MAL-Fmoc-NHS. Since our heterobifunctional agent (MAL-Fmoc-NHS) is highly specific to amino side chains in non-SH-containing peptides and proteins (*21–23*) and ANP is a non-lysine-containing peptide agonist (*3*), only the N-terminal α-amino group of ANP is available for acylation. The synthetic procedure applied (Experimental Procedures section) was followed by extensive dialysis and HPLC purification to remove any residual ANP expected, thus yielding a monomodified homogeneous conjugate. Indeed, MALDI-TOF mass spectral analysis shows a main peak having 1:1 PEG_{30}-Fmoc/ANP stoichiometry. The molecular mass of synthesized ANP was 3081 Da as determined by ESMS. PEG_{30}-SH had an average molecular mass of 32 300 Da. The spacer molecule following conjugation has a MW of 387 Da, and the conjugate yielded a major peak corresponding to a molecular mass of 35 675 Da. Acid hydrolysis and amino acid analysis of PEG_{30}-Fmoc-ANP revealed the content of 31 ± 3 μg ANP rather than 86 μg ANP per mg solid material as has been calculated for this molecular weight. This suggests that our preparation also contains PEG_{30}-Fmoc that has not been linked to ANP. Further dosage calculations, however, were based on the value of 31 ± 3 μg ANP per mg solid material, namely, that determined by amino acid analysis following acid hydrolysis.

Receptor Binding Capacity of ANP Conjugates. HeLa cells bind [^{125}I]-ANP with high affinity and the displacement of the ligand by unlabeled ANP yielded an IC_{50} value of 1.3 ± 0.096 nM (data not shown). Previous studies demonstrated that this binding is associated with elevation in the cellular cGMP level (*27, 28*). Table 2 summarizes the receptor binding capacities of the native and pegylated derivatives of ANP in HeLa cells. Relative IC_{50} values obtained revealed that both conventional pegylated ANP and PEG_{30}-Fmoc-ANP have ~1% of the receptor binding affinity of the native peptide. PEG_{30}-Fmoc-ANP, however, undergoes reactivation upon incubation at physiological conditions. This was valid for PEG_{30}-Fmoc-ANP incubated either in 0.1 M borate buffer (pH 8.5, 37 °C) or in PBS buffer containing 1% w/v BSA (pH 7.4, 37 °C).

Release of ANP upon Incubation at Physiological Conditions. PEG_{30}-Fmoc-ANP (322 μg/mL, 10 μg covalently linked ANP/mL) was incubated in 0.1 M borate buffer, pH 8.5, at 37 °C (see Discussion). Aliquots were withdrawn at different time points and analyzed both for the amount of ANP released and for receptor-binding potency using the [^{125}I]-ANP displacement assay in HeLa cells (Figure 2). Under these incubation conditions, peptides are hydrolyzed from PEG-Fmoc-peptide conjugates at a rate that is nearly identical to that obtained in normal human serum at 37 °C (*21, 22*). Upon incubation, ANP has been hydrolyzed from the conjugate in a nearly linear fashion with the concomitant increase in receptor binding potency (Figure 2). About 7% (0.78 ± 0.03 μg) of ANP has been released on day 1 (Figure 2). Based on this value and preliminary results, we calculated that 1 mg of PEG_{30}-Fmoc-ANP (namely, 31 ± 3 μg covalently linked ANP) per rat or more is required for the *in vivo* experiments.

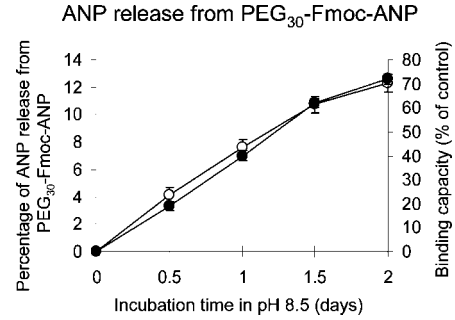

Figure 2. Rate of ANP release from PEG_{30}-Fmoc-ANP. PEG_{30}-Fmoc-ANP (10 μg covalently linked ANP) was incubated in borate buffer (pH 8.5) at 37 °C. Aliquots were withdrawn at the indicated time points and analyzed for the amount of ANP released (○) and for receptor binding capacity (•) (Experimental Procedures section). Binding capacity is calculated as the IC_{50} for the ANP released, versus the IC_{50} of the same quantity of the native hormone. The data are presented as mean ± SD of 4 experiments.

Effect of ANP on Mean Arterial and Systolic BP. Following infusion of adrenaline (3.3 μg/kg/min) for 30 min, rats were injected with native ANP at a dose of 3 and 100 μg/kg. These treatments elicited significant reductions in mean arterial and systolic BP (Figure 3A,B). As expected, ANP effects were transient, and even at the high dose (100 μg/kg), BP returned to control values 20–25 min after the injection. These reductions in mean arterial and systolic BP were accompanied with insignificant, minor changes in diastolic BP and HR (data not shown). These results are in agreement with many studies demonstrating the hypotensive transient effects of ANP (*29, 30*). Notably, a fall in BP at the lower ANP dose (3 μg/kg) was not detected in rats that were not pretreated with adrenaline (data not shown). Therefore, the increase in sensitivity to ANP and its derivatives following adrenaline pretreatment has been subsequently applied.

Prolonged Hypotensive Effects Following Administration of PEG_{30}-Fmoc-ANP. Mean arterial and systolic BP of control animals receiving only adrenaline infusion (3.3 μg/kg/min) decreased slightly by about 10 mmHg within 2 h (Figure 4A,B). This reduction is probably due to time-dependent desensitization of the adrenergic receptors as reported previously (*31*). The administration of PEG_{30}-Fmoc-ANP at a dose of 96 ± 7 μg covalently linked ANP/kg body weight did not change the mean arterial and systolic BP until about 50 min after injection. Mean arterial and systolic BPs decreased markedly and remained low over a period exceeding 60 min (Figure 4A,B). For comparison, the effect of continous infusion of native ANP at a rate of 0.83 μg/kg/min is demonstrated as well (Figure 4A,B). As shown previously (*30, 32*), this treatment yields an immediate effect on lowering both mean and systolic BP in rats, which persists as long as ANP is being infused. Indeed, as reported here, a marked reduction in BP is obtained over a period of 10 to 95 min. Bolus injection of PEG_{30}-Fmoc-alanine at a dose of 200 μg/kg body weight showed insignificant effect on BP that did not differ from that obtained in a saline-treated group (data not shown). Thus, a single administration of PEG_{30}-Fmoc-ANP at a dose of ~100 μg covalently linked ANP/kg facilitates a marked and prolonged BP lowering action in rats,

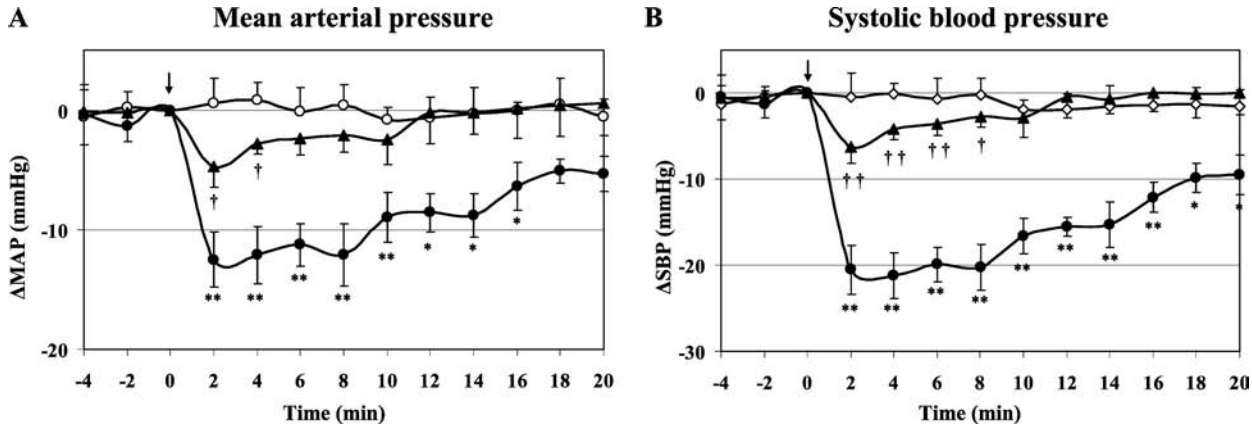

Figure 3. Effect of ANP on BP parameters in anesthetized rats. Animals were anesthetized with urethane, and BP was recorded from the right femoral artery as described in the Experimental Procedures section. All animals received an infusion of 3.3 μg/kg/min of adrenaline throughout the experiment. After 30 min (indicated by an arrow), saline (○), 100 μg/kg ANP (•), and 3 μg/kg ANP (▲) were administered intravenously by 100 μL bolus injection. Values are expressed as mean ± SE ($n = 6$). *$P < 0.05$ vs control; **$P < 0.01$ vs control; $^{\dagger}P < 0.05$ vs baseline; $^{\dagger\dagger}P < 0.01$ vs baseline.

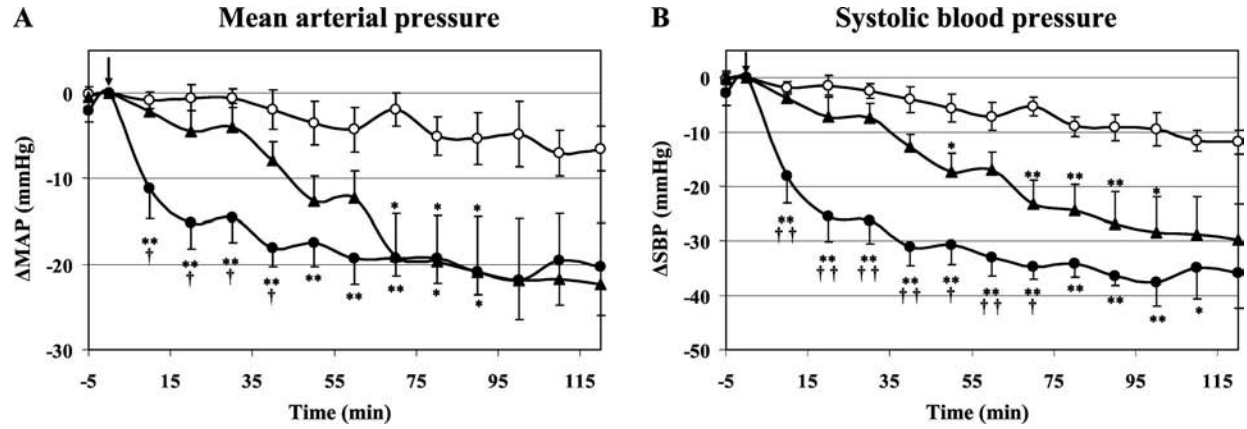

Figure 4. Effect of PEG_{30}-Fmoc-ANP on BP in anesthetized rats. Animals were anesthetized with urethane and BP was recorded from the right femoral artery as described in the Experimental Procedures section. All animals received an infusion of 3.3 μg/kg/min of adrenaline throughout the experiment. After 30 min (indicated by an arrow), the animals received 100 μL bolus injection of saline (○), 96 ± 7 μg/kg covalently linked PEG_{30}-Fmoc-ANP (▲), or infusion of 0.83 μg/kg/min ANP (•). Values are expressed as mean ± SE ($n = 6$). *$P < 0.05$ vs control; **$P < 0.01$ vs control; $^{\dagger}P < 0.05$ vs PEG_{30}-Fmoc-ANP; $^{\dagger\dagger}P < 0.01$ vs PEG_{30}-Fmoc-ANP.

which starts at 50 min after administration and resembles the pattern obtained by continuous infusion of ANP.

DISCUSSION

Since the pioneering work of de Bold and his colleagues (*29*), demonstrating the natriuretic response to atrial extracts in rats, many attempts were made to utilize the active substance from that extract (i.e., ANP) as a natural hypotensive agent. It has become clear that continuous infusion of ANP yields natriuresis, diuresis, and hypotension in animal models and in humans (*1, 7*), indicating that this natural peptide may have a significant therapeutic value. However, ANP is a short-lived species *in vivo*, as it undergoes proteolysis in the circulatory system by NEP and NPR-C and is rapidly cleared by the kidneys (*3, 8, 9*). Therefore, the hypotensive effect of ANP is a transient phenomenon (*29*). The rapid degradation of ANP in the serum poses a serious limitation on its practical use. Therefore, developing a long-acting version of this hormone is a prerequisite for its therapeutic application in the future.

The covalent attachment of PEG to peptides/proteins (pegylation) was shown to dramatically prolong the lifetime of the PEG−peptide conjugate and shield them from proteolysis *in vivo* (*18–20, 33*). Therefore, we first attempted this strategy by covalently linking PEG_{30}-SH to ANP through the nonreversible linker MIB-NHS. A PEG chain of 30 kDa has been selected, since lower molecular weight PEG chains are considerably less effective in preventing clearance by kidney filtration (*34*). Indeed, PEG_{30}-Fmoc and PEG_{30}-Benz-ANP, having calculated molecular weights of ∼36 kDa, migrated as a ∼68 kDa species on SDS gel electrophoresis (Table 1 A), indicating a substantial enlargement in the hydrodynamic volume and therefore in the effective molecular weight of these conjugates. This value is very close to the ∼70 kDa cutoff for glomerular filtration of native globular proteins (*35*).

In spite of those profound advantages, a major obstacle of conventional pegylation is the inactivation that often takes place, particularly with regard to short peptide agonists upon derivatization. A proportionally larger section of low MW peptide agonists participate in and must be accessible to receptor binding. Indeed, as found here, irreversible pegylation of ANP nearly fully abolished its receptor binding to HeLa cells (Table 2).

The remaining alternative was therefore to apply the strategy of reversible pegylation. In this study, we have linked PEG_{30}-SH to the single α-amino side chain of ANP via the heterobifunctional spacer MAL-Fmoc-NHS (Figure 1A). The latter was designed on the basis of the Fmoc principle by which the peptide is released from the conjugate in its native active form. The Fmoc group is used in organic and peptide synthesis for the protection of amino groups and can be removed following basic

treatment, such as with piperidine, within several minutes (*36, 37*). In neutral, aqueous solutions, Fmoc moieties undergo slow, spontaneous hydrolysis, resulting in the regeneration of the native proteins. Since ANP is a non-lysine-containing peptide, an homogeneous 1:1 monomodified PEG-Fmoc-ANP conjugate, where the PEG chain is linked exclusively to the α-amino function of the hormone, has been obtained (Table 1).

As expected, PEG_{30}-Fmoc-ANP is an inactive conjugate as well, and therefore a classical prodrug. This derivative, however, releases ANP and is reactivated upon incubation at physiological conditions (Figure 2). Although this process takes place at a slow rate, receptor binding capacity showed a nearly 7-fold increase within two days of incubation at pH 8.5 and 37 °C (Table 2). Previously, we have shown that the rate of hydrolysis of Fmoc-derived species at pH 8.5, 37 °C, is nearly similar to that obtained at pH 7.4 in the presence of physiological conditions of albumin. We did attribute this finding to the catalytic function of albumin (*21–23*). A linear relationship was obtained between receptor binding potency and the amount of ANP detached from the conjugate (Figure 2). Following the completion of these *in vitro* studies, we investigated whether this conjugate could facilitate a prolonged effect *in vivo.*

Administration of ANP at a dose of 0.1–3 μg/kg to normotensive rats failed to lower BP at any time point following injection (data not shown). Thus, native rats do not provide a suitable experimental pharmacological model to study ANP-induced hypotension. We therefore took advantage of the observation that ANP effects can be intensified by catecholamines (*38–40*). Accordingly, we infused adrenaline to all our animal groups to elevate BP and sensitize the effect of ANP. Indeed, the administration of 3 μg/kg of ANP, which by itself does not affect BP in naive animals, reduced it significantly in rats receiving constant infusion of adrenaline (Figure 3). Notably, this *in vivo* experimental system appears to reflect well the short half-life of ANP ($t_{1/2}$ = 2–5 min, (*7*)). Even with the intravenous administration of a relatively high dosage of ANP (100 μg/kg, 30 μg/rat), BP returned to control levels within 20–25 min following administration (Figure 3). This is in complete agreement with other studies (*29, 30*).

The protracted action of PEG_{30}-Fmoc-ANP in lowering BP is demonstrated in Figure 4. Note should be taken that our *in vivo* experimental system limits the measurement of BP up to a period of 2 h. BP, however, has reached its lowest value 2 h after PEG_{30}-Fmoc-ANP administration. Extrapolation of these data reveals that a low level of BP could be maintained for a period well exceeding ∼10 h as we previously documented with related PEG_{30}-Fmoc-peptide analogues (*21, 23*). Rough calculation based on (1) the administration of 30 μg covalently linked ANP/rat, with a 10× dilution shortly after administration, and (2) the rate of ANP released found *in vitro* (Figure 2) reveals that a level of about 6–10 ng/mL of free ANP is expected to be maintained in the circulatory system at any time point following a lag period of ∼1 h. This ANP level is well within the K_d value for *in vitro* ANP binding affinity to intact cellular systems, ($K_d \approx 2$ nM, (*28*)).

CONCLUSION

In summary, we managed to overcome several obstacles that prevent the designing of prolonged, continuous, therapeutically active ANP. The strategy of conventional pegylation has been replaced by reversible pegylation, an approach that resembles a continuous ANP infusion by the continuous release of the hormone over a prolonged period following administration. Our results show that the novel compound PEG_{30}-Fmoc-ANP release ANP under physiological conditions prolonging the action of the active peptide.

ACKNOWLEDGMENT

We thank Dr. U. Shpolansky for his help in setting up the *in vivo* experimental system. M.F. is the Lester Pearson Professor of Protein Chemistry. Y.S. is the incumbent of the C.H. Hollenberg Chair in Metabolic and Diabetes Research, established by the friends and associates of Dr. C.H. Hollenberg of Toronto, Canada.

Received August 18, 2007; Revised Manuscript Received October 27, 2007

Flurbiprofen (FLU) lipophilic prodrugs with lipoamino acids (LAA) **6a**−**e** were synthesized for brain delivery. Chemical and plasmatic stability of prodrugs **6a**−**e** as well as pharmacokinetic distribution studies for the prodrugs **6b** and **6d** were carried out. FLU prodrugs **6a**−**e** were compared to the parent drug for their ability to inhibit binding of [F-18]FDDNP to *in vitro* formed *β*-amyloid protein (A*β* fibrils). FLU−LAA conjugates showed a typical prodrug stability profile, being stable in PBS at pH 7.4 and releasing the active drug in plasma. Compound **6d** yielded a slow accumulation of FLU in the brain. In the *in vitro* inhibition assay, all prodrugs except for the prodrug with the longest alkyl side chain (**6e**) were effective as inhibitors of [F-18]FDDNP binding to A*β* fibrils with EC50 values in the 10−300 nM range. The different brain accumulation kinetics shown by FLU and its LAA conjugate **6d** suggested a possible slow-releasing activity of FLU by these prodrugs in the brain or a differential pharmacological effect deserving further, detailed studies on their biodistribution and pharmacological profile.

INTRODUCTION

Brain inflammation is one of the biochemical processes contributing to neurodegeneration in Alzheimer's disease (AD) (*1*). Recent studies have demonstrated that mediators of inflammatory reaction in AD, such as cytokines, free radicals, adhesion molecules, and prostaglandins, were neurotoxic in experimental models (*2*). These compounds were hypothesized to act as extracellular signals promoting neuronal degeneration (*3, 4*). The formation of extracellular senile plaques, neuropathological fibrillar deposits of *β*-amyloid protein (A*β*), has been associated with a variety of proteins which may also be potential propagators of inflammation (*5*).

A possible role of inflammation in AD pathogenesis and development is also supported by clinical evidence indicating that administration of nonsteroidal anti-inflammatory agents (NSAIDs) to AD patients slows deterioration of cognitive functions (*6*), reduces the incidence of AD (*7*), and exerts a neuroprotective effect (*8, 9*). Direct NSAID interaction with fibrillar *β*-amyloid protein (A*β*) has also been shown *in vitro* (*10*).

Since cyclooxygenase-2 inducible isoform (COX-2), one of the target enzymes of NSAIDs, has been detected at high levels in the brain of AD patients (*11*), it has been hypothesized that NSAIDs primarily exert their neuroprotective effect by inhibition of COX-2 mediated synthesis of pro-inflammatory prostanoids (*8*). Experimental evidence further suggests that inhibition of high expression levels of both COX-1 and COX-2 isoforms produces beneficial effects against brain inflammation (*12*).

Some NSAIDs have been shown to decrease the production of A*β*42, the major component of senile plaques of AD brain, and counteract the progression of A*β*42 pathology in transgenic mouse models of AD (*13*). The proposed mechanism for this activity is an allosteric modulation of *γ*-secretase activity, the enzyme responsible for the formation of *β*-amyloid. The inhibition of A*β*42 production is independent from the anti-COX activity and is related to the chemical structure of the compounds, with some NSAIDs being active (ibuprofen, sulindac, flurbiprofen, indomethacin, diclofenac) and others not (naproxen, aspirin, celecoxib) (*14, 15*).

NSAID availability in the brain is crucial to the efficiency of these drugs as neuroprotective agents. In order to enhance brain availability of NSAIDs, we investigated amphiphilic conjugates with lipoamino acids (LAA). In this report, we focus our interest on flurbiprofen (FLU, **1**) a drug that, because of its anti-inflammatory and analgesic activities attributed to the inhibition of both COX isoforms, has been considered as a potential neuroprotective agent in AD therapy (*16–21*). Furthermore, FLU reduced the secretion of both A*β*42 and A*β*40 peptides in Neuro-2a cells and rat primary cortical neurons (*12, 22*) as well as in the brain of tg2576 *β*-amyloid transgenic mice (*13, 14*).

FLU was modified with LAA residues; this was aimed at increasing its availability in the brain. LAA are α-amino acids bearing alkyl side chains, whose length and structure can be modified to achieve the desired physicochemical properties (*23*). Because of the presence of an alkyl chain and a polar amino acid head, LAA conjugation yields amphiphilic derivatives, with a membrane-like character that can favor their interaction with and penetration through biological membranes and barriers (*24–26*).

Recent pharmacological studies have focused attention on the *R*-enantiomer of FLU (*R*-FLU) as a possible agent for AD treatment. *R*-FLU, in fact, lacks the side effects of NSAIDs mediated by their inhibition of COX. However, both *S*- and *R*-FLU have been shown to be equipotent in lowering A*β*42 levels in mouse brain and share the same mechanism of

interaction with the γ-secretase complex (*13*). In this first study, we thus chose to perform the chemical derivatization using the racemic form of FLU; a further exploitation of the potentiality of FLU−LAA prodrugs could be made using pure *R*-FLU.

LAA with different alkyl side chains ranging from 4 to 12 carbon atoms were linked to FLU through an ethanolamine spacer via an ester bond between FLU and the spacer and an amide bond between the LAAs and the spacer. The chemical stability profiles of all synthesized conjugates (**6a**−**e**) were determined in pH 7.4 phoshate buffer, while the pharmacokinetic and biodistribution patterns were evaluated for **6b** and **6d** after intravenous administration to mice.

The capacity of FLU and prodrug **6** to interact with the insoluble fibrillar aggregates of β-amyloid (1–40) protein was also tested using radiofluorinated [F-18]FDDNP in a competition assay with *in vitro* formed β-amyloid (1–40) fibrils. [F-18] FDDNP (2-(1-{6-[(2-[F-18]fluoroethyl)(methyl)amino]-2-naphthyl}ethylidene)malononitrile) is a positron-emitting radiofluorinated molecular imaging probe with binding affinity for neuropathological lesions found in AD, β-amyloid senile plaques, and neurofibrillary tangles, used for *in vivo* positron emission tomography (PET) imaging of the neuropathology load in AD patients' brains (*27*).

EXPERIMENTAL PROCEDURES

Materials. FLU (racemic form), (±)*N*-Boc-2-aminohexanoic acid (**4a**), (±)2-aminoalkanoic acids, and the other reactants and solvents were purchased from Sigma-Aldrich Chimica Srl (Milan, Italy). The 2-aminoalkanoic acids were Boc-protected before use following a published procedure (*28*) to give compounds **4b**−**e**. All solvents were dried by distillation according to standard methods (*29*) and stored over 4 Å molecular sieves activated at 400 °C for at least 24 h.

[F-18]FDDNP was prepared by tosyloxy-to-fluorine nucleophilic substitution from cyclotron-produced [F-18]fluoride anion and 2-{[6-(2,2-dicyano-1-methylvinyl)-2-naphthyl](methyl) amino}ethyl 4-methylbenzenesulfonate as described elsewhere (*30*) and immediately used for competitive binding assays with FLU and prodrugs **6a**−**e**.

The male Balb/c mice weighing 22 ± 2 g used for the *in vivo* studies had free access to food and were housed at the Department of Pharmaceutical Sciences, University of Padua. Animal experiments were performed in accordance with Italian law (D.L. 116/92) and European guidelines (EEC n. 86/609).

Instrumentation. TLC analysis was used to check the purity of compounds using silica gel aluminum plates (Merck $F_{254-366}$); the spots were detected by spraying the plate with ninhydrin or an acid–base reactant. Elemental analysis was carried out on a Carlo Erba 1106 analyzer; samples were kept under vacuum for 24 h over P_2O_5 before analysis. FT-IR spectra were recorded as nujol mulls with a Perkin-Elmer 1600 spectrophotometer. ^{1}H NMR spectra were obtained in $CDCl_3$ at 200 MHz using a Varian Innova instrument. Chemical shifts are reported in ppm, using TMS as internal standard. Mass spectra were measured with a triple quadripole instrument (IPE sciex API 3000) operating in SIM mode with positive ion electrospray.

The partition and distribution coefficients (cLog *P* and cLog $D_{7.4}$) of FLU and prodrugs were calculated using the *ACD/LogP 5.15* software (Advanced Chemistry Development Inc., Toronto, Canada) and the *Pallas 3.0* software package (CompuDrug International, Inc., Sedona, AZ), respectively (Table 1).

Synthesis of FLU−EA Intermediate (3). FLU (**1**) (0.82 mmol, 200 mg) was dissolved in 20 mL of anhydrous dichloromethane (DCM), and 1-hydroxybenzotriazole (HOBt) (0.82 mmol, 123 mg) and triethylamine (TEA) (1.64 mmol, 227 μL) were added. The solution was treated with 1.64 mmol (232 mg) of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDAC) and the mixture was kept at 0 °C in an ice–water bath for 2 h. *N*-Boc-ethanolamine [*tert*-butyl-*N*-(2-hydroxyethyl)carbamate] (190 μL, 1.23 mmol) in 10 mL of DCM was added to the reaction mixture and stirred at 0 °C for 2 h. The mixture was brought to room temperature and stirred for an additional 4–6 h. The solvent was removed under vacuum, and the oily residue was dissolved in 20 mL DCM, washed twice with 20 mL aliquots of water, followed by 5% $NaHCO_3$ solution, 5% aqueous acetic acid, and finally brine. The organic phase was separated, dried over anhydrous sodium sulfate, and evaporated. The final residue was purified by flash chromatography on silica gel with ethyl acetate/cyclohexane, 40:60 (v/v) to obtain compound **2**.

Table 1. General Structure and Properties of FLU−EA−LAA Conjugates 6a−e

					HPLC method

[a] Predictions were made using the *ACD LogP 5.15* software. [b] Calculated using the *Pallas 3.0* software.

The Boc protective group was finally removed with 10% (v/v) solution of TFA in DCM for 30 min at room temperature. The solvents were evaporated under a nitrogen flow, and the residue was treated with 20 mL of 5% sodium hydrogen carbonate and extracted with 20 mL DCM. The organic phase was separated, dried as described above, and evaporated to dryness to give FLU−EA [**3**; 2-(2-fluoro-4-biphenyl)propionic acid 2-aminoethyl ester] (Scheme 1). The oily compound was kept refrigerated until use. Elemental analysis for $C_{17}H_{18}FNO_2$, % found (theoretical): C 70.70 (71.06), H 6.22 (6.31), N 4.86 (4.87). IR (cm^{-1}): 1733.7 (ester *C*=O), 3302.2 (amine); MS (*m*/*z*): 288 $[M + 1]^+$ (100%); ^{1}H NMR (ppm): 7.49–7.30 (m, 6H, aromatic), 7.08 (m, 1H, ∅-H), 7.04 (s, 1H, ∅-H), 4.26 (t, 2H, OCH_2), 3.68–3.54 (q, 1H, $\underline{CH}$-CH_3), 3.08 (m, 2H, $\underline{CH_2}$-NH_2), 1.39 (d, 3H, CH_3).

Synthesis of FLU−EA−LAA Derivatives (6a−e): General Procedure (Scheme 1). A Boc-LAA derivative (**4a**−**e**, 0.25 mmol) was dissolved in 10 mL DCM, and HOBt (0.16 mmol, 24.5 mg) and TEA (0.32 mmoles, 44 μL) were added. The chosen LAA was then activated by adding EDAC (0.32 mmol, 45.4 mg) and stirring the mixture for 2 h in an ice–water bath. A solution of **3** (0.25 mmol, 68.9 mg) in 10 mL DCM was then added, and the mixture was kept at 0 °C for 2 h and then at room temperature for 18–24 h. Upon completion of the conjugation (TLC), the mixture was extracted as reported above, and the waxy residue was purified by column chromatography, using an ethyl acetate/cyclohexane gradient from 50:50 to 60:40 (v/v) to isolate compounds **5a**−**e**. The obtained product was deprotected by 20% TFA in DCM, and the residue was purified by semipreparative TLC (0.5 mm layer silica gel plates, SIL G-50, Macherey-Nagel GmbH & Co., Düren, Germany) eluted with an 80:20 DCM/methanol mixture. Compounds **6** were stored in closed amber glass containers at 4 °C.

Analytical Characterization of Compounds 6a−e. 6a (n = 3): 2-(2-fluoro-4-biphenyl)propionic acid 2-(2-aminohexanoyl)aminoethyl ester. Elemental analysis for $C_{23}H_{29}FN_2O_3$, % found (theoretical): C 69.21 (68.98), H 7.31 (7.30), N 7.00 (6.99). IR (cm^{-1}): 1678.9 (amide *C*=O), 1750.1 (ester *C*=O). MS (*m*/*z*, %): 401.6 $[M + H]^+$ (100), 313 (13), 288 (7). ^{1}H NMR (ppm): 7.99 (broad, 1H, NH), 7.76–7.40 (m, 6H, aromatic), 7.22 (m, 1H, ∅-H), 7.15 (s, 1H, ∅-H), 4.41 (m, 2H, OCH_2), 3.72 (q, 1H, CH-CH_3), 3.42 (m, 2H, CH_2-NH_2), 1.79 (m, 2H, CH_2), 1.61 (d, 3H, CH_3), 1.35–1.24 (t, 4H, CH_2), 0.85 (t, 3H, ω-CH_3).

6b (n = 5): 2-(2-fluoro-4-biphenyl)propionic acid 2-(2-aminooctanoyl)aminoethyl ester. Elemental analysis for $C_{25}H_{33}FN_2O_3$, % found (theoretical): C 69.80 (70.07), H 7.77 (7.76), N 6.50 (6.54). IR (cm^{-1}): 1679.8 (amide *C*=O), 1741.8 (ester *C*=O). MS (*m*/*z*, %): 429.5 $[M + H]^+$ (100), 368 (4), 340 (5). ^{1}H NMR (ppm): 7.97 (broad, 1H, NH), 7.52–7.34 (m, 5H, aromatic), 7.26 (s, 1H, ∅-H), 7.11 (m, 1H, ∅-H), 7.05 (s, 1H, ∅-H), 4.10 (m, 2H, OCH_2), 3.72 (q, 1H, CH-CH_3), 3.45 (m, 2H, CH_2-NH_2), 1.77 (m, 2H, CH_2), 1.48 (d, 3H, CH_3), 1.25–1.21 (t, 8H, CH_2), 0.82 (t, 3H, ω-CH_3).

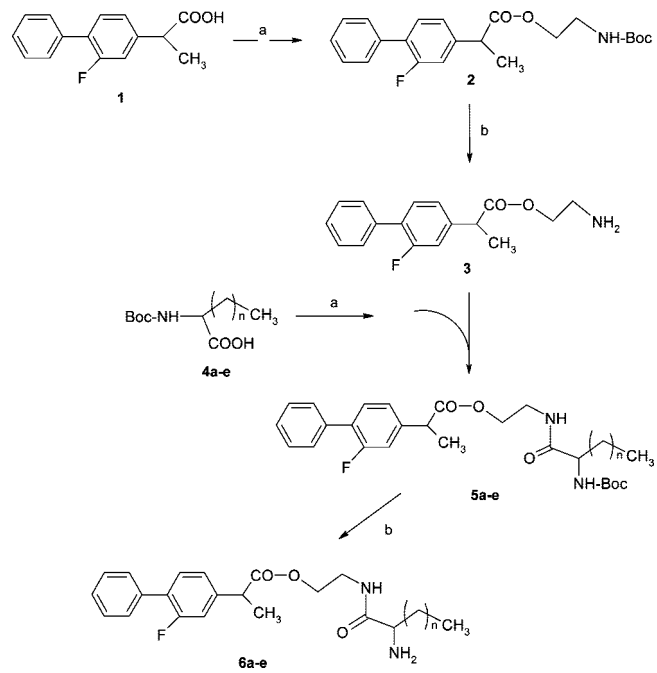
6c (n = 7): 2-(2-fluoro-4-biphenyl)propionic acid 2-(2-aminodecanoyl)aminoethyl ester. Elemental analysis for $C_{27}H_{37}FN_2O_3$, % found (theoretical): C 70.80 (71.02), H 8.16 (8.17), N 6.11 (6.14). IR (cm^{-1}): 1679.6 (amide *C*=O), 1739.3 (ester *C*=O). MS (*m*/*z*, %): 457.7 $[M + H]^+$ (100), 396 (8), 368 (7). ^{1}H NMR (ppm): 8.04 (broad, 1H, NH), 7.62–7.38 (m, 5H, aromatic), 7.56 (s, 1H, ∅-H), 7.09 (m, 1H, ∅-H), 7.02 (s, 1H, ∅-H), 4.30 (broad m, 2H, OCH_2), 3.90 (q, 1H, CH-CH_3), 3.49 (m, 2H, CH_2-NH_2), 1.66 (m, 2H, CH_2), 1.56 (d, 3H, CH_3), 1.32–1.17 (t, 12H, CH_2), 0.88 (t, 3H, ω-CH_3).

6d (n = 9): 2-(2-fluoro-4-biphenyl)propionic acid 2-(2-aminododecanoyl)aminoethyl ester. Elemental analysis for $C_{29}H_{41}FN_2O_3$, % found (theoretical): C 71.59 (71.87), H 8.56 (8.53), N 5.81 (5.78). IR (cm^{-1}): 1667.1 (amide *C*=O), 1734.1 (ester *C*=O). MS (*m*/*z*, %): 485.6 $[M + H]^+$ (100), 486 (35), 396 (9). ^{1}H NMR (ppm): 7.98 (broad, 1H, NH), 7.54–7.39 (m, 6H, aromatic), 7.21 (m, 1H, ∅-H), 6.88 (s, 1H, ∅-H), 4.34 (m, 2H, OCH_2), 3.76 (q, 1H, CH-CH_3), 3.48 (m, 2H, CH_2-NH_2), 1.77 (m, 2H, CH_2), 1.63 (d, 3H, CH_3), 1.32–1.21 (m, 16H, CH_2), 0.86 (t, 3H, ω-CH_3).

6e (n = 11): 2-(2-fluoro-4-biphenyl)propionic acid 2-(2-aminotetradecanoyl)aminoethyl ester. Elemental analysis for $C_{31}H_{45}FN_2O_3$, % found (theoretical): C 72.88 (72.62), H 8.88 (8.85), N 5.45 (5.46). IR (cm^{-1}): 1664 (amide *C*=O), 1728 (ester *C*=O). MS (*m*/*z*, %): 513.9 $[M + H]^+$ (100), 485 (55), 457 (20), 420 (12). ^{1}H NMR (ppm): 8.04 (broad, 1H, NH), 7.50–7.26 (m, 5H, aromatic), 7.46 (s, 1H, ∅-H), 7.12 (m, 1H, ∅-H), 6.97 (s, 1H, ∅-H), 4.24 (m, 2H, OCH_2), 3.75 (q, 1H, CH-CH_3), 3.46 (m, 2H, CH_2-NH_2), 1.79 (m, 2H, CH_2), 1.60 (d, 3H, CH_3), 1.30–1.22 (t, 20H, CH_2), 0.88 (t, 3H, ω-CH_3).

Chemical Stability Assay. Each prodrug **6a**−**e** (1 mg) was dissolved in DMSO (100 μL) and diluted to 1 mL with isotonic phosphate buffer (PBS, pH 7.4). The mixture was incubated at 37 ± 1 °C, and 100 μL aliquots were withdrawn at regular time intervals (every 7–8 days). HPLC analysis was performed to determine the amount of intact prodrugs as well as the amounts of released FLU (**1**) and FLU−EA (**3**), products of hydrolytic cleavage of the FLU−EA ester bond or the EA−LAA amide bond, respectively. A Varian ProStar chromatograph equipped with a Varian 410 autosampler and a Waters C18 Symmetry column (5 μm, 4.6 × 150 mm), connected to a Waters C18 Symmetry precolumn, was used for the analysis. The UV detector was set at 247 nm. 10 μL aliquots were injected by means of a Varian 410 autosampler and the compounds eluted at 1 mL/min under isocratic conditions with different water/acetonitrile (ACN) mixtures, as summarized in Table 1.

Scheme 1. General Procedure for the Synthesis of FLU−EA−LAA Prodrugs



Plasma Stability Evaluation. Three heparinized mouse whole blood samples (300 μL) were mixed with 150 μL of 50:50 water/ACN containing 9 μg of either FLU, **6b** or **6d**, and kept at 37 °C. At scheduled times (30, 60, 120, 180, 240, and 300 min), 50 μL of the samples were withdrawn and added of 100 μL of ACN to precipitate proteins. The samples were centrifuged for 5 min at 4 °C and 14 000 rpm, and the supernatant was analyzed according to the procedure reported below. The drug and prodrug contents were referred to the standard titration curves.

Analytical Procedure. The content of FLU, FLU−EA (**3**), and prodrugs **6b** and **6d** in the tissue extraction samples was evaluated by reverse-phase HPLC using an analytical C-18 column (Luna, Phenomenex, 250 × 4.6 mm). NAP standard solution (50 μL) was added to the samples as an internal standard. The column was eluted with a gradient of water (eluent A) and ACN (eluent B), both containing 0.05% TFA, according to the following gradient scheme: 40% eluent B for 3 min, up to 60% eluent B in 20 min, to 90% eluent B in 2 min, and back to the initial conditions in 2 min. The UV detector was set at 247 nm. FLU, **6b**, **6d**, and NAP retention times were 20.5, 14.7, 25.5, and 13.9 min, respectively. Standard curves were calculated for each compound in the range 0.08–40 μg/mL with r^2 = 0.996 – 0.999. The amounts of the compounds **6b** and **6d** and their hydrolysis products FLU and FLU−EA were determined from the standard curves using the corresponding peak areas.

In the case of solid tissues, the blood contribution was evaluated and subtracted according to the procedure reported in the literature (*31*).

Extraction Tests from Plasma and Organs. The recovery of compounds **1**, **6b**, and **6d** from mouse liver, kidney, brain, spleen, and plasma was evaluated.

100 μL of heparinized whole blood was withdrawn from mice by retrobulbar puncture and added to 100 μL of 50:50 (v/v) ACN/water mixture containing different amounts (1, 2, and 3 μg) of FLU or FLU equivalent amounts of prodrugs, and 50 μL of naproxen standard solution (NAP) (0.1 μg/μL in the same solvent mixture). The samples were mixed and centrifuged for 3 min at 3000 rpm. Aliquots of 50 μL of clear supernatant were

withdrawn, mixed with 100 μL of ACN, vortex-mixed, and finally centrifuged for 3 min at 14 000 rpm. The supernatants containing the extracted compounds were analyzed by HPLC as reported above.

Liver, kidney, brain, and spleen taken from the same mouse were washed with physiological solution and gently dried on paper. Different volumes (10, 20, 30, 40, and 50 μL) of ACN solutions containing 50 ng/μL of each compound were added to 50 mg of liver, kidney, brain, and spleen samples. The samples were mixed with 50 μL of NAP standard solution (0.1 μg/μL) and 1 mL of 50:50 (v/v) ACN/water mixture. The samples were homogenized and then centrifuged for 5 min at 4000 rpm. The supernatants were collected by suction and the pellets treated three times with 1 mL of ACN/water mixture and once with 1 mL of ACN. All five supernatants were combined and centrifuged for 3 min at 14 000 rpm. The final volume was lyophilized, and the residue was dissolved in 200 μL of 50:50 (v/v) ACN/water mixture, centrifuged for 5 min at 14 000 rpm, and finally analyzed by reverse-phase HPLC according to the gradient elution reported above.

Pharmacokinetic Assay. Solutions containing 4 mg of FLU (**1**) or FLU equivalent compounds **6b** or **6d** in 1 mL of DMSO were diluted with 3 mL of phosphate-buffered saline (0.15 M NaCl, 20 mM phosphate buffer), pH 7.4. 110 mice were divided into 3 groups of 35 animals (test groups) and 1 group of 5 animals (control group). Each group received one of the above solutions; the animals were injected via the tail vein with 100 μL of the respective solution. The 5 animals in the control group were intravenously injected with 100 μL of the vehicle (1:3 DMSO/saline solution). At scheduled times, 50 μL of blood samples were randomly withdrawn by retrobulbar puncture; at least three animals were used per each time point. The blood samples were immediately mixed with 50 μL of a NAP standard solution (0.1 μg/μL). Aliquots of the supernatant (50 μL) were mixed with 50 μL of ACN, centrifuged for 5 min at 14 000 rpm to precipitate proteins, and analyzed by reverse-phase HPLC as described above.

At scheduled times (30, 60, 180, 420, and 560 min) seven animals/group were bled and sacrificed and liver, spleen, kidney, and brain were taken. The collected blood was processed as described above. The whole organs were washed in saline and gently dried with absorbent paper, weighed, spiked with 50 μL of the above standard NAP solution, and processed according to the procedure previously reported. The amounts of recovered FLU−EA−LAA prodrugs, FLU−EA (**3**), and free FLU were determined by HPLC analysis as described above.

Radioactive [F-18]FDDNP Competitive Binding Assay with Aβ(1–40) Fibrils. Aβ(1–40) Fibril Formation. β-amyloid(1–40) fibrils were prepared *in vitro* from the commercially available Aβ(1–40) peptide (Biosource, Camarillo, CA) according to published methods (*30*). Briefly, 1.0 mg of Aβ(1–40) peptide was dissolved in 1 mL of phosphate buffered saline (PBS), pH 7.4, and stirred with a magnetic stirring bar for 3–4 days at 37 °C, after which a visibly cloudy solution was obtained. This mixture was further diluted to 10 mL with PBS, pH 7.4, and used as such for competitive binding assays of FLU and prodrugs **6a**−**e** against [F-18]FDDNP. The fibril formation was confirmed using Congo red (*32*) and Thioflavine T (*33*) UV spectrophotometric assays. Fibrils were used immediately after their production was confirmed.

Competition Binding Assays. The methodology published for determination of competition binding assays with NAP and ibuprofen (IBU) was used (*10*). Fresh 5 mM ethanol solutions of FLU and of all prodrugs were prepared for each competitive binding assay. Solutions of each compound in 1% ethanol/PBS, pH 7.4, in the range from 0.1 pM to 300 nM were incubated with 9.25 MBq/mL of [F-18]FDDNP (specific activity >74 GBq/μCi) and with 0.875 μg/mL of Aβ(1–40) fibrils for 60 min. The fibrils were isolated by filtration through Anodisc 25 alumina membrane filters (0.2 μm particle retention; Whatman International Ltd., Maidstone, England) in a 1225 sampling manifold (Millipore, Bradford, MA) that was modified with stainless steel support screens (Millipore) and glass sample chambers. Each filter was washed twice with 3 mL of PBS, pH 7.4. The radioactivity retained by the filters was measured and decay-corrected to a common reference time with a Packard Cobra II Auto-Gamma gamma counter (Packard, Meriden, CT). The binding of [F-18]FDDNP to Aβ(1–40) fibrils without a competitor determined 100% specific binding.

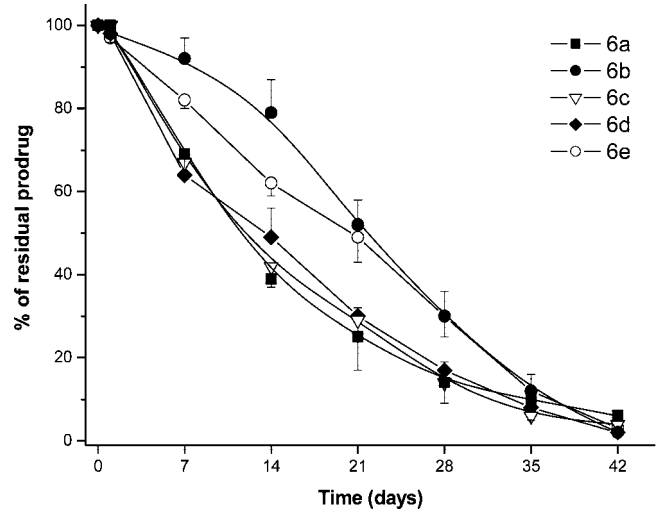


Figure 1. Degradation profiles of compounds **6a**−**e** in isotonic phosphate buffered saline at pH 7.4.

Competition results were analyzed and K_i values then calculated using the ligand binding module for *SigmaPlot 2001* (SPSS, Chicago, IL). The comparison of one- and two-site models for binding involved calculating the *F* statistic with a significance level of $P < 0.05$. All radioactive binding assays were performed in triplicate.

RESULTS AND DISCUSSION

Chemistry and Stability Tests. The lipophilic prodrugs of FLU were synthesized according to a procedure used for the preparation of other LAA conjugates, using water-soluble carbodiimide-assisted coupling reactions (*34–36*). Compounds **6a**−**e** were obtained in 50–80% yield and with high purity using semipreparative TLC. No attempt was made at this level to separate the eventual diastereomers formed by using racemic FLU and Boc-LAA as starting compounds.

Spectroscopic and mass analyses confirmed the assigned structure; in particular, IR spectroscopy showed the disappearance of the stretching peak of the FLU carboxyl group (at 1697 cm^{-1} in nujol) and appearance of two new peaks, around 1720–1750 cm^{-1}, due to the FLU−EA ester bond, and 1665–1680 cm^{-1}, related to the EA−LAA amide bond. The increasing lipophilicity of prodrugs with the increasing length of the side alkyl chain of the LAA residue is shown by the calculated Log *P* and Log $D_{7.4}$ values (Table 1).

The chemical stability of compounds **6a-e** was tested in phoshate buffered saline at 37 °C and pH 7.4 (Figure 1). Lengthening of the LAA alkyl side chain, and therefore of compound lipophilicity, was associated with an increasing stability to chemical hydrolysis, except for compound **6b**, which showed the highest stability. Hydrolytic cleavage of all prodrugs was completed after 7 weeks. The HPLC analysis showed that all the prodrugs **6** were hydrolyzed predominantly into FLU

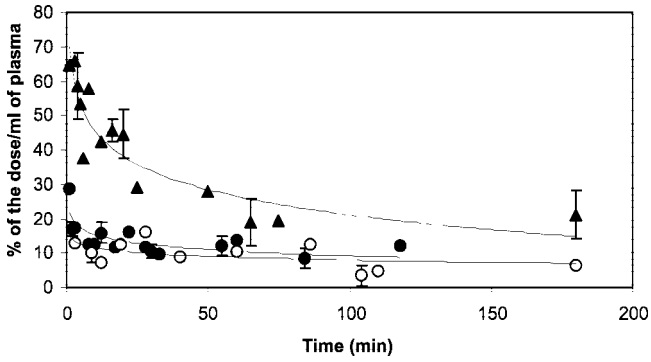

Figure 2. Plasma FLU levels after i.v. administration of the free drug (▲) or conjugates **6b** (○) and **6d** (•) (100 μg FLU equivalent/mouse). In the case of **6b** and **6d**, FLU levels refer to the amount of injected FLU equivalents.

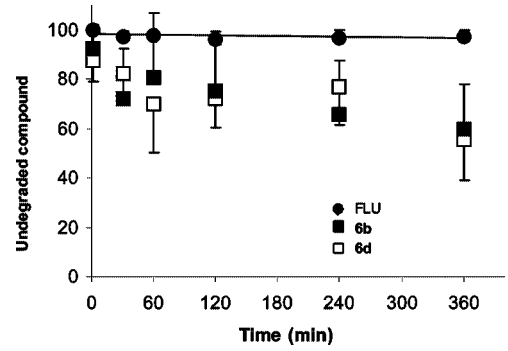

Figure 3. Stability of FLU or prodrugs **6b** and **6d** after incubation in mouse plasma at 37 °C.

from the earliest incubation times on, since the intermediate FLU-EA (**3**) was detected only at very low concentrations. Compound **3** was also very susceptible to hydrolysis in PBS, and a very rapid conversion into FLU was observed within 24 h of incubation (data not shown). As expected, the ester bond in the prodrugs **6a**−**e** was more susceptible to hydrolysis than the amide link between the spacer and the LAA residue.

The sensitivity to chemical hydrolysis of the ester bond in the prodrugs was verified by incubating compounds **6a**−**e** in a 3:1 (v/v) 2 M KOH/methanol mixture at 37 °C. After 15 min, the complete hydrolysis of the prodrugs into the parent FLU was observed (HPLC) (data not shown).

***In Vivo* Biodistribution Tests.** Based on their alkyl side chain length, prodrugs **6b** and **6d** were chosen as representatives of the short- and long-chain LAA conjugates to carry out pharmacokinetic and biodistribution tests.

Preliminary validation studies demonstrated the reliability of the extraction and analytical procedures adopted in the experimental protocols. The recovery of FLU and prodrugs **6b** and **6d** from blood spiked with these compounds was 89.7 ± 4.3%, 91.5 ± 6.8%, and 94.9 ± 4.2%, respectively. The recovery from the homogenized tissues was in the range 86–94% for all analyzed organs (liver, kidney, brain, lungs, and spleen). These values were used in the elaboration of the pharmacokinetic data to normalize the value of recovered products. Neither FLU nor FLU−EA were detected in blood and homogenized organ samples supplemented with **6b** and **6d**, indicating that these prodrugs were not hydrolyzed during the extraction procedure.

Figure 2 shows the time-course FLU levels in plasma after i.v. administration of the parent drug or prodrugs **6b** and **6d** to mice. In the case of the latter compounds, no intact prodrug was detected in blood 2 min after injection. After the same amount of time, low levels of free FLU were observed after administration of both **6b** and **6d**.

The fast disappearance of the prodrugs (Figure 2) can be only partially ascribed to their plasma degradation, since preliminary studies demonstrated that both conjugates are relatively stable upon *in vitro* incubation in plasma (about 25% degradation after 2 h and 40% degradation after 6 h) (Figure 3). The absence of the prodrug in plasma and the low FLU levels in liver and kidneys can thus be ascribed to a quick partition into peripheral compartments, namely, endothelial tissue, from which the following hydrolysis by endothelial lipases justifies the prolonged and stable drug levels observed in the circulation. A more likely alternative is the liver release of the hydrophobic compounds via the bile, release into the small intestine, and reabsorption prior to hydrolysis via endothelial lipases. A detailed pharmacokinetic or radiolabeled prodrug study would answer the question and is planned as a further step of this research.

In contrast, after i.v. injection, free FLU did not undergo a rapid partition into the peripheral compartments and maintained prolonged high plasma drug levels compared with the drug levels reached after the administration of prodrugs **6b** and **6d**.

To get information about the *in vivo* fate of **6b** and **6d**, prodrug and free FLU contents in the main organs were measured. The experiments were carried out for 9 h, since prodrug degradation made longer time evaluations difficult.

Figure 4 shows the extracellular accumulation of FLU in the main organs after FLU, **6b**, or **6d** i.v. administration to mice. After i.v. administration, free FLU rapidly distributed to the various tissues with concentration distributions in the order liver > brain > kidney > spleen. FLU concentration in these organs was almost constant up to 3 h, follow by a slow decline. Only negligible amounts of the drug were detected after 7 h.

In the case of prodrugs **6b** and **6d**, only the released parent FLU was observed. The intact prodrugs could not be detected in the homogenized tissues, similarly to what was observed in the blood. The two prodrugs, however, displayed a markedly different behavior with regard to FLU availability to various organs. From the first times after administration of **6b**, only small amounts of FLU were detected in the liver, kidneys, and spleen, while negligible disposition was observed in the brain. Conversely, the higher homologue **6d** led to accumulation of higher amounts of released FLU in the various organs. In general, after **6d** administration the maximal FLU concentration in the main tissues was reached later than after free FLU injection. The **6d** derivative yielded maximal FLU accumulation in the liver and spleen after 1 and 3 h after administration, respectively. The FLU levels in the kidneys also increased throughout 9 h, indicating that the drug was constantly released from the peripheral compartments and possibly eliminated by glomerular filtration or distributed to other kidney tissues. Again, more detailed studies are required to determine the exact elimination routes of the drug after i.v. administration of these prodrugs, for instance, by determining their concentration vs time in urine or feces.

Concerning the presence of FLU in the brain, injection of the parent drug led to constant brain levels for 3 h; therafter, the drug rapidly disappeared from this area. Such a pattern conforms to the levels of FLU in plasma, where the drug was detectable only for 3 h (Figure 2). After injection of compound **6d**, the released FLU appeared in the brain after 1 h, and the intracerebral FLU levels continued to rise up to the ninth hour, reaching higher values than those observed in the first 3 h after the injection of free FLU. The maximum brain/liver ratio (about 12% brain/plasma concentration) was reached 1 h after injection.

These pharmacokinetic findings suggest that the prodrugs dispersed rapidly and massively into a peripheral compartment. In the case of **6b**, which was found to be more stable than the upper homologues in plasma, the parent drug was not released into the brain; with **6d**, free FLU was released and accumulated

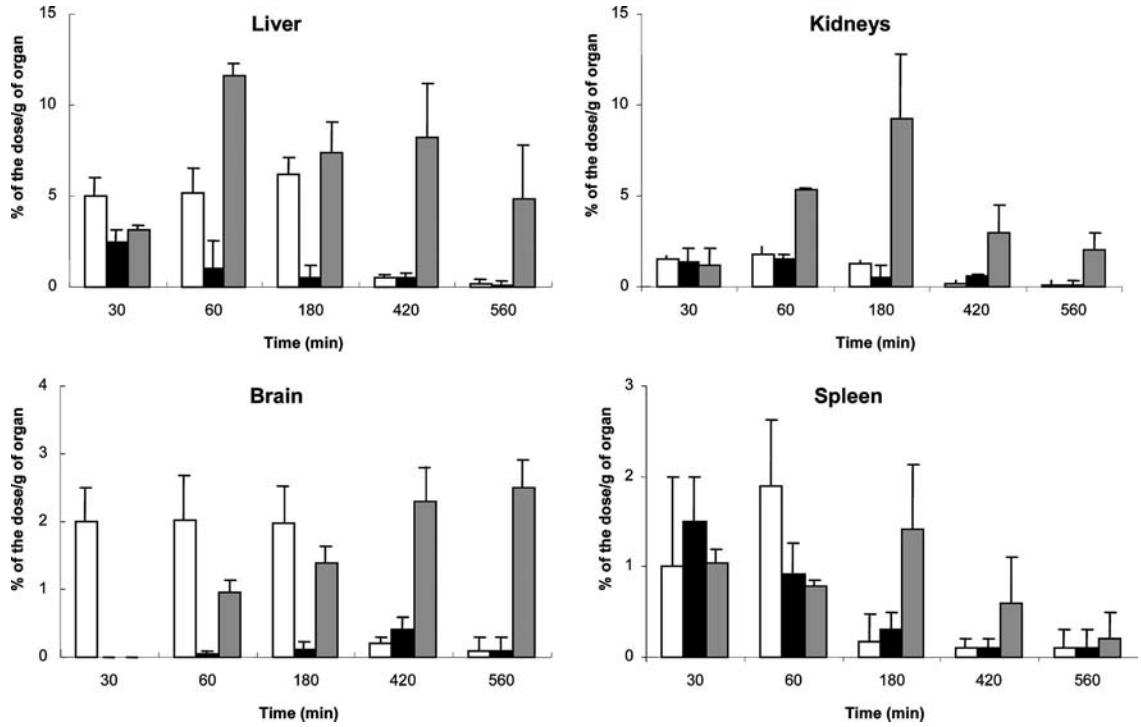

Figure 4. FLU concentrations in liver, brain, kidneys, and spleen after i.v. administration (100 μg FLU equiv/mouse) of the free drug (white) or conjugates **6b** (black) and **6d** (gray). In the case of the latter compounds, FLU levels were referred to the amount of FLU released from the prodrugs *in vivo*.

preferentially in the brain tissue; actually, the brain/plasma FLU concentration obtained with **6d** increased over time to reach about 30% 420 min from injection.

The different tissue distribution obtained with the various FLU derivatives is probably due to their dissimilar *in vivo* pathway/metabolism, such as the previously mentioned enterohepatic reticulation or association with vessel endothelium. However, a profound characterization of the pharmacokinetic profile of prodrugs **6** was beyond the intent of this paper; thus, further *in vivo* pharmacological studies will be started to elucidate the fate of these compounds.

The stark differences observed in the *in vivo* behavior between the two prodrugs highlight the effect that the LAA residue can exert on their biopharmaceutical profiles. In particular, a relatively small difference in the chain length (four methylene groups) in the side alkyl chain of the LAA promoiety of **6b** and **6d** led to a considerably different distribution profile.

The combined analysis of the chemical and plasmatic stability tests confirmed the validity of these conjugates as possible prodrugs for FLU. Compounds **6**, in fact, showed good stability in aqueous buffer and a slow release of the active drug in plasma.

[F-18]FDDNP Binding Assay. IBU and NAP showed competitive inhibition of [F-18]FDDNP binding with *in vitro* β-amyloid fibrils, with weak binding for IBU ($K_i = 11.3 \pm 5.2$ μM for *S*-IBU and 44.4 ± 17.4 μM for *R*-IBU) and with 3 orders of magnitude higher binding affinity for NAP ($K_i = 2.76 \pm 0.95$ nM for *S*-NAP and $K_i = 5.71 \pm 1.31$ nM for *R*-NAP) (*10*, *30*, *37*). In contrast to NAP and IBU, FLU proved to be ineffective in blocking [F-18]FDDNP from binding to its two specific binding sites on *in vitro* formed Aβ(1–40) fibrils in the concentration range of competitors used (0.1 pM to 300 nM). This apparent lack of binding can be better understood if structural factors are taken into consideration. The structure of FLU is related to that of IBU, i.e., they both have a central phenyl ring and propanoic acid residue. However, while IBU possesses an isobutyl group in the para position to the alkyl carboxilic acid chain, FLU has a phenyl ring in the para position and a fluorine meta substitution. Such an arrangement of substituents in FLU most likely pushes both phenyl rings out of plane due to steric and electrostatic interactions between the para phenyl ring and the meta fluorine atom.

The consequent lack of planarity may then decrease the probability of FLU interaction with the [F-18]FDDNP binding site. FLU−EA, the intermediate FLU ester with 2-aminoethanol, also showed no apparent competition in the *in vitro* assays.

The FLU prodrugs **6a** (C4 alkyl chain), **6b** (C6 alkyl chain), **6c** (C8 alkyl chain), and **6d** (C10 alkyl chain), on the other hand, demonstrated competitive inhibition of [F-18]FDDNP binding to β-amyloid(1–40) fibrils. Prodrug **6e** (C12 alkyl chain) did not compete with [F-18]FDDNP binding. Prodrugs **6a**, **6b**, and **6d** competed with [F-18]FDDNP for low-affinity binding (K_i values: **6a** 0.386 μM; **6b** 3.65 μM; and **6d** 0.017 μM), prodrug **6c**, on the other hand, showed competition for both high- and low-affinity binding sites with $K_i = 25.3$ pM and 0.396 μM, respectively. The results are shown in Figure 5.

Conjugation of the LAA residues to FLU changes the nature of its interaction with the Aβ(1–40) fibril surface. Hydrophobic interaction between the alkyl side chain with the hydrophobic areas on the surface of the fibrils becomes important and may overcome the effects of steric hindrance allowing the prodrugs to bind to the [F-18]FDDNP binding site(s). We also cannot underestimate interactions of the free amino group with the anionic side chains on the fibril. There are several aspartate and glutamate residues in the structure of the Aβ protein which can form strong electrostatic interactions and anchor the prodrugs **6a**−**d** on the surface.

The capacity of prodrug **6c** to bind to both [F-18]FDDNP binding sites on the fibrils and also the complete absence of competition suggested different hypotheses. The processes involved may include micellization of the hydrophobic prodrugs at higher concentrations (high nanomolar) under the conditions used for the competition assays (1% ethanol in PBS) and interactions of the micelles with the fibril surface. Formation

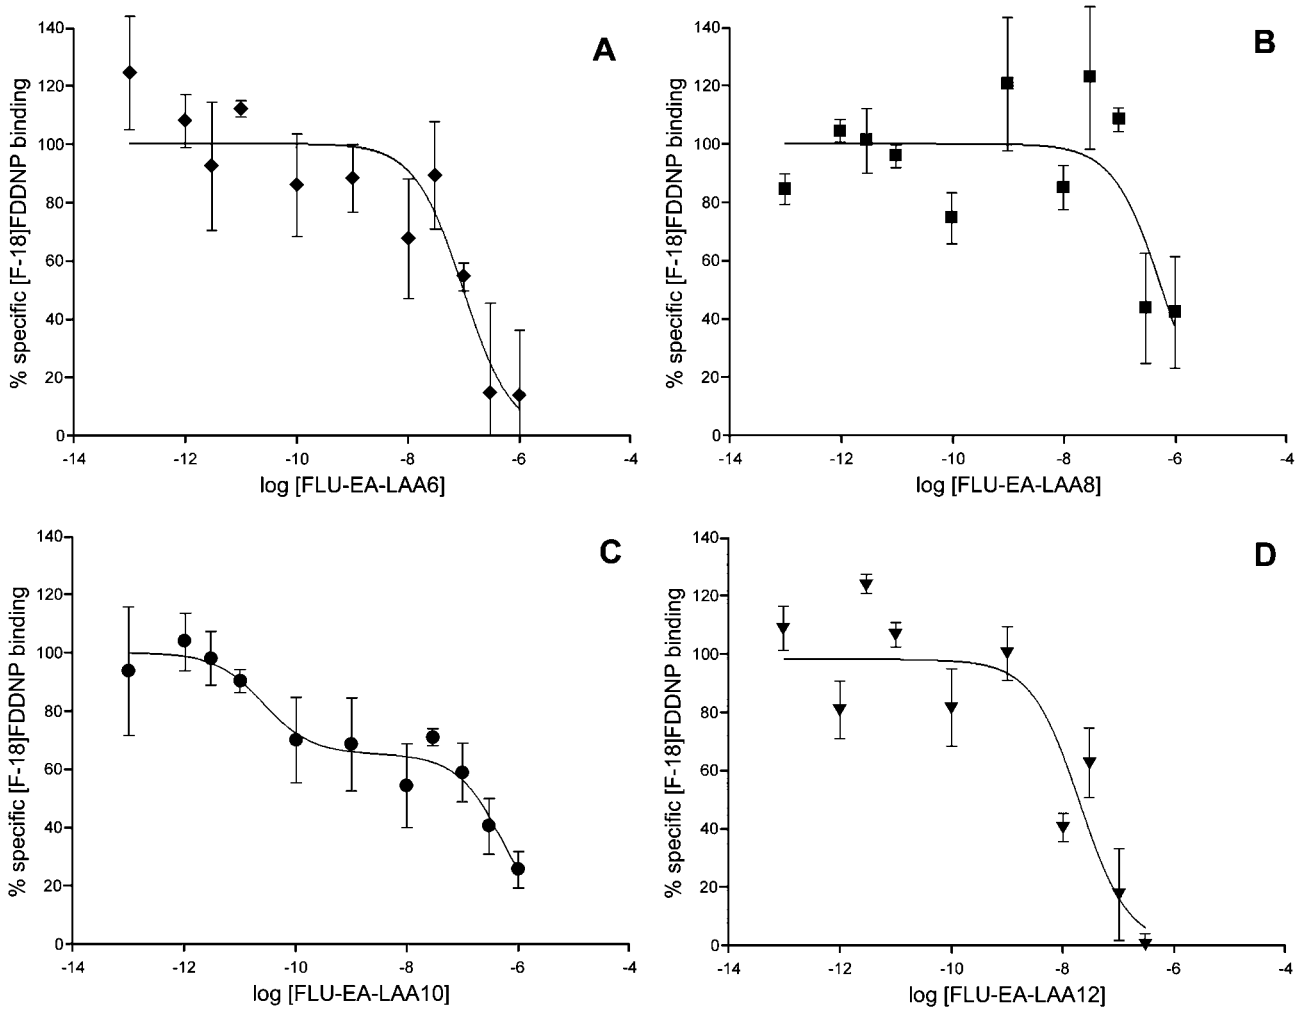

Figure 5. Prodrugs **6a**−**d** inhibition [F-18]FDDNP binding profile to the *in vitro* formed β-amyloid(1–40) fibrils. Compounds **6a** (A), **6b** (B), and **6d** (D) competed with [F-18]FDDNP for one binding site. Compound **6c** (C) blocked [F-18]FDDNP from both binding sites.

of micelles or other types of lipophilic aggregates can also be taken into consideration to explain the pharmacokinetic profile observed for prodrugs **6** and discussed previously. This statement implies that the amount injected in these studies is large and the pharmacokinetics would be altered by a mass effect. The amount administered for the present studies had to be reasonably high to permit chemical analysis, but *in vivo* studies using radiolabeled derivatives of these compounds (e.g., subnanogram/kg injected) may produce different and more reliable (e.g., mass independent) results.

CONCLUSIONS

The combined analysis of chemical and plasmatic stability data indicate these conjugates as possible prodrugs for FLU. They showed, in fact, good stability in buffer solution and a gradual release of the active drug in plasma, most probably upon enzymatic intervention. Compound **6d**, in particular, behaved as a slow-release FLU prodrug of FLU.

Even though their physicochemical properties were not optimized, it is possible to speculate that selected structural changes, e.g., the kind of spacer between the drug and the LAA promoiety, could lead to novel, more selective compounds for brain delivery of FLU. The inhibitory activity of [F-18]FDDNP binding to *in vitro* formed β-amyloid protein fibrils confered a structure−binding affinity relationship to these compounds; this study demonstrates that, if any differential pharmacological effect was observed with respect to FLU, it is not because of direct binding to the fibrils, but rather to other mechanisms (e.g., anti-inflammatory mechanisms), suggesting FLU−EA−LAA derivatives as potential prodrugs for AD treatment.

Experimental results showed that only FLU was found in specific organs even when prodrugs **6b** and **6d** were injected. A possible explanation is that the lipophilic prodrugs accumulated in a specific peripheral compartment, e.g., bile and following enterohepatic recirculation, from where FLU was released; thereafter, it entered the brain and was slowly eliminated by kidneys and liver. In addition, compounds **6b** and **6d** possess different lipophilic/hydrophilic balance and structure that may affect their pharmacokinetic properties and stability, in particular, the high stability in buffer that seems unusual for an ester linkage.

Similarly, the different distribution kinetics recorded in the brain after the administration of either the prodrugs or parent FLU deserve a detailed pharmacological study, for instance, by using radiolabeled forms of FLU−LAA conjugates.

As discussed above, the probable development of this study will be to apply the same synthetic strategy to *R*-FLU, e.g., the drug enantiomer that is currently under clinical trial as a potential agent in AD therapy. The issue of FLU−LAA prodrug stereochemistry, in fact, deserves attention, since their stability in plasma and organs can also be affected by stereochemical differences related to the enzymes involved in the metabolism and/or bioconversion to FLU.

ACKNOWLEDGMENT

Professor Istvan Toth, at the School of Pharmacy, University of Queensland, Brisbane (Australia), is gratefully acknowledged for mass analysis. We would like to thank Gerald Timbol at the David Geffen School of Medicine at UCLA, Los Angeles (USA), for performing the Aβ fibril binding assays and Professor Paolo Caliceti, at the University of Padua (Italy), for his helpful discussion in the manuscript preparation. This work was partially supported by the USA Department of Energy grant DE-FC03-02ER63420.

Selection of Reaction Additives Used in the Preparation of Monomeric Antibody−Calicheamicin Conjugates

Irwin Hollander, Arthur Kunz, and Philip R. Hamann*

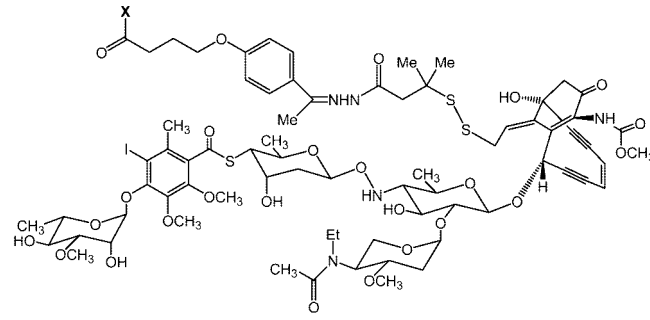
Wyeth Research, 401 N. Middletown Road, Pearl River, New York 10965. Received August 24, 2007; Revised Manuscript Received September 24, 2007

The formation of protein aggregates can be a major problem during the preparation of antibody−drug conjugates. Herein is described the methods by which reaction additives were selected, which reduce the tendency of antibodies to aggregate during the attachment of the cytotoxic agent calicheamicin to form an immunoconjugate. Reaction conditions were delineated that produced optimized yields of monomeric conjugates. These conditions were used in the preclinical preparations of gemtuzumab ozogamicin (Mylotarg), the first commercially available chemotherapeutic immunoconjugate.

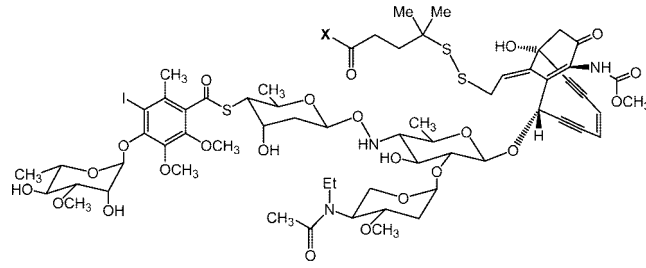
INTRODUCTION

In the more than thirty years since the development of methods for preparing monoclonal antibodies, there have been numerous attempts to use these proteins as effective vehicles for targeting cytotoxic agents to human cancers. Although there are now six antibodies and two radioimmunoconjugates approved for cancer treatment in the United States, the only conjugate of a cytotoxic agent, such as a phytotoxin, a cytotoxic oncology agent, or a natural product analogue, is gemtuzumab ozogamicin (gem-ozo[1] , Mylotarg, **2** (Figure 1), antibody = hP67.6) (*1*), in spite of numerous agents being examined in the clinic (*2*). Gem-ozo is a conjugate of the anti-CD33 antibody hP67.6 and NAc-gamma calicheamicin DMH, a derivative of the naturally occurring gamma calicheamicin. The calicheamicins are members of the enediyne family of antitumor antibiotics that, even at subpicomolar concentrations, produce double-stranded DNA cleavage (*3, 4*).

In gem-ozo, the antibody and calicheamicin derivative are covalently attached by a bifunctional linker referred to as the AcBut linker (*5*). This linker allows for attachment of the calicheamicin to the lysines on the antibody and forms an acyl hydrazone with the calicheamicin derivative that supplies a site of hydrolytic release in the lysosomes of the CD33-positive target cells. In preclinical models of acute myeloid leukemia, for which gem-ozo is approved, a hydrazone linkage was required for potent, selective cytotoxicity and gave conjugates superior to the amide conjugate (**4**), which does not contain that linkage (*6*). This is not required for all calicheamicin conjugates (*7*). Unfortunately, the introduction of the AcBut linker made conjugation to antibodies problematic, in that the maximum usable amount of the cosolvent DMF produced only modest yields of low-loaded, monomeric conjugates because of aggregation (Figure 2A). Although this material was used in the initial biological characterization of gem-ozo, scale up for development activities required a dramatic improvement in the loading and yield of monomeric conjugates. This article details how the use of various unique additives in the conjugation reaction solved this problem.



1 NAc-gamma calicheamicin DMH AcBut OSu, **X** = N-hydroxysuccinimide ("AcBut OSu")
2 NAc-gamma calicheamicin DMH AcBut conjugate, **X** = antibody ("AcBut Conjugate")



3 NAc-gamma calicheamicin DM OSu, **X** = N-hydroxysuccinimide ("DM OSu")
4 NAc-gamma calicheamicin DM conjugate, **X** = antibody ("Amide Conjugate")

Figure 1. Structures of calicheamicin derivatives and conjugates. In both conjugates, the natural product, gamma calicheamicin, is modified to contain an NAc group and a disulfide stabilized by two methyl groups (DM = dimethyl). The conjugates differ in the presence of the hydrolyzable hydrazone bond in the AcBut conjugates.

EXPERIMENTAL PROCEDURES

Reagents. Antibody hP67.6 (CDP771/2, anti-CD33 humanized IgG_4) was produced by cell culture in CHO cells and purified with affinity and ion exchange column chromatography by Lonza Biologics. The purity of the antibody was greater than 95%.

The synthesis of NAc-gamma calicheamicin DMH AcBut OSu (**1**; see Figure 1 for structures) and the original procedures for making conjugates have been published (*5*).

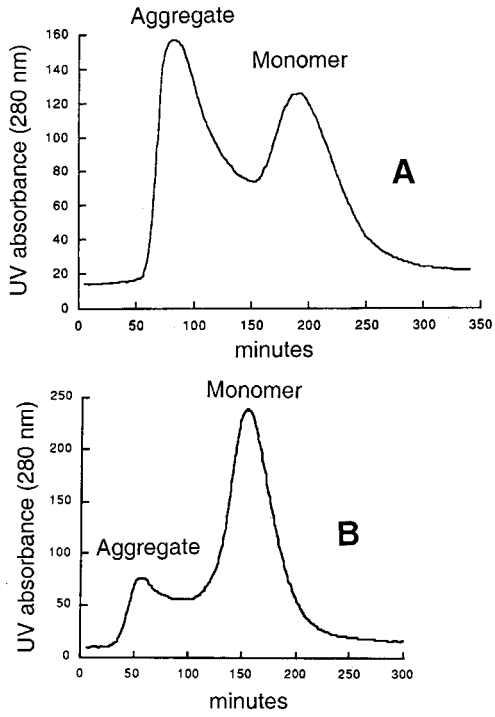

Figure 2. Size-exclusion chromatography trace of conjugation reactions. Representative profiles of conjugation reactions performed on 30 mg of antibody hP67.6 and 6 equivalents of the AcBut OSu (**1**) with 20% DMF and no additives (A) or with 5% DMF, 20% propylene glycol, and 80 mM octanoic acid (B). Pooled monomer for the conjugation shown in A was about 1 mol/mol, while in B, the loading was 2.5 mol/mol.

Tween-80, glycine, maltose, histidine, Pluronic F-68, octanoic acid, *N*-acetyl tryptophan, benzyl alcohol, propylene glycol, glycerol, benzoic acid, isopropanol, and *t*-butanol were all reagent grade (Sigma Chemical).

The PBS used is 50 mM sodium phosphate and 100 mM NaCl at pH 7.4, prepared using reagent grade mono and dibasic sodium phosphate salts and sodium chloride (Sigma Chemical).

Aggregated Conjugate. Aggregated antibody−calicheamicin conjugate with the AcBut linker (**2**) was prepared using the published procedure as follows (*5*).

To a 10 mg/mL solution of antibody hP67.6 in PBS was added additional buffer and the cosolvent DMF to give a solution of 5 mg/mL antibody and 20% DMF. To this solution was added 6 mol equiv of NAc-gamma calicheamicin DMH AcBut OSu (**1**) in DMF at 10 mg/mL. The mixture was shaken gently at room temperature for 16 h and then purified by size-exclusion chromatography on a Sephacryl S-200 (GE Healthcare) column eluted with PBS. The eluted protein was fractionated on the basis of its 280 nm absorbance. Fractions were further analyzed by high-performance liquid chromatography on a Zorbax GF-250 column (Dupont) in 0.2 M sodium phosphate and 25% propylene glycol at pH 7.0. Fractions containing aggregate (Figure 2A) were selected to give conjugate (**2**) having approximately 25% aggregated protein as measured by peak areas at 280 nm. This material was concentrated to ∼1 mg/mL using Amicon Centriprep 30 ultrafiltration devices.

Aggregate Dissociation Assay. Each additive was aliquoted as a 10X concentrate to a 50 μL aliquot of the aggregate fraction prepared as described above, to give the desired percent of additive as listed in Table 1. The mixtures were incubated overnight at room temperature and then analyzed by size-exclusion chromatography (SEC). SEC was performed both on a Zorbax (Dupont) GF-250 column eluted with 0.2 M sodium phosphate containing 25% propylene glycol and on a Superose 12 HR (Pharmacia) column eluted with PBS. Both columns were monitored by UV absorbance at 280 and 333 nm to determine protein and calicheamicin profiles.

Table 1. Additives Examined and Their Concentrations

additive	concentration
Tween-80	1%
glycine	300 mM
glycine maltose	200 mM/2%
glycine histidine	100 mM/100 mM
Pluronic F-68	1%
octanoic acid	80 mM
octanoic acid *N*-acetyl tryptophan	40 mM/6 mM
benzyl alcohol	1%
sodium benzoate	0.5%
propylene glycol	33%
glycerol	25%

Conjugation Experiments. To a 10 mg/mL solution of antibody hP67.6 in PBS was added additional buffer and one or more of the additives to give a solution of 3.25 mg/mL antibody (∼250 μL). To this solution was added 6 mol equiv of NAc-gamma calicheamicin DMH AcBut OSu (1) in DMF at 10 mg/mL (5% DMF final concentration). The mixture was shaken gently at room temperature for 16 h and then purified by size-exclusion chromatography on a Superose 200 (Pharmacia) column eluted with PBS. The eluted protein was fractionated on the basis of its 280 nm absorbance. Fractions were further analyzed by high-performance liquid chromatography on a Zorbax GF-250 column (Dupont) in 0.2 M sodium phosphate and 25% propylene glycol at pH 7.0. Fractions containing predominantly monomer were pooled to give the final conjugate (**2**).

Optimized Large-Scale Conjugation Conditions. To 30 mg of hP67.6 antibody at 6.5 mg/mL in PBS was added propylene glycol (30% final concentration) and 1 M octanoic acid (final concentration 60 mM). The pH was then adjusted to ∼7.75 with 1 M NaOH. Six molar equivalents of NAc-gamma calicheamicin DMH AcBut OSu (**1**) in propylene glycol at 6 mg/mL was then added. The mixture was shaken gently at 25 °C for 3 h before filtering through a Millex HV filter to remove particulates and purifying by SEC on a Sephacryl S-200 column eluted with PBS (Figure 2B). Monomeric fractions were then pooled to give conjugate (**2**) with <4% dimer and a loading of 2.5 mol/mol in 60% protein yield.

RESULTS

The agents chosen for this study were chosen, to a significant extent, from a list of FDA-approved excipients for protein formulation. This was done because it was not known if the additives found to be effective in preventing aggregate formation would need to be present to keep the final purified, monomeric conjugate from aggregating and because it was anticipated that some of these agents would be difficult to remove completely. The concentrations chosen for initial screening were consistent with their normal usage and are shown in Table 1.

The AcBut OSu (**1**) derivative is poorly utilized in conjugations of the hP67.6 antibody with DMF as the cosolvent, that is, much of the OSu ester is hydrolyzed instead of conjugated. Because some of the additives might, hopefully, increase the efficiency of the conjugation, it was anticipated that comparing conjugation reactions might be difficult and time-consuming. Therefore, it was decided to see initially if the selected additives would function to disassociate the aggregate that had been isolated from a previous conjugation. That this was possible was supported by the previous observation that diluting conjugate fractions containing aggregate led to a slow conversion of some of the aggregate to monomer and that reconcentration

25% *t*-butanol	10	3.6	54
25% isopropanol	17	2.6	64

increased the aggregate content again. Also, it had been shown by SDS−PAGE that the aggregates were noncovalent.

Pooled conjugate fractions containing about 25% dimer, the fraction considered to be the easiest to disassociate, and a smaller amount of higher-ordered aggregate were treated overnight as indicated in Table 2 at room temperature and assessed for the amount of remaining aggregate. The amount of aggregate seen by the two methods was relatively consistent, but with some unexplained deviations for certain additives. All the additives had either no effect or reduced the amount of aggregate except for Tween-80, which, surprisingly, caused increased aggregation. The three most successful agents were octanoic acid, glycerol, and propylene glycol, which decreased the amount of aggregate by as much as 90%.

On the basis of this experiment, it was decided to use the top three candidates in small-scale conjugation reactions to see if they would prevent aggregation during conjugation. Two alcohols, *t*-butanol and isopropanol, were added to these possibilities at this time, and the results are shown in Table 3. All the additives used alone had very significant effects on the amount of aggregate and the yield. Most of them improved the loading, except for glycerol, which led to no detectable conjugation for unknown reasons. A combination of the two best additives, propylene glycol and octanoic acid, was also used, leading to an almost 95% reduction in the amount of aggregation, more than 15% increase in the final loading, and a 3-fold increase in the protein yield. Subsequent experiments (results not included) showed that *t*-butanol was incompatible with octanoic acid at the concentrations used and that isopropanol was less effective than propylene glycol.

Although at this point in time a basic conjugation procedure using a combination of propylene glycol and octanoic acid was in hand that was suitable for initial development work, further variables were examined (detailed comparative results not included). It had been observed that the conjugation reactions with octanoic acid took much longer to go to completion than the *t*-butanol or propylene glycol reactions (16 h vs 3 h), presumably because of a shift in pH from 7.4 to ~6.9 upon adding the octanoic acid. Readjusting the pH to 7.4 before addition of the AcBut OSu ester increased the rate of these conjugation reactions, and increasing the pH to 7.9 increased it even more. At the same time, the total amount of calicheamicin attached to antibody (monomer and aggregate) increased. However, when the amount of AcBut OSu ester was adjusted to give comparable loading to that seen at the lower reaction pH, there was little difference in the amount of aggregate formed or the ultimate yield of conjugate.

DMF had been used for the stock of the AcBut OSu ester and hence as a reaction cosolvent because of its successful use in conjugation procedures prior to the development of the AcBut linker (*6*). However, when the use of DMF was examined with the new additives, reducing or eliminating DMF was found to give somewhat higher conjugation efficiency. The AcBut OSu stocks were thereafter made in either propylene glycol or ethanol, either one performing equally well. Finally, only minor differences in the conjugation results were seen when the concentration of propylene glycol was varied from 20 to 30% or when the octanoic acid concentration was varied from 50 to 80 mM. Below these concentrations, the beneficial effects were slowly lost, and incompatibilities were seen in some cases at higher concentrations. The final optimized procedure for this antibody as detailed in the Experimental Procedures section is 30% propylene glycol at pH 7.75, 60 mM octanoic acid, and 6 equiv of NAc-gamma calicheamicin DMH AcBut OSu, which gives a 60% yield (protein) of monomeric antibody conjugate containing 2.5 mol/mol of calicheamicin (Figure 2B).

DISCUSSION

The conjugation of low molecular weight, hydrophobic, cytotoxic agents (such as the calicheamicins) to large hydrophilic antibodies is complicated by their dramatically different physical properties. While antibodies prefer their natural, buffered, aqueous environment and only tolerate limited amounts of certain organic cosolvents, agents such as the calicheamicins have severely limited or no aqueous solubility and prefer polar organic solvents (*8*). Even after conjugation has been accomplished, the same solubility issues still present themselves in the tendency of the conjugates to form aggregates by the lipophilic association of the calicheamicins conjugated to the surface of the antibody. Although sometimes low-order aggregates such as a dimerized conjugate retain antibody binding activity, they have unacceptable pharmacokinetic properties in vivo and must be minimized or removed because of the possible increase in toxicity they may cause if present in larger amounts.

The formation of these aggregates during the conjugation reaction also leads to a reduction in yield of both protein and calicheamicin due to the consumption of materials in nonuseful forms and by the loss of monomers during the necessary process of aggregate removal. Unfortunately, it is the more highly loaded species that have the greatest tendency to aggregate, which leads to lower loading on the monomeric conjugate. This aggregation tendency for calicheamicin conjugates was greatly exacerbated when using the AcBut linker, and therefore, an improved procedure was needed that would minimize these aggregates during conjugation.

Our starting point for the hybrid linker reaction was taken from the successful conditions established for the conjugation for the previous NAc-gamma calicheamicin DM OSu (**3**) derivative (*6*). This derivative readily reacted with antibodies in the presence of 25% of an organic cosolvent such as DMF to give over 80% yield of both protein and calicheamicin and with a loading on monomeric conjugate (**4**) of 2 to 3 mole of drug/mol antibody with low aggregate. When these conditions were used with the AcBut linker, unacceptable levels of aggregate were formed, and, subsequently, poor loadings and yields of monomeric conjugate (**2**) were obtained. Variations in the reaction conditions in terms of the concentration of antibody, temperature, equivalents of calicheamicin, and the

concentration of DMF were of little help. Attempts to make the calicheamicin derivative more soluble, such as by using HEPES instead of phosphate buffer or adding the salting-in salt perchlorate also did not improve conjugation. It was therefore decided to investigate the use of different reaction additives that might help dissolve or disassociate calicheamicin so that it could react more efficiently with the antibody while at the same time preventing the aggregation of the product.

Since aggregate formation was one obvious problem in the conjugation reaction, it was decided to use as the first screening method an analysis wherein preformed aggregate was tested for dissociation by a variety of additives. The additives were selected on the basis of their potential for solublizing hydrophobic moieties, compatibility with proteins, and their status as FDA-approved parenteral additives since there was the possibility that an effective excipient would need to be present in the conjugates to prevent reaggregation. It was noted that the deaggregation process was relative slow, requiring hours to see any effects and overnight treatment to reach apparent completion. It was also noted that the untreated control conjugate responded less to the additives as it was aged, that is, that aggregation appears to become stronger with time. The lower amount of aggregate indicated in Table 2 may, therefore, represent the minimum deaggregation possible.

On the basis of these results, octanoic acid, propylene glycol, and glycerol were used during trial conjugations in place of most of the DMF. In addition, isopropanol and *t*-butanol were also tested because of their similarity to propylene glycol and glycerol in chemical properties and previous use as cosolvents for proteins. A combination of propylene glycol and octanoic acid was tested, combining what seemed to be the best two deaggregators. Interestingly, the ability of these additives to give a clear conjugation reaction did not seem to correlate with the outcome, as *t*-butanol gave the clearest reaction but not the best conjugation results. The final results indicate that the combination of propylene glycol and octanoic acid produced the least aggregate and highest protein recovery with excellent drug loading. Conditions for conjugating an AcBut-linked calicheamicin derivative to antibodies were determined, which gave a yield of monomeric conjugate of up to 90% and with drug loadings of around 3 mol/mol. (See the Experimental Procedures section for details.)

When these specific conditions were varied within a reasonably narrow range, minor variations in the amount of aggregate, the loading, and the efficiency of conjugation occurred with respect to the crude product. However, the amount of calicheamicin isolated on monomer remained relatively constant. Experience has shown that higher calicheamicin loading is offset by a somewhat higher aggregate and lower monomer yield. Further testing indicated that these conditions did not affect immunoreactivity or specific cytotoxicity (data not included) and were used in preclinical preparations of Mylotarg. These conditions were applicable to larger scale conjugation reactions (30 mg) with only slight increases in the amount of aggregate seen, and the results were dramatically improved compared with that obtained with DMF alone (Figure 2).

The ultimate question is why these additives greatly improve the conjugation reaction to make the AcBut conjugates. The AcBut OSu derivative (**1**) is less soluble in buffer containing 25% DMF than the DM OSu derivative (**3**), but the difference is not dramatic enough to offer a satisfying explanation. However, it is very possible that these calicheamicin derivatives do not exist as a true solution during the conjugation but as some sort of aggregated state (*8*). Perhaps one effect of the additives is to alter any aggregated state of the calicheamicins in solution to make the OSu ester more accessible for conjugation.

The final conjugates remain as monomer constructs even after purification and concentration, even though the additives have been removed to the limit of detection. In the conjugate, the AcBut linker itself, which is the new part of the conjugate, is closest to the antibody and, therefore, may not be as solvent exposed as the calicheamicin portion of the conjugates, which is the portion that the amide and AcBut conjugates have in common. Perhaps the AcBut linker forces this calicheamicin portion to be a little farther away from the protein surface and to be more solvent exposed. It would, therefore, be more likely to interact with any unconjugated calicheamicin that exists in an associated state, and multiple conjugate molecules could interact with the same cluster of unconjugated calicheamicin, leading to aggregation. The aggregate would, therefore, have unusually high, partially noncovalent loading, and that has indeed been observed.

Whatever the reasons for the benefit of these additives, these conjugation conditions have proven applicable to the AcBut-linked conjugates of other antibodies, even though some adjustment of conditions is necessary for each new antibody. Those further adjustments and additional optimizations will be reported in due course. It is hoped that the process used in this study to find acceptable additives may prove useful in the development of other protein−drug conjugates, for which significant problems have been reported (*9*).

ACKNOWLEDGMENT

We are grateful to Marty Kunstmann for useful discussions and suggestions.

Novel Single-Chain Fv′ Formats for the Generation of Immunoliposomes by Site-Directed Coupling

Sylvia K. E. Messerschmidt,[†] Anke Kolbe,[†] Dafne Müller,[†] Michael Knoll,[‡] Jürgen Pleiss,[‡] and Roland E. Kontermann*,[†]

Institut für Zellbiologie und Immunologie, Universität Stuttgart, Allmandring 31, 70569 Stuttgart, Germany, and Institut für Technische Biochemie, Universität Stuttgart, Allmandring 31, 70569 Stuttgart, Germany. Received September 10, 2007; Revised Manuscript Received October 2, 2007

Immunoliposomes generated by coupling of antibodies to the liposomal surface allow for an active targeting of entrapped compounds to diseased areas. Single-chain Fv fragments (scFv) represent the smallest part of an antibody containing the entire antigen-binding site. They can be coupled in a defined and site-directed manner through genetically engineered cysteine residues, for example, those added at the C-terminus. Here, we have performed a comparative analysis of various scFv′ variants with cysteine residues present at the end of a C-terminal extension of varying length and composition (HC variants) or introduced in the linker sequence connecting the variable heavy and light chain domain (LC variants). Using a scFv fragment directed against fibroblast activation protein (FAP) as a model antibody, we could show that all variants can be employed for the generation of active immunoliposomes, although the presence of three additional cysteine residues in one scFv′ molecule resulted in decreased binding of immunoliposomes compared to that of immunoliposomes generated with scFv′ molecules containing only one additional cysteine residue. In order to further improve the scFv′ format by reducing the number of additional amino acid residues, we also generated molecules with the hexahistidyl-tag incorporated into the linker sequence together with a cysteine residue either at position 1 or 3 of the linker sequence (LCH variants). These newly designed scFv′ molecules may be particularly suitable for the generation of immunoliposomes and other antibody conjugates, limiting the number of additional residues in these antibody molecules to a minimum.

INTRODUCTION

Immunoliposomes have been developed for targeted drug delivery, for example, the delivery of chemotherapeutic drugs to tumor tissues (*1*). These immunoliposomes are generated by coupling antibodies or antibody fragments to the surface of liposomal drugs (*2*). Initially, whole antibodies were used for this purpose. However, several studies have shown that whole antibodies, for example, monoclonal antibodies of murine origin, induce immune responses, which can lead to neutralization (*3, 4*). Furthermore, immunoliposomes composed of whole antibodies are rapidly cleared from circulation because of Fc-receptor mediated uptake by cells of the reticulo-endothelial system (*5*). Hence, new approaches have emerged that employ antibody fragments, such as Fab′ fragments, which can be obtained from whole antibodies by proteolytic cleavage and subsequent reduction or by production in recombinant form, for example, in bacteria (*6*). Immunoliposomes composed of Fab′ fragments have shown reduced immunogenicity and improved therapeutic effects compared to IgG immunoliposomes (*7*).

Progress in antibody engineering technologies has led to the establishment of various methods to obtain antibodies with desired binding properties from combinatorial antibody libraries, for example, using phage display technology (*8*). These approaches also allow for the isolation of human antibody molecules, which further reduce or even avoid immunogenicity in humans. Thus, a large variety of such antibodies has been already isolated and is available for the generation of targeted therapeutics. Routinely, these antibodies are present as single-chain Fv (scFv) fragments. This format represents the smallest part of an antibody with full antigen-binding activity and is therefore sufficient for the generation of targeted therapeutics. Hence, scFv molecules are ideally suited for the generation of immunoliposomes, and various studies have already demonstrated their feasibility (*6*).

To achieve site-directed and defined coupling, one or more additional cysteine residues have been introduced into the scFv molecule, mainly at the C-terminus, which allow conjugation to sulfhydryl-reactive reagents (*9, 10*). Such scFv′ molecules, that is, scFv possessing free sulfhydryl groups, have been successfully employed for the generation of immunoliposomes (*9–11*) but also for other applications, for example, site-directed PEGylation to improve pharmacokinetic properties and the generation of immunosensors and targeted gold nanoparticles (*12–16*).

Different scFv′ formats have been described in the literature, differing in the position and number of additional cysteine residues. Thus, up to three cysteine residues have been added to the C-terminus of a scFv molecule (*9, 10, 16–20*). These scFv′ molecules also varied in the length and composition of the C-terminal extension. In addition, a few studies have described monovalent or bivalent scFv molecules with an additional cysteine residue introduced in the linker sequence connecting the variable domains (*14, 21*).

Recent studies have shown that the position and number of the cysteine residues incorporated can influence the coupling efficiency and functionality of the generated immunoliposomes (ref *10*; unpublished observations). Here, we performed a comparative analysis of scFv′ variants with one or three additional cysteine residues introduced either at a C-terminal extension of varying length or at different positions in the linker peptide using a scFv fragment directed against fibroblast activation protein (FAP) as model antibody (*22*). The novel

finding that scFv′ molecules with a linker cysteine can be used for the generation of immunoliposomes prompted us to generate optimized scFv′ molecules with a hexahistidyl-tag sequence as well as the additional cysteine located in the linker sequence, thus reducing the number of additional residues in a scFv′ molecule to a minimum.

MATERIALS AND METHODS

Materials. All lipids were purchased from Avanti Polar Lipids (Alabaster, USA). DiI was purchased from Sigma (Taufkirchen, Germany). HRP-conjugated anti-His-tag antibody was purchased from Santa Cruz Biotechnology (USA) and FITC-conjugated anti-His antibody from Dianova (Hamburg, Germany). Human plasma (stabilized with citrate/phosphate/dextrose solution (CPD)) was kindly provided by the blood center of Katharinenhospital (Stuttgart, Germany). The stably transfected human FAP-expressing fibrosarcoma cell line HT1080-13.8 (HT1080-FAP_{mo}) expressing mouse FAP as well as HT1080 wild-type cells was grown in RPMI, 5% FCS, and 2 mM glutamine.

Cloning and Expression of scFv′ Variants. The scFv′ 36 HC constructs (HC2–4) were generated by PCR amplification of scFv′ 36-encoding DNA present in bacterial expression vector pABC4 (*22*) using primers LMB3 (5′-CAG GAA ACA GCT ATG ACC-3′) and HC2-Eco-For (5′-GCG CAT CAT CAC CAT CAC CAT GGC GGA TCG AGT GGC TCA GGA TGC TAA GAA TTC CAC TGG-3′), HC3-Eco-For (5′-GCG CAT CAT CAC CAT CAC CAT GGC GGA TCG AGT GGC TCA TGC GGA TGT AGT TGC TAA GAA TTC CAC TGG-3′), or HC4-Eco-For (5′-CAT CAT CAC CAT CAC CAC GGC GGA TCC AGC GGC GGA TCC AGC GGC TCC GGA TGC TAA GAA TTC CGG-3′), respectively. The resulting PCR products were digested with SfiI and *Eco*RI and cloned into vector pAB1 digested with the same enzymes. For generating the LC variants (LC1–3), scFv′ molecules were amplified from pAB1-scFv36 with primer LMB2 (5′-GTA AAA CGA CGG CCA GT-3′) and LC1-Xho-Back (5′-ACC GTC TCG AGT TGC GGA GGC GGT TCA GGC GGA GGT GGC TCT-3′), LC2-Xho-Back (5′-ACC GTC TCG AGT GGT TGC GGC GGT TCA GGC GGA GGT GGC TCT-3), and LC3-Xho-Back (5′-ACC GTC TCG AGT GGT GGA TGC GGT TCA GGC GGA GGT GGC TCT-3′), respectively. PCR products were digested with XhoI and NotI and cloned into pAB1-scFv36 digested with the same enzymes. LCH variants were generated in the same manner using primers LCH1-Xho-Back (5′-ACC GTC TCG AGT TGC GGA GGC GGT CAT CAT CAC CAT CAC CAT GGA GGC GGT AGT GCA CAA ATT CTG ATG-3′) and LCH3-Xho-Back (5′-ACC GTC TCG AGT GGT GGA TGC GGT CAT CAT CAC CAT CAC CAT GGA GGC GGT AGT GCA CAA ATT CTG ATG-3′) as back primers. Antibody fragments were purified by immobilized metal ion affinity chromatography (IMAC) as described elsewhere (*23*). Protein concentration was determined by measuring the absorbance at 280 nm. scFv′ were analyzed by SDS−PAGE under reducing and nonreducing conditions and stained with Coomassie brilliant blue R250 or immunoblotted with a HRP-conjugated anti-His-tag antibody.

Generation of scFv Immunoliposomes by the Postinsertion Method. Immunoliposomes were generated by postinsertion of scFv′-conjugated micelles into preformed PEG-liposomes. All liposomes were prepared by the film hydration−extrusion method and were composed of EPC/Chol/mPEG-DSPE at a molar ratio of 6.5:3:0.5. In addition, all liposomes contained 0.3 mol % DiI as fluorescent dye. Lipids and DiI were dissolved in chloroform, and a thin lipid film was formed by removing the chloroform in a rotary evaporator at 42 °C and drying under vacuum for at least 1 h. The lipid film was hydrated with 1 mL of 10 mM Hepes buffer at pH 6.7. The final lipid concentration was 10 μmol lipid per mL of buffer. The resulting multilamellar vesicle dispersion was extruded 21 times through 50 nm polycarbonate membranes using a LiposoFast extruder (Avestin, Ottawa, Canada). For the preparation of Mal-PEG-DSPE micelles, chloroform was removed by incubation at RT and lipid dissolved in ddH_2O to a final concentration of 10 mg/mL. For the coupling of scFv′ to Mal-PEG-DSPE micelles, purified scFv were reduced in 2 mM tris(2-carboxyethyl)phosphine (TCEP) for 2 h at room temperature followed by the removal of TCEP by dialysis against O_2 free 10 mM Na_2HPO_4/NaH_2PO_4 buffer, 0.2 mM EDTA, and 30 mM NaCl (pH 6.7) overnight at 4 °C. Micellar lipid and reduced scFv′ were mixed at a molar ratio of 4.67:1 (*24*). The coupling reaction was performed at room temperature for 30 min The reaction was quenched with 1 mM L-cysteine and 0.02 mM EDTA at pH 5.5. The scFv′-coupled micelles were inserted into preformed PEGylated liposomes by incubation at 55 °C for 30 min (0.6 mol % and 2 mol % micellar lipid with respect to liposomal lipid). Unbound scFv molecules were removed by gel filtration using a Sepharose CL4B column (Amersham, Braunschweig, Germany). Liposome size and ζ-potenial were measured using a ZetaSizer Nano ZS (Malvern, Herrenberg, Germany).

Analysis of Coupling Efficiency. The scFv′-coupled micelles were analyzed by SDS−PAGE under reducing conditions and stained with Coomassie Brilliant Blue R250. The coupling efficiency was determined by quantifying the intensity of the protein bands before and after coupling to micelles using the software ImageQuant (GE Healthcare, Germany).

Determination of Protein Melting Points. The melting point of the scFv′ 36 variants was determined with ZetaSizer Nano ZS (Malvern, Herrenberg, Germany). Approximately 150 μg of purified scFv′ protein was diluted in PBS to a total volume of 1 mL and sterile filtered into a quartz cuvette. Dynamic laser light scattering intensity was measured while the temperature was increased in 1 °C intervals from 30 to 70 °C with 2 min equilibration for each temperature step. The melting point was defined as the temperature at which the light scattering intensity dramatically increased.

Flow Cytometry. Cells were detached from cell culture dishes using 0.05% trypsin and 0.02% EDTA (GIBCO). Approximately 250,000 cells were incubated with DiI-labeled immunoliposomes (10 nmol lipid) in PBS containing 2% FCS and 0.02% sodium azide (PBA) for 1 h at room temperature. After washing cells three times with PBA buffer (4 °C), cells were resuspended in 500 μL of PBA buffer and analyzed by flow cytometry (Epics XL-MCL, Beckmann). The binding of purified scFv′ molecules was determined by incubating detached cells with antibody molecules (10 μg/mL) in PBA buffer for 1 h at room temperature. Cells were then washed three times as described and incubated with FITC-conjugated anti-His-tag antibody diluted 1/200. Data were evaluated with WinMDI, version 2.8.

In Vitro Plasma Stability. To analyze plasma stability, immunoliposomes (10 nmol lipid) were preincubated in the presence of 50% human plasma for 4 days at 37 °C in a total volume of 50 μL. Subsequently, the binding of immunoliposomes to cells was analyzed by flow cytometry as described above.

Modeling of scFv 36 Variants. A model of scFv 36 without the linker was generated using the Web Antibody Modeling (WAM) server (*25*). A linker of 14 amino acids connecting the V_H and V_L subunits was modeled using MODELER 6v2 (*26*). The linker region did not contain secondary structure as expected from the distance between the C-terminus of V_H and the N-terminus of V_L along the surface of the protein. The quality of the scFv 36 model was checked by PROSA2003's knowledge-

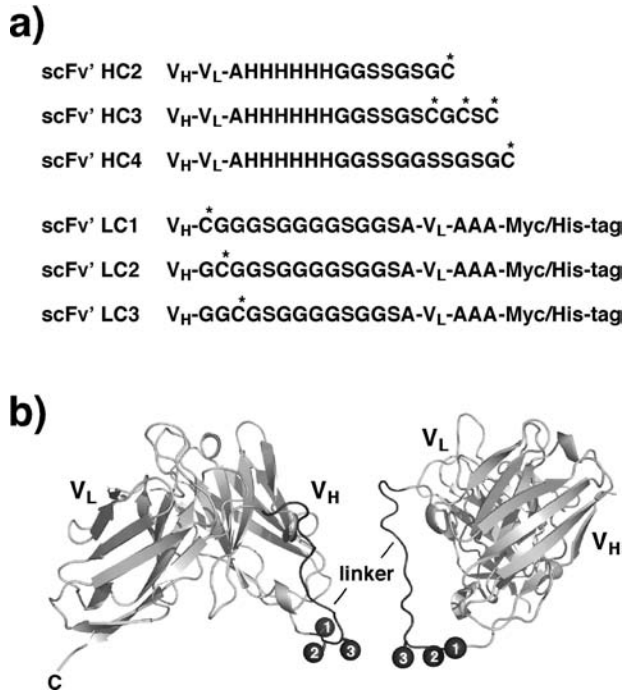

Figure 1. Composition of scFv′ variants. (a) C-terminal sequences of constructs HC2, HC3, and HC4 as well as the linker sequences of constructs LC1, LC2, and LC3. Cysteine residues are marked with an asterisk. The Myc/His-tag has the sequence -EQKLISEEDLNGAAH-HHHHH-. (b) Model structure of anti-FAP scFv′ 36 with the positions of the three linker modifications LC1–3 shown from two sides. Sulfur atoms of the three cysteine residues incorporated into the linker peptide are shown as spheres (*1–3*).

based potentials (*27*), and stereochemical checks were carried out with the PROCHECK package (*28, 29*).

RESULTS

Generation and Characterization of scFv′ Variants. Six different scFv′ variants of anti-FAP scFv 36 were designed (Figure 1a). The variants HC2 and HC4 contain one additional cysteine residue at the C-terminus and vary in the length of the C-terminal extension, which also contains a hexahistidyl-tag for purification. Variant HC3 contains three additional cysteine residues at the C-terminal extension. In addition, we designed three scFv′ variants (LC1–3) containing an additional cysteine residue in the peptide linker (position 1, 2, or 3, respectively). These variants are also provided with a vector-encoded Myc-tag and hexahistidy-tag at the C-terminus. In order to show that the cysteine side chains are accessible for coupling reactions, a model of scFv′ 36 including the linker connecting the variable domains was generated. This model structure of scFv′ 36 indicated that the linker modifications are located at the bottom of the scFv′ molecule opposite the antigen-binding site and that the side-chain sulfhydryl groups are accessible for coupling (Figure 1b).

All six scFv′ variants could be expressed in bacteria and purified from periplasmic preparations by IMAC. Yields of 0.2–0.8 mg of purified protein per liter culture were obtained. These yields are similar to yields typically obtained for unmodified scFv 36 (0.3–0.7 mg/L culture). A single band with an apparent molecular weight of 32 kDa was detected in SDS−PAGE under reducing conditions (Figure 2a). Two bands of 30 and 60 kDa were seen under nonreducing conditions for the HC constructs, while the LC constructs showed only one prominent band of 30 kDa (Figure 2c). The identity of these protein bands was further confirmed by immunoblotting with an anti-His-tag antibody (Figure 2b and d). This experiment

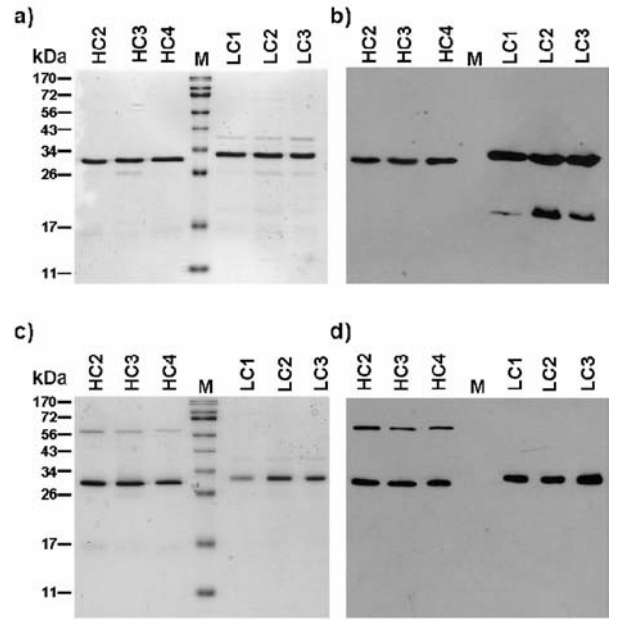

Figure 2. SDS−PAGE and immunoblot analysis of purified scFv′ variants. Purified scFv′ variants HC2–4 and LC1–3 were analyzed by 15% SDS−PAGE under nonreducing (c and d) or reducing (a and b) conditions and either stained with Coomassie or immunoblotted with an anti-His-tag antibody (2 μg/lane were used for Coomassie staining and 1 μg/lane for immunoblotting).

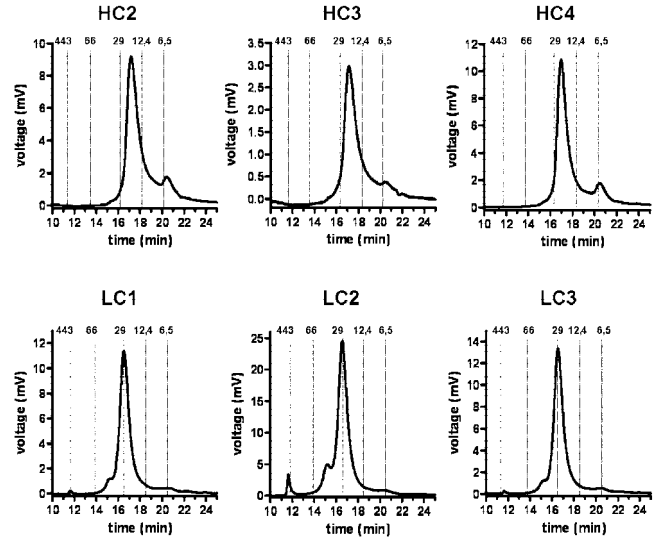

Figure 3. Size exclusion chromatography. scFv′ molecules were analyzed by HPLC size exclusion chromatography using a BioSep-Sec-2000 column. Peak positions of standard proteins are indicated.

also revealed for the LC1–3 preparations a second protein band of approximately 20 kDa, probably due to proteolytic cleavage. Therefore, LC variants appeared to be more susceptible to proteolytic cleavage than the HC variants. The cleavage band was strongest for the LC2 variant.

All scFv′ variants showed a single major peak in size exclusion chromatography (Figure 3). The three HC variants eluted with an apparent molecular mass of 22.5 kDa (calculated molecular mass, 28 kDa), while all LC variants eluted with an apparent molecular mass of 29 kDa (calculated molecular mass, 28 kDa).

The thermal stability of the scFv′ variants was deduced from their melting points as measured by dynamic light scattering (Figure 4). For all HC constructs, the melting point was

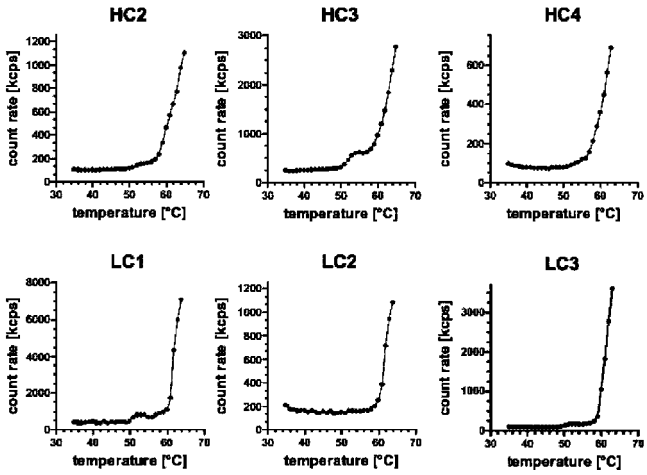

Figure 4. Thermal stability. Protein melting curves of the scFv′ variants were determined by dynamic light scattering using 1 °C intervals.

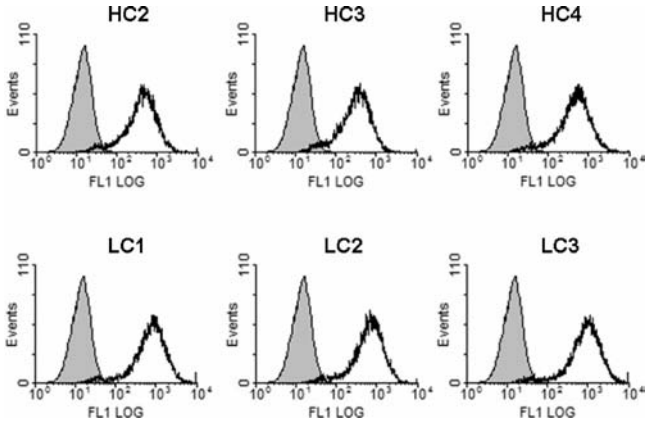

Figure 5. Binding of scFv′ variants to FAP-expressing cells. scFv′ molecules were analyzed by flow cytometry for binding to HT1080-FAP_{mo} cells. Gray areas, cells incubated without scFv′; solid line, cells incubated with scFv′ molecules.

determined to be around 56–57 °C. The LC constructs showed a slightly higher melting point with 58–59 °C.

All scFv′ variants specifically recognized FAP-expressing cells (HT1080-FAP_{mo}) in flow cytometry experiments, indicating that the incorporation of additional cysteine residues at the C-terminus or linker region does not interfere with antigen binding activity (Figure 5).

Coupling of scFv′ Fragments to Mal-PEG-DSPE Micelles. Next, we analyzed the coupling of the scFv′ fragments to Mal-PEG-DSPE micelles using a molar scFv′ to lipid ratio of 1:4.67. The coupling reaction was performed at room temperature for 30 min. SDS−PAGE analysis demonstrated efficient coupling of all constructs (Figure 6). Coupling efficiency was in the range of 80–98% as determined by densitometric quantification (Table 1). Highest coupling efficiency was achieved with construct HC3. All constructs possessing one additional cysteine showed after coupling an increase in apparent molecular mass of approximately 3 kDa, while the mass of HC3 was increased by approximately 10 kDa. This finding indicates that one Mal-PEG-DSPE chain is conjugated to HC2, HC4, and LC1–3, while three chains are conjugated to HC3.

Generation of scFv Immunoliposomes by the Post-insertion Method. scFv′-coupled micelles were used to generate scFv immunoliposomes, applying the postinsertion method. In this method, scFv′-coupled micelles are inserted into preformed PEGylated liposomes by incubation at 55 °C for 30 min (*30, 31*). Two different micelle to liposome ratios (0.6 mol % and 2 mol % micellar lipid with respect to liposomal lipid) were used for the preparation of immunoliposomes. In both cases, the generated immunoliposomes had a size of 90–106 nm, similar to the size of the acceptor liposomes used for the postinsertion of micelles (108 nm) (Table 2). All immunoliposomes had a slightly negative ζ-potential, while the ζ-potential of plain liposomes was slightly positive (Table 2). ScFv density was calculated to be in the range of 1.1–1.2 nmol scFv/μmol lipid at 0.6 mol % micellar lipid and 3.7–3.9 nmol scFv/μmol lipid at 2 mol % micellar lipid.

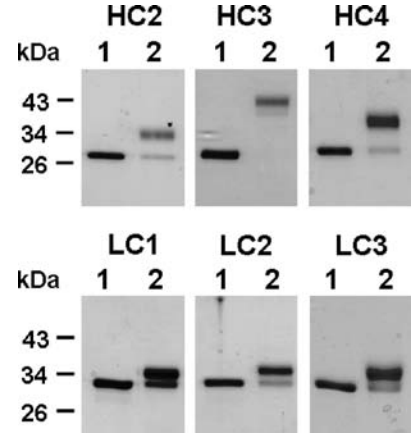

Figure 6. Coupling of scFv′ variants to Mal-PEG-DSPE micelles. SDS−PAGE analysis of scFv′ fragments before (1) and after (2) coupling to Mal-PEG_{2000}-DSPE micelles at a molar ratio of antibody to lipid of 1:4.67. Gels were stained with Coomassie. Coupling of the antibody molecules to the lipid is indicated by reduced mobility.

Table 1. Coupling Efficiencies of scFv′ Variants[a]

construct	coupling efficiency (%)
scFv′ 36-HC2	86.7 ± 4.5
scFv′ 36-HC3	97.8 ± 0.2
scFv′ 36-HC4	82.0 ± 7.5
scFv′ 36-LC1	79.7 ± 4.7
scFv′ 36-LC2	81.8 ± 3.9
scFv′ 36-LC3	90.2 ± 2.4

[a] Coupling efficiencies were determined by quantitative analysis of scFv′ fragments before and after coupling to micelles (see Figure 6).

Table 2. Size, Polydispersity Index (PDI) and ζ-Potential of scFv Immunoliposomes[a]

construct	size (nm)	PDI	ζ-potential (mV)
	108 ± 2.3	0.123 ± 0.038	5.2 ± 3.5
scFv′ 36-HC2	90 ± 1.5	0.159 ± 0.058	−12.6 ± 5.4
scFv′ 36-HC3	96 ± 1.2	0.134 ± 0.032	−12.5 ± 2.8
scFv′ 36-HC4	102 ± 2.8	0.156 ± 0.034	−15.0 ± 0.5
scFv′ 36-LC1	106 ± 3.7	0.178 ± 0.021	−8.8 ± 1.5
scFv′ 36-LC2	105 ± 7.6	0.149 ± 0.004	−11.2 ± 7.9
scFv′ 36-LC3	105 ± 7.7	0.112 ± 0.054	−2.8 ± 2.3

[a] Immunoliposomes were generated by postinsertion of scFv-conjugated micelles (2 mol % lipid) into preformed PEG-liposomes.

All immunoliposomes specifically bound FAP-expressing HT1080-FAP_{mo} cells (Figure 7). No binding to these cells was observed for plain (untargeted) liposomes. None of the liposomes showed binding to FAP-negative HT1080 cells. Binding was stronger when higher micellar concentrations were used for postinsertion. Binding intensity was similar for all immunoliposomes, except for scFv HC3-derived immunoliposomes, which showed a reduced binding activity (approximately 50% of the other immunoliposomes based on the mean fluorescence intensity) (Table 3). Furthermore, the binding of all immunoliposomes to HT1080-FAP_{mo} cells could be completely blocked by soluble scFv36 (10 μg/mL), while no blocking was seen with an irrelevant scFv molecule directed against another antigen

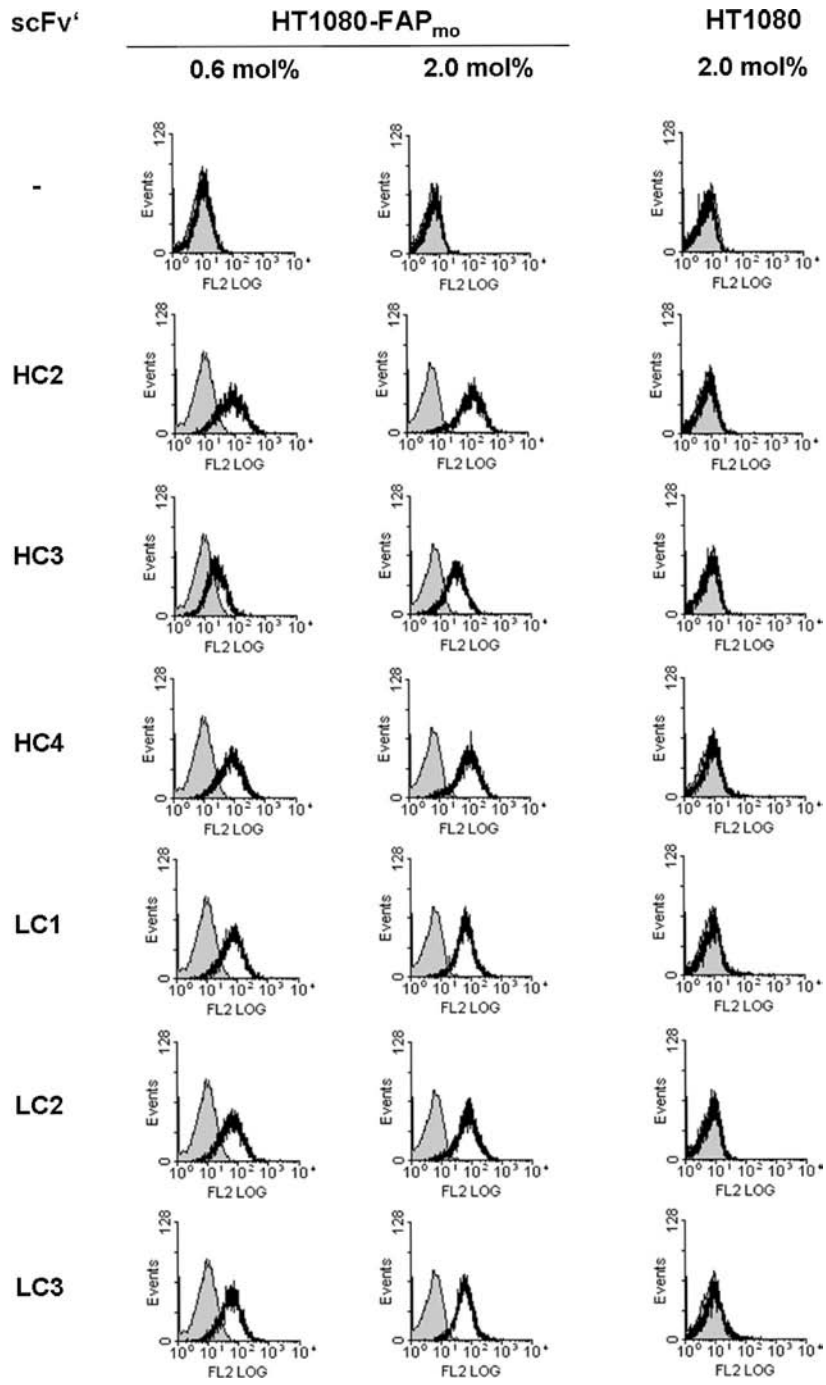

Figure 7. Binding of scFv-immunoliposomes to FAP-expressing cells. Micelle-coupled scFv′s were inserted at two concentrations (0.6 mol % and 2 mol % micellar lipids) into preformed PEGylated liposomes and analyzed for binding to FAP-expressing HT1080 cells (HT1080-FAP$_{mo}$) or to wild-type HT1080 cells. Plain liposomes (-), i.e., untargeted liposomes, were included as the negative control. Gray areas, cells alone; thick line, cells incubated with liposomes at 10 nmol lipid per 250.000 cells.

expressed by these cells (not shown). All immunoliposomes were highly stable in human plasma, showing no or only marginal reduction in binding after incubation in human plasma at 37 °C for 4 days (not shown).

scFv′ Formats Combining a Cysteine Residue and Hexahistidyl-Tag in the Linker. In order to reduce the number of additional amino acids in the scFv′ molecule, we generated new scFv′ variants with the hexahistidyl-tag incorporated into the linker sequence together with an additional cysteine residue either at position 1 or 3 of the linker sequence (Figure 8a). These LCH variants (LCH1 and LCH3) terminate at the C-terminus with residue Arg107 of the V_L domain, thus containing only 14 amino acid residues of the linker sequence as additional residues. Both variants could be expressed in bacteria and purified by IMAC with yields of 0.3 mg/L culture, similar to the HC and LC variants (Figure 8b and c). For both variants, SDS−PAGE analysis showed a predominant band of 26 kDa under reducing and nonreducing conditions. Both variants also formed dimers. In addition, some proteolytic cleavage products were observed (corresponding to 15–25% of the intact molecules). Although detection with anti-His-tag antibodies of cell-bound scFv′ LCH variants was strongly reduced (not shown), immunoliposomes generated with both LCH variants (size, 103.0 ± 2.1 nm for LCH1 and 105.6 ± 1.7 nm for LCH3) showed strong and specific binding to FAP-expressing cells (Figure

Table 3. Binding of scFv Immunoliposomes to FAP-Expressing Cells[a]

construct	MFI
	9.0 ± 3.1
scFv′ 36-HC2	104.8 ± 20.5
scFv′ 36-HC3	48.5 ± 10.4
scFv′ 36-HC4	108.2 ± 35.4
scFv′ 36-LC1	97.7 ± 35.5
scFv′ 36-LC2	109.8 ± 52.2
scFv′ 36-LC3	96.8 ± 41.8

[a] Binding is shown as mean fluorescence intensity (MFI) derived from four preparations of each immunoliposome.

8d). Binding was similar to that observed for LC variants (Figure 8d) and could be blocked with soluble anti-FAP scFv (not shown).

DISCUSSION

Here, we investigated two strategies for the generation of scFv′ molecules suitable for site-directed coupling via reactive sulfhydryl groups. Strategy 1 is based on scFv′ molecules having one or more additional cysteine residues at the end of a C-terminal extension of varying length. These C-terminal extensions introduce some additional spacing as well as flexibility between the antibody molecule and the reactive partner. Strategy 2 is based on molecules having one additional cysteine residue incorporated into the peptide linker connecting the V_H and V_L domains, thus not requiring any additional C-terminal extension.

Using an anti-FAP scFv as the model antibody, we could show that all these scFv′ derivatives could be expressed in *E. coli* and purified in soluble form with the majority of the molecules present in monomeric form. Yields of the scFv′ molecules were similar to those obtained for the unmodified scFv 36. Thus, the addition of one or three cysteine residues either to the C-terminus or to the linker sequences does not lead to reduced expression levels of this scFv molecule, as described for other scFv′ molecules that showed markedly reduced expression levels (*32*). Some scFv′ dimers could be observed in SDS−PAGE and immunoblotting analysis, especially for the three HC constructs but also for the LCH constructs, indicating that the cysteine residues are accessible for the formation of disulfide-linked homodimers. Furthermore, all molecules were functional, active, and possessed similar melting points. These findings demonstrate that the addition of one or three cysteine residues as well as C-terminal extensions does not influence expression, conformation, stability, and binding activity.

All scFv′ constructs could be coupled to maleimide-containing lipids. Coupling efficiencies and binding activity of the resulting immunoliposomes were similar for all constructs containing one additional cysteine residue, irrespective of whether it is present at the C-terminus or in the linker sequence. In contrast, the presence of three cysteine residues at the C-terminus resulted in immunoliposomes with reduced binding activity. SDS−PAGE analysis indicated that this variant (HC3) reacts with three Mal-PEG-DSPE molecules. After insertion into liposomes, this might lead to unfavorable orientation on the lipid bilayer, resulting in reduced accessibility and cell binding.

All scFv immunoliposomes described in the literature so far have been prepared from scFv′ molecules with the additional cysteine(s) located at the C-terminus (*9, 10, 18, 20, 22, 33, 34*) or have been conjugated through amino-reactive coupling reagents (*35, 36*). The use of cysteine residues engineered into the recombinant antibody molecule allows for a site-directed and oriented coupling compared to coupling to amino groups, which is undirected and might thus influence antigen-binding activity. Because the C-terminus of a scFv molecule is located

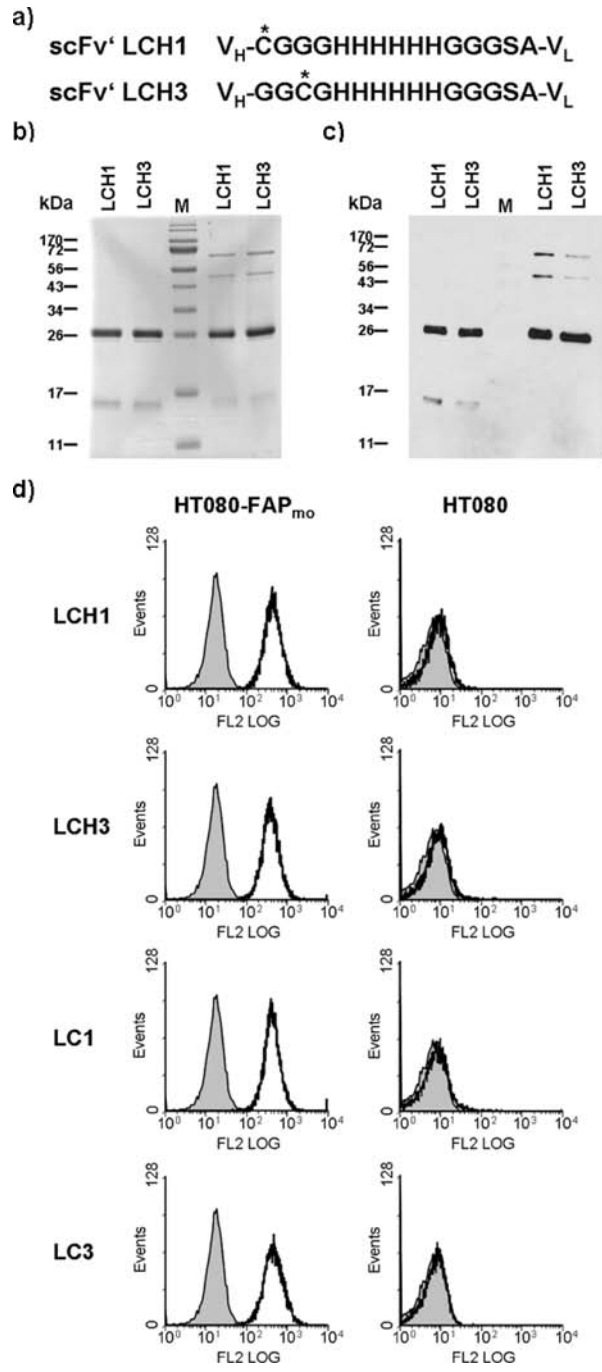

Figure 8. LCH variants. (a) Sequence of the linker of constructs LCH1 and LCH3 with the additional cysteine and the hexahistidyl-tag present in the linker peptide. (b) Coomassie-stained SDS−PAGE (2 μg/lane) and (c) immunoblot experiments (1 μg/lane) with the anti-His-tag antibody of purified LCH1 and LCH3 analyzed under reducing (left side of marker) or nonreducing (right side of marker) conditions. (d) Flow cytometry analysis of binding of LCH1 and LCH3 immunoliposomes to FAP-expressing HT1080 cells or FAP-negative HT1080 wild-type cells. The binding of LC1 and LC3 immunoliposomes was included for direct comparison. Gray areas, cells alone; thick line, cells incubated with liposomes at 10 nmol lipid per 250.000 cells.

opposite the antigen-binding site, coupling to reactive lipids or PEG chains should not interfere with the recognition of target cells. This was further confirmed in our study applying three constructs with C-terminal cysteines.

Interestingly, functional immunoliposomes could also be prepared with scFv′ molecules with an additional cysteine residue present in the linker sequence. For this approach, we compared three positions (1–3) of the linker peptide. No

differences in coupling efficiency and binding to target cells were observed between these three constructs or in comparison to the HC2 and HC4 constructs. The structural models of the anti-FAP scFv′ molecules indicate that these three positions are located at the bottom of the scFv′ molecule opposite the antigen-binding site. Recently, a similar scFv′ fragment possessing an additional cysteine residue at position 1 of a 15 residue linker was applied for the generation of a piezoimmunosensor for the detection of low concentrations of antigen in complex samples (*14*). Our study confirmed the suitability of site-directed coupling and has extended the application of scFv′ linker variants for the generation of targeted nanoparticulate carrier systems.

This approach was further developed by applying scFv′ molecules with the additional cysteine residue and the hexahistidyl-tag present in the linker sequence. These novel molecules have the advantage that except for the linker sequence no additional amino acid residues are present. Thus, these scFv′ molecules are reduced to the minimal length and composition required for easy one-step purification via IMAC and site-directed coupling to sulfhydryl-reactive molecules. Indeed, we could show that these LCH variants are produced in soluble and active forms in bacteria and that these molecules could be efficiently purified from periplasmic extracts by IMAC. Although recognition by anti-His-tag antibodies is impaired, they could be used to generate immunoliposomes that bind strongly to target cells. These newly designed scFv′ molecules may be particularly suitable for the generation of immunoliposomes and other antibody conjugates, limiting the number of additional residues in these antibody molecules. Instead of the hexahistidyl sequence, one can envisage that other short purification and/or detection tags, such as Strep-tag, poly Arg-tag, or FLAG-tag, may be integrated into the linker sequence, thus implementing further approaches for detection and purification (*37*).

In summary, we performed a comparative study of various scFv′ molecules designed for defined and oriented conjugation to sulfhydryl-reactive molecules. We could show that both genetically introduced single C-terminal cysteine residues as well as single cysteine residues in the linker sequence are equally suitable for the generation of scFv immunoliposomes for target-cell-specific binding and delivery.

ACKNOWLEDGMENT

We would like to thank Ronny Rüger (University of Jena) for helpful suggestions and discussions. This work was supported by a grant from Landesstiftung Baden-Württemberg ("Kompetenznetz funktionelle Nanostrukturen", project C11).

A Novel Class of Intrinsic Proteasome Inhibitory Gene Transfer Peptides

Molly E. Martin and Kevin G. Rice*

Division of Medicinal and Natural Products Chemistry, College of Pharmacy, University of Iowa, Iowa City, Iowa 52242.
Received September 21, 2007; Revised Manuscript Received October 30, 2007

Proteasomes are multisubunit enzymes responsible for the degradation of many cytosolic proteins. The inhibition of the proteasome has been the subject of intense interest in the development of drug therapies. We have previously demonstrated that simultaneous administration of a tripeptide aldehyde proteasome inhibitor (MG115 or MG132) with a peptide (Cys-Trp-Lys_{18}) DNA condensate boosted gene expression by 30-fold in cell culture. In the present study, we have developed a convergent synthesis to allow the incorporation of a proteasome inhibitor tripeptide into the C-terminal end of a gene delivery peptide. The resulting peptides formed DNA condensates that mediated a 100-fold enhancement in gene expression over a control peptide lacking all or part of the tripeptide inhibitor. Gene transfer peptides possessing intrinsic proteasome inhibitors were also found to be nontoxic to cells in culture. These results suggest that intrinsic proteasome inhibition may also be used to boost the efficiency of peptide-mediated nonviral gene delivery systems in vivo.

INTRODUCTION

The proteasome is a multisubunit complex that is responsible for the degradation of many cytosolic proteins such as damaged or misfolded proteins (*1, 2*), degradation of cyclins for cell cycle control (*3, 4*), destruction of transcription factors that control cell differentiation (*3, 4*), and processing of foreign proteins for the generation of cellular immune responses (*1, 5*). The 26S proteasome complex is composed of the barrel-like 20S catalytic core capped at the ends by the 19S regulatory subunits (*2, 6*). The 19S regulatory particles are responsible for substrate recognition, unfolding, and translocation of proteins into the catalytic core. The proteolytic sites of the proteasome are contained inside the core of the 20S complex (*7, 8*). Unlike many other proteolytic enzymes, the proteasome has multiple peptidase activities that can be classified into three main groups: cleavage after hydrophobic side chains (chymotrypsin-like), cleavage after basic residues (trypsin-like), and cleavage after acidic residues (peptidylglutamyl peptide hydrolysis or PGPH) (*6, 7*).

Previous work by Duan et al. established the proteasome to be a key route of metabolism for viral gene delivery vectors (*9*). In studies of airway epithelial cells, it was found that the adeno-associated virus (AAV) vector was ubiquitinated after endocytosis and targeted for degradation by the proteasome. Coadministration of tripeptide proteasome inhibitors increased gene expression from the apical surface by over 200-fold in cell culture and also increased AAV-mediated gene transfer in the liver and lung (*9*).

Nonviral vectors are often composed of cationic peptides, polymers, and lipids that interact with the negatively charged backbone of DNA to form nanometer sized particles that spontaneously transfect cells in culture (*10*). The intracellular dissociation and subsequent metabolism of a cationic peptide polymer leads to the release and premature metabolism of plasmid DNA by DNase leading to a low level and short duration of expression (*11*). The enzymes responsible for the metabolism of peptide-mediated nonviral delivery systems are believed to be in the lysosomes (*12*); however, recent evidence has implicated the involvement of the proteasome (*13*).

Kim et al. hypothesized that peptide−DNA condensates could follow a route of metabolism similar to that of viruses because of their comparable size and susceptibility to serine proteases (*13*). Transfection of HepG2 cells in the presence of tripeptide proteasome inhibitors resulted in a 30-fold increase in luciferase expression for peptide−DNA condensates, whereas lipofectamine and polyethylenimine transfections were not enhanced. However, simultaneous uptake of condensate and inhibitor can be difficult, and these tripeptide inhibitors are very cytotoxic, with an LD_{50} of approximately 2 μM (*13*).

Peptide vinyl esters are a new class of proteasome inhibitors that are suggested to work through a mechanism similar to that of the well-known peptide vinyl sulfone inhibitors such as NLVS (*14–17*). The C-terminal vinyl ester covalently modifies the active site of the proteasome by serving as a substrate for a Michael addition with the catalytic threonine residue at the N-terminus of the β subunit (*14*). We hypothesize that gene delivery peptides containing an intrinsic C-terminal vinyl ester moiety may resist metabolism by the proteasome and thereby increase the gene transfer efficiency of peptide−DNA condensates. Here, we describe the synthesis and testing of gene delivery peptides containing a variety of intrinsic peptide vinyl ester sequences that condense DNA, mediate cellular uptake, inhibit the proteasome, and boost gene transfer efficiency. Incorporation of the peptide inhibitor sequence into the DNA condensate provides a mechanism for cointernalization of the proteasome inhibitor with the peptide−DNA condensate without the cytotoxic effects of giving a separate inhibitor.

MATERIALS AND METHODS

(Benzotriazol-1-yloxy)tris(dimethylamino)phosphonium hexafluorophosphate, *N*-terminal Fmoc-protected amino acids, *N*-terminal Boc-protected amino acids, 1-hydroxybenzotriazole, diisopropylcarbodiimide, and 2-chlorotrityl chloride resin for peptide synthesis were obtained from Advanced ChemTech (Lexington, KY). Triethylamine, ether, trifluoroacetic acid, hexane, ethyl acetate, and acetonitrile were purchased from Fisher. Dichloromethane, *N*,*O*-dimethylhydroxylamine hydro-

chloride, lithium aluminum hydride, tetrahydrofuran, triethylphosphonoacetate, potassium *tert*-butoxide, acetic acid, 2,2,2-trifluoroethanol, diisopropylethylamine, and thiazole orange were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO). HepG2 cells were provided by the Center for Gene Therapy of CF in the University of Iowa. DMEM, Hams-F12, sodium pyruvate, penicillin/streptomycin, and inactivated fetal bovine serum (FBS) were from Invitrogen Life Technologies Inc. (Carlsbad, CA). A 5.6 kbp plasmid (pCMVL) encoding the reporter gene luciferase was a gift from Dr. Hickman at the University of California (Davis, CA). Endotoxin-free plasmids were purified from *Escherichia coli* on a Qiagen ultrapure column according to the manufacturer's instructions. Luciferase from *Photinus pyralis*, D-luciferin, and ATP were purchased from Roche Diagnostics Corporation (Indianapolis, IN). The BCA assay kit was from Pierce Biotechnology Inc. (Rockford, IL). MG 115 (Z-Leu-Leu-Nva-CHO) was purchased from Calbiochem (San Diego, CA).

Synthesis of Leu-ve and Nva-ve. Leu-ve and Nva-ve were synthesized by modification of methods by Fehrentz and Castro (*18*). The peptide aldehyde was converted to the vinyl ester according to the procedure of Hover et al. (*19*). Briefly, triethylamine (2.2 g, 22 mmol) was added to a solution of Boc-amino acid **1** (5.0 g, 22 mmol) in 90 mL of dichloromethane (DCM), followed by the addition of (benzotriazol-1-yloxy)tris-(dimethylamino)phosphonium hexafluorophosphate (BOP; 9.6 g, 22 mmol). After 5 min, *N*,*O*-dimethylhydroxylamine hydrochloride (2.3 g, 24 mmol) and triethylamine (2.4 g, 24 mmol) were added, and the reaction was stirred at RT under nitrogen. Approximately 0.5 mL of additional triethylamine was added to the reaction to raise the pH to 7. The reaction was monitored by TLC (1:1 ethyl acetate/hexane, $R_f = 0.52$) and reached completion within 45 min. The mixture was diluted to 150 mL with DCM and washed successively with 3 N HCl (3 × 50 mL), saturated $NaHCO_3$ (3 × 50 mL), and saturated NaCl (3 × 50 mL). The organic layer was dried over $MgSO_4$ and evaporated to give **2**.

Lithium aluminum hydride (LAH; 0.95 g, 25 mmol, 5 equiv) was added to 150 mL of tetrahydrofuran (THF) under nitrogen. The LAH slurry was then added dropwise to **2** in 50 mL of THF and mixed for 20 min under nitrogen. The mixture was hydrolyzed with potassium hydrogen sulfate (4.77 g, 35 mmol) in 100 mL of water, and THF was evaporated. Ether (200 mL) was added, and the aqueous layer was separated and extracted with 3 × 50 mL ether. The organic phases were combined, washed with 3 N HCl (3 × 50 mL), saturated $NaHCO_3$ (3 × 50 mL), and saturated NaCl (3 × 50 mL), and dried over $MgSO_4$. The solvent was then evaporated to give **3**.

Triethylphosphonoacetate (3.11 g, 15.5 mmol) was added to 58 mL of THF and cooled to 0 °C. Potassium *tert*-butoxide (1.56 g, 13.9 mmol) in 14 mL of THF was added and stirred at room temperature for 1 h. The mixture was then cooled to 5 °C, aldehyde **3** was added in 23 mL of THF, and the reaction was stirred for 2 h at room temperature until the reaction was shown to be complete by TLC (9:1 hexane/ethyl acetate, $R_f = 0.25$). The solvent was evaporated, and the residue was dissolved in 200 mL of 50% ether in water. The aqueous phase was then extracted with ether (2 × 100 mL), the combined organic layers were dried over $MgSO_4$, and the solvent was evaporated. The residue was then purified by flash chromatography using 9:1 hexane/ethyl acetate to give **4**. The Boc-protected vinyl ester **4** was then treated with 90% trifluoroacetic acid (TFA) in water for 40 min followed by evaporation of TFA. The residue was precipitated with ether, and the resulting solid was separated by centrifugation to give vinyl ester **5** in an overall yield of 40%.

The product was characterized by proton NMR (300 MHz, acetone-d_6): $\delta = 6.98$ (dd, $J = 7.2$ Hz, 15.9 Hz, 1H), 6.17 (dd, $J = 1.2$ Hz, 15.9 Hz, 1H), 4.90 (m, 1H), 4.16 (q, $J = 7.2$ Hz, 2H), 1.98–2.10 (m, 1H), 1.64–1.76 (m, 2H) 1.24 (t, $J = 7.2$ Hz, 3H), 0.95 (dd, $J = 3.6$ Hz, 6.3 Hz, 6H). MS: $M + H^+ = 186.1$.

Nva-ve was synthesized by an identical approach with an overall yield of 48%. ^{1}H NMR (300 MHz, acetone-d_6): $\delta = 6.99$ (dd, $J = 6.9$ Hz, 15.9 Hz, 1H), 6.14 (dd, $J = 0.9$ Hz, 15.9 Hz, 1H), 4.86 (m, 1H), 4.16 (q, $J = 7.2$ Hz, 2H), 1.80–1.95 (m, 2H), 1.35–1.50 (m, 2H), 1.25 (t, $J = 7.2$ Hz, 3H), 0.93 (t, $J = 7.5$ Hz, 3H). MS: $M + H^+ = 172.1$.

Intrinsic Proteasome Inhibitory Gene Transfer Peptide Synthesis. Peptides of the following sequences WK_{18}, WK_{18}LL, WK_{18}VS, WK_{18}VQ, WK_{18}FQ, WK_{18}YVQ, and WK_{18}FVQ were synthesized on 2-chlorotrityl chloride resin at a 30 μmol scale. Standard Fmoc procedures were used with 1-hydroxybenzotriazole and diisopropylcarbodiimide double couplings on an Apex 396 Advanced ChemTech solid-phase peptide synthesizer. *N*-terminal and side-chain protected peptides were cleaved from the resin by reaction with acetic acid/2,2,2-trifluoroethanol/DCM (1:1:8 (v/v/v)) for 30 min at RT. Fifteen volumes of hexane were then added, and the solvent was evaporated to give the crude protected peptide.

Each protected peptide (4 μmol) was dissolved in THF, and diisopropylethylamine (DIPEA; 4 μmol), BOP (12 μmol), and HOBt (24 μmol) were added. Vinyl ester **5** (20 μmol) and DIPEA (20 μmol) were added, and the reaction was stirred at room temperature for 1.5 h. The solvent was then evaporated, and the peptide was deprotected with 90% TFA for 1 h. Following evaporation, the peptide was dissolved in water for purification. Peptides were purified on RP-HPLC by injection onto a Vydac C_{18} semipreparative column (2 × 25 cm) eluted at 10 mL/min with 0.1% TFA and a 20–30% gradient of acetonitrile over 30 min while monitoring absorbance at 280 nm. The major peak was collected and pooled from multiple runs, concentrated by rotary evaporation, and lyophilized. Purified peptides were reconstituted in water and quantified by absorbance ($\varepsilon_{280} = 5600\ M^{-1}\ cm^{-1}$) to determine the isolated yield, which ranged from 18 to 45%. The peptides were characterized on an Agilent 1100 LC-ESI-ion trap by injecting 2 nmol onto a Vydac C_{18} analytical column (0.47 × 25 cm) eluted at 0.7 mL/min with 0.1% TFA and a 5–55% gradient of acetonitrile over 30 min The RP-HPLC eluent was directly infused into the electrospray ionization source, and mass spectral data were obtained in the positive mode for all peptides. Peptides containing a *C*-terminal nor-Val vinyl ester (Nva-ve) were also synthesized using the same method described above.

Preparation and Characterization of Peptide−DNA Condensates. Peptide−DNA condensates were prepared by combining 50 μg of pCMVL in 500 μL of Hepes-buffered mannitol (HBM; 5 mM Hepes, 0.27 M mannitol at pH 7.5) with 20 nmol of peptide in 500 μL of HBM while vortexing to create DNA condensates possessing a charge ratio (NH_4^+/PO_4^-) of approximately 2:1. The particle size of DNA condensates was measured by quasi-elastic light scattering (QELS) on a Brookhaven ZetaPlus particle sizer (Brookhaven Instruments Corporation, NY). The relative binding affinity of the peptides for DNA was monitored by two methods. In the first method, peptide−DNA condensates (40 μL) of varying stoichiometries were added to 960 μL of HBM containing 0.1 μM thiazole orange. The fluorescence of the intercalated dye was measured using a LS50B fluorometer (Perkin-Elmer) by exciting at 498 nm while monitoring emission at 546 nm with both the excitation and emission slit widths set at 8.5 (*20*). Peptide-mediated condensation was also monitored by a band-shift assay. Condensates with increasing peptide to DNA ratios (0–1 nmol

peptide per μg of DNA) were electrophoresed on an agarose gel (1 μg DNA per well) and visualized by ethidium bromide staining (*21*).

In Vitro Gene Expression. HepG2 cells (5×10^5) were plated on 6 × 35 mm wells and grown to 40–70% confluency in DMEM supplemented with 50% Hams-F12, 10% FBS, 250 U/mL penicillin, and 250 μg/mL streptomycin at 37 °C in a humidified 5% CO_2 incubator. Transfections were performed in DMEM (1 mL/35 mm well) supplemented with 2% FBS, sodium pyruvate (1 mM), penicillin, and streptomycin (100 U and 100 μg/mL). Peptide−DNA condensates (10 μg of DNA in 0.2 mL of HBM) were added dropwise to triplicate wells. After a 4 h incubation at 37 °C, the medium was replaced with 2 mL of fresh culture medium (DMEM containing 50% Hams-F12 and 10% FBS). Following a total of 24 h of incubation, the cells were washed twice with 2 mL of ice-cold PBS (calcium- and magnesium-free) and then treated with 0.5 mL of lysis buffer (25 mM Tris hydrochloride at pH 7.8, 1 mM EDTA, 8 mM magnesium chloride, and 1% Triton X-100) for 10 min at 4 °C. The cell lysate was scraped, transferred to a 1.5 mL microcentrifuge tube, and centrifuged for 10 min at 13,000*g* at 4 °C to pellet the cell debris. Lysis buffer (300 μL), sodium-ATP (4.3 μL of a 165 mM solution at pH 7, 4 °C), and cell lysate (100 μL, 4 °C) were combined in a test tube, briefly mixed, and immediately placed in the luminometer. Luciferase relative light units were measured by Lumat LB 9501 (Berthold Systems, Germany) with 10 s integration after automatic injection of 100 μL of 0.5 mM D-luciferin. The relative light units were converted to fmol using a standard curve generated by adding a known amount of luciferase to 35 mm wells containing 40–70% confluent HepG2 cells. The resulting standard curve had an average slope of 1×10^5 relative light units/fmol of enzyme. Protein concentrations were measured by BCA assay using bovine serum albumin as a standard (*22*). The amount of luciferase recovered in each sample was normalized to milligrams of protein and reported as the mean and standard deviation obtained from triplicate transfections.

Cytotoxicity Assay. The in vitro toxicity of the vinyl ester peptides was evaluated by the MTT reduction assay (*23*). HepG2 cells were plated on 6 × 35 mm wells at 5×10^5 cells/well and grown to 40–70% confluency. The culture media was then replaced with 1 mL of fresh DMEM supplemented with 2% FBS, and the cells were treated with either 0.4 nmol peptide/μg DNA condensates or varying concentrations of peptide alone. After 4 h of incubation with condensates or peptide, the media was removed and replaced with 2 mL of the original growth media, and the cells were allowed to incubate for another 20 h. The media were then removed and replaced with 2 mL fresh culture media, and 500 μL of 0.5% (w/v) MTT in PBS solution was added and allowed to incubate at 37 °C for 1 h to promote the formation of formazan crystals. The media containing MTT were removed, and the crystals were dissolved by the addition of 1 mL of DMSO and 250 μL of Sorenson's glycine buffer (0.1 M glycine, 0.1 M NaCl at pH 10.5) and measured spectrophotometrically at 595 nm on a microplate reader (Bio-Rad, Bethesda, MD). The percent viability was determined relative to untreated cells.

RESULTS

Proteasomes play a major role in the degradation of intracellular proteins and peptides (*2, 8*). Previous studies by Kim et al. demonstrated that simultaneous administration of peptide−DNA condensates and a proteasome inhibitor, such as the peptide aldehyde MG115, could increase gene expression by 30-fold over that of the control (*13*). The proposed mechanism involves blocking the premature metabolism of the peptide−DNA condensates in the cell.

Although tripeptide aldehydes such as MG115 or MG132 were shown to increase gene transfer, they simultaneously induced apoptosis and produced dose-dependent cell toxicity. In an effort to inhibit the proteasome to increase gene transfer while avoiding cell toxicity, we hypothesized that a single DNA condensing peptide containing an intrinsic proteasome inhibitor would potentially block the proteasome, avoid cellular toxicity, and could be used to increase gene transfer efficiency in vivo.

We first attempted the synthesis of WK_{18} with a *C*-terminal LLnV-aldehyde similar to MG115 using a Weinreb-amide resin. Although the synthesis was successful, the purified WK_{18}-LLnV-aldehyde formed intramolecular Schiff's-bases with the K_{18} side chains resulting in a mixture of isomers. The mixture of peptides was also found to be a poor inhibitor of the proteasome that did not provide enhanced gene transfer.

The strategy was refined by incorporating a less reactive *C*-terminal vinyl ester proteasome inhibitor sequence into the gene delivery peptide (*14, 15*). Tripeptide analogues possessing a *C*-terminal vinyl ester have been shown to act as a Michael acceptor for the nucleophilic hydroxyl group of the catalytic threonine residue at the active site of the proteasome (*14, 15*).

We first approached the synthesis of WK_{18}LLnV-vinyl ester (ve) by releasing the fully protected WK_{18}LLnV-aldehyde from the Weinreb-amide resin with LAH, followed by its direct conversion to the vinyl ester using a Horner−Wadsworth−Emmons reaction (*19, 24–26*). This strategy was successful but only afforded 1% yields of the desired WK_{18}LLnV-ve and proved difficult to optimize.

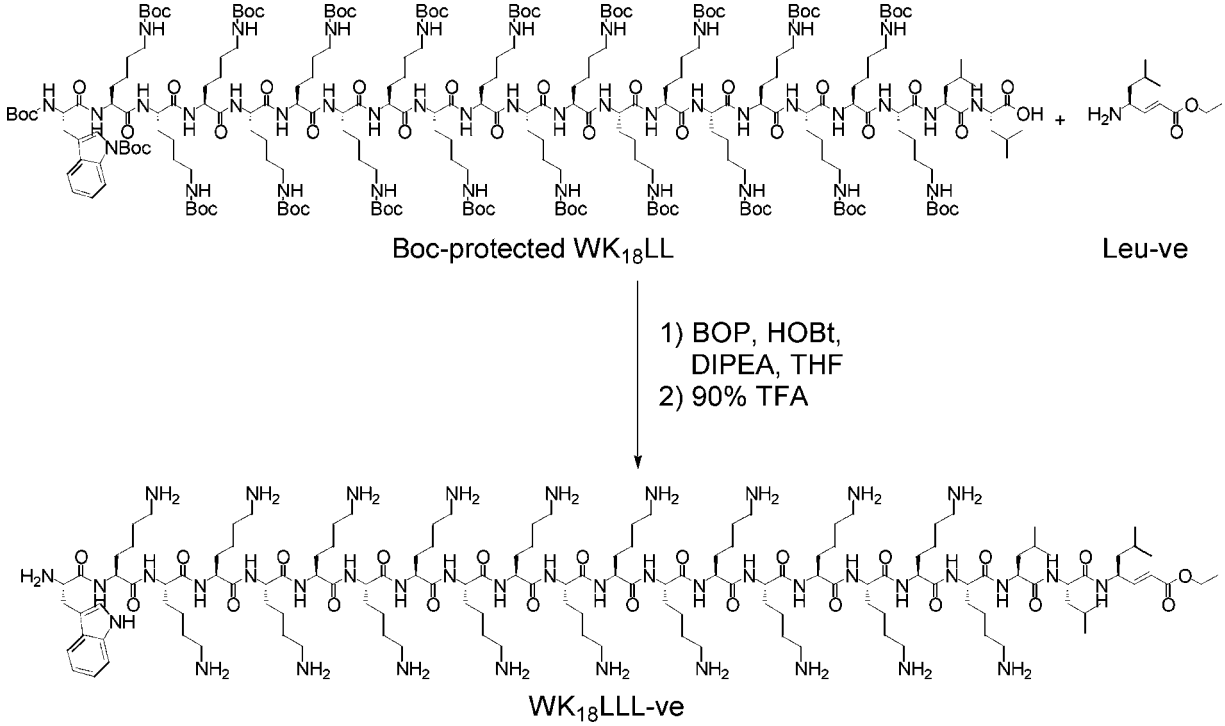
A higher yielding more general strategy involved the solid-phase synthesis of WK_{18}LL on a 2-chlorotrityl chloride resin followed by a mild acid cleavage to release the fully protected peptide from the resin (Scheme 1). Subsequent coupling of the *N*-terminus of a chemically synthesized Leu-ve or Nva-ve to the *C*-terminus of the protected peptide, followed by deprotection and purification, established a general convergent high-yielding pathway to the desired WK_{18}LLnV-ve (42%) and related peptides (18–45%) (Table 1). During the coupling of the head group to the protected peptide with BOP, it was essential to use excess HOBt to suppress racemization at the α-carbon of the *C*-terminal leucine of the WK_{18}LL. Without the excess HOBt, the reaction produced two products of identical mass that represent the L−D isomerization.

The chemical synthesis of the Leu-ve and Nva-ve head groups proved to be efficient, high yielding, and general for most amino acid starting materials (Scheme 2). Using a commercially available Boc amino acid (**1**), the *C*-terminus was converted into the Weinreb amide (**2**), then reduced with LAH to give the aldehyde (**3**). This intermediate was converted via the Horner−Wadsworth−Emmons reaction to Boc-Leu-ve (**4**) and finally deprotected to provide the desired Leu-ve (**5**) with an overall 40% yield. The same synthetic strategy was also applied to the synthesis of the Nva-ve head group resulting in a 48% overall yield.

Preparative HPLC-purified peptides were rechromatographed on analytical RP-HPLC to determine yield and establish structure on the basis of mass determined by LC-MS. The RP-HPLC analysis of purified WK_{18}LLL-ve demonstrates purity analysis based on monitoring Trp in eluting peaks by absorbance and fluorescence (Figure 1). For each purified peptide, a single major peak demonstrated >95% purity that also produced a doubly charged positive ion in the ESI-MS (Figure 1, inset) corresponding to the calculated mass of the desired peptide (Table 1).

Seven different peptides were prepared containing different head groups and subterminal amino acids (Table 1). Since it is not known which site is responsible for the degradation of gene delivery peptides, a variety of head groups were designed to

Scheme 1. Convergent Synthesis of WK_{18}LLL-ve Gene Transfer Peptide[a]



[a] The *C*-terminus of the fully protected WK_{18}LL peptide prepared on chlorotrityl resin is conjugated with the *N*-terminus of Leu-ve, then deprotected to form WK_{18}LLL-ve.

Table 1. Vinyl Ester Peptides

sequence	mass (obs/calc)	particle size (nm)[a]
WK_{18}LLL-ve	2904.9/2904.8	100 ± 20
WK_{18}LLnV-ve	2890.0/2891.6	112 ± 26
WK_{18}VSL-ve	2864.8/2866.0	103 ± 18
WK_{18}VQL-ve	2905.8/2906.8	182 ± 45
WK_{18}FQL-ve	2953.9/2955.0	104 ± 23
WK_{18}YVQL-ve	3069.0/3070.0	110 ± 24
WK_{18}FVQL-ve	3053.0/3054.2	117 ± 22

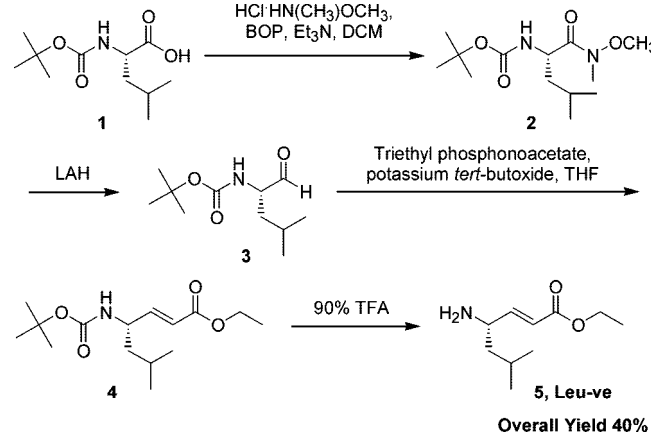
act at either the chymotrypsin- or trypsin-like site of the proteasome. The first two peptides with the LLL-ve and LLnV-ve head group sequences were designed on the basis of the sequences of the commercially available peptide−aldehyde inhibitors MG132 (Z-LLL-H) and MG115 (Z-LLnV-H). Both the MG132 and MG115 tripeptide inhibitors are known to selectively inhibit the chymotrypsin-like site of the proteasome and were synthesized for this purpose. The other five head groups, VSL-ve, VQL-ve, FQL-ve, YVQL-ve, and FVQL-ve, have been shown by Marastoni et al. to selectively inhibit the trypsin-like site of the proteasome when used as tri and tetrapeptide inhibitor sequences (*14, 15*).

We have previously shown that WK_{18} is sufficient to condense DNA and form small condensates (*27*). Each proteasome inhibitor gene transfer peptide was compared for its ability to bind DNA by thiazole orange displacement and gel retardation. The thiazole orange exclusion assay was performed by titrating increasing amounts of peptide with a constant amount of DNA. The displacement of the thiazole orange intercalator dye leads to a decrease in fluorescence intensity until an asymptote is reached, representing the stoichiometry for complete condensation (Figure 2). WK_{18} and WK_{18}FQL-ve each reached an asymptote at 0.4 nmol peptide/μg DNA, indicating complete condensation of the DNA. Each proteasome inhibitor

Scheme 2. Chemical Synthesis of the Leu-ve Head Group[a]



[a] Starting with Boc-Leu (**1**), the *C*-terminus is converted into the Weinreb amide (**2**). Reduction leads to the formation of aldehyde (**3**), and Horner−Wadsworth−Emmons coupling results in the formation of vinyl ester (**4**). Final deprotection of Boc results in an overall yield of 40% for Leu-ve (**5**). The same approach was utilized to synthesize nor-Val vinyl ester (Nva-ve) with comparable yields.

gene transfer peptide illustrated in Table 1 had a result comparable with that of WK_{18}FQL-ve.

The migration of DNA on an agarose gel was compared following the addition of increasing amounts of WK_{18}FQL-ve (Figure 2). Complete retardation of DNA was observed for both WK_{18} and WK_{18}FQL-ve at 0.2 nmol peptide/μg DNA.

To examine the influence of intrinsic proteasome inhibition on gene expression, HepG2 cells were transfected with DNA condensates prepared with each peptide in Table 1. Luciferase expression was measured for each of the vinyl ester peptides and compared to the controls WK_{18} and PEI. As illustrated in Figure 3, each peptide−DNA condensate mediated a significant increase in expression relative to WK_{18}, with WK_{18}FQL-ve

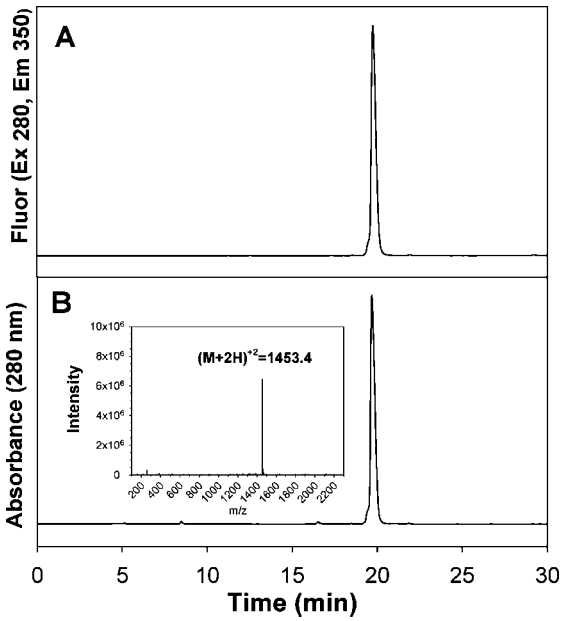


Figure 1. LC-MS characterization of purified WK_{18}LLL-ve. The rechromatograph of purified WK_{18}LLL-ve on RP-HPLC eluted with 0.1% TFA and acetonitrile is illustrated. The chromatogram was monitored by fluorescence (panel A), absorbance (panel B), and by ESI-MS. The major peak (>95%) at 19.8 min produced a doubly charged positive ion at 1453.4 *m*/*z* (inset) corresponding to a mass of 2904.8 amu.

having a 100-fold increase over WK_{18} and transfection efficiency similar to that of PEI.

Since other proteasome inhibitors are known to be cytotoxic, each vinyl ester peptide was examined for cytotoxic effects using the MTT assay. HepG2 cells were treated with either peptide−DNA condensates or varying concentrations of free peptide or proteasome inhibitor for 4 h to model the exposure during gene transfer experiments. The results established that a peptide−DNA condensate dose of 4 nmol of peptide and 10 μg of DNA was not cytotoxic to HepG2 cells (Figure 4A). A similar result was obtained when treating HepG2 cells with varying concentrations of either WK_{18} or WK_{18}FQL-ve, which established the lack of toxicity even at the highest concentration of 8 μM (Figure 4B). These results are in contrast to the peptide inhibitor MG115 that produces an LD_{50} of 2 μM.

DISCUSSION

The proteasome is an important enzyme that degrades cellular proteins and has recently been implicated in the metabolism of both viral and nonviral gene delivery systems (*9*, *13*). It was first shown that proteasome inhibitors could enhance gene expression mediated by an adeno-associated virus in CF/T1 cells (*9*). More recently, the addition of a tripeptide aldehyde proteasome inhibitor, such as MG115 or MG132, resulted in a significant increase in gene expression when cells were transfected with peptide−DNA condensates (*13*). This increase in gene transfer was not observed for nonpeptide systems, such as PEI or lipofectamine, or in the presence of lysosomal enzyme–inhibitors, therefore indicating the proteasome's involvement in the degradation of the peptide delivery systems. However, these peptide−aldehyde inhibitors are cytotoxic with an LD_{50} of 2 μM or less. Therefore, we hypothesized that an intrinsic proteasome inhibitor sequence could be built into the gene delivery peptide to inhibit the proteasome, reduce the cytotoxicity of the inhibitor, and increase gene transfer efficiency.

In support of this hypothesis, several peptides were designed with an *N*-terminal cationic region for DNA binding and a

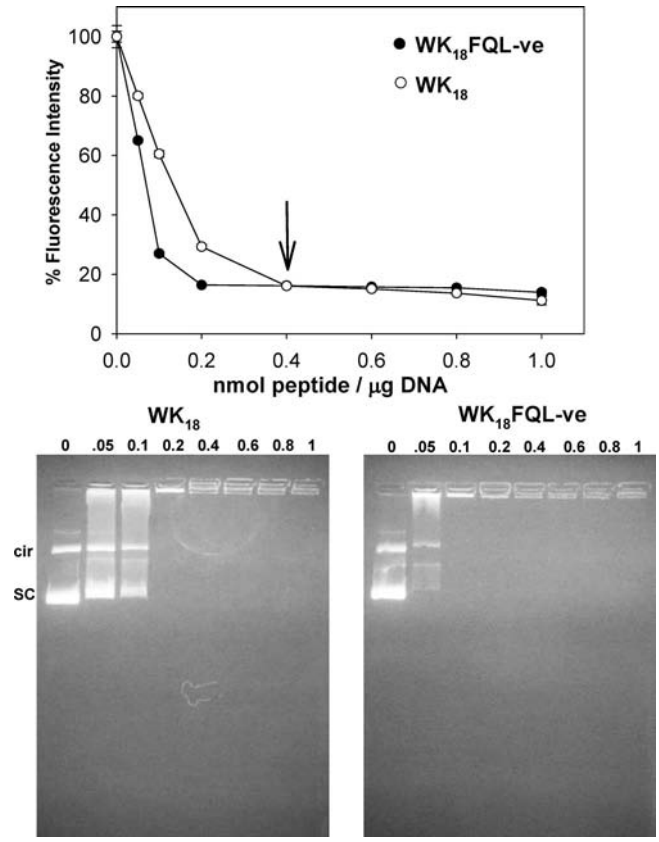

Figure 2. DNA condensation with proteasome inhibitor gene transfer peptides. DNA condensates were formed in triplicate by the addition of 0–1 nmol of WK_{18} or WK_{18}FQL-ve to 1 μg of plasmid DNA in 1 μM thiazole orange. The fluorescence intensity of thiazole orange was measured (ex 498, em 546) at each ratio of peptide to DNA (upper panel). An asymptote in the fluorescent intensity was observed at a ratio of 0.4 nmol peptide/μg DNA, indicating complete condensation. The results observed for WK_{18} and WK_{18}FQL-ve are representative of those observed for each peptide in Table 1. Similarly, peptide-mediated condensation of DNA was monitored by a band shift assay (lower panels). Complete retardation of DNA was observed at 0.2 nmol of peptide per μg of DNA.

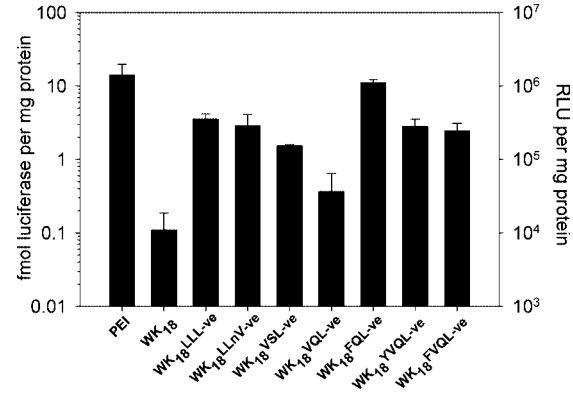

Figure 3. Efficiency of proteasome inhibitor gene transfer peptides. HepG2 cells were transfected in triplicate with 10 μg of DNA condensed with 4 nmol of each proteasome inhibitory gene transfer peptide and compared to transfections with dose-matched controls of PEI:DNA (N/P 9:1) and WK_{18}:DNA. The results establish that WK_{18}FQL-ve mediated a 100-fold increase in gene transfer relative to WK_{18}.

C-terminal head group sequence for proteasome inhibition. Originally, this design included an aldehyde at the *C*-terminus of the peptide in an effort to build in either the MG115 or MG132 proteasome inhibitor sequence. However, the aldehyde proved to be difficult to synthesize in high yields along with

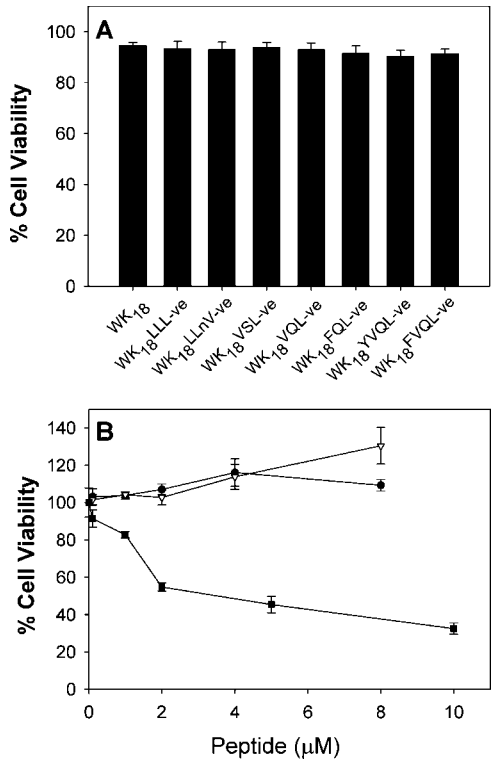

Figure 4. Relative toxicity of proteasome inhibitory gene transfer peptides. HepG2 cells were treated for 4 h with 10 μg of DNA condensed with 4 nmols of each proteasome inhibitory gene transfer peptide. The cell toxicity was assessed by the MTT assay. The results illustrated in panel A demonstrate a lack of cytotoxicity on HepG2 cells. Similarly, the results presented in panel B demonstrate that treatment of HepG2 cells with increasing concentrations of $WK_{18}FQL$ (•) or WK_{18} (▲) results in no toxicity up to 8 μM, where the tripeptide MG115 (■) is toxic to cells at 2–5 μM.

being quite reactive with the side chain amines of the lysine residues in forming a variety of intramolecular Schiff's bases. To solve this problem, we incorporated a vinyl ester inhibitor sequence recently developed by Marastoni et al. (Schemes 1 and 2, and Figure 1) (*14–17*). The vinyl ester head group is similar to the well-known vinyl sulfone class of proteasome inhibitors and is believed to function through a similar mechanism of Michael addition with the γ-hydroxyl group of the threonine side chain on the proteasome. Marastoni's group synthesized several tri and tetrapeptide sequences optimizing the P2−P4 positions and the *N*-terminal protecting group for potent and selective inhibition at the trypsin-like site of the proteasome. They concluded that a glutamine in the P2 position was favorable for trypsin-like selectivity, along with the presence of aromatic and hydrophobic residues in the P3 and P4/*N*-terminal-protecting group position. Another important discovery is that the vinyl ester inhibitors are nontoxic and do not affect cell proliferation, unlike other classes of proteasome inhibitors (*14*).

The enhanced gene transfer by cationic peptides was dependent on the presence of a vinyl ester head group (Figure 3). These results in HepG2 cells were consistent with a similar enhancement in gene transfer observed when treating cells with an MG115, a known tripeptide proteasome inhibitor. There is no direct evidence that cationic peptides containing a vinyl ester are exclusive in their inhibition of the intracellular proteasome. The inhibition of other proteolytic enzymes could also result in enhanced gene transfer.

Since three types of proteolytic acitivites within the proteasome are known, we synthesized several different sequences targeting both the trypsin-like and chymotrypsin-like catalytic activities. On the basis of Marastoni's results, we designed peptides that incorporated the most potent vinyl ester tri and tetrapeptide inhibitor sequences aimed at targeting the trypsin-like activity of the proteasome. We also included two sequences based on those of MG115 (Leu-Leu-Nva) and MG132 (Leu-Leu-Leu) to target chymotrypsin-like activity, as they are both selective for this site in the form of a peptide−aldehyde inhibitor and are weakly inhibitory at the trypsin-like and PGPH sites (*28*). However, the proteasome is a complex enzyme with allosteric interactions between its subunits (*29, 30*). Inhibition of one site within the enzyme can lead to activation and/or inhibition of either of the other sites. The gene delivery peptides contain multiple lysine residues, which would suggest that degradation would most likely occur by the trypsin-like site that cleaves after basic residues. As seen in Figure 3, the peptide $WK_{18}FQL$-ve gives over 100-fold increase in gene expression over that of the control, suggesting that inhibition presumably at the trypsin-like site leads to the highest levels of gene expression. However, there are many interactions within the proteasome between the subunits that could be inhibiting other catalytic activities as well that could be contributing to this increase in expression. Also, the two peptides targeting the chymotrypsin-like site, $WK_{18}LLL$-ve and $WK_{18}LLnV$-ve, both gave significant levels of increased gene expression over that of the control, indicating that inhibition of the chymotrypsin-like site also positively affects peptide-mediated gene expression.

In agreement with the data presented by Marastoni, the gene delivery peptides containing a vinyl ester head group were not toxic to cells as determined by the MTT assay (Figure 4). The peptides were tested in the MTT assay as condensates with DNA and dosed as free peptide at increasing concentrations. Both the condensates and free peptide gave no toxicity, unlike MG115, which had an IC_{50} of 2–5 μM. The peptide−aldehydes are highly potent at inhibiting the chymotrypsin-like activity of the proteasome (*8*) but are also very toxic to cells (*13*). By changing to a vinyl ester head group, we are able to significantly decrease the cytotoxicity of the proteasome inhibitor. Even though Michael addition-type inhibitors are thought to be less potent than MG115, they bind covalently to the catalytic threonine residue for long-term inhibition unlike the reversible aldehyde that only provides transient inhibition (*8*). However, when used to condense DNA at a 0.4 nmol peptide per μg DNA ratio, a 1 μM concentration of the inhibitor is present in the transfection media. Data by Kim et al. showed that a 10 μM dose of MG115 is needed to achieve maximal luciferase expression in HepG2 cells (*13*). Therefore, less of the inhibitor may be required to achieve the inhibition needed to see a significant increase in gene expression. In addition, MG115 only mediated a 30-fold increase in expression over that of the control, while the most potent vinyl ester derivative could produce a 100-fold increase in luciferase expression.

Proteasome inhibitors are able to prevent premature degradation of peptide−DNA condensates and give over a 30-fold increase in luciferase expression. However, these inhibitors are highly toxic and induce apoptosis in cells. Incorporation of an intrinsic proteasome inhibitor sequence into a gene delivery peptide results in a nonviral vector that is able to condense DNA, transfect cells, inhibit the proteasome, and increase gene transfer over control peptides without the cytotoxic effects seen with other inhibitors. With these capabilities, the vinyl ester gene delivery peptides may be able to boost the efficiency of peptide-mediated nonviral gene delivery systems in vivo.

TECHNICAL NOTES

Application of an Environmentally Sensitive Fluorophore for Rapid Analysis of the Binding and Internalization Efficiency of Gene Carriers

Jamie M. Bergen, Ester J. Kwon, Tammy W. Shen, and Suzie H. Pun*

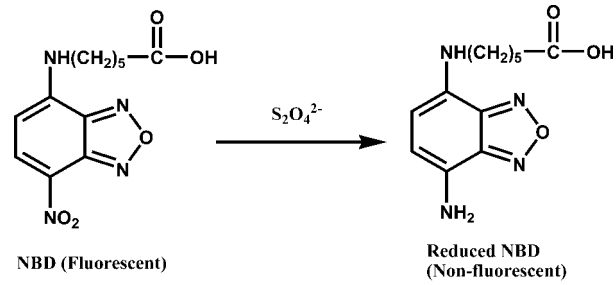
Nonviral gene carriers must associate with and become internalized by cells in order to mediate efficient transfection. Methods to quantitatively measure and distinguish between cell association and internalization of delivery vectors are necessary to characterize the trafficking of vector formulations. Here, we demonstrate the utility of nitro-2,1,3-benzoxadiazol-4-yl (NBD)-labeled oligonucleotides for discrimination between bound and internalized gene carriers associated with cells. Dithionite quenches the fluorescence of extracellular NBD-labeled material, but is unable to penetrate the cell membrane and quench internalized material. We have verified that dithionite-mediated quenching of extracellular materials occurs in both polymer- and lipid-based gene delivery systems incorporating NBD-labeled oligonucleotides. By exploiting this property, the efficiencies of cellular binding and internalization of lipid- and polymer-based vectors were studied and correlated to their transfection efficiencies. Additionally, spatiotemporal information regarding binding and internalization of NBD-labeled gene carriers can be obtained using conventional wide-field fluorescence microscopy, since dithionite-mediated quenching of extracellular materials reveals the intracellular distribution of gene carriers without the need for optical sectioning. Hence, incorporation of environmentally sensitive NBD−oligos into gene carriers allows for facile assessment of binding and internalization efficiencies of vectors in live cells.

INTRODUCTION

Nonviral gene carriers offer the potential to safely and efficiently mediate the delivery of nucleic acid based therapeutics into targeted cells (*1*, *2*). Nonviral vectors are typically based on cationic polymers or lipids, which upon self-assembly with plasmid DNA form complexes termed polyplexes or lipoplexes, respectively. Despite efforts to design more efficient nonviral gene carriers, viral vectors remain the leading candidates for gene therapy due to their significantly higher gene transfer efficiencies compared to synthetic vectors. A number of physical barriers hinder the progress of gene carriers from the cell surface to the nucleus (*3*). Toward the design of more efficient nonviral gene carriers, it is important to quantitatively compare various vectors and formulations for their abilities to overcome each of the intracellular barriers. The initial barrier encountered upon arrival at targeted cells, cellular internalization, is a prerequisite to achieving transgene expression. A technique to reliably measure the degree of internalization of gene carriers into cells would facilitate the establishment of structure–function relationships in the development of improved nonviral gene carriers.

Here, a strategy is described for differentiating between extra- and intracellular gene carriers using 7-nitro-2,1,3-benzoxadiazol-4-yl (NBD)-labeled oligonucleotides as environmentally sensitive probes. NBD is a highly fluorescent compound that is irreversibly quenched by exposure to the reducing agent dithionite (Scheme 1). It was previously demonstrated that NBD-labeled lipids are useful tools to monitor lipid asymmetry at the plasma membrane

Scheme 1. Dithionite-Mediated Reduction of the Fluorophore Nitro-2,1,3-benzoxadiazol-4-yl (NBD) to a Nonfluorescent Derivative



since cell membranes are relatively impermeable to dithionite (*4*). By the same principles, we demonstrate here that NBD-labeled oligonucleotides can be incorporated into polymer- or lipid-based nonviral gene carriers to distinguish between extra- and intracellular materials. Current protocols to quantify vector internalization include cell treatment with polyion wash buffers to remove cell-associated materials or cell exposure to antifluorophore antibodies or Trypan blue to quench extracellular fluorescence. The NBD/dithionite approach presented here offers a reliable, cost-effective alternative that is compatible with downstream analysis by flow cytometry, fluorescence microscopy, and fluorimetry in whole cells or lysates.

To demonstrate the utility of NBD-labeled oligonucleotides, the internalization efficiencies of a series of lipoplex and polyplex formulations were evaluated in a high-throughput, fluorescence-based assay and compared to overall transfection efficiency. Additionally, we show that dithionite-mediated

quenching of extracellular NBD-labeled gene carriers enables discrimination between bound and internalized materials associated with small-diameter neurites using wide-field fluorescence microscopy, an application that was previously hindered by technical limitations. Hence, NBD-labeled oligonucleotides are a useful tool for investigating the binding and internalization profiles of nonviral gene carriers.

EXPERIMENTAL PROCEDURES

2.1. Incorporation of NBD-Labeled Oligonucleotides into Nonviral Gene Delivery Systems. *2.1.1. Synthesis of NBD−Oligos and TR−Oligos.* Oligonucleotides with a 5′ amino group (5′-NH_2-TTC TCC GAA CGT GTC ACG TT-3′) were synthesized and desalted by Integrated DNA Technologies (Coralville, IA). Oligonucleotides were conjugated to succinimidyl ester derivatives of either 6-(*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)hexanoate (NBD-X) or Texas Red-X (TR) (Invitrogen, Carlsbad, CA) following guidelines provided by the manufacturer. Briefly, oligonucleotides were purified by chloroform extraction to remove interfering compounds such as tris(hydroxymethyl) aminomethane (Tris). 100 μg of purified oligonucleotide was then diluted in 0.1 M sodium tetraborate buffer, pH 8.5, and the dye, freshly dissolved in DMSO, was added to this solution at a 40:1 or 20:1 dye/oligo ratio for NBD and TR, respectively. The conjugation reaction proceeded overnight at room temperature, and then free dye was separated from oligonucleotides by ethanol precipitation. Yields and conjugation efficiencies were determined on the basis of absorbance measurements at 260, 465, and 595 nm to measure oligonucleotide, NBD, and TR concentrations, respectively. The NBD-labeled oligonucleotide was recovered with a 90% yield, and the labeling efficiency was 81%. For the TR-labeled oligonucleotide, the yield and labeling efficiency were 75% and 85%, respectively.

2.1.2. Formulation of Lipoplexes and Polyplexes Incorporating Labeled Oligonucleotides. Lipofectamine 2000 (L2K) was purchased from Invitrogen (Carlsbad, CA) and poly(ethylenimine) (PEI; 25 000 MW, branched) was obtained from Sigma (St. Louis, MO). Lipoplexes were formulated by condensing labeled oligonucleotides with L2K according to the manufacturer's instructions. Briefly, oligonucleotides were diluted in phosphate-buffered saline (PBS) (for fluorimeter-based quenching studies) or in OptiMEM (Invitrogen) (for cell binding and internalization studies) to a concentration of 0.01 μg/μL, and were added to an equal volume of L2K diluted in PBS or OptiMEM. The ratio of DNA (μg) to L2K (μL) was varied from 1:0.5 to 1:3. The mixture was incubated for 20 min at room temperature to allow lipoplex self-assembly. To formulate polyplexes, oligonucleotides were diluted to a concentration of 0.02 μg/μL in PBS or F12-K medium with no supplements (ATCC; Manassas, VA), and an equal volume of PEI diluted in PBS or F12-K medium was added. This mixture was incubated for 20 min at room temperature to allow particle formation. PEI amine to DNA phosphate (N/P) ratios were calculated on the basis of the monomer molecular weights of 43 and 330 Da for PEI and DNA, respectively, and polyplexes were formulated at N/P ratios from 3 to 10.

2.1.3. Fluorescence Measurements of Dithionite-Mediated NBD Quenching in Gene Carriers. Lipoplexes and polyplexes were formulated as described in the previous section using NBD-labeled oligonucleotides. To evaluate dithionite-mediated quenching of NBD-labeled gene carriers, lipoplexes were formulated at a L2K/DNA ratio of 3 and polyplexes were formulated at an N/P ratio of 5. Sodium dithionite was purchased from EMD Chemicals (Gibbstown, NJ), and was prepared as a 1 M stock solution in 1 M Tris, pH 10, immediately prior to use. Fluorescence measurements were obtained using a TECAN Safire II microplate reader (Tecan Systems, Inc., San Jose, CA). NBD was excited at a wavelength of 465 nm, and emission was read at 535 nm. Initial fluorescence measurements were taken in wells containing 100 μL of the lipoplex solution, polyplex solution, or a solution containing an equivalent amount of free oligonucleotide. Subsequently, 9.6 μL of either 1 M dithionite in 1 M Tris (for a final dithionite concentration of 88 mM) or 9.6 μL of 1 M Tris alone (as a negative control) was added to the wells containing lipoplexes or polyplexes and incubated for 2 min at room temperature prior to repeating NBD fluorescence measurements. The pH sensitivity of NBD emission was tested by measuring the emission intensities of NBD−oligos in PBS (pH 7.4), Tris buffer (pH 10.0), and acetate buffer (pH 4.5). To verify that dithionite-mediated quenching was specific to NBD, lipoplexes formulated using a 90/10 mixture of NBD/TR were also analyzed. TR samples were excited at 595 nm, and emission was read at 615 nm.

2.2. Binding and Uptake of NBD-Labeled Lipoplexes and Polyplexes in Cultured Cells. *2.2.1. Cell Culture.* HeLa cells were purchased from ATCC (CCL-2) and cultured in minimum essential medium (MEM) supplemented with 10% fetal bovine serum and antibiotics. Cells were passaged every 3–4 days.

2.2.2. Microscopy-Based Binding and Uptake Assay. HeLa cells were seeded on a 24-well plate at 5×10^4 cells/0.5 mL/well and allowed to attach overnight. NBD-labeled polyplexes (N/P = 5) and lipoplexes (L2K/DNA = 3) were formulated as described in section 2.1.2. Cells were rinsed with PBS, and medium was replaced with 500 μL/well OptiMEM. Polyplexes or lipoplexes incorporating 1 μg NBD−oligo were added to each well and incubated for either 1 h at 4 °C or for 3 h at 37 °C. Following the specified incubation period, medium was removed and the cells were rinsed once with PBS. Then, dithionite in Tris buffer or an equivalent volume of Tris buffer was diluted to a concentration of 88 mM in PBS and incubated with the cells for 5 min. Following incubation, cells were rinsed three times with PBS and imaged immediately by bright-field and fluorescence microscopy using a standard FITC filter set.

2.3. Measurement of Internalization and Transfection Efficiencies. *2.3.1. Validation of Internalization Measurements by Fluorimetry and Flow Cytometry.* HeLa cells were seeded at 8×10^4 cells/well on a 24-well plate for fluorimetry or at 3×10^5 cells/well on a 6-well plate for flow cytometry and allowed to attach overnight. Cells were rinsed with PBS and preincubated in OptiMEM at 4 or 37 °C for 1 h. NBD-labeled polyplexes (N/P = 5) were formulated as described in section 2.1.2., with the exception that polyplexes were formulated in water. After polyplex addition, cells were incubated at 4 or 37 °C for an additional hour. Medium was removed and cells were incubated with cold 10 mM Tris in PBS with or without 10 mM dithionite for 2 min. Cells were then rinsed 2 times with PBS. For flow cytometry, cells were harvested by trypsinization, and cell populations in each sample were analyzed for mean fluorescence using a BD FACScan analyzer. Cell lysate was prepared for fluorimetry by resuspending cells in 0.1% Triton X-100 in water. After one freeze–thaw cycle, 10× PBS was added to the lysate for a final concentration of 1× prior to fluorescence measurements. Experiments were performed in triplicate, and values are reported in relative fluorescence units.

2.3.2. Measurement of Internalization and Transfection Efficiencies for Polyplexes and Lipoplexes. HeLa cells were seeded at 8×10^4 cells/well on a 24-well plate and allowed to attach overnight. Cells were rinsed with PBS and preincubated with OptiMEM at 37 °C for 1 h. Polyplexes (N/P ratios of 10,

7, 5, and 3) and lipoplexes (L2K/DNA ratios of 3:1, 1:1, and 0.5:1) were formulated using NBD-labeled oligonucleotides or gWiz Luciferase plasmid (Aldevron; Fargo, ND) as described previously. Cells were incubated with polyplex or lipoplex solutions at 37 °C for 5 h. For internalization measurements, dithionite treatment and lysate preparation were performed as described in section 2.3.1. For transfection efficiency measurements, media was replaced after 5 h and reporter gene expression was measured 48 h later. To measure luciferase reporter gene expression, cells were lysed with Reporter Lysis Buffer (Promega; Madison, WI) and luciferase activity was measured using Promega's luciferase assay system. Total protein in lysate samples was measured using a Micro BCA Protein Assay Kit (Pierce; Rockford, IL). Values are reported in relative light units (RLU)/mg protein and are the mean ± standard deviation of triplicate samples.

2.4. Ratiometric Imaging To Differentiate between Intracellular and Extracellular Material in Neuron-Like Cells. *2.4.1. Culture of Neuron-Like PC-12 Cells.* PC-12 cells were obtained from ATCC (CRL-1721) and were cultured in F12-K medium supplemented with 15% horse serum, 2.5% fetal bovine serum, and antibiotics in a 37 °C, 5% CO_2 environment. Cells were fed by replacing the growth medium every 2–3 days and were passaged when ~80% confluent. Cells were detached from the flask by exposure to trypsin-EDTA for 2 min and were collected in 1 mL of F12-K medium. To obtain a single-cell suspension, cells were passed through a series of fire-polished glass pipettes of decreasing diameter. For differentiation to a neuron-like phenotype, cells were plated on a poly(D-lysine)-coated flask in differentiation medium consisting of F12-K medium supplemented with 1% horse serum, antibiotics, and NGF at a concentration of 100 ng/mL.

2.4.2. Ratiometric Imaging To Differentiate between Intracellular and Extracellular Material. NBD/TR-double-labeled oligonucleotides were complexed with L2K at an L2K/DNA ratio of 3 as described in previous sections. Lipoplexes were adsorbed to the surface of wells of a 96-well plate by incubation for 1 h at room temperature. Dithionite was added to samples at a final concentration of 88 mM and incubated for 5 min at room temperature before rinsing with PBS. As a negative control for NBD quenching, an equivalent volume of Tris buffer was added to lipoplexes in separate wells. Green and red fluorescence images were taken in each sample using identical image acquisition settings. Ratio analysis was performed using *MetaMorph* software to measure the green/red signal ratio for individual particles in dithionite-treated and untreated wells. Specifically, a particle was selected in the red image, and the integrated pixel intensity was measured using the Region Measurements function in *MetaMorph*. The integrated pixel intensity for the particle was corrected for background fluorescence based on the integrated pixel intensity of a background region near the particle. Background-subtracted integrated pixel intensity values measured in both the green and red channels were used to calculate the green/red signal ratio.

Six-day differentiated, neuron-like PC-12 cells were plated sparsely on a poly(L-lysine)-coated 24-well plate to allow separation between cells and were allowed to attach overnight. TR/NBD-double-labeled lipoplexes were formulated using a 90/10 NBD−/TR−oligo mixture. Cells were incubated with lipoplexes for 3 h at 37 °C. Cells were then rinsed with PBS, incubated with PBS containing 88 mM dithionite for 5 min, rinsed 3 times, and imaged by bright-field and fluorescence microscopy. Internalized material was confirmed using the image analysis techniques described above.

RESULTS

3.1. Packaged NBD-Labeled Oligonucleotides Are Quenched by Dithionite. NBD fluorescence is irreversibly quenched upon exposure to dithionite by the reaction illustrated in Scheme 1. It was previously demonstrated that brief exposure to dithionite at concentrations up to 100 mM is nontoxic to cells, and that the NBD nitro group reduction occurs efficiently at a dithionite concentration of 88 mM (*4*). As shown in Figure 1A, brief exposure of NBD-labeled oligonucleotides to 88 mM dithionite quenched their fluorescence by 99%.

NBD-labeled oligonucleotides were also examined for their susceptibility to dithionite-mediated quenching when incorporated into lipid- or polymer-based gene delivery systems, termed "lipoplex" and "polyplex", respectively (Figure 1A). Condensation of NBD-labeled oligonucleotides by cationic lipids or polymers caused slight fluorescence quenching prior to the addition of dithionite. Quenching is commonly observed upon condensation of fluorophore-labeled DNA with polycations, as tight packing leads to fluorophore self-quenching. Still, the remaining NBD fluorescence was readily detectable above background. Dithionite exposure reduced the fluorescence signal by 99% and 98% for lipoplexes and polyplexes, respectively, and the resulting fluorescence levels were only slightly above background.

To serve as a useful probe that discriminates between extra- and intracellular gene carriers, NBD−oligos must be insensitive to pH fluctuations such as the acidification that occurs when gene carriers are transported through the endo/lysosomal pathway. The fluorescence emission from NBD−oligos was compared at pH values of 4.5, 7.4, and 10.0 to determine the effect of pH on fluorescence emission. Exposure to acidic or basic environments did not significantly influence the NBD emission intensity (Figure 1B).

3.2. NBD-Labeled Gene Carriers Exposed To Cells Function as an Environmentally Sensitive Probe. To validate NBD-labeled gene carriers as a tool for distinguishing between bound and internalized material in cells, polyplexes incorporating NBD-labeled oligonucleotides were incubated with HeLa cells at either 4 or 37 °C and were subsequently exposed to dithionite to quench extracellular fluorescence. Since endocytosis is inhibited at 4 °C, it was expected that the labeled material would bind to, but remain outside of, cells. In contrast, it was expected that the gene carriers would be internalized by cells during incubation at 37 °C. As shown in Figure 2A,B, the fluorescence signal from NBD-labeled polyplexes that bound to cells at 4 °C was quenched by exposure to dithionite. In contrast, when cells were incubated with NBD-labeled polyplexes at 37 °C, polyplexes underwent internalization into cells, and the signal from internalized polyplexes was not quenched due to the inability of dithionite to penetrate cellular membranes (Figure 2C,D). Similar results were obtained for NBD-labeled lipoplexes (data not shown).

3.3. Validation of Internalization Measurements Based on Quenching of Extracellular NBD Fluorescence. The degree of cellular internalization of gene carriers, determined the amount of unquenched NBD−oligo in dithionite-treated cell populations, was measured both by flow cytometry and by fluorescence measurements in cell lysates. To validate internalization measurements based on NBD fluorescence remaining after dithionite treatment, internalization was also measured by inhibiting endocytosis in samples that were not treated with dithionite (Figure 3). Since endocytosis is inhibited at 4 °C, the fluorescence of internalized polyplexes can be calculated by subtracting total cell-associated fluorescence. The fluorescence of internalized polyplexes is calculated by subtracting total cell-associated fluorescence of cells incubated with polyplexes at 4 °C from total cell-associated fluorescence of cells incubated

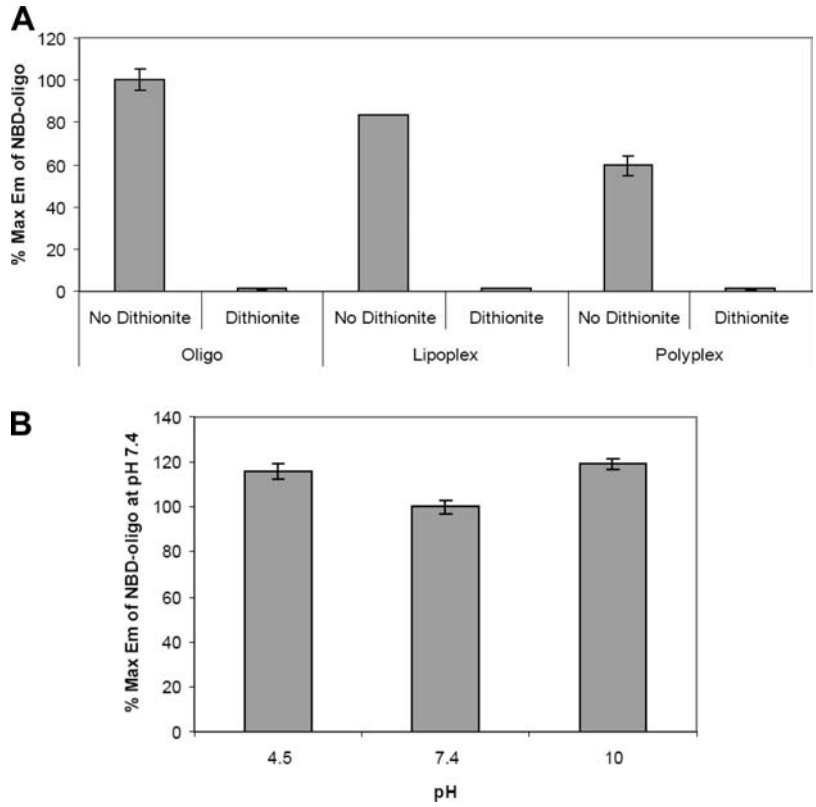

Figure 1. Effect of dithionite treatment and pH on NBD fluorescence emission intensity. (A) Fluorescence emission of NBD-labeled oligonucleotides and lipid- and polymer-based gene carriers incorporating NBD-labeled oligonucleotides was measured in the presence and absence of dithionite. Values are presented as the percentage fluorescence emission compared to an equivalent amount of uncomplexed, unquenched NBD−oligo ± standard deviation. (B) Fluorescence emission of NBD−oligos was measured in acidic, neutral, and basic buffers. Values are presented as the percentage fluorescence emission compared to an equivalent amount of NBD−oligo in PBS (pH 7.4) ± standard deviation.

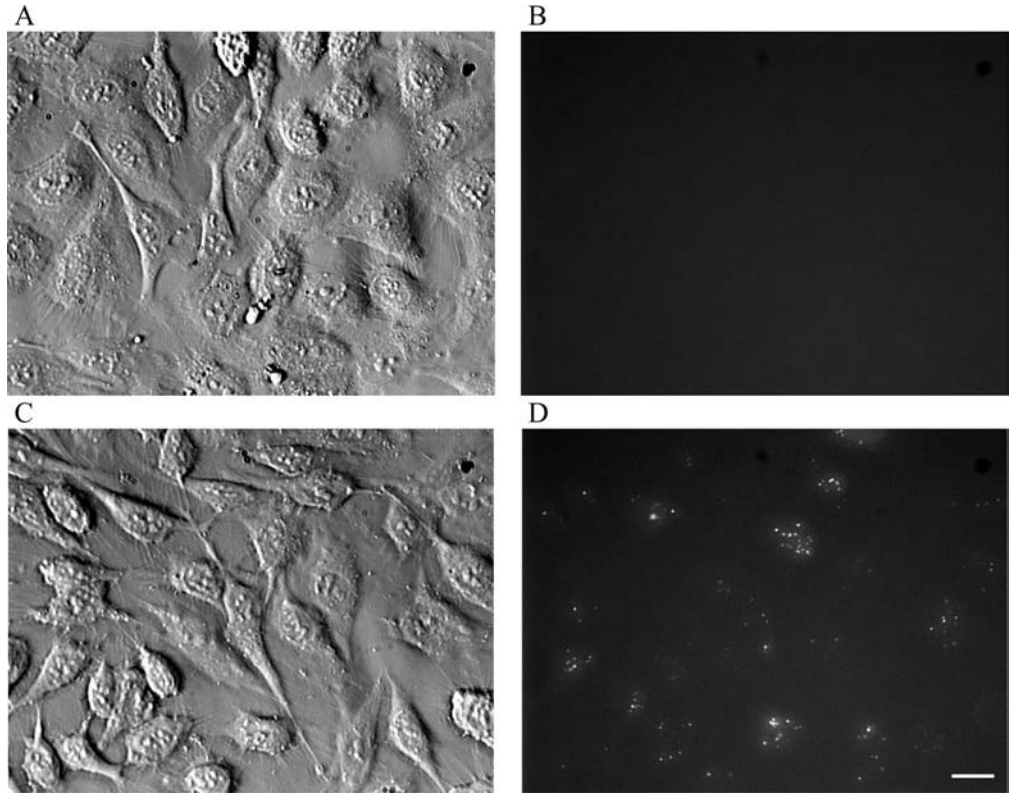

Figure 2. Selective quenching of cell-associated, uninternalized gene carriers in HeLa cells. NBD-labeled polyplexes that were bound to HeLa cells at 4 °C, but not internalized, were quenched by dithionite (A,B), while polyplexes incubated with cells for 3 h at 37 °C were internalized and protected from dithionite-mediated quenching (C,D). Bright-field and corresponding fluorescence images are shown (scale bar = 20 μm).

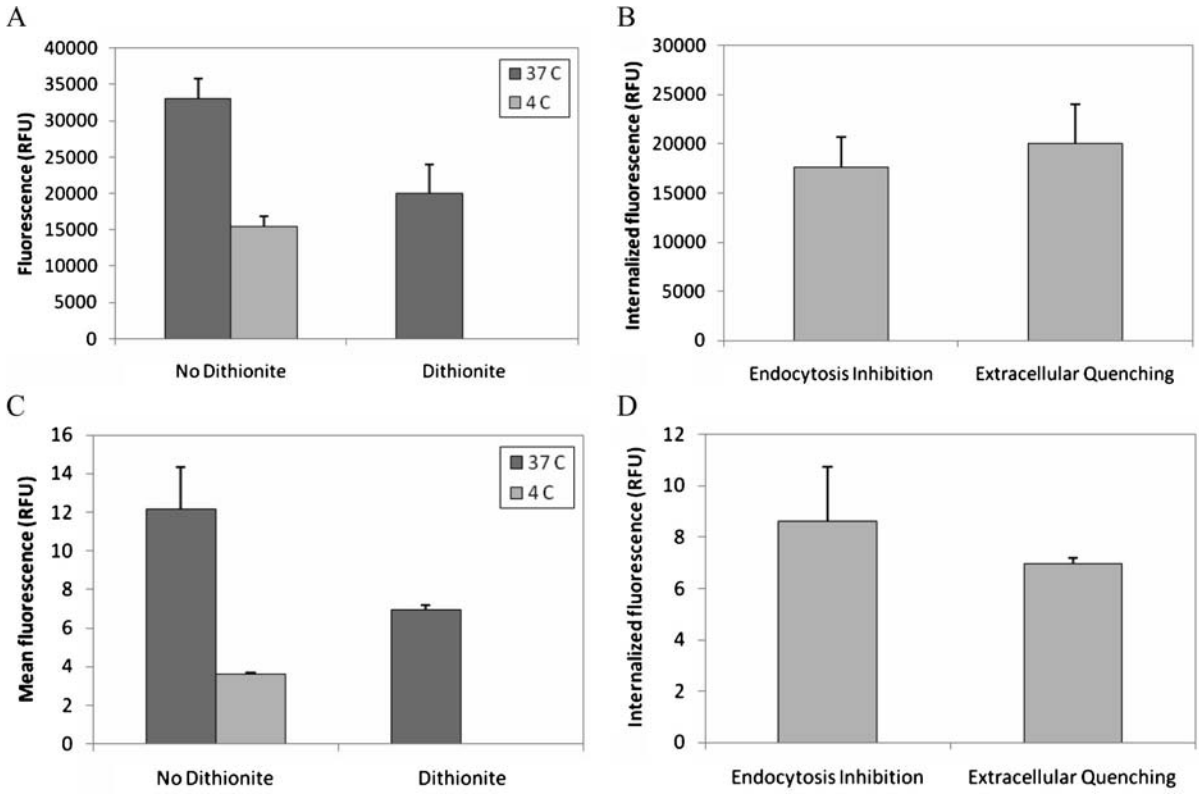

Figure 3. Quantification of vector internalization by endocytosis inhibition vs extracellular quenching with dithionite treatment. Cells were incubated with NBD-labeled polyplexes at 37 °C to allow binding and endocytosis of gene carriers. For endocytosis inhibition, a separate cell sample was incubated with polyplexes at 4 °C. For extracellular quenching with dithionite treatment, cells were incubated with polyplexes at 37 °C and then briefly treated with dithionite to quench extracellular fluorescence. NBD fluorescence was measured in cell lysates using a plate reader (A) and in suspensions of whole cells based on flow cytometry analysis (C). The degree of cellular internalization of polyplexes was measured either by subtracting cell-associated fluorescence at 4 °C from cell-associated fluorescence at 37 °C (No Dithonite) or by measuring unquenched fluorescence associated with cells following dithionite treatment (Dithionite). Differences in the degree of polyplex internalization measured on the basis of endocytosis inhibition vs dithionite quenching were not statistically significant using either fluorescence measurements in lysate (B) or flow cytometry data (D).

with polyplexes at 37 °C. Dithionite treatment of cells incubated with polyplex at 4 °C abolishes all fluorescence (Figure 3A,C). Therefore, it was hypothesized that the amount of internalized polyplex can also be determined quantitatively by simply measuring the total cell fluorescence from dithionite-treated cells. As shown in Figure 3B,D, internalization measurements derived from dithionite-treated cells were in close agreement with those based on a comparison between cell-associated fluorescence in samples incubated with polyplexes at 37 °C with those incubated at 4 °C ($p > 0.05$) with both flow cytometry and fluorescence measurements of cell lystates. Similar data were obtained when cells were treated with NBD-labeled lipoplexes (data not shown). Thus, dithionite treatment of cells exposed to NBD-labeled vectors can be used as a rapid method to quantify internalization. It should be noted that, for studies involving the quantification of internalized vectors, dithionite treatment methods were modified to reduce the extent of exposure of cells to dithionite. Specifically, the dithionite concentration was reduced from 88 mM to 10 mM and the incubation time was reduced from 5 min to 2 min. Under these conditions, extracellular materials were efficiently quenched, while the quenching of internalized materials due to leakage of dithionite across the cell membrane was minimized.

3.4. Degree of Internalization of Gene Carriers Varies with Formulation Parameters. The degree of internalization of various polyplex and lipoplex formulations was compared to the transfection efficiency mediated by the same formulation. As shown in Figure 4, both internalization and transfection efficiencies differed significantly between lipoplexes and polyplexes. Interestingly, while lipoplex internalization by cells was at least 4-fold less efficient than polyplex internalization, reporter gene expression in the lipoplex-treated samples was 2 orders of magnitude higher. Although some fluorescence quenching occurs upon condensation of NBD−oligos by cationic polymers and lipids (Figure 1), exposure of NBD-labeled lipoplexes and polyplexes to cell lysate containing 150 mM NaCl resulted in full vector unpackaging and fluorescence recovery (data not shown). Hence, the internalization data reported here are not confounded by differences in the degree of NBD−oligo self-quenching.

3.5. NBD/Texas Red Double-Labeled Gene Carriers Enable Discrimination between Internalized and Cell-Associated Materials in Neuron-Like Cells. In order to simultaneously image surface-bound and internalized vectors, lipoplexes were double-labeled with the nonquenchable, pH-insensitive dye, Texas Red (TR), along with NBD. As expected, the NBD signal in double-labeled lipoplexes was quenched by dithionite, while the TR signal remained unaffected (Figure 5). To quantitatively differentiate between uninternalized and internalized particles, ratiometric analysis methods were established using microscopy images of NBD/TR-double-labeled lipoplexes. A comparison of dithionite-treated versus untreated lipoplexes revealed that the green/red fluorescence emission ratios obtained were significantly different between treated and untreated lipoplexes (Figure 6A). By applying ratiometric analysis to images NBD/TR-lipoplex-exposed, dithionite-treated cells and by comparing green/red fluorescence ratios of individual particles to the values obtained from quenched or unquenched particles in Figure 6A, it was possible to confirm internalization

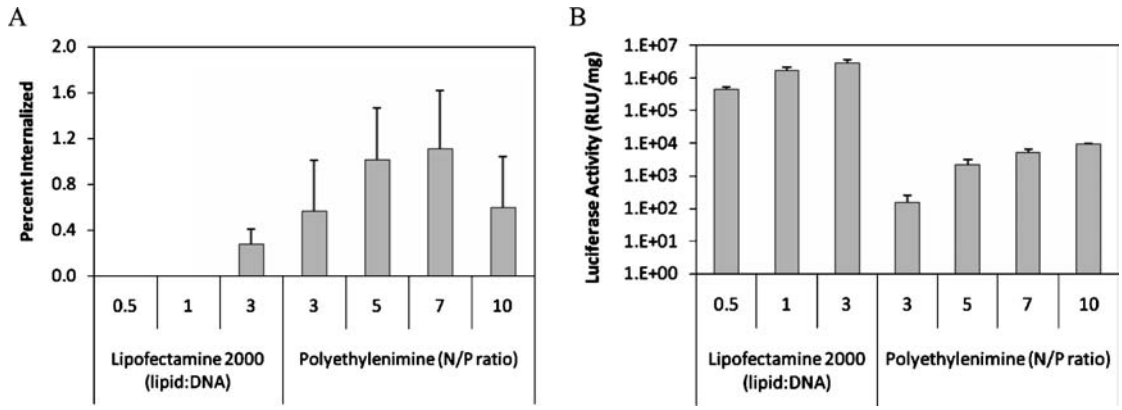

Figure 4. Correlation between the degree of vehicle internalization and transfection efficiency. (A) The degree of cellular internalization of various lipoplex and polyplex formulations incorporating NBD−oligos was determined on the basis of the amount of unquenched NBD fluorescence following dithionite treatment, and was normalized by the total NBD fluorescence added to the cells. (B) Transfection efficiencies of identical formulations incorporating luciferase-encoding plasmid DNA are presented as mean RLU/mg protein ± standard deviation.

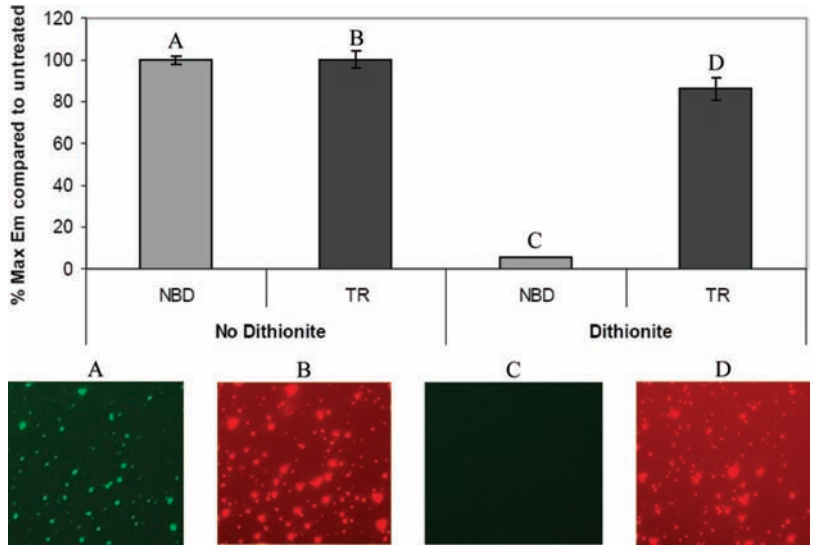

Figure 5. Selective quenching of NBD in double-labeled lipoplexes. NBD/TR-double-labeled lipoplexes were examined by fluorimetry and fluorescence microscopy.

of a fraction of the lipoplexes that bound to neuron-like PC-12 cells (Figure 6B,C).

DISCUSSION

Efficient intracellular delivery of DNA or RNA is critical for the success of nucleic acid based therapies. A method to rapidly determine the efficiency of delivery vector uptake in mammalian cells would contribute toward the design and selection of promising delivery vehicles. For example, screening of polymer suites and libraries has yielded new materials with improved delivery efficiencies (*5–7*). Subsequent determination of the efficiency of specific cellular trafficking steps would provide valuable insights on structure–function relationships. Since most carriers form positively charged nanoparticles upon complexation with nucleic acids, and since these particles are known to bind robustly to the cell membrane through electrostatic interactions, methods are necessary to distinguish between carriers that are internalized by cells and those which remain associated with the cell surface but fail to internalize. Additionally, the ability to discriminate between extra- and intracellular materials would enable evaluation of the spatiotemporal distribution of gene carriers in cells using standard wide-field microscopy.

Various methods have been described to discriminate between surface-bound and internalized materials. Notably, several dye/quencher combinations have been employed to eliminate fluorescence from uninternalized materials associated with cells. For example, antibodies raised against fluorescent dye molecules, such as fluorescein, can selectively quench extracellular fluorescence due to tight binding of the antibody to the dye (*8, 9*). Additionally, treatment of cells with Trypan Blue eliminates extracellular green fluorescence through an energy transfer mechanism (*10, 11*). This technique has been employed to quench extracellular fluorescence associated with gene carriers and fluorescent microspheres (*12–14*). Finally, washing cells with buffers containing high salt concentrations has been utilized to dissociate complexes adsorbed to the cell surface through electrostatic interactions (*15, 16*). While implementation of these quenching techniques has provided important insight into the internalization efficiencies of various macromolecules, these techniques have limitations for the analysis of gene carrier internalization. First, it is unclear how efficiently antibodies can access fluorophores that are packaged within nanoparticles consisting of cationic lipids or polymers and nucleic acids. Additionally, the efficiency of quenching with Trypan Blue has been shown to depend on the specific brand of Trypan Blue used (*17*). Finally, since previous methods to quench extracellular fluorescence have employed fluorescein-labeled gene carriers, it is important to consider that the pH sensitivity of fluorescein can confound measurements of internalization, since

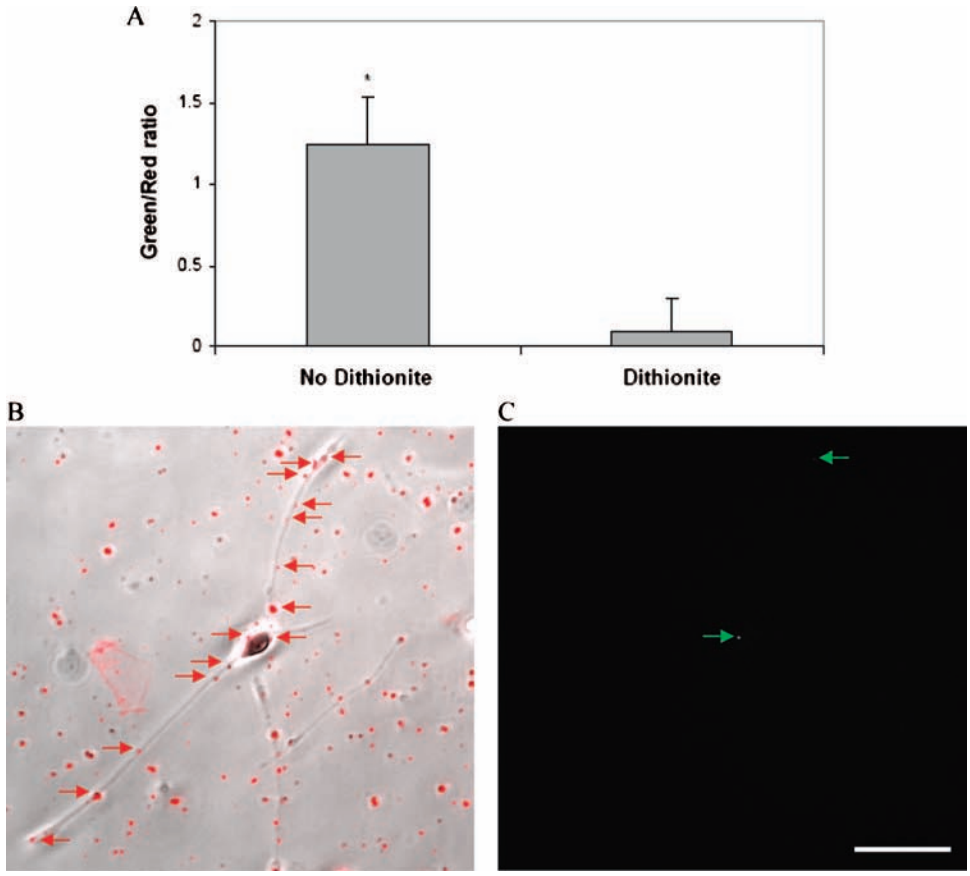

Figure 6. Ratiometric analysis distinguishes between intracellular and extracellular lipoplexes in neuron-like PC-12 cells. (A) The ratio of NBD to TR fluorescence signals is significantly different between dithionite-treated and untreated particles (*$p < 0.001$). NBD/TR-double-labeled lipoplexes that associated with the cell are indicated by red arrows in the bright-field/fluorescence overlay image (B), while lipoplexes that were internalized retained NBD fluorescence and are indicated by green arrows (C) (scale bar = 50 μm).

its fluorescence may also be reduced in acidic intracellular compartments. The NBD/dithionite combination described here offers a reliable and cost-effective alternative.

In this work, NBD-labeled oligonucleotides were incorporated into polymer- and lipid-based nonviral gene carriers to differentiate between internalized vehicles and uninternalized vehicles associated with the cell plasma membrane. NBD-labeled gene carriers were quenched by exposure to dithionite but retained their fluorescence in the intracellular milieu due to the relative impermeability of the cell plasma membrane to dithionite. As a demonstration of the utility of NBD−oligos in formulation screening, the internalization efficiencies of various polyplex and lipoplex formulations were measured. Internalization measurements were then compared to the efficiency of reporter gene expression mediated by the same formulation. Interestingly, while lipoplexes were internalized less efficiently than polyplexes, they mediated significantly higher transfection efficiencies in the cell line tested. This phenomenon was previously observed by Varga et al. (*18*) and is likely due to the enhanced intracellular trafficking efficiency of lipoplexes compared to polyplexes. Consequently, while internalization measurements may serve as an initial, rapid screen to identify formulations with high binding and internalization efficiencies, transfection screening should also be performed to uncover differences in the intracellular trafficking efficiencies of internalized materials.

It should be noted that slow diffusion of dithionite through cell membranes has been observed and can result in intracellular fluorescence quenching (*4*). However, NBD quenching of extracellular material occurs within seconds, whereas leakage through the cell membrane takes place on the order of minutes. The timing of fluorescence measurements may require optimization, especially for systems where perturbations to the integrity of the cell membrane can occur. Protocols have been described to account for the permeability of cellular membranes by measuring the initial rate of quenching, rather than the extent of quenching, and could be utilized if a highly precise determination of gene carrier internalization were required (*19*). Nonetheless, the NBD/dithonite combination described here offers a means for facile evaluation of gene carrier internalization that does not suffer from the limitations of previously described approaches.

NBD−oligos are also useful to distinguish between extracellular and internalized materials by fluorescence microscopy. Confocal laser scanning microscopy is routinely employed to study the intracellular distribution of nonviral gene carriers in cells. By taking optical slices as thin as 0.5 μm, confocal imaging has revealed the intracellular distribution of fluorescently labeled gene carriers in fibroblasts and other cell types with subcellular detail (*20*). However, this technique is not reliable for imaging gene carriers in neuronal projections, where the depth of field is similar in size to the typical neurite diameter. This limitation was encountered by Suk et al. (*21*) in a study of the intracellular transport of PEI/DNA polyplexes in rat primary neurons. Although it is possible to narrow the slice depth in confocal images by applying digital deconvolution algorithms, it would be beneficial to develop an alternative method for differentiating between internalized and surface-bound gene carriers that can be implemented using conventional wide-field fluorescence microscopy. By incorporating mixtures of NBD- and TR-labeled oligonucleotides into gene carriers and employing ratiometric imaging, it was possible to reliably differentiate

between extra- and intracellular lipoplexes in the neurites of NGF-differentiated PC-12 cells. This concept is similar to ratiometric imaging of fluorescein/Cy5-labeled gene vectors to measure the pH environments of gene carriers in the cell, which has been described previously (*8*, *22*), but it investigates a different step in the delivery pathway.

In future applications, the NBD/dithionite system can potentially be exploited to measure the efficiency and dynamics of cell binding, internalization, and vesicular escape of gene carriers. While brief exposure of cells to dithionite quenches primarily extracellular NBD fluorescence, exposure beyond 30 s begins to slowly quench cytoplasmic fluorescence at a rate of approximately 4% per minute due to slow leakage of dithionite across the outer plasma membrane (*4*). However, NBD enclosed by intracellular vesicles such as endosomes remains largely unquenched by dithionite that leaks into the cytoplasm (*23*). By exposing cells to NBD-labeled gene carriers and measuring the quenching kinetics of NBD, it may be possible to measure the percentages of surface-bound, vesicle-enclosed, and cytosolic gene carriers. Since it is of interest to compare different gene vectors for their abilities to escape from endosomes, comparative studies using NBD-labeled oligonucleotides condensed by various polymers or lipids would elucidate structure–function relationships, while avoiding more time-consuming techniques such as subcellular fractionation.

Well-Defined Nanoassemblies Using Gold Nanoparticles Bearing Specific Number of DNA Strands

Wei Jie Qin and Lin Yue Lanry Yung*

Department of Chemical and Biomolecular Engineering, National University of Singapore, 10 Kent Ridge Crescent, Singapore 119260. Received May 18, 2007; Revised Manuscript Received October 10, 2007

The accurate assembly of nanoparticles into specially designed structures is important for the application of nanoparticle-based materials. Here we report the fabrication of well-defined nanoparticle assemblies via the grouping of gold nanoparticles bearing a specific number of short DNA per particle. Furthermore, we explored various conditions that affect the grouping. Our results show that direct linkage of two nanoparticle-bound DNA without the use of linker DNA yields 80% grouping, which is the highest of all conditions tested. Longer hybridization times and buffer conditions with higher ionic strength also increase grouping formation. These results provide key knowledge that controls the hybridization of nanoparticle-bound DNA for achieving well-defined nanoassemblies with high yield.

INTRODUCTION

Driven by the need from nanotechnology, materials science, and biological and biomedical applications, various approaches for the fabrication of defined nanostructures have been developed in recent years (*1, 2*). Among them, the bottom up approach in which nanometer-scaled building blocks are assembled into larger entities attract the most attention (*3*). Within these areas, great efforts have been directed to the self-assembly of hybrid materials from inorganic nanoparticles and biomolecules, such as DNA, RNA, and proteins (*4, 5*). Metallic, semiconductor, and magnetic nanoparticles are commonly used components in the bottom up self-assembly. Because of their small size, nanoparticles show unique chemical and physical properties and have great potential in the development of functional nanoassembly (*6–9*), chemical sensors (*10*), biomolecular electronics (*11, 12*), and biological applications (*3, 13*).

The realization of above applications requires deliberate and accurate arrangement of nanoparticles into predesigned structures. DNA molecules, which possess unique molecular recognition capability and mechanical rigidity as well as high-precision enzyme processibility, are particular attractive for applications demanding accurate arrangement and a high degree of structural control (*14–16*). Furthermore, DNA molecules can be synthesized readily in a predesigned length and sequence with various functional groups for the conjugation or fluorescent detection. Thus, DNA is a highly promising molecule for directing programmable self-assembly and has been extensively used to fabricate nanostructured scaffolds as well as position proteins, metal, or semiconductor nanoparticles and other molecular devices (*17–19*). The combination of DNA molecules with inorganic nanoparticles has led to the development of novel hybrid materials that incorporate the sequence specific recognition capability of DNA molecules with the size-dependent optical, electrical, magnetic, and catalytic properties of nanoparticles.

