value of 7.0. Hydrophobicity of side groups and conformation of polyelectrolytes are known to affect the dielectric constant around charged groups, thereby imparting different ionization characteristics (*25*−*27*). Because CHexPG has highly hydrophobic side groups, hydrophobic interactions among these side groups might engender a compact conformation, which enhances charge−charge interactions, resulting in suppression of dissociation of carboxyl groups (*27*).

Hydrophobicity of carboxylated polymers affects their precipitation behaviors (*28*). For that reason, we estimated the pH at which the polymers precipitate using the following optical densities (ODs) of these polymer solutions as the pH of the solution was decreased (Figure 1). These polymers were soluble in water at neutral pH; their solutions were transparent. However, the polymer solutions suddenly became turbid at a specific pH, which was defined as the precipitation pH. The precipitation pH thresholds for these poly(glycidol) derivatives were estimated as listed in Table 2. Apparently, the precipitation pH shifted to higher pH values as the number of carbon atoms in the side chains of the polymers increased. This result indicates that the precipitation pH increases with increasing hydrophobicity of the polymer side groups and is consistent with previous observation for methacrylic acid copolymers with varying hydrophobicities (*28*). Acid−base titration for these polymers indicated that the degree of protonation for their carboxyl groups was at pH 0.93−0.99 of the precipitation pH: most carboxyl groups must be protonated to elicit precipitation of these polymers.

Hydrophobicity of the polymers was further investigated using fluorescence of pyrene. An emission intensity ratio of the first (373 nm) to the third (384 nm) peaks of pyrene, I_1/I_3, is known to be sensitive to the microenvironmental polarity surrounding the pyrene molecule (*19*). Consequently, this ratio has been widely used to estimate the hydrophobic nature of polymers (*20, 21*). Figure 2 depicts the I_1/I_3 ratio of pyrene fluorescence in the buffer dissolving various polymers as a function of pH. In buffers dissolving SucPG and GluPG, the I_1/I_3 ratios of pyrene were appropriately 1.8 at any pH and were the same as the ratio in the buffer without polymers. This result suggests that these polymers formed no domains with a hydrophobic nature, even

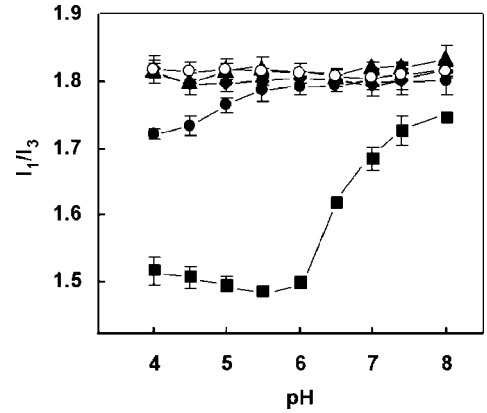

Figure 2. I_1/I_3 of pyrene fluorescence in MES 25 mM and NaCl 125 mM solution with SucPG (▲), GluPG (◆), MGluPG (●), and CHexPG (■), and without polymer (○). Concentration of polymers and pyrene were 0.2 mg/mL and 1 μM, respectively. I_1/I_3 was defined as the fluorescence intensity ratio of the first band at 373 nm to the third band at 384 nm.

after protonation of most carboxyl groups of the polymer chain. The presence of MGluPG affected the I_1/I_3 ratio, which tends to decrease below pH 5.5, indicating that this polymer formed domains with a hydrophobic nature. A more significant decrease in the I_1/I_3 ratio was shown by the presence of CHexPG, which caused a marked decrease in the ratio below pH 8.0. This polymer formed hydrophobic domains, even at physiological pH.

Interaction of Poly(glycidol) Derivatives with Lipid Membrane. We investigated the ability of these polymers to interact with liposomal membranes. The poly(glycidol) derivatives were added to liposomes encapsulating both pyranine and its fluorescence quencher DPX suspended in the buffer of varying pHs; leakage of pyranine from the liposomes was monitored by following pyranine fluorescence. Figure 3A,B depicts the time course and pH dependence of the pyranine release from the liposomes induced by the polymers. Although CHexPG induced a marked release at pH 6.5, other polymers exhibited no ability to induce a release of pyranine at any pH, indicating that SucPG, GluPG, and MGluPG have very weak or no ability to destabilize liposomal membrane.

In contrast, when their counterparts with anchor moieties, namely, SucPG-C10, GluPG-C10, MGluPG-C10, and CHexPG-C10, were added to the pyranine-loaded liposomes, an intensive release of the contents was observed for all polymers (Figure 3C,D). Considering that most of these polymers without anchors failed to induce content release, even at acidic pH, these polymers are necessarily associated with the liposome membranes before their protonation to induce content release from the liposomes. Because their backbone with PEG-like structure can form hydrogen bonding with carboxyl groups, both the polymer backbone and side-chain carboxyl groups might not efficiently interact with liposomal membranes when the polymer chains are dissolved in solution. However, when bound onto the liposome membrane, these polymers might strongly interact with the liposome membrane through hydrogen bonding between the side-chain carboxyl groups and the phosphate groups of the liposomal lipid and hydrophobic interaction between the polymer backbone and the lipid membrane, generating structural defects in the liposome membrane (*13*).

As shown in Figure 2D, the pH region in which the content release was triggered increased in the order of SucPG-C_{10}, GluPG-C_{10}, MGluPG-C_{10}, and CHexPG-C_{10}. Apparently, the polymers with higher hydrophobicity trigger the release at higher pH. Actually, CHexPG caused the release, even at neutral pH, whereas other polymers induced the release below pH 6.5 or 6,

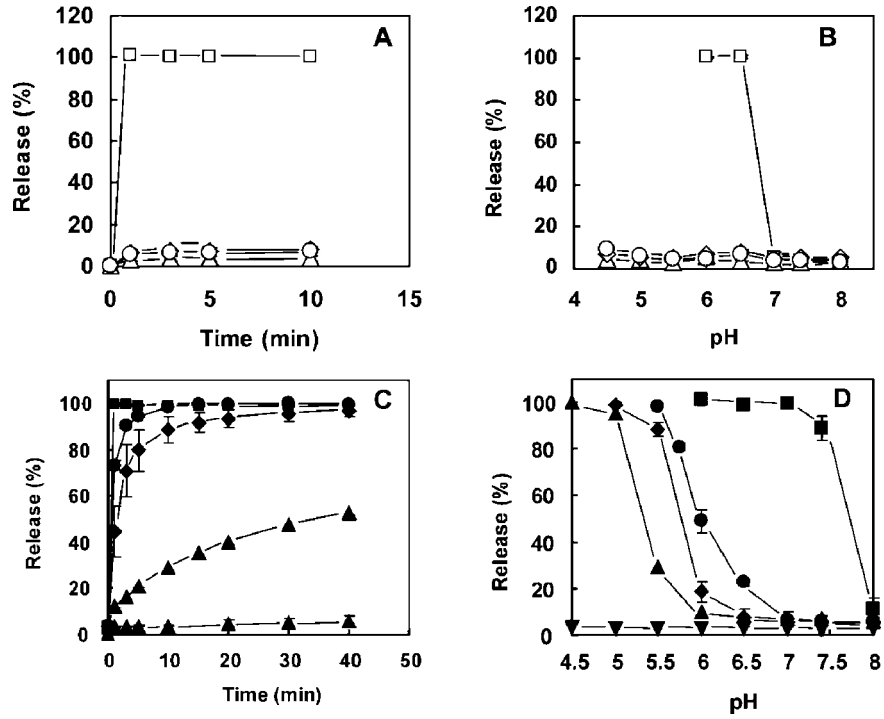

Figure 3. Pyranine release from egg yolk phosphatidylcholine liposomes induced by various poly(glycidol) derivatives. Time course at pH 6.5 (A) and pH dependence (B) of pyranine release induced by SucPG (△), GluPG (◇), MGluPG (○), and CHexPG (□). Time course at pH 6.5 (C) and pH dependence (D) of pyranine release induced by SucPG-C_{10} (▲), GluPG-C_{10} (◆), MGluPG-C_{10} (●), and CHexPG-C_{10} (■), and without polymer (▼). Measurements were performed in MES 25 mM and NaCl 125 mM solution at 25 °C. Percent release of pyranine after 10 min incubation was shown (B,D). Polymer and lipid concentrations were 0.1 mg/mL and 2.0×10^{-5} M, respectively. Each point is the mean ± SD ($n = 3$).

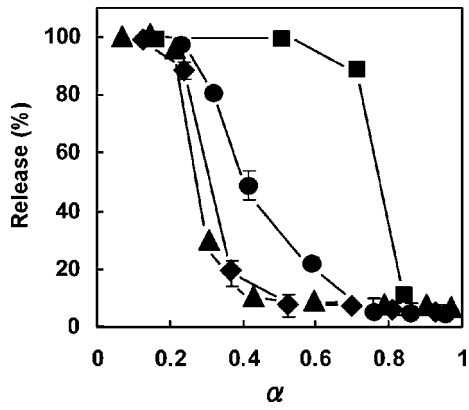

Figure 4. Correlation between dissociation degree (α) of polymers and their induced content release of liposomes. Percent release of pyranine after 10 min incubation with SucPG-C_{10} (▲), GluPG-C_{10} (◆), MGluPG-C_{10} (●), and CHexPG-C_{10} (■) was plotted against α of polymer.

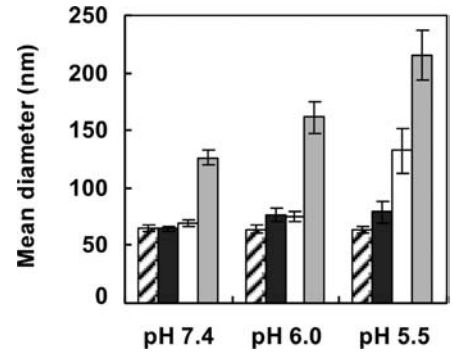

Figure 5. Mean diameters of egg yolk phosphatidylcholine liposomes after overnight incubation with SucPG-C_{10} (closed bars), MGluPG-C_{10} (open bars), and CHexPG-C_{10} (gray bars) at varying pHs. Mean diameters of the same liposomes after overnight incubation without polymer were also shown (diagonal bars). Measurements were performed in MES 25 mM and NaCl 125 mM solution at 25 °C. Polymer and lipid concentrations were 0.83 mg/mL and 1.7×10^{-4} M, respectively. Each point is the mean ± SD ($n = 3$).

which corresponds to the pH of endosome. In addition, their ability to destabilize the liposome membrane in the neutral and weakly acidic region increased with increasing hydrophobicity of the polymer side chains.

Because these polymers acquire the ability to destabilize the liposome membrane upon protonation of carboxyl groups on the side chains, we examined the correlation between the protonation degree and their membrane-destabilizing ability. Figure 4 depicts the percent release induced by the polymer as a function of dissociation degree α of the polymers evaluated using acid−base titration. Highly hydrophobic CHexPG can acquire the ability to induce the content release when only about 25% of carboxylate anions are protonated. In contrast, hydrophilic SucPG cannot induce the release until about 70−80% of carboxylate anions lose their negative charges by protonation. Indeed, dissociation of carboxyl groups might be affected in the peripheral region of the liposome. Therefore, the result indicated that polymers with higher hydrophobicity acquire membrane-destabilizing activity on a state with a lesser degree of protonation.

Interaction of the polymers with the liposomes was also investigated through inspection of the liposome size change. The EYPC liposomes with 60 nm diameter were incubated with SucPG-C_{10}, MGluPG-C_{10}, or CHexPG-C_{10} at varying pH overnight; their diameters were evaluated using DLS (Figure 5). The liposome size only slightly changed after incubation with SucPG-C_{10}, even at pH 5.5. Similarly, the liposome size was not affected when incubated with MGluPG-C_{10} at pH 7.4 and 6.0, but incubation at pH 5.5 caused an increase in diameter. Interaction with this polymer might induce destabilization of the liposome membrane, engendering their aggregation. Ag-

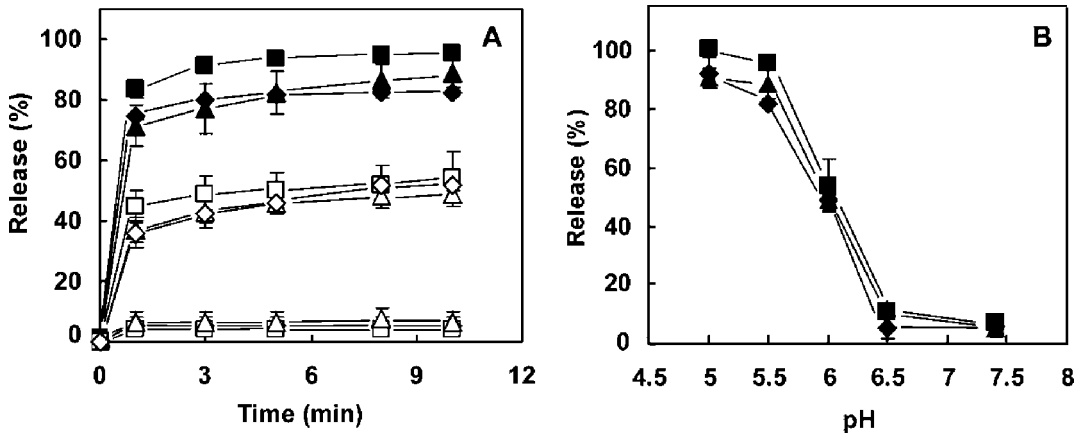

Figure 6. Pyranine release behaviors of egg yolk phosphatidylcholine liposomes modified with SucPG-C_{10} (triangles), GluPG-C_{10} (diamonds), and MGluPG-C_{10} (squares). (A) Time course at pHs 7.4 (open symbols), 6.0 (gray symbols), and 5.5 (closed symbols). (B) Percent release of pyranine from the polymer-modified liposomes after 10 min incubation as a function of pH. Lipid concentrations were 2.0×10^{-5} M. Each point is the mean ± SD ($n = 3$).

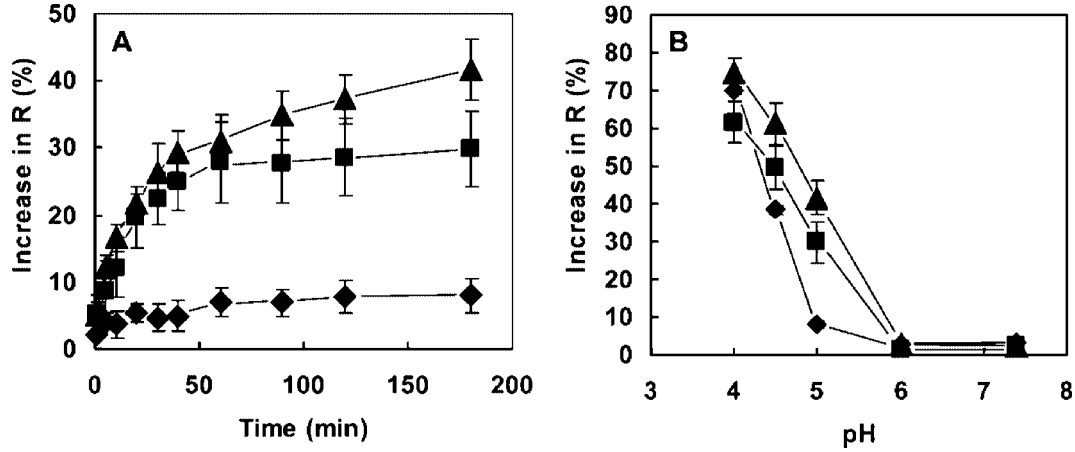

Figure 7. pH-sensitive fusogenic properties of polymer-modified liposomes. Time course at pH 5.0 (A) and pH dependence of percent increase in *R* values after mixing of fluorescent lipid-labeled liposomes modified with SucPG (◆), GluPG (■), and MGluPG (▲) after 3 h incubation at varying pHs. Measurements were performed in 25 mM MES and 125 mM NaCl at 37 °C. Each point is the mean ± SD ($n = 3$).

gregation of liposomes became more intensive when incubated with CHexPG-C_{10}. Indeed, polymer-induced aggregation was enhanced with decreasing pH, but this polymer exhibited the ability to induce liposome aggregation, even at neutral pH.

Preparation of pH-Sensitive Liposomes with Poly(glycidol) Derivatives. Results of a previous study showed that modification of liposomes with pH-sensitive polymers is an efficient means to prepare pH-sensitive liposomes (*10, 13, 24, 29*). Especially, modification with SucPG provided pH-sensitive fusion ability, which is useful for cytoplasmic delivery of membrane-impermeable molecules (*14*). Therefore, we next examined the ability of poly(glycidol) derivatives to render stable EYPC liposomes pH-sensitive. For this purpose, polymers are necessary to exhibit activity only under mildly acidic conditions. However, CHexPG exhibits membrane-destabilizing activity even at neutral pH; we examined three poly(glycidol) derivatives aside from CHexPG.

The liposomes were incubated with varying amounts of the polymers for varying periods and the liposomes were separated from the free polymers using gel filtration to achieve modification of EYPC liposomes with the polymers. Comparison of their content release performance revealed that incubation of liposomes (17.5 mM) in more than 2 mg/mL of the polymer solutions (pH 7.4) for more than 60 min yielded the highest performance (Supporting Information Figure S1). In addition, the zeta potential of these polymer-modified liposomes with the highest performance showed a constant value of about −31 mV (Supporting Information Figure S1). These results indicate that the polymer chains were fully incorporated into the liposome surface by incubation under these conditions. On the basis of these results, we prepared EYPC liposomes modified with the poly(glycidol) derivatives by incubating the liposomes in 10 mg/mL of the polymer solutions for 1 h, with subsequent gel filtration.

Figure 6 depicts pH-sensitive content release behaviors of liposomes modified with the SucPG-C_{10}, GluPG-C_{10}, and MGluPG-C_{10}. All liposomes retained pyranine at pH 7.4, indicating that they are stable at physiological pH. However, these liposomes enhanced their content release below pH 6.0; almost complete release was achieved at pH 5.5. This result demonstrates that these liposomes were able to destabilize the inside of early and late endosomes, which have respective environments with pH 6.5−6.0 and pH 6.0−5.0 (*30*). As portrayed in Figure 6, all liposomes exhibited a similar pH response. This observation differs greatly from the case of content release induced by addition of these polymers into the liposome suspensions, in which MGluPG-C_{10}, GluPG-C_{10}, and SucPG-C_{10}, respectively, exhibited content release enhancement around 6.5, 6.0, and 5.5 (Figure 3D). Apparently, the content release was enhanced in a higher pH region for the polymers attached to the liposomes than for the free polymers. Protonation of carboxylate anions of these polymers might be enhanced in

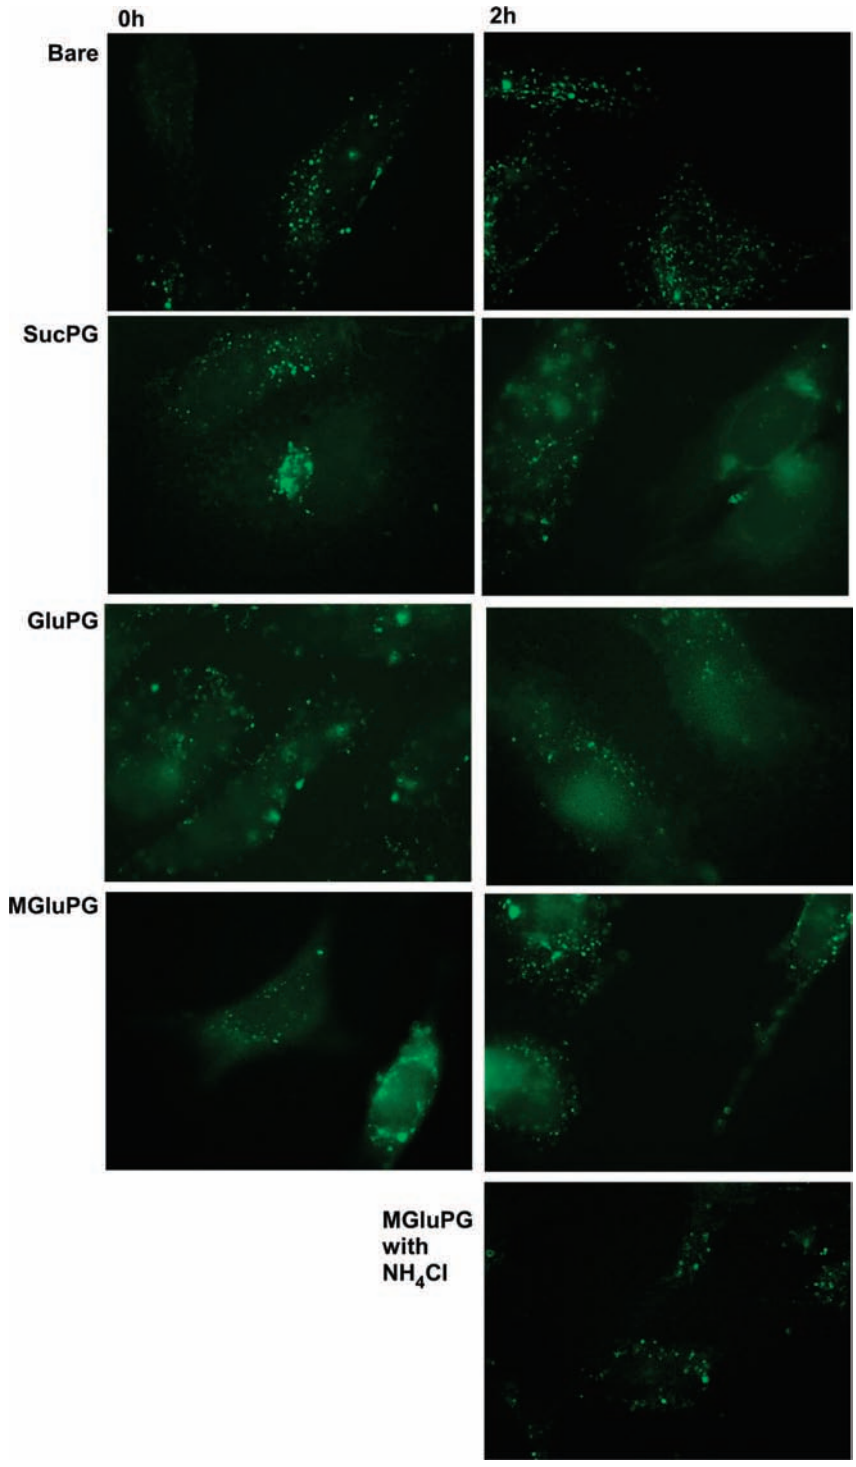

Figure 8. Fluorescence micrographs of HeLa cells treated with calcein-loaded liposomes modified with varying polymers or without polymer modification. The cells were incubated with liposomes for 4 h at 37 C° and were washed with PBS. Then, the cells were observed just after washing (left column) or after additional incubation in DMEM with 10% FCS at 37 C° for 2 h (right column) using a fluorescence microscope. Cells treated with liposomes in the presence of NH_4Cl were also shown.

the peripheral region of the liposome membrane, which is an environment with lower polarity than the aqueous medium. Therefore, the difference in hydrophobicity of these polymers' side chains might not reflect the pH region, where their protonation took place.

We also examined the pH response of these polymer-modified liposomes with respect to fusion ability. For this purpose, we prepared polymer-modified EYPC liposomes containing NBD-PE and Rh-PE, which have been used widely to detect fusion of liposomes (*18*). Fusion of the labeled liposomes with unlabeled liposomes causes dilution of these fluorescent lipids in the membrane. Therefore, their fusion results in decreased resonance energy transfer efficiency between these fluorescent lipids. In addition, previous results have shown that the fluorescence intensity ratio of NBD-PE to Rh-PE (*R*) is useful to monitor liposome fusion (*14, 15*).

Polymer-modified liposomes with the fluorescent lipids were mixed with the unlabeled EYPC liposomes and the fluorescence intensity ratio of NBD-PE to Rh-PE (*R*) for the mixed liposome suspension was calculated (Figure 7). Figure 7A depicts the

percentage increase in the *R*-value (see the Materials and Methods section) for the liposome suspensions at pH 5.0. The liposomes modified with SucPG exhibited a slight increase in the *R*-value, suggesting that this polymer increases the fusion ability of the liposome only slightly at pH 5.0. However, the liposomes modified with GluPG showed a marked increase in the *R*-value with time; the MGluPG-modified liposomes exhibited an even more significant increase in *R*, indicating that these polymers have a higher ability to render the stable liposomes fusogenic than SucPG. Their ability is influenced by differences of side-chain structures.

Figure 7B portrays the percent increase in the *R*-value after 3 h incubation for polymer-modified liposomes and plain liposomes. Irrespective of the polymer, these liposomes displayed no change in *R*-value at pH 7.4−6.0, but the *R*-values increased below pH 6.0, which indicates that these liposomes became fusogenic in the mildly acidic environment. Their fusion ability varies depending on the polymer attached to liposomes around pH 5.0. However, a further decrease in the ambient pH strengthened their fusion ability, and these polymer-modified liposomes acquired similar and strong fusion ability around pH 4.5−4.0. Actually, SucPG has fewer hydrophobic side chains than other polymers. For that reason, this polymer, with many charged groups, might not strongly destabilize the lipid membrane to cause liposome fusion. In contrast, GluPG and MGluPG, which possess hydrophobic side chains, might destabilize the liposome membrane even through their side chains are partly charged. Therefore, MGluPG, of which side chains are most hydrophobic among these polymers, produced liposomes with the highest fusion capability.

Interaction of Polymer-Modified Liposomes with Cells. Finally, we estimated their potential as a cytplasmic delivery vehicle for membrane-impermeabile molecules. For this purpose, we loaded calcein, which is a water-soluble fluorescent dye, in the polymer-modified EYPC liposomes. It is well-known that fluorescence of calcein is strongly quenched when encapsulated in the liposome at a high concentration, but becomes highly fluorescent once released from the liposome (*31*). Therefore, intracellular localization of calcein molecules released from the liposomes can be estimated from their fluorescence.

We incubated HeLa cells with the calcein-loaded liposomes for 4 h and washed them with PBS. Then, the treated cells were observed using a fluorescence microscope just after washing or after additional incubation in the medium for 2 h. As is seen in Figure 8, the cells treated with the calcein-loaded bare liposome displayed punctuate fluorescence. Considering that the liposomes were generally taken up by a cell via endocytosis, it is highly likely that calcein molecules were still trapped in endosome and/or lysosome (*14, 32*). In contrast, the cells treated with the calcein-loaded, polymer-modified liposomes showed diffused fluorescence, indicating that calcein molecules existed in cytoplasm. Because these liposomes have the ability to destabilize and fuse with lipid membranes under a weakly acidic environment, it is likely that calcein molecules were released from endosome or lysosome into cytoplasm.

On the basis of the comparison of calcein fluorescence observed in the liposome-treated cells, it seems that the ability of cytoplamic calcein delivery may differ among these polymer-modified liposomes. Punctuate fluorescence was mainly observed in the cells just after the incubation with SucPG-C_{10}-modified liposome, though additional 2 h incubation caused diffused fluorescence in the cell. In contrast, intensive diffused fluorescence was observed in the cells treated with MGluPG-C_{10}-modified liposomes, indicating that these polymers might possess a stronger ability to destabilize endosomal and lysosomal membranes than SucPG-C_{10}. In addition, when the treatment with the MGluPG-C_{10}-modified liposomes was performed in the presence of ammonium chloride, which is known to inhibit acidification of endosome and lysosome, punctuate fluorescence appeared in the cells, suggesting that acidification of these intracellular organelles is necessary for the transfer of calcein molecules into cytosol. These results demonstrate that modification of stable liposomes with fusogenic polymers, which strongly destabilize lipid membranes at weakly acidic pH, can produce pH-sensitive liposomes that achieve efficient cytoplasmic delivery of membrane-impermeable molecules.

CONCLUSION

We have previously used SucPG for pH sensitization of stable liposomes. In this study, we newly synthesized three pH-sensitive poly(glycidol) derivatives with side chains of varying hydrophobicities, GluPG, MGluPG, and CHexPG, and investigated a correlation between their side-chain structure and their ability to render stable liposomes pH-sensitive. Their ability for pH sensitization of liposomes was enhanced with increasing side-chain hydrophobicity. In particular, MGluPG, which possesses side chains with appropriate hydrophobicity, produced highly pH-sensitive liposomes that undergo content release and membrane fusion at mildly acidic pH, which corresponds to endosomal and lysosomal pH. Such properties of the liposomes are important for efficient cytoplasmic delivery of membrane-impermeable molecules because destabilization and fusion with endosome and/or lysosome membranes improves the transfer of liposomal contents to cytosol. In fact, MGluPG-modified liposomes encapsulating calcein efficiently delivered their contents into the cytosol of a cell. Considering their application into body, the increased hydrophobicity of the polymer may affect biodistribution of the liposomes. However, further incorporation of poly(ethylene glycol) grafts to the liposomes might cover the liposome surface and produce liposomes with high pH sensitivity and long circulating properties. Information obtained from this study is expected to be useful for development of highly efficient pH-sensitive liposomes and related vehicles for efficient cytoplasmic delivery of bioactive molecules, such as proteins and genes.

Direct Site-Specific Labeling of the Cys-Tag Moiety in scVEGF with Technetium 99m

Zoia Levashova,[†] Marina Backer,[‡] Joseph M. Backer,[‡] and Francis G. Blankenberg*[,†]

Department of Radiology/MIPS, Stanford University School of Medicine, Stanford, California 94305, and Sibtech, Inc., Brookfield, Connecticut 06804. Received December 27, 2007; Revised Manuscript Received March 12, 2008

Angiogenesis is a fundamental feature of tumor development, and therefore, the tracers for molecular imaging of specific angiogenic biomarkers are expected to be useful for diagnostics, patient monitoring, and drug development. We have created a new class of imaging agents based on the most important mediator of angiogenesis, vascular endothelial growth factor (VEGF). Our latest version is a single-chain (sc) VEGF protein containing an N-terminal Cys-tag designed for site-specific modification with a variety of imaging and therapeutic moieties. We have recently found that the Cys-tag itself can form a stable chelate with ^{99m}Tc using tin-tricine as an exchange reagent. This self-chelation approach yields a highly stable and fully functional form of radiolabeled scVEGF that can be used as a SPECT tracer for tumor angiogenesis. Also of note is that directly labeled scVEGF has less than one-half the nonspecific renal uptake of ^{99m}Tc-HYNIC-scVEGF. The simple production of scVEGF for direct chelation of ^{99m}Tc makes it a promising molecular imaging agent for the oncology clinic.

INTRODUCTION

Angiogenesis is a fundamental feature of tumor growth, and the onset and/or presence of angiogenesis could be used for diagnostic purposes. On the other hand, since angiogenesis is critical for tumor growth, it is a target of massive drug development efforts. Current antiangiogenic drugs given in combination with chemotherapy or radiotherapy provide positive clinical effects in subsets of patients (*1*−*3*). As antiangiogenic treatments are quite expensive and are not without serious side effects (*4, 5*), there is a great desire for better diagnostic tools to guide the development as well as the efficient and safe use of these new drugs in cancer patients. In particular, clinical development of antiangiogenic drugs and combination therapeutic regimens need imaging tracers that can follow therapeutic targets in angiogenic vasculature (see refs (*6*−*8*) for review). Among such imaging targets, receptors for vascular endothelial growth factor (VEGF) are particularly attractive for several reasons. First, VEGF is the most important regulator of angiogenesis. Its signaling pathway, initiated by binding of VEGF to its cognate receptors VEGFR-1 and VEGFR-2, is the primary target of most anti- and pro-angiogenic therapeutic agents (*9*−*12*). Second, the receptors for VEGF, and most notably, VEGFR-2 (KDR/Flk-1), are selectively overexpressed by the endothelial cells of angiogenic tumor vessels (*9, 13*), providing an opportunity for enhanced tracer accumulation. Finally, VEGF receptors are in direct contact with the microcirculation of a tumor and are also internalized upon VEGF binding, allowing for receptor-mediated accumulation and trapping of VEGF-based imaging agents within target tissue.

To enable VEGF receptor imaging, we have recently developed a novel class of VEGF-based imaging agents (*14*−*17*). We have taken the $VEGF_{121}$ isoform of VEGF-A as the framework with which to engineer a single-chain (sc) fusion VEGF protein containing an N-terminal Cys-tag (*17*). Cys-tag is an α-helical 15-aa long N-terminal fragment of human ribonuclease I, in which arginine in position 4 is substituted for cysteine, providing a unique site for conjugation of a wide variety of payloads to Cys-tagged targeting proteins (*15, 16, 18*−*22*). For imaging in different modalities, we have site-specifically derivatized scVEGF with fluorescent dyes for near-infrared fluorescent (NIRF) imaging and with radionuclide chelators for positron emission tomography (PET) with ^{64}Cu and single photon emission computed tomography (SPECT) with ^{99m}Tc (*17*). Experiments with scVEGF-based tracers revealed VEGF receptor-mediated selective accumulation of such tracers by endothelial cells in tumor and surrounding host vasculature (*17*). Importantly, endogenous VEGF did not prevent enhanced uptake of the tracers in these compartments (*17*).

Although scVEGF-based targeted tracers displayed favorable imaging properties and relatively low uptake in nontargeted organs, we were concerned that making chelator/protein conjugates requires additional production steps that would present a separate set of obstacles for clinical tracer development.

Over the years, several groups reported that proteins engineered to have an additional cysteine with a free thiol group might be directly radiolabeled with ^{99m}Tc (*23*−*25*). Therefore, we tested whether Cys-tag in scVEGF can be directly radiolabeled with ^{99m}Tc and whether it would lead to a tracer with favorable imaging, biodistribution, and stability profile. We report here that direct labeling of scVEGF with ^{99m}Tc is a highly efficient process, providing a stable tracer with good imaging characteristics and a great reduction in nonspecific uptake, most notably in the kidney, as compared with HYNIC-labeled scVEGF. We expect that the simplicity of direct radiolabeling of the Cys-tag would be beneficial for the development of scVEGF and other protein-based SPECT tracers.

EXPERIMENTAL PROCEDURES

Production of Cys-Tagged scVEGF. The construction, expression, and purification of Cys-tagged scVEGF have been described recently (*17, 19, 22*). The protein was refolded in red-ox buffer containing glutathione, and therefore, in the final preparation of scVEGF the C4 thiol group in the Cys-tag was "protected" in a mixed disulfide bond with glutathione. Prior

to radiolabeling, the C4 thiol group in scVEGF was "deprotected" by incubating scVEGF with equimolar amounts of DTT at 25 °C for 20 min in 0.1 M Tris−HCl pH 8.0 (*17*). Free SH groups were detected and quantitated by reaction with *N*-(1-pyrene)-maleimide as previously described elsewhere (*26*).

scVEGF Direct Radiolabeling with ^{99m}Tc. Deprotected scVEGF was radiolabeled, using [^{99m}Tc]-tricine as a precursor complex (*27*). Briefly, lyophilized tin-tricine reagent was reconstituted with 0.25 mL of degassed saline to give a final $SnCl_2 \cdot 2H_2O$ concentration of 3 mg/mL and a final tricine concentration of 100 mg/mL (pH 7.1). 2.5−5.0 μL tin-tricine was mixed with 30−50 μg of deprotected scVEGF and 10−20 mCi of ^{99m}Tc-pertechnetate in a final volume of 50−100 μL. After 30 min of incubation at 37 °C, radiolabeled protein, named scVEGF/Tc, was purified by gel-filtration on PD-10 Sephadex-25 columns. Specific activities ranged from 130 to 200 μCi/μg protein. Radiopurity was determined by ITLC using PBS as a solvent, and we observed ^{99m}Tc batch-dependent variations in the range 90−95%. The impurities were migrating with the front and appeared to arise from small and variable amounts of colloidal forms of ^{99m}Tc that were coeluted with scVEGF/Tc from PD-10 column.

Animals and Tumor Models. 5−6 week old female BALB/c mice were purchased from Charles River Laboratories (Wilmington, MA). 4T1*luc* cells were implanted into the left axillary fat pad, 10^4 cells per mouse. The protocol for the animal studies was approved by the Stanford University Institutional Animal Care and Use Committee.

Stability of scVEGF/Tc in Vitro and in Vivo. Testing was done as described in Backer et al. (*17*) for scVEGF labeled with ^{64}Cu. Briefly, Balb/c mice ($n = 3$) were injected i.v. with scVEGF/Tc (90 μCi/0.5 μg per mouse) and sacrificed 2 min later. Blood was collected and clarified by centrifugation. Plasma samples were incubated at 37 °C. After 15, 30, and 60 min of incubation, 1 μL plasma aliquots were analyzed by ITLC for a rough estimation of protein-bound radioactivity. Stability of scVEGF/Tc was tested by incubation of the probe in PBS at room temperature or at 95 °C with consequent analysis by ITLC and SDS-PAGE.

Structural and functional integrity of scVEGF/Tc recovered from blood was tested by its ability to bind to soluble VEGFR-2 receptor KDR-Fc (R&D Systems, Minneapolis, MN) immobilized on Protein A Sepharose as described previously (*17*). Briefly, Balb/c mice ($n = 3$) were injected via tail vein with scVEGF/Tc (1.2 mCi, 11 μg protein). At 3, 15, and 45 min after injection of tracer, blood samples were collected via supraorbital bleed, placed in citrate buffer, and clarified by centrifugation. Plasma aliquots containing equal amounts of radioactivity were mixed with Protein A Sepharose, either empty or loaded with KDR-Fc. After 1 h binding at 4 °C, Sepharose beads were spun down, extensively washed with RIPA buffer, separated by reducing SDS-PAGE on 10% gel, and analyzed by Western blotting with VEGF-specific mouse monoclonal antibody (BD Biosciences Pharmingen, San Jose, CA).

Scatchard Analysis of scVEGF/Tc Binding to Cellular VEGFR-2. Binding analysis was performed as described elsewhere for scVEGF-PEG-DOTA conjugate radiolabeled with ^{64}Cu (*17*). Briefly, 293/KDR cells overexpressing VEGFR-2 grown on 12-well plates were shifted to serum-free medium at room temperature for 45 min. Varying amounts of scVEGF/Tc were added to cells in triplicate wells for 90 min, followed by two PBS and one high-salt (0.5 M NaCl in PBS) wash. Cells were lyzed in 1% Triton X-100 containing buffer and assayed for ^{99m}Tc activity in a scintillation well counter (140 keV level, 20% window). Nonspecific binding was determined for the same amounts of scVEGF/Tc supplemented with 100-fold molar excess of nonradiolabeled scVEGF.

Blood Clearance and Biodistribution Studies. For blood clearance and biodistribution studies, 0.1−0.15 mCi of scVEGF/Tc per mouse ($n = 4$) was injected via the tail vein, and serial ~50 μL blood samples were taken via supraorbital sinus at various time points after injection. Tissue samples taken 1 and 3 h after injection were counted in a gamma counter along with three samples of standard activity (1/100 of injected dose). Results were calculated as the average of the percentage of injected dose (ID) or %ID per gram (g) of tissue ± 1 standard deviation of the mean.

A-SPECT-Imaging and Autoradiography. For SPECT imaging, 1.2 mCi of scVEGF/Tc per mouse ($n = 4$) was injected via tail vein. SPECT images were obtained 1 h after injection with the following parameters: 360° rotation, 64 steps, 30 s per step, 0.5 mm pinhole aperture, a 64 × 64 image matrix, and a 2.7 cm FOV using a small animal SPECT imaging gamma camera (A-SPECT, LumaGEM, Gamma Medica, Los Angeles). For autoradiography, tumors and pectoralis muscle from the healthy chest side were snap-frozen immediately after imaging, cryosectioned (60 μm thickness), and exposed to a phosphor storage screen for 16 h. The phosphor screen images were read out with a laser digitizer at a resolution of 50 μm per pixel. ROI analysis of radiotracer activity was performed using *ImageQuant TL* software. The maximal cts/pixel of the rim and the average cts/pixel of the center of the tumor were normalized to corresponding contralateral pectoral muscle uptake (minimum cts/pixel).

Tumor uptake analysis was performed using parametric 3-D regions of interest (ROI), interactively placed and sized, but geometric as described previously (*28*). ROIs of the rim, center, and contralateral axillary soft tissue (BKG) were drawn. The sum of the total number of counts adjusted for volume of the rim (upper 95th percentile) and soft tissue BKG (lower fifth percentile) was tabulated from the histograms of the rim and contralateral soft tissue ROI, respectively, for each tumor-bearing animal. The sums from the 34th and 68th percentiles (central portion of histogram) determined from the ROIs of the center of each tumor were also tabulated. The uptake of the rim and center of each tumor was then divided by the contralateral soft tissue uptake and presented as ratios of rim/BKG and center/BKG, respectively.

RESULTS

Direct Radiolabeling of Cys-Tagged scVEGF with ^{99m}Tc. scVEGF is functionally active single chain version of VEGF consisting of two 3−112 amino acid fragments of human $VEGF_{121}$ genetically fused head-to-tail and expressed with N-terminal Cys-tag for site-specific modification (*17*). Since scVEGF was refolded in the red-ox buffer containing glutathione, the thiol group in Cys-tag was "protected" in mixed disulfide bond with glutathione (*17*), and therefore, it was deprotected by incubation with equimolar amounts of DTT. This was immediately followed by radiolabeling with ^{99m}Tc using tin-tricine as a precursor complex. We found that the specific activity of a typical scVEGF/Tc preparation ranged from 130 to 200 μCi/μg protein, which compared favorably to the values obtained from the radiolabeling of scVEGF-HYNIC conjugates with ^{99m}Tc.

Activity and Stability of scVEGF/Tc. We then evaluated whether scVEGF/Tc retained its native affinity for the VEGFR-2 receptor using a radioligand binding assay performed with 293/KDR cells; a cell line that constitutively overexpresses VEGFR-2 (*29*). Scatchard analyses ($n = 3$) revealed a disassociation constant (K_d) of 1.28 ± 0.12 nM. The measured affinity of scVEGF/Tc for VEGFR-2 was similar to the K_d values reported previously for the scVEGF-PEG-DOTA/^{64}Cu complex (*17*) and iodinated $VEGF_{165}$ (*30*). We then tested the stability of scVEGF/Tc with several assays as outlined below.

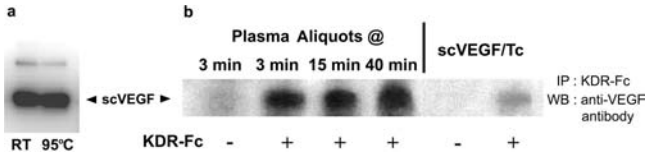

Figure 1. scVEGF/Tc stability in plasma. (A) scVEGF/Tc withstands nonreducing SDS-PAGE conditions even after a short incubation at 95 °C. Autoradiograph of nonreducing SDS-PAGE gel with scVEGF/Tc incubated at room temperature (RT) for 5 h or at 95 °C for 7 min; (B) scVEGF/Tc retains the ability to interact with soluble receptor after at least 40 min in the circulation. Western blot analysis of the SDS-PAGE gel with scVEGF/Tc was collected with KDR-Fc from blood volumes containing similar amounts of radioactivity. Free scVEGF/Tc at the indicated concentrations was similarly collected with KDR-Fc. (See Materials and Methods for experimental details.)

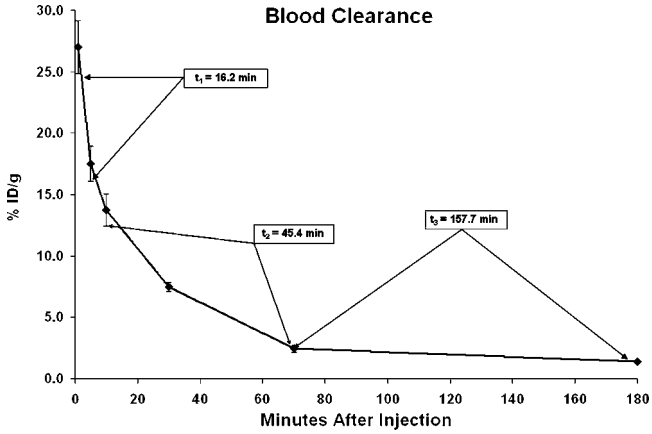

Figure 2. Blood Clearance of scVEGF/Tc. scVEGF/Tc was injected via the tail vein, 0.15 mCi per mouse ($n = 4$), and serial ~50 μL blood samples were taken via supraorbital bleed at various time points after injection. Results were calculated as the average of the percentage of injected dose (ID) per gram (g) of tissue ± standard deviation of the mean. t = half-life (in minutes). %ID/g = percent of injected dose per gram of blood.

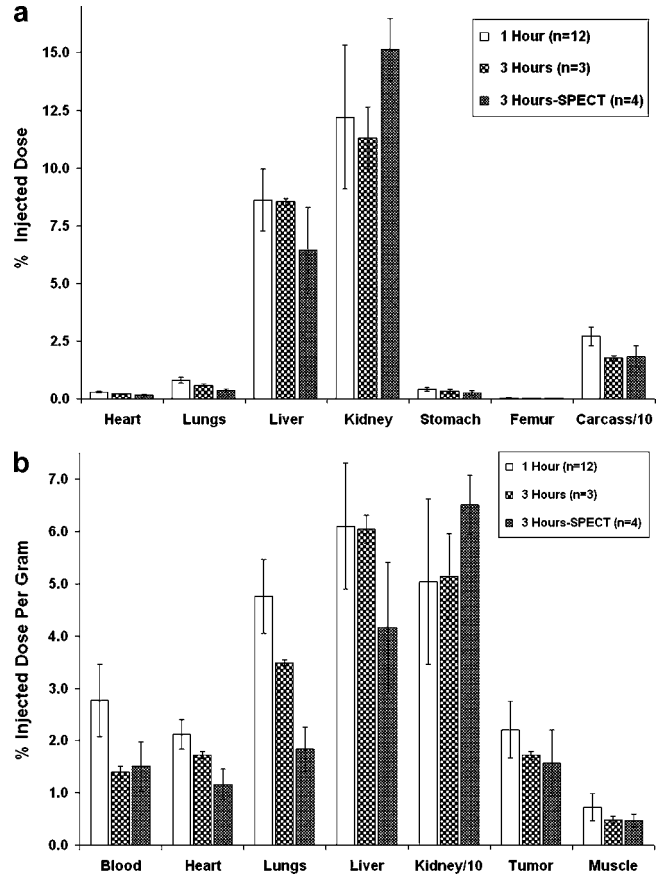

Figure 3. Biodistribution assay at 1 and 3 h after Injection of Tracer. scVEGF/Tc was injected as described in the legend to Figure 2. Biodistribution analysis was done 1 and 3 h postinjection. Three Hours-SPECT, mice received a 10-fold increased dose of tracer (1.2 mCi of radioactivity) and underwent SPECT imaging before sacrifice at 3 h. Standard deviations of the mean values are shown.

Table 1. Average Uptakes (%ID/g @ 1 h) of scVEGF-Based SPECT Tracers

tracer	kidney (%ID/g)	liver (%ID/g)
scVEGF/Tc ($n = 12$)	50.4 ± 15.8	6.1 ± 1.2
scVEGF-HYNIC/^{99m}Tc (*17*) ($n = 12$)	117.1 ± 14.0	5.9 ± 3.0
scVEGF-PEG-DOTA/^{99m}Tc (*17*) ($n = 4$)	28.0 ± 3.3	4.6 ± 1.0

The stability of scVEGF/Tc was initially tested in PBS at room temperature, and ITLC analysis indicated that over 90% of radioactivity remained bound to protein for at least 5 h. Then, we performed a 5 min incubation on an additional set of samples at 95 °C and found that at least 50% of radioactivity comigrated with scVEGF on the nonreducing SDS-PAGE gel (Figure 1a). scVEGF/Tc stability in the circulation of normal Balb/c mice was also tested. Since stability of scVEGF/Tc in vivo is dependent on the dissociation of ^{99m}Tc from protein as well as the integrity of scVEGF itself, we tested both using approaches described previously for scVEGF-HYNIC/^{99m}Tc and scVEGF-PEG-DOTA/^{64}Cu complexes (*17*). Citrated plasma was first obtained at 3, 15, and 40 min postinjection of tracer, and scVEGF/Tc complexes were then precipitated from the plasma aliquots containing the same amounts of radioactivity with a soluble form of VEGFR-2 receptor, KDR-Fc. Since binding to KDR-Fc requires structural integrity of scVEGF, we reasoned that this procedure should only select functionally active scVEGF/Tc complexes. Western blot analysis of the samples revealed that similar amounts of scVEGF were collected from each plasma sample, indicating that circulating scVEGF/Tc remained stable and capable of being a VEGF receptor for at least 40 min (Figure 1b). In this respect, the stability of scVEGF/Tc was similar to that reported for scVEGF-HYNIC/^{99m}Tc.

Blood Clearance and Biodistribution of scVEGF/Tc. scVEGF/Tc cleared rapidly from the circulation, with >95% tracer cleared within 1 h (Figure 2) after tail vein injection of tracer. The clearance rate could be best characterized by three separate exponential decay functions consisting of a rapid component in the first 10−15 min followed by a slower intermediate (20−70 min) and a prolonged terminal (80−180 min) component. The decrease in heart and lung uptake (Figure 3) paralleled the decrease in blood activity, while the tracer uptake of the remaining organs was essentially unchanged between 1 and 3 h. As summarized in Table 1, uptake in kidney obtained with scVEGF/Tc tracer was approximately one-half that seen with scVEGF-HYNIC/^{99m}Tc (*17*). We also prepared scVEGF-PEG-DOTA/^{99m}Tc tracer, based on previously described scVEGF-PEG-DOTA conjugate that proved to be efficient in decreasing nonspecific renal uptake (*17*) and found that pegylated tracer displayed kidney uptake only marginally below that of scVEGF/Tc (Table 1). Interestingly, the tumor uptake of scVEGF/Tc ranged from 1.7 to 2.5%ID/g with a relatively constant ratio of tumor/muscle uptake of 3.1 to 3.5 at 1 and 3 h, respectively.

