Cl_2$ (11 mg, 0.0152 mmol, 0.1 equiv) in dioxane (5 mL) was heated at 95 °C for 4 h. The solution was cooled and evaporated, and the mixture was purified by flash chromatography eluting with CH_3CN:H_2O (80:20). **17a** was obtained as a yellow solid (102 mg, 97% yield).

ESI-MS (*m/z*): 716.8 $[M + Na^+]$ (calcd for $C_{38}H_{34}N_2O_7S_2$ + Na 717). ^{1}H NMR (400 MHz, DMSO-d_6) δ 9.5 (brs, 1H), 7.92 (s,1H), 7.38 (d, 7.2 Hz, 2H), 7.30–7.10 (m, 9H), 6.99 (d, 3.6 Hz, 1H), 6.94 (dd, 3.6 Hz, 1H), 6.76–6.71 (m, 5H), 6.19 (t, 6.5 Hz, 1H), 4.49–4.47 (m, 1H), 4.15–4.12 (m, 1H), 3.65 (s, 6H), 3.45–3.41 (m, 1H), 3.35–3.31 (m, 1H), 2.05–1.95 (m, 1H), 2.35–2.25 (m, 1H).

5-(5-[2,2′]Bithiophenyl)-2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)uridine-3′-*O*-(2-cyanoethyl-*N*,*N*-diisopropyl)phosphoramidite (18a). 5-(5-[2,2′]Bithiophenyl)-2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)uridine (**17a**) (100 mg, 0.144 mmol, 1 equiv) and ethyl-*N*,*N*-diisopropylamine (123 μL, 0.72 mmol, 5 equiv) were stirred in THF (1 mL) and treated with 2-cyanoethyl-*N*,*N*-diisopropylchlorophosporamidite (48 μL, 0.216 mmol, 1.5 equiv) under nitrogen. After 30 min at rt, the reaction mixture was diluted with dichloromethane (5 mL) and washed with sat $NaHCO_3$ (5 mL). The aqueous phase was re-extracted twice with CH_2Cl_2 (2 × 5 mL), and the combined organic phases were dried over Na_2SO_4. After solvent evaporation, the crude residue was purified by flash chromatography (silica gel, column eluted with EtOAc/TEA/*n*-hexane 80:1:19) to give **18a** (102 mg, 80% yield) as a yellow solid mixture of diasteroisomers.

^{31}P NMR (80 MHz, $CDCl_3$) δ 150.27, 149.77 (R_L + R_H). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 9.60 (bs, 2H, R_H + R_L), 7.98 (s, 1H, R_H), 7.93 (s, 1H, R_L), 7.69–7.63 (m, 2H, R_H + R_L), 7.57–7.51 (m, 2H, R_H + R_L), 7.48–7.15 (m, 20H, R_H + R_L), 6.98–6.93 (m, 4H, R_H + R_L), 6.76–6.67 (m, 10H, R_H + R_L), 6.38 (t, 7.2 Hz, 1H, R_L), 6.37 (t, 7.2 Hz, 1H, R_H), 4.65 (m, 2H, R_H + R_L), 4.40 (m, 4H, R_H + R_L), 3.71 (s, 12H, R_L + R_H), 3.64–3.45 (m, 8H, R_H + R_L), 2.63–2.15 (m, 4H, R_H + R_L), 2.42–2.38 (m, 4H, R_H + R_L), 2.35–2.20 (m, 4H, R_H + R_L), 1.18 (d, 6.5 Hz, 12H, R_L), 1.16 (d, 6.0 Hz, 12H, R_H).

5-(5-[2,2′],[5′,2″]Terthiophene)-2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)uridine (17b). A mixture of 5′-*O*-(4,4′-dimethoxytrityl)-5-iodo-2′-deoxyuridine (230 mg, 0.35 mmol, 1 equiv), 5-(tributylstannyl)-[2,2′],[5′,2″]terthiophene (**16b**) (*22*) (750 mg, 1.4 mmol, 4 equiv), and $Pd(PPh_3)_2Cl_2$ (25 mg, 0.035 mmol, 0.1 equiv) in dioxane (10 mL) was heated at 95 °C for 4 h. The solution was cooled and evaporated, and the mixture was purified by chromatography on reversed-phase C-18 silica gel, eluting with CH_3CN/H_2O (80:20). **17b** was obtained as a yellow solid (109 mg, 40% yield).

ESI-MS (*m/z*): 774.7 $[M - H]^+$ (calcd for $C_{42}H_{35}N_2O_7S_3$ 775). ^{1}H NMR (400 MHz, DMSO-d_6) δ 11.8 (s, 1H), 7.97 (s, 1H), 7.4–7.3 (m, 4H), 7.30–7.14 (m, 9H), 7.09 (dd, 3.6 Hz, 1H), 7.03 (d, 4.0 Hz, 1H), 6.99 (d, 4.0 Hz, 1H), 6.80 (dd, 5.6 Hz, 4H), 6.19 (t, 6.5 Hz, 1H), 4.45 (brs, 1H), 3.95–3.90 (m, 1H), 3.65 (s, 6H), 3.40 (m, 1H), 2.70–2.90 (m, 1H), 2.25–2.35 (m, 1H), 1.60 (m, 2H).

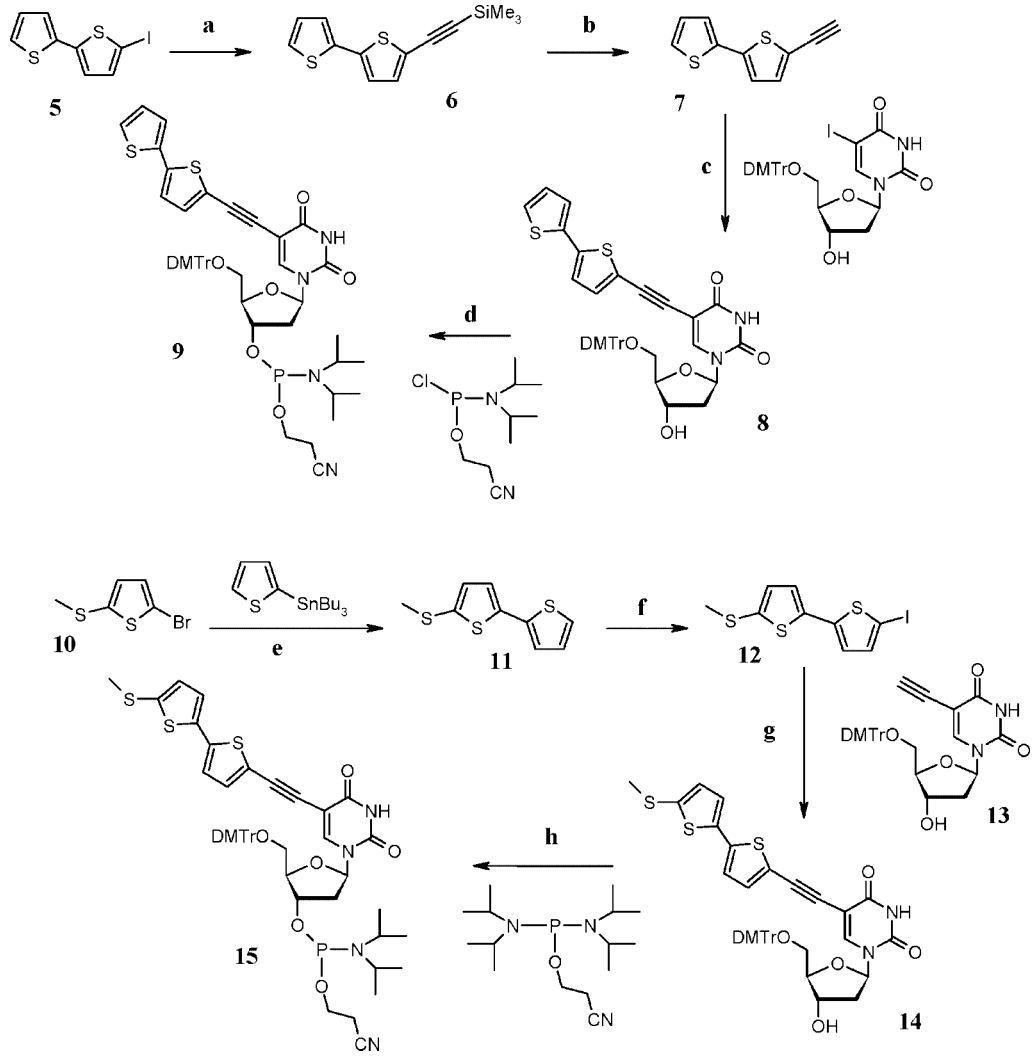
5-(5-[2,2′],[5′,2″]Terthiophenyl)-2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)uridine-3′-*O*-(2-cyanoethyl-*N*,*N*′-diisopropyl)phosphoramidite (18b). A 0.45 M solution of tetrazole (0.07 mmol, 0.157 mL, 1 equiv) in anhhydrous CH_3CN was added at rt, stirring under N_2 atmosphere, to a solution of 2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)-5-[-[2,2′],[5′,2″]terthiophene]uridine (**17b**) (55 mg, 0.07 mmol, 1 equiv) in 350 μL of anhydrous CH_3CN followed by 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite (0.0708 mmol, 22.5 μL, 1 equiv). TLC analysis showed that the reaction was completed within 45 min with formation of two diastereoisomers. The precipitated diisopropylammonium tetrazolide was removed by filtration and the solution diluted with CH_3CN (350 μL) to give a 0.1 M solution of **14**, which was immediately used in the following step without further purification.

RESULTS AND DISCUSSION

Synthesis. The 5′-dimethoxytrityl derivatives of compounds **1**–**4** were prepared from the corresponding 5′-dimethoxytrityl of 5-iodouridine (*18*, *19*) applying Sonogashira's or Stille's coupling. The compounds were then converted to phosphoramidites using the 2-cyanoethyl-*N*,*N*-diisopropylchlorophosphoramidite or the 2-cyanoethy *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite. The synthetic pathways are showed in Schemes 1 and 2.

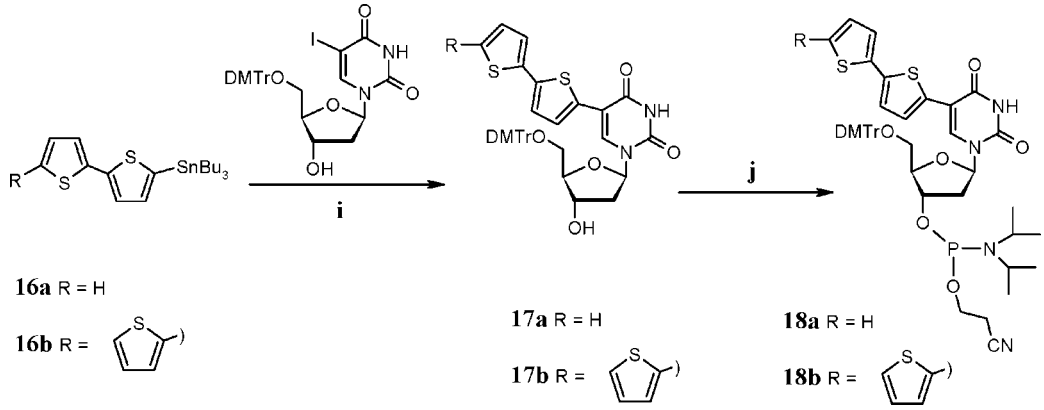
Compound **8** was obtained via Sonogashira's coupling of the ethynyl bithiophene **7** with the dimethoxytritylated iodouridine (*18, 19*); the S-Me analogue **14** was prepared with the same methodology but a reverse strategy, in which the ethynyl moiety

Scheme 1. Synthesis of 5-Alkinyl-Oligothiophene-Deoxyuridine Phosphoramidites[a]



[a] **a.** trimethylsilyl acetylene, $Pd(PPh_3)_4$, CuI, TEA in DMF, 20 min microwave irradiation, (79% yield); **b.** K_2CO_3 in 8/2 hexane/MeOH, 2 h rt, (74% yield); **c.** $Pd(PPh_3)_4$, CuI, TEA in DMF, 3 h rt, (60% yield), **d.** DIPEA in CH_2Cl_2, 30 min rt (76% yield); **e.** $Pd(PPh_3)_4$ in toluene, 45 min microwave irradiation, (70% yield), **f.** NIS dropwise in 1:1 CH_2Cl_2/AcOH at −15 °C then 2 h at rt (74% yield); **g.** $Pd(PPh_3)_4$,CuI, TEA in DMF, 3 h rt, (66% yield); **h.** 1/1 CH_2Cl_2/CH_3CN, tetrazole, 45 min rt, (yield >90% on TLC, compound not isolated).

Scheme 2. Synthesis of 5-Oligothiophene-Deoxyuridine Phosphoramidites[a]



[a] **i.** $Pd(PPh_3)_2Cl_2$ in dioxane, 4 h 95°C, (yields: **17a** 97%, **17b** 40%); **j.** [(**a** 2-cyanoethyl-chloro-diisopropylaminophosphoramidite, DIPEA in THF, 30 min rt, 80% yield). (**b.** 2-cyanoethyl *N,N,N′,N′*-tetraisopropylphosphorodiamidite, tetrazole in 1/1 CH_2Cl_2/CH_3CN, 45 min rt, yield >90% on TLC, compound not isolated)].

was previously linked to the uridine nucleoside, since this allowed an easier purification step. Furthermore, compound **14**, available in a limited amount (80 mg left after analysis) was phosphitylated by using 1 equiv of 2-cyanoethyl *N,N,N′,N′*-tetraisopropylphosphorodiamidite and 1 equiv of tetrazole. This gave, after the filtration of the diisopropylammonium tetrazolide, a concentrated solution that was diluted with CH_3CN to a formal concentration of 0.1 M and immediately used for the automated

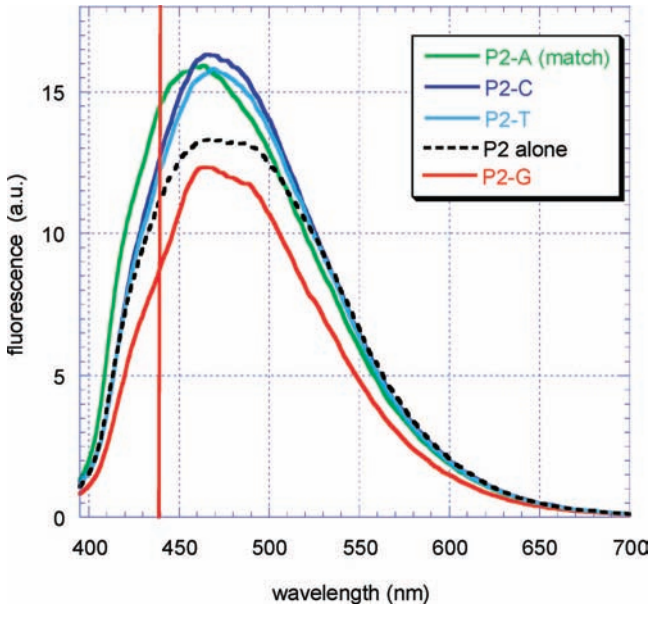

Figure 3. Fluorescence emission of **P2** alone and hybridized with the four targets after irradiation at 375 nm.

synthesis of the probe **P2**. This procedure (*23*) allowed us to carry out the synthesis of the probe without risking any loss of the amidite **15** (due to hydrolysis or manipulation) in the purification steps.

Compounds **17**(**a** and **b**) were obtained using the Stille's coupling of dimethoxytrityliodouridine with the tributhylstannyl derivative of the bi- or terthiophene **16**. The coupling gave an almost quantitative yield in the case of the bithiophene derivative **17a**, but a moderate yield in the case of the compound **17b** probably due to a lower reactivity of the larger oligothiophene and to severe product loss during the chromatographic purification step. Phosporoamidite **18b** was obtained by use of 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite without isolation step.

All the probes were synthesized on a Pharmacia Gene Assembler 2, repeating two times the coupling step for the modified uridine, without the intervening capping, with a 2 min longer coupling time, on a 1.3 μmol scale. With these precautions, we did not notice any lowering of efficiency in the coupling steps.

The oligonucleotide targets (**A**, **C**, **G**, **T**) were prepared on the same synthesis scale using commercial reagents. All the oligonucleotides were deblocked by treatment with 30% aqueous ammonia at 50 °C for 16 h, then lyophilized. The targets were purified by precipitation with *n*-BuOH and judged sufficiently pure by reversed-phase HPLC analysis at 260 nm (80–85%). The probes were purified by reversed-phase HPLC using double detection: UV at 260 nm and fluorescence at the maximum of emission of every derivative. Final compounds were judged more than 90% pure by UV and more than 95% pure by fluorescence. The identity of the probes was determined by a careful analysis of the UV–vis spectra (giving the expected ratio UV/vis) and from ESI-MS analysis: **P1** calcd *m*/*z* for $C_{184}H_{225}N_{62}O_{108}P_{17}S_2$ 5623.88, found 5624.02; **P2** calcd *m*/*z* for $C_{185}H_{227}N_{62}O_{108}P_{17}S_3$ 5669.97, found 5669.17; **P3** calcd *m*/*z* for $C_{182}H_{225}N_{62}O_{108}P_{17}S_2$ 5599.86, found 5599.64; **P4** calcd *m*/*z* for $C_{186}H_{227}N_{62}O_{108}P_{17}S_3$ 5681.98, found 5682.00.

UV and Fluorescence Experiments. The UV–vis and the fluorescence emission spectra of the each probe were registered at 25 and at 70 °C at 1 μM concentration in an aqueous buffer containing 100 mM NaCl and 10 mM sodium cacodylate at pH 7.0. They did not reveal any significative changes but a 10–15% loss of fluorescence emission at the higher temperature. This behavior was already observed in our previous work (*15*) with this class of fluorophores and was attributed to a slight loss of coplanarity of the thiophene rings and increasing collisional quenching due to the heating.

Three more cuvettes were prepared for each probe at 1 μM concentration in the same buffer and checked against the first sample, UV and fluorescence intensity were found in a range of less than 0.5–1% difference. To each cuvette of 3000 μL was then added 1.2 equiv (10–20 μL from concentrated aqueous solution) of the four complementary strands. The samples were heated to 90 °C and left to cool in a beaker (in about 3 h) to favor the annealing. The UV-melting profile was then recorded at 260 nm during both heating and cooling, in the range 10–75 °C, at a rate of 0.5 °C/min. The found melting temperatures are reported on Table 2.

After the melting experiments, the very same samples were used to measure the variation of fluorescence of the four hybrids of the **P1**–**P4** probes. These measurements are the core of this research and show interesting features that will be presented on the same scale and discussed in detail. All the probes were excited at the maximum of their visible absorption. To ensure that the measurements of the mixtures were not affected by the presence of accidental quenchers in the target solutions, we recorded the fluorescence of every mixture at 70 °C and found them equal to those obtained with the corresponding isolated probe at the same temperature.

Fluorescence of **P1** *(ethynyl-t_2) and Its Hybrids.* Fluorescence emissions of **P1** alone and hybridized with the four targets are shown in Figure 2.

The graph shows that **P1** is able to discriminate between the perfect match with **target-A** (−20% in the emitted intensity

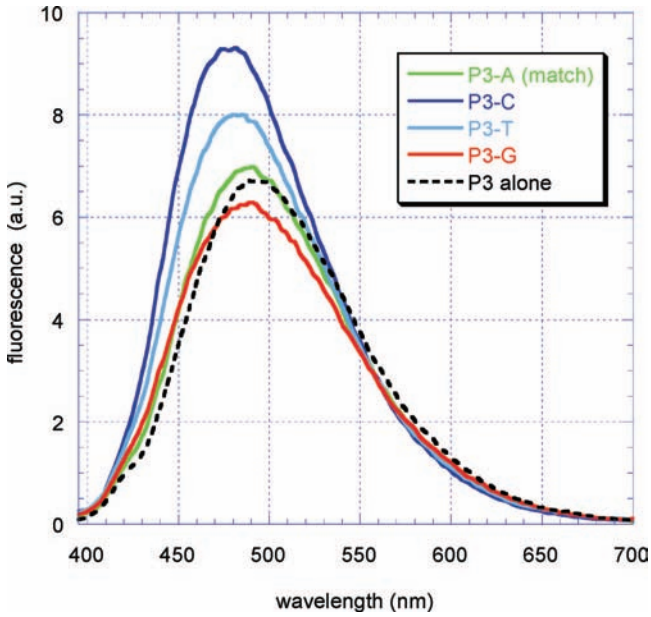

Figure 4. Fluorescence emission of **P3** alone and hybridized with the four targets after irradiation at 360 nm.

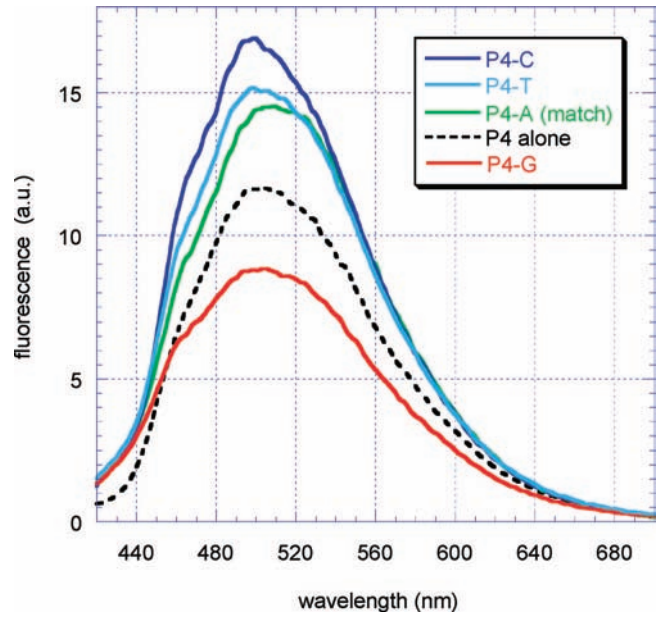

Figure 5. Fluorescence emission of **P4** alone and hybridized with the four targets after irradiation at 400 nm.

respect to unhybridized **P1**), **target-G** (−35%), and the pair of **targets C** and **T** (+15, +18%).

Fluorescence of **P2** *(ethynyl-t_2-SMe) and Its Hybrids.* The fluorescence characteristics of **P2** and its hybrids are reported in Figure 3.

Compared to the previous probe, **P2** shows lower and broader signals, reflecting the increased dimension of the molecular orbital, now including an S-Me substituent. Here, we can see that hybrids formed with **probes C** and **T** show very similar signals; the hybrid with **probe A** has a similar intensity to the previous two, but its maximum is blue-shifted by about 10 nm. The three signals are about 18% more intense than the isolated probe. The hybrid with **probe G** shows a signal 10% weaker than that showed by the single-strand probe. If we look at the value of the emitted light at 440 nm, we can easily observe that the emission of the probe alone is halfway between that of the mismatch with **probe G** (−20%) and that of the match with **probe A** (+36%). Again, the mismatches with **probes C** and **T** (+18%) are too close to be distinguished. This can be considered an ideal probe to look for a G to A transition: it is sufficient to record the emission of the probe alone and hybridize it with the unknown target; then, if the emission is higher than before, this reveals a match, and if it is lower, it is a G mismatch (besides, C and T mismatch can also be detected with a careful measurement).

Fluorescence of **P3** *(t_2) and Its Hybrids.* The graphics of the fluorescence emission of **P3** and its hybrids are reported in Figure 4.

There is no clear difference in intensity between the signal of the single strand and those of the hybrids with **A** and **G targets**; instead, the intensities of the maxima of the hybrids with **targets T** (+18%) and **C** (+44%) can clearly be distinguished. Small differences perhaps exploitable for the recognition of the formed hybrids can be seen in the positions of the maxima: they move from 492 (**P3** alone), to 488 (**P3-G**, **P3-A**), to 482 (**P3-T**), to 478 (**P3-C**).

By comparing the emission of this probe with those of **P1**, it can be seen that the intensity of the emission is between three and four times lower in the absence of the ethynyl linker.

Fluorescence of **P4** *(t_3) and Its Hybrids.* The graphics of the fluorescence emissions of **P4** hybrids and isolated **P4** are reported in Figure 5.

These emissions are the widest and the most structured among the four probes. Compared to the signal of the **P4** probe alone, hybrids with **targets C** (+47%), **T** (+30%), and **A** (+26%) are clearly distinguishable even if the last two are closely grouped; the hybrid with **target G** can also be neatly recognized (−22%). Furthermore, all compounds have an emission maximum centered at 500 nm except for the hybrid with **target-A** that is shifted to 510 nm.

Only a few methods of mismatch detection based on fluorescence of the facing base have been reported in the literature. Among the most recent ones, Tor reports the use of 1,10-phenantroline-ethynyl-5-uridine (*11*) and demonstrates a fair sensitivity in recognizing the pairing nucleosides comparing the emission ratio at two different wavelengths in a range from 0.95 for the match with adenosine to 1.2 for the worst tolerated mismatch with cytidine; Kim shows the ablility to appreciate with the naked eye the correct pairing of a 5-(1-ethynylpyrenyl)-2′-deoxyuridine incorporated into an oligonucleotide with respect to the three possible mismatches (*12*); however, all of them are not very fluorescent and their emissions quite similar.

With the aim to explore the potentialities of oligothiophenes as markers for biomolecules, we have developed the synthesis of oligothiophene-5-labeled deoxyuridines. (Compound **3** was previously obtained, by a different strategy, by Van Aerschot's group (*24*), and studied for its antiviral properties.) Our results demonstrate that the new uridines, integrated into an oligonucleotide, are apt to discriminate between the correct pairing and mispairings.

Despite the steric hindrance of the labels, uridines did not interfere significantly with the hybridization process (differences between the match and mismatches are less than 3 °C); neither showed any tendency to intercalate between base pairs, as demonstrated by lack of variance of absorbance in the visible part of the spectra and by structures obtained by the modeling of **P3** with all the probes (not shown). Akin to the case of molecular beacons (*15*), the emissions of oligothiophene derivatives are exquisitely sensitive to the local environment, and this characteristic is potentially exploitable for the analysis of SNPs. Usually, the mutation to be analyzed is well-known and consists of a single nucleoside exchange: A to G (as in our case), but if different exchanges are possible, probes like **P3** and **P4** can be used to reveal each of them.

In our case, we observed the lowest emission when any of the probes was facing G, a feature common to several fluorophores (*15*, *25*, *26*). The behavior of the single probes with **C**, **T**, and **A** is still unclear and might be the object of a future communication. At this stage, the prevision of a higher or lower fluorescence emission, in case of a match or a mismatch, cannot easily be made, and more experimental studies are required. In particular, it could be interesting to see what kind of results are obtained by tagging nucleosides other than dU.

CONCLUSION

We have synthesized four different probes containing a deoxyuridine modified with oligothiophene derivatives at the 5-position. All the probes fluoresce at different wavelengths, and all show variations of emission intensity (from 10% to 47% higher or lower than those of the isolated probes), upon hybridization with targets containing all four bases opposite the uridine. These variations are comparable or even superior to those reported in similar studies and could be potentially exploited for an easy SNP recognition in biological laboratories equipped with a bench spectrofluorimeter or automatic high-throughput devices.

ACKNOWLEDGMENT

We thank Giorgia Brancolini (ISOF-CNR) for modeling studies performed on hybrids of **P3**. This work was partially funded by FIRB RBNE03S7XZ_005 (SYNERGY) project.

BRET-Based Method For Detection of Specific RNA Species

Zachary F. Walls[†] and Sanjiv S. Gambhir*[,‡]

Received July 23, 2007; Revised Manuscript Received September 24, 2007

RNA detection and quantitation is a common necessity in modern molecular biology research. Most methods, however, are complex and/or time-intensive. Presented here is a BRET (bioluminescene resonance energy transfer)-based method that can accomplish the task of RNA identification quickly and easily. By conjugating BRET enzymes to two different oligonucleotides that are complementary to the same target sequence, probes were developed that could detect RNA using a solution-based assay. This assay was optimized for spacer length between the binding sites (found to be 10 nucleotides), and sensitivity was determined to be 1 μg for a specific species of RNA within a mixed population. Specificity of the assay was assessed using *in vitro* transcribed cRNA and found to be statistically siginificant ($p = 3.11 \times 10^{-6}$, ANOVA, multiple range test). This assay represents a possibility for a less technically demanding, streamlined alternative to canonical RNA assays.

INTRODUCTION

Seqeunce-specific RNA detection and quantitation have become increasingly critical components of biological research since the completion of the human genome sequencing project. Recently, a number of efforts have been made to look at global levels of gene transcripts, while many other investigators have looked specifically at transcription levels of a few key genes under different conditions. Several methods currently exist to accomplish this task with varying levels of complexity. The Northern blot was developed several decades ago and represents one of the first efforts to detect specific RNA sequences using isotopic DNA probes (*1*). Since then, many other methods have been developed to accomplish essentially the same task including, but not limited to, RNase-protection assays, RT-PCR, and multiwell plate-based sandwich assays (*2–4*). All of these assays require time and effort to optimize and can often frustrate and sometimes deter inexperienced researchers. In an attempt to simplify the process of RNA detection, a BRET (bioluminescence resonance energy transfer)-based method for RNA detection in solution has been developed.

BRET is a phenomenon originally described in several marine organisms and developed as a technique to monitor protein–protein interactions, among other molecular events (*5*). In its classical form, a bioluminescent enzyme is fused to one protein and a fluorescent protein to another. If and when the two proteins interact, the BRET proteins become colocalized. Then, if the bioluminescent enzyme's emission spectrum overlaps with the excitation spectrum of the fluorescent protein, an energy transfer reaction occurs producing emission of photons at the fluorescent protein's emission wavelength. The advantage of using BRET over the more traditional fluorescence resonance energy transfer is that the bioluminescent enzyme catalyzes the energy needed for the reaction by oxidizing its substrate, hence obviating the need for input photons and eliminating the risk of photobleaching. The necessity of a laser to produce excitation photons increases costs and limits generalizability. Additionally, the omission of input photons makes BRET-based technologies more amenable to imaging of living subjects, due to the absorptive properties of tissue for lower wavelengths of light (*6–8*).

In order to apply BRET technology to RNA detection, a pair of BRET proteins (RL8 and GFP^2) were produced in bacteria and purified using several rounds of chromatography. RL8 is a thermostable variant of *Renilla* luciferase, and GFP^2 is a spectral variant of green fluorescent protein (*7*, *9*). These proteins were then chemically conjugated to two different functionally derivatized antisense oligonucleotides, each complementary to a different portion of the same target RNA. The target then served as a scaffold upon which the bioconjugates could bind. Thus, in the presence of the target RNA, the enzymes were able to colocalize and carry out the BRET reaction (Figure 1). However, in the absence of the target, only light from the BRET donor (RL8) was seen. A solution-based assay was developed to demonstrate specificity and sensitivity, as well as determine the optimal spacing between binding sites.

METHODS

Protein Production. RL8, a thermostable mutant of *Renilla* luciferase, containing an N-terminal pelB signal sequence and a C-terminal 6×His tag was periplasmically expressed in bacteria as previously described (*7*). Briefly, bacteria transformed with the expression plasmid were grown at 32 °C until an OD_{600} of 0.7 was reached. The cells were induced with 0.2% arabinose and harvested 12–14 h later. The periplasmic fraction was isolated by osmotic shock and then purified by affinity chromatography using Ni-NTA agarose resin. Further purification was unnecessary due to the initial purity of the elution fraction. GFP^2, a spectral mutant of GFP, was cloned into the pBAD/myc-HisA vector (Invitrogen) using PCR to append an NcoI site to the 5′ end and a *Hin*dIII site onto the 3′ end. LMG-bacteria transformed with the expression plasmid were grown at 37 °C until an OD_{600} of 0.6 was reached. The cells were induced with 0.2% arabinose, and the cultures were incubated at 30 °C with shaking (200 rpm) for 24 h. Cells were pelleted by centrifugation at 6000 × *g* for 15 min at 4 °C. The

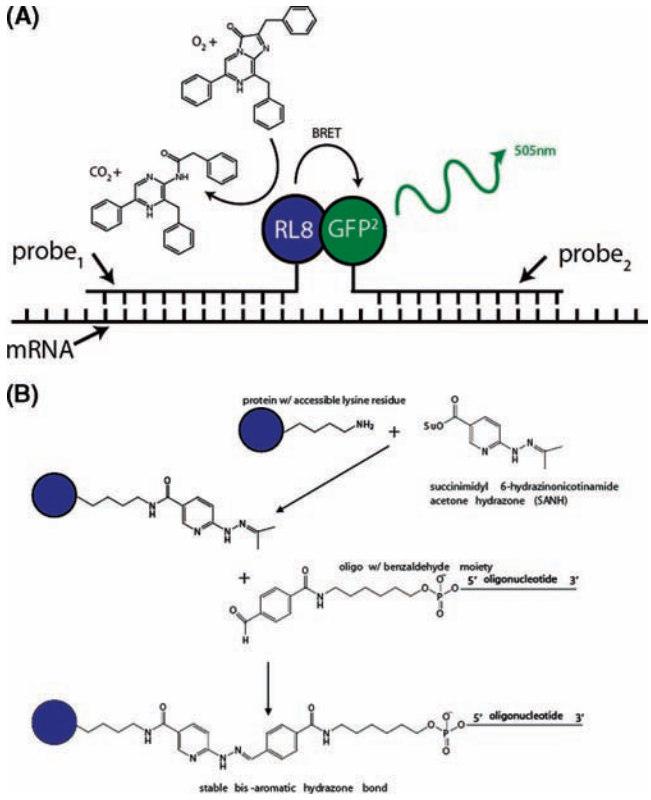

Figure 1. (a) General strategy for BRET-based RNA detection. Probe$_1$ consists of a 20-mer oligonucleotide conjugated at the 5′ end to the thermostable bioluminescent protein (RL8). Probe$_2$ consists of a 20-mer oligonucleotide conjugated at the 3′ end to the fluorescent protein GFP^2. Both probes are complementary to different portions of the same mRNA target gene. Thus, the target mRNA serves as a scaffold upon which the probes can bind, bringing the proteins into proximity with one another. When RL8 oxidizes its substrate, the energy produced is nonradiatively transferred to GFP^2, which then emits photons at a characteristic wavelength as its chromophore returns to the ground state. (b) Chemical scheme for conjugation. SANH is used to modify endogenous lysines on the protein to contain hydrazone moieties. The modified proteins are then reacted with benzaldehyde-modified oligonucleotides to produce bioconjugates joined by a stable bis-aromatic hydrazone bond.

supernatant was decanted and the pellets stored at −20 °C overnight. Pellets were resuspended 1:20 (volume depended on original culture volume) in lysis buffer (50 mM NaH_2PO_4, 300 mM NaCl, 10 mM imidazole, pH 8.0) plus 1 mg/mL lysozyme and allowed to incubate at RT for 1 h. The resuspended cells were then sonicated with six 10 s bursts, with 10 s intervals on ice. Insoluble material was then pelleted by centrifugation at 10 000 × *g* for 30 min, 4 °C. The soluble fraction was incubated with a Ni-NTA agarose (Qiagen) slurry for 1 h with rotation at 4 °C and then poured into an empty column and allowed to flow through the settled resin. The resin was then washed with wash buffer (50 mM NaH_2PO_4, 300 mM NaCl, 20 mM imidazole, pH 8.0) and the protein eluted with elution buffer (50 mM NaH_2PO_4, 300 mM NaCl, 250 mM imidazole, pH 8.0). The elution fraction was buffer-exchanged into 20 mM Tris, pH 8.0, using PD-10 columns and then purified using Source 15Q media and an AKTA basic (GE Healthcare). Fractions containing GFP^2 were pooled and concentrated.

Chemical Conjugation of Proteins to Oligonucleotides. Proteins (<200 μg) were reacted with 60 mol equiv of succinimidyl 6-hydrazinonicotinate acetone hydrazone (SANH, SoluLink) at RT with rotation in 130 μL total volume, made up with PBS for >2 h. The modified proteins were then desalted into conjugation buffer (100 mM MES, 150 mM NaCl, pH 4.7) using Zeba desalt spin columns, 0.5 mL (Pierce), according to the manufacturer's protocol. Protein concentration was remeasured following desalting using BioRad protein assay reagent. 20-mer oligonucleotides with a phosphodiester backbone and containing either a 5′ or 3′ aldehyde moiety were synthesized by TriLink. The sequences of the oligos used in this study are as follows: AS-1a, 5′*Ald*TGCATACGACGATTCTGTGA3′ (sequence graciously provided by Dr. Tracie Pierce, University of Melbourne); AS-1b, 5′*Ald*TCACAGAATCGTCGTATGCA3′; AS-2a, 5′AGAAGTTAAGAAATACGGCC *Ald*3′; AS-3, 5′CCGGCATAAAGAATTGAAGA *Ald*3′. These sequences are either complementary (AS-1a:585-604, AS-3:615-634) or homologous (AS-1b:585-604) to the firefly luciferase gene sequence (M15077). AS-2a is the reverse sequence of AS-3. Modified proteins were reacted with 1.5 mol equiv of oligonucleotide at RT with rotation in conjugation buffer for >2 h. These reaction conditions are in general agreement with a previously described report using this conjugation method to link proteins with oligonucleotides (*8*). The degree and efficiency of conjugation were assessed by reducing SDS-PAGE and stained using Imperial protein stain (Pierce) according to the manufacturer's protocol.

Luciferase Assay. Purified RL8 and oligonucleotide-conjugated RL8 were subjected to a luciferase assay using a Turner 20/20n luminometer. Equal mass amounts of the conjugated and unconjugated protein were combined with 100 μL of assay buffer (5 mM Tris, 0.5 mM EDTA, 0.6 M NaCl, 50 mM KPO_4, 0.1 g/L BSA, 0.03 mM NaN_3). 1 μL of coelenterazine (0.5 μg/μL in 50:50 methanol/propylene glycol) was added to the solution, vortexed briefly, and then placed inside the luminometer. Photon flux was collected over 10 s.

Assay Development for Probe Validation. Two separate assays were used to determine the properties of the oligo−protein conjugates described above. For the single probe experiments, target DNA oligonucleotides were 5′-end-labeled with biotin by the PAN facility at Stanford University. These target oligonucleotides (<125 pmol/well) were bound to 96-well, black, streptavidin-coated plates (Pierce). The wells were first washed 3 times with 200 μL PBST (phosphate buffered saline, pH 7.4, plus 0.05% Tween 20), and then the oligonucleotides, diluted in a total of 100 μL PBST/well, were dispensed into each well and incubated at RT for 1 h. The wells were then washed 3 times with 200 μL PBST. RL8-conjugated probes (to either AS-1a or AS-1b) were diluted in PBST and then aliquoted into the appropriate wells (3.38 μM, 100 μL/well). The plates were sealed with tape to prevent evaporation and allowed to hybridize at 45 °C for 30 min. Wells were washed 3 times with 200 μL PBST. Prior to imaging, wells were kept in 50 μL assay buffer (5 mM Tris, 0.5 mM EDTA, 0.6 M NaCl, 50 mM KPO_4, 0.1 g/L BSA, 0.03 mM NaN_3). Immediately prior to imaging, 50 μL of assay buffer plus 2 μL/mL of coelenterazine (0.5 μg/μL in 50:50 methanol/propylene glycol, 10 μM final concentration) was added to each well. The plate was imaged in an IVIS-50 (Caliper Life Sciences Inc., Alameda, CA) for 15 s using the highest binning. For assays involving dual probes, experiments were carried out using regular 96-well, black plates. Target oligonucleotides or *in vitro* transcribed cRNA were diluted in 50 μL PBST and aliquoted into each well. Target oligonucleotides for the dual probe assay were 5′-end-labeled with biotin and synthesized by the PAN facility at Stanford University. Their sequences are as follows: 1b/2a, 5′TCACAGAATCGTCGTATGCA(N)$_n$AGAAGTTAAGAAATACGGCC3′; 1b/2b, 5′TCACAGAATCGTCGTATGCA(N)$_n$GGCCGTATTTCTTAACTTCT3′, where N is a random base and *n* is 10, 20, 30, or 40. Probes were diluted in PBST to 50 μL/well and added to the appropriate wells (2.54 μM final concentration). The plate was sealed and incubated at 40 °C for 30 min. Immediately prior to imaging, 50 μL of assay buffer

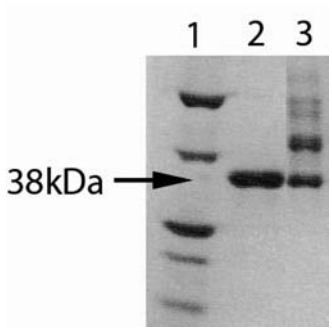

Figure 2. Results of conjugation reaction between SANH-modified RL8 and 20-mer aldehyde-functionalized oligo visualized by reducing SDS-PAGE using bis-tris 4–15% polyacrylamide gels and stained with Imperial Stain. Lane 1: ladder. Lane 2: unconjugated RL8 protein at 38 kDa. Lane 3: conjugation reaction products showing unconjugated RL8, monoconjugates at 45 kDa, and polyconjugates at 7 kDa intervals. This reaction condition produced a majority of monoconjugates.

plus 2 μL/mL of bisdeoxycoelenterazine (DBC, 0.5 μg/μL in 50:50 methanol/propylene glycol, 1.28 μM final concentration) was added to each well. DBC is a coelenterazine analogue, which, when oxidized by RL8, produces photons with a peak at 395 nm, compared to the 480 nm emission peak produced by the oxidation of native coelenterazine (*7*). The plate was imaged in an IVIS-200 (Caliper Life Sciences Inc.) for 15 s using the highest binning and a GFP^2-specific filter (500–570 nm), and then for 15 s using the highest binning and an RL8/DBC-specific filter (370–450 nm). Both the IVIS-50 and IVIS-200 use a cooled CCD (charge-coupled device) camera to detect photons of light. The IVIS-200 is additionally equipped with BRET-specific filters.

***In Vitro* Transcription.** Firefly luciferase (Fluc) cRNA was transcribed *in vitro* by linearizing a plasmid containing the gene downstream of the prokaryotic T7 promotor. Promega's T7 RiboMAX express kit was used according to the manufacturer's protocol to produce Fluc cRNA as well as RNA from the pGEM linear control DNA supplied with the kit. Following DNase treatment, the *in vitro* transcription reactions were purified using Qiagen's RNeasy mini kit for enzymatic cleanup according to the manufacturer's protocol. Quality and quantity of RNA was assessed spectrophotometrically using 10 mM Tris, pH 7.5, as the dilution buffer.

Data Analysis and BRET Calculations. Images using both the IVIS-50 and IVIS-200 were analyzed using *LivingImage 2.50* software. Absolute values were reported in photons/seconds/square centimeters/steradian (p/s/cm^2/sr). Regions of interest (ROIs) of equal size were drawn over each well and then measured for average radiance. To calculate BRET signal from samples that contained both RL8 and GFP^2, the following formula was used:

$$\mathrm{BRET}_{\mathrm{signal}} = \frac{\mathrm{Em}_{\mathrm{GFP2}} - \mathrm{Cf} \times \mathrm{Em}_{\mathrm{RL8}}}{\mathrm{Em}_{\mathrm{RL8}}}$$

where $\mathrm{Cf} = \mathrm{Em}_{\mathrm{GFP}}{}^2/\mathrm{Em}_{\mathrm{RL8}}$ for a control sample which has the same conditions, but in which RL8 cannot transfer energy to GFP^2 (*10*).

RESULTS

Chemical Conjugation of Proteins to Oligonucleotides. RL8 and GFP^2 were expressed and purified such that no other proteins could be visualized by Imperial protein staining (Figure 2). Yields for RL8 were typically >100 mg/L and >10 mg/L for GFP^2. To determine the appropriate molar ratios of protein, succinimidyl 6-hydrazinonicotinate acetone hydrazone (SANH), and oligonucleotide necessary for efficient conjugation, a series of experiments were performed varying the concentration of SANH and oligo while keeping the mass amount of RL8 constant. SANH was reacted with RL8 at 20-, 40-, 60-, 80-, and 100-fold molar excess, and then each condition was buffer-exchanged and reacted with either 1- or 10-fold molar excess of AS-1a. No change was seen between the 1× and 10× oligonucleotide conditions. The 60× SANH condition produced the greatest fraction of monoconjugated species while also limiting the number of polyconjugated species as determined by visual inspection following reducing SDS-PAGE (Figure 2). The time of the SANH-modification reaction was also varied to determine its effect on conjugation efficiency. Reactions were allowed to progress 2, 4, 6, or 8 h, desalted, and then conjugated to oligonucleotides. Extending the reaction time beyond 2 h had no significant effect on the conjugation reaction.

Using the 60 × SANH/1 × oligonucleotide condition with a 2 h conjugation reaction time, conjugates were produced to assess the loss of luminescence as a result of the conjugation reaction. The luciferase assay revealed that the conjugation reaction was able to retain ~20% of the bioluminescence compared to unconjugated RL8 subjected to identical reaction conditions.

Assay Development for Probe Validation. To assess the retention of both luciferase activity and nucleic acid binding potential following conjugation, the RL8/AS-1a probe was first tested by itself. An assay was developed to determine the bifunctionality of the bioconjugate. Single-stranded biotinylated DNA target oligos were bound to the wells of streptavidin-coated plates, then RL8-conjugated probes were hybridized to the targets and the excess probe was washed away. Coelenterazine was added to the wells and the plate was imaged briefly in the IVIS-50 (Figure 3). Target oligos were hybridized with probe sequences that were either exactly homologous or exactly complementary. Significant signal was seen only from wells in which complementary oligos had been hybridized ($p < 0.04$, Kruskal–Wallis test).

After demonstrating that the bioconjugate probes retained dual functionality, the assay was modified to test the potential of the two-probe approach. For this purpose, target oligos were constructed that contained either one or both binding sites for the probes, separated by *n* random nucleotides. Target oligos and probe conjugates (sequences AS-1a and AS-2a) were combined in solution and allowed to hybridize as before. Without washing, DBC was added to the wells and imaged briefly in the IVIS-200 using BRET-specific filters. BRET signal was observed only in wells for which both binding sites were present (Figure 4). For each spacer length, the experimental group was statistically different from its control ($p < 0.004$, paired, two-tailed *t* test). The BRET signals for each spacer length were also statistically different ($p = 1.15 \times 10^{-6}$, ANOVA) and the groups signified by different letters in Figure 4 were statistically different from each other (multiple range test).

To show that this assay was compatible with RNA detection, two species of cRNA were transcribed *in vitro*. As before, the cRNA was hybridized with dual BRET probes and imaged using BRET-specific filters (Figure 5). Only when the correct probes were combined with the target RNA (Fluc) was a significant BRET signal observed ($p = 3.11 \times 10^{-6}$, ANOVA, multiple range test). To investigate the sensitivity of the assay, different amounts of target and control RNA were combined (keeping the total amount of RNA constant) and probed as previously described (Figure 6). It was found that as little as 5.5 pmol (1

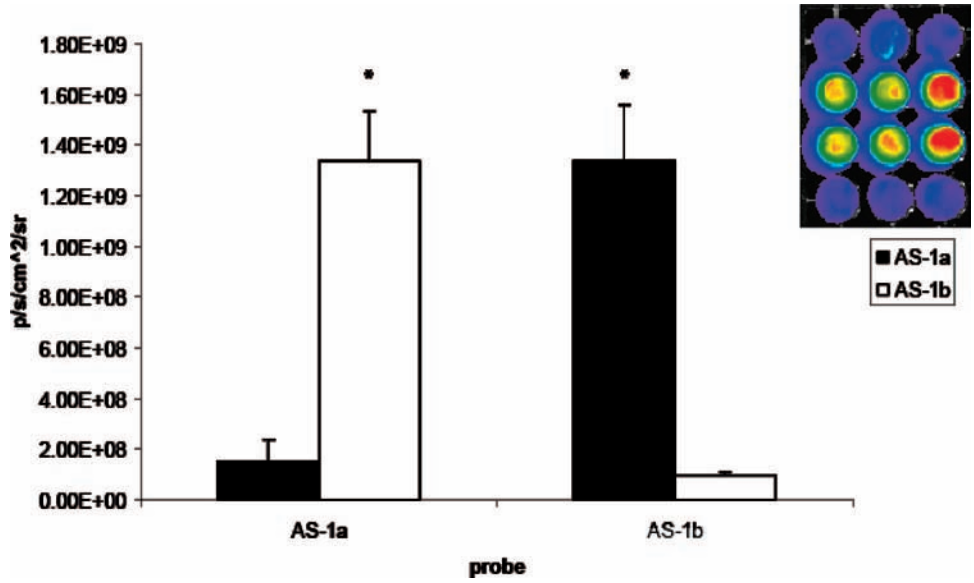

Figure 3. Single probe assay demonstrating retention of both antisense binding and RL8 activity of probes (avg ± s.d.). RL8 was conjugated with one of two different oligonucleotides (AS-1a and AS-1b, complementary to one another), and then used to probe either homologous or complementary sequences using a multiwell plate-based assay. Only when complementary probes were mixed with one another was significant signal observed. Inset: raw image obtained by the IVIS-50. Rows top to bottom match columns left to right of figure. *$p < 0.04$, Kruskal–Wallis, multiple comparison test.

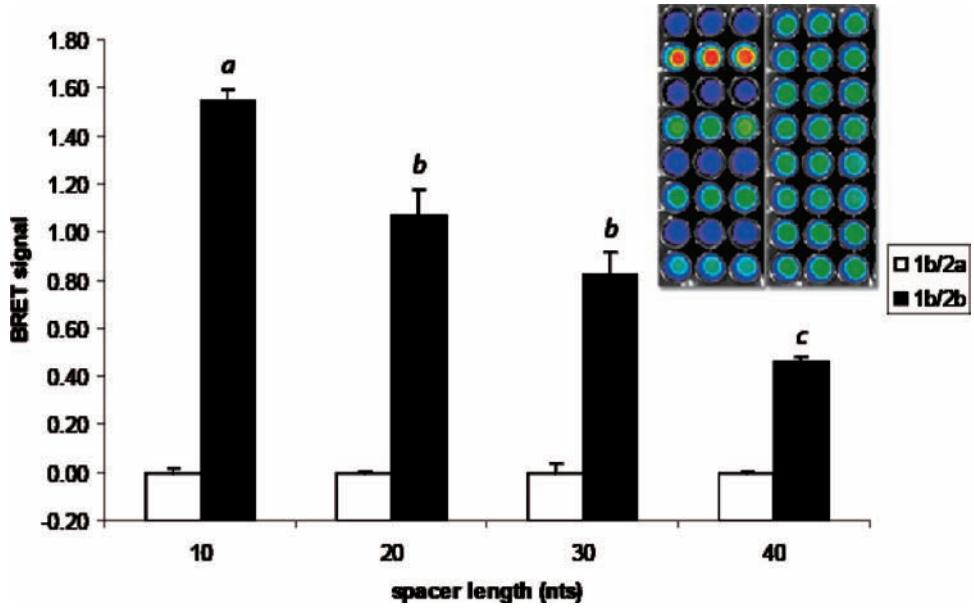

Figure 4. Dual probe assay using DNA oligos as targets to optimize spacer length between binding sites (avg ± s.d.). RL8 was conjugated with AS-1a (complementary to AS-1b) while GFP^2 was conjugated with AS-3 (complimentary to AS-2b). Both bioconjugates were combined with either a target that contained one binding site (1b/2a) or a target with both binding sites (1b/2b), separated by *n* random nucleotides (where $n = 10$, 20, 30, or 40). Significant BRET signal was seen for all targets that contained both binding sites, and statistical differences were seen between groups using different spacer lengths. Inset: raw image obtained in IVIS-200. Rows top to bottom match columns left to right of figure; image on left shows GFP^2 filter, image on right shows RL8 filter. Letters *a*, *b*, and *c* denote groups with statistical difference from one another ($p = 1.15 \times 10^{-6}$, ANOVA).

μg) of RNA in a mixed population could be statistically detected ($p < 0.05$, *t* test against "0 μg target RNA" group).

DISCUSSION

A multiprobe, BRET-based solution assay for the detection of specific RNA has been developed. The strategy detailed in this study required the successful optimization of several different variables (Figure 1). The conjugation of enzymes and oligonucleotides was accomplished using a bis-aromatic hydrazone chemistry scheme. This method was able to preserve the bioluminescent and fluorescent activity of the proteins used, as well as the nucleotide-binding properties of the oligos. Due to its generalizability, both the sequence of the oligos and the identity of the enzymes could be changed without altering the efficiency of the reaction. Thus, this method could be applied to detect any mRNA of interest, simply by changing the sequence of the oligos, and could even be used to simultaneously detect several different species of mRNA by using multiple BRET pairs (*11*). In addition to the conjugation chemistry, the optimal spacing between the probes was assessed. If the binding sites of the two probes are too near one another, steric hindrance prevents both probes from binding at the same time. However,

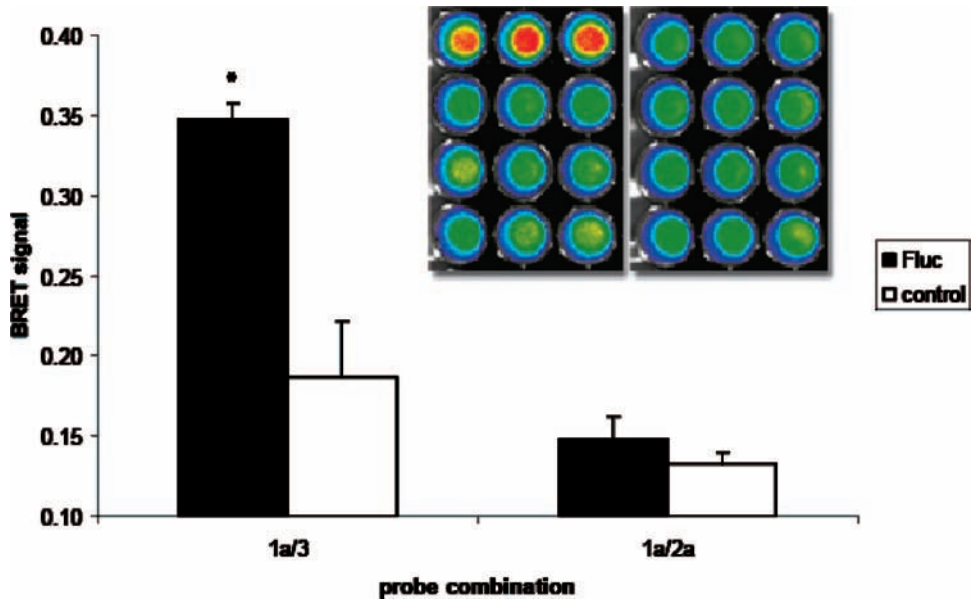

Figure 5. Dual probe assay using *in vitro* transcribed cRNA as targets (avg ± s.d.). RL8 was conjugated with AS-1a (complementary to Fluc cRNA) and GFP^2 was conjugated to either AS-3 (complementary to a different portion of Fluc cRNA) or AS-2a (reverse sequence of AS-3). RL8-1a was combined with either GFP^2-2a or GFP^2-3 and hybridized to either Fluc cRNA or nontarget cRNA. Only in wells containing Fluc target cRNA, RL8-1a, and GFP^2-3 was significant signal observed. Inset: raw image obtained in IVIS-200. Rows top to bottom match columns left to right of figure; image on left shows GFP^2 filter; image on right shows RL8 filter. $*p = 3.11 \times 10^{-6}$, ANOVA, multiple range test.

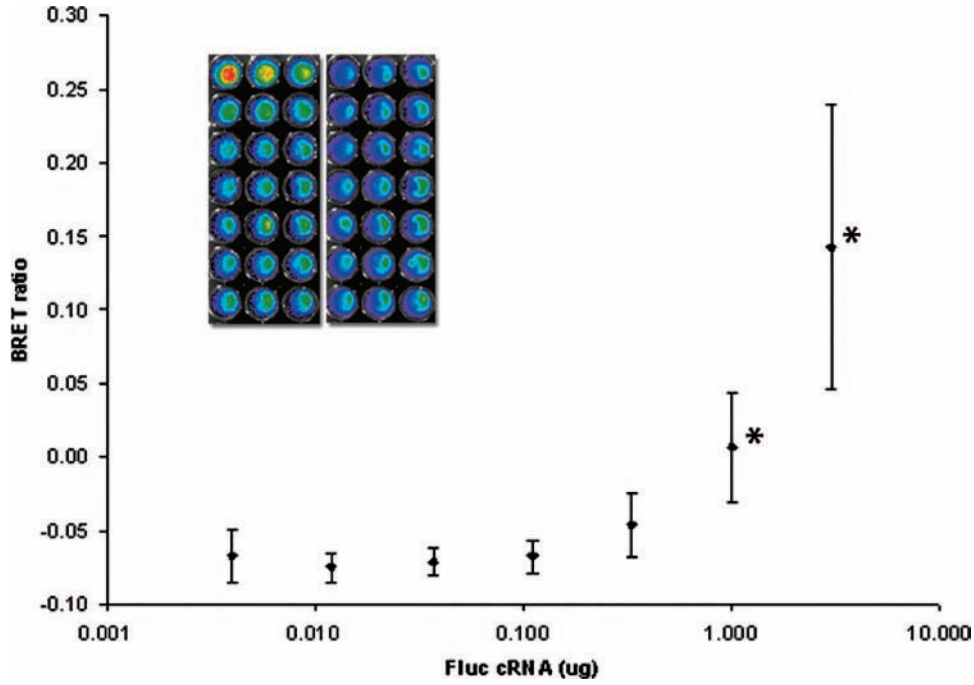

Figure 6. Dual probe assay testing sensitivity with mixed populations of *in vitro* transcribed cRNA as targets (avg ± s.d.). RL8-1a and GFP^2-3 were combined with various amounts of Fluc cRNA, while keeping the level of total cRNA constant by supplementing with nontarget cRNA. Statistically significant BRET signal was seen for as little as 1 μg Fluc cRNA. Inset: raw image obtained in IVIS-200. Rows top to bottom match columns left to right of figure; image on left shows GFP^2 filter; image on right shows RL8 filter. $*p < 0.05$, *t* test against "0 μg Fluc cRNA" group.

if the binding sites are two far apart, the BRET enzymes cannot undergo energy transfer. This variable was optimized for the firefly luciferase mRNA, and the result (10 nucleotides) can be reasonably extrapolated to other targets.

The concept of using multiple probes to increase the specificity of nucleic acid detection has been demonstrated previously, although typically with FRET (*12–19*). FRET has particular advantages for high-magnification imaging, given that its resolution is theoretically limited by the emission wavelength of the acceptor fluorophore. However, its utility is limited for many applications due to the required input of excitation photons. As with any fluorescence-based technique, FRET is incompatible with photoresponsive cells and is restricted in many cases by autofluorescence and photobleaching. In addition, the simultaneous excitation of the donor and acceptor fluorophores can add noise to the system. FRET is especially ill-suited for imaging in small animals due to the light-absorbing properties of living tissue. BRET, on the other hand, does not require input photons, thus eliminating many of the issues delineated above, and has been demonstrated

to be a powerful research tool for investigating molecular events in living animals (*20*).

In order to apply this methodology to RNA imaging, several challenges had to be overcome. The first challenge was the production of bioconjugates that retained the functionality of both the enzyme (luciferase) and antisense components. These types of conjugates have been described before, specifically for the detection of nucleic acids and with varying levels of success (*21–26*). The method of conjugation presented here is not regioselective with respect to the enzyme, nor is the degree of conjugation easily controlled. However, it is relatively rapid, and the reaction conditions are amenable to the retention of enzymatic activity. Monoconjugates were not purified away from unconjugated enzyme or polyconjugated probes, as the design of the assays did not require such purification and each additional step of purification could potentially diminish enzymatic activity. Future studies may explore different methods of conjugation, including those that are regioselective. The advantage of such a method would be the increased generalizability of the overall method. Since the chemistry displayed here capitalizes on the manipulation of exposed lysine residues of the enzyme being conjugated, it was fortunate that both RL8 and GFP^2 did not require these residues to carry out their functions. However, it is possible that other proteins may not have available lysines for conjugation, limiting the utility of the method.

After constructing the bioconjugate probes, the appropriate distance between binding sites had to be established. Since the BRET phenomenon is distance-dependent, we used estimates to determine the physical space occupied by both the oligos and proteins, hypothesizing that 32nts would be the most optimal spacer to produce an efficient BRET signal. This estimate was made using approximations of protein space based on crystal structures (2.48 $Å^3$/Da, personal communication with Duilio Cascio, University of California at Los Angeles). Then, assuming that the proper spacing would be achieved by spacing the enzymes apart such that there was no overlap, and using the 3.4 Å base pair spacing for double-stranded DNA (*27*), the estimate of 32 nucleotides between binding sites was calculated. This estimate assumed that the proteins would take a spherical shape, the optimal configuration for resonance energy transfer was nonoverlapping, and that the nucleotide spacer would remain somewhat linear. By experimentation, however, we found that a much smaller spacer (10nts) produced the greatest signal. The discrepancy between our predictions and observations can most likely be explained by the lack of rigidity not taken into account when we performed our calculations. Due to the floppy nature of the tripartite signal generator (RNA target plus two probes), our calculations of distance and space were rendered suboptimal. It was found that the lack of a spacer between binding sites, however, did not produce a BRET signal (data not shown). This is most likely due to steric hindrance of two bioconjugate probes attempting to bind immediately adjacent to one other. As with any method predicated on antisense binding, the binding sequence must be determined largely empirically. However, as the RNA used in this protocol was heated prior to hybridization to relax the secondary structure, these concerns were rendered moot. Thus, as long as the protocol includes a step that linearizes the target RNA, the identity of the binding sequence should remain largely inconsequential.

A surprising result from the spacer optimization experiment was the linear relationship between distance and BRET signal. Since the Förster equation states that the degree of resonance energy transfer is inversely proportional to the sixth power of the distance between the proteins, it is unclear exactly why the results shown here do not mirror the expectations of the formula (*28*). Our observations might be explained by the floppy nature of the target oligos. Although the number of nucleotides between the binding sites changes, it does not necessarily relate to the distance between the binding sites given that the oligonucleotides can fold into various conformations in space, bringing the binding sites closer together than their spacer length might predict. Another possible explanation is the presence of polyconjugated probes. Since a small fraction of the conjugation reaction products contained multiple oligonucleotides per protein, it is possible that these polyconjugates could bind to multiple target oligos, effectively altering the ratio of RL8 to GFP^2 from 1:1 and altering the efficiency at which the energy is transferred.

Currently, this approach is limited as a reliable *in vitro* method by sensitivity. Despite its ability to image as little as 1 μg of Fluc cRNA ($\sim$5.5 pmol), this quantity is far less than the level of gene expression in a transiently transfected population of mammalian cells. Real-time RT-PCR analysis (data not shown) demonstrated that a 100 ng sample of total RNA purified from cells transfected with the Fluc gene contained 7.42 pg of Fluc RNA. Therefore, in order to obtain even 100 ng of Fluc RNA (one-tenth of the current detection limit) in a transiently transfected sample, more than 1 mg of total RNA would have to be harvested, much more than the typical 30 μg usually obtained from 5×10^6 cells.

Several factors may be contributing to the sensitivity limits. One of the central problems is the inefficiency with which RL8 oxidizes DBC. According to published reports, the quantum yield of RL8 with native coelenterazine is approximately 60 times greater than that of RL8 with DBC (*7*). The reasons the RL8/DBC-GFP^2 BRET system was used in this study were the availability of appropriate filters and the known stability of RL8 compared to other bioluminescent proteins. It is quite possible that using a different BRET system, newer substrates, or even a split-reporter system (*29*) could improve the sensitivity of the assay. However, there are no guarantees that the same methods of protein purification and/or bioconjugation would be compatible with any other pair of proteins.

If the sensitivity of this assay is improved, these probes could also be applied to imaging mRNA in living subjects. BRET has proven its value as a molecular imaging tool in small animal imaging. By using an amino acid based delivery method, these bioconjugates could be engineered to cross biological membranes and colocalize with target mRNA. Cell-penetrating peptides have been shown to be able to deliver a variety of biological cargos (*30, 31*), and membrane translocating antibodies have also been applied for similar purposes (*32*). This method is particularly appealing because the amino acid sequence coding for the delivery agent could be fused directly to the reporter enzyme and expressed as a single protein. Alternatively, it has been shown that large macromolecules can be delivered via hydrodynamic injection, and this may prove to be a reliable substitute (*33*).

This assay represents a new possibility for the detection of RNA. In contrast with other widely used methods, it does not require any washing steps or RNA manipulation postpurification. Given its ease of use and amenability to automation, this technique could fulfill all the requisites of a routine diagnostic assay. The material costs of the probes are negligible, and although a dedicated small animal imaging system was used in this study for the spectral detection of photons, there is every reason to anticipate the evolution of stand-alone gene chips or multiwell plates that are capable of spectral detection (*34*), thus obviating the need for a separate detection device and making the technique more cost-effective. Unlike fluorescent methods, the BRET-based technique does not require the presence of a laser to excite the donor probe. This alone has the potential to

reduce costs and increase the ease of manipulation. And unlike isotopic methods, this assay does not have the potential hazards associated with radioactivity or the instability of an isotopic probe. Overall, the BRET-based detection of RNA described here is more rapid than most methods of RNA detection and involves significantly fewer steps. With improvements to its sensitivity, it could easily become a part of the molecular biology canon and possibly much more.

Novel FRET-Based Assay to Detect Reverse Transcriptase Activity Using Modified dUTP Analogues

Joseph F. Krebs* and Anilkumar R. Kore

Ambion/Applied Biosystems, Research and Development Department, 2130 Woodward Austin, Texas 78744. Received July 27, 2007; Revised Manuscript Received December 11, 2007

We have developed a novel continuous assay to measure reverse transcriptase (RT) polymerase activity. The assay uses fluorescence energy transfer measurements to detect the incorporation of complementary pairs of fluorescently labeled deoxyuridine into cDNA product. The fluorescently labeled dUTP substrates were prepared using commercially available reagents with a simple coupling reaction. The fluorescent dye pairs have significant spectral overlap which allows FRET interaction between dyes incorporated into the cDNA. Using a polyA/oligo dT primer/template, the assay can readily detect DNA polymerase activity from any viral reverse transcriptase enzyme. The reaction proceeds linearly over time, and the rate is proportional to the enzyme concentration. We used the assay to compare the thermostability of a number of wild-type and mutant viral RT enzymes. Our results indicate that the wild-type AMV (avian myeloblastosis virus) enzyme is slightly more stable at 43 °C than the HIV-1 (human immunodeficiency virus) or MMLV (Moloney murine leukemia virus) enzymes. The thermostability of the RT enzyme was dramatically increased by the presence of primer/template with the enzyme. We also used the assay to study the effects of inhibitors on HIV-1 RT polymerase activity. This assay may be highly useful for the identification and characterization of potent RT inhibitors which could be candidates for development as therapeutic antiviral agents.

INTRODUCTION

Reverse transcriptases (RT) are RNA-directed DNA polymerases that synthesize DNA complementary to RNA sequences. These enzymes are essential for retroviral replication in infected cells and are important targets for the development of new drugs to fight retroviruses such as HIV-1, the human immunodeficiency virus (*1*). Drugs which target RT enzymes usually function by inhibiting the polymerase activity of the enzyme. Some RT inhibitors are nucleotide analogues which directly compete with dNTP monomers to block extension of the cDNA, while others are structurally unrelated to nucleotides and noncompetitively bind to a regulatory site on the enzyme (*2*). While both of these inhibitor classes can provide substantial benefit in slowing the progression of viral replication, over time all drugs targeting RT enzymes lose therapeutic efficacy due to the high rates of retroviral mutation which produces resistant strains of virus. The inevitable loss of drug efficacy necessitates the continual development of new RT inhibitor drugs to block replication of drug resistant viruses (*3*, *4*).

Currently, RT enzymatic activity is typically measured using discontinuous multistep assays which are cumbersome, expensive, and difficult to scale up. These assays generally involve the use of radioactive isotopes and usually require extensive sample handling to remove aliquots at various time points to study the time course of the reaction (*5*). These issues make detailed kinetic and mechanistic characterization of large numbers of drug candidates difficult. While a few continuous assays have been developed (*6*, *7*), they generally have relatively high background signal, which can limit their sensitivity. Also, some RT assays require the use of DNA templates which can mask potential effects of RNase H activity and other contaminating nucleases on polymerase activity. The development of direct, continuous-format enzyme activity assays will enhance identification and characterization of new RT inhibitors.

Fluorescence resonance energy transfer (FRET) is a phenomenon that can be used to measure the physical proximity of chemical moieties in solution. This method relies on the observation that excited fluorophores (donors) can transfer energy to neighboring ($<$100 Å) complementary chromophores or fluorophores (acceptors) (*8*). If the acceptor is itself fluorescent, energy transferred from the donor is emitted from the acceptor as light (*9*). This method allows identification of binding or proximity events in complex mixtures, since the spectral properties of the FRET enabled complexes are fundamentally different than those of the uncomplexed free fluorophores. FRET methods have been used to characterize many complex biochemical processes such as protein–protein association, nucleic acid hybridization, and ligand binding. An analogous method has been used to measure the ligation of labeled DNA molecules by DNA ligase (*10*). Since fluorescently modified nucleotides can be incorporated into nucleic acids by polymerases, it is possible that FRET-based detection methods could be adapted to study DNA polymerases.

We have developed a novel FRET-based method for the continuous real-time measurement of reverse transcriptase activity. This method utilizes dUTP analogues modified with complementary fluorescent groups and works for all RT enzymes tested. We have used this method to measure the thermostability of several RT enzymes and characterize the inhibition of RT by the inhibitor 3′-AZT triphosphate.

EXPERIMENTAL PROCEDURES

Biochemicals and Enzymes. Reverse transcriptase (RT) enzymes: HIV RT (10 U/μL), AMV RT (10 U/μL) and ArrayScript (200 U/μL), MMLV-RT (100 U/μL), *Tth* polymerase (10 U/μL), and 10X RT reaction buffer were obtained from Applied Biosystems (Foster City, CA). Sodium pyrophosphate was obtained from Invitrogen (Carlsbad, CA). With the exception of the reagents listed below, all other reagents are from Sigma-Aldrich.

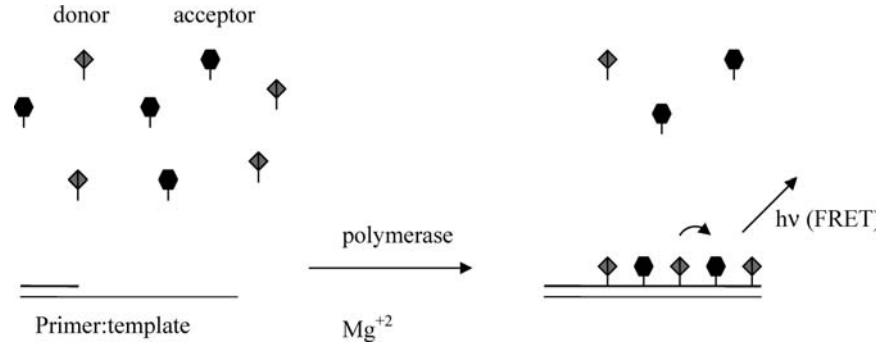

Figure 1. Continuous FRET-based assay to measure DNA polymerase activity. Dye-conjugated nucleotide pairs in solution do not interact to produce a FRET signal. Addition of polymerase to the reaction causes incorporation of the dye−nucleotides into the cDNA. The close proximity of the two dyes in the polymer allows interaction between the dyes causing the generation of a FRET signal proportional to the amount of cDNA produced in the sample.

General Procedure for Conjugation of AA-dUTP with PyMPO, SE, and 7-MCC, SE. In a typical reaction, aminoallyl-dUTP (**1**) (Ambion, Inc.) (4.7 mg, 0.0079 mmol) in 2 mL of 0.1 M sodium borate buffer (pH 8.0) was treated with (5 mg, 0.0089 mmol) of the 1-(3-(succinimidyloxycarbonyl)benzyl)-4-(5-(4-methoxyphenyl)oxazol-2-yl)pyridinium bromide (**2**), i.e., PyMPO, SE (Invitrogen Inc.) in 2 mL of DMSO. While for 7-MCC, SE, AA-dUTP (**1**) (42 mg, 0.071 mmol) in 4 mL of 0.1 M sodium borate buffer (pH 8.0) was treated with (25 mg, 0.0788 mmol) of 7-methoxycoumarin-3-carboxylic acid, succinimidyl ester (**4**) (Invitrogen, Inc.) in 4 mL of DMSO. The reaction mixture was stirred at room temperature for 4 h in the dark. The pH of the crude reaction was adjusted to 5.0 and purified using a Strata column (Phenomenox) as per the manufacturer's protocol. Both products **3** and **5** were analyzed by LC/MS: For compounds (**3**), MS (*m*/*z*) 891.4 $[M]^+$; and for compound (**5**) MS (*m*/*z*) 724 $[M]^+$. The purity of the final products was determined using anion-exchange HPLC analysis with a 250 × 4.6 mm Hypersil SAX (5 um) column using a using linear gradient system from 0% to 100% of buffer B over a period of 35 min. Buffer A was 5 mM $(NH_4)H_2PO4$, pH 2.8, and buffer B was 750 mM $(NH_4)H_2PO4$, pH 3.7. Using this method, compounds **3** and **5** were determined to be greater than 98% pure.

Polymerase Activity Measurements. All experiments using reverse transcriptase were performed using oligo dT_{18} primer (IDT) and poly A template (GE Healthcare) at final concentrations of 2 ng/μL and 17 ng/μL, respectively. The primer and template were annealed in RT reaction buffer and heated to 65 °C for 3 min. The mixture was cooled to 42 °C and mixed with 0.5 volume 3X master mix (150 mM Tris Cl, pH 8.3, 225 mM KCl, 9 mM $MgCl_2$, 3 mM DTT, and the two fluorescent dUTP substrates, **3** and **5**, were at concentrations of 22.5 μM and 90 μM, respectively in the 3X mix). 56−59 μL of this reaction mix was mixed with 40–200 units of reverse transcriptase (1−4 μL) in 96 well plates. The polymerase reaction was monitored for 20 min via the fluorescence increase (ex 348 nm, em 560 nm) in each well at 26 °C using a SpectraMax Gemini fluorescence plate reader (Molecular Devices).

RT Thermostability Measurements. RT enzymes were diluted 1:12−1:25 into 400 μL RT reaction buffer and incubated at 43 °C. At various time points (0–135 min), 40 μL sample aliquots were removed from the incubator and stored on ice. After the last time point was collected, a 30 μL aliquot from each time point was transferred to a 96 well round-bottom polypropylene plate. 30 μL of a 2X master mix (4 ng/μL oligo dT, 34 ng/uL polyA, 60 μM 7-MCC dUTP (compound **5**), 15 μM pyMPO dUTP (compound **3**), 100 mM TrisCl pH 8.3, 150 mM KCl, 6 mM $MgCl_2$, 2 mM DTT). The fluorescence increase (ex 348 nm, em 560 nm) in each well was measured for 20 min at 26 °C as described above. Control experiments indicated that no detectable loss of enzymatic activity occurs during incubation on ice.

AZT Inhibition Measurements. AZT triphosphate (100 mM stock, Calbiochem) was diluted to 4 μM in 1X RT buffer and then serially diluted to 40 nM in the same buffer. The diluted AZT solutions were mixed with an identical volume of pyMPO dUTP (**5**) and 7-MCC dUTP (**3**) (at concentrations of 2 and 8 μM, respectively). 30 μL of the AZT/dUTP mixtures were then mixed in duplicate with 30 μL of 1X RT reaction buffer containing oligo dT/polyA and HIV RT (200 nM final concentration). The fluorescence increase was measured for 20 min at 26 °C. The plotted data of the enzyme inhibition as a function of AZT-triphosphate concentration was fit to a quadratic equation (eq 1) to determine the inhibition constant (K_i) and the enzyme concentration (*11*).

Equation 1: FRET increase $= A \times ([E] - ((([E] + [AZT] + K_i) - (([E] + [AZT] + K_i)^2 - (4 \times [E]) \times [AZT]))^{0.5})/2))$ where A is a scalar constant, [E] is the concentration of enzyme, K_i is the inhibition constant for the inhibitor (15 nM) (*12*), and [AZT] is the concentration of AZT-triphosphate in the reaction.

Protein concentrations were determined in duplicate using the BCA kit from Pierce (Rockford, IL) per the manufacturer's instructions using BSA as a calibration standard.

RESULTS

Measurement of Reverse Transcriptase Polymerase Activity Using Complementary Fluorescent dUTP Analogues. FRET (fluorescence resonance energy transfer)-based fluorescence techniques measure a fluorescence signal generated from the specific interaction between physically associated donor and acceptor fluorophores. They are often used to study the physical proximity of fluorescently labeled groups even in the presence of free, unincorporated fluorophores. Potentially, this process could be used to measure nucleic acid synthesis, since a number of polymerases can incorporate dye-modified nucleotide analogues into nucleic acid products (*13*, *14*). If two spectrally overlapping pairs of dye-modified nucleotides (donor and acceptor) could be incorporated into nucleic acids by a polymerase, it might be possible to monitor nucleic acid synthesis using FRET-based fluorescence signals (Figure 1).

Therefore, we sought to examine whether polymerases such as reverse transcriptase could incorporate FRET-compatible pairs of dye-modified deoxynucleotides into cDNA products. Specifically, we examined whether pyMPO- and 7-MCC-modified dUTP (compounds **3** and **5**) could be synergistically used by RT to make cDNA. These compounds are derived from aminoallyl dUTP, a parent compound which has been previously used to create functional nucleotide substrates for polymerase enzymes (*15*). The emission wavelength of the 7-MCC fluorophore (415 nm) overlaps the excitation wavelength of the

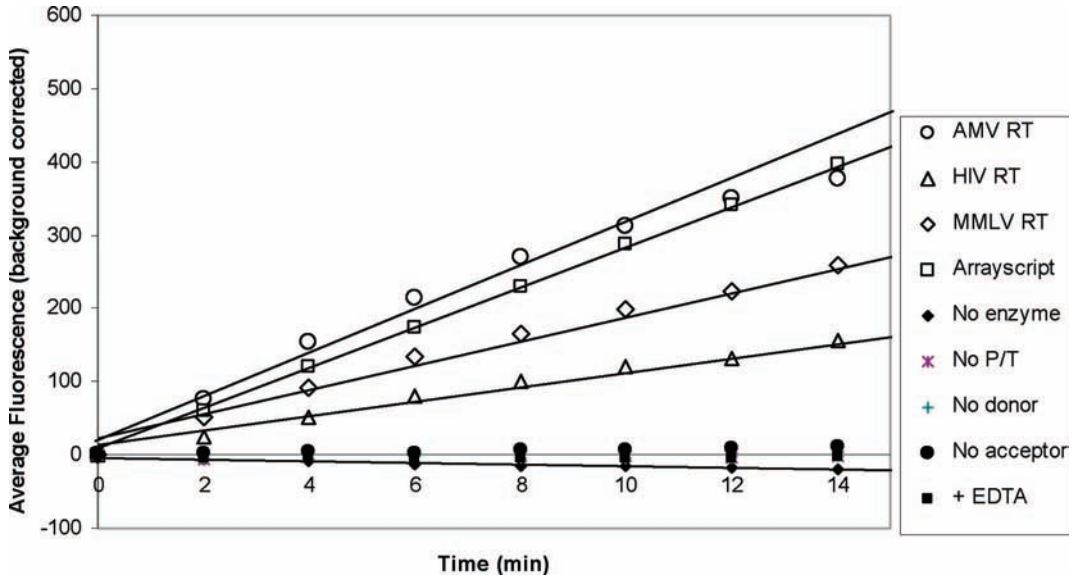

Figure 2. Reaction time course for polymerase activity measured using the FRET assay for four reverse transcriptase enzymes. 1–4 μL of enzyme was added in duplicate to 56–59 μL of reaction mix of RT buffer containing 3 mM $MgCl_2$, 2 ng/uL oligo dT, 17 ng/ μL polyA, 7.5 uM pyMPO dUTP, and 30 uM 7-MCC-dUTP in 96 well plates. After addition of the enzyme, the fluorescence increase (ex = 348 nm, em = 560 nm) was continually measured every two minutes at 26 °C. A lack of activity is observed in control reactions which contain either 7.5 uM pyMPO dUTP or 30 uM 7-MCC-dUTP.

pyMPO group (420 nm). When pure retroviral RT enzyme, from HIV-1, AMV, or MMLV or ArrayScript (an MMLV variant), was added to a reaction buffer containing these nucleotides, $MgCl_2$, and primer/template (oligo-dT/polyA RNA), a time-dependent increase in fluorescence was observed (Figure 2). The fluorescence is derived from a FRET interaction, since the time-dependent increase in fluorescence is greatest at the excitation wavelength of 348 nm and an emission wavelength of 560 nm, which correspond to the excitation and emission wavelengths of the 7-MCC and pyMPO fluorophores, respectively. Although a slight increase in fluorescence is observed in reactions containing the donor (7-MCC dUTP) alone, both nucleotides are required for robust activity (Figure 2). Omission of the RT enzyme completely eliminates the fluorescence increase (Figure 2). Addition of EDTA completely abolishes the fluorescence increase (Figure 2), indicating that, as expected, the reaction is Mg ion dependent. Likewise, template (polyA) and primer (oligo-dT) are absolutely required for the FRET activity (Figure 2). Although the progress curve for the AMV RT enzyme is somewhat nonlinear after 10 min (Figure 2), the curvature is not due to pyrophosphate product inhibition, since the RT enzymes are not inhibited by pyrophosphate in the concentration range ($<$100 μM) used for the nucleotide substrates in the reaction ((*16*) and Supporting Information). Dramatically decreased signal was observed when heteropolymeric templates were used in the reaction. Little activity was observed in the assay for the thermophilic enzyme *Tth* DNA polymerase at 30 °C (see Supporting Information).

We next varied the fluorescent nucleotide concentrations (1–50 μM) to achieve optimal enzymatic activity, maximal FRET signal, and minimal background fluorescence. During these optimization studies, we noticed that increased FRET signals were generally obtained when using pyMPO-dUTP:7-MCC-dUTP ratios of $<$1 in the reaction (Figure 3). This effect was especially prominent for the AMV reverse transcriptase enzyme where low pyMPO:7-MCC ratios produce much higher FRET increases compared to reactions using equimolar levels of the nucleotides (Figure 3). This phenomenon could be caused by several different reasons (*17*) including inner-filter effects, self-quenching of the fluorophores after incorporation, or preferential interactions of RT enzymes between the two

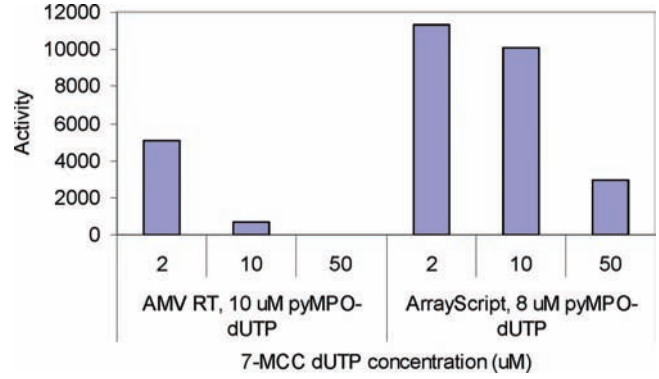

Figure 3. Effect of varying the ratio of 7-MCC-dUTP to pyMPO-dUTP nucleotides on the FRET signal from the MMLV-RT and AMV-RT polymerases. The concentration of the acceptor (pyMPO-dUTP) nucleotide was varied in the range 2–50 μM, while the concentrations of the donor nucleotide (7-MCC dUTP) were held constant at 8 μM (ArrayScript) or 10 μM (AMV RT).

nucleotide conjugates. We subsequently analyzed this phenomenon to determine its source. These studies indicate that, for the reasons described below, the decreased FRET emissions observed for reactions utilizing increased levels of pyMPO-dUTP arise from differential binding interactions between the two different dUTP conjugates and the enzyme rather than from inner filter or self-quenching effects. First, the effect cannot likely be attributed to an inner filter effect (*17*), since the pyMPO fluorophore does not absorb light at the emission wavelength (560 nm) and significant decreasing FRET signal is observed even at pyMPO-dUTP concentrations below 10 μM (Supporting Information). Second, the effect does not appear to be caused by self-quenching because spiking nonfluorescent nucleotides (dTTP, aminoallyl dUTP, and biotin in the range 0.2$-$100 μM) into the reaction to decrease the density of fluorescent nucleotides along the length of the cDNA did not increase the fluorescence signal (Supporting Information). Finally, it should be noted that the severity of the effect is enzyme-dependent: The AMV RT catalyzed reactions are strongly affected by increasing the pyMPO concentration above 10 μM, while the assay signals observed using ArrayScript (MMLV variant) are

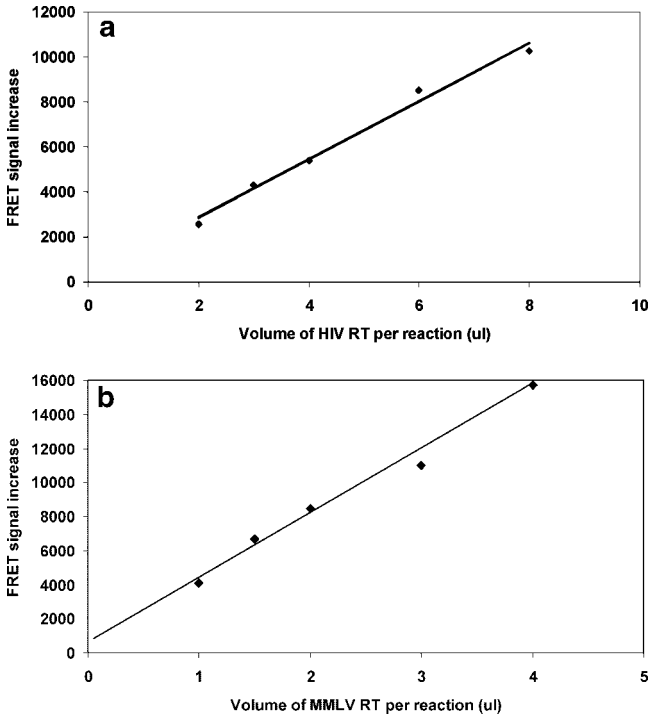

Figure 4. FRET signal increase of the FRET RT assay is linearly dependent on the enzyme concentration. HIV RT (panel A) or MMLV RT (panel B) enzymes were serially diluted into RT buffer, and then duplicate aliquots were mixed with an equal volume (30 uL) of 2X master mix (6 mM $MgCl_2$, 4 ng/uL oligo dT, 34 ng/μL polyA, 15 uM 7-methoxycoumarin AA dUTP, and 60 uM pyMPO AA dUTP). The fluorescence increase in 15 min for each of the dilutions is plotted as a function of the volume of enzyme stock added to each reaction.

only modestly affected (Figure 3 and Supporting Information). These results strongly suggest that the RT enzymes interact differentially with the two fluorescent nucleotides. In addition to improving the FRET signal generated by the enzyme, reducing the pyMPO-dUTP nucleotide also dramatically lowers the background fluorescence (time zero) for the reaction. Therefore, in most subsequent experiments, we employed final concentrations of 30 uM and 7.5 uM for the 7-MCC and pyMPO-labeled nucleotides to obtain near-maximum assay signal and sensitivity for the retroviral enzymes tested.

Characterization of RT DNA Polymerase Activity Using the FRET-Based Assay. To investigate the versatility of the FRET method to detect RT polymerase activity, we tested a range of RT enzymes. The FRET-based signal can be used to measure the polymerase activity of any RT enzymes tested: MMLV RT, AMV RT, and HIV RT. The progress curves for the reaction are fairly linear for all enzymes tested over a 15 min time interval (Figure 2). Under our assay conditions, the fluorescence increase is linearly proportional to the amount of enzyme added to the reaction (Figure 4). The linearity of the reaction with respect to time and enzyme concentration suggests that the assay should be highly useful for quantitative measurements such as enzyme inhibition by small molecules.

Characterization of RT Thermostability Using the FRET Assay. Since the reaction rate is linearly proportional to the enzyme concentration (Figure 4), we realized that the FRET assay could be used to measure and compare the thermostability of RT enzymes. RT enzyme was diluted into reaction buffer and incubated at elevated temperature. At various time points, aliquots were removed and placed on ice. After collection of the last time point, the polymerase activity of each of the samples was measured using the assay (Figure 5). The activity of the aliquots was stable on ice, since under these

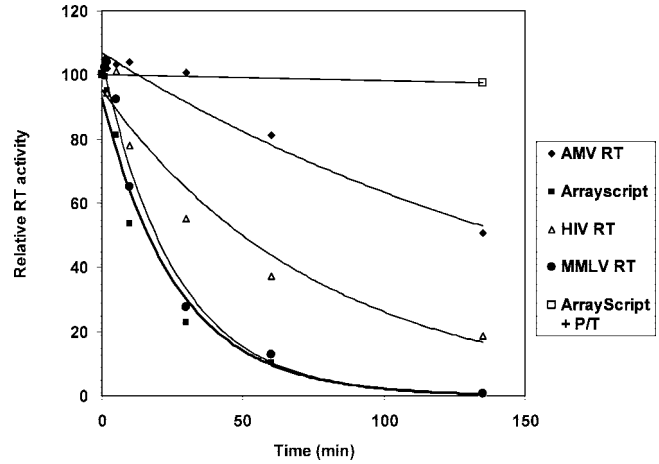

Figure 5. Measurement of thermal inactivation of pure RT enzymes using the continuous FRET assay. Diluted RT enzymes were incubated for various times at 43 °C, and the remaining enzymatic activity in each aliquot was determined by mixing with an equal volume of 2X reaction mix containing RT buffer primer/template and dye-modified nucleotides. For each enzyme, the time-dependent loss of enzymatic activity was plotted using a single exponential decay function (line fits shown). The half-lives of each enzyme at 43 °C determined from these fits are as follows: AMV RT, 133 min; HIV RT, 54 min; ArrayScript, 21 min; and MMLV RT, 18 min. Addition of primer/template to the ArrayScript enzyme before heating at 43 °C completely prevents the loss of activity (open squares).

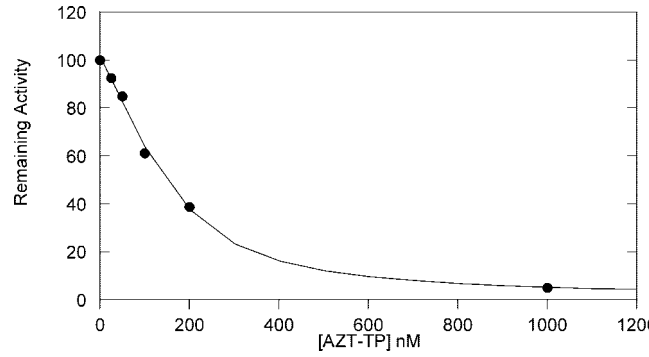

Figure 6. Detection of HIV RT inhibition by AZT triphosphate using the FRET assay. AZT triphosphate was serially diluted to 40−4000 nM in RT buffer and mixed with an identical volume of dye-labeled AA nucleotides. 30 μL of the AZT/dUTP mixtures were then mixed in duplicate with 30 μL of 1X RT reaction master mix containing HIV RT (196 nM final concentration by BCA protein assay). Enzyme activity was measured for 15 min at 26 °C. The titration data, when fit to a quadratic binding model (*12*) is consistent with an enzyme concentration of 202 nM.

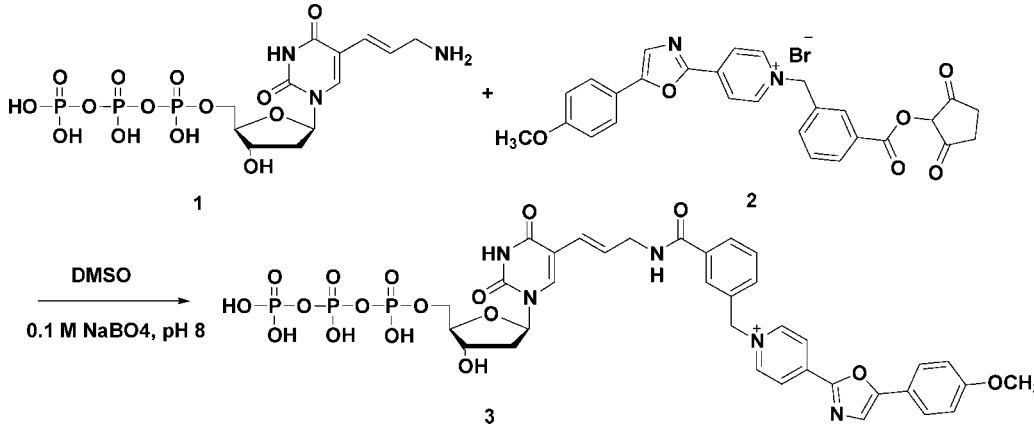
conditions, no detectable loss of enzyme activity was observed for enzyme aliquots incubated on ice for 2 h (data not shown). A range of half-lives was observed for the various enzymes tested: the half-life of the wild-type MMLV RT at 43 °C was near 18 min, while the half-life of AMV RT enzyme was >2 h (Figure 5). Including polyA/dT (primer/template) during the incubation at elevated temperatures prevents the thermal inactivation of the RT enzymes (Figure 5, open squares).

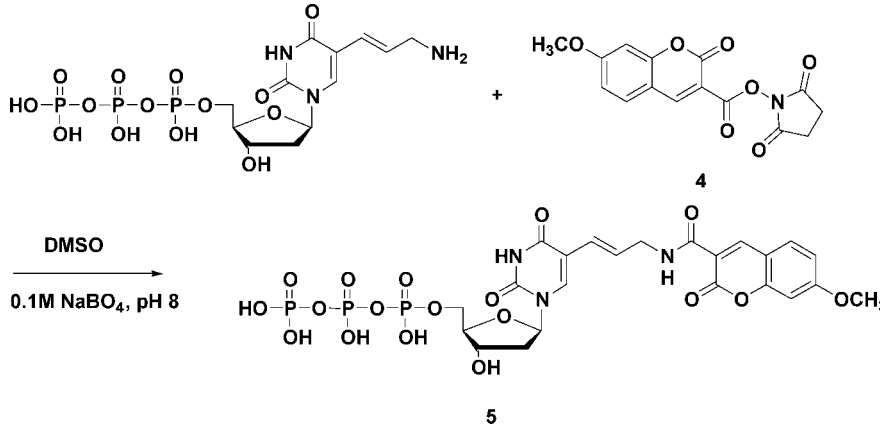
Inhibition of RT Polymerase by 3′ AZT Triphosphate. We next used the FRET assay to analyze the inhibition of RT by inhibitors. As a model system, we chose to measure the inhibition of HIV-1 RT by AZT triphosphate. The inhibitor was serially diluted and added to the reaction master mix (10–1000 nM concentration range). A dose-dependent decrease in enzymatic activity was observed (Figure 6). The linear characteristics of the inhibition curve reflect the high affinity of the inhibitor for the enzyme ($K_i \approx 15$ nM (*12*)). We used these inhibition

Scheme 1. Conjugation of AA-dUTP with PyMPO, SE[a]



[a] Conditions: 5-Aminoallyl dUTP, PyMPO SE, 0.1 M sodium borate buffer (pH 8.0), DMSO, 4 h, at RT.

Scheme 2. Conjugation of AA-dUTP with 7-Methoxycoumarin-3-Carboxylinc Acid SE[a]



[a] Conditions: 5-Aminoallyl dUTP, 7-methoxycoumarin-3-carboxylinc acid SE, 0.1 M sodium borate buffer (pH 8.0), DMSO, 4 h, at RT.

data to measure (titrate) the concentration of functional HIV RT enzyme in the sample; we determined that the concentration of active enzyme in the reaction is 202 nM (*11*). This value is in good agreement with the enzyme concentration determined using the BCA protein concentration assay (194 nM). These results suggest that the commercial enzyme preparation is highly active and contains little or no inactive protein.

DISCUSSION

We have developed a novel FRET-based enzymatic assay to measure the polymerase activity of RT enzymes using an RNA-based template (polyA). Unlike other assays which measure the incorporation of dNTPs into the cDNA, our assay has a continuous format which allows real-time monitoring of the polymerization reaction. Our assay uses complementary pairs of fluorescently labeled dUTP analogues. The fluorescent groups have overlapping spectra in which the emission wavelength of donor overlaps the excitation wavelength of the acceptor fluorophore.

The fluorescently labeled dUTP analogues are readily synthesized from commercially available precursors using a facile conjugation procedure (Schemes 1 and 2). The aminoallyl dUTP precursor is a versatile synthetic reagent capable of producing a wide variety of other fluorescently modified nucleotides. In this study, we used 7-MCC and pyMPO-conjugated dUTP analogues to generate a FRET emission derived from the cDNA product. We selected these fluorophores for our study for three reasons: (1) their spectral overlap, (2) the commercial availability of amine-reactive forms of the dyes, and (3) their large cumulative Stoke's shift (>200 nm). By selecting fluorophores which possess these properties, we were able to rapidly develop a highly sensitive assay with low background signal. While we have not tested other pairs of fluorescent nucleotides, we are confident that this methodology could be adapted using other pairs of fluorophores to develop other assays for RT enzymes, since aminoallyl-dUTP has been shown to be an excellent backbone for the synthesis of conjugates which are efficiently incorporated by reverse transcriptase enzymes into cDNA (*15, 18–20*). Since a number of other polymerases can utilize dye-modified dUTP and dCTP substrates (*15*), it is possible that our FRET-based approach could be used to develop similar assays for non-RT enzymes using poly(dA) templates.

Our assay has improved performance characteristics compared to previously developed methods to detect reverse transcriptase activity (*5, 6*). Many existing methods are discontinuous and require extensive sample manipulation, which is time-intensive and error-prone. Some of these methods also use undesirable radioactive substrates (*5*). Our simple one-pot method allows accurate, scaleable measurement of RT activity in a matter of minutes in an ordinary fluorescence plate reader. Many existing methods suffer from high background signal in the absence of enzyme. Because of the very large Stoke's shift associated with our FRET based method, at lower nucleotide concentrations, the background fluorescence is very low and highly consistent between days. This characteristic is a significant benefit of FRET-based assay methods which provides high signal to background ratios and increasing the accuracy of the activity measurement.

Maximal assay signal is generally observed by lowering the concentration of the FRET acceptor (pyMPO-dUTP) below 10 μM in the reaction, while higher concentrations of the FRET donor permit higher activity (Figure 3 and Supporting Information). Subsequent analysis of this phenomenon revealed that it arises from the differential interactions of the two labeled nucleotides with RT enzymes. At low nucleotide concentrations, the pyMPO-dUTP is a better substrate than the 7-MCC-dUTP substrate for RT enzymes. At higher concentrations (>10 μM), the high binding affinity of the pyMPO-dUTP nucleotide substantially hinders the FRET signal from AMV RT (Supporting Information). We were somewhat surprised by this binding preference, since the size of the pyMPO moiety is significantly larger than the methoxycoumarin group of the 7-MCC-nucleotide (Schemes 1 and 2). Perhaps the positively charged pyMPO group is better able to interact with polar solvent molecules at the surface of the active site. Alternatively, the preferential incorporation of the pyMPO nucleotide may result from the increased flexibility of the extended pyMPO moiety compared to the aromatic napthyl structure of the coumarin-based fluorophore. Elucidation of the basis of the substrate preference will likely require detailed molecular modeling studies or additional structural modifications of the nucleotide conjugates and/or the enzymes.

We have used this assay to measure and compare the thermostability of RT enzymes. Our results indicate that, of the wild-type RT enzymes, AMV-RT has the longest half-life, followed by HIV-RT and then by MMLV RT (Figure 5). These results are in good agreement with those from other published studies (*21*). Interestingly, the addition of primer/template to the enzyme dramatically enhanced the half-life of the MMLV RT enzyme at 43 °C (Figure 5, square symbols). In contrast, addition of dNTP to the enzyme did not enhance thermostability, even at high concentrations of nucleotide (data not shown). These results are consistent with those of Gerard et al. which suggest that binding interactions between the enzyme and the primer/template (but not dNTPs) confer structural stability on the RT (*21*). The results of our thermostability measurements can best be interpreted in the context of the accepted kinetic mechanism of RT enzymes (*22*). The free RT binds the substrates in a specific order: first, the enzyme binds the primer/template and then the dNTP substrate to form the ternary catalytic complex. Given this mechanism, it is likely that the primer/template could bind to the RT to form and stable, extended complex while dNTP substrates are incapable of forming stable interactions with the enzyme, even at high temperature.

We also used the FRET assay to measure the inhibition of the HIV-1 RT enzyme by AZT triphosphate. The convenient real-time format of the assay allows rapid and sensitive detection of enzyme–inhibitors. The binding curve for the titration is consistent with the high binding affinity of the AZT triphosphate to the enzyme. Titration of enzymatic activity with the AZT inhibitor indicated that the concentration of active enzyme was nearly identical to the concentration as measured using a protein assay (Figure 6). RT enzyme preparations have been shown to sometimes contain significant levels of inactive or suboptimally active protein (*23, 24*). Our real-time titration method may prove to be a convenient, economical means to measure the amount of active enzyme in RT samples as well as the shelf life of RT enzymes over time.

Agonist−Antagonist Dilemma in Molecular Imaging: Evaluation of a Monomolecular Multimodal Imaging Agent for the Somatostatin Receptor

W. Barry Edwards, Baogang Xu, Walter Akers, Philip P. Cheney, Kexian Liang, Buck E. Rogers, Carolyn J. Anderson, and Samuel Achilefu*

Department of Radiology, Washington University School of Medicine, St. Louis, Missouri 63110. Received August 1, 2007; Revised Manuscript Received October 4, 2007

The combination of different imaging modalities, each providing information according to its strengths, can be a powerful method for diagnosing diseases. We have synthesized a monomolecular multimodal imaging agent (MOMIA), LS172, containing a subtype-2 somatostatin receptor (SSTr2)-avid peptide (Y3-octreotate or Y3-TATE), a radiometal chelating group (DOTA) and a near-infrared (NIR) fluorescent dye (cypate). In addition to optical methods, radiolabeling LS172 with ^{64}Cu and ^{177}Lu provides a strategy for in vitro evaluation or in vivo multimodal imaging by positron emission tomography (PET) and single photon emission computed tomography (SPECT), respectively. Determination of the binding affinity of LS172, ^{nat}Cu- and ^{nat}Lu-LS172 in SSTr2-transfected A427 cells (A427-7) showed that they all displayed high binding affinity toward SSTr2 with K_i values of 0.234 nM, 11.5 nM, and 2.15 nM respectively. In contrast to cypate-labeled Y3-TATE (cytate), fluorescence microscopy showed that LS172 and ^{nat}Cu-LS172 accumulate modestly in A427–7 cells by SSTr2-mediated endocytosis, in spite of their relatively high binding affinity. In vivo, the biodistribution of the SSTr2 receptor specific ^{64}Cu- and ^{177}Lu-LS172 in AR42J tumor-bearing rats exhibited low (≤1% ID/g) accumulation in tumor tissue. Clearance from circulation was predominantly hepatobiliary (>90% ID/liver). Both optical and radionuclear biodistribution studies showed a similar in vivo distribution profile. Surprisingly, the strong binding of LS172 to SSTr2 did not translate into high SSTr2-mediated endocytosis in cells or uptake in tumor in vivo. Considering that LS172 is a putative antagonist, the poor accumulation of the labeled MOMIAs in SSTr2 positive tumor tissue supports the paradigm that agonists with their concomitant internalization favors appreciable target tissue accumulation of receptor-specific ligands.

INTRODUCTION

Accurate diagnosis and treatment of diseases may be achieved by integrating a multimodal imaging strategy as part of the therapeutic regimen. With the aid of fast computational methods and algorithms for image reconstruction, coregistration of diseased tissue images can yield complimentary information, thus enhancing diagnosis. For example, computed tomographic images (CT) can be coregistered with positron emission tomographic images (PET) or single photon emission computed tomography (SPECT) (*1, 2*). In this way, the combination of anatomical information from CT with functional information from PET or SPECT allows cancers to be staged and precisely localized.

Optical imaging is an emerging method that could act synergistically with another imaging modality. Optical imaging itself is a highly sensitive technique that can detect, in vitro as well as in vivo, minute quantities of light-emitting materials. Additionally, it uses low energy radiation in the visible or near-infrared (NIR) regions of light to assess biological processes. As the light penetrates deeper in tissues, tissue chromophores, cellular organelles, and the matrix mediate scattering and absorption of emitted light. While algorithms can deconvolute light propagation through tissues, accurate models of the complex photon migration in heterogeneous biological systems are not available. This limitation would benefit from pairing optical with another imaging modality such as PET. By coupling together an optical and a radionuclear method, the location of a target tissue could first be confirmed by PET then monitored longitudinally by optical imaging for such changes as tumor response to therapy.

Previously, we and others have developed near-infrared fluorescent and radiolabeled monomolecular multimodal imaging agents (MOMIAs) for combined optical radionuclear small animal imaging (*3–5*). Typically, these MOMIAs were labeled with gamma-emitting ^{111}In for scintigraphy or SPECT. These studies demonstrated the capability of obtaining coregistered images of the distribution of the MOMIAs in small animals by both fluorescence and gamma imaging methods. However, previous studies focused on using the MOMIA strategy for multimodal imaging. Interestingly, the ability of some radionuclides to emit photons for imaging and therapeutic applications provides a strategy to incorporate therapeutic radionuclides into the MOMIA concept. This can be accomplished by using ^{177}Lu or ^{64}Cu radiometals in MOMIA constructs.

^{177}Lu ($t_{½}$ = 6.65 days) has gamma emissions (208 keV; 11%) for SPECT imaging and therapeutic properties (β^-, 497 keV; 78%). A peptide conjugate of this radiometal, ^{177}Lu-DOTA-Y3-TATE, has demonstrated excellent tumor localization and good clearance properties as well as significant tumor regression in an animal model (*6, 7*). SPECT has many advantages as an imaging method, but PET is the current method of choice for both human and small animal molecular imaging because of its exceptionally high sensitivity and in vivo quantitative measurements of the early kinetics of drug distribution. A widely used radiometal for PET is ^{64}Cu because of it is convenient half-life ($t_{½}$ = 12.7 h) and decay properties (β^+ (19%); β^- (39%)) that are suitable for PET as well as radiotherapy. Both radiometals form stable complexes with tetraazamacrocycle

DOTA, which can be conjugated to bioactive molecules such as peptides and proteins for specific delivery to target tissue (*7–10*).

To take advantage of the multimodal approach, we have developed a single imaging agent that contains reporters for both optical and SPECT or PET imaging modalities as well as radiotherapeutic properties. These MOMIAs offer minimization of data analysis errors due to differences in the pharmacokinetics of two different imaging agents used for each modality, sources of error resulting from the interaction of the two imaging probes in vivo, and patient toxicity from repeated administration of multiple probes.

Toward this goal, we chose the well characterized somatostatin receptor subtype-2 (SSTr2) as a target and an oactapeptide Y3-TATE as the targeting ligand (*11, 12*). Y3-TATE has been labeled with a variety of radiometals for diagnostic imaging and radiotherapy, utilizing macrocyclic chelators usually conjugated to the *N*-terminal amine (*6, 7*). For optical imaging, we used the near-infrared fluorescent dye cypate (*13*). Cypate, when conjugated to the *N*-terminus of Y3-TATE (cytate, Figure 1), was shown by optical imaging to be localized in subcutaneous SSTr2-positive tumors in rat with high selectivity (*14*). The NIR spectral properties of cypate match the low absorption of intrinsic naturally occurring molecules, resulting in an overall enhancement of the signal.

The three-component molecular design (receptor-avid peptide, radiometal chelate, and NIR fluorescent dye) was synthesized on solid support, where DOTA was conjugated to the *N*-terminal amine of D-Phe and cypate was conjugated to the ε-amino group of a *C*-terminal lysine. The resultant MOMIA, LS172 (Figure 1), was evaluated for its ability to displace ^{111}In-DTPA-Y3-TATE in an in vitro binding assay. After radiolabeling with either ^{64}Cu- or ^{177}Lu-, LS172 was evaluated in a well characterized tumor model (AR42J) for in vivo tumor localization and clearance properties (*9, 10, 15, 16*). Finally, the cellular internalization of LS172 and ^{nat}Cu-LS172 was determined by fluorescence microscopy. Together, the results demonstrate that the measured high receptor binding affinity of LS172 did not translate into high cellular internalization or in vivo tumor uptake mediated by somatostatin receptor, suggesting that LS172 is an antagonist.

EXPERIMENTAL PROCEDURES

Materials. Chemicals were obtained from Sigma-Aldrich (St. Louis, MO) unless noted differently. Amino acids were purchased from Novabiochem (San Diego, CA). Cypate and cytate were synthesized as previously described (*14, 17*). ^{64}Cu was produced on a CS-15 biomedical cyclotron at the Washington University School of Medicine. ^{177}Lu was obtained from Missouri Resource Reactor (Colombia, MO). The SSTr2-positive A427-7 cells were supplied by B.E. Rogers (*18*). ^{125}I-SS-14 (^{125}I-iodotyrosil-11-somatostatin-14) was purchased from GE Healthcare (Piscataway, NJ). Protein assays were performed using the BCA assay (Pierce, Rockford, IL). Peptides were analyzed by reversed-phase HPLC (RP-HPLC) on a system consisting of a binary pumping system (Shimadzu LC-10AD, solvent A = H_2O and 0.1% TFA, and solvent B = acetonitrile and 0.1% TFA), UV/vis (Shimadzu SPD-20AV), and fluorescence (Shimadzu RF-10AXL) detectors, and electrospray ionization mass spectrometer (Shimadzu LCMS-2010A).

Peptide Synthesis. LS172 was synthesized entirely on resin with an ACT APEX 396 peptide synthesizer by standard Fmoc protocols as previously described (*14, 19*). Briefly, starting with Rink Amide resin (30 μmol), the Fmoc-protected *C*-terminal amino acid (lysine; 75 μmol) was activated with a mixture of the coupling reagents HOBt (75 μmol) and HBTU (75μmol) in the presence of DIEA (150 μmol). Deprotection of the Fmoc protecting group was accomplished with 20% piperidine in DMF. The free carboxylic acid of tri-*t*-butyl-DOTA was coupled to the *N*-terminal amine. The orthogonal 4,4-dimethyl-2,6-dioxocyclohex-1-ylidene (Dde) protecting group, which was used to protect the ε-amino group of the *C*-terminal lysine, was removed selectively with 2% hydrazine in dimethylformamide (DMF) before coupling cypate to the resultant free ε-amino group via a carboxylic acid of cypate. Simultaneous removal of side-chain protecting groups and cleavage of the product from solid support was accomplished with a mixture of 95% TFA and 5% water. After lyophilization, the crude product was obtained as a green powder and purified by semipreparative HPLC. The purity of LS172 was greater than or equal to 96% after RP-HPLC purification (based on UV peak areas of 217 and 280 nm); calculated, M = 2169; observed, $[M]^{2+}$, 1085; $[M]^{3+}$, 724. LS172 was quantified on the basis of the extinction coefficient of cypate in 20% DMSO (224, 000 M^{-1} cm^{-1}) (*17*).

Preparation of ^{nat}Cu- and ^{nat}Lu-LS172. LS172 (26 μg, 12 nmol, 0.91 μg/μL, 20% DMSO) was added to reaction buffer (278 μL, 100 mM NH4OAc, pH 4.0) containing DMSO (80 μL). $LuCl_3$ (14 nmol, 0.4 mg $LuCl_3-6H_2O$/mL, 100 mM HCl) was added to prepare ^{nat}Lu-LS172 (*20*). ^{nat}Cu-LS172 was prepared similarly with $CuCl_2$ (14 nmol, 0.2 mg $CuCl_2-2H_2O$/mL, 100 mM HCl) in a more alkaline reaction buffer (279 μL, 100 mM NH_4OAc, pH 5.5) (*21*). The reactions were monitored by RP-HPLC (Supelco ABZ plus, C-18, 3 μm, 4.6 × 150 mm, linear gradient of 35–55%B, 20 min). ^{nat}Lu-LS172 was formed in >99% conversion and identified by LCMS, but the formation of ^{nat}Cu-LS172 was incomplete (80% conversion), as determined

by UV/vis (780 nm). Therefore, an aliquot of the reaction mixture (325 μL) was treated with additional $CuCl_2$ (65 nmol, 56.9 μL, 0.2 mg $CuCl_2-2H_2O$/mL, 100 mM HCl) and heated (50 °C, 1 h), but no additional conversion was observed. ^{nat}Cu-LS172 was purified by RP-HPLC (3 × ~4 μg portions, Supelco ABZ plus, C-18, 3 μm, 4.6 × 150 mm, linear gradient of 35–55% B, 20 min). The purity of ^{nat}Cu-LS172 was 95% after HPLC purification (based on UV peak area, 780 nm). ^{nat}Lu-LS172 was used without purification because of the complete conversion of LS172 to the metal complex. ^{nat}Cu-BS29, calculated, [M] = 2232; observed, $[M]^{3+}$, 744; $[M]^{2+}$, 1115; ^{nat}Lu-LS172, calculated [M] = 2169, observed, $[M]^{3+}$, 781; $[M]^{2+}$, 1170.

Radiochemistry. LS172 was radiolabeled with ^{64}Cu as previously described (*21*). Radiochemical purity of ^{64}Cu-LS172 was ≥95% after heating (95 °C, 60 min), and final specific activities were 153 μCi/ug (332 μCi/nmol). ^{177}Lu (100 μCi) was added to labeling buffer (ammonium acetate, 100 mM, pH 5.5) along with LS172 (8 μg, 3.7 nmol) and DMSO (final concentration of 20% by volume). Purity was determined by radio-RP-HPLC (A = water, 0.1%TFA; B = acetonitrile 0.1% TFA; Vydac 201HS5415, 4.6 × 150 mm, linear gradient 30% to 70% B in 10 min, 1 mL/min). Radiochemical purity of ^{177}Lu-LS172 was ≥99% after heating (80 °C, 80 min), and final specific activity was 12.5 μCi/μg (27 μCi/nmol). For receptor-binding assays, DTPA-Y3-TATE was radiolabeled with ^{111}In (100 mM NH4OAc, pH 5.5) at a specific acitivity of 700 μCi/μg. Purity was >99% (10% to 75% B, 10 min, linear gradient). Gentisic acid (2,5-dihydroxy-benzoic acid) was added at a final concentration of 1 mM to prevent radiolysis (*22*).

Spectral Properties of LS172. Excitation and emission spectra were performed on a Jobin-Yvon Flurolog 3 and absorption measurements were performed in Beckman DU-145. Stock solutions (~1 mM) of indocyanine green (ICG) and LS172 were prepared in DMSO, and serial dilutions were made to obtain an absorbance level of ~0.02 (720 nm). The quantum yield of LS172 (Φ_{LS172}) relative to ICG was determined by the equation $\Phi_{LS172} = \Phi_{ICG}$ (slope$_{LS172}$/slope$_{ICG}$), where the slope is determined from a linear regression of integrated fluorescence intensity (735 to 830 nm) versus the absorbance (720 nm) of serially diluted LS172 in DMSO (*23, 24*).

Cell Culture. The A427-7 cell line expressing the human SSTr2 receptor was maintained at 37 °C in a humidified atmosphere containing 5% CO_2 in Eagle's minimal essential medium (EMEM) containing 4 mmol/L L-glutamine, 0.1 mM NEAA, 1.0 mM sodium pyruvate, 500 μg/mL G418, 100 U/mL penicillin, and 10% fetal bovine serum. HEK293 cells were grown in Dulbecco's modified Eagle's medium (DMEM) containing 100 U/mL penicillin, 4 mmol/L L-glutamine, and 10% fetal bovine serum at 37 °C in a humidified atmosphere containing 5% CO_2.

Fluorescence Microscopy and Internalization Assays. A427-7 and HEK293 cells were grown in 8-well chambers and incubated in EMEM and DMEM culture media (0.2 mL/well) overnight at 37 °C in a humidified atmosphere containing 5% CO_2. Cytate, LS172, and ^{nat}Cu-LS172 were incubated with A427-7 cells at 25 or 50 nM in the presence or absence of 5 μM Y3-TATE as a competitor. After 0, 15, 30, 60, and 90 min of incubation (37 °C), the slides containing the cells were placed on ice to stop the internalization process, washed (3×) with PBS (4 °C, 1 mM Ca^{2+}), fixed (4% paraformaldehyde), and air-dried. The fixed cells were then imaged with a confocal microscope (Olympus FV1000) equipped with excitation (775nm/50nm) and emission filters (845nm/55nm) for fluorescence detection in the NIR region. To generate values of relative fluorescence units (rfu) for internalized dye-conjugated peptides, a region of interest was generated by drawing a line (that excluded the cell membrane) spanning the cytoplasm and transversing the region of greatest fluorescence intensity (Olympus FV10-ASW 1.4 software). The rfu are reported as an average of intensity of the drawn line. A cell was arbitrarily chosen from each corner as well as the center of the field as a representative sample (n = 5). Because the background fluorescence was negligible, it was not subtracted from the total fluorescence.

In Vitro Binding Assay. The receptor binding assays were carried out as previously described (*14*). For the inhibition assays, varying concentrations of the competitor were incubated with ^{111}In-DTPA-Y3-TATE and membranes enriched in SSTr2 receptor (A427-7, 2 h, ambient temperature). Membrane levels were adjusted so that no more than 10% of the added radioactivity was bound (2.5 μg protein/well). To determine B_{max}, increasing concentrations of ^{125}I-SS-14 were incubated with A427-7 membranes from either cultured cells or from xenografted tumors. Bound radiotracers were separated from unbound radiotracers by filtration through fiberglass filter pads (Millipore Multiscreen system). After rinsing, radioactivity in the pads was assessed by gamma counting. The data were fit by nonlinear regression to the following equation: Y = bottom + (top-bottom)/(1+ 10 exp(X log IC$_{50}$)), where Y is cpm bound and X is log concentration. K_i values were obtained with the Cheng−Prussof equation. To determine K_D and B_{max} values, data were fit by nonlinear regression to total saturation binding with ligand depletion, where X is the amount of ^{125}I-SS-14 (cpm) added, and Y is the total amount (cpm) of radiotracer bound. Nonlinear regression calculations were determined with GraphPad Prism (version 4.00 for Windows, GraphPad Software, San Diego, CA).