The collective properties of nanoparticles are mainly dependent on their hierarchical arrangements and interparticle distance. For example, noble metallic nanoparticles have plasmon resonances in the visible range and do not blink or bleach. The wavelength of this plasmon resonance shifts upon varying the distance between nanoparticles. Applying the shifting of plasmon resonance as the nanoscale distance monitoring tool requires precise control over the distance between nanoparticles to allow the propagation of light along a defined path efficiently (*20, 21*). However, there have been only a limited number of studies focused on fabricating nanoparticle−DNA assemblies with very well-defined structure, such as dimer, trimer, and other higher order multimers (*22, 23*).

Previously we have shown that gold nanoparticle−DNA (nAu-DNA) conjugates bearing specific number of short DNA can be prepared by gel electrophoresis isolation followed by restriction endonuclease manipulation of the nanoparticle (nAu)-bound DNA (*24*). Here, we further demonstrate how these conjugates can be used to construct well-defined nanogroupings. The effects of interparticle spacing as well as nAu−linker DNA interactions on the final conjugate grouping were studied. In our approach, two sets of specially designed nAu-DNA conjugates are first modified with a specific number (1, 2, 3. . .) of short single stranded DNA (ssDNA) that are not directly complementary to each other. These conjugates do not recognize each other until a complementary linker DNA, which hybridizes to the DNA on both sets of conjugates, is introduced. Only conjugate groupings with defined structure (dimer or trimer) can form due to the fixed number of DNA on each nAu. The resulting conjugate groupings are analyzed and quantified by agarose gel electrophoresis. The size differentiation ability of gel electrophoresis enables separation and identification of different nAu grouping structures, such as monomers, dimers, and trimers.

MATERIALS AND METHODS

Materials. Hydrogen tetrachloroaurate (III) trihydrate, trisodium citrate dihydrate, tannic acid, 4,4′-(phenylphosphinidene) bis-(benzenesulfonic acid) (PPBS), dithiothreitol (DTT), NaCl, $MgCl_2$, and tris-borate-EDTA (TBE) buffer were purchased from Sigma-Aldrich. The synthetic DNA (modified with thiol linker at the 5′ end) was purchased from Integrated DNA Technologies (IDT). Restriction endonuclease EcoR V (500000 unit/mL) was obtained from New England Biolabs. Acrylamide/Bis solution (30%) (29:1) and ethidium bromide were obtained from Bio-Rad Laboratories. Agarose was purchased from

Cambrex. Dialysis tubing (Float-A-lyzer, MWCO: 3500) was obtained from Spectra/Por. Milli-Q water with resistance >18 MΩ/cm was used throughout the experiments.

Synthesis and Characterization of Gold Nanoparticles. Gold nanoparticles (nAu) were synthesized by the reduction of hydrogen tetrachloroaurate (III) trihydrate by trisodium citrate dihydrate and tannic acid (*25*). In order to determine the size and size distribution of the resulting nAu, TEM characterization was performed on a Philips CM300 FEG system operating at 200 kV. At least 200 particles were sized from TEM micrographs via the graphics software Image-Pro Express (Media Cybernetics). The mean particle diameter was 10 nm, and the size distribution was within 15% of the mean diameter.

Preparation of nAu-DNA Conjugates. The DNA sequences used in this study are shown in Figure 1 (complete sequences are shown in Figure S1, Supporting Information). Two complementary single-stranded DNA (ssDNA), one modified with a thiol linker, were allowed to hybridize to form a double-stranded DNA (dsDNA). Strand A′, strand B′, and strand revB2′ were modified with a 5′ thiol linker, whereas strand revA′ and strand revB1′ were with a 3′ thiol linker. These dsDNA were used to prepare different sets of conjugates (nAu-A′ and nAu-revA′, nAu-B′ and nAu-revB1′, and nAu-B′ and nAu-revB2′) for grouping studies. The detailed procedure of conjugate preparation can be found in our previous work (*24*). Briefly, 2 μM dsDNA was mixed with nAu for 2 h followed by 5-T ssDNA for surface passivation. Excess reagents were then removed by repeated washing and centrifuging the conjugates with 0.5× TBE.

Agarose Gel Electrophoresis Isolation and Extraction of nAu-DNA Conjugates. Agarose gel electrophoresis (3% agarose at 5 V/cm and 0.5× TBE as running buffer) was carried out for 4 h to separate the conjugates bearing from one to three dsDNA molecules. Discrete bands can easily be identified because of the wine-red color of nAu. Desired bands were extracted from the gel, and the conjugates were then recovered by electrophoretic dialysis (*26*). After recovery from agarose gel, the conjugates were purified by repeated washing (with 50 mM tris buffer, pH 8.0) and centrifuging to ensure the complete removal of EDTA, which may deactivate the restriction endonuclease.

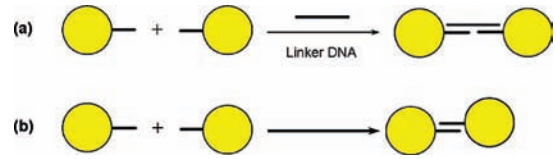

Figure 2. Schematic picture of the formation of nAu-DNA conjugate groupings. (a) Either the pair nAu-A + nAu-revA or nAu-B + nAu-revB1 with linker DNA. (b) Direct pairing of nAu-DNA conjugate using nAu-B + nAu-revB2 without linker DNA.

Enzyme Manipulation of nAu-Bound DNA and Digestion Efficiency. The restriction endonuclease digestion of nAu-bound dsDNA (strand A′ to strand A, strand revA′ to strand revA, etc.) was performed by incubating the conjugates with 100 units of EcoR V at 37 °C in a 200 μL reaction buffer for 20 h. After incubation, the enzyme was deactivated by adding 50 mM EDTA. As shown previously, the digested conjugates (nAu-A, nAu-revA, etc.) were analyzed by polyacrylamide gel electrophoresis (PAGE) to confirm the digestion efficiency and yield of nAu conjugates with a specific number of DNA strands (*24*). Briefly, the digested samples were first centrifuged (13000*g* for 15 min) to separate digested DNA from nAu, and the digested DNA was loaded into a 12% gel for electrophoresis (0.5× TBE as running buffer). The DNA bands were stained with ethidium bromide and visualized by a Syngene GeneGenius UV/white light gel documentation system. The enzyme digestion efficiency was calculated by quantifying digested DNA fragments using gel analysis software from the manufacturer.

Formation and Analysis of nAu-DNA Conjugate Groupings. A pair of nAu-DNA conjugates (nAu-A with nAu-revA, nAu-B with nAu-revB1, etc.), each carrying a single DNA strand (1.5 pmol of each), were mixed in a buffer containing 50 mM tris at pH 8.0, 100 mM NaCl, and 2 mM $MgCl_2$ at a 1:1 molar ratio. Different linker DNA molecules (Figure 1) were then added to the mixture to allow the hybridization of linker DNA with the complementary strands attached to the nAu surface in a tail-to-tail configuration (Figure 2a). The hybridization of cDNA to link nAu conjugates was carried out by first heating the sample to 70 °C for 2 min to ensure complete melting of the DNA strands followed by slow cooling down to 25 °C at a rate of 0.2 °C/min. After the formation of conjugate groupings, agarose gel electrophoresis (3% agarose at 5 V/cm, 0.5× TBE as running buffer) was carried out at 4 °C to characterize and quantify the conjugate groupings. Desired bands of conjugate groupings were visualized by a Syngene GeneGenius UV/white light gel documentation system or a Bio-Rad GS-800 calibrated densitometer. The grouping percentage of nAu-DNA conjugates was calculated by quantifying the relative optical intensity of the gel bands using gel analysis software from the manufacturer, more specifically, dividing the amount of conjugate groupings by the total amount of conjugates in the same lane (unbound conjugates + conjugate groupings). Each value reported was the average of three individual tests. For the study on the relative mobility of conjugate groupings in 3% agarose gel, the elapsed time and the corresponding position of the conjugate groupings were monitored and recorded during electrophoresis. The positions of the gel bands from seven different electrophoretic durations (1 to 5 h) were then measured. The conjugate

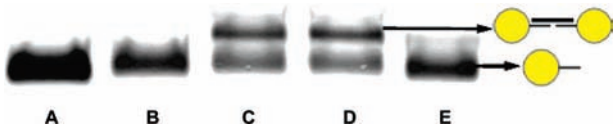

Figure 3. Conjugate grouping of nAu-DNA conjugates with various lengths of DNA linker. Lane A corresponds to the conjugate without DNA modification, and lanes B, C, D, and E correspond to conjugates nAu-A + nAu-revA with no linker, with 26-, 24-, and 22-base linker DNA respectively. The stoichiometric ratio of nAu-A, nAu-revA, and linker DNA is 1:1:1.

groupings were next extracted from the gel and recovered by electrophoretic dialysis (*26*) for TEM characterization.

RESULTS AND DISCUSSION

Grouping percentage of nAu-DNA conjugates using linker DNA of different lengths. As reported earlier by Alivisatos and co-workers (*27*), agarose gel electrophoresis can only be used to isolate nAu-DNA conjugates bearing specific numbers of long DNA molecules. For DNA with 50 bases or less, electrophoresis fails since the electrophoretic mobility difference between conjugates bearing different numbers of DNA strands is insignificant. To obtain nAu-DNA conjugates bearing specific numbers of short DNA, we have used an approach that combines both agarose gel electrophoresis and endonuclease digestion (*24*). First, agarose gel electrophoresis is used to isolate nAu-DNA conjugates bearing different numbers of long DNA strands. Subsequently, the conjugates with specific numbers of DNA strands are treated with EcoR V digestion to cleave DNA into shorter strands. In this way, the number, length, and sequence of the DNA strands on the resultant conjugates are precisely controlled. Restriction endonucleases are enzymes that recognize short specific DNA sequences and cleave the DNA (*28*). Their use on nAu-bound DNA has been reported by several groups (*29–32*) including us (*24, 33*). The enzyme digestion efficiency of 10 nm nAu-bound DNA obtained from PAGE (data not shown) shows that above 90% digestion can be achieved for all of the five dsDNA (strands A′, revA′, B′, revB1′, and revB2′). The high digestion efficiency leads to short and homogeneous DNA on nAu that is critical for the subsequent conjugate assembly formation.

When nAu-A and nAu-revA conjugates were mixed with linker DNA, a tail-to-tail dimer configuration (Figure 2a) was formed to reduce the steric hindrance and allow maximum grouping. Since both nAu-A and nAu-revA were bound with only a single DNA strand, other higher order structures (trimers, tetramers, etc.) were not obtained. The identification of these conjugate groupings is shown in Figure 3. The stoichiometric ratio of nAu-A, nAu-revA, and linker DNA used for assembling is 1:1:1. Since strand A and strand revA are not complementary to each other, a linker is needed for the formation of conjugate groupings. Lane A corresponds to the conjugates without strand A or revA modification (control). Lanes B, C, D, and E correspond to conjugates nAu-A and nAu-revA with no linker, 26-, 24-, and 22-base linker DNA, respectively. Using the band in lane B, which contains only nAu-DNA conjugate monomers, we can identify that the bands on the bottom of lanes C and D correspond to the unbound conjugate monomers (share exactly the same mobility with the band in lane B), and the bands on the top (with slower mobility) correspond to the conjugate dimers. The dimers with two nAu particles exhibit slower mobility due to the overall larger size that slows their movement through the gel. Dimer formation using two different sizes of nAu can also be achieved (see Figure S2 in Supporting Information). The presence of a single band in lane B also indicates no dimer formation due to nonspecific binding among the conjugates. Therefore, the hybridization of the cDNA linker with nAu-A and nAu-revA drives this dimer formation.

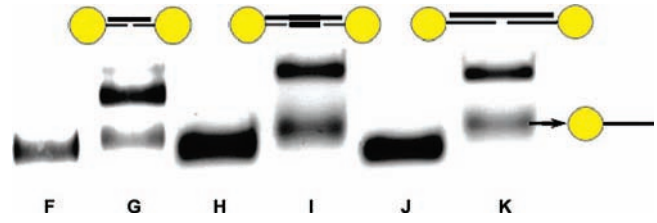

Figure 4. Conjugate grouping of nAu-DNA conjugates with various lengths of DNA linker. Lanes F, H, and J correspond to the conjugate without DNA modification, and lanes G, I, and K correspond to conjugates nAu-A and nAu-revA with 26-base, 48b + 22 bp, and nAu-B and nAu-revB1 with 60-base linker DNA, respectively. The gel pictures shown are combined results from different sets of experiments.

Inherently, cDNA hybridization is highly efficient; however, for dimerization of nAu conjugates via linker DNA, a mixture of monomers and dimers is found in the gel. As seen in lanes C and D in Figure 3, with linker DNA of different lengths, the yields of groupings using the 26- and 24-base linkers are only 55.6% and 55.3%, respectively, and even the nAu-A/nAu-revA/linker ratio is 1:1:1. Similar results were previously reported by Alivisatos and co-workers in which a complete grouping of nAu-DNA conjugates could not be achieved when a linker with a complementary sequence of 100 bases was used (*22, 23*). In addition, we have recently demonstrated in a separate study that using linkers to form dimer conjugates exhibits a linear relationship that allows quantitative measurement of the amount of linkers (*34*). However, this linear relationship only holds at a linker ratio of 0.5 or lower. At higher linker ratios, the grouping efficiency of the dimers starts to drop.

There are a number of factors that may affect the grouping efficiency (and percentage) of nAu conjugates, such as the length of the complementary bases of nAu-bound DNA to linker DNA, the length of linker DNA (distance between nAu conjugates in the resultant groupings), and the ways of formation of linkage (either through linker DNA or via direct hybridization of two nAu-bound DNA as shown in Figure 2b). Determining the dominant factor controlling the nAu grouping is crucial for achieving precisely organized nanoassemblies with high yield. The assembly of nAu conjugates using various kinds of linker DNA is shown in Figure 4. Lanes F, H, and J correspond to nAu without DNA conjugation (control), and lanes G and I correspond to conjugates nAu-A and nAu-revA with 26-base and 48b + 22 bp linkers (see Figure 1), respectively. Lane K is nAu-B and nAu-revB1 with the 60-base linker. Note that the 48 + 22 bp linker is a double stranded DNA with sticky ends that are complementary to the nAu-bound strands A and revA. The use of 48b + 22 bp dsDNA and 60-base ssDNA linkers (Lanes I and K) yields similar gel band distribution and grouping percentage compared with conjugates linked by 26-base ssDNA (lane G). All three conjugate dimer bands yield the maximum grouping percentages of approximately 55%. Increasing interparticle distance (Lane I) should reduce the charge repulsion between nAu conjugates, and increasing the number of complementary base pairing (Lane K) should lead to more stable grouping structure. However, higher grouping percentage is not found in Figure 4 for both cases.

Interestingly, an improved grouping percentage is obtained when direct hybridization between nAu-bound DNA is adopted without the linker DNA. In lanes M, N, and O of Figure 5, conjugate grouping structures (dimers, trimers, and tetramers) appear to be the primary product, and the monomer bands are extremely faint, implying a higher consumption of the monomers. The grouping percentages are found to be 70–80% for lanes M, N, and O, which are obviously higher than those

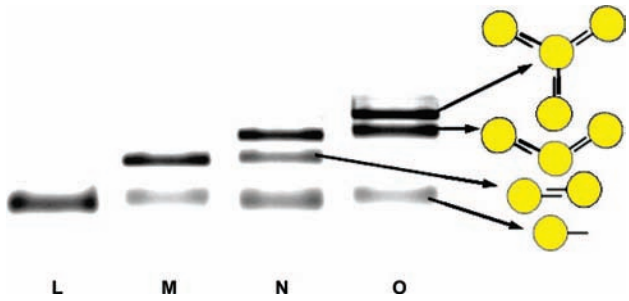

Figure 5. Conjugate grouping formation via the direct linkage of two nAu-bound DNA. Lanes L, M, N, and O correspond to nAu-B, nAu-B + nAu-revB2, nAu-B + nAu-2XrevB2, and nAu-B + nAu-3XrevB2, respectively. 2XrevB2, two strand revB2 per nAu; 3XrevB2, three strand revB2 per nAu.

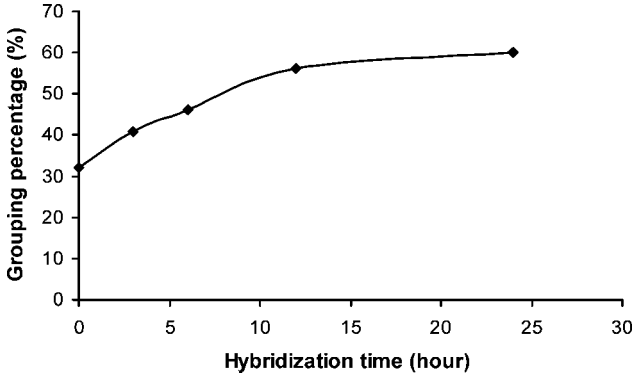

Figure 6. Study on the grouping percentage of nAu-DNA conjugates under various hybridization times.

obtained in the three-strand hybridization system shown in Figure 4. We attribute this increased grouping efficiency to two possible reasons: (1) Compared with free DNA in solution, the translational mobility of nAu-bound DNA is relatively low. This may lead to a low collision rate between cDNA. In addition, the low number of DNA bound on nAu (1–3 DNA per nAu) relative to more than 100 DNA strands per nAu reported previously (*35*) may further reduce the collision probability with complementary nAu-bound DNA to form linkage. Direct linkage between two nAu-bound DNA may be more favorable since it may require shorter collision time compared with grouping via linker DNA, where the linkage of two nAu-bound DNA to the same complementary linker DNA is required. (2) A high salt buffer condition (100 mM NaCl and 2 mM $MgCl_2$) was used in the grouping experiments to screen the charge repulsion between nAu and to facilitate grouping formation. At the same time, however, the linker DNA may tend to form a self-dimer and compete with the conjugate grouping formation. Therefore, a higher grouping percentage cannot be reached when linker DNA is involved.

Effect of Hybridization Conditions on Final Grouping Percentage. A further study on the grouping efficiency under different postannealing hybridization period at 25 °C was carried out using nAu-B, nAu-revB1, and 60-base linker DNA (ratio of 1: 1: 1), and the results are shown in Figure 6. It can be found that the grouping percentage is proportional to the length of hybridization time. With increasing hybridization time, the grouping percentage increases, and the maximum grouping of approximately 60% is obtained after 24 h. This percentage almost doubles compared with the case without postannealing hybridization (hybridization time of zero). This increase in grouping percentage further confirms the low collision rate argument described in the previous section. Longer times allow more collision and therefore facilitate the correct grouping

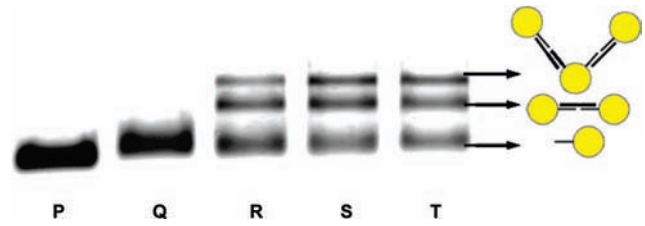

Figure 7. Study on the effect of the ion strength of the hybridization buffer on the nAu-DNA conjugate grouping percentage. Lane P corresponds to the conjugate without DNA modification, and lanes Q−T correspond to the hybridization buffer with 0, 2, 10, and 30 mM $MgCl_2$.

Table 1. Relative Mobility of Conjugate Groupings Linked by Different Linker DNA

DNA linker	26-base ssDNA	48 + 22 bp dsDNA	direct linkage without linker DNA	60-base ssDNA
relative mobility of conjugate dimer	0.66	0.60	0.57	0.54
relative mobility of conjugate trimer	0.45	0.41	0.39	0.35

formation. However, prolonged hybridization does not further improve the grouping percentage much. For example, less than 4% increase is observed as the hybridization time extends from 12 to 24 h.

Ion strength in the hybridization buffer is another important factor that affects the nAu conjugate grouping efficiency. Buffer with high ion strength is commonly used to screen the electrostatic repulsion between nAu conjugates and facilitate the assembly process. To determine the effect of ion strength on the grouping of DNA-linked nAu conjugates, we investigated the grouping percentage as a function of $MgCl_2$ concentration in hybridization buffer. In this test, nAu-A, nAu-2XrevA (two strand revA per nAu), 26-base linker DNA (nAu-A/nAu-2XrevA/linker DNA = 2:1:2), and 50 mM NaCl were used in all samples. As shown in Figure 7, when 2 mM or more $MgCl_2$ is used, the nAu conjugates assemble into dimer and trimer structures, and at least a 50% grouping percentage can be achieved. However, no grouping structure is formed when the salt concentration drops to 50 mM NaCl and no $MgCl_2$ (lane Q). In contrast, cDNA of the same sequences in the absence of nAu hybridizes into dsDNA well in 50 mM NaCl or less and without $MgCl_2$. Such a significant difference in grouping percentage was not unexpected. The 5-T ssDNA passivation of nAu leads to a highly negatively charged surface and stronger electrostatic repulsion among nAu when they come close to each other during DNA hybridization. Bivalent ions, such as Mg^{2+}can efficiently screen this electrostatic repulsion and allow more hybridization events to take place, leading to an improved grouping percentage. Our results clearly show that electrostatic repulsion between nAu-nAu conjugates and nAu-linker DNA play a critical role in the assembly process of the conjugates. The repulsion can be easily tailored by adjusting the ion strength in the hybridization buffer to reversibly control the grouping and ungrouping of nAu-DNA conjugates. Two millimolar $Mg^{2+}$is found to be sufficient for efficiently screening electrostatic repulsion. Less than 10% further improvement in grouping percentage is obtained when Mg^{2+}concentration increases from 2 mM to 30 mM (lanes R−T).

Electrophoretic Mobility of Conjugate Groupings Linked by Various Lengths of Linker DNA. The electrophoretic mobilities of conjugate dimers and trimers linked by different lengths of linkers were compared using the relative mobility of gel bands containing different conjugate groupings (see Figure S3 in Supporting Information). The relative mobility is deter-

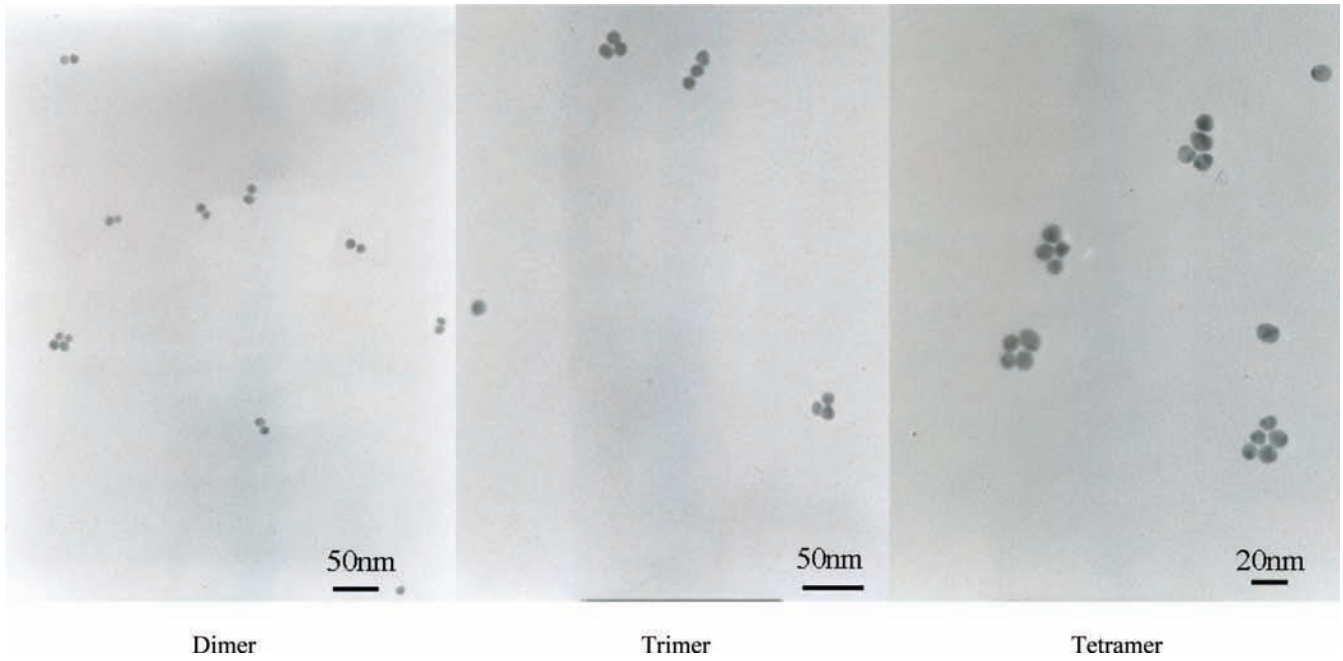

Figure 8. TEM images of nAu-DNA conjugate groupings.

mined as the ratio of migration distance of conjugate groupings relative to that of the nAu without DNA modification. The relative mobility of the groupings can be considered as an indicator of the size of each grouping and is found to be a function of the length of linker DNA and the number of nAu involved in the grouping. Longer linker DNA or a higher number of nAu results in an enlarged size of the grouping and therefore slower relative mobility. However, as shown in Table 1, the difference in the relative mobility between the 26-base and 60-base linker DNA linked grouping dimers/trimers is only 0.1, even though there is a 34 base difference in linker length (approximately 11 nm on the basis of Watson–Crick pairing). The addition of an extra 10 nm nAu and the formation of higher order of structure is more effective in reducing the mobility than using a longer DNA linker because of the bulky size and rigid shape of nAu. This can be seen from the approximately 0.2 relative mobility difference between conjugate dimers and trimers among the same linker cases. It is worth pointing out that conjugate groupings via the direct linkage of nAu-bound DNA (nAu-B and nAu-revB2) have an actual spacing of 50b between two nAu; however, they exhibit slower mobility compared with conjugate groupings linked by 48 + 22 bp dsDNA (actual spacing between two nAu is 58b). These phenomena can be seen for both conjugate dimer or trimer cases. As reported by previous studies, the mobility of conjugate groupings in agarose gel is decided by their size (*22, 27*). This abnormal mobility behavior may be attributed to the formation of a more rigid DNA duplex by direct linkage compared with the use of linker DNA. The presence of linker DNA results in additional hinges in the middle of the DNA duplex and may make the resultant conjugate grouping more flexible in going in between pores of the gel during electrophoresis.

To give a direct correlation between conjugates with different electrophoretic mobility and their actual structure, conjugate groupings were recovered from the gel and visualized by TEM. Figure 8 shows the structures of conjugate dimer, trimer, and tetramer extracted from corresponding gel bands. A large majority of the conjugates participated in the same grouping structure, indicating that each discrete gel band does contain a single type of grouping and not a mixture of several conjugate structures. A small number of monomers and high-order groupings observed in the TEM images may be due to the interruption by the extraction of conjugate samples from the gel as well as TEM preparation processes (See Figure S4 in Supporting Information for more TEM images of the nAu-DNA conjugate groupings.).

CONCLUSIONS

In this work, nAu conjugates bearing specific numbers of short DNA were used to construct nanoassemblies with well-defined structure. Various factors that affect the grouping percentages of nAu-DNA conjugates were investigated. The conjugate groupings were analyzed by gel electrophoresis, and discrete gel bands corresponding to groupings with defined structures were observed. The results show that the direct linkage of two nAu-bound DNA, longer hybridization times, and higher ion strength buffer lead to a higher grouping percentage of nAu-DNA conjugates. Furthermore, the number of nAu involved in the grouping structure is more effective in deciding its electrophoretic mobility than the length of linker DNA. TEM characterization further demonstrates that conjugate groupings extracted from each gel band consist of the expected grouping structure. This confirms that gel electrophoresis is an efficient tool for the isolation of small grouping structures of nAu-DNA conjugates. The results obtained in this study provide additional characteristics of the hybridization pattern of nAu-bound DNA and can be useful toward achieving a more defined and complex assembly of nanoparticles. Finely tailored nanoparticle assemblies can find application in a wide range of areas, such as fabrication of nanomaterials, nanoelectronics, and nanomechanical systems.

ACKNOWLEDGMENT

We thank the National University of Singapore for providing the doctoral scholarship for W.J.Q. and the research funding (R-279-000-125-112 and R-279-000-205-112) for this work.

REVIEWS

The Synthesis and Chelation Chemistry of DOTA−Peptide Conjugates

Luis M. De León-Rodríguez and Zoltan Kovacs*

University of Texas Southwestern Medical Center, Advanced Imaging Research Center, 2201 Inwood Road NE 4.2, Dallas, Texas 75390-8568. Received August 28, 2007; Revised Manuscript Received October 11, 2007

Metal complexes of DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid)−peptide conjugates are increasingly used as targeted imaging and therapeutic radiopharmaceuticals and MRI contrast agents. This review covers the bifunctional derivatives of DOTA, the solution and solid-phase synthesis of DOTA−peptide conjugates, their coordination and chelation chemistry, and the biomedical applications of various DOTA−peptide conjugate metal complexes.

INTRODUCTION

Peptide-based targeting vectors are becoming increasingly popular for diagnostic and therapeutic applications. They offer several advantages over antibodies including more favorable pharmacokinetics and better tumor penetration. Peptide sequences that are capable of binding to their target with affinities comparable to those of monoclonal antibodies can be generated by chemical or phage display libraries. Affinity selection of random phage display peptide libraries is a very powerful way of identifying novel targeting sequences for a receptor from billions of peptides (*1*).

While diagnostic nuclear imaging is currently dominated by ^{99m}Tc, there is no single isotope that is perfectly suitable for the treatment of all cancers. The half-lives and energies of the available radioisotopes cover a wide range, and the best-suited therapeutic isotope has to be selected according to the size, type, and stage of the tumor (*2*). Due to their favorable nuclear properties, ^{90}Y and radiolanthanide isotopes such as ^{177}Lu and ^{153}Sm are frequently chosen for therapeutic applications. Unlike their nuclear properties, the chemical behavior of all lanthanide and yttrium isotopes is quite similar. The most stable oxidation state of these elements is 3+, and the solution chemistry of the hard, trivalent Ln(III) cations is characterized by their strong tendency to form complexes with hard donor atoms (O, F^-, and N). Their coordination number is usually 8 or 9, and they form thermodynamically very stable complexes with polyamino polycarboxylate-type ligands that have 8 or 9 donor atoms (Figure 1). Among these ligands, the macrocyclic 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) (**1**) stands out, as it forms complexes with Ln(III) ions with extraordinary thermodynamic stability and kinetic inertness. It should be emphasized that DOTA complexes are significantly more inert kinetically than chelates of DTPA (*3*–*6*), and although both DOTA and DTPA complexes have been used as imaging agents and radiopharmaceuticals, DTPA complexes have been shown to dissociate and release metal under physiological conditions. This may not be of concern in the case of an MRI exam with Gd-DTPA when clearance of the contrast agent is rapid (*7*, *8*), but for targeted radiopharmaceutical applications, when the clearance of the complex is slow, DOTA (**1**) and not DTPA (**3**) should be the ligand of choice.

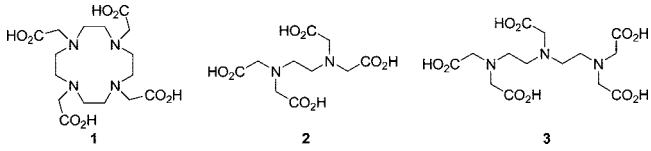

Figure 1. Polyamino polycarboxylate ligands.

A large number of DOTA−peptide conjugates have been synthesized so far, and some of them are already in clinical applications (*9*). Some reviews (see references cited in the Applications section) have covered the nuclear medicine applications of DOTA−peptide conjugate based radiopharmaceuticals, while their synthetic and coordination chemistry has not been reviewed in detail. Therefore, this review is focused on the synthesis and chelation chemistry of DOTA−peptide conjugates.

BIFUNCTIONAL LIGANDS AND LINKERS

Construction of a targeted radiopharmaceutical involves the covalent attachment (conjugation) of the chelate of the radioactive isotope to the targeting vector using a bifuctional chelator. Bifunctional ligands therefore have a reactive functionality, usually an aromatic isothiocyanate group or an activated ester, which will react with nucleophilic sites (-NH_2, -SH, or -OH) of the targeting vector (*10*). A linker may be incorporated between the chelator and the targeting vector to influence the pharmacokinetic properties of the conjugate (*10*). Hydrocarbon, PEG, or polypeptide linkers can alter the pharmacokinetics and biodistribution by changing the overall charge and hydrophilicity of the drug (*11–13*). Peptide-based linkers can also incorporate specific metabolizable sequences. An elegant method based on an "on-demand cleavable" peptide sequence has been developed recently to minimize the radiation delivered to normal tissues. A short peptide linker (rqYKYkf) identified from combinatorial peptide libraries was incorporated between the DOTA moiety and the targeting vector (ChL6 monoclonal antibody) of a targeted radiopharmaceutical. This sequence can specifically be cleaved by the thrombolytic enzyme TNKase that is restricted to the blood pool. After adequate tumor localization of the drug, the enzyme was administered intravenously. Since the enzyme stayed in the blood pool, it released the radioactive DOTA chelate only from the circulating radiopharmaceutical. The rapid renal clearance of the small-molecule DOTA complex resulted in diminished radiation dose to normal tisssues (*14*).

SYNTHESIS OF DOTA PEPTIDES

Conjugating DOTA to Antibodies. Initial strategies to attach DOTA to peptides emerged from earlier methodologies developed for antibody labeling. Proteins are most commonly modified on the primary amino groups of lysine sidechains. Due to their polar and hydrophilic nature, these are usually located on the surface of proteins and thus are easily functionalized. *p*-Isothiocyanatobenzyl DOTA (**4**) was the first DOTA bifunctional chelator developed for protein labeling and continues to be the most widely used DOTA bifunctional for antibody labeling (*15–17*). It is water-soluble and reacts easily with lysine side chains in slightly basic solutions (pH 8–9) (*18*). Encouraged by the success of this bifunctional, other DOTA derivatives with an aromatic SCN group have been developed (**5**−**9**) (Figure 2), but these do not show significant improvements in labeling yield or in vivo stability (*19–21*).

The synthesis of these SCN derivatives, especially the backbone substituted compounds, is fairly lengthy and tedious, and so other approaches based on the in situ activation of the much more readily available DOTA have been developed. A simple procedure is based on the activation of one of the acetic acid sidearms of DOTA with isobutyl chloroformate in the presence of tetramethyl guanidine to form a mixed anhydride derivative (*22*). In situ preparation of NHS and sulfo-NHS esters of DOTA were also reported (*23, 24*). Although proteins were successfully labeled with these mixtures under very mild conditions, this approach has two disadvantages. First, in order to suppress the cross-linking due to the activation of more than one acetate sidearm, a large excess of DOTA has to be used. Second, these activated esters are quite sensitive to hydrolysis, and thus the labeling results are unpredictable.

Both problems can be overcome by using preformed DOTA−NHS ester (**10**) (Figure 3) that can be standardized before conjugation (*25*). Since the preformed DOTA−NHS is synthesized using a selective protection−functionalization−deprotection approach to ensure that only one of the acetate sidearms be activated, the formation of cross-linked side products during bioconjugation is eliminated. While DOTA−NHS can label proteins at neutral pH under milder conditions than *p*-isothiocyanatobenzyl DOTA (*26*), it hydrolyzes rapidly in water (*27*). To minimize the hydrolysis problems mentioned above, several DOTA phenolic-activated ester derivatives were prepared (**11**−**18**) from the corresponding phenol, DOTA, and EDC or DCC, followed by HPLC purification (*28*) (Figure 3). Some of these derivatives showed higher hydrolitic stabilities (**11**, **14**, and **17**) compared to DOTA−NHS (**10**) (*28*), as well as good labeling efficiencies with albumin (*29*).

Although in proteins the lysine side chain amino groups are the most commonly labeled, conjugation of DOTA through the thiol groups of cystein residues with DOTA maleimide derivatives under relatively mild conditions (pH ∼7) has also been reported (*30, 31*).

Solution-Phase Conjugation. In solution, peptides and peptide derivatives can be conjugated to DOTA in the same manner as antibodies using water-soluble bifunctional ligands. For example, an *E. coli* heat-stable peptide analogue was conjugated in aqueous solution at pH 8.5 with the isothiocyanate derivative **6** through an aminocaproic acid linker (*32*). In situ prepared DOTA−NHS ester was also used to conjugate DOTA to the N-terminus of protected octreotide and octreotate derivatives in a water−DMF mixture in which both DOTA and the protected peptide were soluble (*33, 34*). This method can be especially advantageous when the peptide is not available in the protected form as was the case with certain cyclic RDG peptide derivatives. Good coupling yields (up to 79%) of DOTA to RGD peptide monomers and multimers were obtained by using an excess of a mixture of DOTA/EDC/sulfo-NHS (10:5:4). Activation of DOTA in the form of the sulfo-NHS ester was allowed to run for 30 min at 4 °C in water followed by the addition of the peptide. The pH was adjusted to 8.5 for the coupling (*35, 36*).

A new DOTA derivative, α-amino-DOTA (**19**) (Figure 4) was prepared with the objective of attaching DOTA to the C-terminus of a peptide, since in some scenarios, the peptide function might be compromised because of DOTA conjugation to the N-terminus or to lysine side chains. Thus, (**19**) was conjugated through the NH_2 group to the C-terminus of a MMP-2 targeting heptamer oligopeptide in NMP solution using HBTU/HOBT in the presence of triethylamine (*37*). However, usage of (**19**) might be problematic for peptide sequences containing amino or carboxylic functional groups in the lateral chains. Additionally, the racemic nature of (**19**) will result in the formation of a mixture of enantiomers after conjugation, which may adversely affect the bioactivity of the conjugate.

Solid-Phase Conjugation. Since most peptides are generated by solid-phase peptide synthesis (SPPS), it is much more convenient to perform the conjugation step on the solid support. While this approach offers the advantages of the solid-phase

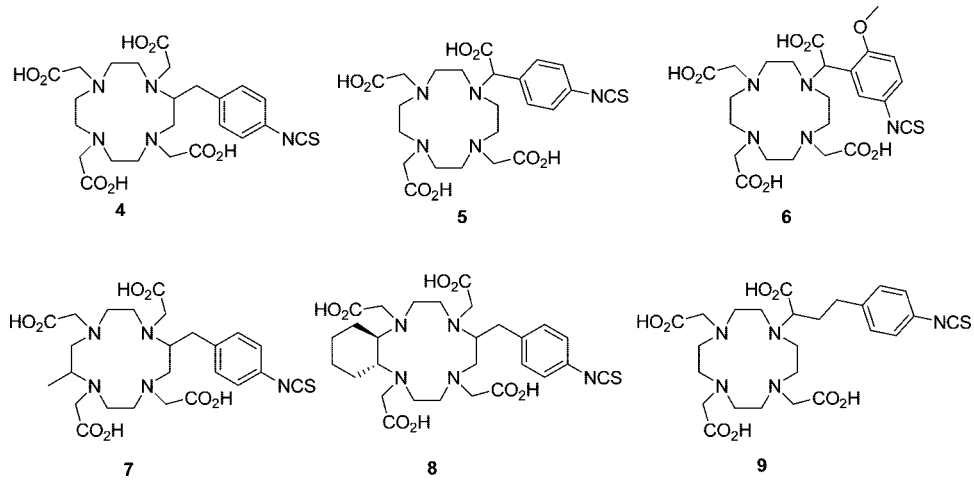

Figure 2. Bifunctional DOTA derivatives with an aromatic isothiocyanate group.

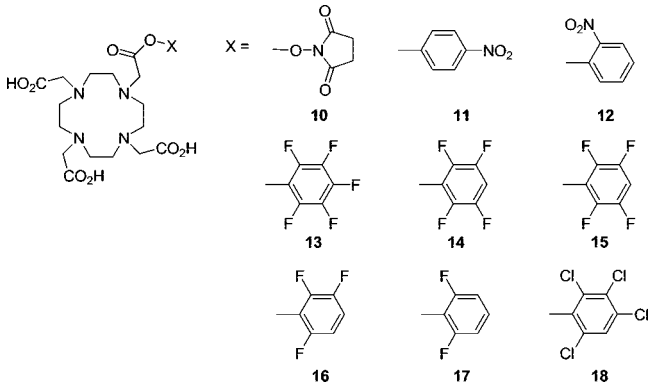

Figure 3. Activated esters of DOTA.

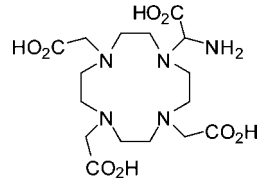

Figure 4. The structure of α-amino-DOTA.

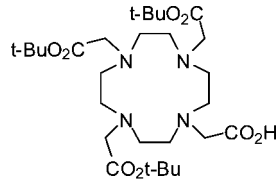

Figure 5. DOTA-tris(*tert*-butyl ester).

synthesis technique, it also presents special challenges for the bifunctional ligand. Most importantly, the ligand has to be compatible with the chemistry used for the peptide synthesis and should preferably be soluble under the conditions of SPPS. The tris-*tert*-butyl ester of DOTA (**20**) (Figure 5) satisfies these requirements. This bifunctional ligand (in the salt free, zwitterionic form) is readily soluble in most organic solvents and the *tert*-butyl ester protection is fully compatible with standard SPPS techniques.

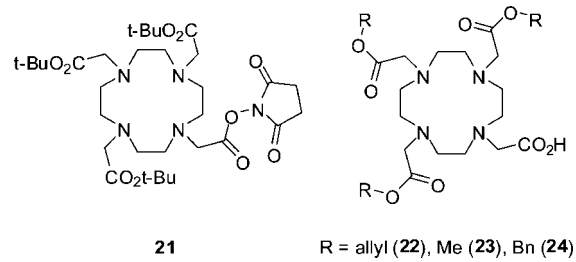

Figure 6. DOTA−tris(*tert*-butyl)-NHS ester and other DOTA−tris(protected) derivatives.

First reported in 1999 (*38*), DOTA−tris(*tert*-butyl ester) is now commercially available and has become the most popular bifunctional ligand for attaching a DOTA unit to a peptide on solid support. It can easily be coupled to free amino groups using tetramethyluronium-type coupling agents such as HBTU or HATU. The most convenient way of conjugation comprises the addition of DOTA−tris(*tert*-butyl ester) to the N-terminus of the protected peptide chain as the last amino acid in an automated peptide synthesizer followed by cleavage from the resin and removal of the acid-labile protecting groups. It can also be attached to Lys side chains, but this requires the use of orthogonal protection strategies (see later). The preformed activated NHS ester of DOTA−tris(*tert*-butyl ester) (**21**) (Figure 6) has also been synthesized (*25*), and this reagent does not require a coupling agent to couple DOTA to free amino groups (*39*). A disadvantage of DOTA−tris(*tert*-butyl ester) is the problems associated with the relatively long deprotection times necessary for the complete cleavage of the *tert*-butyl esters (*40*). There have been several attempts to improve upon this bifunctional chelator by replacing the *tert*-butyl with other groups that can be removed under milder or different conditions. Thus, the following derivatives have been reported: DOTA−tris (allyl ester) (**22**) (can be cleaved with a Pd catalyst) (*40*), DOTA−tris(methyl ester) (**23**) (can be cleaved by basic treatment) (*41*), and DOTA−tris(benzyl ester) (**24**) (can be deprotected with H_2, Pd on C) (*42*). However, these DOTA derivatives have not found widespread applications yet. Unprotected DOTA in the form of its tris(tetrabutyl ammonium) salt, which is soluble in some organic solvents, has also been coupled to peptides in SPPS (*43*). In all these derivatives, the DOTA unit is linked to peptides through one of the acetate sidearms, and the conjugate has four amino, three carboxylates, and one amide group available for metal binding. The ligand forms neutral complexes with lanthanides and Y(III), and the amide oxygen of the conjugating sidearm also coordinates. DOTA derivatives that leave all four acetate sidearms intact

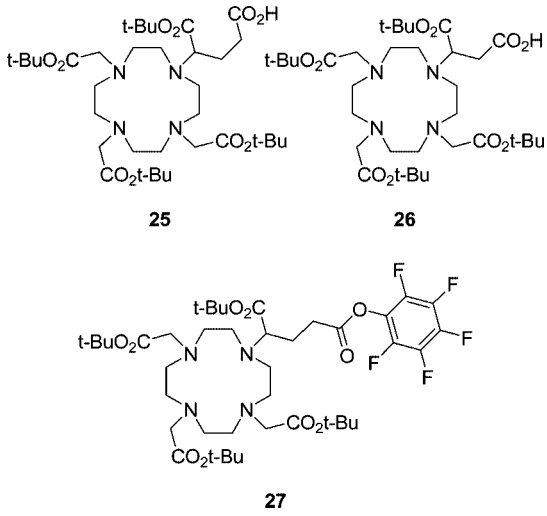

Figure 7. Structures of DOTAGA, DOTASA, and DOTAGA pentafluorophenyl ester.

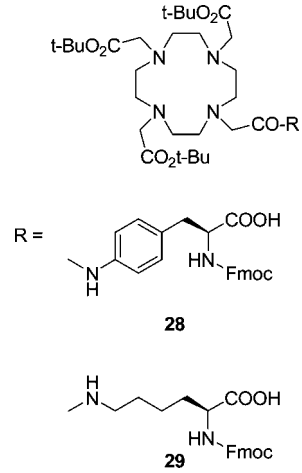

Figure 8. Fmoc-protected DOTA−Phe and DOTA−Lys derivatives.

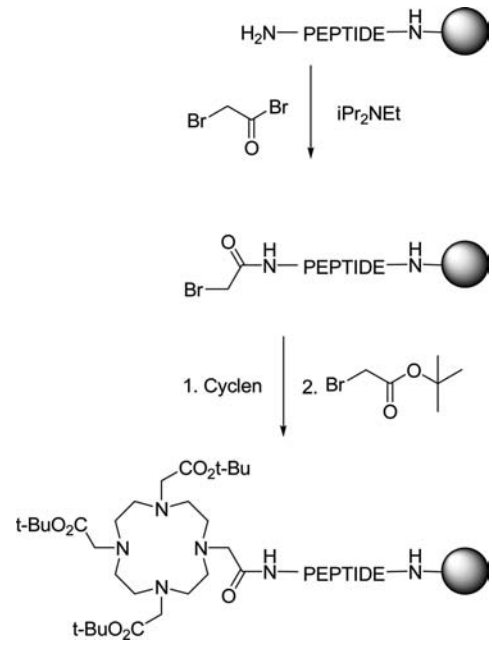
Scheme 1. DOTA Construction in SPPS



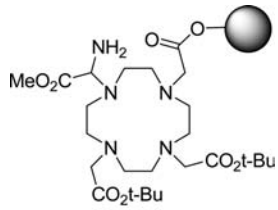
have also been synthesized and conjugated to peptides (Figure 7). These include DOTAGA (**25**) and DOTASA (**26**) as well as the pentafluorophenyl ester of DOTAGA (**27**) (*44–46*).

While with DOTA−tris(*tert*-butyl ester) it is relatively easy to conjugate DOTA to the N terminus of the peptide chain attached to the solid support, attaching a DOTA moiety to Lys side chains requires the synthesis of orthogonally protected peptides. Peptides with Dde [1-(4,4-dimethyl-2,6-dioxocyclohex-1-ylidene)ethyl] or, more preferably, ivDde [1-(4,4-dimethyl-2,6-dioxocyclohex-1-ylidene)-3-methylbutyl] protected lysine in the desired position were synthesized using Fmoc chemistry. Selective removal of the Dde or ivDde protection with hydrazine afforded the resin-bound peptide with the free Lys ϵ-NH_2, which were coupled to DOTA−tris(*tert*-butyl ester) (*47–49*). Using this approach, octreotate derivatives with up to nine Lys residues were synthesized and subsequently labeled with DOTA (*49*). Obviously, conjugation of DOTA by this method is limited to the N-terminal position or Lys side chains. DOTA can be conjugated to other positions using amino acid derivatives and/or novel SPPS techniques designed specifically for the desired target peptides as was demonstrated by the C and N functionalization of Tyr^3-octreotate with DOTA (*50*) and the use of a *p*-formylamido phenylalanine for the specific conjugation of DOTA to Phe residues (*51*). However, these approaches are limited in scope. A more general method involves the use of preformed DOTA−amino acid derivatives which allows the introduction of a DOTA unit into any desired position in the peptide sequence without the need of orthogonal protection (*52, 53*). Protected DOTA−Lys (**28**) (*52, 53*) and DOTA−Phe (**29**) (Figure 8) derivatives that are fully compatible with standard SPPS conditions (*N*-α-Fmoc protection, free carboxyl for the coupling, and acid-labile *tert*-butyl protection of the remaining acetate sidearms of the DOTA unit) have been synthesized. These DOTA−amino acids can be used in SPPS to build peptides that incorporate the DOTA moiety in any desired position (*52*). Interestingly, the type of solid support appears to have a significant effect on the coupling efficiency of the subsequent amino acid beyond the DOTA−amino acid. When Rink amide resin was used, successful coupling after the DOTA amino acid was achieved only with Fmoc amino acid pentafluorophenyl (OPfp) esters (*52*), but HBTU-type activating agents worked satisfactorily on an XAL−PEG−PS solid support (*53*). PEG−PS resins have polar poly(ethylene glycol) (PEG) chains grafted onto microporous styrene−divinyl benzene copolymer and have been shown to be superior to conventional supports for the synthesis of hydrophobic peptides, suggesting that the *tert*-butyl ester groups of DOTA may cause the aggregation of the protected peptide chain.

DOTA−tris(*tert*-butyl ester) can also be used for solution-phase couplings if the peptide is soluble in nonaqueous solvents such as DMF or NMP. A recent Nature Protocol gives a detailed procedure on the small-scale (1–5 mg peptide) solution-phase conjugation of (**20**) (*54*).

Instead of using DOTA bifunctional or DOTA amino acid derivatives, an alternative approach to DOTA peptides involves the construction of the DOTA unit on the resin-bound peptide chain as outlined in Scheme 1 (*55*). Expensive bifunctional ligands are not needed, but it requires three consecutive steps on the solid support to build the DOTA moiety, and the yields were somewhat low, probably due to slow cyclen derivatization.

Protected α-amino−DOTA loaded Wang resin (**30**) (Figure 9) was used to obtain a DOTA−peptide conjugate (NH_2-Asp-Glu-Val-Asp-DOTA) in which the chelator is conjugated to the C-terminus. This methodology can also be adapted to the



30

Figure 9. α-Amino-DOTA−loaded Wang resin.

synthesis of peptide derivatives that contain the DOTA moiety at an *endo* position of the peptide chain (*56*).

COORDINATION AND CHELATION CHEMISTRY

Coordination Chemistry. There are relatively few reports on the structural features of metal complexes of DOTA−peptide conjugates. Y(III) and the lanthanides are most likely coordinated by the four N and four O atoms, including the amide oxygen with the macrocyclic ring adopting a square [3333] conformation. Isostructural complexes of lanthanide(III) ions and yttrium(III) with the parent ligand DOTA crystallize with a capped square antiprism geometry where the basal plane is occupied by four amine nitrogens of the macrocycle, the capped plane is occupied by four carboxylate oxygens of the acetate sidearms, and the capping position is occupied by a water molecule (*57, 58*). In aqueous solution, the relative orientation of the acetate sidearms and the macrocyclic ring results in two coordination isomers that differ in the torsion or twist angle between the basal N4 and capped O4 squares. A torsion angle around 39° defines a square antiprismatic while an angle of –29° defines a twisted square antriprismatic coordination geometry. These coordination isomers can interconvert by arm rotation or ring inversion (*59*). Lanthanide(III) chelates of other DOTA derivatives also exist in the two interconverting diastereomeric forms of square antiprism and twisted square antiprism. The ratio of the two forms depends on the size of the lanthanide cation as well as the stereochemistry of the ligand (*60, 61*).

The Y(III) complex of the model ligand DOTA−D-PheNH_2 has been prepared, and the X-ray crystal structure revealed that the metal is eight-coordinated and the complex exists in the twisted square antiprismatic form (*38*). On the other hand, the complex with the much smaller Ga(III) appears to have a completely different structure with a distorted octahedral geometry. The macrocyclic ring adopts a [2424] conformation, and only two carboxylates coordinate leaving the amide oxygen and a carboxylate free (*38*). The In(III) complex of the mono(*p*-aminoanilide) derivative of DOTA was shown to have the twisted square antiprismatic geometry in the solid state, but NMR studies indicated that in solution the amide oxygen does not coordinate and the complex exhibits a fluxional behavior (*62*). The major difference between Y(III) and In(III) or Ga(III) is the size. While yttrium(III) (ionic radii ∼1.02 Å) fits perfectly in the cavity of the octadentate ligand, Ga(III) and In(III) are significantly smaller and they prefer ligands with fewer donor atoms. The experimentally observed differences in the biodistribution, clearance, and lipophilicity of the Y, In, and Ga complexes of the same DOTA peptide may in fact be due to the different coordination geometries (*62*).

Chelation Chemistry. The chelation of the radioactive metal ion by the DOTA−peptide conjugate (radiolabeling) is an integral part of the construction of the radiopharmaceutical. The formation rates of the Ln^{3+} complexes with macrocyclic ligands, especially with DOTA, are typically slow. Kinetic measurements suggest the first step in the formation of Ln complexes with DOTA derivatives involves the rapid formation of a mono- or diprotonated intermediate, and the rate-determining step is the base assisted rearrangement of this intermediate (*63*). In some cases, these protonated intermediates have directly been observed by UV–vis, luminescence, and NMR spectroscopy. The slow formation kinetics of DOTA-based ligands can be a significant disadvantage that may limit the practical use of DOTA-based radiopharmaceuticals (*64*). To speed up the chelation process, high temperatures have often been used during the complexation (*18, 65*). For example, DOTA-conjugated somatostatin analogues have been labeled with ^{111}In, ^{90}Y or ^{177}Lu by heating the solution at 95 °C for 25 min or at 80 °C for 20 min, and DOTA−affibodies have been labeled with ^{90}Y and ^{177}Lu at 60 °C for 15 min, giving nearly 100% labeling efficiency (*66–68*). The ^{166}Ho complex of DOTA was prepared in less than a minute by microwave-assisted synthesis, suggesting that this method may be useful for the labeling of DOTA peptides as well (*69*). As one might expect, the pH plays a critical role in the chelation. The rate of complex formation increases with pH, but above pH 6, the lanthanide ions start to form insoluble hydroxo complexes. Thus, the optimal pH for the labeling is between pH 5 and 6. The pH is usually maintained by a sodium acetate or ammonium acetate buffer (50 mM to 0.5 M), and the acetate buffer does not appear to have a significant effect on the complexation (as long as the pH is controlled) even when its concentration is very high (0.5 M) (*70*). Very often, only a small fraction of the available chelator sites is labeled, and the large excess of ligand prevents the formation of insoluble metal−hydroxo species through the rapid formation of intermediary complexes, and the complexation can be performed at higher pH values (pH 7–8) (*71*).

The activity of a radiopharmaceutical is characterized by the specific activity, which refers to the number of radioactive disintegrations per second (Bq, becquerel) per unit amount (grams or moles) of material. For receptor imaging and especially for therapeutic applications, high specific activity is preferred, since the number of receptors as well as their affinity to the radiopharmaceutical is limited (*65*).

Metal ion contaminants coming from the radiometal stock solution or from other reagents and glassware can have a significant effect on the radiolabeling yield if they compete with the desired radiometal for the ligand. These are mainly transition metals or other lanthanides (Al, Ce, Co, Cr, Cu, Fe, La, Ni, Pb, Zn) present as trace metals in the radiolanthanide stock solution, and the total concentration of trace metals can be much higher than that of the desired radiometal. Zr(IV) and Hf (IV), which are the decay products of ^{90}Y and ^{177}Lu, respectively, have been reported to have no effect on the chelation of these radiometals (*65, 72–74*). Often, free radical scavengers such as ascorbic acid or gentisic acid are added as stabilizers to the chelation mixture to prevent radiolytic degradation of the product (*75*).

Certain peptide sequences can bind Ln(III) ions with surprisingly high affinity (50 nM) (*76, 77*), and this may interfere with the complexation in spite of the fact that the thermodynamic stability of the DOTA chelates is several orders of magnitude higher than that of the peptide−metal complexes.

In summary, it is possible to label DOTA−peptide conjugates with radiometal ions such as ^{90}Y(III) or ^{177}Lu(III) to high specific activity, but in each case, the conditions such as pH, temperature, ligand to metal ratio, and choice of buffer have to be carefully optimized.

APPLICATIONS

Complexes of DOTA peptides, depending on the metal ion, have found applications in three major areas: magnetic resonance imaging [GdIII), Eu(III)], nuclear imaging [^{111}In(III), ^{68}Ga(III), $^{64/67}$Cu(II)], and therapeutic radiopharmaceuticals [^{90}Y(III), ^{177}Lu(III)].

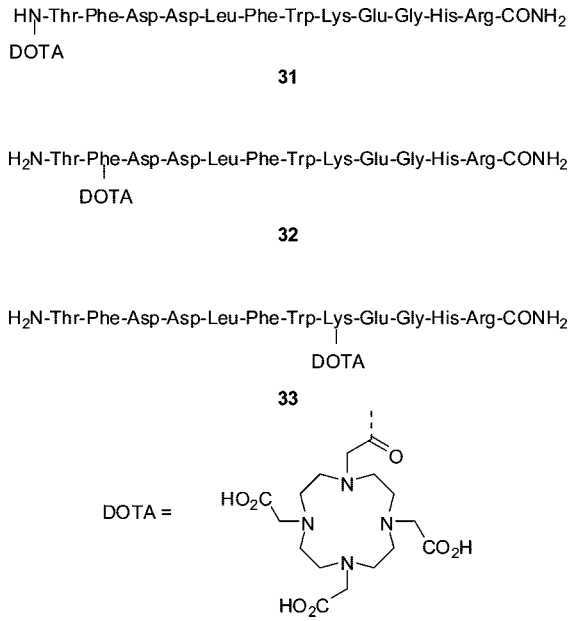


Figure 10. DOTA−Gal80 binding peptide conjugates.

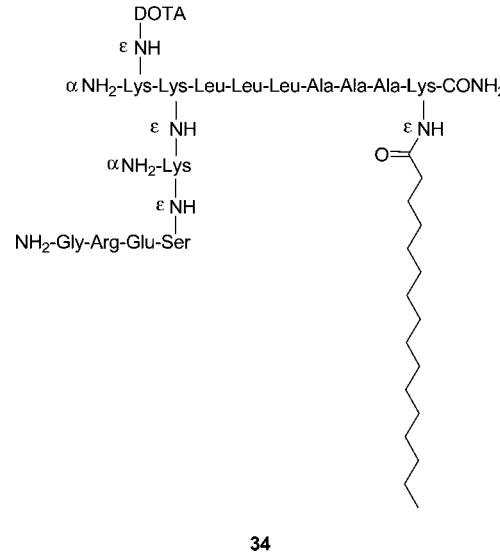

Figure 11. DOTA-labeled peptide amphiphile.

Gd(III)-Labeled DOTA−Peptide Conjugates as MRI Contrast Agents. Although MRI has excellent spatial and temporal resolution, its sensitivity is significantly lower than that of nuclear imaging methods, and so targeted and molecular imaging is still not feasible with MRI (*78*). Early attempts were aimed at increasing the number of DOTA chelates conjugated on antibodies to achieve target-specific contrast enhancement. Thus, DOTA was linked to polylysine using the mixed anhydride method, and the Gd(III)-labeled polylysine was conjugated to human serum albumin (*22*). However, it was estimated that over a hundred Gd−DOTA units per targeting protein is necessary to reach detectable concentrations, which undoubtedly would significantly alter the targeting properties of any biological vector. A much more promising approach is based on the dependence of relaxivity of a gadolinium agent on the rotational correlation time (tumbling rate) of the molecule. According to the Solomon−Bloembergen theory, the rotational correlation times for small Gd chelates are much shorter than optimal for maximum relaxivity, and it has been shown that slowing down the tumbling rate can dramatically improve relaxivity. This can be achieved by covalently linking the chelate to a macromolecule such as a dendrimer or, more advantageously, exploiting noncovalent binding of small, specific chelates to high molecular weight substrates. The latter mechanism is the basis of the receptor-induced magnetization enhancement (RIME) (*79*). Because of their potentially high binding affinities for their targets, Gd−DOTA−peptide derivatives are excellent candidates for this approach.

This concept is well-illustrated by the MRI detection of the specific binding of the Gd−DOTA−Gal80 binding peptide (**31**) (Figure 10) to the galactose regulatory protein Gal80. The binding event results in about 5-fold relaxivity increase and was successfully demonstrated by MRI at concentration levels as low as 10 μM (*80*). The Gal80 binding peptide was previously identified by phage display (*81*). Additionally, a small DOTA−Gal80 peptide library was created by SPPS using compounds (**28**) and (**29**) (Figure 8), and it was shown that conjugates (**32**) and (**33**) (Figure 10) did not show specific binding to Gal80 (*52*). This approach can obviously be adapted to the detection of other proteins by simply generating the specific peptide sequence.

DOTA−peptide conjugates with peptide sequences cleavable by proteolytic enzymes have also been synthesized. Short sequences that are substrates of certain matrix metalloproteinases are preferentially cleaved between an Ala and Leu residue by the enzyme. Thus, Gd-DOTA peptides like Gd-DOTA-Pro-Met-Ala-Leu-Trp-Met-Arg will be cleaved by the enzyme yielding Gd-DOTA-Pro-Met-Ala. It was suggested that the resultant shorter Gd−DOTA−peptide conjugates have faster water exchange rates and thereby higher relaxivities than the original complexes, and therefore the agent will be turned on in the presence of the enzyme (*82*). The change in relaxivity, however, is not nearly as dramatic as in the case of Gd-(**31**).

Interesting self-assembling branched DOTA−peptide conjugate amphiphiles such as (**34**) (Figure 11) were synthesized by SPPS. The branching points were introduced using an orthogonal protection strategy with Fmoc-Lys(Mtt)-OH (Mtt = 4-methyltrityl). Due to the β-sheet forming sequence $(Leu)_3$-$(Ala)_3$ and the hydrophobic palmitoyl tail, the Gd complex of (**34**) gives rise to long cylindrical nanostructures (nanofibers) in aqueous solution that trap water and form a hydrogel. Gd-(**34**) formed homogeneous gels with other peptide amphiphiles, and the relaxivity of Gd-(**34**) gels was about three times higher than that of a control gel mixed with Gd-DTPA as the tumbling rate of the peptide bound Gd complex slows down (*83*).

Since small Gd complexes are ionic and do not cross cell membranes, Gd-DOTA has also been conjugated to transmembrane peptides such as HIV-tat or varying-length polyarginine oligomers that successfully delivered the ionic contrast agent inside the cell (*47, 48, 84*).

DOTA−Peptide Conjugates as Radiopharmaceuticals. Over the past decade, a large number of DOTA peptides have been synthesized and labeled with various radioactive metal ions for both diagnostic and therapeutic purposes, and a comprehensive review of these compounds is well beyond the scope of this article. Instead, we will focus on some of the highlights of this dynamically developing field and will give a brief summary on the latest results on DOTA-labeled somatostain analogues, RGD peptides, and affibody derivatives.

There has been considerable activity in the area of radiolabeled somatostatin analogues, as clinical trials are in progress in Europe with ^{90}Y- and ^{177}Lu-labeled DOTA derivatives for the therapy of neuroendocrine tumors and other cancers (*85*). Octreotide, octreotate, and lanreotide somatostatin analogues are agonists of the somatostatin receptor, and they mimic the action of somatostatin (*86, 87*). Therefore, the binding event triggers the internalization of the ligand–receptor complex, which so far has been believed necessary for successful targeting. This

Figure 12. Trifunctional DOTATOC conjugates (Ahx = 6-aminohexanoic acid).

may not be the case, as it has been shown recently that ^{111}In-DOTA labeled sst3-ODN-8, [DOTA-*cyclo*(DCys-Phe-Tyr-DAgl^8(Me,2-naphthoyl)-Lys-Thr-Phe-Cys)-OH] and sst2-ANT, [DOTA-(p-NO_2-Phe)-*cyclo*(DCys-Tyr-DTrp-Lys-Thr-Cys)-DTyr-NH_2] antagonists, compounds that bind to the receptor without producing the biochemical effects of somatostatin, have significantly higher tumor uptake than the DOTA-labeled agonists (*88*). These results suggest that radiolabeled antagonists of other receptors, such as cholecystokinin, gastrin-releasing peptide, vasoactive intestinal peptide, and neurotensin receptors, could also offer higher tumor uptake and improved in vivo stability and, therefore, could be used advantageously as diagnostic and therapeutic radiopharmaceuticals (*88*).

A new generation of DOTA−somatostatin analogues capable of performing three different functions have been reported recently (*89*, *90*). They consist of a somatostatin analogue (Tyr^3-octreotide, TOC) that is capable of receptor binding and internalization in sstr-positive tissues, a heptapeptide (Pro-Lys-Lys-Lys-Arg-Lys-Val-OH) nuclear localization signal (NLS) that targets the cell nucleus and the DOTA unit that chelates the Auger emitter ^{111}In(III) (Figure 12). These conjugates were designed to enhance cellular and nuclear uptake, to have prolonged retention time in tumors and to localize in the cell nucleus to improve the efficiency of cell killing by the low-energy Auger electrons. Compounds (**35**), (**36**), and (**37**) have been synthesized by SPPS on 2-chlorotrityl chloride resin by coupling DOTA−tris(*tert*-butyl ester) to the N-terminus of the growing peptide chain with HATU in the presence of *i*Pr_2NEt. During the synthesis of (**35**), a protected fragment [Fmoc-Lys(ivDde)-Ahx-Tyr^3-octreotide] was assembled by stepwise elongation and DOTA−tris(*tert*-butyl ester) was coupled to the N-terminus after the removal of Fmoc. The ivDde was then removed with hydrazine, and the peptide synthesis was continued by branching off the Lys side chain. Alternatively, (**35**) was also synthesized following a convergent approach that involved the solution-phase coupling of Tyr^3-Lys^5(ivDde)-octreotide and an appropriately protected DOTA(t-Bu)$_3$-Lys(NLS)-Ahx-OH fragment (*90*). This mixed solid-phase−solution-phase approach did not offer any advantages, presumably because the coupling of the two large fragments was not very efficient. The location of the chelate moiety had a significant effect on the bioactivity: modification of DOTATOC at the C-terminus (compound **37**), resulting in a significant loss of binding affinity for both rat and human sstr2 receptors, but N-terminal functionalization (**35** and **36**) preserved the pharmacological activity.

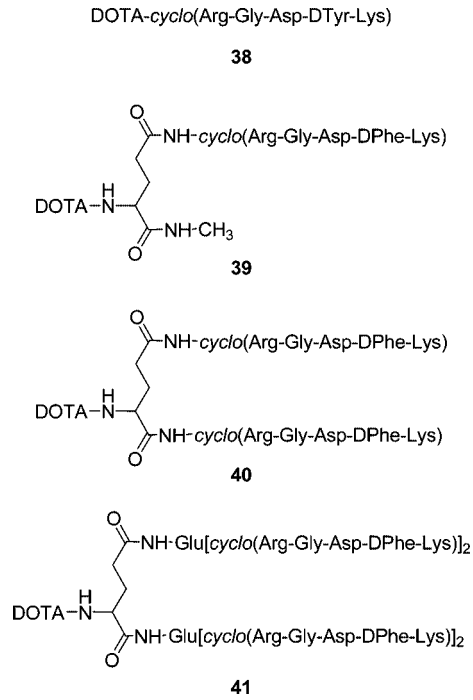

Figure 13. DOTA−RGD peptide conjugates.

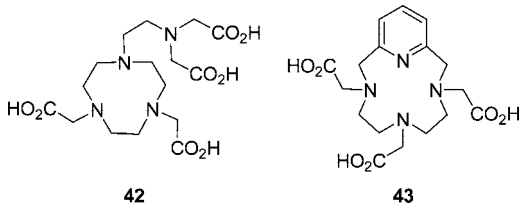
Integrin receptors are a group of transmembrane proteins that participate in many vital biochemical processes including signal transduction and the interaction with the extracellular matrix. It has been shown that $\alpha_V\beta_3$ integrin plays a key role in the angiogenesis of growing solid tumors by supporting endothelial cell growth (*91*). Ligands of integrin receptors include the matrix proteins such as fibronectin, tenascin, vitronectin, and collagen, and receptor binding is mediated by a three amino acid sequence (RGD). Short peptides with RGD motif are powerful antagonists of the integrin receptors and inhibit angiogenesis and induce apoptosis by blocking the interaction with the extacellular matrix proteins (*92, 93*). Cyclic RGD peptides have higher selectivity than the linear analogues, and inclusion of D amino acids will increase the biological stability. Cyclopentapeptides like *cyclo*(Arg-Gly-Asp-DPhe-Lys) or *cyclo*(Arg-Gly-Asp-DTyr-Lys) can easily be functionalized at the Lys side chain amino group. Dimers and tetramers of *cyclo*(Arg-Gly Asp-DPhe-Lys) attached together by Glu linkers have also been synthesized (Figure 13). DOTA conjugation to the Lys side chain (**38**) or α-NH_2 of the Glu linker (**39**) was achieved in reasonable yields by using either in situ prepared DOTA−sulfo-NHS (*35*, *36*) or DOTA−tris(*tert*-butyl ester) and a coupling agent (*71*).

The in vitro binding affinity of the monomer (**39**) and dimer (**40**) for $\alpha_V\beta_3$ integrin is six and four times lower, respectively, than that of the tetramer (**41**) (19.6 nM). Tumor uptake of the ^{111}In-labeled tetramer was significantly higher than that of the monomer and dimer (*94*) probably due to multivalent interaction (*95*, *96*)



42 **43**

Figure 14. Ligands with fast complex formation kinetics.

with the receptor. The ^{90}Y-DOTA-labeled cyclopentapeptide dimer induced significant tumor growth delay in the mouse xenograft model and has potential as a therapeutic radiopharmaceutical for solid tumors (*97*).

Monomeric, dimeric, and tetrameric dendrimers of *cyclo*(Arg-Gly-Asp-DPhe-Lys) have been synthesized by click chemistry using the N-ϵ-azido derivative of the cyclopentapeptide. As expected, the ^{111}In-DOTA labeled multimeric derivatives have shown enhanced uptake in tumors overexpressing $\alpha_V\beta_3$ integrins (*98*).

The cyclic RGD peptide *cyclo*(Arg-Gly-Asp-DTyr-Lys) was also labeled with ^{64}Cu-DOTA, and microPET imaging revealed receptor-specific tumor accumulation; but the agent also had persistent activity accumulation in liver and kidneys (*35*). Inclusion of a poly(ethylene glycol) linker significantly improved the pharmacokinetics, and ^{64}Cu-DOTA-PEG-*cyclo*(Arg-Gly-Asp-DTyr-Lys) conjugate has been used to image brain and lung tumors (*12, 99, 100*).

Affibodies are small proteins that display binding surfaces similar to antibodies, and by varying the amino acids in their recognition site, affibodies targeting a specific protein can be identified by phage display. Affibodies can be synthesized by standard SPPS, and they rapidly and spontaneously fold after synthesis. They have been proposed for therapy of tumors with nonreceptor markers and imaging of receptors that do not have naturally occurring ligands (*101–104*). Recently, a HER2 receptor-specific 58 amino acid affibody modified with DOTA at the N-terminus was synthesized (*105*). The DOTA-labeled derivative binds to the HER2 cell surface receptor in the picomolar range. In vivo molecular imaging of HER2 expressing carcinomas has been demonstrated with the ^{111}In- and ^{68}Ga-labeled derivatives and the ^{90}Y/^{177}Lu-labeled conjugates showing high antigen binding capacity and cellular retention in HER2/neu expressing urinary bladder carcinoma (*68*).

Many other radiolabeled DOTA−peptide conjugates have been developed for imaging and therapeutic purposes. These have been reviewed elsewhere, and the reader is referred to several excellent recent reviews (*106–119*).

CONCLUSION AND FUTURE PROSPECTS

Due to the high thermodynamic stability and kinetic inertness of DOTA complexes, DOTA-based bifunctional chelators will continue to be the ligand of choice for labeling peptides and antibodies with ^{90}Y and radiolanthanides. Future research efforts will focus on new DOTA-like bifunctional derivatives with improved formation kinetics while retaining satisfactory kinetic inertness for biomedical applications. New approaches to site- or residue-specific labeling will be developed. Compounds (**42**−**47**) represent interesting new ideas, and although originally they have not been intended for peptide conjugation, it is easy to realize their potential for attaching DOTA-based ligands and chelates to appropriately modified peptides. Chelator (**42**) (Figure 14) has the same number of donor atoms as DOTA, but it consists of a macrocyclic triazacyclonane-diacetic acid and an acyclic iminodiacetic acid moiety connected together by an ethylene bridge. Preliminary data showed that this ligand chelated Y(III) much faster than DOTA while the ^{88}Y complex

appeared stable in serum for 14 days. The cooperative binding of the macrocyclic and acyclic components to the metal ion speeds up the complexation without compromising the stability of the complex (*64*). Detailed kinetic studies on the chelation properties of the ligand PCTA (**43**) (Figure 14) revealed that this interesting chelator has the fastest formation rates with Ln(III) ions among all the 9–14-membered tri- or tetraazamacrocyclic ligands (*120*). The fast formation kinetics is probably due to preorganization of the ligand by the pyridine ring, which also serves as a built-in chromophore sensitizer for luminescent lanthanides such as Eu(III) and Tb(III). The extremely long luminescent lifetimes (milliseconds) of these ions allow the separation of the lanthanide emission from the background fluorescence by time-gating imaging techniques (*121*). Thus, PCTA−peptides could be useful in the construction of in vivo optical imaging probes as well.

The yttrium complex of acryloylamido derivative (**44**) (Figure 15) represents a conceptually different approach to protein labeling. This complex binds to monoclonal antibody 2D12.5 with a K_d approximately 10^{-8} M. When a Gly residue in the proximity of the binding site is substituted for a Cys, the acryloyl group on the DOTA will form a covalent bond through a Michael-type addition, converting a weak binder into and infinite binder (*122–124*).

Ligands (**45**–**49**) (Figures 16 and 17) have functional groups that selectively react with other groups, potentially allowing chemoselective labeling at specific positions. The aminooxy functional group selectively reacts with aldehydes and ketones to form oximes, and so the aminooxy-functionalized DOTA derivative (**45**) can be used to label biomolecules through a carbonyl group (*125*). Alternatively, a DOTA derivative with a ketone functional group (**46**) has been reported to label aminooxy-modified peptides (*126*). Although (**46**) maintains all four acetate arms for metal complexation, conjugation results

in the formation of enantiomeric mixtures. Peptides with dehydroalaninyl residues, formed by base-catalyzed β-elimination of the phosphate group from the corresponding phosphorylated serine analogues, react with DOTA mercaptoethyl amide (**47**) in a Michael addition (*127*).

DOTA propargylamide (**48**) (Figure 17) and its *tert*-butyl ester have recently been reported (*128*) to specifically label azidophenylalaline residues in a Cu(I) catalyzed [3 + 2] cycloaddition ("click chemistry") (*129*). In a similar concept, an alkyne-functionalized DOTA derivative (**49**) with the four acetate arms was reported and applied to label azido-modified peptides (*126*). However, the "click chemistry" involved in these couplings has two disadvantages: first, a Cu(I) catalyst is required, which in turn complicates the purification of the final product due to the complexation of this metal by DOTA; second, the cycloaddition between the alkyne and azide can lead to the formation of two triazol isomers.

Finally, we believe that the trend of designing and synthesizing DOTA conjugates of more complex structures such as multimers, multifunctional constructs, protein fragments, and nanoparticles will continue, eventually leading to the creation of more efficient diagnostic and therapeutic agents.

Tumor-Targeted Gene Delivery Using Molecularly Engineered Hybrid Polymers Functionalized with a Tumor-Homing Peptide

Kris C. Wood,[†] Samira M. Azarin,[†] Wadih Arap,[§] Renata Pasqualini,[§] Robert Langer,*[,†,‡] and Paula T. Hammond*[,†]

Department of Chemical Engineering, Biological Engineering Division, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, Department of Genitourinary Medical Oncology, University of Texas M.D. Anderson Cancer Center, Houston, Texas 77030. Received November 3, 2007; Revised Manuscript Received December 12, 2007

Before gene therapy can be used in clinical settings, safe and efficient DNA delivery systems must be developed to overcome a range of extra- and intracellular transport barriers. As a step toward the development of a modular, multifunctional gene delivery system to overcome these diverse barriers, we have developed a family of linear−dendritic "hybrid" polymers which contain functionalities for tissue targeting, minimization of nonspecific interactions, endosomal buffering, and DNA binding. Here, we demonstrate the rapid three-step, room-temperature, aqueous synthesis of hybrid polymers, as well as the functionalization of these polymers with a peptide targeting ligand that specifically binds to glucose-regulated protein-78 kDa (GRP-78), a clinically relevant tumor antigen identified in human cancer patients. These polymer systems can condense plasmid DNA into small nanoparticle structures (<210 nm) and transfect cells expressing GRP-78 with efficiencies that exceed that of branched polyethylenimine (bPEI), one of the best commercially available polymers for *in vitro* transfections. The synthetic approach described here may be useful for the rapid synthesis and optimization of polymer gene delivery systems bearing a range of diverse functional domains, and the specific GRP-78-targeted systems developed in this study may potentially have clinical applications in cancer gene therapy.

One approach toward the development of improved nonviral nucleic acid delivery systems involves the rational design of integrated, multifunctional systems containing domains which can be used to impart diverse functions such as DNA binding, endosomal buffering, and tissue or intracellular targeting (*1, 2*) Unfortunately, many early attempts to build such multifunctional systems have been unsuccessful because the addition of new domains results in the direct modification of existing domains, adversely affecting their properties. For example, the conjugation of poly(ethylene glycol) (PEG) to polyethylenimine (PEI) via primary and secondary amines, while improving the colloidal stability of polymer−DNA complexes, also dramatically decreases transfection efficiency by directly altering the polymer's DNA binding and endosomal buffering properties (*3*).

In response to these well-established problems, we set out to design a gene delivery system possessing multiple functional domains arranged together in a modular fashion, such that new domains could be added, modified, or removed while only minimally affecting existing properties. In order to make this possible, we required that all domains be physically separated from one another, that no domains possess overlapping functions, and that domains be assembled using complementary (orthogonal) chemistries (Figure S1a). Here, we demonstrate the rapid synthesis and *in vitro* validation of a system which fulfills all of the above criteria. This system, based on linear−dendritic "hybrid" polymers consisting of linear PEG and dendritic poly(amidoamine) (PAMAM), possesses functional domains for electrostatic DNA condensation, endosomal escape (via the proton sponge mechanism), reduction of nonspecific tissue interactions, and tissue targeting (Figure S1b) (*4*). In order to functionalize hybrid polymers with sensitive biological functional domains such as peptides, antibodies, and nucleic acids, we have developed a synthetic scheme that uses commercially available starting materials and a rapid (three reaction steps, two days), aqueous chemical conjugation (*1, 5*). To examine the utility of this approach, we synthesize hybrid polymers modified with a peptide ligand (denoted peptide **1**, sequence = WIFPWIQL) capable of selectively targeting glucose-regulated protein-78 kDa (GRP-78) (*6*). GRP-78 is a functional tumor antigen identified in human cancer patients, and peptide **1** has been used to target GRP-78 in tumors *in vitro*, *in vivo* (in mouse models of breast and prostate cancer), and in human patient-derived tumor samples (*6, 7*). We show here that peptide **1** functionalized hybrid polymer systems can electrostatically condense DNA into small nanoparticle structures with low, positive zeta potentials and the ability to transfect cells expressing GRP-78 more efficiently than branched polyethylenimine (bPEI), one of the best commercially available polymers for *in vitro* transfections.

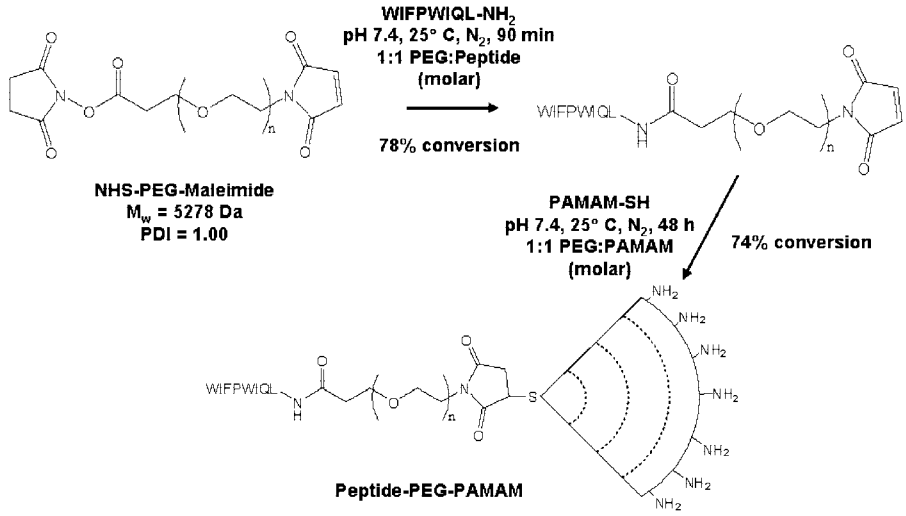
Scheme 1. Synthesis of Peptide-Functionalized Hybrid Polymers



The aqueous synthetic approach developed in this work is shown in Scheme 1. Critical to this approach is the availability of cystamine-core PAMAM dendrimers (generation 4.0), which can be reduced to yield dendrons with a single, free thiol in the interior (*8*). Briefly, dendrimers were first reduced by addition to a molar excess of dithiothreitol (DTT) with overnight stirring under N_2 gas, followed by dialysis against pure water to remove the reducing agent. Ellman's assay was used to quantify the fraction of dendrimers reduced prior to the PEG conjugation (see Supporting Information). In a separate vessel, peptide **1** was added to a bifunctional maleimide-PEG-NHS ester for 90 min, followed by addition of a molar equivalent of reduced dendrimer at pH 7.4 (phosphate buffered saline) with stirring for 24–48 h to yield the final conjugate. Note that peptide **1** was dissolved in dimethylsulfoxide (DMSO) prior to the PEG conjugation reaction only because it is insoluble in water.

Quantitatively, PAMAM reduction proceeded at conversions of 95–100% (based on total thiol concentration as measured by Ellman's method). The peptide−PEG conjugation reaction proceeded at 78% conversion (Figure S2), and the final PEG−PAMAM conjugation step went at 74% conversion (based on the disappearance of thiols; see Table S1). To ensure that the disappearance of free thiols during the PEG−PAMAM conjugation step was a result of a reaction with the PEG maleimide group instead of the reformation of dendritic disulfides, a sample of the final product was incubated overnight with a 10-fold molar excess of DTT, dialyzed, and analyzed again for thiol content. No additional thiols were observed, suggesting that all originally reacted thiols had formed stable thioether linkages with the maleimide group. Additionally, each conjugate was also verified using NMR (see Supporting Information).

A range of techniques was used to measure the physical properties of polymer−DNA complexes. In Figure 1a, gel electrophoresis demonstrates binding and charge neutralization of plasmid DNA (pCMV-Luciferase) by hybrid polymers at polymer/DNA mass ratios greater than 1:1 (N:P 0.8:1), with complete charge neutralization occurring at mass ratios equal to or greater than 5:1 (N:P 3.9:1). Zeta potential measurements indicate that complexes formed at polymer/DNA ratios of up to 40:1 (N:P 31:1) have low, positive zeta potentials, and dynamic light scattering shows that small particles (<210 nm) are formed with diameters equal to or less than the reported cutoff of ~200 nm for efficient cellular uptake *in vivo* (Figure 1b) (*9*). Particle size showed some sensitivity to the polymer/DNA mass ratio, with small ratios yielding smaller (~140–150 nm) particles and larger ratios yielding slightly larger particles (180–210 nm), likely due to increased steric or charge repulsion in complexes formed at high mass ratios.

To test for the ability of these peptide-functionalized hybrid polymers to target and deliver plasmid DNA to cells expressing GRP-78, we transfected DU145 prostate carcinoma cells, which have been shown to bind and internalize peptide **1** in a GRP-78-dependent manner (*6*). As shown in Figure 2, peptide-functionalized hybrid polymers can transfect DU145 cells at levels nearly 10-fold higher than an optimized formulation of

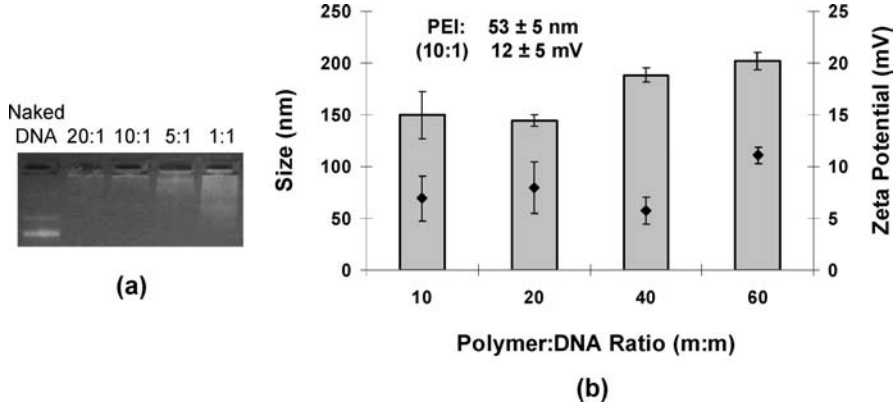


Figure 1. Physical properties of hybrid polymer−DNA complexes. (a) 1% agarose gel electrophoresis demonstrates DNA binding at indicated mass ratios. (b) Size (nm, bars) and zeta potential (mV, diamonds) of polymer/DNA complexes measured by dynamic light scattering (DLS). Error bars indicate 1 standard deviation in measured values.

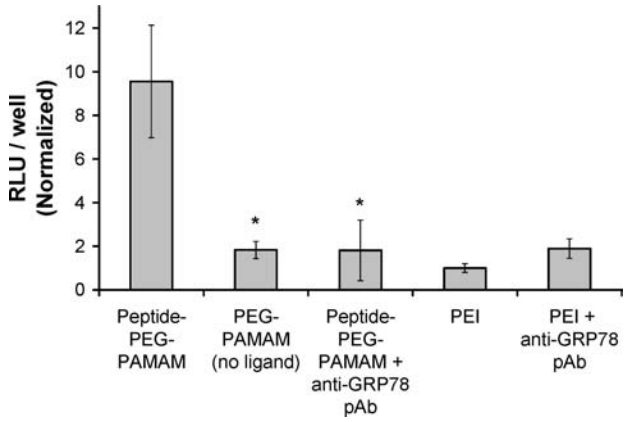

Figure 2. Transfection of DU145 prostate carcinoma cells expressing GRP-78 using peptide-modified hybrid polymers. Polymers with and without the peptide ligand, and peptide-modified polymers transfected in the presence of polyclonal anti-GRP-78 antiserum to block receptor binding, are shown (*6*). * indicates $p < 0.1$. Results normalized to an optimized formulation of PEI (2:1 PEI/DNA ratio (m:m)). All results are given as average +/− standard error.

branched PEI (25 kDa). Moreover, this process is receptor-mediated, as evidenced by the fact that cells transfected using polymers lacking a peptide ligand, as well as cells transfected with peptide-functionalized polymers in the presence of polyclonal anti-GRP-78 antiserum (to block receptor–ligand binding), yielded significantly lower levels of transfection (Figure 2). (For more information on serum stability and cytotoxicity of hybrid polymer systems, see ref (*4*).)

In conclusion, we have developed a rapid and simple aqueous synthesis to construct multidomain, biomolecule-functionalized polymers for nonviral gene delivery applications. Unlike previous efforts to functionalize spherical dendrimers with PEG, targeting groups, or other moieties through DNA binding peripheral amines, this approach allows for the synthesis of asymmetric polymers with well-controlled architectures whose DNA binding and endosomal buffering properties are not directly altered in the functionalization process (*10–12*). As a demonstration of this design and its utility, we synthesized hybrid polymers functionalized with short peptides which efficiently target and transfect cells expressing GRP-78, a clinically relevant tumor antigen. Preliminary *in vivo* bioluminescence imaging experiments performed using mice bearing EF43-*FGF4* tumors demonstrate that a single, intravenous injection of these GRP-78-targeted systems can also lead to transient, tumor-specific transgene expression (data not shown). In the future, the peptide-functionalized hybrid polymers developed in this study may potentially find use in clinical applications involving the targeted delivery of "suicide" transgenes to solid tumors (*13*). More broadly, the general synthetic approach described here could be a useful tool for the rapid synthesis and optimization of next-generation gene delivery systems bearing biological functional domains such as nuclear localization sequences, adjuvants, and protein transduction domains (*2*).

ACKNOWLEDGMENT

Received August 28, 2007; Revised Manuscript Received November 3, 2007

Activation of the A_{2A} receptor, a G protein-coupled receptor (GPCR), by extracellular adenosine, is antiaggregatory in platelets and anti-inflammatory. Multiple copies of an A_{2A} agonist, the nucleoside CGS21680, were coupled covalently to PAMAM dendrimers and characterized spectroscopically. A fluorescent PAMAM-CGS21680 conjugate **5** inhibited aggregation of washed human platelets and was internalized. We envision that our multivalent dendrimer conjugates may improve overall pharmacological profiles compared to the monovalent GPCR ligands.

Small-molecule ligands for a G protein-coupled receptor (GPCR) generally bind within its heptahelical transmembrane domain to trigger intracellular signaling pathways (*1, 2*). Accordingly, the surface contact of a distal structural unit of a bound ligand, away from the pharmacophore region, with a GPCR at/near its extracellular domain (i.e., a secondary interaction) may impart additional selectivity and affinity. An approach to designing ligands for GPCRs by applying structural modification at their permissive distal sites has led to the concept of functionalized congeners (*3, 4*). For instance, ligands for GPCRs may require attachment to a carrier molecule for delivery, and the chemical functional groups and geometry of a linker moiety can be varied, as guided by receptor affinity.

Dendrimers (*5–7*) are treelike macromolecules which possess favorable characteristics: structural integrity, control of the component functional groups and their corresponding physical properties by chemical synthesis, feasibility to conjugate multiple functional units at the periphery and the interior, and a low enzymatic degradation rate. For the past 15 years, dendrimers have been used for biomedical research (*8–12*) including gene transfection (polycationic nature) (*13–16*), drug delivery (targeted/controlled release, encapsulation, or covalent/electrostatic attachment) (*17–21*), protein−carbohydrate interactions (multivalent effect) (*22–27*), medical diagnostics (signal amplification) (*12, 28*), and tissue engineering (*29–31*). Poly(amidoamine) (PAMAM) dendrimer is composed of aliphatic amino and amido groups, and its relatively biocompatible nature has found many applications in biomedicine (*32–35*). Although the heterogeneity of commercial PAMAM dendrimers may hinder the structural characterization at the monomolecular level (*36*), usage of PAMAM dendrimers may provide quick and easy access to gauge the applicability of dendrimers as advanced therapeutic agents before progressing to tailor-made dendrimers.

Here, we report the first example of dendrimer applications to induce the multivalent intracellular signal transduction across GPCRs. Adenosine receptors (ARs) are members of the Group A GPCR family that are involved in various disease states such as inflammation, cancer, cardiovascular damage, and nervous system disorders (*37–39*). Four subtypes of ARs, A_1, A_{2A}, A_{2B}, and A_3, have been identified to date, with each manifesting a unique pharmacological profile, tissue distribution, and effector coupling. To test the feasibility of our approach, the carboxylic acid derivative CGS21680[1](**1** (*40–42*)), an A_{2A} AR agonist, was selected as a ligand for the attachment to the peripheral amino groups of a third generation (G3) PAMAM dendrimer with an ethylenediamine core (**2**). Here, the PAMAM dendrimer linked to CGS21680 through its aliphatic amino end group can be considered a part of the distal modification under the functionalized congener concept to modulate the biological activity of the original ligand (*3, 4*).

Our plan for the conjugation of CGS21680 to the PAMAM dendrimer was to utilize its distal carboxylic acid group extending from the C-2 position of the adenine base, which was shown to be a site suitable for attachment that is tolerated in receptor binding (*3*). The synthetic feasibility to make PAMAM-CGS21680 conjugates through a peptide coupling method was first examined at a monomeric level using CGS21680 in its unprotected form. For peptide coupling, PyBOP[1] was adopted as a coupling reagent. PyBOP generally allows rapid condensation in high yield unless a significant steric challenge is involved. Unlike a somewhat sluggish and unselective carbodiimide-mediated coupling, which acts essentially through dehydration (i.e., forming urea as a byproduct), PyBOP does not generate any esterified products between a free hydroxyl and a carboxylic acid. Thus, CGS21680 **1** was treated with an excess of base, followed by an equimolar amount of *N*-Boc-ethylenediamine[1] in DMF[1] (Scheme 1). PyBOP (0.8 equiv) was added to this mixture to form an activated intermediate in situ and to achieve the coupling exclusively at the primary aliphatic amine. Thus, the preactivation step of the carboxylic acid group commonly applied before the addition of amine was avoided in order to minimize the formation of intra- or intermolecular cross-coupled products involving the adenine N^6amine. Indeed, neither the ^{1}H NMR nor the mass spectrum of the crude mixture showed the formation of any unwanted side products, and this reaction produced the desired compound **3** in 90% isolated yield.

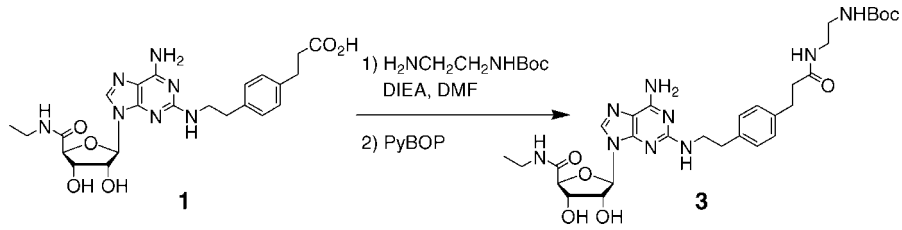
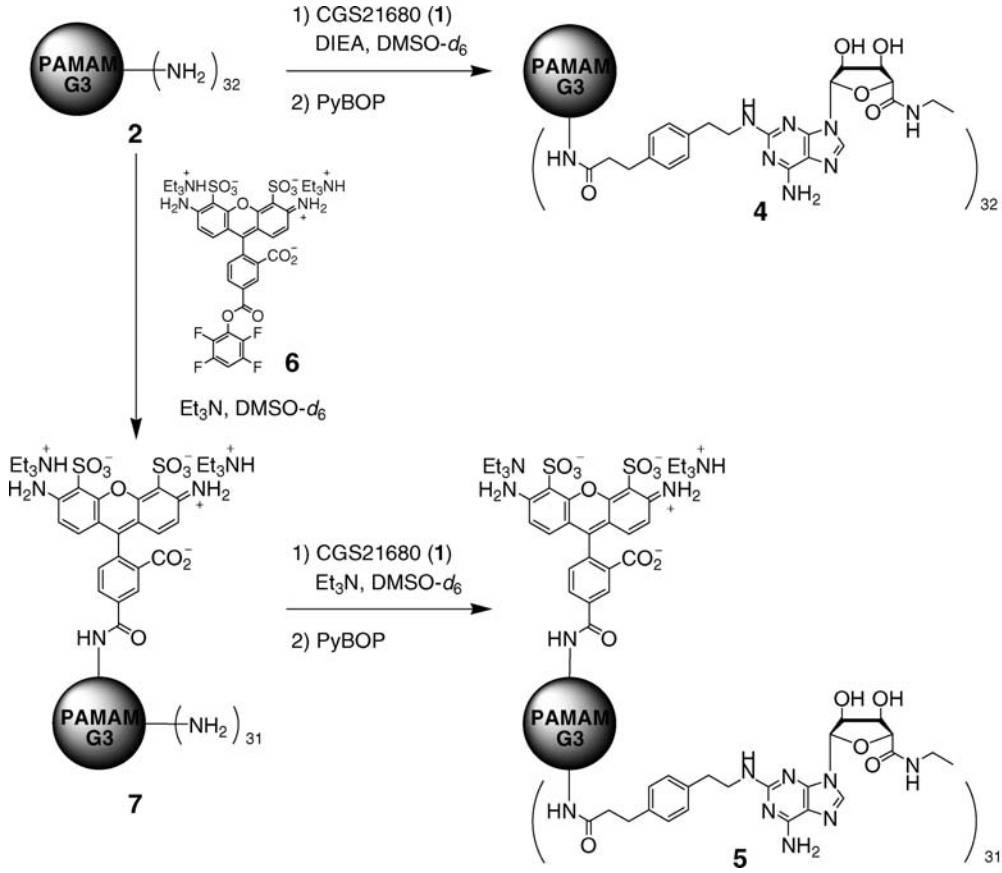
Scheme 1



Scheme 2



Next, this PyBOP coupling strategy was applied to the PAMAM dendrimer. We began by preparing the dendrimer conjugate **4**, which was fully amide-coupled with CGS21680 (Scheme 2). A slight excess of CGS21680 was added to a basic solution of PAMAM **2**, which was then treated with 32 equiv of PyBOP as a DMSO-d_6[1] solution. Deuterated DMSO was used as the reaction solvent in order to avoid later complications in the NMR analysis based on integration in DMSO-d_6. The reaction continued for 22 h, and the product was purified by size exclusion chromatography (SEC) in DMF to give the desired compound **4** in quantitative yield as confirmed by ^{1}H NMR. Here, the peak corresponding to the methylene α- to the carbonyl at the CGS21680 linker terminus was well-resolved at 2.33 ppm and exhibited the maximal shift upon coupling, similar to the result observed for the monomeric analogue **3**. The integration value of a methyl peak from CGS21680 at 0.95 ppm (96.3 H) relative to a PAMAM methylene peak "c" at 2.18 ppm (120 H)—an internal standard of PAMAM G3 for characterization by integration—indicated that the reaction proceeded completely to produce the desired product **4** bearing 32 CGS21680 groups.

To aid in the microscopic visualization in biological assays, a fluorescent dendrimer derivative **5** was then prepared. We chose Alexa Fluor 488 as a fluorophore, which has similar absorption/emission maxima to those of fluorescein, but is reported to have a higher photostability, pH insensitivity, and good water solubility (*43*, *44*). Thus, an equimolar amount of Alexa Fluor 488 was added to PAMAM dendrimer **2** as a 5-carboxy tetrafluorophenyl ester **6** in DMSO-d_6 (Scheme 2). A small amount of red precipitate was observed almost instantly upon addition of **6**. However, removal of this precipitate by filtration did not affect the recovery of an anticipated mass balance when calculated after the full conjugation of the ligands in the next step to prepare **5**. Analysis of the fluorescent intermediate **7** by ^{1}H NMR integration was difficult, and thus, the conjugation of 1 equiv of Alexa Fluor 488 was assumed on the basis of the stoichiometry of addition. The filtered crude mixture **7** was used for the next step without any purification. Subsequent attachment of CGS21680 to **7** was carried out using the same PyBOP coupling strategy as for **4**, but by adding 31 equiv of PyBOP instead. The fluorescent PAMAM-GS21680 conjugate **5** was purified by SEC and was similarly characterized by ^{1}H NMR integration to confirm that, on average, 31 CGS21680 groups were attached to the dendrimer (Supporting Information).

PAMAM-CGS21680 conjugates **4** and **5** were then characterized by matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry (see Supporting Information).

Table 1. Comparison of Molecular Weights and the Number of CGS21680 Groups Attached Determined by NMR and MALDI MS

			MALDI

[a] Counterions of sulfate groups for Alexa Fluor 488 were assumed to be protons. [b] PAMAM dendrimer **2** used for calculation here was assumed to have 32 peripheral amino groups and no structural defects. [c] Number-average molar mass. [d] Weight-average molar mass. [e] Polydispersity index. [f] No matrix adduct was considered for the estimation.

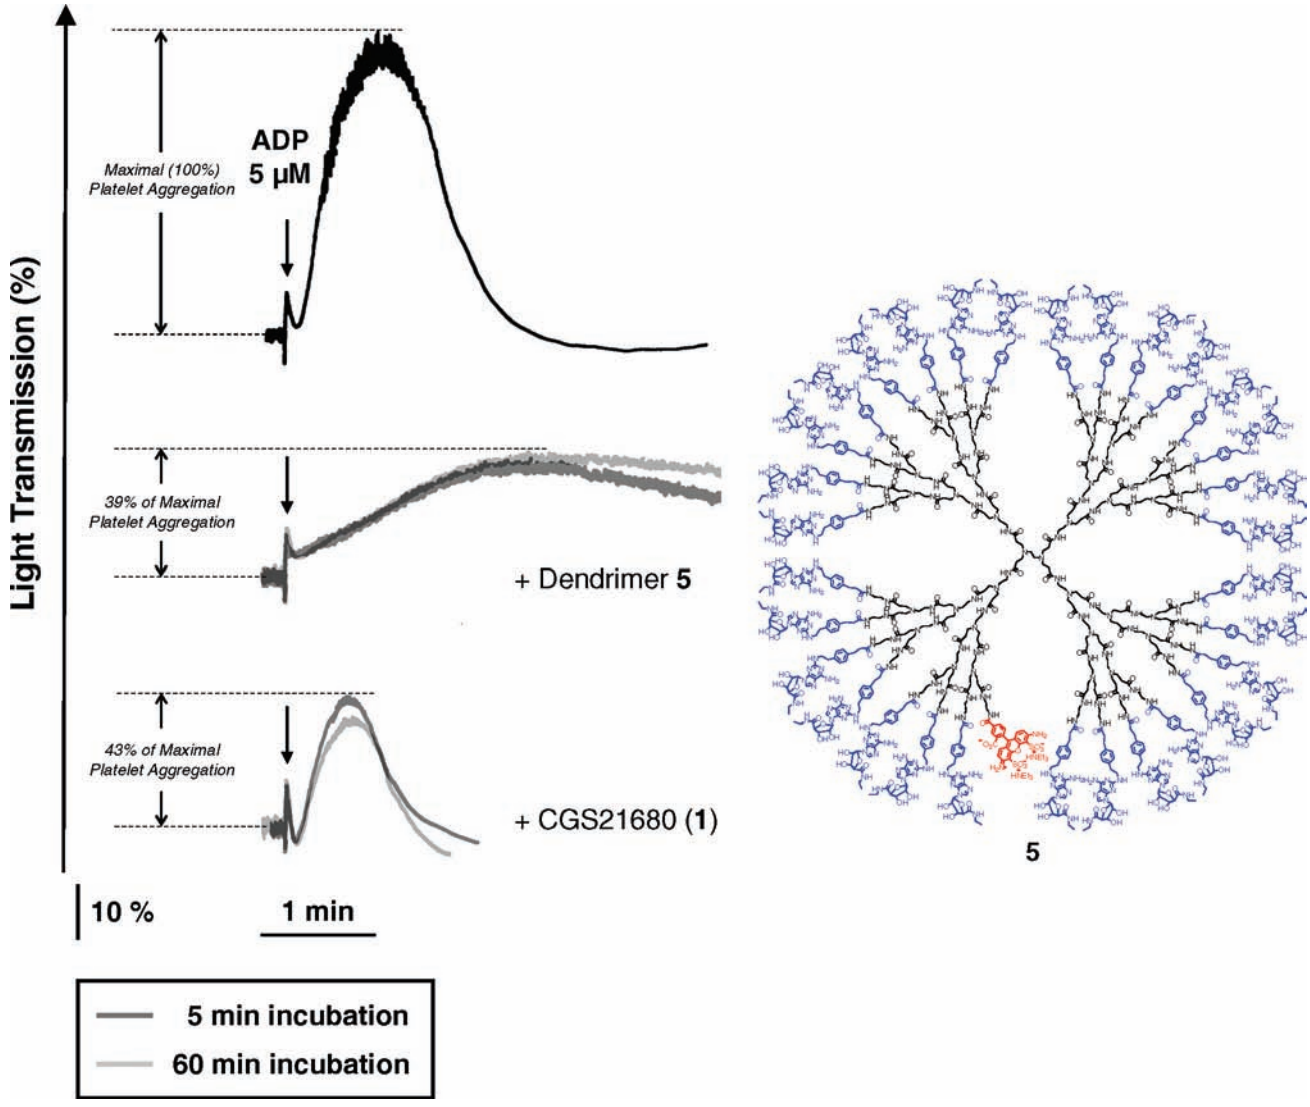

Figure 1. Platelet aggregation studies at 37 °C in the presence or absence of dendrimer **5** (Supporting Information). A suspension of human washed platelets was incubated with DMSO (top), dendrimer **5** (middle), or CGS21680 **1** (bottom) (each added as a DMSO solution), to which ADP was then added to induce the platelet aggregation. An increase in light transmission indicates increased aggregation. The final concentration of dendrimer **5** or CGS21680 **1** in the media was 2 μM, and the total content of DMSO in the media was 0.4% (v/v) in all cases.

Various MALDI matrices were attempted; however, in all cases, the intensity of the desired peak was generally weak, and the peak shape was overly broad due to the heterogeneity and possible fragmentation of PAMAM under the applied MALDI condition. Among those attempted matrices, DHB[1] and THAP[1] gave the best results for analysis. A broad peak corresponding to the half-size of the desired compound **4** or **5** was detected, which may have originated from either a doubly charged species or the fragmentation of the desired compound at the middle of the ethylenediamine core as suggested previously (*45*). In comparison to the ^{1}H NMR integration-based characterization, MALDI underestimated the average molecular weights (MWs) for both **4** and **5** in either matrix when the broad peak region above the MW of a half-size dendrimer was considered for calculations (Table 1). MALDI of a commercial PAMAM dendrimer **2** obtained under similar conditions also underestimated the average MW by ca. 1000 Da. When the MALDI-estimated average MW of PAMAM **2** was subtracted from those of **4** and **5**, dendrimers **4** and **5** were found to have 28–30 and 27–28 CGS21680 attachments, respectively, thus a slight underestimation when compared to those calculated by NMR. The deviations in MALDI-estimated MWs from those determined by NMR integration may have resulted from the difference in the tendency to form multiple matrix-adducts

between **2**, with many free amino groups, and the fully conjugated dendrimer **4** or **5**. In either matrix, the polydispersity of PAMAM-CGS21680 conjugate **4** or **5** was relatively low, ca. 1.02–1.03, and was similar to the value obtained for PAMAM dendrimer **2**. This result further supports that the conjugation of CGS21680 was nearly complete for both **4** and **5**, by reacting at most of the available peripheral amino groups of the PAMAM dendrimer.

Preliminary conformational studies of PAMAM-CGS21680 conjugate **4** were performed by nuclear Overhauser enhancement (NOE) experiments and computer modeling (see Supporting Information). PAMAM interiors were predicted to maintain a relatively compact structure by forming exchangeable multiple hydrogen bonds in water or methanol (*32*). Unlike water molecules, which may interact mostly with the charged ammonium ions at the surface of PAMAM, polar aprotic DMSO may be more likely to penetrate into the PAMAM interior to disrupt the hydrogen-bonded network. Indeed, NOE cross-peaks were observed between methylene groups of PAMAM ("b" and "c") and the protons from the ribose moiety (i.e., methyl, H-1′, H-2′, H-3′, and H-4′) of CGS21680 in DMSO-d_6 (Supporting Information), suggesting a possible internalization of the ligand into the PAMAM interior. In addition, the energy-minimized structure of **4** (*HyperChem7.5.2*, Amber force field) exhibited a relatively large volume in the interior, which is sufficiently spacious to accommodate several internalized ligands simultaneously (*46*). Eighteen hydrogen bonds were detected in the interior of the PAMAM-CGS21680 conjugate **4**. The overall shape of **4** was somewhat ellipsoidal (*32*), with the diameter ranging ca. 65–85 Å.

Next, our fluorescent PAMAM-CGS21680 conjugate **5** was subjected to in vitro functional assays. We specifically chose the platelet aggregatory system (*47–49*) to examine the potential pharmacological value of our dendrimer-based multivalent ligand carriers for GPCR signaling. CGS21680, an A_{2A} AR agonist, is already known to display a potent antiaggregatory effect in human platelet preparations (*48*, *49*). The degree of platelet aggregation was determined by aggregometry after addition of ADP[1] to a washed human platelet suspension (*50*) containing either the PAMAM-CGS21680 dendrimer conjugate **5** or CGS21680 monomer **1** as a DMSO solution (2 μM) or the same volume of pure DMSO as a control (Figure 1) (Supporting Information). Our preliminary findings indicated that ADP-induced platelet aggregation, which occurs through the nucleotide binding to P2Y receptors on the platelet surface, was inhibited in the platelet suspension containing either dendrimer **5** or monomer **1** to a similar degree (i.e., 61% inhibition by **5**; 57% inhibition by **1**, both at 2 μM), whereas platelets treated with DMSO alone aggregated in response to ADP. The inhibitory effect was the same whether the dendrimer conjugate was incubated for 5 or 60 min. Interestingly, the platelet aggregation response in the presence of dendrimer **5** exhibited a slower onset in comparison to that of control or the platelet suspension treated with monovalent CGS21680. Moreover, the fluorescent dendrimer conjugate **5** was clearly observed inside the platelets under a fluorescent confocal microscope (Figure 2), when the platelet suspension was incubated with dendrimer **5** and washed to remove any free dendrimer **5** in the extracellular medium. Thus, the extracellularly administered dendrimer conjugate is effectively internalized in platelets. The internalization of intravenously injected macromolecules into platelet granules has been described (*53*). Future studies will be directed toward determining the structural features of the dendrimer conjugates that affect internalization.

In summary, in an effort to develop highly potent agonists acting through multivalent signaling across GPCRs, PAMAM dendrimer conjugates **4** and **5** loaded with multiple copies of

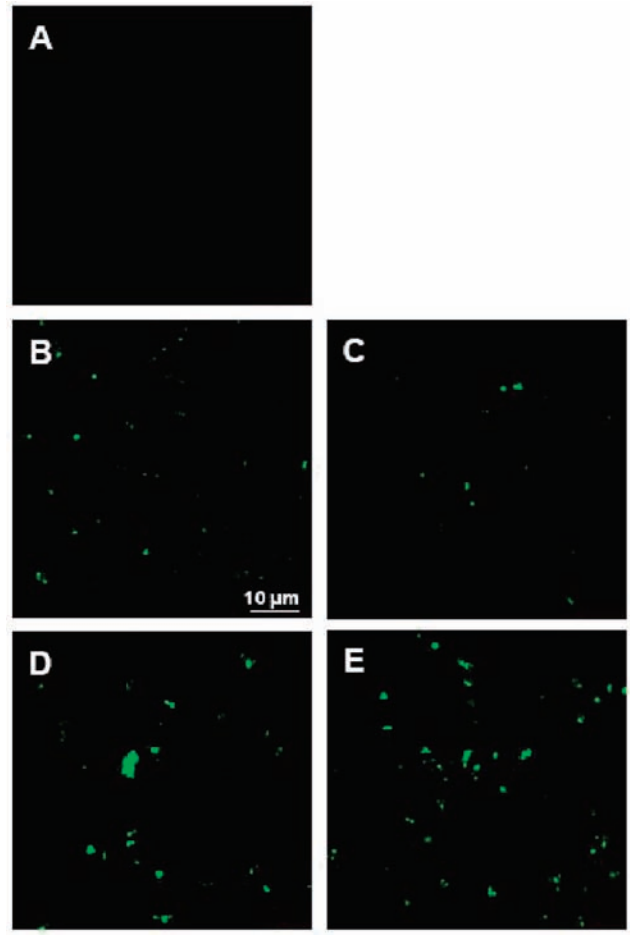

Figure 2. Fluorescence confocal microscopy of human washed platelets incubated with either (A) DMSO or (B−E) dendrimer **5** (Supporting Information). Incubation time: (B) 5 min, (C) 15 min, (D) 30 min, and (E) 60 min. The final concentration of dendrimer **5** in the media was 2 μM, and the total content of DMSO in the media was 0.4% (v/v) in all cases.

CGS21680 were synthesized using a peptide coupling method and purified by SEC. The average MWs and the degree of ligand attachments for dendrimers **4** and **5** were determined by ^{1}H NMR integration and MALDI. Both analyses support the formation of nearly fully loaded dendrimers. Our preliminary functional assay clearly demonstrated a potent antiaggregatory effect of the PAMAM-CGS21680 dendrimer **5** on the platelet aggregation induced by ADP. In addition, the fluorescent dendrimer **5** was found to be internalized into the platelet as shown by the fluorescent confocal microscopy studies. The approach described here to develop multivalent ligands for GPCRs can be extended to create a dendrimer containing a set of heterogeneous agonists/antagonists, in order to induce combined synergistic biological effects via binding to different receptor subtypes simultaneously on a cellular membrane (*51*, *52*). A detailed investigation on the pharmacological effects of our dendrimers on platelet aggregation will be reported in due course.

ACKNOWLEDGMENT

This research was supported in part by the Intramural Research Program of the NIH, NIDDK. We thank Dr. Herman Yeh for the helpful advice on the NMR experiments. We are grateful to Drs. Ratna Dutta and Haijun Yao at the Mass Spectrometry Laboratory of the University of Illinois, for numerous attempts to obtain MALDI spectra of our PAMAM

dendrimer derivatives. Y.K. thanks the Can-Fite Biopharma for financial support.

Mathews Avenue, Urbana, IL 61801. Received October 22, 2007; Revised Manuscript Received November 27, 2007

Design of smart MRI contrast agent based on superparamagnetic iron oxide nanoparticles and aptamers has been described for the detection of human α-thrombin protein. The contrast agent is based on the assembly of the aptamer functionalized nanoparticles in the presence of thrombin. A detectable change in MRI signal is observed with 25 nM thrombin in human serum. Changes were neither observed with control analytes, streptavidin, or bovine serum albumin, nor with inactive aptamer functionalized nanoparticles.

Magnetic resonance imaging (MRI) is advancing rapidly, as it provides noninvasive, three-dimensional examination of biological events in living organisms. A particularly active area of research in the MRI field is the development of MRI contrast agents for image enhancement (*1–9*). Superparamagnetic iron oxide nanoparticles (SPIOs) are attractive, since they are shown to be effective in enhancing magnetic resonance image contrast (*4*). The applications of SPIOs in MRI have ranged from nontargeted detection of diseases by accumulating at certain tissues to targeted detection of biomolecular markers in cells (*10–16*). Target-specific MRI detection using SPIOs is particularly interesting, as it helps monitor several cellular or molecular processes (*16–18*). For example, cross-linked dextran-coated superparamagnetic iron oxide (CLIO) nanoparticles have been functionalized with different biomolecules and used for detection of different targets including oligonucleotides (*19, 20*) proteins (*17, 20, 21*), enzymatic activities (*22*), viruses (*23*), and enantiomeric impurities (*24*). It has been shown that CLIO nanoparticle assemblies create a distinctive magnetic phenomenon called magnetic relaxation switching (MRS), where the core of a single nanoparticle in the assemblies becomes more effective in enhancing T2 relaxation time of adjacent water protons, when compared to dispersed nanoparticles (*4, 19*). This mechanism has been widely used in many magnetic detection schemes either going from a disperse state to an assembled state of nanoparticles or visa versa (*19, 20, 22, 24*). For instance, it has been shown that oligonucleotide functionalized dispersed CLIO nanoparticles can be used for the sequence-specific detection of complementary oligonucleotides simply by hybridizing oligonucleotides and assembling CLIO nanoparticles into clusters (*19*). This process enhances the T2 relaxation of the nearby water protons and can be detected by MRI. While this approach is effective in oligonucleotide detection, it would be very interesting if this nucleic acid-based approach could be expanded beyond nucleic acid detection to MRI of even broader classes of targets.

Aptamers are single-stranded functional nucleic acid molecules which can bind a variety of chemical and biological molecules with high affinity and selectivity (*25–28*). They are obtained through a combinatorial biology technique called systematic evolution of ligands by exponential enrichment (SELEX), by isolating the active species from a large random pool of DNA or RNA molecules (*25, 26*). They are often analogous to antibodies due to their selectivity and sensitivity in binding to a broad range of molecules (*29–32*). When compared to antibodies, aptamers serve several advantages such as the relative ease with which they can be selected for any target analyte and their stability against biodegradation and denaturation. Due to these properties, aptamers are good candidates for building chemical and biological sensors in many fields such as medical diagnostics and environmental monitoring. Therefore, these aptamers have been transformed into fluorescent (*33–47*), colorimetric (*48–57*), and electrochemical sensors (*58–60*). Although these aptamer sensors have been widely investigated *in vitro*, their applications *in vivo* remain a significant challenge because light penetration through skin is difficult and signal interference from cellular components is common. Recently, we reported a method for combining adenosine aptamer and CLIO nanoparticles into a system to detect adenosine in the micromolar range via MRI. The contrast in MR image of the nanoparticle solution increases as the adenosine concentration increases in the environment (*61*). Herein, we describe a new method for combining magnetic relaxation switching properties of CLIO nanoparticles with aptamer technology in order to create MRI contrast agents with nanomolar detection limit. The advantage of this technique over other sensing methods is that MRI signal is much less vulnerable to changes in background colors or fluorescence from biological media, such as serum and cell suspensions. In contrast to our previously reported system with adenosine, which depends on analyte-induced disassembly of particles to produce an increase in brightness, this method is based on assembly of particles leading to a decrease in brightness of MR image. This change in signal from bright to dark is a significant advantage, as this is preferred in T2-weighted MR imaging. Furthermore, instead of a metabolite, we demonstrate the detection of a protein in the current system, as proteins constitute most enzymes and biomolecular markers in living systems.

To demonstrate the use of aptamer functionalized CLIO nanoparticles for protein detection we chose to detect thrombin

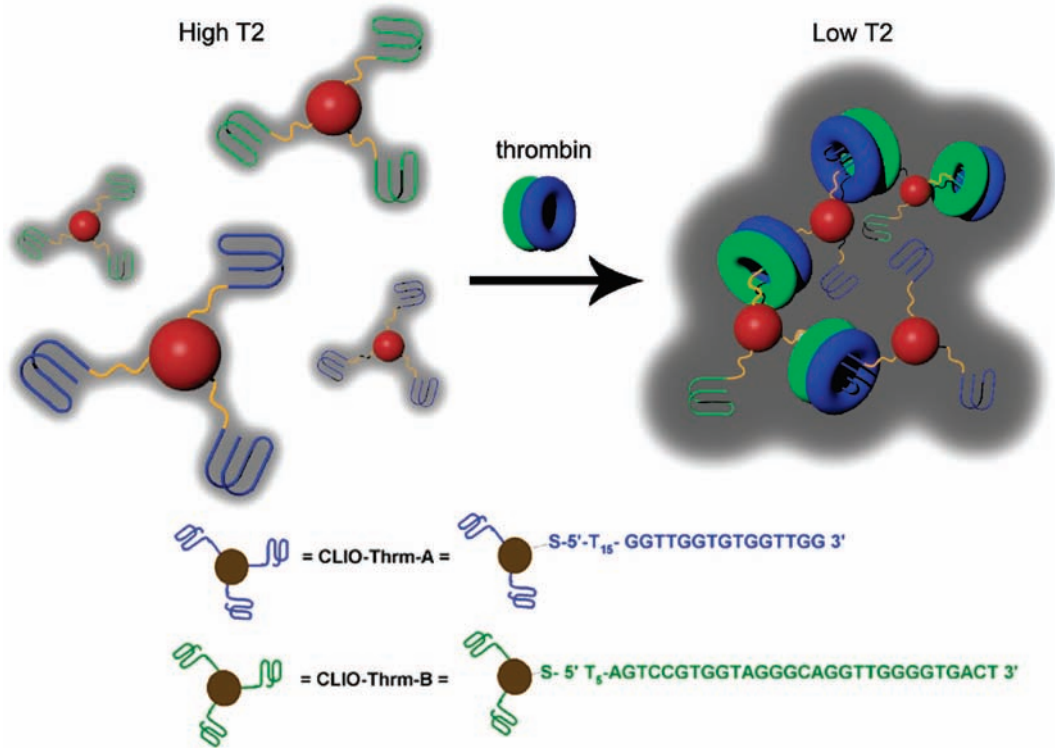
Scheme 1. Schematic Illustration for Thrombin Detection Using MRI[a]



[a] The CLIO nanoparticles (shown as red spheres) have been modified with either Thrm-A, a DNA aptamer (shown as blue lines) that binds to fibrinogen-recognition exosite of thrombin, or Thrm-B, a DNA aptamer (shown as green lines) that binds to the heparin-binding exosite of thrombin. Addition of thrombin consisting of both fibrinogen (as blue donuts) and heparin (as green donuts) exosites resulted in aggregation of CLIO nanoparticle assembly, reducing the T2 relaxation time. The DNA sequences are shown at the bottom. The drawing is not to scale.

via MRI . We combined the CLIO nanoparticles with thrombin aptamers, Thrm-A, which binds to the fibrinogen-recognition exosite of thrombin, and Thrm-B, which binds to the heparin-binding exosite of thrombin, as shown in Scheme 1 (*62*, *63*).

Materials: All DNA samples were purchased from Integrated DNA Technologies Inc. (Coralville, IA). The thiol-modified DNA molecules were purified by the standard desalting method. Human alpha thrombin was purchased from Haematologic Technologies Inc. (Essex Junction, VT). BSA was purchased from Aldrich (St. Louis, MO). Streptavidin was purchased from SouthernBiotech (Birmingham, AL). N-Succinimidyl-3-(2-pyridylthio)-propionate (SPDP) was purchased from Molecular Biosciences (Boulder, CO). Cross-linked dextran coated superparamagnetic iron oxide nanoparticles (CLIO, 500 μg Fe mL^{-1}) were synthesized and coupled to SPDP according to literature procedure and purified with PD-10 column (*17*). The thiol modified oligos, Thrm-A (5′ SH-T_{15}-GGTTGGTGTGGTTGG 3′), Thrm-B (5′ SH-TTTTTAGTC-CGTGGTAGGGCAGGTTGGGGTGACT 3′), CNT-Thrm-A (5′ TCA-CAGATGAGT-A_{12}-SH 3′), and CNT-Thrm-B (5′ SH-CCCAGGT-TCTCT 3′) were activated by incubating with eight equivalent of tris (2-carboxyethyl) phosphine hydrochloride (TCEP). Excess TCEP was removed by desalting using a SepPak C-18 catridge. TCEP-activated thiol modified DNA (50 μM final concentration) was mixed with CLIO-SPDP (400 μg Fe mL^{-1}) in 100 mM phosphate buffer at pH 8.0 overnight. Excess DNA was removed by magnetic separation column (Miltenyi Biotec, Auburn, CA) from CLIO-DNA conjugates. Sample preparation and MRI detection: CLIO-Thrm-A and CLIO-Thrm-B were mixed in 1:1 ratio and diluted in 100 mM NaCl, 25 mM KCl, and 25 mM tris-HCl buffer at pH 7.4. 250 μL of sample (12 μg Fe mL^{-1}) was aliquoted into the wells of a microplate and varying amounts of analyte was added in each well. T2-weighted MR images were obtained on a 4.7 T NMR instrument using a spin–echo pulse sequence with variable echo time (TE = 25–100 ms) and repetition time (TR) of 3000 ms. Light-scattering experiments: DLS measurements were performed using Nicomp 380 ZLS Particle Sizer (Particle Sizing Systems, Santa Barbara, CA). An intensity-weighted value was used to report the average particle diameter.

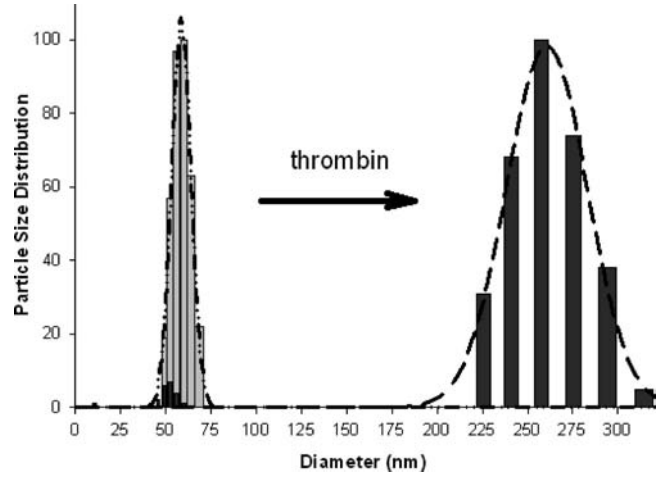


Figure 1. Particle size distribution of 1:1 CLIO-Thrm-A and CLIO-Thrm-B mixture before (light gray bars) and after (dark gray bars) addition of 50 nM thrombin.

The contrast agent designed for thrombin detection is composed of a 1:1 mixture of Thrm-A and Thrm-B functionalized CLIO nanoparticles (CLIO-Thrm-A and CLIO-Thrm-B, respectively) in aqueous solution. In the presence of thrombin, aptamer sequences fold into a G-quadruplex arrangement in order to bind to thrombin (*64*, *65*). After attachment of the CLIO nanoparticles to thrombin, the disperse nanoparticles assemble into aggregates, changing the magnetic relaxation properties of nearby water protons, thereby reducing the T2 relaxation time. This event can be monitored as a decrease in brightness of T2-weighted MR image of the solution via MRI (*24*).

To confirm that the aptamer functionalized nanoparticles bind to thrombin, 1 μM thrombin was added into the 1:1 homoge-

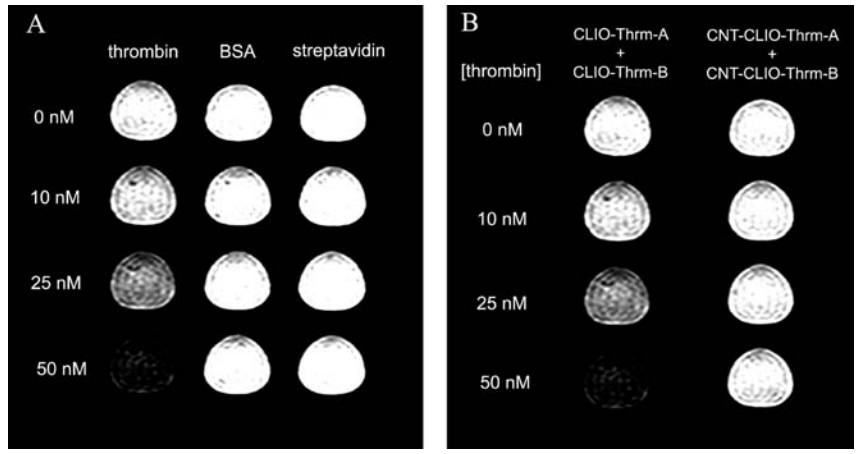

Figure 2. (A) Contrast change in T2-weighted MR image in 1:1 CLIO-Thrm-A and CLIO-Thrm-B mixture with 0, 10, 25, and 50 nM thrombin (first column), BSA (second column), and streptavidin (third column). (B) Contrast change in T2-weighted MR image with 0, 10, 25, and 50 nM thrombin in CLIO-Thrm-A and CLIO-Thrm-B mixture (first column), and in CNT-CLIO-Thrm-A and CNT-CLIO-Thrm-B mixture (second column).

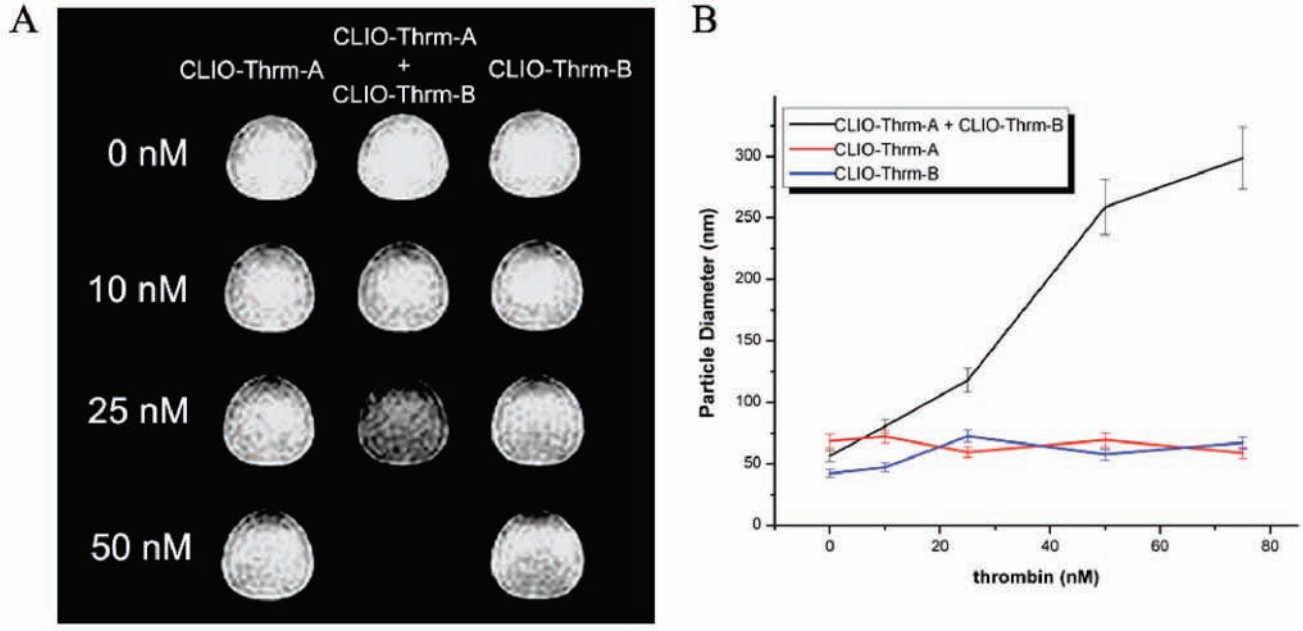

Figure 3. (A) Contrast change in T2-weighted MR image with 0, 10, 25, and 50 nM thrombin in CLIO-Thrm-A (first column), CLIO-Thrm-A and CLIO-Thrm-B mixture. (Note: The image is completely dark at 50 nM thrombin) (second column) and in CLIO-Thrm-B (third column). (B) Particle diameter change with CLIO-Thrm-A, 1:1 CLIO-Thrm-A and CLIO-Thrm-B mixture, or CLIO-Thrm-B with addition of thrombin.

Figure 4. T2-weighted MR image of 1:1 CLIO-Thrm-A and CLIO-Thrm-B mixture in human serum.

neous mixture of CLIO-Thrm-A and CLIO-Thrm-B (150 μg Fe mL^{-1}), which resulted in rapid precipitation in seconds (data not shown). Similar behavior was not observed when bovine serum albumin (BSA) or streptavidin was used as an analyte. This result indicates that the precipitation of nanoparticles is due to the binding event of analyte and its aptamer. Particle size analysis also showed that, upon addition of 50 nM thrombin into a mixture of CLIO-Thrm-A and CLIO-Thrm-B (12 μg Fe mL^{-1}), the average diameter of CLIO nanoparticles immediately increased from 58.9 $\pm$ 4.4 nm to 259.5 $\pm$ 22.5 nm. Figure 1 shows the intensity-weighted particle size distribution of CLIO nanoparticles obtained with dynamic light scattering (DLS), which indicates that the nanoparticles are cross-linked by thrombin molecules, therefore increasing the average diameter. At this CLIO nanoparticle concentration, precipitation of nanoparticles was not observed (*19*). These results strongly suggest that thrombin binding to aptamers on CLIO nanoparticles induces the assembly of nanoparticles.

After confirming thrombin-induced assembly of nanoparticles via DLS, we proceeded to check its utility as an MRI contrast agent. The binding of CLIO-Thrm-A and CLIO-Thrm-B to thrombin, assembled the nanoparticles into clusters, resulting in a decrease of the T2 relaxation time of the neighboring water protons in the medium. We have tested the system at different thrombin concentrations from 0 to 50 nM. A decrease in brightness of the MR image of the samples was observed as the concentration of thrombin was increased (Figure 2A), which was attributed to a decrease in T2 relaxation time (*24*). A

noticeable change in contrast was observed even as low as 10 nM thrombin, and a significant change was observed at 50 nM thrombin.

To ensure that the contrast is solely due to the binding event and not any other artifact, the system was tested with BSA and streptavadin. The MR images obtained with these two analytes did not show a difference in contrast when their concentration was increased from 0 to 50 nM. This result suggests that the change in contrast is due to thrombin and not any other effect. In order to check if the change in contrast is due to aptamer and analyte binding and not thrombin molecule itself, we have tested random DNA sequences of different lengths that do not bind to thrombin. To do so, we prepared a 1:1 mixture of random DNA sequence (CNT-Thrm-A and CNT-Thrm-B) functionalized CLIO nanoparticles (CNT-CLIO-Thrm-A and CNT-CLIO-Thrm-B). The control samples were subjected to the same procedure as was used in preparing CLIO-Thrm-A and CLIO-Thrm-B, and then placed into the wells of a microplate. Thrombin was added to both systems with an increasing concentration from 0 to 50 nM. The obtained MR images showed a change in brightness for samples with CLIO-Thrm-A and CLIO-Thrm-B, but no change with CNT-CLIO-Thrm-A and CNT-CLIO-Thrm-B (see Figure 2B). This result suggests that the change in the MR signal is due to active thrombin binding aptamers and not any other nonspecific interaction of DNA with thrombin. The two control experiments taken together strongly indicate that the change in MR signal is solely due to the binding event of thrombin to the aptamers, which results in assembly of CLIO nanoparticles into clusters, decreasing the T2 relaxation time of the environment.

In order to demonstrate that thrombin molecule requires a mixture of CLIO-Thrm-A and CLIO-Thrm-B to generate a MR signal, we tried to use only CLIO-Thrm-A or CLIO-Thrm-B to detect thrombin. As seen in Figure 3A, the MR signal did not change with neither of these nanoparticle suspensions, but a clear change in MR signal was observed with the 1:1 mixture of nanoparticles. The particle size analysis confirms this result, as an increase in particle diameter was observed when thrombin was added into the 1:1 mixture of nanoparticles, but such an increase was not observed with CLIO-Thrm-A or CLIO-Thrm-B alone (see Figure 3B). MR data and particle size analysis together suggest that both CLIO-Thrm-A and CLIO-Thrm-B are necessary for detection of thrombin with magnetic relaxation switching.

To check the utility of this system in biological fluids, we tested our sample in 50% human serum. A clear change in the MR signal was observed with 25 nM, and a significant change was seen with 75 nM thrombin (Figure 4). This result demonstrates that the system works in human serum without interference of biological components in serum.

In conclusion, we demonstrated aptamer functionalized superparamagnetic iron oxide nanoparticles for detection of an analyte, which is dependent upon the binding event of aptamer conjugated CLIO nanoparticles and the target molecule. The system demonstrated here is specific to thrombin and the sensitivity is as low as 10 nM. Similar approaches can be applied to other aptamer and CLIO nanoparticle systems.

ACKNOWLEDGMENT

The authors thank Natasha Yeung for helpful discussions and for comments on the manuscript and Dr. Boris Odintsov for his help in operating the MRI equipment. Received December 10, 2007; Revised Manuscript Received December 21, 2007

DNA transfections are widely performed in research laboratories and *in vivo* gene delivery holds the promise for curing many diseases. The synthetic carriers or vectors for DNA are typically cationic lipids. However, in biology, the recognition of nucleic acids by proteins involves both electrostatic and stacking contributions. As such we have prepared a series of new lipophilic peptide vectors that possess lysine and tryptophan amino acids for evaluation. These lipophilic peptides show minimal cytotoxicity and enhanced *in vitro* gene transfection activity.

The complexation of cationic amphiphiles with DNA or RNA and the resulting supramolecular structures are of interest for the delivery of nucleic acids to cells. As such, a means to correct a defective gene, introduce a new gene, or knock-down a gene is provided for a specific *in vitro* or *in vivo* application (*1–7*). This complexation between cationic amphiphiles and nucleic acids is governed by electrostatic interactions between the positively charged amphiphiles and the negatively charged phosphate backbone of the nucleic acid and the hydrophobic chain−chain packing forces between the individual assembled amphiphiles. In biology, the recognition of nucleic acids by proteins involves more than electrostatic interactions (*8–10*). Examination of these protein nucleic acid recognition motifs typically reveals structures rich in basic and aromatic amino acids that provide important electrostatic and stacking contributions to binding. With this inspiration in mind, we are designing peptide-based amphiphiles for gene delivery. Herein we describe a series of lipophilic peptides including the synthesis, physiochemical properties, cytotoxicity, and *in vitro* gene transfection activity.

To mimic structural characteristics present in nucleic acid binding proteins, we selected the tripeptide Lys-Trp-Lys, **KWK**, to be the headgroup for the amphiphile because it possesses cationic charges and an aromatic side chain and is relatively small in size. Moreover, this peptide is known to bind DNA with a binding constant on the order of 10^4 M and is a model peptide used to study protein−nucleic acid interactions, and lysine and tryptophan provide important interactions in a number of structurally characterized DNA binding domains of proteins (*11–14*). In addition, lysine-based small molecule amphiphiles and macromolecules (e.g., polylysine) are being explored and used for gene transfection (*15–24*). In order to perform a systematic study to identify the key molecular components responsible for transfection activity with these new lipophilic peptides, we prepared a series of amphiphiles where the headgroup (charge, aliphatic content, aromatic content) and fatty acid chain length (C12:0, C14:0, C16:0, and C18:0) were varied. As shown in Figure 1, fourteen different lipophilic peptides were synthesized and investigated. The lipophilic peptides were synthesized in good yield. First, the fatty acids were coupled to 3-*t*-butyldiphenylsilylglycerol using EDCI and DMAP in CH_2Cl_2. The silyl protecting group was removed with TBAF and then the corresponding Boc-protected amino acids were coupled to the free primary hydroxyl. The complete synthetic and characterization details as well as the reaction scheme can be found in the Supporting Information document.

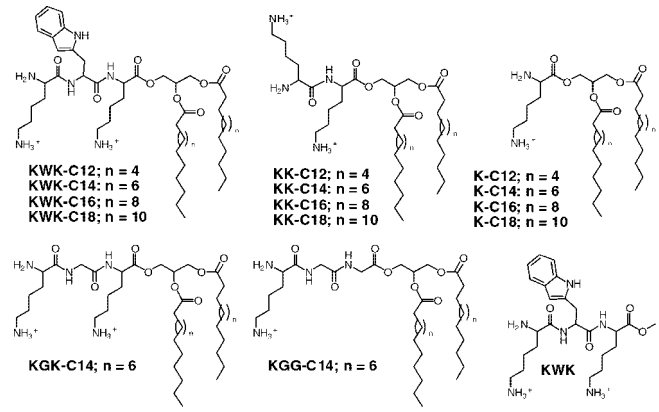

Figure 1. Lipophilic peptides under investigation for gene delivery.

To determine whether the lipophilic peptides bind DNA, we performed a standard ethidium bromide-DNA displacement fluorescence assay. All of the lipophilic peptides bind DNA with approximately the same affinity 10^6 M as measured by displacement of ethidium bromide. Most of the lipophilic peptides form DNA complexes with a cation to anion ratio between 1.5 and 2, except for the C18:0 analogues which have a cation to anion ratio of 3. Binding curves for all of the lipophilic peptides can be found in the SI.

These lipophilic peptides are likely to form bilayer vesicles in aqueous solution, given the polar headgroup and long hydrophobic acyl chains present in the structure. We prepared liposome solutions of all the lipophilic peptides with and without DNA by sonicating a hydrated film of the lipid in an aqueous solution (see SI for details). Dynamic light scattering measurements revealed the average diameter to range from 170 to 850 nm for the various lipophilic peptides. As expected, vesicles were not observed with the tripeptide alone, **KWK**. Next, X-ray

diffraction experiments were performed at 25 °C on samples in the absence and presence of DNA to characterize the supramolecular structure (see SI). A hydrated vesicle pellet was obtained for all samples except **K-C14**, **KK-C16**, **K-C16**, and **KGG-C14**. For the specimens that formed pellets, oriented multilayers were prepared for X-ray analysis by placing the pellets on a curved glass substrate and incubating at 66% relative humidity. All of the samples that did diffract showed multiple reflections indexing as orders of lamellar repeat periods, characteristic of lipid bilayers. For a specific headgroup the lamellar repeat period systematically increased with increasing fatty acid chain length. For example, the repeat periods for **KK-C12**, **KK-C14**, and **KK-C18** were 3.7 nm, 4.1 nm, and 5.1 nm, respectively. For these **KK** samples the repeat period did not increase appreciably upon the addition of DNA, indicating that DNA was not present within the multilayers. The lipophilic peptides **KWK-C14** and **KWK-C16**, possessing the tripeptide headgroup and either the C14:0 or C16:0 acyl chains, gave larger lamellar repeat periods in the presence of DNA. The addition of DNA increased the repeat periods from 4.4 to 7.3 nm and 6.6 to 7.1 nm for **KWK-C14** and **KWK-C16**, respectively. For **KGK-C14** a repeat period of 4.1 nm was obtained without DNA and a satisfactory pellet with DNA was not obtained. For **KGG-C14** the repeat period in the presence of DNA was 6.8 nm. These data with the tripeptide headgroups are consistent with a structural model where a smectic phase is formed with the DNA chains located between the adjacent lipid bilayers within the multilamellar liposome. This structural model has been reported for complexes of DNA with DOTAP (*25*) and cationic triesters of phosphatidylcholine (*26*).

Transfection experiments using the reporter gene, β-galactosidase (β-gal, pVax-LacZ1, Invitrogen), were performed with chinese hamster ovarian (CHO) and NIH 3T3 cells (see SI for details). Gene transfection results were determined after 48 h as a function of both lipophilic peptides and cation/anion ratio. Only those lipophilic peptides possessing the tripeptide headgroup afforded significant transfection of the reporter gene. The peptide itself does not transfect. As shown in Figure 2 for the CHO cells, lipophilic peptides **KWK-C14** and **KWK-C16** were more effective synthetic vectors than the **KWK-C12** and **KWK-C18** based lipids. To assess the role of the aromatic tryptophan and lysine in the headgroup, we tested peptidic amphiphile **KGK-C14** where the W was replaced with a glycine (G) residue and **KGG-C14** where the alpha K was also replaced with a G. As shown in Figure 2, good transfection activity was observed with **KGK-C14**, and higher levels were obtained with the **KGG-C14** transfection agent. The lipophilic peptide **KGG-C14** was comparable to our positive control. Successful transfection was also observed with the NIH 3T3 cells as shown in Figure 2 with the **KWK-C16** being the most active. The lipophilic peptides transfected a large number of cells in the population as confirmed by histochemical staining (Figure 3). Cytotoxity experiments performed with all the tripeptide lipophilic peptides showed no significant cytotoxicity, similar to nontreated cells and significantly better than Lipofectamine 2000 when exposed to chinese hamster ovarian (CHO) or NIH 3T3 cells (see SI).

In summary, a series of new lipophilic peptides are reported and those possessing a cationic tripeptide headgroup are effective nonviral vectors for gene delivery. A number of observations can be made for these lipophilic peptides including (1) the necessity for lipophilicity in the vector as the tripeptide itself does not form vesicular structures nor afford transfection (**KWK-C14** vs **KWK**); (2) more cationic charges are not the sole contributor to efficient transfection (**K-C16** vs **KK-C16** vs **KWK-C16**); (3) a peptide-based headgroup containing an aromatic residue capable of DNA intercalation is not required as substitution by an aliphatic residue gives activity; (4) spacing

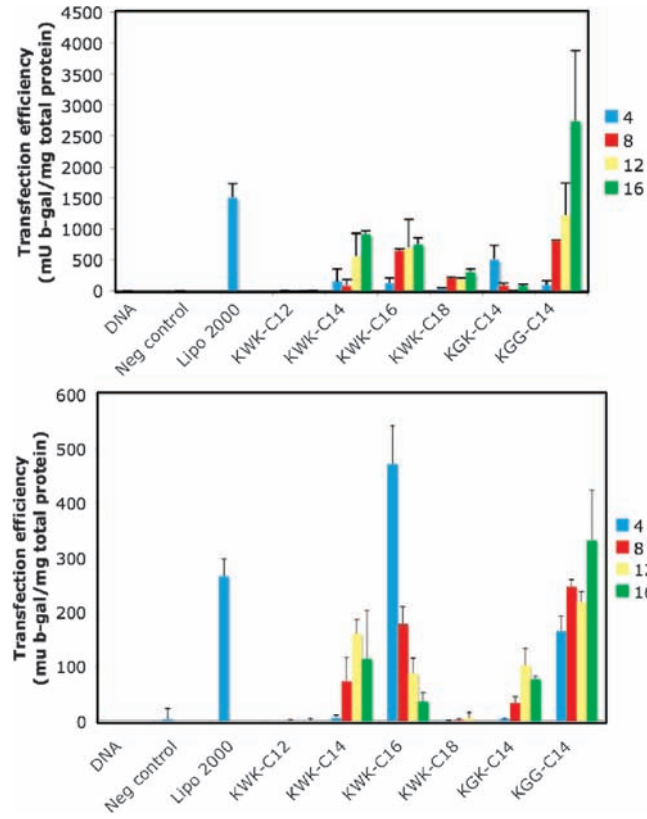

Figure 2. Gene transfection results after 48 h in CHO cells (top) and in NIH 3T3 (bottom) as a function of lipophilic peptide and mole ratio. $N = 3$.

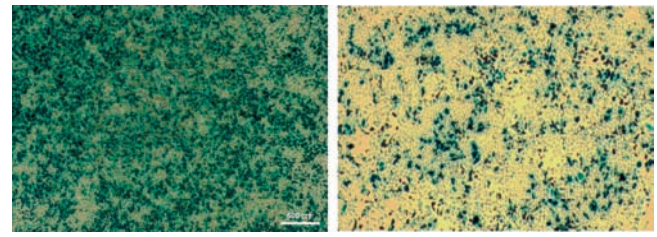

Figure 3. Photograph of CHO cells transfected with the reporter gene, β-galactosidase (β-gal) using **KWK-C14** (right) and Lipofectamine 2000 (left).

of the cationic charges within the headgroup affords better transfection performance (**KWK-C14** vs **KK-C14**); and (5) lipoplexes forming a lamellar structure with DNA which possess >6 nm repeat periods perform better compared to the structures that do not (**KWK-C14** vs **KK-C14**). These results highlight the sensitivity of gene transfection to subtle changes in chemical structure and the importance of identifying the optimized noncovalent interactions between the transfection agent and DNA. Importantly, these results with the lipophilic peptides expand the current repertoire of efficient transfection vectors available for use. Continued research with synthetic nonviral vectors will facilitate the design, development, and subsequent *in vitro* and *in vivo* evaluation toward the goal of efficient and safe delivery of nucleic acids.

Applications of Mesenchymal Stem Cells Labeled with Tat Peptide Conjugated Quantum Dots to Cell Tracking in Mouse Body

Yun Lei,[†,‡] Haiyang Tang,[§] Lide Yao,[†] Richeng Yu,[‡] Meifu Feng,*[,§] and Bingsuo Zou*[,†]

Micro-Nano Technologies Research Center and State Key Lab of CBSC, Hunan University, Changsha 410082, China, Institute of Physics and Institute of Zoology, Chinese Academy of Sciences, Beijing 100080, China. Received February 28, 2007; Revised Manuscript Received September 15, 2007

Fluorescent quantum dots have great potential in cellular labeling and tracking. Here, PEG encapsulated CdSe/ZnS quantum dots have been conjugated with Tat peptide, and introduced into living mesenchymal stem cells. The Tat peptide conjugated quantum dots in mesenchymal stem cells were assessed by fluorescent microscopy, laser confocal microscope and. flow cytometry. The result shows that Tat peptide conjugated quantum dots could enter mesenchymal stem cells efficiently. The Tat-quantum dots labeled stem cells were further injected into the tail veins of NOD/SCID beta2 M null mice, and the tissue distribution of these labeled cells in nude mice were examined with fluorescence microscope. The result shows that characteristic fluorescence of quantum dots was observed primarily in the liver, the lung and the spleen, with little or no quantum dots accumulation in the brain, the heart, or the kidney.

INTRODUCTION

Stem cells have generated a great deal of excitement as a potential source of cell-based therapies (*1, 2*). The development of stem cell therapies requires a quantitative and qualitative assessment of stem cell fate and their distribution in the host organism. The uses of traditional organic fluorophores and green fluorescent protein are subject to certain limitations in living cells. Quantum dots (QDs) as a new generation of fluorescent markers have shown tremendous advantage in biological research, especially cellular labeling and imaging (*3, 4*). Many efforts have been directed toward introducing QDs into cells. Strategies have been used such as microinjection (*5*), electroporation (*6*), phagocytosis (*7, 8*), cationic lipid transportation (*9*), and peptide-mediated transfection (*10–15*). Therefore, peptide-mediated transfection has attracted more and more attention for the efficient cellular transmembrane delivery and labeling (*16, 17*). Though the mechanism of peptide-mediated membrane translocation remains unclear, increasing evidence indicates the involvement of several types of endocytosis (*18–20*).

Here, we used the cell-penetrating peptide Tat modified with a linker and the C-terminus followed by a reactive cysteine, which was covalently attached to QDs via the cross-linking reagent. Moreover, considering the cytotoxicity of QDs in the biological system, CdSe/ZnS QDs have been investigated for different surface modification (*21*) such as coating with mercaptoacid, silane, and polymer. Recently, PEG-coated QDs were investigated (*22, 23*), and the results show that PEG-coated QDs have minimal impact on cells. Thus, in our work, 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[amino(poly(ethylene glycol)) 2000] (DSPE-PEG 2000 amine) was selected to coat QDs with amine groups as functional groups for further covalent bonding to the cysteine-modified Tat peptide. PEG-coated QD-Tat peptide complexes were transported into living mesenchymal stem cells (MSCs) and assessed by fluorescent microscopy, laser confocal microscopy, and flow cytometry. The QD–Tat peptide labeled MSCs were further assessed with stem cell engraftment in nude mice, and the result shows that Tat peptide covalently conjugated QDs may not only act as an effective probe for stem cell observation in vitro, but also serve as a long-term tracer for stem cell based transplantation in the mouse body. Thus, the purpose of our study was to evaluate the internalization of Tat peptide conjugated QDs MSCs and the tissue distribution of these labeled stem cells in a nude mouse.

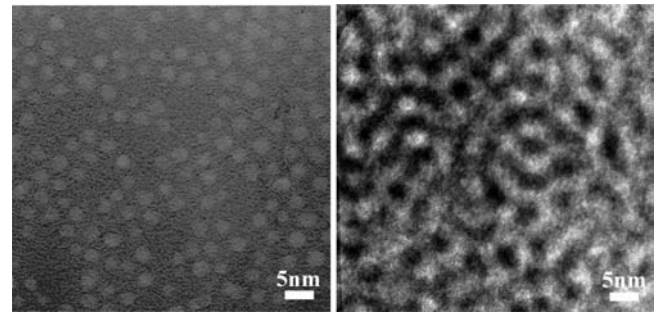

Figure 1. TEM images of the as-prepared TOPO-capped CdSe/ZnS QDs (left, about 3 nm) and DSPE-PEG-coated QDs (right, about 4 nm).

MATERIALS AND METHODS

Materials. *n*-Trioctylphosphine oxide (TOPO) (90%), bis(trimethylsilyl) sulfide (95%), $Cd(CH_3)_2$ (97% hexane solution), $Zn(CH_3)_2$ (1.0 M heptane solution), and *n*-trioctylphosphine (TOP) were purchased from Acros Chemicals Corporation. Se

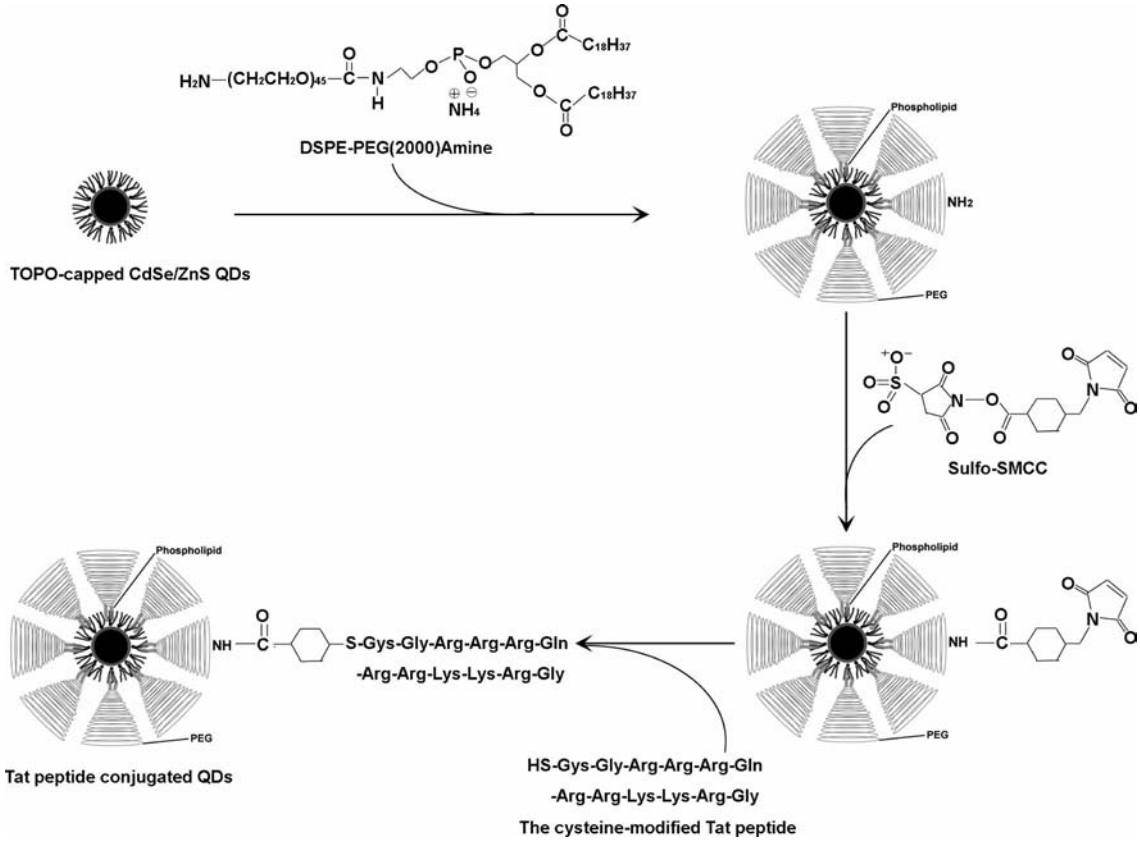

Figure 2. Schematic illustration of peptide-conjugated QDs for stem cell targeting and imaging. The first step involves the coating of TOPO-capped QDs with DSPE-PEG 2000 NH_2. After coating, DSPE-PEG-coated QDs are water-soluble with amine on the surface. Then, the DSPE-PEG-coated CdSe/ZnS QDs were reacted overnight with the cysteine-modified Tat peptides via the Sulfo-SMCC cross-linker. Sulfo-SMCC has an *N*-hydroxysuccinimide (NHS) ester at one end, which reacts with a primary amine on the QDs to form an amide bond and a maleimide group at the other, which reacts with a thiol on the cysteine-modified Tat peptide to form a thioether.

powder (99%), $CHCl_3$ (AR), and methanol (AR) were purchased from Beijing Chemical Reagents Corporation. Sulfosuccinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (Sulfo-SMCC) were purchased from Pierce Biotechnology. Cell-penetrating peptide Tat custom-modified with a linker at the C-terminus followed by a reactive cysteine was purchased from Beijing Scilight Biotechnology Limited Corporation. 1,2-Distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[amino(poly(ethylene glycol)) 2000] (DSPE-PEG 2000 amine) was purchased from Avanti Polar Lipids Inc.

Preparation of DSPE-PEG-Coated CdSe/ZnS QDs. An encapsulation strategy was used for hydrophobic CdSe/ZnS QDs. This approach exploits the hydrophobic nature of the nanoparticle surface by utilizing an amphiphilic poly(ethylene glycol)-phospholipid (PEG-phospholipid), whose hydrophobic portion interacts with the nanoparticle surface to create micelles, resulting in a self-assembled monolayer coating. The PEG portion of the coating confers them aqueous solubility and biocompatibility, at the same time the use of modified PEG allows for bioconjugation (*24*).

CdSe/ZnS QDs were prepared using a synthetic route reported earlier (*25, 26*). Since the quality of TOPO affected the nucleation and growth process seriously, TOPO was purified at the temperature of 400 °C in argon before use. All other reagents were used without any further purification. The prepared TOPO-capped QDs were added with equal volume of methanol and cooled to −10 °C for 2 h. After vigorous centrifugation, the precipitation from the cold solution was collected for the further use.

50 mg DSPE-PEG 2000 amine was dissolved in 2 mL chloroform, and 2.5 mg TOPO-capped CdSe/ZnS QDs were added. QDs coated with DSPE-PEG 2000 amine was dried under argon gas and left in a vacuum desiccator for 48 h to remove all trace of organic solvent.

Bioconjugation of DSPE-PEG-Coated CdSe/ZnS QDs. To functionalize CdSe/ZnS QDs for bioconjugation and subsequent delivery and imaging studies, we used the cysteine-modified Tat peptide and heterobifunctional cross-linking reagent Sulfo-SMCC. First, Sulfo-SMCC was dissolved in 500 μL phosphate-buffered saline (PBS, pH 7.4, NaCl 50 mM) at a concentration of 20 μM, and then DSPE-PEG-coated CdSe/ZnS QDs were dispersed in the PBS solution of Sulfo-SMCC cross-linker at a concentration of 1 μM. After incubating for 60 min at room temperature, excess cross-linker molecules were removed by using a Sephadex G-25 column. The 10-fold concentration of Tat peptide (10 μM) was added to the above PBS solution and reacted overnight with the DSPE-PEG-coated CdSe/ZnS QDs via the Sulfo-SMCC cross-linker.

Cell Cultures. MSCs were isolated from fetal bone marrow. The cells were grown in complete Dulbecco's Modified Eagle'S Medium—high glucose (10% fetal bovine serum, 100 U/mL penicillin, and 100U/mL streptomycin sulfate) on a 6-well plate predeposited with a slide.

Cell Labeling with Bioconjugated CdSe/ZnS QDs. 500 μL Tat peptide-conjugated QDs were added to the culture of MSCs (5×10^6). The Tat peptide-conjugated QDs and MSCs were incubated at 37 ° for 60 min.

MSC Transplantation and Bioluminescent Imaging. For studies on systemic distribution and engraftment of QD–Tat peptide labeled stem cells, approximately 10^6 labeled stem cells suspended in 0.2 mL PBS were injected intravenously into the tail veins of NOD/SCID beta2 M null mice (male, 8 weeks of

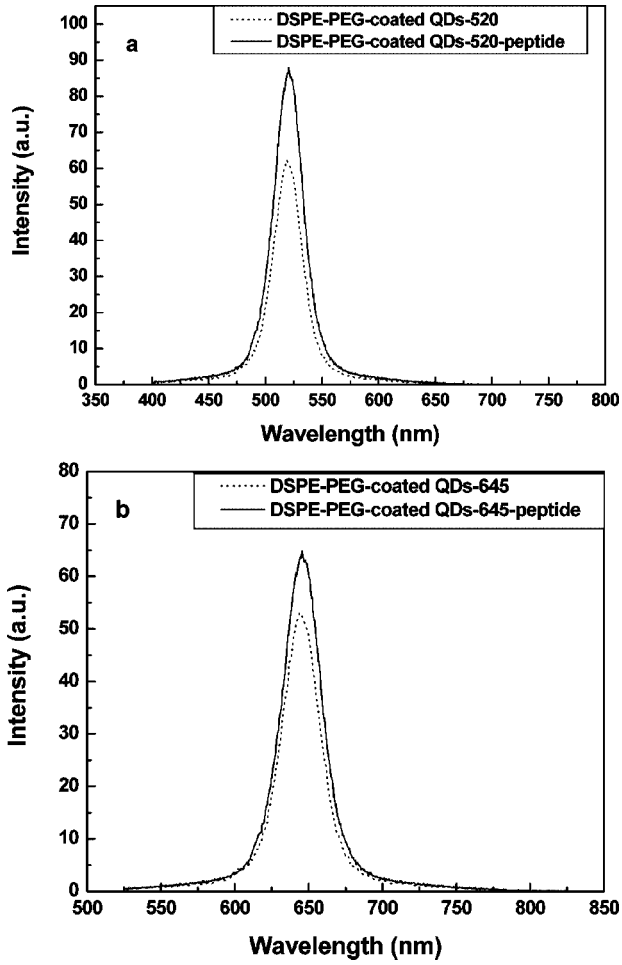

Figure 3. PL spectra of DSPE-PEG-coated QDs and Tat peptide-conjugated QDs. The PL intensity of Tat peptide-conjugated QDs-520 (solid line) enhances by 41% compared to simple DSPE-PEG-coated QDs-520 (dotted line). Similarly, the PL intensity of Tat peptide-conjugated QDs-645 (solid line) increases by 22% as compared to simple DSPE-PEG-coated QDs-645 (dotted line). The PL spectra were recorded with an excitation at 380 nm.

age). Mice were killed after 24 h, and major organs (heart, lung, spleen, liver, kidney, and brain) were removed and washed three times with PBS to remove retained erythrocytes. Collected tissues were frozen in liquid nitrogen and embedded into paraffin. To assess histological QD uptake and distribution of transplanted stem cells, tissue collections were cryosectioned into sections 5–10 μm thick, fixed with acetone at 0 °C, and examined with a fluorescence microscope.

Characterizations. The morphologies of CdSe/ZnS QDs were observed on a JEM2010 transmission electron microscope. The photoluminescence (PL) spectra were recorded on a PTI-601 fluorescence spectrophotometer. The fluorescence images were taken on a fluorescence microscope (Olympus IX71) excited by an ultraviolet source, and the confocal images were recorded on a Zeiss LSM510 laser confocal microscope excited by an argon laser (488 nm).

To investigate the location of QD–Tat peptides into MSCs, the MSCs were treated for transmission electron microscope (TEM) observation. MSCs were fixed with 2.5% glutaraldehyde for 4 h at room temperature and rinsed with phosphate-buffered saline (PBS), and then the cells were fixed with 1% osmium tetraoxide for 1 h and washed with distilled water. The samples were dehydrated through a graded ethanol and acetone series, and finally embedded with epoxy resin. The epoxy resin samples were polymerized at 60 °C for 24 h. Thin sections were made using an ultramicrotome and collected on copper grids. The samples on copper grids were observed on a Philips CM200 transmission electron microscope (TEM) at 80 KV.

To assess the labeling efficiency of QD–Tat peptides, the MSCs incubated with QD–Tat peptides were trypinized and washed with PBS three times, and then analyzed using flow cytometry (FACSCaliblur, BD Biosciences, San Diego, CA, USA) with a 488 nm Ar laser.

RESULTS AND DISCUSSION

Monodispersed CdSe/ZnS QDs capped with TOPO were characterized by transmission electron microscopy (Figure 1 left), and the corresponding size distribution (σ) is 2.72%. After coating with DSPE-PEG 2000 amine (Figure 1 right), the size distribution of DSPE-PEG-coated QDs is 11.3% due to the effect of the solvent polarity.

The scheme of DSPE-PEG coating and Tat peptide conjugation for cellular targeting and imaging is shown in Figure 2. The first step involves the coating of TOPO-capped QDs with DSPE-PEG 2000 amine. After coating, DSPE-PEG-coated QDs are water-soluble with amine on the surface. Then, the DSPE-PEG-coated CdSe/ZnS QDs reacted overnight with the cysteine-modified Tat peptides via the Sulfo-SMCC cross-linker.

Tat peptide conjugated QDs were prepared with two distinct QDs (QDs-520 and QDs-645). The PL spectra were measured after the first reaction with DSPE-PEG 2000 amine, and the PL intensity of QDs changed during the peptide coupling process. As shown in Figure 3a, the PL intensity of QDs-520 was enhanced remarkably after the secondary coupling with the Tat peptides, increasing by 41%. Clearly, this increase was also observed in QDs-645 (Figure 3b) after conjugating with Tat peptides, enhanced by 22%. The enhancement might be attributed to the covalent bonding between the thiol groups of cysteine-modified Tat peptides and the amide groups of DSPE-PEG 2000 amine capped QDs. Coating QD with a high molecular weight polymer such as polypeptides might prohibit electron leakage through the surface NH_2 groups and might contribute to the continuously electron-rich condition of whole QDs (*10*).

MSCs were incubated with Tat peptide-conjugated QDs and observed by fluorescent microscopy. The fluorescent microscopy images (Figure 4a–c) show that MSCs incubated with QD–Tat peptides emit fluorescence. A punctate and vesicular QD fluorescence pattern was observed within perinuclear spaces. For comparison, DSPE-PEG-coated QDs were directly incubated with MSCs without the assistance of Tat peptides. The fluorescent microscopy images are shown in Figure 4d–f. No intracellular QD fluorescence was observed in MSCs. Similarly, control experiments performed with a random peptide resulted in no noticeable cellular uptake (Figure 4g–i). The results suggest that Tat peptide is an effective vehicle for labeling QDs entering stem cells. The reactive cysteine sequence allows Tat peptides to conjugate with DSPE-PEG-coated QDs via cross-linking reagent while the oligoarginine sequence allows QD delivery across the cellular membrane and intracellular labeling.

The QD–Tat peptide labeled stem cells were further studied on a laser confocal microscope (Figure 5). In contrast to our previous observations using fluorescence microscopy, the more sensitive confocal observation technique used here indicated a higher intensity of intracellular QD fluorescence than what was previously measured above (a punctate and vesicular QD fluorescence pattern in Figure 4). The fluorescent QD–Tat peptides dispersed nearly homogeneously throughout the cytoplasm in the periphery of the nucleus. To demonstrate the use of QD–Tat peptides in a multiplexing experiment, two color quantum dots (QDs-520 and QDs-645) are designed to bind to

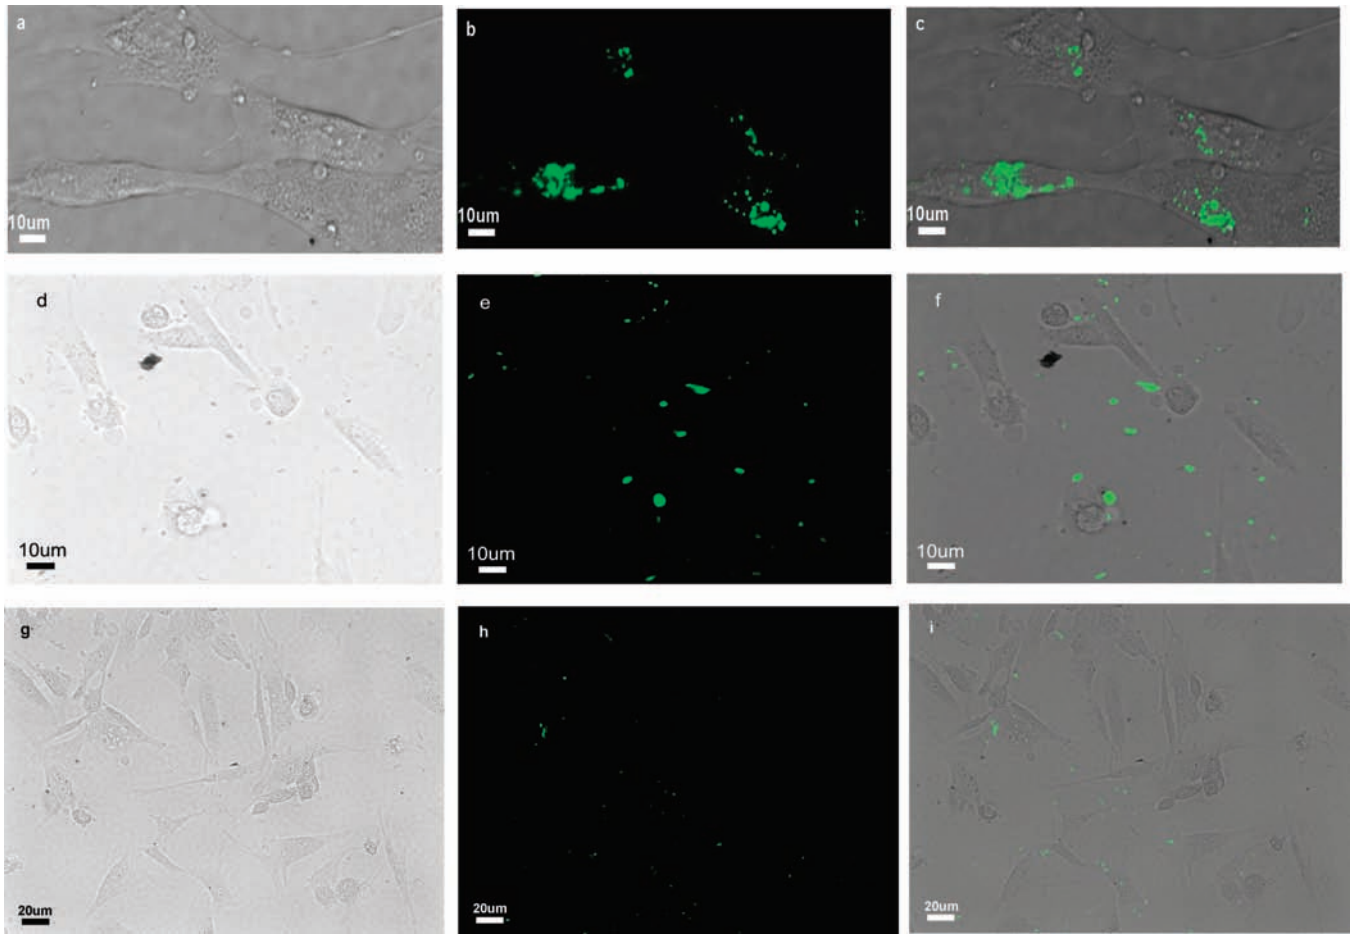

Figure 4. Fluorescent microscopy images of MSCs incubated with DSPE-PEG-coated QDs. With the use of Tat peptides, MSCs labeled by the green QD–Tat peptides are shown in parts a–c. As compared, DSPE-PEG-coated QDs were directly incubated with MSC without the assistance of Tat peptides, and the images are shown in parts d–f. A control experiment was performed to use QDs with a random peptide, and the images are shown in parts g–i. Therefore, a, d, and g are the images in the bright field; b, e, and h are the corresponding fluorescent images; and c, f, and I are the merged images.

Tat peptides and introduced into the same stem cells simultaneously. After excitation with a 488 nm laser line, both populations of bioconjugated QDs were identified in stem cells using confocal laser microscopy. The confocal images of MSCs labeled with two color QD–Tat peptides are shown in the Supporting Information. The green (Figure S1a) and red (Figure S1b) fluorescence of QD–Tat peptides are superimposed as yellow dots, which are shown in the merged fluorescent image of Figure S1d.

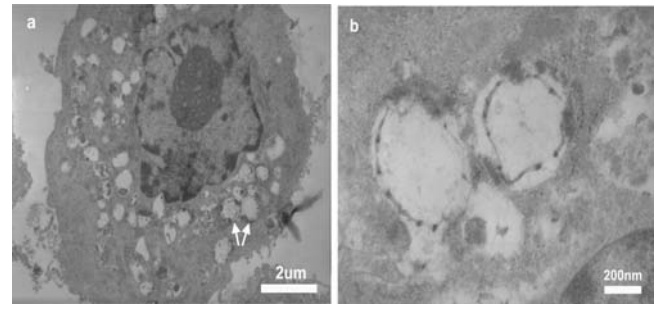

Figure 6. TEM analysis of the internalized QD–Tat peptides in MSCs. (a) TEM images of MSCs labeled by QD–Tat peptides, and the white arrowheads indicate endosomes. (b) A magnified view of endosomes in (a). QD–Tat peptides are seen as black dots surrounding the interior of the vesicles.

The internalization of QD–Tat peptides was further observed by transmission electron microscopy, which provided an even higher resolution than confocal microscopy. Figure 6a,b provides TEM images of intracellular QD–Tat peptides. The white arrowheads in Figure 6a indicate endosomes, which are magni-

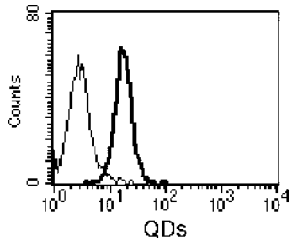

Figure 7. Flow cytometry analysis for the Tat peptide-conjugated QDs in MSCs. The left curve represents MSCs treated as control, and the right curve represents the responding sample treated with Tat peptide-conjugated QDs.

fied in Figure 6b. QD–Tat peptides are seen as black dots, surrounding the interior of the endosomes. The electron micrographs provide direct evidence that at least a portion of the internalized QD–Tat peptides were colocalized within endosomes. This result is consistent with the work reported by Delehanty et al. (*12*). They not only confirmed that QD signal dispersed nearly homogeneously throughout the cytoplasm on confocal microscopy, but also observed partial colocalization of QDs within endosomes. The partial colocalization of QDs within endosomes suggests a role for endocytosis in the uptake of the QD–Tat peptides. Other reports using live-cell imaging and FACS analysis have also established the role of endocytosis in the uptake of arginine-rich cell-penetrating peptides and their cargos (*27–29*).

The MSCs incubated with Tat peptide-conjugated QDs were trypinized and washed with PBS three times, and then analyzed using flow cytometry. Flow cytometry analysis (Figure 7) in the left curve represents the MSCs treated as control, and that in the right curve represents the responding sample treated with green QD–Tat peptides emitted at 520 nm. The flow cytometry data indicate that Tat peptide-conjugated QDs could enter MSCs with high efficiency (>95%). Although flow cytometry cannot distinguish between surface-bound and intracellular QD–Tat peptides, confocal and TEM data do confirm the uptake of the QD–Tat peptides by the MSCs. Furthermore, steps were taken to wash away the surface-bound QD–Tat peptides and ensure that data from flow cytometry were from the internalized QD–Tat peptides.

The internalized QD–Tat peptides in MSCs were further assessed with stem cell engraftment in nude mouse. Because red luminescent QDs were easier to distinguish from the

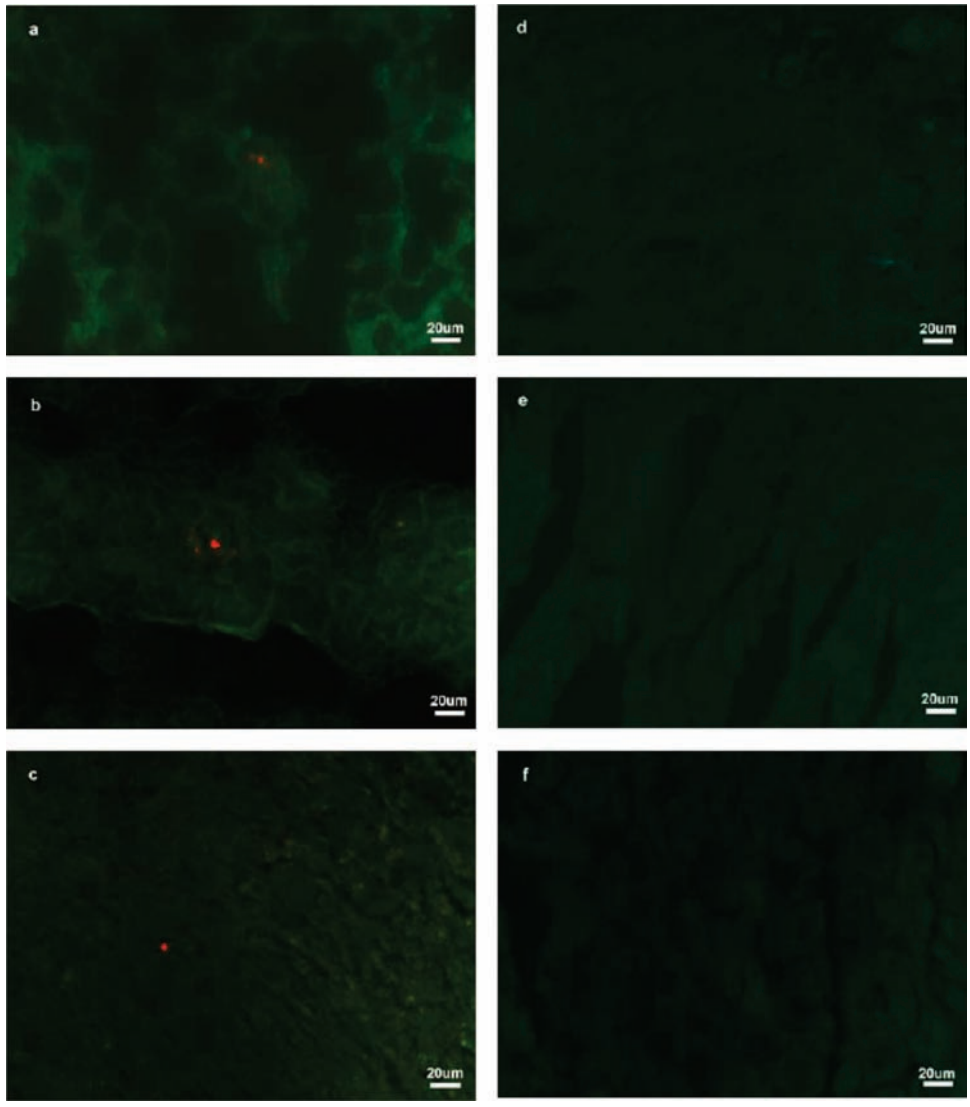

Figure 8. Intracellular labeling of stem cells by QD–Tat peptides permits in vivo imaging despite tissue autofluorescence. MSCs labeled with Tat peptide-conjugated QDs were intravenously injected into mice, and tissue sections of six normal host organs were observed via fluorescent microscopy. The characteristic red fluorescence of QD–Tat peptides were detected primarily in the lung (a), the liver (b), and the spleen (c), with little or no QD accumulation in the brain (d), the heart (e), or the kidney (f). All other signals were due to background autofluorescence.

autofluorescent tissue background than the green luminescent QDs, we injected the tail veins of NOD/SCID beta2 M null mice with QD-645-Tat peptide-labeled MSCs. After 24 h, the mice were killed and major organs (heart, lung, spleen, liver, kidney, and brain) were extracted and fixed in formalin. Representative images (Figure 8a) were obtained from 5 to 10 μm optical tissue sections on a fluorescence microscope excited by an ultraviolet source. The characteristic red fluorescence shows the presence of labeled MSCs in the lung. Tissues from other organs including liver (Figure 8b) and spleen (Figure 8c) were examined for the presence of QD-645-Tat peptide labeled stem cells. The presence of QD–Tat peptide labeled stem cells in other tissues indicated that not all the stem cells are trapped in the lung. A population of stem cells is able to circumnavigate the lung capillary network and seed other organs. However, the number of stem cells per field labeled with red QD–Tat peptide tracer was lower in the spleen and liver than in the lung tissues. The sections of the brain (Figure 8d), the heart (Figure 8e), or the kidney (Figure 8f) were also observed in fluorescence microscopy; no red luminescent spots appeared on these three kinds of organs. The results are in line with the report by Simon et al. after injecting QDs-labeled tumor cells into the tail vein of a rat (*9*).

CONCLUSIONS

In summary, PEG-QDs with covalently coupled Tat peptides produce nanometer-sized materials with biological function, which can penetrate the cellular membrane for cellular labeling and imaging. To assess the technique qualitatively and quantitatively, we combined the use of laser confocal microscopy and transmission electron microscopy to evaluate intracellular quantum dot localization in single cells and flow cytometry to quantify the delivery efficiency over a population of live mesenchymal stem cells. The result shows that Tat peptide-conjugated quantum dots could enter MSCs efficiently. The QD–Tat peptide labeled stem cells were injected intravenously into the tail veins of NOD/SCID beta2 M null mice, and the tissue distribution of these labeled stem cells in nude mice was examined by fluorescence microscopy. The result shows that characteristic fluorescence of QD–Tat peptides was observed primarily in the liver, the lung, and the spleen, with little or no QD accumulation in the brain, the heart, or the kidney. The labeled stem cells can be visualized by fluorescent imaging at the single-cell level, which offers a promising approach in stem cell transplantation and will hold a significant impact on the advancement of stem cell based therapy.

General Structure–Activity Relationship for Poly(glycoamidoamine)s: The Effect of Amine Density on Cytotoxicity and DNA Delivery Efficiency

Chen-Chang Lee, Yemin Liu, and Theresa M. Reineke*

Department of Chemistry, University of Cincinnati, Cincinnati, Ohio 45221-0172. Received May 8, 2007; Revised Manuscript Received October 5, 2007

Herein, two new series of poly(glycoamidoamine)s (branched and linear) have been synthesized by polycondensation. The polymer repeat units have been designed to contain D-glucaramide, *meso*-galactaramide, D-mannaramide, or L-tartaramide structures and five or six ethyleneamine units to investigate the amine density effects on the bioactivity as compared to a similar series of poly(glycoamidoamine)s previously described that contain four ethyleneamines. These delivery vehicles were created to examine the effects that the number of secondary amines in the polymer repeat unit and the polymer structure (branched and linear) have on plasmid DNA (pDNA) binding affinity, polyplex formation, cell viability, and gene expression in the absence and presence of serum in the culture medium. The results reveal that the new polymers with higher amine density in the repeat unit do not significantly enhance the transfection efficiency compared to that of previous models containing four ethyleneamines, but an increase in cytotoxicity is noticed. Linear polymers reveal higher pDNA neutralization efficacy, gene expression, and toxicity than the branched versions containing a similar chemical structure, which may be caused by a higher protonation of the amine groups. With these new vectors, some interesting trends emerged. The galactaramide and tartaramide analogues revealed higher delivery efficiency than the glucaramide and mannaramide structures. In addition, the branched and linear structures containing five ethyleneamines in the repeat unit formed polyplexes at higher N/P ratios, which had lower zeta potential and lower delivery efficacy than the analogues with six ethyleneamines, and also the linear structures generally revealed higher delivery efficiency and toxicity when compared to those of their branched analogues.

INTRODUCTION

Viral vectors and nonviral vectors are currently being explored for genetic drug delivery. Nonviral systems are gaining widespread attention due to the many issues that have surfaced with viral-based systems (*1–6*). Theoretically, there are many advantages of using synthetic polymers. For example, their versatility allows them to be tailored to carry various types and sizes of nucleic acids for a variety of delivery applications (*5, 7*). However, it is well-known that small changes in the polymer chemical and structural properties can affect efficiency, toxicity, and the cellular mechanisms involved in delivery (*8–10*). Also, the delivery efficiency is often cell-type dependent (*11–13*), which also may be related to the polymer structure. To find a proper synthetic vector for a particular therapeutic target, medicinal chemistry-like studies will help determine the proper efficacious delivery system.

Among the many cationic vectors with amine functionalities, poly(ethylenimine) (PEI) (*14, 15*), PAMAM dendrimer (*16*), poly L-lysine (PLL) (*17*), and chitosan (*18*) are widely studied DNA carriers. The amines within these materials enable them to form tight and small complexes (termed polyplexes or dendriplexes) with DNA through electrostatic binding and neutralization of the DNA backbone (*19*). The amine groups within these materials also play important roles in delivery efficiency; they facilitate cell-membrane binding and internalization via various endocytotic routes. In addition, it has been hypothesized that the amine groups, which can be protonated at physiological pH, enable the systems to escape from the endosomes via the "proton sponge" effect (*14*). Unfortunately, the high amine density in polymers such as PEI can cause cytotoxicity *in vitro* and *in vivo* because highly charge-dense materials can likely destabilize the cellular membrane (*20, 21*). In addition, previous studies also have found that the transfection efficiency of PEI is dependent on several factors including the physical structure (branched or linear) and the molecular weight (*22–26*). For example, Colledge et al. found that the gene delivery efficiency of branched and linear PEI is significantly dependent on the polymer structure where linear PEI was generally found to be more efficient (*24*). Conversely, vectors that have a lower amine density are typically better tolerated in biological systems. A well-known example is chitosan, a copolymer of glucosamine and *N*-acetyl-D-glucosamine, and a commonly studied DNA carrier. However, the poor solubility of chitosan, lack of buffering capacity, and high polydispersity are major drawbacks for its use as a nucleic acid carrier (*27*). A series of polymers inspired by the structures of PEI and chitosan, termed poly(glycoamidoamine)s, has been previously designed and synthesized by our research group as shown in Figure 1. This polymer series has allowed us to understand how subtle chemical properties can profoundly affect polymer bioactivity. For example, we have shown that as the secondary amine number increases from one to four, the transfection increases significantly, while retaining similar biocompatibility (*28–31*). We have also found that altering the hydroxyl number and stereochemistry displayed by the carbohydrate moieties (either D-glucarate, *meso*-galactarate, D-mannarate, or L-tartarate) results in dissimilar gene expression profiles, which is likely related to differences in the polymer−pDNA binding affinity, the ability of the vector to decrease nuclease degradation, and/or cellular internalization efficiency (*31*).

Herein, our aim was to further investigate the amine density effect by increasing the secondary amine number in the poly(glycoamidoamine) repeat unit to five and six and examine

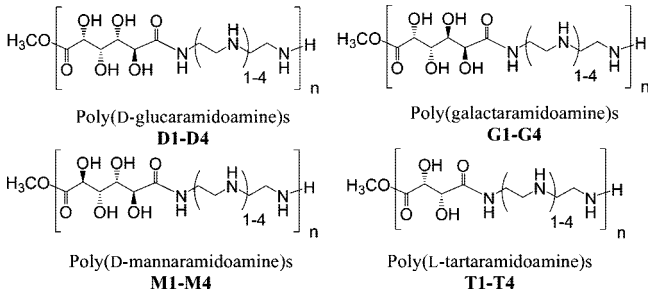

Figure 1. Library of 16 poly(glycoamidoamine)s previously studied (*24–26*). The polymers are divided into four families and are named according to the carbohydrate moieties and the number of secondary amines per repeat unit.

the bioactivity profiles in the absence and presence of serum in the medium. In addition, we have synthesized both branched and linear versions of these structures to compare how the polymer geometry affects the biological properties. To synthesize the target polymers, we have employed four esterified carbohydrate units (D-glucarate (**D**), *meso*-galactarate (**G**), D-mannarate (**M**), and L-tartarate (**T**)) in a manner similar to that in our previous studies and polymerized them with 4 novel oligoethyleneamine monomers (by utilizing protected and deprotected versions of hexaethyleneheptamine and heptaethyleneoctamine) to obtain 16 different polymer structures (8 branched and 8 linear). We have analyzed the structural properties of each polymer by ^{1}H NMR, gel permeation chromatography (GPC), light scattering, and viscometry studies. To compare these data with the results obtained from the poly(glycoamidoamine)s previously synthesized (containing 1 to 4 secondary amines per repeat unit (*28–30*)), the novel polymers synthesized herein have been made with a similar degree of polymerization (between 9 and 15). We have observed through dynamic light scattering (DLS) and gel electrophoresis experiments that there are considerable differences in the binding and compaction of pDNA when polymers containing five and six ethyleneamine units are compared. In addition, the polymer geometry appears to significantly affect bioactivity. It was also discovered that the gene expression level appears to reach a plateau with the polymers that have four ethyleneamine groups in the repeat unit. This work presents our continued efforts to understand the structure−bioactivity relationships with these poly(glycoamidoamine) models, which will advance the knowledge in this field toward the rational design of novel synthetic polymers for effective nucleic acid delivery.

EXPERIMENTAL PROCEDURES

1. General. The carbohydrate monomers (dimethyl *meso*-galactarate, D-mannaro-1,4:6,3-dilactone, esterified D-glucaric acid) used in the polymerization were synthesized according to previous reported methods (*32–34*). Dimethyl L-tartarate used in the polymerization was obtained from Acros Chemical Co. (Morris Plains, NJ). All reagents used in the synthesis, if not specified, were obtained from Aldrich Chemical Co. (Milwaukee, WI) and used without further purification. Methanol, triethylamine (TEA), and dichloromethane (CH_2Cl_2) were purified according to conventional methods. Plasmid DNA (pDNA), pCMVβ (7.2 kbp), was purchased from Plasmidfactory (Bielefeld, Germany), and gWiz-luc (6.7 kbp) was purchased from Aldevron (Fargo, ND). Mass spectra were obtained with an IonSpec ESI mass spectrometer in positive ion mode. IR spectra were measured with a Perkin-Elmer Spectrum One Fourier transform infrared spectrometer, and the samples were prepared as KBr pellets. ^{1}H and ^{13}C NMR were recorded on a Bruker AV-400 MHz spectrometer. The ^{1}H NMR data were reported as follows: chemical shift (δ ppm), multiplicity, J coupling constant (Hz), and peak integration. Cell culture media and supplements were purchased from Gibro/Invitrogen (Carlsbad, CA). pCMVβ was labeled with a Cy5 nucleic acid labeling kit (Mirus, Madison, WI), and purified by QIAquick PCR purification kit (QIAGEN, Valencia, CA). HeLa cells were purchased from ATCC (Rockville, MD). The luciferase assays were completed with a Promega Luciferase Assay Kit (Madison, WI). The toxicity assays were performed with a Bio-Rad DC Protein Assay Kit (Hercules, CA).

2. Monomer Synthesis. *2.1. Synthesis of Hexaethyleneheptamine. 2.1.1. N^1,N^5-Dibenzyl-N^2,N^3,N^4-tris(tert-butoxycarbonyl)-tetraethylenepentamine (***2a***).* Compound **1a** (4.08 g, 8.40 mmol), synthesized according to a previously reported procedure (*35, 36*), was dissolved in 70 mL of methanol and stirred in an ice bath for 10 min. Benzaldehyde (1.69 mL, 16.7 mmol) was added dropwise at 0 °C to produce the imines, and the mixture was stirred for another 30 min. TLC was used to monitor reaction completion. Next, $NaBH_4$ (0.63 g, 16.7 mmol) was added slowly over 30 min to the solution at 0 °C to reduce the imines to amines, and the mixture was stirred for another 2 h at 0–5 °C. The solvent was then evaporated under reduced pressure, the residue was thoroughly mixed with 50 mL of EtOAc and 30 mL saturated sodium bicarbonate, and the mixture was separated. The water portion was extracted with 2 × 20 mL of EtOAc, and the combined organic layers were dried with anhydrous $MgSO_4$. The drying agent was filtered and the product concentrated *in vacuo*. The residue was purified via flash column chromatography ($CH_3OH/CH_2Cl_2/NH_4OH$ = 10/100/1; R_f = 0.31) to yield the titled compound as a light yellow oil (4.75 g, 84%). ^{1}H NMR ($CDCl_3$): δ = 1.40 (s, 9H, C(C$\underline{H}_3$)$_3$), 1.44 (s, 18H, C(C$\underline{H}_3$)$_3$), 2.77 (brs, 4H, NHC$\underline{H}_2$CH$_2$N), 3.33 (brs, 12H, NHCH$_2$C$\underline{H}_2$N, NC$\underline{H}_2$C$\underline{H}_2$N), 3.78 (s, 4H, C$\underline{H}_2$Ph), 7.19–7.23 (m, 2H), 7.24–7.32 (m, 8H). ^{13}C NMR ($CDCl_3$): δ = 28.35, 28.39, 45.34, 45.62, 47.02. 47.33, 47.62, 53.47, 53.57, 79.53, 79.55, 126.87, 127.63, 128.28, 139.98, 140.18, 155.26, 155.45. FT-IR (KBr pellet, cm^{-1}): 3459.6, 2972.5, 2923.1, 1695.5, 1473.3, 1415.7, 1160.5. ESI-MS: calcd. for $(M + H)^+$ $C_{37}H_{60}N_5O_6$, 670.4543; found, 670.4535.

*2.1.2. N^1,N^5-Dibenzyl-N^1,N^5-bis(ethylphthalimido)-N^2,N^3,N^4-tris(tert-butoxycarbonyl) tetraethylenepentamine (***3a***).* To a stirred solution of KF-celite (4.24 g) and **2a** (4.75 g, 7.10 mmol) in CH_3CN (30 mL) at room temperature, *N*-bromoethyl phthalimide (14.4 g, 56.8 mmol) was added in one portion and refluxed for 14 h. The KF-celite was then filtered with celite after reaction completion. The solvent was removed under reduced pressure, and the residue was purified via flash chromatography (EtOAc/Hex = 1/1; R_f = 0.57) to yield **3a** as a waxy solid (5.25 g, 73%). ^{1}H NMR ($CDCl_3$): δ = 1.41 (s, 18H, C(C$\underline{H}_3$)$_3$), 1.45 (s, 9H, C(C$\underline{H}_3$)$_3$), 2.73 (t, J = 6.4 Hz, 8H, NC$\underline{H}_2$C$\underline{H}_2$N), 3.21–3.36 (m, 12H, NC$\underline{H}_2$C$\underline{H}_2$N, Ph(CO)$_2$NCH$_2$C$\underline{H}_2$N), 3.60–3.65 (m, 4H, C$\underline{H}_2$Ph), 3.74 (t, J = 6.4 Hz, 4H, Ph(CO)$_2$NC$\underline{H}_2$CH$_2$N), 7.02–7.14 (m, 10H), 7.71 (s, 4H), 7.79 (s, 4H). ^{13}C NMR ($CDCl_3$): δ = 28.25, 35.78, 44.43, 44.83, 45.01, 45.42, 45.83, 46.08, 51.27, 51.40, 51.84, 58.41, 58.59, 79.08, 79.20, 79.26, 122.84, 126.58, 126.67, 127.79, 127.89, 128.45, 128.48, 131.96, 133.56, 138.86, 154.94, 155.08, 167.76. FT-IR (KBr pellet, cm^{-1}): 3472.5, 2972.5, 2934.1, 1769.6, 1711.9, 1695.5, 1467.8, 1418.4, 1163.3. ESI-MS: calcd. for $(M + H)^+$ $C_{57}H_{74}N_7O_{10}$, 1016.5419; found, 1016.5497.

*2.1.3. N^2,N^3,N^4-Tris(tert-butoxycarbonyl)-hexaethyleneheptamine (***4a***).* To a solution of compound **3a** (5.22 g, 5.10 mmol) in MeOH (47 mL), hydrazine monohydrate (5.90 mL) was added and refluxed for 3 h yielding the primary amines. Then, CH_3Cl (45 mL) and 4 N NH_4OH (45 mL) were added to the reaction, and the mixture was stirred for another 30 min at room temperature. The organic and aqueous layers were separated, and the aqueous layer was extracted with 3 × 25 mL CH_3Cl.

The combined organic layers were dried with anhydrous $MgSO_4$. The drying agent was then filtered, and the filtrate was evaporated to yield the crude product as a viscous liquid (3.49 g, 90%). The next step to deprotect the benzyl groups was carried out without further purification. The product from the previous step (3.49 g, 4.60 mmol) was dissolved in MeOH (40 mL) and $Pd(OH)_2$ (0.40 g) was added to the solution. The reaction was shaken in a Parr hydrogenator under 50 psi of H_2(g) for 48 h, and reaction completion was monitored via TLC. The $Pd(OH)_2$ was then filtered with celite, and the solvent was evaporated. The residue was purified via flash chromatography (EtOAc/MeOH/NH_4OH = 3/1/1; R_f = 0.40) to obtain the waxy solid product **4a** (1.90 g, 71%). ^{1}H NMR (DMSO-d_6): δ = 1.38 (s, 27H, C(C$\underline{H}_3$)$_3$), 2.55–2.80 (brs, 8H, $NH_2C\underline{H}_2C\underline{H}_2NH$), 2.61–2.68 (brs, 4H, $NHC\underline{H}_2CH_2N$), 3.10–3.28 (m, 12H, $NC\underline{H}_2C\underline{H}_2N$). ^{13}C NMR (DMSO-$d_6$): δ = 28.49, 41.74, 45.09, 45.24, 45.38, 47.78, 48.23, 52.43, 78.89, 79.12, 154.91, 154.94, 155.00. FT-IR (KBr pellet, cm^{-1}): 3423.1, 3274.7, 2978.0, 1709.2, 1690.0, 1465.0, 1415.7, 1163.3. ESI-MS: calcd. for (M + H)$^+$ $C_{27}H_{58}N_7O_6$, 576.4449; found, 576.4174.

*2.1.4. Hexaethyleneheptamine (***5a***).* Compound **4a** (2.60 g, 4.50 mmol) was dissolved in 4 N HCl in dioxane (50 mL) and stirred for 3 h in an ice bath to remove the Boc protecting groups. The final product was dried *in vacuo* and purified via exhaustive dialysis (100 MW cutoff membrane) against ultra pure H_2O for 24 h. The final deprotected oligoamine was lyophilized to dryness to yield a fluffy white solid (0.478 g, 39%). ^{1}H NMR (D_2O with one drop of DCl): δ = 3.44 (t, J = 7.2 Hz, 4H, $NH_2C\underline{H}_2CH_2NH$), 3.54 (t, J = 7.2 Hz, 4H, $NH_2CH_2C\underline{H}_2NH$), 3.59–3.64 (m, 16H, $NHC\underline{H}_2C\underline{H}_2NH$). ^{13}C NMR ($D_2O$ with one drop of DCl): δ = 38.24, 46.20, 46.32, 47.59. FT-IR (KBr pellet, cm^{-1}): 3413.1, 2980.6, 2948.9, 2688.9, 2436.0, 1059.9. ESI-MS: calcd. for (M + H)$^+$ $C_{12}H_{34}N_7$, 276.2876; found, 276.2977.

*2.2. Synthesis of Heptaethyleneoctamine. 2.2.1. N^1,N^6-Dibenzyl-N^2,N^3,N^4,N^5-tetra(tert-butoxycarbonyl)-pentaethylene-hexamine (***2b***).* Compound **1b** (16.3 g, 25.8 mmol), synthesized according to a reported procedure (*35*, *36*), was dissolved in 165 mL of MeOH/CH_2Cl_2 (10:1) and stirred in an ice bath for 10 min. Benzaldehyde (0.78 mL, 77.3 mmol) was added dropwise at 0 °C to produce the imines, and the mixture was stirred for another 30 min. Reaction completion was monitored via TLC. Next, $NaBH_4$ (2.93 g, 77.3 mmol) was added slowly over 30 min to the previous solution at 0 °C to reduce the imines to amines, and the mixture was stirred for another 2 h at 0–5 °C. The solvent was then evaporated under reduced pressure, the residue was thoroughly mixed with 120 mL of EtOAc and 100 mL of saturated sodium bicarbonate, and the mixture was separated. The water portion was then extracted with 2 × 60 mL of EtOAc, and the combined organic layers were dried with anhydrous $MgSO_4$. The drying agent was filtered and the product concentrated *in vacuo*. The residue was purified via flash column chromatography ($CH_3OH/CH_2Cl_2/NH_4OH$ = 10/100/1; R_f = 0.37) to yield the desired compound as a light yellow oil (8.06 g, 62%). ^{1}H NMR ($CDCl_3$): δ = 1.36 (s, 36H, C(C$\underline{H}_3$)$_3$), 2.69 (brs, 4H, $NHC\underline{H}_2CH_2N$), 3.23 (brs, 16H, $NHCH_2C\underline{H}_2N$, $NC\underline{H}_2C\underline{H}_2N$), 3.87 (s, 4H, $\underline{CH}_2$Ph), 7.11–7.13 (m, 2H), 7.17–7.21 (m, 8H). ^{13}C NMR ($CDCl_3$): δ = 28.38, 28.40, 45.43, 45.78, 47.56, 53.55, 79.55, 126.83, 127.96, 128.26, 140.22, 155.18, 155.46. FT-IR (KBr pellet, cm^{-1}): 3439.6, 2978.0, 2928.6, 1687.3, 1467.8, 1418.4, 1168.8. ESI-MS: calcd. for (M + H)$^+$ $C_{44}H_{73}N_6O_8$, 813.5490; found, 813.5494.

*2.2.2. N^1,N^6-Dibenzyl-N^1,N^6-bis(ethylphthalimido)-N^2,N^3,N^4,N^5-tetra(tert-butoxycarbonyl)-pentaethylenehexamine (***3b***).* To a stirred solution of KF-celite (3.20 g) and **2b** (3.72 g, 4.60 mmol) in CH_3CN (32 mL) at room temperature, *N*-bromoethyl phthalimide (9.29 g, 36.6 mmol) was added in one portion and refluxed for 14 h. After reaction completion (monitored via TLC), the KF-celite was removed via filtration with celite. The filtrate was removed under reduced pressure, and the residue was purified via flash chromatography (EtOAc/Hex = 1/1; R_f = 0.57) to yield **3b** as a waxy solid (2.21 g, 48%). ^{1}H NMR ($CDCl_3$): δ = 1.39 (s, 9H, C(C$\underline{H}_3$)$_3$), 1.40 (s, 9H, C(C$\underline{H}_3$)$_3$), 1.43 (s, 18H, Boc), 2.60–2.70 (brs, 4H, $NC\underline{H}_2CH_2N$), 2.70 (t, J = 5.2 Hz, 4H, $NCH_2C\underline{H}_2N$), 3.15–3.33 (m, 16H, $NC\underline{H}_2C\underline{H}_2N$, Ph(CO)$_2$-$NCH_2C\underline{H}_2N$), 3.60 (brs, 4H, $\underline{CH}_2$Ph), 3.71 (t, J = 5.2 Hz, 4H, Ph(CO)$_2$$NC\underline{H}_2CH_2NH$), 6.98–7.14 (m, 10H), 7.69 (s, 4H), 7.77 (s, 4H). ^{13}C NMR ($CDCl_3$): δ = 28.43, 36.00, 45.17, 45.55, 45.97, 51.41, 51.60, 52.01, 52.11, 58.57, 58.78, 79.35, 79.55, 123.08, 126.75, 126.83, 126.92, 127.98, 128.08, 128.65, 132.18, 133.74, 139.04, 155.17, 155.29, 168.04. FT-IR (KBr pellet, cm^{-1}): 3467.0, 2972.5, 2939.6, 1775.0, 1711.9, 1692.7, 1465.0, 1415.7, 1166.0. ESI-MS: calcd. for (M + H)$^+$ $C_{64}H_{87}N_8O_{12}$, 1159.6365; found, 1159.6443.

*2.2.3. N^1,N^6-Dibenzyl-N^2,N^3,N^4,N^5-tetra(tert-butoxycarbonyl)-heptaethyleneoctamine (***4b***).* To a solution of compound **3b** (2.08 g, 1.80 mmol) in MeOH (16 mL), hydrazine monohydrate (2.10 mL) was added, and the mixture was refluxed for 3 h to yield the primary amines. Next, CH_3Cl (14 mL) and 4 N NH_4OH (14 mL) were added to the reaction, and the mixture was stirred for another 30 min at room temperature. The organic and aqueous layers were separated, the aqueous layer was extracted with 3 × 8 mL CH_3Cl, and the combined organic layers were dried with anhydrous $MgSO_4$. The drying agent was filtered, and the solvent was evaporated to yield the crude product as an oil (1.44 g, 89%). The resulting product (1.33 g, 1.47 mmol), utilized without further purification, was then dissolved in MeOH (20 mL), and $Pd(OH)_2$ (0.30 g) was added to the solution. The reaction was shaken in a Parr hydrogenator under 50 psi of H_2(g) for 48 h to remove the benzyl groups. After reaction completion (monitored via TLC), the $Pd(OH)_2$ was removed via filtration with celite, and the solution was evaporated. The residue was purified via flash chromatography (EtOAc/MeOH/NH_4OH = 3/1/1; R_f = 0.21) to obtain compound **4b** as a waxy solid (0.823 g, 68%). ^{1}H NMR (DMSO-d_6): δ = 1.39 (s, 36H, C(C$\underline{H}_3$)$_3$), 2.00–2.40 (brs, 6H, N$\underline{H}_2$, N$\underline{H}$C$\underline{H}_2$-CH_2N), 2.48–2.52 (m, 4H, $NH_2C\underline{H}_2CH_2NH$), 2.56–2.64 (m, 8H, $NH_2CH_2C\underline{H}_2NH$, $NHC\underline{H}_2C\underline{H}_2N$), 3.10–3.33 (brs, 16H, $NC\underline{H}_2C\underline{H}_2N$). ^{13}C NMR (DMSO-$d_6$): δ = 28.46, 41.89, 44.83, 45.30, 45.34, 45.40, 45.45, 45.73, 47.17, 47.86, 48.30, 52.69, 78.91, 79.14, 154.89, 155.01. FT-IR (KBr pellet, cm^{-1}): 3434.1, 3263.7, 2978.0, 1692.7, 1481.5, 1415.66, 1166.0. ESI-MS: calcd. for (M + H)$^+$ $C_{34}H_{71}N_8O_8$, 719.5317; found, 719.5087.

*2.2.4. Heptaethyleneoctamine (***5b***).* Compound **4b** (2.08 g, 2.9 mmol) was dissolved in 4 N HCl in dioxane (30 mL) and stirred for 3 h in an ice bath to remove the Boc groups. The final product was dried *in vacuo* and purified via exhaustive dialysis (100 MW cutoff membrane) against ultra pure H_2O for 24 h. The final deprotected oligoethyleneamine was lyophilized to dryness to yield a fluffy white solid (0.516 g, 56%). ^{1}H NMR (one drop of DCl in D_2O): δ = 3.42–3.46 (m, 4H, $NH_2C\underline{H}_2CH_2NH$), 3.54 (t, J = 7.2 Hz, 4H, $NH_2CH_2C\underline{H}_2NH$), 3.59–3.65 (m, 20H, $NHC\underline{H}_2C\underline{H}_2NH$). ^{13}C NMR (one drop of DCl in D_2O): δ = 38.25, 46.21, 46.32, 47.60. FT-IR (KBr pellet, cm^{-1}): 3435.1, 2980.4, 2951.0, 2680.9, 2432.8, 1285.3. ESI-MS: calcd. for (M + H)$^+$ $C_{14}H_{39}N_8$, 319.3219; found, 319.3609.

3. Polymerization. *3.1. Branched Polymer Synthesis. 3.1.1.* **G5$_B$.** Dimethyl *meso*-galactarate (20.0 mg, 0.08 mmol) was mixed with a methanol solution (0.42 mL) containing triethylamine (60 μL) and **5a** (23.2 mg, 0.08 mmol) and stirred at room temperature for 48 h. The solution was exhaustively dialyzed in ultrapure water and solution was lyophilized to dryness, yielding the final polymer product (10.9 mg, 29%). ^{1}H NMR (D_2O): δ = 2.95 (brs, 18H), 3.47 (brs, 6H), 3.95 (s, 1H), 4.00

(s, 1H), 4.04 (s, 1H), 4.24–4.27 (m, 1H), 4.45 (s, 2H). IR (KBr pellet, cm^{-1}): 3374.2, 2945.0, 2846.1, 1652.9, 1644.8, 1547.1, 1415.3, 1045.2.

3.1.2. **G6$_B$.** Dimethyl *meso*-galactarate (20.0 mg, 0.08 mmol) was mixed with a methanol solution (0.34 mL) containing triethylamine (60 μL) and **5b** (27.0 mg, 0.08 mmol) and stirred at room temperature for 48 h. The solution was exhaustively dialyzed in ultrapure water, and the solution was lyophilized to dryness, yielding the final polymer product (11.5 mg, 28%). ^{1}H NMR (D_2O): δ = 2.93 (brs, 22H), 3.47 (brs, 6H), 3.95 (s, 1H), 4.00 (s, 1H), 4.03–4.06 (m, 1H), 4.24–4.26 (m, 1H), 4.45 (s, 2H). IR (KBr pellet, cm^{-1}): 3388.9, 2954.2, 2852.3, 1642.8, 1602.6, 1541.8, 1417.5, 1048.5.

3.1.3. **D5$_B$**. Esterified D-glucaric acid (20.0 mg, 0.08 mmol) was mixed with a methanol solution (0.34 mL) containing triethylamine (68 μL) and **5a** (23.2 mg. 0.08 mmol) and stirred at room temperature for 36 h. The solution was exhaustively dialyzed in ultrapure water, and the solution was lyophilized to dryness, yielding the final polymer product (9.50 mg, 25%). ^{1}H NMR (D_2O): δ = 2.96 (brs, 16H), 3.46 (brs, 8H), 3.91–3.98 (m, 2H), 4.05–4.07 (m, 1H), 4.10–4.15 (m, 2H), 4.26–4.31 (m, 1H), 4.34–4.37 (m, 1H). IR (KBr pellet, cm^{-1}): 3357.4, 2964.3, 1646.8, 1543.2, 1123.3.

3.1.4. **D6$_B$.** Esterified D-glucaric acid (20.0 mg, 0.08 mmol) was mixed with a methanol solution (0.34 mL) containing triethylamine (68 μL) and **5b** (26.7 mg. 0.08 mmol) and stirred at room temperature for 36 h. The solution was exhaustively dialyzed in ultrapure water, and the solution was lyophilized to dryness, yielding the final polymer product (13.7 mg, 36%). ^{1}H NMR (D_2O): δ = 2.96 (brs, 20H), 3.46 (brs, 8H), 3.92–3.95 (m, 1H), 3.96–4.00 (m, 2H), 4.06–4.09 (m, 1H), 4.12–4.15 (m, 2H), 4.25–4.31 (m, 2H), 4.34–4.39 (m, 2H). IR (KBr pellet, cm^{-1}): 3390.8, 2945.4, 2848.4, 1645.1, 1540.3, 1125.1.

3.1.5. **M5$_B$.** D-Mannaro-1,4:6,3-dilactone (20.0 mg, 0.11 mmol) was mixed with a methanol solution (0.60 mL) containing triethylamine (78 μL) and **5a** (35.0 mg, 0.11 mmol) and stirred at room temperature for 72 h. The solution was exhaustively dialyzed in ultrapure water, and the solution was lyophilized to dryness, yielding the final polymer product (10.5 mg, 32%). ^{1}H NMR (D_2O): δ = 3.02 (brs, 16H), 3.52 (brs, 8H), 3.96 (s, 2H), 4.05–4.07 (m, 1H), 4.11–4.13 (m, 1H), 4.20–4.28 (m, 2H). IR (KBr pellet, cm^{-1}): 3393.8, 2932.1, 2868.1, 1643.9, 1580.2, 1539.1, 1361.5, 1123.5.

3.1.6. **M6$_B$.** D-Mannaro-1,4:6,3-dilactone (12.8 mg, 0.07 mmol) was mixed with a methanol (0.73 mL) solution containing triethylamine (65 μL) and **5b** (25.0 mg, 0.09 mmol) and stirred at room temperature for 72 h. The solution was exhaustively dialyzed in ultrapure water, and the solution was lyophilized to dryness, yielding the final polymer product (19.5 mg, 39%). ^{1}H NMR (D_2O): δ = 2.93 (brs, 20H), 3.45 (brs, 8H), 3.94–3.98 (m, 2H), 4.03–4.06 (m, 1H), 4.09–4.13 (m, 1H), 4.21–4.27 (m, 2H). IR (KBr pellet, cm^{-1}): 3366.5, 2834.1, 1645.7, 1541.8, 1410.0, 1122.2.

3.1.7. **T5$_B$.** Dimethyl L-tartarate (20.0 mg, 0.11 mmol) was added to a methanol solution (0.17 mL) containing triethylamine (89 μL) and **5a** (30.0 mg, 0.11 mmol) and stirred at room temperature for 96 h. The solution was exhaustively dialyzed in ultrapure water, and the solution was lyophilized to dryness, yielding the final polymer product (6.70 mg, 16%). ^{1}H NMR (D_2O): δ = 2.98 (br, 16H), 3.50 (br, 8H), 4.10–4.12 (m, 1H), 4.33–4.35 (m, 1H), 4.59 (s, 2H). IR (KBr pellet, cm^{-1}): 3411.5, 2931.6, 2856.1, 1650.9, 1539.0, 1121.3.

3.1.8. **T6$_B$.** Dimethyl L-tartarate (20.0 mg, 0.11 mmol) was added to a methanol solution (0.17 mL) containing triethylamine (89 μL) and **5b** (35.0 mg, 0.11 mmol) and stirred at room temperature for 96 h. The solution was exhaustively dialyzed in ultrapure water, and the solution was lyophilized to dryness, yielding the final polymer product (7.40 mg, 16%). ^{1}H NMR (D_2O): δ = 2.91 (br, 20H), 3.45 (br, 8H), 4.32–4.33 (m, 1H), 4.57 (s, 2H). IR (KBr pellet, cm^{-1}): 3393.5, 2933.4, 2848.1, 1653.1, 1536.6, 1133.1.

3.2. Linear Polymer Synthesis. 3.2.1. **G5$_L$.** Dimethyl *meso*-galactarate (27.0 mg, 0.11 mmol) was mixed with a methanol solution (0.57 mL) containing triethylamine (81 μL) and **4a** (66.0 mg, 0.11 mmol) and stirred at room temperature for 48 h. The product was dialyzed against methanol using a 1000 MW cutoff membrane and dried under vacuum, yielding 53.4 mg (0.06 mmol, 53%) of protected polymer. The resulting polymer was then treated with 1 mL of dry 4 N HCl in dioxane for 3 h to remove the Boc groups. The final polymer product was dialyzed against ultra pure water using a 100 MW cutoff membrane and lyophilized to dryness, yielding 19.6 mg (0.06 mmol, 72%) of polymer. ^{1}H NMR (D_2O): δ = 3.36 (br, 4H), 3.68 (br, 20H), 4.06 (s, 2H), 4.49 (s, 2H). FT-IR (KBr pellet, cm^{-1}): 3515.5, 2976.2, 1763.8, 1577.6, 1308.5.

3.2.2. **G6$_L$.** Dimethyl *meso*-galactarate (20.7 mg, 0.09 mmol) was mixed with a methanol solution (0.35 mL) containing triethylamine (62 μL) and **4b** (62.4 mg, 0.09 mmol) and stirred at room temperature for 48 h. The product was dialyzed against methanol using a 1000 MW cutoff membrane and dried under vacuum, yielding 53.4 mg (0.02 mmol, 28%) of protected polymer. The resulting polymer was then treated with 1 mL of dry 4 N HCl in dioxane for 3 h to remove the Boc groups. The final polymer product was dialyzed against ultra pure water using a 100 MW cutoff membrane and lyophilized to dryness, yielding 27.6 mg (0.06 mmol, 94%) of polymer. ^{1}H NMR (D_2O with one drop of DCl): δ = 3.32–3.39 (m, 4H), 3.51–3.72 (m, 24H), 4.06 (s, 2H), 4.48 (s, 2H). FT-IR (KBr pellet, cm^{-1}): 3791.7, 3087.0, 1668.5, 1548.8, 1331.1.

3.2.3. **D5$_L$.** Esterified D-glucaric acid (23.0 mg, 0.1 mmol) was mixed with a methanol solution (0.32 mL) containing triethylamine (68 μL) and **4a** (55.8 mg. 0.1 mmol) and stirred at room temperature for 24 h. The product was dialyzed against methanol using a 1000 MW cutoff membrane and dried under vacuum, yielding 24.1 mg (0.03 mmol, 33%) of protected polymer. The resulting polymer was then treated with 1 mL of dry 4 N HCl in dioxane for 3 h to remove the Boc groups. The final polymer product was dialyzed against ultra pure H_2O using a 100 MW cutoff membrane and lyophilized to dryness, yielding 7.90 mg (0.02 mmol, 55%) of polymer. ^{1}H NMR (D_2O with one drop of DCl): δ = 3.35 (t, J = 5.6 Hz, 4H), 3.54–3.67 (m, 20H), 3.98 (t, J = 5.2 Hz, 1H), 4.28 (m, 1H), 4.18 (d, J = 5.2 Hz, 1H), 4.30 (m, 1H). FT-IR (KBr pellet, cm^{-1}): 3264.4, 3022.2, 1666.1, 1549.1, 1329.5.

3.2.4. **D6$_L$.** Esterified D-glucaric acid (22.6 mg, 0.1 mmol) was mixed with a methanol solution (0.38 mL) containing triethylamine (67 μL) and **4b** (68.1 mg. 0.1 mmol) and stirred at room temperature for 36 h. The product was dialyzed against methanol using a 1000 MW cutoff membrane and dried under vacuum, yielding 43.9 mg (0.05 mmol, 52%) of protected polymer. The resulting polymer was then treated with 1 mL of dry 4N HCl in dioxane for 3 h to remove the Boc groups. The product was dialyzed against ultra pure water using a 100 MW cutoff membrane and lyophilized to dryness, yielding 22.9 mg (0.05 mmol, 95%) of polymer. ^{1}H NMR (D_2O with one drop of DCl): δ = 3.35 (t, J = 6.0 Hz, 4H), 3.52–3.68 (m, 24H), 4.00 (t, J = 5.2 Hz, 1H), 4.15–4.16 (m, 1H), 4.13 (d, J = 5.2 Hz, 1H), 4.42–4.43 (m, 1H). FT-IR (KBr pellet, cm^{-1}): 3398.1, 3012.2, 1665.9, 1548.6, 1333.7.

3.2.5. **M5$_L$.** D-Mannaro-1,4:6,3-dilactone (17.0 mg, 0.11 mmol) was mixed with a methanol solution (0.65 mL) containing triethylamine (20 μL) and **4a** (56.0 mg, 0.11 mmol) and stirred at room temperature for 72 h. The product was dialyzed against methanol using a 1000 MW cutoff membrane and dried

under vacuum, yielding 27.2 mg (0.04 mmol, 37%) of protected polymer. The resulting polymer was then treated with 1 mL of dry 4 N HCl in dioxane for 3 h to remove the Boc groups. The final polymer product was dialyzed against ultra pure water using a 100 MW cutoff membrane and lyophilized to dryness, yielding 8.0 mg (0.02 mmol, 50%) of polymer. ^{1}H NMR (D_2O with one drop of DCl): $\delta = 3.35$ (t, $J = 5.6$ Hz, 4H), 3.53–3.65 (m, 20H), 3.98 (d, $J = 6.4$ Hz, 2H), 4.28 (d, $J = 6.4$ Hz, 2H). FT-IR (KBr pellet, cm^{-1}): 3407.4, 3011.2, 1653.1, 1561.3, 1330.3.

3.2.6. **M6$_L$.** D-Mannaro-1,4:6,3-dilactone (13.9 mg, 0.08 mmol) was mixed with a methanol (0.40 mL) solution containing triethylamine (18 μL) and **4b** (58.0 mg, 0.08 mmol) and stirred at room temperature for 72 h. The product was dialyzed against methanol using a 1000 MW cutoff membrane and dried under vacuum, yielding 27.9 mg (0.03 mmol, 39%) of protected product. The resulting polymer was then treated with 1 mL of dry 4 N HCl in dioxane for 3 h to remove the Boc groups. The final polymer product was dialyzed against ultra pure H_2O using a 100 MW cutoff membrane and lyophilized to dryness, yielding 8.90 mg (0.02 mmol, 60%) of polymer. ^{1}H NMR (D_2O with one drop of DCl): $\delta = 3.35$ (t, $J = 5.6$ Hz, 4H), 3.54–3.67 (m, 24H), 3.98 (d, $J = 6.4$ Hz, 2H), 4.28 (d, $J = 6.4$ Hz, 2H). FT-IR (KBr pellet, cm^{-1}): 3398.6, 3012.2, 1666.2, 1554.9, 1330.5.

3.2.7. **T5$_L$.** Dimethyl L-tartarate (15.0 mg, 0.08 mmol) was added to a methanol solution (0.13 mL) containing triethylamine (68 μL) and **4a** (48.3 mg, 0.08 mmol) and stirred at room temperature for 96 h. The product was dialyzed against methanol using a 1000 MW cutoff membrane and dried under vacuum, yielding 22.8 mg (0.03 mmol, 39%) of protected polymer. The resulting polymer was then treated with 1 mL of dry 4 N HCl in dioxane for 3 h to remove Boc groups. The final polymer product was dialyzed against ultra pure H_2O using a 100 MW cutoff membrane and lyophilized to dryness, yielding 8.40 mg (0.02 mmol, 67%) of polymer. ^{1}H NMR (D_2O with one drop of DCl): $\delta = 3.31$–3.38 (m, 4H), 3.51–3.64 (m, 18H), 3.65–3.71 (m, 2H), 4.64 (s, 2H). FT-IR (KBr pellet, cm^{-1}): 3398.2, 3010.2, 1665.8, 1547.4, 1333.9.

3.2.8. **T6$_L$.** Dimethyl L-tartarate (15.6 mg, 0.09 mmol) was added to a methanol solution (0.135 mL) containing triethylamine (71 μL) and **4b** (63.1 mg, 0.09 mmol) and stirred at room temperature for 96 h. The product was dialyzed against methanol using a 1000 MW cutoff membrane and dried under vacuum, yielding 40.3 mg (0.05 mmol, 55%) of protected polymer. The resulting polymer was then treated with 1 mL of 4 N HCl in dioxane for 3 h to remove the Boc groups. The final polymer product was dialyzed against ultra pure water using a 100 MW cutoff membrane and lyophilized to dryness, yielding 18.1 mg (0.04 mmol, 87%) of polymer. ^{1}H NMR (D_2O with one drop of DCl): $\delta = 3.31$–3.40 (m, 4H), 3.52–3.73 (m, 24H), 4.63 (s, 2H). IR (KBr pellet, cm^{-1}): 3398.8, 3011.2, 1666.4, 1547.2 1330.3.