A-SPECT-imaging and Autoradiographic Studies with scVEGF/Tc. SPECT imaging revealed marked tumor uptake as compared with soft tissue (Figure 4) in a fashion similar to our previously described forms of radiolabeled scVEGF (*14, 16, 17*). The uptake of tracer was particularly high in the tumor

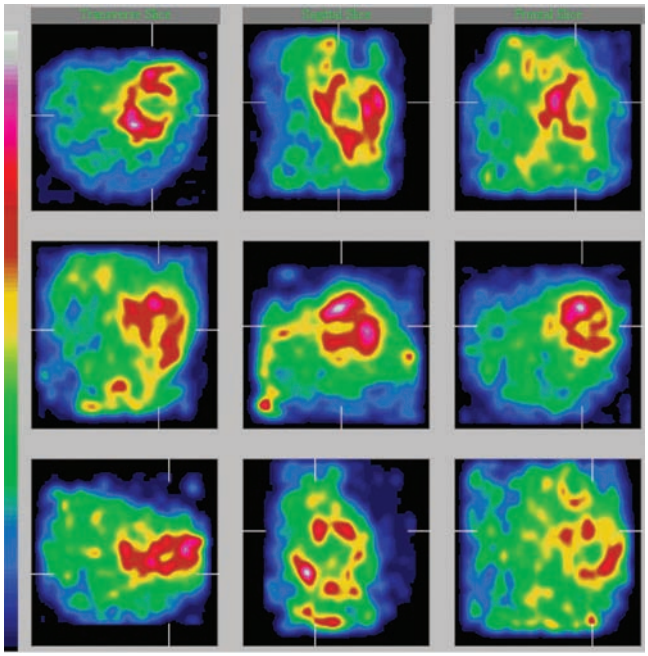

Figure 4. SPECT imaging with scVEGF/Tc. Representative transverse, sagittal, and frontal images of three 4T1 tumor-bearing mice are shown. Note the intense rim uptake of tracer at the tumor periphery that at ROI analysis was 7 to 10 times greater than soft tissue uptake of the contralateral axilla (see Figure 5). The central portions of tumor also had 3- to 4-fold greater uptake of tracer as compared with soft tissue background. Tumors weighed between 0.3 and 0.5 g (8 to 10 mm in diameter).

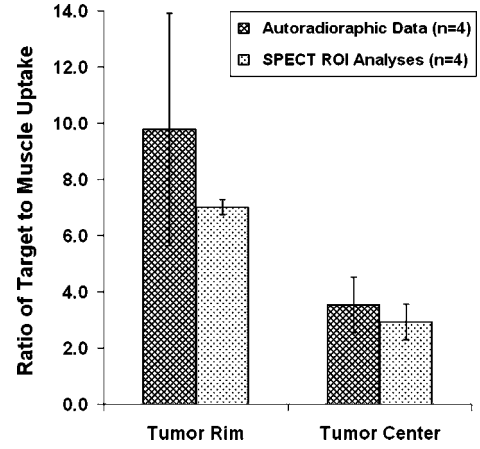

Figure 5. ROI analysis of SPECT and autoradiographic data. Multiple three-dimensional ROIs were placed on the rim and central portions of tumor from each animal that underwent SPECT imaging. Soft tissue background uptake was taken from an ROI placed in the contralateral axilla (muscle) expressed as unity. A similar type of ROI analysis was performed of histologic sections of these same tumors seen with autoradiography. The contralateral pectoralis major muscle was used for the calculation of the soft tissue background uptake of tracer. Standard deviation of mean values for the angiogenic rim and central portions of tumor are shown for both SPECT and autoradiographic ROI analyses.

periphery, in the so-called "angiogenic rim", where VEGF receptors are usually expressed at high levels. In addition, histological examination of tumor sections revealed visibly functional tumor tissue in the central portions of tumor, thereby excluding the possibility that low tracer uptake in these areas might be due to necrosis. ROI analyses of tumor and its margins seen at SPECT imaging demonstrated a rim uptake 7 to 10 times greater than muscle as well as a central tumor to muscle uptake ratio of 3 to 4 (Figure 5). Similar ratios were observed with autoradiography.

DISCUSSION

We report here that the Cys-tag in scVEGF can be directly radiolabeled with ^{99m}Tc in a site-specific fashion, yielding a tracer suitable for SPECT imaging. Over the years, several groups reported that proteins engineered to have an additional cysteine with a free thiol group could be directly labeled with ^{99m}Tc (although with different exchange agents such as tin-glucoheptonate) without modifying the protein with chelators such as HYNIC, DTPA, or DOTA (*23*−*25*). As these investigators found, the preparation of a tracer via direct site-specific radiolabeling is far less complicated than a two-step process that requires the synthesis of protein/chelator conjugate prior to radiolabeling. Direct site-specific radiolabeling of scVEGF produces a tracer with a high specific activity, high in vivo stability, rapid blood clearance, and favorable imaging characteristics similar to those of previously described scVEGF-HYNIC/^{99m}Tc (*17*). Furthermore, given the simplicity and short production time of directly labeled scVEGF, we suggest that the Cys-tag might be suitable for direct radiolabeling with ^{94}Tc for PET imaging at facilities equipped with on-site cyclotrons ($t_{1/2}$ of ^{94}Tc = 52.5 min). Unexpectedly, scVEGF/Tc displayed a superior biodistribution, with an approximately 2-fold decrease in kidney uptake of tracer, as compared to scVEGF-HYNIC/^{99m}Tc. This of course is a distinct advantage with respect to the further development of scVEGF as a new radiopharmaceutical for SPECT imaging.

In addition to the simplicity in preparation, scVEGF/Tc has several other potential advantages over several VEGF-based tracers tested by other groups for the imaging of VEGF receptors in ischemic and tumor angiogenic vasculature in humans, mice, and rabbits (*31*−*38*). These tracers were prepared by random ^{123}I-iodination of $VEGF_{121}$ and $VEGF_{165}$ (*31*−*34*), by random conjugation of ^{64}Cu chelator to a wild-type and mutant $VEGF_{121}$ (*35, 36*), by site-specific conjugation of ^{111}I chelator to Cys-116 in $VEGF_{121}$ (*37*), and by constructing transferrin-$VEGF_{165}$ fusion protein for exchange loading with ^{111}I (*38*). As our scVEGF/Tc, other tracers selectively accumulated in the areas of angiogenic vasculature with tumor uptake in the range from 1% to 7%ID/g (*31*−*34*) and reaching 15%ID/g for very small tumors (*36*). As expected, the random modification of VEGF resulted in nonuniform preparations of tracers with a significant decrease in functional activity (see, for example, refs ,*36*), as compared with unmodified protein. The decreased functional activity of radiolabeled VEGF means the loss of the ability to selectively bind to and specifically image VEGF receptors, which compromises the whole idea of molecular targeted imaging. Of note, we have previously used random modification of scVEGF with biotin to create an inactive protein control to study the specificity of scVEGF binding in vivo (*17*). Another concern with all but one (*37*) of the previously described VEGF-based tracers is the high liver uptake of these constructs (more than 30%ID/g in refs (*37, 38*) and more than 15% in refs *35, 36*).

In summary, we have found that the Cys-tag of scVEGF can be used to site-specifically attach ^{99m}Tc without the need for a bifunctional chelator such as HYNIC. The labeling process is both fast and efficient and has no demonstrable effect on the native binding affinity of scVEGF to VEGFR-2. The tracer also is stable in vivo with rapid blood clearance and has half the renal uptake of ^{99m}Tc-HYNIC-scVEGF. scVEGF/Tc also displays excellent SPECT imaging characteristics and is able to define both central tumor uptake and its angiogenic rim in a fashion similar to that observed at autoradiography. The ease of labeling and the simplicity of production make scVEGF/Tc

a promising tracer for the oncology clinic in the near future. Furthermore, considering that direct radiolabeling described here depends on Cys-tag, rather than on the nature of Cys-tagged protein, we expect that this strategy might be used as a standardized approach to the development of protein-based SPECT tracers.

Evaluation of Cationic Assemblies Constructed with Amino Acid Based Lipids for Plasmid DNA Delivery

Yosuke Obata, Daisuke Suzuki, and Shinji Takeoka*

Department of Life Science and Medical Bioscience, Graduate School of Advanced Science and Engineering, Waseda University, Tokyo 169-8555, Japan. Received November 13, 2007; Revised Manuscript Received February 13, 2008

We synthesized cationic lipids bearing lysine, histidine, or arginine as a cationic headgroup for use in gene transfer studies. The cationic assemblies formed from lysine- or arginine-type lipids gave unilamellar vesicles (∼100 nm diameter), whereas the morphology of the histidine-type lipids was tube-like. The competences of the cationic assemblies were sufficient to form lipoplexes, and the resulting lipoplexes were evaluated in terms of gene expression efficiencies with COS-7 cells. The lysine- or arginine-type lipids exhibited higher gene expression efficiencies than that of Lipofectamine2000, a conventional transgenic reagent, indicating that stable lipoplexes could be prepared between spherical cationic assemblies and plasmid DNA. The gene expression efficiency in relation to the cationic headgroup of the lipids was as follows: lysine ≥ arginine > histidine. In addition, gene expression efficiency was enhanced by decreasing the length of the alkyl chain of the hydrophobic moiety. Unlike Lipofectamine2000, no reduction in transfection efficiency in the presence of fetal bovine serum was observed for the lipoplexes formed using synthetic cationic lipids. Moreover, the synthetic cationic lipids revealed remarkably low cytotoxicity compared with Lipofectamine2000. In conclusion, cationic assemblies formed from 1,5-ditetradecyl-*N*-lysyl-L-glutamate or 1,5-ditetradecyl-*N*-arginyl-L-glutamate can be used as an effective plasmid DNA delivery system.

INTRODUCTION

Gene therapy has become an important alternative approach for the treatment of diseases that until recently were considered incurable. Viral vectors such as adenovirus vectors, adeno-associated virus vectors, or retrovirus vectors have been utilized in clinical trials. However, some side effects including immunoresponse and infection have been reported (*1*). Therefore, the development of nonviral vectors for practical gene therapy is keenly awaited.

Nonviral vectors constructed using synthetic polymers or amphiphiles have been explored for the delivery of nucleic acid to living cells. However, nonviral vectors constructed from cationic polymers such as poly(L-lysine) (PLL) (*2–4*), polyethyleneimine (PEI), (*5–8*) or chitosan (*9–11*) generally exhibit quite low expression efficiencies in comparison to viral vectors. Moreover, cationic polymers usually display high levels of cytotoxicity as a result of their slow rate of degradation in transfected cells, resulting in long-term stress. To reduce the problem of toxicity, cationic amphiphiles have been utilized as an alternative to cationic polymers. Lipoplexes are generally formed by electrostatic complexation between negatively charged nucleic acids and positively charged liposomes. Both preclinical and clinical studies (Phase I and II) have shown lipoplexes to be a less toxic delivery system than those composed of cationic polymers (*12–15*). However, despite these promising developments the expression level of current cationic lipid-based transgenic regents, such as LipofectaminePlus, is several thousand-fold lower than that of adenovirus vectors (*16, 17*).

To enhance gene expression efficiency, various cationic liposomes have been utilized to investigate the mechanism of intracellular delivery of nucleic acids to the cytoplasm or nucleus (*18–20*). When lipoplexes are taken up by the target cell, membrane fusion occurs between the cationic liposomal components and the endosomal membrane of early endosomes (pH 6.0–6.5), leading to the release of nucleic acids into cytoplasm. The released nucleic acids generally accumulate in the nucleus (*21*). Critical factors for intracellular delivery of nucleic acids include the size of the lipoplex, the ratio of lipid to nucleic acid, morphology of the lipoplex, and liposome composition. Generally, the cationic liposomes must be less than about 100 nm in diameter for efficient uptake into cells. The lipid-to-nucleic acid ratio is estimated from the ratio of the nitrogen groups of the cationic compound to the phosphate groups of the nucleic acid (N/P ratio). An appropriate N/P ratio is dependent on the headgroup structure of the cationic lipids. Dioleoylphosphatidylethanolamine (DOPE) has been utilized as a helper lipid of the liposomal membrane because it alters the assembling state of the cationic lipids due to the bilayer-to-hexagonal phase transition of DOPE triggered by lowering pH (*22–24*). However, DOPE-containing liposomes cannot be used in the presence of serum proteins, which reduce their fusogenic potential (*25*). Moreover, Bhattacharya et al. focused on a spacer between the headgroup of cholesterol-based gemini lipids to reduce the influences of serum proteins on lipoplex (*26–28*). Cationic lipids are generally composed of a cationic headgroup and a hydrophobic moiety such as a hydrocarbon chain (*29–32*) or cholesterol derivative (*26, 33*). The hydrophobic moiety is linked to the lipid backbone by an amide, ester, or ether bond. Spermine or spermidine has been widely utilized as the headgroup to condense nucleic acid. The representative components are 2,3-dioleyloxy-*N*-[2(sperminecarboxamide)ethyl]-*N*,*N*-dimethyl-1-propanaminium-trifluoroacetate (DOSPA) and dioctadecylamidoglycyl spermine (DOGS). The high level of cytotoxicity of these compounds was confirmed by experiments using Lipofectamine2000 reagent containing DOSPA. Kim et al. recently reported a cationic lipid having an aspartate backbone and a lysine headgroup that gave an efficient gene expression efficiency and reduced cytotoxicity (*34*). Subsequently, they reported in the following study that the glutamate

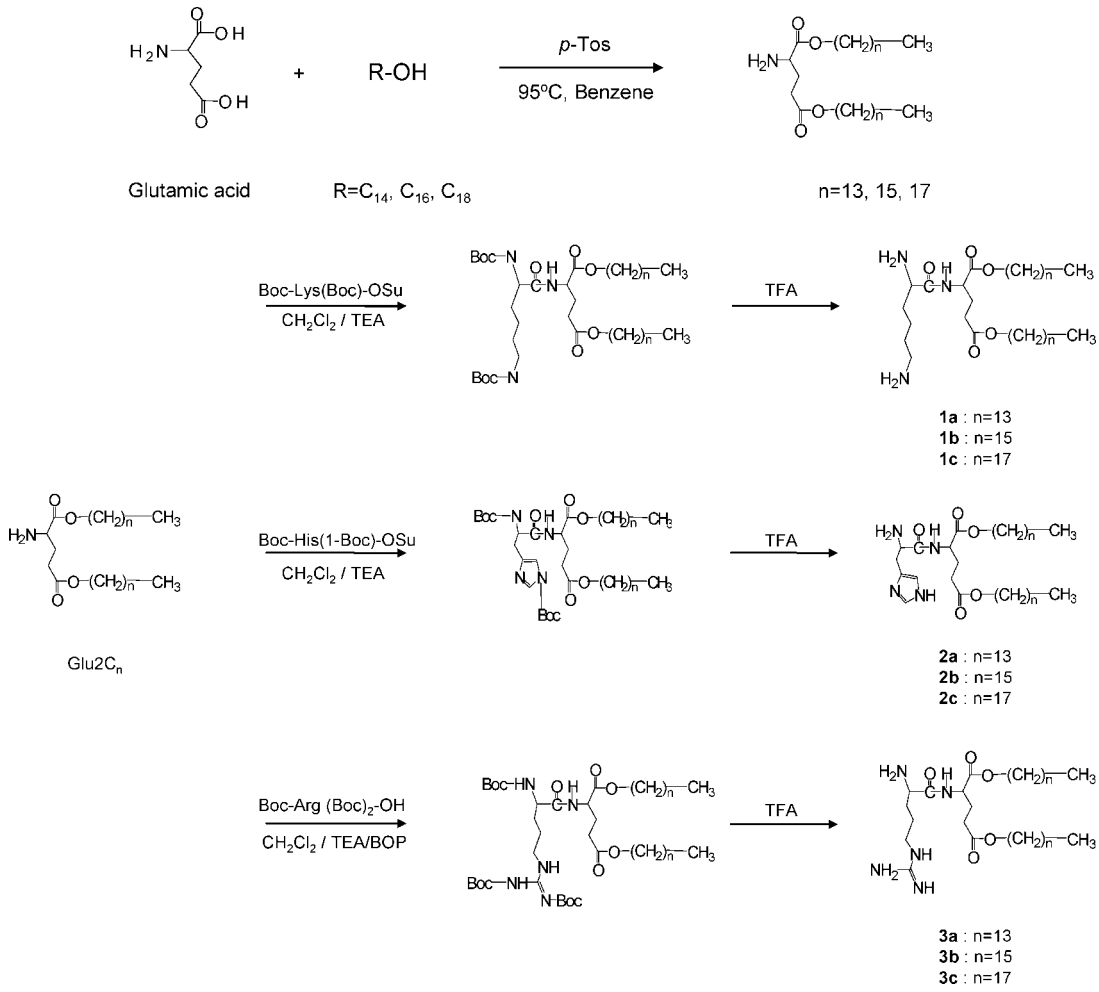
Scheme 1. Synthesis of Amino Acid Based Cationic Lipids Bearing Lysine, Histidine, or Arginine as a Cationic Head Group



backbone had a higher potency to transfer nucleic acid than the aspartate backbone (*35*). We have also demonstrated the utilities of the lipids having a glutamate backbone and investigated their potential as a liposomal gene delivery system (*36, 37*).

In this study, we focus on the cationic lipid-based nucleic acid carriers without using phospholipid. We synthesized a series of cationic lipids having a glutamate backbone and a cationic amino acid such as lysine, histidine, or arginine as the headgroup. Assemblies of these compounds were then investigated in terms of morphology, complexation profiles with plasmid DNA (pDNA), and the dispersion state of the resulting lipoplexes by altering the cationic headgroup and length of the alkyl chains of the cationic lipids. Lipoplexes containing pDNA-encoding luciferase were constructed with a series of amino acid based lipids and various lipid-to-pDNA ratios. Cytotoxicities of these pDNA carriers were then compared with conventional Lipofectamine2000. The appropriate structure of the cationic lipid was soaked.

MATERIALS AND METHODS

Materials. The following reagents were purchased from Kanto Chemical Inc. (Tokyo, Japan): L-glutamic acid, *p*-toluenesulfonic acid monohydrate (*p*-Tos), benzotriazol-1-yloxytris(dimethylamino)phosphonium hexafluorophosphate (BOP), tetradecyl alcohol, hexadecyl alcohol, or octadecyl alcohol. N_α,N_ϵ-Di-*tert*-butoxycarbonyl-L-lysine hydroxysuccinimide ester (Boc-Lys(Boc)-OSu), N_α,N_ϵ-di-*tert*-butoxycarbonyl-L-histidine hydroxysuccinimide ester (Boc-His(1-Boc)-OSu), and N_α,N_δ,N_ω-tri-*tert*-butoxycarbonyl-L-arginine (Boc-Arg(Boc)$_2$-OH) were purchased from Kokusan Chemical (Tokyo, Japan). All organic reagents employed in the synthesis of the amino acid based cationic lipids were obtained from Kanto Chemical.

Synthesis of Amino Acid Based Cationic Lipids. a (1,5-ditetradecyl-L-glutamate), **b** (1,5-dihexadecyl-L-glutamate), and **c** (1,5-dioctadecyl-L-glutamate) were synthesized as a hydrophobic moiety, and then they were conjugated to the cationic head-groups such as lysine, histidine, and arginine as shown in Scheme 1. The syntheses of the cationic lipids and their characterization are shown in Supporting Information.

Preparation of Cationic Assemblies Formed from the Synthetic Lipids. The lyophilized lipid powder (10 mg) was hydrated in deionized water (1 mL) for 2 h and extruded with a LIPEX EXTRUDER (Northern Lipids Inc.; Vancouver, Canada) with membrane filters (cellulose acetate filters with pore sizes of 3.00, 0.80, 0.65, 0.45, 0.22, 0.10 μm, Millipore Inc., Bedford, MA) at 60 °C. The cationic assemblies were prepared from the lysine- (**1a**−**1c**), histidine- (**2a**−**2c**), or arginine- (**3a**−**3c**) type lipids. The lipid concentration of the cationic assemblies was determined by estimating the lipid weight after the freeze-drying the cationic assembling dispersion.

Microscopic Observation of the Cationic Assemblies. The cationic assemblies were observed by transmission electron microscopy (TEM). A drop of the sample dispersion was placed on a 100 mesh copper grid, and then the excess dispersion was removed with a filter paper. A drop of 2% phosphotungstic acid solution (pH 7.4) was added to the grid and then dried for 12 h in a desiccator. The morphology of the cationic assemblies was observed by TEM (JM-1011, JEOL).

Preparation of Lipoplexes. The cationic assemblies were mixed with a phRL-TK plasmid vector (4045 bp, HSV promoter; Promega, Madison, WI) encoding renilla luciferase. The mixed solutions were gently agitated and incubated at room temperature for 15 min. The solutions were then diluted with an appropriate amount of Dulbecco's modified Eagle's medium (DMEM) with or without fetal bovine serum (FBS) for analyzing the gene transferring efficiency. Lipofectamine2000 (Invitrogen, Carlsbad, CA) was used for gene transfer studies according to the manufacturer's guidelines.

Measurement of Size Distribution and Zeta-Potential of the Lipoplexes. The dispersion of the cationic assemblies (150 nmol as lipid concentration) was diluted with distilled water (1 mL). The mean particle diameter was then measured using a dynamic light scattering spectrophotometer (N4 PLUS Submicron Particle Size Analyzer; Beckman-Coulter Inc., Fullerton, FL). The zeta-potential of the lipoplexes dispersed in distilled water was measured with a Zetasizer (Zetasizer4; Malvern, UK). The lipoplex dispersed in water (15 μmol as lipid concentration, 1 mL) was loaded in the capillary cell mounted on the apparatus and measured three times at 37 °C.

Gel Retardation Assay of the Lipoplexes. The lipoplexes prepared by varying the lipid-to-pDNA ratio were applied to a 1% seaplaque GTG agarose gel (Takara Bio. Inc., Otsu, Japan) in 1% Tris−acetate−EDTA (Invitrogen). After electrophoresis for 30 min, the agarose gel was rinsed in an ethidium bromide (EtBr) solution for 10 min. The gel was then rinsed in distilled water for 15 min and visualized on a UV transilluminator (GelDoc XR system; Bio-Rad, Hercules, CA).

Measurement of Gene Expression Efficiency of the Lipoplexes by COS-7 Cells. COS-7 cells (transformed African green monkey kidney fibroblast cells) were utilized for evaluating the gene expression efficiency of various lipoplexes. The COS-7 cells (1×10^4 cells) were seeded on 96-well plates and incubated at 37 °C under 5% CO_2 for 12 h. The COS-7 cells were cultured with DMEM containing 10% FBS. The medium in the cell culture dishes was changed to a fresh medium (100 μL) in the presence of lipoplexes containing 2 μg/mL of pDNA as a final concentration. After incubation at 37 °C for 24 h, the cells were washed twice with an ice-cold PBS solution and then lysed with a lysis buffer from the luciferase assay kit (Promega, Madison, WI). The luciferase activity in a 10 μL aliquot of the cell lysate was measured with a Microlumat Plus (EG&G Berthold, BadWilbad, Germany). The protein concentration of each well lysate was determined by a standard protein assay (Bio-Rad Protein Assay; Bio-Rad). The luciferase activity in each sample was normalized to the relative light unit (RLU) per microgram of protein.

Calorimetric Analysis of the Cationic Assemblies. A gel-to-lipid crystalline phase transition temperature (T_c) of the cationic assemblies from the synthetic amino acid based cationic lipids was investigated using a differential scanning calorimeter (DSC). The dispersion containing 40 μmol lipids of cationic assemblies was added to a silver pan and sealed. A reference pan was mounted with 30 μL of distilled water. The sample pan and the reference pan were placed in a DSC cell compartment (Differential Scanning Colorimeter Q2000; TA Instruments, Newcastle, DE). The measurement was usually started from 0 °C, and the temperature was raised at a rate of 2 °C/min up to 80 °C. The transition temperature was estimated from the DSC curve.

Fusion Assay of the Cationic Assemblies with Model Membrane. The membrane fusion between the cationic assemblies and liposomes with biomembrane-mimicking lipid composition was investigated to explore the gene transfer mechanism of the prepared lipoplexes by using a fluorescence resonance energy transfer (FRET) assay. The model liposomes constructed with DOPC/DOPE/DOPS/cholesterol (45:20:20:15, wt %) were labeled with *N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)-phosphatidylethanolamine (NBD-PE) and rhodamine-phosphatidylethanolamine (Rho-PE), of which concentrations were 1 mol %. For the fusion assay, 500 μL of the labeled liposomes (500 μM as lipid concentration) was added to 500 μL of the prepared lipoplexes (500 μM as lipid concentration). The mixed solution was then incubated at 37 °C for an appropriate period of time. Fluorescence intensity was recorded using an excitation wavelength of 460 nm and an emission wavelength of 525 nm. The time course of the lipid mixing percentage between the model membrane and the cationic assemblies was determined using the following equation:

$$\text{Lipid Mixing \%} = ((F_t - F_0)/(F_{TX} - F_0)) \times 100$$

where F_t is the fluorescence intensity at an appropriate time, F_0 is the fluorescence intensity just after dilution with distilled water, and F_{TX} is the fluorescence intensity after the addition of Triton X-100 to solubilize the liposomes.

Table 1. Size Distribution of Cationic Assemblies Constructed with the Cationic Lipids after Extrusion

lipid composition	particle size (nm)
1a	89 ± 37
1b	38 ± 31
1c	116 ± 54
2b	93 ± 34
2c	97 ± 37
3a	90 ± 32
3b	93 ± 34
3c	92 ± 40

Cytotoxicity of the Lipoplexes. The cytotoxicity of the lipoplexes constructed with the cationic assemblies and pDNA was investigated with COS-7 cells. The COS-7 cells (1×10^4 cells) were seeded on a 96-well plate and incubated at 37 °C under 5% CO_2 for 12 h. The COS-7 cells were cultured with DMEM containing 10% FBS. The medium in the cell culture dish was changed to a fresh medium (100 μL) containing an appropriate concentration of the lipoplexes diluted with a medium containing 10% FBS. After incubation at 37 °C for 24 h, the medium was changed to a medium (110 μL) containing a tetrazolium salt (WST-1) and incubated for 30 min. Formazan (absorbance at 540 nm) is then produced by succinate−tetrazolium reductase in living cells. The absorbance at 540 nm was monitored using a microplate reader (Perkin-Elmer Japan Co. Ltd., Tokyo, Japan).

RESULTS

Synthesis of the Amino Acid Based Cationic Lipids. We synthesized a series of amino acid based cationic lipids that were expected to display gene transferring capacity by utilizing the headgroup amino acid (lysine, histidine, or arginine) as shown in Scheme 1. Two long-chain alcohol molecules of varying chain length were esterified to the carboxyl groups of glutamic acid (**a**−**c**). The yield of **a**−**c** after recrystallization was high (i.e., >70%). Protected amino acid reagents, such as Boc-Lys(Boc)-OSu, Boc-His(1-Boc)-OSu, or Boc-Arg(Boc)$_2$-OH, were reacted with the amino group of **a**−**c** via an amide linkage. Deprotection with trifluoroacetic acid led to the formation of the amino acid based cationic lipids. Thus, we succeeded in devising an efficient synthetic route to generate cationic lipids using a minimal number of steps, followed by recrystallization to give a cost-effective purification method.

Cationic Assembling Structures. The cationic assemblies formed from the synthetic amino acid based cationic lipids were prepared by an extrusion method (Table 1) and were observed using TEM (Figure 1). In addition, we confirmed that the

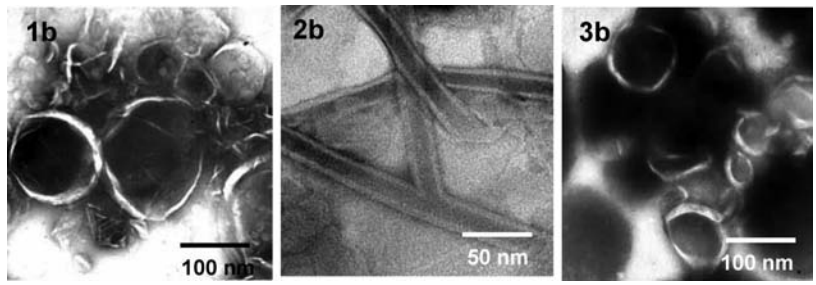


Figure 1. Transmission electron microscopic images of the cationic assemblies constructed with (a) **1b**, (b) **2b**, or (c) **3b** lipid, stained with 2% sodium phosphotungstic acid.

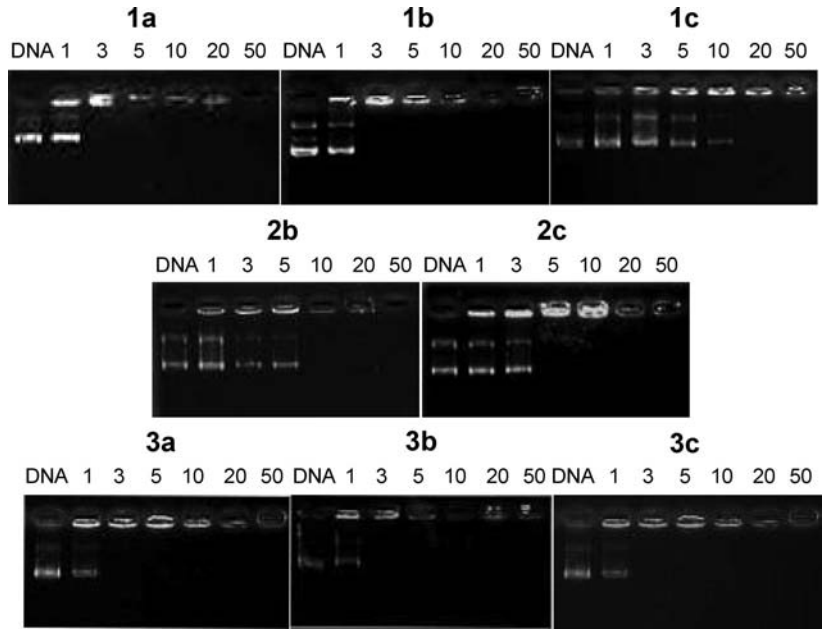

Figure 2. Gel retardation of lipoplexes constructed with cationic assemblies and pDNA with various lipid-to-pDNA ratios (w/w).

structure of the cationic assemblies was influenced by the headgroup of the lipids. Assemblies prepared from the lysine-(**1a**−**1b**) or arginine-type lipid (**3a**−**3c**) formed unilamellar vesicles with a diameter of approximately 100 nm by DLS measurements but more than 100 nm in size for the cationic assembly of **1c**. By contrast, morphology of the histidine-type lipids (**2b**, **2c**) was tube-like. The histidine-type lipid **2a** aggregated when dispersed in distilled water and could not permeate through a membrane filter of pore size 3 μm. No further characterization of **2a** was performed in this study. Moreover, morphologies of the unilamellar vesicles formed from lysine-, arginine-, or histidine-type lipids were less influenced by variations in the length of alkyl chains.

Lipoplex Formation of the Cationic Assemblies with pDNA. We analyzed lipoplex formation between the cationic assemblies by varying the lipid-to-pDNA ratio and pDNA using agarose gel retardation assays (Figure 2). The abilities of all the cationic assemblies were enough to form lipoplexes. Excess pDNA was barely detectable using a lipid-to-pDNA ratio of 3 in the cationic assemblies of **1a**, **1b**, and **3a–3c**. For **1c**, **2b**, and **2c**, the lipid-to-pDNA ratios had to be increased to 20, 10, and 10, respectively. Having prepared the lipoplexes, spontaneous pDNA released into the solution was scarcely detectable even after several hours.

In particular, we investigated the lipoplexes composed of **1a** and **3a** with respect to size distribution and zeta-potential (Figure 3). The apparent size of the lipoplex composed of **1a** and pDNA continuously increased with increasing lipid-to-pDNA ratios from 1 to 5. However, any further increase in the lipid-to-pDNA ratio resulted in a reduction in the size of lipoplex. The 90 nm unilamellar vesicles of **1a** increased in size to 390 nm lipoplexes at a lipid-to-pDNA of 10. The zeta-potential of the lipoplex composed of **1a** dramatically increased as the lipid-to-pDNA ratio was raised from 1 to 3. However, additional increases in the lipid-to-pDNA ratio from 3 to 50 resulted only in a gradual rise in zeta-potential, reaching a maximum of around +40 mV. The size of the lipoplexes composed of **3a** also increased as the lipid-to-pDNA ratio was raised to 5, although the zeta-potential was constant (+25 mV) at ratios greater than 5.

Luciferase Activity of the Cationic Assemblies. We evaluated the gene transferring efficiency of lipoplexes composed of the synthetic lipids using COS-7 cells (Figure 4). Lipoplexes composed of each cationic assembly and luciferase-encoding pDNA were prepared by varying the lipid-to-pDNA ratio with fixing the pDNA concentration of 2 μg/mL. The lipoplexes were then transfected into COS-7 cells. For the lysine-type lipids, gene expression efficiency exhibited a maximum value at a **1a**-to-pDNA ratio of 10, which was 2.2-fold higher compared with that for Lipofectamine2000 reagent in the absence of FBS (Figure 4A). The gene expression level after transfection with **1a**, **1b**, and **1c** tended to increase with shorter alkyl chains. The gene transferring efficiency with **1c** was the lowest of the three lysine-type lipids. In addition, gene expression efficiency with Lipofectamine2000 was considerably reduced in the presence of FBS (Figure 4B). By contrast, gene expression levels determined using lipoplexes formed from **1a**−**1c** displayed

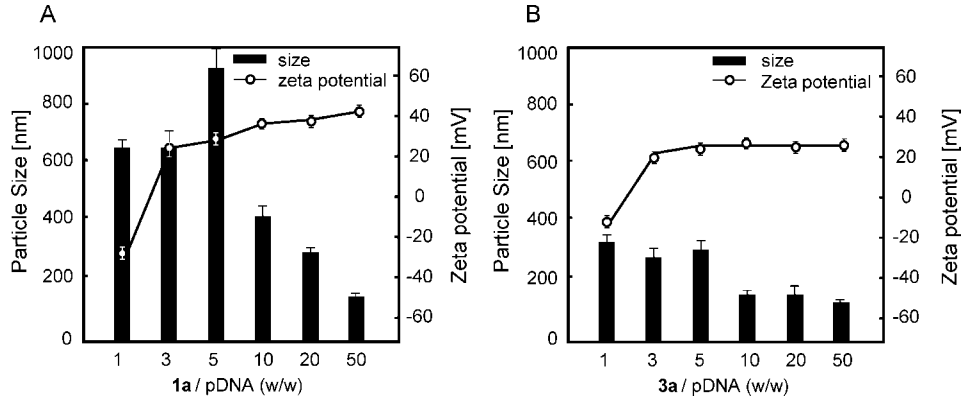

Figure 3. Size distribution and zeta-potential of the lipoplex constructed with (A) **1a** or (B) **3a** lipid. The lipoplexes were dispersed in distilled water at 37 °C.

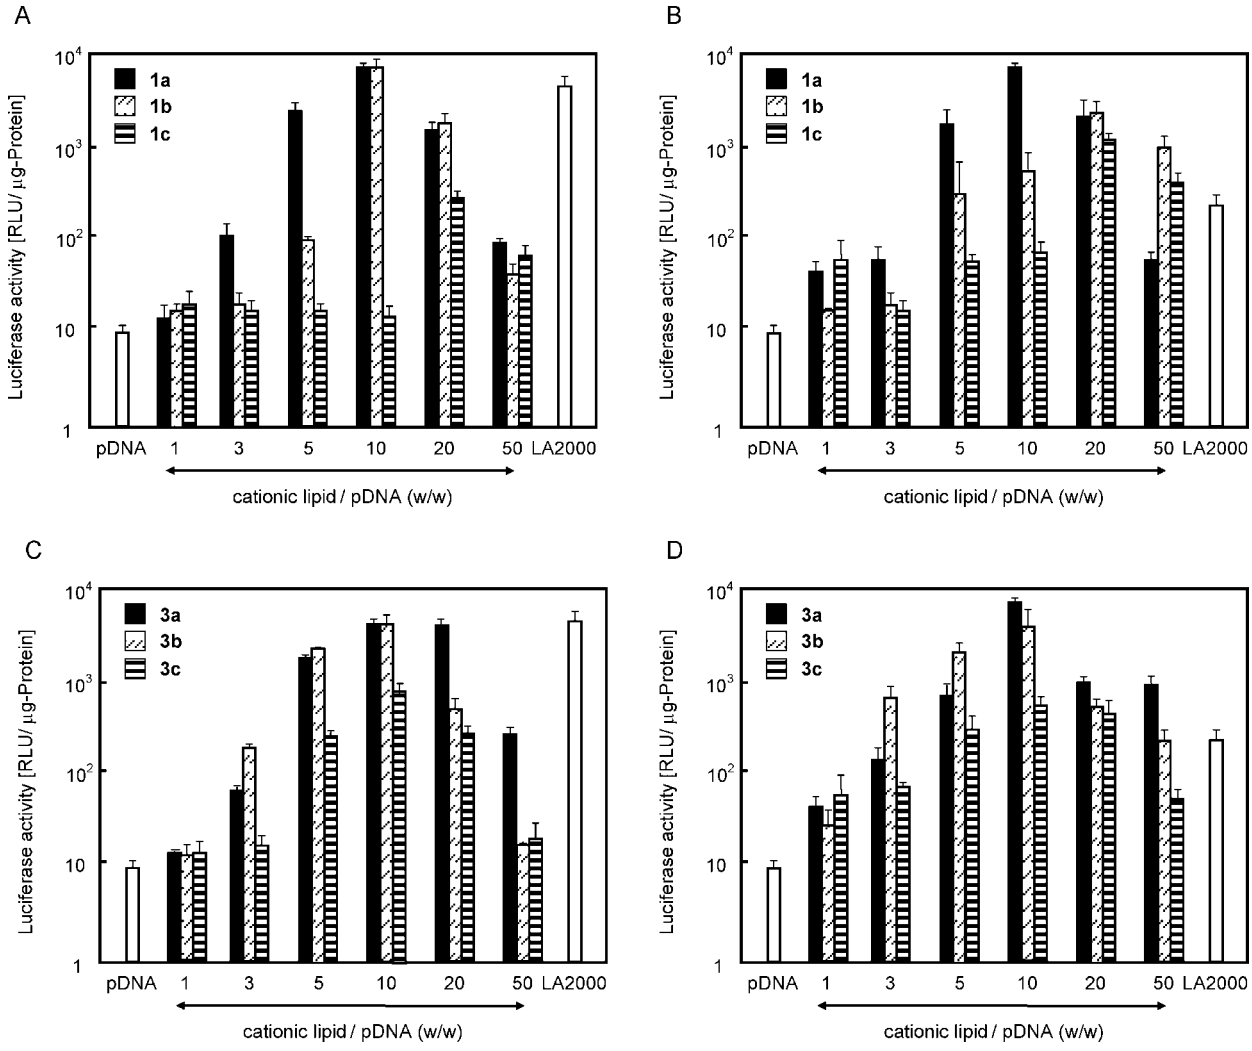

Figure 4. Luciferase activity of COS-7 cells transfected with the lipoplexes. The luciferase activities varied according to the lysine-type lipid-to-pDNA ratio in the (A) absence or (B) presence of fetal bovine serum. The luciferase activity with the lipoplexes varied according to the arginine-type lipid-to-pDNA ratio in the (C) absence or (D) presence of fetal bovine serum.

no significant difference in the presence/absence of FBS. Consequently, in the presence of FBS the expression level of **1a** at a lipid-to-pDNA ratio of 10 was 12-fold higher than that observed using lipofectamine2000.

In addition, we investigated the gene transferring efficiencies of cationic assemblies prepared from the other cationic lipids having a histidine or an arginine as the cationic headgroup. Cationic assemblies formed from histidine-type lipids **2b** or **2c** did not give detectable levels (ca. 200 RLU at all lipid-to-pDNA ratios) of gene expression. The gene expression efficiencies for the arginine-type lipids were as high as those obtained for the lysine-type lipids. The arginine-type **3a**−**3c** also showed a maximum gene expression efficiency at a lipid-to-pDNA ratio of 10 (Figure 4C). Furthermore, the gene expression efficiency for **3a**−**3c** increased as the length of the alkyl chain was reduced. In addition, the gene expression efficiency with the arginine-type lipids was not significantly affected by the presence of FBS (Figure 4D).

Effect of the Hydrophobic Moiety of the Cationic Assemblies on Fusogenic Potential to a Biomembrane. The fusogenic potential of the cationic assemblies to biomembrane mimicking liposomes was investigated (Figure 5). We confirmed that the difference in the fusogenic potential of the prepared cationic assemblies was based on fluidity. The transition temperatures of the lysine-type lipids **1a**, **1b**, and **1c** were 26.3, 43.3, and 53.2 °C, respectively (Figure 5A). For the arginine-type lipids **3a**, **3b**, and **3c**, the transition temperatures were 24.7, 42.5, and 52.7 °C, respectively. Similar analyses of **2b** and **2c** were conducted to obtain the transition temperatures of 34.4 and 42.3 °C, respectively. Our results indicate that the transition temperature of the cationic assemblies increased with increasing alkyl chain length. Thus, the hydrophobic moiety appears to have a direct effect on fusogenic potential. There was no significant difference in transition temperature between the lysine-type and the arginine-type series of lipids having the same alkyl chain length. Among the lysine-type lipids, **1a** exhibited the highest fusogenic potential (Figure 5B). The fusogenic ratio of **1a** gradually increased and reached about 13% after incubation for 30 min at 37 °C. **1b** showed a slightly lower fusogenic potential than **1a**. However, the fusogenic potential of **1c** was significantly diminished compared to those of **1a** and **1b**. A similar trend was also observed for the arginine-type lipids (Figure 5C). The fusogenic potentials of **3a** and **3b** were almost the same, whereas that of **3c** was significantly lower. The fusogenic potentials of the lysine-type lipids were slightly higher than those of the arginine-type lipids. Our data would highlight the influence of the hydrophobic moiety on fusogenic potential.

Cytotoxicities of the Lipoplexes. We investigated the cytotoxicities of the lipoplexes constructed with the various synthetic cationic lipids (Figure 6). All cationic lipids were revealed to have low toxicity. Lipoplex composed of lipofectamine2000 reagent at a lipid-to-pDNA ratio of 3 was toxic to around 100% of COS-7 cells at a lipid concentration of 100 μg/mL. By contrast, lipoplexes constructed of the cationic assemblies of **1a**, **1b**, **3a**, or **3c** exhibited significantly lower toxicities. For example, more than half of the cells seeded on a

culture dish survived even in the presence of 1 mg/mL lipid concentration of lipoplex (i.e., ~50 times higher lipid concentration compared to the experiment using Lipofectamine2000).

DISCUSSION

Our objective in this study was to develop cationic lipids with a high gene transferring efficiency that could be readily and inexpensively synthesized. We analyzed amino acid based cationic lipids and tested their ability to form lipoplex. Initially, we focused on the molecular assemblies formed from synthetic cationic lipids. The lysine- or arginine-type lipids formed unilamellar vesicles, whereas the histidine-type lipid formed a tube-like structure. These results indicate that the overall architecture of the assemblies is largely determined by the nature of the hydrophilic headgroup. It was reported that assemblies formed from amino acid based lipids with an asymmetric carbon can adopt various structures such as a tube, fiber, or ribbon (*38, 39*). Here, we confirmed that the synthetic amino acid based lipids with two asymmetric carbon atoms would be expected to take various assembling structures. After extrusion, the histidine-type lipid initially formed a vesicular structure that was observed by TEM (data not shown). However, the ratio of tube-like assemblies gradually increased over a period of a week during storage at 4 °C. If the transition temperature is exceeded during the extrusion procedure, a rearrangement of lipid molecules into unstable bilayer vesicles might occur. Subsequent incubation at low temperatures will then cause the vesicles to gradually aggregate and fuse into a more stable state, that is, in this case a tube-like structure (*40*). Therefore, we conclude that **2a**, **2b**, and **2c** cannot form stable vesicle dispersions because of an unfavorable balance of hydrophilic and hydrophobic characteristics and the particular structure of the histidine moiety.

All the cationic assemblies were confirmed to form lipoplexes with pDNA from a gel retardation assay. When the lipid-to-pDNA ratio was >3, no excess pDNA was detected for **1a**, **1b**, **3a**, and **3b** (the estimated N/P ratio of 2.7). Because the unilamellar vesicles comprise both an outer and an inner layer, the more accurate N/P ratio is about 1.4 if there were no change of inner- and outer-lipid composition after lipoplex formation. Therefore, a proportion of the amino groups of the outer layer of the liposome do not have access to the phosphate groups of the pDNA. When **1c** was utilized as a component of the cationic assembly, more lipids were required to form lipoplexes. Indeed, the size of cationic assembly of **1c** was large in comparison to that of **1a** or **1b**. If **1c** would take a unilamellar structure, the portion of the amino groups of the vesicle, which can access pDNA, should be equal to those of **1a** and **1b**. However, more **1c** lipid was required to form a lipoplex with the pDNA. Therefore, we regarded the cationic assemblies of **1c** as multilamellar structures. Therefore, we defined the cationic assemblies as multilamellar structures. Cationic assemblies from the histidine-type lipids formed a stable complex with the pDNA at a lipid-to-pDNA ratio of 10 (N/P = 8). More histidine-type lipid based cationic assemblies were required to form lipoplex than the lysine- or arginine-type lipids. On the basis of pK_a values of the different amino groups, electrostatic interaction of the tertiary amino group of histidine will be much weaker than that of the primary amino group of lysine or arginine. Thus, we might anticipate that the competence of the histidine-type lipids to form lipoplexes will be relatively low. Indeed, this conclusion is further supported by previous studies using cationic amino-acid derivatives derived from tryptophan-type lipids, which exhibited low levels of gene expression in transfection experiments (*41*). Moreover, tube-like assemblies might be unable to form a lipoplex with pDNA. No further analysis of the histidine type-lipids was performed in this study. Therefore, our analysis shows that assemblies with a lysine or arginine headgroup are the most appropriate to form lipoplexes.

The maximum values of gene expression efficiency for **1a**−**1c** and **3a**−**3c** were obtained at a lipid-to-pDNA ratio of 10. The zeta-potential of lipoplexes exhibiting the highest level of gene expression was about +38 mV for **1a** and +22 mV for **3a** at a lipid-to-pDNA ratio of 10. Under the transfection conditions used in this study, the amino groups of the lysine or arginine moieties would be fully protonated. Therefore, the difference in zeta-potential between the lipoplexes of **1a** and those of **3a** must be caused by variation in the length of the alkyl side chains of the cationic amino acids. The amino group of lysine has a higher zeta-potential than that of arginine because it is located at the terminus of a relatively long side chain.

Comparison of gene transfer efficiency with respect to the headgroup of the cationic lipids is as follows: lysine ≥ arginine > histidine. Thus, both lysine and arginine form appropriate headgroups to bind pDNA and display a high affinity for the cell membrane. Although the lipoplex formation using histidine-type lipids was confirmed by gel retardation, the level of gene expression was quite low. This low level of gene expression might be due to poor cellular uptake of the tube-like assemblies, which were several micrometers in length and 10 nm in diameter. Furthermore, after endocytosis the electrostatic interaction between the tertiary amino group of the histidine and the phosphate group of pDNA is presumably very weak in the acidic environment of the endosome. Thus, delivery of pDNA into the nucleus will be very inefficient.

In our study, uniform vesicles from **1a**−**1c** or **3a**−**3c** having a glutamate backbone showed high levels of gene transfer efficiency. Kim et al. reported lysine-type lipid derivatives (*O*,*O*′-dimyristyl-*N*-lysyl aspartate (DMKD) and *O*,*O*′-dimyristyl-*N*-lysyl glutamate (DMKE)) (*34, 35*), and DMKD showed a maximum gene expression at a lipid-to-pDNA ratio of 5. We traced their experiments using the same aspartic acid derivatives and clarified that the lipid assemblies formed a mixture of ribbon-like and vesicular structures (data not shown). So far, there has been no definite to instruct a difference in molecular assembly between the glutamate- and aspartate-based lipids. From this comparison, we adopted the glutamate backbone rather than the aspartate backbone. The cationic liposomes composed of cholesterol and DMKE or **1a** were also evaluated in vivo to indicate the usefulness of the glutamate backbone (*35*).

The gene expression efficiencies of our cationic lipids were also dependent on the length of the alkyl chain. Order of gene expression efficiency in terms of the number of carbon atoms in the alkyl chain was as follows: 14 > 16 > 18. The gene expression efficiency of a lipoplex is generally known to be dependent on the T_c of the cationic lipid (*42, 43*). Two independent studies involving a series of cationic lipids of different alkyl chain lengths showed the expression efficiency to be: $C_{14} > C_{oleyl} > C_{18} > C_{16} > C_{12}$ by Felgner et al. (*44*) or $C_{14} > C_{oleyl} > C_{16} > C_{18}$ by Floch et al. (*45, 46*). However, because lipoplexes utilize helper lipids, such as DOPE or cholesterol, the fluidity of the liposomal membrane is not solely dependent on the fluidity of the pure cationic lipids. Lipid membranes of high fluidity tend to promote fusion with a biological membrane, leading to high gene expression efficiency (*18, 42, 43*). Thus, we also analyzed the fusogenic potential of the cationic assemblies using a model membrane that mimics a biomembrane. The fusogenic potentials of the lipoplexes from **1c** (T_c, 53.2 °C) or **3c** (T_c, 52.7 °C) with low fluidity were quite low, resulting in quite low gene expression efficiency in comparison with that of **1a** (T_c, 26.3 °C) or **3a** (T_c, 24.7 °C) of high fluidity. In our study, cationic assemblies with high fluidity led to high gene expression.

A low level of gene expression efficiency in the presence of FBS has been a major barrier to the medical application of gene therapy (*25*). In general, the phospholipid molecules in the liposomal membrane are thought to be removed by high density lipoproteins (HDL) in serum (*47*). This would result in poor fusogenic ability to the biological membrane in the presence of FBS, leading to low gene expression efficiency, particularly when DOPE was utilized as a liposomal component. In our study, the reduction in gene expression with DOPE-containing transgenic reagents was also confirmed in the presence of FBS. However, cationic assemblies formed from the synthetic lipids under optimal conditions displayed no reduction in gene expression efficiency in the presence of FBS. This observation suggests that the amino acid based cationic lipids are not influenced by FBS. Thus, we succeeded in constructing cationic carriers based on non-DOPE.