Radiochemical Biodistribution of MOMIAs. AR42J tumors were implanted bilaterally in the legs of male Lewis rats from donor rats (*9*). After 10–14 days, the tumors had grown ~1.5 to 2.0 g. ^{64}Cu-LS172 was formulated in 20% DMSO in PBS by volume to prevent the adherence of the radioligand to the vessel. ^{64}Cu-LS172 (4 μCi/27 ng/12 pmol/rat, n = 5) was administered via the tail vein. Y3-TATE (100 μg/95 nmol/rat, n = 4) was included as a competitive dose. ^{177}Lu-LS172 (6.2 μCi/500 ng/230 pmol/rat) was formulated in 20% DMSO in PBS by volume with 10 μg/μL gentisic acid to prevent radiolysis. Y3-TATE (100 μg/95 nmol/rat, n = 5) was included as a competitive dose.

Optical Imaging and Biodistribution. Six 4-week-old male NCR nu/nu mice were anesthetized with ketamine (87 mg/kg) and xylazine (13 mg/kg) via intraperitoneal injection. About 5 × 10^5 A427-7 cells were injected subcutaneously in the right and left flanks of each mouse. Tumors were allowed to grow to 5–10 mm maximum diameter before treatment. For in vivo imaging, mice were anesthetized with a ketamine/xylazine cocktail as described above. LS172 (2 nmol in 100 μL of 20% DMSO) was injected intravenously via the lateral tail vein, alone (n = 3) and with a competitive dose of Y3-TATE (100 μg/95 nmol/mouse) (n = 2). In vivo imaging of the treated mice was performed with a multimodal planar imaging system (IS4000MM Eastman Kodak Company, New Haven, CT). Broadband illumination from a 150 W halogen lamp was filtered by a 755/35 nm optical bandpass filter (Eastman Kodak Company, New Haven, CT), and the emitted light captured via cooled CCD camera after 830 wide-angle long-pass filter (e830WA, Eastman Kodak Company, New Haven, CT). Brightfield and NIR fluorescence images were collected at 1, 4, 8, and 24 h postinjection. Regions of interest (ROIs) were drawn within the areas related to the liver, kidneys, tumor, and a control region on the opposite flank for comparison of relative in vivo fluorescence distribution at each time point. After 24 h, the mice were euthanized by cervical dislocation under anesthesia. Tissue

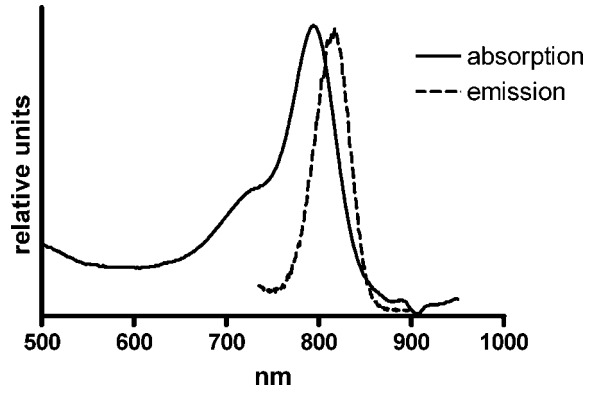

Figure 2. Absorption and emission spectra of LS172 (100% DMSO). $\lambda_{max,abs} = 793$ nm, $\lambda_{max,em} = 816$ nm, and $\Phi_F = 0.12$.

samples from muscle, liver, kidney, adrenal gland, pancreas, spleen, brain, skin, and tumor were harvested for ex-vivo fluorescence biodistribution imaging using the same settings as those described above.

Statistical Methods. Mean fluorescence intensities for the two experimental and control groups were compared with unpaired *t*-tests performed using GraphPad Prism version 4.00 for Windows (GraphPad Software, San Diego, CA).

RESULTS

Synthesis and Spectral Properties. Y3-TATE is widely used to target somatostatin receptors that are up-regulated in cancer and other pathologic conditions (*6, 10, 19, 20*). This peptide is typically labeled with radiometal chelators or fluorescent probes for imaging applications. To design radionuclear optical MOMIA, it would be easier to incorporate a lysine residue at the *N*-terminus of the peptide to provide two amino groups for conjugating DOTA and cypate. However, in a previous study, we showed that this molecular construct can compromise the peptide's binding affinity for SSTr2 (*14*). In developing a macrocyclic scaffold for molecular optical imaging, we found that adding lysine to the *C*-terminus of Y3-TATE (Y3-K9-TATE) retained the binding affinity of Y3-TATE (*17*) and provided a second reactive group for coupling cypate at a distal position to DOTA. Thus, LS172 was prepared by conjugating DOTA and cypate at the *N*- and *C*-terminal positions of Y3-K9-TATE, respectively. To construct the entire molecule on solid support, we had to use the orthogonal Dde protecting group for lysine. This allowed us to complete the peptide synthesis and DOTA coupling before Dde removal and subsequent conjugation of cypate. The procedure is advantageous because cypate, which is unstable under basic conditions, was added toward the end of MOMIA synthesis. Thus, exposure of cypate to basic conditions was minimized, and the subsequent cleavage of the product from solid support was carried out under acidic conditions, where the NIR fluorescent dye is very stable. The structures of LS172 and other compounds used in this study are shown in Figure 1.

LS172 exhibited excellent spectral properties, including similar absorption and emission spectra to the precursor dye cypate (Figure 2). Typical of many heptamethine dyes, LS172 has a narrow Stokes shift (23 nm), but the broad excitation and emission bands allow for a wide range of wavelength choices for excitation or fluorescent detection in biological assays or in vivo imaging (*25*). The relative quantum yield of LS172 ($\Phi_F = 0.12$) was the same as the reported quantum yield of ICG, indicating that conjugation of cypate to MOMIA did not compromise detection sensitivity. ^{nat}Cu-LS172 was highly fluorescent and maintained the same fluorescent properties of the parent analogue LS172 with minimal Cu-mediated quenching. Both natural and radioactive Cu and Lu were incorporated into LS172 with high radiochemical purity and specific activities for the radiometals.

Table 1. Heterologous Competitive Binding of ^{111}In-DTPA-Y3-TATE to A427-7 Cell Membranes ($n = 3$ for Each Data Point)[a]

competitor	IC_{50} (nM)	95% CI (nM)	K_i (nM)	95% CI (nM)
cytate	1.32	0.953 to 1.83	0.234	0.169 to 0.324
Y3-TATE	2.42	1.80 to 3.25	0.427	0.318 to 0.575
SS-14	0.375	0.265 to 0.531	0.0660	0.0469 to 0.0939
LS172	8.13	5.62 to 11.7	2.03	1.14 to 2.94
^{nat}Cu-LS172	45.9	33.7 to 62.4	11.5	8.40 to 15.6
^{nat}Lu-LS172	8.60	4.36 to 17.0	2.15	1.09 to 4.24

[a] K_i values were calculated from the Cheng−Prussof equation.

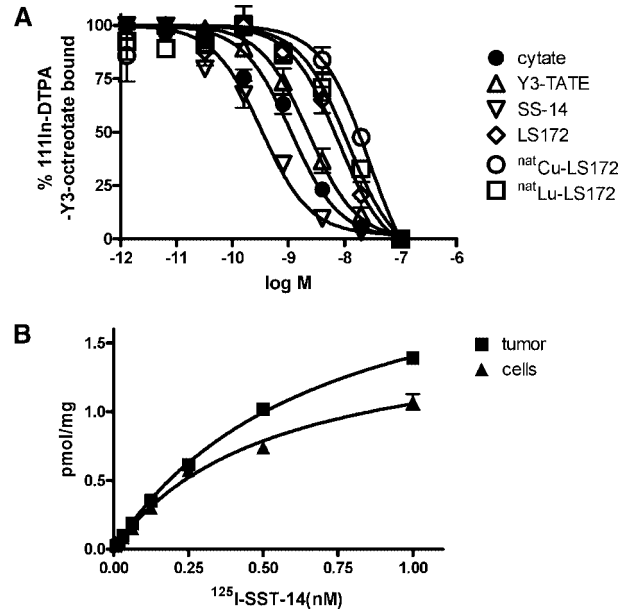

Figure 3. (A) Heterologous competitive inhibition assays with ^{111}In-DTPA-Y3-TATE on A427-7 cell membranes. (B) Saturation binding assays of 125I-SS-14 on membranes from A427-7 cells harvested from xenografts (tumor) or from cultured cells (cells).

In Vitro Receptor Binding Assays. A heterologous receptor binding assay was performed with A427-7 cell membranes, where ^{111}In-DTPA-Y3-TATE was displaced by various competitors (Table 1, and Figure 3A). Utilizing a value of $K_D = 0.13$ nM and a concentration of 0.39 nM, the Cheng−Prussof equation was used to calculate the K_i values for all of the competitors. Cytate, SS-14 and Y3-TATE display affinity for SStr2 in the subnanomolar region. The K_i values indicate that LS172 has strong affinity for SSTr2 ($K_i = 2.03$ nM), and the complexation with lutetium had very little effect on the affinity ($K_i = 2.15$ nM). However, the addition of copper to the chelator decreased affinity by approximately 5-fold ($K_i = 11.5$ nM).

^{125}I-SS-14 was used to assess the receptor densities of SSTr2 on xenografted and cultured A427-7 cells (Figure 3B). The xenografted cells expressed 2.3 pmol/mg (0.5 to 4.0 pmol/mg 95%CI), while the cultured cells expressed 1.0 pmol/mg (0.3 to 1.7 pmol/mg 95% CI). The K_D of ^{125}I-SS-14 was essentially the same ($p < 0.05$, F-test) for both membrane preparations (0.3 nM, 0.03 to 0.5 nM, 95% CI, cultured A427-7 cells). The nonspecific binding was ~2%.

Internalization by Fluorescence Microscopy. The internalization of the MOMIAs LS172 and ^{nat}Cu-LS172 was evaluated by fluorescence microscopy in the near-infrared region in A427-7 and negative control HEK293 (SSTr2 negative) cells and compared with cytate. Cytate was strongly internalized in a time-dependent manner (Figures 4 and 5), and the internaliza-

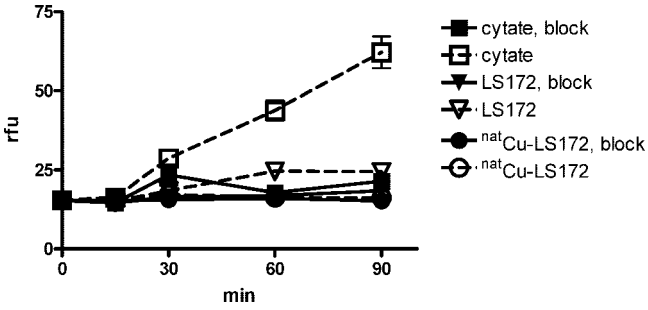

Figure 4. Uptake of cypate-conjugated Y3-TATE analogues determined by confocal fluorescence microscopy. Cypate-conjugated Y3-TATE analogues (25 nM) incubated (37 °C) with A427-7 cells with and without a competitive concentration of Y3-TATE (5 μM).

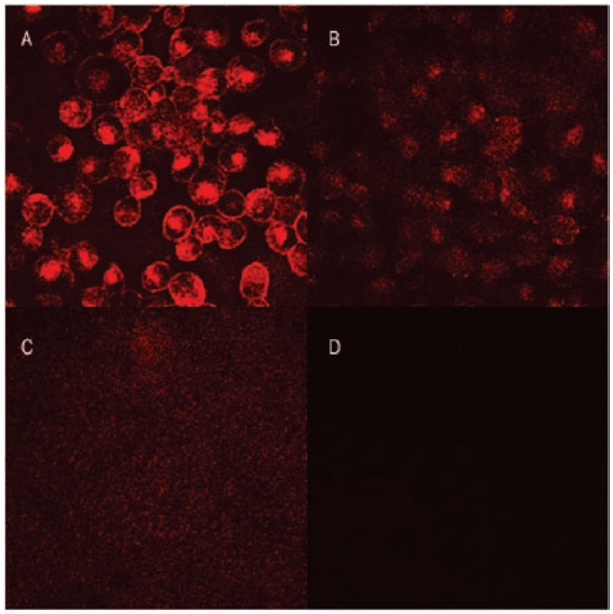

Figure 5. Cellular uptake of NIR dye-labeled peptides in either SSTr2-positive A427-7 cells (A and B) or SSTr2-negative HEK cells (C and D) incubated with 50 nM cytate (A and C) or LS172 (B and D) for 90 min. All of the images were normalized to the highest fluorescent intensity from the image in panel A.

tion was successfully blocked with a competitive dose of Y3-TATE. In contrast, LS172 was weakly internalized at 25 nM. A competing dose of Y3-TATE inhibited its accumulation until later time points (Figure 5). Surprisingly, ^{nat}Cu-LS172 was not internalized to any significant extent in the cells (Figure 5). The apparent externalization of some of the ligands at 30 min could be attributed to an error arising from the inherently low fluorescence intensities at this early time point.

Radiochemical Biodistribution. Both ^{64}Cu- and ^{177}Lu-LS172 displayed relatively similar pharmacokinetic profiles with a rapid blood clearance of 0.151 ± 0.027 and 0.228 ± 0.047% ID/g, respectively, at 1 h postinjection (Table 2). Clearance was predominately hepatic for both ^{64}Cu-LS172 (16.824 ± 1.520% ID/g, 95.8 ± 7.12% ID/liver, 1 h) and ^{177}Lu-LS172 (17.862 ± 3.286% ID/g, 89.6 ± 3.16% ID/live, 1 h) with relatively low kidney accumulation (~1 to 2% ID/g). Accumulation of activity for both radiolabeled MOMIAs in the SSTr2-positive tissues of adrenal, pituitary, pancreas, and tumor (average of left and right) were relatively low (≤1% ID/g) in all cases. ^{64}Cu-LS172 accumulation in tumor decreased with the coadministration of a competitive dose of Y3-TATE in the tumor ($P < 0.05$), but the observed decrease in other SSTr2-positive organs was not significant. The decreases in the accumulation of ^{177}Lu-LS172 in SSTr2-positive tissues with the coadministration of a competitive dose of Y3-TATE were significant ($P < 0.05$) in all target tissues except the bone.

Table 2. Biodistribution of ^{64}Cu-LS172 and ^{177}Lu-LS172 in AR42J Tumor Bearing Rats at 1 h, with and without the Coadministration of a Competing Dose of Y3-TATE[a]

tissue	^{64}Cu, 1 h	^{64}Cu, 1 h block	^{177}Lu, 1 h	^{177}Lu, 1 h block

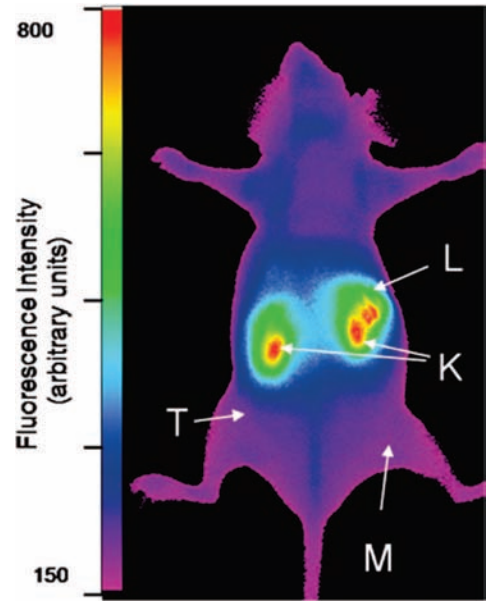

Figure 6. Optical Biodistribution of LS172 in nude mice xenografted with A427-7 cells (24 h). Representative fluorescence intensity image of a living mouse bearing a subcutaneous A427-7 xenograft 24 h after an injection of LS172. Liver (L), kidney (K), muscle (M), and tumor (T) regions of interest are indicated by arrows. The tumor is indistinguishable from surrounding muscle tissue by fluorescence intensity. Illumination light was selected with optical bandpass filter centered at 755 nm, and emission was captured with a cooled CCD camera after the 830 nm long-pass filter.

Optical Imaging. The receptor-binding assay suggests that Cu chelation reduces the affinity of LS172. Because cypate in this MOMIA provides the NIR fluorescence signal, we were able to assess its relative biodistribution in vivo and ex vivo without metal chelation to delineate the effect of radiolabeling on LS172. Thus, we noninvasively evaluated the biodistribution of LS172 in A427-7 tumor-bearing mice at 1, 4, 8, and 24 h. LS172 rapidly accumulated in the liver and kidneys, with low concentrations detected in the tumor and muscle tissues (Figures 6−8). At 24 h, representative tissues and organs were harvested and imaged ex-vivo to determine the relative tissue uptake of LS172 (Figure 9). In addition to the liver and kidneys, LS172 accumulated in the spleen and accounted for 35% of the fluorescence intensity relative to the liver (Figure 9). LS172 accumulation in mouse kidney was somewhat higher than that of the radiolabeled analogues in rat kidney, possibly indicating

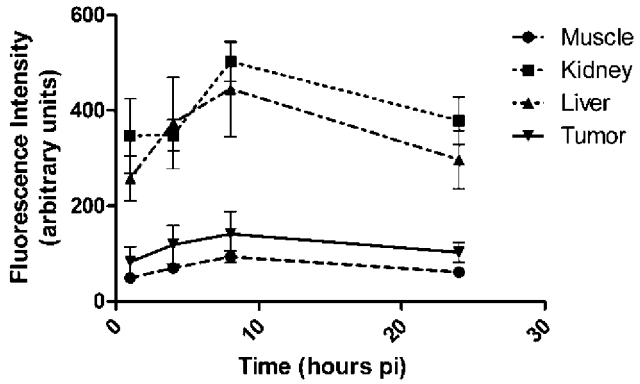

Figure 7. Measured fluorescence intensity of selected regions of interest that indicate the accumulation of LS172 in normal muscle, kidney, liver, and tumor tissues at specified time after an injection of contrast agent ($n = 3$). Fluorescence detected in the regions of the liver and kidney was significantly higher than muscle or tumor intensity for all time points. Accumulation of contrast agent in tumor tissue paralleled that of normal tissues as determined by NIR fluorescence imaging in living mice. Error bars represent SEM.

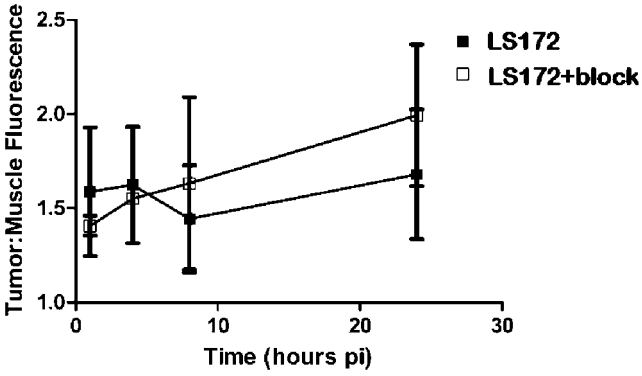

Figure 8. Ratios of tumor to muscle fluorescence intensities measured in living mice at given time points after an injection of LS172 ($n = 3$) or LS172 with Y3-TATE as blocking agent ($n = 2$). Linear regression of each data set showed that the slopes were not significantly nonzero, indicating that tumor accumulation of LS172 was not different from that of normal muscle tissue. Error bars represent SEM.

the reduction of overall charge on the DOTA upon chelation with a metal.

In spite of the high SSTr2, in vivo imaging did not show significant tumor accumulation of LS172 relative to normal tissue at different time points (Figure 7), and competitive inhibition with Y3-TATE did not significantly alter the tumor-to-muscle uptake ratio (Figure 8). The uptake and blood clearance profiles of LS172 in tumor-bearing A427-7 mice were similar to that of ^{177}Lu-LS172 and ^{64}Cu-LS172 in tumor-bearing AR42J rats. Inhibition studies with a competitive dose of Y3-octreotate showed that the observed uptake of LS172 in all tissues examined is attributable to nonspecific accumulation, including SSTr2-positive adrenal, pancreas, and tumor tissues (Figure 9).

DISCUSSION

Somatostatin peptide analogues are well characterized as radioimaging and therapeutic agents for the somatostatin receptor (*6, 7, 10, 15*). Previous studies have shown that labeling these peptides with fluorescent dyes provides a method to image SSTr2-positive tumors in mice (*14, 19, 26*). The goal of this work was to determine whether a somatostatin peptide analogue, labeled with a radiometal and a NIR fluorescent dye, would localize in a receptor-specific manner to a target tissue, such as a xenografted tumor. The somatostatin analogue was chosen on the basis of the structure of Y3-TATE, where the tetraazamacrocycle, DOTA, was conjugated to the *N*-terminal D-phenylalanine residue, and the near-infrared dye, cypate, was conjugated to the ε-amino group of lysine at the *C*-terminus. This compound, LS172, was used for NIR fluorescence imaging or labeled with ^{64}Cu and ^{177}Lu and evaluated in tumor-bearing rats by nuclear methods. In addition, LS172 was also metallated with the natural Cu and Lu for receptor-binding studies as well as cell-uptake experiments.

In the receptor-binding studies, ^{nat}Cu-LS172 and ^{nat}Lu-LS172 were used to displace ^{111}In-DTPA-Y3-TATE (Table 1 and Figure 3A). The IC_{50} values were converted to K_i values and compared to those of Y3-TATE, cytate, and SS14. The addition of cypate to the *N*-terminus of Y3-TATE (cytate) did not significantly change the binding affinity. However, modifications of both the *N*- and *C*-termini decreased the binding affinity of LS172 by about 10- and 5-fold relative to cytate and Y3-TATE, respectively. Moreover, while the complexation of ^{nat}Lu with DOTA had little effect on affinity, complexation of ^{nat}Cu reduced the affinity of LS172 by approximately 5-fold. In spite of the fact that the SSTr2-binding amino acid sequence of the peptide, the Phe (or Tyr)-D-Trp-Lys-, is relatively isolated from the termini, modifications at these sites still can affect binding. Previous studies have shown that the addition of the peptide PKKKRKV(OH) via an aminohexanoic acid linker to the *C*-terminal threonine residue of DOTA-Y3-TATE resulted in a relatively weak binding peptide when labeled with ^{111}In (K_D ~280 nM) (*27*). Furthermore, DOTA-Y3-octreotide was a weaker competitor ($IC_{50} = 14 \pm 2.6$, SEM) toward radioiodinated SS-14 than DOTA-Y3-TATE ($IC_{50} = 1.5 \pm 0.4$ nM, SEM), indicating that the relatively small change from the *C*-terminal alcohol to that of the carboxylic acid can result in a nearly 10-fold increase in affinity (*28*). Changing the radiometal in the chelator can also affect affinity. ^{nat}Ga-DOTA-Y3-octreotide bound the SSTr2 subtype with 5-fold higher affinity than the corresponding Y^{3+} derivative. This difference was ultimately attributed to a conformational change in the *N*-terminal D-Phe residue of the Y^{3+} analogue as a result of the binding of the amide D-Phe carbonyl oxygen in the metal-coordination sphere (*29*). Nevertheless, the observed affinities of ^{nat}Cu-LS172 and ^{nat}Lu-LS172 are sufficiently strong for receptor imaging, and therefore, they were radiolabeled with the corresponding radioisotopes and investigated in animal cancer models.

A well characterized tumor model, AR42J rat pancreatic xenografts, was chosen for evaluating the radiolabeled MOMIA. This model has been successful and reliable in the evaluation of a variety of radiolabeled somatostatin analogues targeted to the SSTr2 with the added benefit of confirming receptor-specific uptake in SSTr2-rich organs of the adrenal, pituitary, and pancreas (*9, 10, 15, 16*). Previous investigations of radiolabeled somatostatin analogues showed uptakes in AR42J xenografts that ranged from low ~1% ID/g up to ~6% ID/g. For example, the accumulation of ^{64}Cu-DOTA-D-Y1-octreotate ($K_D = 0.2$ nM) at 1 h was 1.52% ID/g and decreased to 0.468% ID/g with a competing dose of D-Y1-TATE (*9*). However, SSTr2-positive tissue uptake in pituitary, adrenal, and pancreas was 1.99, 1.37, and 1.49% ID/g, respectively, with concomitant decreases upon coadministration of a competing dose of unlabeled Y1-TATE. In another study, ^{64}Cu-TETA-Y3-TATE accumulation in AR42J xenografts at 1 h was ~1.7% ID/g with observed accumulation in pancreas and adrenals ~3.0 and 2.5% ID/g, respectively. A competing dose of Y3-TATE resulted in >90% inhibition of accumulation in these tissues (*16*). The observed accumulation of ^{64}Cu-LS172 in AR42J xenografts was lower, uniformly less than 1% (Table 2). Furthermore, while coadministration of a

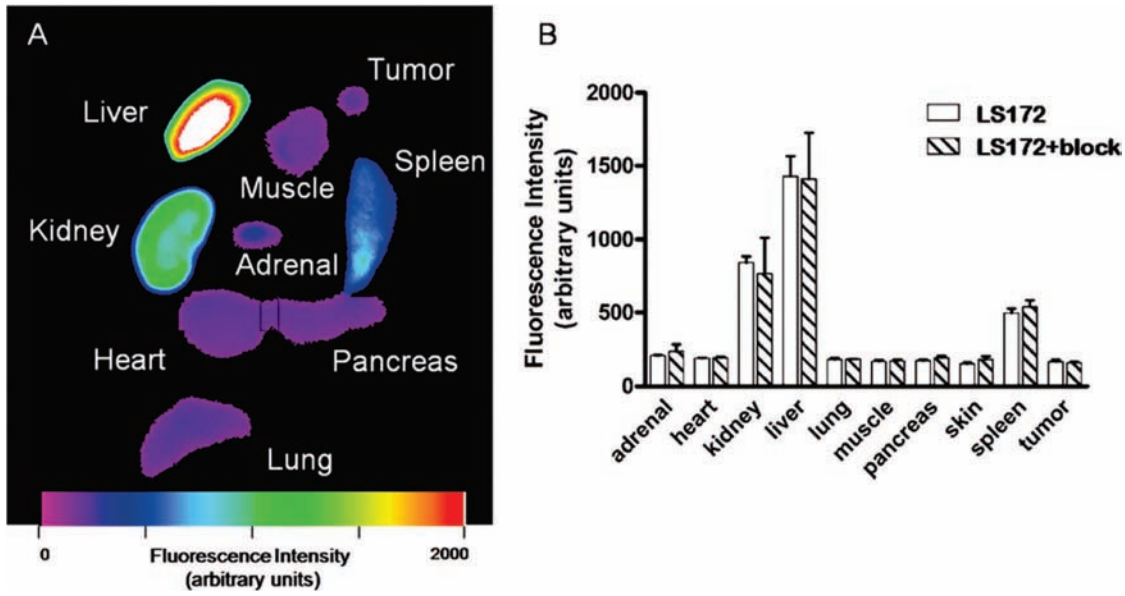

Figure 9. (A) Fluorescence intensity image of ex vivo organ tissues 24 h after an injection of LS172 representative of molecular probe biodistribution in mice. Liver, kidney, and spleen tissues showed high fluorescence intensity relative to that of other organs. (B) Optical biodistribution of LS172 in nude mice xenografted with A427-7 cells (24 h).

competing dose of Y3-TATE resulted in decreased uptake in all SSTr2-positive tissues, the results were significant only for the xenografted AR42J tumors ($P < 0.05$, two-tailed unpaired *t*-test). Other features of the ^{64}Cu-LS172 biodistribution included relatively rapid blood clearance (1 h), predominantly hepatobiliary clearance, and relatively high spleen uptake.

The biodistribution of ^{177}Lu-LS172 bore many similarities to that of ^{64}Cu-LS172, including clearance pathways and rates, high spleen uptake, and lower SSTr2-positive tissue uptake (≤1%; Table 2). The exception was that SSTr2-positive tissue uptake of ^{177}Lu, except for bone, was inhibited by a competitive competing dose of Y3-TATE ($P < 0.05$, two-tailed unpaired *t*-test). For comparison, the accumulation of ^{177}Lu-DOTA-Y3-TATE in pancreas, adrenals, and bone (femur) at 1 and 4 h was ≥10% (*6, 7*). Competing doses of octreotide at later time points confirmed that the accumulation was receptor-specific (*6*). Specific activity is not considered a likely confounding factor in this study because the specific activity was 3.5-fold less (27 μCi/nmol) than the reported specific activity (94 μCi/nmol) where high accumulation in bone and pancreas were observed (*7*). While saturation assays on dissected AR42J xenografts were not performed to verify that they retained expression of SSTr2, the low accumulation of both ^{64}Cu- and ^{177}Lu-LS172 in other SSTr2-positive tissues demonstrates the poor specific uptake of LS172 in vivo. For these reasons, biodistribution of the radiolabeled LS172 at later time points was not performed in this study.

Surprised by the in vivo outcome using AR42J cells, we explored the use of an alternative cell line rich in SSTr2. We recently developed a new cell line, A427-7 (A427 clone 7) that meets our need (*18*). SSTr2 was transfected into A427 cells with relatively large receptor numbers (~7.0 pmol/mg protein). The transfected receptor appeared to function in identically to the wild type receptor because recent studies with SSTr2-avid ^{64}Cu-TETA-octreotide showed it was internalized by A427-7 cells and had relatively high SSTr2 specific accumulation in vivo (*18*). Therefore, this cell line provides a method to evaluate the MOMIAs in another cell line.

Considering that the SSTr2 binding assay demonstrated that radiolabeling of LS172 with Cu reduced the affinity, we imaged the distribution and uptake of the NIR fluorescent LS172 in A427-7 tumor-bearing nude mice by fluorescence imaging. LS172 was administered to the mice with and without a competing dose of Y3-TATE. This allowed us to determine whether the radiometal played a role in the relatively low tumor accumulations in AR 42J cells in rat.

Longitudinal, noninvasive optical imaging provided relative biodistribution data at multiple times during the 24 h after injection (Figure 7). Despite these changes, in vivo optical imaging showed that LS172 accumulation paralleled that of the radiochemical biodistribution with relatively rapid blood clearance and predominant hepatobiliary clearance with no apparent receptor-specific accumulation in the A427-7 tumor or other SSTr2-positive tissues. In vivo and ex vivo fluorescence imaging did not show significantly higher LS172 accumulation in tumor tissue relative to healthy tissues (Figures 6−9). The observed increase in kidney retention relative to radionuclear biodistribution could be attributed to species differences. Alternatively, the absence of metals in LS172 increases the net negative charge on DOTA, thereby favoring kidney uptake.

To determine whether the low accumulation of LS172 in the A427-7 cells was due to receptor downregulation, saturation assays with ^{125}I-SS-14 were performed on homogenized A427-7 tumors dissected from mice. The results showed robust expression of SSTr2 (2.3 pmol/mg), indicating that receptor loss in the xenografts was not the cause of the low observed tumor accumulation (Figure 3B). Our observed values of SSTr2 receptor densities in the xenografted tumors were lower than the reported values (*18*). The difference could be attributed to differences in the method used for these measurements. Whereas we determined receptor expression level with ^{125}I-SS-14, the reported values were determined with ^{64}Cu-TETA-octreotide.

Recently, saturation assays with radiolabeled SSTr2 agonists and antagonists identified differing receptor densities, raising the intriguing possibility that there are differing active receptor conformations that are dependent on the radioligand (*27*). These observations may further explain the differing levels of receptor identified in this work relative to that previously determined (*18*).

Because it was unusual that ligands with such high affinity failed to localize to receptor-rich tissues in vivo, we investigated the uptake of LS172 and ^{nat}Cu-LS172 relative to cytate in A427-7 cells in vitro. Cytate was included as a reference because of its high SSTr2-specific accumulation in a xenografted tumor

(CA20948) in as little as 90 min (*14*, *19*). The internalization of LS172 and ^{nat}Cu-LS172 by A427-7 cells was directly observed by NIR fluorescence microscopy because they are both conjugated to cypate (Figures 4 and 5). Expectedly, cytate was rapidly internalized in A427-7 cells. While LS172 also internalized, it did so at a far slower rate and to a much lower extent than cytate. Internalization of cytate and LS172 was inhibited with a competitive dose of Y3-TATE, thus demonstrating that endocytosis was mediated by the SSTr2 receptor. Lack of observed internalization of either cytate or LS172 in the SSTr2-negative HEK293 cells further confirmed the involvement of SSTr2-specific uptake in A427-7 cells. However, it should be noted that HEK293 cells express low levels of SSTr2 (*30*).

The hallmark of agonism is the internalization of the receptor–ligand complex (*12*, *15*). Antagonists do not stimulate internalization. LS172, with its extremely weak internalization properties, and Cu-LS172 appear to be antagonists and cytate an agonist. Recently, the correlation between agonism, defined as the ability of a putative agonist to inhibit forskolin-stimulated cAMP production, and internalization was investigated (*31*). The concentration required to stimulate internalization was determined by ELISA. Both methods linked these abilities to the concentration required to obtain 50% effect (EC_{50}). The EC_{50} ratio of internalization to cAMP inhibition of SS-28 and SS-14 was ∼1. However, for other ligands, such as octreotide, the ratio rose to ∼10, indicating that octreotide is 10-fold better at stimulating adenylate cyclase than at stimulating receptor internalization. These results show that inhibition of cAMP production may not be the best approach to determine the ability of an agonist to stimulate receptor internalization.

Internalization is considered a key feature for successful in vivo accumulation of the radiotracer at the target site (*15*). The rationale is that after binding of the radiotracer, the receptor–ligand complex internalizes into an endocytotic pathway while the unbound ligand clears from blood and nontarget tissues. Recently, a high degree of correlation between the rate of internalization of SSTr2-avid ligands in vitro and accumulation in SSTr2-enriched xenograft (AR42J) and natural organ (pancreas) in vivo was observed (*10*). Moreover, successful imaging and therapy with radiolabeled somatostatin analogues in humans have utilized tracers that were internalized in vitro (*32*, *33*). Therefore, the low accumulation of LS172 and ^{64}Cu-LS172 in xenografted tumors in vivo appeared to be due to a lack of internalization of these apparent antagonists, while the high receptor-specific accumulation of cytate is due to its ability to internalize.

This result stands in sharp contrast to a recent observation that an antagonist (^{111}In-DOTA-SSTr2-ANT) accumulated to a high level (∼29% ID/g, 4 h) in SSTr2-positive tumor xenografts (HEK-SSTr2 transfected tumors in nude mice) (*34*). The accumulation exceeded that of ^{111}In-DOTA-Y3-TATE (∼16% ID/g, 4 h). The authors determined that ^{nat}In-DOTA-SSTr2-ANT was an antagonist by its inability to inhibit forskolin-stimulated cAMP production as well as by its inability to stimulate SSTr2 internalization (immunofluorescence microscopy). Part of the explanation was that the higher number of receptors identified by the antagonist (15-fold more than the agonist) offset the internalization effect. Unfortunately, the receptor concentrations were not normalized to protein weight, which makes a comparison with our current results difficult. The A427-7 cell line maintained robust expression of the SSTr2 as a xenograft, and this high expression level (2.3 pmol/mg) did not offset the lack of internalization of LS172.

In conclusion, LS172, a monomolecular multimodal imaging agent, was radiolabeled with both ^{64}Cu and ^{177}Lu and evaluated as an SSTr2 receptor-imaging agent by both optical and radionuclear methods in vitro and in vivo. All of the compounds have high SSTr2 binding affinity and retained their fluorescence properties before and after labeling with metal. In spite of the high expression level of the target, LS172 along with its radiolabeled analogues, ^{64}Cu- and ^{177}Lu-LS172, did not accumulate in levels commensurate with their high affinity and high target expression in tumor xenografts. Moreover, accumulation in tissues endogenously expressing SSTr2 was also very low. We attribute the low accumulation to a lack of internalization of the labeled ligands in a receptor–ligand complex characteristic of successful SSTr2 imaging agents. Although the anticipated receptor-mediated accumulation in target tissues was not observed, the excellent agreement between the optical and radiochemical biodistributions demonstrates the utility of multimodal monomolecular imaging agents (MOMIAs). In addition, the quantitative radionuclear method is useful for validating data from the high throughput qualitative planar optical imaging method. Overall, high receptor binding affinity in vitro is a necessary but not sufficient criterion for selecting ligands for in vivo imaging application. The use of dual radioimaging and therapeutic radiometals provides a strategy for monitoring treatment response, initially by either PET or SPECT, followed by optical imaging at later time points.

ACKNOWLEDGMENT

We thank Dr. Yunpeng Ye for preparing cypate and Mr. Christopher Sherman for performing the radio-biodistribution study. This study was supported in part by the NIH (grants R33 CA100972, R01 EB1430, R21 CA123537, and R01 CA64475).

Received August 8, 2007; Revised Manuscript Received October 7, 2007

In this report, we present *in vitro* and *in vivo* evaluation of three ^{111}In-labeled DTPA conjugates of a cyclic RGDfK dimer: DTPA-Bn-SU016 (SU016 = E[c(RGDfK)]$_2$; DTPA-Bn = 2-(*p*-isothioureidobenzyl)diethylenetriaminepentaacetic acid), DTPA-Bn-E-SU016 (*E* = glutamic acid) and DTPA-Bn-Cys-SU016 (Cys = cysteic acid). The integrin $\alpha_v\beta_3$ binding affinities of SU016, DTPA-Bn-SU016, DTPA-Bn-E-SU016, and DTPA-Bn-Cys-SU016 were determined to be 5.0 ± 0.7 nM, 7.9 ± 0.6 nM, 5.8 ± 0.6 nM, and 6.9 ± 0.9 nM, respectively, against ^{125}I-c(RGDyK) in binding to integrin $\alpha_v\beta_3$, suggesting that E or Cys residue has little effect on the integrin $\alpha_v\beta_3$ affinity of E[c(RGDfK)]$_2$. It was also found that the ^{111}In-labeling efficiency of DTPA-Bn-SU016 and DTPA-Bn-E-SU016 is 3–5 times better than that of DOTA analogues due to fast chelation kinetics and high-yield ^{111}In-labeling under mild conditions (e.g., room temperature). Biodistribution studies were performed using BALB/c nude mice bearing U87MG human glioma xenografts. ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 all displayed rapid blood clearance. Their tumor uptake was comparable between 0.5 and 4 h postinjection (p.i.) within experimental error. ^{111}In-DTPA-Bn-E-SU016 had a significantly lower ($p < 0.01$) kidney uptake than ^{111}In-DTPA-Bn-SU016 and ^{111}In-DTPA-Bn-Cys-SU016. The liver uptake of ^{111}In-DTPA-Bn-SU016 was 1.69 ± 0.18% ID/g at 24 h p.i., while the liver uptake values of ^{111}In-DTPA-Bn-E-SU016 and ^{111}In-DTPA-Bn-Cys-SU016 were 0.55 ± 0.11% ID/g and 0.79 ± 0.15% ID/g at 24 h p.i., respectively. Among the three ^{111}In radiotracers evaluated in this study, ^{111}In-DTPA-Bn-E-SU016 has the lowest liver and kidney uptake and the best tumor/liver and tumor/kidney ratios. Results from metabolism studies indicated that there is little metabolism (<10%) for three ^{111}In radiotracers at 1 h p.i. Imaging data showed that tumors can be clearly visualized at 4 h p.i. with good contrast in the tumor-bearing mice administered with ^{111}In-DTPA-Bn-E-SU016. It is concluded that using a glutamic acid linker can significantly improve excretion kinetics of the ^{111}In-labeled E[c(RGDfK)]$_2$ from liver and kidneys.

INTRODUCTION

Integrin $\alpha_v\beta_3$ plays a critical role in tumor angiogenesis and metastasis (*1–5*). The highly restricted expression of integrin $\alpha_v\beta_3$ during tumor growth, invasion, and metastasis makes it an interesting molecular target for development of the integrin $\alpha_v\beta_3$-targeted radiotracers (*6–9*). In the past decade, many radiolabeled cyclic RGD peptides have been evaluated as potential radiotracers for early detection of the integrin $\alpha_v\beta_3$-positive tumors by single photon emission computed tomography (SPECT) or positron emission tomography (PET). [^{18}F]Galacto-RGD has become the first PET radiotracer under clinical investigation for noninvasive visualization of integrin $\alpha_v\beta_3$ expression in cancer patients (*10–12*). The integrin $\alpha_v\beta_3$-targeted radiotracers have been reviewed extensively (*13–18*).

We and others have been using cyclic RGD dimers, such as E[c(RGDfK)]$_2$ (SU016), to develop integrin $\alpha_v\beta_3$-targeted diagnostic (^{64}Cu, ^{99m}Tc, and ^{111}In) and therapeutic (^{90}Y and ^{177}Lu) radiotracers (*19–36*). It has been found that the radiolabeled cyclic RGD dimers have much better tumor uptake than monomeric analogues due to their higher integrin $\alpha_v\beta_3$ binding affinity. Recently, we reported the impact of pharmacokinetic modifying (PKM) linkers on biological properties of the ^{99m}Tc-labeled HYNIC-PKM-SU016 (HYNIC= 6-hydrazinonicotinamide; PKM = glutamic acid (E), lysine (K), or PEG$_4$ (15-amino-4,7,10,13-tetraoxa-pentadecanoic acid)) (*23*). Even though they have minimal impact on the integrin $\alpha_v\beta_3$ affinity of SU016, all three PKM linkers are able to reduce the radiotracer uptake in blood, kidneys, liver, and lungs, and increase target-to-background (T/B) ratios. E and K have advantages over PEG$_4$ due to lower liver uptake and higher tumor/liver ratios of the ^{99m}Tc-labeled E[c(RGDfK)]$_2$ (*23*). For ^{111}In-labeled DOTA-PKM-E[c(RGDfK)]$_2$ (DOTA = 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid), however, PEG$_4$ appears to be a better linker than E and K, since ^{111}In-DOTA-PEG$_4$-E[c(RGDfK)]$_2$ has the highest tumor-to-blood ratio and lowest uptake in liver and kidneys (*33*).

The disadvantage of using DOTA as the bifunctional chelator (BFC) for ^{111}In-labeling of small biomolecules is its slow chelation kinetics and low radiolabeling efficiency (*33, 37, 38*). In contrast, DTPA has higher radiolabeling efficiency (*37–39*),

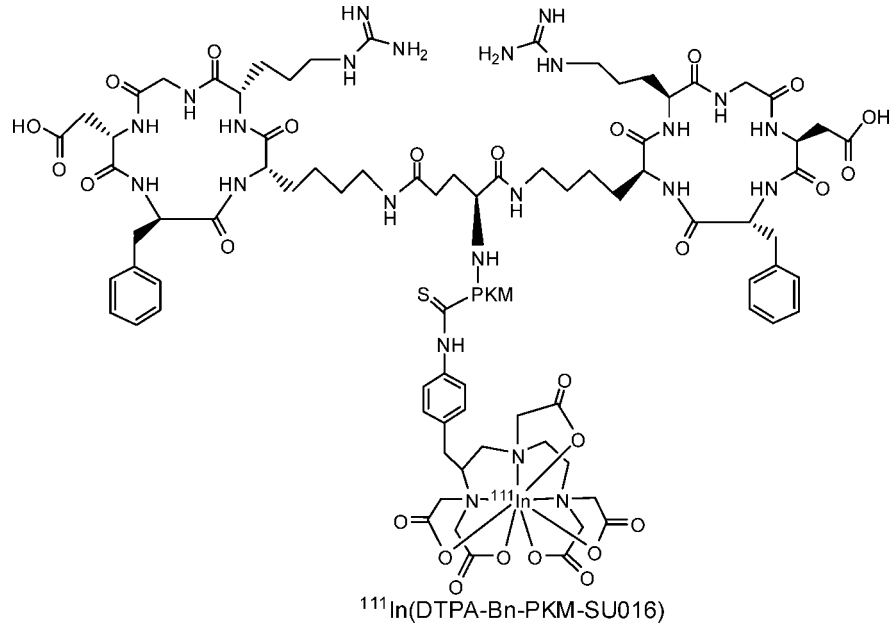

Figure 1. Schematic presentation of ^{111}In-labeled cyclic RGDfK dimer DTPA conjugates: ^{111}In(DTPA-Bn-PKM-SU016) (PKM = direct bond, glutamic acid (E) and cysteic acid (Cys); SU016 = E[c(EGDfK)]$_2$).

and has been successfully used for ^{90}Y, ^{177}Lu, and ^{111}In-labeling of biomolecules, including antibodies (*40–44*) and small peptides (*39, 40, 45, 46*). In this study, we report three new cyclic RGDfK dimer DTPA conjugates (Figure 1), DTPA-Bn-SU016(DTPA-Bn=2-(*p*-isothiocyanobenzyl)diethylenetriaminepentaacetic acid), DTPA-Bn-E-SU016, and DTPA-Bn-Cys-SU016 (Cys = cysteic acid), and the evaluation of their ^{111}In complexes (Figure 1) as the integrin $\alpha_v\beta_3$-targeted radiotracers in the BALB/c nude mice bearing U87MG human glioma xenografts. ^{111}In is of particular interest to us, since it has been widely (second only to ^{99m}Tc) used for SPECT imaging, and the ^{111}In-labeled E[c(RGDfK)]$_2$ can be used as the imaging surrogate to evaluate the potential of the ^{90}Y-labeled E[c(RGDfK)]$_2$ as the integrin $\alpha_v\beta_3$-targeted radiotracer for tumor radiotherapy. The main objective of this study is to explore the effect of linkers (E and Cys) on biodistribution characteristics of the ^{111}In-labeled E[c(RGDfK)]$_2$. The ultimate goal of using different linkers is to increase T/B ratios by minimizing radiotracer uptake in non-cancerous organs while maintaining high tumor uptake.

EXPERIMENTAL SECTION

Materials. All chemicals were purchased from Sigma/Aldrich, unless specified otherwise. The cyclic pentapeptide, c(RGDfK), was obtained from Peptides International, Inc. (Louisville, KY). 2-(*p*-Isothiocyanobenzyl)diethylenetriaminepentaacetic acid (*p*-SCN-Bn-DTPA) was purchased from Macrocyclics (Dallas, TX). $^{111}InCl_3$ was obtained from Perkin-Elmer Life and Analytical Sciences (North Billarica, MA). E[c(RGDfK)]$_2$ and E-E[c(RGDfK)]$_2$ were prepared according to the procedure described in our previous communications (*21, 23*). The reversed-phase C-18 SepPak cartridges were obtained from Waters (Milford, MA). The ammonium acetate buffer for ^{111}In-labeling studies was passed over a Chelex-100 column (1 × 15 cm) to minimize the trace metal contaminants.

HPLC and ITLC Methods. HPLC method 1 used a LabAlliance semiprep HPLC system equipped with a UV/vis detector (λ = 254 nm) and a reverse-phase Zorbax C_{18} column (9.4 mm × 250 mm, 100 Å pore size). The flow rate was 2.5 mL/min. The mobile phase was isocratic with 90% solvent A (0.1% acetic acid in water) and 10% solvent B (0.1% acetic acid in acetonitrile) at 0–5 min, followed by a gradient mobile phase going from 90% solvent A and 10% solvent B at 5 min to 60% solvent A and 40% solvent B at 20 min. The radio-HPLC method (method 2) used a HP Hewlett Packard series 1100 HPLC system equipped with Radioflow Detector LB509 and Agilent Zorbax SB-C18 column (4.6 mm × 250 mm, 5 μm). The flow rate was 1.0 mL/min. The mobile phase was isocratic with 90% solvent A (25 mM NaOAc buffer, pH = 5.0) and 10% solvent B (acetonitrile) at 0–2 min, followed by a gradient mobile phase going from 10% solvent B at 2 min to 15% solvent B at 5 min and to 20% solvent B at 20 min, then to 10% solvent B at 25 min. The radio-ITLC method used GelmanSciences silica-gel paper strips and a 1:1 mixture of acetone and saline as the eluant. Using this method, the ^{111}In-labeled cyclic RGDfK peptide dimer migrates to the solvent front, while the "free" or "unchelated" ^{111}In remains at the origin.

DTPA-Bn-SU016. DTPA-Bn-SCN (2.7 mg, 4 μmol) and SU016 (3.0 mg, 2 μmol) were dissolved in 1 mL of anhydrous dimethylformamide (DMF). The pH in the reaction mixture was adjusted to 8.5–9.0 with DIEA. The reaction mixture was stirred at room temperature for ~6 h. After addition of 3 mL of 100 mM NH_4OAc buffer (pH = 7.0), the resulting solution was filtered, and the filtrate was subjected to HPLC purification (method 1). The fraction at ~15 min was collected. Lyophilization of the collected fractions afforded the expected product as a white power. The yield was 1.8 mg (48%). ESI-MS (positive mode) for DTPA-Bn-SU016: m/z = 1859.62 for $[M + H]^+$ (M = 1858.82 calcd for $C_{81}H_{116}N_{23}O_{26}S$).

DTPA-Bn-E-SU016. DTPA-Bn-SCN (2.7 mg, 4 μmol) and E-E[c(RGDfK)]$_2$ (3.0 mg, 2 μmol) were dissolved with anhydrous DMF (1 mL). The mixture was stirred at room temperature for 10 min. DIEA was added to adjust pH to ~8.0. The reaction mixture was stirred at room temperature for 6 h. After addition of 100 mM NH_4OAc buffer (3 mL, pH = 7.0), the resulting solution was subjected to semiprep HPLC purification (method 1). The fractions at ~17.5 min were collected. Lyophilization of collected fractions gave the desired product as a white powder. The yield was 1.5 mg (38%). ESI-MS (positive mode) for DTPA-Bn-E-SU016: m/z = 1989.68 for $[M + H]^+$ (M = 1988.87 calcd for $C_{86}H_{124}N_{24}O_{29}S$).

BOC-Protected Cysteic acid (Boc-Cys-OH). To a solution of cysteic acid hydrate (0.56 g, 3 mmol) and triethylamine (0.61 g, 6 mmol) in anhydrous DMF (10 mL) was added a solution of di-*tert*-butyl dicarbonate (0.78 g, 3.6 mmol) in 5 mL of DMF. The mixture was stirred at room temperature for 48 h. Evaporation of the solvent under vacuum gave a colorless oil. The residue was dissolved in methylene chloride (10 mL). Upon addition of diethyl ether (30 mL) with vigorous stirring, a white precipitate was formed. Solvents were decanted and discarded. The solid residue was washed with anhydrous diethyl ether (10 mL) and dried under vacuum to give a foamlike white solid. The yield was 0.89 g (80%). ^{1}H NMR (δ in ppm, $CDCl_3$): 6.60 (d, NH, J = 5.4 Hz), 3.78 (m, 1H, CH), 2.45 (m, 2H, CH_2), 1.15 (s, 9H, t-Bu).

BOC-Protected Cysteic Acid Succinimidyl Ester (Boc-Cys-OSu). To a solution of Boc-Cys-OH (as its triethylamine salt) (0.89 g, 2.4 mmol) and NHS (0.345 g, 3 mmol) in anhydrous DMF (20 mL) was added DCC (0.618 g, 3 mmol). The resulting mixture was stirred at room temperature for 24 h. Acetic acid (1.0 mL) was added into the mixture above, and the stirring was continued for 3 h. The precipitate DCU was filtered off. The filtrate was evaporated to dryness. The residue was dissolved in methylene chloride (15 mL). Upon removal of a small amount of DCU precipitate, the expected product was precipitated out by adding the filtrate into anhydrous diethyl ether (30 mL). The solid was washed with diethyl ether (20 mL) and dried under vacuum to give a white solid. The yield was 1.20 g (100%). ^{1}H NMR (δ in ppm, $CDCl_3$): 6.46 (s, 1H, NH), 4.88 (m, 1H, CH), 3.40 (m, 2H, CH_2), 2.80 (s, 4H, CH_2CH_2), 1.42 (s, 9H, t-Bu).

Boc-Cys-SU016. To a solution of Boc-Cys-OSu (7.2 mg, 0.015 mmol) in DMF (1 mL) was added SU016 (13.2 mg, 0.01 mmol). DIEA was added to adjust pH in the reaction mixture to 8.5–9.0. The resulting mixture was stirred at room temperature for 30 min, and the pH was adjusted to ~8.5, if necessary. The reaction was stirred at room temperature overnight. The desired product was isolated from the reaction mixture by HPLC purification (method 1). The collected fractions at ~15 min were combined. Lyophilization of the combined fractions afforded the expected product as a white powder. The yield was 6.4 mg (41%). ESI-MS (positive mode) for Boc-Cys-SU016: m/z = 1570.75 for $[M + H]^+$ (M = 1569.71 calcd for $C_{67}H_{101}N_{20}O_{22}S$).

Cys-SU016. Boc-Cys-SU016 (5 mg, 0.003 mmol) was treated with 2 mL of anhydrous trifluoroacetate (TFA) at room temperature for 30 min. Volatiles were completely removed under vacuum. The residue was dissolved in 100 mM NH_4OAc buffer (3 mL). The resulting solution was filtered, and the filtrate was purified by HPLC (method 1). The fractions at ~15.5 min were collected. Lyophilization of collected fractions gave the desired product as a white powder (3.5 mg). ESI-MS (positive mode) for Cys-SU016: m/z = 1469.57 for $[M + H]^+$ (M = 1468.65 calcd for $C_{62}H_{92}N_{20}O_{20}S$).

DTPA-Bn-Cys-SU016. DTPA-Bn-SCN (2.7 mg, 4 μmol) and Cys-SU016 (3.0 mg, 2 μmol) were dissolved in anhydrous DMF (1 mL). The mixture was stirred at room temperature for 10 min. DIEA was used to adjust pH in the mixture to 8.5–9.0. The reaction mixture was stirred at room temperature for another 6 h while maintaining pH at 8.5–9.0. Upon addition of 100 mM NH_4OAc (3 mL, pH = 7.0), the resulting solution was filtered. The filtrate was subjected to HPLC purification (method 1). The fractions at ~15.5 min were collected. Lyophilization of collected fractions gave the desired product as a white powder. The yield was 1.5 mg (35%). ESI-MS (positive mode) for DTPA-Bn-Cys-SU016: m/z = 2012.08 for $[M + H]^+$ (M = 2010.81 calcd for $C_{84}H_{122}N_{24}O_{30}S_2$).

^{111}In-Labeling and Solution Stability. To a clean Eppendorf tube were added 200 μL of DTPA-Bn-SU016 or DTPA-Bn-E-SU016 or DTPA-Bn-Cys-SU016 solution (0.2–0.5 mg/mL in 0.2 M NaOAc buffer, pH = 5.5), and 15 μL of $^{111}InCl_3$ solution (1–5 mCi, in 0.05 M HCl). The reaction mixture was kept at room temperature for 20 min. A sample of the resulting solution was analyzed by radio-HPLC and ITLC. The solution stability of all three radiotracers was determined in saline and 6 mM EDTA solution (pH = 5.0). Samples were analyzed by radio-HPLC at 2, 8, 12, and 24 h after Sep-Pak C-18 purification.

Doses Preparation. All ^{111}In radiotracers for animal studies were purified with a Sep-Pak C-18 cartridge. To chelate free ^{111}In, 30 μL of EDTA (6 mM, pH = 5.5) was added to the reaction mixture 5 min before purification. The cartridge was activated with ethanol (10 mL), followed by H_2O (10 mL). After the radiotracer was loaded, the cartridge was washed with saline (10 mL). The radiotracer was eluted with 80% ethanol (0.4 mL). Volatiles were completely removed under vacuum. Doses for animal studies were made by dissolving the purified radiotracer in saline to 80 μCi/mL for biodistribution studies and 2.0 mCi/mL for metabolism or imaging studies. For the blocking experiment, E[c(RGDfK)]$_2$ was used as the blocking agent. Doses were prepared by dissolving E[c(RGDfK)]$_2$ in saline to give a final concentration of 3.0 mg/mL. Each tumor-bearing mouse was injected with 0.1 mL of solution (~15 mg/kg).

Water−Octanol Partition Coefficient. All three ^{111}In radiotracers were purified with a Sep-Pak C-18 cartridge to avoid interference from radioimpurities. The purified radiotracer was dissolved in an equal volume mixture of 25 mM phosphate buffer (3 mL, pH = 7.4) and *n*-octanol (3 mL). After stirring for ~20 min at room temperature, the mixture was centrifuged at a speed of 8000 rpm for 5 min. Samples (in triplicate) from aqueous and *n*-octanol layers were counted in a γ-counter (Wallac 1470–002, Perkin-Elmer, Finland). Partition coefficients were calculated. The log P value was measured three times and reported as an average of three independent measurements plus the standard deviation.

Integrin $\alpha_v\beta_3$ Receptor Binding Assay. The in vitro integrin-binding affinities and specificities of cyclic RGD peptides were determined in a whole-cell displacement assay using ^{125}I-c(RGDyK) as the integrin-specific radioligand. ^{125}I-c(RGDyK) was prepared in high specific activity (~1200 Ci/mmol) according to the literature method (*55*). The receptor binding experiments were performed using U87MG human glioma cells. In short, the U87MG glioma cells were seeded in 24-well plates (2×10^5 cells/well) and incubated overnight at 37 °C and 5% CO_2 in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal bovine serum (FBS) to allow adherence. During the cell-binding experiments, the plates were rinsed twice with binding buffer (20 mM Tris, pH 7.4, 150 mM NaCl, 2 mM $CaCl_2$, 1 mM $MgCl_2$, 1 mM $MnCl_2$, 0.1% BSA). The glioma cells were incubated with ^{125}I-c(RGDyK) in the presence of a cyclic RGD peptide (0–1000 nM). The total incubation volume was then adjusted to 300 μL. After the glioma cells were incubated at 4 °C for 2 h, the supernatant was removed. The glioma cells were washed three times with cold binding buffer, were then dissolved with 2 M NaOH at 37 °C. The cell-associated radioactivity was collected and determined using a γ-counter (Wallac 1470–002, Perkin-Elmer, Finland). The same experiments were carried out twice with quadruple samples for each. The IC_{50} values were calculated by fitting the data by nonlinear regression using *GraphPad Prism 4.0*, San Diego, CA). The IC_{50} values are reported as an average of samples plus the standard deviation.

Animal Model. The human U87MG human glioma cells from Professor Jingde Zhu (Shanghai Cancer Research Institute) were maintained at 37 °C and 5% CO_2 in Dulbecco's modified

Eagle's medium (DMEM) containing 10% fetal bovine serum (FBS). Female BALB/c nude mice (4–5 weeks of age) were purchased from Department of Animal Experiment, Peking University Health Center. The U87MG cells (5×10^6) were implanted subcutaneously into the right upper flanks of mice. When tumors reached ~0.8 cm in mean diameter, the tumor-bearing mice were used to biodistribution and imaging studies.

Biodistribution. Biodistribution studies were performed by Dr. Wang's group in accordance with guidelines of Peking University Health Science Center Animal Care Committee. Sixteen tumor-bearing mice were randomly divided into four groups. Each animal was administered intravenously with ~8 μCi of ^{111}In radiotracer via tail-vein. Four animals were anesthetized with intraperitoneal injection of sodium pentobarbital (45.0 mg/kg), and sacrificed by cervical dislocation at 0.5, 1, 4, and 24 h p.i. Blood, heart, liver, spleen, kidney, stomach, intestine, muscle, bone, and tumor were harvested, weighed, and measured for radioactivity in a γ-counter (Wallac 1470–002, Perkin-Elmer, Finland). Organ uptake was calculated as a percentage of injected dose per gram of tissue (%ID/g). In the blocking experiment, each animal was administered with excess E[c(RGDfK)]$_2$ 30 min prior to injection of ^{111}In-DTPA-Bn-E-SU016. Four animals were sacrificed at 4 h p.i. for biodistribution using the same procedure.

Gamma Imaging. The imaging study was performed by administering with 200 μCi of ^{111}In-DTPA-Bz-E-SU016 in 0.1 mL saline into each animal via tail vein. Animals were anesthetized with intraperitoneal injection of sodium pentobarbital at a dose of 45.0 mg/kg, then were placed supine on a two-head γ-camera (SIEMENS, E. CAM) equipped with a parallel-hole, middle-energy, and high-resolution collimator. Anterior images were acquired at 4 and 24 h p.i. and stored digitally in a 128 × 128 matrix. The acquisition count limits were set at 200 K. After completion of imaging, animals were sacrificed by cervical dislocation.

Metabolism. The metabolic stability of all three ^{111}In radiotracers was evaluated in normal BALB/c mice. Each mouse was administered with 200 μCi of the radiotracer in 0.1 mL saline via intravenous injection. Urine samples were collected at 1 h postinjection, and were mixed with 100 μL of 6 mM EDTA (pH = 5.0). The mixtures were centrifuged at a speed of 1500 rpm for 15 min. The supernatants were collected and filtered through a 0.22 μm Millex-LG syringe-driven filter unit. The filtrates were analyzed by radio-HPLC (method 2).

Statistical Analysis. Biodistribution data and target-to-background ratios are reported as an average plus the standard variation. Comparison between two different radiotracers was also made using the two-way ANOVA test (*GraphPad Prism 4.0*, GraphPad Software, San Diego, CA). The level of significance was set at $p < 0.05$.

RESULTS

DTPA Conjugates. DTPA-Bn-SU016 was prepared by reacting E[c(RGDfK)]$_2$ with excess *p*-SCN-Bn-DTPA in DMF under slightly basic conditions (pH = 8.0–9.0). The same procedure was used for preparation of DTPA-Bn-E-SU016 and DTPA-Bn-Cys-SU016. All three conjugates were purified by HPLC with the purity >98% before being used for radiolabeling and animal studies. The ESI-MS data were completely consistent with the proposed formula for DTPA-Bn-SU016, DTPA-Bn-E-SU016, and DTPA-Bn-Cys-SU016.

Integrin $\alpha_v\beta_3$ Binding Affinity. The integrin $\alpha_v\beta_3$ binding affinities of DTPA-Bn-SU016, DTPA-Bn-E-SU016, and DTPA-Bn-Cys-SU016 were determined using the integrin $\alpha_v\beta_3$-positive U87MG human glioma cells. For comparison purposes, c(RGDyK) and SU016 were also evaluated in the same assay. Figure 2 shows the displacement curves of c(RGDyK), SU016, DTPA-Bn-SU016, DTPA-Bn-E-SU016, and DTPA-Bn-Cys-SU016 against the binding of ^{125}I-c(RGDyK) to integrin $\alpha_v\beta_3$ on U87MG glioma cells. The IC_{50} values were calculated to be 31.9 ± 4.0 nM for c(RGDyK, 5.0 ± 0.7 nM for SU016, 7.9 ± 0.6 nM for DTPA-Bn-SU016, 5.8 ± 0.6 nM for DTPA-Bn-E-SU016, and 6.9 ± 0.9 nM for DTPA-Bn-Cys-SU016.

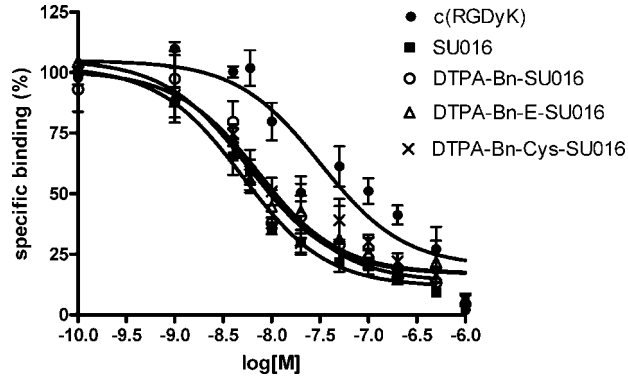

Figure 2. Inhibition of ^{125}I-c(RGDyK) binding to $\alpha_v\beta_3$ integrin on U87MG human glioma cells by c(RGDyK) (●), SU016 (■), DTPA-Bn-SU016 (○), DTPA-Bn-E-SU016 (Δ), and DTPA-Bn-Cys-SU016 (×). IC_{50} values were calculated to be 31.9 ± 4.0 nM for c(RGDyK), 5.0 ± 0.7 nM for SU016, 7.9 ± 0.6 nM for DTPA-Bn-SU016, 5.8 ± 0.6 nM for DTPA-Bn-E-SU016, and 6.9 ± 0.9 nM for DTPA-Bn-Cys-SU016, respectively.

Radiochemistry. ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 were prepared by reacting $^{111}InCl_3$ with the DTPA conjugate in NH_4OAc buffer (200 mM, pH = 5.5). Radiolabeling was almost instantaneous at room temperature, particularly at higher concentrations of the DTPA conjugate. Their radiochemical purity (RCP) was >99% after Sep-Pak purification. The specific activity was in the range 100–150 mCi/μmol, which is consistent with that obtained for the ^{111}In-labeled DTPA conjugate of a cyclic RGDfK monomer (*40*). The specific activity obtained at room temperature for all three ^{111}In radiotracers in this study was 3–5 times better than that of the ^{111}In-labeled DOTA conjugates (~30 mCi/μmol obtained at 100 °C) (*33*). It should be noted that the radiolabeling conditions used in this study are not optimized. The specific activity of ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 could be further improved at elevated temperatures. All three ^{111}In radiotracers were analyzed using the same HPLC method (method 2). Their HPLC retention times were 18.2, 11.3, and 11.7 min, respectively. Their log *P* values were determined in an equal volume mixture of *n*-octanol and 25 mM phosphate buffer (pH = 7.4), and were calculated to be −2.7 ± 0.1 (n = 3), −3.4 ± 0.1 (n = 3), and −3.3 ± 0.2 (n = 3), respectively. Both HPLC retention time and log *P* values suggest that incorporation of E and Cys amino acid linkers increases hydrophilicity of the ^{111}In-labeled cyclic RGDfK dimer.

Solution Stability. High solution stability is a requirement for both diagnostic and therapeutic radiotracers. In this study, we studied solution stability of ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 both in saline and in the presence of EDTA challenge. Figure 3 shows their solution stability data in saline (a) and 6 mM EDTA solution (b). It was clear that all three ^{111}In radiotracers remained stable for >24 h in saline and in aqueous solution of 6 mM EDTA.

Biodistribution Characteristics. Biodistribution properties of ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 were evaluated using the BALB/c nude mice bearing the U87MG human glioma xenografts. Selected biodistribution data are listed in Tables 1, 2, and 3. Figure 4

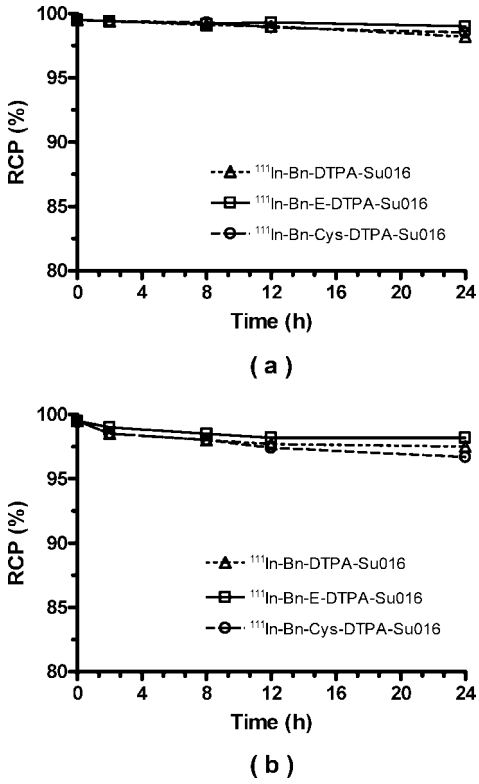

Figure 3. Solution stability data of ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 in saline (a) and 6 mM EDTA solution (b).

[a] The organ uptake is expressed %ID/g. Each data point represents an average of biodistribution data in four animals.

in their biodistribution and excretion characteristics is caused by the linker (E and Cys).

In general, all three ^{111}In radiotracers displayed a rapid blood clearance predominantly via the renal route. Their blood clearance curves were almost identical (Figure 4), and their bone uptake was relatively low (Tables 1,, and 3). The tumor uptake of ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 was comparable between 0.5 and 4 h p.i. within the experimental error. At 24 h p.i., however, ^{111}In-DTPA-Bn-SU016 had the tumor uptake (1.69 ± 0.18% ID/g) that was significantly higher ($p < 0.05$) than that of ^{111}In-DTPA-Bn-E-SU016 (0.89 ± 0.17% ID/g) and ^{111}In-DTPA-Bn-Cys-SU016 (0.98 ± 0.29% ID/g). The kidney uptake of ^{111}In-DTPA-Bn-E-SU016 was much lower ($p < 0.001$) than that of ^{111}In-DTPA-Bn-SU016 and ^{111}In-DTPA-Bn-Cys-SU016 over the 24 h study period. The liver uptake of ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 was comparable between 0.5 and 1 h p.i. (Figure 4), but it was significantly higher ($p < 0.001$) for ^{111}In-DTPA-Bn-SU016 than that for ^{111}In-DTPA-Bn-E-SU016 and ^{111}In-DTPA-Bn-Cys-SU016 at 24 h p.i. For example, the liver uptake of ^{111}In-DTPA-Bn-SU016 was 1.69 ± 0.18% ID/g at 24 h p.i., and the liver uptake of ^{111}In-DTPA-Bn-E-SU016 and ^{111}In-DTPA-Bn-Cys-SU016 was only 0.55 ± 0.11% ID/g and 0.79 ± 0.15% ID/g at 24 h p.i., respectively. Among the three ^{111}In radiotracers evaluated in this animal model, ^{111}In-DTPA-Bn-E-SU016 has the lowest uptake in liver and kidneys, and the best tumor/liver and tumor/kidney ratios (Figure 4) at 24 h p.i.

The blocking experiment was used to demonstrate tumor specificity of the radiotracer. In this experiment, E[c(RGDfK)]$_2$ (15 mg/kg or ~300 μg/mouse) was used as the blocking agent. Such a high dose was used to make sure that the integrin $\alpha_v\beta_3$ is almost completely blocked. Figure 5 illustrates biodistribution data of ^{111}In-DTPA-Bn-E-SU016 at 4 h p.i. in the presence of E[c(RGDfK)]$_2$. Apparently, pre-injection of excess E[c(RGDfK)]$_2$ significantly reduced the tumor uptake of ^{111}In-DTPA-Bn-E-SU016, suggesting that its tumor uptake is indeed integrin $\alpha_v\beta_3$-mediated. However, its uptake in liver, spleen, stomach, gut, and kidneys was also reduced significantly, most likely due to the blockage of integrin $\alpha_v\beta_3$ in these organs.

Metabolism. Metabolism studies on ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 were performed using normal BALB/c nude mice. Urine samples were analyzed to determine whether they are able to retain their chemical integrity at 1 h p.i. We also tried to analyze feces samples at 1 h p.i., but the radioactivity level was too low to be detected. Figure 6 shows HPLC chromatograms of ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 in the urine at 1 h p.i. It is quite clear that there is little metabolite (<10%) in urine during the 1 h study period.

Imaging Study. A planar image study was performed on ^{111}In-DTPA-Bn-E-SU016 using the BALB/c nude mice bearing

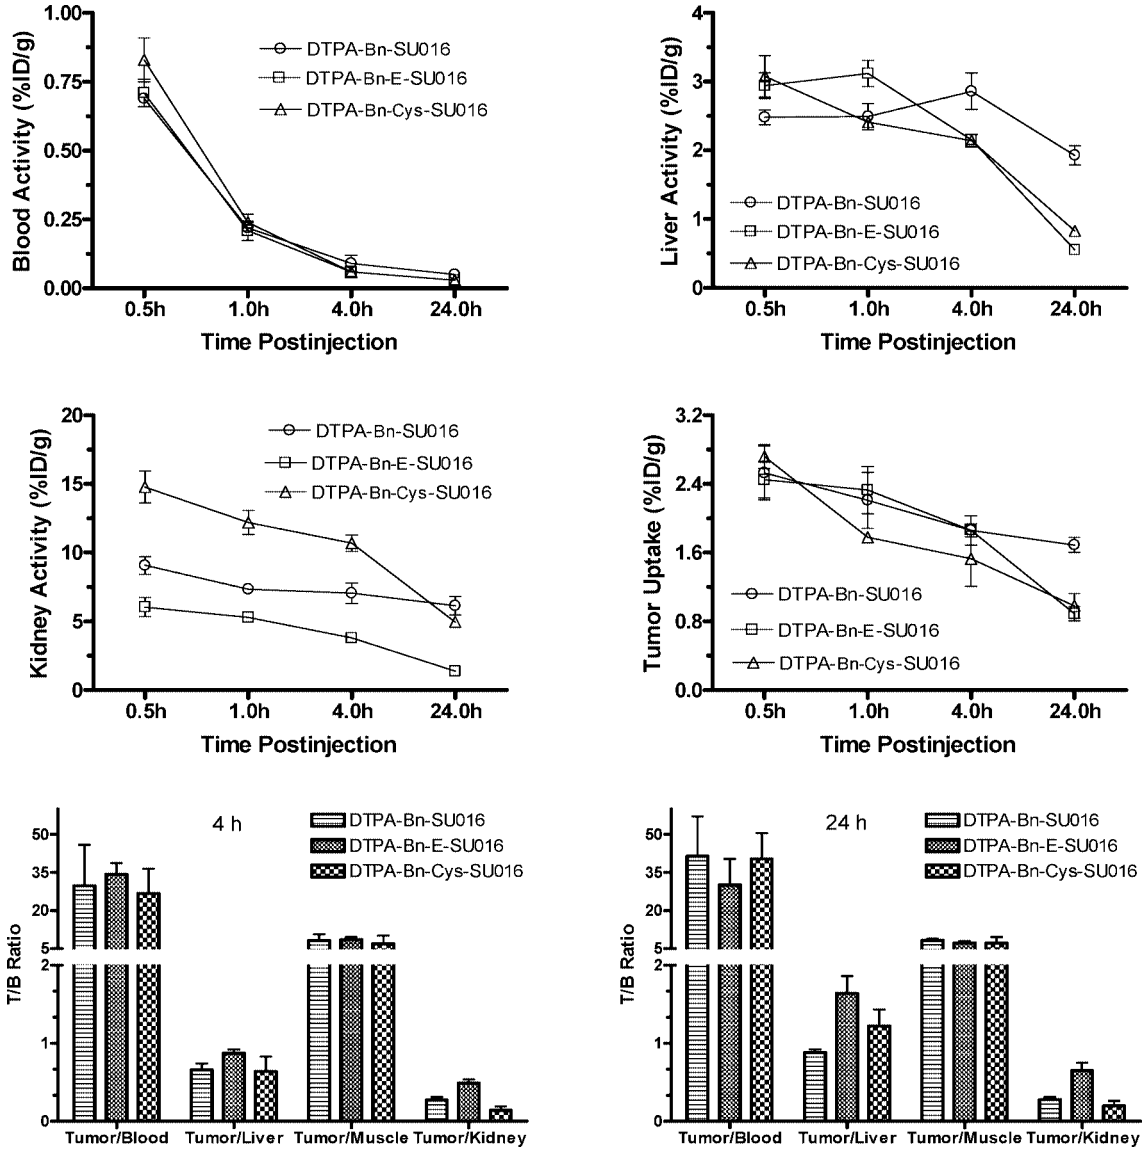

Figure 4. Direct comparison of the excretion kinetics and tumor-to-background ratios between ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 in selected organs of the BALB/c nude mice bearing the U87MG human glioma xenografts.

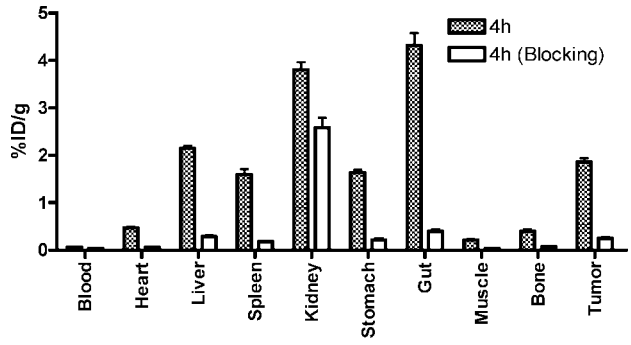

Figure 5. Biodistribution data of ^{111}In-DTPA-Bn-E-SU016 at 4 h p.i. with/without the presence of excess E[c(EGDfK)]$_2$ in BALB/c nude mice bearing the U87MG human glioma xenografts.

U87MG human glioma xenografts. Figure 7 illustrates representative scintigraphic images of the tumor-bearing mouse administered with ~200 μCi ^{111}In-DTPA-Bn-E-SU016 at 4 and 24 h p.i. The tumor was visualized as early as 1 h p.i. (data not shown). The tumor/muscle ratio was 5.6 ± 1.2 (n = 3) at 4 h p.i. and 6.1 ± 1.1 (n = 3) at 24 h p.i., which were in good agreement with that obtained from direct tissue sampling (Tables 1 and 3). Because of high kidney and liver activity, the tumor/kidney and tumor/liver ratios were relatively low (0.4 ± 0.1 and 1.0 ± 0.1 at 4 h, 1.9 ± 0.4 and 2.3 ± 0.3 at 24 h, respectively).

DISCUSSION

Many factors may influence the tumor uptake and tumor retention of a radiotracer (*13–15*). These include binding affinity, receptor population, protein binding, and pharmacokinetics. The fact that [^{18}F]Galacto-RGD has been successfully used as the first PET radiotracer for noninvasive visualization of integrin $\alpha_v\beta_3$ in cancer patients strongly suggests that there is sufficient integrin $\alpha_v\beta_3$ expressed in tumor for PET or SPECT imaging. While the radiolabeled cyclic RGD peptide monomers, such as c(RGDfK), are useful for imaging the integrin $\alpha_v\beta_3$ expression in tumors, they will have limited clinical utility in visualizing tumors in the lower abdomenal region due to their relatively low tumor uptake and partial hepatobiliary excretion. Therefore, there is a continuing need to further improve the tumor targeting capability and excretion kinetics of radiotracers.

To improve integrin $\alpha_v\beta_3$ binding affinity, the multivalent concept has been successfully used to prepare multimeric cyclic RGD peptides, such as E[c(RGDfK)]$_2$ and E{E[c(RGDfK)]$_2$}$_2$,

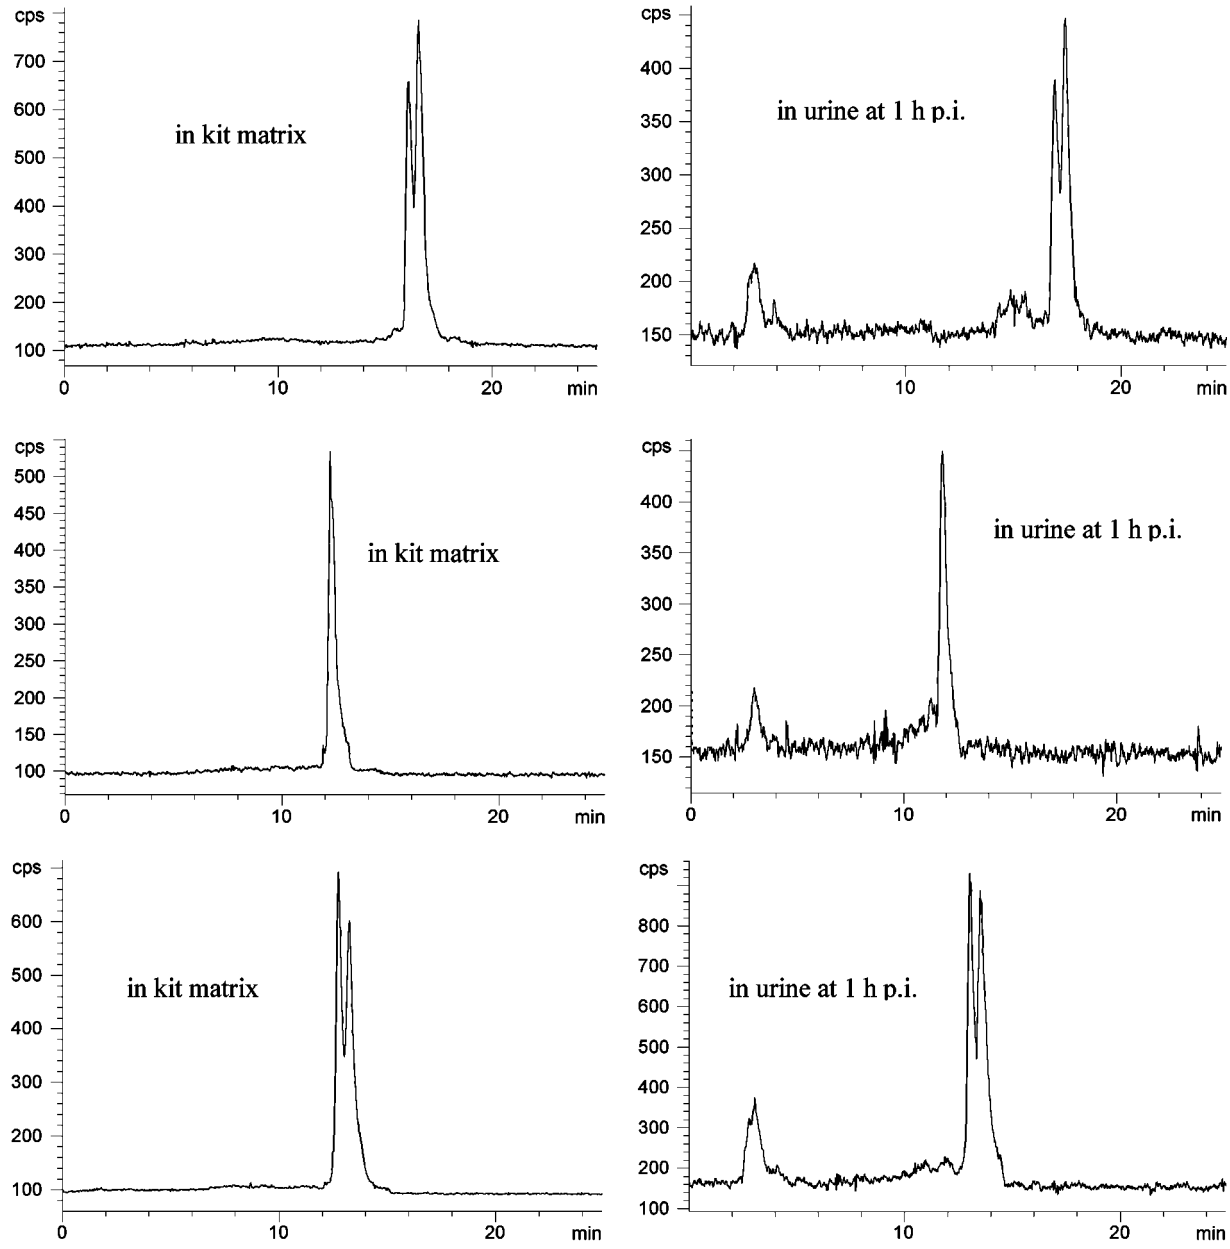

Figure 6. Radio-HPLC chromatograms of ^{111}In-DTPA-Bn-SU016 (top), ^{111}In-DTPA-Bn-E-SU016 (middle), and ^{111}In-DTPA-Bn-Cys-SU016 (bottom) in the kit matrix and urine at 1 h p.i. Each normal BALB/c mouse was administered with 200 μCi of radiotracer. Two mice were used for each radiotracer.

for development of the integrin $\alpha_v\beta_3$-targeted diagnostic (^{64}Cu, ^{99m}Tc, and ^{111}In) and therapeutic (^{90}Y and ^{177}Lu) radiotracers (*19–36*). Different PKM linkers have been used to improve excretion kinetics of the radiolabeled peptides. For example, a sugar moiety was used to increase T/B ratios of ^{125}I- and ^{18}F-labeled cyclic RGD peptides (*47–50*). The sugar moiety has also been used to improve tumor uptake and TB ratios of the ^{111}In-labeled DOTA-somatostatin peptide conjugates (*51*). Small peptides, such as di(cysteic acid), have been used to improve blood clearance and to minimize liver accumulation of radiolabeled peptides and nonpeptide integrin $\alpha_v\beta_3$ antagonists (*38, 52–54*). It has been reported that introduction of the poly(ethylene glycol) (PEG) linker can improve not only tumor uptake but also excretion kinetics of ^{125}I- and ^{18}F-labeled c(RGDyK) and ^{64}Cu-labeled E[c(RGDyK)]$_2$ (*55, 56*). PEG$_4$ and amino acid linkers, such as E and K, have also been used to improve excretion kinetics of ^{111}In- and ^{99m}Tc-labeled E[c(RGDfK)]$_2$ (*23, 33*). PKM linkers and their applications to improve excretion kinetics of radiolabeled small biomolecules have been reviewed recently (*15, 16, 37*).

In this study, we prepare ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 with high specific activity (100–150 mCi/μmol). We are particularly interested in DTPA as the BFC because of its high ^{111}In-labeling efficiency. The specific activity obtained for these three ^{111}In radiotracers was 3–5× better than that of the ^{111}In-labeled DOTA-PKM-E[c(RGDfK)]$_2$ (PKM = E, K, and PEG$_4$) conjugates (*33*). We also examined the effect of E and Cys linkers on integrin $\alpha_v\beta_3$ binding affinity of the cyclic RGDfK dimer DTPA conjugate, and found that the integrin $\alpha_v\beta_3$ binding affinity of DTPA-Bn-SU016, DTPA-Bn-E-SU016, and DTPA-Bn-Cys-SU016 was almost identical (Figure 2). This suggests that introduction of the E and Cys linker does not affect the integrin $\alpha_v\beta_3$ binding affinity of E[c(RGDfK)]$_2$. A similar conclusion has been made for the HYNIC and DOTA conjugates of E[c(RGDfK)]$_2$ (*23*).

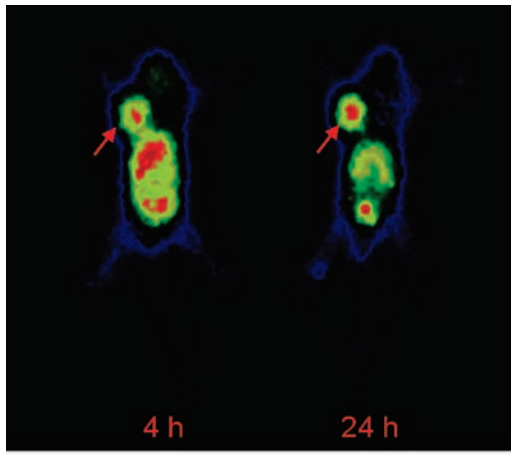

Figure 7. A representative scintigraphic image of the tumor-bearing mouse administered with ~200 μCi of ^{111}In-DTPA-Bn-E-SU016. The arrow indicates presence of tumor.

The main difference among ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 is the linker group. Data from both HPLC and log *P* suggest that the use of E and Cys linker groups increases hydrophilicity of the ^{111}In radiotracer. The tumor-targeting capability of ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 has been evaluated by direct tissue sampling and gamma imaging in BALB/c nude mice bearing U87MG human glioma xenografts. Results from biodistribution studies show that there is no significant difference in their tumor uptake during the first 4 h p.i. (Figure 4), suggesting that E and Cys linkers have little impact on targeting capability of the ^{111}In-labeled E[c(RGDfK)]$_2$. This conclusion is supported by similar integrin $\alpha_v\beta_3$ binding affinity of SU016, DTPA-Bn-SU016, DTPA-Bn-E-SU016, and DTPA-Bn-Cys-SU016 (Figure 2). The blood clearance patterns of ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 are almost identical over the 24 h study period, indicating that introduction of E and Cys linkers did not significantly affect their protein binding. In addition, ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 are also able to retain their chemical integrity with <10% metabolism detected in the urine samples at 1 h p.i. The fact that very little radioactivity was detected in feces samples from the mice administered with ^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016 suggests that they are excreted mainly via the renal route.

Despite their similarities, E and Cys linkers have a significant impact on organ uptake and excretion kinetics of the ^{111}In-labeled cyclic RGDfK dimer. For example, the kidney uptake follows the order of ^{111}In-DTPA-Bn-E-SU016 < ^{111}In-DTPA-Bn-SU016 < ^{111}In-DTPA-Bn-Cys-SU016 (Figure 4). The tumor/kidney ratios of ^{111}In-DTPA-Bn-E-SU016 and ^{111}In-DTPA-Bn-Cys-SU016 are significantly lower ($p < 0.05$) than that of ^{111}In-DTPA-Bn-SU016 at 24 h p.i. In general, small biomolecules in the blood plasma are filtered through glomerular capillaries in kidneys and may be subsequently reabsorbed by the proximal tubular cells (*33*). Membranes of renal tubular cells contain negatively charged sites to which the positively charged groups (such as guanidine in the RGD sequence) are expected to bind. The carboxylic group of the glutamic acid residue is deprotonated under physiological conditions. Therefore, it is not surprising that the use of E linker in ^{111}In-DTPA-Bn-E-SU016 results in the reduced kidney uptake (Figure 4). However, it is not clear why ^{111}In-DTPA-Bn-Cys-SU016 has higher kidney uptake than ^{111}In-DTPA-Bn-E-SU016 even though their log *P* values and HPLC retention times (Figure 6) are very similar.

Another significant difference is the liver uptake. Both ^{111}In-DTPA-Bn-E-SU016 and ^{111}In-DTPA-Bn-Cys-SU016 have lower liver uptake and better tumor/liver ratios ($p < 0.05$) than ^{111}In-DTPA-Bn-SU016 at 24 h p.i. These data strongly suggest that the liver uptake could be reduced by introducing the negatively charged amino acid residues due to increased hydrophilicity of the radiotracer. A similar conclusion has been made for the ^{99m}Tc-labeled HYNIC-PKM-SU016 (PKM = E, K, or PEG$_4$) conjugates (*23*). However, this conclusion seems to contradict to that made by Dijkgraaf and co-workers (*33*) for the ^{111}In-labeled DOTA-PKM-E[c(RGDfK)]$_2$ (PKM = E, K, and PEG$_4$) conjugates. Apparently, the impact of PKM linkers on both liver uptake and liver clearance kinetics of the radiotracer may vary with the change of bifunctional chelator and its radiometal chelate.

CONCLUSION

In this study, we evaluated the integrin $\alpha_v\beta_3$ binding affinities of SU016, DTPA-Bn-SU016, DTPA-Bn-E-SU016, and DTPA-Bn-Cys-SU016. It was found that introduction of the glutamic acid and cysteic acid linkers did not affect the integrin $\alpha_v\beta_3$ binding affinity of the cyclic RGDfK dimer DTPA conjugate. Another important finding of this study is that the ^{111}In-labeling efficiency of all three DTPA conjugates (DTPA-Bn-SU016, DTPA-Bn-E-SU016, and DTPA-Bn-Cys-SU016) is significantly better than that of DOTA analogues. In this regard, DTPA has the advantage over DOTA due to its fast chelation kinetics and high-yield ^{111}In-labeling under mild conditions (e.g., room temperature). All three radiotracers (^{111}In-DTPA-Bn-SU016, ^{111}In-DTPA-Bn-E-SU016, and ^{111}In-DTPA-Bn-Cys-SU016) have high in vitro and in vivo solution stability. Results from biodistribution studies show that incorporation of the glutamic acid linker between DTPA and E[c(RGDfK)]$_2$ increases the clearance of ^{111}In-labeled E[c(RGDfK)]$_2$ from the liver and kidneys. Among the three radiotracers evaluated in this study, ^{111}In-DTPA-Bn-E-SU016 has the best tumor/liver and tumor/kidney ratios.

ACKNOWLEDGMENT

Authors would thank Professor Jingde Zhu, Shanghai Cancer Research Institute, for providing the U87MG human glioma cells. This work is supported, in part, by Peking University Health Science Center (F.W.) and research grants: 30640067 (F.W.) from NSF (China), 1R01 CA115883-01A2 (S.L.) from National Cancer Institute (NCI), BCTR0503947 (S.L.) from Susan G. Komen Breast Cancer Foundation, AHA0555659Z (S.L.) from the Greater Midwest Affiliate of American Heart Association, R21 EB003419-02 (S.L.) from National Institute of Biomedical Imaging and Bioengineering (NIBIB) and R21 HL083961-01 (S.L.) from National Heart, Lung, and Blood Institute (NHLBI).

Modification of DNA with Octadiynyl Side Chains: Synthesis, Base Pairing, and Formation of Fluorescent Coumarin Dye Conjugates of Four Nucleobases by the Alkyne−Azide "Click" Reaction

Frank Seela,* Venkata Ramana Sirivolu, and Padmaja Chittepu

Laboratory for Bioorganic Chemistry and Chemical Biology, Center for Nanotechnology, Heisenbergstrasse 11, 48149 Münster, Germany, and Laboratorium für Organische and Bioorganische Chemie, Institut für Chemie, Universität Osnabrück, Barbarastrasse 7, 49069 Osnabrück, Germany. Received August 9, 2007; Revised Manuscript Received October 1, 2007

Oligonucleotides incorporating 5-(octa-1,7-diynyl)-2′-deoxycytidine **1a**, 5-(octa-1,7-diynyl)-2′-deoxyuridine **2a** and 7-deaza-7-(octa-1,7-diynyl)-2′-deoxyguanosine **3a**, 7-deaza-7-(octa-1,7-diynyl)-2′-deoxyadenosine **4a** were prepared. For this, the phosphoramidites **7**, **10**, and **13** were synthesized and employed in solid-phase oligonucleotide synthesis. The octa-1,7-diynyl nucleosides **1a**−**4a** were obtained from their corresponding iodo derivatives using the palladium-assisted Sonogashira cross-coupling reaction. The T_m values demonstrated that DNA duplexes containing octa-1,7-diynyl nucleosides show a positive influence on the DNA duplex stability when they are introduced at the 5-position of pyrimidines or at the 7-position of 7-deazapurines. The terminal alkyne residue of oligonucleotides were selectively conjugated to the azide residue of the nonfluorescent 3-azido-7-hydroxycoumarin (**38**) using the protocol of copper(I)-catalyzed [3 + 2] Huisgen−Sharpless−Meldal cycloaddition "click chemistry" resulting in the formation of strongly fluorescent 1,2,3-triazole conjugates. The fluorescence properties of oligonucleotides with covalently linked coumarin−nucleobase assemblies were investigated. Among the four modified bases, the 7-deazapurines show stronger fluorescence quenching than that of pyrimidines.

INTRODUCTION

The chemical modification of DNA of defined sequence is an invaluable tool to study DNA structure and recognition. Modified DNAs find applications as therapeutic and diagnostic agents. Areas of antisense and antigene therapy (*1–3*) or DNA detection and sequencing (*4, 5*) are studied intensively; new fields such as DNA-based nanotechnology are emerging (*6–9*). The most common DNA modification sites are the sugar moieties, the phosphodiester backbone, and the nucleobases. Minimal changes of the DNA-duplex structure by nucleoside-shaped mimics (*10–13*) are the prerequisites for a modified DNA to behave as the parent molecule. However, in a number of cases, larger residues, e.g., dye reporters, have to be introduced that can alter the structure of DNA. The 5-position of the pyrimidine bases (*14–17*) and 7-position of 7-deazapurines (*18, 19*) are "ideal" sites for DNA modifications (purine numbering is used throughout the discussion). Such groups are well-accommodated in the DNA major groove of the B-DNA duplex not disturbing the DNA helical structure. The introduction of substituents of moderate size–7-substituents into 7-deazapurines or 5-substituents into pyrimidines–can even cause duplex stabilization when compared to the canonical DNA constituents. These residues strengthen the base pairs as was shown for halogeno or alkynyl groups (*20–25*). A series of such modified nucleosides containing propynyl groups (**1b**−**4b**) have been synthesized and incorporated into DNA (*26–32*).

Recently, the copper(I)-catalyzed Huisgen−Sharpless−Meldal alkyne−azide 1,3-dipolar cycloaddition reaction has gained significant importance because of its applications in organic synthesis, molecular biology, and materials science (*33, 34*). The high potential energy of the azide and alkyne components make this a thermodynamically favored reaction ($\Delta H^\circ = -45$ to -55 kcal/mol). Although both azides and alkynes are highly reactive, they are orthogonal to a broad range of reagents, solvents, and other functional groups. Copper(I) dramatically enhances the reaction rate of azides with terminal alkynes leading to the formation of stable regiospecific 1,4-disubstituted-[1,2,3]-triazoles. To apply this chemistry to the four building blocks of DNA, nucleosides bearing the octa-(1,7-diynyl) group at the 5-position of pyrimidine bases (**1a**, **2a**) or at the 7-position of 7-deazapurines (**3a**, **4a**) were synthesized (Scheme 1).

In a recent Communication, we reported on the synthesis and properties of 5-(octa-1,7-diynyl)-2′-deoxyuridines and performed the "click" reaction with AZT or aromatic azides (*35*); we outlined the principle for dG, dC, and dT modification (*36*). Now, we present the syntheses of the three building blocks related to dC, dG, and dA in order to complete a set of canonical DNA building blocks bearing octadiynyl side chains and report on their duplex stability. They all contain the same Watson–Crick recognition sites as those of canonical DNA. For dye labeling, we introduce a nonfluorescent coumarin reporter molecule for the above-mentioned octadiynyl derivatives, which becomes fluorescent after the "click" reaction (Scheme 2). These reporter groups occupy well-defined positions within the DNA helix, without disturbing the native DNA structure (*35–38*). On the basis of this principle of the 1,3-dipolar cycloaddition, we performed the "click" reaction on oligonucleotides containing nucleoside residues bearing side chains with terminal triple bonds (**1a**−**4a**) with the nonfluorescent coumarin azide **38** to generate strongly fluorescent 1,2,3-triazole coumarin conjugates. The dye conjugates containing the 7-deazapurines show a strong photoinduced intramolecular electron transfer between the coumarin dye and the 7-deazapurine system, which is almost negligible in the case of pyrimidines. A general outcome of the work is the design of the four DNA building blocks **1a**−**4a** showing the same recognition pattern as the canonical DNA constituents; they can be labeled with almost any reporter group

or an otherwise active moiety leading to the structurally "undisturbed" DNA duplexes.

EXPERIMENTAL SECTION

General. All chemicals were purchased from Acros, Sigma-Aldrich (Sigma-Aldrich Chemie GmbH, Deisenhofen, Germany). Solvents were of technical grade and freshly distilled before use. Thin layer chromatography (TLC): aluminum sheets, silica gel 60 F_{254}, 0.2 mm layer (VWR, Germany). Column flash chromatography (FC): silica gel 60 (VWR, Germany) at 0.4 bar; sample collection with an UltroRac-II fraction collector (LKB Instruments, Sweden). UV spectra: U-3200 spectrometer (Hitachi, Tokyo, Japan); λ_{max} (ϵ) in nm. NMR spectra: Avance-DPX-250 or AMX-500 spectrometers (Bruker, Karlsruhe, Germany) at 250.13 MHz for ^{1}H and ^{13}C; chemical shifts (δ) are in ppm relative to Me_4Si as internal standard or external 85% H_3PO_4 for ^{31}P; *J* values in Hz. Elemental analyses were performed by Mikroanalytisches Laboratorium Beller (Göttingen, Germany). Electron spray ionization (ESI) MS for the nucleosides: Bruker-Daltonics-MicroTOF spectrometer with loop injection (Bremen, Germany). The molecular masses of the oligonucleotides were determined by MALDI-TOF-MS with a Biflex-III mass spectrometer (Bruker Saxonia, Leipzig, Germany) and Applied Biosystems Voyager DE PRO with 3-hydroxypicolinic acid (3-HPA) as a matrix. The detected masses were identical to the calculated values. The fluorescence measurements were performed in bidistilled water at 20 °C. Fluorescence spectra were recorded in the wavelength range between 320 and 600 nm using the fluorescence spectrophotometer F-2500 (Hitachi, Tokyo, Japan).

Synthesis, Purification, and Characterization of the Oligonucleotides. The oligonucleotide synthesis was performed on a DNA synthesizer, model 392–08 (Applied Biosystems, Weiterstadt, Germany) at 1 μmol scale using the phosphoramidites **7**, **10**, and **13** following the synthesis protocol for 3′-(2-cyanoethyl phosphoramidites) (user's manual for the 392 DNA synthesizer, Applied Biosystems, Weiterstadt, Germany). The coupling efficiency was always higher than 95%. After cleavage from the solid support, the oligonucleotides were deprotected in 25% aqueous NH_3 solution for 14–16 h at 60 °C; during this process, the amine protecting groups of the nucleobases—adenine, cytosine with tBPA (4-tert-butylphenoxy)acetyl) protecting group, and guanine, **4a** with iB (isobutyryl)—were removed. The purification of 5′-dimethoxytrityl oligomers was carried out on reversed-phase HPLC (Merck-Hitachi-HPLC; RP-18 column; gradient system (A = 0.1 M (Et_3NH)OAc (pH 7.0)/MeCN 95:5, B = MeCN): 3 min 20% B in A, 12 min 20–50% B in A, and 25 min 20% B in A; flow rate 1.0 mL/min. The purified "trityl-on" oligonucleotides were treated with 2.5% $CHCl_2COOH/CH_2Cl_2$ for 5 min at 0 °C to remove the 4,4′-dimethoxytrityl residues. The detritylated oligomers were purified again by reversed-phase HPLC (gradient: 0–20 min 0–20% B in A; flow rate 1 mL/min). The oligomers were desalted on a short column (RP-18, silica gel) and lyophilized on a Speed-Vac evaporator to yield colorless solids which were frozen at −24 °C.

Melting curves were measured with a Cary-1/3 UV/vis spectrophotometer (Varian, Australia) equipped with a Cary thermoelectrical controller. The temperature was measured continuously in the reference cell with a Pt-100 resistor, and the thermodynamic data of duplex formation were calculated by the *Meltwin 3.0* program. The Cary 100 Bio UV–vis spectrophotometer was used for the UV-melting curves of oligonucleotides containing **4a** with a heating rate of 1 °C.

The enzymatic hydrolysis of the oligonucleotides containing **1a** and **3a** was performed as described (*9*) with snake venom phosphodiesterase (EC 3.1.15.1, *Crotallus adamanteus*) and alkaline phosphatase (EC 3.1.3.1, *Escherichia coli* from Roche Diagnostics GmbH, Germany) in 0.1 M Tris−HCl buffer (pH 8.3) at 37 °C, which was analyzed by reversed-phase HPLC (RP-18, at 260 nm) showing the peaks of the modified and unmodified nucleosides (Figure 1a,b). Quantification of the constituents was made on the basis of the peak areas, which were divided by the extinction coefficients ϵ_{260} of the nucleosides: dA 15 400 (H_2O), dC 7300 (H_2O), dG 11 700 (H_2O), dT 8800 (H_2O), **1a** 4900 (MeOH), **3a** 7300 (MeOH). For the fluorescence quenching experiments, the enzymatic hydrolysis was performed using 1.7 μM single-stranded oligonucleotide dissolved in 1 mL of 0.1 M Tris−HCl buffer (pH 8.3). To this solution, 3–10 μL of snake venom phosphodiesterase and 3–10

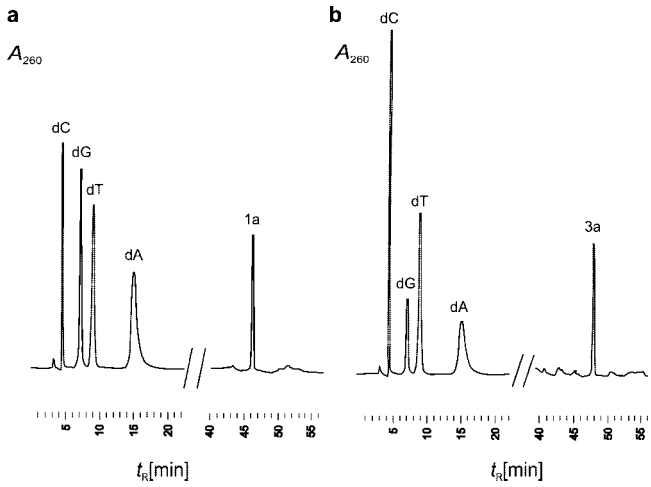

Figure 1. HPLC profiles of the enzymatic hydrolysis products (a) of the oligonucleotide 5′-d(TAG GT**1a** AAT ACT); (b) of oligonucleotide 5′-d(A**3a**T ATT GAC CTA) obtained by digestion with snake venom phosphodiesterase and alkaline phosphatase in 0.1 M Tris−HCl buffer (pH 8.3) at 37 °C. Gradient for (a) 25 min 100% A, 25–60 min 0–50% B in A; (b) 25 min 100% A, 25–60 min 0–60% B in A; flow rate 0.7 mL/min (A = 0.1 M (Et_3NH)OAc (pH 7.0)/MeCN 95:5, B = MeCN).

μL alkaline phosphatase were added and the fluorescence spectra measured at different time intervals with an emission 479 nm.

1-(2-Deoxy-β-D-*erythro*-pentofuranosyl)-5-(octa-1,7-diynyl)-cytosine (1a). To a suspension of 5-iodo-2′-deoxycytidine (0.6 g, 1.7 mmol) and CuI (65.5 mg, 0.34 mmol) in anhydrous DMF (9 mL) was added successively [$Pd(PPh_3)_4$] (196 mg, 0.17 mmol), anhydrous Et_3N (344 mg, 3.4 mmol), and octa-1,7-diyne (1.8 g, 17.0 mmol). The mixture was stirred at room temperature under argon atmosphere and allowed to proceed until the starting material was consumed (TLC monitoring). The reaction mixture was diluted with MeOH/CH_2Cl_2 1:1 (20 mL), and Dowex 1 × 8 (100–200 mesh; 0.6 g, hydrogen carbonate form) was introduced. After additional stirring for 1 h, the mixture was filtered and the resin washed with MeOH/CH_2Cl_2 1:1 (30 mL). The combined filtrate was concentrated and the residue purified by FC (silica gel, column 15 × 3 cm, CH_2Cl_2/MeOH 96:4): **1a** (0.42 g, 75%). Colorless amorphous solid. TLC (CH_2Cl_2/MeOH 9:1): R_f 0.40. UV λ_{max} (MeOH)/nm (ϵ/dm^3 mol^{-1} cm^{-1}) 236 (15900), 299 (7200). ^{1}H NMR ((D$_6$) DMSO): 1.54–1.62 (m, 4 H, 2CH_2), 2.0–2.15 (m, 3 H, H$_\alpha$-C(2′), CH_2), 2.22–2.44 (m, 3 H, H$_\beta$-C(2′), CH_2), 2.76 (s, 1 H, C≡CH), 3.54–3.62 (m, 2 H-C(5′)), 3.79 (m, H-C(4′)), 4.20 (m, H-C(3′)), 5.04 (t, J = 4.96, OH-C(5′)), 5.20 (d, J = 4.1, OH-C(3′)), 6.12 (t, J = 6.5, H-C(1′)), 6.71 (s, NH_a), 7.67 (s, NH_b), 8.07 (s, H-C(6)). Anal. Calcd for $C_{17}H_{21}N_3O_4$ (331.15): C 61.62, H 6.39, N 12.68. Found: C 61.44, H 6.77, N 12.45.

2-Amino-7-(2-deoxy-β-D-*erythro*-pentofuranosyl)-5-(octa-1,7-diynyl)-3,7-dihydro-4-*H*-pyrrolo[2,3-*d*]pyrimidin-4-one (3a). As described for **1a**, with 7-deaza-7-iodo-2′-deoxyguanosine (0.7 g, 1.78 mmol) and CuI (68 mg, 0.36 mmol) in anhydrous DMF (10 mL) were added successively [$Pd(PPh_3)_4$] (208 mg, 0.18 mmol), anhydrous Et_3N (360 mg, 3.56 mmol), and octa-1,7-diyne (1.89 g, 17.8 mmol). FC (silica gel, column 15 × 3 cm, CH_2Cl_2/MeOH 94:6), afforded **3a** (0.47 g, 71%) as a colorless amorphous solid. TLC (CH_2Cl_2/MeOH 9:1): R_f 0.19. UV λ_{max} (MeOH)/nm (ϵ/dm^3 mol^{-1} cm^{-1}) 238 (22600), 273 (10600), 290 (8800). ^{1}H NMR ((D$_6$) DMSO): 1.46 (m, 4 H, 2 CH_2), 1.95–2.18 (m, 3 H, H$_\alpha$-C(2′), CH_2), 2.25–2.38 (m, 3 H, H$_\beta$-C(2′), CH_2), 2.64 (s, 1 H, C≡CH), 3.28 (m, 2 H-C(5′)), 3.62 (m, H-C(4′)), 4.14 (m, H-C(3′)), 4.81 (t, OH-C(5′)), 5.11 (d, OH-C(3′)), 6.14 (t, J = 6.3 Hz, H-C(1′)), 6.20 (s, NH_2), 7.01 (s, H-C(8)), 10.31 (s, NH). ESI-HR-MS: 393.15 ([M + Na])$^+$, $C_{19}H_{22}N_4O_4^+$; calcd 370.16.

1-[2-Deoxy-5-*O*-(4,4′-dimethoxytrityl)-β-D-*erythro*-pentofuranosyl]-5-(octa-1,7-diynyl)cytosine (5). Compound **1a** (0.5 g 1.5 mmol) was dried by repeated coevaporation with anhydrous pyridine (2 × 5 mL) before dissolving in anhydrous pyridine (10 mL). Then, 4,4′-dimethoxytrityl chloride (0.61 g, 1.80 mmol) was added in three portions to the remaining solution at room temperature under stirring for 6 h. Thereupon, MeOH (2 mL) was added, and the mixture was stirred for another 30 min. The reaction mixture was dissolved in CH_2Cl_2 (2 × 50 mL) and extracted with 5% aqueous $NaHCO_3$ solution (100 mL) followed by H_2O (80 mL), dried over Na_2SO_4, and then concentrated. Purification by FC (silica gel, column 15 × 3 cm, CH_2Cl_2/acetone 70:30) gave a colorless foam of **5** (0.82 g, 86%). TLC (CH_2Cl_2/MeOH 95:5): R_f 0.25. UV λ_{max} (MeOH)/nm (ϵ/dm^3 mol^{-1} cm^{-1}) 235 (32000), 83 (6500), 299 (6600). ^{1}H NMR ((D$_6$) DMSO): 1.39 (m, 2 CH_2), 2.06–2.26 (m, 6 H, H-C(2′)), 2 CH_2), 2.74 (s, 1 H, C≡CH), 3.10–3.23 (m, 2 H-C(5′)), 3.73 (s, 6 H, 2 MeO), 3.92 (m, H-C(4′)), 4.27 (m, H-C(3′)), 5.33 (d, J = 3.9, OH-C(3′)), 6.12 (t, J = 6.5, H-C(1′)), 6.76 (s, NH_a), 6.86–7.42 (m, H-arom), 7.71 (s, NH_b), 7.89 (s, H-C(6)). Anal. Calcd for $C_{38}H_{39}N_3O_6$ (633.28): C 72.02, H 6.20, N 6.63. Found: C 71.86, H 6.20, N 6.58.

N^4-Acetyl-1-[2-deoxy-5-*O*-(4,4′-dimethoxytrityl)-β-D-*erythro*-pentofuranosyl]-5-(octa-1,7-diynyl)cytosine (6). To a suspension of compound **5** (200 mg, 0.32 mmol) in *N*,*N*-dimethylformamide (2 mL) was added acetic anhydride (36 μL, 0.38 mmol) and the reaction mixture stirred at room temperature for 20 h. After evaporation of DMF under reduced pressure, the residue was applied to FC (silica gel, column 15 × 3 cm, CH_2Cl_2/acetone 80:20). Compound **6** was isolated as colorless foam (0.18 g, 84%). TLC (CH_2Cl_2/MeOH 95:5): R_f 0.73. UV λ_{max} (MeOH)/nm (ϵ/dm^3 mol^{-1} cm^{-1}) 236 (40000), 282 (4200), 317 (5300). ^{1}H NMR ((D$_6$) DMSO): 1.42 (m, 2 CH_2), 2.10–2.17 (m, 2 H-C(2′)), 2.22 (s, 3 H, COMe), 2.36 (m, 2 CH_2), 2.77 (s, 1 H, C≡CH), 3.20 (m, 2 H-C(5′)), 3.75 (s, 6 H, 2-MeO), 4.0 (m, H-C(4′)), 4.3 (m, H-C(3′)), 5.39 (d, J = 4.0, OH-C(3′)), 6.10 (t, J = 6.2, H-C(1′)), 6.89–7.44 (m, H-arom), 8.24 (s, H-C(6)), 9.24 (s, NH). Anal. Calcd for $C_{40}H_{41}N_3O_7$ (675.29): C 71.09, H 6.12, N 6.22. Found: C 71.15, H 6.20, N 6.35.

N^4-Acetyl-1-[2-deoxy-5-*O*-(4,4′-dimethoxytrityl)-β-D-*erythro*-pentofuranosyl]-5-(octa-1,7-diynyl)cytosine 3′-(2-Cyanoethyl)-*N*,*N*-diisopropylphosphoramidite (7). A stirred solution of **6** (250 mg, 0.37 mmol) in anhydrous CH_2Cl_2 (5 mL) was preflushed with argon and treated with (i-Pr)$_2$EtN (100 μL, 0.58 mmol) followed by 2-cyanoethyl-*N*,*N*-diisopropylphosphoramidochloridite (130 μL, 0.60 mmol). After stirring for 45 min at room temperature, the solution was diluted with CH_2Cl_2 (30 mL) and extracted with 5% aqueous $NaHCO_3$ solution (20 mL). The organic layer was dried over Na_2SO_4 and concentrated. FC (silica gel, column 10 × 2 cm, CH_2Cl_2/acetone 95:5) gave **7** (260 mg, 80%). Colorless foam. TLC (CH_2Cl_2/acetone 95:5): R_f 0.74. ^{31}P NMR ($CDCl_3$): 150.25, 149.6.

7-(2-Deoxy-β-D-*erythro*-pentofuranosyl)-5-(octa-1,7-diynyl)-3,7-dihydro-2-[(*N*,*N*-dimethylamino)methylidene]amino-4*H*-pyrrolo[2,3-*d*]pyrimidin-4-one (8). To a solution of **3a** (400 mg, 1.08 mmol) in MeOH (12 mL) was added *N*,*N*-dimethylformamide dimethylacetal (425 μL, 3.2 mmol). The reaction mixture was stirred at 40 °C for 1 h, and the solvent was evaporated to dryness. The resulting residue was applied to FC (silica gel, column 15 × 3 cm, CH_2Cl_2/MeOH 95:5). Compound **8** was isolated as a colorless solid (335 mg, 73%). TLC (CH_2Cl_2/MeOH, 9:1): R_f 0.31. UV λ_{max} (MeOH)/nm (ϵ/dm^3 mol^{-1} cm^{-1}) 232 (17000), 253 (24000), 316 (18000). ^{1}H NMR ((D$_6$) DMSO): 1.60 (m, 2 CH_2), 2.20 (m, 3 H, H$_\alpha$-C(2′), CH_2), 2.39 (m, 3 H, H$_\beta$-C(2′), CH_2), 2.77 (s, 1 H, C≡CH), 3.01 (s, 3 H, NCH_3),

3.14 (s, 3 H, NCH_3), 3.50 (m, 2 H-C(5′)), 3.76 (m, H-C(4′)), 4.30 (m, H-C(3′)), 4.91 (t, OH-C(5′)), 5.25 (d, OH-C(3′)), 6.41 (t, J = 6.3, H-C(1′)), 7.27 (s, H-C(8)), 8.54 (s, H, N=CH), 11.05 (s, NH). Anal. Calcd for $C_{22}H_{27}N_5O_4$ (425.21): C 62.10, H 6.40, N 16.46. Found: C 62.14, H 6.50, N 16.34.

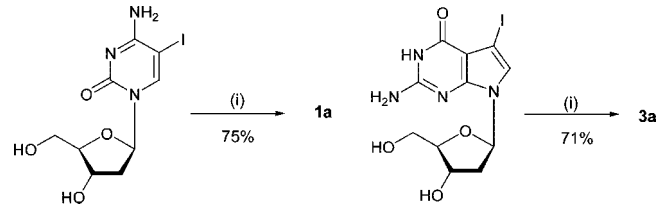
7-(2-Deoxy-5-*O*-(4,4′-dimethoxytrityl)-*β*-D-*erythro*-pentofuranosyl)-5-(octa-1,7-diynyl)-3,7-dihydro-2-[(*N*,*N*-dimethylamino)methylidene]amino-4 *H*-pyrrolo-[2,3-*d*]pyrimidin-4-one (9). As described for **5**, compound **8** (0.35 g 0.82 mmol) in anhydrous pyridine (6 mL) was treated with 4,4′-dimethoxytrityl chloride (370 mg, 1.09 mmol). Purification by FC (silica gel, column 15 × 3 cm, CH_2Cl_2/acetone, 1:1) gave a colorless foam of **9** (0.45 g, 75%). TLC (CH_2Cl_2/MeOH 97:3): (B): R_f 0.25: UV λ_{max} (MeOH)/nm (ϵ/dm^3 mol^{-1} cm^{-1}) 232 (45000), 279 (16000), 296 (15000). ^{1}H NMR ((D$_6$) DMSO): 1.61 (m, 2 CH_2), 2.09–2.19 (m, 3 H, H$_\alpha$-C(2′), CH_2), 2.40 (m, 3 H, H$_\beta$-C(2′), CH_2), 2.77 (s, 1 H, C≡CH), 3.02 (s, 3 H, NCH_3), 3.15 (s, 3 H, NCH_3), 3.74 (s, 6 H, 2-MeO), 3.90 (m, H-C(4′)), 4.31 (m, H-C(3′)), 5.33 (d, OH-C(3′)), 6.46 (t, J = 6.52, H-C(1′)), 6.85–7.32 (m, H-arom), 7.4 (s, H-C(8)), 8.57 (s, H, N=CH), 11.09 (s, NH). Anal. Calcd for $C_{43}H_{45}N_5O_6$ (727.34): C 70.96, H 6.23, N 9.62. Found: C 71.08, H 6.26, N 9.70.