4. Polymer and Polyplex Characterization. *4.1. Gel Permeation Chromatography (GPC).* The molecular weight, polydispersity index, and the Mark–Houwink-Sakurada (MHS) parameter (α) for the two series of polymers were measured with a Viscotek GPCmax instrument equipped with a GMPW$_{XL}$ column coupled to a triple detection system (static light scattering, viscometry, and refractive index). A solution of 0.5 M sodium acetate containing 20% acetonitrile was used as the mobile phase. Each sample was dissolved in the mobile phase, injected into the column (100 μL), and eluted at 0.8 mL/min. A PEO ($M_w = 22$ kDa) standard was used for calibration.

4.2. Gel Electrophoresis Shift Assays. The ability of these polymers to bind pDNA (pCMVβ) was measured by gel electrophoresis at 60 V. Agarose gel (0.6%, w/v) containing SYBR Safe DNA gel stain was prepared in TAE buffer (40 mM Tris-acetate, 1 mM EDTA). Each polymer was dissolved in nuclease-free water (Gibco, Carlsbad, CA). Plasmid DNA (10 μL, 0.1 μg/μL) was mixed with the same volume of polymer solution at *N*/*P* ratios between 0 and 50 (N = moles of polymer amine groups that can be protonated; P = moles of phosphate groups on the pDNA) and incubated for 30 min at room temperature before the addition of loading buffer (2 μL of Blue Juice, Invitrogen, Carlsbad, CA). An aliquot of each sample was loaded into the well of the gel. A stable polymer−DNA complex is shown by the lack of migration of the pDNA in the electrophoretic field.

4.3. Dynamic Light Scattering and Zeta Potential Measurements. Polyplex sizes were measured at 633 nm on a Zetasizer (Nano ZS) dynamic light scattering instrument (Malvern Instruments, Malvern, UK) at room temperature. Polyplexes were formed at an *N*/*P* ratio of 20 (150 μL) by incubating each polymer with pCMVβ (150 μL, 0.02 μg/μL) for 30 min. The z-average particle size was determined by cumulant fit of the data with a detection angle of 173°. Each sample was diluted to 0.9 mL with nuclease-free water or supplemented Dulbecco's modified eagle medium (DMEM) (containing 10% FBS), and the particle size was measured at intervals of 0, 20, and 60 min after DMEM addition in triplicate. The zeta potential measurements were also performed using the same instrument with a detection angle of 17°. The polyplexes were formed in water using the same procedure described above. After 45 min of incubation time, each sample was then diluted to 0.9 mL with nuclease-free water, and the zeta potential was measured.

4.4. Flow Cytometry. HeLa cells were seeded on 12-well plates at 1.0×10^5 cells/well and allowed to incubate in supplemented DMEM at 37 °C and 5% CO_2 for 24 h. The polyplexes were prepared by combining 100 μL of Cy5-labeled pDNA (0.02 μg/μL) and 100 μL of **M4**, **M5$_B$**, **M6$_B$**, **M5$_L$**, **M6$_L$**, **T4**, **T5$_B$**, **T6$_B$**, **T5$_L$**, or **T6$_L$** at an *N*/*P* of 20. The cells were then transfected with 0.5 mL of polyplex solution (2 μg of pDNA/well) in 0.4 mL of serum-free media (Opti-MEM) or DMEM containing 10% FBS. The cells were incubated with each solution for 4 h to allow endocytosis and internalization of the polyplexes. After transfection, the cells were rinsed with PBS multiple times to remove the cell-surface-bound polyplexes. Supplemented DMEM was then added, and the cells were incubated for another 30 min to allow further polyplex internalization. Four and half-hours after initial transfection, the cells were rinsed again with PBS, trypsinized, pelleted, the supernatant aspirated off, and the cells again resuspended in PBS containing 2% FBS for fluorescent activated cell sorting (FACS) analysis. A FACSCanto II (Becton Dickenson, San Jose, CA) equipped with an helium−neon laser to excite Cy5 (633 nm) was used. Ten thousand events were collected in duplicate for each sample. The positive fluorescence level was established by visual inspection of the histogram of negative control cells such that less than 1% appeared in the positive region.

4.5. Luciferase Reporter Gene Expression and Cell Viability Assays. HeLa cells were seeded on 24-well plates at 5×10^4 cells/well and allowed to incubate in supplemented Dulbecco's modified Eagle medium (DMEM, supplemented with 10% FBS, 100 units/mg penicillin, 100 μg/mL streptomycin, and 0.25 μg/mL amphotericin) at 37 °C and 5% CO_2 for 24 h. Polymer solutions (150 μL) were incubated with gWiz-Luc (150 μL, 0.02 μg/μL) at *N*/*P* ratios of 10, 20, and 30 at room temperature for 1 h to form the polyplexes. The mixtures were then diluted to 900 μL with serum-free media (Opti-MEM) or DMEM containing 10% FBS. Each well of cells was transfected with 300 μL of the polyplex solution containing 1 μg of gWiz-Luc pDNA complexed with each poly(glycoamidoamine). Each sample was tested in triplicate. Untransfected

cells and cells transfected with naked gWiz-Luc (1 μg pDNA, $N/P = 0$) were used as negative controls. Four hours after the transfection, 800 μL of the supplemented DMEM was added to each well. Twenty-four hours after transfection, the media was replaced with fresh supplemented DMEM (1 mL). Forty-seven hours after initial transfection, the media was removed, and the cells were washed with 500 μL of PBS and treated with cell culture lysis buffer (Promega, Madison, WI). The amount of protein in the cell lysates (as mg of protein) was determined against a standard curve of bovine serum albumin (98%, Sigma, St. Louis, MO), using a Bio-Rad DC protein assay kit (Hercules, CA).

Cell lysates were analyzed for luciferase activity with Promega's luciferase assay reagent (Madison, WI). For each sample, luminescence was measured over 10 s in duplicate with a luminometer (GENios Pro, TECAN US, Research Triangle Park, NC), and the average was utilized. The cell viability profiles were characterized by the amount of protein in the cell lysates. The protein levels of the transfected cells were normalized to the protein amount obtained for untransfected cells.

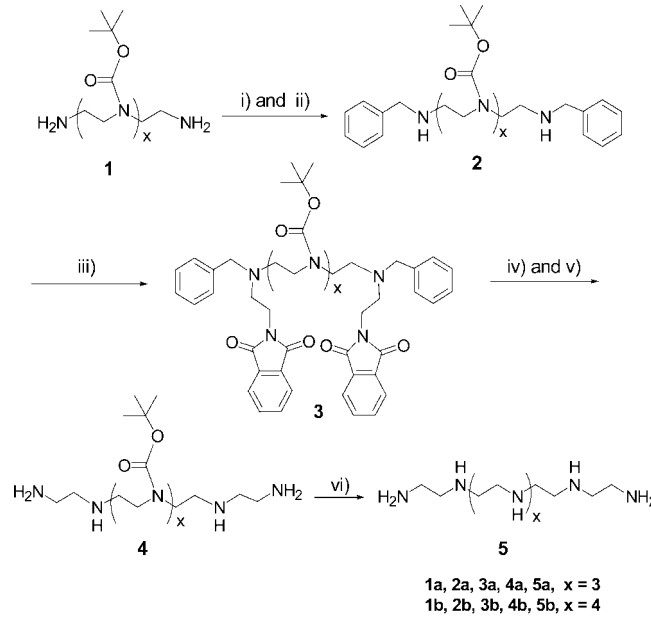
RESULTS AND DISCUSSION

Synthesis and Characterization of the Poly(glycoamidoamine)s. Here, we have synthesized two series of poly(glycoamidoamine)s, both branched and linear, based on a variety of carbohydrate comonomers and an oligoethyleneamine moiety containing five or six amines in the polymer repeat unit. This study was undertaken to examine how the amine stoichiometry and polymer physical structure affects cell viability and transfection efficiency. From our previous studies (*28–31*), we have discovered that increasing the number of secondary amines in the polymer repeat unit from one to four significantly increases the cellular uptake and gene expression. Many other studies in this field have also revealed that amines with a buffering capacity may play an important role in increasing the transfection efficiency; however, in general, the higher amine density and positive charge usually results in higher cytotoxicity (*22,23,37*). Previous studies in this field have also shown that the polymer structure can also significantly affect bioactivity (*22–26*). For example, Wightman and co-workers found that linear PEI usually reveals higher transfection efficiency than branched PEI *in vitro* (in Neuro 2a, MCA-38, and C26 cells) (*25*).

The current polymers were designed to investigate whether further increasing the amine number to five and six can further increase the cellular uptake and transfection efficiency without increasing the toxicity associated with poly(glycoamidoamine)s. To this end, 16 new polymers, based on our original carbohydrate monomers, were created to investigate the role of amine number and branching. As shown in Scheme 1, four new oligoethyleneamine monomers with five and six secondary amines were synthesized by first protecting the primary amine end groups of tetraethylenepentamine or pentaethylenehexamine with trifluoroacetyl units and then protecting the internal secondary amines with *tert*-butoxycarbonyl (Boc) according to a previously published method (*35, 36*). The trifluoroacetyl units were removed under mildly basic conditions to liberate the terminal primary amines, which were then protected again with benzyl (Bn) groups. By using Gabriel synthesis, the total amine number in the oligoethyleneamines was increased by two, yielding the Boc-protected monomers **4a** and **4b** (utilized to synthesize the linear polymers). To obtain the deprotected monomers (**5a** and **5b**) for the synthesis of the branched structures, the protecting groups on **4a** and **4b** were cleaved by a conventional method.

The four esterified carbohydrate monomers were then polymerized with these four new oligoethyleneamines via two different methods highlighted in Schemes 2 and 3 to yield the small library of 16 new structures. The first method, shown in Scheme 2, uses the fully deprotected oligoethyleneamines (monomers **5a** and **5b**), and the second method, shown in Scheme 3, uses the partial-Boc-protected oligoethyleneamines (monomers **4a** and **4b**) in the polymerization. In Scheme 2, both the primary and secondary amine groups can theoretically react with the esterified carbohydrate monomers, which results in slightly branched polymers. Conversely, as shown in Scheme 3, there are less free secondary amines in the oligoethyleneamines monomers (**4a** and **4b**), and the polymerization proceeds to yield linear polymers. Although there are still two free secondary amines in the oligoethyleneamines in Scheme 3, the steric hindrance of the neighboring Boc groups likely discourages polymerization from these functional groups.

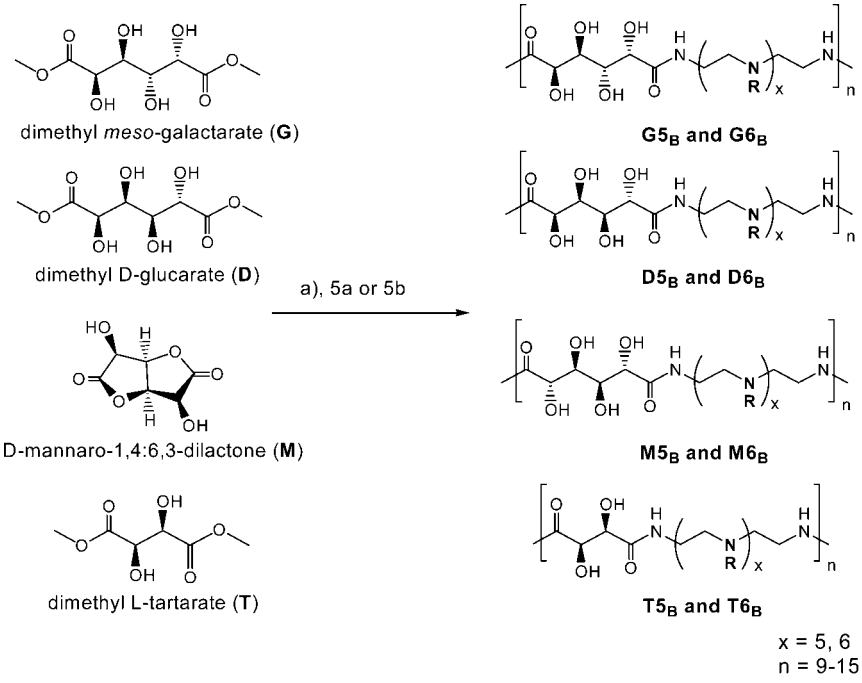
Scheme 1. Synthesis of the Four Oligoethyleneamine Monomers 4a, 4b, 5a, and 5b[a]



[a] Conditions: (i) PhCHO, MeOH, (ii) $NaBH_4$, (iii) *N*-(2-bromoethyl) phthalimide, KF-celite, CH_3CN, (iv) $H_2NNH_2.H_2O$, MeOH (v) $Pd(OH)_2$/C, H_2 (50 psi), MeOH, (vi) 4N HCl in dioxane.

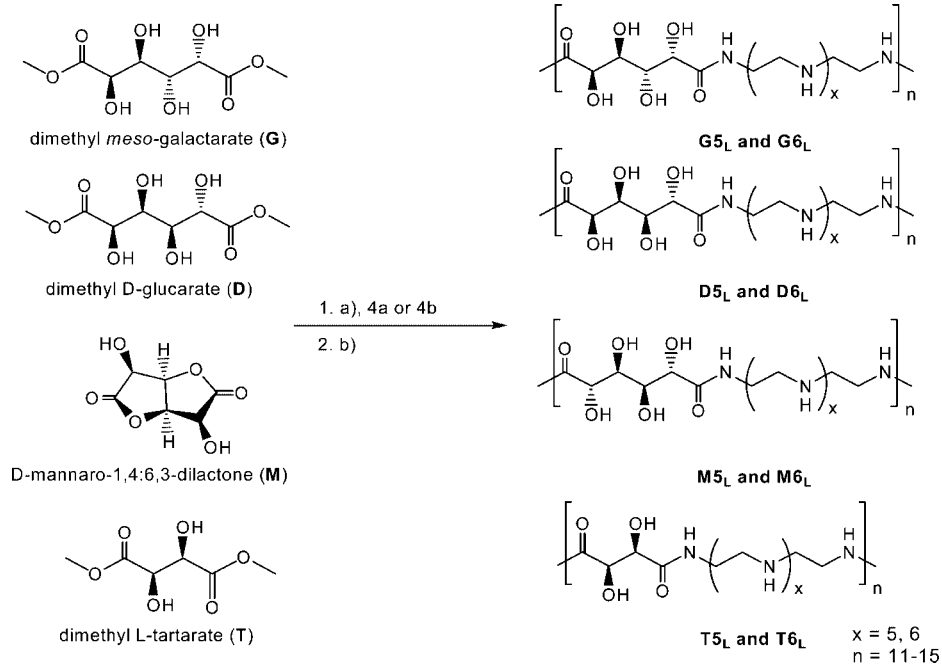
The polymerization reactions to create the linear and branched polymers were monitored via GPC containing a triple detection system (static light scattering, viscometry, and refractive index). The reaction conditions were optimized to yield polymers with similar degrees of polymerization (n_w, Table 1). The n_w values were between 9 to 15, thus ensuring that the biological properties of these polymers could be accurately compared to the previous polymers synthesized by our group. GPC/light scattering/viscometry results confirmed that the final polymers synthesized via Scheme 2 (branched) had lower Mark–Houwink−Sakurada (MHS) α values than the polymers synthesized via Scheme 3 (linear), as shown in Table 1. The lower α values shown in Table 1a, calculated from the MHS equation ($[\eta] = KM^{\alpha}$), reveal that the polymers synthesized via Scheme 2 appear to be more branched than the polymers synthesized via Scheme 3 (Table 1b). It is interesting to note that the polymers formed with the tartarate and galactarate monomers appear to be less branched than their mannarate and glucarate analogues because of the higher α values in Table 1a. In general, all of the linear polymers synthesized via Scheme 3 had higher MHS values than their branched analogues synthesized via Scheme 2. It should also be noted here that the linear polymers could have higher α values because HCl was used during the deprotection step. This could cause a higher amine fraction in the polymer backbone to be protonated, causing

Scheme 2. Synthesis of the Branched Poly(glycoamidoamine) Analogues with Monomers 5a or 5b[a]



[a] Conditions: (a) TEA, MeOH, R = H or point of branching.

Scheme 3. Synthesis of the Linear Poly(glycoamidoamine) Analogues with Monomers 4a or 4b[a]



[a] Conditions: (a) TEA, MeOH; (b) 4 N HCl in dioxane.

an electrostatic repulsion effect, thus discouraging random-coil solution morphologies and encouraging stiff-chain solution structures (yielding higher α values). Studies to understand the degree of protonation via titration are currently in progress to investigate this possibility.

When comparing the ^{1}H NMR spectra of the analogous structures, several interesting features were observed. For example, it was noticed that there are more peaks in the spectrum of **G5$_B$** than the spectrum of **G5$_L$** in the carbohydrate region of ^{1}H NMR (shown in Figure 2), which indicated a higher degree of branching in the **G5$_B$** structure. Also, in the spectra of all of the linear structures, the peaks were all sharper than the peaks in the spectra of the branched structures, which revealed broader peak widths. In addition, the methylene protons between the secondary amines and the methylene protons adjacent to the amides in the linear polymers had different chemical shift values in the ^{1}H NMR spectrum as compared to the branched polymers (Figure 2). The methylene protons adjacent to the amines in the linear analogues (likely to be more protonated) are shifted further downfield than the methylene protons adjacent to the amines in the branched polymers (less protonated). Lastly, it was also interesting to find that the linear polymers had a different final

Table 1. Molecular Weight (M_w), Polydispersity (M_w/M_n), MHS Parameter (α), Degree of Polymerization (n_w), and the *N*/*P* Ratios of Polymer−pDNA Binding and Charge Neutralization Obtained from Gel Electrophoresis Assays for the (a) Branched ($G5_B$–$T6_B$) and (b) Linear ($G5_L$–$T6_L$) Poly(glycoamidoamine)s

material form as compared to their branched analogues. For instance, after lyophilizing the final products, **$G5_B$** resulted in a fluffy powder, while **$G5_L$** was a sticky solid.

Polymer−DNA Binding, Particle Size, and Zeta Potential. The efficient compaction of pDNA into nanoparticles is an essential process that mediates the endocytosis of polyplexes, where cells typically uptake polyplexes ranging from 50 to several hundred nanometers (*7*, *38*). The ability of each polymer to bind, charge neutralize, and compact pDNA is typically dependent on the *N*/*P* ratio and the degree of branching. The 16 structures presented here were examined for their ability to bind and compact pDNA via gel electrophoresis shift assays and dynamic light scattering (DLS). Because there are less amines capable of being protonated in the branched polymers (due to the formation of amides during branching) than in the linear series of polymers, the linear structures may have stronger electrostatic interactions with the negative phosphate groups on the pDNA. Table 1 summarizes the results of the gel electrophoresis shift assays (*N*/*P* ratios of polymer−pDNA binding and charge neutralization). As shown, the linear polymers bind and neutralize pDNA at lower *N*/*P* ratios than the branched polymers. It should be noted that the degree of branching for these polymers is very difficult to determine and is not known at this time.

As shown in Figure 3, most of the polymers synthesized here can form nanoparticles with pDNA with less than 250 nm as determined via DLS at $N/P = 20$ in nuclease-free water. However, it was interesting to find that most polyplexes formed with the linear polymers yielded larger particle sizes than the branched polymers, which could be related to their high amine (cation) density and polycation repulsions. Zeta potential measurements were conducted on aqueous solutions containing the polyplexes formed at $N/P = 20$. Figure 3 (lines) reveals that all of the polyplexes have high positive surface charge, especially, polyplexes formed with the linear polymers (in excess of 40 mV). The high zeta potentials observed with the polyplexes formed with the linear polymers may be due to the protonated amines caused by the acid-mediated deprotection step (Scheme 3).

To understand the stability of polyplexes formed with this new series of polymers in the presence of media containing serum, polyplex size (for all polymers analogs) at $N/P = 20$ was examined via DLS at 0, 20, and 60 min after dilution with DMEM (supplemented with 10% FBS), as shown in Figure 4. Upon the addition of DMEM, most of the polyplexes grew in size to about 250 nm. After 20 min, the polyplexes formed with the **D_B** and **M_B** series further increased in size to about 700–800 and 400–600 nm, respectively. After exposure in serum-containing media, the polyplex size in the **D_B** and **M_B** series continued to grow, especially in the **D_B** series (increase to over 1000 nm). These data revealed that polyplexes formed with the **T_B** and **G_B** polymers were more stable from aggregation than the polyplexes formed with the **M_B** and **D_B** series. These results supported our previously published results that the stereochemistry of carbohydrate can affect polyplex stability from aggregation (*39*). In the linear analogues, the DLS data indicated that the polyplexes also were more stable from aggregation after dilution with DMEM (containing 10% FBS). It was found that polyplexes formed with the linear polymers followed a different trend than the branched analogues (polyplexes formed with the **D_L** and **G_L** polymers appeared to be slightly more stable from aggregation than polyplexes formed with the **M_L** and **T_L** polymers).

Cellular Delivery and Toxicity Studies. The cellular uptake facilitated by the new series of poly(glycoamidoamine)s based on mannarate and tartarate (**M4**, **$M5_B$**, **$M6_B$**, **$M5_L$**, **$M6_L$**, **T4**, **$T5_B$**, **$T6_B$**, **$T5_L$**, and **$T6_L$**) were investigated by flow cytometry. This study quantifies both the number of cells that uptake Cy5-labeled pDNA and the average intensity of Cy5 fluorescence (relative amount of pDNA) in the cell population. This experiment was performed in both serum-free (Opti-MEM) and DMEM containing 10% serum at an *N*/*P* ratio of 20. HeLa cells were incubated with each polyplex solution for 4 h to allow endocytosis. After removing the cell-surface-bound polyplexes and further incubating for 30 min, the cells were trypsinized and isolated for FACS analysis. The mean fluorescence intensity and the percentage of positive cells in both transfection conditions are shown in Figure 5. It was found that all of the polymers significantly enhanced the cellular uptake of pDNA in both conditions, with the exception of **$M5_B$**, whose result may be due to the fact that **$M5_B$** appears to have a low binding affinity to pDNA (Table 1a). The polyplexes formed with **$M5_B$** may dissociate during cell surface binding to the negatively charged glycosaminoglycans, which would result in low cellular uptake profiles. When comparing the bioactivity of polyplexes formed with both the linear and branched **M** and **T** series of polymers in the serum-free condition (Figure 5a), it was observed that the linear polymers facilitated much higher cellular entry than the branched versions of the same structure with the exception of polymer **T6** (statistical significance shown by the symbol * on the top of linear version in Figure 5a). For example, the mean fluorescence intensity of the cells transfected by **$M6_L$** was twice as high as that of **$M6_B$**, and the number of transfected cells also increased from 85% to almost 100%. Second, polymers that carry six amine functionalities demonstrated higher cellular uptake profiles than polymers with five amine groups in the polymer repeat unit (with the exception of polymer **$T6_L$**, statistical significance shown by the symbol ◇ in Figure 5a). Third, polyplexes formed with the **T** series of polymers were shown to enter the cell membrane more efficiently than the **M** series of polyplexes (statistical significance shown by the symbol ^ for the **T** series in Figure 5a). This could be due to the more efficient binding between the **T** series of polymers and pDNA shown by the gel shift assays (Table 1). When comparing the cellular entry facilitated by both the **M** and **T** series of polymers in DMEM containing 10% serum (Figure 5b), a systematic trend was not noticed. However, the mean fluorescence intensity data correlated well to the polyplex sizes formed with these polymers (Figure 4). For example, polyplexes

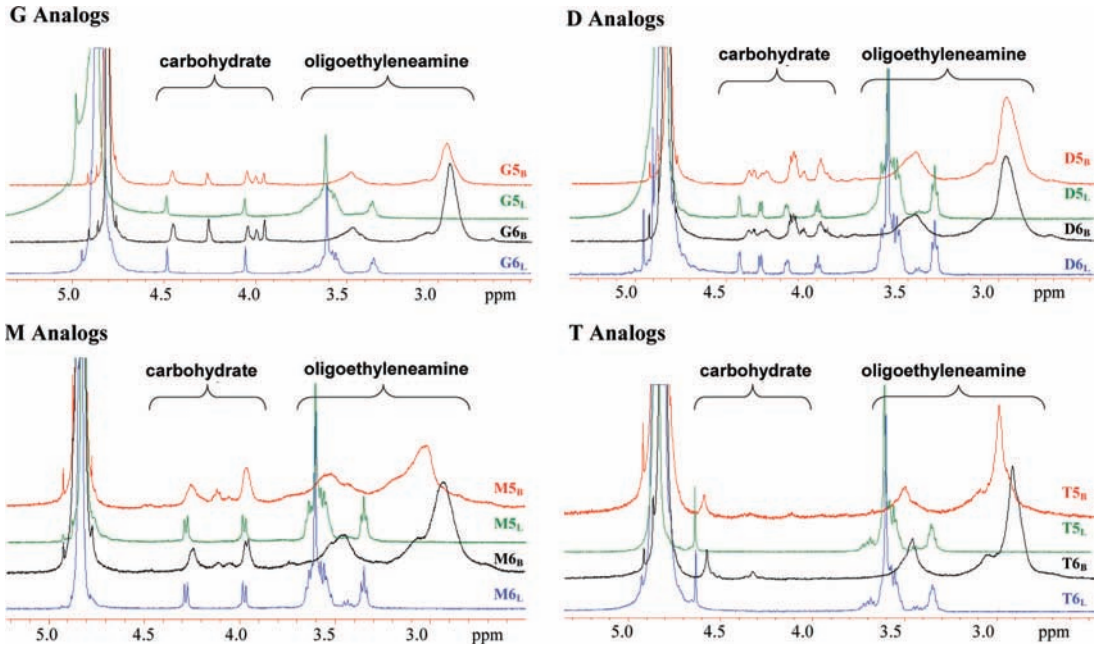

Figure 2. [1]H NMR for the branched and linear poly(glycoamidoamine)s. The spectra are labeled as follows: red, branched polymers obtained from **5a**; green, linear polymers obtained from **4a**; black, branched polymers obtained from **5b**; and blue, linear polymers obtained from **4b**. All spectra were taken in D_2O (large HOD peak at 4.85 ppm), and the region between 3.9 to 4.7 ppm represents the carbohydrate proton resonances, and the region between 2.8 to 3.7 ppm represents the oligoethyleneamine resonances.

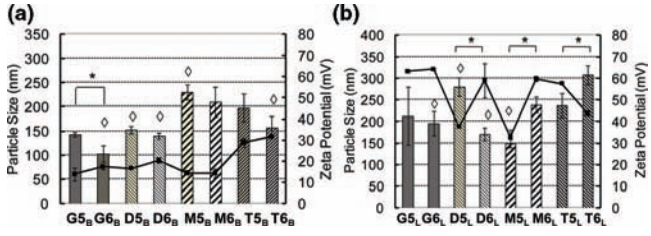

Figure 3. Polyplex size (bars) and the zeta potential (line) for the polyplexes formed with (a) branched and (b) linear polymers at $N/P = 20$ in nuclease-free water. Data are reported as the mean ± standard of deviation of three replicates. Statistical significances of particle size are shown with * or ◊ as $p < 0.05$. The symbol * shows that a significant difference in particle size was observed between polymers with the same carbohydrate moiety but with a variation of amine number in the repeat unit (e.g., $G5_B$ vs $G6_B$). The symbol ◊ indicates a significant difference with the same amine number and same carbohydrate but different physical structures (e.g., $G5_B$ vs $G5_L$).

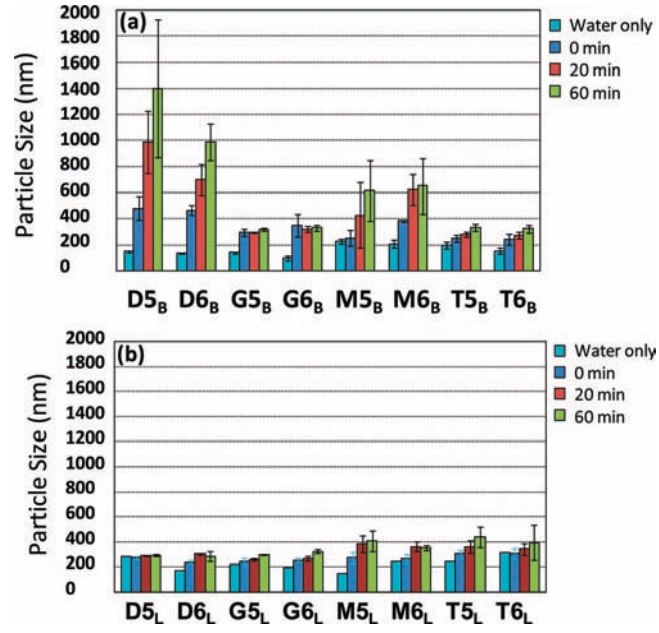

Figure 4. Polyplex size for the polymer−pDNA complexes formed with (a) branched and (b) linear polymers at $N/P = 20$ in water only and then at 0 min, 20 min, and 60 min after dilution with DMEM (containing 10% FBS). Data are reported as the mean ± standard of deviation of three replicates.

formed with $\mathbf{T5_B}$ and $\mathbf{T6_B}$ were shown to be smaller and more stable in DMEM containing 10% serum than polyplexes formed with $\mathbf{M5_B}$ and $\mathbf{M6_B}$, which correlated to the higher cellular uptake facilitated by polymers $\mathbf{T5_B}$ and $\mathbf{T6_B}$. Polymers $\mathbf{M5_L}$ and $\mathbf{M6_L}$ delivered a similar amount of Cy5-pDNA into the cells as did polymers $\mathbf{T5_L}$ and $\mathbf{T6_L}$, which could be also attributed to the similar size and stability of these polyplexes. Polymers $\mathbf{T5_B}$ and $\mathbf{T6_B}$ were shown to have the highest cellular uptake profile in DMEM containing 10% serum.

To promote the intracellular delivery of genetic materials, nucleic acids need to bypass many destructive obstacles besides cellular entry (*40*). Hence, luciferase reporter gene expression experiments were also performed within HeLa cells to examine the gene expression levels of the polyplexes formed with the linear and branched polymers containing either five or six amines per repeat unit. In this experiment, the previously synthesized polymers with four secondary amines in the polymer repeat unit (**G4**, **D4**, **M4**, and **T4**) (*28–31*) were used as positive controls, and naked pDNA was used as a negative control. Luciferase reporter gene expression results showed that the *N*/*P* ratio that displayed optimal transfection efficiency with these polyplexes was at $N/P = 20$ (considering both gene expression and cytotoxicity). As shown in Figure 6a, in serum-free transfection conditions, we first noticed that the analogues with six ethyleneamines (in both the linear and branched series) yielded higher gene expression than the analogues with five ethyleneamines (statistical significance was shown by the symbol ◇ in Figure 6a). Second, the linear analogues facilitated higher gene expression than the branched analogues with the exception of $\mathbf{T6_L}$ (statistical significance shown by the symbol * in Figure 6a). In addition, there was no obvious enhancement in the gene expression levels when comparing the branched and linear

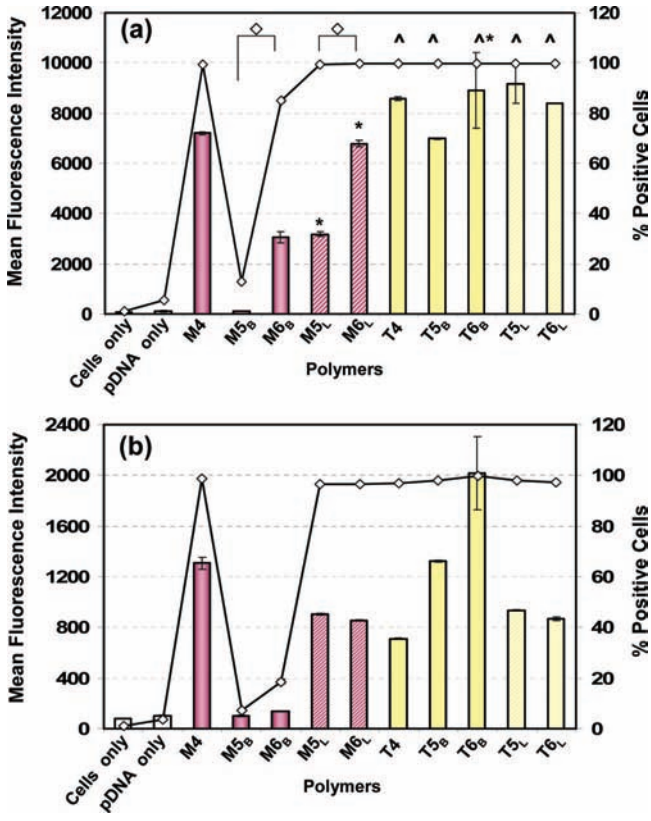

Figure 5. Cellular uptake of Cy5-labeled pDNA complexed with **M4**, $\mathbf{M5_B}$, $\mathbf{M6_B}$, $\mathbf{M5_L}$, $\mathbf{M6_L}$, **T4**, $\mathbf{T5_B}$, $\mathbf{T6_B}$, $\mathbf{T5_L}$, and $\mathbf{T6_L}$ in HeLa cells. (a) Mean fluorescence intensity (bars) and the percentage of cells positive for Cy5 (line) in serum-free transfection. Statistical significances in the mean fluorescence intensity are shown with *, ◇, or ^ as $p < 0.05$. The symbol * indicates that a significant difference in the mean fluorescence intensity was observed between the linear and the branched version of the polymers (e.g., $\mathbf{M5_L}$ vs $\mathbf{M5_B}$). The symbol ◇ indicates that a significant difference in the mean fluorescence intensity was observed between polymers with the same carbohydrate moieties but different amine stoichiometry (e.g., $\mathbf{M6_L}$ vs $\mathbf{M5_L}$). The symbol ^ indicates that a significant difference in the mean fluorescence intensity was observed between polymers with the same amine stoichiometry but different carbohydrate moieties (e.g., $\mathbf{T6_L}$ vs $\mathbf{M6_L}$). (b) Mean fluorescence intensity (bars) and the percentage of cells positive for Cy5 (line) in serum-containing transfection.

polymers to the previously published positive controls (**D4**, **G4**, **M4**, and **T4**). This may be due to the fact that the gel shift assays indicate that these new systems (with higher amine stoichiometry) do not appear to bind pDNA with higher affinity. This was especially true for the branched vectors, where high *N*/*P* ratios were needed to bind and charge neutralize pDNA. Previous work in our group has indicated a relationship between poly(glycoamidoamine) binding affinity and transfection efficiency (*28–31*). Polymers that bind pDNA in a stronger manner can protect it more efficiently from the nuclease degradation and premature release (polyplex dissociation) by negatively charged cell-surface glycosaminoglycans. It was also interesting to observe a similar hydroxyl stereochemistry effect on the gene delivery efficiency (that was noticed in previous studies) when comparing the results obtained with the analogues containing the same amine stoichiometry but different carbohydrate units (*28–31, 39*). Both the linear and branched polymers created with the tartarate and galactarate moieties generally facilitated higher gene expression than the polymers synthesized with the glucarate and mannarate monomers (with the exception of $\mathbf{D6_L}$). These results support our previous studies that the hydroxyl number and hydroxyl stereochemistry can play a role in delivery efficacy. This trend was very pronounced with the branched polymers where $\mathbf{D5_B}$, $\mathbf{D6_B}$, $\mathbf{M5_B}$, and $\mathbf{M6_B}$ yielded very low delivery efficacy. This effect could be partially due to their lower amine density because of branching. As shown in Table 1, the α values for $\mathbf{D5_B}$, $\mathbf{D6_B}$, $\mathbf{M5_B}$, and $\mathbf{M6_B}$ were lower than those for $\mathbf{G5_B}$, $\mathbf{G6_B}$, $\mathbf{T5_B}$, and $\mathbf{T6_B}$, indicating a higher degree of branching in the analogues synthesized with glucarate and mannarate. In addition, the linear analogues in this study obviously had higher gene expression levels than the branched versions, which may be attributed to their higher zeta potential values (Figure 3) and their stronger pDNA binding as suggested by the gel shift assays (Table 1). Better binding affinity may prevent pDNA from nuclease degradation during intracellular transport (*39*), and higher zeta potentials may enable polyplexes to strongly interact with the negatively charged cell-surface proteoglycans (*43*), leading to an increase in cellular uptake and DNA delivery. For the transfection performed in DMEM containing 10% serum (Figure 6b), we have noticed that almost all of these new poly(glycoamidoamine)s can significantly enhance gene delivery over the previously published analogues with four ethyleneamines (with the exception of polymers $\mathbf{D5_B}$, $\mathbf{D6_B}$, $\mathbf{M5_B}$, and $\mathbf{M6_B}$). Also, the linear versions of these polymers generally yielded higher gene expression than the branched analogues with serum (statistical significance is shown by the symbol * in Figure 6b). Gene expression appeared to also be affected by the carbohydrate type in the branched polymers, where the tartarate and galactarate series generally facilitated higher gene expression than the glucarate and mannarate series. This may be related to the stability of the tartarate and galactarate polyplexes in the serum-containing media (Figure 4a). Also in the 10% serum, the polymers with six ethyleneamines (in both the linear and branched series) did not show higher gene delivery profiles compared to their analogues with five ethyleneamines, except for $\mathbf{D6_B}$ and $\mathbf{T6_B}$, which demonstrated significantly higher gene expression than $\mathbf{D5_B}$ and $\mathbf{T5_B}$.

In both the presence and absence of serum, we have noticed that the luciferase gene expression level promoted by **M** and **T** polymers correlate to their cellular internalization (shown by the Cy5 fluorescence intensity in Figure 5). The polymer that facilitates better cell membrane internalization generally yields higher luciferase gene expression. This observation implies that the cellular uptake of the polyplexes formed with these new series of polymers is the key step that determines the efficacy of the pDNA delivery process.

The cell viability of HeLa cells exposed to polyplexes formed with both the linear and branched polymers in two transfection conditions is shown in Figure 7a and 7b. Cell viability in the experiment was characterized by the fraction of cell survival normalized to the untransfected cells. In general, the new series of poly(glycoamidoamine)s appeared to yield high cell viability at high $N/P = 20$. In addition, it was noticed that HeLa cell viability after exposure to polyplexes formed with the branched polymers was generally higher (between 70 and 100%) as compared to the linear analogues, particularly in the absence of serum. These results indicated that increasing the amine stoichiometry within the branched structures does not increase cytotoxicity, which is likely a result of the lower number of secondary amines (due to the formation of amides from branching units) (*28–31*). The exception was $\mathbf{T6_B}$ (60% cell survival), which may be related to the lower number of hydroxyl groups and thus increased amine density. The higher cytotoxicity of the linear analogues in the absence of serum may be attributed to the higher zeta potential of polyplexes formed with the linear polymers and the higher number of free amines in these structures, which may cause disruptions in the negatively charged cell membrane. Previous work in this area has shown that a high density of positive charges may cross-bridge cell-surface receptors, interfering with critical intracellular processes

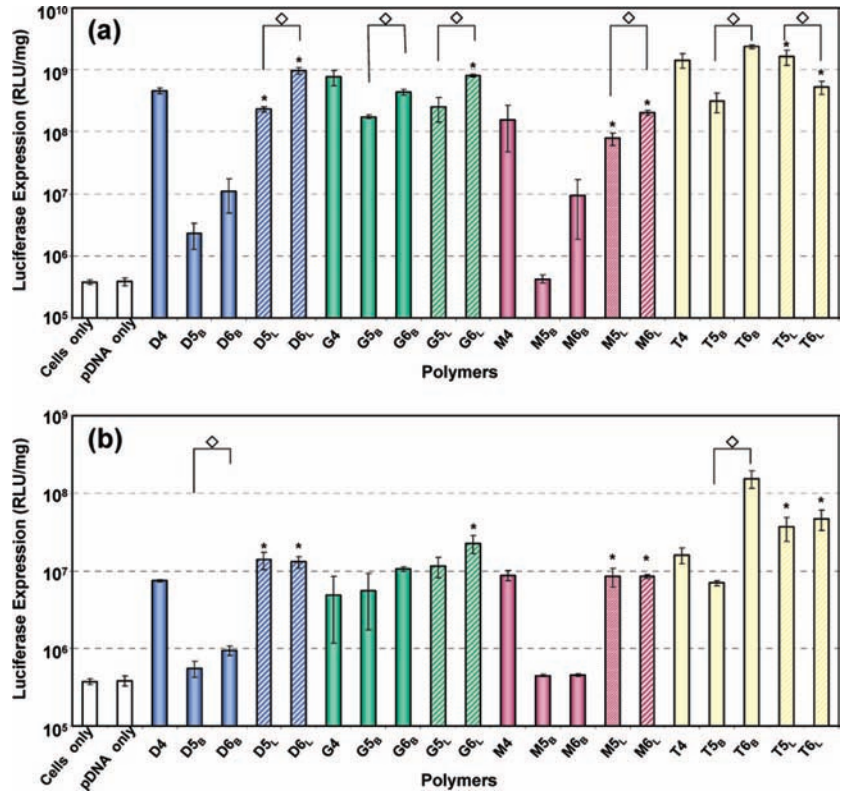

Figure 6. Luciferase gene expression observed with polyplexes formed with pDNA and each poly(glycoamidoamine) at $N/P = 20$. (a) Transfection in the absence of serum (Opti-MEM). (b) Transfection in DMEM containing 10% serum. The gene expression values are shown as relative light units (RLU) per milligram of protein. The data are reported as the mean ± standard of deviation of three replicates. Statistical significances in luciferase expression are shown with * or ◇ as $p < 0.05$. The symbol * indicates that a significant difference in gene expression was observed between the linear and the branched version of the polymers (e.g., $\mathbf{D5_L}$ vs $\mathbf{D5_B}$). The symbol ◇ indicates that a significant difference in gene expression was observed between polymers with the same carbohydrate moieties but different amine stoichiometry (e.g., $\mathbf{D6_L}$ vs $\mathbf{D5_L}$).

(b) Transfection in DMEM containing 10% of serum. The fraction of cell survival values were normalized to untransfected cells. The data are reported as the mean ± standard of deviation of three replicates, and statistical significances are shown with * or ◇ as $p < 0.05$. The symbol * indicates that a significant difference in cell survival was observed between the linear and the branched analogues (e.g., $\mathbf{D5_L}$ vs $\mathbf{D5_B}$). The symbol ◇ indicates that a significant difference in cell survival was observed between polymers with the same carbohydrate moieties but different amine stoichiometry (e.g., $\mathbf{D6_L}$ vs $\mathbf{D5_L}$).

(*21*, *41*, *42*). For example, with L929 cells exposed to polycations, Fischer et al. showed that membrane leakage and a decrease in the metabolic activity occurs (*37*), which are initialized by the electrostatic interactions between cationic macromolecules and the negatively charged cell membrane. When comparing the polymers with six ethyleneamines and their analogues with five ethyleneamines in the repeat unit, a significant difference in the cell viability profiles was not observed even though polymers with six ethyleneamines seemed to facilitated higher gene expression (Figure 6).

CONCLUSIONS

The poly(glycoamidoamine) nucleic acid delivery vectors were originally designed by our group as models that combine the structural characteristics of chitosan (carbohydrate) and PEI (ethyleneamine). Several prior works by our group have shown that these structures have high delivery efficiency and biocompatibility (*28–31*). In a related examination, Nagasaki and co-workers synthesized a modified chitosan derivative that contained an additional primary amine in the C-6 position of the repeat unit, which revealed higher gene expression than chitosan while retaining low cytotoxicity (*44*). Another similar copolymer with increasing amine density, PEI-g-chitosan, yielded higher gene expression than branched PEI (25 kDa) and retained low cytotoxicity as compared to branched PEI (25 kDa) (*44*). Conversely, Kim and co-workers found that increasing the amine stoichiometry in their reducible poly(amidoethyleneimine) repeat unit, decreased the gene expression profile because of the increase of cytotoxicity (*45*). Here, this new series of poly(glycoamidoamine)s with higher amine stoichiometry has shown that the transfection efficiency remains about the same in serum-free media but is higher in the presence of serum. However, similar to that in the study by Kim et al., an increase in cytotoxicity was observed with the increase in amine density (Figures 6 and 7).

With this study, we have learned that significant differences in delivery efficacy are noticed between branched and linear polymers of similar chemical structure in both the absence and presence of serum. In general, similar to PEI, branched structures tend to be less toxic but have lower delivery efficacy than linear analogues in both conditions. This is likely due to a decrease in secondary amine density from branching units. We also noted that the $\mathbf{T_B}$ series had higher transfection profiles than the $\mathbf{M_B}$ series in both the absence and presence of serum, which is likely due to the higher cellular uptake and serum stability of the $\mathbf{T_B}$ polymers when compared to those of the $\mathbf{M_B}$ series. It was also interesting to find that even though the $\mathbf{T_L}$ series has serum stability and cellular uptake similar to those of the $\mathbf{M_L}$ series, the $\mathbf{T_L}$ series still has significantly higher transfection efficiency than that of the $\mathbf{M_L}$ analogues. Moreover, we have discovered that a certain limitation in amine density exists with our poly(glycoamidoamine) vectors. Our previous work has shown that as the amine stoichiometry increases from one secondary amine in the repeat unit to four, the delivery efficiency is significantly enhanced without compromising biocompatibility. With the poly(glycoamidoamine) models created herein, we have observed that as amine stoichiometry is further increase to five and six, gene expression reaches a certain point, and cytotoxicity starts to increase. Our studies with these poly(glycoamidoamine) models reveal that there is a fine balance between delivery efficiency and toxicity. Overcoming this issue will likely be a challenge in the field of nucleic acid delivery and efficacious vector design.

Synthesis and Evaluation of ^{18}F- and ^{11}C-Labeled Phenyl-Galactopyranosides as Potential Probes for *in Vivo* Visualization of LacZ Gene Expression using Positron Emission Tomography

Sofie Celen,[†] Christophe Deroose,[‡] Tjibbe de Groot,[‡] Satish K. Chitneni,[†] Rik Gijsbers,[§] Zeger Debyser,[§] Luc Mortelmans,[‡] Alfons Verbruggen,[†] and Guy Bormans*[,†]

Laboratory for Radiopharmacy, Faculty of Pharmaceutical Sciences, and Department of Nuclear Medicine, U.Z. Gasthuisberg, and Division of Molecular Medicine, Katholieke Universiteit Leuven, Leuven, Belgium. Received June 18, 2007; Revised Manuscript Received October 22, 2007

3-Hydroxy-2-nitrophenyl 2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranoside, a derivative of the chromogenic β-galactosidase (β-gal) substrate *o*-nitrophenyl β-D-galactopyranoside (ONPG) was synthesized using a Koenigs−Knorr glycosylation reaction. It was alkylated with 2-[^{18}F]fluoroethyl triflate or [^{11}C]methyl triflate, followed by deacetylation of the sugar hydroxyl groups to obtain radiolabeled 3-(2′-[^{18}F]fluoroethoxy)-2-nitrophenyl β-D-galactopyranoside ([^{18}F]-**2c**) and 3-[^{11}C]methoxy-2-nitrophenyl β-D-galactopyranoside ([^{11}C]-**3c**), which were evaluated as potential reporter probes for *in vivo* visualization of LacZ gene expression with positron emission tomography (PET). *In vitro*, [^{18}F]-**2c** and [^{11}C]-**3c** were good substrates of β-gal and showed, respectively, a 7.5- and 2.5-fold higher uptake into β-gal expressing cells (LacZ cells) compared to control cells. However, reversed-phase HPLC analysis of the LacZ cell lysate and supernatant showed that labeled 3-(2′-[^{18}F]fluoroethoxy)-2-nitrophenol, the hydrolysis product formed by β-gal-mediated cleavage of [^{18}F]-**2c**, substantially leaked out of the cells, which would lead to loss of PET signal. In a μPET study of [^{18}F]-**2c** in a mouse with a β-gal expressing tumor, high retention was observed in liver and kidneys, but only negligible accumulation was seen in the tumor. As a general conclusion, it can be stated that the synthesized PET tracers [^{18}F]-**2c** and [^{11}C]-**3c** are not suitable for use as LacZ reporter probes. Further structural modifications to improve the diffusion over the tumor cell membrane and to increase retention in β-gal expressing cells may lead to more favorable *in vivo* imaging probes.

INTRODUCTION

Given progress in molecular biology and genetics as well as advances in imaging technology, it is possible to visualize cellular processes in space and time at a molecular or genetic level (*1*). One of the most studied molecular imaging targets to date is the expression of genes. *In vivo* imaging of the location, the magnitude, and the time variation of gene and transgene expression is important in the development of transgenic animal models of disease, in trafficking and targeting of cells, and in gene therapy (*2, 3*). Many promising methods are being developed to image gene expression by using an appropriate combination of a reporter transgene and a reporter probe (*4, 5*). The most commonly used reporter systems include β-galactosidase (*6–8*), β-glucuronidase (*6, 9*), chloramphenicol acetyltransferase (*6,10*), green fluorescent protein (*6,11,12*), and luciferases (*6, 13–15*). Among these, the LacZ gene, which encodes *E. coli* β-galactosidase (β-gal), is one of the most attractive reporter genes due to its widespread use in different vectors, convenient *in vitro* and histological detection methods, split protein systems, and its presence in many transgenic mouse models (*16*). Up to now, this reporter system has been frequently used for *in vitro* evaluation of gene expression using substrates allowing colorimetric (*17, 18*), fluorescence (*19–22*), chemiluminescence (*23*), or bioluminescence (*24*) detection. All these optical imaging modalities are very useful in superficial tissues and have extensive applications in small animals, but application to larger animals is limited by the depth of light penetration.

Monitoring reporter gene expression in larger animals and ultimately in humans is possible with the use of specific radiotracers combined with nuclear imaging techniques like positron emission tomography (PET *2, 25*) or single-photon emission computed tomography (SPECT (*26*)) and magnetic resonance imaging (MRI) in combination with paramagnetic reporter probes (*27–29*). The group of Mason et al. (*30, 31*) have been developing MRI probes by introducing a fluorine atom or a trifluoromethyl group in the colorimetric indicator *ortho*-nitrophenyl β-D-galactopyranoside (ONPG) and demonstrated the usefulness of these fluorogalactopyranosides to detect β-gal activity *in vitro* with ^{19}F NMR spectroscopy.

Well-known and established PET and SPECT reporter systems are herpes simplex virus type 1 thymidine kinase (HSV1-tk) in combination with ^{18}FHBG, human dopamine type 2 receptor (hD_2R) in combination with [^{18}F]fluoroethylspiperone, and human sodium iodide symporter (hNIS) in combination with $^{124}I^-$, $^{123}I^-$, or $^{99m}TcO_4^-$ (*4, 5*). However, little progress has been made in the development of radioprobes that target LacZ gene expression. Lee et al. (*32*) described the use of a radiolabeled competitive inhibitor 2-(4-[^{125}I/^{123}I]iodophenyl) ethyl 1-thio-β-D-galactopyranoside to detect β-gal activity in mice bearing LacZ expressing tumors using SPECT. The disadvantage of this system is the low sensitivity using an inhibitor probe and the poor cell membrane permeability. Bormans et al. (*33*) synthesized 2′-[^{18}F]fluorodeoxylactose (^{18}FDL) using an enzymatic method starting from 2-[^{18}F]fluoro-2-deoxy-D-glucose (^{18}FDG). The yield of the enzymatic synthesis was rather low, and a biodistribution study in Rosa-26

mice compared to control mice showed a lack of tissue retention, probably due to the inability of ^{18}FDL to cross the cell membrane.

In our study, a derivative of ONPG was synthesized, labeled with ^{18}F or ^{11}C, and both radiolabeled agents were evaluated as potential reporter probes for *in vivo* visualization of LacZ gene expression with PET.

MATERIALS AND METHODS

General. All reagents and solvents were obtained commercially from Acros (Geel, Belgium), Aldrich, Fluka, Sigma (Sigma-Aldrich, Bornem, Belgium), Merck (Darmstadt, Germany), or Fischer Bioblock Scientific (Tournai, Belgium) unless otherwise specified. For ascending thin layer chromatography (TLC), precoated aluminum-backed plates (silica gel 60 with fluorescent indicator, 0.2 mm thickness; Macherey-Nagel, Düren, Germany) were used and developed using mixtures of ethyl acetate and hexane, CH_2Cl_2 and hexane, or acetonitrile as mobile phase. After evaporation of the solvent, compounds were detected under UV light (254 nm). The sugar compounds were additionally visualized by staining in oxidative medium (5% H_2SO_4 in ether), followed by heating. ^{1}H and ^{13}C NMR spectra were recorded on a Gemini 200 MHz spectrometer (Varian, Palo Alto, CA, USA) using $CDCl_3$ or DMSO-d_6 as solvent. Chemical shifts are reported in parts per million relative to tetramethylsilane ($\delta = 0$). Coupling constants are reported in hertz. Splitting patterns are defined by s (singlet), br s (broad singlet), d (doublet), dd (double–doublet), t (triplet), dt (double triplet), or m (multiplet). High-performance liquid chromatography (HPLC) analysis was performed on an XTerra RP C_{18} column (5 μm, 4.6 mm × 250 mm; Waters, Milford, USA) eluted with mixtures of water or 0.1 M ammonium acetate pH 4 and acetonitrile. The column effluent was monitored for absorbance with a UV-spectrometer (Waters 2487 Dual γ absorbance detector) set at 254 nm and for radioactivity using a 2 in. NaI(Tl) scintillation detector coupled to a single-channel analyzer (Medilab-Select, Mechelen, Belgium). Output of both detectors was analyzed using RaChel analysis software (Lablogic, Sheffield, UK). The radioactivity counting for biodistribution studies, log *P* determinations, and cell-uptake studies was done using an automated gamma counter equipped with a 3 in. NaI(Tl) well crystal coupled to a multichannel analyzer (Wallac 1480 Wizard 3″, Wallac, Turku, Finland). Exact mass measurements were performed on a time-of-flight spectrometer (LCT, Micromass, Manchester, UK) equipped with a standard electrospray ionization (ESI) interface. Samples were infused in acetonitrile/water mixtures with a Harvard 22 syringe pump (Harvard Apparatus, Holliston, Massachusetts, USA). Accurate mass determination was done by coinfusion with a 10 μg/mL solution of ONPG in acetonitrile/water as an internal calibration mass in positive mode (ES+). Acquisition and processing of the data were done with *Masslynx* software (version 3.5, Waters). Melting points (mp) were determined using an IA9000 digital melting point apparatus (Electrothermal, Southend-on-Sea, England).

The experiments in mice were carried out in compliance with the national laws relating to the conduct of animal experimentation and with approval of the local ethical committee for animal experiments.

Synthesis.*3-Hydroxy-2-nitrophenyl 2,3,4,6-tetra-O-acetyl-β-D-galactopyranoside (**1**).* To a solution of 0.42 g (2.7 mmol) 2-nitroresorcinol in a mixture of 10 mL quinoline and 5 mL CH_2Cl_2 was added 1 g (3.65 mmol) Ag_2CO_3 and 1 g (2.43 mmol) 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide. The flask was shielded from light, and the suspension was stirred for 3 h. The reaction mixture was poured into 50 mL methanol/dichloromethane (1:9 v/v) followed by filtration over celite. The filtrate was successively washed with 50 mL HCl (1 M), 50 mL water, 50 mL saturated $NaHCO_3$ solution, and 50 mL brine. After drying over $MgSO_4$, the solution was filtered and the filtrate was concentrated in vacuo and applied on a silica gel column eluted with ethyl acetate/hexane (1:1 v/v). Yield: 0.37 g (0.76 mmol, 31%) of a yellow solid.

^{1}H NMR ($CDCl_3$) δ 2.02, 2.07, 2.12, 2.19 (12H, 4× s, 4× *CH$_3$CO*), 4.09 (1H, t, $^3J_{H5\text{-}H6} = 6$ Hz, *H-5*), 4.17–4.28 (2H, m, 2× *H-6*), 5.10 (2H, d, $^3J_{H1\text{-}H2} = 8$ Hz, *H-1*; dd, $^3J_{H3\text{-}H2} = 10.6$ Hz, $^3J_{H3\text{-}H4} = 3$ Hz, *H-3*), 5.48 (1H, d, $^3J_{H4\text{-}H3} = 3$ Hz, *H-4*), 5.58 (1H, dd, $^3J_{H2\text{-}H3} = 10.6$ Hz, $^3J_{H2\text{-}H1} = 8$ Hz, *H-2*), 6.82 (1H, d, $^3J = 8.4$ Hz, *H$_{ar}$-4*), 6.86 (1H, d, $^3J = 8.4$ Hz, *H$_{ar}$-6*), 7.39 (1H, t, $^3J = 8.4$ Hz, *H$_{ar}$-5*).

^{13}C NMR ($CDCl_3$) δ 20.52, 61.28, 66.68, 67.80, 70.56, 71.42, 100.31 (*anomeric C-1*), 109.05, 113.73, 134.97, 154.64, 170.24.

Exact Mass (ESI-MS) for $C_{20}H_{22}NO_{13}Na$ $[M + Na]^+$: found 508.1048, calculated 508.1062. mp: 167–169 °C.

3-(2′-Fluoroethoxy)-2-nitrophenol (2a). A solution of 0.25 g (1.6 mmol) 2-nitroresorcinol, 0.094 mL (1.6 mmol) 2-fluoroethanol, and 0.42 g (1.6 mmol) triphenylphosphine in 15 mL tetrahydrofuran was stirred for 10 min at room temperature under an atmosphere of nitrogen, and 0.32 mL (1.6 mmol) diisopropylazodicarboxylate was added in one portion. After stirring for 4 h at room temperature under nitrogen, a small amount of silica gel was added, and the solvent was evaporated. The silica gel impregnated with the crude product was applied on a silica gel column that was eluted with a mixture of ethyl acetate/hexane (3:7 v/v), yielding 0.18 g (0.9 mmol, 56%) of a yellow solid.

^{1}H NMR ($CDCl_3$) δ 4.26 (2H, dt, $^3J_{H\text{-}F} = 26.8$ Hz, $^3J = 4.2$ Hz, -*C$\underline{H_2}$CH$_2$F*), 4.74 (2H, dt, $^2J_{H\text{-}F} = 46.8$ Hz, $^3J = 4.2$ Hz, -*CH$_2$C$\underline{H_2}$F*), 6.47 (1H, d, $^3J = 8.4$ Hz, *H$_{ar}$-6*), 6.68 (1H, d, $^3J = 8.4$ Hz, *H$_{ar}$-4*), 7.32 (1H, t, $^3J = 8.4$ Hz, *H$_{ar}$-5*), 10.1 (br s, OH).

^{13}C NMR ($CDCl_3$) δ 70.05, 83.01, 105.02, 111.54, 135.39, 156.46.

3-(2′-Fluoroethoxy)-2-nitrophenyl 2,3,4,6-tetra-O-acetyl-β-D-galactopyranoside (2b). The title compound was prepared from 3-(2′-fluoroethoxy)-2-nitrophenol (**2a**) using the same procedure as described for compound **1**. Yield: 0.19 g (0.35 mmol, 31%) of a white solid.

^{1}H NMR ($CDCl_3$) δ 2.01, 2.08, 2.13, 2.18 (12H, 4× s, 4× *CH$_3$CO*), 4.1 (1H, t, $^3J_{H5\text{-}H6} = 6$ Hz, *H-5*), 4.18–4.40 (4H, m, 2× *H-6*; -*C$\underline{H_2}$CH$_2$F*), 4.72 (2H, dt, $^2J_{H\text{-}F} = 46.8$ Hz, $^3J = 4.2$ Hz, -*CH$_2$C$\underline{H_2}$F*), 5.02 (1H, d, $^3J_{H1\text{-}H2} = 8$ Hz, *H-1*), 5.07 (1H, dd, $^3J_{H3\text{-}H2} = 10.6$ Hz, $^3J_{H3\text{-}H4} = 3.2$ Hz, *H-3*), 5.42–5.52 (2H, m, $^3J_{H2\text{-}H3} = 10.6$ Hz, $^3J_{H2\text{-}H1} = 8$ Hz, *H-2*; *H-4*), 6.8 (1H, d, $^3J = 8.4$ Hz, *H$_{ar}$-6*), 6.93 (1H, d, $^3J = 8.4$ Hz, *H$_{ar}$-4*), 7.34 (1H, t, $^3J = 8.4$ Hz, *H$_{ar}$-5*).

^{13}C NMR ($CDCl_3$) δ 20.39, 61.25, 66.65, 67.71, 68.74, 70.47, 71.36, 82.98, 100.88 (*anomeric C-1*), 108.84, 110.72, 131.09, 149.03, 150.69, 170.15.

3-(2′-Fluoroethoxy)-2-nitrophenyl β-D-galactopyranoside (2c). To a solution of 0.136 g (0.26 mmol) 3-(2′-fluoroethoxy)-2-nitrophenyl 2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranoside (**2b**) in 14 mL methanol was added 0.385 mL of a solution of 100 mg sodium in 20 mL methanol, and stirring was continued for 30 min. A small amount of silica gel was added, and the solvent was evaporated. The silica gel impregnated with the crude product was applied on a silica gel column that was eluted with acetonitrile, yielding 0.065 g (0.178 mmol, 70%) of a white solid.

^{1}H NMR (DMSO) δ 3.45–3.69 (6H, m, *H-2*; *H-3* ; *H-4*; *H-5*; 2× *H-6*), 4.38 (2H, dt, $^3J_{H\text{-}F} = 30.2$ Hz, $^3J = 3.6$ Hz, -*C$\underline{H_2}$CH$_2$F*), 4.69 (2H, dt, $^2J_{H\text{-}F} = 47.6$ Hz, $^3J = 3.6$ Hz, -*CH$_2$C$\underline{H_2}$F*), 4.99 (1H, d, $^3J_{H1\text{-}H2} = 7.4$ Hz, *H-1*), 6.95 (1H, d,

^3J = 8.4 Hz, H_{ar}-*6*), 6.98 (1H, d, ^3J = 8.4 Hz, H_{ar}-*4*), 7.45 (1H, t, ^3J = 8.4 Hz, H_{ar}-*5*).

^{13}C NMR (DMSO) δ 60.33, 68.1, 69.07, 70.04, 73.54, 75.9, 83.551, 101.09 (*anomeric C-1*), 107.07, 108.53, 131.63, 149.29, 150.12.

Exact Mass (ESI-MS) for $C_{14}H_{17}FNO_9Na$ $[M + Na]^+$: found 386.0844, calculated 386.0858. mp: 123–125 °C.

3-Methoxy-2-nitrophenol (3a). The same procedure was used as described for compound **2a**, using methanol instead of 2-fluoroethanol. Yield 0.17 g (1 mmol, 62%) of a yellow solid.

^{1}H NMR ($CDCl_3$) δ 3.95 (3H, s, -*OCH*$_3$), 6.55 (1H, d, ^3J = 8.4 Hz, H_{ar}-*6*), 6.71 (1H, d, ^3J = 8.4 Hz, H_{ar}-*4*), 7.41 (1H, t, ^3J = 8.4 Hz, H_{ar}-*5*), 10.22 (s, *OH*).

3-Methoxy-2-nitrophenyl 2,3,4,6-tetra-O-acetyl-β-D-galactopyranoside (3b). The title compound was prepared from 3-methoxy-2-nitrophenol (**3a**) using the same procedure as described for compound **1**. Yield: 0.13 g (0.26 mmol, 39%) of a yellow solid.

^{1}H NMR ($CDCl_3$) δ 2.1 (12H, 4× s, 4× *CH*$_3$*CO*), 3.82 (3H, s, -*OCH*$_3$), 4.01 (1H, t, $^3J_{H5\text{-}H6}$ = 6.2 Hz, *H-5*), 4.1–4.24 (2H, m, 2× *H-6*), 4.92 (1H, d, $^3J_{H1\text{-}H2}$ = 8 Hz, *H-1*), 5.0 (1H, dd, $^3J_{H3\text{-}H2}$ = 10.6 Hz, $^3J_{H3\text{-}H4}$ = 3.2 Hz, *H-3*), 5.36–5.45 (2H, m, $^3J_{H2\text{-}H3}$ = 10.6 Hz, $^3J_{H2\text{-}H1}$ = 8 Hz, $^3J_{H4\text{-}H3}$ = 3.2 Hz, *H-2*; *H-4*), 6.71 (1H, d, ^3J = 8.4 Hz, H_{ar}-*6*), 6.82 (1H, d, ^3J = 8.4 Hz, H_{ar}-*4*), 7.27 (1H, t, ^3J = 8.4 Hz, H_{ar}-*5*).

^{13}C NMR ($CDCl_3$) δ 20.55, 56.51, 61.28, 66.65, 67.65, 70.47, 71.29, 100.83 (*anomeric C-1*), 107.35, 109.78, 131.12, 151.73, 170.42.

3-Methoxy-2-nitrophenyl-β-D-galactopyranoside (3c). The same procedure was used as described for compound **2c**, using 3-methoxy-2-nitrophenyl 2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranoside (**3b**) as starting material. Yield 0.03 g (0.09 mmol, 45%) of a yellow solid.

^{1}H NMR (DMSO) δ 3.38–3.7 (6H, m, *H-2*; *H-3*; *H-4*; *H-5*; 2× *H-6*), 3.86 (3H, s, -*OCH*$_3$), 4.58 (d, *OH*), 4.66 (t, *OH*), 4.87 (d, *OH*), 4.98 (1H, d, $^3J_{H1\text{-}H2}$ = 7.4 Hz, *H-1*), 5.11 (d, *OH*), 6.92 (1H, d, ^3J = 8.4 Hz, H_{ar}-*6*), 6.96 (1H, d, ^3J = 8.4 Hz, H_{ar}-*4*), 7.45 (1H, t, ^3J = 8.4 Hz, H_{ar}-*5*).

^{13}C NMR (DMSO) δ 56.81, 60.33, 68.13, 70.04, 73.54, 75.9, 101.06 (*anomeric C-1*), 106.07, 108.14, 131.69, 149.2, 150.21.

Exact Mass (ESI-MS) for $C_{13}H_{16}NO_9Na$ $[M + Na]^+$: found 354.0823, calculated 354.0796. mp: 130.5–132 °C.

Radiolabeling. *Production of [^{18}F]fluoride and Radiosynthesis of [^{18}F]-2c using 2-[^{18}F]fluoroethyl Triflate ([^{18}F]FEtOTf).* $[^{18}F]F^-$ was obtained using an $^{18}O(p,n)^{18}F$ reaction by irradiation of 0.5 mL of 97% enriched $[^{18}O]H_2O$ (Rotem HYOX^{18}, Rotem Industries, Beer Sheva, Israel) in a niobium target with 18 MeV protons from a Cyclone 18/9 cyclotron (Ion Beam Applications, Louvain-la-Neuve, Belgium). After the irradiation, $[^{18}F]F^-$ was separated from $[^{18}O]H_2O$ using a SepPak Light Accell plus QMA anion exchange cartridge (Waters). The $[^{18}F]F^-$ was then eluted from the cartridge with a solution containing 2.47 mg potassium carbonate and 27.92 mg Kryptofix 222 dissolved in 0.75 mL of H_2O/CH_3CN (5:95 v/v) into a reaction vial.

After evaporation with a stream of helium of the solvent from the reaction vial, $[^{18}F]F^-$ was further dried by azeotropic distillation using 1 mL of dry acetonitrile. A volume of 5 μL 2-bromoethyl triflate in 0.7 mL *o*-dichlorobenzene was added to the vial containing $[^{18}F]F^-$. The resulting 2-[^{18}F]fluoroethyl bromide was then distilled at 120 °C with a helium flow (3–4 mL/min) and subsequently passed over a silver triflate column (6 mm × 50 mm) at 250 °C to obtain [^{18}F]FEtOTf. The resulting [^{18}F]FEtOTf was bubbled into another reaction vial containing 1 mg of the precursor (**1**) and 5 μL NaOH 1 M in 0.3 mL acetone. After distillation of a sufficient amount of radioactivity in the solution, the reaction vial was closed and heated at 90 °C for 10 min. After cooling, deprotection of the sugar hydroxyl groups was done by addition of 0.3 mL NaOH 33 mM and incubation for 5 min at room temperature. The reaction mixture was subsequently neutralized with 0.5 mL 0.5 M phosphate buffer pH 5, and the mixture was heated at 90 °C for 4 min with a flow of helium to remove the unreacted [^{18}F]FEtOTf or [^{18}F]FEtOH which is formed as a side product. The resulting mixture was purified by HPLC on a μBondapak C_{18} column (10 μm, 7.8 mm × 300 mm; Waters), eluted with 0.05 M sodium acetate buffer pH 5.5/ethanol (85:15 v/v) at a flow rate of 4 mL/min. The radiolabeled compound [^{18}F]-**2c** eluted after 6.35 min and was obtained with a decay-corrected radiochemical yield of approximately 59% relative to starting activity of [^{18}F]FEtOTf. Radiochemical purity and specific activity were assayed using HPLC on an XTerra RP C_{18} column (5 μm, 4.6 mm × 250 mm; Waters) eluted with gradient mixtures of water/acetonitrile (0 min, 90:10 v/v; 20 min, 30:70 v/v; linear gradient) at a flow rate of 1 mL/min. [^{18}F]-**2c** elutes after 11 min and was obtained with an average specific activity of 64.6 GBq/μmol at the end of synthesis (EOS) and a radiochemical purity of >99%.

Production of [^{11}C]methyl Triflate ([^{11}C]MeOTf) and Radiosynthesis of [^{11}C]-3c. Carbon-11 was produced by a $^{14}N(p,\alpha)^{11}C$ nuclear reaction. The target gas (a mixture of 95% N_2 and 5% H_2) was irradiated using 18 MeV protons at a beam current of 25 μA for about 30 min, to yield $[^{11}C]CH_4$. The $[^{11}C]CH_4$ was then reacted with vaporous I_2 at 650 °C in a home-built recirculation synthesis module to convert it to [^{11}C]MeI. Subsequently, [^{11}C]MeOTf was obtained by passage of the [^{11}C]MeI over a silver triflate column (6 mm × 50 mm) at 180 °C. The resulting [^{11}C]MeOTf was bubbled through a solution of 1 mg precursor (**1**) in a mixture of 5 μL NaOH 1 M and 0.3 mL acetone. When the amount of radioactivity in the vial had stabilized, the sugar hydroxyl groups were deprotected by addition of 0.3 mL NaOH 33 mM and incubation for 5 min at room temperature. The reaction mixture was subsequently neutralized with 0.5 mL 0.5 M phosphate buffer pH 5 and purified by HPLC on a μBondapak C_{18} column (Waters), eluted with 0.1 M ammonium acetate pH 4/ethanol (90:10 v/v) at a flow rate of 4 mL/min. [^{11}C]-**3c** eluted after 10.2 min and was obtained with a decay-corrected radiochemical yield of approximately 94% relative to [^{11}C]MeOTf starting activity. The product was analyzed by HPLC on an XTerra RP C_{18} column (Waters) eluted with gradient mixtures of water/acetonitrile (0 min, 90:10 v/v; 20 min, 30:70 v/v; linear gradient) at a flow rate of 1 mL/min. [^{11}C]-**3c** elutes after 10.5 min and was obtained with an average specific activity of 26.1 GBq/μmol at the end of synthesis (EOS) and a radiochemical purity of >99%.

Log *P* (*n*-Octanol/Phosphate Buffer pH 7.4). The partition coefficient was determined using a modification of the method described by Vanbilloen et al. (*34*). An aliquot of 30 μL of RP-HPLC purified tracer solution containing 185 kBq of [^{18}F]-**2c** or 555 kBq [^{11}C]-**3c** was added to a polypropylene tube (Sarstedt, Nümbrecht, Germany) containing 2 mL 0.025 M sodium phosphate buffer pH 7.4 and 2 mL *n*-octanol (density = 0.827 g/mL). The tube was vortexed at room temperature for 2 min, followed by centrifugation at 3000 rpm (1837 g) for 5 min (Eppendorf centrifuge 5810, Eppendorf, Westbury, USA). Aliquots of 50 μL and 500 μL were drawn from the *n*-octanol and aqueous phases, respectively, taking care to avoid cross-contamination between the two phases. The samples were weighed, and radioactivity was counted using an automated gamma counter. The experiments were performed at least in triplicate.

***In Vitro* Hydrolysis of [^{18}F]-2c and [^{11}C]-3c by β-gal.** An aliquot of 0.4 mL HPLC purified [^{18}F]-**2c** (5.9 MBq) or 0.4 mL HPLC purified [^{11}C]-**3c** (9.6 MBq) was added to 0.6 mL of a solution containing HEPES buffer pH 7.0 (120 mM),

$MgSO_4$ (4 mM), NaCl (180 mM), and 6 μg (1 U) β-gal (*E. coli*, E.C.3.2.1.23, 165 U/mg, Fluka). The solution was incubated at 37 °C in an oil bath, and 50 μL samples were collected at different time points ranging from 30 s to 45 min after the start of the incubation. Enzymatic activity was stopped by cooling the samples in ice. Each sample was analyzed for release of the radiolabeled aglycon using HPLC coupled to radiometric detection using an XTerra RP C_{18} column eluted with mixtures of 40% acetonitrile ([^{18}F]-**2c**) or 30% acetonitrile ([^{11}C]-**3c**) in 0.1 M ammonium acetate pH 4 at a flow rate of 1 mL/min. Intact [^{11}C]-**3c** elutes at 4 min, the carbon-11 labeled aglycon 3-[^{11}C]methoxy-2-nitrophenol ([^{11}C]-**3a**) resulting from enzymatic hydrolysis elutes at 11.5 min. Intact [^{18}F]-**2c** elutes at 3.5 min and the fluorine-18 labeled hydrolysis product 3-(2′-[^{18}F]fluoroethyl)-2-nitrophenol ([^{18}F]-**2a**) at 8 min. The percentage of conversion of [^{18}F]-**2c** and [^{11}C]-**3c** as a function of the incubation period was calculated from the integrated HPLC chromatograms.

Biodistribution Study in Normal Mice. Solutions of [^{18}F]-**2c** and [^{11}C]-**3c** obtained after RP-HPLC purification were diluted using 0.9% NaCl for injection to concentrations of 3.7 MBq/mL and 37 MBq/mL, respectively. The biodistribution of both tracers was determined in male NMRI mice (body mass 30–40 g). The mice were anesthetized by intraperitoneal injection of 0.1 mL of a solution containing 3 mg ketamine and 0.225 mg xylazine. A volume of 0.1 mL of the diluted tracer solution was then injected via a tail vein, and the mice were sacrificed by decapitation at 2 or 60 min postinjection (p.i., $n = 3$ per time point). All organs and body parts were dissected. Blood was collected in tared tubes, and the masses of all organs and body parts were determined. The radioactivity in each organ was counted using a 3 in. NaI(Tl) well counter, corrected for background radioactivity and expressed as a percentage of the injected dose (% ID) or as a percentage of the injected dose per gram tissue (% ID/g). For the calculation of total radioactivity in blood, blood mass was assumed to be 7% of the body mass.

Metabolism of [^{18}F]-2c and [^{11}C]-3c in Normal Mice. The metabolic stability of [^{18}F]-**2c** and [^{11}C]-**3c** was studied in normal mice by determination of the relative amounts of the parent tracer and metabolites in plasma. An aliquot of 3.7 MBq of [^{18}F]-**2c** or 18 MBq of [^{11}C]-**3c** was injected intravenously via a tail vein of anesthetized mice. The animals ($n = 2$ per tracer) were sacrificed by decapitation at 30 min p.i., and blood was collected into a BD vacutainer (containing lithium heparin; BD, Franklin Lakes, USA). After centrifugation at 3000 rpm (1837 g) for 5 min (Eppendorf centrifuge 5810), plasma was collected, diluted with an equal volume of acetonitrile, and again centrifuged for 5 min at 3000 rpm. The plasma was filtered through a 0.22 μm filter (Millipore, Bedford, USA), and the filter was rinsed with an equal volume of water. Finally, the filtered plasma was mixed with authentic **2a** and **2c** or authentic **3a** and **3c** and analyzed using HPLC on an XTerra RP C_{18} column eluted with mixtures of 40% acetonitrile ([^{18}F]-**2c**) or 30% acetonitrile ([^{11}C]-**3c**) in 0.1 M ammonium acetate pH 4 at a flow rate of 1 mL/min. After passing through an inline UV detector, the HPLC-eluate was collected in 1 mL fractions, and their radioactivity was measured using a gamma counter.

Cell Uptake Studies. A lentiviral vector (LV) encoding the cDNA of β-gal linked to the puromycin-N-acetyl transferase (*pac*) gene from *Streptomyces alboniger* through an encephalomyocarditis virus internal ribosome entry site (IRES) was produced as described (*35*) and denominated LV-LacZ-I-P. A similar vector encoding the firefly luciferase (fluc) gene or the varicella zoster virus thymidine kinase (VZV-tk) was used as the control (LV-fluc-I-P and LV-VZV-tk-I-P).

Human embryonic kidney cells (293T) transduced with LV-LacZ-I-P and with LV-fluc-I-P were maintained in culture in medium containing 1 μg/mL puromycin. They were plated in triplicate at a density of 200 000 cells per well in 24-well plates. After 24 h, the medium was discarded, and 0.25 mL of fresh medium with HPLC-purified tracer (185 kBq of [^{18}F]-**2c** or 1.11 MBq of [^{11}C]-**3c** per well) was added. The cells were then incubated at 37 °C in a 5% CO_2 atmosphere for time intervals of 30, 60, 90, or 120 min ($n = 3$ per time point, per vector). Earlier time points were not investigated. Following incubation and removal of the medium, the cells were washed three times with 0.4 mL of ice−cold phosphate-buffered saline (PBS). The cells were then lysed with 0.25 mL of Cell Culture Lysis Reagent 1× solution (Promega Corporation, Madison, USA) for 10 min, after which the lysate was collected, followed by a 0.125 mL rinse using the same solution. The cell fractions (lysate and rinse) as well as the wash fractions (medium and PBS) were collected separately for each well, and the radioactivity was measured using a gamma counter. This procedure was repeated for each incubation period. The protein concentration of each cell fraction was determined using the Bio-Rad Protein Assay (Biorad, München, Germany) and a spectrophotometer (Bio Synchron-Anthos 2010, Anthos LabTec Instruments, Austria) at 595 nm. Tracer uptake was normalized for total protein content in the cell fraction for each individual well and expressed as percentage of total radioactivity per milligram protein.

HPLC Analysis of Cell Lysates and Supernatants of LacZ Gene- and VZV-tk Gene-Transduced Cells after 30 min Incubation with [^{18}F]-2c. Cells expressing β-gal or VZV-TK as control were grown to near confluency in 75 cm^2 flasks, in the conditions described above. The medium was discarded, and the monolayer was incubated with 4 mL of fresh medium containing 22 MBq of [^{18}F]-**2c** for each flask. After 30 min incubation at 37 °C and removal of the medium, the cells were washed with cold PBS (3 × 5 mL). Intracellular components from the cells in both flasks were harvested by treatment with 1.5 mL of Cell Culture Lysis Reagent solution, followed by a rinse with 1 mL of the same solution. An aliquot of 1 mL of the cell suspension was diluted with an equal volume of acetonitrile, and the mixture was centrifuged at 3000 rpm (1837 g) for 5 min (Eppendorf centrifuge 5810). 1.5 mL of the centrifuged cell suspension was filtered through a 0.22 μM filter (Millipore), and the filter was rinsed with an equal volume of water. Finally, the filtrate was mixed with authentic **2a** and **2c** and analyzed using HPLC on an XTerra RP C_{18} eluted with a mixture of 30% acetonitrile in 0.1 M ammonium acetate pH 4 at a flow rate of 1 mL/min. After passing through an inline UV detector, the HPLC eluate was collected in 1 mL fractions, and the radioactivity of all fractions was measured using a gamma counter. The supernatant from both flasks was analyzed in the same way, with the only difference that these fractions were first centrifuged (prior to addition of acetonitrile) to remove the small number of cells that might have been detached from the bottom of the flask during the rinse steps.

μPET Imaging in a β-gal Expressing Tumor Mouse Model. Five million SHSY5Y (human neuroblastoma) cells stably transduced with LV-LacZ-I-P were implanted in the flank of female nude mice. Tumor growth and body mass were monitored on a regular basis. The mice were housed on a 12 h/12 h light/darkness cycle and had access to food and water ad libitum. When the tumor reached a volume over 500 mm^3, imaging was performed. Dynamic μPET imaging was performed with a Focus 220 micro-PET scanner (Concorde Microsystems, Knoxville, TN, USA). The mouse was anesthetized with isoflurane (2%) in oxygen at a flow rate of 1 L/min and subsequently injected with 13 MBq [^{18}F]-**2c** via a lateral tail vein. A μPET image was acquired for 215 min, and reconstruc-

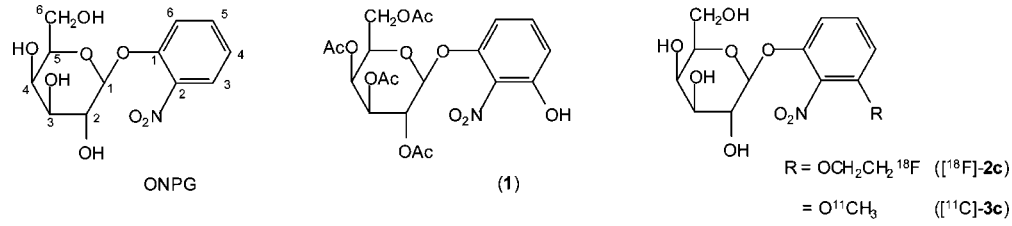

Figure 1. Structure of ONPG, 3-hydroxy-2-nitrophenyl 2,3,4,6-tetra-*O*-acetyl-*β*-D-galactopyranoside (**1**) and the radiolabeled probes 3-(2′-[^{18}F]fluoroethoxy)-2-nitrophenyl *β*-D-galactopyranoside ([^{18}F]-**2c**) and 3-[^{11}C]methoxy-2-nitrophenyl *β*-D-galactopyranoside ([^{11}C]-**3c**).

tion was done using filtered back-projection with a RAMP 0.5 filter. The images were displayed in AMIDE (*36*).

RESULTS AND DISCUSSION

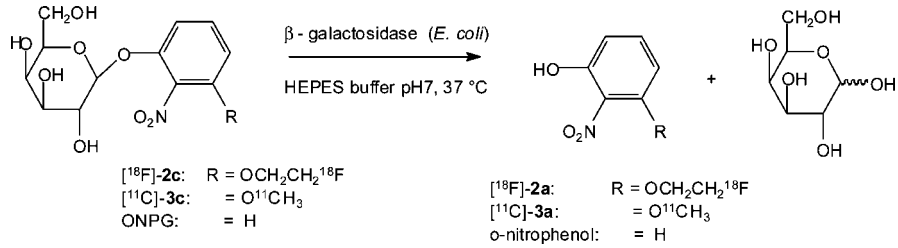
β-Galactosidase (*β*-gal), the enzyme encoded by the LacZ gene, catalyzes hydrolysis of galactopyranosides by cleavage of the C−O bond between the sugar and the aglycon with overall retention of anomeric configuration (*37, 38*). As indicated by the diversity of substrates that can be used to detect *β*-gal activity, this enzyme has a broad substrate specificity. The only prerequisite is the conservation of the galactose structure, since it has been observed that hydrogen bonding between the active site of the enzyme and the hydroxyl groups of the glycosidic substrate is important in the formation of the enzyme–substrate complex (*37–40*). On the basis of these findings, we derivatized in the present study *o*-nitrophenyl *β*-D-galactopyranoside (ONPG) in the phenyl moiety in order to minimize interference with its binding affinity, labeled it using [^{18}F]FEtOTf or [^{11}C]MeOTf and evaluated the two tracers as potential reporter probes for *in vivo* visualization of LacZ gene expression with PET. The structures of ONPG, the precursor **1**, and the PET-tracers [^{18}F]-**2c** and [^{11}C]-**3c** are shown in Figure 1.

The ONPG-derived precursor **1** was synthesized following the procedure described by Oyama et al. (*41*), which involved a Koenigs−Knorr glycosylation reaction of 2-nitroresorcinol with acetobromo-α-D-galactose in the presence of silver carbonate in quinoline at room temperature. Inversion of the configuration at the anomeric center resulted in the sole formation of the *β*-anomer in a 30% yield. Compound **1** was identified using mass spectrometry, and its structure was confirmed with ^{1}H and ^{13}C NMR. The presence of the anomeric H-1 at 5.1 ppm as a doublet with an axial−axial coupling ($^{3}J_{H1\text{-}H2}$) of 8 Hz, the coupling of H-2 with H-3 with a coupling constant ($^{3}J_{H2\text{-}H3}$) of 10.6 Hz in the ^{1}H NMR spectrum, and the resonance of the anomeric carbon atom at 100.31 ppm in the ^{13}C NMR spectrum proved the *β*-configuration of the precursor (*42*). To prevent alkylation of the sugar hydroxyl groups, hydrolysis of the protective acetate groups was performed after radiolabeling. Since the synthesis of the cold reference compounds by alkylation of **1** with 2-fluoroethyl tosylate or methyl triflate and subsequent deprotection failed or resulted in a negligible yield, we first synthesized the alkylated phenols (**2a** and **3a**) via a Mitsunobu coupling between 2-nitroresorcinol and the corresponding alcohol (2-fluoroethanol or methanol) using triphenylphosphine and diisopropylazodicarboxylate in tetrahydrofuran. The structure of these compounds was confirmed with ^{1}H and ^{13}C NMR. In a second step, the alkylated phenols were coupled to acetobromo-α-D-galactose in the same way as described for the synthesis of **1**, yielding **2b** and **3b** in a moderate yield. Subsequent deprotection of the sugar hydroxyl groups using sodium methoxide resulted in the desired reference compounds **2c** and **3c**. The anomeric *β*-configuration, essential for substrate affinity for *β*-galactosidase, was again confirmed by the characteristic chemical shifts (**2c**, $\delta_{H\text{-}1} = 4.99$ ppm, $\delta_{C\text{-}1} = 101.09$ ppm; **3c**, $\delta_{H\text{-}1} = 4.98$ ppm, $\delta_{C\text{-}1} = 101.06$ ppm) and coupling constants ($^{3}J_{H1\text{-}H2} = 7.4$ Hz) in the ^{1}H and ^{13}C NMR spectra. High-resolution mass spectrometry (HRMS) yielded the exact mass as calculated for the precursor (**1**) and the reference compounds (**2c**, **3c**).

Previous attempts to label a derivative of ONPG bearing a tosyl-ethoxy substituent in ortho position of the nitro group directly with [^{18}F]fluoride failed because of decomposition of the precursor under the applied labeling conditions (Kryptofix 222 in combination with K_2CO_3 or $KHCO_3$ at 110 or 60 °C). These failures prompted us to use the secondary labeling agents 2-[^{18}F]fluoroethyl triflate ([^{18}F]FEtOTf) and [^{11}C]methyl triflate ([^{11}C]MeOTf), which do not require the use of a strongly alkaline solution of kryptofix and a potassium salt at elevated temperatures. [^{18}F]FEtOTf and [^{11}C]MeOTf were synthesized following reported procedures (*43, 44*). Labeling with carbon-11 was done by alkylation of precursor **1** with [^{11}C]MeOTf in acetone in the presence of NaOH at room temperature. Labeling with fluorine-18 was done in a similar way with [^{18}F]FEtOTf as alkylating agent. However, heating to 90 °C was required to effect the reaction. At 70 °C, slightly lower yields were obtained, and at room temperature, less than 20% of the protected tracer was formed (Scheme 1). For both tracers, labeling was followed by deprotection of the sugar hydroxyl groups under basic conditions. For the fluorine-18 labeled tracer, the unreacted [^{18}F]EtOTf or [^{18}F]EtOH was evaporated, and both tracers were purified using preparative RP-HPLC. Chemical and radiochemical purity of both HPLC purified tracers was examined on an analytical RP C_{18} column and were found to be >99%. The identity of the tracers was confirmed by coelution with authentic nonradioactive compounds after coinjection on analytical RP-HPLC.

The lipophilicity of the tracers was determined by measuring their *n*-octanol/water partition coefficients, which were found

Scheme 2. Schematic Representation of Enzymatic Cleavage of the Galactopyranosides into Their Corresponding Phenol−Aglycons and D-Galactose



to be −0.8 and −0.7, respectively, for [^{18}F]-**2c** and [^{11}C]-**3c**. This reflects the polarity of the sugar backbone. The optimal theoretical log *P* value of a compound for passive diffusion over the blood−brain barrier is situated within the range 1–2.5 (*45*, *46*). Extrapolating this to diffusion over a cell membrane suggests that the labeled galactose derivatives may not be lipophilic enough to efficiently enter the cells through passive diffusion. In literature, no evidence of active transport for this type of galactose derivative was found. However, the cell uptake studies (*vide infra)* suggest that [^{18}F]-**2c** and [^{11}C]-**3c** do enter the cells.

In an *in vitro* test (Scheme 2), both tracers were found to be good substrates of β-gal with results in a comparable range as reported by Cui et al. (*30*) for a similar compound (Figure 2). After 30 s of incubation at 37 °C, already 89% of [^{18}F]-**2c** was hydrolyzed. Complete hydrolysis was reached after about 15 min. For the C-11 labeled tracer, the enzymatic conversion was somewhat slower. After 30 s of incubation, 60% of [^{11}C]-**3c** was hydrolyzed, and almost complete hydrolysis (90%) was reached after 15 min. In a similar test with the reference substrate ONPG (1 mg), 100% conversion was also reached within 15 min (results not shown). In a control experiment under identical conditions, but in the absence of β-gal, no hydrolysis of the labeled galactose derivatives was observed.

These results suggest that the labeled galactose derivatives were specifically hydrolyzed by β-gal, with a rate comparable to that for ONPG.

The biodistribution of [^{18}F]-**2c** and [^{11}C]-**3c** was evaluated in normal male NMRI mice at 2 and 60 min p.i. for both tracers. Data are shown in Tables 1 and 2. Both tracers have a similar behavior *in vivo*, but the clearance from blood, defined as the 2-min-to-60-min ratio of the blood activity, was slower for [^{18}F]-**2c** than for [^{11}C]-**3c** (1.7 and 4.7, respectively). Blood clearance occurred mainly through the renal pathway with 33.2% of the injected dose (ID) ([^{18}F]-**2c**) and 45.8% ID ([^{11}C]-**3c**) in the urine at 60 min p.i. Negligible uptake was seen in the brain, which was expected in view of the negative log *P* value. The slow blood clearance may interfere with successful *in vivo* imaging.

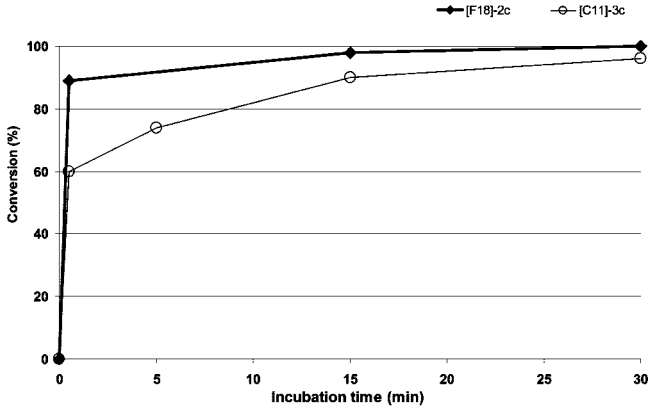


Figure 2. *In vitro* hydrolysis of [^{18}F]-**2c** (♦) and [^{11}C]-**3c** (○) by β-gal (1U) in HEPES buffered solution at 37 °C.

The metabolic stability was determined in normal mice, having low levels of endogenous β-galactosidase (*47*). Plasma analysis of [^{18}F]-**2c** and [^{11}C]-**3c** at 30 min p.i. revealed that, respectively, 98% and 97% of the activity was present as intact tracer, indicating high *in vivo* stability. Negligible traces of hydrolysis product were found, indicating little degradation by endogenous mammalian β-galactosidase.

The results of the cell uptake studies are shown in Figure 3a ([^{18}F]-**2c**),b ([^{11}C]-**3c**). A maximal uptake was observed after 30 min incubation for [^{18}F]-**2c** with a 7.5-fold higher uptake in the β-gal-expressing cells (3.2%/mg protein) compared to the control cells (0.4%/mg protein). This uptake ratio is comparable with the maximal uptake ratio of the iodine-123 labeled β-gal inhibitor of the group of Lee et al. (*32*).

For [^{11}C]-**3c**, the maximal uptake was reached after 90 min of incubation with a 2.5-fold higher uptake in the β-gal expressing cells (5.2%/mg protein) compared to the control cells (2.1%/mg protein). [^{18}F]-**2c** was further evaluated *in vitro* and *in vivo*.

The uptake of [^{18}F]-**2c** in the β-gal-expressing cells decreases significantly as a function of time, from 3.2%/mg protein after

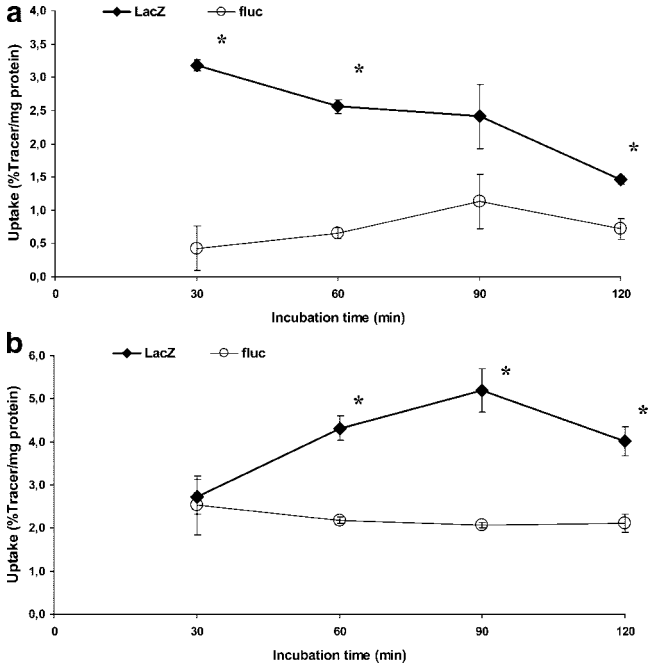

Figure 3. a. Time-dependent uptake levels of [^{18}F]-**2c** in LacZ gene (♦)- and fluc gene (○)-transduced 293T cells. Data are expressed as % tracer/mg protein and are mean values of triplicate samples. Values with asterisk are significant different; $p < 0.006$, unpaired bidirectional Student *t* test. b. Time-dependent uptake levels of [^{11}C]-**3c** in LacZ gene (♦)- and fluc gene (○)-transduced 293T cells. Data are expressed as % tracer/mg protein and are mean values of triplicate samples. 30 min of incubation to 1.5%/mg protein after 120 min of incubation (Figure 3a). This may be due to leakage of the radiolabeled aglycon ([^{18}F]-**2a)** out of the transduced cells. To test this hypothesis and to check the nature of the metabolites present in the transduced cells, the cell lysates and supernatant fractions of both the β-gal expressing cells as well as the control cells were analyzed using RP-HPLC, after incubation with [^{18}F]-**2c** for 30 min. The HPLC chromatograms of the supernatants and cell lysates of the LV-LacZ-I-P and LV-VZV-tk-I-P transduced cells are shown in Figure 4a (supernatants) and b (cell lysates). The cold intact (**2c**) and hydrolyzed (**2a**) reference compounds were added to the cell lysates and supernatant fractions prior to HPLC analysis. In this way, the signals in the reconstructed radiometric HPLC chromatogram could be assigned by correlation to the signals in the UV absorption chromatogram. The component eluting in fractions 4 to 6 is the intact tracer [^{18}F]-**2c**. The metabolite eluting in fractions 14 to 16 is the aglycon 3-(2′-[^{18}F]fluoroethoxy)-2-nitrophenol ([^{18}F]-**2a**). In the LacZ cell lysate, 63.5% of the radioactivity was recovered as radiolabeled aglycon (Table 3). In the VZV-tk control cells, only negligible amounts of hydrolysis product were found in the cells and in the supernatants. This suggests that the labeled aglycon (50.7%) found in the supernatant fraction of the β-gal expressing cells must have leaked out of the LacZ expressing cells, which would result in loss of PET-signal. This back-diffusion can be explained in terms of the pK_a of the hydrolysis product ([^{18}F]-**2a**). The pK_a of nonsubstituted *o*-nitrophenol is 7.23 (*48*); the dissociation constant of [^{18}F]-**2a** is therefore estimated to be in a similar range. Ideally, the dissociation constant should be an order of magnitude lower than 7.4 (physiological pH) to direct the equilibrium to the dissociated form, resulting in a higher retention of the ionized aglycon in LacZ transduced cells.

To test the potential of [^{18}F]-**2c** as a PET reporter probe for detecting LacZ gene expression *in vivo*, a mouse growing

	LacZ	VZV-tk	LacZ	VZV-tk
[^{18}F]-**2c** (intact)	36.5	97.8	49.3	94.4
[^{18}F]-**2a** (aglycon)	63.5	2.2	50.7	5.6

[a] Data are expressed as % of recovered activity.

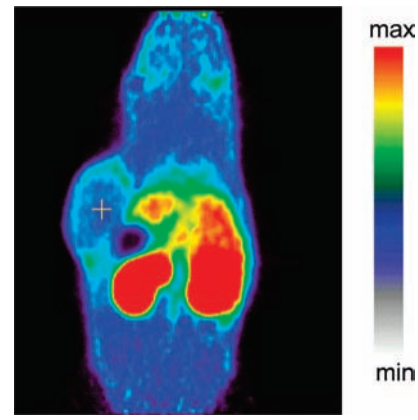

Figure 5. μPET image, selected from a 3D data set (summed image from 0 to 215 min p.i.), of the distribution of [^{18}F]-**2c** in a β-gal-expressing tumor mouse model. The position of the tumor is marked with a cross.

β-galactosidase-expressing SHSY5Y-LacZ-I-P xenografts was injected with [^{18}F]-**2c** and a μPET image was acquired for 215 min. Figure 5 shows the summed image from 0 to 215 min. In analogy with the mice biodistribution study, high uptake is seen in the liver and the kidneys. Only negligible accumulation is observed in the LacZ-transduced tumor, despite the pronounced difference in uptake between β-gal expressing cells and control cells *in vitro*. The absence of tracer accumulation in the LacZ tumor can be due to poor passive diffusion over the tumor cell membrane. This would be in accordance with the results of Liu

et al. (*49*) who needed to perform direct intratumoral injection of their fluoronitrophenyl galactopyranoside MRI probe to observe any contrast.

CONCLUSION

A derivative of the chromogenic β-gal substrate ONPG was efficiently synthesized and labeled with [^{18}F]FEtOTf or [^{11}C]MeOTf to obtain [^{18}F]-**2c** and [^{11}C]-**3c**, which were evaluated as reporter probes for detection of LacZ gene expression with PET. Metabolic stability analysis of plasma collected 30 min after injection of [^{18}F]-**2c** or [^{11}C]-**3c** in mice showed high *in vivo* stability for both tracers. In an in *vitro* experiment, [^{18}F]-**2c** and [^{11}C]-**3c** were found to be good substrates with complete conversion after about 15 min of incubation with β-galactosidase. Cell uptake studies revealed that [^{18}F]-**2c** had a 7.5-fold higher uptake into LacZ gene-transduced cells compared to control cells. For [^{11}C]-**3c**, this difference was only 2.5. RP-HPLC analysis of the cell lysates and supernatant fractions from β-gal expressing cells and control cells after 30 min of incubation with [^{18}F]-**2c** showed substantial leakage of the β-gal cleavage product of [^{18}F]-**2c** out of the transduced cells, which would lead to loss of PET signal. In a μPET study of [^{18}F]-**2c** in a LacZ expressing tumor mouse model, only negligible accumulation was observed in the LacZ transduced tumor, despite the significant difference in uptake between β-gal expressing cells and control cells *in vitro*. As a general conclusion, it can be stated that the synthesized PET tracers [^{18}F]-**2c** and [^{11}C]-**3c** are not suitable for use as LacZ reporter probes. Further modifications to improve diffusion over the tumor cell membrane and to increase the retention in β-gal expressing cells may lead to better *in vivo* imaging results.

ACKNOWLEDGMENT

We gratefully thank Marva Bex and Sigrid Ruymen for their assistance in the labeling experiments and Christelle Terwinghe, Kim Deliège, and Peter Vermaelen for their help in the *in vivo* studies. This work was supported by SBO grant (IWT-30 238) of the Flemisch Institute supporting Scientific-Technological Research in industry (IWT), the IDO grant (IDO/02/012) of the Katholieke Universiteit Leuven, and by the EC-FP6-project DiMI, LSHB-CT-2005-512146.

Labeling of Fatty Acid Ligands with the Strong Electrophilic Metal Fragment $[^{99m}Tc(N)(PNP)]^{2+}$ (PNP = Diphosphane Ligand)

Emiliano Cazzola,[†] Elisa Benini,[†] Micol Pasquali,[†] Peter Mirtschink,[‡] Martin Walther,[§] Hans-Jurgen Pietzsch,[‡] Licia Uccelli,[†] Alessandra Boschi,[†] Cristina Bolzati,[△] and Adriano Duatti*[,†]

Received June 25, 2007; Revised Manuscript Received November 28, 2007

The electrophilic metal fragment $[^{99m}Tc(N)(PNP)]^{2+}$ (PNP = diphosphane ligand) has been employed for the labeling of fatty acid chains of different lengths. To provide a site-specific group for the attachment of the metallic moiety, the fatty acid derivatives were functionalized by appending a bis-mercapto or, alternatively, a dithiocarbamato π-donor chelating systems to one terminus of the carbon chain to yield both dianionic and monoanionic bifunctional ligands (L). The resulting complexes, $[^{99m}Tc(N)(PNP)(L)]^{0/+}$, exhibited the usual asymmetrical structure in which a Tc≡N group was surrounded by two different bidentate chelating ligands. Dianionic ligands gave rise to neutral complexes, while monoanionic ligands afforded monocationic species. Biodistribution studies were carried out in rats. An isolated perfused rat heart model was employed to assess how strucural changes in the radiolabeled fatty acid compound affect the myocardial first pass extraction. Results showed that only monocationic complexes accumulated in myocardium to a significant extent. Conversely, neutral complexes were not efficiently retained into the heart region and rapidly washed out. In isolated perfused rat heart experiments, monocationic complexes exhibited a behavior similar to that of the monocationic flow tracers ^{99m}Tc-MIBI and ^{99m}Tc-DBODC with almost identical extraction values, a result that could be attributed to the presence of the monopositive charge. Instead, a slightly lower myocardial extraction was found for neutral complexes. Comparison of the observed kinetic behavior of neutral complexes in the isolated perfused rat heart model with that of the myocardial metabolic tracer [^{123}I]IPPA revealed that the introduction of the metallic moiety partially hampers recognition of the labeled fatty acids by cardiac enzymes, and consequently, their behavior did not completely reflect myocardial metabolism.

INTRODUCTION

The search for a Tc-99m labeled fatty acid derivative has been actively pursued in the past years in the attempt to find a suitable alternative to radiopharmaceuticals labeled with positron emitter radionuclides or iodine radioisotopes for monitoring heart metabolism (*1, 2*). A Tc-99m imaging agent sensitive to alterations in fatty acid metabolism in myocardium would be highly desirable because of the ideal nuclear properties of this radionuclide and its easy availability through the ^{99}Mo/^{99m}Tc generator system. A number of different Tc-99m complexes incorporating fatty acid chains of different lengths have been reported, but none of them were shown to have potential use in clinical practice (*3, 9*).

An ideal Tc-99m agent for heart imaging should possess some key features that are essential for visualizing the cardiac region. For instance, one of the most critical requirements is a rapid and quantitative washout of activity from nontarget organs surrounding the heart, such as blood, lungs, and liver, to avoid interference with the activity localized into the myocardium. In particular, liver uptake always constitutes a rather difficult problem, which may become even more important when the radioactive agent is employed for targeting some subtle metabolic process. Indeed, a common drawback plaguing the biodistribution behavior of Tc-99m tracers for imaging fatty acid metabolism proposed so far is attributable to high and persistent liver uptake. A few years ago, we discovered that a large class of Tc-99m complexes, having the general structure sketched in Figure 1b, are easily extracted by the myocardium, but rapidly and quantitatively washed out from nontarget organs, in particular, from the liver (*10, 12*). These complexes can be thought to be composed essentially by two parts: (a) a metal-containing fragment, $\{[^{99m}Tc(N)(PNP)]^{2+}\}$, formed by the technetium atom coordinated to a terminal nitride group (N^{3-}) and a bidentate diphosphane ligand (PNP), and (b) a bidentate ligand having a suitable set, (X,Y), of coordinating donor atoms. In this representation, the metallic portion $[^{99m}Tc(N)(PNP)]^{2+}$ can be viewed as a strong electrophilic molecular fragment capable of selectively interacting with bidentate electron-rich ligands (XY) through the overlap of its empty π-antibonding orbitals with the filled π-orbitals of the donor ligand (*13, 14*).

The favorable properties for cardiac imaging of this new category of Tc-99m complexes were particularly apparent in the study of the biological behavior of the complex $[^{99m}Tc(N)(PNP5)(DBODC)]^{+}$ {PNP5 = bis[(dimethoxypropylphosphanyl)ethyl]ethoxyethylamine; DBODC = *N,N′*-bis(ethoxyethyl)dithiocarbamato}. It was found that this complex rapidly accumulates in myocardium of various animal species and in humans, and washout from nontarget organs was extremely fast and quantitative. In particular, heart/liver ratio was 1 order of magnitude higher than those observed for commercial Tc-99m heart imaging agents (*15, 16*).

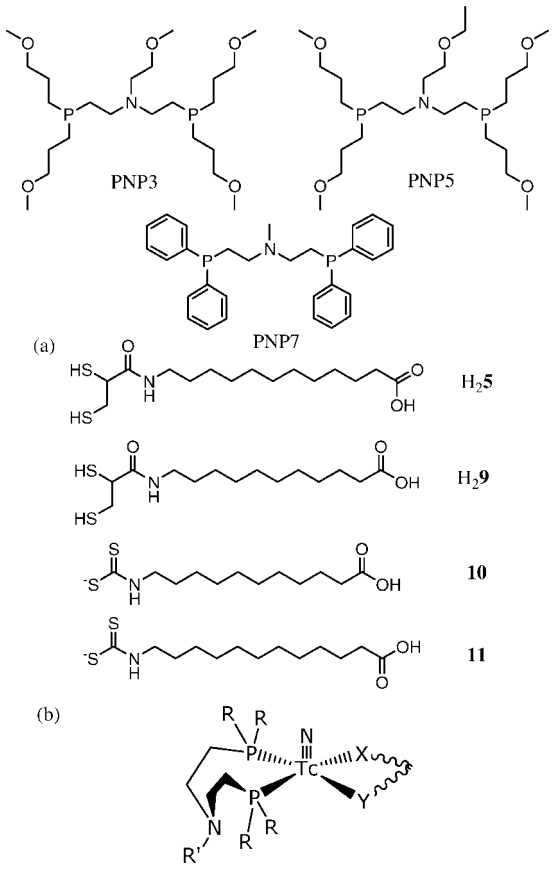

Figure 1. (a) The ligands utilized in this study and (b) general structure of asymmetrical nitride Tc(V) complexes.

Based on these findings, we speculated that, presumably, the $[^{99m}Tc(N)(PNP)]^{2+}$ basic molecular motif characterizing this class of complexes might be a key factor favoring the fast liver elimination. This consideration prompted us to exploit this chemistry for designing new Tc-99m radiopharmaceuticals for in vivo monitoring of cardiac metabolism, which should incorporate the $[^{99m}Tc(N)(PNP)]^{2+}$ building block together with a suitable bidentate ligand bearing a lateral fatty acid chain. In our strategy, the combination of these two molecular pieces would allow the development of myocardial tracers targeting fatty-acid-heart metabolism while concomitantly showing a fast liver clearance.

This paper describes the synthesis of new bifunctional ligands (L) derived from fatty acids having different lengths in their carbon backbone and their reactions with the metal synthon $[^{99m}Tc(N)(PNP)]^{2+}$ to afford new asymmetrical complexes of the type $[^{99m}Tc(N)(PNP)(L)]^{0/+}$. The chemical characterization and full biological evaluation in animals of these new Tc-99m agents will be also reported.

EXPERIMENTAL SECTION

Materials. Technetium-99m was eluted from a $^{99}Mo/^{99m}Tc$ generator provided by Amersham Sorin (Saluggia, Italy). The diphosphane ligands bis[(dimethoxypropylphosphanyl)-ethyl]methoxyethylamine (PNP3), bis[(dimethoxypropyl-phosphanyl)ethyl]ethoxyethylamine (PNP5), and bis[(diphe-nylphosphanyl)ethyl]methylamine (PNP7) (Figure 1a) were purchased from Argus Chemicals (Florence, Italy) or prepared according to literature procedures (*17*). All commercially available compounds and solvents were reagent grade and were used without further purification.

Labeling of *p*-iodophenylpentadecanoic acid (EMKA-CHE-MIE, Markgröningen, Germany) with ^{123}I was performed through Cu(I)-assisted nucleophilic exchange to give the final [^{123}I]IPPA radiocompound as described previously (*18*).

Table 1. Cromatographics Results

	TLC (R_f)	(R_t, min)	
complex	^{99m}Tc	Re	^{99m}Tc
syn, anti-[M(N)(PNP3)(5)]	0.33, 0.43[a]	14.50, 15.23[d]	15.37, 16.02[d]

[a] C_{18}, CH_3CN/0.1-M Et_3N (pH =3 adjusted with 1 M H_3PO_4) (70:30). [b] SiO_2, ETOH/CH_3Cl/toluene/0.5 M NH_4OAc (l.5:3:3:0.5). [c] C_{18}, saline/CH_3OH/THF/HOAc (glacial) (2:8:1:1). [d] Reversed-phase C_{18} column, gradient: A = MeOH, B = phosphate buffer (0.01 M, pH 7.4), t = 0 min, A = 50%, t = 15 min, A = 100%.

Instruments. FT IR spectra were recorded on a Nicolet 510P Fourier transform spectrometer, in the range 4000−400 cm^{-1} and in KBr mixture using a Spectra-Tec diffuse reflectance collector accessory. Elemental analyses (C, H, N, S) were performed on a Carlo Erba 1106 elemental analyzer. ^1H, ^{13}C, and ^{31}P NMR spectra were collected on a Brucker 400 instrument using $SiMe_4$ as internal reference (^1H, ^{13}C) and 85% aqueous H_3PO_4 as external reference (^{31}P).

Chromatography. The radiochemical purity (RCP) of the final Tc-99m compounds were determined by thin-layer chromatography (TLC) on SiO_2 plates and reversed-phase C18 plates (Merck). The activity on the plates were located and measured by a Cyclone instrument (Packard). High-performance liquid chromatography (HPLC) was performed on a Beckman System Gold instrument equipped with a radioisotope detector (model 170). HPLC analysis was carried out using a reversed-phase ODS precolumn (45 × 4.6 mm) and a reversed-phase ODS column (250 × 16 mm) (Beckman) at flow rate of 1 mL/min. Chromatographic results are reported in Table 1.

Synthesis of ω-[(2,3-Dimercaptopropanoyl)amino] Fatty Acid Ligands. In the following the symbol, **H_2n** (where **n** = **5**, **9**) stands for the protonated dimercapto fatty acid ligand, while **n** represents the resulting deprotonated dianionic ligand. When applied, the standard workup procedure for product isolation involved quenching of the reaction mixture in aqueous solution followed by extraction thoroughly with chloroform and washing of the extracts with saturated saline. The combined extracts were then dried over $MgSO_4$, filtered, and the solvent removed under reduced pressure.

Preparation of 11-{[2,3-Bis(acetylthio)propanoyl]amino}undecanoic Acid ($H_2$5). The synthesis of this ligand was conducted according to the reaction scheme illustrated in Figure 2.

*Methyl-11-[(2,3-dibromopropanoyl)amino]undecanoate (***3***).* Dibromopropionic acid (**1**) (1.00 g, 4.31 mmol) and DCC (890 mg, 4.31 mmol) were dissolved in 80 mL of iced chloroform (0 °C). Another solution, prepared separately by dissolving the ω-amino fatty acid ester hydrochloride **2** (1.10 g, 4.37 mmol) and ethyldiisopropylamine (738 μL, 4.31 mmol) in 20 mL of chloroform, was added dropwise to the first solution under stirring. The reaction mixture was stirred overnight without further cooling and then weakly acidified (pH ∼ 3.5) with a few drops 2 M hydrobromic acid. Finally, it was filtered off and evaporated under reduced pressure to remove the solvent. After completing the standard workup procedure for product isolation, purification was carried out by column chromatography (silicagel, $CHCl_3$/Et_2O/HOAc (150/10/0.15)] yielding 1.41 g (76%) of a colorless solid (**3**).

^1H NMR (δ ppm, $CDCl_3$). 6.28 (br, 1H, N*H*), 4.46 (dd, $^3J_1$ = 4.5 Hz, $^3J_2$ = 8.3 Hz, 1H, C*H*Br), 3.97 (dd, $^3J_1$ = 8.4 Hz,

Synthesis of ω-[(Dithiocarbamato)amino] Fatty Acid Ligands. In the following, the symbol $\mathbf{Xn^\bullet}$ (where $\mathbf{X = Ba, 2K}$ and $\mathbf{n^\bullet = 10^\bullet, 11^\bullet}$) stands for the salt of the doubly deprotonated dithiocarbamato fatty acid ligand as represented by $\mathbf{n^\bullet}$. The monoanionic form of $\mathbf{n^\bullet}$, involving only a deprotonated sulfur atom at the dithiocarbamato group, is represented by the symbol **n** (**10**, **11**). The preparation of dithiocarbamato derivatives of fatty acid ligands was performed according to reactions reported in Figure 4.

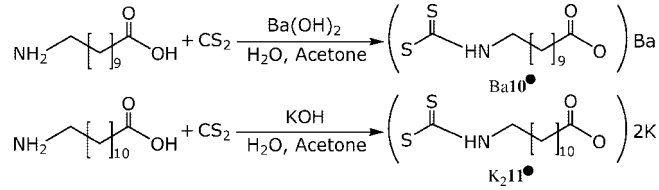

Figure 4. Reaction diagram for the synthesis of the ligands $\mathbf{Ba10^\bullet}$ and $\mathbf{K_2 11^\bullet}$.

*Barium 11-(carbodithioatoamino)undecanoate (***$\mathbf{Ba10^\bullet}$***).* Barium hydroxide (1.85 g, 5.88 mmol) was dissolved in 100 mL of water and, to the resulting solution, 11-aminoundecanoic acid (1.00 g, 4.9 mmol) and acetone (50 mL) were added under stirring. The reaction mixture was cooled at 0 °C, and carbon disulfide (0.50 mL, 6.37 mmol) was then added dropwise under stirring. The reaction was kept at 0 °C and stirred overnight. Precipitation of a colorless solid was observed, which was filtered off. Additional precipitate was collected after evaporation of the solvent under reduced pressure. The combined solids were then washed with CH_2Cl_2, ethanol, and diethyl ether to afford 1.1 g of $\mathbf{Ba10^\bullet}$ as a colorless solid. (Yield, 80%).

^{1}H NMR (δ ppm, D_2O). 3.76 (t, $^3J = 7.1$ Hz, 2H, CH_2COO), 3.68 (br, 1H, N*H*), 2.45 (t, $^3J = 7.4$ Hz, CH_2N), 1.81 (br, 2H, CH_2CH$_2$COO), 1.80 (br, 2H, CH_2CH$_2$NH), 1.57 (br, 6H, CH$_2$CH_2CH$_2$).

Synthesis of Rhenium Complexes with Fatty Acid Ligands. Rhenium complexes with fatty acid ligands were prepared at the macroscopic concentration level (>10^{-6} mol dm^{-3}) starting from the precursor complex [Re(N)(PNP7)Cl$_2$] and following the reaction scheme described in Figure 5. The precursor complex [Re(N)(PNP7)Cl$_2$] was obtained according to procedures reported previously (*13, 17*).

Re(N)(PNP7)(L) (L = **5**, **9***; PNP = PNP7).* A 2-fold molar excess of the appropriate dimercapto fatty acid ligand was added to 75 mg of the precursor complex [Re(N)(PNP7)Cl$_2$] suspended in a mixture of chloroform (10 mL) and ethanol (10 mL) containing triethylamine (55.0 μL, 395.0 μmol). The reaction mixture was heated under reflux and the course of the reaction monitored by TLC [silicagel, CHCl$_3$/EtOAc (1:1)]. Approximately after 2 h, the conversion of the precursor complex was almost complete. Then, the mixture was neutralized by 2 M citric acid, and the solvent removed under reduced pressures. The crude precipitate was washed with CH$_2$Cl$_2$, EtOH, and Et$_2$O. The resulting complexes were further purified through steps, *a* and *b*, carried out by column chromatography [(*a*) silicagel, mobile phase, CHCl$_3$/MeOH (10:1), (*b*) silicagel, CHCl$_3$/MeOH/acetone (20:1:1)]. After purification, the resulting product was washed with diethyl ether.

*[Re(N)(PNP7)(***5***)].* Yield, 72% (72 mg). Light-yellow solid collected as *syn*/*anti* stereoisomeric mixture.

*[Re(N)(PNP7)(**11**)]*$^+$. 23 mg (70.2 mmol) of the dithiocarbamate fatty acid ligand **$K_2$11$^•$** were added to a chloroform (10 mL)/ethanol (10 mL) mixture containing 150.0 mg (195.7 μmol) of [Re(N)(PNP7)Cl_2]. This mixture was refluxed for 1 h and then neutralized by addition of 2 M citric acid. After removal of the solvent under reduced pressure, the crude product was isolated by applying the standard workup procedure. The resulting light yellow solid was dissolved in acetone followed by addition of an ethanolic solution of [BF_4]Na (2.0 mg in 10 mL). The final product was recovered as BF_4 salt by slow evaporation of the solvent. Yield, 77% (80 mg).

^{1}H NMR (δ ppm, $CDCl_3$). 7.95–7.80 (m, 8H, CH_{ar}), 7.46–7.20 (m, 20H, CH_{ar}), 7.06–6.98 (m, 4H, CH_{ar}), 6.96–6.86 (m, 8H, CH_{ar}), 4.21 (br, 1H, N*H*), 3.73 (t, ^3J = 7.1 Hz, 2H, CH_2COO), 2.88 (t, ^3J = 7.4 Hz, CH_2N), 2.08 (s, 3H, NCH_3), 2.01 (br, 2H, CH_2CH_2NH), 1.85 (br, 2H, CH_2CH_2COO), 1.61 (br, 7H, CH_2CH_2CH_2).

Elemental analysis for $C_{42}H_{55}N_3O_2P_2ReS_2BF_4$ (mm, 1033.01). Calcd: C, 48.83, H, 5.37, N, 4.07, S, 6.21. Found: C, 48.22, H, 5.30, N, 3.98, S, 6.03.

Preparation of ^{99m}Tc-Complexes. A three-step procedure was employed for the preparation of ^{99m}Tc-complexes.

In all preparations, the first two steps were carried out as follows. Freshly generator eluted [$^{99m}TcO_4$]Na (0.250 mL, 50.0 MBq to 3.0 GBq) was added to a vial containing 5.0 mg of succinic dihydrazide (SDH) and 0.1 mg of $SnCl_2$ suspended in a mixture of 0.1 mL of saline and 1.0 mL of ethanol. The reaction solution was kept at room temperature for 30 min. Then, 1.0 mg of the appropriate diphosphane ligand (PNP = PNP3, PNP5), dissolved in 0.2 mL of ethanol was further added to the reaction vial, which was left at room temperature for an additional 30 min to afford the precursor metal fragment [^{99m}Tc(N)(PNP)]$^{2+}$.

The third step was conducted according to the procedure detailed below for each category of ^{99m}Tc-nitride complexes.

*[^{99m}Tc(N)(PNP)(L)] (L = **5**, **9**, PNP = PNP3).* The intermediate precursor [^{99m}Tc(N)(PNP)]$^{2+}$ was almost immediately converted into the final neutral complex [^{99m}Tc(N)(PNP)(L)] by adding an ethanolic solution of the appropriate dithiol ligand (**$H_2$5**, **$H_2$9**) (1.0 mg in 0.2 mL) to the reaction vial heated at 50 °C. Chromatographic characterization revealed the formation of an isomeric pair (**a** and **b**) of the same complex. Total yield determined by HPLC chromatography was approximately 95% (**a**, 45%; **b**, 50%). A representative HPLC chromatogram for this class of complexes is reported in Figure 6a.

[^{99m}Tc(N)(PNP)(L′)]$^+$ *(L′ = **10**, **11**, PNP = PNP3, PNP5).* Conversion of the precursor [^{99m}Tc(N)(PNP)]$^{2+}$ into the final monocationic complex [^{99m}Tc(N)(PNP)(L′)]$^+$ was similarly obtained by adding an ethanolic solution of the appropriate dithiocarbamate ligand (**Ba10$^•$**, **$K_2$11$^•$**) (1.0 mg in 0.2 mL) to the reaction vial heated at 60 °C. Yield, 96% (determined by HPLC). A representative HPLC chromatogram for this class of complexes is reported in Figure 6b.

Purification. To avoid interference of excess of reagents and free ligands on the biological evaluation of the new ^{99m}Tc-complexes, the following purification procedures were applied.

[^{99m}Tc(N)(PNP)(L)] Complexes. The reaction mixture was diluted with 8.0 mL of water and loaded onto a C18 SepPak cartridge (Waters) previously activated with ethanol (95%, 5.0 mL) and water (5.0 mL). The cartridge was rinsed with water (20.0 mL) and ethanol (60%, 3.0 mL). Finally, the desired ^{99m}Tc-complex was recovered by repeated elution with ethanol (0.4 mL followed by 3 × 1.0 mL). The first fraction was not utilized for biological studies. The remaining fractions were combined, and the total radiochemical purity (RCP) (measured by HPLC) was approximately 100% (**a**, 48%; **b**, 52%).

[^{99m}Tc(N)(PNP)(L′)]$^+$ *Complexes.* The reaction mixture was diluted with 8.0 mL of water and loaded onto a C18 SepPak cartridge (Waters) previously activated with ethanol (95%, 5.0 mL) and water (5.0 mL). The cartridge was rinsed with water (20 mL) and an ethanolic solution containing [N(*n*-Bu)$_4$]Br (10% w/w, 1.0 mL). The final ^{99m}Tc-complex was eluted by repeated elution with the same [N(*n*-Bu)$_4$]Br solution (1 × 0.4 mL followed by 3 × 1.0 mL). The first fraction was not utilized for biological studies. The remaining fractions were combined, and RCP (measured by HPLC) was approximately 100%.

Serum Stability. The selected ^{99m}Tc-complex (100 μL), purified as described above, were added to a propylene test tube (5.0 mL) containing rat serum (900 μL) or, alternatively, saline (900 μL). The resulting mixture was incubated at 37 °C for 2 h. RCP changes in time were monitored by TLC at 15, 30, 60, and 120 min. No significant changes of RCP were observed in saline. Conversely, a slow decrease of RCP occurred in rat serum (RCP, 82% at 15 min and 45% at 120 min after incubation).

In Vitro Reaction with Glutathione (GSH) and Cysteine. An aliquot of a stock aqueous solution of GSH (50.0 μL, 10.0 mM) was added to a propylene test tube (5.0 mL) containing a phosphate buffer (250.0 μL, 0.2 M, pH = 7.4), water (100.0 μL), and the appropriate ^{99m}Tc-complex (100.0 μL) purified as described above. The mixture was incubated at 37 °C for 2 h. For the blank, an equal volume of water was added in place of GSH solution. Aliquots of the resulting mixtures were withdrawn at 15, 30, 60, and 120 min after incubation, and analyzed by TLC chromatography. The complexes were found to be inert toward substitution by GSH.

An identical procedure was employed with aqueous solutions of cysteine hydrochloride (10.0 mM and 1.0 mM). ^{99m}Tc-complexes were found to be stable toward transchelation by cysteine.

Biological Evaluation. Animal experiments were performed according to the animal welfare regulations of the Italian and German local authorities.

Biodistribution Studies. Female Sprague–Dawley rats, weighing 200−250 g, were housed for 1 week under a 12 h light/12 h dark cycle with free access to food and water for subsequent biodistribution studies. Animals were fasted before experiments for 12 h and then anesthetized with an intramuscular injection of a mixture of ketamine (80 mg kg^{-1}) and xilazine (19 mg kg^{-1}). After purification, the selected ^{99m}Tc-complex was diluted with a physiological solution containing 5% human serum albumin (HSA). The final solution was less than 5% ethanol

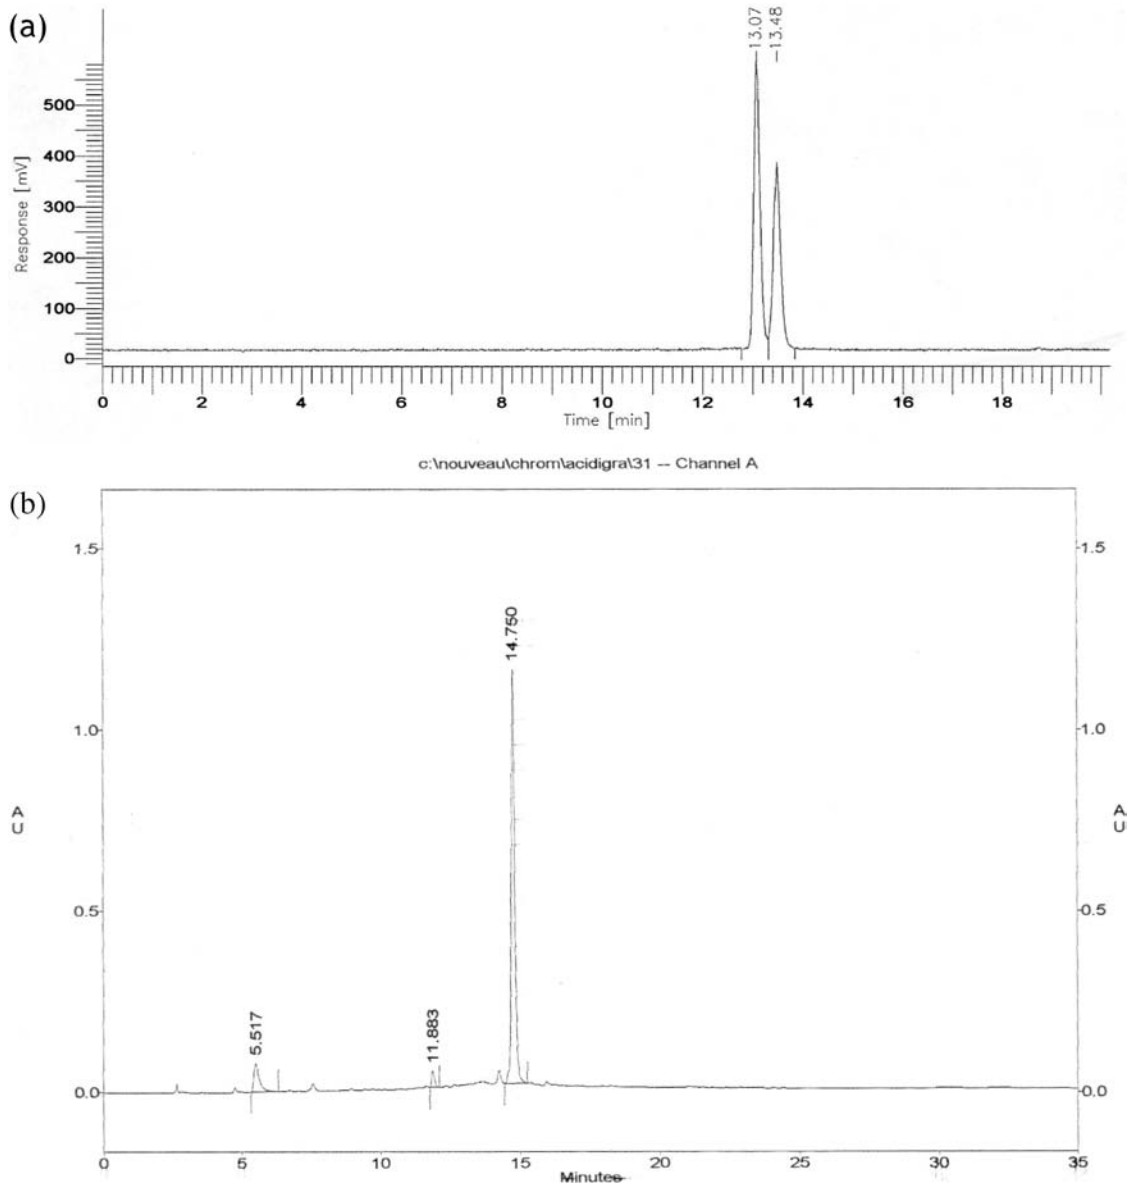

Figure 6. Representative HPLC chromatograms of complexes (a) [^{99m}Tc(N)(PNP3)(**9**)] and (b) [^{99m}Tc(N)(PNP5)(**10**)]$^{+}$.

content. Radioactivity (100 μL, 300−370 kBq) was administered through the jugular vein. The animals ($n = 3$) were sacrificed by dislocation at 5, 30, and 60 min time intervals postinjection. The blood was withdrawn from the heart through a syringe immediately after sacrifice and counted for the radioactivity. Organs were excised, rinsed with saline, weighed, and radioactivity determined with a NaI well counter. The percent injected dose per gram (%ID g^{-1}) for each organ and blood was calculated and results are reported in Tables 2 and 3.

Isolated Perfused Rat Heart Experiments. Female Wistar rats (250−350 g) were obtained from Charles River Laboratories, Sulzfeld, Germany.

Anesthesia was performed in two steps as follows. After resting for a short time in a chamber flushed with diethyl ether, deep anesthesia was achieved by intraperitoneal (i.p.) injection of 2–3 mL of urethane (15%). In addition, 1000 U/kg i.p. heparin was injected before opening the peritoneal cavity. Hearts were rapidly removed during continuous cooling and mounted vertically via the aorta on a perfusion cannula (this operation required less than 1 min after removal). Perfusion was immediately started according to the Langendorff technique with a modified KHB containing NaCl (116.0 mmol L^{-1}), KCl (4.6 mmol L^{-1}), $MgSO_4$ (1.2 mmol L^{-1}), KH_2PO_4 (1.2 mmol L^{-1}), $NaHCO_3$ (25.0 mmol L^{-1}), $CaCl_2$ (2.5 mmol L^{-1}), glucose (11.0 mmol L^{-1}), and pyruvate (2.0 mmol L^{-1}). The buffer was continuously bubbled with a mixture of 95% O_2/5% CO_2 (pH, 7.38−7.43), equilibrated with fatty-acid-free bovine serum albumin (BSA 0.1%, 14.9 μmol L^{-1}), and maintained at 37 °C in a water bath. Total coronary flow was measured using an ultrasonic transit-time flow-meter (T206 Transonic Systems Inc., Ithaca, NY) inserted in the arterial perfusion line and kept constant at 10 mL/min. Coronary perfusion pressure (CPP) was measured through a pressure transducer (Gould Statham, USA) connected to the perfusion cannula. Heart rate was calculated manually from a CPP printout. "Arterial" and "venous" perfusate samples collected anaerobically were analyzed for pO_2, pCO_2, pH, and HCO_3^- (AVL 990S, AVL Scientific Corporation, Roswell, GA) before each intervention.

The experimental procedure was performed as already described (*7*, *19*). In brief, Tc-99m labeled fatty acids were diluted in a ratio of 1:2 with KHB enriched with 6% BSA and left to equilibrate at room temperature for 30 min. After a period of 30 min to achieve hemodynamic stabilization of the beating heart, the selected ^{99m}Tc-labeled fatty acid complex was infused proximal to the perfusion cannula in a 1:1000 ratio. Starting with the infusion, the venous effluent perfusate was completely

recovered in successive 15 s collecting periods. Infusion was stopped after 180 s, while continuing the collection of venous effluate for further 60 s to rinse out the residual radiolabeled substance from the coronary vessels, which were not taken up into the extravasal space. Then, perfusion was stopped and hearts instantaneously removed and separated into ventricles and atria. For input calculation (A_{in}) five 15-s perfusate samples were collected under identical radioactivity infusion and flow settings directly from the perfusion cannula in the absence of a heart. All perfusate and heart samples were measured with a gamma counter (Wallac 1470 Wizard, Perkin-Elmer, Freiburg, Germany). Only experiments in which the calculated amounts of counts per minute were in the expected experimental range (±20%) were included in the final analysis. Measurements were corrected for radionuclide decay.

Metabolic Analysis. After intravenous administration of ^{99m}Tc fatty acid complexes (50 MBq) into normal rats, the animals were sacrificed at 60 min postinjection, and intestine homogenates were obtained. Analysis was performed by HPLC as detailed before.

RESULTS AND DISCUSSION

Neutral and monocationic nitride Tc(V) complexes of the type ^{99m}Tc(N)(PNP)(L)]$^{0/+}$ (PNP = PNP3, PNP5; L = **5**, **9**, **10**, **11**) were successfully obtained by reacting the strong electrophilic precursor [^{99m}Tc(N)(PNP)]$^{2+}$ with bidentate chelating ligands bearing lateral fatty acid chains of different lengths (Figure 1a). These bifunctional ligands were prepared by appending a dimercapto or, alternatively, a dithiocarbamato chelating group to one terminus of a fatty acid chain containing eleven or twelve carbon atoms following the reaction schemes illustrated in Figures 2–4. Dimercapto derivatives (**5**, **9**) coordinated to the [^{99m}Tc(N)(PNP)]$^{2+}$ metal fragment as dianionic bidentate ligands, thus affording neutral complexes. Instead, dithiocarbamato derivatives (**10**, **11**) bound to the same fragment as monoanionic bidentate ligand, and consequently, the resulting complexes were monocationic. Structural characterization of Tc-99m complexes was carried out by comparison with the corresponding rhenium complexes. These compounds were synthesized starting from the mixed halogeno−phosphino complex [Re(N)(PNP)Cl$_2$]. The reaction scheme utilized for the synthesis of rhenium complexes is illustrated in Figure 5. In particular, rhenium complexes with the diphosphane ligand PNP7 were used as model compounds because of their ability to precipitate in a microcrystalline form that allowed an easier characterization by spectroscopic methods. Conversely, the diphosphane ligands PNP3 and PNP5 usually gave rise to oily compounds, which were difficult to isolate and characterize after chromatographic purification. Analytical and spectroscopic data, conjoined with results obtained previously with other similar dimercapto and dithiocarbamato complexes (*12, 20*), clearly showed that these complexes possess the usual asymmetrical structure with two different bidentate ligands coordinated to the same M≡N (M = Tc, Re) group as illustrated in Figure 5. Specifically, one diphosphane ligand PNP binds to the M≡N core through the two π-donor phosphorus atoms, while one dimercapto (or dithiocarbamato) ligand is linked to the same core through the two π-donor sulfur atoms. At both macroscopic and tracer levels, dimercapto complexes were isolated as a *syn*/*anti* isomeric pair. This isomerism arises from the relative orientation of the pendant fatty acid chain with respect to the M≡N group, and is related to the sp^3 tetrahedral hybridization of the carbon atom of the ethyl bridge connecting the two sulfur atoms and also linked to the fatty acid chain (Figure 5). When the fatty acid chain is tethered to the planar sp^2 carbon atom through the amino nitrogen atom of the dithiocarbamato moiety,

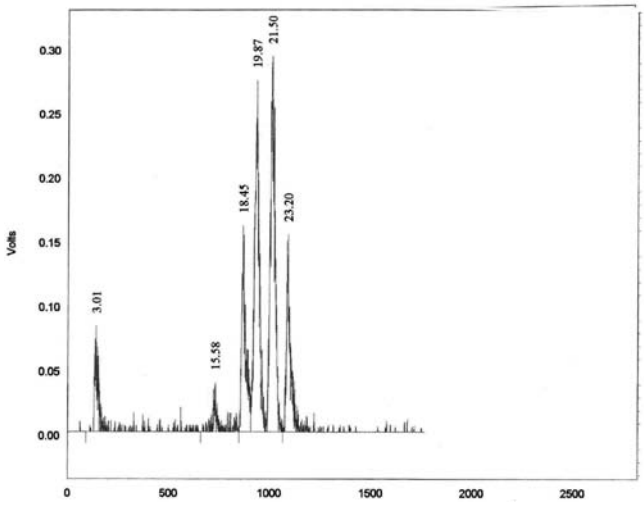

Figure 7. Representative HPLC analysis of intestine homogenates 60 min after intravenous administration of [^{99m}Tc(N)(PNP3)(**9**)] in normal rats.

this isomerism cannot be generated, and only a single species was isolated (Figure 5). Representative chromatographic profiles of these two types of fatty acid asymmetrical nitride Tc-99m complexes are reported in Figure 6.

Stability studies demonstrated that the Tc-99m complexes reported here are highly stable in solution and in human plasma, and resistant to transchelation by cysteine and glutathione.

Since liver washout was considered as a key issue for developing a suitable metabolic myocardial imaging agent, derivatives containing the ligand PNP7, bearing two phenyl groups on each of the two phosphorus atoms, were not further evaluated because of the poor liver washout showed by this category of complexes. Biological evaluation in animals was conducted only for Tc-99m complexes containing the diphosphane ligands PNP3 and PNP5. After purification, the resulting Tc-99m complexes were dissolved in saline containing 5% HSA. Biodistribution data (Tables 2 and 3) confirmed the fast and quantitative liver washout usually exhibited by this type of complexes. Elimination of liver activity into the intestine was relevant for all complexes as well as the rapid washout from lungs and blood. However, some significant heart uptake was found only for monocationic complexes with dithiocarbamato ligands, with neutral complexes being only slightly retained by the myocardium at 5 min post injection, and then completely washed out from this tissue after 30 min from injection. On the contrary, a slow elimination of myocardial activity was observed for monocationic complexes, and approximately 50% of the activity found in the myocardium at 5 min postinjection was still retained after 60 min from administration (Table 3).

In view of the facts that most of the radioactivity was excreted via the hepatobiliary pathway and concentration of radioactivity in urine was too low for a reliable metabolic analysis, we focused on metabolites in intestine homogenates. Metabolic stability of both neutral and monocationic Tc-99m fatty acid complexes described here was studied by HPLC analysis of intestine homogenates collected at 60 min postinjection. Results showed that these complexes undergo a significant metabolic transformation in the liver as illustrated in the representative example reported in Figure 7.

The monocationic complexes [^{99m}Tc(N)(PNP)(L)]$^+$ (PNP = PNP3; L = **10**, **11**) and the neutral complex [^{99m}Tc(N)(PNP5)(**9**)] were evaluated on the isolated heart model. As a reference, the ventricular extractions of the well-established iodinated metabolic cardiac tracer [^{123}I]IPPA, and of the monocationic myocardial flow tracers ^{99m}Tc-MIBI and the recently reported

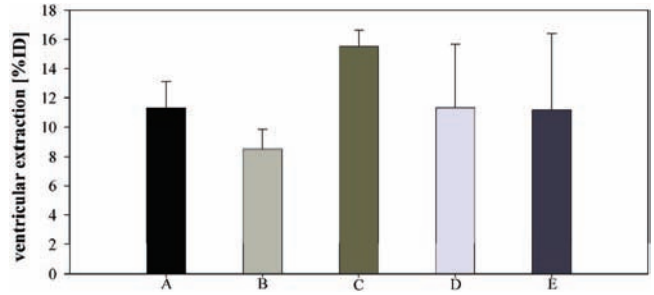

Figure 8. Ventricular extractions of the dodecanoic fatty acid complexes [^{99m}Tc(N)(PNP3)(**11**)]$^+$ (A) and [^{99m}Tc(N)(PNP5)(**9**)] (B), and of the metabolic tracer [^{123}I]IPPA (C) and flow tracers ^{99m}Tc-MIBI (D) and ^{99m}TcN-DBODC (E) as determined in the same isolated perfused rat heart model.

agent ^{99m}TcN-DBODC (*15*, *16*), were determined. As shown in Figure 8, the monocationic dodecanoic fatty acid derivative [^{99m}Tc(N)(PNP3)(**11**)]$^+$ achieved the highest ventricular extraction (11.33 ± 1.79% ID) among the newly synthesized compounds. For the undecanoic fatty acid complex [^{99m}Tc(N)(PNP3)(**10**)]$^+$ only a slightly lower extraction (10.24% ID) was obtained. As compared to the corresponding PNP3 analogue, the neutral PNP5 derivative [^{99m}Tc(N)(PNP5)(**9**)] clearly showed a lower ventricular extraction (8.52 ± 1.3% ID). The highest ventricular extraction was measured for the tracer [^{123}I]IPPA (15.51 ± 1.10% ID) (*7*). The myocardial extractions of the new agent ^{99m}TcN-DBODC and of ^{99m}Tc-MIBI were 11.20 ± 5.19% ID and 11.34 ± 4.33% ID, respectively and, thus, fall in the same range of the monocationic Tc-99m fatty acid complexes reported here.

The so-called "metal fragment approach" may be worth consideration as an extension of the original concept of the "bifunctional approach", which is commonly used for designing new radiolabeled diagnostic probes, when applied to the labeling of bioactive molecules with metallic radioisotopes. The introduction of this more sophisticated chemical method was mostly prompted by the need to obtain high specific activity labeling in preparations of radiotracers for monitoring in vivo receptor density. The key feature of the metal fragment approach lies in the use of metallic functional groups possessing an intrinsically high electronic stability but that display a selective reactivity toward specific classes of coordinating atoms and ligands through substitution reactions. The metallic group [^{99m}Tc(N)(PNP)]$^{2+}$, composed of a Tc≡N core bound to a bidentate diphosphane ligand, nicely represents this category of molecular moieties that can be conveniently employed for the high specific activity labeling of bioactive molecules. It is highly stable toward redox reactions but interacts selectively only with ligands containing soft π-donor atoms as a result of its strong electrophilic character. This means that a biomolecule having a suitable set of π-donor atoms is capable of coordinating readily to this fragment.

In the present study, the above strategy was applied to the design and synthesis of a new class of Tc-99m radiopharmaceuticals for monitoring fatty acid metabolism in myocardial tissue. Since similar studies on Tc-99m-labeled fatty-acid complexes with different chelating systems showed that derivatives incorporating a C12 carbon chain exhibited the highest myocardial uptake (*7*, *9*, *20*), C11 and C12 chain lengths were selected here as the most appropriate. A possible explanation for this observation could be found by considering the greater sterical size of the chelating system containing the metal atom as compared to iodophenyl substituents. In fact, it was calculated that ^{99m}Tc compounds substituted with C11 or C12 fatty acids ligands have approximately the same size of ω-(*p*-[^{123}I]iodophenyl fatty acids. Furthermore, it should be noted that prolongation

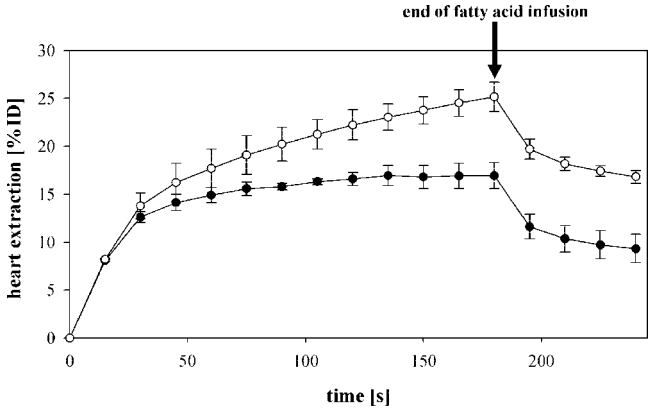

Figure 9. Extraction kinetic curves of the dodecanoic fatty acid neutral complex [^{99m}Tc(N)(PNP5)(**9**)] (•) and [^{123}I]IPPA (○).

of the carbon chain length usually does not prevent the competitive fast and high liver uptake of labeled fatty acids.

The choice of the specific diphosphane ligand was dictated by the requirement to achieve a rapid and quantitative liver washout necessary to improve target-to-background ratio. All biological data available so far on Tc-99m complexes with PNP3 and PNP5 (*10*, *11*, *14*, *16*, *20*, *22*) clearly indicate that these ligands usually impart to the resulting complexes the property of being rapidly washed out from the liver.

Biodistribution studies on [^{99m}Tc(N)(PNP)(L)]$^{0/+}$ (PNP = PNP3, PNP5) complexes reported here sharply confirmed this prediction. Both neutral and monocationic species exhibit a fast liver elimination associated with a rapid washout from blood and lungs. Unfortunately, these favorable properties were counteracted by the relatively low heart uptake of these complexes, which did not exceed 1.07% of injected activity. In particular, only monocationic derivatives showed some significant myocardial accumulation and retention. Conversely, neutral complexes were rapidly washed out from the heart after a first slight accumulation at 5 min postinjection. Generally, dodecanoic fatty acid derivatives showed higher cardiac uptake than undecanoic analogues.

The above findings contrasted with results obtained in isolated perfused rat heart experiments. This model provides a suitable method for evaluating the uptake and extraction of radiolabeled compounds without the presence of disturbing effects always occurring in whole animal studies, e.g., effects of stress having an influence on the endocrinological system that regulates metabolic processes. Based on bidistribution results, the two monocationic complexes [^{99m}Tc(N)(PNP3)(**10**)]$^+$ and [^{99m}Tc(N)(PNP3)(**11**)]$^+$, which showed the highest heart accumulation, and the neutral complex [^{99m}Tc(N)(PNP5)(**9**)] were evaluated in the isolated rat heart model. Even though the well-established iodinated fatty acid tracer [^{123}I]IPPA achieved the highest outcome, some of the new Tc-99m fatty acid complexes showed remarkable values of myocardial extraction. In particular, there was almost no difference in the incorporated activity between the monocationic fatty acid complexes [^{99m}Tc(N)(PNP3)(**11**)]$^+$ and [^{99m}Tc(N)(PNP3)(**10**)]$^+$ and the recently discovered flow tracer ^{99m}TcN-DBODC. The similarity between the extraction values of ^{99m}Tc-MIBI and ^{99m}TcN-DBODC had been demonstrated previously in animal studies (*15*, *16*).

The present study on the isolated heart also offered a simple possibility to investigate myocardial first pass extraction kinetics. This is demonstrated in Figure 9, which reports a more detailed analysis of the uptake and extraction kinetics of the neutral derivative [^{99m}Tc(N)(PNP5)(**9**)] as compared to [^{123}I]IPPA. In the rapid, almost linear initial uptake occurring during the first 30 s of tracer infusion, both radiolabeled compounds showed a similar amount of uptake (12.60 ± 0.56% ID for [^{99m}Tc(N)(PNP5)(**9**)] vs 13.78 ± 1.32% ID for [^{123}I]IPPA). In the subsequent period of tracer infusion, corresponding to the net accumulation by the myocardium including influx, efflux, and intracellular metabolism (*23*), the extraction kinetic curve of [^{99m}Tc(N)(PNP5)(**9**)] continued to increase but with a perceptible lower slope as compared to [^{123}I]IPPA. This fact points to an accelerated efflux of the evaluated Tc-99m fatty acid analogue, which could be, presumably, attributed to a disturbed recognition by intracellular enzymes of fatty acid transport and metabolism. The observed increased efflux was also evidenced by a faster washout of the radiolabeled ^{99m}Tc compound out of the myocardium at the end of infusion. Whereas during the first 60-s period of labeled fatty acid perfusion only 8.35% ID of [^{123}I]IPPA left the infused heart, this value increased up to 7.62% ID for [^{99m}Tc(N)(PNP5)(**9**)]. Thus, at the end of the infusion process, only 33.17% of [^{123}I]IPPA activity washed out from perfused heart, while this washout was 44.97% for [^{99m}Tc(N)(PNP5)(**9**)].

The apparently altered metabolic behavior of ^{99m}Tc-labeled fatty acid was also confirmed by metabolic studies performed on intestine samples. These data revealed that these complexes are quantitatively metabolized in the liver. Interestingly, this process did not transform each Tc-99m complex to a single metabolite, but rather to a mixture of undetermined species, a result that is difficult to be attributed to a specific metabolic pathway.

The comparative analysis of the kinetic behavior of [^{99m}Tc(N)(PNP5)(**9**)] and [^{123}I]IPPA may allow a tentative interpretation of biodistribution data in rats. As mentioned above, the fast washout of [^{99m}Tc(N)(PNP5)(**9**)] suggests that the resulting radiolabeled fatty acid has partially lost its original biological properties, thus becoming a poor substrate for cardiac enzymatic activity. This may readily explain the in vivo behavior of neutral complexes characterized by some initial uptake followed by a rapid washout. Evidently, this behavior is mostly driven only by passive diffusion as a consequence of the lack of an efficient metabolic trapping. Conversely, the situation appears substantially different for monocationic complexes in which the presence of a positive charge permits their blockage on the mitochondrial membrane of myocites through the action of a well-established mechanism (*24*, *25*). However, further studies are required to assess whether this retention could favor an easier recognition of the labeled fatty acid by cardiac enzymes and promote some metabolic activity.

CONCLUSIONS

The design and preparation of a new class of asymmetrical nitride Tc-99m complexes incorporating a lateral fatty acid chain have been successfully carried out. The selective affinity of the strong electrophilic metal fragment [^{99m}Tc(N)(PNP)]$^{2+}$ allowed us to obtain the final radiopharmaceuticals in high specific activity and almost quantitative yields (>95%), thus giving further support to previous studies showing the strong efficiency of this fragment as a labeling moiety for small biomolecules.

However, biological evaluation of the resulting complexes in an isolated perfused heart model showed that the tethering of the metal fragment to the fatty acid chain caused some significant perturbation of its original biological properties. In particular, the comparison between the behavior of the metabolic tracer [^{123}I]IPPA and the neutral complex [^{99m}Tc(N)(PNP5)(**9**)], in which the potential effect of the presence of a monopositive charge on the heart uptake mechanism was ruled out, clearly demonstrated that recognition of the labeled fatty acid as a substrate for β-oxidation was partially hampered, presumably as a result of some steric hindrance brought about by the metallic moiety onto the bioactive molecule. Additional studies are

required to assess whether the metabolic activity could be restored by increasing the separation between the metal fragment and the fatty acid chain through the insertion of some suitable linker.

PEGylated Dendrimers with Core Functionality for Biological Applications

Steven J. Guillaudeu,[†] Megan E. Fox,[†] Yarah M. Haidar,[†] Edward E. Dy,[‡] Francis C. Szoka,[‡] and Jean M. J. Fréchet*,[†]

College of Chemistry, University of California, Berkeley, California 94720-1460, and Department of Biopharmaceutical Sciences and Pharmaceutical Chemistry, University of California, San Francisco, California 94143-0446. Received July 14, 2007; Revised Manuscript Received November 29, 2007

The synthesis of a variety of core functionalized PEGylated polyester dendrimers and their in vitro and in vivo properties are described in this report. These water-soluble dendrimers have been designed to carry eight functional groups on their dendritic core for a variety of biological applications such as drug delivery and in vivo imaging as well as eight solubilizing groups. Using a common symmetrical aliphatic ester dendritic core and trifunctional amino acid moieties, a library of dendrimers with phenols, alkyl alcohols, alkynes, ketones, and carboxylic acid functionalities has been synthesized without the need for column chromatography. The amines were PEGylated, leaving the other functionality of the amino acid available for further manipulation such as the attachment of drugs and/or labels. Radiolabeling experiments with the PEGylated dendrimers showed that they had a long circulation half-life in mice, confirming the potential of this class of dendrimers for therapeutic and/or diagnostic applications. A carboxylic acid functionalized dendrimer was elaborated to carry doxorubicin bound via a hydrazone bond. The drug-loaded carrier accumulated more in tumors and less in healthy organs than the clinically used PEGylated liposomal formulation Doxil. The efficient synthesis, high versatility, and favorable biological properties make these PEGylated polyester dendrimers promising structures for therapeutic and/or imaging applications.

INTRODUCTION

Dendritic polymers are currently being evaluated for many in vivo biological applications including drug delivery, tissue growth scaffolding, imaging (magnetic resonance, near-infrared, positron emission), and boron−neutron capture therapy (*1–4*). PEGylated dendrimers, in which a multifunctional dendritic core is conjugated to polyethylene glycol (PEG, or polyethylene oxide) chains, are an interesting subclass of dendritic polymers for these applications (*5*). Various PEG−dendrimer hybrids have shown lower toxicity and hemolytic properties, long blood circulation times, low organ accumulation, and high accumulation in tumor tissue due to the enhanced permeation and retention (EPR) effect (*6–14*).

PEG−dendrimer hybrids can be constructed by two basic architectures: PEG (linear or branched) can be attached to the apex (*10*) (Figure 1a) or the peripheral groups (*15*) (Figure 1b and c) of dendrimers. In the former, the dendrimer periphery (if compatible with the solvent) is more exposed to the surrounding environment, while in the latter, a PEG shell is the most solvent accessible. From the reported works cited above, it appears that both show great promise for biotechnological applications, but the latter has shown the best performance with respect to long blood circulation half-lives and low organ accumulation (*7–9, 12, 16*). In our previous work exploring PEG−dendrimer hybrids (*10, 12, 15–21*), we have found that a nontoxic, biodegradable, asymmetric polyester dendrimer with eight PEG chains of 5000 Da molecular weight and multiple sites for drug attachment, a bow-tie dendrimer, is efficient at delivering the chemotherapeutic agent doxorubicin (Dox) to C26 tumors in mice; this led to complete tumor regression in all of the treated mice with only a single dose (*16*). The effective tumor therapy with the bow-tie is believed to stem from the highly branched dendritic architecture that lowers the rate of filtration through renal membranes and the PEG−shell/drug−core structure that shields the therapeutic from recognition by the reticuloendothelial system (*12, 16*). Such a system, with a PEG shell and functional core, may prove useful in many of the above applications where a long circulation time, accumulation at leaky blood vessel sites such as in tumors, inflammation sites, or arterial injuries, and biocompatibility and biodegradability are desired. Dendrimers with a PEGylated periphery that have accessible functionality on the dendrimer have been produced by substoichiometrically PEGylating amine-terminated dendrimers such as PAMAM or polylysine (*7–9, 22–28*), by using elegant control of the reactivity on melamine dendrimers (*6*), through ether formation on bifunctional polyether dendrimers (*18, 19*), and by PEGylating an asymmetrically protected ester dendrimer (*15*).

We now describe the high-yielding column-free synthesis of a family of PEGylated ester dendrimers bearing some analogy in terms of functionality and architecture to the bow-tie dendrimer. However, these new dendrimers are symmetric about the core, with different multifunctional handles easily incorporated at their periphery, thereby increasing their ease of preparation and versatility for potential biomedical applications. One generation of bis-2,2-hydroxymethylpropanoic acid (bisH-MPA) building block was attached to a pentaerythritol core, followed by eight copies of a trifunctional amino acid molecule via EDCI-mediated coupling of their carboxylic acid functionality. Following deprotection, the terminal amines were PEGylated using a carbamate linkage, leaving the third functionality of the amino acid available for further elaboration. Because the amino acid-terminated dendrimers do not require column chromatography for purification, these compounds are more readily accessed than the functionally analogous bow-tie dendrimers we have successfully used in cancer chemotherapy. In this article, we demonstrate the versatility of this approach by presenting structures with ketones, alkynes, carboxylic acids, alkyl alcohols, and phenols present at the core of the macro-

molecule. Because of our interest in the potential of these compounds for drug delivery to tumors, the stability of these PEGylated dendrimers in buffer and plasma was studied, and biodistributions of the radiolabeled phenolic dendrimer in nontumored mice and of the carboxylate dendrimer conjugated to Dox in tumored mice were determined.

MATERIAL AND METHODS

Materials. Materials were used as obtained from commercial sources unless otherwise noted. Dimethylformamide (DMF), pyridine, and CH_2Cl_2 for syntheses were purged for 1 h with nitrogen and further dried by passing them through commercially available push stills (Glass Contour). Benzene was distilled from CaH_2. Monomethoxy polyethyleneglycol *p*-nitrophenyl carbonate (PEO-PNP) (*29*) and **1** (*30*) were synthesized according to published procedures. Solvents were removed under reduced pressure using a rotary evaporator or by vacuum pump evacuation.

Characterization. NMR spectra were recorded on Bruker AV 300, AVB 400, AVQ 400, or DRX 500 MHz instruments. Fourier transform infrared (FTIR) spectroscopic analyses were performed using a thin film cast from an appropriate solvent on a NaCl plate. Elemental analyses were performed at the UC Berkeley Mass Spectrometry Facility. MALDI-TOF MS was performed on a PerSeptive Biosystems Voyager-DE, generally using the following matrices: *trans*-3-indoleacrylic acid (IAA) for *tert*-butyloxycarbonyl (Boc)-protected dendrimers or 2,5-dihyroxybenzoic acid (DHB) for amine-terminated dendrimers. Samples were prepared by diluting dendrimer solutions (~1 M) 40-fold in 100 mM matrix solutions in tetrahydrofuran and spotting 0.5 μL on the sample plate. Size exclusion chromatography (SEC) system A consisted of a Waters 515 pump, a Waters 717 autosampler, a Waters 996 Photodiode Array detector (210–600 nm), and a Waters 2414 differential refractive index (RI) detector. SEC was performed at 1.0 mL/min in a PLgel Mixed B (10 μm) and a PLgel Mixed C (5 μm) column (Polymer Laboratories, both 300 × 7.5 mm), in that order, using DMF with 0.2% LiBr as the mobile phase and linear PEO (4,200–478,000 MW) as the calibration standards. The columns were kept at 70 °C. SEC system B consisted of the same equipment as that in system A and was performed at 1.0 mL/min in two SDV Linear S (5 μm) columns (Polymer Standards Service, 300 × 8 mm) using DMF with 0.2% LiBr as the mobile phase. The columns were kept at 70 °C. SEC system C consisted of a Waters Alliance separation module 2695 and a Waters 410 differential RI detector. SEC was performed in a G2500 PWXL (6 μm) and a G3000 PWXL (6 μm) column (TosoHaas, both 300 × 7.8 mm), in that order, at ambient temperature using phosphate buffered saline (pH 7.4) as the mobile phase. Radioactivity from ^{125}I was quantified with 1480 Wallac Wizard 3 Automatic Gamma Counter. Counts emitted from samples contained in screw-cap scintillation vials were measured over the course of 1 min and were recorded as counts per minute (cpm).

Animal Experiments. All animal experiments were performed in compliance with the National Institutes of Health guidelines for animal research under a protocol approved by the Committee on Animal Research at University of California (San Francisco, CA) (UCSF). C-26 colon carcinoma cells obtained from the UCSF cell culture facility were cultured in RPMI medium 1640 containing 10% FBS.

Nomenclature. A pentaerythritol core (PE) with one generation of *bis*-2,2-hydroxymethylpropanoic acid (G1) and serine protected as a benzyl ether for the side chain and with a Boc on the amine (Ser(Bn)Boc) is abbreviated PE-G1-(Ser(Bn)Boc)$_8$ because there are eight serines. Standard nomenclature is used for other amino acids Xaa and their protecting groups (PG). The PEGylated versions are abbreviated as PE-G1-(Xaa(PG)-PEO)$_8$. In the title of this article, we term the final polymers core functionalized because the reactive functionalities used to attach the drugs and or imaging labels are located near the core of the macromolecules, which is surrounded and engulfed by long PEG linear chains.

General Procedure for the Acylation of 1 with Amino Acids. Synthesis of PE-G1-(Ser(Bn)Boc)$_8$ (3b). Compound **1** (201 mg, 0.334 mmol), L-Boc-Ser(Bn)-OH (946 mg, 3.20 mmol), and 4-dimethylaminopyridine (DMAP) (195 mg, 1.60 mmol) were dissolved in DMF (2.7 mL), and then 1-ethyl-3-[3-dimethylaminopropyl]carbodiimide hydrochloride (EDCI) (613.3 mg, 3.20 mmol) was added. After 4 h, the reaction was complete as determined by MALDI. The solution was diluted with diethyl ether (75 mL) and washed with 1 M $NaHSO_4$ (3 × 50 mL), 1 M NaOH (3 × 50 mL), and water (2 × 50 mL). The organic layer was dried with $MgSO_4$, and filtered, and the solvent was removed to yield a white solid (903 mg, quant). ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.16 (s, 12), 1.41 (s, 72), 3.64 (m, 8), 3.81 (m, 8), 4.01 (d, 4, J = 11.1), 4.10 (d, 4, J = 11.1), 4.19 (dd, 8, J = 10.6, 11.2), 4.44 (m, 32), 5.47 (s, 8), 7.28 (m, 40). ^{13}C NMR (100 MHz, $CDCl_3$): δ 17.52, 28.36, 46.78, 53.97, 61.73, 65.30, 65.46, 69.91, 73.25, 79.87, 127.72, 127.80, 128.44, 137.59, 155.39, 170.14, 171.59. MALDI-TOF MS. $[M + Na]^+$ ($C_{145}H_{196}N_8O_{48}Na$) Calcd: m/z = 2840.3. Found: m/z = 2839.9. Anal. ($C_{145}H_{196}N_8O_{48}$) C, H, N.

PE-G1-(Tyr(Bn)Boc)$_8$ (3a). Yield 92%. ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.12 (s, 12), 1.35 (s, 72), 2.87 (m, 8), 3.04 (m, 8), 4.18–4.37 (m, 24), 4.51 (m, 8), 4.93 (s, 16), 5.16 (s, 8), 6.84 (d, 16, J = 7.0), 7.04 (d, 16, J = 7.0), 7.28–7.38 (m, 40). ^{13}C NMR (100 MHz, $CDCl_3$): δ 17.70, 28.36, 37.15, 46.68, 54.59, 65.61, 69.97, 70.65, 79.79, 115.00, 127.51, 127.92, 128.41, 128.56, 130.36, 137.12, 155.20, 157.93, 171.76. MALDI-TOF MS. $[M + Na]^+$ ($C_{193}H_{228}N_8O_{48}Na$) Calcd: m/z = 3449.6. Found: m/z = 3446.3. Anal. ($C_{193}H_{228}N_8O_{48}$) C, H, N.

PE-G1-(Asp(Bn)Boc)$_8$ (3c). The synthesis was performed as described in the general procedure. Following the extractions, a small amount of benzyl alcohol was present; it was removed by two precipitations of the dendrimer from ether into excess hexanes. Because the product stuck to the glass surfaces as a white gummy material, the hexanes were decanted, and the residual solvent was removed under vacuum to yield a white solid (95%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.19 (s, 12), 1.40 (s, 72), 2.88 (m, 16), 4.13–4.38 (m, 24), 4.61 (br s, 8), 5.09 (m, 16), 5.61 (s, 8), 7.31 (br s, 40). ^{13}C NMR (100 MHz, $CDCl_3$): δ 17.74, 28.32, 36.62, 43.01, 46.48, 50.02, 62.25, 65.71, 66.85, 79.98, 128.32, 128.57, 135.54, 155.31, 170.55, 170.78, 171.74. MALDI-TOF MS. $[M + Na]^+$ ($C_{153}H_{196}N_8O_{56}Na$) Calcd: m/z = 3064.3. Found: m/z = 3065.1. Anal. ($C_{153}H_{196}N_8O_{56}$) C, H, N.

PE-G1-(PropargylGlyBoc)$_8$ (3d). ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.31 (s, 12), 1.45 (s, 72), 2.14 (d, 8, J = 2.5), 2.72 (s, 16), 4.13–4.48 (m, 28), 5.45 (d, 8, J = 7.9). ^{13}C NMR (100 MHz, $CDCl_3$): δ 17.19, 22.58, 28.30, 46.62, 52.02, 62.10, 65.74, 72.15, 78.70, 80.20, 155.01, 170.25, 171.62. MALDI-TOF MS. $[M + Na]^+$ ($C_{105}H_{148}N_8O_{40}Na$) Calcd: m/z = 2185.4. Found: m/z = 2183.6. Anal. ($C_{105}H_{148}N_8O_{40}$) C, H, N.

PE-G1-((4-AcetylPhe)Boc)$_8$ (3e). ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.19 (s, 12), 1.35 (s, 72), 2.55 (d, 24, J = 1.8), 3.01 (br s, 8), 3.19 (m, 8), 4.16–4.35 (m, 24), 4.59 (br s, 8), 5.30 (br s, 8), 7.25 (d unresolved from solvent, 16, J = 7.5), 7.86 (d, 16, J = 8.1). ^{13}C NMR (100 MHz, $CDCl_3$): δ 17.69, 28.28, 37.85, 46.55, 54.17, 61.93, 65.66, 77.26, 80.08, 128.65, 129.53, 135.97, 141.91, 155.15171.42, 171.76, 197.78. MALDI-TOF MS. $[M + Na]^+$ ($C_{153}H_{196}N_8O_{48}Na$) Calcd: m/z = 2936.3. Found: m/z = 2934.3. Anal. ($C_{153}H_{196}N_8O_{48}$) C, H, N.

General Deprotection by Anhydrous HCl. PE-G1-(Ser(Bn)NH$_3$Cl)$_8$ (b). Compound **3b** (98.8 mg, 0.35 mmol) was dissolved in ethanol (0.5 mL) and cooled to 0 °C. Acetyl chloride (0.4 mL) was added dropwise over 2 min. After 30 min, the reaction was complete as determined by MALDI (IAA). The solvents and remaining acetyl chloride were removed by rotary evaporation, and the white solid product was dried under high vacuum.

General Deprotection by Trifluoroacetic Acid. PE-G1-(Asp(Bn)NH$_3$TFA)$_8$ (c). Compound **3c** (251.2 mg, 82.6 μmol) was dissolved in a 1:1 mixture of trifluoroacetic acid (TFA) and CH_2Cl_2. After 30 min, deprotection was complete as determined by MALDI (DHB). The solvents were removed under vacuum.

General PEGylation Reaction. PE-G1-(Asp(Bn)PEO)$_8$ (4c). PEO-PNP (3.678 g, 700 μmol), DMAP (38 mg, 310 μmol), *N*,*N*-diisopropylethylamine (520 μL, 3.0 mmol), pyridine (2.5 mL), and benzene (5 mL) were added to deprotected **3b** (described above, 82.6 μmol). After 3 days, piperidine (600 μL, 6.1 mmol) was added to quench excess PEO-PNP, and the reaction was stirred for an additional 16 h. The solution was diluted with benzene (25 mL) and the product was precipitated into ether (600 mL). The white solid was collected by filtration, rinsed with ether, and dialyzed against water in 3500 molecular weight cutoff (MWCO) regenerated cellulose membranes (Spectra-Por) for 18 h. The retained water solution was lyophilized to yield a white powder (3.15 g). ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.13 (br s, 12), 2.9 (m, 16), 3.38 (s, 24), 3.65 (br m, ~4300), 4.2–4.4 (br m, 42), 4.62 (br s, 8), 5.07 (m, 16), 5.9 (br s, ~6), 7.31 (m, unresolved from solvent, ~40).

PE-G1-(Tyr(Bn)PEO)$_8$ (4a). ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.16 (s, 12), 2.88 (br s, 8), 3.03 (br s, 8), 3.38 (s, 24), 3.65 (br m, ~4380), 4.0–4.4 (br m, 42), 4.53 (br s, 8), 4.93 (s, 16), 5.45 (br s, ~6), 6.84 (d, 16, J = 6.5), 7.02 (d, 16, J = 7.6), 7.2–7.4 (m, unresolved from solvent, ~40).

PE-G1-(Ser(Bn)PEO)$_8$ (4b). ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.13 (s, 12), 3.38 (s, 24), 3.65 (br m, ~3900), 4.1–4.5 (br m, 55), 5.74 (br s, ~5), 7.20–7.35 (br m, unresolved from solvent, ~40).

PE-G1-(PropargylGlyPEO)$_8$ (4d). ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.30 (s, 12), 2.15 (s, unresolved from residual water, ~8), 2.74 (s, 16), 3.38 (s, 24), 3.65 (br m, ~4500), 4.1–4.6 (br m, 38), 5.78 (br s, ~4).

PE-G1-((4-AcetylPhe)PEO)$_8$ (4e). ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.14 (s, 12), 2.54 (s, 24), 3.02 (br s, 8), 3.17 (br s, 8), 3.38 (s, 24), 3.65 (br m, ~4100), 4.0–4.3 (br m, 42), 4.6 (br s, 8), 5.66 (br s, ~5), 7.28 (m, unresolved from solvent), 7.86 (br s, 16).

PE-G1-(AspPEO)$_8$ (5). Compound **4c** (96.4 mg) was deprotected in CH_3OH (5 mL) by hydrogenolysis using Pd/C (10 wt%, 10 mg) at 1 atm for 16 h. The solution was filtered through celite, and the solvent was removed under reduced pressure. ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.27 (s, 12), 2.80 (br s, 8), 2.97 (br s, 8), 3.38 (s, 24), 3.64 (br m, ~3600), 4.0–4.4 (br m, 42), 4.62 (br s, 8), 6.22 (br s, ~4).

***N*′-(4-Hydroxymethyl-benzyl)-hydrazinecarboxylic Acid *tert*-Butyl Ester (6).** 4-(Hydroxymethyl) benzoic acid (0.760 g, 5 mmol), HOBt (0.341 g, 2.5 mmol, 0.5 equiv), and *tert*-butyl carbazate (0.925 g, 7 mmol, 1.4 equiv) were suspended in CH_2Cl_2 (25 mL) at 0 °C. EDCI (1.06 g, 5.5 mmol, 1.1 equiv) was added, and the mixture was stirred for 24 h. The mixture became almost homogeneous after a few hours, and the product later precipitated. The white solid was filtered, rinsed with CH_2Cl_2 (3 × 5 mL), and dried (790 mg, 59%). ^{1}H NMR (MeOD-d_3): δ 1.49 (s, 9), 4.66 (s, 2), 7.45 (d, 2, J = 8), 7.83 (d, 2, J = 8). ^{13}C NMR (MeOD-d_3): δ 27.34, 63.19, 80.63, 126.40, 127.37, 131.00, 146.02, 156.63, 168.34. IR (cm^{-1}): 3726.8, 1720.2, 1664.1, 860.3. mp = 159–160 °C (dec.). Calcd: $[M + H]^+$ ($C_{13}H_{19}N_2O_4$) m/z = 267.1345. Found: FABHR MS: $[M + H]^+$ m/z = 267.1350. Anal. ($C_{13}H_{18}N_2O_4$) C, H, N.

PE-G1-(Asp(BnCONNBoc)PEO)$_8$ (7). Coumpound **5** (200 mg, 38 μmol COOH) was dissolved in DMF (0.75 mL). Coumpound **6** (300 mg, 1.13 mmol), *N*,*N*′-dicyclohexylcarbodiimide (245 mg, 1.19 mmol), and DMAP *p*-toluenesulfonate salt (13 mg, 44 μmol) were added. After 24 h, the solution was diluted with water (10 mL), filtered through celite, and dialyzed against water in 3500 MWCO membranes for 18 h. The retained water solution was lyophilized to yield a white powder (172 mg). By ^{1}H NMR, comparing the OMe peak at δ 3.38 to the Boc peak at δ 1.48, it was determined that ca. 50% of the COOH groups reacted with the linker. ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.11 (s, 12), 1.49 (s, 37), 2.34 (unresolved from residual water in solvent), 2.95 (br m, ~12), 3.38 (s, 24), 3.65 (br m, ~3100), 4.0–4.4 (br m, 25), 4.63 (br s, 3), 4.75 (s, 1), 5.11 (br s, ~5), 6.1 (br s, ~2), 7.81 (br m, ~8).

PE-G1-(Asp(BnCONNDox)PEO)$_8$ (8). Coumpound **7** (15.2 mg, 1.5 μmol NNBoc) was dissolved in 1:1 TFA/CH_2Cl_2 for 2 h. The solvent was removed under a stream of N_2. Residual TFA was removed by dissolving the solid in CH_3OH and evaporating it under a stream of N_2. The polymer was then dissolved in CH_3OH (1 mL) and Dox (4.5 mg, 7.8 μmol) was added. The reaction was stirred at 60 °C in the dark for 16 h. The polymer was eluted on an LH-20 column with CH_3OH. The first dark red band (high MW material) was collected, the solvent was removed by evaporation under a stream of N_2, and the product was further purified on a PD-10 column using water as the eluent. The collected dark red fraction was lyophilized to yield a red powder (10 mg). The loading of Dox was determined by the absorbance at 486 nm (ε = 11,500) (*31*) to be 2.9 wt %, or ~50% of the maximum theoretical loading.

PE-G1-TyrPEO$_8$ (9a). Compound **4a** (195 mg) was dissolved in a mixture of TFA (2 mL) and thioanisole (0.25 mL). After 16 h, TFA was removed under reduced pressure, and NEt_3 (0.5 mL) was added. The solution was diluted with CH_3OH (6 mL) and dialyzed 24 h against CH_3OH in a 3500 MWCO regenerated cellulose membrane. After removing the retentate solvent under reduced pressure, the product was purified on a PD-10 column and lyophilized (yield: 135 mg, 69%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.03 (s, 12), 2.95 (br s, 16), 3.38 (s, 24), 3.65 (br m, ~4350), 3.9–4.3 (br m, 34), 4.49 (br s, 8), 5.55 (br s, ~6), 6.76 (br s, 16), 6.94 (br s, 16), 7.52 (br s, ~6).

Polymer Aqueous Buffer Hydrolysis Study. Compound **4b** was dissolved at a concentration of 1 mg/mL in a solution of PBS, pH 7.4, with 30 mM $NaNO_3$. The polymer solutions were incubated at 37 °C, and samples were taken periodically over a period of 20 days. Samples were frozen at −80 °C until they could be prepared for molecular weight determination by SEC. Samples were prepared for SEC (system B) by running solutions through PD-10 desalting columns in distilled water, followed by lyophilization.

Polymer Plasma Degradation Study. A stock polymer solution of **4a** in PBS with 30 mM $NaNO_3$, pH 7.4, was made at a concentration of 20 mg polymer/mL. Lyophilized human plasma (Sigma) was reconstituted in PBS, and the pH was adjusted to 7.4 using 1 M HEPES containing 9 g/L NaCl and 13.5 g/L NaOH. The choice of buffer is important to prevent a change in plasma pH over the course of the experiment. For each time point, 40 μL of polymer solution was added to 160 μL of preheated human plasma in a 1.5 mL centrifuge vial and vortexed briefly. Samples were incubated at 37 °C. At the desired time point, 200 μL of a 1:1 methanol/water with 2 wt % $ZnSO_4$ solution was added to the vial to precipitate the proteins. The sample was briefly vortexed, centrifuged at 14,100 rcf for 5 min, then frozen at −80 °C until it could be prepared

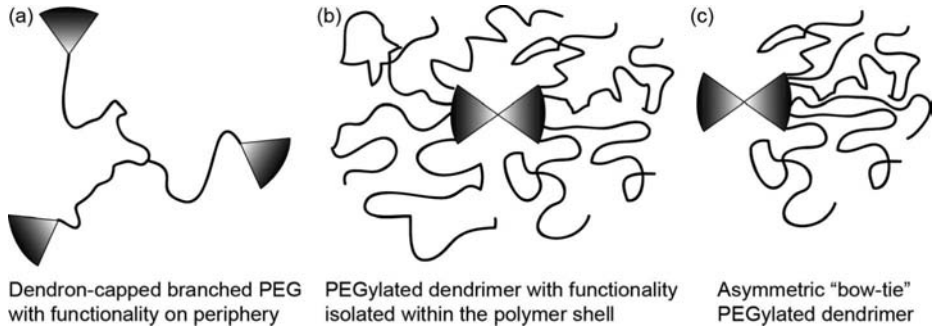

Figure 1. Schematic representations of the PEG−dendrimer hybrid structures. PEG can be attached (a) at the dendrimer apex or the periphery of (b) symmetric or (c) asymmetric bow-tie dendrimers.

for molecular weight determination by SEC. Individual samples were prepared for SEC (system C) by filtering the supernatant through 0.2 μm pore size PTFE syringe filters.

Radioiodination of the Free Phenols on Tyrosine (Tyr)-Functionalized PE Dendrimers (9b). For tracing of the dendrimer in biodistribution studies, the free phenols of **9a** were radiolabeled with ^{125}I using a published procedure (*32*). Briefly, **9a** (3 mg, 75 pmol) was dissolved in 0.49 mL of boric acid buffer (0.1 M, pH 8.5). A solution of potassium iodide in water (1 μM) was added (136 μL), followed by chloramine T in boric acid buffer (1 μM, 272 μL). The mixture was allowed to react for 15 min, then sodium bisulfite solution (50 μM, 6.8 μL) was added to stop the reaction. The material was purified on a PD-10 column and lyophilized overnight to yield 3 mg of iodinated polymer. The polymer was iodinated at 1 μCi per PEGylated dendrimer. A solution of iodinated polymer was combined with a solution of non-iodinated polymer, resulting in a final solution of 5 mg polymer/mL and with an activity of 14.2 μCi/mL.

Biodistribution Studies in Nontumored Mice. Radioiodinated polymer solutions (200 μL, ~6.5 million cpm/mouse) were injected intravenously in the tail vein of 6–8 week old female CD-1 mice. The mice were sacrificed at three different times following injection for biodistribution analyses: 30, 540, and 2880 min postinjection (three mice per experimental group). The blood (collected by heart puncture), heart, lungs, liver, stomach, spleen, intestines, kidneys, and carcass (divided into three portions) were collected for analyses. Each were weighed, and the amount of radioactivity present in each organ was quantified. For the 2880 min time point, the mice were housed in metabolic cages and the urine and feces collected. Additionally, retro-orbital (RO) bleeds were taken at four different time points to construct a blood concentration curve. A 10 min RO bleed was taken from the 30 min sacrifice mice, 60 and 1440 min RO were taken from the 2880 min sacrifice mice, and a 180 min RO bleed was taken from the 540 min sacrifice mice. All samples were weighed and the amount of radioactivity present quantified.

Urine was analyzed by running 1 mL of urine from each polymer biodistribution through a G-50 Sephadex column (column volume ~10 mL). Fractions were collected and analyzed for radioactivity to determine whether radioactivity in the urine was polymer-associated or low MW-associated. A set of PEO polymers with known MW polymers was also run on the G-50 column for comparison.

The % injected dose per gram (%ID/g) of blood versus time curve was analyzed using a two compartment model described by eq 1. The two compartment model (*33*) was chosen as the blood concentration curve showed two distinct rates of decay. The pharmacokinetic parameters *A*, α, *B*, and β for the two-compartment model were estimated using the residuals model. All pharmacokinetic quantities were calculated from these parameters.

$$C_p = Ae^{-\alpha t} + Be^{-\beta t} \quad (1)$$

Biodistribution Studies in Tumored Mice. Six to eight week old female Balb/C mice were injected in the right rear flank with C26 colon carcinoma cells by subcutaneous administration (3×10^5 cells in 50 μL media). Tumors were allowed to grow 13 days.

Mice were injected intravenously in the tail vein with one of the following solutions in PBS: **8** (8 mg Dox equiv/kg), DOXIL (8 mg Dox equiv/kg), or free Dox (8 mg/kg) (three mice per experimental group). Two control mice were also injected with 200 μL of PBS. The mice were sacrificed 2880 min postinjection. The blood (collected by heart puncture), heart, lungs, liver, spleen, kidney, muscle, and tumor were collected for analyses. Each organ was weighed, and 200–300 mg of the collected organs were combined with ~0.6 mL zirconia beads and 1 mL of acidified isopropyl alcohol (0.075 M HCl, 90% IPA) in 2.0 mL centrifuge tubes. The samples were homogenized for 30 s and incubated at 4 °C for 24 h. Samples were then frozen at −80 °C in a freezer until quantification of Dox content by fluorescence measurements could be made. At measurement time, samples were thawed and centrifuged for 5 min at 14,000 rpm (15,400*g*). Then, 80 μL of supernatant was combined with 920 μL of acidified IPA for fluorescence measurements. Dox fluorescence (ex 485 nm, em 595 nm) was measured on a Spex Fluorolog fluorimeter. Calibration curves were made from organ samples collected from the control mice.

RESULTS AND DISCUSSION

Synthesis of the PEGylated Dendrimers. The synthesis of the core functional PEGylated dendrimers is straightforward and nearly quantitative at all dendronization steps (Scheme 1). The first generation pentaerythritol bisHMPA dendrimer **1** (PE-G1-OH_8) was synthesized as previously described (*30*). This molecule was chosen as a core because a large number of radially emanating functional groups could be attained in a minimum number of steps on a large scale, and the biodegradable ester backbone is desirable for biological applications. Attachment of the amino acids **2a**−**e** using DMAP catalyzed EDCI coupling provided analytically pure dendrimers (**3**), requiring only an extractive workup for most versions. None of the dendrimers required column chromatography for analytically pure material, thus facilitating scale up. The reaction was monitored by MALDI-TOF MS to detect incomplete couplings (Figure 2a for **3c**). In all cases, the reaction went to completion, normally within 4 h. Occasionally, loss of either a single *tert*-butyl group or a number of Boc groups was seen in the MALDI-TOF spectrum, but the peaks associated with a loss of 8 Boc groups, however, were higher than those associated with 7 or 6, indicating that this was an artifact of the ionization process because of the use of an acidic matrix. In the workup of **3c**, some benzyl alcohol was produced, likely due to the ester

hydrolysis of some of the water-soluble starting amino acid. This was removed by precipitation of the material into hexanes. These dendrimers are soluble in a variety of common organic solvents (CH_2Cl_2, $CHCl_3$, CH_3OH, EtOAc, etc.). Dialysis in 3500 molecular weight cutoff regenerated cellulose membranes against methanol is an alternative purification procedure to extractive workups, generally producing yields greater than 80%. All of the amino acids attached are commercially available, although the unnatural amino acids are more expensive and may not be readily available on a large scale. By using this variety of amino acids, PEGylated dendrimers ready for radiolabeling, esterification, amidation (with limitations, vida infra), click reactions, Pd coupling, and hydrazone/oxime formation are easily accessible.

Deprotection of the amine-protecting Boc groups could be monitored by MALDI-TOF MS (Figure 2b for **3c**). Products were isolated by the removal of the solvent and used in the next step without further purification. In the MALDI-TOF spectrum of **3a**, the loss of a single benzyl group was seen, but this was a minor event that did not interfere with the PEGylation reaction. Monomethoxy-PEO-*p*-nitrophenyl carbonate (PEO-PNP, 5000 MW) (*29*) was used in ~5% excess to fully cover the amine periphery of the dendritic core. After 3 days, size exclusion chromatography in DMF showed a peak around 38,000 Da, and another at 6,000 Da corresponding to the excess PEO-PNP (Figure 3 for **4c**). A ninhydrin test indicated that all primary amines were reacted in each case. For applications where excess PEO-PNP could be problematic, the addition of a slight excess of piperidine to the crude reaction mixture, followed by 12 h of stirring, effectively capped the remaining activated 5000 Da PEO. At this stage, the products could be purified from small molecules by dialysis in water. We have shown previously (*15*) that excess linear PEG can be removed from the PEGylated dendrimer by careful dialysis, but in this work, no such purification was attempted as it leads to a significant lowering of the yield of the PEGylated dendrimer, and the small amount of lower molecular weight linear PEG impurity should not alter the in vivo characteristics of the PEGylated dendrimers.

Scheme 2. Linker Synthesis, Attachment, and Dox Loading[a]

Dox Loading of the PEGylated Dendrimers. To demonstrate that the dendritic cores are accessible for further chemical manipulation, **4c** was elaborated to contain Dox conjugated through a hydrazone bond (Scheme 2). This linkage shows promise for releasing Dox in its biologically active form after endocytosis but is stable at physiological pH 7.4 (*34–37*). Although the most straightforward route to a hydrazide-containing polymer would be attachment of *tert*-butylcarbazate directly to the aspartate moiety, we found that the α-amido ester bonds were not completely stable in the presence of excess amine and some degradation of the dendrimer occurred. It should be noted that piperidine, the secondary amine used to deactivate excess PEO-PNP, does not cause ester degradation. Similar results were seen when deprotecting the ε-Cbz of a lysine version of the dendrimer (data not shown). No further attempts were made to optimize the conditions to amidate with primary amines. To circumvent this degradation by a nucleophilic amine, hydroxyl-hydrazide linker **6** was synthesized and, following hydrogenolysis of the benzyl ester-protecting group of **4c** to afford **5**, was attached to the dendrimer. A comparison of the Boc peak at 1.48 ppm against the OMe of the PEG chains at 3.38 ppm in the ^{1}H NMR spectrum indicated that roughly 50% coverage (4 molecules of **6** attached to **7**) is achieved under these conditions. Such coverage is sufficient for the intended application.

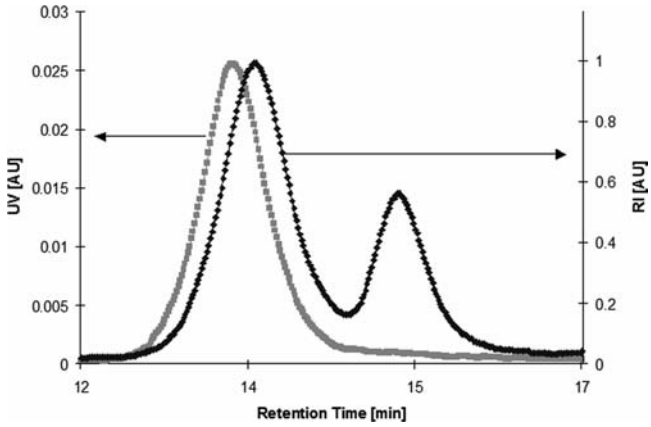

Figure 4. SEC of **8** in DMF. The delay between the UV (abs 584 nm) and RI traces is due to the sequential placement of the detectors.

Deprotection of the hydrazide Boc group followed by hydrazone formation with Dox in methanol afforded polymer **8** containing 2.9 wt % Dox. This value is 50% of the theoretical loading, consistent with previous work in our laboratories (*16*). Such partial loading may result from the presence of residual trifluoroacetic acid in the reaction mixture from the deprotection step, which lowers the pH of the solution below the ideal level for hydrazone formation. Optimization of the reaction conditions for linker attachment and drug conjugation should result in significantly higher (∼4-fold) loadings. Although some linear PEG was still present in the reaction mixture, the absorbance at 584 nm (in 0.2% LiBr in DMF) in the size exclusion chromatogram shows that, as expected, Dox was only attached to the PEGylated dendrimer and not to free PEG (Figure 4). The refractive index (RI) trace of the drug-loaded carrier (Figure 4) appeared different from that of the initial PEGylated dendrimer (Figure 3) and all the intermediates in terms of the amount of excess linear PEG. Initially, when the carboxylate groups were protected, ca. 5% excess PEG was seen, as expected. As the core was deprotected, linker added, and drug added, the ratio of the PEGylated dendrimer peak area to the linear PEG area decreased. The peaks were eluted at the same retention time for each, indicating that the molecular weight did not change and that degradation had not occurred. Therefore, we believe this was an artifact related to the changing refractive index of the material and that the amount of residual free PEG did not actually change. The drug-loaded material **8** was highly water soluble.

In Vitro Biodegradability of the PEGylated Dendrimers. While prior work has shown that PEGylated ester dendrimers can be hydrolyzed in aqueous solutions (*12*), we carried out experiments to determine if these PEGylated dendrimers could be degraded by enzymes since it has been suggested that PEGylation can inhibit access of enzymes and physiological fluids to a dendritic core (*38*). The properties of **4a** in biologically relevant situations was evaluated by tracking its stability in pH 7.4 buffer and in human plasma at 37 °C. As expected, over the course of 20 days in buffer, the PEG chains were hydrolyzed leading to a mixture of molecules with lower overall molecular weight and higher polydispersity than that of the starting **4a**. However, a significant portion of the material was still of higher molecular weight, suggesting that it had remained intact. Initial studies in plasma reconstituted using distilled water, as instructed by the manufacturer, showed that complete degradation of the ester dendrimer took place within only 48 h, leading to a product in which the largest molecules appeared to be 5 kDa PEG chains. However, it was found that the reconstituted plasma had a pH of ∼9, and thus, the high level of ester degradation seen was likely a result of the basic pH and not enzymatic degradation. After careful adjustment of the pH to 7.4 using a nonvolatile buffer such as HEPES buffer, the plasma samples showed degradation profiles essentially identical to those in PBS, pH 7.4. Therefore, this preliminary work does not shed light on the accessibility of the polyester dendritic core itself to enzymes.

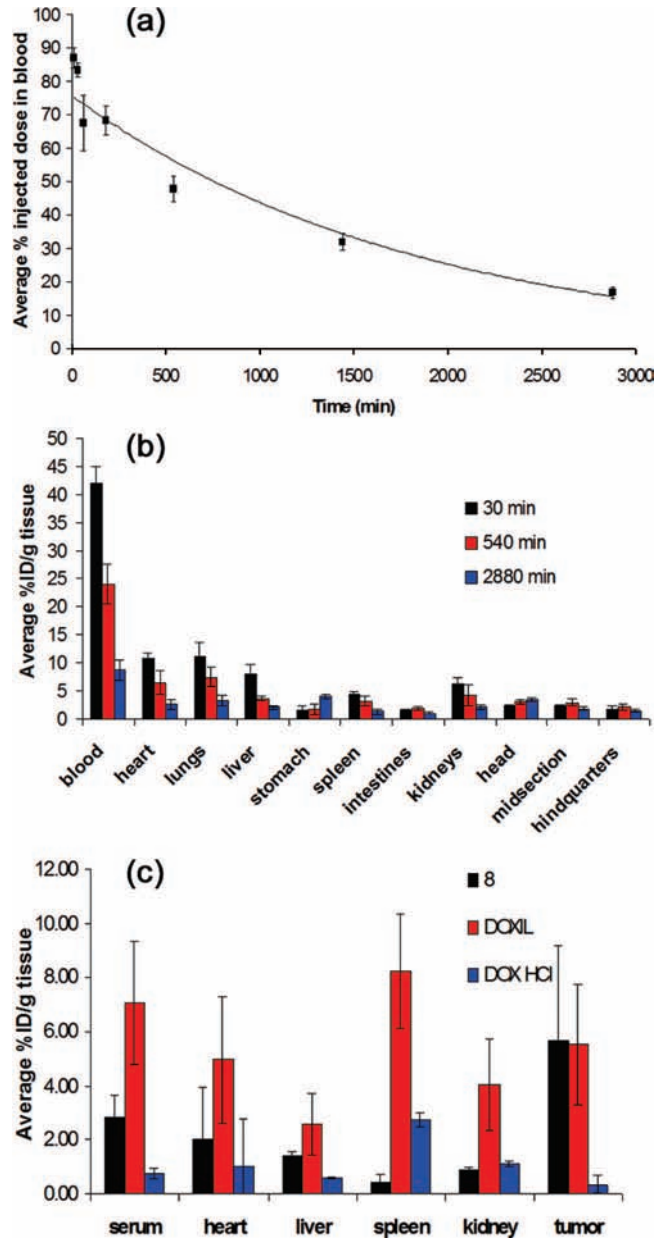

Figure 5. (a) Blood circulation profile of radiolabeled **9b** given as the average percent ID of polymer in the blood over time (three mice per time point). The line represents the fit curve resulting from the calculated pharmacokinetic parameters detailed in Table 1. (b) Biodistribution of radiolabeled **9b** in nontumored mice taken at three time points: 30, 540, and 2880 min postinjection (three mice per time point). (c) Forty-eight hour biodistribution, given as the average %ID Dox/g tissue, of **8** in mice tumored subcutaneously in the right flank with C26 colon carcinoma. DOXIL and Dox HCl were run as controls (three mice per treatment group).

Biodistribution Studies of Radiolabeled Polymer. To follow the fate of the PEGylated dendrimer in vivo, the phenolic groups of **4a** were deprotected and radiolabeled with ^{125}I (compound **9b**, not shown). Six to eight week old female Balb/C mice were injected intravenously with polymer solutions, and the distribution of the radiolabel in tissues was followed over time. The blood concentration profile (Figure 5a), given as the

Table 1. Pharmacokinetic Data for Radiolabeled 9b

$t_{1/2,\alpha}$ (h)	0.32 ± 0.11
$t_{1/2,\beta}$ (h)	23.8 ± 2.5
V_1 (g blood)	1.94 ± 0.07
$AUC_{0\rightarrow\infty}$ (%ID·h/g)	$1{,}200 \pm 100$
k_{21} (L/min)	0.024 ± 0.012
k_{12} (L/min)	0.01 ± 0.02
k_{el} (L/min)	0.0007 ± 0.0004

average %ID of radioactivity, shows >16%ID remained in the blood after 48 h. A two-compartment pharmacokinetic model (*33*) was fitted to the data, and from this the pharmacokinetic parameters were determined. In particular, the blood circulation half-life $t_{1/2\beta}$ was found to be 23.8 ± 2.5 h (Table 1), and the area under the curve, $AUC_{0\rightarrow\infty}$, was determined to be $1{,}200 \pm 100$%ID·h/g blood. The long circulation half-life and large $AUC_{0\rightarrow\infty}$ are indicative of high levels of polymer in the blood and increased opportunity for accumulation in a tumor due to the EPR effect. This is consistent with previously reported results for PEGylated bow-tie dendrimers of similar molecular weight (*12*) and is more favorable than results obtained with linear 50 kDa PEO (*39*). The biodistribution study of **9b** (Figure 5b) showed low levels of polymer in all vital organs after 48 h, less than 5%ID/g tissue.

However, despite the long blood circulation half-life, 28.5%ID and 5.0%ID were found in the urine and feces, respectively, after 48 h. To determine whether this radioactivity was polymer-associated (>5,000 Da) or low MW-associated (<5,000 Da), urine samples were run on a G-50 size exclusion column. The results showed that 35% of the radioactivity eluted was polymer-associated, and 65% of the radioactivity eluted was low-MW-associated (data not shown). While some whole polymer can be filtered from the blood by the kidneys, it is likely that the excreted radioactivity can be attributed to the hydrolysis of the polymer in the blood. It was unclear, however, what the radiolabeled low MW material might be. Li et al. observed a similar phenomenon with their radiolabeled antibody single-chain Fv, where the radioactivity in the urine was dissociated from the antibody, and believed that radioactive iodine was being removed by deiodinases present in the plasma membrane of renal tubule cells, which recognize iodinated tyrosine (*40*). As little iodine was found in the thyroid (<0.5%ID) (data not shown), it is most likely that iodine was being removed preferentially from the tyrosine handles of **9b** as it passed through the kidneys before excretion. Therefore, we believe the biodistribution reflects the polymer distribution and not the distribution of free iodine.

Biodistribution Studies of Dox-Loaded Polymer. A biodistribution of the Dox-loaded **8** was completed to confirm that its distribution behavior had not changed significantly by the change of the functional handle at the core and the attachment of a drug payload. Six to eight week old female Balb/C mice were tumored with the C26 murine colon carcinoma in their right flank. Mice were injected with **8** at a dose of 8 mg Dox/kg. After 48 h, less than 5%ID/g tissue had accumulated in the vital organs, similar to what was seen with radiolabeled **9b**. Furthermore, the Dox-loaded polymer **8** (Figure 5c) delivered 5.7 ± 3.5%ID/g tissue, or 1.2 ± 0.5%ID, to the tumor. This was comparable with the Dox delivered to the tumor from the clinically used PEGylated liposomal formulation DOXIL, both of which delivered approximately 20 times more drug to the tumor than is achieved without carrier. In addition, dendritic carrier **8** showed lower accumulation in the spleen than that observed with free Dox and, in all tested vital organs, than that observed with DOXIL. Lower accumulation of Dox in the vital organs should result in less toxicity, while the high concentration in the tumor may result in chemotherapy treatment as effective as that of DOXIL.

CONCLUSIONS

A variety of biodegradable PEGylated dendrimers with various core functionalities has been synthesized in a scalable process. The use of trifunctional amino acids on the biologically tolerated ester dendrimers is a simple way of incorporating functionality at the core of PEGylated dendritic macromolecules and tailoring them for different applications. This method is general and can be applied to any of the common amine-terminated dendrimers such as the polyamidoamines, polylysine, polypropyleneimine, etc. Clearly, it can also be adapted for use with other families of dendrimers with other types of terminal groups. The core functionalities, if protected during synthesis, are easily deprotected and elaborated further. Radiolabeling the phenolic version facilitated the determination of in vivo biodistribution and pharmacokinetics. It was found that this system has a long circulation half-life and does not accumulate in normal tissue, as was also the case for previous PEGylated dendrimers (*10*, *12*, *15*, *16*). A hydrazide linker was attached to the carboxylate version, and Dox was conjugated to it by a hydrazone. The drug carrier was found to deliver as much Dox to a tumor as the clinically used PEGylated liposomal formulation DOXIL, while less drug was found in healthy tissue. Explorations of the efficacy of the Dox-loaded carrier in tumor therapy, the use of these systems in imaging, and the reactivities of the variants of this system (such as alkyne or ketone functionalized dendrimers) are currently underway.

ACKNOWLEDGMENT

Financial support of this research by the National Institutes of Health (GM 65361 and EB 002047) is gratefully acknowledged. We thank Dr. Marian Snauko (UC Berkeley) for assistance with size exclusion chromatography and Dr. Cameron Lee (UC Berkeley) for insightful discussions.

Biomolecular self-assembly provides a basis for the bottom-up construction of useful and diverse nanoscale architectures. DNA is commonly used to create these assemblies and is often exploited as a lattice or an array. Although geometrically rigid and highly predictable, these sheets of repetitive constructs often lack the ability to be enzymatically manipulated or elongated by standard biochemical techniques. Here, we describe two approaches for the construction of position-controlled, molecular-scale, discrete, three- and four-way DNA junctions. The first approach for constructing these junctions relies on the use of nonmigrating cruciforms generated from synthetic oligonucleotides to which large, biologically generated, double-stranded DNA segments are enzymatically ligated. The second approach utilizes the DNA methyltransferase-based SMILing (sequence-specific methyltransferase-induced labeling of DNA) method to site-specifically incorporate a biotin within biologically derived DNA. Streptavidin is then used to form junctions between unique DNA strands. The resultant assemblies have precise and predetermined connections with lengths that can be varied by enzymatic or hybridization techniques, or geometrically controlled with standard DNA functionalization methods. These junctions are positioned with single nucleotide resolution on large, micrometer-length templates. Both approaches generate DNA assemblies which are fully compatible with standard recombinant methods and thus provide a novel basis for nanoengineering applications.

INTRODUCTION

Diverse materials including nanotubes (*1*), organic molecules (*2*), and biomolecules (*3*) are being employed to form novel nanoscale devices. Of these approaches, biomolecules offer a promising route to form complex and well-defined structures due to their highly convergent, self-assembling capabilities. DNA-based constructs provide many unique properties which make them ideal candidates for nanoscale devices. First, the self-assembling nature of DNA provides a bottom-up approach for synthesis with exquisite specificity and selection. Second, the physical dimensions of DNA, 2 nm in diameter and anywhere from 5 to 5000 nm in length, make this biomolecule an attractive template for wires in the nanometer regime despite its intrinsically poor conductivity (*4*). Third, commercially available DNA modifying enzymes (e.g., polymerases, ligases, endonucleases, and methyltransferases) and DNA binding proteins (e.g., zinc finger containing proteins) are compatible with such architectures facilitating their controlled static and dynamic manipulation.

The specific interactions between base pairs of DNA have been used to create nanostructures and direct the assembly of materials on the angstrom to micrometer scale (*5*–*7*). An emerging application of DNA nanostructures is the development of molecular electronics through the use of bottom-up approaches (*3*) (*8*) (*9*). In this context, the ability to construct discrete three- and four-way junctions will become increasingly important as more complex electronic architectures are sought. Novel DNA architectures for nanotemplating have been prepared, most notably by Seeman and co-workers (*6*). These DNA architectures are most frequently made up of highly repetitive, blocklike lattices or scaffolds (*7*) (*10*). These geometrically defined structures are repetitive and relatively rigid in both structure and sequence, making further recombinant manipulation problematic. For example, it is extremely difficult to introduce site-specific modifications to a small number of positions in such highly repetitive assemblies. Similarly, restriction enzymes, DNA ligases, and DNA polymerases are not always able to gain access to these highly interwoven assemblies. The methods described here can be used in conjunction with lattices or arrays in order to increase their versatility, or as a stand-alone assembly method yielding flexible constructs.

DNA-based molecular electronics have included conductive nanowires as well as electroless plating techniques (*3*) (*4*). An important electronic feature common to many devices relies on the use of junctions for signal splitting and amplification as well as for control gates. To this end, we have constructed isolated three-way and four-way DNA junctions at predetermined positions. One approach uses a nonmigrating cruciform as the core structure to which long, flexible DNA arms are enzymatically ligated (Figure 1). This recombinant approach differs from a similar method where 5′-biotinylated DNA was joined together by a streptavidin linkage to create a discrete four-way junction (*11*). Such structures are readily positioned onto metal electrodes via 5′ or 3′ functionalization to the ends of DNA (*3*) (*4*). Another approach positions one or more biotins or other labels *within biologically isolated DNA*. This position-controlled and selective placement of biotin was achieved with the SMILing DNA method (sequence-specific methyltransferase-induced labeling of DNA) (*12*) (*13*), which uses modified AdoMet analogues

and sequence-specific DNA methyltransferases to deliver the biotin moiety.

EXPERIMENTAL PROCEDURES

Cruciform Preparation. Large DNA cruciforms were constructed by ligating PCR-derived DNA molecules to a small synthetic core junction. The small core cruciform was constructed by annealing four synthetic 36 bp DNA molecules (5′-GGGAGGTAGGACCGCAATCCTGAGCACGTCTCAACG-3′, 5′-GGGACCACCAGTGCCATAGTGGATTGCGGTCCT-ACC-3′, 5′-GGGAGGAACTGTGCATTCGGACTATGGCAC-TGGTGG-3′, and 5′-GGGACGTTGAGACGTGCTCACCGAAT-GCACAGTTCC-3′) with a 5′ overhang of 5′-GGGA-3′ on each arm. Oligonucleotides purchased from Midlands DNA were HPLC purified and kinased with dATP (Sigma) and T4 DNA kinase (NEB) extensively to ensure that all strands were fully phosphorylated at the 5′ end. These oligos were then repurified by phenol−chloroform extraction and annealed by boiling a mixture of equal molar ratios of each strand in STE buffer (100 mM NaCl, 10 mM Tris pH 8.0, 1 mM EDTA) for 5 min before being slowly cooled to room temperature. Proper annealing was confirmed by PAGE stained with SYBR gold (Invitrogen).

Large cruciform arms were made using pBR322 as a template for PCR. Amplicons 899 bp in length were generated with the primers 5′-CCCCCTTACACGGAGGCATCAGTGACC-3′ and 5′-GCTATGAGAAAGCGCCACGCTTCCCGAAGG-3′, respectively. The resulting amplicon had a single BsmBI recognition site 226 bp from one end. Up to 10 mL of PCR mixture was made using Taq DNA polymerase, 2.5 mM dNTPs, 2 ng/μL of each primer, 1 ng/μL of template, and was thermocycled: (1) 30 s at 95 °C, (2) 30 s at 95 °C, (3) 1 min at 55 °C, (4) 2 min at 74 °C, (5) repeat 30 times from step 2. PCR product was purified using the Qiaquick PCR Clean-up Kit (Qiagen) followed by phenol−chloroform precipitation. The concentration of the amplicon in TE (10 mM Tris, pH = 8.0, 1 mM EDTA) buffer was determined by A_{260}. Purified amplicon was digested with BsmBI (NEB) for up to 12 h to ensure completion. Once fully cut, the two fragments were isolated and purified by agarose gel extraction. DNA bands were cut from an agarose gel run in TBE buffer (10 mM Tris pH 8.0, 10 mM boric acid, 1 mM EDTA) and placed into 10 000 MWC dialysis tubing (Spectrum) for further electrophoresis. After 1 h, the current was reversed for 30 s and the TBE buffer within the dialysis tubing, which contained the isolated DNA fragments, was removed and ethanol precipitated. The concentration of amplicon fragments in TE buffer was determined by A_{260}.

Ligation reactions were made between synthetic core cruciforms and PCR-derived arms with T4 DNA ligase (NEB) at 4 °C. These reactions were usually done in large amounts so small aliquots could be removed and analyzed by agarose gel to monitor progress. Initially, PCR fragments had a 5-fold higher molar concentration than core cruciforms. As the reaction progressed, additional arm, core cruciform, or ligase could be added. Core cruciforms with four ligated arms were isolated from an agarose gel in the same manner as the PCR fragments. Construction was confirmed by digestion with T7 endonucleases I (NEB), which specifically cleaves DNA junctions (data not shown).

(C) Schematic and AFM image of four-way junctions created by incubating SM1 and STV at a ratio of 1:1.

SMILing DNA Preparation. Plasmid pBR322 (NEB) was used as a template for PCR amplifications, using the forward primer 5′-CCAAGTCATTCTGAGAATAGTGTA-3′ and reverse primer 5′-CGCCGAAACAAGCGCTCATGAGCCCG-3′, respectively, to generate a 1017 bp dsDNA fragment (SM1, Figure 3A(a)) with one centrally located (164 and 182 nm away from each end) recognition sequence for the DNA methyltransferase M.BseCI. This amplicon was also formed with a 5′-biotin (5B1, Figure 3A(c)) by using the forward primer listed above with the reverse biotinylated primer 5′-[BioTEG]CGCCGAAA-CAAGCGCTCATGAGCCCG-3′. Plasmid pUC19 (NEB) was

also used as a template for PCR using the primers 5′-AGGCATGCAAGCTTGGCGTAATCATGG-3′ and 5′-CCC-CGACACCCGCCAACACC-3′, respectively, to generate a 2383 bp dsDNA fragment (SM2.4, Figure 3A(b)) with two recognition sequences for the DNA methyltransferase M.TaqI, 160 nm from either end. All primers were ordered from Operon. Each PCR amplicon was purified with a Qiagen QIAquick PCR purification kit followed by phenol−chloroform extraction and ethanol precipitation.

SMILing DNA Modification. SM1 (1 μg), with one recognition site for M.BseCI at position 531–536 (30 nM), M.BseCI (303 nM), and 6BAz (80 μM, Figure 3B) were incubated in buffer (50 μL containing 10 mM Tris/HCl, pH 7.4, 20 mM $MgCl_2$, 50 mM NaCl, 50 μM EDTA, and 2 mM 2-mercaptoethanol) at 55 °C for 3 h. The reaction mixture was then heated to 70 °C for 20 min. Control reactions without M.BseCI and 6BAz were performed in parallel. After analysis by agarose gel electrophoresis, SM1 was purified using QIAquick PCR purification kits (QIAGEN) according to the instructions of the manufacturer. Similar protocols were used to create SM2.4.

To test the integrity of the DNA, aliquots of the SMILing reaction and the control reactions (10 μL, 0.2 μg DNA) were treated with Proteinase K (1 μL, 20 mg/mL in 10 mM Tris/HCl, pH 7.5, QIAGEN Proteinase K) and incubated at 37 °C for 1 h. Afterward, 6× loading buffer (2.2 μL, 30% glycerin, and 0.25% bromophenol blue) was added to each aliquot and the DNA was visualized by agarose gel electrophoresis (data not shown). Restriction analysis was performed by taking aliquots of the SMILing reaction and the control reactions (10 μL, 0.2 μg DNA) supplemented with water (1.3 μL), BSA (1.0 μL, 1.5 mg/mL), 10× NEB 2 buffer (1.5 μL, 100 mM Tris/HCl, pH 7.9, 100 mM $MgCl_2$, 500 mM NaCl, 10 mM DTT), and R.ClaI (1.2 μL, 4 units in NEB 2 buffer) and incubated at 37 °C for 1 h. Afterward, Proteinase K (1 μL, 20 mg/mL in 10 mM Tris/HCl, pH 7.5, QIAGEN Proteinase K) was added to each aliquot and the solutions were incubated at 37 °C for 1 h. Finally, 6× loading buffer (3.2 μL) was added to each aliquot. Results of the restriction digest were visualized by agarose gel electrophoresis (Supporting Information). To ensure biotin function, aliquots of the SMILing reaction and the control reactions (10 μL, 0.2 μg DNA) were supplemented with streptavidin (5 μL, 5 mg/mL in PBS buffer: 100 mM sodium phosphate, 100 mM NaCl, 2 mM sodium azide, pH 7.5) and incubated at 37 °C for 1 h. Afterward, 6× loading buffer (3.2 μL) was added to each aliquot. DNA mobility was visualized on a 0.8% agarose gel (Supporting Information).

Four-Way SMILing Junctions. These junctions were constructed using SM1 and streptavidin (STV) (Figure 3C) at a molar ratio of 1:1. DNA samples (150 nM) were incubated for 48 h at 4 °C. The long incubation time maximized the assembly of the desired junction, which was slow to form in solution. The desired construct was confirmed by both agarose gel electrophoresis and AFM analysis (Figure 3C and Supporting Information). Further distance analysis by AFM also showed that the location of the four-way junction is consistent with the SMILing DNA-directed placement of the biotin group onto SM1 (Figure 3).

Three-Way SMILing Junctions. These junctions were constructed with SM1, 5B1, and STV (Figure 4A,C). The highest yields were obtained with a stepwise addition of STV to SM1 in a ratio of SM1:STV of 1:5, followed by the addition of 5B1. AFM analysis verified that the location of the three-way junction is consistent with the SMILing DNA-directed placement of the biotin onto SM1 (Figure 4A,C). To create a double-three-way junction (Figure 4B,D), 5B1 and STV were incubated at a ratio of 1:5 followed by addition of SM2.4 at a ratio of 5B1/SM2.4 of 2:1. The anticipated placements of the three-way junctions on this larger element are also consistent with the SMILing DNA-directed placement of the two biotin moieties on SM2.4 (Figure 4A).

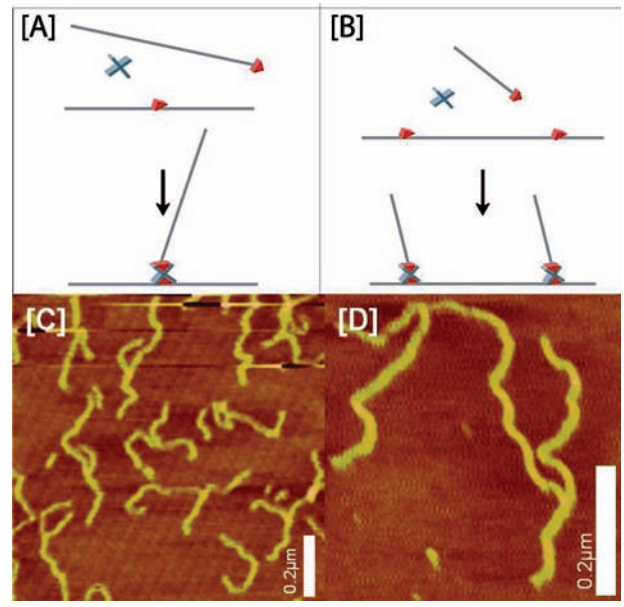

Figure 4. Schematic and AFM of three-way junctions. (A) Schematic of a single three-way junction formation. STV was preincubated with SM1 at a 5:1 ratio with subsequent addition of 5B1 to achieve the desired construct. (B) Schematic of double three-way junction formation. 5B1 was preincubated with 5-fold molar excess STV. SM2.4 was added at half the concentration of 5B1 to form junctions. (C) Tapping-mode AFM image of single three-way junctions described in A. (D) AFM image of a double three-way junction described in B.

AFM Sample Preparation. Desired DNA constructs were assembled in solution prior to immobilization for AFM. The resulting DNA (10 ng) was incubated in 20 μL of 1 mM $MgCl_2$ for 30 min at 22 °C. The resulting 20 μL solution was then deposited on freshly cleaved mica and left for 5 min. The sample was then washed using 3 mL of filtered and doubly distilled deionized water. Water remaining on the mica was wicked away and further dried with nitrogen. All AFM imagining was done on a Digital Instrument Multimode Dimension 3000.

RESULTS AND DISCUSSION

Cruciform-Based Junctions. Our initial four-way DNA junction was constructed by using a core, immobile cruciform from a set of previously published sequences (Figure 1) (*14*). These sequences were modified slightly to incorporate additional four base overhangs on the 5′ ends. The annealing of this cruciform showed a few aberrant secondary structures by PAGE, but the correct cruciform was still the most abundant form (Figure 2A). The successful ligation of the long arms to the core cruciform required several purification steps. PCR amplicons that formed the basis of the arm were purified away from residual primers which showed inhibitory affects toward the DNA ligase. The resulting purified amplicons were then digested with BsmBI to yield small (315 b.p.) and large (584 b.p.) DNA fragments. The large DNA fragment was isolated by gel purification followed by phenol−chloroform extraction and ethanol precipitation. The large DNA fragment was ligated back to the small DNA fragment to confirm the presence of the 5′ overhang (5′-TCCC-3′) essential for cruciform ligation.

Large four-way DNA junctions were successfully assembled by T4 DNA ligase as shown by agarose gel in Figure 2B. Initial cruciform ligation reactions contained roughly 5-fold molar excess of arm to core cruciform. As the reaction progress was monitored over time, subsequent additions of either core or arm

were made to the reaction mixture. The addition of free arm, although already in excess, led to more of the 4-way junctions. Isolation and purification of the large cruciforms was accomplished by gel excision. Due to the nature of this technique and the cruciform structure, large quantities of ligated cruciform were often required in order to recover a discernible amount. Various methods including the QIAquick Gel Extraction Kit (Qiagen) were attempted, but electrophoresis followed by concentration by ethanol precipitation gave the best results. Once purified, the final product was confirmed by successful digestion with T7 endonucleaseI, which exclusively cleaves DNA junctions.

The long, flexible DNA arms may find novel nanotechnology applications due to their extended linear nature and ability to be modified at unique and predetermined positions. For example, we have placed single metallic nanoparticles at specific positions on such structures with a goal toward creating electronic components (*36*). Although the structure of the DNA is not novel (*11*), our procedure to create the cruciform is unique. We have exploited the convergent capabilities of using DNA and DNA modifying enzymes in order to achieve higher-order structures. In this regard, using PCR-derived DNA that is manipulated by a restriction endonuclease is much more cost-effective than ordering synthetic arms or 5′ biotinylated primers. Further, we have shown that the immobile cruciform can be manipulated by enzymatic means. The construction approach demonstrated here should also be applicable for three-way junctions and junctions involving arms of various lengths.

SMILing-Based Junctions. The SMILing approach relies on cofactor analogues that deliver a small molecule from modified S-adenosylmethionine (AdoMet) to a site-specific location on the DNA (*12*) (*13*). This DNA methyltransferase-directed assembly of DNA junctions is schematically shown in Figures 3 and 4. DNA methyltransferases are responsible for many biological functions in prokaryotes and eukaryotes, including prokaryotic restriction-modification systems (*15*), DNA mismatch repair (*16*), chromosome replication (*17*), gene regulation (*18*), mammalian development (*19*), oncogenesis (*20*), and the organization of chromatin structure (*21*). Because these enzymes are structurally and mechanistically well-understood, they provide a sound basis for the types of bionanoengineering described here.

The SMILing method's replacement of an aziridine ring for the amino acid in AdoMet allows for the covalent incorporation of diverse ligands (*12*) (*13*) (*22*). Here, we applied the SMILing DNA approach to form novel, branching DNA structures. M.BseCI and M.TaqI use the natural cofactor AdoMet to methylate the amino group of the starred adenine residue in the sequences 5′-ATCGA*T-3′ and 5′-TCGA*-3′, respectively. In our studies, these enzymes were used to catalyze a nucleophilic aziridine ring opening of the cofactor analog 6BAz (Figure 3B) and covalently attach a single biotin at the target adenine in their respective recognition sequences (Figure 3A). The reaction of M.BseCI with the AdoMet analogue 6BAz results in the selective placement of biotin at one position within the 1017 bp dsDNA fragment (164 and 182 nm from each end). The M.TaqI reaction incorporated a biotin at two positions on the 2383 bp dsDNA (160 nm from either end). Biotin incorporation was verified by showing that the corresponding restriction endonuclease was incapable of digesting the modified DNA (Supporting Information).

The tetravalent binding capacity of streptavidin (STV) (*23*) suggests that the reaction between SM1 molecules and STV can lead to four-, six-, and eight-way junctions. However, we saw no evidence for six- or eight-way junctions (Supporting Information). Further, the formation of the four-way junction occurred after a 48 h incubation at 4 °C. The lengthy reaction time for four-way junctions and lack of six- and eight-way junctions is most likely due to the steric hindrance and electrostatic repulsion between the negatively charged DNA phosphate groups. To optimize the assembly of the desired four-way junction, we varied both the STV to biotinylated DNA ratio and a prebound DNA-STV to biotinylated DNA ratio. There was a clear dependence on these two ratios and how well junctions were formed (Supporting Information). At high concentrations of STV, few junctions were formed most likely due to all biotins being bound by individual STV. Conversely, high DNA concentrations yielded more junctions. In the case of the four-way junction, a 1:1 ratio of STV to biotinylated DNA gave the best results for formation of the desired DNA construct.

Contrary to the single incubation for four-way junctions, two reaction steps were necessary for the assembly of three-way junctions. For a single three-way junction, excess STV was allowed to bind to SM1 followed by the addition of the 5B1 to the reaction mixture (Figure 4A). Junction formation of the STV to the 5′-biotinylated DNA occurred much faster in comparison with the SMILing-modified DNA alone (data not shown), suggesting that steric interactions between DNA molecules may play a significant role in determining the rate and extent of reaction. A stepwise addition was also used for the construction of the double three-way junction (Figure 4B). 5B1 was preincubated with excess STV followed by addition of SM2.4.

The use of biotin−streptavidin linkages to form DNA structures is well-understood (*11*) (*24–27*); however, we have used a DNA-modifying enzyme to incorporate a biotin site specifically within long, native DNA derived from PCR. Li et al. reports a 2.1-fold increase in height upon STV binding to bare DNA (*28*). Cross-section analyses of our biotin−streptavidin linkages reveal a similar change in height; however, this is not easily seen in the SMILing DNA figures. We propose that this could be due to dehydrating AFM conditions that have been previously seen with DNA (*29*) and DNA binding proteins (*30*) or differences in tips used for AFM. However, the presence of the STV in our images can be further validated by the lengths of the DNA branches seen in Figures 3 and 4. The lengths correlate well with the site-specific positioning of the biotin and are consistent throughout many structures. The mere probability of this occurrence is highly unlikely.

Our current ability to assemble DNA junctions via biotin−streptavidin linkages provides constructs which are topologically but not geometrically defined. The lack of geometric constraint comes from the long DNA "arms" which extend from the junctions and go well beyond the persistence length of double-stranded DNA. Importantly, any approach making use of DNA junctions (*31*) will be faced by the breakdown of the geometric constraints when used with long DNA "arms". However, this may be overcome by using surfaces to which the complementary oligonucleotides are directed, forcing the hybridization of specific arms to particular surfaces in a geometrically defined manner. Additionally, PCR-derived DNA retains the ability to be end-functionalized, enabling placement of arms across electrodes or other devices.

Recent studies have described novel methods of creating finite DNA structures (*10*) (*27*) (*32*) (*33*). Although successful, these studies are still dependent on tightly packed, non-native forms of DNA, which make further manipulation by recombinant methods difficult. Our approach is further distinguished from DNA tiling and DNA array methods (*6*) (*27*) (*34*) (*35*), which normally result in assemblies with variable lengths or dimensions. Notably, Tian et al. recently described a long, flexible 4-way DNA junction (*11*). However, their approach relied solely upon 5′-biotinylated DNA brought together by the tetravalent binding capability of streptavidin. Our approaches use enzymatic manipulation (ligation, SMILing) independent of 5′ modifications to achieve similar higher-order structures. We argue that

our approaches offer more control with site-specific biotin incorporations within DNA in addition to the versatility associated with recombinant methods of manipulating biomolecules. Furthermore, the use of biologically derived DNA is more cost-effective and does not require the types of purification normally needed for synthetic DNA. Finally, the relative homogeneity of synthetic DNA oligonucleotide sequences means that kinetic traps may interfere with the assembly of a particular structure; this is less likely to be a problem with the highly heterogeneous biologically derived DNA.

Our construction of a set of novel, discrete nucleic acid architectures shows promise for directing the assembly of a variety of nanomaterials into higher-order structures using bottom-up assembly. This approach shows a level of molecular control which is essential for the construction of robust nanomaterials. Additionally, this approach also incorporates the use of recombinant techniques such as PCR and the use of DNA-modifying enzymes to achieve novel DNA architectures. The application of this approach to fabricate hybrid structures using carbon nanotubes and nanoparticles is being pursued. Ultimately, the retention of DNA molecules that can be manipulated by recombinant DNA methods provides a further basis for subsequent design and functionalization.