The cytotoxicity of the lipoplexes was evaluated using COS-7 cells. Compared with conventional Lipofectamine2000, cytotoxicity of the lipoplexes constructed with the synthetic amino acid based cationic lipids was very low. Toxicity of the conventional reagent is probably related to the presence of multivalent cationic compounds such as DOGS or DOSPA. Specifically, after dissociation of the pDNA the multivalent cationic compounds aggregate with various intracellular organelles, leading to cell death. By contrast, amino acid based cationic lipids are easily dissociated and metabolized. Furthermore, the ester bond in the linker region of the amino acid based cationic lipids is readily hydrolyzed in the cell, thereby lowering their cytotoxicity (*48*).

In conclusion, we constructed pDNA carriers with synthetic amino acid based cationic lipids. In particular, cationic lipids having lysine or arginine as a headgroup and two C_{14} alkyl chains as hydrophobic moieties were shown to display a high level of gene transfer efficiency equal to that of standard Lipofectamine2000 in the absence of FBS. Additionally, in the presence of FBS, our pDNA carriers provided much higher efficiency than that of Lipofectamine2000. Moreover, the cytotoxicity of our cationic lipids was only one-fifth that of Lipofectamine2000. Thus, results from our in vitro experiments show that lipoplexes formed from these amino acid based cationic lipids are promising candidates for further investigations in vivo. We are currently constructing cationic lipids focusing on the moiety between the lysine headgroup and the hydrophobic moiety to enhance gene expression.

End Modification of a Linear DNA Duplex Enhances NER-Mediated Excision of an Internal Pt(II)-Lesion

Tracey McGregor Mason,[†] Michael B. Smeaton,[†] Joyce C. Y. Cheung, Les A. Hanakahi, and Paul S. Miller*

Department of Biochemistry and Molecular Biology, Johns Hopkins Bloomberg School of Public Health, Johns Hopkins University, 615 North Wolfe Street, Baltimore, Maryland 21205. Received November 27, 2007; Revised Manuscript Received February 11, 2008

The study of DNA repair has been facilitated by the development of extract-based *in vitro* assay systems and the use of synthetic DNA duplexes that contain site-specific lesions as repair substrates. Unfortunately, exposed DNA termini can be a liability when working in crude cell extracts because they are targets for DNA end-modifying enzymes and binding sites for proteins that recognize DNA termini. In particular, the double-strand break repair protein Ku is an abundant DNA end-binding protein that has been shown to interfere with nucleotide excision repair (NER) *in vitro*. To facilitate the investigation of NER in whole-cell extracts, we explored ways of modifying the exposed ends of synthetic repair substrates to prevent Ku binding and improve *in vitro* NER efficiency. Replacement of six contiguous phosphodiester linkages at the 3′-ends of the duplex repair substrate with nuclease-resistant nonionic methylphosphonate linkages resulted in a 280-fold decrease in binding affinity between Ku and the modified duplex. These results are consistent with the published crystal structure of a Ku/DNA complex [Walker et al. (2001) *Nature 412*, 607−614] and show that the 3′-terminal phosphodiester linkages of linear DNA duplexes are important determinants in DNA end-binding by Ku. Using HeLa whole-cell extracts and a 149-base pair DNA duplex repair substrate, we tested the effects of modification of exposed DNA termini on NER-mediated *in vitro* excision of a 1,3-GTG-Pt(II) intrastrand cross-link. Methylphosphonate modification at the 3′-ends of the repair substrate resulted in a 1.6-fold increase in excision. Derivatization of the 5′-ends of the duplex with biotin and subsequent conjugation with streptavidin to block Ku binding resulted in a 2.3-fold increase excision. By combining these modifications, we were able to effectively reduce Ku-derived interference of NER excision *in vitro* and observed a 4.4-fold increase in platinum lesion excision. These modifications are easy to incorporate into synthetic oligonucleotides and may find general utility whenever synthetic linear duplex DNAs are used as substrates to investigate DNA repair in whole-cell extracts.

INTRODUCTION

Studies of DNA repair often use damaged plasmid DNA or lesion-containing, double-stranded, linear DNA duplexes as repair substrates. Plasmid DNA is problematic as a substrate for *in vitro* repair studies because the size of the substrate makes it difficult to characterize and quantify the repair process. Unlike plasmid DNA, synthetic linear duplexes that contain site-specific lesions are readily synthesized and can be labeled in a variety of ways for high-sensitivity detection of repair activity. Such synthetic linear DNA duplexes provide convenient and easily manipulatable substrates for carrying out detailed studies of DNA repair. For example, linear DNA duplexes of ∼150 bp in length that contain a 1,3-diammineplatinum(II) intrastrand cross-link have been instrumental in the study of nucleotide excision repair (NER) in whole-cell extracts derived from Chinese hamster ovary (CHO) and human (HeLa) cell lines (*1*, *2*). Similar synthetic DNA duplexes have been employed in the study of psoralen interstrand cross-link repair in whole-cell extracts and in fully reconstituted reactions using purified repair proteins (*3*–*6*).

A potential problem with using linear duplexes in repair studies is the presence of exposed DNA termini, which are targets for DNA end-modifying enzymes, such as nucleases or phosphatases, and binding sites for proteins that recognize DNA ends. In particular, proteins involved in the recognition and repair of DNA double-strand breaks (DSB) have been shown to bind at exposed DNA termini of synthetic duplexes (*7*). The DSB repair protein Ku70/80 (Ku), which participates in both DSB repair and in immunoglobulin gene recombination, is a DNA end-binding protein that is abundant in whole-cell extracts (*8*–*12*). Previous studies have suggested that Ku not only binds DNA ends, but once bound can translocate along the DNA duplex. This makes it possible for several Ku molecules to occupy a single linear duplex and to potentially interfere with damage recognition or processing (*13*).

In this article, we present strategies that can improve efficiency in extract-based DNA repair assay systems by preventing recognition of DNA termini by end-binding and -modifying factors. Introduction of nuclease-resistant, nonionic methylphosphonate linkages at the 3′-termini of the duplexes significantly reduces Ku binding. Derivatization of the 5′-ends of the duplex with biotin and subsequent conjugation with streptavidin is known to block binding of Ku to linear DNA duplexes (*14*). We have found that, in combination, these two modifications significantly enhance NER-mediated excision of an internal 1,3-Pt(II) intrastrand cross-link from a 149 bp linear duplex when incubated with a HeLa whole cell extract.

High performance liquid chromatography (HPLC) was performed on a Varian instrument using a 0.4 × 25 cm Dionex strong anion exchange (SAX) column. MALDI-TOF mass spectra were obtained on an Applied Biosystems Voyager mass spectrometer at the AB Mass Spectrometry/Proteomics Facility, Johns Hopkins School of Medicine, with support from a National Center for Research Resources shared instrumentation grant 1S10-RR14702. Talon metal affinity resin beads were purchased from BD Biosciences, Inc., and the Hi-trap heparin and Hi-trap Q columns were obtained from General Electric Health Sciences, Inc. Coomassie Fluor Orange was a product of Molecular Probes, Inc. Surface plasmon resonance experiments were performed on a BIACORE 3000 instrument. Streptavidin-coated sensor chips (Sensor Chip SA) and Surfactant P20 were purchased from Biacore, Inc. Phosphorimage screens were read on a Typhoon 9200 phosphorimager.

Oligonucleotide Synthesis. The sequences of the oligodeoxyribonucleotides used in these studies are shown in Table 1. The oligonucleotides and biotin-conjugated oligonucleotides were synthesized on controlled pore glass (CPG) supports by standard phosphoramidite chemistry using an Applied Biosystems model 392 or model 3400 DNA/RNA synthesizer. Phosphoramidite concentrations were 0.15 M; coupling times were 120 s; and the activator was 5-ethylthiotetrazole. In the case of the methylphosphonate-derivatized oligonucleotides, the standard oxidizing agent was replaced with a solution containing 1.27 g iodine, 12.5 mL 2,6-lutidine, and 100 μL water in 37.5 mL tetrahydrofuran, and standard Cap B reagent was replaced with a solution containing 1.25 g of 4-*N*,*N*′-dimethylaminopyridine in 50 mL of anhydrous pyridine. The DNA synthesizer was programmed to remove the 5′-terminal dimethoxytrityl group after the final coupling step. The oligonucleotides were cleaved from their CPG supports and deprotected by treating the support with 400 μL of 95% ethanol/concentrated ammonium hydroxide (1:3 v/v) at 55 °C for 3.5 h. In the case of the methylphosphonate-derivatized oligonucleotides, a two-step deprotection procedure was used. The CPG support was first treated with 95% ethanol/concentrated ammonium hydroxide (1:3 v/v) for 2.5 h at room temperature. The supernatant was removed from the support and evaporated. The residue was treated with a solution containing 22.5 μL 95% ethanol, 22.5 μL acetonitrile, and 50 μL ethylenediamine for 6 h at room temperature. The solution was cooled to 4 °C and neutralized with 600 μL of ice-cold 2 N hydrochloric acid. The oligonucleotide was then desalted on a C-18 SEP PAK cartridge (Waters, Inc.) or C-18 Clarity column (Phenomenex, Inc.) and eluted from the column with 50% aqueous acetonitrile. Oligonucleotides 30 nucleotides in length or shorter were purified by SAX HPLC using a 30 min linear gradient of 0−0.5 M sodium chloride at a flow rate of 1 mL/min. Longer oligonucleotides were purified on 20 cm × 20 cm × 0.75 mm 20% polyacrylamide gels containing 7 M urea in a TBE running buffer that consisted of 89 mM Tris, 89 mM boric acid, and 2 mM ethylenediaminetetraacetic acid, pH 8.0. The oligonucleotides were located on the gel by UV shadowing and extracted from the gel by incubating the gel overnight at 37 °C in a buffer containing 20% acetonitrile in 0.1 M ammonium acetate, pH 6.2. The gel-purified oligonucleotides were desalted on C-18 cartridges as described above and their compositions were confirmed by MALDI-TOF mass spectrometry.

Platinated oligonucleotide X (upper strand of duplex **X**) was prepared by incubating 26.5 nmol of the oligonucleotide in a solution containing 36 μM (54 nmol) *cis*-diamminedichloroplatinum (II) in 1.5 mL of Tris-EDTA buffer at 37 °C for 16 h. The reaction mixture was desalted using a SEP PAK cartridge and the platinated oligonucleotide, whose retention time is less than that of the nonplatinated oligomer, was purified by SAX HPLC using a linear gradient of 0.0−0.5 M sodium chloride in

buffer containing 20% acetonitrile in 50 mM Tris, pH 7.8. The purified oligonucleotide was desalted on a SEP PAK cartridge and its composition was confirmed by MALDI-TOF mass spectrometry, *m*/*z* calcd 4078.64, *m*/*z* found 4079.36.

Preparation of Oligonucleotide Duplexes. Duplexes **1**−**3** were prepared by annealing their component oligonucleotides in a buffer containing 70 mM Tris, pH 7.5, 10 mM magnesium chloride, and 5 mM dithiothreitol. The 149-mer duplexes **4**−**6** were prepared by ligation of their component duplexes following a procedure described by Huang et al. (*1*) The upper, platinated strand of duplex **X** (10 pmol) was first phosphorylated with [γ-^{32}P] ATP (6000 Ci/mmol) using T4 polynucleotide kinase. After excess ATP was removed using a G-10 spin column, the phosphorylated duplex was annealed to 15 pmol of its phosphorylated complementary strand to form duplex **X**. This duplex was then mixed with 15 pmol each of the appropriate phosphorylated component duplexes in 1X ligase buffer (New England Biolabs, Inc.) supplemented with 1 mM ATP incubated with 1000 units of T4 DNA ligase for 30 min at room temperature followed by overnight incubation at 16 °C. The reaction mixture was concentrated to <5 μL; dissolved in 25 μL of 80% formamide, containing 0.05% xylene cyanol and 0.05% bromophenol blue; and electrophoresced on a 6% denaturing polyacrylamide gel. Products were located by autoradiography of the wet gel. The slowest migrating band was excised, and the duplex was extracted from the gel by incubating the gel slice overnight at 37 °C in 1 mL of buffer containing 20% acetonitrile in 0.1 M ammonium acetate, pH 6.2. The buffer containing the 149-mer was lyophilized to 200 μL; the DNA was precipitated by addition of ethanol and 20 μg of oyster glycogen; and the resulting pellet was washed with 70% ethanol. The duplex was then dissolved in a buffer containing 100 mM KCl in Tris-EDTA buffer and annealed by heating at 90 °C for 5 min followed by slow cooling to <30 °C. Duplexes containing biotin as well as their control, phosphodiester-ended duplexes were incubated with streptavidin (Invitrogen) at a ratio of 1 μg streptavidin per 20 fmol of substrate for a minimum of overnight at 4 °C. Solutions of each duplex were stored at 4 °C and used before significant decay of the ^{32}P had occurred.

Cell Culture. HeLa cells (Biovest International Inc., National Cell Culture Center) were grown in suspension at (2.5−5) × 10^5 cells/mL in Jolick's MEM, 5% newborn calf serum, 100 units/mL penicillin, and 100 μg/mL streptomycin (PenStrep). Adherent CHO AA8 cells (a gift from Dr. Michael Seidman) were grown to large scale using a 10-layer CellSTACK culture chamber (Corning) to yield ~10^9 cells. Ku 80 deficient XR-V15B cells (obtained from ATCC) were grown in minimal essential medium, alpha modification, 10% FBS, and PenStrep in T-175 flasks.

Preparation of HeLa Whole-Cell Extracts. Large-scale preparations (~10^9 cells) of whole cell extracts from HeLa and CHO AA8 cells for the NER experiments were prepared as described by Manley et al. (*15*) using helpful procedural information described by Wood et al. (*16*) and by Reardon and Sancar (*17*). Nucleotide excision repair competent extracts were obtained when the cells were harvested in log phase growth. Protease inhibitors were added during the extract preparation to a final concentration of 1 mM phenylmethylsulfonyl fluoride (PMSF), 10 μg/mL aprotinin, 5 μg/mL leupeptin, and 100 μg/mL soybean trypsin inhibitor. Protein concentrations were determined using a BCA protein assay kit (Pierce Chemical Co.) and the extracts were stored at −80 °C in buffer containing 25 mM HEPES, pH 7.9, 100 mM potassium chloride, 12 mM magnesium chloride, 0.5 mM EDTA, 2 mM dithiothreitol, and 12.5% glycerol (v/v). A mini-NER whole cell extract method (*18*) was used to prepare and concentrate NER active extracts from ~5 × 10^7 XR-V15B cells.

Preparation of Ku70/80. Baculovirus expression vectors for Ku 70, pBacKu70, and Ku 80, pBac-his$_6$Ku80 were prepared as described in (*12*). Human Ku70 cDNA was amplified by PCR with primers 5′-d-GATCAAGGAGATACATATGTCAGGGTG GGAG-3′ and 5′-d-GCACTAGTTCAGTCCTGGAAGTG-3′ and TOPO cloned into pCR 8/GW/TOPO (Invitrogen) to produce pENTKu70, which was recombined into pDEST8 (Invitrogen) to produce pBacKu70. Human Ku80 cDNA (a generous gift from M. Lieber) was amplified with primers 5′-d-GGGGA-CAAGTTTGTACAAAAAAGCAGGCTCTTAAGAAGG AG-ATATACCATG-3′ and 5′-d-GGGGACCACTTTGTACAA-GAAAGCTGGGTCCTATATCATGTCCAATAAATC-3′, which include *att* sites for recombination into pDONR221 (Invitrogen). The N-terminal 5 amino acids were restored by site-directed mutagenesis (Stratagene) to generate pREhis$_6$Ku80, which was recombined into pDEST8 to create pBac-his$_6$Ku80. Baculoviruses for independent expression of Ku70 and his$_6$Ku80 were generated using the Bac-to-Bac Baculovirus Expression system (Invitrogen) according to manufacturer's instructions.

One liter of Sf-21 insect cells (10^6 cells/mL) was coinfected with Ku70 virus (MOI 10) and his$_6$Ku80 virus (MOI 5) for 4 days. Cells were harvested by centrifugation at 1000*g* for 15 min at 4 °C and the pellets were stored at −80 °C. Cells were resuspended in Buffer L, which contained 50 mM Tris pH 7.5, 0.3 M sodium chloride, 0.4 M ammonium acetate, 10% glycerol, 2 mM β-mercaptoethanol, and 0.1 M phenylmethylsulfonyl fluoride supplemented with 0.2% NP-40 and 20 mM imidazole; lysed by 30 strokes in a Dounce homogenizer with a loose-fitting pestle, and the lysate sonicated and cleared by centrifugation at 10 000*g* for 10 min at 4 °C. Cleared lysates were bound in batch to Talon metal affinity resin beads for 1 h at 4 °C. The beads were washed in Buffer L containing 20 mM imidazole, packed into a column, and fractions were eluted with Buffer L containing 0.5 M imidazole. Peak fractions were dialyzed against Buffer A, which contained 50 mM Tris pH 7.5, 50 mM sodium chloride, 1 mM dithiothreitol, and 1 mM sodium metabisulfite (NaMBS) supplemented with 5% glycerol; loaded onto a 5 mL Hi-trap heparin column; and eluted with a 0.05−1 M gradient of sodium chloride. Peak fractions were dialyzed against Buffer A containing 5% glycerol; loaded onto a 1 mL Hi-trap Q column; and eluted with a 0.05−1 M gradient of sodium chloride. Peak fractions were dialyzed into Buffer A containing 0.5 mM EDTA and 10% glycerol and stored at −80 °C.

Surface Plasmon Resonance Binding Experiments. Binding experiments were carried out in running buffer containing 84 mM potassium monohydrogen phosphate, pH 7.0, 10 mM sodium bicarbonate, 1 mM magnesium sulfate, 4 mM potassium chloride, 1% glycerol, 2 mM dithiothreitol, 0.5 mM EDTA, and 0.005% Surfactant P20 (Biacore, Inc.) at 25 °C. Biotinylated duplexes **1**−**3** were each immobilized on the surface of a streptavidin-coated sensor chip. The amount of DNA added was such that the level of Ku bound corresponded to 75−150 response units. Ku70/his$_6$-Ku80 was then diluted into the running buffer at final concentrations of 1, 5, 10, 25, 50, or 100 nM; and the solutions were injected onto the DNA surface at a flow rate of 90 μL/min. The second lowest and second highest concentrations were injected in duplicate with each kinetic run. Ku was allowed to first pass through a control cell with a naked streptavidin surface, followed by the experimental cell immobilized with the desired DNA−substrate. The association phase lasted 45 s with a dissociation phase of 1800 s or longer in which only running buffer was flowed over the surface. The chip was regenerated with a 1 min injection of 0.005% SDS at 30 μL/min. Kinetic data were obtained by fitting the sensograms to a 1:1 Langmiur binding model using the Biacore BiaEvaluation software (version 4.1). Apparent association, K_A,

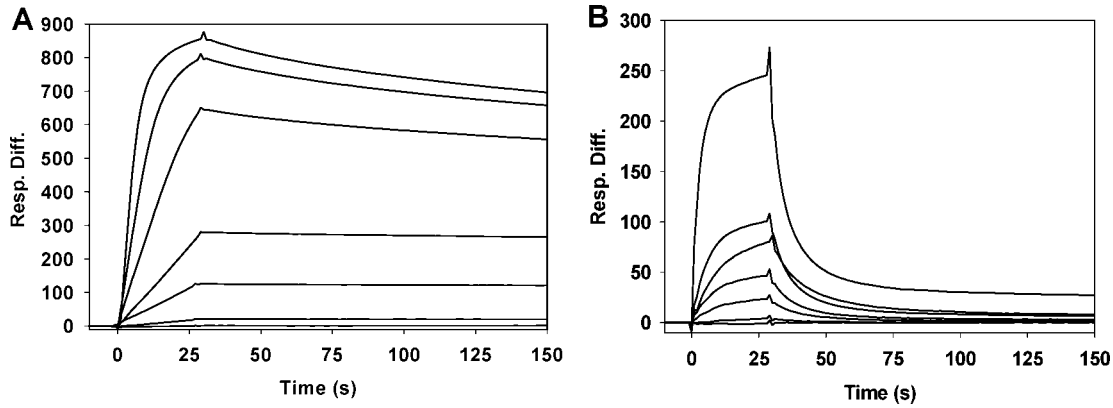

Figure 1. Effects of increasing Ku concentration, 0, 1, 5, 10, 25, 50, and 100 nM, on the rates of formation and dissociation of complexes formed with (A) duplex **1** and (B) duplex **3** as measured by surface plasmon resonance.

and dissociation, K_D, constants were then calculated from the observed rates of association, k_a, and dissociation, k_d.

Excision Assay in Whole-Cell Extract. Excision reactions were carried out as previously described (*1, 17*) with minor modifications. The reactions were performed in silanized Eppendorf tubes in 25 μL of a buffer containing 25 mM HEPES, pH 7.9, 4.4 mM magnesium chloride, 0.1 mM EDTA, 1 mM dithiothreitol, 70 mM potassium chloride, 4 mM ATP, 200 μg/mL bovine serum albumin, 2.5% glycerol, 40 ng of pGEM3Z plasmid DNA, and 5−10 μL (75−150 μg) of HeLa whole-cell extract or 2.5 μL (~50 μg) of AA8 or XR-V15B extract. Where indicated, recombinant Ku protein was added to a final concentration of 16 nM. The solution was held on ice for 10 min. The reactions were then initiated by addition of 10 fmol of ^{32}P-labeled substrate followed by incubation at 30 °C for 1 h. The reactions were stopped by incubating with 10 μg of proteinase K in the presence of 0.3% SDS for 15 min at 37 °C, diluted with water to a volume of 200 μL, and then extracted once with phenol/chloroform/isoamyl alcohol (25:24:1 v/v) using phase lock gel tubes (Eppendorf) followed by extraction with chloroform/isoamyl alcohol (24:1). The DNA was precipitated by addition of 2.5 volumes of absolute ethanol, 0.12 M sodium acetate, and 20 μg of oyster glycogen in a silanized Eppendorf tube. The precipitate was washed with 70% ethanol and dissolved in 10 μL of loading buffer. Samples were electrophoresced on a prerun (1.5 h) 20 cm × 45 cm × 0.4 mm 10% denaturing polyacrylamide sequencing gel at 1800 V until the bromophenol blue dye was 12 cm from the bottom of the gel. The gel was fixed in a solution containing 5% methanol, 5% acetic acid, and 90% water for 5 min; dried on a gel dryer; and exposed to a phosphorimager screen overnight. The intensity of the excision products was quantified and normalized to the total signal in the lane using *Image Quant 5.2* software. Quantification of the level of excision products was done on samples in which saturation of the signal had not been reached.

RESULTS AND DISCUSSION

Interaction of Methylphosphonate-Modified Oligonucleotide Duplexes with Ku70/80. The ends of linear DNA duplexes are potential binding sites for DNA end-binding proteins such as Ku. A recent crystal structure of the complex formed between Ku and the end of a 14-bp DNA duplex (*19*) showed that a limited number of contacts are made between the protein and the sugar−phosphate backbone of the duplex, whereas no contacts were observed between either subunit of the protein and the bases of the duplex. Of these, four ionic contacts are made between arginine residues 258, 403, and 404 of Ku70 and the first, second, and third internucleotide phosphates from the 3′-end of the duplex. The third, fourth, and fifth internucleotide phosphates from the 5′-end of the duplex make nonionic contacts with serine 78, asparagine 275, and glutamine 278, respectively, of Ku70 and the fourth internucleotide phosphate from the 5′-end makes an ionic contact with arginine 431 of Ku80. It appeared likely that disruption of these contacts, especially the ionic contacts, could attenuate binding of Ku to DNA. To test this hypothesis, we prepared oligonucleotide duplexes in which the negatively charged internucleotide phosphate linkages at the 3′- or 5′-ends of the duplex were replaced with nonionic methylphosphonate groups and examined the interactions of these methylphosphonate-modified duplexes with purified recombinant Ku using surface plasmon resonance (SPR). Because methylphosphonate linkages are completely resistant to hydrolysis by exo- and endonucleases, their presence at the ends of the duplex would also be expected to protect the duplex from exonucleolytic digestion when incubated in cellular extracts.

We prepared a series of methylphosphonate-modified oligodeoxyribonucleotide duplexes, whose sequences are shown in Table 1. Duplexes **1**−**3** are 22 bp in length, a size that is sufficient to accommodate a single Ku heterodimer (*20, 21*). One end of each duplex contains a 5′-biotin moiety. Duplex **2** has a tract of five contiguous methylphosphonate linkages one nucleotide in from the 5′-teminus of the nonbiotinylated end, and duplex **3** has six contiguous methylphosphonate linkages starting at the 3′-terminus of the nonbiotinylated end. Introduction of methylphosphonate linkages on one strand at the ends of the duplex results in a small decrease (~5 °C) in the thermal stability of the duplex as measured by UV melting experiments (data not shown).

The effects of methylphosphonate modification on the interactions of Ku with the linear DNA duplexes were determined using surface plasmon resonance to measure the kinetics of binding between Ku and the 22-bp duplexes, **1**−**3**. Streptavidin-coated SPR sensor chips were conjugated with the biotin-modified duplexes. The rate of association was determined by flowing increasing concentrations of Ku over the chip and measuring the response relative to a control channel that lacked the duplex. The rate of dissociation was then measured by flowing buffer that lacked Ku over the chip. Sensograms for unmodified duplex **1** and modified duplex **3** obtained at different concentrations of Ku are shown in Figure 1. Because these duplexes can only accommodate a single Ku heterodimer, rate constants for the association and dissociation steps were determined by fitting the data from the sensograms to a 1:1 Langmiur binding model (*21, 22*). The results are presented in Table 2.

Ku rapidly associates with unmodified duplex **1**, and the resulting complex shows a relatively slow rate of dissociation. The apparent

Table 2. Ku Binding Parameters Derived from SPR Experiments

duplex	k_a (M^{-1} s^{-1})	k_d (s^{-1})	K_D (nM)	K_A (M^{-1})	χ^2
1	2.3×10^6	1.5×10^{-3}	0.65	1538×10^6	564
2	1.4×10^6	4.3×10^{-3}	3.1	323×10^6	346
3	0.11×10^6	20×10^{-3}	182	5×10^6	50

dissociation constant, K_D, of the complex, 0.65 nM, calculated from these measured rate constants is similar to that previously reported for the complex formed between Ku and a 22-bp DNA duplex, 0.16 nM (*21*). Introduction of methylphosphonate linkages at the 5′-end of duplex **2** decreases the association rate by a factor of 1.6 and increases the dissociation rate by a factor of 2.9. The calculated K_D consequently increases by a factor of 4.8. A more significant effect is seen when methylphosphonate linkages are introduced at the 3′-end of duplex **3**. In this case, the association rate decreases by a factor of 20.9 while the dissociation rate increases by a factor of 13.3 resulting in a K_D that is 280 times greater than that of the complex formed by Ku and unmodified duplex **1**.

As described above, the crystal structure of a Ku/DNA duplex identifies contacts between amino acid residues of Ku70 and the phosphodiester linkages at positions 3, 4, and 5 of the strand at the 5′-end and positions 1, 2, and 3 of the strand at the 3′-end. Because methylphosphonate internucleotide linkages lack the negative charge found in natural phosphodiester linkages, they cannot bind through ionic interactions with positively charged side chains of amino acids such as arginine. In addition, the methyl group of the methylphosphonate linkage, whose size is slightly greater than that of the nonbridging phosphodiester oxygen it replaces, could provide steric hindrance to side-chain binding and/or interfere with hydrogen bonding interactions. Replacement of the phosphodiester groups at the end of the duplex with methylphosphonate linkages could therefore interfere with the initial interactions necessary for Ku to gain access to the DNA end and thus reduce overall binding affinity.

Placement of methylphosphonate linkages on the 3′- or 5′-end of the duplex affects Ku binding in different ways. The presence of 3′-methylphosphonate linkages, as in duplex **3**, results in an almost 300-fold decrease in the apparent binding affinity of the methylphosphonate-modified duplex compared to that of unmodified duplex **1**. On the other hand, placing the methylphosphonate linkages on the 5′-end of the duplex, as in duplex **2**, results in only a 4.8-fold decrease in binding affinity. This difference may reflect the greater number of ionic contacts, four, that are made between arginines 258, 403, and 404 of the 70S subunit and the phosphates at the 3′-end of the duplex versus the single ionic contact between arginine 431 of the 80S subunit and the phosphate at the 5′-end of the duplex. When methylphosphonate linkages are placed on both the 3′- and 5′-ends of the duplex, the binding affinity (K_D 69 nM) is approximately 2.6 times higher than that seen for duplex **3** (data not shown). Possibly, the presence of the methylphosphonate linkages on both strands of the duplex causes fraying or distortion of the ends, which enables Ku to bind.

Effects of Terminal Modifications on NER-Mediated Excision. Linear DNA duplexes that contain a platinum(II) 1,3, -GNG- type intrastrand cross-link are excellent substrates for nucleotide excision repair-mediated processing in HeLa cell extracts (*2*). We examined the ability of HeLa whole cell extracts to process platinum lesions in 149-bp duplexes that terminated with phosphodiester linkages (duplex **4**) or with methylphosphonate linkages on either the 5′- (duplex **5**) or 3′- (duplex **6**) ends of the duplex. The platinated -GTG- lesion was located on one strand in the middle of the duplex and the duplex carried a ^{32}P label, which was positioned on the platinated strand at the junction of the **C** and **X** duplexes. These labeled, 149-bp duplexes were prepared by ligating shorter, component duplexes using T_4 DNA ligase and purified by electrophoresis on denaturing polyacrylamide gels.

As shown in Figure 2A, lane 1, incubation of unmodified duplex **4** with the HeLa extract produced a series of oligonucleotides 26−30 nucleotides in length. These oligonucleotides result from dual incisions made by the NER endonucleases XPF and XPG on the 5′- and 3′-sides, respectively, of the strand carrying the platinum intrastrand cross-link. Identical dual incisions were observed when methylphosphonate-derivatized duplexes **5**, lane 2, or **6**, lane 3, were incubated with the HeLa whole-cell extract, although the intensities of the excised oligonucleotides varied significantly from those derived from duplex **4**.

The excision experiments for each duplex were run in triplicate and the intensities of the excision products relative to the total amount of duplex loaded on the gel were quantified by phosphorimaging. It should be noted that excision efficiency is dependent upon the amount of extract used and, equally important, upon the activity of the extract. We have found, not unexpectedly, that the inherent repair activity of a particular extract varies from preparation to preparation. For this reason, we have used the same extract preparation for a single set of experiments and within that set have compared the excision efficiencies of the modified duplexes to that of an unmodified control duplex. This procedure controls for the inherent differences in repair activity when different preparations of extract are used.

As shown in Figure 2B, a significant increase, approximately 60%, in the amount of excision products was observed for 3′-methylphosphonate-derivatized duplex **6** relative to unmodified duplex **4**. This result is consistent with the reduced binding of Ku to the ends of this modified duplex. In contrast, the duplex containing 5′-methylphosphonates, **5**, did not show an increased level of excision products. This result is not entirely unexpected if one considers the amount of Ku protein present in the extracts. On the basis of the amount of Ku found in HeLa cells (*23*), we estimate that the concentration of Ku in the excision reaction is approximately 70 nM, which is 175-fold greater than the duplex concentration (0.4 nM). In the case of duplex **6**, the Ku concentration is less than the expected dissociation constant (182 nM) of the Ku/**6** complex calculated from the SPR data. Consequently, Ku would not be expected to bind to duplex **6** to any significant extent under the conditions of the excision experiment. On the other hand, the concentration of Ku is significantly higher than the expected K_D (3.1 nM) of the Ku/**5** complex. Under these conditions, Ku would be expected to be able to bind and interfere with excision.

The binding experiments described in the previous section showed that 3′-terminal methylphosphonate linkages significantly impair the ability of Ku to bind to the ends of linear DNA duplexes. These results together with the results from excision experiments with 3′-methylphosphonate-derivatized duplex **6** suggested that interference with Ku binding to linear substrates might allow more efficient excision of the platinated oligonucleotide. To test this, we prepared a biotinylated derivative of duplex **4**, **biotin-4**, in which biotins were attached to both 5′-ends of the duplex. Conjugation of biotinylated ends of the duplex with streptavidin creates a linear duplex that can no longer bind Ku (*14*). As shown in Figure 2C, incubation of duplex **4**, lane 1, or duplex **biotin-4**, lane 2, in the HeLa whole-cell extract in the presence of streptavidin produced the expected excision products. However, in agreement with the results obtained with duplex **6**, the excision reaction proceeded approximately 2.3 times more efficiently when access to the

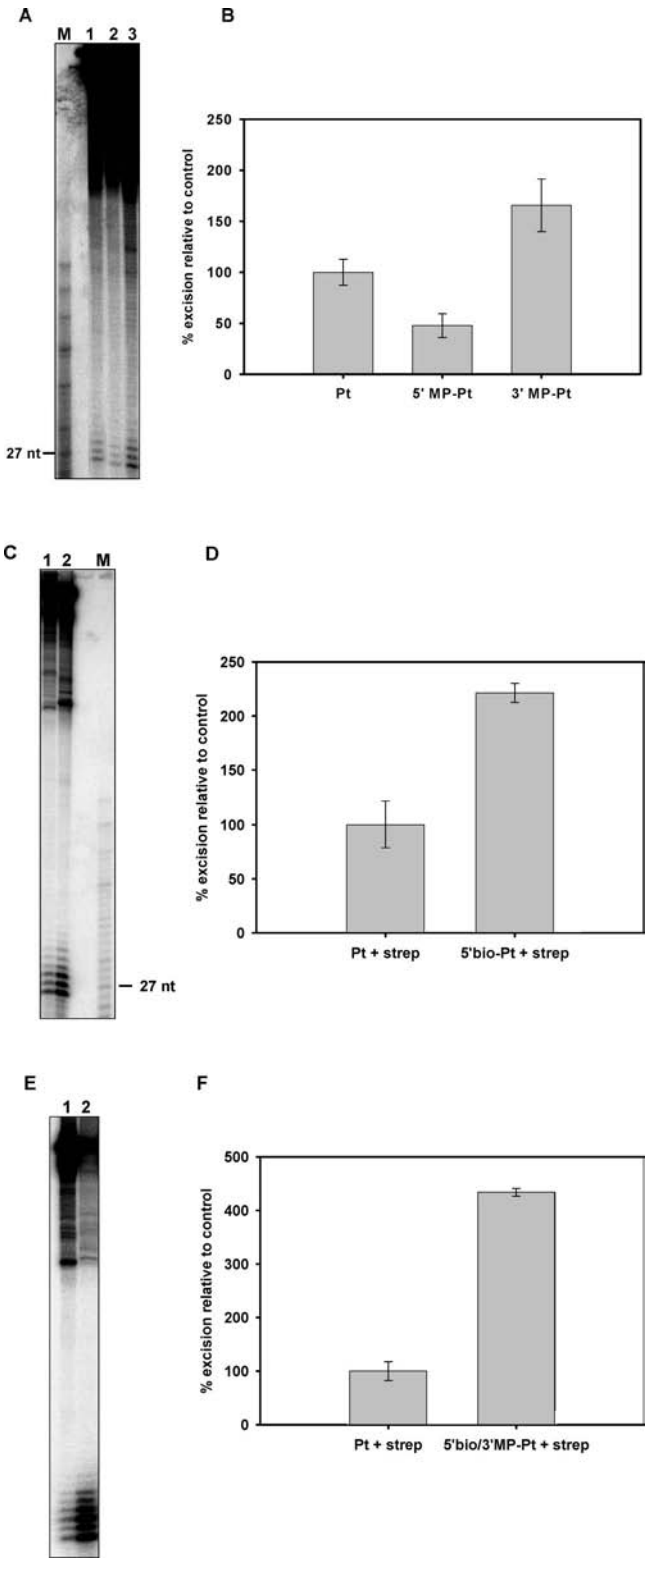

Figure 2. Effect of end-modification on NER-mediated excision. Duplexes were each incubated with HeLa whole-cell extract for 60 min at 30 °C and the products analyzed by denaturing PAGE as described in the Experimental Procedures. Molecular weight markers are shown in lane M. The excision products are 26−30 nucleotides in length. Excision products were quantified from three independent experiments and were plotted as the percentage of the excision products derived from an unmodified control duplex. Error bars represent the standard error from the mean. (A,B) NER-mediated excision on duplex **4** (lane 1) (Pt), **5** (lane 2) (5′-MP-Pt), or **6** (lane 3) (3′-MP-Pt). (C,D) NER-mediated excision on duplex **4** (lane 1) (Pt + strep) or the 5′-biotinylated derivative of duplex **4** (**biotin-4**, lane 2) (5′-bio-Pt + strep) in the presence of streptavidin. (E,F) NER-mediated excision on duplex **4** (lane 1) (Pt + strep) or duplex **biotin-6** (lane 2) (5′-bio/3′-MP-Pt + strep) in the presence of streptavidin.

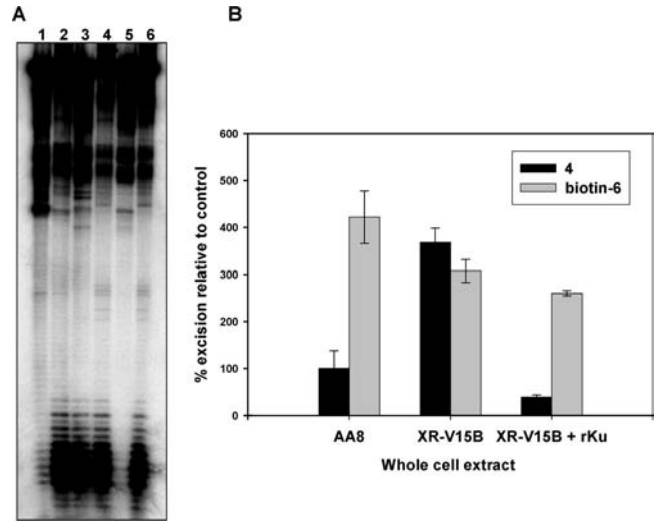

Figure 3. Blocking the ends of linear duplexes increases NER-mediated excision activity in CHO extracts through inhibition of Ku binding. (A) Duplex **4** (lanes 1, 3, and 5) or duplex **biotin-6** (lanes 2, 4, and 6) were each incubated in the presence of streptavidin in whole-cell extracts derived from CHO wild-type AA8 (lanes 1 and 2) or Ku80-deficient XR-V15B (lanes 3 and 4) cells, or in XR-V15B extract that had been supplemented with recombinant Ku (rKu) protein (lanes 5 and 6). (B) Quantification of excision products from three or four independent experiments. The levels of excision products were normalized to the total counts in the lane and plotted as the percentage of the excision products derived from control duplex **4** when incubated in wild-type AA8 extract. Error bars represent the standard error from the mean.

exposed DNA termini was prevented by the conjugating streptavidin to **biotin-4** (Figure 2D).

An even greater increase in NER excision efficiency was seen when both 5′-ends of duplex **6**, which contains six 3′-methylphosphonate linkages, were derivatized with biotin (**biotin-6**). As shown in Figure 2E, excision products identical to those of unmodified duplex **4**, lane 1, are produced when **biotin-6**, lane 2, is incubated with HeLa whole-cell extract in the presence of streptavidin. However, the efficiency of excision is 4.4 times greater for **biotin-6** compared to that of duplex **4** (see Figure 2F). It appears that the combination of the two modifications, 5′-biotin/streptavidin and 3′-methylphosphonate linkages, acts in a synergistic manner to enhance overall NER excision without affecting the nature of the products that are formed. Thus, on average, the incision efficiency increased from ∼4% for the unmodified duplex, **4**, to ∼16% for the modified duplex, **biotin-6**. This synergy may result from the effects of both modifications on Ku binding (and possibly other end binding proteins in the extract) and the ability of the 3′-methylphosphonate linkages to protect the substrate from degradation by 3′-exonucleases.

Further evidence that Ku is responsible for reduced NER excision activity was obtained from the following experiments. Unmodified duplex **4** or 5′-biotinylated duplex **6** (**biotin-6**) were each incubated in whole-cell extracts prepared from a wild-type Chinese hamster ovary (CHO) cell line, AA8, or in extracts derived from a CHO cell line deficient in Ku80, XR-V15B. As shown in Figure 3A and B, the efficiency of excision for duplex **biotin-6**, lane 2, was approximately 4.2 times that of unmodified duplex **4**, lane 1, a result that is comparable to that seen in the HeLa whole-cell extract. In contrast to this result, similar excision efficiencies were seen when duplex **4**, lane 3, or duplex **biotin-6**, lane 4, were incubated in an extract prepared from a Ku80-deficient cell line, XR-V15B. This mutant contains an internal deletion of amino acids 372−417 which results in loss of function. When this mutant extract is supplemented with

recombinant Ku, the difference in excision efficiencies between duplex **4**, lane 5, and duplex **biotin-6**, lane 6, is restored to that seen in the wild-type cell extract. These results further demonstrate that Ku inhibits the NER-mediated excision reaction and that 5′-biotin-streptavidin/3′-methylphosphonate modifications protect the substrate from this inhibition by blocking Ku end-binding.

CONCLUSIONS

Synthetic linear DNA duplexes that contain site-specific lesions are useful substrates for studying DNA repair processes in whole-cell extracts. The ends of these synthetic repair substrates, however, can serve as recognition sites for end-binding and end-modifying proteins. Because end-binding by these proteins may affect lesion recognition or processing in whole-cell extracts, use of synthetic repair substrates may be accompanied by reduced efficiency or low signal-to-noise. Our results show that Ku uses the phosphodiester linkages at the 3′-termini of linear DNA duplexes as an important determinant in DNA end-binding and that replacement of these linkages with nonionic methylphosphonate linkages significantly reduced the ability of Ku to bind to modified duplexes. Conjugation of streptavidin to the 5′-biotinylated ends of the repair substrate sterically blocks binding by Ku and, presumably, other end-binding proteins. Incorporation of both these modifications into a linear duplex repair substrate significantly increased the efficiency of NER-mediated excision in whole-cell extracts. This approach may find general utility in the study of DNA repair processes in extract-based assays.

ACKNOWLEDGMENT

The authors wish to thank Drs. Joyce Reardon and Aziz Sancar for providing guidance in preparing HeLa whole-cell extracts; Ms. Maggie Wear for assisting in the preparation of the methylphosphonate-modified oligonucleotides; and Dr. Terry Brown for allowing us to use his Typhoon phosphorimager. This research was supported by grants form the National Cancer Institute, CA CA082785, (P.S.M.) and the National Institutes of Health, GM070639 (L.A.H.). T.M.M. was supported by a Ruth L. Kirchstein National Research Service Award (CA108326).

Protein Conjugation with Amphiphilic Block Copolymers for Enhanced Cellular Delivery

Xiang Yi,[†] Elena Batrakova,[†] William A. Banks,[‡] Serguei Vinogradov,[†] and Alexander V. Kabanov*[,†,§]

Department of Pharmaceutical Sciences and Center for Drug Delivery and Nanomedicine, College of Pharmacy, University of Nebraska Medical Center (UNMC), Omaha, Nebraska 68198-5830, Geriatric Research Education and Clinical Center, Veterans Affairs Medical Center and Saint Louis School of Medicine, Department of Internal Medicine, Division of Geriatrics, St. Louis, Missouri 63106, and Faculty of Chemistry, M.V. Lomonosov Moscow State University, 119899 Moscow, Russia. Received November 30, 2007; Revised Manuscript Received March 18, 2008

Modification of a model protein, horseradish peroxidase (HRP), with amphiphilic block copolymer poly(ethylene oxide)-*b*-poly(propylene oxide)-*b*-poly(ethylene oxide) (Pluronic), was previously shown to enhance the transport of this protein across the blood−brain barrier *in vivo* and brain microvessel endothelial cells *in vitro*. This work develops procedures for synthesis and characterization of HRP with Pluronic copolymers, having different lengths of poly(ethylene oxide) (PEO) and poly(propylene oxide) (PPO) blocks. Four monoamine Pluronic derivatives (L81, P85, L121, P123) were synthesized and successfully conjugated to a model protein, HRP, *via* biodegradable or nondegradable linkers (dithiobis(succinimidyl propionate) (DSP), dimethyl 3,3′-dithiobispropionimidate (DTBP), and disuccinimidyl propionate (DSS)). The conjugation was confirmed by HRP amino group titration, matrix-assisted laser desorption/ionization-time of flight spectroscopy, and cation-exchange chromatography. HRP conjugates containing an average of one to two Pluronic moieties and retaining in most cases over 70% of the activity were synthesized. Increased cellular uptake of these conjugates was demonstrated using the Mardin-Derby canine kidney cell line and primary bovine brain microvessel endothelial cells. The optimal modifications included Pluronic L81 and P85. These copolymers have shorter PPO chains compared to Pluronic P123 and L121, which were less efficient. There was little if any dependence of the uptake on the length of the hydrophilic PEO block for the optimal modifications. The proposed modifications may be used to increase cellular uptake of other proteins.

INTRODUCTION

Use of proteins as therapeutic agents in many cases is hindered by an inability of protein molecules to cross cell membranes and physiological barriers, such as the blood−brain barrier (BBB) (*1*, *2*). To address this limitation, we have proposed to covalently modify proteins with amphiphilic groups, in particular, triblock copolymers, poly(ethylene oxide)-*b*-poly(propylene oxide)-*b*-poly(ethylene oxide) (PEO-PPO-PEO), also known as Pluronic or poloxamers (*3*). Using *in vitro* and *in vivo* models, we have shown that a model protein, horseradish peroxidase (HRP), modified with Pluronic P85 (P85) *via* a degradable disulfide linker can cross the BBB and accumulate in the brain (*4*). Pluronic P85 alone is readily transported into cells *via* caveolae-mediated endocytosis (paper in preparation). Evidently, it also can serve as a synthetic transduction modulator that facilitates cell transport of a protein as large as HRP. The transport efficiency of protein−Pluronic conjugates should strongly depend on the lengths of Pluronic hydrophobic (PPO) and hydrophilic (PEO) blocks (*5*) . Therefore, to develop optimal protein modifications one needs to establish robust procedures for (i) protein conjugation with the block copolymers with different lengths of PPO and PEO blocks and (ii) characterization of these conjugates. This work uses HRP as a model protein for conjugation with the block copolymers that differ in the (1) lengths of PPO block (L81 and P85 vs L121, and P123) and (2) overall hydrophobicity (L81 and L121 vs P85 and P123). The conjugates were synthesized by attaching one end of a Pluronic molecule to HRP amino groups via either degradable (disulfide) or nondegradable linkers. The products are characterized by amino group titration and matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) spectroscopy. The uptake of the conjugates in the Mardin-Derby canine kidney (MDCK) cell line and primary bovine brain microvessel endothelial cells (BBMEC) is characterized to establish the most promising modifications. On the basis of these studies, L81 and P85 were identified as the best copolymers to enhance cell uptake of HRP.

EXPERIMENTAL PROCEDURES

Materials and Devices. HRP type VI-A, MW 43 kDa, 4-methoxyltrityl chloride (MTr-Cl), 1,1′- carbonyldiimidazole (CDI), 1,2-ethylenediamine (EDA), 2,4,6-trinitrobenzenesulfonic acid (TNBS), ninhydrin, hydrindantin, 2-methyoxy ethanol, trifluoroacetic acid (TFA), triethylamine, anhydrous acetonitrile, anhydrous pyridine, methanol, dichloromethane, toluene, acetone, ethanol, and dimethylformamide were purchased from Sigma-Aldrich Co. (St. Louis, MO). Pluronic block copolymers, L81 (lot no. WSOO-25087), P85 (lot no. WPOP-587A), L121 (lot no. WPAC-550B), and P123 (lot no. WPIV-612B) were kindly provided by BASF Corp. (Paris-pany, NJ). Their characteristics are summarized in Table 1. Dithiobis(succinimidyl propionate) (DSP), dimethyl 3,3′-dithiobispropionimidate (DTBP), and disuccinimidyl propionate (DSS) were from Pierce Biotech Co. (Rockford, IL). Sephadex LH-20 gel and Illustra

P123	$EO_{19}-PO_{69}-EO_{19}$	5750	8	0.0025

[a] Hydrophilic−lipophilic balance (HLB). [b] Critical micelle concentration (CMC) in aqueous solution values at 37 °C as determined using pyrene probe.

NAP-25 columns were from Amersham Biosciences (Pittsburgh, PA). Toyopearl MD-G SP column (10 mm ID × 6.8 cm) was from Tosoh Co. (Japan). Amicon ultra-15 centrifugal filter, MWCO 30K, membrane NMWL was from Millipore Co. (Billerica, MA). Spectro/Por membrane (MWCO 2000) was from Spectrum Laboratory Inc. (New Brunswick, NJ). Flexible thin-layer chromatography (TLC) plates were from Whatman Ltd. (Mobile, AL).

Monoamine P85 Derivative. To produce monoamine P85, first, the hydroxyl group at one end of the P85 chain was protected by MTr-Cl. Second, the hydroxyl group at the other end was activated using CDI and then reacted with EDA (Scheme 1) (*6*). The monoamine P85 was obtained after deprotecting the hydroxyl group in the presence of TFA. In detail, 3 g of P85 (MW 4600) was dried overnight *in vacuo* at 50 °C and then dissolved in 15 mL of anhydrous pyridine. One molar equivalent of MTr-Cl (200 mg) was dissolved in 10 mL of anhydrous pyridine and added to the P85 solution. The reaction was allowed to proceed for 3 h at 25 °C and then stopped by adding 1 mL of methanol. The pyridine was removed *in vacuo* by coevaporation with 3 × 15 mL of toluene. The mono-MTr-P85 was isolated from nonreacted copolymer and bis-MTr-P85 by adsorption chromatography on Silicagel column (3 × 20 cm) using stepwise gradient elution of 200 mL of dichloromethane containing 2%, 5%, and 10% methanol. Fractions containing bis-substituted MTr-Pluronic eluted first ($R_f = 0.8$), followed by monosubstituted MTr-Pluronic ($R_f = 0.6$) and free Pluronic ($R_f = 0.4$). The products were then analyzed by TLC in dichloromethane/MeOH, 9:1, and detected in TFA vapors (a test for MTr-group). The collected mono-MTr-P85 was dried by coevaporation with 2 × 15 mL of anhydrous acetonitrile *in vacuo* and then reacted with 5-fold molar excess of CDI (530 mg) in 10 mL of anhydrous acetonitrile. After incubation for 2 h at 25 °C, the reaction mixture was treated with 0.2 mL of water for 20 min to neutralize the nonreacted CDI, and then added to an excess of EDA in 20 mL of ethanol upon stirring. The mixture was kept overnight at 25 °C and then diluted by 50 mL of water and dialyzed for 18 h using a membrane with MWCO 2000 kDa against 20% aqueous ethanol (2 × 2 L) to remove small molecular mass reagents including EDA. After the dialysis, the polymer was concentrated *in vacuo*, coevaporated twice with methanol (10 mL), and redissolved in 50 mL of 2% TFA in dichloromethane. After incubation for 1 h at 25 °C, the bright yellow solution was concentrated *in vacuo* and neutralized by 5 mL of 10% triethylamine in methanol. The resulting monoamine P85 was isolated by gel filtration on a Sephadex LH-20 column (2.5 × 30 cm) and analyzed by TLC in dichloromethane/MeOH, 9:1. The monoamine P85 develops a blue color after spraying with 1% ninhydrine solution in ethanol (a test for an amino group).