7-(2-Deoxy-5-*O*-(4,4′-dimethoxytrityl)-*β*-D-*erythro*-pentofuranosyl)-5-(octa-1,7-diynyl)-3,7-dihydro-2-[(*N*,*N*-dimethylamino)methylidene]amino-4-*H*-pyrrolo-[2,3-*d*]pyrimidin-4-one 3′-(2-Cyanoethyl)-*N*,*N*-diisopropylphosphoramidite (10). As described for **7**, with **9** (200 mg, 0.27 mmol), (i-Pr)$_2$EtN (72 μL, 0.42 mmol), and 2-cyanoethyl-*N*,*N*-diisopropylphosphoramidochloridite (103 μL, 0.47 mmol). FC (silica gel, 10 × 2 cm, solvent system, CH_2Cl_2/acetone 93:7) gave a colorless foam of **10** (160 mg, 62%). TLC (CH_2Cl_2/acetone 90:10): R_f 0.68. ^{31}P NMR ($CDCl_3$): 149.95, 149.65.

7-(2-Deoxy-*β*-D-*erythro*-pentofuranosyl)-4-(iso-butyrylamino)-5-(octa-1,7-diynyl)-7-*H*-pyrrolo[2,3-*d*]pyrimidine (11). To a solution of compound **4a** (*19*) (248 mg, 0.7 mmol) in anhydrous pyridine (4 mL) was added Me_3SiCl (910 μL, 7.14 mmol) and stirred at room temperature. After 45 min, the isobutyric anhydride (770 mg, 4.9 mmol) was introduced, and the solution stirred for another 2 h. The mixture was cooled to 0 °C, diluted with H_2O (3 mL), and stirred for 10 min. After the addition of 12% aq NH_3 (3 mL), stirring was continued for 1 h at room temperature. The solution was evaporated, and the residue was applied to FC (silica gel, column 10 × 3 cm, CH_2Cl_2/MeOH 95:5). Compound **11** was isolated as a colorless solid (210 mg, 71%). TLC (CH_2Cl_2/MeOH, 90:10): R_f 0.64. UV λ_{max} (MeOH)/nm (ϵ/dm^3 mol^{-1} cm^{-1}) 213 (19000), 241 (26000), 305 (7000). ^{1}H NMR ((D$_6$) DMSO): 1.17 (s, 2 CH_3), 1.60 (m, 2 CH_2), 2.20 (m, 3 H, H$_\alpha$-C(2′), CH_2), 2.38–2.58 (m, 3 H, H$_\beta$-C(2′), CH_2), 2.77 (s, 1 H, C≡CH), 2.88 (m, 1 H, CH), 3.50 (m, 2 H-C(5′)), 3.83 (m, H-C(4′)), 4.35 (m, H-C(3′)), 4.99 (t, J = 4.87, OH-C(5′)), 5.30 (d, OH-C(3′)), 6.61 (t, J = 6.7, H-C(1′)), 7.98 (s, H-C(6)), 8.59 (s, 1 H, H-C(2)), 9.96 (s, 1H, NH). Anal. Calcd for $C_{23}H_{28}N_4O_4$ (424.21): C 65.08, H 6.65, N 13.20. Found: C 65.22, H 6.70, N 13.11.

7-(2-Deoxy-5-*O*-(4,4′-dimethoxytrityl)-*β*-D-*erythro*-pentofuranosyl)-4-(isobutyrylamino)-5-(octa-1,7-diynyl)-7-*H*-pyrrolo-[2,3-*d*]pyrimidine (12). As described for **5**, compound **11** (250 mg 0.59 mmol) in anhydrous pyridine (5 mL) was treated with 4,4′-dimethoxytrityl chloride (275 mg, 0.81 mmol). Purification by FC (silica gel, column 12 × 3 cm, CH_2Cl_2/acetone, 7:3) gave a colorless foam of **12** (365 mg, 85%). TLC (CH_2Cl_2/MeOH 95:5) R_f 0.33. UV λ_{max} (MeOH)/nm (ϵ/dm^3 mol^{-1} cm^{-1}) 214 (36400), 237 (42000), 275 (9400). ^{1}H NMR ((D$_6$) DMSO): 1.17 (s, 2 CH_3), 1.58 (m, 2 CH_2), 2.14–2.41 (m, 6 H, H-C(2′), 2 CH_2), 2.77 (s, 1 H, C≡CH), 2.88 (m, 1 H, CH), 3.2 (m, 2 H-C(5′)), 3.72 (s, 6 H, 2-MeO), 3.96 (m, 1 H-C(4′)), 4.39 (m, H-C(3′)), 5.37 (d, J = 4.20, OH-C(3′)), 6.62 (t, J = 6.7, H-C(1′)), 6.82 (m, 4 H, H-arom), 7.20–7.38 (m, 9 H, H-arom), 7.86 (s, 1 H, H-C(6)), 8.57 (s, 1 H, H-C(2)), 9.96 (s, 1 H, NH). Anal. Calcd for $C_{44}H_{46}N_4O_6$ (726.34): C 72.71, H 6.38, N 7.71. Found: C 72.82, H 6.48, N 7.70.

Scheme 3[a]



[a] (i) [Pd^0(PPh$_3$)$_4$], CuI, Et$_3$N, DMF, octa-1,7-diyne, rt.

7-(2-Deoxy-5-*O*-(4,4′-dimethoxytrityl)-*β*-D-*erythro*-pentofuranosyl)-4-(isobutyrylamino)-5-(octa-1,7-diynyl)-7-*H*-pyrrolo-[2,3-*d*]pyrimidine-3′-(2-cyanoethyl)-*N*,*N*-diisopropylphosphoramidite (13). As described for **7**, with **12** (300 mg, 0.41 mmol), (i-Pr)$_2$EtN (150 μL, 0.87 mmol), and 2-cyanoethyl-*N*,*N*-diisopropylphosphoramidochloridite (210 μL, 0.96 mmol). FC (silica gel, 10 × 2 cm, solvent system, CH_2Cl_2/acetone 94:6) gave colorless foam of **13** (230 mg, 60%). TLC (CH_2Cl_2/acetone 90:10): R_f 0.70. ^{31}P NMR ($CDCl_3$): 149.97, 149.81.

Huisgen−Sharpless−Meldal [3 + 2] Cycloaddition Performed in Aqueous Solution for Oligonucleotides 23, 30, 34, and 42 with the Nonfluorescent Coumarin Azide 38. To the single-stranded oligonucleotide (5 A_{260} units), $CuSO_4$−TBTA ligand complex (35 μL of a 20 mM stock solution in *t*-BuOH/H_2O 1: 9), tris(carboxyethyl)phosphine (TCEP) (35 μL of a 20 mM stock solution in water), 3-azido-7-hydroxycoumarin (**38**; 50 μL of a 20 mM stock solution in dioxane/H_2O 1: 1), and 35 μL of DMSO were added, and the reaction was run at room temperature for 15–20 h. The "click" products **39**, **40**, **41**, and **43** were further purified by reversed-phase HPLC in the trityl-off modus (see above). The molecular masses of the oligonucleotides were determined by MALDI-TOF spectroscopy.

RESULTS AND DISCUSSION

Synthesis and Physical Properties of Monomers. The nucleosides **1a** and **3a** were synthesized from the corresponding 5-iodo 2′-deoxycytidine or 7-deaza-7-iodo-2′-deoxyguanosine (*23*) employing the Sonogashira cross-coupling reaction. The reaction was carried out in dry DMF in the presence of triethylamine using the palladium catalyst Pd^0(PPh$_3$)$_4$ and CuI. An excess amount of octa-1,7-diyne was used for the efficient cross-coupling reaction (*20*), leading to the exclusive formation of the monofunctionalized octa-1,7-diynyl nucleosides **1a** and **3a** in 75% and 71% yield, respectively (Scheme 3). The synthesis of the corresponding c^{7}dA$_d$ (**4a**) and 2′-deoxyuridine (**2a**) nucleosides were already reported (*20*, *35*). Reaction at the second terminal C≡C bond can be accomplished when compounds **1a**−**4a** are isolated and employed as intermediates in a second cross-coupling reaction to form bis-nucleosides (*7*). The structure of the isolated nucleosides was confirmed on the basis of ^{1}H and ^{13}C NMR spectroscopy as well as by elemental analysis or mass spectra. The characteristic signal for the terminal C≡C proton at δ(H) 2.76 (for **1a**) and 2.64 (for **3a**) reveals the formation of 5- or 7-octa-1,7-diynylated nucleosides. The chemical shifts and the terminal triple bonds of the nucleosides can be clearly identified on the basis of coupling pattern taken from the gated-decoupled ^{1}H/^{13}C NMR spectra. The side chain carbon atom of terminal C≡C of **1a** showed a C, H coupling (^1J(C,H) = 250 Hz).

The physical and biological properties of oligonucleotides can be influenced by introducing various alkyne or diyne

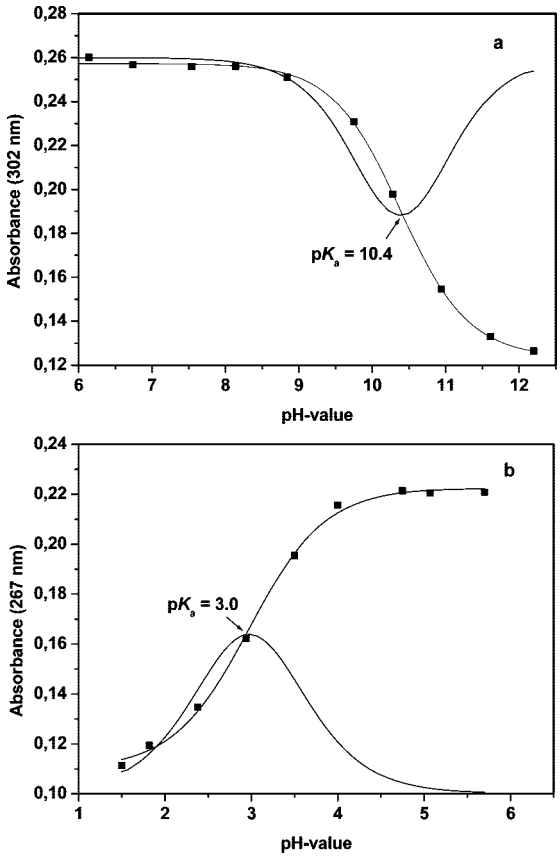


Figure 2. UV spectra of compounds **3a** and **1a** measured in phosphate buffer (7.8 g $NaH_2PO_4 \cdot H_2O$ in 500 mL H_2O). Absorbance (a) of compound **3a** as a function of pH values measured at 302 nm from pH 1.5 to 12.5 and (b) of compound **1a** at 267 nm.

substituents at the 5-position of pyrimidine or at the 7-position of 7-deazapurine nucleosides. To evaluate the impact of these side chain units on the hydrophobicity, the log *P* values are calculated and compared for the heterocyclic bases with the help of *ACD/log P 1.0* program. For the natural bases, the log *P* values are negative, which reflects the hydrophilicity of these compounds. The maximum log *P* value is observed for the octa-1,7-diynyl nucleosides (1.23 ± 0.75 for **1a**, 1.51 ± 1.30 for **3a**, 2.69 ± 1.43 for **4a**) when compared with the propynylated nucleosides (−0.24 ± 0.75 for **1b**, 0.03 ± 1.29 for **3b**, 1.22 ± 1.42 for **4b**). Moreover, the presence of long-chain hydrophobic substituents enhances the polarizability, $\alpha_m/10^{-24}$ cm^3; the calculated data (*ACD/ChemSketch 2.51*) are of the nucleobases (25.36 for **1a**, 29.22 for **3a**, and 27.87 for **4a**). These values are higher when compared with the propynylated nucleobases (16.23 for **1b**, 20.08 for **3b**, and 19.56 for **4b**).

In order to understand the relative base-pairing strength of DNA duplexes, it is necessary to know the pK_a values of the monomeric donor and acceptor residues involved in hydrogen bonding (*39*). The effect of octa-1,7-diynyl residue on the pyrrolo[2,3-*d*]pyrimidine as well as on the pyrimidine system was studied. The pK_a values were determined by spectrophotometric titration (*40*) (pH 1.5 to 11.50) at 220–350 nm (see Figure 2). The octa-1,7-diynyl group of **1a** (pK_a = 3.0), **2a** (pK_a = 8.7), **3a** (pK_a = 10.4), and **4a** (pK_a = 4.4) does not change the pK_a value significantly when compared with the propynylated nucleosides (3.3 for **1b**, 8.7 for **2b**, 10.2 for **3b**, and 4.3 for **4b**). The pK_a values of the natural pyrimidine 2′-deoxyribonucleosides dC (pK_a = 4.2) and dT (pK_a = 9.3) and purine 2′-deoxyribonucleosides dG (pK_a = 9.2) and dA (pK_a = 3.8) (*41*) are significantly different when compared to the octadiynylated nucleosides. The octa-1,7-diynyl side chains of pyrimidine 2′-deoxyribonucleosides make them more acidic than the parent compounds and have an impact on the base pair stability and base discrimination. Moreover, the octadiynyl side-chain containing nucleosides show rather different UV spectra and extinction coefficients than those of natural nucleosides (Figure 3a−d and Table 1).

Phosphoramidite Synthesis. In order to investigate the properties of oligonucleotides containing the octa-1,7-diynyl nucleosides, a series of phosphoramidites **7**, **10**, and **13** were prepared. The synthesis of 5-octadiynyl 2′-deoxyuridine phosphoramidite has already been reported (*35*). Various protecting groups were studied for the protection of the amino group of different monomers. First, we used the transient protection protocol to protect the amino group of **1a** with a benzoyl residue at the nucleoside level but obtained a rather low yield. Next, isobutyric anhydride was employed for protection and was also discarded for poor reactivity and hygroscopic nature. Thus, it became clear that the presence of a bulky alkynyl side chain influences protection. To avoid this, nucleoside **1a** was first converted into the 4,4′-dimethoxytrityl derivative **5**, which increased the solubility, and then the amino group was protected with the less bulky acetyl group using acetic anhydride in DMF. This results in the formation of the derivative **6** in 84% yield, which was subsequently converted into the phosphoramidite buiding block **7** (Scheme 4).

In the case of 7-deaza-2′-deoxyguanosine **3a**, the amino group was protected with the formamidine residue furnishing compound **8**, which is subsequently converted into the DMT derivative **9**. Phosphitylation of the DMT derivative results in the formation of phosphoramidite building block **10** (Scheme 5). We have already reported on the use of different protecting groups for the amino group of 7-alkynylated 7-deaza 2′-deoxyadenosines (*21*). In the case of **4a**, formamidine and acetamidine protection was not successful due to the unstable products which turned brown when exposed to the light. On the basis of these observations, the isobutyric residue was chosen. The nucleoside **4a** was treated with trimethylsilyl chloride in pyridine followed by isobutyric anhydride (transient protection) (*42*), yielding the derivative **11**. The protected nucleoside was obtained in 71% yield, which was further converted into phosphoramidite building block **13** via the DMT derivative **12** (Scheme 6).

All the compounds were characterized by ^1H, ^{13}C, and ^{31}P NMR spectra and by elemental analysis (Table 2 and Experimental Section). The δ(C) of the C≡C bonds were in good agreement with the literature data of the related compounds (*20, 35*). Moreover, the nucleobase as well as the protecting group carbon atom signals of 7-deazapurines and pyrimidines were assigned on the basis of literature data (*31*). The above synthesized phosphoramidites were further employed in solid-phase oligonucleotide synthesis.

Duplex Stability of Tridentate "dG−dC" Base Pair Modified by 5-Octadiynyl-2′-deoxycytdine (1a) and 7-Deaza-7-octadiynyl-2′-deoxyguanosine (3a). To evaluate the influence of base-modified nucleosides on the duplex stability, hybridization experiments were performed by using the oligonucleotide duplex 5′-d(TAGGTCAATACT)-3′ (**14**) 3′-d(ATCCAGTTATGA)-5′ (**15**) as a reference. Earlier, it was reported from our laboratory that the pyrimidine nucleoside **1b** increase the thermal stability of duplexes by 2–3 °C per modification (*32*) when incorporated in the place of dC (motif I, Figure 4). Herein, we studied the role of octa-1,7-diyne in the duplexes **14** and **15** by incorporating compound **1a** instead of 2′-deoxycytidine. The 5-(octa-1,7-diynyl) nucleoside **1a** enhances the stability of a dG−dC base pair by 2–3 °C per modification (Table 3).

[a] Measured in MeOH.

The oligonucleotides with longer alkynyl chains linked to the 7-position of 7-deaza-2′-deoxyguanosine show an unfavorable influence on the DNA duplex stability (*24*). Moreover, it was found that introduction of the propynyl group at this position enhances the DNA duplex stability significantly (*31*). Recently, we reported the single-crystal X-ray analysis of the 7-propynylated nucleoside **3b** (*43*) which shows an anti [$\chi = -117.2$ (5)°] orientation of the nucleobase related to the sugar moiety with pseudorotational parameters $P = 152.5°$ and $\tau_m = 41.9°$. The linear 7-propynyl residue is placed almost in-plane with the base moiety and protruding into the major groove with steric freedom. From these findings, it was concluded that the duplex stability can be tuned by an appropriate selection of a 7-substituent. To evaluate this, nucleoside **3a** was incorporated in the standard duplex 5′-d(TAGGTCAATACT)-3′ (**14**) 3′-d(ATCCAGTTATGA)-5′ (**15**) in place of dG. The incorporation of the **3a** residue results in a T_m increase of 2–3 °C per modification (Table 3). These values are more or almost similar when compared with the oligonucleotides containing the 7-propynyl derivative **3b** (Table 1 in Supporting Information). Thus, it is shown that the octa-1,7-diynyl group is a more effective substituent for duplex stabilization. These results led us to study the influence of the octa-1,7-diynyl group at the 7-position of 7-deazaadenine.

Duplex Stability of the Bidentate dA−dT Base Pair Modified by 7-Deaza-7-octadiynyl-2′-deoxyadenosine (4a) and 5-Octadiynyl-2′-deoxyuridine (2a). The 7-deaza-7-(octa-1,7-diynyl)-2′-deoxyadenosine **4a** was introduced into the duplex 5′-d(TAGGTCAATACT)-3′ (**14**) 3′-d(ATCCAGTTATGA)-5′ (**15**) replacing dA. From Table 4, it is concluded that single or double incorporation of **4a** (motif VI, Figure 4) does not show much influence on the stability, whereas three incorporations enhances the T_m value by 3 °C (**30•31**) when compared to the standard sequence in high-salt buffer (Table 4). In the low-salt buffer, there is no significant influence of this side chain on the duplex stability when compared to **4b** (data not shown). In the case of 5-octadiynyl 2′-deoxyuridine (**2a**), a T_m increase of 1–2 °C per modification was observed, similar to that of **2b** (motif VIII, Figure 4).

The above results clearly demonstrate that the octa-1,7-diynyl nucleosides with side chains located at the 7-position of 7-deazapurine nucleosides or at the 5-position of pyrimidine nucleosides show a very similar behavior to that of four canonical DNA constituents with a tendency of duplex stabilization. From the above data, it can be concluded that bidentate base pair reacts more sensitively to this change than the

tridentate pair. The octa-1,7-diynyl groups are protruding into the major groove, which does not distort the base pairs significantly. The higher stability for such a long chain is due to the presence of terminal triple bonds.

Functionalization of Terminal C≡C Bonded Oligonucleotides in Solution with the Coumarin Azide 38 Employing the Huisgen−Sharpless−Meldal [3 + 2] Cycloaddition ("Click" Chemistry). The Huisgen−Sharpless−Meldal "click" chemistry is defined as a selective chemical reaction between alkynes and organic azides (*44*). The reaction is tolerant of a variety of solvents and functional groups to form stable 1,2,3-triazoles. Independently, the Sharpless (*45*) and Meldal (*46*) groups reported the copper(I)-catalyzed coupling protocol which enhances the reaction rate significantly and leads to regioselective ring closure. Previous work includes the demonstration of this chemistry in nucleic acids (*36, 47–49*) for the construction of fluorescent oligonucleotides for DNA sequencing (*50*), for the intramolecular circularization and catenation of DNA (*51*), and also to attach oligonucleotide probes on monolayers (*52*). Recently, we reported on the functionalization of alkynyl-modified 2′-deoxyuridines using "click" chemistry at the nucleoside as well as at the oligonucleotide levels (*35*).

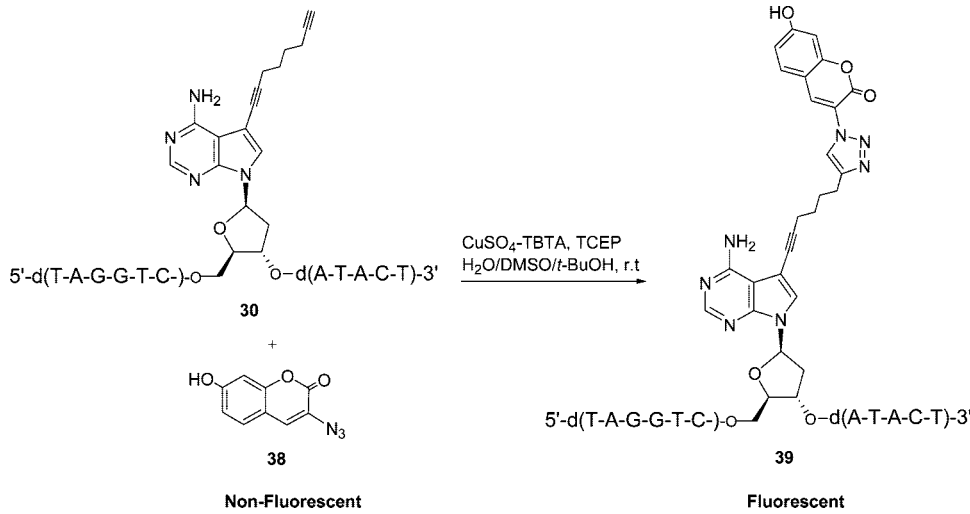
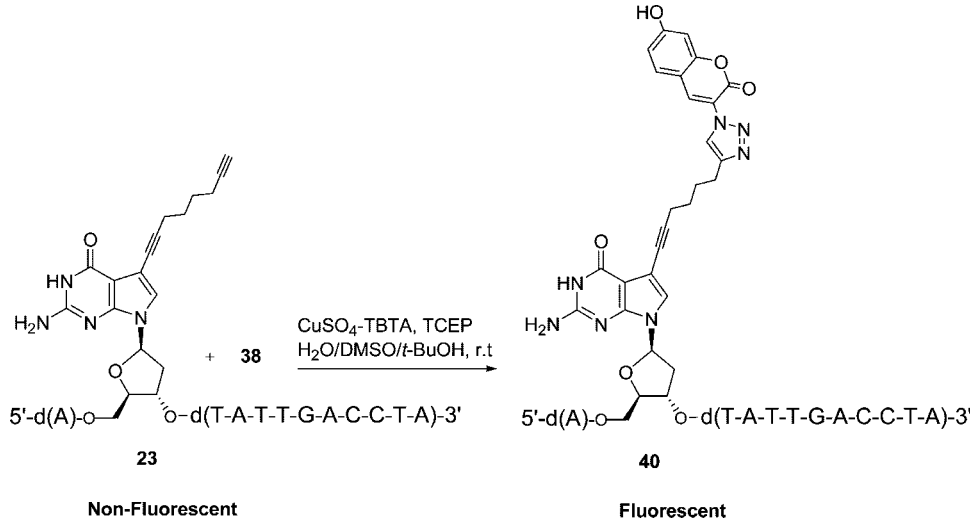
Here, we report on the use of oligonucleotides containing octa-1,7-diynyl nucleosides **1a**−**4a** with terminal C≡C bonds for further functionalization using the protocol of [3 + 2] cycloaddition with a nonfluorescent coumarin azide to produce highly fluorescent 1,2,3-triazolyl oligonucleotides. Coumarin is a compound found in many plants, notably as the sweet scent of newly mown hay. It has clinical value as the precursor for several anticoagulants and is used as a gain medium in some dye lasers. Among many fluorophores, coumarin derivatives have been extensively studied because of their special photophysical properties with no low-lying electronic states that interact with their first excited states (*53*). Moreover, the fluorescence properties of coumarin derivatives depend on the nature of the substituents present at the 6- or 7-position of the coumarin ring (*54*–*56*) and can be explained in terms of the intramolecular charge transfer (ICT) mechanism (*57*). Coumarins were used as potential fluorescent probes to study the structural dynamics of DNA (*58*), for the specific labeling of nucleic acids (*59*) and mainly as nucleobase-specific quenchers (*60, 61*).

At first, the "click" reaction was performed using the purified oligonucleotide **30** containing one 7-deaza-7-(octa-1,7-diynyl)-2′-deoxyadenynyl residue and the nonfluorescent coumarin azide **38**. The reaction was carried out in aqueous solution (H_2O/*t*-BuOH/DMSO) in the presence of a 1:1 complex of $CuSO_4$−TBTA (tris(benzyltriazoylmethyl)amine) (*62*) and TCEP (tris(carboxyethyl)phosphine), a water-soluble reducing agent, to give the strongly fluorescent functionalized

Scheme 7



Scheme 8



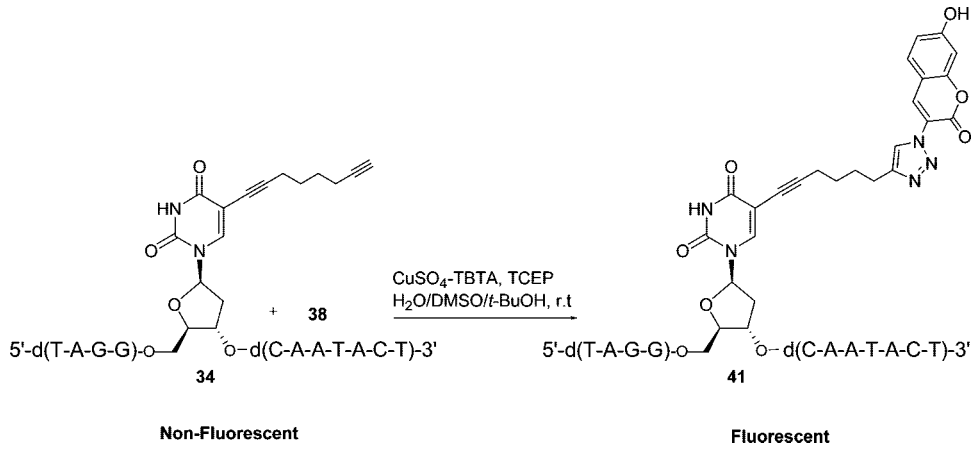
oligonucleotide **39**. The reaction was complete in 15 h at room temperature when an excess molar ratio of coumarin azide was used. The reaction mixture was purified by reversed-phase HPLC, and the strongly fluorescent oligonucleotide **39** was isolated (Scheme 7). The 1,2,3-triazole ring formed by the 1,3-dipolar cycloaddition of the alkyne and azido derivatives of coumarin was found to be strongly fluorescent (*63*). Such reactions are already used for the preparation of fluorogenic probes (*64*) and also for the fluorescence visualization of synthesized mammalian proteins (*65*).

Next, a similar reaction was performed on the oligonucleotide 5′-d(A**3a**T ATT GAC CTA)-3′ (**23**) containing one 7-deazaguanine residue **3a** resulting in the formation of the highly flourescent 7-deazaguanine coumarin conjugate **40** (Scheme 8). The same reaction conditions were used for the click reaction as mentioned above. After the reaction was performed on the 7-deazapurine derivatives, the corresponding pyrimidines were investigated. For this, the oligonucleotide **34** containing **2a** was used, which was conjugated with the coumarin azide **38** to give the click product **41** (Scheme 9). In a similar fashion, 5′-d(AGT ATT GA**1a** CTA)-3′ (**42**) containing 5-(octa-1,7-diynyl)-2′-deoxycytidine was functionalized with the coumarin azide **38** to give **43** (Scheme 10). The ligated 1,2,3-triazolyl "click" oligonucleotides were identified by MALDI-TOF mass spectrometry (Table 3, Supporting Information).

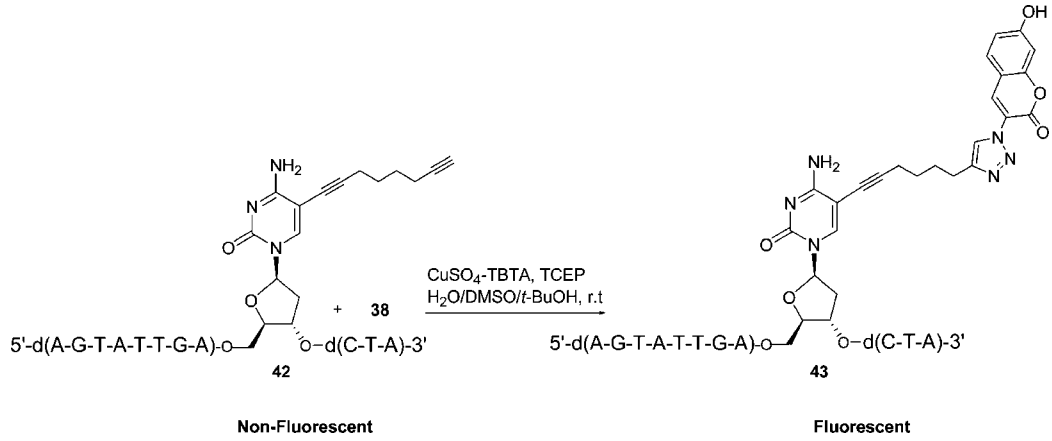
Fluorescence Properties of Oligonucleotides Containing 1,2,3-Triazole Coumarin Derivatives. The fluorescence spectra of the single-stranded oligonucleotide **39** show a strong fluorescence with an emission at 479 nm and an excitation at 400 nm. In the case of the DNA duplex **15•39**, the fluorescence was strongly decreased, a quenching of 85% is observed (Figure 5). This arises from the stacking of dye with the neighboring bases, which is significantly higher in duplex DNA when compared to the single-stranded DNA. In the case of single strands, the dye has a higher degree of steric freedom with negligible stacking with the nucleobases, leading to a higher fluorescence.

It has been reported that the fluorescence of some fluorescent dyes is quenched by the interaction between the dyes and the nucleobases. This quenching is useful to monitor the conformational dynamics of oligonucleotides in solution. However, the dependency of fluorescence quenching is mainly based on the distance between a dye and a nucleobase; in this perspective, several fluorescent dyes like acridine, stilbene, and pyrene were studied (*66*, *67*). Moreover, the quenching of coumarin dyes by nucleobase derivatives in aqueous solution is caused by the photoinduced electron transfer, which is dependent on the oxidation and reduction potential values of the nucleobases (*60*) and the dye. In order to understand the quenching behavior of coumarin dye attached to the modified canonical nucleosides **1a**−**4a** on single-stranded DNA, a series of the above-prepared

Scheme 9



Scheme 10



click-functionalized oligonucleotides were used, and the fluorescence quenching properties of such covalently linked coumarin-nucleobase assemblies were investigated by performing enzymatic hydrolysis. The oligomer **39** containing 7-deazaadenine conjugate was digested with snake venom phosphodiesterase and alkaline phosphatase, and fluorescence spectra were measured before and after 3–10 h of cleavage (Figure 6) with an emission observed at 479 nm. Surprisingly, we observed a decrease in fluorescence intensity after addition of enzyme from 3 to 10 h; even after the addition of excess enzyme, the fluorescence was further decreased by 10% and remained constant afterward.

Then, the oligonucleotide **40** containing the 7-deazaguanine conjugate was subjected to enzymatic hydrolysis, and fluorescence emission was recorded at different time intervals (Figure 7) with an emission observed at 479 nm, when excited at 400 nm. From Figure 7, it is clear that the 7-deazaguanine moiety strongly quenches the fluorescence of the coumarin dye attached to it, similar to that of the 7-deazaadenine moiety. Apparently, an intramolecular photoinduced electron transfer plays a role in fluorescence quenching. The 7-deazapurines can act as electron donors, and the 7-deazapurine nucleobase quenches the triazolyl coumarin dye attached to it. The purine bases quench

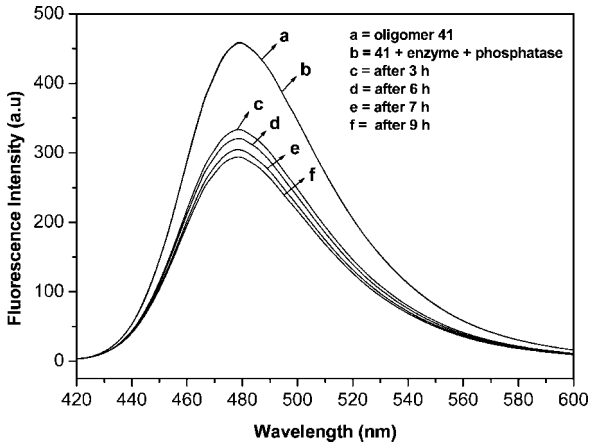

Figure 8. Enzymatic digestion of 1.7 μM single-stranded oligonucleotide **41** with snake venom phosphodiesterase followed by alkaline phosphatase in 0.1 M Tris−HCl buffer (pH 8.3) at 37 °C.

the excited singlet state of coumarins more effectively than pyrimidine bases (*68*). The above results prompted us to study the quenching properties of pyrimidine nucleoside dye conjugates. For that purpose, the enzymatic hydrolysis of the single-stranded oligonucleotide **41** containing the uracil moiety was performed under conditions as described earlier. When oligonucleotide **41** was cleaved, an unexpected fluorescence quenching was observed (Figure 8). However, this quenching was less effective than that observed for the oligonucleotides containing the 7-deazapurine nucleosides **3a** and **4a**. From the HPLC profile of the enzymatic digest of oligomer **41** which contains additional unidentified peaks, it can be concluded that side reactions occurred during irradiation. Such side reactions could be caused by the photoinduced cycloaddition involving the dT−coumarin conjugate within the oligonucleotide chain (*69*). The monomeric click product of octadiynyl 2′-deoxyuridine with azidocoumarin did not form side products under those conditions (data not shown).

In contrary to the above results, a rather different result was observed for oligonucleotide **43** (Figure 9), after the enzymatic digestion for 12 h. There is very little quenching for the 5-(octa-1,7-diynyl)-2′-deoxycytidine dye conjugate when compared with 7-(octa-1,7-diynyl) 7-deazapurines. This shows that the 7-deazapurine bases are strong quenchers of fluorescence when compared to pyrimidines. By changing the oligonucleotide concentration of **40** and **43** from 1.7 μM to 4 μM without changing the enzyme concentration, similar results were obtained in both series of experiments (Figures 7, 9, 10, and 11).

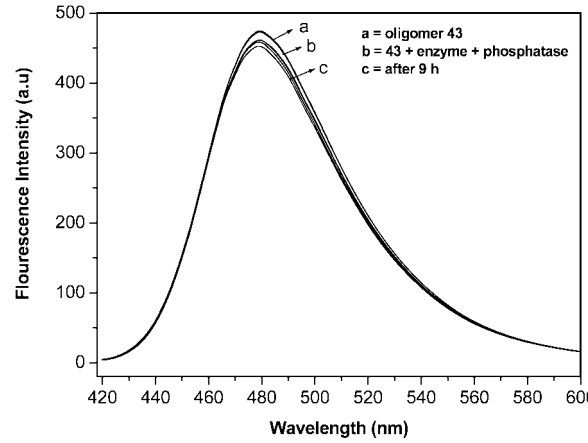

Figure 9. Enzymatic digestion of 1.7 μM single-stranded oligonucleotide **43** with snake venom phosphodiesterase followed by alkaline phosphatase in 0.1 M Tris−HCl buffer (pH 8.3) at 37 °C.

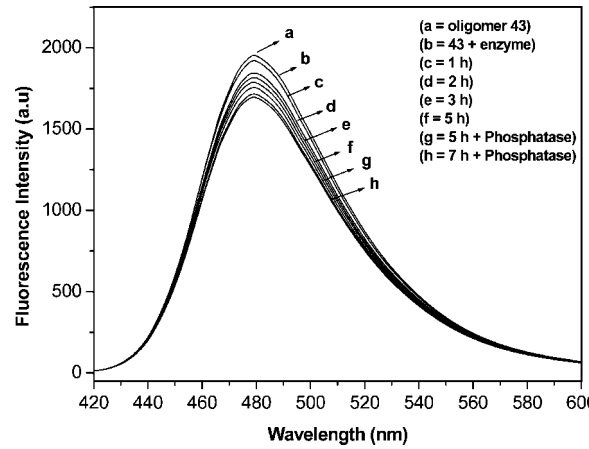

Figure 10. Enzymatic digestion of 4 μM single-stranded oligonucleotide **43** with snake venom phosphodiesterase followed by alkaline phosphatase in 0.1 M Tris−HCl buffer (pH 8.3) at 37 °C.

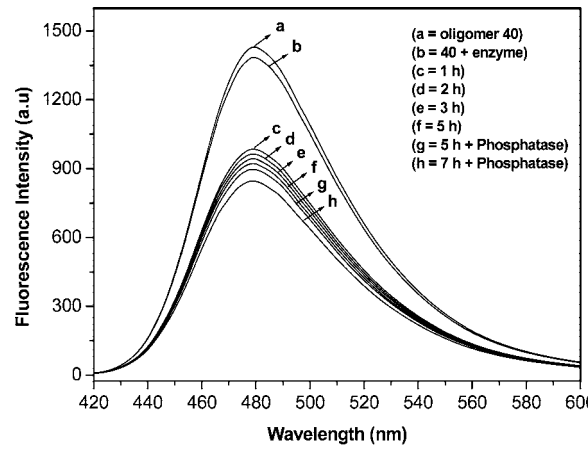

Figure 11. Enzymatic digestion of 4 μM single-stranded oligonucleotide **40** with snake venom phosphodiesterase followed by alkaline phosphatase in 0.1 M Tris−HCl buffer (pH 8.3) at 37 °C.

The HPLC profile of the enzymatically digested oligonucleotide **43** clearly indicates the formation of free nucleosides, and the complete digestion pattern was observed after 7 h.

The most probable reason for this behavior can be explained in terms of intramolecular photoinduced electron transfer from the nucleobase to the coumarin dye attached to it, which strongly quenches the fluorescence when they are in close proximity (Figure

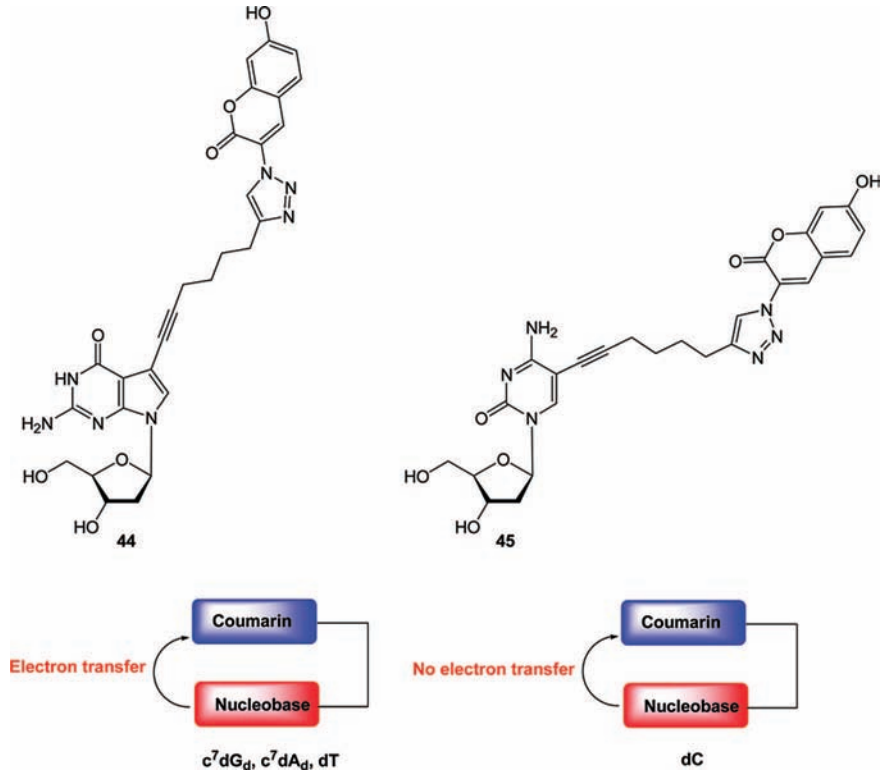

Figure 12. Electron transfer between the nucleobases and coumarin dye attached to it when they are in close proximity.

12). This is evidenced from the fluorescence quantum yield measurements of the monomeric nucleoside−coumarin conjugates in bidistilled water. The 7-deaza-2′-deoxyguanosine−coumarin conjugate **44** shows a quantum yield (Φ) of only 0.11 when compared to that of 2′-deoxycytidine−coumarin conjugate **45** (Φ = 0.22). The quantum yield of fluorescence for nucleoside−dye conjugates was determined relative to quinine sulfate in 0.1 N H_2SO_4 as the standard with Φ = 0.53. The excited coumarins serve as an electron acceptor and the nucleobase as a ground-state donor. A stacked arrangement of the nucleobase and the coumarin dye appears to be a prerequisite for fluorescence quenching. This quenching occurs much more efficiently in the monomeric nucleosides dye conjugates than within a single-stranded oligonucleotide. The latter already shows a preformed helical structure with weakly stacked nucleobases. In this form, the bases are positioned in a way that they are apparently not able to interact with the coumarin dye, while in the duplex structure, the dye molecule interacts with the stacked base pair. Consequently, quenching occurs either in the form of a duplex or within the coumarin−nucleobase assembly, which is generated after the enzymatic digestion of the oligonucleotide. The intramolecular quenching is highly efficient only at short distances; collisional quenching is expected to be comparably inefficient. One should note that the octadiynyl groups might have an influence on the redox potentials of the nucleobases.

CONCLUSION

Nucleosides containing the octa-1,7-diynyl residue at the 5-position of 2′-deoxycytidine or at the 7-position of 7-deazapurines were synthesized by the palladium-assisted Sonogashira cross-coupling reaction resulting in a selective monoderivatization of the diyne starting material. The oligonucleotides incorporating the octa-1,7-diynyl derivatives of 2′-deoxycytidine and 7-deazapurines stabilize the DNA duplexes significantly when compared with the alkynyl counterparts. This group enhances the stability more or equal to that of propynyl residue. Such oligonucleotides containing octa-1,7-diynyl derivatives **1a**−**4a** were further annelated with the nonfluorescent coumarin azide **38** by Huisgen−Sharpless−Meldal "click" chemistry to generate a set of highly fluorescent oligomers **39**, **40**, **41**, and **43**. The enzymatic hydrolysis of such 1,2,3-triazolyl oligonucleotide conjugates revealed that strong fluorescence quenching was observed for 7-deazapurines compared to pyrimidines. The quenching efficiency is in the order $c^7dA_d \approx c^7dG_d > dU > dC$. So, the nucleobase specific quenching of base-modified nucleosides is useful to monitor conformational dynamics of oligonucleotides in solution. The click methodology allows the introduction of various reporter groups like dyes or other functionalized residues, which do not change the water shells of a DNA molecule by retaining stable duplexes. The generation of fluorescence by the "click" reaction can be used for the footprinting of DNA accessible in solution or buried in DNA–protein complexes. The reaction kinetics of this bioorthogonal chemical reporter strategy (nonfluorescent dye becomes fluorescent) can be used for the labeling and visualization of biomolecules in vivo.

ACKNOWLEDGMENT

We thank Dr. H. Rosemeyer and S. Budow for measuring the NMR spectra and Dr. P. Leonard for providing nucleobase precursors. We also thank Mr. K. I. Shaikh and Dr. T. Koch from Roche Diagnostics GmbH, Penzberg, Germany, for the measurement of the MALDI spectra and Mrs. E. Michalek for the oligonucleotide syntheses. Financial support by ChemBiotech, Muenster, Germany, is gratefully acknowledged.

Supporting Information Available: T_m values and thermodynamic data of oligonucleotide duplexes containing propynyl nucleosides **1b**−**4b** (Tables 1 and 2); molecular masses ($[M + H]^+$) of oligonucleotides measured by MALDI-TOF mass spectrometry (Table 3). This material is available free of charge via the Internet at http://pubs.acs.org.

Novel Near-Infrared Fluorescent Integrin-Targeted DFO Analogue

Yunpeng Ye, Sharon Bloch, Baogang Xu, and Samuel Achilefu*

Department of Radiology, Washington University, 4525 Scott Avenue, St. Louis, Missouri 63110. Received August 9, 2007

Desferrioxamine (DFO), a siderophore initially isolated from *Streptomyces pilosus*, possesses extraordinary metal binding properties with wide biomedical applications that include chelation therapy, nuclear imaging, and antiproliferation. In this work, we prepared a novel multifunctional agent consisting of (i) a near-infrared (NIR) fluorescent probe-cypate; (ii) an integrin $\alpha_v\beta_3$ receptor (ABIR)-avid cyclic RGD peptide, and (iii) a DFO moiety, DFO-cypate-cyclo[RGDfK(∼)] (**1**, with ∼ representing the cypate conjugation site at the side chain of lysine; f is D-phenylalanine). Compound **1** and two control compounds, cypate-cyclo[RGDfK(∼)] (**2**) and cypate-DFO (**3**), were synthesized by modular assembly of the corresponding protected RGD peptide cyclo[R(Pbf)GD(OBut)fK] and DFO on the dicarboxylic acid-containing cypate scaffold in solution. The three compounds exhibited similar UV–vis and emission spectral properties. Metal binding analysis shows that DFO as well as **1** and **3** exhibited relatively high binding affinity with Fe(III), Al(III), and Ga(III). In contrast to Ga(III), the binding of Fe to **1** and **3** quenched the fluorescence emission of cypate significantly, suggesting an efficient metal-mediated approach to perturb the spectral properties of NIR fluorescent carbocyanine probes. In vitro, **1** showed a high ABIR binding affinity (10^{-7} M) comparable to that of **2** and the reference peptide cyclo(RGDfV), indicating that both DFO and cypate motifs did not interfere significantly with the molecular recognition of the cyclic RGD motif with ABIR. Fluorescence microscopy showed that internalization of **1** and **2** in ABIR-positive A549 cells at 1 h postincubation was higher than **3** and cypate alone, demonstrating that incorporating ABIR-targeting RGD motif could improve cellular internalization of DFO analogues. The ensemble of these findings demonstrate the use of multifunctional NIR fluorescent ABIR-targeting DFO analogues to modulate the spectral properties of the NIR fluorescent probe by the chelating properties of DFO and visualize intracellular delivery of DFO by receptor-specific peptides. These features provide a strategy to explore the potential of **1** in tumor imaging and treatment as well as some molecular recognition processes mediated by metal ions.

INTRODUCTION

Recent research efforts have demonstrated that molecular imaging is a powerful tool for localizing, identifying, and characterizing a host of disease-specific targets. Examples include imaging molecular interactions, cell trafficking, tumor vitality, cell proliferation, apoptosis, angiogenesis, and response to treatment. In particular, optical molecular imaging holds great promise to accelerate drug discovery and development, including compound screening, lead discovery, optimization, pharmacokinetic studies, and clinical trials (*1–3*).

An attractive feature of optical imaging is its ability to unravel the molecular basis of cancers and other diseases, thereby providing vital information for diagnosing, staging, and monitoring therapeutic response (*4–6*). These applications emanate from numerous advantages of optical methods, including high detection sensitivity, real-time monitoring, convenience, and accessibility. In contrast to other established imaging methods such as radionuclear and X-ray-computed tomography, the use of low-energy (nonionizing) radiation for optical imaging provides additional benefit, especially in longitudinal studies. Over the past few years, tremendous progress has been made in the development of optical contrast agents for in vivo tumor optical imaging. For instance, we and others have developed NIR fluorescent probes such as cyanine dyes and their bioconjugates, including somatostatin and RGD peptide analogues, as optical contrast agents for in vitro and in vivo tumor optical imaging (*7–13*). These results have inspired us to further apply optical imaging and related optical contrast agents in the discovery and development of novel, multifunctional, and targeted oncologic drugs. For example, the biological properties of therapeutic agents such as desferrioxamine (DFO) can be altered by linkage to a target-specific NIR fluorescent probe and the intracellular transport visualized by optical methods.

DFO, a siderophore initially isolated from *Streptomyces pilosus*, is a selective iron chelator (*14*). This siderphore and some analogues have been used in chelation therapy to treat iron-overload diseases, such as thalassemia, sickle-cell anemia, and hemochromatosis (*15–17*). DFO has also been shown to possess antiproliferative activities, and clinical studies have demonstrated its potential as an adjunct to chemotherapy regimens (*18–21*). Its radiosensitizing activities have been utilized in radiation oncology (*22*). DFO has also served as a good chelator for radioactive metals in cancer nuclear imaging as demonstrated by the use of radioactive ^{67}Ga/^{68}Ga-[DFO]-octreotide to image somatostatin receptor-positive tumors by positron emission tomography (*23*). Despite its lack of oral bioavailability and difficulties in patient compliance, the continued use of DFO in clinical settings strongly attests to its great potential in biomedical applications. It further suggests the potential use of DFO as a lead compound for discovering and developing novel DFO analogues and synthetic mimetics with improved biological properties and activities (*24–27*). However, the biological activity of DFO is not targeted to a specific molecular process and its hydrophilic nature limits its internalization in cells. For these reasons, conjugation of DFO with a receptor-specific ligand such as $\alpha_V\beta_3$ integrin receptor (ABIR)-avid RGD peptide could overcome these problems.

Integrins are heterodimeric cell-surface receptors that mediate cell−cell and cell−matrix adhesion, metastasis, and angiogenesis processes (*28–31*). In particular, the overexpression of ABIR

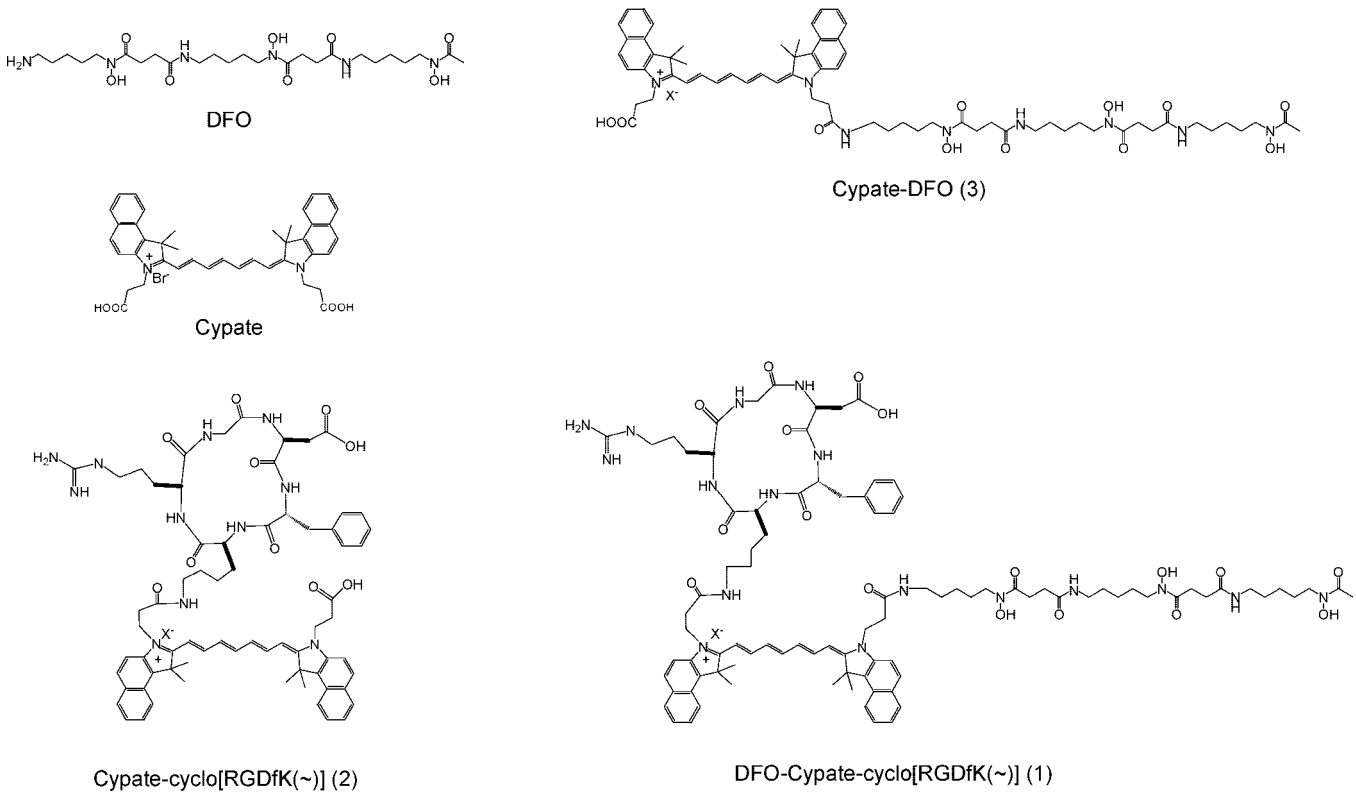

Figure 1. Structures of DFO-cypate-[RGDfK(∼)] (**1**) and the related compounds.

on activated endothelial cells in the neovasculature of tumors such as breast cancer, lung carcinomas, melanomas, and glioblastomas has been correlated with tumor growth, invasion, and metastasis. Therefore, ABIR is an attractive molecular target for tumor imaging, early diagnosis, and therapy (*32*–*37*). Diverse ligands, including peptides and peptidomimetics have been found to interact with ABIR. Some of the high ABIR-binding peptides have been successfully used to elucidate the structure and mechanisms as well as targeted delivery of NIR fluorescent probes, radionuclides, and anticancer agents (*38*–*44*).

In this study, we report the synthesis and in vitro evaluation of **1** and its two analogues, that is, cypate-[RGDfK(∼)] (**2**) and cypate-DFO (**3**) for targeting ABIR (Figure 1). The RGD peptide in the novel multifunctional NIR fluorescent RGD-bearing DFO (**1**) enhanced the cellular uptake of DFO. We also found that the metal-chelating properties of DFO can modulate the NIR fluorescence emission of cypate.

EXPERIMENTAL PROCEDURES

General. All reagents and solvents were purchased from commercial sources. Solvents and chemicals were reagent grade and used without further purification. Cypate was prepared as previously reported (*45*). Analytical (Vydac C-18 column; 250 × 4.6 mm) and semipreparative (Vydac C-18 column; 25 × 2.2 cm) HPLC were performed at a flow rate of 1.0 mL/min and 9.5 mL/min, respectively. HPLC solvents consisted of solvent A (water containing 0.05% trifluoroacetic acid (TFA)) and solvent B (acetonitrile (ACN) containing 0.05% TFA). Linear gradient elution protocol for analytical HPLC started from 90% A to 30% A in B for 20 min. The gradient for semipreparative HPLC ranged from 90% A to 30% A over 15 min and was held at 30% for 30 min. The elution profile was monitored by UV/vis at 214 and 254 nm. Mass spectra (ES-MS) were obtained using a Shimadzu mass spectrometer (LCMS-2010A) in the positive electrospray mode.

Solid Phase Peptide Synthesis. All the peptides were assembled manually on resin using conventional Fmoc chemistry (*46*). The coupling reactions were carried out by adding a preactivated solution of N-α-Fmoc-protected amino acid (3 equiv), 1-hydroxybenzotriazole (HOBt, 3 equiv), 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU, 3 equiv), and *N*,*N*-diisopropylethylamine (DIEA, 6 equiv) in anhydrous *N*,*N*-dimethylformamide (DMF, 3–5 mL/g resin) to the resin (1 equiv) and mixing for 2 h. The progress of the coupling was monitored by the Kaiser test. The Fmoc-protecting group was removed by treating the product with a solution of 20% piperidine in DMF for 10 min (2×). The resin was washed with methanol (1 min, 3 mL, 2×) and DMF (1 min, 3 mL, 6×) and used in subsequent reactions.

Cyclo[Asp(OBut)-phe-Lys-Arg(Pbf)-Gly]. The resin-bound protected peptide (H-Asp(OBut)-phe-Lys-Arg(Pbf)-Gly resin) was assembled manually from H-Gly-2-chlorotrityl resin (1.0 g, 0.54 mmol/g) as described above. The side-chain-protected peptide was cleaved by mixing the resin with 1% TFA in dichloromethane (DCM) for 5 min. The filtrate was added to a solution of pyridine (5 mL)/methanol (10 mL). and the resin was washed with methanol and dichloromethane. The cleavage procedure was repeated 5 times. The combined filtrates were concentrated and washed with water to afford the desired protected RGD pentapeptide H-Asp(OBut)-phe-Lys-(Dde)-Arg-(Pbf)-Gly-OH; 561 mg, 95% yield; ES-MS: $[MH]^+/[MH]^{2+}$ 1094.5/547.8).

The linear peptide obtained was dissolved in DMF (10 mL) and added dropwise into a solution of benzotriazole-1-yl-oxy-tris-pyrrolidino-phosphonium hexafluorophosphate (PyBOP, 520 mg, 1.0 mmol), HOBT (135 mg, 1.0 mmol), and DIEA (207 mg, 1.6 mmol) in DMF (80 mL)/DCM (720 mL). The mixture was stirred overnight, concentrated, and washed with water to give the crude product cyclo[Asp(OBut)-phe-Lys(Dde)-Arg-(Pbf)-Gly] (ES-MS: $[MH]^+$ 1076.3). The solid was dissolved in ACN (47.5 mL)/water (2.5 mL), followed by the addition of hydrazine (2.5 mL). The mixture was stirred for 15 min, concentrated, washed with water, and dried. The product, cyclo[Asp(OBut)-phe-Lys-Arg(Pbf)-Gly], was further purified

by column chromatography (silica gel, methanol/dichloromethane) to afford the desired compound (295 mg, 60% yield; ES-MS: $[MH]^+$ 912.3).

Cypate-cyclo[phe-Lys(~)-Arg(Pbf)-Gly-Asp(OBut)] and Cypate-cyclo[phe-Lys(~)-Arg-Gly-Asp] (2). The protected cyclic peptide obtained above (50 mg, 0.05 mmol) was swirled with a mixture of cypate (141 mg, 0.2 mmol), HOBT (13 mg, 0.1 mmol), and *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (EDCI, 29 mg, 0.15 mmol) in DMF (2.0 mL) overnight. The mixture was concentrated to afford the crude product (ES-MS: $[MH_2]^{2+}$ 759.8) and split into two portions, one of which was dissolved in a mixture of TFA/water (95:5) and deblocked for 4 h. The TFA mixture was added to cold methyl *tert*-butyl ether (MTBE, 10 mL). Finally, the solid precipitate was collected by filtration and purified by HPLC to afford the desired product cypate-cyclo[phe-Lys(~)-Arg-Gly Asp] (9.0 mg, 13% yield; ES-MS: $[MH]^+/[MH_2]^{2+}$ 1210.3/606.0).

DFO-cypate-cyclo[phe-Lys(~)-Arg(Pbf)-Gly-Asp(OBut)] and DFO-cypate-cyclo[phe-Lys(~)-Arg-Gly-Asp] (1). A mixture of DFO (106 mg, 0.15 mmol) and DIEA (19.4 mg, 0.15 mmol) in DMSO (3 mL) was sonicated to obtain a clear solution. The solution was added to cypate-cyclo[phe-Lys(~)-Arg(Pbf)-Gly-Asp(OBut)] (80 mg, 0.05 mmol) in DMF (3 mL), followed by the addition of EDCI (29 mg, 0.15 mmol) and HOBT (21 mg, 0.15 mmol). The mixture was stirred for 3 h and concentrated under high vacuum. Addition of the residue to water (5 mL) precipitated the product, which was collected and purified by HPLC to obtain DFO-cypate-cyclo[phe-Lys(~)-Arg(Pbf)-Gly-Asp(OBut)] (27 mg, 25% yield; ES-MS: $[MH]^{2+}$ 1031.6). The resultant solid (20 mg) was dissolved in TFA (1 mL) and kept at room temperature for 2 h. The TFA solution was concentrated and purified by HPLC to afford DFO-cypate-cyclo[phe-Lys(~)-Arg-Gly-Asp] (7 mg, 40% yield; ES-MS: $[MH]^{2+}/[MH_2]^{3+}$ 877.2/585.1).

Cypate-DFO (3). Deferoxamine mesylate salt (131 mg, 0.2 mmol) was dissolved in DMSO (3 mL) in the presence of DIEA (26 mg, 0.2 mmol) by sonication, followed by the addition of HOBT (27 mg, 0.2 mmol), cypate (141 mg, 0.2 mmol), and EDCI (38 mg, 0.2 mmol). The mixture was stirred at room temperature for 2 h and added with stirring to ether. The precipitate was collected by filtration, one-third of which was purified by HPLC to afford cypate-DFO (25 mg, 30%; ES-MS: $[MH]^+/[MH]^{2+}$ 1167.1/584.4).

Absorption and Emission Spectral Analysis. Absorption and fluorescence spectra were recorded on a DU 640 UV–visible spectrophotometer and Fluorolog-3 fluorometer, respectively. Stock solutions (1.0 mM) were prepared by dissolving each sample in 80% aq DMSO, unless otherwise stated. UV–vis and fluorescence measurements were carried out by sequentially adding 5.0 μL aliquots of the stock solutions via a micropipette into 3 mL of 20% aq DMSO solution in a quartz cuvette. The fluorescence quantum yields of **1**, **2**, **3**, cypate, and ICG in DMSO were determined according to an established protocol and referenced to ICG in DMSO (Q.Y. = 0.13). The absorbance of five serial dilutions of each compound was measured in the concentration range between 0.1 and 1.0 μM. The quantum yield (Φ) was determined according to the following equation (*47*):

$$\Phi_s = \Phi_r(\mathrm{Grad}_s)/(\mathrm{Grad}_r)(\eta_s^2/\eta_r^2)(q_s/q_r)$$

where the subscripts s and r refer to sample and reference ICG (obtained by HPLC purification of commercially available ICG from Aldrich), respectively. η represents the refractive index of the solvent, and q represents a correction factor for the excitation wavelength used. q_s/q_r was assumed to be 1 under similar excitation conditions.

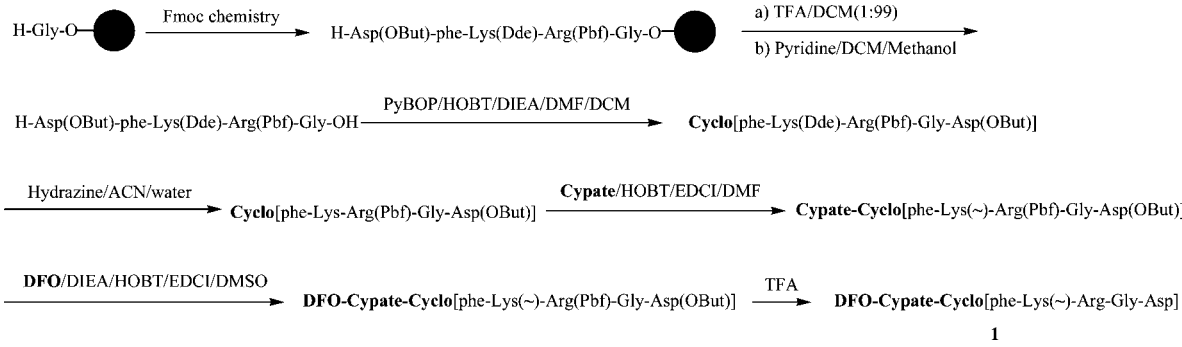
Metal Binding Studies. Stock solutions (1 mM) of compounds **1**, **3**, and DFO were first prepared with 50% aq ACN. We also prepared stock solutions (1 mM) of the following metal salts in distilled water: $Fe(NO_3)_3$, $FeSO_4$, $Al_2(SO_4)_3$, $Ga_2(SO_4)_3$, $InCl_3$, $GdCl_3$, $CuSO_4$, $ZnSO_4$, $Co(NO_3)_2$, $NiCl_2$, $MnCl_2$, $CaCl_2$, $MgCl_2$, and $MgSO_4$. All test solutions (100 μL each) containing 100 μM ligand and 200 μM metal ion were prepared by mixing compounds **1**, **3**, or DFO (10 μL, 1.0 mM) and a metal ion (20 μL, 1.0 mM) in 70 μL of 50% aq ACN. After the solutions were stirred for 2 h, 20 μL of the resulting solutions were subjected to ESI-MS analysis. Each solution (30.0 μL) was added to 2970.0 μL of 20% aq DMSO for UV–vis and fluorescence emission analysis.

ABIR Binding Affinity. Receptor binding assays were performed by using human-purified ABIR protein from Chemicon International, Inc. (Temecula, CA) using the method reported previously (*48*). Briefly, assays were carried out in the Millipore Duropore membrane 96-well plates and the Millipore MultiScreen system (Bedfore, MA). ^{125}I-echistatin was purchased from Amersham Biosciences (Piscataway, NJ). The specific activity of the radiolabeled peptide was ~2000 Ci/mmol. Radiochemical purity (90%) was determined by reverse-phase HPLC. The 96-well membrane plate was blocked with 0.1% polyethylenimine blocking solution overnight at 4 °C. ^{125}I-echistatin (50 nmol/L) was added to the binding buffer (50 mM Tris-HCl, pH 7.4, 100 mM NaCl, 2 mM $CaCl_2$, 1 mM $MgCl_2$, 1 mM $MnCl_2$, and 1% BSA) containing integrin ABIR protein (50 ng per well in 96-well membrane plate) and ligands in a total volume of 200 μL per well. The concentration range of ligand was between 0.01 μM and 100 μM. The mixtures were incubated for 2 h at room temperature, filtered by centrifugation at 1500*g*, and washed with 0.20 mL of ice-cold binding buffer (3×). The filters containing radioactivity-bound ABIR were removed using a punch apparatus and counted using a Packard Cobra II Autogamma counter (Meriden, CT). Nonspecific binding of ^{125}I-echistatin was between 5 to 10% of the total binding. The 50% inhibitory concentrations (IC_{50}) were calculated by nonlinear regression analysis using GraphPad Prism 4 data fitting software (GraphPad Software, Inc., San Diego, CA). Three independent binding assays were performed in triplicate per sample.

Cell Culture. The human nonsmall cell carcinoma cell line A549 is widely used to study the role of integrins in normal and pathophysiological processes. These cells were purchased from ATCC and grown in 75 cm tissue culture flasks or on Laboratory-Tek chambered slides in Ham's F12K medium with 2 mM L-glutamine supplemented with 1.5 g/L sodium bicarbonate, 10% fetal calf serum, 100 units/mL penicillin, and 100 units/mL streptomycin under humidified atmosphere containing 5% CO_2 at 37 °C.

Internalization and Fluorescence Microscopy. A549 cells were grown on Laboratory-Tek slides. The culture medium was replaced, and the cells were incubated for different times up to 24 h at 37 °C in the presence of the cypate-labeled DFO probes (1 μM in 0.02% DMSO). After treatment, cells were washed (3×) with PBS containing 1 mM $CaCl_2$ and mounted with Prolong Gold containing DAPI mounting medium and coverslipped (Invitrogen). For fluorescence microscopy, cells were visualized with an Olympus FV1000 microscope using a 60X/1.20M, 0.13–0.21 NA water immersion objective. Fluorescence emission was detected from 805–830 nm using a 780 nm laser at 100% transmission for excitation. Images of each group of slides were acquired with the same microscope settings during a single imaging session, allowing for qualitative comparison of the relative fluorescence. The relative fluorescence intensity of five regions of interest for each image was determined with Slidebook software from Olympus and the results averaged. The

Scheme 1. Synthesis of DFO-cypate-[RGDfK(∼)] (1)



results were normalized to the average relative fluorescence of DFO-cypate treated cells.

For mitochondrial staining, 5 nm Mitotracker Green (Invitrogen) was added during the last 15 min of incubation. For lysosomal staining, cells were stained with anti-LAMP1 antibody as described in the literature (*49*). Briefly, cells were fixed for 15 min with 4% paraformaldehyde for 15 min, after which they were washed 3× with PBS containing 1 mM $CaCl_2$. Slides were incubated for 1 h at room temperature with 10% rabbit serum to block nonspecific binding after which they were incubated overnight at 4 °C with 2 μg/mL anti-LAMP1 goat polyclonal IgG (Santa Cruz). After washing 3× with PBS, slides were incubated for 1 h at room temperature with 10 μg/mL Cy3 conjugated rabbit antigoat IgG (Zymed). After washing 3× with PBS, slides were mounted with Prolong Gold and coverslipped. Cells were visualized with an Olympus FV1000 microscope using a 60X/1.20M, 0.13–0.21 NA water immersion objective. Fluorescence emission was detected by using a 488 nm laser at 5% transmission and 500–600 nm emission (Mitotracker green) or by using a 543 nm laser at 15% transmission and 555–655 nm emission (LAMP-1).

RESULTS AND DISCUSSION

Molecular Design. Previously, we reported the synthesis and applications of a dicarboxylic acid-containing carbocyanine fluorophore (cypate) (*10, 45*). The facile synthesis of cypate and its excellent NIR spectral properties have allowed us to conveniently label diverse peptides and other bioactive molecules with cypate in solution and on solid support. Particularly, the two carboxylic acid groups of cypate have facilitated its use as an optical scaffold to construct diverse bioactive NIR fluorescent molecular probes, such as monomeric, dimeric, macrocyclic, and multivalent analogues (*8,45,50,51*). Conjugation of cypate with small peptides that target specific cell-surface receptors, such as ABIR and the somatostatin receptor, allows site-specific targeting of diseased tissues for optical imaging (*9, 10, 51*). In particular, previous reports have shown that cyclic RGD pentapeptide cyclo(RGDfV) and some of its analogues bind to ABIR with high affinity and selectivity. Further modification of the biological properties of cypate-labeled RGD peptides could be obtained by incorporating another bioactive molecule such as DFO.

The metal-binding properties and the related biological activities of DFO have been ascribed to its three hydroxamate groups (*26, 52*). Therefore, the amino group of DFO provides a desirable site for its structural modification. In this work, we used cypate to construct a three-pronged architecture bearing both the DFO motif and ABIR-targeting RGD peptide (cyclo[RGDfK(∼)] (Figure 1). We anticipated that the new NIR fluorescent RGD-bearing DFO compound (**1**) would serve as a multifunctional platform for biomedical applications. For example, the RGD peptide motif could be used for the targeted delivery of DFO to ABIR positive tumors, while cypate serves as the optical antenna to track, visualize, and quantify the fate of **1** in cells and in vivo by NIR fluorescence imaging. In addition, the integration of DFO and RGD peptide into cypate could cooperatively enhance the related biological activities. Finally, the metal-binding DFO could modify the structure, function, and regulation of divalent, cation-dependent ABIR (*28, 38*). Together, these potential applications of NIR fluorescent DFO compounds motivated the design, synthesis, and evaluation of the compounds described in this article.

Synthesis. As shown in Scheme 1, synthesis of the multifunctional compound **1** consists of three major steps: (i) synthesis of the protecting RGD peptide, (ii) cypate conjugation, and (iii) DFO conjugation. The resin-bound protected RGD penta-peptide, H-Asp(OBut)-phe-Lys(Dde)-Arg(Pbf)-Gly-O-Resin (**1**), was first assembled on a H-Gly-loaded 2-chlorotrityl resin using conventional Fmoc chemistry. Cleavage of the protected peptide with 1% TFA in DCM afforded the desired protected RGD pentapeptide, H-Asp(OBut)-phe-Lys(Dde)-Arg-(Pbf)-Gly-OH. This linear peptide was cyclized to form cyclo-[phe-Lys(Dde)-Arg(Pbf)-Gly-Asp(OBut)] in the presence of PyBOP, HOBT, and DIEA in solution. Removal of the ε-amino lysine-protecting Dde group with hydrazine in aqueous acetonitrile afforded cyclo[phe-Lys-Arg(Pbf)-Gly-Asp(OBu^t)], which was further purified by flash column chromatography. The conjugation of the cyclic peptide (1 equiv) and cypate (3 equiv) was achieved in the presence of EDCI and HOBT in anhydrous DMF. Similarly the crude product, cypate-[Arg(Pbf)-Gly-Asp(OBut)-phe-Lys(∼)], was coupled with DFO, as reported previously (*53*). Aqueous TFA was used to deblock the resultant product, DFO-cypate-[Arg(Pbf)-Gly-Asp(OBut)-phe-Lys(∼)], which was then purified by HPLC to give the desired compound **1**, DFO-cypate-cyclo[Arg-Gly-Asp-phe-Lys]. The identity and purity of the compound were confirmed by both HPLC and ES-MS. A combination of solution and solid-phase reactions facilitated the preparation of all compounds used in this study.

Spectral Properties. Stock solutions (1 mM) of the DFO-containing compounds were prepared in DMSO, and spectral measurements were carried out by adding 5 μL aliquots of the stock solutions via a micropipette into 3 mL of DMSO solution in a quartz cuvette. All of the compounds showed similar spectral features, with minor spectral shifts in the absorption and emission maxima (Figure 2). The attachment of cyclo-[RGDfK(∼)] to cypate increased the molar absorptivity (ε) while the DFO attachment decreased ε (Table 1). Compound **1** containing both DFO and cyclo[RGDfK(∼)] showed similar ε with cypate. Overall, conjugation of the highly hydrophilic DFO to cypate improved the water solubility of the dye without effect on its spectral properties.

Metal Binding Studies. Siderophores such as DFO are good ligands for Fe(III), and the biological activities of DFO are

Table 1. Optical Properties of the Compounds in DMSO

compds	$\lambda_{max(ab)}$	$\lambda_{max(em)}$	ε (cm^{-1} M^{-1})	Φ (excited at 730 nm)
1	793	816	2.0×10^5	0.10
2	792	817	2.3×10^5	0.10
3	788	815	1.4×10^5	0.17
cypate	791	814	2.1×10^5	0.12
ICG	794	820	1.9×10^5	0.13

related to its metal-binding properties (*20*, *54–56*). Previous studies have shown that DFO and the related hydroxamate compounds also possess high binding affinities with Al(III) and Ga(III) (*26*, *53*). Therefore, we evaluated the metal-binding properties of **1** and the related effects on the corresponding optical properties of DFO-bearing fluorescent compounds. Because of its high sensitivity, we used ES-MS to study metal coordination with DFO, as described previously (*26*, *57*). This method is suitable for screening the relative metal-binding selectivity and affinity of some compounds, especially those in limited supply.

Compounds **1**, **3**, and DFO (100 μM in 50% aq acetonitrile) were screened for their binding with 13 different metal ions, Fe(III), Al(III), Ga(III), In(III), Gd(III), Cu(II), Zn(II), Co(II), Ni(II), Mn(II), Fe(II), Ca(II), and Mg(II), at 200 μM in water. All the three DFO-bearing compounds exhibited high binding affinity and selectivity for Ga(III), Al(III), and Fe(III) compared to the other metal ions. The ES-MS spectra of **1** and the metal chelates shown in Figure 3 are representative of the trend observed for these compounds. Compound **1** showed two typical doubly and triply charged peaks at 876.7 and 584.9 in its ES-MS spectrum. Upon metal binding, these peaks were replaced by the corresponding doubly charged (903.5, 889.0, and 910.1) and triply charged (602.2, 592.8, and 607.5) peaks of the resulting Ga(III), Al(III), and Fe(III) complexes, respectively. These peaks were correlated with the theoretical masses based on $[(L\text{-}3H)MH_n]^{n+}$, where L and M represent the molecular weight of a ligand and a metal, respectively. The high abundance of the desired metal chelate peaks with negligible residue from the starting DFO ligands strongly suggests the complete formation of 1:1 metal complexes in aq ACN.

We further calculated the relative metal-binding affinity (%) of each ligand as a percentage of the relative abundance of the metal-binding ligand peaks with the total ligand-related peaks in a positive ES-MS spectrum according to the following equation, as reported previously (*26*, *58*):

$$[LFe^2 + LFe^3]/[L^2 + L^3 + LFe^2 + LFe^3 + L]\times 100\%$$

where L^2 and LFe^2 are the doubly charged peak abundance of a ligand and its complex, while L^3 and LFe^3 are the triply charged peak abundance of a ligand and its complex. The related peaks associated with the addition of sodium ions were also calculated. As shown in Figure 4, the ES-MS analysis clearly demonstrated the relative metal binding selectivity and affinity with Fe(III), Fe(II), Ga(III), Al(III), and In(III). Despite their structural differences, the metal binding selectivity of **1**, **3**, and DFO was similar, indicating that the chelating property of DFO was maintained, independent of the molecular design.

In contrast to the ES-MS spectra of Ga(III) and Al(III), the addition of Fe(III) and Cu(II) resulted in complicated ES-MS spectra with multiple peaks around the doubly and triply charged peaks. This observation suggests that Cu(II) had weaker binding with **1**, but might greatly impact the ionization of **1** and the stability of the resulting ions in gas phase. In addition, the low abundance of the related 1:1 ligand/metal complex indicates that Cu(II) binding might occur between two or more ligands of **1** with two or more Cu(II).

The relatively high binding affinity of DFO-bearing compounds with Fe(III), Al(III), and Ga(III) makes it possible to further functionalize **1** via metal binding. Therefore, we prepared and isolated the Ga(III) complex of **1** to demonstrate the feasibility of obtaining fluorescent DFO chelates. By mixing **1** with excess Ga(III) in aq ACN, the Ga(III) complex was obtained by HPLC purification and further characterized by ES-MS. The metal complex has a longer retention time than **1**, suggesting that the coordination of Ga(III) by the three DFO hydroxamates reduces the hydrophilicity of **1** (Figure 5). The successful preparation and characterization of the Ga(III) complex provide an exciting dimension for exploring additional applications of this compound in biomedicine.

Spectrally, there was no significant change in the green color of **1** upon the additions of the metals, with the exception of Fe(III), Fe(II), and Cu(II), where a change was observed (Figure 6). Clearly, the addition of Cu(II) and Fe(III) markedly decreased the UV–vis absorption and quenched the fluorescence emission of **1** as shown in Figure 6. On the basis of the ES-MS analysis discussed above, it is likely that spectral changes by these metals occurred by different

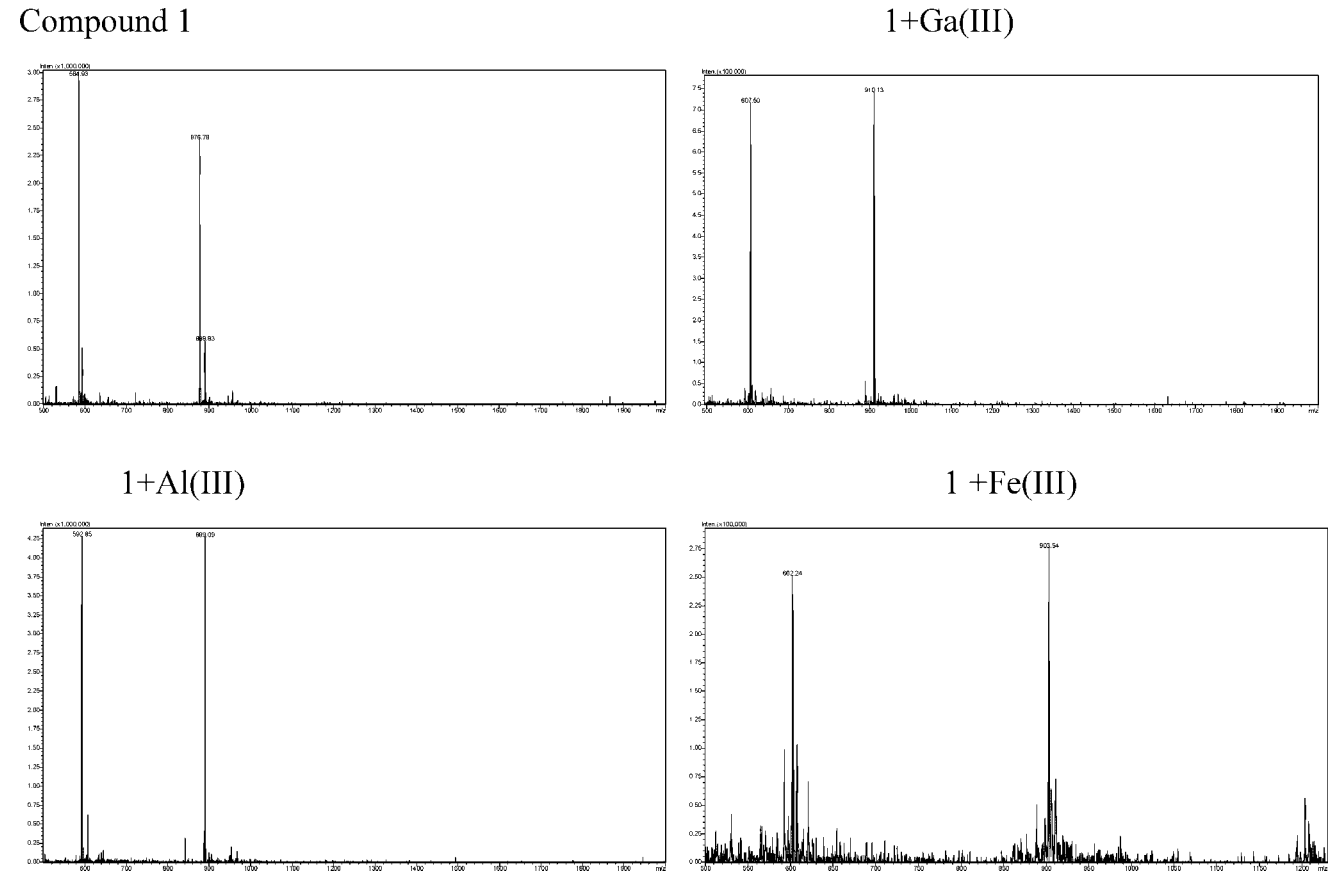

Figure 3. ES-M spectra of **1** and its Ga(III), Al(III), and Fe(III) complexes (100 μM) in 50% aq ACN.

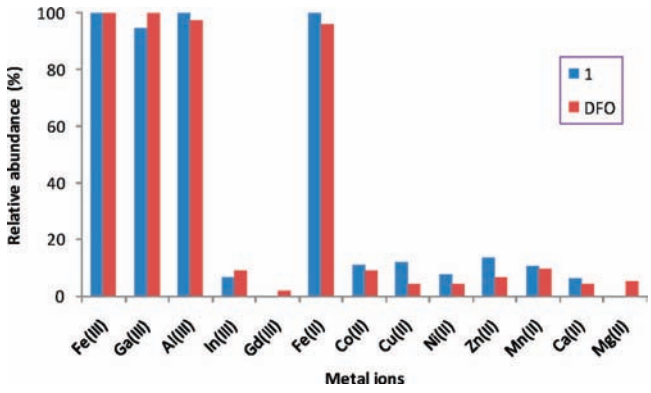

Figure 4. Relative binding affinities of **1**and DFO with different metal ions at a molar ratio of 1:2 as determined by ES-MS.

mechanisms. While Cu (II) appears to quench fluorescence by interacting directly with the cypate motif, the stable Fe complex may quench fluorescence by the photoinduced electron transfer mechanism. In contrast to Fe(III) and Cu(II), Ga(III) binding did not significantly alter the UV–vis absorbance of **1**. Interestingly, Ga(III) seemed to enhance light emission to some extent. This finding is in agreement with a previous study with **3**, where a similar enhancement was observed (*53*). Considering that a DFO chelate of radioactive Ga(III) has been used previously for nuclear imaging, the Ga(III)-mediated fluorescence enhancement favors the use of the Ga(III) complex of compounds **1** and **3** to develop a dual optical-nuclear imaging agent. In addition, the contrasting effects of Fe(III) and Ga(III) on the optical properties of cypate provide an efficient approach to perturb the spectral properties of NIR fluorescent carbocyanine probes via metal binding.

Receptor Binding Assays. Among the diverse RGD peptides that have been developed for targeting ABIR, the lactam-based cyclic penta-peptide cyclo(RGDfV) and its analogues are well known for their high binding affinity and selectivity with ABIR. In this study, commercially available ABIR-avid peptide cyclo(RGDfV) was used as a reference compound to study the effect of DFO on the ABIR binding affinity of **1** and **2**. The IC_{50} values of these compounds were determined by competitive inhibition of Echistatin binding to purified ABIR, as described previously (*48, 59*). Echistatin is a polypeptide that binds irreversibly with high affinity and specificity to the ABIR and the radiolabeled analogue. ^{125}I-echistatin was used as a tracer in the binding assay. Compounds **1**, **2**, and cyclo(RGDfV) were found to have IC_{50} values of 1.8×10^{-7} M, 7.7×10^{-8} M, and 4.1×10^{-7} M, respectively. Under similar conditions, the presence of the DFO motif in **1** decreased the ABIR affinity of **2** by a factor of about 2, but the resulting affinity was comparable to that of the reference cyclic RGD compound. These findings indicate that the RGD peptide can modulate the biological activities of DFO through receptor-mediated delivery of this otherwise nonspecific drug to target tissue and cells.

Cell Internalization. Uptake and distribution of drugs and contrast agents in cells provide a key index for understanding the functions and predicting the in vivo behavior of fluorescent compounds. Therefore, labeling DFO with fluorescent dye allows the use of the resultant molecule as molecular probe for imaging DFO distribution in cells. Considering that the ABIR binding assay revealed the retention of RGD peptide binding affinity by **1**, we assessed the internalization and subcellular distribution of **1**, **2**, and **3** in an ABIR-positive cell line, A549. The incubation of A549 cells with **3** (1 μM) in medium containing 0.02% DMSO showed minimal uptake of the compound, with normalized fluorescence similar to the back-

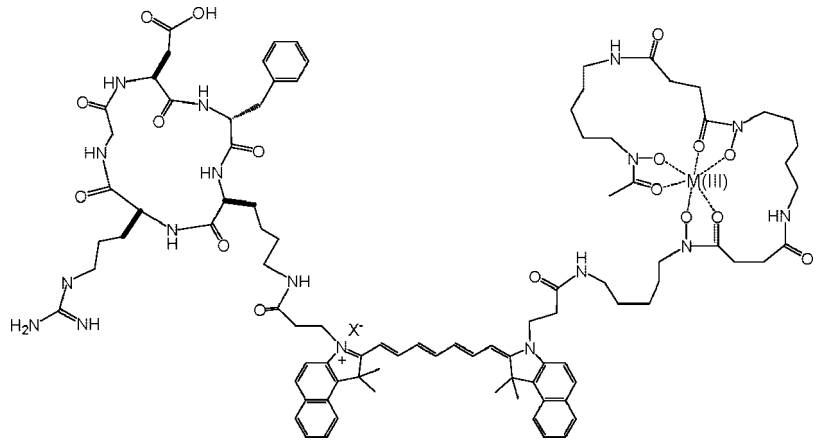

Figure 5. Proposed metal complex structure of **1**.

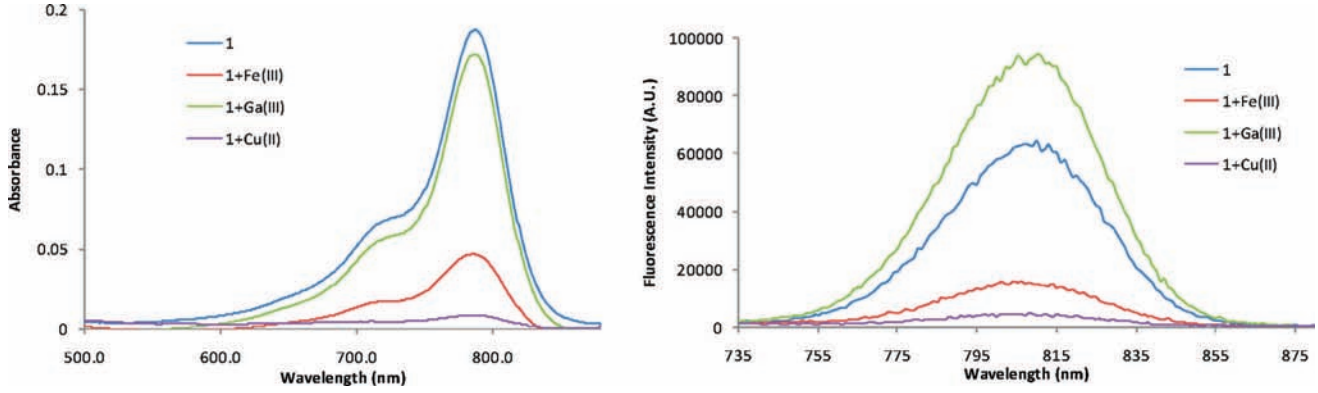

Figure 6. Effects of Ga(III), Fe(III), and Cu(II) ions on UV–vis and emission spectra of 1 in 20% aq DMSO.

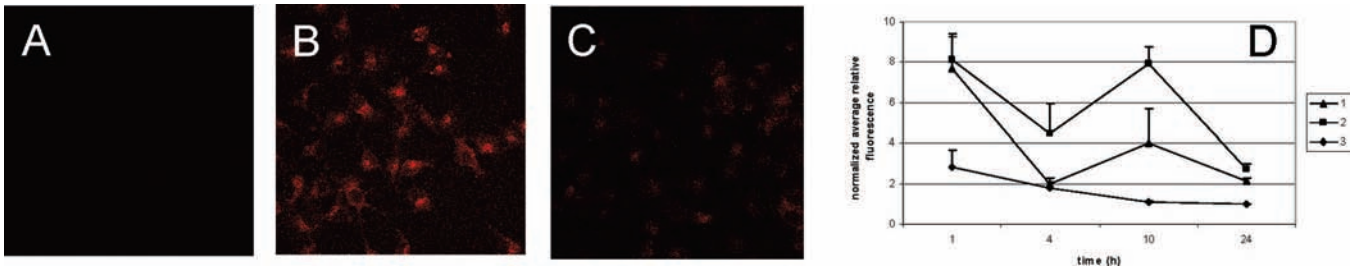

Figure 7. Internalization in A549 cells treated for 10 h with 1 μM of compounds **3** (A), **2** (B), or **1** (C) and quantitation of the internalization of each compound as a function of time (D).

ground signal (Figure 7). Expectedly, hydrophilic molecules such as DFO have difficulty crossing the plasma membranes of cells without an active transport mechanism. In contrast, both **1** and **2** internalized rapidly within 1 h post incubation and remained in the intracellular space up to 10 h. The enhanced internalizations of **1** and **2** could be ascribed to the interaction of the RGD peptide with ABIR in the cell membranes. Thus, the RGD peptide provided an endocytotic pathway for DFO. At 1 h postincubation, the internalization of **1** and **2** in A549 cells was similar to each other, but the retention of **1** in the cells was lower at longer incubation times than that of **2** (Figure 7D). The differences in the internalization rate appear to correlate with their ABIR binding affinity, with **2** having higher affinity than **1**. Once internalized, however, the rates of subsequent efflux of the two compounds from the cell were similar, with the intracellular fluorescence intensity for both compounds approaching background at 24 h post incubation. The fluctuations in fluorescence shown in Figure 7D could be attributed to changes in receptor density as a function of time.

On the basis of the dissimilarity in structural features, ABIR binding affinity, and internalization rates, we expected differences in the intracellular distribution of compounds **1**, **2**, and **3**. Interestingly, once inside the cell, all three compounds appeared to localize in the mitochondria, the lysosomes, and the cytosol (Figures 8 and 9). The absence of identifiable uptake in the cell nuclei favors using the fluorescent DFO compounds as imaging agents because of the need to minimize nuclear translocation of imaging agents, thereby preventing the potential mutagenic effect on the cells.

CONCLUSIONS

We have developed a novel multifunctional molecular probe consisting of a metal-chelating DFO, a NIR fluorescent cypate, and an ABIR-avid cyclic RGD peptide. Each component synergistically contributes to the overall properties of new compound **1**. Cypate provides a detectable signal for imaging purposes; the RGD peptide effectively delivers both cypate and DFO into cells; and metal-binding DFO efficiently

modulates the optical properties of cypate. The impressive ABIR-mediated internalization of **1** in cells without permeating the cell nucleus is advantageous for imaging applications, where nuclear uptake can be detrimental to the cells and living organisms. This work represents our initial effort toward the discovery and development of novel ABIR-targeting DFO compounds for optical imaging. Specifically, **1** provides a multifunctional molecular platform for optimizing the structure, improving biological activities, exploring new applications, and understanding the mechanisms of action. The synthetic approach we used is amenable to combinatorial chemistry and the parallel synthesis of diverse NIR fluorescent DFO analogues.

Received August 15, 2007; Revised Manuscript Received October 4, 2007

Affibody molecules are a new class of small (7 kDa) scaffold affinity proteins, which demonstrate promising properties as agents for *in vivo* radionuclide targeting. The Affibody scaffold is cysteine-free and therefore independent of disulfide bonds. Thus, a single thiol group can be engineered into the protein by introduction of one cysteine. Coupling of thiol-reactive bifunctional chelators can enable site-specific labeling of recombinantly produced Affibody molecules. In this study, the use of 1,4,7,10-tetraazacyclododecane-1,4,7-tris-acetic acid-10-maleimidoethylacetamide (MMA-DOTA) for ^{111}In-labeling of anti-HER2 Affibody molecules His_6-$Z_{HER2:342}$-Cys and $Z_{HER2:2395}$-Cys has been evaluated. The introduction of a cysteine residue did not affect the affinity of the proteins, which was 29 pM for His_6-$Z_{HER2:342}$-Cys and 27 pM for $Z_{HER2:2395}$-Cys, comparable with 22 pM for the parental $Z_{HER2:342}$. MMA-DOTA was conjugated to DTT-reduced Affibody molecules with a coupling efficiency of 93% using a 1:1 molar ratio of chelator to protein. The conjugates were labeled with ^{111}In to a specific radioactivity of up to 7 GBq/mmol, with preserved binding for the target HER2. In vivo, the non-His-tagged variant ^{111}In-[MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$-Cys demonstrated appreciably lower liver uptake than its His-tag-containing counterpart. In mice bearing HER2-expressing LS174T xenografts, ^{111}In-[MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$-Cys showed specific and rapid tumor localization, and rapid clearance from blood and nonspecific compartments, leading to a tumor-to-blood-ratio of 18 ± 8 already 1 h p.i. Four hours p.i., the tumor-to-blood ratio was 138 ± 8. Xenografts were clearly visualized already 1 h p.i.

INTRODUCTION

A growing number of cellular genotype and phenotype changes associated with the malignant transformation of cells have been identified. This knowledge is utilized for development of drugs that target particular alterations in gene expression. Due to the diversity of cancer phenotypes, only a fraction of all patients may benefit from a given targeted therapeutic drug. Therefore, targeting medicines need to be personalized, i.e., adapted to the cancer phenotype of the individual patient. For example, the HER2 tyrosine kinase receptor is the target for the humanized monoclonal antibody trastuzumab (Herceptin), which is approved for the clinical treatment of breast cancer. However, only 25–30% of all breast cancer patients display tumor disease overexpressing HER2, and *in vivo* detection of HER2 overexpression is therefore necessary (*1*, *2*). Radionuclide molecular imaging of HER2 expression in tumors may help to avoid problems associated with biopsies, such as sampling errors and discordance of HER2 expression in primary tumors and metastases. Initial attempts for radionuclide imaging were done using ^{111}In-labeled trastuzumab to identify potential responders to trastuzumab therapy (*3*). However, the sensitivity of detection was low (*4*). Generally speaking, low sensitivity is a problem when using full-size IgG antibodies as targeting agents for imaging, since their long residence time in blood causes high background and reduces contrast of imaging. The use of smaller targeting proteins, e.g., $(Fab')_2$, Fab, and scFv antibody fragments, with more rapid tumor localization and more rapid clearance is considered a promising way to increase the radionuclide imaging contrast.

One class of promising candidates for *in vivo* targeting agents are Affibody molecules, small (7 kDa) proteins based on a modified scaffold of the B-domain of protein A (*5*). Affibody molecule libraries are constructed by randomization of 13 amino acids in helix 1 and 2 of the modified domain B. Selection is performed, e.g., by phage display and enables development of high-affinity binders to protein targets. The selection of the Affibody molecule $Z_{HER2:342}$, binding the extracellular domain of HER2 with an affinity of 22 pM, was described earlier (*6*), and high-contrast imaging of HER2-expressing xenografts after indirect radioiodination was demonstrated. However, indirect radioiodination is a two-step labeling procedure followed by purification, which might complicate its translation into hospital radiopharmacy and delay introduction into routine clinical use. A coupling of suitable chelators and the use of radioactive metals, such as, e.g., ^{111}In ($T_{1/2}$ = 2.8 days), as labels enables kit formulation and simplifies logistics of radiopharmaceutical distribution and preparation. The use of benzyl isothiocyanate derivatives of DTPA (*7*) and DOTA (*8*) has been evaluated for labeling of recombinant $Z_{HER2:342}$ with ^{111}In. Both types of chelator could be used to make conjugates capable of specific imaging of HER2 *in vivo*, but ^{111}In-benzyl-DTPA-$Z_{HER2:342}$ (further referred to as ^{111}In-Bz-DTPA-Z_{342}) provided better tumor-to-blood ratio (50 ± 14 vs 23 ± 5) and tumor-to-liver

ratio (3.2 ± 0.6 vs 1.5 ± 0.1) than ^{111}In-Bz-DOTA-Z_{342} in a direct head-to-head comparison 4 h p.i. in mice bearing HER2-expressing xenografts (*8*). Isothiocyanate reacts to amino groups. The $Z_{HER2:342}$ Affibody molecule contains 7 amino groups, 1 at the N-terminus and 6 on lysine residue side chains. As expected, coupling with isothiocyanate produced a heterogeneous mixture of conjugates, containing different numbers of chelators, attached randomly at different positions. Clearly, a controlled site-specific attachment of chelator is more desirable, since it provides a homogeneous product with high batch-to-batch reproducibility. The spontaneously folding cysteine-independent structure of Affibody molecules enables a complete peptide synthesis of this protein and site-specific incorporation of different functional groups (*9*). Synthetic Affibody molecules $Z_{HER2:342}$ with chelators incorporated at the N-terminus have been prepared and characterized *in vivo* (*10*−*12*). DOTA has been used for labeling with ^{111}In (*10*) and mercaptoacetyl-containing peptide-based chelators maGGG and maSSS for labeling with ^{99m}Tc (*11, 12*). *In vivo* molecular imaging using synthetic ^{111}In-DOTA-$Z_{HER2:342}$ (further referred to as ^{111}In-DOTA-Z_{342}) resulted in specific and high-contrast targeting of HER2-expressing xenografts in mice (tumor-to-blood ratio of 7 already 1 h p.i.). Moreover, the clinical utility of this tracer in SPECT and PET has been confirmed, following labeling with ^{111}In or ^{68}Ga, respectively (*13, 14*).

Chemical production is only suitable for production of small proteinaceous agents such as monovalent Affibody molecules. Larger molecules, including dimeric or bispecific Affibody molecules, have to be produced recombinantly. Also, in this case, site-specific labeling is desirable. The absence of cysteines in the Affibody molecule provides the possibility to obtain a unique attachment site by introduction of a single cysteine, e.g., as a C-terminal residue. The use of a bifunctional chelator, linker molecule, or other reporter with a thiol-reactive moiety, e.g., maleimide or iodoacetamide, enables directed conjugation with this particular cysteine. This has been used previously for coupling of, e.g., Oregon Green 488 or horseradish peroxidase (HRP) to the dimeric Affibody molecule $(Z_{HER2:477})_2$-Cys (*15*) for *in vitro* detection of HER2. The use of the ((4-hydroxyphenyl)ethyl)maleimide (HPEM) linker molecule enabled site-specific labeling of a dimeric form of a previous generation of the HER2-binding Affibody molecule with radiobromine (*16*) and radioiodine (*17*).

The goal of the present study was to evaluate site-specific labeling of cysteine-containing Affibody molecules with ^{111}In using the chelator maleimide-monoamide-DOTA (MMA-DOTA; 1,4,7,10-tetraazacyclododecane-1,4,7-tris-acetic acid-10-maleimidoethylacetamide). For this purpose, several cysteine-containing variants of Affibody molecules were produced, conjugated with MMA-DOTA, and labeled with ^{111}In. In a comparative biodistribution, a His-tag containing variant, ^{111}In-[MMA-DOTA-Cys^{61}]-His_6-$Z_{HER2:342}$-Cys (further referred to as ^{111}In-DOTA-H_6-Z_{342}-C), was compared with non-His-tagged ^{111}In-[MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$-Cys (further referred to as ^{111}In-DOTA-Z_{2395}-C) and synthetic ^{111}In-DOTA-Z_{342} variants. The tumor-targeting properties of the best recombinant cysteine-containing site-specifically labeled variant, ^{111}In-DOTA-Z_{2395}-C, were compared in tumor-bearing mice with the synthetic ^{111}In-DOTA-Z_{342} and the best previous recombinantly produced conjugate with non-site-specific coupling of the chelator, ^{111}In-Bz-DTPA-Z_{342}.

MATERIALS AND METHODS

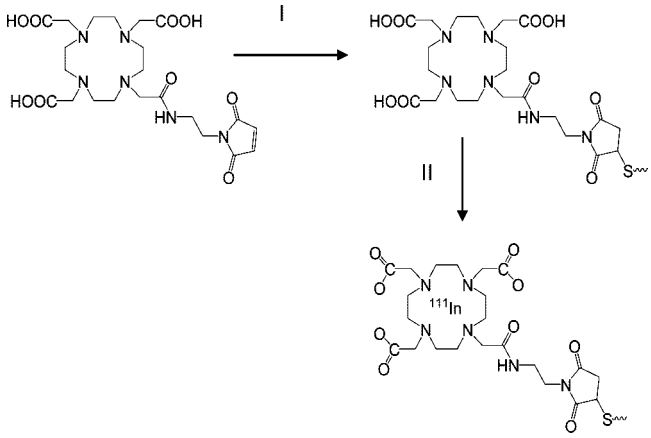
Materials. MMA-DOTA was purchased from Macrocyclics (Dallas, TX, USA). A synthetic DOTA-$Z_{HER2:342}$ was made by standard Fmoc peptide synthesis in a single chemical process by Bachem (Bubendorf, Switzerland) and labeled as described by Orlova et al. (*10*). A recombinant ^{111}In-Bz-DTPA-Z_{342} was produced and labeled according to Tolmachev et al. (*6*). Buffers, such as 0.1 M phosphate buffered saline (PBS), pH 7.5, and 0.2 M ammonium acetate, pH 5.5, were prepared using common methods from chemicals supplied by Merck (Darmstadt, Germany). High-quality Milli-Q water (resistance higher than 18 MΩ/cm) was used for preparing solutions. Buffers, which were used for conjugation and labeling, were purified from metal contamination using Chelex 100 resin (Bio-Rad Laboratories, Richmond, CA, USA). PD-10 and NAP-5 size exclusion columns were from Amersham Biosciences, Uppsala, Sweden. [^{111}In]indium chloride was purchased from Tyco. Silica gel impregnated glass fiber sheets for instant thin-layer chromatography (ITLC SG) were from Gelman Sciences Inc. Cells in the *in vitro* experiments were detached using trypsin-EDTA solution (0.25% trypsin, 0.02% EDTA in buffer, Biochrom AG, Berlin, Germany). Ketalar (50 mg/mL, Pfizer, NY, USA), Rompun (20 mg/mL, Bayer, Leverkusen, Germany), and Heparin (5000 IE/mL, Leo Pharma, Köpenhamn, Danmark) were obtained commercially. Data on cellular uptake, biodistribution, and gamma camera images were analyzed by unpaired, two-tailed *t*-test using *GraphPad Prism* (version 4.00 for Windows GraphPad Software, San Diego, California, USA) in order to determine any significant differences ($P < 0.05$).

Instrumentation. The radioactivity was measured using an automated gamma counter with 3 in. NaI(Tl) detector (1480 WIZARD, Wallac Oy, Turku, Finland). ^{111}In was measured with the use of both photopeaks and summation peak (energy setting from 140 to 507 keV). Distribution of radioactivity along the ITLC strips and SDS-PAGE gels was measured on a Cyclone Storage Phosphor System (further referred to as PhosphorImager) and analyzed using the *OptiQuant* image analysis software. Cells were counted using electronic cell counter (Beckman Coulter). The Affibody molecule were analyzed by high-performance liquid chromatography and online mass spectrometry (HPLC-MS) using an Agilent 1100 HPLC/MSD. The mass spectrometer was equipped with electrospray ionization (ESI) and single quadropol. The software used for analysis and evaluation was *Chemstation Rev. B.02.01*. (Agilent). For HPLC-MS analysis, 60 μL of diluted sample (1:1 dilution with solution A: 0.1% TFA in MQ-water) was loaded onto a Zorbax 300SB-C18 (4.6 × 150, 3.5 μm) RPC column equilibrated with solution A with 15% solution B (0.1% TFA in acetonitrile) at a flow rate of 1 mL/min. After 2 min with 15% B solution, the proteins were eluted using a linear gradient, 15–65% solution B in 22 min. The mass spectrometer was run according to the manufacturer's recommendations. SDS-PAGE analysis was performed using NuPAGE 4–12% Bis-Tris Gel (Invitrogen) in MES buffer (200 V constant). Affinity of Affibody molecules to HER2 was analyzed using a Biacore 2000 instrument (Biacore, Uppsala, Sweden) according to the method described earlier (*10*). Melting point analysis was performed using a JASCO J-810 spectropolarimeter (JASCO, Tokyo, Japan) as described earlier (*11*).

Protein Expression and Purification. A C-terminal cysteine was introduced into Affibody molecules according to a method described earlier (*16*). *Escherichia coli* BL21(DE3)/pAY01662 was run in an 800 mL batch fermentor cultivation (System Greta, Belach Bioteknik AB, Sweden) at 37 °C using TSB+YE-medium (30 g/L Tryptic Soy Broth (Merck), 5 g/L Yeast Extract (Merck)) supplemented with 50 mg/mL Kanamycin. The culture was automatically induced at an OD (600 nm) of 1 by the addition of IPTG to a concentration of 0.5 mM. Five hours after induction, the culture was automatically cooled to <10 °C and harvested by centrifugation (20 min at 15 900*g*).

His_6-tagged proteins were IMAC purified under denaturing conditions using QIAfilter 96 Plates Ni-NTA Superflow kit and

Scheme 1. Conjugation of the MMA-DOTA to Cysteine-Containing Affibody Molecules and Labeling of the Conjugate[a]



[a] Reagents and conditions: (I) Affibody molecule reduced by DTT, in 0.02 M ascorbic acid; acetate buffer, pH 5.5; 37 °C; overnight; purification on NAP-5, elution in 0.2 M ammonium acetate, pH 5.5. (II) ^{111}In-$InCl_3$, 0.2 M ammonium acetate buffer, pH 5.5, 60 °C, 30 min.

QIAsoft 4.1, medium-scale protein/Ni-NTA Superflow 96 Denat program on a Biorobot 3000 (Qiagen). The protein samples refolded when dialyzed in PBS using Slide-A-Lyzer (Pierce) according to the manufacturer's recommendations.

For purification of $Z_{HER2:2395}$-Cys without His_6-tag, the bacterial pellet was first resuspended in 20 mL 20 mM Tris pH 7.5 and then incubated at 90 °C for 3 min. After centrifugation (25 000*g*, 20 min, 4 °C), the supernatant was loaded onto a 20 mL Q Sepharose FF packed in a XK16 column, at a flow rate of 2 mL/min. The flowthrough was collected and DTT added to a final concentration of 20 mM. After incubation for 30 min at room temperature, acetonitrile (ACN) was added to a final concentration of 10%, and the solution was loaded onto a 1 mL Resource 15RPC column. The Affibody molecule was eluted using a linear gradient of 0–50% B in 15 min (A, 0.1% TFA/H_2O, 10% ACN/H_2O; B, 0.1% TFA, 80% ACN in H_2O). The buffer of the eluate was changed to PBS on a PD-10 column, and the protein concentration was calculated from the measured absorption values at 280 nm. Extinction coefficients were theoretically calculated from the primary amino acid sequence. A non-HER2-specific Z_{Taq}-Cys Affibody molecule was produced similarly to $Z_{HER2:2395}$-Cys. All proteins were analyzed by HPLC-MS and SDS-PAGE, as described in the Instrumentation section.

Conjugation and Labeling Chemistry. The conjugation of MMA-DOTA to the Affibody molecules was performed according to Scheme 1.

Before labeling, a solution of Affibody molecules (2 mg/mL in PBS) was treated with dithiothreitol (DTT, E. Merck, Darmstadt, Germany) in order to reduce spontaneously formed intermolecular disulfide bonds. Typically, 0.5 mL of stock Affibody solution (2 mg/mL in PBS) was mixed with 15 μL of DTT (1 M solution in water, freshly prepared) and incubated for 120 min at 37 °C. Thereafter, the mixture was applied to NAP-5 size-exclusion columns, pre-equilibrated and eluted with well-degassed 0.02 M ascorbic acid in MilliQ water, and the first 900 μL of the high-molecular-weight (HMW) fraction were used for coupling. For the coupling with a calculated chelator-to-Affibody molecule ratio of 1:1, 300 μL of the solution of reduced $Z_{HER2:2395}$ was mixed with 34 μL MMA-DOTA solution in MilliQ water (1 mg/mL), and 100 μL 1 M ammonium acetate buffer, pH 5.5 was added. The vial was filled with argon gas and incubated at 37 °C overnight. Purification from nonconjugated chelators and the change to a 0.2 M ammonium acetate buffer, pH 5.5, was made on a disposable NAP-5 size exclusion column. The conjugate solution was frozen and stored at −18 °C before labeling. The coupling efficiency was analyzed by HPLC-MS.

To evaluate kinetics of labeling, experiments were performed at 60 °C at least in duplicates. Conjugate (25 μg in 0.2 M ammonium acetate) was mixed with 7.5 MBq ^{111}In in 0.05 M HCl and incubated for 60 min. At predesignated time points (15, 30, and 60 min), a sample of 0.5 μL was taken and analyzed using ITLC SG with 0.2 M citric acid as the mobile phase. Additionally, radiolabeled Affibody molecules were analyzed using SDS-PAGE.

In further experiments, specific radioactivity was increased up to 1 MBq/μg (7 GBq/μmol).

For biodistribution experiments and cell studies, 60 min incubation was used for the labeling. For cell studies and biodistribution experiments, the sample was diluted with PBS.

Affibody molecules used in comparison experiments, i.e., [MMA-DOTA]-Z_{Taq}-Cys, and DOTA-H_6-Z_{342}-C, were conjugated and labeled in the same way as DOTA-Z_{2395}-C. Labeling yield after 60 min was analyzed using ITLC.

As a label stability test, two samples of ^{111}In-DOTA-Z_{2395}-C were mixed with a 1000-fold molar excess of EDTA in PBS. The samples were incubated at room temperature. After 3 h, the samples were analyzed using ITLC.

***In Vitro* Cell Binding and Retention.** Binding specificity of ^{111}In-DOTA-Z_{2395}-C and ^{111}In-DOTA-H_6-Z_{342}-C were tested on HER2-expressing SKOV-3 ovarian cancer cells. For each conjugate, two groups of Petri dishes (3 dishes/group; diameter, 3.5 cm; $\sim 3 \times 10^5$ cells/dish) were incubated using a 1:1 molar ratio of the radiolabeled Affibody molecule to HER2 receptors (1.2×10^6 receptors per cell (*18*)). The cells in one group were presaturated with 1000-fold excess of nonlabeled $Z_{HER2:342}$ for 5 min before the radiolabeled conjugate was added. Cells were incubated with labeled conjugate for 1 h at 37 °C before incubation medium was collected. The cells were washed once with cold serum-free medium followed by treatment with 0.5 mL trypsin-EDTA solution for 10 min at 37 °C. When cells were detached, 0.5 mL complete media was added to each dish, and the cells were resuspended and collected. The radioactivity associated with the cells and medium, respectively, was measured in an automatic gamma counter.

To study cellular retention and internalization of radioactivity, cultured SKOV-3 cells were incubated for 3 h at 4 °C using a 5:1 molar ration of ^{111}In-DOTA-Z_{2395}-C to HER2 receptors. All procedures were performed on ice. Thereafter, the incubation media was discarded, and the cells were washed three times using ice-cold serum-free medium. After addition of 1 mL complete medium, the cells were incubated further at 37 °C. At designated time points, up to 24 h, one group of three dishes was analyzed for cell-associated radioactivity. Medium was collected; cells were washed three times with ice-cold serum-free medium (these two steps were omitted for time point 0 h) and treated with 0.5 mL 4 M urea solution in 0.2 M glycine buffer, pH 2.5, for 5 min on ice. The acid fraction was collected, and cells were washed with additional 0.5 mL acid solution. The radioactivity in the acid wash fraction was considered membrane-bound radioactivity. After addition of 0.5 mL 1 M NaOH, the cells were incubated at 37 °C for at least 0.5 h, and basic solution was collected. Dishes were washed with additional 0.5 mL basic solution. The radioactivity in the alkaline fractions was considered internalized radioactivity. The radioactivity content of the samples was measured as mentioned above. To evaluate if the radioactivity in the media presented intact dissociated ^{111}In-DOTA-Z_{2395}-C or externalized radiocatabolites, the media, taken at 4, 8, and 24 h after start of incubation, was

Table 1. Characterization of Recombinant Cysteine-Containing Affibody Molecules

peptide	molecular weight[a] (Da)	k_a[b] (1/Ms)	k_d[b] (1/s)	K_D[b] (M)	T_m (°C)
His_6-$Z_{HER2:342}$-Cys	8317	4.72×10^6	1.38×10^{-4}	2.92×10^{-11}	65
$Z_{HER2:2395}$-Cys	6994.6	1.35×10^7	3.63×10^{-4}	2.68×10^{-11}	70

[a] Molecular weight was determined after reduction with DTT. [b] For Biacore measurement of affinity to HER2-Fc, Affibody molecules were reduced with DTT, and cysteine was capped with *N*-ethylmaleimide.

analyzed using NAP-5 disposable size-exclusion columns (cutoff for globular proteins 5 kDa), pre-equilibrated with 2% albumin in PBS.

Animal Studies. The animal experiment were planned and performed in accordance with national legislation on laboratory animals' protection. The animal study plans have been approved by the local Ethics Committee for Animal Research in Uppsala. Biodistribution studies in non-tumor-bearing mice were performed in female immunocompetent Naval Medical Research Institute (NMRI) mice. In all experiments on tumor-bearing mice, female outbreed BALB/c nu/nu mice were used. The mice were kept using standard diet, bedding, and environment with free access to food and water. All mice were acclimatized for one week at the Rudbeck Laboratory animal facility before any experimental procedures. Xenografts of HER2-expressing LS174T colon adenocarcinoma cell line were subcutaneously implanted in the right hind leg. For xenografting, 7×10^5 LS174T cell were used. At the time of experiment, the average tumor size was 0.26 ± 0.08 g.

In each experiment, mice were randomized into groups of four. Animals were injected intravenously with 1 μg conjugate (50 kBq) in 100 μL PBS. In all biodistributions, the mice were sacrificed at the predetermined time point, 4 h postinjection (p.i.) (except one group of animals, bearing LS174T xenografts, which was sacrificed 1 h p.i.). After an intraperitoneal injection of Ketalar-Rompun solution (20 μL of solution per gram body weight; Ketalar [ketamine]: 10 mg/mL; Rompun [xylazin]: 1 mg/mL), the mice were euthanized with heart puncture using a 1 mL syringe, prewashed with diluted heparin (5000 IE/mL). Blood was collected in preweighed vials. Lung, liver, spleen, colon, kidneys, tumor (from xenografted mice), muscle, bone, gastrointestinal tract (with its content), and remaining carcass were excised and collected in preweighed plastic vials. Organs and tissue samples were weighed and measured for radioactivity using an automatic gamma counter. The tissue uptake values were calculated as percent injected activity per gram tissue (% IA/g) except for the gastrointestinal tract and the carcass, which were calculated as % IA per whole sample. The radioactivity in the gastrointestinal tract with its content was used as a measure of hepatobiliary excretion, while the small (about 100 mg) part of the colon provided information concerning radioactivity accumulation in the intestine wall.

The biodistributions on NMRI mice were performed as a comparison of three different labeled constructs, two recombinant, ^{111}In-DOTA-H_6-Z_{342}-C and non-His-tagged ^{111}In-DOTA-Z_{2395}-C, along with one synthetic ^{111}In-DOTA-Z_{342} for one time point, 4 h p.i.

In the study on animals bearing LS174T xenografts, tumor targeting and biodistribution of ^{111}In-DOTA-Z_{2395}-C at 1 and 4 h p.i. was performed. Animals in the blocking experiments were subcutaneously injected with 600 μg of unlabeled His_6-$Z_{HER2:342}$ 45 min before injection of radiolabeled Affibody molecule. Mice in the blocking group were killed 4 h after injection. As another specificity test, the biodistribution of non-HER2-specific ^{111}In-[MMA-DOTA-Cys^{61}]-Z_{Taq}-Cys (further referred to as ^{111}In-DOTA-Z_{Taq}-C) was studied 4 h p.i. in mice bearing LS174T xenografts. For comparison, biodistributions of synthetic ^{111}In-DOTA-Z_{342} and recombinant ^{111}In-Bz-DTPA-Z_{342} were studied in the same batch of LS174T-grafted mice, 4 h p.i.

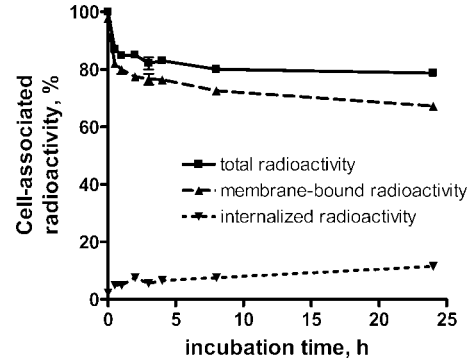


Figure 1. Cell-associated radioactivity as a function of time after interrupted incubation of SKOV-3 cells with ^{111}In-[MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$-Cys. The cell-associated radioactivity at time zero after the interrupted incubation was considered to be 100%. The radioactivity, which was removed from cells by treatment with 4 M urea solution in 0.2 M glycine buffer, pH 2.5, was considered membrane-bound, and the rest, internalized. Data are presented as mean $\pm$ SD ($n = 3$). Error bars might not be seen because they are smaller that point symbols.