ACKNOWLEDGMENT

We thank Dr. Nadrian Seeman for insights into cruciform construction. This work was supported by a grant from the Institute for Collaborative Biotechnologies (DAAD19-03-D-0004), U.S. Army Research Office (Reich), and a UC GREAT Grant (Reich). This work made use of MRL Central Facilities supported by the MRSEC Program of the National Science Foundation under award No. DMR00-80034. We thank Basar Gider for helping in the initial synthesis of 6BAz, Kerstin Glensk for performing the SMILing reactions, and Prof. Dr. Michalis Kokkinidis for providing M.BseCI. We also thank Dr. Debra Fygenson for her suggestions.

Note Added after ASAP Publication: The author's name has changed since the original Web posting on December 11, 2007. The correction was made and the article reposted on January 9, 2008.

Supporting Information Available: Details on the SMILing modified DNA and the concentration and ratio dependencies on junction formation are given. This material is available free of charge via the Internet at http://pubs.acs.org.

Enzyme-Directed Positioning of Nanoparticles on Large DNA Templates

Gary Braun,[†] Michael Diechtierow,[†] Stephanie Wilkinson,[†] Falk Schmidt,[§] Michael Hüben,[§] Elmar Weinhold,[§] and Norbert O. Reich*[,†,‡]

Department of Chemistry and Biochemistry, Biomolecular Science and Engineering Program, University of California, Santa Barbara, California 93106-9510, and Institute of Organic Chemistry, RWTH Aachen University, Germany. Received July 20, 2007; Revised Manuscript Received November 5, 2007

A method to position nanoparticles onto DNA with high resolution using an enzyme-based approach is described. This provides a convenient route to assemble multiple nanoparticles (e.g., Au and CdSe) to specific positions with a high level of control and expandability to more complex assemblies. Atomic force microscopy is used to analyze the nanostructures, which have potential interest for biosensor, optical waveguide, molecular electronics, and energy transfer studies.

INTRODUCTION

The ability to position nanoparticles and quantum dots onto molecular scaffolds with nanometer control has potential applications for biosensors, optical waveguides, molecular electronics, energy transfer, and surface-enhanced Raman spectroscopy (SERS) (*1, 2*). The development of nanoscale molecular electronics is being pursued using nanowires, nanotubes (*3–6*), conducting organic molecules, as well as biomolecular approaches (*7–13*). Many of these approaches rely on the incorporation of nanoparticles (NPs) to enhance the electronic features of the particular nanoarchitecture. For example, the construction of nanoparticle-based single electron tunneling devices requires the positioning of a single nanoparticle within nanometer distance to the conducting wires and, to work at room temperature, a NP size small enough that the Coulomb charging energy exceeds the thermal energy. Several biomolecular routes to controlling electronic elements rely on DNA structures that spontaneously self-assemble into repeating polymeric patterns that can direct nanoparticles (*14–17*). Depositing the DNA between electrodes on a substrate is a separate challenge, although promising strategies include incorporating thiol groups to bind gold surfaces, using hybridization through terminal single stranded overhangs onto short complimentary DNA coatings (*18*), or using electric fields to orient and stretch long DNA across an electrode gap in solution (*19*). In this article, we complement these methods by enabling targeted placement of single or multiple chemical modifications onto large DNA templates and show their capacity to control the positioning of nanoparticles. We used biotin−streptavidin interactions to drive a gold NP to the biotinylated nucleotide(s) and electrostatic assembly of a separate NP type, small metallic, or semiconductor quantum dots to fill in the remaining DNA backbone. These hybrid materials are of particular interest for studying electronic interactions through controlled spacing and geometry. Multiple enzymes, each recognizing a unique recognition sequence, may be used to further extend this approach.

RESULTS AND DISCUSSION

We used the SMILing DNA approach to incorporate biotin molecules at predetermined positions for binding NPs within stretches of thousands of base pairs (*20–23*). The approach relies on the use of bacterial DNA methyltransferases known to methylate specific DNA sites using the natural cofactor *S*-adenosyl-L-methionine (AdoMet). SMILing DNA uses aziridine-modified AdoMet analogues to deliver a desired functionality in place of the methyl group. The synthetic analogue 6Baz allows the site-specific incorporation of biotin through an ∼2 nm linker composed of the opened aziridine ring (attached to the targeted position of the nucleotide) and the extended adenosyl structure with an aminobutyl group attached to the 6 position of the adenine ring (Figure 1a and Supporting Information). Binding to streptavidin (STV) was recently demonstrated after DNA biotinylation with a related aziridine cofactor giving a similar linker length (*23*). In addition, this linker length is similar to amine-reactive PEG-biotin labeling reagents commonly used for protein modification and is expected to lower steric hindrance when binding STV while negligibly affecting the positional resolution of the method. The DNA methyltransferases M.*Taq*I and M.BseCI recognize the sequences 5′-TCGA-3′ and 5′-ATCGAT-3′, respectively (the modified adenine is

underlined). Successful biotinylation of the DNA with both enzymes was verified using agarose gel analysis and showed quantitative coupling efficiency (Supporting Information).

Biotinylated binding sites were incorporated within two lengths of DNA templates to demonstrate versatility in the positioning of nanoparticles. Plasmid pBR322 was used to generate a 1017 bp DNA fragment (~346 nm) with one recognition site for M.BseCI positioned 164 and 182 nm away from the ends (SM1, Figure 1b and Supporting Information). Plasmid pUC19 was used to create a 2.4 kb fragment (~810 nm, SM2) with two internal recognition sites for M.*Taq*I positioned 160 nm inward from each end (*21*). In addition, 5′-biotinylated primers were used during the PCR amplification for SM2, yielding a total of four sites (Figure 1c). (For targeting the DNA to substrate-surface features, one would make use of unique functional groups conjugated to the primers, or their hybridization sequence, as the primers reside at the ends of the DNA template.) In each system, STV linkages were used to attach biotinylated gold nanoparticles (AuNP).

AuNP were prepared with a passivating layer for stability in buffer and for resisting nonspecific interactions with DNA by coating them with the anionic bis(*p*-sulfonatophenyl)phenylphosphine (BSP, Strem). Small numbers of biotin ligands were introduced through the use of the disulfide moiety *N*-[6-(biotinamido)hexyl]-3′-(2′-pyridyldithio)propionamide (Biotin-HPDP, Pierce), functionalizing the Au at a ratio of 1:3 biotin/NP. A low ratio was used to minimize the cross-linking of DNA when combined with STV and DNA in solution, while the anionic ligand BSP was expected to reduce nonspecific interactions.

Biotinylated SM1 DNA was incubated with a 3-fold excess of STV, combined with a 20-fold excess of biotin-AuNP and then deposited onto mica for AFM visualization (Figure 2a). A low concentration of $ZnCl_2$ (1 mM) was added for depositing the DNA onto freshly cleaved mica while minimizing the background level of free NPs. The DNA constructs in Figure 2b clearly show the central positioning of NPs (Supporting Information). The bent conformation of the construct is most likely due to the liquid flow during washing.

Anticipated uses of such NP−DNA constructs for nanoelectronics could require immobilization onto SiO_2/Si surfaces (*14, 25*). We therefore tested SiO_2/Si substrates derivatized with hexamethyldisilizane (HMDS) for the bottom-up assembly of DNA−NP structures. HMDS functionalizes the SiO_2 surface with trimethylsilyl groups, which are useful for molecular combing of double stranded DNA, a common immobilization and alignment strategy, while the hydrophobic passivation layer also limits nonspecific deposition of NPs (*14, 26, 27*). In Figure 2c, a single 13 nm biotin-AuNP is bound to the center of combed STV-SM1. The incubation with biotin-AuNP does not appear to significantly disrupt the combed DNA template. Figure 2 parts d and e present the height analyses of the 6 and 13 nm NP constructs on mica and HMDS-SiO_2/Si, respectively.

To explore metal/semiconductor heterostructure assembly, nanoparticles were deposited stepwise onto STV-SM1 templates previously combed onto HMDS-SiO_2/Si. The templates were first modified with a 13 nm biotin-AuNP (as in Figure 2c) followed by electrostatically coating the rest of the DNA with cationic 2-aminoethanethiol 3.3 nm CdSe/ZnS core/shell QD (AET-CdSe/ZnS) prepared by ligand exchange of hexadecylamine-passivated CdSe/ZnS (*28*). The anionic phosphate backbone of the DNA attracts the cationic QD similar to previous studies with positively charged AuNP and DNA (*27, 29–31*). The large difference in size between the two is evident through AFM analysis (Figure 2f) indicating successful assembly. The ability to pattern hybrid nanostructures, for example, metal, insulator, and semiconductor quantum dots (QD) onto the same

template is of interest for exploring novel plasmonic materials. For example, QD coupling with localized metal surface plasmons has been shown to occur for closely spaced metal nanoparticles near a single QD, where the characteristic optical feature of the plasmon was detected in the QD emission spectrum (*32–34*). Similar structures could be achieved using a directed-assembly approach by using a STV-functionalized QD at the central position and cationic gold nanoparticles along the DNA.

To further test the binding site integrity of the SMILing approach, STV-SM1 was combed onto the HMDS-Si/SiO_2 surface and nonspecifically coated with cationic thiocholine 3.5 nm AuNP (tcAuNP) (*27*). This was followed by a back-filling at the central STV with a 13 nm biotin-AuNP (Figure 2g). Apparently, the initial electrostatic NP coating step does not affect the biotin binding capability of STV-SM1 nor significantly affect the specificity of the interaction. Because of the large size difference of the particles, it is clear that biotin-AuNP binds only at the center of the template.

We also tested the ability for STV-AuNP to bind to the biotin site within combed DNA, as a variation of stepwise assembly. Here, 6 nm STV-functionalized AuNP binds to biotin-SM1, which had been deposited on SiO_2 by combing. This scheme and resultant structure are presented in Figures S1 and S2 (Supporting Information). We conclude that the spacer connecting the biotin to the DNA base is indeed sufficient for attachment of STV postcombing. Metal nanowires with a height of ~20 nm were grown from these templates using a tcAuNP coating as a seed layer (Figure S3, Supporting Information) (*10, 27*).

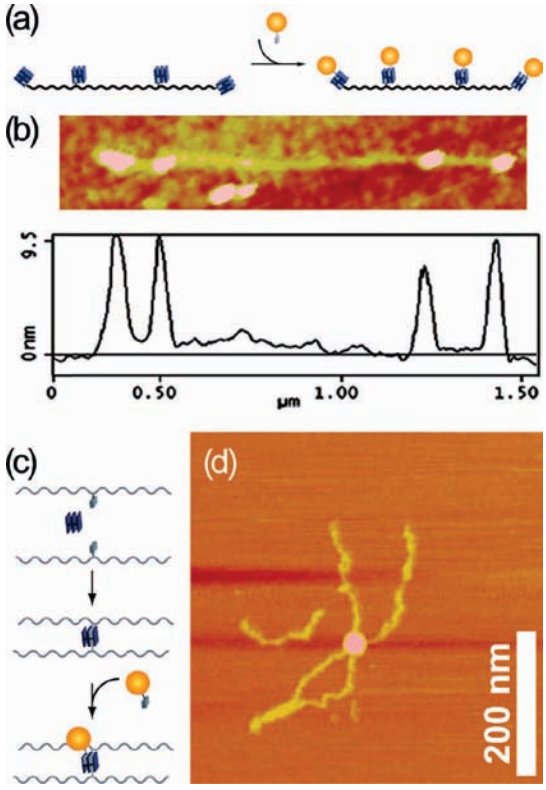

Figure 3. (a) Scheme for SM2 templating of AuNP. (b) AFM image and cross-section of SM2 bound with four 6 nm biotin-AuNP, taken along the structure axis. Two sites obtained by enzymatic biotinylation are internal, and two sites are external 5′ biotins from the synthetic primers. (c) Four-way junction scheme using STV with central AuNP. (d) Junction decorated with 6 nm biotin-AuNP on mica.

We could not discern a central gap by AFM, although this may be due to tip resolution limits (∼10–20 nm tip radius). We note that TEM imaging has previously been used to show that STV masking of reductively grown NP seeds is possible on a DNA template, and such analysis is underway (*10*).

A DNA template with two internally positioned biotins and biotins at the ends was generated by enzymatic SMILing modification of a PCR product created with biotinylated primers (SM2). This 810 nm construct was designed with recognition sites 160 nm inward from each end. Templates were incubated with excess STV and combed onto HMDS/Si/SiO_2, and then reacted with 6 nm biotin-AuNP. Figure 3b shows AFM height and cross-section analysis of a complete construct, while Figure S4 (Supporting Information) shows an example of a defect structure bound with only one AuNP (Supporting Information). The template appears stretched due to combing (*35*), as the overall length is ∼1075 nm compared to the theoretical 810 nm. The stretched center-to-center distance between the right two particles is measured at 195 nm rather than 160 nm (∼120% of theoretical), which is consistent with an overall DNA stretching of ∼130%.

Formation of intricate nanostructures through molecular lithography is likely to require interconnecting junctions (*14*,*36*,*37*). Using the SMILing DNA approach, novel four-way junctions can be created using STV (*24*). SM1 and STV combined at a molar ratio of 1:1 was used to form four-way junctions. A single NP was positioned at the junction by incubation with biotinylated 6 nm AuNP (Figure 3d). This template could be envisioned as an electronic junction if the DNA arms are directed to bind to separate surface electrodes, metallized, and a functional nanomaterial (e.g., semiconductor) attached at the central streptavidin (*10*, *36*).

In summary, we have demonstrated a new method for controlling the placement of nanoparticles onto DNA scaffolds. This enzymatic approach may be extended to position NPs onto biological or synthetic DNA constructs. More complex DNA constructs may be designed by using multiple enzymes, each recognizing a unique recognition sequence and delivering one of a variety of chemical groups through synthetic cofactors. As such, this approach shows promise for directing the assembly of a variety of nanomaterials into organized structures with applications including nanoelectronics, biosensors, plasmon wave guides, and SERS-active materials.

ACKNOWLEDGMENT

This work was supported by a grant from the Institute for Collaborative Biotechnologies (DAAD19-03-D-0004, U.S. Army Research Office (Reich) and NIH (5RO1EB000832). This work made use of MRL Central Facilities supported by the MRSEC Program of the National Science Foundation under award No. DMR00-80034. We thank Kerstin Glensk for performing the SMILing reactions and Professor Michaelis Kokkinidis for supplying M.BseCI. We also thank Daniel Neuman for providing hexadecylamine-CdSe/ZnS.

Semisynthetic Analogues of PSC-RANTES, a Potent Anti-HIV Protein

Hubert Gaertner, Robin Offord,[†] Paolo Botti,[‡] Gabriel Kuenzi, and Oliver Hartley*

Department of Structural Biology and Bioinformatics, Centre Médical Universitaire, 1 rue Michel Servet, 1211 Geneva 4, Switzerland. Received August 13, 2007; Revised Manuscript Received October 8, 2007

New HIV prevention methods are needed, and among those currently being explored are "microbicides", substances applied topically to prevent HIV acquisition during sexual intercourse. The chemokine analogue PSC-RANTES (N^{α}(*n*-nonanoyl)-*des*-Ser^{1}-[L-thioprolyl^{2}, L-cyclohexylglycyl^{3}]-RANTES(4–68)) is a highly potent HIV entry inhibitor which has shown promising efficacy in its initial evaluation as a candidate microbicide. However, a way must be found to produce the molecule by cheaper means than total chemical synthesis. Since the only noncoded structures are located at the N-terminus, a possible solution would be to produce a protein fragment representing all but the N-terminal region using low-cost recombinant production methods and then to attach, site specifically, a short synthetic fragment containing the noncoded N-terminal structures. Here, we describe the evaluation of a range of different conjugation chemistries in order to identify those with potential for development as economical routes to production of a PSC-RANTES analogue with antiviral activity as close as possible to that of the parent protein. The strategies tested involved linkage through oxime, hydrazone/hydrazide, and $\Psi[CH_2-NH]$ bonds, as well as through a peptide bond obtained either by a thiazolidine rearrangement or by direct α-amino acylation of a protein fragment in which 4 of the 5 lysine residues of the native sequence were replaced by arginine (the fifth lysine is essential for activity). Where conjugation involved replacement of one or more residues with a linker moiety, the point in the main chain at which the linker was introduced was varied. The resulting panel of 22 PSC-RANTES analogues was evaluated for anti-HIV activity in an entry inhibition assay. The [Arg^{25,45,56,57}] PSC-RANTES analogue has comparable potency to PSC-RANTES, and one of the oxime linked analogues, 4L-57, has potency only 5-fold lower, with scope for improvement. Both represent promising leads for development as microbicide compounds that could be produced at low cost via semisynthesis.

INTRODUCTION

New prevention methods are urgently required to combat the HIV/AIDS pandemic, which is currently running at a rate of approximately 5 million new infections per year (*1*). One of the strategies currently being developed relates to the use of "microbicides"—antiviral products that can be applied topically to genital mucosa prior to sexual intercourse, thereby preventing HIV transmission from person to person (*2*).

PSC-RANTES (*3*) is a chemokine analogue that has shown promising efficacy in preclinical studies related to its use as a microbicide (*4*). In its totally synthetic form, however, PSC-RANTES is likely to be impossibly expensive for worldwide use (*5*). Since the non-natural structures in PSC-RANTES are all located within an N-terminal pharmacophore, semisynthetic strategies could be envisaged in which a protein fragment representing all but the N-terminus of the sequence is produced by low-cost microbial fermentation, followed by site-specific conjugation of a short synthetic peptide containing the N-terminal pharmacophore.

One strategy to produce PSC-RANTES semisynthetically would involve the use of native chemical ligation (*6*) between a protein fragment beginning at Cys^{10} and an N-terminal fragment with a C-terminal thioester that contains the noncoded pharmacophore. We chose not to consider this route, however, since it would involve the production of a long and relatively expensive thioester peptide, as well as a folding step (formation of disulfide bridges) after the ligation. Instead, we chose to focus on approaches involving conjugation conditions that are compatible with the presence of the native disulfide bonds in the protein fragment and which could be adapted to the use of shorter, less expensive synthetic N-terminal fragments. Hence, the first set of strategies we envisaged involved the formation of oxime, hydrazone/hydrazide, and $\Psi[CH_2-NH]$ bonds. These require N-terminal Ser or Thr residues to be engineered into the protein fragment (see linker-based strategy in Figure 1). With N-terminal Ser or Thr, periodate oxidation of the amino alcohol to a glyoxylic acid residue, O=CH—CO-, allows the specific conjugation to an aminooxy- or hydrazide-functionalized peptide through the formation of an oxime or hydrazone bond. In an another linker strategy, reductive amination under slightly acidic conditions was used to conjugate the short synthetic N-terminal peptide fragment functionalized with an aminoacetaldehyde moiety to the protein fragment. This approach, though less specific because it is only based on the difference of reactivity between α- and ε-amine groups toward aldehydes, has the advantage of generating the shortest linker—involving the substitution of only one amino acid residue—but the disadvantage of introducing a positively charged group into the protein backbone (Scheme 1). All of the linker-based strategies lead to modification to both the backbone and the side chains of the

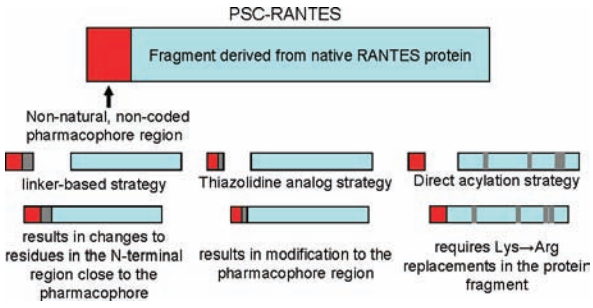

Figure 1. Schematic representation of the semisynthetic strategies used in this study. PSC-RANTES (upper panel) can be considered to consist of a protein fragment derived from native RANTES (cyan), and which could be produced cheaply by biosynthesis, to which a short, synthetic N-terminal pharmacophore region containing non-natural, noncoded structures (red) is joined. All three of the semisynthesis strategies we evaluated in this study necessitate the introduction of modifications (indicated in gray) to the PSC-RANTES protein.

protein at the linkage site, and some of them also change the register of the backbone by adding atoms (Scheme 1). Hence, we opted to create panels of analogues for each linkage type, varying the site at which the linkage was introduced (Table 1).

Yet another possible strategy requires the protein fragment to have N-terminal cysteine. The resulting 1-amino, 2-thiol structure at the N-terminus can be specifically conjugated to a glycolaldehyde-functionalized ester of the short synthetic N-terminal fragment through formation of a thiazolidine, which can be further rearranged to a 2-hydroxymethyl-thioproline with the generation of an authentic peptide bond (Scheme 2). The drawback here is that the structure of the pharmacophore unit of PSC-RANTES cannot be precisely reproduced (see thiazolidine analogue strategy in Figure 1).

Our last strategy involved direct acylation of the amino terminus of protein fragments in which either four or five of the five lysine residues present in native RANTES had been replaced by arginine (see direct acylation strategy in Figure 1). This approach has the advantage of generating a natural peptide bond at the linker site but the disadvantage of changing structures elsewhere in the protein that may be important for activity.

The PSC-RANTES analogues from the different groups were evaluated for their anti-HIV activity. We discuss the results obtained with regard to structure–activity relationships at the anti-HIV pharmacophore of PSC-RANTES and suggest that two of the above strategies have potential for development as economic routes to production of semisynthetic PSC-RANTES analogues that could be effective microbicides.

EXPERIMENTAL PROCEDURES

Reagents and Chemicals. Unless otherwise specified, all solvents and reagents were obtained from Fluka (Buchs, Switzerland), were of analytical or higher grade, and were used without further purification. All amino acids were purchased from Orpegen (Heidelberg, Germany). The resins were from NeoMPS (Strasbourg, France) or Bachem (Bubendorf, Switzerland). Water was repurified using a Milli-Q system (Millipore, Inc., Bedford, MA).

HPLC. Analytical RP-HPLC (reverse-phase high-performance liquid chromatography) was performed using a column 250 × 4 mm i.d. packed with Nucleosil 300-A, 5 μm C8 particles. The flow rate was 0.7 mL/min, and effluent was monitored at 214 nm. Peptides were purified on a C8 semi-preparative column (250 × 10 mm i.d. Nucleosil 300-A, 5 μm particle size) at a flow rate of 4 mL/min monitored at 214 nm, or purified on a Vydac C8 preparative column (250 × 22 mm i.d., 10 μm particle size) at 15 mL/min monitored at 214 nm. Solvents used in RP-HPLC were as follows: A, 0.1% TFA (1 g TFA in 1 L H_2O); B, 0.1% TFA in 90% acetonitrile (1 g of TFA mixed with 100 mL of H_2O and then brought to 1 L with acetonitrile). Generally, the conditions used in analytical work were 2 min isocratic at 20% B followed by a linear gradient to 65% B over 45 min. In preparative work, a linear gradient (usually of the same slope) was used after 2 min at initial conditions. All peptide components were collected manually at the detector exit, evaporated at room temperature under reduced pressure, frozen, and then recovered by lyophilization.

Mass Spectrometry. Electrospray ionization mass spectrometry (ESI-MS) was performed in positive ion mode on a Platform-II instrument (Micromass, Manchester, England). Samples were introduced at 10 μL/min in solvent acetonitrile/water/formic acid (49.9:49.9:0.2). MALDI-TOF mass spectrometry was performed in linear mode using sinapinic acid as the matrix on a Voyager Elite machine (Applied Biosystems, Foster City, CA) equipped with delayed extraction. External calibration was performed on the electrospray machines using a solution of horse heart apomyoglobin and on the MALDI-TOF machine using the mixture of peptides supplied by the manufacturer.

Synthesis of RANTES Fragments. Although the route to bulk manufacture of the larger RANTES fragments would ultimately be biosynthesis, for exploratory experimental purposes it was more rapid and convenient to prepare them by total chemical synthesis. The two proteins and ten protein fragments described in Table S1 of the Supporting Information were prepared by polymer-supported organic synthesis of the two segments that would have been formed if they had been cleaved between residues 33 and 34. *t*-Butoxycarbonyl chemistry was used, as described in ref (*7*). The segments were coupled in a native chemical ligation (*6*). Folding of the resulting molecule with concomitant disulfide formation was carried out in the presence of a Cys-SH/$(Cys\text{-}S)_2$ redox couple except for [Cys^2]-RANTES(2-68), where conjugation to the N-terminal peptide fragment was performed before the folding step. Purity and integrity of the resulting analogues were routinely verified by HPLC and mass spectrometry.

Synthesis of *n*-Nonanoyl Peptides. The short N-terminal synthetic fragments that contain the pharmacophore all possess an N-terminal *n*-nonanoyl group as in PSC-RANTES (Scheme 1). These *n*-nonanoyl peptides were synthesized as described in ref (*8*). Crude material obtained after ether precipitation (following HF resin cleavage) was used without HPLC purification for further C-terminal functionalization. For synthesis of *n*-nonanoyl-PrS-Chg-Ser-Ser-Asp^6, Boc-Asp(OPse)-OH was used to maintain side-chain protection during further C-terminal modification of the peptide. Because of difficulties with the deprotection, this peptide was also synthesized using Fmoc chemistry, using 2-chlorotrityl chloride resin and cleaving the fully protected peptide with acetic acid/trifluoroethanol/dichloromethane (2:2:6) for 2 h.

Synthesis of Heterobifunctional Spacer Reagents Containing Aminooxy Groups (Scheme 3). *I. 2-(Boc-aminooxy)ethylamine (III). N-[2-(Tert-butyl-N-hydroxycarbamoyl)ethyl]phthalimide (I).* Conditions of synthesis are similar to those described in ref (*9*). *tert*-Butyl *N*-hydroxycarbamate (1.32 g, 10 mmol) was dissolved in anhydrous DMF (7 mL), NaH (380 mg, 60% dispersion in mineral oil, 9.5 mmol) was added at room temperature, and the mixture stirred for 1 h, then cooled to 0 °C, treated with 2-bromoethylphthalimide (2.03 g, 8 mmol) for 2 h at 0 °C, and then left at room temperature overnight. The material was precipitated in cold water (100 mL) and the precipitate redissolved in EtOAc. The organic layer was

successively washed with a saturated NaCl solution and then water. The crude product (**I**) was dried over $MgSO_4$ and solvent removed. Yield 1.3 g (53%).

N-[2-(tert-butyl-N-hydroxycarbamoyl)ethyl]amine (III). A mixture of 1.1 g of *N*-[2-(*tert*-butyl-*N*-hydroxycarbamoyl)ethyl]phthalimide (**I**) and 1.4 mL hydrazine hydrate in 20 mL ethanol was refluxed overnight at 90 °C. The solution was cooled, and the precipitated phthalyl hydrazide was separated by centrifugation. The supernatant was diluted with water and acidified with 10% TFA. A further precipitate was separated by centrifugation and the deprotected material isolated from the supernatant by preparative HPLC (yield 215 mg, 0.75 mmol, 21%), showing the expected mass (ESI-MS M + H found 177.2, theor. M + H 177.0).

II. 4-(Boc-aminooxy)butylamine (IV). The same protocol was used starting from *tert*-butyl *N*-hydroxycarbamate (400 mg, 3 mmol), NaH (114 mg, 2.85 mmol), and 4-bromobutylphthalimide (675 mg, 2.4 mmol). The recovered *N*-[4-(*tert*-butyl-*N*-hydroxycarbamoyl)butyl]phthalimide (**II**) (630 mg, 1.7 mmol, 70%) was treated with a 2-fold molar excess of hydrazine

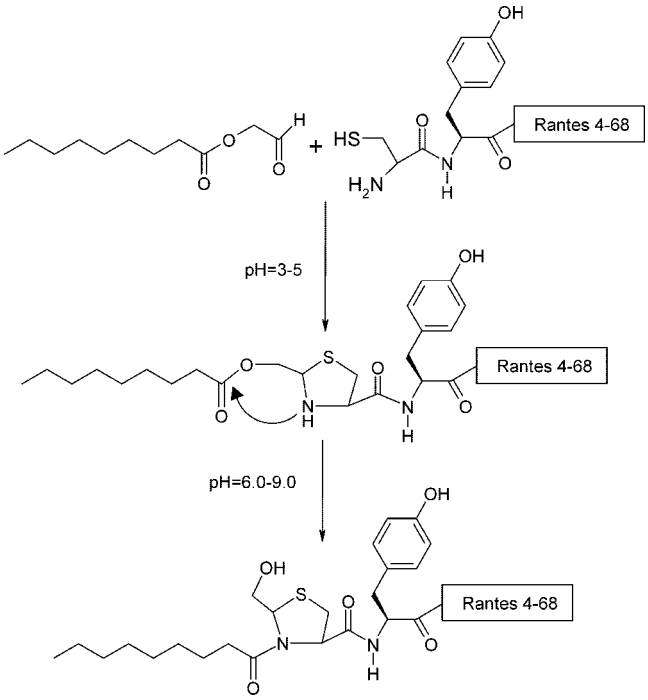
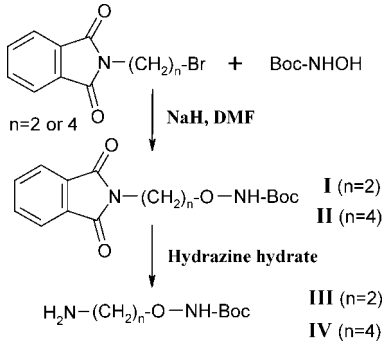


Scheme 3. Synthesis of Heterobifunctional Spacer Reagents Containing Aminooxy Groups



hydrate to afford, after isolation and HPLC purification as above, an oily product (**IV**) (105 mg, 0.33 mmol, 19%) with the expected mass (ESI-MS M + H found 204.8, theor. M + H 205.0).

Synthesis of Aminooxy-Functionalized n-Nonanoyl Peptides. Coupling of the 2- and 4-Carbon Linkers to the C-Termini of the n-Nonanoyl Peptides. *n*-Nonanoyl peptide (25 μmol) was dissolved in 50 μL DMF and mixed with equimolar amounts of solid NHS and diisopropylcarbodiimide. A 3-fold molar excess of Boc-aminooxy-linker (**III** or **IV**) was dissolved in 50 μL DMF and added to the *n*-nonanoyl peptide solution, and diisopropylethylamine, equivalent to a 4-fold molar excess over *n*-nonanoyl peptide, was added to the reaction mixture which was then incubated overnight at room temperature. The mixture was then acidified with 10 μL acetic acid and the conjugation product isolated by preparative HPLC using a gradient of 30−70% B over 40 min. In the case of *n*-nonanoyl-PrS-Chg-Ser-Ser-Asp(OPse)-OH, the (OPse) protecting group was removed afterward by 2 h treatment at 37 °C in 3 mL of 0.1 M $NaHCO_3$, 10% α-mercaptoethanol, 40%CH_3CN, pH 9.0 (*10*). The lyophilized material was deprotected by a 5 min treatment in 1 mL neat TFA. The TFA was evaporated under N_2, the material redissolved in CH_3CN/water and freeze-dried.

Synthesis of Hydrazide-Functionalized *n*-Nonanoyl Peptides. These were made manually at the 0.1 mmol scale according to standard techniques of Fmoc peptide chemistry (*11*) starting with 2-methoxy-4-alkoxybenzyloxycarbonyl hydrazide resin (Bachem, Switzerland). The *n*-nonanoyl peptides were deprotected and cleaved from the resin by vortexing with 1.5 mL of a mixture consisting of TFA (95%), 2.5% H_2O, and 2.5% triisopropylsilane (v/v) for 1 h at room temperature and filtered to remove resin. The solution was evaporated under N_2, and the oily material taken up in CH_3CN−water and lyophilized. The resulting *n*-nonanoyl peptides could be used in the conjugation reaction without any further purification.

Synthesis of Aldehyde-Functionalized Reagents and *n*-Nonanoyl Peptides. *n*-Nonanoyl-2,2′-dimethoxyethyl ester was prepared by reaction of *n*-nonanoic acid cesium salt with bromoacetaldehyde dimethylacetal in dimethylformamide (DMF) at 60 °C for 48 h (*12*). *n*-Nonanoyl peptide (25 μmol) dissolved in 200 μL DMF was mixed with a 5-fold excess of aminoacetaldehyde diethylacetal and an equimolar amount of (benzotriazol-1-yloxy)tripyrrolidinophosphonium hexafluorophosphate (PyBOP) reagent. The solution was incubated for 3 h at room temperature, acidified, and the conjugation product isolated by preparative HPLC using a gradient of 30–70% B over 40 min. The acetal group was cleaved by a 5 min treatment in 1 mL neat TFA. The TFA was evaporated under N_2, the *n*-nonanoyl glycoaldehyde ester was redissolved in CH_3CN/ water, freeze-dried, and used immediately for the conjugation step. In the case of the aldehyde derivative of the fully protected peptide, *n*-nonanoyl-PrS-Chg-Ser(tBu)-Ser(tBu)-Asp(OtBu), the protecting groups were removed all at once by a 1 h treatment in neat TFA.

Conjugation through Oxime and Hydrazone Bonds. The truncated proteins with N-terminal serine residues were dissolved in water at 2 mg/mL, mixed with an equal volume of 2% (w/v) NH_4HCO_3 buffer, containing 40 mM methionine, pH 8.3, and oxidized in the presence of a 20-fold excess of sodium metaperiodate. After 10 min incubation in the dark, the reaction was quenched by the addition of a 10 000-fold excess of ethylene glycol. The oxidized protein was retained on a Sep-Pack cartridge, eluted with 80% CH_3CN in 0.1% TFA, and freeze-dried. The protein was redissolved (4 mg/mL) in a 0.1 M acetate (Na) buffer containing 20 mM methionine, 40% CH_3CN, apparent pH 4.6, and either a 2-fold excess of aminooxy-functionalized *n*-nonanoyl peptide or a 6-fold excess of hydrazide-functionalized *n*-nonanoyl peptide was added, dissolved in the same buffer at a concentration of 4 mg/mL. After overnight incubation, the conjugation product was isolated by semipreparative HPLC, using a 1 × 25 cm Macherey-Nagel column at 4 mL/min. In the case of hydrazone conjugates, the hydrazone bond could be reduced by incubation of the recovered and lyophilized material in 400 μL of 0.4 M $NaBH_3CN$ in the same buffer as used previously for 4 days in the dark (*13*), before HPLC purification.

Conjugation through a Thiazolidine Analogue. Unfolded [Cys^2]RANTES(2-68) was dissolved in 0.1 M sodium phosphate, 6 M GnCl, pH 6.0, to a concentration of approximately 5 mg/mL, a 50 molar excess of freshly TFA-deprotected *n*-nonanoyl glycolaldehyde ester was added and the pH readjusted to 5.0. After a 1 h incubation, the conjugation product was isolated by preparative HPLC and freeze-dried. The thiazolidine conjugate was then redissolved in 0.1 M sodium phosphate, 6 M GnCl, pH 7.5, at 4 mg/mL and the solution incubated for 4 days at 37 °C, with daily readjustment of the pH to 7.5. The solution was acidified to pH 3.0 and further incubated with 5 mg tris(2-carboxyethyl)phosphine for 1 h, before isolation of the rearranged thiazolidine analogue by

semipreparative HPLC. The material was then refolded under the same conditions as given above.

Conjugation through a Methylene Amino, Ψ[CH_2−NH] Bond. Truncated RANTES (2 mg/mL in water) was reacted at a molar ratio of 1:10 with 5 mg/mL solution freshly deprotected *n*-nonanoyl aminoacetaldehyde peptide in 80% acetonitrile and mixed with an equal volume of 0.2 M acetate(Na) buffer containing 50% acetonitrile, pH 5.2. The reaction took place at room temperature for 15 h. Sodium cyanoborohydride (1 M) dissolved in the same buffer was added to the reaction to a final cyanoborohydride concentration of 0.3 M. The reaction medium was further incubated at room temperature for at least 6 h before isolation of the conjugation product by semipreparative HPLC.

Conjugation via N-Terminal Acylation of Protein Fragments in Which Lysine Residues Had Been Replaced by Arginines. The complementary short N-terminal peptide, *n*-nonanoyl-PrS-Chg, was activated with NHS by a 1 h incubation with equimolar amounts of HO-Su and EDC in DMSO. The modified protein fragment, [$Arg^{25,45,56,57}$] RANTES-(4–68) (see Table S1 in the Supporting Information), was dissolved in 0.1 M MES buffer containing 50% DMSO, apparent pH 5.5, to a concentration of approximately 4 mg/mL, a 20 molar excess of freshly activated peptide was added, and the solution stirred over 15 h. The solution was then acidified with acetic acid, diluted 10-fold with water, and the conjugation product isolated by semipreparative HPLC using a 1 × 25 cm Macherey-Nagel column at 4 mL/min.

HIV Entry Inhibition Assay. Envelope-mediated cell fusion assays were carried out as described in ref (*14*) with HeLa-P5L (*15*) and HeLa-Env-ADA (*16*) cell lines. Experiments were performed in triplicate, and dose-inhibition curves were fitted by using *Prism* software (GraphPad, CA).

RESULTS

Production of Oxime Analogues. Construction of the oxime analogues was driven by the idea of synthesizing the shortest possible stable linker, functionalized with an amine and an aminooxy group. Our initial strategy involved using a one-carbon linker, which would have entailed the replacement of only two residues and would have kept the backbone of the semisynthetic protein in register with that of PSC-RANTES (Scheme 1). However, these compounds proved inaccessible due to their high instability (data not shown), and it was therefore necessary to investigate linkers with two or more carbon atoms. As shown in Scheme 1, incorporation of a two- or four-carbon linker results in the replacement of two or three residues, respectively. While the two-carbon linker has the advantage of substituting one less residue that the four-carbon linker, it has the disadvantage of introducing a one-atom shift, relative to PSC-RANTES, of the register of the backbone of the N-terminal region of the semisynthetic protein (Scheme 1). Since it is likely that linker position will influence the biological activity of the resulting protein, we opted to generate a panel of analogues for each linker, moving the site of the linker within the N-terminal region of the protein. The nomenclature used for this series of analogues was 2L-*x*,*y* for the two-carbon linker and 4L-*x*,*y* for the four-carbon linker, with *x* and *y* denoting the positions of the first and last substituted residue (Table 1).

We chose to produce the aminooxy-functionalized *n*-nonanoyl peptides through reaction of N-(bromoalkyl)phthalimides with *tert*-butyl *N*-hydroxycarbamates. A 2-fold excess of aminooxy-functionalized peptide was sufficient to drive the conjugation reaction to completion. All intermediates in the construction of the different conjugates were characterized by mass spectrometry and described in Table S1 in the Supporting Information.

Production of Hydrazone and Hydrazide Analogues. We used 2-methoxy-4-alkoxybenzyloxycarbonyl-hydrazide resin to produce a range of *n*-nonanoyl peptides hydrazide-functionalized with a two-carbon linker. These could be reacted with N-terminal Ser or Thr protein fragments that had been oxidized with periodate to generate a range of hydrazone-linked PSC-RANTES analogues. Reduction of the hydrazone bond with $NaBH_3CN$ gave us easy access to the corresponding methyl hydrazine linked analogues, which allow more backbone flexibility at the linkage site. The nomenclature used for this group of compounds is 4L-*x*,*y*H for the hydrazone analogues and 4L-*x*,*y*HR for the reduced methyl hydrazine analogues, with *x* and *y* denoting the positions of the first and last substituted residue (Table 1).

Production of Ψ[CH_2−NH] Analogues. Reductive amination, in which an aldehyde reacts with the N-terminal α-amino group of a target protein in the presence of sodium cyanoborohydride as a reducing agent, has been recently explored as a route to selectively modify proteins at the α-amino group without protecting the ϵ-amino groups on lysine residues (*17*–*19*). This approach is less restrictive than other established semisynthetic strategies, since it does not require the presence of an N-terminal residue such as Ser, Thr, or Cys. Under only slightly acidic conditions, the α-amino group (pK_a in the region of 8) is deprotonated to a significantly greater extent than the ϵ-amino groups of lysine residues (pK_a in the region of 10). Reaction of a peptide aldehyde with the α-amino group results in the replacement of one residue in the peptide chain by an aminoethylene moiety (Scheme 2).

We opted to test this conjugation approach using the same group of protein fragments that was used to generate the oxime and hydrazone analogues, together with a corresponding group of aminoacetaldehyde-conjugated *n*-nonanoyl peptides. The nomenclature used for this series of analogues was 1L-*x*, with *x* and *y* denoting the positions of the substituted residues (Table 1). It was necessary to change the strategy for the functionalization of one of the *n*-nonanoyl peptides, namely, *n*-nonanoyl-PrS-Chg-Ser-Ser-Asp(OPse)-OH, since the Asp deprotection step carried out under basic conditions resulted in an almost quantitative dehydration of the compound with the formation of an aspartimide. While we opted to retain the *n*-nonanoyl peptide carrying the aspartimide modification and use it to produce an extra analogue (1L-7 *des*, Table 1), it was possible to obtain the desired Asp analogue by using the orthogonal (OtBu) protecting group for the Asp side chain, with the fully protected peptide being cleaved from the 2-chlorotrityl chloride resin with acetic acid.

Not unexpectedly, given the limited selectivity of the approach, each conjugation reaction gave rise to detectable overreaction products resulting from the conjugation of the aminoacetaldehyde-functionalized *n*-nonanoyl peptides with the ϵ-amino groups of the protein (Figure 2).

Production of Thiazolidine Analogues. Proteins carrying an N-terminal cysteine residue can be site-specifically modified at the N-terminus with an aldehyde under acidic conditions (*20*), and the use of a glycolaldehyde ester opens the way to a rearrangement that regenerates a true peptide bond (*21*), although both the condensation and rearranged products give a mixture of two diastereoisomers due to the creation of a new asymmetric carbon at position 2 of the thiazolidine ring. We chose to use this approach to generate two PSC-RANTES analogues. First, conjugation of an *n*-nonanoyl glycolaldehyde ester to [Cys^2]-RANTES(2-68) generates as the final product N^{α}*n*-nonanoyl-[2-hydroxymethythiazolidine^2]RANTES(2-68), an analogue very similar in structure to N^{α}(*n*-nonanoyl)-RANTES(2-68), the molecule known as NNY-RANTES. This was a lead compound, already quite potent in itself, identified during the development of PSC-RANTES (*3*). Second, since the technology developed by the group of Schultz (*22*) enables a single noncoded amino

Peak 1, [Asp^6]RANTES(6-68); Peak 2, the formed conjugate, *n*-nonanoyl-PrS-Chg-Ser^4-NH-CH_2-CH_2-RANTES(6-68); Peak 3, excess *n*-nonanoyl-PrS-Chg-Ser^4-NH-CH_2-CHO; Peak 4, the overreaction bisubstituted conjugate.

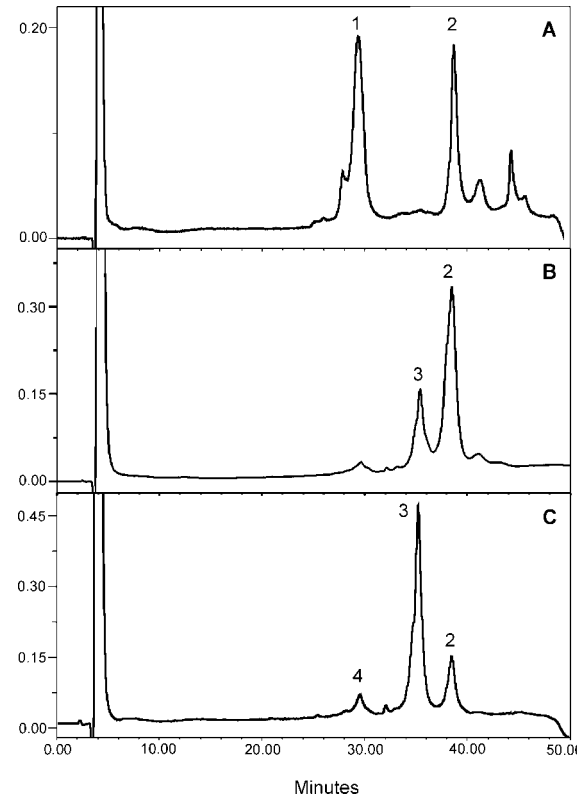


Figure 3. Progress in the construction of *n*-nonanoyl-HMThiaz^2-Chg^3-RANTES(4-68). (A) Reaction of [Cys^2, Chg^3]RANTES(2-68) with *n*-nonanoyl glycolaldehyde ester after 45 min incubation at pH.5.0. (B,C) The O to N acyl transfer at pH 7.5 after 1 and 4 days incubation at 37 °C, respectively. Peak 1, [Cys^2, Chg^3]RANTES(2-68); Peak 2, the thiazolidine conjugate; Peak 3, the O,N acyl rearranged conjugate; Peak 4, the hydrolyzed condensation product [HMThiaz^2, Chg^3]RANTES(2-68).

acid to be site-specifically incorporated into recombinant proteins and works particularly well with aromatic or cyclic residues, we opted to perform the same reaction on [Cys^2, Chg^3]RANTES(2-68), in order to produce the analogue N^{α}(*n*-nonanoyl)-[2-hydroxymethylthazolidide^2, Chg^3]RANTES(2-68), an analogue for which the only structural difference relative to PSC-RANTES is a hydroxymethyl side chain (present in two diastereisomeric forms) on the carbon at position 2 of the thiazolidine ring. If the latter analogue were found to have useful biological properties, the methods of Schultz and co-workers could presumably be adapted to the production of the [Cys^2, Chg^3]RANTES(2-68) as a totally recombinant molecule, onto which, as we have just seen, the *n*-nonanoyl 2-hydroxymethythazoline moiety could be introduced with total site specificity.

For the purposes of this part of the study, the folding of the protein with concomitant formation of disulfide bridges was performed after conjugation of the peptide to enable us to avoid the need to develop the new folding conditions for totally synthetic protein fragments carrying an N-terminal cysteine residue. For both conjugation reactions, incubation with a 50-fold excess of the *n*-nonanoyl glycolaldehyde ester resulted in an HPLC shift of the protein of more than 8 min, as shown in Figure 3A for the [Cys^2, Chg^3]RANTES(2-68). The isolated thiazolidine ester derivatives were resolubilized in a sodium phosphate buffer pH 7.5 to allow O to N acyl rearrangement, as previously described (*21*). This reaction was stopped after 4 days of incubation (Figure 3C), since no improvement could be observed over a longer period of time (data not shown). The incomplete reaction may be related to the presence of contaminating *n*-nonanoyl glycolaldehyde ester, which is difficult to detect and totally eliminate after the first reaction step due to its very low optical absorbance, and which would be highly reactive with the protein's ϵ-amino groups under the more basic conditions of the second reaction. Starting with 15 mg unfolded protein, 5 mg of condensation product were isolated, which finally gave 1 mg of the rearranged compound.

Anti-HIV Activity of PSC-RANTES Analogues. The anti-HIV activity of the full set of PSC-RANTES analogues, together with reference compounds AOP-RANTES, NNY-RANTES, and PSC-RANTES, was determined in a series of cell fusion assays. Each compound was assayed in at least four independent experiments, with PSC-RANTES used as an internal standard in each experiment. Results are shown in Figure 5. The measured potency of PSC-RANTES across the total of 41 independent assays (mean IC_{50} value of 24 pM) is in agreement with previously published values (*3*), as are those for AOP-RANTES and NNY-RANTES (mean IC_{50} values of 0.96 nM and 190 pM, respectively).

Oxime-Based Analogues. In general, the oxime-based analogues with two-carbon linkers were less potent than the corresponding analogues with four-carbon linkers (both 2L-45 and 2L-56 are less potent than 4L-46; both 2L-56 and 2L-67 are less potent than 4L-57; both 2L-67 and 2L-78 are less potent than 4L-68). While a number of the analogues in this series show anti-HIV activity that compares well to the earlier lead molecules, AOP-RANTES and NNY-RANTES, the best analogue in this series, 4L-57 (IC_{50} value of 130 pM), is still approximately 5-fold less potent than PSC-RANTES.

Hydrazone/Methyl Hydrazine-Based Analogues. Each of the hydrazone analogues showed comparable (4L-46H) or lower

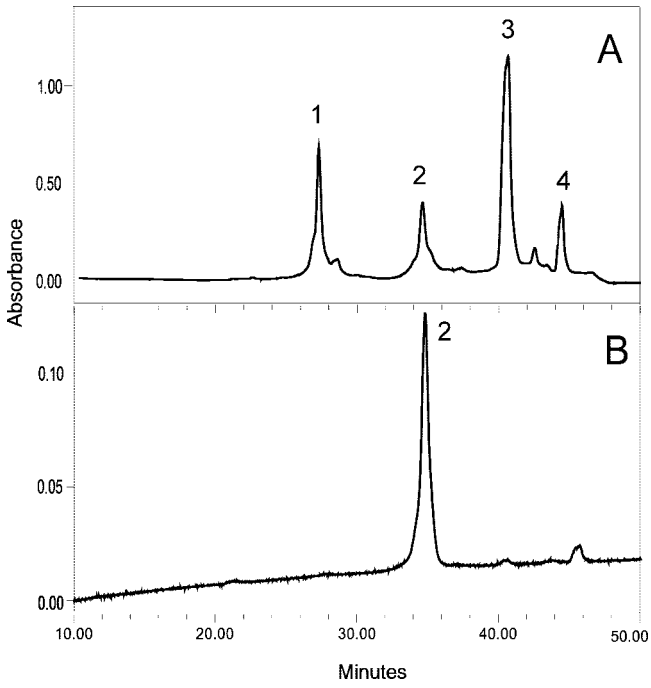

Figure 4. Production of PSC-RANTES[$Arg^{25,45,56,57}$] via direct acylation of [$Arg^{25,45,56,57}$]RANTES(4-68) with *n*-nonanoyl-PrS-Chg. Analytical HPLC of the reaction medium after 15 h incubation at room temperature (A) and after isolation of the conjugation product (B). Peak 1, unreacted [$Arg^{25,45,56,57}$]RANTES(4-68); Peak 2, PSC-RANTES[$Arg^{25,45,56,57}$]; Peak 3, excess *n*-nonanoyl-PrS-Chg. Peak 4 is presumed to be the product of over-reaction, with acylation of both the α- and ϵ-amino groups of the protein fragment.

activity (4L-57H, 4L-68H) to the corresponding four-carbon linker oxime analogues. Reduction to methyl hydrazide did not affect the activity of two of the analogues (4L-57HR, 4L68HR), but strongly reduced the activity of a third (4L-46HR).

Ψ[CH_2−NH] Analogues. The use of the reductive amination approach gave us access to a one-carbon linker strategy, which has the advantages of retaining backbone register while requiring replacement of only one residue. Interestingly, this strategy provided little advantage over the four-carbon linker oxime approach, which also retained backbone register but necessitated the replacement of three residues. While 1L-4 shows slightly higher potency than 4L-46, 1L-5 was less potent than any of the 4L oxime compounds, 1L-6 showed lower potency than 4L-57, and 1L-7 showed lower potency than both 4L-57 and 4L-68.

Thiazolidine Analogues. The protein N^{α}(*n*-nonanoyl)-[HMThiaz^2]RANTES(2-68) shows considerable anti-HIV activity (IC_{50} value of 120 pM), a value comparable to that of our earlier lead compound, NNY-RANTES, to which it has a strong structural resemblance (see Discussion section). When in addition to the substitution of 2-hydroxymethyl thiazolidine for Pro^2 we replaced Tyr^3 by cyclohexylglycine, the potency of the new analogue was less (IC_{50} value of 0.98 nM) by an approximately 40-fold reduction compared to the lead compound PSC-RANTES in spite of the close structural resemblance of the two proteins.

"All-Arg" Analogues. If the protein fragment were to contain no lysine residues, acylation by the short N-terminal fragment would be totally site-specific onto the α-amino group of the protein fragment. This could be achieved by replacing all the lysine residues in the native sequence of the protein fragment (positions 25, 33, 45, 56, and 57) with arginine. Had the properties of the resulting protein [$Arg^{25,33,45,56,57}$]PSC-RANTES been as attractive as those of PSC-RANTES itself, it might well have led to a highly economic production process, in spite of the noncoded residues. However, upon synthesis and testing of this analogue, we found that, despite its having an N-terminal region identical to that of PSC-RANTES, it has an approximately 15-fold reduction in potency relative to PSC-RANTES (Figure 5, IC_{50} value of 380 pM). This prompted us to speculate that one or more of the lysine residues in the protein, although distant in the linear sequence of the protein from its putative pharmacophore, may play an important role in its anti-HIV activity. On the basis of ongoing studies of a different group of PSC-RANTES analogues (*23*), as well as studies in which Lys residues of native RANTES were substituted (*24*), we postulated that Lys^{33} might be a key component of the PSC-RANTES pharmacophore. We found, in agreement with this hypothesis, that [$Arg^{25,45,56,57}$]PSC-RANTES showed potency indistinguishable from that of PSC-RANTES (IC_{50} value of 35 pM). It was therefore desirable to see if, despite the presence of one ϵ-amino group in the relevant protein fragment as well as the α-amino group, acylation by the short N-terminal peptide

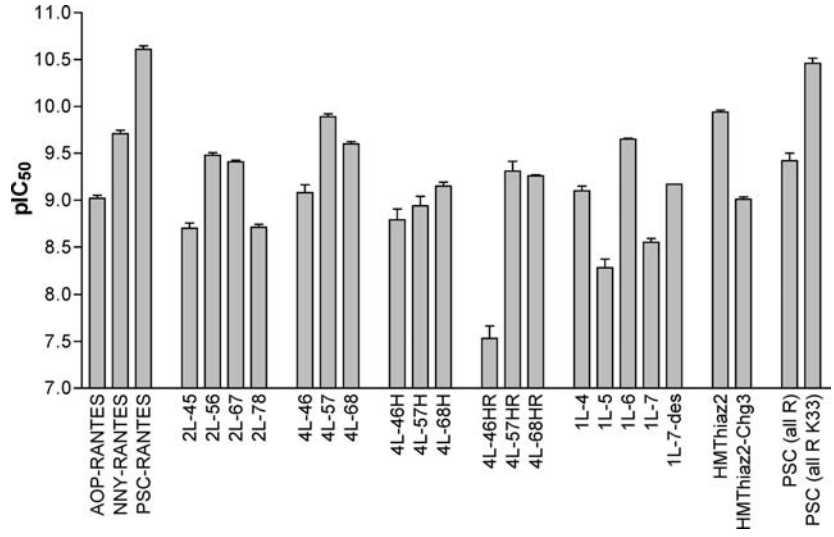

Figure 5. Anti-HIV potency of semisynthetic PSC-RANTES analogues and reference compounds. At least four independent dose–response experiments were performed for each compound using a cell fusion assay, Bars represent the mean potency from the group of experiments performed (pIC_{50}; −log(molar IC_{50} value)), with error bars representing the SEM. See text for the definition of the linker nomenclature. HMThiaz2 = N^{α}(*n*-nonanoyl)-[HMThiaz^2]RANTES(2-68), HMThiaz2-Chg3 = N^{α}(*n*-nonanoyl)-[HMThiaz^2, Chg^3]RANTES(2-68).

could be directed to the α-amino group alone by an appropriate choice of reaction conditions (see below).

Production of Analogues by N-Terminal Acylation of Protein Fragments Having No, Or Few, Lysines. The satisfactory potency of [$Arg^{25,45,56,57}$]PSC-RANTES, mentioned above, led us to consider a pH-controlled acylation of the α-amino group of [$Arg^{25,45,56,57}$]RANTES(4-68) with *n*-nonanoyl-PrS-Chg to produce the full-length construct. The reaction had to be performed in a semiorganic medium to solubilize the highly hydrophobic N-terminal peptide. DMSO turned out to be the most appropriate cosolvent for this reaction, leading to the formation of the wanted product, eluting at approximately 35 min (Figure 4A). The other solvents investigated (DMF, THF) resulted in the formation of a double peak in this region (data not shown). However, even in DMSO, while the higher reactivity of the α-amino group was clearly responsible for a high yield of the wanted product, under the reaction conditions investigated there was some formation of overreaction products, eluting at approximately 44 min (Figure 4A).

DISCUSSION

In this study, we set out to identify strategies with potential for development as economical routes to production of a PSC-RANTES analogue with antiviral activity as close as possible to that of the parent protein. The bulk of the protein would be produced at low cost by biosynthesis prior to attachment to a short N-terminal pharmacophore region that contains the non-natural, noncoded structures and which would be synthesized separately. High-yield production of recombinant RANTES fragments has been demonstrated using *E. coli* with expression methods directed toward inclusion body formation (*24*), and we have successfully used this approach to produce samples of N-terminally truncated derivatives of RANTES (O.H. et al., unpublished results). While expression of proteins via inclusion body formation often leads to incomplete cleavage of the initiating methioine (e.g., ref *25*), this problem can be overcome by the use of N-terminal peptide tags featuring specific enzymatic cleavage sites (e.g., ref *26*). The criteria we chose to adopt when exploring the suitability of the different ligation strategies were as follows: ease and cost of production of the N-terminal fragment, ease and yield of the conjugation reaction, and anti-HIV activity of the resulting analogue. These considerations led us to decide not to explore semisynthesis of PSC-RANTES via native chemical ligation; while it would certainly be a feasible approach, it would necessitate the production of a long and relatively expensive thioester peptide, as well as a folding step after the ligation.

We therefore considered several semisynthesis approaches, some of which necessitate the introduction of a nonpeptide linker region into the protein. Since incorporation of the linker leads to the replacement of backbone and side chain atoms of the protein, and the likelihood of inactivation of a protein increases with the number of substitutions introduced into key regions, we attempted to keep the linkers as short as possible. We varied the site of introduction of the linker, and hence the site at which atoms of the original protein would be changed.

Taken together, study of the three linker-based strategies that we used shows that certain parts of the N-terminal region would appear to be more amenable to the introduction of linker moieties than others. We found overall that substitution at positions 4 and 8 led to a greater reduction in biological activity than substitution at positions 5, 6, and 7. Finally, we did not find that use of a shorter linker necessarily leads to better retention of activity. Indeed, the most potent protein that we constructed with a linker, the oxime-linked analogue 4L-57, has the longest linker region tested, one which requires three residues to be replaced. This four-carbon oxime linker performed generally better than the shorter two-carbon linker that we tested, perhaps because the two-carbon linker modifies the backbone register of the semisynthetic protein with respect to PSC-RANTES.

It was not our purpose in this exploratory study to completely optimize the processes evaluated. In the case of the four-carbon linkers, a useful next step might be to use molecular diversity (library) methods to change the pharmacophore: it is possible that changes there could offset the effect of the linker on activity.

It was possible to directly compare the four-carbon linker oxime linkage strategy with the corresponding one using hydrazones. The activity of the hydrazone analogues was generally lower than that of the corresponding oxime ones, indicating that the activity of the protein is influenced by either the composition or flexibility of the linkers, or both. Reducing the hydrazone linker to methyl hydrazide would be expected to increase linker flexibility, and at certain positions in the protein, this led to a slight increase in activity. In the case of 4L-46HR, however, reduction to a hydrazide led to a more than 10-fold loss in potency. This loss might be related to the fact that in this case the secondary -NH- group in the reduced linker could, when ionized, place a positive charge in proximity to the negative charge of the Asp^6 side chain in the native protein and a strong ionic interaction here might distort the configuration of the whole pharmacophore.

Further evidence that introduction of a positive charge into the backbone can affect activity is provided by results obtained with Ψ[CH−NH] analogues. While these analogues have the shortest linker region that we tested, one which requires the replacement of only one residue, they introduce a full positive charge into the backbone, since reduction of the Schiff base results in a secondary amine with a pK_a in the 10.0–11.0 range. Once again, 1L-5, the analogue in the Ψ[CH_2−NH] series in which the backbone charge is introduced adjacent to Asp^6, shows the greatest reduction in activity. The highest activity in this series of conjugates was obtained for 1L-6, which means that replacement of Asp^6 by an aminoethylene moiety with concomitant alkylation of the nitrogen of Thr^7 is better tolerated. Overall, however, the performance of the Ψ[CH_2−NH] analogues suggests that use of a cumbersome but uncharged linker region does less harm to activity than introduction of a shorter linker carrying a positive charge.

Ligation According to Tam's Thiazolidine Strategy. This method (*21*) yields a native peptide bond in the backbone structure with, however, the introduction of a hydroxymethyl thiazolidine residue immediately C-terminal to the junction site. This residue can be thought of as an analogue of proline (present at position 2 of RANTES and of the earlier lead protein NNY-RANTES) and of thioproline (present at this position in the current lead PSC-RANTES). We therefore used the strategy to incorporate 2-hydroxymethyl thiazolidine at position 2 of NNY-RANTES, and it was encouraging to find that it retains the potency (IC_{50} value of 120 pM) of the parent molecule. We also produced a 2-hydroxymethyl thiazolidine^2 analogue of our best protein lead PSC-RANTES using the same chemistry. This time the protein fragment was [Cys^2-Chg^3]RANTES(2-68), which should be possible to obtain in recombinant form using the Schultz technology (*22*). The conjugation was successful, but the resulting molecule exhibited a significant loss of activity (IC_{50} value of 0.98 nM) compared to the parent PSC-RANTES (IC_{50} value of 24 pM). This apparently paradoxical result recalls previous observations that certain modifications at position 3 of RANTES analogues that are normally beneficial lead to a significant loss in potency when made in the presence of normally beneficial or neutral changes at position 2 (*3*). Thus, PSC-RANTES itself is the result of simultaneously replacing Pro^2 of NNY-RANTES ((*N*$^{\alpha}$(*n*-nonanoyl)-*des*-Ser^1-RANTES(2-

68)) with thioproline and Tyr^3 by cyclohexylglycine. Substitution of position 2 alone in NNY-RANTES had given only a slight improvement in potency, substitution of position 3 alone had given a 3.4-fold improvement, while in PSC-RANTES substitution of both together gave a 5-fold improvement. However, if position 2 was substituted by 4-hydroxyproline, which also gave no significant change in potency if introduced alone into NNY-RANTES, the simultaneous introduction of cyclohexylglycine in position 3 led neither to an improvement nor to the maintenance of potency, but to an approximately 100-fold decrease (*3*).

All-Arg Analogues. Had [$Arg^{25,33,45,56,57}$]PSC-RANTES (in which all the lysines in the sequence are replaced by arginines) shown comparable activity to PSC-RANTES itself, it would have been possible to use the short N-terminal pharmacophore peptide to acylate with complete specificity the sole amino group of the corresponding protein fragment, namely, the α-amino group. Unfortunately, it showed a significant loss in activity relative to PSC-RANTES. However, [$Arg^{25,45,56,57}$]PSC-RANTES showed activity comparable with that of PSC-RANTES, confirming earlier indications as to the importance of Lys^{33} for the anti-HIV activity of PSC-RANTES (*23*). [$Arg^{25,45,56,57}$]PSC-RANTES therefore represents a potent candidate molecule that could be produced by semisynthesis given sufficient selectivity of acylation between the protein fragment's one α-amino group and its one ϵ-amino group. In an initial practical test of this strategy, we obtained a sufficient degree of selectivity to offer the hope that optimization might lead to a practically useful process. We would not expect the replacement of the four lysines by arginine to increase the immunogenicity of the protein, but this point would need to be investigated experimentally.

We conclude that, in particular, both the four-carbon oxime linker and the direct acylation of [$Arg^{25,45,56,57}$]RANTES (4-68) represent routes to powerful semisynthetic anti-HIV compounds that show potential for optimization.

Received August 26, 2007; Revised Manuscript Received November 24, 2007

A preorganized cleft dinuclear zinc(II) complex of 2,6-bis(1-methyl-1,4,7-triazacyclonon-1-yl)pyridine **1** as an artificial nuclease was prepared via an improved method. The interactions of **1**, **2** [1,4,7-triazacyclononane (TACN)], and their zinc(II) complexes with calf thymus DNA were studied by spectroscopic techniques, including fluorescence and CD spectroscopy. The results indicate that the DNA binding affinities of these compounds are in the following order: Zn^{II}_2−**1** > Zn^{II}−**2** > **1** > **2**. The binding constants of the Zn^{II}_2−**1** and Zn^{II}−**2** complexes are 3.57×10^6 and 1.43×10^5 M^{-1}, respectively. Agarose gel electrophoresis was used to assess the plasmid pUC 19 DNA cleavage activities in the presence of the dinuclear Zn^{II}_2−**1** complex, which exhibits powerful DNA cleavage efficiency. Kinetic data for DNA cleavage promoted by the Zn^{II}_2−**1** complex under physiological conditions give the observed rate constant (k_{obs}) of 0.136 h^{-1}, which shows an 10^7-fold rate acceleration over uncatalyzed supercoiled DNA. The comparison of the dinuclear Zn^{II}_2−**1** complex with the mononuclear zinc(II) complex of 1,4,7-triazacyclononane indicates that the DNA cleavage acceleration promoted by the Zn^{II}_2−**1** complex is due to the efficient cooperative catalysis of the two proximate zinc(II) cation centers. A hydrolytic mechanism of the cleavage process was suggested, and a preliminary study of the antitumor activity was also conducted.

INTRODUCTION

Artificial nucleases have recently received considerable interest for their potential applications in the fields of molecular biological technology and drug development (*1–10*). Among them, transition metal complexes as synthetic metallonucleases have been studied extensively due to their diversity in structure and reactivity (*11–26*), and some of them also exhibit antitumor or anti-HIV activities (*27–32*). Dinuclear or multinuclear complexes have especially attracted attention as artificial nucleases (*33–37*) since dinuclear or multinuclear metal centers are often found in natural nucleases and the metal centers may demonstrate synergistic effects in the activation and recognition of the active phosphodiesters and nuclear acids (*38, 39*). In Nature, there are many phosphoesterases that are activated by two or more metal ions, such as the 3′,5′-exonuclease from the Klenow fragment of DNA polymerase I (*40*), Rnase H from HIV reverse transcriptase (*41*), P1 nuclease (*42*), alkaline phosphatase (*43*), and phospholipase C (*44*). *Tetrahymena* ribozyme (*45, 46*) is also thought to be activated by at least two metal ions. Over the years, interesting dinuclear Cu(II), Co(III), and La(III) complexes that cleave activated phosphate esters and RNA have been reported (*33–39*). Especially, the dinuclear zinc(II) complexes of bis(1,4,7-triazacyclononane) [bis(TACN)] exhibit an excellent ability to cleave the phosphate ester bond of active phosphodiesters and RNA model compounds (*38, 39, 47–49*). Breslow (*50*) first prepared the dinuclear Zn(II) complex of bis(TACN) with a rigid spacer (4,4′-biphenyl group) and demonstrated that its cleaving activity toward active phosphodiester BNP (bis-*p*-nitrophenyl phosphate), RNA model HPNP (2-hydroxypropyl-*p*-nitrophenyl phosphate), and UpU dinucleoside is 5 times more effective than that of the corresponding mononuclear zinc(II) complex. The dizinc complex of bis(TACN) with a pyrazolate bridge reported by Kaden and Richard (*51*) has a 200-fold rate acceleration for BNP hydrolysis over the background reaction. The dinuclear zinc(II) complex of bis(TACN) containing a 2,2′-dimethylbipyridine bridge reported by Bencini, Lippolis, and co-workers (*52*) has a 350-fold rate acceleration for BNP hydrolysis. However, DNA-cleaving dinuclear metallic systems based on zinc(II) are scare (*26*). It is well-known that phosphodiester backbones in DNA are enormously stable, and their half-life under physiological conditions is estimated to be 200 million years (*53–57*). Therefore, DNA hydrolysis promoted by artificial nucleases is still a challenging subject. Recently, Scrimin and co-workers (*58*) reported that the dinuclear TACN zinc(II) complex of heptapeptide exhibits a remarkable hydrolytic cleavage activity of plasmid DNA with a first-order rate constant of 1.0×10^{-5} s^{-1} under physiological conditions, which is 20 times more reactive than its monometallic counterpart. Inspired by Scrimin's work, we synthesized a preorganized cleft molecule 2,6-bis(1-methyl-1,4,7-triazacyclonon-1-yl)pyridine **1** and investigated the DNA cleavage activity promoted by **1** and its bisnuclear zinc complex (Zn^{II}_2−**1**) under physiological conditions. We report here the detailed studies of the DNA binding and plasmid DNA hydrolysis process promoted by the Zn^{II}_2−**1** complex, including the complex concentration dependence, pH dependence, ionic strength dependence, cleavage kinetics, and comparison of the activity of the dinuclear zinc(II) Zn^{II}_2−**1** complex and the mononuclear TACN **2**−zinc(II) complex (Scheme 1). The mechanism of the cleavage process is suggested, and a preliminary study of the antitumor activity was also conducted.

EXPERIMENTAL PROCEDURES

Materials. All reagents and chemicals were of analytical grade and used without further purification. Plasmid pUC 19 DNA was purchased from TaKaRa Biotechnology Co. Ltd., and

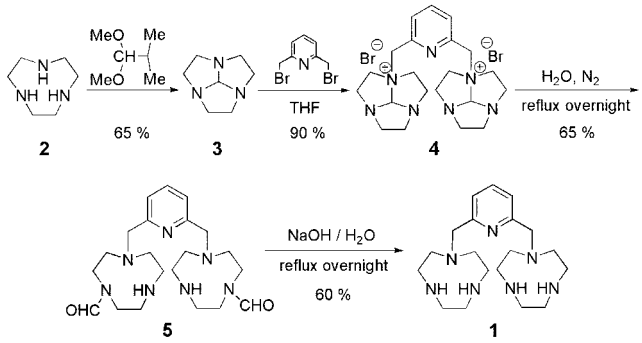
Scheme 1. Synthesis of Dinuclear Ligand 1



the purity was checked by agarose gel electrophoresis; their concentrations were determined by UV spectroscopy using the extinction coefficient appropriate for double-stranded DNA (1.0 OD_{260} = 50 μg/mL). Agarose was from Oxoid Limited (Basingstoke, U.K.). Ethidium bromide (EB) was from Amresco Inc. Tris(hydroxymethyl)aminomethane (Tris-Base) was from Robiot Co. Ltd. Bromophenol blue, glycerol, and ethyldiaminetetraacetic acid (EDTA) were commercially available. Deionized water was obtained from an ionized column from doubly distilled water. All solvents were purified by the standard procedure.

Apparatus. ^{1}H NMR and ^{13}C NMR data were recorded on a Brucker AM 300 spectrometer. Elemental analyses were performed on a Perkin-Elmer 240C instrument. Mass spectra were obtained on an electrospray mass spectrometer (LCQ, Finnigan) in positive mode. The pH value was confirmed with an ORION868 pH meter with an Ag/AgCl electrode as the reference electrode in a saturated KCl solution at room temperature. Agarose gel electrophoresis was conducted with a DYY-5 electrophoresis apparatus. Bands were visualized by UV light and photographed using a DigiDoc-It gel imaging and documentation system (version 1.1.23, UVP, Inc., Unpland, CA). The intensity of the DNA bands was estimated by TotalLab image analysis software (version 2.01).

Fluorescence Measurements. The fluorescent spectral studies were performed by the measurement of the emission intensity of ethidium bromide (EB) on an AMINCO Bowman Series 2 luminescence spectrometer. The experiments were carried out by adding 0−21 μM **2**, **1**, Zn^{II}−**2**, or Zn^{II}_2−**1** into the EB (1.0 μM)-bound CT-DNA (30 μM) solution in 5 mM Tris-HCl buffer (pH 6.8), and the fluorescence was measured and normalized to 100% relative fluorescence.

Circular Dichroism Measurements. All CD spectroscopic studies were carried out with a continuous flow of nitrogen purging the polarimeter, and the measurements were performed at room temperature with 1 cm pathway cells. The CD spectra were run from 320 to 220 nm at a speed of 20 nm/min, and the buffer background was automatically subtracted. Data were recorded at an interval of 0.1 nm. The CD spectrum of CT-DNA alone (50 μM) was recorded as the control.

DNA Cleavage Assays. Cleavage reactions of supercoiled pUC 19 DNA (0.05 mM bp) were carried out at 37 °C in 50 mM Tris-HCl/10 mM NaCl buffer in a total volume of 15 μL. The results of cleavage reactions were monitored by agarose gel electrophoresis (80 V for 1.5 h), and the supercoiled plasmid DNA values were corrected by a factor of 1.3 on the basis of average literature estimates of weakened binding of EB to this structure.

Synthesis of 1,4,7-Triazacyclononane (2). The synthesis of 1,4,7-triazacyclononane was achieved according to the literature method (*59*): ^{1}H NMR (300 MHz, $CDCl_3$) δ 2.00 (s, 3H, NH_2), 2.79 (s, 12H, CH_2); ^{13}C NMR (75 MHz, D_2O) δ 41.2 (CH_2).

Synthesis of 1,4,7-Triazatricyclo[5.2.1.0^{4,10}]decane (3). A stirred solution of 1,4,7-triazacyclononane **2** (1 g, 7.75 mmol) and $HC(OMe)_2NMe_2$ (0.93 g, 7.83 mmol) in anhydrous benzene (12.5 mL) was heated at 90 °C for 6 h. The mixture was then allowed to cool to room temperature and filtered. After the solvent was removed, the residue (0.70 g, 5.04 mmol) was distilled at 4 mmHg and the fraction boiling at 56 °C was collected: yield 65%; ^{1}H NMR (300 MHz, $CDCl_3$) δ 2.40–2.52 (m, 6H, $3CH_2$), 2.70–2.77 (m, 6H, $3CH_2$), 4.66 (s, 1H, CH); ESI-MS *m*/*z* $[M + H]^+$ calcd 140.1, found 140.4.

Synthesis of 2,6-Bis(1-methyl-1-azonia-4,7-diazatricyclo [5.2.1^{4,10}]decane)pyridine dibromide (4). A stirred solution of compound **3** (0.33 g, 2.37 mmol) in anhydrous THF (1 mL) was cooled to 0 °C, and then a solution of 2,6-bis(bromomethyl)pyridine (0.30 g, 1.13 mmol) in anhydrous THF (1.5 mL) was added slowly. The mixture was stirred at 0 °C for 48 h. Then, the mixture was filtered, and the residue was washed with THF (2 × 1 mL) and ether (1 mL). A white solid (0.39 g, 1.01 mmol) was obtained: yield 90%; ^{1}H NMR (300 MHz, D_2O) δ 2.99–3.09 (m, 8H, $4CH_2$), 3.32–3.54 (m, 8H, $4CH_2$), 3.86–3.93 (m, 8H, $4CH_2$), 4.54 (s, 4H, $2ArCH_2$), 5.89 (s, 2H, 2CH), 7.69 (d, J = 7.8 Hz, 2H, 2ArH), 7.82 (t, J = 7.8 Hz, 1H, ArH); ESI-MS *m*/*z* $[M - Br]^+$ calcd 462.2, found 462.2.

Synthesis of 2,6-Bis(1-carboxaldehyde-4-methyl-1,4,7-triazacyclonon-4-yl)pyridine (5). Compound **4** (0.55 g, 1.01 mmol) was dissolved in water (6 mL) and the mixture stirred overnight at room temperature under an atmosphere of dry N_2. The mixture was filtered, and the filtrate was extracted with $CHCl_3$ (3 × 10 mL). The organic layer was treated with charcoal and filtered. Then, the solvent was removed under vacuum to give compound **5** as a pale yellow oil (0.27 g, 0.65 mmol): yield 65%; ^{1}H NMR (300 MHz, $CDCl_3$) δ 2.52–2.83 (m, 8H, $4CH_2$), 3.10–3.37 (m, 8H, $4CH_2$), 3.44 (s, 2H, 2NH), 3.50–3.71 (m, 8H, $4CH_2$), 3.82 (s, 4H, $2ArCH_2$), 7.15–7.24 (m, 2H, 2ArH), 7.51–7.80 (m, 1H, ArH), 8.03 (s, 2H, CHO); ^{13}C NMR (75 MHz, D_2O) δ 45.1 (CH_2), 46.7 (CH_2), 48.3 (CH_2), 48.8 (CH_2), 53.9 (CH_2), 62.3 ($ArCH_2$), 123.4 (Ar C), 138.8 (Ar C), 158.7 (Ar C), 166.5 (CHO); ESI-MS *m*/*z* $[M + H]^+$ calcd 418.3, found 418.5.

Synthesis of 2,6-Bis(1-methyl-1,4,7-triazacyclonon-1-yl)-pyridine (1). Compound **5** (0.27 g, 0.65 mmol) was dissolved in a sodium hydroxide solution (20 mL, 2.5 M) and the mixture stirred overnight at room temperature under an atmosphere of dry N_2. The mixture was filtered, and the residue was extracted with $CHCl_3$ (3 × 10 mL). All of the organic layers (including the filtrate and the extractant) were merged and dried. The solvent was removed under vacuum to give compound **1** as a pale yellow oil (0.14 g, 0.39 mmol): yield 60%; ^{1}H NMR (300 MHz, $CDCl_3$) δ 2.58–2.62 (m, 8H, $4CH_2$), 2.66–2.74 (s, 16H, $8CH_2$), 3.23 (br s, 4H, 4NH), 3.82 (s, 4H, $2ArCH_2$), 7.17 (d, J = 7.6 Hz, 2H, 2ArH), 7.54 (t, J = 7.6 Hz, 1H, ArH); ^{13}C NMR (75 MHz, D_2O) δ 43.8 (CH_2), 48.3 (CH_2), 50.6 (CH_2), 61.7 ($ArCH_2$), 123.6 (Ar C), 138.7 (Ar C), 158.2 (Ar C); ESI-MS *m*/*z* $[M + H]^+$ calcd 362.3, found 362.4. Anal. Calcd for $C_{19}H_{35}N_7$: C, 63.12; H, 9.76; N, 27.12. Found: C, 63.36; H, 9.63; N, 27.01.

Preparation of the Zinc(II) Complex Storage Solution. A mixture of ligand **1** (or **2**) and $ZnCl_2$ at a 2:1 (or 1:1) molar ratio in methanol (10 mL) was stirred for 5 h at room temperature and then evaporated to remove the solvent. The residue was dissolved in deionized water as the zinc(II) complex storage solution.

Materials and Methods of Cytotoxic Assays. *Cell Lines.* A murine B16 melanoma cell line and a human HL-60 promyelocytic leukemia cell line were obtained from American Type Culture Collection (ATCC, Rockville, MD), maintained in DMEM (Life Technologies Inc., Grand Island, NY) and

RPMI 1640 (Gibco, Scotland, U.K.), respectively, supplemented with penicillin (100 units/mL), streptomycin (100 μg/mL), and 10% fetal bovine serum (Life Technologies) at 37 °C in a humidified atmosphere containing 5% CO_2 in air.

MTT Assays for Cell Viability. Cells were cultured in 96-well plates for 72 h with various compounds. Cell viability was evaluated with a modified MTT assay (*60*). Briefly, 20 μL of 4 mg/mL 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT, Sigma) in medium was added for a further 4 h incubation. After the supernatant had been removed, 200 μL of DMSO was added to dissolve the formazan crystals. The absorbance was read on an ELISA reader (Tecan) at 540 nm. The relative survival rate was determined in relation to that of untreated cells, which was set as 100%.

RESULTS AND DISCUSSION

General Aspects. Compound **1** is a bis-triazacrown ether, in which the rigid 2,6-dimethylenepyridine is employed as the bridging group to construct a preorganized cleft receptor for phosphodiester. The cleft zinc(II) complex affords a cavity to accommodate, recognize, and bind the phosphodiesters of DNA because the two zinc(II) ion centers are kept at a certain distance. On the other hand, the proximate pyridyl nitrogen atom can coordinate to one of the two metal ions (*61, 62*), which makes the zinc(II) ion center more immovable for the efficient binding and recognizing of the DNA phosphodiester backbone. Therefore, high DNA cleavage activity can be expected due to the quite efficient cooperative catalysis of two zinc(II) ions in a rigid cleft molecule system.

The organic ligand **1** was prepared according to the literature method (*63*) with some modifications in good yield via a four-step reaction starting from **2** (Scheme 1). The reaction of 2 equiv of the 1,4,7-triazacyclononane orthoamide with 2,6-bis(bromomethyl)pyridine in THF followed by hydrolysis gave a new intermediate product **5**. Then, compound **5** was treated with an aqueous NaOH solution to give ligand **1**. The zinc(II) complexes of **1** and **2** were prepared by mixing methanol solutions of the organic ligands and $ZnC1_2$. The metal-bound chlorides in Zn^{II}_2−**1** and Zn^{II}−**2** complexes can be displaced spontaneously by water molecules in aqueous solvents (*64–66*). The ESI-MS spectrum (Figure S1, Supporting Information) of the zinc(II) complex of ligand **1** demonstrates that **1** coordinates two zinc(II) ions in water when 2 equiv of $ZnCl_2$ is added.

DNA Binding Assays. DNA binding is the critical step for DNA cleavage in most cases. Therefore, the binding of the ligands (**1** and **2**) and their complexes (Zn^{II}_2−**1** and Zn^{II}−**2**) to CT-DNA was studied by using fluorescence and circular dichroism spectroscopy. UV–vis absorption spectroscopy is also one of the convenient tools for examining the interaction between small molecules and nucleic acids, but these complexes have very UV absorbances similar to that of calf thymus (CT-DNA) at 260 nm; thus, the DNA binding studies were not carried out by using UV–vis absorption spectroscopy.

Fluorescence Spectroscopic Studies. The binding of the compounds to CT-DNA was studied by evaluating the fluorescence emission intensity of the ethidium bromide (EB)−DNA system upon the addition of the four compounds. If these compounds added to the EB−DNA system replace the bound EB, the emission intensity will be reduced. The fluorescence quenching of EB bound to DNA by **2**, **1**, Zn^{II}−**2**, and Zn^{II}_2−**1** is shown in Figure S2 (Supporting Information), in which the fluorescence intensity at 610 nm (λ_{ex} = 518 nm) of EB in the bound form was plotted against the compound concentration. The relative binding propensity of the compounds to CT-DNA was determined by the classical Stern−Volmer equation $I_0/I = 1 + Kr$ (*67–70*), where I_0 and I are the fluorescence intensities in the absence and presence of the quencher, respectively, K is the linear Stern−Volmer quenching constant dependent on the ratio of r_{bE} (the ratio of the bound concentration of EB to the concentration of DNA), and r is the ratio of the total concentration of the quencher to that of DNA (*67–70*). Figure 1 is the plot of I_0/I versus [quencher]/[DNA], and quenching constant K is given by the slope. The K values obtained for **2**, **1**, Zn^{II}−**2**, and Zn^{II}_2−**1** are 0.053 ± 0.010, 0.157 ± 0.015, 0.259 ± 0.005, and 0.827 ± 0.022, respectively. These results demonstrate that Zn^{II}−**2** and Zn^{II}_2−**1** complexes have stronger affinity for DNA than the corresponding ligands **2** and **1**. Moreover, the dinuclear Zn^{II}_2−**1** complex possesses much better DNA binding ability than the mononuclear Zn^{II}−**2** complex. The apparent binding constant (K_{app}) was also calculated from the equation K_{EB}[EB] = K_{app}[complex], where the complex concentration was the value at a 50% reduction of the fluorescence intensity of EB and $K_{EB} = 1.0 \times 10^7$ M^{-1} ([EB] = 1.0 μM) (*71*). The K_{app} values are 1.43×10^5 M^{-1} for Zn^{II}−**2** and 3.57×10^6 M^{-1} for Zn^{II}_2−**1** (Figure S3, Supporting Information). It is noticed that the binding constant of Zn^{II}_2−**1** is 30-fold higher than that of Zn^{II}−**2**.

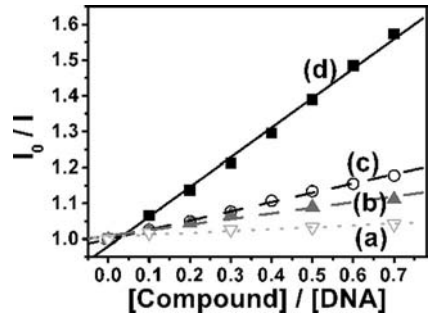


Figure 1. Stern−Volmer quenching plots of EB bound to DNA by (a) **2**, (b) **1**, (c) Zn^{II}−**2**, and (d) Zn^{II}_2−**1**, which give the quenching constants K. The experiments were conducted by adding 0−21 μM **2**, **1**, Zn^{II}−**2**, or Zn^{II}_2−**1** to the EB-bound CT-DNA solution in 5 mM Tris-HCl buffer (pH 6.8).

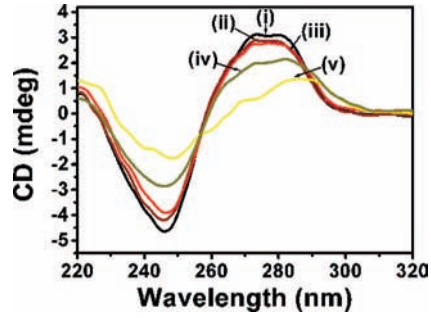

Figure 2. Circular dichroism spectrum of (i) CT-DNA (5.0×10^{-5} M) and the interaction with (ii) **2**, (iii) **1**, and (iv) Zn^{II}−**2** at a [compound]/[CT-DNA] ratio of 1 and (v) Zn^{II}_2-**1** at a [compound]/[CT-DNA] ratio of 0.5. All the spectra were recorded in Tris-HCl buffer at pH 6.8.

Circular Dichroism Studies. CD spectroscopy is a useful technique for assessing whether nucleic acids undergo conformational changes as a result of complex formation or changes in the environment. Figure 2 displays the CD spectra of CT-DNA treated with **2**, **1**, and Zn^{II}−**2** with a ratio ([compound]/[DNA]) of 1 and Zn^{II}_2−**1** with the ratio of 0.5. Both the positive (~275 nm) band and the negative (~245 nm) band decreased in intensity in the presence of the zinc(II) complexes except for those with ligands **2** and **1**. Both the positive and negative CD bands decreased in intensity with the increase in the concentrations of the added complexes Zn^{II}−**2** and Zn^{II}_2−**1** (Figure S4, Supporting Information). This suggests that Zn^{II}−**2** and Zn^{II}_2−**1** can unwind the DNA helix and lead to the loss of

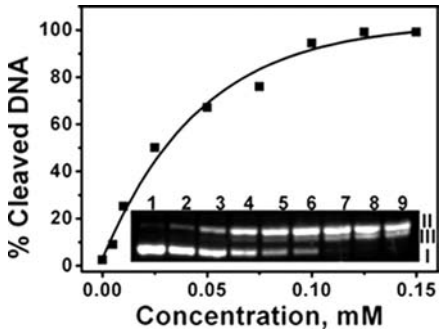

Figure 3. Plot of percent cleaved DNA vs different concentrations of Zn^{II}_2−**1**. The inset is the agarose gel (1%) of the concentration-variable reaction products [incubated in Tris-HCl buffer (pH 6.8) for 15 h at 37 °C]: lane 1, DNA control; and lanes 2–9, concentrations of Zn^{II}_2−**1** of 0.005, 0.010, 0.025, 0.050, 0.075, 0.100, 0.125, and 0.150 mM, respectively.

helicity (*72, 73*). The largest decrease in the CD band intensity caused by Zn^{II}_2−**1** (each triaza-crown ether unit) compared to those of the other compounds at the same concentration implies that Zn^{II}_2−**1** is more effective than **1**, **2**, and Zn^{II}−**2** in perturbing the secondary structure of DNA.

From the results of these fluorescence and CD spectroscopic studies, we conclude that the abilities of the compounds to bind to CT-DNA are in the following order: Zn^{II}_2−**1** > Zn^{II}−**2** > **1** ≈ **2**.

Cleavage of Plasmid DNA. The affinities of 1,4,7-triazacyclononane (TACN) **2** and compound 2,6-bis(1-methyl-1,4,7-triazacyclonon-1-yl)pyridine **1** for zinc(II) ion have been reported by Kimura (*74*) and Beneini (*62*), respectively. The stability constant of the 1:1 complex of **2** (TACN) and zinc(II) is 11.3 (*74*), indicating a very high stability. In Bencini and Lippolis's work (*62*), two TACN units of compound **1** can simultaneously coordinate zinc(II) ions to form a 1:2 dinuclear complex with an extremely large stability constant (log K = 26.2) in aqueous solution at pH 6−7. Therefore, in this investigation, when the ratios of ligands **1** and **2** to zinc(II) are 1:2 and 1:1, respectively, the dinuclear Zn^{II}_2−**1** and mononuclear Zn^{II}−**2** complexes are main species existing under the experimental pH condition, respectively.

To assess the DNA cleaving behavior of Zn^{II}_2−**1**, cleavage reactions of supercoiled pUC 19 DNA (0.05 mM bp) were carried out at 37 °C in 50 mM Tris-HCl/10 mM NaCl buffer in a total volume of 15 μL. The results of cleavage reactions were monitored by agarose gel electrophoresis (80 V for 1.5 h), and the supercoiled plasmid DNA values were corrected by a factor of 1.3 on the basis of average literature estimates of weakened binding of EB to this structure (*75, 76*). The inset of Figure 3 is the agarose gel of the DNA cleavage promoted by Zn^{II}_2−**1**, which indicates that Zn^{II}_2−**1** cleaves DNA efficiently. The supercoiled DNA (form I) relaxes to form a nicked circular DNA (form II) in the presence of Zn^{II}_2−**1**, and then the linear DNA (form III) forms when the complex concentration increases. The concentration dependence plot exhibits a saturation profile (Figure 3), which suggests that the DNA cleavage activity of Zn^{II}_2−**1** is increased with the increase in the complex concentration, and it is closed to be saturated at a complex concentration of 0.10 mM. To improve our understanding of whether the metal ions or ligand **1** alone is able to cleave DNA, control assays were carried out under the same conditions with the metal ions alone or ligand **1** alone, respectively. Figure S5 and Table S1 (Supporting Information) show the results of pUC 19 DNA cleavage (incubated for 12 h at 37 °C) in the presence of different metal ions (0.20 mM). Little cleavage (15%) was found. A similar result was reported by Barton (*77*). On the other hand, when DNA was incubated for 12 h at 37 °C in the

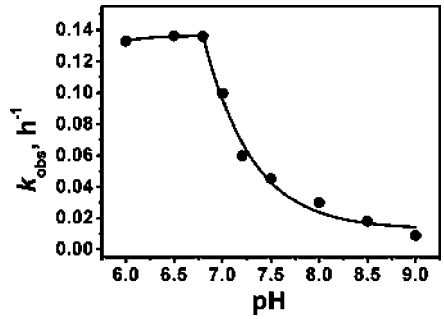

Figure 4. pH-dependent profile for DNA cleavage promoted by Zn^{II}_2−**1** (0.10 mM) at 37 °C.

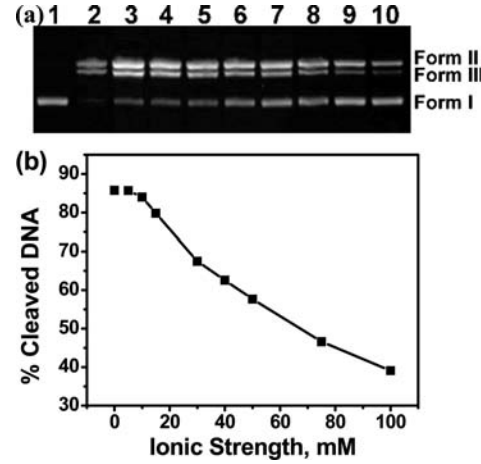

Figure 5. (a) Agarose gel (1%) of the DNA cleavage reaction products promoted by Zn^{II}_2−**1** (0.10 mM) for 12 h at 37 °C and pH 6.8 under different ionic strength conditions: lane 1, DNA control; lane 2, no NaCl; and lanes 3–9, ionic strengths of 5, 10, 15, 30, 40, 50, 75, and 100 mM, respectively. (b) Ionic strength-dependent profile for DNA cleavage promoted by Zn^{II}_2−**1** (0.10 mM).

presence of ligand **1** (0.10 mM) alone, only 12% supercoiled DNA was cleaved (see the Supporting Information, page S12), indicating that ligand **1** alone can hardly cleave DNA, while the Zn^{II}_2−**1** complex (0.10 mM) caused 80% cleavage of DNA under the same conditions (Supporting Information, page S16).

Figure 4 presents the pH-dependent profile for DNA cleavage promoted by Zn^{II}_2−**1** (0.10 mM) at 37 °C, which indicates that a pH range of 6.0−6.8 is the optimal pH condition, and the cleavage rate decreases with an increase in the pH value (pH 6.8−9.0). The species distribution diagrams of the Zn(II)-bound water for the dimetallic Zn^{II}_2−**1** complex was reported by Bencini (*62*), which shows that two and three hydroxide anions can be bound to zinc(II) ion with the increasing pH condition (pH >6.8). Indeed, the decrease in reactivity above pH 6.8 may be related to the deprotonation of a second water molecule on the complex, which may result in a competition for the complexation of the substrate phosphodiester anion. As a result, the Tris-HCl buffer at pH 6.8 was used for all of the DNA cleavage reactions. Ionic strength always affects the DNA cleavage significantly. Ionic strength dependence assays show that the cleavage activity decreases with an increase in the ionic strength (Figure 5a,b), which implies that the positively charged zinc(II) centers bind with the anionic sites in the phosphodiester of DNA, rather than with the DNA bases, via electrostatic interactions (*78*). Thus, a relatively low NaCl concentration (10 mM) was selected to control the ionic strength in all experiments.

Kinetics of DNA degradation have been studied. Figure 6a shows the agarose gel of the supercoiled plasmid DNA cleavage promoted by Zn^{II}_2−**1** (0.10 mM) in Tris-HCl/NaCl buffer (pH 6.8) at 37 °C into nicked and linear forms. The time course

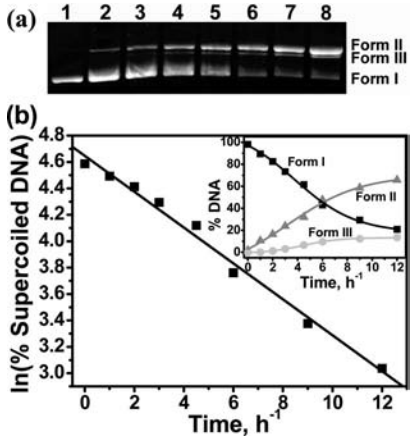

Figure 6. Time course of pUC 19 DNA (0.05 mM bp) cleavage promoted by Zn^{II}_2−**1** (0.10 mM). (a) Agarose gel (1%) of the time-variable reaction products: lanes 1–8, reaction times of 0, 1.0, 2.0, 3.0, 4.5, 6.0, 9.0, and 12.0 h, respectively. (b) Plot of ln(% supercoiled DNA) vs reaction time. The inset of Figure 4b is the plot of percent DNA vs time.

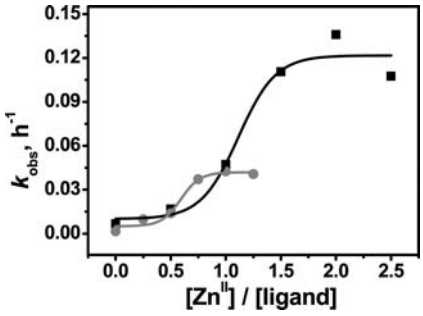

Figure 7. Dependence of the rate of DNA cleavage on the [Zn^{II}]/[ligand] ratio at a constant ligand concentration (0.10 mM) at 37 °C (pH 6.8, 50 mM Tris-HCl/10 mM NaCl buffer): **1** () and **2** (•).

plot indicates that the extension of supercoiled DNA cleavage varies exponentially with reaction time, giving pseudo-first-order kinetics with an apparent first-order rate constant of 0.136 ± 0.005 h^{-1} (Figure 6b), which shows 10^7-fold rate acceleration over that of uncatalyzed supercoiled DNA (*53–57, 60*).

To confirm that the cooperative catalysis of the dinuclear complex is an efficient strategy as expected, the dependence of the DNA cleavage rate on the [Zn^{II}]/[ligand] ratio at a constant ligand concentration (0.10 mM) has been measured (Figure 7). For ligand **2**, the rate of DNA hydrolysis increases to a plateau that is reached when 1 equiv of zinc(II) ion has been added, indicating that one zinc(II) ion per ligand **2** is required for maximum activity; for ligand **1**, limiting reactivity is reached at 2 equiv of zinc(II) ion. The observed maximum cleavage rate constants of **1** and **2** in the presence of zinc(II) ion (2:1 and 1:1) are 0.136 ± 0.005 h^{-1} (k_{obs}^1) and 0.0425 ± 0.0014 h^{-1} (k_{obs}^2), respectively (Table S2, Supporting Information). We notice that the DNA cleavage efficiency of 1 equiv of Zn^{II}_2−**1** is higher than that of 2 equiv of Zn^{II}−**2** (k_{obs}^1 is 3 times greater than k_{obs}^2), which indicates that the acceleration by Zn^{II}_2−**1** is due to the efficient cooperative catalysis of the two proximate zinc(II) cation centers (*38, 39, 79*). That is to say, having two preorganized metal ion centers connected by a rigid bridging structure in one system is a more efficient strategy for DNA cleavage.

Mechanism. To verify if reactive oxygen species (ROS) are, at least in part, responsible for the cleavage of DNA promoted by Zn^{II}_2−**1**, reactions were carried out in the presence of typical scavengers (*37, 80*) for singlet oxygen (NaN_3, 10 mM), for superoxide (KI, 10 mM), and for hydroxyl radical (1 mM DMSO and 1 mM *t*-BuOH) (see Figure S6 and Table S3 of the Supporting Information). Figure 8 shows that there is no evident inhibition effect on the DNA cleavage in the presence of all scavengers (NaN_3, DMSO, *t*-BuOH, and KI), which rules out the involvement of these reactive oxygen species, at least in a free and diffusible form. On the other hand, zinc(II) complexes generally cleave DNA by the hydrolytic pathway (*81*). Therefore, DNA cleavage promoted by Zn^{II}_2−**1** might not occur by an oxidative pathway but takes place by a hydrolytic pathway.

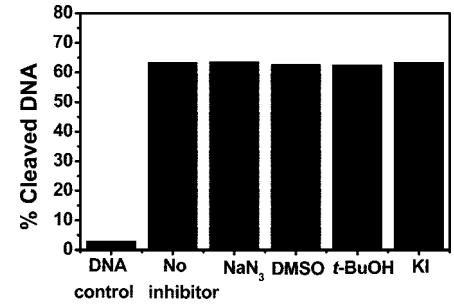

Figure 8. Histogram representing of pUC19 plasmid DNA (0.05 mM bp) cleaved by Zn^{II}_2−**1** (0.10 mM) in the presence of standard radical scavengers incubated for 8 h at 37 °C in pH 6.8 buffer (50 mM Tris-HCl/10 mM NaCl).

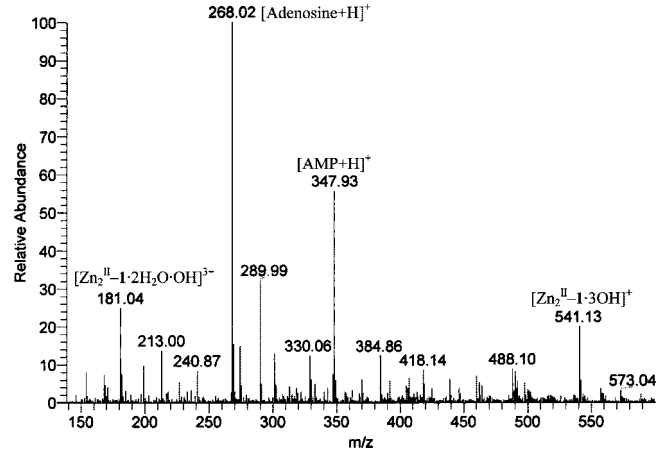

Figure 9. ESI-MS analysis of ApA hydrolysis promoted by Zn^{II}_2−**1**.

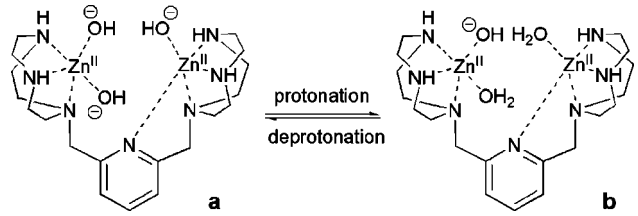
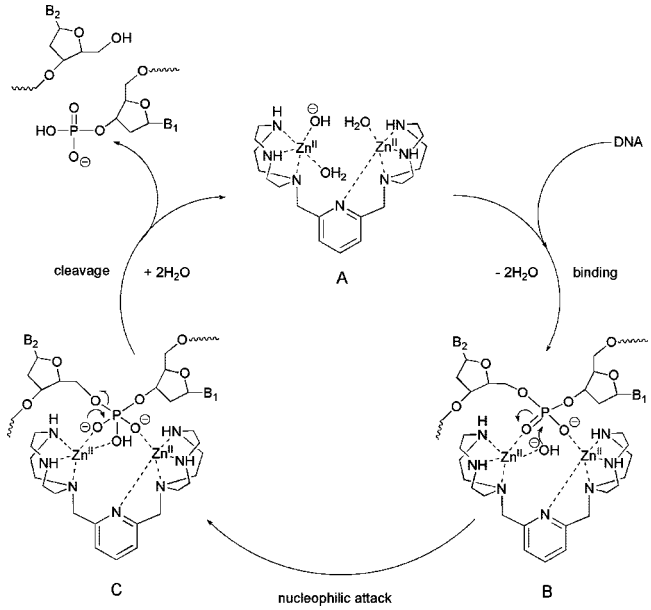
To further prove the hydrolysis pathway, a small dinucleotide model system adenylyl(3′–5′)phosphoadenine (ApA) was used as the nucleic acid mimic. ApA (0.10 mM) and Zn^{II}_2−**1** (0.01 mM) were dissolved in deionized water, and after equilibration for 8 h at room temperature, ESI-MS analysis was carried out. In the ESI-MS spectrum (Figure 9), the signals at *m*/*z* 268.02 and 347.93 show the presence of ApA cleavage products adenosine (calcd *m*/*z* 268.10) and adenine monophosphate (AMP, calcd *m*/*z* 348.06). The generation of the adenosine and AMP indicates that the phosphodiester bonds of ApA were cleaved by Zn^{II}_2−**1** via the hydrolysis pathway (*38*). Therefore, as in ApA, the hydrolysis pathway should be the possible mechanism for DNA cleavage promoted by Zn^{II}_2−**1**. As a comparison, ESI-MS analysis of ApA treated with ligand **1** was also carried out under the same conditions (Figure S7, Supporting Information), and there were no signs of cleavage products (adenosine and AMP). Therefore, it is concluded that the hydrolysis of ApA was caused by the cooperativity of the two zinc(II) ions in Zn^{II}_2−**1**.

In the ESI-MS spectrum of Zn^{II}_2−**1** in a neutral aqueous solution (Figure S1, Supporting Information), the peaks at *m*/*z* 540.90 and 180.96 show the signals of species **a** ([Zn_2^{II}−

Scheme 2. Equilibration between a and b



Scheme 3. A Plausible Mechanism for DNA Cleavage Promoted by Zn^{II}_2···C1



1·3OH]$^+$, calcd *m*/*z* 540.16) and **b** ([Zn_2^{II}−**1**·2H_2O·OH]$^{3+}$, calcd *m*/*z* 180.73), respectively (Scheme 2), which indicates the existence of the zinc(II)-bound OH in the aqueous solution. This fact is also consistent with the result reported by Beneini and Lippolis (*62*). In addition, Chuburu and co-workers (*61*) reported that the N atom of the pyridine is involved in the coordination of one copper(II) ion in the monocrystal structures of the dinuclear copper(II) complex of 2,6-bis(1,4,7,10-tetraazacyclododecylmethyl)pyridine. Therefore, a similar status is achieved in the dinuclear zinc(II) complex presented here. According to the ESI-MS spectrum of Zn^{II}_2−**1** and some reports from the literature (*33–37, 61, 62*), a plausible mechanism for DNA cleavage promoted by Zn^{II}_2−**1** is schematically depicted in Scheme 3. It is well-known that dinuclear metal complexes bind the phosphodiester backbone of DNA much more tightly than 2 equiv of the corresponding mononuclear complex due to the two-point DNA binding mechanism (*82*). Therefore, the first step of DNA cleavage promoted by Zn^{II}_2−**1** is that in which two zinc(II) cations recognize and bind the phosphodiester bond of DNA through the coordinate linkage and electrostatic interaction, and the synergistic effect between the two zinc(II) ions activates the central phosphorus atom. Then, the activated phosphorus atom is nucleophilically attacked by the proximate zinc(II)-bound OH, resulting in the formation of the trigonal bipyramidal phosphorus intermediate. Finally, one of the P−O ester bonds of the phosphodiester is broken by the intramolecular charge delivery to complete the DNA cleavage and the catalyst regeneration.

Consequently, DNA cleavage promoted by Zn^{II}_2−**1** takes place via a hydrolytic pathway with the observed maximum rate constant k_{obs}^1 of 0.136 ± 0.005 h^{-1}. This value is comparable to the value of 1×10^{-5} s^{-1} (0.36 h^{-1}) reported by Scrimin and co-workers (*58*) for the dinuclear zinc(II) complexes with a heptapeptide as the artificial nuclease. Recently, Yu and co-workers (*83*) reported that dimetallic zinc(II) complexes made by linking two cyclen ligands with pyridinic or phenolic moieties can completely cleave plasmid DNA to give form II after only 5 min. However, the complexes appear active only in the presence of the reducing agent vitamin C, and thus, the cleavage mechanism could be a nonhydrolytic pathway (*26*).

Table 1. Percentage of Growth Inhibition

	B16 cells[a]			HL-60 cells[a]		
	10^{-3} M	10^{-4} M	10^{-5} M	10^{-4} M	10^{-5} M	10^{-6} M
Zn^{II}	89	13	0	8	4	0
1	61	8	0	32	3	0
2	23	2	0	16	2	0
Zn^{II}_2−**1**	91	88	36	97	97	3
Zn^{II}−**2**	89	13	0	23	3	0

[a] Tumor cells were treated with different compounds for 72 h and incubated with 4 mg/mL MTT for 4 h. The amount of MTT formazan produced was determined by measuring the absorbance at 540 nm.

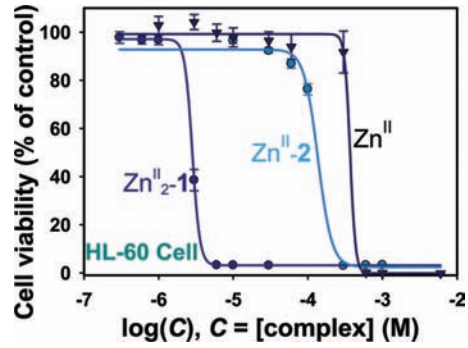


Figure 10. Inhibitory effect of zinc(II) ion, Zn^{II}−**2**, and Zn^{II}_2−**1** on the proliferation of HL-60 cells. Cells were exposed to the compounds for 72 h. The relative survival rate was determined in relation to that of untreated control cells, which was set to 100%. Data are means ± the standard deviation of three experiments, and each experiment included triplicate wells.

Cytotoxic Activities. To evaluate the antitumor activity, B16 and HL-60 cells were exposed to different concentrations of ligand **1**, **2**, zinc(II) ion, and the zinc(II) Zn^{II}_2−**1** and Zn^{II}−**2** complexes for 72 h. Cell viability was determined by MTT assays (*84*). The inhibition percentages are listed in Table 1. According to these results of the cytotoxic assays, we conclude that the two zinc(II) complexes (Zn^{II}_2−**1** and Zn^{II}−**2**) exhibit much stronger cytotoxic effects than the corresponding ligands (**1** and **2**), and HL-60 cells prove to be more sensitive to these compounds than B16 cells. The antitumor activities are shown to follow the order **2** < **1** < Zn^{II}−**2** < Zn^{II}_2−**1**. Heavy metal ions are cytotoxic to cells at 10^{-3} M (*85*). Table 1 and Figure 10 show that zinc(II) ions also exhibit antitumor activity at this level, but when zinc(II) ions are diluted to 3×10^{-4} M, the percentage inhibition decreases sharply ($IC_{50} = 3.70 \times 10^{-4}$ M). On the other hand, Zn^{II}_2−**1** still kept its antitumor activity toward HL-60 cells even at 10^{-6} M. To further evaluate the antitumor activity of the Zn^{II}_2−**1** and Zn^{II}−**2** complexes, IC_{50} values against HL-60 cells were calculated as shown in Figure 10. The IC_{50} values are 1.36×10^{-4} M for Zn^{II}−**2** and 2.54×10^{-6} M for Zn^{II}_2−**1**. We notice that the IC_{50} value against HL-60 cells of Zn^{II}_2−**1** is 50-fold larger than that of Zn^{II}−**2**.

CONCLUSIONS

In conclusion, a preorganized cleft bis(1,4,7-triazacyclononane)−Zn^{II} complex Zn^{II}_2−**1** as an artificial nuclease was prepared via an improved method. The interactions of **1**, **2**, and

their zinc(II) complexes with calf thymus DNA were studied by spectroscopic techniques (fluorescence and CD spectroscopy). The results indicate that the DNA binding affinities of these compounds are ordered as follows: Zn^{II}_2−**1** > Zn^{II}−**2** > **1** > **2**. The binding constant of Zn^{II}_2−**1** is 3.57×10^6 M^{-1}. Complex concentration, pH, and ionic strength dependences of the DNA cleavage promoted by Zn^{II}_2−**1** were studied by agarose gel electrophoresis. Kinetic data of DNA cleavage promoted by Zn^{II}_2−**1** (0.10 mM) under physiological conditions give an observed rate constant k_{obs} of 0.136 h^{-1}, which shows 10^7-fold rate acceleration over that of uncatalyzed supercoiled DNA. The DNA cleavage rate versus different [Zn^{II}]/[ligand] ratios at a constant ligand concentration was also studied to compare the DNA cleavage efficiencies between mononuclear **2** and dinuclear **1** zinc(II) complexes, and the result shows that the acceleration of the DNA cleavage promoted by Zn^{II}_2−**1** is due to the efficient cooperative catalysis of the preorganized two-proximate zinc(II) cation centers. ESI-MS analysis of the dinucleotide hydrolysis and radical scavengers' inhibition studies indicates the hydrolytic mechanism of the cleavage process. Furthermore, a preliminary study of the antitumor activity shows that the antitumor activity of the dinuclear zinc(II) complex is 50-fold higher than that of the mononuclear complex. The IC_{50} value against HL-60 cells of Zn^{II}_2−**1** is 2.54×10^{-6} M.

Disulfide Cross-Linked Polyethylenimines (PEI) Prepared via Thiolation of Low Molecular Weight PEI as Highly Efficient Gene Vectors

Qi Peng, Zhenlin Zhong,* and Renxi Zhuo

Key Laboratory of Biomedical Polymers of Ministry of Education, Department of Chemistry, Wuhan University, Wuhan 430072, P. R. China. Received August 26, 2007; Revised Manuscript Received November 30, 2007

Ring-opening reaction of low molecular weight polyethylenimine with an M_w of 800 Da (800 Da PEI) with methylthiirane produced thiolated polyethylenimine (PEI−SH_X). The thiolation degree X, which is the average number of thiol groups on a PEI molecule, was readily adjusted by the methylthiirane/PEI ratio. Oxidation of the thiolated PEIs with DMSO afforded disulfide cross-linked PEIs (PEI−SS_X). The molecular weights of PEI−SS_X were estimated by viscosity measurement to be 7100, 8000, and 8400 for $X = 2.6$, 6.5, and 9.4, respectively. The PEI−SS_X series can bind and condense plasmid DNAs effectively forming nanosized polyplexes. The size of dry polyplexes is less than 100 nm on the TEM pictures. In solution, the size of the polyplexes was measured by DLS to be about 400 nm. In vitro experiments showed that the PEI−SS_X series have a lower cytotoxicity and higher gene transfection efficiency compared with the high molecular weight PEI with M_w of 25 KDa. The presence of fetal bovine serum did not decrease the transfection efficiency. The results proved the hypothesis that reductively degradable disulfide-containing PEIs could possesses simultaneously higher gene transfection efficiency and lower cytotoxicity than the nondegradable ones.

INTRODUCTION

Recent years have witnessed rapid development of nonviral vectors based on polyethylenimine (PEI) and derivatives associated with gene therapy (*1–3*). The cationic polymer PEI has been widely used for nonviral transfection in vitro and in vivo and has an advantage over other polycations in that it combines strong DNA compaction capacity with an intrinsic endosomolytic activity. It is one of the most effective vectors among the synthetic polycations due to its proton sponge effect (*4–7*). High molecular weight PEI (HMW PEI) can form tight complexes with DNA. It attracts special interest due to its lysosomal buffering capacity and potential ability to protect DNA from degradation by lysosomal enzymes. Although gene delivery efficiency increases with the molecular weight of PEI, cytotoxicity also increases. HMW PEI/DNA polyplexes can exist in very small dense particles, thereby limiting the unpacking of DNA once inside the nucleus (*8*). On the other hand, low molecular weight PEI (LMW PEI), which has demonstrated a low toxicity in cell culture studies (*9, 10*), can not effectively condense DNA and displays very poor transfection activity (*11*).

To circumvent these problems, it is supposed that enhancement in gene delivery efficiency with minimal cytotoxicity may be achieved by cross-linking small PEIs with linkages that are potentially biodegradable (*12–14*). Such linkages include esters, amides, orthoesters, acetals, glycosides, and disulfides. Almost all these synthetic degradable PEIs have been designed to solve the following two problems: first, the contradiction between tight complex formation outside cells and the easy dissociation of complexes inside cells; second, preparation of the nonviral gene vector with high transfection efficiency and low cytotoxicity (*15*).

The strategy of reversible cross-linking of small PEIs with disulfide bonds that are cleavable in intracellular reductive environments is especially attractive. A disulfide bond could be cleaved by reduced glutathione, and the intracellular glutathione concentration is 50–1000 times higher than that in extracellular milieu (*16, 17*). It provides a way to maintain stability of the cross-linked polymer and form compact polyplexes with pDNA in the extracytoplasmic environment, while inducing the efficient release of entrapped pDNA from the polyplexes after their movement into the reductive cytoplasmic compartment. This would achieve efficient gene expression in vivo while limiting effects of toxicity. The disulfide bond has been successfully applied in preparation of environmentally sensitive polycations such as modified PEIs (*12, 18–20*), PLL (*21, 22*), and peptides (*23, 24*) for gene delivery. In the first report describing the transfection properties of cross-linked LMW PEI by disulfide bonds, branched PEI with an M_w of 800 Da was cross-linked by the reaction with either dithiobis(succinimidylpropionate) (DSP) or dimethyl 3,3′-dithiobispropionimidate dihydrochloride (DTBP), resulting in greatly increased gene transfection efficiency (*12*). The DTBP cross-linked LMW PEI has showed a significantly lower cytotoxicity compared to a HMW PEI (*18*). More recently, disulfide-connected linear polyethylenimines were reported to have gene transfection efficiency close to nondegradable high molecular linear PEI, while their cytotoxicity is very low or negligible compared to the latter (*20*).

Though the results in the literature are very encouraging, no disulfide-containing PEI was reported to have a gene transfection efficiency surpassing an unmodified HMW PEI. Moreover, early cytoplasmic DNA release might result in gene digestion by cytosolic nucleases (*25*). So, it is still unclear whether a disulfide-containing PEI possesses an advantage in gene transfection efficiency over the normal nondegradable PEIs. This paper would introduce a new strategy for preparation of disulfide-containing PEIs by oxidation of thiolated LMW PEI with the polyethylenimine structure intact. The results proved the hypothesis that reductively degradable disulfide-containing

PEIs could possess simultaneously higher gene transfection efficiency and lower cytotoxicity than the nondegradable ones.

MATERIALS AND METHODS

Materials. PEIs with M_W of 800 Da and 25 KDa were purchased from Aldrich. Methylthiirane was synthesized by literature procedure (*26*). pEGFP-5.3 kb, a plasmid DNA containing the green fluorescent protein gene under the control of human cytomegalovirus (CMV) immediate early promoter, and encoding a red-shifted variant of wild-type green fluorescent protein (GFP), was purchased from Clontech, Mountain View, CA. Plasmid pGL3 under the control of SV40 promoter and with enhancer sequences encoding luciferase was obtained from Promega, Madison, WI. Plasmids were propagated in *Escherichia colia* in Luria–Bertani (LB) medium containing 50 μg/mL kanamycin or 60 μg/mL ampicillin at 37 °C. The mixture was shaken overnight at 250 rpm. The plasmid was purified using E. Z. N. A. Fastfilter Endofree Plasmid Midi kits (Omega) according to the manufacturer's instruction. The DNA concentration was determined by measuring the UV absorbance at 260 nm. The purity of DNA was assessed spectrophotometrically by measuring absorbance at wavelengths of 260 and 280 nm (OD_{260}/OD_{280} 1.8 or greater). Concentration and purity of DNA were confirmed using 0.7% agarose gel electrophoresis containing GelRed. DNA aliquots were stored at −20 °C prior to use. Dubelcco's Modified Eagle's Medium (DMEM), penicillin−streptomycin, trypsin, Dubelcco's phosphate buffered saline, and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were purchased from Sigma. Other commercially available reagents were used as received.

Synthesis of Thiolated LMW PEI (PEI−SH_X). In a 25 mL flask, 1.00 g of PEI (800 Da) was dissolved in 5 mL of deionized water. Next, 0.1 N HCl was added dropwise to the PEI solution while stirring until pH was regulated to 7.2. After removal of water by evaporation under reduced pressure, the yellow solid thus obtained was dispersed in 3 mL of CH_3OH in an ampule. After the sample was purged with argon for 5 min, a calculated amount of methylthiirane was added to the ampule. The ampule was sealed and kept in a 50 °C oil bath for 24 h with magnetic stirring. The content of the ampule was transferred to a flask and evaporated to dryness under reduced pressure and kept under argon. The thiol group content was determined by Ellman's method (*27*, *28*). ^{1}H NMR (300 MHz, D_2O): δ 3.15–2.55 (m, NCH_2CH_2N, NCH_2CHMeS), 1.18–1.05 (m, CH_3).

Synthesis of Disulfide Cross-Linked PEI (PEI−SS_X). A solution of 1.50 g of PEI−SH_X in 3 mL of methanol and 1.5 mL of dimethyl sulfoxide (DMSO) was stirred for 48 h. The reaction solution was precipitated in diethyl ether three times, and dried under high vacuum to give a light yellow viscous glue. ^{1}H NMR (300 MHz, D_2O): δ 3.14–2.66 (m, NCH_2CH_2N, NCH_2CHMeS), 1.25–1.05 (m, CH_3).

Cytotoxicity Assay of PEI−SS_X. The cytotoxicity assay was carried out on the basis of an MTT assay on HeLa cells. HeLa cells were seeded in 96-well plates at an initial density of 5000 cells/well in 200 μL of DMEM complete medium. The cells were allowed to grow for 24 h. The original media were replaced with 100 μL of fresh media. The PEI−$SS_{2.6}$, PEI−$SS_{6.5}$, PEI−$SS_{9.4}$, or 25 KDa PEI solution was added to the media at concentrations ranging from 0.001 to 0.5 mg/mL. Each dosage was replicated in 4 wells. Treated cells were incubated at 37 °C under a humidified atmosphere of 95% air and 5% CO_2 for 24 h. MTT reagent (20 μL in PBS, 5 mg/mL) was added to each well, and the cells were incubated for another 4 h at 37 °C. 100 μL of DMSO was added to each well until all crystals dissolved. The absorbance at 570 nm of the solution in each well was recorded using a Microplate Reader (Bio-Rad model 550). Cell viability was calculated according to the following equation: cell viability (%) = $(OD_{sample} - OD_{blank})/(OD_{control} - OD_{blank}) \times 100$ where OD_{sample} is the absorbance of the solution of the cells cultured with the polymer and PEI; OD_{blank} is the absorbance of the medium; and $OD_{control}$ is the absorbance of the solution of the cells cultured with the medium only.

Viscosity Measurements. Capillary viscosity measurements were carried out to estimate molecular weights (*29*, *30*). The polyamine polymers were neutralized with hydrochloric acid and dissolved in 150 mM NaCl at concentration from 20 mg/mL to 5 mg/mL. Viscosity measurements were carried out using a capillary viscometer at 25 °C. The molecular weights of cross-linked polymers were calculated using the Mark–Houwink equation $[\eta] = KM^{\alpha}$ where M is the molecular weight and K and α are Mark–Houwink parameters determined from PEI standards of known molecular weights.

Preparation of PEI−SS_X/pDNA Polyplexes and Agarose Gel Retardation. A 0.1 mg/mL aqueous solution of plasmid DNA (pEGFP or pGL3) was diluted to designed concentration (usually 20 μg/mL) using 150 mM NaCl solution under vortexing. Designed aqueous solutions of PEI−SS_X were added slowly to the pDNA solutions. The amount of polymer added was calculated on the basis of chosen N/P ratios of PEI−SS_X/DNA (nitrogen atoms of the polymer over phosphates of pDNA). The mixture was incubated at room temperature for 30 min for the complex formation. A 5 μL sample of the polyplex solution mixed with 1 μL of 6× loading buffer was loaded to agarose gel. The polyplexes were electrophoresed on a 0.7% agarose gel containing GelRed with Tris-acetate (TAE) running buffer (pH 8) at 80 V for 80 min. DNA bands were visualized by an UV (254 nm) illuminator and photographed with a Vilber Lourmat imaging system (France). The shapes of the complexes of polymer/DNA were observed at 25 °C using a transmission electron microscope.

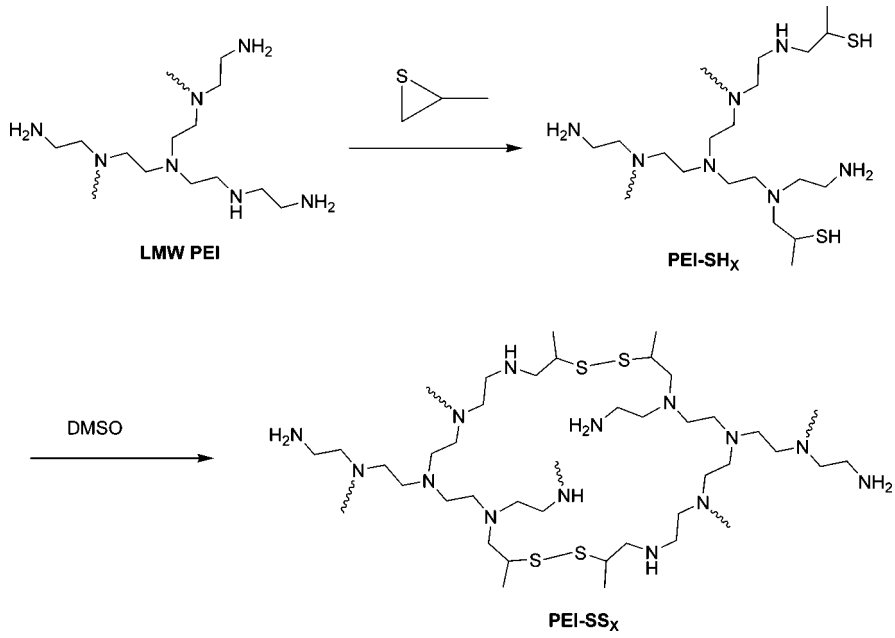
DTT Reduction of Disulfides and its Impact on Stability of the PEI Polyplexes. To the solution of PEI−$SS_{2.6}$/pDNA polyplex at N/P ratio of 10 prepared as described above was added 1,4-dithio-DL-threitol (DTT) at different concentrations from 0.1 to 310 mM. Polyplexes were incubated at room temperature for 30 min. Then the polyplexes were electrophoresed on a 0.7% agarose gel containing GelRed with Tris-acetate (TAE) running buffer at 80 V for 80 min.

Particle Size and Zeta Potential Measurements. The particle size and zeta potential were measured on a Nano-ZS ZEN3600 (Malvern) instrument at room temperature. The polyplexes at various N/P ratios were prepared by adding appropriate volume of pEGFP DNA solution (0.1 mg/mL in 40 mM Tris−HCl buffer) to appropriate volumes of PEI−SS_X solution (in 150 mM NaCl). Then the polyplexes were incubated at room temperature for 30 min. After that, the polyplexes were diluted with 150 mM NaCl solution or pure water to 1.0 mL volume prior to measure. The final sample containing 1 μg of pDNA is in 150 mM NaCl for size measurements or in 10 mM NaCl for zeta potential measurements.

Determination of in Vitro Transfection Efficiency. The in vitro transfection efficiency of PEI−SS_X was evaluated in 293T and HeLa cells, using the polyplexes of PEI−SS_X with pGL3 or pEGFP DNA.

As for pGL3, a typical procedure is as follows: Cells were seeded at a density of 70 000–80 000 cells/well into 24-well plates. They were incubated at 37 °C in a humidified atmosphere of 95% air and 5% CO_2 until the cells reached about 70% confluence. At the time of transfection, the medium in each well was replaced with 1 mL of DMEM without containing FBS. The polyplexes of polymer/DNA at N/P ratios ranging from 10:1 to 40:1 prepared as described above were added and incubated with cells for 4 h at 37 °C. The amount of DNA added

Scheme 1. Schematic Representation of the Preparation of the Disulfide-Cross-Linked LMW PEIs (PEI−SS$_X$)



to each well was 1 μg. The medium was replaced with 1 mL of fresh complete medium, and the cells were further incubated for 48 h. After incubation, cells were permeabilized with 200 μL of cell lysis buffer. After two cycles of freezing and thawing, the lysate was transferred into microtubes and centrifuged for 5 min. Then the luciferase activity of the supernatants were measured using 100 μL of luciferase assay reagent on a Lumat LB 9507 tube luminometer (Berthold) for 30 s. The light units (LU) measured using a protein assay kit (Pierce) were normalized against protein concentration in the cell extracts. Luciferase activity was expressed as relative light units (RLU/mg protein). The data were reported for triplicate samples.

pEGFP transfection efficiency was estimated using a flow cytometry (Beckman Coulter XL, USA). HeLa cells were seeded at a density of 70 000–80 000 cells/well in a 24-well tissue culture plate. The cells were incubated at 37 °C in a humidified atmosphere of 95% air and 5% CO_2 until the cells reached about 70% confluence. The cells were transfected with polymer/pEGFP polyplexes at N/P ratios ranging from 10:1 to 40:1 prepared as described above. For comparison, cells transfected with naked pEGFP and branched 25 KDa PEI were used as a control at the N/P ratio of 10. The total amount of plasmid in each well was kept at 1.0 μg. The process of transfection is as described above. After the transfection, cells were separately harvested from each well by the trypsin-EDTA treatment, and suspended in 1 mL of PBS in microcentrifuge tubes. The cells expressing green fluorescent protein were enumerated by the fluorescence-activated cell sorting. The nontransfected cells were used as a negative control.

In Vitro Transfection Experiment in Serum. The process of transfection experiments was the same as described above, except that the medium at the time of transfection was replaced with DMEM containing 10% FBS (fetal bovine serum).

Preparation of PEI−SS$_{2.6}$/pDNA Polyplexes by in Situ Air Oxidation and Determination of in Vitro Transfection Efficiency. At designed time intervals prior to the transfection experiments, calculated amounts of PEI−SH$_{2.6}$ and pDNA were mixed in 150 mM NaCl at pDNA concentration of 20 μg/mL in a 1.5 mL centrifuge tube. The mixed solutions in the tubes were incubated in air at room temperature for in situ oxidation of the thiol groups and polyplex formation. The transfection efficiency of the polyplexes thus prepared with different oxidation times was determined parallel on a 24-well plate by the previously described process.

RESULTS AND DISCUSSION

Design and Preparation of PEI−SS$_X$ via Thiolation and Cross-Linking of 800 Da PEI. The strategy for preparation of the disulfide cross-linked PEIs is shown in Scheme 1 in two steps. First, a LMW PEI is thiolated by ring-opening reaction with methylthiirane. Second, the thiolated PEI is cross-linked into higher molecular weight structures by disulfide-forming oxidation of the thiol groups. Langer et al. (*7*) have proven that the high transfection efficiency of PEI is greatly attributed to the high buffering capacity in the endosomal pH range 5–7. Therefore, it is important to keep the buffering property of PEI unaffected during disulfide cross-linking. The disulfide-containing cross-linking reagents DSP and DTBP (*12*) or thiolation reagents iminothiolane (*19*) and *N*-succinimidyl-3-(2-pyridyldithio)propionate (*22*) used in the literature, however, would transfer an amino group to either a neutral amide group or a strong basic α-amino imino group, inevitably affecting the polyamine structure and lowering the endosomal buffer capacity of PEI. We designed the two-step route as shown in Scheme 1 using methylthiirane as a thiolation reagent based on the consideration that the thiolation reaction would not significantly change the acid–base property of the PEI, because it only transfers a primary or second amine group into a higher order amine by adding a mercaptoalkyl group without causing a significant change in pK_a.

Thiolation of LMW PEI (M_w = 800 Da) was achieved through the ring-opening reaction of methylthiirane with the primary and secondary amino groups of PEI at pH 7.2, resulting in the introduction of 2-mercaptopropyl groups on the amine groups (Scheme 1). The products with variable thiol group contents thus prepared were presented as PEI−SH$_X$, where X stands for the average number of thiol groups on each 800 Da PEI molecule. The thiolation degree X was determined by Ellman's test (*28*, *29*). With methylthiirane/PEI feed ratios (mol/mol) of 3, 8, and 12, the thiolation degree (X) of the product PEI−SH$_X$ were found to be 2.6, 6.5, and 9.4, respectively.

It was found that keeping a neutral or slightly acidic pH is critical for this reaction. The thiol-generating ring-opening

reaction of a thiirane with an amine group is always competed by the sulfide-generating ring-opening polymerization reaction. Under the basic condition of a free PEI, the main reaction is ring-opening polymerization of methylthiirane resulting in a polysulfide with very few thiol groups only at the chain ends, because a thiol group is deprotonated as a thiolate anion that is a much more active nucleophile than an amine group. Under a condition of neutral or slightly acidic, a great portion of amine groups exist in the active free form while most thiol groups remain in a less active neutral form. Therefore, the thiolate-initiated ring-opening polymerization reaction would be negligible under the neutralized condition.

Thiolated LMW PEIs were cross-linked by oxidation with DMSO at room temperature, and the final products PEI−SS_X were subjected to Ellman's test for the estimation of residual thiol groups. After 2 days of the cross-linking reaction in DMSO, the amount of remained thiol groups was found to be less than 10% of the initial value for all samples, indicating the formation of covalent disulfide bonds.

All the three oxidized products PEI−SS_X ($X = 2.6$, 6.5, and 9.4) were water-soluble, indicating that the cross-linking is constrained within a definite number of LMW PEI molecules. For PEI−$SH_{2.6}$ and PEI−$SH_{6.5}$, the reaction mixtures were clear solutions during the whole oxidation process. For PEI−$SH_{9.4}$, however, gelation was observed during the cross-linking process. The gel became a clear solution again gradually in one to two days at room temperature. This phenomenon may be explained by the interchange of intramolecular and intermolecular disulfide bonds. At a high thiolation degree, a cross-linked network might be formed through intermolecular disulfide bonds resulting in gelation. The gel gradually dissolved with the destruction of the infinite network, probably because some intermolecular disulfide bonds transferred into intramolecular ones under the experimental conditions.

Molecular weights of the disulfide cross-linked PEI−SS_X were estimated by viscosity measurements using a capillary viscometer. In 150 mM NaCl aqueous solution (pH 7.4, 20 °C), the intrinsic viscosities of PEI−$SS_{2.6}$, PEI−$SS_{6.5}$, and PEI−$SS_{9.4}$ were measured to be 6.96, 7.16, and 7.22 L/g, respectively; while those of 800 Da PEI and 25 KDa PEI purchased from Aldrich were measured to be 4.22 and 7.29 L/g, respectively. Thus, the molecular weights of PEI−$SS_{2.6}$, PEI−$SS_{6.5}$, and PEI−$SS_{9.4}$ were estimated to be 7100, 8000, and 8400, respectively. Surprisingly, the disulfide cross-linked PEIs have very similar intrinsic viscosities regardless of their thiolation degree in the range from 2.6 to 9.4. This result suggests that the majority of disulfide cross-links are intramolecular when the thiolation degree is high. It should be noted that the molecular weights of the PEI−SS_X, especially those with high thiolation degrees, might be underestimated because of their more compact structure compared to the non-cross-linked PEI.

As expected, the acid–base titration curves of the PEI−SS_X series are almost identical with that of 25 KDa PEI, showing good buffering capacity in the pH range 5−7.

Cytotoxicity of PEI−SS_X. MTT assay was carried out to determine the cytotoxicity of the PEI−SS_X series. Figure 1 shows that the PEI−SS_X series, regardless of the thiol group content, had a lower cytotoxicity compared to 25 KDa PEI in HeLa cells. Their IC_{50} values are all about 25 μg/mL being around nearly four times higher than the IC_{50} of 7 μg/mL of 25 KDa PEI, though greatly lower than the IC_{50} of 800 Da PEI (>200 μg/mL). The cytotoxicity of cationic polymers was probably caused by polymer aggregation on cell surfaces impairing the important membrane function (*31*). Also, polymers may interfere with critical intracellular processes of cells. PEI−SS_X has an amine constitution similar to 25 KDa PEI; therefore, its relatively low cytotoxicity should be caused by

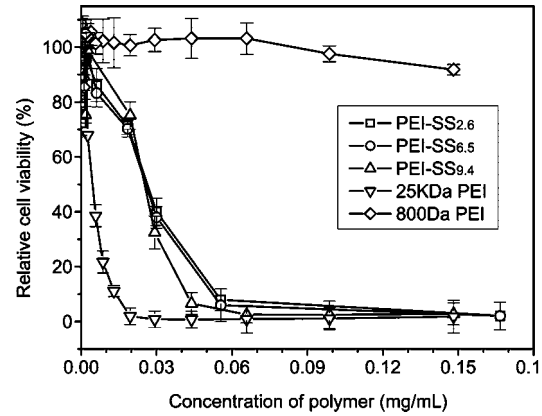


Figure 1. Relative cell viability at 24 h after the addition of PEI−SS_X and 25 KDa PEI.

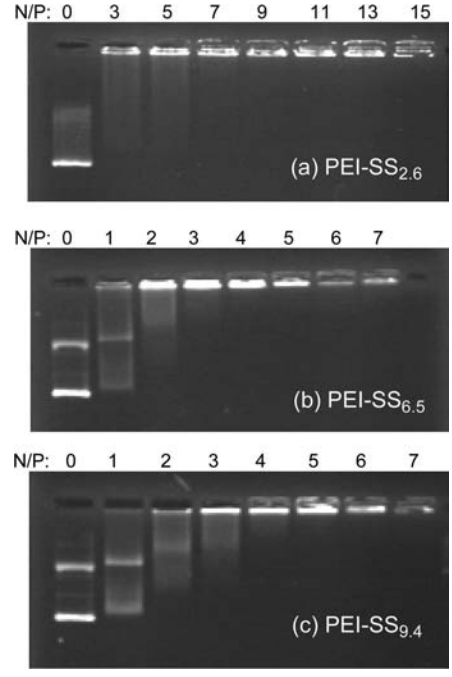

Figure 2. The effect of increasing concentration of PEI−SS_X on the electrophoretic migration of pEGFP through an agarose gel. The polyplex composition (N/P ratio) was expressed as PEI nitrogen atoms per DNA phosphate.

the lower molecular weight as reported for lower molecular weight PEI and the lower amine content (*12*). In addition, PEI−SS_X should degrade into low molecular weight PEI with low toxicity. Therefore, the biocompatibility and long-term safety of PEI−SS_X should be improved significantly as compared to the widely used 25 KDa PEI.

Formation and Charaterization of PEI−SS_X/pDNA Polyplexes. The polyplex of a disulfide cross-linked LMW PEI with a pDNA was prepared by adding PEI−SS_X aqueous solution slowly to the pDNA solution. The amount of polymer added was calculated on the basis of chosen N/P ratios, nitrogen atoms of the polymer over phosphates of pDNA, in PEI−SS_X/DNA. Formation of the polyplexes was investigated by agarose gel retardation and TEM measurements.

As shown in Figure 2, as the concentration of the polycation increased, the mobility of pEGFP was reduced by increasing DNA condensation and compaction. PEI with M_w of 800 Da used for the preparation of PEI−SS_X could not form stable complexes with DNA, even at N/P ratios higher than 20 (data not shown). In contrast, 25 KDa PEI was the most efficient

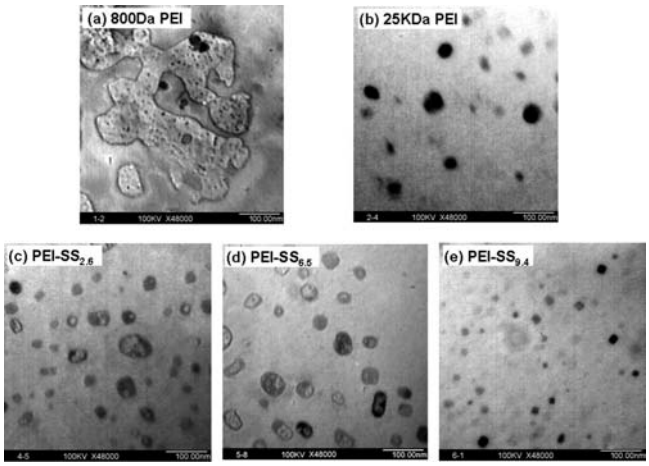

Figure 3. Transmission electron microscope of polyplexes of pEGFP with (a) 800 Da PEI, (b) 25 KDa PEI, (c) PEI−$SS_{2.6}$, (d) PEI−$SS_{6.5}$, and (e) PEI−$SS_{9.4}$ at N/P = 30.

that it could completely retard DNA migration at a N/P ratio of 1, while the required N/P ratios were 7, 3, and 5, for PEI−$SS_{2.6}$, PEI−$SS_{6.5}$, and PEI−$SS_{9.4}$ to completely retard the pDNA, respectively. These results demonstrated that this kind of disulfide cross-linked LMW PEI can bind a pDNA effectively in a wide range of thiol group contents. While the DNA binding capacity of these disulfide cross-linked polymers is not very sensitive to the thiol group content, PEI−$SS_{6.5}$, the one with 6.5 disulfide bonds on each 800 Da PEI, showed a higher binding capacity than PEI−$SS_{2.6}$ and PEI−$SS_{9.4}$. This result suggests that a disulfide bond density that is too low or too high is not good for DNA binding.

The size and shape of the polyplexes were then evaluated by TEM measurements (Figure 3). All of the polyplexes, regardless of the cross-linking and charge densities, have diameters below 100 nm at N/P ratio of 30. In the pictures, very few nanosized spherical structures and mainly anomalous congeries with a size of several micrometers were observed in 800 Da PEI/DNA (Figure 3a). In contrast, small granules mainly with a short axis of 30–60 nm were found in 25 KDa PEI/DNA (Figure 3b). It illustrates that 25 KDa PEI forms compact polyplex particles with plasmid DNA, in good agreement with earlier reports (*32*, *33*). Oval structures in the size range 10–100 nm in the PEI−SS_X/DNA polyplexes were shown in Figure 3c−e. They did not show obvious differences in their morphology as compared to 25 KDa PEI/DNA polyplex. PEI−$SS_{9.4}$/DNA particles were found to be smaller than those of PEI−$SS_{2.6}$ and PEI−$SS_{6.5}$ on the TEM photographs.

The particle sizes of the polyplexes in 150 mM NaCl solution were determined by DLS as shown in Figure 4. At N/P ratios above 10, the pDNA polyplexes of the three PEI−SS_X polymers all have a size of about 400 nm. 25 KDa PEI forms the most compact pDNA polyplex with a size about 200 nm, and 800 Da PEI forms the loosest polyplex with a size of about 1000 nm. The trend of the sizes is in accordance with the results of molecular weight measurements and gel retardation experiments.

Zeta potentials of the polyplexes were measured in 10 mM NaCl solutions and shown in Figure 5. At N/P ratios below 3, the zeta potentials are negative showing an incomplete complexation. With increasing N/P ratio, zeta potentials of the polyplexes rapidly increase and reach plateaus at N/P ratios between 10 and 20. The 25 KDa PEI polyplex has the highest zeta potential of 35 mV, and the 800 Da PEI polyplex has the lowest zeta potential of 10 mV. All three PEI−SS_X (X = 2.6, 6.5, and 9.4) polyplexes have very similar zeta potentials of about 25 mV.

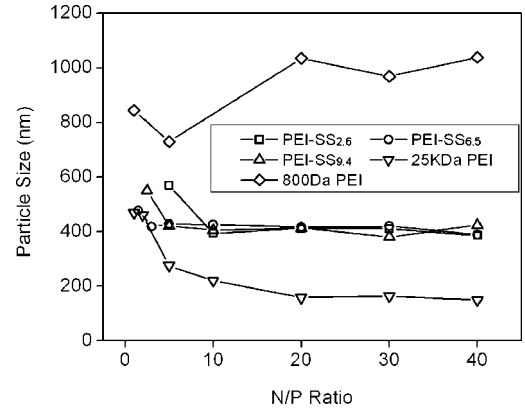

Figure 4. Particle size of the PEI/pDNA polyplexes measured by DLS in 150 mM NaCl solution.

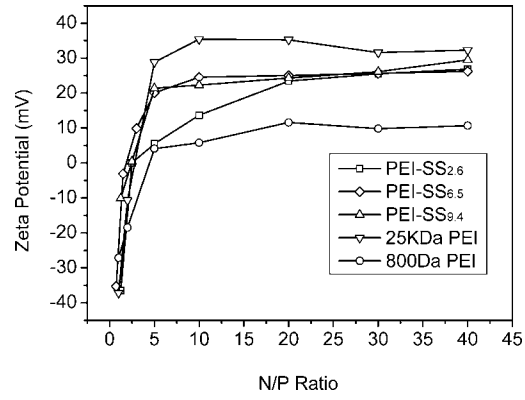

Figure 5. Surface charge of the PEI/pDNA polyplexes in 10 mM NaCl solution at various N/P ratios.

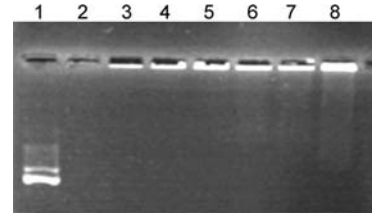

Figure 6. Gel retardation analysis of PEI−$SS_{2.6}$/pEGFP (N/P = 10) complex pretreated with various concentration of DTT. Lane 1, pEGFP only; lane 2, PEI−$SS_{2.6}$/pEGFP; lanes 3–8, PEI−$SS_{2.6}$/pEGFP pretreated with 0.1, 0.5, 2.5, 12.5, 62.5, and 310 mM DTT for 30 min.

Effect of DTT on Stability of PEI−SS_X/pDNA Polyplex. The stability of the PEI−SS_X/pDNA polyplexes in reductive media was investigated using 1,4-dithio-DL-threitol (DTT) as a reductive reagent. PEI−$SS_{2.6}$/pEGFP polyplex at N/P ratio of 10 was added pretreated for 30 min with DTT at a wide concentration range from 0.1 to 310 mM, and then checked by gel retardation analysis. As shown in Figure 6, with the increase of DTT concentration, the DNA band at the sample loading hole became more and more bright. At high DTT concentration, a "tail" outside the hole was visible. No band of the free pDNA, however, was observed even when the DTT concentration was as high as 310 mM. Therefore, it is not clear whether or to what extent the intracellular reductive environments with several millimolars of glutathione can help the release of pDNA from the disulfide cross-linked polyplexes.

In Vitro Transfection Efficiency. The gene delivery efficiency of the disulfide cross-linked LMW PEIs was evaluated by in vitro transfection experiments of pGL3 and pEGFP into HeLa and 293T cells. Branched 25 KDa PEI, which is the most

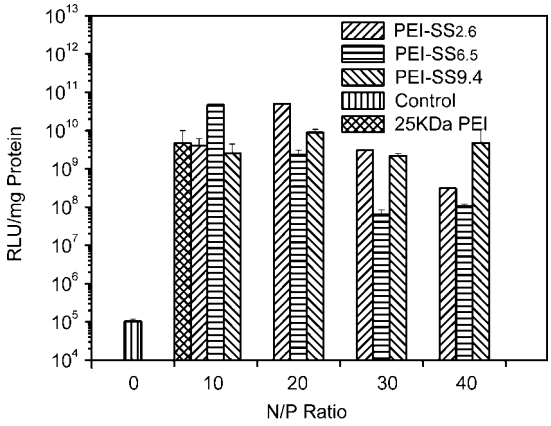

Figure 7. In vitro transfection efficiency of the polyplexes of pGL3 with PEI−SS_X series in HeLa cells in comparison with 25 KDa PEI. The transfection efficiency of 25 KDa PEI was obtained at an optimal N/P ratio of 10:1. Data are averages of three parallel experiments.

widely used polycation gene vector and considered highly efficient, was used for comparison. Our own experiments (data not shown) and literature report (*12*) showed that 25 KDa PEI yields optimal gene expression at N/P ratio around 10.

The transfection results of pGL3 to cultured HeLa cells were presented in Figure 7. The polyplexes of PEI−SS_X series showed transfection efficiencies comparable to or even significantly higher than that of 25 KDa PEI. Within the range of N/P ratios tested, PEI−$SS_{6.5}$ showed a maximum efficiency at an N/P ratio of 10, while PEI−$SS_{2.6}$ and PEI−$SS_{9.4}$ showed their maxima at a relatively higher N/P ratio of 20. This result is consistent with the gel retardation results showing that PEI−$SS_{6.5}$ has the highest DNA binding capacity among the three. At their own optimal N/P ratios, the PEI−$SS_{2.6}$ and PEI−$SS_{6.5}$ systems achieved nearly 10 times higher luciferase expression as compared with the optimal value of 25 KDa PEI. This result is notable compared with the literature reports in which the gene transfection efficiency of either branched or linear low molecular weight PEI was greatly enhanced by disulfide linkages but still significantly lower than that of their high molecular weight analogues (*12, 20*).

Excellent transfection ability of the PEI−SS_X series was further confirmed in the transfection of pEGFP to 293 T and HeLa cells.

The transfection of pEGFP in 293T and HeLa cells by PEI−SS_X was first visualized with a fluorescent microscope (Figure 8). 25 KDa PEI was also used for comparison, and naked pEGFP was used as a control. The cells transfected with PEI−SS_X/pEGFP and 25 KDa PEI/pEGFP showed many bright green fluorescent spots, while the 293T control transfected with naked pEGFP had only a few dim fluorescent spots. As shown in Figure 8, both 293T and HeLa cells with PEI−$SS_{2.6}$ as a pEGFP gene vector expressed much more fluorescent proteins than those with 25 KDa PEI. Moreover, PEI−$SS_{2.6}$ showed much lower cytotoxicity than 25 KDa PEI even at a higher N/P ratio. Under a microscope (pictures not shown), the appearance of the cells transfected with PEI−SS_X/pEGFP at N/P ratio of 30 was as normal as those with naked pEGFP, while the cells with 25 KDa PEI/pEGFP had a decreased cell density with some cells lumped together.

The transfection efficiency of pEGFP in HeLa was further quantified using a flow cytometry in terms of cell population expressing GFP. Figure 9 shows the percentage of the HeLa cells expressing GFP. It reveals again that the PEI−SS_X has apparently higher transfection efficiency than 25 KDa PEI. Within the N/P ratios of 10, 20, 30, and 40 tested, all the three PEI−SS_X/pEGFP polyplexes (X = 2.6, 6.5, and 9.4) showed

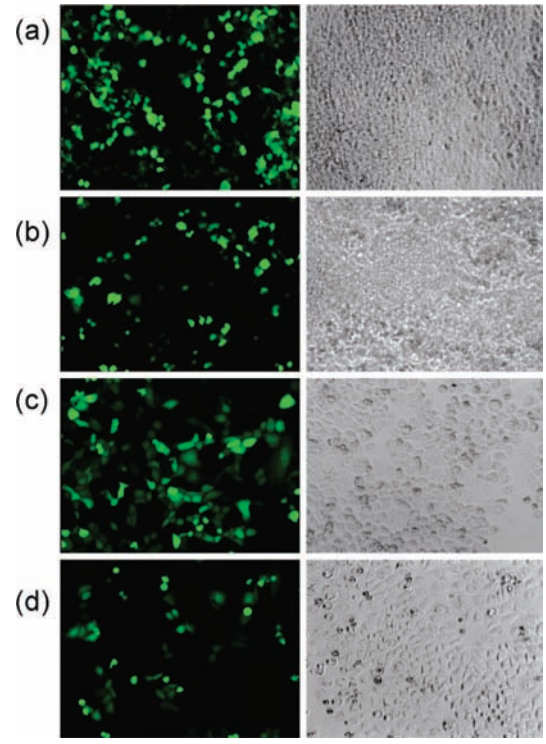

Figure 8. Fluorescent microscope images of pEGFP-transfected cells: (a) PEI−$SS_{2.6}$ in 293T at N/P = 30, (b) 25 KDa PEI in 293T at N/P = 10, (c) PEI−$SS_{2.6}$ in HeLa at N/P = 30, and (d) 25 KDa PEI in HeLa at N/P = 10.

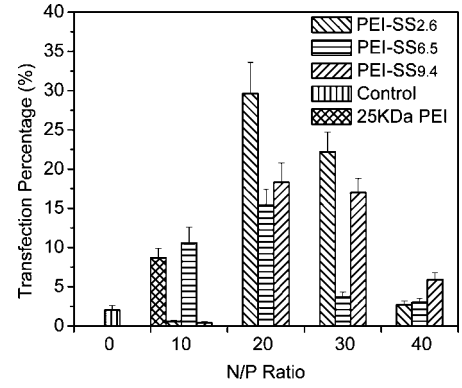

Figure 9. Transfection efficiency of the pEGFP polyplexes with PEI−SS_X to HeLa cells in terms of the percentage of cells expressing GFP.

their maximum efficiency values at N/P ratio of 20, with 15–30% cells expressing detectable GFP. In the case of 25 KDa PEI/pEGFP at an optimal N/P ratio of 10, the percentage of the cells expressing detectable GFP was 9%.

It is proven that the high buffering capacity in the endosomal pH range 5–7 originating from the unique polyamine structure is very important for the high transfection efficiency of PEI (*7*). Also, it is reported that reductive agents such as glutathione at an intracellular concentration can help the release of pDNAs from the polyplexes with disulfide-containing PEIs (*12, 20*). Therefore, the remarkably higher transfection efficiency of PEI−SS_X compared with 25 KDa PEI might be attributed to the introduction of reductively cleavable disulfide bonds, while the high density polyamine structure and buffering property of PEI are almost intact.

Since therapeutic gene transfection is in vivo, it is important to investigate the influence of serum on the transfection efficiency. For comparison, parallel transfection experiments of

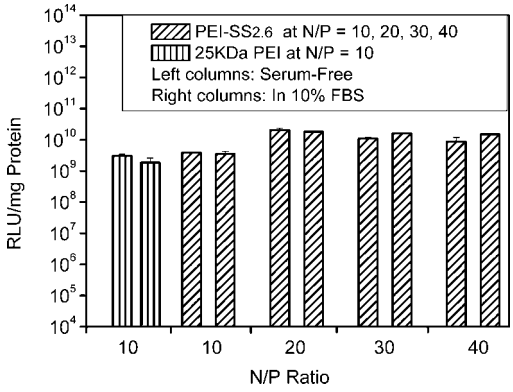

Figure 10. Comparison of transfection efficiency pGL3 to HeLa cells in serum-free and serum-supplemented DMEM media.

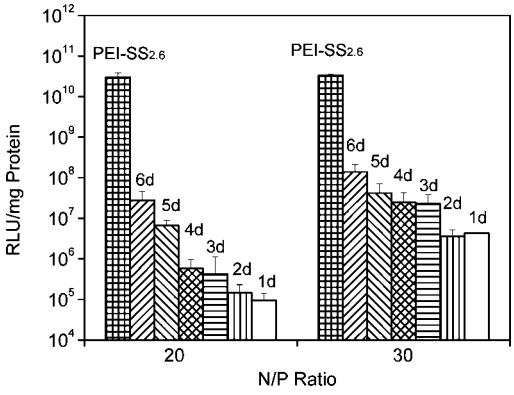

Figure 11. Comparison of the polyplexes prepared by in situ air oxidation of PEI−$SH_{2.6}$ for 1 to 6 days with the polyplexes prepared from DMSO-preoxidized PEI−$SS_{2.6}$ for transfection of pGL3 to HeLa cells.

pGL3 to HeLa cells in the absence or presence of 10% FBS were performed using PEI−$SS_{2.6}$ as a vector (Figure 10). For PEI−$SS_{2.6}$ at an N/P ratio of 10 and 20, no significant difference could be observed between the efficiencies in serum-free medium and serum-supplemented medium. At N/P ratio of 30 and 40, the efficiency in the serum-supplemented medium was even slightly higher than that in serum-free medium. For 25 KDa PEI at an N/P ratio of 10, however, the presence of 10% FBS decreased the efficiency slightly by about 50% of luciferase expression level. These results imply that PEI−SS_X might be suitable for in vivo gene transfection.

It was reported that monomolecular pDNA nanoparticles were successfully prepared through in situ air-oxidation of amphiphilic thiol compounds (*34*, *35*). Therefore, it is attractive to investigate whether the polyplexes prepared by in situ air oxidation of thiol PEI with pDNA possess any advantage over those prepared with the pre-cross-linked PEI−SS_X. Comparative transfection experiments about PEI−$SH_{2.6}$/DNA polyplexes oxidized in air for a different period of time with PEI−$SS_{2.6}$/DNA polyplexes were performed (Figure 11). The efficiency of the in situ air-oxidized polyplexes increased gradually with the oxidation time from 1 to 6 days, suggesting a very slow oxidation process. Even after oxidation for six days, the efficiency was still a few orders of magnitude lower than the polyplexes from the PEI−$SH_{2.6}$ preoxidated in DMSO at both N/P ratios of 20 and 30.

CONCLUSION

Designed amounts of thiol groups were readily introduced to LMW PEI using methylthiirane as an effective thiolation agent cross-linking reagent. Since thiol groups and amino groups are competent in the ring-opening reaction of a thiirane, it is important to adjust the basic reaction medium to a neutral pH in order to preventing the thiol groups from sulfide-forming polymerization. The thiolated LMW PEIs were transferred to disulfide cross-linked polyethylenimines, PEI−SS_X, by oxidation of the thiol groups with DMSO. The structure and buffering property of PEI were kept almost intact in PEI−SS_X because the thiol groups were introduced by the ring-opening alkylation on amino groups which does not significantly change the acid–base property. In vitro experiments demonstrated that the PEI−SS_X series have lower cytotoxicity and much higher gene transfection efficiency than 25 KDa PEI. The results proved that reductively degradable disulfide cross-linked low molecular weight PEIs could possess simultaneously higher gene transfection efficiency and lower cytotoxicity than their nondegradable high molecular weight analogues.

Received September 10, 2007; Revised Manuscript Received November 13, 2007

Herein, we present the efficient cellular uptake of immobilized virus-like particles (VLPs) made of recombinant JC virus capsid proteins. VLPs expressed in *Escherichia coli* were labeled with fluorescein isothiocyanate (FITC). We compared two approaches for the cellular uptake of the FITC-VLPs. In the first approach, FITC-VLPs were immobilized on a polystyrene substrate, and then NIH3T3 cells were cultured on the same substrate. In the second approach, cells were cultured on a polystyrene substrate, and FITC-VLPs were then added to the cell culture medium. Flow cytometric analysis and confocal laser microscopic observation revealed that immobilized VLPs were incorporated into the cells with higher efficiency than were the diffusive VLPs suspended in solution. The cellular uptake of VLPs on the substrate was increased in a VLP density-dependent manner. As a control, disassembling VLPs to form VP1 pentamers abolished incorporation into the cells. Displaying sialic acid on the substrate enhanced VLP density through the specific affinities between the VLPs and sialic acid, resulting in efficient incorporation into the seeded cells. These techniques can be applied to the development of novel drug delivery systems and cell microarrays not only of nucleic acids but also of small molecules and proteins through their encapsulation in VLPs.

INTRODUCTION

Recently, much emphasis has been placed on the use of cell microarrays as effective tools for the study of a range of phenomena in mammalian cells, as they provide a rapid and simple method for the high-throughput analysis of multiple gene functions (*1*–*3*). Cell microarray technology is based on a "reverse transfection" (*4*) or "substrate-mediated drug delivery" (*5*) system, in which preimmobilized plasmid DNAs are transfected directly from the substrate into seeded cells. Compared with the conventional method, in which cells are cultured in a medium containing plasmid DNAs, the reverse transfection method has advantages such as easy handling, low cytotoxicity, and enhanced gene expression even in the presence of serum (*6*, *7*). Several problems, however, remain to be solved with regard to drug-immobilization techniques. For example, in the initial method of reverse transfection established by Sabatini et al. (*4*), usage was limited to gene delivery, as only DNAs could be coated onto the substrate by mixing with gelatin. Microarrays of small molecules, such as drugs and peptides, have also been constructed through the use of biodegradable polymers or chemolabile linkers as drug reservoirs on the surface of the substrates (*8*, *9*). These methods, however, were limited in that the drugs were only incorporated into cells through a passive (and sometimes time-consuming) process because their release from the substrates depended on free diffusion. To prevent cross-contamination of compounds, immobilization at low density and concentration was required, thus affording only a small number of samples spotted in the array and decreased cellular uptake. The future application of cell microarrays requires a high-performance drug carrier that can be uniformly immobilized on the substrates, while providing active and efficient entry of various drugs into a broad variety of cells.

Therefore, we propose a new substrate-mediated delivery approach using virus-like particles (VLPs) as potential carriers of various drug components (Figure 1). We focused on the JC virus (*10*), which belongs to the Polyomavirus family and can enter a broad range of mammalian cells (*11*). Since it is a

nonenveloped virus, it is better able to tolerate dry conditions than enveloped viruses; thus, it is suitable for immobilization and preservation on the substrates. The capsid of the JC virus is composed of three capsid proteins: VP1, VP2, and VP3. VP1, the 39 kDa major capsid protein of the JC virus, can be expressed recombinantly in *E. coli* or insect cells. It is known that recombinant VP1 pentamers self-assemble to form VLPs (*12*). Since VP1 is known to recognize sialic acid receptors on the cellular surface (*13, 14*), cellular uptake of VLPs through receptor-mediated endocytosis can be expected. Moreover, VLPs are capable of internalizing not only genes but also proteins, small molecules, and peptides (*15, 16*). For example, the encapsidation of green fluorescent protein (GFP) and methotrexate (MTX) into Polyoma VLPs has been carried out using VP2 as an anchor molecule (*17*). In this way, VLPs have a potential as carriers of various drug components to several kinds of mammalian cells.

Although some cell microarray systems employing adenoviruses or lentiviruses solely as carriers of DNAs and RNAs have been developed (*18, 19*), there has been no detailed study of cellular uptake efficiency that compares diffusive viruses in solution with those immobilized on substrates. Herein, as a first step in the fabrication of a cell microarray based on VLPs, we report the efficient cellular uptake of immobilized VLPs on a substrate, compared with that of diffusive VLPs in solution, by means of flow cytometric analyses and confocal laser microscopic observations. We also report the effective immobilization of VLPs using the specific affinity between the VLPs and sugar moieties, which enhanced the cellular incorporation of VLPs.

EXPERIMENTAL PROCEDURES

General Methods. Fluorescein isothiocyanate (FITC), fetuin, and asialo fetuin were obtained from Sigma-Aldrich Corp. (USA). Poly(*N-p*-vinylbenzyl-6-*O*-carboxymethyl-6′-*O*-carboxymethyl-*O*-*β*-D-galactopyranosyl-(1→4)-D-gluconamide) (PV-LACOOH) and Poly(*N-p*-vinylbenzyl-*O*-2-acetoamide-2-deoxy-*β*-D-glucopyranosyl-(1→4)-2-acetoamide-2-deoxy-D-gluconamide) (PV-GlcNAc) were purchased from Seikagaku Corp. (Japan). UDP-galactose (UDP-Gal) and CMP-*N*-acetylneuraminic acid disodium salt (CMP-NANA, 2Na) were obtained from Yamasa Corp. (Japan) and Nacalai Tesque, Inc. (Japan), respectively, and *β*1,4-galactosyltransferase (GalT) and α2,6-sialyltransferase (SiaT) were obtained from Toyobo Co. Ltd. (Japan), and Japan Tobacco, Inc. (Japan), respectively. All samples were prepared with ultrapure water (Milli-Q, Millipore, USA) and used without further purification.

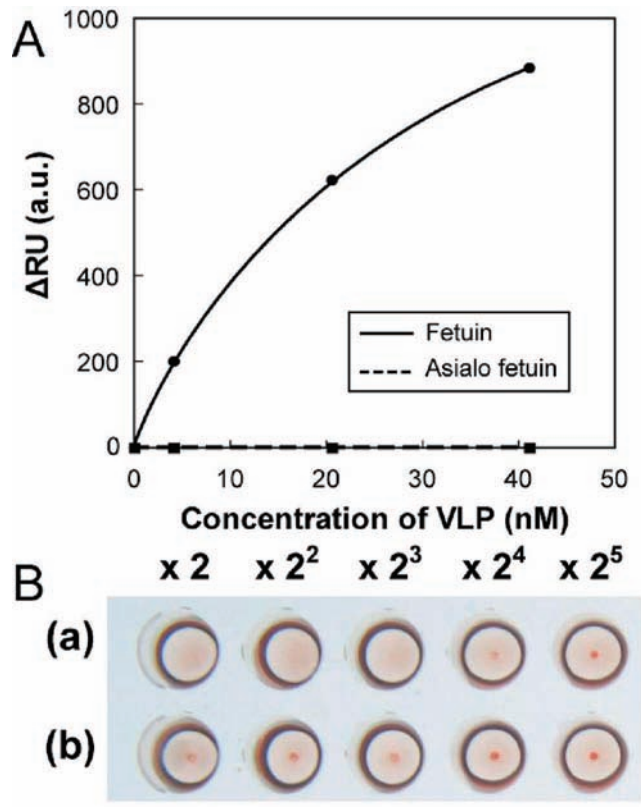

Figure 3. Measurements of the binding affinity between the VLPs and sialo-glycoprotein using surface plasmon resonance (SPR) and hemagglutination (HA) assay. (A) Concentration dependence of maximum response units obtained from the SPR measurements. Fetuin (—) or asialo fetuin (---) were immobilized on the sensor chip. (B) HA assay of (a) original and (b) predissociated VLPs. Twenty-five micoliters of serially diluted aqueous solutions of VLPs were examined. The number represents the reciprocal of the dilution factor.

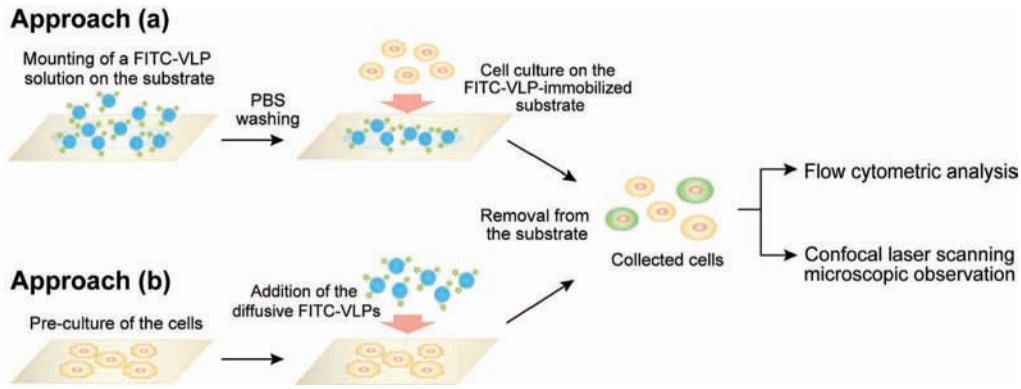
Expression and Purification of JC VLPs. JC VLPs were prepared as previously described (*11*). Briefly, the pET15b plasmid (Novagen, USA) including the JC virus VP1 DNA was transformed into *E. coli*, BL21 (DE3) pLysS (Stratagene, USA). After overnight colony culture at 37 °C in Terrific broth, the expression of VP1 was induced with 1.0 mM isopropyl-*β*-D-thiogalactopyranoside (IPTG) for 4 h at 30 °C, and the mixture was collected by centrifugation at 4,000*g* for 15 min. The pellet was resuspended in reassociation buffer (pH 7.4, 20 mM Tris-HCl, 150 mM NaCl, and 1 mM $CaCl_2$) containing 1 mg of lysozyme/mL and kept on ice for 30 min, and then 1% sodium deoxycholate was added. After incubation for 10 min on ice, the sample was treated with DNaseI (100 U/mL) for 30 min at 30 °C and lysed by five cycles of sonication for 30 s. After centrifugation of the lysate at 10,000*g* for 20 min at 4 °C, the supernatant was centrifuged at 25,000 rpm (SW28 rotor, OptimaL, Beckman Coulter, USA) for 3 h at 4 °C. The white layer in the tube was lysed in a reassociation buffer containing CsCl at a final concentration of 1.29 g/mL and then centrifuged at 32,000 rpm (SW41 rotor, OptimaL, Beckman Coulter, USA) for 16 h at 4 °C. The resultant fractions were dialyzed in reassociation buffer at 4 °C overnight.

Dissociation of VLPs/FITC Labeling of VLPs. For the dissociation of particle structures, VLPs were mixed in PBS

Scheme 1. Cellular Uptake of (a) Immobilized or (b) Diffusive FITC-VLPs through the Two Approaches



containing 3 mM dithiothreitol (DTT) and 10 mM EGTA at 4 °C overnight.

For the conjugation of VLPs with FITC, 2.5 mg of VLPs was dissolved in 0.1 M carbonate−bicarbonate buffer (pH 9.0), mixed with 250 μg of FITC, and incubated at room temperature for 2 h. The mixture was dialyzed twice in PBS (pH 7.4) containing 1 mM $CaCl_2$.

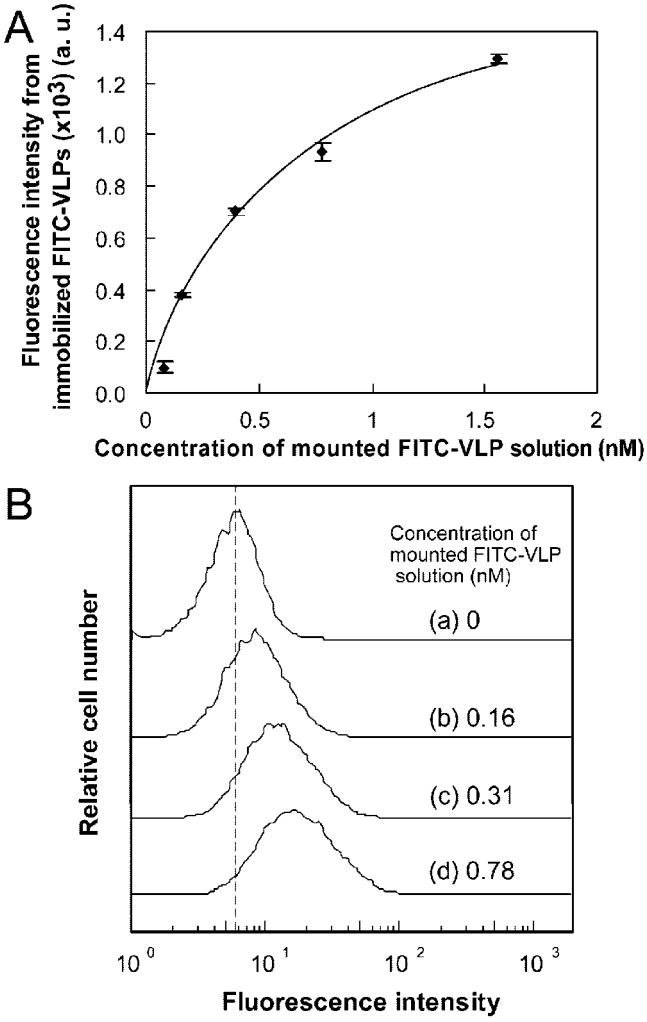


Figure 4. Immobilization of FITC-VLPs and their subsequent cellular uptake via the substrate-mediated approach using polystyrene substrates. (A) Measurement of the fluorescence intensity of immobilized FITC-VLPs at various concentrations. (B) Flow cytometric analysis of NIH3T3 cells cultured on the FITC-VLP-coated substrates. The histograms of the cellular uptake of FITC-VLPs are shown. The initial concentration of the mounted FITC-VLP solution was (a) 0 nM, (b) 0.16 nM, (c) 0.31 nM, and (d) 0.78 nM.

Electron Microscopy/Dynamic Light Scattering (DLS) Analysis. Before observation, 2 μL of the samples was dropped on carbon-coated TEM grids and then negatively stained with 2% phosphotungstic acid. After desiccation overnight, the morphology of the VLPs was confirmed by scanning transmission electron microscopy (STEM) (HD-2000, Hitachi, Japan).

Particle size analysis of the VLPs in reassociation buffer was performed by dynamic light scattering (FDLS-3000, Otsuka Electronics, Japan) with measurements taken at 25 °C.

Surface Plasmon Resonance (SPR) Measurement. The measurement of the interactions between the VLPs and glycoproteins were carried out using SPR techniques (Biacore X, Biacore, USA). The sensor chip was equilibrated with a running buffer (pH 7.4, 10 mM Tris-HCl, 150 mM NaCl, and 1 mM $CaCl_2$). Fetuin and asialo fetuin were adsorbed onto an Au-coated sensor chip (SIA Kit Au, Biacore, USA) prior to measurement. The buffer solution containing various VLP concentrations (4−40 nM) was then injected onto the glycoprotein-coated sensor chip, and the signal was recorded.

Hemagglutination (HA) Assay. The hemagglutination assay was performed to estimate the functional efficiency of VLPs, as described elsewhere (*20*). Briefly, 25 μL of serially diluted aqueous solutions of VLPs were prepared in a 96-well V-shaped microplate, using 25 μL of PBS (pH 7.15) containing 0.2% bovine serum albumin (BSA). After incubation at 37 °C for 1 h, 25 μL of 0.5% type-O red blood cells were added to each well. The 96-well plate was kept at 4 °C for 3 h and the end point attained. The HA titer was defined as the reciprocal of the greatest dilution of VLP suspension for which complete hemagglutination was observed.

Synthesis of Sugar-Displaying Polymers. Enzymatic synthesis of PV-LacNAc was carried out in 10 mM Hepes-NaOH (pH 7.4), 10 mM $MnCl_2$, 50 mM NaCl, 6.8 mM PV-GlcNAc, 20 mM UDP-Gal, and β1,4-galactosyltransferase (170 mU/mL). The enzymatic reaction mixture was slowly rotated at 30 °C overnight. The prepared crude PV-LacNAc solution was next applied to a glycosyltransferase reaction after simple purification using spin filtration. Then, the sialic acid-displaying polymer (PV-Sia) was synthesized in 20 mM cacodylate buffer (pH 7.5), 3.4 mM PV-LacNAc, 5 mM CMP-NANA, and 50 mU/mL α2,6-sialyltransferase. The enzymatic reaction mixture was slowly rotated at 30 °C overnight.

Preparation of FITC-VLP-Coated Substrates. PV-LACOOH, PV-LacNAc, and PV-Sia were diluted to 0.17 mM with ultrapure water. After sonication for 1 min, 2 mL of each solution was applied to a 6-well cell culture plate (Nunc, USA). The plate was incubated at room temperature for 1 h and then rinsed twice with PBS. The FITC-VLP solution was diluted with PBS to a final concentration of 0−1.57 nM and added to the plate pretreated with PBS or PV-sugar. The plate was incubated in the dark for 1 h and washed twice with PBS.

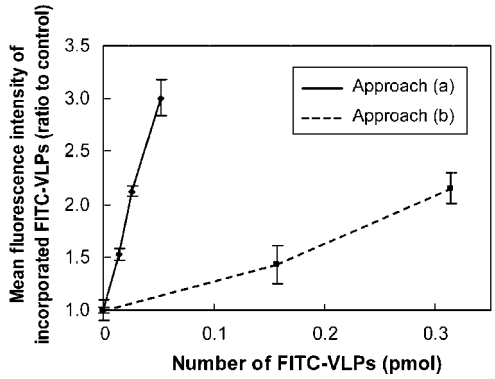

Figure 5. Mean fluorescence intensity of incorporated FITC-VLPs in NIH3T3 cells through approaches (a) and (b). The relative fluorescence intensity was estimated by taking the intensity of untreated cells as 1.0. The solid line represents the mean cellular uptake of immobilized FITC-VLPs on the substrates (approach (a)), and the dashed line represents that of diffusive FITC-VLPs in culture medium (approach (b)).

Plate Reader Measurements. The fluorescence intensities of each sample were measured by a plate reader (Ex. 485 nm/Em. 535 nm, Infinite 2000, Tecan, Switzerland) using an optical bottom plate (Nunc, USA) with a clear bottom and black side walls. The fluorescence intensity derived from the FITC-VLPs was estimated by taking the intensity of PBS as a baseline.

Cell Culture. NIH3T3 cells were seeded on the FITC-VLP-coated substrate and grown in Dulbecco's modified essential medium (DMEM) supplemented with 10% fetal bovine serum (FBS) and 1% antibiotics (penicillin/streptomycin) (Sigma-Aldrich, USA) in 5% CO_2 for 4 h. After rinsing several times with PBS, the cells were treated with trypsin (Gibco, USA) and collected by centrifugation.

Flow Cytometry/Confocal Laser Microscopy. The cells were resuspended in PBS and analyzed using a fluorescence-activated cell sorter (FACS canto, Becton Dickinson, USA). For each analysis, 10,000 events were monitored.

The collected cells were also seeded onto an 8-well chamber slide (Nunc, USA) and cultured for 4 h under the same conditions. After rinsing with PBS, the chambers were removed, and the cells were fixed with 4% paraformaldehyde for 10 min. For staining the cell nuculei, 4′,6′-diamidino-2-phenylindole (DAPI) dihydrochloride solution (Dojindo, Japan) was added to a final concentration of 1 μg/mL. The slides were observed using a confocal laser scanning microscope (FV-300, Olympus, Japan).

RESULTS

A. Characterization of Virus-Like Particles (VLPs). JC virus VP1 recombinantly expressed in *E. coli* spontaneously self-assembles into virus-like particles (VLPs) in the presence of calcium ions. Assembled VLPs were purified by CsCl density gradient centrifugation. The purified VLPs were electrophoresized on 5% SDS−polyacrylamide gels (Figure 2A). The main band was observed at around 40 kDa, which is in good agreement with the molecular weight of native JC virus VP1 (39 kDa). The morphology of the VLPs was examined by electron microscopy after negative staining (Figure 2B). A relatively homogeneous population of particles of around 40 nm in diameter was observed. Particle size analysis was also performed by dynamic light scattering (DLS). The mean diameter of the VLPs was estimated to be 41.0 ± 12.1 nm (Figure 2C). These results were similar to those reported in previous literature (*21*).

Although it has been reported that JC VLPs preferentially bind to *N*-linked glycoproteins containing terminal sialic acid (*22*), the quantitative binding constant has not yet been determined. Therefore, we measured the binding affinity between the VLPs and sialo-glycoprotein by surface plasmon resonance (SPR) measurements on a Biacore instrument. As a target glycoprotein, we chose fetuin, which is a 48-kDa-protein possessing 8.9 wt% of sialic acid moieties (*23, 24*). Asialo fetuin, a sialic acid-free protein, was used as a negative control. The two glycoproteins were separately adsorbed onto an Au-coated sensor chip through hydrophobic interactions. Different

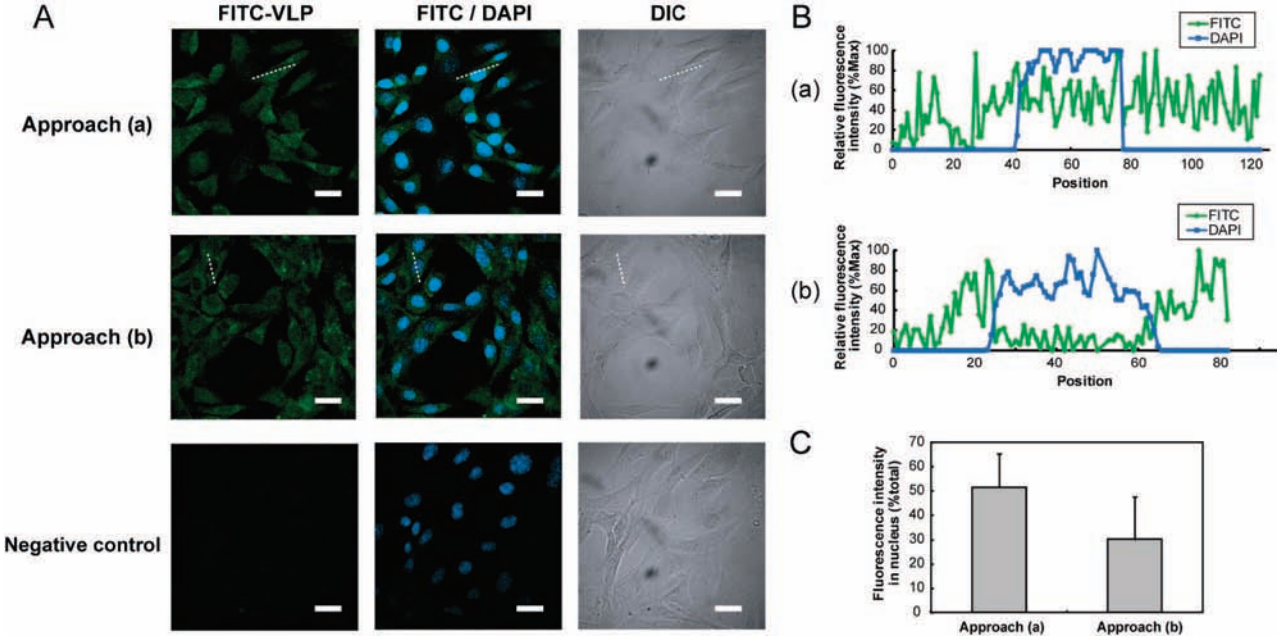

Figure 6. Comparision of the localization of FITC-VLPs incorporated into NIH3T3 cells through approaches (a) and (b). (A) Fluorescence images (left), merged fluorescence and nuclear staining images (middle), and differential interference contrast images (right) showing cells after FITC-VLP incorporation through approaches (a) and (b). Images of the negative control using untreated cells are also displayed. The cells were observed by confocal laser scanning microscopy. The scale bars are 20 μm. (B) Relative fluorescence intensities of FITC and DAPI along the dotted lines drawn on the images for approaches (a) and (b) in (A), respectively. (C) Ratio of fluorescence intensities of FITC in the nucleus. The total fluorescence intensity of FITC in the cell was taken as 100%.

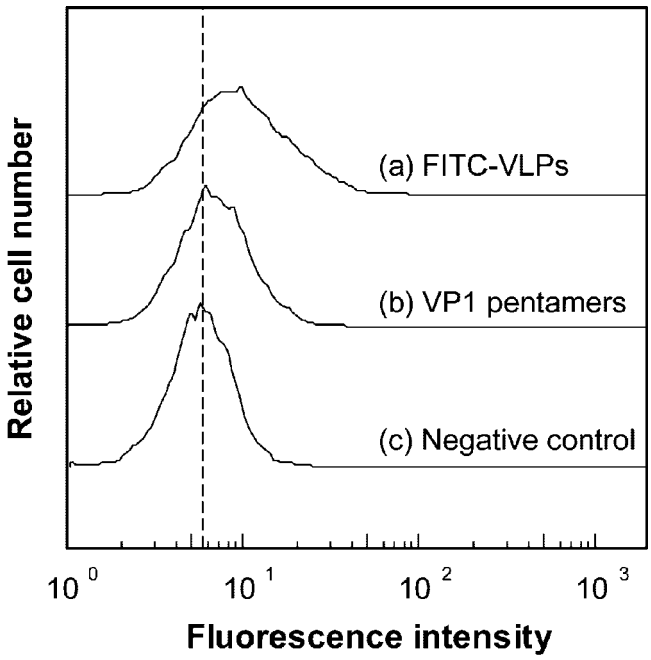

Figure 7. Flow cytometric analyses of substrate-mediated cellular uptake of (a) FITC-VLPs and (b) FITC-VLPs disassembled to form VP1 pentamers. The histogram of the negative control using untreated cells is shown as (c).

concentrations of the VLPs were passed over the surface to determine the concentration-dependent maximum response units (ΔRU) (Figure 3A). The binding constant of 4.1×10^7 M^{-1} estimated from the ΔRU curve demonstrates the high selectivity of the VLPs to the sialic acids. This value was similar in order to that of another lectin, SSA (1.4×10^7 M^{-1}) (*25*). To confirm the ability of our recombinant VLPs to recognize sialic acid, we also performed the hemagglutination (HA) assay (Figure 3B). The HA titer of VLPs obtained from *E. coli* was 512 HA/μL, suggesting a relatively high binding affinity between the VLPs and sialic acids present in red blood cells. The samples that were predissociated to VP1 pentamers by treatment with EGTA and DTT did not show any HA activity, probably because they no longer had the ability to bridge blood cells (Figure 3B).

B. Introduction of VLPs Deposited on a Polystyrene-Based Substrate. In order to quantify cellular uptake, VLPs were conjugated with FITC through a stable covalent linkage with the amine group on the VLPs, and the reaction mixture was then dialyzed to remove the unreacted FITC. The two approaches to the cellular uptake of FITC-labeled VLPs are illustrated in Scheme 1. In our novel approach (a), the FITC-VLPs were first immobilized on the substrate and washed with PBS, and then the cells were seeded onto the substrate. In this approach, the immobilized FITC-VLPs were directly introduced from the substrate to the cultured cells. Approach (b) represents a conventional method, in which the cells were cultured on the substrate prior to the addition of FITC-VLPs into the culture medium.

First, we investigated the immobilization of FITC-VLPs and their subsequent cellular uptake in approach (a). We employed a tissue culture polystyrene plate to immobilize the FITC-VLPs for cell culture. An aqueous solution of FITC-VLPs was mounted on a polystyrene substrate and incubated for 1 h, and then the substrate was rinsed well with PBS. The fluorescence intensities of the substrate before and after rinsing with PBS were measured using a fluorescence plate reader. Approximately 1/10 of FITC-VLPs in the mounted solution were deposited on the substrate even after rinsing with PBS (data not shown).

Various concentrations of FITC-VLP in aqueous solutions were also mounted on the substrate, followed by washing with PBS and measurement of fluorescence intensities (Figure 4A). The fluorescence intensity curve shows that the number of FITC-VLPs immobilized on the substrate increased exponentially with increases in the initial concentration of FITC-VLPs in the aqueous solution, up to the saturation of the FITC-VLP binding sites on the polystyrene substrate.

NIH3T3 cells were cultured on the FITC-VLP-coated substrate in DMEM containing 10% FBS for 4 h and then removed from the substrate by treatment with trypsin. After collection, the cellular uptake of FITC-VLPs was analyzed by flow cytometry. The histogram shown in Figure 4B indicates the introduction of FITC-VLPs into the cells cultured on the FITC-VLP-coated substrates. The cellular uptake of FITC-VLPs increased with increases in the initial concentration of FITC-VLPs because of an increase in the number of VLPs immobilized on the substrate.

We next compared the efficiency of cellular uptake of FITC-VLP through approaches (a) and (b). Mean cellular uptake using various quantities of FITC-VLPs (0−0.32 pmol) is plotted in Figure 5. The number of FITC-VLPs used in the two approaches was calculated as follows. Aqueous solutions of FITC-VLPs at identical concentrations were first mounted in both approaches. In approach (a), as the substrate was rinsed with PBS, some of the FITC-VLPs in the mounted solution were washed out. Therefore, the number of FITC-VLPs immobilized on the substrate was estimated from the relative fluorescence intensity at each concentration as previously determined by plate reader measurement. However, in approach (b), the number of FITC-VLPs was estimated only by culture volume of the mounted solution. We used 2 mL of FITC-VLP-containing DMEM for approach (b), which is the minimum volume required for cell culture, and the number of FITC-VLPs in solution was considered to be sufficient compared with that in previous reports (*26*). Surprisingly, the introduction of FITC-VLPs through approach (a) was possible at a much lower quantity than was possible through approach (b). While approach (b) requires more than 0.1 pmol of FITC-VLPs for the detection of cellular uptake, less than 0.1 pmol of FITC-VLPs was sufficient for high cellular uptake in approach (a). This result suggests that immobilization on the substrate leads to efficient cellular uptake of FITC-VLPs.

Cellular uptake of FITC-VLPs was further confirmed by confocal laser scanning microscopy (Figure 6A). To eliminate the fluorescence derived from FITC-VLPs retained on the substrate, the cells were removed from the substrate by trypsin treatment and cultured again on new glass slides for a further 4 h. The observation of cells prepared by approaches (a) and (b) showed that FITC-VLPs were internalized into the cells, not just attached to the cell surface. Interestingly, the VLPs from the substrate were more dispersed into the nucleus than were those from the solution (Figure 6B and C).

As a control, FITC-VLPs were disassembled to VP1 pentamers by the addition of DTT and EGTA prior to immobilization on the substrate (Figure 7). In this case, there was little incorporation of the disassembled sample from the substrate as compared to that of the original VLPs, suggesting that VLP formation is necessary for cellular uptake from the substrate.

C. Increased Cellular Uptake Using Sialic-Acid Displaying Substrate. On the basis of our results using polystyrene-based substrates, deposition of a large number of VLPs on the substrate was significant enough to increase the cellular uptake of the immobilized VLPs. Therefore, we sought to enhance cellular uptake through increasing the number of VLPs immobilized on the substrate using their specificity to sialic acid (*22*).

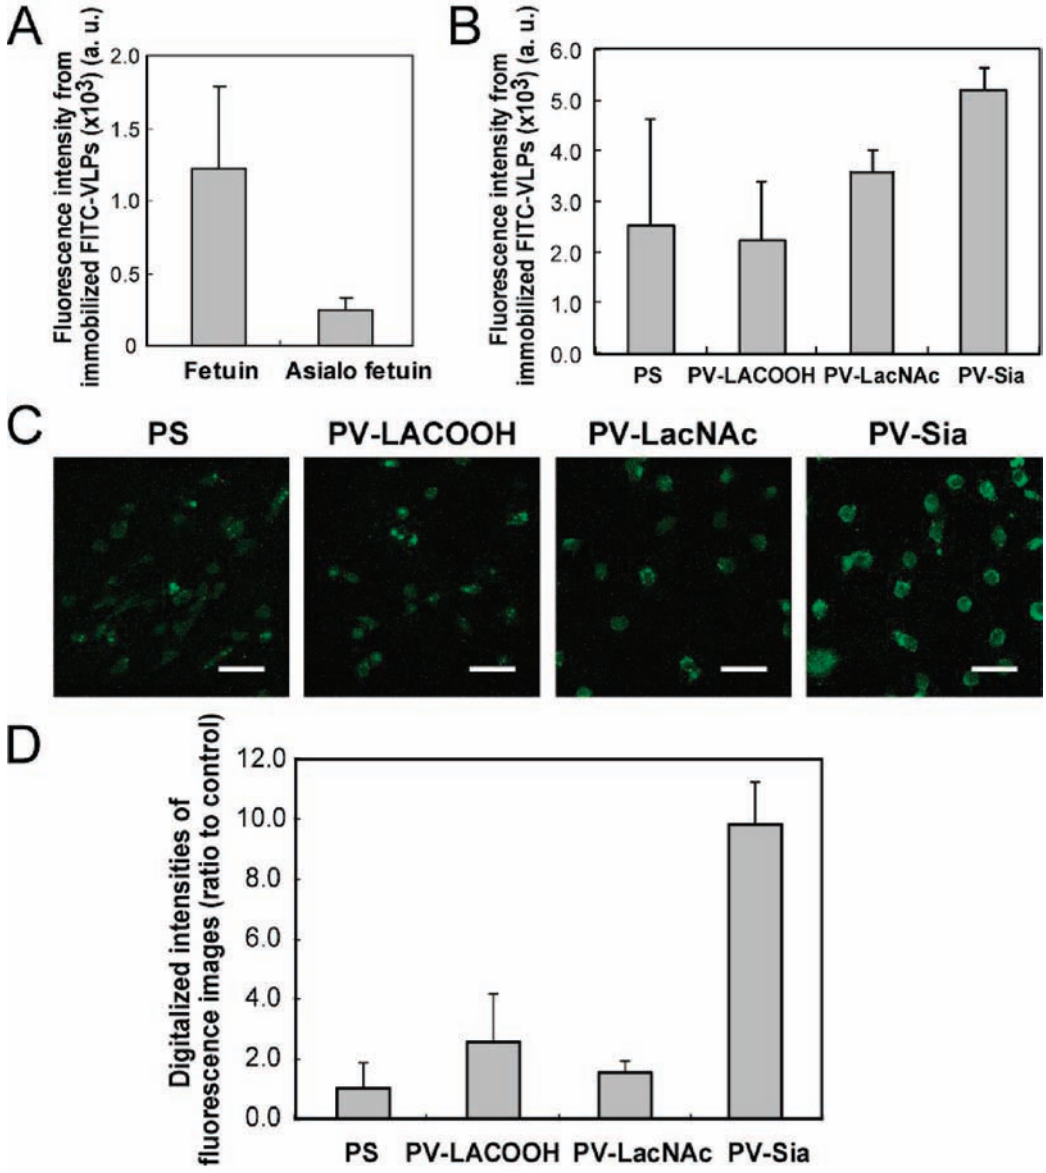

Figure 8. Immobilization of FITC-VLPs and subsequent cellular uptake via the substrate-mediated approach using sugar-displaying substrates. (A) Fluorescence intensities of FITC-VLPs attached to the substrate precoated with 0.5 mg/mL fetuin and asialo fetuin. (B) Comparison of the fluorescence intensities of FITC-VLPs immobilized on the polystyrene (PS) and sugar-displaying substrates. (C) Fluorescence images of NIH3T3 cells cultured on the FITC-VLP-coated sugar-displaying substrates. The cells were observed by confocal laser scanning microscopy. The scale bars are 50 μm. (D) Comparison of the NIH3T3 cellular uptake of FITC-VLPs attached to the sugar-displaying substrates. Whole fluorescence intensities of the confocal images were estimated using image analysis, and the mean values obtained from three images are shown. The relative fluorescence intensity was estimated by taking the intensity of PS as 1.0.

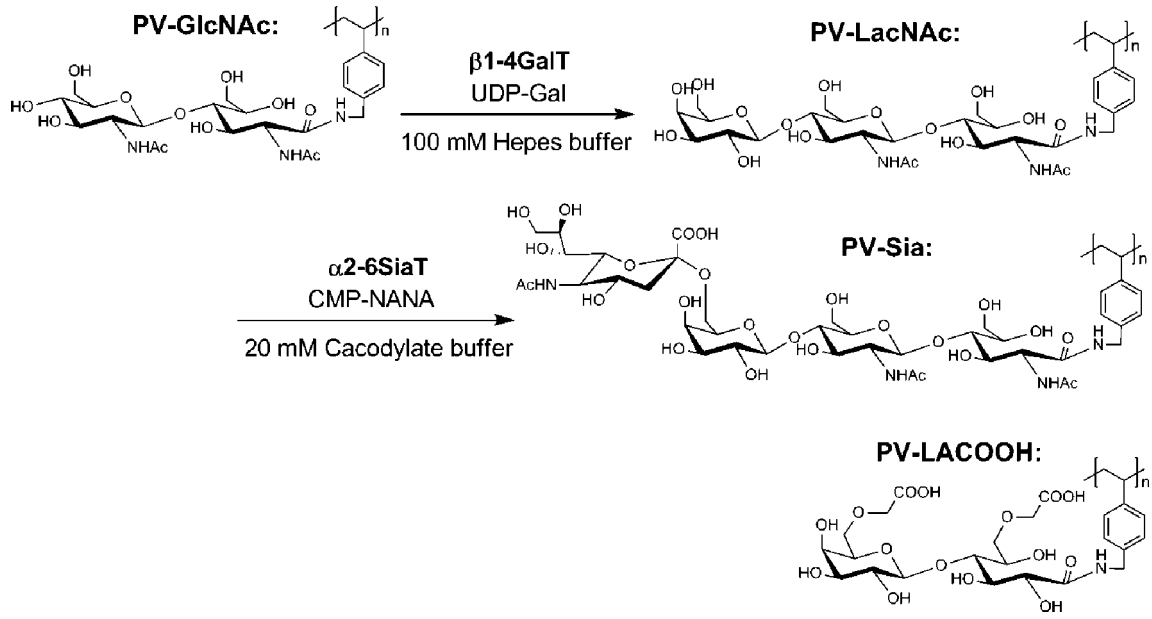
Using fetuin and asialo fetuin, we initially confirmed that displaying sialic acid from the polystyrene substrate could increase the number of immobilized FITC-VLPs (Figure 8A). The result shows that the FITC-VLPs were more effectively immobilized onto the fetuin-coated substrate than that coated with asialo fetuin, which is in good agreement with the results of the SPR measurement. This suggests that displaying sialic acid from a polystyrene substrate is effective in increasing FITC-VLP immobilization.

For the preparation of a sugar-displaying substrate more appropriate for cell culture, we next used PV-sugars, which are synthetic sugars grafted to polystyrene (*27, 28*). PV-sugars are reported to dissolve in water, forming a characteristic bottlebrush conformation composed of a polystyrene backbone covered with sugar brushes (*29*). Mounting aqueous solutions of PV-sugars onto substrates can provide a uniform glycopolymer-coated surface, which has good biocompatibility for cell culture (*30, 31*).

The synthesis of PV-sugar containing sialic acid (PV-Sia) was performed by two-step glycosyltransferase reaction (Scheme 2). In the first stage, an aqueous solution of PV-GlcNAc was treated with β1,4-galactosyltransferase (GalT) in the presence of UDP-Gal, providing the formation of PV-LacNAc. The product was further treated with α2,6-sialyltransferase (SiaT) in the presence of CMP-NANA, generating the final product PV-Sia. Since the polymers formed a micelle structure, they were not identifiable by NMR. Therefore, glycosylation was confirmed both by the specific binding of lectins for galactose and by resorcinol assay sensitive to sialic acid. FITC-labeled RCA120, which is a lectin that specifically associates with Galβ1-4GlcNAc (*32, 33*), did not bind to the PV-GlcNAc-coated substrate but strongly bound after the galactosyltransferase reaction (see Supporting Information). Subsequent sialylation of the polymer by sialyltransferase caused a large decrease in RCA120 binding since the lectin only slightly associates with

Scheme 2. Enzymatic Syntheses of Sialic Acid-Displaying PV-Sugars



sialic acid (*34*). The content of sialic acid in the polymer was then determined by colorimetry using the resorcinol assay (*35*). The sialic acids released from glycosidic linkage by heating in a strong aqueous acid solution were quantified by absorption at 580 nm. The ratio of side chains possessing a sialic acid in PV-Sia was estimated to be around 19% (see Supporting Information). These experiments showed that carbohydrates were transferred step by step, and that almost 20% of sialic acids were finally displayed on the polymer chain. We otherwise used PV-LACOOH as a control for the electrostatic interaction of PV-Sia. Ellipsometric measurements were carried out in order to detect the film thickness of each polymer (see Supporting Information). Glass slides were spin-coated with PV-sugars and washed well with water. After drying overnight, the thickness of the films was examined. The thicknesses of the PV-LACOOH, PV-LacNAc, and PV-Sia films were 79.3 ± 3.7, 77.7 ± 4.3, and 79.6 ± 3.7 nm, respectively, indicating that the polymers were tightly fixed to the surface of the substrates.

Plate reader measurements after the binding of the FITC-VLPs showed that the fluorescence intensity obtained from the PV-Sia-coated substrate was 2-fold higher than that obtained from the polystyrene substrate (Figure 8B). The difference in fluorescence intensity between the PV-Sia-coated and the polystyrene substrates was in good agreement with that between the substrates coated with fetuin and asialo fetuin (Figure 8A). The PV-LacNAc-coated substrate provided a moderate increase in FITC-VLP immobilization. FITC-VLP immobilization onto the PV-LACOOH-coated substrate was approximately equivalent to that onto the polystyrene substrate. These results indicate that FITC-VLPs were effectively immobilized on the PV-Sia-displaying substrate because of their specific interaction with sialic acid, not because of electrostatic interaction.

Finally, the introduction of FITC-VLPs from sugar-displaying substrates was investigated using confocal laser scanning microscopy as described above. Fluorescence images of NIH3T3 cells cultured on the FITC-VLP-coated sugar-displaying substrates are shown in Figure 8C. Seeded cells adhered well to all sugar-displaying substrates showing no cytotoxicity (data not shown). The cellular uptake of FITC-VLPs was also observed on all sugar-displaying substrates. The digitalized intensities of the fluorescence images demonstrate that the cells cultured on the PV-Sia-displaying substrate provided the significantly highest fluorescence intensity (Figure 8D). Our results show that coating the substrate with sialic acid-displaying biomaterials leads to more effective cellular uptake of VLPs.

DISCUSSION

JC virus VP1 recombinantly expressed in *E. coli* spontaneously self-assembles into virus-like particles (VLPs), which can be isolated by CsCl density gradient centrifugation. Surface plasmon resonance (SPR) measurements indicated that the VLPs have specific affinity to the sialic acid moiety of glycoprotein. We investigated the immobilization of VLPs and their subsequent cellular uptake in approach (a) using a tissue culture polystyrene plate. A comparison of this approach with the control, approach (b), revealed that immobilized VLPs were incorporated into the cells with higher efficiency than were the diffusive VLPs suspended in solution. When VLPs are added to a solution, a limited number of VLPs can access the cell surface because of their Brownian movements. However, when introduced from a substrate, a large number of VLPs can spontaneously come into contact with the cellular surface, leading to more effective uptake. Another possible explanation of this enhanced cellular uptake from the substrate is cell adhesion. There have been some reports on reverse transfection showing that increased cell adhesiveness through the addition of an extracellular matrix (ECM) enhances gene expression (*36, 37*). In our study, cell adhesion to the VLP-coated substrates was actually increased in comparison to that to the untreated substrates (data not shown). This indicates that VLPs themselves acted as an ECM and strengthened cell adhesion, resulting in the enhanced cellular uptake of the VLPs.

Subsequent confocal laser microscopic observation indicated that VLPs introduced from the substrate were more dispersed into the nucleus than were those from the solution (Figure 6). In this study, we used JC virus-derived VLPs, containing a nuclear localizing signal at the C-terminus, known to localize in the nucleus after cellular uptake (*26*). We speculated that FITC-VLPs from the substrate could be localized into the nucleus faster than those from the solution since the cellular uptake from the substrate occurred more rapidly. Previously, Shea et al. demonstrated that the expression of immobilized DNAs leveled up to 100-fold greater than bulk delivery of DNAs (*38*). Our results showing rapid cellular uptake of VLPs from the substrate and subsequent dispersion into the nucleus could

explain the fact that substrate-mediated transfection induces efficient and enhanced gene expression.

We next proved that VLP formation was necessary for cellular uptake from the substrate. Even if VP1 pentamers bind to the receptors on the cell surface, they might be incapable of inducing structural change in the receptor, thus they cannot induce endocytosis. In addition, size effect is also important for the incorporation of VLPs. According to the report of Aoyama et al., the optimal size of nanoparticles for endocytosis is around 50 nm (*39*), which is almost the same size as that of the VLPs in this study.

Finally, PV-Sia was enzymatically synthesized and used for the immobilization of FITC-VLPs, resulting in enhancement of the cellular uptake of FITC-VLPs. Two factors are thought to be mainly responsible for this enhancement using PV-Sia: increased FITC-VLP immobilization and strengthened adhesion of seeded cells. Akaike et al. reported that PV-LA, a PV-sugar, acts as an ECM and enables progressive hepatocyte adhesion (*40*). This function of PV-sugar as an ECM might be crucial to the enhancement of cell adhesion. Though various factors are thought to contribute to the efficiency of cellular uptake, we demonstrated that increased VLP immobilization using sialic acid significantly increased the incorporation of VLPs from the substrate.

In conclusion, we report the efficient cellular uptake of immobilized VLPs. VLPs expressed in *E. coli* were labeled with FITC and immobilized on the substrate. Flow cytometric analysis and confocal laser microscopic observation revealed that immobilized VLPs were incorporated into the cells with higher efficiency than were diffusive VLPs suspended in solution. Our approach was extended to sialic acid-displaying surfaces aimed at increasing the number of FITC-VLPs immobilized on the substrate via the specific affinity between VLPs and sialic acid. These techniques have potential applications to the fabrication of cell microarray systems using VLPs as multiple carriers of nucleic acids, small molecules, and proteins.

ACKNOWLEDGMENT

We appreciate Associate Professor Yoshiko Miura of JAIST for kindly providing a PV-sugar sample. We also thank Professor Kohei Uosaki and Assistant Professor Satoru Takakusagi of Hokkaido University for their help with ellipsometric measurements. Noriko Ohtake and Tadaki Suzuki appreciate the financial support provided by JSPS. This study was supported in part by grants from the Program of Founding Research Centers for Emerging and Reemerging Infectious Diseases, MEXT, Japan.

Controlling the dynamics of growth factor signaling is a challenge in regenerative medicine for various tissues including the central nervous system. Here, we report on the development of the biomolecular system that facilitates sequential regulation of growth factor signals acting on neural stem/progenitor cells. Recombinant technology was employed to synthesize the multifunctional chimeric protein that contained multiple domains, including epidermal growth factor (EGF), ciliary neurotrophic factor (CNTF), globular capping domain, thrombin-cleavable sequence, and substrate-binding domain with affinity for Ni(II) ions. The chimeric protein is expected to expose CNTF upon elimination of the capping domain by digestion with endogenous thrombin in vivo. When the multifunctional chimeric protein was immobilized onto a substrate through the coordination of the substrate-binding domain with surface-immobilized Ni(II) ions, the substrate served to proliferate neural stem cells, maintaining the population of undifferentiated cells at 85%. This effect is primarily due to the activity of EGF, while CNTF activity is temporally veiled with the capping domain. Upon digesting the thrombin-cleavable sequence to remove the capping domain, the activity of CNTF emerged to induce differentiation of astrocytes in situ from the proliferated neural stem cells. The fraction of differentiated astrocytes reached 68% of total cells. These results demonstrate the feasibility of the system for controlling the dynamics of growth factor signals.

INTRODUCTION

Transplantation of neural progenitor cells is considered a potential modality for the structural and functional restoration of the central nervous system (CNS) (*1, 2*). An alternative strategy is to recruit and stimulate endogeneous neural stem cells (NSCs) by the local administration of appropriate agents (*3*). In these approaches, the tight regulation of transplanted or recruited cell behavior is a challenging task because cell proliferation, migration, differentiation, and network formation must be regulated temporally and spatially for orchestrating the chronological processes toward tissue reconstruction (*4, 5*).

In the mammalian CNS, a variety of neurotrophins and mitogens operate in a time-dependent manner to modulate the dynamics of cellular differentiation and tissue organization (*6*). Toward the regeneration of neural tissues, the transplantation of cells with biomaterials that provide microenvironments mimicking natural extracellular stimuli may improve the outcome after transplantation. To date, biodegradable scaffolds that incorporate adhesive peptides (*7, 8*), growth factors (*9*), and Notch ligands (*10*) were reported for this purpose. However, the biomaterials that facilitate the temporal regulation of multiple signal presentation remain to be developed for more precisely modulating the hierarchically complex process of tissue reorganization.

In this study, we aimed at establishing the chimeric protein system that permits the switching of growth factor presentation for the tightly regulated proliferation and differentiation of NSCs. Our approach is to utilize the multifunctional chimeric protein (MCP) that contains two different growth factors fused to each other. To sequentially regulate the signaling of two growth factors, the terminal of the second growth factor is capped by a globular polypeptide with a protease-cleavable linker peptide in between so that the capping polypeptide temporally hinders the active site of the second growth factor until the linker is cleaved by protease. The MCP further contains a peptide sequence that binds specifically to substrates for the oriented presentation of the protein. Such a MCP was rationally designed and synthesized using recombinant technology.

Our future goal is to extend this system for use in tissue engineering of the central nervous system. The MCP will be incorporated into biodegradable polymer networks carrying its binding site and used as a scaffold for neural stem/progenitor cells. Because the sequential administration of multiple growth factors requires repeated intervention to the brain, a single component system such as MCP will have an advantage in such an application. As a key component, a thrombin-cleavable peptide is incorporated to the MCP. To optimize the dynamics of growth factor actions, the peptide sequence can be readily replaced with peptides cleavable with other proteases involved in tissue reconstruction processes such as matrix metalloproteinases.

To examine the feasibility of our approach, we synthesized the chimeric protein that contains epidermal growth factor (EGF) and ciliary neurotrophic factor (CNTF). It is reported that EGF exhibits mitogenic activity for NSCs (*11*), while CNTF promotes the glial specification of NSCs (*11*). To elicit the effects of growth factor switching, several types of control proteins were synthesized, and all of these proteins were subjected to biological assays using the cell-based microarray method (*12*). The MCP was further immobilized onto glass-based substrates for quantitative assays. The results of these assays provided a proof of principle for our approach toward the sequential regulation of NSC differentiation.

EXPERIMENTAL PROCEDURES

Chimeric Proteins. Figure 1 shows the domain structure of MCP and control proteins synthesized in this study. The MCP contains full length sequences of human CNTF (200 aa) and human EGF (53 aa). These polypeptides were linked with a

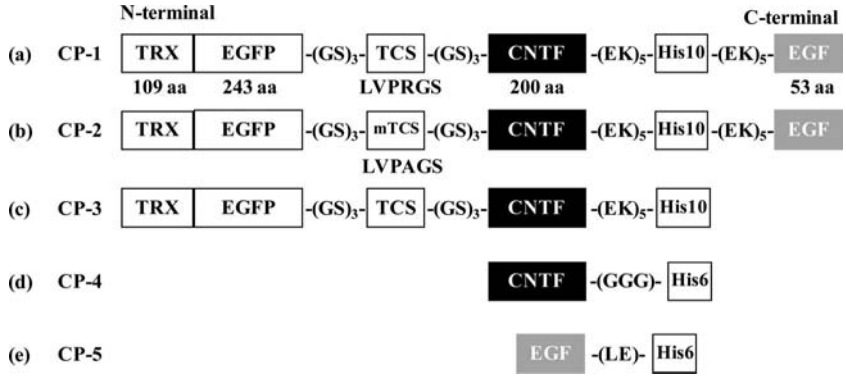

Figure 1. Domain structure of multifunctional chimeric proteins (CP-1) and control proteins (CP-2 to CP-5) synthesized in this study. TRX, thioredoxin; EGFP, enhanced green fluorescent protein; TCS, thrombin cleavage site; mTCS, mutated-TCS; CNTF, ciliary neurotrophic factor; EGF, epidermal growth factor.

decahistidine linker sequence (His10) that facilitates specific binding of the chimeric protein to the substrates carrying Ni(II) ions through coordination (*13*). As a capping polypeptide, enhanced green fluorescent protein (EGFP; 243 aa) was fused to the N-terminal of CNTF with a thrombin-cleavable site (TCS; LVPRGS) (*14*) incorporated in between. At the N-terminal of EGFP, thioredoxin (TRX; 109 aa) was further added because this polypeptide is frequently used to enhance the solubility of fusion partners (*15*). In addition, amino acid sequences, $(GS)_3$ and $(EK)_5$ (*16*), were inserted at both ends of TCS and His10, respectively, as flexible linkers. The total number of amino acid residues reached 668 aa. The MCP protein is referred to as CP-1. The other control proteins include a MCP with a mutated TCS (mTCS; LVPAGS) instead of the authentic TCS described above (Figure 1b; CP-2), a MCP lacking EGF (Figure 1c; CP-3), and either EGF or CNTF fused with a hexahistidine sequence (Figure 1d and e; CP-4 and CP-5, respectively).

Outline of the preparation of chimeric genes is depicted in Figure S1 (Supporting Information). Sequences of primers and oligonucleotides used for the construction of the CP-1 gene are shown in Table S1 (Supporting Information). The conditions of thermal cycling employed in polymerase chain reaction (PCR) amplification are shown in Table S2 (Supporting Information). First, synthetic oligonucleotides were subjected to overlap extension and PCR to prepare DNA encoding an $(EK)_6$-His10-$(EK)_6$ sequence containing an EcoR I site at the 5′-end and 22-mer oligonucleotides at the 3′-end that overlapped with the 5′-region of the EGF gene. The EGF gene was amplified by PCR from pET-22b-EGF (*12*) using specific primer sets (Table S1). The 5′-end of the forward primer was flanked with 20-mer oligonucleotides that overlapped with the 3′-region of $(EK)_6$-His10-$(EK)_6$. In addition, the reverse primer contained the Xho I site at the 5′-end. The products of overlap extension PCR were annealed, extended again by overlap extension, and amplified by PCR to obtain the $(EK)_6$-His10-$(EK)_6$-EGF gene. The chimeric gene was digested with EcoR I and Xho I and unidirectionally ligated to the pET-32b vector (Novagen) previously digested with the same restriction enzymes. The plasmid (pET-32b-His10-EGF) was cloned in *Escherichia coli* (*E. coli*) strain DH5α and purified with Qiagen MiniPrep Purification Kit. The correctness of the chimeric gene was checked by sequencing.

At the second step, cDNAs for EGFP and CNTF were amplified by PCR from pEGFP-C1 (Clontech) and pET-16b-NidLBD-CNTF (*18*), respectively. The forward primer used for the EGFP gene contained the Msc I site, while the reverse primer contained a sequence for $(GS)_3$-TCS-$(GS)_3$ and a 21-mer sequence that overlapped with the 5′-region of the CNTF gene. Similarly, the forward primer used for the CNTF gene contained a 22-mer sequence that overlapped with 3′-region of the EGFP gene and a sequence for $(GS)_3$-TCS-$(GS)_3$, while the reverse primer contained the EcoR I site. The PCR products were annealed, extended by overlap extension, and amplified by PCR to obtain the EGFP-$(GS)_3$-TCS-$(GS)_3$-CNTF gene. The chimeric gene was digested with Msc I and EcoR I and unidirectionally ligated downstream of the TRX sequence in pET-32b-His10-EGF linearized by digesting with the same restriction enzymes. The plasmid was cloned in *E. coli* strain DH5α and purified with Qiagen MiniPrep Purification Kit. The correctness of the chimeric gene was checked by sequencing.

For constructing the plasmid for CP-2, the EGFP-$(GS)_3$-mTCS-$(GS)_3$-CNTF gene was prepared using primers with mutation in the TCS site. First, EGFP-$(GS)_3$-mTCS and mTCS-$(GS)_3$-CNTF genes were amplified using pET-32b-EGFP-TCS-CNTF-His10-EGF as a template. Amplified DNAs were extended by overlap extension PCR to obtain EGFP-$(GS)_3$-mTCS-$(GS)_3$-CNTF and inserted into the Msc I-EcoR I site of pET-32b-His10-EGF. For CP-3, EGFP-$(GS)_3$-TCS-$(GS)_3$-CNTF was inserted downstream of TRX in original pET-32b. The gene for CP-4 was amplified by PCR from pET-16b-NidLBD-CNTF (*18*) and ligated to Nde I-Xho I sites in pET-22b (Novagen). For CP-5, previously constructed pET-22b-EGF (*12*) was used.

The MCP (CP-1) and control proteins (CP-2 to CP-5) were expressed in *E. coli* strain BL21-CodonPlus (Stratagene) using Overnight Express Autoinduction System (Novagen). The MCP and control proteins obtained as inclusion bodies were extracted with 8 M urea and purified by Ni-chelated affinity chromatography (His Trap HP column; Amersham) using a Prime AKTA chromatography system (Amersham). These proteins were refolded by dialyzing against a solution of reduced and oxidized forms of glutathione. The details of dialysis conditions are provided in Table S3 (Supporting Information). The purity and the molecular size of MCP and control proteins were analyzed by sodium dodecylsulfate−polyacrylamide gel electrophoresis (SDS−PAGE). The biological activity of EGF contained in MCP and control proteins was assessed from the mitogenic activity in neurosphere culture (*19*). The biological activity of CNTF contained in CP-1, CP-3, and CP-4 was assessed from the efficiency of glial induction from NSCs cultured on fibronectin-coated dishes (*19*). The assays for CNTF activity in CP-1 and CP-3 were conducted after the capping domain was removed by thrombin digestion.

Thrombin Digestion. MCP and control proteins (MCP with mTCS and EGF-deficient MCP) were separately dissolved to the concentration of 50 μg/mL in 20 mM tris-HCl buffer (pH 8.4) containing 0.6 unit/mL thrombin from bovine serum (POLA Pharma, Tokyo, Japan), 150 mM NaCl, and 2.5 mM $CaCl_2$. The mixed solutions were kept at 37 °C for typically 45 min to allow for the digestion of TCS. The reaction was stopped by adding an equal volume of SDS−PAGE sample buffer contain-

ing 10% β-mercaptoethanol. The digestion products were analyzed by SDS−PAGE with coomassie brilliant blue (CBB) staining.

Microarray Preparation. Microarrays were prepared as reported previously (*10*). In brief, a thin gold film was deposited on two types of glass plates: glass slides (26 × 22 × 0.5 mm; Matsunami Glass Ind., Ltd., Osaka, Japan) for cell culture and S-LAL10 glass plates (25 × 25 × 1 mm, reflective index = 1.720) for surface plasmon resonance (SPR) imaging. The self-assembled monolayer (SAM) of 1-hexadecanethiol was prepared on gold and photolytically micropatterned to create an array of 4 × 4 circular spots (2 mm in diameter and 4 mm in center-to-center distance) presenting bare gold. Then, the SAM of 11-mercapto-1-undecanoic acid was formed within the spots. The carboxylic acid within spots was derivatized with *N*-(5-amino-1-carboxypentyl) iminodiacetic acid and then chelated with Ni(II) ions. Solutions of MCP and control proteins (7 μM) in phosphate buffered saline (PBS) were manually pipetted (1.2 μL per spot) to separate spots on a single plate under sterile conditions. The plate was kept at room temperature for 2 h to allow the binding of decahistidine or hexahistidine sequence to the surface-immobilized Ni(II) ions. Finally, the plate was washed with PBS to remove unreacted proteins. Prior to cell culture experiments, the protein-immobilized plates were blocked with 2% Pluronic F127 (Sigma) solution.

Surface Plasmon Resonance (SPR). SPR imaging was performed to detect immobilized proteins on the microarray. The details of a homemade SPR imaging apparatus are reported elsewhere (*20*). A protein-immobilized array prepared as described above was mounted on a triangular glass prism. A p-polarized, collimated white light was radiated to the back of the array through the prism (Kretschmann configuration) at a constant incident angle ca. 0.5° smaller than the angle for the occurrence of surface plasmon resonance at the region between spots on the array. To obtain a two-dimensional (2D) reflection image, reflected light was passed through a narrow band interference filter (center wavelength: 905 nm) and then collected with a charge-coupled device (CCD; C2400–79, Hamamatsu Photonics). The reflection image represents local changes in the reflective index in the vicinity of the sample surface and hence reflects the distribution of protein over the microarray. Imaging was carried out under PBS at 30 °C.

For monitoring protein immobilization and thrombin digestion, a homemade SPR sensor (*21*) was used. A Ni(II)-chelated surface was prepared using mixed SAM consisting of 16-mercapto-1-hexadecanoic acid and (1-mercaptoundec-11-yl) triethyleneglycol (molar ratio, 1:9) formed on the entire surface of a BK7 glass plate (25 × 25 × 1 mm, reflective index = 1.515) by chemistry similar to that described above. The plate was mounted to the SPR sensor with a flow cell, and the resonance angular shift was continuously monitored during the following procedures. After equilibrating with PBS, the surface was exposed to 10 mg/mL bovine serum albumin solution in PBS in a flow cell for 10 min, and then pure PBS was circulated for 5 min to wash the surface. PBS was switched with 20 mM sodium phosphate buffer (pH 7.4) containing 20 mM imidazole (binding buffer) and circulated for 7 min, then 50 μg/mL MCP solution in binding buffer was circulated for 45 min followed by washing with pure binding buffer for 10 min. The surface was then exposed to 0.5 unit/mL thrombin solution in binding buffer for 50 min and washed with pure binding buffer. Finally, 20 mM sodium phosphate buffer (pH 7.4) containing 500 mM imidazole was circulated for 25 min to desorb protein fragments remaining on the surface and then switched with fresh PBS. The resonance angular shift was converted to the surface density of protein, assuming the unit angular shift of 0.5 μg/cm^2/DA (*22*).

Cell Isolation and Culture. The striatum was isolated from the fetuses (E16) of Fischer344 rats according to the guidelines of the Animal Welfare Committee of the institute and dissociated into single cells by treating with 0.05% trypsin solution containing 0.53 mM ethylenediamine-*N*,*N*,*N*′,*N*′-tetraacetic acid (EDTA). The single cells obtained were suspended in DMEM/F12 (1:1) (Gibco) containing 5 μg/mL heparin, 100 unit/mL penicillin, and 100 μg/mL streptomycin (base medium), supplemented with 2% B27 supplement (Gibco), 20 ng/mL basic fibroblast growth factor (bFGF), and 20 ng/mL EGF, and cultured for 4–5 days to form neurospheres.

Neurospheres at passage 2 were dissociated into single cells by treating with 0.05% trypsin-EDTA solution. The cells were suspended in the base medium containing 2% B27 supplement and then seeded onto the microarrays or the protein-immobilized glass plates at 3.0 × 10^4 cells/cm^2. The cells were cultured in an incubator at 37 °C under 5% CO_2. After 3 days, 1 unit/μL thrombin solution was added to the medium to a final concentration of 0.6 unit/mL and incubated for 45 min at 37 °C under 5% CO_2, followed by washing with base medium to remove thrombin. Then, fresh base medium containing 2% B27 supplement was added to the culture, and cells were incubated for an additional 2–3 days at 37 °C under 5% CO_2. Finally, cells were washed gently with DMEM/F12 (1:1) to remove weakly adhering cells and observed with a phase-contrast optical microscope (DP51, Olympus Optical CO., Ltd., Tokyo, Japan).

Immunocytochemistry. Cells on the substrate were fixed with PBS containing 4% paraformaldehyde and 0.1% glutaraldehyde, and permeabilized by treating with 0.5% TritonX-100 solution at room temperature for 20 min. Then, the cells were treated with 2% skim milk solution for 2 h to block nonspecific adsorption of antibodies, followed by binding of primary antibodies against nestin (1:200, mouse monoclonal Rat 401, BD Pharmingen), glial fibrillary acidic protein (GFAP, mouse monoclonal, MAB3402, Chemicon), or class III β-tubulin (βIII; 1:600, rabbit polyclonal, Covance, Princeton, NJ) for 1 h at room temperature. After washing with PBS containing 0.05% Tween-20, cells were treated by Alexa Fluor 594 antimouse IgG and Alexa Fluor 488 antirabbit IgG (both from Molecular Probes) at a dilution of 1:500 for 1 h at room temperature and washed with PBS containing 0.05% Tween-20. Then, cell nuclei were counterstained with 1 mg/mL Hoechst33258. The localization of secondary antibodies was analyzed with an epifluorescent microscope (DP70, Olympus). Cells reactive for antibodies against nestin, GFAP, and βIII were counted on the microphotographs for the area of 340 × 460 μm^2, which contained at most approximately 500 total cells. Cells were counted on five different microphotographs obtained from the same sample, and these data were averaged. The data are shown as the mean ± standard deviation for five independent samples.

Gene Expression Analysis. Total RNA was isolated from cells cultured on the protein-immobilized surfaces using the SV Total RNA Isolation system (Promega), and 100 ng RNA was used per reverse transcription (RT) reaction using Ready-to-Go You-Prime First-Strand Beads (Amersham) primed by oligo(dT)$_{15}$ (Promega). First-strand cDNA was then amplified by PCR using the specific primers listed in Table S4 (Supporting Information). The number of thermal cycles was determined so as to maintain the targeted sample population in the exponential amplification phase for each gene. All samples were run in triplicate, and the products were analyzed by electrophoresis in 2% agarose gel with ethidium bromide staining. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was also

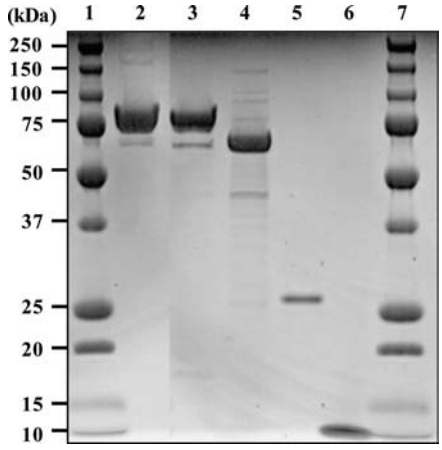

Figure 2. SDS−PAGE analysis of MCP and control proteins expressed in *E. coli* and purified by metal chelate chromatography. Proteins were electrophoresed in 12.5% polyacrylamide gel at 200 V for 40 min and visualized by CBB staining. Lanes 1 and 7, molecular weight standard; lane 2, CP-1; lane 3, CP-2; lane 4, CP-3; lane 5, CP-4; and lane 6, CP-5.

amplified as the reference gene. The electrophoresed DNA was imaged with Gel Doc 2000 and Integration Control Unit (Bio-Rad).