Monoamine L81, L121, and P123 Derivatives. The monoamine derivatives of L81, L121, and P123 were synthesized using a modified procedure. In particular, to remove excess of EDA, modified L121 and P123 were dialyzed against 30−40% aqueous ethanol using a membrane with MWCO 2000 kDa. L81 was dialyzed against 30% aqueous ethanol using a membrane with MWCO 1000 kDa.

Amino Group Determination by Ninhydrin Assay. The stock solution of ninhydrin was prepared by adding 1.03 g of ninhydrin, 0.18 g of hydrindantin, 12.8 mL of 4 N sodium acetate buffer (pH5.5) to 38.5 mL of methylcelosolve. For the standard calibration curve, 0.5 mL of glycine (10^{-4} to 10^{-5} M) in acetate buffer (pH 5.5) was mixed with 0.25 mL the ninhydrin solution. The mixture was heated at 100 °C for 15 min and supplemented with 0.75 mL 50% aqueous ethanol. The absorbance was measured at 570 nm.

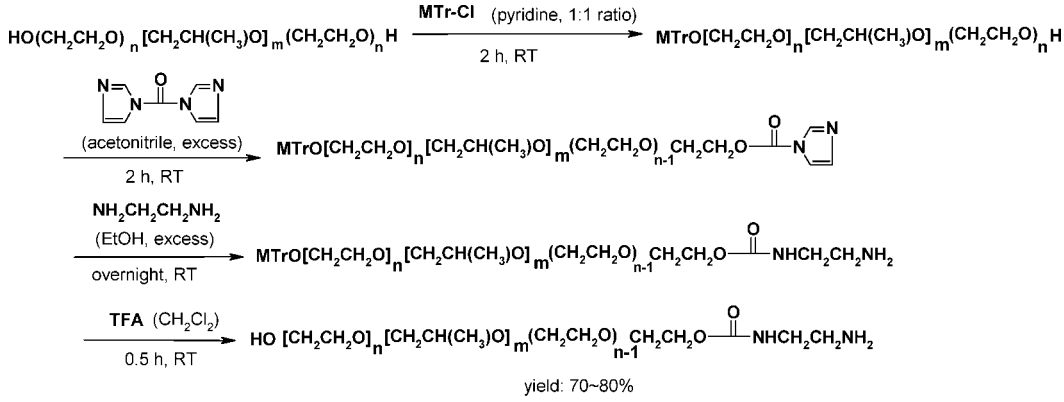
Conjugation of HRP with Monoamine Pluronic. Monoamine P85 (200 mg) in 0.5 mL of methanol was mixed with DSP (105 mg, 6-fold molar excess) solution in 0.5 mL of DMF stored over molecular sieves (4 Å). The mixture was supplemented with 0.1 mL sodium borate buffer (0.1 M, pH 8) and incubated for 30 min at 25 °C. Excess of DSP was removed by gel filtration on a Sephadex LH-20 column (2.5 × 30 cm) in methanol, and the solvent was removed *in vacuo*. Activated copolymer was dissolved in 1 mL 20% aqueous ethanol and mixed with HRP (16 mg) in 0.5 mL of 0.1 M sodium borate (pH 8). The homogeneous reaction mixture was incubated overnight at 4 °C. The activated monoamine L81, L121, or P123 (200 mg) was dissolved in 1 mL of 30−40% aqueous ethanol and reacted with HRP in 0.5 mL of 0.1 M sodium borate (pH 8). Modifications of HRP with monoamine P85 *via* DSS and DTBP were carried out using a similar procedure. DTBP was directly dissolved in 0.5 mL of sodium borate buffer (0.1 M, pH 8) and reacted with monoamine P85 in 0.5 mL of 20% aqueous ethanol.

Purification of HRP−Pluronic Conjugates. The conjugates were precipitated in cold acetone to remove the excess of nonreacted copolymers. Briefly, about 1 mL of the above reaction mixtures was added dropwise to 25 mL of cold acetone upon stirring. After incubating for 1 h at 4 °C, the brown precipitate containing HRP conjugates was collected at 3000 rpm for 10 min at 4 °C, washed by cold ethanol (2 × 10 mL), and dried *in vacuo*. Alternatively, the conjugates were washed with 20% aqueous ethanol and separated using Amicon ultra-15 centrifuge filter (MWCO 30 kDa) at 3800 rpm at 4 °C for 15 min. The extent of separation of nonreacted copolymers was assayed by TLC on silica gel plates in dichloromethane/methanol, 9:1. In this system, copolymers migrated ($R_f = 0.4$), while the conjugate was immobile. If free copolymer was detected, the purification procedure was repeated. To separate unmodified HRP, the conjugates were further purified on Toyopearl SP cation exchange column (1 cm × 6.8 cm) equilibrated with 10 mM CH_3COONa/10 mM NaCl/5% EtOH, pH 4.1, in the gradient of 0.2 M NaCl in 10 mM CH_3COONa/5% EtOH, pH 4.1. The final conjugates were desalted in Amicon ultra-15 centrifuge tube (MWCO 30 kDa) and freeze-dried.

MALDI-TOF spectra. Mass values of HRP−Pluronic conjugates were determined using a Voyager-DE Pro STR MALDI-TOF mass spectrometer (Applied Biosystems/MDS SCIEX, Foster City, CA). Samples were prepared by (1) plate coating with 0.5 μL saturated sinapinic acid in 50% acetonitrile with 0.1% TFA; (2) depositing 0.5 μL solution of HRP−Pluronic conjugates in water (10^{-5} M); and, finally, (3) coating with 0.5 μL saturated sinapinic acid in 50% acetonitrile with 0.1% TFA. External calibration was performed using bovine serum albumin (Applied Biosystems, Foster City, CA). Mass spectra were recorded with the laser intensity set between 5000 to 10 000 au Typically, three acquisitions (100 shots each) were pulled together for each sample.

Enzymatic Activity of HRP−Pluronic Conjugates. *o*-Phenylenediamine was used to measure the HRP enzymatic activity as described earlier (*7*). Briefly, 1 to 20 ng/mL HRP−Pluronic conjugates were mixed with 20 μL of a fresh *o*-phenylenediamine solution (0.05 mg/mL) in citrate buffer (0.1 M, pH 5.0)

Scheme 1. Synthesis of Monoamine Pluronic



containing 0.01% Triton X-100, 0.1 g/mL BSA, and 0.2% H_2O_2. The reaction mixture was added to 96-well plates to a final volume of 200 μL in citrate buffer (0.1 M, pH 5.0). After incubating at 37 °C for 5 min, the reaction was stopped by adding 20 μL of a 0.5% Na_2SO_3 solution in 2 N H_2SO_4, and the absorbance was measured at 490 nm in the microplate reader Multiskan MCC/340 (Fisher Scientific, Pittsburgh, PA).

Degree of Modification by TNBS Assay. Ten microliter aliquots of HRP−Pluronic conjugate solutions (protein concentration 0.1−0.6 mg/mL) were mixed with 10 μL of TNBS solution (1.7 mM) in 80 μL of sodium borate buffer (0.1 M, pH 9.5) and incubated at 37 °C for 2 h. The absorbance was measured at 405 nm using the microplate reader. The protein content was measured using a BCA kit from Pierce (Rockford, IL). The degree of modification (average number of amino groups modified) was calculated according to the equation

$$S(\text{modification degree}) = 7 \times \frac{A_{\text{native}}/C_{\text{native}} - A_{\text{modified}}/C_{\text{modified}}}{A_{\text{native}}/C_{\text{native}}}$$

where A_{native} and A_{modified} were the absorbences and C_{native} and C_{modified} the concentrations of native and modified HRP, respectively. The total number of primary amino groups including lysine residues and terminal amine group in HRP is 7.

Cells. MDCK cells (from ATCC, CCL-34) were seeded in 24-well plates at a density of 50 000 cells/well in Dulbecco's Modified Eagle Medium (DMEM) (Invitrogen, Carlsbad, California, cat no 41500−034) supplemented with 0.5% penicillin/streptomycin and 10% fetal bovine serum (Invitrogen, Carlsbad, California). The cells were cultured at 37 °C with 95% humidity and 5% CO_2, and grown for two days until 80−90% confluence. BBMEC were isolated from the gray matter of the bovine cerebral cortex by enzymatic digestion followed by subsequent centrifugations (*8*). Cells were seeded onto collagen-coated, fibronectin-treated 24-well plate at a density of 50 000 cells/well and grown to confluence (typically 10−12 days) in a culture media consisting of 45% minimum essential medium (MEM), 45% Ham's F-12 nutrient mix (Gibco, Life Tech., Grand Island, NY), 10 mM HEPES, pH 7.4, 13 mM sodium bicarbonate, heparin, gentamicin, amphotericin B (Sigma), and 10% horse serum.

Cellular Uptake. MDCK cell and BBMEC monolayers in 24-well plates were washed twice in assay buffer containing 122 mM NaCl, 25 mM $NaHCO_3$, 10 mM glucose, 3 mM KCl, 1.2 mM $MgSO_4$, 0.4 mM K_2HPO_4, 1.4 mM $CaCl_2$, and 10 mM HEPES. Cells were exposed to unmodified or modified HRP in assay buffer for various time intervals at 37 °C, then washed with cold phosphate-buffered saline five times and lysed in 1% Triton X-100. No cellular toxicity was observed during treatment. Aliquots of cell lysates (20 μL) were taken for HRP activity determination as described above. Separate calibration curves were used for unmodified or modified HRP. The amounts of cell-associated HRP were normalized for the cell protein as determined by Pierce BCA.

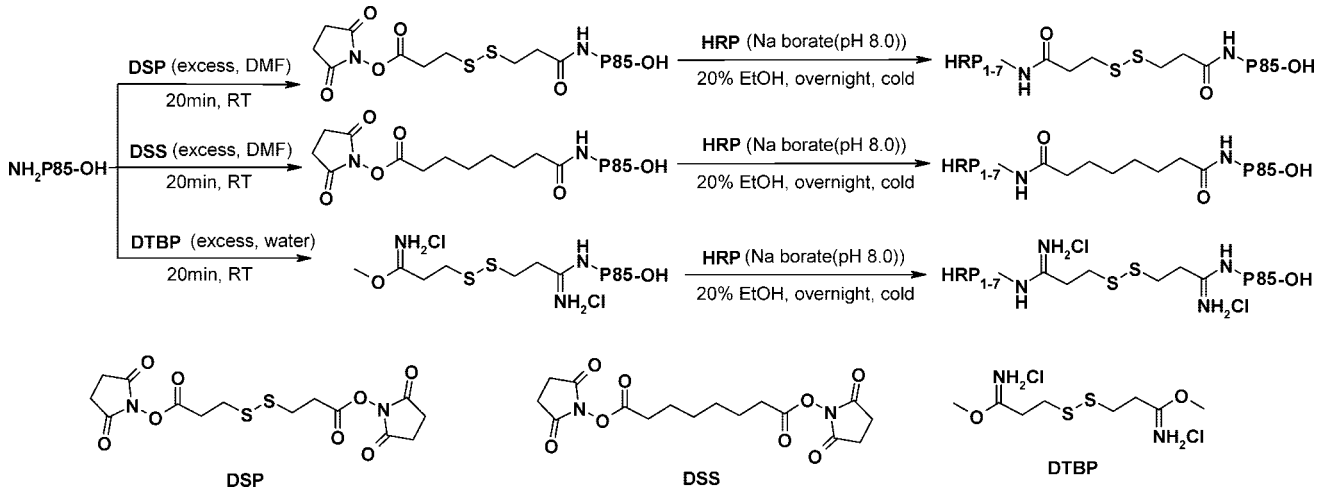
RESULTS AND DISCUSSION

Synthesis of Pluronic Monoamine Derivatives. A general procedure for introduction of amino group in Pluronic is presented in Scheme 1. Good separation of monosubstituted MTr-Pluronic from bis-substituted and free Pluronic was achieved using a silicagel column for each copolymer used (L81, P85, L121, and P123). The purity of the fractions was assessed by TLC. For all polymers, the monosubstituted MTr-Pluronic exhibited $R_f = 0.6$, the bis-substituted MTr-Pluronic $R_f = 0.8$, and free Pluronic $R_f = 0.4$. Fractions containing the monosubstituted MTr-Pluronic were collected, and these fractions did not contain bis-substituted MTr-Pluronic or free Pluronic. Subsequent transformation of the end-protected MTr-Pluronic to the amino derivatives using CDI and EDA proceeds in mild conditions and is well-established for conjugation of poly(ethylene glycol) to amino groups of peptides (*9*). The reaction yields were from 70% to 80% by weight. The modification degrees (number of amino groups per copolymer molecule) were 0.96 (L81), 0.74 (P85), 0.74 (L121), and 0.81 (P123) as determined by ninhydrin assay. No trace of EDA was detected by TLC. The NMR spectra, before and after modification, show no change in $-CH_2CH_2O-$ and $-CH_2CH(CH_3)O-$ signals, suggesting that the copolymer backbone remained intact (data not shown).

Synthesis and Purification of HRP−P85 Conjugates. Three types of homobifunctional cross-linking reagents, DSP, DSS, and DTBP, were used to conjugate HRP and monoamine P85 (Scheme 2). Two reagents, DSP and DTBP, contain disulfide bond and are degradable in the reducing environments, such as intracellular glutathione (*10*). In contrast, DSS produces a stable nondegradable link. The water-insoluble DSP and DSS were reacted with monoamine P85 derivatives in DMF/methanol, while DTBP was reacted in water. After purification, the activated P85 derivatives were conjugated to HRP in 20% aqueous ethanol. The resulting conjugates were purified, first, by acetone precipitation or filtration and, second, by cation exchange chromatography. In the case of DSP-activated P85 derivative, the reaction yield depended on pH, with pH 8.0 being optimal (Figure 1). Similar results were obtained for DSS-activated P85 (data not shown). However, DTBP-activated P85 was more stable at higher pH and, therefore, produced high yield of the protein conjugate at pH 8.0 and 9.0.

Table 2 summarizes the characteristics of the HRP−Pluronic conjugates obtained with different reagents and modification conditions. The residual enzymatic activity of HRP−P85

Scheme 2. Conjugation of HRP with Monoamine P85 through Biodegradable Linkers DSP, DTBP and Nondegradable Linker DSS



conjugates was relatively higher for DSP and DSS-linked conjugates (70% to 85% of initial HRP), but somewhat lower for DTBP-linked conjugates (56%). The average modifications degrees of HRP-P85 as determined by TNBS titration assay were from ca. 1 to 2. However, MALDI-TOF revealed that the conjugates contained a mixture of unmodified HRP and HRP−P85 conjugates with 1, 2, and 3 P85 chains attached (Figure 2a). The presence of the free P85 in these conjugates depended on the purification procedure. No free copolymer was detected for HRP−P85 precipitated by acetone, while the filtration could not separate the free copolymer completely.

Conjugation of HRP with Monoamine L81, L121, and P123. The reaction conditions were modified for conjugation of HRP with L81, L121, and P123, which are more hydrophobic compared to P85. In these cases, the DSP-activated copolymers were conjugated to the protein in aqueous ethanol (30% to 40%

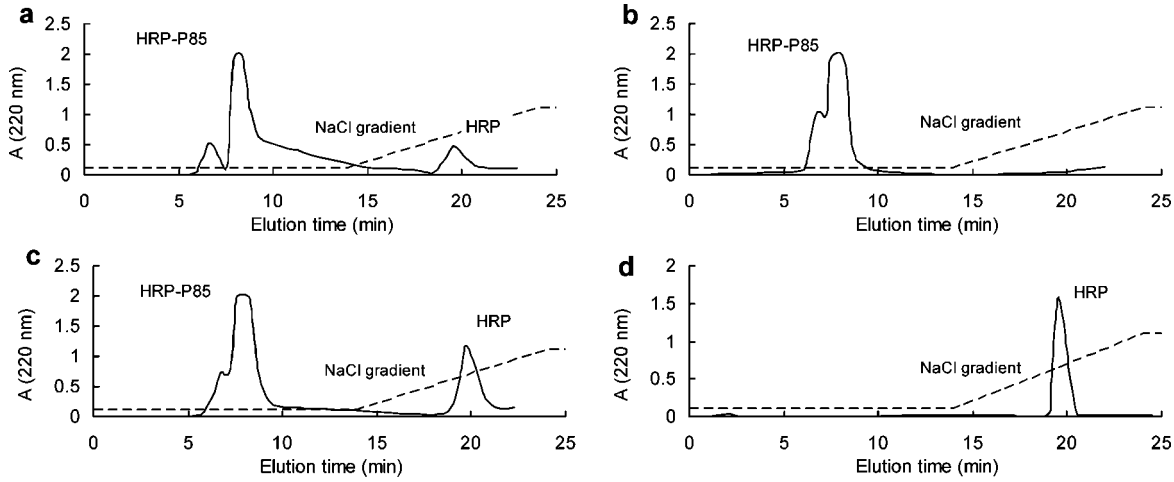


Figure 1. Chromatographic profiles of HRP−P85 conjugates obtained using DSP at different pH: (a) 7.4, (b) 8.0, (c) 9.0, and (d) unmodified HRP. Chromatography conditions: Toyopearl MD-G SP column (10 mm i.d. × 6.8 cm) in NaCl salt gradient (0.01−0.2 M) (pH 4.3, elution rate 1 mL/min, detection at 220 nm).

Table 2. Characteristics of HRP−Pluronic Conjugates

Pluronic	linker	Pluronic/HRP molar ratio during the reaction	reaction conditions time/ temperature/pH[a]	purification method[b]	modification degree[c]	residual activity[d]
P85	DSP	120	24 h/4 °C/pH8.0	F	1.3	85
P85	DSP	240	24 h/4 °C/pH8.0	A	1.39	ND
P85	DSP	240	36 h/4 °C/pH8.0	A	1.41	ND

[a] Last stage of conjugation of HRP with activated derivative. [b] The excess of Pluronic was removed by acetone precipitation (A) or filtration of the conjugate in the aqueous ethanol solution (F). [c] Number of copolymer chains per HRP as determined by TNBS titration of amino groups. [d] Residual activity was determined by *o*-phenylenediamine reaction and calculated on the basis of the percentage of the activity of the native HRP.

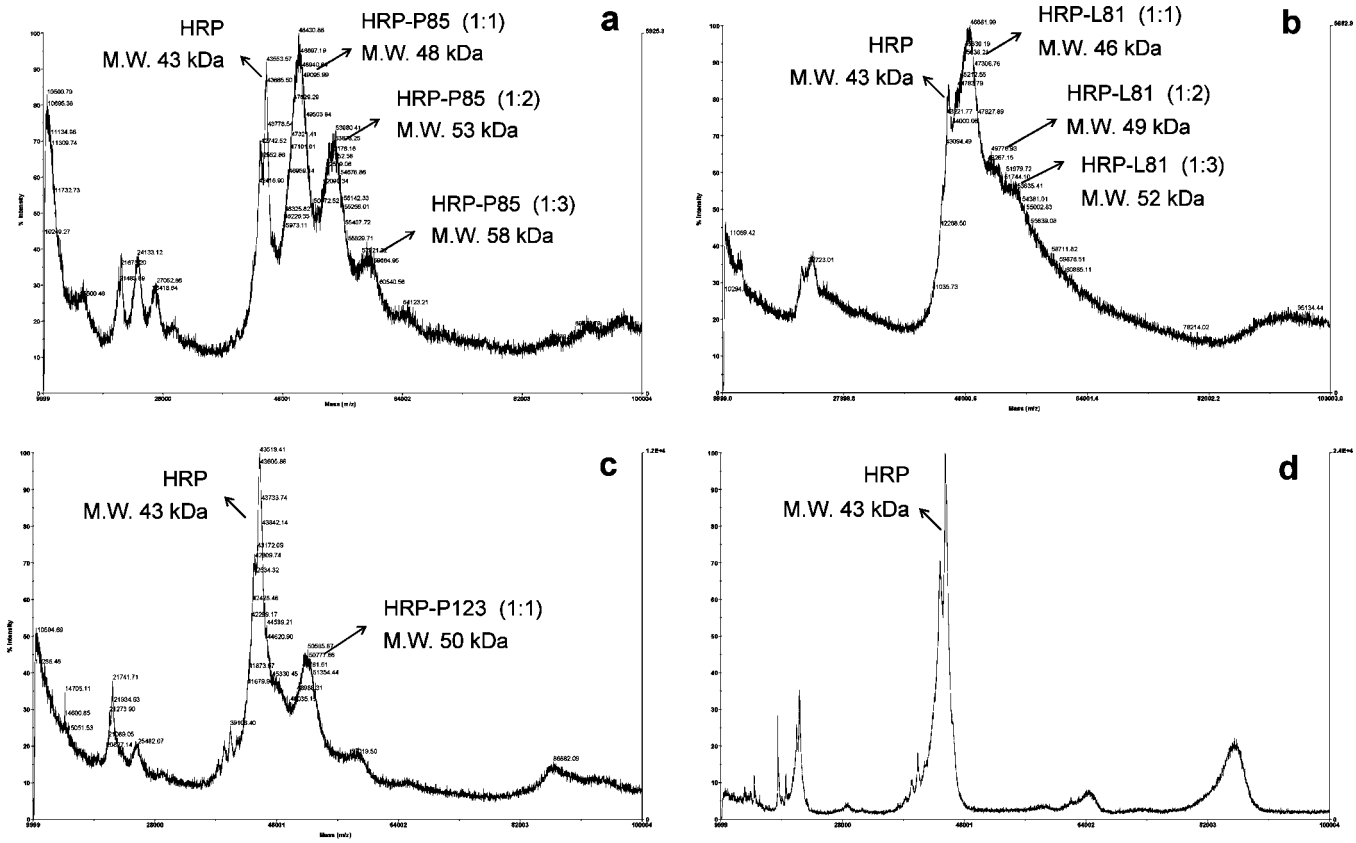

Figure 2. Mass spectra of HRP−Pluronic conjugates obtained by MALDI-TOF: (a) HRP−P85; (b) HRP−L81; (c) HRP−P123; and (d) unmodified HRP. (a) HRP−P85 MW 48 kDa (1:1), 53 kDa (1:2), and 58 kDa (1:3); (b) HRP−P81 MW 46 kDa (1:1), 49 kDa (1:2), and 52 kDa (1:3); (c) HRP−P123 MW 50 kDa (1:1); (d) HRP MW 43 kDa.

v/v) mixtures to decrease hydrophobic association between the PPO chains. Furthermore, especially in the case of the most hydrophobic L121, the modification degrees considerably increased when the conjugation was carried out at lower temperature and for longer exposure time (Table 2). The PPO segment exhibits a lower critical solution temperature (LCST), and therefore, the decrease of the temperature (4 °C) favors disaggregation of Pluronic molecules (*11*). Notably, the excess of L81, L121, and P123 was completely removed during purification of the conjugates in cold acetone but not by the filtration (data not shown). Furthermore, even for the samples with the lower modification degrees, there was poor separation between the conjugates and unmodified HRP. However, the unmodified protein was observed along with various HRP−L81 and HRP−P123 conjugates in the mass spectra (Figure 2b,c). Obviously, separation of free HRP from the conjugates on a cation exchange column was only partial, as the mass spectra demonstrated. A possible reason was that under the separation conditions the modified HRP formed aggregates that also entrapped unmodified HRP and were eluted within the column elution volume. Increasing the ethanol content in the elution buffer from the original 5% to 20% could be a future solution to dissociate the aggregates and enhance the separation. HRP−L121 conjugates were not detectable in MALDI-TOF, possibly due to high hydrophobicity of such conjugates (data not shown in the figure). The remaining activity of HRP after conjugation was high (81% to 96% of initial HRP), except for the HRP−L121 conjugate with higher modification degree, which was purified by precipitation in acetone (65%) (Table 2). Altogether, the procedures described in most cases resulted in HPR−Pluronic conjugates with relatively high yield, purity, and enzymatic activity.

Cellular Uptake of HPR−Pluronic Conjugates. The uptake of unmodified HRP in both MDCK cells (Figure 3) and BBMEC

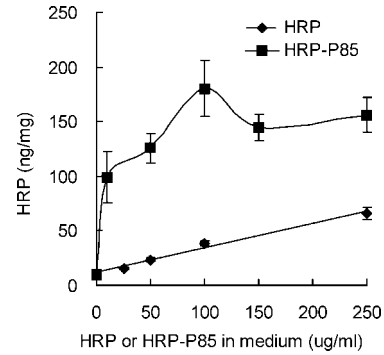

Figure 3. Uptake of HRP and HRP−P85 conjugate with DSP link in MDCK cells at 60 min as a function of the enzyme concentration in cell culture medium. The amount of HRP is normalized for the total cellular protein (ng/mg). Data were obtained in quadruplicate and presented as means ± SEM.

(data not shown) increased almost linearly as the protein concentration increased up to ca. 250 μg/mL. This behavior is characteristic of fluid-phase endocytosis (*12*). Contrary to that, the cellular uptake of HRP−P85 was bimodal, with an initial sharp increase in uptake at 10 μg/mL followed by a slower increase up to 250 μg/mL. This suggests a different mechanism for the uptake of the modified protein and may indicate adsorption endocytosis (*13*). Clearly, the uptake was greatly increased after the modification, possibly due to binding of hydrophobic PPO chains with the cell membranes. (Notably, the studies presented in this work report the total uptake, which combines membrane binding and internalization components. A detailed characterization of the uptake mechanisms will be reported separately.)

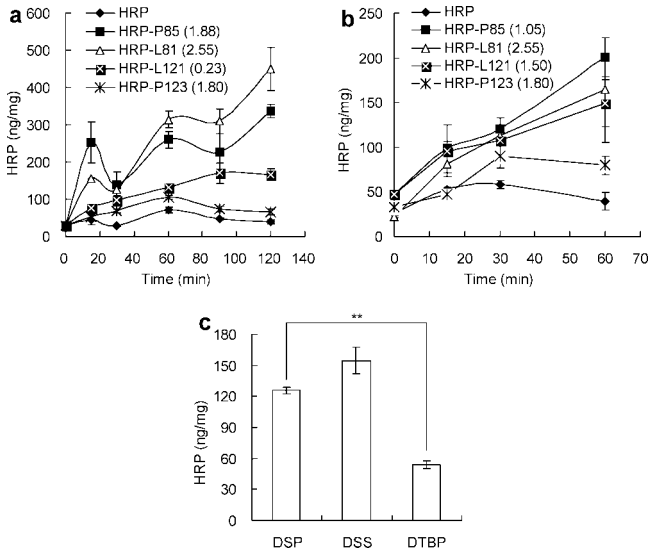

Figure 4. Uptake of HRP−Pluronic conjugates in (a,c) MDCK cells and (b) BBMEC monolayers. The conjugates were prepared using (a,b) DSP or (c) different cross-linkers as shown in the figure. The modification degree of the conjugates was indicated in the brackets. Data were obtained in quadruplicate and presented as means ± SEM. Statistical analysis was done using the Student *t* test. The symbol ** indicates statistical significance ($p < 0.01$).

Further, 50 μg/mL was selected as the concentration for the comparison of the unmodified and different conjugated HRP. In both cell models, there was a considerable increase (4- to 5-fold) in the uptake of HRP−P85 and HRP−L81 conjugates compared to the unmodified HRP (Figure 4a,b). Furthermore, the HRP−L121 conjugate also exhibited significant uptake increase, especially in the BBMEC monolayers. The least efficient uptake was observed in the case of HRP−P123. Evidently, the length of the hydrophobic PPO block is an important factor for the membrane binding and/or cell internalization of HRP conjugates. P85 and L81 contained about 40 propylene oxide units, whereas L121 and P123 contained about 70 propylene oxide units (Table 1). Therefore, the copolymers with shorter PPO chains overall appeared to be more efficient than those with longer PPO chains. This may be due to the anchoring of long PPO chains in the membranes that can prevent internalization of the corresponding conjugates in the cells. Notably, in the case of the free Pluronic the cellular uptake was also less efficient for the copolymers with longer PPO chains compared to the copolymers with shorter PPO chains because of strong binding of long PPO chains in the membranes (*5*). No aggregates were observed for all of the four conjugates in the concentration that were used in cellular experimentation when detecting in the sedimentation experiment (data not shown). Obviously, during the cellular uptake the conjugates were exposed to the membrane in the unimer form. It is also interesting that the length of the PEO chain had little if any effect on the uptake of the HRP−P85 and HRP−L81 conjugates having the same size of the PPO chains. At the same time, one may expect that the length of PEO chain could have a significant effect on the pharmacokinetics and distribution of the modified protein in the body (*14*). This will be examined for these conjugates in subsequent studies. Finally, in MDCK cells there was no difference in the uptake of HRP−P85 conjugates with degradable DSP and nondegradable DSS linkers (Figure 4c). However, the HRP−P85 conjugate with degradable positively charged DTBP linker was taken up much less efficiently than the conjugate with the degradable uncharged DSP linker. Since it is well-known that cationic compounds are generally transported more efficiently into cells, the reason for the decreased uptake of HRP−P85 conjugate with DTBP linker may be, for example, modification of different lysine amines in HRP compared to other conjugates. The differences in localization of the P85 chain in the HRP molecule may have a profound effect on the conjugate's transport characteristics due to the effects of the neighboring amino acids.

In summary, we have generated four monoamine Pluronic derivatives and successfully conjugated them to a model protein, HRP, *via* biodegradable or nondegradable linkers. The formation of covalent conjugates was demonstrated qualitatively by mass spectroscopy and quantitatively by TNBS assay. The purification procedures have been established. Using these methods, we obtained HRP conjugates containing an average of ca. 1 to 2 Pluronic moieties per protein molecule and retaining in most cases over 70% of the activity of the native HRP. The increased cellular uptake of the conjugates was demonstrated using MDCK cells and BBMEC monolayers. As a result of these modifications, a very hydrophilic protein, HRP, more efficiently bound with these cells than the unmodified analogue. The optimal polymers for modifications included P85 and L81. Between these two conjugates, there was little if any dependence of the uptake on the length of the hydrophilic PEO block of Pluronic, suggesting that its hydrophobic PPO block plays a decisive role in the conjugate interactions with cells. The results of this work will facilitate development of a novel method for the cellular delivery of proteins (*4*).

ACKNOWLEDGMENT

This study was supported by National Institute of Health RO1 NS051334. We also gratefully acknowledge the UNMC Mass Spectrometry and Proteomics Core Facility for assistance in MALDI-TOF experiments and Dr. Xiaobin Zhang (UNMC) for assistance in BBMEC isolation and culture.

Branched polypeptides with polylysine backbone are promising candidates for selective delivery of drugs, epitopes. or reporter molecules. We reported earlier that polylysine-based polypeptides with polyanionic character were internalized by murine bone marrow derived macrophages via class A scavenger receptor. In the present studies, our investigations were extended to seven polypeptides with different amino acid composition and charge properties. We report on our findings on the concentration-dependent influence of these compounds on survival and chemotaxis of the murine macrophage-like cell line J774 and internalization properties of the polypeptides by J774 cells. Our observations indicate that the polypeptides regardless of their charge properties were essentially nontoxic and did not alter significantly the chemotaxis of J774 cells; therefore, the polypeptides suit the requirements for nontoxic and "neutral" carrier molecules. We also demonstrated that the polypeptides were internalized efficiently by J774 cells, depending on their chemical structure and charge properties. Using the scavenger receptor–ligand fucoidan as inhibitor, we established that the scavenger receptor played a role–in accordance with findings on murine bone marrow derived macrophages in the internalization only of the polyanionic polypeptides.

INTRODUCTION

Most of the compounds recently applied therapeutically for tumors and infectious diseases are small molecules that enter the cells via diffusion. Coupling of drugs to macromolecular carriers would not only improve their solubility but also could decrease side effects and offers a new possibility of cell- or tissue-specific introduction (*1*). The conjugation of these agents alters the mechanism of their internalization, because the larger conjugates cannot penetrate the cell membrane by diffusion but are internalized by a more specific active transport mechanism, e.g., macropinocytosis or receptor-mediated endocytosis, depending on the properties of the carrier (*2*, *3*). Synthetic polymers have been widely used as carriers of bioactive compounds, epitopes, or reporter molecules. Most of the polymeric carriers like the nonbiodegradable HPMA (*N*-(2-hydroxypropyl)methacrylamide copolymer) (*4*, *5*) and DIVEMA (divinyl ether−maleic anhydride copolymer) (*6*) or biodegradable polymeric carriers like poly(α-amino acids), poly[Lys], poly[Glu], or poly[Tyr]) (*7*–*9*), do not possess a specific targeting moiety. In our laboratory, several groups of poly(L-lysine)-based branched polypeptides were developed and applied as macromolecular carriers of drugs and epitopes (*3*). The first group of the polymeric polypeptides studied in the present work can be described with the general formula of poly[Lys(X_i)][1]; X_iK, possesses a single amino acid coupled to the ϵ-amino groups of the lysine residues. The other group of polypeptides, poly[Lys(DL-Ala_m)] (*10*), contain a short oligo[DL-alanine] side chain or an additional amino acid coupled to the α-amino group of the terminal alanines with the general formula poly[Lys(X_i-DL-Ala_m)], XAK, where $i \cong 1$ and $m \cong 4$ (*11*). *In vitro* and *in vivo* physiological properties of poly[L-lysine]-based polymeric polypeptides like *in vitro* and *in vivo* cytotoxicity (*12*, *13*), biodistribution (*14*, *15*), blood clearance (*13*), immunogenicity (*16*), and immunomodulatory effect (*17*, *18*); chemotaxis (*19*) and class-A scavenger receptor (SR-A)-mediated cellular uptake have been investigated systematically over the past few years (*20*). Physicochemical properties of the polypeptides as interaction with phosphoplipid bilayers were also examined recently (*21*, *22*). Our previous data confirmed that amino acid composition and length of the side chains and charge of the terminal amino acid greatly influence the biological properties of the polypeptides and their drug conjugates, e.g., with daunomycin (*23*, *24*) and methotrexate (*25*). We have also demonstrated that polylysine-based polypeptides with polyanionic character (SuccEAK and

[1] Abbreviations: Abbreviations of amino acids and their derivatives follow the revised recommendation of the IUPAC-IUB Committee on Biochemical Nomenclature entitled "Nomenclature and Symbolism for Amino Acids and Peptides" (recommendations of 1983). Nomenclature of branched chain polypeptides is used in accordance with the recommended nomenclature of graft polypeptides (*26*). For the sake of brevity codes of branched chain polypeptides were constructed by us using the one-letter codes of amino acids. All amino acids are L configuration unless otherwise stated. The other abbreviations in this paper are the following: Pcp, pentachlorophenyl; HOBt, 1-hydroxybezotriazole; DMSO, dimethyl sulfoxide; DMF, *N*,*N*-dimethyl-formamide; TEA, triethylamine; PBS, phosphate-buffered saline; Ac, acetyl; Succ, succinyl; Mal, maleyl; CF, 5(6)-carboxyfluorescein.

MalEAK) enter murine bone marrow derived macrophages via SR-A-mediated endocytosis, and not only the charge density but also the chemical structure of the anionic end group have an influence on the efficacy of the internalization (*20*). In this article, we describe our findings on the effect of seven structurally related polypeptides with different characteristics according to their amino acid composition and charge properties on survival and chemotaxis of the J774 murine macrophage cell line. In order to determine the correlation between efficient cellular uptake and chemical structure of polypeptide carriers, we investigated the internalization of the polypeptides in several aspects. In order to find the carrier that can be most efficiently internalized by macrophages, we carried out the comparative study of the polypeptides with different charge properties on the macrophage cell line J774. We also wanted to clarify whether the scavenger receptor is involved in the uptake of the polyanionic polypeptides, using the scavenger receptor–ligand fucoidan as inhibitor. Our results indicate that the polypeptides elicited only moderate toxicity on J774 cells except the control polypeptide poly(L-lysine). They did not alter significantly the chemotaxis of the cells either. We demonstrated that the polypeptides were internalized efficiently by J774 cells depending on their chemical structure and charge properties. Taken together, the polypeptides suit the requirements for nontoxic and nonchemotactic macromolecular carriers. We established that the scavenger receptor played a role only in the internalization of two polyanionic polypeptides, poly[Lys(Succ-$Glu_{1.0}$-DL-$Ala_{3.8}$)], SuccEAK, and poly[Lys(Mal-$Glu_{1.0}$-DL-$Ala_{3.8}$)], MalEAK; thus, these polypeptides can be promising candidates as macromolecular carriers in drug conjugates applied for cell-specific delivery into macrophages.

MATERIALS AND METHODS

Reagents. Amino acids used for this study, HCl, acetic anhydride, succinic anhydride, and DMF were purchased from REANAL (Budapest, Hungary). Pentachlorophenol, 1-hydroxybenzotriazole, triethylamine, and DMSO were from Fluka (Buchs, Switzerland). Acetonitrile was from Merck (Darmstadt, Germany). Fucoidan from *Fucus vesiculosus* and 5(6)-carboxyfluorescein succinimide ester were obtained from Sigma-Aldrich Hungary Ltd. (Budapest, Hungary).

Synthesis of Poly[Lys(X_i)], X_iK and Poly[Lys(X_i-DL-Ala_m)], XAK-Type Polypeptides. Poly[Lys(X_i)] (X_iK) where X = Pro and XAK-type polypeptides where X = Ser or Glu were prepared according to Mezö et al. (*27*). Briefly, poly[Lys(DL-Ala_m)], AK, was synthesized by grafting short oligomeric DL-Ala chains to the $^{\epsilon}NH_2$ group of lysine residues using *N*-carboxy-DL-Ala-anhydride. Polymerization was continued at room temperature for 2 days. Terminal amino acids (X) were coupled to the $^{\alpha}NH_2$ groups of the terminal amino acid of the oligoalanine chains, where X = Glu or Ser. In the case of X_iK polypeptides, terminal amino acid was coupled to the $^{\epsilon}NH_2$-groups of polylysine as Z-X-OPcp, where X = Pro. The coupling reaction was carried out by *in situ* active ester method using an equivalent amount of 1-hydroxybenzotriazole (HOBt) dissolved in DMF as activating reagent (*28*). The polypeptides were purified by dialysis against distilled water for two days using a Visking tube (cutoff = 10000 Da) and isolated by freeze-drying.

Synthesis of Polyanionic Derivatives of Poly[Lys(Glu_i-DL-Ala_m)], (EAK). Synthesis of polypeptides of polyanionic character was performed via modification of EAK polypeptide as described previously (*20*, *29*). Briefly, acetylation was carried out in DMF/water = 9:1 solvent mixture using 5 equiv freshly prepared imidazolyl acetate (*30*). Succinylation and maleylation were performed in 0.1 M carbonate buffer (pH 9.2) using 0.022 g (0.22 mmol) succinic anhydride or 0.02 g (0.2 mmol) maleic anhydride dissolved in DMSO (c = 100 mg/mL). The reaction was continued for 4 h at RT, followed by dialysis against distilled water for 2 days and then freeze−drying.

Amino Acid Analysis. Amino acid composition of the polymeric polypeptides was determined by amino acid analysis using a Beckman 6300 analyzer (Fullerton, USA) after hydrolysis in 6 M HCl in sealed and evacuated tubes at 105 °C for 24 h.

Labeling of Polymeric Polypeptides with 5(6)-Carboxyfluorescein. Ten milligrams (6×10^{-7} to 1.9×10^{-7} mol) polypeptides was dissolved in 2 mL sodium carbonate buffer (0.1 M; pH 9.4). 5(6)-Carboxyfluorescein succinimide ester was dissolved in DMF (c = 10 mg/mL, 0.21 mM) and was added to the polypeptide solution in 20 μL aliquots. The reaction was continued for 1 h at room temperature with continuous stirring. The product was purified by gel filtration on a PD10 column filled with Sephadex G25 using distilled water as eluent. The samples were then freeze-dried, and they were resolved in PBS (0.1 M, pH 7.4) before use. Carboxyfluorescein content of the samples was determined by RP-HPLC as described earlier (*20*).

Cell Culturing. J774 murine macrophage cell line of Balb/c origin was maintained in RPMI 1640 medium containing 10% FCS, 2 mM L-glutamine, and 0.16 mg/mL streptomycin at 37 °C in 5% CO_2 atmosphere. Cells were harvested in the logarithmic phase of growth.

Cytotoxicity of the Polypeptides on J774 Cells. Cells were divided into 96 well tissue-culture plates in 200 μL culture medium (RPMI 1640, 10% FCS, 2 mM L-glutamine, and 0.16 mg/mL streptomycin) with initial cell number of 10^5 cells/well. The polypeptides were dissolved in fresh culture medium and were added to the cells at final concentrations of 0.2, 2.0, 20, and 200 μg/mL. After 1 and 24 h incubation at 37 °C, cell viability was determined by MTT assay using 0.37 mg/mL final concentration of MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) in each well. After 3 h incubation, the absorbance was measured with an ELISA reader (Labsystems MS Reader) at 540 and 620 nm as reference wavelengths. Statistical analysis of data was performed by ANOVA of *Origin 7.5*.

Chemotaxis of J774 Cells. Chemotactic ability of compounds was analyzed in a 96 well NeuroProbe chamber (96 well Boyden chamber) in the 0.02–20 μg/mL concentration range. A polycarbonate filter with 5 μm pore diameter was placed between the inner chambers containing the polypeptide solution and the outer chambers, in which J774 cells were placed (10^5 cells/well). The chamber was incubated at 37 °C for 3 h. The amount of the viable cells was determined by MTT assay using 24 h incubation with MTT. Statistical analysis was performed by ANOVA of *Origin 7.5*.

Uptake of Polypeptides by Nonattached Cells. Cells were plated on 24 well tissue culture plate (10^5 cells/well) 24 h prior to the experiment. Cells were incubated with 5(6)-CF-labeled polypeptides at 0.02, 0.2, 2, and 20 μg/mL for 60 min concentration or at 20 μg/mL for 1, 15, 30, 45, and 60 min. Extracellular fluorescence was quenched using 0.5% (m/V) trypane blue solution. Cells were washed twice with PBS (0.1 M; pH 7.4) then fixed with 4% (m/V) formaldehyde dissolved in PBS (0.1 M; pH 7.4). Change of fluorescence of the cells was determined by flow cytometry (FACSCalibur, Becton Dickinson, or BD LSR II) measuring 5000 or 10 000 cells. Data were analyzed with *CellQuest Pro* or *FACS DiVa* software. The mean fluorescence of untreated control cells was subtracted from the mean fluorescence of treated samples under all assay conditions applied. Statistical analysis of data was performed using Student's t test at the 95% confidence level.

Uptake of Polypeptides by Adherent Cells. Cells were plated into 24 well tissue culture plate (10^5 cells/well) 24 h

[a] Code of branched chain polymeric polypeptides, based on one-letter symbol of amino acids. K represents lysine, A represents alanine, and X is a proteinogenic amino acid in the side chain; *m* characterizes the average length of the oligo-DL-alanine side chains ($m \cong 4$), whereas *i* describes the average degree of substitution of amino acid X ($i \cong 1$) (*26*). [b] Amino acid composition was determined by amino acid analysis after hydrolysis in 6 M HCl at 105 °C for 24 h. [c] Average degree of polymerization determined by sedimentation equilibrium measurements. [d] Average molecular mass of polymers; calculated from the average degree of polymerization (DP_n) of poly[Lys] and of the side chain composition. [e] Average degree of substitution for 5(6)-carboxyfluorescein (CF) was determined by reverse-phase HPLC after hydrolysis of the samples in 6 M HCl at 105 °C for 24 h.

before treating with the polypeptides. Before the addition of CF-labeled polypeptides, cells were washed with serum-free medium and then incubated with the solution of the CF-labeled polypeptides in serum-free RPMI 1640 for 1 h at 37 or 4 °C. In case of inhibition, cells were pretreated with fucoidan dissolved in RPMI 1640 at 20 μg/mL concentration for 30 min. The presence of the inhibitor was maintained throughout the experiment (*30*). After 1 h incubation with the polypeptides at $c = 20$ μg/mL, cells were washed twice with RPMI. Cells were washed 2 times with PBS (0.1 M; pH 7.4) and then fixed with 4% (m/V) formaldehyde/PBS (0.1 M; pH 7.4). Cells were examined by flow cytometry (FACSCalibur and LSR II, Becton Dickinson). Data were recorded measuring 5000–10 000 cells, and fluorescence mean values were calculated. Statistical analysis of data was performed using Student's *t* test at the 95% confidence level.

Study of Uptake by Confocal Microscopy. For the microscopic studies, cells were mounted onto microscopic coverslips and placed into a 24 well tissue culture plate and allowed to attach for 24 h. Cells were treated with the CF-labeled polypeptides in serum-free RPMI 1640 medium for 1 h. Then, cells were fixed with 4% (m/V) formaldehyde/PBS (0.1 M; pH 7.4) and the coverslips were placed onto microscopic slides. The mounted cells were analyzed in a BIO RAD MRC 1024 confocal scanning laser microscope equipped with a krypton/argon mixed-gas laser as a light source. Excitation was carried out at $\lambda = 480$ nm.

RESULTS

Branched Chain Polypeptides. Branched polypeptides with the general formula poly[Lys(X_i)] or poly[Lys(X_i-DL-Ala_m)], ($m \cong 4$, $i \cong 1$) were used for these studies. Poly[Lys($Pro_{0.95}$)] (P_iK) and poly[Lys(DL-$Ala_{3.8}$)] (AK) and XAK type polypeptide poly[Lys($Ser_{0.9}$-DL-$Ala_{3.8}$)] (SAK) possessed polycationic character. Poly[Lys($Glu_{1.0}$-DL-$Ala_{3.8}$)] (EAK), an amphoteric polypeptide carrying free α-amino and γ-carboxyl groups, and its three polyanionic derivatives, in which the $^{\alpha}NH_2$ groups of the terminal glutamic acid residues were modified by acetyl, succinyl, and maleyl groups, were also examined. The three polyanionic polypeptides possess slightly different charge properties. Poly[Lys(Ac-$Glu_{1.0}$-DL-$Ala_{3.8}$)] (AcEAK) carries one negative charge per monomer unit, whereas poly[Lys(Succ-$Glu_{1.0}$-DL-$Ala_{3.8}$)] (SuccEAK) and (poly[Lys-(Mal-$Glu_{1.0}$-DL-$Ala_{3.8}$)] (MalEAK) polypeptides contain two negative charges in their each monomer unit. The polypeptides were characterized with their amino acid composition and their relative average molar mass, determined by sedimentation equilibrium analysis. Chemical characteristics of the polypeptides are shown in Table 1.

Cytotoxicity of Polylysine-Based Polypeptides on J774 Cells. Cytotoxicity of the polypeptides was tested on J774 cells at the concentration range 0.2−200 μg/mL by MTT assay using polylysine as a control. Time dependence of the cytotoxic effect was also examined. Results are expressed as a percentage of optical density measured in the case of the untreated cells. Cytotoxicity proved to be dependent on the charge of the *N*-terminal amino acid of the side chains and on the distance of the charged group from the polylysine backbone. We found that after a 1 h incubation only the control polypeptide (poly[Lys]) was toxic (cytotoxicity = 88 ± 0.14% at 200 μg/mL, $LC_{50} = 65.7$ μg/mL). After the 24 h treatment, two other polycationic polypeptides like poly[Lys($Pro_{0.95}$)] (P_iK) (cytotoxicity = 54.6 ± 12% at $c = 200$ μg/mL, $LC_{50} = 153.65$ μg/mL), poly[Lys($Ser_{0.9}$-DL-$Ala_{3.8}$)] (SAK) (cytotoxicity = 15.2 ± 9% at $c = 200$ μg/mL) and also polyanionic poly[Lys(Succ-$Glu_{1.0}$-DL-$Ala_{3.8}$)] (SuccEAK) exhibited a moderate cytotoxicity (38.4 ± 1.4% at $c = 200$ μg/mL) at the highest concentration studied (Figure 1).

Chemotaxis of J774 Cells. Chemotaxis of the polypeptides was studied using a 96 well NeuroProbe chamber at 0.02, 0.2, 2.0, and 20 μg/mL concentration. The amount of the viable migrated cells was determined by MTT assay. Two polycationic polypeptides, poly[Lys($Pro_{0.95}$)] (P_iK) and poly[Lys($Ser_{0.9}$-DL-$Ala_{3.8}$)] (SAK) induced a slight but significant chemotactic response on J774 cells, in both in an optimal concentration, which is characteristic of each polypeptide. Poly[Lys($Pro_{0.95}$)] (P_iK) elicited a repellent effect at $c = 20$ μg/mL, whereas SAK proved to be slightly chemoattractant at $c = 0.2$ μg/mL and 2.0 μg/mL (Table 2).

Uptake of Carboxyfluorescein-Labeled Polypeptides by J774 Cells. The internalization properties of polylysine-based polypeptides were studied on J774 cells under different conditions. The influence of polypeptide concentration, incubation time, and temperature was investigated on the uptake of CF-labeled polypeptides. We also studied the involvement of the scavenger receptor in the internalization process in inhibition assays.