For gamma camera imaging, four LS174T xenograft-bearing mice were injected with 4.5 MBq ^{111}In-DOTA-Z_{2395}-C (amount of protein 3 μg). Two of the animals, used as a blocking group, were preinjected with unlabeled Affibody molecules as described above. Immediately before imaging, 1 h postinjection, the animals were sacrificed by overdosing Ketalar/Rompun. After euthanasia, the urine bladders were dissected. Imaging was performed at the department of Nuclear Medicine at Uppsala University Hospital using a Millenium GE gamma camera equipped with a medium-energy general purpose (MEGP) collimator. Static images (10 min), obtained with a zoom factor of 3, were digitally stored in a 256×256 matrix. The evaluation of the images was performed using a Hermes system (Nuclear Diagnostics, Stockholm). In each animal, a region of interest (ROI) was drawn around the tumor. The same region was copied to a contralateral thigh. Tumor-to-contralateral thigh ratios were calculated on the basis of total counts in the ROIs.

RESULTS

Analysis of Peptides. Data concerning characterization of Affibody molecules are presented in Table 1. All purified proteins demonstrated a single peak on LC-MS with a mass, coinciding with the theoretically calculated accuracy of ± 1.5 Da, which is within the accuracy of the instrument. All proteins also demonstrated one single band on SDS-PAGE gel. Apparently, an introduction of a cysteine at the C-terminus did not have any effect on the binding to HER2, since the dissociation constant of both cysteine-containing derivatives did not deviate from the dissociation constant (K_D) of the parental $Z_{HER2:342}$ Affibody molecule, within the accuracy of the measurement method.

Conjugation and Labeling Chemistry. The LC-MS analysis showed that a coupling efficiency of 93% was obtained using a 1:1 molar ratio of chelator to Affibody molecule, and that a single chelator was attached per protein. In the case of chelators-to-protein molar ration 3:1, no unconjugated Affibody molecules were detected in the product. The ^{111}In labeling kinetics of DOTA-Z_{2395}-C was monitored by ITLC, and yields of 95 $\pm$

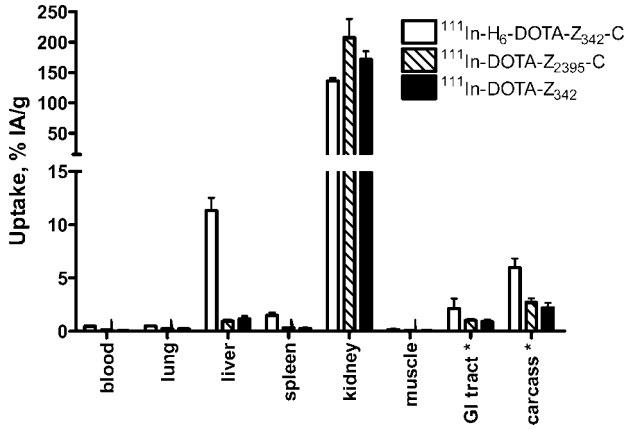

Figure 2. Biodistribution of radiolabeled recombinant ^{111}In-[MMA-DOTA-Cys^{61}]-His$_6$-Z$_{HER2:342}$-Cys (^{111}In-DOTA-H$_6$-Z$_{342}$-C), a non-His-tagged ^{111}In-[MMA-DOTA-Cys^{61}]-Z$_{HER2:2395}$-Cys (^{111}In-DOTA-Z$_{2395}$-C), and a synthetic ^{111}In-DOTA-Z$_{HER2:342}$ (^{111}In-DOTA-Z$_{342}$) Affibody molecules in NMRI normal mice 4 p.i. Data are expressed as % IA/g (percent of injected radioactivity per gram tissue) and presented as an average from four animals ± SD *Data for the gastrointestinal tract (with its content) and for carcass are presented as % IA per whole sample.

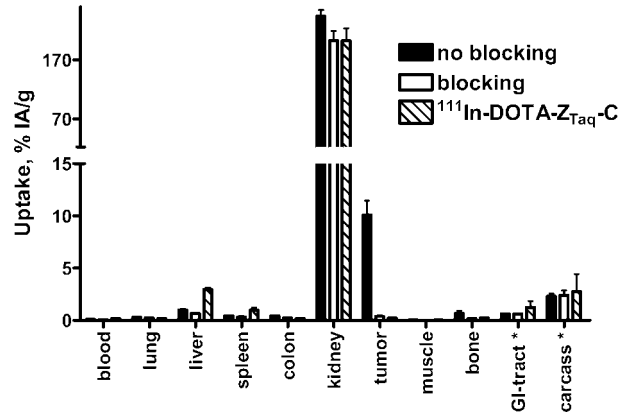

Figure 3. Specificity of ^{111}In-[MMA-DOTA-Cys^{61}]-Z$_{HER2:2395}$-Cys tumor uptake in LS174T xenografts, 4 h p.i. In order to saturate HER2 receptors in tumors, one group of animals was preinjected with 600 μg nonlabeled Z$_{HER2:342}$ 45 min before injection of radiolabeled conjugate (designated as blocking). As another negative control, one group was injected with non-HER2-specific ^{111}In-[MMA-DOTA-Cys^{61}]-Z$_{Taq}$-Cys (designated as ^{111}In-DOTA-Z$_{Taq}$-C). All animals were injected with 1 μg of labeled Affibody molecules. Data are expressed as % IA/g (percent of injected radioactivity per gram tissue) and presented as an average from four animals ± SD. *Data for the gastrointestinal tract (with its content) and for carcass are presented as % IA per whole sample.

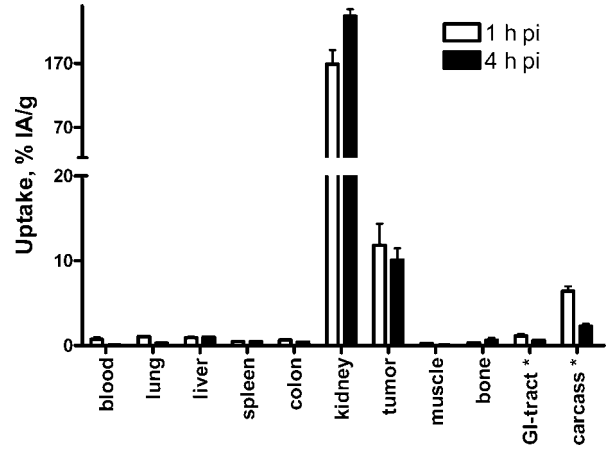

Figure 4. Biodistribution of ^{111}In-[MMA-DOTA-Cys^{61}]-Z$_{HER2:2395}$-Cys (^{111}In-DOTA-Z$_{2395}$-C) in BALB/C nu/nu mice bearing LS174T xenografts 1 and 4 p.i. Data are expressed as % IA/g (percent of injected radioactivity per gram tissue) and presented as an average from four animals ± SD. *Data for the gastrointestinal tract (with its content) and for carcass are presented as % IA per whole sample.

6%, 97 ± 1%, and 100% ^{111}In-DOTA-Z$_{2395}$-C were obtained after 15, 30, and 60 min, respectively. A specific radioactivity of 7 GBq/μmol was obtained. A PhosphorImager analysis of radioactivity distribution on an SDS-PAGE gel demonstrated a single radioactivity peak at a position of DOTA-Z$_{2395}$-C. The conjugate was stable. After 3 h challenge with 1000-fold molar excess of EDTA, 97.1 ± 0.6% of the radioactivity was still associated with ^{111}In-DOTA-Z$_{2395}$-C. Labeling of other MMA-DOTA-conjugated Affibody molecules, such as DOTA-H$_6$-Z$_{342}$-C or nonspecific control Affibody molecule DOTA-Z$_{Taq}$-C, provided radiochemical purity of more than 95% after 60 min labeling at 60 °C. For biological experiments, all conjugates were used without additional purification.

***In Vitro* Binding and Retention.** In the specificity test, 42 ± 1% of the added radioactivity was cell-bound to the nonblocked HER2-expressing SKOV-3 cells after 1 h of incubation at 37 °C. In the group where the HER2 receptors were saturated with nonlabeled Affibody molecules, the cell-bound radioactivity was significantly reduced to 1.3 ± 0.3% ($p < 1 \times 10^{-5}$). This demonstrated that binding of ^{111}In-DOTA-Z$_{2395}$-C to HER2-expressing cells was specific. Similarly, the binding of ^{111}In-DOTA-H$_6$-Z$_{342}$-C to SKOV-3 cells was also found to be specific.

The result of the cellular retention and internalization test of ^{111}In-DOTA-Z$_{2395}$-C is presented in Figure 1. The conjugate was efficiently retained by HER2-expressing cells. The internalization was, however, slow and inefficient. The percentages of nondegraded Affibody molecules in the incubation media were 77.3 ± 1.0%, 69.2 ± 0.8%, and 54.9 ± 0.6%, after 4, 8, and 24 h, respectively.

Apparently, cellular retention of the total radioactivity was quite good, with 78.7 ± 0.6% of cell-associated radioactivity after 24 h of incubation at 37 °C. On the other hand, the internalization of ^{111}In-DOTA-Z$_{2395}$-C was relatively slow, with less than 12% of internalized radioactivity after 24 h. An increasing fraction of low-molecular-weight radioactivity indicates, however, that at least a part of the conjugate was intracellularly degraded and radiocatabolites were externalized. Still, this fraction accounts even after 24 h for only about 10% of the radioactivity, initially bound to the cells.

Animal Studies. A comparison of the biodistributions of three different labeled constructs, two recombinant, ^{111}In -DOTA-H$_6$-Z$_{342}$-C and non-His-tagged ^{111}In-DOTA-Z$_{2395}$-C, as well as one synthetic ^{111}In-DOTA-Z$_{342}$ in NMRI mice at 4 h after i.v. injection is presented in Figure 2.

The biodistribution data of ^{111}In-DOTA-Z$_{342}$ were in very good agreement with the previously published data (*10*). The general pattern of all three conjugates is characterized by quick clearance of radioactivity from blood as well as the majority of organs and tissues, but accumulation in kidneys due to predominantly renal excretion and reabsorption in the proximal tubulae. The biodistributions of the recombinant ^{111}In-DOTA-Z$_{2395}$-C and the synthetic ^{111}In-DOTA-Z$_{342}$ were nearly identical. The only significant difference between these two conjugates was a lower level of blood radioactivity of ^{111}In-DOTA-Z$_{342}$, 0.06 ± 0.02 vs 0.10 ± 0.01 ($p < 0.05$) at 4 h p.i. The biodistribution of ^{111}In-DOTA-H$_6$-Z$_{342}$-C differed appreciably from the biodistributions of the two other conjugates. Although radioactivity accumulation in muscle and gastrointestinal tract did not differ significantly, the blood levels were 5−8-fold higher. The level of radioactivity in the organs, which are in

[a] Data are presented as an average from four animals ± SD. [b] Significant difference ($p < 0.05$) between tumor-to-organ ratios at 1 and 4 h p.i. for ^{111}In-[MMA-DOTA-Cys^{61}]-His$_6$-$Z_{HER2:342}$-Cys (^{111}In-DOTA-Z_{2395}-C). [c] Significant difference ($p < 0.05$) between tumor-to-organ ratios 4 h p.i. for ^{111}In-DOTA-Z_{2395}-C and synthetic ^{111}In-DOTA-$Z_{HER2:342}$ (^{111}In-DOTA-Z_{342}). [d] Significant difference ($p < 0.05$) between tumor-to-organ ratios 4 h p.i. for ^{111}In-DOTA-Z_{2395}-C and ^{111}In-benzyl-DTPA-$Z_{HER2:342}$ (^{111}In-Bz-DTPA-Z_{342}).

equilibrium with blood, such as lung and spleen, was higher accordingly. Furthermore, the clearance from the rest of the body was slower. However, the largest difference was seen in the liver uptake, which was about 10-fold higher for His-tagged ^{111}In-DOTA-H_6-Z_{342}-C than for the other two conjugates. Most likely, an arrest of radioactivity in the liver was the reason for reduced renal uptake of ^{111}In-DOTA-H_6-Z_{342}-C (136 ± 4% IA/g) in comparison with ^{111}In-DOTA-Z_{2395}-C and ^{111}In-DOTA-Z_{342} (194 ± 17% IA/g and 172 ± 13% IA/g, respectively). Overall, the biodistributions indicated that ^{111}In-DOTA-H_6-Z_{342}-C was considerably less suitable for future imaging applications compared to ^{111}In-DOTA-Z_{2395}-C, wherefore the His-tagged conjugate was excluded from further evaluation.

To investigate whether the tumor uptake *in vivo* was receptor-mediated, a biodistribution of ^{111}In-DOTA-Z_{2395}-C in nude mice bearing LS174T xenografts was compared with biodistribution of non-HER2-specific Affibody molecule ^{111}In-DOTA-Z_{Taq}-C, which was labeled in the same way and had the same structure, but 12 amino acids in the binding site were different. In addition, another group of mice was preinjected with a large amount of nonlabeled His6-$Z_{HER2:342}$ in order to saturate HER2 receptors in the xenografts. The results of *in vivo* specificity tests are presented in Figure 3. Presaturation of receptors led to more than a 26-fold decrease in tumor uptake of radioactivity, from 10.7 ± 0.6% IA/g to 0.4 ± 0.1% IA/g ($p < 0.0001$). Somewhat lower uptake in other organs after blocking indicates, probably, saturation of murine counterpart of HER2. In the mice injected with ^{111}In-DOTA-Z_{Taq}-C, the tumor uptake was also much lower, 0.21 ± 0.05% IA/g ($p < 0.0001$). The results of these two independent tests demonstrate specific uptake of ^{111}In-DOTA-Z_{2395}-C in tumor xenografts.

A comparison of the biodistribution of ^{111}In-DOTA-Z_{2395}-C in nude mice bearing LS174T xenografts 1 and 4 h p.i. is presented in Figure 4. The conjugate was characterized by quick blood clearance, with 0.73 ± 0.24% IA/g remaining in the blood 1 h p.i. and only 0.10 ± 0.03% IA/g 4 h p.i. High renal uptake indicates that the substance was cleared almost exclusively through the kidneys. The radioactivity in the gastrointestinal tract (with its content) was low at both time points, showing the minor role of the hepatobiliary clearance. The radioactivity in the kidneys increased between 1 and 4 h p.i., along with clearance from carcass and nonspecific tissues, such as blood, lung, colon, and muscle. Besides kidneys, the only site of high uptake was the tumor. A high tumor uptake (11.8 ± 2.6% IA/g) was already detected 1 h after injection and did not change significantly during the experiment, showing rapid tumor localization of the tracer. At this time point, the radioactivity concentrated in the tumor significantly exceeded the concentration in all organs and tissues, including blood (see tumor-to-blood ratios, Table 2). The only exception from this was the kidneys. Generally, tumor-to-organ ratios increased between 1 and 4 h p.i. due to decrease of the radioactivity in nonspecific organs.

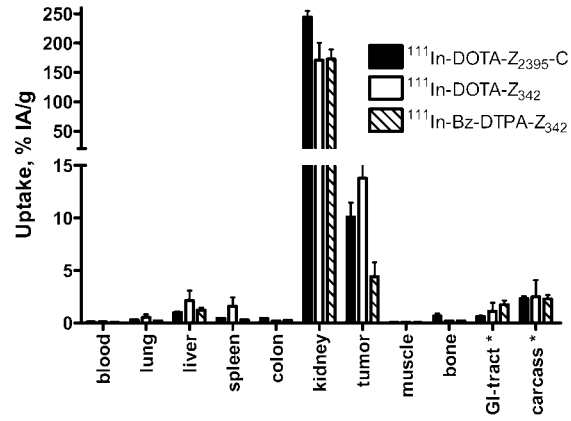

Figure 5. Biodistribution of a radiolabeled ^{111}In-[MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$-Cys (^{111}In-DOTA-Z_{2395}-C), synthetic ^{111}In-DOTA-$Z_{HER2:342}$ (^{111}In-DOTA-Z_{342}), and randomly coupled ^{111}In-benzyl-DTPA-$Z_{HER2:342}$ (^{111}In-Bz-DTPA-Z_{342}) Affibody molecules in BALB/C nu/nu mice bearing LS174T xenografts 4 p.i. Data are expressed as % IA/g (percent of injected radioactivity per gram tissue) and presented as an average from four animals ± SD. *Data for the gastrointestinal tract (with its content) and for carcass are presented as % IA per whole sample.

The comparison of biodistribution of ^{111}In-DOTA-Z_{2395}-C with biodistribution of the recombinant ^{111}In-Bz-DTPA-Z_{342} and the synthetic ^{111}In-DOTA-Z_{342} in nude mice bearing LS174T xenografts (4 h p.i.) are shown in Figures 5, 6 and Table 2. The radioactivity uptake of ^{111}In-Bz-DTPA-Z_{342} and ^{111}In-DOTA-Z_{342} in normal tissues was in good agreement with the data on these conjugates published earlier (*5, 8, 10*). Generally, the overall pattern of biodistribution of all three conjugates was similar. All conjugates were cleared rapidly from blood and normal tissues. The clearance was predominantly renal, with a high degree of reabsorption in kidneys. The degree of hepatobiliary clearance, as indicated by radioactivity in gastrointestinal tract, was low. Still, there were some distinct features of the conjugates. For example, tumor uptake of ^{111}In-Bz-DTPA-Z_{342} (with a randomly coupled chelator) was significantly ($p < 0.01$) lower than uptake of both conjugates with a site-specific attachment of DOTA. On the other hand, this conjugate provided significantly lower radioactivity content in blood, lung, spleen, colon, and kidneys in comparison to the ^{111}In-DOTA-Z_{2395}-C. Recombinant ^{111}In-DOTA-Z_{2395}-C had significantly lower accumulation in liver, spleen, and colon in comparison to synthetic ^{111}In-DOTA-Z_{342}, but higher in kidneys and bones. The tumor uptake of both conjugates did not differ significantly.

Gamma Camera Imaging. Images acquired 1 h after the i.v. injection of the ^{111}In-DOTA-Z_{2395}-C into immunodeficient

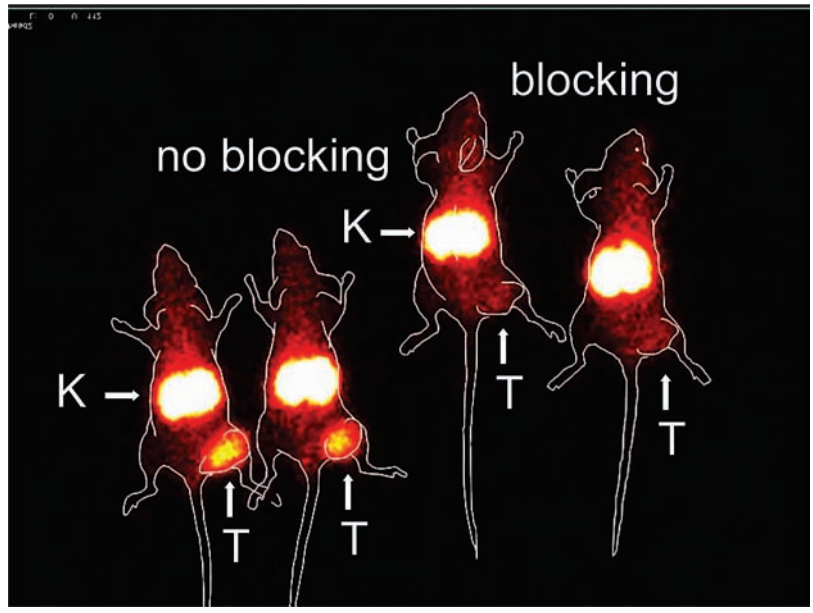

Figure 6. Imaging of HER2 expression in LS174T xenografts in BALB/c nu/nu mice using ^{111}In-[MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$-Cys (^{111}In-DOTA-Z_{2395}-C). In the blocking experiment, the HER2 receptors were saturated through a preinjection of 600 μg nonlabeled Affibody molecules. Planar gamma images were collected 1 h after administration of ^{111}In-DOTA-Z_{2395}-C. Tumors (right hind leg) were clearly visualized without blocking but were not seen in the blocking experiment, indicating specific HER2 binding of ^{111}In-DOTA-Z_{2395}-C. Animal contours were derived from a digital photograph and superimposed over γ-camera image to facilitate interpretation. Arrows point at tumors (T) and kidneys (K).

mice bearing subcutaneous LS174T xenografts confirmed feasibility of tumor visualization already at this time point (Figure 6). As predicted from the biodistribution studies, described above, the renal route of elimination of the conjugates also led to substantial kidney retention. Other organs and tissues were not visualized, and the contrast was high. Tumor-to-contralateral thigh ratio was 11.8 $\pm$ 1.2 (average $\pm$ max error). Specificity of HER2 imaging using ^{111}In-DOTA-Z_{2395}-C was also confirmed in this experiment, since LS174T xenografts on mice preinjected with nonlabeled Affibody molecule to saturate HER2 receptors were not visualized. Tumor-to-contralateral thigh ratio was 2.9 $\pm$ 0.3 in the case of receptor saturation.

DISCUSSION

Earlier, several commercially available chelators, such as isothiocyanatobenzyl-DTPA (*7*), isothiocyanatobenzyl-DOTA (*8*), and CHX-A″-DTPA (*19*) have been coupled to amino groups of recombinantly produced anti-HER2 Affibody molecules. This resulted in ^{111}In-labeled conjugates with good imaging properties, although some important differences have been observed. For example, at the same degree of coupling, the use of acyclic chelators provided lower liver uptake and higher tumor-to-liver ratios in comparison with DOTA. This is important, since the liver is a common site for metastases from many different malignancies, and high tumor-to-liver contrast is desirable. Although successful with the HER2-binding Affibody molecule, other Affibody molecules and targeting agents might contain lysines in the binding site, which due to conformational features could be more prone to coupling to isothiocyanate, resulting in conjugates with reduced targeting capacity. To obtain a pure homogeneous product becomes a challenge as soon as there is more than one amine group available for coupling, unless the protein is made by peptide synthesis.

Although site-specific labeling at the N-terminal amine of Affibody molecules has been obtained by peptide synthesis, site-specific coupling of a chelator to a C-terminal cysteine may be a more generally applicable method than N-terminal modification of Affibody molecules, because the C-terminus is located further away from the binding site.

The use of commercially available MMA-DOTA enabled a straightforward coupling of the chelator to Affibody molecules with a high yield. The use of slightly acidic conditions enabled a high degree of coupling specificity due to protonation of the amino groups (a maleimide might couple to deprotonated amines). By the use of chelator-to-protein ratio of 3 in the reaction mixture, a uniform conjugate was obtained.

A labeling of the conjugate with ^{111}In was rapid and efficient at the modestly elevated temperature, 60 °C. Earlier, we showed that even warming up to 90 °C did not decrease binding capacity of parental Affibody molecule $Z_{HER2:342}$ (*10*). The results of the EDTA challenge indicate that, after labeling during 30 min at 60 °C, ^{111}In is stably bound to the Affibody ligand *via* the chelator and not by occasional binding sites on the protein backbone or by unstable off-cage binding to DOTA. The results of the *in vitro* studies on HER2-expressing SKOV-3 carcinoma cells indicated that both ^{111}In-DOTA-H_6-Z_{342}-C and ^{111}In-DOTA-Z_{2395}-C preserved their binding specificity after labeling. The cellular retention of ^{111}In-DOTA-Z_{2395}-C by SKOV-3 was good during the whole experiment (24 h) and was mainly due to a high-strength membrane binding, not due to intracellular trapping. Although an internalization of a targeting peptide with an residualizing label was generally considered a prerequisite for successful retention (*20*), the recent finding with somatostatin analogues suggest that noninternalizing antagonists may enable sufficient targeting provided that affinity is high enough (*21*).

Although the *in vitro* experiments demonstrated high stability of the conjugate and its firm binding, a biodistribution characterization is an important step. It is known that changes of chelator or a few amino acids in somatostatin analogues may change the biodistribution of the tracer (*22*). Moreover, conformation changes due to change of nuclide affect both their affinity and biodistribution (*23*). Although Affibody molecules are substantially bigger, we have observed that a change of chelator may affect the biodistribution. For example, appreciable shifts in excretion pathways have been observed in the case of the change of a single amino acid in ^{99m}Tc-labeled Affibody molecules (*11, 12, 24*).

One aspect of the current study was to obtain a straight comparison between two alternative methods of site-specific

labeling *in vivo*. The biodistribution of ^{111}In-DOTA-Z_{2395}-C was very similar to the biodistribution of the synthetic ^{111}In-DOTA-Z_{342}, but the liver uptake of the recombinant protein was lower. With lower background levels, the tumor-to-background situation is more favorable. Another aspect of the current study was to evaluate if a His tag may be added onto the N-terminus, something which is attractive if several candidate proteins are to be produced and compared. Unfortunately, the addition of a His tag on the N-terminus had a dramatic negative effect on the biodistribution properties, leading to appreciable uptake in the liver. The mechanism of an elevated liver uptake is not known but might be associated with lipophilicity of histidines, which would create a local lipophilic "patch" at the N-terminus. Interestingly, we have previously observed high liver uptake in murine models of His-tag-containing Affibody molecules, which were labeled using $[^{99m}Tc(CO)_3]^+$ to the His tag (*25*). For this reason, only a variant ^{111}In-DOTA-Z_{2395}-C, which does not contain the His tag, was evaluated in tumor-bearing mice.

The specificity of ^{111}In-DOTA-Z_{2395}-C tumor uptake *in vivo* was confirmed by two independent methods, by the presaturation of receptors and by the use of non-HER2-specific structural analogue Z_{Taq}, labeled with the same methods as ^{111}In-DOTA-Z_{2395}-C. ^{111}In-DOTA-Z_{2395}-C displayed rapid tumor targeting and rapid clearance from nonspecific tissues, which enabled high-contrast imaging already 1 h p.i. (Figure 6). The tumor-to-organ ratios were increasing up to 4 h p.i., enabling further increase of the contrast during the day of injection. The only organ with the higher radioactivity accumulation than tumor was kidneys. A high kidney accumulation is a general feature of small targeting proteins (<60 kDa) labeled with residualizing radiometals (*26*). Two problems associated with high renal uptake are high renal radiation dose and difficulty of visualizing targets localized close to kidneys due to reconstruction artifacts. The first is important in radionuclide therapy using high-energy beta emitters but only a minor concern in radionuclide imaging using low levels of ^{111}In radioactivity, since Auger and conversion electrons, emitted by ^{111}In, are less damaging for the kidneys than beta particles (*27*). In clinical trials on the use of ^{111}In octreotide for therapy, renal doses as high as 45 Gy (after more than 90 GBq injected radioactivity) did not cause negative kidney side effects (*27, 28*). For imaging, only 100–200 MBq would be injected, resulting in several orders of magnitude lower renal doses. The problem of reconstruction artifacts in visualization of metastases in the vicinity of the kidney may be reduced with the use of new iterative SPECT reconstruction algorithms. In addition, several substances have been proposed, e.g., cationic amino acids (*29*), polyglutamic acid (*30*), or gelofusine (*31*), which are efficient in blocking of renal uptake of radiopeptides.

In the mice bearing LS174T xenografts, ^{111}In-DOTA-Z_{2395}-C provided as good tumor-to-blood ratios as synthetic ^{111}In-DOTA-Z_{342}. It provided better tumor-to-spleen ratios, even though the tumor-to-bone ratio was lower. Tumor-to-organ ratios for ^{111}In-DOTA-Z_{2395}-C appreciably exceeded values reported for this early time point after administration of radiometal-labeled HER2-targeting antibody fragments (*32, 33*). The nonspecifically labeled ^{111}In-Bz-DTPA-Z_{342} displayed lower blood concentration and lower tumor uptake than ^{111}In-DOTA-Z_{2395}-C. As a result, the tumor-to-blood ratio of ^{111}In-DOTA-Z_{2395}-C was not significantly better than that of the best recombinant protein with lysine-attached chelator. However, the important tumor-to-liver ratio was appreciably better for the site-specific conjugate. The significantly better tumor uptake of ^{111}In-DOTA-Z_{2395}-C can be also important, since it would provide a better signal in the SPECT camera. Another advantage of a DOTA-containing conjugate is the potential for labeling with positron-emitting generator-produced ^{68}Ga ($T_{1/2}$ = 68 min), which creates a precondition for the use of PET imaging with its advantages. The conjugates with acyclic chelators do not allow stable gallium labeling due to lower stability against transchelation of gallium to transferrin (*34*).

In conclusion, coupling of MMA−DOTA to an Affibody molecule with a single C-terminal cysteine provides a homogeneous conjugate which can be labeled with ^{111}In with preserved binding activity and specificity to HER2 and reduced liver uptake compared to with the corresponding construct containing a DOTA moiety attached at the N-terminus. The conjugate provides efficient targeting of HER2-expressing xenografts, while it is cleared rapidly from all normal tissues, except kidneys. The presence of an N-terminal His tag is not advisable, because this causes elevated liver uptake. The biodistribution and targeting properties of ^{111}In-DOTA-Z_{2395}-C are similar to properties of synthetic ^{111}In-DOTA-Z_{342}. In comparison to non-site-specifically labeled ^{111}In-Bz-DTPA-Z_{342}, ^{111}In-DOTA-Z_{2395}-C provides better tumor-to-liver ratio and higher tumor uptake. The method has a potential for site-specific labeling of Affibody molecules, which cannot be made by peptide synthesis, e.g., multimeric constructs, and for labeling of other proteinaceous tracers.

ACKNOWLEDGMENT

This research was financially supported by a grant from Swedish Cancer Society (Cancerfonden). Sara Ahlgren expresses her gratitude to Schuberts fond for a research scholarship. The authors expressed their genuine gratitude to staff of the animal department of the Rudbeck Laboratory for excellent care about the animals.

HER2 Targeted Polyplexes: The Effect of Polyplex Composition and Conjugation Chemistry on in Vitro and in Vivo Characteristics

Oliver Germershaus,[†] Michael Neu,[†] Martin Behe,[‡] and Thomas Kissel*[,†]

Department of Pharmaceutics and Biopharmacy, Philipps Universität Marburg, Ketzerbach 63, 35032 Marburg, Germany, and Department of Nuclear Medicine, Philipps Universität Marburg, Baldingerstrasse, 35043 Marburg, Germany. Received August 17, 2007; Revised Manuscript Received October 10, 2007

Knowledge of the influence of targeting ligands on pharmacokinetics and biodistribution of polymeric nonviral vectors is presently limited. We investigated the properties of three structurally different conjugates of polyethylenglycol-modified polyethylenimine coupled to the HER2 specific antibody Trastuzumab. Unlike polyethylenimine, conjugates formed small (100–230 nm) DNA polyplexes with zeta-potentials of ± 2 mV at a broad range of N/P ratios. Stability as assessed by heparin displacement was slightly improved compared to unmodified copolymers. Erythrocyte aggregation and hemolysis were strongly reduced with conjugates. Conjugate polyplexes showed significant differences in specificity and transfection efficiency in vitro. These could be attributed to differences in cell binding and uptake assessed by flow cytometry. Pharmacokinetics of conjugates in mice revealed significant improvements over free plasmid DNA and polyethylenimine. Area under the plasma level−time curve of conjugates was increased up to 48% or 114% compared to that of polyethylenimine or free plasmid DNA, respectively. Deposition of conjugate polyplexes in lung and spleen was significantly reduced compared to that of polyethylenimine. Differences could be attributed to antibody conjugation since no significant differences in pharmacokinetics and biodistribution were found between conjugates. These findings demonstrate that conjugated antibodies not only confer active targeting but also significantly improve in vivo properties of polyplexes.

INTRODUCTION

Therapeutic nonviral gene delivery holds great potential for the treatment of many acquired and inherited diseases, such as viral infections and cancer (*1*). To efficiently achieve in vivo cancer gene therapy, especially to distant tumors or disseminated metastases, systemic administration of such vector systems is indispensable. For this purpose, the vector system should be efficient, nontoxic, and specific to its target cells. The vector should also be easily producible in a tailor-made fashion in large quantities. Cationic polymers, namely, poly(ethylene imine) (PEI), are exceptionally suitable for this purpose. PEI is known to exhibit superior transfection properties in vivo because of its ability to efficiently package, protect, and deliver DNA (*2, 3*). Unfortunately, the cationic nature of polymer/DNA complexes (polyplexes) causes aggregation with blood components and opsonization in vivo (*4*). Unmodified polyplexes are quickly cleared by first pass organs of the reticuloendothelial system such as liver and spleen or are trapped in lung capillaries (*5–8*). To achieve a stealth effect similar to that of polyethylenglycol (PEG)-modified liposomes (*9*), hydrophilic polymers such as PEG or poly(*N*-(2-hydroxypropyl)methacrylamide) (pHPMA) were attached before or after complex formation with DNA (*4, 10–12*). This strategy led to a reduction of surface charge, increased circulation times (*4, 10*), decreased unspecific transfection (*11, 13*), and improved biocompatibility, solubility, and stability for freeze-drying (*14*). Such stealth vectors are able to passively target tumor tissues because of the enhanced penetration and retention effect (*7*). To facilitate active tumor targeting in vivo, gene delivery vectors need to be recognized and taken up by the target cells. This can be achieved by the coupling of cell-binding ligands, such as antibodies or peptides (*15–17*).

Several studies using cationic polymers for in vivo gene delivery have been published (*2, 4, 6, 18–20*). The in vivo pharmacokinetics and/or biodistribution of these vectors was less often addressed (*4, 6–8, 10, 12, 21–23*). Only a minority of the studies dealt with the influence of hydrophilic polymers on polyplex disposition and kinetics (*4, 8, 10, 12, 21, 22*). The results of these studies were controversial. While Mullen et al. (*8*), Oupicky et al. (*12*), and Merdan et al. (*21*) found decreased polyplex stability in circulation after modification with hydrophilic polymers, Ogris et al. (*4*), Kunath et al. (*10*), and Hildebrandt et al. (*22*) reported increased tumor association and/or prolonged kinetics. Because of significant differences in study design, direct comparison of these results proved to be difficult.

Further modification of relatively small cationic polymers or copolymers (typically about 25–75 kDa) with large targeting molecules such as transferrin (∼80 kDa) or IgG (∼150 kDa) caused significant changes of polyplex properties. We hypothesized that targeting ligands not only mediate active targeting of tumor cells but also affect in vivo disposition and pharmacokinetics of the vector system. These changes may in effect be as important for efficient transfection of tumors in vivo as efficient binding to the target cells. A literature search on the contribution of targeting antibodies on pharmacokinetics and biodistribution of nonviral vector systems in vivo showed that this question was not systemically addressed so far.

We synthesized three structurally different conjugates consisting of branched PEI, PEG, and an antibody, Trastuzumab, directed against HER2. We determined sizes, zeta-potentials, and stability parameters of the resulting complexes with DNA at different charge ratios (N/P: polymer nitrogen/DNA phosphate). HER2-positive and -negative cell lines were used to evaluate transfection efficiencies and specificities of conjugates in vitro. Cell binding and uptake was studied by flow cytometry.

In vivo pharmacokinetics and biodistribution were determined following tail vein injection of polyplexes in BALB/c mice in a 120 min time frame.

MATERIALS AND METHODS

Materials. Branched Polyethylenimine (Polymin, 25 kDa) was a gift from BASF (Ludwigshafen, Germany). Luciferase plasmid pCMV-Luc was purchased from Plasmid Factory (Bielefeld, Germany). *N*-succinimidyl-3-(2-pyridyldithio)propionate (SPDP) was obtained from Sigma-Aldrich (Taufkirchen, Germany). *N*-hydroxysuccinimidyl ester of 2 kDa orthopyridyl-disulfide polyethylenglycol (SPA-PEG(2 kDa)-OPSS) was purchased from Nektar Therapeutics (San Carlos, CA, USA). YOYO-1 iodide was obtained from Invitrogen (Karlsruhe, Germany). Trastuzumab (Herceptin) was purchased from Roche (Basel, Switzerland). All other chemicals used were of analytical grade.

Cell Culture. SK-BR-3 and OVCAR-3 cells were purchased from ATCC, Teddington, U.K. and maintained in RPMI 1640 (PAA Laboratories, Cölbe, Germany) supplemented with 10% and 20% fetal calf serum (Cytogen, Sinn, Germany), respectively, in humidified atmosphere with 5% CO_2 at 37 °C.

Synthesis of Conjugates. Polyethylenglycol (2 kDa)$_{10}$-graft-polyethylenimine (25 kDa) (abbreviated as PEG(2)-PEI) and polyethylenglycol (30 kDa)$_{1.1}$-graft-polyethylenimine (25 kDa) (abbreviated as PEG(30)-PEI) copolymers were synthesized and characterized as described previously (*24*). For the synthesis of conjugates based on PEG-PEI copolymers, the method described was refined (*16*). PEG(2 kDa)$_{10}$-PEI or PEG(30 kDa)$_1$-PEI (0.11 μmol) was dissolved in 0.5 mL reaction buffer consisting of 150 mM sodium chloride and 20 mM 4-(2-hydroxyethyl)-1-piperazine ethane sulfonic acid (HEPES) at pH 7.5. SPDP (0.2 μmol) in 20 μL of 100% ethanol was added while stirring and allowed to react for 60 min at RT. Purification of the product was performed by gel chromatography on a PD-10 column (Amersham Pharmacia Biotech, Freiburg, Germany) in reaction buffer. SPDP-activated PEG-PEI was reduced for 1 h at 37 °C using an excess of dithiothreitol (DTT) to yield PEG-PEI-SH. The degree of substitution with SH-reactive ortho-pyridyl groups was determined by pyridine-2-thione release upon addition of an excess of DTT (*25*).

In a second synthesis route, we used unmodified PEI (25 kDa) and covalently coupled Trastuzumab via a heterobifunctional PEG linker (SPA-PEG(2 kDa)-OPSS). Reactivity of SPA-PEG-OPSS was determined by pyridine-2-thione release and base-catalyzed NHS-ester hydrolysis. PEI (0.12 μmol) was dissolved in 1 mL of reaction buffer, and 1.2 μmol SPA-PEG-OPSS was added in 100 μL of 100% ethanol while stirring. The mixture was allowed to react for 1 h at room temperature, and the product was purified by gel chromatography and reduced as described above to yield PEI-PEG-SH. The degree of substitution was determined by pyridine-2-thione release as described above.

Trastuzumab (0.15 μmol) in reaction buffer was allowed to react with 0.24 μmol of SPDP (10 mM in pure ethanol) under stirring at room temperature and was purified as described above. SPDP-activated Trastuzumab was added to purified, activated PEG-PEI and allowed to react for 24 h at room temperature.

Purification of the conjugates was performed by a modified ion-exchange chromatography method first described by Kircheis et al. (*16, 26*). PEI concentration was quantified by copper complexation (*27*). The concentration of Trastuzumab was determined by UV-spectrometry at 280 nm with background correction using a solution of PEG-PEI or PEI of equal concentration.

Formation of Polyplexes. Polyplex formation was performed as described earlier (*16*). Briefly, pDNA was diluted with 150 mM sodium chloride, 10 mM HEPES at pH 7.4 to 0.04 g/L and mixed in equal parts with the appropriate amount of polymer in the same buffer. All experiments were performed at a N/P ratio of 6 and a final pDNA concentration of 0.02 g/L unless stated otherwise.

Size and ζ-Potential. Hydrodynamic diameters and ζ-potentials of freshly prepared polyplexes were determined using a Zetasizer Nano ZS (Malvern Instruments, Herrenberg, Germany) equipped with a 4 mW He-Ne laser at a wavelength of 633 nm at 25 °C. Scattered light was detected at a 173° backward scattering angle. The viscosity and refractive index of water at 25 °C was used for data analysis. Five hundred microliters of polyplex solution was prepared and incubated for 10 min at RT. Measurements were performed in a folded capillary cell in triplicate. DTS software 4.10 was used for data acquisition and analysis. The accuracy of the instrument was maintained using reference polymer particles (nanosphere size standards of 50, 100, and 200 nm, Duke Scientific Corp., Palo Alto, CA, USA) and with the zeta potential transfer standard (Malvern Instruments, Herrenberg, Germany).

Agarose Gel Electrophoresis. For heparin displacement, 50 μL of polyplex solutions were prepared at N/P 6 and incubated for 10 min at RT. Then, polyplexes were challenged with 0.05 to 0.35 U heparin for 30 min at RT. Glycerol (10% v/v) was added, and 10 μL of the solution was carefully applied to a 1% agarose gel in TAE (40 mM Tris/HCl, 1% acetic acid, and 1 mM EDTA at pH 7.4) containing 0.6 μg/mL of ethidium bromide. Electrophoresis (Electro-4, Thermo Electron, Waltham, MA, USA) was carried out at a constant voltage of 80 V for 1 h in TAE buffer. Ethidium bromide fluorescence was detected using a gel documentation system (BioDocAnalyze, Biometra, Göttingen, Germany) and images were processed with ImageJ 1.37v (http://rsb.info.nih.gov/ij/) (*28*).

Erythrocyte Aggregation and Hemolysis. The hemolytic activity and erythrocyte aggregation of polyplexes were investigated as reported earlier (*29*). Briefly, human erythrocytes were isolated from fresh citrated blood from healthy volunteers by centrifugation at 850 $\times$ *g*. Red blood cells were washed in HEPES-buffered saline (HBS) until the supernatant was clear and colorless. Erythrocytes were diluted with HBS to 5×10^8 cells/mL. Polyplexes were prepared at N/P 6 in a total volume of 125 μL (DNA concentration 0.1 μg/μL). Triton X-100 (1%) in HBS (100% lysis) and pure HBS (0% lysis) were used as control. Aliquots (40 μL) of polyplex solutions were mixed with 40 μL of erythrocyte suspension. Samples were incubated for 30 min at 37 °C under constant shaking. After centrifugation at 850 $\times$ *g*, the supernatant was analyzed for hemoglobin release at 415 nm (Ultrospec 3000, GE Healthcare, Munich, Germany). The Pellet was resuspended with 500 μL of HBS and used for microscopic evaluation of erythrocyte aggregation.

Transfection Experiments. For transfection experiments SK-BR-3 and OVCAR-3 cells were plated at a density of 1×10^4 cells per well in a 96-well plate. After 24 h of growth, the medium was replaced with 0.2 mL of fresh, complete cell culture medium containing 0, 10, 50, or 250 μg of free Trastuzumab. Cells were incubated for 15 min at 37 °C. Polyplexes were prepared in a final volume of 30 μL (containing 0.63 μg pDNA) per well, incubated for 10 min at RT, and subsequently added to the wells. The medium was exchanged again after 4 h, and cells were incubated for an additional 44 h.

Luciferase gene expression was quantified using a commercial kit (Promega, Mannheim, Germany) and photon counting on a luminometer (Sirius, Berthold, Pforzheim, Germany). Results were measured in relative light units per second (RLU/s) and converted to nanograms of luciferase using a standard curve of recombinant luciferase (Promega, Mannheim, Germany). Protein concentration was determined using a modified BCA assay

(Perbio Science, Bonn, Germany) with bovine serum albumin as a standard (*30*). All experiments were performed in quadruplicate, and results were normalized to the transfection efficiency of unmodified PEG-PEI copolymers.

Flow Cytometry. For flow cytometry experiments, cells were seeded in 24-well plates at a density of 6×10^4 cells per well. After 24 h of growth, the cell culture medium was exchanged with 0.5 mL of fresh medium. Polyplexes were prepared in a final volume of 150 μL (containing 2.5 μg YOYO-1 labeled pDNA (*31*)) at N/P 6, incubated for 10 min at room temperature, and then added to the wells. In the case of polyplex binding experiments, cells were incubated at 4 °C for 15 min before and after the addition of polyplexes. Subsequently, cells were washed 2 times with ice cold PBS. For the uptake experiments, cells were incubated with the polyplexes for 3 h at 37 °C. Cells were then washed 4 times for 3 min with 0.5 mg/mL heparin in PBS to remove surface-bound polyplexes. Cells were detached with trypsin and suspended in an ice-cold 1:1 mixture of FACS-Flow (BD Biosciences, San Jose, USA) and 4% paraformaldehyde in PBS.

Flow cytometry was performed using FACScan (BD Biosciences, San Jose, USA) equipped with a 488 nm argon-ion laser. The emission filter setting was 530/30 bandpass. Viable cells were gated according to forward and sideward scatter of untreated cell samples. At least 5000 gated events were collected and subjected to further analysis. All experiments were performed in triplicate. Results were normalized to binding or uptake efficiency of the respective unmodified PEG-PEI copolymers. CellQuest 3.3 software (BD Biosciences, San Jose, USA) was used for data acquisition. Analysis was performed with FCS Express V3 (De Novo Software, Thornhill, Canada).

In Vivo Experiments. All animal experiments were carried out according to the German law of protection of animal life and approved by an external review committee for laboratory animal care.

Pharmacokinetic and Biodistribution Studies. 100 ng pCMV-Luc were labeled with 32-P-α-CTP (Hartmann, Germany) using a Nick translation kit N5000 (GE Healthcare, Germany) according to the manufacturer's protocol. The reaction mixture was purified using microspin columns (Wizard SV Gel and PCR Clean-Up System, Promega, Germany) and the labeled plasmid was used immediately after synthesis.

Polyplexes were prepared using 25 μg of the pCMV-Luc plasmid spiked with the ^{32}P-labeled plasmid as described earlier (*21*). A volume equal to a dose of 1 μg of pCMV-Luc per gram of mouse of the polyplex solution was injected in anesthetized male balb/c mice via the tail vein. Blood samples of 25 μL were drawn from the retrobulbar plexus 1, 3, 5, 15, 30, 60, and 120 min postinjection. After 120 min, mice were sacrificed by cervical dislocation, and organs were excised. Organ samples were dissolved in Soluene 350 (PerkinElmer, Germany), and blood samples were dissolved overnight in a 1:1 mixture of isopropanol/Soluene 350 at 55 °C and subsequently bleached with 200 μL of hydrogen peroxide. After the addition of 15 mL of scintillation cocktail (Hionic Fluor, PerkinElmer, Germany), the activity of ^{32}P in each sample was determined using a TriCarb 2900 liquid scintillation counter (PerkinElmer, Germany) with a counting time of 10 min, active static controller, and half-life correction. Disintegrations per minute (DPM) were calculated with a ^{32}P quench curve using tSIE/AEC as the quench indicator. The injected dose was calculated on the basis of activity measurements of the injected solution. All experiments were performed at least in triplicate, and the AUC was determined using a noncompartmental mixed logarithmic linear algorithm. Concentration−time data were fitted to a biexponential disposition function ($C(t) = A\ e^{-\alpha t} + B\ e^{-\beta t}$, iterative reweighing with $1/C_{obs}$) using the software Kinetica 1.1. from Simed (Créteil Cedex, France). Plasmid concentrations in the samples were calculated as the percent of the injected dose per organ or as percent injected dose per milliliter of blood.

RESULTS

Synthesis of Conjugates. Conjugates were prepared using two different polyethylenglycol−polyethylenimine copolymers (*24*). To study the influence of PEGylation, these copolymers represent two extremes concerning the degree of PEGylation and PEG chain length while keeping the weight ratio of PEG to PEI approximately constant. In both cases, the targeting moiety was coupled to PEI via the heterobifunctional linker *N*-succinimidyl-3-(2-pyridyldithio)propionate (SPDP). The degree of substitution with SPDP, determined by pyridine-2-thion release, was 1.5 and 1.7 mol of 2-pyridyl disulphide per mole of PEI for PEG(2)-PEI and PEG(30)-PEI, respectively. A third conjugate was prepared by modifying PEI with a heterobifunctional PEG linker. This synthesis resulted in a degree of substitution of ∼10 mol of PEG per mole of PEI. The degree of substitution with 2-pyridyl disulphide was determined to be 5 moles per mole of PEI. The reaction of SPDP with Trastuzumab resulted in a degree of substitution of 1.3 mol of 2-pyridyl disulphide per mole of antibody. Finally, the degree of substitution of conjugates with Trastuzumab was determined to be 0.74, 1.5, and 0.38 mol/mol Trastuzumab/PEI for PEG(2)-PEI-Trastuzumab, PEG(30)-PEI-Trastuzumab, and PEI-PEG(2)-Trastuzumab, respectively (Figure 1). The overall polymer yield after purification varied between 50 and 70% as determined by copper complexation.

Size and ζ-Potential. Hydrodynamic diameters decreased with increasing N/P ratio for all complexes (Figure 2a). At N/P 6 and 12, all complexes revealed a similar size of 100−230 nm, facilitating efficient uptake by absorptive endocytosis (*32*). At N/P 3, PEI formed large complexes of about 1200 nm. Because of efficient shielding, PEG-PEI and conjugate polyplexes were significantly smaller than PEI complexes with sizes of only 100−300 nm.

In contrast to PEI polyplexes, which showed high ζ-potentials of about +27 mV at N/P 6 and 12, the surface charge of PEG-PEI polyplexes was significantly reduced (Figure 2b). Modification of PEG-PEIs with Trastuzumab further decreased ζ-potentials. These polyplexes were near neutral at all N/P ratios tested.

Stability against Heparin Displacement. To evaluate polyplex stability against displacement of pDNA by competing polyanions, the polyplexes were challenged with free heparin (Figure 3). Heparin amounts as low as 0.1 U displaced DNA from the complex in the case of PEI and PEG-PEI copolymers. Trastuzumab conjugate complexes showed a slightly improved stability against heparin displacement. With these polyplexes, free plasmid DNA was observed at heparin concentrations of 0.20 U and above.

Erythrocyte Hemolysis and Aggregation. Interactions with blood components, namely, erythrocytes, are likely to occur after injection of polyplexes into the bloodstream (*4, 33*). The hemolytic activity of polyplexes and the tendency to form aggregates with erythrocytes was studied in an in vitro assay using freshly purified human red blood cells.

For polyplexes prepared with unmodified PEI at N/P 6, hemolysis of 16% of the erythrocytes was found, which is in good correlation with earlier reports (Figure 4) (*34*). PEGylation of PEI significantly reduced hemolysis both in the case of short (PEG(2)-PEI) and long (PEG(30)-PEI) PEG chains. Modification of PEG-PEI copolymers with Trastuzumab significantly decreased erythrocyte lysis compared to the unmodified PEG-

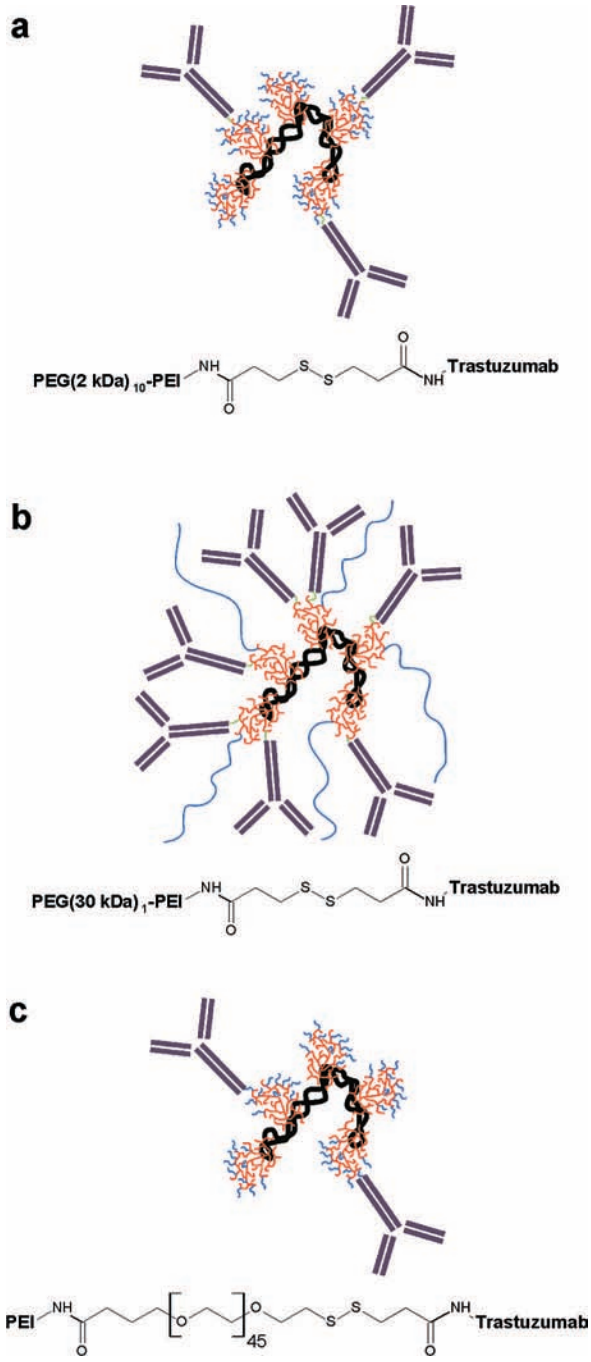

Figure 1. Chemical structure of conjugates and illustration of hypothetical complexes with plasmid DNA (black). Branched PEI (25 kDa) (red) was substituted with PEG (light blue) of different molecular weights to different degrees, and Trastuzumab (dark blue) was coupled directly to PEI via SPDP (green) in the case of (PEG(2)-PEI-Trastuzumab (a) and PEG(30)-PEI-Trastuzumab (b). PEI-PEG(2)-Trastuzumab (c) was prepared by the modification of branched 25 kDa PEI with a heterobifunctional PEG linker, and Trastuzumab was coupled to the distal end of the PEG chains.

PEI copolymers. Only 1.0 to 2.4% hemolysis was observed with Trastuzumab conjugates.

Erythrocyte suspensions were then microscopically examined for aggregate formation (Figure 4). The addition of PEI polyplexes resulted in rapid and extensive erythrocyte aggregation. Interaction with erythrocytes was decreased using PEG-PEI polyplexes but still moderate to severe aggregate formation was found. Using Trastuzumab-modified copolymers, no erythrocyte aggregation was seen.

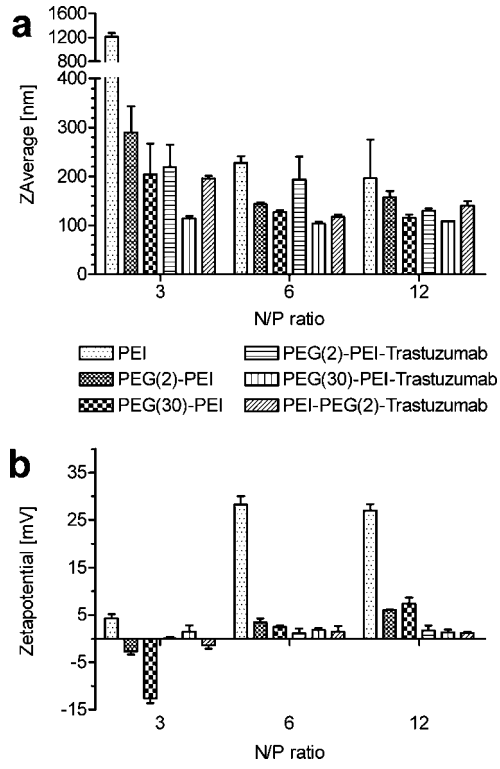

Figure 2. Hydrodynamic diameters (a) and zeta-potentials (b) of polyplexes prepared with pDNA and unmodified polymers or Trastuzumab conjugates at the indicated N/P ratios. Polyplexes were prepared as described in the Materials and Methods section and were measured in a folded capillary cell in quintuplicate (a) or triplicate (b). Values are given as the means + SD.

Transfection Experiments. For transfections in vitro, two different cell lines with different HER2 expression levels were used. OVCAR-3 cells were shown to express only low amounts of HER2 and therefore served as a negative control (*16*). In contrast, SK-BR-3 cells are known to overexpress HER2 (*16, 35*). Specificity of transfection was evaluated by competitive inhibition with free Trastuzumab during incubation with polyplexes.

In SK-BR-3 cells, PEG(2)-PEI-Trastuzumab showed a significant ($p < 0.01$) 6.6-fold increase in reporter gene expression compared to PEG(2)-PEI. Significant inhibition ($p < 0.05$) was seen with at least 1.69 μmol/L free Trastuzumab (Figure 5a). By contrast, transfection efficiency of PEG(30)-PEI-Trastuzumab was not significantly increased compared to PEG(30)-PEI, and no significant inhibition was seen with free Trastuzumab in cell culture media (Figure 5c). PEI-PEG(2)-Trastuzumab had a reporter gene expression 34-fold higher compared to that of PEG(2)-PEI. Significant inhibition ($p < 0.001$) was achieved with Trastuzumab concentrations as low as 0.34 μmol/L (Figure 5e). None of the conjugates showed a specific reporter gene expression in HER2-negative OVCAR-3 cells (Figures 5b, d, and f).

Flow Cytometry. Binding efficiencies of Trastuzumab conjugates relative to those of unmodified PEG-PEI copolymers at 4 °C are depicted in Figure 6a. Increased binding to SK-BR-3 cells was observed for all conjugates. Compared to the respective untargeted copolymer, PEI-PEG(2)-Trastuzumab showed the most efficient binding, followed by PEG(2)-PEI-Trastuzumab and PEG(30)-PEI-Trastuzumab. A smaller increase of the binding of conjugates was also found for OVCAR-3 cells. HER2 expression of OVCAR-3 cell was found to be very low but still detectable by flow cytometry (*16*), which may explain the slightly increased binding efficiencies.

To evaluate the uptake of particles, OVCAR-3 and SK-BR-3 cells were incubated with polyplexes for 3 h at 37 °C. Cell-

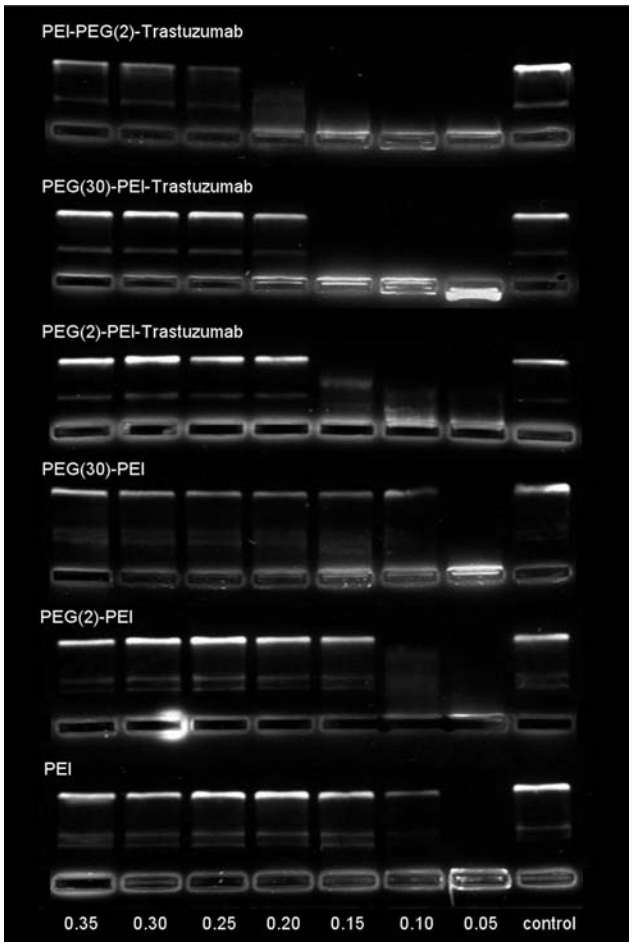

Figure 3. Heparin displacement assay using PEI, copolymer, and conjugate polyplexes. Polyplexes were formed at N/P 6 and incubated for 30 min with increasing heparin concentrations. Free plasmid DNA is shown to the right.

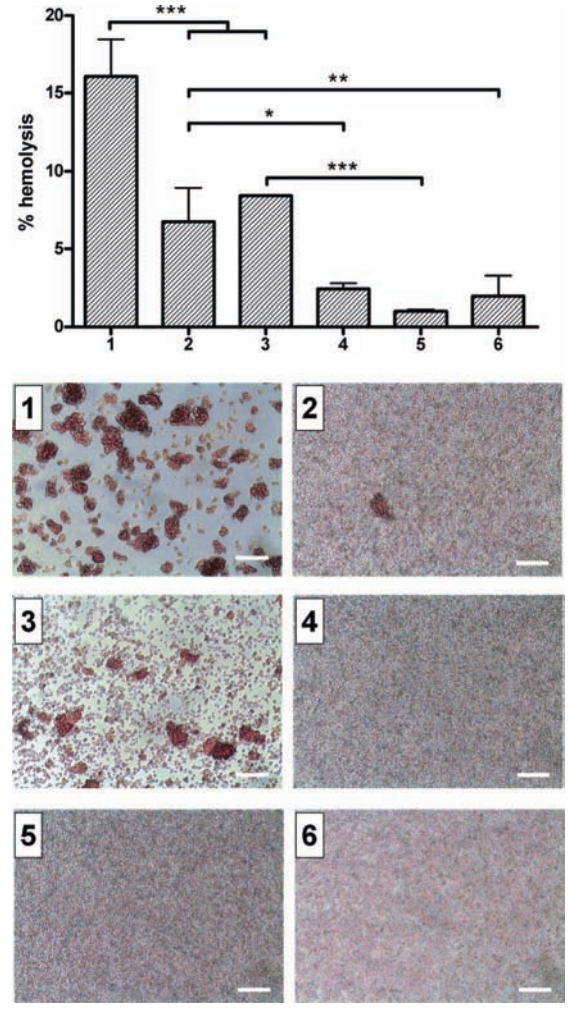

Figure 4. Lysis and aggregation of human erythrocytes induced by polyplexes prepared at N/P 6 with PEI (1), PEG(2)-PEI (2), PEG(30)-PEI (3), PEG(2)-PEI-Trastuzumab (4), PEG(30)-PEI-Trastuzumab (5), and PEI-PEG(2)-Trastuzumab (6). Values are given as the means + SD of triplicates. Significance was tested using one-way ANOVA with Bonferroni's multiple comparison test (* $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$). Scale bars represent 100 μm.

surface-bound polyplexes were then removed, and intracellular fluorescence was determined by flow cytometry as well. Figure 6b shows the uptake efficiencies of conjugates relative to unmodified PEG-PEI copolymers. A very efficient and specific uptake can be observed for PEI-PEG(2)-Trastuzumab with a 4.3-fold increased uptake compared to that of the Trastuzumab-free copolymer. PEG(2)-PEI-Trastuzumab also showed a modest increase in uptake efficiency (2.8-fold). PEG(30)-PEI-Trastuzumab showed only a 1.9-fold increase in uptake.

Pharmacokinetics and Biodistribution in Mice. For in vivo experiments, polyplexes were injected into the tail vein of male BALB/c mice at a dose of 1 μg/g of radiolabeled DNA per mouse. To ensure the integrity of labeled plasmid, DNA was used immediately after performing the labeling reaction and subsequent purification procedures.

Free pDNA was removed quickly and efficiently from the blood stream. After 60 min, only about 1% of the injected dose per mL (ID/mL) was found in the blood (Figure 7a), which is in good agreement with earlier reports (*36*). If pDNA was complexed with unmodified PEI, a biphasic disposition with a very rapid decay in the alpha phase was observed. With PEI, the onset of the β phase was earlier, and the *B* value was significantly increased compared to that of pDNA alone (Table 1). The area under the curve (AUC) was thereby increased from 532.16 to 770.10% ID min^{-1} mL^{-1}, which again is in excellent agreement with earlier findings (*21*).

All Trastuzumab conjugates were found to improve pharmacokinetics of pDNA with minor differences between conjugates. Complexes composed of PEG(2)-PEI-Trastuzumab showed a significant increase in the *B* value and AUC compared to those of PEI polyplexes. Pharmacokinetics of the block-copolymer like PEG(30)-PEI based conjugate were slightly improved compared to PEI. The *B* value was increased to 7.71% ID mL^{-1}, and AUC was significantly increased over PEI. PEI-PEG(2)-Trastuzumab showed similar kinetics, but differences compared to PEI were less pronounced. An increase in *B* value and AUC compared to those of PEI was seen, but differences were not statistically significant in this case.

The biodistribution of labeled plasmid DNA was assessed 120 min postinjection (Figure 7b). The uptake of uncomplexed DNA was negligible in most organs. PEI polyplexes accumulated mainly in the liver, lung, kidneys, and spleen. When conjugates were used to prepare polyplexes, the main uptake occurred in the liver as well. However, the uptake into the lung and spleen was significantly decreased for all Trastuzumab conjugates compared to that of PEI.

DISCUSSION

Several studies on the pharmacokinetics and biodistribution of PEI- (*37, 38*) as well as PEG-PEI/DNA (*4, 10, 21*) polyplexes have been undertaken. Until now, the influence of targeting

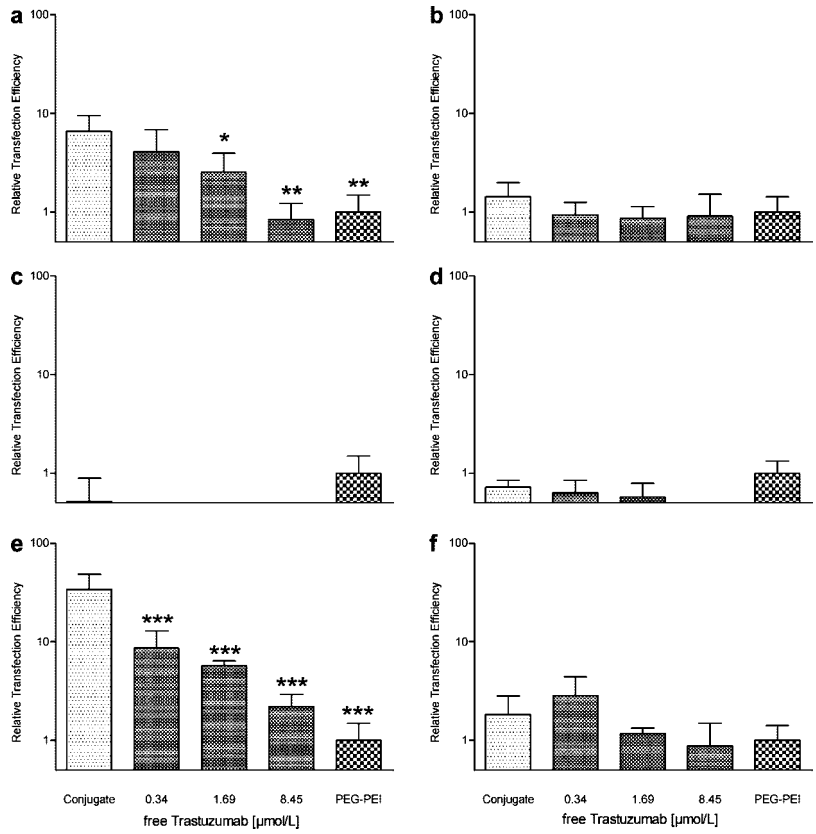

Figure 5. Transfection efficiencies and specificity of conjugates compared to the respective unmodified copolymer in HER2-positive SKBR-3 cells (b, c, and e) and HER2 negative OVCAR-3 cells (b, d, and f). Polyplexes were formed with pDNA and PEG(2)-PEI-Trastuzumab (a and b), PEG(30)-PEI-Trastuzumab (c and d), and PEI-PEG(2)-Trastuzumab (e and f) at N/P 6. To test the specificity of transfection, cells were incubated with indicated concentrations of free Trastuzumab for 15 min before the addition of the polyplexes. Values are given as the means + SD of quadruplicates. Significance was tested using one-way ANOVA with Dunnett's multiple comparison test with transfection efficiency of conjugate set as control (* $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$).

ligands such as antibodies, antibody fragments, or peptides on the pharmacokinetics and biodistribution of the resulting vector system was not systemically evaluated. Achievement of high and long lasting blood levels is considered to be a prerequisite for the efficient use of nonviral vectors under in vivo conditions. The final goal for the gene delivery system presented in this study was the targeting of tumor tissues, which will be the subject of a separate investigation. Before addressing this goal, the effects of targeting ligands and PEGylation on in vivo pharmacokinetics and distribution needed to be clarified. To elucidate the effects of PEG and antibody, three conjugates were synthesized. These were composed of branched PEI (25 kDa) as the condensing agent, PEG as the nonspecific interaction reducing agent, and Trastuzumab as a targeting ligand. Variations included linker chemistry, PEG chain length, and substitution degree (Figure 1).

The efficacy of nonviral gene delivery systems administered via the intravenous route depends on several crucial parameters: polyplex size, surface charge, stability in the bloodstream, and interaction with blood components. One impediment for successful transfection of tumor tissue in vivo is early entrapment of the polyplexes after intravenous injection. Ogris et al., Merdan et al., and Hildebrandt et al. stressed the importance of polyplex size and aggregation behavior in terms of organ distribution (*4, 21, 22*). These investigations showed that deposition in the lung, which is the first capillary bed reached after i.v. injection, as well as lethality after treatment depends on polyplex size and aggregation behavior. It was shown by Petersen et al. that PEI does not produce stable polyplexes especially at low N/P ratios, and an increase in complex size over time was observed. In contrast, PEG-PEI copolymers with PEG chains longer than 550 kDa formed stable complexes under these conditions, and no aggregation over time occurred (*24*). In our study, unmodified PEI polyplexes formed large particles in micrometer range at N/P 3 in vitro. In contrast, all PEG-PEI copolymers and Trastuzumab conjugates produced small complexes with DNA with sizes not exceeding 300 nm in a wide range of N/P ratios. After i.v. injection, PEI is known to form aggregates with blood components, such as erythrocytes or albumin (*39*). Erythrocyte aggregation and hemolysis studied using human red blood cells showed severe aggregation of erythrocytes with PEI polyplexes. In contrast, PEGylated PEIs showed reduced erythrocyte aggregation and hemolysis, which is in accordance with the findings of Petersen et al. (*24*). Most importantly, Trastuzumab-modified PEG-PEI copolymers even surpassed PEG-PEI in these experiments and showed virtually no aggregation or hemolysis of erythrocytes.

The surface charge of polyplexes is an important parameter closely related to the above-mentioned characteristics. ζ-potentials of polyplexes prepared with Trastuzumab conjugates were lower than those of polyplexes prepared with unmodified PEI or with the respective PEG-PEI copolymers. Actually, conjugate polyplexes remained close to neutral in a wide range of N/P ratios because of the additional steric shielding by the coupled antibody. Similar shielding effects were observed with transferrin-PEI polyplexes subsequently modified with PEG (*4*) and with PEG-PEI covalently modified with anti-OA3 Fab′ (*25*). Ward et al. and Ogris et al. showed that shielded complexes decreased nonspecific interactions with blood components and nontargeted cells (*4, 40*). Plank et al. found that positively charged DNA complexes can activate the alternative complement system (*41*). The authors also showed that modification

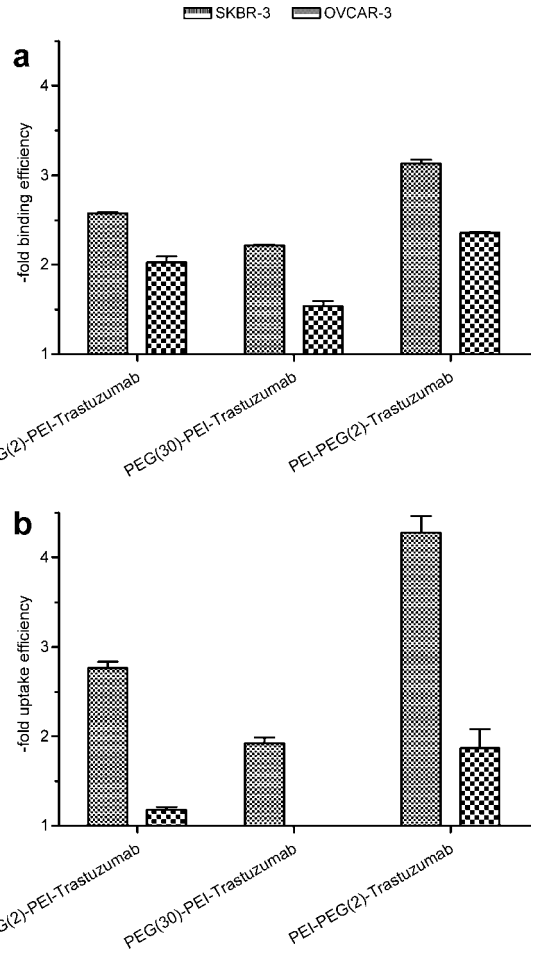

Figure 6. Binding (a) and uptake efficiencies (b) of polyplexes prepared at N/P 6. Conjugate uptake or binding is shown relative to the corresponding unmodified PEG-PEI copolymer. Polyplexes were incubated with the cells for 15 min at 4 °C (a) or 3 h at 37 °C (b). In the case of the uptake experiment (b), cells were washed 4 times with heparin in PBS to dissociate and remove surface bound polyplexes. Cells were then analyzed for mean fluorescence intensity by flow cytometry. Values are given as the means + SD of triplicates.

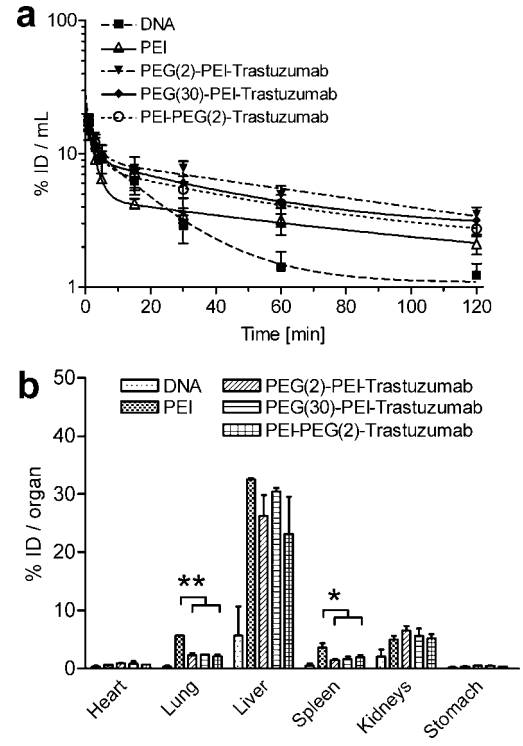

Figure 7. Pharmacokinetic profiles (a) and biodistribution (b) of PEI (open triangle, solid line), PEG(2)-PEI-Trastuzumab (filled triangle, dashed-dotted line), PEG(30)-PEI-Trastuzumab (filled square, solid line), and PEI-PEG(2)-Trastuzumab (open circle, dotted line) polyplexes compared to those of free plasmid DNA (filled square, dashed line) in male BALB/c mice. Polyplexes were prepared at N/P 6 with 1 μg/g pDNA per mouse and injected via the tail vein in a volume of about 200 μL. Blood samples were taken at indicated time points from the retrobulbar plexus. Organs were withdrawn after 120 min, and the amount of radiolabeled plasmid was determined by liquid scintillation counting. Significance was tested using one-way ANOVA and Dunnett's multiple comparison test with PEI polyplexes set as control (* $p < 0.05$; ** $p < 0.01$).

of polylysine/DNA complexes with PEG can considerably reduce complement activation. We speculated that further reduction of surface charge in the case of Trastuzumab-modified PEG-PEI polyplexes could result in reduced complement activation.

Polyplexes injected into circulation encounter relatively harsh conditions, such as shear stress during injection and circulation, lytic enzymes, and a multitude of salts and proteins, that may negatively influence complex integrity and DNA stability (*42, 43*). To investigate complex stability, we tested the susceptibility of polyplexes to heparin displacement. The polyanion heparin releases DNA from polyplexes and is a good measure for complex stability against competing anions. All Trastuzumab conjugates were slightly less susceptible to heparin displacement compared to PEI and their respective unmodified copolymers. We hypothesize that the dense shell formed by PEG and Trastuzumab may prevent heparin from entering the complex as easily as in the case of unmodified PEI polyplexes.

Therefore, all Trastuzumab conjugate complexes appear sufficiently stable to remain intact during circulation and are at the same time less susceptible to aggregation and nonspecific interaction than unmodified PEI.

Apart from size and stability, tumor specificity of polyplexes is crucial. The target tissue should ideally be transfected with high efficiency while leaving nontargeted tissues unaffected. Strehblow et al. showed that conjugation chemistry may have a significant effect on transfection efficiency and specificity in vitro (*44*). In this study, three different linkers were used to prepare HER2 or CD90 targeted conjugates. Using these linkers, major differences in the degrees of conjugation and in target cell specificity of the resulting conjugates were found. Interestingly, none of the conjugates prepared with SPDP as a linker showed target cell specificity. In contrast, SPDP was successfully used as a linker by Merdan et al. and Kircheis et al. under comparable conditions (*25, 26*). Kunath et al. showed that if RGD peptide was used as a targeting moiety, only direct coupling of the peptide to PEI via SPDP mediated efficient and specific transfection, while a RGD-PEG-PEI conjugate was inefficient (*45*). In contrast, Moffatt et al. successfully utilized a PEG linker for coupling anti-PSMA antibody to PEI/DNA polyplexes (*17*).

In this study, we used three structurally different conjugates which were comparable in physicochemical properties but different in transfection, binding, and uptake efficiencies. Two conjugates were based on presynthesized PEG-PEI copolymers. Trastuzumab was in these cases coupled to the PEI core via SPDP. The PEG(2)-PEI copolymer was well established for conjugation purposes in our laboratory (*16, 25*). To study the influence of PEGylation, PEG(30)-PEI with fewer but longer PEG chains was used as a second copolymer. The PEG content of both copolymers was comparable (45% vs 56%). PEG-PEI with a lower substitution degree was used to promote substitution with antibody and possibly increase specificity. It was found

[a] All values given as the means + SD. [b] Significance was tested using 1way ANOVA with Bonferroni's multiple comparison test with DNA or PEI (vs DNA/vs PEI) set as control (ns: not significant; * $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$). [c] Concentration−time data was fitted to a biexponential disposition function. [d] AUC was determined using a noncompartmental mixed logarithmic linear algorithm.

that the substitution degree could be increased 2-fold by using PEG(30)-PEI rather than PEG(2)-PEI. This in turn decreased reporter gene expression compared to that of PEG(2)-PEI-Trastuzumab, and transfection was nonspecific. This result can be explained by a comparably lower binding to target cells and most importantly by lower uptake efficiency as shown by flow cytometry. It was hypothesized that longer PEG chains may hinder target recognition by partial masking of antigen binding domains. The decrease in uptake efficiency may be attributed to the cross-linking of several receptors on the cell surface or intercellular cross-linking due to the comparably high antibody substitution degree of this conjugate. For the third conjugate, a PEG linker was used. This enhanced the presentation of the targeting moiety and increased the specificity and efficiency of the resulting Trastuzumab conjugate. We herein showed by flow cytometry analysis that this conjugate was the most efficient in binding and uptake.

As a result, the efficiency of PEG-PEI-antibody conjugates strongly depends on copolymer composition and conjugation chemistry. In our study, the presentation of antibody at the distal end of a PEG spacer was most efficient. Our second approach of using presynthesized PEG-PEI copolymers showed that long PEG chains may hinder the proper presentation of the antibody. In contrast, good results were obtained with a PEG-PEI copolymer consisting of shorter PEG blocks with a higher PEG grafting ratio.

In vivo behavior of conjugate polyplexes was compared with unmodified PEI polyplexes as well as with uncomplexed plasmid. Blood levels followed a biexponential disposition curve with a rapid distribution phase and a subsequent prolonged elimination phase. PEI polyplexes showed a pronounced distribution phase with a comparably low remaining DNA concentration in blood after distribution. In contrast, Trastuzumab conjugates were more rapidly distributed and higher concentrations remained in circulation after distribution. Elimination half-lives of PEI and Trastuzumab conjugate complexes were comparable. Consequently, the AUC of Trastuzumab conjugate polyplexes were 18 to 48% higher than the AUC of PEI polyplexes and 70 to 114% higher than that of free DNA.

In a previous study, Merdan et al. determined the pharmacokinetic profiles of PEI and PEG(2)-PEI complexes under similar conditions. At a DNA dose of 25 μg/mouse, no significant differences in pharmacokinetics were found between PEI and PEG(2)-PEI polyplexes. Furthermore, the pharmacokinetic profiles showed that DNA is associated with both PEI and PEG(2)-PEI at least until 60 min postinjection under these conditions (*21*). At a lower DNA dose of 1.5 μg/mouse, significantly increased blood levels were found for pDNA complexed with PEG(2)-PEI compared to that of PEI. However, at this low dose, complex dissociation indicated by differing pharmacokinetic profiles of radioactively labeled polymer and DNA was observed.

PEI polyplexes are known to rapidly distribute to and remain in highly perfused organs, such as the liver, lung, and spleen. (*20*) These phenomena seem to be in part due to the aggregation of polyplexes, interaction with blood components such as erythrocytes, and recognition by the reticulo-endothelial system (*4, 24, 39, 43*). By using stealth polyplexes, in vivo toxicity, aggregation, and complement activation can be reduced (*4, 10*). However, studies on PEG-PEI copolymers have shown that PEGylation alone does not significantly improve pharmacokinetics compared to that of unmodified PEI (*21, 46*). De Wolf et al. recently hypothesized that polyplexes prepared using PEG-grafted PEI (pre-PEGylation approach) are still prone to opsonization and therefore are relatively rapidly eliminated (*46*). Interestingly, post-PEGylated polyplexes, where DNA is first condensed with the unmodified polycation and polyplexes are subsequently PEGylated, seem to be more efficient in improving pharmacokinetics (*7, 40*). However, from our point of view, this approach has serious drawbacks regarding polyplex preparation and characterization, especially in a clinical setting.

In our study, Trastuzumab modified PEG(2)-PEI at the same dose used by Merdan et al. significantly improved pharmacokinetics compared to that of PEI polyplexes (*21*). Comparable pharmacokinetics were observed for all Trastuzumab conjugates despite their different structure. Trastuzumab modification decreased the surface charge and increased polyplex stability in the case of all three conjugates. Most importantly, aggregation with erythrocytes was strongly decreased with all conjugates. Thereby, entrapment of polyplexes in small capillaries and recognition by the reticulo-endothelial system is reduced, and AUC increases. We hypothesized that in the case of the PEG-PEI copolymer used in the study of Merdan et al., PEGylation alone could not sufficiently inhibit erythrocyte aggregation. This might be one of the major reasons that no significant difference between PEI and PEG-PEI was found in this study. This suggests that the additional steric shielding introduced by antibody modification has a stronger effect on pharmacokinetics than the structure of PEG-PEI copolymers or linker chemistry.

The biodistribution of polyplexes was assessed 120 min after injection. Using a free, uncomplexed plasmid, only minor amounts of radioactivity were found in the liver and in the kidneys, which both are involved in plasmid excretion (*47*). Polyplexes prepared with PEI were taken up mainly by the liver and to a minor extent by the lung, spleen, and kidneys. The accumulation of polyplexes tended to be increased in highly perfused organs, such as the liver and kidneys (*47*). Furthermore, the liver and spleen possess discontinuous or fenestrated endothelia, which may facilitate the accumulation of polyplexes (*48*). Finally, positively charged polyplexes can activate the alternative complement system, which will result in the enhanced uptake in the liver and spleen (*41, 49*). Lung deposition is most likely due to the aggregation of polyplexes themselves, with erythrocytes, or both (*4, 21*). With all Trastuzumab conjugates, lung and spleen deposition was significantly reduced compared to that of PEI. We assume that the nearly neutral ζ-potential and the decreased erythrocyte aggregation mainly accounted for these changes in organ distribution as well.

In summary, the composition of polyplexes affected both in vitro specificity and in vivo pharmacokinetics. Concerning in vitro transfection efficiency and target cell specificity, PEGylation and linker chemistry were of major importance. Long PEG chains, as used in PEG(30)-PEI-Trastuzumab, hindered proper antigen recognition. The uptake of these polyplexes was

decreased potentially due to the high degree of substitution. In contrast, conjugates composed of PEG-PEI with shorter PEG chains or synthesized using a PEG linker successfully transfected the target cells with high specificity. Concerning the situation in vivo, it was found that antibody modification, irrespective of the linker chemistry or the PEG-PEI copolymer used, governed pharmacokinetics and biodistribution. Antibody modification in all cases resulted in higher AUC and lower disposition in lung and spleen compared to that of PEI polyplexes, which is potentially due to decreased ζ-potentials, improved polyplex stability, and decreased interaction with blood components.

ACKNOWLEDGMENT

We are grateful to Cornelia Brendel (FACS laboratory, Department of Hematology, Oncology and Immunology, University Hospital Marburg) for the generous use of equipment. We are indebted to Eva Mohr (Department of Pharmaceutics and Biopharmacy, Philipps Universität Marburg) for her technical support concerning cell culture. We are grateful to Terry Steele and Olivia Merkel (Department of Pharmaceutics and Biopharmacy, Philipps Universität Marburg) for the critical review of this manuscript.

In Vivo Production of scFv-Displaying Biopolymer Beads Using a Self-Assembly-Promoting Fusion Partner

Katrin Grage and Bernd H. A. Rehm*

Institute of Molecular Biosciences, Massey University, Private Bag 11222, Palmerston North 4442, New Zealand. Received September 10, 2007; Revised Manuscript Received October 29, 2007

Recombinant production and, in particular, immobilization of antibody fragments onto carrier materials are of high interest with regard to diagnostic and therapeutic applications. In this study, the recombinant production of scFv-displaying biopolymer beads intracellularly in *Escherichia coli* was investigated. An anti-β-galactosidase scFv (single chain variable fragment of an antibody) was C-terminally tagged with the polymer-synthesizing enzyme PhaC from *Cupriavidus necator* by generating the respective hybrid gene. The functionality of the anti-β-galactosidase scFv-PhaC fusion protein was assessed by producing the respective soluble fusion protein in an *Escherichia coli* AMEF mutant strain. AMEF (antibody-mediated enzyme formation) strains contain an inactive mutant β-galactosidase, which can be activated by binding of an anti-β-galactosidase antibody. *In vivo* activation of AMEF β-galactosidase indicated that the scFv is functional with the C-terminal fusion partner PhaC. It was further demonstrated that polymer biosynthesis and bead formation were mediated by the scFv-PhaC fusion protein in the cytoplasm of recombinant *E. coli* when the polymer precursor was metabolically provided. This suggested that the C-terminal fusion partner PhaC acts as a functional insolubility partner, providing a natural cross-link to the bead and leading to *in vivo* immobilization of the scFv. Overproduction of the fusion protein at the polymer bead surface was confirmed by SDS−PAGE and MALDI-TOF/MS analysis of purified beads. Antigen binding functionality and specificity of the beads was assessed by analyzing the binding of β-galactosidase to scFv-displaying beads and subsequently eluting the bound protein at pH 2.7. A strong enrichment of β-galactosidase suggested the functional display of scFv at the bead surface as well as the applicability of these beads for antigen purification. Binding of β-galactosidase to the scFv-displaying beads was quantitatively analyzed by enzyme-linked assays measuring β-galactosidase activity. These indicated that the anti-β-galactosidase scFv-displaying beads bound a maximum of 38 ng of β-galactosidase per 1 μg of bead protein, showing an apparent equilibrium dissociation constant (K_D) of 12×10^{-7} M. This study clearly demonstrated that anti-β-galactosidase scFv-displaying polymer beads can be produced in engineered *E. coli* in a one-step process by using PhaC as a self-assembly-promoting fusion partner.

INTRODUCTION

Recombinant production and engineering of antibodies enable a variety of new diagnostic and therapeutic applications. Most research now focuses on recombinant antibody fragments, which retain full antigen binding capacity and are easier to produce than the structurally more complex complete immunoglobulins (Igs). Some examples are scFv (single-chain variable fragment), Fab (antigen-binding fragment of antibodies) and V_{HH} (variable domain of heavy chain antibodies), with the scFv now being the most widely used fragment in bioengineering applications. Antibody fragments can be produced in a variety of hosts, including mammalian cells, yeast, and bacteria. Particular attention has been paid to production in the bacterial cytoplasm for several reasons. On the one hand, this is an attractive system because it is comparatively inexpensive and can give high yields for recombinant proteins. On the other hand, there is a definite need for further improvement because the bacterial cytoplasm has the disadvantage of providing a reducing environment, which does impair antibody disulfide bond formation. Approaches to overcome this problem have included refolding from inclusion bodies (*1, 2*), mutagenesis of antibody fragment-encoding genes (*3–5*), use of *E. coli* host strains with a more oxidizing cytoplasm (*trxB gor* mutant strains), coproduction of molecular chaperones, and fusion of antibody fragments to solubility-enhancing tags (*6–11*). Apart from further improving recombinant production systems for antibody fragments, a lot of research is currently focusing more directly on applications, one important tool being the immobilization of antibody fragments onto surfaces or carriers for use as, for example, biosensors or in immunotargeting (*12–16*).

There have been a few recent examples of proteins that could be overproduced at the surface of intracellular reserve polymer inclusions in bacteria by fusing the protein of interest to the polymer-generating enzyme PhaC (*17, 18*). PhaC is the key enzyme of this bacterial reserve polymer biosynthesis pathway, and it catalyzes the polymerization of (*R*)-3-hydroxyacyl-CoA to the respective polyester (polyhydroxyalkanoate) (*19*). The enzyme remains covalently attached to the growing polymer chain. Eventually, the self-assembly of several polyester chains leads to the formation of a spherical polymer bead with a hydrophobic polyester core and PhaC covalently attached to its surface (*20, 21*). Various protein engineering approaches have demonstrated that it is possible to (a) produce these polymer inclusions recombinantly in *E. coli* and (b) fuse other proteins to the N-terminus of PhaC without impairing PhaC activity and polymer bead assembly. The fusion partners, that is, proteins of interest, have been found to be displayed at the bead surface (*22, 23*). The beads that have a diameter of between 100 and 500 nm can be isolated from the production host and retain their integrity outside of the cell. In all examples reported

so far, the fusion partners retained their function, and some data suggested an even improved stability (*17, 18, 24*).

In this study, the natural cross-linking ability of the polymer-synthesizing enzyme PhaC was harnessed to generate polymer beads that display a functional scFv, an anti-β-galactosidase scFv, covalently bound to the bead surface (Scheme 1). This was achieved by constructing a hybrid gene of the scFv gene and *phaC* from *C. necator* and expressing it in a suitable, that is, polymer-accumulating metabolic background of *E. coli*. The used antibody fragment, scFv13R4, originates from a mutagenesis approach screening for improved expression (*5*). Anti-β-galactosidase scFv-displaying beads were isolated and successfully used for specific and reversible binding of their antigen β-galactosidase, enabling, for example, antigen purification or removal as well as assessment of the binding affinity by an enzyme-linked assay. To our knowledge, this is not only the first example of *in vivo* assembly of antibody fragment displaying polymer beads but also the first example of covalent and oriented scFv immobilization on beads in a one-step procedure.

EXPERIMENTAL PROCEDURES

Bacterial Strains and Growth Conditions. The bacterial strains used in this study are listed in Table 1. All *E. coli* strains were grown at 37 °C unless other conditions are specifically described. When required, antibiotics were used at the following concentrations: ampicillin, 75 μg/mL; chloramphenicol, 30 μg/mL; and tetracycline, 12.5 μg/mL.

Induction of gene expression was achieved by the addition of 1 mM IPTG (isopropyl β-D-thiogalactopyranoside) to the culture medium in the case of the *lac* and T7 promoters or by the addition of 20 μg/mL IAA (3 β-indoleacrylic acid) in the case of the *trp* promoter. For scFv13R4-PhaC overproduction and PHA granule formation, *E. coli* BL21(DE3) bearing the respective plasmids was grown in LB medium containing 1% (w/v) glucose. After induction at an OD_{600} (optical density at 600 nm) of 0.4–0.5, cultures were shifted from 37 to 30 °C and incubated for approximately 48 h.

MacConkey agar (Merck) was prepared according to the manufacturer's instructions. M9 lactose minimal medium was prepared as described elsewhere (*25*). X-gal agar contained 0.004% (w/v) x-gal (5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside) and 1 mM IPTG.

Plasmids, DNA Constructs, And Oligonucleotides. All plasmids and oligonucleotides used in this study are listed in Table 1. General cloning procedures were performed as described elsewhere (*26*). DNA primers, deoxynucleoside triphosphate, and *Taq* and Platinum *Pfx* polymerases were purchased from Invitrogen (CA). The DNA sequences of new plasmid constructs were confirmed by DNA sequencing according to the chain termination method using an ABI310 automatic sequencer.

The gene encoding scFv13R4 was amplified from plasmid pPM163R4 using primers scFv13R4-fwd and scFv13R4-rev. The PCR product was ligated into the cloning vector pGEM-T Easy (Promega, WI), and a spacer consisting of two 5′-phosphorylated oligonucleotides was inserted using restriction sites *Cla*I and *Hind*III. The scFv13R4-spacer fragment was then subcloned into the *Spe*I restriction site of $pCWE_{Spe}$ to generate $pCWE_{Spe}$-scFv13R4. This plasmid encodes a translational fusion of scFv13R4 and PhaC in which the fusion partners are connected by a $SerGly_4SerGly_4SerGly_4Ser$ linker. Plasmid pHAS-scFv13R4 was constructed by subcloning an *Xba*I/*Bam*HI fragment containing the scFv13R4-*phaC* gene from $pCWE_{Spe}$-scFv13R4 into pET-14b.

Isolation of Polymer Beads. Polymer bead isolation was carried out as described previously (*18*). Briefly, cells were harvested by centrifugation, resuspended in 50 mM potassium phosphate buffer at pH 7.2, and disrupted by passage through a cell disrupter Z Plus (Constant Systems, UK). The whole-cell lysate was subjected to centrifugation at 4000*g* for 15 min at 4 °C to sediment polymer beads. To enhance purity, the sediment was again resuspended in potassium phosphate buffer and loaded onto a glycerol gradient (88% and 44% (v/v) glycerol in potassium phosphate buffer). After ultracentrifugation for 2.5 h at 100,000*g* and 10 °C, beads could be isolated from a layer at the boundary between 88% and 44% glycerol. The polymer beads were washed once more with potassium phosphate buffer (50 mM, pH 7.2) and centrifuged at 100,000*g* for 1 h at 10 °C. The sediment containing the beads was suspended in potassium phosphate buffer containing 20% (v/v) glycerol and stored at 4 °C. For storage over longer time periods, protease inhibitor (EDTA-free protease inhibitor cocktail (Roche, Germany)) was added to the bead suspension.

***In Vivo* Functionality of the Polymer-Synthesizing Enzyme PhaC.** *In vivo* PhaC activity was obtained by analyzing the polyester content of the respective bacterial cells. The amount of accumulated polyester corresponds to the relative *in vivo* PhaC activity. Polyester contents were qualitatively and quantitatively determined by gas chromatography/mass spectrometry (GC/MS) after the conversion of the polyester into 3-hydroxymethylester by acid-catalyzed methanolysis (*27*).

Transmission Electron Microscopy (TEM) Analysis. Cells or beads were prepared for electron microscopy as follows: samples were fixed in primary fixative (3% glutaraldehyde and 2% formaldehyde in 0.1 M phosphate buffer) for 1 h, sedimented, and resuspended in 20% (w/v) BSA. Cells or beads were incubated again for 1 h in the primary fixative. After incubation, excess fixative was removed by washing three times with 0.1 M phosphate buffer. Osmium tetroxide (1% (w/v)) was applied as secondary fixative for 30 min. Excess fixative was removed as described above. Samples were then dehydrated in serially increased acetone concentrations and embedded in Procure 812 epoxy resin. Resin blocks were cured for 48 h at 60 °C. Light microscope sections (1 μm thick) were cut and stained with 0.5% (w/v) toluidine blue to locate concentrated areas of cells in the pellet, and the corresponding blocks were trimmed and TEM sections cut using a diamond knife and a Leica Ultracut R Ultramicrotome. Sections were stained with uranyl acetate and lead citrate, and studied using a Philips CM10 TEM.

Protein Analysis. Protein samples were routinely analyzed by SDS−PAGE (sodium dodecyl sulfate−polyacrylamide gel electrophoresis) as described elsewhere (*28*). The gels were

stained with Coomassie brilliant blue G250. Protein bands of interest were cut out off the gel and analyzed by matrix assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS). Protein concentrations were determined using the Bio-Rad Protein Assay.

MALDI-TOF Mass Spectrometry. Mass spectrometric analyses of tryptic peptides were carried out on a MALDI VOYAGER DE-PRO time-of-flight mass spectrometer from PerSeptive BioSystems (Framingham, MA), utilizing a nitrogen laser, emitting at 337 nm, and an accelerating voltage of 25 kV. Measurements were performed in the delayed extraction mode using a low mass gate of 2000. The mass spectrometer was used in the positive ion detection and linear modes. Samples of the digestion mixture were placed directly on a 100-position sample plate and allowed to air-dry after the addition of an equal volume of a saturated solution of 3,5-dimethoxy-4-hydroxycinnaminic acid (sinapinic acid) in 50% (v/v) acetonitrile and 0.3% (v/v) TFA.

Acidic pH Treatment of scFv-Displaying Beads. In order to remove any β-galactosidase of the *E. coli* production host that may have remained bound to the anti-β-galactosidase-scFv during the bead isolation process, scFv-displaying and control beads were treated with low pH. A volume of beads corresponding to 3 mg of bead protein was sedimented by centrifugation and resuspended in 1 mL of 50 mM glycine at pH 2.7. After another centrifugation, beads were washed once in 1 mL of 50 mM potassium phosphate buffer at pH 7.2 and once in 1 mL of PBS/Tween (phosphate buffered saline (10 mM potassium phosphate buffer at pH 7.2 and 0.5% (w/v) NaCl) and 0.05% (v/v) Tween 20) before being resuspended in the original volume of potassium phosphate buffer containing 20% (v/v) glycerol.

Reversible Binding of β-Galactosidase to Anti-β-galactosidase-scFv-Displaying Beads. scFv-displaying and control beads displaying only PhaC were sedimented by centrifugation, resuspended in PBS/Tween, and then mixed with β-galactosidase (27 μg) and BSA (50 μg) in a total volume of 600 μL. In each case 660 μg of bead protein was used in each case. Samples were incubated for 3 h at room temperature while slight rocking kept the beads in suspension. Beads were sedimented by centrifugation and subjected to a series of washes, either once in PBS/Tween, twice in high salt buffer (50 mM Tris at pH 7.4 and 500 mM NaCl), once in low salt buffer (10 mM Tris at pH 7.4 and 37.5 mM NaCl), and once in PBS/Tween or simply five times in PBS/Tween. Elution of β-galactosidase from the beads was achieved by resuspension in 80 μL of 50 mM glycine at pH 2.7. The eluate was centrifuged once more to ensure the removal of any residual beads and only 70 μL kept as the final eluate. The same beads were then subjected to a second elution step with 50 mM glycine at pH 1.9.

β-Galactosidase Activity Assay to Assess scFv Functionality. ScFv-displaying beads and control beads displaying only PhaC were diluted to the desired concentration in potassium phosphate buffer. *E. coli* β-galactosidase (Calbiochem) was diluted in blocking buffer (2% (w/v) skim milk powder in PBS/Tween). For a standard assay, 100 μL of beads (100 μg of protein) and 100 μL of β-galactosidase (1 μg) were added to 300 μL of blocking buffer in a microtube. All assays were carried out in triplicate. Samples were incubated for 1 h or 90 min at room temperature while slight rocking kept the beads in suspension. Beads were then sedimented by centrifugation, washed three times in PBS/Tween, and resuspended in 700 μL of Z-buffer (60 mM Na_2HPO_4, 40 mM NaH_2PO_4, 10 mM KCl, 1 mM $MgCl_2$, and 50 mM β-mercaptoethanol). Upon the addition of 100 μL of ONPG (2-nitrophenyl β-D-galactopyranoside; stock solution of 8 mg/mL in Z-buffer), samples were incubated at 37 °C for 5−15 min and the reaction stopped by addition of 400 μL of a 1 M Na_2CO_3 solution. Samples were clarified by centrifugation and absorbance of the supernatant measured at 420 nm (Libra S5 spectrophotometer, Biochrom). If beads had been pretreated at pH 2.7, the same volume as

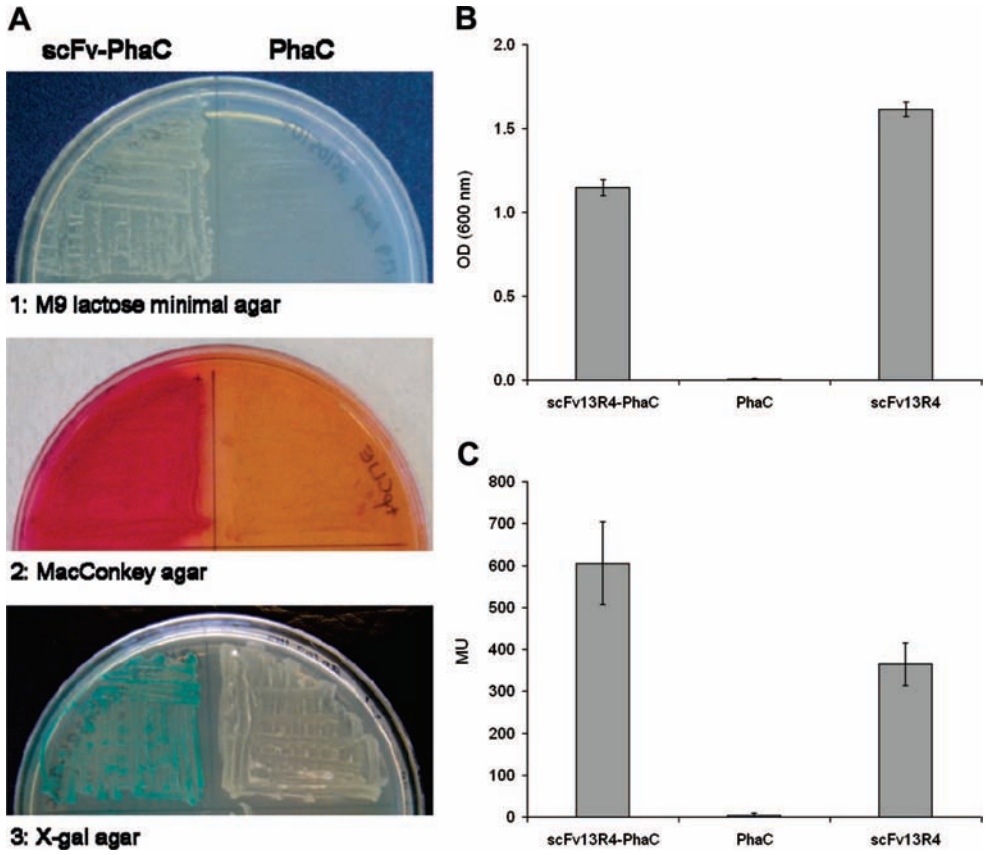

Figure 1. (A) Growth phenotyes of *E. coli* AMEF on different media, demonstrating *in vivo* activation of AMEF β-galactosidase by recombinantly produced anti-β-galactosidase scFv-PhaC fusion protein. *E. coli* AMEF 6101 harboring pCWE-scFv13R4 or pCWE (negative control) was streaked out on M9 lactose minimal, MacConkey, and X-gal agar plates. Growth on lactose as sole carbon source as well as color changes on MacConkey and X-gal agar require an activated AMEF β-galactosidase and thus a functional scFv-PhaC fusion protein. (B) *In vivo* rescue of *E. coli* AMEF in M9 lactose minimal medium by recombinantly produced anti-β-galactosidase scFv-PhaC fusion protein. Displayed is the final OD_{600} after 24 h of growth. Strains used were AMEF 959 harboring pCWE-scFv13R4, AMEF 959 harboring pCWE (negative control), and AMEF 959 harboring pPM163R4 (positive control). (C) Quantification of β-galactosidase activity after *in vivo* activation of AMEF β-galactosidase by recombinantly produced anti-β-galactosidase scFv-PhaC fusion protein. *E. coli* AMEF 959 harboring pPM163R4 (positive control), pCWE-scFv13R4, and pCWE (negative control), respectively, was cultivated, and cells were used to determine β-galactosidase activity by measuring conversion of ONPG into nitrophenol at 420 nm, enabling the calculation of MU (Miller units).

that of the original beads was used regardless of the protein concentration.

For the determination of the binding capacity of the scFv-displaying beads and the apparent equilibrium dissociation constant (K_D), the assay was performed with different β-galactosidase concentrations ranging from 0.067 to 10.65 μg, while the bead concentration remained unchanged (70 μg of protein). Control beads were only incubated with the highest β-galactosidase concentration. In order to test the temperature stability of the beads, they were incubated at increasing temperatures for 15 min, and scFv functionality was then assessed by measuring the binding of β-galactosidase as described above. All assays were carried out in triplicate.

***In Vivo* Activation of AMEF Proteins.** For qualitative assessment of *in vivo* AMEF activation, *E. coli* AMEF 959 or *E. coli* AMEF 6101 harboring plasmids $pCWE_{Spe}$-scFv13R4, pPM163R4, or pCWE was streaked out on MacConkey agar, M9 lactose minimal agar, and X-gal agar or incubated in liquid M9 lactose minimal medium. For a more quantitative assessment, essentially the same β-galactosidase activity assay as that for isolated beads was used. Tests were done in triplicate. *E. coli* AMEF 959 bearing the different plasmids was grown in LB medium overnight and the final OD_{600} of each culture recorded. An aliquot of each culture was harvested by centrifugation. Cells were resuspended in Z-buffer and permeabilized by adding CTAB (hexadecyltrimethylammonium bromide) and sodium deoxycholate. After the addition of ONPG, samples were incubated at 37 °C until sufficient yellow color had developed, and Na_2CO_3 was added to stop the reaction. The reaction time was recorded. After centrifugation, absorbance of the supernatant at 420 nm and at 550 nm was measured. MU (Miller units) were calculated as described elsewhere (*29*).

RESULTS

***In Vivo* Activation of AMEF β-Galactosidase by Soluble Anti-β-galactosidase scFv-PhaC Fusion Protein.** The plasmid $pCWE_{Spe}$-scFv13R4 was generated by inserting the anti-β-galactosidase scFv (scFv13R4) encoding gene into $pCWE_{Spe}$ immediately upstream of *phaC*, generating a hybrid gene under *lac* promoter control. Expression of this hybrid gene should enable the production of an anti-β-galactosidase scFv-PhaC fusion protein in which the fusion partners are connected by a 16 amino acid linker ($SerGly_4SerGly_4SerGly_4Ser$). In order to investigate whether the anti-β-galactosidase scFv retains its functionality when C-terminally fused to another protein, $pCWE_{Spe}$-scFv13R4 was tested for *in vivo* activation of AMEF β-galactosidase. AMEF (antibody-mediated enzyme formation) β-galactosidases are mutant β-galactosidases, which are inactive but can be activated by the binding of an anti-β-galactosidase antibody (*30*, *31*). Two different *E. coli* AMEF strains were used: AMEF 959 and AMEF 6101. Plasmids $pCWE_{Spe}$-scFv13R4 and pCWE were introduced into *E. coli* AMEF 6101 and the strains streaked out on MacConkey, M9 lactose minimal,

and X-gal agar (Figure 1A). Similarly, AMEF 959 harboring $pCWE_{Spe}$-scFv13R4, pCWE, or pPM163R4 was inoculated in liquid M9 lactose minimal medium (Figure 1B). Plasmid pCWE encodes only PhaC and served as a vector control, and pPM163R4 encodes the original unfused scFv13R4 and was used as a positive control.

Growth on lactose as the sole carbon source as well as color changes on MacConkey and X-gal agar require an activated AMEF β-galactosidase and thus a functional anti-β-galactosidase scFv. Here, both proteins, the scFv13R4 and the scFv13R4-PhaC, mediated growth on M9 lactose minimal medium (Figure 1A and 1B), whereas only PhaC did not. The observed color change of AMEF 6101 harboring $pCWE_{Spe}$-scFv13R4 on MacConkey agar indicated a pH drop caused by lactose fermentation and thus also confirmed that the scFv13R4-PhaC fusion protein bound and activated AMEF β-galactosidase (Figure 1A). Similarly, the cleavage of X-gal by β-galactosidase was observed only in the presence of scFv13R4-PhaC, as indicated by the blue color (Figure 1A). All these results demonstrated that the anti-β- galactosidase scFv as part of a scFv-PhaC fusion protein retained its antigen-binding functionality.

For a more quantitative assessment of the performance of scFv13R4-PhaC, β-galactosidase activity of overnight cultures of *E. coli* AMEF 959 harboring $pCWE_{Spe}$-scFv13R4, pCWE, or pPM163R4 was measured by monitoring the conversion of ONPG into nitrophenol. Both scFv13R4-PhaC and scFv13R4 clearly activated AMEF β-galactosidase. β-Galactosidase activity of AMEF 959 producing scFv13R4-PhaC reached on average 606 MU (Miller units), and on average 365 MU were obtained with AMEF 959 producing unfused scFv13R4 (Figure 1C). Almost no background β-galactosidase activity (4 MU) was detected for AMEF 959 bearing only the control plasmid pCWE. The relatively high difference between the *in vivo* AMEF activation achieved with scFv13R4-PhaC and scFv13R4 can probably be at least partly attributed to the different plasmids from which the respective genes were expressed. Plasmid pPM163R4 has a *trp* promoter, while in plasmid pCWE and its derivatives, genes are under the control of the *lac* promoter. Previous promoter strength analyses indicated that the strength of the *trp* promoter is about 30–40% of the strength of the *lac* promoter (*32*).

Overproduction of scFv13R4-PhaC at the Surface of Polymer Beads. To enable overproduction of the fusion protein under T7 promoter control, the scFv13R4-*phaC* hybrid gene from $pCWE_{Spe}$-scFv13R4 was inserted into pET-14b. In the activation experiments described above, no polymer beads were formed because of the absence of plasmid pMCS69. Plasmid pMCS69 carries the genes encoding two proteins, PhaA and PhaB, which mediate the provision of the polymer precursors and are thus required for polymer biosynthesis. In order to enable bead production and overproduction of the fusion protein at the bead surface, plasmid pHAS-scFv13R4 was introduced into *E. coli* BL21(DE3) harboring pMCS69. This recombinant strain mediated the production of anti-β-galactosidase scFv-displaying beads, which were isolated for further analysis. Control beads were isolated from *E. coli* BL21(DE3) (pMCS69 and pHAS). GC/MS analysis confirmed that the scFv-PhaC fusion protein mediates polymer production (data not shown). Polymer-accumulating cells as well as isolated beads were subjected to TEM in order to confirm the presence and shape of the beads (data not shown). Beads were found to be within the size range as previously described (*19–21*). On average, between 1.2 and 1.5 g (wet weight) of beads were obtained per 1 L of culture, corresponding to 92–108 mg of total bead protein.

Proteins attached to the beads were separated by SDS−PAGE (Figure 2). Plasmid pHAS-scFv13R4 mediated the production of beads showing an overproduced prominent protein with an apparent molecular weight of about 92 kDa. This corresponded to the predicted molecular weight of the fusion protein. The protein was identified as scFv13R4-PhaC by MALDI-TOF/MS analysis of tryptic peptide fragments (Table 2). In addition, the prominent protein found on the control beads, which corresponds to unfused PhaC, is absent from the scFv-displaying beads.

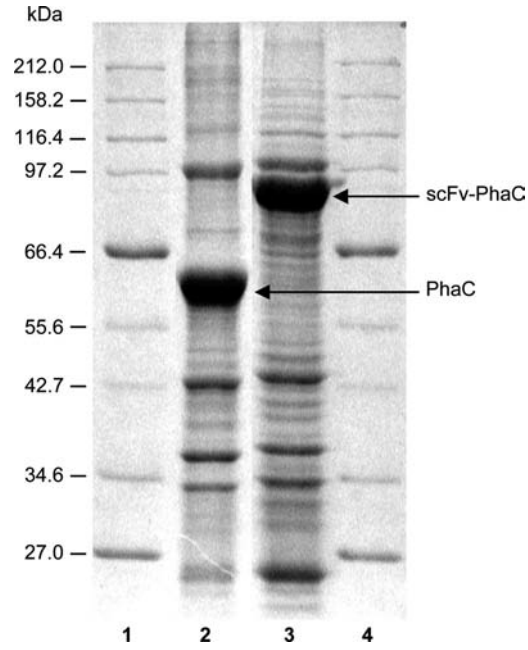

Figure 2. SDS−PAGE analysis of polymer beads produced in *E. coli* BL21(DE3). Lanes 1 and 4, molecular weight standard; lane 2, beads isolated from *E. coli* BL21(DE3) harboring pHAS (only PhaC); lane 3, beads isolated from *E. coli* BL21(DE3) harboring pHAS-scFv13R4 (scFv13R4-PhaC). The arrows indicate PhaC and the anti-β-galactosidase scFv-PhaC fusion protein, which was confirmed by peptide mass fingerprinting using MALDI-TOF MS.

Reversible Binding of β-Galactosidase to Anti-β-galactosidase scFv-Displaying Beads. In order to demonstrate that immobilized anti-β-galactosidase scFv is functional and retains its antigen-binding properties, beads were used to purify β-galactosidase from a mixture of β-galactosidase and bovine serum albumin (BSA). Beads were incubated with the protein mixture, washed several times, and bound proteins eluted with glycine at pH 2.7 and glycine at pH 1.9. Only a protein corresponding in size to β-galactosidase was eluted from scFv-displaying beads, the majority of it during the pH 2.7 elution step (Figure 3). The protein was identified as β-galactosidase by MALDI-TOF/MS analysis of tryptic peptide fragments (Table 2). No β-galactosidase was eluted from control beads not displaying the scFv (Figure 3). This indicates that β-galactosidase was specifically and reversibly bound to the scFv displayed as scFv-PhaC fusion protein on the bead surface and that no unspecific binding to the remaining bead surface occurred.

Enzyme-Linked Assays Using Anti-β-galactosidase scFv-Displaying Beads.*In Vitro Detection of β-Galactosidase Activity.* One of the main objectives of this study was to test the performance of scFv-displaying beads in enzyme-linked assays, similar to ELISA but taking advantage of the bead as a carrier material. In all assays, β-galactosidase activity was measured to assess the binding of β-galactosidase to the scFv. In order to establish a standard assay, beads were incubated with β-galactosidase for 1 h or 90 min, washed several times, and incubated with the β-galactosidase substrate ONPG. Conversion of ONPG into nitrophenol was determined by measuring the absorption at 420 nm (Abs_{420}). This assay showed that β-galactosidase bound to the scFv on the bead surface and converted ONPG

into nitrophenol (Figure 4). Control beads not displaying the scFv did not convert ONPG.

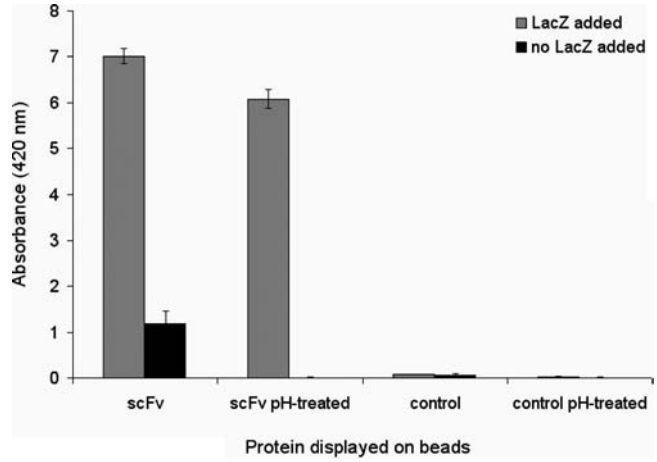

Figure 4. Enzyme-linked assay using β-galactosidase-mediated conversion of ONPG to detect specific binding of β-galactosidase by scFv13R4 displayed on the bead surface. Anti-β-galactosidase scFv-displaying and control beads were either used without prior acidic pH treatment or washed with glycine buffer at pH 2.7. Beads were then incubated with β-galactosidase (light gray), or no β-galactosidase was added (dark gray), and absorption at 420 nm was measured to determine the conversion of ONPG into nitrophenol.

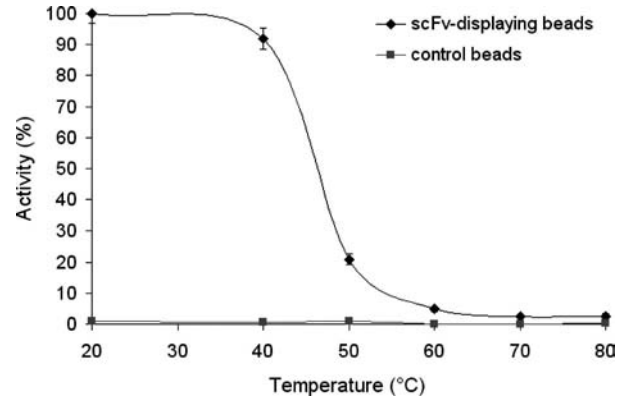

Figure 5. Temperature stability of anti-β-galactosidase scFv-displaying beads. Beads were incubated at increasing temperatures for 15 min, and β-galactosidase activity was subsequently measured to assess the remaining anti-β-galactosidase scFv functionality.

Acidic pH Treatment for Additional Purification of Anti-β-galactosidase scFv-Displaying Beads. Since the beads were produced in a commercially available *E. coli* BL21(DE3), which possesses a *lacZ* gene, it was investigated whether any β-galactosidase derived from the host strain binds to the scFv on the bead surface inside the cell and also remains bound after bead isolation. In order to address this question, β-galactosidase activity assays of scFv-displaying and control beads were carried out with and without the addition of β-galactosidase. Control beads showed no significant β-galactosidase binding. Anti-β-galactosidase scFv-displaying beads showed a weak background β-galactosidase activity corresponding to $Abs_{420} = 1.2$, whereas the same beads incubated with β-galactosidase showed a maximum $Abs_{420} = 7.0$ (Figure 4). In order to remove the residual β-galactosidase, beads were washed with glycine buffer at pH 2.7, which successfully eliminated any background β-galactosidase activity. Upon addition of β-galactosidase, these pretreated beads again showed a high absorbance at 420 nm, indicating that the β-galactosidase binding ability of the scFv was not impaired by exposure to acidic pH (Figure 4).