RESULTS

Characterization of Chimeric Proteins. Figure 2 shows the result of SDS−PAGE analysis for the MCP and control proteins. The molecular weight estimated from the mobility of protein bands are as follows: CP-1 (79 kDa), CP-2 (79 kDa), CP-3 (63 kDa), CP-4 (26 kDa), and CP-5 (7.5 kDa). Because low molecular weight CP-5 could not be separated appropriately with 12.5% polyacrylamide gel (Figure 2, lane 6), SDS−PAGE was additionally performed for CP-5 with 16% polyacrylamide gel to more precisely determine the molecular size (Figure S2, Supporting Information). The molecular weights estimated for CP-1 to CP-5 are in accordance with those expected from the theoretical amino acid numbers. These chimeric proteins exhibited the bioactivity of CNTF and/or EGF when qualitatively assessed in proliferation and differentiation assays with NSCs (data not shown). In CP-5, hexahistidine sequence was fused to the C-terminal of EGF, whereas decahistidine sequence was fused to the N-terminal of EGF in CP-1 and CP-2. Our separate experiments showed that the differences in the length and the position of a histidine tag had minor effects on the bioactivity of EGF fusions (data not shown).

CP-1, CP-2, and CP-3 were digested with 0.6 unit/mL thrombin at 37 °C for 45 min. Digested products were analyzed by SDS−PAGE (Figure 3). As shown in Figure 3A, digestion of CP-1 resulted in the formation of protein fragments of approximately 40 and 35 kDa, corresponding to the N- and C-terminal regions spanning from TCS, respectively. Similarly, CP-3 produced approximately 40 kDa (from N-terminal to TCS) and 25 kDa fragments (from TCS to C-terminal) (Figure 3C). In contrast, CP-2 containing mTCS (LVPAGS) remained intact even after treatment with thrombin (Figure 3B). These results are reasonable because thrombin recognizes the TCS (LVPRGS) to hydrolyze the peptide bond between arginine and glycine (*14*). There is no consensus sequence in the other regions of CP-1. Thrombin digestion of CP-1, CP-2, and CP-3 in a culture medium gave results similar to those in buffer solution (Figure S3, Supporting Information). The higher concentration of thrombin (5 unit/mL) or prolonged reaction (90 min at 0.6 unit/mL) gave rise to the formation of much smaller fragments (data not shown), probably because of nonspecific hydrolysis at other arginine−glycine linkages contained in the proteins. In addition, NSCs cultured on the CP-1-immobilized surface (see below for immobilization) were totally detached from the substrate upon contacting with 1.5 unit/mL thrombin. From these findings, we decided to digest the TCS with 0.6 unit/mL thrombin for 45 min in the later experiments.

Immobilization of Chimeric Proteins. Chimeric proteins were immobilized on the micropatterned surface through the coordination of His10 with Ni(II) ions fixed on the spots. A microarray thus obtained was analyzed with the SPR imaging technique (Figure 4A). As can be seen, brightness is higher in all of the protein-immobilized spots than in the control spot, confirming the immobilization of proteins. The intensity of reflected light is varied depending on the amount of chimeric proteins immobilized (Figure 4B), with a linear correlation to the molecular size of immobilized proteins.

To examine whether the capping domain can be removed from the immobilized chimeric protein by thrombin digestion, the immobilization of CP-1 and its digestion were performed in a flow cell of the SPR sensor while resonance angular shift was monitored. As can be seen from the sensorgram (Figure 5), CP-1 was immobilized to the Ni(II)-chelated surface pretreated with BSA. The resonance angular shift due to CP-1 immobilization reaches 1.4 DA, which corresponds to the surface density of 0.7 μg/cm^2 (*22*). The resonance angle was gradually reduced by exposing the surface to thrombin solution ($g \rightarrow h$ in Figure 5). The ratio of the resonance angular shifts due to decapping and total recovery of decapped CP-1 by imidazole exposure was determined to be 0.57, which is in accordance with the ratio (0.54) of the numbers of amino acid residues corresponding to N- and C-terminal regions spanning from TCS. These results indicate that TCS was cleaved by thrombin, leaving decapped CP-1 on the surface.

Microarray-Based Assay. NSCs were cultured on the microarray that displayed MCP and control proteins. The microarray also contained spots onto which CP-3 and CP-5 or CP-4 and CP-5 were coimmobilized from their equimolar mixture. After a 3-day culture, an entire array was treated with 0.6 unit/mL thrombin for 45 min, and then cells were cultured for an additional 2 days. Markers for undifferentiated cells (nestin) and differentiated neurons (βIII) and astrocytes (GFAP) were immunologically stained, while nuclei were stained with Hoechst dye (Figure 6). The microarray-based method facilitated parallel and rapid assays under the same conditions for every experimental variation. Furthermore, the planar surface of the microarrays enabled us to distinguish reasonably small differences in marker expression, in marked contrast to the conventional culture systems with plastic dishes or microplates.

As shown in Figure 6A, substantial numbers of cells are seen on the spots with immobilized CP-1, CP-2, and CP-5. In contrast, a few cells are seen on the spots with CP-3, CP-4, CP-3/CP-5, and CP-4/CP-5, being similar to the spot with bare SAM. Taking into account the structure of chimeric proteins, these results indicate that the presence of the EGF domain is crucial for the effective adhesion and proliferation of the cells. This is reasonable because NSCs are considered to be trapped initially on the surface by EGF−EGF receptor (EGFR) interactions, receiving the EGF signal for proliferation (*17*). However, the coimmobilization of CP-5 could not improve cell adhesion and proliferation on the spots with CP-3/CP-5 and CP-4/CP-5. Because coimmobilization requires separate binding sites for each component, the surface density of coimmobilized CP-5 on the spots with CP-3/CP-5 and CP-4/CP-5 may be smaller than that on the spot with CP-5 alone. This is confirmed by the observation (Figure 4B) that the total amount of proteins on spots with CP-3/CP-5 and CP-4/CP-5 was approximately half

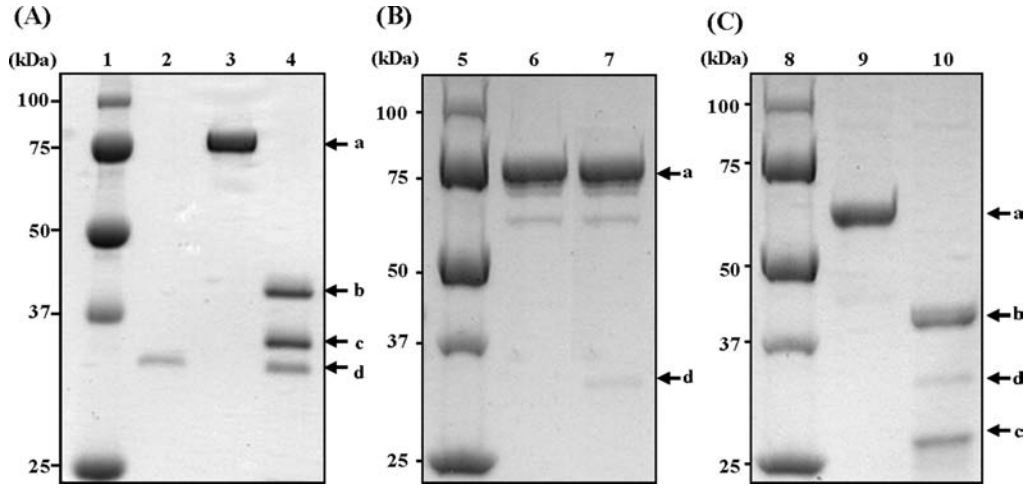

Figure 3. SDS−PAGE analysis of chimeric proteins digested by thrombin. (A) CP-1, (B) CP-2, and (C) CP-3 were digested with 0.6 unit/mL thrombin at 37 °C for 45 min. Then the products were analyzed with SDS−PAGE with 12.5% polyacrylamide gels with CBB staining. Lanes 1, 5, and 8, molecular weight standard; lane 2, thrombin; lane 3, 6, and 9, intact protein; lane 4, 7, and 10, proteins digested with thrombin. Arrows represent the protein band for (a) intact protein, (b and c) digested fragments, and (d) thrombin.

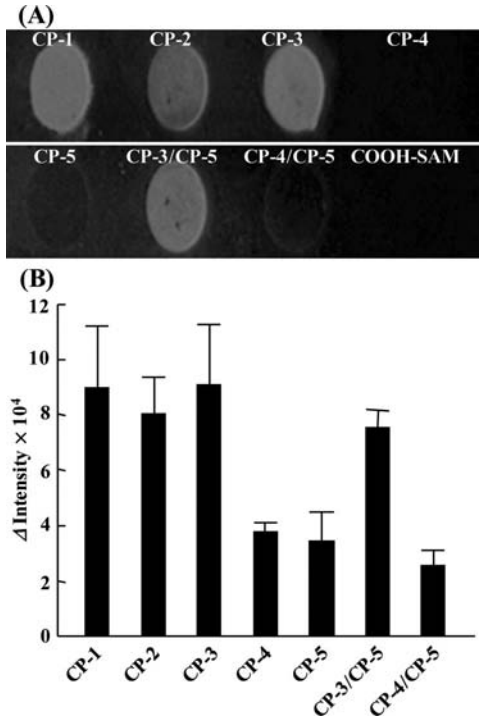

Figure 4. Surface plasmon resonance (SPR) imaging of the microarray. (A) SPR image of the microarray onto which various chimeric proteins were immobilized. Protein identification was indicated on the image. CP-3/CP-5 and CP-4/CP-5 represent the fact that equimolar mixtures of these proteins were used for immobilization. COOH-SAM represents a control spot without immobilized protein. (B) Intensity of reflected light determined on the spots. The difference from the intensity on the control spot (COOH-SAM) was plotted. The data are expressed as the mean ± standard deviation for three independent experiments.

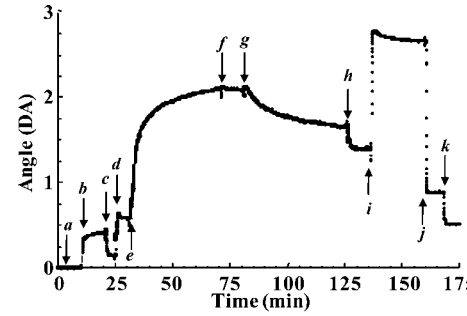

Figure 5. Surface plasmon resonance (SPR) analysis for the immobilization and thrombin treatment of multifunctional chimeric protein. Arrows (a−k) represent the time when the following solutions were injected to the Ni(II)-chelated surface: (a) PBS, (b) 1% BSA in PBS, (c) PBS, (d) 20 mM sodium phosphate containing 20 mM imidazole (pH 7.4; binding buffer), (e) 50 μg/mL CP-1 in binding buffer, (f) binding buffer, (g) 0.6 unit/mL thrombin solution in binding buffer, (h) binding buffer, (i) 20 mM sodium phosphate containing 500 mM imidazole (pH 7.4), (j) binding buffer, and (k) PBS.

of the sum on the spots with CP-3 and CP-5 and on the spots with CP-4 and CP-5, respectively.

The results of immunocytochemical staining are shown in Figure 6B and C. The comparison between Figure 6A and B shows that the majority of cells expressed nestin regardless of the spots. A striking result is that GFAP expression is most notable on the spot with CP-1 and moderate to negligible on the other spots (Figure 6C). Given the fact that CNTF strongly induces astrocytic differentiation from NSCs (*11*), the result just described gives evidence that the CNTF domain in the immobilized CP-1 was unveiled upon decapping to act effectively on the cells.

Quantitative Assay of Differentiation. Cells were cultured on the glass substrate onto which CP-1 was immobilized (Figure 7). In this experiment, the entire surface of a glass plate was modified with the protein for precise quantification. The results of comparable experiments for the CP-5-immobilized substrate are given in Figure S4 (Supporting Information). From these microphotographs, the total number of cells and the fraction of cells positive for nestin, βIII, and GFAP were determined (Figure 8). On the CP-5-immobilized surface, cells proliferated rapidly, and more than 95% of total cells expressed nestin with negligible expression of βIII and GFAP (<5% for both markers), being in good agreement with our previous study (*17*). Cells on the CP-1-immobilized surfaces reduced their proliferation rate and the level of nestin expression (85%). This is probably due to the effect that a large globular polypeptide (TRX-EGFP-TCS-CNTF) in CP-1 reduces the surface density of the EGF domain, compared to the surface with CP-5 alone. On the CP-1-immobilized surface, the expression of βIII was at a low level, similar to the surface with CP-5. However, a large number of cells expressed GFAP when the substrate was treated with thrombin (68 ± 3.9%). This result suggests that a large part of

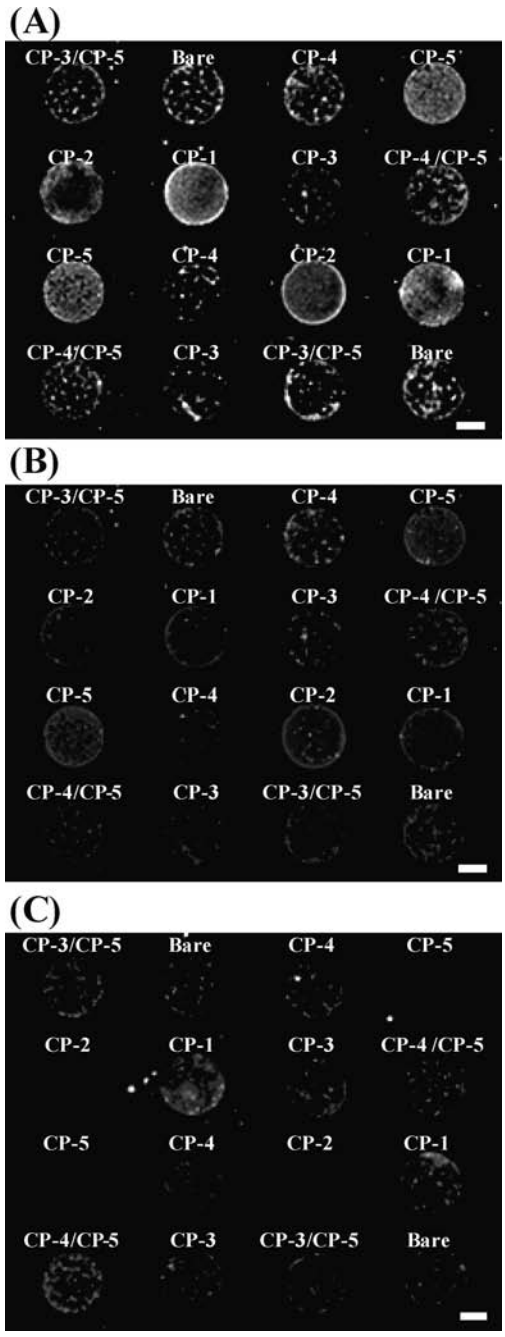

Figure 6. Fluorescent microphotographs of cells cultured for 6 days on the microarray that displayed various chimeric proteins. (A) Nuclear staining with Hoechst. Immunocytochemical staining of (B) nestin and (C) GFAP. The immobilized proteins are indicated above each spot. Bare represents spots with a pristine SAM terminated with carboxylic acid. Scale bar: 1 mm.

cells expressed both nestin and GFAP. In contrast, a smaller number of cells expressed GFAP (18 ± 2.4%), when thrombin treatment was omitted. These results again demonstrate that CNTF action can be temporally controlled by thrombin digestion. However, the number of GFAP-expressing cells is significantly larger than that for the surface with immobilized CP-5 (2.7 ± 1.8%).

Analysis of Gene Expression. In Figure 9, the results of semiquantitative RT-PCR are shown for cells obtained after a 6-day culture on the CP-1-immobilized surfaces with and without thrombin treatment. For comparison, data are further shown for cells cultured on the CP-5-immobilized surface for 5 days and for cells immediately after neurosphere culture.

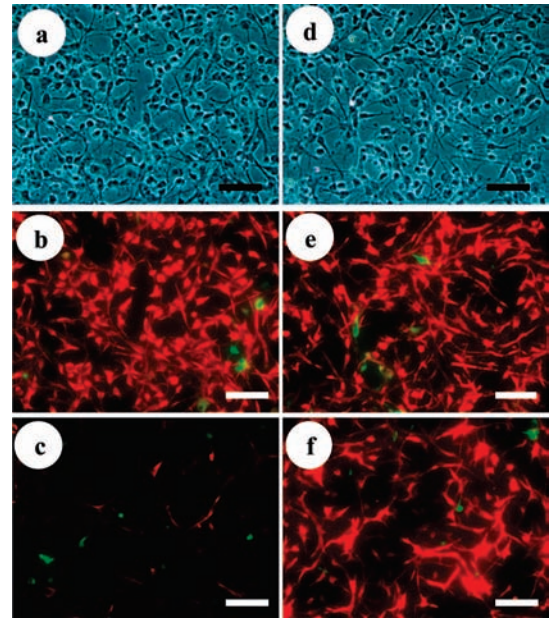

Figure 7. Immunocytochemistry of NSCs cultured on the CP-1-immobilized surfaces with or without thrombin digestion. (a−c) Cells were stained 6 days after cell seeding without thrombin treatment. (d−f) Cells were cultured for 3 days, treated with 0.6 unit/mL thrombin at 37 °C for 45 min, and then additionally cultured for 3 days. Images a and d are recorded at the same view as that for b and e, respectively. Cells were stained with antibodies against (b and e) nestin (red) and βIII (green), and (c and f) GFAP (red) and βIII (green). Scale bar: 100 μm.

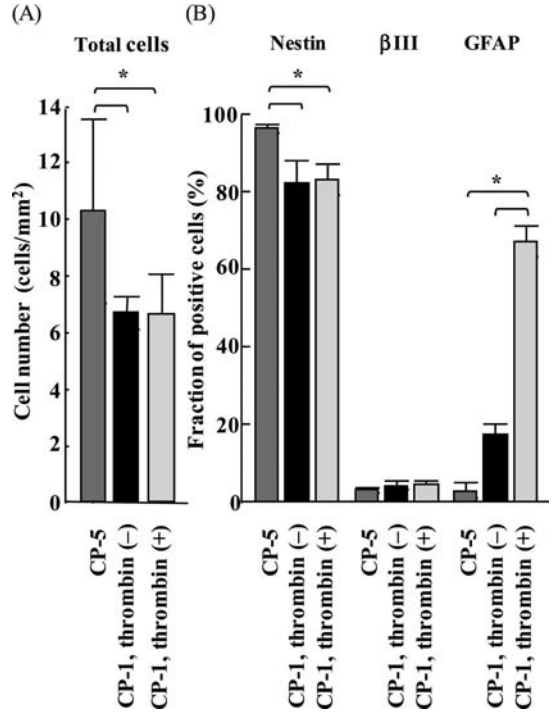

Figure 8. Quantitative evaluation for (A) total number of cells and (B) the fraction of cells expressing nestin, GFAP, and βIII. Cells were cultured on the surface with immobilized (gray) CP-5, (closed) CP-1 without thrombin treatment, and (light gray) CP-1 with thrombin treatment. The data are expressed as the mean ± standard deviation for $n = 6$. The asterisk indicates the statistical significance ($P < 0.05$, true significant difference test) compared to the CP-5 spot.

No difference was observed for every sample in the expression of mRNA for EGFR, CNTF receptor (CNTFR), leukemia inhibitory factor receptor (LIFR), and gp130. EGFR is a tyrosine

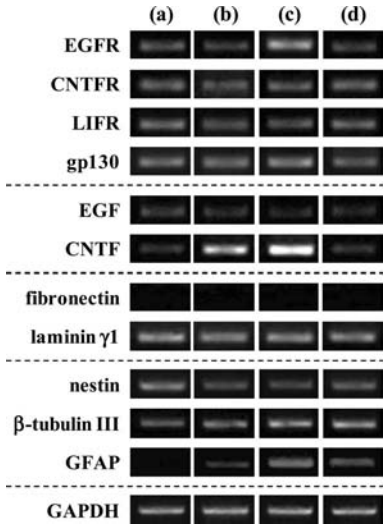

Figure 9. RT-PCR analysis of genes expressed in cells cultured for 5–6 days on the surface with immobilized (a) CP-5, (b) CP-1 (without thrombin treatment), and (c) CP-1 (with thrombin treatment). Cells were cultured for 3 days followed by treatment with 0.6 unit/mL thrombin at 37 °C for 45 min. Then cells were additionally cultured for 3 days. (d) Cells obtained from neurosphere culture.

kinase receptor for EGF (*23*), while CNTFR forms a complex with LIFR and gp130 to bind CNTF (*24*). These results suggest that cells are always ready for receiving the signals from EGF and CNTF if they are available.

A similar level of mRNA for βIII is seen for all types of cells. mRNA for nestin was expressed at a slightly higher level in cells on CP-5-immobilized surface among the sample studied. The expression of mRNA for GFAP is seen most abundantly in the cells on the CP-1-immobilized surface with thrombin treatment, with moderate expression on CP-1 without thrombin treatment and neurosphere cells. No mRNA for GFAP was amplified from cells on the CP-5-immobilized surface. These results are in accordance with those obtained by the immunostaining of marker proteins.

mRNA for EGF was expressed at a similar level regardless of the type of spots, suggesting that EGF-responsive self-renewing cells produce EGF by themselves. CNTF mRNA expression increased in cells at the CP-1-immobilized surface after thrombin treatment, though low but significant expression was also observed even without thrombin treatment. The difference in the expression level between these two conditions was obvious when assessed from the band intensities analyzed using an imaging software (data not shown). Since astrocytes are known to synthesize CNTF (*25*), the result supports our observation that CNTF stimulation triggers astrocytic differentiation, as described in the earlier sections.

mRNA for fibronectin was not detected in any samples tested, while mRNA for the laminin γ1 chain was abundantly expressed. The laminin γ1 chain is a component of laminin subtypes 1, 2, and 4 (*26*) and is present in a variety of tissues including the brain (*27*). The results of RT-PCR suggest that cells, initially attached through interactions of EGFR with the immobilized EGF, secreted laminin by themselves to enhance cell adhesion to the surface.

DISCUSSION

Controlling the dynamics of growth factor signaling is a challenge in regenerative medicine for various tissues including the CNS (*6*). For this purpose, the biomolecular engineering approach is promising, because artificial proteins with multiple functions can be rationally designed using recombinant technology. In this study, we designed the conjugate of two different growth factors, EGF and CNTF, with the removable capping system. The results presented here demonstrate that the sequential actions of EGF and CNTF could be achieved because of the capping domain being removable upon protease treatment (Figures 6, 7, and 8). The temporal capping of CNTF and the subsequent decapping were shown to be effective for inducing the glial differentiation of NSCs previously expanded by the mitogenic activity of a fusion partner, EGF. These processes could be simply demonstrated here by microarray-based assays as well as a more-detailed quantitative analysis.

In a protease-cleavable capping system, a thrombin-susceptible TCS sequence (LVPRGS) was located between the capping domain and CNTF. Our results showed that thrombin specifically digested the TCS sequence to eliminate the TRX-EGFP domain, leaving the CNTF-His10-EGF domain (Figures 3 and 5). The result of temporally controlled glial differentiation indicates that a relatively large domain of TRX-EGFP effectively hinders the accessibility of the CNTFR-LIFR-gp130 complex toward CNTF. Thrombin is a member of serine proteases and plays a key role in the coagulation cascade (*28*). Investigators have reported that thrombin is implicated in neurodegeneration (*29*), especially in Alzheimer's disease microvessels (*30*), though the local concentration of thrombin in the CNS lesion is not available. From these investigations, we expect that CNTF is decapped in response to the availability of endogenous thrombin in degenerative lesion sites, as in the case with fibrin gels (*31*). Different kinetics of growth factor switching may be achieved by replacing the TCS with a cleavage site for matrix metalloproteinase (MMP). For example, Kim et al. reported that the active form of MMP-3 was released from stressed dopamine neurons in Parkinson's disease (*32*).

It is well recognized that EGF is a strong activator for the self-renewal of NSCs in vitro (*11, 19*). Our previous study (*17*) showed that the oriented immobilization of CP-5 provided substrates for the efficient propagation of NSCs. Comparable results were obtained with CP-1 without thrombin treatment (Figure 8). The presence of GFAP-positive cells on the CP-1 surface without thrombin digestion ($18 \pm 2.4\%$; Figure 8) suggests incomplete hindrance by the globular capping domain or protease cleavage during the course of the assay. Upon thrombin digestion, cells started to receive a stimulus from CNTF, giving rise to directed specification into GFAP-positive astrocytes, with the low level of neuronal differentiation. CNTF is known to bind to a specific, nonsignaling receptor (CNTF receptor alpha) as well as signaling receptors including LIFR and gp130 to transmit signals into cells (*25*). It was shown that the exposure of rat embryonic CNS stem cells to CNTF led to their differentiation into type 1 astrocytes via tyrosine phosphorylation of STAT1 and STAT3 (*25*). In addition, a 2-fold increase in the rate of astrocytic differentiation was reported in CNTF-exposed cells derived from human neurospheres (*11*). The results obtained in our study are in accordance with these previous observations. In our system, EGF is present at the surface even after decapping. The incorporation of a protease-cleavable site between the His10 and EGF domains may improve the clear switching of growth factor actions.

The MCP developed in this study provides the biomolecular means to achieve the sequential actions of two growth factors. Different types of growth factors will be required depending on clinical settings for cell replacement therapy in the CNS. The biomolecular systems for these purposes can be engineered rationally with recombinant technology, taking advantage of our design concept for MCP. The chimeric protein can be incorporated into the scaffolds made of synthetic or natural biodegradable polymers that possess metal ions for chelate formation with His10 in the protein. The combination of the scaffold

materials and progenitor cells will provide an efficient strategy for cell-based therapy in the CNS. A study on such an intelligent scaffold system is currently underway.

CONCLUSIONS

Recombinant technology was employed to synthesize the MCP consisting of two growth factor domains (EGF and CNTF), a globular capping domain (TRX-EGFP), a protease-cleavable domain (TCS), and a substrate-binding domain (His10). When immobilized to the surface of the substrate through the coordination of His10, the MCP served NSCs for proliferation, maintaining their undifferentiated state. This effect is due to the activity of EGF, while CNTF activity is temporally veiled with the capping domain. Upon digesting TCS with thrombin, the activity of CNTF emerged to induce the differentiation of astrocytes in situ from previously expanded NSCs. These results demonstrate the feasibility of the system for controlling the dynamics of growth factor signals.

Synthesis, Characterization, Antitumor Activity of Pluronic Mimicking Copolymer Micelles Conjugated with Doxorubicin via Acid-Cleavable Linkage

Yuhan Lee, Sung Young Park, Hyejung Mok, and Tae Gwan Park*

Department of Biological Sciences, Korea Advanced Institute of Science and Technology, Daejeon 305-701, Republic of Korea.
Received October 15, 2007; Revised Manuscript Received November 12, 2007

Pluronic mimicking poly(ethylene oxide)-poly(propylene oxide)-poly(ethylene oxide) (PEO-PPO-PEO) triblock copolymer having multiple hydroxyl groups in the PPO middle segment (core-functionalized Pluronic: CF-PLU) was synthesized for conjugation of doxorubicin (DOX). DOX was conjugated on the multiple hydroxyl groups of CF-PLU via an acid-labile hydrazone linkage (CF-PLU-DOX). In aqueous solution, CF-PLU-DOX copolymers self-assembled to form a core/shell-type micelle structure consisting of a hydrophobic DOX-conjugated PPO core and a hydrophilic PEO shell layer. The conjugated DOX from CF-PLU-DOX micelles was released out more rapidly at pH 5 than pH 7.4, indicating that the hydrazone linkage was cleaved under acidic condition. CF-PLU-DOX micelles exhibited greatly enhanced cytotoxicity for MCF-7 human breast cancer cells compared to naked DOX, while CF-PLU copolymer itself showed extremely low cytotoxicity. Flow cytometry analysis revealed that the extent of cellular uptake for CF-PLU-DOX micelles was greater than free DOX. Confocal image analysis also showed that CF-PLU-DOX micelles had a quite different intracellular distribution profile from free DOX. CF-PLU-DOX micelles were mainly distributed in the cytoplasm, endosomal/lysosomal vesicles, and nucleus, while free DOX was localized mainly within the nucleus, suggesting that CF-PLU-DOX micellar formulation might be advantageously used for overcoming the multidrug resistance (MDR) effect, which gradually develops in many tumor cells during repeated drug administration.

INTRODUCTION

Doxorubicin (DOX), a topoisomerase inhibitor, is a widely used anticancer drug in the treatment of many types of cancer (*1–4*). However, systemic administration of DOX itself elicits severe cardiac toxicity due to the lack of ability to target cancer cells, and also shows the multidrug resistance (MDR) effect (*5–7*). To improve pharmacokinetic/dynamic profiles, enhance passive tumor targeting, and alleviate the MDR effect, various nanoscale DOX formulations such as polymeric nanoparticles, polymer conjugates, liposomes, polymeric micelles, and dendrimer conjugates have been reported to maximize its therapeutic efficacy (*8–22*). Polymeric and lipid nanoparticles containing DOX, when they are injected systemically, significantly alter their biodistribution profiles, thereby preferably targeting to the tumor tissue in a passive manner by the "enhanced permeation and retention (EPR)" effect (*23*). DOX has been physically encapsulated and/or chemically conjugated within poly(ethylene glycol) (PEG)-decorated biodegradable polymeric nanoparticles and micelles to prolong circulation time in the bloodstream as well as to increase the extent of extravascular accumulation in the tumor region. As an attempt to overcome the MDR effect that continuously pumps out intracellular free DOX molecules through the P-glycoprotein (P-gp) pump on the cell membrane, DOX was chemically conjugated onto water-soluble polymers, nanoparticles, and micelles via an acid-cleavable linkage, to change subcellular trafficking of DOX within cells (*24, 25*). Free DOX is taken up by cells via a passive diffusion mechanism, which is highly susceptible for the MDR effect. In contrast, DOX-conjugated nanoparticles and micelles are transported into cells via an endocytosis process, possibly reducing the concentration of cytosolic free DOX for the P-gp pumping action. It is conceivable that DOX molecules conjugated to nanoparticles and micelles are cleaved within the acidic endosomal vesicles and then transported into the cytosol, resulting in bypassing the MDR effect to some extent (*26, 27*).

Poly(ethylene oxide)-poly(propylene oxide)-poly(ethylene oxide) (PEO-PPO-PEO) triblock copolymers (Pluronic) have been widely used as biocompatible drug carriers (*28, 29*). In aqueous solution, Pluronic copolymers self-assemble to form a spherical micelle above a critical micelle concentration and temperature. Pluronic micelles with ~40 nm in diameter are composed of a hydrophobic PPO core and hydrophilic PEO corona. Various hydrophobic anticancer drugs have been physically entrapped within the PPO core of the Pluronic micelles to increase the drug solubility as well as enable passive targeting to the solid tumor. However, Pluronic copolymer micelles are not stable enough to maintain structural integrity for loading the moderately hydrophobic DOX within the inner core. This is partly due to the fact that hydrophobic self-association of PPO middle blocks in the core is not so strong in comparison to other polymeric micelles such as biodegradable poly(lactic acid)-*b*-PEG copolymer micelles. As a result, Pluronic copolymer micelles are easily disintegrated upon dilution below the critical micelle concentration after injection in the bloodstream, limiting their practical uses for systemic delivery of DOX. Nevertheless, it was recently demonstrated that Pluronic copolymer micelles, when administered together with various anticancer drugs, showed enhanced cytotoxic activities by sensitization of MDR cells (*30–32*). The sensitization effect to MDR cancer cells by Pluronic copolymers was attributed to the inhibition of P-gp activity by depletion of ATP.

In this study, a Pluronic-mimicking copolymer having multiple hydroxyl groups on the PPO middle segment was

synthesized and chemically conjugated with DOX via an acid-labile linkage. DOX was conjugated on the multiple hydroxyl groups on the PPO segment via a hydrazone linkage to form a more stable self-assembled micellar structure through $\pi-\pi^*$ interaction between polyaromatic ring structures in DOX buried in the core. It was expected that DOX was specifically released out in an intact form from the copolymer carrier under acidic physiological conditions such as an intracellular endosomal compartment within the tumor cells. The synthesized Pluronic F127 mimicking copolymer micelles were characterized using ^{1}H NMR, transmission electron microscopy (TEM), and light scattering. In vitro cytotoxicity and cellular uptake behavior of the DOX-conjugated copolymer micelles were evaluated for the MCF-7 human breast cancer cell line using free DOX as a control.

EXPERIMENTAL PROCEDURES

Materials. Doxorubicin hydrochloride was purchased from Wako Chemicals (Japan). Epichlorohydrin, anhydrous 1,4-dioxane, methoxy-poly(ethylene glycol) (mPEG) (MW: 5000), poly(propylene oxide) (PPO) (Mw: 2000), *N*,*N*′-dimethylethylenediamine, sodium chloride, triethylamine, anhydrous dimethylsulfoxide (DMSO), deutrium oxide (D_2O), and dimethylsulfoxide-d_6 (DMSO-d_6) were purchased from Sigma-Aldrich (Milwaukee, WI). Sodium sulfate and sodium hydroxide were purchased from Junsei (Japan). *p*-Nitrophenyl chloroformate (*p*-NPC) was purchased from TCI (Japan). The MCF-7 cell line of human breast cancer cells was obtained from Korean Cell Line Bank (Seoul, Korea).

Synthesis of PEO-PPO-PEO Triblock Copolymer Having Hydroxyl Groups on PPO Segment. *Synthesis of Epoxide-Terminated PPO and Epoxide-Terminated mPEG.* Epichlorohydrin (7.44 g, 0.08 mol) was added dropwise to a mixture of PPO (40 g, 0.04 mol) and pulverized NaOH (5 g, 0.25 mol) in 50 mL of anhydrous 1,4-dioxane. The reaction mixture was heated to 65 °C and stirred magnetically for 6 h. The cooled reaction mixture was filtered, and the product was extracted in methylene chloride. The organic layer was dried over Na_2SO_4, concentrated by evaporation of methylene chloride, and further dried under vacuum. Synthesis of epoxide-terminated mPEG was also carried out similarly using the method described in the preparation of epoxide-terminated PPO.

^{1}H NMR ($CDCl_3$): δ = 3.88–3.08 (br, 2H of PPO), 3.08 (m, oxirane), 2.78 (m, OCH_2), 2.42 (m, oxirane), and 1.16−1.03 (br, 3H of PPO).

Synthesis of PPO Multiblock Having Multiple Hydroxyl Groups on the Chain. A PPO multiblock copolymer having multiple hydroxyl groups in the backbone was prepared by step-growth polymerization of epoxide-terminated PPO (21.1 g, 0.01 mol) and *N*,*N*′-dimethylethylenediamine (0.088 g, 0.01 mol) in refluxing ethanol (200 mL) for 40 h. After reacting for 40 h, an excess amount of *N*,*N*′-dimethylethylenediamine was added to introduce terminal amine groups in the PPO multiblock copolymer, and further reacted overnight in the refluxing solvent. After the reaction, the solvent was removed under vacuum and the remaining viscous solution was dissolved in methylene chloride (80 mL) followed by washing with saturated NaCl solution (10 mL). The organic phase was dried over $MgSO_4$ and the solvent was evaporated under vacuum. The product was dissolved in deionized water, dialyzed to remove unreacted diamine, and lyophilized for 48 h.

^{1}H NMR ($CDCl_3$): δ = 3.88–3.06 (br, 2H of PPO), 2.3–2.25 (br, (CH_3)CH_2CH_2N(CH_3)), and 1.14−1.04 (br, 3H of PPO).

Synthesis of PEO-PPO-PEO Triblock Copolymer. A triblock copolymer having multiple hydroxyl groups in the PPO backbone (core-functionalized Pluronic, CF-PLU) was prepared by reacting the amine-terminated multiblock PPO (15 g, 0.0036 mol) to the epoxide-terminated mPEG (55 g, 0.01 mol) in refluxing ethanol (100 mL) for 40 h. The product was precipitated in excess cold diethyl ether. The triblock copolymer was purified by dialysis (molecular weight cutoff 6000–8000, Spectrum Laboratories, Inc., USA) in a cold room for 2 days, and lyophilized.

^{1}H NMR (D_2O): δ = 5.21–5.14 (br, 1H of lactide), 3.88–3.06 (br, 2H of PPO and PEO), 2.3–2.25 (br, (CH_3)CH_2CH_2N(CH_3)), and 1.2−1.05 (br, 3H of PPO).

Synthesis of DOX-Conjugated PEO-PPO-PEO Copolymer via a Hydrazone Bond. *Synthesis of Amine-Reactive PEO-PPO-PEO Copolymer.* PEO-PPO-PEO copolymer was activated using *p*-NPC. Briefly, PEO-PPO-PEO copolymer (1 g, 0.071 mmol) was dissolved in distilled methylene chloride (20 mL), and triethylamine (0.049 mL, 0.071 mmol) was added in the solution. The copolymer solution was dropped into *p*-NPC (0.049 mg, 3 equiv) solution in methylene chloride (5 mL) for 1 h and reacted for 48 h with vigorous stirring. After evaporating methylene chloride, an excess amount of methanol was added to remove unreacted *p*-NPC. After removing methanol, the product was purified by extraction with sodium chloride saturated deionized water and precipitated in cold diethyl ether (−20 °C) and dried in vacuo.

Conjugation of Hydrazine on PEO-PPO-PEO Copolymer. Amine-reactive PEO-PPO-PEO copolymer (1 g, 0.07 mmol) dissolved in methylene chloride (20 mL) was slowly dropped into hydrazine monohydrate (0.22 mL, 10 equiv) solution in methylene chloride (5 mL) and reacted for 24 h. After evaporating methylene chloride, the product was dissolved in deionized water and dialyzed against water and then lyophilized.

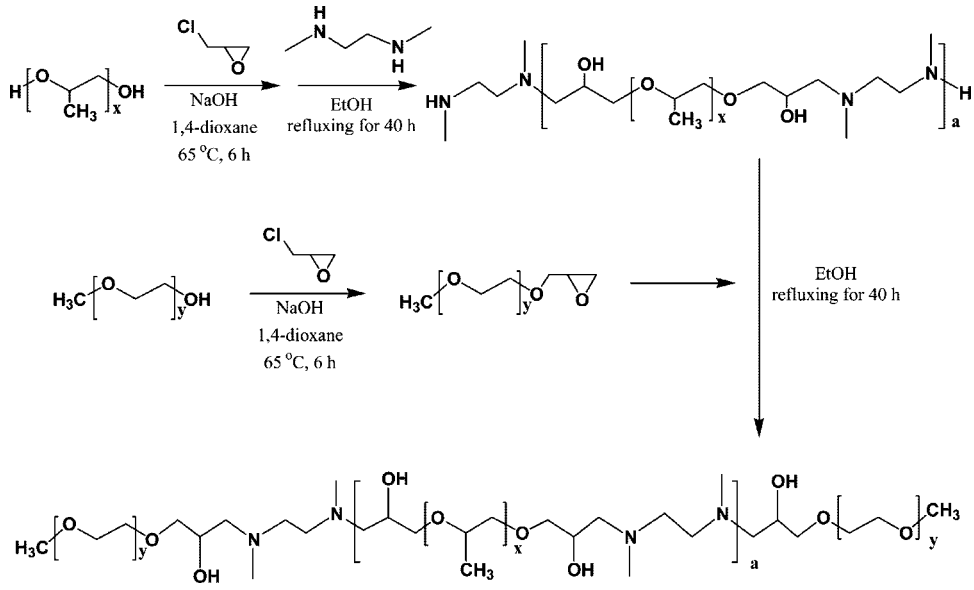
Conjugation of DOX on PEO-PPO-PEO Copolymer. Hydrazine-conjugated PEO-PPO-PEO copolymer (100.58 mg) and DOX (10 mg, 1 equiv) were dissolved in anhydrous DMSO (10 mL). The reaction was kept for 48 h at 60 °C. Unreacted DOX and DMSO were removed using dialysis for 12 h at 4 °C against pH 9.0 distilled–deionized water adjusted with 0.1 M NaOH, and the product was lyophilized. All reactions were performed in a dark room. DOX conjugation was confirmed by gel permeation chromatography (GPC, Waters) detected by both an RI detector (RI-71, Shodex) and a UV detector (Waters 486 tunable absorbance detector, Waters) at absorbance 480 nm using chloroform as an eluant. The degree of substitution of DOX was determined using a spectrophotometer (Shimadzu UV-1601, Japan) at 480 nm.

NMR Spectroscopy. Micelle formation of DOX-conjugated PEO-PPO-PEO copolymer via a hydrozone bond (core-functionalized Pluronic conjugated with DOX, CF-PLU-DOX) was confirmed by ^{1}H NMR spectroscopy (Bruker Avance 400 spectrometer operating at 400 MHz). D_2O and DMSO-d_6 were used as solvents to compare the NMR spectra of DOX containing micelles and free DOX, which were prepared at a concentration of 0.1 (w/v) %.

Transmission Electron Microscopy (TEM) Image Analysis. Transmission electron microscopy (TEM, CM-20, Philips, The Netherlands) was used to visualize the morphology of CF-PLU and CF-PLU-DOX micelles. For comparison, Pluronic F127 micelles were used as controls. Each sample was dropped onto a TEM copper grid covered with a carbon film (300 mesh, Ted Pella, U.S.A.) for 10 min and air-dried overnight.

Size Distribution Using Dynamic Light Scattering. Dynamic laser light scattering (DLS) measurement was carried out using a Brookhaven laser light scattering instrument (ZetaPlus, Brookhaven Instruments Corporation, New York, USA), with a He−Ne laser operating at a wavelength of 677 nm at required temperature. A scattering angle of 90° was used for all measurements. The concentration of the sample was 0.005 (w/

Scheme 1. Synthesis of Core-Functionalized PEO-PPO-PEO Copolymer (CF-PLU)



v) % in deionized water, and the solution temperature was equilibrated for more than 30 min before measurement.

DOX Release Experiment. pH-dependent DOX release profiles from CF-PLU-DOX micelles were determined using a previously described method (*27*). Briefly, CF-PLU-DOX micelles (1 mg/mL) were prepared in pH 5.0 and pH 7.4 phosphate buffered saline (PBS) solutions. One milliliter of the solution was placed inside a dialysis membrane (molecular weight cutoff 3500, Spectrum Laboratories, Inc., USA) and dialyzed against 10 mL of pH 5.0 and pH 7.4 PBS solutions. The outer buffer solution containing released DOX was collected at predetermined time points and replaced with 10 mL of fresh buffer solutions. The amount of the released DOX was measured using UV–vis spectroscopy (Shimadzu, Japan) at a 480 nm wavelength and calculated on the basis of a calibration curve using DOX solutions with various concentrations as standards. The experiment was carried out in triplicate.

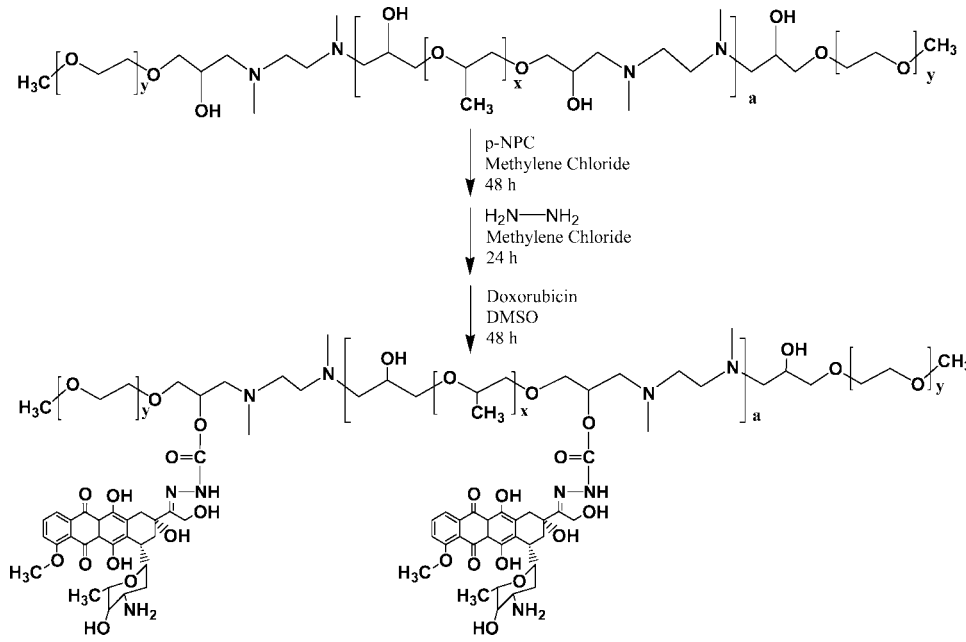
In Vitro Cell Cytotoxicity, Confocal Image Analysis, and Flow Cytometry Studies. MCF-7 breast cancer cell line was used in this study. Cells were maintained in DMEM media containing 10% fetal bovine serum (FBS) in humidified air containing 5% CO_2. Cells in each culture dish were exposed to various concentrations of free DOX and CF-PLU-DOX for 48 h and cell viability was examined. Cell viability was determined using the conventional MTT assay method. For confocal laser microscopy (Zeiss, Germany) images, cells on a slide glass were exposed to an equivalent DOX concentration of 5 μM for 15 min, washed out thoroughly, and visualized to observe the early stage of cellular uptake. The extent of cellular uptake was also quantified by flow cytometry (FACSCalibur, NJ) after exposure of the cells to the equivalent DOX concentration of 5 μM for 15 min.

RESULTS AND DISCUSSION

Core-functionalized PEO-PPO-PEO (CF-PLU) was synthesized using an epoxide−amine reaction method as shown in Scheme 1. Two terminally functionalized epoxide groups in the precursor PPO chain were reacted with secondary amine groups of *N*,*N*′-dimethylethylenediamine as a chain extender, producing a multiblock PPO chain with six hydroxyl groups on the backbone. Using GPC, it was confirmed that two epoxide-terminated PPO chains (Mw 2000) were chain-extended via the epoxide−amine reaction, producing the multiblock PPO chain having weight-average molecular weight of 4090 (number of precursor PPO: 2). By conjugating an epoxide-terminated mPEG to the two terminal amine groups of the multiblock PPO chain, Pluronic-mimicking PEO-PPO-PEO copolymer with multiple hydroxyl groups on the PPO segment was synthesized. The weight-average molecular weight of the synthesized triblock copolymer was 14 348 (Mw of PPO segment 4090 and Mw of PEO segment 10 258) as determined by GPC. The balance of molecular weight between the PPO and PEO segments in the copolymer was similar to that in Pluronic F127. The copolymer had six hydroxyl groups in the PPO segment in total, resulting from four hydroxyl groups in the multiblock PPO chain (two epoxide-terminated PPO chains in series) and two hydroxyl groups in the two end-capped mPEG chains that had terminal epoxide groups before reaction. The multiple hydroxyl groups on the PPO segment of the CF-PLU copolymer were further modified with DOX via a hydrazone linkage, an acid-labile bond, using a sequential *p*-NPC-mediated hydroxyl−amine coupling reaction followed by an amine−ketone reaction as shown in Scheme 2. The degree of substitution (DS) for DOX was 67.9% (~4.1 DOX per CF-PLU) as determined using a UV–vis spectrometric method. The conjugation of DOX to CF-PLU was confirmed by GPC analysis as shown in Figure 1. CF-PLU-DOX as detected by UV absorbance at 480 nm was eluted earlier than CF-PLU that was detected by RI, suggesting that DOX was covalently conjugated onto the PPO backbone of CF-PLU.

The formation of a core/shell-type micelle structure for CF-PLU-DOX copolymer in aqueous solution was confirmed by ^{1}H NMR spectra using two different solvents (D_2O and DMSO-d_6). For the spectra of CF-PLU-DOX copolymer using DMSO-d_6 as the solvent (Figure 2a), characteristic peaks of DOX (multiple peaks at 4.5–5.4 ppm and 0.8–1 ppm) were detected, indicating that the copolymer molecules were fully dissolved in the solvent while exposing the conjugated DOX in the solvent. In contrast, in the spectra taken in D_2O as a solvent, the DOX peaks disappeared while characteristic PEO and PPO peaks still appeared, suggesting that DOX molecules conjugated to the hydrophobic PPO segment were buried within the core. The results supported that the CF-PLU-DOX copolymers self-assembled into core/shell-type micelles in aqueous solution. The effective diameter of CF-PLU-DOX micelles measured by dynamic light scattering was 164.9 ± 34.4 nm, while that of CF-PLU micelles was 88.5 ± 6.8 nm, indicating that the conjugated DOX in the core increased micelle size. The

Scheme 2. Synthesis of Doxorubicin-Conjugated Core-Functionalized PEO-PPO-PEO Copolymer via a Hydrazone Bond (CF-PLU-DOX)



theoretical drug loading efficiency was 13.7% as calculated on the basis of the degree of substitution of CF-PLU-DOX (67.9%).

To further investigate the morphology of core/shell-type CF-PLU-DOX micelles, TEM images of CF-PLU-DOX or CF-PLU micelles were taken. Figure 3a,b clearly shows the core/shell structure of CF-PLU-DOX copolymer micelles in aqueous solution, which were composed of a dark core (average diameter: ca. 90 nm) surrounded by a relatively bright shell layer (average thickness: ca. 15 nm). At lower magnification (Figure 3c), tightly packed nanospheres having an average size of about 120 nm were observed. On the other hand, CF-PLU copolymer micelles were irregular in shape and showed an average size of about 90 nm, consistent with the size obtained from the DLS study. The irregular morphology with multiple nuclei might be caused by interfering hydrophobic interactions of PPO segments by multiple hydroxyl groups present in the synthesized PEO-PPO-PEO copolymer. It was likely that water molecules associated with the hydroxyl groups could not be completely removed from the core during the self-assembly process of the copolymers, resulting in the inner nuclei-like water pockets. Considering that Pluronic F127 micelles are about 40 nm in diameter in aqueous solution, the increased micelle sizes of CF-PLU and CF-PLU-DOX could be attributed to the modified and core-functionalized PEO-PPO-PEO structure. It was likely that hydrophobic interaction and/or $\pi-\pi^*$ stacking of conjugated DOX molecules in the core were responsible for the self-assembling core/shell structure of CF-PLU-DOX micelles. This core/shell structure is promising for cancer therapy, because the PEG shell can provide a stealth property with prolonged circulation time in the bloodstream, while the stabilized inner core can prevent early DOX release from the micelles during the circulation.

DOX release from CF-PLU-DOX micelles was evaluated at pH 5.0 and pH 7.4 conditions. CF-PLU-DOX micelles are expected to exhibit pH-responsive DOX release profile due to the acid-labile nature of the hydrazone linkage between DOX and PPO middle backbone. As shown in Figure 4, CF-PLU-

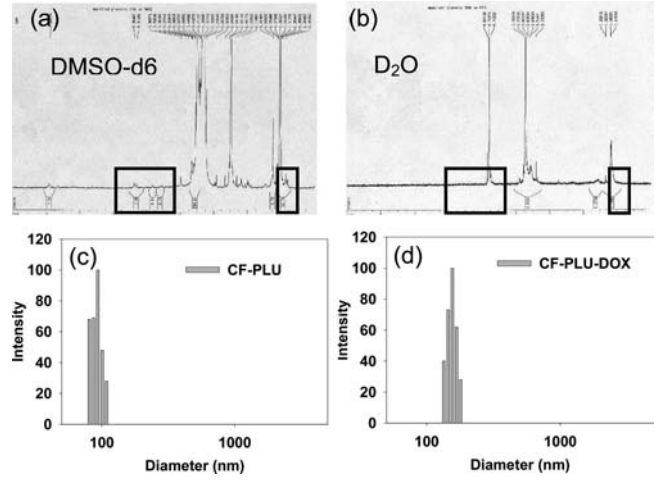

Figure 2. Micellization of DOX-conjugated PEO-PPO-PEO copolymer as confirmed by ^{1}H NMR spectroscopy using (a) DMSO-d_6 and (b) D_2O as solvents. The size was determined by dynamic light scattering (DLS) analysis: (c) CF-PLU and (d) CF-PLU-DOX at a concentration of 0.05 (w/v) %.

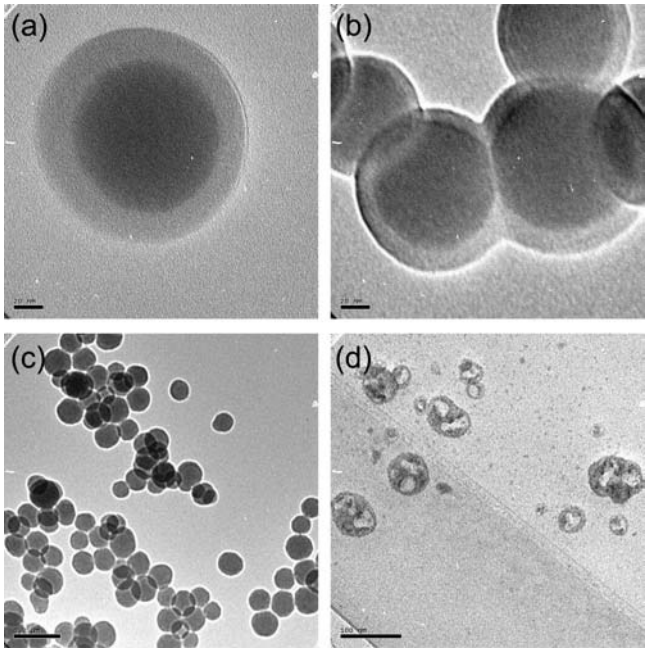

Figure 3. TEM images of CF-PLU-DOX (a−c) and CF-PLU (d).

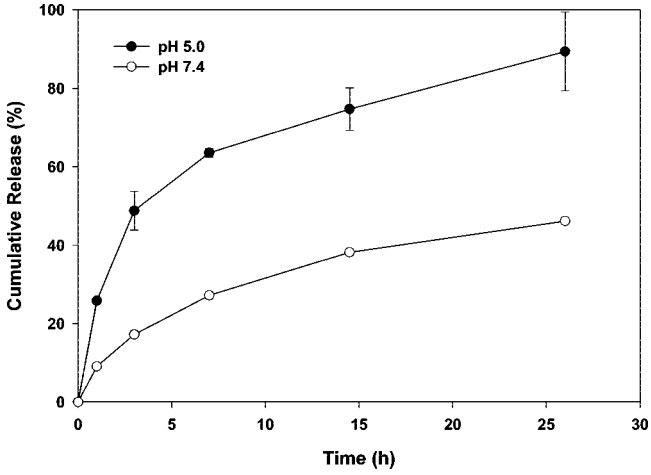

Figure 4. In vitro release profiles of DOX from CF-PLU-DOX micelles at pH 7.4 (○) and pH 5 (•).

DOX micelles showed much faster DOX release at pH 5.0 than at pH 7.4. At pH 5.0, CF-PLU-DOX micelles released out about 50% of the initially loaded DOX for the first 3 h, and liberated 84% after 26 h. However, at pH 7.4, the micelles released out only 15% of DOX for 3 h and less than 40% after 26 h. The accelerated DOX release in acidic pH condition is highly desirable for effective treatment of cancer. It is conceivable that CF-PLU-DOX micelles are passively targeted to the tumor tissue through the enhanced permeation and retention (EPR) effect with minimized DOX release during circulation in the bloodstream. There would be two beneficial effects for the acid-sensitive DOX release: (1) after accumulation in the vicinity of the tumor cells, DOX could be cleaved and released from the CF-PLU-DOX micelles selectively in the acidic solid tumor microenvironment for passive cellular uptake (*27, 29, 30*); (2) and more importantly, intact CF-PLU-DOX micelles would be taken up by tumor cells through nonspecific endocytosis, and located preferentially in the acidic endosome compartments, where DOX could be cleaved, escaped from the endosome, and released out in the cytosol. The second cellular uptake mechanism of DOX conjugated to CF-PLU micelles via endocytosis

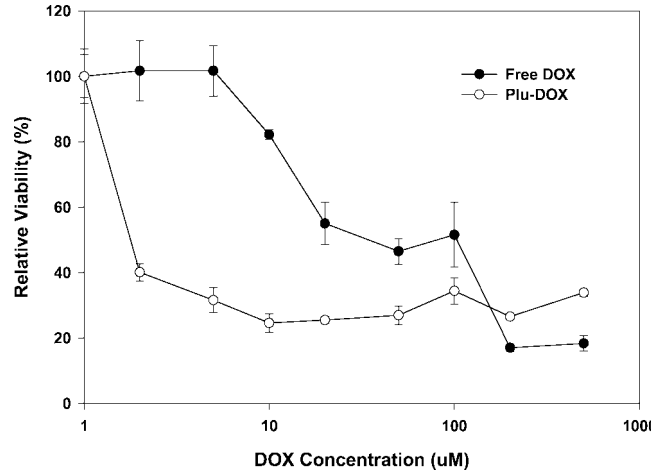

Figure 5. Cytotoxicities of CF-PLU-DOX micelles (○) and free DOX (•) using MCF-7 cell line.

could bypass the MDR effect often observed for the cellular uptake of free DOX bypassive diffusion.

Cytotoxicity effects of CF-PLU-DOX micelles were evaluated using the MCF-7 human breast cancer cell line. Cells were treated with free DOX or CF-PLU-DOX micelles with an equivalent concentration of DOX. As shown in Figure 5a, CF-PLU-DOX micelles exhibited far greater cytotoxicity than free DOX. The inhibition concentration (IC_{50}) of CF-PLU-DOX micelles was 1.2 μM, which is 15-fold lower than that of free DOX (18.5 μM). In addition, it was evident that the enhanced cytotoxicity of CF-PLU-DOX micelles was not due to the cytotoxicity of the carrier polymer (CF-PLU). The CF-PLU copolymer exhibited very low cytotoxicity (more than 90% of the cells survived) over the same polymer concentration range (data not shown).

To further investigate the cellular uptake efficiency of CF-PLU-DOX micelles, FACS analysis and confocal laser microscopy were used to quantitatively evaluate and visualize CF-PLU-DOX micelles internalized within cells. As shown in Figure 6a, FACS analysis taken after treating for 15 min clearly showed that the cellular uptake extent of CF-PLU-DOX micelles was greater than that of free DOX, indicating that the enhanced cellular uptake of CF-PLU-DOX micelles was responsible for the increased cytotoxicity as shown in Figure 5a. Figure 6b,c shows confocal images of the cells treated with free DOX and CF-PLU-DOX micelles for 15 min. MCF-7 cells treated with free DOX showed that DOX was predominantly accumulated in the nuclei (left panel), while the cells treated with CF-PLU-DOX micelles showed scattered intense small red dots and red fluorescence in the cytosol and nuclei (right panel). The different confocal images clearly suggested that the CF-PLU-DOX micelles were taken up by endocytosis-mediated cellular uptake, while free DOX was transported into cells via a passive diffusion mechanism. The intense DOX accumulation only in the nuclei for free DOX, not in the cytosol, was because intracellular DOX molecules in the cytosol were rapidly transported to the nucleus and avidly bound to the chromosomal DNA. In contrast, it appears that CF-PLU-DOX micelles were initially located within the endosome vesicles, releasing cleaved DOX in the cytosol region in a sustained manner. This suggests that the enhanced cytotoxicity for CF-PLU-DOX micelles was mainly due to their endocytic intracellular transport (*33*), increasing the extent of cellular uptake.

Lastly, it should be noted that Pluronic-mimicking copolymers used in this study might also contribute to the sensitization of MCF7 cells, additionally influencing the extent of DOX-induced apoptotic cell death. Earlier studies reported that a physical

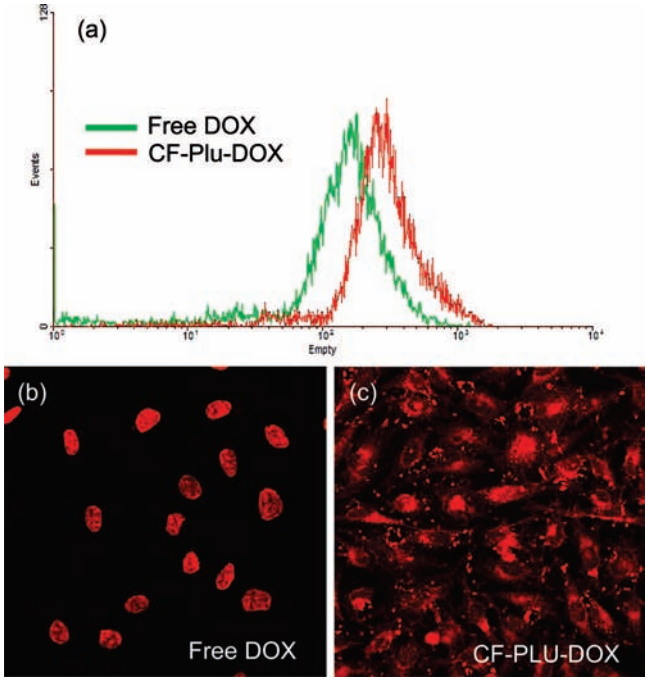

Figure 6. Cellular uptake of CF-PLU-DOX micelles. (a) FACS analysis using MCF-7 cells treated with free DOX (green line) and CF-PLU-DOX (red line). Confocal laser microscopy images for HeLa cells treated with (b) free DOX, and (c) CF-PLU-DOX micelles.

mixture formulation of DOX and Pluronic copolymers treated to MCF7 cells significantly changed its genome expression patterns: up-regulating the ATP-associated genes involved in the respiratory chain and genes involved in the apoptotic signal transduction pathway. In addition, Pluronic copolymers are known to suppress the overexpression of MDR-related genes for various non-MDR cancer cells (*34*, *35*). Structurally similar to Pluronic copolymers, CF-PLU copolymers are also expected to exhibit the similar MDR suppression effect in MCF7 cells with initiation of apoptotic signal transduction. Thus, it is likely that the CF-PLU-DOX micelles might have significant effects on overcoming the MDR barrier in cancer cells. We are currently investigating the anticancer effect of CF-PLU-DOX micelles using MDR cells.

In conclusion, a new class of Pluronic mimicking micelles was synthesized to release DOX in a pH-responsive manner. PEO-PPO-PEO copolymer having multiple hydroxyl groups on the PPO segment was synthesized and DOX molecules were conjugated via an acid-labile hydrazone linkage. The DOX-conjugated copolymer self-assembled in aqueous solution to form tightly packed spherical micelles or micellar aggregates having a core–shell structure composed of a DOX core and PEG shell. The copolymer micelles released DOX to a greater extent under acidic condition. The cytotoxicity of CF-PLU-DOX micelles was 15-fold greater than that of free DOX for MCF-7 human breast cancer cells. The enhanced cytotoxicity was mainly due to the increased cellular uptake of DOX-conjugated micelles that were taken up by endocytosis. It was possible that core-functionalized Pluronic mimicking copolymers synthesized in this study could be similarly conjugated with other hydrophobic anticancer drugs such as paclitaxel. Self-assembled nanoscale CF-PLU micelles conjugated with potent antitumor agents are expected not only to improve solubility in aqueous solution, but also to enhance targeting capacity to the solid tumor.

Bandeirantes 3900, CEP, 14040-901 Ribeirão Preto, Brazil. Received October 29, 2007; Revised Manuscript Received November 15, 2007

Photodynamic therapy involves administration of a photosensitizing drug and its subsequent activation by visible light of the appropriate wavelength. Several approaches to increasing the specificity of photosensitizers for cancerous tissues and, in particular, through their conjugation to ligands that are directed against tumor-associated antigens have been investigated. Here, we have studied the delivery of the photocytotoxic porphyrin compound TPP(p-O-β-D-GluOH)$_3$ into tumor cells that overexpress the glycosphingolipid Gb3, using the Gb3-binding nontoxic B-subunit of Shiga toxin (STxB) as a vector. To allow for site-directed chemical coupling, an STxB variant carrying a free sulfhydryl moiety at its C-terminal end has been used. Binding affinity, cellular uptake, singlet oxygen quantum yield, and phototoxicity of the conjugate have been examined. Despite some effect of coupling on both the photophysical properties of TPP(p-O-β-D-GluOH)$_3$ and the affinity of STxB for its receptor, the conjugate exhibited a higher photocytotoxic activity than the photosensitizer alone and was exquisitely selective for Gb3-expressing tumor cells. Furthermore, our data strongly suggest that STxB-mediated retrograde delivery of the photosensitizer to the biosynthetic/secretory pathway is critical for optimal cytotoxic activity. In conclusion, a strong rationale for using retrograde delivery tools such as STxB in combination with photosensitizing agents for the photodynamic therapy of tumors is presented.

INTRODUCTION

Anticancer therapy often relies on the use of chemotherapeutic agents that efficiently eliminate dividing cancer cells. However, in many cases, chemotherapy fails to eradicate tumors, and even when chemotherapy is successful, systemic cytotoxicity often results in deleterious side effects. To overcome these limitations, novel strategies have been developed that aim at increasing the selectivity of tumor treatment. In this context, antibodies, hormones, growth factors, lectins, and toxins have been explored as tools for delivering therapeutic compounds to cancer cells (*1*, *2*).

The bacterial Shiga toxins and verotoxins (or Shiga-like toxins) share a cellular receptor, the glycosphingolipid globotriaosylceramide (Gb3[1] or CD77), that is expressed on a number of human malignancies, such as Burkitt's lymphoma (*3*) and cancers of the breast (*4*), brain (*5*), ovary (*6*), colon (*7*), and testis (*8*). Shiga toxin is produced by *Shigella dysenteria*, and verotoxins are produced by enterohemorrhagic strains of *Escherichia coli* (*9*). These toxins are composed of an enzymatic component (A subunit) that inhibits protein biosynthesis by modifying rRNA and a nontoxic homopentameric component (B subunit or STxB). The A subunit cannot enter cells by itself. For plasma membrane binding and internalization, it requires a noncovalent interaction with STxB. In toxin sensitive cells, STxB delivers the holotoxin from the plasma membrane to the endoplasmic reticulum, via the early endosome and the Golgi apparatus, a transport pathway termed the retrograde route (*10*, *11*). Trafficking through the retrograde route allows STxB to escape degradation in lysosomes and recycling to the plasma membrane, resulting in its stable association with cells.

Recently, the possibility of using STxB as a delivery tool for Gb3-expressing tumors has been addressed. It was shown that upon oral uptake or intravenous injection, STxB targets adenocarcinomas of the intestine in a transgenic mouse model (*12*). In the context of the holotoxin, an antineoplasic activity has been detected upon injection of verotoxin-1 into xenografted tumors (*5*, *13–15*), and verotoxin-1 eliminates clonogenic tumor cells in purging applications (*16*). However, the use of holotoxin as a therapeutic agent in humans may be limited by the fact that the catalytic effect of the A subunit is not tumor specific. STxB has therefore directly been linked to therapeutic com-

pounds that have selective antitumor activity (*17*) or that can be activated locally (*18*).

Photodynamic therapy (PDT) is based on the preferential accumulation of a photosensitizing molecule in malignant tissue after its systemic administration. Illumination using light of an appropriate wavelength excites the photosensitizer, and subsequent photoactivation results in the release of cytotoxic species such as singlet oxygen and free radicals which are responsible for the destruction of target tissue (*19*). Several major issues continue to limit the wider application of PDT as a cancer treatment modality, including deleterious effects related to accumulation of the photosensitizer in normal tissue as well as in tumor tissue. To overcome this problem, one strategy which is receiving considerable attention is to covalently link the photosensitizer to a carrier molecule to localize the PDT effect (for reviews, see refs *20* and *21*).

In this work, we have synthesized a new glycoporphyrin that was covalently linked to STxB. We have demonstrated that the photocytotoxic properties of the conjugate depend critically on its subcellular delivery via the retrograde route.

MATERIALS AND METHODS

Materials. All solvents were reagent grade. Dry MeOH was kept over 3 Å sieves; methylene chloride was distilled from calcium hydride and kept over 4 Å sieves, and chloroform was distilled from calcium chloride and kept over 4 Å sieves. Column chromatography was performed with the indicated solvents and using E. Merck silica gel 60 (particle size of 0.035–0.070 mm). Macherey-Nagel precoated plates (SIL G-200, 2 mm) were used for preparative thin layer chromatography. Yields refer to chromatographically and spectroscopically pure compounds. ^{1}H spectra were recorded on a Bruker AC-300 spectrometer at room temperature using an internal deuterium lock. Acidic impurities in $CDCl_3$ were removed by treatment with anhydrous K_2CO_3. Mass spectrometry analysis was performed using a MALDI-TOF mass spectrometer (PerSeptive Biosystem Voyager Elite, PerSeptive Biosystem, Framingham, MA). Quantitative UV–visible spectra were obtained using a Varian DMS 200 spectrometer. Microanalyses were performed by the ICSN-CNRS Elemental Analysis Center at Gif-sur-Yvette, France. STxB-Cys and STxB-Glyc-KDEL were prepared as previously described (*28*, *36*). PD-10 gel exclusion columns (Amersham Pharmacia Biotech), 1-phenyl-2-hexadecanoylamino-3-morphorpholin-1-propanol (PPMP) (Calbiochem), secondary fluophore-coupled antibodies (Jackson Immunresearch), and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) (Sigma Aldrich) were obtained from the indicated commercial sources. The protein concentration was determined by the Bio-Rad assay (Bio-Rad Laboratories). HeLa cells were cultured as published previously (*28*).

Synthesis of TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$Br). *5,10,15-Tris[4-(2′,3′,4′,6′-tetraacetyl-O-β-D-glucosyloxyphenyl)]-20-(4-bromomethylphenyl)porphyrin (**3**).* Freshly distilled pyrrole (205 μL, 2.9 mmol) in chloroform (7.50 mL), 4-O-(2′,3′,4′,6′-tetraacetyl-β-D-glucopyranosyloxy)benzaldehyde (1 g, 2.2 mmol), and 4-bromomethylbenzaldehyde (0.147 g, 0.74 mmol) in chloroform (7.5 mL) were added to chloroform (750 mL) purged with argon for 30 min. The mixture was stirred under argon for a further 10 min. Then a BF_3-etherate solution in chloroform (317 μL, 0.5 M) was added, and the mixture was stirred under argon. The mixture was stirred at room temperature for 2 h. Triethylamine (305 μL) was added, and the mixture was stirred at room temperature 15 min. *o*-Chloranil (1.385 g, 5.6 mmol) was added, and the solution was stirred at room temperature for 2 h. Silica gel (10 g) was added to the dark solution, and the solvent was evaporated. The absorbed crude products were placed on the top of a chromatographic silica gel column. The porphyrin mixture was eluted with methylene chloride and acetone (10/1, v/v). The third red fraction was collected and purified again by preparative thin layer silica gel chromatography eluted with methylene chloride and acetone (10/1, v/v). The titled pure triglycosylated porphyrin **3** was obtained as red crystals after crystallization from methylene chloride and heptane (300 mg, 31% yield). Anal. $C_{87}H_{85}BrN_4O_{30}\cdot 3H_2O$. Calcd: C, 58.03; H, 5.09; N, 5.09. Found: C, 58.07; H, 4.77; N, 2.74. UV–visible spectrum in methylene chloride: λ_{max} (nm) [ϵ (mmol^{-1} cm^{-1})] 419.5 (414.3), 516 (17.9), 552 (10.5), 591 (6.9), 647 (5.9). ^{1}H NMR spectrum in $CDCl_3$: δ 8.88 (s, 8 H, pyrrole), 8.26 (d, 2 H, *o*-phenyl), 8.16 (d, 6 H, *o*-phenoxy), 7.82 (d, 2 H, *m*-phenyl), 7.42 (d, 6 H, *m*-phenoxy), 5.50 (m, 9 H, H "ose"), 5.33 (m, 3 H, H "ose"), 4.88 (s, 2 H, CH_2Br), 4.45 (dd, 3 H, H_aC_6 "ose"), 4.33 (d, 3 H, H_bC_6 "ose"), 4.08 (m, 3 H, HC_5 "ose"), 2.24 (s, 9 H, acetyl), 2.14 (s, 9 H, acetyl), 2.13 (s, 18 H, acetyl), −2.79 (s, 2 H, NH).

*5,10,15-Tris(4-O-β-D-glucosyloxyphenyl)-20-(4-bromomethylphenyl)porphyrin (**4**).* To a solution of **3** (50 mg, 28.6 μmol) in dry MeOH (10 mL) and dry CH_2Cl_2 (10 mL) was added a solution of NaOMe in MeOH (100 μL, 1 M), and the mixture was stirred for 1.5 h at room temperature. IWT TMD-8 ion-exchange resin (0.310 g) was then added, and gentle stirring was continued for 1.5 h. The reaction mixture was filtered, and the recovered resin was washed with MeOH. The combined filtrate and washings were then evaporated to dryness and crystallized from MeOH and 1,2-dichloroethane. Product **6** (33 mg, 93%) was obtained as a red powder. Anal. $C_{63}H_{61}BrN_4O_{18}\cdot 11H_2O$. Calcd: C, 52.54; H, 5.81; N, 3.89. Found: C, 52.77; H, 4.81; N, 4.08. Chemical Coupling of STxB with TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$Br). STxB-Cys (5 mg/mL) in 20 mM borate buffer (pH 9) and 150 mM NaCl was incubated volume to volume with a 5-fold molar excess of TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$Br) dissolved in DMSO. The reaction was carried out in the dark for 2 h at room temperature. The TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate was separated from monomeric TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$Br) by gel filtration chromatography using PD-10 columns equilibrated with PBS and 10 mM EDTA buffer (pH 8.0).

Mass Spectrometry Analysis. All analyses were performed on a Voyager-DE PRO MALDI-TOF mass spectrometer (Applied Biosystems, Framingham, MA) operated in the delayed extraction and linear mode. A solution of sinapinnic acid in acetonitrile and TFA (30%/0.1%) was used as a matrix. Samples were prepared by mixing them with the matrix at a sample: matrix ratio of 1:1. The mixture (1 μL) was spotted onto a MALDI plate and allowed to dry.

Immunofluorescence Analysis. Immunofluorescence experiments were performed as previously described (*28*). Briefly, cells were incubated for 30 min at 4 °C with 1 μM STxB or TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate, washed, incubated for 45 min at 37 °C, fixed in 4% *p*-formaldehyde for 15 min at

room temperature, quenched with ammonium chloride, and permeabilized with 0.05% saponin. STxB was labeled with the monoclonal anti-STxB antibody (13C4) and revealed by the Cy3-coupled secondary antibody. Then coverslips were mounted and analyzed on a Leica wide field fluorescence microscope.

Receptor Binding Assay. STxB-Glyc-KDEL was iodinated using iodobeads as previously described (*28*). The binding affinities of the TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate and STxB-Cys for cells were compared in competition experiments. These were performed in 24-well plates (10^5 cells per well). Briefly, HeLa cells in triplicate were incubated for 30 min at 4 °C in complete DMEM medium with 20 nM [^{125}I]STxB-Glyc-KDEL (6000 cpm/ng) in the absence or presence of increasing concentrations (4 nM to 2.5 μM) of TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate or STxB-Cys. Cells were washed three times with complete DMEM medium and lysed in 2 × 0.5 mL of 0.1 M KOH buffer. Cell-associated radioactivity was determined using a gamma counter.

Assessment of Singlet Oxygen Formation. The singlet measurements were based on the direct determination by luminescence measurement at 1270 nm of the amount of photosensitizer-generated singlet oxygen [$\Phi_\Delta(^1O_2)$] (*37*). A frequency double Nd:YAG laser (Continuum, Santa Clara, CA) was used for excitation (8 ns half-life), and the luminescence decay kinetics were detected using a germanium detector operating at liquid nitrogen temperature. A silicon filter was used to prevent any fluorescence signal from interfering with the singlet oxygen measurement. Transient decays were averaged using a Tektronix TDS 340 digital oscilloscope and analyzed with software from Edinburgh Instruments. The experiments were conducted using pheophorbide-*a* in deuterated ethanol as a reference [$\Phi_\Delta(^1O_2) = 0.59$] (*38*). Quantum yields of singlet molecular oxygen were determined in oxygen-saturated solutions.

Phototoxicity Assay. HeLa cells were seeded in 96-well plates at a density of 10^5 cells/mL (0.2 mL/well) and allowed to grow for 24 h in an incubator (5% CO_2, 37 °C, humidified atmosphere). On the day of the experiment, the culture medium was removed, and 200 μL of fresh DMEM medium with 2% FCS containing photosensitizers at a final concentration between 1 and 6 μM was added to each well. Cells were incubated at 37 °C for 24 h and then washed before fresh complete medium was added. Illumination was performed in sterile form for 15 min (1.8 J/cm^2) through the bottom of the culture plates using a "light box" made of six Philips TL 13 W tubes (total fluence of 3.8 mW/cm^2) covered by a diffusing glass fitted with an orange filter (0% T at 520 nm and 80% T at 590 nm), leading to a final fluence of 2 mW/cm^2. Controls were as follows: wells containing cells treated with the photosensitizer but not exposed to light, wells containing cells without photosensitizer and without light, and wells containing cells without photosensitizer and exposed to light. Cell viability was measured after 24 h by determination of mitochondrial activity using the MTT assay. At the time of counting, 100 μL of a DMEM/MTT (0.5 mg/mL) solution was added to each well and replaced 4 h later with 200 μL of DMSO. Optical densities of microplates were determined at 540 nm with a Bio-Rad microplate reader (model 450); survival was expressed as a percentage of untreated controls. Each experiment was carried out in triplicate.

Brefeldin A Treatment. Cells were incubated with the TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate (64 μg/mL) for 1 h, alone or in the presence of brefeldin A (BFA, 5 μg/mL). Cells were then washed three times at 4 °C with ice-cooled medium and illuminated as described above before reincubation at 37 °C for 24 h. Cell survival was assessed as described above and compared to unirradiated cultures as well as to BFA-treated cells without photosensitizer and untreated controls.

Statistical Analysis. Results are expressed as the means ± the standard error of the mean. Comparisons were made using an unpaired *t* test; a p of <0.05 was considered to be significant.

RESULTS

Synthesis of Glycoconjugated Photosensitizer. The triglucosylated porphyrin **3** (Scheme 1) is prepared by condensing pyrrole, *p*-2,3,4,6-tetraacetyl-O-β-D-glucosyloxybenzaldehyde (*22*), and bromo-*p*-tolualdehyde (*23*) (4, 3, and 1 equiv, respectively) in moderate yield (31%), using Lindsey's method (*24*). Compound **3** was purified by preparative thin layer chromatography on silica gel and characterized by physical methods. The unprotected glucoconjugated compound **4** (Scheme 1) was obtained quantitatively from **3** by treatment with MeONa and MeOH (*25*) (for experimental details, see Materials and Methods). TPP(p-O-β-D-GluOH)$_3$ (Scheme 1), the unconjugated analogue of the TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate was prepared using Oulmi's method (*26*).

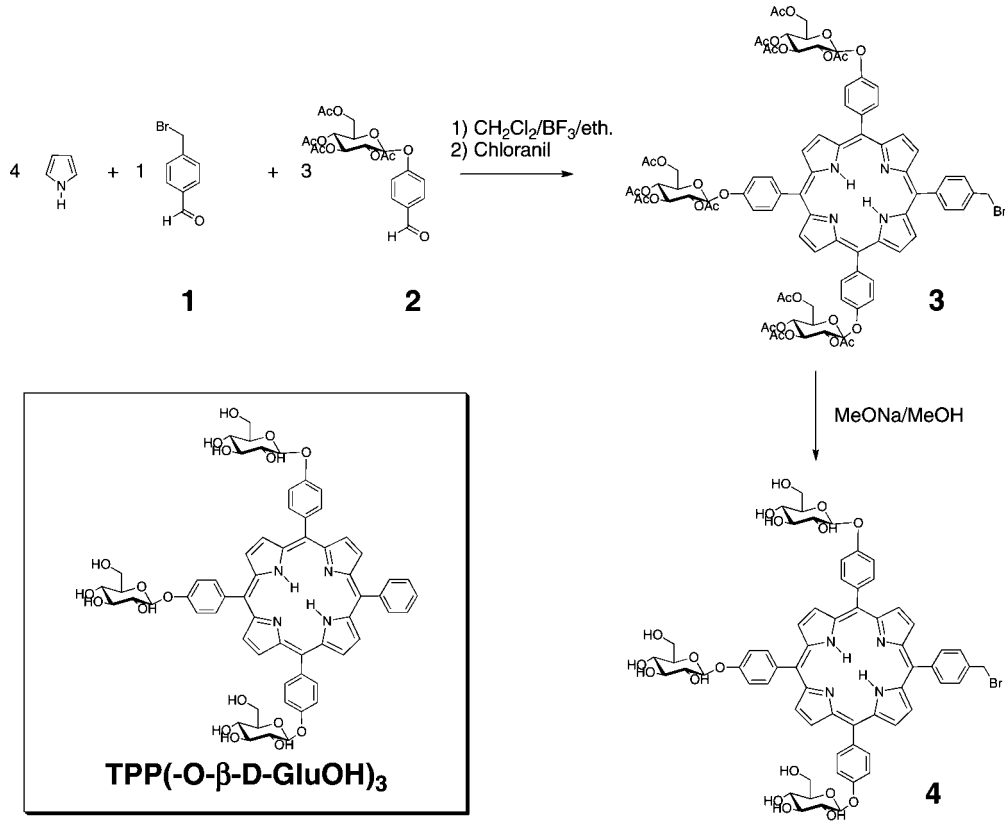
Preparation of Glycoporphyrin−STxB Conjugates. To couple the photosensitizer **4** via its *p*-bromobenzyl substituent to a defined acceptor site on STxB, a cysteine residue was added to the C-terminal part of the protein, yielding STxB-Cys (*27*). The coupling reaction was carried out at room temperature for 2 h using a 5-fold molar excess of glycoporphyrin **4** over STxB-Cys pentamer in borate buffer containing 50% DMSO to minimize glycoporphyrin aggregation. The TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate was separated from nonconjugated compound **4** using gel filtration chromatography and analyzed using MALDI-TOF mass spectrometry. The MALDI-TOF mass spectra displayed two major peaks, one at *m*/*z* 8956 and the other at *m*/*z* 7792 corresponding to the conjugate and the nonmodified STxB-Cys, respectively (Figure 1A). Other, much less intense peaks were observed at *m*/*z* 10120, which could correspond to the coupling of two glycoporphyrin molecules to STxB, and at *m*/*z* 10389, which probably results from the reaction of the double conjugate with the sinapinnic acid matrix used for MALDI-TOF analysis.

In the next step, we examined the intracellular trafficking of the conjugate. Using immunofluorescence analysis, we could show that TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB accumulated as efficiently in the Golgi apparatus as STxB-Cys (Figure 1B), demonstrating that the functional properties of STxB were preserved.

Characterization of the Gb3 Binding Capacity of the Conjugate. The immunofluorescence experiment indicated that the TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate could still efficiently bind to its cellular receptor, despite the drastic coupling conditions using high DMSO concentrations and the hydrophobic nature of the glycoporphyrin. To obtain a quantitative measure of receptor binding, we performed in vitro displacement assays using an iodinated Gb3 ligand, termed [^{125}I]STxB-Glyc-KDEL (*28*). The iodinated ligand was incubated with cells in the presence of increasing concentrations of STxB-Cys or TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate (Figure 2). The conjugate was an efficient competitor, albeit with an IC$_{50}$ that was 5-fold higher than that of STxB-Cys. However, this slight decrease in affinity is not specific to the TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate, as it is also observed with STxB conjugates that involve antigenic proteins (not shown).

Quantum Yield of Singlet Oxygen Formation. Light-triggered generation of singlet oxygen by porphyrins, and other tetrapyrrole-based molecules, is the basis for the photodynamic therapy approach to eradicating cancer cells. We compared the photoefficiency of the TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate to that of analogous unconjugated TPP(p-O-β-D-GluOH)$_3$ and found that the singlet oxygen producing ability

Scheme 1. Structure of TPP(p-O-β-D-GluOH)$_3$ and Reaction Scheme for the Synthesis of Glycoconjugated Porphyrin 4



of the conjugate (0.13) was 3 times lower than that of the reference molecule (0.4). It appears that chemical coupling of **4** to STxB induces a reduction of the glycoporphyrin singlet oxygen quantum yield.

Cellular Phototoxicity. The phototoxicity of the free photosensitizer TPP(p-O-β-D-GluOH)$_3$ and the TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate was determined on HeLa cells after exposure to >540 nm light with a fluence of 1.8 J/cm^2. The presence of the STxB receptor in this cell line is well established and was confirmed using receptor binding experiments. Cells were treated with equimolar concentrations of free TPP(p-O-β-D-GluOH)$_3$ and the TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate. We observed that the conjugate was more efficient at photodynamic cell killing than TPP(p-O-β-D-GluOH)$_3$ (Figure 3). Expressed in molar concentration of photosensitizer, the LD$_{50}$ for the conjugate was 0.6 μM, and that of free TPP(p-O-β-D-GluOH)$_3$ was 3 μM, corresponding to a 5-fold sensitization. In the absence of light, toxicity was found to be negligible in all cases, with a survival fraction close to 100% (not shown). Similarly, in the absence of the TPP(p-

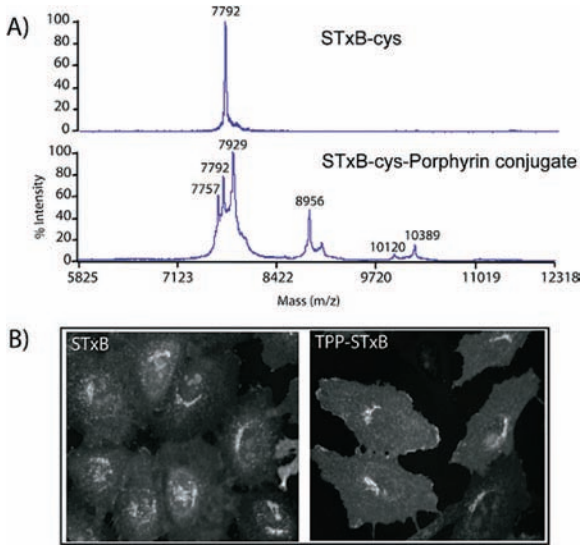


Figure 1. (A) MALDI-TOF mass spectra of STxB-Cys and the TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate. STxB-Cys: *m/z* 7793 (calcd) and 7792 (found). TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate: *m/z* 8954 (calcd) and 8956 (found). Note that in conjugated STxB-Cys, statistically at least one B fragment per homopentamer is modified by a TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$) group. (B) Cellular uptake of STxB-Cys and the TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate. After binding at 4 °C, HeLa cells were washed and incubated at 37 °C for 45 min. The subcellular localization of STxB was determined using a mouse monoclonal anti-STxB antibody (13C4). Note that in both cases, STxB can be detected in perinuclear Golgi membranes.

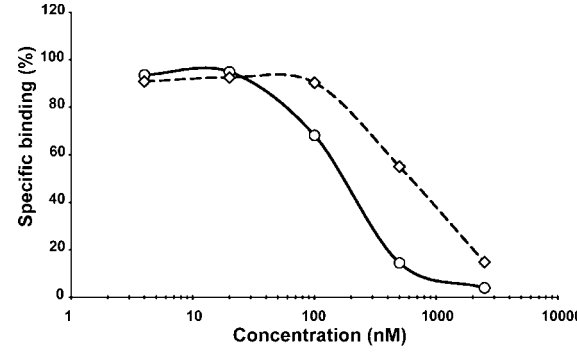

Figure 2. Displacement of [^{125}I]STxB-Glyc-KDEL from binding to Gb3-expressing cells by increasing concentrations of unlabeled STxB-Cys or TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate. HeLa cells were incubated for 30 min at 4 °C with 20 nM [^{125}I]STxB-Glyc-KDEL (6000 cpm/ng) either in the presence or in the absence of the indicated concentrations of unlabeled proteins. Means of two experiments carried out in triplicate: STxB-Cys (○) and TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate (◇).

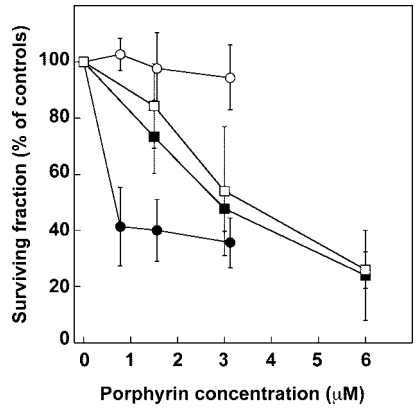

Figure 3. Photodynamic killing of HeLa cells with free TPP(p-O-β-D-GluOH)$_3$ or the TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate. Control or PPMP-treated HeLa cells were incubated for 24 h at 37 °C in the dark with increasing concentrations of free TPP(p-O-β-D-GluOH)$_3$ or TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate. The cells were washed three times, followed by irradiation (λ > 540 nm) at a fluence rate of 2 mW/cm^2 and a light dose of 1.8 J/cm^2. The extent of cell death was measured by determination of mitochondrial activity using the MTT assay. The error bars represent the standard error of the mean of at least three experiments. Reported are effects of free TPP(p-O-β-D-GluOH)$_3$ in control (■) or PPMP-treated HeLa cells (□) and effects of the TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate in control (●) or PPMP-treated HeLa cells (○).

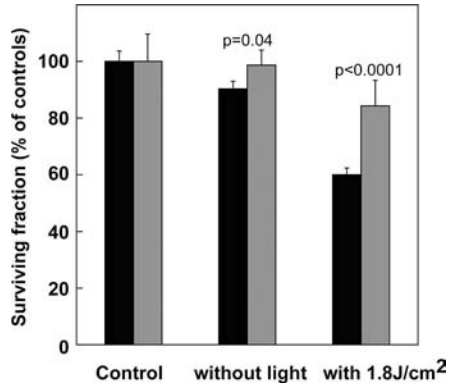

Figure 4. Effect of brefeldin A (BFA, 5 μg/mL) on the photocytotoxicity (1.8 J/cm^2) of the TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate (64 μg/mL, corresponding to 0.3 μM free porphyrin): (black bars) without BFA and (gray bars) BFA-treated.

O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate, cell survival was 100%, a value independent of light exposure (not shown).

To determine whether the phototoxicity of the conjugate was receptor-mediated, we performed the same experiment described above in HeLa cells in which Gb3 expression was inhibited using 1-phenyl-2-hexadecanoyl-amino-3-morphorpholin-1-propanol (PPMP) (*29*). We found that the unconjugated TPP(p-O-β-D-GluOH)$_3$ induced cell death to the same extent in Gb3-expressing and Gb3-deficient cells (Figure 3). In contrast, the conjugate induced a toxic effect in only Gb3-expressing cells, indicating that coupling to STxB provides selective means for the delivery of the photosensitizer to tumor cells (Figure 3).

Intracellular Compartmentalization of Phototoxicity. To measure the importance of optimal phototoxicity of retrograde delivery of TPP(p-O-β-D-GluOH)$_3$ to membranes of the biosynthetic/secretory pathway, we exploited our previous findings that treatment of cells with brefeldin A induces the accumulation of STxB in early endosomes (*30*). As shown in Figure 4, the light-induced phototoxicity of TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)-STxB was significantly higher in cells in which the conjugate was accumulated in the Golgi apparatus (column 5), when compared to cells in which the conjugate was accumulated in endosomes (column 6). In the absence of light (columns 3 and 4), the difference was much lower, and in the absence of conjugate (columns 1 and 2), it was inexistant. These data strongly suggest that the targeting of the conjugate to Golgi membranes places the photosensitizer in a molecular environment that is optimal for transducing its phototoxic effect.

DISCUSSION

Classical cancer treatments, including surgery, radiation therapy, and chemotherapy, all cause serious side effects by the loss of normal cell function. These phenomena arise because of the lack of unambiguous, identifiable biochemical differences between normal and malignant cells. Even antibody-based approaches are confronted with severe problems that limit their use (*31*). This includes the fact that antibodies are large proteins and do not penetrate well into the tumor mass. Furthermore, antibodies remain in many cases at the cell surface or are degraded in lysosomes, thereby reducing the efficiency by which the active principle reaches intracellular sites of action. To start addressing these limitations, we have developed a PDT approach that exploits the naturally evolved capacity of STxB, a small protein, to target specific intracellular sites (*10*).

The most innovative contribution of our study consists of the demonstration that the phototoxic effect of the glycoconjugated photosensitizer directly depends on its retrograde delivery to membranes of the biosynthetic/secretory pathway. While at this stage we do not have a molecular interpretation of this finding, it is an established fact that many critical cellular functions are regulated on Golgi membranes, such as cell migration (*32*) and signaling (*33*). The localized production of short-lived singlet oxygen species and free radicals may therefore have a profound effect. Retrograde transport also provides access to the endoplasmic reticulum, which has recently been identified as a potential target for anticancer therapy (*34*). The reduced cytotoxic activity of the endosomal photosensitizer may also stem from nonoptimal pH conditions or from exposure to degrading conditions in late endosomes and/or lysosomes.

In a previous study, Tarrago-Trani et al. began exploring the use of STxB for the delivery of the photosensitizing compound chlorin e6 (*18*). However, this work was limited by the fact that no receptor-free condition was tested. In our work, we could demonstrate that the conjugated photosensitizer to Gb3-expressing cells is highly selective in that the phototoxic effect is totally lost on cells in which receptor expression has been inhibited.

As glycoporphyrins are poorly water soluble compounds, one of the principle challenges resides in making them amenable for biodistribution. Toward this end, we first exploited the fact that STxB is a very stable molecule that retains its structural integrity under extreme medium conditions and that readily recovers its native state after unfolding (*35*). Coupling and purification could therefore be conducted in 50% DMSO without significant loss of cell binding and intracellular trafficking activity. Furthermore, STxB resists extracellular inactivation and is capable of crossing tissue barriers (*12*), which should also facilitate the in vivo distribution of photosensitizers onto tumors.

The solubilization effect likely also explains why the TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate is more potent than the glycoporphyrin alone. The immunofluorescence results show that the TPP(p-O-β-D-GluOH)$_3$(p-CH$_2$)−STxB conjugate still efficiently binds to the cellular receptor Gb3. Remarkably, TPP(p-O-β-D-GluOH)$_3$ alone did not provoke any toxicity at the same dose at which the conjugate induced 50% cell death. We notice that the photosensitizing activity of the conjugated glycoporphyrin is 5 times higher than that of the parent molecule, and this despite a reduction in quantum yield after coupling.

In conclusion, our study establishes a strong rational for the use of STxB as a delivery tool for photosensitizing molecules in the development of PDT applications for the treatment of human cancers.

^{111}In-Labeled Lactam Bridge-Cyclized α-Melanocyte Stimulating Hormone Peptide Analogues for Melanoma Imaging

Yubin Miao,*[,†,‡] Fabio Gallazzi,[§] Haixun Guo,[†] and Thomas P. Quinn[§,△,⊥]

College of Pharmacy, Cancer Research Treatment Center, and Department of Dermatology, University of New Mexico, Albuquerque, New Mexico 87131, Departments of Biochemistry and Radiology, University of Missouri, Columbia, Missouri 65211, and Harry S. Truman Memorial Veteran Hospital, Columbia, Missouri 65201. Received August 21, 2007; Revised Manuscript Received November 27, 2007

The purpose of this study was to examine the influence of the lactam bridge cyclization on melanoma targeting and biodistribution properties of the radiolabeled conjugates. Two novel lactam bridge-cyclized α-MSH peptide analogues, DOTA-CycMSH (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid-c[Lys-Nle-Glu-His-DPhe-Arg-Trp-Gly-Arg-Pro-Val-Asp]) and DOTA-GlyGlu-CycMSH (DOTA-Gly-Glu-c[Lys-Nle-Glu-His-DPhe-Arg-Trp-Gly-Arg-Pro-Val-Asp]), were synthesized and radiolabeled with ^{111}In. The internalization and efflux of ^{111}In-labeled CycMSH peptides were examined in B16/F1 melanoma cells. The melanoma targeting properties, pharmacokinetics, and SPECT/CT imaging of ^{111}In-labeled CycMSH peptides were determined in B16/F1 melanoma-bearing C57 mice. Both ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH exhibited fast internalization and extended retention in B16/F1 cells. The tumor uptake values of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH were 9.53 ± 1.41% injected dose/gram (% ID/g) and 10.40 ± 1.40% ID/g at 2 h postinjection, respectively. Flank melanoma tumors were clearly visualized with ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH by SPECT/CT images at 2 h postinjection. Whole-body clearance of the peptides was fast, with greater than 90% of the radioactivities cleared through urinary system by 2 h postinjection. There was low radioactivity (<0.8% ID/g) accumulated in blood and normal organs except kidneys at all time points investigated. Introduction of a negatively charged linker (-Gly-Glu-) into the peptide sequence decreased the renal uptake by 44% without affecting the tumor uptake at 4 h postinjection. High receptor-mediated melanoma uptakes coupled with fast whole-body clearance in B16/F1 melanoma-bearing C57 mice demonstrated the feasibility of using ^{111}In-labeled lactam bridge-cyclized α-MSH peptide analogues as a novel class of imaging probes for receptor-targeting melanoma imaging.

INTRODUCTION

Skin cancer is the most commonly diagnosed cancer in the United States. Malignant melanoma is the most lethal form of skin cancer and the most commonly diagnosed malignancy among young adults with an increasing incidence. It is predicted that there will be 59 940 cases of malignant melanoma newly reported and 8110 fatalities in 2007 (*1*). There is a great need to develop novel imaging probes and treatment approaches for melanoma detection and therapy since early diagnosis and prompt surgical removal are a patient's best hope for a cure. Although 2-[^{18}F]fluoro-2-deoxy-D-glucose ([^{18}F]FDG) is commonly used for positron emission tomography (PET) diagnosis and staging of melanoma, [^{18}F]FDG is not melanoma-specific and some melanoma cells are not detected by [^{18}F]FDG since they use substrates other than glucose as energy sources (*2, 3*). Alternatively, the G-protein-coupled melanocortin-1 (MC1) receptors have been used as targets for melanoma imaging peptides due to their overexpression on human and mouse melanoma cells (*4–8*). Radiolabeled α-melanocyte stimulating hormone (α-MSH) peptide analogues, derived from wild-type α-MSH, are very promising candidates for melanoma imaging and therapy due to their nanomolar MC1 receptor binding affinities and high receptor-mediated tumor uptakes in murine melanoma-bearing mice and human melanoma xenografts (*9–13*).

The strategy of peptide cyclization was used to improve binding affinity, *in vivo* stability, and receptor selectivity of the α-MSH peptides (*14–16*). Compared to the linear peptides, the cyclic peptides possess less conformational freedom due to the stabilization of secondary structures such as beta turns, which results in greater receptor binding affinities. Furthermore, the constrained cyclic peptides confer higher stability against the proteolytic degradations *in vivo* (*17*). Peptide cyclization strategies can be generally classified into four types, namely, (1) backbone to backbone; (2) N-terminus to C-terminus; (3) one side chain to C-terminus or N-terminus; (4) two side chains via disulfide or lactam bridges. Over the past several years, peptide cyclization through metal coordination has been successfully employed in developing radiolabeled cyclic α-MSH peptide analogues for melanoma imaging and therapy. Metal cyclization made the α-MSH peptide analogues resistant to chemical and proteolytic degradation *in vivo* (*18, 19*). ^{111}In-DOTA-Re[Cys^{3,4,10}, D-Phe^{7}]-α-MSH$_{3-13}$} (^{111}In-DOTA-ReCCMSH) exhibited 11.4 ± 2.89% injected dose/gram (% ID/g) tumor uptake 2 h postinjection in the B16/F1 murine melanoma mouse model (*19*). A comparison of biodistribution data between ^{111}In-labeled DOTA-conjugated metal-cyclized and disulfide bridge-cyclized α-MSH peptide analogues demonstrated that the metal cyclization resulted in more favorable pharmacokinetics

of radiolabeled peptides, such as higher tumor uptake and lower renal uptake values (*19*), indicating that the different cyclization strategies might dramatically affect the biodistribution properties of peptides with comparable *in vitro* binding affinities.

In this study, Lys-Asp lactam bridge cyclization was employed to the α-MSH peptides to examine its effect on melanoma targeting and pharmacokinetics of the radiolabeled peptides. Two novel DOTA-conjugated lactam bridge-cyclized α-MSH peptide analogues, namely, DOTA-CycMSH and DOTA-GlyGlu-CycMSH, were synthesized and characterized by liquid chromatography–mass spectrometry (LC-MS). A negatively charged linker of -Gly-Glu- was introduced between DOTA and CycMSH sequences to determine its effect in reducing the renal uptake value of the radiolabeled peptide. The pharmacokinetics and SPECT/CT imaging of ^{111}In-labeled lactam bridge-cyclized α-MSH peptides were determined in B16/F1 melanoma-bearing C57 mice to evaluate their potential as SPECT imaging probes for melanoma detection.

EXPERIMENTAL PROCEDURES

Chemicals and Reagents. Amino acid and resin were purchased from Advanced ChemTech Inc. (Louisville, KY) and Novabiochem (San Diego, CA). DOTA-tri-*t*-butyl ester was purchased from Macrocyclics Inc. (Richardson, TX). $^{111}InCl_3$ was purchased from Mallinckrodt, Inc. (St. Louis, MO). All other chemicals used in this study were purchased from Thermo Fischer Scientific (Waltham, MA) and used without further purification. B16/F1 murine melanoma cells were obtained from American Type Culture Collection (Manassas, VA).

Peptide Synthesis. Intermediate scaffold of H_2N-Lys(Dde)-Nle-Glu(OtBu)-His(Trt)-DPhe-Arg(Pbf)-Trp(Boc)-Gly Arg(Pbf)-Pro-Val was synthesized on Val-2-Chlorotrityl Chloride (Val-2ClTrt) resin using standard 9-fluorenylmethyloxycarbonyl (Fmoc) chemistry by an Advanced ChemTech multiple-peptide synthesizer (Louisville, KY). A small aliquot of the scaffold material was cleaved and characterized by LC-MS. Gly Glu-(OtBu) and DOTA-tri-*t*-butyl ester were manually attached to the intermediate scaffold using standard Fmoc chemistry, respectively. Protected branched peptide was cleaved from the resin treating with 25% hexafluoroisopropanol (HFIP) and 5% triisopropylsilane (TIS) in dichloromethane (DCM) and characterized by LC-MS. Peptide cyclization between the acid moiety of Val and the amino group of Asp coupled to the Lys side chain was achieved by overnight reaction in DMF in the presence of 1 mM 1-hydroxybenzotriazole (HOBT), 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetranethyluronium hexafluorophosphate (HBTU), and *N*,*N*-diisopropylethylamine (DIEA) mixture. The protecting groups were totally removed by treating with a mixture of trifluoroacetic acid (TFA), thioanisole, phenol, water, ethanedithiol, and triisopropylsilane (87.5:2.5:2.5:2.5:2.5:2.5) for 2 h at room temperature (25 °C). The peptides were precipitated and washed with ice-cold ether for four times. The final products were purified by RP-HPLC and characterized by LC-MS.

***In Vitro* Competitive Binding Assay.** The IC_{50} values of DOTA-CycMSH and DOTA-GlyGlu-CycMSH were determined by using methods described previously (*8*). B16/F1 cells were harvested and seeded into a 24-well cell culture plate (5×10^5/well) and incubated at 37 °C overnight. After being washed once with binding media (MEM with 25 mM HEPES, pH 7.4, 0.2% BSA, 0.3 mM 1,10-phenathroline), the cells were incubated at room temperature (25 °C) for 2 h with approximately 50 000 cpm of ^{125}I-Tyr^2-[Nle^4, D-Phe^7]-α-MSH {NDP-MSH} (GE HealthCare, Piscataway, NJ) in the presence of increasing concentrations of DOTA-CycMSH or DOTA-GlyGlu-CycMSH in 0.3 mL of binding media. The reaction media were aspirated after incubation. Cells were rinsed with 0.5 mL of ice-cold pH 7.4, 0.2% BSA/0.01 M PBS twice and lysed in 0.5 mL of 1 N NaOH for 5 min. The activities in cells were measured in a gamma counter. The IC_{50} values for the peptides were calculated by using the Grafit software (Erithacus Software Limited, UK).

Complexation of the Peptide with ^{111}In. ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH were prepared using a 0.5 M NH_4OAc-buffered solution at pH 5.4. Briefly, 50 μL of $^{111}InCl_3$ (18.5–37.0 MBq in 0.05 M HCl), 10 μL of 1 mg/ml DOTA-CycMSH or DOTA-GlyGlu-CycMSH aqueous solution, and 400 μL of 0.5 M NH_4OAc (pH 5.4) were added into a reaction vial and incubated at 75 °C for 45 min. After the incubation, 20 μL of 0.5% EDTA aqueous solution was added into the reaction vial to scavenge potential unbound ^{111}In. The radiolabeled complexes were purified to single species by Waters RP-HPLC (Milford, MA) on a Grace Vadyc C-18 reverse-phase analytical column (Deerfield, IL) using a 20 min gradient of 16–26% acetonitrile in 20 mM HCl aqueous solution with a flow rate of 1 mL/min. Purified peptide samples were purged with N_2 gas for 20 min to remove the acetonitrile. The pH of final solution was adjusted to 7.4 with 0.1 N NaOH and normal saline for animal studies. The stability of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH was determined by incubation in mouse serum at 37 °C according to the published procedure (*20*) for various time periods, and monitored for degradation by RP-HPLC.

Cellular Internalization and Efflux of ^{111}In-labeled Peptides. Cellular internalization and efflux of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH were evaluated in B16/F1 cells as described by Miao et al. (*21*). After being washed once with binding media (MEM with 25 mM HEPES, pH 7.4, 0.2% BSA, 0.3 mM 1,10-phenathroline), B16/F1 cells in cell culture plates were incubated at 25 °C for 20, 40, 60, 90, and 120 min ($n = 4$) in the presence of approximately 200 000 counts per minute (cpm) of HPLC-purified ^{111}In-DOTA-CycMSH (0.019 pmol) or ^{111}In-DOTA-GlyGlu-CycMSH (0.019 pmol). After incubation, the reaction media were aspirated and cells were rinsed with 2×0.5 mL of ice-cold pH 7.4, 0.2% BSA/0.01 M PBS. Cellular internalization of radiolabeled peptides was assessed by washing the cells with acidic buffer [40 mM sodium acetate (pH 4.5) containing 0.9% NaCl and 0.2% BSA] to remove the membrane-bound radioactivity. The remaining internalized radioactivity was obtained by lysing the cells with 0.5 mL of 1 N NaOH for 5 min. Membrane-bound and internalized ^{111}In activities were counted in a gamma counter. Cellular efflux of radiolabeled peptides was determined by incubating B16/F1 cells with ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH for 2 h at 25 °C, removing nonspecific-bound activity with 2×0.5 mL of ice-cold pH 7.4, 0.2% BSA/0.01 M PBS rinse, and monitoring radioactivity released into cell culture media. At time points of 20, 40, 60, 90, and 120 min, the radioactivities in media, on cell surface, and in cells were separately collected and counted in a gamma counter.

Biodistribution Studies. All the animal studies were conducted in compliance with Institutional Animal Care and Use Committee approval. The pharmacokinetics of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH were determined in B16/F1 murine melanoma-bearing C57 female mice (Harlan, Indianapolis, IN). C57 mice were inoculated subcutaneously with 1×10^6 B16/F1 murine melanoma cells in the right flank. After 10 days, when the weight of tumors reached approximately 0.2 g, 0.037 MBq of ^{111}In-DOTA-CycMSH or ^{111}In-DOTA-GlyGlu-CycMSH was injected into each mouse through the tail vein. Groups of 5 mice were sacrificed at 2, 4, and 24 h postinjection, and tumors and organs of interest were harvested, weighed, and counted. Blood values were taken as 6.5% of the whole-body weight. The tumor uptake specificity of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH was de-

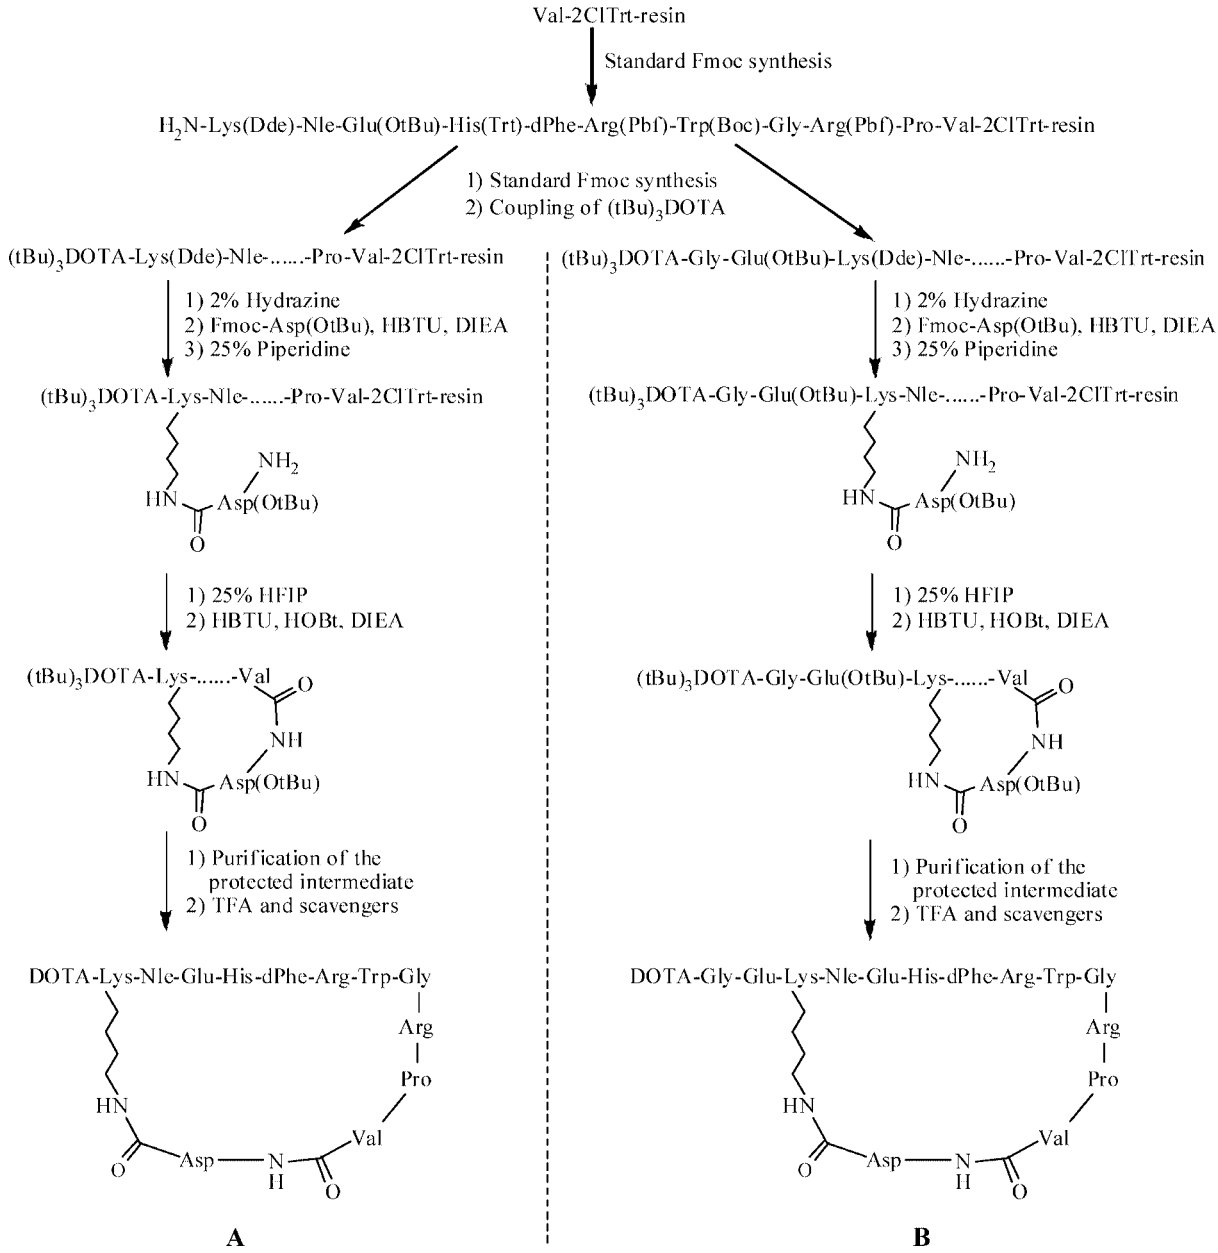

Figure 1. Synthetic schemes of DOTA-CycMSH (A) and DOTA-GlyGlu-CycMSH (B).

termined by blocking tumor uptake with the coinjection of 10 μg (6.07 nmol) of unlabeled NDP-MSH, a linear α-MSH peptide analogue with picomolar affinity for the MC1 receptors present on murine melanoma cells. Statistical analysis was performed using the Student's *t* test for unpaired data. A 95% confidence level was chosen to determine the significance between radiolabeled compounds, with $p < 0.05$ being significantly different.

Imaging Melanoma with ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH. Two B16/F1 melanoma-bearing C57 mice were injected with 13.7 MBq of ^{111}In-DOTA-CycMSH or ^{111}In-DOTA-GlyGlu-CycMSH via the tail vein, respectively. The mice were euthanized for micro-CT imaging immediately followed by micro-SPECT imaging at 2 h postinjection. Micro-SPECT scans of 60 frames for each animal were acquired and total counts acquisitions of 524 672 and 278 242 counts (2 h acquisition) were achieved for both SPECT scans, respectively. The micro-SPECT images were obtained using the Micro-CAT II CT/SPECT (Siemens) unit equipped with high-resolution 2 mm pinhole collimators (*22*). Reconstructed data from SPECT and CT were visualized and coregistered using Amira 3.1 (Ascent Media System & Technology Service, Northvale, NJ).

Urinary Metabolites of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH. 100 μL of HPLC-purified ^{111}In-DOTA-CycMSH (0.74–1.11 MBq, 0.82–1.12 ng) or ^{111}In-DOTA-GlyGlu-CycMSH (0.74–1.11 MBq, 0.90–1.35 ng) was injected into each B16/F1 murine melanoma-bearing C57 mouse through the tail vein. At 2 h after dose administration, mice were sacrificed and the urine was collected. The radioactive metabolites in the urine were analyzed by injecting aliquots of urine into HPLC. A 20 min gradient of 16–26% acetonitrile/20 mM HCl was used for the urine analysis.

RESULTS

DOTA-CycMSH and DOTA-GlyGlu-CycMSH were synthesized and purified by RP-HPLC, and the identities of peptides were confirmed by electrospray ionization mass spectrometry. The synthetic schemes are presented in Figure 1. The competitive binding curves of DOTA-CycMSH and DOTA-GlyGlu-CycMSH are shown in Figure 2. The IC_{50} values of DOTA-

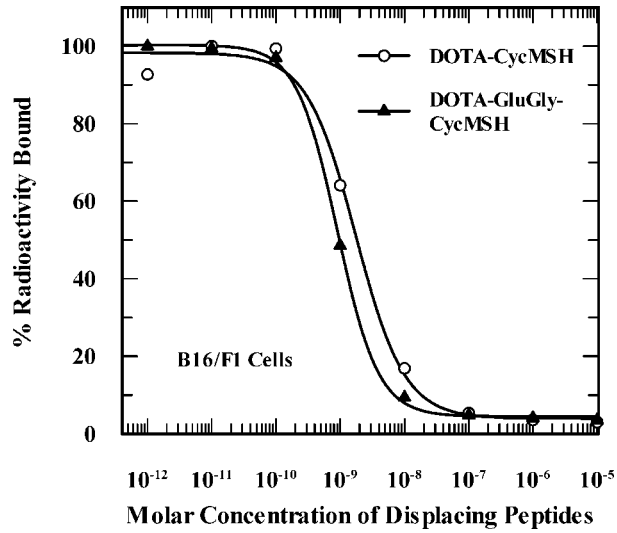

Figure 2. The competitive binding curves of DOTA-CycMSH and DOTA-GlyGlu-CycMSH in B16/F1 murine melanoma cells. The IC_{50} values of DOTA-CycMSH and DOTA-GlyGlu-CycMSH were 1.75 nM and 0.90 nM.

CycMSH and DOTA-GlyGlu-CycMSH were 1.75 nM and 0.90 nM in B16/F1 cells. The peptides were labeled with ^{111}In using a 0.5 M NH_4OAc-buffered solution at pH 5.4. The radiolabeling yields were greater than 95% for both peptides. ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH were completely separated from their excess nonlabeled peptides by RP-HPLC. The retention times of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH were 15.4 and 18.0 min, respectively. The specific activities of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH were 9.03×10^8 and 8.23×10^8 MBq/g, respectively. ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH were stable in mouse serum at 37 °C. Only the ^{111}In-labeled peptides were detected by RP-HPLC after 24 h of incubation (Figure 3).

Cellular internalization and efflux of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH were evaluated in B16/F1 cells at 25 °C. Figure 4 illustrates cellular internalization and efflux of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH. Both ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH exhibited rapid cellular internalization and extended cellular retention. There were 73.71 ± 1.71% of the ^{111}In-DOTA-CycMSH and 66.19 ± 2.12% of the ^{111}In-DOTA-GlyGlu-CycMSH activity internalized in the B16/F1 cells 40 min postincubation. There were 81.98 ± 2.02% of the ^{111}In-DOTA-CycMSH and 78.93 ± 0.64% of the ^{111}In-DOTA-GlyGlu-CycMSH activity internalized in the cells after 2 h incubation. Cellular efflux experiments demonstrated that 90.26 ± 1.71% of the ^{111}In-DOTA-CycMSH activity and 90.00 ± 1.10% of the ^{111}In-DOTA-GlyGlu-CycMSH activity remained inside the cells 2 h after incubating cells in culture media at 25 °C.

The pharmacokinetics and tumor targeting properties of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH were determined in B16/F1 murine melanoma-bearing C57 mice. The biodistribution of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH are shown in Table 1. Both ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH exhibited very rapid and high tumor uptakes. At 2 h postinjection, ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH reached their peak tumor uptake values of 9.53 ± 1.41 and 10.40 ± 1.40% ID/g, respectively. There were 7.54 ± 0.70% ID/g of the ^{111}In-DOTA-CycMSH and 7.40 ± 0.43% ID/g of the ^{111}In-DOTA-GlyGlu-CycMSH activity remained in the tumors 4 h postinjection. The tumor uptake values of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH decreased to 2.22 ± 0.51 and 2.37 ± 0.28% ID/g at 24 h postinjection. In competition studies, the tumor uptakes of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH with 10 μg (6.07 nmol) of nonradiolabeled NDP coinjection were only 3.0% and 2.6% of the tumor uptake without NDP coinjection at 2 h after dose administration ($p < 0.01$), demonstrating that the tumor uptakes were specific and receptor-mediated. Whole-body clearance of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH was very rapid, with approximately 90% of the injected radioactivity cleared through the urinary system by 2 h postinjection (Table 1).

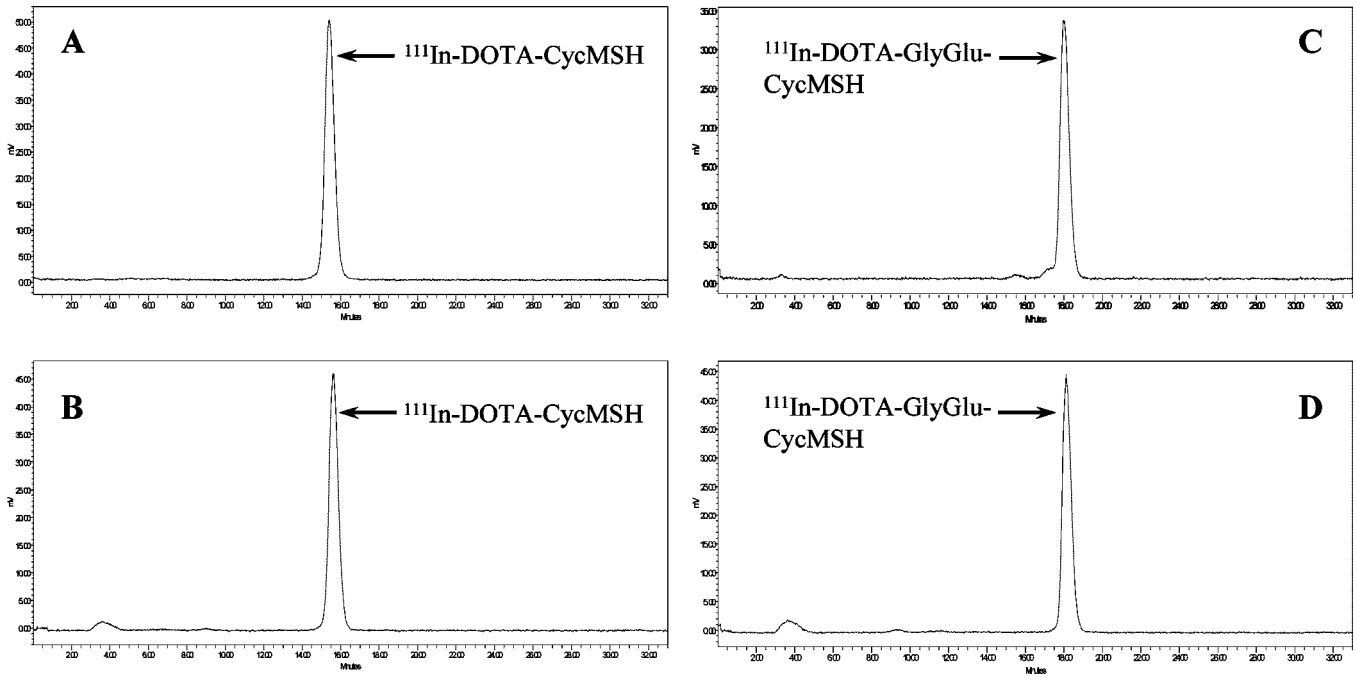

Figure 3. HPLC profiles of radioactive ^{111}In-DOTA-CycMSH (A), ^{111}In-DOTA-GlyGlu-CycMSH (C) and mouse serum stability of ^{111}In-DOTA-CycMSH (B), ^{111}In-DOTA-GlyGlu-CycMSH (D) after 24 h incubation at 37 °C, respectively. The retention times of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH were 15.4 and 18.0 min, respectively.

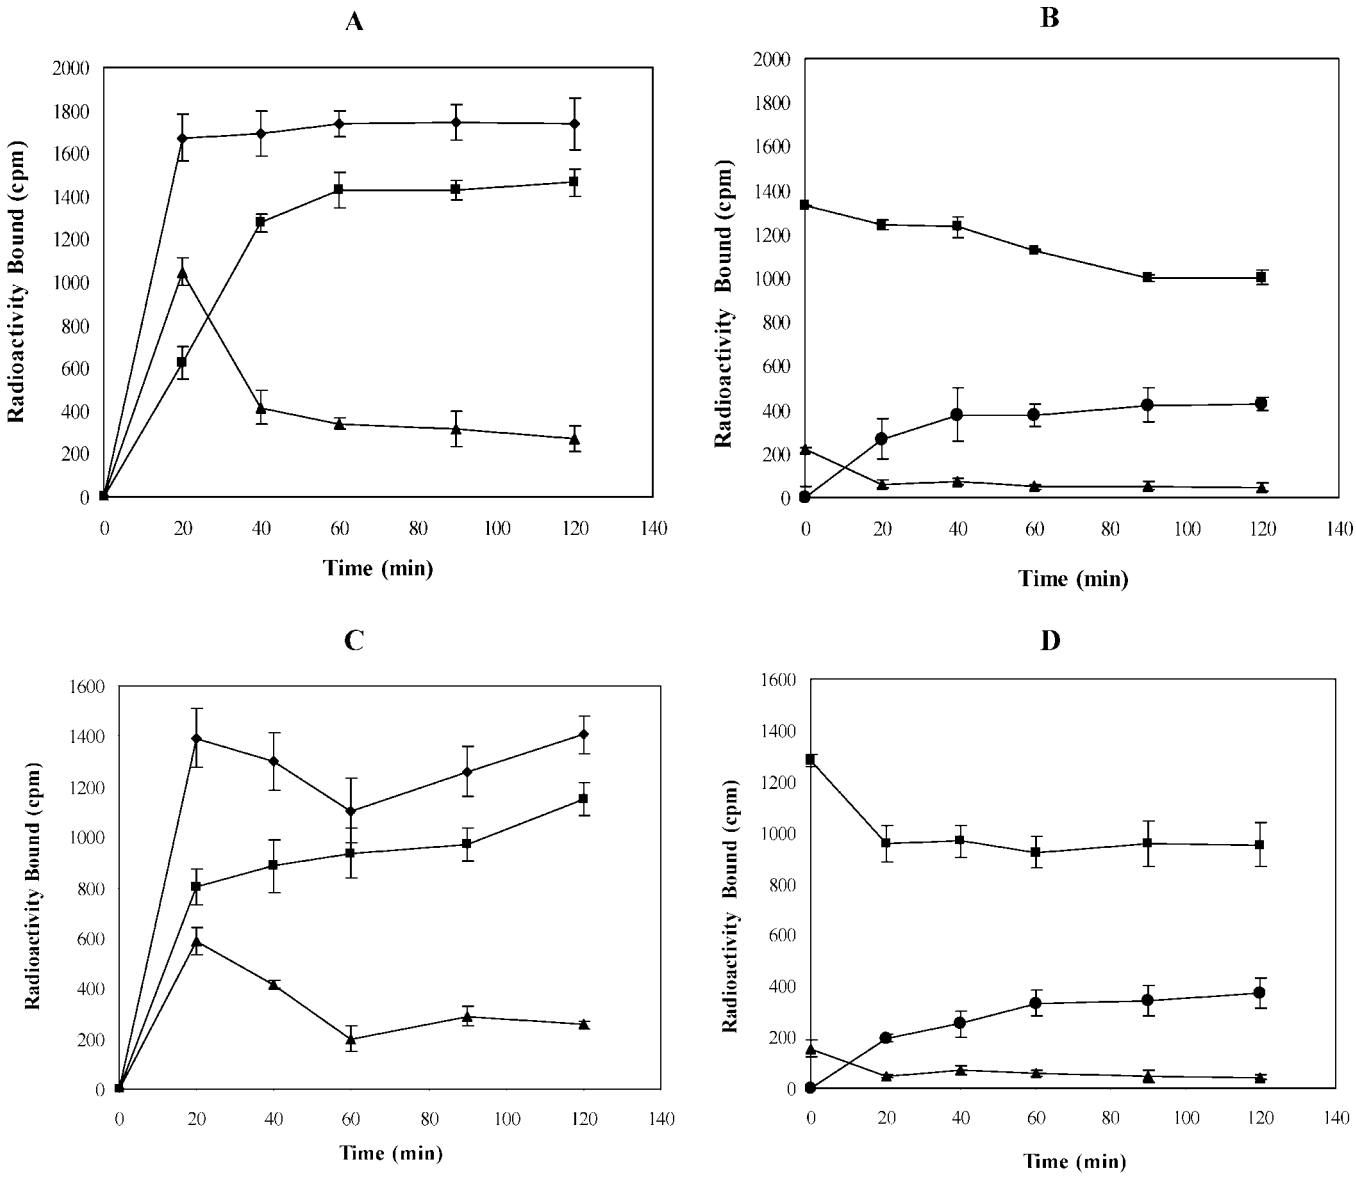

Figure 4. Cellular internalization and efflux of ^{111}In-DOTA-CycMSH (A and B) and ^{111}In-DOTA-GlyGlu-CycMSH (C and D) in B16/F1 murine melanoma cells at 25 °C. Total bound radioactivity (♦), internalized activity (■), cell membrane activity (▲), and cell culture media activity (●) were presented as counts per minute (cpm).

Normal organ uptakes of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH were generally very low (<0.8% ID/g) except for the kidneys at all time points investigated in this study. High tumor/blood and tumor/normal organ uptake ratios were demonstrated 2 h postinjection (Table 1). Although there was no statistical difference in tumor uptake between ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH, the renal uptake of ^{111}In-DOTA-GlyGlu-CycMSH was significantly lower ($p < 0.05$, Table 1) than that of ^{111}In-DOTA-CycMSH at 2, 4, and 24 h postinjection. ^{111}In-DOTA-GlyGlu-CycMSH displayed 44% lower renal uptake than ^{111}In-DOTA-CycMSH at 4 h postinjection. At 24 h after dose administration, the kidney uptake values of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH decreased to 16.00 ± 2.30 and 9.06 ± 1.82% ID/g, respectively. Bone uptake values of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH were low (<0.2% ID/g) at all time points investigated in this study.

Two B16/F1 murine melanoma-bearing C57 mice were separately injected with ^{111}In-DOTA-CycMSH (13.7 MBq, 15.2 ng) and ^{111}In-DOTA-GlyGlu-CycMSH (13.7 MBq, 16.6 ng) through the tail vein to visualize the tumors at 2 h after dose administration. The whole-body SPECT images of the mice were fused with CT images, respectively. The transaxial tumor images and the whole-body images are presented in Figure 5. Flank melanoma tumors were visualized clearly by both ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH at 2 h postinjection. Both ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH exhibited high tumor to normal organ uptake ratios except for the kidney, which was coincident with the trend observed in the biodistribution results. In view of the substantial renal uptake values of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH in the biodistribution results, the urinary metabolites of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH were analyzed by RP-HPLC at 2 h postinjection. The HPLC elution profiles of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH are shown in Figure 6. All of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH were transformed to two more polar metabolites at 2 h postinjection, respectively.

DISCUSSION

Previous publications have demonstrated that the cyclization of α-MSH peptide analogues was able to improve the binding affinities and *in vivo* stability of peptides (*14–16*). The cyclic

[a] The data were presented as percent injected dose/gram or as percent injected dose (mean ± SD, $n = 5$). [b] $P < 0.05$, significance comparison between ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH at 2, 4 and 24 h postinjection.

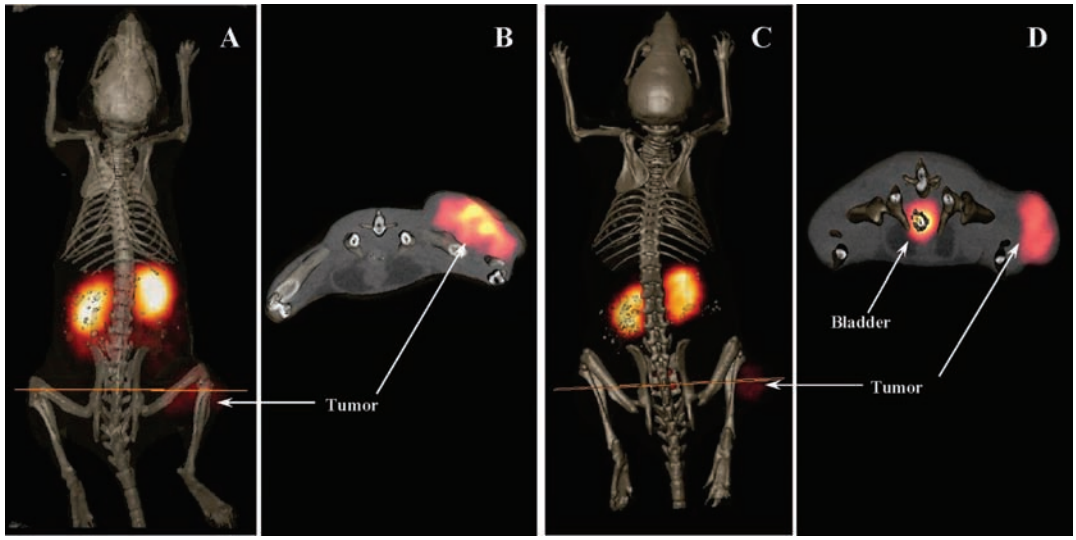

Figure 5. Whole-body and transaxial images of ^{111}In-DOTA-CycMSH (A,B) and ^{111}In-DOTA-GlyGlu-CycMSH (C,D) in B16/F1 flank melanoma-bearing C57 mice at 2 h postinjection.

peptides possess less conformational freedom and higher stability than the linear peptides due to the stabilization of secondary structures, such as beta turns. The stabilization of secondary structures makes the cyclic peptides a better fit to the receptor binding pocket, enhancing the binding affinities of the cyclic peptides. Peptide cyclization can be achieved through disulfide bridges, lactam bridges, covalent bonds such as N−N and N−C bonds, or metal coordination. Site-specific bond formation or metal coordination allows one to control the ring size of the cyclic peptide, which is critical for optimal receptor binding. Over the past several years, we have successfully employed radiometal to cyclize CCMSH peptides through radiolabeling processes (*6*, *7*, *18*). Labeling the CCMSH peptides with ^{99m}Tc or ^{188}Re simultaneously completed the peptide cyclization and the coupling of radionuclides to the peptides for melanoma imaging or therapy. The metal cyclization made α-MSH peptide analogues resistant to chemical and proteolytic degradation *in vivo* (*18*, *19*). Furthermore, the metal cyclization resulted in greater tumor uptake and lower renal uptake values of the radiolabeled peptides compared to the disulfide bridge cyclization (*19*), demonstrating that the different cyclization strategies affect the biodistribution properties of radiolabeled peptides with similar *in vitro* receptor binding affinities.

Two novel lactam bridge-cyclized α-MSH peptide analogues were synthesized to examine the effect of lactam bridge cyclization on the tumor targeting and pharmacokinetics of the radiolabeled peptides. DOTA-CycMSH and DOTA-GlyGlu-CycMSH displayed IC_{50} values of 1.75 and 0.9 nM, that were comparable to metal- and disulfide-cyclized α-MSH peptide analogues previously reported (*19*). The lactacm bridge cyclization remained the nanomolar receptor binding affinities of the peptides, demonstrating its suitability and feasibility as a strategy to cyclize the peptides. Both ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH exhibited rapid cellular internalization and extended cellular retention in B16/F1 cells, with approximately 70% of the activity internalized in the cells 40 min

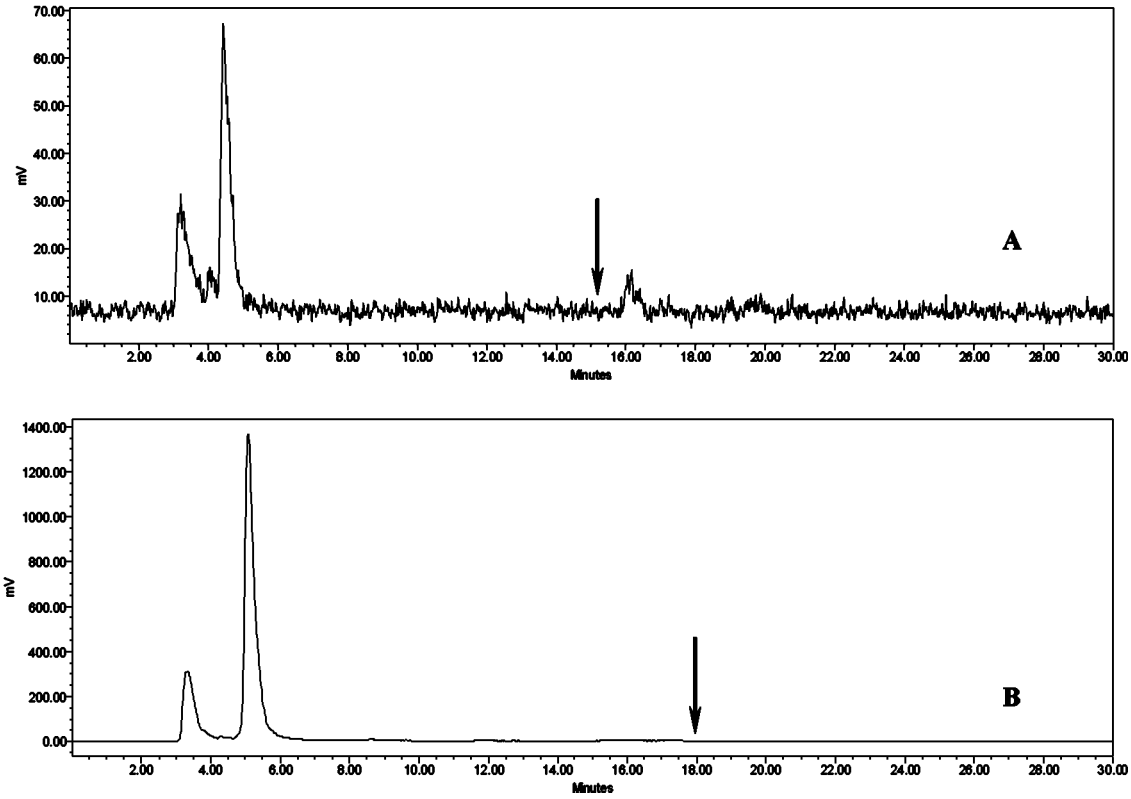

Figure 6. HPLC profiles of radioactive urine samples of B16/F1 murine melanoma-bearing C57 mice at 2 h postinjection of ^{111}In-DOTA-CycMSH (A) and ^{111}In-DOTA-GlyGlu-CycMSH (B). Arrows indicate retention time of the original compound of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH prior to the tail vein injection.

postincubation and 90% of internalized activity remained in the cells after 2 h incubation in culture media. Efficient cellular internalization coupled with extended retention made the lactam bridge-cyclized α-MSH peptide analogues suitable for melanoma imaging and therapy (*6, 23*).

Both ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH exhibited high receptor-mediated tumor uptakes of 9.53 ± 1.41 and 10.40 ± 1.40% ID/g at 2 h postinjection, respectively. The tumor uptakes of ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH (lactam bridge-cyclized α-MSH peptides) were comparable to that of ^{111}In-DOTA-ReCCMSH (a metal-cyclized α-MSH peptide), but slightly higher than the tumor uptake of ^{111}In-DOTA-[Cys^{4,10}, D-Phe^{7}]-α-MSH$_{4-13}$ (^{111}In-DOTA-CMSH, a disulfide bridge-cyclized α-MSH peptide) (*19*). Two novel ^{111}In-labeled DOTA-conjugated linear α-MSH peptide analogues, [Nle^{4}, Asp^{5}, D-Phe^{7}, Lys^{11}(DOTA)-^{111}In]-α-MSH$_{4-11}$ (^{111}In-DOTA-NAPamide) and ^{111}In-DOTA-[β-Ala^{3}, Nle^{4}, Asp^{5}, D-Phe^{7}, Lys^{10}]-α-MSH$_{3-10}$ (^{111}In-DOTA-MSH$_{oct}$), were reported for melanoma imaging (*11, 12*). ^{111}In-DOTA-NAPamide displayed greater tumor uptake values and better pharmacokinetics than ^{111}In-DOTA-MSH$_{oct.}$ The tumor uptake values of ^{111}In-DOTA-NAPamide were 7.56 ± 0.51% ID/g at 4 h and 2.32 ± 0.28% ID/g at 24 h postinjection in the B16/F1 melanoma mouse model (*12*). Both ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH exhibited comparable tumor uptake values with ^{111}In-DOTA-NAPamide at 4 and 24 h postinjection. Flank melanoma tumors were clearly visualized with ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH at 2 h postinjection by SPECT/CT images (Figure 5). The SPECT imaging of tumors accurately matched the anatomical information from CT images. ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH displayed high tumor to normal organ uptake ratios except for the kidney, which was coincident with the trend observed in biodistribution results. The high receptor-mediated tumor uptake and tumor to normal organ uptake ratios highlighted the potential of radiolabeled lactam bridge-cyclized α-MSH peptides as a novel class of peptide radiopharmaceuticals for melanoma imaging.

Both biodistribution results and SPECT/CT images demonstrated that the kidney was primary excretion pathway of the radiolabeled lactam bridge-cyclized α-MSH peptides. The strategy of infusing basic amino acids such as lysine or arginine has been employed to decrease the renal uptakes of radiolabeled peptides by shielding the electrostatic interaction between positively charged peptides and negatively charged surface of tubule cells (*7, 24, 25*). Recently, it has been reported that different pathways may play roles in the mechanism of the renal uptake of radiolabeled peptides besides the electrostatic interaction between the positively charged peptides and negatively charged tubule cells (*26, 27*). For instance, the use of colchicine, which prevents endocytosis in tubular cells, has successfully decreased the renal uptake up to 25% in a rat model (*27*). Moreover, transmembrane glycoproteins, such as megalin, have been reported to be involved in the renal uptakes of radiolabeled somatostatin analogues (*28*). Since the extracellular domains of megalin can accommodate a variety of ligands, megalin may be involved in the renal uptakes of other radiolabeled peptides. Glutamic acid has been introduced into the peptide sequences to reduce the renal uptakes of radiolabeled metal-cyclized α-MSH peptides (*29*), as well as a PKM linker to modify the biodistribution of radiolabeld RGD peptides (*30–35*). In this study, the structural modification of increasing the overall negative charge of the peptide (introducing a glutamic acid) was investigated to demonstrate whether the structural modification could reduce the renal uptake values of the radiolabeled peptides. As a matter of fact, the introduction of a negatively charged glutamic acid as a linker significantly ($p < 0.05$) decreased the renal uptake of ^{111}In-DOTA-GlyGlu-CycMSH by 44% compared to ^{111}In-DOTA-CycMSH (Table 1) 4 h postinjection, suggesting that the electrostatic interaction played an important role in the renal uptakes of ^{111}In-DOTA-CycMSH

and ^{111}In-DOTA-GlyGlu-CycMSH. The urine analysis showed that both ^{111}In-DOTA-CycMSH and ^{111}In-DOTA-GlyGlu-CycMSH were metabolized into two moieties that might be responsible for the activity retention in kidneys. The kidney uptake value of ^{111}In-DOTA-GlyGlu-CycMSH was 29% higher than ^{111}In-DOTA-ReCCMSH at 4 h postinjection. However, the renal uptake value of ^{111}In-DOTA-GlyGlu-CycMSH was only 34% of that of ^{111}In-DOTA-CMSH at 4 h postinjection, demonstrating that the lactam cyclization was better than the disulfide cyclization in terms of less renal uptake value. Introduction of one more negatively charged glutamic acid or lysine coinjection might further decrease the renal uptake of ^{111}In-DOTA-GlyGlu-CycMSH. Another potential strategy to further reduce the kidney uptake would be to use shorter lactam bridge-cyclized α-MSH peptide, since lower molecular weight ^{111}In-DOTA-NAPamide exhibited less kidney uptake than ^{111}In-DOTA-GlyGlu-CycMSH. Further reduction of the renal uptakes will facilitate the clinical evaluations of this novel class of radiolabeled α-MSH peptides as melanoma imaging probes, as well as promote the potential use of this novel class of radiolabeled α-MSH peptides as therapeutic agents for peptide-targeted radionuclide therapy of melanoma.

In conclusion, ^{111}In-labeled DOTA-conjugated lactam bridge-cyclized α-MSH peptides exhibited high receptor-mediated tumor uptake coupled with fast whole-body clearance in B16/F1 murine melanoma model. Introduction of a negatively charged linker (-Gly-Glu-) into the peptide sequence decreased the renal uptakes by 44% without affecting the tumor uptakes 4 h postinjection. ^{111}In-labeled lactam bridge-cyclized α-MSH peptide analogues appear to be a novel class of very promising peptide radiopharmaceuticals for receptor-targeting melanoma imaging.

Received September 5, 2007; Revised Manuscript Received November 20, 2007

Local and controlled DNA release is a critical issue in current gene therapy. As viral gene delivery systems are associated with severe security problems, nonviral gene delivery vehicles were developed. Here, DNA-nanoparticles using grafted copolymers of PLL and PEG to increase their biocompatibility and stealth properties were systematically studied. Ten different PLL-based polymers with no, low, and high PEG grafting and PEG molecular weights as well as different PLL backbone lengths were complexed with plasmids containing 3200 to 10,100 base pairs. Stable complexes were formed and selected for cytotoxicity and transfection efficiency. Predominantly, PLL-g-PEG-DNA nanoparticles grafted with 4 or 5% PEG moieties of 5 kDa transfected 40% COS-7 cells without reduction of cell viability when formed at N/P ratios between 0.1 and 12.5. The molecular weight of PLL did not significantly affect transfection efficiency or cytotoxicity indicating that a specific cationic charge-density-to-PEG-ratio is important for efficient transfection and low cytotoxicity. The PLL-g-PEG-DNA nanoparticles were spherical with a diameter of ∼100 nm and did not aggregate over 2 weeks. Moreover, they protected included plasmid DNA against serum components and DNase I digestion. Therefore, such storage stable and versatile PLL-g-PEG-DNA nanoparticles might be useful to deliver differently sized therapeutic DNA for *in vivo* applications.

1. INTRODUCTION

Gene transfer using nonviral vectors is a promising approach for the safe delivery of therapeutic DNA in genetic and acquired human diseases (*1–6*). In contrast to viral vectors, nonviral vectors benefit from low immunogenecity, the absence of endogenous recombination, low production costs, and reproducibility (*2*). Furthermore, they have no size limitation in DNA packaging. Unfortunately, nonviral DNA delivery vehicles often affect cell viability and have poor transfection efficiency. Gene expression only results when the DNA is delivered into the cell nucleus of the target cell. On its way, the DNA has to pass several biological barriers beginning with the plasma membrane, followed by avoidance of the endosomal pathway, and finally passage through the nuclear pores (*1, 2*). Today, there is still a huge need for carriers that transport DNA quickly and efficiently and release it in a controlled manner. Moreover, the storage stability of such carriers becomes an issue.

Currently, three different strategies for nonviral application of therapeutic DNA have been developed. The simplest way is the use of naked DNA, which is injected directly into the target tissue (*7*), applied via electroporation or ultrasound (*8*), or loaded onto nanosize particles of heavy metal and brought into the cell by gene gun applications (*9*). Enzymatic degradation of the unprotected DNA and poor cell transfection efficiencies are the major drawbacks (*7*). Another approach is the use of lipoplexes that are lipid-based DNA vehicles, entering the cytoplasm by cell membrane fusion (*10, 11*). Many different modifications for specific cell targeting and intracellular routing have been developed (*12, 13*). However, the primary drawback is the rapid clearance of lipoplexes in the blood system and their short-term stability (*14*). The third approach is to use polycationic substances, such as poly L-lysine (PLL), poly L-ornithin, polyethyleneimine (PEI), and chitosan, to complex plasmid DNA (*2, 15–21*). Although polymers with high cationic charge density condense the DNA into structures amenable to cellular internalization, the high charge density is one factor that contributes to their cytotoxicity as interactions of polycations with cell membranes induce nanoscale hole formation and enhance membrane permeability (*22–24*). To reduce cytotoxicity, different block copolymers between PEG and PLL, PEG and PEI, and PEG and chitosan as well as PEG and poly aspartic acid were used to form DNA vehicles (*15, 18–21, 23, 25*). Moreover, peptide-based DNA vectors or covalent complexes between PEG−peptides and PEG−glycopeptides were developed (*17, 26–29*). However, low cationic charge density can reduce or eliminate DNA condensation capability. The balance between cationic charge density and DNA condensation is complicated even further when endosomal escape moieties and nuclear translocation sites are considered (*30–32*).

Here, a systematic and quantitative study of grafted PLL-PEG copolymers is presented, illustrating how PLL backbone length, PEG molecular weight, and degree of PLL grafting with PEG affect (a) PLL-g-PEG-DNA nanoparticle formation for *in vitro* transfection; (b) size and stability of the formed nanoparticles; and (c) cytotoxicity of the transfection vehicle. Furthermore, the stability of such DNA-containing nanoparticles with time and the release of functional plasmid DNA were investigated as it is crucial for any medical application.

Table 1. Names and Composition of the PLL-g-PEG-Copolymers Used Here to Form PLL-g-PEG-DNA Condensates[a]

polymer name	PLL (kDa)	PEG (kDa)	PEG/PLL (absolute number)	PEGylation (g) (%)
PLL_{300}	300 (=1435 lysine residues)			
PLL_{300}-g_4-PEG_1	300	1	55.8	4
PLL_{300}-g_{24}-PEG_1	300	1	341.7	24
PLL_{300}-g_4-PEG_5	300	5	59.5	4
PLL_{300}-g_{20}-PEG_5	300	5	287.0	20
PLL_{20}	20 (=96 lysine residues)			
PLL_{20}-g_7-PEG_1	20	1	6.7	7
PLL_{20}-g_{24}-PEG_1	20	1	23.2	24
PLL_{20}-g_5-PEG_5	20	5	5.1	5
PLL_{20}-g_{28}-PEG_5	20	5	27.1	28

[a] Molecular weights of PLL and PEG are indicated in (kDa), whereas the ratio between PEG and PLL (PEGylation, g) is indicated in percent. PEGylation was calculated using the absolute numbers of PEG moieties per lysine of the PLL-molecule.

2. MATERIALS AND METHODS

2.1. Polymer Synthesis. Eight different PLL-g-PEG-polymers (Table 1) were used in this study. They were synthesized using poly L-lysine hydrobromide with molecular weights of 20 and 300 kDa (Sigma), referred to as PLL_{20} and PLL_{300}, respectively, and the *N*-hydroxysuccinimidyl ester of methoxy-terminated poly(ethylene glycol) (Nektar, USA, molecular weights 1 and 5 kDa). PLL_{20} contains 96 lysine residues, and PLL_{300} contains 1435. The grafting ratio (g) was calculated using the absolute number of PEG moieties per lysine of the PLL backbone, expressed in percent form. Synthesis and analysis were performed as described previously (*33*). Reaction rates were determined by ^{1}H NMR (D_2O) (β, γ, and δ CH_2 peaks of lysine at 1–2 ppm, CH_2CH_2O of PEG at 3.3–3.9 ppm). The polymers were stored at −20 °C until further use.

2.2. Formulation of PLL-g-PEG-DNA Condensates. Transfection studies were performed in 24 well plates (TPP, Switzerland). PLL-g-PEG-DNA condensates were formed by using either a vector expressing enhanced green fluorescent protein (pEGFP-N1, Clontech), β-galactosidase (pSV-β-galactosidase, Promega), pHisTrx (*34*), or plasmid #343 (kindly provided by Markus Kuenzler, Institute for Microbiology, ETH Zurich, Switzerland) at a final DNA concentration of 1 μg/150 μL (=6.7 μg/mL) in PBS and a PLL-g-PEG concentration according to NH_4^+/PO_4^{3-} (amino group in PLL/phosphate group in DNA; N/P) charge ratios between 0.1 to 25. PLL-g-PEG was provided in 75 μL of PBS (0.01 M phosphate buffered saline, pH 7.4, Sigma), and DNA dissolved in 75 μL of PBS was added dropwise into the polymer solution. The complexes were equilibrated for 30 min at room temperature and were always freshly prepared prior to use.

2.3. Plasmid Propagation. The vectors pEGFP-N1, pSV-β-galactosidase, pHISTrx, and #343 used in this study were transformed into *E. coli* strain Top10 (Invitrogen), grown in LB media supplemented either with 30 μg/mL kanamycin for pEGFP-N1 and pSV-β-galactosidase or with 50 μg/mL ampicillin for all other plasmids. The plasmid DNA was purified using a Maxiprep kit (Qiagen), and the concentration was determined photometrically at 260 nm.

2.4. Stability of Condensates: Release of DNA by Heparin Replacement, DNase I Protection Assay, and Serum Stability. The stability of PLL_{20}-g_5-PEG_5-DNA complexes was analyzed, and the release of the plasmid DNA by heparin displacement was studied. PLL_{20}-g_5-PEG_5-DNA condensates were made at a final DNA concentration of 1 μg/150 μL (=6.7 μg/mL) in PBS and PLL_{20}-g_5-PEG_5-DNA with N/P ratios = 3.125 and 25. After 30 min of incubation, 750 μg of heparin (15 μL of a 50 mg/mL stock solution, 181 USP units/mg, H-9399 Sigma) and 5 μL of 5 M NaCl were added. The samples were analyzed on a 1% agarose gel containing 0.5 μg/mL ethidium bromide in TAE buffer (40 mM Tris, 40 mM acetic acid, 1 mM EDTA) for 1 h and visualized on an UV-transilluminator. As controls, PLL_{20}-g_5-PEG_5-DNA nanoparticles (N/P ratio = 3.125 and 25) without heparin and NaCl addition were treated in an analogous manner.

The stability of PLL_{20}-g_5-PEG_5-DNA and PLL_{20}-DNA condensates against DNase I (New England Biolabs) and serum compounds was analyzed. For both, 5 μg of pEGFP-N1 plasmid was complexed with PLL_{20} (Sigma) and PLL_{20}-g_5-PEG_5 with the N/P charge ratios ranging from 0.1 to 25. For the determination of DNase I stability, $MgCl_2$ (2.5 mM final concentration) and 5 U DNase I were added to the condensates. After 10 min of incubation at 37 °C, the enzyme reaction was stopped by the addition of 10 μL of 0.3 M EDTA (15 mM final concentration), and the samples were transferred on ice. As controls, 5 μg of naked DNA was digested with DNase I, and PLL_{20}-g_5-PEG_5-DNA nanoparticles (N/P ratio = 3.125) without DNase I were treated in the same way. In order to release the DNA from the nanoparticles, 150 μL of heparin (stock solution 50 mg/mL) and 5 μL of 5 M NaCl were added to the condensates for 30 min at 4 °C. The samples were analyzed on 1% agarose gels as described above.

To determine the serum stability of the polymer−DNA condensates, 150 μL of DMEM (Cat. No. 21885, GibcoBRL) containing 10% fetal bovine serum (F7524, Sigma) was added and incubated at 4 and 37 °C for 7 days. The DNA of the PLL_{20}-g_5-PEG_5 nanoparticles was released and analyzed as stated for DNase I protection assays.

2.5. Cells and Cell Culture. COS-7 (SV 40 transformed kidney cells of African green monkey, ATCC CRL 1651, ATCC Rocksville, MA) cells were cultured as exponentially growing subconfluent monolayers at 37 °C containing 5% CO_2. The cell culture was maintained in 25 cm^2 culture flasks in DMEM (Cat. No. 21885, low glucose, glutamax I, GibcoBRL) supplemented with 10% heat inactivated FBS (F7524, Sigma) and 1% ABAM (Cat. No.: 15240, GibcoBRL). COS-7 cells were seeded at a constant density of 7500 cells/cm^2 on 8-well chamber slides (Labtek), 24-, and 96 well plates. For all experiments, cells were used 24 h post seeding.

2.6. *In Vitro* Gene Expression in COS-7 Cells. Polymer−DNA condensates were prepared as described above. Briefly, 1 μg of pEGFP-N1 plasmid per well (24-well plate) was complexed with PLL_{20}, PLL_{300}, and all PLL-g-PEG polymers using N/P charge ratios 0.1 to 25, yielding a volume of 150 μL. After removing the tissue culture medium and rinsing the cells with PBS once, the polymer−DNA condensates were added onto the cells and incubated for 30 min at 37 °C and 5% CO_2, then 450 μL DMEM, containing 2% FBS, was added for 24 h. The transfection medium was replaced with DMEM supplemented with 10% FBS, and the cells were incubated for another 24 h before the cells were analyzed for GFP expression by fluorescence microscopy. Hoechst 33342 nuclear stain (Invitrogen) was used to identify the total cell number, and ethidium bromide (AppliChem) was used to determine the potential cytotoxicity of the polymer−DNA condensates. Briefly, the cells were incubated for 2 min in DMEM with 10% FBS containing 4 μg/mL Hoechst 33342 and 10 μg/mL ethidium bromide. After rinsing the cells three times with PBS, the transfection efficiency was analyzed by counting the GFP-expressing cells in 3 nonoverlapping areas of 500 mm^2 in relation to the total cell number as determined by Hoechst nuclear stain. The software ImageJ 1.2 was used. As positive control, DEAE dextran (Cat. No.: 30461, Fluka) transfection was performed: 1.25 μg of pEGFP-N1 DNA was complexed

with 50 μg of DEAE dextran in 150 μL of PBS and added to the cells that were rinsed with PBS and incubated for 30 min at 37 °C and 5% CO_2. Then, 450 μL of DMEM with 10% FBS and 0.9 μL of chloroquine (Sigma) from a stock solution of 50 mM in PBS were added. Cells were incubated for 2.5 h at 37 °C and 5% CO_2, and subsequently, they were treated with 10% DMSO in DMEM with 10% FBS for 2.5 min. The DMSO-containing medium was removed, and the cells were cultured for 48 h in DMEM containing 10% FBS. Transfection efficiency was analyzed by fluorescence microscopy as described above.

2.7. Determination of Nanoparticle Cytotoxicity. In order to quantify the cytotoxicity of the PLL-g-PEG-DNA nanoparticles, WST-1 proliferation assay (Roche) was performed. The following polymers and controls have been used to form polymer−DNA condensates containing 0.167 μg of pEGFP-N1 per well of a 96-well plate: PLL_{20}-g_5-PEG_5, PLL_{300}-g_4-PEG_1, PLL_{300}-g_4-PEG_5, PLL_{20}, and PLL_{300} with the N/P ratios 0.1−25. As controls, COS-7 cells were transfected with naked DNA (0.167 μg pEGFP-N1 per 96-well plate), DEAE dextran, and incubated with PBS alone. COS-7 cells were transfected in 96-well plates. Forty-eight hours after transfection, 20 μL of WST-1 reagent was applied to each well containing 200 μL of DMEM supplemented with 10% FBS, and the cells were incubated for another hour at 37 °C and 5% CO_2. Absorption at 440 nm was measured using a microplate reader, Infinite M200 (Tecan). Each condition was performed in quadruple and repeated three times.

2.8. Particle Size Analysis. The particle size of the PLL_{20}-g_5-PEG_5-DNA nanoparticles was measured with dynamic light scattering (DLS) at a scattering angle of 90° on a Brookhaven BI-SM200 instrument. The wavelength of the laser beam was $\lambda = 532$ nm, emitted from a Laser Quantum (UK) ventus LP 532. The nanoparticles were prepared as stated for the transfection studies with a final DNA concentration of 10 μg/mL. The PLL_{20}-g_5-PEG_5-to-DNA concentration corresponded to an N/P ratio of 3.125, 6.25, 12.5, and 25. Plasmids pEGFP-N1, pSV-β-galactosidase (Promega), pHISTrx (*34*), and #343 were used for DLS analysis (N/P ratio = 3.125). Each measurement was performed for 5 min, and the hydrodynamic diameters of three independent samples for each condition were analyzed. To obtain the 7 and 14 day values, PLL_{20}-g_5-PEG_5-DNA nanoparticles were stored at 4 °C between the measurements.

2.9. Fluorescence Dye Exclusion Assay. The maximal condensation of polymers and DNA was assayed using PicoGreen (Invitrogen), which binds to soluble double-stranded DNA. Nanoparticles with either PLL_{20}-g_5-PEG_5 or PLL_{20} were produced as stated above using pEGFP-N1 and pSV-β-galactosidase vectors at a concentration of 10 μg/mL. The polymer-to-DNA ratios corresponded to the N/P charge ratios of 0.1 to 25. Nanoparticles were mixed with 100 μL of PicoGreen solution (PicoGreen stock solution diluted 1:200 in PBS) and incubated for 5 min at room temperature in the dark. The fluorescence of PicoGreen was determined according to the manufacturer's protocol using a microplate reader, Infinite M200 (Tecan), with excitation at 480 nm while monitoring emission at 520 nm. Decreasing fluorescence indicated less free double-stranded DNA and was regarded as the amount of DNA that was incorporated into the polymer−DNA nanoparticles. The measurements were performed in duplicate and repeated three times.

2.10. Negative Stain Transmission Electron Microscopy (TEM). For the visualization of the polymer−DNA condensates, negative staining TEM was performed. PLL_{20}-g_5-PEG_5-DNA condensates were prepared in ddH_2O using 5 μg of pEGFP-N1 plasmid complexed at the N/P ratio = 3.125. A twenty microliter nanoparticle solution was applied for 2 min on Formvar and carbon-coated 300 mesh copper-grids, which were freshly glow discharged. The remaining ddH_2O was removed by suction with filter paper, and the condensates were negative stained for 3 × 15 s on drops of 2% phosphor tungsten acid in ddH_2O. Finally, the excess staining solution was removed by suction with filter paper, and the grid was air-dried. The samples were analyzed with a transmission electron microscope (Philips 208) using high voltage (80 kV) at magnifications of 44,000 to 110,000. Samples with either polymer or DNA only were prepared in a similar way.

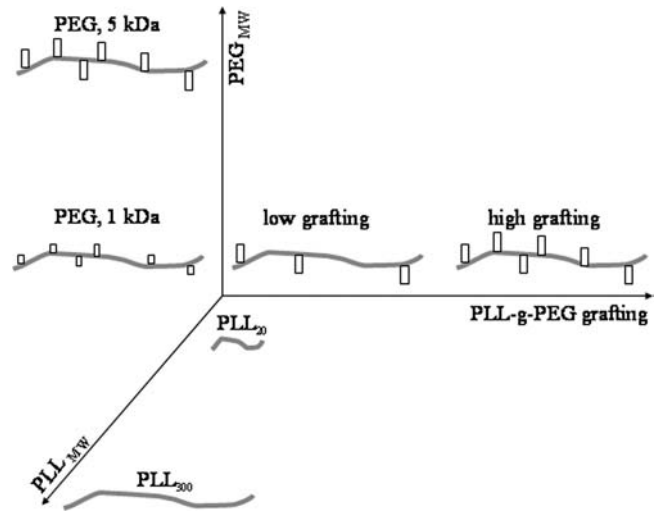

Figure 1. Schematic of the composition of PLL-g-PEG-copolymers used in this study. Eight different PLL-g-PEG polymers that varied in the molecular weight of the PLL-backbone, the amount of PLL grafting with PEG, and the molecular weight of PEG were used to form PLL-g-PEG-DNA condensates.

3. RESULTS

3.1. *In Vitro* Transfection Efficiencies of DNA-Containing Condensates Formed with Different PLL-g-PEG Copolymers. The aim of this study was to systematically analyze different grafted PLL-g-PEG copolymers and determine their potential in the formation of DNA-containing condensates. For this purpose, 10 different polymers were selected that varied in their PLL backbone length, PEG molecular weight, and the amount of PLL grafting (Figure 1 and Table 1). Two different PLL molecular weights (20 and 300 kDa) were chosen to determine the influence of PLL backbone length on the formation of DNA-containing condensates. The PLL backbone was grafted with short and long PEG-moieties (1 and 5 kDa, respectively), and different amounts of grafted PEG moieties were studied. Nongrafted PLL_{20} and PLL_{300} were compared to low grafted (4–7%) and high grafted (20–28%) PLL_{20} and PLL_{300}. PLL-g-PEG condensates were formed using an NH_4^+/PO_4^{3-} (N/P) ratio of 3.125, and the *in vitro* transfection efficiency of COS-7 cells was determined. Figure 2A compares transfection efficiencies of all 10 polymers condensed with plasmid DNA encoding the information for the expression of enhanced green fluorescent protein (pEGFP-N1). Polymers PLL_{300}-g_4-PEG_1, PLL_{300}-g_4-PEG_5 (Figure 2A, a) and PLL_{20}-g_5-PEG_5 (Figure 2A, b) showed the best transfection efficiencies. All three polymers had a low amount of PEGylation (4 and 5%, respectively). PLL_{300}-g_4-PEG_1 contained the low molecular weight PEG (1 kDa), resulting in ~10% transfection efficiency, whereas PLL_{300}-g_4-PEG_5 and PLL_{20}-g_5-PEG_5 were grafted with high molecular weight PEG (5 kDa) leading to 20 and 40% transfection efficiency, respectively. These results indicate a strong influence of the amount and molecular weight of PEG moieties on transfection efficiency, less so of the molecular weight of the PLL backbone. Highly PEGylated polymers containing 20–28%

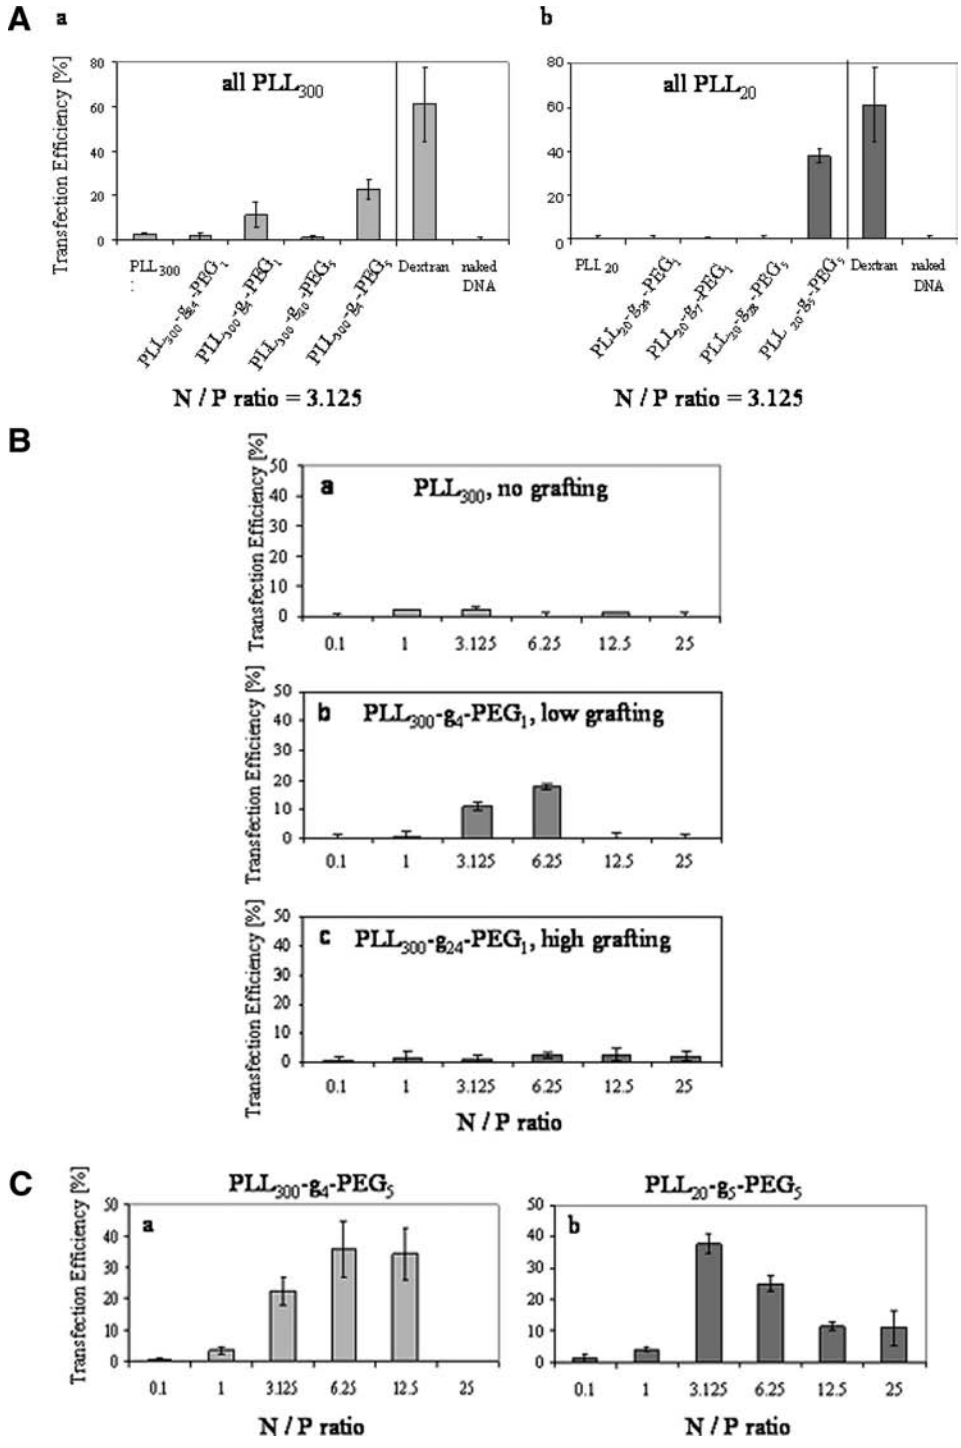

Figure 2. Transfection efficiencies of PLL-g-PEG-DNA condensates with different PLL backbones (A), PEG grafting (B), and N/P ratios (C). (A) (a) Grafted and nongrafted PLL with a molecular weight of 300 kDa (PLL_{300}) was used to form polymer−DNA condensates for transfection of COS-7 cells with a plasmid coding for the expression of green fluorescent protein (pEGFP-N1). All PLL_{300}-based PLL-g-PEG condensates were compared. The N/P ratio was 3.125 for all condensates. DEAE-dextran transfection and naked DNA applied in PBS were used as control. (A) (b) Grafted and nongrafted PLL with a molecular weight of 20 kDa (PLL_{20}) was used to form polymer−DNA condensates for transfection of COS-7 cells. All PLL_{20}-containing PLL-g-PEG condensates were compared. The N/P ratio used was 3.125 for all condensates. DEAE-dextran transfection and naked DNA were used as controls. (B) Polymer−DNA condensates formed with PLL_{300} displaying different grafting ratios were compared for their transfection capability. (B) (a) Nongrafted PLL_{300} was used to form PLL-DNA condensates; (b) PLL_{300}-g_4-PEG_1 with 4% PEG grafting was used to form PLL-g-PEG-DNA; and (c) PLL_{300}-g_{24}-PEG_1 with 24% PEG grafting was used. For a, b, and c, the N/P ratios to form the polymer−DNA condensates were 0.1 to 25. COS-7 cells were cultured on tissue culture polystyrene for 24 h and transfected with DNA-containing condensates. Transfection efficiencies were determined after a total of 48 h by fluorescence microscopy. The ratio between the total cell numbers as determined by Hoechst nuclear stain to the numbers of green fluorescent cells was analyzed. The data represent mean values ± SD of three independent experiments carried out in duplicate. (C) Comparison of transfection efficiencies of PLL-g-PEG-DNA condensates formed with PLL_{20} and PLL_{300} polymers with low grafting (4 and 5% PEG) but high molecular weight of the grafted PEG moiety (5 kDa). (a) Shows the transfection efficiency of PLL_{300}-g_4-PEG_5-DNA condensates formed with PLL_{300} grafted with 4% of 5 kDa PEG moieties. (b) Demonstrates the transfection efficiencies of DNA-containing polymer condensates formed with PLL_{20} grafted with 5% of 5 kDa PEG moieties (PLL_{20}-g_5-PEG_5-DNA). For (a) and (b), six different N/P ratios were used to form the condensates.

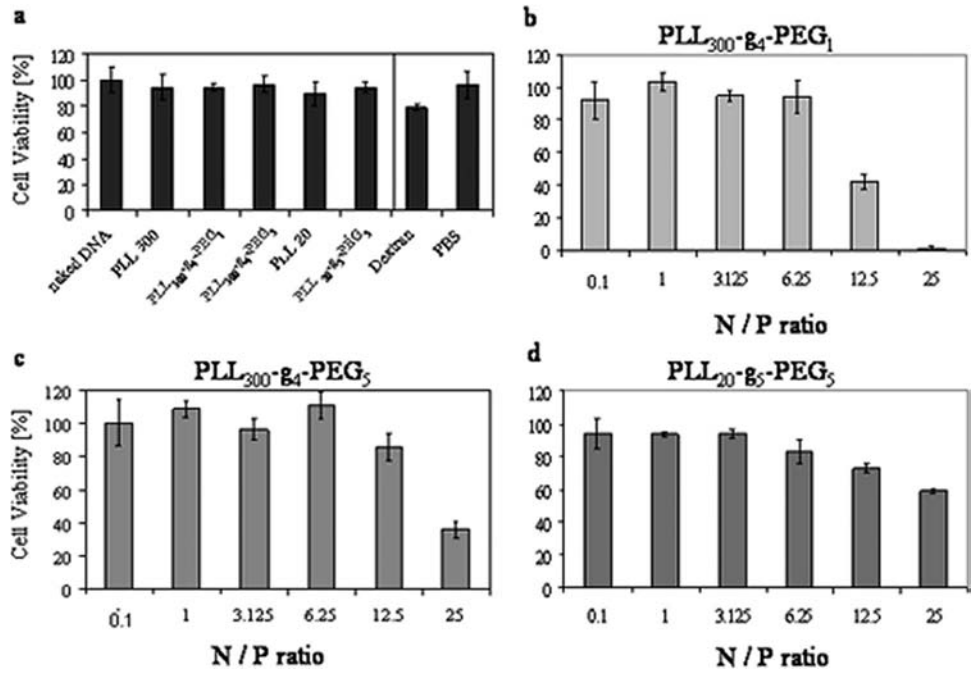

Figure 3. Cell viability of COS-7 cells after transfection with PLL-DNA and PLL-g-PEG-DNA condensates. Cell viability of COS-7 cells 48 h after transfection was determined by analysis of the mitochondrial activity using a WST-1 cell proliferation assay. (a) Nongrafted PLL_{300}- and PLL_{20}-, as well as all grafted PLL-g-PEG-DNA condensates that showed significant transfection efficiencies in COS-7 cells (in Figure 2A, a and b) were compared. The N/P ratio for all condensates was 3.125. Transfection with DEAE dextran and PBS only treatment were used as controls. Cell viability was determined 48 h after transfection with PLL_{300}-g_4-PEG_1-DNA (b), PLL_{300}-g_4-PEG_5-DNA (c), and PLL_{20}-g_5-PEG_5-DNA condensates (d). N/P ratios between 0.1 to 25 were used to form the condensates.

PEG showed poor transfection rates (below 2%) independent from the grafted PEG molecular weight. DEAE dextran complexed with plasmid DNA and transfection with naked DNA were performed in parallel. DEAE dextran showed transfection efficiencies of 61 ± 17%, whereas the application of naked DNA did not result in any GFP expression.

Different PLL_{300}-containing polymers with no, low (4%), and high (24%) PEG grafting were used to form DNA condensates with N/P ratios between 0.1 and 25. For all grafted polymers, PEG with 1 kDa was used (Figure 2B). Only when COS-7 cells were exposed to low PEGylated PLL_{300} (PLL_{300}-g_4-PEG_1), significant expression of green fluorescent protein could be observed (Figure 2B, b). The transfection efficiencies were found to be 10% for N/P ratio 3.125 and 20% for N/P ratio 6.25. Highly grafted PLL_{300} (Figure 2B, c) and non-PEGylated PLL_{300} (Figure 2B, a) were used to form polymer−DNA condensates; however, transfection resulted in very poor (<2%) expression of green fluorescent protein for all N/P ratios tested. These experiments indicate that not only the amount of PEG grafting is decisive for the transfection of COS-7 cells but also the formation of condensates with a medium charge ratio.

Since transfection efficiency is related to low PEGylation, the influence of the PLL backbone length (20 kDa vs 300 kDa PLL) was determined (Figure 2C). Interestingly, the polymers PLL_{300}-g_4-PEG_5 and PLL_{20}-g_5-PEG_5 showed comparable transfection efficiencies when PLL-g-PEG-DNA condensates were formed with N/P ratios between 0.1 and 25. The transfection efficiencies were found to be around 40% for PLL_{300}-g_4-PEG_5 formed at N/P ratio = 6.25 (Figure 2C, a) and for PLL_{20}-g_5-PEG_5 formed at N/P ratio = 3.125 (Figure 2C, b).

3.2. Determination of Cell Viability after Transfection with Polymer−DNA Condensates. Cell viability of COS-7 cells was analyzed using a proliferation assay that monitors mitochondrial activity as an indication for living cells (Figure 3). Cell viability was determined 48 h after transfection with different PLL_{300}- and PLL_{20}-containing DNA condensates formed at an N/P ratio of 3.125 (Figure 3a). Cell viability was not affected (>95% living cells) and was comparable to cell viability without any transfection. However, when COS-7 cells were transfected with DEAE dextran−DNA condensates, cell viability was impaired as only 78 ± 2% cells remained alive. Transfection with PLL_{300}-g_4-PEG_1, PLL_{300}-g_4-PEG_5, and PLL_{20}-g_5-PEG_5 containing DNA-condensates formed at N/P ratios between 0.1 and 25 demonstrated that cell viability depends strongly on the N/P ratio used to form the polymer−DNA condensates. Figure 3b and c shows that when condensates were formed with N/P ratios higher than 12.5 cell viability is significantly impaired, whereas cell viability remained significantly higher when PLL_{20}-g_5-PEG_5-DNA condensates were formed with N/P ratios higher than 12.5 (Figure 3d).

All findings displayed in Figures 2 and 3 indicated that polymer PLL_{20}-g_5-PEG_5 performed best with respect to transfection efficiency and cell viability over a wide range of N/P ratios as well as in ease of synthesis. In all further experiments, PLL_{20}-g_5-PEG_5 was used to form DNA-containing condensates, and particle size distribution and storage stability were characterized.

3.3. Determination of Size and Storage Stability of PLL_{20}-g_5-PEG_5-DNA Condensates. Particle size and storage stability of PLL_{20}-g_5-PEG_5-DNA condensates formed with N/P ratio = 3.125 were determined. To investigate the diameter of the condensates as a function of the size of the condensed plasmid, four different plasmids with 3200 to 10,100 base pairs (bp) were used. The hydrodynamic diameter of the polymer−DNA condensates was measured using dynamic light scattering (DLS) at a scattering angle of 90 ° (Figure 4a). The condensates displayed a mean diameter between 90 and 110 nm independent of the plasmid size used. The size of PLL_{20}-g_5-PEG_5-DNA condensates was determined after different storage times at 4 °C by DLS and found to be stable for at least 14 days in PBS (Figure 4b). When condensates were formed between PLL_{20}-g_5-PEG_5-DNA and plasmid DNA (pEGFP-N1) at N/P ratios increasing from 3.125 to 25, the hydrodynamic diameter remained at around 90 nm (Figure 4c).

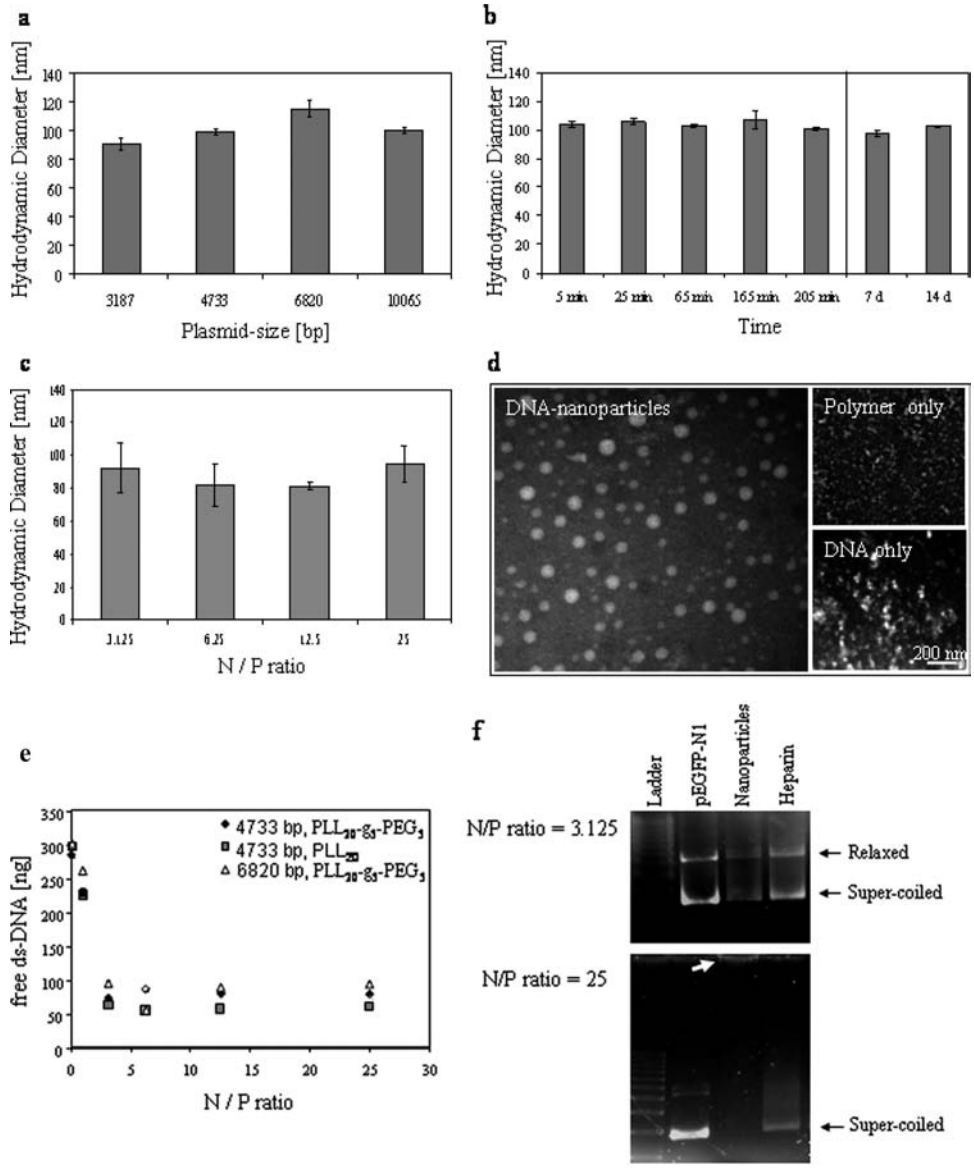

Figure 4. Size and storage stability of PLL_{20}-g_5-PEG_5-DNA condensates. (a) The size of PLL_{20}-g_5-PEG_5-DNA condensates was analyzed by dynamic light scattering. The hydrodynamic diameter of the condensates was determined as a function of the number of base pairs (bp) of the complexed plasmid DNA. PLL_{20}-g_5-PEG_5-DNA was used to form nanoparticles with an N/P ratio of 3.125 in PBS with four different plasmids: pHisTrx (3187 bp), pEGFP-N1 (4733 bp), pSV-β-galactosidase (6820 bp), and #343 (10065 bp). The data represent mean values ± SD of three independent experiments carried out in triplicate. (b) Size stability with time of PLL_{20}-g_5-PEG_5-DNA condensates formed with pEGFP-N1 (4733 bp) at an N/P ratio = 3.125 in PBS. The hydrodynamic diameter was determined during a time period of 0–14 days as indicated. The data represent the mean values ± SD of three independent experiments carried out in triplicate. (c) Hydrodynamic diameters of DNA-containing condensates formed with pEGFP-N1 (4733 bp) were determined. PLL_{20}-g_5-PEG_5-DNA condensates were formed with N/P ratios = 3.125, 6.25, 12.5, and 25 in PBS. The data represent the mean values ± SD of three independent experiments. (d) Negative stain transmission electron microscopy (TEM) images of PLL_{20}-g_5-PEG_5-DNA condensates (DNA-nanoparticles) formed with an N/P ratio of 3.125, PLL_{20}-g_5-PEG_5 polymer only (polymer only), and pEGFP-N1 plasmid only (DNA only). (e) Determination of the polymer-to-DNA ratio to form maximal condensed polymer−DNA condensates. The optimal N/P ratio between the polymers and DNA moieties was determined by PicoGreen, which binds to soluble double-stranded DNA. Polymer−DNA condensate formation was measured as a decrease in fluorescence intensity. Two different polymers, nongrafted PLL_{20} and PLL_{20}-g_5-PEG_5-DNA, were complexed with pEGFP-N1 (4733 bp). PLL_{20}-g_5-PEG_5 was also condensed with the plasmid pSV-β-galactosidase (6820 bp). N/P ratios between 0.1 and 25 were analyzed. The figure represents mean values ± SD of three independent experiments carried out in duplicate. (f) Determination of the stability of PLL_{20}-g_5-PEG_5-DNA nanoparticles formed with pEGFP-N1 (4733 bp) at N/P ratios = 3.125 and 25. Plasmid DNA was released from the nanoparticles by the addition of 750 μg of heparin separated by 1% agarose gel electrophoresis. The arrow indicates large particles in the loading slot.

To visualize the PLL_{20}-g_5-PEG_5-DNA nanoparticles, negative stain transmission electron microscopy was used. The particles were found to be spherical and homogeneously distributed, and they did not aggregate (Figure 4d). For controls, naked plasmid DNA and plain polymer were analyzed indicating that distinct DNA-containing nanoparticles form only when PLL_{20}-g_5-PEG_5 and plasmid DNA were combined.

In order to determine the polymer-to-DNA ratio for optimal DNA condensation, the interaction of PicoGreen with soluble double-stranded plasmid DNA was measured. By increasing the amount of polymer, the availability of free DNA for binding with PicoGreen was reduced as DNA was incorporated into the condensates, and a decrease in fluorescence intensity was observed. Condensates were formed between PLL_{20}-g_5-PEG_5 and plasmid pEGFP-N1 (4733 bp), and PLL_{20} and pEGFP-N1 as well as for PLL_{20}-g_5-PEG_5 and pSV-β-galactosidase (6820 bp). The N/P ratios equal to and higher than 3.125 showed maximal DNA condensation as indicated by stable low fluo-

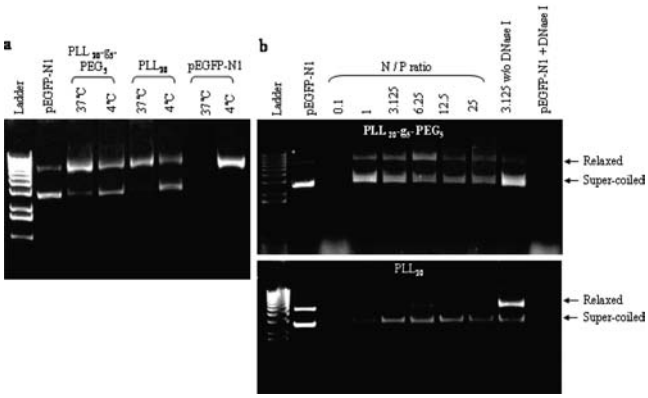

Figure 5. Serum stability of PLL_{20}-g_5-PEG_5-DNA nanoparticles and protection against DNase I digestion. (a) Stability of DNA-containing nanoparticles, consisting of PLL_{20} and PLL_{20}-g_5-PEG_5-DNA nanoparticles (formed with N/P ratio = 3.125). Particles and naked DNA were incubated for 7 days either at 4 °C or at 37 °C in 10% serum-containing tissue culture medium. DNA was released from the condensates by the addition of 15 μL of 50 mg/mL heparin and 5 μL of 5 M NaCl and separated by 1% agarose gel electrophoresis. (b) DNase I protection assay of PLL_{20}-g_5-PEG_5-DNA- and PLL_{20}-DNA-containing nanoparticles formed with different N/P ratios as indicated. Five micrograms of the pEGFP-N1 plasmid was used as a control. The nanoparticles were incubated for 10 min with 5 U DNase I, which was stopped by the addition of 0.3 M EDTA. DNA was released by 50 mg/mL heparin and 5 M NaCl addition and separated by gel electrophoresis as described above.

rescence (Figure 4e). Maximal plasmid condensation seems to be independent of the size of the incorporated plasmid as both plasmids with 4733 and 6820 bp performed equally well. These findings were in good agreement with data obtained for DLS. Furthermore, the release of plasmid DNA from the condensates was determined by heparin replacement (Figure 4f). Condensates were formed between PLL_{20}-g_5-PEG_5 and plasmid pEGFP-N1 at N/P ratios = 3.125 and 25. The DNA was released by 750 μg heparin and analyzed by agarose gel electrophoresis. Interestingly, even at such high heparin concentrations released plasmid DNA from condensates formed with N/P ratio = 25 appeared only as supercoiled structures, whereas plasmid DNA released from condensates formed at N/P ratio = 3.125 released relaxed and supercoiled plasmids to a similar extent. These findings might be relevant for transfection studies where plasmid DNA needs to be released in the nucleus to become physiologically active.

A gene delivery system should not only deliver DNA but also protect the incorporated DNA; therefore, polymer−DNA nanoparticles and naked plasmid DNA were exposed to serum components and DNase I treatment. Nanoparticles formed by PLL_{20}, PLL_{20}-g_5-PEG_5, and naked plasmid DNA were exposed to 10% fetal bovine serum (FBS) for 7 days at 4 and 37 °C, respectively (Figure 5a). Naked plasmid DNA was degraded at 37 °C, whereas DNA-containing nanoparticles formed with PLL_{20}-g_5-PEG_5 or PLL_{20} protected the incorporated plasmid DNA efficiently. In order to test the functionality of the complexes after storage at 4 and 37 °C in the presence of serum components, COS-7 cells were transfected with the nanoparticles and showed successful expression of green fluorescent protein (data not shown).

When nanoparticles formed with PLL_{20}-g_5-PEG_5 or PLL_{20} were exposed to DNase I, plasmid DNA remained intact for particles produced with N/P ratios between 1 to 25 (Figure 5b). Especially, the supercoiled form of the plasmids was preserved. Plasmid DNA was completely degraded when DNA-containing nanoparticles were formed with N/P ratio = 0.1. To confirm DNase I activity, naked DNA was completely digested during the time of the experiment. These findings suggest that plasmid DNA incorporated into the nanoparticles is protected by the structure and positive charge of PLL_{20}-g_5-PEG_5 and partially by PLL_{20} polymers.

4. DISCUSSION

Gene transfer using polymer-based DNA condensates is a promising approach for the safe delivery of therapeutic DNA in genetic and acquired human diseases. Many studies have been performed, but poor *in vivo* and *in vitro* transfection efficiencies and high cytotoxicity are still important issues (*2*, *11*, *35*). For these reasons, this project aimed to circumvent the inherent cytotoxicity of polycationic DNA condensates by forming polymer−DNA nanoparticles using grafted copolymers of poly L-lysine (PLL) and poly(ethylene glycol) (PEG). PEGylation improves the solubility and stability of PLL-g-PEG-DNA nanoparticles in watery solutions, and the steric effects of exposed PEG chains result in nanoparticles with reduced nonspecific protein adsorption as compared to charged polymer−DNA complexes (*36*). In addition, PEGylation might contribute to their cellular uptake (*23*, *25*, *31*, *37*, *38*).

Several studies using grafted PLL-g-PEG copolymers to form DNA complexes were carried out; however, a systematic analysis of the influences of PLL backbone length, the molecular weight of grafted PEG, and the amount of PEG grafting is still lacking. Here, eight different grafted PLL-g-PEG copolymers were explored for their capability to complex plasmid DNA and transfect COS-7 cells *in vitro*. The polymers were selected to have very different molecular weights of the PLL backbone (20 and 300 kDa), as low molecular weight PLL with less than 3 kDa do not form stable complexes with DNA (*26*), and very high molecular weight PLL-DNA (<700 kDa) complexes demonstrated high cytotoxicity and a tendency to aggregate and precipitate depending on the ionic strength (*39*). Here, the molecular weight of grafted PEG was 1 and 5 kDa, respectively, and no, low, and high grafting were compared. Successful gene expression combined with high cell viability (>94% living cells) was observed only when PLL was grafted with a low amount (4 or 5%) of PEG at medium N/P ratios of 3.125–12.5. The molecular weight of the PEG moieties seemed to be important (5 kDa), whereas the molecular weight of PLL did not affect transfection efficiency. Cell viability was only affected when condensates were formed at N/P ratios higher than 12.5 where low molecular weight PLL (PLL_{20}) showed lower cytotoxicity than high molecular weight PLL (PLL_{300}). However, these findings were not relevant for N/P ratios 3.125 and 6.25 where transfection efficiencies were best. Therefore, we could identify two polymers that performed best in the formation of polymer−DNA condensates, namely, PLL_{300}-g_4-PEG_5 and PLL_{20}-g_5-PEG_5. Other studies that used PLL of 20 kDa grafted with 5, 12, and 30 kDa PEG at 5 or 10% grafting ratio (*37*, *38*, *40*) demonstrated the highest cell viability and transfection efficiency for complexes formed between PLL_{20} grafted with 10% PEG of molecular weight of 5 kDa (*37*), whereas Mannistö et al. (*40*) found similar values for 20 kDa PLL grafted with 5 or 12 kDa PEG at 5% or 10% grafting. In our hands, high grafting of 20–28% PEG (1 or 5 kDa) on PLL_{20} or PLL_{300} did not show any successful transfection of COS-7 cells. These studies indicate that the equilibrium between lengths and probably the flexibility of the attached PEG moieties contribute to high transfection efficiency and stealth properties of the DNA-containing nanoparticles. Our study demonstrated that effective transfection and low cytotoxicity were correlated to a well-defined N/P ratio, which ranges from 3.125 to 12.5 for PLL_{300}-g_4-PEG_5 and from 3.125 to 6.25 for PLL_{20}-g_5-PEG_5, as polymer−DNA complexes formed with lower or higher N/P ratio did not transfect COS-7 cells. With increasing N/P ratios, especially for PLL_{300}-g_4-PEG_5, cytotoxicity increased signifi-

cantly, leaving no living cells at N/P ratio = 25. Efficiently transfecting and nontoxic polymer−DNA condensates contain 3–6 times more amino groups from PLL as compared to phosphate groups from DNA. At physiological conditions, these amino groups are positively charged and mediate maximal DNA condensation, shown here by fluorescence dye exclusion as well as cell surface attachment. These findings correlate nicely with the data of other authors that have found positive zeta potentials (∼40 mV) for condensates formed between cationic polymers and DNA (*20*, *24*, *37*, *40*).

Transfection efficiencies of PLL_{20}-g_5-PEG_5 at N/P ratio 3.125 and of PLL_{300}-g_4-PEG_5 at N/P ratio 6.25 were comparable to those of DNA complexes formed with DEAE-dextran; however, our PLL-g-PEG condensates formed at N/P ratio = 3.125 were found to be 20% less toxic. DEAE-dextran transfection is not suitable for *in vivo* applications as efficient transfection requires a toxic fusogeneic substance such as chloroquine and an osmotic shock to let the DNA condensates enter into COS-7 cells (*41*, *42*). In contrast, PLL_{20}-g_5-PEG_5 and PLL_{300}-g_4-PEG_5 might be well suited for bolus injections for DNA vaccines or other *in vivo* applications.

As PLL_{20}-g_5-PEG_5 performed best when transfection rate, cytotoxicity over a wide range of N/P ratios, and simplicity of polymer synthesis and DNA condensate production are considered, we performed our further studies with PLL_{20}-g_5-PEG_5-DNA condensates.

PLL_{20}-g_5-PEG_5-DNA condensates displayed a hydrodynamic diameter of ∼100 nm that was stable for at least 14 days. Interestingly, the diameter seems to be independent of the size of the incorporated plasmid DNA, as it remains almost constant for condensed plasmids between 3200 and 10100 bp. Values found in the literature vary between 80 to 200 nm when using standard plasmids (∼5000 bp) (*2*, *15*, *38*). When PLL_{20}-g_5-PEG_5-DNA condensates were visualized by negative stain transmission electron microscopy, particles appeared uniformly distributed and not aggregated. These findings were in accordance with our DLS measurements. Similar data were obtained for PLL_{20} grafted with 12 kDa PEG at 10% grafting when polymer−DNA complexes were analyzed by atomic force microscopy (*37*).

A particle diameter of ∼100 nm is able to circulate in the blood stream and lies within the favorable range for cellular uptake (*2*, *27*, *40*, *43*, *44*). This very interesting characteristic provides a clear advantage toward the limited packaging size of viral gene delivery systems and is an important criterion to consider when choosing such polymer−DNA condensates for further gene delivery applications. Similar studies have been performed by Mao et al. (*45*), when PEG chain length of poly(ethylene glycol) to grafted poly ethyleneimine (PEI) was analyzed for the delivery of siRNA. Their findings underline that the stability and size of the complexes are clearly influenced by the polymer-to-PEG structure, and high degrees of substitution resulted in larger, diffuse complexes that showed condensation only at high N/P ratios. Condensates formed with PEI at 25 kDa grafted with PEG at 2 kDa were very similar to the polymer structures used in our study. Condensation was complete when N/P ratios of 3 were reached. Interestingly, their polymer-to-siRNA condensates were larger in diameter (150 nm) as compared to our findings. These results might be explained by other studies that showed that siRNA, although being very short (21–23 bp), is very stiff an does not allow further condensation (*32*). However, in our study we were able to condense plasmid DNA between 3200 and 10,100 bp, which formed very homogeneous condensates between 90 and 110 nm. These findings suggest that condensation properties, capabilities, and necessities of siRNA and plasmid DNA are very different as siRNA needs to be released from the condensate already in the cytosol, whereas plasmids need to be delivered to the cell nucleus to be physiologically active (*32*). Therefore, our study selected specifically for DNA-containing nanoparticles that are stable, well condensed, nontoxic, and able to transfect cells efficiently.

As it is important for plasmid gene delivery systems to provide protection of therapeutic DNA in biological systems, for example, within the blood stream of a patient or when exposed to endogenous DNases in the vicinity of ruptured cells in a wound site, the polymer−DNA nanoparticles developed here and naked plasmid DNA were exposed to serum components at 37 and 4 °C for 7 days and to DNase I treatment in an *in vitro* setup. The DNA, incorporated in PLL_{20} and PLL_{20}-g_5-PEG_5 complexes, remained stable at 4 and 37 °C for 7 days, whereas naked DNA was degraded at 37 °C. It could be shown that polymer−DNA complexes were stable against DNase I treatment from N/P ratios 1 to 25. These findings indicate the high tolerance of PLL_{20}-g_5-PEG_5-polymer-DNA condensates against enzymatic degradation and serum proteins, which makes them suitable for direct injection into the blood stream or a wound site. These findings might be explained by reduced protein adsorption due to PEGylation of the DNA−polymer nanoparticles. Systematic studies on serum protein adsorption on differentially PEGylated-PLL adsorbed onto Nb_2O_5 surfaces demonstrated that the higher the PEG content of the surface the lower the amount of serum proteins adsorbed (*33*, *36*). Future studies might reveal a correlation between the amount of adsorbed serum proteins or DNase I on the surface of polymer−DNA nanoparticles and their stability.

5. CONCLUSIONS

In summary, the PLL-g-PEG-DNA nanoparticles used here showed excellent transfection efficiency combined with low cytotoxicity in COS-7 cells. Furthermore, we demonstrated that the PLL_{20}-g_5-PEG_5-DNA condensates displayed outstanding long-term stability that allows for their preparation a few weeks before actual use. Moreover, this study provides new insights into the rational design of novel DNA delivery vehicles that can be used to package DNA of different sizes without a change in DNA condensation, the final particle diameter, and their storage stability. All of these characteristics are advantageous compared to plasmid size limitations in viral gene delivery systems and stability issues in lipid-based gene delivery systems.

Future work will have to address surface functionalization with cell recognition and/or intracellular routing molecules as well as nuclear localization sequences (*2*, *38*, *43*, *46*). In addition, recent work with cationic polymer-based DNA delivery vehicles illustrated the importance of specific modification for cell targeting (*47*, *48*) as the treatment of many diseases could benefit from local application and transient expression of therapeutic proteins.

Received October 17, 2007; Revised Manuscript Received December 1, 2007

This study aimed to investigate the feasibility of using a cationic nonviral gene carrier in endothelial cells for enhancing gene expression by the addition of an integrin-binding RGD peptide. A 4-branched cationic polymer of poly(*N*,*N*-dimethylaminopropylacrylamide) (star vector), developed as a gene carrier, could complex with the luciferase-encoding plasmid DNA under a charge ratio of 5 (vector/pDNA) to form polymer/DNA complexes (polyplexes). The addition of the RGD-containing peptide (GRGDNP) to the polyplex solution led to a decrease in the ζ-potential from ca. +30 to +20 mV along with the reduction in the particle size from ca. 300 to 200 nm. Additionally, a marked inhibition of polyplex aggregation was observed, indicating the coating of the polyplex surface with RGD peptides. A transfection study on endothelial cells showed that the luciferase activity increased with the amount of RGD peptides added to the polyplexes and exhibited minimal cellular cytotoxicity. The transfection activity further increased when cyclic RGD peptides (RGDFV) were used; the activity with RGD peptide addition was approximately 8-fold compared to that without RGD peptide addition. Gene delivery to endothelial cells was significantly enhanced by only the addition of RGD peptides to star vector-based polyplexes.

INTRODUCTION

Cationic polymers such as poly(ethylenimine) (PEI) (*1–4*) and poly(*N*,*N*-dimethylaminopropyl acrylamide) (PDMAPAAm) (*5–8*) can generate nanoparticles by the formation of polyion complexes, i.e., "polyplexes" with DNA. These polymers are highly expected to be among the major carriers in nonviral gene delivery systems due to the many advantages they offer over viral systems (*9–13*). These advantages include blocking of specific immune responses, no restrictions in DNA size, and ease of large-scale production.

We attempted to investigate the usefulness of star-shaped cationic polymers as a base chemical structure for a novel high-performance gene carrier (*5–8*). These polymers, known as star vectors, were prepared by initiator-transfer agent-terminator (iniferter)-based living radical polymerization (*14*, *15*) of DMAPAAm, using the respective multidithiocarbamate-derivatized benzenes (multifunctional iniferters) (*5*, *7*). The gene expression efficiency was enhanced with the increase in the number of branching in COS-1 cells. Recently, it was shown that grafting of each cationic branch in the star vector with nonionic block chain resulted in a considerable improvement in the gene transfection efficiency (*7*). On the other hand, it was shown that introducing a ligand to the star vector was effective in delivering the target to specific cells. For example, for targeting resting macrophages, the star vector was incorporated with C45D18 peptide, which is an oligopeptide with an active site derived from Vpr of human immunodeficiency virus type-1 (*6*).

The vitronectin receptor $\alpha_V\beta_3$ is highly upregulated in endothelial cells of tumors, while it is minimally expressed in resting or normal blood vessels (*16*). The tripeptide sequence, arginine (Arg)-glycine (Gly)-aspartic acid (Asp) (RGD) found in the active site of vitronectin binds to $\alpha_V\beta_3$ and almost half of the 22 known integrins (*17*). RGD peptides are exploited for cell entry by pathogenic microorganisms such as the foot-and-mouth disease virus (*18*). A great advantage of integrin targeting is that internalization occurs by a "zippering" mechanism (*19*) that allows the uptake of relatively large structures such as bacteria. Therefore, several cationic polymer vectors combined with RGD peptides were developed for tumor-targeted gene delivery (*20–23*). For example, RGD-containing peptides were coupled with PEI with or without a PEG spacer. The RGD-modified PEI showed a significant increase in transfection efficiency as compared to only PEI in endothelial cells. Almost all RGD-mediated gene delivery systems have been described with the chemical derivatization of RGD peptides to vector compounds.

In this paper, we report the influence of the addition of RGD to star vector-based polyplexes on the physicochemical and biological properties of the polyplexes that comprised plasmid DNA and 4-branched cationic star vector with a molecular weight of ca. 18 000. As a model, an RGD-containing peptide GRGDNP and cyclic RGD peptides were used. We strongly believed that if the coating of the polyplex surface with the RGD peptides occurs only by the addition of these peptides, then the gene transfection efficiency to endothelial cells would be enhanced, similar to that in the case of chemical derivatization of the RGD peptides.

MATERIALS AND METHODS

Materials. RGD-containing peptide (GRGDNP) was purchased from Wako Pure Chemical Industry (Osaka, Japan) and cyclic RGD peptide (RGDFV) were from Peptide Institute, Inc. (Osaka, Japan).

Synthesis of Cationic 4-Branched Polymer. The cationic 4-branched polymer, 1,2,4,5-tetrakis(*N*,*N*-diethyldithiocarbamyl(poly(*N*-[3-(dimethylamino)propyl]acrylamide)benzene was synthesized by iniferter-based living radical photopolymerization from 1,2,4,5-tetrakis(*N*,*N*-diethyldithiocarbamylmethyl)benzene

as a multifunctional iniferter with DMAPAAm as cationic monomer, according to the method previously reported by us (*5, 7*). Brifely, to 6 mL of a benzene solution of 1,2,4,5-tetrakis(*N,N*-diethyldithiocarbamylmethyl)benzene (72 mg, 0.1 mmol) DMAPAAm (72 mg, 0.1 mmol) was added; this was diluted to a final volume of 20 mL with methanol and placed into a 50-mL quartz crystal tube. After bubbling with dry N_2 gas for 5 min to exclude air, the solution was irradiated for 90 min with a 200-W high-pressure mercury lamp (SPOT CURE; USHIO, Tokyo, Japan) under an N_2 atmosphere at room temperature. The light intensity was set to 1 mW/cm^2 at a wavelength of 250 nm (UVR-1; TOPCON, Tokyo, Japan). The reaction mixture was concentrated and adjusted to an appropriate concentration in order to facilitate purification by precipitation in a large volume of ether. Reprecipitation was carried out in a methanol−ether system. The final precipitate was dried under vacuum to yield a PDMAPAAm 4-branched polymer (conversion, 13%). The molecular weight (Mn) as determined by GPC analysis was 18 000 g·mol^{-1}. ^{1}H NMR: δ 1.7–1.5 (br, 3H, -C$\underline{H}_2$-CH- and -CH$_2$-C$\underline{H}_2$-CH$_2$-), 2.0–1.8 (br, 1H, -C$\underline{H}$-CO), 2.2–2.1 (br, 6H, -N-C$\underline{H}_3$), 2.4–2.2 (br, 2H, -C$\underline{H}_2$-N(CH$_3$)$_2$), 3.2–3.0 (br, 2H, -NH-C$\underline{H}_2$-), 7.8–7.4 (br, 1H, -NH).

Preparation of Polyplexes. The cationic 4-branched polymer was dissolved in a saline solution. Aliquots of these solutions (60 μL) were added to the plasmid DNA (pGL3-control) dissolved in 90 μL of Tris-HCl buffer (pH 7.4) to obtain polymer/DNA ratios of 5 or 10, which correspond to cation/anion (C/A) ratios. The solutions (total volume, 150 μL; plasmid concentration, 20 mg/mL) were mixed using a pipet. After 10 min of complex formation, 25 μL of the complex solutions were added into each well of 24-well plates for transfection (the amount of DNA added to a well, 0.5 μg/well).

Biophysical Characterization of Polyplexes. The ζ-potentials and mean diameters of the polyplexes in a saline solution having the same concentration that was used for transfection at a C/A ratio of 5 were determined by employing DLS on an ELS-8000 system (Otuska Co., Osaka, Japan) equipped with a 10-mW He-Ne laser.

***In Vitro* Transfection and Cell Viability Assays.** COS-1 cells (approximately 3 × 10^4 cells per well) were seeded prior to treatment in 24-well plates and grown for 24 h in DMEM (Gibco, Invitrogen Corp., Carlsbad, CA) containing 10% fetal calf serum (Hyclone Laboratories Inc., Logan, UT), penicillin (200 units/mL; ICN Biomedicals Inc., Aurora, OH), and streptomycin (200 mg/mL; ICN) in an atmosphere of 5% CO_2 at 37 °C. Transfections were performed with 0.5 μg of the DNA in 24-well plates in 0.2 mL of OPTI-MEM I (Gibco). After 3 h of incubation, the cells were washed once with PBS(−) and cultured in 1 mL of DMEM containing 10% fetal calf serum for an additional 48 h. The medium was removed and the cells were washed twice with PBS(−). The cells were lysed with 0.2 mL of cell lysis buffer (Promega, Madison, WI) and mixed by vortexing. The lysate was centrifuged at 15 000 rpm for 1 min at 4 °C and 5 μL of the supernatant was analyzed for luciferase activity using a Luminous CT-9000D (Dia-Iatron, Tokyo, Japan) luminometer. The relative light unit/s (RLU) were converted into the amount of luciferase (pg) using a luciferase standard curve, which was obtained by diluting recombinant luciferase (Promega) in lysis buffer. The protein concentrations of cell lysates were measured by performing a Bio-Rad protein assay (BIO-RAD, Hercules, CA) using bovine serum albumin as a standard. The expressed luciferase represented the amount (mole quantity), which is standardized for the total protein content of the cell lysate. The data are presented as means ± SD (n = 5).

Cytotoxicity was assessed by performing a cell viability assay using the WST-8 method (Dojindo, Kumamoto, Japan). COS-1 cells were seeded 24 h prior to treatment in 96-well plates at 5000 cells per well. Cells were treated under the same conditions used for luciferase assay with 6.2 μL of the transfection mixture including 0.124 μg of pDNA added to each well. They were treated under appropriate conditions for 3 h, washed once with PBS, and cultured in 50 μL of DMEM (Gibco) containing 10% fetal calf serum for an additional 24 h. To each well, 10 μL of WST-8 reagent (5 mmol/l) was added. After 2 h of incubation at 37 °C, absorbance at 450 nm was read in a BIO-RAD microplate reader (model 680). The data are presented as means ± SD (n = 5).

RESULTS AND DISCUSSION

Interaction of Polyplex and RGD Peptide. The cationic 4-branched polymer with a molecular weight of ca. 18 000 was prepared by iniferter-based living radical polymerization (*5, 7*). The polymer had an extremely low polydispersity of less than 1.7. When the saline solution of cationic 4-branched polymer (7.9 μg/60 μL) was mixed with a tris-HCl buffer of luciferase-encoding pDNA (3 μg/90 μL) under a charge ratio of 5 (polymer/DNA), polyplexes in the form of approximately 300-nm nanoparticles were formed by electrostatic affinity (Figures 1, 2); this observation was similar to that of our previous study (*5, 7*).

First, we evaluated the interaction between the polyplexes and GRGDNP by measuring the change in the particle size. When the solution of the polyplexes, which were formed by mixing the polymer and the pDNA, was allowed to stand at 37 °C, the particle size significantly increased with time due to the aggregation of the polyplexes (Figure 2). The nanosized particles became microsized ones within 10 min. On the other hand, when the saline solution of RGD peptide was added to the polyplex solution immediately after preparation, the size of polyplexes reduced to approximately 200 nm. When the obtained polyplex solution was allowed to stand at 37 °C, the aggregation of the polyplexes was prevented depending on the amount of RDG peptide added. This indicated the interaction between the RGD peptide and the polyplexes. The saturation of the prevention effect was observed at approximately 30 μg.

To examine the surface electric property of the polyplexes, their ζ-potential in the presence or absence of RGD peptide

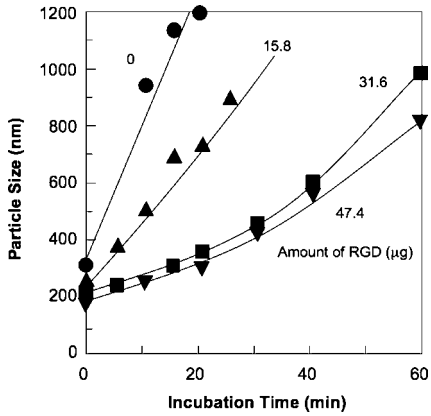

Figure 2. Incubation time-dependent cumulant diameter changes in aqueous solutions of polyplexes prepared by mixing DNA (pGL3-control, 3 μg) and PDMAPAAm 4-branched polymer (star vector, 7.9 μg) under a charge ratio of 5 at pH 7.4 in the presence of RGD peptides, whose amounts ranged from 0 to 47.7 μg.

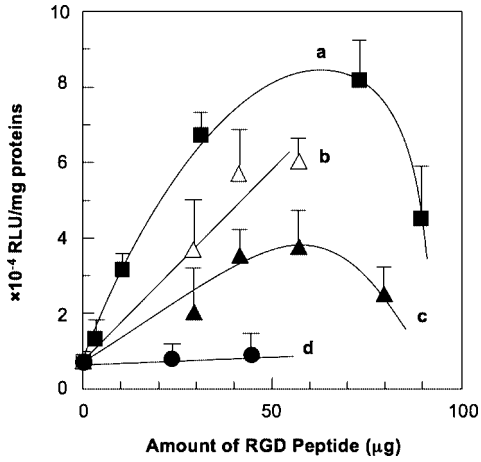

Figure 3. Transfection efficiency to endothelial cells of the polyplexes prepared by mixing DNA (pGL3-control, 3 μg) and PDMAPAAm 4-branched polymer (star vector, 7.9 μg) under a charge ratio of 5 in the presence of GRGDNP peptides (**b**, **c**, **d**) or cyclic RGD peptide (**a**) under charge ratio of 5 (vector/pDNA) in **a**, **c**, and **d**, or 10 in **b**. The RGD peptide was added before contact of the polyplexes with the endothelial cells (**c**).

was measured using DLS. In the RGD peptide-free polyplexes, the ζ-potential was approximately +30 mV, whereas it was decreased to approximately +20 mV after the addition of the RGD peptide (47.4 μg). The reduced surface potential might be due to the coating of the polyplex surface with the peptide. Although the driving force for the binding between the polyplexes with a positive charge and the RGD peptide with a lower electrical potential is still unknown, it was estimated that the surface coating occurred due to a physical interaction such as adsorption of the RGD peptide on the polyplexes without any chemical binding. These particle size and ζ-potential data lead to the conclusion that the aggregation of the polyplexes was prevented by the coating of the polyplexes with the RGD peptide in order to reduce the positive charge of the surface and to use almost all of the 30 μg of the RGD peptide added. The amount was about 4 times of that of cationic polymer used to form the polyplexes completely.

***In Vitro* Transfection Efficiency.** The gene transfection efficiency of the polyplexes coated or not coated with the RGD peptide was tested on model cell line of mice vascular endothelial cells (ECs). The result is summarized in Figure 3. The cells transfected with the luciferase-encoding plasmid (pGL3) in the absence of the RGD peptide exhibited a low luciferase expression, whereas those transfected with polyplexes + RGD peptide exhibited a higher luciferase expression and this expression increased with the amount of RGD peptide added (curve **c** in Figure 3). Upon an increase in C/A ratio from 5 to 10 further increase in the luciferase expression was observed (curve **b** in Figure 3). The highest luciferase expression occurred when approximately 50 μg RGD peptide was added. However, further addition of the RGD peptide led to a decrease in the luciferase expression.

The enhancement of luciferase expression by the addition of the RGD peptide was considered to be due to 2 major reasons—the stabilization of the polyplex particles and the RGD-mediated internalization of the polyplexes into the cells. The DNA expression observed using polyplexes occurred via the following 5 sequential steps: (1) attachment of the polyplexes onto the cell surface, (2) internalization of the polyplexes into the cell, (3) endosomal escape of polyplexes, (4) DNA release from polyplexes, and (5) internalization of the DNA into the nucleus. Almost all of the cationic polymers, including PEI, can conjugate with DNA to form nanosized polyplexes by an electrostatic affinity immediately after mixing. However, the polyplexes gradually aggregate with the increase in incubation time to grow from nanosized to macrosized particles by a similar electrostatic affinity, as demonstrated in Figure 2. In general, it was reported that the transfection efficiency was low in large particles because such particles could not easily internalize into the cells, which is the above-mentioned second step. In this study, indeed, polyplex particles became stable by the addition of the RGD peptide and synchronously, the transfection efficiency increased. However, the enhancement of gene transfection by the stabilization effect of the polyplex particles was eliminated by the following experiment.

When approximately 50 μg of RGD peptide was added to the cultured cells before the addition of the solution containing the RGD peptide-coated polyplexes, little change in the luciferase expression was observed (curve **d** in Figure 3). This indicated that little internalization of the polyplexes into the cells occurred even by polyplex stabilization. The reason for such an observation was considered to be that integrin receptors on the cellular membrane were capped and as a result little polyplex was recognized by the cells. Therefore, we believed that the enhancement of the gene transfection efficiency was due to the RGD-mediated internalization. The changes in cellular morphology and motility were not noticed even after RGD capping of integrin receptors within our observation period including medium change after 3 h of incubation with the polyplexes, although it was reported that integrins regulate several cellular functions including cell migration, growth, and differentiation (*25*, *26*).

On the other hand, when cyclic RGD (cRGD) peptide was added to the polyplexes, a further increase in gene transfection efficiency was observed (curve **a** in Figure 3). Cyclization of the RGD peptides is known to increase receptor affinity and selectivity by providing a conformational restraint (*17*). In addition, we observed that compared to the noncyclic RGD peptide, the use of the cRGD peptide increased the gene transfection efficiency by approximately 3 times. For both RGD and cRGD peptides, excessive addition of the peptides led to a decrease in the transfection efficiency. From the result presented in Figure 2, the amount of RGD peptide required for completely coating the polyplexes was approximately 30–50 μg. The surplus amount of RGD peptide might bind to the integrin receptor and prevent binding with the RGD peptide coating the polyplexes.

Cytotoxicity of Polyplexes with RGD Peptide. By using the WST-8 assay, the *in vitro* cytotoxicity of the RGD-added polyplexes for the EC cells was studied as a function of the amount of the RGD peptide added. The polyplexes with a charge

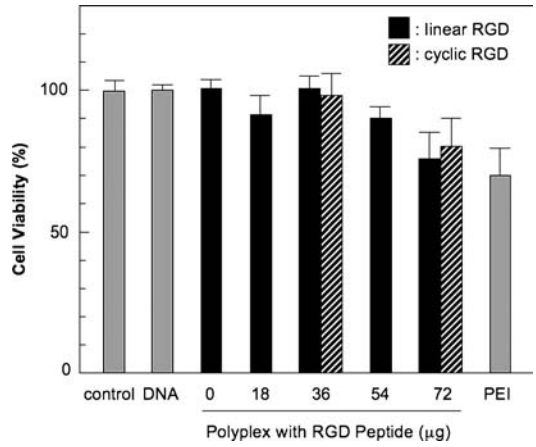

Figure 4. Cytotoxicity of the polyplexes prepared by mixing DNA (pGL3-control, 3 μg) and PDMAPAAm 4-branched polymer (star vector, 7.9 μg) when different amount of linear RGD or cyclic RGD peptides are added. For comparison, the cytotoxicity data of polyplexes of linear PEI (ExGen 500) at the charge ratio of 5 are also provided. Cell viability was determined by the WST assay.

ratio of 5 exhibited little toxicity (Figure 4). The addition of up to approximately 40 μg of RGD peptide also demonstrated little toxicity. At higher amounts of RGD peptide (72 μg), permissible viability, which was higher than that with PEI at a charge ratio of 6, was observed. Very low cytotoxicity was also demonstrated in cRGD peptide (Figure 4). There was little difference in cytotoxicity between RGD and cRGD peptides.

CONCLUSIONS

Our study is the first to report that cationic polymer-based gene transfer to EC cells is markedly enhanced in the presence of the RGD peptide. This peptide was only added to the solution of the polyplexes, which was prepared by mixing the cationic polymer and pDNA, without derivatization of the peptide to the polymer by chemical binding, as demonstrated in almost all other reports. The enhancement of gene transfer by the addition of the RGD peptide may be applied even for other cationic polymer vectors because the RGD peptide could coat the cationic surface of the polyplexes. The surface coating ability may be enhanced by the introduction of anionic amino acids such as aspartic acid or glutamic acid to the RGD peptide.

TECHNICAL NOTES

Effect of Ligand Density on the Spectral, Physical, and Biological Characteristics of CdSe/ZnS Quantum Dots

Samuel J. Clarke,[†] C. A. Hollmann,[†] Faisal A. Aldaye,[‡] and Jay L. Nadeau*[,†]

Department of Biomedical Engineering, McGill University, Montreal, QC Canada H3A 2B4, Department of Chemistry, McGill University, Montreal, QC Canada H3A 2K6. Received March 8, 2007

Chemical modification of the surface of CdSe/ZnS quantum dots (QDs) with small molecules or functional ligands often alters the characteristics of these particles. For instance, dopamine conjugation quenches the fluorescence of the QDs, which is a property that can be exploited for sensing applications if the conjugates are taken up into living cells. However, different sizes and/or preparations of mercaptocarboxylic acid solubilized QDs show very different properties when incubated with cells. It is unknown what physical parameters determine a QDs ability to interact with a cell surface, be endocytosed, escape from endosomes, and/or enter the nucleus. In this study, we examine the surface chemistry of QD−dopamine conjugates and present an optimized method for tracking the attachment of small biomolecules to the surface. It is found that the fluorescence intensity, surface charge, colloidal stability, and biological interactions of the QDs vary as a function of the density of dopamine on the surface. Successful targeting of QD−dopamine to dopamine receptor positive PC12 cells correlates with greater homogeneity of particle thiol layer, and a minimum number of ligands required for specific association can be estimated. These results will enable users to develop methods for screening QD conjugates for biological activity before proceeding to experiments with cell lines and animals.

INTRODUCTION

Quantum dots (QDs) are growing in popularity for use in biological systems. A survey of recent scientific literature is a testimony to the enormous research effort devoted to these types of studies (for reviews, see *1–5*). Part of the reason for the immense popularity of QDs, and to a lesser extent other nanoparticles (NPs), is that their unique optical properties are vastly superior to the properties of more conventional biological fluorophores. Indeed, the wide absorption spectrum, narrow emission, and large extinction coefficients are some of the most attractive characteristics. There has been much work toward engineering stable QD coatings that are biologically compatible and that possess a high number of functional groups such as amino (*6*), hydroxyl (*7*), carboxyl (*8*), and thiol (*9*). Despite this, most of these functionalization strategies increase the hydrodynamic radius of the particles by an order of magnitude, significantly lower the quantum yield, or are appropriate only for certain types of particles (e.g., cysteamine is stable on CdTe particles but not on CdSe/ZnS).