Uptake of the Polypeptides by Nonattached Cells. The uptake of the polypeptides by nonattached J774 cells was examined using flow cytometry and confocal microscopy as well. The polycationic polypeptide (poly[Lys($Pro_{0.95}$)] (P_iK) possessing short side chains was taken up already at 2 μg/mL concentration. The uptake of poly[Lys($Ser_{0.9}$-DL-$Ala_{3.8}$)] (SAK) with polycationic character was significant only at the highest concentration studied, whereas the presence of amphoteric EAK (poly[Lys-($Glu_{1.0}$-DL-$Ala_{3.8}$)]) was not detectable in the cells. The polycationic AK (poly[Lys(DL-$Ala_{3.8}$)]) and P_iK ((poly[Lys($Pro_{0.95}$)]) were taken up the most efficiently. As poly[Lys(DL-$Ala_{3.8}$)] (AK)

[a] Chemotactic ability of the cells was analyzed in a 96 well NeuroProbe chamber. The number of migrated cells was determined by MTT assay. Chemotactic index was expressed as percentage of control ± SD. Data represent the mean of 8 parallels. Statistical analysis of data was performed by one-way ANOVA of *Origin5* (*$p < 0.05$).

was one of the polypeptides that could be detected the best in the cells, time dependence of the uptake of this polypeptide was also examined by confocal microscopy (Figure 2). In the microscopic images, the binding of the CF-labeled AK (poly[Lys-(DL-$Ala_{3.8}$)]) polypeptide to the cell surface could be observed even after 1 min incubation. The vesicles containing the labeled polypeptide appear within the cells after 30 min incubation, and the number of the vesicles increased after 60 min incubation time (Figure 2).

Uptake of the Polypeptides by Adherent Cells. The rate of the uptake was influenced by the charge and the polypeptide concentration. Uptake of polycationic polypeptides and poly[Lys-(Succ-$Glu_{1.0}$-DL-$Ala_{3.8}$)] (SuccEAK) was dependent on the polypeptide concentration, whereas SAK (poly[Lys($Ser_{0.9}$-DL-$Ala_{3.8}$)]), EAK (poly[Lys($Glu_{1.0}$-DL-$Ala_{3.8}$)]), and AcEAK (poly-[Lys(Ac-$Glu_{1.0}$-DL-$Ala_{3.8}$)]) were ingested only at the highest concentration applied (c = 20 μg/mL) (Figure 3). The kinetics of the uptake was examined by flow cytometry after 0, 5, 15, 30, 45, and 60 min incubation with the polypeptides. The internalization of the polyanionic polypeptides by J774 cells was in direct proportion to the incubation period, except (poly[Lys($Pro_{0.95}$)] (P_iK), where the kinetics of the uptake was exponential, and we could observe a saturation kinetics in the case of poly[Lys($Ser_{0.9}$-DL-$Ala_{3.8}$)] (SAK) polypeptide (Figure 4). An increased uptake of the polycationic AK, poly[Lys(DL-$Ala_{3.8}$)], the polyanionic SuccEAK (poly[Lys(Succ-$Glu_{1.0}$-DL-$Ala_{3.8}$)]), and MalEAK (poly[Lys(Mal-$Glu_{1.0}$-DL-$Ala_{3.8}$)]) could be observed after attachment of the cells to the surface (Figure 5). Images taken by confocal microscopy also confirmed that CF-SuccEAK, poly[Lys(Succ-$Glu_{1.0}$-DL-$Ala_{3.8}$)] was ingested by the adherent cells at a higher level compared to nonadherent cells (Figure 5). By contrast, polycationic polypeptides like P_iK poly[Lys($Pro_{0.95}$)]), SAK (poly[Lys($Ser_{0.9}$-DL-$Ala_{3.8}$)]), AK (poly-[Lys(DL-$Ala_{3.8}$)]) were ingested at a higher level by the nonadherent J774 cells (Figure 6). The uptake of the polypeptides proved to be dependent also on temperature. By analyzing data obtained for two different temperatures, we detected a significant decrease in the internalization at 4 °C compared to 37 °C (Figure 7).

Effect of SR-Antagonist Fucoidan on the Uptake of the Polypeptides. We examined the role of the scavenger receptor in the internalization of the polypeptides; therefore, the uptake was inhibited with a SR ligand, the sulfated polysaccharide fucoidan. We found that 30 min pretreatment ($c_{fucoidan}$ = 20 μg/mL) significantly inhibited the uptake of polyanionic polypeptides, SuccEAK (poly[Lys(Succ-$Glu_{1.0}$-DL-$Ala_{3.8}$)]) and MalEAK (poly[Lys(Mal-$Glu_{1.0}$-DL-$Ala_{3.8}$)]) but did not alter the uptake of polyanionic AcEAK (poly[Lys(Ac-$Glu_{1.0}$-DL-$Ala_{3.8}$)]) and polycationic AK (poly[Lys(DL-$Ala_{3.8}$)]). These results indicate that scavenger receptors play a role in the internalization of the two polyanionic polypeptides that possess two negative charges per monomer unit (Figure 8).

DISCUSSION

Recently, studies on cell-specific introduction of drugs is one of the most actively developing areas of drug delivery research. Numerous antitumor and antiparasitic agents as methotrexate or anthracyclines entering the cell membrane by diffusion are toxic not only to the target cells but also to the other cell types

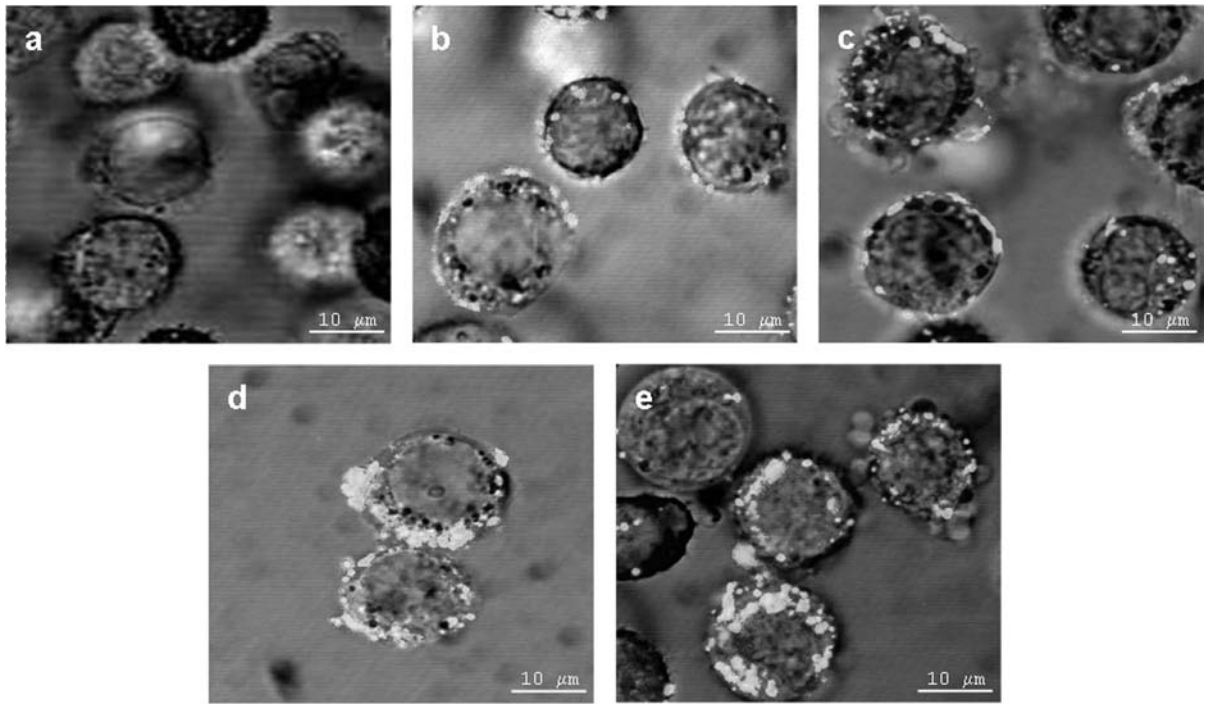

Figure 2. Time dependence of the endocytosis of CF-poly[Lys(DL-$Ala_{3,8}$)] (AK) polypeptide by nonattached J774 cells. The cells were analyzed by confocal microscopy (λ_{ex} = 488 nm): (a) untreated control, (b) CF-AK 1 min, (c) CF-AK 15 min, (d) CF-AK 30 min, (e) CF-AK 60 min.

of the organism (*31*). On the other hand, small hydrophilic molecules like peptides, oligonucleotides, and small proteins with low membrane permeability cannot reach the site of action (*32*). These problems can be solved by applying macromolecular carriers that can decrease the toxicity and improve the specificity of drugs or can deliver hydrophilic compounds through the cell membrane. The use of macromolecular carriers can also break multidrug resistance (*33*) and enhance the immunogenicity of the original compound (*34*). There are some important requirements for the ideal macromolecular carrier. It must not be toxic or immunogenic; it should possess reactive groups that can be modified by a simple chemical reaction; the carrier has to retain its specificity after conjugation and must not alter the efficacy of the active compound coupled to it (*35*).

J774 cells have been used for several cell physiological studies related to macrophages. Their inflammatory response (*36*), signal transduction (*37*), killing activity, and phagocytosis (*37–39*) and chemotactic activity (*40*) have been investigated in detail. Claus et al. characterized the activity of their endosomal enzymes (*41*). Maturation of phagosomes (*42*) and the effect of antimycobacterial agents (*43*) were also studied on *Mycobacterium*-infected J774 cells. J774 cells were used for modeling macrophages in several investigations on cell-specific delivery of active compounds via scavenger receptors (*44–46*).

The aim of our studies was to examine the effect of a group of systematically developed chemically related polypeptides on the macrophage like cell line J774. Our previous studies indicated that the chemical structure of the polypeptides, especially the charge and length of the side chains, influenced markedly the biological effects and physicochemical characteristics of the polypeptides (*12, 17*). Our present results show that charge and structure of the side chains both have a marked influence on *in vitro* toxicity and uptake of polylysine based

Statistical analysis of data was performed by Student's *t* test; $*p < 0.05$.

polypeptides, whereas the structure of the terminal amino acid derivative could determine the chemotactic character of the molecule.

We determined the cytotoxicity of the branched-chain polypeptides after 1 and 24 h. We found that the branched chain polypeptides elicited moderate cytotoxicity at the highest concentration in contrast with control poly[Lys] containing free ε-amino groups that induced a marked cell death after 1 and 24 h incubation as well. We also observed a difference between the polyanionic polypeptides. AcEAK (poly[Lys(Ac-$Glu_{1.0}$-DL-$Ala_{3.8}$)]) and MalEAK poly[Lys(Mal-$Glu_{1.0}$-DL-$Ala_{3.8}$)] elicited a markedly lower toxicity on J774 cells than SuccEAK poly-[Lys(Succ-$Glu_{0.9}$-DL-$Ala_{3.8}$)]. Taken together, cytotoxicity of the polypeptides proved to be dependent on the charge of the *N*-terminal amino acid of the side chains, and in the case of polyanionic polypeptides, on the structure of the anionic end group.

Various molecules like bacterial peptides (e.g., fMLF) (*47*), chemokines, nucleotides (ADP), and molecules of the complement system (C5a) (*40*) can activate the chemotaxis of monocytes and macrophage-like cells. We would apply carriers that are able to elicit a chemotactic response and draw the cells to the target cell population, but these molecules usually induce an immune response as well. To avoid immunogenicity, it is advisable to choose a neutral carrier that does not induce chemotaxis but rather contains a nonchemotactic targeting moiety. Our previous studies on *Tetrahymena pyriformis* (*19*) demonstrated that the character of the terminal amino acid of the branches determined the chemotactic activity of the model organism. Compared to *Tetrahymena*, chemotactic activity of J774 cells was markedly lower. In summary, the polypeptides did not influence significantly the chemotaxis of the J774 cells, so they can be applied as neutral, nonchemotactic macromolecular carriers of drug targeting with respect to chemotactic drug targeting, a special type of drug delivery described recently (*48*).

Results of the internalization studies obtained by flow cytometry and confocal laser scanning microscopy illustrated that J774 cells ingested polypeptides depending on the polypeptide concentration, the incubation time, and the temperature. The charge of the side chains influenced markedly the rate and kinetics of the uptake. We observed a difference between the polypeptide internalization of nonadherent and adherent cells. Floating J774 cells internalized polycationic polypeptides more effectively than polyanionic ones, whereas the uptake of polyanionic polypeptides was significantly increased by the adherent cells. As adherent cells express certain receptors that

play a role in the internalization process (e.g., scavenger receptors) to a greater extent than nonadherent cells (*49*), the more effective uptake of polyanionic polypeptides (SuccEAK and MalEAK) imply a receptor-dependent uptake mechanism. Examination of the internalization by confocal microscopy seems to confirm that uptake of the polypeptides occurs by endocytosis: the polypeptides were ingested by the cells in vesicles can be observed in the microscopic images well.

In order to clarify whether a scavenger receptor is involved in the internalization of the polypeptides, we carried out inhibition experiments using a class A scavenger receptor ligand, the sulfated polysaccharide fucoidan as inhibitor (*30*). We observed that pretreatment with fucoidan reduced the uptake of both polyanionic polypeptides that possessed two anionic groups per monomer unit, but the internalization of AcEAK bearing only one negatively charged group on each monomer, and polycationic AK used as negative control was taken up at the same level after the inhibition. We can presume that the charge density (e.g., the number of negative charges per unit in the polyanionic polypeptides) influences the internalization of the polypeptides. These observations indicate that MalEAK and SuccEAK are taken up by J774 cells via scavenger receptor but AcEAK could be recognized by the same receptor with a much lower affinity, or AcEAK and polycationic polypeptides as well are ingested by a different process.

In conclusion, on the basis of results presented and discussed above we could select an appropriate polypeptide with the chemical characteristics that are essential for intracellular delivery. These polypeptides are essentially nontoxic, neutral macromolecular carriers for drugs that are to be introduced to specific cell types. We can presume that polyanionic polypeptides will be able to transport the drugs coupled to them into the macrophage cells via scavenger receptor. On the other hand, by further investigation of the polycationic polypeptides we can find an application that requires a non-cell-specific but effective delivery of reporter molecules, nucleotides, or small proteins into the cell.

Received January 2, 2008; Revised Manuscript Received February 13, 2008

Through the development and application of a unique approach for producing Re-metallopeptides, a new class of peptide-derived probes that are designed to target β-amyloid plaques was developed. Derivatives of a class of β-breaker peptides having the core sequence lvffa or affvl (lower case letters represent D-amino acids) and the single amino acid chelate quinoline (SAACQ) ligand which can bind Re and ^{99m}Tc were prepared on an automated peptide synthesizer. Both monomeric and dimeric peptides were synthesized in modest to good yields where in select examples a biotin-containing amino acid derivative was included to act as a linker point for further conjugation to carrier proteins. The Re complexes for all reported peptides were prepared similarly and screened for their ability to inhibit fibrillogenesis. Two of the reported compounds showed excellent inhibitory properties (**8a**: 40 ± 5% amyloid formation versus control; **16**: 40 ± 4%) and warrant further investigation. For one of these leads, the ^{99m}Tc analogue was synthesized and the product showed high stability toward histidine and cysteine challenges, making it a viable candidate for *in vivo* biodistribution studies.

INTRODUCTION

Alzheimer's disease (AD) is a progressive neurodegenerative affliction that involves the formation of plaques and neurofibrillary tangles, which ultimately lead to neuronal death in both the hippocampus and frontal cortex (*1, 2*). Senile plaques can occupy up to 15% of the brain volume in some advanced AD patients and are composed primarily of β-amyloid peptides ($A\beta^{1-40,42,43}$) (*1, 3*). Amyloid peptides are naturally occurring entities, but in AD patients, the peptides form plaques in the brain: a process that stems from a change in the mechanism of cleavage of the amyloid precursor protein (*1, 4, 5*). The formation of senile plaques has been correlated with the progression of the disease and has therefore emerged as a promising target for the treatment of AD (*1, 6, 7*).

There has been a major effort put into developing radioimaging agents that allow for serial monitoring of the progression of AD and for assessing the impact of therapy. ^{18}F-deoxyglucose (FDG) is used to diagnose the early onset of disease by visualizing reduced metabolism of glucose associated with cell death in the brains of AD patients (*2*). Unfortunately, FDG is not able to specifically identify β-amyloid plaques; therefore, to better characterize changes in plaque load, work in the field has been geared toward developing plaque-targeting PET and SPECT agents (*8*−*12*).

Maggio and co-workers reported that $A\beta^{1-40}$ labeled with ^{125}I rapidly deposits on β-amyloid plaques in isolated tissue. Not surprisingly, the labeled peptide showed particularly poor brain uptake *in vivo* (*13*). However, conjugation of an $A\beta^{1-40}$-biotin derivative to a streptavidin-tagged monoclonal antibody (mAb) for the human insulin receptor markedly improved transport across the BBB (*14, 15*). Uptake of the mAb-^{125}I-biotin-$A\beta^{1-40}$ conjugate in rhesus monkey brains was observed using autoradiography.

Structure−activity relationships (SARs) have shown that fragments of the full $A\beta^{1-40}$ peptide can exhibit binding to plaques and inhibition of β-amyloid fibrillogenesis (*4, 16*−*21*). β-sheet breaker peptides having as few as four amino acids (LVFF) have been able to significantly inhibit fibril formation (*22*). The key hydrophobic motif, LVFF, which is common to most AD β-sheet breaker peptides, binds amyloid plaques and can prevent soluble Aβ peptides from forming structured aggregates (*4, 16*−*19*). Given that strategies for enabling peptides to cross the BBB exist, radiotracers based on β-breaker peptides would offer a new means for imaging β-amyloid plaques and for assessing therapies aimed at solubilizing plaques.

The traditional approach for developing ^{99m}Tc-labeled probes of this type would involve appending a technetium chelator to the N-terminus of a core β-breaker peptide sequence. After isolation, attempts would be made to prepare the rhenium complex of the product, which would serve as a reference standard for the ^{99m}Tc analogue and as a compound to test the ability of the metallopeptide derivative to bind plaques and/or inhibit amyloid fibrillogenesis. This linear discovery approach is time-consuming with respect to isolating and fully characterizing the Re complexes and identifying the optimal sequence for the vector and site of derivatization on the peptide backbone.

We report here a new approach in which an organometallic complex of an amino acid analogue is used to insert the metal into various positions in lvffa and affvl sequences. A synthetic methodology was developed such that multivalent (i.e., dimeric) peptides could be prepared and biotin incorporated into the backbone of the peptide as a linker site for conjugation to carrier proteins. The ability of the Re complexes to prevent fibril

formation was subsequently determined *in vitro* in order to identify lead compounds for further testing.

EXPERIMENTAL PROCEDURES

Instrumentation. All peptides were prepared on an Advanced ChemTech 348Ω peptide synthesizer using a 40-well reaction vessel. Peptides were analyzed by electrospray mass spectrometry using a Micromass Quattro Ultima instrument in positive ion mode. Samples were dissolved in 50% CH_3CN /H_2O prior to analysis. FTIR spectra were acquired on a Bio-Rad FTS-40 FTIR spectrometer.

Analytical HPLC was performed using a Varian Pro Star model 330 PDA detector, model 230 solvent delivery system, and a C-18 Microsorb column (4.6 × 250 mm, 300 Å−5 μm). Semipreparative HPLC was carried out using a Varian Pro Star HPLC fitted with a model 320 UV detector, a model 215 solvent delivery system, and a C-18 Microsorb column (10 × 250 mm, 300 Å−5 μm). Peptides (**1**−**16**) were analyzed using a gradient of 5% to 100% CH_3CN containing 0.1% TFA over 40 min at flow rate of 1.0 mL min^{-1}. All runs were monitored at λ = 254 and 214 nm. For the reactions involving ^{99m}Tc, HPLC experiments were performed on a Varian Prostar model 230 HPLC instrument coupled to a Bio-Rad IN/US γ-detector using a Varian Nucleosil (L × ID = 250 × 4.6 mm) analytical column (300 Å − 5 μm, RP-C18). The mobile phase for the analysis of $[Tc(CO)_3(H_2O)_3]^+$ consisted of solvent A, triethylammonium phosphate buffer (pH = 2−2.5); solvent B, CH_3OH. Gradient: 0−3 min, 100% A; 3−6 min, 100% A to 75% A; 6−9 min, 75% A to 67% A; 9−20 min, 67% A to 0% A; 20−22 min, 0% A; 22−25 min, 0% A to 100% A; 25−30 min, 100% A. For the labeled peptide, the elution conditions were 5−100% CH_3CN containing 0.1% TFA over 30 min at flow rate of 1.0 mL min^{-1}.

Materials and Methods. Unless otherwise stated, all reagents and solvents were ACS grade or higher and used without further purification from commercial suppliers. Polystyrene-based N-α-9-fluorenylmethoxycarbonyl (Fmoc)-glycine loaded Wang resin (0.82 mmol g^{-1}, 1% divinylbenzene, 200−400 mesh) was obtained from NovaBiochem Inc. Fmoc-protected amino acids were purchased from NovaBiochem Inc., Bachem Inc., and Advanced ChemTech Inc. Peptides were prepared on an Advanced Chemtech 348 synthesizer. The $A\beta^{1-40}$ was purchased from rPeptide (cat# A-1001-1, lot# 3120440A).

Caution: ^{99m}Tc is radioactive and should only be handled in an appropriately equipped and licensed facility.

Solid-Phase Peptide Synthesis. Fmoc-glycine loaded Wang resin (0.82 mmol/g; 100 mg/well) was added to 16 wells in the reaction block, washed with DMF (2 mL/well), and shaken at 600 rpm for 1 min. The wells were then filtered and the resin washed with THF (2 mL/well) three times, shaking at 600 rpm for 1 min and draining for 90 s per wash. The same washing was repeated two additional times with DMF to complete the general wash cycle. This general wash cycle was used between every deprotection and coupling step.

Fmoc deprotection was accomplished by adding a 20% v/v piperidine−DMF solution (2 mL/well) and shaking for 5 min at 600 rpm. After draining the reaction wells, the deprotection procedure was repeated this time with shaking for 10 min. The deprotected resin-bound amino acid was then washed with the general wash cycle. For amino acid coupling reactions, standard methods involving HBTU were employed. The linear peptides were prepared by adding DMF (200 μL) to the active vessels followed by a 4-fold excess of the appropriate protected amino acid as a 0.5 M solution in DMF. Four equivalents of HBTU as a 0.5 M solution in DMF was then added, followed by an 8-fold excess of DIPEA as 2.0 M solution in DMF. The reaction vessel was subsequently shaken for 80 min at 600 rpm. Following filtration, the resin was washed as described above and the cycles repeated to prepare peptides **1**−**8a**.

The branched peptides were prepared using the same HBTU coupling strategy described above. At the point of branching, Fmoc-D-Lys(Mtt)-OH was introduced into the peptide where, prior to Mtt deprotection, THF (2 mL) was added to the appropriate reaction wells and the suspension shaken at 600 rpm for 4 min. After filtration, the THF wash was repeated twice to ensure that no residual DMF was present. The Mtt group (Mtt = 4-methyltrityl) was selectively removed by the manual addition of 2 mL of a freshly prepared cocktail of 1% TFA and 3% TIS in DCM (v/v/v), followed by shaking for 15 min at 600 rpm. After filtration, the procedure was repeated, this time shaking for 30 min. The resin was then tested for complete deprotection by adding a small amount of resin to a 1:1 (v/v) solution of TFA and DCM. When the resin did not turn yellow, Mtt deprotection was assumed to be complete, and the next amino acid was added in 8-fold excess. Eight equivalents of HBTU as a 0.5 M solution in DMF and a 16-fold excess of DIPEA as a 1.0 M solution in DMF were added and the mixture shaken at 600 rpm for 80 min, then filtered. The same conditions were used to add each subsequent amino acid in compounds **9**−**16**.

At the end of the synthesis, resin-bound peptides were removed from the reaction block and transferred to 20 mL glass vials. EDT (2%), water (2%), and TIS (2%) in TFA (v/v/v/v) cooled to 0 °C were added to the resin samples and the vials shaken at 400 rpm for 90 min at room temperature. The reaction vessels were subsequently filtered into cold diethyl ether and the heterogeneous mixtures centrifuged at 3000 rpm and −5 °C for 10 min. The resultant pellets were washed with cold diethyl ether (3 × 25 mL), dissolved in distilled−deionized water, and lyophilized to yield white solids for the peptides containing the free ligand and pink solids if rhenium was present (Table 1).

Preparation of $[^{99m}Tc(CO)_3(OH_2)_3]^+$. A 10 mL penicillin vial fitted with a rubber septum and containing $K_2[BH_3{\cdot}CO_2]$, (8.5 mg, 63 μmol), $Na_2B_4O_7{\cdot}10H_2O$ (2.9 mg, 8.0 μmol), Na/K-tartrate (15.0 mg, 53 μmol), and Na_2CO_3 (4.0 mg, 38 μmol) was flushed with N_2(g) for 15 min. $^{99m}TcO_4^-$ (370 MBq) in 500 μL of saline was added by syringe, and the solution heated at 95 °C for 30 min. After cooling in an ice bath, the solution was neutralized by the addition of 12 M HCl. Gradient HPLC was performed to assess purity and yield.

Radiolabeling of Compound **7.** Compound **7** (1.0 mg, 0.71 μmol) in 200 μL of distilled−deionized water and 300 μL of CH_3CN was added via a syringe to the solution containing $[^{99m}Tc(CO)_3(OH_2)_3]^+$ (346 MBq) and the mixture heated to 55 °C for 3 h. The reaction mixture was subsequently loaded onto a solid-phase extraction cartridge (Waters, C_{18}), which had been conditioned with absolute ethanol (10 mL), CH_3CN (10 mL), 1:1 CH_3CN /10 mM HCl (10 mL), and 10 mM HCl (10 mL) prior to use. Small (1 mL) fractions were collected from the following gradient elution protocol: 10 mM HCl (7 × 1 mL), 1:4 CH_3CN/10 mM HCl (2 × 1 mL), 1:1 CH_3CN/10 mM HCl (2 × 1 mL), 4:1 CH_3CN/10 mM HCl (2 × 1 mL), and finally CH_3CN (5 × 1 mL). Compound **8b** eluted in fractions 11 and 12, which were concentrated to 200 μL, and the product was isolated by HPLC. The radiochemical yield of **8b** was 25%, and the radiochemical purity was >98%.

Ligand Challenge Experiments. Two vials each containing 3.7−7.4 MBq of purified **8b** in distilled−deionized water (100 μL) were incubated separately with 500 μL of solutions containing cysteine (0.010 M in 100 mM sodium phosphate buffer, pH = 7.2) and histidine (0.010 M in 100 mM sodium

[a] Peptides containing a single targeting sequence are written with the N-terminal group on the left. For the dimeric peptides, the first sequence is written with the N-terminus on the left, while the second group is written beginning with the amino acid attached to lysine at the branching point. [b] Indicates peak in the MS appears as m/2 and m/3 in positive ion mode.

phosphate buffer, pH = 7.2). The reaction mixtures were heated to 37 °C for 24 h after which aliquots were taken and analyzed by HPLC.

In Vitro Screening. Aβ^{1-40} (0.5 mg, rPeptide) was initially dissolved in 100 μL of 0.1% TFA and then 250 μL of 10 mM EDTA added (solution A). The presence of premature fibril formation was checked routinely by taking an aliquot of the solution (10 μL) and adding it to 500 μL of 2 μM Thioflavin T (ThT). The fluorescence was then measured at excitation and emission wavelengths of 440 and 485 nm, respectively, using 10 nm band-pass filters. After ensuring that no fibrils were present, an additional 250 μL of 20 mM sodium phosphate buffer (pH 7.4)/10 mM EDTA was added to solution A to form the Aβ^{1-40} stock solution (solution B). Rhenium-labeled peptides (**2**, **4**, **6**, **8a**, **10**, **12**, **14**, and **16**) were then dissolved in DMSO and diluted with 20 mM sodium phosphate buffer (pH 7.4) so that the final DMSO concentration was 25%. The required volume of rhenium peptide solution was then added to 40 μL of the Aβ^{1-40} stock solution (solution B) so that there was a 1:1 molar ratio of Aβ^{1-40} peptide and the desired rhenium peptide. The resulting solutions were then incubated for 5 days at 37 °C in duplicate. Following incubation, 40 μL of each solution was added to 500 μL of 2 μM ThT and fluorescence measured using a PerkinElmer LS55 luminescence spectrometer (10 nm slit widths). The percentage of amyloid (Table 2) was then calculated by dividing the fluorescence measurements by those found for the control consisting of 25% DMSO in 20 mM sodium phosphate buffer (pH 7.4)/10 mM EDTA and 40 μL of the Aβ^{1-40} stock solution (solution B).

RESULTS

The target peptides were prepared containing the single amino acid chelate−quinoline (SAACQ) ligand, which is an amino acid analogue that is capable of binding Tc and Re. The reported compounds were derived from the targeting sequence lvffa and the reverse sequence affvl, which are both reported to bind to β-amyloid plaques. The library consisted of 16 unique compounds, half of which possess a single targeting vector (Figure 1), while the remainder possess two targeting sequences (Figure 2). Biotin was introduced into select peptides to provide a convenient means to conjugate the peptides to vectors that facilitate crossing the BBB. For compounds **1**−**8a**, biotin and the SAACQ ligand were incorporated adjacent to the N-terminus of each peptide, as this site is known to tolerate introduction of large groups without affecting binding (*4*, *16*−*19*), while for compounds **9**−**16**, they were incorporated adjacent to the terminus that is distant to the two targeting sequences.

Peptides **1**−**16** (Table 1) were prepared in parallel on an automated 348 ACT synthesizer using a 40-well reaction block using all D-amino acids. Starting with Fmoc-glycine loaded Wang resin, peptides **1**−**8a**, which contain a single targeting sequence, were synthesized using standard Fmoc/HBTU peptide coupling and deprotection strategies (Scheme 1). In cases where biotin was introduced into the peptides, Fmoc-D-Lys(N$^{\epsilon}$-Biotin)-OH was added to the N-terminal amino acid again using standard coupling procedures.

Preparation of peptides containing two targeting sequences was accomplished using Fmoc-D-Lys(N$^{\epsilon}$-Mtt)-OH (Mtt = 4-methyltrityl) as a bridging site (Scheme 2). Mtt was selectively removed during peptide synthesis using a solution of 1% TFA and 3% TIS in DCM (v/v/v). The time required for complete deprotection was monitored by adding a small amount of resin to a 1:1 (v/v) solution of TFA and DCM. In the case where a yellow color appeared, which suggested the presence of Mtt, the reaction was allowed to continue (*23*, *24*). Following complete Mtt deprotection, the Fmoc group was then removed using 20% piperidine/DMF and the two targeting sequences built up simultaneously using an 8-fold excess of the appropriate Fmoc-protected amino acid derivatives per coupling step.

Conjugates **1**−**16** were cleaved from the solid support using a standard cleavage cocktail, precipitated from cold diethyl ether and collected by centrifugation (−5 °C, 10 min, 3000 rpm). Peptides were washed three times with cold diethyl ether, dissolved in water, and lyophilized to yield white solids. HPLC and mass spectrometry analysis confirmed the purity and molecular weight of the peptides (Table 1).

***In Vitro* Screening—Thioflavin T Inhibition Assay.** The Re-containing peptides **2**, **4**, **6**, **8a**, **10**, **12**, **14**, and **16** were incubated with the native peptide Aβ^{1-40} in a 1:1 ratio (10 μM) at 37 °C for 5 days in parallel with controls containing no competitor and 25% DMSO. It was found that 25% DMSO was required

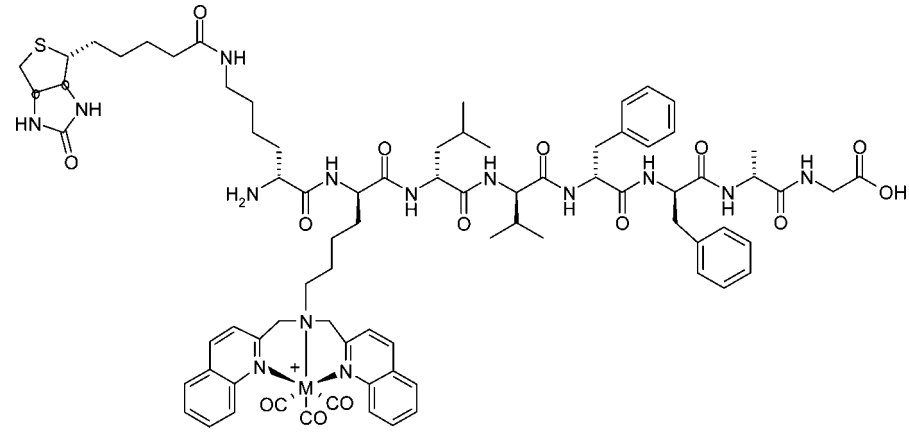

Figure 1. General structure for agents containing a single targeting sequence and biotin (k(N$^{\epsilon}$Biotin)-ReSAACQ-lvffag).

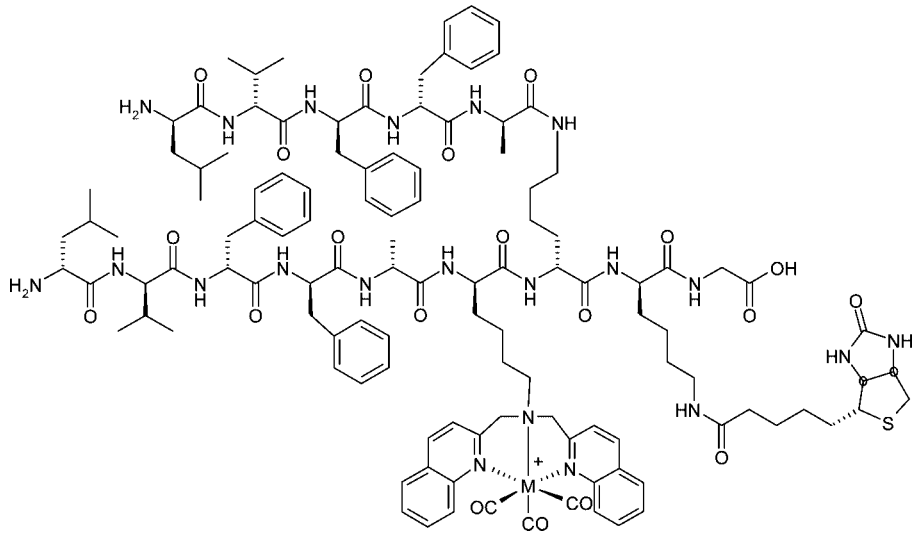

Figure 2. General structure for agents containing two identical targeting sequences and biotin (lvffa-ReSAACQ-k(N$^{\epsilon}$affvl)k(N$^{\epsilon}$Biotin)g).

in order to solubilize the peptide conjugates at the required concentration. Consequently, this solvent composition was used as the reference solution to calculate the percentage of amyloid. CH_3CN was initially considered, but test experiments demonstrated that the presence of this solvent increased the formation of fibrils when compared to controls. Following incubation with the peptides, 40 μL aliquots of each mixture were added to 500 μL of 2 μM ThT (giving a final DMSO content that was less than 2%) and the fluorescence intensity measured at excitation and emission wavelengths of 440 and 485 nm, respectively. The percentages of amyloid present (Table 2) were found by dividing the fluorescence intensities observed in the presence and absence of the competitor. Therefore, 100% amyloid would indicate that the peptide was unable to inhibit the formation of fibrils and would correspond to the largest fluorescence intensity.

Technetium Labeling. To demonstrate that sufficient quantities of the radiolabeled peptides could be produced for *in vivo* imaging studies, compound **7** in a mixture of water and CH_3CN was added to a solution containing $[^{99m}Tc(CO)_3(OH_2)_3]^+$ and the mixture heated at 55 °C for 3 h (Scheme 3). The labeled product **8b** was isolated by solid-phase extraction followed by semipreparative HPLC in 25% radiochemical yield in greater than 98% radiochemical purity. The retention time of **8b** in the γ-HPLC matched that for the Re reference standard **8a**, which was detected by UV (Figure 3).

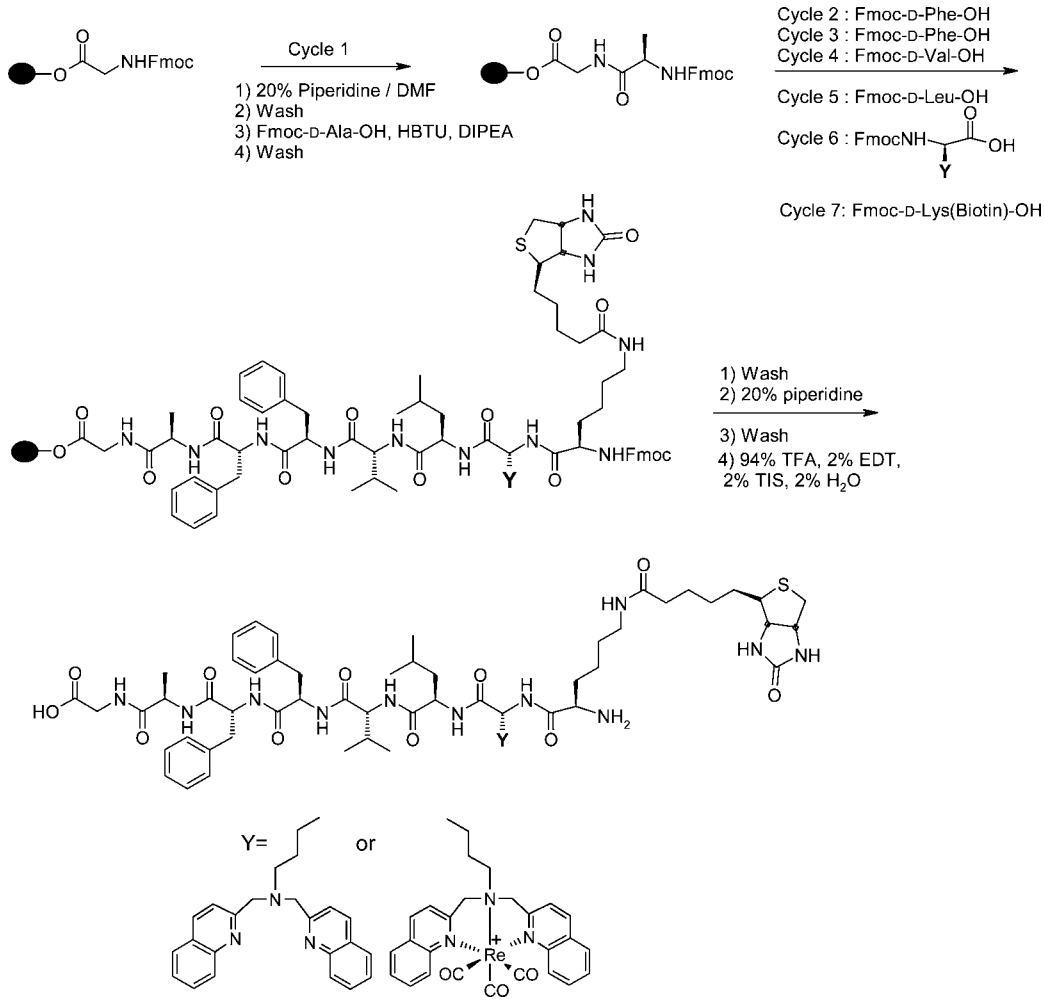
Cysteine and histidine challenge studies were performed to test the robustness of the metal complex. A large excess of each amino acid was added to solutions of **8b** and the mixtures heated at 37 °C for 24 h. The ^{99m}Tc complex showed only very minor signs of degradation (less than 2%) in either test (Figure 4).

DISCUSSION

β-breaker peptides are under investigation as an experimental therapeutic strategy for reducing amyloid plaque loads. Radioactive analogues labeled with ^{99m}Tc would afford the opportunity to study the distribution of variants of this class of compounds *in vivo*, and if they are capable of targeting amyloid plaques, the tracers could also be used to assess the impact of other emerging plaque-reducing treatment strategies. The advantages to using ^{99m}Tc over other isotopes are that it is widely available at a low cost and the vast majority of hospitals have the capacity to image Tc labeled compounds.

Our group recently described a new and robust method for derivatizing peptides with a chelating system (referred to as the single amino acid chelate quinoline or SAACQ) that is capable of binding ^{99m}Tc. The approach is flexible in that the chelate, which is derived from lysine, can be introduced at any position within the backbone of the peptide. A further advantage is that the chelate forms a robust metal complex with rhenium, which can also be incorporated into peptides. As a result, it is conceivable that libraries of all manners of chelate−peptide conjugates and the nonradioactive Re analogues of the target ^{99m}Tc complexes can be prepared in parallel. This would make it possible to screen an exact and nonradioactive replica of any peptide-targeted agent *in vitro* prior to undertaking an evaluation of the ^{99m}Tc analogue *in vivo*.

Scheme 1. Synthesis of Single Vector Peptides (3, 4) Containing Biotin



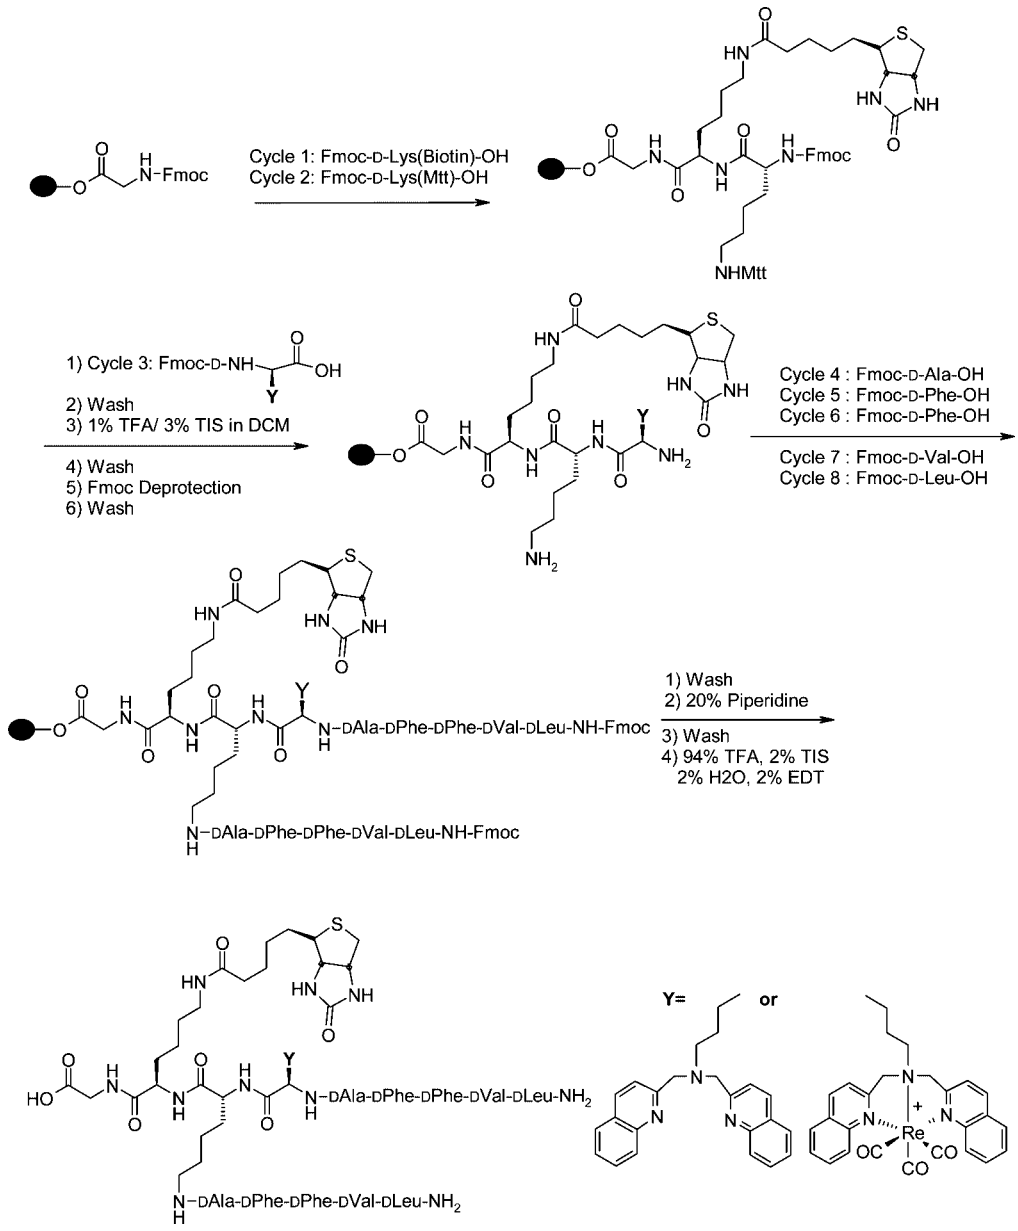
The peptide conjugates **1**−**16** were successfully prepared in parallel using standard peptide coupling strategies on an automated synthesizer. The peptides were constructed from an Fmoc-glycine loaded Wang resin using D-amino acids, which were employed to avoid future issues of premature degradation of the targeting agent *in vivo*. Peptides **1**−**8a** were prepared with a single copy of the lvffa or affvl sequences, while compounds **9**−**16** contained two copies. The introduction of the two vectors was made possible through the incorporation of Fmoc-D-Lys(Mtt)-OH, which provided a branching point. The preparation of multivalent peptides containing a single chelate group in the backbone of the probe as opposed to conjugated to the N-terminus or a pendent lysine is not commonly observed in radiopharmaceutical chemistry because the appropriately functionalized chelates have not been available until recently. For the bivalent peptides presented here, two identical targeting sequences were used. However, it is easy to see how two unique vectors could be introduced by removing the Mtt group after the first peptide has been synthesized. This type of approach could be used to incorporate a second sequence to improve affinity for the target or to alter the pharmacokinetics.

All peptide conjugates (**1**−**16**) were cleaved using a standard cleavage cocktail, and the conjugates were isolated in modest to good yields (Table 2) as white solids if they contained SAACQ and as pink solids if they contained Re. HPLC analysis indicated that both monomers and dimers containing SAACQ were prepared such that they did not require further purification. Analogues prepared with ReSAACQ were isolated in greater than 90% purity whereupon HPLC was used to increase this value to 99%. Despite the structural complexity of peptides, particularly compounds **9**−**16**, it was possible to prepare multimilligram quantities (greater than 50 mg) of each of the products. The ability to scale up reactions, which can be readily accomplished using the reported approach, is an important consideration for compounds that are going to move on to preclinical and clinical evaluation.

Peptide conjugates **2**, **4**, **6**, **8a**, **10**, **12**, **14**, and **16** were tested for their ability to inhibit fibrillogenesis using a standard assay for determining the ability of compounds, particularly peptides, to bind to β-amyloid plaques (*4*, *17*, *20*, *25*). Thioflavin T (ThT) is a dye used to stain amyloid fibrils found in the brains of AD patients postmortem (*26*). When ThT binds to plaques, there is a unique red shift in its absorption spectrum, which is distinct from the unbound dye. The unbound dye has excitation and emission maxima of 385 and 445 nm, which shift to 450 and 485 nm, respectively, upon binding (*17*, *27*). As a result, the formation of ordered $A\beta^{1-40}$ fibrils can be quantitated *in vitro* by measuring the increase in fluorescence intensity at the different wavelengths (*20*, *28*, *29*). β-breaker peptides have been evaluated using this technique and demonstrated good inhibition of ThT binding (*16*, *19*, *20*, *25*, *28*, *29*).

In order to solubilize the hydrophobic peptides, 25% DMSO was required, which was not problematic, as control experiments using 0%, 5%, and 25% DMSO did not show significant differences in the extent of fibril formation. All peptides studied demonstrated some inhibition of fibrillogenesis where somewhat surprisingly the peptides containing one copy of the targeting sequence were generally more effective than the dimers with the exception of compound **16**. In general, the peptides showed inhibition numbers that were as good as if not superior to the

Scheme 2. Synthesis of Peptides (11, 12) Containing Two Targeting Sequences and Biotin



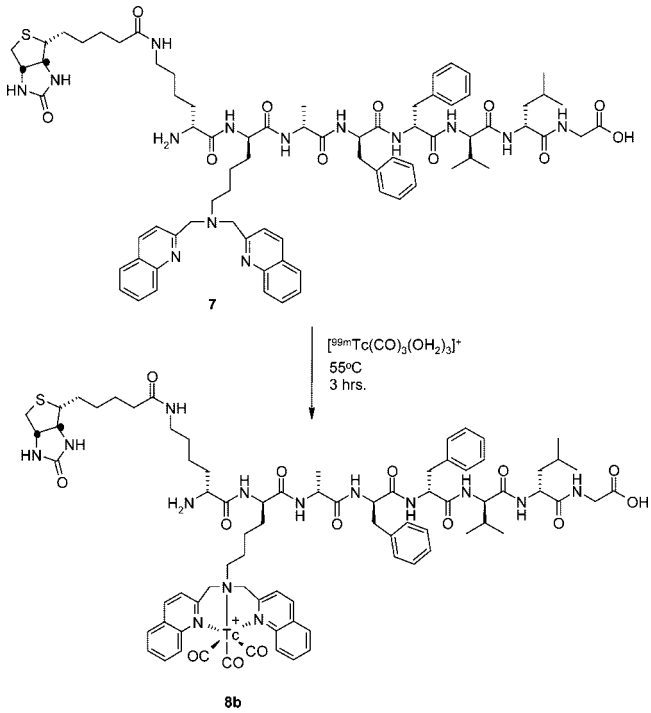
values reported for the parent peptides. For example, Soto and co-workers found lvffa had 89 ± 2.7% amyloid when present in a 10-fold excess compared to Aβ^{1-40}, while Zhang et al. prepared the D-analogue of klvff and reported the extent of amyloid formation as 76% (*17*). The rhenium analogue Re-SAACQ-lvffag was more potent and showed 48 ± 4% inhibition when used in a 1:1 ratio with Aβ^{1-40}. These results indicate that the presence of the metal complex and/or biotin derivative did not have a detrimental impact on the ability of the peptide to bind to amyloid. The most promising agents for further evaluation are compounds **8a** and **16**, both of which contain biotin as a site for further derivatization.