Antigen-Binding Characteristics. In order to assess the stability, that is, antibody functionality, of the scFv-displaying beads, β-galactosidase binding assays were repeatedly conducted

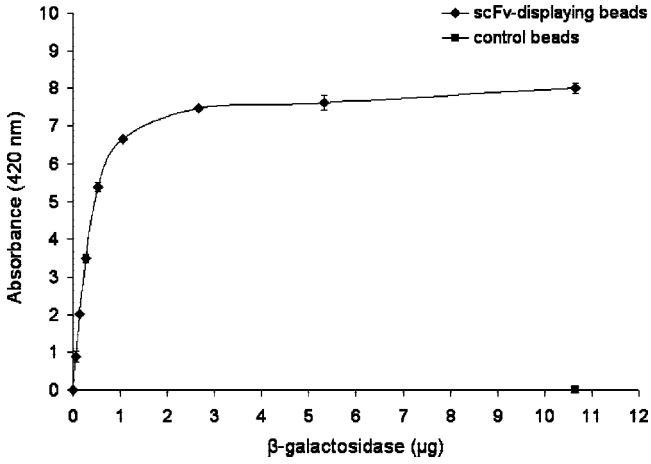

Figure 6. Determination of the binding capacity of anti-β-galactosidase scFv-displaying beads. Beads were incubated with increasing concentrations of β-galactosidase, and the conversion of ONPG was measured to detect β-galactosidase activity. Control beads were only incubated with the highest β-galactosidase concentration. An absorption maximum was observed for $\geq$2.66 μg of β-galactosidase.

(data not shown). After three months of storage at 4 °C, no decrease in antigen (β-galactosidase)-binding ability was detectable.

Temperature stability was tested by subjecting anti-β-galactosidase scFv-displaying beads to increasing temperatures and then assessing scFv functionality by standard β-galactosidase activity assays (Figure 5). The beads retained almost full binding capacity (92%) up to 40 °C. It then dropped quickly to about 21% at 50 °C, and no more binding was detectable at 70 °C.

The binding capacity of anti-β-galactosidase scFv-displaying beads and the apparent equilibrium dissociation constant (K_D) were determined by β-galactosidase activity assays using varying concentrations of β-galactosidase. Beads corresponding to 70 μg of protein and 0.067–10.65 μg of β-galactosidase were used. Beads were incubated with β-galactosidase for 1 h, washed, and incubated with the β-galactosidase substrate ONPG. The mean absorption at 420 nm was measured. An absorption maximum of 7.5 was observed for amounts $\geq$2.66 μg of β-galactosidase, which is approximately the amount of β-galactosidase that can be bound by 70 μg of bead protein (Figure 6). The half-maximum binding capacity can thus be determined at an absorption of 3.75, which corresponds to 300 ng of β-galactosidase (Figure 6). Taking into account the molecular weight of β-galactosidase (465.396 g/mol) and the assay volume (525 μL), an apparent equilibrium dissociation constant (K_D) of 12×10^{-7} M could be deduced.

DISCUSSION

In this study, the display of a functional scFv at the surface of biopolymer beads intracellularly assembled in *E. coli* by a protein engineering approach using a favorable insolubility fusion partner was investigated. The fusion partner mediated the *in vivo* self-assembly of polymer beads with a hydrophobic polymer core surrounded by the fusion partner, enabling surface display of the scFv (Figure 7). Here, an anti-β-galactosidase scFv was C-terminally fused to the polymer bead forming enzyme PhaC from *C. necator* by constructing the respective hybrid gene. Production of this fusion protein in *E. coli* led to the formation of the desired scFv-displaying beads, which can then be isolated by a simple centrifugation step and are ready to use straight after isolation (Figure 7).

Assessment of the *in vivo* functionality of the anti-β-galactosidase scFv-PhaC fusion protein using *in vivo* activation of the AMEF β-galactosidase clearly suggested that the fusion protein binds to the AMEF β-galactosidase (Figure 1). Activation of the AMEF β-galactosidase by the anti-β-galactosidase scFv-PhaC fusion protein enabled growth of the respective recombinant AMEF strain on lactose as the sole carbon source (Figure 1A and 1B) and the detection of AMEF β-galactosidase activity (Figure 1C). When polymer precursors were metabolically provided, polymer bead formation was mediated by the anti-β-galactosidase scFv-PhaC fusion protein as assessed by TEM and GC/MS. Protein analysis of isolated beads demonstrated a strong overproduction of anti-β-galactosidase scFv-PhaC fusion protein at the bead surface (Figure 2). The functionality of the bead-bound fusion protein was clearly confirmed by applying the beads for batch purification of β-galactosidase to electrophoretic homogeneity from a protein mixture (Figure 3). Specific β-galactosidase binding was further

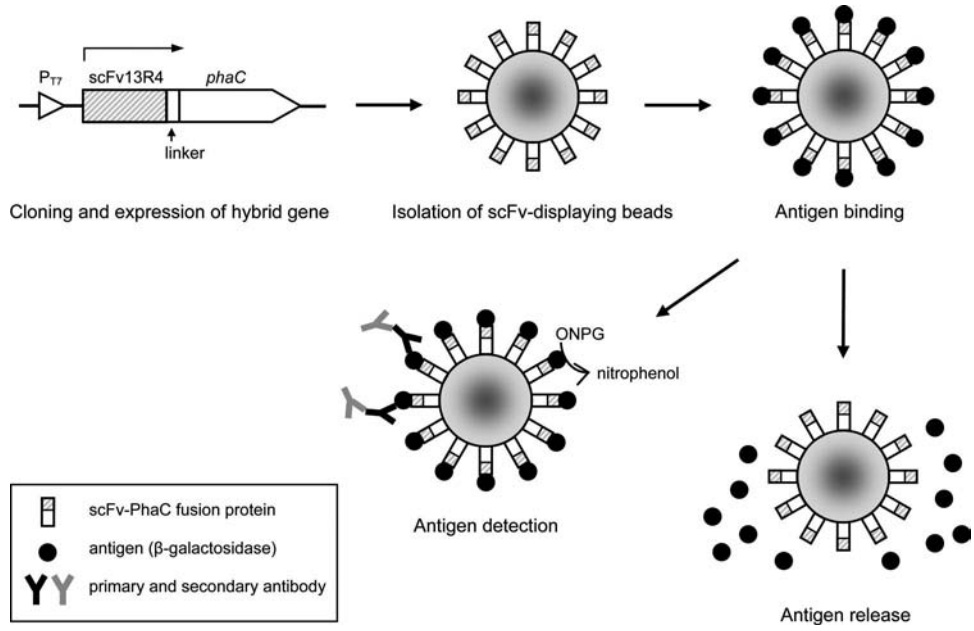

Figure 7. Schematic overview of the *in vivo* self-assembly of scFv-displaying polymer beads as well as possible applications of the respective isolated beads.

confirmed by assessment of the β-galactosidase activity of β-galactosidase bound to the beads (Figure 4). The beads themselves did not show unspecific binding of β-galactosidase (Figures 3 and 4). However, analysis of scFv-displaying beads isolated from recombinant *E. coli* BL21(DE3) showed that some β-galactosidase molecules were already bound (Figure 4). Acidic pH 2.7 treatment completely removed bound β-galactosidase, while maintaining bead and scFv functionality for the subsequent binding of β-galactosidase. The anti-β-galactosidase scFv-displaying beads showed a strong decline in β-galactosidase binding capacity when incubated at temperatures above 40 °C (Figure 5). This rather low thermal stability is presumably due to the lack of one set of disulphide bonds in this particular scFv (*5*). Similar observations were made in a previous study analyzing the thermal stability of the respective soluble scFv13R4. An apparent equilibrium dissociation constant (K_D) of 1.2 μM suggested an ~75-fold increase in binding affinity, when compared to that of the soluble scFv13R4 (*33*). Consistently, it was previously demonstrated in binding assays that nanoparticles diplaying an antibody at high-density show a higher binding affinity than the antibody itself, enhancing the sensitivity of a diagnostic assay (*34*).

This study demonstrated the feasibility of a novel approach for one-step *in vivo* scFv immobilization. Emerging key requirements for the immobilization of antibody fragments include stable, that is, covalent, attachment and directed versus random orientation to minimize loss of functionality as well as preservation of native state (*35*). Several sophisticated approaches have been reported, for example, the fusion of different antibody fragments to cutinase followed by the binding of these fusion proteins to phosphonate capture ligands presented on self-assembled monolayers; fusion of a scFv to a C_L domain with a C-terminal cysteine residue and cross-linking to a gold surface by a maleimide linker; recrystallization of a bacterial S-layer protein fused to a V_{HH} on a gold surface precoated with thiolated SCWP (secondary cell wall polymer); and cross-linking of a cysteine-tagged scFv to immunoliposomes by a maleimide linker (*12–15*). However, all these examples require separate tagging and coating or cross-linking steps. In addition, apart from the immunoliposomes, they all result in planar functionalized surfaces. A nonplanar organization, for example, spherical beads, can have significant advantages such as an increased binding surface, leading to a wide range of applications in laboratory methods. Another example for scFv-coated beads is the immobilization of scFv-CBD fusion proteins to chitin beads for immunoaffinity chromatography, but this again is not a covalent interaction (*36*). The scFv-displaying polymer beads described here meet the criteria of covalent and oriented binding of the immobilized antibody fragment. Furthermore, they can be generated by a simple one-step process without the need for additional coating or cross-linking of a preformed bead, suggesting a novel and economic production strategy (Figure 7). Further investigations will be required to elaborate the simultaneous display of different functionalities on the bead surface, analogous to fusions of soluble antibody fragments to other molecules such as drugs or toxins for immunotargeting (*37, 38*). In addition, the hydrophobic bead core could provide a significant payload for water-insoluble drugs, the targeted delivery of which could be mediated by display of the desired binding affinity.

ACKNOWLEDGMENT

We thank Pierre Martineau for providing the plasmid pPM163R4 and the *E. coli* AMEF strains, the latter with the kind permission of Franco Celada. This study was supported by research funding from Institute of Molecular Biosciences at Massey University as well as Massey University.

Received March 22, 2007; Revised Manuscript Received October 9, 2007

Obtaining highly specific and active ribonuclease activities is an important goal with numerous medical and biochemical applications. As a step toward more active and specific ribonucleases, we describe the preparation and the enzymatic and structural properties of RNase S monomers and dimers conjugated to DNA and PNA molecules. Poly(dT)$_n$ (2′-oligodeoxyribonucleotides, $n = 8$, 15) and t_8 peptide nucleic acid (PNA) chains have been conjugated to the S-peptide of ribonuclease S. Monomers and dimers of the conjugated enzyme have been obtained and characterized by ^{1}H NMR spectroscopy, showing that DNA or PNA conjugation does not alter the native structure of ribonuclease S. The oligonucleotide-conjugated RNase S monomer and dimer show significant activity against single-stranded RNA and very low/negligible hydrolysis of double-stranded poly(A)·poly(U). In contrast, the t_8-conjugated RNase S monomer and dimer show substantial activity against both ssRNA and dsRNA. These results highlight the importance of positive charges near but not in the active site in enhancing activity against dsRNA and reveal the promise of PNA−RNase conjugates for modulating RNase activity.

INTRODUCTION

Many natural ribonucleases (RNases[1]) play key roles in RNA processing (*1*), splicing (*2*), and, as more recently discovered, in gene silencing (*3*). In the latter case, formation of an RNA-induced silencing complex (*4*) that incorporates an RNA chain allows the recognition and specific cleavage of RNA molecules whose sequence is complementary to that of the nucleic acid component. This natural example suggests that catalytically active and specifically targetable RNases can be generated by linking a complementary oligonucleotide to a ribonuclease. Such active and targetable RNases are expected to have many uses in medicine and biotechnology. Alternatively, specific RNA cleavage has been achieved by coupling DNA strands to groups with ribonucleolytic activity, such as imidazole groups (*5*), or coordinated copper (*6*) or lanthanide ions (*7*). However, the reaction times of these artifical RNases is slow (hours time scale), and their *in vivo* effectiveness has not been established yet.

Among the many ribonucleases that can be conjugated to a nucleic acid chain, bovine pancreatic ribonuclease A exhibits several interesting advantages (*8*). First, this protein is a highly active monomeric enzyme, whose domain-swapped oligomers have a potent cytotoxic activity against human tumors transplanted onto nude mice (*9*). The basis of the selective cytotoxicity of RNase oligomers is not completely understood yet, but one contributing factor seems to be their enhanced activity against duplex RNA. This augmented activity is due to a higher density of positive charges on the surface of the oligomers relative to the monomer, rather than a cooperativity or synergy between the active sites in the oligomer (*10*). Second, bovine pancreatic RNase A can be specifically cleaved by subtilisin between residues 20 and 21. The two fragments, called S-peptide (residues 1–20) and S-protein (residues 21–124) remain noncovalently bound together, and their complex (RNase S) retains the same enzymatic activity of uncleaved RNase A (*11*). This property of RNase S has been used in many studies on protein stability, folding and enzyme catalysis (*12–14*). Both RNase A and RNase S monomers have a very strong specificity for pyrimidines at the position 5′ to the scissile bond, prefer A at the position 3′ to the scissile bond, and prefer purines at the following position (*15, 16*) and possess low activity against dsRNA (*17*). Recently, we have shown that RNase S can also form domain-swapped dimers with the same enhanced activity against dsRNA as does the corresponding "C-dimer" of RNase A (dimeric form of RNase A in which the C-terminal residues (115–124) are swapped between two monomers) (*18*).

These peculiar features of RNase S are very attractive for protein−nucleic acid conjugation, since the short length of the S-peptide facilitates the synthesis of variants of S-peptide that recombine with S-protein to produce semisynthetic RNase S. Previous work has shown that conjugating oligonucleotides to monomeric Ribonuclease S can endow the enzyme with a greatly enhanced, restriction enzyme-like specificity against the complementary RNA (*19*). In the same way, the covalent linkage of an oligonucleotide or a nucleic acid recognizing component

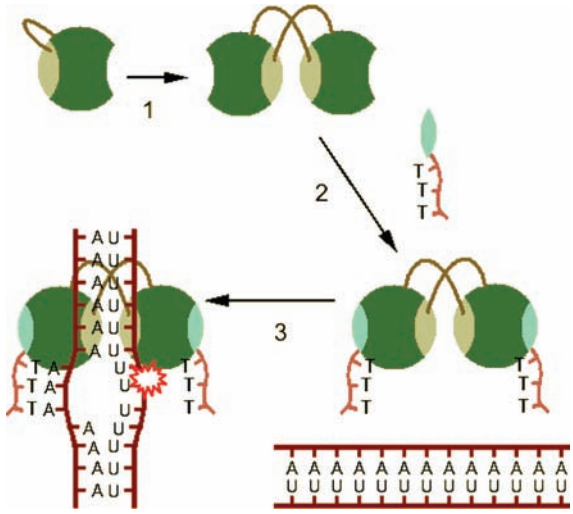

Figure 1. Strategy followed to modulate RNase activity by conjugation to oligothymines. Step 1, S-protein is dimerized by lyophilization from 40% aq acetic acid. During this process, the protein cores (dark green) are linked to form a metastable dimer by swapping of the C-terminal β-strand (light green). Step 2, the dimeric RNase S is reconstituted by addition of S-peptide conjugated to polythymine, whose backbone can be negatively charged (2′-oligodeoxyribonucleotides) or neutral (peptide nucleic acid). Step 3, interaction of polythymine component with a complementary region in dsRNA promotes degradation by the RNase.

to RNase oligomers should increase their specificity and improve their chemotherapeutic properties. In addition, this conjugated, complementary sequence could help disrupt double-helical regions of cellular RNA, leading to enhanced cleavage by RNase (Figure 1).

The main purpose of this work is to take a first step toward developing highly selective RNase S conjugates with the enhanced dsRNase activity of RNase A oligomers. We have prepared RNase S monomers and dimers from S-peptide molecules conjugated to nucleic acid recognizing molecules to assess the effect of the appending chain on RNase activity. Positive charges on the surface of the RNase, which are near the active site but not part of it, are thought to stabilize transient open regions of duplex RNA, that are subsequently cleaved by the enzyme (*10*, *17*, *20*, *21*). Since the negative charges on the phosphodiester backbone might interact with the positively charged groups of the enzyme and interfere with its activity, we have conjugated RNase S to both a polyanionic and a neutral chain, namely, 2′-oligodeoxyribonucleotides and a peptide nucleic acid (PNA). The latter offers the additional advantage that peptide nucleic acids are known to form very stable complexes with complementary sequences of RNA or DNA (*22*). Although PNA conjugation has been extensively employed to enhance PNA activities or for delivery in biological systems (see, for instance, refs *23*−*27*), the present work is, to our knowledge, the first report of an RNase conjugated to PNA.

EXPERIMENTAL PROCEDURE

DNA−S-Peptide Conjugate Preparation. The DNA−S-peptide conjugates, dT_8-KETAAAKFERQHMDSSTSAA and dT_{15}-KETAAAKFERQHMDSSTSAA, were prepared following the recently reported Diels–Alder approach (*28*). Briefly, the oligonucleotide chains were synthesized on controlled-pore glass using the standard phosphite triester methodology, which was also used to incorporate the phosphoramidite derivative of the diene. After deprotection with concentrated aqueous ammonia (4 h, room temperature), the target products were purified by reversed-phase medium-pressure liquid chromatography. MALDI-TOF mass spectrometric characterization (trihydroxyacetophenone/ammonium citrate, negative mode, linear) gave the following values: diene-$^{5'}$dTTTTTTTT, *m*/*z* 2530.56 $[M - H]^-$ (calc mass: 2530.44); diene-$^{5'}$dTTTTTTTTTTTTTTT, *m*/*z* 4652.88 $[M - H]^-$ (calc mass: 4658.76).

Solid-phase synthesis on a 2-chlorotrityl chloride polystyrene−1% divinylbenzene resin (Novabiochem, loading: 1.49 mmol Cl/g) was used to prepare the maleimide−peptide. The peptide chain was elongated using N^{α}-Fmoc derivatives [Arg(Pbf), Asp(O*t*Bu), Gln(Trt), Glu(O*t*Bu), His(Trt), Lys(Boc), Ser(*t*Bu), and Thr(*t*Bu)] and *N*,*N*′-diisopropylcarbodiimide/1-hydroxybenzotriazole activation, which was followed by incorporation of 3-maleimidepropionic acid. The desired product was obtained after cleavage with a 1:1:98 mixture of trifluoroacetic acid, 1,2-ethanedithiol, and dichloromethane (5 × 30 s, room temperature), deprotection with 2.5:2.5:2.5:1:91.5 thioanisole/H_2O/1,2-ethanedithiol/triisopropylsylane/trifluoroacetic acid mixture (4.5 h, room temperature), and purification by reversed-phase medium-pressure liquid chromatography. MALDI-TOF mass spectrometric characterization (2,5-dihydroxybenzoic acid, positive mode, reflector) gave a *m*/*z* ratio for the product of 2316.98 $[M + H]^+$ (calc mass: 2316.04).

The products were conjugated by reacting equimolar amounts of maleimide−peptide and diene−oligonucleotide in water, at 37 °C. After 20 h, an aliquot was removed from the reaction mixture and analyzed by reversed-phase HPLC. If the conversion of diene−oligonucleotide to peptide–oligonucleotide conjugate after that time was not quantitative, an amount of maleimide−peptide equimolar to the amount of unreacted diene−oligonucleotide was added, and the mixture was left to react for an additional period of 4 to 8 h. The target conjugates were isolated after gel filtration (Sephadex G-25) or HPLC. MALDI-TOF mass spectrometric characterization (trihydroxyacetophenone/ammonium citrate, negative mode, linear): dT_8-KETAAAKFERQHMDSSTSAA, *m*/*z* 4842.21 $[M - H]^-$ (calc mass: 4847.89); dT_{15}-KETAAAKFERQHMDSSTSAA, *m*/*z* 6968.32 $[M - H]^-$ (calc mass: 6974.80).

Synthesis of Diene-t_8. The peptide nucleic acid was assembled on 100 mg of 2-chlorotrityl chloride resin (see above). For the incorporation of the first monomer, 0.6 equiv of Fmoc-*t*-OH (Applied Biosystems), 5 equiv of *N*,*N*-diisopropylethylamine and anhydrous dichloromethane were added to the solid matrix, and the mixture was stirred for 45 min. After filtration and washings, the remaining reactive sites were capped by reaction with 100 μL of methanol. Removal of the Fmoc group from an aliquot of Fmoc-T-resin (20% piperidine in DMF, 2 × 10 min) and spectrophotometric quantification of the *N*-(9-fluorenylmethyl)piperidine formed indicated that the loading of Fmoc-T-resin was 0.21 mmol Fmoc/g. Subsequent t monomers were incorporated following standard PNA synthesis procedures. The Fmoc group was removed as indicated above. Two solutions were prepared before each coupling. Solution A was obtained by dissolving 5 equiv of Fmoc-*t*-OH in the minimum amount of *N*-methylpyrrolidone; solution B was prepared by adding 5.5 equiv of *N*,*N*-diisopropylethylamine and 5.5 equiv of 2,6-lutidine to a solution of 4.5 equiv of HATU in the minimum amount of anhydrous DMF. Immediately prior to coupling, the two solutions (A and B) were mixed and stirred at room temperature for 2 min, and the resulting mixture added to the solid matrix. After 45 min, the resin was washed (dichloromethane, DMF, and methanol), and an aliquot of support was withdrawn to determine the loading (see above). The coupling yield of the second Fmoc-*t*-OH monomer was about 40%, but a second coupling did not improve the yield. The coupling yield for the incorporation of the subsequent monomers ranged between 92% and 98%. A capping step was performed after each coupling by reaction with a 5:6:89 mixture of Ac_2O/2,6-lutidine/DMF (5 min).

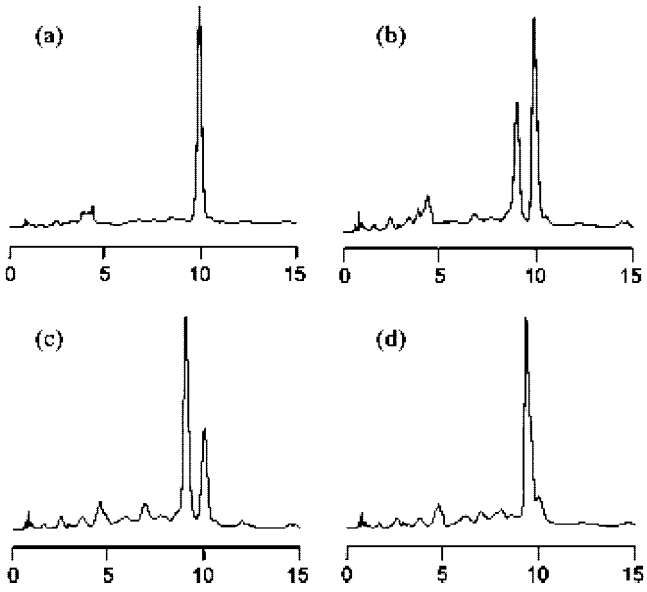

Figure 2. Reversed-phase HPLC traces of crude diene-t_8 (a), and conjugation reaction between diene-t_8 and maleimide-Lys-Glu-Thr-Ala-Ala-Ala-Lys-Phe-Glu-Arg-Gln-His-Met-Asp-Ser-Ser-Thr-Ser-Ala-Ala-OH after 24 h (b), 3 days (c), and 4 days (d).

(4*E*)-Hepta-4,6-dienoic acid was prepared following the described procedures (*29*)with minor modifications. Purification of ethyl (4*E*)-hepta-4,6-dienoate was carried out by silica gel column chromatography eluting with hexanes and increasing amounts of dichloromethane (5% to 40%). Ester hydrolysis was accomplished by treatment with 5 equiv of LiOH in a 3:1 (v/v) ethanol/water mixture for 2 h at 50 °C. Ethanol was removed in vacuo, and the resulting aqueous solution was extracted with dichloromethane, acidified with 10% aq HCl to pH 2–3, and reextracted with dichloromethane. The organic solution was dried over $MgSO_4$, filtered, and evaporated to dryness, which afforded the target acid in 84% yield.

Incorporation of (4*E*)-hepta-4,6-dienoic acid onto t_8-resin (85 mg, loading 0.06 mmol Fmoc/g): 10 equiv of the acid was coevaporated from anhydrous ACN (3×) and dissolved in the minimum amount of *N*-methylpyrrolidone (solution A). HATU (9 equiv) was dissolved in the minimum amount of anhydrous DMF, followed by addition of *N*,*N*-diisopropylethylamine (11 equiv) and 2,6-lutidine (11 equiv) (solution B). The two solutions were mixed and stirred at room temperature for 2 min, added to t_8-resin, and the mixture stirred for 45 min. Filtration and washings were followed by the capping step.

Cleavage from the solid support was carried out by reaction with a 1:99 trifluoroacetic acid/dichloromethane mixture (5 × 30 s treatment). Trifluoroacetic acid and most of the dichloromethane were removed by bubbling N_2 into the solution, and the resulting residue was poured onto cold ether to precipitate the target diene-t_8. The resulting pellet was insoluble in water and in most organic solvents (acetonitrile, tetrahydrofurane, dioxane) but completely soluble in hexafluoroisopropanol. Reverse-phase HPLC analysis and MALDI-TOF MS confirmed high homogeneity (92%) and the identity of the target diene-t_8, respectively. Due to insolubility problems, diene-t_8 was used in the Diels–Alder conjugation without further purification.

Diene-t_8: anal. HPLC (A: 0.045% trifluoroacetic acid in water, B: 0.036% trifluoroacetic acid in acetonitrile, linear gradient from 10% to 40% of B in 15 min, X-terra C18 column, 2.5 μm, 1 mL/min): t_R 10.0 min (Figure 2a); MALDI-TOF MS (synapinic acid, positive mode, reflector): *m*/*z* 2278.10 $[M + Na]^+$, 2294.04 $[M + K]^+$ (calc mass: 2254.88).

Diels–Alder Conjugation between Maleimide-Lys-Glu-Thr-Ala-Ala-Ala-Lys-Phe-Glu-Arg-Gln-His-Met-Asp-Ser-Ser-Thr-Ser-Ala-Ala-OH and Diene-t_8. 643.2 nmol of maleimide−peptide and 214.4 nmol of crude diene-t_8 (3:1 ratio) were dissolved in a 1:1 (v/v) water/hexafluoroisopropanol mixture and reacted at 40 °C (diene-t_8 concentration in the reaction medium: 0.21 mM). The progress of the reaction was monitored by reversed-phase HPLC, showing a 36% conjugation yield after 24 h (Figure 2b). An additional 4 equiv of S-peptide was added, and the HPLC traces showed that the yield increased to 66% after 3 days and 89% after 4 days (Figure 2c,d, respectively). The t_8−S-peptide conjugate was purified by reversed-phase HPLC (same solvents as analysis conditions, 30 min gradient, Hamilton PRP-1 polystyrene−divinylbenzene column, 10 μm, 2 mL/min).

t_8−S-peptide: anal. HPLC (A: 0.045% trifluoroacetic acid in water, B: 0.036% trifluoroacetic acid in acetonitrile, linear gradient from 10% to 40% of B in 15 min, X-terra C18 column, 2.5 μm, 1 mL/min): t_R 9.2 min; MALDI-TOF MS (synapinic acid, positive mode, reflector): *m*/*z* 4571.30 $[M + H]^+$ (calc mass: 4570.92).

Formation of DNA−RNase and PNA−RNase Dimers and Monomers. The formation of DNA−RNase S dimers followed the procedures used previously to obtain RNase S dimers containing unmodified S-peptide (Figure 1) (*18*). S-protein, obtained from Sigma, was incubated in 40% (v/v) acetic acid/water at a concentration of 15 mg/mL for 1 h, and then the solution was lyophilized. The resulting dry powder was redissolved in a solution containing an excess of the $(dT)_n$−S-peptide conjugate or t_8−S-peptide conjugate and 0.20 M sodium phosphate buffer (pH 6.7). The mixture of $(dT)_n$−RNase S dimers, $(dT)_n$−RNase S monomers, and the excess $(dT)_n$−S-peptide conjugate (or t_8−RNase S dimer, monomer, and excess t_8−S-peptide conjugate) were separated by gel filtration chromatography using a Superdex 75 column on an Amersham Biosystems ÄKTA FPLC system.

Assays for Enzymatic Activity. To assess the sequence specificity of cleavage, RNAs were purchased from Dharmacon RNA Technologies (2′OH form, purified and desalted). The names and sequences of the RNAs are

Substrate 1: 5′-GGCGGCGGAAAAAAAAGGCGGCGG-3′
Substrate 2: 5′-CCGCCGCCUUUUUUUUCCGCCGCC-3′
Control 1: 5′-GGCGGCGGAUAUAUAUGGCGGCGG-3′
Control 2: 5′-CCGCCGCCUAUAUAUACCGCCGCC-3′

These sequences were chosen so that the "substrate RNAs" would contain a segment (eight consecutive As) that is complementary to the stretch of eight Ts in the conjugate. Whereas the "control dsRNAs" have the same overall G + C: A + U ratio as the "substrate dsRNAs", the As and Us alternate so that it is not expected that this RNA will be recognized by the conjugate. The sequences were designed to avoid hairpin or homoduplex formation. GC-rich segments are placed at termini to minimize fraying when substrate 1 and substrate 2 or control 1 and control 2 are combined to form double-stranded RNA. To test the importance of a single stranded region within a dsRNA for efficient cleavage by RNase A species, the central region of substrate dsRNA is complementary, whereas that of control dsRNA is not.

RNase activity against single-stranded RNAs was measured using the Kunitz assay (*30*). The Kunitz spectroscopic assay is based on the blue shift in the ultraviolet spectrum of single-stranded RNA upon hydrolysis at pH 5, which produces a decreased absorbance at 300 nm. This assay was also used to monitor the hydrolysis of *Saccharomyces cerevisiae* RNA, product no. R6750 from Sigma, which is a purification of all RNA species in yeast. It contains mainly rRNA and tRNA species, which are rich in single-stranded regions, but also possess some double-stranded regions.

The hydrolysis of the double-stranded, sequence-specific substrate and control RNAs, and of synthetic, double-stranded

Table 1. Activity of RNase A Monomer and C-Dimer against Specific Target RNAs[a]

enzyme species	substrate	specific activity
RNase A	substrate 1	110
RNase A	substrate 2	940
RNase A	control 1	250
RNase A	control 2	4600
RNase A	substrate dsRNA[b]	0.058
RNase A C-dimer	substrate dsRNA	0.46
RNase A	control dsRNA	110
RNase A C-dimer	control dsRNA	540

[a] RNA sequences:

```
Substrate 1: 5′-GGCGGCGGAAAAAAAAGGCGGCGG-3′
Substrate 2: 5′-CCGCCGCCUUUUUUUUCCGCCGCC-3′
  Control 1: 5′-GGCGGCGGAUAUAUAUGGCGGCGG-3′
  Control 2: 5′-CCGCCGCCUAUAUAUACCGCCGCC-3′
```

[b] Whereas double-stranded substrate RNA is fully complementary, control double-stranded RNA contains a central single-stranded "bubble" region:

```
Substrate dsRNA:  5′-GGCGGCGGAAAAAAAAGGCGGCGG-3′
                  3′-CCGCCGCCUUUUUUUUCCGCCGCC-5′

                                AUAUAUAU
Control dsRNA:    5′-GGCGGCGG         GGCGGCGG-3′
                  3′-CCGCCGCC         CCGCCGCC-5′
                                AUAUAUAU
```

Table 2. Activity of RNase and Conjugated RNase Species against Yeast ssRNA and ds poly(A)·poly(U)[a]

enzyme species	specific activity on yeast ssRNA	specific activity on dsRNA poly(A)·poly(U)
RNase A	100	1.4
RNase S	115	1.4
RNase A C-dimer	79	7.6[b]
$(dT)_8$-RNase S	92	0.06
$(dT)_{15}$-RNase S	93	0.23
$[(dT)_8$-RNase S$]_2$	82	0.10
S-protein	<0.02	<0.02
t_8 - S-peptide	<0.02	0[c]
t_8-RNase S	111	1.6
$[t_8$-RNase S$]_2$	185	10.5

[a] The assays were conducted at 28 °C using 5 μg of RNase moiety per mL of enzyme species. The experimental uncertainties are ±10% (ssRNA) and ±15% (dsRNA). [b] The RNase A C-dimer and RNase S dimer have highly similar activities against poly(A)·poly(U). [c] The t_8−S-peptide induces spectral changes in poly(A)·poly(U), which appears to reflect the formation of a complex, but does not seem to be due to cleavage. See text for more details.

RNA substrate poly(A)·poly(U) was assessed using the method of Libonati and Sorrentino at neutral pH (*31*). In this assay, ribonucleolytic activity is detected as an increased absorbance at 260 nm, due to the reduced hypochromism of cleaved dsRNA. Typically, reactions were initiated by adding RNase species (1 μg of ribonuclease moiety) to a buffered RNA solution (200 μL), mixing, and then recording the absorbance change at 300 or 260 nm. The summarized results presented in Tables 1 and 2 represent the average of at least two independent experiments. Both RNA substrates were obtained from Sigma, and the data were acquired on a temperature-regulated Shimadzu UV-2100 UV/vis spectrometer interfaced to a PC. Additional assays were performed and monitored using denaturing (8 M urea) 20% polyacrylamide gel electrophoresis. Gels were stained with toluidine blue to detect nucleic acids. After mixing RNase species (0.10 to 0.30 fmol) and target RNA (10 to 200 pmol), aliquots were withdrawn after certain times and the reaction was stopped by adding SDS (final concentration = 2.5%). The size of the RNA fragments generated by cleavage was gauged using standard-length single-stranded DNA oligos containing 4, 8, 12, 16, 20, and 24 bases. RNA fragments smaller than 4 bases are undetectable. These DNA oligos were ordered from Isogen and have base composition of G = A = T = C = 25% and sequences which were designed to avoid stem loop formation.

Nuclear Magnetic Resonance Spectroscopy. NMR spectra were acquired on a Bruker Advance spectrometer operating at 800 MHz and equipped with a quadruple resonance probe, at 25 °C in neutral pH buffer (100 mM MOPS, 200 mM NaCl) containing 90% H_2O and 10% D_2O. The spectra were transformed, analyzed, and integrated using the Bruker TOPSPIN software.

RESULTS AND DISCUSSION

Formation of DNA− and PNA−RNase Conjugates. S-peptide was conjugated to $(dT)_8$ or $(dT)_{15}$ 2′-oligodeoxyribonucleotides (Figure 3a) or t_8 PNA (Figure 3b) using the Diels–Alder cycloaddition reaction in aqueous solution (*28*). This reaction, unlike conjugates of DNA and S-peptide prepared using disulfide bond formation (*19*), has the advantage of producing a link that is stable in reducing environments such as the interior of living cells. Although a t_8−S-peptide conjugate could have been prepared by stepwise solid-phase assembly, the Diels–Alder methodology was always used to obtain conjugates with the same linkage between the two moieties, in order to avoid possible activity differences which might arise from a different linkage. The overall synthesis yields were: diene−dT_8 39%; diene−dT_{15} 21%; dT_8−S-peptide 60%; dT_{15}−S-peptide 62%, diene−t_8 29%; t_8−S-peptide 18%. DNA- or PNA-conjugated RNase S dimers were formed by adding the $(dT)_n$−S-peptide conjugate or t_8−S-peptide conjugate in 0.20 M sodium phosphate buffer (pH 6.7) to S-protein that had been dimerized by lyophilization from 40% aq acetic acid. DNA conjugated RNase S monomers and dimers were separated from the free DNA−S-conjugate by gel filtration chromatography (Figure 3c). The yield of RNase S dimer to monomer (1.0:3.0) was similar to that obtained when native S-peptide is used (*18*). A similar chromatogram was observed for the isolation of PNA conjugates of dimeric and monomeric RNase S, though a lower dimer/monomer ratio was obtained (Figure 3d). An excess of S-peptide was previously observed to decrease RNase S dimer disassociation (*18*). The lower yield of t_8−RNase S dimer relative to its monomer (1.0:9.0) is likely due to greater dissociation of the dimer during purification, due to a smaller excess of t_8−S-peptide conjugate.

NMR Characterization of $(dT)_n$−RNase Conjugates. NMR spectroscopy was used to gain insight into how the conjugation of a DNA strand affected the structural properties of the RNase S. ^{1}H NMR spectra of the monomer of RNase S and its $(dT)_8$ conjugate were recorded and analyzed. The polypeptide resonances, as revealed by 1D ^{1}H and 2D ^{1}H NOESY spectra, are essentially equivalent in RNase S as compared to $(dT)_8$-conjugated RNase S (data not shown). This indicates that the tertiary structure of the RNase S moiety is practically identical to that of the unmodified protein. The thymidine resonances in the complex are very poorly dispersed. As can be seen in Figure 4a, all H6 protons are clustered close together around 7.7 ppm and the H1′ around 6.3 ppm. All the thymidine methyls and H2′/H2″ protons lie at virtually identical chemical shifts. No ^{1}H NOE signals between the thymidine and the polypeptide moieties of RNase S were observed. This suggests that the thymidine bases of the DNA moiety are mainly disordered and do not adopt a particular conformation on the surface of the protein. This is an interesting result, since thymine bases might enter into the active site and inhibit the enzyme, as occurs in many ribonuclease complexes with mono- and dinucleotides (*32,33*).

Although ^{1}H NMR spectra indicate that oligonucleotide conjugation does not affect appreciably the structure of the

enzyme, some evidence of interaction between the oligonucleotide and S-protein moieties of the complex could be detected by ^{31}P NMR (Figure 4b). The $(dT)_{15}$−S-peptide spectrum shows one major peak, arising from phosphorus nuclei in phosphodi-

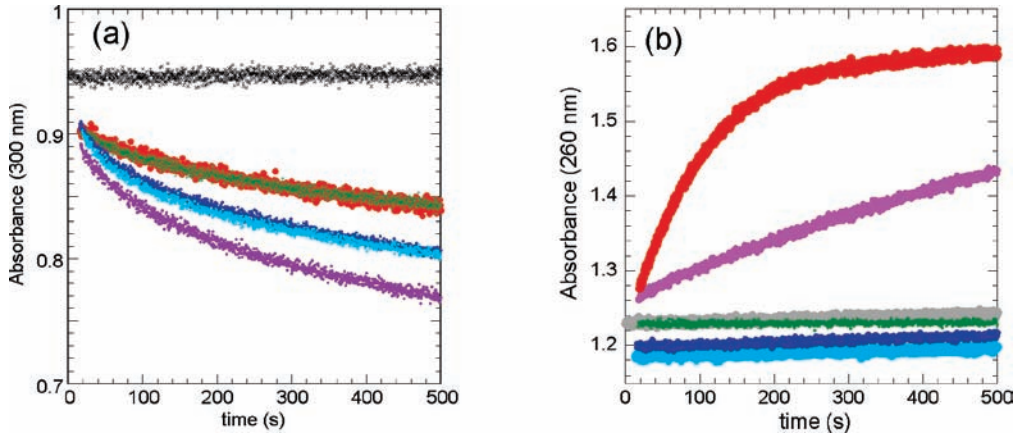

Figure 5. Activity of $(dT)_n$−RNase conjugates. a. Representative assays for ribonucleolytic activity against ssRNA at 28 °C. Data were offset vertically for ease of comparison. Typical assay results for hydrolysis of poly(A)·poly(U) RNA at 28 °C. gray poly(A)·poly(U) alone, red RNase A C-dimer, green $(dT)_{15}$−RNase S monomer, dark blue $(dT)_8$−RNase S dimer, light blue $(dT)_8$−RNase S monomer, purple RNase A monomer.

ester bonds, and two small signals which could arise from the 5′- and 3′-terminal phosphorus nuclei. Upon binding to S-protein, the ^{31}P resonances of the $(dT)_{15}$−S-peptide conjugate broaden. This likely reflects a slower tumbling time for the bound conjugate. In addition, the major peak acquires a shoulder that contains five to six phosphate groups, as estimated by peak integration. This shoulder could arise from the interaction of phosphate groups with positively charged residues in the protein moiety. The charged residues involved are probably a subset of the residues; namely, K7, K31, K33, K39, K41, K66, R85, K91, and K98, in monomeric RNase A, which were observed to interact with polydeoxyadenosine by X-ray crystallography (*20*). The ^{1}H and ^{31}P NMR data suggest that the DNA chain does not bind at the active site but does affect the electrostatic environment around the protein, possibly screening the positive charges necessary for efficient cleavage of dsRNA.

Activity of RNase Species Against Sequence-Specific RNAs. Using the Kunitz assay, the activity of monomeric RNase A toward the sequence-specific substrates was found to vary in the order (from highest to lowest activity) control 2> sustrate 2> control 1> substrate 1 (Table 1). The lower activity of monomeric RNase A for substrate 1 is consistent with the fact that the enzyme is specific for a pyrimidine base 5′ to the scissile bond; therefore, the stretch of 8 consecutive As in the center of the sequence should be relatively resistant to hydrolysis catalyzed by RNase A. To investigate this point in more detail, we also monitored the activity of monomeric RNase A against the specific target RNAs using denaturing polyacrylamide gel electrophoresis. Substrate 2 and control 2 RNAs were degraded within 30 s and control 1 RNA was hydrolyzed within several minutes, whereas substrate 1 RNA was slowly cleaved over 15–25 min time, producing fragments containing 14 to 20 bases (Supporting Information Figure 1). These 14 to 20 base fragments could well contain the poly(A) stretch of substrate 1. Additional gel-monitored assays of the activity of the monomeric t_8−RNase S conjugate on single-stranded substrate 1, substrate 2, and control 2 RNAs were performed and revealed relative activities of control 2> substrate 2 ≈ substrate 1.

Next, equimolar amounts of substrate 1 and substrate 2 RNAs were combined to form a double-stranded RNA. Likewise, equimolar amounts of control 1 and control 2 were combined to form a dsRNA containing an internal single-stranded region. The activity of RNase A and the RNase A C-dimer on the sequence-specific substrate and control dsRNAs was determined (Table 1). The RNase A C-dimer was 8.0 and 4.8 times more active than monomeric RNase A on substrate and control dsRNAs, respectively. Both enzymes are more than a thousand times more active on control RNA than on the substrate RNA, which strikingly illustrates the importance of small single-stranded regions for efficient cleavage of a dsRNA by RNase A. This validates our approach (Figure 1) to increase dsRNA cleavage by designing a RNase conjugate that can recognize and stabilize transient ssRNA regions within dsRNA.

Activity of $(dT)_n$−RNase Conjugates Against ssRNA. The ribonucleolytic activity of the $(dT)_n$-RNase conjugates was tested against yeast ssRNA; some typical data are shown in Figure 5a. The $(dT)_8$−RNase S dimer and monomer conjugates were slightly less active against yeast ssRNA (Table 2) than the unmodified dimer and monomer, as determined using the Kunitz assay (*30*). The substantial catalytic activity of $(dT)_n$−RNase conjugates against ssRNA indicates that the DNA moiety neither blocks the active site nor inhibits the ribonucleolytic action of the enzyme. The lower activity of unconjugated dimers relative to monomers toward ssRNA has been described previously (*10*). Neither the S-protein nor the $(dT)_8$−S-peptide conjugate exhibited any significant activity against ssRNA.

Activity of $(dT)_n$−RNase Conjugates Against dsRNA. The cleavage of the double-stranded RNA poly(A)·poly(U) was gauged following the protocol of Libonati and Sorrentino (*31*). In a control experiment, the RNase A C-dimer activity was first tested against the poly(A)·poly(U), and the results were in agreement with those reported previously (Figure 5b). In contrast, the activity of the DNA−RNase S dimer conjugate against poly(A)·poly(U) was reduced to background levels. One hypothesis that can account for these results is that the negative charges in the DNA moiety could be interacting with the positive charges on the surface of RNase S that are required for efficient cleavage of dsRNA, as suggested by the NMR results (see above).

Activity of the t_8−RNase Conjugates Against ssRNA. The enzymatic activity of t_8−RNase conjugates against ssRNA was evaluated using the Kunitz assay. Some representative data are shown in Figure 6a, and the average results are given alongside those of the $(dT)_n$−RNase conjugates in Table 2. The S-protein alone and the t_8−S-peptide conjugate alone show negligible activity. As seen previously, both monomeric RNase A (100) and RNase S (115) are highly active against ssRNA, while the RNase A C-dimer (79) is somewhat less active. The activity of the t_8−RNase S monomer (111) is similar to that of the RNases A and S and higher than that of the $(dT)_n$−RNase S conjugates.

Interestingly, the t_8−RNase S dimer shows a remarkably high activity (185). Natural RNase A cleaves polypyrimidine chains

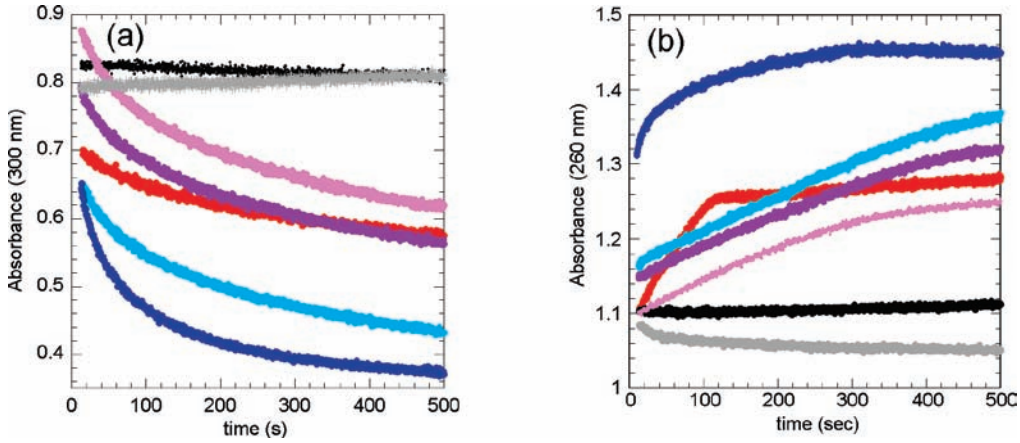

Figure 6. Activity of t_8−RNase Conjugates. a. Typical assay results for hydrolysis of yeast ssRNA at 28 °C by t_8−RNase conjugates and control species: black S-protein alone, gray t_8−S-peptide, fuschia RNase S monomer, magenta RNase A monomer, red RNase A C-dimer, light blue t_8−RNase monomer, dark blue t_8−RNase dimer. b. Libonati−Sorrentino assay for hydrolysis of poly(A)·poly(U) at 28 °C by t_8−RNase conjugates and control species. black S-protein alone, gray t_8−S-peptide, fuschia RNase S monomer, magenta RNase A monomer, red RNase A C-dimer, light blue t_8−RNase monomer, dark blue t_8−RNase dimer.

in a distributive manner; that is, it binds RNA, cleaves RNA, and then releases RNA before rebinding and recleaving the resulting fragments (*34*). In contrast, progressive enzymes, such as DNA polymerase, bind a polymeric substrate and catalyze multiple reactions before releasing it. The increased ssRNase activity shown by the t_8−RNase S dimer could possibly arise from an increased progressivity due to binding of the t_8 moiety to short complementary sequences within the ssRNA, which acts to maintain the hydrolyzed fragments near the active site.

Activity of the t_8−RNase Conjugates Against dsRNA. Some representative assays of t_8−RNase activity against poly(A)·poly(U) are depicted in Figure 6b, and the mean specific activity values are summarized in Table 2. As expected, the S-protein fragment alone shows little or no activity. A curious decrease in the absorbance reading at 260 nm occurs when the t_8−S-peptide molecule is added to the dsRNA substrate. This decrease might arise from a stabilization of the double-stranded structure of poly(A)·poly(U) by positive charges in the S-peptide moiety or from the formation of a complex between the dsRNA and the t_8 moiety, or both. Unconjugated and monomeric RNase S and RNase A show modest activity when assayed against dsRNA; the calculated specific activity value is 1.4. The t_8−RNase S monomer, in contrast to the corresponding DNA conjugate which is essentially inactive (see above), shows a specific activity value of 1.6 toward dsRNA, which is similar to the activity of monomeric RNase A or RNase S.

As observed previously, the RNase A C-dimer shows a much higher activity against dsRNA (specific activity = 7.6) as compared to monomeric RNase A or S. Interestingly, the t_8−RNase S conjugate dimer shows a specific activity of 10.5, which is marginally higher than the activity shown by the RNase A C-dimer. To test if the enhanced activity of the t_8−RNase S conjugate dimer against poly(A)·poly(U) is due to its dimeric state, an aliquot was heated to 53 °C for 15 min, then allowed to cool to room temperature. This heat treatment, which is known to completely monomerize RNase S dimers (*18*), reduced the dsRNase activity to levels typical of monomeric species. As noted in the Experimental Procedures section, aliquots of t_8−RNase S conjugate dimer always contained an excess of free t_8−S-peptide to maintain the stability of the quaternary complex. If this excess free conjugate were to form a complex with the poly(A)·poly(U) substrate, it might displace a single-stranded segment of the poly(U) substrate. As single-stranded poly(U) is a good substrate for RNase A, it is possible that the enhanced activity of the t_8−RNase S dimer conjugate might be due to the presence of the excess free t_8−S-peptide conjugate, rather than the complex. To check this possibility, assays were performed with monomeric RNase A and C-dimer in the presence of excess free t_8−S-peptide. For monomeric RNase A and the C-dimer, the presence of excess free t_8−S-peptide increased the activity against dsRNA by about 35% and 10%, respectively, with the latter value being within the threshold of the experimental uncertainty. Taken together, these results suggest that the increased dsRNase activity of t_8−RNase S conjugate dimer is not due the excess t_8−S-peptide but arises from the combination of the dimeric state of the RNase with conjugation to t_8.

The observation of hydrolysis of poly(A)·poly(U) in the t_8−RNase S conjugate monomer and dimer supports the idea that negative charges in the DNA conjugate do indeed screen the positive charges in RNase that are essential for cleavage of dsRNA.

CONCLUSIONS

Some novel conclusions can be drawn from the results reported here. Ribonuclease S monomers and dimers conjugated to $(dT)_{8 \text{ or } 15}$ (DNA) or t_8 (PNA) have been prepared, and their ability to cleave ssRNA and dsRNA has been determined. Conjugation to DNA essentially completely impedes the cleavage of dsRNA. However, conjugation to PNA endows dimeric RNase with enhanced activity against both ssRNA and dsRNA, although the increase is marginal in the latter case. Since conjugation does not affect the structure of the protein moiety, as shown by NMR spectroscopy and the observation of activity against ssRNA, we conclude that the inhibition of dsRNA hydrolysis provoked by the DNA conjugation is due to interactions between the negative charges on the DNA moiety and positive charges on the surface of RNase, which have previously been implicated in efficient hydrolysis of dsRNA. Therefore, our results show that PNA conjugation to RNase offers clear advantages over DNA conjugation as an approach to modulating ribonucleolytic activity.

Received August 15, 2007; Revised Manuscript Received September 18, 2007

The modification of proteins by chemical methods is well-established, however usually difficult to control. In this paper, we describe the posttranslational modification of different IgGs via the Lys or Gln side chains catalyzed by bacterial and human tissue transglutaminase (BTGase and TG2). For proof of concept, different IgG1s (commercial bovine IgG1, and L1CAM targeting chCE7 and $chCE7_{aglycosylated}$) were enzymatically functionalization with different fluorescent TGase substrates based on the CY3 analogue Dy547. The optimal reaction conditions were determined in order to assess the two enzymes. The efficiency of the enzymatic method was also compared with a standard chemical method employing a reactive NHS ester of Dy547. Three new TGase substrates were synthesized for this study including Lys–substrate **1** useful for BTGase and TG2 and two Gln–substrates tailor-made for BTGase (substrate **2**) and TG2 (substrate **3**). Of the two TGases tested, BTGase incorporated Lys–substrate **1** more efficiently than TG2. On the other hand, both enzymes reacted equally efficiently with the corresponding Gln–substrates **2** and **3**. Reproducible labeling could be achieved in a broad concentration "window" of the substrates (up to 400 μM) without the risk of overlabeling of chCE7 or $chCE7_{aglycosylated}$. The biological activities of the functionalized antibodies were unaltered as shown by in vitro antigen affinity measurements and cell internalization experiments using confocal laser scanning microscopy. A maximum label-to-protein ratio of approximately 1 was achieved with $chCE7_{aglycosylated}$ and substrate **1** using BTGase. It is important to recognize that the enzymatic activity of TGases enables the stable functionalization of proteins via the side chains of Gln, which is not possible by any chemical method available today. In addition, we could prove that the enzymatic modification of all antibodies occurred selectively at the heavy chain whereas the chemical method led to labeling of both the heavy and the light chains.

INTRODUCTION

The functionalization of antibodies for the imaging of molecular processes as well as for diagnostic and therapeutic applications is an integral part of biochemical and biomedical research. Today, the decoration of proteins with various probes of interest is predominantly achieved by applying chemical functionalization strategies (*1*–*3*). However, the modification of proteins by chemical methods is often difficult to control, and laborious optimizations are necessary to achieve reproducible results. Chemically reactive probes usually display a limited selectivity with respect to the different functional parts of an antibody (Fc, Fv region) and can attack at different amino acid side chains. Thus, the risk of heterogeneous modification and overlabeling is inherent. This can have deleterious effects on the biological activity of the protein (*4*, *5*).

Part of our research efforts focus on the development of radiometal-labeled antibodies for use in radio immunodiagnosis and therapy (RID/RIT). We are particularly interested in the antibody chCE7, a high-affinity, chimeric, and internalizing monoclonal antibody (IgG1) directed against the cell adhesion molecule L1 (L1-CAM), which is overexpressed by a number of cancer cells (*6*). Radiolabeled chCE7 and an aglycosylated form $chCE7_{agl}$ (as the result of the single-site mutation Asn297Gln) have shown promising characteristics for application in RIT. In radiolabeled form, optimal pharmacokinetics and high tumor accumulation were achieved with a moderate degree of functionalization of the antibodies with metal chelates (*7*, *8*). We have experienced that the modification of such proteins with a defined number of metal chelators is difficult to reproduce by conventional chemical labeling protocols (e.g., with NHS esters or isothiocyanates). Therefore, the development of alternative approaches for the controlled functionalization of proteins is of significant interest.

Enzymes of the family of transglutaminases (TGase, EC 2.3.2.13) catalyze the formation of stable isopeptidic bonds between the side chains of glutamine (Gln) and lysine (Lys), with the loss of ammonia (*9*). TGases have emerged as a powerful biotechnological tool for the modification of proteins. For example, TGases have been used for the attachment of small-molecule probes to proteins (*9*) and cell surfaces (*10*), and two examples of the enzymatic modification of antibodies have been reported (*11*, *12*). To date, most TGase applications have been carried out with bioengineered proteins presenting an accessible, TGase-recognizable peptide sequence at the N- or C-terminus which contains Lys-(K-tag) or Gln-(Q-tag) residues (see, e.g., ref (*13*)). Yet, a systematic investigation of TGase-mediated labeling of whole antibodies using both Lys- and Gln-substrates and different TGases has not been described.

The mild reaction conditions for protein modification are attractive features of TGases. In addition, employment of TGases is the only method, which allows the functionalization of

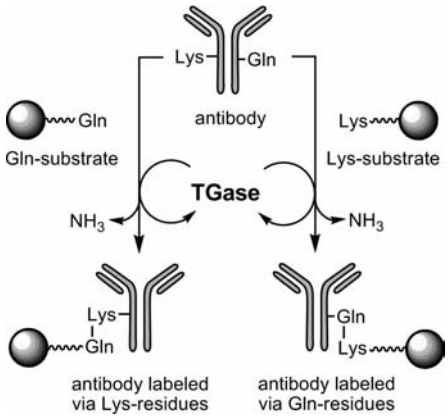

Figure 1. Schematic drawing of the TGase-mediated protein (antibody) modification via the side chains of Gln or Lys. Spheres represent various probes (e.g., fluorophores) to be attached to the protein, and squiggled lines symbolize different spacers.

proteins via the side chain of Gln, an amino acid not available for chemical modification. For proof of concept, we set out to investigate the utility of two different TGases to covalently attach a fluorescent probe (CY3 analogue) to antibodies in general and our chCE7 antibody formats in particular (Figure 1).

EXPERIMENTAL PROCEDURES

General Methods. Infrared spectra were recorded on a Jasco FT/IR-6200 ATR-IR and UV spectra on a Cary 300 (Varian). NMR spectra were recorded with a Bruker 400 MHz spectrometer with the corresponding solvent signals as an internal standard. Chemical shifts are reported in parts per million (ppm) relative to tetramethylsilane (0.00 ppm). Values of the coupling constant, *J*, are given in hertz (Hz). Low-resolution mass spectra (LR-MS) were recorded with a Micromass Quattro micro API LC-ESI and high-resolution mass spectra (HR-MS) with a Bruker FTMS 4.7T BioAPEXII (ESI). HPLC was performed on a Merck-Hitachi L-7000 system equipped with an L-7400 tunable absorption detector and an XTerra column (MSC18, 5μm, 4.6 × 150 mm, Waters). All HPLC were performed with the following solvent system: 0.1% TFA_{aq} (solvent A), acetonitrile (solvent B), 1 mL/min; 0–5 min, 95% A; 5–20 min, 95% → 40% A; 20–22 min, 40% → 10% A; 22–24 min, 10% A; 24–25 min, 10% → 95% A. Gel electrophoresis was performed with a mini-PROTEAN 3 Electrophoresis System (Bio-Rad) and EPS 600 power supply (Pharmacia Biotech). The gels (12% acrylamide) were analyzed with a Diana III Camera System (Ray test) using CY3 optical filters followed by computational analysis of the obtained pictures with the freeware SCION. Size exclusion chromatography was performed with the above-described HPLC system and a Superdex 200 10/300 GL column (cross-linked agarose und dextran, 13 μm, 1 × 30 cm, Amersham Biosciences) with PBS (0.15 M, pH 7.4, 0.44 mL/min, 45 min/run). Confocal data sets were sampled on a Zeiss LSM 510 META inverted microscope. Image processing was done with the *IMARIS* software (Bitplane AG, Zurich, Switzerland).

Recombinant bacterial transglutaminase (BTGase), recombinant His-tagged human transglutaminase 2 (TG2), ZGlnGly OPF **7**, and ZGlnGlnProLeu-Cadavarine **10** were purchased from N-Zyme BioTec GmbH and Dy547-NHS **4** from Dyomics. Antibodies chCE7 and $chCE7_{agl}$ were provided by the group of Dr. Ilse Novak-Hofer at the Paul Scherrer Institute, Villigen, Switzerland. HEK293 cells were obtained from the German Collection of Microorganisms and SKOV3ip human ovarian carcinoma cells were a gift from Prof. P. Altevogt (German Cancer Center, Heidelberg, Germany). Cell media and additives were obtained from BioConcept, goat antihuman IgG-FITC from LabForce, Moviol from Hoechst Pharmaceuticals, and pcDNA3.1+ and G418 from Invitrogen. All other chemicals and reagents were purchased from Sigma-Aldrich or Hänseler AG and used as supplied. Generation of transfected HEK293 cells with human L1-CAM antigen was performed according to the literature (*7*).

Chemical Syntheses.*Synthesis of Lys–Substrate, Cadavarine-DY547 (***1***).* To DY547-NHS **4** (1 mg, 1.35 μmol) were added at rt stock solutions of DIPEA (5.7 μmol in 20 μL DMF) and mono-Boc-protected cadaverine **5** (1.35 μmol in 82 μL DMF). The resulting solution was kept in the dark at rt overnight. The product was purified by HPLC, and the collected fractions containing the coupling product **6** were treated with TFA (10%) overnight at rt. Quantitative conversion of intermediate **6** to Lys–substrate **1**, cadavarine-DY547, was confirmed by HPLC. The solution was evaporated and the obtained red solid dissolved in a defined volume of buffer yielding a stock solution of Lys–substrate, cadavarine-DY547 (1) (52% yield by UV spectroscopy: $\lambda = 557$ nm, $d = 1$ cm, $\varepsilon = 150\,000\ M^{-1}\ cm^{-1}$): purity according to HPLC >96%; LR-MS $[M + H]^+ = 701.39$ (calcd for $C_{35}H_{49}N_4O_7S_2$: 701.30).

Synthesis of Compound **8.** Mono-Boc-protected cadaverine **5** (50 mg, 0.25 mmol) and ZGlnGly OPF **7** (126 mg, 0.25 mmol) were dissolved in dry DMF (3 mL) and DIPEA (215 μL, 1.24 mmol) was added at 0 °C. After 30 min, the reaction mixture was warmed to rt, stirred for additional 4 h, and evaporated under reduced pressure. Flash chromatography on silica gel with CH_2Cl_2/MeOH (9:1) yielded product **8** as a white powder (107 mg, 84%): mp 166–168 °C; IR (neat) υ 3302, 2934, 1681, 1637, 1531, 1240, 1169, 1047 cm^{-1}; ^1H NMR (DMSO-d_6) δ 8.17 (t, 1H, $J = 5.6$ Hz), 7.65 (t, 1H, $J = 5.3$ Hz), 7.57 (d, 1H, $J = 7.2$ Hz), 7.40–7.22 (m, 6H), 6.80–6.69 (m, 2H), 5.05 (d, 1H, $J = 12.7$ Hz), 5.01 (d, 1H, $J = 12.7$ Hz), 3.95 (dd, 1H, $J = 13.6$ und 7.3 Hz), 3.65 (d, 2H, $J = 5.48$ Hz), 3.10–2.94 (m, 2H), 2.95–2.80 (m, 2H), 2.17–2.04 (m, 2H), 1.95–1.83 (m, 1H), 1.80–1.64 (m, 1H), 1.44–1.27 (m, 4H), 1.36 (s, 9H), 1.27–1.10 (m, 2H) ppm; ^{13}C NMR (DMSO-d_6) δ 173.7, 171.9, 168.4, 156.1, 155.6, 136.9, 128.3, 127.8, 127.6, 77.3, 65.5, 54.6, 42.1, 39.7, 38.5, 31.4, 29.1, 28.7, 28.2, 27.3, 23.6 ppm; HR-MS $[M + Na]^+ = 544.2748$ (calcd for $C_{25}H_{39}N_5O_7Na$: 544.2742).

Synthesis of Compound **9.** Intermediate **8** (53 mg, 0.10 mmol) was dissolved in TFA/CH_2Cl_2 (1:3, 4 mL) and stirred at rt overnight. Evaporation under reduced pressure yielded the TFA salt of product **9** as a colorless oil (61 mg, 98%): IR (neat) υ 3288, 3198, 3073, 2940, 1667, 1541, 1456, 1258, 1205, 1133 cm^{-1}; ^1H NMR (MeOH-d_4) δ 7.40–7.25 (m, 5H), 5.13 (d, 1H, $J = 12.3$ Hz), 5.09 (d, 1H, $J = 12.7$ Hz), 4.06 (dd, 1H, $J = 8.2$ und 5.9 Hz), 3.85 (d, 1H, $J = 17.09$ Hz), 3.79 (d, 1H, $J = 16.6$ Hz), 3.28–3.10 (m, 2H), 2.90 (t, 2H, $J = 7.52$ Hz), 2.34 (t, 2H, $J = 7.5$ Hz), 2.14–2.03 (m, 1H), 2.03–1.90 (m, 1H), 1.70–1.58 (m, 2H), 1.58–1.48 (m, 2H), 1.43–1.31 (m, 2H) ppm; ^{13}C NMR (MeOH-d_4) δ 177.9, 175.29, 171.7, 158.96, 138.2, 129.7, 129.2, 128.9, 68.0, 56.8, 43.9, 40.7, 40.0, 32.6, 29.7, 28.5, 28.2, 24.6 ppm; HR-MS $[M]^+ = 422.2400$ (calcd for $C_{20}H_{32}N_5O_5$: 422.2398).

*Synthesis of BTGase Gln–Substrate, ZGlnGly Cadavarine-DY547 (***2***).* Stock solutions of intermediate **9** (1.35 μmol in 82 μL DMF) and DIPEA (5.7 μmol in 20 μL DMF) were added to Dy547-NHS **4** (1 mg, 1.35 μmol) at rt. The resulting red solution was kept in the dark at rt overnight. The mixture was purified by HPLC, and collected fractions containing product **2** were evaporated under reduced pressure. The obtained red solid was dissolved in a defined volume of buffer yielding a stock solution of BTGase Gln–substrate, ZGlnGly cadavarine-DY547 (**2**) (40% yield by UV spectroscopy: $\lambda = 557$ nm, $d = 1$ cm, ε

$= 150\,000\ M^{-1}\ cm^{-1}$): purity according to HPLC >96%; LR-MS $[M]^+ = 1020.17$ (calcd for $C_{50}H_{65}N_7O_{12}S_2$: 1020.22).

*Synthesis of TG2 Gln–Substrate, Z-GlnGlnProLeu-Cadavarine-DY547 (**3**).* Stock solutions of the TFA salt of ZGlnGlnProLeucadavarine **10** (1.3 μmol in 82 μL DMSO) and DIPEA (5.7 μmol in 20 μL DMSO) were added to DY547-NHS **4** (1 mg, 1.35 μmol) at rt. The resulting red solution was kept in the dark at rt overnight. The mixture was purified by HPLC, and collected fractions containing product **3** were evaporated under reduced pressure. The obtained red solid was dissolved in a defined volume of Tris buffer (0.15 M, pH 8) yielding a stock solution of TG2 Gln–substrate, ZGlnGlnProLeu-cadavarine-DY547 (**3**) (40% yield by UV spectroscopy: $\lambda =$ 557 nm, $d = 1$ cm, $\varepsilon = 150\,000\ M^{-1}\ cm^{-1}$): purity according to HPLC > 94%; HR-MS $[M+H]^+ = 1301.5939$ (calcd for $C_{64}H_{89}N_{10}O_{15}S_2$: 1301.5945).

Enzymatic Antibody Labeling. Unless stated otherwise, reactions with BTGase were conducted in PBS (0.15 M) at pH 8 and 37 °C. Due to the solubility of the required cofactor Ca^{2+}, experiments with TG2 were conducted in Tris (0.15 M containing 10 mM $CaCl_2$ and 15 mM glutathione) at pH 8 and 37 °C. For all experiments, an antibody concentration of 0.5–1.0 mg/mL was used. To ensure that >90% of the maximal labeling degree was achieved by the time samples were taken for analysis, experiments with bovine IgG and chCE7 were run for at least 20 min in the case of TG2 and 2 h for BTGase. The reaction time for experiments conducted with BTGase and $chCE7_{agl}$ was set to 5 h even though a slightly higher labeling degree was achieved after 7 h (see kinetics in Figure 5). Optimized reaction conditions refer to the following: (i) For BTGase: 10 μM BTGase, 100 μM Lys–substrate **1**, or 400 μM Gln–substrate **2**. (ii) For TG2: 80 nM TG2, 400 μM Lys–substrate **1**, or 100 μM Gln–substrate **3**.

In a typical enzymatic labeling experiment, defined amounts of TGases (reconstituted in water and stored at −20 °C) and the corresponding substrates (stock solutions in buffer, stored at 4 °C) were added to solutions of antibodies in buffer. The pH was adjusted by addition of buffer of pH 12, in amounts determined previously by titration. The reaction mixtures were incubated at 37 °C while being gently shaken. To obtain kinetic data, samples were taken after the indicated time periods and denatured for 10 min at 95 °C in the presence of mercaptoethanol. All experiments were monitored by SDS-PAGE and fluorescence imaging followed by Coomassie staining of the gels. Data was analyzed with the freeware SCION and the *GraphPad Prism* program.

For determination of the labeling degree and for use of labeled antibodies in in vitro experiments, labeled antibodies were purified by size exclusion chromatography. Retention times were as follows: 15–20 min (minor peaks of antibody aggregates formed upon storage and not due to TGase-mediated cross-linking); 24 min (antibodies), 28 min (TG2) or 32 min (BTGase), respectively; 41 min (unreacted substrates). Determination of labeling degrees of purified fluorescent conjugates was performed by UV/vis spectroscopy, measuring the concentration of both the fluorophore DY547 ($\lambda = 557$ nm, $d = 1$ cm, $\varepsilon = 150\,000\ M^{-1}\ cm^{-1}$) and the protein ($\lambda = 280$ nm, $d =$ 1 cm, $\varepsilon = 210\,000\ M^{-1}\ cm^{-1}$), the latter of which was corrected according to literature by the fraction of the absorbance attributed to the fluorophore (*24*). Obtained solutions of labeled antibodies (ca. 0.1 mg/mL) were stored at 4 °C and used for in vitro experiments the following day. For longer storage (−20 °C), 0.1% BSA was added to prevent aggregation.

Chemical Antibody Labeling. The chemical labeling of antibodies (1 mg/mL) was performed in PBS buffer at pH 8 and 37 °C by adding freshly prepared solutions of DY537-NHS **4** in buffer. Comparison of the achieved labeling degrees with those of the enzymatic labeling method was done by SDS-PAGE and fluorescence imaging of the gels.

In Vitro Binding Affinity Experiments. Competition binding assays were performed with $chCE7_{agl}$ and $chCE7_{agl}$-(**1**) (1 DY547/antibody) on SKOV3ip cells. Triplicate samples of fixed concentration of ^{125}I-labeled chCE7 (50 ng) and increasing concentrations of $chCE7_{agl}$ and $chCE7_{agl}$-(**1**) (1 ng to 3000 ng) with 0.5×10^6 SKOV3ip were suspended in 500 μL PBS containing 0.5% bovine serum albumin (BSA) on a shaking platform for 2 h at 37 °C. Nonspecific binding was determined by parallel incubations in the presence of 10 μg $chCE7_{agl}$ and $chCE7_{agl}$-(**1**). After incubation, 2 mL of PBS containing 0.5% BSA was added, and the suspension was centrifuged for 5 min at 2000 rpm and the supernatant was aspirated from the cells. Two milliliters of PBS containing 0.5% BSA was added, and the suspension was again centrifuged to remove unbound immunoconjugates. Displacement was measured with a gamma counter. Nonspecific binding was subtracted, and data were analyzed with the *GraphPad Prism* program using nonlinear regression with one site competition.

In Vitro Cell Uptake and Fluorescence Microscopy. HEK293 cells or stably transfected HEK293 cells expressing the human full-length L1-CAM were grown on poly(L-lysine) (100 μg/mL) coated 12 mm glass coverslips. Cells were incubated with DMEM (0.5% FCS, 15 mM HEPES) containing either 10 μg/mL chCE7 or $chCE7_{agl}$ in its labeled or unlabeled form for 2 h at 4 °C. Unbound antibody was then washed off with PBS and incubation continued for 3 h at 37 °C to allow for L1 endocytosis. After 2 washes with PBS, cells were fixed with 4% paraformaldehyde in PBS for 20 min, quenched with 50 mM NH_4Cl for 10 min, and permeabilized with 0.5% Triton-X100 in PBS for 10 min at rt. After washes, cells were blocked with 1% BSA–PBS for 1 h at rt, followed by incubation with goat antihuman-IgG-FITC (1:100) for 1 h in the dark. Cells were washed twice with PBS and then incubated with 1 μg/mL Hoechst33258 for 10 min for nuclear staining. Cells were finally washed once more, embedded in MOVIOL, viewed, and photographed through a confocal microscope.

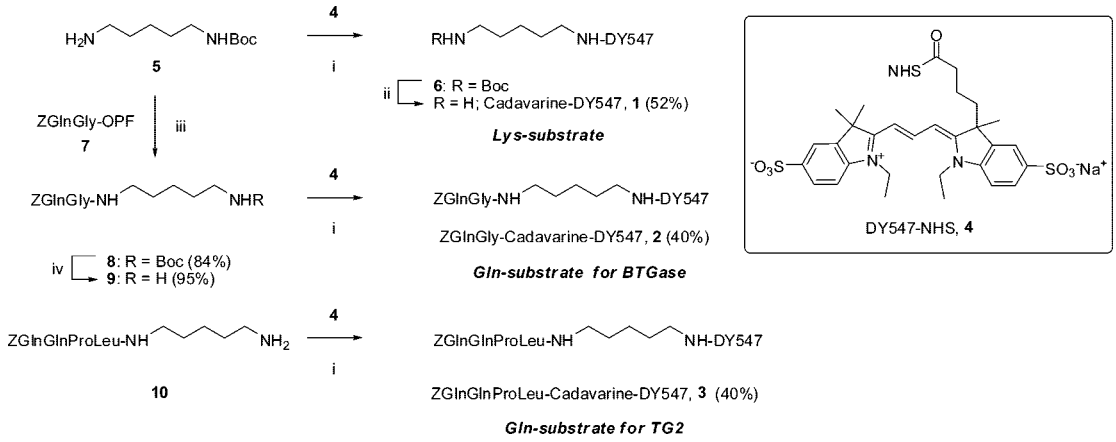
RESULTS

Syntheses. The synthesis of the fluorescent TGase substrates is outlined in Scheme 1. In brief, mono-Boc-protected cadaverine **5** was coupled with DY547-*N*-hydroxysuccinimide ester (DY547-NHS) **4** to afford, after deprotection of intermediate **6**, Lys–substrate cadavarine-DY547 (**1**). Coupling of substrate **5** with the reactive intermediate **7** afforded intermediate **8**. After deprotection, the resulting amine **9** was reacted in an equimolar ratio with **4** to yield the BTGase Gln–substrate ZGlnGly cadavarine-DY547 (**2**). Similarly, coupling of ZGlnGlnProLeu-cadaverine **10** with DY547-NHS **4** gave TG2 Gln–substrate ZGlnGlnProLeu-cadavarine-DY547 (**3**). Intermediates **8** and **9** were fully characterized by spectroscopic methods (NMR, IR, MS), and the identity of final products (purity >90% according to HPLC) was confirmed by mass spectroscopy.

Optimization of the pH, the Enzyme, and the Substrate Concentrations. All reactions were monitored by SDS-PAGE. Samples for analysis were taken after time periods that ensured that >90% of the maximal labeling degree was achieved (see Experimental Procedures section). Protein concentrations were set to 0.5–1 mg/mL for all experiments. In the following, only representative examples of conducted experiments are illustrated.

First, we investigated the effect of the pH of the reaction media on the enzymatic labeling. Figure 2 shows the labeling degrees achieved at different pH values by the BTGase-mediated modification of chCE7 and $chCE7_{agl}$ with Gln–substrate **2**. The most efficient labeling was detected at slightly basic reaction conditions (pH 8). The labeling of antibodies with Lys–substrate

Scheme 1. Structure of DY547-NHS 4, and Synthesis of Fluorescent TGase Substrates[a]



[a] (i) DIPEA, DMF, rt; (ii) H_2O/TFA (10%), rt; (iii) DIPEA, DMF, 0 °C to rt; (iv) CH_2Cl_2/TFA (20%), rt.

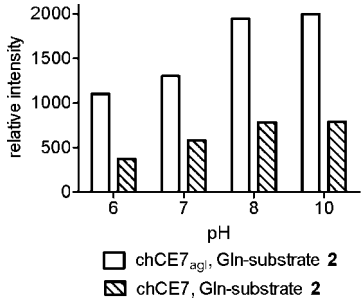


Figure 2. Labeling of chCE7 and chCE7$_{agl}$ (0.8 mg/mL) with BTGase (10 μM) and Gln–substrate **2** (100 μM) at different pH values.

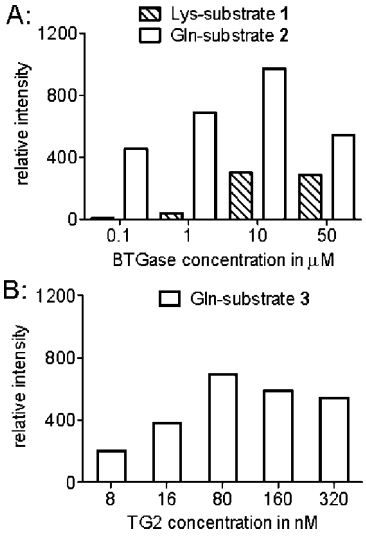

Figure 3. Labeling of bovine IgG (1 mg/mL) with Lys–substrate **1** and Gln–substrates **2** or **3** (100 μM) at pH 8 and different concentrations of BTGase (A) and TG2 (B).

1 was less influenced by the pH, and similar labeling degrees were achieved at pH 6–10. Similar observations were made with bovine IgG as well as for the labeling of antibodies with TG2 (data not shown).

Next, the effect of enzyme concentrations was investigated. Figure 3A shows the labeling of bovine IgG with Lys–substrate **1** and Gln–substrate **2** employing different concentrations of BTGase. Figure 3B depicts the labeling of bovine IgG with Gln–substrate **3** at different concentrations of TG2; the combination TG2/Lys–substrate **1** resulted in a very weak labeling of the antibody at all enzyme concentrations and is thus not

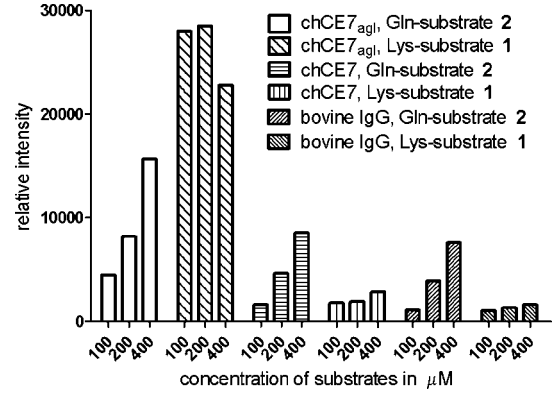

Figure 4. Labeling of bovine IgG, chCE7, and chCE7$_{agl}$ (0.8 mg/mL) with BTGase (10 μM) at pH 8 and different concentrations of Lys–substrate **1** and Gln–substrate **2**.

displayed. Higher labeling yields were achieved with increasing enzyme concentrations for both BTGase (0.1–10 μM) and TG2 (8–80 nM). At concentrations above 10 μM (BTGase) and 80 nM (TG2), respectively, the labeling yields decreased for yet unknown reasons. Labeling experiments of tumor-targeting chCE7 and chCE7$_{agl}$ with Lys– and Gln–substrates at varying concentrations of BTGase or TG2 gave similar results (data not shown).

As a further parameter for optimization, we examined the effect of the substrate concentration. Figure 4 shows the labeling of bovine IgG, chCE7, and chCE7$_{agl}$ with BTGase employing varying concentrations of Lys–substrate **1** and Gln–substrate **2**. Increasing concentrations of the substrates resulted in a higher labeling yield for all substrates, proteins, and enzymes examined with the exception of the combination chCE7$_{agl}$ and substrate **1**. The best labeling of the antibodies was achieved with Gln–substrate **2** at the highest concentration applied (400 μM) and with Lys–substrate **1** at a concentration of 100–200 μM. Because of the limited solubility of the TGase substrates in aqueous buffer (containing a maximum of 10% DMSO), higher concentrations could not be investigated. With TG2, a maximum labeling of antibodies was achieved with Gln–substrate **3** at a concentration of 50–100 μM, whereas only weak labeling was observed with Lys–substrate **1** for all antibodies even at the highest possible substrate concentration (data not shown).

Time Dependence of the Enzymatic Labeling and Determination of the Average Labeling Degrees. Bovine IgG, chCE7, and chCE7$_{agl}$ were labeled with BTGase or TG2 and the corresponding substrates under optimized reaction conditions as determined above. The reaction profiles were monitored by

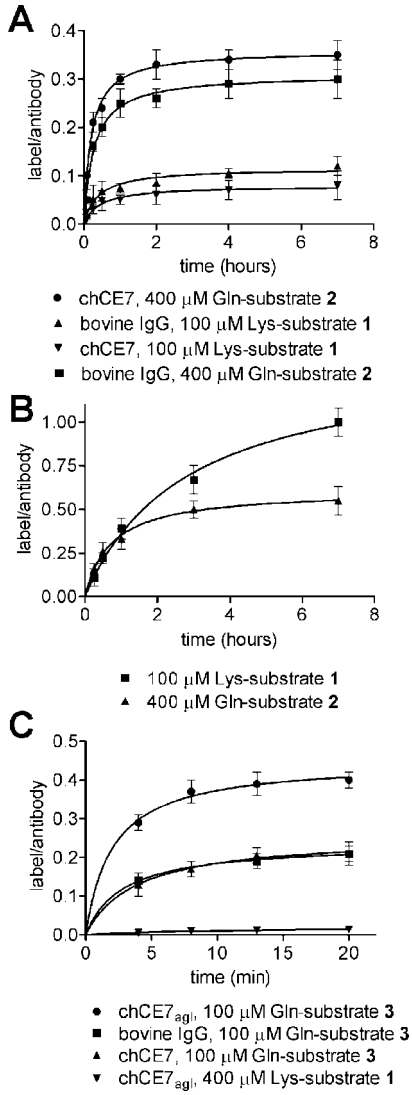

Figure 5. Comparison of kinetics and labeling efficiencies of the enzymatic antibody modification under optimized reaction conditions. (A) Labeling of bovine IgG and chCE7 (each 1 mg/mL) with BTGase (10 μM). (B) Labeling of chCE7$_{agl}$ (0.85 mg/mL) with BTGase (10 μM). (C) Labeling of bovine IgG, chcE7, and chCE7$_{agl}$ (each 0.9 mg/mL) with TG2 (80 nM); number of experiments $n = 2$–3. Because the TG2-mediated labeling of antibodies with Lys–substrate **1** resulted in a weak labeling with all three antibodies, only one example is shown in part C. Note the different time scale.

SDS-PAGE of samples taken at indicated time points. For determination of the average labeling degrees, reactions were stopped after 20 min for TG2 experiments, after 2 h for BTGase experiments with bovine IgG and chCE7, and after 5 h for BTGase experiments with chCE7$_{agl}$. Labeled antibodies were separated from the enzymes and unreacted substrates by size exclusion chromatography, and the average labeling degrees of purified conjugates were determined by UV/vis spectroscopy. Figure 5 shows the kinetics of the enzymatic modification of antibodies as well as the average labeling degrees achieved.

The labeling of bovine IgG, chCE7, and chCE7$_{agl}$ with BTGase reached a plateau after 2 h, culminating in an average label/antibody ratio of approx 0.3–0.5 for Gln–substrate **2** (Figure 5A and B). Employment of BTGase with Lys–substrate **1** resulted in an average label/antibody ratio of 0.1 for bovine IgG and chCE7 within 2 h (Figure 5A), whereas with chCE7$_{agl}$, the highest labeling degree of 1 label/antibody was obtained after a prolonged reaction time of approximately 5 h (Figure 5B). For all antibodies, a maximum labeling degree of 0.2–0.4 label/antibody was achieved with TG2 and Gln–substrate **3** after 20 min, while only low labeling was observed with Lys–substrate **1** (Figure 5C).

Comparison of the Enzymatic Labeling versus Chemical Modification. Bovine IgG, chCE7, and chCE7$_{agl}$ were labeled using the chemically reactive probe DY547-NHS **4** (see Scheme 1) at varying concentrations. Samples were taken after 10 min, a time after which no further increase of the labeling degree was observed. A comparison of the labeling degrees achieved by the chemical modification of chCE7$_{agl}$ with **4** and the enzymatic labeling method performed with BTGase under optimized reaction conditions is shown in Figure 6 A. A concentration of approximately 2–5 μM of **4** was required to obtain a labeling degree in the range of those achieved by the enzymatic method. Similar results were obtained from experiments with bovine IgG and chCE7 (data not shown).

Data obtained by SDS-PAGE analysis of the experiments described above also allowed a comparison of the selectivity of two methods with regard to the labeling of the antibodies' heavy and light chains (Figure 6B). For example, the chemical modification of chCE7$_{agl}$ resulted in a labeling ratio of heavy-to-light chain of approximately 7:3. The same ratio was found for all concentrations of **4** examined (1–100 μM; data not shown). On the other hand, the enzymatic labeling of chCE7$_{agl}$ with BTGase or TG2 and Gln– or Lys–substrates resulted in an almost exclusive labeling of the antibodies' heavy chains (>90%) in all cases. Similar results were obtained with bovine IgG and chCE7 (data not shown).

Affinity Measurements and Cell Internalization Experiments. chCE7 and chCE7$_{agl}$ were labeled with BTGase under optimized reaction conditions, purified by size exclusion chromatography, and the average labeling degree of the conjugates determined by UV/vis spectroscopy. The solutions of fluorescent conjugates chCE7-(**2**), chCE7$_{agl}$-(**1**), or chCE7$_{agl}$-(**2**) (as a mixture with unlabeled antibodies) were further examined for their biological activity in vitro. For affinity measurements, increasing concentrations of unmodified chCE7$_{agl}$ and labeled chCE7$_{agl}$-(**1**) (1 label/antibody) were used to displace ^{125}I-labeled intact chCE7 bound to SKOV3ip cells. The results showed a typical sigmoid curve when the log of the concentration of competitors is plotted versus % displaced activity on the cells (data not shown). Complete displacements were achieved with 3000 ng of the competitor. 50% displacement (IC_{50}) occurred with 22 ng of unmodified chCE7$_{agl}$ and 28 ng of chCE7$_{agl}$-(**1**). Cell internalization studies were performed using L1-CAM expressing HEK-293 cells. Antigen binding and cell internalization of chCE7$_{agl}$-(**1**) (1 label/antibody), chCE7$_{agl}$-(**2**) (0.4 label/antibody), and chCE7-(**2**) (0.3 label/antibody) were compared with those of unlabeled chCE7 and chCE7$_{agl}$ (detected with a secondary, FITC-labeled, antihuman antibody) (*14*) Analysis of cell samples by confocal laser scanning microscopy revealed similar cell surface binding and internalization of all antibodies and antibody conjugates tested (Figure 7).

DISCUSSION

Commercial recombinant bacterial TGase (BTGase, from *Streptomyces mobaraensis*) and human tissue transglutaminase 2 (TG2, from *E. coli*) were selected for the enzymatic modification of antibodies as two representative examples of enzymes of the family of TGases. As TGase substrates, we used known Lys(mimicking) (*15*) and Gln–derivatives (*16, 17*) to which the fluorophore DY547 (CY3 analogue) was conjugated (*25*). Lys–substrate cadaverine-DY547 (**1**) and Gln–substrates (ZGlnGly cadaverine-DY547 (**2**) and ZGlnGlnProLeu-cadavarine-DY547 (**3**), respectively) were synthesized by standard peptide coupling reactions as outlined in Scheme 1. TGase substrates **1**–**3** were obtained in 1–3 synthetic steps in good overall yields after HPLC purification.

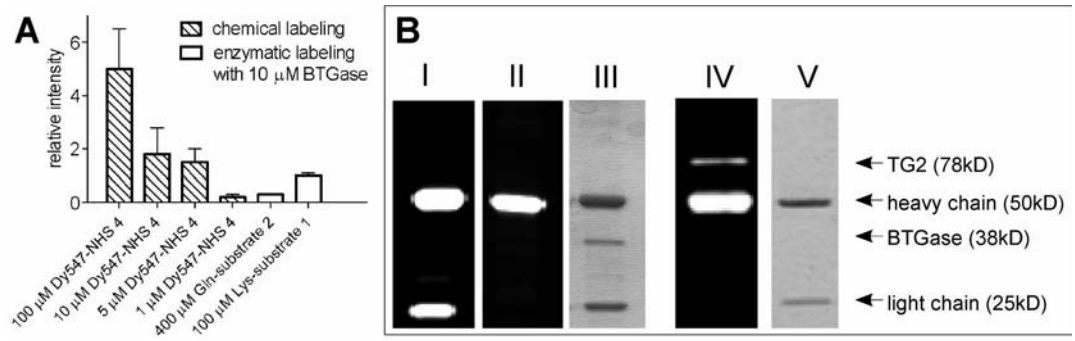

Figure 6. (A) Chemical modification of chCE7$_{agl}$ (0.75 mg/mL) with varying concentrations of DY547-NHS **4** (1–100 μM) and comparison of the labeling degrees with the one achieved by the BTGase-mediated labeling under optimized conditions (number of experiments $n = 2$). (A) Detection of DY547 fluorophore using a rhodamine optical filter (red). (B) Detection via secondary FITC-labeled antihuman antibody using a FITC optical filter (green). (C) Overlay (yellow). Cell nuclei (blue) were additionally stained with a DAPI analogue in the case of chCE7$_{agl}$-(**1**).

With fluorescent TGase substrates in hand, we studied and optimized the labeling of model antibody bovine IgG as well as the tumor-targeting antibodies chCE7 and chCE7$_{agl}$ by enzymatic modification of the proteins via their Lys and Gln side chains, respectively. The influence of several reaction parameters such as pH, substrate and enzyme concentration, and time was carefully investigated for both enzymes. We observed that slightly basic reaction conditions (pH 8) gave the best results for the antibody labeling with Gln–substrates with both TGases (Figure 2) while modifications with Lys–substrate **1** were less influenced by the pH. Optimal enzyme concentrations were found to be 10 μM for BTGase and, considerably lower, 80 nM for TG2 (Figure 3). Under all conditions examined, no high molecular weight aggregates as the result of cross-linking of proteins were detected by SDS-PAGE analyses. Self-labeling of the enzymes with fluorescent substrates was only observed in the case of TG2 (Figure 6). Such self-labeling of mammalian TGase is known (*18*). For BTGase, the most efficient labeling was achieved with Gln–substrate **2** at the highest concentration applicable (400 μM). The effect of substrate concentration on the labeling degree was less pronounced with Lys–substrate **1**, and a maximal labeling of antibodies was achieved at a concentration of 100–200 μM (Figure 4). In comparison, labeling of antibodies with TG2 and Gln–substrate **3** peaked at a substrate concentration of 50–100 μM, while only a negligible labeling of antibodies was obtained with Lys–substrate **1** even at the highest possible concentration (Figure 5C).

For both bovine IgG and chCE7, employment of TGases together with their corresponding Gln–substrates **2** and **3** resulted in an up to 6-fold higher labeling degree compared to Lys–substrate **1** (Figure 5). (*26*, *27*).These results may reflect the more abundant Lys residues exposed on the surface of antibodies (*11*) or, alternatively, the known specificity of TGases toward certain amino acid sequences neighboring the Gln residues (*19*). A maximum labeling degree of 0.2–0.3 fluorescent label per antibody was achieved with Gln–substrates in less than 2 h in the case of BTGase and after approximately 20 min with TG2. Even though TG2 was very efficient, we experienced that this enzyme is more delicate to handle than BTGase, which led to variable results (*20*, *28*).

To our surprise, the antibody chCE7$_{agl}$ exhibited a quite different labeling behavior (Figure 5B). We found that employment of BTGase and Lys–substrate **1** gave rise to a label/protein ratio of approximately 1:1. On the other hand, antibody modification with TG2 and Lys–substrate **1** resulted in a very low labeling degree (Figure 5C). These findings may illustrate the higher Gln–substrate specificity of TG2 compared to that of BTGase. While the labeling with BTGase and Gln–substrate **3** still gave reasonable results, no attachment of fluorophores to antibodies was observed when the combination TG2/Gln–substrate **2** was employed. The use of Gln–substrates **2** and **3** with TG2 and BTGase, respectively, culminated in a labeling degree of 0.4–0.5 label per chCE7$_{agl}$ (Figure 5C). We attribute the higher labeling degrees achieved with chCE7$_{agl}$ to the single-site mutation (Asn297Gln) which potentially introduces an additional Gln coupling site or may result in subtle structural changes of the protein, which make other Gln residues more accessible. Similar effects of single-site mutations introducing Gln residues on TGase-mediated protein modification have been reported (*21*).

Next, we compared the enzymatic labeling of antibodies with chemical modifications using the NHS–ester **4**. Clearly, more Lys residues are prone to be labeled by the chemical modification than by the enzymatic labeling using TGases. Thus, in order to achieve the same labeling degree as observed for the enzymatic method (100–400 μM substrate), a concentration of only 2–5 μM of the chemically reactive probe DY547-NHS **4** was required (Figure 6A). While the labeling with DY547-NHS **4** proceeded very efficiently, SDS-PAGE analysis of the conjugates revealed that the chemical modification led to attachment of fluorescent probes to the antibodies at the heavy (70%) and light (30%) chain, a ratio which corresponds to their

size (~80 kDa and ~25 kDa, respectively). The enzymatic reaction, on the other hand, resulted in an almost exclusive labeling of the heavy chain (>90% for model bovine IgG and chCE7, and >95% for $chCE7_{agl}$) with either combination of TGase and substrate. Such selectivity could not be achieved by the chemical labeling protocol using the NHS ester. Site-specific modification of monoclonal antibodies at the heavy chain via a chemical method is reported in the literature and uses the oligosaccharide attached to the hinge region of the antibody (*22*). However, this chemical protocol is quiet laborious, requiring delicate periodate oxidation of carbohydrate 1,2-diols to aldehydes (*23*) and two or more purification steps.

Binding assays performed with ^{125}I-labeled $chCE7_{agl}$ on SKOV3ip cells showed that $chCE7_{agl}$-(**1**) (revealing the highest labeling degree) competed almost equally effectively for the antigen than did unmodified $chCE7_{agl}$, indicating unaltered affinity (*29*).

Analysis of cell samples by confocal laser scanning microscopy revealed that the enzymatic modification of chCE7 and $chCE7_{agl}$ with fluorescent substrates had no influence on their cell binding and internalization. Figure 7 shows the characteristic formation of endosomes as the result of internalization of fluorescent antibodies by endocytosis. $chCE7_{agl}$-(**1**) and $chCE7_{agl}$-(**2**) (and unlabeled chCE7/ $chCE7_{agl}$) were codetected with the FITC-labeled, secondary antibody as a control. Overlay of the pictures obtained with a rhodamine (detection of DY547, Figure 7A) and FITC optical filter (detection of secondary antibody, Figure 7B) shows the correlation of DY547-labeled and unlabeled antibodies bound and internalized into HEK-293 cells (Figure 7A). Good overlap of the fluorescence was observed for $chCE7_{agl}$-(**1**) indicating that the majority of bound and internalized antibodies were indeed labeled with the DY547 fluorophore (~1 DY547 per antibody). As expected, some mismatch of the fluorescence was observed for the in vitro experiment with $chCE7_{agl}$-(**2**) due to the lower labeling degree (~0.3 DY547 per antibody) which translates into the presence of approximately 60% of unmodified $chCE7_{agl}$ in the protein fraction isolated from size exclusion chromatography.

CONCLUSION

In conclusion, we have shown that the TGase-mediated labeling of different IgG1 antibodies proceeds under mild reaction conditions with different TGases and both fluorescent Lys– and Gln–substrates. The enzymatic modification of model bovine IgG and tumor-targeting antibodies chCE7 and $chCE7_{agl}$ occurred selectively at the heavy chain of the antibodies, seemingly without influencing their biological activities as shown by in vitro cell experiments. Reproducible labeling can be achieved in a broad concentration "window" of the substrates and enzymes without the risk of overlabeling the antibodies. Of the two TGases tested, BTGase incorporated the Lys–substrate **1** more efficiently than did TG2. On the other hand, both enzymes were equally efficient with the corresponding Gln–substrate (**2** or **3**, respectively). Because TG2 is more delicate to handle, employment of BTGase is preferred for our purposes. The labeling degrees of antibodies achieved so far by the enzymatic method were moderate, but sufficient for optical imaging of cell samples and are also likely to be adequate for other applications. Further investigations of the enzymatic labeling of proteins aimed toward application of TGase substrates attached to probes other than fluorophores, including metal chelating moieties for SPECT, PET, and MRI, are currently ongoing.

(25) Initially, the antibody labeling experiments were conducted with similar results using BTGase and commercial cadavarine-dansyl and ZGlnGly cadavarine-dansyl substrates. However, the dansyl fluorophore proved to be unsuitable for fluorescence microscopy of cell samples.

(26) Similar results were obtained with commercial human and chicken IgG.

(27) Interestingly, Josten et al. have reported a labeling degree of 1.1 to 1.4 labels per antibody for the BTGase-mediated biotinylation of a monoclonal IgG using a Lys–substrate (*11*).

(28) For example, storage of solutions of TG2 on ice for 1 h resulted in a decrease of the enzyme's activity by 50% (data not shown, loss of activity of mammalian TGases has previously been reported by Jeitner et al. (*20*)). No loss of activity was observed for BTGase even after storage of solutions at rt for several hours.

(29) Josten et al. (*11*) and Takazawa et al. (*12*) also report unaltered antigen binding of antibodies and antibody fragments that were modified by TGases.

Received August 27, 2007; Revised Manuscript Received October 23, 2007

A straightforward method to enhance water solubility of fluorescent organic dyes (cyanines and rhodamines) by a postsynthetic chemical derivatization of their carboxylic acid functionality with an original disulfonated heterobifunctional linker is described. Significant water solubility enhancement is achieved without compromising either the photophysical properties (especially large molar extinction coefficients and high quantum yields) or bioconjugation efficiency of the parent non-water-soluble fluorophores. The results both demonstrate the strong potential of these new compounds as fluorescent labels for a broad range of biotechnology and biomedical applications and illustrate the utility of such an easy-to-handle water-solubizing group.

INTRODUCTION

Fluorescent organic dyes are the central focus of numerous chemical, analytical, biological, and spectroscopic studies, since their use as powerful detection tools for life science applications is now well-established (*1*). Among the multitude of available fluorophores, those absorbing and emitting in the relatively long wavelength range (i.e., around or beyond 600 nm) are more desirable; especially as probes for emerging and more challenging biotechnology and biomedical applications such as DNA sequencing (*2*), diagnostic imaging (*3*), and photodynamic therapy (*4*). Indeed, the advantages of a fluorescence occurring in the low-energy region of the electromagnetic spectrum are numerous and have been extensively discussed (*2, 5*). Prominent among these advantages is the absence or the significant reduction of background absorption, fluorescence, and light scattering, along with the availability of low-cost sources of irradiation. To obtain new analogues of longer-wavelength absorption and emission, the most popular synthetic strategy consists in the extension of the π-conjugation system of some widely used fluorophore precursors, such as fluorescein, rhodamine, BODIPY, and so forth. However, the attachment of one or more aromatic poly(hetero)cycles to these latter fluorescent cores often leads to molecules poorly or not soluble in aqueous media and therefore not suitable for biolabeling applications. Consequently, recent efforts have been devoted to the development of water-soluble analogues of some long-wavelength fluorophores belonging to the BODIPY (*6, 7*), cyanine (*3, 8, 9*), oxazine (*10*), and rhodamine (*11–13*) families. A modification in the molecular structure by adding ionizable hydrophilic groups such as carboxylic acid, phosphonic acid, sulfonic acid, hydroxyl, and ammonium groups to the dye improves the water solubility but diversely affects the quantum yield and photostability. Moreover, for the majority of fluorophores, modulation of such physicochemical properties requires restarting the synthesis of the fluorescent core from the beginning with building blocks bearing the water-solubilizing groups (for a recent example, see (*14*)). Such a *de novo* approach has three main drawbacks which dramatically affect the overall yield of the synthetic process: (1) the laborious and time-consuming handling and purification of highly polar synthetic intermediates, (2) the extent of byproducts resulting from undesirable side reactions of some free reactive groups (i.e., carboxylic acid, phosphonic acid, and hydroxyl groups), and thus (3) in most cases, the requirement of additional protection/deprotection steps. To overcome these limitations and to speed up the development of new beneficial water-soluble fluorophores, an alternative synthetic approach is preferred, based on the postsynthetic functionalization of hydrophobic fluorescent precursors ("convertible organic dyes") readily available through convenient and high-yield synthetic protocols. Indeed, after completion of the fluorescent core synthesis, the specific chemical derivatization of the reactive group (typically a carboxylic acid group) of this convertible organic dye with a hydrophilic heterobifunctional linker enables the introduction of both water-solubilizing moieties and a terminal reactive group for bioconjugation. Thus, the laborious workup and purification steps of polar fluorescent materials are limited to the isolation of the final water-soluble fluorophore. Recently, we have used this "post-synthetic derivatization" approach for the synthesis of a novel analogue (Figure 1, dye **1**) of commercially available cyanine dye Cy 5.5 (*8, 15, 16*). Acylation of the amino group of a cyanine-based amino acid with *N*-hydroxysuccinimidyl ester of trisulfonated linker **2** derived from 3,5-diaminobenzoic acid (Figure 1), afforded **1** in good yield. However, linker **2** is not easily accessible in high yields, and its aromatic core negatively affects the fluorescence properties (i.e., quantum yield) of the resulting water-soluble fluorophore. To circumvent these problems, the use of a hydrophilic alkyl linker derived from a peptidic architecture is an interesting alternative to explore and can rely on the numerous and efficient methods described for the peptide coupling reactions. To our knowledge, only one publication from Meltola et al. describes the postsynthetic derivatization of fluorophores with a hydrophilic peptide linker

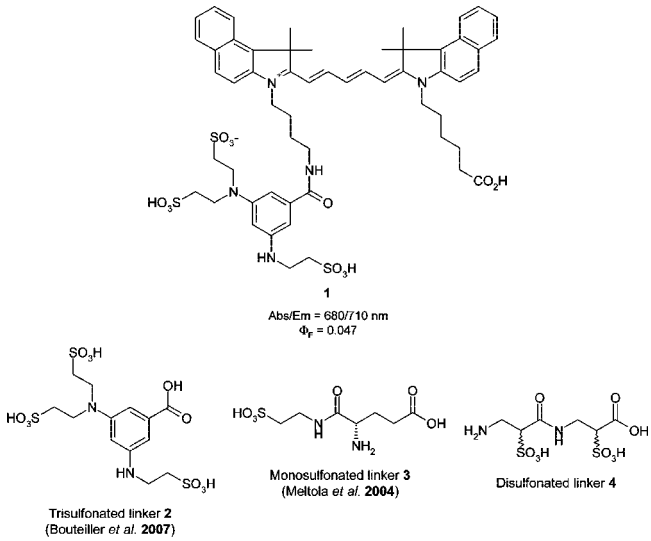

Figure 1. Structures of Cy 5.5 analogue **1** and of the hydrophilic linkers.

(*6*). Monosulfonated linker **3** derived from L-glutamic acid (Figure 1) has been synthesized and attached to the carboxylic acid side chain of some BODIPY dyes to get fluorescent labels for two-photon excited fluorometry. However, this strategy limits the number of additional sulfonic acid moieties to one, which is insufficient for an efficient enhancement of the water solubility of fluorescent cores bearing four or more aromatic rings.

In this article, we wish to report the synthesis and use of an original disulfonated linker **4** resulting from the coupling between two α-sulfo-β-alanine units and its use in the preparation of novel water-soluble analogues of cyanine dye Cy 5.5, rhodamine 6G, and sulforhodamine 101 (i.e., Texas Red). This strategy results in an unchanged carboxylic group available for bioconjugation reactions, and allows grafting of additional sulfonic acid moieties.

EXPERIMENTAL PROCEDURES

Chemicals and Reagents. Reversed-phase column flash chromatographies were performed on octadecyl-functionalized silica gel (mean pore size 60 Å) from Aldrich. DMF was dried by distillation over BaO. DIEA and TEA were distilled from CaH_2 and stored over BaO. Cyanine dye **7** was prepared in four steps from 1,1,2-trimethyl-1*H*-benz[*e*]indole by using the convergent synthetic scheme recently reported by us (*8*). Rhodamine carboxylic acid derivative **10** was prepared from rhodamine 6G (Aldrich, dye content ~95%) by using the three-step synthetic procedure developed by Afonso et al. (i.e., pyrolysis, alkylation with benzyl bromoacetate, and hydrogenolysis of benzyl ester) (*17*). Alexa Fluor 594 carboxylic acid was synthesized by using a multistep synthetic procedure described in a PCT International Application from Invitrogen (formerly Molecular Probes, Inc.) and entitled "Sulfonated xanthene derivatives synthesis and applications as fluorescent stains" (*18*). The two isomers of this water-soluble rhodamine derivative were resolved by flash chromatography on a RP-C_{18} silica gel column. The first eluted isomer (i.e., the most polar) was named isomer I and the second one isomer II. Structural assignment of each isomer was achieved by ^{1}H NMR spectroscopy: isomer I corresponds to the 1,4-dicarboxylic acid derivative, whereas isomer II is the 1,3-dicarboxylic acid derivative. Sulforhodamine 101 (free acid, 99%, laser grade) was purchased from Acros. Glycine *tert*-butyl ester hydrochloride (H-Gly-OtBu·HCl) was from Alfa Aesar. Recombinant human caspase-3 enzyme (5.52 U/mg) was purchased from Sigma. The HPLC-gradient-grade CH_3CN was obtained from Panreac. Buffers (bicarbonate, borate, caspase-3, and phosphate buffer saline (PBS)) and aq mobile phases for HPLC were prepared using water purified with a Milli-Q system (purified to 18.2 MΩ.cm). Triethylammonium acetate (TEAA, 1.0 M) and triethylammonium bicarbonate (TEAB, 1.0 M) buffers were prepared from distilled triethylamine and glacial acetic acid or CO_2 gas.

Instruments. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker DPX 300 (Bruker, Wissembourg, France). Chemical shifts are expressed in parts per million (ppm) from D_2O (δ_H = 4.79) or DMSO-d_6 (δ_H = 2.50, δ_C = 39.52) (*19*). *J* values are expressed in Hz. Analytical HPLC was performed on a Thermo Electron Surveyor instrument equipped with a PDA detector. Semipreparative HPLC was performed on a Finnigan SpectraSYSTEM liquid chromatography system equipped with UV–vis 2000 detector. UV–vis spectra were obtained on a Varian Cary 50 scan spectrophotometer. Fluorescence spectroscopic studies were performed either in a semimicrofluorescence cell (Hellma, 104F-QS, 10 × 4 mm, 1400 μL) or in an ultramicrofluorescence cell (Hellma, 105.51-QS, 3 × 3 mm, 45 μL) with a Varian Cary Eclipse spectrophotometer. Mass spectra were obtained with a Finnigan LCQ Advantage MAX (ion trap) apparatus equipped with an electrospray source.

HPLC Separations. Several chromatographic systems were used for the analytical experiments and the purification steps. Each one of these systems was optimized in order to improve separation conditions.

System A: RP-HPLC (Thermo Hypersil GOLD C_{18} column, 5 μm, 4.6 × 150 mm) with CH_3CN and 0.1% aq trifluoroacetic acid (aq TFA, 0.1%, v/v, pH 2.0) as eluents [100% TFA (5 min), linear gradient from 0% to 80% (40 min) of CH_3CN] at a flow rate of 1 mL/min. UV detection was achieved at 260 nm.

System B: System A with the following gradient [80% TFA (5 min), linear gradient from 20% to 40% (5 min) and 40% to 64% (20 min) of CH_3CN]. Triple UV–vis detection was achieved at 530, 595, and 675 nm.

System C: RP-HPLC (Thermo Hypersil GOLD C_{18} column, 5 μm, 4.6 × 150 mm) with CH_3CN and TEAA buffer (100 mM, pH 7.0) as eluents [80% TEAA (5 min), linear gradient from 20% to 40% (5 min) and 40% to 64% (20 min) of CH_3CN] at a flow rate of 1 mL/min. Triple UV–vis detection was achieved at 260, 595, and 675 nm.

System D: RP-HPLC (Varian Kromasil C_{18} column, 10 μm, 21.2 × 250 mm) with CH_3CN and 0.1% aq TFA as eluents [90% TFA (5 min), linear gradient from 10% to 30% (10 min) and 30% to 80% (50 min) of CH_3CN] at a flow rate of 20 mL/min. UV detection was achieved at 260 nm.

System E: RP-HPLC (Varian Kromasil C_{18} column, 10 μm, 21.2 × 250 mm) with CH_3CN and TEAB buffer (50 mM, pH 7.5) as eluents [90% TFA (5 min), linear gradient from 10% to 80% (70 min) of CH_3CN] at a flow rate of 20 mL/min. UV detection was achieved at 300 nm.

System F: RP-HPLC (Waters XTerra MS C_{18} column, 5 μm, 7.8 × 100 mm) with CH_3CN and TEAB buffer (50 mM, pH 7.5) as eluents [75% TEAB (2 min), linear gradient from 25% to 30% (3 min) and 30% to 75% (60 min) of CH_3CN] at a flow rate of 1.5 mL/min. UV detection was achieved at 260 nm.

α-Sulfo-β-alanine. Oleum (25% SO_3) (40 mL) was added to β-alanine (2.7 g, 30.30 mmol) with cooling in an ice−salt bath. The resulting reaction mixture was left at room temperature for 4 days, and then diluted cautiously with cold water (80 mL). The solution was left overnight at 4 °C to crystallize. The white solid was isolated by filtration, washed with cold deionized water. After drying by lyophilization, racemic α-sulfo-β-alanine was obtained as a white powder (2.77 g, 16.4 mmol, yield 54%). mp >260 °C. IR (KBr) 3190 (broad), 1727, 1613, 1589, 1504,

1459, 1303, 1204 (broad), 1111, 1043. ^{1}H NMR (300 MHz, D_2O): δ 3.56 (m, 2H, H-3 and H-3′), 4.16 (t, $J = 6.4$ Hz, 1H, H-2). ^{13}C NMR (75.5 MHz, D_2O): δ 37.8 (1C, C-3), 61.9 (1C, C-2), 169.0 (1C, C-1). MS (ESI, positive mode) *m/z*: 169.93 $[M + H]^+$. MS (ESI, negative mode) *m/z*: 168.06 $[M - H]^-$, calcd mass for $C_3H_7NO_5S$ 169.16. Anal. Calcd for $C_3H_7NO_5S$: C 21.30, H 4.17, N 8.28, S 18.96. Found: C 20.06, H 4.04, N 7.78, S 19.76 ($C_3H_7NO_5S \cdot H_2SO_4$, 94/6).

***N*-(9-Fluorenylmethyloxycarbonyl)-α-sulfo-*β*-alanine (5).** Racemic α-sulfo-*β*-alanine (0.5 g, 1.87 mmol) was dissolved in 8.5% sodium carbonate solution (aq) (7 mL) and cooled to 4 °C. A solution of Fmoc-OSu (0.5 g, 1.49 mmol) in 1,4-dioxane (5 mL) was added in one portion to the stirred solution, and the mixture was left at room temperature overnight. The reaction was checked for completion by RP-HPLC (system A) and the mixture was acidified to pH ∼2 with 10% HCl (aq). After partial removal of 1,4-dioxane under reduced pressure, the reaction mixture was lyophilized. The resulting residue was purified by flash chromatography on an RP-C_{18} silica gel column (20 g) with a stepwise gradient of CH_3CN (0–30%) in aq TFA as the mobile phase. The product-containing fractions were lyophilized to give protected amino acid **5** as a white amorphous powder (0.69 g, yield 95%). IR (KBr) 3372 (broad), 1723, 1538, 1449, 1236 (broad), 1048. ^{1}H NMR (300 MHz, DMSO-d_6): δ 3.39–3.60 (m, 3H), 4.20 (bs, 3H), 7.02 (bs, 1H, N*H*), 7.29–7.89 (m, 8H, *H*-Fmoc). ^{13}C NMR (75.5 MHz, DMSO-d_6): δ 38.3 (masked by DMSO peak), 46.7, 65.0, 65.6, 120.1 (2C), 125.4, 127.1 (2C), 127.7 (2C), 140.7 (2C), 143.9 (2C), 156.0, 169.5 (2C). HPLC (system A): $t_R = 25.17$ min, purity >95%. MS (ESI, negative mode) *m/z*: 390.00 $[M - H]^-$, calcd mass for $C_{18}H_{17}NO_7S$ 391.40. Compound **5** proved to be too hygroscopic for a suitable elemental analysis.

***N*-(9-Fluorenylmethyloxycarbonyl)-α-sulfo-*β*-alaninyl-α-sulfo-*β*-alanine (6).** (a) Preparation of *N*-hydroxysuccinimidyl ester. A mixture of **5** (368 mg, 0.94 mmol) and *N*-hydroxysuccinimide (108 mg, 0.94 mmol) was dissolved in dry DMF (5 mL). DCC (194 mg, 0.94 mmol) was added, and the resulting reaction mixture was stirred at room temperature for 24 h. The reaction was checked for completion by RP-HPLC (system A), DMF (0.5 mL) was added and the solution was transferred in 1.5 mL Eppendorf tubes and centrifuged to remove the major amount of DCU. The clear liquid phase containing the active ester was used in the coupling reaction without further purification. Yield was assumed to be quantitative. HPLC (system A): $t_R = 27.5$ min (compared to $t_R = 25.2$ min for the free acid **5**).

(b) Coupling reaction. α-Sulfo-*β*-alanine (191 mg, 1.13 mmol) was dissolved in 6.8% sodium bicarbonate solution (aq) (4.2 mL) and cooled to 4 °C. The crude solution of *N*-hydroxysuccinimidyl ester in DMF was added dropwise to the stirred solution, and the mixture was left at room temperature for 1 h. The reaction was checked for completion by RP-HPLC (system A), and the mixture was acidified to pH ∼2 with 10% HCl (aq). The reaction mixture was evaporated under reduced pressure. The resulting residue was purified by flash chromatography on an RP-C_{18} silica gel column (30 g) with a stepwise gradient of CH_3CN (0–30%) in aq TFA as the mobile phase. The product-containing fractions were lyophilized to give the dipeptide **6** as a white amorphous powder (435 mg, yield 85%, mixture of two racemic diastereomers). IR (KBr) 3396 (broad), 1711, 1544, 1534, 1247 (broad), 1042. ^{1}H NMR (300 MHz, DMSO-d_6): δ 3.12 (m, 1H), 3.35–3.70 (m, 5H), 4.20 (bs, 3H), 6.98 (bd, 1H, N*H*), 7.01, 7.30–7.89 (m, 8H, *H*-Fmoc). ^{13}C NMR (75.5 MHz, DMSO-d_6): δ 38.3 (1C, *β*-CH_2, two diastereomers), 38.4 (1C, *β*-CH_2, two diastereomers), 46.7 (1C, CH-Fmoc, two diastereomers), 64.7 (1C, α′-CH, two diastereomers), 64.9 (1C, α-CH, one diastereomer), 65.0 (1C, α′-CH, one diastereomer), 65.8 (1C, CH_2-Fmoc, two diastereomers), 120.2 (2C, Fmoc, two diastereomers), 125.5 (1C, Fmoc, two diastereomers), 127.3 (2C, Fmoc, two diastereomers), 127.7 (2C, Fmoc, two diastereomers), 140.7 (2C, Fmoc, two diastereomers), 144.0 (2C, Fmoc, two diastereomers), 155.8 (1C, Fmoc, two diastereomers), 167.1 (1C, two diastereomers), 169.2 (1C, two diastereomers), 169.3 (1C, two diastereomers). HPLC (system A): $t_R = 21.7$ and 22.0 min (two diastereomers), purity >95%. MS (ESI, negative mode) *m/z*: 269.93 $[M - 2H]^{2-}$, 541.00 $[M - H]^-$, calcd mass for $C_{21}H_{22}N_2O_{11}S_2$ 542.54. Anal. Calcd for $C_{21}H_{22}N_2O_{11}S_2$: C 46.49, H 4.09, N 5.16, S 11.82. Protected dipeptide **6** proved to be too hygroscopic for a suitable elemental analysis.

α-Sulfo-*β*alaninyl-α-sulfo-*β*-alanine (4). *N*-Fmoc α-sulfo-*β*-alanine dipeptide **6** (88 mg, 0.16 mmol) was dissolved in DMF (1 mL) and cooled to 4 °C. Et_2NH (0.1 mL, 0.96 mmol) was added and the resulting reaction mixture was stirred at room temperature for 1 h. The reaction was checked for completion by RP-HPLC (system A), and the mixture was evaporated under reduced pressure. The resulting residue was taken up in deionized water (10 mL) and washed with CH_2Cl_2 (2 × 5 mL). Finally, the aq solution was lyophilized to give the α-sulfo-*β*-alanine dipeptide linker **4** as a white amorphous powder (66 mg, yield 87%, mixture of two racemic diastereomers). ^{1}H NMR (300 MHz, D_2O): δ 1.23 (t, $J = 7.5$ Hz, 12H, N-CH_2-C*H*$_3$), 3.03 (q, $J = 7.5$ Hz, $J = 14.7$ Hz, 8H, N-C*H*$_2$-CH_3), 3.45–3.63 (m, 3H), 3.78–3.97 (m, 2H), 4.06 (t, $J = 6.4$ Hz, 1H). ^{13}C NMR (75.5 MHz, D_2O): δ 10.9 (4C, N-CH_2-C*H*$_3$), 37.9 (1C, *β*-CH_2, two diastereomers), 39.6 (1C, *β*′-CH_2, two diastereomers), 42.6 (4C, N-C*H*$_2$-CH_3), 61.8 (1C, α-CH, two diastereomers), 61.9 (1C, α′-CH, two diastereomers), 166.5 (1C, two diastereomers), 166.7 (1C, two diastereomers). HPLC (system A): $t_R = 4.8$ min (broad peak, two diastereomers), purity >95%. MS (ESI, negative mode) *m/z*: 159.00 $[M - 2H]^{2-}$, 319.00 $[M - H]^-$, calcd mass for $C_6H_{12}N_2O_9S_2$ 320.30. Dipeptide **4** proved to be too hygroscopic for suitable IR and elemental analyses.

NIR5.5-WS. (a) Preparation of *N*-hydroxysuccinimidyl ester **8**. Cyanine dye **7** (71.2 mg, 0.10 mmol) was dissolved in dry DMF (1.7 mL). TSTU reagent (31.0 mg, 0.10 mmol) and DIEA were added (0.31 mmol). The resulting reaction mixture was protected from light and stirred at room temperature for 30 min. The reaction was checked for completion by RP-HPLC (system B), and the resulting *N*-hydroxysuccinimidyl ester was used without further purification. HPLC (system B): $t_R = 20.5$ min (compared to $t_R = 19.5$ min for cyanine dye carboxylic acid **7**).