In our work, we have used short chain thiol-terminated molecules in order to preserve the small intrinsic size of the particles and their ability to transfer energy and electrons to neighboring or covalently bound molecules (*10–12*). These minimally passivated particles are extremely environmentally sensitive in ways that are potentially useful, such as in their ability to indicate cellular redox potential (*13*). However, this sensitivity also means that great variability is seen among different sizes of QDs, different synthetic batches, and among different bioconjugation reactions. Such variability makes biological experiments often "hit or miss" and leads to loss of time and costly reagents. We have chosen the ligand dopamine (DA) and its receptor as a model system to evaluate the effect of the conjugation of DA to QDs and the resulting biological activity of the functionalized particles. The primary amino reactive compound *o*-phthaldialdehyde (OPA) is used to quantify the number of dopamine (DA) ligands that can be bound to QDs of different sizes and under different incubation conditions. The relationship between ligand density and efficient cellular association is established, providing guidelines for the number of ligands needed to create a high-affinity small-molecule−QD conjugate. These results demonstrate the usefulness of this protocol to characterize QD conjugates before they are used in biological experiments.

EXPERIMENTAL SECTION

Chemicals. All chemicals were of the highest grade available and were purchased from Sigma-Aldrich Canada unless otherwise noted. Solvents were purchased from Fisher Scientific. Sodium phosphate buffer was used at a final reaction concentration of 50 mM at pH 7.2.

Synthesis of QDs. CdSe/ZnS QDs were synthesized using a method adapted from Asokan et al. (*14*), and based on the noncoordinating solvent 1-octadecene (ODE). Briefly, 0.05 g of cadmium oxide (CdO) and 2 mL oleic acid (OA) were added to a three-neck flask containing 20 mL of ODE. This mixed was degassed and heated under an atmosphere of nitrogen to 250 °C. The mixture turned colorless around 150 °C. The

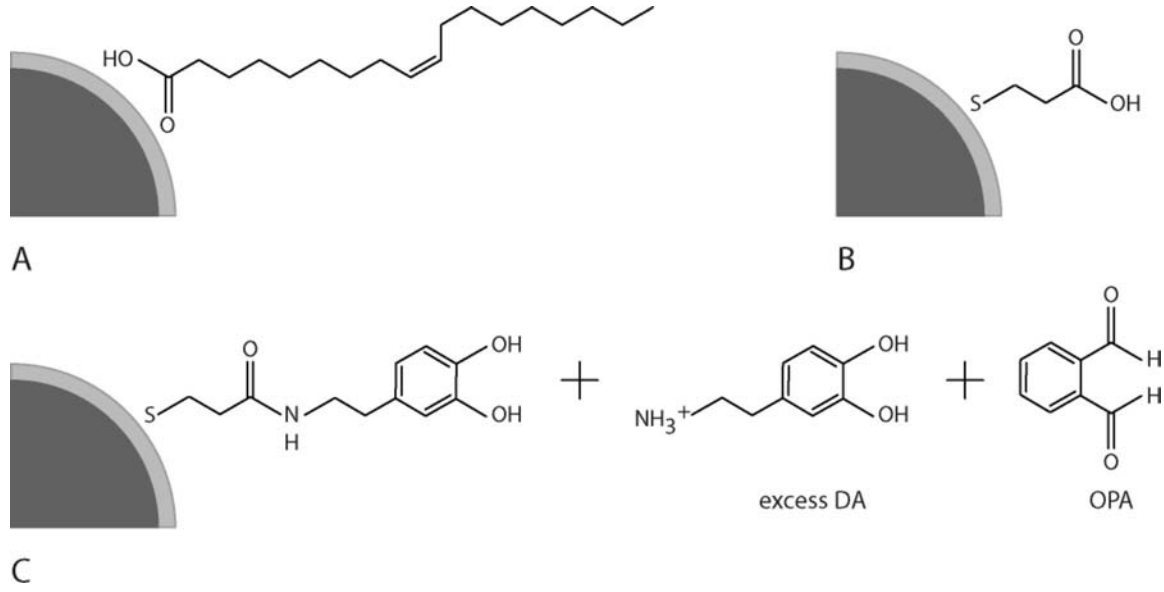

Figure 1. QD modification scheme. (A) As-synthesized QDs are stabilized with hydrophobic OA ligands. (B) A thiol-exchange reaction replaces the OA with hydrophilic MPA ligands. (C) DA is attached to the QDs through an EDC-mediated coupling reaction. OPA reacts with the free amines of unreacted dopamine and forms a fluorescent moiety that can be quantified through spectrometry and used to determine the extent of surface modification.

selenium (Se) precursor was prepared by mixing 0.016 g of Se with 0.75 mL trioctylphoshine (TOP), under inert atmosphere, followed by sonication until the solution became transparent. The zinc sulfide (ZnS) precursors were prepared as follows: 0.75 mL of TOP was combined with 0.2 mL hexamethyldisilathiane [$(TMS)_2S$] and 0.3 mL dimethylzinc [$Zn(CH_3)_2$] under inert atmosphere and diluted to 5 mL with ODE. Once the CdO/OA/ODE mixture reached 250 °C, the heat was turned off, and the Se precursor was injected rapidly using a needled syringe. The ZnS precursor was injected over a time course of 5 min during the desired stage of QD growth. Afterward, the temperature was allowed to drop to 100 °C and it was maintained at this temperature for several hours. To purify the quantum dots, repeated extractions with equivolume hexanes/methanol were performed. The purified QDs were finally stored in the ODE/hexanes phase until further use.

Mercaptocarboxylic Acid Functionalization of QDs. Mercaptopropionic acid (MPA) was used to replace the OA surfactant by a thiol-exchange reaction. One milliliter of concentrated QDs (OD > 5 at first exciton peak) in ODE/hexanes was diluted to 5 mL using methanol. MPA was added to a final concentration of 1 M and the pH was adjusted to 10 using tetramethylammonium hydroxide pentahydrate (TMAH). This solution was stirred at room temperature for 72 h. The thiol-modified QDs were separated from excess MPA ligand by precipitation and several washings with ethyl acetate. The QDs were dried at room temperature for several hours under air and resuspended in Milli-Q water (Millipore).

EDC Coupling of Dopamine. Dopamine hydrochloride (DA) was coupled to the QDs by a 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC) mediated reaction. During a typical reaction, QDs in water were dialyzed against phosphate buffer for 1 h and diluted to a final concentration of 1 μM in 20 mM phosphate buffer. EDC and DA were added to the reaction mixture at a final ratio of 5000:1000:1 (EDC:DA:QD). These numbers are typical, as we varied the ratio of EDC in order to obtain different levels of QD modification. Reactions were performed under inert atmosphere or ascorbic acid (AA) was added to the reaction solution at an equivalent ratio to the DA to prevent the autoxidation of DA. The mixture was reacted for 30 min under gentle shaking and purified from excess DA and EDC side products by precipitation with THF and resuspension in phosphate buffer.

Quantum Yield Estimation. Quantum yields (QY) were obtained by comparing the integrated emission value of the QDs to a standard dye, Rhodamine 6G (QY = 0.95) in ethanol. The sample absorbance were matched to 0.030 ± 0.003 at the excitation wavelength of 480 nm. The concentrations of our QD solutions were determined from published (*15*) extinction coefficients based on the CdSe core.

Gel Electrophoresis. Gel electrophoresis was performed on 0.5% agarose gels in 0.5× TAE buffer (20 mM Tris, 20 mM acetate, 0.5 mM EDTA, pH 8.3). QD samples were diluted to 100 nM in 3% glycerol loading buffer immediately before use. A 20 V/cm electric field was applied for 20 s followed by 10 V/cm electric field for 15 min. Gels were imaged by fluorescence detection using a model 120 Electrophorisis Analysis System (Kodak, Rochester, NY).

OPA Assay. An *o*-phthaldialdehyde (OPA) stock solution was prepared by dissolving 1 mg/mL of OPA in phosphate buffer and the addition of 2 μL/mL β-mercaptoethanol (βME). The assay was adapted for use in a 96 well microplate by mixing 250 μL of OPA stock with 25 μL of the desired sample and allowing the solution to react for 1 min. Emission spectra were excited at 350 nm and collected at 460 nm. In order to calculate the amount of bound DA to each of the NPs surface, control experiments with no EDC were conducted and compared to equivalent reactions containing EDC (Figure 2). The difference in fluorescence intensity from the OPA reagent was used to calculate the number of bound DA to the particle surface. Controls for interference from the QDs and EDC showed negligible interactions or quenching (Supporting Information Figure S1).

Cell Culture and Treatment. PC12 cells with D2 DA receptors were a generous gift from Stuart Sealfon, Mount Sinai School of Medicine. The cells were confirmed to have D2 receptors by immunofluorescence staining (available in Supporting Information Figure S2). PC12 cells were maintained at 37 °C /5% CO_2 in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 5% fetal bovine serum and 10% horse serum with 500 μg/mL G418, 100 U/mL penicillin, 100 μg/mL streptomycin, and 2 mM L-glutamine. Control cells

Table 1. Quantum Dot Parameters

	quantum yield (%)			
sample	oleic acid	MPA	diameter (nm)	extinction coefficient (*15*)
QD560	36.1	19.3	3.21 ± 0.21	87 600
QD600	26.2	5.7	4.68 ± 0.54	230 000

without dopamine receptors were HEK293T cells, mouse A9 epithelial cells, and 3T3 fibroblasts. Control cell lines were maintained at 37 °C/5% CO_2 in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% fetal bovine serum, 100 U/mL penicillin, 100 μg/mL streptomycin, and 2 mM L-glutamine.

For QD labeling experiments, the cell medium was replaced with Optimem serum-free medium. QDs were added to the cells at a concentration of 5 nM. Cells were incubated for 45 min at 37 °C/5% CO_2. Before analysis, cells were washed extensively with phosphate buffered saline (PBS) pH 7.4 and imaged in PBS.

Spectroscopy and Microscopy. Absorbance and emission spectra were recorded on SpectraMax Plus and SpectraMax Gemini readers from Molecular Devices. Cells were examined and imaged with an Olympus IX-71 microscope and a Nuance multispectral imaging system. The objective lens was a Nikon LCPlanF 40× (NA = 0.60). UV illumination was through a "quantum dot" filter cube set (excitation = 380–460 nm, dichroic = 475 nm, emission = 500 LP).

RESULTS AND DISCUSSION

Properties of QDs and Degree of Surface Passivation. Synthesis of CdSe/ZnS QDs using the solvent ODE is advantageous over methods that use trioctylphoshine oxide (TOPO) (*14*). This is because TOPO is a waxy solid at room temperature, complicating preparative and purification steps. The combination of OA and ODE provide a safer and easier synthetic route that yields high-quality QDs with OA as the surfactant (Figure 1A). In this work, we prepared two distinct batches of QDs with emission maxima at 560 and 600 nm, denoted as QD560 and QD600, with QY values of >25% in organic solvent (Table 1).

Specific association of a QD probe with target cells depends on numerous factors, which include both efficiency of specific binding (receptor–ligand interactions) and reduction in nonspecific binding. Nonspecific binding of QDs is a problem that has been poorly addressed, particularly because uptake of nonfunctionalized QDs is sometimes desired. However, in order to target specific cell populations such as cancer cells (*16*, *3*), uptake of QDs without a targeting ligand is undesirable. Our hypothesis in this work is that the specificity of the QD probe to its target is related to the number of available functionalized groups on the QD particle surface and also the degree of thiol layer homogeneity. Historically these parameters have not been measured or controlled for in QD experiments.

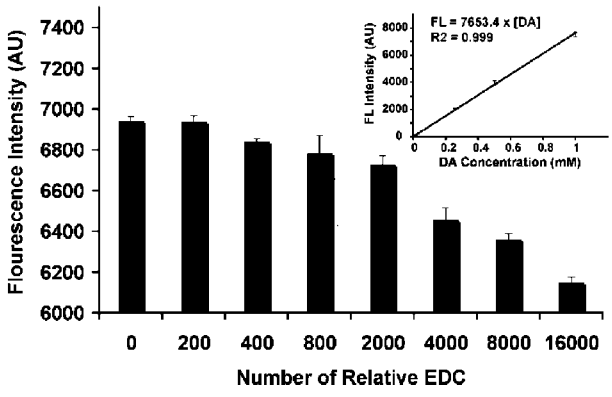

Figure 2. Reaction of QD600-DA with OPA. For a fixed ratio of QD:DA (1:2500), increasing levels of EDC lead to a reduction in OPA intensity due to covalent binding of the DA to the surface of the QDs. Inset: The fluorescent emission of OPA increases linearly with the amount of DA in solution. Data are an average of four experiments with error bars indicating the standard error of the mean.

We found that ligand exchange reactions with MPA for at least 72 h were required to reduce nonspecific binding. Replacement of the OA surfactant with MPA (Figure 1B) resulted in a significant reduction in quantum yields due to hole-trapping (46.5% for QD560 and 78.2% for QD600, Table 1) on the thiols (*17*) without significant changes in peak location or shape (absorbance and emission spectra are available in Supporting Information Figure S3). This reduction in brightness was also correlated with lack of nonspecific binding to all cell lines tested (293T, 3T3, A9, and PC12). QDs showing <90% reduction in QY, or solubilized for less than 72 h, showed extensive binding to cell membranes with formation of large clusters, typical of nonspecific adhesion (*13*) (Supporting Information Figure S5). These results indicate the importance of a well-passivated, homogeneous surfaces before the binding of biomolecules to the QDs. It is likely that the hydrophobic ligands (in this case OA) were not completely displaced; a residual fraction of the original surfactant remains on the surface of the nanoparticle during most ligand-exchange reactions (*18*). However, after sufficient reaction time (i.e., 72 h) it is assumed that a few enough of such ligands remain so that adhesion of the long carbon chains to the cell's membrane is minimized.

Surface Modification by Dopamine. Carbodiimide based reactions are useful zero-length cross-linkers that form amino-reactive intermediates on carboxylate groups (*19*). EDC reagents have been particularly popular for cross-linking NPs to a range of biomolecules. Despite its widespread use, there is a lack of techniques for the assessment of the reaction product that are bound to particles. UV–vis absorption measurements can be used to qualitatively assess molecules bound to a particle surface (*20*, *21*). However, a drawback of absorbance measurements is that many small molecules do not absorb light sufficiently in order to qualify for this analysis.

We have used the compound OPA to characterize several aspects of the EDC reaction. OPA in the presence of βME reacts rapidly with primary amino groups in order to form highly fluorescent products. Ninhydrin and fluorescamine reagents have a similar reactivity toward primary amines, but OPA is more stable in aqueous solution and more sensitive (*22*). Rosenthal and co-workers (*23*) have used fluorescamine to characterize the binding of poly(ethylene glycol) (PEG) to commercially produced amphiphilic QDs. For assays that contain QDs, OPA has an additional advantage over colormetric measures. QDs absorb strongly in the visible range and are likely to interfere with these reagents. The fluorescence emission of OPA is in the blue region (ca. 460 nm) and sufficiently far away from the emission of the QDs in this study (ca. >560 nm) to avoid interference. Because DA contains a primary amine, it causes OPA to react and fluoresce with an intensity that is linear in emission intensity over a wide range. For our experimental setup, the emission was linear over the range 0–1 mM DA (inset, Figure 2). Thus, in order to estimate the number of DA molecules that bound to the QDs, OPA was reacted with the coupling reaction in the presence and absence of EDC. As expected, there was a reduction in the intensity of the OPA signal in the presence of EDC resulting from the conversion of the DA amino groups to an amide bond with the carboxylate group on MPA (Figure 2). The amount by which the OPA signal

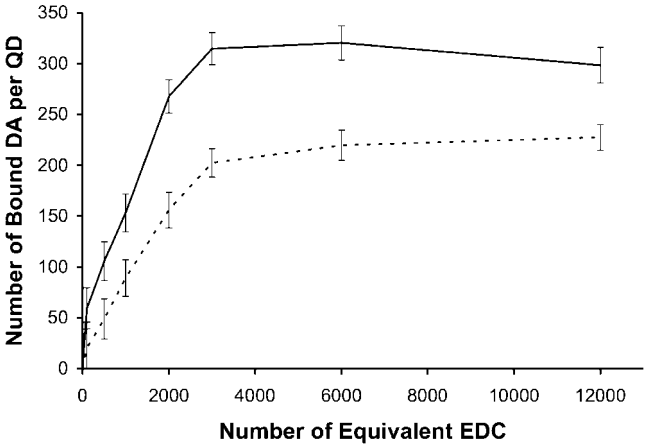

Figure 3. Number of bound DA molecules as a function of the number of equivalent EDC molecules added to the coupling reaction for QD560 (dashed line) and QD600 (solid line) as measured by OPA assay. Data are an average of four experiments with error bars indicating the standard error of the mean.

difference from the EDC negative samples was used to calculate the number of DA ligands that have bound to the surface of the QDs.

The relationship between the relative number of EDC molecules, in the reaction, along with the number of DA molecules that are bound to the QDs is depicted in Figure 3. A similar trend for both QD560 and QD600 is observed. The number of bound DA ligands increases almost linearly with the number of EDC molecules added to the reaction until a plateau is reached. The plateau can be interpreted as a saturation of the available carboxylate groups on the QD surface with DA and this is an indirect measure of the number of carboxylate groups that occupy the surface of the QD. In these calculations, the error reported along with the estimation of bound DA is related to the variation of the OPA reagent rather than an actual distribution of modification within the sample.

If the QD is modeled as a sphere using the TEM sizing parameters (Table 1 and Supporting Information Figure S4), the surface area of QD560 and QD600 are 32.35 nm^2 and 68.77 nm^2, respectively. Since the sulfur group on a short-chain thiol has a molecular area of 0.025 nm^2 (*24*), QD560 has a theoretical capacity to bind approximately 647 MPA molecules and QD600 has a capacity for 1375 MPA molecules on the surface of the particle through Zn−S bonds. Our results from Figure 3 suggest that the number of available MPA molecules on the surface of the QDs is considerably lower than what the physical size permits. There are a number of reasons to account for this. The conformation of the MPA molecule on the surface of the QD may not always have its carboxylate group oriented in a position that is favorable or accessible for reaction with the EDC molecule. Steric limitations can be excluded, as both the DA and EDC molecules are small and unlikely to hinder the reaction based on their size. Surface defects are present on the surface of QDs and since larger particles have a higher number of surface defects (*25*) this may explain why the larger red QD600 has a lower density of MPA molecules to surface area than the green QD560. Finally, the accuracy of our method to calculate the QD concentration cannot be eliminated as a source of error. This absorbance-based method is widely used and is based on published extinction coefficients (*15*).

Interestingly, the most heavily modified particles (ca. 200 DA molecules for QD560 and ca. 300 DA molecules for QD600) were not as stable as those with only partial modification and these particles visibility precipitated out of solution after a short time. MPA passivated QDs are stabilized in solution by the negatively charged carboxylate groups on the surface of the

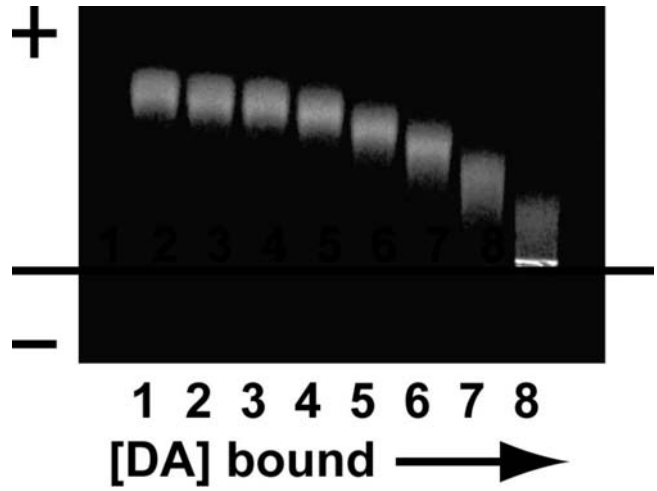

Figure 4. Agarose gel electrophoresis showing the change in QD600 surface charge with increasing levels of bound DA. Lane 1, 0; lane 2, 1.0 ± 4.9; lane 3, 28.8 ± 3.2; lane 4, 45.1 ± 12.4; lane 5, 61.6 ± 6.7; lane 6, 139.6 ± 8.9l; lane 7, 167.4 ± 4.9; lane 8, 228.1 ± 4.4. Loss of stability correlates with broadening of the gel band and aggregation (particles remain in the loading well). The horizontal black line indicates the loading postion.

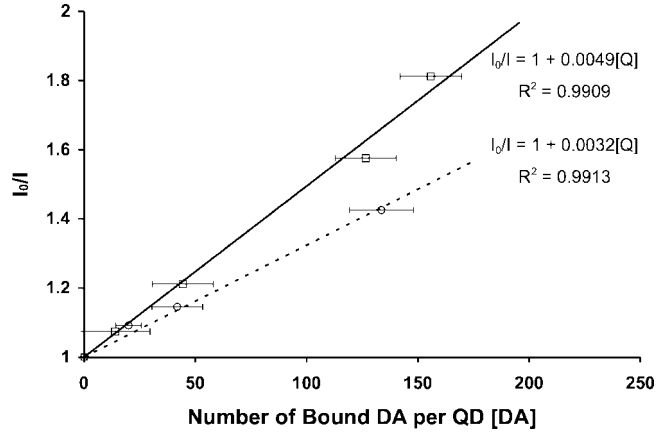

Figure 5. Relationship between the number of DA particles bound to the surface of the QD and the resulting emission intensity. For both QD560 (dashed line, cross marker) and QD600 (black line, square marker) the relationship can be fitted to the linear equations depicted on the graph. Data are an average of four experiments with error bars indicating the standard error of the mean.

particles. Modification of these carboxylate groups by an uncharged small molecule such as DA (it is uncharged when the amino group is blocked by conjugation) has the effect of neutralizing the surface charge. We used gel electrophoresis to investigate the effect of the density of DA on the surface charge of QD600. As expected, the negatively charged QDs migrate toward the positive electrode in a single narrow band consistent with a homogeneous and monodisperse population of QDs (Figure 4, lane 1). Increasing modification of the particles leads to a corresponding shift in the mobility of the particles under the influence of an electric field. In the samples with the highest levels of DA, broadening of the fluorescent bands and aggregation is evident (Figure 4, lanes 7 and 8) due to loss of colloidal stability following the loss in surface charge. Conjugation of DA to a QD population is expected to lead some distribution of modification by DA within the sample. However, in the samples that were stable (Figure 4, lanes 1–6), conjugation of DA did not lead to observable broadening of the bands in the gel and indicates a mostly uniform distribution of DA modification across the samples.

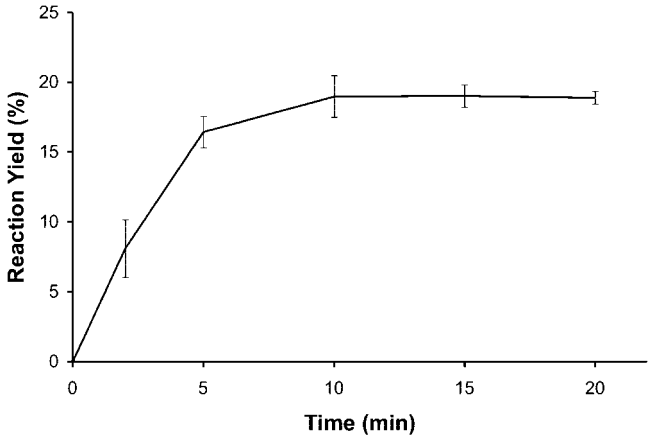

Figure 6. Time scale of the EDC coupling reaction as measured by OPA assay. Results are typical; data shown are from a coupling reaction with a ratio of 12000:1000:1 EDC:DA:QD. Data are an average of three experiments with error bars indicating the standard error of the mean.

Effect on Spectral Characteristics. Manipulating the extent of ligand coverage of the QD surface can be an effective way to modulate its fluorescent properties. In Figure 5, we demonstrate the effect of the number of bound DA ligands and the subsequent reduction in the fluorescent emission intensity of the QDs. Fluorescence static quenching can be modeled using the Stern-Volmer equation:

$$\frac{I_0}{I} = 1 + K[Q] \quad (1)$$

In this equation, I_0 and I are the fluorescent intensity in the absence and presence of the quencher Q and K is the quenching constant. Deviations from this linear relationship are often attributed to a combination of static and dynamic quenching (collisional) (*26*) and this type of relationship is not suitable for fitting to a linear Stern-Volmer model. To eliminate the effect of collisional dynamic quenching by free DA, EDC, or AA, we purified the conjugates from excess unbound ligand and reaction products. Static quenching remains as the predominant quenching mechanism (*27*). In Figure 3, the quenching data for QD560 and QD600 were fitted to a linear equation over the full range of DA modification. The quenching constant for QD560 was $K = 0.0032$ molecules^{-1} and $K = 0.0049$ molecules^{-1} for QD600. These results indicate that the larger QD600 particles were more efficiently quenched than QD560. When we repeated these experiments using QDs from different synthetic batches we found that the quenching data was quite unique for each QD and generally independent of size (data not shown). The chemical and physical properties of QDs are known to vary widely across different synthetic reactions and these data further underscore the importance of characterizing a QD-conjugate. Knowledge of the ligand-quenching relationship is useful for designing a QD bioprobe. Our recent work has utilized these particles in the region of high modification by DA and maximum emission quenching and these particles behaved as efficient cellular sensors of redox conditions (*13*). However, if the QD bioprobe were to be designed as a static fluorescent marker, then it would be more practical to modify the surface with a smaller number of DA ligands in order to preserve the fluorescent intensity of the QDs.

Optimization of the Coupling Reaction. In addition to quantifying the number of DA ligands on the surface of the particles, we have also utilized the OPA assay to measure the kinetics of the coupling reaction. The thiol surfactant layer is quite sensitive to even mild reaction conditions (*28*); therefore, we have used these results to maximize the yield and minimize the reaction time. Figure 6 demonstrates the rate of reaction for a typical reaction with 1000 DA equivalents and QD560. The reaction was largely complete after 10 min, consistent with a recent report (*29*) demonstrating a similar reaction time scale. In the literature, there is a wide disparity among the suggested reaction conditions for the EDC mediated reaction. Most protocols have reported incubation times of several hours, while some even perform the reaction overnight. These results imply that shorter duration reaction times are just as effective as much longer times. In addition, we observed that the efficiency of the coupling reaction was drastically reduced when our QD samples had small levels of free MPA due to incomplete purification of the QDs. Washing of the particles with ethyl acetate and dialysis against phosphate buffer was required to eliminate these free thiol molecules. Short chain thiols are typically used to quench the EDC reaction (*19*), so it is no surprise that the free thiolate groups hinder the desired reaction.

Incubation with Cells. We investigated the effect of DA ligand coverage and corresponding association to D2 receptor expressing PC12 cells. As expected, cells that were treated with

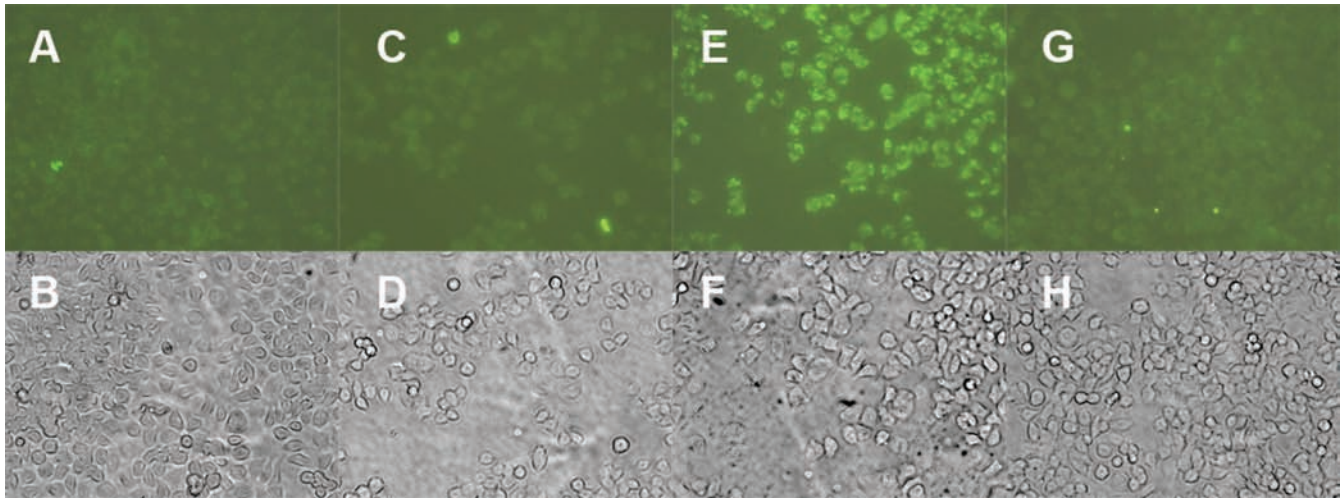

Figure 7. Cellular uptake of QD560 by dopamine-receptor-expressing PC12 cells as investigated by fluorescence microscopy. Scale bar = 20 μm and applies to all panels. (A,B) Unmodified MPA QD560 does not associate with cells. (C,D) QD560 with 50 ± 8.6 DA ligands has little specificity for cells. (E,F) With 100 ± 9.3 DA ligands, QD560 had a high specificity for the surface DA receptors. (G.H) 1 mM free DA is an effective competitor for QD560 with ca. 100 DA ligands. QD association was seen within 30 min of treatment.

QDs alone did not show any visible QD association when examined by fluorescence microscopy (Figure 7A,B). Again, little association was seen with QD560−DA conjugates with ca. 50 ligands (Figure 7C,D). A striking difference was visible with QD conjugates bearing ca. 100 DA ligands (Figure 7E,F). These QDs were visible as bright green fluorescence on the surface of the cells and the labeling is consistent with the targeting of the surface receptors. To further confirm the specificity of this reaction, we also incubated this sample in the presence of 1 mM free DA. No QD association was seen (Figure 7G,H) indicating the ability of free DA to compete for receptor binding on the cell surface. As a further control, no QD association was apparent in HEK293T cells lacking D2 receptors (Supporting Information Figure S5). A striking improvement in targeting was seen when we compare the cellular association of QD560 with 50 and 100 DA ligands. This data is consistent with recent experiments where an increase in the density of the ligands was sufficient to improve the affinity of the probes by several orders of magnitude (*17*). The enhancement was attributed to a multivalent interaction involving multiple ligands interacting with multiple cell receptors to greatly enhance the affinity of a nanoparticle conjugate. An estimate of the number of molecules that are required for efficient cell association can serve to maximize the efficiency of existing QD conjugates as well as design future probes. The requirement for efficient displacement of the hydrophobic surfactant as well as binding of 100 DA ligands explains the failure of labeling experiments with QDs of low surface quality or minimal DA coverage. It will be interesting to observe the relationship between the initial number of bound ligands and the number of ligands that persist under high-intensity UV or blue light irradiation, which causes photoenhancement and possibly surfactant decay (*13, 30*). Some preparations or colors of QDs may show faster degradation (*31*) and thus loss of biological activity resulting in limited absolute cellular association. It is also apparent, however, that 100 DA ligands represent only a portion of the available surface sites, and that some of the functional groups on the surface are available for alternative purposes. Indeed, we have also demonstrated that free carboxylate groups on the surface of the particles are required for a stable colloidal solution. Most QD probes in the literature are simple configurations based on a single ligand. With these results in mind, we can begin to design smarter probes with multiple ligands that may serve several purposes such as recognition and drug delivery (*32*).

This study has shown that OPA is a sensitive assay for characterizing the surface of QDs when they are decorated with a simple molecule such as DA. Manipulating the degree of ligand coverage is important for exploiting changes in the spectral properties of the QDs, for preserving the colloidal stability of the particles and optimizing cellular association by receptor-mediated processes. These results suggest important guidelines for designing NP based probes. Although this study focused strictly on CdSe/ZnS particles, the results and techniques are valid for a host of different particle compositions ranging from gold to iron to synthetic NPs.

Convenient Preparation of ^{68}Ga-Based PET-Radiopharmaceuticals at Room Temperature

I. Velikyan,*[,†] H. Maecke,[‡] and B. Langstrom[†,§]

Uppsala Applied Science Lab, GEMS PET Systems AB, GE Healthcare, SE-752 29 Uppsala, Sweden, Division of Radiological Chemistry, University Hospital, CH-4031 Basel, Switzerland, and Department of Biochemistry and Organic Chemistry, BMC, Uppsala University, SE-75124 Uppsala, Sweden. Received September 5, 2007; Revised Manuscript Received November 13, 2007

A straightforward labeling using generator produced positron emitting ^{68}Ga, which provides high quality images, may result in kit type production of PET radiopharmaceuticals and make PET examinations possible also at centers lacking accelerators. The introduction of macrocyclic bifunctional chelators that would provide fast ^{68}Ga-complexation at room temperature would simplify even further tracer preparation and open wide possibilities for ^{68}Ga-labeling of fragile and potent macromolecules. Gallium-68 has the potential to facilitate development of clinically practical PET and to promote PET technique for individualized medicine. The macrocyclic chelator, 1,4,7-triazacyclononanetriacetic acid (NOTA), and its derivative coupled to an eight amino acid residue peptide (NODAGA-TATE, [NODAGA^0, Tyr^3]Octreotate) were labeled with ^{68}Ge/^{68}Ga-generator produced positron emitting ^{68}Ga. Formation kinetics of ^{68}Ga-NOTA was studied as a function of pH and formation kinetics of ^{68}Ga-NODAGA-TATE was studied as a function of the bioconjugate concentration. The nearly quantitative radioactivity incorporation (RAI > 95%) for ^{68}Ga-NOTA was achieved within less than 10 min at room temperature and pH 3.5. The concentrations of NODAGA-TATE required for RAI of >90% and >95% were, respectively, 2–5 and 10 μM. In both cases the purification of the ^{68}Ga-labeled products was not necessary since the radiochemical purity was >95% and the preparation buffer, 4-(2-hydroxyethyl) piperazine-1-ethanesulfonic acid (HEPES) is suitable for human use. In order to confirm the identity of the products, complexes comprising ^{nat}Ga were synthesized and analyzed by mass spectrometry. The complex was found to be stable in the reaction mixture, phosphate buffer, and human plasma during 4.5 h incubation. Free and peptide conjugated NOTA formed stable complexes with ^{68}Ga at room temperature within 10 min. This might be of special interest for the labeling of fragile and potent macromolecules and allow for kit type preparation of ^{68}Ga-based radiopharmaceuticals.

INTRODUCTION

The long shelf life generator produced positron-emitting ^{68}Ga ($T_{1/2}$ = 68 min) is of potential interest for clinical PET. It is readily available on demand and it decays by 89% through positron emission resulting in images with high resolution and potential accurate quantification. Its half-life of 68 min might be sufficient for production and application of tracers and it minimizes the radiation dose to the patient. It also allows repetitive examinations. The only stable chemical form in solution at physiological conditions is Ga (III) cation that can form stable complexes with chelators, naked or conjugated with macromolecules or small organic molecules. It is established that macrocyclic chelator, 1,4,7,10-tetraazacyclododecanetetraacetic acid (DOTA), either free or coupled to macromolecules forms very stable complexes with ^{68}Ga. However, the complex formation with DOTA derivatives requires elevated temperature (*1*, *2*). A fast, reliable method comprising preconcentration and purification of the ^{68}Ge/^{68}Ga generator eluate and microwave heating was developed for automated production of peptide based tracers with higher specific radioactivity (*2–4*). The introduction of macrocyclic chelators that would provide fast ^{68}Ga-complexation at room temperature would simplify even further the tracer preparation and allow for kit type labeling analogous to one carried out with the SPECT isotope ^{99m}Tc in addition–offering the sensitivity and quantification advantages of the PET technique. The fast ^{68}Ga-labeling reaction at room temperature might also become an attractive tool when producing fragile temperature sensitive macromolecular tracers. The recognized potential of PET technique and ^{68}Ga-based radiopharmaceuticals for use in oncology, cardiology, neurology, and infection diseases strongly motivates the development of such a production procedure (*5–10*). The worldwide interest toward ^{68}Ga is increasing quickly and, for example, in Europe at least 40 centers have already introduced the generator. Moreover, the struggle for more efficient authorization of radiopharmaceuticals by legislative institutions is progressing steadily (*11*). The introduction of ^{68}Ga-based radiopharmaceutical kit production that would not require cyclotron and qualified chemists would make the PET radiopharmaceuticals readily available and might accelerate the expansion of nuclear medicine and promote PET examinations for personalized medicine worldwide.

Macrocyclic chelators that form very stable complexes with metal cations are of paramount interest for radiopharmaceutical design. Gallium complexes with NOTA (*12–14*) and its various derivatives, namely, 1,4,7-tris(2-mercaptoethyl)-1,4,7-triazacyclononane (TACN-TM) (*15*), 1,4,7-triazacyclononane-1-succinic acid-4,7-deacetic acid (NODASA) (*16*), 1,4,7-triazacyclononane-*N*,*N*′,*N*″-tris(methylenephosphonic) acid (NOTP) (*17*, *18*), 1,4,7-triazacyclononane-*N*,*N*′,*N*″-tris(methylenephosphonate-monoethylester) (NOTPME) (*17*, *18*) have demonstrated octahedral coordination geometry, high thermodynamic stability and similar plasma and *in vivo* stability. It has been reported that the

biodistribution and clearance pattern of ^{67}Ga-NOTA phosphonate analogues depend on the overall charge of the complexes (*17*). The thermodynamic stability constant (log *K*) of Ga(III)-DOTA (*19*) and Ga(III)-NOTA (*12*, *14*) complexes was determined, respectively, to be 21.33 and 30.98. It is the compactness of the triazanonane ring and the steric efficiency of the pendant acetate groups that lead to the formation of complexes of unusually high stability and selectivity for the Ga(III) (*14*). However, it should be stressed that the high stability of macrocyclic complexes is provided by the extremely slow dissociation reactions. Typical dissociation constant values are 10^5 to 10^7 times lower than those of open-chain analogues. The hole-size effects influence both thermodynamics and kinetics of macrocyclic complexes. This is because a chelator in its minimum energy metal-binding conformation will be optimized for a particular size of a metal ion, and when other metal ions are bound, the chelator conformational energy will rise with a resultant decrease in stability of the complex. Thus, macrocycles are selective for metal ions (*20–22*). For a given ionic size the stability of the complex increases with increasing charge. Another factor which influences the complexation rate and the stability is the presence of pendant arms, which help to achieve the full coordination number of the metal ion. The above-mentioned characteristics make NOTA very attractive for radiopharmaceutical development. In this work we investigated the potential of ^{68}Ga in combination with NOTA for a simple kit type production of radiopharmaceuticals at room temperature.

EXPERIMENTAL PROCEDURES

Materials. HEPES (4-(2-hydroxyethyl)piperazine-1-ethanesulfonic acid), sodium acetate, and double distilled hydrochloric acid (Riedel de Haën) were obtained from Sigma-Aldrich Sweden (Stockholm, Sweden). Sodium dihydrogen phosphate, disodium hydrogen phosphate, and trifluoroacetic acid (TFA) were obtained from Merck (Darmstadt, Germany). The purchased chemicals were used without further purification. Deionized water (18.2 MΩ), produced with a Purelab Maxima Elga system (Bucks, UK) was used in all reactions.

^{68}Ga Production. ^{68}Ga ($T_{1/2}$ = 68 min, β^+ = 89%, and EC = 11%) was available from a ^{68}Ge/^{68}Ga-generator-system (Cyclotron Co., Ltd., Obninsk, Russia) where ^{68}Ge ($T_{1/2}$ = 270.8 d) was attached to a column of an inorganic matrix based on titanium dioxide. The ^{68}Ga was eluted with 6 mL of 0.1 M hydrochloric acid.

^{68}Ga-Labeling of NOTA. HEPES (7–14 mg) or sodium acetate (16 mg) buffering agents was added to 200 μL of ^{68}Ga and the pH was adjusted with HCl and NaOH to give pH values between 2 and 7. NOTA (50 nmol, synthesized at Grove Centre, GB) was added and the reaction mixture was incubated at room temperature. The reaction mixture was analyzed by thin layer chromatography (TLC) applying the analyte to a polyethyleneimine cellulose plate (PEI-Cellulose F, Merck, Germany) and using 0.4 M NaH_2PO_4 (pH = 3.5) as running buffer. Autoradiography was employed to image the TLC strips. A phosphor storage plate (Molecular Dynamics, Amersham Biosciences, U.K.) was placed on top of the strips. The plate was scanned with PhosphorImager (PI) SI unit (Molecular Dynamics, Amersham Biosciences, U.K.) and analyzed using *ImageQuant 5.1* software. The nonincorporated (free) ^{68}Ga stayed at the origin and R_F of the ^{68}Ga-complex was 0.9.

^{68}Ga-Labeling of NODAGA-TATE. The pH of the ^{68}Ge/^{68}Ga-generator eluate was adjusted to 3.5–5.0 by adding either HEPES to give finally a 1.0 M solution with regard to HEPES or sodium acetate to give finally a 0.4 M solution with regard to sodium acetate. Then 0.2–20 nmol of NODAGA-TATE (received as lyophilized powder from Helmut Maecke, Division of Radiological Chemistry, University Hospital, Basel, Switzerland, and dissolved in deionized water to give stock solutions of 0.1 mM and 1 mM concentration) were added and the reaction mixture was incubated at room temperature. The reaction mixture was analyzed on an HPLC system from Beckman (Fullerton, CA) consisting of a 126 pump, a 166 UV detector, and a radiation detector coupled in series. Data acquisition and handling was performed using the Beckman System Gold Nouveau Chromatography software package. The column used was a Vydac RP 300 Å HPLC column (Vydac, USA) with the dimensions 150 mm × 4.6 mm, 5 μm particle size. The applied gradient elution was as follows: A = 10 mM TFA; B = 70% acetonitrile (MeCN), 30% H_2O, 10 mM TFA with UV-detection at 220 nm; flow was 1.2 mL/min; 0–2 min isocratic 20% B, 20–90% B linear gradient 8 min, 90–20% B linear gradient 2 min.

LC-ESI-MS Analysis. Electrospray ionization mass spectrometry (ESI-MS) was performed using a Fisons Platform (Micromass, Manchester, UK) with positive mode scanning and detecting $[M + 1H]^{1+}$, $[M + 2H]^{2+}$, $[M + 3H]^{3+}$, and $[M + NH_4]^+$ species. NOTA was detected at m/z = 304 for $[M + 1H]^{1+}$. The analysis of ^{69,71}Ga-NOTA was performed by direct infusion. Two different systems, namely, formic acid and ammonium acetate, were used resulting in the detection of m/z = 370.23, m/z = 372.1 for $[M + H]^+$ and m/z = 387.16, m/z = 389.26 for $[M + NH_4]^+$, respectively. NODAGA-TATE was detected at m/z = 704 for $[M + 2H]^{2+}$ and 470 for $[M + 3H]^{3+}$, and ^{69,71}Ga-NODAGA-TATE was detected at m/z = 738 for $[M + 2H]^{2+}$. The ^{69,71}Ga-NOTA and ^{69,71}Ga-NODAGA-TATE were synthesized under conditions indentical to radiolabeling and were used for the identification of the radio-HPLC chromatogram signals. The coupled HPLC system was from Alliance (Waters 2695, UK) with photodiode array UV detector. The column used was an Atlantis, dC 18, HPLC column with the dimensions 100 mm × 2.1 mm, 3 μm particle size. Isocratic elution was applied with the following parameters: A = 10 mM formic acid; B = 100% acetonitrile (MeCN), with UV-detection at 210–400 nm; flow was 0.3 mL/min, A/B = 80/20.

Stability in Human Plasma. The reaction mixture of ^{68}Ga-NOTA (RAI > 95%, 50 μL) was added to the prewarmed (37 °C) plasma (500 μL) and incubated for 270 min. The samples (100 μL) were taken at 10, 30, 60, 120, and 270 min time points and acetonitrile (400 μL) was added to sediment the proteins present. Then the samples were centrifuged at 14 000 rpm for 10 min at +4 °C (Allegra X-22R Centrifuge, Beckman Coulter, USA). The supernatant was collected and filtered through a 0.2 μm nylon membrane at 13 200 rpm for 1 min at +4 °C. The radioactivity of the pellets, supernatant, and filters was measured in a well counter and ionization chamber. The data was used to calculate the extraction efficiency. The supernatant was analyzed by TLC applying the analyte to a polyethyleneimine cellulose plate (PEI-Cellulose F, Merck, Germany) and using 0.4 M NaH_2PO_4 (pH = 3.5) as running buffer. Autoradiography was employed to image the TLC strips.

Stability in Reaction Mixture and PBS. The stability of the ^{68}Ga-NOTA and ^{68}Ga-NODAGA-TATE complexes was monitored in PBS and reaction mixture. The samples (5–20 μL) were taken at 10, 30, 60, 120, and 240 min time points. ^{68}Ga-NOTA was analyzed by PEI-cellulose F TLC followed by autoradiography imaging of the strips. ^{68}Ga-NODAGA-TATE was analyzed by UV-radio-HPLC.

RESULTS AND DISCUSSION

The general structure of NOTA derivative chelators is given in Figure 1 and consists of three macrocyclic amine groups and three carboxylic groups for coordination to Ga(III) and an additional functional group (Y_1) such that the chelate can be conjugated to a vector, e.g., preferably alkylamine, alkylsulfide, alkoxy, alkyl carboxylate, arylamine, aryl sulfide, or α-halo-

where R = D-Phe-Cys-Tyr-D-Trp-Lys-Thr-Cys-Thr

Figure 1

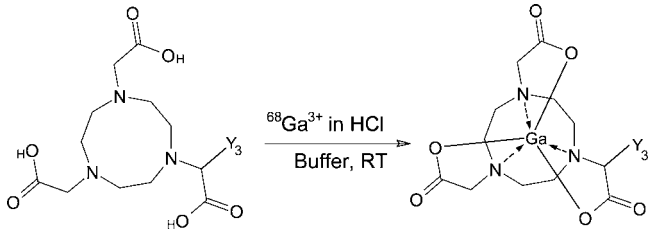

Figure 2. Reaction scheme for the complexation of ^{68}Ga(III) with NOTA (Y_3=H) and NODAGA-TATE (Y_3 = $CH_2CH_2C(O)R$, where R = Tyr^3-octreotate).

acetyl; Y_2 and Y_3 can be H or contain one or more functional moieties that would on one hand improve the complexation depending on a particular metal cation and on the other hand change the overall charge and hydrophilicity of the complex in order to modify the pharmacokinetics and blood clearance rates, e.g., alkylamine, alkoxy, alkyl carboxylate, phenol, hydroxamate, aryl sulfide, and alkyl.

In this particular work, ^{68}Ga-labeling of 1,4,7-triazacyclononanetriacetic acid (NOTA) and its derivative coupled to an eight amino acid residue peptide (NODAGA-TATE, [NODAGA^0, Tyr^3] octreotate) was performed at room temperature considering the possibility for a simple kit type tracer production as well as preparation of tracers based on temperature sensitive fragile macromolecules (Figure 2). Formation kinetics of ^{68}Ga-NOTA was studied during 1 h at room temperature as a function of pH values covering the range from 2 to 7. The aliquots of the reaction mixture sampled at 1, 3, 10, 30, and 60 min time points were analyzed by thin layer chromatography (TLC) both directly after the aspiration and later after the reaction was first quenched in water. The radioactivity incorporation at early time points was slightly higher in the case of the quenched samples, indicating most probably that the complexation reaction continued even after 200–1000-fold dilution of the reaction mixture. In addition, the reproducibility of the direct analysis was higher with relative standard deviation (RSD) values of ~1% and ~4%, respectively, for the direct and quenched cases. Thus the TLC analysis performed directly after the aspiration of the aliquots was preferred. The nonincorporated (free) ^{68}Ga stayed at the origin and R_F of the ^{68}Ga-complex was 0.9.

The time course of ^{68}Ga complexation reaction with NOTA at room temperature for varied buffer and pH conditions is presented in Figure 3A. Radioactivity incorporation reached a plateau within 10 min independent of the pH. The radioactivity incorporation (RAI > 95%) for ^{68}Ga-NOTA was achieved within less than 10 min at room temperature and pH 3.5 using HEPES buffer (Figure 3B).

In order to confirm the identity of the product, the complex comprising stable gallium isotopes (^{69,71}Ga) was synthesized and analyzed by mass spectrometry (ESI-MS). ^{69,71}Ga-NOTA was synthesized under the same conditions as its radioactive counterpart, but using a mixture of ^{68}Ga and ^{69,71}Ga cations. The aim of the use of a mixture of radioactive and stable gallium isotopes was twofold: (1) to create a reaction condition identical to the labeling procedure; (2) to allow following the reaction.

The formed neutral complex was expected to be difficult to protonate in order to observe it by ESI-MS. However, it was possible to optimize the analysis conditions and confirm the formation of ^{69,71}Ga-NOTA using two different systems, namely, formic acid and ammonium acetate and detecting respectively m/z = 370.23, m/z = 372.1 for $[M + H]^+$ and m/z = 387.16, m/z = 389.26 for $[M + NH_4]^+$. The production of the complex was also indirectly verified by the consumption of NOTA and the drastic decrease of the corresponding signal at m/z = 304 for $[M + 1H]^{1+}$. The stability of the ^{68}Ga-NOTA complex was monitored in PBS, reaction mixture, and human plasma and was found stable and in agreement with literature data (*12–15, 18, 23*). The complex extraction efficiency from the plasma was 65 ± 4% at 10, 30, 60, 120, and 270 min time points, and the only intact complex was detected after the incubation at 37 °C during 4.5 h. The choice of the time frame was dictated by the half-life of ^{68}Ga and consequent useful tracer application time ($4 \times T_{1/2}$).

Formation kinetics of ^{68}Ga-NODAGA-TATE was studied for varied concentration of the bioconjugate. The graph (Figure 4) presents the time course of ^{68}Ga complexation reaction with NOTA conjugated peptide at room temperature in sodium acetate buffer for varied concentration of the bioconjugate. Radioactivity incorporation reached a plateau within 10 min. The nearly quantitative radioactivity incorporation (>95%) required 10 μM and higher concentration of the bioconjugate. This concentration exceeded 4× the one required when using microwave heating (*2*).

The formation of ^{68}Ga-NODAGA-TATE was monitored by HPLC with UV- and Radio-detection (Figure 5). The authentic reference substance (^{69,71}Ga-NODAGA-TATE) was synthesized under the same conditions as its radioactive counterpart, but using a mixture of ^{68}Ga and ^{69,71}Ga cations for the same reason as described above for ^{69,71}Ga-NOTA.

The identity of the authentic reference substance (^{69,71}Ga-NODAGA-TATE) was confirmed by LC-ESI-MS detecting m/z = 704 for $[M + 2H]^{2+}$, m/z = 470 for $[M + 3H]^{3+}$ of NODAGA-TATE, and m/z = 738 for $[M + 2H]^{2+}$ of ^{69,71}Ga-NODAGA-TATE. The stability of the ^{68}Ga-NODAGA-TATE was monitored in the reaction mixture and PBS. The UV and radio signals corresponded to the tracer and no additional signals were detected indicating the stability of the molecule.

In both cases of ^{68}Ga-NOTA and ^{68}Ga-NODAGA-TATE the purification of the product was not necessary since the radiochemical purity was >95% and the preparation buffer, 4-(2-hydroxyethyl)piperazine-1-ethanesulfonic acid (HEPES) is suitable for intravenous injections. For example, HEPES is currently used as an ingredient of indium(In-111)oxin GE Healthcare radiopharmaceutical (manufacturer, GE Healthcare Limited; registration number, 800820; approval date, 1990–06–21; Medical Products Agency, Sweden).

Previously, the high similarity of the geometry of gallium complexes with NOTA and NODASA independent of the pendant arm modification has been demonstrated by X-ray

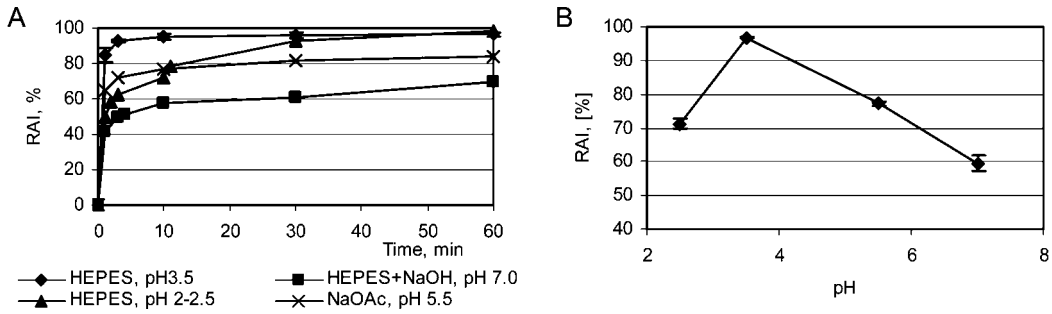

Figure 3. (A) Time course of ^{68}Ga complexation reaction with NOTA at room temperature and varied pH conditions ($N = 2–3$, the error bars are omitted for simplicity). (B) Radioactivity incorporation after 10 min incubation at room temperature as a function of pH.

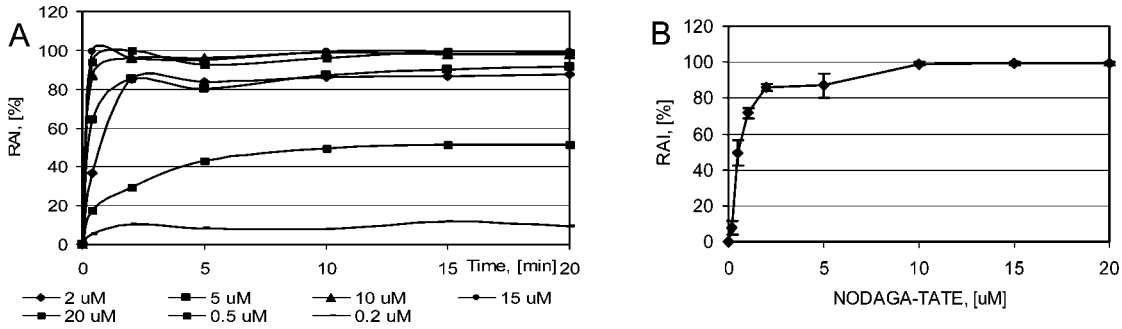

Figure 4. (A) Time course of ^{68}Ga complexation reaction at room temperature for varied concentration of NODAGA-TATE ($N = 2–3$, the error bars are omitted for simplicity). (B) Radioactivity incorporation as a function of the bioconjugate concentration (10 min incubation, RT).

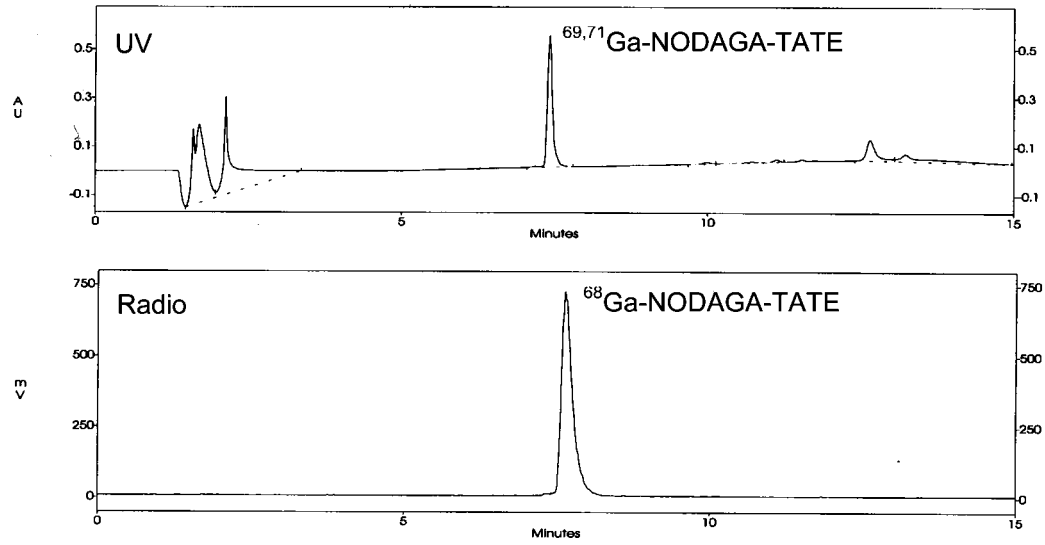

Figure 5. A typical example of an UV- and radio-HPLC chromatograms, respectively, for ^{69,71}Ga-NODAGA-TATE and ^{68}Ga-NODAGA-TATE. The reaction mixture was spiked with the stable reference. (The UV-signals at R_t of 12.66 and 13.33 are systematic and not related to the analyte.)

crystallography (*12*, *13*, *16*). In this study the complexation yields and conditions were similar for NOTA and NODAGA-TATE indicating that most probably the labeling is affected only by the macrocyclic chelator and consequently the latter might be coupled to a number of biologically active vectors resulting in a simple production of wide range of PET radiopharmaceuticals. The fast and nearly quantitative labeling results in higher specific radioactivity which might be crucial for the accurate quantification of PET examinations as well as in the application of expensive and highly potent macromolecular tracers. The labeling at room temperature allows the production of tracers comprising temperature sensitive and fragile macromolecules like antibodies. The nearly quantitative radioactivity incorporation at room temperature and reaction solution constitution compatible with human use promise a very simple kit type production.

CONCLUSIONS

The complexation of ^{68}Ga with NODAGA-TATE and NOTA was observed at RT and pH 3.5 within 10 min with the yield of >95%. The product purification was not necessary since the incorporation was nearly quantitative and the HEPES buffer is suitable for human use. Formation of ^{68}Ga-NOTA and ^{68}Ga-NODAGA-TATE was confirmed by the synthesis and subsequent ESI-LC-MS analysis of the counterparts comprising stable gallium isotopes.

^{68}Ga-NOTA was confirmed to be stable in human plasma at 37 °C during 4.5 h. The suggested ^{68}Ga and NOTA based labeling procedure might be of special interest for the labeling of fragile and potent macromolecules and might allow for a simple kit type preparation of ^{68}Ga-based radiopharmaceuticals.

ACKNOWLEDGMENT

A fluorescence resonance energy transfer (FRET) model using two-photon excitable small organic molecule DMAHAS as energy donor has been constructed and tried in an assay for avidin. In the FRET model, biotin was conjugated to the FRET donor, and avidin was labeled with a dark quencher DABS-Cl. Binding of DABS-Cl labeled avidin to biotinylated DMAHAS resulted in the quenching of fluorescence emission of the donor, based on which a competitive assay for free avidin was established. With using such donors that are excited in IR region, it is capable of overcoming some primary shortcomings of conventional one-photon FRET methods, especially in bioassays, such as the interference from background fluorescence or scattering light, the coexcitation of the energy acceptor with the donor. And such small molecules also show advantages over inorganic up-converting particles that also give anti-Stokes photoluminescence and have been applied as FRET donor recently. The results of this work suggest that two-photon excitable small molecules could be a promising energy donor for FRET-based bioassays.

INTRODUCTION

Fluorescence resonance energy transfer (FRET)[1]is defined as the nonradiative transfer of the excited-state energy from a fluorescent donor to an acceptor, which may be fluorescent or not. FRET is considered as a sensitive and reliable "ruler" over distances of 10—100 Å (*1*) and has broad applications in studying interactions of biological macromolecules (*2*), in immunoassay (*3*), and so on. However, it is often seen that the energy acceptor is coexcited with the energy donor because of the overlap of their excitation spectra (*4, 5*). Meanwhile, autofluorescence or scattering light always arises from biomolecules upon the excitation of energy donor. Therefore, new pairs of energy donor–acceptor are desired for FRET methods, especially in bioassays.

Recently, two-photon (TP) excitation has attracted a lot of attention in biological applications. In such a nonlinear optical process, two low-energy photons are simultaneously absorbed to reach the excited state (*6*). TP excitable materials can be excited in IR region to give emission in the visible region. Under TP excitation with IR light, the autofluorescence of biomolecules and the scattered excitation light could be eliminated, thus the sensitivity is significantly improved. Besides, the IR light causes much less photobleaching off the focal plane and less photodamage to biological samples (*7, 8*). The above unique features have led to the wide use of TP excitation, notably in microscopic imaging (*9, 10*). Because of the anti-Stokes photoluminescence nature of TP excitation which avoids the direct excitation of energy acceptor, one can expect two-photon excitable materials to be promising energy donors for FRET microscopy. TP-FRET microscopy has been used to characterize the intranuclear dimerization of protein molecules in living cells (*11*) and to illuminate protein interactions in tissue (*12*). In biological imaging applications combined with microscopy, TP-FRET has shown higher energy transfer efficiency, less background, and deeper imaging depth than confocal FRET. TP-FRET also has advantages over wide-field FRET as there is less photodamage above and below the focal plane (*13*).

While efforts are being made to apply the anti-Stokes photoluminescence in biological imaging, TP-FRET based quantitative bioassays in homogeneous solutions have been studied much less. So far there have been several reports on FRET bioassays using up-converting phosphors (UCPs) as donors. UCPs are kinds of inorganic particles that give anti-Stokes photoluminescence via the sequential absorption of two or more low-energy photons, which is similar to TP excitation. Kuningas et al. (*14, 15*) and Li et al. (*16*) have developed bioassays based on upconversion fluorescence resonance energy transfer (UC-FRET). Most recently, luminescent quantum dots (QDs)-based FRET driven by a two-photon process, which eliminates the direct excitation of the acceptor and thus results in a near-zero background, has also been reported (*17*). The significance of using the IR light excitable UCPs as energy donor in bioassays has been proved in these papers. Nevertheless, the relatively large size of UCPs has caused some negative effects (*15, 18*), such as signal variation, reabsorptive energy transfer of ions in the core, instability of the phosphor bioconjugates, and nonspecific binding interactions. These have reduced the sensitivity of UC-FRET and restricted its applications.

Therefore, TP excitable small organic molecules would be a better alternative to UCPs in some aspects as the FRET donor, especially when the nonspecific binding/adsorbing of target

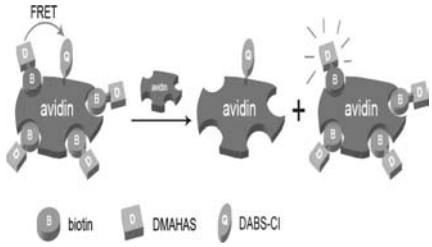

Figure 1. Schematic representation of the model FRET system with biotinylated DMAHAS as donor and DABS-Cl conjugated avidin as acceptor. FRET occurred upon the binding of DABS-Av to biotinylated DMAHAS, resulting in the quenching of the donor. With the addition of free avidin, the labeled avidin was partially replaced due to the competition towards biotin, which led to partial recovery of the fluorescence of donor.

molecules on the surface of particles, which always causes false positive results, is considered. Small molecules are capable of overcoming the problems resulted from the size effect of UCPs and thus improve the sensitivity and specificity of quantitative assays. What's more, organic molecules are structurally more flexible so that it is much easier to configure the molecules and motifs for the purpose of improving FRET efficiency and conjugating with biomolecules. Herein in this work, we have constructed a model assay for avidin (see Figure 1) to demonstrate the merits of TP excitation in FRET-based bioassays. Organic molecule *trans*-4-(*N*-2-hydroxyethyl-*N*-ethyl amino)-4′-(dimethyl amino)stilbene (DMAHAS) was employed as energy donor since it is convenient to conjugate with biotin through the reactive hydroxyl group. 4-(Dimethylamino)azobenzene-4′-sulfonyl chloride (DABS-Cl) is a nonfluorescent quencher with high molar extinction coefficient, which makes it a good acceptor in FRET. It was chosen as the acceptor in this work because it has a maximum absorption around 470 nm (*19*), which matches well with the emission spectrum of DMAHAS. To the best of our knowledge, such TP excitation FRET model for bioassay using small organic molecule as energy donor has not yet been reported in literature.

EXPERIMENTAL PROCEDURES

Synthesis of DMAHAS and Biotinylated DMAHAS. DMAHAS was synthesized according to a reported pathway (*20*), and then biotinylated DMAHAS was prepared with a normal labeling method (*21*). Biotin (29.3 mg, 0.12 mmol), DMAHAS (31 mg, 0.1 mmol), *N*,*N*′-dicyclohexylcarbodiimide (24.8 mg, 0.12 mmol), and 4-dimethylaminopyridine (1.23 mg, 0.01 mmol) were dissolved in anhydrous dichloromethane (10 mL). The mixture was stirred at room temperature for 5 days under argon atmosphere, after which the solution was filtered and the filtrate was evaporated. The residue was purified by column chromatography on silica gel using a 20:1 (v/v) ethyl acetate/methanol as eluent, and a yellow crystal was obtained (structures shown in Figure 2).^{1}H NMR ($CDCl_3$), δ: 7.35 (m, 4H), 6.83 (s, 2H), 6.71 (m, 4H), 5.20 (s, 1 H, NH), 4.87 (s, 1 H, NH), 4.44 (m, 1H), 4.25 (m, 3H), 3.56 (m, 2H), 3.41 (m, 2H), 3.08 (m, 1H), 2.96 (s, 6H), 2.90—2.67 (m, 2H), 2.31 (t, 2H), 1.63 (m, 4H), 1.38 (m, 2H), 1.17 (t, 3H). HRMS (ESI-TOF) calcd for $C_{30}H_{40}N_4O_3S$ $[M + H]^+$ 537.2899, found 537.2901.

Preparation of DABS-Cl Conjugated Avidin. DABS-Av conjugate was prepared using a method analogous to others (*22*). Avidin was dissolved in 0.1 M sodium carbonate-sodium bicarbonate buffer, pH 9.1, at a concentration of 1 mg/mL. DABS-Cl was dissolved in DMF at a concentration of 1 mg/mL. The DABS-Cl solution was protected from light and used immediately. With gentle shaking, 30 μL of the DABS-Cl solution was slowly added to the avidin solution. After reacting

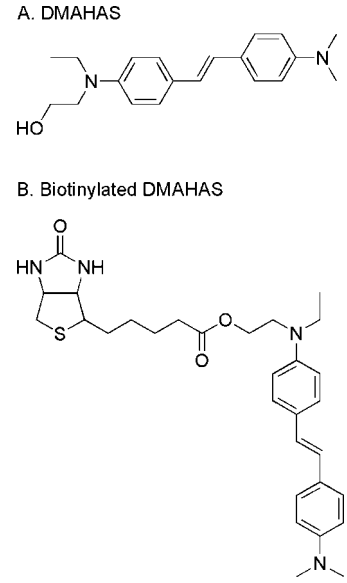

Figure 2. Structures of (A) DMAHAS, (B) biotinylated DMAHAS.

at room temperature for 2 h in the dark, the unbound DABS-Cl molecules were removed by exhaustive dialysis against the above buffer overnight at 4 °C.

The dye to protein ratio was estimated as follows: the concentration of DABS-Cl was determined by the absorbance at 474 nm, using the molar extinction coefficient of 3.3×10^4 M^{-1} cm^{-1}. Since DABS-Cl has a contribution to the absorbance at 280 nm, the concentration of avidin was determined by the absorbance at 280 nm after deducting the contribution of DABS-Cl at this wavelength, using the molar extinction coefficient of 8.88×10^4 M^{-1} cm^{-1} (*23*).

Preparation of DABS-BSA Conjugate. Similar to the process for making DABS-Av, BSA was dissolved in 0.1 M sodium carbonate-sodium bicarbonate buffer, pH 9.1, at a concentration of 1 mg/mL. And DABS-Cl was also dissolved in DMF at a concentration of 1 mg/mL, which was protected from light and used immediately. With gentle shaking, 100 μL of the DABS-Cl solution was slowly added to the BSA solution. After reacting at room temperature for 2 h in the dark, the unbound DABS-Cl molecules were removed by exhaustive dialysis against the above buffer overnight at 4 °C.

The dye-to-protein ratio was determined with the same manner as DABS-to-avidin ratio described above.

Measurement of TP Excited Fluorescence. Two-photon excited fluorescence detection system included two parts. The excitation light was provided by a mode-locked pulsed laser (Mira 900, Coherent) to provide high instantaneous photon flux density. The photoluminescence was recorded on a liquid-nitrogen cooled CCD detector (SPEC-10, Princeton) through a monochromator (Spectrapro 2500i, Acton). Two-photon fluorescence was excited at 800 nm with ~3 ps pulse width and 76 MHz repetition rate. The fluorescence intensity was given in normalized form, i.e., the maximum emission of each group of data was set as 1, and others were calculated proportionally. A LS 55 fluorometer (Perkin-Elmer) equipped with 1 cm cell was used for one-photon fluorescence measurements.

In a typical FRET experiment, 1×10^{-4} M biotinylated DMAHAS in DMF was diluted to 1×10^{-6} M with phosphate buffer, thus the solvent was a mixture of aqueous buffer (0.1 M phosphate buffer, pH 7.4) and 1% DMF (v/v). Under room temperature, DABS-Cl labeled avidin (0.145 μM avidin with the dye-to-protein ratio as 1.6) was added to the solution, which was then vortexed and incubated for 15 min. Then the fluorescence emission of biotinylated DMAHAS was recorded under excitation at 800 nm. For the fluorescence recovery, $1 \times$

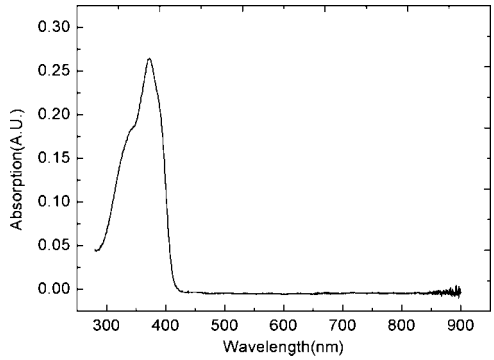

Figure 3. Linear absorption spectrum of DMAHAS (1×10^{-5} M in DMF).

10^{-6} M free avidin was added to another tube containing the same amount of biotinylated DMAHAS and DABS-Cl labeled avidin, which had been allowed to react for 15 min. After thoroughly mixing and incubating for another 15 min, the mixture was subjected to fluorescence measurement.

In the control experiments which were performed to exclude nonspecific interactions of biomolecules, 1×10^{-6} M biotinylated DMAHAS was incubated, also for 15 min under room temperature, with DABS-Cl labeled BSA (0.122 μM BSA with the dye-to-protein ratio as 1.6) and 0.18 μM free avidin, respectively. And the fluorescence of the donor was detected likewise.

For competitive assay of avidin, varying concentrations of free avidin (0, 0.1 μM, 0.4 μM, 0.8 μM, 1.3 μM, 1.9 μM, and 2.6 μM) were incubated with 1×10^{-5} M biotinylated DMAHAS and DABS-Cl labeled avidin (concentration fixed at 2.4 μM) for 15 min, and then the same fluorescence detecting procedure as above was followed for each sample.

RESULTS

Spectral Properties of the Donor. In order to confirm the TP excitation luminescence of the donor, the linear absorption spectrum of DMAHAS was examined first. From Figure 3, it is seen that its maximum absorption locates at 372 nm and there is no linear absorption in the range from 430 to 900 nm, which indicates that the photoluminescence of DMAHAS excited with 800 nm is purely the two-photon induced fluorescence. The TP excited fluorescence of the organic molecule is structurally originated from its symmetrical D-π-D conjugate motif. The biotinylation on the terminal hydroxyl group does not destroy the symmetrical charge transfer within the conjugated chain or the rigid plane of the molecule. Therefore, the biotinylation did not alter the nonlinear photoluminescence of DMAHAS. The fluorescence emission of both DMAHAS and biotin-conjugated DMAHAS under TP excitation model at 800 nm are presented in Figure 4, which shows that the TP fluorescence emission of biotinylated DMAHAS did not differ much from that of DMAHAS.

Optimization of the DABS-to-Avidin Ratio. The FRET efficiency can be adjusted by altering the dye-to-protein ratio. Generally speaking, increasing the dye-to-protein ratio will enhance the overall FRET efficiency due to the increased overlap integral (*24*). However, high dye-to-protein ratio does not always work well because labeling with more than one fluorophore may also result in problems, like concentration-dependent quenching, which will limit the detection sensitivity. Besides, the solubility and activity of the complex may be decreased in cases when coupling water-insoluble molecules to the surface of proteins owing to the hydrophobicity of the conjugate (*22*). In our experiments, we also found that adding excessive DABS-Cl to avidin solution would cause severe aggregation of the protein.

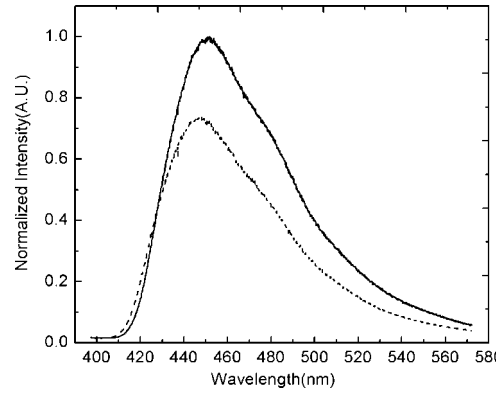

Figure 4. Two-photon excitation fluorescence spectra. (—) DMAHAS (1×10^{-2} M in DMF), (□) biotinylated DMAHAS (1×10^{-2}M in DMF). Excitation wavelength = 800 nm.

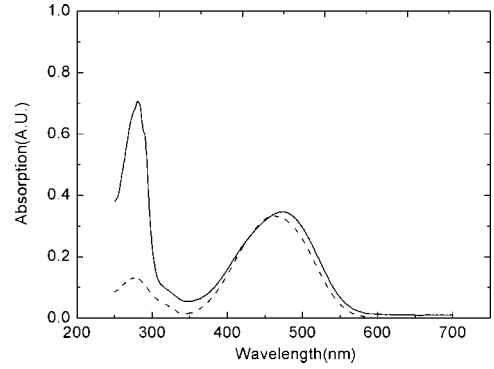

Figure 5. UV–vis absorption spectra for the calculation of DABS-to-avidin ratio. (—) the DABS-Av conjugate, (□) DABS-Cl (1×10^{-5} M in acetonitrile).

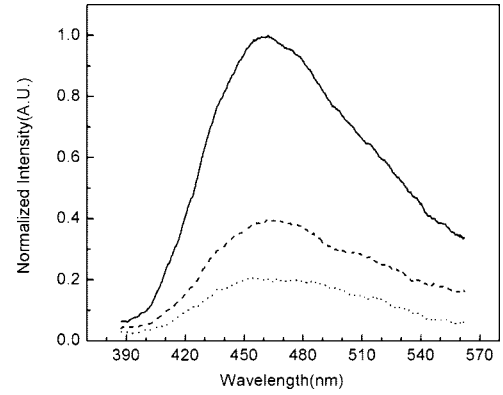

Figure 6. Two-photon excitation fluorescence spectra of the FRET model. (—) biotinylated DMAHAS (1×10^{-6} M), (. . .) biotinylated DMAHAS + DABS-Av (0.145 μM avidin with the dye-to-protein ratio as 1.6), (□) biotinylated DMAHAS + DABS-Av + unlabeled avidin (1×10^{-6} M). Excitation wavelength = 800 nm.

In this case, the dye-to-protein ratio should be scaled back. The UV–vis absorption spectra of pure DABS-Cl and the DABS-Av complex are illustrated in Figure 5, based on which the DABS-to-avidin ratio was calculated as 1.6.

Construction of the TP Excitation FRET Model. FRET occurred upon the addition of DABS-Cl conjugated avidin to the biotinylated DMAHAS solution, since DMAHAS and DABS-Cl were in proximity due to the specific binding of biotin and avidin. As is shown in Figure 6, when avidin conjugate was present, the two-photon excited fluorescence of biotinylated DMAHAS, the donor, was quenched by the acceptor. With adding free avidin to the above system, the fluorescence intensity

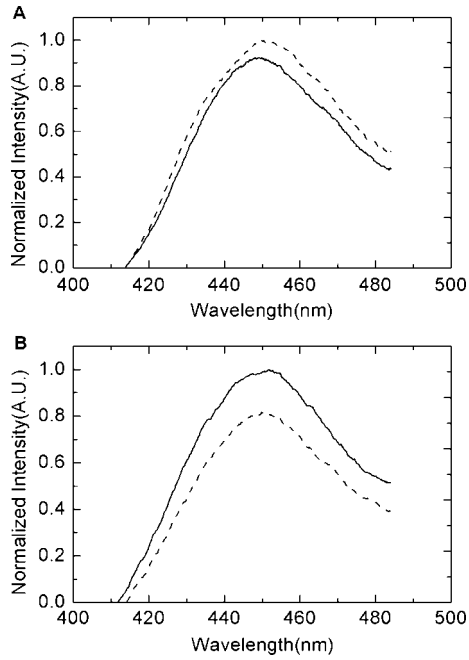

Figure 7. Two-photon excitation fluorescence spectra of control experiments. (A) (—) biotinylated DMAHAS (1×10^{-6} M), (□) biotinylated DMAHAS + DABS-Cl labeled BSA (0.122 μM BSA with the dye-to-protein ratio as 1.6). (B) (—) biotinylated DMAHAS (1×10^{-6} M), (□) biotinylated DMAHAS + unlabeled avidin (0.18 μM). Excitation wavelength = 800 nm.

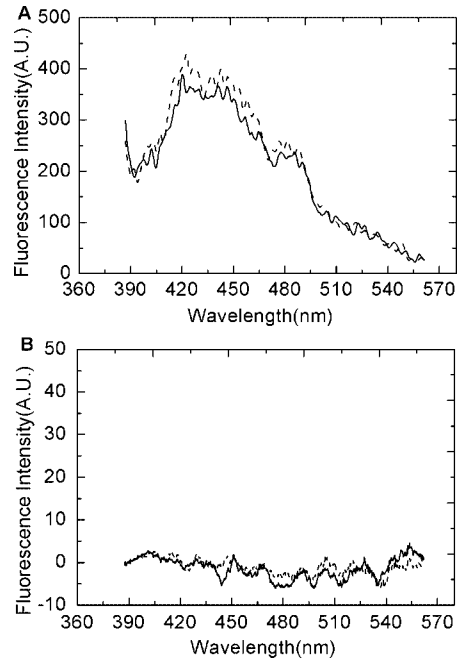

Figure 8. Comparison on the background signal under one-photon and two-photon excitation. (A) one-photon excitation. (—) DABS-Cl labeled avidin (0.145 μM avidin with the dye-to-protein ratio as 1.6), (□) avidin (1×10^{-6} M). Excitation wavelength = 372 nm, Excitation slit = 5 nm, Emission slit = 15 nm. (B) two-photon excitation. (—) DABS-Cl labeled avidin (0.145 μM avidin with the dye-to-protein ratio as 1.6), (□) avidin (1×10^{-6} M). Excitation wavelength = 800 nm.

recovered partially, which resulted from the competition between the labeled and unlabeled avidin toward biotin. The replacement of labeled avidin with free avidin is due to the stronger biotin binding ability of the latter (*25*).

Examination on the Specificity of the TP-FRET Model. Two control experiments were performed to exclude nonspecific interactions of biomolecules, in which biotinylated DMAHAS was incubated with DABS-Cl labeled BSA or with free avidin. DABS-BSA conjugate was prepared with the same method as DABS-Av. The dye-to-protein ratio was also determined to be 1.6. The fluorescence of biotinylated DMAHAS was not quenched by DABS-Cl labeled BSA which had almost the same concentration as avidin used to quench the fluorescence of biotinylated DMAHAS in the FRET model, i.e., 0.122 μM BSA versus 0.145 μM avidin (Figure 7A). And in another experiment, the fluorescence of biotinylated DMAHAS was not directly enhanced with 0.18 μM free avidin either (Figure 7B). These results indicated that the quenching and the recovery of the fluorescence of the donor were not induced by any nonspecific interactions of macromolecules, which is always a troublesome problem in large-size-particle-based biosensors (nanometer to micrometer magnitude), such as the UCPs described above.

In order to illustrate the ability of TP excitation FRET to exclude interferences from autofluorescence or scattering light, the background signal of biomolecules under one-photon and two-photon excitation was compared. Figure 8A indicates that in the case of one-photon excitation, when exciting avidin and DABS-Cl labeled avidin at the optimum excitation wavelength of DMAHAS at 372 nm, the background light around 420–480 nm could not be ignored, which would interfere the luminescence of DMAHAS and thus reduce the sensitivity. While under two-photon excitation at 800 nm there was only noise signal from the instrument, which could be negligible (Figure 8B).

Competitive Assay for Avidin. Finally, the TP-FRET model was tried to investigate the dependence of the relative fluorescence intensity (FL/FL_0) of the donor on the concentration of free avidin (where FL_0 represents the fluorescence intensity in the absence of free avidin and FL represents the fluorescence intensity under different concentrations of free avidin). As shown in Figure 9, the FL/FL_0 of the donor is dependent on avidin concentration and is linear to the concentration in a certain range (0.4−2.6 μM) with a correlation coefficient of 0.9947, which suggests that the two-photon FRET model could be a candidate for quantitative bioassay.

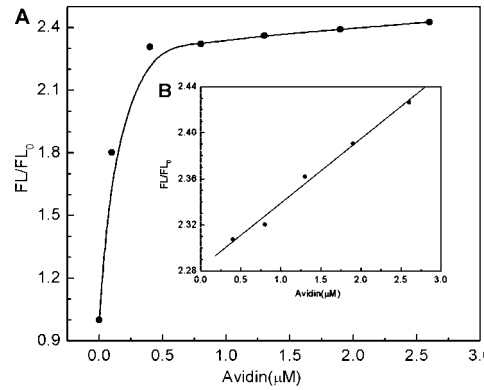

Figure 9. Competitive assay for avidin. (A) The dependence of FL/FL_0 of biotinylated DMAHAS on the concentration of free avidin. (B) The linear calibration curve of FL/FL_0 to the concentration of free avidin within the range 0.4−2.6 μM.

DISCUSSION

The results show that TP-FRET bioassays can overcome the shortcomings of conventional one-photon-FRET and that small organic molecules have advantages over the newly reported inorganic particles as the energy donor in bioassays. They have supported the hypothesis that TP excitable small organic molecules could be a kind of competent energy donor for FRET in homogeneous bioassays. However, it must be pointed out that, as a start of investigating the applicability of TP-FRET

with small molecule as energy donor in bioassay, the biocompatibility of the donor molecule used here and the analytical performance of the model have not been considered intensively. As a quantitative bioassay, the linear range for avidin is somewhat narrow, and the sensitivity is not as good as the reported UCPs-based biosensors. This might be mainly caused by the rather poor solubility of biotinylated DMAHAS in aqueous solution, which results in aggregation or precipitation out of water at high concentrations. Besides, the moderate TP absorption cross section of DMAHAS also restricted the detection sensitivity. An ideal TP-FRET donor molecule is expected to have large TP absorption cross section, high fluorescence quantum yield as well as good biological compatibility such as water solubility. Although the investigations on the relationship between molecular structure and TP absorption property over the past few years have enabled people to design and synthesize molecules with large TP absorption cross section (*26*, *27*), most of them have poor solubility in water preventing them from biological applications. Whereas many of the water soluble fluorophores commonly used as fluorescent tags in biological samples, if TP excitable, only have a small TP absorption cross section (*28*, *29*), for example, the value for fluorescein in water at pH 13 is only 36 GM (*30*) (1 GM = 1×10^{-50} cm^4 s $photon^{-1}$). Therefore for further research concerning TP-FRET methods in quantitative bioassay, emphasis should be put on development of donor molecules with both high water solubility and larger TP absorption cross section. It seems there is a conflict between the two aspects because, generally speaking, a larger absorption cross section requires a larger hydrophobic conjugated motif within the molecule, which always leads to the decrease of water solubility. Nevertheless, great efforts are being made and some exciting results have already been obtained in most recent years. For instance, by encapsulating the hydrophobic TP excitable molecules into the hydrophobic interior of micelles, large TP absorption cross section in water is achieved (*31*–*33*). Recently, a new type of fluorescent chromophores with efficient TP absorption cross sections and high fluorescence quantum yield in aqueous medium as well as in organic medium have been successfully developed (*34*). As such examples are so limited, it remains a challenge for scientists to investigate the effect of solvent especially water on the properties of two-photon excited molecules and to develop molecules with large TP absorption cross section in aqueous solutions.

O_2 Binding to Human Serum Albumin Incorporating Iron Porphyrin with a Covalently Linked Methyl-L-Histidine Isomer

Akito Nakagawa,[†] Teruyuki Komatsu,*[,†,‡] Makoto Iizuka,[†] and Eishun Tsuchida*[,†]

Research Institute for Science and Engineering, Waseda University, 3-4-1 Okubo, Shinjuku-ku, Tokyo 169-8555, Japan, and PRESTO, Japan Science and Technology Agency (JST), 4-1-8 Honcho, Kawaguchi-shi, Saitama 332-0012, Japan. Received October 30, 2007; Revised Manuscript Received December 1, 2007

We describe the significant difference in the O_2 binding affinities of human serum albumin (HSA) incorporating 5,10,15,20-tetrakis{α,α,α,α-*o*-(1′-methylcyclohexanamido)phenyl}porphinatoiron(II) with a covalently linked 1-methyl-L-histidine or 3-methyl-L-histidine [HSA-FeP(1-MHis), HSA-FeP(3-MHis)]. The HSA-FeP(3-MHis) showed an extraordinarily high O_2 binding affinity ($P_{1/2}$ = 0.2 Torr, 25 °C, pH 7.4), which is close to those of relaxed-state hemoglobin and myoglobin. However, replacement of the 3-methyl-L-histidine moiety in FeP(3-MHis) by 1-methyl-L-histidine caused a 35-fold reduction in O_2 affinity; the $P_{1/2}$ value of HSA-FeP(1-MHis) (22 Torr, 37 °C, pH 7.4) is almost identical to that of human red blood cells. Results of kinetic studies indicate that the low O_2 binding affinity of FeP(1-MHis) is predominantly manifested in the high O_2 dissociation rate constant. In a toluene solution, an identical relationship in the O_2 binding property was similarly observed for FeP(1-MHis) and FeP(3-MHis). The axial Fe-N(1-MHis) coordination might be restrained by steric interaction between the 4-methylene group of the histidine and the porphyrin plane.

Numerous synthetic model hemes have been prepared to mimic the O_2 binding capability of hemoglobin (Hb) and myoglobin (Mb) over the past few decades (*1*–*3*). In these highly modified iron(II) porphyrins, axial coordination of the nitrogenous base plays a crucial role in regulating O_2 binding affinity. Collman and co-workers demonstrated that picket-fence porphyrin[1] ligating a 1,2-dimethylimidazole (1,2-DMIm) showed a 70-fold lower O_2 binding affinity [$P_{1/2}$ (O_2 partial pressure at which 50% of porphyrin was dioxygenated) = 38 Torr, 25 °C] than that of the complex with 1-methylimidazole (1-MIm) (*4*, *5*). This reduction was ascribed to the steric interaction between the 2-methyl group of the imidazole and the porphyrin plane. Furthermore, they showed that the replacement of imidazole by pyridine in the tailed picket-fence porphyrin lowered the O_2-binding affinity by a factor of 40 (*6*). The weaker π-basicity of pyridine and the increased steric repulsion of the six-atom pyridine ring compared to that of the five-atom imidazole reduced the O_2 binding of the iron(II) porphyrins (*7*–*10*). We previously reported that 2-[{8-*N*-(methylimidazolyl)octanoyloxy}methyl]-5,10,15,20-tetrakis{α,α,α,α-*o*-(1′-methylcyclohexanamido)phenyl}porphinatoiron(II) [FeP(2-MIm)] formed a stable O_2 adduct in toluene solution, and human serum albumin (HSA) incorporating FeP(2-MIm) [HSA-FeP(2-MIm)]

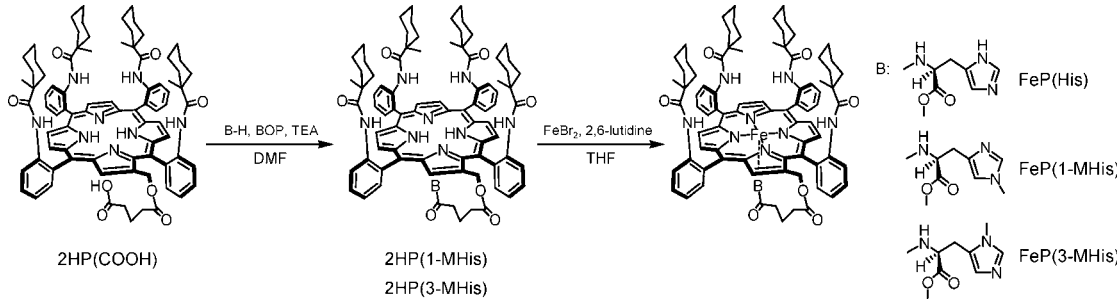

Figure 1. Synthetic scheme of iron(II) porphyrin bearing a covalently linked histidine derivative as an axial base at the β-pyrrolic position.

can bind O_2 not only in aqueous media (pH 7.4) but also in the blood stream as an artificial red blood cell (RBC) substitute (*11, 12*). For practical biomedical applications of the synthetic iron(II) porphyrin as an O_2 carrier, two physiological requirements exist. First, O_2 binding affinity should be close to that of human RBC ($P_{1/2}$ = 27 Torr, 37 °C). Second, it is favorable to use natural histidine as an axial base because some imidazole and pyridine derivatives show toxicity to respiratory organs and the central nervous system (*13*). Nevertheless, few studies have addressed O_2 binding of the synthetic model heme having a histidyl group (*14–16*). We have demonstrated the O_2 binding equilibrium and kinetics of 5,10,15,20-tetrakis{α,α,α,α-*o*-(1′-methylcyclohexanamido)phenyl}porphinatoiron(II) with an ω-histidylalkyl chain [FeP(His)[2]] (*17*). A new class of biocompatible O_2 carriers would be realized if we can regulate O_2 binding affinity by changing the steric and electronic natures of the attached histidine. We now report a significant difference in the O_2 binding properties of HSA hybrid with synthetic iron(II) porphyrin bearing a covalently linked 1-methyl-L-histidine or 3-methyl-L-histidine [HSA-FeP(1-MHis) and HSA-FeP(3-MHis)] (Figure 1) under physiological conditions (pH 7.4, 37 °C).

The 1-methyl-L-histidine methylester or 3-methyl-L-histidine methylester was introduced into the carboxyl group of the parent free-base porphyrin, 2-{(4-carboxybutanoyloxy)methyl}-5,10,15,20-tetrakis{α,α,α,α-*o*-(1′-methylcyclohexanamido)phenyl}porphin [2HP(COOH)] (*11*), via an amide linkage, yielding histidine-terminated porphyrins (>60% yield) (Figure 1). The cyclohexanoyl substituents stabilized the O_2 adduct complex rather than the pivaloy group (*11*). The central iron was inserted as iron(II) using $FeBr_2$ and 2,6-lutidine in anhydrous THF. The analytical data of all compounds were satisfactorily obtained (see Supporting Information).

Both FeP(1-MHis) and FeP(3-MHis) are readily incorporated into HSA (Mw: 66.5 kDa), producing stable artificial hemoproteins: HSA-FeP(1-MHis) and HSA-FeP(3-MHis) [in phosphate-buffered saline (PBS) solution at pH 7.4, [porphyrin]/[HSA] = 4 (mol/mol)]. The UV–vis absorption spectra of the aqueous HSA-FeP(1-MHis) and HSA-FeP(3-MHis) solutions under an N_2 atmosphere showed a similar feature of HSA-FeP(2-MIm) and HSA-FeP(His) (Figure 2) (Table S1) (*11, 17*). The spectral shapes resembled those of the five-N-coordinate high-spin ferrous complex of picket-fence porphyrin and other tetraphenylporphyrin derivatives (*5*). These results indicated that FeP(1-MHis) and FeP(3-MHis) formed a five-N-coordinate high-spin complex with an intramolecularly coordinated methyl-

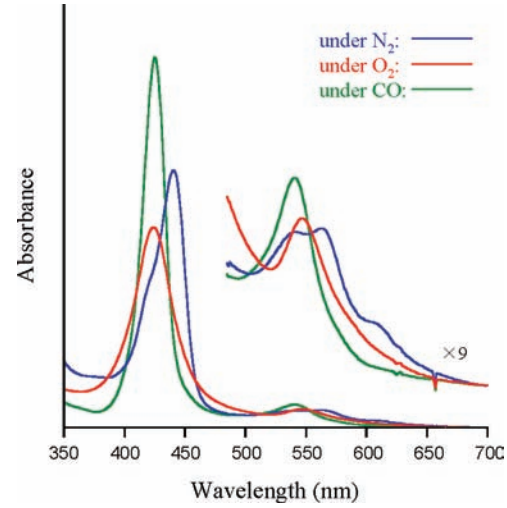

Figure 2. UV–vis absorption spectral changes of HSA-FeP(1-MHis) in PBS solution at 25 °C.

L-histidine moiety in the protein matrix. Upon bubbling of O_2 gas into the solution, the absorption pattern changed immediately to that of the O_2 adduct complex. The dioxygenations of these artificial hemoproteins have been observed reversibly under physiological conditions (pH 7.4, 37 °C). After passing the CO gas, the absorption maxima shifted to that of the carbonyl complex.

The O_2 binding affinities [$K = (P_{1/2})^{-1}$] of HSA-FeP(1-MHis) and HSA-FeP(3-MHis) were determined by the absorption spectral changes at various O_2 concentrations (eq 1).

$$\mathrm{FeP(B)} + \mathrm{O_2} \underset{k_{off}}{\overset{k_{on}}{\rightleftharpoons}} \mathrm{FeP(B)\text{-}O_2} \quad [K = (P_{1/2})^{-1}] \tag{1}$$

The HSA-FeP(3-MHis) showed an extraordinarily high O_2 binding affinity ($P_{1/2}$ = 0.2 Torr, 25 °C), which is 5-fold greater than that of HSA-FeP(His), which was close to the values of the relaxed-state Hb(α) and Mb (Table 1) (*18–20*). However, replacement of the 3-methyl-L-histidine moiety in FeP(3-MHis) by the 1-methyl-L-histidine isomer [FeP(1-MHis)] caused a 35-fold reduction of O_2 binding affinity ($P_{1/2}$ = 7 Torr, 25 °C); the $P_{1/2}$ value of 22 Torr at 37 °C was almost identical to that of human RBC (27 Torr) (*21*).

Laser flash photolysis experiments gave the association and dissociation rate constants for O_2 (k_{on}, k_{off}) (*5, 11*). The time course of the absorption change accompanying the O_2 recombinations to HSA-FeP(1-MHis) and HSA-FeP(3-MHis) after the laser pulse irradiation comprised two phases of first-order kinetics (Figure S1a). The decay was fitted by a double exponential profile, which provided the fast and slow association rate constants of O_2 (k_{on} and k'_{on}) (Table 1). This behavior was similarly observed in HSA-

FeP(His) and HSA-FeP(2-MIm) (*11*). It has been interpreted that the O_2 associations to the iron(II) porphyrins in HSA were affected by microenvironments around the accommodation site (steric hindrance of the amino acid residue and difference in polarity) (*22*). The kinetic data indicated that the low O_2 binding affinity of HSA-FeP(1-MHis) is predominantly manifested in the high O_2 dissociation rate constant (Table 1).

To evaluate the significant differences in FeP(1-MHis) and FeP(3-MHis), their O_2 binding parameters in toluene solution were determined. The UV–vis absorption spectra of ferrous FeP(1-MHis) (λ_{max}, 440, 542, 563 nm) and FeP(3-MHis) (λ_{max}, 440, 540, 565 nm) under an N_2 atmosphere showed the formation of a five-N-coordinate high spin complex. Dioxygenation was sufficiently stable and reversible at 25 °C depending on O_2 partial pressure. The recombination process of O_2 to the iron(II) porphyrins in toluene solution after laser flash photolysis was fitted by a single exponential (Figure S1b). FeP(3-MHis) exhibited a 6-fold higher O_2 binding affinity ($P_{1/2}$ = 0.3 Torr, 25 °C) compared to that of FeP(His) (Table 2) (*11*). Kinetically, this high O_2 binding affinity is attributable to the low O_2 dissociation rate. The high σ-basicity of 3-methyl-L-histidine (p*K*a, 6.48) in comparison to that of histidine (p*K*a, 6.00) (*23*) can serve to increase the electron density on the central metal, which would enhance O_2 uptake. FeP(1-MHis) showed a 90-fold lower O_2 affinity ($P_{1/2}$ = 27 Torr, 25 °C) relative to FeP(3-MHis), which is mainly caused by the high k_{off} value, as observed in aqueous media. In general, the steric hindrance to the axial base coordination deforms the six-coordinate structure of the iron(II) porphyrin and increases the O_2 dissociation rate constant (*1, 2*). For example, the 1,2-DMIm complexes showed 11–58-fold higher k_{off} values than the 1-MIm ligated complexes (*3, 5, 24*).

We simulated the geometry of histidine coordination in dioxygenated porphyrin.[3] The bond angle of N(por)−Fe−N(His) was 90° for FeP(His) and FeP(3-MHis), but it was markedly tilted in FeP(1-MHis) (a maximum of 98°) (Figure 3). On the basis of these results, it can be concluded that the axial coordination of 1-methyl-L-histidine to the central iron is

[3] The esff forcefield simulation was performed using an Insight II system (Molecular Simulations Inc.). The structure was generated by alternative minimizations and annealing dynamic calculations from 1,000 to 100 K.

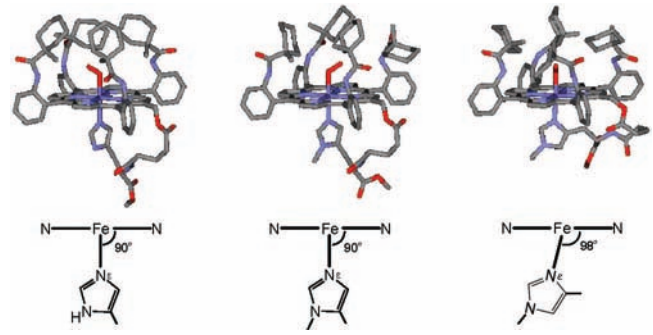

Figure 3. Simulated structures of the O_2 adduct complexes of FeP(His), FeP(3-MHis), and FeP(1-MHis). In FeP(His) and FeP(3-MHis), the bond angles of N(por)−Fe−N(His) were 90°, but 98° in FeP(1-MHis) because of the steric interaction between the 4-methylene group of histidine and the porphyrin plane. Molecular dynamics and minimization (force field: esff) were performed using an Insight II system. Hydrogens were omitted for clarification.

restrained by the steric interaction between the 4-methylene group of the histidine and the porphyrin plane, which significantly increased the dissociation rate of O_2.

In conclusion, a variation in the methyl-L-histidine isomer covalently linked at the porphyrin periphery changed the O_2 binding affinity of the iron(II) porphyrin by a factor of 90 in toluene. This difference is greater than the previous finding for a picket-fence porphyrin (2-MIm) complex-bound O_2 with a 70-fold lower affinity than that of the 1-MIm complex (*4*). The increased k_{off} value of FeP(1-MHis) is caused by steric repulsion between the 4-methylene group of histidine and the porphyrin plane. In aqueous media, the O_2 binding ability of HSA incorporating the iron(II) porphyrin can also be modulated by structural isomerization of the axial methyl-L-histidine. HSA-FeP(1-MHis) with a $P_{1/2}$ value similar to that of human RBC under physiological conditions can become a promising O_2 carrier, which satisfies both the biocompatibility and clinical requirements for efficient O_2 delivery to the tissue cells.

Small-Molecule Reagents for Cellular Pull-Down Experiments

Xiang Wang, Brandon S. Imber, and Stuart L. Schreiber*

Howard Hughes Medical Institute, Broad Institute of Harvard and MIT, 7 Cambridge Center, Cambridge, Massachusetts 02142, and Department of Chemistry and Chemical Biology, Harvard University, 12 Oxford Street, Cambridge, Massachusetts 02138. Affinity purification of interacting proteins from cellular extracts is a powerful technique for identifying the cellular targets of small molecules. Affinity matrix-based small-molecule reagents are usually prepared by conjugating small molecules of interest to a solid support such as agarose. This protocol describes an efficient and robust method to immobilize small molecules containing a primary alcohol, a common functional group in small molecules, especially in small molecules prepared using diversity-oriented synthesis. This method comprises one element of a systematic approach to the target identification problem in chemical biology.

Small molecules that modulate protein function are valuable tools for studying cell circuitry, among others (*1*, *2*). These small-molecule probes are increasingly being identified in cell-based, phenotypic screens (*3*). This discovery route requires effective methods for identifying cellular targets, and the technique of affinity chromatography (*4*), which requires small-molecule-based affinity reagents, has proven to be the most effective approach to accomplish this goal (*5*, *6*).

Many methods have been developed to attach small molecules covalently to beaded agarose containing such functional groups as acids, amines, and so forth (*7*). A complementary pair of functional groups on the beads and small molecules is required for selective immobilization. Recently, Finn and co-workers have shown that small molecules bearing a terminal alkyne or azide can be covalently attached to agarose using a Cu(I)-catalyzed 1,3-dipolar cycloaddition reaction (*8*) with high efficiency and specificity (*9*). Amino- or hydroxyl-containing small molecules are extremely common in modern collections of compounds used in high-throughput screening. Whereas amino-containing small molecules are routinely conjugated to beaded agarose for use in affinity chromatography, hydroxyl-containing small molecules have proven to be more challenging. Although methods exist to immobilize hydroxyl-containing ligands using oxiranes (*10*) or vinyl sulfones (*11*), these suffer from either the poor reactivity of oxiranes or the poor stability of the sulfones.

Diversity-oriented synthesis (DOS, Figure 1) yields small molecules well-suited for the discovery of probes, the optimization of them, and the eventual efficient manufacturing of the optimized variants (*12*, *13*). In our own studies, we have incorporated a hydroxymethyl group into *every* product, resulting from our diversity syntheses. This functional group is poised for further modifications, such as immobilization on the glass surface for small-molecule microarray screens (*14*), covalent modification with biasing elements for targeting classes of proteins (*15*), and, as described here, conjugation to beaded agarose for the identification of cellular targets.

RESULTS AND DISCUSSION

Here, we report an efficient and robust method to immobilize hydroxyl-containing small molecules to beaded agarose. 1,1′-Carbonyldiimidazole (CDI *16*−*18*) reagent has been used to immobilize amino-containing small molecules (*19*). We recognized that the mixed imidazolide intermediate resulting from reaction of this reagent with hydroxyl-containing compounds is inert to most functional groups and stable to a wide range of solvents and temperatures. We reasoned that the resulting carbamate bond would be noncharged and highly stable under conditions used in cellular pull-downs, and thus well-suited for many target identification applications. Hence, we chose to use CDI to activate the hydroxyl-containing compounds. The resulting mixed imidazolide was immobilized on amino-containing beaded agarose after the excess CDI was quenched with water (Figure 2). The excess amine on the agarose surface was blocked by acetylation using *N*-acetoxysuccinamide.

This protocol has been used to synthesize dozens of primary alcohol-containing small molecules (see Figure 3 for representa-

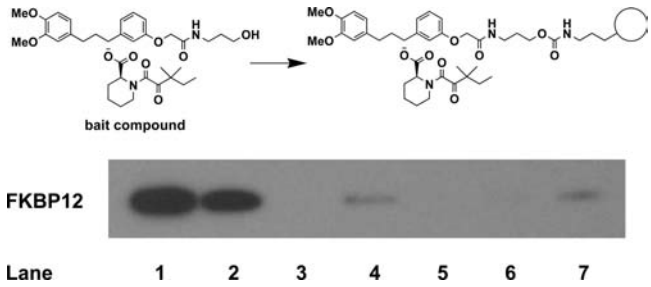

Figure 5. Immobilization of a compound known to bind immunophilin proteins and the affinity purification of FKBP12 from A549 whole cell lysate using the immobilized bait. tive molecules A1−A11) conjugated to beaded agarose with over 85% loading efficiency. Secondary alcohol-containing small molecules such as A12 (Figure 3) may also be conjugated to beaded agarose, albeit with significantly lower efficiency (<40%). The loading efficiency can be determined by high-performance liquid chromatography–mass spectroscopy (HPLC-MS) when a nonreactive small molecule is used as an internal standard. Figure 4 shows the typical LC trace before and after the conjugation reaction in the presence of reserpine. This protocol can tolerate a variety of functional groups, such as esters, amides, acids, phenols, tertiary alcohols, and so forth.

A small molecule known to bind members of the FKBP family of proteins (*20*) (scheme of Figure 5) was conjugated with carboxylink coupling gel using the protocol described above. The conjugate was next used to affinity purify a cellular target of this compound, FKBP12, from the lysate of A549 lung epithelial cells. Electrophoresis followed by Western immunoblotting experiments showed most of FKBP12 (lanes 1 and 2 of Figure 5) was retained by the affinity reagent. The blank beads did not pull down any FKBP12 protein (lane 3 of Figure 5).

In summary, we have developed an efficient and robust method to immobilized primary alcohol-containing small molecules to beaded agarose. Further optimization for secondary alcohols and applications of this method for the target identification of hit molecules derived from high-throughput screenings are in progress and will be reported in due course.

ACKNOWLEDGMENT

We thank the National Cancer Institute (2PO1 CA-78048) for support of this research, Drs. J. Shaw, A. Franz, C. Neumann, R. Looper, R. Mazitschek, N. Kumagai, D. Pizzirani, and Mr. B. Gray for donation of the compounds, and Drs. J. Yang and A. N. Koehler for helpful discussion. S.L.S. is an Investigator of Howard Hughes Medical Institute at the Broad Institute of Harvard and MIT.

Lanthanide-Binding Tags with Unnatural Amino Acids: Sensitizing Tb^{3+} and Eu^{3+} Luminescence at Longer Wavelengths

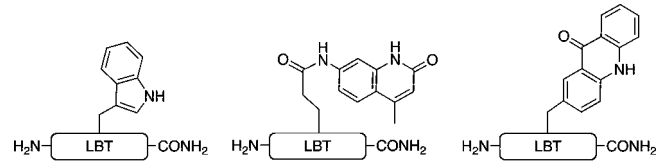
Anne M. Reynolds, Bianca R. Sculimbrene, and Barbara Imperiali*

Departments of Chemistry and Biology, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Cambridge, Massachusetts 02139. Received November 19, 2007; Revised Manuscript Received February 1, 2008

Lanthanide-binding tags (LBTs) are small, genetically encoded, versatile protein fusion partners that selectively bind lanthanide ions with high affinity. The LBT motif features a strategically positioned tryptophan residue that sensitizes Tb^{3+} luminescence upon excitation at 280 nm. Herein, we describe the preparation of new LBT peptides that incorporate unnatural amino acids in place of tryptophan, and which sensitize both Tb^{3+} and Eu^{3+} luminescence at lower energies. We also report the semisynthesis of proteins tagged with these new LBTs using native chemical ligation. This expands the scope of LBTs and will enable their wider use in luminescence applications.

Understanding the localization and fate of proteins *in vivo* is a key research objective in cell biology. Toward this end, fluorescence spectroscopy has become a widely used technique, with much effort devoted toward the development and incorporation of suitable fluorophores into biological molecules. Lanthanide ions represent attractive complements to the more commonly used organic fluorophores, as these species exhibit long-lived (millisecond) luminescence lifetimes, large Stokes shifts, unpolarized luminescence, and sharp emission peaks. Due to these advantages, the use of lanthanide-based probes is becoming more common in applications such as luminescence spectroscopy (*1, 2*) and luminescence resonance energy transfer (LRET) (*3, 4*). To overcome the inherently low absorption of lanthanide ions, researchers have developed sensitizing fluorophores that, upon excitation, transfer energy to the lanthanide (*5, 6*). However, few general methods to incorporate lanthanide-based probes into proteins exist, and these are generally limited to substitution of lanthanides at native calcium-binding sites (*7–9*), incorporation of unnatural amino acids with side-chain chelators (*10*), and covalent labeling of reactive side chains using lanthanide chelates (*11, 12*).

Recent work in our laboratory has been focused on the development of lanthanide-binding tags (LBTs), which are short peptides (17–20 amino acids) that selectively and avidly bind lanthanide ions (*13–16*). Originally based on EF-hand Ca^{2+}-binding loops, LBTs have been optimized for Tb^{3+} binding through multiple rounds of split-and-pool peptide library synthesis (*14, 16*). In these motifs, the indole ring of a strategically positioned tryptophan residue sensitizes Tb^{3+} luminescence (*17*). These multitasking tags have been appended to various proteins and used to detect peptide–protein interactions using LRET (*18*). The paramagnetic lanthanides have also been used to aid in the determination of protein structure by NMR spectroscopy (*19, 20*), and the heavy atoms provide scattering power for phasing X-ray crystallographic data (*21*). While clearly advantageous for these *in vitro* studies, the UV light necessary for tryptophan excitation (280 nm) is not ideal in cellular systems (*22*), and the ability to sensitize only Tb^{3+} limits their more general use in luminescence applications. Herein, we report the development of new LBTs that incorporate non-natural amino acids as sensitizers, which feature lower-energy excitation and sensitize Eu^{3+} as well as Tb^{3+} luminescence.



H_2N-FITDNNDG**X**IEGDELLLEEG-$CONH_2$

Figure 1. Sequences of peptides LBT(Trp), LBT(cs124), and LBT(Acd), where the side chain of the amino acid denoted **X** is illustrated.

In these studies, we targeted two unnatural amino acids as potential lanthanide sensitizers in LBTs. The first is based on carbostyril 124 (cs124), which has been used as a sensitizer of both Tb^{3+} and Eu^{3+} luminescence in the context of polyaminocarboxylate chelates (*23, 24*). The second is based on the acridone (Acd) fluorophore, which has been previously used to sensitize Eu^{3+} luminescence in small molecules (*25–28*). These fluorophores were selected because they are known to sensitize lanthanide luminescence, making them attractive initial targets in the context of LBTs, and they are excited at lower energies (337 and 390 nm, respectively). Finally, the acridone fluorophore is highly photostable, making it particularly attractive for potential *in vivo* applications. For our studies, both of the sensitizers were incorporated into amino acid building blocks for use in solid-phase peptide synthesis (SPPS). The cs124 moiety was coupled to the side chain of glutamic acid via the aniline nitrogen (*29*), while the acridone-containing amino acid was prepared via a literature procedure (*30*). Both of the amino acids were N_α-Fmoc-protected and incorporated into LBT peptides at the optimal position for sensitizing lanthanide luminescence *via* standard SPPS (Figure 1) (*17*). The parent LBT containing tryptophan was also prepared for comparison (*16*).

Luminescence spectra of all three LBT peptides in the presence of lanthanide ions are illustrated in Figure 2. LBT(cs124) sensitizes Tb^{3+} luminescence upon excitation at 337 nm, and the intensity of the emission at 544 nm is higher than that of LBT(Trp) (Figure 2a). The presence of the new sensitizer does not significantly alter the Tb^{3+} affinity, as the dissociation constant (K_D), determined by direct titration, is 34 nM (Table 1) compared to 19 nM for LBT(Trp) (*16*). LBT(cs124) also

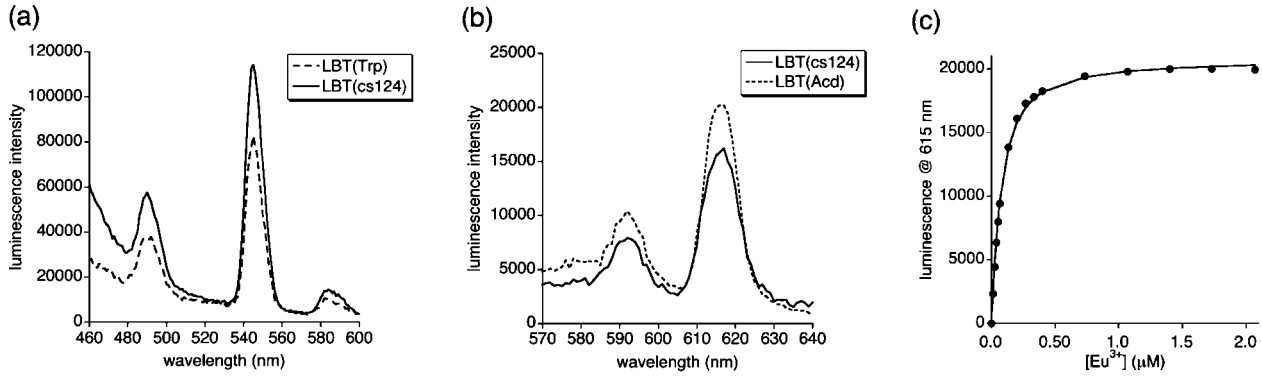

Figure 2. (a) Emission spectra of LBTs (50 nM) in the presence of Tb^{3+} (200 nM) with excitation at 280 nm for LBT(Trp) (---) and 337 nm for LBT(cs124) (—). (b) Emission spectra of LBTs (50 nM) in the presence of Eu^{3+} (200 nM) with excitation at 337 nm for LBT(cs124) (—) and 390 nm for LBT(Acd) (••••). (c) Titration of LBT(Acd) (50 nM) with Eu^{3+} (•), and fit derived from SPECFIT/32 (—).

Table 1. Comparison of Ln^{3+} Binding Affinities of LBT Peptides and Tagged Proteins[a]

construct	$K_D(Tb^{3+})$	$K_D(Eu^{3+})$
LBT(Trp)	19 nM[b]	
LBT(cs124)	34 ± 3 nM	10 ± 2 nM
LBT(Acd)		52 ± 2 nM
LBT(Trp)-Crk(SH2)	35 ± 5 nM	
LBT(cs124)-Crk(SH2)	46 ± 12 nM	69 ± 4 nM
LBT(Acd)-Crk(SH2)		54 ± 17 nM

[a] Titrations performed at a peptide/protein concentration of 50 nM. [b] From ref (*16*).

effectively sensitizes Eu^{3+} luminescence, and titration with Eu^{3+}provides a dissociation constant of 10 nM. This slightly tighter binding of Eu^{3+} versus $Tb^{3+}$was unexpected based on our previous observations that a similar LBT sequence binds lanthanides other than Tb^{3+} with lower affinity (*15*), though the difference is not large between these two lanthanide ions. The cs124-containing amino acid thus allows for the synthesis of new LBTs that sensitize both Tb^{3+} and Eu^{3+} luminescence. The only disadvantage of the cs124 sensitizer in this context is the sensitivity of the fluorophore to photobleaching. Under constant illumination, the luminescence intensities decrease 10–15% over 60 s, but remain nearly constant when O_2 has been removed (Figure S1). Additionally, the initial luminescence intensities nearly double when deoxygenated buffers are used. We therefore used deoxygenated buffers in all experiments with this sensitizer.

LBT(Acd) also sensitizes Eu^{3+} luminescence upon excitation at 390 nm, with a higher overall luminescence intensity than LBT(cs124) (Figure 2b). The spectrum was collected using a 570 nm long-pass filter to reduce interference from acridone fluorescence. The dissociation constant, determined by direct titration of LBT(Acd) with Eu^{3+}, is 52 nM (Figure 2c), which is only slightly weaker than the other LBTs (Table 1). No luminescence was observed in the presence of other lanthanides including Nd^{3+}, Tb^{3+}, Er^{3+}, Tm^{3+}, and Yb^{3+}. Finally, because the acridone moiety is extremely photostable (Figure S1), LBTs featuring this sensitizer such as LBT(Acd) will be extremely useful in applications where continuous irradiation is required; this characteristic was also reported in previous studies in which the acridone amino acid was used as a fluorophore (*31*).

As is the case for other lanthanide-based probes, the luminescence intensities of these new LBTs are lower than typical organic fluorophores, with detection limits in the low-nanomolar range in the case of the peptides sensitizing Eu^{3+} and the picomolar range for peptides sensitizing Tb^{3+}. However, the long-lived lanthanide luminescence provides the ability to perform time-gated experiments that minimize background autofluorescence (*1, 2*), increasing the overall sensitivity.

With these promising results, we next targeted the assembly of full-length proteins tagged with the new LBTs. We chose the SH2 domain of the Crk adaptor protein as the test case, as this is a protein that has been previously tagged with LBTs for LRET experiments (*18*). While several methods exist for incorporating unnatural amino acids into proteins (*32, 33*), we chose to prepare the LBT-tagged proteins *via* semisynthesis using native chemical ligation (NCL) (*34*). In this approach, one fragment bearing a C-terminal thioester is reacted with a second fragment containing an N-terminal cysteine residue. Reversible thioester exchange leads to an S-to-N acyl rearrangement to form a native amide bond. Using the NCL strategy, the desired LBT can be appended to the N-terminus of Crk(SH2), which requires the peptide to be prepared with a C-terminal thioester and the protein to be expressed with an N-terminal cysteine.

Toward this end we synthesized LBTs containing either tryptophan or the unnatural amino acids at the sensitizing position on highly acid-labile TGT resin. This allows the completed peptides to be released from the resin using 0.5% TFA in CH_2Cl_2, while leaving the side-chain protecting groups intact (Figure S2). The free carboxyl termini were then coupled to benzyl mercaptan to generate the protected thioester peptides (*35, 36*). The side-chain protecting groups were removed under standard cleavage conditions to provide the LBT-thioesters, which were purified by reverse-phase HPLC and confirmed by ESI-MS.

Crk(SH2) was overexpressed in *E. coli* as a GST fusion protein construct with a tobacco etch virus (TEV) protease recognition site (ENLYFQC) (*37*), such that proteolytic cleavage affords the desired protein with an N-terminal Cys residue (Figure 3a). After purification on Glutathione Sepharose and subsequent TEV cleavage, the appropriate peptide thioester was added directly to the crude reaction mixture along with sodium 2-mercaptoethanesulfonate (MESNA, 150 mM) to facilitate rapid thioester exchange. From gel electrophoresis analysis, the ligations proceeded to 80–90% completion, and did not progress further after 16 h (Figure 3b). The excess thiol and peptide were removed by dialysis, while the GST and His_6-tagged TEV were removed with Glutathione Sepharose and Ni-NTA agarose, respectively. The LBT-tagged proteins were isolated with >90% purity, with a small amount of unligated protein as the major byproduct.

An advantage of the new sensitizers, particularly in the case of Acd, is that they can be used to visualize the tagged proteins. For example, visualization of an SDS-PAGE gel on a shortwave UV transilluminator (300 nm) reveals a very weak fluorescence signal from the tryptophan residues in LBT(Trp)-Crk(SH2), a stronger signal from the cs124 moiety in LBT(cs124)-Crk(SH2), and very intense fluorescence from the acridone moiety in

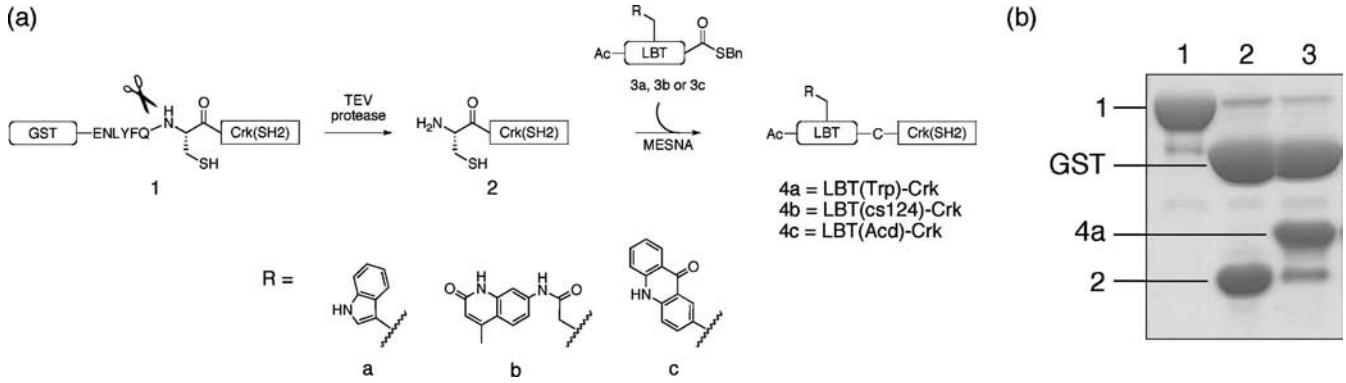

Figure 3. (a) Semisynthesis of LBT-tagged Crk(SH2) proteins. (b) Coomassie-stained SDS-PAGE gel showing GST-TEV-Crk(SH2) (lane 1), products of TEV cleavage (lane 2), and products of NCL with peptide 3a (lane 3). Similar results were observed in the semisynthesis of 4b and 4c.

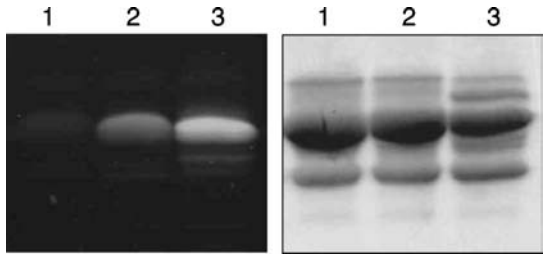

Figure 4. SDS-PAGE gel of semisynthetic LBT-tagged Crk(SH2) proteins, visualized on a transilluminator (300 nm, left), then stained with Coomassie Brilliant Blue (right). Lane 1 = LBT(Trp)-Crk(SH2); Lane 2 = LBT(cs124)-Crk(SH2); Lane 3 = LBT(Acd)-Crk(SH2).

LBT(Acd)-Crk(SH2) (Figure 4). Staining the same gel with Coomassie Brilliant Blue reveals that all proteins are present in approximately the same quantities. The emission of the acridone amino acid was detected with as little as 4.5 μg of protein and is comparable to detection of protein with the Coomassie stain. This provides a simple method for monitoring the ligations using SDS-PAGE using standard laboratory equipment; the sensitivity could likely be significantly improved by using a high-tech imaging instrument.

The luminescence properties of the new LBTs were quite similar in the context of the full proteins, where LBT(Trp)-Crk(SH2) sensitizes Tb^{3+} luminescence, LBT(cs124)-Crk(SH2) sensitizes both Tb^{3+} and Eu^{3+} luminescence, and LBT(Acd)-Crk(SH2) sensitizes only Eu^{3+} luminescence. The trends in overall luminescence intensities are the same, with cs124 being brighter than tryptophan for Tb^{3+} and acridone being brighter than cs124 for Eu^{3+} (Figure S3). Titrations revealed that the binding constants for the respective lanthanides are all in the low nanomolar range and are similar to those of the peptides (Table 1).

An important feature of LBTs is that water molecules are completely excluded from the inner coordination sphere of the bound lanthanide (*15*). This is important for the luminescence properties, as bound water molecules lead to luminescence quenching via energy transfer to the O−H bonds. To ensure that the change of sensitizer and lanthanide has not affected this coordination, luminescence decay experiments were performed in varying ratios of H_2O and D_2O. The luminescence lifetimes obtained from these decay experiments were used to calculate the number of water molecules, q, bound to Eu^{3+} in the new LBT-proteins using a literature procedure (*38*, *39*). The results provided q values of 0.006 for LBT(Acd)-Crk(SH2) and −0.06 for LBT(cs124)-Crk(SH2). (Uncertainties in q values are estimated to be ±0.5, owing to errors in the measured luminescence decay rates and the calculated proportionality constants (*39*).) These results provide further evidence that the coordination environment around Eu^{3+} is similar to that for Tb^{3+} in the optimized LBTs studied to date.

In summary, we have developed LBTs featuring two new sensitizers that are excited at lower energy and sensitize luminescence of Tb^{3+} and Eu^{3+}. Other advantageous photophysical properties of LBTs have not been affected, as these LBTs bind lanthanides tightly and exclude water molecules from their inner coordination spheres. We have established a general method for appending LBTs with lower-energy excitation to the N-terminus of a target protein using native chemical ligation and semisynthesis. This expands the utility of this class of lanthanide-based probes and current work is aimed at using them *in vivo*.

ACKNOWLEDGMENT

This research was supported by the NSF-CRC program (CHE-0304832). A.M.R. and B.R.S. acknowledge the NIH for Ruth L. Kirschstein National Research Service Awards. We also thank Prof. Martin Schwarz (University of Virginia) for a generous gift of the clone expressing the Crk SH2 domain, and Emi Sei for initial synthetic contributions.

Received September 3, 2007; Revised Manuscript Received December 18, 2007

(*E*)-5-[2-(Methoxycarbonyl)ethenyl]cytidine was biotinylated through a diisopropylsilylacetal linkage and attached to the surface of hydrophilic streptavidin-coated microspheres through the high-affinity noncovalent interaction between biotin and streptavidin. The functionalized microspheres form a stable suspension in water. Upon UV irradiation, the nonfluorescent (*E*)-5-[2-(methoxycarbonyl)ethenyl]cytidine on the microspheres undergoes photocyclization to produce highly fluorescent 3-β-D-ribofuranosyl-2,7-dioxopyrido[2,3-*d*]pyrimidine. The fluorescence intensity of the microspheres can be correlated to the particle-specific UV doses applied at different suspension concentrations. The microspheres allow one to measure the UV dose (fluence) distribution in high-throughput water disinfection systems.

INTRODUCTION

Several years ago, we initiated a multidisciplinary project aimed at developing a means for experimentally characterizing continuous-flow UV light disinfection photoreactors. For this project, a mobile UV light actinometer based on a microsphere that has the following three features is required: (i) Under UV irradiation at 254 nm (and other germicidally active wavelengths), the microsphere produces fluorescence when excited with a lower energy light, and the fluorescent intensity on the microsphere is correlated to the dose of germicidal UV light applied to the microspheres over a broad range. (ii) The functionalized microsphere has a hydrophilic surface and forms a relatively stable suspension in water. (iii) The physical properties of the microspheres such as size, shape, and density resemble those of relevant waterborne microbial pathogens. The use of microspheres for measurement of UV dose (fluence) distribution has been reported, but the microspheres were coated with a fluorescent dye whose absorption maximum fell at a much higher wavelength than required for germicidal action, and the measured effect was photobleaching (*1*). Moreover, the magnitude of the change in fluorescence signal was relatively small for the doses of UV radiation that are relevant in disinfection applications. In order to achieve maximum sensitivity and range, a system in which the UV irradiation transforms a nonfluorescent molecule with an absorption maximum in the wavelength range of germicidal lamps to a light-stable fluorescent molecule would be preferable. There are many examples of fluorescent photochromic compounds (*2*–*5*), but relatively few examples of compounds that when irradiated with UV light of wavelength less than 300 nm lead to a single product that is both UV-stable and fluorescent.

In 1982, we reported the preparation and characterization of (*E*)-5-[2-(methoxycarbonyl)ethenyl]cytidine (**1**) (*6*). This cytidine nucleoside analogue is not fluorescent; however, under UV irradiation at 254 nm, its trans-double bond is presumed to undergo trans–cis isomerization to form the intermediate **2**, which cannot be isolated or even observed. In intermediate **2**, the amino group would now be positioned in close proximity to the methyl ester group, which facilitates rapid cyclization through nucleophilic attack to give the stable and highly fluorescent product 3-β-D-ribofuranosyl-2,7-dioxopyrido[2,3-*d*]pyrimidine (**3**, Scheme 1). We have previously reported the use of compound **1** as a chemical actinometer for germicidal UV irradiation (*7*). We reasoned that attaching **1** to 5 μm diameter hydrophilic microspheres would provide mobile actinometers with the desired properties for application in the measurement of UV fluence distribution in flowthrough UV disinfection systems. This manuscript describes the chemistry to accomplish the construction of the derivatized microsphere, while the dosimetry application is described elsewhere (*8*).

EXPERIMENTAL PROCEDURES

General. All reactions were performed under a blanket of dry dinitrogen or argon. Reagents and solvents available from commercial sources were used as received unless otherwise noted. Pyridine and triethylamine were distilled over CaH_2. Acetone was dried over anhydrous Na_2SO_4 and filtered. Thin layer chromatography (TLC) was performed using silica gel on

aluminum 60F-254, 200 μm thickness TLC plates. Flash column chromatography was performed using 40 μm silica gel. NMR spectra were obtained using 250 and 500 MHz NMR spectrometers. Chemical shifts (δ) are reported relative to residual CD_3OH ($\delta = 4.87$ ppm for ^1H and 49.15 ppm for ^{13}C). Infrared spectra were recorded on a FTIR spectrophotometer. Melting points were determined using a Mel-Temp melting point apparatus and are uncorrected. Streptavidin-coated microspheres (1.0% solid content in 100 mM borate, pH 8.5 + 0.1% BSA + 0.05% Tween 20 + 10 mM EDTA buffer with 0.1% NaN_3 antimicrobial agent; mean diameter 5.5 μm; number of microspheres per gram 2.038×10^{10}; number of microspheres per milliliter 2.040×10^8; surface area 1.240×10^{12} μm^2) were manufactured by Polysciences, Inc. (Warrington, PA). TTL buffer: 100 mM Tris−HCl, pH 8.0, and 0.1% Tween 20, 1.0 M LiCl. PBS buffer: 0.1 M, pH 7.0.

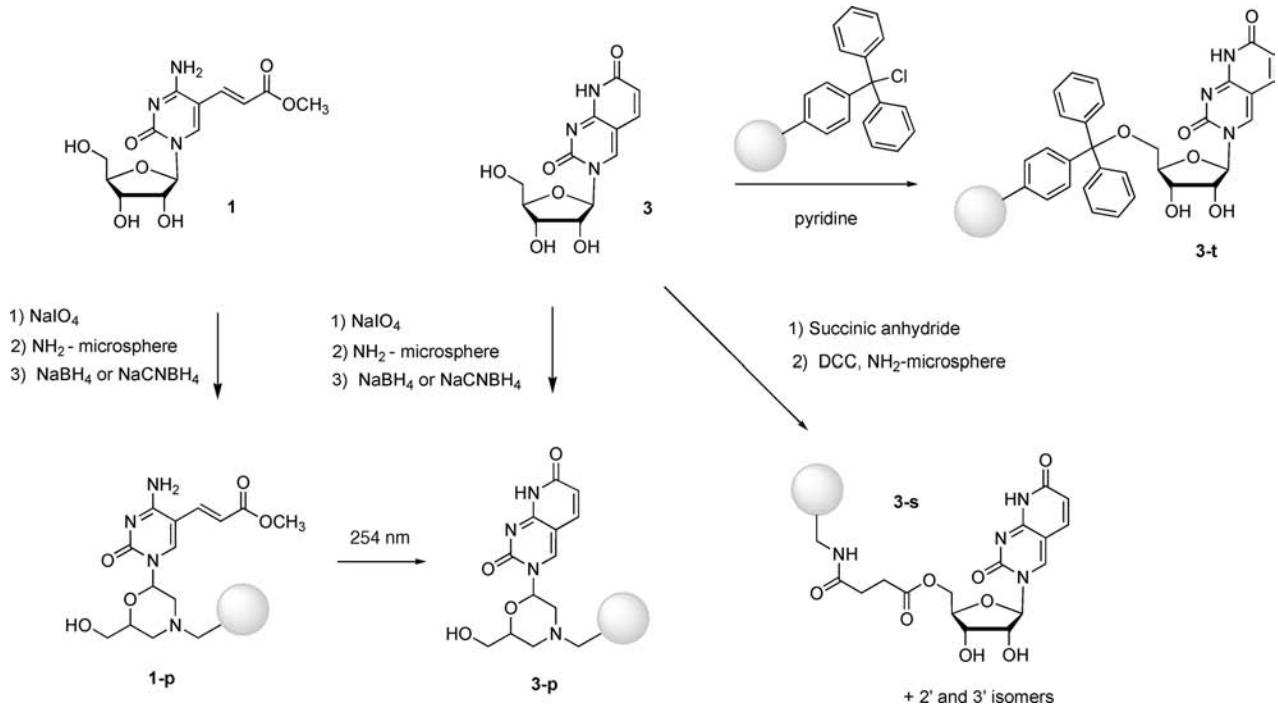
2′,3′-Propylidinonyl-(*E*)-5-[2-(methoxycarbonyl)ethenyl] cytidine (4). A one-neck round-bottom flask was charged with **1** (1.2 g, 3.6 mmol), *p*-toluenesulfonic acid monohydrate (2.1 g, 11.0 mmol), and acetone (20 mL). To this suspension was added DMF (about 5 mL) until insoluble materials were dissolved, forming a light yellow solution. After stirring at room temperature overnight, the reaction mixture was partitioned between saturated Na_2CO_3 solution (20 mL) and CH_2Cl_2 (20 mL × 3). The organic phase was washed with water (20 mL × 2), dried over $MgSO_4$, and solvents were removed under reduced pressure. Flash column chromatography (9:1 EtOAc/MeOH) gave **4** as a white solid (1.16 g, 88%): mp 162–3 °C; $R_f = 0.45$ (9:1 EtOAc/MeOH); IR (KBr, cm^{-1}) ν 3350, 2984, 1646, 1625, 1207; ^1H NMR (CD_3OD, 500 MHz) δ 1.38 (s, 3H), 1.58 (s, 3H), 3.76–3.89 (m, 2H), 3.79 (s, 3H), 4.32 (s, 1H), 4.76–4.95 (m, 2H), 5.95 (s, 1H), 6.37 (d, 1H, $J = 15.8$ Hz), 7.62 (d, 1H, $J = 15.8$ Hz), 8.51 (s, 1H); ^{13}C NMR (CD_3OD, 500 MHz) δ 25.7, 27.7, 52.3, 63.1, 82.2, 87.1, 89.5, 95.7, 104.2, 115.0, 118.4, 137.0, 144.3, 157.2, 165.6, 168.8; HRMS (ESI, M + H^+) Calcd for $C_{16}H_{22}N_3O_7$368.1458, found 368.1476.

Biotinyl Alcohol 7. Biotin (2.00 g, 8.19 mmol), triethylamine (1.72 mL, 12.29 mmol), and DMF (10 mL) were combined in a one-neck round-bottom flask and cooled to 0 °C. To this white suspension, *iso*-butylchloroformate (1.70 mL, 13.10 mmol) was added via syringe, and the reaction mixture was stirred at 0 °C for 1 h. The white suspension was then cooled to −60 °C. A solution of 6-amino-1-hexanol (**6**, 1.55 g, 13.10 mmol) and triethylamine (1.37 mL, 9.83 mmol) in DMF (5 mL) was added slowly via syringe, and the suspension was stirred overnight while gradually warming to room temperature. Anhydrous ether (100 mL) was added; the resulting white precipitate washed with ether (10 mL × 2) and then dissolved in methanol (50 mL) and stirred with Rexyn 201 (OH) resin (10 g) for 1 h. After filtration to remove the resin, the light yellow solution was concentrated under reduced pressure. Addition of ether (30 mL) produced the product as a white solid (2.40 g, 85%): mp 159–60 °C; IR (thin film, cm^{-1}) ν 3301, 2931, 2854, 1684, 1633; ^1H NMR (CD_3OD, 500 MHz) δ 1.36–1.75 (m, 14H), 2.20 (t, 2H, $J = 7.4$ Hz), 2.71 (d, 1H, $J = 12.7$ Hz), 2.93 (dd, 1H, $J = 12.8$, 5.0 Hz), 3.15–3.31 (m, 3H), 3.54 (t, 2H, $J = 6.6$ Hz), 4.31 (dd, 1H, $J = 7.8$, 4.4 Hz), 4.50 (dd, 1H, $J = 7.8$, 5.0 Hz); ^{13}C NMR (CD_3OD, 500 MHz) δ 26.6, 26.9, 27.8, 29.5, 29.8, 30.4, 33.6, 36.8, 40.3, 41.0, 57.0, 61.6, 62.9, 63.4, 166.1, 175.9; EIMS *m/z* 343 (M^+), 299, 283, 226, 179, 124; HRMS (EI) Calcd for $C_{16}H_{29}N_3O_3S$ 343.1930, found 343.1914.

Biotinylated Nucleoside Derivative 8. To a suspension of **7** (1.20 g, 3.48 mmol) in DMF (7.0 mL) and pyridine (2.0 mL) was added diisopropyldichlorosilane (630 μL, 3.48 mmol) via syringe at −60 °C. The colorless solution was stirred for about 5 h while warming to room temperature, and then cooled to −60 °C again. A solution of **4** (427 mg, 1.16 mmol) in DMF (3.0 mL) was added via syringe, and stirred overnight while warming to rt. Addition of ether (50 mL) gave a white precipitate, which was partitioned between sat $NaHCO_3$ (25 mL) and *n*-butanol (20 mL × 5). The organic phase was dried over $MgSO_4$, solvents removed, and the product purified by flash column chromatography (9:1 CH_2Cl_2/MeOH). The product was obtained as a light yellow foam (433 mg, 45%): $R_f = 0.25$ (9:1 CH_2Cl_2/MeOH); IR (thin film, cm^{-1}) ν 2928, 2860, 1699, 1648; ^1H NMR (CD_3OD, 500 MHz) δ 0.88–1.77 (m, 34H), 2.19 (t, 2H, $J = 6.6$ Hz), 2.71 (d, 1H, $J = 12.7$ Hz), 2.92 (dd, 1H, $J = 12.7$, 5.0 Hz), 3.10–3.21 (m, 4H), 3.31 (d, 2H, $J = 1.4$ Hz), 3.54 (t, 1H, $J = 6.6$ Hz), 3.75 (t, 2H, $J = 6.3$ Hz), 3.77 (s, 3H, -OMe), 3.97–4.06 (m, 2H), 4.30 (dd, 1H, $J = 7.8$, 4.4 Hz), 4.36–4.37 (m, 1H), 4.48–4.51 (m, 1H), 4.95 (dd, 1H, $J = 6.2$, 1.8 Hz), 5.81 (d, 1H, $J = 1.7$ Hz), 6.30 (d, 1H, $J = 16.3$ Hz), 7.60 (d, 1H, $J = 15.8$ Hz), 8.19 (s, 1H); ^{13}C NMR (CD_3OD, 500 MHz) δ 13.3, 13.4, 17.9, 17.9, 18.0, 25.7, 26.8, 27.1, 27.6, 28.0, 29.7, 29.9, 30.6, 33.9, 37.0, 40.5, 41.2, 52.4, 57.2, 61.8, 63.5, 64.4, 64.8, 82.6, 87.2, 90.0, 96.8, 104.1, 114.8, 118.6, 137.3, 144.1, 157.1, 165.6, 166.2, 168.6, 176.1; HRMS (ESI, M + H^+) Calcd for $C_{38}H_{63}N_6O_{10}SSi$ 823.4096, found 823.4087.

Biotinyl Nucleoside Derivative 10. Following the procedure for preparation of **8**, biotin derivative **9** (255 mg, 0.52 mmol), DMF (6 mL), imidazole (87 mg, 1.25 mmol), diisopropyldichlorosilane (113 μL, 0.63 mmol) and **4** (230 mg, 0.63 mmol) gave **10** as a white foam after flash column chromatography (9:1 CH_2Cl_2/MeOH, 255 mg, 51%): $R_f = 0.3$ (9:1 CH_2Cl_2/MeOH); IR (thin film, cm^{-1}) ν 3187, 2941, 2862, 1648, 1068; ^1H NMR (CD_3OD, 500 MHz) δ 0.94–1.04 (m, 14H), 1.29–1.31 (m, 6H), 1.36 (s, 3H), 1.43–1.45 (m, 2H), 1.56 (s, 3H), 1.64–1.68 (m, 2H), 1.69–1.80 (m, 2H), 1.82 (t, 2H, $J = 8.3$ Hz), 2.62 (t, 2H, $J = 7.4$ Hz), 2.34–2.37 (m, 2H), 2.76 (d, 1H, $J = 12.7$ Hz), 2.95 (dd, 1H, $J = 12.7$, 7.9 Hz), 3.22–3.24 (m, 1H), 3.38 (t, 4H, $J = 5.4$ Hz), 3.57 (t, 4H, $J = 5.7$ Hz), 3.63 (s, 4H), 3.78 (s, 3H), 4.00–4.05 (m, 2H), 4.36–4.38 (m, 2H), 4.56 (dd, 1H, $J = 7.7$, 5.1 Hz), 4.88 (dd, 1H, $J = 6.3$, 3.3 Hz), 5.03 (dd, 1H, $J = 6.4$, 1.4 Hz), 5.90 (s, 1H), 6.35 (d, 1H, $J = 15.7$ Hz), 7.63 (d, 1H, $J = 15.5$ Hz), 8.22 (s, 1H); ^{13}C NMR (CD_3OD, 500 MHz) δ 14.5, 14.7, 18.27, 18.30, 18.33, 18.4, 25.7, 26.9, 27.6, 29.6, 29.8, 30.3, 30.5, 32.5, 35.5, 36.8, 40.3, 40.4, 41.2, 41.6, 50.0, 52.4, 52.5, 57.0, 61.7, 63.4, 64.5, 70.7, 71.3, 74.9, 82.2, 86.7, 89.5, 95.8, 104.7, 115.0, 119.4, 136.7, 143.6, 165.2, 168.2, 176.2, 176.3; HRMS (ESI, M + H^+) Calcd for $C_{41}H_{74}N_7O_{13}SSi$ 968.4835, found 968.4830.

Scheme 2. Strategies for Directly Linking Compounds 1 and 3 to Microspheres

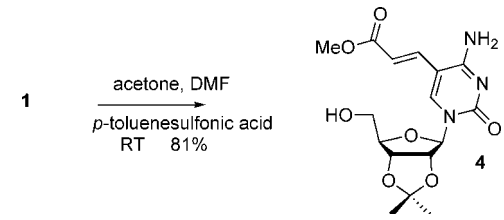


Attachment of Biotinylated Nucleoside Analogues to Streptavidin-Coated Microspheres. The microsphere suspension (1.0 mg, 0.1 mL) was transferred to a centrifuge tube. The storage buffer was removed by first centrifuging and removing the supernatant, leaving the white microspheres, which were washed with 200 μL TTL buffer. The biotinylated nucleosides (**8** or **10**, ~80μg in 25 μL TTL buffer) were added to the microspheres, and incubated at room temperature for 20 min with occasional gentle shaking. The buffer was removed after centrifuging, and the microspheres were washed with PBS buffer (1 mL × 3) and water (1 mL × 3) and stored as a suspension in water at 0 °C in the dark. Microspheres coated with **8** were found to be unstable, even after repeated additional washings with PBS buffer (1 mL × 2) and water (1 mL × 2), fluorescence in the buffer or water was observed under UV light, and fluorescence on the washed microspheres became less and less intense. Microspheres coated with **10** were stable under these washing conditions, after storing at 0 °C for several days in the dark, and no adverse effects were observed in fluorescence studies. Following UV irradiation, the excitation maximum of the fluorescent microsphere suspension in water was 336 nm and the emission maximum fell at 381 nm, which closely matches the excitation and emission maxima of compound **3** (*6*). The determination of the relationship between UV dose and fluorescent intensity of the microsphere suspension in water is reported elsewhere (*8*).

RESULTS AND DISCUSSION

To tether nucleosides **1** and **3** to microspheres, we initially explored the strategies outlined in Scheme 2. Microspheres with nucleoside **1** directly attached would serve as the sensor, but we also required microspheres with compound **3** for calibration. It became clear after considerable effort that simple direct methods for tethering would not yield microspheres with the fluorescence response required for quantification of UV dose. In all cases, the conjugation reaction was either inefficient or there was considerable quenching of the photoreaction and/or fluorescence. Problems associated with quenching when fluorophores are closely spaced within a matrix or on a surface are well-recognized (*9–11*).

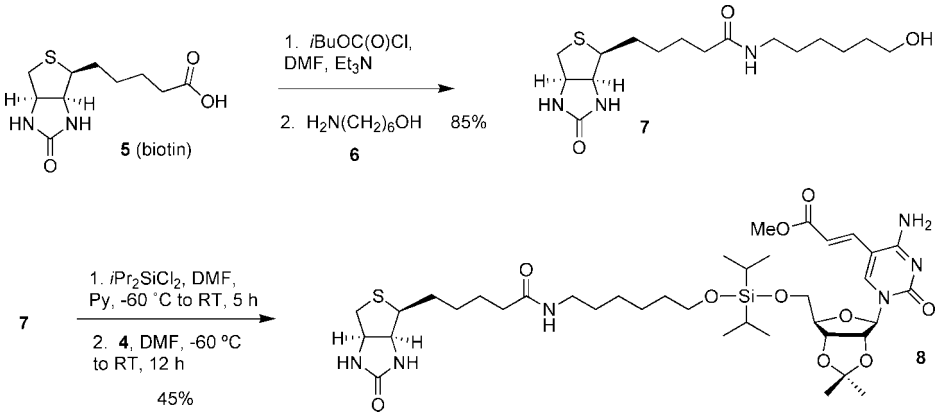
Scheme 3. Preparation of Compound 4



As outlined in Scheme 2, the conjugation methods attempted included periodate oxidation followed by borohydride (*12*) or cyanborohydride (*13*) mediated reductive amination to amine-coated polystyrene and silica microspheres. This method has been shown to enable the conjugation of ribonucleotides, including cytidine derivatives, to solid supports (*12, 14, 15*). However, we were not able to obtain fluorescent microspheres either by attachment of compound **1** to give derivatized beads **1-p** followed by UV irradiation (254 nm) or by direct attachment of fluorescent nucleoside **3**. The final product in both cases should be **3-p**. A variety of solvents (H_2O, DMF, and DMSO), both sodium borohydride and sodium cyanoborohydride, and a number of different silica and polystyrene amine-substituted microbeads were investigated without success. Seela and co-workers have attached ribonucleosides to sepharose beads by first synthesizing 2′,3′-ethylidene derivatives from levulinic acid and then coupling the pendant carboxylic group to 6-amino-hexylagarose using the water-soluble carbodiimide EDC (*16–18*). We attempted a number of variations on this approach (not shown), but were not able to obtain fluorescent microspheres.

Alcohols can be directly linked to polystyrene trityl chloride resin (*19*). However, fluorescent nucleoside **3** did not yield fluorescent microspheres with a polystyrene trityl resin. It is possible that resin **3-t** was formed but we were unable to detect fluorescence. Finally, we attempted to link nucleoside **3** by way of a succinic acid linker (Scheme 2) to give **3-s**, but this approach also failed to give fluorescent microspheres. As a result of these failures, we chose to pursue a biotin−streptavidin conjugation strategy that would significantly reduce the density of nucleoside **1** while at the same time placing each molecule

Scheme 4. Preparation of Biotinyl Cytidine Analogue 8



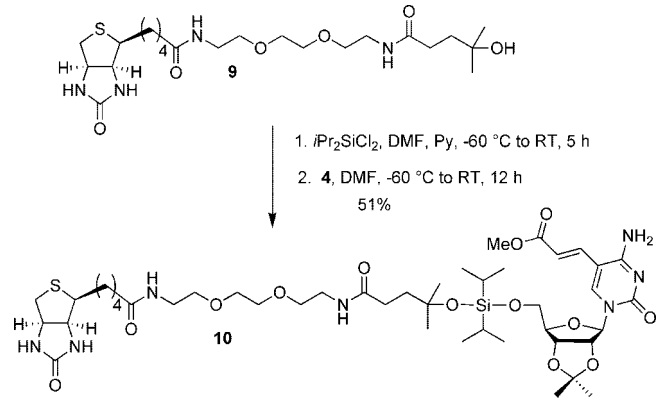
further from the surface of the microsphere. Streptavidin-coated microspheres with a wide range of physical properties are commercially available; and these microspheres are hydrophilic because streptavidin is relatively hydrophilic. The microspheres chosen for this study have a diameter of ~5.5 μm and a specific gravity of 1.05, which would allow them to mimic the movement and trajectories of waterborne microbial pathogens. A study by Buranda et al. on 6.2 μm diameter streptavidin-coated microspheres yielded an estimate of 10^6 binding sites per microsphere (*20*). This translates to an average density of less than one binding site per 100 nm^2.

However, there was yet another issue to be resolved. It has been observed that biotin−fluorophore conjugates are also subject to quenching. When Gruber et al. examined biotin conjugates of fluorescein, tetramethylrhodamine, Cy3, and Cy5, they found that fluorescein and tetramethyrhodamine bound through a 14 atom spacer showed considerable quenching (*21*). With longer spacers (PEG800 and PEG1900), there was considerably less quenching. We chose to investigate a 20 atom spacer that was both more rigid and sterically hindered than simple PEG spacers, rationalizing that the steric bulk and rigidity would function more effectively to separate chromophores than simple incorporation of very long, but highly flexible spacers. It was necessary to link the spacer through the ribose group, since the methoxycarbonyl and 4-amino groups are required for the photochemical reaction. Moreover, the 2′- and 3′-OH groups are conveniently protected by acetal formation, which leaves a single site, the 5′-hydroxy available for attachment of the spacer to biotin. At the same time, a 2′,3′-acetal would be anticipated to considerably increase solubility in organic solvents thereby facilitating the chemistry necessary to functionalize the molecule at the 5′-OH. When nucleoside **1** was stirred in a mixture of acetone and DMF in the presence of *p*-toluenesulfonic acid, compound **4** was obtained in 83% yield as a white solid (Scheme 3) (*22*).

In order to achieve selective coupling between a biotin containing moiety and compound **4** at the 5′-hydroxyl group in the presence of the unprotected cytosine amino group, we pursued a strategy based on the generation of silyl ether linkers. We first prepared biotinyl alcohol **7** by coupling biotin (**5**) to aminoalcohol **6** using *i*BuOC(O)Cl as the carboxylic acid activating agent (*23*). Then, 1 equiv of dichlorodiisopropylsilane was allowed to react with the hydroxyl group in the biotinyl alcohol **7**. The intermediate was not isolated but allowed to then react directly with the cytidine analogue **4** through the formation of a diisopropylsilylacetal functionality as shown in Scheme 4 to give the biotinylated cytidine analogue **8**.

Next, attempts were made to attach **8** to streptavidin-coated microspheres. The microspheres were first washed with two portions of TTL buffer (100 mM Tris−HCL, pH 8.0, and 0.1% Tween 20, 1.0 M LiCl), and then suspended in a TTL buffer containing **8**. The suspension was incubated at room temperature for 20 min with occasional gentle shaking in the dark. The microspheres were then collected by centrifuging, and washed sequentially with PBS buffer and deionized water, and then suspended in deionized water. After exposure of the microspheres to UV light, fluorescence was observed on the microspheres. However, fluorescence was also observed in the washing buffer and continued to appear in the wash solution on repeated washing. Concomitantly, the fluorescence on the microspheres became less and less intense with washing. From these observations, it appeared that the silyl acetal linkage in **8** was not stable in aqueous buffer and water. This was confirmed by shaking **8** in a mixture of water and *n*-butanol, whereupon after 2 h, **8** could no longer be detected in the *n*-butanol phase by TLC.

Scheme 5. Conjugation of Biotin Derivative 9to Nucleoside 4



Since the stability of silyl acetal linkage is dependent on the bulkiness of the alkyl groups attached to silicon (*24, 25*), we also investigated *t*Bu(Ph)$SiCl_2$ as a reagent for linking the nucleoside to biotin (*24, 25*). However, this strategy generated complex mixtures that may be attributed to the generation of a new chiral silicon center as well as less complete transformation because of the lower reactivity of *t*Bu(Ph)$SiCl_2$. Attempts to isolate the desired product in pure form failed. This led us to ultimately design compound **10**. The silyl acetal linkage in this molecule is expected to be more stable than that in **8**, because of the bulky tertiary carbon attached to one of the two oxygen atoms in the linkage. Moreover, in comparison to *t*Bu(Ph)$SiCl_2$, *i*Pr_2SiCl_2 is more reactive, and does not generate a new chiral silicon center. As shown in Scheme 5, under reaction conditions similar to those used to prepare compound **8**, **4** was linked to biotin derivative **9** (*26*) with *i*$Pr_2SiCl_2$to give the target molecule **10** in 51% yield after flash chromatography purification.

We found that only 1.2 equiv of compound **9** were required to achieve effective conversion of nucleoside **4** to compound

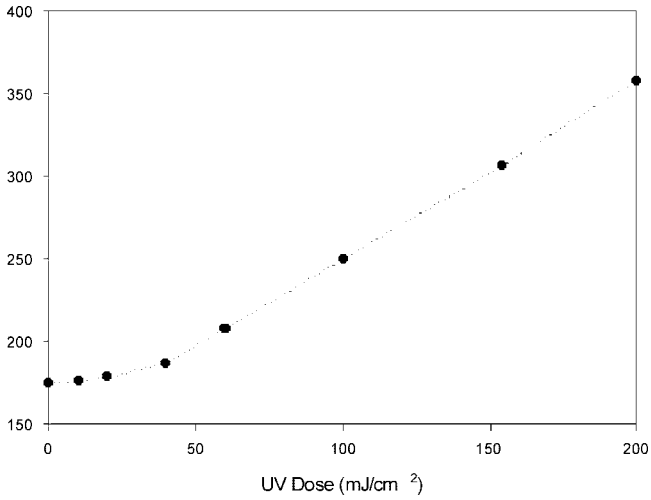


Figure 1. Mean fluorescence intensity (FI) of microspheres as a function of applied UV_{254} dose. Reported FI values represent the mean of measurements collected for roughly 10 000 particles by flow cytometry.

10. The biotinylated nucleoside **10** was obtained as a clean white foam and its structure established by ^1H, ^{13}C NMR, UV, IR, and high-resolution mass spectroscopy. It is stable in air, water, and other commonly used organic solvents, and no decomposition was observed during chromatography on silica gel and storage in desiccator for several months.

With the more stable **10** in hand, attachment to streptavidin-coated microspheres was investigated. Using a procedure similar to that used for attaching **8** to the microspheres, **10** was found to be irreversibly attached. Even after washing extensively with PBS buffer and water, UV irradiation of the microspheres still promoted the cyclization reaction to yield fluorescent microspheres when excited at 320 nm. The relationship between the fluorescence intensity (FI) of a population of microspheres (~10 000) was determined by flow cytometery (Figure 1). Flow cytometry was performed on an Epics Altra cell sorter (Beckman-Coulter) using a 351 nm line of the Argon 5 W Enterprise laser (Coherent, Inc.) with power set at 60 mW for the UV line. FI measurements were collected in linear mode with a band-pass filter at 380 nm. As illustrated in Figure 1, the FI of the population of microspheres increased monotonically with increasing UV dose. The cause of the lag in FI in the limit of low UV dose is unknown; however, this lag is overcome in application of microspheres for measurement of UV dose distribution delivery by preirradiation of microspheres at a dose of 50 mJ/cm^2 or more (*8*).

In conclusion, by using the unique diisopropylsilyacetal linkage and the strong noncovalent interaction between biotin and streptavidin, we successfully attached the highly functionalized cytidine analogue to microspheres. Because of their hydrophilic surface, the microspheres can form a stable suspension in water. The fluorescence intensity of the suspension of these microspheres responds monotonically to applied UV light dose, which demonstrates their suitability for use as a mobile UV light actinometer.

ACKNOWLEDGMENT

This work was funded by the Water Environment Research Foundation (Grant 99-CTS-2-UR) the Showwalter Trust, and the National Institutes of Health (GM53155). Assistance from the Purdue University Cytometry Laboratories and from Eric Cox is greatly appreciated. Support from the National Cancer Institute Grant (P30 CA23168) awarded to Purdue University is also gratefully acknowledged

Received July 12, 2007; Revised Manuscript Received December 4, 2007

Recombinant adenovirus type 5 particles (AdCMVLuc) were labeled with two different bifunctional ligands capable of forming stable complexes with paramagnetic lanthanide ions. The number of covalently attached ligands varied between 630 and 1960 per adenovirus particle depending upon the chemical reactivity of the bifunctional ligand (NHS ester versus isothiocyanide), the amount of excess ligand added, and the reaction time. The bioactivity of each labeled adenovirus derivative, as measured by the ability of the virus to infect cells and express luciferase, was shown to be highly dependent upon the number of covalently attached ligands. This indicates that certain amino groups, likely on the surface of the adenovirus fiber protein where cell binding is known to occur, are critical for viral attachment and infection. Addition of $^{177}Lu^{3+}$ to chemically modified versus control viruses demonstrated a significant amount of nonspecific binding of $^{177}Lu^{3+}$ to the virus particles that could not be sequestered by addition of excess DTPA. Thus, it became necessary to implement a prelabeling strategy for conjugation of preformed lanthanide ligand chelates to adenovirus particles. Using preformed Tm^{3+}-**L2**, a large number of chelates having chemical exchange saturation transfer (CEST) properties were attached to the surface residues of AdCMVLuc without nonspecific binding of metal ions elsewhere on the virus particle. The potential of such conjugates to act as PARACEST imaging agents was tested using an on-resonance WALTZ sequence for CEST activation. A 12% decrease in bulk water signal intensity was observed relative to controls. This demonstrates that viral particles labeled with PARACEST-type imaging agents can potentially serve as targeted agents for molecular imaging.

INTRODUCTION

Magnetic resonance imaging (MRI), one of the most widely used noninvasive imaging modalities, provides contrast in images of soft tissues that depend upon the proton density of tissues and inherent differences tissue water relaxation rates. In the early 1980s, it was discovered that paramagnetic metal chelates could accelerate proton spin–lattice relaxation rates and thereby enhance image contrast. More recently, another method for altering MR image contrast was reported that relies on selective presaturation of chemically exchanging protons involving either endogenous molecules or exogenous probes which then exchange with bulk water protons to reduce its intensity. This new class of contrast media is referred to as CEST agents (*1*). There are numerous types of exchangeable protons in tissue, but the most common are -OH and -NH groups. Unfortunately, the chemical shift difference between these types of exchanging protons and water protons is small, and consequently selective saturation can be problematical. However, the potential advantages of CEST agents over conventional T_1 agents, including the ability to switch contrast "on" and "off" and the sensitivity of CEST to environmental effects such as pH and temperature, provide incentives for continued development of such agents. The concentration of any single chemically exchanging proton or water molecule that is required to produce significant CEST contrast is quite high, but this limitation can partially be compensated for by optimizing the chemical exchange rate (k_{ex}) between the agent and bulk water and by maximizing the number of exchangeable sites available on each agent. A successful example of the latter was reported recently (*2*) where glycogen in mouse liver was imaged by presaturation of the exchanging glycogen -OH protons (glycoCEST) that lie ~1 ppm downfield of tissue water.

Paramagnetic metal complexes having a single, slowly exchanging bound water molecule can function by a CEST mechanism as well (*3*). As the chemical shift of lanthanide-bound water molecules can be shifted as much as 700 ppm away from the bulk water resonance, this offers the possibility of selectively saturating the Ln^{3+}-bound water proton signal with less chance of inadvertently saturating bulk water protons. This large chemical shift difference between the Ln^{3+}-bound and bulk water signals makes this class of CEST contrast agents unique. For this reason, the term "PARACEST" is now used to differentiate such paramagnetic complexes from diamagnetic CEST compounds (*4*). Although paramagnetic systems have this attractive advantage, they do suffer from the same lack of sensitivity as diamagnetic CEST molecules on a proton concentration basis. One obvious method that could be used to increase the sensitivity of a CEST agent is to increase the number of exchangeable sites per molecule (*5*). High molecular weight platforms such as proteins, liposomes, linear and branched polymers, and spherical polymers based on core–shell morphology offer the opportunity to accumulate higher numbers of exchangeable sites per particle and thereby increase their "effective" concentration.

L1 **L2**

There is interest in using viral particles as biodelivery platforms due to their structural and architectural diversity and biological properties. The architecture of the viral particles consists of interior and exterior regions that can be chemically or genetically modified. The interior compartment of the viral particle can provide a naturally constrained cage for encapsulation of inorganic or organic materials (*6*), while chemical modifications of exterior surface capsid proteins have included specific nucleation of inorganic materials on the surface of the particles, and derivatization with PEG (polyethylene glycol) (*7*), fluorescent labels (*8, 9*), peptides (*10*), or MRI contrast agents (*11*). Studies by Allen et al. (*12*) have shown that the naturally occurring, endogenous metal binding sites of cowpea chlorotic mottle virus bind Gd^{3+} ions with a dissociation constant of $K_d = 31\ \mu M$ yielding a nanoparticle template for MRI applications. Anderson and co-workers (*11*) have extended this strategy by labeling the MS2 virus capsid with over 500 GdDTPA moieties (DTPA = diethylenetriaminepentaacetic acid) but did not test the viral bioactivity of the resulting modified nanoparticles.

Human adenovirus is a nonenveloped, double-stranded DNA-containing particle approximately 130 nm in diameter with icosahedral symmetry (*13*). Although over 50 types and 6 subgroups of human adenovirus have been identified, adenovirus type 2 and 5 of subgroup C are most commonly used as vectors in gene transfer. The adenovirus binds to cell surface receptors with high affinity *via* a COOH-terminal globular knob domain of the fiber protein. The recombinant knob domain binds about 4700 sites per HeLa cell with an affinity of $3 \times 10^9\ M^{-1}$ and is capable of blocking adenovirus infection of human cells (*14*). Each capsid protein of the adenovirus particle contains multiple exposed functional groups that can be chemically modified. Adenovirus 5 knob protein chemically modified with succinidyl 6-hydrozinonicotinate (HYNIC) and subsequently radiolabeled with ^{99m}Tc shows high-affinity binding to cells ($K_d = 1.4$ nM) (*15*). Replacement of the E1 region of the viral genome with a foreign gene generates a recombinant vector capable of efficiently infecting a wide variety of cells *in vitro* and tissues *in vivo*. These properties have prompted our interest in the use of adenoviral particles as drug delivery platforms.

The goal of this study was to compare the chemical reactivity of two bifunctional chelating agents **L1** and **L2** (Scheme 1) with replication-defective adenovirus particles and to optimize the labeling of viral particles with PARACEST agents derived from thulium (Tm^{3+}) and **L2** under conditions where viral activity is not totally disrupted. The AdCMVLuc virus (*20*) containing the luciferase reporter gene was chosen for this study so we could follow the infectious activity of the virus using a standard luciferase chemiluminescent assay after chemical modification with either reactive metal-free bifunctional ligands or metal ion preloaded chelates with favorable exchange properties for CEST imaging. Our goal was to create PARACEST-labeled viral particles that retain their infectious biological activity for potential use as tissue targeting agents for combined optical (luciferase) and MR (PARACEST) molecular imaging.

EXPERIMENTAL PROCEDURES

Materials and Methods. All starting reagents and solvents were obtained from commercial sources and used as received unless otherwise indicated. ^1H and ^{13}C NMR spectra were acquired using a JEOL Eclipse 270 operating at 270 and 67.5 MHz, respectively. Chemical shifts are reported in parts per million (δ) relative to TMS at 0 ppm. Infrared spectra were obtained on a Nicolet Avatar 360 FT-IR spectrometer either as KBr pellets or as thin films. UV–vis absorption spectra were recorded using a Pharmacia LKB-Ultrospec III single beam spectrometer. Hydrogenation was performed using a Parr hydrogenation apparatus. Electrospray ionization mass spectroscopy (ESI MS) was performed by HT Laboratories, San Diego, California. Fast atom bombardment mass spectroscopy (FAB MS) was performed by the Mass Spectrometry Facility at the University of Alabama at Tuscaloosa. Elemental analyses and inductively coupled plasma mass spectrometry (ICP MS) measurements were completed by Galbraith Laboratories, Knoxville, Tennessee. Luciferase (relative light units) was quantified using a SIRUS Luminometer V3.1. ^{177}Lu (0.05 N HCl) was obtained from the Research Reactor Center, University of Missouri at Columbia, Missouri. All buffers and reagent solutions for radiolabeling were prepared in Millipore deionized (DI) water and treated with Chelex 100 resin (100–200 mesh, Na^+ form, Bio-Rad Laboratories) for at least 4 h, followed by filtration through 0.22 μm CA membrane (Corning Inc.). Metal-free plastic ware used for all labeling experiments was soaked in 15% HNO_3 for 12 h and rinsed with Millipore DI water prior to use. Quantification of radioactivity was determined using a Rita Star Radioisotope TLC analyzer (Straubenhardt, Germany). Virus concentrations are expressed in particles/mL as measured by absorbance at 260 nm. CEST spectra and T_2 measurements were acquired using Varian INOVA-500 spectrometer at 500 MHz. Prior to data acquisition, samples were allowed to warm to room temperature and equilibrated in the probe at 25 °C for at least 10 min.

Synthetic Methods. 1,4,7-tris(*tert*-butyloxycarbonyl)-1,4,7,10-tetraazacyclo dodecane (*16*), 2-bromo-*N*-methylacetamide, 2-*p*-isothiocyanatobenzyl-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetra (methylcarbonylamide) (*17*), and 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetra(methylcarbonylamide) (referred to as DTMA) (*18*) were prepared as described previously.

1,4,7-Tris(*tert*-butyloxycarbonyl)-1,4,7,10-tetraazacyclododecane-10-benzyl acetate (4). K_2CO_3 (1.54 g, 11.1 mmol) was added to an acetonitrile (20 mL) solution of tris-Boc-protected cyclen 3 (4.3 g, 9.09 mmol). The suspension was heated for 10 min at 60 °C, followed by addition of benzyl bromoacetate (1.76 mL, 11.2 mmol). The reaction mixture was heated for 12 h at 60–70 °C, then filtered, and the solvents removed under reduced pressure. The residue was purified by column chromatography over silica gel eluting with 10% methanol in chloroform to afford the title compound as a colorless solid (5.2 g, 92% yield). $R_f = 0.5$ (SiO_2, MeOH/$CHCl_3$, 1:9). ^1H NMR (270 MHz, $CDCl_3$): $\delta = 1.42$ (18H, s, C $(CH_3)_3$), 1.44 (9H, s, $C(CH_3)_3$), 2.9–3.2 (16H, s br, ring CH_2), 3.5 (2H, s, CH_2CO_2), 5.1 (2H, s, OCH_2Ph), 7.3 (5H, m, Ph). ^{13}C NMR (67.5 MHz, CDCl3) $\delta =$ 28.4 $C(CH_3)_3$, 28.7 $C(CH_3)_3$, 47.3 (CH_2 ring), 49.8 (CH_2 ring), 51.3(CH_2 ring), 53.7(CH_2 ring), 55.0 (NCH_2CO), 66.1 (OCH_2Ph), 79.1 ($C(CH_3)_3$), 79.4 ($C(CH_3)_3$), 128.4 (Ph), 128.5 (Ph), 135.6 (Ph), 155.2 (CONH), 155.7 (CONH), 155.9 (CONH), 170.3 (COO). FTIR (KBr): 3010, 2979, 2932, 2448, 1689, 1464, 1417, 1363, 1243, 1167, 1025, 982, 912 cm^{-1}. *m*/*z* (ESI+) ([M + H]$^+$ 621, [M + Na]$^+$ 643, [M + K]$^+$ 659). Anal. Found C = 60.7%, H = 8.4%, N = 8.8% $C_{32}H_{52}N_4O_8 \cdot H_2O$. Theory: C = 60.6%, H = 8.8%, N = 8.8%.

1,4,7,10-Tetraazacyclododecane1-1-benzyl Acetate Trihydrochloride Salt (5). HCl (12 M, 5 mL) was added dropwise to a solution of **4** (5.0 g, 8.1 mmol) in ethanol (10 mL). The resulting solution was stirred for 3 h at room temperature. The reaction mixture was concentrated to 5–6 mL and the precipitates were filtered. The residue was crystallized from a mixture of water and tetrahydrofuran to afford a colorless crystalline compound (3.0 g, 81% yield).[1] H NMR (270 MHz, D_2O, (pD = 2): δ = 2.9 (16H, s br, ring CH_2), 3.6 (2H, s, CH_2COO), 5.2 (2H, s, OCH_2Ph), 7.4 (5H, m, Ph). ^{13}C NMR (67.5 MHz, D_2O, dD = 2) δ = 41.7 (CH_2 ring), 42.3 (CH_2 ring), 44.3 (CH_2 ring), 49.4 (CH_2 ring), 54.1 (NCH_2CO), 68.0 (OCH_2Ph), 128.9 (Ph), 129.2 (Ph), 135.3 (Ph), 173.3 (CO_2). FTIR (KBr): 3398, 2974, 2645, 2435, 1743, 1611, 1565, 1480, 1460, 1440, 1375, 1351, 1277, 1188, 1167, 1070, 940 cm^{-1}. *m/z* (ESI+) 321 (100% [M + H]$^+$). Anal. Found C = 45.5%, H = 7.7%, N = 12.9% $C_{17}H_{28}N_4O_2 \cdot 3HCl \cdot H_2O$. Theory: C = 45.6%, H = 7.4%, N = 12.5%.

1,4,7,10-Tetraazacyclododecane-1,4,7-tris(methylcarbonylamide), 10-Benzyl Acetate (6). K_2CO_3 (9.0 g, 65 mmol) was added to monoprotected cyclen **5** (2.9 g, 6.5 mmol) in acetonitrile (50 mL). The suspension was heated for 20 min at 60 °C. 2-Bromo-*N*-methylacetamide (2.96 g, 19.6 mmol) was then added in one portion. The reaction mixture was heated overnight at 60 °C then cooled, filtered, and washed with cold acetonitrile (2 × 50 mL). The solids were dissolved in DI water (30 mL), extracted with dichloromethane (3 × 250 mL), and the combined organic fractions dried over Na_2SO_4. The solvents were removed under reduced pressure to afford a colorless product (3.29 g, 95% yield).[1]H NMR (270 MHz, $CDCl_3$): δ = 2.1–2.6 (16H, m br, CH_2 ring), 2.7 (3H, s, CH_3), 2.75 (6H, s, CH_3), 3.11–3.17 (8H, m, CH_2CO), 5.1 (2H, s, OCH_2Ph), 7.3 (5H, m, Ph), 7.8 (4H, s br, $NHCH_3$). ^{13}C NMR (67.5 MHz, $CDCl_3$) δ = 26.1 (CH_3), 26.2 (CH_3), 50.5 (CH_2 ring), 51.5–51.7 (CH_2 ring), 55.2 (CH_2CONH), 57.2 (CH_2CONH), 57.6 (CH_2CO), 67.0 (CH_2Ph), 128.5 (Ph), 128.7 (Ph), 135.5 (Ph), 171.6 (CONH), 171.9 (CONH), 172.4 (COO). FTIR (KBr): 3258, 3076, 2970, 2948, 2823, 1732, 1654, 1553, 1449, 1410, 1370, 1304, 1235, 1192, 1103, 990 cm^{-1}. *m/z* (ESI+) 556 (100% [M + Na]$^+$); Anal. Found C = 46.8%, H = 8.5%, N = 15.0% $C_{26}H_{43}N_7O_5 \cdot 7.5\ H_2O$. Theory: C = 46.7%, H = 8.8%, N = 14.7%.

1,4,7,10-Tetraazacyclododecane-1,4,7-tris(methylcarbonylamide)-10-acetate (1). 10 % palladium on carbon (0.8 g) was added to a solution of **5** (4.3 g, 8.1 mmol) in ethanol (30 mL). The reaction mixture was placed in a hydrogenation vessel for 24 h with the H_2 pressure of 45 psi. The catalyst was filtered through filter agent (Celite545, Aldrich) and the solvents were removed under reduced pressure to afford a colorless solid (2.9 g, 81% yield). ^{1}H NMR (270 MHz, D_2O): δ = 2.7 (6 H, s, CH_3), 2.8 (3H, s, CH_3), 3.0 (4H, s br, ring CH_2), 3.18 (4H, s br, ring CH_2), 3.4 (8H, s br, ring CH_2), 3.5 (4H, s, CH_2CONH), 3.8 (2H, s, CH_2CONH), 4.0 (2H, s, CH_2CO_2). ^{13}C NMR (67.5 MHz, D_2O): δ = 26.2 (CH_3), 26.3 (CH_3), 48.1–51.5 (CH_2 ring, br), 51.9 (CH_2CONH), 54.6 (CH_2CONH), 56.1 (CH_2CO_2), 166.2 (CONH), 169.9 (CONH), 172.4 (CO_2). FTIR (KBr): 3262, 3095, 2967, 2843, 1654, 1561, 1452, 1394, 1157, 1087, 1046, 909 cm^{-1}. *m/z* (ESI−) 442 (100% [M − H]$^-$).

Preparation of Thulium Complexes. An aqueous solution of the ligand **L2** was adjusted to pH = 5.5 using 1 M NaOH. A stoichiometric quantity of a standardized aqueous thulium chloride solution was added and the reaction mixture stirred at room temperature with constant adjustment of pH to 5.0–5.5 using 1 M NaOH. After approximately 1 h, no further drop in pH was observed and the final pH was adjusted to 7 followed by filtration. The absence of free thulium was verified by adding a small aliquot of this equilibrium mixture to a solution of 0.15 M acetate buffer, pH 5.5, containing a drop of xylenol orange as indicator. Once verified, the Tm**L2** solution was freeze-dried and stored in powdered form at −20 °C. Tm-**L2**: FTIR (KBr): 2120 (N═C═S) cm^{-1}; *m/z* (FAB+) 770 [Tm^{3+}**L2 - 2H**]$^+$.

1,4,7,10-Tetraazacyclododecane-1,4,7-tris(methylcarbonylamide)-10-1-*N*-hydroxy Succinimidyl Acetate (7). Acetate (**7**) was obtained by the method of Lewis et al. (*19*). Compound **L1** (2.9 mg, 6.6 μmol) was dissolved in water (1.043 mL, 4 °C), and the pH of the solution adjusted to 5 with 15 μL of 1 M HCl. *N*-Hydroxysuccinimide (0.76 mg, 6.6 μmol) was dissolved in water (0.06 mL, 4 °C) and added. The reaction mixture was stirred for 5 min, followed by addition of 0.05 mL solution of 1-ethyl-3-[3-dimethylaminopropyl]carbodiimide hydrochloride (EDC) (0.63 mg, 3.3 μmol) at 4 °C. The reaction mixture was stirred for 30 min on ice (at 0 °C) and the final pH of the reaction mixture adjusted to 7.4 by addition of 50 μL of 0.2 M Na_2HPO_4. The active ester was used for modification of adenovirus particles without further purification.

Cell Lines. Cell lines were cultured in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% (vol/vol) fetal bovine serum (FBS). Standard cell culture conditions were incubation at 37 °C and 5% CO_2. The 911 cell line used for propagation of recombinant adenovirus is derived from a human embryonic retinoblast and contains an integrated copy of the leftmost portion of the adenovirus 5 genome that complements the defect in E1 replacement vectors. The HT1080 cells used for *in vitro* bioactivity determination of viral particles are a human fibrosarcoma tumor cell line.

Preparation of Purified Recombinant Adenovirus. The AdCMVLuc virus (*20*) used here was chosen for ease of bioactivity analysis. 911 cells were cultured in DMEM containing 10% FBS grown to near 100% confluency. The growth medium was removed, and cells were infected by adding virus stock solution diluted into 2.5 mL DMEM, 2% FBS. The plate was rocked at 15 min intervals for 1 h. DMEM, 2% FBS (15 mL) was added to the dish, followed by incubation at 37 °C for 3–5 days. The cell were lysed by addition of 10% Nonidet P-40 (US Biochemical), and the cell lysate was centrifuged at 10 000 rpm for 10 min at 4 °C in a Sorvall GSA rotor to separate the cell debris. The supernatant was saved and one-half volume of 20% PEG 8000, 2.5 M NaCl, was added to each bottle. The bottles were incubated on ice for 1 h to precipitate the virus particles. The precipitated virus was collected by centrifugation at 10 000 rpm for 10 min at 4 °C. The viral pellet was resuspended in 5 mL of CsCl (d = 1.10 g/mL) in 20 mM Tris HCl pH 8.0 buffer. The suspension was centrifuged for 5 min at 8000 *g* at 4 °C in a Sorval SS-34 rotor. CsCl gradients were prepared as follows: 2.0 mL CsCl (d = 1.40 g/mL) in 20 mM Tris HCl (pH 8.0) buffer on the bottom of a centrifuge tube, and 3.0 mL CsCl (d = 1.30 g/mL) in 20 mM Tris HCl (pH 8.0) buffer on the top of the previous layer. The viral CsCl supernatant in 20 mM Tris HCl (pH 8.0) buffer was layered on the top of the CsCl step gradient and centrifuged at 20 000 rpm for 2 h at 20 °C in a Beckman SW41 swinging bucket ultracentrifuge rotor. The white viral opalescent band, which appeared as a band between the 1.3/1.4 CsCl layers, was collected. Virus was further purified by gel permeation chromatography using Sepharose CL-4B equilibrated with isotonic phosphate (PBS, 137 mM NaCl, 2.74 mM KCl, 4.3 mM Na2HPO4, 1.4 mM KH_2PO_4, pH 7.5) or carbonate (0.05 M Na_2CO_3/$NaHCO_3$, 140 mM NaCl, pH 8.6) buffers. Virus was stored at −80 °C after addition of glycerol to 10% final concentration until use.

Conjugation of L1 to Adenovirus. To a 0.1 mL aliquot of adenovirus particles (1.0 × 10^{13} particles/mL, 1.66 pmol) in PBS buffer was added a solution of active ester **7** in phosphate buffer (2.7 mM) at different molar ratios. Additional buffer was

added as necessary to keep the volume in all vials constant. The reaction mixture was incubated at 4 °C for 4 h on the rocker. Spin columns were prepared for gel permeation chromatography as follows: a 3 mL disposable syringe was plugged with cotton and filled with Sepharose CL-4B equilibrated in acetate buffer (0.15 M CH_3COONH_4, 0.14 M NaCl, pH 7). Those columns were washed by centrifugation at 3000 rpm for 3 min at least 5 times until a constant volume of eluent was obtained prior to conjugate purification. Each reaction mixture was placed on a spin column and centrifuged at 3000 rpm for 3 min in an Eppendorf Centrifuge model 5810 R. After viral loading, the spin column was washed once with 0.2 mL acetate buffer. The two fractions were collected, vortexed, centrifuged, and the absorbance at 260 nm was measured. The samples were analyzed to determine the ligand/adenovirus ratio and bioactivity.

Conjugation of L2 to Adenovirus. L2 (5 mg, 8.3 μmol) was dissolved in water (0.1 mL), followed by addition of 2.86 mL of carbonate buffer previously cooled to 4 °C. To 0.2 mL of adenovirus (1×10^{13} particles/mL, 3.32 pmol) in carbonate buffer (0.05 M $Na_2CO_3/NaHCO_3$, 140 mM NaCl, pH 7.9) were added different amounts of **L2**. The volume of each reaction mixture was adjusted to keep it constant in all vials. The reaction mixtures were placed in a cooled room (4 °C) on the continuous mixing rocker for 6 h. The **L2**-AdCMVLuc conjugates were purified in a manner identical to that of **L1**-AdCMVLuc.

Kinetics of L1 and L2 Conjugation to Adenovirus Particles. To 0.4 mL of adenovirus in PBS (4×10^{12} particles/mL) or carbonate (5×10^{12} particles/mL) buffer was added 61 μL (2.71 mM) of freshly prepared active ester **7** or 49 μL (2.8 mM) of isothiocyanate (**L2**). The reaction mixtures were incubated at 4 °C on the continuous mixing rocker, and at different time intervals 100 μL of each reaction mixture was taken and purified to evaluate the ligand/adenovirus ratio and bioactivity.

Determination of Ligand/Adenovirus Ratio. The number of ligands per adenovirus particle was determined by using Pb(II) as a colorimetric indicator as previously described (*21*). Briefly, the method is based on the decrease in absorbance at 656 nm that occurs upon transchelation of Pb^{2+} from arsenazo III to the virus-bound chelate sites. Experimentally, 100 μL of each conjugate solution was incubated with Pb(II)-Arzenaso III for 30 min to allow sufficient time for binding of Pb^{2+} into all chelate sites on the virus (*21*) prior to measuring the absorbance at 656 nm.. A calibration curve was established by mixing known concentrations of the parent ligand **L1** or **L2** (0.0–2.5 μM) with the lead reagent and measuring the absorbance at 656 nm. The virus concentration was obtained by measuring absorbance at 260 nm (1 OD unit corresponds to 1×10^{12} particles/mL).

Cell Infection and Bioactivity. The bioactivity of the viral preparations and viral conjugates was assessed by infection of HT1080 cells with an adenovirus vector that expresses firefly luciferase from the cytomegalovirus (CMV) promoter. The expression of luciferase activity in the cells infected with adenovirus is directly proportional to the number of infecting virus particles. HT1080 cells were cultured in DMEM with 10% FBS in 12 well plates. The growth medium was removed and 0.5 mL fresh (warmed to 37 °C) medium was added to each well. Aliquots (1, 3, and 10 μL) of a purified adenovirus conjugate or control unmodified adenovirus were added to wells in duplicate. After a 1 h incubation period at 37 °C to allow the virus to bind and infect cells, the infection medium was removed and replaced by 1 mL of fresh medium (warmed to 37 °C). The plates were then incubated for 15–19 h at 37 °C to allow luciferase expression (*22*).

Luciferase Assay. Infected HT1080 cells were assayed for luciferase expression as previously described (*14*). Briefly, cells were lysed by addition of 0.5 mL of lysis buffer (25 mM Tris−phosphate buffer pH 7.8, 2 mM dithiothreitol (DDT), 2 mM 1,2-diaminocyclohexane-*N*,*N*,*N*′,*N*′-tetraacetic acid 10% glycerol, 1% Triton X-100). Extracts (10 μL) were mixed with 0.1 mL of lysis buffer, and to that 50 μL of luciferin reagent (20 mM tricine, pH 7.8, 1.07 mM $(MgCO_3) \times 4Mg(OH)_2$, 2.67 mM $MgSO_4$, 0.1 mM EDTA, 33.3 mM DTT, 270 μM coenzyme A, 470 μM luciferin, 530 μM ATP) was added. Luminescence was measured for 10 s and expressed in relative light units (RLU).

Adenovirus Stability as a Function of Time. To 0.2 mL adenovirus (4×10^{12} particles/mL) in PBS (pH 7.4) or carbonate buffer (pH 7.9) was added 150 μL of PBS (pH 7.4) or carbonate buffer (pH 8.6) and viruses were incubated in the cold room at 4 °C. At different time intervals, aliquots were taken and samples used to infect HT1080 cells in duplicate. After 24 h, cells were extracted and assayed for luciferase expression as a measure of viral infectivity.

^{177}Lu-Adenovirus Binding Assays. The amount of complexed versus free $^{177}Lu^{3+}$ was determined by radio-TLC. 0.5 μL sample of a virus or virus−conjugate solution was spotted onto silica gel 60 TLC plates (EDM Chemicals Inc.) and, after drying with a stream of cold air, eluted with 10% ammonium acetate in methanol (1:3 v/v). Prior to TLC, excess DTPA was added to each virus sample to quantify the amount of radioactivity not associated with the adenovirus. As free uncomplexed $^{177}Lu(Ac)_3$ and $^{177}Lu^{3+}$-conjugated virus particles remain at the origin while $^{177}LuDTPA^{2-}$ moves with the solvent front, it was easy to distinguish $^{177}Lu^{3+}$-conjugated virus and $^{177}Lu^{3+}$ associated with the virus nonspecifically (R_f = 0–0.12) from $^{177}LuDTPA^{2-}$, which migrated with the solvent front (R_f = 0.48–0.50).

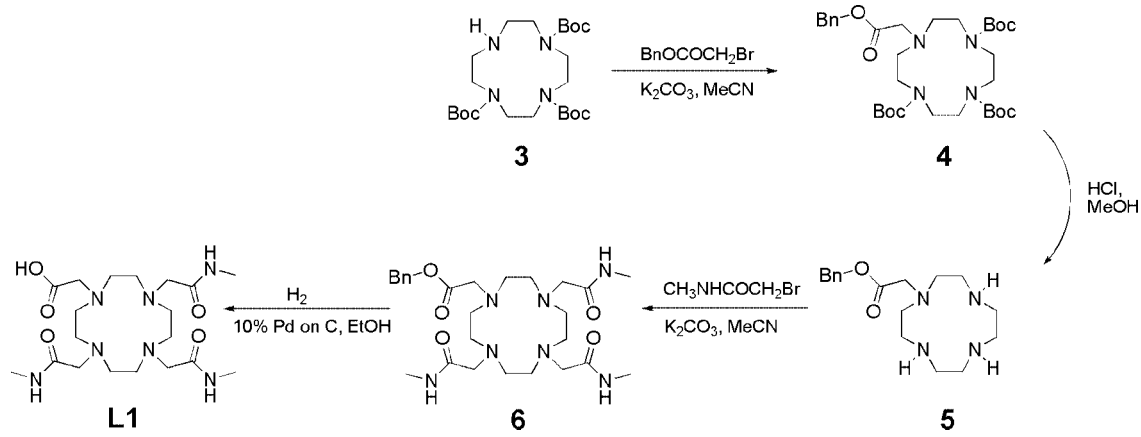
The virus conjugates were loaded with $^{177}Lu^{3+}$ as follows: 5 μL of $^{177}Lu^{3+}$ in 0.05 N HCl (11–12 μCi) was mixed with 15 μL of acetate buffer (0.15 M ammonium acetate, pH 8) then added to 50 μL of adenovirus (1.15×10^{12} particles/mL) in acetate buffer (0.15 M ammonium acetate, 140 mM NaCl). The reaction mixture was incubated at 25 °C for various selected time intervals, then 10 μL of the mixture was challenged with 20 000-fold excess DTPA (10 mM, pH 8). After an equilibration period of 30 min, the samples were analyzed by radio-TLC.

Preparation of TmL2−Adenovirus Conjugates. Adenovirus (2.4 mL, 5×10^{12} particles/mL) in Tris buffer was placed on a Sepharose CL-4B column equilibrated with HEPES buffer (pH 8.6 10 mM HEPES, 135 mM NaCl, 7 mM KCl). Adenovirus (3.1 mL, 3.85×10^{12} part/mL) was mixed with 355 μL of Tm**L2** (2.8 mM) in HEPES buffer (pH 8.6). The reaction mixture was incubated in a cold room at 5 °C with continuous stirring for 3 h, followed by quenching with 1 mL of 10 mM Tris HCl buffer pH 7.4. The adenovirus conjugate was concentrated by CsCl gradient centrifugation (on a discontinuous CsCl gradient of 1.3 and 1.4 g/mL CsCl as before) and gel filtered on a Sepharose CL-4B column equilibrated with HEPES buffer (pH 7.4, 10 mM HEPES, 135 mM NaCl, 7 mM KCl).

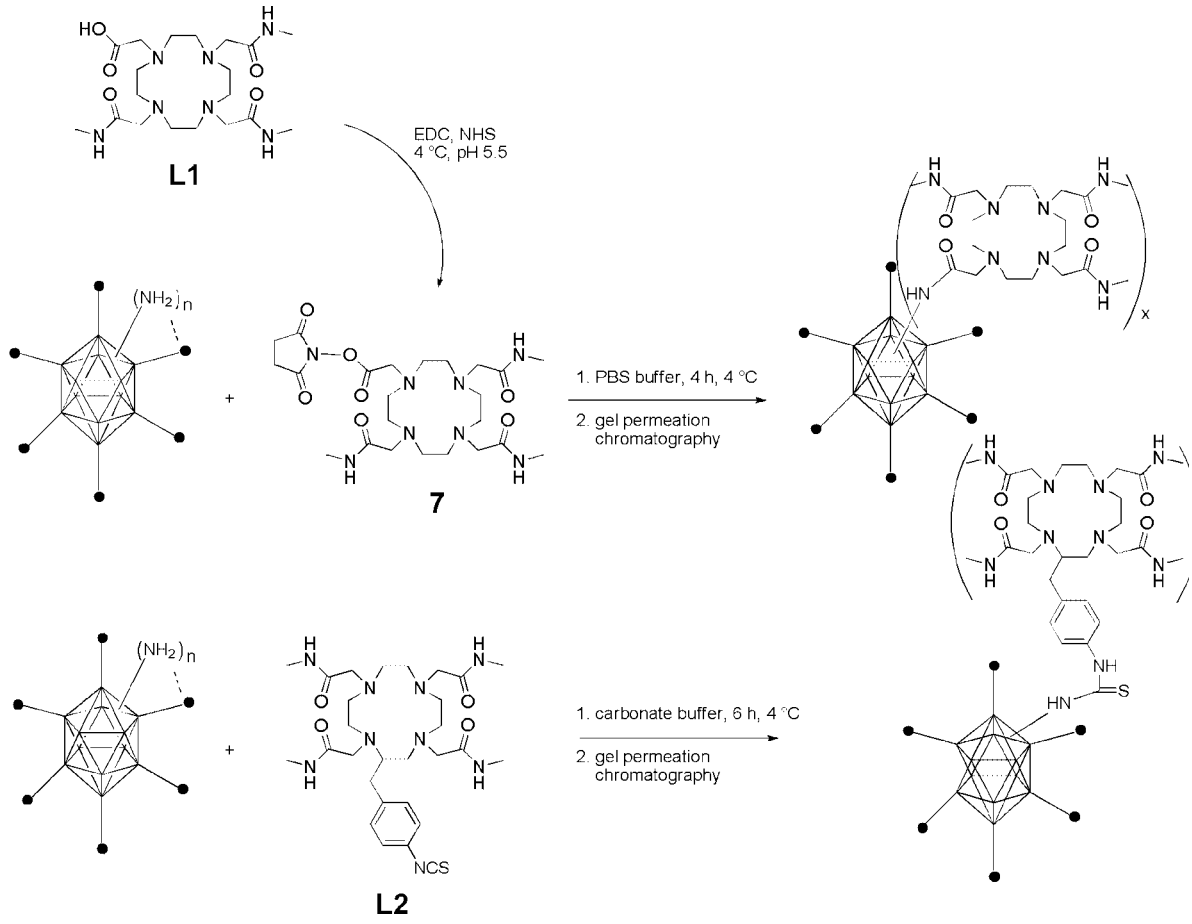
RESULTS AND DISCUSSION

Synthesis. L1 was synthesized as outlined in Scheme 2. Tris-Boc-protected cyclen **3** was obtained by published methods (*16*) followed by monoalkylation of the free amine with benzyloxybromoacetate under standard conditions (K_2CO_3/MeCN). Excess alkylating agent was removed by column chromatography to yield intermediate **4** followed by smooth removal of the Boc groups using an ethanolic hydrochloric acid to generate monobenzyl protected cyclen **5** as the HCl salt. The free amines of **5** were alkylated with 2-bromo-*N*-methylacetamide and 10 equiv of K_2CO_3 to produce **6**. It was not necessary to isolate the monobenzyl protected cyclen **5** in the free base form to perform

Scheme 2



Scheme 3



this reaction. Compound **6** was conveniently isolated in analytically pure form by precipitation from acetonitrile. **L1** was obtained by removal of benzyl protective group by hydrogenolysis with H_2 and 10% palladium on carbon in ethanol. The *N*-hydroxysuccinimide ester of **L1** was generated *in situ* according to a previously published method (*19*). Ligand **2** was synthesized using a previously published method (*17*).

Conjugation of L2 to Adenovirus. The isothiocyanate of DOTA-tetraamide reacts with the ϵ-amino group of viral surface lysine residues to produce a thiourea linkage under basic conditions (Scheme 3). The method of Mirzadeh et al. (*23*) was adapted to generate the **L2**−adenovirus conjugates. To estimate the number of reactive surface lysine residues per adenoviral particle, a set of reactions were run where the amount of added ligand **L2** was varied while the virus concentration was kept constant. Ligand **2** was reacted with adenovirus at [**L2**]:adenovirus ratios ranging from 10^3:1 to 10^6:1. Unreacted bifunctional chelator was removed from the viral conjugates by gel permeation chromatography, which removed >99% of the unreacted bifunctional agent as indicated by ^{177}Lu radiolabeling studies. Incubation of each virus conjugate with $^{177}Lu^{3+}$ and consequent analysis by radio-TLC showed that most of the radioactivity was associated with a fraction having an R_f of ∼0.1 The number of chelates on the adenovirus surface was established using a published Pb^{2+}-arsenazo III colorimetric method (*21*) and the adenovirus concentration was obtained by UV absorbance. Figure 1 shows that the reaction conditions

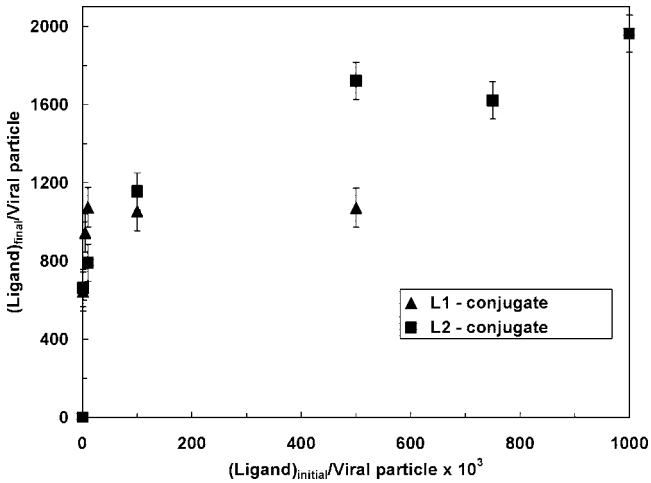


Figure 1. Plot showing the number of ligands attached per virus particle as a function of initial ligand concentration. Ligands **L1** and **L2** were incubated at 4 °C for 4 h (**L1**) and 6 h (**L2**) to allow for virus modification.

described above yielded virus particles with up to ~2000 **L2** chelates per adenovirus particle.

Conjugation of L1 to Adenovirus. The **L1** activated ester (compound **7**) was used to react with surface lysine residues of the adenovirus particles to form amide linkages (Scheme 3). Since the **L1** active ester was not isolated prior to its reaction with virus, the theoretical concentration of bifunctional agent is based on the concentration of EDC as the limiting reagent. To establish the maximum loading number of modified lysine residues with **7**, a similar strategy as described above for ligand **L2** was undertaken. However, due to complete loss in adenovirus bioactivity when using a 5×10^5:1 ratio of **L2**:AdCMVLuc, the reaction stoichiometry was reduced to **7**:AdCMVLuc ratios of 10^3:1, 5×10^4:1, 10^4:1, 10^5:1, and 5×10^5:1. The reaction mixtures were purified by gel permeation chromatography and analyzed by radio-TLC showing >99% radioactivity associated with the fraction having $R_f = 0.07$–0.11. Figure 1 shows that the number of attached chelates gradually increased to a maximum of ~1100 with increasing concentrations of the active ester, **7**. A comparson of the two conjugation experiments shows that the number of attached **L1** ligands maximizes near ~1100 chelators with no significant increase in the number of chelators observed beyond this point, whereas the number of attached **L2** ligands approached a maximum of ~2000. This difference most likely reflects the tendency of the more reactive NHS ester to hydrolyze under these experimental conditions, although the reduced steric demand of **L2** relative to **L1** may also play a role at the higher conjugation efficiency of **L2**.

Optimal Reaction Times for Lower Concentrations of Reactive Bifunctional Agents. In a second series of experiments, the active ester of **L1** (ligand **7**) or **L2** was added to adenovirus in 50 000-fold excess at 4 °C, and after various incubation periods (Figure 2), the reactions were terminated by rapid gel permeation chromatography using spin columns. Although the active ester **7** reacts more rapidly with lysine amino groups initially (Figure 2), after 2 h there was no significant difference in the total number of **L1** versus **L2** ligands attached likely due to competitive hydrolysis of NHS ester at this reaction pH. In separate experiments, it was shown that the active ester **7** was consumed within 2 h. These data show that both reagents modify an equal number of surface lysine groups (~1200) after a 2 h incubation time at 4 °C.

Bioactivity (Luciferase) Assay. In order to be considered useful as a vector for optical imaging, the modified virus must

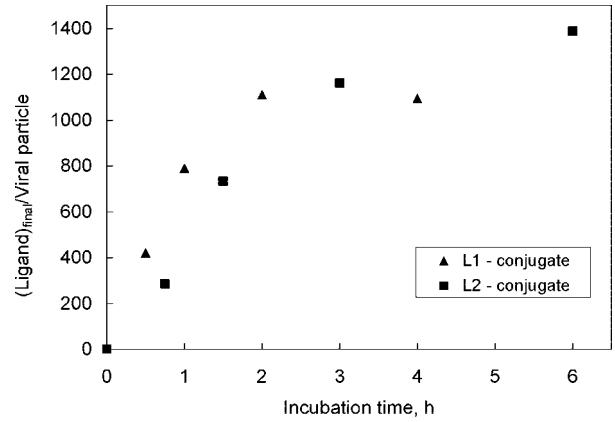

Figure 2. Plot showing the number of ligands attached per virus particle as a function of incubation time for ligands **L1** and **L2**. All modifications were performed at 4 °C.

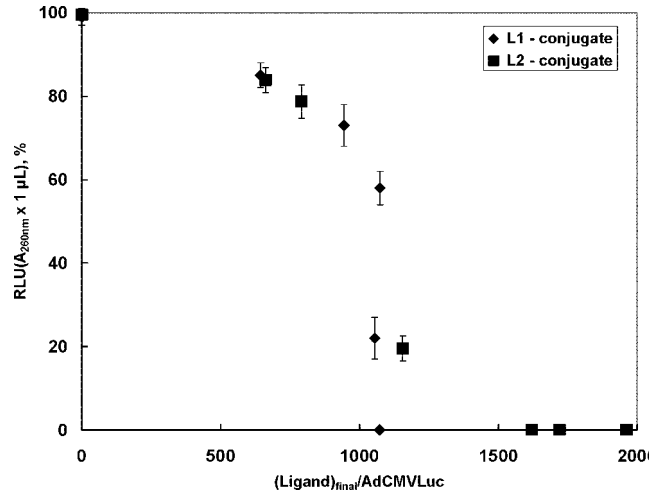

Figure 3. Plot showing the reduction in viral infectivity as a function of the number of ligands attached to virus particles. At each time point shown in Figure 2, an aliquot of modified virus was purified and used to infect HT1080 cells. Unmodified virus was used as a control and the extent of luciferase expression (in RLU) was set to 100%. Luciferase activity measured in each modified virus sample was expressed as a percentage of control.

maintain an ability to infect cells and express luciferase. To evaluate the effects of chemical modification, viral bioactivity was assessed by infecting HT 1080 cells with modified adenovirus particles. As shown in Figure 3, a significant decline in viral bioactivity was observed upon modification of surface lysines with either reactive ligand **L1** or **L2**. Viral bioactivity deceased almost linearly with increasing number of conjugated ligands until about 800 ligands were attached. When the number of attached ligands reached ~1000 per viral particle, viral infectivity dropped precipitously, as these conjugation reactions derivatize not only reactive lysine groups on the hexon capsid proteins of the core viral particle but also the fiber proteins which are responsible for the attachment of the virus to the host cell. The results shown in Figure 3 suggest that 800–900 sites can be modified without a dramatic loss in bioactivity, but further modification has a much more dramatic effect on the ability of the virus to infect cells. In samples where ~1100 molecules of **L1** or 1200 molecules of **L2** were conjugated, viral bioactivity decreased to ~20% of control values (20% residual activity). This amount of residual activity could reflect a subpopulation of particles that are substituted at a fractionally lower level than the average particle in the population, but there is little reason to assume such an anisotropic distribution in the extent of

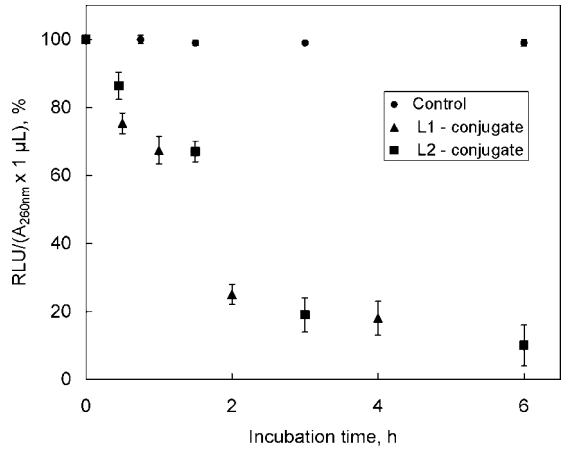

Figure 4. Plot showing the loss in bioactivity as a function of time after addition of 50 000-fold excess ligand (either **L1** or **L2**) to viral particles.. The initial time points (0 h) correspond to the bioactivity of unmodified adenovirus in the corresponding buffer . Control represents the ability of unmodified adenovirus to infect HT1080 cells after incubation at 4 °C.

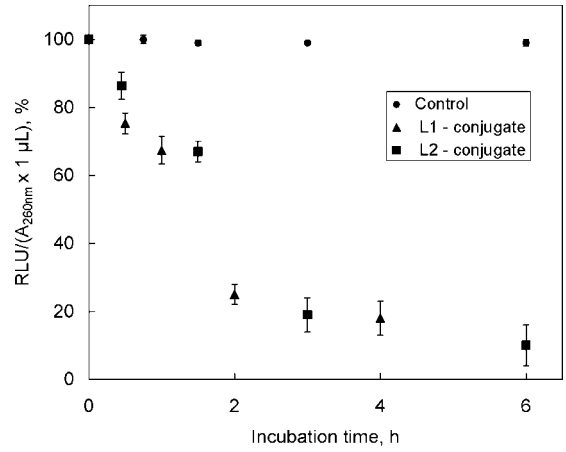

Figure 5. Residual $^{177}Lu^{3+}$ bound to adenovirus particles as a function of incubation time. At the indicated time-points, 20 000-fold excess of DTPA (pH 8) was added to remove weakly bound $^{177}Lu^{3+}$ and the virus was purified by gel filtration chromatography and counted.

substitution across the population of particles given that there are hundreds to thousands of potential substitutions per particle, and a trillion particles per milliliter in the solution. We assume that average level of substitution is reflective of the average level of bioactivity, some with more substitution per particle (and less infectivity), some with less (and more infectivity). For the purposes of this study, a goal of creating labeled virus particles with a minimum of 50% bioactivity was considered acceptable.

To achieve this target, another set of experiments was performed where the amount of excess **L1** or **L2** was lowered to 50 000-fold excess and aliquots of sample were removed as a function of time to follow the progression of the chemical reactions. Those results are reported in Figure 4. After a 1 h conjugation reaction using the active ester **7**, 790 chelators were attached and at the same time ~70% of bioactivity was retained. In comparison, the isothiocyanate, **L2**, showed 730 chelators were loaded per adenoviral particle after a 1.5 h incubation time and this virus maintained ~72% bioactivity. This indicates that, when using an initial excess of 50 000 bifunctional chelators per virus particle, the conjugation reaction should be terminated at 1 and 1.5 h for **L1** and **L2**, respectively, to achieve optimal results. Any potential loss of bioactivity arising from instability of the virus in PBS or carbonate buffer was eliminated by running a set of control reactions. Indeed, the adenovirus maintained a full ability to infect cells upon incubation in PBS (pH 7.4) and carbonate (pH 7.9) for 9 h at 4 °C (Figure 4).

Radiolabeling of Adenovirus. Initial attempts to fill only the conjugated ligand sites on the surface of the adenovirus with either Eu^{3+} or $^{177}Lu^{3+}$ proved unsuccessful because of nonspecific binding of these metal ions at other virus particle locations. To better understand this initial observation, unmodified adenovirus particles were incubated with $^{177}Lu^{3+}$ and then challenged with an excess of DTPA to quantify the amount of radioactivity associated with the viral particle through nonspecific binding. Figure 5 shows that the amount of nonspecific binding of $^{177}Lu^{3+}$ to the virus particles increases with incubation time and maximizes at ~10% after 9 h. This shows that $^{177}Lu^{3+}$ gets trapped by the viral particle, perhaps internally, by binding sites that are inaccessible to DTPA. Similar observations were made by Basu et al. (*24*). where they identified 180 metal binding sites based on the crystal structure of cowpea chlorotic mottle virus. Each binding site is thought to be composed of five amino acid residues from two adjacent protein subunits. Tb^{3+} binding, as measured by fluorescence, was tested both on the wild-type virus and a mutant virus where the RNA had been removed. In both cases, metal binding displayed very similar K_d values (K_d = 19 μM and 17 μM, respectively) suggesting that the encapsidated RNA does not contribute to the metal binding. Even though adenovirus represents a very different class of virus, it is tempting to speculate that the DNA in its interior does not bind metal ions nonspecifically. Heavy metal binding sites have been identified using the crystal structure of hexon, the major coat protein of adenovirus (*25*). These sites are located close to the loops l_1, l_2, or l_3 on the surface of the protein molecule or l_4 which lies underneath the hexon. The loop l_4 of each hexon protein might be particularly inaccessible to DTPA. Since this nonspecific binding of heavy metals might complicate the interpretation of any subsequent imaging experiments, an alternative prelabeling approach was adopted for the **L2** system where the ligand itself could be preloaded with the desired metal ion prior to labeling the virus. This strategy could not be used for the more reactive activated ester form of **L1**.

Conjugation of TmL2 to Virus Particles. Given that the detection limit of thulium-based PARACEST agents has been reported to be in the micromolar range (*26*), adenovirus particles were labeled with the prelabeled reagent, Tm**L2**, to evaluate whether CEST can be detected from samples of surface-labeled virus particles. The Tm**L2**−adenovirus conjugate was prepared using techniques similar to that of the parent ligand (Scheme 3). Two control experiments were run; first, an unmodified adenovirus was prepared in HEPES buffer and incubated with $TmDTMA^{3+}$ (1,4,7,10-tetra(methylcarbonylamide)-1,4,7,10-tetraaza cyclododecane), a nonbifunctional version of Tm**L2**. This control was performed to estimate the effect of entrapment or strong electrostatic interactions of positively charged complexes with viral particles. The control samples were treated in a similar fashion to that of Tm**L2**−adenovirus conjugates. The concentrations of the viral particles were adjusted to maintain a constant 2.5×10^{13} particles/mL, and the thulium concentrations were determined by inductively coupled plasma mass spectrometry (ICP-MS). The Tm**L2**−adenovirus conjugates were found to contain 1140 thulium ions per adenovirus particle, indicating that a result similar to conjugation with nonprelabeled **L2** was obtained (Figure 3). Somewhat unexpectedly, adenovirus particles incubated in the presence of $TmDTMA^{3+}$ for 3 h and consequently purified also contained ~280 entrapped $TmDTMA^{3+}$ complexes. This indicates that the tripositive complex, $TmDTMA^{3+}$, is tightly bound by virus particles and is not removed by simple gel purification procedures. Even though the stability of $TmDTMA^{3+}$ (log K_{TmL} = 14.08) is

Table 1. Experimental T_2 Relaxation Times and M_Z/M_0 for Adenovirus Particles

	T_2, s	M_Z/M_0, %	[Tm^{3+}], μM	[virus], 10^{-7} M
adenovirus	0.244 ± 0.002	80	N/D	0.42
adenovirus−TmDTMA	0.220 ± 0.002	82	11.8	0.42
adenovirus−Tm**L2**	0.127 ± 0.002	68	48	0.42

considerably lower than the parent chelate, $TmDOTA^-$, it has been shown that other lanthanide cations (Ln^{3+}) dissociate much more slowly from tetraamide ligands such as DTMA, **L1**, or **L2** than from DOTA (*26*), so the possibility of Tm^{3+} release from any of these chelates on the adenovirus particle is unlikely. Thus, we feel confident that thulium, as measured by ICP-MS for both the control and conjugation products, reflects Tm-$DTMA^{3+}$ and Tm**L2** and not free Tm^{3+} released from these chelates. The results of the control and radiolabeling experiments show that a significant level of nonspecific binding by any positively charged species, whether it be a simple cation such as $^{177}Lu^{3+}$ or a chelated cation such as $TmDTMA^{3+}$, is difficult to avoid.

CEST Studies. Recently, Vinogradov et al. (*27*) reported that Tm^{3+}-based PARACEST agents can be detected by imaging in the μM (micromolar) range by using a modified on-resonance low-power WALTZ-16 pulse train for activation. To apply this technique to labeled virus particles, the intensity of the solvent–water signal was measured after application of WALTZ-16 pulse train directly on the water resonance and compared to a spectrum collected by placing the WALTZ-16 pulse train far off resonance. Any differences in intensities between those two spectra should then reflect rapid water exchange on and off the viral-bound Tm^{3+} PARACEST agent (*27*). The modified WALTZ-16 pulse sequence depends on the number of parameters including T_1 and T_2 relaxation times of bulk water and the lifetime of water molecule coordinated to thulium ion in the complex (τ_M). Considering the relatively short bulk water transverse relaxation time (T_2, Table 1) of the adenovirus solution (~0.22 ms at [virus] = $(2.5 \pm 0.1) \times 10^{13}$ particles/mL), a WALTZ pulse length of 856 μs and irradiation power of 291 Hz was chosen (*27*).

The solvent–water T_1 relaxation times for these samples were on the order of 2 s, a value considered adequate for this type of WALTZ-16 experiment (*27*). The experimental T_2 values were however considerably shorter, in the range 0.12–0.24 s, and as predicted by theory, the biggest effect on the magnetization will occur whenever T_2 is ~0.4 s. On the basis of those predictions and to subtract out the influence of T_2, the WALTZ-16 experiment was performed first on an unmodified adenovirus

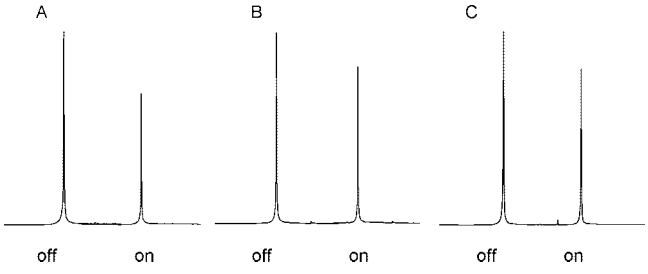

Figure 6. Residual bulk water signal intensities after applying WALTZ-16 pulse train (B_0 = 500 MHz, B_1 = 291 Hz, pulse length 0.856 ms, 25 °C) either "off" resonance where the carrier frequency is set to 1986 Hz away from the water resonance or "on" resonance where the carrier frequency is set at the water frequency. (A) corresponds to a sample containing Tm**L2**−adenovirus in the HEPES buffer (10 mM HEPES, 135 mM NaCl, 7 mM KCl); the total concentration of Tm**L2** in the sample was 48 μM. (B) 48 μM $TmDTMA^{3+}$ in HEPES buffer. (C) an equivalent amount of unmodified adenovirus (as in A) in HEPES buffer.

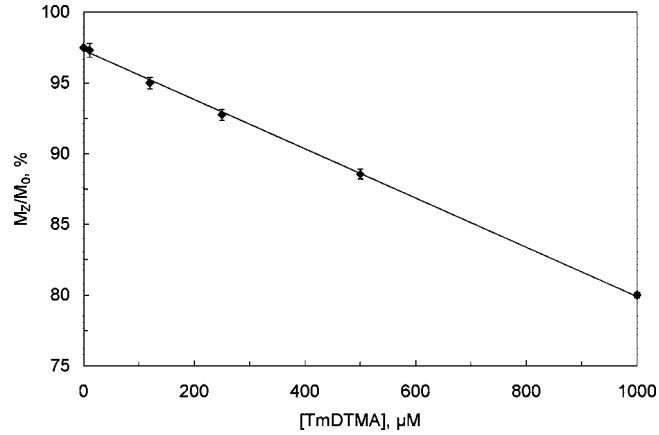

Figure 7. Plot of the decrease in water magnetization (M_Z/M_0) using the WALTZ-16 pulse sequence as a function of $TmDTMA^{3+}$ concentration. The WALTZ-16 pulse train was applied on resonance (B_0 = 500 MHz, B_1 = 291 Hz, pulse length 0.856 ms, 25 °C).

sample (as control) and the Tm**L2**−adenovirus sample. As shown in Figure 6, the water intensity was reduced by ~20% for the unmodified virus sample (Figure 6b) and 18% for adenovirus incubated in the presence of $TmDTMA^{3+}$ (Figure 6c), compared to buffer alone. Although there was considerable entrapment of $TmDTMA^{3+}$ (noncovalent interactions) when incubated with the adenovirus, the presence of this compound did not change M_Z/M_0 compared to unmodified virus. This suggests that the entrapped $TmDTMA^{3+}$ is not exchanging protons rapidly with bulk water and furthermore shows that the adenovirus alone causes a decrease in water intensity using the WALTZ-16 pulse train due to its short T_2. The T_2 of the adenovirus−$TmDTMA^{3+}$ sample was somewhat shorter than adenovirus alone, likely due to the presence of ~280 entrapped $TmDTMA^{3+}$ complexes per adenovirus particle. Interestingly, a substantially larger effect was measured for the TmL2 - adenovirus conjugate, in which a 32% decrease in solvent–water intensity was observed. The 12% difference in water intensity between these two samples can be directly attributed to the presence of the conjugated PARACEST agent on the surface of the adenovirus.

The dependence of $TmDTMA^{3+}$ concentration on the reduction of observed magnetization (M_Z/M_0) using WALTZ 16 pulse train was also investigated as a positive control. Figure 7 summarizes the results and clearly shows that 48 μM Tm-$DTMA^{3+}$ (equivalent to the concentration of Tm**L2** in the virus sample used in Figure 6) produces a modest 2% reduction in signal intensity. Thus, 12% difference in water intensity observed for the Tm**L2** virus particle is not simply due to the presence of conjugated Tm**L2** in solution, but must reflect some exchange advantage of viral-conjugated Tm**L2** compared to the nonconjugated parent complex, $TmDTMA^{3+}$. This suggests that water exchange in Tm**L2** is altered when bound to the surface of virus particles (compared to that seen for $TmDTMA^{3+}$) and this change is advantageous for CEST. Whether this reflects an increased or decreased water exchange rate for the viral-bound Tm**L2** (both could result in a CEST advantage if operating in certain water exchange regimes (*28*)) will require more detailed studies that are beyond the scope of the present investigation.

CONCLUSIONS

Labeling of virus particles with two different bifunctional ligands resulted in diminished viral bioactivity that decreased in proportion to the number of the attached ligands. For in vivo applications where it is desirable to have at least 50% viral bioactivity, it was found that the number of attached ligands

needed to be fewer than ~800 to maintain 75–80% bioactivity. Labeling experiments with $^{177}Lu^{3+}$ and $TmDTMA^{3+}$ at 4 °C (as a free chelate control) showed nonspecific binding of positively charged species to the adenovirus. To circumvent nonspecific metal ion binding to the adenovirus, the isothiocyanate bifunction ligand (**L2**) was preloaded with Tm^{3+} and the resulting chelate was used to label the adenovirus with a conjugation efficiency similar to that of free **L2**. The resulting Tm**L2**−adenovirus conjugate showed a 12% decrease of water signal intensity using a WALTZ-16 sequence for CEST activation. These results demonstrate that PARACEST-labeled virus particles can be prepared that retain high viral infectivity and expression of luciferase activity and, at the same time, are sufficiently sensitive to be detected by WALTZ-16 initiated CEST imaging.

ACKNOWLEDGMENT

This work was supported in parts by grants from the National Institutes of Health (CA-115531 and RR-02584) and the Robert A. Welch Foundation (AT-584). We also thank Julie Poirot for her assistance with the adenovirus preparation.

Received September 4, 2007; Revised Manuscript Received December 11, 2007

Novel hybrid oligonucleotides carrying the G-quadruplex-forming d($^{5'}$TGGGAG$^{3'}$) sequence, conjugated with mono- or disaccharides at the 3′ or 5′-end through phosphodiester bonds, have been synthesized as potential anti-HIV agents, *via* a fully automated, online phosphoramidite-based solid-phase strategy. CD-monitored thermal denaturation studies on the resulting quadruplexes indicated the insertion of a single monosaccharide at the 3′-end as the optimal modification, conferring improved stability to the quadruplex complex. In addition, the 3′-conjugation with glucose or mannose converted the anti-HIV inactive unmodified oligomer into active compounds. On the contrary, the 5′-tethering with these monosaccharides, as well as the conjugation, either at the 5′ or 3′-end, with sucrose, were in all cases detrimental to quadruplex stability and did not improve the biological activity. On the basis of the assumption that the kinetically and thermodynamically favored formation of the quadruplex complex is a prerequisite for efficient antiviral activity, a novel bis-conjugated oligonucleotide was designed. This combined a mannose residue at the 3′-phosphate end with bulky aromatic *tert*-butyldiphenylsilyl (TBDPS) group at the 5′-end, previously shown to markedly favor the formation of quadruplex complexes. The 5′,3′-bis-conjugated 6-mer, for which a detailed biophysical characterization has been carried out, resulted in 3-fold greater antiviral activity against HIV-1 than the sole 3′-glyco-conjugated oligonucleotide.

INTRODUCTION

Glyco-conjugates participate in a variety of biological processes of paramount importance, including molecular recognition, signal trafficking, and recognition of cell surface through carbohydrate-binding proteins, as well as intracellular lectins in a sugar-dependent manner (*1*–*3*). Synthetic glyco-conjugates are therefore useful diagnostic tools to identify and characterize endogenous sugar-binding proteins, but they can also show high potential in several therapeutic applications for specific drug delivery (*4, 5*). Methods to obtain glyco-conjugates—such as neoglycoproteins, glycosylated polymers, or glycopeptides—have been largely developed; on the contrary, synthetic strategies to prepare glyco-oligonucleotides are still far from being fully optimized (*6*).

Indeed, for several *in vivo* applications of oligonucleotides (ODNs), end derivatization with carbohydrates can result in a very convenient strategy to improve their otherwise poor internalization, eliciting specific sugar-binding processes to cell membranes and thus finally enhancing their cellular uptake by endocytosis. Through glyco-conjugation, further desirable properties can be conveyed to oligonucleotide-based drugs, as increased bioavailability, due to protection toward nucleases, and reduction of unwanted aggregation. DNA−carbohydrate conjugates have been prepared by direct, online solid-phase glycosidation of the 5′-end of oligonucleotides with suitable trichloroacetimidate sugar scaffolds (*7, 8*). A convenient procedure involved the use of unprotected carbohydrates, conjugated to 5′-amino-modified oligonucleotides by exploiting a reductive amination procedure (*9*). Recently, site-specifically galactosylated oligonucleotides, obtained from a 2′-deoxyuridine phosphoramidite carrying one galactose unit on the base, were synthesized, and periodic glycoclusters using a half-sliding oligonucleotide strategy could be obtained (*10, 11*). An alternative strategy to efficiently conjugate carbohydrates to ODNs was first explored by Akhtar and co-workers, who synthesized a suitable phosphoramidite derivative of mannose, incorporated onto the 5′-OH terminus of the solid-supported ODN by standard phosphoramidite chemistry (*12*). A similar approach has been recently proposed also by Joyce et al., who designed a new class of DNA−carbohydrate conjugates, called nucleo-glycoconjugates, based on the synthesis of three new phosphoramidite carbohydrate derivatives, inserted at the extremities or at defined, internal positions of the growing oligonucleotide chain (*13, 14*). In this frame, we recently synthesized suitably protected phosphoramidite derivatives of model mono- or disaccharides. When used in conjunction with DMT[1]-protected sugars immobilized on solid supports, they allowed us to prepare, through an online automated oligonucleotide synthesis protocol, a variety of 5′- and 3′-glycoconjugates of ODNs with stable phosphodiester linkages connecting the saccharide residues to one or both OH termini of the oligonucleotide chain (*15, 16*). In all the studied cases, the presence of the saccharide dangling ends was

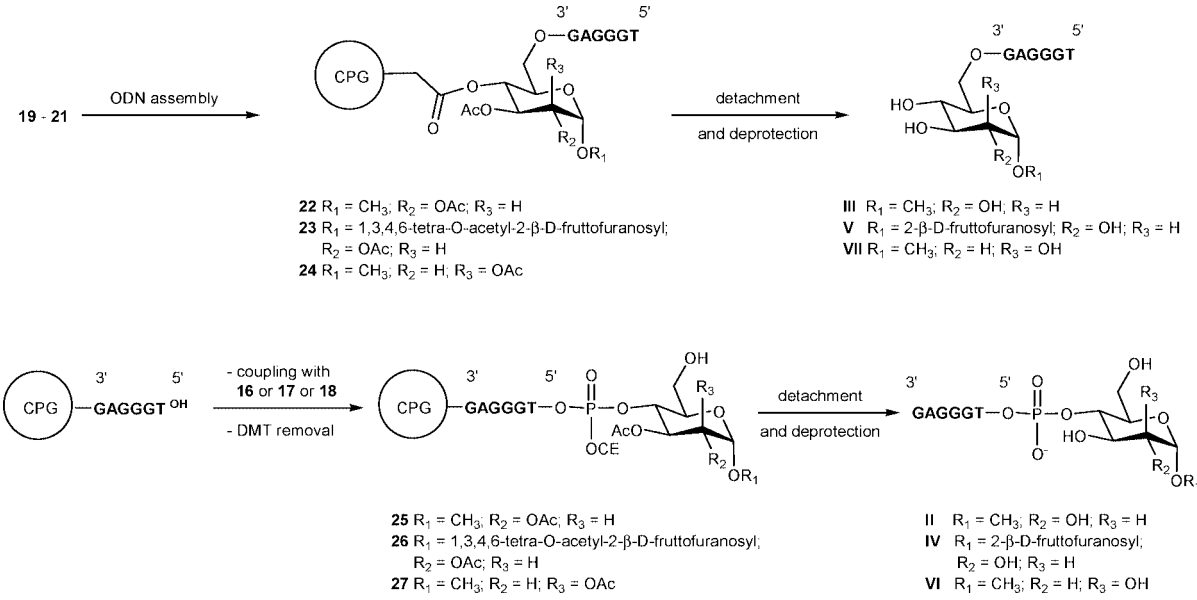
shown to protect the ODN chains from nuclease digestion, while not hampering their specific recognition properties.