The next phase of the work was to demonstrate that the ^{99m}Tc analogues could be prepared and that the products are sufficiently robust to screen *in vivo*. Compound **7** was selected as a model compound and labeled using $[^{99m}Tc(CO)_3(OH_2)_3]^+$, which can be readily prepared in high yield using an instant kit (*30*−*34*). The labeled product, k(N$^{\epsilon}$Biotin)-^{99m}TcSAACQ-lvffag (**8b**) was isolated by solid-phase extraction and HPLC purification. The latter technique was employed to remove any unlabeled ligand, thus affording the product in high effective specific activity. Analytical HPLC in fact indicated that the reaction was quantitative; however, the isolated radiochemical yield after semipreparative HPLC was greatly reduced largely due to absorption of the labeled peptide on the column. Nevertheless, the desired product was isolated in high radiochemical purity (greater than 98%), and its retention time matched that of the Re analogue. Ligand challenge studies on the product showed no significant signs of degradation (Figure 4), which is consistent with the d^6 electronic configuration of the octahedral metal complex.

CONCLUSIONS

An amino acid derived chelating system for ^{99m}Tc and Re was used to create a small library of β-breaker peptide derivatives. The Re complexes, which were synthesized in parallel with the free ligands, were tested for their ability to inhibit fibrillogenesis, and two promising leads were identified. The ^{99m}Tc analogue of one of these was isolated in modest yield but exquisite purity, and it was resistant to ligand challenge against both histidine and cysteine. Amyloid plaques are associated with a number of diseases beyond simply AD,

Scheme 3. Labeling of Compound 7 with ^{99m}Tc



consequently molecular imaging probes for this particular target like those reported here could have significant utility in both clinical applications and in supporting early trials involving emerging therapeutics. Furthermore, the results presented demonstrate that the ReSAACQ system can be used to efficiently generate multiple Re-metallopeptides in parallel, which can be screened directly to identify lead agents in a time and resource efficient manner.

Synthesis and Proteomic Activity Evaluation of a new Isotope-Coded Affinity Tagging (ICAT) Reagent

Annalisa Guaragna,* Angela Amoresano, Vittoria Pinto, Gianluca Monti, Guido Mastrobuoni, Gennaro Marino, and Giovanni Palumbo

Dipartimento di Chimica Organica e Biochimica Università di Napoli Federico II Via Cinthia, 4 I-80126 Napoli, Italy. Received January 9, 2008; Revised Manuscript Received March 4, 2008

During recent years, quantitative proteome profiling has taken advantage of incorporating the traditional stable isotope dilution analysis into global scale or discovery-based proteomic experiments that use mass spectrometers as detectors to allow the pairwise study of differently expressed proteins. Quantitative protein analysis by means of the isotope-coded affinity tag (ICAT) method and tandem mass spectrometry (MS) enables the pairwise comparison of protein expression levels in biological samples. Herein, a modified ICAT reagent, named BAA-ICAT (*beta-alanine-arm*-ICAT) in which the polyether linker is replaced by a more water-soluble polyamide one, was investigated.

INTRODUCTION

Biological sciences are currently experiencing a sort of paradoxical situation in which the protein sequence, the corresponding coding gene, its chromosomic localization, or even the regulation mechanisms may have been elucidated but the biological role of the protein in the cell is still completely obscure. The static nature of the genome, in fact, cannot be compared to the dynamic properties of the proteome; protein expression profiles change several times during the cell cycle and are heavily affected by a number of intra- and extracellular stimuli (temperature, stress, apoptotic signals, etc.) (*1–6*). Moreover, the occurrence of alternative splicing and post-translational modifications led to a complete rethinking of the old paradigm "one gene−one protein". The key to understanding proteins and their behavior in biological systems lies in dramatically improving the analysis of the proteome. However, several classes of proteins, in particular, low-abundance proteins, remain difficult to characterize using standard proteomics techniques.

The driving technology nowadays supporting proteomic investigations is usually mass spectrometry (*7*); often the interest is not only in the identification of a peptide, but also in its quantification. To permit a global characterization of the proteome with more rapid and more detailed investigation, a great deal of intellectual effort has been focused on developing innovative methods (*8, 9*), including staining of proteins separated by two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) (*10*) and their quantitation by fluorescence intensity measurement (*11*) and heavy-isotope-coded affinity tags (ICAT) (*12, 13*). The latter holds several advantages over the gel-based protein quantifications in terms of convenience, reduction in process time, accuracy, and throughput. The ICAT strategy is based on the utilization of isotopically labeled chemical probes (ICAT, Figure 1) which interact with a specific set of proteins and allow the identification of proteins and a quantitative comparison of protein abundances between complex proteomes. ICAT reagent comprises three functional elements:

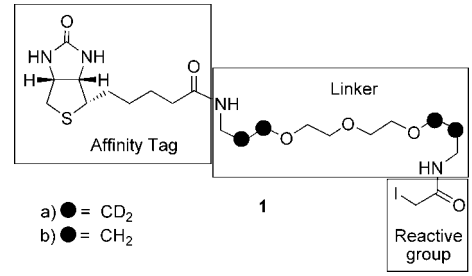

Figure 1. ICAT reagent in "heavy" (1a) or "light" (1b) form.

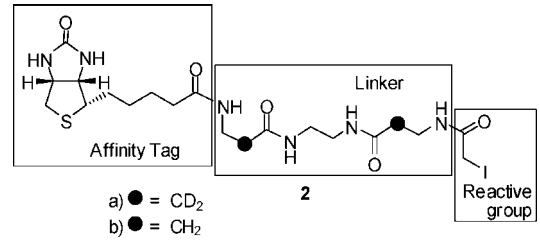

Figure 2. β-alanine-arm-ICAT (BAA-ICAT) structure.

(a) a specific reactive group able to covalently bind a nucleophile active site (e.g., primary alkyl iodide for covalent bond to SH groups of peptide cysteine residues); (b) an ethylene glycol linker that occurs in a "heavy" (see 1a) or "light" (see 1b) form and provides the basis for accurate quantification by MS spectrometry; (c) a biotin group that enables the isolation of the tagged peptides from complex peptide mixtures via avidin affinity chromatography.

This approach makes use of the principle of isotope dilution for analysis. For the quantitative analysis, two proteomes in two different states (e.g., normal and disease state) are labeled with the "light" (nondeuterated) and "heavy" (deuterated) ICAT reagent, respectively. For the quantitative comparison between two proteomes in two different states (e.g., normal and disease state), the "light" (nondeuterated) ICAT reagent is used to covalently tag proteins of one proteome and the "heavy" (deuterated) ICAT reagent is used to covalently tag proteins of a second proteome. The two proteomes are then combined for quantitative analysis. Analysis often involves further steps such

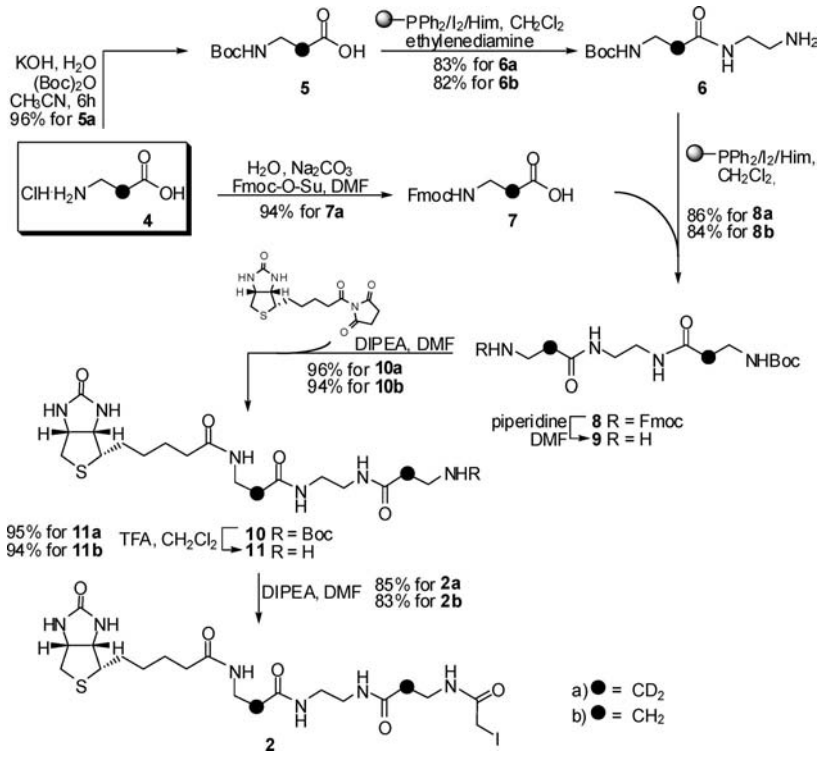
Scheme 1. Synthesis of β-Alanine-Arm-ICAT (BAA-ICAT) Reagents



as digestion of the mixture with a protease (e.g., trypsin), isolation of the ICAT-labeled peptides by affinity purification on avidin, and analysis of the isolated labeled peptide mixture by liquid chromatography–mass spectrometry (LC/MS). Prior mixing of proteins that have been labeled with either "light" or "heavy" ICAT reagents eliminates many of the potential experimental errors associated with postlabeling analysis. ICAT analysis profiles the relative amounts of cysteine-containing peptides derived from tryptic digests of protein extracts, leading to a deeper analysis of a proteome. A nice feature of the ICAT approach is that the in vitro incorporation of a stable isotope into one of the two samples being compared obviates the need to analyze by mass spectrometry the control and experimental samples separately.

Recently, the newest ICAT reagent (Applied Biosystems) has been introduced. This reagent has a thiol-specific reactive group adjacent to an alkyl linker, which contains either nine [^{12}C] or nine [^{13}C] atoms—thus resulting in a mass difference of 9 Da between the control and the corresponding experimental version of the same tryptic peptide (*14*). Compared with the first-generation ICAT reagent, the new cleavable reagent resulted in improved sequence information and gave higher-confidence quantitation in a single experiment. The alkyl linker in the ICAT reagent is connected to a (cleavable) biotin group which allows rapid affinity isolation of cysteine-containing tryptic peptides. Incorporation of ^{13}C into the ICAT heavy reagent molecule promotes coelution of the heavy and light isotopes in reversed-phase chromatography, thereby increasing accuracy of quantification measurements by mass spectrometry. In spite of the intriguing features of the above reagent, the high synthetic cost somewhat reduces its wide applicability.

In this context, a new ICAT reagent, namely, *beta-alanine-arm*-ICAT (BAA-ICAT), has been designed (Figure 2) by a straightforward and convenient synthetic procedure, which keeps most of the advantages from the last ICAT versions (such as high accuracy in analysis and similar chromatographic behavior of the light and heavy forms).

EXPERIMENTAL PROCEDURES

General Methods and Materials. All reagents were used as purchased without further purification except for iodoacetic anhydride purified by recrystallization (petroleum ether/ethyl ether, 7:3). All moisture-sensitive reactions were carried out under a positive pressure of N_2 using oven-dried glassware. Anhydrous DMF was distilled from BaO; anhydrous DCM was distilled from P_2O_5. Triphenylphosphine polymer-bound was purchased from Fluka Chemical Co. and dried under high

vacuum at 70 °C. Thin layer chromatography (TLC) was performed using Silica Gel 60 F254, Merck plates; visualization was achieved by inspection under UV light or with ninhydrin spray. Silica gel column chromatography was performed using Merck Kieselgel 60 (70–230 mesh). Melting points were measured with a capillary apparatus and are uncorrected. ^{1}H and ^{13}C NMR spectra were recorded with the following instruments: Varian Gemini 200, Varian Gemini 300 MHz, and Bruker DRX (400 MHz) spectrometers. ESI-MS: Waters Micromass ZQ were recorded in positive mode. HRMS-EI: Micromass Q-TOF micro.

Heavy and Light BAA-ICAT Synthesis and Characterization. *Preparation of 2,2-^{2}H-β-alanine (**4a**).* A magnetically stirred solution of pure 2,2-^{2}H-*N*-Boc-3-amino-proprionitrile (prepared according to ref (*15*)) (2.5 g, 14.5 mmol) in dioxane (20 mL) and conc aq hydrogen chloride (20 mL) was heated under reflux for 8 h. After cooling, to the solution aq $NaHCO_3$ until pH ∼ 8 (50 mL) was added and extracted with Et_2O (3 × 50 mL). The organic layer was then washed with water until neutral, dried (Na_2SO_4), and evaporated under reduced pressure to afford pure **4a** as a crystalline white solid (1.2 g, yield 93%): mp 122.2–124.4 °C. ^{1}H NMR (200 MHz, D_2O): δ 3.28 (bs, 2H, CH_2N). ^{13}C NMR (50 MHz, D_2O): ppm 34.5 (CD_2), 37.4, 179.3. ESI-MS: *m/z* = 150.04 $[M + Na]^+$. HRMS: calcd for $C_3H_6D_2ClNO_2$ 127.0369, found 127.0375.

*Compound **6a.*** To a magnetically stirred suspension of dry polystyryl diphenyl phosphine (2.0 g, ∼6.2 phosphine units) in anhydrous CH_2Cl_2 (15 mL) at room temperature, a solution of I_2 (1.57 g, 6.2 mmol) in the same solvent (20 mL) was added dropwise in the dark and under dry nitrogen atmosphere. After 15 min, imidazole (1.68 g, 24.8 mmol) and solid dideuterated 2,2-^{2}H-*N*-Boc-β-alanine (**5a**) (1.0 g, 5.2 mmol, prepared using standard conditions) were added in one portion to the suspension. The reaction was kept at room temperature for 3 h (TLC monitoring: $CHCl_3/CH_3OH$, 8:2) until all the starting amino acid was completely consumed. Then, ethylenediamine (5.2 mL, 78.0 mmol) was added in one portion to the mixture. After 1 h, the reaction mixture was filtered through a glass sintered funnel and washed with CH_2Cl_2. The filtrate was treated with a 5 N solution of $Na_2O_3S_2$ (20 mL) and the organic layer washed with brine until neutral. The combined water layers were re-extracted several times with a mixture of CH_2Cl_2/MeOH (95:5). The organic layers were dried (Na_2SO_4) and evaporated under reduced pressure to afford the pure dideuterated **6a** (83% yield): oil. ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.43 (s, 9H, Boc-CH_3), 2.80 (bs, 2H, CH_2N), 3.20–3.45 (m, 4H, 2 × CH_2N), 4.06 (bs, 2H, NH_2), 5.50 (bs, 1H, NH), 7.04 (bs, 1H, NH). ^{13}C NMR (100 MHz, $CDCl_3$): ppm 28.3, 36.1 (CD_2), 36.6, 41.0, 41.7, 79.1, 156.2, 172.1. ESI-MS: *m/z* 234.20 $[M + H]^+$. HRMS: calcd for $C_{10}H_{19}D_2N_3O_3$ 233.1708, found 233.1702.

*Compound **6b.*** Prepared under the same conditions reported above starting from a commercial sample of **5b** and ethylenediamine. (82% yield): mp 140.5–142.6 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ 1.38 (s, 9H, Boc-CH_3), 1.62 (bs, 2H, NH_2), 2.32 (t, *J* = 6.8 Hz, 2H, CH_2CO), 2.76 (t, *J* = 6.8 Hz, 2H, CH_2N), 3.20–3.42 (m, 4H, 2 × CH_2N), 5.52 (bs, 1H, NH), 6.78 (bs, 1H, NH). ^{13}C NMR (50 MHz, $CDCl_3$): ppm 28.2, 36.2, 36.7, 41.2, 41.9, 79.2, 156.2, 171.9. ESI-MS: *m/z* 232.19 $[M + H]^+$. HRMS: calcd for $C_{10}H_{21}O_3N_3$ 231.1583, found 231.1590.

*Compound **8a.*** To a magnetically stirred suspension of dry polystyryl diphenyl phosphine (1.2 g, ∼3.8 phosphine units) in anhydrous CH_2Cl_2 (10 mL) at r.t., a solution of I_2 (0.96 g, 3.8 mmol) in the same solvent (15 mL) was added dropwise in the dark and under dry nitrogen atmosphere. After 15 min, imidazole (1.0 g, 15.2 mmol) and **7a** (1.0 g, 3.2 mmol, prepared using standard conditions) were added in one portion to the suspension. The reaction was kept at room temperature for 3 h (TLC monitoring: $CHCl_3/CH_3OH$, 8:2) until all the starting amino acid was completely consumed. Then, **6a** (0.67 g, 3.5 mmol) was added in one portion to the mixture. After 12 h, the reaction mixture was filtered through a glass sintered funnel and washed with a mixture of CH_2Cl_2/MeOH (95:5). The filtrate was treated with a 5 N solution of $Na_2O_3S_2$ (20 mL) and the organic layer washed with brine until neutral. The organic layers dried (Na_2SO_4)

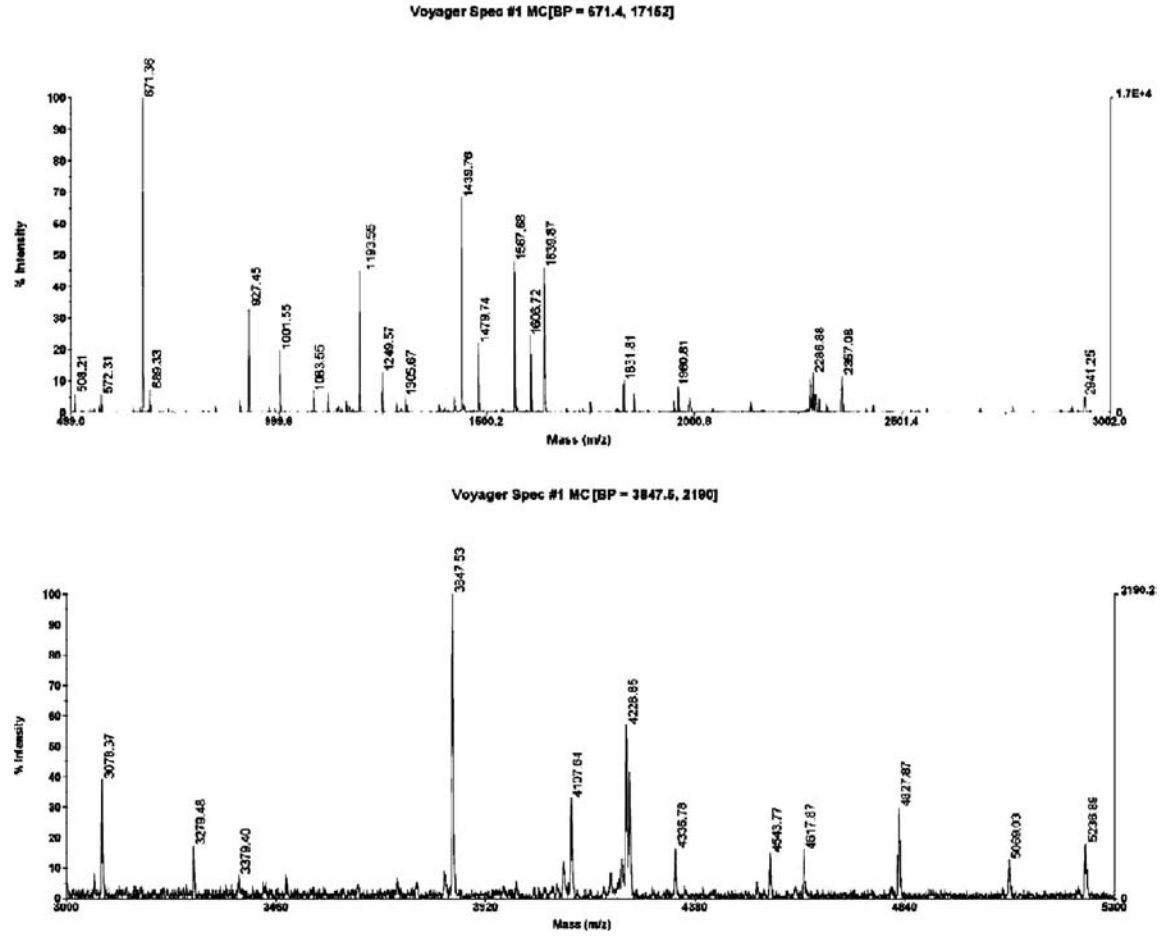

Figure 5. MALDIMS spectrum of triptic BSA digest modified with BAA-ICAT.

and evaporated under reduced pressure afforded a crude product which was purified by crystallization (from EtOAc) giving the pure dideuterated **8a** (1.5 g, 86% yield): mp 137.2–138.7 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ 1.38 (s, 9H; Boc-CH_3), 2.78 (t, J = 6.8 Hz, 2H; CH_2N), 2.90–3.00 (m, 2H; CH_2N), 3.01–3.18 (m, 1H, Fmoc-CH), 4.24–4.42 (m, 6H; 2 × CH_2N, Fmoc-CH_2), 4.10 (bt, 1H; NH), 5.34 (bs, 1H; NH), 6.65 (bs, 1H; NH), 7.22–7.43 (m, 4H; arom-H), 7.56 (d, J = 7.3 Hz, 2H; arom-H), 7.76 (d, J = 7.0 Hz, 2H; arom-H). ^{13}C NMR (50 MHz, $CDCl_3$): ppm 28.2, 35.8 (CD_2 weak multiplet), 36.7 (CD_2 weak multiplet), 38.6, 39.5, 40.2, 40.7, 77.6, 79.1, 109.7, 120.0, 121.4, 127.2, 128.9, 137.4, 139.4 (12 C), 155.4, 157.2, 170.5, 171.5. ESI-MS: m/z 529.32 $[M + H]^+$. HRMS: calcd for $C_{28}H_{32}D_4O_6N_4$ 528.2886, found 528.2895.

*Compound **8b.*** Prepared under the same conditions reported above starting from **6b** and a commercial sample of **7b**. (84% yield), mp 130.5–132.3 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ 1.38 (s, 9H; Boc-CH_3), 2.09–2.23 (m, 4H, 2 × CH_2CO), 2.80 (t, J = 6.8 Hz, 2H; CH_2N), 2.89–3.00 (m, 2H; CH_2N), 3.02–3.16 (m, 1H, Fmoc-CH), 4.22–4.40 (m, 6H; 2 × CH_2N, Fmoc-CH_2), 4.11 (bt, 1H; NH), 5.33 (bs, 1H; NH), 6.64 (bs, 1H; NH), 7.21–7.44 (m, 4H; arom-H), 7.57 (d, J = 7.3 Hz, 2H; arom-H), 7.77 (d, J = 7.0 Hz, 2H; arom-H). ^{13}C NMR (50 MHz, DMSO-d_6): ppm 28.3, 35.6, 36.9, 38.7, 39.4, 40.4, 40.5, 77.5, 79.0, 109.9, 120.2, 121.5, 127.5, 128.8, 137.5, 139.6 (12 C), 155.4, 157.2, 170.4, 171.5. ESI-MS: m/z 525.29 $[M + H]^+$. HRMS: calcd for $C_{28}H_{36}N_4O_6$ 524.2635, found 524.2630.

*Compound **9a.*** To a solution 5% piperidine solution in *N*,*N*-dimethylformamide (DMF) (15 mL) **8a** (1.4 g, 2.6 mmol) is added at room temperature. After 2 h, the solvent was evaporated under reduced pressure to afford a crude product which was purified by silica gel column chromatography ($CHCl_3$/CH_3OH, 8:2) to give the pure **9a** (0.77 g, 95% yield): mp 129.4–131.0 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ 1.43 (s, 9H; Boc-CH_3), 1.78 (bs, 2H; NH_2), 3.10 (s, 2H; CH_2N), 3.38–3.44 (m, 6H; 3 × CH_2N), 5.45 (bt, J = 5.6 Hz, 1H; NH), 6.78 (bs, 1H; NH), 7.50 (bs, 1H; NH). ^{13}C NMR (50 MHz, $CDCl_3$): ppm 28.4, 36.6 (CD_2 weak multiplet), 37.7 (CD_2 weak multiplet), 39.3, 40.1, 79.4, 156.0, 172.2, 173.5. ESI-MS: m/z 329.34 $[M + Na]^+$. HRMS: calcd for $C_{13}H_{22}D_4O_4N_4$ 306.2205, found 306.2213.

*Compound **9b.*** Prepared under the same conditions reported above starting from **8b**. (96% yield), mp 127.8–129.3 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ 1.40 (s, 9H, Boc-CH_3), 1.80 (bs, 2H; NH_2), 2.14–2.40 (m, 4H; 2 × CH_2CO), 2.90–3.13 (m, 2H; CH_2N), 3.38–3.45 (m, 6H; 3 × CH_2N), 5.45 (bt, J = 6.0 Hz, 1H; NH), 6.78 (bs, 1H; NH), 7.70 (bs, 1H; NH). ^{13}C NMR (50 MHz, $CDCl_3$): ppm 28.2, 36.3, 37.9, 39.2, 39.9, 79.3, 156.1, 172.1, 173.3. ESI-MS: m/z 325.25 $[M + Na]^+$. HRMS: calcd for $C_{13}H_{26}O_4N_4$ 302.1954, found 302.1949.

*Compound **10a.*** To a magnetically stirred solution of biotin succinimidyl ester (0.70 g, 2.3 mmol) in anhydrous DMF (5 mL) at room temperature and under nitrogen atmosphere, *N*,*N*-diisopropylethylamine (0.39 mL, 0.05 mmol) and **9a** (15 mg, 0.05 mmol) were added. After 5 h (TLC: $CHCl_3$/MeOH, 8:2), the solvent was removed under reduced pressure to afford a crude product which was purified by crystallization (from $CHCl_3$) giving the pure **10a** (1.2 g, 96% yield). mp 230.0 °C dec. ^{1}H NMR (200 MHz, CD_3OD): δ 1.44 (s, 9H; Boc-CH_3), 1.52–1.79 (m, 6H; 3 × CH_2), 2.18 (t, J = 7.3 Hz, 2H; CH_2CO), 2.71 (d, J = 12.7 Hz, 1H; CH_aS), 2.92 (dd, J = 4.8 Hz, J = 12.7 Hz, 1H; CH_bS), 3.20–3.25 (m,

Proteomic Activity evaluation. *Materials and methods.* Carbonic anhydrase, lysozime, alpha lactalbumine, RNase A, trypsin, EDTA, iodoacetamide and *tert*-butylphosphine were purchased from Sigma and tris(hydroxymethyl)-aminoethane from Fluka. Prepacked PD-10 gel filtration cartridges were from Pharmacia. Prepacked Sep pak C18 cartridges were purchased from Waters. DHB and α-cyano-hydroxycinnamic acid were purchased from Sigma. C18 reverse phase HPLC *narrow bore* (250 × 2.1 mm, 5 μm) was from Phenomenex. Guanidinium chloride and resin conjugated with avidin was from Pierce. All other reagents and solvents were of the highest purity available from Carlo Erba.

Proteins from Pseudoalteromonas haloplanktis TAC 125. The sample of liquid culture of *P. haloplanktis* was centrifuged and the supernatant recovered. The low molecular weight fraction was then eliminated by gel filtration on PD10 columns. The purification was performed as described above in this section, but the temperature was kept at 2.0 °C to minimize proteolytic activity of proteases. The protein containing fractions were then pooled, lyophilized and stored at –20 °C till to the analysis.

Enzymatic hydrolyses. Protein solution was digested with Trypsin in 50 mm ammonium bicarbonate buffer, pH = 8.0, at 37 °C overnight, using a 1:50 w:w enzyme-to-substrate ratio. Peptide mixtures were either directly analyzed by MALDI mass spectrometry or submitted to LC-MS analysis.

MALDI MS Analyses. MALDI-TOF mass spectra were recorded using an Applied Biosystem Voyager DE-PRO instrument. A mixture of analyte and matrix solution (α-cyano-hydroxycinnamic acid 10 mg/mL in 66% acetonitrile, 0.1% TFA, in MilliQ water) was applied to the metallic sample plate and dried down at room temperature. Mass calibration was performed using external peptide standards. Raw data were analyzed using the computer software provided by the manufacturer and reported as monoisotopic masses.

Liquid Chromatography-Electrospray Tandem Mass Spectrometry (LC/ES/MS/MS). Tryptic peptide mixtures obtained from *in situ* digestions as previously described were also analyzed by "on-line" LC/ES/MS/MS using an LCQ ion trap instrument (Finnigan Corp., San José, CA). Proteolytic digests were fractionated on a HP 1100 HPLC apparatus (Hewlett-Packard, Palo Alto, CA) using a narrow-bore Phenomenex Jupiter C18 column (250 × 2.1 mm, 300 Å) (Torrance, CA) with 0.05% TFA, 5% formic acid in H_2O (solvent A), and 0.05% TFA, 5% formic acid in acetonitrile (solvent B) by means of a linear gradient from 5% to 70% solvent B in 65 min at a flow rate of 0.2 mL/min. The effluent was directly inserted into the ion source through the electrospray probe, and both ES/MS and ES/MS/MS spectra were acquired throughout the entire analysis by using the software provided with the instrument.

BAA-ICAT Derivatization. S−S bridge reduction was carried out in denaturing buffer (guanidinium chloride 6 m, Tris/HCl 300 mm, EDTA 5 mm, pH = 8.3) using 100:1 TBP/cysteine molar ratio, under nitrogen for 30 min at 37 °C. Reduced samples were derivatized with BAA-ICAT using 10:1 reactive/cysteine molar ratio under nitrogen for 2 h, at 25 °C in the dark. The sample was purified by gel filtration on a PD10 column in 10 mM AMBIC pH = 8.0. After trypsin digestion, derivatized peptides were purified by an affinity chromatography step using avidin agarose resin. The coupling step was performed in phosphate buffer 0.1 M, NaCl 0.15 m, pH = 7.2, for 2 h at room temperature under stirring. The biotinylated peptides were eluted by using a solution containing acetonitrile 50%, H_2O 50%, TFA 0.5%.

RESULTS AND DISCUSSION

Synthesis of ICAT Reagent Analogue. As a part of our ongoing program directed toward the achievement of new reagents for protein expression analysis, here we describe the synthesis and applications of a novel type of isotope-coded affinity tags (ICAT) reagents **2a** and **2b**, respectively, in "heavy" and "light" form, in which the polyether linker is replaced by

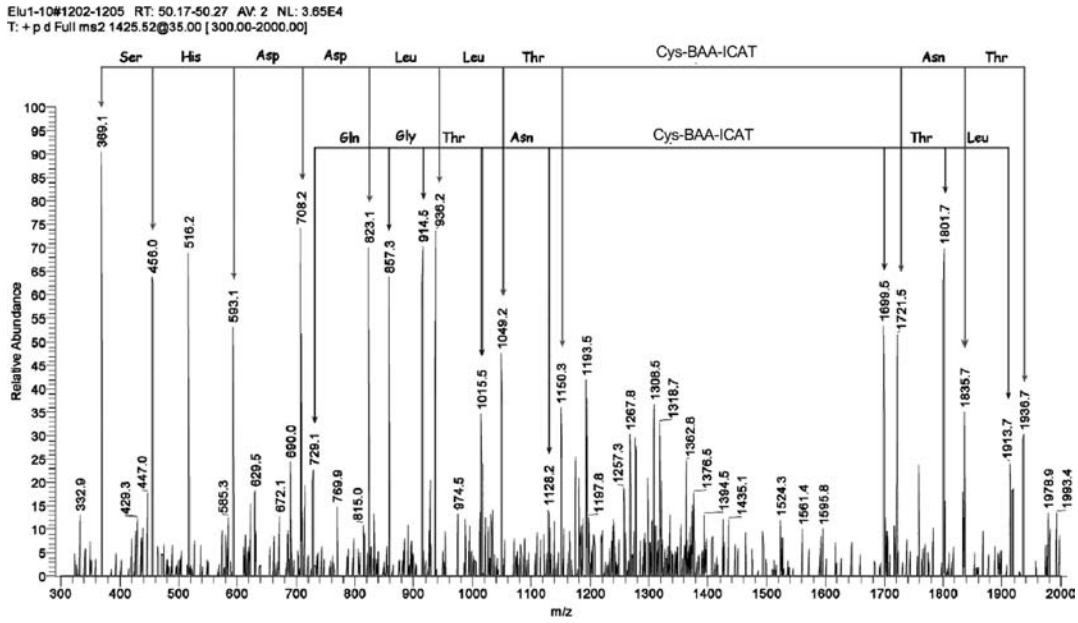

Figure 7. MSMS spectrum of the precursor ion at *m*/*z* 1425.6. Proper annotation of the fragmentations are indicated.

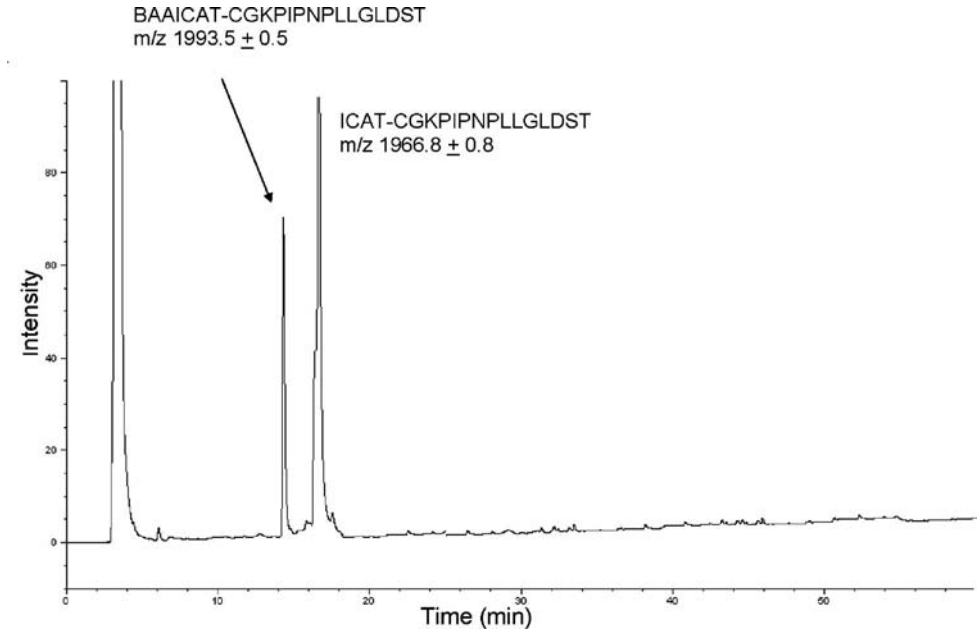

Figure 8. Total ion current profile of peptide mixture constituted of BAA-ICAT (*m*/*z* 1993.5 ± 0.5) and ICAT (*m*/*z* 1966.8 ± 0.8) derivatives.

a more water-soluble polyamide one. We introduce the acronym *beta-alanine-arm*-ICAT (BAA-ICAT) to indicate this novel reagent.

Our strategy is essentially based on the following: (i) preparation of "light" and "heavy" linkers by reaction of ethylenediamine with β-alanine and 2,2-dideuterated β-alanine, respectively; (ii) coupling reaction of activated biotin with the prepared linkers; (iii) addition of the reactive iodoacetyl group to the free amino function of biotinylated linkers.

The first step of our synthesis relies on the preparation of a linker which consists of two β-Ala units bridged by an ethylenediamine spacer. The linker was prepared in both light (d_0) and heavy (d_4) forms; the former was prepared starting from commercially available β-alanine; conversely, the latter (d_4) was obtained using a 2,2-dideuterated-β-alanine specially prepared by a suitably modified α-amino acid homologation procedure (*15*).

Our first attempts in using a free diamine linker failed due to the formation of a bis-biotinylated compound. To ensure monobiotinylation during the coupling reaction with biotin, a large molar excess of diamine linker was used. Unfortunately, the excess of unreacted linker, being quite polar, is difficult to recover from the reaction mixture and results in a significant loss of the diamine. To overcome these problems, we planned to prepare an orthogonally protected diamine linker like **8** (Scheme 1).

The synthesis of the heavy linker was then accomplished as follows. Deuterium-labeled units **5a** (2,2-^{2}H-*N*-Boc-β-alanine) and **7a** (2,2-^{2}H-*N*-Fmoc-β-alanine) were prepared in four steps (starting from commercially available α-glycine) by a suitably modified α-amino acid homologation procedure we have recently reported (*15*). The key step of our methodology is the deuterium incorporation by means of sodium borodeuteride ($NaBD_4$) during the reduction of the α-amino acid carboxylic

function, which enables us to obtain the final compound **4a** with 98% isotopic purity. The protection of the NH_2 functionality with a Boc or Fmoc group, respectively, led to heavy **5a** and **7a**. Carboxylic acid function activation of **5a**, for the amide bond formation, was accomplished by means of the *in situ* formed acyl iodide using a suspension of triphenylphosphine polymer-bound/iodine complex (polystyryl diphenyl iodophosphonium iodide) (*15, 16*) in anhydrous dichloromethane (Scheme 1).

After some minutes, ethylene diamine was added to the suspension affording the amide **6a** in 83% yield. The triphenylphosphine polymer-bound/halogen complex is a Lewis acid and a dehydrating agent widely employed in miscellaneous reactions with low environmental impact (*17*). In fact, it avoids contamination from byproducts and use of non-environmentally friendly solvents in the purification processes. Indeed, under our conditions the phosphine oxide that is linked to the polymeric matrix and imidazolium salt are the only byproducts of the reaction and can thus be easily separated by simple filtration.

The free amine **6a** was then coupled with 2,2-^{2}H-*N*-Fmoc-β-alanine **7a** using the same carboxylic acid activation procedure, so far described, leading to **8a**. Once more, no further purification was necessary; a simple filtration of the suspension allowed us to obtain the pure orthogonally protected diamine linker **8a** in 86% yield. Finally, selective removal of Fmoc protection with piperidine afforded amine **9a** in almost quantitative yield.

The light linker **9b** (d_0) was synthetized using the same synthetic protocol starting from the commercially available *N*-Boc-β-alanine (**5b**) and *N*-Fmoc-β-alanine (**7b**).

Linkers **9a**,**b** were then separately coupled to biotin in the activated form biotin succinimidyl ester in anhydrous dimethylformamide (DMF), in the presence of *N*,*N*′-diisopropylethylamine (DIPEA), to smoothly give **10a**,**b** in 96% and 94% yields, respectively. *N*-Boc protecting group removal, by treatment with TFA, led to biotinylated (d_4)-linker monoamine **11a** and to its analogue in the light form **11b**, which were finally treated with iodoacetic anhydride affording the (heavy) ICAT reagent analogue **2a** in 85% yield and the (light) reagent **2b** in 83% yield.

Specific Proteomic Activity Evaluation. The first step was based on the mass spectral analysis of light and heavy form of the reagent. Equimolar amounts of reagents (1 nmol) were mixed and submitted to LCMS analysis. As shown in Figure 3, a single peak could be observed in the TIC profile. The ESMS spectrum showed the occurrence of two signals at *m*/*z* 597.5 and 601.2 corresponding to the light and heavy forms of BAA-ICAT, respectively, thus indicating the coelution of the reagents. The mass difference within the heavy BAA-ICAT reagent (4 Da) reliably allows a good separation between the molecular ions. The light and heavy molecules are chemically identical; the isotope effect leading to the separation of the species in reversed-phase chromatography seems to be removed. The coelution of the isotopes could probably be attributed to a reduced number of deuterium atoms and to the different chemical nature (polyamide) of the BAA-ICAT. This represents an advantage of this new reagent with respect to commercial ICAT. In fact, in order to solve the isotope effect which complicated quantitation analysis, cleavable ICAT reagents were proposed (*14, 18, 19*). Moreover, the ESMS analysis revealed that the preparation of the d_4 analogue was almost homogeneous. Indeed, only 10% of the d_3 form can be detected on the basis of the isotope distribution of compound **2a** (Figure 3, inset).

In a proof of principle, the novel reagent **2a** was tested by using RNase A as the standard protein. An aliquot of protein was reduced and the eight cysteine residue modified with **2a** as previously described (*20*). The protein was purified by reverse-phase HPLC and directly analyzed by ESMS. Figure 4 shows the corresponding ES spectra transformed on a real mass scale. The analysis of the modified protein sample showed the presence of a major component whose molecular weight was measured as 17438.3 $\pm$ 0.6 Da. This value was attributed to the protein carrying eight modifying groups.

The identification of the modification sites was accomplished by employing the MALDI mapping procedure. Thus, a labeled protein sample was submitted to trypsin digestion and the resulting peptide mixture directly analyzed by MALDIMS.

Table 1 shows the mass signals recorded in the spectra that were assigned to the corresponding peptides within the enzyme sequence on the basis of their mass value and trypsin specificity, taking into account a mass increment of 468.1 Da due to the labeling moiety. The MALDI mass spectrum showed the occurrence of a series of signals attributed to the peptide fragments containing cysteine residues completely modified by the reagent. The peptide mixtures were then purified by affinity chromatography and the resulting mixture analyzed by MALDIMS, thus revealing the absence of signals corresponding to the unmodified peptides.

The fine localization of the modifying group was achieved by LCMSMS analysis of the modified peptide mixture, and the ESMSMS results are summarized in Table 1.

Similar results were obtained when the labeling procedure was carried out on bovine serum albumin, a model protein containing 35 cysteine residues. Figure 5 showed the direct MALDIMS analysis carried out on the peptide mixture. All the assignments were manually performed on the basis of the theoretical mass values of the tryptic peptides within BSA sequence and on the basis of mass increment of 468.1 Da due to the BAA-ICAT moiety. A total sequence coverage of 88% was observed by MALDIMS spectral analysis, leading to the identification of 30 BAA-ICAT modified cysteines (on a total of 35) as summarized in Table 2. No peptides carrying unmodified cysteine residues were detected.

After the affinity purification, only biotinylated species were recovered, indicating the disappearance of the unmodified peptides. As an example, Figure 6 shows an enlargement of the MALDIMS spectrum before (panel A) and after (panel C) the affinity purification step. The yield of the purification step is illustrated in panel B. The MALDIMS spectrum in fact showed the disappearance of modified Cys-containing peptides. The same analysis performed using the ICAT kit from Applied Biosystem gave similar results, allowing the identification of peptides containing 28 biotinylated cysteine residues.

Finally, a mixture of equimolar amount of four proteins (lysozyme, α-lactalbumin, RNaseA, and carbonic anhydrase) was submitted to the proposed strategy, thus leading to the enrichment and fine characterization of the labeled peptides as summarized in Table 3. As a whole, the mass spectra analyses allowed the identification of peptides containing 21 on 24 modified cysteine residues present in the protein mixture tested.

To verify the feasibility of the proposed labeling reactive, the optimized protocol was then applied on the protein sample from *Pseudoalteromonas haloplanktis* as described above. Our group has a long-standing tradition in the study of this antarctic bacterium (*21, 22*) Thus, a proteomic study could by useful in highlighting the molecular processes of this psicrophilic organism. The peptide mixture was directly analyzed by RP-HPLC/ESI-MSMS.

Here, we report preliminary results on the selective labeling of cysteine residues of the soluble secreted proteins of this bacterium. A direct database search was not possible because the *P. haloplanktis* genome is still not available on the Internet. In fact, only recently (*23*) has the genome of the latter been deciphered, but not yet annotated. However, manual interpreta-

tion of the MSMS spectra allowed us to obtain ten internal sequences of cysteine-containing peptides labeled with reagent **2a**.

As an example, we report the spectrum, properly annotated (Figure 7) and obtained by MSMS analysis performed on the precursor ion at *m*/*z* 1425.6. Manual interpretation of the tandem MS spectra led to the internal sequence SHDDLLTCNTGN showing the occurrence of a Cys residue modified with a **2a** moiety. Optimization of labeling conditions and the identification of labeled bacterial proteins by homology search are still in progress.

The labeling strategy has been tuned by using the light form of the reagent. The rational behind the choice of this reagent is its higher water solubility, thus avoiding complications arising from solubility in aqueous buffer with respect to the already proposed ICAT reagents. As an example, two aliquots of a standard Cys-containing peptide (CGKPIPNPLLGLDST, MW 1524.8) were derivatized with standard light ICAT and BAA-ICAT, respectively, and submitted to LCMS analysis. As shown in the Figure 8, a lower retention time was observed for the BAA-ICAT modified peptide (ESMS analysis: *m*/*z* 1993.5, mass shift, 468.1 Da) with respect to the peptide derivatized with ICAT reagent (ESMS analysis: *m*/*z* 1966.8, mass shift, 442.2 Da), thus indicating reduced hydrophobicity for the BAAA-ICAT with respect to the commercial ICAT.

Moreover, the synthesis has been accomplished in a few steps and in reasonable overall yield. The new residues in the sequence were shown to be stable and easily identifiable under general conditions for tandem mass spectrometric sequencing.

As further application, it would be possible to address the problem of quantification, due to the availability of the heavy form of BAA-ICAT. Quantitation analysis could be performed basically following the strategy outlined by Gygi et al. (*12*) The peptides could be quantified by measuring, in the mixture, the relative signal intensities for pairs of peptide−ions of identical sequence differentially labeled with light or heavy BAA-ICAT.

ACKNOWLEDGMENT

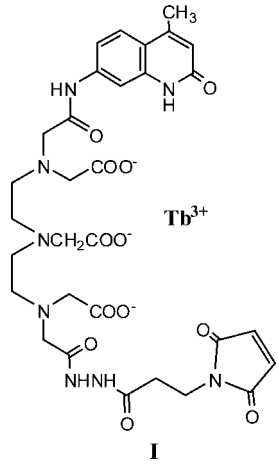
Received January 22, 2008; Revised Manuscript Received March 5, 2008

Polyaminocarboxylate-based luminescent lanthanide complexes have unusual emission properties, including millisecond excited-state lifetimes and sharply spiked spectra compared to common organic fluorophores. There are three distinct sections in the structure of the luminescent lanthanide chelates: a polyaminocarboxylate backbone to bind the lanthanide ions tightly, an antenna molecule to sensitize the emission of lanthanide ions, and a reactive group to attach to biomolecules. We have previously reported the modifications on the chelates, on the antenna molecules (commonly cs124), and on the reactive sites. In searching for stronger binding chelates and better protection from solvent hydration, here we report the modification of the coordination number of the chelates. A series of 9- and 10-dentate chelates were synthesized. Among them, the 1-oxa-4,7-diazacyclononane (N_2O)-containing chelate provides the best protection to the lanthanide ions from solvent molecule attack, and forms the most stable lanthanide coordination compounds. The TTHA-based chelate provides moderately good protection to the lanthanide ions.

INTRODUCTION

Luminescence resonance energy transfer (LRET) is a modification of the widely used technique of fluorescence resonance energy transfer (FRET) and can be used to accurately determine the distance between two sites bearing an energy transfer donor and an energy acceptor in a biomolecule (*1, 2*). In LRET, the energy transfer donor is a luminescent lanthanide atom and the acceptor is a conventional (organic) fluorophore. The lanthanide energy transfer donor typically involves a chelate to bind and protect the lanthanide from solvent quenching effects, a covalently attached organic chromophore to act as an antenna to absorb excitation light and transfer the energy to lanthanide ions, and a covalently attached reactive site to attach to biomolecules (see structure **I**, DTPA-cs124-maleimide, as an example).



I

The fundamental advantages of LRET arise because the donor emission is long-lived with millisecond lifetime and is sharply spiked (peaks of a few nanometer widths) (*1*), has a high quantum yield (*3*), and is unpolarized (*4*). This enables temporal and spectral discrimination against the acceptor (a conventional fluorophore), which has nanosecond-lifetime and is broadly spread in wavelength (*1*).

We have published a number of papers on LRET (partially reviewed in *1, 5*), showing its advantages in model systems such as DNA oligomers (*6, 7*) and the ability to measure distance changes of an angstrom reliably even on large protein complexes such as actomyosin (*8, 9*) and in ion channels in living cells (*10–12*). Other researchers have successfully used the technique on DNA−protein complexes (*13–15*), actomyosin (*16*), protein−protein interactions in cells (*17, 18*), and detection of binding of many different biomolecules (*2, 19*).

The current DTPA (diethylenetriaminepentaacetic acid)-based chelates (**I**) works moderately well with both terbium and europium. The disadvantage of such chelates is that they are 8-dentate chelates; therefore, one or more water molecules can bind to lanthanide ions when these chelates coordinate to lanthanide ions (*20*). Because of the hydration on the lanthanide ions, the lifetime is relatively shortened by the solvent quenching effect. Also, the relatively low stability constant or fast dissociation and trans-metalation kinetics limits their application in the physiological environment. On the other hand, here we show that two different chelates, TTHA (triethylenetetraamine-hexanoic acid) and a chelate made from diazacrown ethers, have more than 8 coordination numbers, minimizing the hydration to the lanthanide.

TTHA-based lanthanide chelate is a 10-dentate ligand and has shown no hydration to lanthanide ions when coordinated (*21*). Although TTHA-based lanthanide chelates with coumarin derivatives as sensitizers (which works for Eu^{3+} only) have been reported (*13*), no TTHA-based amine reactive or thiol reactive lanthanide probes with cs124 as sensitizer (which works with both Tb^{3+} and Eu^{3+}) have been synthesized. Here, we report the syntheses of TTHA-based thiol reactive chelates.

The class of macrocycles known as crown ethers has been widely studied since their metal ion-coordinating capabilities were first reported by Pedersen (*22*). Derivations of the crown ether include the replacement of one or more of the ring's oxygen atoms with nitrogen atoms, resulting in azacrown ethers,

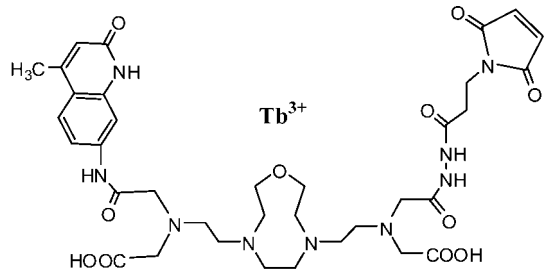
and/or the attachment of one or more side arms to the ring to form a so-called lariat or armed crown ether. There are numerous publications on the metal-complexing properties of diazacrown ethers containing side chains attached to the nitrogen atoms of the macrocycle (*23*). We have synthesized a new type of lanthanide chelate derived from diazacrown ethers. Our chelates contain two ethyliminodiacetic acid side chains and have increased ability to bind lanthanide ions to better protect the lanthanide ions from solvent hydration (see structure **II**) and from other potential chelators such as ATP and EDTA.