(b) Coupling reaction. α-Sulfo-*β*-alanine-α-sulfo-*β*-alanine **4** (52 mg, 0.11 mmol) was dissolved in borate buffer (50 mM, pH 8.2, 1.5 mL) and cooled to 4 °C. The crude solution of *N*-hydroxysuccinimidyl ester in DMF was added dropwise to the stirred solution, and the mixture was left at room temperature overnight. The reaction was checked for completion by RP-HPLC (system C). Finally, the reaction mixture was quenched by dilution with aq TEAB (50 mM, pH 7.5) and purified by flash chromatography on a RP-C_{18} silica gel column (20 g) with a step gradient of CH_3CN (0–60%) in aq TEAB as the mobile phase. The product-containing fractions were lyophilized twice to give the TEA salt of **NIR5.5-WS** as a blue amorphous powder (133 mg, yield 65%, mixture of two racemic diastereomers). ^{1}H NMR (300 MHz, DMSO-d_6): δ 1.13 (t, $J = 7.1$ Hz, 27H, N-CH_2-C*H*$_3$), 1.40 (m, 2H), 1.52 (m, 2H), 1.73 (m, 2H), 1.94 (s, 6H, C*H*$_3$), 1.97 (s, 6H, C*H*$_3$), 2.01–2.06 (m, 4H), 2.63 (t, $J = 6.8$ Hz, 2H), 2.99 (q, $J = 6.8$ Hz, $J = 13.9$ Hz, 18H, N-C*H*$_2$-CH_3), 3.33–3.73 (m, 6H, C*H*$_2$-C*H*(SO_3^-)-CO-), 4.23 (m, 2H), 4.42 (m, 2H), 6.41–6.54 (m, 2H), 6.67 (t, $J = 12.9$ Hz, 1H), 7.47–8.25 (m, 12H), 8.46 (t, $J = 13.2$ Hz, 2H). HPLC (system C): $t_R = 14.5$ min, purity >95%. UV–vis (PBS, pH 7.4, 25 °C): $\lambda_{max} = 679$ nm (197 000 M^{-1} cm^{-1}). UV–vis (DMSO, 25 °C): $\lambda_{max} = 688$ nm (147 000 M^{-1} cm^{-1}). UV–vis (EtOH, 25

°C): λ_{max} = 685 nm (138 000 M^{-1} cm^{-1}). Φ_F (PBS, pH 7.4, 25 °C): 0.066. Φ_F (DMSO, 25 °C): 0.26. Φ_F (EtOH, 25 °C): 0.16. MS (ESI, positive mode): *m/z* 1094.33 $[M + TEA + H]^+$, 1195.13 $[M + 2TEA + H]^+$, 1295.93 $[M + 3TEA + H]^+$. (ESI, negative mode): *m/z* 495.20 $[M - 2H]^{2-}$, 991.27 $[M - H]^-$, calcd for $C_{48}H_{56}N_4O_{13}S_3$ (**NIR5.5-WS**, acid form) 993.19.

R6G-WS. (a) Preparation of *N*-hydroxysuccinimidyl ester. A mixture of **10** (60.9 mg, 0.11 mmol) and *N*-hydroxysuccinimide (13.8 mg, 0.12 mmol) was dissolved in dry DMF (2.5 mL). DCC (24.8 mg, 0.12 mmol) was added, and the resulting reaction mixture was protected from light and stirred at room temperature overnight. The reaction was checked for completion by ESI-MS, and the resulting *N*-hydroxysuccinimidyl ester was used without further purification. MS (ESI, positive mode) *m/z*: 570.33 $[M + H]^+$, calcd for $C_{32}H_{32}N_3O_7^+$ 570.63.

(b) Coupling reaction. α-Sulfo-β-alanine-α-sulfo-β-alanine **4** (56 mg, 0.12 mmol) was dissolved in borate buffer (50 mM, pH 8.2, 1.9 mL) and cooled to 4 °C. The crude solution of *N*-hydroxysuccinimidyl ester in DMF was added dropwise to the stirred solution, a further amount of DMF (0.5 mL) was added, and the mixture was left at room temperature overnight. The reaction was checked for completion by RP-HPLC (system B). Finally, the reaction mixture was quenched by dilution with aq TFA and purified by RP-HPLC (system D, three injections, t_R = 18.5–20.0 min). The product-containing fractions were lyophilized to give **R6G-WS** as a red amorphous powder (yield 38%, mixture of two racemic diastereomers). ^{1}H NMR (300 MHz, DMSO-d_6): δ 1.25 (t, *J* = 7.0 Hz, 6H, N-CH_2-CH_3), 2.09 (s, 6H, CH_3), 3.23 (m, 1H), 3.45–3.62 (m, 9H, N-CH_2-CH_3 and CH_2-$CH(SO_3^-)$-CO-), 4.39 (s, 2H, O-CH_2-CO-), 6.79 (s, 2H), 6.91 (s, 2H), 7.44 (d, *J* = 7.2 Hz, 1H), 7.67–7.93 (m, 6H, 4 × NH and 2 × ArH), 8.47 (m, 1H). HPLC (system B): t_R = 12.8 min, purity >95%. UV–vis (PBS, pH 7.4, 25 °C): λ_{max} = 528 nm (65 000 M^{-1} cm^{-1}). UV–vis (DMSO, 25 °C): λ_{max} = 539 nm (79 000 M^{-1} cm^{-1}). Φ_F (PBS, pH 7.4, 25 °C): 1.02. MS (ESI, positive mode): *m/z* 775.20 $[M + H]^+$. (ESI, negative mode): *m/z* 773.20 $[M - H]^-$, calcd for $C_{34}H_{38}N_4O_{13}S_2$ (**R6G-WS**, acid form) 774.83.

***N*-(Sulforhodamine 101)-L-glycine (12).** (a) Preparation of *N*-(sulforhodamine 101)-L-glycine *tert*-butyl ester **11**. Sulforhodamine 101 (50 mg, 0.08 mmol) was dried under high vacuum for 2 h. The resulting dried powder was mixed with 310 μL of phosphorus oxychloride (3.38 mmol). The mixture was stirred at room temperature under an argon atmosphere for 19 h. Thereafter, $POCl_3$ was removed under vacuum, and the resulting residue was dried under high vacuum at room temperature for 1 h. A 25 mL round-bottom flask containing a solution of H-Gly-OtBu (HCl salt, 31.5 mg, 0.19 mmol) and TEA (58 μL, 0.42 mmol) in dry DMF (0.6 mL) was cooled to 4 °C, and a DMF solution of the crude Texas Red sulfonyl chloride (1.4 mL) was dropwise added over 10 min. The resulting reaction mixture was protected from light and stirred overnight at room temperature under an argon atmosphere. The reaction was checked for completion by TLC (CH_2Cl_2/CH_3OH 9:1, v/v, R_f 0.53). The reaction mixture was evaporated under reduced pressure. The resulting residue was dissolved in CH_2Cl_2 (20 mL) and washed with deionized water (20 mL). The organic layer was dried over Na_2SO_4 and purified by flash chromatography on a silica gel column (silica gel 60A CC, 70–200 μm, Chromagel, SdS, 15 g) with 10% methanol in CH_2Cl_2 as eluant to give 37 mg of *tert*-butyl ester derivative **11**.

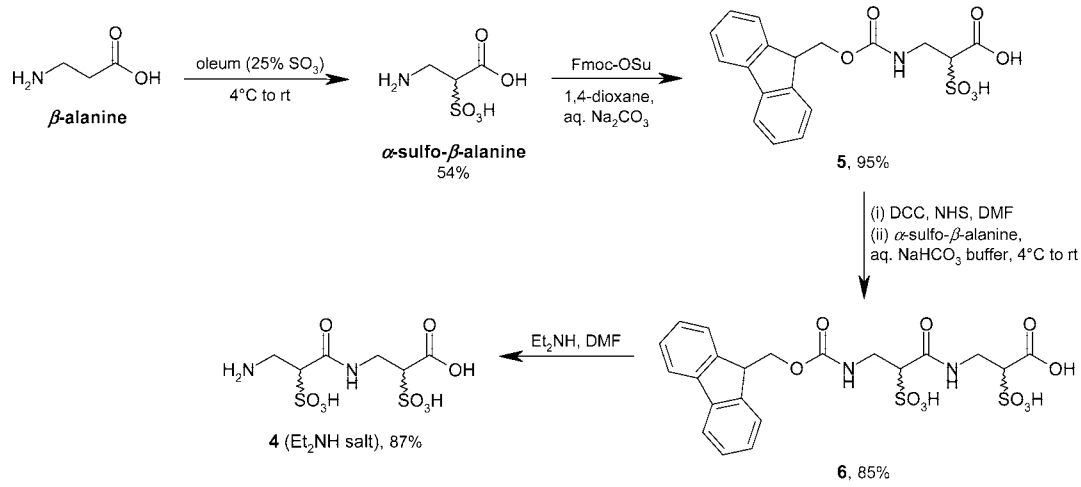
(b) Removal of *tert*-butyl ester. The above *tert*-butyl ester **11** was dissolved in CH_2Cl_2 (2 mL) and cooled to 4 °C. TFA (382 μL) and deionized water (10 μL) were added, and the resulting reaction mixture was warmed to room temperature and stirred for 4 h. The reaction was checked for completion by RP-HPLC (system B), and the mixture was evaporated to dryness. TFA was removed by azeotropic distillation with chloroform (2 × 10 mL). The resulting residue was partially dissolved in deionized water and lyophilized, giving the TFA salt of **12** as a bluish red amorphous powder (46 mg, overall yield 62%, mixture of the two regioisomers in a ratio 8:2). The analytical sample of the dye (TEA salt) was obtained by RP-HPLC purification (system E, t_R = 22.5–24.0 min). ^{1}H NMR (300 MHz, DMSO-d_6): δ 1.11 (t, *J* = 7.1 Hz, 9H, N-CH_2-CH_3), 1.84–2.01 (bm, 8H, 4 × CH_2), 2.50–2.97 (m, 14H, 4 × CH_2 and N-CH_2-CH_3), 3.49 (bm, 10H, 4 × CH_2 and CH_2-Gly), 6.53 (s, 1.55H, major regioisomer), 6.58 (s, 0.45H, minor regioisomer), 7.32 (bd, *J* = 7.9 Hz, 1H, ArH), 7.88–7.98 (m, 1H, ArH), 8.24 (s, 0.22H, ArH, minor regioisomer), 8.37 (s, 0.78H, ArH, major regioisomer). HPLC (system B): t_R = 14.3 and 15.6 min (two regioisomers), purity >90%. MS (ESI, positive mode): *m/z* 664.33 $[M + H]^+$. MS (ESI, negative mode): *m/z* 662.07 $[M - H]^-$, calcd for $C_{33}H_{33}N_3O_8S_2$ 663.77.

TR-WS. (a) Preparation of *N*-hydroxysuccinimidyl ester. Texas Red carboxylic acid (14.2 mg, 16 μmol) was dissolved in dry DMF (300 μL). TSTU reagent (4.80 mg, 16 μmol) and DIEA were added (11 μL, 63.7 μmol). The resulting reaction mixture was protected from light and stirred at room temperature for 90 min. The reaction was checked for completion by RP-HPLC (system B) and ESI-MS. The resulting *N*-hydroxysuccinimidyl ester was used without further purification. HPLC (system B): t_R = 22.0 min. MS (ESI, positive mode), *m/z*: 761.20 $[M + H]^+$, calcd for $C_{37}H_{36}N_4O_{10}S_2$ 760.85.

(b) Coupling reaction. α-Sulfo-β-alanine-α-sulfo-β-alanine **4** (12 mg, 25.6 μmol) was dissolved in bicarbonate buffer (0.1 M, pH 8.2, 0.5 mL) and cooled to 4 °C. The crude solution of *N*-hydroxysuccinimidyl ester in DMF was added dropwise to the stirred solution, a further amount of bicarbonate buffer (0.3 mL) was added, and the mixture was left at room temperature overnight. The reaction was checked for completion by RP-HPLC (system C). Finally, the reaction mixture was quenched by dilution with aq TEAB (50 mM, pH 7.5) and purified by RP-HPLC (system E, two injections, t_R = 19.5–21.0 min). The product-containing fractions were lyophilized thrice to give the TEA salt of **TR-WS** as a bluish red amorphous powder (7.1 mg, yield 34%, mixture of two regioisomers, each consisting of two racemic diastereomers). ^{1}H NMR (300 MHz, D_2O): δ 1.23 (t, *J* = 7.3 Hz, 27H, N-CH_2-CH_3), 1.86 (bm, 8H, 4 × CH_2), 2.56–3.07 (m, 8H, 4 × CH_2), 3.16 (q, *J* = 7.3 Hz, *J* = 14.6 Hz, 18H, N-CH_2-CH_3), 3.27–3.95 (m, 16H, 4 × CH_2, 2 × CH_2-$CH(SO_3^-)$-CO- and CH_2-Gly), 6.47 (s, 1.25H, major regioisomer), 6.51 (s, 0.75H, minor regioisomer), 7.19 (bd, *J* = 8.2 Hz, 0.37H, ArH, minor regioisomer), 7.26 (bd, *J* = 7.3 Hz, 0.63H, ArH, major regioisomer), 8.07 (bd, *J* = 8.4 Hz, 0.63H, ArH, major regioisomer), 8.13 (bd, *J* = 7.5 Hz, 0.37H, ArH, minor regioisomer), 8.48 (s, 0.63H, ArH, major regioisomer), 8.55 (s, 0.37H, ArH, minor regioisomer). HPLC (system C): t_R = 12.4 and 12.5 min (two regioisomers, each consisting of two racemic diastereomers), purity >98%. UV–vis (PBS, pH 7.4, 25 °C): λ_{max} = 590 nm (85 000 M^{-1} cm^{-1}). Φ_F (PBS, pH 7.4, 25 °C): 0.52. MS (ESI, negative mode): *m/z* 964.00 $[M - H]^-$, calcd for $C_{39}H_{43}N_5O_{16}S_4$ (**TR-WS**, acid form) 966.06.

General Procedure for the Conversion of Water-Soluble Fluorophores into Amine-Reactive Derivatives. Water-soluble dye carboxylic acid (1.72 μmol, weighed in a 1.5 mL Eppendorf tube) was dissolved in 50 μL of dry NMP (or DMF). 25 μL of a solution of TSTU reagent in dry NMP (or DMF) (0.51 mg, 1.72 μmol) and 1.2 μL of DIEA (6.88 μmol) were added, and the resulting reaction mixture was protected from light and periodically vortexed for 30 min. The reaction was checked for completion by ESI-MS, and the amine-reactive derivatives (mixture of NHS ester and oxazinone intermediate) were used in the next step without further purification.

Scheme 1. Preparation of Disulfonated Peptide Linker 4



Optical Properties of Water-Soluble Fluorophores. The absorption spectrum of the novel water-soluble cyanine and rhodamine dyes were recorded (220–900 nm) in DMSO, EtOH, and PBS (0.1 M phosphate, 0.15 M NaCl, pH 7.4) (concentration: 1.0–5.0 μM) at 25 °C. Emission spectra were recorded under the same conditions after excitation at the following wavelengths: 488 nm (for **R6G-WS**), 550 nm (for **TR-WS**), and 600 nm (for **NIR5.5-WS**) (excitation and emission slit = 5 nm). Relative quantum yields were measured in DMSO, EtOH, and PBS at 25 °C by a relative method using sulfocyanine dye Cy 5.0 (for **NIR5.5–3**, $\Phi_F = 0.20$ in PBS), rhodamine 6G (for **R6G-WS**, $\Phi_F = 0.90$ in water), or sulforhodamine 101 (for **TR-WS**, $\Phi_F = 0.90$ in EtOH). The following equation was used to determine the relative fluorescence quantum yield:

$$\Phi_F(X) = (A_S/A_X)(F_X/F_S)(n_X/n_S)^2\ \Phi_F(S)$$

Where A is the absorbance (in the range 0.01–0.1 A.U.), F is the area under the emission curve, n is the refractive index of the solvents (at 25 °C) used in measurements ($n = 1.337$ for PBS, 1.361 for EtOH, and 1.479 for DMSO), and the subscripts s and x represent standard and unknown, respectively.

Synthesis of Ac-Lys(NIR5.5-WS)-Asp-Glu-Val-Asp-Lys-(NIR5.5-WS)-NH_2 (15). Hexapeptide Ac-Lys-Asp-Glu-Val-Asp-Lys-NH_2 **14** (0.24 μmol, weighed in a 1.5 mL Eppendorf tube) was dissolved in 0.1 M sodium bicarbonate buffer (pH 8.5, 200 μL) and cooled to 4 °C. A crude solution of the amine-reactive derivatives of NIR5.5-WS **13** (0.50 μmol) was added. The reaction mixture was protected from light and stirred at room temperature for 2 h. Thereafter, 0.1 M borate buffer (pH 8.75, 200 μL) and DMF (200 μL) were added and the reaction mixture was stirred at room temperature overnight. The progress of the reaction was checked by RP-HPLC (system C). Finally, the reaction mixture was quenched by dilution with aq TEAB (50 mM, pH 7.5, 1 mL) and purified by RP-HPLC (system F, 1 injection). The product-containing fractions were lyophilized to give the peptide Ac-Lys(**NIR5.5-WS**)-Asp-Glu-Val-Asp-Lys(**NIR5.5-WS**)-NH_2 **15** as a blue amorphous powder. Stock solution of fluorogenic caspase-3 substrate **15** was prepared in Milli-Q grade water and quantification was achieved by UV–vis measurements in DMSO (to prevent the formation of the intramolecular homodimer between the two **NIR5.5-WS** units) at λ_{max} = 689 nm of **NIR5.5-WS** by using the ϵ value 147 000 M^{-1} cm^{-1} (yield after RP-HPLC purification: 25%). UV–vis (PBS, 25 °C): λ_{max} = 627 nm. UV–vis (DMSO, 25 °C): λ_{max} = 689 nm (147 000 M^{-1} cm^{-1}). HPLC (system C): t_R = 18.4, 18.8, 19.1, and 19.4 min (16 diastereomers), purity >95%. MS (ESI, negative mode): m/z 1361.00 $[M - 2H]^{2-}$, calcd mass for $C_{128}H_{163}N_{17}O_{37}S_6$ 2724.20.

***in Vitro* Peptide Cleavage by Recombinant Human Caspase-3.** A 1.0 μM solution of peptide **15** was prepared in 50 μL of caspase-3 buffer (100 mM NaCl, 40 mM HEPES, 10 mM DTT, 1 mM EDTA, 10% (w/v) sucrose, and 0.1% (w/v) CHAPS, pH 7.4) and transferred into an ultramicrofluorescence cell. 2 μL of human recombinant caspase-3 (3.2 10^{-3} U) was added, and the resulting mixture was incubated at 37 °C. After excitation at 679 (excitation slit = 5 nm), fluorescence emission at 705 nm (emission slit = 5 nm) was monitored over time with measurements recorded every 5 s.

RESULTS AND DISCUSSION

Synthesis. α-Sulfo-β-alanine was chosen as the monomer for the targeted disulfonated peptide linker **4** for the following reasons: (1) the presence of a sulfonic acid moiety which is probably the most popular fluorophore water-solubilizing functionality, (2) chemical reactivity similar to that of natural amino acids especially in the context of peptide synthesis (i.e., protection/deprotection and peptide coupling reactions), and (3) commercial availablility or easy synthesis on a large scale from cheap starting materials (i.e., β-alanine and oleum). Surprisingly, few synthetic applications of this non-natural amino acid have been reported to date in the literature. In the field of nucleic acid chemistry, it has only been successfully used to modify the electrophoretic mobility of fluorescent nucleotides to simplify the implementation of dye-terminator DNA sequencing (*20*).

The target disulfonated linker **4** was prepared as depicted in Scheme 1. A sulfonic acid group was first introduced on β-alanine using fuming sulfuric acid (i.e., oleum) (*21*). Racemic α-sulfo-β-alanine was then converted to the *N*-Fmoc-protected derivative **5** by reaction with *N*-hydroxysuccinimidyl 9-fluorenylmethyl carbonate (Fmoc-OSu) under standard conditions (*22*). Purification by flash chromatography on a RP-C_{18} silica gel column provided **5** in almost quantitative yield. Thereafter, peptide coupling reaction of **5** with a second unit of α-sulfo-β-alanine was achieved by using the DCC/*N*-hydroxysuccinimide (NHS) method (for a recent review on peptide coupling reagents, see (*23*)). To avoid two additional steps (i.e., protection/deprotection of the carboxylic acid function of α-sulfo-β-alanine), **5** carboxylic acid moiety was converted to the NHS active ester and then coupled onto the unprotected α-sulfo-β-alanine under Schotten−Baumann conditions (*22*), providing the *N*-Fmoc-protected dipeptide **6** in 85% yield (mixture of two racemic diastereomers). Removal of the Fmoc protective group by treatment with a six-fold excess of diethylamine in DMF afforded the bis(diethylammonium) salt of α-sulfo-β-alaninyl-

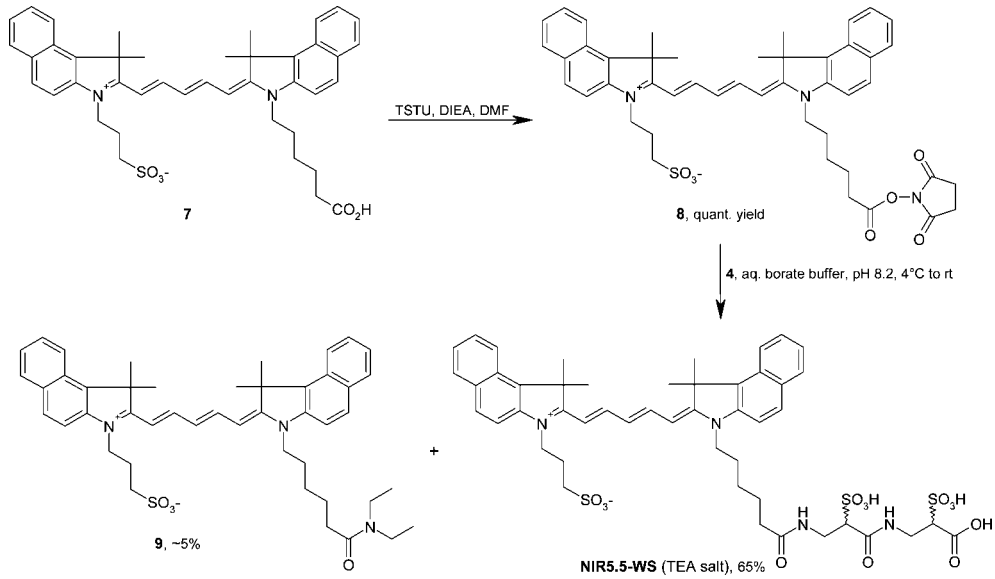
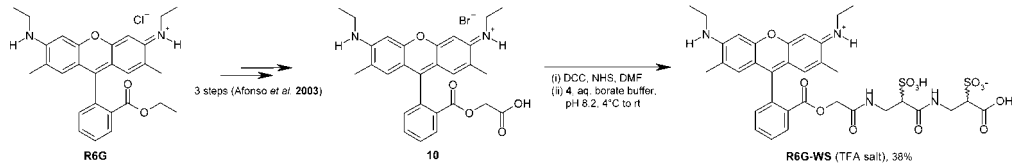
Scheme 2. Synthesis of Cy 5.5 Analogue NIR5.5-WS



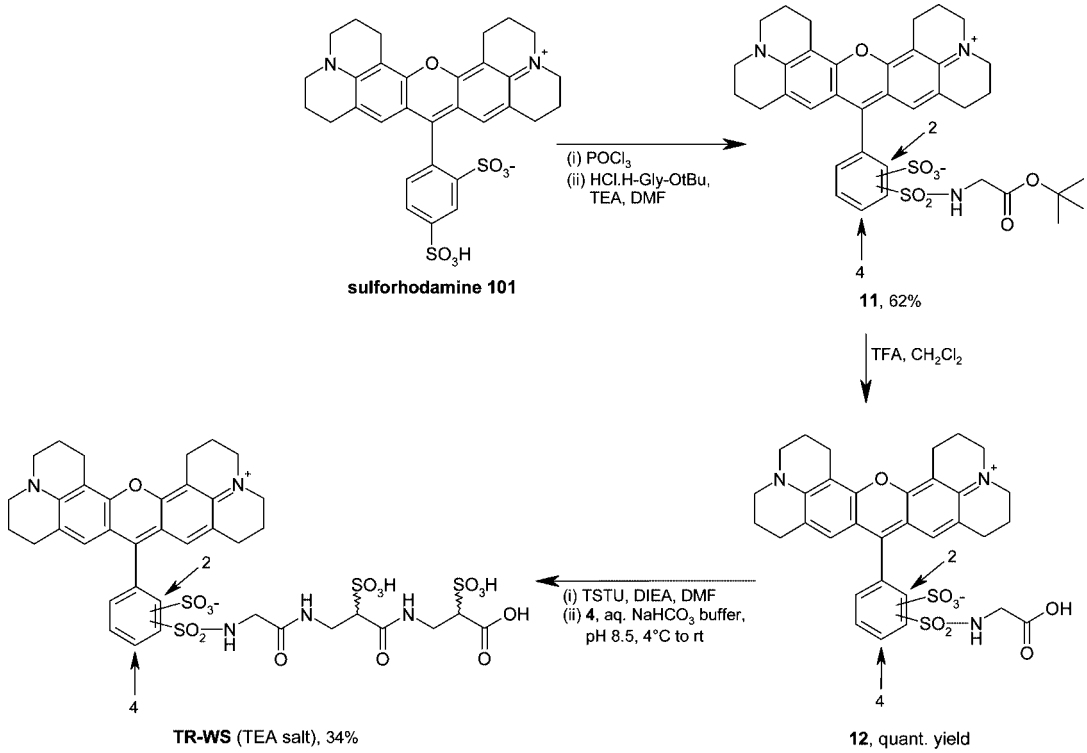
α-sulfo-*β*-alanine **4** as an inseparable mixture of two racemic diastereomers (yield 87%).

To demonstrate the utility of this dipeptide linker as both a highly effective water-solubilizing agent and a reactive spacer for biolabeling applications, we explored the postsynthetic derivatization of three different long-wavelength highly hydrophobic fluorophores. First, the linker was grafted on cyanine dye **7** through a peptide coupling reaction. This near-infrared (NIR) organic dye exhibits the same spectral properties as the widely used sulfobenzoindocyanine dye Cy 5.5 (commercially available from GE Healthcare; Figure 2). It was conveniently prepared using a four-step reaction (overall yield 70%) and could be purified by flash chromatography on a silica gel column at gram quantities, contrary to its parent tetrasulfonated dye Cy 5.5 (*8*). As expected, dye **7** was found to be poorly soluble in water and related aqueous buffers (pH range 2–9). In order to increase its solubility in aqueous solutions, hydrophilic linker **4** was attached to the carboxylic acid side chain in a two-step procedure as described in Scheme 2. Dye **7** was quantitatively converted into the corresponding *N*-hydroxysuccinimidyl ester **8** by treatment with the peptide coupling uronium reagent TSTU and DIEA in dry DMF (*24*). Thereafter, acylation of the primary amino group of **4** with the crude active ester **8** in borate buffer (pH 8.2) containing DMF (to avoid precipitation of **8**) with a controlled slow warming from 4 °C to room temperature, yielded almost exclusively the targeted water-soluble analogue **NIR5.5-WS**. A small amount of (*N*,*N*-diethyl)carboxamide derivative **9** (∼5%) resulting from the acylation reaction of the counterion of disulfonated linker **4**, was also detected in the crude reaction mixture. **NIR5.5-WS** was readily purified by flash chromatog-

Scheme 3. Synthesis of Rhodamine 6G Analogue R6G-WS



Scheme 4. Synthesis of Texas Red Analogue TR-WS



raphy on an RP-C_{18} silica gel column (mixture of two racemic diastereomers, isolated yield 65%) using triethylammonium bicarbonate buffer (TEAB, 50 mM, pH 7.5) and acetonitrile as eluents. The covalent attachment of disulfonated linker **4** to the γ-carboxypentyl arm of cyanine dye **7** was confirmed by detailed measurements, including ESI mass spectrometry and NMR analyses. As expected, **NIR5.5-WS** was found to be perfectly soluble in water and related aqueous buffers in the concentration range (1 μM to 10 mM) suitable for biomolecular labeling applications.

To extend the scope of reagent **4** to the water solubilization of rhodamine derivatives, the efficient postsynthetic sulfonation procedure (described above) was applied to rhodamine 6G (R6G) and sulforhodamine 101 (i.e., Texas Red, TR).

As R6G dye does not contain any free carboxylate functionality, it was first converted to the rhodamine carboxylic acid **10** using a three-step procedure reported by Afonso et al. (*17*). This reactive R6G analogue was coupled to the disulfonated linker **4** in the same manner as described for dye **7** (Scheme 3), to give the desired water-soluble rhodamine **R6G-WS** in a moderate yield (isolated yield 38%). Indeed, a significant amount of starting material **10** was detected in the crude reaction mixture and recovered after RP-HPLC purification. The NHS ester of **10** seems to be more prone to hydrolysis than the NHS ester of **7**. Purification of **R6G-WS** was achieved by semipreparative RP-HPLC using 0.1% aqueous trifluoroacetic acid (TFA, pH 2.0) and acetonitrile as eluents. Contrary to the purification of cyanine dye **NIR5.5-WS**, aqueous TFA afforded better peak resolution than TEAB buffer for the purification of **R6G-WS**.

Conjugation of sulforhodamine 101 to disulfonated dipeptide **4** also required prior functionalization of one of the two sulfonate groups of its lower ring component. The most popular fluorescent labeling reagents derived from this disulfonated rhodamine, Texas Red sulfonyl chloride (TR-SC) (*25*) and Texas Red-X succinimidyl ester (TR-X-SE) (*26*), are of delicate use for bioconjugation. TR-SC is known to be unstable to moisture during storage and prone to hydrolysis in the conjugation reactions, especially those performed in aqueous buffers. TR-X-SE exhibits improved labeling properties, but this compound contains a six-atom-long hydrophobic spacer (i.e., HN-$(CH_2)_5$-) between the fluorescent label and the reactive carboxylic acid group. In order to get a water-soluble Texas Red analogue with a shorter heterobifunctional linker, we envisaged the introduction of a glycine residue (Scheme 4). Sulforhodamine 101 was first converted to TR-SC by treatment with a large excess of phosphorus oxychloride. After removal of $POCl_3$, the crude sulfonyl chloride derivative was directly reacted with glycine *tert*-butyl ester and TEA in dry DMF to give ester **11** in 62% yield. This product was obtained as a 8:2 mixture of two regioisomers (i.e., ortho and para monosulfonamides) which was used in the next steps without chromatographic resolution. Quantitative removal of *t*Bu ester by treatment with TFA (100 equiv) in CH_2Cl_2 provided the sulforhodamine 101 carboxylic acid **12**. Despite the presence of two hydrophilic groups within its rhodamine core, **12** was found to be poorly soluble in aqueous solutions even after conversion to its bis(triethylammonium) salt. Preactivation of **12** with TSTU/DIEA afforded amide bond formation between **12** and linker **4** to give the target water-

Table 1. Optical Properties of Water-Soluble Cyanine and Rhodamine Dyes

compound	solvent	$\lambda_{max,abs}$ (nm)	$\lambda_{max,em}$ (nm)	Stokes shift (nm)	ϵ (M^{-1} cm^{-1})	Φ_F[c]
Cy 5.5[a]	PBS	674	694	20	195 000	0.23
Cy 5.5 analogue 7[b]	DMSO	688	711	23	147 000	0.27
Cy 5.5 analogue 1	PBS	680	710	30	197 000	0.047
NIR5.5-WS	PBS	679	700	21	197 000	0.066
R6G-WS	PBS	528	553	25	65 000	1.00

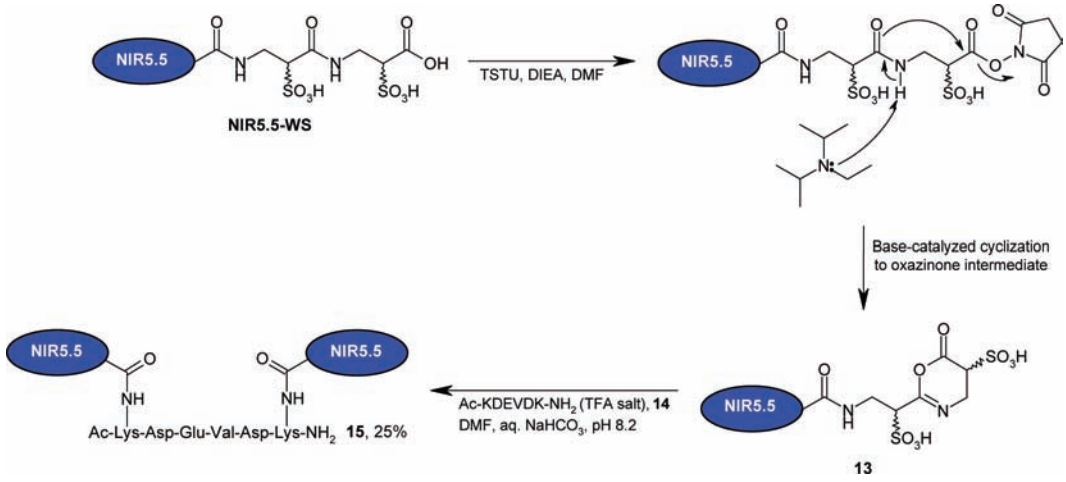
Alexa Fluor 594, isomer II	PBS	585	612	27	73 000	0.56[d]

[a] Values reported by Mujumdar et al. (*37*). [b] Determination of QY in PBS was not possible due to the nonsolubility of this Cy 5.5 analogue in aq buffers even at low concentrations. [c] Determined at 25 °C by using sulfocyanine dye Cy 5.0 (for **NIR5.5-WS**, $\Phi_F = 0.20$ in PBS (*38*)), rhodamine 6G (for **R6G-WS**, $\Phi_F = 0.90$ in water (*39*)), or sulforhodamine 101 (for **TR-WS**, $\Phi_F = 0.90$ in EtOH according to PhotochemCAD database available free of charge at http://omlc.ogi.edu/spectra/PhotochemCAD/html/Sulforhodamine101.html) as a standard. [d] Determined in our conditions but slightly different from the QY value reported by Invitrogen ($\Phi_F = 0.66$ for Alexa Fluor 594 carboxylic acid, succinimidyl ester in 50 mM potassium phosphate, 150 mM NaCl pH 7.2 at 22 °C).

Scheme 5. Fluorescent Labeling of Caspase-3 Cleavable Hexapeptide Ac-Lys-Asp-Glu-Val-Asp-Lys-NH_2 14 with NIR5.5-WS



soluble rhodamine **TR-WS**. RP-HPLC purification using TEAB buffer and acetonitrile as eluents provided **TR-WS** in a pure form (mixture of two regioisomers, each consisting of two racemic diastereomers, isolated yield 34%), together with the recovery of 50% of the sulforhodamine 101 carboxylic acid derivative **12** resulting from the partial early hydrolysis of NHS ester. The structures of **R6G-WS** and **TR-WS** were unambiguously confirmed by ESI mass and NMR analyses. As expected, these rhodamine derivatives show perfect water solubility in the same concentration range as that determined for **NIR5.5-WS**.

Photophysical Properties. The photophysical properties of the three novel water-soluble fluorophores available were evaluated and collected in Table 1 (for their normalized absorption and emission spectra, see Supporting Information). In order to know whether the presence of the hydrophilic dipeptide linker affected the spectral properties of the fluorophore core, fluorescence data were compared with those of the original water-insoluble analogues. **NIR5.5-WS**, **R6G-WS**, and **TR-WS** have absorption and emission bands that match closely those of **7**, R6G, and TR, respectively, in both phosphate-buffered saline (PBS) and DMSO. Furthermore, molar absorption coefficients (ϵ) are comparable to these latter starting materials, and quantum yields (Φ) are good to excellent for the rhodamine derivatives. Interestingly, brightness ($\Phi\epsilon$) of **TR-WS** was found to be similar to that of Alexa Fluor 594 dye (isomer I or II), a water-soluble analogue of Texas Red commercially available from Invitrogen (Figure 2) (*11*). However, the structure of Alexa dye is not directly accessible through the chemical derivatization of sulforhodamine 101. Its synthesis using an original five-step sequence as described (*18*) is more difficult and tedious than that of **TR-WS**, and consequently, the corresponding fluorescent labeling reagent (i.e., NHS ester, two mixed regioisomers) is very expensive. The relative fluorescence quantum yield of cyanine dye **NIR5.5-WS** measured in PBS is slightly higher than the one we obtained for the Cy 5.5 analogue bearing the trisulfonated aryl linker **1** (0.066 compared to 0.047) but significantly lower than the one reported for Cy 5.5 dye (0.066 compared to 0.23). This severe quenching of fluorescence cannot be explained by a photoinduced electron transfer (PET) process or by the self-aggregation of cyanine dye molecules. Indeed, **NIR5.5-WS** does not contain amino-aromatic ring moieties, and its UV–vis absorption maximum is not blue-shifted by about 50 nm as expected when dye-dye aggregation occurs (see Supporting Information) At this stage of the study, we do not have relevant explanation(s) for the fluorescence intensity decrease of **NIR5.5-WS** observed in aqueous solutions.

Labeling Properties. To demonstrate the general applicability of these novel water-soluble organic dyes as biocompatible fluorescent labeling reagents, **NIR5.5-3**, **R6G-WS**, and **TR-WS** were converted into amine-reactive derivatives and subsequently coupled to peptides and proteins. As an illustrative example, caspase-3 cleavable hexapeptide Ac-Lys-Asp-Glu-Val-Asp-Lys-NH_2 **14** (cleavage site after the aspartic acid residue at the C-terminal side) was fluorescently labeled with **NIR5.5-WS** on each side of the cleavage site (Scheme 5) in order to get a novel fluorogenic substrate useful for imaging apoptosis (for other examples of FRET-based probes used for caspase-3 detection, see *27–31*). Indeed, cyanine dyes such as Cy 5.5 (or these analogues) are known to form dimers (i.e., H-aggregates) when two fluorophores are closely associated within a peptide architecture, the spectral characteristics of these H-type dimers are a blue shift in absorption spectrum and the loss of

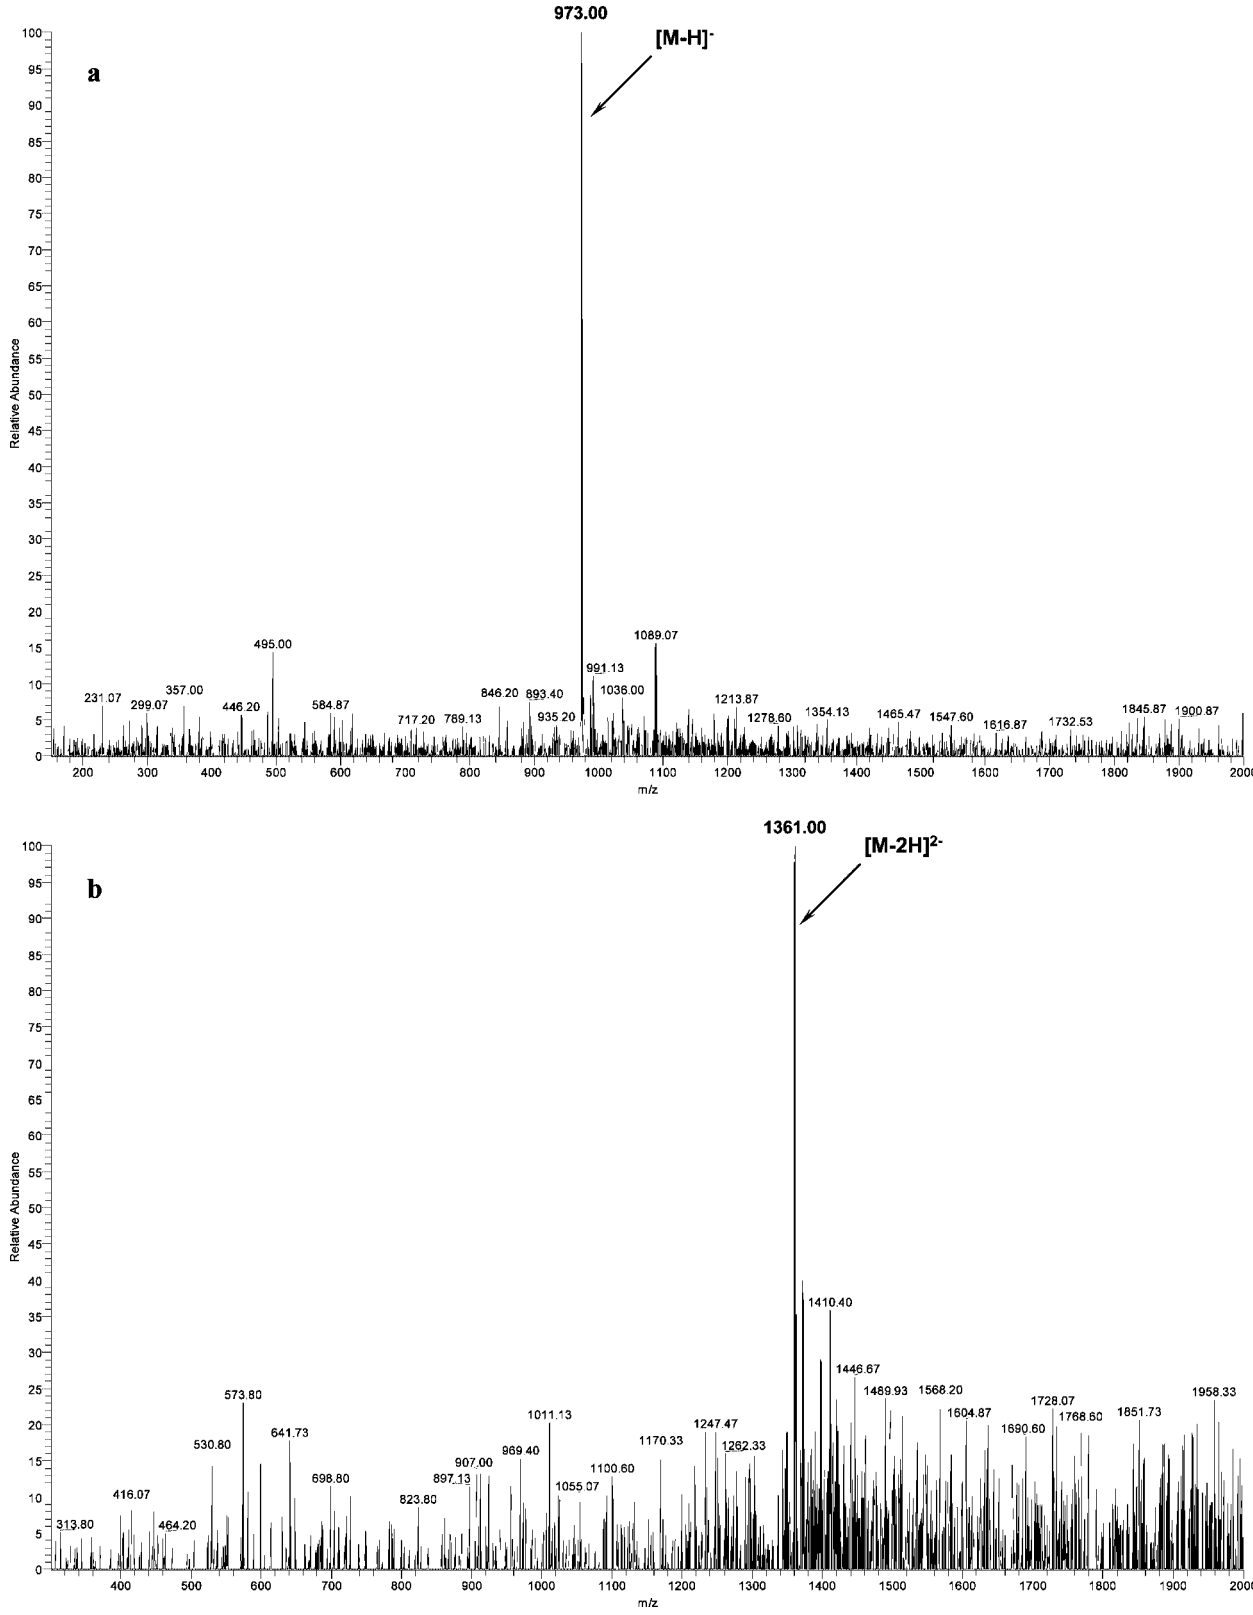


Figure 3. ESI mass spectra of oxazinone intermediate **13** (a) and fluorogenic substrate of caspase-3 **15** (b), in the negative mode. For compound **13** $[M - H]^-$: *m*/*z* calcd mass 973.28, found 973.00. For peptide **15** $[M - 2H]^{2-}$: *m*/*z* calcd mass 1359.98, found 1361.00.

fluorescence (*32*, *33*). Cleavage of such a dual-fluorescent-labeled peptide by the suitable protease results in disruption of the H-type dimer and appearance of fluorescence. The hydrophilic dye **NIR5.5-WS** was converted into an amine-reactive derivative by treatment with TSTU/DIEA in dry DMF. Interestingly, this reaction mainly led to a dehydration product (the molecular ion $[M - 18 - H]^-$ was observed in the ESI mass spectrum of each crude active ester mixture, Figure 3a), probably the oxazinone intermediate **13** (i.e., sulfonated 4,5-dihydro-6*H*-1,3-oxazin-6-one) resulting from base-catalyzed intramolecular cyclization of the generated NHS ester. This side reaction is of no consequence, since the reactivity of **13** toward amine-containing compounds is similar to the NHS ester initially targeted. Acylation of both lysine residues of hexapeptide **14**

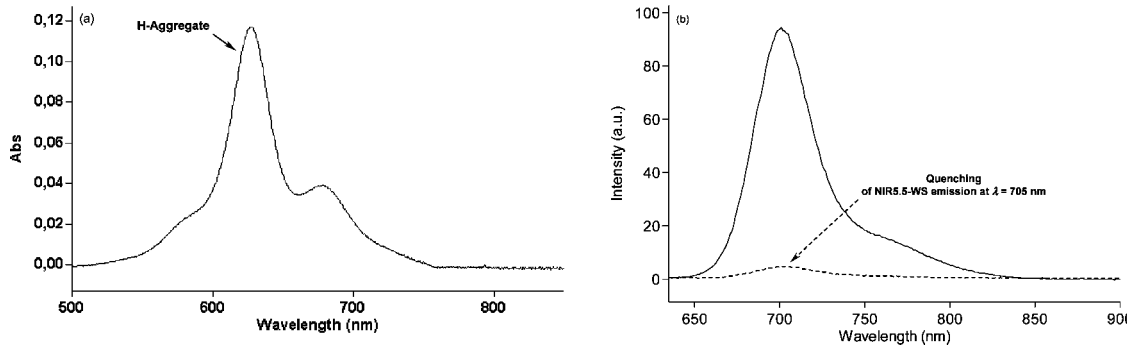

Figure 4. (a) Absorption spectrum of probe **15** at 25 °C in PBS. (b) Emission spectra (Ex. $\lambda = 625$ nm) of **NIR5.5-WS** (—) and probe **15** (---) at 25 °C in PBS (concentration 3.3 μM).

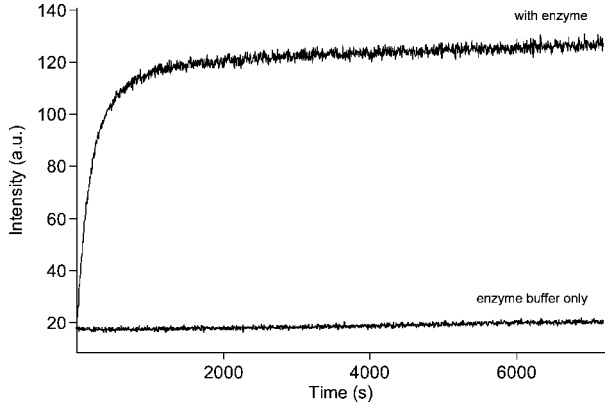

Figure 5. Fluorescence emission time course of probe **15** (concentration 1.0 μM) with recombinant human caspase-3 (3.2 10^{-3} U, incubation time 120 min) in caspase assay buffer (100 mM NaCl, 40 mM HEPES, 10 mM DTT, 1 mM EDTA, 10% (w/v) sucrose and 0.1% (w/v) CHAPS, pH 7.2, 37 °C) at 705 nm (Ex. $\lambda = 679$ nm).

with this reactive oxazinone derivative in a mixture of DMF and bicarbonate buffer (pH 8.5) provided, after RP-HPLC purification, the NIR dye−peptide conjugate **15** (yield 25%, purity >95%). Its structure was confirmed by ESI mass spectrometry (Figure 3b), a single peak at *m*/*z* 1361.00 corresponding to the doubly charged negative ion $[M - 2H]^{2-}$ of **15** was observed. The formation of a H-dimeric complex between the two **NIR5.5-WS** units was inferred from absorption and emission spectra of the probe recorded in PBS (Figure 4). Indeed, a new peak, which is blue-shifted by about 50 nm from the absorption peak of the free **NIR5.5-WS** dye, was observed, and no significant emission at 700 nm corresponding to the **NIR5.5-WS** fluorescence was detected (diminished by 20 fold compared to the fluorescence of free **NIR5.5-WS** dye at the same concentration). Finally, this fluorogenic probe was tested against human recombinant caspase-3. Within 120 min, the fluorescence emission of **15** at 705 nm has increased about 7-fold, while no activation was observed when peptide **15** was incubated only with the caspase-3 buffer (Figure 5). This observation confirms that this fluorogenic peptide-based probe is a substrate for recombinant caspase-3 protease.

CONCLUSION

In conclusion, we have described the synthesis and photophysical properties of three novel water-soluble long-wavelength fluorophores **NIR5.5-WS**, **R6G-WS**, and **TR-WS** which are potential substitutes of commercially available Cy 5.5, Alexa Fluor 532, and Alexa Fluor 594 labels, respectively. The developed "postsynthetic derivatization" approach, involving the selective introduction of a hydrophilic dipeptide linker on the carboxylic acid functionality of fluorescent scaffold, enables straightforward synthetic access to the targeted water-soluble analogues. With this method, it will also be possible to enhance the water solubility of a wide range of highly hydrophobic dyes for which there are no hydrophilic analogues (e.g., boron-stabilized cyanine dyes (*34*), perylene-3,4:9,10-tetracarboxydiimide (PTCDI) chromophores (*35*), etc.), by increasing the number of α-sulfo-β-alanine residues in the linker arm. Furthermore, preliminary experiments have clearly shown that the C-terminal side chain of the disulfonated linker found in **NIR5.5-WS**, **R6G-WS**, and **TR-WS** can be easily converted into an amine-reactive group (i.e., active ester or oxazinone intermediate), a thiol-reactive group (i.e., iodoacetyl derivative), or a terminal alkyne (by coupling with a propargylamine moiety) bioconjugatable through the Huisgen reaction (*36*). Thus, these novel water-soluble bright dyes possess strong potential for a broad range of biolabeling applications. Furthermore, such a poly(α-sulfo-β-alanine) linker can be used as an inert and biocompatible spacer in surface engineering (to make biopolymer microarrays) and in the modification of proteins and peptides for drug delivery.

ACKNOWLEDGMENT

The contribution of Dr. Evelyne Muller (Manteia Predictive Medicine SA) to the total synthesis of Alexa Fluor 594 dye is greatly acknowledged. We thank Annick Leboisselier (CNRS UMR 6014) for the determination of elemental analyses, Dr. Jérôme Leprince (U 413 INSERM/IFRMP 23) for the solid-phase synthesis of hexapeptide **14**, and Dr. Céline Pérollier (University of Geneva) for NMR characterization of both isomers of Alexa Fluor 594 dye. Financial support for this work was provided by "Région Haute Normandie" and by "Fondation pour la Recherche Médicale."

Site-Specific Delivery of Oligonucleotides to Hepatocytes after Systemic Administration

Lin Zhu, Zhaoyang Ye, Kun Cheng, Duane D. Miller, and Ram I. Mahato*

Department of Pharmaceutical Sciences, University of Tennessee Health Science Center, Memphis, Tennessee 38163. Received April 13, 2007; Revised Manuscript Received July 2, 2007

We previously complexed ODN with galactosylated poly(L-lysine) (Gal-PLL) to enhance its site-specific delivery to hepatocytes. To avoid the use of polycations, in this study we conjugated galactosylated poly(ethylene glycol) (Gal-PEG (MW of PEG: 3486 ± 500 Da)) to ODN via an acid-labile ester linkage of β-thiopropionate. Following tail vein injection into rats, Gal-PEG-^{33}P-ODN rapidly cleared from the circulation and 60.2% of the injected dose accumulated in the liver at 30 min postinjection, which was significantly higher than that deposited after injection of ^{33}P-ODNs. The plasma concentration versus time profile of Gal-PEG-^{33}P-ODN was biphasic, with 4.38 ± 0.36 min as $t_{1/2}$ of distribution and 118.61 ± 22.06 min as $t_{1/2}$ of elimination. Prior administration of excess Gal-BSA decreased the hepatic uptake of Gal-PEG-^{33}P-ODN from 60.2% to 35.9%, suggesting galactose triggers the asialoglycoprotein receptor-mediated endocytosis of Gal-PEG-^{33}P-ODN by hepatocytes. A large proportion of the injected Gal-PEG-^{33}P-ODN was taken up by the hepatocytes as evidenced by determination of radioactivity in the digested liver cells upon liver perfusion and separation by centrifugation on a Nycodenz gradient. In conclusion, Gal-PEG-ODN conjugate may be used for treating a variety of liver diseases.

INTRODUCTION

Oligonucleotides (ODNs) have attracted much attention as a new class of therapeutic agents that can be used for gene modulation. However, in vivo gene silencing by ODNs has not yet been successful because of several obstacles, including the nonspecific interaction with plasma proteins, wide distribution, and poor stability against enzymatic degradation. Since phosphodiester ODNs have extremely short half-lives due to degradation by nucleases, phosphorothioate (PS) ODNs are commonly used. PS ODNs are fairly stable in vivo, but readily bind to serum proteins, leading to undesirable biological events. To address these problems, a variety of delivery systems composed of cationic lipids (*1–3*) and cationic polymers (*4–6*) have been developed. Some of these delivery systems substantially enhanced the enzymatic stability and uptake into the target cells in vitro (*7*). However, most of these cationic carriers are inefficient in vivo because of their nonspecific biodistribution in the body.

We and others have shown that ODNs are cleared rapidly from the circulation and accumulated in most of the peripheral tissues, with the highest accumulation in the liver and kidney (*8–12*). The asialoglycoprotein receptor is located on parenchymal liver cells (e.g., hepatocytes) and recognizes terminal galactose (*13*) or lactose residues (*14, 15*). Therefore, we previously used galactosylated poly(L-lysine) (Gal-PLL) for complex formation with ODNs and demonstrated enhanced hepatic uptake of ODNs, which was influenced by the particle size, zeta potential, sugar substitution, and molecular weight of both polycations and ODNs (*16*). Although the uptake of Gal-PLL/ODN complexes by hepatocytes was significantly higher than that of naked ODNs, the difference of their distribution to different liver cells was only moderate. To avoid the use of polycations, Rajur et al. (1997) covalently conjugated ODNs to asialoorosomucoid via a disulfide bond using sulfosuccinimidyl 6-[3′-(2-pyridyldithio) propionamido] hexanoate (sulfo-LC-SPDP), but the authors did not test the conjugate in vivo (*17*).

PEGylation is known to significantly enhance the ODN stability against exonucleases and reduce renal clearance compared to unmodified ODNs (*18*). The in vivo activity of a drug depends in part on its rate of excretion and degradation. PEGylation should promote the bioactivity of an ODN by increasing plasma residence time and decreasing nuclease degradation. PEGylation also shields the inherent negative charge of the ODN, thereby possibly facilitating cellular uptake of the conjugated drug. Additionally, PEGylation could potentially diminish the immunostimulatory effects of the ODNs (*19, 20*). Keeping these benefits in mind, Bonora et al. (1997) conjugated ODNs to poly(ethylene glycol) (PEG) through a covalent linkage (*21*). However, these PEG-ODN conjugates were less effective, since PEG could not be cleaved early from the ODNs in the cytoplasm. Therefore, Oishi et al. conjugated ODN to acrylated or lactosylated PEG through a pH-responsive ester (*22, 23*). However, these authors did not determine the biodistribution of Lac-PEG-ODN and used in conjunction with a cationic polymer like linear polyethyleneimine (PEI), which is likely to promote nonspecific interaction with plasma proteins and uptake by phagocytic cells.

In this study, we used fully phosphorothioate G-rich ODN, which is fairly stable, but binds to serum proteins (*24*). To minimize binding to plasma proteins, enhance stability, and prolong circulation time, we conjugated Gal-PEG to ODN using an acid-labile linker. Gal-PEG is expected to enhance ODN delivery to the hepatocytes whose inflammation and injury lead to progression of liver fibrosis (*25*). In this study, we conjugated ODN to Gal-PEG via an acid-labile ester linkage and used it without any cationic polymers or lipids to avoid cytotoxicity and nonspecific interaction. Following conjugation and in vitro characterization, we determined the biodistribution of Gal-PEG-^{33}P-ODN at whole body, organ (liver), and cellular (liver cells) levels after tail vein injection into rats.

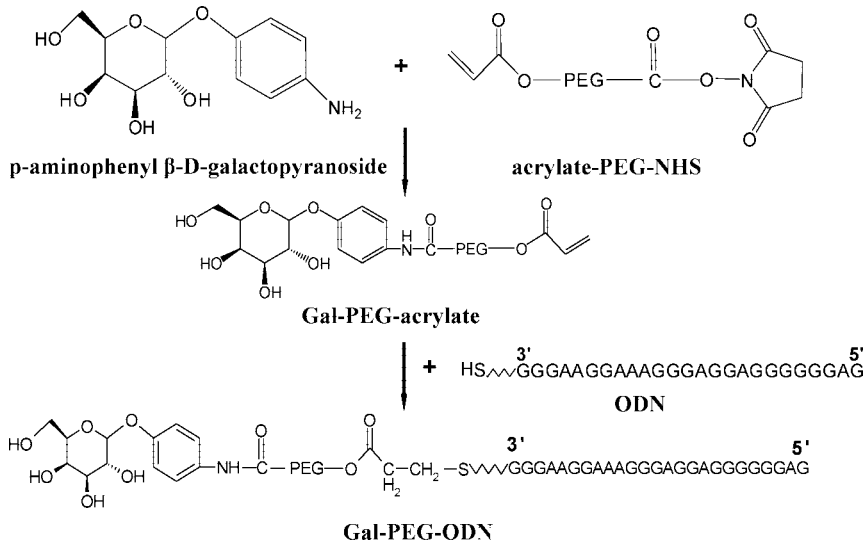

Figure 1. Synthesis scheme of Gal-PEG-ODN. *p*-Nitrophenyl *β*-D-galactopyranoside was reduced to *p*-aminophenyl *β*-D-galactopyranoside and then conjugated to 3′-thiol ODN by Michael addition.

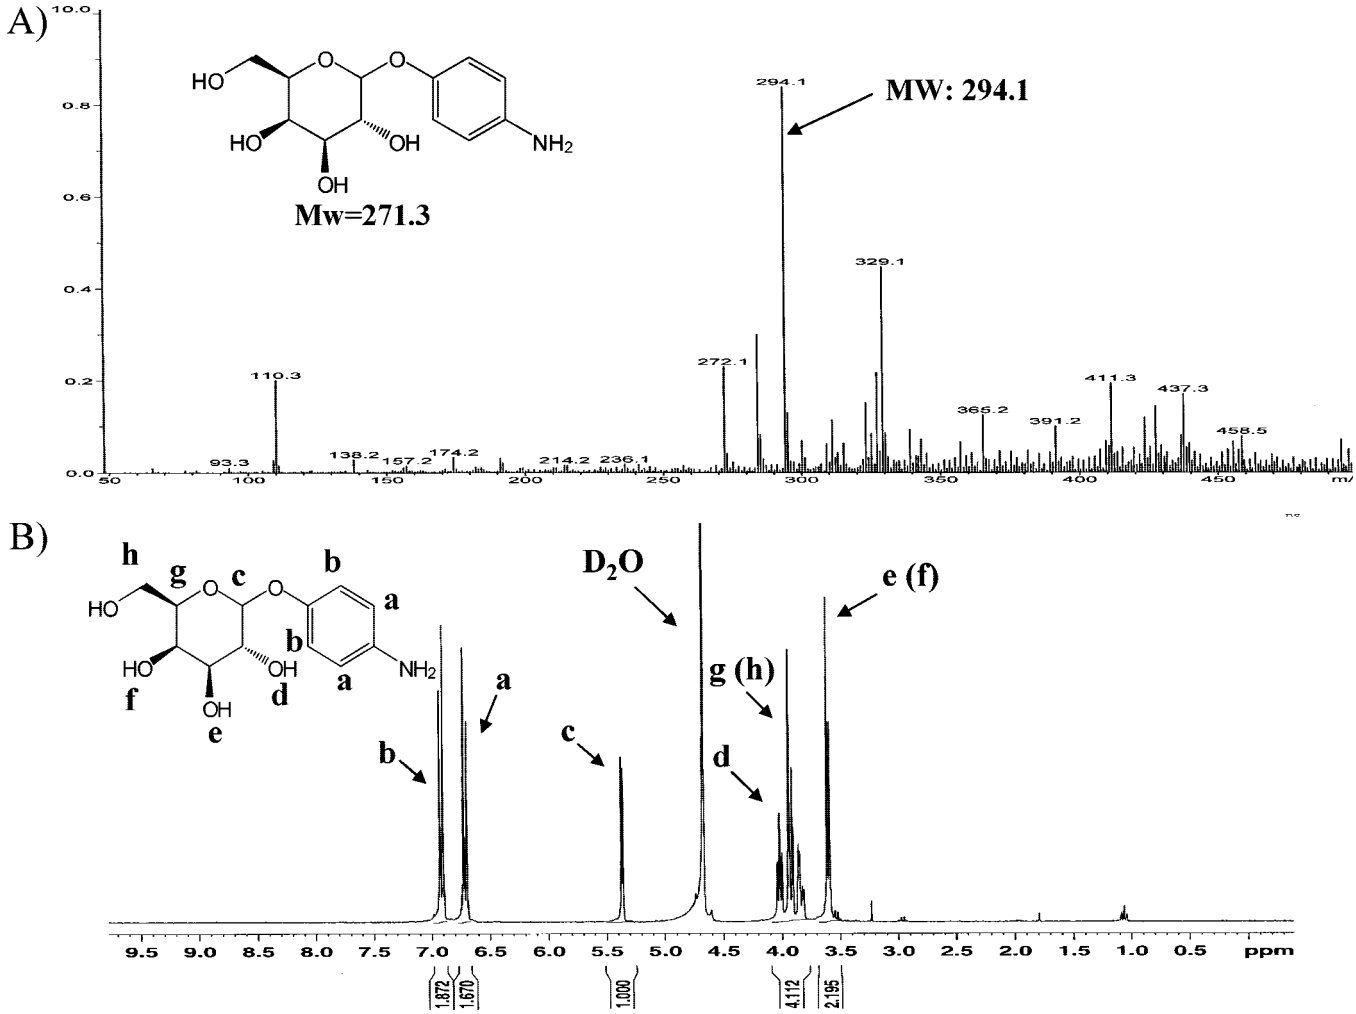

Figure 2. Characterization of *p*-aminophenyl *β*-D-galactopyranoside with electron spray ionization mass spectrometry (ESI-MS) and ^{1}H NMR. (A) Electron spray ionization mass spectra were obtained after dissolving the product in methanol on an ESQUIRE-LC Ion Trap LC/MS system. (B) For ^{1}H NMR, samples were dissolved in D_2O and the spectra were recorded on a Bruker ARX-300 MHz NMR spectrometer at 25 °C.

MATERIALS AND METHODS

Materials. 25-mer ODN (5′ GAG GGG GGA GGA GGG AAA GGA AGG G 3′) modified with a sulfhydryl group at the 3′ end was purchased from Invitrogen Corporation (Carlsbad, CA).[γ-^{33}P]ATP was obtained from MP Biomedicals (Irvine, CA) and T4 polynucleotide kinase (T4-PNK) from New England Biolabs (Beverly, MA). Bio-Gel P-6DG gel was obtained from Bio-Rad Laboratories (Hercules, CA). PD-10 desalting columns

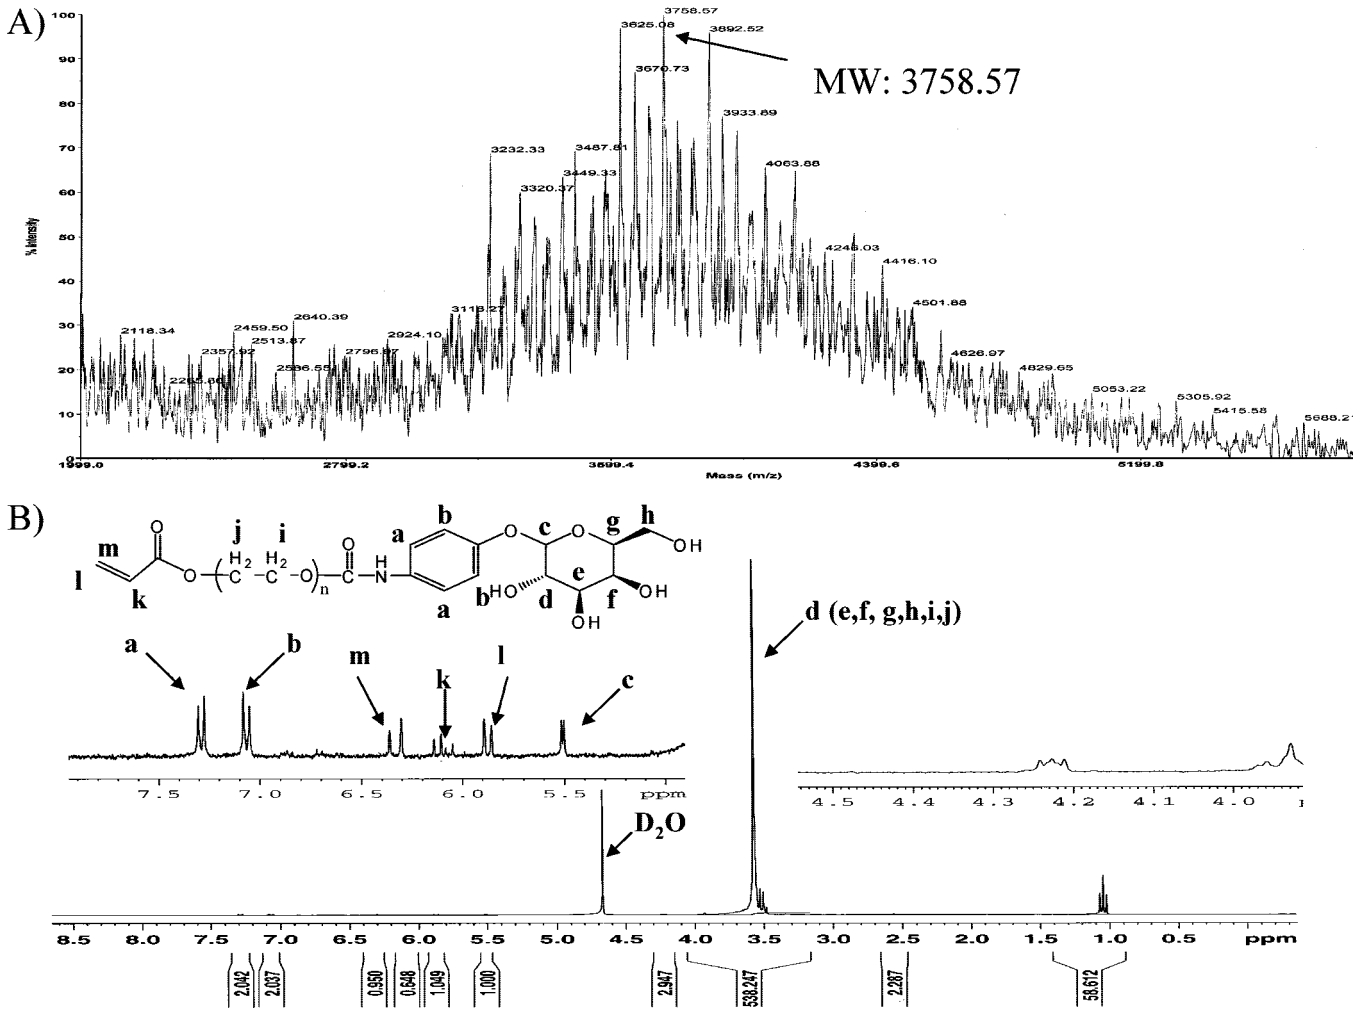

Figure 3. Characterization of Gal-PEG-acrylate with MALDI-TOF—MS and ^{1}H NMR. (A) In MALDI-TOF—MS the ratio between Gal-PEG-acrylate and DHB was 1:2. The spectrum was recorded on Voyager-DE RP (PerSeptive Biosystems Inc., MA). (B) For ^{1}H NMR, samples were dissolved in D_2O, and the spectra were recorded on a Bruker ARX-300 MHz NMR spectrophotometer at 25 °C.

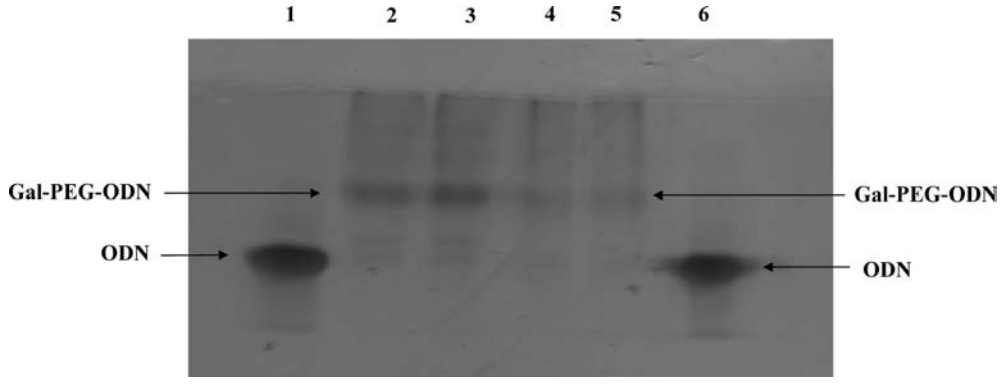

Figure 4. Identification of Gal-PEG-ODN by polyacrylamide gel electrophoresis (PAGE) at 80 V for 100 min, followed by staining with methylene blue for one night. Lanes 1 and 6: ODN 2 μg. Lanes 2 and 3: Gal-PEG-ODN 2 μg. Lanes 4 and 5: Gal-PEG-ODN 1 μg.

were obtained from Pharmacia Fine Chemicals AB (Uppsala, Sweden). Soluene-350 (tissue solubilizer) and Hionic-Fluor (scintillation fluid) were purchased from Perkin-Elmer (Boston, MA). Isoflurane was obtained from Baxter Health Corporation (Deerfield, IL). Type IV collagenase was purchased from Worthington Biochemical Corporation (Lakewood, NJ). Nycodenz AG was obtained from Greiner Bio-One Inc. (Longwood, FL). PE-60 polyethylene tubing was purchased from Becton Dickinson and Company (Sparks, MD) and heparin solution was procured from American Pharmaceutical Partners, Inc. (Los Angeles, CA). Acrylate-PEG-NHS (MW: 3486 ± 500 Da) was purchased from Nektar Therapeutics (Huntsville, AL). Bovine serum albumin (BSA) (fraction V, purity >98%) was purchased from USB Corporation (Cleveland, OH). Palladium (10 wt% on activated carbon), thiophosgene, Brilliant Blue R Staining Solution, dithiothreitol (DTT), *p*-nitrophenyl β-D-galactopyranoside, dimethylformamide (DMF), 2,5- dihydroxy benzoic acid (DHB), methylene blue, deuterium oxide (D_2O), triethylamine (TEA, HPLC grade), and Pronase were purchased from Sigma-Aldrich Chemicals Limited (St. Louis, MO). Dialysis tubing

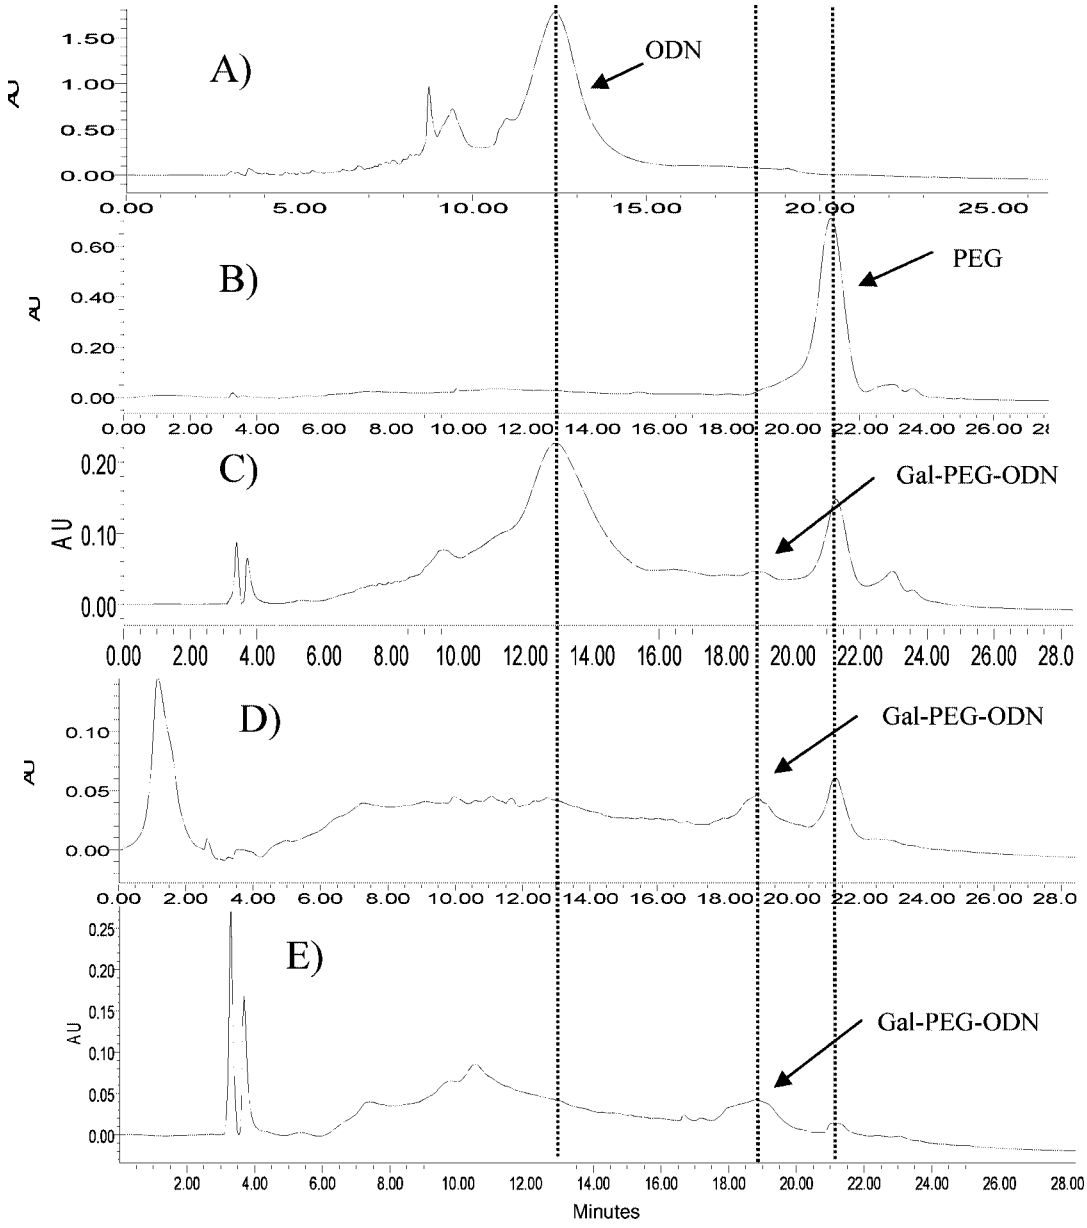

Figure 5. HPLC chromatograms of (A) ODN, (B) PEG, (C) reaction mixture, (D) during purification, and (E) after purification of Gal-PEG-ODN.

(MWCO 1000 Da) was purchased from Spectrum Laboratories, Inc. (Houston, TX). Amicon Centricon filter devices (MWCO 10 000 Da) were purchased from Millipore Corporation (Billerica, MA). Hydrogen peroxide (H_2O_2), acetic acid, acetonitrile (ACN, HPLC grade), and water (HPLC grade) were purchased from Fisher Chemical (Fair Lawn, NJ). Ca^{2+}/Mg^{2+}-free Hank's balanced salt solution (Cellgro) was purchased from Media Tech (Washington, DC).

Animals. Male Sprague−Dawley rats weighing 140–160 g were purchased from Harlan Co. (San Diego, CA) and were housed individually under the controlled light (12/12 h) and temperature conditions and had free access to food and water.

Synthesis of Gal-PEG-ODN Conjugate. *p*-Nitrophenyl β-D-galactopyranoside (200 mg) was reduced with 200 mg of 10% palladium on activated carbon under hydrogen (1 atm) in 30 mL of a 1:1 (v/v) ethanol−water mixture for 2 h, as described by Monsigny et al. (*26*). The product, *p*-aminophenyl β-D-galactopyranoside, was concentrated by solvent removal under vacuum and characterized using ^{1}H NMR and mass spectrometry after dissolving in D_2O, and the NMR spectra were recorded on a Bruker ARX-300 MHz spectrometer at 25 °C. Chemical shifts were recorded in ppm relative to D_2O (δ 4.79, 1H). Electron spray ionization (ESI) mass spectra were obtained after dissolving the product in methanol on an ESQUIRE-LC Ion Trap LC/MS system. Acrylate poly(ethylene glycol) *N*-hydroxysuccinimidyl (NHS) ester (acrylate-PEG-NHS) (58 mg) and *p*-aminophenyl β-D-galactopyranoside (43.4 mg) were dissolved separately in 0.4 mL of DMF, mixed together, and dialyzed in 500 mL water for 48 h with MWCO 1000. The product, galactose (Gal)-PEG-acrylate was characterized by ^{1}H NMR after dissolving the product in D_2O. The molecular weight of Gal-PEG-ODN was determined using matrix assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry with DHB as a matrix.

Modified ODNs were treated with 0.2 M DTT in 0.1 M, pH 9.0 glycine buffer containing 0.1 M NaCl for 3 h at room temperature to generate a 3′-thiol functional group. Excess DTT was removed by extraction with ethyl acetate, and ODN was precipitated by adding 2.6 volume of ethanol after addition of sodium acetate (NaOAc) to 0.3M. The mixture was kept at −30 °C overnight and centrifuged at 13 000 *g* for 30 min. The ODN with 3′-thiol functional group and Gal-PEG-acrylate were

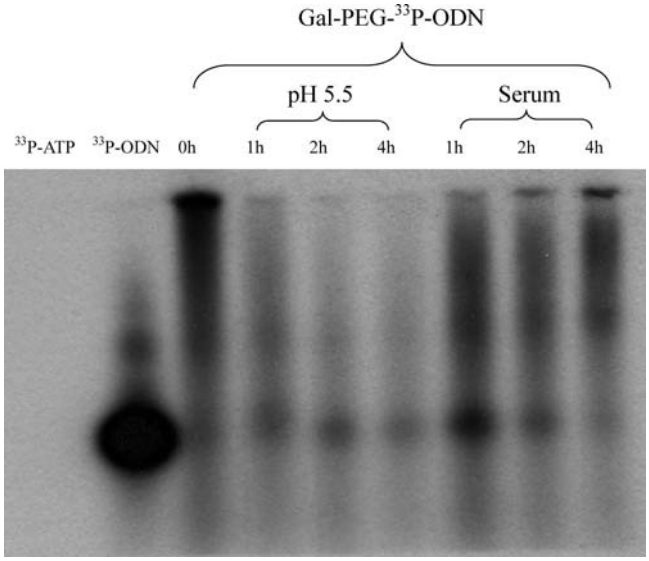

Figure 6. Dissociation and stability study of Gal-PEG-^{33}P-ODN. Dissociation of ^{33}P-ODN from Gal-PEG-^{33}P-ODN was determined by incubating the conjugate at 37 °C in pH 5.5 buffer, while its stability was determined by incubating the conjugate at 37 °C in rat serum. The band for Gal-PEG-^{33}P-ODN decreases with time when incubated at acidic pH.

dissolved in 0.4 mL water at a molar ratio of 1:100, stirred under nitrogen protection at room temperature for 6 h, and the mixture centrifuged by Amicon Centricon filter device (MWCO 10 000 Da) at 2500 *g* for 30 min. The upper solution of the filter device was collected and lyophilized. The formation of Gal-PEG-ODN was verified on 20% native polyacrylamide gel electrophoresis at 8 V/cm for 100 min at room temperature, followed by gel staining with methylene blue. The reaction mixtures and the purity of intermediate and final products were monitored by reverse phase-high performance liquid chromatography (RP-HPLC), which was carried on a reverse phase C18 column (250 mm 4.6 mm, Alltech, Deerfield, IL) by an HPLC system (Waters, Milford, MA) with detection at 260 nm using a gradient of 5% to 80% ACN in 0.1 M triethylammonium acetate at a flow rate of 1.0 mL/min at 56 °C.

Synthesis of Galactosylated Albumin. Gal-BSA was synthesized from *p*-aminophenyl β-D-galactopyranoside and BSA (MW 66 000 Da) using a modified method described by Sando and Karson (*27*). After conjugation, Gal-BSA was purified by PD-10 column and identified by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) followed by staining with Brilliant Blue R Staining Solution. The molar ratio of galactose and BSA was about 15. Sugar (galactose) content was determined by the resorcinol−sulfuric acid method as described by Monsigny et al. (*28*).

Radiolabeling of Oligonucleotides. The 25-mer ODN or Gal-PEG-ODN was labeled by adding γ-^{33}P to the 5′ end using [γ-^{33}P] ATP and T4-PNK, using the manufacturer's protocol. Briefly, 1 μg of ODN or Gal-PEG-ODN was mixed with 5 μL of T4-PNK buffer, 2 μL of T4-PNK, and 4 μL of [γ-^{33}P] ATP. The reaction mixture was incubated at 37 °C for 60 min, followed by incubation at 70 °C for 10 min to stop the reaction. Unincorporated [γ-^{33}P] ATP was removed from radiolabeled ODN or Gal-PEG-ODN by size exclusion chromatography with Bio-Gel P-6DG gel. Radioactivity was measured on a TRI-CARB2000 liquid scintillation analyzer (Packard Instrument Company, Meridon, CT). The incorporation efficiency of the purified ^{33}P-ODN was determined by trichloroacetic acid (TCA) precipitation method and the value was more than 95%. The specific activity of ^{33}P-ODN was about 5×10^5 to 10×10^5 cpm/μg.

Dissociation and Stability. To determine whether ODNs can dissociate from Gal-PEG-ODN conjugate after endocytosis, this conjugate was incubated at 37 °C in Tris−HCl buffer of pH 5.5 for 1, 2, and 4 h. In addition, we also incubated this conjugate in the rat serum at 37 °C to determine its stability. These samples were then detected by 20% polyacrylamide gel electrophoresis and autoradiography.

Biodistribution of Gal-PEG-ODN. The animal protocol was approved by the Animal Care and Use Committee (ACUC), Department of Comparative Medicine, University of Tennessee Health Science Center, Memphis, TN 38163. Male Sprague−Dawley rats weighing 140–160 g were used in this study and four rats were used for each time point. Unlabeled and Gal-PEG-^{33}P-ODN were mixed in saline to give a final concentration of 1 mg/mL and specific activity of 1×10^6 cpm/mL. Rats were anesthetized by inhalation of isoflurane, and Gal-PEG-^{33}P-ODN or ^{33}P-ODN was injected via tail vein at a dose of 0.2 mg/kg body weight. At 2.5, 5, 15, 30, 90, 240, and 1440 min postinjection, 0.5 mL blood was collected by cardiac puncture in heparinized tubes, and urine was collected directly from the bladder using a 0.26 gauge needle syringe. The animals were then sacrificed and major tissues (liver, kidney, spleen, heart, lung, and muscle) were collected, washed, blotted dry, weighed, and stored at −80 °C. The radioactivity of the urine sample was counted directly after adding 10 mL of scintillation fluid. Two hundred microliters of plasma and 200 mg of each tissue were incubated with 2 mL tissue solubilizer for 3 h at 55 °C and overnight at 37 °C in a shaker. Four hundred microliters of H_2O_2 was added and incubated at 55 °C for another 30 min. Ten milliliters of scintillation fluid was added to each sample and the radioactivity was counted using a liquid scintillation counter.

Determination of Pharmacokinetic Profiles. Plasma data were analyzed using *WinNonlin Professional* (version 5.0.1, Pharsight Corporation, Mountainview, CA). The Gal-PEG-^{33}P-ODN plasma concentration data versus time were fitted using one- and two-compartment models, and pharmacokinetic parameters were calculated as area under the curve (AUC), C_{max}, T_{max}, and clearance (CL). The data were best fitted to a two-compartment model where

$$C_t = Ae^{-\alpha t} + Be^{-\beta t} \quad (1)$$

and C_t equals concentration at time t, A and B are the y-axis intercepts, and α and β are the hybrid constants for distribution and elimination, respectively. Tissue distribution data of Gal-PEG-^{33}P-ODN were analyzed in terms of clearance and tissue uptake rate index using biexponential equations as described previously (*8*). The change in the amount of radioactivity in a tissue with time can be described as follows:

$$dT(t)/t = CL_{in}C(t) - K_{out}T(t) \quad (2)$$

where $T(t)$ (% of dose/g) represents the amount of radioactivity in 1 g of the tissue, $C(t)$ (% of dose/mL) is the plasma concentration of radioactivity, CL_{in} (mL h^{-1} g^{-1}) is the tissue uptake rate index from the plasma to the tissue, and K_{out} (h^{-1}) is the rate constant for efflux from the tissue. In the present study, the efflux process can be considered negligible during the initial time points up to 90 min. Hence, eq 1 integrates to

$$CL_{in} = T(t_1)\int_0^{t_1} C(t_1)dt = T(t_1)/AUC_{0-t_1} \quad (3)$$

where t_1 (h) is the sampling time. According to eq 1, the tissue uptake rate index is calculated using the amount of radioactivity in the tissue and the area under the plasma concentration−time curve (AUC). Then, the organ clearance (CL_{org}) is expressed as follows:

$$CL_{org} = CL_{in}W \quad (4)$$

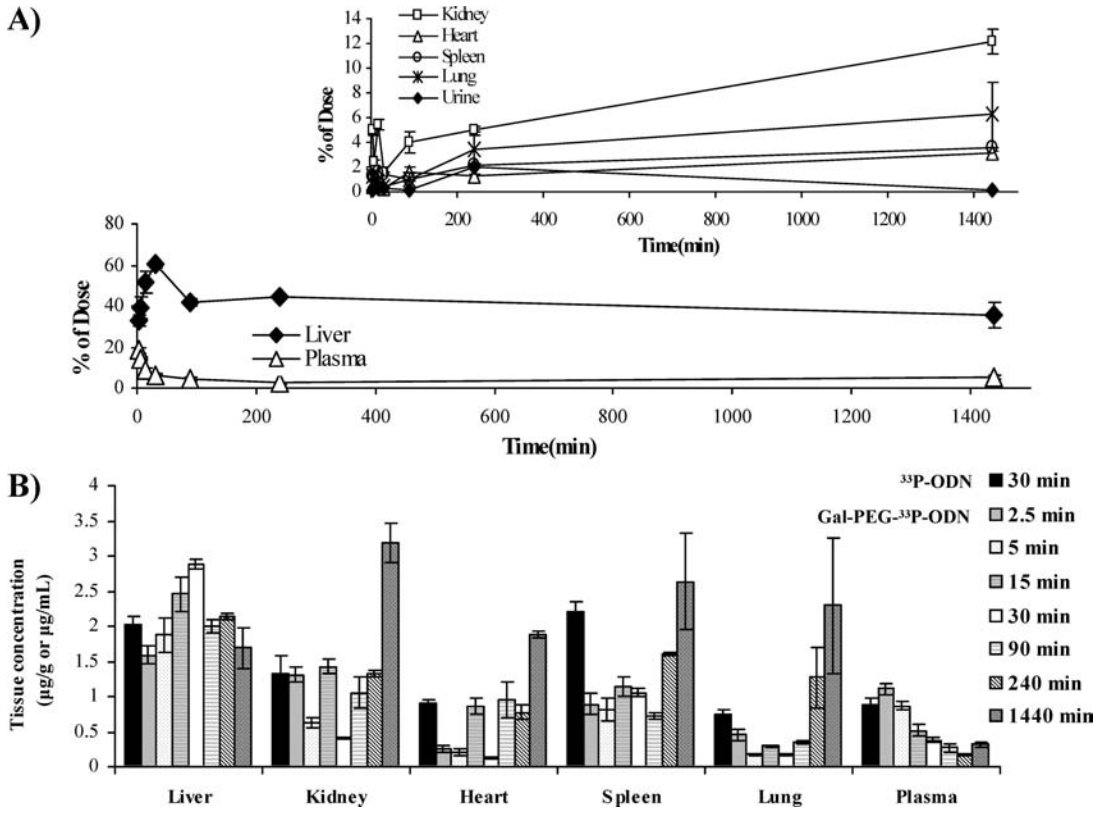

Figure 7. Accumulation (A) and concentration (B) of Gal-PEG-^{33}P-ODN after tail vein injection into rats at a dose of 0.2 mg ODN/kg of body weight. To compare the biodistribution profiles of Gal-PEG-^{33}P-ODN, ^{33}P-ODN was also injected, and ODN accumulation and concentration in different tissues were determined at 30 min postinjection. Following blood collection by cardiac puncture and urine collection from the bladder, the tissues were isolated, digested, and subjected to radioactivity measurement. Results are presented as the mean ± SD ($n = 4$).

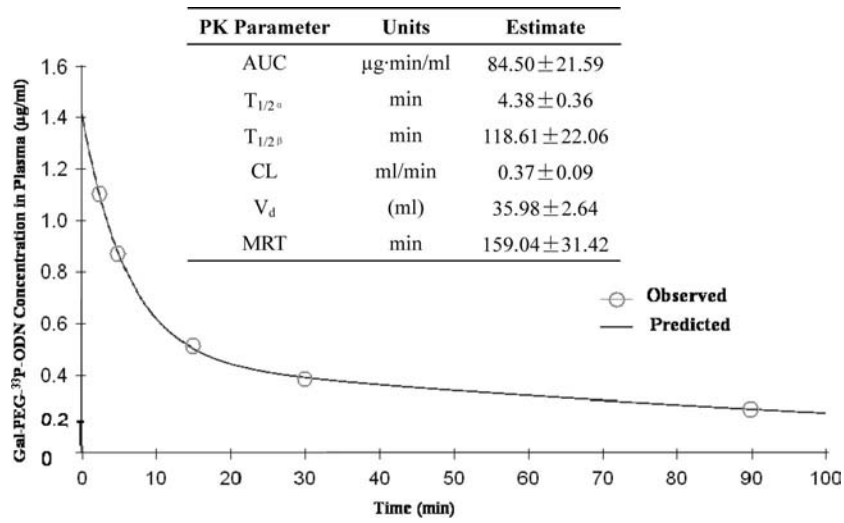

PK Parameter	Units	Estimate
AUC	μg·min/ml	84.50±21.59
$T_{1/2\alpha}$	min	4.38±0.36
$T_{1/2\beta}$	min	118.61±22.06
CL	ml/min	0.37±0.09
V_d	(ml)	35.98±2.64
MRT	min	159.04±31.42

Figure 8. Plasma data was analyzed using a two-compartment model with *WinNonlin Professional* (version 5.0.1) software. Data are represented as the mean ± SD ($n = 4$).

where W (g) is the total weight of the organ. When the tissue uptake process followed nonlinear kinetics, CL_{in} values would represent an average value for the overall experimental period. Total body clearance (CL_{total}) was calculated from AUC for infinite time (AUC_∞) by the following equation:

$$CL_{total} = \text{dose}/AUC_\infty \quad (5)$$

The tissue uptake clearance and index were calculated using the values up to 30 min after injection, assuming that ODNs were fairly stable within this period.

Competition in Hepatic Uptake of Gal-PEG-ODN. Two minutes before the injection of Gal-PEG-^{33}P-ODN at a dose of 0.2 mg/kg (specific activity: 1×10^6 cpm/mL), rats received 10 mg/kg of Gal-BSA via tail vein injection. At 30 min postinjection, blood and urine were collected; other major organs were harvested as described above for radioactive measurement.

Hepatic Cellular Distribution of Gal-PEG-ODN. To determine the effect of conjugation with Gal-PEG on the hepatic uptake of ODNs, the liver was isolated and perfused in situ with Ca^{2+}/Mg^{2+}-free Hank's balanced salt solution containing 0.1% Pronase and 0.05% collagenase at 30 min postintravenous injection of ^{33}P-ODN or Gal-PEG-^{33}P-ODN into rats as described previously (*24*). Briefly, rats (200–250 g) were anesthetized by inhalation of isoflurane, and 100 IU of heparin

Table 1. Tissue Uptake Rate Index and Clearance of ^{33}P-ODN and Gal-PEG-^{33}P-ODN after Systemic Administration into Rats

sample	AUC (μg·min/mL)	tissue uptake rate index (μL·h^{-1}·g^{-1})					organ clearance (μL·h^{-1})				
		liver	kidney	heart	spleen	lung	liver	kidney	heart	spleen	lung
^{33}P−ODN	95.15 ± 5.11	376.15 ± 38.34	235.23 ± 29.39	48.76 ± 3.42	204.73 ± 9.64	55.28 ± 8.90	2218.09 ± 205.68	241.00 ± 41.08	22.96 ± 1.94	82.85 ± 7.32	42.21 ± 8.44
Gal-PEG-^{33}P−ODN	84.50 ± 21.59	2663.27 ± 56.63	376.52 ± 11.16	119.24 ± 10.81	969.26 ± 51.79	161.16 ± 7.00	16674.22 ± 354.55	428.81 ± 12.71	59.67 ± 5.41	395.84 ± 21.15	131.22 ± 5.70

was injected via tail vein, the abdomen was opened, and the portal vein was cannulated with PE-60 polyethylene tubing. The liver was preperfused with 2 mL diluted heparin solution, then with 200 mL Ca^{2+}/Mg^{2+}-free Hank's balanced salt solution and finally with Hank's balanced salt solution containing 0.05% type IV collagenase and 0.1% Pronase for additional 250 mL. All the perfusion solutions were incubated at 37 °C. After perfusion, different liver cell types were separated by Nycodenz gradient (*29*) and radioactivity was measured. The contributions of various cell types to the total liver uptake were calculated as percentage of total hepatic uptake.

Statistical Analysis. Data were expressed as the mean ± standard deviation (SD). The difference between any two groups was determined by ANOVA. $P < 0.05$ was considered statistically significant.

RESULTS

Chronic injury and inflammation of hepatocytes often lead to liver fibrosis and loss of sinusoidal fenestrae, suggesting that liposomal and nanoparticulate delivery systems may not be good for ODN delivery to the hepatocytes. Therefore, we synthesized Gal-PEG and conjugated to ODN by β-thiopropionate, an acid-labile linkage which is easily cleaved at acidic pH, leading to endosomal release of ODNs after endocytosis (*23*). Following synthesis and characterization, we determined the biodistribution at whole body, organ (liver), and cellular (liver cells) levels after systemic administration of Gal-PEG-^{33}P-ODN in rats.

Synthesis and Characterization of Gal-PEG-Acrylate and Gal-PEG-ODN. The synthesis scheme of Gal-PEG-ODN conjugate is shown in Figure 1. *p*-Nitrophenyl β-D-galactopyranoside was reduced to *p*-aminophenyl β-D-galactopyranoside. ESI-MS and ^{1}H NMR results of this intermediate product are shown in Figure 2. ESI-MS (positive ion mode): 294.1 ([M + Na]$^+$) (Figure 2A). ^{1}H NMR (D_2O): δ 6.73 (d, 1H), 6.90 (d, 1H), 5.35 (s, 1H), 3.76–4.09 (m, 4H), 3.61 (m, 2H) (Figure 2B). Gal-PEG-acrylate was synthesized from acrylate-PEG-NHS and identified by MALDI-TOF MS and ^{1}H NMR. For MALDI-TOF MS, DHB was used as a matrix at the weight ratio of 1:2 (Gal-PEG-acrylate/DHB). Molecular weight of Gal-PEG-acrylate was 3758 Da after conjugation between acrylate-PEG-NHS (MW 3486 Da) and *p*-aminophenyl β-D-galactopyranoside (MW 271 Da) (Figure 3A). ^{1}H NMR (D_2O): δ 7.35 (d, 2H), 7.12 (d, 2H), 5.54 (s, 1H), 3.48–3.92 (m, 538H), 5.93 (d, 2H), 6.17(t, 1H), 6.40 (d, 1H) (Figure 3B). Gal-PEG was then conjugated to ODN by Michael addition from *p*-aminophenyl β-D-galactopyranoside and Gal-PEG-acrylate. Gal-PEG-ODN was also identified by native polyacrylamide gel electrophoresis and staining with methylene blue (Figure 4). For the purification process, the RP-HPLC was used to monitor the mixtures and the purity of the intermediate and final products. From the HPLC chromatograms of ODNs, PEG, and Gal-PEG-ODN conjugate shown in Figure 5, almost all PEG and ODNs were removed from the conjugate after purification. G-rich ODNs used in this study has the tendency to form G-quartets, which may decrease the recovery of the conjugate.

Dissociation and Stability. To determine the dissociation and stability of Gal-PEG-^{33}P-ODN, the radioactivity of the samples was measured after gel electrophoresis and autoradiography at 0, 1, 2, and 4 h postincubation of the conjugate in Tris−HCl buffer of pH 5.5 and rat serum, respectively. In the pH 5.5 buffer, the band of Gal-PEG-^{33}P-ODN gradually disappeared along the incubation time, while the band of the ^{33}P-ODN was still there even up to 4 h (Figure 6). In contrast, this conjugate was fairly stable in rat serum for at least 4 h. The result suggests that the conjugate was fairly stable in serum, but its acid-labile ester linkage can be cleaved at acidic pH. Our study also confirmed the previous report about this kind of conjugate by Oishi et al. (*23*).

Biodistribution of Gal-PEG-ODN Conjugate. Following synthesis and purification of Gal-PEG and then conjugation to ^{33}P-ODN, we determined the biodistribution of Gal-PEG-^{33}P-ODN at 2.5, 5, 15, 30, 90, 240, and 1440 min postinjection into the tail vein of rats. Figure 7A shows the time course of radioactivity in the plasma, urine, liver, kidney, lung, heart, and spleen (radioactivity in muscle was too low, not shown here). Gal-PEG-^{33}P-ODN was rapidly cleared from the circulation with less than 10% of radioactivity detected in the plasma at 30 min postinjection. Correspondingly, hepatic uptake of Gal-PEG-^{33}P-ODN increased with time and reached its peak at 30 min postadministration and then decreased with time. To compare the biodistribution profiles of Gal-PEG-^{33}P-ODN, ^{33}P-ODN was also injected into rats, and ODN accumulation and concentration in different organs were determined at 30 min postinjection. Figure 7B shows the tissue concentration of Gal-PEG-^{33}P-ODN in the plasma (μg/mL) and tissues (μg/g) after tail vein injection into rats, while the conjugation of ODN with Gal-PEG significantly increased the accumulation of radioactivity (% of dose) in the liver, as compared to that of ^{33}P-ODN. Gal-PEG-^{33}P-ODN concentration was high not only in the liver, but also in the spleen and kidney (Figure 7). Almost 60.2% (about 2.88 μg ODN/g liver tissue) of the conjugate accumulated in the liver compared to about 40% (data not shown) (about 2.01 μg ODN/g liver tissue) accumulation by free ODNs at 30 min postadministration.

Plasma elimination of Gal-PEG-^{33}P-ODN was biphasic with a distribution half-life ($t_{1/2\alpha}$) of 4.38 ± 0.36 min and elimination half-life ($t_{1/2\beta}$) of 118.61 ± 22.06 min. Figure 8summarizes the pharmacokinetic parameters such as AUC, V_d, CL, and MRT. Consistent with rapid clearance (0.37 ± 0.09 mL/min), Gal-PEG-^{33}P-ODN had a large V_d of 35.98 ± 2.64 mL. Table 1 summarizes the AUC, tissue uptake rate index, and organ clearance for representative organs after systemic administration of ^{33}P-ODN and Gal-PEG-^{33}P-ODN in rats. The liver uptake rate index and clearance of Gal-PEG-^{33}P-ODN were significantly higher than those of ^{33}P-ODN: 2663.27 ± 56.63 versus 376.15 ± 38.34 μL·h^{-1}·g^{-1} and 16674.22 ± 354.55 versus 2218.09 ± 205.68 μL·h^{-1}·g^{-1}, respectively. The spleen was in the second place with the tissue uptake rate index of 969.26 ± 51.79 versus 204.73 ± 9.64 μL·h^{-1}·g^{-1} and CL_{org} of 395.84 ± 21.15 versus 82.85 ± 7.32 μL·h^{-1}. The tissue uptake rate indices and organ clearances of heart, kidney, and lung were significantly higher than those of ^{33}P-ODN, possibly due to increased in vivo stability of ODN upon conjugation with Gal-PEG.

Competition in Hepatic Uptake of Gal-PEG-^{33}P-ODN. The role of asialoglycoprotein receptor on biodistribution of Gal-PEG-^{33}P-ODN in rats was assessed by determining the effect of excess Gal-BSA on the accumulation of Gal-PEG-^{33}P-ODN

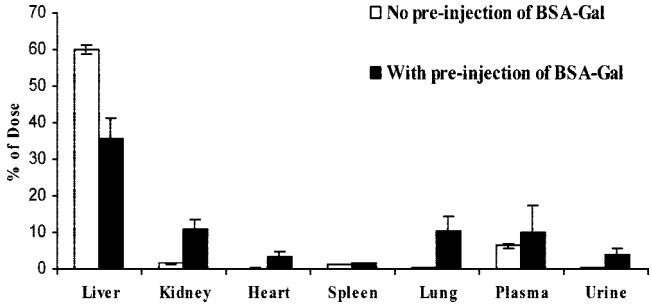

Figure 9. Effect of Gal-BSA on biodistribution of Gal-PEG-^{33}P-ODN after systemic administration into rats. Gal-BSA (10 mg/kg) was injected intravenously into rats 2 min before the injection of Gal-PEG-^{33}P-ODN at a dose of 0.2 mg/kg. At 30 min postinjection, rats were sacrificed, major organs were isolated, and radioactivity was determined. Values are the mean ± SD of 4 rats.

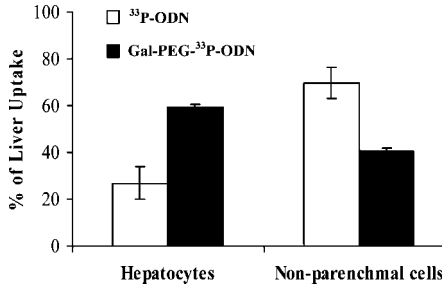

Figure 10. Hepatic cellular localization of ^{33}P-ODN and Gal-PEG-^{33}P-ODNs. The liver was perfused by collagenase/Pronase digestion at 30 min postinjection of ^{33}P-ODN or Gal-PEG-^{33}P-ODN at a dose of 0.2 mg/kg. Parenchymal and nonparenchymal cells were separated and the associated radioactivity was measured. Values are the mean ± SD of 4 rats.

in the liver. Galactosylated proteins or polymeric systems are known to be taken up by asialoglycoprotein receptor-mediated endocytosis. We have previously demonstrated that 1 min preinjection of excess Gal-BSA can saturate asialoglycoprotein receptors present on the surface of hepatocytes, resulting in decreased hepatic uptake of Gal-PLL/ODN complexes. Staud et al. (1999) also injected galactosylated superoxide dismutase (Gal-SOD) 2 min postinjection of excess Gal-BSA and demonstrated significant decrease in the hepatic uptake of Gal-SOD (*13*). Therefore, a 2 min interval between the intravenous injections of Gal-BSA and Gal-PEG-ODN is reasonable for the competition study. Systemic administration of excess Gal-BSA is known to saturate the asialoglycoprotein receptor of the hepatocytes (*30*). Prior administration of Gal-BSA at a dose of 10 mg/kg caused a significant decrease in the hepatic uptake of Gal-PEG-^{33}P-ODN, but increase in the radioactivity in plasma and other organs at 30 min postinjection. The hepatic uptake of Gal-PEG-^{33}P-ODN decreased from 60.2% to 35.9% (Figure 9). This suggests the involvement of asialoglycoprotein receptor in their hepatic uptake.

Hepatic Cellular Localization. To determine the intrahepatic localization of Gal-PEG-^{33}P-ODN and to determine whether the uptake of this conjugate by hepatocytes is mediated by asialoglycoprotein receptors, the liver was perfused at 30 min post tail vein injection of ^{33}P-ODN or Gal-PEG-^{33}P-ODN, and different types of liver cells were isolated for determining the amount of radioactivity in these cells. As shown in Figure 10, the hepatocytes were the major site for the uptake of Gal-PEG-^{33}P-ODN. At 30 min about 58% of the total liver recovery was in the hepatocytes compared to only 30% for the ^{33}P-ODNs (Figure 10). Accordingly, the uptake of Gal-PEG-^{33}P-ODN in the liver nonparenchymal cells (NPC) was 42% compared to 70% for ^{33}P-ODN. This suggests that a large percentage of the injected Gal- PEG-^{33}P-ODN was taken up by the liver via asialoglycoprotein receptor-mediated endocytosis.

DISCUSSION

Systemic delivery of ODNs is promising for treating both genetic and acquired diseases. Phosphorothioate (PS) ODNs are by far the most extensively studied, and significant progress has been made which resulted in one commercial product (Vitravene) as well as several promising clinical trials (*31*). To enhance the cellular uptake of ODNs by HepG2.2.15 cells, which are stably transfected with hepatitis B virus (HBV), Wu and Wu conjugated asialoorosomucoid to poly(L-lysine) and then formed complex with 21-mer ODN complementary to a portion of human HBV. There was significant increase in ODN uptake by HepG 2.2.15 cells, and the concentration of Hepatitis B surface antigen (HBsAg) was 80% lower than controls after 24 h (*32*). However, these authors did not determine the biodistribution of asialooromucoid-PLL/ODN complexes after systemic administration in rodents.

We have previously shown that, although complex formation with Gal-PLL enhances ODN uptake by hepatocytes after systemic administration in mice, the difference in the intracellular distribution of Gal-PLL/ODN and ODN was only moderate, possibly because of the nonspecific ionic interaction due to polycations (*8*). Therefore, in this study, we conjugated ODN to Gal-PEG via an acid-labile ester linkage of β-thiopropionate, which will be cleaved in response to a pH decrease in the endosome. Oishi et al. (2003) demonstrated the hydrolysis of β-thiopropionate linkage (easter linkage) of the PEG-ODN conjugate at pH 5.5, but not at pH 7.4 even after incubation at 37 °C for 24 h (*23*).

Consistent with our results on Gal-PLL/ODN complexes (*8*), the plasma kinetic disposition of Gal-PEG-^{33}P-ODN was characterized by rapid distribution to most peripheral tissues, with the highest disposition in the liver (Figure 7A,B). Bioconjugation with Gal-PEG decreased the urinary clearance of ODNs to a great extent (*8*). The liver accumulation of Gal-PEG-^{33}P-ODN, including radioactivity and ODN concentration, significantly increased within a short time and reached its peak at 30 min postadministration. Generally, after the peak time point the accumulation of the radioactivity and the concentration should decrease along the time. However, in the present study both of them showed a slight increase in the hepatic uptake at 240 min and then decreased, while in other organs, the accumulation and concentration of ODNs increased significantly until 24 h. The possible reason for this phenomenon is that after endocytosis of Gal-PEG-ODN by the liver cells the β-thiopropionate linkage becomes unstable and ODN will be released from conjugate gradually. The degradation reaction makes the cell an ODN depot. Then, some of ODNs can be distributed all over the body.

We determined the role of the asialoglycoprotein receptors on biodistribution of Gal-PEG-^{33}P-ODN in rats by the competition effect of excess Gal-BSA on the hepatic uptake of ODNs. There was significant decrease in ODN deposition to the liver, but an increase in its accumulation to other organs and tissues, suggesting that Gal-PEG-ODN was taken up by hepatocytes via the galactose-specific asialoglycoprotein receptor-mediated endocytosis (Figure 9). The higher uptake of ODNs in hepatocytes compared with nonparenchymal cells in the cellular distribution (Figure 10) and the highest accumulation of ODNs in liver compared with other organs in whole body level biodistribution after ODN conjugated with Gal-PEG (Figure 7) further confirmed this result.

In conclusion, in this study we synthesized a Gal-PEG-ODN conjugate for site-specific delivery to hepatocytes. In contrast to ^{33}P-ODN, Gal-PEG-^{33}P-ODN was efficiently taken up by hepatocytes and less efficiently by nonparenchymal cells (Figure

10). Thus, nonionic Gal-PEG-ODN is a promising delivery system which can be used for targeted delivery of ODN or siRNA into hepatocytes to treat various liver diseases associated with hepatocyte injury and inflammation.

Recombinant interferon alpha-2 (IFN-α2) has proven useful for treating a variety of human cancers and viral diseases. IFN-α2 has a short circulating half-life *in vivo*, which necessitates daily or thrice weekly administration to patients. It is possible to extend the circulating half-life of IFN-α2 by random modification of lysine residues in the protein with polyethylene glycol (PEG); however, such preparations have heterogeneous structures and low specific activities, and may not provide optimal therapeutic benefits to patients. A long-acting, site-specific, monoPEGylated IFN-α2 protein has now been created by targeted attachment of a 20 kDa or a 40 kDa maleimide-PEG to a cysteine analogue of IFN-α2, M111C. *In vitro* bioactivities of the purified 20 kDa and 40 kDa PEG-M111C proteins were within 2- to 3-fold of those of wild type IFN-α2 and 7- to 10-fold better than that of a 40 kDa PEG IFN-α2 protein created using nontargeted, amine-PEGylation methodology. The 20 kDa and 40 kDa PEG-M111C proteins demonstrated 26- to 38-fold longer half-lives, respectively, than IFN-α2 following subcutaneous administration to rats. The 20 kDa PEG M111C protein inhibited growth of human NIH:OVCAR-3 cells transplanted into nude mice by >90%, as measured by tumor size, tumor weight, and number of animals with detectable tumors at necropsy, and was significantly more effective than a comparable dose of IFN-α2. These data extend our previous findings that bioactivity of IFN-α2 can be largely preserved by targeted attachment of PEG moieties to nonessential sites in the protein and provide evidence that site-specific PEGylated IFN-α2 proteins possess enhanced tumoricidal properties *in vivo*.

INTRODUCTION

Interferon alpha 2 (IFN-α2) is a 20 kDa cytokine that is a potent inhibitor of viral replication and tumor cell growth (*1–3*). Recombinant human IFN-α2 proteins have proven useful for treating viral diseases, such as hepatitis B, hepatitis C, and genital warts, and for treating cancers, such as hairy cell leukemia, lymphoma, melanoma, renal carcinoma, and Kaposi's sarcoma. Because of the short circulating half-life of recombinant IFN-α2, frequent administration (daily or thrice weekly) at high concentrations is required to achieve desired outcomes. Therefore, patient discomfort is higher, as are the side effects experienced. Several modified forms of IFN-α2 with improved pharmacokinetic properties have been developed recently (*4–7*). Animal and human studies suggest that the increased half-lives and consequent greater systemic exposure of these longer-acting IFN-α2 proteins enhance their ability to protect against viral infections (*8–12*). These proteins are being tested in animal cancer models and human clinical trials to determine if they possess enhanced tumoricidal properties as well (*4, 12–16*).

Increasing the circulating half-life of IFN-α2 was approached initially by modification of the protein with amine-reactive polyethylene glycol (PEG) reagents and by fusion of IFN-α2 to human albumin (*4–7*). However, these products have heterogeneous structures and/or low specific activities, which increases the cost of the drug and may not maximize the potential therapeutic benefits of the protein to patients. PEG-Intron (Schering Corporation) is modified with a relatively small 12 kDa PEG, which allows the protein to retain significant activity (3- to 4-fold reduction from that of wild type IFN-α2), but confers only a moderate improvement in half-life as compared to that of the unmodified protein (*7, 17–19*). Approximately 47% of the PEG molecules in PEG-Intron are attached to histidine-34 (H34), but the remaining 53% of the PEG molecules are attached to other amino acids, principally lysine residues (K31, K83, K121, K131, and K134) and the N-terminal cysteine residue (*7, 17, 19*). The PEG-H34 bond is unstable and undergoes hydrolysis in aqueous solution, resulting in the dissociation of PEG from the protein. The instability of the PEG-H34 bond limits potential formulations for the protein and contributes to the relatively short half-life of the protein (*7, 18*). A second PEG-IFN-α2 protein, PEGASYS (Roche), is modified with a larger 40 kDa PEG and comprises a complex mixture of four major (K31, K121, K131, and K134) and several minor PEG−protein isoforms, each of which differs in bioactivity (*4, 19, 20*). PEGASYS has a long half-life but possesses only 1–7% of wild type IFN-α2 *in vitro* bioactivity (*4, 19*). The albumin- IFN-α2 fusion protein (Albuferon, Human Genome Sciences) has a long half-life, but possesses only about 1% of the *in vitro* bioactivity of wild type IFN-α2 (*6*).

Recently, it was shown that introducing a cysteine residue into the IFN-α2 protein and using a cysteine-specific PEG reagent (site-specific PEGylation) provided an alternative method for PEGylating IFN-α2 that resulted in a homogeneously modified, monoPEGylated protein (*21*). Three regions of IFN-α2 were identified where a cysteine residue could be introduced and PEGylated without appreciably altering *in vitro* bioactivity of the protein. The cysteine mutein characterized in most detail was Q5C (substitution of cysteine for glutamine at amino acid position 5). In this article, a second site-specific, monoPEGylated IFN-α2 analogue, M111C, that retains near complete *in vitro* bioactivity, even when modified with a large 40 kDa PEG, is

characterized. The M111C protein was modified with PEG moieties of various molecular weights and the PEG-proteins purified to homogeneity. The PEG-M111C proteins possessed significantly longer half-lives than IFN-α2 in rats. One of the PEG-M111C proteins was evaluated for efficacy in an athymic mouse tumor model and shown to be significantly more effective than IFN-α2 at inhibiting the growth of human tumor cells in mice. This study is the first demonstration of *in vivo* efficacy of a site-specific PEGylated IFN-α2 protein therapeutic.

EXPERIMENTAL PROCEDURES

Construction, Expression and Purification of Recombinant IFN-α2-M111C. The IFN-α2b-M111C analogue was constructed by site-directed mutagenesis and expressed in *Escherichia coli* essentially as described (*21*). Induced *E. coli* cells were harvested by centrifugation and the cell pellets stored at −80 °C. Frozen cells from 400 mL cultures were thawed and resuspended in 10 mL of 8 M guanidine, 20 mM cysteine, 2% (v/v) Tween 20, and 20 mM MES at pH 3. After mixing for 3 h, the solution was diluted 20-fold, the guanidine concentration was adjusted to 0.6 M, urea and copper sulfate were added to final concentrations of 1 M and 40 μM, respectively, and the solution was adjusted to pH 6. The refold mixture was incubated for 1–2 d at 4 °C, adjusted to pH 3, and clarified by centrifugation. The supernatant was diluted 4-fold with H_2O and loaded onto a 5 mL HiTrap S-Sepharose column (GE Healthcare, Piscataway, NJ) equilibrated in 20 mM MES at pH 5.0. The bound proteins were eluted with a linear salt gradient from 0 to 100% buffer B (500 mM NaCl, 20 mM MES, and 10% ethylene glycol at pH 5.0). Column fractions enriched for the M111C protein were identified by nonreducing SDS−PAGE. These fractions were pooled and loaded onto a 1 mL Cu^{2+} IMAC Hi Trap column (GE Healthcare) equilibrated in 40 mM sodium phosphate at pH 6.0, 1 M NaCl, and 0.1% (v/v) Tween 20. The M111C protein was eluted with a reverse pH gradient from 5.5 to 4.1 in 40 mM sodium phosphate, 1 M NaCl, and 0.1% Tween 20. Column fractions were analyzed by nonreducing SDS−PAGE ,and fractions containing properly folded M111C protein and no visible contaminants were pooled. The IMAC column pool was equilibrated to room temperature, diluted 1:4 with 20 mM Tris at pH 8.0, and solid ammonium sulfate added to a final concentration of 10% (w/v). The protein was loaded onto a 1 mL Phenyl Sepharose column (GE Healthcare) equilibrated in 20 mM Tris-HCl at pH 8.0 and 10% (w/v) ammonium sulfate. The protein was eluted using a linear reverse salt gradient from 0 to 100% Buffer B (20 mM Tris-HCl and 30% ethylene glycol at pH 8.0). Column fractions were analyzed by nonreducing SDS−PAGE, and fractions containing properly folded M111C protein were pooled, quantitated, and stored at −80 °C.