In the search for ODNs endowed with significant antiviral properties, Hotoda and his group recently investigated a series of G-quadruplex-forming ODNs, finally focusing their research interest on modified oligonucleotides of sequence d($^{5\prime}$TGGGAG$^{3\prime}$). These were found to exhibit potent anti-HIV activity associated with low cytotoxicity when carrying at the 5′-end bulky aromatic residues, as the 3,4-dibenzyloxybenzyl (DBB) or *tert*-butyldiphenylsilyl (TBDPS) groups (*17, 18*). Structure–activity relationship analysis indicated that G-quadruplex formation, as well as the presence of large aromatic substituents at the 5′-end, were both essential for their antiviral activity. In this frame, we studied a selected set of Hotoda's 5′-modified ODNs: our data, combining CD, DSC, and molecular modeling studies on the modified G-quadruplexes in comparison with the unmodified one, showed that the overall stability of the investigated complexes correlated well with the reported IC_{50}values, thus furnishing quantitative evidence, even if still indirect, to the hypothesis that the G-quadruplex structures are the ultimate active species, effectively responsible for the desired antiviral effects (*19*).

Aiming at the preparation of novel oligonucleotide-based antivirals, we adopted the d($^{5\prime}$TGGGAG$^{3\prime}$) sequence as a suitable platform to investigate the effect of glyco-conjugation on both quadruplex formation and biological properties of G-rich ODNs. Here, we here describe the synthesis, biophysical characterization, and biological properties of d($^{5\prime}$TGGGAG$^{3\prime}$) oligomers, carrying a monosaccharide or disaccharide tail (with glucose, mannose, and sucrose chosen here as model carbohydrates) at either the 5′ or 3′-end. The best modification, in terms of both quadruplex formation and antiviral activity enhancement, i.e., the 3′-conjugation with a mannose residue, was then combined with the insertion of TBDPS at the 5′-end. The resulting 5′,3′-bis-conjugated TBDPS-$^{5\prime}$TGGGAG$^{3\prime}$-*p*-mannose was found to be 3-fold more active than the sole 3′-conjugated

Scheme 2. Synthetic Scheme for the Preparation of Glyco-Conjugated Oligonucleotides II-VII



$^{5'}$TGGGAG$^{3'}$-*p*-mannose oligonucleotide. To gain a deeper insight into the thermodynamic and kinetic parameters governing the quadruplex association/dissociation processes in solution, detailed CD analysis and CD-monitored thermal denaturation studies for the 5′,3′-bis-conjugated d($^{5'}$TGGGAG$^{3'}$) have been carried out and discussed.

EXPERIMENTAL PROCEDURES

Synthesis and Characterization of Oligonucleotides I−IX. DMT-protected succinylated sugars **13**, **14**, and **15**; phosphoramidite building blocks **16**, **17**, and **18**; and functionalized solid supports **19**, **20**, and **21** were synthesized following the reactions described in Scheme 1, according to previously reported protocols (*15*, *16*). Oligonucleotides **I**−**IX** were synthesized using standard solid-phase β-cyanoethyl phosphoramidite chemistry on a 15 μmol scale, in all cases adopting DMT-off protocols. In the case of oligomer **I**, starting from 100 mg of commercially available 2′-deoxyguanosine-functionalized controlled pore glass (CPG-dG) support with 0.10 mequiv/g initial loading, the sequence $^{5'}$d(TGGGAG)$^{3'}$was assembled by exploiting standard commercially available 3′-phosphoramidite 2′-deoxynucleoside monomers. As depicted in Scheme 2, the synthesis of oligomers **III**, **V**, and **VII** was realized starting from 100 mg of functionalized CPG supports **19**, **20**, and **21**, respectively, with 0.06–0.08 mequiv/g initial loading, on which the sequence $^{5'}$d(TGGGAG)$^{3'}$ was assembled in a standard manner. In the case of oligomers **II**, **IV**, and **VI**, starting from 100 mg of commercially available CPG-dG support with 0.10 mequiv/g initial loading, after the assembly of the sequence $^{5'}$d(TGGGAG)$^{3'}$, an additional coupling with phosphoramidite building blocks **16**, **17**, or **18**, respectively, was then realized. The synthesis of oligomer **IX** was achieved starting from functionalized support **21**, as described in Scheme 3, which was first used in the solid-phase assembly of the sequence $^{5'}$d(GGGAG)$^{3'}$, then coupled with 5′-TBDPS-thymidine-3′-phosphoramidite building block **29**, synthesized as previously described (*19*). Once the chain elongation was complete, target oligomers **I**−**IX** were detached from the solid support and deprotected by standard treatment with conc aq ammonia at 55 °C for 12 h.

The combined filtrates and washings were concentrated under reduced pressure, redissolved in H_2O, and analyzed and purified by HPLC. Purification of the crude natural oligomer **I** and of conjugated oligonucleotides **II**−**VII** was carried out on an

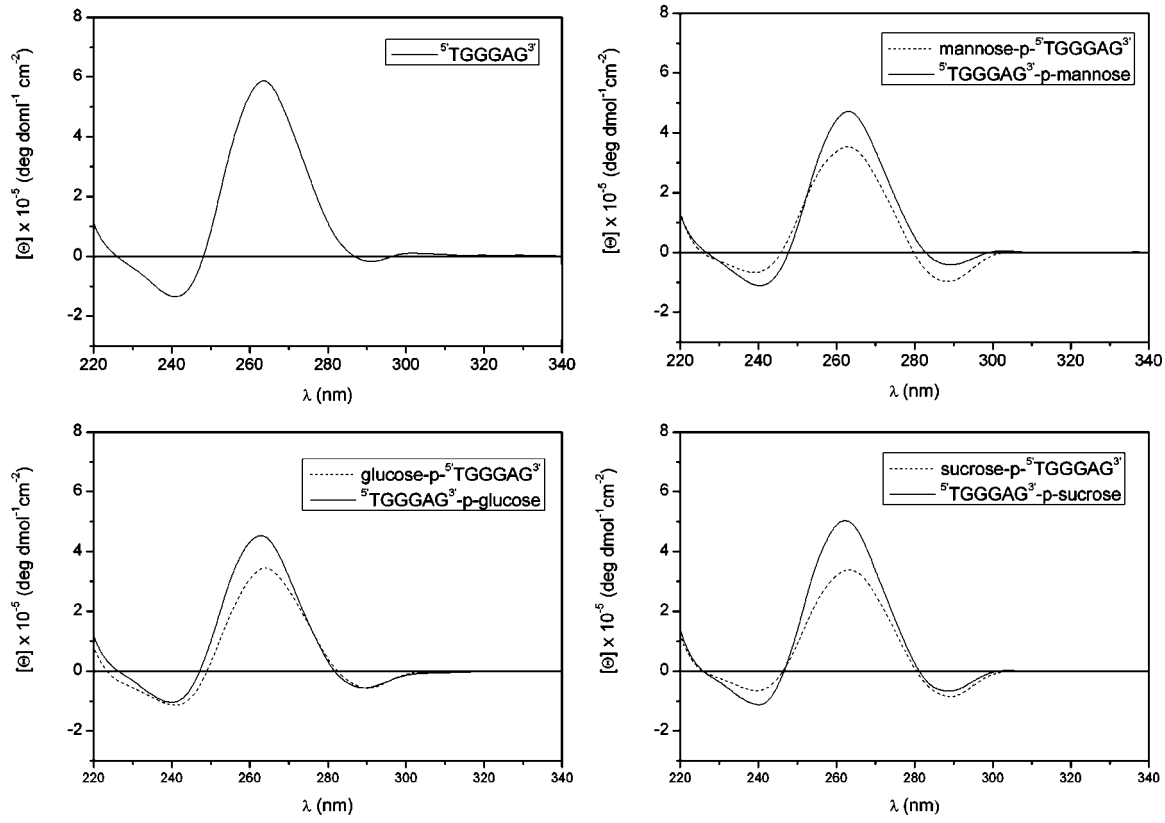

Figure 1. CD spectra of the natural ODN $^{5'}$TGGGAG$^{3'}$ (**I**) and of glyco-conjugated oligonucleotides **II**−**VII**. The spectra were recorded at 20 °C in a 10 mM potassium phosphate buffer (pH 7.0), supplemented with 200 mM KCl, at 5×10^{-5} M quadruplex concentration.

analytical anion exchange Nucleogel SAX column (Macherey-Nagel, 1000–8/46, 4.6 × 50 mm, 5 μm), adopting the following eluents: buffer A, 20 mM KH_2PO_4/K_2HPO_4 aq solution (pH 7.0), containing 20% (v/v) CH_3CN; buffer B, 1 M KCl, 20 mM KH_2PO_4/K_2HPO_4 aq solution (pH 7.0), containing 20% (v/v) CH_3CN. In all cases, using a linear gradient from 0% to 100% B in 40 min, flow rate 0.8 mL/min, and detection at $\lambda = 260$ nm, two main peaks were observed. As previously found (*18, 19*), in all the purification attempts on an anionic exchange HPLC column, the fastest eluting peak, attributed to the single-strand 6-mer, was always accompanied by a major peak, having a higher retention time, due to G-quadruplex aggregates generated under HPLC elution conditions.

Oligonucleotide **VIII**, synthesized as previously described (*19*), was purified by HPLC on a NUCLEOSIL RP18 column (Supelco, 100–5, C18, 4.6 × 250 mm, 7 μm), using a linear gradient of CH_3CN in 0.1 M TEAB in H_2O, pH 7.0, from 20% to 100% in 20 min, flow rate 0.8 mL/min, with detection at $\lambda = 260$ nm. Oligonucleotide **IX** was purified by HPLC on a RP18 Eclipse column (Agilent, XD8-C18); buffer A, 0.1 M TEAB in H_2O, pH 7.0; buffer B, CH_3CN; a linear gradient from 20% to 100% B in 20 min, flow rate 0.8 mL/min, with detection at $\lambda = 260$ nm, was used. The isolated oligomers had the retention times reported in Table 1. After HPLC purification, the oligonucleotide samples were desalted on a Sephadex G25 column eluted with H_2O/EtOH (4:1, v/v). Successively, HPLC analysis of the desalted oligomers **I**−**IX** on a Partisphere Whatman RP18 analytical column (125 × 4.0 mm, 5 μm), eluted with a linear gradient from 0% to 100% in 60 min of CH_3CN in TEAB buffer (0.1 M, pH 7.0), flow = 0.8 mL/min, confirmed the expected purity for all the samples (higher than 98%). The modified oligonucleotides were characterized by ESI-MS mass spectrometry in the negative mode, in all cases giving masses in accordance with the expected values (Table 1).

In a typical experiment, starting from 100 mg of commercially available CPG-dG supports, or of sugar-functionalized supports **19**, **20**, or **21**, 80–120 OD units of purified **I**−**IX** could be obtained.

Quadruplex Preparation. The quadruplex complexes were obtained by dissolving the lyophilized oligonucleotide in the appropriate buffer, annealed by heating at 95 °C for 5 min and slow cooling to room temperature. The buffer used was 10 mM

potassium phosphate, 200 mM KCl, 0.1 mM EDTA at pH = 7.0. The concentration of the dissolved oligonucleotides **I**−**VII** was determined by UV measurements at 260 nm and at 95 °C, using, as the molar extinction coefficients, the values calculated by the nearest neighbor model (*20*) for the sequence $^{5'}$d(TGGGAG)$^{3'}$, assuming the contribution of the terminal sugar residues to be negligible at this wavelength. For oligonucleotide **IX**, the contribution of the TBDPS group at the 5′-end was taken into account, as previously described in the case of **VIII** (*19*).

CD Experiments. All circular dichroism (CD) experiments were registered on a JASCO J-715 spectrophotometer equipped with a thermostatically controlled cuvette holder (JASCO PTC-348), in a 0.2 cm or 0.5 path length cuvette. CD spectra were collected from 220 to 340 nm, at 20 nm/min, with a response time of 4 s and at 1 nm bandwidth. The molar ellipticity was calculated from the equation $[\theta] = 100 \cdot \theta / cl$ where θ is the ellipticity value, c is the quadruplex concentration (5.0×10^{-5} M), and l is the path length of the cell in cm. Thermal dissociation of the studied quadruplexes was monitored by following the CD signal at 263 nm upon increasing the temperature.

The quadruplex dissociation kinetics was measured by rapidly increasing the temperature and following the change of the CD signal at 263 nm with time. All the experiments were performed in a temperature and concentration range where the reassociation reaction can be neglected. The kinetic constants were obtained by fitting the recorded time-dependent decrease in CD signal with a single exponential function. For each sequence, the kinetic constant was determined at five different temperatures.

The structural transition from the single strands to the tetramolecular quadruplex was monitored in the temperature range 10–30 °C by recording the CD spectra as a function of time. The samples were incubated at 90 °C for 5 min and then rapidly cooled. The kinetic constant and reaction order were obtained by analyzing the CD vs time profiles as previously described (*21*).

Biological Assays. For the anti-HIV assays, CEM cells (4.5×10^5 cells/mL) were suspended in fresh culture medium and infected with HIV-1 at 100 $CCID_{50}$ per mL of cell suspension in the presence of appropriate dilutions of the test compounds. After 4 to 5 days incubation at 37 °C, giant cell formation was recorded microscopically in the CEM cell cultures. The 50% effective concentration (EC_{50}) corresponds to the compound concentrations required to prevent syncytium formation by 50% in the virus-infected CEM cell cultures.

To determine the cytostatic activity, all assays were performed in 96-well microtiter plates. To each well were added (5–7.5) $\times 10^4$ CEM cells and a given amount of the test compound. The cells were allowed to proliferate for 72 h at 37 °C in a humidified CO_2-controlled atmosphere. At the end of the incubation period, the cells were counted in a Coulter counter. The CC_{50} (50% inhibitory concentration) was defined as the concentration of the compound that inhibited CEM cell proliferation by 50%.

In the cocultivation assays, 5×10^4 persistently HIV-1-infected HUT-78 cells (designated HUT-78/HIV-1) were mixed with 5×10^4 Sup-T1 cells, along with appropriate concentrations of the test compounds. After 16 to 20 h, marked syncytium formation was noted in the control cell cultures, and the number of syncytia was determined under a microscope.

For determination of the 50% inhibitory concentration (IC_{50}) of the test compounds against HIV-1 RT, the RNA-dependent DNA polymerase assay was performed as follows: the reaction mixture (50 μL) contained 50 mM Tris·HCl (pH 7.8), 5 mM DTT, 300 μM glutathione, 500 μM EDTA, 150 mM KCl, 5 mM $MgCl_2$, 1.25 μg of bovine serum albumin, a fixed concentration of the labeled substrate [^{3}H]dGTP (1.6 μM, 1 μCi; specific activity, 12.6 Ci/mmol; Amersham Pharmacia Biotech), a fixed concentration of the template/primer poly(rC)·oligo(dG)$_{12–18}$ (0.1 mM; Amersham Pharmacia Biotech), 0.06% Triton X-100, 5 μL of the inhibitor solution [containing various concentrations (5-fold dilutions) of the compounds], and 5 μL of the RT preparations. The reaction mixtures were incubated at 37 °C for 30 min, at which time 200 μL of yeast RNA (2 mg/mL) and 1 mL of trichloroacetic acid (5%, v/v) in water were added. The solutions were kept on ice for at least 30 min, after which the acid-insoluble material was filtered over Whatman GF/C glass-fiber filters and washed 10 times with 2 mL of 5% trichloroacetic acid in water and once with 70% ethanol. The filters were then analyzed for radioactivity in a liquid scintillation counter (Canberra Packard, Zellik, Belgium). The

[a] For comparison, data from ref (*18*) for oligonucleotide **VIII**, determined using MT-4 cells, are also reported. [b] EC_{50} = effective concentration or concentration required to protect CEM cells against the cytopathicity of HIV by 50%. [c] CC_{50} = cytotoxic concentration or concentration required to reduce CEM or MT4 cell viability by 50%. [d] S.I. = selectivity index for HIV-1, calculated as the ratio of CC_{50}/EC_{50}. [e] Data from ref (*18*).

Table 6. Inhibitory Activity of the Glyco-Conjugates against Syncytia Formation between Persistently HIV-1-Infected HUT-78/HIV-1 Cells and Uninfected SupT1 Cells

oligonucleotide	EC_{50}[a] (μM)
II	>140
III	>140
IV	>30
V	>140
VI	>140
VII	>140
VIII	>14
IX	1.3 ± 0.49

[a] EC_{50} = 50% effective concentration or compound concentration required to prevent giant (syncytium) cell formation between HUT-78/HIV-1 and SupT1 cells by 50%.

IC_{50} for each test compound was determined as the compound concentration that inhibited HIV-1 RT activity by 50%.

RESULTS

Several modified oligonucleotides have been shown to inhibit HIV-1 in cell culture. If, in most cases, a non-sequence-specific inhibition is hypothesized, sequence-specific effects are also invoked for aptamers (*22*). Particularly, for G-rich ODNs the putative mechanism of action is based on the interference/inhibition of both cell-to-cell and virus-to-cell transmission of HIV-1 by interaction with the V3 loop and the CD4 binding site on viral gp120 (*23–25*). As it is accepted that G-rich ODNs exert their anti-HIV activity through formation of G-quadruplex complexes, the correlation between thermodynamic stability and rate of formation of the quadruplexes, on one end, and the antiviral properties, on the other, was assumed here as the basis for the rational design of novel oligonucleotide-based antivirals.

Starting from the model oligonucleotide d($^{5'}$TGGGAG$^{3'}$), indicated here as **I**, a small library of 5′- and 3′-glyco-conjugates carrying the same sequence was synthesized and their ability to generate four-stranded quadruplexes analyzed by CD-monitored thermal denaturation experiments. 5′- and 3′-conjugated 6-mers **II**−**VII**, as well as unmodified 6-mer **I** (Scheme 2 and Table 1), were synthesized using standard solid-phase β-cyanoethyl phosphoramidite chemistry protocols on a 15 μmol scale (*26*). Glucose and sucrose-containing-phosphoramidites **16** and **17**, as well as sugar-functionalized supports **19** and **20**, were prepared essentially as previously reported (*15, 16*). Novel mannose building block **18** and mannose-functionalized support **21** were synthesized in analogy with the corresponding glucose and sucrose derivatives and exploited for the synthesis of mannose-containing oligomers **VI** and **VII**, respectively, here chosen as examples of glyco-conjugates which can find a direct application for lectin recognition. In all cases, starting from 100 mg of commercially available DMT-protected guanosine-functionalized CPG support (0.10 mequiv/g, used in connection with phosphoramidites **16**–**18** for the synthesis of 5′-conjugated oligomers) or from LCAA-CPG functionalized with the appropriate DMT-protected sugar residue (**19**–**21**, 0.06–0.08 mequiv/g, used for the 3′-conjugation), on average, 80–120 OD units of pure **I**−**VII** could be isolated, after HPLC purification, and characterized by ESI-MS data (Table 1).

CD spectra at 20 °C for all the studied sequences were diagnostic of parallel-stranded quadruplex structures showing a positive band at 263 nm and a negative band at 243 nm (Figure 1) (*18, 19, 27*). The melting temperatures and melting profiles for each system were largely influenced by the scan rate, revealing kinetic control of the quadruplex dissociation process. From the CD-monitored melting profiles for all the samples, registered at 263 nm (see Supporting Information) at the slowest heating rate investigated (0.05 °C/min), the corresponding melting temperature values were determined (see Table 2). Inspection of Table 2 reveals that 6-mers **III** and **VII**, carrying a monosaccharide residue at their 3′-end, formed quadruplex complexes with moderately increased stability with respect to unmodified sequence **I** ($\Delta T_m = +3/+4$ °C). Remarkably, the same modifications at the 5′-end of the ODN chain caused a dramatic destabilization, with ΔT_m of −15 and −10 °C for **II** and **VI**, respectively. When inserted at either the 5′ or 3′-end of the sequence, the disaccharide tail produced quadruplex complexes with comparable thermal stability; however, both **IV** and **V** showed lower melting temperature values than unmodified oligomer **I** ($\Delta T_m = -6/-5$ °C).

The activity of the synthesized glyco-conjugated oligonucleotides against-HIV-1 and HIV-2 was evaluated in human T-lymphocyte (CEM) cell cultures, as well as their cytotoxic properties. Interestingly, the EC_{50} values of the glyco-conjugated oligonucleotides were found to correlate well with the thermal stabilities of the corresponding quadruplex complexes, and activity against HIV-1 in the 10–20 μM range for 3′-glyco-conjugated ODNs **III** and **VII** was observed (Table 3). No obvious correlation was found between the lack of anti HIV RT activity, reported in Table 4, and the anti-HIV activity. These data further confirmed that specific antiviral activity of G-quadruplex-forming ODNs, with well-defined three-dimensional structures, is not due to HIV-1 reverse transcriptase inhibition, but can be attributed to efficient interaction with the viral entry process. From the data in our hands, we concluded that, among the investigated conjugations, the insertion of a monosaccharide, and more specifically, of a mannose residue at the 3′-phosphate end of the studied ODN sequence, was the most promising modification in terms of both quadruplex formation and biological activity.

Assuming **VII** as the best candidate for further drug optimization, we thought of combining the 3′-glyco-conjugation present in this oligomer with an additional 5′-tethering, chosen among the ones previously demonstrated by Hotoda et al. to convert the anti-HIV inactive $^{5'}$TGGGAG$^{3'}$ into an active drug, effective at micromolar concentration (*18*). In our previous work, the *tert*-butyldiphenylsilyl (TBDPS) group at the 5′-end of the $^{5'}$TGGGAG$^{3'}$ sequence (**VIII**) was shown to markedly enhance both the equilibrium and the rate of formation of the quadruplex complexes, in comparison with the unmodified sequence (*19*). In an effort to improve the biophysical and pharmacological profile of this G-rich oligonucleotide, we synthesized the oligonucleotide containing both the TBDPS residue at the 5′-

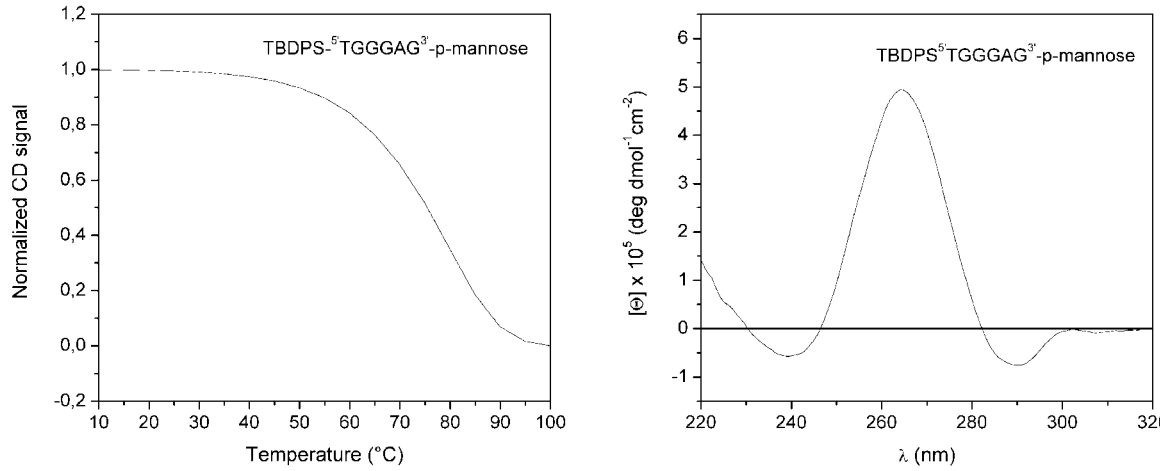

Figure 2. CD melting profile (on the left) and CD spectrum at 20 °C (on the right) of the 5′,3′-bis-conjugated oligonucleotide **IX**, at 5×10^{-5} M quadruplex concentration.

end and the mannose moiety at the 3′-phosphate end, thus obtaining the oligomer TBDPS-$^{5'}$TGGGAG$^{3'}$-*p*-mannose **IX**. The synthetic procedure to obtain **IX**, described in Scheme 3, is based on the usage of functionalized solid support **21** in conjunction with 5′-TBDPS-thymidine-3′-phosphoramidite building block **29** (*18, 19*), exploited in the last coupling of the solid-phase ODN assembly. Antiviral evaluation on **IX** showed that the insertion of the TBDPS group at the 5′-end of $^{5'}$TGGGAG$^{3'}$-*p*-mannose notably affected its biological activity, with a 3-fold increase in the anti-HIV potency, with respect to ODN **VII**, carrying the sole mannose as the tethering group (Table 5). However, bis-conjugate **IX** was found to be 2.3-fold less active than TBDPS-$^{5'}$TGGGAG$^{3'}$ (**VIII**) on HIV-infected CEM cells. When the series of compounds were examined for their inhibitory activity against syncytium formation between persistently HIV-1-infected HUT-78/HIV-1 cells and uninfected SupT1 cells, only **IX** was measurably inhibitory (Table 6). In order to gain a critical insight into the peculiar structural features of bis-conjugated ODN **IX**, a detailed physicochemical characterization of the corresponding quadruplex complex was therefore carried out and comparison with previously studied TBDPS-$^{5'}$TGGGAG$^{3'}$ (**VIII**), to better investigate the role of the mannose−phosphate appendage at the 3′-end on the quadruplex structure, is reported here.

The CD spectrum of TBDPS-5′-TGGGAG-3′-*p*-mannose **IX** is consistent with the formation of a parallel quadruplex structure (Figure 2). From the CD melting profile obtained at 0.05 °C/min, shown in Figure 2, the melting temperature of the quadruplex complex was found to be 81 °C, with a ΔT_m of +40 °C with respect to unmodified **I**, and of +36 °C with respect to the quadruplex formed by **VII**, bearing mannose−phosphate tails at the 3′-ends (Table 2). In order to especially focus on the kinetic aspects, recognized to primarily affect the *in vivo* existence of four-stranded quadruplex complexes, a complete biophysical characterization of the quadruplex formed by ODN **IX** was carried out. The obtained data were compared with those previously determined for TBDPS-$^{5'}$TGGGAG$^{3'}$ **VIII** (*19*). The kinetics of TBDPS-$^{5'}$TGGGAG$^{3'}$-*p*-mannose quadruplex association was investigated in detail. The rate of the association reaction was studied by monitoring the ellipticity at 263 nm as a function of time after heating the sample at 95 °C for 5 min followed by fast cooling. The molar ellipticity vs time profiles are shown in Figure 3. The experimental curves were fitted following a previously described procedure (*21*). All the data were consistent with a reaction order of 4.0. The kinetic experiments were performed over the temperature range 15–30 °C. The activation energy (E_{on}) was derived from the slope of the Arrhenius plot (see Supporting Information). The kinetic parameters are summarized in Table 7. We found that the association rate decreased upon increasing the temperature, due to a negative value for the activation energy, in accordance with previously obtained data for the TBDPS-$^{5'}$TGGGAG$^{3'}$ quadruplex. The activation energy for the formation of the quadruplex complex of **IX** is about half the activation energy determined in the case of **VIII**. In the 15–30 °C temperature range, the kinetic constants for the TBDPS-$^{5'}$TGGGAG$^{3'}$ and TBDPS-$^{5'}$TGGGAG$^{3'}$-*p*-mannose quadruplexes are comparable. However, when the values are extrapolated at higher temperatures, the association reaction for quadruplex formation in **IX** is much faster in comparison to **VIII**, due to the difference in the absolute value of their activation energies. The kinetics of quadruplex dissociation for TBDPS-$^{5'}$TGGGAG$^{3'}$-*p*-mannose was also investigated by performing temperature-jump experiments. In each experiment, the temperature of the sample was rapidly increased and the rate of quadruplex dissociation was monitored by following the change of CD signal with time. The kinetic profiles at different temperatures are shown in Figure 4. The dissociation rate constants were then obtained by fitting these kinetic profiles with a single exponential curve. The activation energy (E_{off}) was derived from the corresponding Arrhenius plot (see Supporting Information). The kinetic parameters for quadruplex dissociation are summarized in Table 8. The quadruplex formed by **IX** has k_{off} values comparable with those previously determined for **VIII**. The E_{off} value for the quadruplex formed by **IX** is about 130 kJ mol^{-1} higher than the value found for **VIII**.

Taken together, these data showed that bis-conjugated TBDPS-$^{5'}$TGGGAG$^{3'}$-*p*-mannose **IX** formed more kinetically and thermodynamically stable four-stranded quadruplex structures than TBDPS-$^{5'}$TGGGAG$^{3'}$(**VIII**). Therefore, we can conclude that the presence of mannose residues at the 3′-phosphate end of the G-rich oligonucleotide chain, in addition to providing several desirable properties for the *in vivo* activity, as increased resistance toward nucleases and improved cellular uptake, also significantly contributes to the overall stabilization of the quadruplex complex. However, contrarily to what we have found for monoconjugated 6-mers **II**−**VII** when referred to unmodified oligonucleotide **I**, in the comparison of **IX** vs **VIII**, the higher thermal stability for the quadruplex complex did not result in improved biological activity.

Further experiments, including a detailed NMR-based conformational analysis study, are currently underway to further

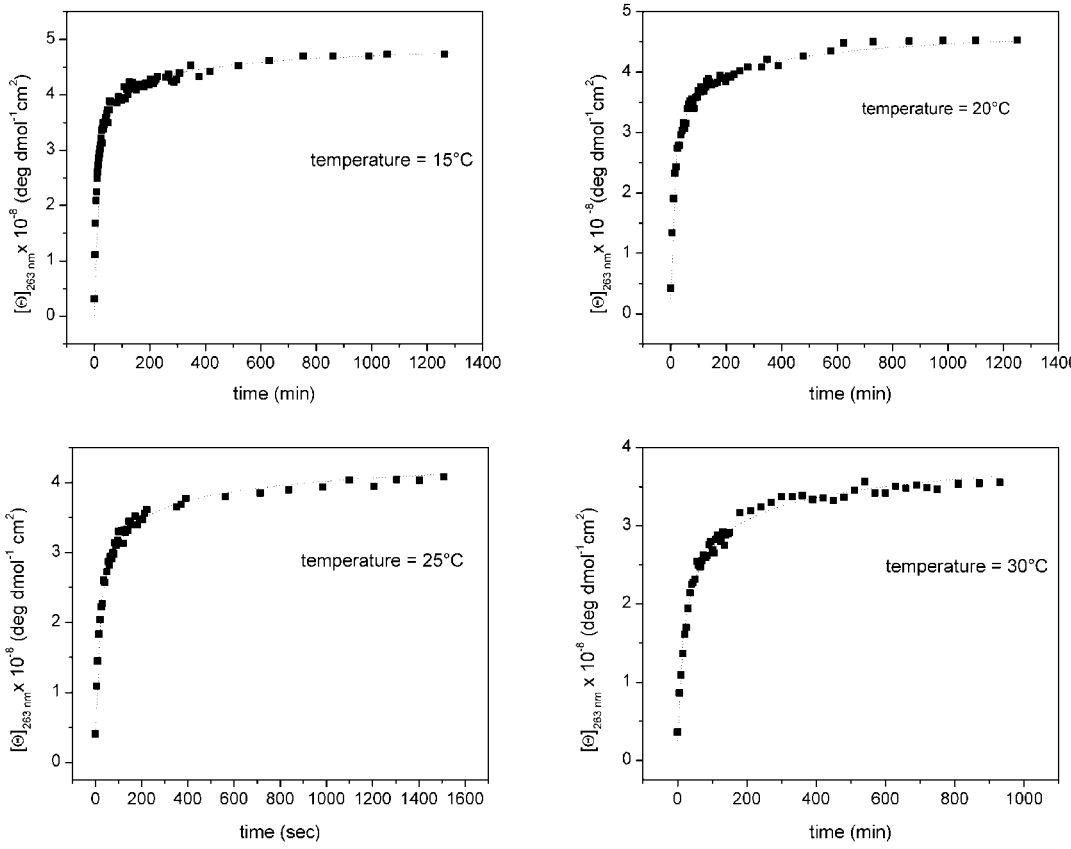

Figure 3. Kinetics of quadruplex formation for 5′,3′-bis-conjugated **IX** at different temperatures. Quadruplex formation leads to an increase of molar ellipticity at 263 nm. Mathematical fits are showed in dotted lines. All the experiments were performed in 10 mM potassium phosphate buffer (pH 7.0), supplemented with 200 mM KCl, at 5×10^{-6} M quadruplex concentration.

clarify the structure–activity relationships of these short, four-stranded G-quadruplex-forming oligonucleotides.

DISCUSSION

After more than two decades, the search for new chemically modified ODNs is a very active field of research, and novel structures are continuously being proposed. Aiming at ODNs endowed with potential anti-HIV activity, end-conjugation with sugars was investigated here as a strategy to improve the pharmacological profile of the oligonucleotide $^{5'}$TGGGAG$^{3'}$, chosen as a model compound. G-rich oligonucleotides are thought to be active against HIV-1 through interactions of the corresponding G-quadruplex complexes with viral gp120 protein. Our results, furnishing an in-depth analysis of the stability and biological activity of the quadruplex structures formed by modified $^{5'}$TGGGAG$^{3'}$ oligonucleotides, further corroborated this hypothesis, showing a good correlation between thermal stability of the corresponding quadruplex complexes and antiviral activity. In detail, the presence of a monosaccharide (glucose or mannose) at the 3′-phosphate end of the ODN chain was identified as the best modification, stabilizing the quadruplex structures and also converting the anti-HIV inactive natural oligomer into moderately active compounds. On the contrary, the same modification, when present at the 5′-end, led to a dramatic destabilization of the quadruplex structure. Still unclear is the reason behind this behavior, but a plausible explanation could be related to the fact that, in the case of 3′-conjugation, the sugar directly interacts with the G-quartet at the 3′-end of the sequence, which in the natural oligonucleotide would be exposed to the solvent. Therefore, in this case, stabilization of the quadruplex complex might arise from removal of the hydration spheres covering the hydrophobic surface of the G quartet due to the presence of the sugar. In the case of 5′-conjugation, this effect is not operative, since the sugar is attached to a dangling thymidine, not directly involved in the four-stranded quadruplex complex, and in turn other steric effects may be effective.

Starting from the most promising modified oligonucleotide investigated here, i.e., oligomer **VII**, further optimization of the target was obtained by conjugating the bulky aromatic group *tert*-butyldiphenylsilyl (TBDPS) group at its 5′-end, previously shown to markedly enhance the formation of quadruplex complexes. The 5′,3′-bis-conjugated TBDPS-$^{5'}$TGGGAG$^{3'}$-*p*-mannose **IX**, onto which a detailed biophysical characterization has been carried out, has been shown to form a four-stranded quadruplex complex with remarkably improved stability, and was 3-fold more active than the sole 3′-glyco-conjugated oligonucleotide **VII**. The mechanism of antiviral action of TBDPS-$^{5'}$TGGGAG$^{3'}$-*p*-mannose is most likely inhibition of

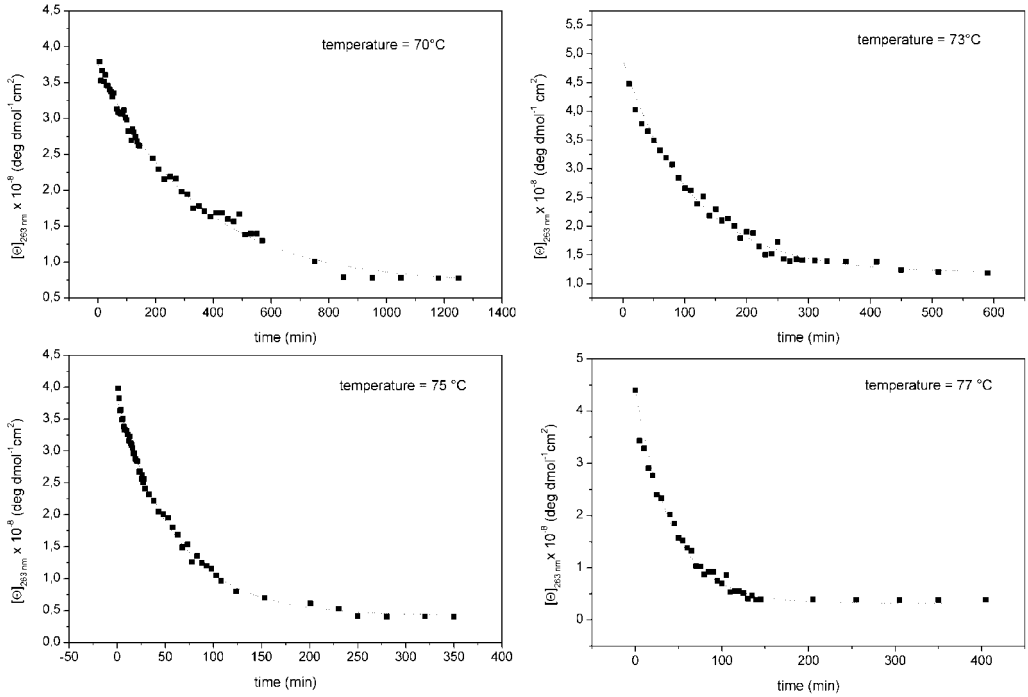

Figure 4. Kinetics of quadruplex dissociation for 5′,3′-bis-conjugated **IX** at different temperatures. Quadruplex dissociation leads to a decrease of molar ellipticity at 263 nm. Mathematical fits are showed in dotted lines. All the experiments were performed at 5×10^{-5} M quadruplex concentration.

	73	0.83 ± 0.02	
	75	1.4 ± 0.4	220 ± 20
	77	2.3 ± 0.1	
	80	3.5 ± 0.3	

[a] All the values have been determined in a 200 mM KCl, 10 mM potassium phosphate, pH 7.0 buffer. [b] k_{off} is defined as $d[S]/dt = d[S_4]/dt + k_{off}[S_4]$. [c] Data from ref (*19*).

viral entry (fusion), as is evident from coculture experiments. When compared to the sole 5′-conjugated TBDPS-$^{5'}$TGGGAG$^{3'}$**VIII**, we determined that the 5′,3′-bis-conjugation sensibly favored—both kinetically and thermodynamically—the quadruplex formation, still **IX** exhibited lower anti-HIV activity.

This last result indicates that the antiviral properties of short G-quadruplex forming oligonucleotides are indeed subordinate to the formation of tetrameric complexes, but the *in vivo* picture is obviously much more complicated than simply expected on the basis of a single point of view. In all cases, the quadruplex formation can be considered as a fundamental prerequisite for the *in vivo* biological activity of G-rich oligomers; however, their activity does not exclusively rely on a favored equilibrium between single strands and quadruplex structures, with other mechanisms also successively involved. Therefore, in the search for antiviral properties in the libraries of modified G-rich oligonucleotides, the correlation between thermal stability of the corresponding quadruplex complexes and their anti-HIV activity can be helpful, but this has to be strictly intended only for a first level of prediction, since a variety of different, complex processes may eventually affect their *in vivo* behavior.

Taken together, these findings further expand the repertoire of known anti-HIV active oligonucleotides and can be useful for the future design of novel modified G-rich ODNs with improved antiviral activity.

ACKNOWLEDGMENT

We acknowledge MUR (PRIN) for grants in support of this investigation. We also thank C.I.M.C.F., Università degli Studi di Napoli "Federico II", for the NMR, MS, and CD facilities, and the Rega Centers of Excellence of the K.U.Leuven. This work is dedicated to Prof. Guido Barone and Matteo Adinolfi on the occasion of their 70th birthdays.

Synthesis of Multifunctional Polyvinylsaccharide Containing Controllable Amounts of Biospecific Ligands

V. Korzhikov,[†] S. Roeker,[‡] E. Vlakh,[†] C. Kasper,[‡] and T. Tennikova*,[†]

Institute of Macromolecular Compounds, Russian Academy of Science, Bolshoy pr. 31, 199004, St. Petersburg, Russia, and Institut für Technische Chemie der Universität Hannover, Callinstr. 3, 30167 Hannover, Germany. Received October 16, 2007; Revised Manuscript Received December 20, 2007

In the present study, the attempt to synthesize a multibiofunctional polymeric vector to be used for construction of composite scaffolds for bone tissue engineering has been undertaken. The polymers based on 2-deoxy-2-methacrylamido-D-glucose were functionalized by a growth factor (BMP-2), GRGDSP peptide, and poly(L-lysine) using aldehyde chemistry. The covalent modification process was quantitatively studied, and a polymer conjugate containing all these ligands was formed. In addition, the impacts of coupled ligands toward the adsorption of polymers on the commercial mineral macroporous matrix Sponceram used in cell culture applications were studied.

1. INTRODUCTION

For a long time, biomaterials used for surgical purposes were generally intended to remain inert, thus, unaffected by the reactions with surrounding tissues (*1–7*). While these approaches were useful in many applications, numerous investigators have been currently addressing the means by which biological recognition might be imported (*3, 8–15*). Therefore, it may be possible to utilize such biologically active materials to control cellular interactions and cell function. For example, the new approach for construction of three-dimensional (3-D) composite scaffolds for bone tissue engineering (*16*) supposes the use of biofunctional polymers. In this case, a suitable mineral support should be adsorptively covered by a biocompatible but nondegradable macromolecular compound bearing covalently coupled special ligands responsible for cell adhesion, growth, and differentiation. In this manner, the general idea of this work is the functionalization of the matrix surface in order to intensify *in vitro* or/and *in vivo* tissue formation.

The biomolecules of interest are growth factors (*17–19*) and adhesive peptides (*20–23*). The former are polypeptides involved in the regulation of a variety of cellular activities such as growth and differentiation. Bone morphogenetic proteins (BMP) belonging to the transforming growth factor-β (TGF-β) family and regulating main cellular functions can be proposed as the most probable candidates for our goals. The latter are the so-called RGD peptides. They represent integrin-binding mediators and contain the Arg-Gly-Asp sequence in their chemical structure. Modification of the scaffold surface with RGD peptides may enhance cell adhesion to the matrix and activate integrin signaling pathways. Additionally, different oligo- and polycations, such as poly(L-lysine), could be used to simplify a nonspecific electrostatic cell adhesion.

There are few basic requirements that should be met while designing the polymer for the purpose described in ref (*24*). First, the polymer has to be biocompatible. Second, it has to possess the required molecular mass (MM). This means that, on one hand, the polymer has to be of sufficient MM to exhibit a tendency to be adsorbed on the mineral matrix, and on the other hand, the polymer MM should not hinder its removal from the body (usually, MM = (20–30) $\times$ 10^3). Finally, the polymer has to have sufficient adsorption capability with regard to the mineral supports and contain reactive groups for ligands covalent conjugating.

For these purposes, the use of a new type of polymer known as polyvinylsaccharides (PVS) (*25–31*), which are carbon backbone polymers containing carbohydrate residues as side groups, looks very promising. The presence of saccharide groups in such polymers gives the possibility of forming a structure that may induce a significant increase of specific interactions (*32–39*) in cells with a scaffold surface. As the reactions of bioligand covalent coupling should proceed at mild conditions without yielding toxic byproducts and considering the fact that proteins and peptides contain amino groups, aldehyde chemistry was chosen for this purpose.

In our previous studies, the new hydrophilic polymers based on 2-deoxy-*N*-methacrylamido-D-glucose (MAG) with a controllable amount of aldehyde groups and the evidence for those to be adsorbed on several mineral supports were obtained (*40*). Nevertheless, the important issue in our studies is the supervised functionalization of the mineral matrix surface, which could be achieved by quantitatively controllable coupling of special ligands to the polymer prior to its adsorption on a solid matrix. Thus, the biological response of the system might be governed. Moreover, the combination of several bioligands with different functions on one polymer chain is of special interest.

In the present work, the detailed study of the obtained polymer modification with the bone morphogenetic protein (BMP-2) model, namely, RNase, RGD-peptide, and poly(L-lysine), as well as the synthesis of a polymeric conjugate containing all these ligands on one polymer chain were carried out. The impact of the introduced ligands on the adsorption parameters of polymers was evaluated. In addition, in order to assay the applicability of synthesized conjugates in bone tissue engineering, the cytotoxicity of the initial and modified polymers was examined.

2. EXPERIMENTAL SECTION

2.1. Materials and Instruments. All buffer salts and other reagents of pro analysi (p.a.) quality were purchased from Fluka (Buchs, Switzerland) and Sigma (Taufkirchen, Germany). The

dialysis bags Spectra/Pore (MWCO: 1000) used for polymer desalting were purchased from Spectra (USA). The separation of nonreacted low- and high-molecular ligands from polymer conjugates was performed in spin-columns (VIVASCIENCE, Sartorius Group, Göttingen, Germany)—membrane MWCO: 3000, 30 000.

For adsorption studies, the macroporous monolithic Sponceram (Sp) (doped ZrO_2 ceramic material; pore size 600 μm; surface area ~1.4 m^2/g) kindly donated by Zellwerk GmbH (Germany) was used as a mineral support.

Poly(L-lysine) (pLL) of MM 15 000 and ribonuclease A (RNase) were the products of Sigma (Germany). Bone morphogenetic protein-2 (BMP-2) was a kind gift of Prof. Dr. W. Sebald (Institut für Physiologische Chemie, Universität Würzburg, Germany).

For UV–vis measurements, the full-spectrum UV/vis spectrophotometer NANO-DROP ND-1000 (peQLab Biotechnologie GmbH, Germany) was used. The fluorescence measurements were performed using Multiscan Fluorimeter FLUOROSCAN ASCENT (Thermo Electron Corp., UK).

2.2. Methods. *2.2.1. Polymer Synthesis and Aldehyde Group Generation.* The samples of water-soluble 2-deoxy-2-methacrylamido-D-glucose (MAG) homopolymer (pMAG) and its copolymer with 1-vinyl-2-pyrrolidone (VP) and acrolein diethylacetal (DAAc) (p(MAG-co-VP-co-DAAc)) were used as functional vectors.

2.2.1.1. Synthesis of pMAG. The synthesis of MAG polymer was performed similarly to a previously published procedure (*31*, *40*). MAG (6 g, 0.024 mol) was dissolved in 57 mL of DMF, and 0.3 g (5 wt % from MAG amount) of AIBN was added. The reaction mixture was purged with nitrogen. Polymerization was carried out in a sealed ampule at 60 °C for 24 h. The product was precipitated in diethyl ether. After filtration and vacuum drying, 5.7 g (95%) of polymer was obtained. The specific viscosity was measured in 0.1 M Na_2SO_4 at 25 °C and was found to be equal to 0.11 dL/g that corresponded to MM_η = 21 000 ($[\eta]^{25\ °C} = 8.29 \times 10^{-4}$. $M^{0.49}$). MM_w(light-scattering) was equal to 25 800.

2.2.1.2. Synthesis of p(MAG-co-VP-co-DAAc). The samples of p(MAG-*co*-VP-*co*-DAAc) were synthesized by free radical polymerization of comonomers in the presence of AIBN in DMF (*40*) as described above. The comonomers ratio was [MAG]:[VP]:[DAAc] = 15:45:40 mol %. The copolymerization proceeded for 72 h. The resulting polymer product was purified *via* dialysis for 24 h against water and then lyophilized. MM_w (light-scattering) was found to be equal to 13 500.

2.2.1.3. Oxidation of pMAG. The synthesis of dialdehyde derivatives of pMAG was carried out as follows (*40*): 0.5 g (0.002 mol) of pMAG was dissolved in 80 mL of water and cooled down to 5 °C. Then, the sodium periodate was added in an amount corresponding to the desirable amount of aldehyde groups to be obtained. Generally, $[NaIO_4]$:[MAG] = 0.5 and 0.7 mol were used to obtain 20 and 30 mol % of aldehyde groups. The reaction was allowed to proceed for 24 h in the dark at 5 °C. Then, the product was purified by dialysis against water (24 h) and dried by lyophilization. The appearance of aldehyde groups in oxidized polymer was registered via IR spectra measurements. There are two small peaks, 1755 and 1735 cm^{-1}, at the foot of wide amide carbonyl band, which might be referred to the absorption of two aldehyde groups arising from α-glycol cleavage.

2.2.1.4. Activation of p(MAG-co-VP-co-DAAc). The activation, e.g., the removal of blocking acetal groups, of p(MAG-*co*-VP-*co*-DAAc) was carried out in aqueous solution of hydrochloric acid containing 5 mg/mL of polymer at 50–60 °C for 2 h, pH 2.0. After the reaction completed, the solution of activated polymer was dialyzed for 12 h against water and lyophilized. In the IR-spectra of activated p(MAG-*co*-VP-*co*-DAAc), the evident swell (in comparison with pMAG spectra) at the foot of the amide carbonyl band is observed that might be referred with confidence to the absorption of aldehyde groups.

2.2.2. Analytical Methods. 2.2.2.1. Quantification of Aldehyde Groups (Schiff'S Test). The molar amount of aldehyde groups was determined by a reaction of polymers with fuchsinsulfite reagent (Shiff's reagent). For this purpose, the calibration curve was plotted using glutaric dialdehyde as a standard, and the extinction coefficient of CHO-groups was calculated. The analytical procedure was carried out as follows: to a sample of 0.5 mL of aldehyde containing substance, 2.5 mL of Shiff reagent was added, and the absorbance of colored complex was measured at 550 nm in 40 min.

2.2.2.2. Iodine test. The molar amount of VP in p(MAG-*co*-VP-*co*-DAAc) and the concentration of this copolymer at adsorption studies was determined using iodine test. For that, 3 mL of 3 mM iodine in 0.2 M sodium acetate buffer, pH 4.6, was added to 0.5 mL of polymer solution. The absorbance of the colored complex was measured immediately at 460 nm.

2.2.2.3. UV Measurements. In addition to the Schiff's test, the direct measurements at 265–270 nm were used to quantify the amount of the polymers and their conjugates with high- and low-molecular mass ligands.

2.2.3. Polymer Modification. All covalent coupling reactions were allowed to proceed at room temperature for 2 h with stirring (400–700 rpm). After polymer functionalization, all modified samples were treated with sodium borohydride, then purified by spin-column dialysis (membrane MWCO: 3000, 30 000) and stored in a refrigerator at 4 °C.

2.2.3.1. Coupling of Low-Molecular Mass Ligand (GRGDSP–Peptide). In this case, the molar proportions of polymer CHO groups and NH_2 groups of peptide were used. 1, 2, 5, and 10 equiv (in the case of p(MAG-*co*-VP-*co*-Ac) modification) and 1 and 2 equiv (in the case of oxidized pMAG modification) of GRGDSP—peptide, calculated according to the molar content of polymer CHO groups, were dissolved in 0.5 mL 0.01 M sodium borate buffer, pH 10.0, and added to the same volume of activated polymer containing 1 equiv of aldehyde groups (aqueous solution, pH 10.0).

To prove quantitatively the covalent coupling of peptide to the polymer, a fluorescent test was carried out. For that, 5 equiv of dansylcadaverine were dissolved in 2 mL of 7 M urea solution containing 7.5% MeOH and added to 1 equiv of polymer—peptide conjugate dissolved in 2 mL of sodium borate buffer, pH 10.0. Then, 10 equiv of water-soluble 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC) dissolved in 1 mL of urea was introduced. The reaction proceeded for 40 min at room temperature. Low-molecular mass components of the reaction mixture were separated by spin-column dialysis, and the determination of fluorescent emission of bound to the peptide marker was carried out at 485 nm (corresponding to excitation wavelength of 355 nm). The preliminary calibration curve for free dansylcadaverine allowed quantitative determination of peptide amount bound to the polymer.

2.2.3.2. Coupling of Macromolecular Ligands. In the case of coupling of proteins and pLL, both containing numerous amino groups, for the reaction mixture preparation the mass proportions were used.

SDS-PAGE characterization of modified products was carried out using 16% gels prepared according to the standard procedure (*41*). Silver staining was used for oxidized pMAG, proteins, and conjugate zone detection (*16*, *41*).

(a) Poly(L-Lysine). To study the coupling of pLL to the polymers, the following model experiment was performed. First, the labeling of pLL with FITC was done. For this, 6 μL of fresh FITC aqueous solution, 1 mg/mL, was added to 1 mg/

mL solution of pLL in 0.01 M sodium borate buffer, pH 10.0. The reaction proceeded for 1 h, and the product was then purified from nonreacted FITC by spin-column dialysis (membrane MWCO: 3000). After that, the calibration curve from fluorescence measurement for the detection of pLL labeled with FITC was plotted. In the second stage of this experiment, the reaction of pLL−FITC with activated polymers at different mass proportions was carried out. 1 mass equiv of pLL−FITC conjugate dissolved in 0.01 M sodium borate buffer, pH 10.0, was added to 1 mL solution containing 5, 10, 20, or 40 mass equiv of activated polymer (borate buffer, pH 10.0). The reaction was allowed to proceed for 2 h with slight stirring (550 rpm). The resulting polymer conjugate was purified from nonreacted pLL−FITC via spin-column dialysis (membrane MWCO: 30 000), and the amount of Lys units coupled to the polymer was evaluated by fluorescence measurement.

(b) Ribonuclease A and BMP-2. RNase A was chosen as a cheap BMP-2 model because of their similar isoelectric points and close molecular masses. Quantitative studies of RNase coupling to aldehyde-bearing polymers were carried out using the same model experiment as was made in the case of pLL. 10 μL of FITC aqueous solution, 1 mg/mL, was added to 2 mg/mL solution of protein in 0.01 M sodium borate buffer, pH 10.0. The labeling reaction was allowed to proceed for 1 h, and the product was purified by spin-column dialysis (membrane MWCO: 3000). For polymer modification, 1 mass equiv of protein−FITC conjugate dissolved in 0.01 M sodium borate buffer, pH 10.0, was added to 1 mL solution containing 2, 5, 10, and 20 mass equiv of activated polymer (borate buffer, pH 10.0). After the spin-column dialysis (membrane MWCO: 30 000), the fluorescence of polymer−(protein−FITC) conjugates was measured, and the molar amount of protein coupled was evaluated using the previously plotted calibration curve.

For construction of composite matrices for cell culture experiments, about 400 mass excess of aldehyde-bearing polymer per amount of BMP-2 was used.

2.2.2.3. Synthesis of Triple Conjugate. The construction of multifunctional polymer conjugate containing RNase, pLL, and RGD−peptide was performed via "step-by-step" addition of ligands to the polymer solution and using the quantitative methods described above. All reactions were carried out in 0.01 M sodium borate buffer, pH 10.0. On the final step, the excess of sodium borohydride was added in order to reduce Schiff's bases and possibly unreacted aldehyde groups.

(a) Coupling of RNase−FITC to Oxidized pMAG. In the first step, 1 mL of oxidized polyMAG solution, 2 mg/mL, was added to 0.1 mL of RNase−FITC solution, 1 mg/mL ([pMAG]:[RNase] = 20:1 mass proportion). The reaction proceeded with slight stirring for 1 h. The product was purified by spin-column dialysis (membrane MWCO: 30 000) and two 0.1 mL aliquots were taken for fluorescence measurements.

(b) Coupling of pLL–FITC to pMAG–(RNase–FITC) Conjugate. In the second step, 1 mg/mL, 1 mL of polyMAG–(RNase–FITC) conjugate solution, 1.6 mg/mL, was added to 0.08 mL of pLL–FITC solution ([pMAG]:[pLL] = 20:1 mass proportion). In all cases, the concentration of polymer was considered to be the concentration of the whole conjugate. The reaction, purification, and fluorescence measurements were realized in the same way as in the case of RNase.

(c,d) Coupling of RNase−FITC and pLL−FITC to p(MAG-co-VP-co-Ac). The modification of p(MAG-VP-Ac) with RNase and pLL was carried out in the same way as was done with oxidized pMAG. The only difference consisted of a larger excess of polymer used in each step, namely, [p(MAG-*co*-VP-*co*-Ac)]:[ligand]=30:1 mass proportion.

(e) Coupling of RGD−Peptide. 0.2 mL of RGD−peptide solution, 1 mg/mL, was added to both conjugates of polymers with RNase−FITC and pLL−FITC. The reaction proceeded for 1.5 h with slight stirring. The product was purified by spin-column dialysis, and the residual solution passed through membrane (MWCO: 3000) was measured at 226 nm. Thus, the amount of nonreacted peptide was evaluated, and the molar quantity of peptide coupled to the polymer was calculated using the previously plotted calibration curve.

2.2.4. Adsorption Studies. In all cases, the study of adsorption kinetics and isotherms building were performed at static conditions. Despite the experiments on covalent modification of aldehyde-bearing polymers by amino-containing ligands being carried out in 0.01 M sodium borate buffer, pH 10.0, it is essential for adsorption studies to be performed at physiological conditions, e.g., at pH 7.0. Therefore, 0.01 M sodium borate buffer, pH 10.0, adjusted to pH 7.0 by boric acid (called borate solution, pH 7.0) was used in all experiments.

2.2.4.1. Adsorption Kinetics and Desorption Studies. 1.5 mL of polymer (or conjugate) solution with concentration 1 mg/mL in borate solution, pH 7.0, was added to 50 mg of mineral support. The adsorption proceeded with slight stirring (300–400 rpm) at 25 °C for 3 h. At regular intervals, the content was centrifuged, and the amount of adsorbed polymer was estimated by measuring its concentration in the supernatant using the methods described above (reaction with Shiff's reagent, iodine test, and UV measurements).

The control of possible polymer desorption was carried out by incubation of mineral supports in 0.01 M PBS 7.0 over 14 days using the same quantitative methods to evaluate the desorbed amount of polymer derivatives.

2.2.4.2. Isotherm Building. For this purpose, several samples containing 50 mg of mineral support each were used. The concentrations of polymers (conjugates) solutions in borate solution, pH 7.0, varied from 0.25 to 3.5 mg/mL. The samples of Sponceram were incubated for 2 h (the time corresponding to the plateau on the kinetics curves) at 25 °C in polymer solution, and the amount of adsorbed polymer at fixed concentration was determined as mentioned above.

2.2.4.3. Statistics. For each point, both for kinetics measurements and isotherm building, the set of three equivalent experiments ($n = 3$), with a pure Sponceram as a control, were performed and three UV–vis measurements were done for each sample. The presented results are given as a mean values and the average deviation is 5%.

2.2.4.4. Adsorption of Polymers and Conjugates for Cell Culture Experiments. For cell culture experiments, the adsorption of initial polymers was performed in 15 mL tubes containing 20 pieces of Sponceram 15–20 mg each, and 5 mL of sterilized (0.2 μm filter) polymer solution in sodium borate buffer, pH adjusted to 7.0, with concentration 0.5 mg/mL was added to the tubes. The tubes were slightly stirred (300 rpm) or rotated (1 rpm) at least overnight. Then, the solution of the polymer was removed, and the pieces of Sponceram were washed twice with phosphate buffering saline (PBS), pH 7.0. Subsequently, the composite materials were incubated with cell culture medium for 2 h at room temperature or overnight at 4 °C.

The conjugates adsorption was carried out in a similar way, except the 2 mL tubes and 1.5 mL of 1.0 mg/mL or 0.5 mg/mL solutions were used.

2.2.5. Cell Culture Experiments. 2.2.5.1. Cultivation of MC3T3-E1 Cells. MC3T3-E1 cells were stored in Dulbecco's modified eagle medium (DMEM), supplemented with 10% fetal bovine serum and antibiotics. For assays in 96-well plates, 5000 cells per well were seeded. For cell seeding onto Sponceram, 15–20 mg pieces of Sponceram were shaken (350 rpm) with 20 μL of a cell suspension (1 mio cells/mL) for 30 min at 37 °C, 5% CO_2. The Sponceram pieces were sterilized by auto-

Table 1. Modification of pMAG (30 mol % CHO groups, MM 20 000) and p(MAG-*co*-VP-*co*-Ac) (7 mol % CHO groups, MM 13 500) with GRGDSP−Peptide[a]

[a] Reaction conditions: 0.01 M sodium borate buffer, pH 10.0, 25 °C, 2 h stirring (550 rpm). Purification: spin-column dialysis (MWCO: 3000). The aldehyde groups conversion (the amount of peptide bound to the polymer) was determined by fluorescent test with use of dansylcadaverine as a fluorescent label ($\lambda_{ex.}$= 355 nm, $\lambda_{em.}$= 485 nm).

claving and incubated with cell culture medium for at least 2 h before cell seeding.

2.2.5.2. MTT Assay. MTT assays were performed with n = 5 and one negative control. The matrices were placed into new wells to measure exclusively the viability of the cells adherent to the Sponceram but not those on the bottom of the well. Cells/matrices were incubated with 100 μL of cell culture medium and 10 μL MTT (5 mg/mL in PBS) for 4 h at 37 °C, 5% CO_2. Formazan crystals were dissolved overnight with 10% SDS in 0.01 M HCl. The formazan absorption was measured at 570 nm subtracted by the 630 nm absorption.

2.2.5.3. Statistical Analysis. A p value of <0.05 was considered statistically significant. In order to confirm the dependence of one variable on another (e.g., whether cell viability is dependent on polymer concentration), a linear regression was performed, considering a p value of <0.01 statistically significant.

3. RESULTS AND DISCUSSION

3.1. Polymer Modification. Following the main idea of this work, the mineral matrix has to be covered by a nondegradable polymer vector covalently modified with ligands which impart bifunctionality to. The water-soluble 2-deoxy-2-methacrylamido-D-glucose (MAG) homopolymer (pMAG) and its copolymer with *N*-vinylpyrrolidone (VP) and acroleyn diethylacetal (DAAc) [p(MAG-*co*-VP-*co*-DAAc)] were used as functional vectors. Also, having the final aim of creating a multifunctional conjugate containing the mixture of several ligands on one polymer chain, we were intending to study the possibility of controlled introduction of these ligands. For this purpose, the analysis of covalent coupling of single ligands to the polymers under investigation was performed.

3.1.1. GRGDSP−Peptide Coupling. Both oxidized pMAG and p(MAG-*co*-VP-*co*-Ac) were modified with GRGDSP–peptide at different molar proportions of aldehyde groups of polymers and amino groups of peptide (Table 1). The idea of this model experiment is presented in Figure 1. The coupling of GRGDSP–peptide was determined by treatment of the conjugate with dansylcadaverine fluorescent label in the presence of water-soluble carbodiimide (EDC). Then, the polymeric conjugate was purified from low-molecular compounds by spin-column dialysis, and the fluorescence of the sample was detected.

The results obtained for oxidized pMAG and those for p(MAG-*co*-VP-*co*-Ac) are shown in Table 1. As this reaction was supposed to be controlled by the diffusion of peptide to the aldehyde groups of polymer, in most cases, an excess of peptide was used. Besides, some steric hindrance caused by glucose side residues and polymer microstructure might occur. One can see that, in the case of oxidized pMAG, containing 30

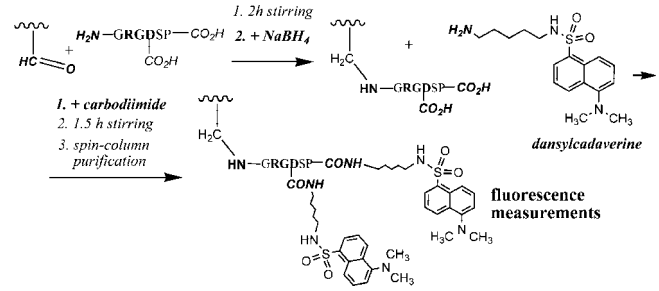

Figure 1. Polymer modification with RGD peptide and evaluation of the molar amount of peptide coupled.

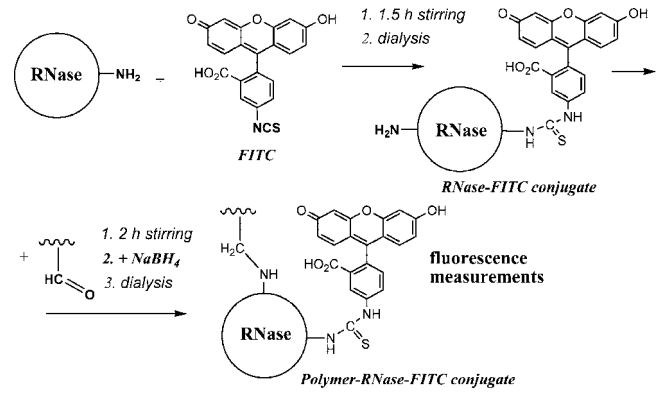

Figure 2. Polymer modification with RNase.

mol % of CHO groups, close to 100% conversion occurs as early as the [CHO]:[NH_2] = 1:2 molar proportion of initial reaction mixture is used. This is not so for p(MAG-*co*-VP-*co*-Ac), which contains much fewer aldehyde groups (7 mol %). In the latter case, the high conversion occurs only at [CHO]:[NH_2] = 1:10 molar proportion of a reaction mixture.

Thus, generally we can conclude that the reactions of GRGDSP peptide with polymers are really controlled by diffusion of peptide to the polymer aldehyde groups; consequently, the increase of peptide concentration leads to higher conversion.

3.2.2. Modification with Macromolecular Ligands. 3.2.2.1. RNase and BMP-2. For qualitative confirmation of pMAG−RNase conjugate formation, SDS-PAGE in 16% gel was used. While the pMAG itself does not move in the gel, the oxidized pMAG and its conjugate with RNase migrates across the gel layer demonstrating a continuous band due to polymer molecular weight distribution. After silver staining of the gel, the bands corresponding to the formation of conjugate were observed.

The quantitative studies of RNase coupling were performed by use of fluorometrical detection. For that, fluorescent labeling with FITC was carried out before coupling to the polymer (Figure 2). As was mentioned above, the use of RNase A as a model of BMP-2 was reasonable because these proteins have nearly the same isoelectric points and molecular mass.

Observing the data in Table 2, one can see that the reaction between polymers and RNase takes place. As the reaction proceeds between two macromolecular compounds, some steric hindrance effects occur. Thus, in order to magnify the protein conversion, the excess of polymers and, consequently, of aldehyde groups, in most cases was applied. Besides, there is the evidence for the fact that RNase binds to p(MAG-*co*-VP-*co*-Ac) to a greater extent than to oxidized pMAG. This result might be explained by p(MAG-*co*-VP-*co*-DAAc) structure peculiarities which provides the greater accessibility of aldehyde groups for protein coupling.

[a] Reaction conditions: 0.01 M sodium borate buffer, pH 10.0, 25 °C, 2 h stirring (550 rpm). Purification: spin-column dialysis (MWCO: 3000). The aldehyde group conversion (the amount of peptide bound to the polymer) was determined by fluorescent test with use of FITC as fluorescent label ($\lambda_{ex.}$ = 485 nm, $\lambda_{em.}$ = 538 nm).

3.2.2.2. Poly(L-Lysin) (pLL). For investigation of quantitative coupling of pLL to the polymers, the same model experiment as in the case with RNase was performed. The data obtained for polyMAG and p(MAG-*co*-VP-*co*-Ac) are presented in Table 3. Likewise to the case with proteins, an excess of polymer per amount of pLL was used. Note that, when less than a 5-fold mass excess of polymer was used, the formation of an insoluble part occurred, which is most likely due to intermolecular cross-linking of aldehyde-containing polymers by polyamino-containing molecules of pLL. Also, it is important to point out that, apart from the cases with proteins, the calculations were carried out not to the molecule of pLL, but to the molar quantity of L-lysine units, because the molecular mass of pLL (like other synthetic polymers) represents a mean value.

Observing the data obtained (Table 3), one can see that the maximum conversion of amino groups was reached in the case of oxidized pMAG that bears greater amount of aldehyde groups. Interestingly, while considering molar ratios of aldehyde groups and amino-bearing lysine units (Table 3), it is becoming evident that amino group conversion and, thus, the reactivity of aldehyde groups are nearly equal for both polymers. This might be explained by the high amount of easily accessible amino groups in pLL, which allows one to overcoming the diffusion limitations occurring in the case of RNase. So, the use of pMAG here might be preferable only due to higher quantity of aldehyde groups in its structure.

3.2.3. Triple Conjugate Formation. As was mentioned above, the final aim of this part of work was to create a polymeric vector containing the so-called "cocktail" of ligands on one polymer chain. Therefore, using the data obtained in single-ligand coupling experiments, the attempt to construct the mixed

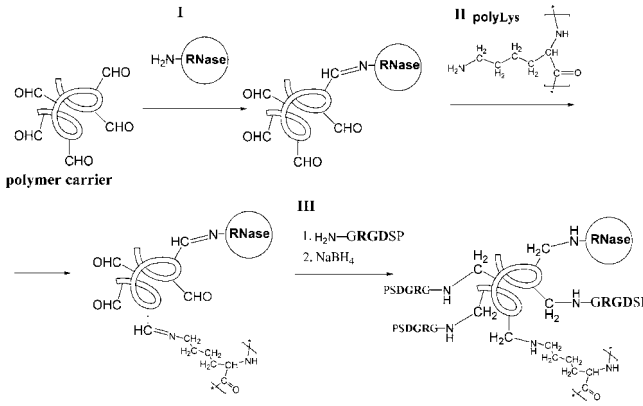

Figure 3. Triple conjugate synthesis.

conjugate was made. The synthesis was performed via "step-by-step" introduction of ligands (Figure 3) to the polymer using the same quantitative methods described above. First, the macromolecular ligands (RNase and then pLL) were added, because their coupling is affected by steric hindrance and an excess of aldehyde groups is required. After that, an excess of RGD−peptide was added, and its coupled amount was qualified by evaluation of the quantity of unreacted peptide. Finally, the conjugate was treated with sodium borohydride to turn Shiff's bases into more stable single bonds and to convert unreacted aldehyde groups to hydroxyls. The latter point is important to prevent subsequent reactions and possible toxic effect for the cells.

The data obtained are collected in Table 4. It is obvious that the conversion of ligands taking place at each step proves the successful construction of the desired triple conjugates.

3.2. Adsorption Studies. As was pointed out in the Introduction, this work was aimed toward obtaining polymers that can be used as the organic part of composite scaffolds for bone tissue regeneration. An important issue in such composites is the interfacial bonding between ceramics and polymer. If the adhesion of the two phases is poor, the biological properties of polymeric conjugates with biomolecules suffer. Thus, it was important to determine the adsorption characteristics of the obtained conjugates and compare them with those of initial polymers.

The mineral support used in our experiments, namely, Sponceram (Sp), has the anionic character of its surface. This fact was also taken into account at the construction of the polymeric part of composite.

3.2.1. Adsorption of Initial Polymers. 3.2.1.1. Adsorption Kinetics and Desorption Studies. The resulting kinetic curves of adsorption of the polymers under study on Sponceram are shown in Figure 4. It is seen that the adsorption process is quite intensive, and it achieves its maximum, the plateau on the curves, within about 100 min. As the shapes of all kinetic curves are nearly the same, for further comparison of adsorption kinetics of conjugates on Sponceram only oxidized pMAG was used.

The data obtained in desorption studies are demonstrated in Table 5. There is evidence for the fact that the polymers in the study do not desorb in noticeable amounts within 14 days, which in turn indicates the adsorption strength.

3.2.1.2. Isotherms Building. The plotted isotherms of adsorption are shown in Figure 5. The acquired values of $Q_{a\ max}$, for which the amount of adsorbed polymer corresponding to the plateau on the isotherm curve was accepted, are presented in Table 5.

Thus, considering the results of adsorption kinetics studies and plotted isotherms, one can see that there are no significant

Table 5. Adsorption/Desorption Parameters of Polymers and Their Conjugates

		desorption, mg/g sorb.	
sample	Q_{max} mg/g sorb.	8 days	14 days
oxidized pMAG	16.5	0.2	0.3
p(MAG-*co*-VP-*co*-Ac)	14.1	0.3	0.5
pMAG−pLL	18.2	0.3	0.4
pMAG−RNase	17.0	0.2	0.3
pMAG−RGD	6.1	0.0	0.1

differences both in the trends of curves and in the quantity of polymers adsorbed. Obviously, the MAG residue seems to be a major cause for all polymers to be adsorbed. This effect might be explained by the ability of MAG to form a large amount of hydrogen bonds with negatively charged oxygen atoms on the surfaces of the mineral matrix.

The absence of significant desorption measured within 14 days at physiological pH confirms the strength of adsorption and, thereafter, a possibility of using such polymers for construction of composite scaffolds for cell culture applications without any risk of polymer leakage from a mineral surface.

3.2.2. Adsorption of Conjugates. The adsorption study of conjugates was performed in the same way and via the same quantitative methods as in the case of aldehyde-containing polymers. Considering the fact that the adsorption characteristics of two pMAG samples and p(MAG-*co*-VP-*co*-Ac) are very similar, in this study we used only pMAG (20 mol % of aldehyde) conjugates.

The obtained kinetics curves and isotherms are demonstrated in Figure 6 and Figure 7, respectively. The observation of kinetic curves approves only a slight difference in their shape, whereas the amounts of conjugates adsorbed are remarkably different. We can suppose that kinetics curves trends are determined by pMAG structure, whereas the Q_{max} at a certain concentration is influenced by the presence of different ligands. This is likely

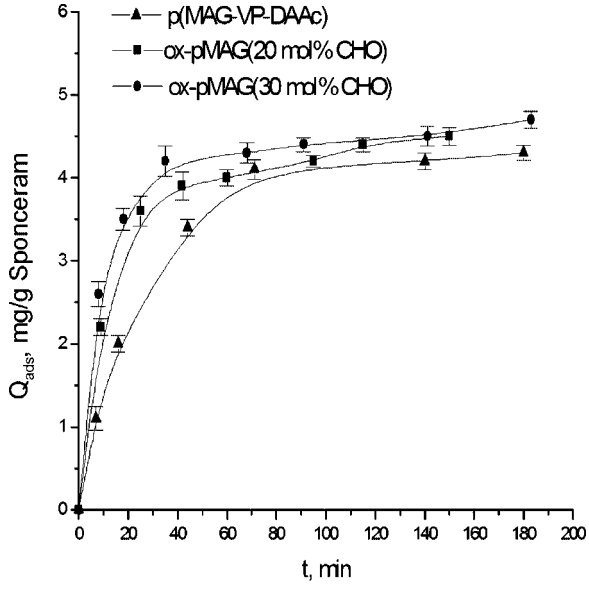

Figure 4. Kinetic curves of oxidized pMAG (20 and 30 mol % [CHO]) and p(MAG-*co*-VP-*co*-Ac) adsorption on Sponceram. The experiment was performed in 0.01 M sodium borate solution, pH 7.0, at 25 °C and with slight stirring, 300 rpm. The concentrations of initial solutions were 1 mg/mL.

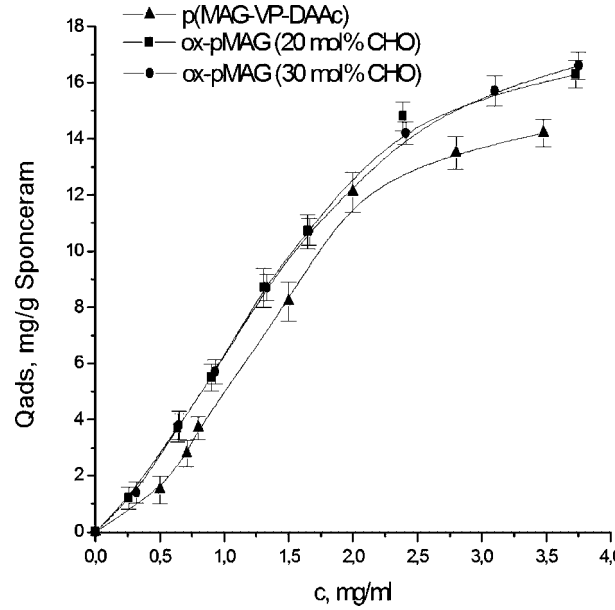

Figure 5. Isotherms of oxidized pMAG (20 and 30 mol % [CHO]) and p(MAG-*co*-VP-*co*-Ac) adsorption on Sponceram. The experiment was performed in 0.01 M sodium borate solution, pH 7.0, at 25 °C and slight stirring, 300 rpm. The reaction time was 4 h.

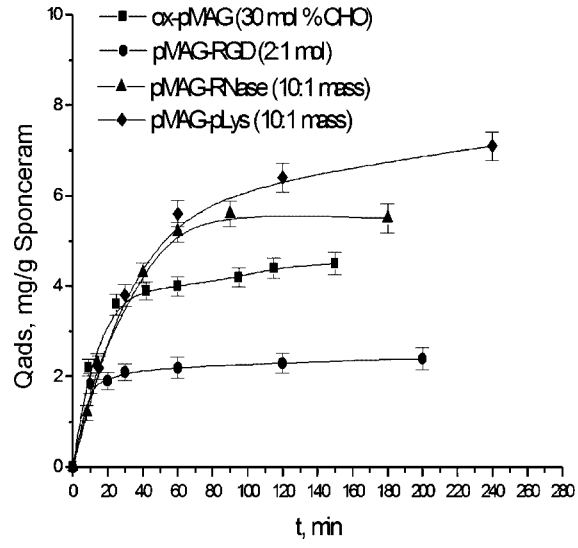

Figure 6. Adsorption kinetic curves of oxidized pMAG and its conjugates with RGD−peptide, RNase, and pLL on Sponceram. The experiment was performed in 0.01 M sodium borate solution, pH 7.0, at 25 °C and at slight stirring, 300 rpm. The concentrations of initial solutions were 1 mg/mL.

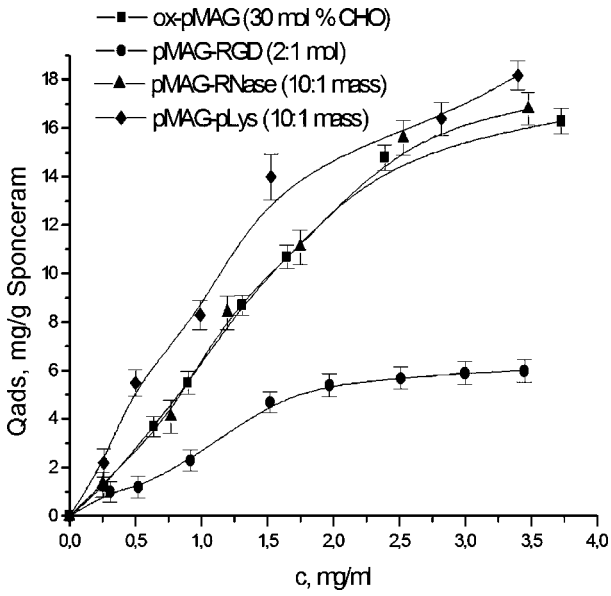

Figure 7. Isotherms of oxidized pMAG and its conjugates with RGD−peptide, RNase, and pLL adsorption on Sponceram. The experiment was performed in 0.01 M sodium borate solution, pH 7.0, at 25 °C and at slight stirring, 300 rpm. The reaction time was 4 h.

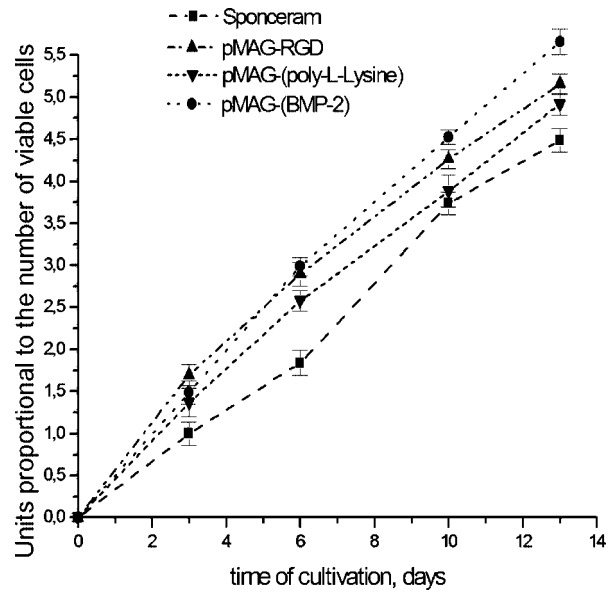

Figure 8. MTT assay−pMAG modified with BMP-2, GRGDSP peptide, and pLL adsorbed on Sponceram.

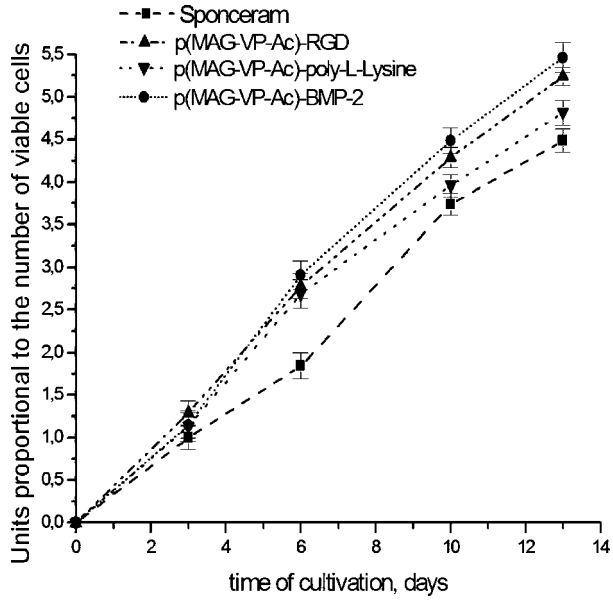

Figure 9. MTT assay−p(MAG-*co*-VP-*co*-Ac) modified with BMP-2, GRGDSP, and pLL adsorbed on Sponceram.

to be true when watching the isotherms of adsorption. A considerable amount of pMAG−pLL conjugate adsorbed is due to the positive charge of poly(L-lysine) causing the ionic interactions with the negatively charged surface of Sponceram. In the latter case, there is no well-marked plateau on the isotherm curve, that might be due to the formation of multilayers. Besides, it is obvious that coupling of RGD−peptide affects the conformation and polymer macrostructure that results in adsorption behavior.

Desorption parameters of adsorbed conjugates are shown in Table 5. It is seen that, as in aldehyde polymer derivatives, the desorption within 14 days is practically equal to zero.

In addition to building the isotherm, the approximate calculations of the polymer coverage on the mineral matrix surface were made by considering the polymers to be adsorbed more or less as stretched threads. The results of these calculations allow to say that at Q_{max} on the isotherm curves the surface of Sponceram is overfilled with polymer.

3.3. Cytotoxicity. Initially, every polymer that was considered for adsorption on the mineral matrix was tested for its cytotoxicity in cell culture medium. MC3T3-E1 cells were used for this purpose. In these studies, the aldehyde forms of the polymers [oxidized pMAG and p(MAG-*co*-VP-*co*-Ac)] were shown to decrease cell viability in comparison with the standard cell culture. At the same time, the nonaldehyde forms of polymers [pMAG and p(MAG-*co*-VP-*co*-DAAc)] did not display such an effect (*40*).

After that, pMAG, oxidized pMAG, and p(MAG-*co*-VP-*co*-Ac) were adsorbed on Sponceram, and the viability of MC3T3-E1 cells on these modified materials was investigated. Sponceram incubated with borate buffer, which was used for the polymer adsorption, served as a control. Cell viability was roughly the same for all tested samples. Unlike the experiments with polymers supplementing the cell culture medium, there was no significant cytoxicity or any difference between polymers containing aldehyde groups and those without (*40*).

Nevertheless, the polymers modified with biospecific ligands, not the initial polymers, were of the primary interest in this work. Herewith, it is essential to note that in target conjugates there are no aldehyde groups, because they are used for the reactions with macromolecules and small ligands and, finally, should be reduced to hydroxylic groups when treated with sodium borohydride.

To test the cytotoxicity of the obtained conjugates, the polymers oxidized pMAG and p(MAG-VP-Ac) were coupled to BMP-2, RGD peptide, and pLL, respectively, and then adsorbed on Sponceram. The viability of the MC3T3-E1 cells was observed on these composite materials over a time period of two weeks and compared to the cell viability on Sponceram treated with borate buffer (Figures 8 and 9). The results showed that the amount of cells adhered onto composite materials was increased in all measurements when compared to pure Sponceram. The investigation of the impact of ligands on cell behavior—cell adhesion pLL and RGD peptide) and differentiation (BMP-2)—is in progress.

CONCLUSIONS

The quantitatively controllable functionalization of polymers based on 2-deoxy-2-methacrylamido-D-glucose with GRGDSP-

peptide, Ribonuclease A (physical model of BMP-2), and poly(L-lysine) was carried out; and the conjugate containing all these ligands was synthesized. The study of adsorption characteristics of initial polymers and their conjugates with the foregoing ligands allows us to conclude that the adsorption process is strong enough for all polymers and their conjugates. Moreover, the first experiments on the viability of cells on the Sponceram covered with polymers and their conjugates with RGD peptide, pLL, and BMP-2 clearly showed that the polymers in use are not cytotoxic when adsorbed on the mineral surface and tend to increase cell adhesion when modified with special ligands. Thus, we can suggest this type of conjugate for development of scaffolds for bone tissue engineering.

ACKNOWLEDGMENT

This work was financially supported by the grants of Russian Foundation of Basic Research (RFBR, 05-03-32310) and German Scientific Society (DFG, KA 1784/4–1). The authors are grateful to the German Academic Exchange Service (DAAD) for providing the scholarship for PhD student Victor Korzhikov for six months work at the Institute of Technical Chemistry, University of Hannover (ITC UH). We are also grateful Prof. Dr. Thomas Scheper for kind cooperation and positive discussions.

Novel Biodegradable Poly(disulfide amine)s for Gene Delivery with High Efficiency and Low Cytotoxicity

Mei Ou,[†] Xu-Li Wang,[‡] Rongzuo Xu,[‡] Chien-Wen Chang,[†] David A. Bull,[§] and Sung Wan Kim*[,†]

Center for Controlled Chemical Delivery (CCCD), Department of Pharmaceutics and Pharmaceutical Chemistry, 421 Wakara Way, Suite 318, University of Utah, Salt Lake City, Utah 84112, and Division of Cardiothoracic Surgery, Room 3C127, School of Medicine, 30N 1900E, University of Utah, Salt Lake City, Utah 84132. Received October 25, 2007; Revised Manuscript Received December 13, 2007

Novel biodegradable poly(disulfide amine)s with defined structure, high transfection efficiency, and low cytotoxicity were designed and synthesized as nonviral gene delivery carriers. Michael addition between *N*,*N*′-cystaminebisacrylamide (CBA) and three *N*-Boc protected diamines (*N*-Boc-1,2-diaminoethane, *N*-Boc-1,4-diaminobutane, and *N*-Boc-1,6-diaminohexane) followed by *N*-Boc deprotection under acidic condition resulted in final cationic polymers with disulfide bonds, tertiary amine groups in main chains, and pendant primary amine groups in side chains. Polymer structures were confirmed by ^{1}H NMR, and their molecular weights were in the range 3.3−4.7 kDa with narrow polydispersity (1.12−1.17) as determined by size exclusion chromatography (SEC). Acid–base titration assay showed that the poly(disulfide amine)s possessed superior buffering capacity to branched PEI 25 kDa in the pH range 7.4−5.1, which may facilitate the escape of DNA from the endosomal compartment. Gel retardation assay demonstrated that significant polyplex dissociation was observed in the presence of 5.0 mM DTT within 1 h, suggesting rapid DNA release in the reduction condition such as cytoplasm due to the cleavage of disulfide bonds. Genetic transfections mediated by these poly(disulfide amine)s were side-chain spacer length dependent. The poly(disulfide amine) with a hexaethylene spacer, poly(CBA-DAH), had comparable transfection efficiency to bPEI 25 kDa in the tested cell lines, i.e., 293T cells, Hela cells, and NIH3T3 cells. This same poly(disulfide amine) mediated 7-fold higher luciferase expression than bPEI 25 kDa in C2C12 cells (mouse myoblast cell line), a cell line difficult to transfect with many cationic polymers. Furthermore, MTT assay indicated that all three poly(disulfide amine)s/pDNA polyplexes were significantly less toxic than bPEI/pDNA complexes.

INTRODUCTION

Gene therapy has broad potential in the treatment of human genetic and acquired diseases through the delivery and application of therapeutic gene-based drugs. The use of safe, efficient, and controllable gene carriers is a requirement for the success of clinical gene therapy (*1, 2*). Although viral vectors are very efficient in gene delivery, their potential safety and immunogenicity concerns raise their risk in clinical applications (*3*). As an alternative to viral vectors, cationic polymers such as poly(L-lysine) (PLL), poly(ethylenimine) (PEI), poly(amidoamine)s dendrimers, and cationic liposomes have been synthesized as gene delivery carriers. The advantages of these cationic polymer carriers include safety, stability, large DNA and RNA loading capacity, and easy and large-scale production (*4–6*). The cationic polymers can condense negatively charged DNA into nanosized particles through electrostatic interactions, and the polymer/pDNA polyplexes can enter cells via endocytosis (*7–9*). As a result, the polymers can protect pDNA from nuclease degradation and facilitate cellular uptake to induce high gene transfection (*10, 11*).

The currently available cationic polymers, however, have significant cytotoxicity concerns, mostly due to their poor biocompatibility and nondegradability under physical conditions. Consequently, the development of hydrolyzable cationic polymers was proposed, such as poly(*β*-amino ester)s (*12–14*), poly(amino ester)s (*15, 16*), and poly(amido amine)s (*17, 18*). For example, the library of poly(*β*-amino ester)s, containing ester bonds in structures, have been reported to improve biodegradability and transfection efficiency and decrease cytotoxicity (*19, 20*). However, their degradation via hydrolysis or enzymatic cleavage is relatively slow in both extracellular oxidizing and intracellular reducing environments. At this point, disulfide bonds are preferred in the design and synthesis of biodegradable polymers. First, disulfide bonds are more hydrolytically stable than ester bonds in the extracellular environment, so the polycations with disulfide bonds can be used to prepare stable complexes with plasmid DNA. Second, disulfide bonds can be cleaved rapidly by glutathione and thioredoxin reductases in cytoplasm. As a result, DNA can be rapidly released from polyplexes to mediate efficient gene expression. Also, cytotoxicity will be decreased by avoiding high charge density and long-term polymer accumulation (*21*). Lin and co-workers have recently synthesized various linear poly(amido amine)s containing repetitive disulfide linkages in structures, which were proven to have significantly increased transfection efficiency and decreased cytotoxicity in COS-7 cells (*22*). However, poly(amido amine)s incorporated only tertiary amine groups, hydroxyl groups, and/or imidazole groups. The tertiary amine groups have limited DNA binding affinity due to steric hindrance, while hydroxyl and imidazole groups contribute little to binding of DNA. Consequently, transfection efficiencies would be decreased by their reduced ability to complex DNA. Therefore, we proposed to incorporate primary or secondary amine groups in such biodegradable

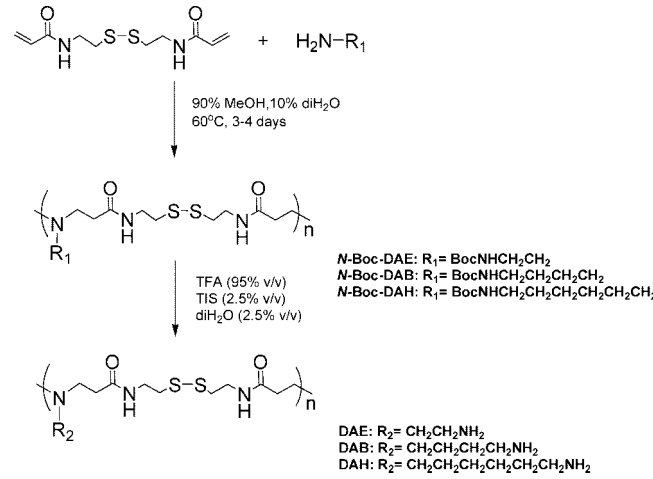
polymers to increase nucleic acid binding affinity and following transfection efficiency. Our laboratory has previously synthesized a new form of poly(amido ethylenimine)s containing disulfide bonds and secondary amine groups in their structures (*23*). Those polymers have been proven to have significant transfection efficiency and low cytotoxicity for both DNA and siRNA delivery (*23, 24*). During the synthesis, however, these polymers will form branches randomly, resulting in significant structural cross-linking and therefore poor solubility in water and some organic solvents.

In this paper, we propose to synthesize and evaluate poly(disulfide amine)s, a novel series of linear cationic polymers with many of the characteristics of ideal polymeric gene delivery carriers that can mediate high gene transfection with low cytotoxicity. The advantages of these polymers are as follows: (1) Defined and improved polymer structures. Prepared by Michael addition and *N*-Boc deprotection under acidic condition, these polymers contain disulfide bonds, tertiary amine groups, and pendant primary amine groups in structures, and they do not form uncontrollable branches and cross-linking in synthesis. These structures aim to meet the fundamental design criteria of good gene carriers: reasonable biodegradability, strong DNA condensation ability, efficient gene transfection and low cytotoxicity. (2) Biodegradability. Poly(disulfide amine)s contain disulfide bonds in main chain, and are relatively stable in the extracellular oxidizing environment while being rapidly degraded in the intracellular reducing environment. Therefore, genetic materials in polyplexes will be released efficiently in the cytoplasm to allow for efficient gene expression. Meanwhile, cytotoxicity will decrease due to polymer degradation. (3) High nucleic acid binding affinity. Introducing unique primary amine side groups into poly(disulfide amine)s improves water solubility and enhances positive charge density. This allows plasmid DNA and other genetic materials, such as antisense oligonucleotides, peptide nucleic acids, and siRNA, to be stably condensed into nanosized particles under physiological pH, which will contribute to endocytosis and consequently efficient gene transfection. (4) High buffering capacity. The combination of tertiary and primary amine groups in poly(disulfide amine)s can promote endosomal−lysosomal escape based on the "proton sponge hypothesis". This characteristic gives poly(disulfide amine)s great potential in gene delivery. In this study, we synthesized poly(disulfide amine)s via Michael addition and *N*-Boc deprotection. Polymers were characterized by ^{1}H NMR, SEC, and acid–base titration. The properties of polymer/pDNA complexes were studied by dynamic light scattering and gel electrophoresis. *In vitro* transfection as well as *in vitro* cytotoxicty of polymer/pDNA complexes were evaluated by luciferase assay, BCA protein assay, and MTT assay using 293T cells (human renal epithelial cell line), Hela cells (human cervical cancer cell line), NIH3T3 (mouse embryonic fibroblasts), and C2C12 cells (mouse myoblast cell line).

MATERIALS AND METHODS

1. Materials. *tert*-Butyl-*N*-(2-aminoethyl)carbamate (*N*-Boc-1,2-diaminoethane, *N*-Boc-DAE), *tert*-butyl-*N*-(4-aminobutyl) carbamate (*N*-Boc-1,4-diaminobutane, *N*-Boc-DAB), *tert*-butyl-*N*-(6-aminohexyl)carbamate (*N*-Boc-1,6-diaminohexane, *N*-Boc-DAH), hyperbranched polyethylenimine (bPEI, M_w = 25 kDa), trifluoroacetic acid (TFA), triisobutylsilane (TIS), dithiothreitol (DTT), ethidium bromide (EtBr), and 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT) were purchased from Sigma-Aldrich (St. Louis, MO). *N,N′*-Cystaminebisacrylamide (CBA) was purchased from PolySciences, Inc. (Warrington, PA). The plasmid pCMV-Luc, containing a firefly luciferase reporter gene which was inserted into a pCI plasmid vector driven by the CMV promoter (Promega, Madison, WI),

Scheme 1. Synthesis of Biodegradable Poly(disulfide amine)s



was amplified in *E. coli* DH5α and isolated by standard Maxiprep kit (Invitrogen, Carlsbad, CA) according to manufacture's instruction. Dulbecco's Modified Eagle's Medium (DMEM), penicillin−streptomycin, fetal bovine serum (FBS), trypsin-like enzyme (TrypLE Express), and Dulbecco's phosphate buffered saline (PBS) were purchased from Invitrogen-Gibco (Carlsbad, CA). Luciferase assay system with reporter lysis buffer was purchased from Promega (Madison, WI). All materials and solvents were used as received without further purification.

2. Polymer Synthesis. The synthetic route of poly(disulfide amine)s was illustrated in Scheme 1. Here, the synthesis of poly(CBA-DAE) is described as the representative procedure. Briefly, *N*-Boc-DAE (0.160 g, 1 mmol) and CBA (0.260 g, 1 mmol) were added into a flask and dissolved in 1 mL MeOH/H_2O mixture (9/1 v/v). Polymerization was conducted in an oil bath at 60 °C in the dark under nitrogen atmosphere for 4 days. Then, 10% mol excess *N*-Boc-DAE was added into the reaction solution to consume any unreacted acrylamide functional groups, and the reaction was performed at 60 °C for at least additional 2 h. After that, the product was precipitated with 40 mL anhydrous diethyl ether and dried. Subsequently, the acid-liable *N*-Boc protection group was removed with a TFA/TIS/H_2O mixture (95/2.5/2.5 v/v) for 30 min. The crude was precipitated in 40 mL anhydrous diethyl ether and dried under vacuum. It was further purified by dialysis (MWCO = 1000) against MilliQ deionized water overnight, followed by lyophilization to obtain poly(CBA-DAE) as a solid powder. Poly(CBA-DAB) and poly(CBA-DAH) were synthesized similarly, except the polymerization took 3 days for them. The poly(disulfide amine)s were analyzed by ^{1}H NMR (400 MHz, D_2O) and the data are listed below.

Poly(CBA-DAE): 2.91 ($NCH_2CH_2NH_2$, 2H), 2.64 ($NCH_2CH_2NH_2$, 2H), 2.63 (NCH_2CH_2CO, 4H), 2.22 (NCH_2CH_2CO, 4H), 3.34 ($CONHCH_2CH_2SS$, 4H), 2.62 (CH_2SSCH_2, 4H).

Poly(CBA-DAB): 3.08 ($NCH_2CH_2CH_2CH_2NH_2$, 2H), 1.58 ($NCH_2CH_2CH_2CH_2NH_2$, 2H), 1.58 ($NCH_2CH_2CH_2CH_2NH_2$, 2H), 2.91 ($NCH_2CH_2CH_2CH_2NH_2$, 2H), 2.82 (NCH_2CH_2CO, 4H), 2.48 (NCH_2CH_2CO, 4H), 3.38 ($CONHCH_2CH_2SS$, 4H), 2.63 (CH_2SSCH_2, 4H).

Poly(CBA-DAH): 3.15 ($NCH_2CH_2CH_2CH_2CH_2CH_2NH_2$, 2H), 1.48 ($NCH_2CH_2CH_2CH_2CH_2CH_2NH_2$, 2H), 1.19 ($NCH_2CH_2CH_2CH_2CH_2CH_2NH_2$, 2H), 1.19 ($NCH_2CH_2CH_2CH_2CH_2CH_2NH_2$, 2H), 1.48 ($NCH_2CH_2CH_2CH_2CH_2CH_2NH_2$, 2H), 2.85 ($NCH_2CH_2CH_2CH_2CH_2CH_2NH_2$, 2H), 2.81 ($NCH_2CH_2CO$, 4H), 2.52 ($NCH_2CH_2CO$, 4H), 3.35 ($CONHCH_2CH_2SS$, 4H), 2.65 ($CH_2SSCH_2$, 4H). The ^{1}H NMR spectra of poly(disulfide amine)s are given in the Supporting Information.

3. Polymer Characterization. The molecular weights of the polymers were determined by size exclusion chromatography (SEC) on an AKTA FPLC system (Amersham Biosciences, Piscataway, NJ) equipped with a Superose 12 column, and UV and refractive index detectors, eluted with Tris buffer (20 mM, pH 7.4) at a rate of 0.5 mL/min. Molecular weights were calibrated with standard poly[*N*-(2-hydroxypropyl)methacrylamide] (pHPMA). The FPLC data of polymers are given in the Supporting Information.

4. Buffering Capacity. The buffering capacities of the poly(disulfide amine)s were determined by acid–base titration. Briefly, 10 mL polymer solution was adjusted initially to pH 11.0 by 0.1 M NaOH. Then, the basic polymer solutions were titrated to pH 3.0 with aliquots of 0.01 M HCl. pH values of the solutions were measured after each addition. The buffering capacity is defined as the percentage of amine groups becoming protonated from pH 7.4 to 5.1 and can be calculated from the following equation (*22*):

$$\text{Buffering capacity (\%)} = \Delta V_{\text{HCl}} \times 0.01M/N \text{ mol} \times 100\%$$

Here, ΔV_{HCl} is the volume of 0.01 M HCl solution which brought the pH value of the polymer solution from 7.4 to 5.1, and N mol is the total moles of amine groups in the known amount of poly(disulfide amine)s.

5. Particle Size Measurement. Polyplexes were prepared by vortexing 1 μg pDNA (25 μL, 40 μg/mL) solution with an equal volume of polymer solution at predetermined nitrogen/phosphate (N/P) ratios, followed by 30 min incubation. The polyplexes were then diluted in 2 mL of dustfree diH_2O and the average particle sizes of polyplexes were measured using a BI-200SM dynamic light scattering instrument (DLS, Brookhaven Instrument Corporation, Holtsville, NY) at a 633 nm incident beam. Measurements were made at 25 °C at an angle of 90°. Measurements for each sample were repeated three times and reported as mean values ± standard deviations.

6. Gel Retardation Assay. Agarose gel (1%, w/v) containing 0.5 μg/mL ethidium bromide (EtBr) was prepared in TAE (Tris−acetate−EDTA) buffer. Poly(disulfide amine)/DNA complexes at predetermined N/P ratios were prepared in HEPES buffer as described above. The samples were mixed with 6 × loading dye and the mixtures were loaded onto an agarose gel. The gel was run at 100 V for 30 min and the location of DNA bands was visualized with a UV illuminator using a Gel Documentation Systems (Bio-Rad, Hercules, CA). The DNA release from poly(disulfide amine)s/DNA polyplexes was evaluated by incubating polyplexes with 5 mM DTT at 37 °C for 1 h. The samples were then analyzed by gel electrophoresis as described above.

7. *In Vitro* Transfection. Synthetic poly(disulfide amine)s mediated transfection was evaluated on 293T cells (human renal epithelial cell line, ATCC), HeLa cells (human cervical cancer cell line, ATCC), NIH3T3 (mouse embryonic fibroblasts, ATCC), and C2C12 cells (mouse myoblast cell line, ATCC) by using the plasmid pCMV-Luc as reporter gene. Cells were maintained in DMEM containing 10% FBS, streptomycin (100 μg/mL), and penicillin (100 units/mL) at 37 °C in a humidified atmosphere with 5% CO_2. Cells were seeded 24 h prior to transfection in 24-well plates at initial density of 8.0×10^4, 4.0×10^4, 4.0×10^4, and 3.5×10^4 cells/well for 293T, HeLa, NIH3T3, and C2C12, respectively. DNA was complexed with the poly(CBA-DAE), poly(CBA-DAB), poly(CBA-DAH), and bPEI at predetermined N/P ratios in HEPES buffer and incubated for 30 min before use. At the time of transfection, the medium in each well was replaced with fresh serum-free medium. Polyplexes (0.5 μg DNA/well) were incubated with the cells for 4 h at 37 °C. The medium was then replaced with 500 μL of fresh complete medium, and cells were incubated for additional 44 h. The cells were then washed with prewarmed PBS, treated with 200 μL cell lysis buffer, and subjected to a freezing−thawing cycle. Cellular debris was removed by centrifugation at 14 000 *g* for 5 min. The luciferase activity in the cell lysate (25 μL) was measured using a luciferase assay kit (100 μL luciferase assay buffer) on a luminometer (Dynex Technologies Inc., Chantilly, VA). The relative luminescent unit (RLU) of luciferase expression was normalized against protein concentration in the cell extracts, measured by a BCA protein assay kit (Pierce, Rockford, IL). All transfection assays were carried out in triplicate.

Table 1. Characteristics of Biodegradable Poly(disulfide amine)s[a]

polymers	M_n (kDa)	M_w (kDa)	PDI	buffering capacity in pH range 7.4–5.1 (%)
poly(CBA-DAE)	2.85	3.34	1.17	52.61
poly(CBA-DAB)	4.23	4.72	1.12	61.20
poly(CBA-DAH)	3.12	3.52	1.13	55.65

[a] FPLC conditions: poly(disulfide amine)s are dissolved in 0.5 mL Tris buffer (pH 7.4) as a concentration of 25 mg/mL. Superose 12 column is used to measure the molecular weight and polydispersity. Flow rate is 0.5 mL/min. Standard calibration is calculated using poly[*N*-(2-hydroxypropyl)methacrylamide] (pHPMA). Acid−base titration conditions: 10 mL of polymer solutions in 0.1 M NaCl was titrated with 0.01 M HCl from pH 11.0 to 3.0.

8. Cytotoxicity. NIH3T3 cells were seeded in a 24-well plate at a density of 4.0×10^4 cells/well and incubated for 24 h. DNA was complexed with the poly(CBA-DAE), poly(CBA-DAB), poly(CBA-DAH), and bPEI at predetermined N/P ratios in HEPES buffer and incubated for 30 min before use. Polyplexes (0.5 μg DNA/well) were incubated with the cells for 4 h in serum-free medium followed by 20 h in complete medium. MTT solution (50 μL, 2 mg/mL) was then added, and cells were further incubated for 2 h. The medium was removed, and 300 μL DMSO was then added to each well. The absorption was measured at 570 nm using a microplate reader (model 680, Bio-Rad Laboratory, Hercules, CA). The percentage relative cell viability was determined relative to control (untreated) cells, which were not exposed to transfection system and taken as 100% cell viability. All cytotoxicity experiments were performed in triplicate.

RESULTS AND DISCUSSION

1. Synthesis and Characterization of Biodegradable Poly(disulfide amine)s. Three novel biodegradable poly(disulfide amine)s were synthesized by Michael addition between *N*,*N*′-cystaminebisacrylamide (CBA) and three different *N*-Boc protected diamine monomers, *N*-Boc-DAE, *N*-Boc-DAB, and *N*-Boc-DAH. After removing *N*-Boc protection groups, three linear comblike polymers, poly(CBA-DAE), poly(CBA-DAB), and poly(CBA-DAH), were synthesized with one disulfide bond, one tertiary amine group in the main chain, and one pendant primary amine group in a side chain in each repeating unit (Scheme 1). All three poly(disulfide amine)s were purified by dialysis and lyophilized as a solid powder and were readily soluble in water, PBS buffer, HEPES buffer, Tris buffer, dimethyl sulfoxide (DMSO), and methanol, but not in chloroform, diethyl ether, and tetrahydrofuran. The final structures of poly(disulfide amine)s were confirmed by ^{1}H NMR (400 MHz, D_2O). The disappearance of signal peaks between δ 5 and 7 ppm indicated that the acrylamide end groups no longer existed in the final polymer products. Additionally, the two-step synthetic procedure avoided the possibility of forming branches or cross-links. These ^{1}H NMR results confirmed that our polymers have defined structures as expected and no branches were observed.

The molecular weight of polymers were measured by fast protein liquid chromatography (FPLC) and calibrated by pHPMA standards (Table 1). The range of the weight average

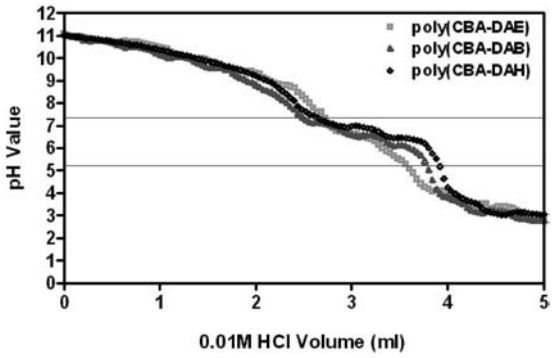


Figure 1. Titration curves were obtained by titrating poly(disulfide amine)s aqueous solutions in 10 mL 0.1 M NaCl from pH 11.0 (initially adjusted by 0.1 M NaOH) to pH 3.0 using 0.01 M HCl. pH of the solutions was measured after each addition.

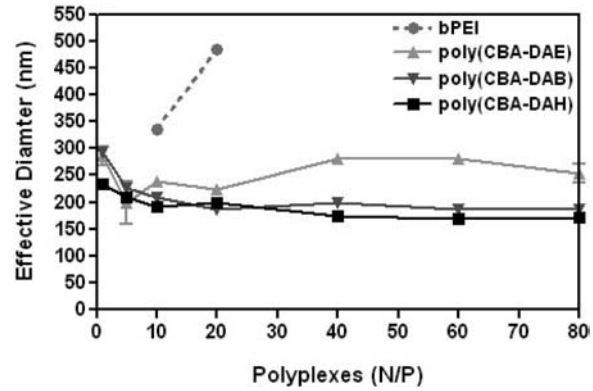

Figure 2. Average particle sizes of poly(disulfide amine)s/pDNA complexes were measured at varying nitrogen/phosphate (N/P) ratios from 1:1 to 80:1, while bPEI (25 kDa)/pDNA complexes were measured at N/P ratios of 10:1 and 20:1. (●) bPEI; (▲) poly(CBA-DAE); (▼) poly(CBA-DAB); (■) poly(CBA-DAH).

molecular weight (M_w) of these polymers was from 3.34 to 4.72 kDa, while the range of the number average molecular weight (M_n) was from 2.85 to 4.23 kDa. The polydispersity index (PDI), ranging from 1.12 to 1.17, indicates that these poly(disulfide amine)s have a narrow molecular weight distribution.

Buffering capacity is an important factor for cationic gene carriers according to "proton sponge hypothesis" proposed by Behr et al. (*10*). It helps polymeric carriers to effectively compact and protect DNA after endocytosis and helps DNA escape from endosomes/lysosomes (*25–27*). Buffering capacities of poly(disulfide amine)s, measured by acid–base titration, were expressed as the percentage of amine groups being protonated from pH 7.4 to 5.1, mimicking the change from the high pH extracellular environment to the low pH endosomal environment (*22, 23, 28*). The results (Table 1 and Figure 1) show that all poly(disulfide amine)s have excellent buffering capacity, ranging from 52.61% to 61.20% protonation, which is much higher than the previously reported results of bPEI 25 kDa, 24% (*22*) and 13.5% (*23*). The high buffering capacities enable poly(disulfide amine)s to facilitate endosomal escape, contributing to an increase in gene transfection efficiency.

There are several attributes of linear poly(disulfide amine)s that make them particularly attractive for the development of new polymeric gene carriers: (1) the polymers contain disulfide bonds for fast degradation; (2) primary and tertiary amine groups can self-assemble with DNA, facilitating endosomal escape and release of DNA to the nucleus efficiently; (3) the presence of primary amine groups at each repeating units for high nucleic acid binding affinity and good water solubility; (4) the capacity to synthesize a variety of analogues directly from commercial available monomer materials; (5) amine concentration can be evaluated for more accurate and efficient gene transfection for the future library of poly(disulfide amine)s.

2. Characterization of Polymer/Plasmid DNA Complexes. To mediate endocytosis through cell membrane, cationic polymers need to condense DNA into nanosized particles via electrostatical interactions between the positively charged polymers and the negatively charged phosphates on DNA backbones (*11, 29*). Dynamic light scattering (DLS) studies showed that three poly(disulfide amine)s can condense plasmid DNA into small particles with effective diameters of less than 300 nm at polymer/pDNA nitrogen/phosphate (N/P) ratios of 1:1 and above. In contrast, the diameters of bPEI/pDNA particles were larger at N/P ratios of 10:1 and 20:1 (336.5 and 484.5 nm) under the same conditions (Figure 2).

Gel retardation assay further verified that poly(disulfide amine)s can condense plasmid DNA at low N/P ratios. All poly(disulfide amine)s were dissolved in HEPES buffer solution (20 mM HEPES, pH 7.4, 5% glucose). One microgram samples of plasmid DNA (pCMV-Luc) with varying amounts of polymers were mixed and incubated at desired N/P ratios followed by performing agarose gel electrophoresis stained with EtBr (Figure 3). In the absence of DTT (Figure 3A), poly(CBA-DAE), poly(CBA-DAB), and poly(CBA-DAH) can completely retard plasmid DNA migration from N/P ratios of 5:1, 3:1, and 3:1, respectively. When the polyplexes were incubated with 5.0 mM DTT at 37 °C for 1 h, mimicking the intracellular reducing environment containing 0.1–10 mM glutathione, pDNA was released from all three poly(disulfide amine)s at all N/P ratios, with bands migrating toward the positive electrode in gel electrophoresis (Figure 3B). For the nondegradable control polymer bPEI 25 kDa, there was no pDNA released from bPEI/pDNA complexes in the presence of DTT. This gel retardation assay proved that all three poly(disulfide amine)s can release pDNA efficiently from polyplexes via disulfide bond cleavage, leading to increased DNA release and increased gene expression.

To facilitate efficient gene expression, cationic polymers should not only strongly condense plasmid DNA extracellularly, but also efficiently release DNA from polyplexes intracellulary. Previously, the hydrolyzable polymers, such as poly(β-amino amine)s and poly(amido amine)s, were synthesized by one-step Michael addition and only contained tertiary amines, hydroxyl, and/or imidazole groups (*12, 22*). The tertiary amine groups have limited DNA binding affinity due to steric hindrance, while hydroxyl and imidazole groups contribute little in binding DNA. As a result, relatively high N/P ratios were required to completely condense DNA. For example, to retard DNA migration in gel electrophoresis, weight ratios equal to or higher than 40:1 were needed for poly(β-amino amine)s (*20*). Similarly, weight ratios of 24:1 or higher are required for poly(amido amine)s, such as pAPOL (*22*). For the poly(disulfide amine)s, on the contrary, the results of the gel retardation assay showed that they can form stable complexes with pDNA at N/P ratios as low as 3:1, suggesting that poly(disulfide amine)s with primary amines have stronger nucleic acid binding affinities than those hydrolyzable polycations as mentioned above. In addition, pendant primary amine groups are more nucleophilic than tertiary amine groups, which will facilitate more efficient gene transfection and expression (*19*). It is also well-known that disulfide bonds can be cleaved rapidly in the presence of a high intracellular concentration of glutathione and thioredoxin reductases. This rapid cleavage of disulfide bonds will ensure DNA release from complexes efficiently to facilitate nuclear import, gene transcription, and gene expression (*22, 23, 30, 31*). In the presence of the reducing agent DTT, the cleavage of disulfide bonds of polymers was expected to dissociate polyplexes and release free DNA which were monitored by the agarose gel electrophoresis. Our poly(disulfide amine)s also

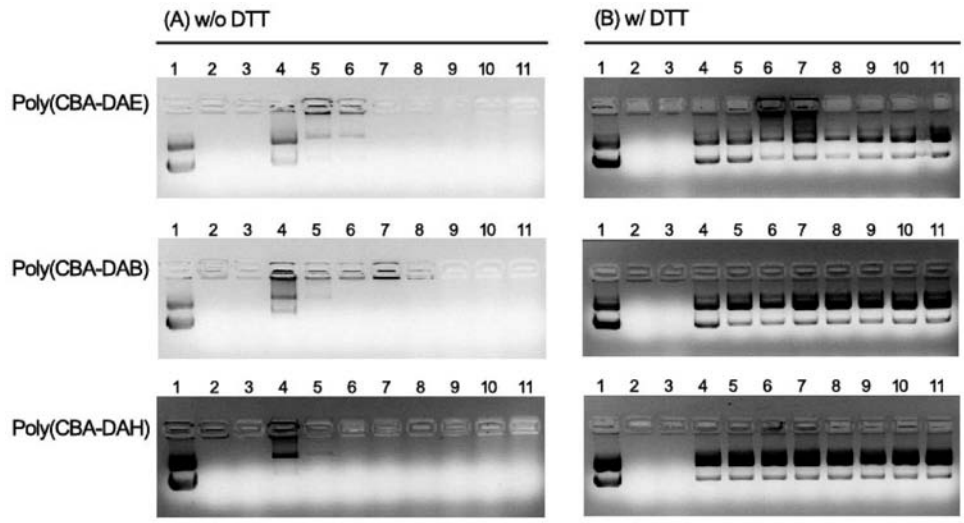

Figure 3. Agarose gel electrophoresis of poly(CBA-DAE), poly(CBA-DAB), and poly(CBA-DAH) with plasmid DNA polyplexes at different nitrogen/phosphate (N/P) ratios at the conditions of (A) without DTT and (B) with 5.0 mM DTT incubation (37 °C, 1 h). Lane 1, naked pDNA; lanes 2 and 3, bPEI/pDNA at N/P ratios of 10:1 and 20:1; lanes 4–11, poly(disulfide amine)s/pDNA at N/P ratios of 1:1, 2:1, 3:1, 5:1, 10:1, 15:1, 20:1, and 40:1.

showed the ability of rapid cleavage in the presence of DTT, mimicking the intracellular reducing environment. In summary, poly(disulfide amine)s demonstrated strong DNA condensing abilities by forming nanosized particles at low N/P ratios. They also showed rapid DNA releasing abilities by rapid disulfide bond cleavage in a reducing environment, which will facilitate the following gene expression (*32–35*).

3. *In Vitro* Transfection and Cytotoxicity of Poly(disulfide amine)s/Plasmid DNA Complexes. To evaluate *in vitro* transfection efficiency of biodegradable poly(disulfide amine)s, their complexes with reporter gene pCMV-Luc (0.5 μg/well) expressing luciferase were produced on four different cell lines, 293T, HeLa, NIH3T3, and C2C12, at five N/P ratios ranging from 5:1 to 80:1 in the absence of serum. bPEI (25 kDa)/pDNA complexes at an N/P ratio of 20:1 was used as a positive control. At this N/P ratio, bPEI showed the highest gene transfection efficiency while maintaining at least 70% cell viability. The transfection efficiency was quantitatively measured as the luciferase enzyme activity and normalized as the total cell protein concentration by BCA protein assay (Figure 4). Among these poly(disulfide amine)s, poly(CBA-DAH) showed the highest level of gene expression in all four cell lines. In 293T, HeLa and NIH3T3 cell lines, poly(CBA-DAH) had a comparable luciferase gene expression level to bPEI 25 kDa, at varying N/P ratios from 5:1 to 80:1. Interestingly, poly(CBA-DAH) expressed up to 7-fold higher gene transfection efficiency than bPEI in the C2C12 cell line at all N/P ratios, which was statistically different. The other two polymers showed overall lower luciferase expression than poly(CBA-DAH), while poly(CBA-DAB) was N/P ratio dependent for gene expression in these four cell lines, suggesting that optimal N/P ratios for gene transfection are different for these three polymers. Until now, many biodegradable polymers containing disulfide bonds have been reported to reduce cytotoxicity; however, most of them have less or only comparable transfection efficiency compared to bPEI 25 kDa (*22, 23, 34, 36, 37*). These results of high transfection efficiency of poly(disulfide amine)s, especially poly(CBA-DAH), support our future studies, since the primary mouse myoblast cell line (C2C12) is generally a cell line which is difficult to transfect with cationic polymers.

It is well-established that polymers containing disulfide bonds have good stability in an oxidative extracellular environment while they are efficiently degraded in reducing intracellular environment. Previous studies indicated that the better dissociation of plasmid DNA from polymers with disulfide bonds will facilitate gene expression (*30, 38, 39*). This characteristic gives our poly(disulfide amine)s a good ability to unpack DNA in the cells and improve transfection efficiency. Additionally, the primary amines are introduced into side chains of poly(disulfide amine)s, which can not only improve water solubility but is also expected to enhance stable complexation of plasmid DNA to mediate highly efficient gene delivery (*31, 40*).

For the three poly(disulfide amine)s, the transfection efficiency sequence is poly(CBA-DAH) > poly(CBA-DAB) > poly(CBA-DAE). The main difference among the three polymers is their side chain lengths. Poly(CBA-DAH) has the longest alkyl side chain and may be more flexible and more hydrophobic than the other two polymers. It was observed previously that the polymers containing more hydrophobic side chains had higher transfection efficiency (*22*), which suggested that the side chains would influence gene delivery (*20, 22, 31*). While the exact mechanisms to explain and the precise methods to measure how side chain structures of polymers affect transfection are unknown, the more flexible and hydrophobic characteristics may assist pDNA complexation or some other unknown transfection steps (*20*). Some hypothesis indicated that the polymers with longer alkyl chains are more flexible and hydrophobic than stiffer polymers, which may contribute to more stable binding of nucleic acids (*31, 41*). It is suggested that these more stable polyplexes will be distracted less by specific negatively charged cell surface proteins (proteoglycans), and therefore these polyplexes will remain intact during cellular endocytosis and consequently induce higher transfection efficiency (*40, 42*).

In vitro cytotoxicity of poly(disulfide amine)s was evaluated by a standard MTT assay on NIH3T3 cells (Figure 5). The experiments were performed in the same manner as the transfection experiments described above, except that the MTT assay was performed at 24 h instead of 48 h post-transfection. As expected, poly(disulfide amine)s showed much lower cytotoxicity than bPEI 25 kDa. The overall profile in Figure 5 showed that bPEI 25 kDa has increasing cytotoxicity with increasing N/P ratios, while cell viability decreased to 7.7% at an N/P ratio of 80:1. In contrast, poly(disulfide amine)s showed no significant toxicity for cells even at an N/P ratio of 80:1, retaining 90% or higher cell viability relative to control cells (nontreated NIH3T3 cells). The results are consistent with the other three cell lines: 293T, HeLa, and C2C12. Reduced cytotoxicity is apparently a significant benefit of poly(disulfide

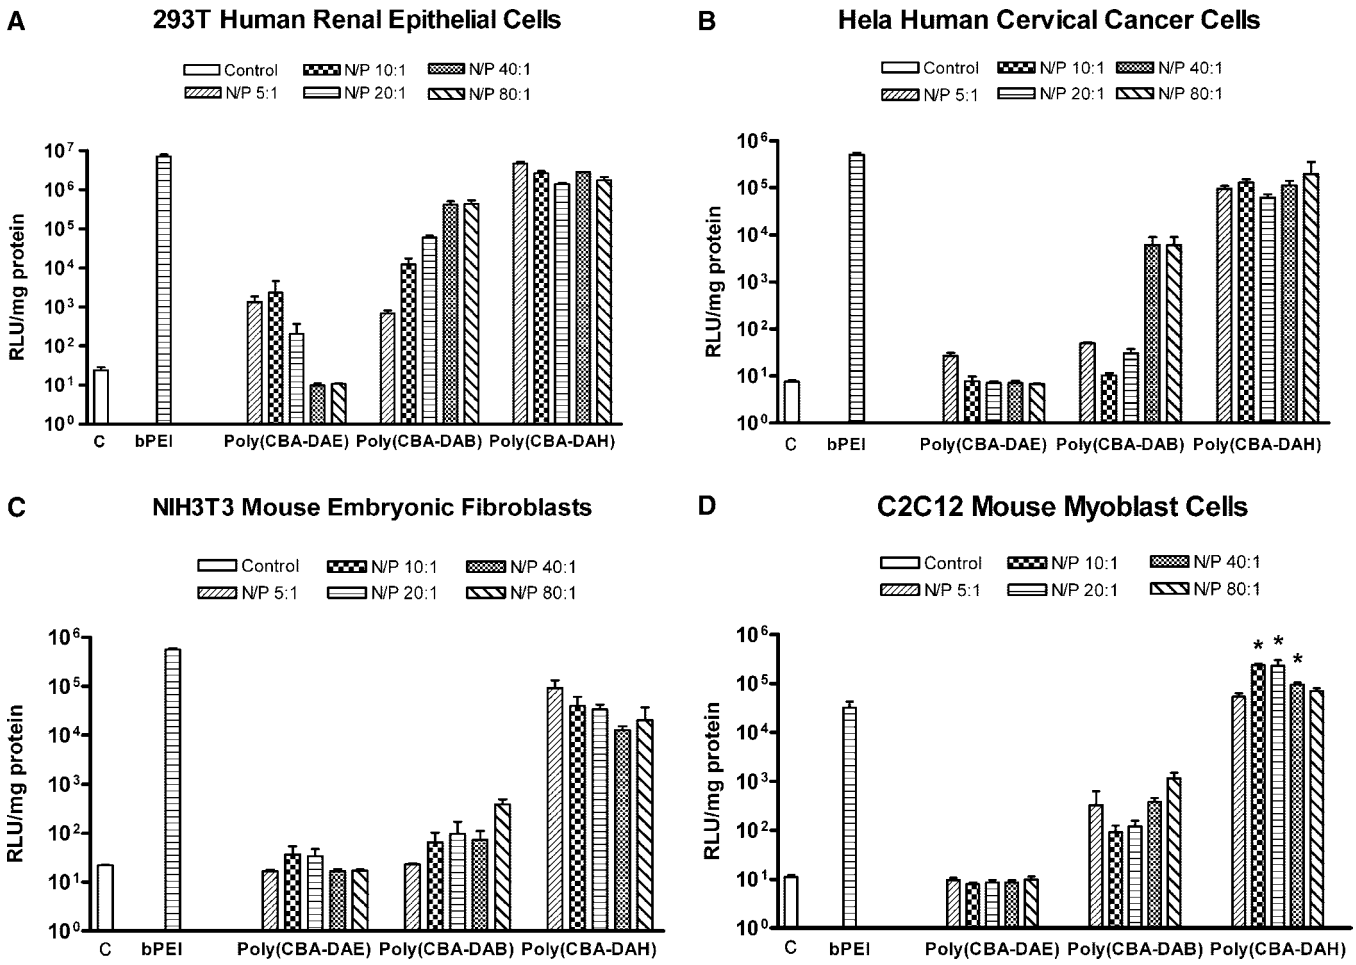

Figure 4. Transfection efficiency of poly(disulfide amine)/pDNA polyplexes in four different cell lines at varying nitrogen/phosphate (N/P) ratios (0.5 μg pDNA/well). Negative control (C): nontreated cells group. Positive control: a bPEI 25 kDa group at N/P ratio of 20:1. The N/P ratios of poly(disulfide amine)/pDNA complexes were 5:1, 10:1, 20:1, 40:1, and 80:1, respectively. Transfection results are expressed in triplicate as the relative luminescent unit (RLU) of luciferase reporter gene expression normalized by the total cell protein content in each well as mean values ± standard deviations. (A) 293T cells: human renal epithelial cell line. (B) HeLa cells: human cervical cancer cell line. (C) NIH3T3: mouse embryonic fibroblasts cell line. (D) C2C12 cells: mouse myoblast cell line.

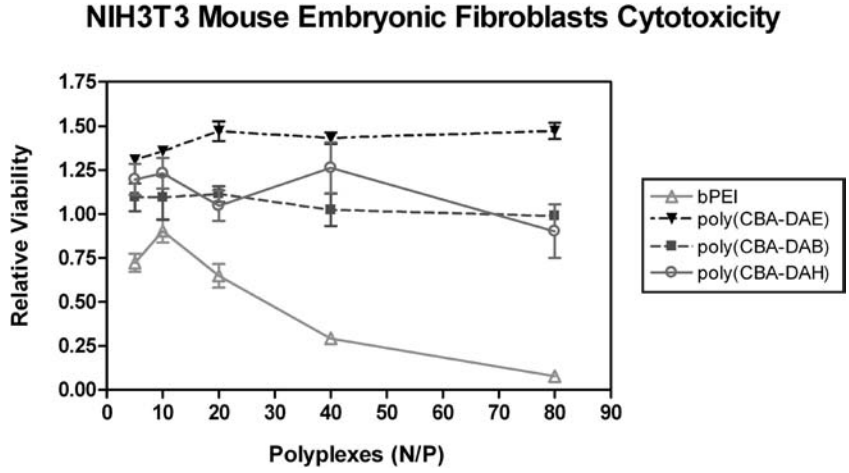

Figure 5. Relative cell viabilities of poly(disulfide amine)s/pDNA polyplexes in NIH3T3 cells at varying nitrogen/phosphate (N/P) ratios compared to a nontreated control group and a bPEI 25 kDa treated group (0.5 μg pDNA/well): (Δ) bPEI, (▼) poly(CBA-DAE), (■) poly(CBA-DAB), and (○) poly(CBA-DAH). Cytotoxicity was determined by MTT assay and represented triplicate as mean values ± standard deviations.

amine)s, though only poly(CBA-DAH) showed superior transfection efficiency compared to bPEI 25 kDa. It suggested that the reduced toxicity is related to polymer degradation. bPEI 25 kDa would accumulate intracellularly, leading to undesirable toxicity. Introducing disulfide bonds into polymers would alleviate these concerns, because they will be degraded to nontoxic, small molecules through cleavage of disulfide bonds. Therefore, DNA would be released to mediate efficient gene transfection, and those low molecular weight fragments of polymers will be cleared easily from the body (*30*). Our transfection and cytotoxicity results of poly(disulfide amine)s accomplish the previous studies.

In summary, these novel poly(disulfide amine)s, especially poly(CBA-DAH), have high gene transfection efficiency and low cytotoxicity and great potential for gene delivery *in vitro*. From the above data, poly(CBA-DAH) has a significantly high gene transfection in primary mouse myoblast cell line (C2C12). This novel poly(disulfide amine) is a promising gene carrier in many other primary cells and stem cells. We have shown that poly(CBA-DAH) has high gene transfection efficiency on SVR cells (mouse pancreatic islet endothelial cells). Besides delivery plasmid DNA, poly(disulfide amine)s can be used as gene carriers to deliver other types of genetic material into human cells, such as antisense oligonucleotides, therapeutic genes, and small interfering RNA (siRNA). Furthermore, poly(disulfide amine)s can be modified with targeting moieties to specifically delivery genetic materials into certain cell types.

CONCLUSION

In this work, we have synthesized and investigated three novel linear and structurally defined poly(disulfide amine)s: poly(CBA-DAE), poly(CBA-DAB), and poly(CBA-DAH). Those poly(disulfide amine)s are readily biodegraded in a reducing environment, releasing DNA rapidly due to the cleavage of disulfide bonds. They also have superior buffering capacity and nucleic acid binding ability based on acid–base titration and gel electrophoresis assay. In addition, all poly(disulfide amine)s showed much lower cytotoxicity than bPEI 25 kDa in NIH3T3 cells. The gene transfection efficiency of these polymers is side-chain spacer length dependent. Among the three polymeric carriers, poly(CBA-DAH), which contains a hexaethylene spacer, has the highest transfection efficiency in 293T cells, HeLa cells, NIH3T3 cells, and C2C12 cells. Specifically, it has a higher transfection efficiency than bPEI 25 kDa in C2C12 cells, a mouse primary myoblast cell line that is otherwise difficult to transfect. These poly(disulfide amine)s, especially poly(CBA-DAH), are promising for delivery of other genetic materials, such as therapeutic genes and siRNA. They also have potential in stem cell gene delivery. We are going to establish *in vivo* models using these poly(disulfide amine)s to further study their potential as gene carriers for gene delivery.

^{99m}Tc-Labeling of HYNIC-Conjugated Cyclic RGDfK Dimer and Tetramer Using EDDA as Coligand

Jianjun Wang, Young-Seung Kim, and Shuang Liu*

School of Health Sciences, Purdue University. Received November 15, 2007; Revised Manuscript Received January 1, 2008

In this study, EDDA (ethylenediamine-*N*,*N*′-diacetic acid) was used as the coligand for ^{99m}Tc-labeling of cyclic RGDfK conjugates: HYNIC−dimer (HYNIC = 6-hydrazinonicotinamide; dimer = E[c(RGDfK)]$_2$) and HYNIC−tetramer (tetramer = E{E[c(RGDfK)]$_2$}$_2$). First, HYNIC−dimer was allowed to react with $^{99m}TcO_4^-$ in the presence of excess tricine and stannous chloride to form the intermediate complex [^{99m}Tc(HYNIC−dimer)-(tricine)$_2$], which was then allowed to react with EDDA to afford [^{99m}Tc(HYNIC−dimer)(EDDA)] with high yield (>90%) and high specific activity (~8.0 Ci/μmol). Under the same radiolabeling conditions, the yield for [^{99m}Tc(HYNIC−tetramer)(EDDA)] was always <65%. The results from a mixed-ligand experiment show that there is only one EDDA bonding to the ^{99m}Tc-HYNIC core in [^{99m}Tc(HYNIC−dimer)(EDDA)]. The athymic nude mice bearing subcutaneous U87MG human glioma xenografts were used to evaluate the impact of EDDA coligand on the biodistribution characteristics and excretion kinetics of the ^{99m}Tc-labeled HYNIC−dimer and HYNIC−tetramer. Surprisingly, [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−tetramer)(EDDA)] had almost identical tumor uptake over the 2 h period. The use of EDDA as coligand to replace tricine/TPPTS (TPPTS = trisodium triphenylphosphine-3,3′,3″-trisulfonate) did not significantly change the uptake of the ^{99m}Tc-labeled HYNIC-dimer in noncancerous organs, such as the liver, kidneys, and lungs; but it did result in a significantly lower kidney uptake for the ^{99m}Tc-labeled HYNIC−tetramer due to faster renal excretion. It was also found that the radiotracer tumor uptake decreases in a linear fashion as the tumor size increases. The smaller the tumors are, the higher the tumor uptake is regardless of the identity of radiotracer.

INTRODUCTION

Radiolabeled RGD peptides represent a new class of radiotracers with the potential for both early tumor detection and monitoring of tumor metastasis and therapeutic response in cancer patients. In the past several years, many radiolabeled RGD peptides have been evaluated as the integrin $\alpha_v\beta_3$-targeted radiotracers for tumor imaging by SPECT or PET in preclinical animal models and human clinical trials (*1–14*). They have been reviewed extensively (*15–21*). Among several promising radiotracers, [^{18}F]Galacto-RGD has become the first PET radiotracer for noninvasive imaging of integrin $\alpha_v\beta_3$-positive tumors in cancer patients (*22–24*). The results from imaging studies in metastatic melanoma patients clearly show that there is a sufficient integrin $\alpha_v\beta_3$ expression for PET imaging. Although radiotracers based on the cyclic RGD monomer are able to target tumors by binding to the integrin $\alpha_v\beta_3$ expressed on tumor cells and endothelial cells of tumor neovasculature, their tumor uptake is relatively low, which may limit their application as tumor imaging agents in clinics.

We have been using multivalent cyclic RGD peptides, such as E[c(RGDfK)]$_2$ (dimer) and E{E[c(RGDfK)]$_2$}$_2$ (tetramer), for development of integrin $\alpha_v\beta_3$-targeted radiotracers (*25–35*). These multimeric cyclic RGD peptides are used as such that the radiotracer tumor uptake can be improved due to their higher integrin $\alpha_v\beta_3$ binding affinity. Recently, we reported the ^{111}In- and ^{64}Cu-labeled cyclic RGDfK tetramer as SPECT and PET radiotracers, respectively (*28, 32*). It was also found that both ^{111}In(DOTA−tetramer) (DOTA = 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid; tetramer = E{E[c(RGDfK)]$_2$}$_2$) and ^{64}Cu(DOTA−tetramer) have a significantly higher tumor uptake due to their higher integrin $\alpha_v\beta_3$ binding affinity than their dimeric analogues (*28, 32*). Similar results were obtained for the ^{99m}Tc-labeled HYNIC−tetramer (HYNIC = 6-hydrazinonicotinamide) using tricine/TPPTS (trisodium triphenylphosphine-3,3′,3″-trisulfonate) as coligands (*27, 31*). However, the kidney uptake of the ternary ligand complex [^{99m}Tc(HYNIC−tetramer)(tricine)(TPPTS)] was very high (>25% ID/g) over the 2 h study period, probably due to the negative charges on the TPPTS coligand (*31*).

EDDA (EDDA = ethylenediamine-*N*,*N*′-diacetic acid) has been used for ^{99m}Tc-labeling of the HYNIC-conjugated somatostatin analogues (*36–38*) and RGD peptide (*39*). It was found that [^{99m}Tc(HYNIC−RGD)(EDDA)] had a high tumor uptake, along with the rapid renal excretion, and low uptake in the liver and muscle. The tumor uptake studies also showed specific targeting of integrin $\alpha_v\beta_3$ in the mice bearing small cell lung tumors. All tumors could be readily visualized by scintigraphic imaging. It was claimed that [^{99m}Tc(HYNIC−RGD)(EDDA)] had tumor/organ ratios comparable to those of [^{18}F]Galato-RGD (*39*). These promising results lead us to explore the use of EDDA as the coligand for ^{99m}Tc-labeling of the HYNIC−dimer and HYNIC−tetramer conjugates. The main objective is to demonstrate whether EDDA is useful for minimizing the kidney uptake of ^{99m}Tc-labeled cyclic RGD dimer and tetramer.

In this study, we used EDDA as coligand for ^{99m}Tc-labeling of both HYNIC−dimer and HYNIC−tetramer. A mixed-ligand experiment was used to determine the number of EDDA ligands bonding to the ^{99m}Tc-HYNIC core. The athymic nude mice bearing U87MG human glioma xenografts were used to evaluate the impact of EDDA coligand on biodistribution properties of the ^{99m}Tc-labeled HYNIC−dimer and HYNIC−tetramer. In addition, we also examined the relationship between the size and tumor uptake of [^{99m}Tc(HYNIC−dimer)(EDDA)], [^{99m}Tc

(HYNIC−tetramer)(EDDA)], and [^{99m}Tc(HYNIC−tetramer)(tricine)(TPPTS)].

EXPERIMENTAL SECION

Materials. Ethylenediamine-*N*,*N*′-diacetic acid (EDDA) and tricine were purchased from Sigma/Aldrich (St. Louis, Missouri). Pentapeptide c(RGDfK) was purchased from Peptides International, Inc. (Louisville, Kentucky). HYNIC−E-[c(RGDfK)]$_2$ (HYNIC−dimer), HYNIC−E{E[c(RGDfK)]$_2$}$_2$ (HYNIC−tetramer), and [^{99m}Tc(HYNIC−tetramer)(tricine)-(TPPTS)] were prepared according to the literature procedures (*29*,*31*). *N*,*N*′-Bis(benzyl)ethylenediamine-*N*,*N*′-diacetic acid (Bn_2EDDA) was prepared according to the literature method (*40*). $Na^{99m}TcO_4$ was obtained from a commercial DuPont Pharma ^{99}Mo/^{99m}Tc generator (N. Billerica, MA).

Instruments and Methods. The radio-HPLC method (method 1) used the LabAlliance HPLC system equipped with a β-ram IN-US detector and Zorbax C_{18} column (4.6 mm × 250 mm, 300 Å pore size). The flow rate was 1 mL/min. The mobile phase was isocratic with 90% solvent A (25 mM NH_4OAc buffer, pH = 5.0) and 10% solvent B (acetonitrile) at 0–2 min, followed by a gradient mobile phase going from 10% solvent B at 2 min to 15% solvent B at 5 min and to 20% solvent B at 20 min. Method 2 was almost identical to method 1 except that the gradient mobile phase was used from 20% solvent B at 5 min and to 40% solvent B at 20 min.

Synthesis of [^{99m}Tc(HYNIC−dimer)(EDDA)]. To a 5 cc vial containing tricine (20 mg in 1 mL of succinate buffer (pH = 5) was added 0.2 mL of HYNIC−dimer solution (100 μg/mL), 0.3 mL of $^{99m}TcO_4^-$ solution in saline, and 25 μL $SnCl_2$ solution (1 mg/mL) in 1 N HCl. The vial containing the reaction mixture was heated at 100 °C for 20 min. A sample of the resulting solution was analyzed by HPLC (method 1). To the vial above was added 0.5 mL of EDDA solution (10 mg/mL, pH ∼ 7.4). The resulting mixture was heated at 100 °C for 20 min. After cooling to room temperature, a sample from the solution was analyzed by HPLC (method 1). The radiochemical purity (RCP) was >95%. The HPLC retention time was 13.2 min.

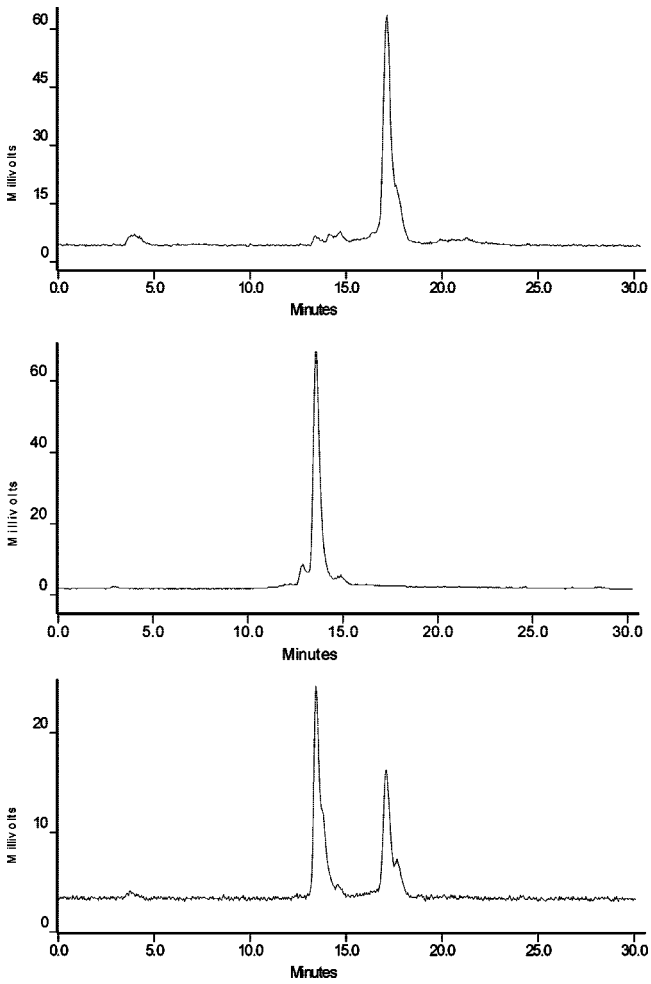

Figure 3. Radio-HPLC chromatograms (method 1) of [^{99m}Tc-(HYNIC−dimer)(Bz$_2$EDDA)] (top), [^{99m}Tc(HYNIC−dimer)-(EDDA)] (middle), and the reaction solution (bottom) containing [^{99m}Tc(HYNIC−dimer)(Bz$_2$EDDA)] and [^{99m}Tc(HYNIC−dimer)-(EDDA)]. The presence of only two sets of peaks at 13.5 and 17.0 min from [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−dimer)(Bn$_2$EDDA)], respectively, clearly demonstrated that there is only one EDDA bonded to the ^{99m}Tc-HYNIC core.

Table 1. Stability Data for [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−tetramer)(EDDA)] in the Presence of Cysteine and Histidine (1 mg/mL in 25 mM phosphate buffer, pH = 7.5)

time post purification	RCP (%) in histidine solution (1 mg/mL, pH = 7.4)		RCP (%) in cysteine solution (1 mg/mL, pH = 7.4)	
	dimer	tetramer	dimer	tetramer
0.5 h	100	99	100	99
1.0 h	100	99	100	99
2.0 h	99	98	98	98
4.0 h	97	98	98	96
6.0 h	95	97	95	96

Synthesis of [^{99m}Tc(HYNIC−dimer)(Bn$_2$EDDA)]. To a clean 5 cc vial containing tricine (20 mg in 1 mL succinate buffer, pH = 5) was added 0.2 mL of HYNIC−dimer solution (100 μg/mL), 0.3 mL of $^{99m}TcO_4^-$ solution in saline, and 25 μL $SnCl_2$ solution (1 mg/mL) in 1 N HCl. The vial containing the reaction mixture was heated at 100 °C for 20 min. To the vial was added 0.5 mL of Bn$_2$EDDA solution (10 mg/mL, pH ~ 7.4). The vial was heated at 100 °C for another 20 min. After cooling to room temperature, a sample from the solution was analyzed by radio-HPLC (method 1). The RCP was >95%. The HPLC retention time was 17.2 min.

Synthesis of [^{99m}Tc(HYNIC−tetramer)(EDDA)]. To a 5 cc vial containing tricine (20 mg in 1 mL succinate buffer, pH = 5) was added 0.2 mL of HYNIC−tetramer solution (100 μg/mL), 0.3 mL of $^{99m}TcO_4^-$ solution, and 25 μL $SnCl_2$ solution (1 mg/mL) in 1 N HCl. The vial containing the reaction mixture was heated at 100 °C for 20 min. To the vial above was added 0.5 mL of EDDA solution (10 mg/mL, pH ~ 7.4). The resulting mixture was heated at 100 °C for 20 min. After cooling to room temperature, a sample from the solution was analyzed by radio-HPLC (method 2). The RCP was ~65%. The HPLC retention time was 15.2 min.

Doses Preparation and Solution Stability. [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−tetramer)(EDDA)] were prepared. Doses were prepared by dissolving the purified radiotracer in saline to give a concentration of 20 μCi/mL for biodistribution studies and 1.0 mCi/mL for metabolism studies. Each animal was injected with 0.1 mL of the dose solution. For cysteine and histidine challenging experiments, the radiotracer was purified by HPLC. Volatiles in mobile phases were removed under vacuum. The residue was dissolved in the cysteine or histidine solution (1 mg/mL, pH = 7.4). Samples of the resulting solution were analyzed by radio-HPLC (method 1 for [^{99m}Tc(HYNIC−dimer)(EDDA)] and method 2 for [^{99m}Tc-(HYNIC−tetramer)(EDDA)]) at 0, 2, 4, and 6 h.

Determination of Log *P* Values. Log *P* values were determined using the following procedure: The radiotracer was purified by HPLC. Volatiles were removed completely under vacuum. The residue was dissolved in a equal volume (3 mL/3 mL) mixture of *n*-octanol and 25 mM phosphate buffer (pH = 7.4). After stirring vigorously for ~20 min, the mixture was centrifuged at a speed of 8000 rpm for 5 min. Samples (in triplets) from both *n*-octanol and aqueous layers were counted in a gamma counter (Perkin-Elmer Wizard - 1480). The log *P* value was measured three different times and reported as an average of three different measurements plus the standard deviation. The log *P* values were −3.59 ± 0.11 and −3.26 ± 0.08 for [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−tetramer)(EDDA)], respectively.

Mixed-Ligand Experiment. To a clean 5 cc vial containing tricine (20 mg in 1 mL of succinate buffer, pH = 5) was added 0.2 mL of HYNIC−dimer solution (100 μg/mL), 0.3 mL of $^{99m}TcO_4^-$ solution in saline, and 25 μL $SnCl_2$ solution (1 mg/mL) in 1 N HCl. The reaction mixture was heated at 100 °C for 20 min. To the mixture above was added 0.5 mL of the solution containing EDDA (10 mg/mL, pH ~7.4) and Bn$_2$EDDA (10 mg/mL, pH ~7.4). The resulting mixture was heated at 100 °C for another 20 min. After cooling to room temperature, a sample of the resulting solution was analyzed by the radio-HPLC (method 1).

Animal Model. Biodistribution studies were performed according to the literature procedures (*30*). These studies were carried out using the athymic nude mice bearing U87MG human glioma xenografts in compliance with NIH animal experiment guidelines (*Principles of Laboratory Animal Care*, NIH Publication No. 86–23, revised 1985). The animal protocol for the animal studies has been approved by the Purdue University Animal Care and Use Committee (PACUC). U87MG human glioma cells were grown at 37 °C in Minimal Essential Medium (Alpha Modification) containing 3.7 g of sodium bicarbonate/L, 10% fetal bovine serum v/v, in a humidified atmosphere of 5% carbon dioxide. Female athymic nu/nu mice were purchased from Harlan (Indianapolis, IN) at 4–5 weeks of age. Each mouse was orthotopically implanted with 5×10^6 U87MG human glioma cells into the mammary fat pad. Four to five weeks after inoculation, animals with tumors in the range 0.1–1.5 g were used for biodistribution studies.

Biodistribution Protocol. 20 tumor-bearing mice (20–25 g) were anesthetized with intraperitoneal injection of a mixture containing Ketamine (40–100 mg/kg) and Xylazine (2–5 mg/kg). Once the animal was in the surgical plane of anesthesia, as noted by the lack of pain response, the radiotracer (∼2 μCi) dissolved in 0.1 mL saline was administered via tail vein. Five animals were sacrificed by sodium pentobarbital overdose (100 mg/kg) at 5, 30, 60, and 120 min postinjection (p.i.). Blood samples were withdrawn from the heart through a syringe. Organs (tumor, brain, eyes, spleen, lungs, liver, kidneys, muscle, and intestine) were excised, washed with saline, weighed, and counted on a gamma counter. The organ uptake was calculated as a percentage of the injected dose per organ (% ID/organ) and a percentage of the injected dose per gram of organ tissue (% ID/g). The biodistribution data and target-to-background (T/B) ratios are reported as an average plus the standard variation. Comparison between two different radiotracers was also made using the one-way ANOVA test (*GraphPad Prism 5.0*, San Diego, CA). The level of significance was set at $p < 0.05$.

Metabolism. Two normal mice were used for metabolism studies. Each mouse was administered the radiotracer at a dose of 100 μCi/mouse. The urine samples were collected at 30 min and 2 h p.i. by manual void, and were mixed with equal volume of acetonitrile. The mixture was centrifuged at 8000 rpm. The supernatant was collected and filtered through a 0.20 μm Millex-LG syringe driven filter unit. The filtrate was analyzed by radio-HPLC (method 1 for [^{99m}Tc(HYNIC−dimer)(EDDA)] and method 2 for [^{99m}Tc(HYNIC−tetramer)(EDDA)]). The feces samples were collected at ∼120 min p.i. The sample was suspended in a mixture of 50% acetonitrile aqueous solution, and the resulting mixture was vortexed for 5–10 min. After centrifuging, the supernatant was collected and passed through a 0.20 μm Millex-LG syringe driven filter unit. The filtrate was analyzed by radio-HPLC.

RESULTS

Radiochemistry. [^{99m}Tc(HYNIC−dimer)(EDDA)]and[^{99m}Tc-(HYNIC−tetramer)(EDDA)] (Figure 1) were prepared in two steps. HYNIC−dimer was first allowed to react with $^{99m}TcO_4^-$ in the presence of excess tricine and stannous chloride to form the [^{99m}Tc(HYNIC−dimer)(tricine)$_2$] intermediate, which was then reacted with EDDA to form [^{99m}Tc(HYNIC−dimer)-(EDDA)]. [^{99m}Tc(HYNIC−tetramer)(EDDA)] was prepared in the same fashion using HYNIC−tetramer. Attempts to prepared [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−tetramer)-(EDDA)] in one step by directly reacting the HYNIC−dimer or HYNIC−tetramer with $^{99m}TcO_4^-$ in the presence of EDDA and stannous chloride were not successful due to their low yield (<50%).

Figure 2 shows representative HPLC chromatograms of [^{99m}Tc-(HYNIC−dimer)(tricine)$_2$] (top) and [^{99m}Tc(HYNIC−dimer)-(EDDA)] (bottom). The key to achieving high RCP for [^{99m}Tc-(HYNIC−dimer)(EDDA)] was the high-yield formation of the intermediate complex [^{99m}Tc(HYNIC−dimer)(tricine)$_2$]. Successful ligand exchange was evidenced by disappearance of multiple peaks at ∼14 min from [^{99m}Tc(HYNIC−dimer)(tricine)$_2$] (Figure 2: top) and formation of a single peak at 13 min (Figure 2: bottom). Small peaks at ∼3 min (Figure 2: bottom) were formed during ligand exchange process due to the instability of [^{99m}Tc(HYNIC−dimer)(tricine)$_2$]. The radiolabeling yield was >90% using 20 μg of HYNIC−dimer (∼1.2 × 10^{-8} mol) and 20 mCi of $^{99m}TcO_4^-$ (∼1.5 × 10^{-10} mol of ^{99m}Tc/^{99}Tc for 24 h generator). The specific activity was ∼8.0 Ci/μmol for [^{99m}Tc(HYNIC−dimer)(EDDA)]. In contrast, the radiolabeling yield was always <65% for [^{99m}Tc(HYNIC−tetramer)(EDDA)] even though the [^{99m}Tc(HYNIC−tetramer)(tricine)$_2$] intermediate was prepared in 95% yield. The log P values were determined to be −3.59 ± 0.11 and −3.26 ± 0.08 for [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−tetramer)(EDDA)], respectively.

In order to determine the number of EDDA in [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−tetramer)(EDDA)], a mixed-ligand experiment was carried out using EDDA and Bn_2EDDA as the competing ligands to react with [^{99m}Tc(HYNIC−dimer)-(tricine)$_2$]. If there is only one EDDA in [^{99m}Tc(HYNIC−dimer)(EDDA)], the radio-HPLC chromatogram of the resulting reaction mixture is expected to show two sets of radiometric peaks: one set from [^{99m}Tc(HYNIC−dimer)(EDDA)] and the other from [^{99m}Tc(HYNIC−dimer)(Bn_2EDDA)]. If there were two EDDA ligands bonding to the ^{99m}Tc-HYNIC core, a third

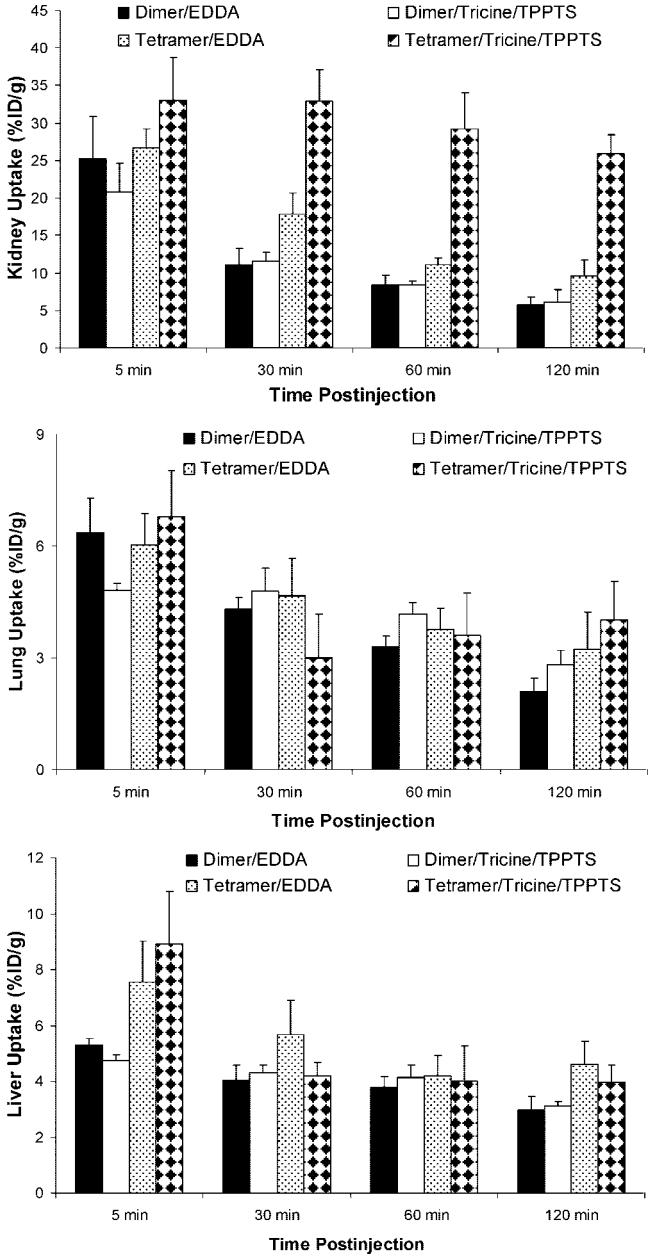

Figure 4. Direct comparison of the organ uptake between [^{99m}Tc(HYNIC−dimer)(EDDA)][^{99m}Tc(HYNIC−dimer)(tricine)(TPPTS)][^{99m}Tc(HYNIC−tetramer)(EDDA)], and [^{99m}Tc(HYNIC−tetramer)(tricine)(TPPTS)] in kidneys, liver, and lungs.

set of peaks from the mixed-ligand complex [^{99m}Tc(HYNIC−dimer)(EDDA)(Bn_2EDDA)] would have been expected. The presence of only two sets of radiometric peaks from [^{99m}Tc-(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−dimer)(Bn_2-EDDA)] in the chromatogram (Figure 3) clearly shows that there is only one EDDA bonded to the ^{99m}Tc-HYNIC core in [^{99m}Tc-(HYNIC−dimer)(EDDA)].

It is important to emphasize that EDDA is tetradentate, and an additional monodentate ligand, such as Cl^-, is required to complete the octahedral Tc coordination sphere. This will result in formation of isomers for [^{99m}Tc(HYNIC−dimer)(EDDA)] when EDDA bonds to Tc. Thus, it is not surprising that [^{99m}Tc-(HYNIC−dimer)(EDDA)] shows 2–3 small satellite peaks in the 12–15 min region of its HPLC chromatogram (Figure 3). Similar results have been reported for a ^{99m}Tc-labeled monomeric cyclic RGD peptide (*40*).

Solution Stability. Their solution stability was studied using the cysteine and histidine challenge experiments. Table 1 summarizes the solution stability data for the HPLC purified [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−tetramer)-(EDDA)] and 6 h in the presence of excess histidine or cysteine (1 mg/mL, pH = 7.4). Obviously, [^{99m}Tc(HYNIC−dimer)-(EDDA)] and [^{99m}Tc(HYNIC−tetramer)(EDDA)] remained stable for >6 h, suggesting that they are intact before being injected into animals.

Biodistribution Characteristics. The athymic nude mice bearing U87MG glioma xenografts were used to study biodistribution properties of [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−tetramer)(EDDA)]. Both [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−tetramer)(EDDA)] were prepared, and purified by HPLC to remove excess "unlabeled" HYNIC conjugate that may compete with the radiotracer in binding to the integrin $\alpha_v\beta_3$ expressed on tumor cells and in normal tissues. Biodistribution data for [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−tetramer)(EDDA)] are summarized in Tables 2 and 3, respectively.

In general, [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc-(HYNIC−tetramer)(EDDA)] have a rapid blood clearance. Their tumor uptake was comparable within the experimental error over the 2 h study period. Their lung uptake also compared favorably during the same study period. The liver uptake of [^{99m}Tc-(HYNIC−dimer)(EDDA)] was 5.29 ± 0.29% ID/g and 2.98 ± 0.48% ID/g at 5 and 120 min p.i., respectively, and was significantly lower ($p < 0.01$) than that of [^{99m}Tc(HYNIC−tetramer)(EDDA)] (7.56 ± 1.48% ID/g and 4.60 ± 0.82% ID/g at 5 and 120 min p.i., respectively). The initial kidney uptake of [^{99m}Tc(HYNIC−dimer)(EDDA)] (25.25 ± 5.64% ID/g at 5 min p.i.) was almost identical to that of [^{99m}Tc(HYNIC−tetramer)(EDDA)] (26.69 ± 2.48% ID/g at 5 min p.i.); but this similarity disappeared at >30 min p.i. The kidney uptake of [^{99m}Tc(HYNIC−dimer)(EDDA)] was 11.70 ± 2.25% ID/g and 5.97 ± 0.94% ID/g at 30 and 120 min p.i., respectively, while the kidney uptake of [^{99m}Tc(HYNIC−tetramer)(EDDA)] was 17.84 ± 2.82% ID/g at 5 min p.i. and 9.54 ± 2.23% ID/g at 120 min p.i. The muscle uptake of [^{99m}Tc(HYNIC−dimer)-(EDDA)] (3.85 ± 0.60% ID/g and 2.02 ± 0.23% ID/g at 5 and 120 min p.i., respectively) was significantly higher than that of [^{99m}Tc(HYNIC−tetramer)(EDDA)] (2.11 ± 0.37% ID/g and 0.92 ± 0.26% ID/g at 5 and 120 min p.i., respectively).

Figure 4 compares the organ uptake (% ID/g) of [^{99m}Tc-(HYNIC−dimer)(EDDA)], [^{99m}Tc(HYNIC−dimer)(tricine)-(TPPTS)], [^{99m}Tc(HYNIC−tetramer)(EDDA)], and [^{99m}Tc-(HYNIC−tetramer)(tricine)(TPPTS)] in the liver, kidneys, and lungs. The biodistribution data for [^{99m}Tc(HYNIC−dimer)-(tricine)(TPPTS)] and [^{99m}Tc(HYNIC−tetramer)(tricine)(TPPTS)] were obtained from our previous studies in the same tumor-bearing animal model (*29*, *31*). Replacing tricine/TPPTS with EDDA did not change the uptake of the ^{99m}Tc-labeled HYNIC−dimer in kidneys, liver, or lungs. [^{99m}Tc(HYNIC−tetramer)(EDDA)] also had the liver and lung uptake very similar to that of [^{99m}Tc(HYNIC−tetramer)(tricine)(TPPTS)]; but it had a much lower kidney uptake than [^{99m}Tc(HYNIC−tetramer)(tricine)(TPPTS)] over the 2 h period (Figure 4).

During biodistribution studies, we noticed a large variation in the tumor uptake for both [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−tetramer)(EDDA)], and their tumor uptakes were largely dependent upon the tumor size. Similar behavior was reported for the ^{99m}Tc-labeled cyclic RGDfK monomer (*11*). To further clarify this relationship, we added extra tumor-bearing mice into the 60 and 120 min groups for both radiotracers. We also performed a biodistribution study on [^{99m}Tc-(HYNIC−tetramer)(tricine)(TPPTS)] at 120 min p.i. The biodistribution data at 60 and 120 min were used for all three

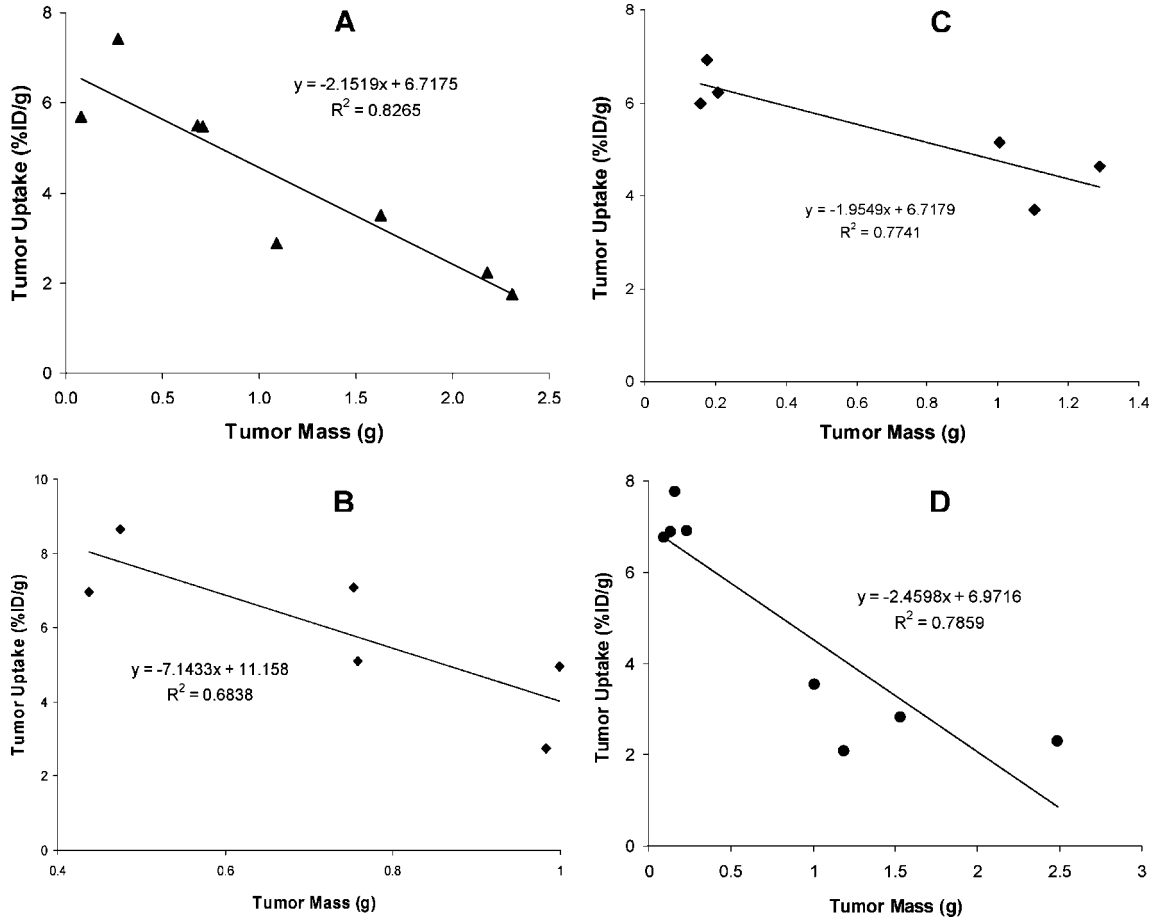

Figure 5. The relationship between the tumor size and tumor uptake (expressed as (% ID/g) for [[99m]Tc(HYNIC−dimer)(EDDA)] at 60 min p.i. (A: $n = 8$) and 120 min p.i. (B: $n = 5$), [[99m]Tc(HYNIC−tetramer)(EDDA)] at 120 min p.i. (C: $n = 6$), and [[99m]Tc(HYNIC−tetramer)(tricine)(TPPTS)] at 120 min p.i. (D: $n = 8$) in the athymic nude mice bearing the U87MG human glioma xenografts.

radiotracers to minimize the interference from their blood activity. Figure 5 shows the inverse linear relationship between the tumor size and tumor uptake (expressed as % ID/g) of [[99m]Tc(HYNIC−dimer)(EDDA)] at 60 min (A) and 120 min (B) p.i., [[99m]Tc(HYNIC−tetramer)(EDDA)] (C), and [[99m]Tc(HYNIC−tetramer)(tricine)(TPPTS)] (D) at 120 min p.i. in the same model. It is clear that the radiotracer tumor uptake (% ID/g) decreases as the tumor size increases. Smaller tumors (<0.5 g) always show higher radiotracer uptake (>5% ID/g) that large tumors (>1.0 g) regardless of the identity of radiotracer.

Metabolic Properties. Normal athymic mice were used to examine metabolic stability of [[99m]Tc(HYNIC−dimer)-(EDDA)] and [[99m]Tc(HYNIC−tetramer)(EDDA)]. Since >85% of [[99m]Tc(HYNIC−dimer)(EDDA)] and [[99m]Tc(HYNIC−tetramer)(EDDA)] was excreted from the renal and hepatobiliary routes by 2 h p.i., we used radio-HPLC to analyze urine and feces samples from the mice administered with the radiotracer (∼100 μCi/mouse). Figure 6 shows radio-HPLC chromatograms of [[99m]Tc(HYNIC−dimer)(EDDA)] (left) and [[99m]Tc(HYNIC−tetramer)(EDDA)] (right) in saline (A), in the urine at 30 min p.i. (B), in the urine at 120 min p.i. (C), and in the feces at 120 min p.i. (D). There were no metabolites detected in the urine at 30 and 120 min p.i. for both radiotracers, indicating that they have a high metabolic stability during excretion from the renal system. Only 35% of [[99m]Tc(HYNIC−dimer)-(EDDA)] and 15% of [[99m]Tc(HYNIC−tetramer)(EDDA)] remained intact in the feces samples, suggesting that they underwent significant metabolism during excretion from the hepatobiliary system.

DISCUSSION

Recently, Decristoforo et al. (*39*) reported the [99m]Tc-labeled cyclic RGD monomer, HYNIC-c(RGDyK) (HYNIC-RGD). It was found that HYNIC-RGD could be labeled with [99m]Tc in high specific activity (∼100 GBq/μmol or 2.7 Ci/ μmol) using EDDA as coligand. Despite the fact that [[99m]Tc(HYNIC-RGD)(EDDA)] had a high tumor uptake, along with the rapid renal excretion, and low uptake in the liver and muscle, it is not known about the composition of [99m]Tc radiotracer even though the LC-MS data suggested that there were two EDDA ligands binding to the [99m]Tc-HYNIC core (*41*). In this study, we used EDDA as the coligand to prepare [[99m]Tc(HYNIC−dimer)(EDDA)] and [[99m]Tc(HYNIC−tetramer)(EDDA)]. The specific activity was ∼300 GBq/μmol or 8 Ci/μmol for [[99m]Tc-(HYNIC−dimer)(EDDA)] using the two-step radiolabeling procedure. Both [[99m]Tc(HYNIC−dimer)(EDDA)] and [[99m]Tc-(HYNIC−tetramer)(EDDA)] have very high *in vitro* solution stability (Table 1).

There are several important findings from this study. The results from a mixed-ligand experiment clearly demonstrate that there is only one EDDA bonding to the [99m]Tc-HYNIC core in [[99m]Tc(HYNIC−dimer)(EDDA)] and [[99m]Tc(HYNIC−tetramer)-(EDDA)] (Figure 3). To our surprise, [[99m]Tc(HYNIC−dimer)-(EDDA)] and [[99m]Tc(HYNIC−tetramer)(EDDA)] have almost identical tumor uptake (Tables 2 and 3). There is no advantage of the [99m]Tc-labeled HYNIC−tetramer over its dimeric analogue when EDDA is used as the coligand. This seems to contradict

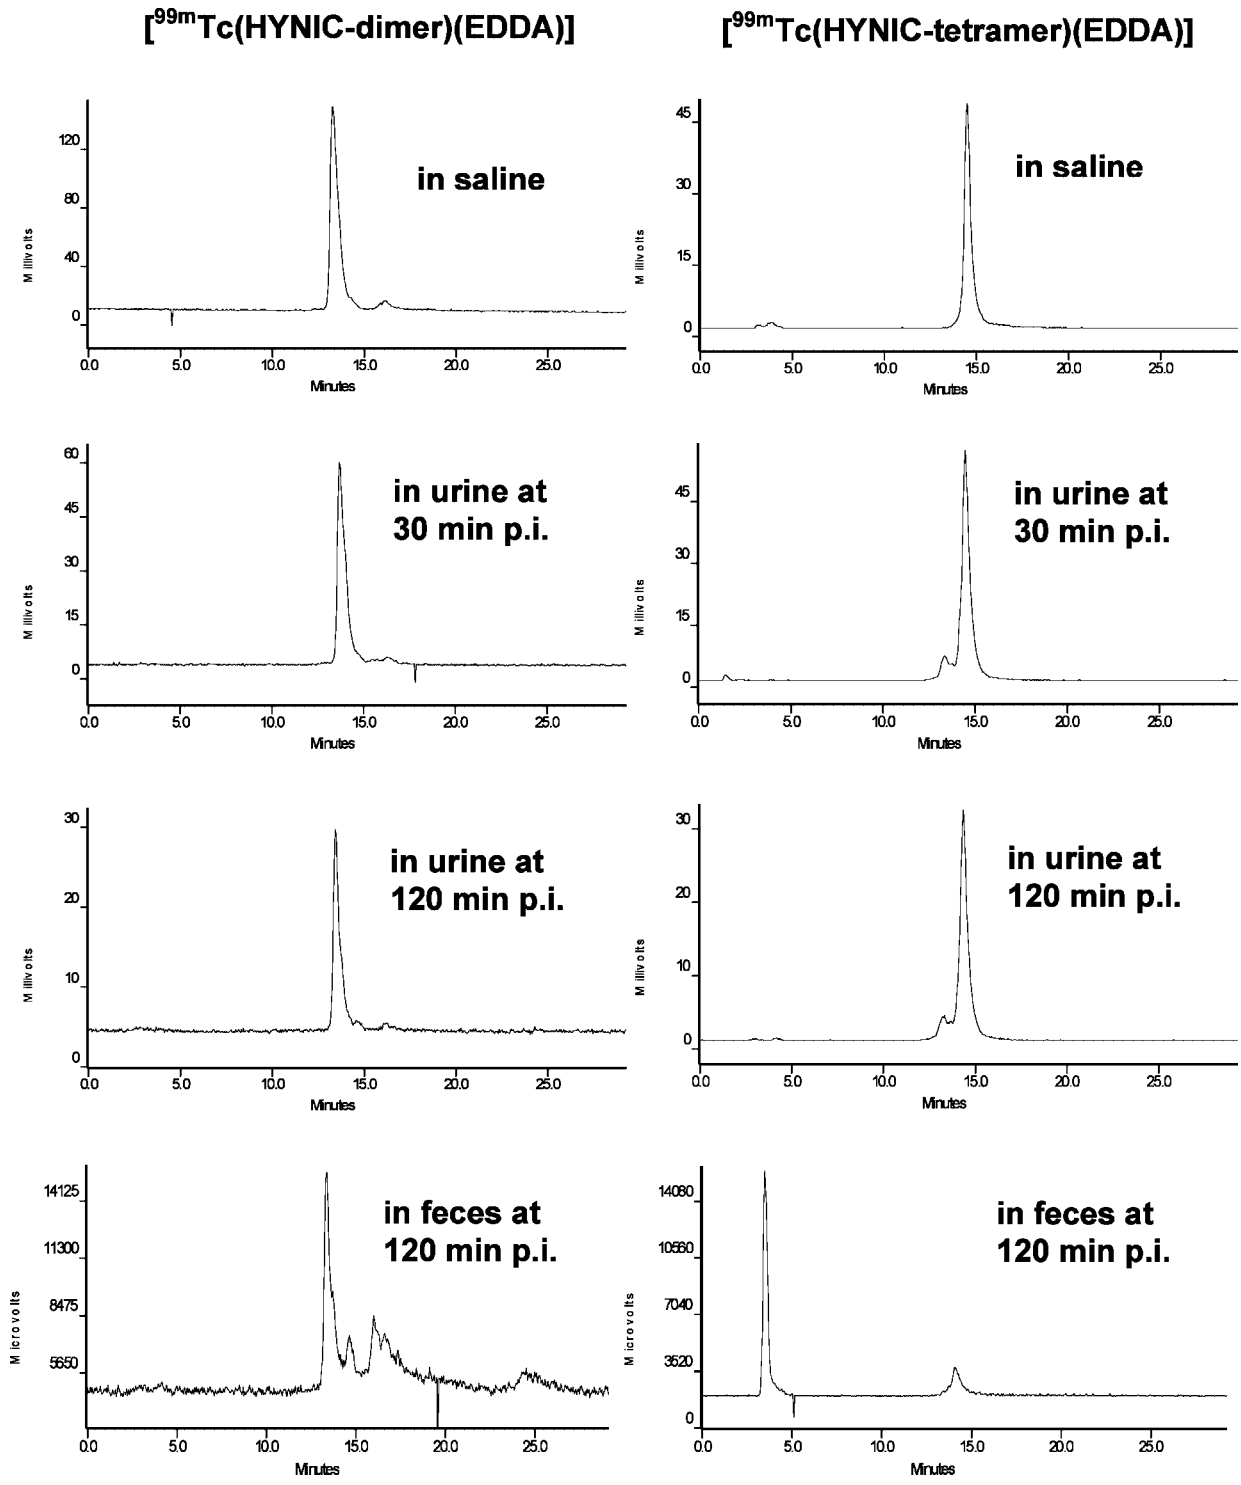

Figure 6. Typical radio-HPLC chromatograms of the HPLC-purified [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−tetramer)(EDDA)] in saline before injection, in urine at 30 min p.i., in urine at 120 min p.i., and in feces at 120 min p.i. Each mouse was administered with ∼ 100 μCi radiotracer. Two normal mice were used for each radiotracer.

the results obtained from ^{111}In(DOTA−tetramer) (*33*), ^{64}Cu(DOTA−tetramer) (*26, 28*), and [^{99m}Tc(HYNIC−tetramer)-(tricine)(TPPTS)] (*29, 31*) over their dimeric analogues. There is no clear explanation for this observation. Replacing tricine/TPPTS with EDDA did not significantly change the uptake of the ^{99m}Tc-labeled HYNIC−dimer in kidneys, liver, and lungs; but it did result in a significantly lower kidney uptake for [^{99m}Tc(HYNIC−tetramer)(EDDA)] due to its faster renal excretion (Figure 4) than [^{99m}Tc(HYNIC−tetramer)(tricine)(TPPTS)]. Apparently, coligands have a significant impact on excretion kinetics of the ^{99m}Tc-labeled HYNIC−tetramer.

It is very important to note that the tumor growth rate varies significantly even though each mouse receives the same number of tumor cells for the same inoculation time. The radiotracer tumor uptake decreases as the tumor size increases in a linear fashion. The smaller the tumors are, the higher the tumor uptake (% ID/g) is regardless of the identity of radiotracer (Figure 5). Since Chen and co-workers have elegantly demonstrated that

the radiotracer tumor uptake is well-correlated with the integrin $\alpha_v\beta_3$ expression levels in tumors (*42*), we believe that the reduced radiotracer uptake (% ID/g) might be related to the integrin $\alpha_v\beta_3$ density.

The radiotracer tumor uptake expressed as %ID reflects the total number of integrin $\alpha_v\beta_3$ receptors expressed on both tumor cells and endothelial cells, while the tumor uptake expressed as %ID reflects the integrin $\alpha_v\beta_3$ density. In small tumors, the microvessel density and the integrin $\alpha_v\beta_3$ density are high. The tumor uptake expressed as % ID/g is high (Figure 5) even though the radiotracer tumor uptake expressed as %ID is low (Supporting Information). As the tumor grows, the total number of integrin $\alpha_v\beta_3$ receptors expressed on tumor cells becomes larger, and the tumor uptake expressed as %ID increases (Supporting Information). In contrast, the microvessel density decreases because of maturity of blood vessels, and the integrin $\alpha_v\beta_3$ density also decreases due to larger interstitial space and higher collagen concentrations (*43*). In addition, part of the tumor tissue may also become necrotic, which may also lead to lower the integrin $\alpha_v\beta_3$ density in larger tumors. As a result, the radiotracer tumor uptake expressed as % ID/g in larger tumors is significantly lower than that of smaller ones (Figure 5). Thus, it is important to select the mice bearing tumors of the same or similar size for biological evaluations. This may become more important when comparing radiotracers for their tumor uptake and tumor-targeting capability. However, this will, to a certain degree, compromise the "random nature" of the evaluation process.

Radiolabeled small peptides often accumulate in kidneys and liver (*44*). Extensive metabolic degradation was observed for the ^{99m}Tc-labeled cyclic RGDfK monomer (*10*), dimer (*29*), and tetramer (*31*), and the ^{64}Cu-labeled cyclic RGDfK tetramer in kidneys and urine samples (*28*). In this study, [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−tetramer)(EDDA)] (Figure 6) show very high metabolic stability during their excretion from the renal system and significant metabolism during their excretion from the hepatobiliary system, probably due to rapid enzymatic degradation of the cyclic RGD peptide and/or the ^{99m}Tc chelate. The difference in the metabolic fate between [^{99m}Tc-(HYNIC−tetramer)(EDDA)] described in this study and [^{99m}Tc-(HYNIC−tetramer)(tricine)(TPPTS)] (*31*) seems to be related to coligands (EDDA vs tricine/TPPTS) in the Tc chelate.

CONCLUSION

In summary, we have described the synthesis and evaluation of [^{99m}Tc(HYNIC−dimer)(EDDA)] and [^{99m}Tc(HYNIC−tetramer)(EDDA)] as potential radiotracers for tumor imaging using athymic nude mice bearing the U87MG glioma xenografts. The key findings of this study are as follows: (1) there is only one EDDA binding to the ^{99m}Tc-HYNIC core; (2) the use of EDDA as coligand to replace tricine/TPPTS does not significantly change the uptake of the ^{99m}Tc-labeled HYNIC-dimer in liver, kidneys, and lungs; but it results in a significantly lower kidney uptake for the ^{99m}Tc-labeled HYNIC−tetramer due to faster radiotracer renal excretion; and (3) the radiotracer tumor uptake decreases as the tumor size increases in a linear fashion.

ACKNOWLEDGMENT

We would like to thank Dr. Sulma I. Mohammed, the Director of Purdue Cancer Center Drug Discovery Shared Resource, Purdue University, for her assistance with the tumor-bearing animal model. Modulation of Antibody Pharmacokinetics by Chemical Polysialylation

Antony Constantinou,[†,§] Agamemnon A. Epenetos,[†] Dale Hreczuk-Hirst,[‡,△] Sanjay Jain,[‡] and Mahendra P. Deonarain*[,†]

Division of Cell and Molecular Biology, Faculty of Natural Sciences, Imperial College London, Exhibition Road, London, SW7 2AZ, United Kingdom, Lipoxen plc, 2 Royal College Street, London NW1 0NH. Received May 16, 2007; Revised Manuscript Received December 14, 2007

Chemical coupling of a variety of polymers to therapeutic proteins has been studied as a way of improving their pharmacokinetics and pharmacodynamics *in vivo*. Conjugates have been shown to possess greater stability, lower immunogenicity, and a longer blood circulation time due to the chemicophysical properties of these hydrophilic long chain molecules. Naturally occurring colominic acid (polysialic acid, PSA) has been investigated as an alternative to synthetic polymers such as poly(ethylene glycol) (PEG) due to its lower toxicity and natural metabolism. Antibodies and their fragments are a good example of the types of proteins which benefit from pharmacokinetic engineering. Here, we chemically attached differing amounts and differing lengths of short (11 kDa) and longer (22 kDa) chain colominic acid molecules to the antitumor monoclonal antibody H17E2 Fab fragment. Different coupling ratios and lengths were seen to alter the electrophoretic mobility of the Fab fragment but have a minor effect on the antibody immunoreactivity toward the placental alkaline phosphatase (PLAP) antigen. Polysialylation generally increased Fab fragment blood half-life resulting in higher tumor uptake in a KB human tumor xenograft mouse model. One H17E2 Fab-PSA conjugate had over a 5-fold increase in blood exposure and over a 3-fold higher tumor uptake with only a marginal decrease in tumor/blood selectivity ratio compared to the unconjugated Fab. This conjugate also had a blood bioavailability approaching that of a whole immunoglobulin.

INTRODUCTION

The use of polymers to modulate the *in vivo* pharmacokinetics of proteins and drugs for therapeutic applications has been shown for many conjugates to enhance their efficacy (*1, 2*). The primary objective of such conjugation is normally to extend the longevity of therapeutic agents in circulation that would otherwise be cleared too rapidly by renal clearance to give a larger therapeutic window. However, other advantages in polymer conjugation include the masking of antigenic sites that would cause clearance by a variety of immune responses, as well as providing stabilizing features that reduce the risk of degradation under physiological conditions or by protease activity (*3, 4*).

The synthetic polymer poly(ethylene glycol) (PEG) represents the most extensively used and investigated form of polymer conjugation for pharmacokinetic engineering of small proteins or drugs (reviewed in (*1*)). Successful examples in the clinic include Oncaspar (PEG-asparaginase) for the treatment of lymphoblastic leukemia (*5*), PEGasys (PEG-interferon α−2a) for the treatment of chronic Hepatitis C infections (*6*), and Macugen (PEG-aptanib sodium), for the treatment macular degeneration (*7*).

Although considered biologically inert moieties, there have been concerns regarding the long-term safety of PEG *in vivo*, and whether chronic accumulation of PEG over prolonged use could lead to toxicity (*4, 8, 9*). Small length polymers of PEG have demonstrated renal clearance; however, larger molecular weight conjugates cannot be easily broken down through any known natural pathway, and there is evidence to suggest that they can accumulate in tissues once they have been taken up by cells through phagocytic processes. Furthermore, exposure from repeat and/or high doses has been shown to elicit an immune response which may lead to problems where long-term treatment is required (*10, 11*).

Recently, polysialic acid (PSA) has been investigated as an alternative to PEG (reviewed in (*12*)). Naturally occurring PSA polymers are carbohydrate chains that have been identified on the surface of a variety of cells from microbes to vertebrates. A specific form of this polymer, colominic acid, is a homopolymer of α-2,8-linked 5-*N*-acetylneuraminic acid (Neu5Ac) residues normally associated with the bacterial capsule of neuroinvasive bacteria such as *Escherichia coli* K1 (*13*). Gregoriadis et al. was the first to postulate and pioneer the use of PSA (colominic acid) as an alternative to PEGylation for conjugation to improve the stability and *in vivo* pharmacokinetics of small drugs and proteins (*14, 15*). Reductive amination of the nonreducing end of the polymer allowed chemical conjugation via the primary amine groups on proteins. In this manner, the therapeutic benefits of PSA conjugation have been demonstrated with aspariginase (*16*) and insulin (*17*) for the treatment of leukemia and diabetes, respectively, and both have shown an increase in enzyme stability and increased serum half-lives. The prolonged residency of polysialylated conjugates increases the potential of the species to reach its target and provide a therapeutic effect before being cleared from circulation, hence extending the duration of action. It has also been demonstrated that, by varying the length of the PSA chain, the number of PSA chains per conjugate, and the PSA conformation used, the half-life of the of the conjugate can be modulated for

optimal therapeutic affect (*17*). Furthermore, a study of immunogenicity involving PSA-conjugated and native asparaginase demonstrated that only the native enzyme elicited an immune response in mice, while polysialylated asparaginase. despite having a 3–4-fold longer clearance rate, did not elicit an immune response, suggesting that PSA conjugation can mask antigenic epitopes (*18*). In addition, given that the source of PSA consists of α-2,8-linked 5-*N*-acetylneuraminic acid, which is the natural component of PSA in mammals, it is not thought that the polymer on its own would elicit an immune response in humans.

Although Siglec and Selectin receptors that recognize sialic acid containing glycans are known to exist, ligand recognition appears to be dependent on neighboring sugar residues within the glycan, and as yet, no receptors with PSA specificity have been identified (reviewed in (*19*)). The apparent lack of PSA receptors and low immunogenicity provides molecular stealth and adds to the nontoxic properties of PSA. PSA conjugates must be desialylated by neuraminidase-like enzymes before they can be cleared via the hepatic asialoglycoprotein receptor and metabolized (*20*).

The biodegradable, nontoxic, and highly hydrophilic properties of PSA are therefore being exploited to increase the serum half-life and consequently the action of small peptides and drugs. These observations are of particular pharmaceutical interest, since polysialylation offers a potentially superior method over current conjugation methods using PEGylation. Potentially, the greatest advantage in increasing the longevity of therapeutic agents would be where long-term specific activity was desired, and could be of immediate benefit to already commercially available therapeutic agents such as the neutralizing antibodies Remicade (Infliximab), used to treat rheumatoid arthritis (*21*), and Avastin (*22*), used in many solid cancers. Also, the conjugation technology could be applied to other common therapeutic agents where improved longevity pharmacokinetics would be beneficial such as insulin (*23*) and erythropoietin (*24*) for the treatment of diabetes and anemic conditions, respectively.

In this study, an analysis of the effect of protein polysialylation was investigated using a Fab antibody fragment. This fragment, which is specific for the placental-like alkaline phosphatase (PLAP) antigen associated with germ cell carcinomas (*25, 26*), was modified and immunoconjugates compared *in vitro* and *in vivo*. Our results indicate polysialylation can extend the half-life of antibody fragments leading to improved tumor uptake without compromising on tumor to tissue specificity.

EXPERIMENTAL PROCEDURES

Materials. H17E2 IgG was a gift from Professor Lemoine (CRUK). Polysialic acid (colominic acid) was from Marukin, Japan, supplied by Sigma, UK, and Camida, Ireland. PLAP antigen was supplied by Calzyme, Inc.; PLAP positive KB cell-line supplied by the EACC and grown in Dulbecco's modified Eagle medium (DMEM) supplemented with 10% fetal calf serum and 50 IU/mL of penicillin and streptomycin (Invitrogen). Unless stated, immunochemicals were from Sigma. Mouse anti-PSA-NCAM monoclonal IgM was from Chemicon. Carrier-free ^{125}I-NaCl was supplied by GE Healthcare, UK.

Production and Purification of H17E2 Fab. H17E2 Fab fragments were derived by papain cleavage using the Immuno Pure Fab preparation kit (Pierce), following the manufacturers instructions. The solublized Fab and Fc fragments were recovered and separated by Protein A. Proteins were further purified using a HiLoad 16/10 Superdex-200 HR 10/30 gel filtration column equilibrated with PBS and compared to previously run protein standards. Samples were further analyzed for the presence of protein by Coomassie staining and Western blotting.

Chemical Polysialylation. The PSA used in this work was colominic acid (linear α-(2,8) linked *N*-acetylneuraminic acid) purified from the capsular coating of *E. coli* K1, supplied in alternative different lengths, 11 and 22 kDa (average molecular weights), which are equivalent to ∼35 and 71 units of sialic acid, respectively. The average molecular weight (nominal mass) of these polymers was determined independently by Viscotek Europe Ltd. (Lipoxen, unpublished; (*17*)).

For the purpose of protein−PSA conjugation by reductive amination, PSA was oxidized with 0.1 M periodate as described (*17*). The oxidized material was dialyzed extensively against a 0.01% ammonium carbonate buffer (pH 7.4) at 4 °C, concentrated by reverse dialysis on a bed of poly(ethylene glycol) (8 kDa), lyophilized, and stored at −80 °C until required. Oxidized PSA was added to 5 mL protein samples to give a 25-fold molar excess in a glass tube. For lower coupling ratios, a 2- to 5-fold molar excess was used. The mixture was mixed gently and supplemented with 20 mg $NaCNBH_3$. The tube was sealed and rotated at 37 °C for 48 h to allow the conjugation reaction to take place whereupon ∼100% conjugation was expected. After incubation, the sample was allowed to cool and the conjugated material was purified from free PSA by addition of $(NH_4)_2SO_4$ to give a 70% saturated solution. The sample was rotated for 5 min at room temperature followed by 30 min on ice. The mixture was then centrifuged at 5000 rpm for 5 min and the resulting pellet resuspended in 1 mL 100% $(NH_4)_2SO_4$. The precipitation procedure was then repeated and the pellet resuspended in minimal PBS. Finally, the conjugated sample was analyzed by PAGE and characterized for polysialylation degree by a resorcinol assay.

Determination of PSA/Fab Ratios. The resorcinol assay, based on the method by Svennerholm (*27*), allowed the amount of colominic acid present in a sample relative to known standards to be measured. The resorcinol agent (0.25 mM cupric sulfate, 0.2% resorcinol, 80% conc HCl made up with dH_2O) was freshly prepared, and at least five colominic acid standards were prepared within the 40–400 μg/mL range. In triplicate, 100 μL of standard and test samples were added to 100 μL of resorcinol agent. The tubes were sealed and the mixture heated for 30 min at 95 °C. Once the tubes had cooled down, 400 μL of ethanol was mixed in. Finally, the absorbance at 560 nm was measured for 250 μL of each sample and standards in a microplate assay. The standard values were used to construct a calibration curve from which the colominic acid content of the test samples could be extrapolated. A molar value was determined according to the PSA length used in test samples, and similarly a protein molar value determined for samples using the Coomassie Plus protein assay kit compared to protein standards. Using these values, a PSA to protein molar ratio was calculated.

Western Blot Analyses. Protein gels for Western blot analysis were transferred to nitrocellulose membrane, blocked in PBS/5% Marvel milk protein made, and then incubated with either anti-mouse Fc-specific or anti-mouse Fab-specific one-step HRP-conjugated antibody. The blot was developed using enhanced chemiluminescence (ECL, GE Healthcre, UK) and exposed to high-performance autoradiography film.

Protein Radio-Iodination. Protein samples were iodinated using the IODO-GEN Iodination Reagent. To precoated tubes, 100 μL of the Tris iodination buffer was added, followed by 10 μL (1.0 mCi) $Na^{125}I$. The activated iodide was then removed and added directly to the protein solution for iodination. The reaction was allowed to take place for 8 min. To end the reaction, 50 μL of scavenging buffer (10 mg/mL tyrosine in PBS) was added and mixed. After 5 min incubation, the iodinated sample was dialyzed against PBS.

Conjugate Stability Assay. Blood was collected from mice, centrifuged at 13 000 rpm for 30 min, and serum was siphoned off for use in protein stability assays. ^{125}Iodine-labeled samples were mixed with an equal volume of serum and incubated at 37 °C over a 24 h period. Aliquots were taken at 0, 0.5, 2, 6, and 24 h points, mixed with SDS-PAGE loading buffer, and frozen until all samples were ready for analysis by SDS-PAGE and autoradiography.

Bioactivity by ELISA Analysis. Flat-bottom 96-well ELISA plates coated with PLAP antigen at 1 μg/mL in PBS were used. After three washes with PBS, one wash with PBS/0.1% Tween, and three more PBS washes, the plate was then blocked with 5% Marvel for 1 h at 37 °C and washed again. Binding activity of the anti-PLAP Fab and conjugates was established by serially diluting samples across test wells in 1% Marvel/PBS for 1 h at 37 °C. For the purpose of testing Fab purity following papain cleavage of whole H17E2 antibody, the plate was then washed as above and incubated with the either antimouse Fc-specific or antimouse Fab-specific one-step HRP-conjugated antibody. For the purpose of PSA detection, the plate was incubated first with primary anti-PSA IgM followed by secondary anti-IgM HRP for 1 h 37 °C. In both cases, incubation with detection antibodies was terminated by washing the plates as described above and binding detected using BM Blue POD substrate (Roche, UK). The reaction was stopped with 10 μL of acid (1 M H_2SO_4) and the absorbance measured at 450 nm.

Sigmoidal curves (four-parameter logistic) were fitted to ELISA data to determine K_d values using *SigmaPlot* using the one-site saturation ligand binding equation.

Pharmacokinetic and Biodistribution Studies. Female nude BALB/C mice, 6–8 weeks old, used for *in vivo* studies were from Harlan UK. All *in vivo* research was carried out under a UK Home Office project license PPL 70/5833. Tumour xenografts were set up by injecting mice subcutaneously into the left flank with 0.1 mL containing up to 10 million KB cells. Tumor growth was monitored and took 3–4 weeks to reach the required 6–8 mm diameter for subsequent work. For tissue analyses, up to 100 μL radiolabeled samples were injected intravenously into the mouse tail vein. At the appropriate time points (typically 0.5, 2, 6, 24, and 48 h), mice were culled by exsanguination under terminal anesthesia. Immediately, blood was collected by cardiac puncture and transferred to a sample tube. The mouse was then dissected, and tissues were collected for biodistribution analysis. Radioactivity was counted using a gamma counter. Values were expressed as a percentage of the initial injected dose per gram of tissue (% id/g). For studying *in vivo* blood clearance pharmacokinetics, data values were fitted using *SigmaPlot* to curves that conform to the two-compartmental intravenous model of clearance, which takes into account the biexponential clearance phases, distribution phase and elimination phase, of single intravenous doses. This is described by the exponential decay, double, four-parameter equation $y = ae^{-bx} + ce^{-dx}$, where the distribution phase clearance rate ($t_{1/2\alpha}$) can be determined by ln 2/b, and the elimination clearance rate ($t_{1/2\beta}$) can be determined by ln 2/d. The area under the curve values were determined using the macros available within *SigmaPlot*.

RESULTS

H17E2 Fab Polysialylation. H17E2 Fab that was free from contaminating Fc portion was used for polysialylation (Figure 1A). Anti-Fab and anti-Fc Western blot confirmed that pure Fab fragment had been obtained (Figure 1B,C). Polysialylations were performed with the 11 and 22 kDa polymers. The PSA/Fab molar ratios for each set of immunoconjugates are shown in Table 1. There are 26 lysine residues available, but not all were expected to be accessible. PAGE analyses of the Fab, Fab-PSA11, and Fab-PSA22H under native conditions showed that both immunoconjugates migrated as a polydispersed smear of higher molecular weight species compared to the unmodified Fab (Figure 1D). This was confirmed by the anti-Fab Western blot which showed a small amount of free noncoupled antibody not visible by Coomassie staining (Figure 1E). A different result was seen when detected with the anti-PSA antibody (Figure 1F): the polydispersed species was again evident, but the larger mass PSA immunoconjugate seemed to migrate more rapidly, possibly due to the higher charge. It is clear from these analyses that polysialylation had altered the size and migration properties of the H17E2 Fab, but their polydispersity and heterogeneity hindered a quantitative analysis of the mass and charge properties.

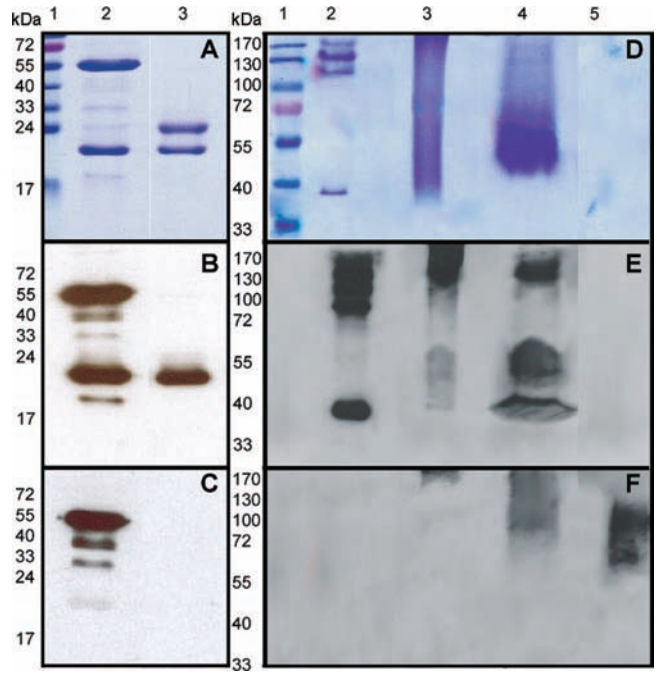

Figure 1. Electrophoretic analyses of H17E2 IgG, Fab, and PSA-Fab conjugates. Left panel: SDS PAGE of markers (lane 1), whole IgG (lane 2), and papain-derived Fab fragments (lane 3) under reducing conditions were analyzed by (A) Coomassie staining, (B) Anti-Fab Western detection, and (C) Anti-Fc Western detection. Right panel: Markers (lane 1), Fab alone (lane 2), and Fab-PSA conjugates (FabPSA11 (lane 3), FabPSA22H (lane 4), and Free PSA22 (lane 5)) were compared by PAGE under native conditions and analyzed by (D) Commassie staining, (E) Anti-Fab Western detection, and (F) Anti-PSA Western detection. Long trail lines observed in conjugates reflect the polydisperse nature of PSA content.

Table 1. Nomenclature and Coupling Ratios of H17E2 Fab-PSA Conjugates[a]

PSA (kDa)	average PSA/Fab molar ratio	abbreviated name
11	9	Fab-PSA11
22	1	Fab-PSA22L (low)
22	5	Fab-PSA22H (high)

[a] The ratios were determined from the resorcinol (PSA) and Coomassie (protein) assays.

Antigen Binding of Immunoconjugates. ELISAs confirmed that the unmodified H17E2 IgG and Fab had binding affinities (K_ds) similar to that already published (*28*). These were compared to the affinities of the PSA immunoconjugates (Figure 2, Table 2). Binding was detected using anti-Fab (Figure 2A) and anti-PSA detection (Figure 2B) antibodies. For the Fab-PSA11 and Fab-PSA22H immunoconjugates detected by anti-Fab antibody, the affinities were slightly reduced by 3.7- and 2.7-fold, respectively.

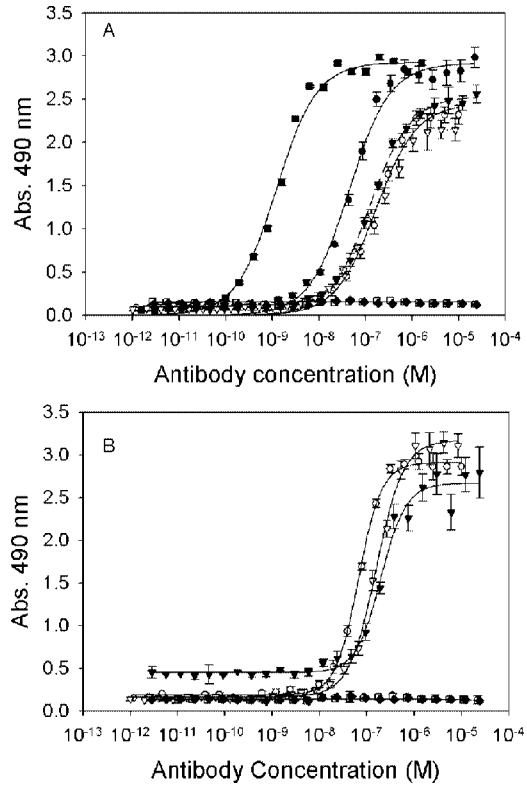

Figure 2. Antigen-binding activity of H17E2 IgG, Fab, and Fab-PSA conjugates. Whole IgG (■), Fab-PSA11 (▽), Fab-PSA22L (○), and Fab-PSA22H (▼) were compared against unconjugated Fab (○) by ELISA. (A) Binding activity was detected by anti-Fab and (B) the presence of PSA on conjugates detected by anti-PSA. Samples were analyzed in triplicate and included control samples MFE-23 (♦), a nonanti-PLAP scFv (detected anti-His), and free PSA22 (□). K_d values were determined by *Sigma Plot*.

Table 2. Immunoreactivity of the H17E2 Fab and PSA Conjugates[a]

antibody	anti-Fab detection K_d (nM)	anti-PSA detection K_d (nM)
unmod. Fab	45	NA
Fab-PSA11	149	61
Fab-PSA22L	145	127
Fab-PSA22H	122	153

[a] The equilibrium dissociation constants for H17E2-PLAP binding were determined by ELISA with both the protein and carbohydrate moieties being detected (Figure 2).

Detection by anti-PSA antibody confirmed that polysialylation had occurred showing a small (1.3–3.4-fold) decrease in affinity. Overall, the addition of long polymers of PSA did not significantly affect the affinity of the Fab antibodies, and the K_ds of the species under study were all very similar among themselves.

Serum Stability. In order to rule out the possibility of protein or carbohydrate degradation occurring, a serum stability assay was carried out *in vitro* using murine serum incubated with a radiolabeled immunoconjugate at 37 °C. Over a 24 h period, no change in the SDS-PAGE banding profile was observed for either the Fab or Fab-PSA22H immunoconjugate, indicating that they were stable in serum (Figure 3).

***In Vivo* Pharmacokinetics.** The effect of polysialylation on the pharmacokinetic behavior of the H17E2 Fab was studied by analyzing blood samples at various time points after IV injection of Fab-PSA conjugates. Data from nude BALB/C mice and tumor-bearing nude BALB/C mice were obtained and pooled. Due to the nature of the coupling chemistry, it was not possible to produce exactly matched immunoconjugates of

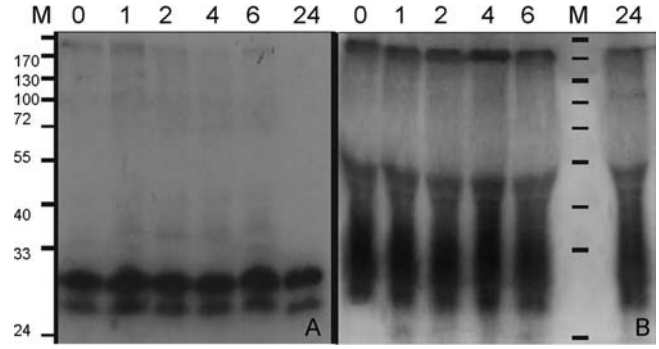

Figure 3. Stability assay of ^{125}I- radiolabeled (A) Fab and (B) Fab-PSA22H samples were incubated with mouse serum at 37 °C. Samples were taken at 0, 1, 2, 4, 6, and 24 h time points and analyzed by SDS-PAGE under reducing conditions. Protein was visualized by exposure of the gel to autoradiographic film.

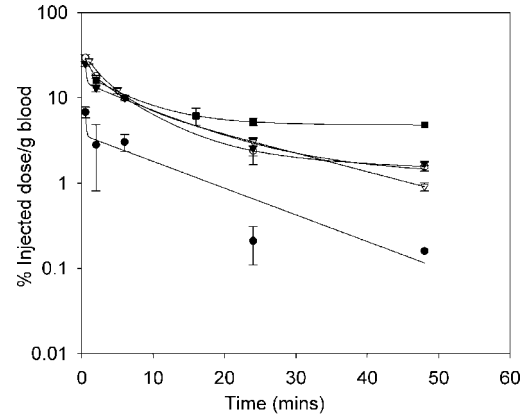

Figure 4. Blood clearance analyses of H17E2 IgG, Fab, and Fab-PSA conjugates. Radioactive cpm values for each sample were measured and calculated as a percentage of the injected dose per gram of blood. Each time point is represented by the mean ± SD of between 3 and 6 mice. The blood clearance of H17E2 (■) whole IgG and (•) Fab is compared graphically with (○) Fab-PSA11, (▽) Fab-PSA22L, and (▼) Fab-PSA22H.

predefined coupling ratios (Table 1). The immunoconjugate present in the blood calculated as the percentage of remaining radioactivity per gram of blood was plotted against time (Figure 4). Pharmacokinetic parameters such as beta-phase clearance rates and total blood exposure (as measured by the area under the curve) were determined and are summarized in Table 3. The stability of the conjugate in serum indicated that the radioactivity represented the intact Fab-PSA conjugate. The results show that, in all cases, polysialylation generally leads to longer blood clearance times compared to the unmodified Fab, resulting in higher blood exposure and hence greater bioavailability. This modulatory effect was generally related to increasing degree of polysialylation, with the Fab-PSA11 having the greater $t_{1/2b}$ (3.2-fold increase compared to Fab) and a high tumor exposure (2.8-fold increase compared to Fab). Similar mass immunoconjugates (Fab-PSA11–150 kDa and Fab-PSA22H-160 kDa) had broadly similar pharmacokinetic properties. Increasing the degree of polysialylation 5-fold using the same length polymer chain (22 kDa) led to an almost 2-fold increase in beta-phase blood clearance half-life with little change in antibody affinity (Figure 2, Table 2). Compared to whole immunoglobulin, which has a very slow blood clearance profile, the immunoconjugates compared favorably, with blood bioavailability (exposure) almost as high as the whole antibody but with better tissue specificity ratios (see below) and potentially lower cross-reactivity. The alpha (distribution) blood

[a] Pharmacokinetic beta-elimination constant, total blood exposure (blood area under the curve), total tumor exposure (tumor area under the curve), and tumor/blood selectivity (ratio) were determined from plots of the biodistribution data in Figures 4 and 5.

clearance rates are presented for guidance and are approximate, as only a few early time points were recorded.

Tumour and Tissue Biodistribution. The uptake or retention of the different immunoconjugates in tumors and tissues, measured as the percentage of injected radioactive material per gram, was determined and presented as an absolute value and a tissue/blood ratio (Figure 5). The key parameters are summarized in Table 3 with total tumor exposure as determined from the area under the curve. These were compared to whole IgG and unmodified Fab. As seen for other whole immunoglobulins, the H17E2 IgG exhibited at least a 7.5-fold increase in blood retention resulting in a 3.5-fold increase in tumor uptake compared to the H17E2 Fab. The tumor/blood ratios, typical for IgGs, were poor with a value greater than 1 not being reached until after 16 h. The Fab demonstrated rapid clearance leading to lower absolute uptake with high tumor/blood ratios (greater than 10) by 24 h.

The Fab-PSA22H immunoconjugate, which had one of the slowest blood clearances, yielded the highest absolute uptake, 3.3-fold higher than the unmodified Fab and approaching that of the whole IgG. The tumor/blood ratio was superior to that of whole IgG and only one-third that of Fab (3.5:1), demonstrating improved selectivity (compared to whole immunoglobulin) toward the tumor with almost as good tumor exposure as whole immunoglobulin. The Fab-PSA11 conjugate, although not as effective as the Fab-PSA22H immunoconjugate, still had higher tumor uptake and better specificity ratios compared to the Fab, resulting from the altered blood pharmacokinetics, which was slightly slower than that of the Fab-PSA22H immunoconjugate. Generally, increased blood exposure led to increased tumor uptake. Increasing the PSA content 5-fold (Fab-PSA22L and Fab-PSA22H) led to an almost 2-fold increase in beta-phase blood clearance rate and a 1.8-fold increase in tumor exposure.

There was no significant uptake by any of the normal tissues, showing that polysialylation had not resulted in undesirable and nonspecific cross-reaction.

DISCUSSION

This research showed that antibody fragments such as the anti-PLAP H17E2 Fab species can be polysialylated to different degrees with little significant change to the binding affinities. The polysialylated immunoconjugates migrated as highly charged heterogeneous species by gel electrophoresis. This is due to the highly heterogenic nature of the naturally isolated colominic acid. Further refinement of the colominic acid purification process to generate species with a smaller range of molecular weights should lead to the generation of more defined immunoconjugates. Polysialylation led to a modulation in the *in vivo* pharmacokinetics demonstrated by decreased blood clearance rates and increased blood bioavailability, tumor uptake, and tumor exposure values. This outcome is similar in principle to the effects of conjugation to other polymers (*29–31*).

The H17E2 anti-PLAP antibody/KB tumor xenograft model was chosen because of our past experience and the reliability of the antigen expression. The affinity of the monovalent Fab was approximately 40 nM, which is deemed moderate for typical recombinant antibodies. This affinity value, not being excessively high, permitted a study of the pharmacokinetic influence of polysialylation. It has been shown that very high affinity antibodies reach a ceiling in terms of tumor uptake at around 1 nM (*32*). The degree of polysialylation was determined using the resorcinol assay after repeated ammonium sulfate precipitation to remove the free, unconjugated PSA. Conjugations were performed at higher molar ratios giving higher subsitituted immunoconjugates, but this also resulted in a high degree of noncovalently associated PSA, which was difficult to remove by repeated ammonium sulfate precipitation. Polysialylation did have a small affect on the affinity of the Fab, but the affinities of the immunoconjugates being compared were all similar in value, allowing a valid comparison between the polysialylated species. Site-specific conjugation is an obvious extension of this approach, especially in cases where there are lysine residues in key positions (such as CDRs) where their modification could lead to loss of function (*33*). This was not a problem for the H17E2 antibody, but we have employed our approach with other antibody fragments and found a loss of binding (Constantinou et al., manuscript in preparation). Recombinant antibodies can easily be engineered to replace lysines which are detrimental to coupling (*33*) or engineered to possess one or more residues for site-specific coupling. One example is the use of cysteine residues for thiol coupling onto therapeutic Fab antibodies (*34*).

Gel electrophoresis suggested that the immunoconjugates' mobility was more influenced by the PSA charge properties than the Fab size and charge. The PSA polymers were supplied as polydispersed mixtures of an average molecular weight, which is reflected in the range of different mobilities when observed by gel electrophoresis. Anti-PSA Western blot again confirmed that the Fab had been covalently modified with the PSA polymer.

Prior to any *in vivo* analyses, it was important to show that the polysialylated immunoconjugates were stable in serum at 37 °C. This was indeed the case, as there was no change in the banding pattern across the times analyzed. During the time of the incubation, serum glycosidases did not remove the PSA chains from the conjugate, which would have been seen as a reduction in the banding pattern back to that of the unmodified Fab. The linkage of the PSA chain to the lysine residue of the protein was expected to be robust, as it consists of the stable secondary amine bond and is attached in the reverse orientation to that of naturally occurring PSA.

The pharmacokinetic values obtained for the control proteins such as the unmodified Fab and whole IgG were comparable to what had been published already (*28*). The immunoconjugates showed an up to 3.2-fold decrease in the blood clearance beta-rate compared to the Fab. This slower clearance leads to greater bioavailability (as measured by the area under the curve, AUC), key to prolonging the action of some drugs. However, the greatest blood bioavailability was seen for the Fab-PSA22L, 5.2-fold higher than for unmodified Fab and 80% that of the whole antibody. This was due to the much slower alpha clearance phase.

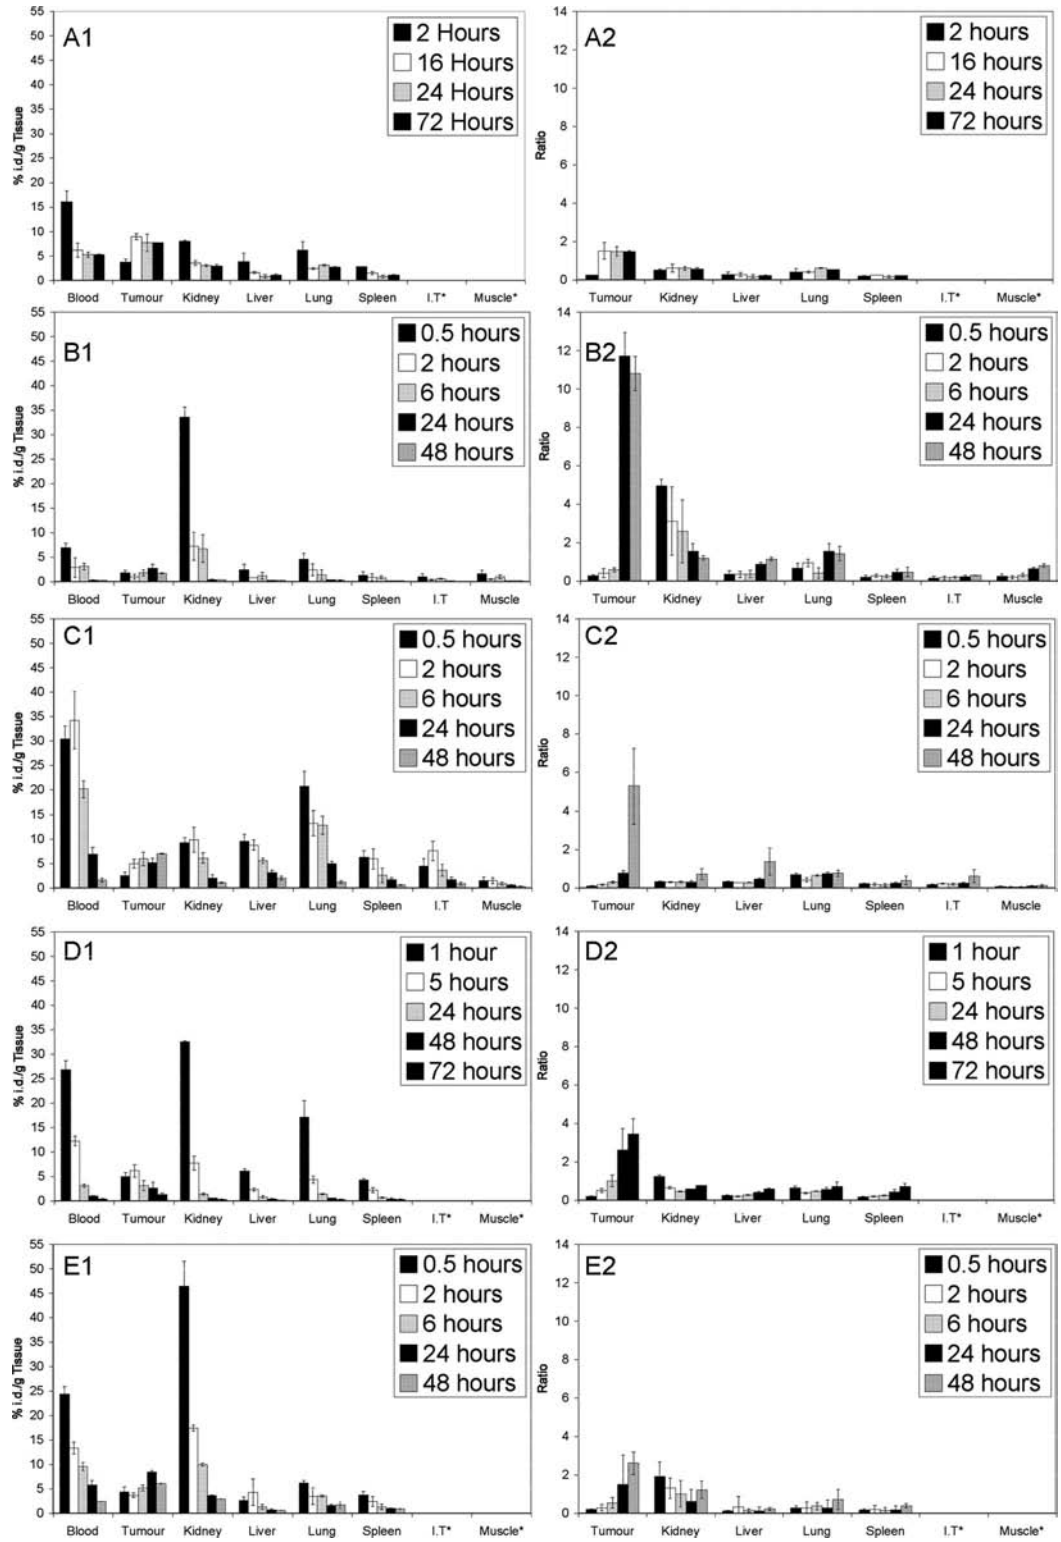

Figure 5. Biodistribution analyses of H17E2 IgG, Fab, and Fab-PSA conjugates. Radioactive cpm values for each sample were measured and calculated as a percentage of the injected dose per gram of tissue. Each bar represents the mean ± SD for three or four mice. Bar charts on the left show the absolute uptake values by each tissue over time, while bar charts on the right show the uptake by each tissue as a ratio to the amount of sample remaining in the blood over time. The bar charts show the biodistributions for **(**A) whole IgG, (B) unconjugated Fab, (C) Fab-PSA11, (D) Fab-PSA22L, and (E) Fab-PSA22H. IT* = intestinal tract.

In general, increased polysialylation led to increased bioavailability, which led to increased tumor exposure approaching that of whole immunoglobulin. The heterogenic nature of these conjugates makes it difficult to identify clear trends; therefore, this work points the way toward site-specific conjugation with polymers of a more defined nature. Polymer conjugation of antibody fragments is seen as a way to increase protein stability and bioavailability (*5–7*, *29–31*) without the limitations of Fc-mediated cross reaction. In addition, less expensive protein production methods available for recombinant fragments such as *E. coli*- and *Pichia pastoris*-expressed single-chain Fvs and Fabs makes polymer conjugation more attractive practically and commercially. However, polysialylation may supersede PEGylation due to its more favorable properties.

Like PEGylation, polysialylation may achieve the observed effects by allowing the protein to possess large hydrodynamic radii by formation of a hydrophilic "watery cloud" (*35*, *36*). This property slows down the blood clearance and prevents excretion through the kidneys. The *in vivo* data did show some high kidney radioactivity at the early time points, which could be attributed to free radioactive iodine which may have been complexed with the PSA and not removed during dialysis. This level quickly reduced. Polysialylation did not lead to aggregate formation, which would have been seen by high liver and spleen uptake caused by metabolism through the reticulo-endothelial system (Figure 5).

The increased blood residency time seen with all immunoconjugates all lead to a corresponding increase in tumor uptake without significant cross-reaction with normal tissues (Figure 5). This supports the premise that PSA is an inert polymer with no natural receptor. The pharmacokinetic distribution (alpha)-phase was not investigated, and it is likely that polysialylation has an effect on how the antibody species distributes within the blood compartment. This needs further investigation.

In conclusion, this study has shown that Fab antibody fragments can be successfully polysialylated with little detriment to its *in vitro* binding properties. We have shown that polysialylation leads to increased blood bioavailability by modulating the clearance rates resulting in increased tumor uptake. Although polysialylation has been used successfully to manipulate drug and protein behavior, this study marks the start of a program of work leading to the better design of PSA antibody conjugates.

ACKNOWLEDGMENT

This work was funded by a Lipoxen Technologies-BBSRC/Case studentship to M.P.D. and A.C. We would like to thank Dr. Peter Laing and Prof. Gregory Gregoriadis for useful discussions and members of the Imperial College CBS Unit for advice and technical help with the *in vivo* experiments.

Received July 20, 2007; Revised Manuscript Received December 13, 2007

Water-soluble gadofullerides exhibited high efficiency as magnetic resonance imaging (MRI) contrast agents. In this paper, we report the conjugation of the newly synthesized gadofulleride, $Gd@C_{82}O_6(OH)_{16}$-$(NHCH_2CH_2COOH)_8$, with the antibody of green fluorescence protein (anti-GFP), as a model for "tumor targeted" imaging agents based on endohedral metallofullerenes. In this model system, the activity of the anti-GFP conjugate can be conveniently detected by green fluorescence protein (GFP), leading to *in vitro* experiments more direct and facile than those of tumor antibodies. Objective-type total internal reflection fluorescence microscopy revealed that each gadofulleride aggregate conjugated on average five anti-GFPs, and the activity of anti-GFPs was preserved after conjugation. In addition, the gadofulleride/antibody conjugate exhibited higher water proton relaxivity (12.0 mM^{-1} s^{-1}) than the parent gadofulleride aggregate (8.1 mM^{-1} s^{-1}) in phosphate buffered saline at 0.35 T, as also confirmed by T_1-weighted images of phantoms. These observations clearly indicate that the synthesized gadofulleride/antibody conjugate not only has targeting potential, but also exhibits higher efficiency as an MRI contrast agent.

INTRODUCTION

Magnetic resonance imaging (MRI) as a noninvasive and convenient imaging technique has been widely applied in clinical diagnosis. Since paramagnetic materials can efficiently reduce the nuclear spin relaxation time of water protons, they have been widely used in clinical MRI to enhance the image contrast and improve the image resolution (*1, 2*). Because clinical MRI contrast agents are administered intravenously to living patients, the basic criteria for designing them are biological safety and high efficiency. Current commercial MRI contrast agents are mainly Gd^{3+} poly(aminocarboxylate) complexes (*1–3*), whose biosafety with reasonable dosages (0.1–0.2 mmol/kg body weight) has been proven by extensive clinical use. However, their proton-relaxing efficiency is far from optimal.