II

EXPERIMENTAL METHODS

Chemicals and Materials. The following were purchased from Sigma-Aldrich: triethylenetetraminehexaacetic acid (TTHA), 7-amino-4-methyl-2-(1*H*)-quinolinone (carbostyril 124, cs124), isobutyl chloroformate, anhydrous dimethyl sulfoxide (DMSO, in sure seal bottle), and triethylamine (for reaction). DMSO and triethylamine were dried over activated molecular sieves before use. 1,7-Diaza-12-crown-4 (N_2O_2) was purchased from Acros Organics. Triethylenetetramine hexaacetic acid dianhydride (caTTHA) (*24*), 1-oxa-4,7-diazacyclononane (N_2O) (*25*), and *N*,*N*-bis[(*tert*-butoxycarbonyl)methyl]-2-bromoethylamine (*26*) were synthesized according to published methods. Glacial acetic acid, methanol, and triethylamine (for making TEAA buffer) were purchased from Fisher Scientific. β-Maleimidopropionic acid hydrazide.TFA (EMPH·TFA) was purchased from Molecular Biosciences (Boulder, CO). (*R*)-2-Amino-2-carboxyethylmethanethiosulfonate (Cys-MTS) was purchased from Toronto Research Chemicals, Inc. (North York, Ontario, Canada). Ubiquitin was a gift from Invitrogen Inc. (Madison, WI). Distilled and deionized (18 MΩ cm^{-1}) water was used throughout. All glassware was washed with a mixed acid solution and thoroughly rinsed with deionized, distilled water. All plastic labware was purchased from Biorad (metal-free). All chemicals were of the purest grade available.

Purification. Most commonly, reverse-phase high-performance liquid chromatography was performed at room temperature on a Waters model 600 system with a Dynamax 60 Å C_{18} column (10 or 25 mm i.d. $\times$ 250 mm) using a linear gradient (solvent A = 0.1 M triethylammonium acetate, pH 6.5; solvent B = methanol/or acetonitrile).

Spectroscopy. Time-resolved and gated luminescence measurements were made on a laboratory-built spectrometer described previously, employing a 5 ns excitation pulse at 337 nm followed by time-resolved detection of lanthanide emission (*27*). The number of waters in the primary coordination sphere of the lanthanide was determined via the method of Horrocks and Sudnick (*28*): # of waters = $q(\tau_{H2O}^{-1} - \tau_{D2O}^{-1})$, ($q = 1.05$ for Eu, 4.2 for Tb).

Synthesis (Charts 1, *2*). *N_2O-Tetracarboxylic Acid.* 1-Oxa-4,7-diazacyclononane (N_2O) (100 mg, 0.77 mmol) and *N*,*N*-bis[(*tert*-butoxycarbonyl)methyl]-2-bromoethylamine (550 mg, 1.56 mmol) were dissolved in 5 mL of CH_3CN. 10 mL of phosphate buffer (2 M, pH 8.0) was added to the mixture. The solution was stirred at room temperature for 36 h. Ethyl acetate (10 mL) was added to the mixture. The aqueous solution was separated and extracted with ethyl acetate 2 $\times$ 5 mL. The combined organic layer was washed with water 3 $\times$ 5 mL. The organic layer was dried over anhydrous Na_2SO_4. The solvent was removed under reduced pressure to afford a colorless oil (458 mg, 89% yield. MS: 673, M + 1, FAB). The product was used for the next step without further purification.

200 mg (0.30 mmol) of the above-prepared material was dissolved in 6 M HCl/MeOH solution (5 mL). The mixture was stirred at room temperature for 2 h. Ether was added to the mixture. White precipitate was formed. The white precipitate was collected by filtration and dried (114 mg, 73% yield. MS: 447, M − 1, ESI).

N_2O_2-tetracarboxylic acid was also synthesized with the same method in similar yield and confirmed by mass spectrometry (MS: 491, M − 1, ESI).

General Procedure for Syntheses of N_2O- and N_2O_2-Based Lanthanide Chelates. 1 equiv of N_2O-tetracarboxylic acid was dissolved in a mixture of DMSO and 7 equiv of Et_3N under N_2. 2.2 equiv of isobutyl chloroformate was added and stirred at room temperature for 1.5 h. 0.7 equiv of cs124 dissolved in DMSO was added slowly to the above solution with vigorous stirring. The reaction was stirred at room temperature for 2 h. The solution was saved for the following steps.

If non-thiol-reactive chelates were to be synthesized, the above solution was quenched by addition of acetic acid and 0.1 M TEAA buffer (pH 6.5). The products were purified by reverse-phase HPLC with a linear gradient (typically 20−40% CH_3CN/TEAA pH 6.5 over 40 min). The yield varies from ~35% to ~50% as judged from the HPLC profiles (Table 1).

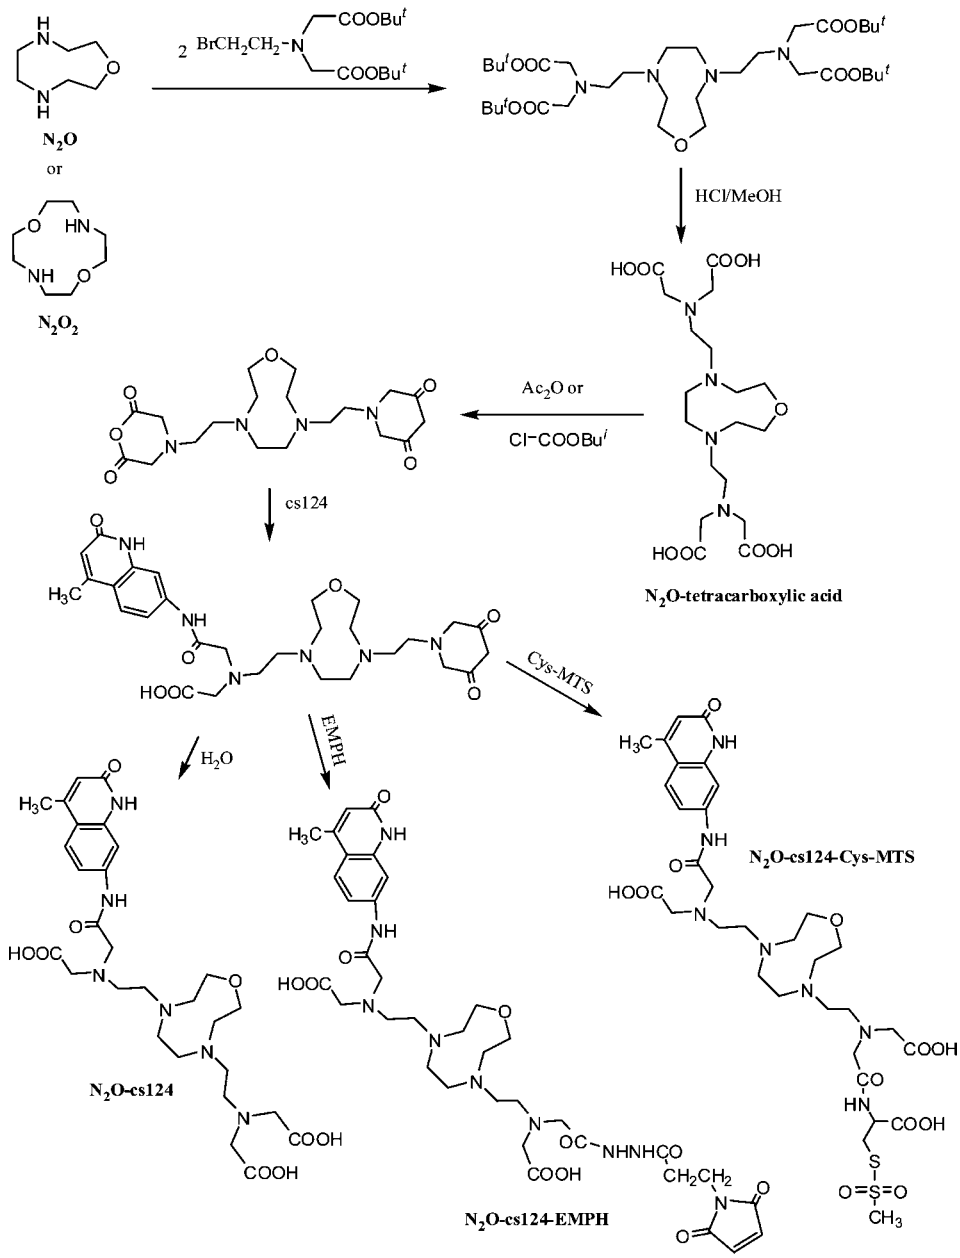
If the thiol-reactive forms of chelates were to be synthesized, the above solution was transferred to a DMSO solution containing 1.3 equiv of EMPH·TFA (or Cys-MTS) rapidly under N_2. The reaction was stirred at room temperature for 1 h. Acetic acid and 0.1 M TEAA (pH 6.5) buffer were added to quench the reaction. The product was purified by reverse-phase HPLC with a linear gradient (typically 20−40% CH_3CN/TEAA pH 6.5 over 40 min). The yield varies from ~20% to ~30% as judged from the HPLC profiles (Table 1).

General Procedure for Syntheses of TTHA-Based Lanthanide Chelates. Triethylenetetramine hexaacetic acid dianhydride (caTTHA) (1 equiv) was dissolved in a mixture of DMSO and 5 equiv of Et_3N under N_2. 0.7 equiv of cs124 dissolved in DMSO was added slowly to the above solution with vigorous stirring. The reaction was stirred at room temperature for 2 h. 1.3 equiv of thiol-reactive reagents (EMPH·TFA or Cys-MTS) dissolved in DMSO was added to the above solution. The reaction was stirred for 1 h at room temperature. Acetic acid and 0.1 M TEAA (pH 6.5) were added to quench the reaction. The product was purified by reverse-phase HPLC with a linear gradient (typically 30−50% MeOH/TEAA pH 6.5 over 40 min). The yield varies from ~20% to 50% as judged from the HPLC profiles (Table 1).

Addition of Metals. $TbCl_3$ or $EuCl_3$ was added to the chelate in a 1:1.2 molar ratio at usually >0.5 mM concentration at pH 6.5−7.5, usually in 0.1 M TEAA, pH 6.5 buffer, and allowed to stand for 30 min at room temperature before use.

Coupling to Biomolecules. Similar labeling conditions for conjugation to muscle proteins (*29*, *30*) were employed. The procedure for labeling Shaker K^+ ion channels in *Xenopus* oocytes has also been published (*10*, *11*). The thiol-reactive chelates were coupled to Ubiquitin (an 8.9 kDa protein containing a single cysteine) at a typical ratio of 10:1 with a protein concentration of ~15 μM. The coupling reaction was carried out at 4 °C overnight in 20 mM HEPES, pH 7.4, 5 mM $MgCl_2$. The excess lanthanide chelates were removed either by

Chart 1



passing the reaction mixture through a Sephadex G-50 size exclusion column or by dialyzing the reaction mixture through Pierce Slide-A-Lyzer Dialysis Cassette.

RESULTS AND DISCUSSION

Syntheses. DTPA-based lanthanide chelates can be readily prepared by reacting commercially available DTPA dianhydride (caDTPA) with 1 equiv of cs124 and 1 equiv of thiol-reactive reagents. The same principle can apply to the new chelate syntheses. The synthesis of the dianhydride form of TTHA has been reported (*24*). TTHA dianhydride was reacted with 1 equiv of cs124 first, followed by addition of 1 equiv of thiol-reactive reagents to form TTHA-cs124-EMPH or TTHA-cs124-Cys-MTS in good yield. 1-Oxa-4,7-diazacyclononane (N_2O) and 1,7-diaza-12-crown-4 (N_2O_2) were reacted with 2 equiv of *N*,*N*-bis[(*tert*-butoxycarbonyl)methyl]-2-bromoethylamine. The resulting tetra-*tert*-butylcarboxylates were then hydrolyzed with HCl in methanol to yield the free acid form of N_2O-tetracarboxylic acid and N_2O_2-tetracarboxylic acid. The two tetracarboxylic acid compounds could react with either acetic anhydride or isobutyl chloroformate to form dianhydride intermediates. These dianhydride intermediates can be either isolated or used for the next step without isolation. Following the sequence by reacting with cs124 first and then thiol-reactive reagents, the lanthanide chelates with N_2O and N_2O_2 in the middle of their backbones were synthesized in satisfy yield.

All of the lanthanide chelates were purified by reverse-phase HPLC and identified by mass spectroscopy, UV−vis, and lanthanide luminescence properties.

Photophysical Properties of the Lanthanide Complexes with the New Chelates. The Tb^{3+} and Eu^{3+} emission spectra are shown in Figure 1. All of the Tb^{3+} and Eu^{3+} complexes exhibit their characteristic sharply spiked asymmetric emission spectra with their most intense luminescent transitions centered at 546 nm ($^5D_4 \rightarrow {}^7F_5$) for Tb^{3+} and 614 nm ($^5D_0 \rightarrow {}^7F_2$). Table 2 lists the excited-state lifetimes of Tb^{3+} and Eu^{3+} measured for their complexes with the new chelates. Table 3 lists the excited-state lifetimes of Tb^{3+} and Eu^{3+} measured for their complexes with the new thiol-reactive chelates labeled to proteins (Ubiquitin, and *Xenopus* oocytes) or glutathione.

Chart 2

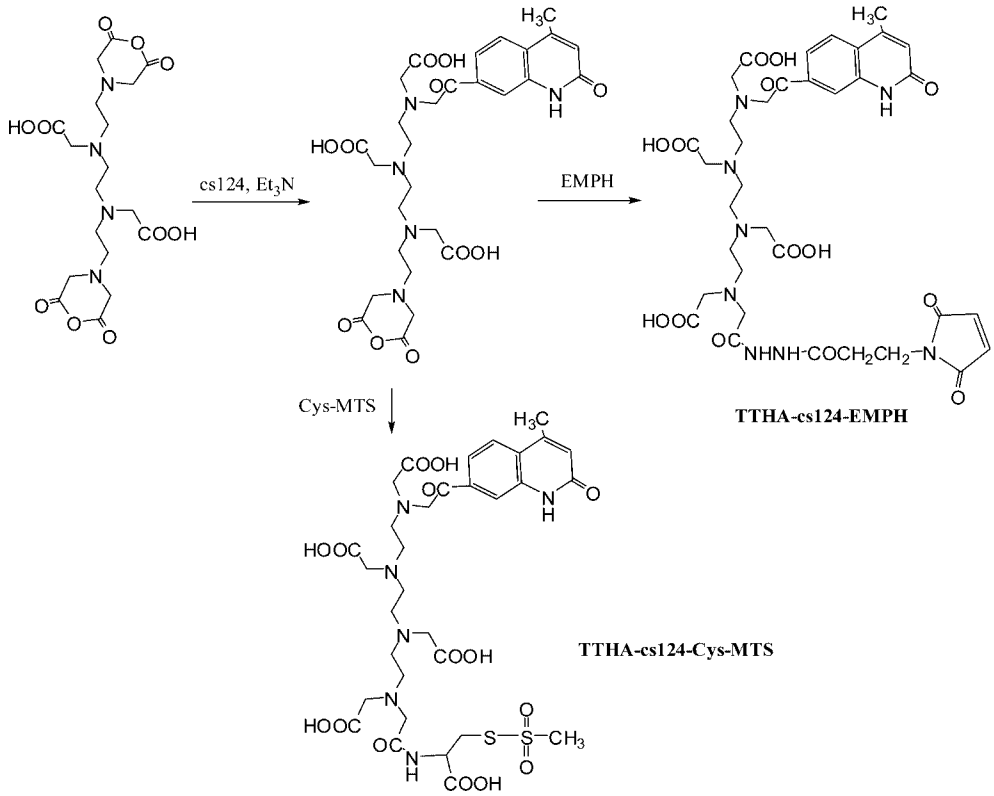


Table 1. Synthesized New Lanthanide Chelates

thiol-reactive chelates	linear gradients	retention time (min)	yield (%)	MS M − 1, ESI⁻
N_2O-cs124	20−40% ACN/TEAA	12	35	603
N_2O_2-cs124	20−40% ACN/TEAA	13	50	647
N_2O-cs124-EMPH	20−40% ACN/TEAA	19	20	768
N_2O-cs124-Cys-MTS	20−40% ACN/TEAA	17	30	784
TTHA-cs124-EMPH	30−50% MeOH/TEAA	22	20	814
TTHA-cs124-Cys-MTS	30−50% MeOH/TEAA	16	30	830

Generally, the Tb^{3+} and Eu^{3+} complexes of these chelates have comparable emission brightness to that of the benchmark chelate, DTPA-cs124. For all (except N_2O_2-cs124) of the non-thiol-reactive chelates, their lanthanide emission intensities are at least 10% higher than that of the reference complex. One apparent reason behind the results is that these chelates are either 9- or 10-dentate chelates. DTPA-cs124 is an 8-dentate chelate. When it coordinates to lanthanide ions, a water molecule is also coordinated to the lanthanide ions in the inner coordination sphere (*20*). The hydration of lanthanide ions is the main source of quenching of lanthanide emission. In contrast, the newly synthesized 9- or 10-dentate chelates can provide enough coordination sites for lanthanide ions that few water molecules can compete to coordinate to lanthanide ions. Therefore, the quenching effect from hydration of lanthanide ions is eliminated. This assumption that little or no water molecules in the lanthanide inner coordination spheres of these new chelate complexes is evident from their corresponding lifetime measurements, as all of these chelates exhibit significantly longer lifetimes than that of DTPA-cs124. Using the Horrocks and Sudnick empirical equation, the number of waters in the primary coordination sphere of Tb^{3+} and Eu^{3+} is found as follows: N_2O-cs124 (0.02, 0.29), N_2O_2-cs124 (0.22, Tb^{3+} only), TTHA-cs124 (0.2, 0.3) (*21*). These data clearly indicate that the new chelates provide better protection to the lanthanide ions from solvent solvation, and limit the accessibility of water molecules to the metal center. Especially for N_2O-cs124, no water molecules coordinate when it binds to Tb^{3+}. Therefore, the new 9- or 10-dentate chelates can shield the lanthanide ions from solvent attack. However, other factors will also contribute to the relative intensity changes. For N_2O_2-cs124, its Tb^{3+} emission intensity is only about 20% that of DTPA-cs124, while its Eu^{3+} emission is undetectable at 1 μM concentration. Yet, its lifetime for Tb^{3+} is significantly longer than that of the reference complex. The calculated number of water molecules coordinated to Tb^{3+} is only 0.22. The facts are that its emission intensity is concentration-dependent and its lifetime is concentration-independent. These observations indicate that the binding stability constant

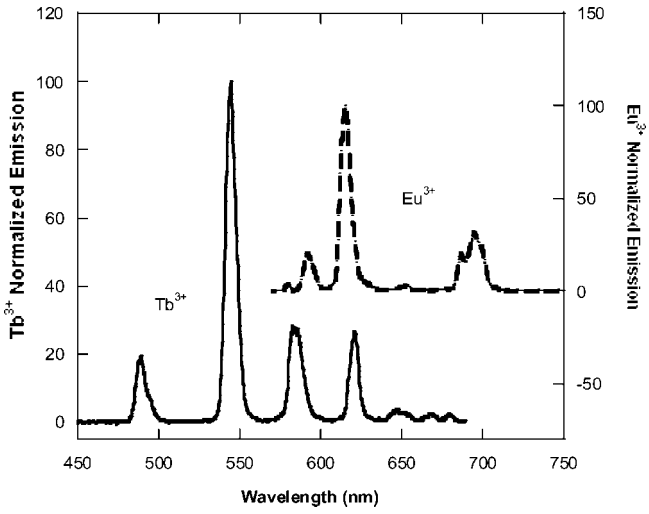

Figure 1. Normalized Tb^{3+} and Eu^{3+} emission spectra of N_2O-cs124 in 0.1 M TEAA pH 6.5 at a concentration of 1 μM. Tb^{3+} and Eu^{3+} display their characteristic sharply spiked spectra. Pulsed excitation was at 40 Hz, 3.5 μJ/pulse for Eu^{3+}, 3.0 μJ/pulse for Tb^{3+}; integration times are 1 s for $Tb^{3+}$and 5 s for Eu^{3+}.

Table 2. Photophysics Data of the New 9- And 10-Dentate Chelates[a]

metal	chelates	τH_2O	τD_2O	$\tau H_2O/\tau D_2O$	no of waters	relative brightness
Tb^{3+}	DTPA-cs124	1.55	2.63	0.59	1.1 (*21*)	1

	TTHA-cs124	1.19	1.79	0.66	0.3 (*21*)	2.7
	TTHA-cs124	1.16				1.45[b]
	TTHA-cs124-8-me	1.15				2.37
	TTHA-cs124-EMPH	1.25				0.89
	TTHA-cs124-Cys-MTS	1.20				0.69

[a] All emissions are measured at 1 μM lanthanide concentration with a slight excess of chelate. [b] From this work. [c] Concentration-dependent. At 1 μM, no emission detected.

Table 3. Lifetimes of Tb^{3+} and Eu^{3+} Complexes of Thiol-Reactive 9-, 10-Dentate Chelates Labeled to Proteins or Glutathione

metal	chelate	protein	lifetimes (ms)
Tb^{3+}	N_2O-cs124-EMPH	Shaker K^+ channels in oocyte cells[a]	1.34 (75%); 0.22 (25%)
		Ubiquitin	1.74 (82%); 0.29 (18%)
	TTHA-cs124-EMPH	Shaker K^+ channels in oocyte cells[a]	1.84 (86%); 0.32 (14%)
		Ubiquitin	1.94 (74%); 0.49 (26%)
		Glutathione	1.89
	TTHA-cs124-Cys-MTS	Ubiquitin	1.92 (63%); 0.33 (37%)
Eu^{3+}	TTHA-cs124-EMPH	Shaker K^+ channels in oocyte cells[a]	0.69 (43%); 0.21 (57%)
		Glutathione	1.04

[a] Details of ion channel expression can be found in [Posson (2005) *Nature 436*, 848−851].

of N_2O_2-cs124 to lanthanide ions is relatively small. There is an equilibrium between lanthanide ion bound and unbound N_2O_2-cs124 in solution. Such results were also observed for TETA-cs124 (1,4,8,11-tetraazacyclotetradecane-1,4,8,11-tetraacetic acid, TETA) (*21*). After converting to the thiol-reactive form, there is a tendency for the emission intensity to decrease.

The 8-methyl cs124 derivative (cs124-8-me) sensitized TTHA chelate (TTHA-cs124-8-me) was also synthesized. It has a slightly increased lifetime compared to TTHA-cs124 (2.27 ms vs 2.14 ms). This is consistent with the observation of blocked back energy transfer from lanthanide emission to antenna molecule by the 8-methyl group observed for DTPA chelate (*5*). Its Tb^{3+} emission intensity is only about 30% that of the corresponding reference complex, as is the TTHA-cs124 chelate which was made in this work. The hypothesis for this intensity decrease is that Tb^{3+} remains 9-coordinated in TTHA-cs124-8-me and TTHA-cs124. The TTHA chelates provide 10-coordinate sites. The terminal carboxylate arm with sensitizer has to compete with other free carboxylic acid arms to coordinate to the lanthanide center, resulting in an equilibrium between bound and nonbound forms of the carboxylate arms coordinating to the metal center. The case where the cs124 is not bound to the lanthanide probably will not sensitize the emission of terbium because the antenna molecule is far away from metal center. On the basis of the fact that the intensity of TTHA chelates is only about 30% that of the reference complex, it is reasonable to assume that the equilibrium is in favor of the nonbound form, probably due to the spatial hindrance and overall charges of the antenna molecule. At ~pH 7, the side arms in TTHA are deprotonated as carboxylates. When neutral antenna molecule (cs124 or cs124-8-me) attached to form an amide bond, the −1 charge from the carboxylate sidearm will be gone. Hence, the coordination capability of the carbonyl oxygen atom from the amide bond will change. However, we reported that the intensity of TTHA-cs124 is 110% that of the reference complex in our previous work (*21*). We believe that this is because the structures of the two TTHA-cs124 chelates are slightly different. In the present work, we converted TTHA into its dianhydride form first, and then reacted TTHA dianhydride with cs124 and derivatives. By doing this, the antenna molecule is exclusively at the terminals of the TTHA backbone chain. In our previous work, the free acid form of TTHA was activated by reacting with isobutyl chloroformate first, followed by reacting with cs124 in a one-pot reaction. All of the carboxylic acid groups in TTHA could be activated, and hence a mixture is formed with the antenna molecule in both the middle and terminals of the TTHA backbone chain. If the antenna molecule is in the middle of the TTHA backbone chain, it probably will coordinate to the lanthanide center, because after the TTHA backbone chain coordinates to lanthanide, it will bring the carboxylate arm with the antenna molecule very close to the metal center. In contrast, the carboxylate arm with the antenna molecule at the terminals of TTHA backbone chain will have greater freedom to move around.

The Eu^{3+} emission intensity of TTHA-cs124 chelates is significantly increased compared the reference complex. The Eu-TTHA-cs124-8-me emission intensity is 237% that of reference, and the Eu-TTHA-cs124 emission intensity is 145% that of reference. The increased emission intensity is a good indication that the coordination number of Eu^{3+} has increased to 10. It is demonstrated that the $^5D_0 \rightarrow {}^7F_2$ emission intensity increase of Eu^{3+} is linearly proportional to the average coordination number of nitrates to Eu^{3+}, regardless of solvents (*20*). In a 0.047 M Eu^{3+} DMF solution, the intensity increases 1.8× per coordination number increase. Although different coordination chelates were used, the further intensity increase

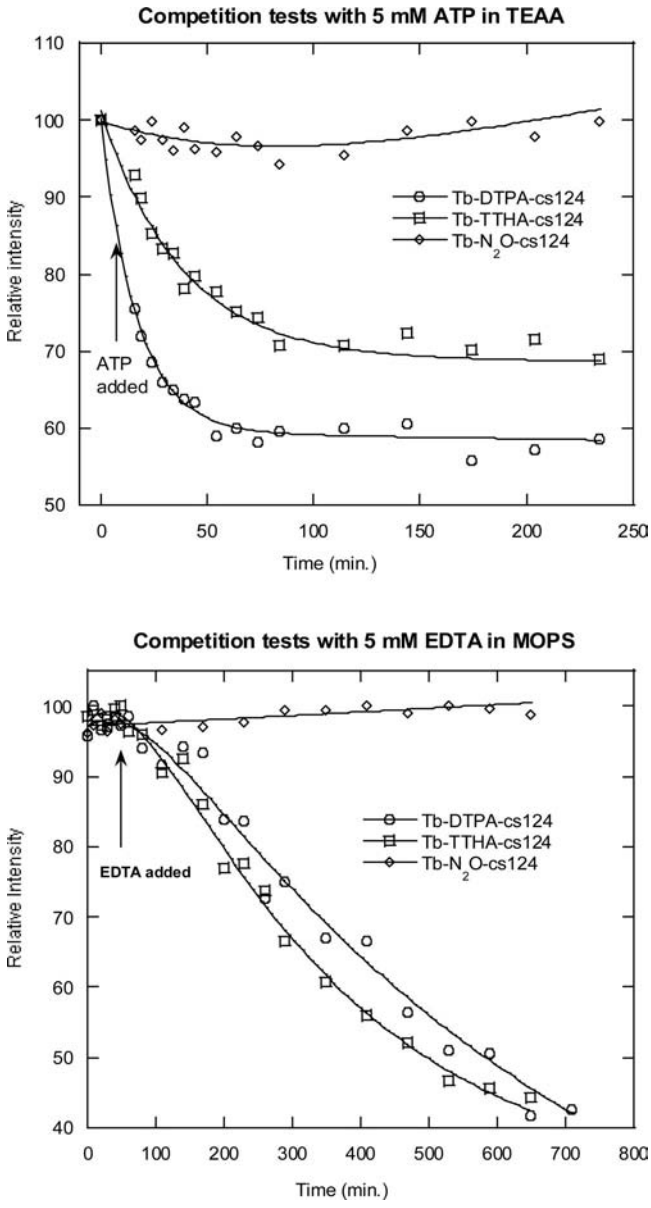

Figure 2. Relative Tb^{3+} emission intensity over time in the presence of EDTA or ATP of chelates of DTPA-cs124, TTHA-cs124, and N_2O-cs124.

of TTHA-cs124-8-me from TTHA-cs124 is probably due to the blocking of energy back transfer effect by the 8-methyl substitute.

To compare the stability of the lanthanide complexes of the new chelates, the Tb^{3+} emission intensity was measured over time in the presence of ATP or EDTA for the nonreactive chelates of DTPA-cs124, TTHA-cs124, and N_2O-cs124 (Figure 2). In the presence of 5 mM of EDTA, the Tb^{3+} emission intensity for both of TTHA-cs124 and DTPA-cs124 decreases to ~50% of the initial intensity in ~8−9 h. In the presence of 5 mM of ATP, the Tb^{3+} emission intensity of DTPA-cs124 decreases to ~60% of its initial intensity in ~50 min after addition of ATP. After this period of time, no further significant intensity decrease was observed, suggesting that equilibrium has been achieved. The Tb^{3+} emission intensity of TTHA-cs124 decreases to ~70% of its initial intensity in ~70 min after addition of ATP, indicating that equilibrium is also achieved at this point. In both cases, the Tb^{3+} emission intensity of N_2O-cs124 virtually does not change. These results suggest that the macrocycle-containing lanthanide chelate, N_2O-cs124, is a much stronger lanthanide binding chelate than the linear DTPA-cs124 and TTHA-cs124 chelates, and its lanthanide complexes are much more stable under physiological conditions.

The thiol-reactive chelates are selectively reacted with Ubiquitin, Shaker potassium ion channel expressed in oocyte, and glutathione. Generally, after labeling to proteins, the luminescent lanthanide emission exhibits a biexponential lifetime decay fit with the majority a long-lifetime component (usually >70%) and the rest a short-lifetime component (<30%). It is interesting to note that, after reacting with glutathione, the originally biexponential thiol-reactive chelates become single-exponential.

CONCLUSIONS

As part of the project to modify the luminescent lanthanide chelate backbone structures to provide stronger and better hydration protection chelates, new 9- and 10-dentate lanthanide chelates have been synthesized. The syntheses of these chelates are straightforward, relatively simple, and in good yields, especially for TTHA-based chelates. The principle for the synthesis is to prepare a backbone precursor similar to DTPA dianhydride. The dianhydride functional groups allow an antenna molecule and a reactive group to attach to the backbone molecule separately. The new chelates provide better protection to lanthanide ions from solvent hydration, as evidenced from their longer lifetimes and relatively higher emission intensity. The 1-oxa-4,7-diazacyclononane (N_2O)-containing chelates provide the best protection to the lanthanide ions from solvent molecule attack. Its Tb^{3+} complex is the most stable complex and does not undergo dissociation in the presence of other competing chelates at relatively high concentration. The TTHA-based chelates provide moderately good protection to the lanthanide ions.

ACKNOWLEDGMENT

This work is supported by NIH grants AR44420 and GM074770. We thank Dr. Kurt Vogel from Invitrogen Inc. for the generous gift of Ubiquitin protein. The labeling experiments to oocytes expressing Shaker ion channels were done by Dr. David Posson. The mass spectrometry was obtained by the Mass Spectrometry Center, University of Illinois at Urbana−Champaign.

Increasing Solubility of Proteins and Peptides by Site-Specific Modification with Betaine

Junpeng Xiao, Alex Burn, and Thomas J. Tolbert*

Department of Chemistry and Interdisciplinary Biochemistry Graduate Program, Indiana University, Bloomington, Indiana 47405. Received February 15, 2008; Revised Manuscript Received May 1, 2008

Proteins and peptides with low solubility and which aggregate are often encountered in biochemical studies and in pharmaceutical applications of polypeptides. Here, we report a new strategy to improve solubility and prevent aggregation of polypeptides using site-specific modification with the small molecule betaine, which contains a quaternary ammonium moiety. Betaine was site-selectively attached to the N-termini of two aggregation-prone polypeptide models, the bacterial enzyme xanthine-guanine phosphoribosyltransferase (CG-GPRT) and the HIV entry inhibitor peptide CG-T20, utilizing native chemical ligation. N-terminal cysteines for the betaine ligation reactions were generated from His-tagged fusion proteins using TEV protease cleavage. Ligation of the betaine thioester (**1**) to the N-terminal cysteine-containing polypeptide models proceeded in high yield, though denaturing conditions were required for CG-T20 due to the hydrophobic nature of this peptide. CD spectroscopy and GPRT activity assays indicate that the betaine modification of CG-GPRT and CG-T20 does not significantly affect structure or activity of the polypeptides. Solubility and turbidity measurements of betaine-modified and unmodified polypeptides demonstrate that betaine modification can greatly increase solubility. Finally, it is shown that betaine-modified CG-T20 acts as an inhibitor of the aggregation of unmodified CG-T20.

Polypeptides with low solubility and high tendency for aggregation have caused many problems in academic and industrial research for several reasons. First, many types of biochemical and biophysical studies, especially structural analyses, are hampered by low solubility. In particular, high-resolution structural studies using NMR spectroscopy and X-ray crystallography usually require millimolar concentrations of protein or peptide samples (*1, 2*), but many proteins and peptides aggregate at millimolar concentrations. In addition, low solubility and aggregation are significant problems in the development of pharmacologically active proteins and peptides. Many bioactive proteins and peptides are abandoned during drug discovery due to low solubility and high tendency for aggregation, although they have good therapeutic potential (*3, 4*). Furthermore, many neurodegenerative diseases such as Alzheimer's, Parkinson's, and prion diseases are characterized by formation of protein or peptide aggregates in brain tissue (*5–8*). Because of this, blocking protein or peptide aggregation is an important therapeutic strategy to counter neurodegenerative diseases.

To overcome problems with polypeptide solubility and aggregation, different strategies have been investigated. Fusion of the target polypeptides to a solubilizing protein fusion partner (*9–13*) such as maltose-binding protein (MBP) (*10, 11*), glutathione S-transferase (GST) (*12*), and green fluorescent

1

protein (GFP) (*13*) have been utilized to increase the solubility of polypeptides. Glycosylation with hydrophilic carbohydrates (*14*) and PEGylation with water-soluble poly(ethylene glycol) (PEG) chains (*15–17*) have also been used to improve the solubility of polypeptides. However, these strategies require introduction of large molecules onto proteins and peptides, which may perturb their structure and function. To overcome this issue, addition of short solubility enhancement peptide tags, which usually contain 5−10 positively charged amino acids, to the N- or C-terminus of proteins and peptides has been reported (*18, 19*). These peptide tags are relatively small for large proteins, but for peptides and small proteins they can be a significant fraction of those polypeptides' molecular weight. Introduction of such peptide tags during solid-phase peptide synthesis adds additional coupling steps that can reduce yields, and introduction of polylysine or polyarginine tags during protein expression may lead to proteolytic complications. Because of these factors, low molecular weight solubility enhancement tags that can be introduced after recombinant protein expression or peptide synthesis would be useful.

Here, we report a new strategy to incorporate a betaine moiety as a small solubility enhancement tag onto the N-terminus of polypeptides utilizing native chemical ligation/expressed protein ligation. The betaine moiety is a small molecule that contains a positively charged quaternary ammonium group with the molecular weight of only 100. We were initially investigating incorporation of the betaine moiety onto the N-terminus of polypeptides as a mass tag. During our investigation, we noticed an interesting side effect of this modification, that betaine-modified polypeptides are more soluble in aqueous solution. To investigate this effect further, we site-specifically modified two aggregation-prone model polypeptides, the 153-residue enzyme xanthine-guanine phosphoribosyltransferase (GPRT) and the 38-residue peptide CG-T20 with the betaine moiety. GPRT is a hydrophobic protein that usually forms a tetramer in its native state (*20, 21*). It is stable in solution at neutral pH, but aggregates and precipitates when the pH is below 6. CG-T20 is a slightly modified version of the HIV entry inhibitor peptide T20 (also called Fuzeon, Enfuvirtide, or DP-178) with a CysGly addition to the N-terminus (*2, 22*). It is also a hydrophobic peptide that exhibits solubility problems at neutral and acidic pH. Thus, both GPRT and CG-T20 are good models to investigate the effect of betaine modification on solubility and aggregation.

The strategy that we utilized for the site-specific modification of polypeptides involves generating an N-terminal cysteine by tobacco etch virus NIa protease (TEV protease) cleavage and then ligating a betaine thioester (**1**) (Scheme 1) onto the N-terminal cysteine by native chemical ligation/expressed protein ligation (Figure 1). Native chemical ligation was first introduced by Kent and co-workers for chemical synthesis of polypeptides (*23*). It is a chemoselective ligation between an N-terminal cysteine and a thioester to form a native peptide bond. In this reaction, only the N-terminal cysteine reacts, all other internal cysteines are unreactive, and so it is chemoselective for N-terminal cysteines. This reaction has been extended to expressed polypeptides by Muir and others for protein modification (*24, 25*). Utilization of this reaction enables site-specific N-terminal modification of our model polypeptides with the betaine moiety.

Generation of N-terminal cysteines for native chemical ligation has been accomplished using TEV protease to cleave N-terminally His-tagged fusion proteins (*26, 27*). A fusion protein of His-CG-GPRT, which contains the TEV protease cleavable sequence, was produced to generate CG-GPRT as described previously (Figure 1a) (*26*). Expression of a TEV-cleavable form of CG-T20 was somewhat more complicated due to the hydrophobic nature of this peptide. The first attempt to express CG-T20 fused with a His-tagged GPRT carrier protein containing a TEV protease cleavable linker was unsuccessful because the fusion protein was expressed as inclusion bodies and could not be resolubilized (*27*). Next, we decided to fuse small ubiquitin-related modifier (SUMO) to the N-terminus of CG-T20 with a TEV protease cleavable linker between SUMO and CG-T20, because of SUMO's ability to enhance protein expression and solubility (*28–30*). Overexpression of SUMO-CG-T20 fusion protein still resulted in inclusion bodies, due to

the insolubility of the CG-T20 peptide. However, after purification by Ni^{2+}-NTA affinity chromatography under denaturing conditions, the purified SUMO-CG-T20 was refolded to afford the soluble SUMO-CG-T20 fusion protein.

N-terminal cysteine-containing CG-GPRT and CG-T20 were prepared by TEV protease cleavage for 24 h followed by purification by reverse-phase HPLC and lyophilization to give white powders. The production of cleaved CG-GPRT and CG-T20 was confirmed by MALDI-TOF mass spectrometry (Figure 2a,c). A two-step cleavage/labeling reaction procedure (*26*) was used to ligate the betaine thioester onto the N-terminal cysteine of CG-GPRT. The ligation gave a high yield of betaine-CG-GPRT conjugate (>95%) after 24 h incubation as observed by MALDI-TOF mass spectrometry (Figure 2b). Although the cleavage of SUMO-CG-T20 was conducted under native conditions, the ligation of CG-T20 with the betaine thioester was conducted under denaturing conditions (7 M guanidine hydrochloride) because of the insolubility of the CG-T20 in native conditions. This ligation gave a high yield of betaine-CG-T20 conjugate (>95%) after 24 h incubation as observed by MALDI-TOF mass spectrometry (Figure 2d). Both the betaine-CG-GPRT conjugate and betaine-CG-T20 conjugate were purified by reverse-phase HPLC and lyophilized to give white powders.

The effects of betaine modification on the structure and function of CG-GPRT and CG-T20 were assessed by far-UV circular dichroism (CD) spectroscopy and enzyme assays. Betaine modification had little or no effect on the CD spectra of CG-GPRT and CG-T20, indicating that betaine modification on the N-terminus of these polypeptides did not alter their structures appreciably (see Supporting Information). GPRT activity assays also showed that betaine modification had little effect on the specific activity of CG-GPRT compared to betaine-modified CG-GPRT (14.90 μmol/min per mg vs 14.16 μmol/min per mg, respectively; see Supporting Information). Overall, these results indicate that addition of a betaine moiety does not significantly affect the structure and function of these polypeptides.

To investigate the effect of betaine modification on aggregation and solubility, the turbidity and percent solubility of CG-GPRT and betaine-CG-GPRT conjugate at different pH values were determined using standard procedures for determining protein solubility and aggregration (Figure 3a,b, square and circle symbols) (*18*, *31*–*33*). The proteins were dissolved to 1 mg/mL concentration in 100 mM sodium phosphate buffer pH 9 followed by pH adjustment to 5, 6, and 7 with 1 M HCl. After 24 h incubation at 4 °C, the turbidity at 400 nm was measured to determine the insoluble aggregates. Then, the precipitate was removed by centrifugation and the concentrations of the supernatants were determined by UV absorbance at 280 nm (*31*–*33*). The percent solubility was determined by comparing the concentration of the supernatant to the initial concentration. As anticipated, both the CG-GPRT and the betaine-CG-GPRT conjugate aggregated and precipitated under acidic conditions after incubation for 24 h. The turbidity of the protein solution was increased for both the CG-GPRT and the betaine-CG-GPRT conjugate as the pH of the solution became more

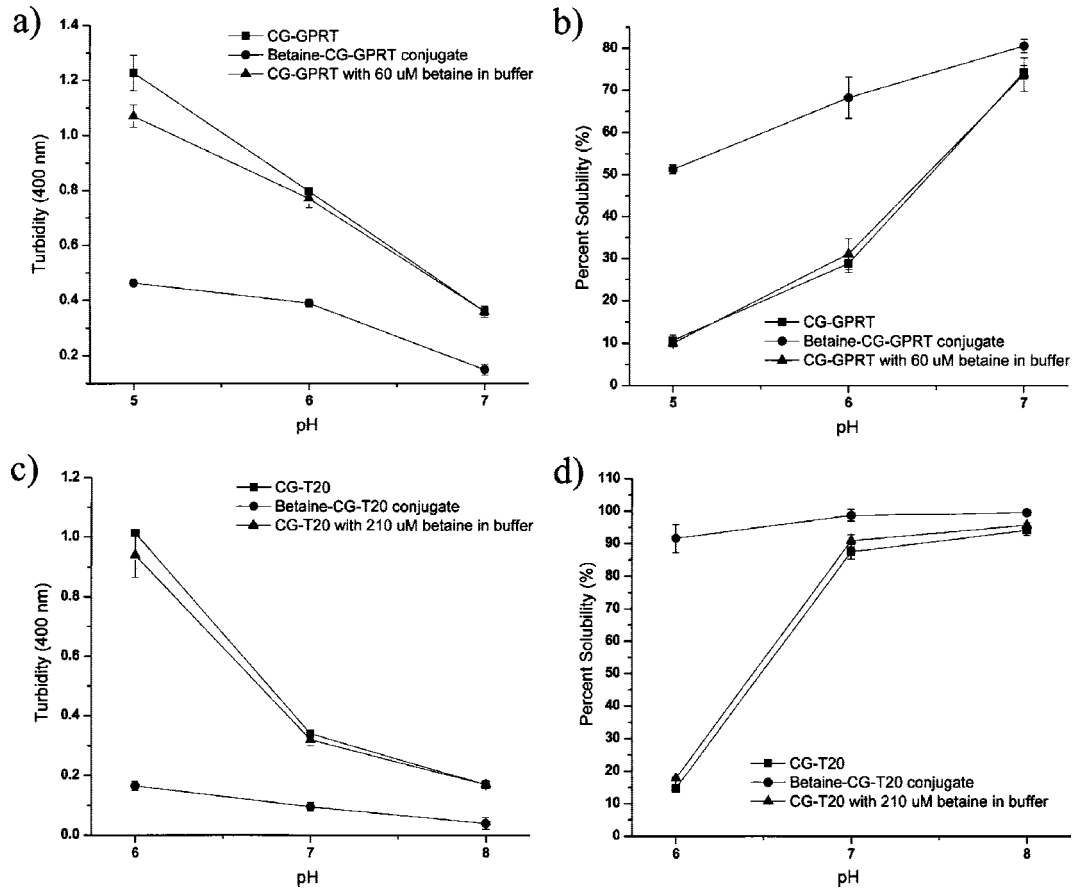

Figure 3. Effects of betaine modification on turbidity and solubility of CG-GPRT and CG-T20. (a) Turbidity (at 400 nm) of CG-GPRT in phosphate buffer (square), betaine-CG-GPRT conjugate in phosphate buffer (circle), and CG-GPRT with 60 μM betaine in phosphate buffer (triangle) at pH 5, 6, and 7. (b) Percent solubility of CG-GPRT in phosphate buffer (square), betaine-CG-GPRT conjugate in phosphate buffer (circle), and CG-GPRT with 60 μM betaine in phosphate buffer (triangle) at pH 5, 6, and 7. (c) Turbidity (at 400 nm) of CG-T20 in phosphate buffer (square), betaine-CG-T20 conjugate in phosphate buffer (circle), and CG-T20 with 210 μM betaine in phosphate buffer (triangle) at pH 6, 7, and 8. (d) Percent solubility of CG-T20 in phosphate buffer (square), betaine-CG-T20 conjugate in phosphate buffer (circle), and CG-T20 with 210 μM betaine in phosphate buffer (triangle) at pH 6, 7, and 8. The concentration of all proteins and peptides are 1 mg/mL.

acidic (Figure 3a). However, at all pHs, the turbidity of the betaine-CG-GPRT conjugate was lower than that of CG-GPRT, especially at lower pH. These results indicate that the betaine-modified CG-GPRT forms a smaller amount of insoluble aggregates than unmodified CG-GPRT under the same conditions. It is possible that some soluble aggregates may have been present in the solution that would not be detected by the turbidity assay, but it is clear from the turbidity data that betaine modification decreases the formation of insoluble aggregates. The solubility of both proteins decreased as the pH of the solution was decreased (Figure 3b), and the solubility of the betaine-CG-GPRT conjugate was higher than that of the CG-GPRT at all pHs, with the difference being greater at lower pH. The consistency between the turbidity results and percent solubility results suggests that the protein concentration changes after incubation are due to protein aggregation and precipitation and not other factors that could cause protein loss such as surface absorbance or loss during centrifugation. Thus, all of these results indicate that the betaine-modified CG-GPRT protein has less aggregation propensity and better solubility than unmodified CG-GPRT protein, especially at acidic pH. As a control, the turbidity and percent solubility of a 1 mg/mL sample of CG-GPRT with the presence of 60 μM betaine (the same concentration of free betaine as there was conjugated betaine in the 1 mg/mL of betaine-CG-GPRT conjugate experiment) were also determined at pH 5, 6, and 7 (Figure 3a,b, triangle symbol). With the presence of free betaine, both the turbidity and the percent solubility of CG-GPRT were almost the same as those of CG-GPRT in the experiment without betaine at all (Figure 3a,b). This suggests that the reduced aggregation and increased solubility of the betaine-CG-GPRT protein were actually caused by the covalent attachment of betaine onto the protein, not caused by the introduction of the betaine moiety into the protein solution.

Next, we also performed the same aggregation, solubility, and control experiments for the CG-T20 peptide and betaine-CG-T20 conjugate at pH 6, 7, and 8. The turbidity and percent solubility measurements gave similar but more pronounced results than the CG-GPRT protein experiments (Figure 3c,d). At pH 7 and 8, over 85% of the CG-T20 and almost 100% of the betaine-CG-T20 conjugate were soluble in solution, which indicated that there was little or no protein loss during the incubation and centrifugation. When the pH was dropped down to 6, most of the CG-T20 (about 85%) aggregated and precipitated. However, about 92% of the betaine-CG-T20 conjugate was still soluble. The turbidity measurements were consistent with the results obtained in the solubility measurements. In the free betaine control experiment, as we observed with CG-GPRT, the present of free betaine in the solution did not change the turbidity and solubility of CG-T20 much (Figure 3c,d). All these results indicate that the covalent betaine modification can reduce the aggregation propensity and increase the solubility of both the CG-GPRT protein and the CG-T20 peptide, especially at acidic pH.

As described above, betaine modification of our aggregation-prone model protein and peptide reduces aggregation

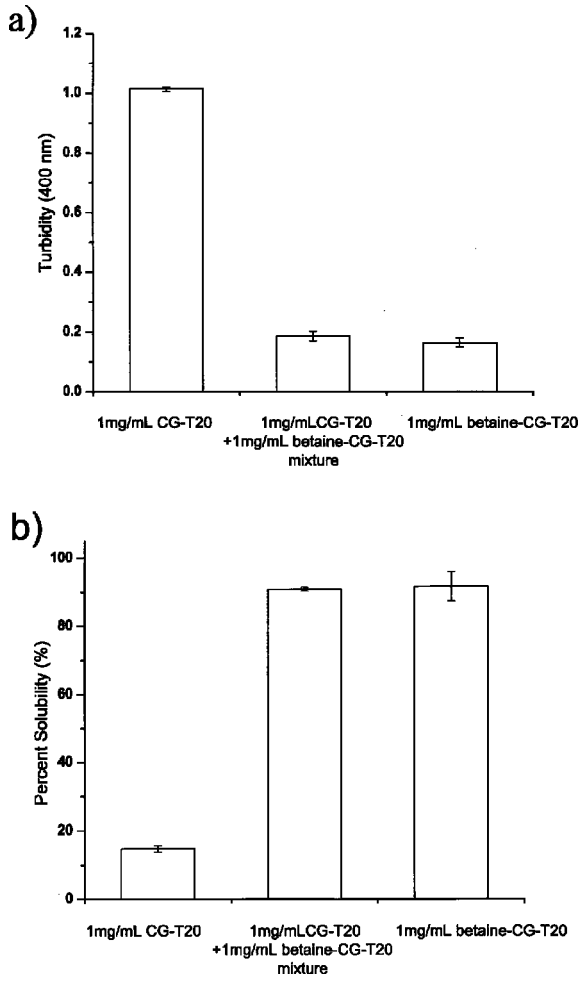

Figure 4. Betaine-CG-T20 conjugate inhibits the aggregation of CG-T20. (a) Turbidity (at 400 nm) of CG-T20 (1 mg/mL), mixture of CG-T20 (1 mg/mL) and betaine-CG-T20 conjugate (1 mg/mL), and betaine-CG-T20 conjugate (1 mg/mL) at pH 6. (b) Percent solubility of CG-T20 (1 mg/mL), mixture of CG-T20 (1 mg/mL) and betaine-CG-T20 conjugate (1 mg/mL), and betaine-CG-T20 conjugate (1 mg/mL) at pH 6.

and increases solubility of the modified polypeptides. To investigate further as to whether the betaine-modified polypeptides can inhibit the aggregation of unmodified polypeptides, an aggregation inhibition assay was performed with CG-T20. In this assay, a mixture of 1 mg of unmodified CG-T20 and 1 mg betaine-modified CG-T20 was dissolved in 1 mL 100 mM sodium phosphate buffer pH 9 followed by pH adjustment with 1 M HCl. After 24 h incubation at 4 °C, the turbidity and percent solubility were determined. Because the largest differences in turbidity and solubility were observed between CG-T20 and the betaine-CG-T20 conjugate at pH 6, the turbidity and percent solubility were measured at pH 6 (Figure 4). Although there was a total of 2 mg/mL of CG-T20 species in the solution, the turbidity of this mixture (0.187) was almost same as that of the betaine-CG-T20 conjugate (0.165) (Figure 4a). The percent solubility of this CG-T20 and betaine-CG-T20 mixture (90.8%) was also as high as that of the betaine-CG-T20 conjugate (91.6%) (Figure 4b). These results indicate that the betaine-modified CG-T20 can not only prevent the aggregation of itself, but it can also inhibit the aggregation of unmodified CG-T20.