Site-Specific PEGylation of IFN-α2-M111C. Small scale (microgram quantities) PEGylation reactions were performed essentially as described (*21*) using TCEP (Tris [2-carboxyethylphosphine] hydrochloride, Pierce Chemical Company, Rockford, IL) to partially reduce the purified M111C protein. To prepare larger quantities (milligrams) of the PEG-M111C protein for animal studies, the purified M111C protein was diluted to a final concentration of 6.6 μM in 25 mM Tris-HCl at pH 8.0 and partially reduced by incubation with a 25-fold molar excess of dithiothreitol (DTT) for 20 min at room temperature. The mixture was then dialyzed against 20 mM MES at pH 5 to remove the DTT. The PEGylation reaction mixtures contained 2.6 μM M111C, a 10-fold molar excess of maleimide PEG reagent, 100 mM Tris at pH 7.5, and 0.5 mM EDTA. After 1 h at room temperature, the PEGylation reaction was stopped by diluting the mixture 1:4 with 20 mM MES at pH 5 and adjusting the pH to ≤4. PEGylated M111C protein was separated from unPEGylated protein by S-Sepharose chromatography using the column chromatography conditions described above, except that 10% glycerol was substituted for 10% ethylene glycol. This method was used to prepare the M111C protein modified with a 20 kDa maleimide PEG and a branched 40 kDa maleimide PEG (Nektar, Inc., Huntsville, AL).

Pharmacokinetic Evaluation of PEG-IFN-α2-M111C in Rats. All animal experiments were performed with the approval of BolderPATH's Institutional Animal Care and Use Committee. The rat pharmacokinetic studies were performed following previously described procedures (*21*), except that plasma levels of the test proteins were quantitated using human IFN-α2 ELISA kits obtained from Research Diagnostics, Inc. (Flanders, NJ, catalog number 41100-1; sensitivity range of 12.5 to 500 pg/mL). Standard curves were prepared for each protein and conjugate in the ELISA and used to adjust the final plasma values. Three male Sprague–Dawley rats were used per test protein. Rats were obtained from Harlan Sprague–Dawley, Inc. (Indianapolis, IN) and weighed ∼350 g each. Pharmacokinetic parameters of the test proteins were determined from plasma concentrations using WinNonlin (Pharsight, Inc., Mountain View, CA, version 4.0.1), using noncompartmental methods following subcutaneous administration.

Mouse Tumor Xenograft Study. The human ovarian carcinoma cell line NIH:OVCAR-3 was obtained from the American Type Culture Collection (Manassas, VA, catalog number HTB-161). Cells were grown *in vitro* in MEM media containing 10% fetal bovine serum, 2 mM glutamine, 50 units/mL penicillin, and 50 μg/mL streptomycin. Female athymic nude (nu/nu) mice, 5 to 6 weeks of age and weighing approximately 23 g at study initiation, were obtained from Charles River (Wilmington, MA). The NIH:OVCAR-3 cells were harvested by trypsinization, washed, and resuspended at a concentration of 25×10^6 cells per mL in a 50:50 mixture of MEM media/Matrigel. Matrigel was purchased from BD Biosciences (Bedford, MA). Animals were randomized to different test groups according to body weight on day 0. Mice received subcutaneous injections of 0.2 mL of the MEM media/Matrigel mixture containing 5×10^6 cells in the axillary area on day 0. One group of 5 mice received no further injections (referred to as untreated controls). The remaining mice (9–11 animals/group) received subcutaneous injections (0.2 mL/animal) of the test compounds beginning on day 1 and continuing through day 69 using a 3×/week dosing schedule (Monday, Wednesday, Friday). Mice were weighed on day 0, prior to the injection of cells, and on the days of tumor measurements. Tumors were measured using calipers at 3–4 day intervals for 10 weeks post injection. Tumor volume was determined using a formula of (width × width) × length)/2. The different treatment groups received injections of vehicle solution [phosphate buffered saline containing 0.1 mg/mL of mouse albumin (Sigma-Aldrich, Inc., St. Louis, MO)], wild type IFN-α2b in vehicle solution (5 μg/injection/mouse), or 20 kDa PEG-M111C in vehicle solution (5 μg/injection/mouse). Wild type IFN-α2b was prepared as described (*21*). Differences between groups were compared using Mann–Whitney statistical methods.

Miscellaneous Methods. Protein samples were analyzed by SDS−PAGE on precast Tris-glycine polyacrylamide gels (Invitrogen Corporation, Carlsbad, CA) and stained with Coomassie Blue or Silver. 2-Mercaptoethanol was added to a final concentration of 1–5% (v/v) in sample buffer to reduce the proteins. Protein concentrations were determined using a Bradford protein assay kit (Bio-Rad Laboratories, Richmond, CA), using bovine serum albumin as the protein standard. *In vitro* bioactivities of the proteins were measured using a Daudi cell growth inhibition assay, essentially as described (*21*). Roferon (Roche, Inc.), PEGASYS (Roche, Inc.), and PEG-Intron (Scher-

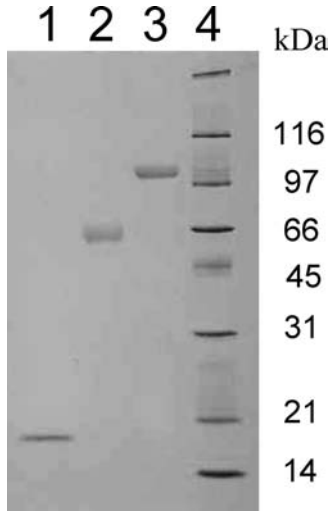

Figure 1. Nonreducing SDS−PAGE analysis of purified IFN-α2-M111C and PEG-M111C proteins. Lane 1, M111C; lane 2, 20 kDa PEG-M111C; lane 3, 40 kDa PEG-M111C; lane 4, molecular weight markers. Gels were stained with Coomassie blue.

ing Corporation) were analyzed in the Daudi assay using similar methods. Roferon was concentrated by S-Sepharose column chromatography as described above, except that 10% glycerol rather than 10% ethylene glycol was used in buffer B. The concentrated protein was stored in aliquots at −80 °C. N-terminal protein sequencing was performed by Macromolecular Resources (Fort Collins, CO) using an Edman degradation procedure.

RESULTS

Expression, Purification and Analysis of IFN-α2-M111C. IFN-α2 has a globular structure comprising 5 α helices joined by nonhelical loops (*22*). The helices are named A−E starting from the N-terminus of the protein, and the loops are named for the helices they join, for example, the C−D loop joins helices C and D. Previously, several IFN-α2 cysteine muteins that retained high *in vitro* bioactivity when modified with a small 5 kDa PEG were reported (*21*). These cysteine analogues were substitutions for amino acids located in the region preceding helix A, the C−D loop, and the region following helix E in IFN-α2. On the basis of these initial findings, a larger set of cysteine analogues constructed in these regions of IFN-α2 were screened. From this screen, the M111C analogue, which is located in the C−D loop, was identified as a promising candidate for further development. The M111C protein was expressed recombinantly in *E. coli* using the STII signal sequence to direct secretion of the protein to the *E. coli* periplasm (*21*). The signal sequence is efficiently cleaved from the protein when the induced *E. coli* cultures are grown at pH 5.5 (*21*). The properly processed M111C protein was present in both the soluble and insoluble fractions of cell lysates. To optimize recovery of the protein, a procedure for refolding the protein from whole cell lysates was developed. The refolded M111C protein was purified by sequential S-Sepharose, Cu^{2+} IMAC, and hydrophobic interaction column chromatography steps, as described in Experimental Procedures. The purified M111C protein migrated as a single band by reducing and nonreducing SDS−PAGE (Figure 1) and comigrated with wild type IFN-α2 under these conditions (data not shown). The identity and purity of the M111C mutein was verified by N-terminal sequencing, reversed-phase high pressure liquid chromatography and silver staining (data not shown). The protein purity was estimated to be >90%, as judged by densometric scanning of SDS−PAGE gels. The protein structural integrity was evaluated by circular dichroism

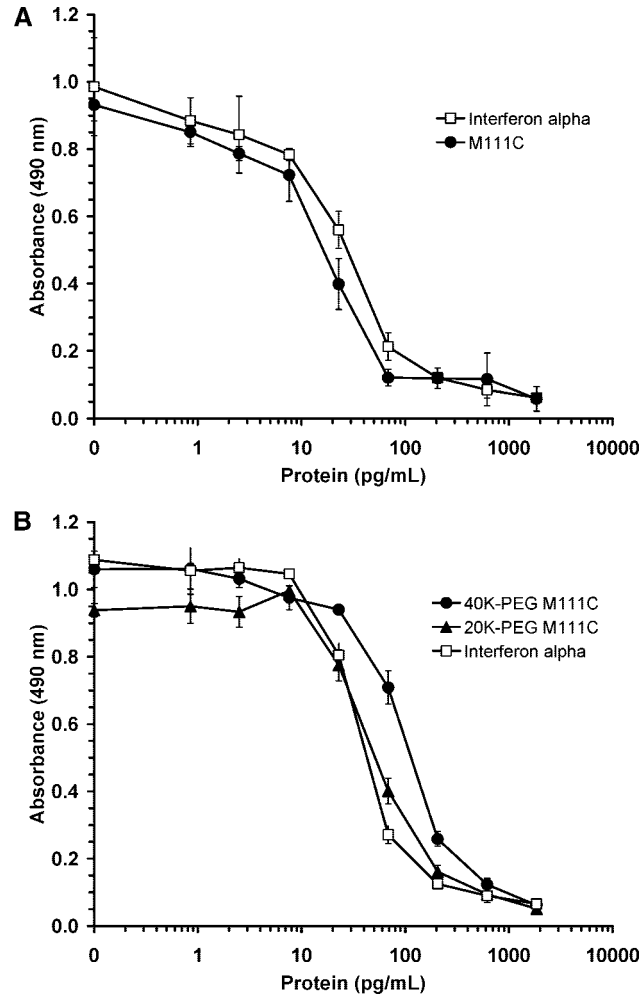

Figure 2. *In vitro* bioactivities of IFN-α2-M111C and PEG-M111C proteins. Serial dilutions of the indicated proteins were incubated with human Daudi cells for 4 days at 37 °C in 96 well tissue culture plates. At this time, an indicator dye was added to the wells and plates incubated for an additional 1–4 h. Absorbance values on the y-axis are proportional to cell number. Data are means ± SD for triplicate wells for each protein dilution. Experiments were repeated at least 3 times for each protein. Panel A compares M111C and IFN-α2 (Roferon). Panel B compares PEG-M111C proteins and IFN-α2 (Roferon).

Table 1. *In vitro* Bioactivities of PEG-M111C Proteins and IFN-α2 for Inhibiting Growth of Human Daudi Cells

protein	IC_{50} (pg/mL)[a]
IFN-α2[b]	31 ± 8
M111C	20 ± 4
20 kDa PEG-M111C	48 ± 18
40 kDa PEG-M111C	91 ± 37

[a] Means ± SD for at least 3 assays for each protein. The IC_{50} is the concentration of protein required for half-maximal inhibition of cell proliferation. [b] Roferon.

spectroscopy and was essentially identical to that of the wild type protein (data not shown). *In vitro* bioactivity of the M111C protein was compared to that of IFN-α2 (Roferon) in a cell growth inhibition assay using human Daudi cells. The M111C protein inhibited growth of Daudi cells with the same potency as that of IFN-α2 (Figure 2A and Table 1).

Site-Specific PEGylation of M111C. The purified M111C protein contains a mixed disulfide formed between M111C and cysteine added during the refold procedure. The mixed disulfide stabilizes the protein during purification, but must be disrupted for efficient modification of the protein with maleimide-PEG reagents. The purified M111C protein was partially reduced with

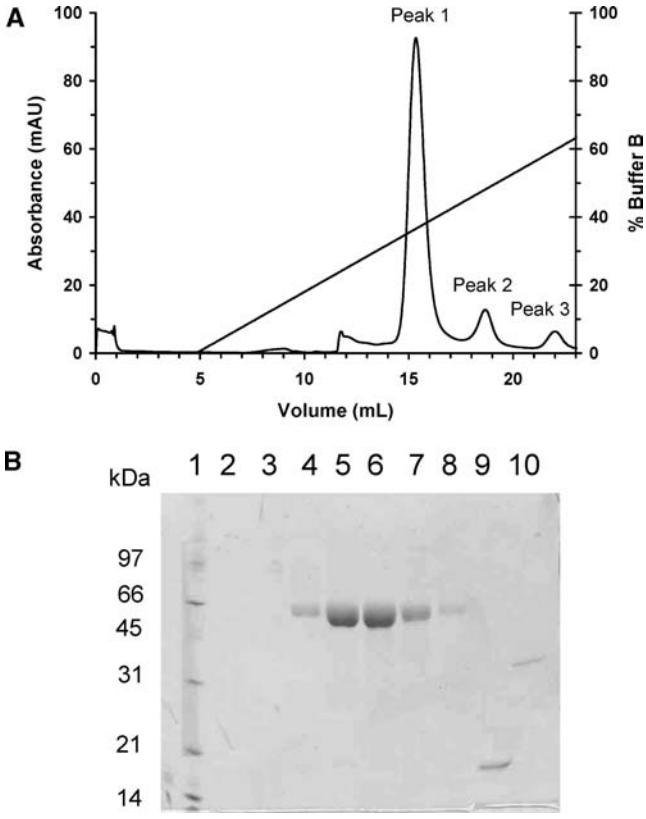

Figure 3. Column fractionation of PEG-M111C from unPEGylated protein. Panel A shows an S-Sepharose column chromatogram of the PEGylation reaction mixture. The large early-eluting peak (Peak 1) is PEG-M111C protein. The smaller trailing peaks represent unmodified M111C protein (Peak 2) and M111C protein dimers (Peak 3). Panel B shows nonreducing SDS−PAGE analysis of fractions from the various column peaks. Lane 1, molecular weight markers; lanes 2–8, fractions across Peak 1, which is monoPEGylated-M111C protein; lane 9, Peak 2, which is unmodified M111C protein; and lane 10, which is Peak 3 and corresponds to M111C protein dimers.

DTT to disrupt the mixed disulfide and allow the protein/maleimide-PEG reaction. The M111C protein PEGylated efficiently with 20 kDa and 40 kDa maleimide PEGs, with typical PEGylation efficiencies of 80% or greater (Figure 3). The PEGylated M111C protein was separated from unmodified protein by S-Sepharose column chromatography. An S-Sepharose column chromatogram of a typical PEGylation reaction with the M111C protein using a 20 kDa maleimide PEG is shown in Figure 3A. The PEG−protein is the large peak (Peak 1) that elutes earlier from the column than the unmodified protein (Peak 2) and disulfide-linked protein dimers (Peak 3) that form during the PEGylation reaction. SDS−PAGE analysis indicated that the PEG−protein peak was monoPEGylated protein (Figure 3B). Fractions consisting predominantly of the monoPEGylated-M111C protein were pooled. Nonreducing SDS−PAGE analysis of the purified M111C protein modified with 20 kDa and 40 kDa PEGs is shown in Figure 1.

Analysis of *in Vitro* Bioactivity of PEG-M111C. *In vitro* potency of the 20 kDa PEG-M111C protein in the Daudi cell growth inhibition assay was reduced less than 2-fold as compared to that of IFN-α2, whereas potency of the 40 kDa PEG-M111C protein was reduced about 3-fold relative to that of IFN-α2 (Figure 2B and Table 1). When potencies of the 20 kDA and 40 kDa PEG-M111C proteins were compared directly to PEG-Intron and PEGASYS in the Daudi cell assay, the PEG-M111C proteins exhibited *in vitro* potencies comparable to that of PEG-Intron and 7- to 10-fold greater than

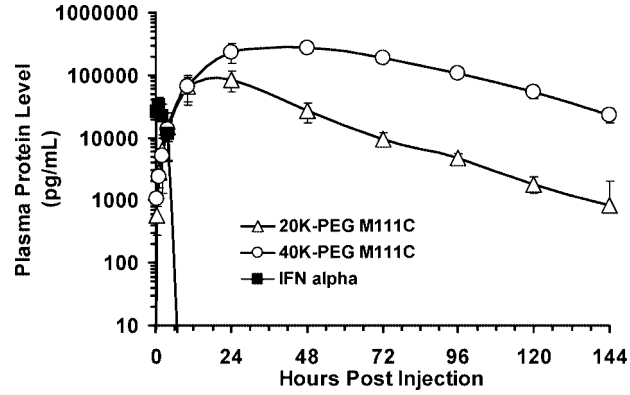

Figure 4. Plasma concentrations of PEG-M111C proteins and IFN-α2 (Roferon) following subcutaneous administration to rats. Data are means ± SD for three rats per group. Each rat received a 100 μg protein/kg subcutaneous dose. Plasma levels of the proteins were measured by ELISA.

that of PEGASYS (data not shown). Similar relative potencies of PEG-Intron, PEGASYS and IFN-α2 were reported previously (*19*).

Analysis of Pharmacokinetic Parameters of PEG-M111C Proteins in Rats. Circulating half-lives of the 20 kDa and 40 kDa PEG-M111C proteins were compared to that of wild type IFN-α2 (Roferon, Roche) following subcutaneous injection in rats (Figure 4). Circulating levels of the proteins were measured using human IFN-α2 ELISA kits. Plasma concentrations of wild type IFN-α2 peaked 1 h postadministration, then decreased rapidly, and were undetectable 10 h postadministration. The terminal half-life of IFN-α2 was 0.7 h, similar to the 1.2 h half-life for IFN-α2 reported previously (*21*). In contrast, maximum plasma levels of the PEG-M111C proteins were not attained until 24 h (20 kDa PEG-M111C) and 48 h (40 kDa PEG-M111C) postinjection (Figure 4). The maximum plasma level of the 40 kDa PEG-M111C protein (275 ng/mL) was higher than that of the 20 kDa PEG-M111C protein (84 ng/mL), both of which were higher than that of IFN-α2 (33 ng/mL). Similarly, the level of systemic exposure ($AUC_{0\rightarrow\infty}$) also was increased from 0.11 μg h/mL for IFN-α2 to 3.4 μg h/mL and 21 μg h/mL for the 20 kDa PEG and 40 kDa PEG-M111C proteins, respectively. Terminal half-lives for the 20 kDa PEG and 40 kDa PEG-M111C proteins were 18 h and 27 h, respectively.

Efficacy of 20 kDa PEG-M111C for Inhibiting Growth of Human Cancer Cells in Athymic Nude Mice. IFN-α2 inhibits the growth of a number of human tumor cell lines such as NIH:OVCAR-3 cells *in vitro* and *in vivo* in athymic mice (*23*). We compared the ability of IFN-α2 and the 20 kDa PEG-M111C protein to inhibit the growth of human NIH:OVCAR-3 tumor cells transplanted into athymic nude mice. The mice received an injection of 5×10^6 NIH:OVCAR-3 cells in Matrigel on day 0. Beginning on day 1, different groups of mice received 3×/week subcutaneous administration of vehicle solution (phosphate buffered saline containing 0.1 mg/mL of mouse serum albumin), wild type IFN-α2 prepared by us (5 μg/injection/mouse), or 20 kDa PEG-M111C (5 μg/injection/mouse). The mice received injections for 10 weeks, and tumor volumes were measured twice per week during this time. One group of control mice received no treatment injections (referred to as untreated controls).

Figure 5 shows the mean tumor volumes for the different test groups over time. Final tumor volumes, weights, and number of viable tumors at necropsy are summarized in Table 2. All of the test groups showed an initial decline in tumor volume through about day 13, which is likely due to absorption of the MEM media/Matrigel scaffold. From about day 13 until the end

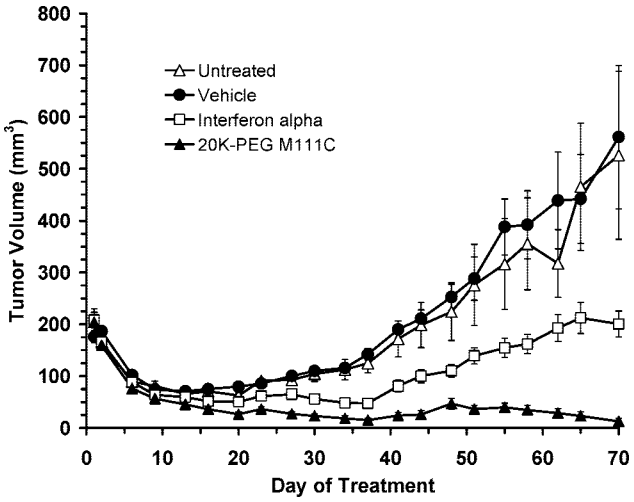

Figure 5. Inhibition of human tumor xenograft growth in athymic mice by PEG-M111C. Tumor volume (mm^3) is plotted vs day of treatment. Data are means ± SE for 9–11 mice per group, except for the untreated control group, which contained 5 mice. Athymic mice received an injection of 5×10^6 NIH:OVCAR-3 cells on day 0. The untreated control group received no further treatments. Mice in the other groups received 3×/week subcutaneous administrations of vehicle solution, wild type IFN-α2 prepared by us (5 μg/injection) or 20 kDa-PEG-M111C (5 μg/injection).

Table 2. Effects of 20 kDa PEG-M111C and IFN-α2 on Human Tumor Xenograft Volume and Weight in Mice after 70 Days of Treatment

treatment group[a]	tumor volume (mm^3)[b]	tumor weight (mg)[b]	animals with visible tumors at necropsy
untreated (5)	526 ± 162	346 ± 123	5/5
vehicle (9)	561 ± 139	354 ± 93	9/9
IFN-α2 (11)	201 ± 25[c]	94 ± 19[c]	11/11
PEG-M111C (11)	13 ± 7[c,d]	9 ± 5[c,d]	1/11

[a] The number of animals in each group is in parentheses. [b] The means ± SE for each group. [c] Significantly different from vehicle using the Mann–Whitney U test. [d] Significantly different from IFN-α2 using the Mann–Whitney U test.

of the study (day 70), mean tumor volumes increased in the untreated control animals and in animals receiving vehicle solution. At the termination of the study, mean tumor volumes and weights in animals receiving vehicle injections were comparable to those of the untreated control animals, indicating that the subcutaneous treatments and vehicle solution did not influence tumor growth in the animals. Mean tumor volumes in animals treated with PEG-M111C and IFN-α2 were significantly smaller (98% and 64%, respectively) than mean tumor volumes in animals treated with vehicle solution. Mean tumor volumes in animals treated with PEG-M111C were significantly smaller (94%) than mean tumor volumes in animals treated with IFN-α2. Tumor volumes in animals receiving 20 kDa PEG-M111C or IFN-α2 were significantly smaller than tumor volumes in animals receiving vehicle solution at all times from about day 16 to day 70. Mean tumor weights at necropsy (day 70) also were significantly reduced in animals receiving 20 kDa PEG-M111C (98% decrease) and IFN-α2 (73% decrease) compared to mean tumor weights in animals receiving injections of vehicle solution. Tumor weights were significantly smaller (90%) in animals treated with 20 kDa PEG-M111C compared to those of animals treated with IFN-α2. Only 1/11 animals in the group receiving 20 kDa PEG-M111C possessed a visible tumor mass at necropsy; the remaining animals showed an area of brown discoloration where the cells had been implanted. In contrast, all untreated control animals (5/5) and all animals receiving injections of vehicle solution (9/9) or IFN-α2 (11/11) had visible tumors at necropsy.

DISCUSSION

An earlier report (*21*) identified several regions in IFN-α2 where a cysteine residue can be introduced and modified with a 5 kDa PEG without appreciably reducing the bioactivity of the protein. One of these regions was the C−D loop, where M111 is located. Following analysis of several cysteine analogues in this region, the M111C protein was chosen for further analysis because it expressed well, displayed wild type *in vitro* biological activity, and PEGylated efficiently. The PEG-M111C protein retains high *in vitro* bioactivity in the Daudi cell growth inhibition assay even when modified with large 20 kDa and 40 kDa PEG moieties (within 2- to 4-fold of wild type IFN-α2). Similar results were reported with the PEG-Q5C protein in which PEG is attached to an amino acid located close to the amino-terminus of IFN-α2 (*21*). Preliminary studies indicate that the 20 kDa and 40 kDa PEG-M111C proteins also possess bioactivities comparable to that of wild type IFN-α2 in an *in vitro* antiviral assay using herpes simplex virus and human lung fibroblast cells (unpublished results). The high *in vitro* potencies of the 40 kDa PEG-M111C and 40 kDa PEG-Q5C (*21*) proteins stand in contrast to the results reported for amine-PEGylated IFN-α2, which shows at least a 14-fold loss of *in vitro* bioactivity (using either the Daudi cell assay or an antiviral assay) when modified with a 40 kDa PEG (*4, 19, 20*). These data and those of others (*4, 17, 19, 20*) indicate that loss of *in vitro* bioactivity upon PEGylation is not an inherent feature of IFN-α2, but is critically dependent upon the site at which the PEG is attached to the protein. The key receptor-binding contacts in IFN-α2 have been localized to the N-terminal end of the A−B loop, helices C and D, and the D−E loop of the protein (*19, 20, 22, 24–26*). The major sites for attachment of PEG in PEG-Intron and PEGASYS are located in these regions of the protein (K31 and H34 in the A−B loop; K83 in helix C; K121 and K131 in helix D; and K134 in the D−E loop). Although H34 retains acceptable activity when modified with a 12 kDa PEG, its activity decreases significantly when modified with a larger 30 kDa PEG (*19*). The low specific activities of these PEG-IFN-α2 isoforms probably results from the large PEG inhibiting proper receptor contacts. M111 and Q5C are located in regions of IFN-α2 that are distant from the identified receptor-binding domains of the protein, and modification of these residues with large PEG molecules seems to have little effect on *in vitro* bioactivity. PEGylation efficiency of M111C appears to be superior to that of the Q5C (*21*). According to details provided by the crystal structure of the protein, Q5 is partially buried in IFN-α2 (*22*), which may account for the lower PEGylation efficiency of Q5C. M111 is located in a surface-exposed, highly flexible region of IFN-α2 (*22, 25*), which may be more amenable to high PEGylation efficiency. Although we have not shown directly that the PEG is attached to the added cysteine in M111C (rather than to a native cysteine), several lines of evidence suggests that this is the case. First, the native C29−C138 disulfide is absolutely required for IFN-α2 bioactivity (*27*). Given the high specific activity of the PEG-M111C protein, it is unlikely that the C29−C138 disulfide is disrupted in the PEG-M111C protein. The C1−C98 native disulfide is not required for IFN-α2 bioactivity (*27, 28*), but PEG-IFN-α2 proteins in which C1 is PEGylated display greater than 10-fold loss of *in vitro* bioactivity (*19*), which is a much greater loss of activity than what we see with PEG-M111C. Random PEGylation of the native cysteines in IFN-α2 reduces *in vitro* bioactivity of the protein by 10- to 38-fold, depending upon whether the modified protein contains one or two PEGs and whether one or both of the native disulfides are disrupted (*29*). Again, this loss of activity is much greater than what we observe

with the PEG-M111C protein. The PEGylation reactions for the M111C protein also yielded predominantly monoPEGylated protein (Figure 3B). We would have expected to see significant amounts of multiply PEGylated species if we were reducing the native disulfides and PEGylating all of the cysteines in the protein. While these data strongly suggest that the PEG is attached to the added cysteine in M111C, detailed peptide mapping studies will be required to prove that this is the case.

The circulating half-life of the PEG-M111C protein varied depending upon the size of the attached PEG moiety, with 40 kDa PEG extending the half-life more than 20 kDa PEG. The 40 kDa PEG-M111C protein also took longer to reach peak plasma levels than the 20 kDa PEG protein, indicating that PEG size influences systemic absorption characteristics of the proteins. Peak plasma concentrations and overall systemic exposure of the proteins also were proportional to PEG size. Similar results were reported for the PEG-Q5C IFN-α2 analogue (*21*). The subcutaneous half-lives of the 20 kDa and 40 kDa PEG-M111C proteins in rats (18 and 27 h, respectively) were shorter than those reported for the 20 kDa and 40 kDa PEG-Q5C protein [27 and 48 h, (*21*)] and 40 kDa amine-PEG IFN-α2 [51 h, (*4*)]. Since half-lives of the proteins have not been compared in the same experiment or over the same time intervals, this result must be considered accordingly. Little is known about how PEG attachment sites influence the shape, hydrodynamic properties, and pharmacokinetic behavior of proteins.

The 20 kDa PEG-M111C protein strongly inhibited the growth of human NIH:OVCAR-3 tumor xenografts in mice when administered 3×/week and was significantly more effective than a comparable dose of IFN-α2, as measured by tumor volume, tumor weight, and the presence of detectable tumors at the termination of the study. Only 1/11 animals treated with PEG-M111C possessed a viable tumor at necropsy, as compared to 11/11 animals treated with IFN-α2 or 9/9 animals treated with vehicle solution. Lindner and Borden (*23*) reported that a daily injection of 5 μg of IFN-α2 inhibited the growth of NIH:OVCAR-3 cells transplanted into athymic mice by about 80% after 10 weeks of treatment. We found that administration of the same dose of IFN-α2 using a less frequent dosing schedule (3×/week) inhibited NIH:OVCAR-3 cell growth in mice by about 50%. Lindner and Borden (*23*) also reported that all of the mice treated with daily injections of IFN-α2 had viable tumors at necropsy, indicating a failure of IFN-α2 to completely suppress tumor growth *in vivo*. They were able to completely suppress tumor growth in the majority of mice by combining IFN-α2 treatment with the antiestrogen drug tamoxifen. Our data suggest that failure of IFN-α2 to completely suppress NIH:OVCAR-3 cell growth in athymic mice is not due to the inability of IFN-α2 to completely suppress tumor growth as a monotherapy, but rather is due to the short half-life of the protein, which results in suboptimal circulating levels of the protein in mice over time. Increasing the half-life of IFN-α2 by PEGylation or other means permits circulating IFN-α2 levels to remain at efficacious levels for longer periods of time, resulting in greater tumor cell death and fewer animals with viable tumors. The 20 kDa PEG-M111C protein, rather than the 40 kDa PEG-M111C protein, was used in the tumor xenograft study because the 20 kDa PEG protein may distribute more effectively from the blood stream into tissues, which is required to inhibit tumor growth in this model. (Human IFN-α2 is inactive in mice and exerts its antitumor effects by directly inhibiting the growth and/or viability of the human tumor cells.) Future tumor xenograft studies will compare the efficacy of the M111C protein modified with PEG molecules of different size.

This study and that of Bailon et al. (*4*) provide evidence that PEG-IFN-α2 proteins possess enhanced tumoricidal properties compared to IFN-α2 and complement studies indicating that PEG-IFN-α2 proteins possess enhanced antiviral properties (*8–12*). The enhanced therapeutic properties of PEG- IFN-α2 proteins likely are due to their longer half-lives and greater systemic exposure compared to those of IFN-α2. The long half-lives and superior efficacy of site-specifically PEGylated IFN-α2 proteins in animal tumor xenograft models support further evaluation of their potential as cancer therapeutics.

Received May 28, 2007; Revised Manuscript Received September 14, 2007

Synthetic vectors represent an alternative to recombinant viruses for gene transfer. We have recently explored the transfection potential of a class of noncationic lipids bearing thiourea moieties as DNA-associating headgroups. The encouraging results obtained with lipopolythioureas derived from serinol prompted us to further investigate this family of vectors. In the present study, we considered the transfection properties of a series of derivatives based on a different thiourea polar headgroup bearing a lysine scaffold. The synthesis of these compounds could be readily achieved in three steps with good yields. We found that these lipopolythioureas (LPT) might be considered as alternative systems for gene transfection since their activity reached the same magnitude range as that of cationic vectors in the presence of serum. LPT with 14-carbon length chains appeared to be more efficient as a transfecting agent than the ones with shorter chains. Toxicity studies proved that the hydration film method led to particles well tolerated both by the cells *in vitro* and by the mice *in vivo*. The ability to induce gene expression *in vivo* was demonstrated by intratumoral injection. Finally, biodistribution studies showed that the quantity recovered in blood circulation, 2 h after systemic injection, was improved as compared to that in cationic lipids.

INTRODUCTION

Gene delivery requires, in most cases, a vector to protect DNA from enzymatic degradation and to allow DNA cellular uptake. Synthetic (*1*) and viral vectors (*2*) are currently being developed as gene delivery systems. Among artificial vectors, cationic lipids (*3*) and polymers (*4*) are particularly attractive as they can be easily prepared and have been extensively characterized (*5*). However, their cationic charges lead to nonspecific interaction with anionic serum components, strongly decreasing their transfection efficiency (*6, 7*) and inducing unspecific delivery *in vivo* (*8*). Numerous studies have been undertaken to improve serum resistance by hiding the cationic charges (*9–11*). Alternative delivery systems have been introduced, using nonelectrostatic interaction with DNA. For instance, Aoyama et al. succeeded in trapping DNA in virus-like saccharidic clusters (*12*), and Barthelemy et al. developed nucleoside-based amphiphile-associating plasmids (*13*). However, with the exception of artificial glycovirus (*14*), these systems required a cationic charge to show some transfection activity *in vitro* (*15*). Strictly neutral systems, such as liposomes (*16*) or spherulites (*17*), have been worked out for gene delivery, but, to the best of our knowledge, they have not shown any transfection properties.

Recent studies from our laboratory (*18, 19*) demonstrated the feasibility of using bis-thiourea as a noncationic lipid headgroup for gene transfer both *in vitro* and *in vivo* (*20*). Thiourea moieties are strong hydrogen bond donors and are able to interact with a wide range of derivatives, including carbohydrates, carboxylates (*21*), and nitrate (*22*) and phosphate groups (*23*). This last acid derivative is known to lead to the strongest interactions (*24*). These properties, together with their structural potential variety, make them good candidates to develop alternative vectors for gene transfer based on nonelectrostatic interaction. In our growing interest in noncationic delivery systems based on thiourea interacting groups, we developed a new family of lipopolythiourea (LPT) lipids designed around a 2,6-bis(thiocarbamoyl-amino)hexanoic acid scaffold. The new transfecting agents, described here, are readily available from lysine. In this article, we describe the synthesis of these compounds, and present their transfection efficiency data, cytotoxicity studies, and *in vivo* behavior.

EXPERIMENTAL PROCEDURES

Materials and Methods. All solvents were purchased from Carlo Erba-SDS (Peypin, France). Dichloromethane was distilled from P_2O_5. DMF was dried over 3 Å molecular sieves and pyridine over KOH. All chemicals were purchased from Sigma-Aldrich-Fluka or Lancaster. Tosyl chloride (petroleum ether) and cholesteryl chloroformate (acetone) were recrystallized, and diglycolic anhydride was dehydrated (P_2O_5) prior to use. Other solvents and products were used without further purification. Reactions were monitored by thin-layer chromatography using Merck precoated 60 F254 silica gel plates. Column chromatography was performed over SDS (Peypin France) 35–70 m silicagel according to the method of Still, Khan, and Mitra (*25*) or by using small column flash chromatography (SFC) according to the following procedure: a plastic syringe was filled with silicagel (product/silicagel, 1/5) and connected to a vacuum pump. The column was equilibrated with heptane, then the sample, dissolved in a minimum of dichloromethane, was added to the top. The column was eluted by 10 fractions (volume equal to the silicagel volume) of a heptane/ethyl acetate mixture. For each fraction, the amount of ethyl acetate was increased (10% to 100% (v/v) heptane in ethyl acetate). Inverse phase SPE was performed on a Supelco Superclean C8 cartridge using an H_2O/CH_3CN/CH_3OH mixture. ^1H and ^{13}C NMR spectra were recorded on a BRUKER Avance DRX-300 spectrometer at 300.13 MHz for the proton and 75.47 MHz for the carbon. NMR spectra were processed using Xwinnmr (Bruker) or SwaN-MR (*26*). MS were carried out on a Shimazu 2010A LC-MS on ESI mode. High resolution MS and elemental analysis were carried out by the Service Central de Micro-analyse du CNRS, Vernaison, France. Dipalmytoylphosphatidylcholine (DPPC),

Dioleylphosphatidylethanolamine (DOPE), and phosphatidylethanolamine–lissamine rhodamine were purchased from Aventi Polar Lipids (Alabaster Alabama). Polyethyleneimine (PEI) was purchased from Sigma-Aldrich-Fluka. The lipopolyamine 2-{3-[bis-(3-amino-propyl)-amino]-propylamino}-*N*-ditetradecylcarbamoyl methyl-acetamide (RPR209120) was previously prepared in our laboratory, the synthesis is described in the supplementary information of ref *9*. The plasmid pVax1 was provided by Invitrogen.

Synthesis of Lipolythioureas.*(S)-tert-Butyl [1-(didecylcarbamoyl)-6-tert-butoxycarbonylamino-hexyl]aminoformate (***3a***).* *N*-hydroxysuccinimide (0.093 g, 0.81 mmol) and *N,N′*-dicyclohexylcarbodiimide (DCC) (0.42 g, 2.03 mmol) were added to a solution of acid **2** (0.28 g, 0.81 mmol) in dry THF (30 mL). The solution was stirred for 1 h before the addition of didecylamine **1a** (0.20 g, 0.68 mmol). The stirring was continued for 17 h, and then the reaction mixture was diluted with dichloromethane and washed twice with water. The organic layer was dried ($MgSO_4$) and evaporated under reduced pressure. The resulting oil was purified first by SFC and then by flash chromatography (heptane/ethyl acetate, 9/1) to yield **3a** as an oil (0.32 g, 63%). ^{1}H NMR ($CDCl_3$) δ 0.88 (t, 6H, J = 6.0 Hz, CH_3), 1.26 (m, 30H, $-CH_2-$), 1.43 (s, 9H, $(CH_3)_3$), 1.45 (m, 2H, $-CH_2-$), 1.55 (m, 4H, $-CH_2-$), 1.80 (m, 2H, CH_2), 3.11 (m, 2H, $-CH_2N$), 3.25 (m, 2H, $-CH_2N$), 3.47 (m, 2H, $-CH_2N$), 4.52 (m, 1H, CH), 4.54 (m, 1H, NH), 5.35 (d, 1H, J = 7.5 Hz, NH). ^{13}C NMR ($CDCl_3$) δ 14.11 (s, CH_3), 22.73 (m, $-CH_2-$), 27.05 (s, $-CH_2-$), 27.67 (s, $-CH_2-$), 28.45 (s, $(CH_3)_3$), 29.62 (m, $-CH_2-$), 31.95 (s, $-CH_2-$), 33.09 (s, CH_2), 40.51 (s, CH_2N), 46.10 (s, CH_2N), 47.86 (s, CH_2N), 49.92 (s, CH), 79.18 (s, $C(CH_3)_3$), 79.80 (s, $C(CH_3)_3$), 155.94 (s, OC=O), 156.31 (s, OC=O), 171.52 (s, NC=O).

*(S)-tert-Butyl [1-(didodecylcarbamoyl)-6-tert-butoxycarbonylamino-hexyl]aminoformate (***3b***).* *N*-hydroxysuccinimide (0.24 g, 2.05 mmol) and DCC (1.06 g, 5.1 mmol) were added to a solution of acid **2** (0.71 g, 2.05 mmol) in dry THF (60 mL). The solution was stirred for 2 h before the addition of didodecylamine **1b** (0.61 g, 1.72 mmol). Stirring was continued for 20 h, and then the reaction mixture was diluted with dichloromethane and washed twice with water. The organic layer was dried ($MgSO_4$) and evaporated under reduced pressure. The resulting oil was purified by flash chromatography (heptane/ethyl acetate, 95/5) to yield **3b** as an oil (0.65 g, 46%). ^{1}H NMR ($CDCl_3$) δ 0.84 (t, 6H, J = 6.0 Hz, CH_3), 1.22 (m, 38H, $-CH_2-$), 1.39 (s, 9H, $(CH_3)_3$), 1.49 (m, 2H, CH_2), 1.54 (m, 6H, $-CH_2-$), 3.06 (m, 2H, $-CH_2N$), 3.22 (m, 2H, $-CH_2N$), 3.45 (m, 2H, $-CH_2N$), 4.49 (m, 1H, CH), 4.68 (m, 1H, NH), 5.36 (d, 1H, J = 8.7 Hz, NH). ^{13}C NMR ($CDCl_3$) δ 14.09 (s, CH_3), 22.65 (m, $-CH_2-$), 26.99 (s, $-CH_2-$), 27.63 (s, $-CH_2-$), 28.42 (s, $(CH_3)_3$), 29.38 (s, $-CH_2-$), 29.62 (m, $-CH_2-$), 31.93 (s, $-CH_2-$), 33.81 (s, CH_2), 40.43 (s, $-CH_2N$), 46.07 (s, $-CH_2N$), 47.83 (s, $-CH_2N$), 49.89 (s, CH), 78.95 (s, $C(CH_3)_3$), 79.39 (s, $C(CH_3)_3$), 155.56 (s, OC=O), 156.03 (s, OC=O), 171.92 (s, C=O). MS (ESI, *m/z*) 682 $(M + H)^+$, 704 $(M + Na)^+$.

*(S)-tert-Butyl [1-(ditetradecylcarbamoyl)-6-tert-butoxycarbonylamino-hexyl]aminoformate (***3c***).* *N*-hydroxysuccinimide (0.17 g, 1.44 mmol) and DCC (0.74 g, 3.60 mmol) were added to a solution of acid **2** in dry THF (50 mL). The solution was stirred for 1 h before the addition of ditetradecylamine **1c** (0.50 g, 1.21 mmol). Stirring was continued for 20 h, and then the reaction mixture was diluted with dichloromethane and washed twice with water. The organic layer was dried ($MgSO_4$) and evaporated under reduced pressure. The resulting oil was purified by flash chromatography (heptane/ethyl acetate, 95/5) to yield **3c** as an oil (0.73 g, 67%). ^{1}H NMR ($CDCl_3$) δ 0.88 (t, 6H, J = 6.0 Hz, CH_3), 1.26 (m, 30H, $-CH_2-$), 1.44 (s, 9H, $(CH_3)_3$), 1.45 (m, 2H, CH_2), 1.58 (m, 6H, $-CH_2-$), 3.11 (m, 2H, $-CH_2N$), 3.25 (m, 2H, CH_2N), 3.49 (m, 2H, $-CH_2N$), 4.52 (m, 1H, CH), 4.54 (m, 1H, NH), 5.39 (d, 1H, J = 7.5 Hz, NH). ^{13}C NMR ($CDCl_3$) δ 14.17 (s, CH_3), 22.76 (m, $-CH_2-$), 27.05 (s, $-CH_2-$), 27.67 (s, $-CH_2-$), 28.45 (s, $(CH_3)_3$), 29.62 (m, $-CH_2-$), 31.94 (s, $-CH_2-$), 33.74 (s, CH_2), 40.40 (s, CH_2N), 46.10 (s, CH_2N), 47.85 (s, CH_2N), 49.90 (s, CH), 79.38 (s, $C(CH_3)_3$), 155.94 (m, OC=O), 171.85 (s, C=O). MS (ESI, *m/z*) 760 $(M + Na)^+$.

*(S)- 2,7-Diamino-N,N-didecyl-heptanamide (***4a***).* A solution of amide **3a** (1.31 g, 2.1 mmol) in dichloromethane (2 mL) was treated with a TFA/CH_2Cl_2 mixture (3:1, 8 mL). The reaction mixture was stirred for 24 h, then treated with solid $NaHCO_3$, filtered, and washed with water, and then 2 N NaOH was added to the aqueous phase until it reached a pH of 9. The water layer was extracted three times with dichloromethane. The organic layers were dried ($MgSO_4$) and evaporated under reduced pressure to yield **4a** (0.9 g, 100%) as a yellow oil, which was used without further purification. ^{1}H NMR ($CDCl_3$) δ 0.87 (t, 6H, J = 6.0 Hz, CH_3), 1.26 (m, 30H, $-CH_2-$), 1.55 (m, 6H, $-CH_2-$), 1.65 (m, 2H, CH_2), 2.03 (m, 4H, NH), 2.72 (m, 2H, CH_2NH_2), 3.11 (m, 2H, $-CH_2N$), 3.24 (m, 2H, CH_2N), 3.52 (m, 2H, CH), 5.40 (m, 1H, NH). δ 14.13 (s, CH_3), 22.74 (s, $-CH_2-$), 23.22 (s, $-CH_2-$), 27.08 (s, $-CH_2-$), 27.78 (s, $-CH_2-$), 29.62 (m, -CH2-), 31.94 (s, $-CH_2-$), 33.06 (s, CH_2), 41.74 (s, CH_2NH_2), 46.28 (s, CH_2N), 47.55 (s, CH_2N), 51.17 (s, CH), 173.05 (s, C=O).

*(S)- 2,7-Diamino-N,N-didodecyl-heptanamide (***4b***).* A solution of amide **3b** (0.65 g, 0.95 mmol) in dichloromethane (2 mL) was treated with a TFA/CH_2Cl_2 mixture (3:1, 5 mL). The reaction mixture was stirred for 3 h, and then it was treated with solid $NaHCO_3$, filtered, and washed with water. NaOH (2 N) was added to the aqueous phase until it reached a pH of 9. The water layer was extracted three times with dichloromethane. The organic layers were dried ($MgSO_4$) and evaporated under reduced pressure to yield **4b** (0.5 g, 100%) as a yellow oil, which was used without further purification. ^{1}H NMR ($CDCl_3$) δ 0.86 (t, 6H, J = 6.0 Hz, CH_3), 1.23 (m, 38H, $-CH_2-$), 1.49 (m, 6H, $-CH_2-$), 2.94 (m, 2H, CH_2NH_2), 3.11 (m, 4H, CH_2N), 3.80 (m, 2H, CH), 6.24 (m, 4H, NH). ^{13}C NMR ($CDCl_3$) δ 14.09 (s, CH_3), 21.89 (s, $-CH_2-$), 22.71 (s, $-CH_2-$), 27.12 (s, $-CH_2-$), 27.51 (s, $-CH_2-$), 29.70 (m,–CH2–), 31.96 (s, $-CH_2-$), 33.94 (s, CH_2), 39.16 (s, CH_2NH_2), 46.50 (s, CH_2N), 47.72 (s, CH_2N), 50.73 (s, CH), 173.10 (s, C=O). MS (ESI, *m/z*) 483 $(M + H)^+$, 262 $((M + 2H + 2Na)/2)^+$.

*(S)-2,7-Diamino-N,N-ditetradecyl-heptanamide (***4c***).* A solution of amide **3c** (0.73 g, 1 mmol) in a TFA/CH_2Cl_2 mixture (4:1, 5 mL) was stirred for 3 h. Then the reaction mixture was treated with solid $NaHCO_3$, filtered, and washed with water. NaOH (2 N) was added to the aqueous phase until it reached a pH of 9. The water layer was extracted three times with dichloromethane. The organic layers were dried ($MgSO_4$) and evaporated under reduced pressure to yield **4c** (0.36 g, 68%) as a yellow oil, which was used without further purification. ^{1}H NMR ($CDCl_3$) δ 0.86 (t, 6H, J = 6.0 Hz, CH_3), 1.23 (m, 30H, $-CH_2-$), 1.47 (m, 6H, $-CH_2-$), 1.88 (m, 2H, CH_2), 2.81 (m, 2H, CH_2NH_2), 3.10 (m, 2H, CH_2N), 3.24 (m, 2H, CH_2N), 3.47 (m, 2H, CH), 5.40 (m, 1H, NH). ^{13}C NMR ($CDCl_3$) δ 14.12 (s, CH_3), 22.72 (m, $-CH_2-$), 27.10 (s, $-CH_2-$), 27.70 (s, $-CH_2-$), 29.70 (m, $-CH_2-$), 31.97 (s, $-CH_2-$), 34.00 (s, $-CH_2-$), 40.91 (s, CH_2NH_2), 46.33 (s, CH_2N), 47.58 (s, CH_2N), 51.48 (s, CH), 171.85 (s, C=O). MS (ESI, *m/z*) 539 $(M + H)^+$.

*(S)-2,7-Bis[(2,2-dimethyl-1,3-dioxolan-4-yl)methylthiocarbamoylamino]-N,N-didecyl-heptanamide (***6a***).* A solution of amine **4a** (0.21 g, 0.5 mmol) and *N,N*-diisopropylethylamine (0.87 mL, 5 mmol) in dichloromethane (5 mL) was stirred for 10 mn before the addition of isothiocyanate **5** (0.22 g, 1.3 mmol). The reaction mixture was stirred overnight and evaporated under reduced pressure. Purification of the crude by SFC

afforded **5a** (0.32 mg, 83%) as a colorless oil. ^{1}H NMR ($CDCl_3$) δ 0.86 (t, 6H, J = 6.0 Hz, CH_3), 1.24 (m, 32H, –CH_2–), 1.31 (s, 6H, $(CH_3)_2$), 1.33 (s, 6H, $(CH_3)_2$), 1.43 (m, 4H, –CH_2–), 1.66 (m, 2H, –CH_2–), 3.20 (m, 4H, CH_2NCO), 3.45 (m, 2H, CH_2NCS) 3.68 (m, 4H, CH_2NCS), 4.01 (m, 4H, CH_2O), 4.27 (m, 4H, CHO), 5.55 (m, 1H, CH), 6.85 (m, 2H, NH), 7.85 (m, 2H, NH). ^{13}C NMR (CDCl3) δ 13.98 (s, CH_3), 22.72 (s, –CH_2–), 23.40 (s, –CH_2–), 25.30 (s, $(CH_3)_2$), 27.05 (s, $(CH_3)_2$), 27.71 (s, –CH_2–), 28.76 (s, –CH_2–), 29.38 (s, –CH_2–), 29.66 (m, –CH_2–), 31.95 (s, –CH_2–), 33.70 (s, CH_2), 44.58 (s, CH_2NCS), 46.78 (m, CH_2NCS, CH_2N), 48.70 (s, CH_2N), 53.77 (s, CH), 68.67 (s, CH_2O), 75.05 (s, CHO), 109.50 (s, $CO_2(CH_3)_2$), 172.91 (s, C=O), 183.26 (s, C=S). Anal. Calcd for $C_{40}H_{77}N_5O_5S_2$: C, 62.22; H, 10.05; N, 9.07; S, 6.30. Found: C, 62.17; H, 10.17; N, 8.94; S, 7.07. MS (ESI, *m/z*) = 794 $(M + Na)^+$, 770 $(M - H)^-$, 808 $(M + Cl)^+$.

*(S)-2,7-Bis[(2,2-dimethyl-1,3-dioxolan-4-yl)methylthiocarbamoylamino]-N,N-didodecyl-heptanamide (***6b***).* A solution of amine **4b** (0.24 g, 0.5 mmol) and *N,N*-diisopropylethylamine (0.44 mL, 2.5 mmol) in dichloromethane (2 mL) was stirred for 10 min before the addition of isothiocyanate **5** (0.095 g, 0.55 mmol). The reaction mixture was stirred overnight and evaporated under reduced pressure. Purification of the crude by SFC afforded **6b** (0.23 g, 55%) as a colorless oil. ^{1}H NMR ($CDCl_3$) δ 0.87 (t, 6H, J = 6.0 Hz, CH_3), 1.25 (m, 40H, –CH_2–), 1.32 (s, 6H, $(CH_3)_2$), 1.34 (s, 6H, $(CH_3)_2$), 1.44 (m, 4H, –CH_2–), 1.68 (m, 2H, –CH_2–), 3.21 (m, 4H, CH_2NCO), 3.47 (m, 2H, CH_2NCS) 3.70 (m, 4H, CH_2NCS), 4.05 (m, 4H, CH_2O), 4.29 (m, 4H, CHO), 5.59 (m, 1H, CH), (m, 2H, NH), 7.86 (m, 2H, NH). ^{13}C NMR (CDCl3) δ 14.13 (s, CH_3), 22.73 (s, –CH_2–), 25.27 (s, $(CH_3)_2$), 26.87 (s, $(CH_3)_2$), 27.71 (s, –CH_2–), 28.71 (s, –CH_2–), 29.07 (s, –CH_2–), 29.68 (m, –CH_2–), 31.98 (s, –CH_2–), 33.68 (s, CH_2), 44.58 (s, CH_2NCS), 46.76 (m, CH_2NCO, CH_2NCS), 48.63 (s, CH_2NCO), 53.77 (s, CH), 66.63 (s, CH_2O), 75.01 (s, CHO), 109.62 (s, $CO_2(CH_3)_2$), 172.76 (s, C=O), 183.23 (s, C=S). Liposome Preparation.*Ethanolic Injection Method.* Lipopolythiourea and DPPC were dissolved in ethanol and were added dropwise to 10 volumes of water under vigorous agitation. The mixture was stirred overnight and then evaporated under reduced pressure at room temperature to obtain a solution of liposomes.

For example, compound **6c** (1.77 mg, 2 μmol) and DPPC (1.47 mg, 2 μmol) were dissolved in 300 μL of ethanol. This solution was added dropwise into 3 mL of stirred, filtered water. The mixture was stirred overnight then evaporated under reduced pressure at RT to obtain a clear suspension of **6c/DPPC** (0.380 mL, 10.5 mM total lipids).

Film Hydration Method. Lipopolythiourea and DPPC were dissolved in chloroform. The solvent was evaporated slowly under vacuum to obtain a thin film on the glass. Water was then added to hydrate the lipids and obtain a solution of liposomes.

For example, compound **6c** (4.0 mg, 4.5 μmol) and DPPC (3.2 mg, 4.3 μmol) were dissolved in chloroform (500 μL). The solvent was evaporated slowly under vacuum to obtain a thin film on the glass. Water (430 μL) was then added to hydrate the lipids and obtain a solution of liposomes (20 mM total lipids).

Size Measurement. Particle diameter was determined by dynamic light scattering on Zeta Sizer NanoSeries Malvern (Malvern Instruments, France). Concentration of the lipids = 0.1 mM in H_2O, and the mean value of 3 runs is given (1 min equilibration, 3 min run).

Preparation of Plasmid DNA. pVax2 is a derivative of the commercial plasmid pVax1 (InVitrogen). pVax1 was digested with the restriction enzymes HincII and *Bam*HI to excise the promoter. The plasmid was then blunted with the Klenow fragment and dephosphorylated with alkaline phosphatase. pCMVbeta (Clontech) was digested with EcoR1 and *Bam*HI to excise the CMV promoter. The CMV promoter was blunted with the Klenow enzyme and ligated into the blunted pVax1 to give pVax2. The plasmid pXL3031 was digested with *Eco*RI and *Bam*HI, and then treated with the Klenow fragment to produce a blunted fragment containing luciferase cDNA. This fragment was ligated into pVax2 after EcoRV digestion and phosphatase alkaline dephosphorylation to give pVax2-Luc.

Preparation of LPT/DNA Complexes. Plasmid DNA (pVax2-luc, 100 μL, 0.02 g/L in H_2O), prepared using the procedure described above, was added dropwise with constant vortexing to various amounts of LPT/DPPC liposomes (in 100 μL of H_2O) at RT. TU/P indicates the ratio in nmol of thiourea function (2 per lipid) versus DNA phosphates. Cationic lipoplexes were formed in the same way from RPR209120/DOPE liposomes (1/1, hydration film method, 4 nmol in 100 μL of 150 mM NaCl) mixed with plasmid DNA at a ratio of N/P = 8 (0.5 μg in 100 μL 150 mM NaCl). PEI/DNA polyplexes were prepared from PEI (1 μg in 100 μL of 5% glucose) mixed with plasmid DNA (0.5 μg in 100 μL 5% glucose) at an N/P ratio = 15.

Gel Retardation Experiments. Complexes were prepared as described above with liposomes made by ethanolic injection (20 μL), and 5 μL of bromophenol blue were added. The mixture was loaded onto a 0.8% agarose gel in TBE buffer (1 M Tris, 0.9 M boric acid, 0.01 M EDTA) at 80 V/cm. DNA was revealed with ethidium bromide and visualized under UV light.

DNA Protection. Twenty microliters of culture medium (MEM with 10% or 50% murine fresh serum) were added to 20 μL of LPT/DPPC/DNA complexes (0.1 g/L DNA, prepared by ethanolic injection) or to cationic lipoplexes made of RPR209120 (0.1 g/L DNA). Samples were incubated at 37 °C. After 6 h, 10 μL of samples were frozen at −20 °C. After 24 h, all the samples were replaced at RT. SDS 2% (5 μL), EDTA (2 μL, 0.5 M), and bromophenol blue (3 μL) were added to each sample (10 μL). The mixture was loaded onto 1% agarose gel containing 0.05% SDS at 80 V/cm. After 24 h of washing in

water, DNA was revealed with ethidium bromide and visualized under UV light.

Transfection Method. B16 murine cells were grown into DMEM supplemented with L-glutamin (29.2 mg/mL), penicillin (50 units/mL), streptomycin (50 units/mL), and 10% fetal bovine serum. One day before transfection, cells were treated with trypsin and deposited into 24-well plates (45,000 cells/well) and incubated for 24 h at 37 °C. Then, 100 μL of LPT/DNA complexes (prepared by ethanolic injection), 100 μL of RPR209120/DOPE/DNA (prepared as above, ratio N/P = 8), and PEI/DNA polyplexes (prepared as above, ratio N/P = 15), all formulations corresponding to 0.5 μg DNA, were loaded onto each well, and the plates were incubated at 37 °C for 48 h. Then the cells were washed twice with PBS and treated with 200 μL of a passive lysis buffer (Promega). After 15 min, the cells were centrifuged for 5 min at 12,000 r/min. Supernatant (10 μL) and iodoacetamide (10 μL) were added to a 96-well plate, which was incubated at 37 °C for 1 h. Protein quantification was performed with the BCA protein assay KIT (PIERCE) and reported to BSA taken as a reference curve. Luciferase activity was quantified using a commercial kit Luciferase assay system (PROMEGA). On 10 μL of the lysed cells, 50 μL of the luciferase substrate was injected via an injector, and the absorbance was read immediately at 563 nm on a Wallac Victor2 1420 Multilabel Counter (Perkin Elmer).

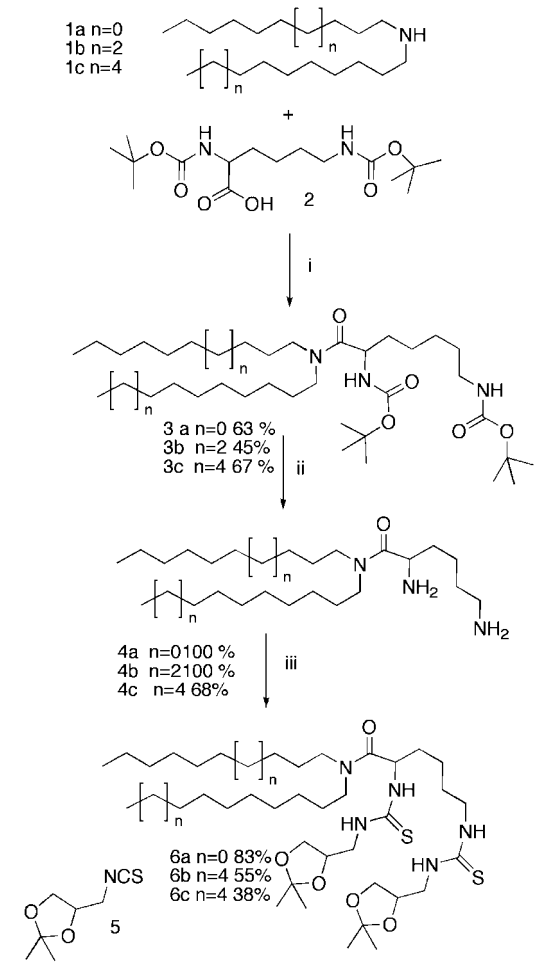
Cytotoxicity on B16 Murine Cells. Murine B16 melanoma cells were grown in DMEM containing 2 mM L-glutamine, 10% fetal bovine serum, 100 U/mL penicillin, and 100 μg/mL streptomycin (37 °C, 5% CO_2). Exponentially growing B16 cells were plated onto 96-well plates at 5000 cells per well in 100 μL of culture medium. Twenty-four hours after plating, 100 μL of medium containing the compound of interest (final concentrations ranging from 1.56 μg/mL to 100 μg/mL, in 2-fold dilutions) was added to the wells (in triplicate) containing the cells and incubated for 48 h at 37 °C and 5% CO_2. After the 48 h exposure period to the test compounds, cell viability was assayed using the MTT test (*27*), and absorbance was read at 562 nm in a microplate reader (BioKinetics Reader, EL340). Appropriate controls with DMEM only and MTT were run to substract background absorbance. Results are presented as percent of controls cells. The concentration of compound that inhibited cell viability by 50% (inhibitory concentration for 50% of cells, or IC_{50}) was determined using the GraphPad Prism software. Results are presented as means ± SEM of 6 independent experiments, each run in triplicate.

***In Vivo* Acute Toxicity Test. 6c**/DPPC particles (0.75 μmol, 200 μL) were injected into Swiss mice tail veins (3 mice for the sample, 3 mice control). The weight, behavior pattern, skin and fur modifications, and somatomotor activity of the animals were observed daily over 16 days (*28*). The dose was considered as toxic if the weight was lower than 80% of that of the controlled mice.

Intratumoral Injection. 6c/DPPC/DNA (40 μL, 10 μg DNA, 40 TU/P, TU/P = mol thiourea functions/mol DNA phosphate group) and RPR209120/DOPE/DNA (prepared as described above; ratio N/P = 6) were injected into 3LL tumors of 3 mice C57BL\6 bearing 3LL tumors. Mice were sacrificed 24 h after injection, then tumors were removed, weighed, crushed in 1 mL of lysis buffer, and centrifuged for 10 min (12,000 rpm, 4 °C). The supernatant (50 μL) was loaded onto a 96-well plates, and luciferase activity was quantified using a commercial kit (Protein Assay). The absorbance was read at 563 nm on a Wallac Victor2 1420 Multilabel Counter (Perkin Elmer).

Biodistribution Study. Experiments were conducted following NIH recommendation for animal experimentation. Rhodamine-labeled **6c**/DPPC/DNA complexes (200 μL, 11 μg DNA, 40 TU/P) were injected into the tail veins of five mice C57BL\6 bearing 3LL tumors. Blood was collected by cardiac puncture after 2 h, and mice were euthanized after samples were obtained. In the distribution study, liver, lungs, spleen, and tumors were removed, weighed, and homogenized in phosphate-buffered saline (PBS, 5 mL/g tissue) at pH 7.4 . Rhodamine-labeled lipids were extracted as previously described (*29*) from 100 μL of blood or tissue homogenates with 3 mL of $CHCl_3$-CH_3OH (1:1, v/v) by vigorous mixing for 30 min for blood and 45 min for tissue homogenates followed by centrifugation (1000 rpm, 10 min). The fluorescence intensity corresponding to rhodamine was assayed on the supernatant with a fluorospectrophotometer (Victor, Perkin Elmer_Wallac multiplate reader; λ_{exc}, 530 nm; λ_{em}, 570 nm). The amount of complexes in the blood or tissue homogenates was evaluated with a calibration curve of the initial **6c**/DPPC/DNA complexes containing 0.5% LPT-rhodamine and expressed as the remaining percentage of injected dose.

Scheme 1. Preparation of Lipopolythiourea[a]



[a] (i) NHS, DCC, THF, RT. (ii) TFA, CH_2Cl_2, RT. (iii) DIPEA, **5**, CH_2Cl_2, RT.

RESULTS

Chemistry. The lipopolythioureas were prepared as shown in Scheme 1. The synthesis started from boc lysine **2** that reacted with dialkylamine **1a**, **1b**, and **1c** to yield dialkylamide **3a–c** (45 to 67%). Boc removal using TFA in dichloromethane led to diamines **4a–c** in good yields (100, 100, and 68%, respectively). Treatment of the diamine with isothiocyanate **5** afforded the protected thioureas (**6a**, 83%; **6b**, 55%; **6c**, 38%). Attempts to remove the acetal group failed, giving only the starting alkylamine **1**. This result suggests a rearrangement leading to a

Table 1. Formulation and DNA association with lipopolythiourea 6a, 6b, and 6c[a]

LPT	chain length	formulation (ethanolic injection)	diameter (nm)	PDI	TU/P for DNA association	LPT/DNA diameter (nm)	PDI
6a	10 C	**6a**/DPPC 1/1	76.5 ± 11	0.337	40	96 ± 2	0.253
6b	12 C	**6b**/DPPC 1/1	102 ± 8	0.329	20	122 ± 6	0.165
6c	14 C	**6c**/DPPC 1/1	141 ± 50	0.239	10	164 ± 3	0.115

[a] The diameter is given as the mean of 3 values. PDI: polydispersity index. TU/P for DNA association is the number of thiourea/DNA phosphate ratio needed to retain DNA in the wells of an agarose gel. The diameters of LPT/DNA complexes are given as the ratio needed for the association.

cyclic thiourea under protic catalysis since such cyclic compounds have been described in literature (*30*). However, despite our efforts, we were unable to identify such a compound.

Formulation Study and DNA Association. The three compounds prepared **6a**, **6b**, and **6c** exhibit the same thiourea headgroup and differentiate themselves by their lipidic length, varying from 10 to 12 to 14 carbons, respectively. First, we tried to evaluate if their hydrophilic/lipophilic balance would allow the formation of homogeneous particles. This was achieved thanks to the adjunction of dipalmytoyl-phosphatidylcholine (DPPC) at a ratio 1 to 1 with the polythiourea lipid. Particle diameter is given in Table 1. The diameter was slightly higher for **6c** as compared to those of **6b** and **6a.** Also, the suspension formed was more homogeneous with compound **6c**, as shown by the polydispersity index. This might suggest a better interaction of compound **6c** with DPPC due to its longer chain length.

Addition of DNA to these particles induced a slight increase in particle diameter. LPT/DNA interaction was evidenced by this size increase along with gel electrophoresis. We relate in Table 1 the ratio between the thiourea and the phosphate functions (TU/P) needed to fully retain DNA on the wells of an agarose gel. As can be seen, all LPT were able to complex the plasmid. Moreover, the longer the lipid chain, the less the amount of LPT needed to obtain a full interaction with DNA, reaching a minimum for **6c** (10 TU/P). This could be linked to the homogeneity of the suspension obtained when DPPC was mixed with lipid **6c**.

Lipoplex Sensitivity to Serum. The complexes formed between LPT and DNA have been submitted to a treatment in fresh mice serum at 37 °C for 6 h and 24 h, and then loaded on a denaturing agarose gel. As observed in Figure 1, free plasmid DNA was partially degraded after 6 h and fully degraded after 24 h under these conditions, whereas complexed DNA was still intact. With regard to the sensitivity of the technique, no difference between the three lipids could be detected. These results confirm that the interaction occurring between LPT and DNA is strong enough to protect plasmid DNA from degradation in the presence of serum.

Transfection Efficiency *in Vitro.* Compounds **6a**, **6b**, and **6c** were further evaluated for their transfection activity. Since the aim of these nonelectrostatic systems is to improve *in vivo* gene delivery, we carried out *in vitro* studies as preliminary tests for *in vivo* experiments. Thus, we performed the experiments in the presence of serum with particles of nanometric size. Two different TU/P ratios were evaluated for the three different formulations and compared to the cationic lipid (RPR209120) (*31*) and the cationic polymer PEI (*32*) (Figure 2) mixed with DNA.

As can be seen in Figure 3, transfection efficiency was dependent on the LPT used. Hence, higher transfection activity was obtained when increasing the lipid length from 10 to 14 carbons, from **6a** to **6c**, respectively. Moreover, increasing the amount of LPT, from TU/P = 20 to 40, also led to improved

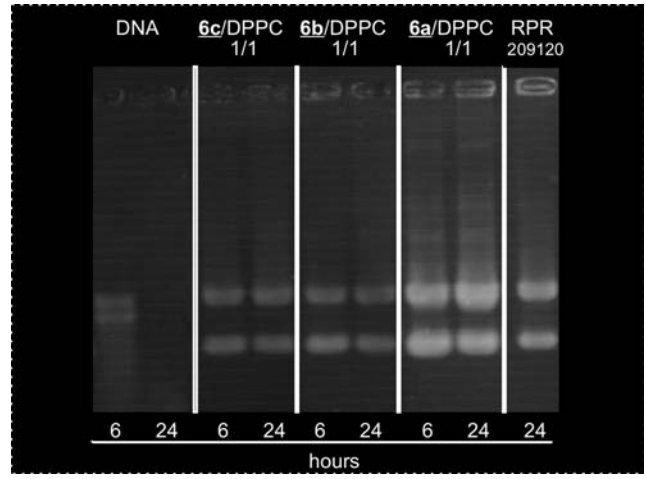


Figure 1. Lipoplex sensitivity to serum. Complexes LPT/DNA (20 LPT/P, prepared by ethanolic injection) as well as the cationic lipoplexes RPR209120/DOPE/DNA were incubated for 6 and 24 h in 10% serum at 37 °C, then treated with 2% SDS and 0.5 M EDTA, and loaded onto a 1% agarose gel containing 0.05% of SDS (80V/cm) in TBE (1×) . Complexes were revealed by ethidium bromide staining.

transfection. However, for higher LPT amounts, we observed a decrease of the protein amount, suggesting some cytotoxicity.

Cytotoxicity. In order to reduce cytotoxicity, we have studied the effect of different formulation protocols. Particles mentioned in the previous experiments were formulated via an ethanolic injection protocol (*33*). We also prepared LPT particles via the film hydration method (*34*). After preparation, we submitted the cells to an MTT test and compared the IC_{50} values of the two different formulations. As can be seen in Figure 4, the cytotoxicity IC_{50} obtained for compound **6a** formulated via an injection method was 15 μM, while no toxicity could be measured when the same compound was formulated via the hydration method. This significant reduction of toxicity might be due to the reduction of the number of thiourea presented at the surface of the liposome since multilamellar vesicles (MLV) are formed by the hydration method, whereas unilamellar vesicles (SUV) are obtained by ethanolic injection (*35*). The *in vitro* efficiency of theses complexes was also evaluated and showed slightly the same level of transfection as compared to the previous one (9900 RLU/μg protein for a ratio TU/P = 20). This good tolerance prompted us to use the hydration method for the following *in vivo* studies.

According to the *in vitro* cytotoxicity results, we evaluated the *in vivo* toxicity of the least toxic and most efficient formulation: **6c**/DPPC, prepared by the hydration film method. The formulation was injected once at $t = 0$, then the weight of the mice as well as different toxicity signs, such as locomotion, behavior, and changes in skin and fur, were followed over a period of 2 weeks. The formulations were considered as nontoxic if weight loss was lower than 20% as compared to that of control mice. The formulation **6c**/DPPC prepared via the hydration method displayed an excellent tolerance since the somatomotor activity, the behavior pattern, and skin and fur characteristics were unchanged as assayed over a period of 16 days. The weight also remained stable from 98.6% at day 2, to 97.6% at day 5, to 98.65% of the controls at day 16.

***In Vivo* Properties.** The absence of toxicity for the formulation **6c**/DPPC prompted us to further investigate the *in vivo* behavior of these particles.

First, we evaluated the transfection activity of the formulation **6c**/DPPC after intratumoral injection and compared it (*36*) to the lipoplexes composed of the lipopolyamine RPR209120. We did not observe a significant difference between the two

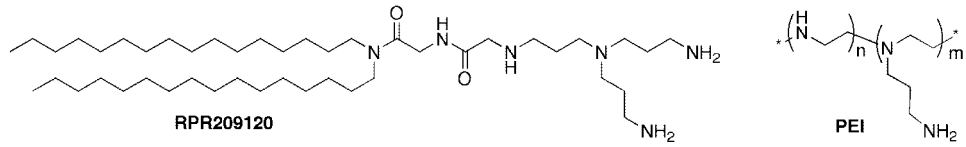

Figure 2. 2-{3-[Bis-(3-amino-propyl)-amino]-propylamino}-*N*-ditetradecylcarbamoyl methyl-acetamide (RPR209120) and polyethyleneimine (PEI) used as reference transfecting agents.

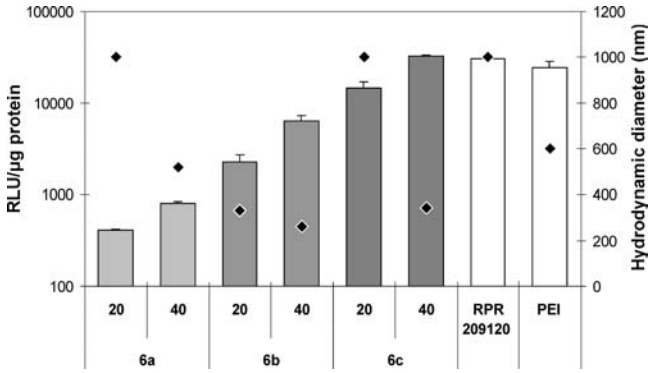

Figure 3. *In vitro* transfection results. Hydrodynamic diameter (lozenge symbols, right scale) and gene transfection (bars, left scale), measured by luciferase activity of LPT/DNA complexes at 20 and 40 TU/P ratios after 48 h of incubation on B16 cells in the presence of serum. LPT/DNA complexes were prepared by ethanolic injection at 20 and 40 TU/P in H_2O. RPR209120/DOPE/DNA lipoplexes was prepared at an N/P ratio = 8 in 150 mM NaCl. PEI/DNA polyplexes were prepared at N/P = 15 in 5% glucose. The complexes were then added to the cells in DMEM + 10% FBS at 37 °C. Results are expressed as the mean of an experiment performed in triplicate, with the error bars indicating the standard error of the mean.

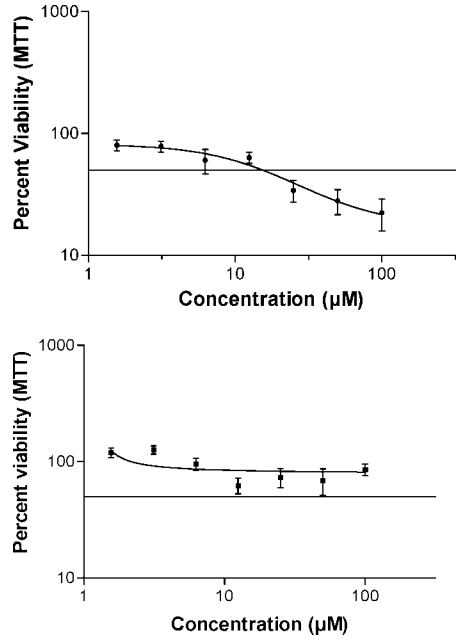

Figure 4. Cytotoxicity *in vitro*. IC_{50} of **6c**/DPPC formulated by (left) ethanolic injection (IC_{50} = 14.96 μM) and (right) hydration method, determined by a MTT test on B16 cells *in vitro*.

formulations; both were able to induce luciferase activity 24 h postinjection.

Biodistribution of **6c**/DPPC was evaluated by the introduction of a fluorescent lipid marker and compared to a cationic formulation of the lipopolyamine RPR209120/DOPE prepared via an identical hydration film procedure. Two hours after injection, different organs were removed and assessed for their fluorescence content. As shown in Figure 5a, significative gain of a factor of 4 to 5 ($p < 0.01$) was obtained in the blood circulation particles using the neutral **6c**/DPPC formulation as compared to the cationic one. Despite this higher circulation time in blood, no significant difference was found in tumor localization. Furthermore, an important difference was observed in the lung ($p < 0.01$). Nonspecific accumulation of the particles in the lung, which has often been reported for cationic particles (*37*), did not occur in the case of the LPT formulation. A similar amount was found in the liver for the two formulations, which was expected because elimination by Kupffer cells is mostly related to particle size (*38*).

DISCUSSION

The above data show that the described lysine-derived polythiourea mixed with DPPC are able to associate to plasmid DNA, to protect it from degradation in the presence of serum and to induce gene expression in cultured cells. Transfection efficiency was shown to be chain-length dependent, the lipid **6c** bearing the longer chain exhibiting the highest transfection activity. Some results have shown that a shorter chain was more appropriate for optimized transfection (*39*). We had also observed that with a lipopolythiourea bearing a serinol headgroup (*20*). Figure 6 represents the comparison of the *in vitro* results mediated by the two lipopolythiourea families. It shows that indeed the transfection level is reversed between the two LPT families: the shorter chain is preferable for the serinol thiourea lipids (compounds **Ia**–**Ic**, Figure 7), while the longer chain is preferable for the lysine thiourea lipids. That could be related to the improved hydrophilic/lipophilic balance in the lipid. In this work, the hydrophobic nature of the LPT required the use of a colipid, and obviously, the colipid effect is of great importance, as was previously reported (*40*). Mixing LPT with DPPC (bearing 16 carbons in the alkyl chain) might be more appropriate for the LPT **6c**, inducing improved lipid packing as the chain length of the LPT increases from 10 to 14 carbons. Indeed, suspension polydispersity decreased from the formulation **6a**/DPPC to **6c**/DPPC. The shorter chain LPT might create disorder in the lipid bilayer, eventually leading to unstable particles (*41*). Alternatively, we can hypothesize that the bulky and unsymmetrical LPT headgroup might also interfere with lipid packing and that a stronger hydrophobic interaction between LPT and the colipid might counterbalance headgroup interference.

Despite its structure, this lysine-based uncharged headgroup allowed for efficient interaction with DNA at an LPT/DNA ratio similar to the one previously obtained for LPT bearing a serinol headgroup (TU/P = 15). This ratio was the lowest for the formulation **6c**/DPPC, as compared to that for **6b** and **6a**, which is probably related to the more homogeneous structure formed between lipid **6c** and DPPC.

The most efficient transfection obtained with lipid **6c** was higher than the previously reported serinol LPT at the ratio used (*20*) (Figure 6) and comparable to that of cationic formulations in the presence of serum. This is of particular interest considering that LPT formulations exhibit no positive charges and might interact less favorably with the anionic cell membranes. The absence of cationic charges was also confirmed by the *in vivo* improved kinetic properties of LPT/DNA complexes, which avoided nonspecific accumulation in the lung and blood

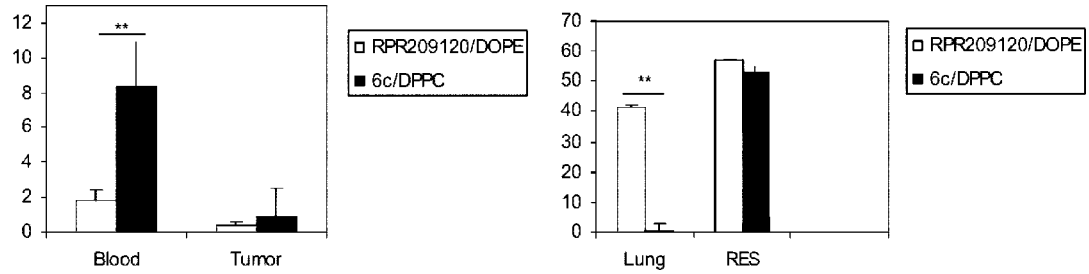

Figure 5. Biodistribution of rhodamine-labeled particles 2 h after intravenous injection in mice bearing 3LL subcutaneous tumors. RPR209120/DOPE and **6c**/DPPC were prepared by the hydration film method. Results are expressed as the percentage of the injected dose. (**$p < 0.01$ by the Mann–Whitney U-test, significant in blood and lung, not in the tumor and RES.)

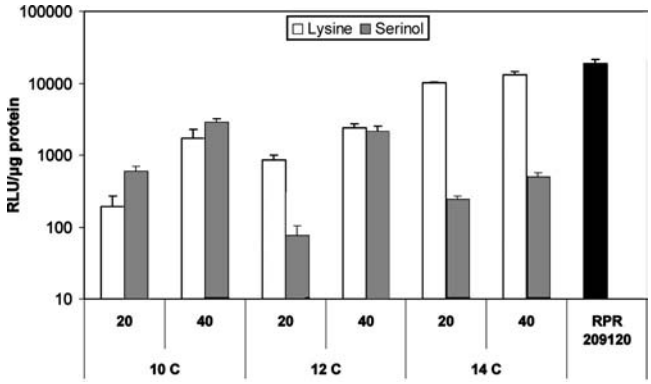

Figure 6. Comparison of gene transfection levels of lysine derivatives LPT (white bars) and previously published LPT (*20*) (gray bars) according to their ratio TU/P and chain length. Lysine LPT structures 10C, 12C, and 14C correspond to **6a**, **6b**, and **6c**, respectively. Previously published LPT structures 10C, 12C, and 14C correspond to compounds Ic, Ib, and Ia, respectively, represented in Figure 7. Luciferase activity of LPT/DNA complexes at 20 and 40 TU/P ratios was measured after 48 h of incubation in B16 cells in the presence of serum. RPR209120/DOPE/DNA lipoplexes were prepared at an N/P ratio = 6 in 150 mM NaCl. Results are expressed as the mean of an experiment performed in triplicate, with the error bars indicating the standard error of the mean.

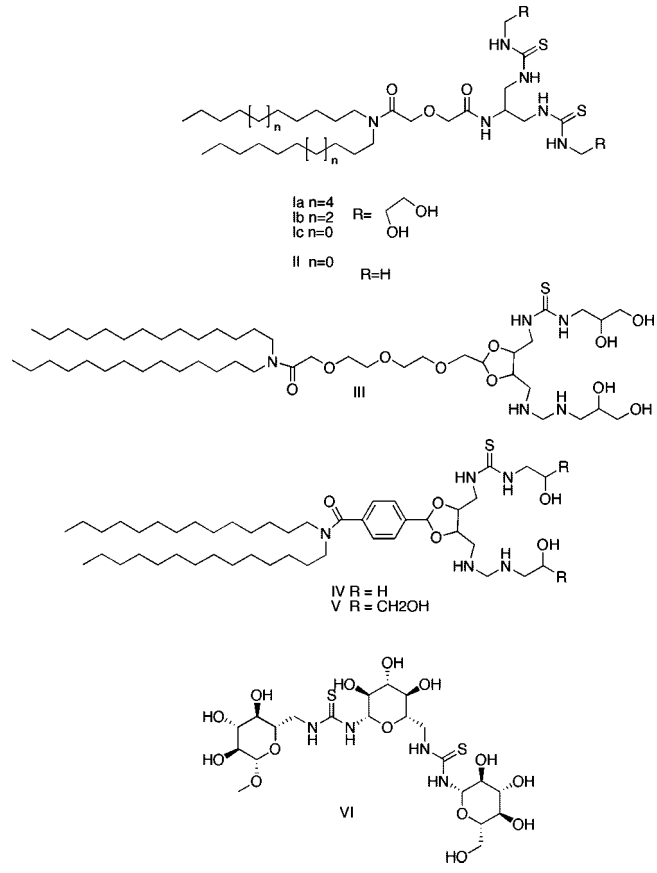

Figure 7. Previously published lipopolythiourea and thiourea compounds: I-II (*20*), III-V (*19*), and VI (*43*).

circulation. However, this stealth advantage did not enhance passive accumulation in our tumor model in opposition to the proposed enhanced permeability and retention effect (*42*). We have already observed this lack of passive accumulation in 3LL tumors after chemical passivation of the cationic charges of lipoplexes (*9*). This points to the use of a targeting ligand at the surface of these DNA/lipid particles in order to deliver DNA at a proper site, especially as this strategy has already been validated in the case of lipopolythiourea (*19*).

In conclusion, we described here new noncationic transfecting agents bearing a polythiourea moiety. From this and previous results, we can deduce that a wide range of geometry and termini allowed LPT/DNA interaction. With the present compound **6c**, this association was found to be strong enough to protect the plasmid in the presence of serum and to obtain *in vitro* efficient cell transfection, comparative to that obtained with cationic lipids. Moreover, we could find a nontoxic window for the *in vivo* use of these complexes. Intratumoral injection of LPT/DNA complexes showed that *in vivo* transfection ability and biodistribution were favorably improved as compared to that of cationic complexes. Finally, we have found in our previous studies that the size of the hydrophobic anchor seemed to be one of the factors controlling the physico-chemical and the transfecting properties of the LPTU. Structural comparison between **6a**–**6c** and **Ia**–**Ic** (Figure 7) shows two main differences between them. First, the lack of a linker and second, the presence of a 1,5-diamine instead of a 1,3-diamine for the headgroups. This suggests that a larger diamino chain would lead to better phosphate/thiourea interactions. This hypothesis is supported by the study of Bianco et al. (*43*) that demonstrate strong thiourea/phosphate interaction for thiourea-linked glycooligomers (Figure 7, compound **VI**). In these molecules, the two thioureas are in a 1,4 relationship favoring their participation in bidentate hydrogen bond interactions with oxoanions. Compounds **III**, **IV**, and **V** (Figure 7) also possess a 1,5 relationship between the two thioureas (*19*). However, their lack of transfecting properties is probably due to their hydrophobicity. In addition, the presence of the acetal ring adds a constraint that could diminish the strength of hydrogen bonds. New models have been synthesized and are now under investigation to verify these hypotheses.

ACKNOWLEDGMENT

Ligand-Modified Aminobisphosphonate for Linking Proteins to Hydroxyapatite and Bone Surface

Robin S. Ehrick,[†] Marcello Capaccio,[†] David A. Puleo,[‡] and Leonidas G. Bachas*[,†]

Department of Chemistry, University of Kentucky, Lexington, Kentucky 40506-0055, and Center for Biomedical Engineering, University of Kentucky, Lexington, Kentucky 40506-0070. Received May 30, 2007; Revised Manuscript Received September 14, 2007

An increase in bone resorption is one of the main symptoms of osteoporosis, a disease that affects more and more individuals every day. Bisphosphonates are known to inhibit bone resorption and thus are being used as a treatment for osteoporosis. Aminobisphosphonates present a functionality that can be easily used for conjugation to other molecules, such as peptides, proteins, and ligands for protein recognition. In this study, an aminobisphosphonate conjugated with biotin was used as a model linker for protein attachment to bone. With this system, the interaction of biotinylated aminobisphosphonate with hydroxyapatite, a major mineral component of bone, was investigated. Quantification of the binding of aminobisphosphonate to hydroxyapatite was performed using a fluorescently labeled antibody for biotin. Additionally, the interaction of the biotinylated aminobisphosphonate with multiple treatments of cortical bone from the midshaft of a cow femur was studied. It was demonstrated that modified aminobisphosphonate reagents can bind hydroxyapatite and bone at high levels, while the biotin functionality is free to be recognized by the fluorescently labeled antibiotin antibody, suggesting that modified aminobisphosphonates could be used to link other peptides or proteins to the bone surface.

INTRODUCTION

In 2000, over 10 million people in the United States had been diagnosed with osteoporosis (*1*), a disease characterized by a reduction in bone mass caused by an increase in bone resorption with minimal regeneration. Another 34 million were affected by low bone mineral density. Two types of bone cells, osteoblasts and osteoclasts, constantly work together to remodel bone. Osteoblasts, or bone-forming cells, regenerate bone tissue, while bone is resorbed by the osteoclast cells (*2*). In healthy individuals, the rate of bone resorption is similar to the rate of bone regeneration. In a patient diagnosed with osteoporosis, the balance of osteoblastic and osteoclastic activity is disrupted in such a way that the rate of bone resorption is higher than the rate of bone regeneration (*3*).

Popular treatments for osteoporosis include calcium and vitamin D supplementation, hormone replacement therapy, and use of bisphosphonates, among others (*4*). Calcium and vitamin D supplementation and hormone replacement therapy have been criticized recently over their inability to prevent fractures (*5, 6*) and the increased side effects with treatment (*7–9*), respectively. It has also been suggested that calcium and vitamin D supplements may result in only minimal increase in bone mineral density (*10, 11*). While this may be beneficial overall, it was found recently that supplementation has little to no effect at preventing fractures and can increase the occurrence of kidney stones (*6*). A high rate of fracture with minimal injury is one of the main symptoms of osteoporosis. Hormone replacement therapy, involving the administration of a combination of estrogen and progestin, had been widely prescribed as a treatment for osteoporosis in postmenopausal women (*7*) because of the effect that estrogen has at inhibiting the action of osteoclast cells (*12, 13*). Unfortunately, the long-term effects of estrogen therapy were found to include an increased risk of breast cancer, heart attack, stroke, blood clots, and Alzheimer's disease and other dementias (*8, 9*). Because of these risks, hormone replacement therapy is now only prescribed for postmenopausal women with extreme osteoporosis, where the benefits outweigh the risks associated with treatment.

A treatment for osteoporosis that is gaining popularity is bisphosphonate therapy. Bisphosphonates are antiresorptive medications that bind to the mineral phase of bone and inhibit the activity of osteoclasts (*14*). Bisphosphonates have a long history with many applications including use as detergent additives in hard water treatment, in toothpaste to prevent tartar buildup, as treatment for Paget's disease, and as a diagnostic tool for bone tumor treatment (*14, 15*). In recent years, they have been mainly studied as an osteoporosis therapy because of their ability to inhibit bone resorption. The complex mechanism of action of bisphosphonates has only recently been understood (*16–18*), but in general, bisphosphonate binds to hydroxyapatite, the main mineral component of bone. When osteoclasts begin to resorb the bone, bisphosphonate is taken up by the cell, which then loses its resorptive function and undergoes apoptosis. The loss in the ability of the osteoclast to resorb bone following the administration of bisphosphonates causes an increase in bone mineral density.

While both osteoblasts and osteoclasts are essential to bone remodeling, a majority of osteoporosis research focuses on inhibiting the osteoclast (*3, 4, 14, 16, 17, 19–24*). The innate structure of bisphosphonates allows for numerous analogues to be produced that can have a wide scale of activities. Nitrogen-containing bisphosphonates, or aminobisphosphonates, have already been shown to have higher antiresorptive effects than bisphosphonates that do not contain a nitrogen atom (*16*). The conjugation of a peptide or protein that can stimulate bone formation to an aminobisphosphonate could produce an agent that would not only slow resorption, but would also help to increase bone mineral density.

Aminomethylene bisphosphonic acid (aminobisphosphonate) presents an amine functionality that can be easily attached to a

biomolecule. Conjugation of aminobisphosphonate to proteins has previously been explored in the literature (*25–29*), demonstrating that various proteins conjugated with bisphosphonate have a high affinity for both hydroxyapatite and bone. In these studies, aminobisphosphonate was conjugated at multiple sites on the proteins leading to more than one bisphosphonate per protein. This results in various binding orientations of the protein on the bone surface. We propose to conjugate aminobisphosphonate with a protein-binding ligand that subsequently can be used to recruit proteins to the bone surface. The linked protein could be presented in a rationally oriented manner based on the attachment site of the ligand. Toward this goal, a novel aminobisphosphonate was synthesized that contains a conjugated biotin moiety. This molecule was explored as a model system for the delivery of a linker for protein attachment to bone. The biotinylated aminobisphosphonate was incubated with both hydroxyapatite and bone. The attachment to the mineral surfaces was quantified using a fluorescently labeled antibiotin antibody. We have demonstrated that a conjugated aminobisphosphonate could be bound to the bone surface and subsequently recognized by a biomolecule.

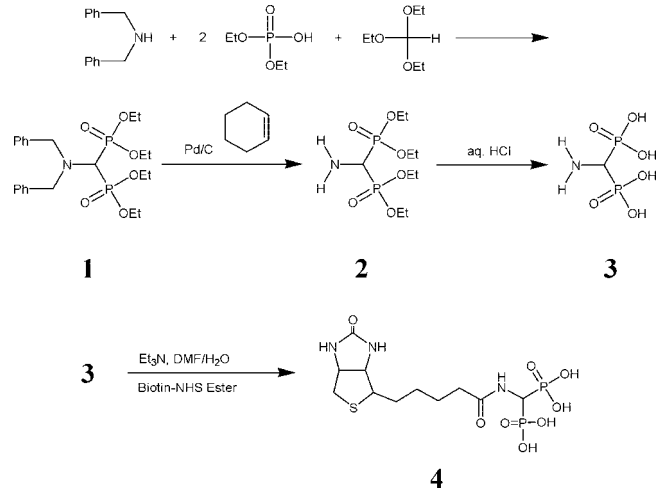
EXPERIMENTAL PROCEDURES

Materials. Dibenzyl amine, triethyl orthoformate, silica gel, palladium on carbon, active carbon, dimethylformamide, reagent-grade hydroxyapatite (HA) powder (catalog number 289396), D-biotin, bovine serum albumin (BSA), casein from bovine milk, and monoclonal antibiotin−FITC antibody were purchased from Sigma-Aldrich (St. Louis, MO). Hexane, methanol, sodium hydroxide, and sodium phosphate dibasic heptahydrate were purchased from Mallinckrodt (Hazelwood, MO). Sodium chloride, sodium sulfate, hydrochloric acid, and triethylamine were obtained from EMD Chemicals (Gibbstown, NJ). Avidin from egg white was purchased from EMD Biosciences (San Diego, CA). Diethyl phosphite and cyclohexene were received from Fluka (Milwaukee, WI). Deuterium oxide NMR solvent was purchased from Cambridge Isotope Laboratories (Andover, MA). Argon gas was supplied through Scott-Gross Company (Lexington, KY). Ethyl acetate and ether were obtained from VWR (Westchester, PA). Fetal bovine serum (FBS) was obtained from Invitrogen (Carlsbad, CA). Tetraethyl(aminomethylene) bisphosphonate was purchased from Epsilon Chimie (Brest, France). 2-Anilinonaphthalene-6-sulfonic acid was obtained from Molecular Probes (Eugene, OR).

Apparatus. ^{1}H NMR spectra were obtained on a Varian INOVA 400 MHz spectrometer (Palo Alto, CA). Electrospray ionization mass spectrometry was performed on a ThermoFinnigan LCQ mass spectrometer (Waltham, MA). Lyophilization was performed using a Christ Alpha 2–4 freeze-dryer (Martin Christ, Osterode am Harz, Germany) equipped with a Pfeiffer Vacuum Pump (Asslar, Germany). Fluorescence readings were performed on a Cary Eclipse fluorescence spectrophotometer (Varian, Walnut Creek, CA). Deionized water was produced using a Milli-Q water purification system (Millipore, Bedford, MA).

Synthesis of Biotinyl-Aminomethylenediphosphonic Acid Triethylammonium Salt (AMB-Biotin). Aminomethylene bisphosphonic acid (aminobisphosphonate) **3** was synthesized following the procedure published by Kantoci et al. (*30*) and outlined in Scheme 1. *N,N*-Dibenzylamine-bisphosphonate tetraethyl ester **1** was synthesized from dibenzylamine, diethyl phosphite, and triethyl orthoformate. The amine was deprotected using Pd/C and hexene to form tetraethyl(aminomethylene) bisphosphonate **2**. Hydrogenation of the ester groups using aqueous hydrochloric acid produced **3**. Biotin *N*-hydroxysuccinimide ester (biotin NHS ester) was conjugated with **3** in a one-step synthesis. Triethylamine (600 μL) was added to a

Scheme 1. Synthesis of Biotinyl-Aminomethylenediphosphonic Acid Triethylammonium Salt (AMB-Biotin)



1 **2** **3** **4**

solution of **3** (100 mg, 0.52 mmol) in deionized water (3 mL). A solution of biotin NHS ester (179 mg, 0.52 mmol) in dimethylformamide (DMF, 6 mL) was added dropwise at 0 °C. The solution was stirred for 30 min at this temperature and then overnight at room temperature. The reaction mixture was evaporated to a minimal volume, and the final product was precipitated with diethyl ether. The solid was collected using a Buchner funnel and washed first with a few drops of DMF, then a few drops of ether, and finally with a few drops of methanol. Biotinyl-aminomethylenediphosphonic acid triethylammonium salt (AMB-Biotin) **4** was obtained as a white solid in 80% yield. Intermediate compound **2** was also purchased from Epsilon Chimie (Brest, France) and used in the synthesis of **4**. ^{1}H NMR (400 MHz, D_2O): δ 1.55 (triplet, S*CH*CH of biotin ring, 1H), δ 1.63 (triplet, S*CH*$_2$CH of biotin ring, 2H), δ 2.58 (triplet, 2H), δ 2.79 (singlet, 6H), δ 3.02 (singlet, PO(OH)$_2$*CH*PO(OH)$_2$ of bisphosphonate, 1H), δ 4.46, 4.63 (multiplets, NH*CHCH*NH of bridge of biotin ring, 2H). Mass spectral data were obtained at the University of Kentucky Mass Spectrometry Facility. *m/z* (ESI-MS) 416 ([M − H]$^-$, 100%).

Preparation of Bone Samples. Bone samples were taken from the midshaft of a cow femur. Cortical bone was cut into a rod approximately 7 mm × 7 mm square. The rod was then sliced into 500 μm thick pieces. Of the bone slices, one-half of the samples were left untreated, while the remaining samples were demineralized by soaking them in 0.6 M hydrochloric acid for 48 h. After 24 h, fresh acid solution was exchanged. After acid treatment, the bone was rinsed thoroughly with deionized water. Additional samples of untreated bone, approximately 7 mm × 7 mm × 1 cm in size, were ashed by heating the bone to 800 °C for 24 h. Subsequently, the ashed bone was crushed into a powder using a mortar and pestle.

Binding Studies of AMB-Biotin on Hydroxyapatite. A 3 mg sample of AMB-Biotin was dissolved in 1 mL of 0.5 M phosphate buffer, pH 7.4. HA, in the amount of 6 mg, was added to this solution, and the sample was incubated overnight at room temperature on a rotator (Glas-Col mini-rotator, Terre Haute, IN). The suspension was centrifuged for 15 min at 13 000 rpm (Eppendorf Centrifuge 5417R, Brinkmann Instruments, Westbury, NY) to collect the insoluble HA, and the pellet was washed twice with buffer and three times with deionized water. The sample was then lyophilized overnight and resuspended in 1 mL of FITC-labeled antibiotin antibody in phosphate buffer at a concentration of 29 μg/mL. The suspension was incubated on a rotator for 3 h at 4 °C. After incubation, the sample was centrifuged again to collect the solid, and the fluorescence of the supernatant was measured. As controls, a 3 mg sample of

aminobisphosphonate (AMB) and a 1 mL sample of 29 μg/mL FITC-labeled antibiotin antibody in phosphate buffer were subjected to the same conditions for incubation with HA as above. All samples were prepared in triplicate.

AMB-Biotin Binding on Hydroxyapatite in the Presence of Free Biotin. Three samples were prepared to study the interactions with HA in the presence of free biotin. These samples were examined to determine whether AMB-Biotin could interact with HA through the bisphosphonate or the biotin moieties. First, a 3 mg sample of AMB-Biotin was prepared in 1 mL phosphate buffer. The second sample contained 3 mg of free biotin in 1 mL phosphate buffer. Finally, a sample was prepared that contained 3 mg each of both AMB-Biotin and free biotin dissolved together in 1 mL phosphate buffer to determine what effect, if any, free biotin had on the interactions between AMB-Biotin and HA. An amount of 6 mg of HA was added to all three samples. Samples were prepared in triplicate and treated as described for AMB-Biotin on HA.

AMB-Biotin Binding on Hydroxyapatite in the presence of BSA or Serum. Because bisphosphonates are administered either orally or intravenously, the ability of the modified bisphosphonate to interact with HA in the presence of biological molecules was examined. For the BSA studies, a total of five samples were prepared to study the effect of BSA on AMB-Biotin binding to HA. The first sample was prepared by dissolving 3 mg of AMB-Biotin in 1 mL phosphate buffer. For the second sample, 0.3 mg of BSA was dissolved in 1 mL phosphate buffer. The third sample contained both 3 mg of AMB-Biotin and 0.3 mg BSA in 1 mL phosphate buffer to determine how the presence of BSA affects the interaction with HA. To each of these three samples, 6 mg of HA was added. These first three samples were treated as described previously for AMB-Biotin.

The final two samples were prepared differently. For these two samples, 3 mg of AMB-Biotin and 0.3 mg of BSA were each preincubated with 6 mg HA. These samples were washed and lyophilized as before. However, after lyophilization, the AMB-Biotin sample was resuspended in a 0.3 mg/mL BSA solution in phosphate buffer, and the BSA sample was resuspended in a 3 mg/mL solution of AMB-Biotin in phosphate buffer. These two samples were incubated for 3 h at room temperature on the rotator before centrifuging to remove the insoluble HA. The sample of (AMB-Biotin + HA) + BSA examined the strength of the interaction of the preincubated AMB-Biotin sample, while the (BSA + HA) + AMB-Biotin sample helped to determine the specificity of the AMB-Biotin interaction with the HA surface.

All five samples were then resuspended in 1 mL of 29 μg/mL FITC-labeled antibiotin antibody in phosphate buffer and incubated on a rotator for 3 h at 4 °C. HA was collected by centrifugation, and the fluorescence of the supernatants was measured and compared to a standard of FITC-labeled antibiotin antibody.

While the BSA studies looked at the effect of a low concentration of albumin (0.3 mg/mL) on AMB-Biotin binding to HA, additional studies were performed to study binding at higher concentrations of protein using fetal bovine serum (FBS). Three milligram samples of AMB-Biotin were prepared in 1 mL solutions of 25%, 50%, and 75% FBS in phosphate buffer along with solutions of 100% buffer and 100% FBS. Six milligrams of HA were added to each of the samples at the various levels of serum. The samples were treated following the procedure for AMB-Biotin.

Binding Studies of AMB-Biotin on Bone. A 3 mg sample of AMB-Biotin was dissolved in 1 mL of 0.5 M phosphate buffer, pH 7.4. To this solution, either a slab of untreated or demineralized bone or 6 mg of crushed ashed bone was added. The sample was incubated overnight at room temperature on a rotator. The sample was centrifuged for 15 min at 13 000 rpm to collect the bone, which was washed twice with buffer and three times with deionized water. The sample was then lyophilized overnight and resuspended in 1 mL of FITC-labeled antibiotin antibody in phosphate buffer at a concentration of 5.8 μg/mL. The suspension was incubated on a rotator for 3 h at room temperature. After the incubation, the sample was centrifuged again to collect the solid, and the fluorescence of the supernatant was measured. As controls, a 3 mg sample of free biotin and a 1 mL sample of FITC-labeled antibiotin antibody in phosphate buffer were subjected to the same conditions as listed for the AMB-Biotin sample.

AMB-Biotin Binding on Ashed Bone in the Presence of Casein. Samples were again prepared to examine the binding of AMB-Biotin in the presence of a biological molecule, this time using casein. Four total samples were prepared to study the interactions of AMB-Biotin and casein with ashed bone. The first sample was prepared by dissolving 3 mg AMB-Biotin in 1 mL phosphate buffer. For the second sample, 5 mg of casein was dissolved in 1 mL of phosphate buffer. The third sample contained both 3 mg of AMB-Biotin and 5 mg of casein in 1 mL phosphate buffer. Ashed bone in the amount of 6 mg was added to all three of these samples, which were treated as previously described for the AMB-Biotin samples on HA.

The final sample was prepared by preincubating 3 mg of AMB-Biotin with 6 mg of ashed bone in 1 mL phosphate buffer. The washes and lyophilization were performed along with the other samples. However, after lyophilization, this sample was resuspended in a 1 mL solution of 5 mg/mL casein in phosphate buffer. The sample was incubated on a rotator at room temperature for 3 h. After incubation, the sample was centrifuged to collect the solid and the supernatant was removed.

All four of the samples were then resuspended in 1 mL each of 5.8 μg/mL FITC-labeled antibiotin antibody, placed on a rotator and incubated for 3 h at room temperature. Subsequently, the samples were centrifuged to collect the bone, and the fluorescence of the supernatant was measured and compared to a standard of FITC-labeled antibiotin antibody.

Kinetics of AMB-Biotin Binding to Ashed Bone. The kinetics of AMB-Biotin binding to bone were established by using a fluorescence assay based on avidin and 2-anilinonaphthalene-6-sulfonic acid (2,6-ANS), where 2,6-ANS occupies the biotin binding sites of avidin (*31*). 2,6-ANS has two different emission wavelengths, depending on whether it is in the bound or unbound state. In the presence of biotin, or in this case AMB-Biotin, the fluorescent probe is released from avidin. The amount of AMB-Biotin remaining unbound in solution can be determined using a calibration plot of increasing concentrations of AMB-Biotin in the presence of the avidin-2,6-ANS complex.

Three milligram samples of AMB-Biotin were incubated with 6 mg each of ashed bone for 0, 15, 30, 60, and 120 min in 1 mL of phosphate buffer. After the designated time period, the samples were centrifuged at 13 000 rpm for 15 min. Aliquots of 12.5 μL of each of the supernatants were incubated with 800 μL of the avidin-2,6-ANS complex that was prepared at 8 μM avidin and 50 μM 2,6-ANS. Samples for the calibration plot were prepared using a solution of 3 mg/mL AMB-Biotin. AMB-Biotin was added to 800 μL of avidin-2,6-ANS in 12.5 μL increments. Ten total samples were prepared ranging from 0.09 mg/mL AMB-Biotin to 0.7 mg/mL. The excitation wavelength was set at 328 nm, while the fluorescence emission was

measured from 400 to 500 nm. 2,6-ANS has an emission maximum at 438 nm when bound to avidin and 462 nm when unbound.

RESULTS AND DISCUSSION

To synthesize AMB-Biotin, aminobisphosphonate was prepared first by following a published procedure (*30*). This compound was subsequently functionalized with biotin. For this, biotin *N*-hydroxysuccinimide ester was used because of its reactivity toward aliphatic amines. AMB-Biotin was produced in high yield, and the NMR and MS data confirmed the production of a ligand-modified aminobisphosphonate.

AMB-Biotin binds to HA through its bisphosphonate portion. This binding can be followed by using a fluorescently labeled antibiotin antibody that recognizes the biotin functionality on AMB-Biotin. Because of the difficulty in measuring fluorescence on the solid microparticles, the extent of binding was determined by measuring the fluorescence remaining in solution after the antibody reaction with the immobilized AMB-Biotin. Excitation of the fluorescent antibody was performed at 490 nm, while the emission was scanned from 500 to 600 nm. Figure 1A shows a representative set of spectra of AMB-Biotin binding on HA and the corresponding controls. The emission spectra have a maximum at 523 nm, which is characteristic of FITC-labeled proteins. The fluorescence intensity at 523 nm was used to calculate relative binding using the following equation:

$$\text{relative binding} = (F_0 - F_{\text{sample}})/(F_0 - F_{\text{highest}})$$

where F_0 is the fluorescence of the solution of antibiotin antibody prior to addition of HA, F_{sample} is the fluorescence remaining in the solution following the binding event, and F_{highest} is the fluorescence of the sample exhibiting the highest binding. Figure 1B shows data for the relative binding calculations for all samples of AMB-Biotin on HA and the controls.

As can be seen in the spectra in Figure 1A, a considerable loss in the solution fluorescence is observed when hydroxyapatite was treated with AMB-Biotin. This suggests that AMB-Biotin is bound to the insoluble hydroxyapatite; antibiotin antibody binds to the immobilized biotin and is removed from solution following centrifugation. When the relative binding is calculated, the AMB-Biotin-treated hydroxyapatite exhibited the highest extent of binding (Figure 1B). This binding is more than twice the binding seen for the nonspecific interaction of the antibody with untreated HA and HA treated with an aminobisphosphonate lacking the biotin moiety. Analysis of variance (ANOVA) and post hoc tests were performed to determine the statistical similarity or difference between the samples. In Figure 1B, the symbol * denotes that there is no statistical difference between the sample of HA treated with AMB and the untreated HA. However, both of these samples are statistically different from the AMB-Biotin + HA sample at a probability (p) of greater than 0.01.

Strong binding of AMB-Biotin is also observed in the presence of free biotin, as can be seen in Figure 2. In this figure, the symbols * and † denote statistically similar samples. There is no statistical difference among the Untreated HA, Free Biotin + HA, and AMB-Biotin + Free Biotin + HA samples, as denoted by the symbol *. There is also no statistical difference between the AMB-Biotin + HA sample and the AMB-Biotin + Free Biotin + HA sample, denoted by the symbol †. There is, however, a statistically significant difference ($p > 0.01$) between the Untreated HA and AMB-Biotin + HA samples. There is also a significant difference between the Free Biotin + HA and AMB-Biotin + HA samples ($p > 0.01$). The difference observed between the free biotin and AMB-Biotin samples demonstrates that the binding of the biotinylated bisphosphonate is indeed through the bisphosphonate moiety and not through the biotin functionality. Binding does not occur through the biotin group, since no statistical difference was found between the Free Biotin + HA and the Untreated HA samples.

The results observed for the binding of AMB-Biotin in the presence of BSA are summarized in Figure 3. The highest

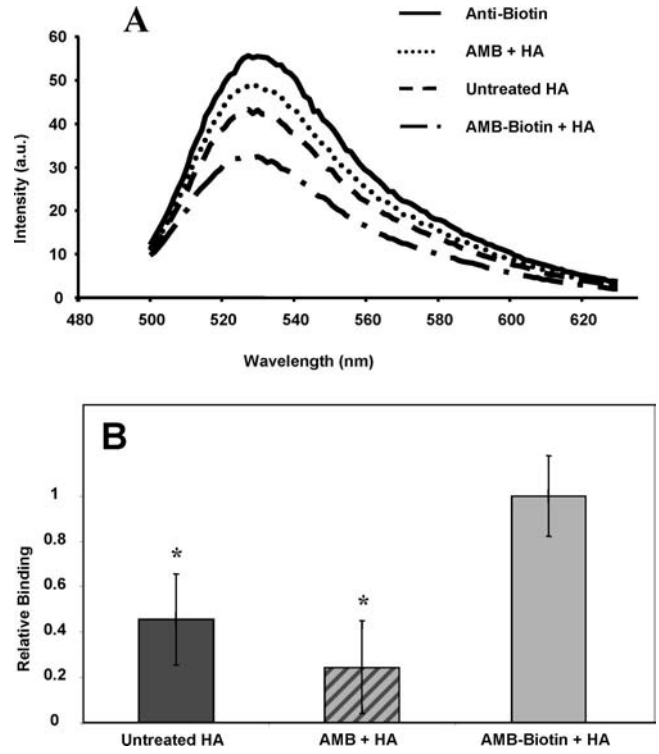


Figure 1. Binding of FITC-labeled monoclonal antibiotin antibody to hydroxyapatite treated with AMB-Biotin and various controls. (A) Fluorescence signal of the supernatants (λ_{ex} 490 nm) after removal of insoluble HA treated with AMB (•••) and AMB-Biotin (— • —), and untreated HA (— — —) compared to the spectrum of the FITC-labeled antibiotin antibody solution used in the experiments (solid line). (B) Relative binding for untreated HA ($n = 5$), AMB treated HA ($n = 6$), and AMB-Biotin treated HA ($n = 6$). The * denotes statistically similar results. AMB-Biotin is statistically different from the AMB-treated and untreated HA samples at $p > 0.01$.

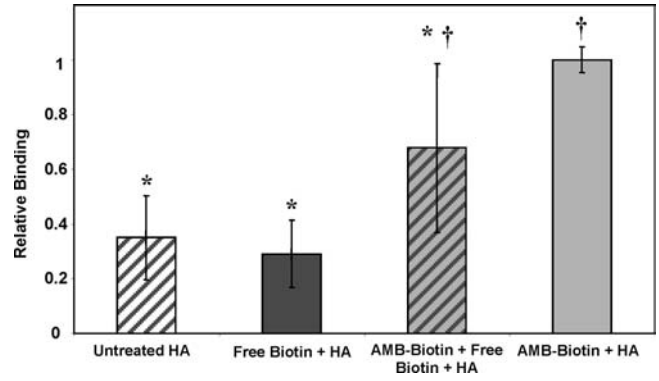

Figure 2. Binding measurements in the presence of free biotin quantified using a fluorescently labeled antibiotin antibody. Relative binding for untreated HA, free biotin treated HA, AMB-Biotin and free biotin incubated together with HA, and HA treated with AMB-Biotin. For all samples, $n = 3$. The symbols * and † denote statistically similar results. There is no statistical difference among the Untreated HA, Free Biotin, and AMB-Biotin + Free Biotin + HA samples, nor is there a difference between the AMB-Biotin + Free Biotin + HA and AMB-Biotin samples. However, there is a statistical difference ($p > 0.01$ for each sample) among the Untreated HA, Free Biotin + HA, and the AMB-Biotin +HA samples.

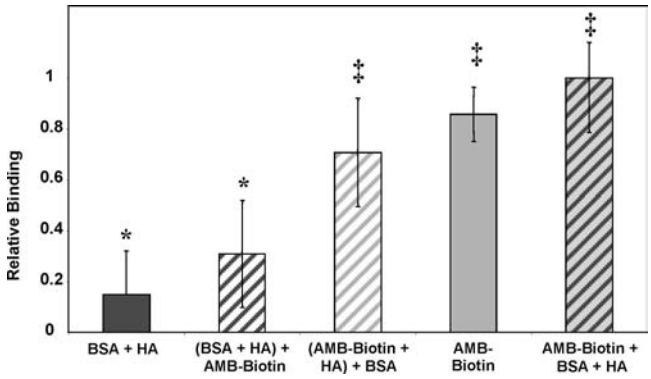

Figure 3. Binding measurements of AMB-Biotin in the presence of BSA based on the loss in fluorescence of the supernatants after incubation with a FITC-labeled antibiotin antibody. Relative binding for BSA, BSA preincubated with HA, AMB-Biotin preincubated with HA, AMB-Biotin alone on HA, and AMB-Biotin and BSA incubated together with HA. All samples were prepared in triplicate. The symbols * and ‡ denote statistically similar samples. The statistically significant difference between the samples denoted with the symbol * and those with the symbol ‡ was at least $p > 0.05$.

relative binding observed was from the sample treated simultaneously with both AMB-Biotin and BSA. High relative binding was also observed for the AMB-Biotin + HA sample at almost 90% and for the sample of HA pretreated with AMB-Biotin and subsequently incubated with BSA at over 70%. In the ANOVA and post hoc calculations, these three samples were found to be statistically similar, as denoted by the symbol ‡. These three samples are statistically different ($p > 0.05$) from the two samples where HA was treated with BSA alone or pretreated with BSA and then exposed to AMB-Biotin, which are statistically similar as denoted by the symbol *. These results emphasize the specific binding ability of AMB-Biotin on HA, even when BSA is present in the sample.

While the BSA studies were performed at a low protein concentration (0.3 g/L), additional studies were carried out at higher levels of protein using FBS. Binding of AMB-Biotin to HA was performed in solutions of FBS in phosphate buffer at concentrations of 0%, 25%, 50%, 75%, and 100% (v/v) FBS. The highest binding was seen for 0% FBS. The sample showing the least amount of binding was the 75% serum sample, which showed binding of only 40% relative to the 0% FBS sample (data not shown). These levels of binding indicate that, even at high concentrations of protein, AMB-Biotin still binds to HA. This leads one to believe that, in the complexity of a living system, where there is a high level of protein and other biomolecules present, there will still be specific interaction of a conjugated aminobisphosphonate with the natural bone matrix.

The initial characterization of the biotinylated aminobisphosphonate was performed under the conditions of a model system, specifically using hydroxyapatite to simulate bone and BSA as a general blocking protein. While this model system is beneficial initially, additional studies were performed to better understand how this bisphosphonate would behave with real bone. Three different treatments were used to prepare the bone samples. Samples of untreated, demineralized, and ashed bone were incubated with AMB-Biotin. Data from the bone samples can be seen in Figure 4. Figure 4A contains the data from the untreated bone samples, Figure 4B summarizes the data for the demineralized bone samples, and Figure 4C displays the results for the ashed bone samples. The symbol * denotes statistically similar binding between samples. Although a positive trend was observed for binding of AMB-Biotin to the untreated bone samples versus free biotin, there was no statistical difference between the samples. Additionally, there is no statistical

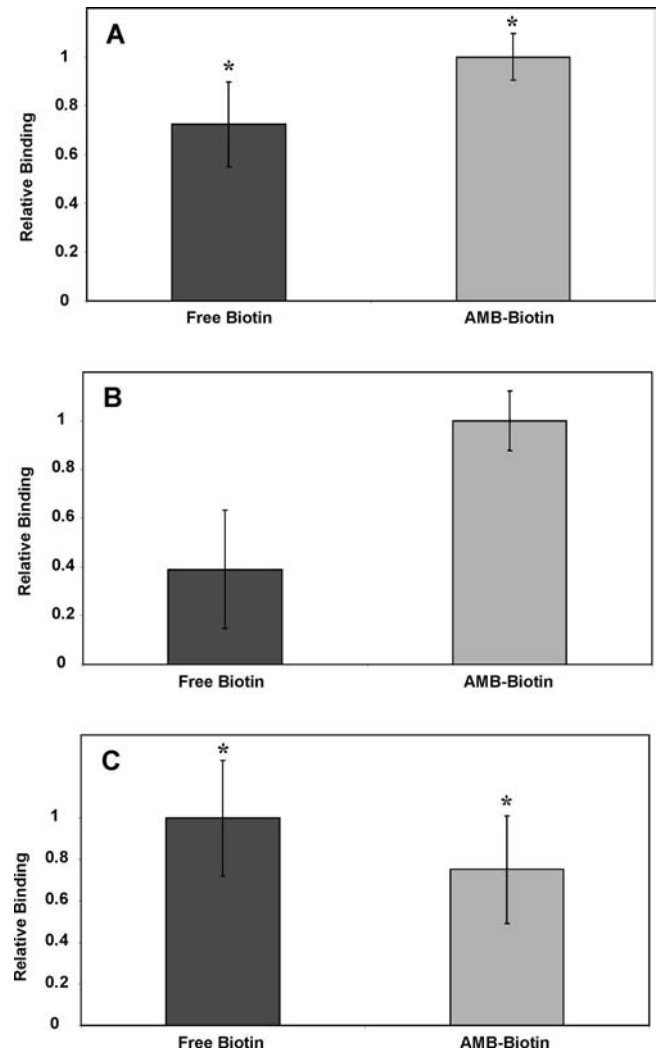

Figure 4. Binding measurements of AMB-Biotin and free biotin on multiple treatments of bone. The three treatments studied were untreated bone (A), demineralized bone (B), and ashed bone (C). Binding was quantified on the basis of the binding of a fluorescently labeled antibiotin antibody. For all samples, $n = 3$. The symbol * denotes statistically similar results. There is no statistical difference between the free biotin and AMB-Biotin samples on untreated and ashed bone. There is only a statistically significant ($p > 0.025$) difference between the AMB-Biotin and free biotin samples on demineralized bone.

difference observed between the samples of ashed bone. The only bone treatment that showed a statistical difference between the free biotin sample and AMB-Biotin sample was the demineralized bone. This difference is observed at $p > 0.025$. It is unclear why there was no difference between biotin and AMB-biotin binding in the case of untreated and ashed bone. The data suggest that biotin is likely attached to the surface of these two samples through ion exchange because of residual positive charges on the surface of the bone samples. Ashing the bone samples removes organic bone matrix that blocks access to the mineral phase (*26*). More binding sites on the mineral surface are exposed, thus increasing the probability of binding through electrostatic interactions.