Recently, the application of water-soluble gadolinium-containing endohedral fullerides as MRI contrast agents has been extensively investigated (*4–18*). Besides the high proton relaxivity (up to 20 times (*6*) and 35 times (*16*) larger than the most popular commercial Gd^{3+}-complex contrast agent), low toxicity is expected for them due to the toxic heavy Gd^{3+} ion being protected by the biocompatible fullerene cage. Therefore, the water-soluble gadolinium-containing endohedral fullerides (gadofullerides) are promising next-generation MRI contrast agents. In addition to high efficiency and low toxicity, metallofullerenes are expected to be modified by various functional groups to endow some novel properties, such as Diels–Alder reaction (*19–21*), Bingel reactions (*16, 22*), Prato reactions (*23–26*), and so on. For traditional Gd-chelates, the chelates indeed are easy to modify, but the limited number of sites for H_2O to complex with Gd-chelated agents (e.g., Omniscan) hampers any dramatic increase in water proton relaxivity.

Recently, gadofullerides were observed to aggregate in aqueous solution, and the large size of gadofulleride aggregates is closely related to their high efficiency as MRI contrast agents, e.g., $Gd@C_{60}[C(COOH)_2]_{10}$ (*9, 11, 12, 18*), $Gd@C_{82}(OH)_x$, $Gd@C_{60}(OH)_x$ (*7,9,10,18*), and $Gd@C_{82}O_6(OH)_{16}$-$(NHCH_2CH_2COOH)_8$ (*13, 14*).Our newly synthesized gadofulleride, $Gd@C_{82}O_6(OH)_{16}(NHCH_2CH_2COOH)_8$ (abbreviated AAD-EMF) (*13, 14*), exhibited relatively uniform ~30 nm nanoaggregates in aqueous solution under biological conditions at pH = 7 and displayed high efficiency for enhancing the proton relaxation rates. In addition, AAD-EMF has two types of functional groups on the molecular surface, i.e., -OH and $-NHCH_2CH_2COOH$; the $-NHCH_2CH_2COOH$ groups provide the active -COOH moieties for conjugation with antibodies (*14*). We consider the AAD-EMF as a protypical MRI contrast agent to explore its conjugation with antibodies.

Regarding the choice of antibody, we did not use a tumor antibody, but rather selected the antibody of the green fluorescence protein (anti-GFP) as a prototype biomolecule to conjugate with the AAD-EMF. However, all immune antibodies have similar Y-type structures and active sites, so the successful conjugation of AAD-EMF with anti-GFP should be extended to tumor antibodies in future studies. Most importantly, the activity of anti-GFP can be conveniently detected by using the GFP as a powerful probe, leading to *in vitro* experiments more facile than those with tumor antibodies.

MATERIALS AND METHODS

Materials. Anti-GFP-biotin was bought from Abcam Ltd. Cambridge, UK; GFP was from the Upstate Company, USA; streptavidin was from Molecular Probes, Eugene, OR, USA; BSA-biotin was from Sigma, St. Louis, MO, USA. All the glass slides (no. 1, 24 × 60 mm^2) and cover glasses (no. 1, 22 × 22

mm^2) were purchased from VWR Scientific Inc. (West Chester, PA, USA). Milli-Q purified water (18.2 MΩ) was used to prepare various aqueous solutions.

A 10^{-8} M stock solution of anti-GFP-biotin was prepared in phosphate buffered saline (PBS) solution (pH = 7.4) and stored at 4 °C. A fresh 0.1 M solution of 1-ethyl-3-(dimethylaminopropyl)carbodiimide hydrochloride (EDC) was prepared with deionized water. The AAD-EMF was prepared and isolated as previously described (*13*). The concentration of the gadolinium in the aqueous solution was 2×10^{-7} M, which was measured by inductively coupled plasma atomic emission spectroscopy (ICP-AES, Prodigy, Leeman Laboratories Inc., 342.247 nm).

Methods. *Synthesis of Gadofulleride/Antibody Conjugate.* The conjugation reaction is shown in Scheme 1. In step 1, 10 μL EDC was added to 40 μL AAD-EMF solution, and the resultant solution was shaken for 15 min under ambient conditions to produce the AAD-EMF/EDC intermediate. In step 2, a 10-fold molar excess of the stock solution of anti-GFP-biotin was added to the AAD-EMF/EDC intermediate at room temperature. After 4 h, the AAD-EMF/antibody conjugate was expected to be formed (*27*). Unfortunately, we could not characterize the conjugate in detail due to the complexity and limited size of the sample. However, the following control experiment supports the formation of the AAD-EMF/antibody conjugate by covalent bonding.

Sample Preparation for the Detection of Antibody Activity. The stock solutions of biotinylated BSA, streptavidin, anti-GFP-biotin, and GFP were stored at 4 °C before use. To avoid self-aggregation of GFP and antibodies, a highly concentrated NaCl solution (600 mM) was used to dilute them to 3.38×10^{-9} M and 1.5×10^{-9} M, respectively.

The sample preparation of the gadofulleride/antibody conjugate for single molecule fluorescence characterization involves four steps as shown in Scheme 2. It is in fact a standard procedure (*28*) to immobilize the antibody-relevant aggregates on a channeled glass plate for further single-molecule fluorescence characterizations. The procedure was performed as follows:

(1) Fix Bovine Serum Albumin (BSA) on the Glass Plate. Biotinylated BSA (1.5 mg/mL, 20 μL) was tiled on a clean glass flow cell to react for 10 min (*28*); then, PBS (pH = 7.4) was used to wash the glass plate thoroughly. In this step, some BSA molecules were deposited in the channels on the glass plate, and the unfixed BSA was washed away by the PBS.

(2) Fix Streptavidin on the Glass Plate. A streptavidin solution (0.25 mg/mL, 20 μL) was dropped onto the glass flow cell to conjugate with biotin of the tiled BSA for 10 min, and the excess streptavidin was washed off by PBS.

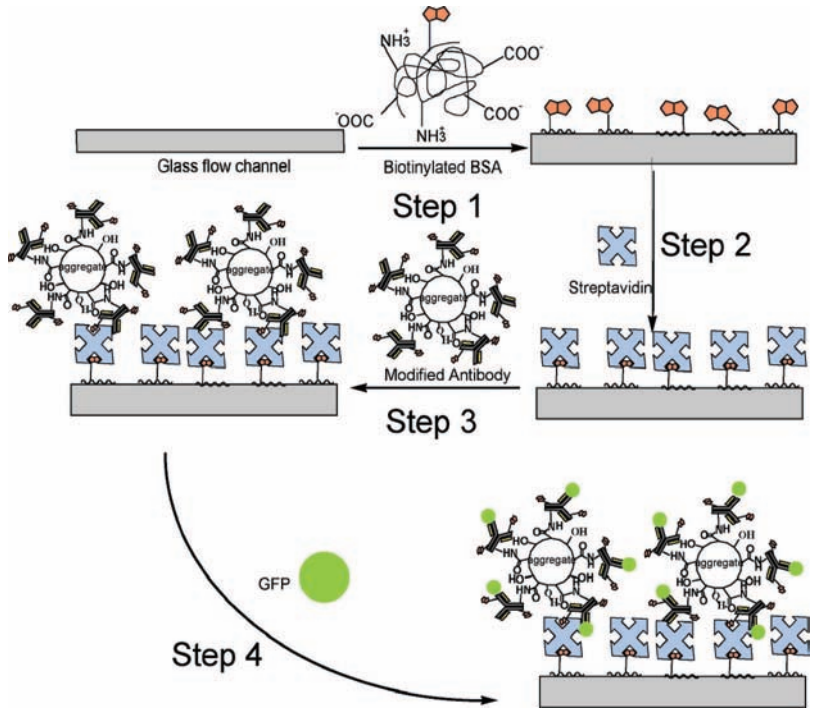
(3) Fix Gadofulleride/Antibody Conjugate on the Glass Plate. The aqueous solution of gadofulleride/antibody conjugate prepared in Scheme 1 was dropped onto the glass flow cell and washed off by PBS after 10 min. In this process, the fixed streptavidin on glass plate conjugated with the biotin on the gadofulleride/antibody conjugate and captured the latter tightly. After reaction, the PBS washing removed the unfixed gadofulleride/antibody conjugate.

(4) Add GFP to Gadofulleride/Antibody Conjugate on the Glass Plate. GFP (3.38×10^{-9} M, 15 μL) was dropped on the glass flow cell to react specifically with the active anti-GFP-biotin on the glass plate; after 10 min, the uncoupled GFP was washed off by PBS.

With the above four steps, the gadofulleride/antibody conjugate was fixed to the glass plate; each conjugate captures several GFP molecules. For comparison, three control experiments on samples with only the anti-GFP-biotin (**I**), only the AAD-EMF aggregates (**II**), and the mixture of anti-GFP-biotin and AAD-EMF aggregates without EDC involvement (**III**) were also prepared following similar four-step procedures except step 3, as shown above.

Detection of Antibody Activity via Fluorescent Probe. An objective-type total internal reflection fluorescence microscope (TIRFM) (*29*) was applied to image the gadofulleride/antibody conjugate on the glass plate at the single-molecule level by using the GFP as a probe. The laser beam (488 nm, Ar^+ laser, 65 w/cm^2, Melles Griot, USA) was introduced into an inverted microscope (IX71, Olympus) through an oil-immersion objective (PlanApo 60×, NA1.45, Olympus) to irradiate the sample on the glass plate, and the fluorescence signals emitting from the GFP were collected by the intensified charge coupled device (ICCD) camera (I-Pentamax, Rofer Scientific, USA). Two filters, i.e., BA510IF (long-pass filter, Chroma, USA) and HQ525/50 (band-pass filter, Chroma, USA), were used to block the

Scheme 2. Flow Chart of Sample Preparation for Fluorescence Measurement



deflected and diffracted laser light. The exposure time of ICCD was set to 100 ms with a gain at 80. The fluorescence images were acquired and analyzed with *MetaMorph 6.0* software (Molecular Devices Corp., USA).

RESULTS AND DISCUSSION

Figure 1 shows a comparison of the fluorescence images of GFP coupled to antibody control (**I**) and the gadofulleride/antibody conjugates. The observed fluorescent signals for the gadofulleride/antibody conjugate revealed that the conjugation was successful and the activity of the anti-GFP-biotin in the gadofulleride/antibody conjugate was preserved. On the contrary, the AAD-EMF control (**II**) had no fluorescent signal (not shown), since the GFP molecules could not be captured without anti-GFP on the glass plate (Scheme 2). Notably, control **III** exhibited fluorescence images similar to that of control **I**, which indicated that PBS wash removes the gadofulleride attached on the anti-GFP-biotin via physical adsorption. This provided indirect evidence for the formation of covalent gadofulleride/antibody conjugates rather than physical adsorption (*30*).

In the experiment, we deliberately maintained low concentrations of BSA and streptavidin. The sparse and irregular patterns of the fluorescent spots in Figure 1 revealed that very few anti-GFPs (in control) or gadofulleride/antibody conjugate were randomly immobilized on the glass plates. Therefore, the probability for two or more fluorescent molecules to locate closely adjacent on the glass surface would be very low, and each fluorescent spot in the images must represent a single molecule. To confirm this supposition, a photobleaching experiment was performed, and the results are shown in Figure 2. The clear-cut one-step bleaching characteristics unambiguously confirmed the single molecular property of each fluorescent spot (*31*).

The AAD-EMF was reported to form minimum aggregates of 30.0 nm in aqueous solution at pH = 7, in which lots of -$NHCH_2CH_2COOH$ chains are located on the aggregate surface and directed outward. In PBS solution, a dynamic light scattering (DLS) experiment demonstrated that the minimum size of the AAD-EMF aggregates was 25.0 nm; the average hydrodynamic radius shifted a little from 72.7 nm in pure water (*14*) to 68.0 nm, indicating that phosphate changed the aggregation size to some extent. If we consider that each -$NHCH_2CH_2COOH$ chain can conjugate one antibody, it is reasonable to deduce that each AAD-EMF aggregate can conjugate several antibodies. In Figure 1, the fluorescence spots corresponding to gadofulleride/antibody conjugate (Figure 1b) show much higher intensity than that of the antibody control (Figure 1a), indicating that in practice each gadofulleride/antibody conjugate may capture several GFPs.

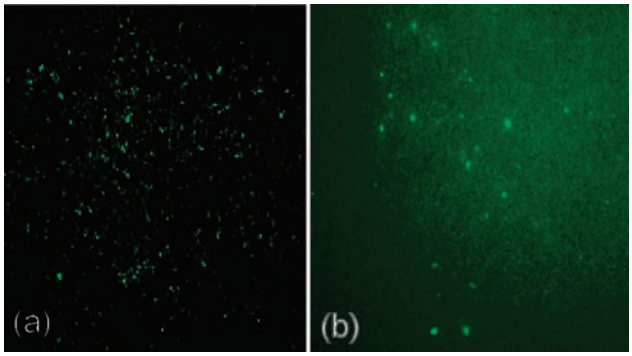


Figure 1. Fluorescence images of (a) the antibody control and (b) gadofulleride/antibody conjugate.

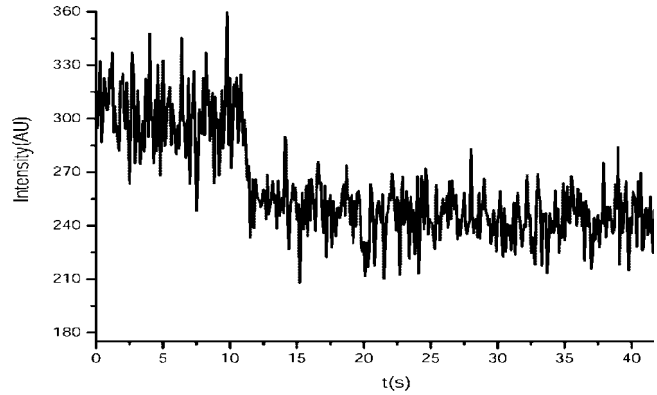

Figure 2. One-step photobleaching curves of single GFP on glass flow cell.

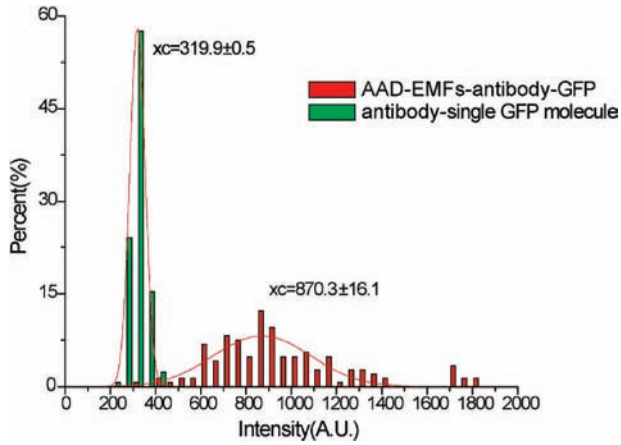

Figure 3. Distribution of fluorescence intensity of the antibody control (green columns) and gadofulleride/antibody conjugate (red columns).

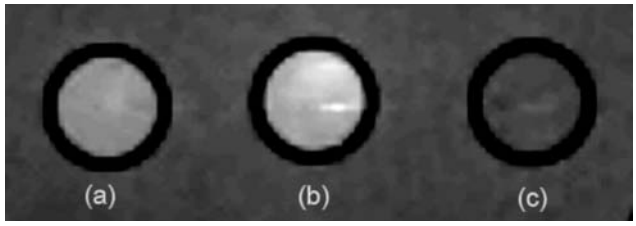

Figure 4. T_1-weighted MRI phantoms of (a) AAD-EMF, (b) gadofulleride/antibody conjugate at a Gd concentration of 17.8 μM, and (c) antibody in PBS at 2.4 T using a spin–echo method with $T_R/T_E = 700$ ms/10 ms, FOV = 3.0 × 3.0 cm^2 at 24 °C.

Because the GFP is greatly overfed in the reactions mentioned above, nearly 100% of the anti-GFPs in the samples were consumed. We then may calculate how many anti-GFPs were conjugated with an AAD-EMF aggregate.

The average number of antibodies conjugated to gadofullerides can be estimated *via* the measured fluorescence intensity. The statistical distribution of fluorescence intensity of antibodies (control **I**) and gadofulleride/antibody conjugates are shown in Figure 3; then, according to eq 1

$$N = (I_{sample} - B_{sample})/(I_{sm} - B_{sm}) \quad (1)$$

the average number of anti-GFPs conjugated with an AAD-EMF aggregate is concluded to be 5. In eq 1, I_{sample} and I_{sm} are the fluorescent intensity of the gadofulleride/antibody conjugate and the antibody control, respectively; B_{sample} and B_{sm} are the measured backgrounds of the two relevant images. Moreover, some fluorescent spots in Figure 1b were observed to have nearly double fluorescence intensity compared with others (Figure 3), which should correspond to dimers of the AAD-EMF aggregates as we already observed in a previous paper (*14*).

Besides confirming the activity of gadofulleride/antibody conjugates, we also measured and compared their water proton relaxivity with unconjugated gadofulleride on a per Gd^{3+} ion basis. In PBS (pH = 7.4) solution, the longitudinal relaxivity (R_1) of AAD-EMF was 8.1 mM^{-1} s^{-1} at 0.35 T with a TEACH SPIN PS1-B instrumentation, whereas after gadofulleride/antibody conjugation, the relaxivity was 12.0 mM^{-1} s^{-1} at the same field strength. In addition, the *in vitro* MRI phantom studies of AAD-EMF and gadofulleride/antibody conjugate at 17.8 μM Gd together with PBS solution were also performed by the T_1-weighted spin–echo method. As shown in Figure 4, the MRI phantom of the gadofulleride/antibody conjugate (Figure 4b) at 2.4 T with a Bruker/Biospec instrumentation indicates enhanced MRI signal efficiency relative to AAD-EMF (Figure 4a), which is consistent with above proton relaxivity analysis of the two contrast agents. These results indicate that gadofulleride/antibody conjugation can improve water proton relaxivity relative to the unconjugated gadofulleride.

Recent studies (*9, 11, 12, 18*) indicate that, besides the number of hydroxyl groups, aggregate size and distance of interaction between the carbon cage and water molecules play predominant roles in proton relaxivity. Recently, Fatouros et al. (*16*) reported an MRI contrast agent based on a trimetallic nitride templated metallofullerene (TNT EMF), $Gd_3N@C_{80}$, which was PEGylated and hydroxylated for medical applications. This compound possessed the highest relaxivity reported so far; this may be due to the cocontribution of three paramagnetic Gd(III) ions in one carbon cage and fast water proton exchange rate together with the slow rotational time caused by the attachment of large moieties in the form of two poly(ethylene glycol) chains via the Bingel cyclopropanation reaction. In contrast, our synthesized gadofulleride/antibody conjugate will possess increased size relative to the unconjugated gadofulleride due to the attachment of the antibody, which leads to slower rotational time and correspondingly higher relaxivity. Notably, the water proton relaxivity of unconjugated gadofulleride in pure water (16.0 mM^{-1} s^{-1}) is higher than that in PBS (8.1 mM^{-1} s^{-1}) at 0.35 T. Laus et al. (*11*) reported that phosphate can disrupt the aggregation of $Gd@C_{60}(OH)_x$ and $Gd@C_{60}[C(COOH)_2]_{10}$ by intercalation of $H_2PO_4^-$ and HPO_4^{2-} ions into the hydrogen-bond network around the malonate or hydroxyl groups of the gadofullerenes. Therefore, the decrease of the relaxivity of the AAD-EMF in PBS can be ascribed to the decrease in aggregate size, as the DLS measurement proved.

As for the relaxivity of the conjugate, although its relaxivity is still too low to image tumor cells, in which antibody receptor sites are typically present at only nanomolar (nM) concentrations (*17, 32*), we can apply the conjugation technique to other analogues with higher relaxivity (*16*) due to the similarity of structure (metal atoms encapsulated in carbon cages), producing targeted, highly efficient MRI contrast agents.

CONCLUSIONS

In summary, we have demonstrated a gadofulleride/antibody conjugate as an MRI contrast agent. By tracing the fluorescent intensity, we concluded that each AAD-EMF aggregate on average captures five antibodies, and the antibody activity is preserved after conjugation. In addition, the gadofulleride/antibody conjugate exhibits higher water proton relaxivity than the parent gadofulleride due to the increased molecular size, which is also confirmed by T_1-weighted imaging. This study represents substantial progress in the development of carbon nanostructures in medicine. Of course, the relaxivity of this material is still far from optimal, but we can extend the conjugation process to functional groups on other analogues with much higher relaxivity, e.g., $Gd_3N@C_{80}$ (*16*). Once this type of conjugated MRI contrast agent with tumor antibody is realized, it will not only greatly improve early tumor diagnosis, but also increase the probability for treatment based on a recent discovery that some gadofullerides can efficiently inhibit tumor cells (*33*).

Cellular Internalization and Distribution of Arginine-Rich Peptides as a Function of Extracellular Peptide Concentration, Serum, and Plasma Membrane Associated Proteoglycans

Michie Kosuge,[†] Toshihide Takeuchi,[†] Ikuhiko Nakase,[†] Arwyn Tomos Jones,[§] and Shiroh Futaki*[,†,‡]

Received July 31, 2007; Revised Manuscript Received December 22, 2007

The exact mechanisms by which arginine-rich cell-penetrating peptides enter cells are still the subject of debate. Here, we have analyzed in detail the effects of serum and extracellular concentration on the internalization of oligoarginines (R*n*; $n = 4, 8, 12, 16$). The presence of serum in the incubation medium had a major influence on the uptake of R12 and R16 peptides but did not affect the uptake of R4 and R8 significantly. Incubation of cells at 37 °C with R12 and R16 peptides in serum-containing medium showed that the majority of labeling was confined to punctate endocytic structures. Performing the same experiments in serum-free media led to a dramatic increase in cytosolic labeling, and similarly diffuse R12 and R16 labeling was observed in cells treated with peptides at 4 °C. This suggests, in both cases, that the peptides were entering via a nonendocytic mechanism. Further studies on R12 peptide suggest that the initiation of nonendocytic uptake and cytosolic labeling is also dependent on serum concentration and extracellular peptide concentration. At relatively low concentrations, the peptide labels endocytic structures, but upon raising the peptide concentration, the fraction labeling the cytosol increases dramatically and this accompanies a nonlinear increase in total cellular fluorescence. Membrane-associated proteoglycans also contribute to increasing the peptide concentration at the cell surface by enhancing their recruitment via electrostatic interactions. These results demonstrate that uptake mechanisms of these compounds are highly dependent on both the presence of serum and the effective extracellular peptide concentration.

INTRODUCTION

The use of cell-penetrating peptides (CPPs, or protein transduction domains, PTDs) for enhancing delivery of molecules across biological barriers has received widespread attention, as they offer a diverse range of therapeutic applications (*1–6*). Among them, arginine-rich peptides including oligoarginine and HIV-1 Tat (48–60) peptides are regarded as one representative class and show high efficiency of translocation through biological membranes (*1–8*). Recent work has shown the applicability of these peptides as intracellular delivery vectors for a wide range of bioactive cargo including synthetic small molecules, peptides, proteins, oligonucleotides, and liposomes. This has been shown in both in vitro and in vivo applications through to clinical trials targeting cancer and allergy (*4, 5*).

Despite their promise and effectiveness, the exact mechanisms by which they breach biological barriers such as the plasma membrane remains to be elucidated. The internalization of HIV-Tat peptide and other arginine-rich peptides, concluded from observations in fixed cells, was thought to occur through temperature- and energy-independent, nonendocytic mechanisms (*8*). However, more recent experiments using intact living cells highlight the importance of endocytic pathways as major routes of internalization (*9, 10*). We and others have proposed that macropinocytosis may be stimulated in cells treated with CPPs (*11, 12*). We have also highlighted the fact that interaction of arginine-rich peptides with membrane-associated proteoglycans such as heparan sulfate and chondroitin sulfate may activate intracellular signals to induce actin organization and thus promote macropinocytosis (*13*). Similar observations were reported in the cellular uptake of oligomers of β-amino acids bearing guanidino moieties (*14*) and amphiphilic peptide vectors (MPG) using a noncovalent complex-formation approach (*15*). Macropinocytosis may therefore be an important uptake mechanism for arginine-rich peptides, but as previously described (*16*), there is strong evidence that other pathways are also utilized including those employing clathrin coats (*10*) and caveolae (*17*); associated cargo is also likely to affect the entry mechanism.

There is, however, accumulating evidence that arginine-rich peptides in particular enter cells in the absence of energy and thus endocytosis (*11, 18, 19*). Fluorescent R8 peptide incubated on ice with a variety of different cell types shows diffuse and often uniform labeling throughout the cytosol and nucleus; the D-R8 isoform also has a strong tendency to label the nucleolus (*11, 18, 19*). In contrast, fluorescent microscopy observations of cells treated with the R8 peptide at 37 °C yield punctate signals that have been identified as endocytic structures. This phenotype is similar to that observed when cells have been fixed following incubation at 37 °C (*8*). This is however an artifact caused by disturbance of plasma membrane during fixation (*9, 11*); arginine-rich peptides have a high tendency to adsorb to cell surface and enter cells through damaged plasma membranes caused by fixation. However, our observation of 4 °C internalization of R8 peptides was using living cells, and the integrity of the plasma membranes was confirmed by the absence of nuclear staining of the membrane-impermeable dye propidium iodide (PI) (*11*). These results strongly suggest that

endocytosis is not the sole internalization mechanism for arginine-rich peptides.

Although the effects of various factors, including temperature (*9, 11, 12, 19*), membrane-associated proteoglycans (*10, 13, 20–25*), and membrane potential (*26*), have been shown to affect the internalization of arginine-rich peptides, very few studies have investigated the influence of serum proteins and culture media components. For example, the influence of serum needs to be carefully assessed if these in vitro models are designed to more closely represent in vivo studies (*27*).

In this report, we examine the effect of serum on the internalization of oligoarginines (R*n*) having different numbers of arginines ($n = 4, 8, 12, 16$). We show that the internalization of the longer R12 and R16 peptides is significantly reduced in the presence of serum. This is a likely consequence of their higher capacity to bind serum proteins. We also show that the peptides can enter cells via at least two mechanisms, and at low concentrations, this leads to labeling of endocytic structures, but at higher concentrations, extensive cytosolic labeling is observed. The prominence of this labeling is dependent on whether incubations are performed in the presence or absence of serum, and finally we confirm that, under defined conditions, energy-independent, direct translocation across the plasma membrane represents a major route of entry for peptides R8, R12, and R16.

EXPERIMENTAL PROCEDURES

Peptides and Proteins. All the peptides used in this study were chemically synthesized by Fmoc (9-fluorenylmethyloxycarbonyl) solid-phase peptide synthesis as reported (*28*). Actual sequences of the synthesized peptides: R*n* ($n = 4, 8, 12, 16$), R*n*-amide; R*n*−Alexa488 ($n = 4, 8, 12, 16$), R*n*-GC(Alexa488)-amide; R12−PAD, RRRRRRRRRRRRGC-CG-D-(KLAKLAK)$_2$-amide. The EGFP protein bearing a $(His)_6$ segment was also prepared as previously reported (*28*). Details of the preparation of peptides and proteins are described in the Supporting Information.

Cell Culture. Human cervical cancer-derived HeLa cells were cultured as exponentially growing subconfluent monolayers on 60 mm dishes in alpha-minimum essential medium (α-MEM) (Invitrogen) supplemented with 10% (v/v) bovine serum (Invitrogen). Chinese hamster ovary (CHO) cells including wild-type CHO-K1, and all glycosaminoglycan-deficient pgsA-745 (A-745) were purchased from the American Type Culture Collection (ATCC) and maintained in F-12 nutrient mixture (Ham's F-12) (Invitrogen) supplemented with 10% (v/v) fetal bovine serum (Biological Industries). Cells were maintained at 37 °C in a humidified 5% CO_2 incubator, and a subculture was performed every 3–4 days.

Confocal Microscopy. Two × 10^5 cells were plated into 35 mm glass-bottomed dishes (Iwaki) and cultured for 48 h. The cells were washed twice with one of three types of incubation buffers (serum-containing medium, serum-free medium, or PBS supplemented with 100 mg/L $CaCl_2$ and $MgCl_2 \cdot 6H_2O$), prior to addition and incubation with peptides and propidium iodide (PI), the latter to assess cell integrity. Intracellular distribution of the fluorescently labeled peptides was immediately analyzed (less than 3 min) *without washing and fixing* using an Olympus FV300 confocal scanning laser system consisting of an Olympus IX81 microscope equipped with a 0.85 NA UPlanApo 40× objective lens. For 4 °C experiments, cells were preincubated in a refrigerator (4 °C) for 1 h; washing and incubation of the cells was then conducted using ice-cold incubation buffer and the 4 °C refrigerator, respectively, prior to observation of the cells, *without washing,* by confocal microscopy. For experiments investigating the role of membrane potential, a buffer PBS(K^+), where the sodium salts in PBS were replaced with equimolar amounts of the equivalent potassium salts, was used (*26, 29*). For experiments employing transferrin, cells were washed twice with an incubation buffer prior to a 30 min incubation with peptides and rhodamine-labeled transferrin (Rho–Tf, 25 μg/mL) (Molecular Probes) diluted with the respective incubation buffer. For the experiments with mitochondrial membrane potential probe JC-1 (Molecular Probes—this exhibits a red-to-green color shift in accordance with depolarization of mitochondrial membrane potential), cells were washed twice with an incubation buffer prior to treatment with R12–PAD (4 μM) for 1 h. After washing twice with PBS and staining with JC-1 (5 μM) for 30 min in α-MEM containing 10% bovine serum, the cells were analyzed by confocal microscopy.

Flow Cytometry. Five × 10^4 HeLa cells were plated into 24 well microplates (Iwaki) and cultured for 48 h. The cells were washed twice with an incubation buffer prior to incubation with peptides in the respective buffers. The cells were then washed twice with PBS containing 0.5 mg/mL heparin and then incubated with 0.01% trypsin for 10 min at 37 °C. The cells were harvested and centrifuged at 3000 rpm for 5 min. The cell pellet was suspended and washed twice with PBS and finally resuspended in PBS for fluorescence analysis with a FACS Calibur flow cytometer (BD Biosciences) using a 488 nm laser excitation and a 515–545 nm emission filter. Each sample was analyzed for 10 000 events.

Cytotoxicity Test. The MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide] assay and the lactate dehydrogenase (LDH) release assay were conducted essentially as previously reported (*29*). Briefly, 5 × 10^3 cells were plated into 96 well microplates (Iwaki) and cultured for 48 h. The cells were washed twice with an incubation buffer and treated with peptides (10 μM) for 30 min at 37 °C. After incubation, cytotoxicity was evaluated with MTT assay and LDH release assay as reported (see Supporting Information).

Interaction of Oligoarginine Peptides with Serum Proteins. R12−Alexa488 was diluted (0–20 μM) with serum-containing medium [α-MEM(+)] or serum-free medium [α-MEM(−)] and incubated for 5 min at room temperature prior to analysis by nondenaturing gel electrophoresis using a 5–20% native polyacrylamide gel (SuperSep, purchased from Wako). Bovine serum albumin (0.25 μg) and EGFP (0.5 μg) were respectively used as protein and fluorescent-protein standards. The gel was analyzed with FluorImager595 (Molecular Dynamics) to obtain fluorescence images using 488 nm laser excitation and 515–545 nm emission filter. Staining for proteins with Coomassie Brilliant Blue (CBB) was then conducted. For the experiment to evaluate the amount of the peptides adsorbed to serum proteins, R8−Alexa488, R12−Alexa488, and R16−Alexa488 were diluted to 10 μM in α-MEM(+), α-MEM(−), or PBS and incubated for 5 min at room temperature. Each peptide solution was then subjected to ultrafiltration using Microcon YM-30 centrifugal filter (Millipore) (molecular weight cutoff 30 000) at 14 000 × *g* for 12 min to separate the "free" peptide (unbound with serum) from the peptide adsorbed with serum proteins. Fractional ratios of peptides (*F*) were calculated using the following equation:

$$F = A/(A + B) \quad (1)$$

where *A* is the number of moles of the peptide adsorbed to serum proteins (the peptide remaining on the ultrafilter membrane) and *B* is the number of moles of the unbound peptide (i.e., the peptide in the filtrate). Concentration of a peptide in each fraction was determined by using extinction coefficient of Alexa488 ($\epsilon = 72\,000$, Molecular Probes).

RESULTS

Effects of Serum on the Internalization of Oligoarginine Peptides. Typically, qualitative and quantitative analysis of CPP uptake is performed after they have been incubated with cells

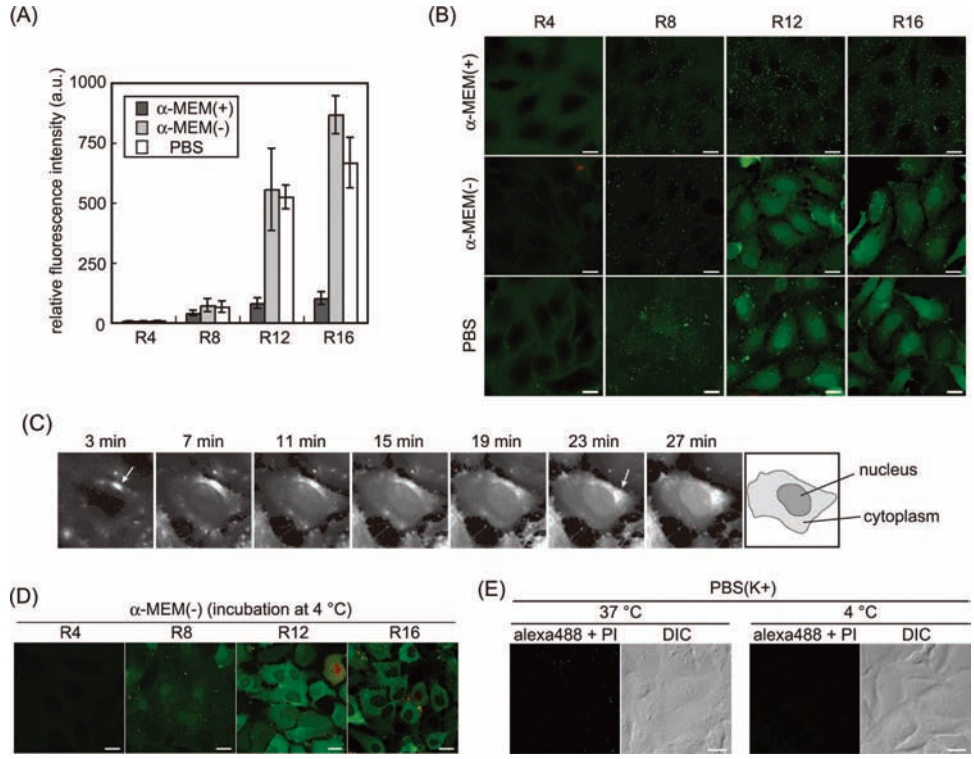

Figure 1. Effects of serum on the internalization of oligoarginine peptides. (A) HeLa cells were incubated with Alexa488-labeled oligoarginine peptides (5 μM) for 15 min in medium containing 10% serum [α-MEM(+)], serum free medium [α-MEM(−)], or PBS prior to trypsin treatment and quantification by flow cytometry. Error bars represent the mean ± standard deviation (SD) of 3 separate experiments. (B) HeLa cells were incubated with oligoarginine peptides (5 μM) for 30 min in α-MEM(+), α-MEM(−), or PBS in the presence of propidium iodide (PI, 1.5 μM) and immediately analyzed by confocal microscopy without washing. All images are merged fluorescence images derived from analysis of Alexa488 (green) and PI (red) labeling. (C) Time course study of R12 (5 μM) internalization in HeLa cells in α-MEM(−) at 37 °C. Arrows indicate the initiation points of the internalization of the R12 peptide. To avoid saturation of the fluorescence signals, the photomultiplier voltage was decreased during the incubation. (D) Confocal microscopic images of HeLa cells incubated with oligoarginine peptides (5 μM) in α-MEM(−) for 30 min at 4 °C in the presence of PI (1.5 μM). (E) Effects of membrane potential on cellular uptake of R12. HeLa cells were incubated with R12−Alexa488 (5 μM) and PI using PBS(K^+) at 37 or 4 °C. Scale bars, 20 μm.

in complete media, serum-free media, or simple buffers such as PBS. Initially, we investigated what effects the addition of serum to the incubation media has on the internalization of peptides of different chain lengths R4, 8, 12, and 16. HeLa cells were treated with Alexa488-conjugated peptides in α-minimal essential medium containing [α-MEM(+)] or lacking [α-MEM(−)] 10% (v/v) bovine serum; phosphate-buffered saline (PBS) was also employed as an alternative incubation buffer. The cells were treated at 37 °C with 5 μM of each respective peptide for 15 min, and the amount of internalized peptides was then quantified by flow cytometry (Figure 1A). R4 showed minimal cellular uptake in both the absence and presence of serum. In the presence of serum, we observed a small increase in internalization R16 > R12 > R8. Performing identical experiments in media lacking serum resulted in a 1.8-fold increase in R8 uptake but a much higher 6.9- and 9.0-fold increase in R12 and R16 uptake, respectively. Performing the same experiments in PBS had effects similar to that of depleting serum from the media.

The presence of serum also had a major impact on the distribution of the peptide inside cells with the greatest effects noted for R12 and R16 (Figure 1B). Earlier studies have shown that fixation prior to microscopic observation, using agents such as paraformaldehyde and acetone/methanol, causes redistribution in the localization of oligoarginine peptides and other arginine-rich peptides (*9, 11*). Additionally, extensive washing with PBS may damage the plasma membrane to affect the cellular localization of these peptides (data not shown). To avoid these experimental artifacts, immediate and direct confocal microscopic observation was conducted in this study *without cell washing and fixation* after incubation of the cells with oligoarginine peptides for 30 min. In complete media incubations, all the peptides typically labeled punctate, endolysosomal-like structures (Figure 1B). However, the R12 and R16 peptides in serum-free incubations displayed marked cytosolic and nuclear labeling together with punctate signals. Time-course imaging of the cells revealed that the initial translocation of the R12 peptide did not occur throughout the cell but at defined locations, and this labeling then diffused through the cytosol and nucleus (Figure 1C). This phenomenon was observed in of the majority of cells, and similar observations were recently reported utilizing a FITC-conjugated R9 peptide (20 μM) incubated with the same HeLa line (*30*).

Provided stringent care is taken to remove surface bound peptide, there is evidence that internalization at 4 °C is marginal or negligible compared with experiments performed at 37 °C (*9–12*). However, we and others have shown significant internalization at 4 °C, but the peptide was localized diffusely through the cytosol and nucleus (*11*, *18*, *19*, *31*, *32*). We similarly incubated HeLa cells with all the peptides at 4 °C and observed significant cytosolic labeling, most notably of R8, R12, and R16 (Figure 1D). Similarly with Figure 1C, internalization of the peptide started at defined locations of the cells followed by the diffusion through cytosol and nucleus (data not shown). Interestingly, nuclear labeling of R12 and R16 peptides in serum-free incubations was less intense at 4 °C as compared with 37 °C and implies that, under these conditions, energy is required for nuclear delivery.

The data so far suggested that, in the absence of serum and at 5 μM concentration, a large fraction of both R12 and R16 peptide was internalized via an energy-independent nonendocytic mechanism. This was not due to peptide-mediated membrane disruption, as all the experiments shown in Figure

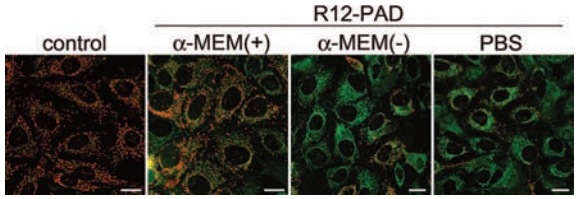

Figure 2. Inhibition of mitochondrial membrane potential by the apoptosis-inducing peptide R12−PAD. HeLa cells were incubated with R12−PAD (4 μM) for 1 h at 37 °C using α-MEM(+), α-MEM(−), or PBS prior to staining with mitochondrial membrane potential-sensitive dye, JC-1 (5 μM). A red-to-green shift of color represents depolarization in membrane potential of mitochondria. Scale bars, 20 μm.

1B,D were conducted in the presence of the membrane-impermeable probe, propidium iodide (PI), that, under all conditions, did not enter the cells.

Since the heterologous distribution of ions on either side of the plasma membrane gives rise to a membrane potential keeping the interior of the cell more negative than the exterior, this may be a driving force for positively charged peptides to translocate across the plasma membrane (*26*, *29*, *33*, *34*). We therefore investigated this further by conducting the same experiments in PBS containing equimolar concentrations of K^+ [PBS(K^+)] rather than Na^+; PBS(K^+) is an isotonic buffer containing potassium concentrations equivalent to that found inside cells, and incubation with this buffer eliminates the membrane potential (*26*). The presence of very few PI-positive cells suggested that eliminating membrane potential had no effect on membrane integrity, but additionally, we found that the internalization and consequent diffuse labeling of the R12 peptide that we observed at 37 °C (Figure 1B) and 4 °C (Figure 1D) was completely blocked under these conditions (Figure 1E). Therefore, membrane potential contribute as a major driving force for the diffuse labeling that we observed at both temperatures.

We next investigated whether the plasma membrane translocating ability of R12 in the absence of serum could be utilized to deliver biologically active cargo. For this, we conjugated R12 to an apoptosis-inducing peptide (pro-apoptotic domain, PAD) (*35*). PAD is an amphiphilic basic peptide that includes 14 residues of D-amino acids, D-$(KLAKLAK)_2$. We previously reported that cytosolic delivery of the PAD peptide using oligoarginine peptides induces mitochondrial membrane disruption and eventual apoptosis (*11*, *28*). Depolarization of mitochondrial membrane potential that accompanies the early stages of apoptosis (*36*) can be monitored using a mitochondrial membrane potential-sensitive probe, JC-1 (*37*). This probe forms aggregates in intact mitochondrial membranes to give a red fluorescence, whereas depolarization of mitochondrial membrane potential induces JC-1 dissociation and green fluorescence. The efficiency of cytosolic delivery of PAD by the R12 peptide was therefore assessed using this probe (Figure 2). In the absence of R12−PAD conjugate, red staining of mitochondria was predominantly observed, suggesting the intactness of mitochondria (Figure 2). When the cells were treated with 4 μM R12-PAD in α-MEM(+) (37 °C, 1 h), a slight shift in JC-1 emission (red to yellow) was observed. However, a dramatic red-to-green shift in fluorescence corresponding to depolarization in mitochondrial membrane potential was observed when the cells were treated with R12−PAD in α-MEM(−) or PBS. These results are in good agreement with an increase in cellular uptake of R12 peptide under serum-free conditions as shown in Figure 1. This suggests that bioactive cargos as well as R12 peptide itself are also efficiently delivered into the cytosol in serum-free conditions.

The absence of PI staining of nucleus after a 30 min incubation with R12 in serum-free medium suggested that there was no significant damage to the plasma membranes when cells were incubated in serum-free conditions (Figure 1B). Incubation of cells in the absence of serum or in PBS could, however, have more long-term detrimental effects. We tested this using an MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide] viability assay (*38*) and lactate dehydrogenase (LDH) release assay (*39*). Figure 3A,B demonstrates that treatment of cells in the absence of serum under these defined conditions had no significant effects on cell integrity or viability.

Transferrin is a marker for endocytosis via clathrin-coated vesicles, and we investigated whether R12 incubations in serum-free conditions affected the uptake of transferrin into endocytic vesicles. Cells were coincubated with R12 peptide and rhodamine-labeled transferrin (Rho–Tf) for 30 min, and the cellular distribution of both labels was monitored by confocal microscopy. Figure 3C shows that the diffuse cytosolic and nuclear labeling of the R12 peptide under serum-depleted conditions does not affect Rho–Tf distribution and this labels, as in control cells, distinct vesicular structures. Thus, under serum-free conditions, R12 peptide at this concentration can be internalized by at least two mechanisms: temperature-dependent endocytic uptake with prominence of peptide in vesicular structures, and temperature-independent direct translocation of the peptide through the membranes yielding the characteristic, diffuse cytosolic labeling.

Interaction of Oligoarginine Peptides with Serum Proteins. From the above experiments, we found that the absence of serum in the medium gives distinct intracellular distribution of the R12 peptide, i.e., diffuse cytosolic, together with the punctate cytoplasmic distribution that we typically observe in the presence of serum. It is known that HIV-1 Tat peptide, another typical arginine-rich CPP, interacts with bovine serum albumin (BSA), a major acidic protein in serum (*40*). Although adsorption of the arginine-rich peptides used here may be expected, there have been no detailed examination of the extent or importance of this to their interaction with cells and cellular distribution.

To assess the extent of the peptide−serum interaction, increasing quantities of R12−Alexa488 was diluted in α-MEM(−) or α-MEM(+), and the samples were incubated for 5 min prior to separating the proteins via *nondenaturing* gel electrophoresis. The gels were then stained with Coomassie Brilliant Blue (CBB) that as expected highlighted the presence of multiple bands including a prominent albumin band (Figure 4A).

These experiments were repeated but the gels analyzed on the FluorImager that allowed detection of proteins associated with the fluorescent peptide; EGFP was also loaded and provided a positive control. Figure 4B demonstrates that a number of fluorescent bands were detected in the α-MEM(+) lanes, and their intensity was increased with increasing peptide concentration. A major fluorescent band, indicated by the arrow, migrated at the same position as the band in the BSA−R12 mixture lane (BSA+R12), suggesting that a significant amount of R12 was binding to this protein. In the control experiment, using α-MEM alone, neither R12-derived fluorescence signals nor CBB staining was detected.

The amount of oligoarginine peptide adsorbing to serum proteins was then evaluated using an ultrafiltration method. R8−, R12−, and R16−Alexa488 peptides were incubated as described above with α-MEM(−), α-MEM(+), or PBS prior to passing the samples through a 30 000 molecular weight ultrafiltration unit. The relative amounts of filtered peptide were then compared with the bound unfiltered fraction (Table 1). The data revealed that a considerable fraction of all these arginine peptides bound to serum proteins, and in the case of R16, this represented 97% of the total peptide load. Together with the previous data, this explains why there is such a difference in

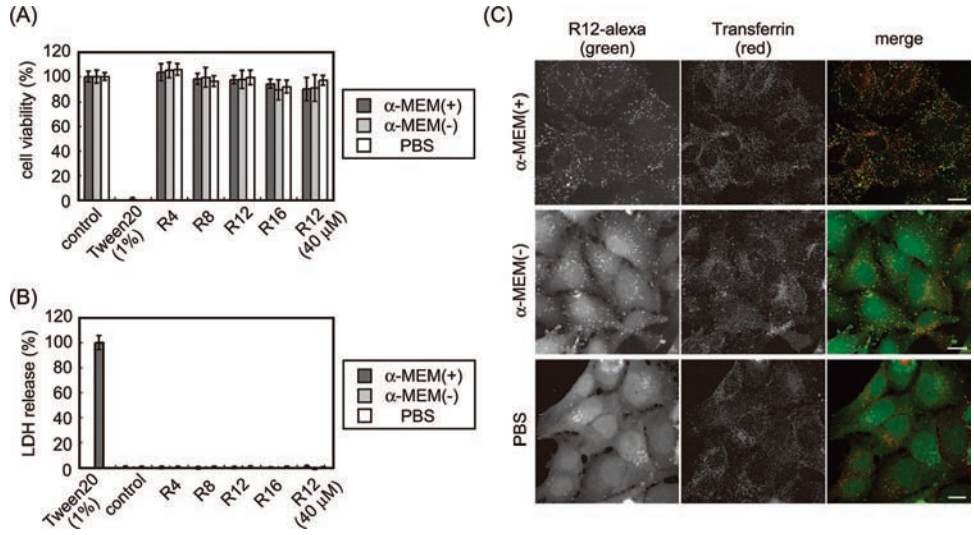

Figure 3. Incubation of cells with oligoarginine peptides in serum-free medium does not affect cell viability, plasma membrane integrity, or endocytosis of transferrin. (A,B) HeLa cells were incubated with nonlabeled oligoarginine peptides (10 μM) for 30 min in α-MEM(+), α-MEM(−), or PBS prior to assessing cell viability (A) and plasma membrane integrity (B). Error bars represent the mean ± SD of a single experiment performed in triplicate. (C) HeLa cells were coincubated with Alexa488-labeled R12 peptide (5 μM) and Rho–Tf (25 μg/mL) for 30 min in α-MEM(+), α-MEM(−), or PBS prior to analysis by confocal microscopy. Scale bars, 20 μm.

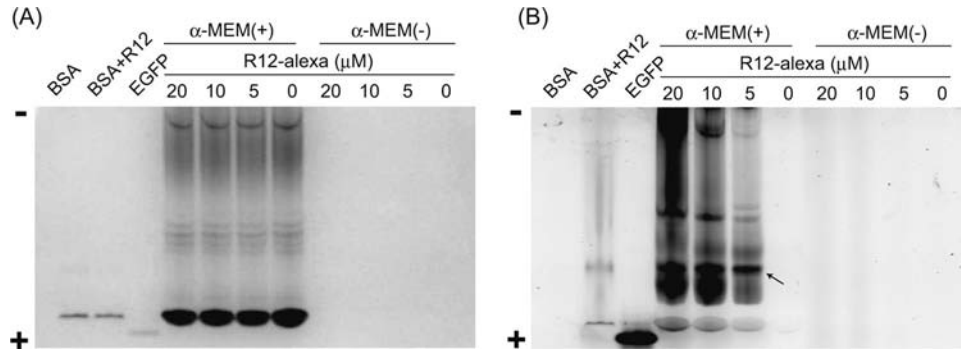

Figure 4. Interaction of oligoarginine peptides with serum proteins. Alexa488-labeled R12 (0–20 μM) was incubated with α-MEM(+) or α-MEM(−) for 5 min at room temperature prior to analysis by *nondenaturing* gel electrophoresis. (A) Proteins detected with CBB. (B) Detection of fluorescently labeled peptide (R*n*−Alexa) as protein complexes. EGFP was used as a positive fluorescent control, and a faint EGFP band is also detected by CBB. The + and − show the direction of the electric field.

Table 1. Percentage of Peptide Bound to Serum Proteins[a]

	R8−Alexa488	R12−Alexa488	R16−Alexa488
α-MEM(+)	64.4 ± 6.8	75.4 ± 11.2	97.4 ± 3.0
α-MEM(−)	0	0	0
PBS	0	0	0

cellular peptide distribution in experiments performed in the absence of serum.

Cytosolic Labeling of R12 Peptide and Concentration of the Peptide Actually Interacting with Plasma Membranes. It is postulated that positive charges on arginine-rich CPPs are one of the most important determining factors for their cellular uptake. This may be due to strong electrostatic interaction with membrane-associated proteoglycans thus concentrating the peptides on cell surfaces. Serum binding of oligoarginine peptides would decrease the effective concentration of the peptides in the medium, and less would be then available to interact with cell surfaces; this could significantly affect the amount internalized. We tested this by incubating R12 peptide with medium supplemented with various concentration of serum (0–10%) and then utilized ultrafiltration to quantify the bound and unbound fraction as described above. Figure 5B shows that decreasing the serum concentration resulted in an increase in the ratios of unbound R12 peptide over serum-bound peptide, and this resulted in an absolute increase in the amount of R12 peptide that was internalized into the cells. This effect was more prominent in experiments performed with the R12 and R16 peptides compared with the R4 and R8 peptides. A 6- to 8-fold increase in cellular uptake of R12 and R16 was observed in the absence of serum in comparison with experiments performed in the presence of 10% serum, whereas only a 1.5-fold increase was observed for the R8 peptide (Figure 5A). Microscopic observations of the cells treated with the R12 peptide in the presence of varying amounts of serum showed that diffuse labeling of the cytosol by the R12 peptide was prominent at lower concentration of serum, especially at ≤2% (Figure 5C). Interestingly, there was only a slight increase (~10%) in the amount of serum-unbound peptide at serum concentration 2% compared with 4%; however, this manifested as a doubling of the amount of internalized peptide (Figure 5B). A marked difference in the distribution of the R12 peptide (diffuse vs punctate) was also observed between serum concentration of 2% and 4% (Figure 5C). These results further support the importance of the effective extracellular peptide concentration on both the internalization mechanism and the final peptide distribution in cells.

Recent published analysis (*19*, *30*) and data presented here suggest that there is a threshold peptide concentration for

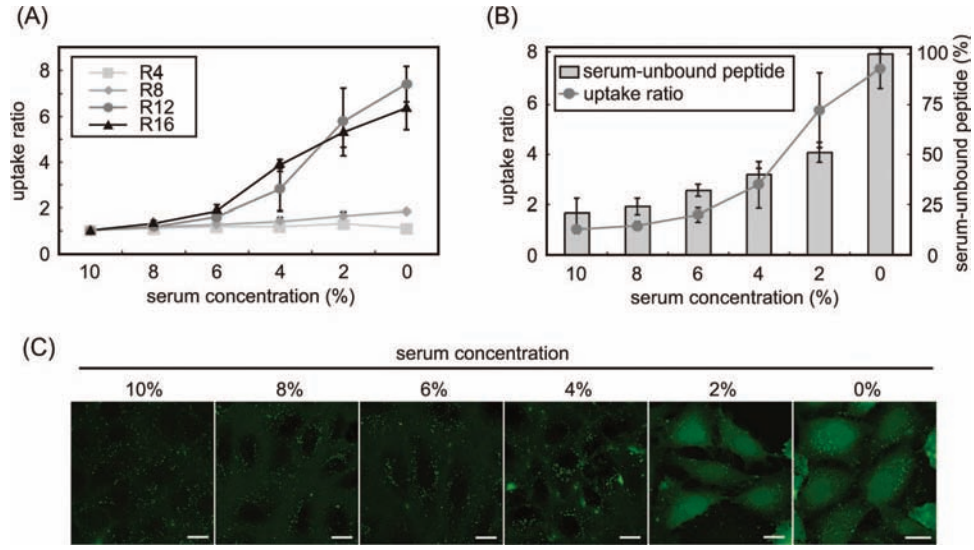

Figure 5. Serum concentration plays a major role in the cytosolic labeling of R12 peptide. (A) HeLa cells were incubated with oligoarginine peptides (5 μM) for 30 min at 37 °C in α-MEM supplemented with various concentration of serum (0–10%) prior to analyzing cell fluorescence by flow cytometry. The data are expressed as the ratio of fluorescence of each condition over the fluorescence of experiments performed in 10% serum. (B) Cells were incubated for 30 min in the presence of α-MEM containing increasing serum concentration. Data show a positive correlation between serum-unbound R12 peptide (columns) and cellular uptake (circles, same data as in (A)). Error bars represent the mean ± SD of 3 separate experiments. (C) HeLa cells were treated with R12−Alexa488 (5 μM) as in (A) and immediately analyzed by confocal microscopy. Scale bars, 20 μm.

cytosolic diffuse labeling. To quantify this threshold value, we measured fluorescence in cells after they had been incubated with increasing concentrations (0.1–40 μM) of R12−Alexa488 in the presence and absence of serum for 30 min. The data in Figure 6A show that in the absence or presence of serum there is a gradual increase in peptide uptake up to 2 μM [α-MEM(−)] and 10 μM [α-MEM(+)], and thereafter fluorescence increased rapidly. Time course study of peptide uptake also suggests the presence of a threshold concentration for diffuse cytosolic labeling (see Supporting Information Figure S1). Following incubation of cells in α-MEM(−) or α-MEM(+) at peptide concentration just below this threshold concentration, we see by fluorescence microscopy that labeling is confined to punctate endocytic structures. However, at higher than threshold concentrations, the labeling is both diffuse/cytosolic and vesicular (Figure 6B). This suggested that endocytic uptake is a dominant pathway for internalization of R12 peptide at lower than the threshold concentration, and diffuse cytosolic labeling is observed when the peptide concentration exceeds this value.

Importance of Membrane-Associated Proteoglycans to Increase Cell-Surface Concentration of the Oligoarginine Peptides. The importance of plasma membrane associated proteoglycans for endocytic uptake of a number of arginine-rich peptides has been reported in several publications (*10, 13, 20–25*). It is assumed that these positively charged peptides accumulate on the cell surfaces by electrostatic interaction with carbohydrate sulfate groups. The ubiquitous occurrence of membrane-associated proteoglycans on the cell surface together with their tight and rapid interaction with the arginine-rich peptides has been considered a primary step in the internalization of these peptides (*22*). We therefore examined whether surface proteoglycans have any role in mediating the difference in distribution of fluorescence that we observed at peptide concentrations lower and higher than the threshold. For this, we utilized two types of Chinese hamster ovary CHO cell lines; the wild-type CHO-K1 line, and its mutant variant, A-745, that is defective in proteoglycan biosynthesis (*13, 21*).

Both cell lines were incubated with increasing concentrations of R12 peptide in the absence of serum at 37 °C for 15 min prior to quantifying cell fluorescence using flow cytometry or analysis by confocal microscopy. Figure 7A shows that internalization of the peptide at ≤1 μM is similar in both cell lines but at higher concentration the mutant cell line accumulates significantly less peptide. Confocal microscopy images of arrowheads a−d in Figure 7A show that diffuse labeling of the cytosol can be achieved in both cell lines but at noticeably different peptide concentrations (Figure 7B). Punctate signals from the R12 peptide suggestive of endocytosis were predominantly observed for A745 cells at 5 μM peptide concentration. Increasing in the concentration to 30 μM yielded the diffuse labeling of cytosol, suggesting that a similar concentration-dependent two-phase internalization of the peptides occurs in this proteoglycan-deficient cell line. In the case of the wild-type CHO-K1 cell line, diffuse cytosolic staining was observed even at the relatively low 5 μM concentration, whereas at 2.5 μM, only punctate structures were visible. The presence of membrane-associated proteoglycans was therefore effective to enhance R12 translocation to give diffuse cytosolic staining, and this we attribute to the increased concentration of the peptides in the vicinity of the cell surfaces.

DISCUSSION

A variety of endocytic pathways have been shown to be utilized by CPP to gain access to cells (*9, 11, 14*). We have however provided evidence that predominantly arginine-rich peptides as used in this study have a propensity to translocate across the plasma membrane when experiments are performed on ice, when defined endocytic pathways cease to function (*11, 18, 19, 41*).

In this study, we have explored the methods of internalization and intracellular distribution of oligoarginine peptides in PBS and medium containing or lacking supplemented serum. We show that serum proteins have considerable effect on the internalization of oligoarginine peptides, especially in the case of the longer R12 and R16 peptides. Incubation of cells with these peptides in serum-free medium significantly enhanced the fraction of the cytosolic peptides that was in marked contrast to the punctate labeling that we observe in identical experiments performed in complete medium. This highlights further the fact that internalization of these peptides can proceed via at least two mechanisms, and we rationalize that only one is dependent

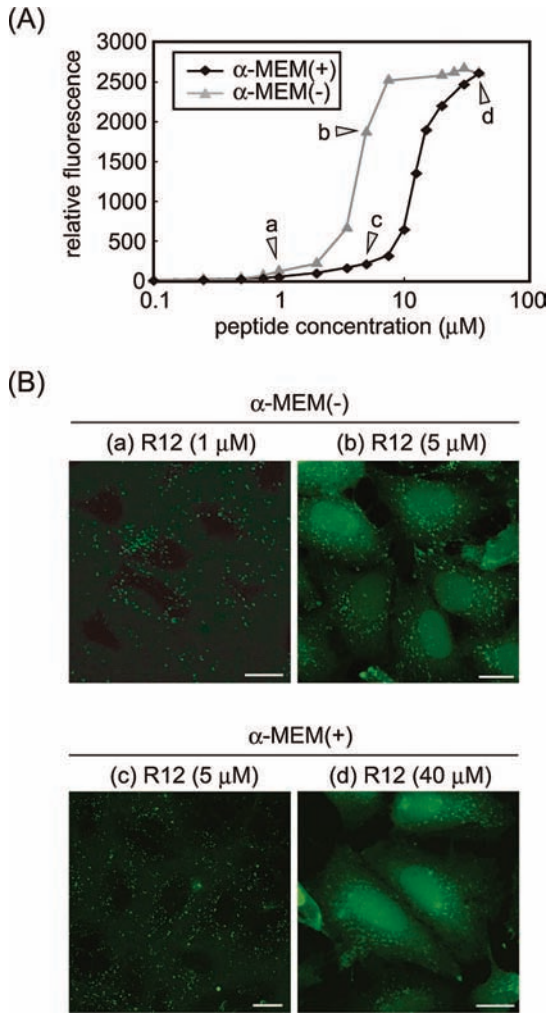

Figure 6. Concentration-dependent two-phase internalization of R12 peptide. (A) HeLa cells were incubated with R12−Alexa488 (0.1–40 μM) for 30 min in α-MEM(+) or α-MEM(−) prior to analysis by flow cytometry. The data represent average values from 2 to 3 separate experiments. (B) Intracellular distributions of the R12 peptide corresponding to a−d in (A). Scale bars, 20 μm.

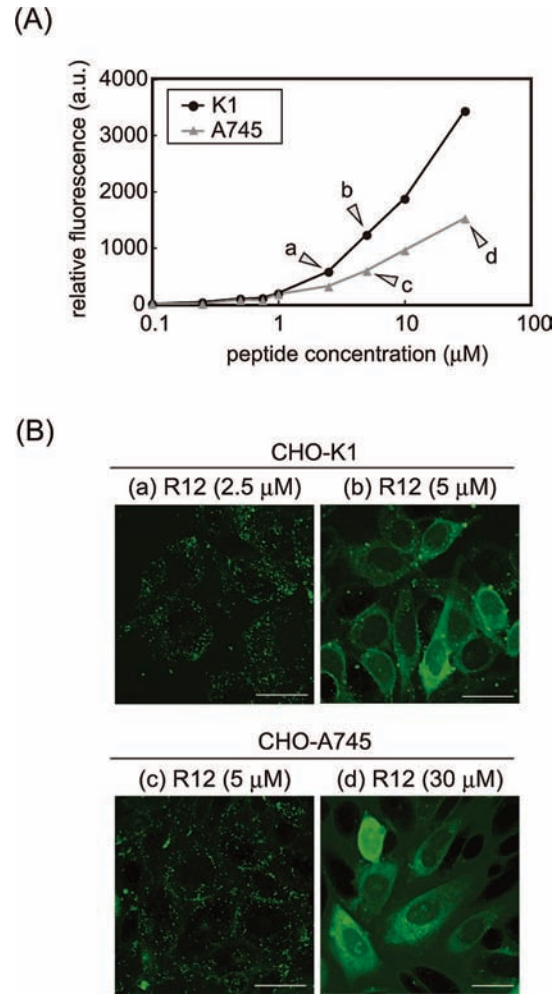

Figure 7. Contribution of surface proteoglycans to intracellular distribution of R12 peptide (A) CHO-K1 cells and proteoglycan-deficient A745 cells were incubated with R12 (0.1–30 μM) in serum-free medium [F-12(-)] at 37 °C for 15 min prior to analysis by flow cytometry. The data represent average values from 2 to 3 separate experiments. (B) Intracellular distribution of the R12 peptide corresponding to arrowheads a−d in (A). Scale bars, 20 μm.

on typical and characterized endocytic pathways. The presence of serum, because it quenches the effective peptide concentration, significantly increases this threshold concentration.

In our previous study, we observed a similar cytosolic labeling of the R8 peptide in PBS in the presence of counteranions such as pyrenebutyrate (*29, 42, 43*). In the presence of pyrenebutyrate, R8 peptide was internalized with high efficiency in a very short period of time to label the cell cytosol, and we proposed that this was via direct translocation through the plasma membrane. Since this efficient internalization was not observed in the absence of the membrane potential, this was proposed as the driving force for peptide translocation. Pyrenebutyrate is sequestered in the membranes via complex formation with the peptides through its carboxylate moiety, and it would neutralize the positive charges of the oligoarginine peptides to decrease the energy barrier on the translocation of the peptides through the membranes. Alternatively, the pyrenebutyrate carboxylate moiety may work to increase the interaction of the peptides with cell surfaces via hydrogen-bond formation with the arginine guanidino moiety.

The internalization of the R12 peptides shown in this study has many aspects in common with translocation of the R8 peptide in the presence of pyrenebutyrate, namely, nonendocytic uptake via plasma membrane translocation, diffuse cytosolic labeling initiating from specific cell locations, internalization at 4 °C, and a dependency on membrane potential (*29*). R12 and R16 peptides would have higher affinities both to serum proteins and cell surfaces than R8 and R4 due to their higher valency of interaction. Oligomerization of 12 residues of arginine may acquire enough affinity to interact with the plasma membrane to achieve direct translocation through the membrane and also to lead a marked increase in their cellular uptake, as is seen for R8 in the presence of pyrenebutyrate. We previously showed that the R8 peptide can partition into chloroform in the presence of the negatively charged phospholipid, phosphatidylglycerol (*44, 45*). Such negatively charged counteranions in the membrane may similarly aid R12 translocation.

It has been reported that membrane-associated proteoglycans are important for the cellular uptake of arginine-rich peptides (*10, 13, 20–25*). We and others also reported that these are critical for peptide-induced actin reorganization and macropinocytosis (*11, 13, 14*). The results obtained here suggest that they have additional roles in enhancing peptide uptake and this is via their capacity to increase the local peptide concentration. Even though oligoarginine peptides may have a higher affinity for sulfate moieties on proteoglycans than plasma membranes (*23*), the increase in local concentration of the arginine-rich peptides in the vicinity of the cell surface would be beneficial to increasing gradient formation across the membranes.

More recently, we reported that a similar diffuse R8 labeling of the cytosol was observed in KG1a leukemia cells, even in the presence of serum, when their plasma membrane cholesterol levels were depleted by methyl-β-cyclodextrin (*19*). In a more recent study, Duchardt et al. showed that depetion of plasma membrane cholesterol promoted the cellular uptake and cytosolic labeling of R9 peptide, but only when the cells were incubated at peptide concentrations ≥ 5 μM (*30*). It could therefore be postulated that endocytic uptake inhibits the accumulation of the peptides on the plasma membrane to reach the threshold levels that then promote translocation to the cytosol. *Inhibitors of endocytic uptake of oligoarginine peptides could therefore contribute to increase the peptide concentration on plasma membrane* and thus promote diffuse cytosolic labeling. Indeed, diffuse cytosolic labeling of R8 peptide was observed when the cells were incubated with peptides at low temperatures (*11, 18, 19*) and, in the presence of the macropinocytosis inhibitor, 5-(*N*-ethyl-*N*-isopropyl)amiloride (EIPA) (*30, 46*).

We previously showed that there is a threshold concentration that needed to be exceeded before visual cytosolic labeling of R8 peptide in nonadherent carcinoma KG1a cells was observed (*19*); similar observations were later shown in adherent cells (*30*). In the present study, detailed analysis of cellular uptake at varying concentration of the peptides similarly showed that the extent of R12 cytosolic labeling is highly dependent on peptide concentration, but we also found that a relatively small increase in peptide concentration beyond this threshold results in a marked increase in cellular uptake and change in intracellular distribution of peptides.

The sigmoidal relationship between R12 peptide concentration and cellular uptake also supports the existence of this threshold concentration that is likely to be different for different cell types. Here, we also discover that a considerable amount of the oligoarginines is associated with serum proteins and the presence of serum in the incubation promotes a right-side shift of the sigmoidal curve, suggesting that adsorption of the peptide with serum protein decreases the concentration of the peptides that can actually interact with the plasma membrane. Curve plateaus at higher peptide concentrations suggest that saturation of the amount internalized can be achieved in the presence and absence of serum, though of different values. The determining factor may be the intracellular peptide concentration that eliminates the peptide gradient between the outside and inside of the cells in the presence of membrane potentials.

The number of arginine residues in the peptide sequence is a major determining factor for interaction with cells and consequent internalization. Diffuse cytosolic labeling was clearly observed with R12 peptide at 5 μM in the absence of serum but not by the R8 peptide; however, in leukemia cells this same peptide was cytosolic at this concentration in serum, whereas only vesicular labeling was observed at 2 μM (*19*). In the present study, the addition of four arginine residues caused a dramatic change in intracellular distribution. The R12 peptide will have a higher propensity to bind negative charge on the cell surface, and its higher concentration on the cell surface will promote comparatively higher membrane translocation compared with R8.

A major goal in our laboratories and many others is to develop novel methods for efficient, direct, and easy delivery of exogenous biofunctional molecules initially to the cell and then to cytosol under serum-containing condition. We have found that the R12 peptide achieves this cytosolic labeling with a threshold concentration of $\sim$20 μM, a value that renders this approach unsuitable for in vivo delivery. However, the design of peptides with minimal interaction with serum proteins and maximal interaction with cell surfaces could lead to the establishment of CPPs with decreased threshold concentrations for cytosolic delivery. Efforts to develop peptides with optimized molecular structures to achieve efficient cytosolic localization with bioactive cargo molecules in low concentration are now ongoing. In addition, as CPP conjugates have shown in vivo responses such as cell transformation (*5, 6*) it could be argued that binding to serum proteins may be favorable for extending the half-life of the peptide and associated therapeutic cargo.

ACKNOWLEDGMENT

This work was supported in part by Grants-in-Aid for Scientific Research from the Ministry of Education, Culture, Sports, Science and Technology of Japan. T.T. is grateful for a JSPS Research Fellowship for Young Scientists. A.T.J. was partly supported by BBSRC grant BB/D013038/1.

Chemical Derivatization of Compact Disc Polycarbonate Surfaces for SNPs detection

María-José Bañuls, Francisco García-Piñón, Rosa Puchades, and Ángel Maquieira*

Instituto de Química Molecular Aplicada, Departamento de Química, Universidad Politécnica de Valencia, Camino de Vera s/n, Valencia, Spain. Received September 7, 2007; Revised Manuscript Received December 7, 2007

Compact discs have been proposed as an efficient analytical platform, with potential to develop high-throughput affinity assays for genomics, proteomics, clinics, and health monitoring. Chemical derivatization of CD surfaces is one of the keys to developing highly efficient microarraying-based assays on discs. Approaches for mild chemical modification of polycarbonate (PC) disc surface based on nitration, reduction, and chloromethylation reactions have been developed. Derivatized surfaces as amino and thiol are obtained for PC, maintaining unchanged the mechanical and optical properties of the discs. Studies of covalent attachment of oligonucleotide probes (5′ Cy5-labeled, 3′ NH_2-ended) on the modified surfaces have been performed to develop microarraying assays based on hybridization of cDNA strands and single nucleotide polymorphism discrimination (SNPs). A demonstration of the applicability to the compact disc audio/video technology for its use as analytical system is performed, including the employment of a commercial CD player to read the results on disc.

INTRODUCTION

Biologists, chemists, material scientists, and engineers have collaborated to develop bioassays, mainly DNA and protein microarraying chips. The development of surface-based assays in which numerous probes are immobilized in a spatially addressable manner has been one of the keys of these technologies. Such assay formats lend themselves well to miniaturization and multiplexing (*1, 2*). Nucleic acids (NAs) chip technology uses microscopic arrays of oligonucleotides immobilized on solid supports, as glass or silicon, for gene expression analysis (*3*), polymorphism (*4, 5*) or mutation detection (*6, 7*), DNA sequencing (*8, 9*), and gene discovery (*10, 11*).

Microarraying technologies have been developed quickly from the 1990s, but there are still a lot of improvements to be achieved. New immobilization ways, different assay formats, and alternative detection modes to improve microarraying methodologies are necessary.

Although glass is a popular support for DNA chip technology (*12*), efforts have led to the use of polymeric materials in the preparation of chip-based devices (*13, 14*). Solid polymers offer attractive mechanical and chemical properties, presentations, low cost, fabrication facility and flexibility, biocompatibility, and so forth. Attention has mainly been focused on the applications of microfluidic devices, and their fabrication techniques (*15*), alternative to glass as integrated platforms accomplishing sample manipulation and other analytical steps. Devices as biomicroelectromechanical systems (BioMEMS), laboratory-on-a-chip, and compact disc (CD) are being proposed for different applications (*16, 17*).

Standard CDs are composed of a polycarbonate (PC) substrate (1.2 mm thick), a reflective metalized layer (100 nm thick), and a poly(methyl methacrylate) (PMMA) protective lacquer (10 μm thick) as the ISO:9660 industry standard describes (*18*). Among the advantages of audio/video CD as analytical platform, one can highlight their big surface to spot thousands of capture probes; a low fluorescent background; the availability of high-quality materials at very low cost; the quadratic, circular, and spiral indexing; the easy handling and manufacture; and the possibility to use the top side for detection and the down side for recording; and further use of CD and DVD audio/video players as detectors making possible their application as point-of-care systems, especially interesting for the developing countries.

From the arraying applications of standard CDs, we must point out the seminal work of Kido et al. (*17*) demonstrating the potential to develop micro-ELISAs by surface adsorption of immunoreagents. Adsorption is a useful mode for protein immobilization; however, for nucleic acids it is necessary to use electrostatic forces (e.g., glass supports) or, more preferably, covalent attachment (*19*). In previous works, we showed the possibilities of using compact disc surfaces as high-throughput screening platforms for DNA microarraying (*20*) and for detection of low-abundancy pesticide residues (*21*). Considering all these features, the chemical derivatization of PC, the main CD constituent, to be applied on raw discs for microarraying-based assays can be achieved by means of different chemical or physical processes; the most common techniques include plasma-ion beam treatment, electric discharge, spin-coating, adsorption (*22*), surface grafting, chemical reaction, photoactivation (*23*), vapor deposition of metals, and flame treatment (*24, 25*). The problem is that most of the methods employed for the chemical surface modification of this polymer affect their optical (transparency) and mechanical (resistance, hardness, roughness, etc.) properties, not being applicable to compact discs without perturbing the original performance. The covalent attachment of probes, on the contrary, offers the advantage of a robust resulting surface while retaining its chemical integrity over an extended period of time. Besides, covalent interactions allow the performance of highly homogeneous and reproducible surfaces as self-assembled monolayers.

There are few works studying the chemical modification of CDs to attach probes on the surface. Remacle (*26*) developed DNA microarrays on CD by surface activation employing basic hydrolysis of polycarbonate. Acid groups generated on the polymeric surface allowed the attachment of DNA after treatment with a diamine. The information regarding this procedure

Table 1. Nucleotide Sequence of Probes and Targets Used

name	sequence (5′ to 3′)	5′ end	3′ end
SYM8	AATGCTAGCTAATCAATCGGG	Cy5	none
SYM22	$(T)_{15}$CCCGATTGATTAGCTAGCATT	none	C_7-NH_2
SYM23	TTACGATCGATTAGTTAGCCC$(T)_{15}$	Cy5	C_7-NH_2
SYM25	AATGCTAGCTAATCAATCGGG	biotin	none
SYM26	AATGCTAGATAATCAATCGGG	biotin	none

is limited and fragmentary. LaClair (*27*) proposed a screening method for the recognition between small-molecule ligands and biomolecules. It consists of the phosphorylation of the PC surface employing dichlorophosphate to achieve the covalent attachment of hydroxyl-ended ligands. Recognition between surface-expressed moieties and biomolecules is screened by an error determination routine. This innovative approximation shows the limitation in which each drive manufacturer has its own propietary firmware for error correction displaying a different sensitivity and thus different ability for analysis; thus, it necessary to always employ the same disc player to read the results. Also, they use a PTFE mask to perform the assays in wells on the disc surface.

Recently, Li (*28*) reported a polycarbonate surface-activation protocol by UV/ozone treatment which allows the covalent attachment of DNA microarrays and further hybridization assays. This method employs compact discs but cuts them into sheets and not in their original shape, and for the detection uses conventional optical drives (as microarray scanning).

Other authors performed high-quality self-assembled monolayers of alkanethiols on the gold side of CDs, employing them to fabricate inorganic material microstructures (*29, 30*). Likewise, they proposed the idea of DNA micropatterning by a tip-contact CD printer and water-resistant ink onto the gold CD substrate, and subsequent treatment with aqueous gold-etching reagent (*31*).

Recently, our group has reported the procedure for covalently attaching aminated oligonucleotides on PMMA isocyanate-modified compact discs to perform hybridization assays, carrying out the detection with a CD player (*32*).

In the present work, several approaches of covalent modification of PC discs are carried out, in order to get NH_2- and SH-modified surfaces. Results are applied for DNA probe immobilization, hybridization, and SNP (single nucleotide polymorphisms) discrimination assays on polycarbonate disc surface. A CD player is also integrated as a detection system to demonstrate the feasibility of the developed methodology.

EXPERIMENTAL PROCEDURES

Reagents. Ethylenediamine was purchased from Acros (Barcelona, Spain). Glutaraldehyde, Tween 20, 11-mercaptoundecanoic acid, gold-conjugated streptavidin from *Streptomyces avidinii*, and silver enhancer (solutions A and B) liquid substrate from membranes were purchased from Sigma-Aldrich (Madrid, Spain). Hibridization and SNP oligonucleotides (Table 1) were from Sigma-Genosys (Suffolk, UK). Oligonucleotide solutions were tip-contact printed onto the surfaces using a stamper (6 × 4 pins) from V&P Scientific, Inc. (San Diego, CA, USA).

Buffers employed were as follows: Saline sodium citrate (10xSSC, 0.9 M sodium chloride, 0.09 M sodium citrate, pH 7); carbonate buffer (10xCB, 0.5 M sodium carbonate, pH 9.6); phosphate buffer saline (10xPBS, 0.08 M sodium phosphate dibasic, 0.02 M sodium phosphate monobasic, 1.37 M sodium chloride, 27 M potassium chloride, pH 11); MES buffer (0.1 M 2-morpholinoethanesulfonic acid monohydrate, pH 6.5).

Apparatus. Fluorescent-arrayed probes were detected by both a microarray scanner, Genepix 4000B, from Axon Instruments (Union City, CA) at λ_{exc} 635 nm and λ_{em} 670 nm, and a homemade disc fluorescence reader (DFR) (*33*). Hybridization assays were detected by employing a standard CD player modified as described below.

Sessile drop contact angle measurements were performed with a Data Physics contact angle system OCA (Filderstadt, Germany). Two solvents were employed: water 18 MΩ and glycerol 99.9%.

The attenuated total reflectance Fourier transform infrared (ATR-FTIR) spectra were obtained using a Nicolet-Nexus FTIR with Multi-Bounce HATR, ZnSe 45° (Madrid, Spain). Each spectrum represents the average of 256 scans in 4 cm^{-1} resolution. The energy dispersion spectra (EDS) were collected on scattering electron microscopy JASCO-SEM, resolution 59 eV (Easton, MA).

Compact Discs. Golden CD-Rs partially transparents (30% reflectivity) provided by U-Tech Media Corp. (Tau-Yuan Shien, China) were used as platforms. These low-reflectivity recordable compact discs (L-CD, 1.2 mm thick polycarbonate discs, with a gold reflective layer of 30 nm, 12 cm diameter) allow the laser (780 nm) two functions: (a) reflected light (30%) lets the laser to follow the track, maintaining the rotation of the disc (autotracking) and, (b) transmitted light (70%) reaches the microarray spots located on the upper side of the CD, detecting the hybridization intensities by the amount of precipitate produced by an catalytic marker (gold) and a substrate (silver developer).

Disc Reader. A standard CD player from Plextor LLC (Fremont, CA) was used as the detector. The drive uses the servo control system to center and focus the beam on the spiral data track across the whole disc surface. The CD reader uses the original design of the CD players, taking advantage of the CD driver optical system to illuminate accurately the polycarbonate face of the L-CD (partially reflecting the laser and transmitting the rest through the PC surface to the photodiode). The controlled parameters of the optical disc drive include positioning of the laser toward the disc, scanning the whole disc surface while controlling the spatial resolution, and the linear rotation velocity of the disc. A planar photodiode (SLSD-71N6, Silonex, Montreal, Canada), 25.4 mm long, with a spectral sensitivity of 0.55 A/W at 940 nm and a spectral range between 400 and 1100 nm, absorbs the transmitted laser light and converts it into an analog electrical signal.

A reflective photosensor (EE-SY125, Omron, Scahumburg, USA) used to detect the analytical areas includes an infrared led of 950 nm and a phototransistor, with a sensing distance ranging from 0.5 mm to 2 mm. The operational principle of the photosensor is based on the detection of the different reflectivity between the sensing object and the disc. For that, the analytical areas are marked in the outer rim of the disc by low-reflectivity trigger footprints of 3.5 cm size. Because the unmarked perimeter presents higher reflectivity, the photosensor detects the marked areas, providing a trigger signal to the data acquisition board in order to start capturing data exclusively from those zones.

A custom-built electronic board (DAB) incorporates the planar photodiode and the photosensor. The function of the board is twofold: first, the detection of analytical areas, and second the amplification of the analog signal. Both functions are carried out at the same time the CD drive performs its original function of reading and writing data. In this way, during the data acquisition process only the signals from the detection areas are digitized by the data acquisition board (DAQ), stored in the computer, and deconvoluted into an image to further quantify. A scheme of the developed detection system is shown in Figure 1. The detector system is controlled by software running on a Windows-based computer connected to the PC through a universal serial bus interface (USB2.0) to become portable.

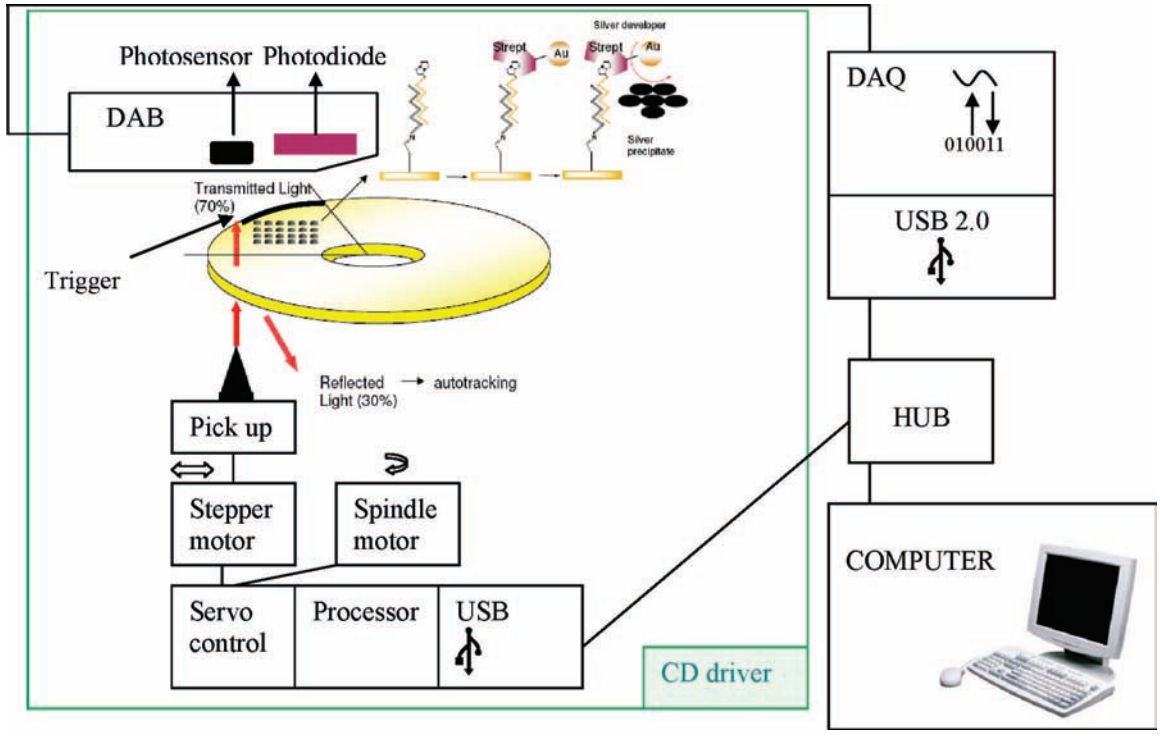

Figure 1. Detection system. The set of servo systems of the CD drive allows disc rotation and laser scanning. The transmitted light through the disc is transformed by the photodiode into an analog electrical signal (RF signal). At the same time, the photosensor detects the trigger footprints, starting the data collection on disc. The amplification/detection board (DAB) is integrated into the CD drive unit and contains the planar photodiode and the photosensor. The data acquisition board (DAQ) digitizes the analog signals and transfers them to the computer for processing.

Custom software was writing in Visual C++. The software provides the control to the CD/DVD driver to scan the surface of the disc, to modulate the disc linear rotation velocity to a specified spatial resolution, and to write data in the CD or DVD. Also, the software provides the control to the data acquisition board to configure the sampling frequency according to the disc rotation speed and desired angular resolution. To scan completely the surface of the L-CD, the software simulates the writing process of a 700 MBytes size file to a controlled disc rotation speed. The scan begins from the inner tracks of the disc, following the continuous spiral toward the outer tracks. The captured data of each detection area are represented within a sector that is formed by a set of arcs centered over a radial direction, starting from the inner toward the outer radio. The software collects the data of each area and stores them in independent files in uncompressed binary format, and displays them into a graphical gray scale code image.

Due to the spatial difference between samples taken horizontally (each 13 μm) and vertically (each 1.6 μm), a graphical horizontal adjustment is done to display a proportional $x-y$ image. This software allows export of the image in a gray-scale code to a compressed tif format or bitmap. Then, the images were processed with *Photoshop 7.0* (Adobe Systems Inc., San Jose, CA), to map the lightest and darkest pixels into black and white before quantifying with *GenePix* software (Axon Inst., Union City, CA). Signal intensities of each spot were calculated by background subtraction.

Disc Surface Modification. *Approach 1. Amination.* Transparent polycarbonate discs (PC1) were stirred in aqueous 30% HNO_3 solution for 30 min at 65 °C. The chips were washed with abundant distilled water (PC2). To reduce the nitro groups, chips were immersed into a solution of $NaBH_4$ 10% in 1xPBS and stirred at room temperature for 6 h, washed first with 1xPBS and finally with distilled water (PC3).

Approach 2. Glutaraldehyde Cross-Linking of Aminated PC. NH_2-functionalized PC discs (PC3, approach 1) were immersed into a solution of aqueous glutaraldehyde (5%, 1xPBS, pH 7) and stirred for 2 h at room temperature. Finally, they were thoroughly washed with 1xPBS and water, and air-dried (PC4). Tollen's and *p*-anisaldehyde tests were used to confirm the presence of aldehyde groups (*34*). Freshly prepared aldehyde-modified discs were always employed for DNA assay.

Approach 3. Thiolation. SH-modified discs were prepared as follows: aminated PC3 chips (approach 1) were immersed into an aqueous solution of 5 mM ethylenecarbodiimide (EDC), 5 mM sulfo-*N*-hydroxysuccinimide (NHSS), and 5 mM 11-mercaptoundecanoic acid in 0.1 M MES buffer, pH 6.5 (100 mL), and stirred at room temperature for 3 h. SH-modified discs were washed with water and ethanol and dried. The presence of SH groups on the treated surface was detected by Ellman's test (*34*). Material obtained was named PC5.

Approach 4. Chloromethylation. In a round-bottomed-flask, 2 g of $ZnCl_2$ and 2 mL of chloromethyl methyl ether were added to polycarbonate slides (PC1) immersed in cyclohexane (80 mL). The mixture was allowed to react at 60 °C for 2 h. Then, the slides were washed with distilled water (PC6).

Oligonucleotide Arraying. Six 5′ Cy5-labeled, 3′ NH_2-ended oligonucleotide (SYM23) solutions (1 and 10 μM) were prepared by employing different solvents: SSC (1x, 10x) pH 7, CB (1x, 10x) pH 9.6, and PBS (1x, 10x) pH 11. Afterward, 3 $\times$ 3 microarrays of each solution were printed onto the PC disc surface and incubated in a wet, dark chamber for 1 h at 42 °C or 4 h at room temperature. Finally, discs were thoroughly rinsed with PBS-T and water and dried. Immobilization results were read with a microarray scanner (cutting the discs in slides of 55 $\times$ 25 mm^2 size) or using the homemade DFR detector (whole disc).

Hybridization Assays. Amino-ended oligonucleotide SYM22 (0.1, 0.5, 1, and 5 μM) was covalently immobilized on the PC

surface as described above. After that, 35 μL of OVA in 1xCB (pH 9.6) was dispensed on each printed area, spread under a coverslip, and incubated for 30 min at room temperature in a moist chamber. After washing 5 min with PBS-T and water (5 min), discs were air-dried. Cy5-labeled target oligonucleotide (SYM8) was serial diluted between 0.001 and 0.2 μM in a mixture containing 6xSSC, 0.6% SDS, 0.1% salmon sperm DNA, and 2% BSA. 35 μL of the complementary oligonucleotide solution was dispensed on the microarrays and spread under a coverslip (22 $\times$ 22 mm^2). The temperature of hybridization was 37 °C, performing the incubation in a dark and humidified chamber for 1 h. After that, the discs were washed with PBS-T for 15 min, then water (5 min), and air-dried to be read.

For hybridization assays employing the CD player as detector, the biotin-ended target oligonucleotide (SYM25) was used following the procedure describe above. After the incubation and washing steps, 35 μL of 10 μg/mL streptavidin−gold in 1xPBS was deposited on each zone of the disc and again incubated for 20 min under a coverslip, in a moist chamber at 37 °C. After rinsing with PBS-T (15 min), water (5 min), and drying, 20 μL of silver developer solution was dispensed, and after 12 min, black spots appeared on the microarrays (*35*, *36*). The transparent polycarbonate disc was placed on a gold metallized CD and read with the CD driver as before.

Single Nucleotide Polymorphism Assays. SYM22 0.1, 0.5, 1, and 5 μM was covalently immobilized on polycarbonate aldehydized discs (PC4). After the OVA blocking step, different solutions (0.05 μM to 0.0005 μM) of SYM25 and SYM26 in 6xSSC, 0.6% SDS, 0.1% salmon sperm DNA, 2% BSA, and 25% formamide were prepared, dispensed on each printing zone, and spread under a coverslip. Discs were incubated for 1 h at 40 °C in a moist, dark chamber, washed with PBS-T then water, and air-dried. Treatment with streptavidin−gold and silver developer was carried out as described before.

RESULTS AND DISCUSSION

All the chemical modifications of chip materials including CD surfaces must consider two key points. First of all, they must maintain the mechanical and optical properties of the raw polymer, as otherwise, optical disc reading and chemical detection using a CD player is inapplicable. Moreover, the functionalization must perform the biomolecule covalent attachment in aqueous media, working at pH and ionic strength values close to the physiological ones, because proteins and nucleic acids can change their behavior in denaturing conditions. These requirements restrict the chemical treatments to mild reaction media.

Amine and thiol functionalizations have been chosen because they offer a well-known chemistry in the conjugation of biomolecules to different surfaces (*37*). They can be converted into suitable moieties for covalent immobilization of amino-ended biomolecules, making use of different cross-linkers such as dialdehydes or diisocyanates. Thiol functionalization is also of interest, because it can directly attach sulfhydryl-ended molecules through the formation of disulfide bridges.

Surface Modifications. Chemical derivatizations successfully developed are divided in four groups: amination, glutaraldehyde cross-linking, thiolation, and chloromethylation. Figure 2 shows the principal steps for each approach and the denomination of the transformed materials as well as the reaction conditions employed for amination, aldehydization, thiolation, and chloromethylation of PC.

The effect of solvents on plastic properties (diethyl ether, dichloromethane, hexane, cyclohexane, methanol, 2-propanol, water) was studied in order to select the most gentle with polycarbonate. It was found that cyclohexane, 2-propanol, and

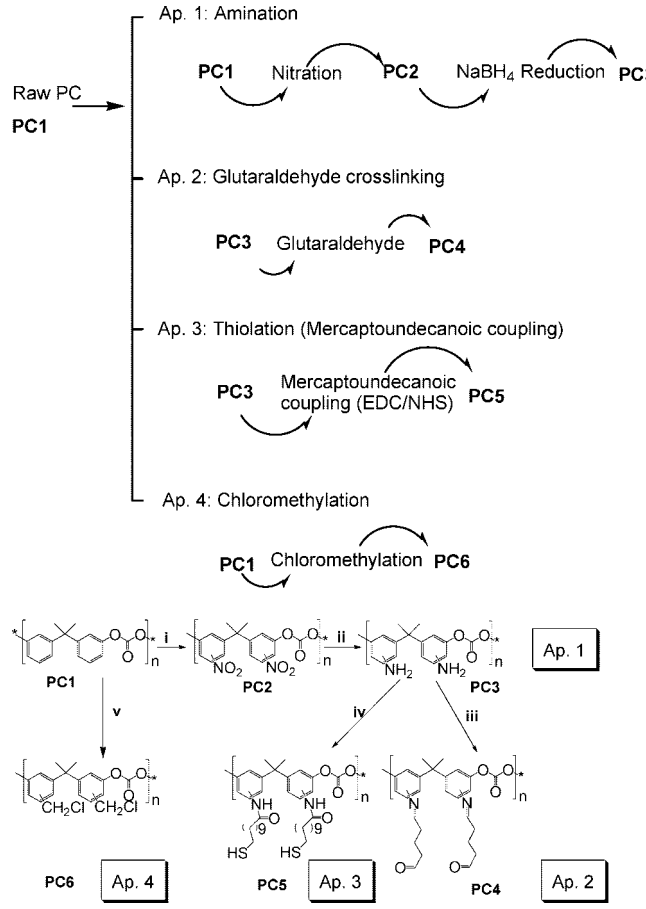

Figure 2. Scheme of surface chemical modifications performed to obtain PC2, PC3, PC4, PC5, and PC6. Reaction conditions employed for approaches 1, 2, 3, and 4.

water maintained the physical properties of PC discs without curling or cracking. Pieces of 55 $\times$ 25 mm^2 were immersed from 3 to 7 days in these solvents, confirming that the slides remained unaltered after these treatments.

In approach 1 (Figure 2), nitration of PC by heating at 65 °C in 30% aqueous HNO_3 for 30 min followed by reduction with $NaBH_4$ afforded an NH_2-modified surface. For approaches 2 and 3, NH_2-modified surfaces (PC3) were treated with glutaraldehyde to give CHO-modified PC and with 11-mercaptoundecanoic acid and EDC/NHSS to give SH-modified PC (approaches 2 and 3, Figure 2).

On the other hand, for the chloromethylation of PC (approach 4, Figure 2), reaction times from 1 to 24 h were studied. It was observed that, applying long exposure times, the roughness of chip surface increased. It resulted in cracking, and the slide became more fragile. Similar effects of fissuring were noticed when working at high temperatures (80–100 °C) for prolonged times (more than 2 h). Although the extent of the surface derivatization was larger when hard conditions were applied, we concluded that 2 h at 60 °C was optimal to reach enough surface modification without alteration of the physical properties of the material (Figure S4 in Supporting Information).

In order to confirm the success of NH_2, CHO, SH, and CH_2Cl modifications, and to study their surface and optical properties, several techniques were employed: contact angle, ATR-FTIR, EDS, and SEM.

Contact Angle. For all the raw and treated polymers, the water and glycerol contact angles were measured. The results are summarized in Table 2. The left and right contact angles of the solvent drops were measured immediately after its placement on the polymeric surface; no differences between contact angles

Table 2. Sessile Drop Contact Angles

surface	θ water	θ glycerol
PC1	78 ± 2	71.6 ± 0.9
PC2	57 ± 2	58 ± 7
PC3	66 ± 2	69 ± 1
PC4	59 ± 2	61.7 ± 0.9
PC5	63 ± 2	74.9 ± 1.5
PC6	53.9 ± 0.6	60.8 ± 1.5

were found. The reported values are the average of five separated water drops on a given substrate, and no significant variation among a set of substrates was found, so we asserted the homogeneity of the modifications carried out.

The measured values correlated well with those found in the literature for unaltered and treated PC surfaces. After chemical modification, a decrease in the water contact angle values was experimentally observed due to the presence of polar groups that increase the hydrophility of the materials.

ATR-FTIR. The attenuated total reflectance−Fourier transform infrared spectra were registered for PC1, PC2, PC3, PC4, PC5, and PC6 (Figure S1 of Supporting Information). PC3 showed a prominent peak around 3200–3400 cm^{-1} characteristic of OH and NH_2 stretching. Because the slides were baked at 40–50 °C before taking the spectra and they remained unaltered after several weeks, the possibility that these peaks were due to the surface solvatation or humidity was discarded. Besides, the derivatized surfaces containing neither amine nor hydroxyl groups (PC1, PC2, PC5, and PC6) did not show any peak around 3200 cm^{-1} after the baking process.

EDS. Energy dispersion spectra were collected for PC1, PC2, PC3, PC4, PC5, and PC6 (Figure S2 of Supporting Information). The successful incorporation of 11-mercaptoundecanoic acid and chloromethyl subunits was clearly observed in PC5 and PC6, respectively, because of the presence of heavy atoms such as S or Cl that are not present in the raw material.

On the other hand, as the reaction with 11-mercaptoundecanoic acid might lead to partial polymerization of the bifunctional acid and to the adsorption of the (hydrophobic) polymer on the substrate, a control experiment was performed to asses the amide formation. For that, PC1 was treated with 11-mercaptoundecanoic acid in a similar manner as PC3. After the reaction, both surfaces were washed exhaustively with a basic aqueous solution (NaOH 0.5 M), then with water, and ED spectra were registered; again for PC5, the existence of S was detected, while in the case of PC1, the presence of S was not observed.

The SEM images of derivatized PC surfaces showed smooth and defect-free surfaces; those images confirmed the homogeneity of the reactions (Figure S2 of Supporting Information).

Oligonucleotide Immobilization Studies. In order to demonstrate the viability of the developed chemical modifications for the covalent attachment of oligonucleotide probes on CD supports, PC discs were treated following the approaches 2 and 4 (Figure 2), because those approaches leave on the surfaces functional moieties (aldehyde and chloromethyl) able to covalently attach aminated probes. Preliminary studies of Cy5-labeled, NH_2-ended oligonucleotides arraying onto PC1, PC2, PC3, and PC4 (approaches 1 and 2, Figure 2) were done employing the above-described method.

Results obtained for every surface showed that no signal was detected for PC1 (raw material) and PC2 (approach 1, Figure 2). For PC3, the fluorescence reading gave some signal, although the oligonucleotide covalent attachment on PC3 was not possible. It was in agreement with the establishment of hydrogen bonds as well as electrostatic interactions between the oligo and the aminated surface.

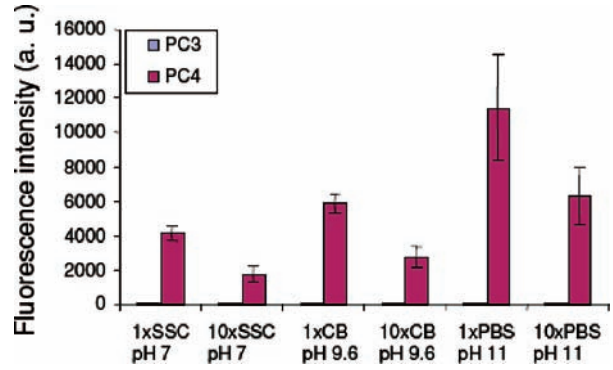

Figure 3. PC3 and PC4 fluorescence emission intensities for 10 μM Cy5-labeled, NH_2-ended oligonucleotide immobilized using different pH and ionic strength conditions. After washings, no significant fluorescence signal was obtained for PC3, while for PC4, the highest-intensity values are obtained for 1xPBS, pH 11.

PC4 provided significant signal (Figure 3); in this case, covalent attachment between NH_2-ended oligonucleotide and aldehydized surface was possible. Theoretically, the reaction should produce a Schiff base. However, the reaction is irreversible. Glutaraldehyde yields polymers in solution (*38*) that at acidic pH are cyclic hemiacetals. At neutral or slightly alkaline pHs at which cross-linking occurs, the α,β-unsaturated aldehyde polymers are formed which increase in length as pH is raised. It is probably the unsaturated polymer that cross-links the amino group of oligonucleotides. The interaction of the Schiff base with adjacent double bonds provides stability toward hydrolysis. With an excess of amino groups, nucleophilic addition of the ethylenic double bond is possible. Thus, it was noted (Figure 3) that the more basic the pH (*11*) is the more effective the covalent attachment.

On the other hand, it was also observed that an increase in the ionic strength of the printing solution decreased the effectiveness of the attachment. In order to eliminate possible electrostatic and hydrophobic/hydrophilic interactions between the surface and Cy5-labeled oligonucleotides, slides were treated with an acidic solution (aq 5% HCl). A 100% signal diminution was observed for PC3, while the signal in PC4 only suffers a reduction between 15% and 30%). This fact also confirmed the existence of covalent attachment for PC4. In all cases, SYM8 was used as a control to test the nonspecific interaction, and a fluorescence signal was almost inexistent for PC1, PC2, PC3, and PC4.

For PC6, derivatized following approach 4, attachment of aminated oligos via nucleophilic attack to the chloromethyl benzene rings was tried. Several times (0, 2, 4, and 16 h) and incubation temperatures (room temperature and 42 °C) were assayed. The best results were obtained for 4 h at 25 °C.

The registered fluorescence signal remained unchanged after washings for PC6 (Figure 4) indicating the existence of covalent interactions. However, the signal of PC1, used as control, was low and disappeared when the chips were exhaustively washed with water. In conclusion, derivatized polycarbonate PC6 seemed to also be appropriate for covalent attachment of the aminated oligonucleotides. This strategy has not been employed before for DNA microarraying, nor on glass. Thus, it is a novel and promising way to develop new surfaces to perform a stable link with DNA probes, and surely with proteins. The main advantage of this approach is that, by using one chemical modification step, the chip is ready for the oligonucleotide covalent attachment. On the other hand, this chemical modification could be successfully applied in other aromatic polymers such as polystyrene. The problem is that the reagents employed are more hazardous than for approach 2: organic solvent is used

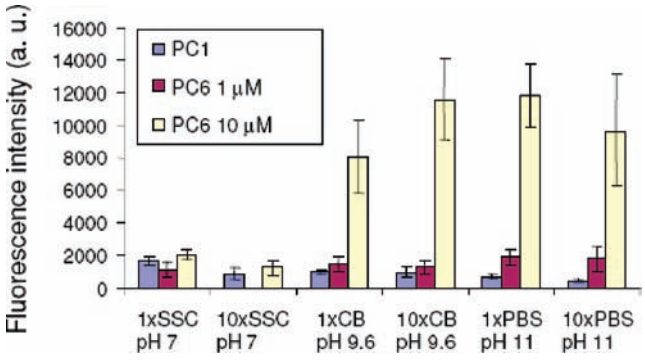

Figure 4. PC1 and PC6 fluorescence emission intensities (neat fluorescence) for 1 μM and 10 μM Cy5-labeled, NH_2-ended oligonucleotide immobilized at different pH and ionic strength conditions. For PC6, the best results are obtained for 1xPBS, pH 11. For PC1, there exists some remaining signal; this signal decreases after exhaustive washings, but not for PC6.

Table 3. Advantages and Disadvantages of Approaches 2 and 4 for Their Employment in Aminated Oligonucleotide Attachment on PC and Application to CD Technology

approach	advantages	disadvantages
2	aqueous solutions mild conditions better signal-to-noise ratio immobilization	three steps functionalization
4	one step functionalization applicable to other aromatic polymers higher neat fluorescence	very toxic reagents employed organic solvent required

instead of aqueous solutions, and chloromethyl ethyl ether is highly toxic. For that, approach 2 providing PC4 was chosen to perform the application to CD supports. In Table 3, the advantages and disadvantages of the proposed approaches are summarized.

Application to CD Supports. *(a) Hybridization Tests.* To demonstrate the applicability of the method to CD technology, PC transparent discs 0.6 mm thick were employed to perform the bioassay. The PC disc was derivatized according to the procedure involving nitration and reduction of the polycarbonate (approach 1), and then treated with glutaraldehyde (approach 3).

Due to the big sample spotting CD surface, eight different zones, each one also with four different probe concentrations, were printed. After the covalent attachment of SYM22, hybridization was performed employing serial dilutions of SYM 25 (0.2 to 0.001 μM). Afterwards, the CD was treated with gold-conjugated streptavidin for 20 min, washed, and revealed with silver enhancer for 12 min. The black precipitate was detected by the CD player. For this, the PC disc was fixed on the metallic layer of a standard gold metallized and unlacquered CD, partially transparent (70% light transmission) to 780 nm laser wavelength (this disc would allow the laser device to follow the track).

To set up the hybridization conditions, different concentrations of probe (from 0.1 to 20 μM) and target (from 0.5 to 100 nM), times, and temperatures were assayed. Black spots were obtained until 2.5 μM of target for all the probe concentrations. Also, several controls were performed avoiding the following: glutaraldehyde treatment, covalent attachment of probe, OVA blocking, hybridization solution, and streptavidin−gold incubation. None of them developed black spots except in the case of the control avoiding the treatment with OVA, as was expected.

Once the hybridization assay was finished, positive spots were obtained for all the target concentrations observable even to the naked eye. Results are shown in Figure 5.

The ammount of precipitate is directly related with the transmitted light of the CD player laser (the greater the precipitate, the less the light transmission). Thus, it is possible to establish a relationship between the hybridization effectiveness and the transmitted (or absorbed) light.

In Figure 6, probe and target saturation curves are shown. The optimal values were found for 5 μM of probe concentration, with it being possible to detect target concentrations of 2.5 nM. Also, it was possible to detect hybridization with probe concentrations as low as 0.1 μM. The sensitivity and efficiency reached with our procedure produced results slightly better than that obtained on PC CD surfaces employing other methodologies such as adsorption immobilization of probes and target hybridization reading with a fluorescence microarray scanner (*20*). In this case, 25 nM of target was detected by employing probe concentrations between 0.5 and 1.0 μM. This demonstrated the feasibility of our detection system, which provides results as good as or even better than those from the standard techniques.

(b) SNPs Assays. Finally, the application of the methodology to discriminate single nucleotide polymorphism was attempted. Two oligonucleotide strands with different sequences were selected: SYM25, the complementary strand of the immobilized probe on the PC disc (SYM22), and SYM26 differs from SYM25 in the base number nine, substituting cytosine for adenine (see Table 1). For that, different conditions were assayed

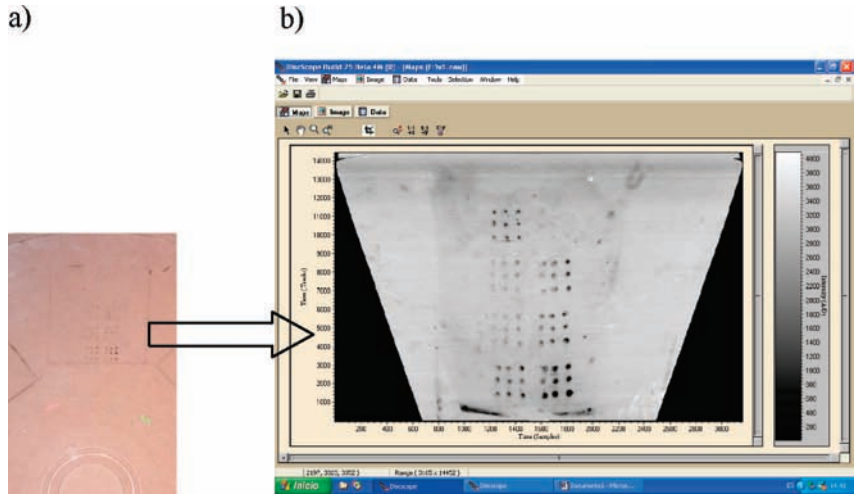

Figure 5. (a) Microarray spots developed on the PC disc after the chemical treatment and the hybridization assays. (b) Computer screen image displayed by the CD reader after the bioassay detection.

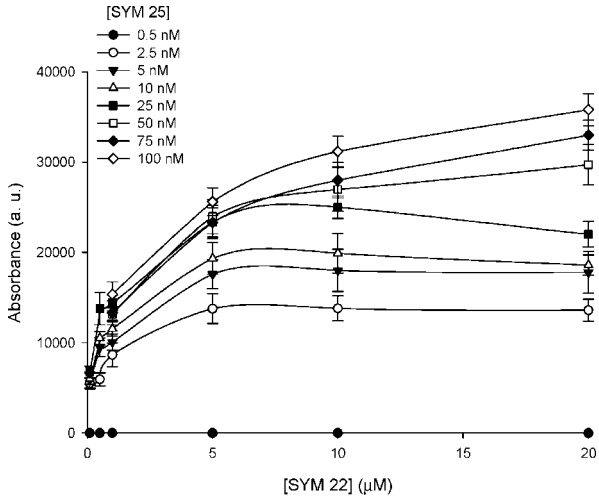

Figure 6. Probe saturation curves for chemically modified polycarbonate discs (approach 1). Reported data are from replicates of nine spots of each oligonucleotide concentration for each CD. (Experiment performed in triplicate).

(concentrations of probe and target; the use of formamide, temperature, and time) to find the optimal discrimination medium.

At the best assay conditions, SNPs resulted at 40 °C, for 1 h and 25% of formamide in the hybridization solution, with it being possible to discriminate between SYM25 and SYM26 at concentrations of 2.5 nM using probe concentrations ranging from 0.1 to 5 μM. These results agreed with our previous equivalent assays employing conventional methodologies.

The conditions employed for these hybridization assays are quite conventional, but they are useful for the aim of this work, that is to prove the principle identified in the introduction: the employment of CDs as suitable analytical platforms and CD players as effective and competitive detection systems. Further work focusing on the improvement of the bioassays to achieve better performance is currently in progress.

CONCLUSION

In this paper, successful modification of the PC surface has been demonstrated in a practical, mild, and clean way to be applied on compact discs as well as other supports that need to maintain their original physical properties. We have shown that modification of PC converts the surface into a suitable platform for covalently building DNA arrays on a standard CD. Among the derivatization approaches, amine-modified discs, by nitration of PC followed by reduction, were selected for the microarraying assays, because it is an easy and clean approach and employs only aqueous solutions, avoiding organic solvents.

One important point to note is that chemical modifications do not affect the general optical properties of the polymeric material, as can be seen from UV–vis or IR spectra of the chip. Also, the fluorescence background remains low. This fact is interesting in order to use different detection devices to read the bioanalytical results obtained on the compact disc.

Considering that polymeric materials can be fabricated into very different presentations and at competitive cost in comparison to glass, this is a promising approach for DNA microarraying chip development also with highly potential applications in fields such as protein, biomedical, genetics, drug discovery, or clinical diagnostic.

The feasibility of the method is fully demonstrated by the successful development of hybridization and SNP assays, which are read employing a standard CD player. The sensitivity and efficiency reached combining polymer chemical activation and CD reader agrees with that obtained for similar assays employing adsorption immobilization methodologies and fluorescence reading detectors.

The described procedure has potencial applications beyond merely the use of biotinylated targets; this strategy has been chosen as a proof of principle, but a big number of potential applications and variations can be easily envissoned; in general, every reaction providing a dark precipitate can be used as developer (e.g., oligonucleotides HRP, phosphatase alkaline, or gold labeling could be used with the proposed methodology). Besides, the employment of DVD technology (650 nm) as detector should allow the reading of fluorescence-labeled (Cy5) targets; in addition, Blu-ray technology (405 nm) could be employed. This work is now in progress. Finally, the search for suitable markers compatible with the CD player wavelength could be of great interest as well.

Purification of His-Tagged Proteins with [Desthiobiotin−BSA−EDTA] Conjugates Exhibiting Resistance to EDTA

Guy Patchornik*

Affisink Biotechnology Ltd, 11 Hamaccabee St. Kiryat-Ono 55572, Israel. Received October 2, 2007; Revised Manuscript Received December 5, 2007

Two His-tagged proteins (His_6-P38 and His_6-Protein A) were purified by specific precipitation utilizing nonsoluble macrocomplexes composed of: BSA conjugates (modified with desthiobiotin−NHS and EDTA−dianhydride), tetrameric avidin, and Cu^{2+} ions. The generated pellets containing bound His-tagged proteins are washed with EDTA (25–100 mM) and then eluted in relatively high purity (≥90%) devoid the macrocomplexes. Three different BSA conjugates were synthesized (DB−BSA−EDTA, DB−BSA−EDTA-A, DB−BSA−EDTA-B) and their adsorption capacities (3.8–6.4 μmol/g of BSA conjugate) as well as the recovery yields of His-tagged proteins obtained with them (44–84%) determined. The data demonstrate that capacity is dependent on the stochiometric ratio of modifying reagents (i.e., desthiobiotin−NHS and EDTA−dianhydride) used during the synthesis of the BSA conjugates. Copper ions were found to be significantly superior to Zn^{2+}, Co^{2+}, and Ni^{2+}. BSA conjugates could be regenerated in moderate yields (74–83%) by incubating them at 88 °C in the presence of biotin (10 mM) at pH 7. The absence of resins leads to formation of small pellets (1–5 mg) and utilization of minute volumes of elution buffer (50–100 μL). Hence, concentrated preparations can be obtained, and a reconcentration step may be circumvented.

INTRODUCTION

Immobilized metal-affinity chromatography (IMAC) has become a universal approach for isolation of native as well as recombinant proteins possessing surface-exposed amino acid residues capable of binding immobilized metal ions (Scheme 1, A). The approach was first demonstrated on metalloproteins (*1*) but became widespread after the extensive work of Porath (*2–4*) and Sulkowski (*5–7*).

Specific adsorption is accomplished when stable ternary complexes are formed between electron donor groups from the protein and metal ions bound on different chromatographic supports (Scheme 1, A). Most of these commercial supports are modified with tridentate (e.g., iminodiacetic acid-IDA), tetradentate (e.g., nitriloacetic acid (NTA), carboxymethylated aspartic acid (CM-Asp)), or pentadentate (e.g., *N*,*N*,*N*′-tris-carboxymethyl ethylene diamine (TED)) metal chelators. The terms tridentate, tetradentate, and pentadentate describe the number of occupied coordination bonds formed between a metal ion and a particular chelator; for example, a tridentate chelator would form three bonds with a metal ion leaving five additional coordinating sites (in the octahedral complex) available for binding. These would be generally occupied by water molecules but will be displaced by appropriate electron donor groups from a protein. Whereas tetradentate and pentadentate chelators bind metal ions with high affinity, exhibit low levels of leached metal, and possess low binding capacities (due to the limited number of coordination sites available for protein binding), tridentate chelators bind metal ions with lower affinity, lead to greater metal leakage, but result in greater binding capacities (*8*, *9*).

Although divalent metal ions are generally used (Cu^{2+}, Ni^{2+}, Zn^{2+}, Co^{2+}), trivalent metal cations were found useful as well. For example, Fe^{3+} ions enabled purification of phosphoproteins and organophosphates (*10–12*). Among the different amino acids capable of binding immobilized metal ions (Glu, Asp, Tyr, Cys, Arg, His, Lys, Met, Trp, Tyr), His was found to be the major participant both in proteins (*13, 14*) and in peptides (*15–17*). Nevertheless, it has been shown that the presence of aromatic residues (Trp, Tyr, Phe) in proximity to the histidine residue contribute to the binding affinity (*6, 18*).

The limitation of the approach to naturally surface exposed His residues was circumvented with the advent of recombinant DNA technology which provided a practical route to introduce His residues at defined sites. It was Hochuli et al. (*19, 20*) who demonstrated that expression of proteins with sequential His sequences (i.e., His-tag) at the N or C terminal, together with a resin modified with NTA and loaded with Ni^{2+} ions, leads to a general and efficient isolation process for His-tagged recombinant proteins. Moreover, the observation that the binding affinity increases with the number of water-exposed His residues (*5*) implied that recombinant His-tagged proteins would bind with high affinity and may allow the presence of weak chelators (e.g., imidazole) during the isolation process. The latter would suppress nonspecific binding of impurities containing naturally occurring His residues and increase the purity.

In addition to the compatibility of the His-tag in most prokaryotic and eukaryotic expression systems (*21*), the IMAC approach was found to possess several major advantages over biospecific affinity chromatography: these include high adsorption capacities, high stability of the ligand, mild eluting conditions, applicability to proteins under denaturing conditions, and the capability to regenerate the columns at low cost (*18*).

Scheme 1A illustrates the dependence of the IMAC approach with respect to water-insoluble resins which ideally would exhibit (a) high permeability to the target, (b) hydrophilic characteristics, (c) chemical inertness, and (d) microbiological resistance and cost effectiveness (*4*). Currently, no such ideal resin is available, and the ones which are exhibit some of the above characteristics but not all. For example, silica-based supports provide excellent mechanical properties but tend to lead to irreversible nonspecific adsorption (*22*).

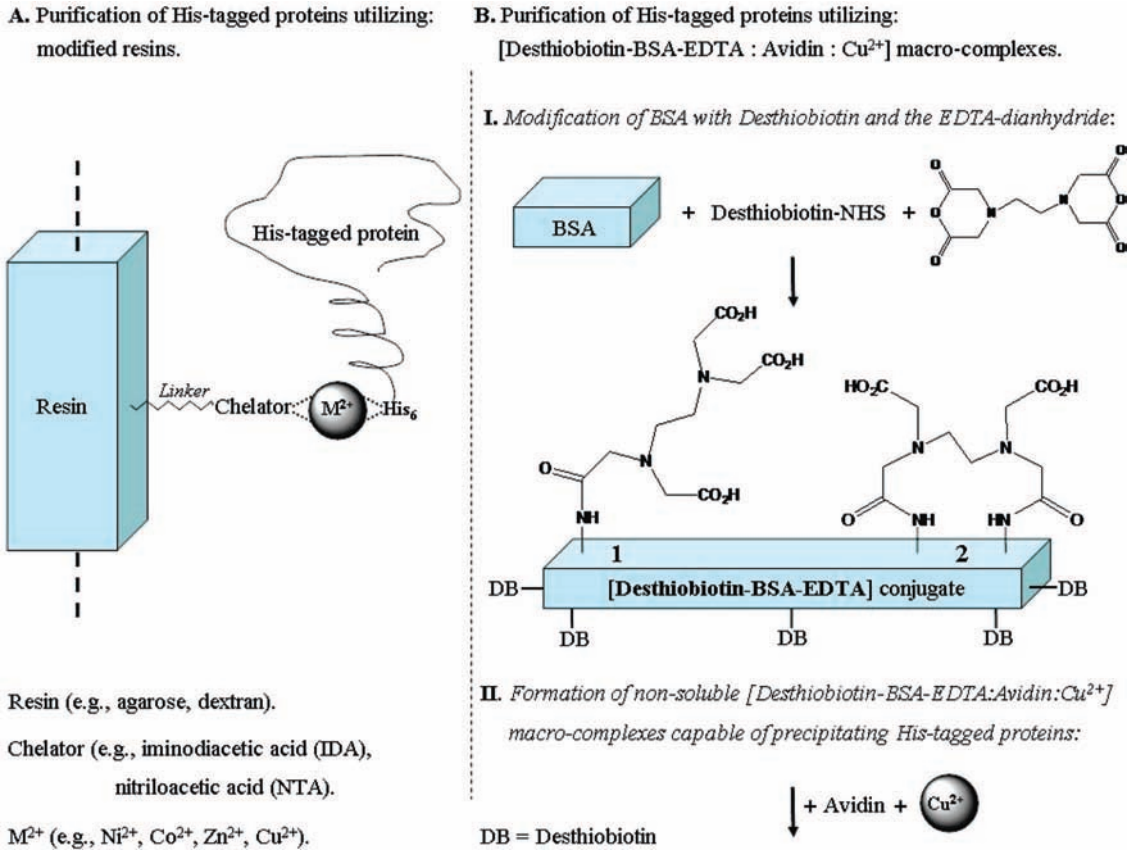
Scheme 1. Schematic Illustration of His-Tagged Protein Purification Utilizing Modified Resins (A) or Nonsoluble [Desthiobiotinylated-BSA-EDTA: Avidin: Cu^{2+}] Macrocomplexes (B)



This state of affairs motivated us to initiate the presented study with the objective of developing an alternative platform for IMAC where no resins are utilized and thus no columns are required. The approach is based on specific precipitation of His-tagged proteins together with insoluble macrocomplexes comprising modified BSA[1] conjugates (desthiobiotinylated−BSA−EDTA (DB−BSA−EDTA)), tetrameric avidin, and Cu^{2+} ions. Impurities present in the supernatant are removed by centrifugation; the pellet is washed with EDTA and the His-tagged protein is eluted with imidazole, whereas the [DB−BSA−EDTA: Avidin] macrocomplexes are not.

EXPERIMENTAL PROCEDURES

Materials. For SDS-PAGE, prestained protein markers and Tris were from Bio-Rad. All other reagents were of analytical grade. Avidin, biotin, BSA, ethylenediaminetetraacetic dianhydride, octyl-β-D-glucopyranoside, *n*-dodecyl-β-D-maltopyranoside; urea, and EDTA were from Sigma. Desthiobiotin *N*-hydroxysuccinimidyl ester was from Berry and Associates, Michigan/Illinois. Recombinant His_6-tagged protein A was from BioVision, Inc., Palo Alto, California. Recombinant His_6-tagged P38 was expressed and purified according to Diskin et al. (*23*).

Protein Analysis. Modified BSA conjugates concentration was determined by UV quantitative analysis at 280 nm.

Electrophoresis and Densitometry. Samples were loaded onto a 10% Bis-Tris SDS-polyacrylamide gel (1 mm thickness) according to Laemmli (*24*) and developed for 1 h at constant 120 V. All gels were stained with Coomassie Brilliant Blue R250, and the intensity of bands was measured by densitometry using the Scion Image program. These measurements were used for determining purity and quantification of recovery yields of the target His-tagged proteins.

Preparation of Desthiobiotin−BSA−EDTA (DB−BSA−EDTA) Conjugates. Native BSA (10.6 mg/mL) was modified simultaneously with desthiobiotin *N*-hydroxysuccinimidyl ester (4.2 mg/mL) and ethylenediaminetetraacetic dianhydride (0.85 mg/mL) in the presence of 0.1 M NaPi at pH 8. Both desthiobiotin−NHS and EDTA−dianhydride were first dissolved in DMSO and only then was BSA added slowly to their mixture with constant vortexing. The stochiometric ratio among desthiobiotin−NHS, BSA, and EDTA−dianhydride was 80:1:20, respectively. The mixture was rotated at room temperature for 4 h, the excess of reagents was removed by extensive dialysis in the presence of 50 mM Tris at pH 8, and the preparation was kept at −20 °C until use.

Preparation of DB−BSA−EDTA-A and DB−BSA−EDTA-B Conjugates. These were synthesized according to the above protocol used for DB−BSA−EDTA but with different stochiometric ratios. For the DB−BSA−EDTA-A conjugate, the stoichiometric ratio among the desthiobiotin−NHS, BSA, and EDTA−dianhydride was 50:1:50, and for the DB−BSA−EDTA-B conjugate, the stochiometric ratio was 20:1:80, respectively.

Preparation of Desthiobiotin−BSA (DB−BSA) Conjugates. This protocol is identical to the one described for DB−BSA−EDTA but was performed in the absence of EDTA−dianhydride.

[1] Abbreviations: BSA, Bovine serum albumin; DB, Desthiobiotin; DB-BSA, Desthiobiotinylated BSA conjugate; DB-BSA-EDTA, Desthiobiotinylated-BSA-EDTA conjugate; DDM, *n*-dodecyl-β-D-maltopyranoside; EDTA, Ethylenediamine tetraacetic acid; HMW, high molecular weight; IDA, Iminodiacetic acid; MALDI-TOF, Matrix assisted laser desorption ionization time-of-flight; NTA, Nitriloacetic acid; OG, Octyl-β-D-glucopyranoside; PAGE, polyacrylamide gel electrophoresis; SDS, sodium dodecyl sulfate; TED, Tris(carboxymethyl)ethylene diamine.

General Purification Protocol for His_6-Tagged Proteins Utilizing DB−BSA−EDTA Conjugates. Purification requires four sequential steps. Step I. Preparation of water-insoluble [DB−BSA−EDTA: Avidin: Cu^{2+}] macrocomplexes: Into a medium (100 μL total volume) containing 50 mM Tris at pH 8 and DB−BSA−EDTA (0.75–1.5 mg/mL), a freshly prepared avidin solution (4 mg/mL) was added with constant vortexing. Copper ions (50 mM) were added and a centrifugation step (14K, 1 min) was applied. The supernatant was excluded and the pellet was resuspended again in 50 μL of Tris 50 mM at pH 8. An additional spin (14K, 1 min) was performed, and the supernatant was removed. Step II. Binding: The pellet was resuspended in 50 mM Tris pH 8, 25 mM NaCl, and a cell lysate containing the target His-tagged protein in a total volume of 100 μL. After a short incubation (5–10 min), the supernatant was removed (14K, 1 min). Step III. Washing: The pellet was washed with 50 mM Tris pH 8, 25 mM NaCl, and 25–100 mM EDTA in a total volume of 100 μL. A spin was applied and the supernatant excluded. Step IV. Elution: The His-tagged protein was eluted from the pellet into 50–100 μL of 50 mM imidazole and 100 mM Tris pH 7 within 5–10 min. All steps were performed at 4 °C. Purity may be increased by washing the pellet twice, loading lower concentrations of copper ions during the preparation step of the macrocomplexes or by addition of mild detergents (e.g., 1% of βOG) during the binding and washing steps.

Inhibition of Purification. The purification process was suppressed when (a) no Cu^{2+} was added to the medium, (b) imidazole (25 mM) was present during the binding step, or (c) the DB−BSA conjugate (0.75 mg/mL) was used instead of the DB−BSA−EDTA.

Purification with Other Metal Cations. Isolation was performed according to the general purification protocol but in the presence of 50 mM of Zn^{2+}, Ni^{2+}, or Co^{2+} ions.

The effect of Octyl-β-D-glucopyranoside (βOG) and Urea on Process Efficiency. Into the above general purification protocol, increasing concentrations of βOG (1%, 3%, and 6%) and urea (1 M, 3 M, and 8 M) were added. Both reagents were dissolved in 50 mM Tris pH 8 prior to their use.

Regeneration of DB−BSA−EDTA, DB−BSA−EDTA-A, and DB−BSA−EDTA-B Conjugates. All three BSA conjugates were regenerated in 74–83% yield by incubating the pellet at 88 °C for 5 min in 0.1 M Tris pH 7 and 10 mM of biotin. These recycling conditions are similar to those described earlier with other modified albumins (*25*).

Electron Spray Analysis (ESI). Peptide fingerprinting was performed on a Bruker Reflex III matrix assisted laser desorption ionization time-of-flight mass spectrometer (Bruker, Bremen, Germany) equipped with a delayed extraction ion source, a reflector, and a 337 nm nitrogen laser.

RESULTS

Purification of Recombinant His_6-P38 with [DB−BSA−EDTA: Avidin: Cu^{2+}] Macrocomplexes. Isolation of His-tagged proteins requires the synthesis of DB−BSA−EDTA conjugates from BSA, desthiobiotin−NHS, and EDTA−dianhydride. These conjugates were expected to possess higher molecular weight than the native BSA and to exhibit a different migration pattern. The results in Figure 1 (lanes 1–2) show that the majority of the native BSA was indeed converted into higher molecular weight entities. To bind and precipitate His_6-P38, we prepared insoluble [DB−BSA−EDTA: Avidin: Cu^{2+}] macrocomplexes and added them to the medium. After a short binding step and a spin, the generated pellets were washed with EDTA (25 mM) and the target was eluted with imidazole (50 mM) at pH 7. When we increased the EDTA concentration from 25 mM to 50, 75, and 100 mM, we found that the reductions in the yield relative to the one obtained in the presence of 25 mM EDTA were 23%, 34%, and 48%, respectively (Figure 1, lanes 4–7). Hence, the greater the EDTA concentration during the washing step, the greater the reduction in yield. Nevertheless, it was surprising to find out that, even in the presence of 100 mM of EDTA, 52% of the His_6-P38 was still present in the pellet. It should be noted that when higher NaCl concentrations were employed (e.g., 50–200 mM) the efficiency of the process was decreased due to solubilization of the macrocomplexes (not shown). Yield may be improved by altering the avidin concentration; increasing the BSA conjugate concentration or inclusion of mild detergents (e.g., 1% of βOG) during the elution step.

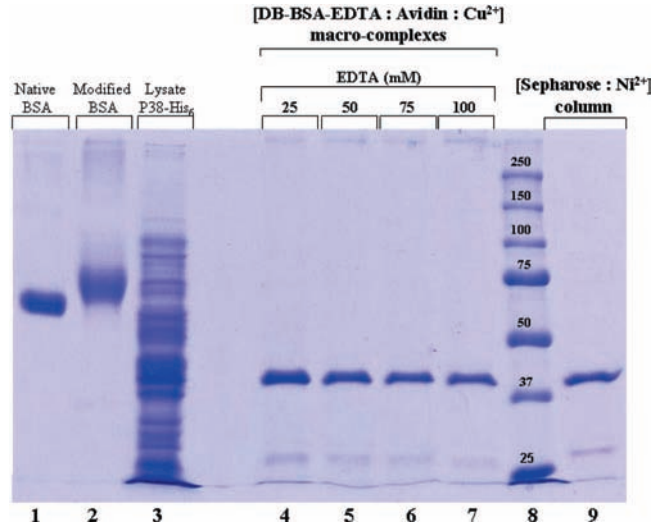


Figure 1. Purification of His_6-P38 with [DB−BSA−EDTA: Avidin: Cu^{2+}] macrocomplexes. Lane 1, native BSA; lane 2, DB−BSA−EDTA conjugates; lane 3, lysate containing His_6-P38; lanes 4–7, recovered protein after washing the pellets with indicated EDTA concentrations followed by elution with 50 mM imidazole; lane 8, Bio-Rad prestained protein markers; lane 9, recovered protein from the same lysate utilizing a [Sepharose: Ni^{2+}] column. The gel is Coomassie stained.

Purification of Recombinant His_6-P38 with a [Sepharose: Ni^{2+}] Column. When the same lysate containing His_6-P38 was applied on a [Sepharose: Ni^{2+}] column, a band with a similar migration pattern to the one observed with the macrocomplexes was observed (Figure 1, lane 9). This was the first indication suggesting that the same His-tagged protein was recovered by the commercial Ni $^{2+}$column and the macrocomplexes.

Electron Spray Ionization (ESI) Analysis. Purified bands obtained via the [DB−BSA−EDTA: Cu^{2+}] macrocomplexes or via the [Sepharose: Ni^{2+}] column were analyzed by ESI. High sequence identity to the known sequence of the MK14_HUMAN Mitogen-activated protein kinase 14 (EC 2.7.11.24) was observed with both approaches (42% for the macrocomplexes and 46% for the [Sepharose: Ni^{2+}] column), thus implying that the same His-tagged protein was isolated.

Requirement for Cu^{2+} Ions and Covalently Bound EDTA. Two independent experiments demonstrated the participation of Cu^{2+} ions in the process: (a) Purification of His_6-P38 was achieved only when Cu^{2+} ions were added to the [DB−BSA−EDTA: Avidin] macrocomplexes (Figure 3A, lanes 3–4). (b) The presence of imidazole (25 mM) during the binding step inhibited the process. Imidazole was expected to compete on immobilized Cu^{2+} ions and inhibit the binding of His_6-P38 to the macrocomplexes. The results obtained in Figure 3A, lane 5 support this speculation. The dependence of the approach on covalently bound EDTA was demonstrated by performing the process with a BSA conjugate (DB−BSA) lacking EDTA. As expected, no band corresponding to the target His_6-P38 was obtained (Figure 3A, lane 6).

Figure 2. Electron spray ionization (ESI) analysis. Purified proteins were analyzed by ESI, and the obtained peptide fragments were compared to the known sequence of the MK14_HUMAN Mitogen-activated protein kinase 14 (EC 2.7.11.24). Isolated proteins recovered via the presented approach (A) or via a [Sepharose: Ni^{2+}] column (B) exhibited 42% and 46% sequence identity, respectively. Matched peptides are shown in bold red.

Comparing Process Efficiency with Other Divalent Cations. Four metal cations are generally utilized in purification of His-tagged proteins; these include Cu^{2+}, Zn^{2+}, Ni^{2+}, and Co^{2+} (*15*). When we tested the above, we found that Cu^{2+} ions were significantly more efficient than Zn^{2+}, Co^{2+}, and Ni^{2+} (Figure 3B, lanes 3–6).

Effect of Octyl-β-D-glucopyranoside (OG) and Urea. The gel in Figure 3C evaluates the effect of a mild detergent (OG) and urea on the process. Whereas the presence of 1–6% of OG did not show any significant effect (Figure 3C, lanes 4–6), the addition of 1 M of urea decreased the process efficiency (Figure 3C, lane 7). When urea concentration was raised to 8 M, the process was quantitatively abolished (Figure 3C, lane 9). This implies that the approach may not be applicable for purification of His-tagged proteins under denaturing conditions.

Binding Capacities of DB−BSA−EDTA, DB−BSA−EDTA-A, and DB−BSA−EDTA-B Conjugates. Capacity experiments were performed by precipitating increasing concentrations of the commercial highly purified His_6-tagged protein A at constant concentrations of the three BSA conjugates (0.4 mg/mL). The presence of His_6-tagged protein A in the supernatant after the precipitation step defined the maximum capacity of the particular BSA conjugate. The data suggest that the higher the EDTA−dianhydride concentration utilized during the synthesis of the BSA conjugates, the greater the capacity value (Table 1).

DISCUSSION

This study investigates an alternative approach for immobilized metal affinity chromatography (IMAC) outlined in Scheme 1A, which does not entail the usage of resins. The approach is based on specific precipitation of His-tagged proteins together with insoluble macrocomplexes composed of BSA conjugates (DB−BSA−EDTA), avidin, and Cu^{2+} ions (Scheme 1B, I−II). The strategy requires preparation of modified BSA conjugates by simultaneous modification of BSA with desthiobiotin−NHS and EDTA−dianhydride. These conjugates possess two unique features: (a) the ability to become water-insoluble in the presence of free avidin (this phenomenon, previously demonstrated with a series of albumins, derives from the capability of free tetrameric avidin to cross-link desthiobiotinylated albumins via their covalently bound desthiobiotins and to generate HMW macrocomplexes which precipitate (*25*)) (b) the capacity to bind His-tagged proteins via immobilized Cu^{2+} ions (Scheme 1B, I−II).

Purification can then be accomplished in four sequential steps. Step I: Synthesized DB−BSA−EDTA conjugates are interconnected with native avidin to form insoluble macrocomplexes of [DB−BSA−EDTA: Avidin] which are then loaded with Cu^{2+} ions. The formation of insoluble macrocomplexes enables efficient removal of free or weakly bound Cu^{2+} ions (by centrifugation) and is equivalent to washing IMAC columns with binding buffer prior to the binding step. Step II: Addition of the [DB−BSA−EDTA: Avidin: Cu^{2+}] macrocomplexes to a medium containing the His-tagged protein will allow specific binding, whereas impurities are removed by centrifugation. Step III: The pellet containing the adsorbed His-tagged protein is washed once to remove nonspecifically adsorbed contaminants. Step IV: The His-tagged protein is eluted in the presence of imidazole. Under these conditions, the [DB−BSA−EDTA: Avidin] macrocomplexes do not dissociate and are kept in the pellet.

Indeed, incubation of [DB-BSA-EDTA: Avidin: Cu^{2+}] macrocomplexes with a cell lysate containing His_6-P38 leads to the recovery of a major band (Figure 1 lane 4) which was shown to be His_6-P38 by two independent experiments: (a) The lysate containing the expressed His_6-P38 was loaded on a commercial [Sepharose: Ni^{2+}] column and a band with a similar migration pattern was observed (Figure 1, lane 9). (b) Electron spray analysis of the protein recovered with DB−BSA−EDTA conjugates (Figure 2A) exhibited high sequence coverage (42%) to the known sequence of the P38 protein kinase (MK14_HUMAN Mitogen-activated protein kinase 14 (EC 2.7.11.24)) and matched as well the amino acid sequence of the recovered protein obtained with the commercial [Sepharose: Ni^{2+}] column (Figure 2B). Hence, both purification approaches recovered the same His-tagged protein.

Unexpected results were observed while searching for conditions postulated to increase the purity of the recovered protein. We found that macrocomplexes with bound His_6-P38 can be washed with EDTA solutions if applied after the precipitation step. For example, a decrease of 23%, 34%, and 48% in yield was observed when the pellets were washed with 50, 75, and 100 mM of EDTA, respectively, in comparison to 25 mM (Figure 1 lanes 4–7). These washing conditions are similar to those generally applied for regeneration of IMAC columns or for total elution of His-tagged proteins (*4*). We speculate that this resistance to EDTA may be the result of the following: I. Possible formation of two different metal chelators on the same BSA (structures **1**–**2** in Scheme 1B). Whereas structure **1** is generated when a single Lys residue attack the EDTA−dianhydride, structure **2** is obtained when two Lys residues from the same BSA participate in the nucleophilic reaction. Structure **1** is the chemical structure of the strong pentadentate chelating ligand TED, known to form octahedral complexes with divalent metal ions (*22*) and is used for isolation of His-tagged proteins (*26*), while structure **2** to the best of our knowledge is novel. It is therefore likely that at least a single strong metal chelator is present. II. Electrostatic effects—the accessibility of EDTA to the ternary complex may be limited by electrostatic repulsions between the negatively charged residues of BSA (pI $\sim$ 4.6) and the carboxylates of EDTA. Moreover, the absence of linkers between the metal chelators and the BSA imply that negatively charged residues of BSA could be in proximity to the ternary complex and may be more efficient in limiting the access of

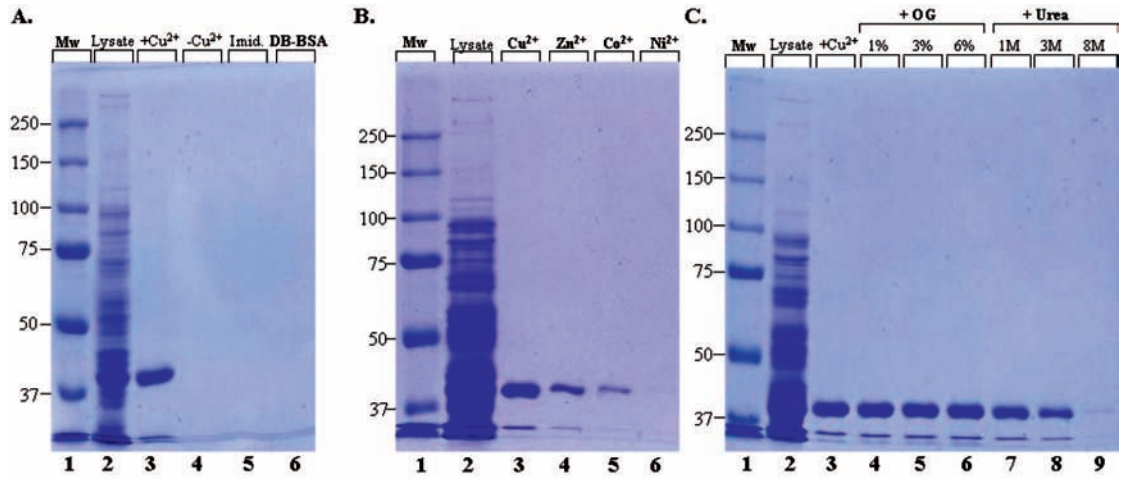

Figure 3. Characterization of BSA conjugates. A. Dependence of the process on Cu^{2+} ions and covalently bound EDTA. Lane 1, Bio-Rad prestained protein markers; lane 2, cell lysate containing His_6-P38; lanes 3 and 4, recovered His_6-P38 in the presence or absence of Cu^{2+} ions, respectively; lane 5, the effect of imidazole (25 mM) during the binding step; lane 6, the effect of replacing BD−BSA−EDTA with DB−BSA conjugates. B. Process efficiency with other metal cations. Lane 1, Bio-Rad prestained protein markers; lane 2, cell lysate containing His_6-P38; lanes 3–6, recovered His_6-P38 with indicated metal cations under identical purification conditions described in the Experimental Procedures. C. Effect of octyl-β-D-glucopyranoside (OG) and urea on the process. Lane 1, Bio-Rad prestained protein markers; lane 2, cell lysate containing His_6-P38; lane 3, control—recovered His_6-P38 in the absence of OG; lanes 4–6, effect of OG at indicated concentrations; lanes 7–9, effect of urea at indicated concentrations. The three gels are Coomassie stained.

Table 1. Characteristics of Different BSA Conjugates

type of BSA conjugate	stochiometric ratios used in the synthesis Desthiobiotin−NHS: BSA:EDTA−dianhy dride	adsorption capacity for His_6-protein A	avidin[a] (mg/mL)	yield[b] at indicated His_6-protein A concentration (mg/mL)

[a] Avidin concentration utilized during macrocomplex formation. [b] Range of recovery yields obtained from four independent experiments.

EDTA. III. Increased binding affinity due to additional interactions with BSA and or avidin—this argument is supported by previous studies demonstrating the existence of four types of interactions between His-tagged proteins and metal ions immobilized on membranes (*27*, *28*). We, therefore, speculate that similar interactions may occur between the bound His-tagged protein and residues of BSA and avidin.

A series of experiments demonstrated the dependence of the approach on Cu^{2+} ions and covalently bound EDTA. When Cu^{2+} ions were not added to the medium during the binding step (Figure 3A, lanes 3 vs 4) or when 25 mM of imidazole were present in addition to Cu^{2+} ions, the process was quantitatively suppressed (Figure 3A, lanes 3 vs 5). Furthermore, the requirement for covalently bound EDTA was demonstrated by replacement of DB−BSA−EDTA with DB−BSA conjugates. The latter were prepared by modification of BSA only with desthiobiotin−NHS and represent BSA conjugates lacking covalently bound EDTA. These failed to recover His_6-P38 (Figure 3A, lane 6) and thus provide direct evidence for the presence of covalently bound EDTA in DB−BSA−EDTA conjugates and its participation in the process. A more efficient process to the one presented could be achieved if the binding step would have been performed under homogeneous conditions. For such a scenario, the DB−BSA−EDTA conjugates, Cu^{2+} ions, and His_6-P38 would have to be incubated in the absence of avidin, which would be added at the end of the binding step to initiate specific precipitation. Unfortunately, this preferable route utilizing different metal ions (Cu^{2+}, Zn^{2+}, Co^{2+}, Ni^{2+}) demonstrated that a high contamination background was unavoidable. The major contributors for this observation were free metal ions which promoted nonspecific precipitation even at relatively low concentrations (0.25−5 mM). Hence, formation of insoluble BSA conjugates, prior to the binding step, which enable removal of free or weakly bound metal ions, seems to be a prerequisite for a successful process.

Other metal ions (e.g., Zn^{2+}, Co^{2+}, Ni^{2+}) commonly used in IMAC (*15*) were compared to the performance of Cu^{2+} ions and were found to be significantly less efficient (Figure 3B). The superiority of Cu^{2+} ions seems to be consistent with the order of metal affinities found, for example, with the tridentate chelator IDA (i.e., $Cu^{2+} > Ni^{2+} > Zn^{2+} > Co^{2+}$) (*22*), but fails to explain the dramatic decrease in efficiency with the other cations. The applicability of the approach for isolation of membrane proteins was investigated by addition of mild detergents generally used in purification (*29*) or crystallization (*30*, *31*) of membrane proteins. We found that 1–6% of octyl-β-D-glucopyranoside (OG) had no significant effect on process efficiency (Figure 3C, lanes 4–6) and that *n*-dodecyl-β-D-maltopyranoside leads to similar results (not shown). Therefore, utilization of mild detergents seems to be compatible with the approach. Conversely, high concentrations of urea (8 M) generally applied for purification of His-tagged proteins under denaturing conditions (*32*) had a pronounced negative effect on process efficiency (Figure 3C, lanes 6–9). Since similar results were observed as well with guanidinium–HCL (at 1 M), we conclude that the approach may not be applicable for isolation of His-tagged proteins under denaturing conditions. These results may not be surprising, as both urea and guanidinium–HCL are known chaotropic agents capable of increasing protein solubility (*33*–*35*) and, as such, can promote solubilization of the generated macrocomplexes composed primarily of avidin, BSA, and the His-tagged protein, thereby leading to suppression of the process.

Utilization of proteins rather than synthetic polymers as the insoluble scaffold may possess several limitations deriving from the inherent chemical and physical instability of proteins in

general (*36*). These could include deamidation, disulfide cleavage, oxidation, as well as aggregation, adsorption to surfaces, and protein unfolding. Therefore, one could argue that under harsh purification conditions or after prolonged storage periods, as well as repeated use of the macrocomplexes, the process efficacy would be significantly affected.

Evaluation of the binding capacity of DB−BSA−EDTA conjugates was determined with a commercial highly purified (≥99% by HPLC) recombinant His_6-protein A. The data obtained suggest that each gram of the DB−BSA−EDTA conjugate is capable of adsorbing 3.8 μmol of His_6-protein A (Table 1). In an attempt to increase the binding capacity, two additional BSA conjugates were synthesized: DB−BSA−EDTA-A and DB−BSA−EDTA-B. These were modified under conditions favoring the concentration of EDTA−dianhydride relative to that of the desthiobiotin−NHS (see Experimental Procedures). The data presented in Table 1 show that the binding capacity of the latter BSA conjugates increased in comparison to the DB−BSA−EDTA and that the values obtained (3.8–6.4 μmol/g) are in the range of those generally observed in IMAC (*4*). In addition, the greater recovery yields and lower consumption of avidin of the latter BSA conjugates imply that they should be preferred over DB−BSA−EDTA (Table 1).

Interestingly, whereas IMAC generally requires higher salt concentrations (0.1–1 M NaCl) to suppress nonspecific electrostatic binding (*22*), the presented approach is performed at low ionic strength (25 mM NaCl) and still leads to relatively high purity. This observation can be explained by the (a) absence of resins, (b) absence of linkers between the chelator and the BSA which could provide a site for nonspecific adsorption (*37*), (c) possibility of washing the pellets with EDTA (25–100 mM), or (d) reduction of free metal ions in the medium by BSA, which could suppress nonspecific precipitation. This argument is supported by the findings of Anderson et al. (*26*), who demonstrated the ability of different albumins to abstract immobilized metal ions from chromatographic supports (e.g., Zn^{2+}-IDA or Co^{2+}-IDA) and to lead to the metal ion transfer phenomenon.

CONCLUSIONS

An alternative platform for purification of His-tagged proteins at low ionic strength has been presented. The high purity observed derives from the ability to wash the pellets with EDTA. The absence of resins leads to formation of small pellets (1–5 mg) and the requirement of minute volumes of elution buffer (50–100 μL). Therefore, concentrated preparations of purified His-tagged proteins can be obtained and a reconcentration step may be circumvented. It is hoped that the approach may provide an additional route for isolation of His-tagged proteins.

Conjugation of the Photoluminescent Silicon Nanoparticles to Streptavidin

Jonghoon Choi,[†,‡] Nam Sun Wang,[†] and Vytas Reipa*[,‡]

Department of Chemical and Biomolecular Engineering, University of Maryland, College Park, Maryland 20742, and Biochemical Science Division, National Institute of Standards and Technology, Gaithersburg, Maryland 20899. Received October 5, 2007; Revised Manuscript Received January 25, 2008

We have covalently attached multiple photoluminescent silicon nanoparticles (SNs) to streptavidin molecules. Conjugation of SNs to a target protein is achieved using the multistage photoassisted procedure. In a first step, the terminal hydrogen in the freshly prepared SNs is substituted with an alkane monolayer that serves as a platform for chemical linkage to a heterobifunctional cross-linker: 4-azido-2,3,5,6-tetrafluorobenzoic acid, succinimidyl ester. A resulting surface coating stabilizes nanoparticles against oxidation and aggregation. Next, an open end of bifunctional cross-linker−diazirine succinimidyl ester is reacted with carboxyl moieties of streptavidin and forms an amide bond. Gel and capillary electrophoresis of the SN−streptavidin complex demonstrated separate elution of the conjugation product and unreacted protein. Then, the number of SNs per protein molecule was determined by measuring complex charge variation by capillary electrophoresis. Conjugate functionality was tested by allowing it to interact with biotinylated polystyrene microbeads. Intense photoluminescence at carefully washed microbeads demonstrated selective binding of silicon nanoparticle bearing streptavidin to biotinylated microbeads. The high quantum yield of streptavidin−SN conjugate in combination with the small size and biocompatibility of silicon nanoparticles presents an attractive platform for the fluorescence labeling in diverse bioassays.

INTRODUCTION

Semiconductor quantum dots were recently recognized to have distinct advantages over organic fluorescent materials in biological tagging applications. Organic dyes are prone to photobleaching under intense laser excitation and are vulnerable to environmental factors such as temperature, oxidation, and acidity, and interaction with certain ions that hamper their application in biological assays. In this regard, stable and efficient binary semiconductor quantum dots offer an attractive platform free of the above problems. Typically, they have size-dependent narrow emission bands and a wide excitation range that permits a multicolor bioanalysis under single-wavelength excitation.

Various approaches of conjugating semiconductor quantum dots to biomolecules have been reported (*1–14*) (for review, see refs *1*−*5*). Water solubility, high fluorescence yield, and compatibility with the analytical protocol media are principal requirements for the practical fluorophore−biomolecule complexes. Binary quantum dot surface modifications for biological applications can be categorized to hydroxyls (*6*), peptides/proteins (*7–9*), thiols (*10, 11*), block copolymers (*12, 13*), and dendrimers (*14*). However, regardless of surface derivatization, the bioapplication of binary quantum dots is hampered by their inherent chemical toxicity (*15–19*) (for review, see ref (*15*)). Consequently, the core materials (Cd/Se, Cd/S, In/P, etc.) require thick, complicated surface coating procedures to prevent content of toxic material with the biosystem. Typically, this leads to a significant increase in the final particle size, and can markedly reduce their application area. Furthermore, such surface modifications often affect the fluorescence quantum yield and spectral properties, both of which hamper the analysis stability and reproducibility. In this context, the need for simple and efficient bioconjugation strategies using nontoxic photoluminescent nanoparticles is evident.

Photoluminescent silicon nanoparticles (SNs) are very appealing in the development of smaller biocompatible probes (*20–23*), as they are expected to be less hazardous than binary semiconductor based quantum dots. Moreover, the silicon surface is open to various chemical functionalizations, thus offering numerous stabilization and bioconjugation options (*24*). Sato et al. (*25*) reacted hydrogen-terminated silicon nanocrystals with acrylic acid to form surface carboxyl functionalities, while Warner et al. used amine termination to ensure SN water solubility (*22*). Such approaches allow engineering of the desired functionality into silicon nanoparticles, increasing nanoparticle monodispersity, and preventing aggregation that may complicate a bioanalysis. Here, we explore a cross-linker-bridged covalent attachment of octane-modified SNs to streptavidin molecules that could be implemented in hybridization-based assays, as these often rely on streptavidin–biotin interactions.

Previously, we reported a conjugation process that describes anchoring of photoluminescent Si nanoparticles to a single-stranded DNA in aqueous solutions (*20*). In this study, we describe the procedure to covalently link SNs to streptavidin molecules that offers access to protein biolabeling, and may find application in *in vitro* assays that rely on antibodies, cell receptors, and cell tracing probes. Covalent bonding between the heterobifunctional cross-linker and a nanoparticle ensures complex stability throughout preparative sample treatments.

We employ 4-azido-2,3,5,6-tetrafluorobenzoic acid, succinimidyl ester (ATFB, SE), which is a bifunctional cross-linker with a photoreactive diazirine and an amine-reactive functionality. The four-step process scheme is shown in Figure 1. Following nanoparticle preparation, hydrogen termination of SNs is substituted with a hydrocarbon moiety using a hydrosilylation reaction. Next, the ATFB bifunctional linker is attached under UV activation and provides a bond to protein amine groups. Subsequently, the SN−succinimidyl ester conjugate is exposed to streptavidin and form a SN−streptavidin complex via amide linkage. Since the cross-linker has the UV-reactive

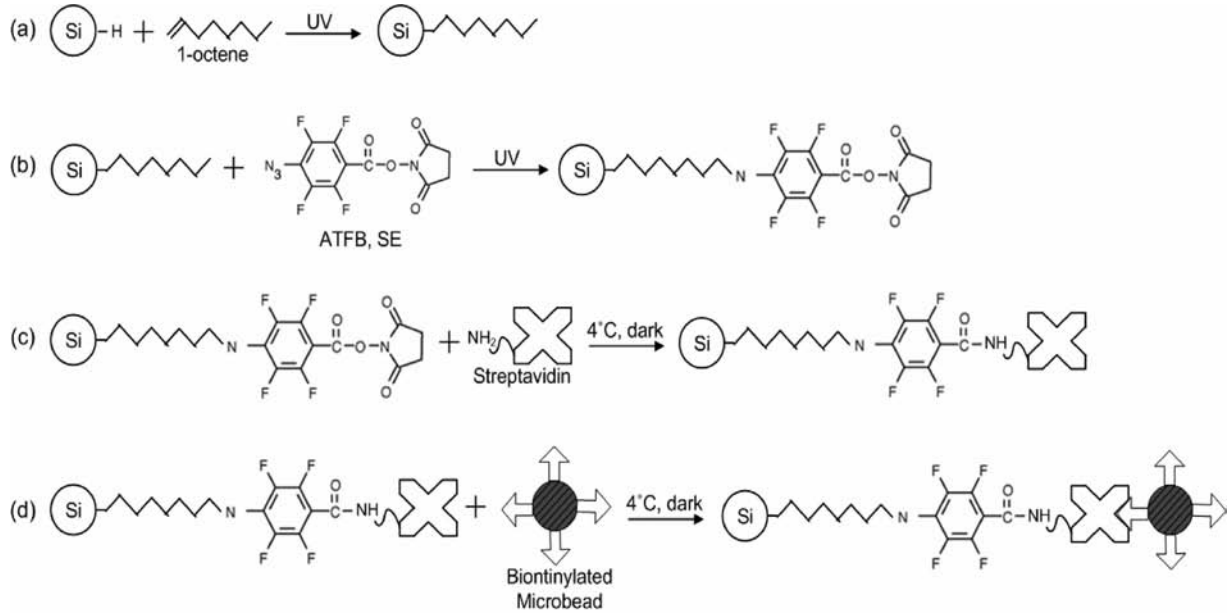

Figure 1. Schematic representation of the silicon nanocrystal and protein molecule covalent conjugation: (a) octane attachment to SNs, (b) bifunctional cross-linker (ATFB, SE) reaction with the octane methyl groups, (c) amide bond formation between the streptavidin and activated cross-linker, (d) test of the SN-streptavidin complex functionality by exposing it to the biotinylated polystyrene microbeads.

end, it allows selective coupling of the diazirine group to the methyl groups of the SN-bound hydrocarbon. SN photoluminescence measurements after each step of the procedure verify both conjugation and photoluminescence efficiency. Finally, we test the tagged streptavidin functionality by reacting the nanoparticle−protein complex with the biotinylated polystyrene microbeads.

The reported straightforward and efficient conjugation strategy and assessment of tagged protein functionality demonstrate silicon nanoparticle potential as an efficient, stable, and biocompatible nanoprobe.

EXPERIMENTAL SECTION

Silicon nanoparticles were prepared using wafer anodic etch in HF-based electrolyte. Both sides of the silicon wafer (As doped, ⟨111⟩ oriented, 0.001 ohm-cm to 0.01 ohm-cm conductivity, Virginia Semiconductor, Inc., Fredericksburg, VA[1]) were electrochemically etched in the HF/H_2O/ethanol (2:1:1, volume ratio) mixture. A lateral etching (*20*, *21*, *26*–*28*) was performed in the Teflon cell that accommodates a 100 mm diameter round Si wafer placed between two Si cathodes. Electric contact was provided to the top edge of the vertically mounted wafer and electrolyte was slowly pumped into the cell, hence providing a solution/air boundary, rising along the wafer surface. Total etch time typically was about 4 h per 100 mm diameter wafer at 120 mA constant current, supplied by a galvanostat (model 363, EG&G Inc., Princeton, NJ). Following anodic etching, the wafer was rinsed several times in deionized water, methanol (HPLC grade, Mallinckrodt Chemicals, Phillipsburg, NJ), and blown dry with nitrogen gas. Dry wafers displayed an intense orange−red luminescence when excited with a 360 nm light. Next, the wafers were sonicated (Neytech, Bloomfield, CT) in a deaerated 10:1 (v/v) mixture of toluene/1-octene for two hours under vigorous N_2 purging. The resulting particle suspension exhibited broadband red−orange photoluminescence under 365 nm excitation.

Following sonication, 20 mL of the Si nanoparticle suspension in toluene/1-octene was placed in the quartz cuvette (Rayonet, Branford,CT) under the N_2 blanket and exposed to 250 nm UV light for 30 min, inside the photochemical reactor (RMR-600) (Rayonet, Branford,CT). The PL color turned to intense blue as a result of the photoassisted hydrosilylation. Finally, the 1-octane derivatized silicon nanoparticle suspension was filtered by passing through the silica gel column.

In the next step of the conjugation protocol, the bifunctional cross-linker 4-azido-2,3,5,6-tetrafluorobenzoic acid succinimidyl ester (ATFB, SE) (Invitrogen, Carlsbad, CA) is attached to the surface of SNs. A 100 μL batch of octane-covered SNs suspension was mixed with 10 μL of 4-azido-2,3,5,6-tetrafluorobenzoic acid succinimidyl ester (ATFB, SE) solution (c = 15 mM) in anhydrous carbon tetrachloride. The reaction mixture was exposed to UV light (λ = 365 nm) inside the UV reactor for 5 min. followed by complete solvent evaporation under N_2 flow. Consequently, fluorinated aryl azide of ATFB reacts with methyl groups of silicon-bound octane and forms a C−N bond (Figure 1b).

The covalent link to the protein molecules was completed by producing the amide bond between the bilinker succinimidyl ester functionality and available streptavidin amine groups (protein molecule has about 100 exposed amines (*29*)). Dry, succinimidyl ester terminated SNs were redissolved in 100 μL of anhydrous DMSO and slowly added to 100 μL of 0.1 M sodium bicarbonate buffer, containing 10 μg of purified streptavidin (Pierce, Rockford, IL). The reaction was carried out in the dark for 1 h under magnetic stirring. Reaction products were analyzed using the native gel electrophoresis. A 15% Tris-HCl polyacrylamide gel (Bio-Rad, Hercules, CA) was injected in 1 μL samples containing the reaction product and the native streptavidin as control in the separate wells. After 2 h of native gel electrophoresis at 150 V in Tris buffer, the gel was dyed using MicrowaveBlue protocol (Protiga, Frederick, MD) for protein staining, and imaged in the MultiImage light cabinet (Alpha Innotech, San Leandro, CA), using both visible light and UV-excited fluorescence modes.

[1] Certain commercial equipment, instruments, materials, or companies are identified in this paper to specify adequately the experimental procedure. Such identification does not imply recommendation nor endorsement by the National Institute of Standards and Technology, nor does it imply that the materials or equipment identified are the best available for the purpose.

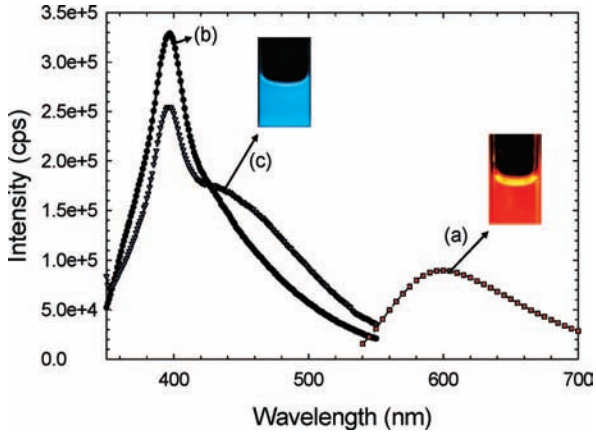

Figure 2. Photoluminescence spectra of freshly prepared silicon nanoparticles in toluene (a), following octane surface derivatization (b), and streptavidin conjugation (c); $\lambda_{exc} = 340$ nm. Insets show the fluorescence images of fresh and derivatized particles under UV excitation.

Functionality of the silicon nanoparticle−streptavidin complex was tested by mixing SN−streptavidin conjugates with a suspension of biotin-coated polystyrene microbeads (average diameter $d = 2$ μm) (Polysciences, Warrington, PA). Prior to mixing, fresh microbeads were separated from their native supernatant by spinning at 10,000 *g* for 5 min. Next, microbeads were washed 3 times by resuspending them in PBS/BSA blocking buffer (0.1 M, pH 7.4), followed by centrifugation. A batch of diluted microbead solution was incubated with the SN−streptavidin conjugate for 30 min at 4 °C, and the supernatant was separated from the mixture by centrifugation. Finally, biotinylated beads were washed in PBS/BSA binding buffer at least three times.

FTIR spectra of reaction products and intermediates were recorded using samples deposited on PTFE IR cards (ICL, Garfield, NJ) on a Bruker IFS 66 (Bruker optics Inc., Billerica, MA) spectrometer.

Fluorescence spectroscopy was used to assess silicon nanoparticle photoluminescent properties after each step of the conjugation procedure. Emission spectra were acquired using 360 nm excitation on a SLM LM800 spectrofluorimeter (SLM Inc., Rochester, NY). Samples were contained in the 3 mm optical path-length quartz cells. Polystyrene microbeads were imaged with fluorescence microscope (Olympus BX50, Tokyo, Japan), using samples spread on glass microscope slides. Images were recorded with SPOT-RT KE digital cameras (Diagnostic Instruments, Sterling Heights, MI) and processed using imaging software (SPOT, version 4.0, Diagnostic Instruments, Sterling Heights, MI).

RESULTS AND DISCUSSION

Fresh silicon nanoparticles, suspended in toluene/octene mixture, displayed red−orange photoluminescence with maximum emission at 600 nm (Figure 2). However, the emission experienced a blue shift with maximum at 400 nm following UV-assisted derivatization with 1-octene. A similar effect was reported previously by Ruckenstein, who suggested a change in emission mechanism upon hydrosilylation (*30*). The blue emission intensity slightly decreased after anchoring to the protein molecule (Figure 2). Decreased intensity at 400 nm, which is typical of octane-derivatized SNs, and the appearance of a new broad feature around 450 nm in the emission spectrum of the final product suggests perturbations in nanocrystal electronic structure due to the covalent bond to the target protein.

Figure 3 shows the FTIR spectra of silicon nanoparticles recorded during various stages of the protein conjugation

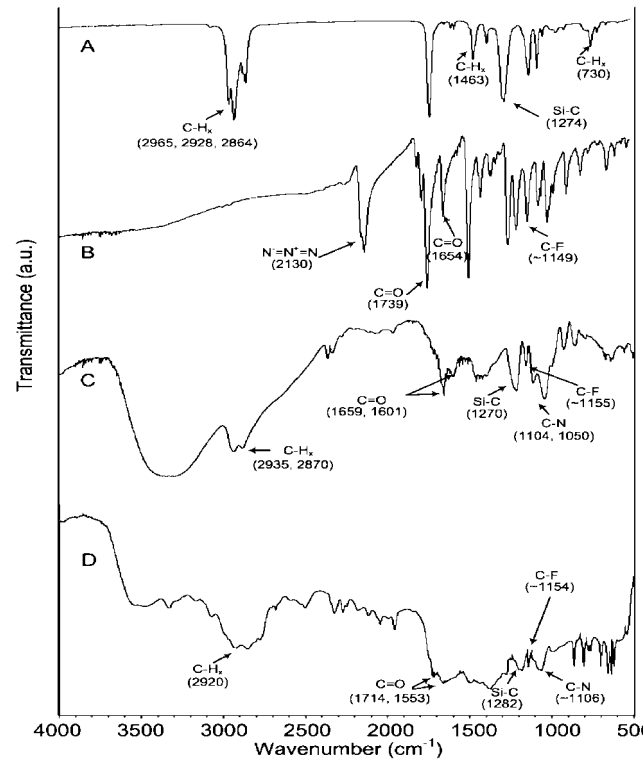

Figure 3. FTIR transmission spectra for dried films of (A) silicon nanoparticles, following the reaction with 1-octene (step a in Figure 1); (B) spectrum of pure bilinker ATFB, SE; (C) silicon nanoparticles subsequent to UV-assisted reaction with bilinker (step b in Figure 1), and (D) product of the conjugation reaction (step c in Figure 1).

procedure. Spectrum recorded following the UV-assisted hydrosilylation (Figure 3A) contains features, assigned to Si−C stretch (1274 cm^{-1}), C−H stretch (2965, 2928, 2964 cm^{-1}), and methylene bending (1463 cm^{-1}) modes, and is consistent with the silicon nanoparticle surface-bound alkane. Vibrational spectrum gets more complicated subsequent to the reaction with the 4-azido-2,3,5,6-tetrafluorobenzoic acid succinimidyl ester (ATFB, SE) (Figure 3C), suggesting the anchoring of the bilinker molecule to the octane-derivatized silicon particles. Notably, the disappearance of the aryl azide stretch at 2130 cm^{-1}, a prominent peak in the pure compound spectrum (Figure 3B) indicates that this group has been converted to nitrene in a photocatalyzed reaction. In addition, several peaks represent the fluorobenzoic acid moiety (1104, 1648, and 1155 cm^{-1}) and octane (1275, 2395 cm^{-1}) that was conjugated in the prior step.

The native electrophoresis gel image in Figure 4 contains separate bands corresponding to the SN−streptavidin complex and free streptavidin. Compared to free streptavidin, the protein−nanoparticle complex elutes earlier and displays an elongated band. The elution time in the native electrophoresis experiment is governed by the analyte morphological shape and charge; therefore, earlier elution of the SN−streptavidin complex is consistent with the extra negative charge due to linked SNs. The polydispersity in the eluted complex charge and molecular weight notably broadens conjugate gel features. One likely source of such polydispersity is silicon nanoparticle size polydispersity prior to conjugation (*26*) that is typical for SNs, produced by breaking up of the nanoporous silicon film. Also, variation in nanoparticle binding efficiency will result in conjugate composition distribution. Complexes with a higher number of SNs per protein molecule will carry a larger net negative charge and, consequently, will elute earlier. Additional experiments will be required to establish a quantitative relationship between the eluted band position and the conjugate molecular weight/charge ratio. Nevertheless, the current gel

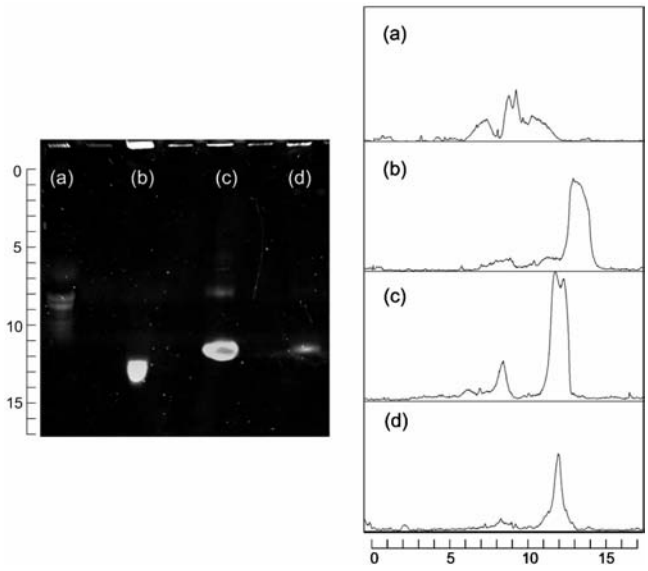

Figure 4. Native gel electrophoresis image and fluorescence intensity profiles from the eluted bands of neat streptavidin (a), and SN−streptavidin conjugates (b,c,d). Variation of elution times among (b), (c), and (d) wells reflect different relative concentrations of the cross-linker tagged SNs to the streptavidin in the final reaction mix (v/v); (b) 1:2, (c) 1:1, and (d) 2:1. Electrophoresis conditions: $U = 200$ V, $t = 2$ h. Mobile buffer: Tris-HCl, pH 8.0. Peaks between 8 and 9 represent neat streptavidin, and from 12 to 14 conjugation products.

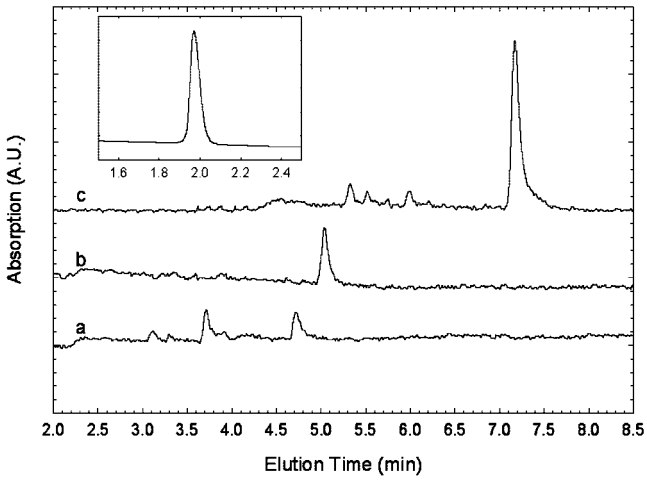

Figure 5. Capillary electrophoresis analysis of silicon nanoparticle/streptavidin conjugation reactants: (a) SNs with attached heterobifunctional cross-linker (ATFB, SE), (b) neat streptavidin, (c) SN−streptavidin conjugate. Inset shows the elution of a neutral molecule (mesityl oxide, see text). Running buffer: Tris−glycine 0.2 M, pH 8, capillary dimensions: $L = 50$ cm, ID = 0.1 mm. Applied voltage: $U = 20$ kV, absorbance detector at $\lambda = 200$ nm.

result confirms the formation of the covalent SN−protein complex and suggests the pathway for further conjugate purification. Gel electrophoresis demonstrates that SN−streptavidin conjugates have higher negative net charge compared to the neat streptavidin (Figure 4).

Further analysis of the conjugation products was performed using capillary electrophoresis (CE). High sensitivity, small samples, and rapid elution facilitated CE application in various fields of analytical chemistry (*31–34*) (for review, see ref (*31*)). Recently, Eckhoff et al. demonstrated CE separation of amine-functionalized silicon nanoparticles, using fluorescence detection (*33*). The analyte surface charge determines its mobility inside the CE capillary and allows charge-based nanoparticle separations. Consequently, the elution time series, produced by UV absorbance detection, can be related to the discrete silicon nanoparticle charges. Separation of surface-derivatized silicon nanoparticles, free streptavidin, and conjugate complex based on their net charge allows assessment of the conjugation efficiency. Given that streptavidin charge varies with the coupled SN number and affects the elution time, it also allows estimatation of the number of conjugated nanoparticles in the protein−SN complex.

Both capillary and gel electrophoresis rely on charge mobility in the electric field; therefore, we have maintained similar conditions in both experiments (buffer, pH, and temperature). In a first step, we have determined the apparent velocities v_{ap} for our sample components: SNs, streptavidin, SN−streptavidin conjugates

$$v_{ap} = \frac{L_{id}}{t_m} \tag{1}$$

where L_{id} is distance from the inlet to the detector, and t_m is travel time of the sample from inlet to the detector point in the capillary. In order to account for the electroosmotic component, we have calibrated our CE system using a neutral molecule, mesityl oxide (SigmaAldrich Inc., St. Lewis, MO), at identical experimental conditions and have estimated the electroosmotic velocity, v_{eo} (eq 2)

$$v_{eo} = \frac{L_{id}}{t_{m,n}} \tag{2}$$

Where v_{eo} is electroosmotic velocity and $t_{m,n}$ is the time for a neutral to arrive at the detector. Consequently, the actual sample velocity inside the capillary (v_{ac}), can be calculated

$$v_{ac} = v_{ap} - v_{eo} = \frac{L_{id}}{t_m} - \frac{L_{id}}{t_{m,n}} \tag{3}$$

Sample mobility μ_{eq} is a product of velocity and electrical field inside the capillary $\mu_{ep} = v_{ac}E$ and can be calculated when the net charge q and Stokes radius r are both known

$$\mu_{ep} = \frac{q}{6\pi\eta r} \tag{4}$$

Here, η is solvent viscosity. By combining eqs 3 and 4, we obtain a relationship between the charge q and sample elution time, t_m

$$q = 6\pi \cdot \eta \cdot r \cdot \left(\frac{L_{id}}{t_m} - \frac{L_{id}}{t_{m,n}}\right) \cdot E \tag{5}$$

where electric field strength $E = V/L_t$; V is total applied voltage, and L_t is total capillary length. Consequently, based on eq 5, we can assign each detected CE peak a net charge value and estimate the number of nanoparticles in the SN−protein complex.

Figure 5 shows the CE trace recorded using the UV absorbance detector ($\lambda = 200$ nm). The capillary inlet was connected to the anode; hence, negative analytes will elute later than neutral or positive molecules. Silanol (Si−OH) groups of the silica capillary interior wall turn into negatively charged silanoates (Si−O−) at pH 8, and attract buffer cations, forming a positive solution layer. This layer is dragged toward the cathode due to the electroosmosis, while negatively charged analytes move in the opposite direction and experience a delayed elution (Figure 5).

Four elution peaks at 3.1, 3.3, 3.7, and 4.8 min (Figure 5a) were analyzed within the range of expected nanoparticle size and surface charge. Based on the photoluminescence emission wavelength and nanocrystal size relationship (*23*), we have estimated that silicon particles with radiuses $r < 0.84$ nm should be responsible for the observed blue photoluminescence of our

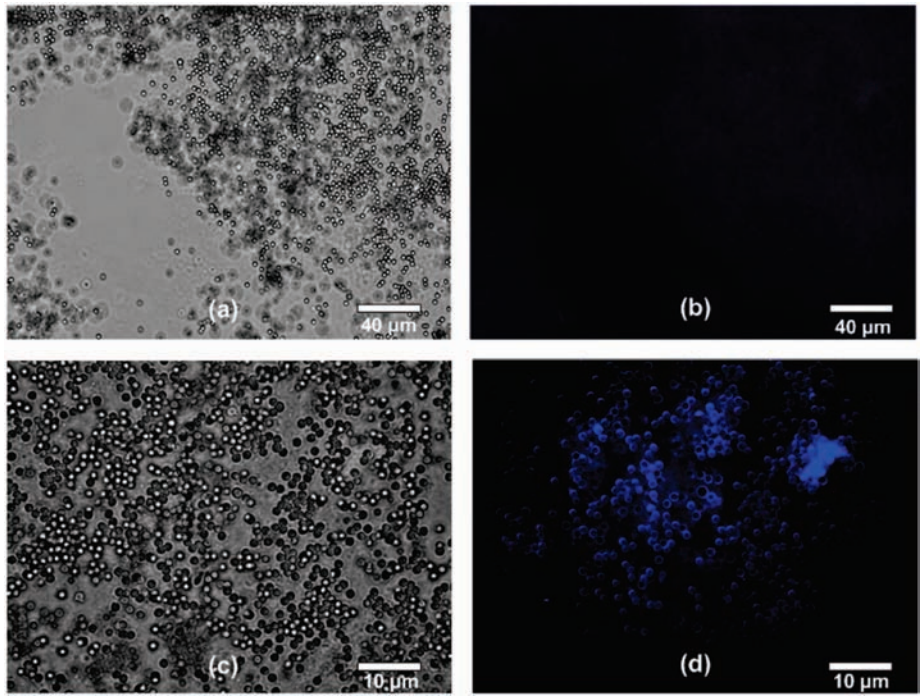

Figure 6. Fluorescence microscopy images of 2 μm diameter biotinylated polystyrene microbeads, following their exposure to silicon nanoparticle−streptavidin complex: (a) biotinylated polystyrene beads, exposed to the neat streptavidin (control) phase image, and (b) fluorescence image; (c) polystyrene beads exposed to a silicon nanoparticle−streptavidin complex phase image, and (d) fluorescence image.

samples (Figure 2). However, a change in emission mechanism due to surface functionalization can markedly affect this relationship (*30*). The two strongest elution peaks at 3.7 and 4.8 min were assigned net charges $q_1 = -1$ and $q_2 = -2$ that correspond to particles with $r_1 = 0.5$ nm and $r_2 = 0.84$ nm, respectively. The elution peak of the neat streptavidin (Figure 5b, at time 5.2 min), corresponds to a net charge of −13 at our experimental conditions (pH 8). Recently, Bradley et al. discussed the possible origin of the net negative streptavidin charge in basic solutions (*29*) and concluded that multiple exposed histidine residues are deprotonated at elevated pH. Notably, our CE derived protein charge estimate ($q_{St} = -13$ at pH 8.0) is consistent with the neat streptavidin zeta potential value (∼50 mV) (*35*).

The strongest feature in Figure 5c ($t = 7.2$ min) corresponds to the net charge from −17 to −18, depending on the associated nanoparticle radius (0.5 or 0.84 nm); therefore, the streptavidin molecule acquires an additional net charge from −4 to −5 due to silicon nanoparticle attachment.

Strong association between streptavidin and biotin is widely exploited in biological assays, and we have to ensure that streptavidin retains its binding capacity after attachment to silicon nanoparticles. The fluorescence microscopy image in the right panel of the Figure 6d displays streptavidin/SN conjugate binding to the biotinylated polystyrene microbeads, following incubation as described in the Experimental Section. Comparison of images on Figure 6 (a,b vs c,d panels) shows that the majority of complex exposed microbeads are associated with the photoluminescent silicon nanoparticles. The photoluminescence intensity variations between biotinylated beads reflect the heterogeneity in nanoparticle brightness and/or binding efficiency. A slight polystyrene bead aggregation, visible in c,d panels of Figure 6 may be caused by the multivalent streptavidin–biotin interactions.

CONCLUSION

We have covalently coupled streptavidin with the photoluminescent silicon nanoparticles using a multistep photoassisted reaction and a bifunctional cross-linker. The characteristic blue nanoparticle photoluminescence was retained in the silicon quantum dot−protein complex. Faster elution of the nanoparticle−streptavidin complex in the native gel electrophoresis indicates extra negative charge of the conjugate due to linked silicon nanoparticles. Typically from 4 to 5 silicon nanoparticles are bound to streptavidin molecule as determined from the capillary electrophoresis analysis. Streptavidin molecules retain their binding capability to the biotin subsequent to the conjugation protocol. Covalent attachment of small, efficient, and nontoxic photoluminescent silicon quantum dots to streptavidin provides a convenient pathway for biomolecule labeling in biotin−streptavidin affinity based assays.

ACKNOWLEDGMENT

Authors thank Dr. Jayne B. Morrow for her assistance with the fluorescence microscopy, and Dr. Karen W. Phinney for capillary electrophoresis. J.C. thanks Dr. Andrea M. Rossi and Mr. Peter Niarhos for helpful discussion.

Optical imaging of bacterial infection in living animals is usually conducted with genetic reporters such as light-emitting enzymes or fluorescent proteins. However, there are many circumstances where genetic reporters are not applicable, and there is a need for exogenous synthetic probes that can selectively target bacteria. The focus of this study is a fluorescent imaging probe that is composed of a bacterial affinity group conjugated to a near-infrared dye. The affinity group is a synthetic zinc (II) coordination complex that targets the anionic surfaces of bacterial cells. The probe allows detection of *Staphylococcus aureus* infection (5×10^7 cells) in a mouse leg infection model using whole animal near-infrared fluorescence imaging. Region of interest analysis showed that the signal ratio for infected leg to uninfected leg reaches 3.9 ± 0.5 at 21 h postinjection of the probe. Ex vivo imaging of the organs produced a signal ratio of 8 for infected to uninfected leg. Immunohistochemical analysis confirmed that the probe targeted the bacterial cells in the infected tissue. Optimization of the imaging filter set lowered the background signal due to autofluorescence and substantially improved imaging contrast. The study shows that near-infrared molecular probes are amenable to noninvasive optical imaging of localized *S. aureus* infection.

INTRODUCTION

Optical imaging of bacterial infection in living animals is emerging as a powerful method to study preclinical models of infectious disease. In most cases, genetic reporter systems such as light-emitting luciferase enzymes, or fluorescent proteins like GFP, have been employed with some notable success (*1*). However, pathogenic bacteria in their native environments do not express endogenous optical reporters. Furthermore, numerous microbes are not amenable to genetic manipulation or DNA transfection. In these cases, alternative optical imaging strategies must be developed such as the use of exogenous synthetic probes that selectively target the bacteria. While the most immediate application of these synthetic probes is the study of preclinical infection models in mice, they also have long-term clinical potential for imaging bacteria in shallow tissue. For example, prosthetic materials like mesh grafts or catheters are common sites of colonization by invasive bacteria such as MRSA (methicillin-resistant *Staphyloccus aureus*) (*2*), but they are difficult systems to image.

To date, only a small number of bacterial targeting probes have been reported for any imaging modality, and very few have been studied in vivo. A key design component is the bacteria targeting group, and previous studies have employed antibodies (*3*), lectins (*4*), sugars (*5*), antibiotic drugs (*6*–*8*), and peptides (*9*). Antibodies are popular, since they can bind tightly to specific molecular targets on the surfaces of both Gram-positive and Gram-negative bacterial cells (*10*). While antibodies have the potential advantage of high specificity, their large molecular size (~150 kD) is a limitation for in vivo imaging because of slow tissue diffusion and blood clearance rates.

A more general way to target bacteria is to employ cationic molecules that are electrostatically attracted to the negatively charged cells (*11*, *12*). The negative surface charge is a characteristic feature of nearly all bacterial membranes, and results from the high fraction of anionic phospholipids and related amphiphiles (*13*). For example, the plasma membrane which surrounds the Gram-positive bacterium *Staphylococcus aureus* is composed of approximately 75% anionic phosphatidylglycerol. Extending from this membrane are anionic glycerophosphate polymers called lipoteichoic acids that weave through and anchor the surrounding peptidoglycan cell wall (*14*). Gram-negative bacteria such as *Escherichia coli* are differentiated by the presence of a second outer bilayer membrane. The external leaflet of this outer membrane is composed of lipopolysaccharide whose core structure, known as lipid A, contains two anionic phosphates (*15*). The anionic surfaces of bacteria are in contrast to the exterior membrane surfaces of most healthy mammalian cells, which contain primarily zwit-

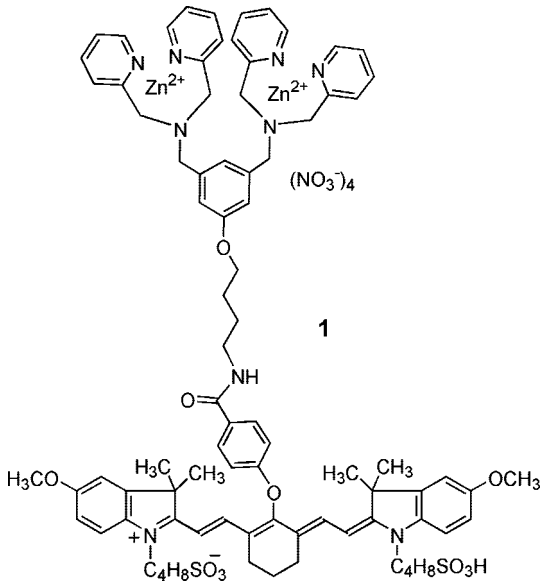
terionic phospholipids and thus have a near-neutral charge (*16*). For imaging purposes, a drawback with cationic peptides is their propensity to penetrate (and be retained by) mammalian cells (*17, 18*), while a limitation with antimicrobial peptides is poor signal-to-noise since they actively degrade the bacterial cell membrane target (*19*).

We have discovered that zinc (II) coordination complexes with dipicolylamine (DPA) ligands exhibit remarkably selective affinities for anionic cell membranes (*20*). For example, DPA-Zn(II) based probes allow fluorescent visualization of apoptotic mammalian cells, as they expose anionic phosphatidylserine during the programmed cell death process (*21*). In addition, these DPA-Zn(II) probes are highly selective stains for bacteria even in the presence of human epithelial cells (*22*). The specific focus of this study is fluorescent probe **1** which contains a DPA-Zn(II) affinity group conjugated to a near-infrared (NIR) carbocyanine fluorophore (ex. 794 nm, em. 810 nm). NIR fluorophores are optimal for in vivo imaging purposes given the favorable tissue penetration properties of photons at these wavelengths (*23*). In a preliminary report, we showed that **1** can identify infection sites in living mice, the first demonstration of in vivo bacterial detection using a fluorescent probe (*24*). We now describe a detailed optical imaging investigation of *S. aureus* infection using region of interest analysis to characterize the pharmacokinetics of probe uptake and clearance from the whole animal. We also provide biodistribution and histology data that measures organ and cell selectivity. Overall, we find that **1** is an effective *in vivo* optical imaging probe for localized infection of *S. aureus* in living mice.



EXPERIMENTAL PROCEDURES

Synthesis. Compound **1** was prepared as previously reported (*24*).

In Vivo Leg Infection Model. An aliquot of *Staphylococcus aureus* NRS11 (5×10^7 colony forming units (CFUs) in 50 μL of Luria–Bertani growth media) was injected intramuscularly into the muscles that overlay the tibia bone in a posterior leg of an athymic nude mouse (strain nu/nu, Taconic, New York). It is worth noting that this anatomical location is not the thigh, which is closer to the body of the mouse. The same location on the contralateral leg was injected with 50 μL of LB media as a vehicle control. The infection was allowed to incubate for 6 h before intravenous injection with probe **1** via the tail vein. After imaging experiments, the mice were anesthetized and euthanized by cervical dislocation.

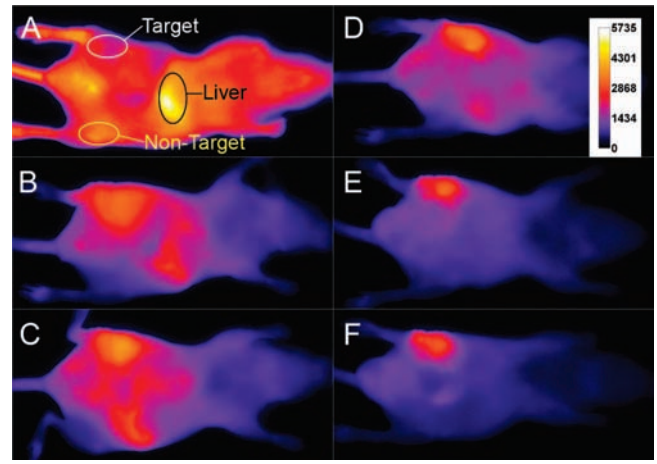


Figure 1. Optical images of a mouse with a *S. aureus* infection in the left posterior leg. Images were acquired following intravenous injection of probe **1** (75 μL of a 1 mM stock) at 0 h (A), 3 h (B), 6 h (C), 12 h (D), 18 h (E), and 21 h (F). Calibration bar (a.u.) applies to all images in the montage. Frame A shows labels for each region of interest (ROI): target (T), non-target (NT), and liver (L).

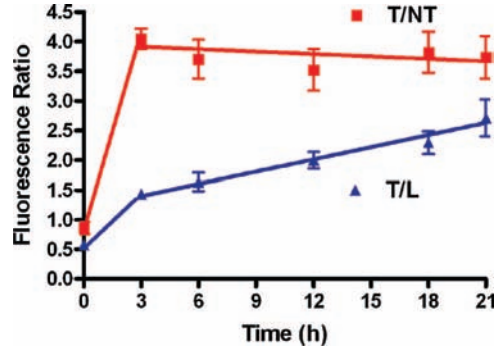

Figure 2. Target to nontarget (T/NT) and target to liver (T/L) fluorescence ratios at each imaging time point ($n = 4$; error bars are standard error of the mean). The lines are provided to guide the eye.

In Vivo Fluorescence Imaging. Imaging was achieved by placing an anesthetized mouse (1.5% isofluorane inhalation) inside a Kodak 4000MM imaging station configured for epi-illumination. The entire animal was irradiated with filtered light of wavelength 755 ± 20 nm, and a 16-bit image of emission intensity at 830 ± 10 nm was collected by a CCD camera during a 60 s acquisition period (F-stop = 2.4, focal plane 2.5 mm, FOV 200 mm no binning). In some cases, the mouse was also imaged using a filter set with excitation at 720 ± 10 nm and emission at 790 ± 35 nm. Mice were imaged before and immediately after injection of **1**, and at subsequent time points as detailed in the text.

Image Preparation and Quantitative Analysis. Images were processed using the *ImageJ 1.37v* program available for free download at http://rsb.info.nih.gov/ij/. Figures 1, 4, 6, and 7 were prepared as follows. First, the original 16-bit images (presented as panels in each figure) were sequentially opened and then converted to an image stack using the "convert images to stack" software command. Next, the stack of images was background-subtracted using the rolling ball algorithm (radius = 500 pixels) that is a feature of the software. This tool calculates the average pixel intensity of any signal emanating from a "non-mouse" region of the image, and then subtracts this calculated value from every pixel in the image. The radius was selected to exceed the maximum width of the mouse; otherwise, the mouse itself will be included in the background calculation. Next, the image stack was set to the "Fire"

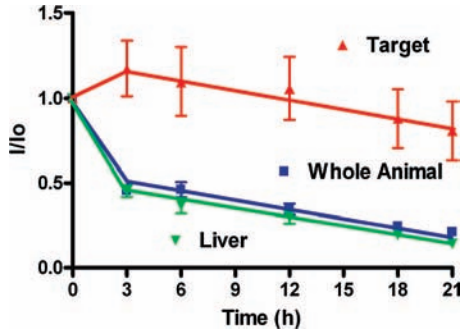

Figure 3. Fluorescence emission time course for the infection target, whole animal, and liver ROIs ($n = 4$; error bars are standard error of the mean). The lines are provided to guide the eye.

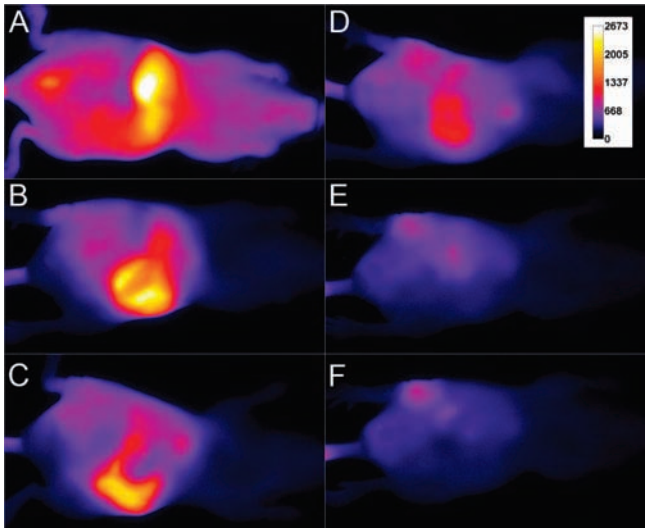

Figure 4. Optical images of a mouse with a *S. aureus* infection in the left posterior leg. Images were acquired following intravenous injection of a low dose of probe **1** (75 μL of a 0.2 mM stock) at 0 h (A), 3 h (B), 6 h (C), 12 h (D), 18 h (E), and 21 h (F). Calibration bar (a.u.) applies to all images in the montage.

fluorescence intensity scale (under "Lookup Tables" menu), which color-codes the fluorescence counts contained in each pixel. After that, the stack of images was converted to a montage using the "convert stack to montage" command. At this point, region of interest (ROI) analysis was performed by selecting a circle ROI from the *ImageJ* tool bar, and drawing it to circumscribe the appropriate anatomical location of each mouse, as shown in Figure 1. The average pixel intensities of the target (T), nontarget (NT), and liver (L) were measured by *ImageJ* (CTRL-M) and recorded for each mouse in *Excel 2003*. In addition, an ROI was drawn around the whole mouse (excluding the target site) and the integrated density recorded. Statistical analysis was performed to acquire the average of each ROI ($n = 4$) with the standard error of the mean (SEM), and the resulting values plotted in *Graphpad Prizm 4*. Two-way ANOVA analysis was also performed in *GraphPad* version 4 to calculate the *p*-values reported in the text. After ROI analysis, a calibration bar was added to the montage using the "calibration bar" command in the *ImageJ* program.

Biodistribution. After imaging studies, the mice were anesthetized by isofluorane inhalation (1.5%) and euthanized by cervical dislocation. The major organs were dissected, placed on a glass plate, and imaged as described above. The biodistribution image was analyzed in *ImageJ* by first subtracting the background (rolling ball method, 100 pixel width). Manual regions of interest (ROIs) were drawn around each organ, and the mean pixel intensity calculated for each. ROIs were drawn around the discrete site of infection. The averages for each organ ($n = 3$) and each infected site ($n = 4$) were calculated and plotted as detailed above.

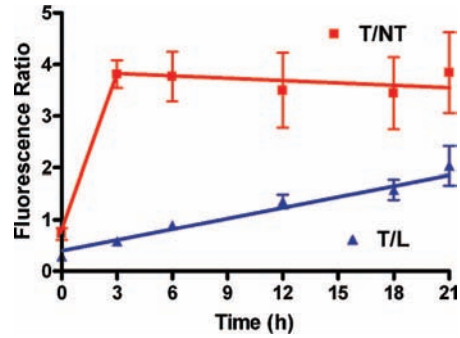

Figure 5. Target to nontarget (T/NT) and target to liver (T/L) fluorescence ratios at each imaging time point after injection with a 0.2 mM stock of **1** ($n = 4$, error bars are standard error of the mean).

Histology. The first analysis used mice with a 9 h infection in one of the posterior legs, but no treatment with probe **1**. Tissue was sampled, including the skin, subcutis, and muscle from the leg which had been administered bacteria; a similar sample was also obtained from the contralateral uninfected leg. The tissue was fixed in 10% neutral buffered formalin for 24 h and then transferred to 70% ethanol. Following embedding in paraffin, tissue was sectioned at 4–5 μm and stained with hematoxylin and eosin. The second analysis used mice that had been infected with bacteria and also injected with probe **1**. Sections at 10 μm from the infected leg and the uninfected contralateral leg were stained with a Texas Red-labeled antibody to *Staphyloccus aureus* protein A (250 μL of a 100 μg/mL solution in buffer: 5 mM TES (*N*-tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid), 145 mM NaCl, pH = 7.4), (Abcam Inc., Goa pAb to protein A (TR) ab7247–1). Microscopy was performed at 600× magnification on a Nikon Eclipse 2000TE microscope with a Photometrics Cascade 512B camera to aquire 16 bit images. Each image was processed using the *ImageJ* software suite. A control in vitro microscopy study confirmed that the Texas-red labeled antibody targets the surface of the *S. aureus*, as expected, with no emission in the Cy7 filter set.

RESULTS AND DISCUSSION

In Vivo Imaging. The bacteria were injected into the muscles that overlay the tibia bone in a posterior leg of athymic nude mice. This infection model was chosen for the following reasons (*1*): (a) The posterior leg is well-separated from all major organs, and bacterial migration from the site is slow, thus reducing any confusion as to the origin of the fluorescent signal. (b) The lack of hair produces less scattering of the light. (c) The inhibited immune system simplifies interpretation of the imaging and histology data.

A cohort of four mice was each infected with a bolus of 5×10^7 colony forming units (CFUs) of *S. aureus* NRS11 in a 50 μL aliquot of Luria–Bertani (LB) growth media. The contralateral leg was injected with LB alone to serve as the vehicle control. After a 6 h incubation, each mouse was injected intravenously, via the tail vein, with probe **1** (75 μL of an aqueous 1 mM stock solution). Assuming a blood volume of 1 mL, the final concentration of **1** in the blood was approximately 75 μM or about 4 mg/kg. Each animal was subsequently imaged on its ventral side at 0, 3, 6, 12, 18, and 21 h using a Kodak 4000MM Imaging Station designed to acquire 16 bit planar fluorescence images. The images were subsequently processed using the *ImageJ* V1.37 software suite (see methods). It is important to note that colors in these images do not represent

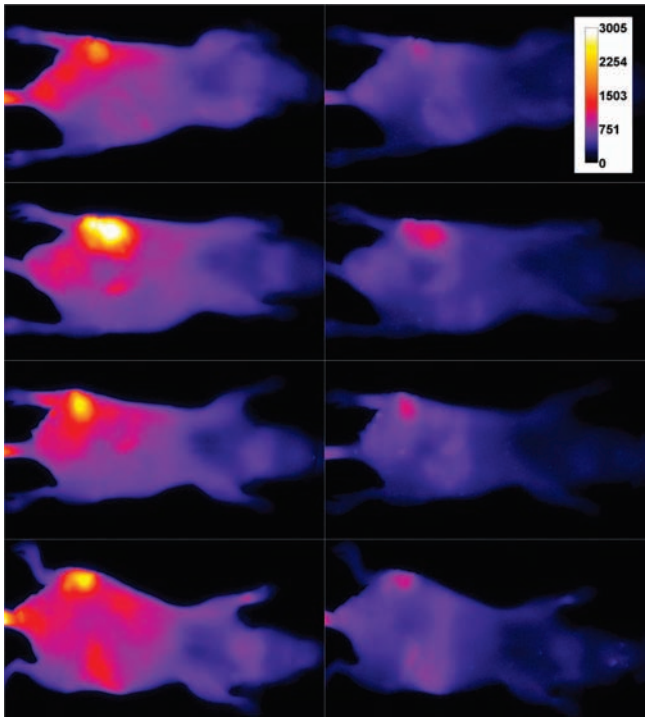

Figure 6. Optical images of four mice each with a *S. aureus* infection in the left posterior leg and acquired 21 h postinjection of probe **1** (75 μL of a 1 mM stock). Left column: animals were imaged using an excitation of 755 nm and emission of 830 nm. Right column: the same animals were imaged using an excitation of 720 nm and emission of 790 nm. Calibration bar (a.u.) applies to all images in the montage.

wavelengths of light, but rather the fluorescence intensity of each pixel in the image.

In Figure 1 are typical fluorescence images (ex: 755, em: 830 nm) obtained for one mouse during the time course of one experiment. Immediately after injection with **1**, there is a bright, confluent fluorescence emanating from most parts of the animal. A region of interest (ROI) analysis was derived from the average pixel intensities at the three anatomical locations shown in frame A: the target leg infection site (T), the contralateral leg as a nontarget site (NT), and the liver (L). At time zero, the target to nontarget (T/NT) fluorescence ratio was 0.85 ± 0.1 ($n = 4$, standard error of the mean), indicating that less probe diffuses through the infected leg relative to the control leg immediately following injection. The cause of this small decrease is unknown, but it may be the result of *S. aureus* induced ischemic damage to the local vasculature, as observed for other Gram-positive microbes (*25*). Localization of **1** can be observed at the target site within 3 h postinjection, and the image continues to sharpen as the probe clears from the mouse body over the subsequent 18 h. Figure 2 shows the average target to nontarget (T/NT) and target to liver (T/L) fluorescence ratios for the cohort of four mice at each imaging time point during the study. The lines that connect the points are to guide the eye and do not represent a mathematical fit. A salient point is that the T/NT ratio reaches a value close to 4 after just 3 h and is sustained for the remainder of the experiment (at 21 h, T/NT $= 3.9 \pm 0.5$, $n = 4$). The T/L ratio also rises quickly during the first 3 h, and then continues to increase slowly with time such that T/L $= 2.7 \pm 0.4$ ($n = 4$) at 21 h.[1]It is important to appreciate the difference between

[1]The values of T/NT and T/L reported here compare favorably with an imaging study that utilized radiolabeled antimicrobial peptides and reported T/NT ratios as high as 4.1 ± 0.7 (*30*). A value for T/L could not be determined, since most of the signal originated from the body of the mouse and not the target site.

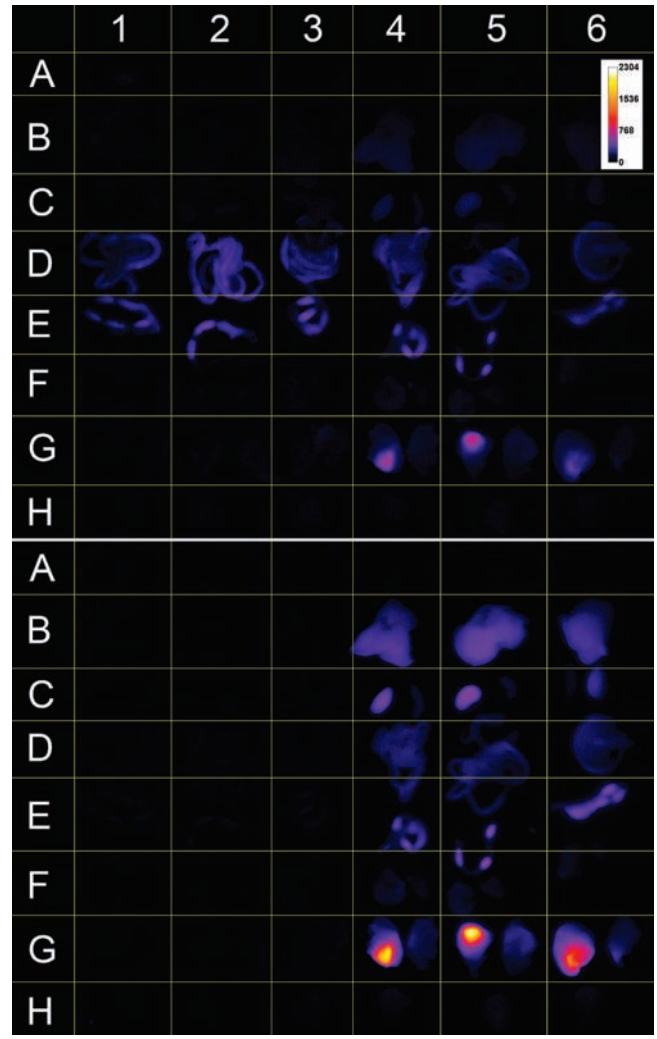

Figure 7. Ex vivo image of mouse tissues from three uninfected mice (columns 1–3) and three infected mice that were injected with **1** (colums 4–6). The organs and blood are given in the following rows of Figure 5: (A) blood, (B) liver, (C) kidney (left) and spleen (right), (D) small intestine, (E) large intestine, (F) lungs (left) and heart (right), (G) left and right posterior leg tissue, and (H) brain. Images were acquired with the 720/790 nm (top frame) and 755/830 nm (bottom) filter sets. Calibration bar (a.u.) set for both frames.

T/NT and T/L. The T/NT ratio is a measure of targeting at the infection site relative to the contralateral control site, whereas the T/L ratio is a measure of the imaging contrast observed between the infection site and the whole mouse. Thus, while the T/NT ratio reaches a maximum in the first 3 h of imaging, the continued linear increase in T/L up to 21 h time reflects the improving contrast that helps identify the infection site relative to the mouse body.

Plotted in Figure 3 are the average changes in total fluorescence emission (I/I_0) from the target site and also the whole animal over the course of the imaging experiment ($n = 4$). These data show that the fluorescence emission from the infection site increased by approximately 20% over the first three hours of the experiment, whereas, the total animal fluorescence decreased by 50% over the same period. This indicates that most of probe **1** binds to the target within the first 3 h, and that after this initial phase, the infection site, liver, and whole animal lose fluorescence at the same apparent linear rate.

In Vivo Imaging with Lower Probe Concentration. Additional in vivo imaging studies were performed to assess the sensitivity of probe **1**. The main goal was to determine whether

useful imaging results could be obtained with a lower dose.[2] Thus, a cohort of four mice were each given a leg infection of *S. aureus* as described above, but this time they received a 5-fold lower intravenous concentration of **1** (15 μM estimated final blood concentration). As shown in Figure 4, the overall signal from the infected leg was less intense. The T/L ratio in Figure 5 increased linearly with time to reach a value of 1.9 $\pm$ 0.4 after 21 h, which is 70% of the value obtained using the higher dose of **1**. Although the signal contrast is lower, the T/NT ratio (Figure 5) mirrors the higher probe dose profile and reaches a value close to 4 after 3 h. These data indicate that the lower probe dose can be used to effectively image a leg infection because this anatomical location has an inherently low background signal that is primarily due to tissue autofluorescence. However, other infection sites, like the kidney and liver which avenues for probe clearance, would be more difficult to image at this lower probe concentration since there is a higher background signal due to some nonselective accumulation of probe.

Optimizing the Imaging Filter Set. A drawback with the popular 2D planar imaging technique used in this study is the attenuation of fluorescence signal with tissue depth. Furthermore, the photophysical properties of carbocyanine fluorophores vary with both solvent polarity and the presence of serum components of blood (*26*). Therefore, it was important to gauge image variability between separate animals and also to check how much the image quality changed with different instrument filter sets. Our previous preliminary study of probe **1** (λ_{max} abs: 794 nm, em: 810 nm) employed a 720/790 nm filter set (excitation at 720 $\pm$ 10 nm, emission at 790 $\pm$ 35 nm) (*24*); however, the imaging data reported above used a more optimal 755 $\pm$ 20/830 $\pm$ 35 nm filter set. The benefit gained by using this longer-wavelength filter set is illustrated in Figure 6, which compares images of four mice at the 21 h time point. With each animal, the *S. aureus* infection site in the left posterior leg is readily discerned, demonstrating the excellent reproducibility of probe **1**. Comparatively, the contrast using the 755/830 nm filter set (Figure 6, left column) is clearly greater for each mouse than that observed with its corresponding image in the 720/790 nm filter set (Figure 6, right column). ROI analysis confirmed that the T/NT ratio for these mice is 3.8 $\pm$ 0.4 with the 755/830 nm set, which is 36% better than the T/NT ratio of 2.8 $\pm$ 0.2 obtained with the 720/790 set ($p = 0.014$). In addition, the T/L ratio values improved from 2.3 $\pm$ 0.2 (720/790 nm set) to 2.8 $\pm$ 0.5 (755/830 nm set) for a 22% average gain ($p = 0.021$). The longer-wavelength filter set enhances contrast for two reasons. First, the deeper red 755/830 nm filter set produces increased probe excitation in deeper tissues, with a corresponding enhancement of fluorescence emission. Second, there is a lower background signal from nonprobe autofluorescence.

Ex Vivo Imaging. Ex vivo fluorescence analysis of the mouse organs was performed to assess the biodistribution of probe **1**. Three mice from the cohort in Figure 3 (i.e., treated with the higher probe concentration) were euthanized by cervical dislocation at the 21 h time point and their organs gathered to determine the distribution of probe **1** (Figure 7, columns 4–6). Three additional mice, that were neither infected nor injected, were used as controls (columns 1–3). The organs and blood were placed on a glass plate and imaged using the Kodak Imaging Station with the 720/790 nm (top frame) and 755/830 nm (bottom frame) filter sets. The fluorescent images are given in the following rows of Figure 5: (A) blood, (B) liver, (C) kidney (left) and spleen (right), (D) small intestine, (E) large intestine, (F) lungs (left) and heart (right), (G) left and right posterior leg muscle, and (H) brain. The infected tissue is immediately obvious upon inspection of row G which shows the left (infected) and right (uninfected) posterior leg muscles. The fluorescence emission emanates from one area of the leg tissue, indicating that probe **1** is localized to the initial site of bacterial injection. Moderate fluorescence intensity also emanated from the liver and small and large intestine, indicating that this is a major excretion pathway for **1**.

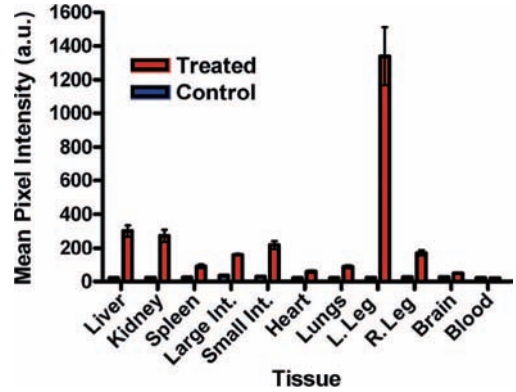

Figure 8. Ex vivo organ quantification of Figure 7 imaged with the 755/830 nm filter set ($n = 3$, error bars are the standard error of the mean).

Inspection of the images in Figure 7 shows that image contrast due to staining by probe **1** is enhanced significantly by changing the 720/790 nm filter set to the longer-wavelength 755/830 nm filter set. In particular, the strong gut autofluorescence (due to food (*27*)) for control mice 1–3 in rows D and E is almost completely eliminated, whereas the fluorescence intensity of every organ containing probe **1** is greater. In other words, the fluorescence ratio of the infected to uninfected leg (T/NT) was increased from 4.5 to 7.8 by changing to the longer-wavelength filter set. Figure 8 shows the average fluorescence intensity of the pixels in each organ as determined by ROI analysis ($n = 3$) from image taken using the optimized 755/830 nm filter set. The left leg gave about 8-fold more signal than the contralateral uninfected leg tissue. Furthermore, the infected leg had a minimum 4-fold greater intensity when compared to other organs like the liver and kidneys. Taken together, the data show that compound **1** selectively targets the leg of each animal that has a localized infection of *S. aureus*.

Histology. Two types of analyses were performed. The first was a general histological comparison of tissue sections from mice with a 9 h infection in one of the posterior legs. After fixation and embedding in paraffin, the tissue samples were sectioned at 4–5 μm and stained with hematoxylin and eosin. As expected, tissue sections from the contralateral uninfected legs were normal and showed no signs of necrosis or inflammation. Tissue sections from infected legs showed evidence of mild to moderate inflammation and some hyaline degeneration; however, there were no pyknotic nuclei or other cellular debris associated with cell death and necrosis.

The second analysis was an immunohistochemical assessment of the selectivity of probe **1** for bacterial cells. Thus, 10 μm sections were processed from the infected and uninfected leg tissue of mice that were injected with **1** (see Experimental Procedures). The sections were counter-stained with a Texas Red labeled antibody with selectivity for protein A (Abcam), an antigen present the surface of *S. aureus*. Microscopy data from one infected tissue section are shown in Figure 9. In the left panel is a phase contrast image. The region containing small dark spots (highlighted in the red box) indicates the presence

[2] A lower probe dose would, of course, lower the chance of chemical toxicity. While a complete toxicity study has not yet been conducted, it is worth noting that the nude mice easily tolerate the presence of probe **1** (4 mg/kg) for at least 24 h, as judged by their continued grooming and nesting activities.

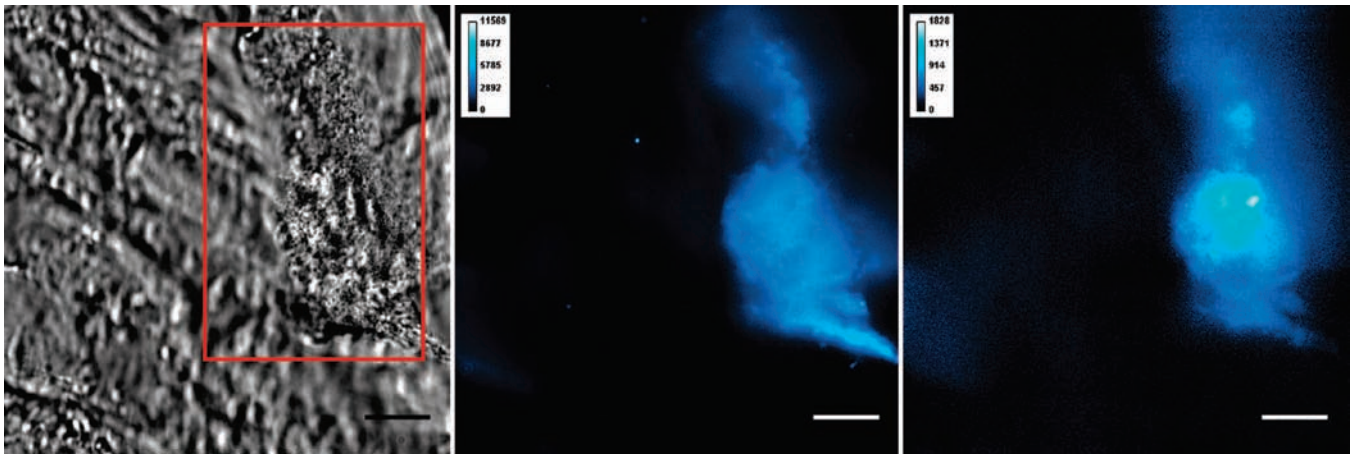

Figure 9. Histological section of infected leg muscle as viewed at 600× in the phase contrast (left), red (center), and NIR Cy7 (right) filter sets. The red box at left designates a patch of spots that mark the presence of bacteria. Infected tissue was sectioned 21 h postinjection of **1**. Scale bar equals 20 μM for each frame. Calibration bar is in arbitrary units.

of bacterial cells. The center picture shows the same section in the red filter set (ex. HQ535/50X, em. HQ610/75m). The colocalized emission from the Texas Red antibody conjugate establishes the presence of *S. aureus*. The right panel shows the section viewed with a NIR Cy7 filter set (ex. 710/75X, em. 810/90m) that selectively detects emission from **1**. The NIR fluorescence intensity in the bacterial cluster was approximately 3-fold higher than in the surrounding tissue. Images of tissue sections from the uninfected contralateral leg of the same mouse were treated with the same antibody stain, but there was no fluorescent signal in the red (antibody) or NIR (probe) channels (data not shown).

The histology data indicate that the DPA-Zn(II) affinity group in compound **1** targets the anionic membrane surfaces of the bacteria cells and not the relatively small number of dead and dying mammalian cells in the leg tissue that surrounds the infection site. Even though the amount of muscle cell death increases as the infection progresses, we expect that probe **1** continues to act as a bacterial imaging agent for two reasons. The first pertains to the increased surface to volume ratio of bacteria compared to mammalian cells. *S. aureus* cells have a diameter of approximately 750 nm, while tubular muscle cells are considerably larger with an effective diameter of over 50 μm and a length of at least 1 mm. Thus, millions of bacteria can occupy the space of one small muscle cell, with over 2 orders of magnitude more cell surface area. Second, bacterial cell surfaces typically have a higher fraction of negatively charged lipids than do mammalian cell surfaces. In the present case, *S. aureus* membranes are about 75% phophatidylglycerol, while the typical mammalian cell has about 15% phophatidylserine (*21*).

CONCLUSIONS

Fluorescent conjugate **1** is a robust imaging probe for the detection of localized *S. aureus* infection. The probe is easily visualized at a leg infection site within 3 h of administration. The probe selectively targets the bacterial cells in the infected tissue, as judged by immunohistochemical analysis. The image contrast was lower with decreased probe dosage; however, this technical limitation can be addressed with new and brighter NIR fluorophores (*28*). The focus of this study was on the Gram-positive *S. aureus*, a common source of secondary infection in healthcare facilities (*29*); however, probe **1** can likely be used to image almost all strains of bacteria because the DPA-Zn(II) affinity group targets the anionic surfaces that are a characteristic feature of nearly all bacterial membranes. One of the future goals of this research is to noninvasively detect and monitor bacterial pathogensis in various infection models, such as the urinary tract, lungs, or brain and spine. Eventually, probe **1**, or the next-generation versions, may have clinical applications. For example, optical imaging would be a useful tool for the clinician seeking information on low-grade infections that occur in mesh grafts or catheter sites, where it is often very difficult to distinguish infection from sterile inflammation.

Extracellular Barriers to *in Vivo* PEI and PEGylated PEI Polyplex-Mediated Gene Delivery to the Liver

Rob S. Burke and Suzie H. Pun*

Department of Bioengineering, University of Washington, 1705 NE Pacific Street, Seattle, Washington 98195. Received October 20, 2007; Revised Manuscript Received November 10, 2007

Polyplex-mediated gene therapy is a promising alternative to viral gene therapy. One challenge to these synthetic carriers is reduced transfection efficiencies *in vivo* compared to those achieved *in vitro*. Many of the intracellular barriers to gene delivery have been elucidated, but similar quantification of extracellular barriers to gene delivery remains a need. In this study, the unpackaging of polyplexes by serum proteins, soluble glycosaminoglycans, and an extracellular matrix extract was demonstrated by a YOYO-1 fluorescence quenching assay. Additionally, exposing polyplexes to serum or proteoglycans before *in vitro* transfection caused decreased cellular uptake of DNA. Lastly, PEI polyplexes and PEGylated PEI polyplexes were injected into the portal vein of mice, and the intrahepatic distributions of labeled DNA and polymer were assessed by confocal microscopy. PEI polyplexes delivered DNA to the liver, but extensive vector unpackaging was observed, with PEI primarily colocalized with the extracellular matrix. PEGylated polyplexes mediated less DNA delivery to the liver, possibly due to premature vector unpackaging in the blood. Through this work, both the blood and the extracellular matrix have been determined to be significant extracellular barriers to polyplex-mediated *in vivo* gene delivery to the liver.

INTRODUCTION

The field of gene therapy first gained momentum with the use of viral gene delivery vectors (*1, 2*). However, interest in the development of nonviral vectors remains high because of challenges associated with the use of viruses in humans, including safety and large-scale production issues (*3, 4*). One of the main classes of nonviral gene delivery vectors that has been extensively investigated is complexes of cationic polymer and DNA, termed polyplexes (*5*). Polycations condense DNA through electrostatic interactions to form particles with sizes on the order of 100 nm. One of the most popular cationic polymers used to form polyplexes is the commercially available polyethylenimine (PEI) (*6*). The use of PEI to deliver DNA has become widespread after several groups showed that it generates particularly high *in vitro* transfection efficiencies compared to those of other nonviral gene delivery vectors by mediating endosomal release (*6–11*).

Branched PEI (bPEI) and linear PEI (lPEI) can both be used effectively for gene delivery. Although lPEI is generally preferred for *in vivo* applications because of its advantageous toxicity profile (*12*), bPEI contains a higher percentage of primary amines and is thus more suitable to modifications. Examples of modifications include incorporation of targeting ligands to increase the specificity of delivery, labeling the polymer with fluorophore to track its location through fluorescence microscopy, or grafting of poly(ethylene glycol) (PEG) to the polymer to increase polyplex stability. Incorporation of PEG in polyplex formulation, a process known as PEGylation, increases the salt stability of the particles and reduces interaction with blood components, resulting in decreased uptake by the reticuloendothelial system and prolonged circulation time of the PEGylated polyplexes (*13*). However, at the same time, PEGylation has been shown to reduce uptake by cells, which in turn reduces the level of gene expression (*14, 15*).

Much of the work investigating the mechanism of nonviral gene delivery has focused on the intracellular barriers that a delivery vector must overcome to deliver its cargo to the nucleus, including binding to the cell surface and internalization (*16–19*), escape from the endosomal pathway (*9, 10, 20, 21*), transport in the cytoplasm (*22–25*), nuclear entry (*26–29*), and vector unpackaging (*30, 31*). However, the extracellular barriers to gene delivery are important to consider for *in vivo* applications. For organ-specific delivery after systemic administration, the vectors must successfully extravasate from the vasculature and maneuver through the extracellular matrix (ECM) to reach the target cells. Because polyplexes are held together electrostatically, other charged species may disrupt the interaction between DNA and polymer. Indeed, Huth et al. showed that polyplexes released from endosomes could unpackage in the cytoplasm by competition with cytosolic RNA (*31*). Additionally, Schaffer et al. found that chromosomal DNA inside the cell nucleus is capable of participating in vector unpackaging (*30*). Taken together, these studies illustrate that polymeric properties such as the molecular weight, which affects how tightly the polymer binds DNA, influence where the polyplexes unpackage after intracellular delivery. However, charged species that are able to compete the polymer off the DNA do not only exist inside cells. Polyplex vector interactions with extracellular and cell surface glycosaminoglycans (GAGs) also result in vector unpackaging and a decrease in gene delivery efficiency (*32–35*).

In vitro transfection studies with PEI polyplexes have shown high gene delivery efficiencies; in contrast, *in vivo* data obtained by various researchers shows that *in vitro* transfection is a poor predictor of *in vivo* success (*12, 36, 37*). The rationale for this work is that, although many polymeric vectors have been optimized *in vitro* to overcome intracellular barriers, there are many extracellular barriers that must be overcome in order to achieve successful *in vivo* gene delivery. An understanding of the limiting barriers to *in vivo* gene delivery will facilitate the design of improved vectors able to overcome these barriers, thus increasing the efficiency of gene delivery. In this work, the integrity of PEI and PEGylated PEI polyplexes is examined both

in vitro and *in vivo* through dual-fluorescence labeling of polymer and DNA. The *in vivo* studies focused on the assessment of intrahepatic distributions of polymer and delivered DNA because other studies have shown that polyplexes accumulate primarily in the liver after injection but that transgene expression is relatively low (*38–41*). Our results reveal that both the serum and the ECM pose barriers to gene delivery. Systemically injected PEI polyplexes are found to be unpackaged in the liver, thus accounting for suboptimal gene delivery efficiencies.

EXPERIMENTAL PROCEDURES

Materials. All materials were purchased from Sigma-Aldrich unless otherwise stated.

Synthesis of PEI-Dinitrophenyl (PEI-DNP). bPEI (25,000 g/mol, 12.7 mg) was dissolved in 0.15 M $NaHCO_3$ at pH 8.3, at 10 mg/mL. To this solution was added 5 mg (25 equiv) of 6-(2,4-dinitrophenyl)aminohexanoic acid, succinimidyl ester (DNP-NHS, from Invitrogen) dissolved at 10 mg/mL in DMF, followed by stirring overnight at room temperature. The polymer was then protonated by the addition of HCl and dialyzed in a Slide-A-Lyzer 10K MWCO dialysis cassette (Pierce) against dH_2O to remove solvent and excess reactants. The solution was lyophilized to yield a fluffy yellow solid. The polymer was redissolved in dH_2O, the PEI concentration was determined by a copper (II) acetate assay as described previously (*42*), and the DNP concentration was measured by absorbance at 360 nm.