The binding of AMB-Biotin to bone was further investigated in the presence of protein. In four different sets of experiments, ashed bone was treated with (a) casein, (b) AMB-Biotin, (c) AMB-Biotin followed by exposure to casein, and (d) simultaneous exposure to AMB-Biotin and casein. The results of this study can be seen in Figure 5. Casein proves to be a good blocking protein, allowing 15% of the binding of the antibiotin

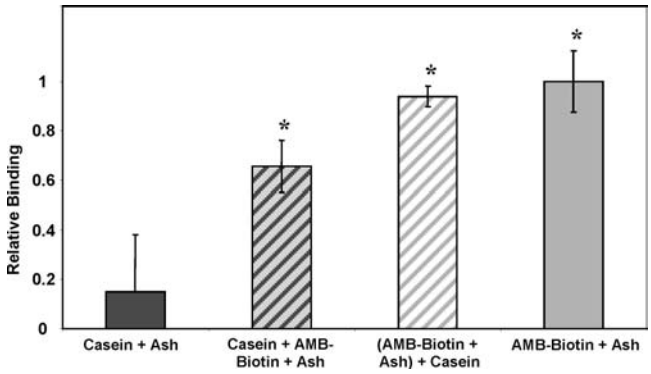

Figure 5. Binding measurements of AMB-Biotin in the presence of casein. Binding was measured using FITC-labeled antibiotin antibody. Relative binding on ashed bone of casein, casein and AMB-Biotin, AMB-Biotin preincubated with bone, and AMB-Biotin. Samples were prepared in triplicate. The symbol * denotes statistically similar samples. There is no statistical difference among the Casein + AMB-Biotin + Ash, (AMB-Biotin + Ash) + Casein, and AMB-Biotin + Ash samples. All are statistically different from the Casein + Ash sample by at least $p > 0.05$.

antibody on the ashed bone relative to the ashed bone treated with AMB-Biotin. The extent of binding of AMB-Biotin on ashed bone was the highest for this sample set. On the basis of the ANOVA and post hoc tests, it was found that there was no statistical difference among the Casein + AMB-Biotin + Ash, (AMB-Biotin + Ash) + Casein, and AMB-Biotin + Ash samples. This similarity is denoted in Figure 5 by the symbol *. All three of these samples were found to be statistically different from the Casein + Ash sample by a probability of at least >0.05. Again, this suggests that the binding of AMB-Biotin has the greater impact on the system, because there is still strong binding of the biotinylated aminobisphosphonate in the presence of protein.

It is generally accepted that conjugation of a therapeutic agent to bisphosphonate affects the properties of the bisphosphonate in terms of kinetics, affinity, and its ability to function as a drug (*32, 33*). Therefore, the kinetics of AMB-Biotin association to bone were determined. To evaluate the kinetics of the interaction between AMB-Biotin and ashed bone, a study was performed under pseudo first-order conditions, where the ashed bone was present in excess over the AMB-Biotin. A calibration plot was used to determine the concentration of AMB-Biotin remaining in solution after incubation with ashed bone at various time intervals. The rate constant of the reaction was calculated to be 5.7 ($\pm$1.7) $\times$ 10^{-4} min^{-1}, where the error is the standard deviation of the data set. After 2 h of incubation with ashed bone, the amount of AMB-Biotin remaining in solution was negligible. Since in all experiments described the bisphosphonate samples were incubated with either HA or bone overnight, there was sufficient time allowed to ensure binding of the bisphosphonate to the matrix material.

This work shows that a ligand-modified aminobisphosphonate can bind bone successfully. While this is a model system used to explore the conjugation of a protein-linking molecule to an aminobisphosphonate, it may also help deliver peptides and proteins to the bone surface by linking them with a biotin-binding protein, such as an antibiotin antibody. The availability of "humanized" antibodies overcomes the immunogenic challenges of avidin and streptavidin. A humanized antibody or antibody fragment could be conjugated to a therapeutic agent for delivery to the bone surface. Antibodies can also be used to introduce sites for the delivery of small molecules, such as drug carriers and anticancer, antibacterial, and antiresorptive agents (*34*).

Overall, the applications for bisphosphonates in the field of osteoporosis research are endless. The novel biotinylated aminobisphosphonate prepared herein retains its ability to bind to both hydroxyapatite and bone. The binding is specific enough that competing reagents, such as free biotin, or protein blocking agents, such as BSA, FBS, or casein, do not inhibit the affinity of the biotinylated bisphosphonate for bone. Aminomethylene bisphosphonic acid was chosen because it has a simple structure and fairly straightforward synthesis. The conjugation with biotin was performed using NHS ester chemistry. This technique could be performed on a variety of other bisphosphonates that are currently prescribed for osteoporosis treatment, such as pamidronate, alendronate, olpadronate, and ibandronate (*34*). Any of these molecules could be functionalized with biotin in the manner described and could therefore also be used to target proteins to the bone surface. While currently prescribed bisphosphonates function mainly to inhibit further bone resorption by the osteoclast, linking a molecule with osteogenic properties to a bisphosphonate would not only inhibit resorption but also stimulate regeneration.

Amino Acid Analysis of Peptide Loading Ratios in Conjugate Vaccines: A Comparison of Direct Electrochemical Detection and 6-Aminoquinolyl-*N*-Hydroxysuccinimidyl Carbamate Pre-Column Derivatization Methods

Deborah D. Nahas,* Jennifer S. Palladino, Joseph G. Joyce, and Robert W. Hepler

Merck Research Laboratories, 770 Sumneytown Pike, P.O. Box 4, WP16-107, West Point, Pennsylvania 19486. Received June 22, 2007; Revised Manuscript Received September 24, 2007

Amino acid analysis using direct electrochemical detection was compared with precolumn fluorescent derivatization using 6-aminoquinolyl-*N*-hydroxysuccinimidyl carbamate (AQC) for evaluation of the degree of covalent coupling of peptides to a carrier–protein complex derived from the bacteria *Neisseria meningitidis*. AQC derivatization was found to give superior sensitivity compared to electrochemical detection, with less interference from sample components such as carbohydrates or buffer salts. Hydrolysis time and temperature were optimized for maximal recoveries of the marker amino acid 6-aminohexanoic acid (ε-Ahx) and the unique amino acids *S*-dicarboxyethyl cysteine (SDCEC) and *S*-carboxymethyl homocysteine (SCHMC), which are generated upon the hydrolysis of the covalent linkage between the peptide and the carrier protein. Quantitation of these amino acids enabled the determination of the ratio of peptide to protein in the conjugate samples.

INTRODUCTION

Certain classes of antigens, including peptides, carbohydrates, or polysaccharides, are often covalently coupled to carrier proteins in order to enhance their poor native immunogenicity. Such bioconjugates can be used as potential vaccine candidates or, in the cases of small peptides, as immunogens to generate antibodies against a particular target protein (*1–3*). The conjugation of poorly immunogenic molecules to carrier proteins, such as keyhole limpet hemocyanin (KLH), diphtheria toxoid, and *Neisseria meningitidis* outer membrane protein complex (OMPC), has been demonstrated to facilitate the induction of T-cell-dependent immune responses (*4–6*).

OMPC is a multiprotein complex with associated lipids that has proven to be an excellent carrier in several licensed and experimental conjugate vaccines because of its unique immunostimulatory properties (*7–9*). Studies have shown that OMPC also possesses adjuvant-like properties based on its ability to activate B-cells through its lipopolysaccharide and protein components (*4, 10*). Additionally, neisserial porins are capable of activating B-cells by mediating toll-like receptor (TLR) signaling through the effector molecule MyD88 (*11*).

Our group has prepared a number of covalent OMPC–peptide conjugates employing two different thiol-based coupling strategies. In the first strategy, OMPC was thiolated on surface-exposed lysines with *N*-acetyl homocysteine thiolactone (NAHT) and then reacted with a bromoacetylated peptide. In the second strategy, lysine residues in OMPC were derivatized using the heterobifunctional cross-linker sulfosuccinimidyl 4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate (sSMCC) in order to introduce a maleimide group for reaction with a cysteine-containing peptide. These thiol-based conjugation chemistries allow directional coupling due to the fact that the reactive thiol or haloacetyl functionality can be added at either the N-terminus or at the C-terminus of the peptide of interest. Another advantage is that the levels of activation can be monitored and controlled, which is often critical to maintaining the solubility and stability of peptide–carrier conjugates.

In the current study, the OMPC–peptide conjugates were analyzed by amino acid analysis, which is the technique most commonly employed to quantitate the molar ratio of peptide to protein in a conjugate (*12, 13*). This ratio is critical for calculating doses to be administered in immunization studies and assessing the comparability of different vaccine preparations. Amino acid analysis is also useful for monitoring the level of incorporation of the activating functionality on the protein carrier. In the case of sSMCC-mediated maleimidation, this is equivalent to the amount of tranexamic acid (Txa) generated upon acid hydrolysis of the conjugate. In this way, activation levels can be controlled, which is often critical to maintaining the solubility and stability of peptide–carrier conjugates.

RP-HPLC with precolumn derivatization using 6-aminoquinolyl-*N*-hydroxysuccinimidyl carbamate (AQC) is compared with direct electrochemical detection of amino acids by high pH anion exchange chromatography with pulsed amperometric detection (HPAE-PAD) for the analysis of OMPC–peptide conjugates. The gradient separations were optimized for both HPLC methods in order to resolve all 17 common amino acids: the peptide-derived spacer amino acid, 6-aminohexanoic acid (ε-Ahx); the activation reporter residue, tranexamic acid (Txa); and the coupling chemistry-specific amino acids *S*-dicarboxyethyl cysteine (SDCEC) and *S*-carboxymethyl homocysteine (SCMHC) generated by hydrolysis of the peptide–protein conjugate bond. The effects of hydrolysis time and temperature on the recovery of all relevant amino acids are also reported.

EXPERIMENTAL PROCEDURES

Preparation of Peptide–OMPC Conjugates. Synthetic peptides were prepared by standard *t*-Boc or Fmoc solid phase synthesis. The spacer ε-Ahx was incorporated in the peptide between the primary sequence and the amino terminal cysteine or between the primary sequence and bromoacetyl group on the carboxy terminus. The thiol-based conjugation chemistries

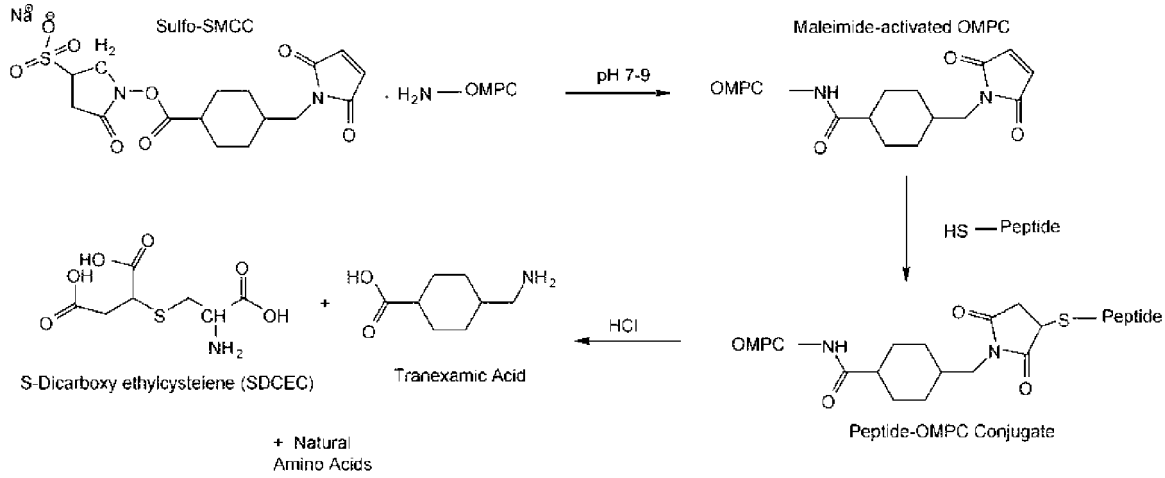
Scheme 1[a]



[a] A carrier protein is maleimide-activated with sSMCC, which reacts with primary amines (Lys residues and N-terminus). Then a cysteine-containing peptide reacts with the maleimide-activated carrier protein to form a peptide–protein conjugate. Acid hydrolysis of the resulting conjugate liberates SDCEC and tranexamic acid in addition to the constituent amino acids of the peptide and the carrier protein. Quantitation of SDCEC by amino acid analysis can be used to determine the ratio of peptide to carrier protein.

used to couple the synthetic peptides to OMPC have been previously described in detail. Cysteinylated peptide Ac-EKTNE-KFHQIEKEFSEVEGRIQDLEKYVENTKINLWSYNAEL-Ahx-C-NH_2 was conjugated to OMPC that had been maleimidated with sSMCC according to the method of Fan, et al. (*1*), and the peptide bromoacetyl-Ahx-(Peg)AEDVGSNK-(Peg)-DAEFRHDS-NH2 was conjugated to OMPC that had been thiolated using NAHT (*14*). For each conjugation protocol, a sample of activated OMPC without added peptide was carried through the reaction and desalting steps as a control.

Amino Acid Analysis. Vapor phase hydrolysis of the OMPC peptide conjugates was performed with constant-boiling 6N HCl, 1% phenol at 110 °C for 20–70 h using an ELDEX (Napa, CA) H/D workstation. Protein hydrolysates and amino acid standards were derivatized with AQC using the Waters AccQ Tag Chemistry Package according to the manufacturer's directions (*15*). AQC reacts with primary and secondary amines to form stable, fluorescent derivatives that can be separated by RP-HPLC (*16–19*). The fluorescent AQC derivatives were separated on an AccQ Tag Nova-Pak C18, 4 μM, 3.9 × 150 mm column using a modified gradient program (Modified Chromatography for Cell Culture Analysis; http://www.waters.com). Alternatively, protein hydrolysates and amino acid standards were dissolved in high purity deionized water and directly injected onto an AminoPac PA10 2 × 250 mm analytical column with a 2 × 50 mm AminoPac PA10 guard column (*20, 21*).

Calculation of Peptide to OMPC Ratio. The amino acid composition of OMPC was empirically determined as the micromoles of each amino acid detected in a known amount of OMPC total protein (as determined independently by modified Lowry protein assay (*23*)). The following 11 hydrolysis-stable residues were used for routine quantitation: Ala, Arg, Asp, Glu, Gly, His, Ile, Leu, Lys, Phe, and Val. The amount of OMPC in the OMPC–peptide conjugate sample was calculated from the empirically determined amino acid composition using those acid-stable residues not present within the sequence of the peptide.

The two thiol-based conjugation chemistries employed in this study result in conjugates that liberate unique, non-natural amino acids upon acid hydrolysis, in addition to the constituent amino acids of the peptide and the carrier protein (*23*). Conjugates prepared with a cysteinylated peptide and maleimide activated OMPC liberate SDCEC and tranexamic acid (Scheme 1), and conjugates prepared from NAHT-activated OMPC and a bromoactelyated peptide liberate SCMHC (Scheme 2) (*14*). Quantitation of these unique residues by amino acid analysis was used to determine the ratio of peptide to carrier protein. Also, since each mole of peptide contained a fixed and known amount of ε-Ahx (typically 1 or 2 mol ε-Ahx/ mol peptide), the molar amount of peptide in the conjugate was equivalent to the molar concentration of ε-Ahx, assuming complete removal of free peptide. Finally, the molar ratio of peptide to protein was calculated by quantitative comparison of conjugate and OMPC-only compositions using the modified least-squares algorithm described by Shuler, et al. (*12*).

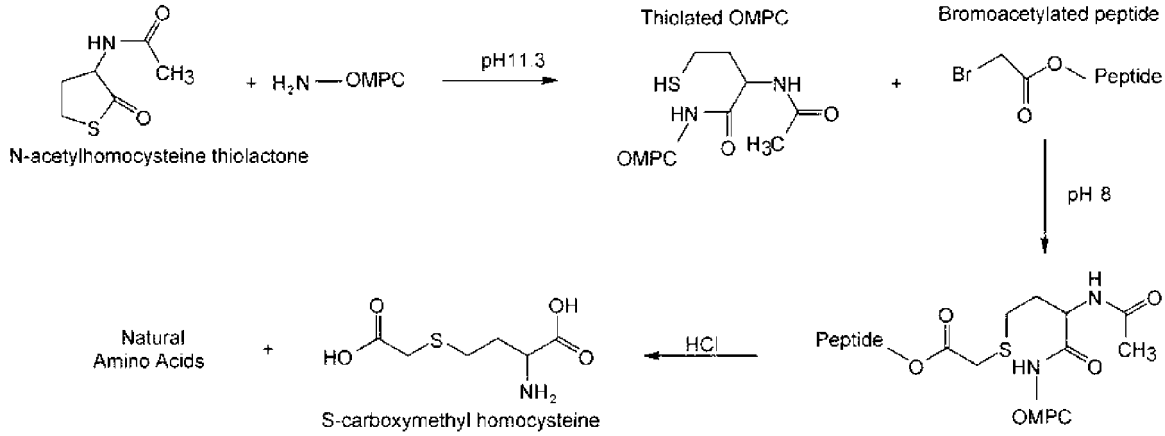
RESULTS

The modified elution conditions developed for amino acid analysis of cell culture supernatants by RP-HPLC proved suitable for resolving the unique conjugate-specific amino acids SDCEC, SCMHC, ε-Ahx and Txa from the 17 common peptide- and protein-derived amino acids within a single 60 min run. RP-HPLC analysis of the AQC derivatives provided a linear response for all components between 1.5 pmol and 50 pmol injected on the column.

AAA Direct amino acid analysis by HPAE-PAD did not prove useful for the analysis of OMPC–peptide conjugates because of peaks that interfered with the detection of Arg and His, and the fact that HEPES buffer, which was used for conjugate preparation, interfered with the detection of leucine and caused excessive fouling of the gold electrode surface. Also, the method was considerably less sensitive than fluorescent detection of AQC-derivatized amino acids. The limit of detection for all amino acids using the AAA Direct method was 50 pmol, compared with 1.5 pmol for the AccQTag method.

Comparison of Amino Acid Analysis by Direct Detection versus Precolumn Derivatization. The amino acid composition of a single lot of OMPC was determined following acid hydrolysis by an independent contract laboratory, using cation exchange chromatography with postcolumn ninhydrin derivatization (AAASL, Boring, OR). The results were compared with those obtained from the RP-HPLC method with precolumn AQC derivatization and direct analysis of hydrolyzed samples by HPAE-PAD (Table 1). In general, the differences between our AccQTag results and those of the contract laboratory were within experimental error (3–12% RSD). However, significant differences were observed between the

Scheme 2[a]



[a] A carrier protein, such as OMPC, is activated with *N*-acetylhomocysteine thiolactone \(NAHT\), which reacts with primary amines \(Lys residues and N-terminus\). Then a bromoacetylated peptide can react with the NAHT-activated carrier protein to form a peptide–protein conjugate. Acid hydrolysis of the resulting conjugate liberates SCMHC in addition to the constituent amino acids of the peptide and the carrier protein. Quantitation of SCMHC by amino acid analysis can be used to determine the ratio of peptide to carrier protein.

[a] Quantitation of acid-stable residues reported as the average μmol residue/mg OMPC $\pm$ standard deviation. [b] Nine replicates were analyzed in a single run, using postcolumn ninhydrin detection. [c] Three replicates were analyzed on three separate days. [d] An unresolved peak that is also present in the buffer blank interferes with the detection of arginine.

AAA Direct method and the other methods. The AAA Direct method resulted in significantly lower values for alanine, glycine, valine, isoleucine, and leucine, and 2-fold higher concentrations for arginine (because of an interfering peak). The average variability observed with the AAA Direct method (8% RSD) was also twice as high as the average variability of the AccQTag method (4% RSD).

Optimization of Hydrolysis Conditions for Peptide/Carrier Conjugates. Because the AAA Direct analysis was less sensitive and was affected by interferences from buffer components, we focused hydrolysis optimization efforts solely on the AccQTag method. Hydrolysis time and temperature were evaluated in order to maximize the recoveries of the conjugate-specific unique amino acids. Acid hydrolysis of amino acid standards with 6 N HCl and 1% phenol revealed a 24% reduction in peak area for SCMHC and a 13% reduction in peak area for SDCEHC within 20 h at 110 °C. However, peak areas for SCMC, SDCEC, ε-Ahx, and Txa remain stable even after 70 h of hydrolysis.

Peptide–carrier conjugates prepared from both thiolated and maleimide-activated OMPC were also analyzed with hydrolysis times ranging from 20 to 70 h at 110 °C. The average results for the ε-Ahx/OMPC ratio, SDCEC/OMPC ratio, and SCMHC/OMPC ratio were then calculated for the various different hydrolysis conditions, along with the peptide loading determined by the LSA spreadsheet method. For both conjugates, the total protein concentrations did not vary significantly with increasing

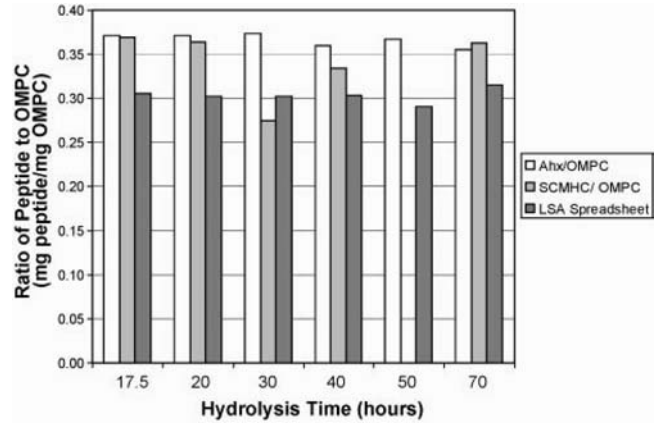

Figure 1. A conjugate prepared from a bromoacetylated peptide and thiolated OMPC was hydrolyzed at 110 °C for 17.5–70 h. The hydrolyzates were derivatized with AQC and analyzed by RP-HPLC. The ratio of peptide to OMPC was then calculated from either (a) the amount of ε-Ahx linker, (b) the amount of SCMHC, or (c) using the least-squares regression method of Shuler, et al.

hydrolysis time (data not shown). The ratio of peptide to OMPC calculated from the concentration of SCMHC was essentially constant with hydrolysis time, as was the ratio of ε-Ahx to OMPC (Figure 1), even though a standard of SCMHC was shown to degrade at hydrolysis times longer than 20 h. Interestingly, for the conjugate sample that was prepared from

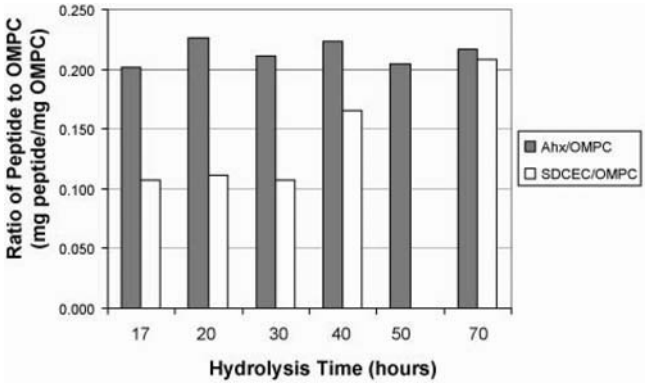

Figure 2. A conjugate prepared from a cysteine containing peptide and maleimide-activated OMPC was hydrolyzed at 110 °C for between 17.5 and 70 h. The hydrolyzates were derivatized with AQC and analyzed by RP-HPLC. The ratio of peptide to OMPC was then calculated from either the amount of ε-Ahx linker or the amount of SDCEC.

maleimide-activated OMPC, 70 h of hydrolysis at 110 °C was required to obtain maximal recovery of SDCEC (Figure 2). The need for extended hydrolysis times in order to quantitatively recover SDCEC from thiol–maleimide adducts has been previously demonstrated (*23*).

DISCUSSION

Amino acid analysis provided a reliable means for assessing the covalent attachment of peptide to carrier protein because acid hydrolysis of the nascent conjugate bonds generates novel amino acids such as SDCEC or SCMHC, depending on the choice of chemistry used. The total amount of peptide in the complex can also be quantified by monitoring the concentration of a unique peptide-specific component, such as the ε-Ahx linker described here. In the current report, ratios of peptide to OMPC carrier protein were calculated using both methods, with equivalent results. Of the methods for calculating the peptide content of the conjugate, only measurement of the unique amino acid formed upon hydrolysis of the conjugate bond provides conclusive evidence of the covalent attachment of the peptide to the protein. Incomplete removal of aggregated peptide from OMPC conjugate samples during dialysis can lead to overestimation of the amount of peptide incorporated into the carrier when this ratio is calculated using either the LSA approach or the quantitation of ε-Ahx.

Importantly, our results clearly demonstrate that optimization of the hydrolysis conditions used for amino acid analysis is critical to obtaining consistent and accurate results when utilizing unique amino acid residues. In our hands, ε-Ahx was quantitatively recovered following the hydrolysis of peptide–OMPC conjugates under relatively standard conditions (15–20 h), whereas a more extensive hydrolysis time of 70 h was required for SDCEC. In contrast, SCMHC was recovered quantitatively in hydrolysates prepared at 20 h, and the ratio of SCMHC to OMPC did not change significantly with longer hydrolysis times. Our observations, to a large degree, are likely related to the complex nature of a multicomponent lipoprotein carrier such as OMPC, and the results of a similar comparison may be quite different for peptides coupled to a soluble monomeric protein carrier such as bovine serum albumin, even when employing the same conjugation chemistries. These differences exemplify the requirement for rigorous optimization of experimental parameters when seeking to employ these quantitative methods in a reliable and reproducible manner.

ACKNOWLEDGMENT

We thank Jay Gambee at AAA Service Laboratory, Inc. for performing amino acid analysis, Chengwei Wu for peptide synthesis, and Dr. Craig Przysiecki for providing unique amino acid standards.

Enzymatic ligation methods are useful in the diagnostic detection of DNA sequences. Here, we describe the investigation of nonenzymatic phosphorothioate−iodoacetyl DNA chemical ligation as a method for the detection and identification of RNA and DNA. The specificity of ligation on the DNA target is shown to allow the discrimination of a single point mutation with a drop in the ligation yield of up to 16.1-fold. Although enzymatic ligation has very low activity for RNA targets, this reaction is very efficient for RNA targets. The speed of the chemical ligation with an RNA target achieves a 70% yield in 5 s, which is equal to or better than that of ligase-enzyme-mediated ligation with a DNA target. The reaction also exhibits a significant level of signal amplification under thermal cycling in periods as short as 100–120 min, with the RNA or DNA target acting in a catalytic way to ligate multiple pairs of probes.

INTRODUCTION

Much work has been carried out recently to develop molecular strategies for sensing nucleic acid sequences and distinguishing single nucleotide differences (*1–3*). Enzymatic methods are one of the most common strategies in current use (*4–6*). cDNAs treated with PCR-based amplification are analyzed with these methods. Of the enzymes used, DNA ligases such as T4 and T*th* are quite sensitive to base mismatches and can amplify DNA signals under thermal cycling conditions, in the ligase chain reaction (LCR) (*7, 8*). Although they are quite useful, enzymatic ligation methods for sequence detection also have some limitations. For example, ligases have low activities for RNAs (*9*). Furthermore, although very short probes have the highest sequence specificity, ligase enzymes are inefficient with short oligonucleotides (*10*).

As a result, the consideration of alternatives to enzymatic methods, such as those involving ligases, seems justified for some applications. DNA template chemical ligation might be one candidate for a general approach to the detection of oligonucleotides (*11, 12*). Removing the need for an enzyme can lower the cost, and RNA samples can be targeted directly without reverse transcription to the corresponding cDNA. A number of ligation chemistries have been developed (*13–16*). Some methods require the addition of ligating reagents to the oligonucleotide probes. Autoligation chemistries that do not require added reagent are even simpler for these applications. Photochemical ligation (*17, 18*) or 1,3-dipolor cycloaddition (*19*) on a DNA template, and also ligation based on the nucleophilic displacement of the sulfur on the bromoacetyl (*20, 21*), maleimide (*22*), tosyl (*23, 24*), or iodo nucleoside groups (*25, 26*). have been reported. Among these strategies, the chemical reaction between the phosphorothioate and the bromoacetyl group offers the fastest ligation, within 20 min (*27*). However, it is still slower than the ligase enzymatic reaction, which is completed within 2 min in the LCR method. A faster chemical ligation reaction must be developed to achieve thermal cycling amplification.

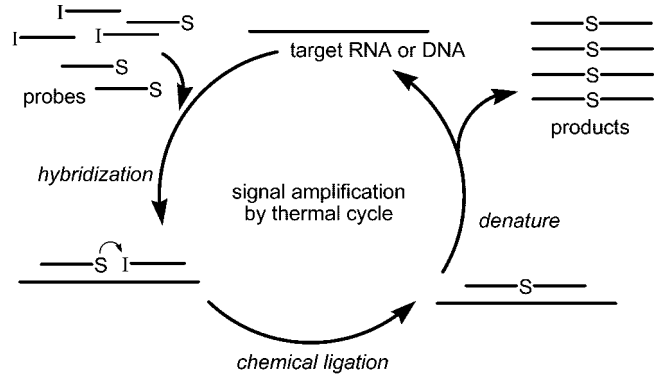

Figure 1. Signal amplification by multiple chemical ligations. The reaction is carried out in a thermal cycler instrument designed for PCR. DNA probes bind to the DNA or RNA target, and ligate together. After this step, the reaction mixture is heated to promote the dissociation of the ligated products from the target. The reaction then proceeds to the second round.

Here, we describe a chemical ligation using a pair of phosphorothioate and iodoacetyl groups. The reaction is almost complete within 60 s and achieves a turnover under thermal cycling conditions (Figure 1). The chemistry was applied to single-base discrimination and direct RNA sensing with signal amplification.

EXPERIMENTAL PROCEDURES

Preparation of Probes and Target. DNA and RNA oligonucleotides were synthesized on a 0.2 μmol scale on a Gene World (Tokyo, Japan) H-8 DNA synthesizer using standard β-cyanoethylphosphoramidite coupling chemistry. Phosphorylation was carried out using Phosphate-ON reagent from Glen Research (Sterling, VA). For the 3′-phosphorothioate sequence,

the first nucleotide added on 3′-phosphate CPG column (Glen Research) was sulfurized with a sulfurizing reagent (Glen Research), and further synthesis was carried out according to normal protocol. For the 5′-amino-dT sequence, after normal DNA synthesis, 5′-amino-dT phosphoroamidite (Glen Research) was attached on the oligonucleotides at the last step. The oligonucleotides were treated with concentrated ammonia for 4 h at 55 °C and purified on a Sep-Pak column and then by reversed-phase high-performance liquid chromatography (HPLC; 0−30% acetonitrile/50 mM triethylammonium acetate buffer). To incorporate the iodoacetyl group, 100 nmol of the 5′-amino-dT sequence in 500 μL of 0.075 M sodium tetraborate (pH 8.5) was incubated for 10 m at room temperature with 4 μmol of *N*-succinimidyl iodoacetate (Sigma-Aldrich) in 375 μL of DMF. The probes were purified by reversed-phase HPLC (0−30% acetonitrile/50 mM TEAA buffer). The probe structures were analyzed by MALDI-TOF mass spectrometry. Iodoacetyl probe (8-mer): Calcd mass $C_{80}H_{101}IN_{31}O_{47}P_7$, 2591.37(MH+); found 2592.38.

Ligation Reaction. To trace the reaction, the phosphorothioate probe was labeled with ^{32}P isotope at the 5′ terminus using T4 polynucleotide kinase (Roche) and γ-^{32}P-ATP. The reaction was carried out with 1 μM probe and target concentrations in Tris−borate buffer (pH 8.0) containing 10 mM $MgCl_2$ and 10 mM DTT at 25 °C. To stop the reaction, 90% formamide loading buffer was added to the reaction mixture. The reactions were analyzed by 20% denaturing polyacrylamide gel electrophoresis using a 0.35 mm thick gel (length 40 cm), in Tris−borate−EDTA buffer, with electrophoresis at 30 W for 1.5 h. The radioactive ligation bands were visualized and quantitated with a BAS-2000 image analyzer (Fuji Film, Japan). The templated ligation signal was calculated with the subtraction of the background signal without target.

Turnover Experiments. Experiments were carried out on the com-DNA target or com-RNA target using a ^{32}P-labeled 6-mer phosphorothioate probe and an 8-mer iodoacetyl probe. For each equivalent of target strand, 1–1000 equiv of probe were present, with a target concentration of 1–1000 nM. Reactions were performed under the following cycling conditions using a thermal cycler designed for PCR: DNA target (55 cycles for 2 h), chemical ligation step at 25 °C for 120 s and denaturation step at 55 °C for 15 s; RNA target (99 cycles for 100 min), chemical ligation step at 30 °C for 10 s and denaturation step at 60 °C for 10 s. The reactions were then analyzed by denaturing gel electrophoresis. Turnover number is given as equivalents of radioactive signal per mole of target strand.

Thermal Denaturation. Solutions of 2.0 μM DNA were prepared as 600 μL samples in melt buffer (10 mM $MgCl_2$ in 70 mM Tris−borate buffer, pH = 7.0). The melting studies were carried out in Teflon-stoppered 1 cm path length quartz cells under nitrogen atmosphere on a JASCO V-550 UV–vis spectrophotometer equipped with a Peltier temperature controller. Absorbance was monitored at 260 nm, while temperature was increased from 10 to 90 °C at a rate of 1.0 °C/min. In all cases, the complexes displayed sharp, apparently two-state transitions.

RESULTS

Design and Synthesis of Chemical Ligation Probes. We chose the iodoacetyl group and the phosphorothioate group for ligation probes, because these functional groups are most reactive and seem to offer the best ligation rate (Figure 2). *N*-Succinimidyl iodoacetate was reacted with the 5′-amino group of the DNA probe to prepare an electrophilic iodoacetyl probe (*21*). The 3′-phosphorothioate probe was prepared according to the procedure reported previously (*25*). The ligated product has an extra linker consisting of acetamide, compared with the native

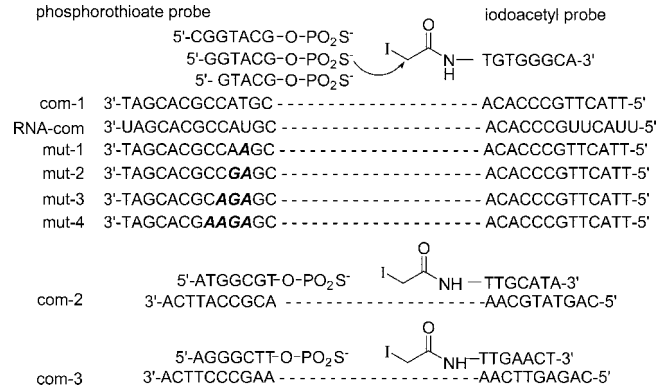

Figure 2. Structures and sequences of the DNA probes and targets. Chemical ligation proceeds, involving the S_N2 reaction between the phosphorothioate probe and iodoacetyl probe, on a DNA or RNA template. The phosphorothioate probe was designed to be a 5-mer, 6-mer, or 7-mer, and the iodoacetyl probe to be an 8-mer; these are complementary to the com-1 or RNA−com target. A series of mutant targets was also designed, such that mut-1−mut-4 had mismatches of 1–4 bases, respectively. The phosphorothioate probes and iodoacetyl probes were also designed to be 7-mers and are complementary to the com-2 or com-3 target.

DNA strand. Letsinger reported that the linker does not destabilize the resulting double strand (*20*), so thermal cycling to dissociate the ligated products from the target strand is required to achieve multiple turnovers (Figure 1). Relatively short probes were designed for high sequence selectivity and to minimize product inhibition. For the com-1 target, the iodoacetyl probe was designed as an 8-mer and the length of the phosphorothioate probe varied from a 5-mer to a 7-mer. Com-1 and RNA−com-1 were fully complementary to the probes, and the mutated DNAs, mut-1−mut-4, had a mismatch of from one to four bases, respectively, relative to the phosphorothioate probe. The iodoacetyl probe and phosphorothioate probe for the com-2 target were also designed as 7-mers. The com-3 target sequence is a junction site of the *bcr*/*abl* gene translocation between chromosomes 9 and 22, which is seen in about 20% of patients with acute lymphoblastic leukemia (*28*). Thus, detection of the *bcr*/*abl* gene is very important for clinical applications. Probes for the com-3 target were designed as 7-mers.

Ligation to DNA and RNA Templates. To optimize the ligation rate, we tested a series of phosphorothioate probes: 5-mer, 6-mer, or 7-mer. A synthetic 26-mer DNA (com-1) was used as the target sequence. Ligations were carried out at 25 °C with 1.5 μM iodoacetyl probe, 1.0 μM phosphorothioate, and 1.0 μM com-1, in a Tris−borate buffer (pH 8.0) containing 10 mM Mg^{2+}. The phosphorothioate probe was labeled at the 5′ terminus with ^{31}P for the trace. The reactions were stopped by the addition of 80% formamide solution, followed by 20% polyacrylamide gel electrophoretic analysis.

The initial slopes of the product yields were measured as a function of time. The 6-mer phosphorothioate probe produced the fastest ligation rate of 24% yield per 15 s compared with that of the 7-mer (20% per 15 s) and the 5-mer (2% per 15 s) (Figure 3A). The temperature of the ligation reaction was varied from 15 to 55 °C to determine the optimal temperature (Figure 3B). In the temperature range 15−35 °C, the 6-mer probe showed a better yield than did the 5-mer or 7-mer probes. Ligation of the 6-mer probe produced its best yield at 25 °C. Therefore, we considered the best temperature for the ligation reaction to be 25 °C and used the 6-mer probe for further experiments, because the shorter 6-mer probe offers higher selectivity in mismatch discrimination than the 7-mer probe.

To investigate the differences in ligation between an RNA target and a DNA target, we prepared a synthetic 26-mer RNA

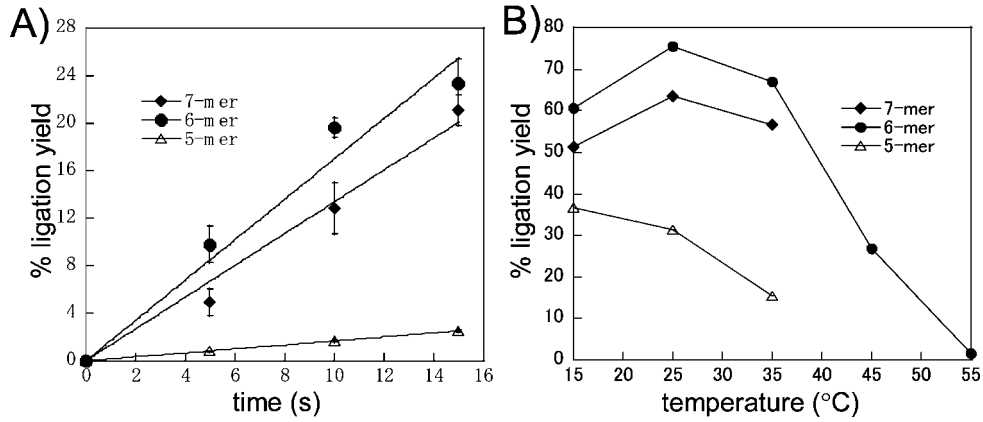

Figure 3. Effects of probe length and temperature on the ligation reaction. (A) Comparison of the initial ligation rates of the 5-mer, 6-mer, and 7-mer phosphorothioate probes for 15 s. (B) Comparison of the effects of temperature on ligation yield for 5 min with the 5-mer, 6-mer, and 7-mer phosphorothioate probes. The reaction was performed under the following conditions: iodoacetyl probe (1.5 μM), phosphorothioate probe (1.0 μM), com−DNA (1.0 μM) in 70 mM Tris−borate buffer (pH 7.0) containing $MgCl_2$ (10 mM) and DTT (1 mM).

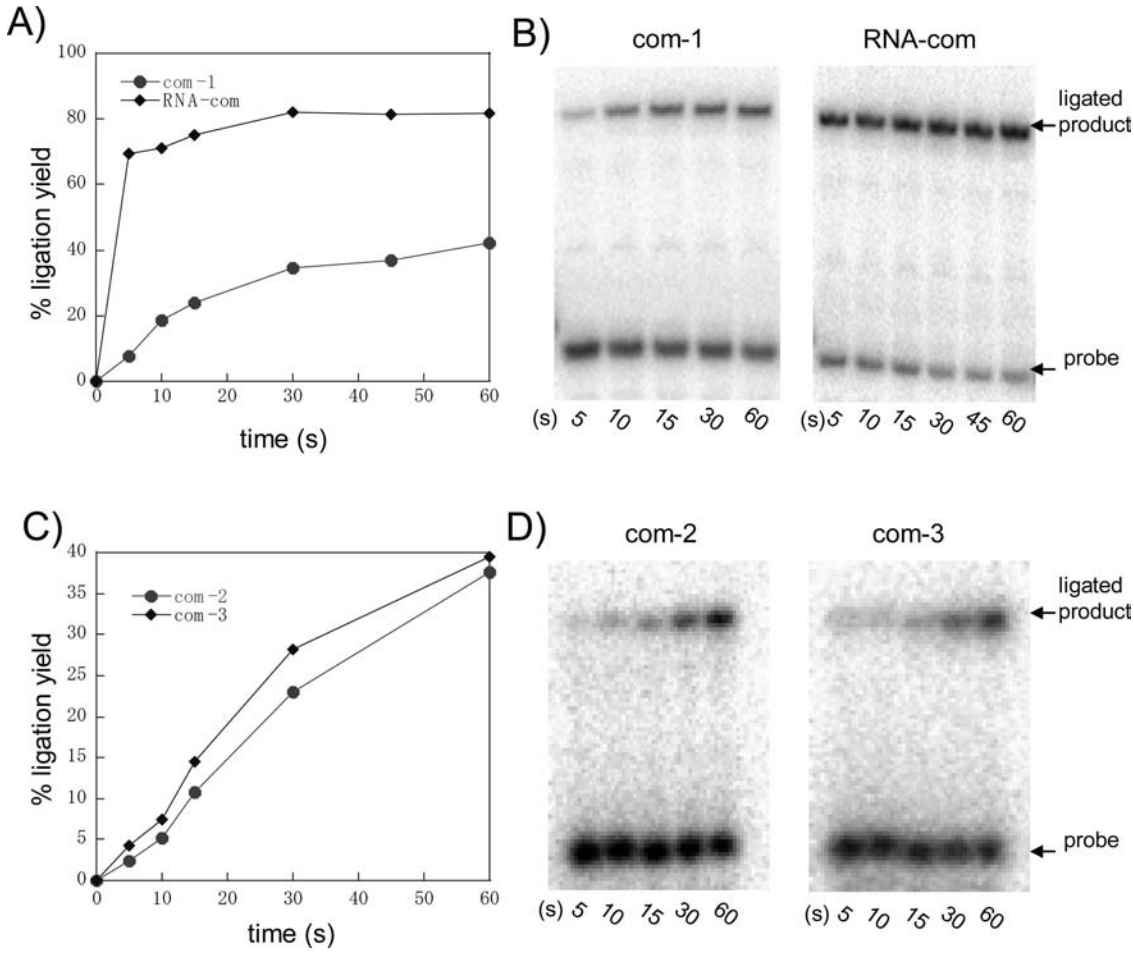

Figure 4. Comparison of the ligation reactions using RNA target or DNA targets. The reaction was performed under the same conditions described for Figure 3, with RNA−com or com-1 as the target. The reactions for the com-2 and com-3 targets were also performed. (A) Time course of the ligation reaction for 60 s with com-1 (circle) and RNA−com (diamond). (B) 20% gel electrophoretic analysis of the ligation reactions in the com-1 or RNA−com target. Phosphorothioate probe was labeled with ^{32}P for the trace. (C) Time course of the ligation reaction for 60 s with com-2 (circle) and com-3 (diamond). (D) 20% gel electrophoretic analysis of the ligation reaction of the com-2 or com-3 target.

target (RNA−com) corresponding to DNA com-1, and performed the ligation reaction (Figure 4A). The reaction took place over a period of 60 s on com-1, reaching a 40% yield. Significantly, the reaction on RNA−com occurred roughly seven times faster in the initial stage than that on com-1, reaching a 70% yield in 5 s, and plateauing at an 80% yield after 30 s. Com-2 DNA and com-3 DNA showed moderate reaction rates with a 37% yield in 60 s and a 40% yield in 60 s, respectively (Figure 4C,D).

Thermal Stability of Probes and Ligated Products. It is important to know the melting temperatures (T_m) between probes and the target DNA or between the corresponding ligated product and the target DNA to optimize the ligation reactions and thermal cycling conditions, because the ligation reaction

Table 1. Melting Temperatures of Probes and Ligation Products[a]

	com-1	com-2	com-3
probe	37.2	38.4	34.8
ligation product	67.8	61.6	61.9

[a] Probes or ligated products were tested for their binding to the target DNAs com-1, com-2, and com-3. Conditions: 5.0 μM oligonucleotide, 10 mM $MgCl_2$ in 70 mM Tris−borate buffer (pH 7.0).

proceeds well at temperatures below the T_m of the probe, whereas thermal cycling conditions require temperatures higher than the T_m of the ligated product in the denaturing step to overcome product inhibition. To evaluate the T_m, we synthesized a series of DNA sequences corresponding to the probes and ligated products. Native DNA structures were used for T_m measurements instead of the iodoacetyl probe or ligated product with a thio-acetamide linkage. The resulting melting curves and T_m values are shown in Supporting Information Figure S1 and Table 1, respectively. In the case of probes, both the phosphorothioate probe and DNA probe which corresponds to the iodoacetyl probe were mixed together before the measurement of the T_m. The T_m values of the probes for com-1, com-2, and com-3 were 37.2, 38.4, and 34.8 °C, respectively. The T_m of the ligated products was higher for com-1 (67.8 °C) than for com-2 (61.6 °C) or com-3 (61.9 °C).

Discrimination of Mismatches. To investigate the ability of the process in sequence discrimination, we tested the ligation reaction with a series of mutant targets, mut-1−mut-4. At first, the reaction was performed at 25 °C for 5 min (Figure 5A). Mut-1, with a single base difference, gave a 37% product yield, equivalent to one-half the yield achieved with the com-1 target. Very small amounts of product were observed after the ligation reactions with mut-2 and mut-3, which have two and three base mutations, respectively. The mut-4 target showed the same level of signal as the reaction without target DNA. To achieve higher selectivity in single-base discrimination, the ligation reaction was tested at various temperatures (Figure 5B). The results show the ratio of ligation yield achieved with com-1 to that with mut-1. The lowest selectivity of 1.41 was observed at 15 °C. The selectivity increased with increasing temperature, reaching a maximum of 16.3 at 45 °C, and dropping off to 9.0 at 55 °C. Thus, we conclude that high sequence selectivity can be achieved by controlling the reaction temperature.

Signal Amplification under Thermal Cycling Conditions. DNA templates have been observed in some cases to facilitate the ligation of multiple equivalents of ligating strands, by dissociation of the ligated product followed by the binding and ligation of a new pair of ligating strands (Figure 1). This turnover is commonly inhibited when the binding of the product to the template is favored over the binding of the unligated strands to the template. To overcome this product inhibition, thermal cycling conditions were used for the ligase-enzyme-mediated ligation to achieve multiple turnovers. (*7*) This should be valuable in possible diagnostic applications, because one target would produce more than one ligated signal. Iodoacetyl−phosphorothioate probe pairs offer very rapid ligation, equal to the ligation achieved with ligase enzyme, and the reaction also accepts an RNA template, which the ligase enzyme cannot. This suggests the possibility of turnover under thermal cycling conditions.

Turnover, and the associated signal amplification, is useful when target concentrations are low. Under these conditions, one would typically use a large excess of probes relative to the number of targets. To measure turnover with the current probes, we compared the number of equivalents of signal to moles of target. This required the development of a method of carefully quantitating the signal, and confirming that the signal arises from true template-dependent intermolecular ligation reactions rather than from background sources, such as intermolecular ligation independent of the target strand. To evaluate this, we performed ligations using a radiolabeled phosphorothioate probe at various target concentrations, and we separated the products from excess unreacted probes by gel electrophoresis. The radioactivity in the ligated product bands was quantitated by digital phosphorimaging. We first prepared a standard dilution curve to make a ^{32}P-labeled phosphorothioate oligonucleotides in a gel lane. This plot showed good linearity and allowed us to take a given signal and, from the plot, determine the number of moles of radioactive oligonucleotide product in a given band on the gel (*29*).

We carried out a ligation reaction using 1–1000 equiv of probe per equivalent of DNA or RNA target strand, and investigated the yields of ligated product as a function of target concentrations in the range 1–1000 nM. This was performed with the same synthetic DNAs: the com-1, com-2, com-3, and RNA−com targets. To determine the optimal cycling conditions, ligation reactions on the DNA target (com-1) were performed in the temperature range from 15 to 55 °C with the 6-mer phosphorothioate probe (Figure 3B). Efficient ligation occurred at 25 °C and less efficient ligation at temperatures higher than 45 °C, because the probes dissociated from the target at temperatures higher than the T_m (37.2 °C). The double strand between the ligated product and com-1 had a T_m of 67.8 °C

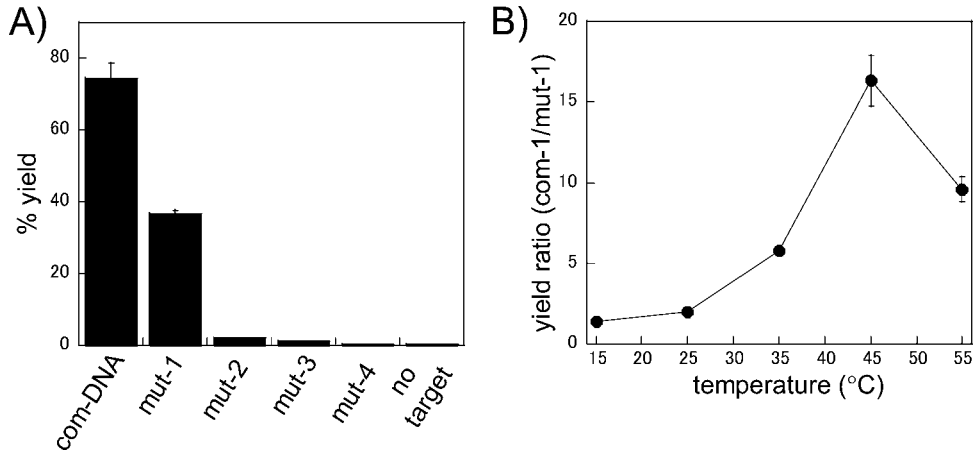

Figure 5. Effect of mutant target and temperature on the ligation reaction. (A) Comparison of ligation yield with various mutant targets. Ligations were performed with mutant targets mut-1−mut-4 or with no target, under the following conditions: iodoacetyl probe, 1.5 μM; 6-mer phosphorothioate probe 1.0 μM; target DNA, 1.0 μM at 25 °C for 5 min. (B) Effects of temperature on the discrimination of a single base difference. The ratio of com−DNA yield to mut-1 yield was calculated for each temperature.

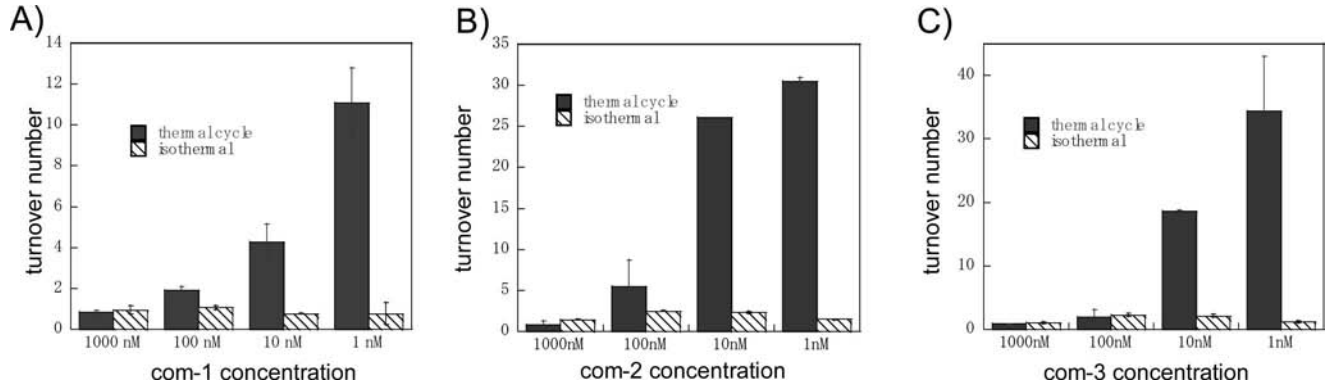

Figure 6. Effects of target DNA concentration and temperature on turnover. Turnover number is given in equivalents of radioactive signal per mole of target DNA. The concentration of the target DNA was varied from 1000, 100, 10, to 1 nM in 70 mM Tris−borate buffer (pH 7.0) containing 1.5 μM iodoacetyl probe, 1.0 μM phosphorothioate probe, 10 mM $MgCl_2$, and 1 mM DTT. Thermal cycling conditions were as follows: ligation at 25 °C for 120 s and denaturation 55 °C for 15 s (55 cycles for 120 min). Isothermal conditions were 25 °C for 120 min. The reactions were analyzed by 20% polyacrylamide gel electrophoresis. (A) com-1 target. (B) com-2 target. (C) com-3 target. The reactions were repeated at least twice, and the data were averaged. Error bars show standard deviations.

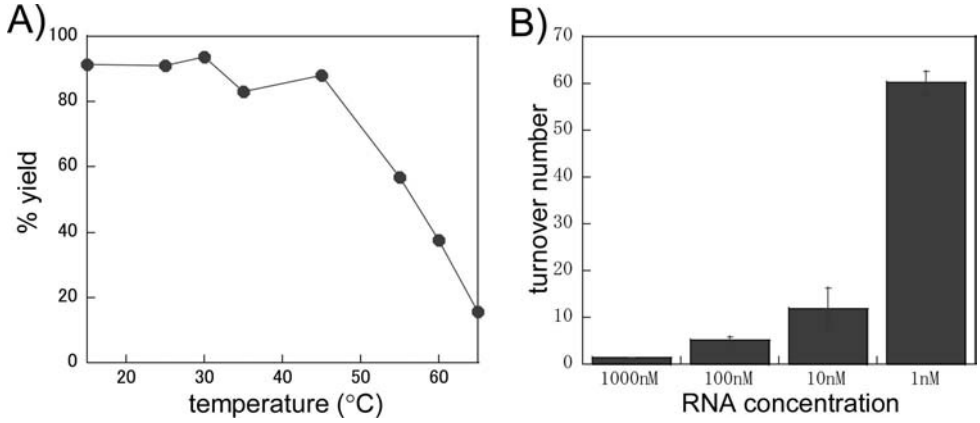

Figure 7. Effects of temperature and target RNA concentration on turnover. Turnover number is given as equivalents of radioactive signal per mole of target RNA. The concentration of the RNA−com was varied from 1000, 100, 10, to 1 nM in 70 mM Tris−borate buffer (pH 7.0) containing 1.5 μM iodoacetyl probe, 1.0 μM phosphorothioate probe, 10 mM $MgCl_2$, and 1 mM DTT. Thermal cycling conditions were ligation at 30 °C for 10 s and denaturation at 60 °C for 10 s (100 cycles for 100 min).

when the concentration of the DNA double strand was 5 μM. Although it is important to know the T_m of the ligated product to determine the temperature of the denaturation step in the thermal cycle, the target concentration is different from that under the actual experimental conditions, which achieve the best turnover number, when 1 nM target DNA is used against excess probe (1 μM). The actual T_m value must be lower than 67.8 °C. Moreover, the iodoacetyl probe is unstable at higher temperatures because of hydrolysis. Therefore, we used a temperature of 55 °C for the denaturation step, which is slightly lower than the experimental T_m. The thermal cycling conditions for the com-1 target were as follows: chemical ligation step at 25 °C for 120 s, denaturation step at 55 °C for 15 s (55 cycles for 120 min). There was significant turnover at the lower target concentrations (Figure 6A). The turnover number increased at the lower target concentrations. We observed eleven turnovers at the lowest concentration of the com-1 target (1 nM) under thermal cycling conditions for 120 min. In contrast, there was no significant turnover without thermal cycling (isothermal at 25 °C), even at the lowest concentration. Other DNA sequences were also tested under these thermal cycling conditions. The same thermal cycling conditions as those used for com-1 were used for the com-2 and com-3 targets. The results are shown in Figure 6B, C. Again, a significant turnover number was observed under these thermal cycling conditions and a low turnover number under isothermal conditions. Higher turnover numbers were observed at lower target concentrations. The high turnover numbers were 30 for the com-2 target and 35 for the com-3 target, when the target concentration was 1 nM.

Next, we performed ligation reactions with the RNA−com target, which corresponds to the DNA com-1 target. To determine the optimal cycling conditions for the RNA target, the ligation reactions were tested in the temperature range 15−65 °C for 5 min (Figure 7A). No significant change was seen in the conversion yield from 15 to 45 °C. However, the conversion yield decreased at temperatures higher than 55 °C, because of the dissociation of the probes. Furthermore, ligation with the RNA target was 70% complete within 5 s (Figure 4A). Thus, the following thermal cycling conditions were used to amplify the com−RNA target: chemical ligation step at 30 °C for 10 s, denaturation step at 60 °C for 10 s (99 cycles for 100 min). The turnover was more efficient than that achieved with the DNA target. Similarly, as with the DNA target, the turnover number increased at the lower target concentrations. The maximum turnover number of 60.1 was observed at the lowest target concentration under thermal cycling for 100 min (Figure 7).

DISCUSSION

The iodoacetyl-phosphorothioate probes described here allow very rapid reactions. Ligation with the DNA target proceeded to a 10% yield in 5 s. Notably, the RNA target allows a substantial increase in the ligation rate over that of the DNA

target, reaching a 70% yield in 5 s. One reason for the rate enhancement on the RNA target is presumably the thermal stability of the RNA−DNA double strand, which is more stable than the DNA−DNA double strand. This tendency is shown in Figure 3B and Figure 7A, in which the ligation reaction with the RNA target gives a better yield, even at higher temperatures (>45 °C), than the reaction with the DNA target with the 6-mer phosphorothioate probe. The surprising reaction speed can be explained because the iodoacetyl group is the most reactive electrophile and the thioxide anion of the phosphorothioate group is the most reactive nucleophile. We are unaware of any other chemical ligation method with such a rapid reaction rate. This reaction rate is equal to or better than that of ligase-enzyme-mediated ligation, although the DNA ligase enzyme shows very low activity for RNA targets (*9*).

The present probe shows moderate mismatch selectivity, which is similar or a little worse than that of other chemical ligation methods (*11, 25*). The discrimination of a single base difference was achieved by controlling the reaction temperature. In the case of a T→A point mutation, maximum selectivity was achieved at 45 °C, with a 16-fold drop in ligation yield. This probe could potentially be used to identify DNA or RNA sequences, although further optimization is required.

The amplification of nucleic acid signals should clearly be helpful in detecting RNAs or DNAs at low concentrations or at low copy numbers. Several laboratories have recently investigated strategies for using pairs of modified oligonucleotides to generate amplified products or signals under isothermal conditions. Kool has reported a ligation chemistry with significant amplification using the iodo or dabsyl group as the leaving group (*25, 29*). Seitz has developed peptide nucleic acid (PNA) probes that ligate by native chemical ligation (*30*). Other ligation approaches have been investigated by von Kiedrowski (*31*) and by Lynn (*16*). These approaches use denaturation cycles (unlike thermal cycling) and a separate reagent for turnover, respectively. In another novel approach that does not require ligation, Taylor and Kramer have described the combination of hydrolysis catalysis on one oligonucleotide with a leaving group on the other, resulting in the release of multiple leaving groups for each targeted DNA (*32–34*). Seitz has recently described the transfer of a reporter group from one probe to another probe on the DNA target, resulting in multiple products (*35*). Although all these methods succeed in isothermal amplification, they take a long time (∼24 h) to achieve turnovers, because the reaction rates are relatively slow. In contrast, the current strategy is based on thermal cycling and achieves significant turnovers in a short time (100–120 min) by using a thermal cycler instrument designed for PCR. When RNA is targeted, 60.1 turnovers were achieved in 100 min. The very rapid chemical reaction, similar to the enzymatic reaction, makes this strategy possible.

There are numerous enzymatic amplification strategies, such as PCR and RT-PCR, for genetic detection. In the PCR methods, the signal is amplified exponentially. Conversely, the current method amplifies the signal linearly. Therefore, our method is inferior to PCR in terms of turnover and sensitivity. However, PCR cannot directly detect target RNA. Although the RNA signal can be amplified and detected by RT-PCR, this method is time-consuming (RT-PCR usually requires 3–4 h) and consists of several amplification steps that require cumbersome procedures to prevent carryover contamination. Therefore, the chemical ligation method has some advantages in genetic detection compared with PCR-based detection. Furthermore, the chemical ligation probes can be readily modified with fluorescent dyes to make the signal detectable.

CONCLUSION

The present study demonstrates a very rapid chemical ligation method that amplifies a DNA or RNA signal. The method uses commercially available thermal cyclers designed for PCR for amplification and uses cycling condition similar to those used in the LCR method. A few femtomoles of RNA were detected using a radioisotope-labeled probe under thermal cycling conditions. Discrimination of a single base difference was achieved with a 16.1-fold drop in the ligation yield, although this technique still requires optimization. Ongoing work will be aimed at developing a dye-labeled probe for detecting RNA in real time.

Glucagon-like peptide-1 (GLP-1) (7–36) is a type of incretin hormone with unique antidiabetic potential. The introduction of orally active GLP-1 offers substantial benefits in the treatment of type 2 diabetes over conventional injection-based therapies. Because the intestinal absorption of GLP-1 is restricted by its natural characteristics, we developed a series of GLP-1 analogues via the site-specific conjugation of biotin−NHS and/or of biotin−poly(ethylene glycol)−NHS at Lys^{26} and Lys^{34} of GLP-1 (7–36), respectively, in order to improve oral delivery. The resultant GLP-1 analogues, $Lys^{26,34}$-DiBiotin-GLP-1 (DB-GLP-1) and Lys^{26}-Biotin-Lys^{34}-(Biotin-PEG)-GLP-1 (DBP-GLP-1), were prepared and studied in terms of their chemical, structural, and biological properties. DBP-GLP-1 demonstrated superior proteolytic stability against trypsin, intestinal fluid, and the major GLP-1 inactivation enzyme (dipeptidyl peptidase-IV (DPP-IV)) to native GLP-1 or DB-GLP-1 ($p < 0.001$). The in vitro insulinotropic effects of DB-GLP-1 and DBP-GLP-1 showed potent biological activity in a dose-dependent manner, which resembled that of native GLP-1 in terms of stimulating insulin secretion in isolated rat islets of Langerhans. Intraperitoneal glucose tolerance tests (IPGTT) after the oral administration of GLP-1 analogues in diabetic db/db mice demonstrated that DB-GLP-1 and DBP-GLP-1 significantly reduced the $AUC_{0-180\ min}$ of glucose for 3 h by 14.9% and 24.5% compared to that of native GLP-1, respectively ($p < 0.01$). In particular, DBP-GLP-1 concentration in plasma rapidly increased 30 min after oral administration in rats, presumably due to improved intestinal absorption. These findings revealed that site-specific biotinylated and biotin−PEGylated GLP-1 is absorbed by intestine and that it has biological activity in vivo. Therefore, we propose that this orally active bioconjugated GLP-1 might be considered as a potential oral antidiabetic agent for type 2 diabetes mellitus.

INTRODUCTION

Glucagon-like peptide-1 (GLP-1) is the product of the glucagon gene, and is secreted from enteroendocrine L-cells of the intestinal mucosa in response to orally ingested nutrients (*1, 2*) GLP-1 is viewed as an interesting antidiabetic agent for the treatment of type 2 diabetes because of its marked glucose-dependent insulinotropic effect. GLP-1 has a number of beneficial effects in type 2 diabetes; for example, it inhibits glucagon secretion and gastric emptying and suppresses appetite (*3–6*) In addition, GLP-1 has strong disease-modifying possibilities in type 2 diabetes, as it inhibits β-cell apoptosis and stimulates β-cell proliferation and/or neogenesis (*7, 8*). Overall, GLP-1 is viewed as a potent therapeutic agent for type 2 diabetic patients, but its short half-life in physiological environments and limited oral bioavailability remain critical hurdles to its successful clinical application (*3, 9*).

The short biological half-life (∼2 min) of GLP-1 is mainly due to its rapid inactivation by the ubiquitous protease (dipeptidyl peptidase-IV (DPP-IV)), which acts on its two N-terminal amino acids, histidine and alanin (*10–12*). To overcome this limitation, several GLP-1 receptor agonists have been developed and investigated to improve the therapeutic value of GLP-1 (*13,14*). However, although these injectable GLP-1 receptor agonists have produced promising results, there is a continuous demand for an orally active GLP-1, as such an agent offers significant advantages in terms of therapeutic and patient acceptability. Furthermore, since the absorption of orally active GLP-1 occurs in the intestine, a DPP-IV resistant GLP-1 efficiently absorbed in the intestine would have the potential to mimic the physiological effects of native GLP-1, which is secreted by intestinal L-cells.

However, the development of such an orally active peptide drug presents an arduous challenge, due to the low intestinal absorption and proteolytic stability of GLP-1 in the gastrointestinal (GI) track (*15, 16*). Thus, the successful oral delivery of this peptide involves increasing its intestinal membrane permeability and overcoming the barrier of enzymatic degradation. Site-specific bioconjugation offers a convenient means of developing orally active peptide drugs. Many different types of peptide bioconjugation, with vitamins, fatty acids, bile acids, and PEG, have been used to develop orally active peptide agents (*16–19*).

Here, we describe new strategies for producing orally active GLP-1 derivatives using site-specific biotinylation and biotin−PEGylation. As a member of the vitamin B family, biotin can be recognized and absorbed through the Na^+-dependent multivitamin transporter (SMVT) systems (*20–22*). Moreover, the natural physicochemical properties of biotins have been utilized to facilitate the intestinal absorption of peptide drugs through passive transport via enhanced hydrophobicity resulting from biotin conjugation and a predominant SMVT absorption

system (*22–24*). We previously reported that site-specific PEGylated GLP-1 at the Lys^{34} position profoundly improves its enzymatic stability while retaining its biological activities, and thus enhances its therapeutic potential in type 2 diabetic db/db mice (*25–27*). The conjugation of water soluble polymers on the lysine residues GLP-1 also showed the preserved insulinotropic activity on pancreatic islets (*28, 29*). In view of these observations that site-specific PEGylated GLP-1 can increase enzymatic stability but retain biological activity, we hypothesized that site-specific biotinylation and biotin−PEGylation might enhance the intestinal absorption of GLP-1 due to its increased permeability and stability without prominent activity loss. In this study, we prepared and characterized site-specifically bioconjugated GLP-1s using sequential biotin and biotin−PEG conjugations on Lys^{26} and Lys^{34} of GLP-1, respectively. The therapeutic potentials of these bioconjugated GLP-1s were then investigated by examining their metabolic stabilities and insulinotropic activities in vitro and their hypoglycemic effects and intestinal absorptions in type 2 diabetic db/db mice.

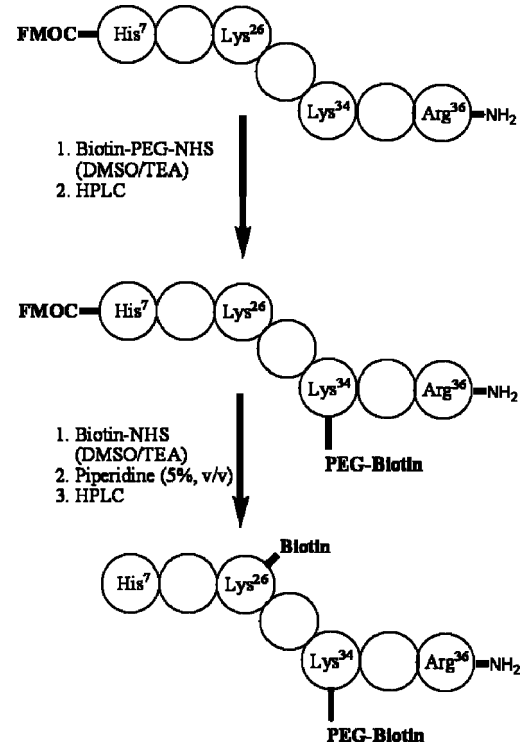
MATERIALS AND METHODS

Materials. GLP-1 was purchased from Bachem (Torrance, CA, USA), Fmoc-GLP-1 from the American Peptide Company (Sunnyvale, CA), and biotin−poly(ethylene glycol) *N*-hydroxysuccinimide ester (biotin−PEG, MW 3400) from Nektar Therapeutics (Huntsville, AL). Dipeptidyl peptidase inhibitor and GLP-1 radioimmunoassay (RIA) kits were purchased from Linco Research (St. Charles, MO), and insulin enzyme immunoassay (EIA) kits from Mercodia (Uppsala, Sweden). All other reagents, unless otherwise indicated, were purchased from Sigma-Aldrich Co. (Saint Louis, MO) and were used as received. Type 2 diabetic C57BL/6 db/db mice (male, 7–8 weeks old) were obtained from the Korea Research Institute of Bioscience and Biotechnology (Daejon, Korea), and male Sprague–Dawley (SD) rats (150–200 g) were purchased from the Hanlim Experimental Animal Laboratory (Seoul, Korea).

Preparation of $Lys^{26,34}$-DiBiotin-GLP-1 (DB-GLP-1). DB-GLP-1 was synthesized by a coupling reaction between N-hydrosuccinimide-activated biotin (biotin−NHS) and the lysine residues (Lys^{26} and Lys^{34}) of GLP-1 in organic solvent. Briefly, 20 μL of biotin−NHS (2 mg/mL in dimethylsulfoxide (DMSO) containing 0.3% triethylamine (TEA)) was reacted with 380 μL of GLP-1 (5 mg/mL in DMSO with 0.3% TEA) (GLP-1/biotin−NHS molar ratio of 2) with gentle mixing at room temperature for 1 h. The reaction was then stopped by adding 100 μL of stop solution (deionized water containing 1% trifluoroacetic acid (TFA)). DB-GLP-1 was finally obtained by preparative high-performance liquid chromatography (HPLC).

Preparation of Lys^{26}-Biotin-Lys^{34}-(Biotin-PEG)-GLP-1 (DBP-GLP-1). DBP-GLP-1 was prepared by the stepwise conjugation of biotin−PEG and biotin on Lys^{34} and Lys^{26} of GLP-1, respectively, using procedures similar to that described above for DB-GLP-1 synthesis. Detailed of the procedures used are illustrated in Scheme 1. First, N^{ter}-FMOC-GLP-1 (FMOC-GLP-1, 1 mg/mL in DMF with 0.3% TEA) was reacted with a 1.5 times molar excess of biotin−PEG−NHS (6 mg/mL in DMF with 0.3% TEA) for 1 h at room temperature. After stopping the reaction with stop solution, Lys^{34}-(Biotin-PEG)-FMOC-GLP-1 was separated by reverse-phase HPLC (RP-HPLC). The product was obtained from the collected fraction by lyophilization. Second, Lys^{34}-(Biotin-PEG)-FMOC-GLP-1 (2 mg/mL in DMF containing 0.3% TEA) was further reacted with a 3-fold molar excess of biotin−NHS for 1 h at room temperature, as described above, following deprotection of the FMOC group of the final product by adding piperidine to a final concentration of 5% for 20 min, and then stopping the reaction with stop solution. DBP-GLP-1 was obtained by preparative HPLC.

Scheme 1. Schematic Diagram of the Preparations of Site-Specific Biotinylated and Biotin−PEGylated GLP-1



Purification of DB-GLP-1, Lys^{34}-(Biotin-PEG)-FMOC-GLP-1, and DBP-GLP-1. The bioconjugated GLP-1 analogues mentioned above were isolated and purified from their reaction mixtures by preparative RP-HPLC using a Capcell-pak RP-18 column (250 × 4 mm, 5 μm, Shiseido, Japan) at ambient temperature at a constant flow rate of 1.0 mL/min under UV absorbance monitoring at 215 nm. The mobile phase consisted of 0.1% TFA in deionized water (eluent A) and acetonitrile (AN) containing 0.1% TFA (eluent B), and these were as linear gradients, as follows: DB-GLP-1, 35−42% B for 20 min; Lys^{34}-(Biotin-PEG)-FMOC-GLP-1, 40−43% B for 20 min; DBP-GLP-1, 38−43% B for 15 min. HPLC fractions corresponding to respective peaks were collected separately, flushed off with nitrogen, and concentrated using an ultrafiltration unit (Ultracel YM3, MWCO 3000, Millipore, Billerica, MA). The products obtained were characterized by HPLC and MALDI-TOF mass spectroscopy, and stored at −70 °C until required for further experiments.

Characterization of Bioconjugated GLP-1s. Bioconjugation and site-specific modification were confirmed by MALDI-TOF MS of GLP-1 analogues before and after lysyl endoproteinase Lys-C digestion, as reported previously (*25*). Bioconjugations were confirmed using MALDI-TOF-MS molecular weight measurements using a Voyager-RP Biospectrometry workstation (PerSeptive Biosystems, Cambridge, MA). Briefly, the sample−matrix solution was prepared by mixing 1 μL of aliquot with 2 L of the matrix solution (a saturated solution of α-cyanohydroxycinnamic acid (CHCA) in 50% of water/ACN containing 0.1% (v/v) TFA). 1 μL of the sample−matrix solution was then deposited onto a well of a sample plate and dried by rapid vacuum evaporation. Data generated by 2 ns pulses of the 337 nm nitrogen laser were averaged for each spectrum in linear mode; positive-ion TOF detection was performed using on accelerating voltage of 25 kV.

To determine the locations of the biotinylation and PEGylation sites, Lys-C digestion experiments were performed, as described previously (*27*). Briefly, 10 μL of Lys-C (10 μg/mL,

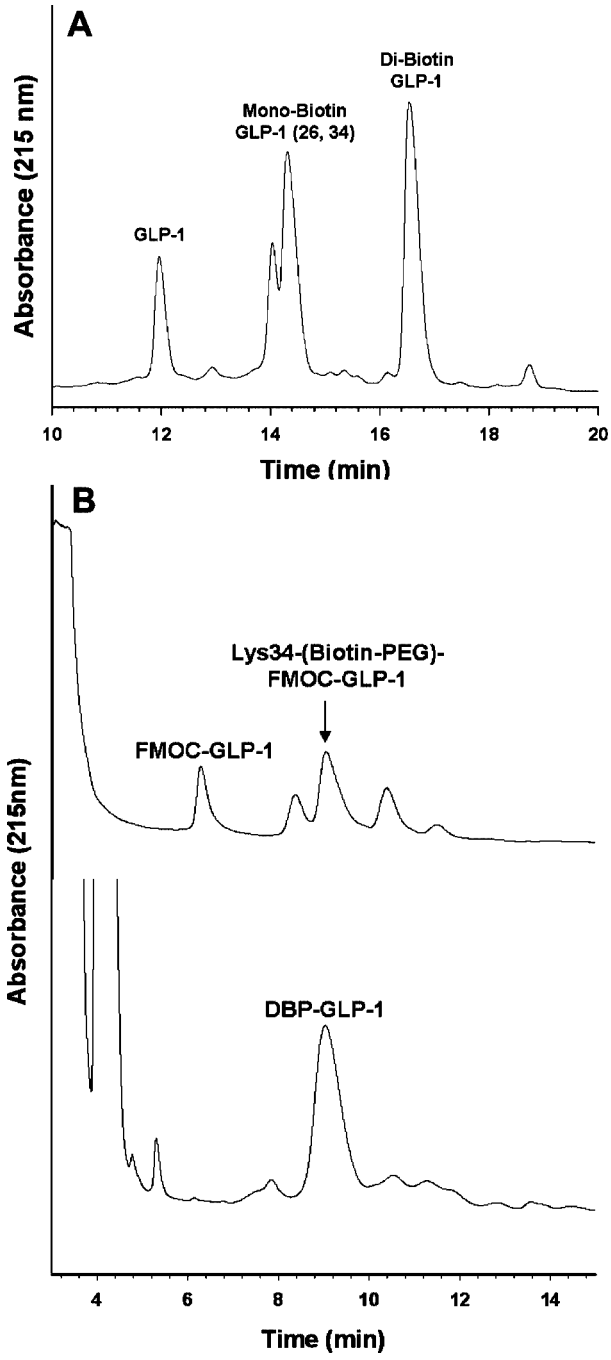


Figure 1. RP-HPLC analysis of DB-GLP-1 and DBP-GLP-1. (A) Chromatogram of the biotinylation reaction mixture; and (B) Lys^{26}-(biotin-PEG)-FMOC-GLP-1 and DBP-GLP-1.

pH 7.4) was added to 20 μL of sample solution (50 mM Tris−HCl, buffer pH 8.5) containing each positional isomer of bioconjugated GLP-1s (10 μg/mL). Reaction mixes were incubated at 37 °C for 60 min, and after digestion, individual samples were analyzed by MALDI-TOF-MS.

Proteolytic Stability Studies of the Bioconjugated GLP-1s. The proteolytic stabilities of the bioconjugated GLP-1s against trypsin, DPP IV, and intestinal fluid were evaluated as previously described with slight modification (*25*). Intestinal fluid was obtained from 24 h prefasted SD rat intestine (jejunum) by flushing with PBS and centrifugation. A portion (20 μL) of either GLP-1 or bioconjugated GLP-1s (200 μg/mL each) were mixed with the same volume of enzyme solution (2 mM trypsin in PBS pH 6.5, 25 mU/mL DPP IV in Tris−HCl buffer pH 7.4, and intestinal fluid, preincubated at 37 °C for 30 min), and

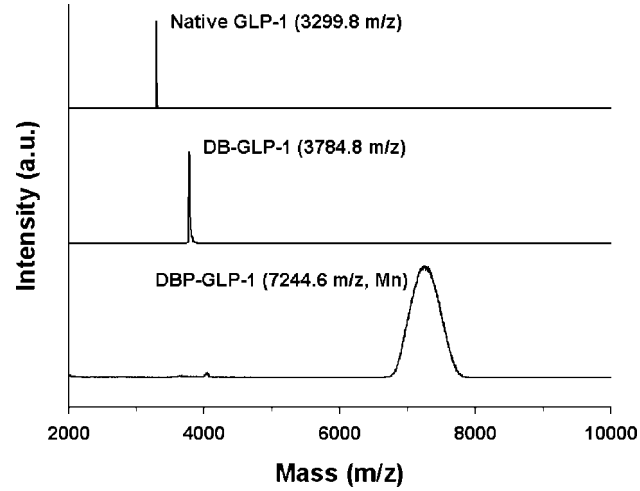

Figure 2. MALDI-TOF mass spectra of native GLP-1, DB-GLP-1, and DBP-GLP-1.

further incubated at 37 °C. At predetermined times, the incubations were stopped by adding 100 μL of chilled stop solution (1% TFA in DW). The mixtures were then centrifuged at 12 000 rpm for 5 min, and supernatants were analyzed by RP-HPLC. Degradation half-lives were then calculated, assuming first-order kinetics.

Biological Activities of the Bioconjugated GLP-1s. Insulinotropic activities of GLP-1 and bioconjugated GLP-1s on rat pancreatic islets were assessed as previously described (*25*–*27*). Briefly, male SD rats (250–270 g) were anesthetized with ketamine and xylazine (90/10 mg/kg, i.p.). The donor pancreas was swollen by injecting cold Hank's balanced buffered salt solution (HBSS, pH 7.4, Sigma) containing 1.5 mg/mL of type V collagenase (Sigma). Isolated islets were purified by centrifugation in a discontinuous Ficoll (Amersham Biosciences AB, Uppsala, Sweden) gradient at 2400 rpm for 25 min. Purified islets were cultured in RPMI-1640 culture medium (Sigma) supplemented with 10% fetal bovine serum (Gibco, Carlsbad, CA) and 1% penicillin−streptomycin (Gibco) at 37 °C in a 95% air/5% CO_2 atmosphere for 2 days. The islets were then washed, incubated in Krebs-Ringer bicarbonate (KRB) buffer, seeded at 20 islet/well on a 24 well plate in 1 mL of KRB containing 16.8 mM glucose, and incubated with various concentrations of GLP-1 and bioconjugated GLP-1s (0.1, 1, 10, and 100 nM) for 2 h. Insulinotropic activities were evaluated by measuring the amount of insulin released to media using an enzyme immunoassay kit (Rat insulin ELISA kit, Mercodia AB, Uppsala, Sweden).

The in vivo bioactivities of the bioconjugated GLP-1s were evaluated using oral glucose tolerance tests (OGTT) in type 2 diabetic db/db mouse (8−10 weeks old), after intraperitoneal drug administration (*26*, *27*). In brief, 18 h fasted mice were administered bioconjugated GLP-1s (10 nmol/kg, i.p., at 30 min prior to oral glucose administration). A 1.0 g/kg dose of glucose was then administered orally to each mouse. At predetermined times, blood glucose levels were monitored using a glucometer (Accu-Chek Sensor, Roche Diagnostics Corp., Mannheim, Germany).

Evaluation of the Hypoglycemic Efficacies of the Bioconjugated GLP-1s. The hypoglycemic efficacies of the bioconjugated GLP-1s administered orally were investigated using an intraperitoneal glucose tolerance test (IPGTT). Briefly, 18 h fasted mice were injected with a glucose solution (1.0 g/kg, 100 μL, at time 0 min, i.p.), and then orally administered gastric neutralizer (0.1 mL of 3% $NaHCO_3$) and bioconjugated GLP-1s (15 nmol/mouse, 200 mL, in a PBS/propylene glycol 50/50 mixture) at 30 min before glucose injection. Blood glucose levels

were then monitored using the above-mentioned glucometer. As controls, vehicle or GLP-1 were administered in an identical manner. Areas under the curve (AUC) were calculated in concentration per minute for the total experimental periods (0−180 min).

Pharmacokinetics in Vivo. To investigate oral absorption, pharmacokinetic profiling of the bioconjugated GLP-1s was performed, as described previously (*25*). For this study, a jugular vein was cannulated in male SD rats at one day before the experiment. The animals were randomly divided into three groups and GLP-1 mol equiv amount of the bioconjugated GLP-1s (DB-GLP-1 and DBP-GLP-1) was dissolved in PBS (20 nmol/rat) and administered i.v. or perorally (p.o.), respectively. Blood samples, drawn at predetermined times, were placed in ice-cold polyethylene tubes containing DPP IV inhibitor (10 μL per mL of blood; Linco Research Inc., St. Charles, MO). Plasma samples were obtained by centrifugation and stored at −70 °C until required for assay. Concentrations of GLP-1 in rat plasma were analyzed using a commercial GLP-1 radioimmunoassay kit (active GLP-1 RIA kit, Linco Research Inc., St. Charles, MO).

RESULTS AND DISCUSSION

Preparation and Characterization of Bioconjugated GLP-1s. Unlike chemical conjugations to proteins where the degree of substitution plays a major role in their biological and pharmaceutical characteristics, peptide drug modifications, such as PEGylation, biotinylation, acylation, and other conjugations, show stronger relationships between conjugate position and therapeutic efficacy and potential (*27*, *30*, *31*). In particular, the chemical attachment of functional moieties to the primary amine groups of GLP-1 resulted in position-dependent characteristics. GLP-1 possesses three different sites for nucleophilic substitution via a primary amine group located at the N-terminal, i.e., His^{7}, Lys^{26}, and Lys^{34}. In previous, we monitored the effect of the PEGylated GLP-1 on biological activity. Compared to the native GLP-1, the in vitro insulinotropic activity of Nter-PEG-GLP-1 and Lys-PEG-GLP-1 were 44.1% and 83.1%, respectively (100 nM peptide, 16.8 mM glucose) (*25*, *26*). More detailed investigations revealed that the PEGylation on Lys^{34} of GLP-1 resulted in 93% activity remaining (*27*). On the basis of these results, we concluded that conjugation of bulky biotin−PEG on the Lys^{34} and small m.w. of biotin on the Lys^{26} position could minimize the loss of GLP-1's activity among the various combinations.

To prepare the described bioconjugated GLP-1s, Lys-amine specific conjugation reactions were conducted in an organic medium, as described previously (*25–27*). The biotin modification of GLP-1 resulted in a mixture of biotinylated GLP-1 isomers, as illustrated in the RP-HPLC chromatogram shown in Figure 1A. Of the four distinct HPLC peaks observed in the biotinylated reaction mixture, the first three peaks were attributed to native GLP-1 (elution time 11.96 min) and monobiotin-GLP-1 (14.03 and 14.30 min), which had mass values of 3299.8 *m*/*z* and 3542.8 *m*/*z*, respectively. The fourth peak (16.53 min)

Table 2. Summary of GLP-1, DB-GLP-1, and DBP-GLP-1 Stabilities in Various Digestive Systems

	trypsin		intestinal fluid		DPP IV	
samples	half-life (s)	folds increase	half-life (s)	folds increase	half-life (s)	folds increase
GLP-1	11.6 ± 0.8		0.57 ± 0.06		49.8 ± 3.6	
DB-GLP-1	85.6 ± 1.4	7.4	4.38 ± 0.79	7.7	117.4 ± 9.4	2.4
DBP-GLP-1	210.0 ± 5.3	18.1	13.94 ± 1.14	24.5	495.0 ± 9.3	9.9

represented $Lys^{26,34}$-Dibiotinylated GLP-1 (DB-GLP-1), which had a mass of 3784.8 *m/z*, as illustrated in Figure 2. Further investigations of DB-GLP-1 using Lys-C digestion assays and following MALDI-TOF confirmed the biotinylation of GLP-1 at Lys^{26} and Lys^{34} (Table 1).

To prepare heterogeneously bioconjugated GLP-1 with biotin and biotin−PEG at different lysine residues, N-terminal protected GLP-1 was utilized to improve reaction yield and selectivity (*30*, *31*). Of the various N-terminal protected GLP-1s examined, 9-fluorenylmethyl carbamate (FMOC) protected GLP-1 was found to have several advantages, e.g., superior stability in acidic HPLC conditions and ease of deprotection under mild basic conditions. By using FMOC-GLP-1, heterogeneous bioconjugations were conducted using sequential coupling reactions between lysine residues and biotin−PEG−NHS and biotin−NHS. As illustrated in Figure 1B, biotin−PEG conjugation on FMOC-GLP-1 resulted in the formation of monoconjugated positional isomers (second and third peaks) and diconjugated GLP-1 on at Lys^{26} and Lys^{34}. MALDI-TOF and Lys-C digestion assays revealed that the third peak was Lys^{34}-(Biotin-PEG)-FMOC-GLP-1 (Table 1). The Lys^{34}-conjugated portion was separated, purified, and used as a substrate for further bioconjugation with biotin−NHS. Biotinylation at Lys^{26} and removal of the FMOC protecting group were conducted by sequentially reacting Lys^{34}-(Biotin-PEG)-FMOC-GLP-1 with biotin-NHS for 1 h and then treating with piperidine (final concentration 5%). HPLC of the reaction mixtures revealed that heterobioconjugated GLP-1 had been formed in high yield (Figure 1B, about 90% yield). MALDI-TOF and Lys-C digestion analysis confirmed the successful heterobioconjugations by biotin and biotin−PEG at Lys^{26} and Lys^{34}, respectively. The observed mass of Lys^{26}-Biotin-Lys^{34}-(Biotin-PEG)-GLP-1 (DBP-GLP-1) was 7244.5 (Mn, calcd. 7192.3). Moreover, DBP-GLP-1 did not produce fragments when treated with Lys-C (Figure 2 and Table 1).

Proteolytic Stabilities of GLP-1 and Bioconjugated GLP-1s. The protection of peptide drugs from enzymatic digestion in the intestinal compartment must be accomplished to realize oral peptide drug delivery (*1011*). To investigate the effect of the described bioconjugations on the enzymatic stability of the GLP-1, a series of enzyme stability tests were conducted.

Bioconjugations to the lysine residues of GLP-1 enhanced its gastrointestinal stability (Figure 3 and Table 2). In case of the trypsin, one of the most abundant pancreatic digestive enzymes, bioconjugation resulted in a dramatic improvement in proteolytic stability (Figure 3A), and this was further improved by introducing PEG in DBP-GLP-1. DB-GLP-1 and DBP-GLP-1 were found to have more than 7 and 18 times better proteolytic stabilities, respectively, than GLP-1 according to our trypsin degradation tests. Moreover, similar enhancements of proteolytic resistance (7- and 24-fold, respectively) were observed in the presence of intestinal fluid, which more closely represents intestinal enzymatic digestion.

For GLP-1-based incretin mimetics, stability in the systemic circulation is also key for an efficient oral delivery system. The instability of GLP-1 in the circulation is mainly attributable to its degradation by DPP IV (*1011*). As shown in Figure 3, native GLP-1 was rapidly degraded by DPP IV with a half-life of 49.8 min. As previously reported, DPP IV mediated GlP-1 degradation resulted in the truncation of the two N-terminal amino acids and destroyed its insulinotropic activity (*25*). However, biotinylation and biotin−PEGylation enhanced the proteolytic resistances of DB-GLP-1 and DBP-GLP-1 against DPP IV by 2.4- and 9.9-fold, respectively, as compared with native GLP-1.

Biological Activities of the Bioconjugated GLP-1s. Chemical modifications of protein or peptide biopharmaceuticals invariably alter their biological and pharmacological characteristics (*17–19*), and thus, such chemical modifications require meticulous investigation. One of the most prominent biological effects of GLP-1 is that it stimulates insulin secretion by pancreatic β-cells. Furthermore, this insulinotropic activity is strongly dependent on glucose concentration, and in fact, it has no effect on insulin secretion at glucose concentrations below 4.5 mM (*32*). Therefore, we performed experiments using isolated pancreatic islets in high-glucose media (16.8 mM glucose in KRH buffer). As shown in Figure 4A, GLP-1 and the bioconjugated GLP-1s showed concentration-dependent insulinotropic activity on pancreatic islets. As we reported previously for PEGylated GLP-1 derivatives (*26, 27*), GLP-1 and the two bioconjugated GLP-1s potentiated insulin secretion in a concentration-dependent manner and reached saturation at around 10 nM. Moreover, our results demonstrated that DB-GLP-1 and DBP-GLP-1 robustly retained biological activity, and that they have insulinotropic effects on pancreatic islets.

The in vivo bioactivities of GLP-1, DB-GLP-1, and DBP-GLP-1 administered intraperitoneally into diabetic db/db mice were evaluated by performing oral glucose tolerance tests, as described previously (*27*). As was found by in vitro bioactivity testing, all three agents showed similar kinetic patterns of glucose clearance. As shown in Figure 4B, blood glucose levels in the placebo group (saline i.p. injection) rapidly increased to ca.450 mg/dL at 15 min after glucose administration and then decreased slowly. On the other hand, mice pretreated with GLP-1, DB-GLP-1, or DBP-GLP-1 showed rapid glucose clearance kinetics and maximum plasma glucose levels of ca. 300 mg/dL, mainly due to stimulated insulin secretion. Therefore, the in vitro insulinotropic activity tests and in vivo hypoglycemic activity tests performed during this study show that DB-GLP-1 and DBP-GLP-1 substantially maintained the biological activity of native GLP-1.

Oral Hypoglycemic Effects of DB-GLP-1 and DBP-GLP-1. To evaluate the therapeutic efficacies of orally administered (p.o.) DB-GLP-1 and DBP-GLP-1, we used the intraperitoneal glucose tolerance test (IPGTT). Unlike the results described above after i.p. administration, p.o. administrations of GLP-1, DB-GLP-1, or DBP-GLP-1 had remarkably different glucose clearance kinetics. As illustrated in Figure 5A, the saline (placebo) and GLP-1 administered groups (30 min prior to glucose administration) showed a rapid increase in plasma glucose levels after the i.p. administration of glucose solution (0 min). 30 min after i.p. glucose administration, plasma glucose levels in saline and GLP-1 treated animals reached ca. 440 and 410 mg/dL, respectively, whereas in DB-GLP-1 and DBP-GLP-1 treated animals, they reached only 315 and 296 mg/dL, respectively.

Moreover, DB-GLP-1 and DBP-GLP-1 both enhanced glucose tolerance during the experimental periods, which we attribute to enhanced intestinal absorption, and although DBP-GLP-1 treated animals showed initial blood glucose elevations that were similar to those observed for DB-GLP-1, DBP-GLP-1 treated animals achieved the normal glycemic state more quickly. Statistical analysis revealed that the mean glucose levels in DBP-GLP-1 treated animals at 90 and 120 min after glucose injection were significantly lower than in DB-GLP-1 treated animals ($p < 0.05$, t test). We attribute this enhanced stability of DBP-GLP-1 vs DB-GLP-1 to its enhanced proteolytic stability and biotin-facilitated intestinal absorption. Owing to the absence of a natural biotin synthesis system, humans and other mammals must obtain the vitamin exogenously through intestinal absorption (*20, 21*). Although the exact molecular mechanism is still unsolved, it is evident that the biotin intake is reliant on the carrier-mediated mechanism (SMVT system).

Table 3. Pharmacokinetic Parameters after Administering GLP-1, DB-GLP-1, or DBP-GLP-1 to SD Rats[a]

sample	AUC (ng × min × mL^{-1})	C_{max}(ng/mL)	T_{max}(min)	$t_{1/2}$(min)
GLP-1 (i.v.)	9892 ± 913	N.A.[b]	N.A.	5.33 ± 0.76
DB-GLP-1	507 ± 81	N.A.	N.A.	N.A.
DBP-GLP-1	998 ± 104	7.72 ± 1.54	28.0 ± 3.1	39.45 ± 10.15

The enhanced cellular and intestinal absorption of biotin-based peptides also have been reported (*22–24*). Sinco et al. reported that more than 3-fold enhanced absorption of R.I.-K-Tat9 peptide was achieved by biotin conjugation through passive and predominantly SMVT pathway (*22*). On the basis of these ideas, it can be expected that the effect of enhanced intestinal absorption and the following antidiabetic effect of DBP-GLP-1 is related to the SMVT system; however, the relationship between DBP-GLP-1 and the SMVT system should be elucidated.

Pharmacokinetic Profiles of DB-GLP-1 and DBP-GLP-1 in the Rat. The pharmacokinetic characteristics of orally administered bioconjugated GLP-1s were also investigated, and the results are illustrated in Figure 6 and Table 3. As a control experiment, native GLP-1 was administered i.v., and its plasma concentrations were then monitored vs time. The plasma concentrations of GLP-1 rapidly reduced and reached the basal level at 3 h after injection, which we attribute to the rapid systemic clearance and DPP IV mediated inactivation. Orally administered DB-GLP-1 showed the maintenance of basal levels around 1−2 ng/mL. Compared to the blank plasma levels of GLP-1 (1.28 ± 0.32 ng/mL, time 0 point), the plasma GLP-1 concentrations observed by oral DB-GLP-1 administration revealed the negligible intestinal absorptions, except at the 15 min point (2.12 ± 0.35 ng/mL). Typical intestinal absorption patterns were observed for orally administered DBP-GLP-1. Active GLP-1 plasma concentrations in rats peaked at 7.72 ng/mL (C_{max}) at 28 min (T_{max}) after DBP-GLP-1 oral administration. After 120 min, the plasma levels of DBP-GLP-1 groups also returned to the basal level. On the basis of their pharmacokinetic profiles, the calculated average AUCs for i.v. GLP-1, oral DB-GLP-1, and oral DBP-GLP-1 were 9892, 507, and 998 $ng \cdot min \cdot mL^{-1}$, respectively. Although oral administration might provoke the intestinal secretion of natural GLP-1, the existence of apparent absorption peaks in plasma and the higher AUC value of DBP-GLP-1 strongly support its enhanced intestinal absorption. Moreover, the introduction of PEG molecules in DBP-GLP-1 also appeared to significantly increase plasma half-life, which concurs with our previous investigations (*25–27*). Moreover, as compared with GLP-1 administered i.v., orally administered DBP-GLP-1 had a plasma half-life that was more than 7-fold greater.

CONCLUSION

In this report, we found that DB-GLP-1 and DBP-GLP-1 show enhanced GLP-1 intestinal absorption. $Lys^{26,34}$-DiBiotin-GLP-1 (DB-GLP-1) and Lys^{26}-Biotin-Lys^{34}-(Biotin-PEG)-GLP-1 (DBP-GLP-1) were prepared using lysine-specific coupling reactions following HPLC separations. Both DB-GLP-1 and DBP-GLP-1, but especially DBP-GLP-1, had markedly better proteolytic stabilities than native GLP-1. Derivatization also preserved the biological and pharmacological activities of DB-GLP-1 and DBP-GLP-1. Furthermore, DBP-GLP-1 showed typical intestinal absorption patterns by pharmacokinetic profiling and a dramatically enhanced oral hypoglycemic effect versus native GLP-1. On the basis of these findings, we believe that DBP-GLP-1 is a good candidate antidiabetic peptide drug.

Reversible Pegylation Prolongs the Hypotensive Effect of Atrial Natriuretic Peptide

Maoz Nesher,[†] Yelena Vachutinsky,[‡] Gil Fridkin,[§] Yehuda Schwarz,[†] Keren Sasson,[‡] Mati Fridkin,[§] Yoram Shechter,[‡] and David Lichtstein*,[†]

Natriuretic peptides (NP), including atrial natriuretic peptide (ANP), induce potent natriuresis and vasodilation and thereby generate hypotension *in vivo*. Despite intensive efforts, clinical application of NP as an antihypertensive agent is limited because of their short biological half-life and poor bioavailability. Recently, we have developed a strategy that facilitates slow release of peptides from PEG−peptide inactive conjugates, based on reversible pegylation. Peptides prepared by this approach undergo slow, spontaneous chemical hydrolysis at physiological conditions, releasing the native active peptide/protein drug from the inactive conjugates over prolonged periods. A PEG chain of 30 kDa was linked covalently to the α-amino side chain of the hormone via a MAL-Fmoc-NHS spacer, yielding PEG_{30}-Fmoc-ANP, a prodrug that releases the native hormone upon incubation at physiological conditions. Bolus administration of native ANP to Wistar rats receiving adrenaline yields a short, transitory effect in lowering blood pressure (BP), reaching a maximum at 2 min, and then returning to control values after 12 to 25 min. In contrast, administration of PEG_{30}-Fmoc-ANP lowered BP following a lag period of 50 min, and maintained low BP for a period exceeding 60 min. Saline or PEG_{30}-Fmoc-Alanine were not effective in lowering BP in Wistar rats. These results show that the novel compound, PEG_{30}-Fmoc-ANP, is a reversible pegylated prodrug derivative that facilitates a prolonged BP lowering effect in rats and may be considered as a candidate for development into an antihypertensive drug.

INTRODUCTION

Natriuretic peptides (NP), including atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), and C-type natriuretic peptide (CNP) induce potent natriuresis and vasodilation and thereby generate hypotension *in vivo* both in humans and in other mammals (*1*, *2*). ANP stimulates natriuresis by increasing renal glomerular filtration rate and inhibiting Na^+ reabsorption at the collecting duct. ANP also suppresses secretion of aldosterone, vasopressin, and renin, thereby stimulating both natriuresis and diuresis (*3*, *4*). In the vasculature, ANP relaxes norepinephrine-, angiotensin II-, and K^+-induced vascular smooth muscle contraction causing an immediate hypotensive effect (*5*). Consequently, ANP plays a central role in controlling blood pressure (BP) and volume regulation (*6*). Despite intensive efforts, clinical application of the natriuretic peptide family members as antihypertensive agents is limited because of their short biological half-life and poor bioavailability. The $t_{1/2}$ of ANP is 2 to 5 min in human and even less in the rat (*7*). Of the three major natriuretic peptide receptors, natriuretic peptide receptors A, B, and C (NPR-A, -B, -C, respectively), NPR-A and NPR-B are guanylyl cyclase-linked, which utilize cGMP as the intracellular messenger (*7*). The third receptor, NPR-C, is not linked to guanylyl cyclase but appears to act as clearance receptor of the peptides from the circulation (*8*). Inactivation of circulating ANP also involves neutral endopeptidase (NEP), a membrane-bound metallopeptidase widely expressed in the vasculature (*9*). NPR-C and NEP rapidly eliminate ANP from the circulation leading to its short $t_{1/2}$ and, therefore, limit its suitability as a drug. Nevertheless, intravenous administration of ANP or BNP reduces arterial BP and improves central hemodynamics in patients with chronic heart failure (*10*, *11*). Furthermore, preliminary results indicate that combined inhibition of angiotensin converting enzyme (ACE) and NEP by vasopeptidase inhibitors is an effective strategy in the treatment of hypertension and other cardiovascular diseases including heart failure (*12*). In addition, Nesiritide (Natrecor; SCIOS, Sunnyvale, CA), a recombinant form of human BNP, has been approved for the treatment of acutely decompensated heart failure by the US Food and Drug Administration since 2001 (*13*), and ANP is commercially available in Japan under the brand name Carperitide (Astellas Pharma, Fujisawa, Japan) (*14*). Unfortunately, clinical data suggest that the incidence of angioedema may increase upon vasopeptidase inhibition (*15*). Moreover, Sackner-Bernstein and co-workers showed that Nesiritide treatment may be associated with increased risk of worsening renal function (*16*) and even death (*17*) after treatment of acutely decompensated heart failure. Thus, the development of stable-prolonged-acting ANP is of significant therapeutic value.

Modifications of peptide/protein can lead to prolonged plasma half-life times. One common method of peptide modification is the covalent attachment of poly(ethylene glycol) (PEG) chain to peptides and proteins (*18*, *19*). Pegylation was shown to improve delivery of drugs and reduce adverse effects (*18*). Pegylated peptides are shielded from proteolytic enzymes, antibodies, or antigen processing cells (*18*). The feature gained by pegylation is predominantly a significant lifetime prolongation, in some instance from minutes to hours or even days (*20*).

The major obstacle, however, is the inactivation that often takes place upon the covalent attachment of PEG chain to a protein and moreso to peptide drugs.

Recently, we developed a strategy, named reversible pegylation, for prolonging the lifetime of peptides and proteins (*21*). Conjugate prepared by this approach turn into a "prodrug" which undergoes slow, spontaneous hydrolysis at physiological conditions, releasing the native active peptide/protein drug from the inactive conjugate over prolonged periods. This approach was successfully applied to protract the action of exendin-4 (*21*), interferon α2 (*22*), peptide YY_{3-36} (*23*) and insulin (in preparation). In this study, we initially found that conventional (irreversible) pegylation inactivates ANP. We, therefore, applied the strategy of reversible pegylation to this hormone and investigated its characteristic features *in vitro* and its potency of facilitating a long-lasting hypotensive effect *in vivo*.

EXPERIMENTAL PROCEDURES

Materials. *N*-α-9-Fluorenylmethoxycarbonyl (Fmoc)-protected amino acids, Fmoc-Tyr(tBu)-preloaded Wang resins, *N*-hydroxybenzotriazole (HOBt), and benzotriazol-1-yl-oxytripyrrolidinophosphonium hexafluorophosphate (PyBOP) were purchased from Novabiochem (Laufelfingen, Switzerland). *N*,*N*-dimethylformamide (DMF), dichloromethane (DCM), *N*-methyl-2-pyrrolidone (NMP), *t*-butylmethyl ether, and HPLC-grade acetonitrile and trifluoroacetic acid (TFA) were from JT Baker (Phillipsburg, NJ). Dicyclohexylcarbodiimide (DCC) and piperidine were from Merck (Darmstadt, Germany). *N*-methylmorpholine (NMM) and triethylsilane (TES) were from Fluka (Buchs, Switzerland). PEG_{30}-SH (MPEG-SH-30K) was purchased from Nektar Transforming Therapeutics and contained 0.4 ± 0.03 mol SH per mole solid material as determined by 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB). BSA, SDS, urethane, and dialysis bags were from Sigma (Rehovot, Israel) and adrenaline from Teva (Debrecen, Hungary). All other materials used in this study were of analytical grade.

Solid-Phase ANP Synthesis. ANP was synthesized using manual Fmoc-solid-phase methodology on Wang resin preloaded with the Fmoc-protected C-terminal amino acid, i.e., Tyr. DMF and NMP were used as solvents. Double couplings were achieved by reacting 3 Fmoc-AA-OH equivalents with either 3 equiv of PyBOP and 6 equiv of NMM or 3 equiv of HOBT and DCC. The completion of the coupling reaction was indicated by a negative ninhydrin test. N^{α}-Fmoc deprotection was carried out with 20% piperidine in dimethylformamide. Cleavage of the peptides from the solid support and simultaneous side chain deprotection was achieved by a 4 h treatment with trifluoroacetic acid in the presence of triethylsilane, thioanisole, and water (85/5/5/5, v/v). After 24 h at room temperature, the cleavage solution was collected and the crude peptides were precipitated from the solution with *t*-butylmethyl ether at 0 °C. After several washings with ether, the precipitated peptides were dissolved in a solution of water/acetonitrile with 1% TFA and then lyophilized.

The peptide containing cysteine residues was cyclized by intramolecular oxidation. This peptide (0.2 mg/mL) was dissolved at high dilution in 0.1 M ammonium acetate containing potassium ferricyanide (0.01 mM; 1.4 equiv) and stirred overnight. Reduction in the content of cysteine moieties was followed using DTNB. The crude peptide was purified by reversed-phase HPLC (see below) on a semipreparative C18 column and characterized by ESMS and amino acid analysis. The product appeared as a single peak on analytical HPLC chromatography (R_t = 3.3 min), having identical R_t value as that of commercially available human ANP, indicating that the synthesis, cyclization, and purification yielded the desired product. Amino acid analysis following acid hydrolysis showed the expected amino acid composition. Mass spectrometry analysis (see below) revealed a mass $[M - H]^+$ of 3081.21 ± 0.43 Da. Calcd. 3081.44 Da.

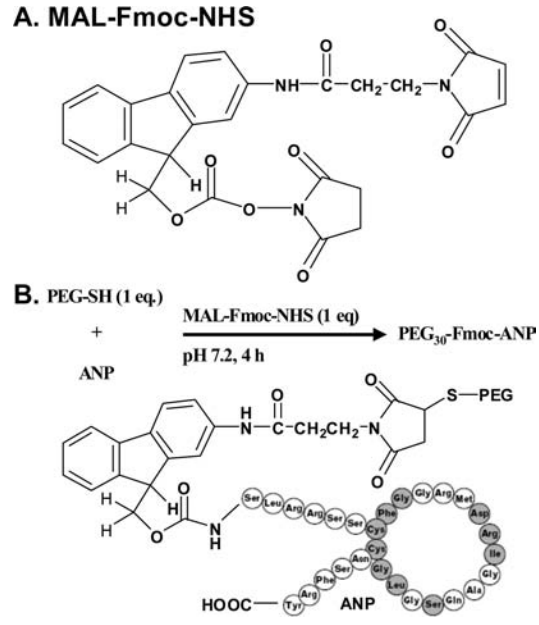

Figure 1. Structure of 9-hydroxymethyl-2-(amino-3-maleimidopropionate)-7-*N*-hydroxysuccinimide (MAL-Fmoc-NHS) (A). Schematic presentation of the steps involved in the preparation of PEG_{30}-Fmoc-ANP (B).

ANP Conjugates Preparation. *Preparation of PEG_{30}-Fmoc-ANP.* MAL-Fmoc-NHS (Figure 1A) is a heterobifunctional agent consisting of fluorenemethoxycarbonyl *N*-hydroxysuccinimide ester that reacts with amino groups of peptides and proteins. A maleimide group, attached to the fluorenyl backbone, enables its coupling to any sulfhydryl-containing compound. Figure 1B shows the optimal procedure found for preparing PEG_{30}-Fmoc-ANP. Accordingly, to a stirred solution of ANP (1 mg) in 100 μL of 0.1 M phosphate buffer, pH 7.2 (3.24 mM), 10 mg of PEG_{30}-SH in 100 μL phosphate buffer was added to obtain a final concentration of 3.33 mM. MAL-Fmoc-NHS (15 μL) from a fresh solution of MAL-Fmoc-NHS (10 mg/mL in DMF, 150 μg) was then added. The reaction was carried out for 4 h followed by dialysis for 2 days against distilled H_2O to remove residual DMF, phosphate buffer, and free ANP. Alternatively, the product was purified by HPLC. The product was characterized by MALDI-TOF mass spectrometry. Effective molecular weight of the conjugate was obtained by SDS gel electrophoresis (see below). The amount of ANP in the conjugate was determined by acid hydrolysis of a 20 μL of 2 mg/mL aliquot, followed by amino acid analysis. ANP concentration was calculated according to alanine (1 residue), tyrosine (1 residue), isoleucine (1 residue), leucine (2 residues), and phenylalanine (2 residues). MALDI-TOF mass spectral analysis showed 1:1 PEG_{30}-Fmoc/ANP stoichiometry. The molecular mass ($[M - H]^+$) of synthesized ANP was 3081.21 Da as determined by ESMS. PEG_{30}-SH had an average molecular mass of 32 300 Da. The spacer molecule following conjugation had a MW of 387 Da, and the conjugate yielded a major peak corresponding to a molecular mass of 35 675 Da. PEG_{30}-Fmoc-ANP migrates on analytical HPLC column (see below) as a wide peak with R_t value of 43 min.

Nonreversible Pegylation of ANP. A stable, nonreversible PEG−ANP conjugate was prepared using the same procedure described for PEG_{30}-Fmoc-ANP, except for the use of 3-maleimidobenzoate-*N*-hydroxysuccinimide ester (MIB-NHS, Pierce, Rockford, USA) to link PEG_{30}-SH to ANP.

High Performance Liquid Chromatography (HPLC) and Mass Spectrometry. Reverse-phase HPLC was performed with a Spectra-Physics SP8800 liquid chromatography system (Spectro-Physics, San Jose, CA) equipped with an Applied Biosystem 757 variable-wavelength absorbance detector. The column effluents were monitored by UV absorbance at 220 nm, and chromatograms were recorded on a chromJet integrator (Thermo-Separation, Riviera Beach, FL). Compounds were analyzed by analytical reversed-phase HPLC using an RP-18, 100 × 4.6 mm Chromolith column (Merck, Darmstadt, Germany). HPLC prepacked columns were either Vydac RP-18, 250 × 22 mm, bead size 10 μm for ANP purification, or Vydac RP-4, 250 × 22 mm, bead size 10 μm, for pegylated ANP derivative purification (Bucher Biotec AG, Basel, Switzerland). Linear gradients were formed between solution A (0.1% TFA in H_2O) and solution B (0.1% TFA in acetonitrile−H_2O 75:25). The analytical column was eluted with a binary gradient of 10–100% solution B over 14 min at a flow rate of 3 mL. Purifications were achieved with a 10–100% B gradient over 50 min, with a flow of 10.0 mL/min.

Mass spectra were determined using matrix-assisted laser-desorption/ionization time-of-flight (MALDI-TOF) mass spectroscopy (Micromass UK Ltd.) and electrospray ionization mass spectra (ESMS) techniques, performed on a Micromass Platform LCZ 4000 (Manchester, UK). Amino acid composition was analyzed following acid hydrolysis in 6 N HCl at 110 °C for 24 h by Dionex amino acid analyzer (Dionex Corporation, CA. USA).

SDS-PAGE Electrophoresis. To determine effective molecular weight of PEG_{30}-Fmoc-ANP/PEG-ANP conjugates, SDS-PAGE was performed using 15% polyacrylamide slab gel according to the Laemmeli method. 10 μg of each sample and a standard protein solution were boiled for 3 min, centrifuged, and loaded on a SDS-PAGE. Pegylated ANPs were specifically stained with a barium iodide solution according to the method of Kurfurst (*24*). This specific staining is based on the formation of a barium iodide complex with the poly(ethylene glycol) molecule. After electrophoresis, the gel was soaked in a 5% glutaraldehyde solution for 15 min at room temperature for fixation and then immersed in 20 mL of 0.1 M perchloric acid for 15 min. After these washes, 10 mL of a 5% barium chloride solution was added, followed by 4 mL of 0.1 M iodine solution. The stained PEG bands appeared within a few minutes. After 15 min, the staining solution was replaced and the gel was put into water.

Biological Methods.*[^{125}I]-ANP Binding to HeLa Cells.*

Cell Culture. NPR-A expressing HeLa cells were obtained from Professor Haim Garty (Departments of Biological Chemistry, The Weizmann Institute of Science, Rehovot, Israel) and grown at 35 °C in a 5% CO_2 humidified incubator in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal calf serum, penicillin, and streptomycin (100 U/mL of each). The binding assay was performed on subconfluent cell monolayers in 24-well dishes at a density of $4 \cdot 10^5$ cells/well preincubated for 24 h.

[^{125}I]-ANP Binding. ANP was iodinated by the chloramine T procedure of Hunter and Greenwood (*25*). HeLa cell monolayers were washed twice with PBS buffer (pH 7.4) containing 1% bovine serum albumin and then incubated in the same buffer containing [^{125}I]-ANP (100 000 cpm/well) and increasing concentrations (0.74 to 37 nM) of either native ANP or PEGylated ANP derivatives for 2 h at 4 °C. Nonspecific binding was measured in the presence of excess, unlabeled ANP (1.5 μM). The cells were then washed twice with ice-cold buffer and solubilized with 0.2% w/v sodium dodecylsulphate (SDS). Following incubation (37 °C for 30 min), the solubilized cells were transferred to counting vials, and radioactivity was counted (γ-counter, Packard Cobra, GMI, USA). All experiments were performed in duplicate, and each experiment was repeated at least three times. Specific binding is defined as total radioactive content (in the absence of native ANP) minus that obtained at high (1.5 μM) concentration of unlabeled ANP. Receptor binding capacity was determined by calculating the concentration of unlabeled ANP or its derivative that was required to displace 50% of specifically bound [^{125}I]-ANP.

Table 1. Molecular Weight of PEG_{30}-Fmoc-ANP, as Determined by MALDI-TOF and by SDS Gel Electrophoresis[a]

mass (g/mol) (calculated)	$[M + H^+]$ (g/mol) (found by MALDI-TOF)	effective MW according to SDS gel electrophoresis
35 768	35 675	~68 000

[a] Molecular mass was determined by MALDI-TOF and by SDS gel electrophoresis as described in the Experimental Procedures section.

In Vivo Studies.*Animals.* Experiments were performed on male Wistar rats weighing 300–350 g. The rats were housed according to a 12 h light/dark cycle and were allowed at least a 3 day acclimatization period with normal rat chow and tap water *ad libitum*. All procedures were carried out according to the guidelines of the Hebrew University-Hadassah Medical School Animal Care Committee for the use and care of laboratory animals.

Experimental Methods. Animals were anesthetized with urethane (1 g/kg, i.p.) and placed on a heated pad. Rectal temperature was adjusted to 37.5–38 °C by a rectal probe. Following tracheotomy (PE260 catheter), the two femoral veins and the right femoral artery were cannulated with a PE50 heparanized tube. Blood pressure (BP) was recorded from the right femoral artery using SP 844 pressure transducer (MEMSCAP, Skoppum, Norway) coupled to an amplifier (Laboratory linc V, Coulbourn instruments, Allentown, PA). The analog signal was converted to a digital recording by a PowerLab 16SP integration system, and the data were stored on a personal computer by *Chart 4.0* software (Adinstruments, Castle Hill, Australia). Heart rate (HR) was calculated from the BP beats. All animals received an infusion of 3.3 μg/kg/min of adrenaline throughout the experiment using syringe pump (Stoelting, IL). After 30 min, the test compounds (3 μg/kg ANP, 100 μg/kg ANP, 200 μg/kg PEG_{30}-Fmoc-alanine, and PEG_{30}-Fmoc-ANP 96 ± 7 μg covalently linked ANP/kg) were administered by a bolus injection through the second femoral vein cannula in 100 μL saline. In some experiments, 0.83 μg/kg ANP, in 30 μL saline/min, was administered by infusion. The animals were monitored for 120 min after the treatments and then sacrificed. Animals manifesting unstable BP, irregular heart beats, or breathing abnormalities during the experiments were excluded.

Statistical Analysis. Mean arterial blood pressure (MAP), systolic blood pressure (SBP), and HR were calculated by *Chart 4.0* software. Statistical analysis was performed for the changes in BP parameters between sequential measurements and time 0 (just before compound administration) of the experiment in 2 min intervals. This allowed for direct comparison of the responses to treatment between groups when baselines differed (*26*). One-way analysis of variance (ANOVA) was used to compare differences among groups, and two-way ANOVA for repeated measures, followed by Tukey posthoc test. Student's paired *t* test was used to compare differences in the same group. *SPSS 11.5* for windows (SPSS Inc., Chicago, IL) was used to perform the statistical analyses.

RESULTS

ANP Conjugates Syntheses. Table 1 summarizes several characteristic features of the PEG_{30}-Fmoc-ANP conjugate. ANP contains N-terminal α-amino group available for acylation by

Table 2. Receptor Binding Capacities of ANP and Its Conjugates[a]

	IC_{50} (nM)	biological potency (%)
ANP	1.31 ± 0.01	100
PEG_{30}-ANP (nonreversibly PEGylated)	$127^b \pm 7.4$	1.03
PEG_{30}-Fmoc-ANP	$89^b \pm 10.37$	1.47
PEG_{30}-Fmoc-ANP incubated in PBS-1% BSA pH = 7.4 (2 d, 37 °C)	$12^b \pm 0.51$	10.91
PEG_{30}-Fmoc-ANP incubated in 0.1 M borate buffer, pH = 8.5 (2 d, 37 °C)	$11^b \pm 0.44$	11.9

[a] [^{125}I]-ANP binding to HeLa cells was performed as described in Experimental Section. [b] ANP concentration was calculated based on the amount of covalently linked ANP in the conjugate, as measured by amino acid analysis following acid hydrolysis. IC_{50} are expressed as mean ± SD of 4 experiments. Biological potency was calculated as (IC_{50} of ANP/IC_{50} of test compound) × 100.