In conclusion, we have investigated the effect of site-specific betaine modification on the aggregation and solubility of polypeptides, using the enzyme CG-GPRT and the HIV entry inhibitor peptide CG-T20 as models. The site-specific modification was achieved by native chemical ligation between a betaine thioester and TEV protease generated N-terminal cysteines on CG-GPRT and CG-T20. As demonstrated here, the betaine modification can reduce the aggregation propensity and increase the solubility of both the CG-GPRT protein and the CG-T20 peptide without significantly affecting their structures and functions. Compared to the unmodified polypeptides, betaine modification increased the solubility of CG-GPRT approximately 4.8-fold at pH 5, and the solubility of CG-T20 was increased 6.2-fold at pH 6 (Figure 3). This compares favorably with solubility increases that have been reported for polyarginine and polylysine tags of five and six residues (*18*), but with a much smaller molecular weight 100 betaine modification achieving similar solubility enhancements. In addition, our investigation demonstrated that the betaine-CG-T20 conjugate is able to function as an inhibitor of the aggregation of unmodified CG-T20. Thus, the betaine modification strategy presented here may prove useful for alleviating aggregation and solubility problems of many hydrophobic proteins and peptides to facilitate biochemical, structural, and pharmaceutical studies.

A chimeric protein consisting of a cell-adhesive peptide derived from a neural cell adhesion molecule and a collagen-binding domain was synthesized using recombinant DNA technology. Here, we demonstrate that the chimeric protein binds to type I collagen and promotes the adhesion and neurite extension of hippocampus neurons. These results suggest that the chimeric protein has potential to provide microenvironments for neurons to adhere and survive in collagen-based matrices for use in cell-based therapies for central nervous disorders.

INTRODUCTION

Stem cell-based therapy is recognized as a potential therapeutic strategy for neurodegenerative diseases (*1, 2*). However, the low level of cell survival following transplantation is the major problem associated with current techniques (*3*). Cell death after transplantation is attributed in part to anoikis-induced apoptosis caused by the destruction of cell−substrate and cell−cell interactions upon cell preparation (*4*). Other factors include inflammatory reactions caused by activated microglia infiltrating into injection sites (*5*).

To overcome these adverse effects, we are involved in the development of collagen-based biodegradable matrices that act as temporal barriers against the infiltration of inflammatory cells and, at the same time, initially provide substrates for neuronal cell adhesion mediated by cell adhesion molecules. To date, several research groups utilized collagen matrices (*6–9*) to provide favorable microenvironments for the proliferation and controlled differentiation of neural stem/progenitor cells. However, current technologies have simply used collagen matrices as physical carriers without expectation for adhesion signaling in neural cells.

Our approach is to design collagen matrices containing a peptide sequence that facilitates neural cell adhesion molecule (NCAM)-mediated signaling in neurons. To efficiently incorporate the peptide into the collagen matrix, a chimeric protein consisting of a NCAM-related peptide and the A3 domain of the von Willebrand factor (vWF) was synthesized by means of recombinant DNA technology. Since the vWF A3 domain has an affinity for type I collagen (*10*), the chimeric protein is expected to specifically bind to collagen matrices, displaying the peptide toward neurons.

As a NCAM-related peptide, we chose a 12 amino acid residue peptide (GRILARGEINFK), termed P2, derived from NCAM (*11–13*). NCAM is abundantly expressed on neurons and their progenitors, and plays a pivotal role in neuronal development, synaptic plasticity, and regeneration (*14, 15*). NCAM belongs to the immunoglobulin (Ig) superfamily, and its extracellular domain is composed of N-terminal five Ig-like modules with two consecutive fibronectin type III modules. The double-reciprocal, homophilic interactions of NCAMs activate intracellular signaling pathways in neurons, leading to neurite outgrowth. The P2 peptide sequence contained in the second Ig (IgII) module was identified as a binding site for the first Ig (IgI) module and interestingly shown to act as an agonist for NCAM, promoting neuronal differentiation and survival (*11–13*).

In this communication, we describe the preparation and characterization of a chimeric protein that consists of the P2 peptide and the collagen-binding A3 domain of vWF (P2-vWFCBD). The affinity of P2-vWFCBD to type I collagen was studied by surface plasmon resonance (SPR) analysis. The feasibility of P2-vWFCBD for the promotion of neuronal adhesion and its outgrowth on collagen was examined using the primary culture of hippocampus neurons.

EXPERIMENTAL PROCEDURES

Chimeric Gene Construct. The cDNA (cDNA) encoding the human vWF A3 domain [189 amino acids (aa)] (*10*) was generated by polymerase chain reaction (PCR) using human pancreas cDNA library as a template. The PCR primers were designed to introduce an EcoR I restriction site at the 5′ end (CGAATTCGACTGCAGCCAGCCCCTGGAC) and an Xho I restriction site at the 3′ end (for P2-containing protein: GCTCGAGCTTGAAGTTGATTTCCCCGCGGGCCAGGATCCTGCCAGAGCACAGTTTGTGGAGGAAGG; for control protein: GCTCGAGAGAGCACAGTTTGTGGAGGAAGG). The underlined sequences encode P2 peptide. The chimeric cDNA was digested with EcoR I and Xho I and ligated to pET32a (Novagen) that had been linearized by digestion with the same enzymes. As shown in Figure 1, the EcoR I−Xho I site in pET32a was located downstream of hydrophilic thioredoxin tag (Trx-tag; 105 aa), N-terminal hexahistidine tag (His-tag), and S-peptide tag (S-tag; 15 aa); and upstream of C-terminal His-tag. A thrombin cleavage site (LVPAGS) was inserted between the N-terminal His-tag and S-tag. The plasmids, pET32-P2-vWFCBD and pET32-vWFCBD, were amplified in *E. coli* strain DH5α. The correctness of the plasmids was verified by sequencing.

Protein Expression and Purification. *E. coli* strain BL21-(DE3)pLysS (Novagen) was transformed with pET32-P2-vWFCBD and pET32-vWFCBD. Chimeric and control proteins were expressed using the Overnight Express Autoinduction System (Novagen). Proteins expressed as soluble forms were purified over His Trap HP column (Amersham). The proteins were then digested with thrombin (50 unit per mg protein) to remove the Trx-tag and N-terminal His-tag followed by

purification using S-tag Purification Kit (Novagen). The purity and molecular size of the proteins were analyzed by sodium dodecylsulfate−polyacrylamide gel electrophoresis (SDS-PAGE). Protein identity was assessed by Western blot using antibody against hexahistidine tag (Abcam Ltd., Cambridge, UK) and horseradish peroxidase-linked secondary antibody against mouse immunoglobulin G (GE Healthcare UK Ltd., Buckinghamshire, UK).

SPR Analysis. The self-assembled monolayer of 11-mercaptoundecanoic acid was formed on the glass plate having a 49-nm-thick gold layer, as reported before (*16*). The glass plate was mounted to an SPR sensor equipped with a flow cell (*16*). The light reflectance was continuously monitored at a constant incident angle 0.5° smaller than the angle for the occurrence of SPR during the following procedures. Type I collagen (Sigma) was dissolved in 0.1 M acetic acid buffer (pH 4.6) to a concentration of 0.1 mg/mL, and the solution was circulated to adsorb collagen onto the monolayer. After washing with acetic acid buffer and phosphate buffered saline (PBS), PBS containing 1 mg/mL bovine serum albumin (BSA; Sigma) was circulated to block the nonspecific adsorption of proteins. Then, the solution of P2-vWFCBD or vWFCBD in PBS (20 μg/mL) was circulated to bind these proteins to collagen. Finally, the light reflectance was converted to the resonance angular shift. All measurements were carried out at 37 °C.

Circular Dichroism (CD) Spectroscopy. CD spectra of P2-vWFCBD and vWFCBD were recorded using JASCO J-805 spectropolarimeter. P2-vWFCBD and vWFCBD were dissolved in Dulbecco's PBS (pH 7.4) to a mean residue concentration of 757 and 930 μM, respectively. Spectra were acquired in a 0.5 cm path length cell at a response time of 0.5 s, a bandwidth of 1 nm, a scan speed of 100 nm/min, and 20 °C with an accumulation of eight scans.

Cell Isolation. The hippocampus was isolated from fetus of Wistar rats (E18) and dissociated into single neurons by trypsin digestion (*17*). Animal experiments were conducted according to the guidelines of the Animal Experimentation Committee of the Institute. Neurons were suspended in Neurobasal medium (Gibco) containing 2% B27 supplement (Gibco), 100 U/mL penicillin, and 100 μg/mL streptomycin, and used immediately for cell culture assays.

Cell Culture. A two-well culture slide coated with type I collagen (BioCoat, BD Biosciences) was blocked with BSA. Then, the solution of P2-vWFCBD and vWFCBD (3.0 μM) were added to the wells and incubated at 37 °C for 3 h to allow the binding of these proteins to collagen. After washing the slide with PBS, hippocampus neurons were seeded at a density of 10 000 cells/cm^2 and incubated at 37 °C under 5% CO_2 atmosphere. In some wells, a synthetic peptide GRILARGEINFK (Invitrogen) was added to a final concentration of 7.2 μM. After 3-day culture, cells were fixed with paraformaldehyde, and cell membranes were permeabilized with TritonX-100. Then, cells were immunocytochemically stained using an

antibody to class III β-tubulin (Covance, NJ) and a fluorescently labeled secondary antibody. Cells were observed with an Olympus IX71 fluorescent microscope. The number of adhered cells was determined on four different fluorescent images and averaged.

RESULTS

Characterization of Proteins. As shown in Figure 2A, single bands were visualized by the SDS-PAGE analysis of proteins expressed in *E. coli* and purified by nickel chelate chromatography before thrombin digestion (Trx-P2-vWFCBD and Trx-vWFCBD). These bands split into two bands 26−27 kDa and 13 kDa by thrombin digestion. The former bands correspond to P2-vWFCBD and vWFCBD, whereas the latter to the segments containing the Trx-tag and the N-terminal His-tag. Further purification using the S-tag resulted in single bands corresponding to P2-vWFCBD and vWFCBD. Molecular weights estimated from the mobility of these bands are 27 kDa for P2-vWFCBD and 26 kDa for vWFCBD, in accordance with those expected from amino acid compositions. Figure 2B shows the results of Western blotting performed for Trx-P2-vWFCBD and Trx-vWFCBD after digestion with thrombin. In both cases, two protein bands were visualized at the positions of 26−27 kDa and 13 kDa, similar to the results of SDS-PAGE for corresponding samples (Figure 2A).

As shown in Figure 3, the CD spectra of P2-vWFCBD and vWFCBD are characteristic of α-helical and β-sheet secondary structure with minima at 208 and 222 nm both for α-helix and at 216 nm for β-sheet, although signal-to-noise ratios are small due to the relatively low concentration of proteins.

Binding to Collagen. The affinity of P2-vWFCBD and vWFCBD for collagen was studied by SPR analysis. As shown in Figure 4, the sensorgrams indicate the adsorption of collagen onto the carboxylic acid-terminated alkanethiol monolayer and also BSA to the surface with preadsorbed collagen. The subsequent circulation of P2-vWFCBD (Figure 4A) or vWFCBD (Figure 4B) resulted in the shift of the resonance angle, indicating the binding of these proteins. The presence of polypeptide segments containing the Trx-tag and N-terminal His-tag (proteins before thrombin digestion) hindered the binding of these proteins to collagen, even though CD spectra for these proteins obviously exhibited α-helical and β-sheet secondary structure (data not shown). The surface density of P2-vWFCBD and vWFCBD was estimated to be approximately 0.1 μg/cm^2 when adsorbed from 20 μg/mL solution, under the assumption that no replacement takes place with preadsorbed BSA and the unit angle shift corresponds to 0.5 μg/cm^2 (*18*). It was found that SPR sensorgrams decayed with time in washout phases of collagen, BSA, and fusion proteins. The gradual decrease in the resonance angles may be attributed to the intermolecular association of collagen initiated in neutral buffer solution at 37 °C. This makes it impossible to precisely determine the affinity constants for the binding of P2-vWFCBD and vWFCBD with collagen.

Adhesion of Neurons and Neurite Outgrowth. P2-vWFCBD and vWFCBD were bound to collagen-coated glass substrates. Hippocampus neurons were cultured on these surfaces for 3 days. It is obvious that cells adhered to and extended neurites on the collagen-coated surface with P2-vWFCBD (Figure 5A). In marked contrast, a small number of neurons were adhered to the collagen with vWFCBD during the entire culture periods, with poor neurite outgrowth (Figure 5B). This result is similar to our observation on untreated collagen (data not shown). These results suggest that the surface-bound P2 peptide has promotive effects on the adhesion of neurons and neurite outgrowth. The addition of soluble P2 peptide to the medium resulted in the inhibition of cell adhesion and neurite outgrowth on the surface with P2-vWFCBD (Figure 5C), indicating that the promotive effects of P2-vWFCBD involve the interaction of surface-bound P2 peptide with cell surface NCAM. The removal of the Trx-tag and the N-terminal His-tag by thrombin digestion was crucial for the adhesion of neurons and neurite outgrowth (data not shown), presumably due to the effect that the bulky segments hindered the binding

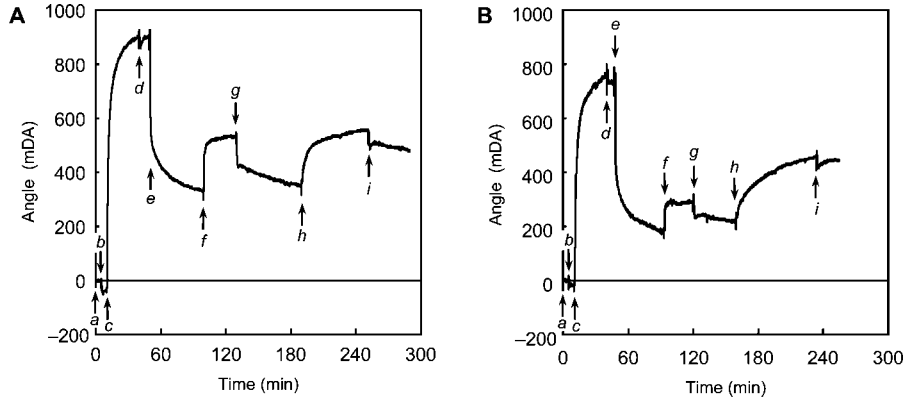

Figure 4. Representative SPR sensorgram recorded for the sequential adsorption of collagen and BSA onto the glass surface with a self-assembled monolayer of COOH-terminated alkanethiol, and the subsequent binding of (A) P2-vWFCBD and (B) vWFCBD. Proteins and buffers circulated: (a) PBS (pH 7.4), (b) sodium acetate buffer (pH 4.6), (c) 0.1 mg/mL collagen in sodium acetate buffer (pH 4.6), (d) sodium acetate buffer (pH 4.6), (e) PBS (pH 7.4), (f) 1 mg/mL BSA in PBS (pH 7.4), (g) PBS (pH 7.4), (h) 20 μg/mL P2-vWFCBD or vWFCBD in PBS (pH 7.4), and (i) PBS (pH 7.4). Measurements were carried out at 37 °C.

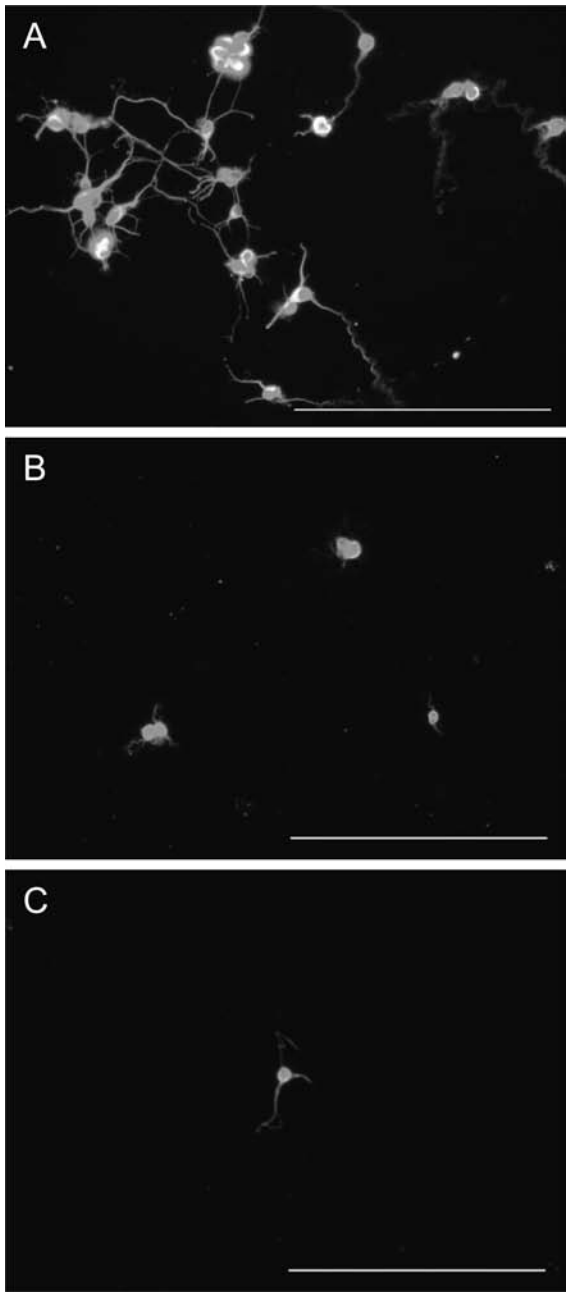

Figure 5. Fluorescent microphotographs of hippocampus neurons cultured for 3 days on the collagen-coated glass surface with (A) P2-vWFCBD and (B) vWFCBD. Cells were visualized by immunofluorescent staining using antibody against class III β-tubulin. Scale bar: 200 μm.

of vWFCBD to collagen and/or P2 to NCAM. Figure 6 shows the quantitative data obtained from the adhesion assay. It is seen that the number of adhered cells was much larger on the collagen-coated surface with P2-vWFCBD than on that with vWFCBD. In addition, soluble P2 significantly reduces the number of cells adhering to the collagen-coated surface with P2-vWFCBD.

DISCUSSION

The incorporation of protein-based components or the related small peptides have potential for designing collagen-based biomaterials capable of directly regulating neuronal adhesion and neurite outgrowth. Our previous study (*19*) revealed that the vWFCBD-containing chimeric protein enables us to densely

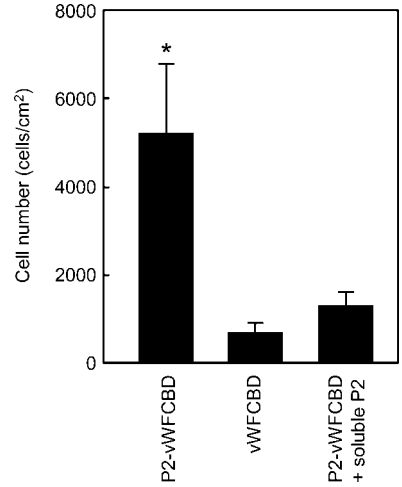

Figure 6. The number of neurons adhered to the collagen-coated glass surface with P2-vWFCBD and vWFCBD. The data are also shown for cells cultured on collagen with P2-vWFCBD in the presence of soluble P2 peptide. Cell numbers were determined 3 day after seeding. Error bars represent standard error of the mean ($n = 4$). *Statistically significant compared to the other two conditions ($p < 0.05$, Student's *t* test).

display the functional fusion partner on collagen fibrils. This strategy based on specific molecular recognition is also adapted in the present study. The chimeric protein containing a terminal anchoring domain can be immobilized onto substrates in the proper orientation by simple procedures under physiological conditions (*20*). These features form a marked contrast to covalent immobilization achieved by chemical reactions.

It was reported that the A3 domain of vWF has an affinity for type I collagen (*10*) with an association constant of the order of 10^8 M^{-1} (*21*). It was revealed from our SPR analysis that P2-vWFCBD and vWFCBD bind to collagen, suggesting the minor effect of additional sequences such as N-terminal S-tag and C-terminal His-tag. Furthermore, the binding is not affected by fusing the 12-aa residue P2 peptide at the C-terminus. In addition, the CD spectra shown in Figure 3 are in accordance with that previously reported for the recombinant A3 domain (*22*), suggesting the high conformational integrity of our proteins. To improve much more the structural stability of chimeric proteins, it is interesting to use collagen-binding peptides of shorter length, for instance, a 10-aa sequence within the D2 domain of vWF (*23*) and a 35-aa sequence in bone sialoprotein (*24*).

The results of cell culture demonstrate that the adhesion of neurons was promoted because of the P2 peptide displayed on the collagen substrate that is originally inert for neurons. It is known that the double-reciprocal binding of IgI and IgII modules of NCAMs promotes cell−cell adhesion and activates intracellular signaling pathways (*15*). Therefore, we expect that the P2-vWFCBD/collagen composite mimics the surface of neurons interacting with adjacent cells through NCAM−NCAM homophilic binding. P2 is a small peptide contained as a consecutive sequence of the FG loop in the NCAM IgII module (*13*). Our data suggest that the fusion with vWFCBD and the His-tag has minor effects on the function of the small P2 peptide.

In summary, we have reported here the synthesis of the collagen binding mimetic of NCAM, P2-vWFCBD, that mediates adhesion of neurons to a collagen matrix. The experimental data indicate that the P2-vWFCBD binds to collagen through vWFCBD, while the P2 peptide facilitates adhesion of neurons through interaction with NCAM. These findings suggest that P2-vWFCBD has the potential to provide favorable microenvironments for neurons to adhere and survive in collagen-based

matrices. Although this paper focuses on the utilization of the chimeric protein for controlling neuronal behaviors, the CBD-mediated modification of collagen will find a broad range of applications by appropriately selecting fusion partners.

To study conformational changes within a single protein molecule, sp-FRET (single pair fluorescence resonance energy transfer) is an important technique to provide distance information. However, incorporating donor and acceptor dyes into the same protein molecule is not an easy task. Here, we report a strategy for the efficient double-labeling of a protein on a solid support. An ubiquitin mutant with two Cys mutations, one with high solvent accessibility and the other with low solvent accessibility, was constructed. The protein was bound to magnetic beads and reacted with the dyes. The first dye reacted with the side-chain of the Cys with the high solvent accessibility and the second with the other Cys under partially denaturing conditions. Using this method, we can easily label two dyes in a site-specific way on ubiquitin with a satisfied yield. The labeling sites for donor and acceptor dyes can be easily swapped.

As a spectroscopic ruler, the FRET (fluorescence resonance energy transfer) technique can provide invaluable information on structural dynamics and has been widely used in studying protein−protein interactions using donor and acceptor dyes attached to different protein molecules (*1, 2*). To study conformational changes within a single molecule, two dyes have to be added to the same molecule, which is a challenge in the case of proteins (*3, 4*). Cysteine (Cys) is the most common residue used for labeling due to its unique functional group. Labeling a short peptide with two dyes is straightforward and can be achieved by synthesizing the peptide chemically and adding the dye during the procedure (*5*). In contrast, labeling a protein with two different dyes is more difficult. Small labeled proteins can be obtained by chemical ligation of a short labeled segment to the rest of the protein (*6*). For big proteins, one method is to mix the protein with both dyes and purify the double-labeled protein from unlabeled protein, donor-labeled protein (labeled at either one or two sites), and acceptor-labeled protein (labeled at either one or two sites) (*7–9*). Another more popular method for protein labeling is to add one dye first, then react the labeled protein with the second dye. (*10, 15*) This method has been used to double-label the cold shock protein (Csp) with Alexa-488 and Alexa-594 (*13, 14, 16*) and chymotrypsin inhibitor 2 (CI2) and acyl-CoA binding protein (ACBP) with Alexa-532 and Alexa-647 (*15*). One disadvantage of this method is that protein labeled at a single site with the first dye must be separated from the unlabeled protein and protein labeled at both sites with the first dye. To avoid the formation of the two sites-labeled protein, a substoichiometric quantity of the first dye is usually used, which makes the coupling yield low. However, it cannot control the position where the first dye is added. Hong and Maret (*17*) labeled metallothionein in a more specific way. The donor dye, Alexa-488, was added to the N-terminal amino group of metallothionein and the acceptor dye, Alexa-546, was reacted with the Cys residue in the linker region of the protein. Ha et al. (*18*) also used this method to label the Cys residue and N-terminus of Staphylococcal nuclease with TMR and Cy5, respectively.

Here, we report a strategy for the efficient double-labeling of a protein on a solid support (Scheme 1). The choice of labeling sites is the most critical point in making the labeling more site-specific. Because the yield of the labeling reaction depends on the degree of exposure of the sulfhydryl group of the Cys residue to the environment, we can easily add the first dye to a more exposed Cys, then add the second to a less exposed Cys with the aid of denaturant.

Haas and co-workers (*11*) measured the reactivity of six Cys in adenylate kinase by determining the rate constants for the reaction of the six single-Cys mutants with 5,5′-dithiobis(2-nitrobenzoic acid), then chose one highly reactive cysteine and one less reactive cysteine as the labeling sites. Based on the measured reactivity, they showed that the reactivity of reaction sites could be predicted using a computer program (*19*). Here, we chose the 76 amino acid protein, ubiquitin, which has no cysteine residues, as our target and used commercial software to predict the side-chain solvent accessibility of different sites after mutation to Cys. We aimed to add one Cys in the N-terminal region and one in the C-terminal region. One ubiquitin mutant with a single Cys insertion between Met1 and Gln2, named m[C]q, was predicted, using *Discovery Studio* software (version 1.7, Accelrys, USA), to have a higher solvent accessibility. Its side-chain solvent accessible surface was predicted as 56.1 ± 8.7 Å and the percentage of residue solvent accessibility as 46.5 ± 7.3% based on 20 energy-minimized structures. A Ser65 → Cys mutant, named S65C, had a predicted side-chain solvent accessible surface of 28.0 ± 7.0 Å and a percentage of residue solvent accessibility of 21.0 ± 5.4%.

Another important feature of our strategy is the use of magnetic beads, which can tolerate high concentrations of denaturants, such as 6 M GdnHCl and 8 M urea. The advantages of carrying out the reaction on a solid support include the

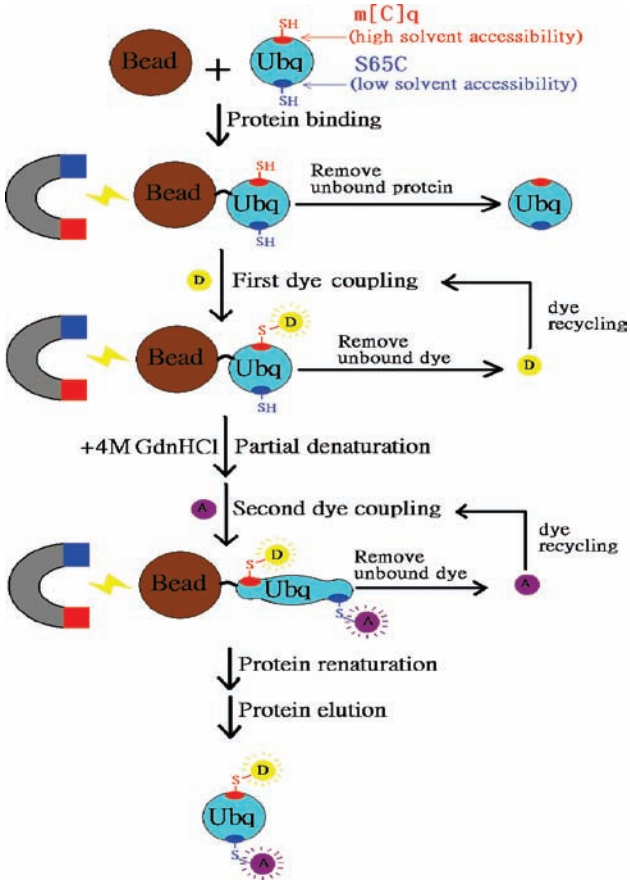
Scheme 1. Design of Labeling Strategy



following: (1) avoiding disulfide bond formation in the protein; (2) easy removal of free dye after reaction for reuse, thus saving on cost; and (3) avoiding protein aggregation under partially denaturing conditions. A 6-His tail was added to the end of ubiquitin for bead binding. For the dye pair, we selected Alexa Fluor 488 and Alexa Fluor 594 as our donor and acceptor dyes, respectively.

The mutant proteins m[C]q and S65C were expressed separately. As predicted, m[C]q was easily labeled with dye. Met1 in m[C]q was found to be removed by cell proteases, but its removal did not affect the reactivity of Cys2 with reagent. The dye coupling reaction was almost complete within two hours (Figure 1A). In contrast, S65C could not be labeled without the aid of denaturant (Figure 1B). When 4 M GdnHCl was added to the reaction mixture, the coupling yield of S65C was ≥76%.

A mutant for double-labeling needs one Cys with high solvent accessibility and one with low solvent accessibility. These two sites with different reactivities were therefore selected as our labeling sites. The double mutant protein, named m[C]q/S65C, was constructed and expressed and showed the same structure and structural stability as wild-type ubiquitin using circular dichroism spectroscopy and nuclear magnetic resonance (see Supporting Information).

Importantly, our method can also be used to easily swap the dye labeling positions. When Alexa-488 was added first and Alexa-594 second to m[C]q/S65C, a double-labeled protein with the donor dye at the N-terminal end and the acceptor dye at the C-terminal end, denoted A488-m[C]q/S65C-A594, was obtained. The emission spectra of A488-m[C]q/S65C-A594 showed acceptor emission due to energy transfer when the donor was excited (Figure 2A). When the labels were swapped and Alexa-594 added to m[C]q/S65C before Alexa-488, the protein A594-m[C]q/S65C-A488 was obtained. The excitation spectra of

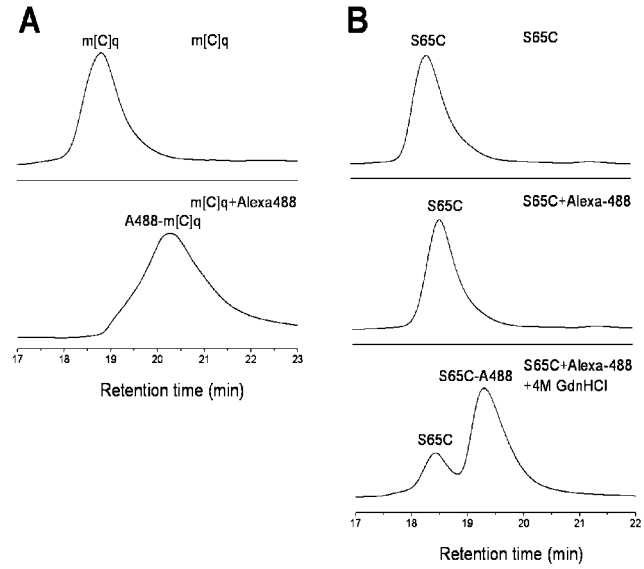


Figure 1. HPLC profiles of the dye coupling reactions of the proteins m[C]q (A) and S65C (B). The samples were analyzed by HPLC on a Vydac C18 column and the proteins detected by their absorbance at 220 nm. The proteins were resolved using a 30 min gradient of acetonitrile (15% for 5 min; 15−27% for 5 min; 27−35% for 20 min) in 0.1% trifluoroacetic acid.

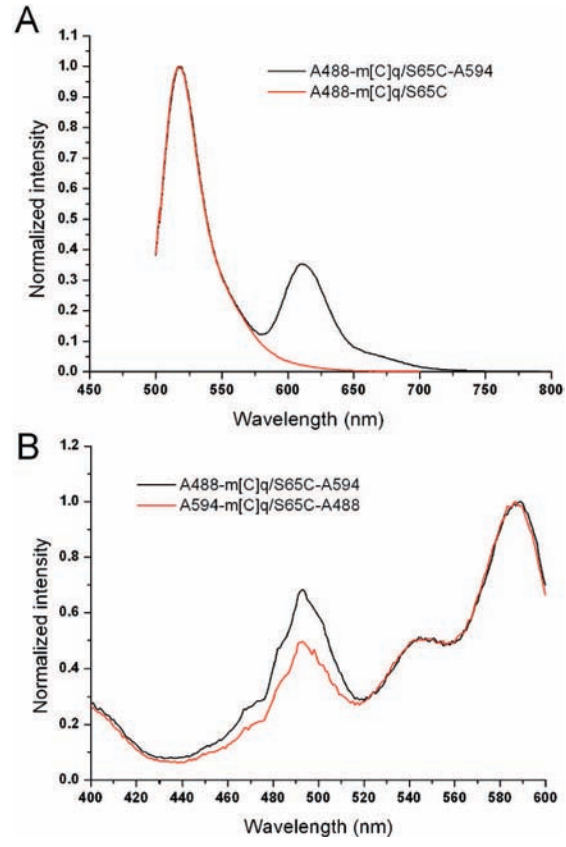

Figure 2. (A) Fluorescence emission scan of A488-m[C]q/S65C-A594 and A488-m[C]q/S65C. The excitation wavelength is 493 nm. (B) Fluorescence−excitation scan of A488-m[C]q/S65C-A594 and A594-m[C]q/S65C-A488. The emission wavelength is 620 nm. Samples were dissolved in distilled water with 0.1% Tween-20 and 5 mM DABCO (1,4-diazabicyclo[2.2.2]octane).

A488-m[C]q/S65C-A594 and A594-m[C]q/S65C-A488 were compared in Figure 2B. From the comparison of the spectra, different contributions of the donor dye in the acceptor

fluorescence suggested that the dye-labeling position can affect the efficiency of energy transfer. In protein-labeling studies, heterogeneity of the donor and acceptor labeling sites can only be ignored if each dye does not interact with the surface of the protein and is able to rotate freely or if the interaction does not interfere with the photophysics of the fluorophores and the stability of the protein. Using the normal Cys-labeling strategy, site-specific labeling is not easy to achieve, but our strategy makes this possible and can also be used to make the reversely labeled protein for comparison.

Site-Specific Modification of *Candida antarctica* Lipase B via Residue-Specific Incorporation of a Non-Canonical Amino Acid

Sanne Schoffelen, Mark H. L. Lambermon, Mark B. van Eldijk, and Jan C. M. van Hest*

Department of Bioorganic Chemistry, Institute for Molecules and Materials, Radboud University Nijmegen, The Netherlands.
Received January 15, 2008; Revised Manuscript Received April 13, 2008

In order to modify proteins in a controlled way, new functionalities need to be introduced in a defined manner. One way to accomplish this is by the incorporation of a non-natural amino acid of which the side chain can selectively be reacted to other molecules. We have investigated whether the relatively simple method of residue-specific replacement of methionine by azidohomoalanine can be used to achieve monofunctionalization of the model enzyme *Candida antarctica* lipase B. A protein variant was engineered with one additional methionine residue. Due to the high hydrophobicity and low abundance of methionine, this was the only residue out of five that was exposed to the solvent. The use of the Cu^{I}-catalyzed [3 + 2] cycloaddition under native conditions resulted in a monofunctionalized enzyme which retained hydrolytic activity. The strategy can be considered a convenient tool to modify proteins at a single position as long as one solvent-exposed methionine is available.

The introduction of novel functionalities into proteins has been extensively studied in recent decades. Chromophores, polymers, and polypeptides have been coupled to proteins to study or manipulate their function (*1, 2*). In most of these cases, the side chain functionalities of the amino acids cysteine and lysine were targeted for conjugation reactions because of the reactivity of the free thiol and amine moieties, respectively (*3–5*). However, cysteines are often involved in disulfide bonds that occur inside proteins. Breakage of these bonds can easily lead to loss of structural integrity and, hence, function. Lysine residues are positively charged, predominantly located at the protein surface, and relatively abundant. As a consequence, it is very likely that multiple functional handles are introduced when this residue is targeted for modification (*6*). Since the properties of the bioconjugates thus generated are influenced by the degree and site of modification, it is highly desirable to introduce new functional groups in a more defined manner (*7, 8*).

One approach to achieve this involves the modification of proteinogenic amino acids of which only some residues are exposed to the solvent. As an example, Francis et al. have shown that tyrosine can be functionalized using π-allylpalladium complexes (*9*). Only 4 tyrosines are present in their model protein chymotrypsinogen (245 amino acids in total). Two residues are surface-accessible and were therefore selectively modified. This strategy is somewhat limited, since most hydrophobic amino acids have no suitable reactivity in the side chain. One way to overcome this limitation is by replacing natural amino acids with non-canonical analogues with similar structure. This replacement can be performed in a residue-specific manner using auxotrophic bacterial strains. The bacteria, being unable to produce one of the natural amino acids, incorporates the supplied non-canonical analogue at each position in the protein where normally the natural amino acid would be present (*10*). In this way, there are still multiple reactive handles introduced. Non-natural amino acids can also be introduced in a site-directed way via in vivo techniques such as the amber suppressor method (*11–13*). One of the drawbacks of the latter method is that it involves complicated and time-consuming molecular biology procedures.

We hypothesized that, as an alternative to tyrosine, methionine would be a good candidate for monofunctionalization of proteins. It is one of the least abundant amino acids in proteins and is among the most hydrophobic residues. Except for the N-terminal residue, it is expected to be predominantly buried inside proteins (*14, 15*). The methyl thioether is not very reactive, but it has been shown that the non-natural amino acid azidohomoalanine can efficiently replace methionine when a methionine auxotrophic *E. coli* strain is used for protein production (*16*). Upon introduction of the azide moiety, it is possible to apply the bioorthogonal Cu^{I}-catalyzed [3 + 2] cycloaddition (*17*), which has been shown before to work very well for protein modification (*18–21*).

Although the replacement of methionine by reactive analogues has been well-established, it has not been investigated whether the limited availability of this residue can be used to control the number of conjugation sites. Previously, recombinant proteins were chemoselectively modified by replacing methionine with azidohomoalanine, followed by the Staudinger ligation under denaturing conditions (*22*). The presence of eight azides led to the formation of at least five different ligation products in a reduced environment. The use of native conditions during the ligation reaction is expected to limit the labeling to solvent-exposed azide residues only.

In order to study whether this relatively simple method can be used to site-specifically functionalize proteins, we have investigated the model enzyme *Candida antarctica* lipase B (CalB). The protein variant that was used contains five methionine residues, four of which are buried inside the protein. We show that replacing methionine **1** with azidohomoalanine **2** (Scheme 1) leads to the introduction of only one accessible azide for reaction with alkynes via the Cu^{I}-catalyzed [3 + 2] cycloaddition, also known as the click reaction. Thus, a residue-specific substitution leads effectively to an enzyme which can be functionalized at a single defined position. Importantly, we found that the enzyme remains active after non-natural amino acid incorporation and click chemistry.

CalB (EC 3.1.1.3) is widely used in organic synthesis as a biocatalyst with broad substrate specificity. The enzyme main-

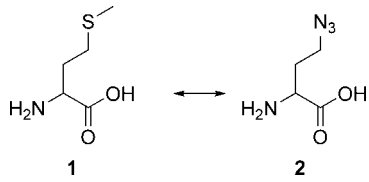
Scheme 1. Non-Canonical Amino Acid Azidohomoalanine 2 as a Structural Analogue of Methionine 1



tains its activity in organic solvents and is used for various applications such as amidation reactions, dynamic kinetic resolution, esterification, and ring-opening polymerization (*23, 24*). The processed protein consists of 317 amino acids and has a molecular weight of 33 kDa. We cloned the gene encoding this polypeptide in an expression plasmid containing an N-terminal periplasmic localization signal and a C-terminal histidine tag (*25*). As a consequence of the cloning strategy we used, our CalB gene encoded 5 methionine residues, whereas wild-type CalB contains 4. The extra residue was the first amino acid after cleavage of the periplasmic localization peptide (Figure 1).

Protein synthesis was induced in methionine auxotrophic *E. coli* bacteria. Residue-specific incorporation of **2** was achieved using the method described elsewhere (*16*). The mass of CalB containing azidohomoalanine (AHA-CalB) had to be 25 Da less than the mass of CalB with methionine residues (Met-CalB), i.e., 5 Da for each methionine−azidohomoalanine replacement. This mass difference was detected by ESI-TOF mass spectrometry (Figure 2). Additional peaks appeared as well, with a mass difference of 63 Da between adjacent peaks. This is due to the presence of traces of Cu ions most probably coordinated to the histidine tag.

To investigate whether the azide moieties in the protein were reactive toward alkynes, AHA-CalB was incubated with alkyne-functionalized dansyl **3** (20 equiv) in the presence of 1 mM $CuSO_4$, sodium ascorbate, and bathophenanthroline ligand **4** (all 30 equiv). The reaction was allowed to proceed overnight at room temperature in phosphate buffer (pH 7.0). Met-CalB was used as a negative control. Protein samples were dialyzed against buffer to remove unreacted dansyl and click reagents. Proteins were separated by electrophoresis, and labeling was verified by

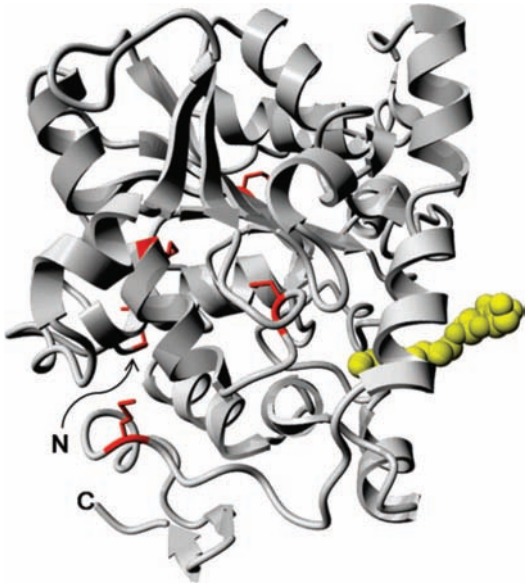


Figure 1. Structure of mature CalB with methionine residues shown in red and a substrate (yellow) positioned near the active site. The N and C termini are indicated as well. The conformation was derived from the PDB file '1tca' with addition of a methionine and a glycine to the N-terminus.

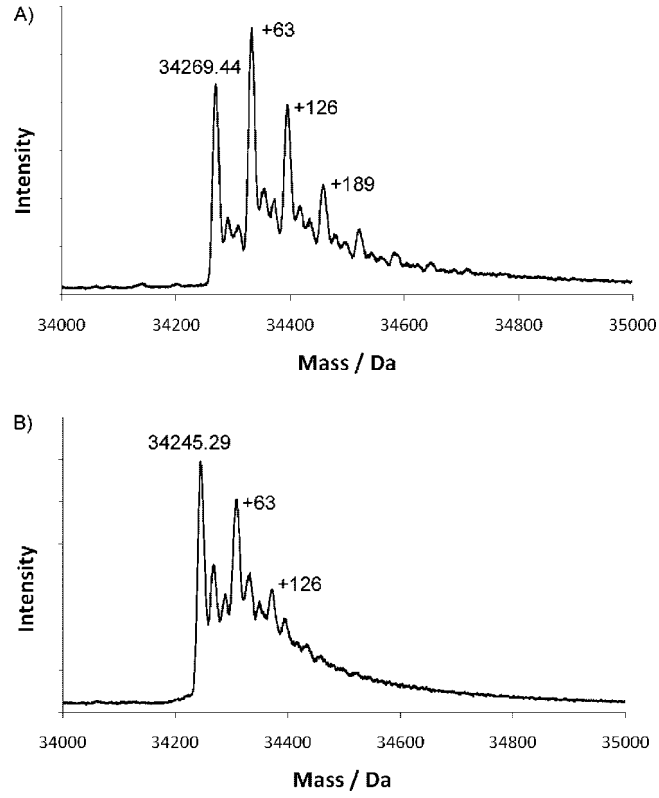

Figure 2. ESI-TOF mass spectra of (A) Met-CalB and (B) AHA-CalB. Upon deconvolution, peaks corresponding to the calculated masses (34 269.72 Da for Met-CalB and 34 244.93 Da for AHA-CalB) were detected.

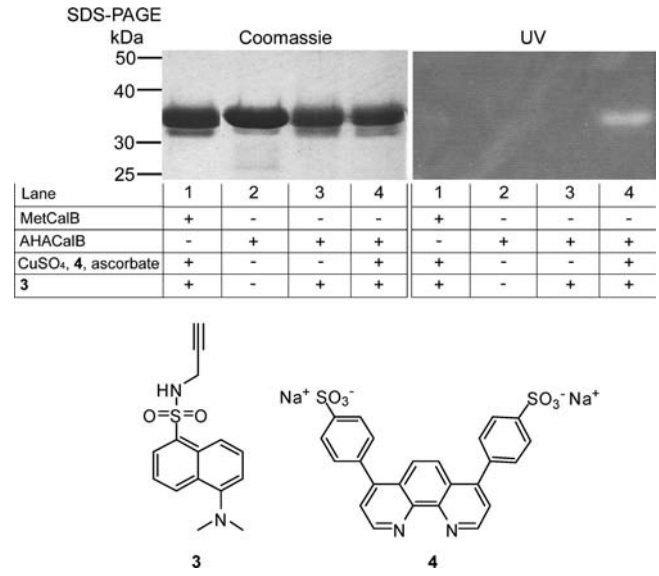

Figure 3. Labeling of AHA-CalB with alkynyl−dansyl **3** in the presence of $CuSO_4$, ascorbate, and bathophenantroline ligand **4**. Reactions were analyzed by SDS-PAGE, with gels stained with Coomassie after fluorescence visualization by UV.

visualizing the fluorescent bioconjugate by UV (Figure 3). Only AHA-CalB treated with Cu catalyst and **3** turned out to be specifically labeled.

To identify which of the azides were reactive toward the alkyne-functionalized dansyl, reacted and nonreacted AHA-CalB and Met-CalB samples were treated with trypsin, and digests were analyzed by MALDI-TOF mass spectrometry. As expected, fragments containing methionine in Met-CalB proved to be five units lower in mass in the AHA-CalB sample, due to

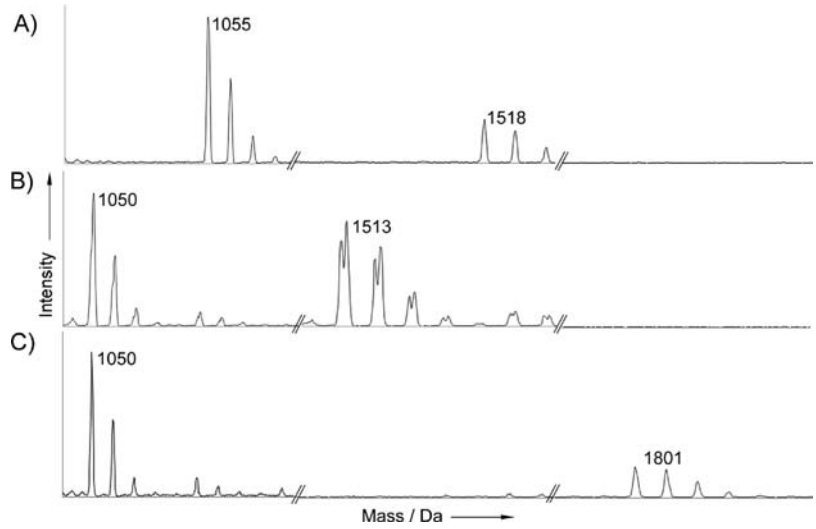

Figure 4. MALDI-TOF spectra of two tryptic fragments derived from (A) Met-CalB incubated with dansyl, (B) AHA-CalB, and (C) AHA-CalB reacted with dansyl. The peak at 1055/1050 Da comes from the peptide fragment with residue numbers 130−138. The peak at 1518/1513 Da originates from the N-terminal peptide fragment (residue numbers 1−15) to which alkynyl−dansyl can be linked. Attachment of dansyl causes a mass shift of 288 Da, leading to a peak at 1801 Da.

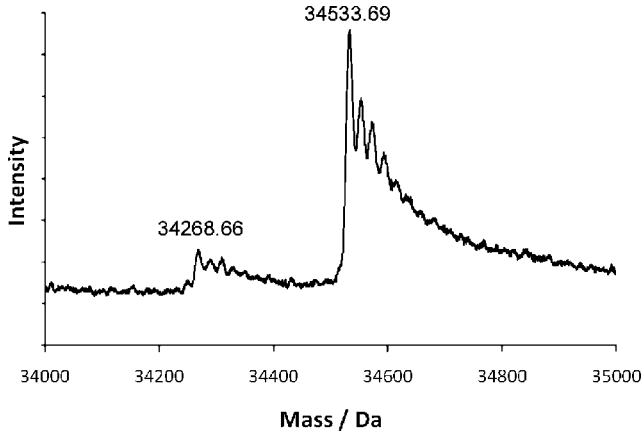

Figure 5. ESI-TOF mass spectrum of AHA-CalB reacted with dansyl. One dansyl was attached to AHA-CalB resulting in addition of 288 Da to the AHA-CalB mass of 34 245 Da. As expected, the nonreactive fraction of Met-CalB was detected at 34 269 Da.

the presence of azidohomoalanine (Figure 4). For example, the peptide fragment of residues 130−138 containing methionine at residue number 131 (1055 Da) was detected as a fragment of 1050 Da in the tryptic digest of unreacted AHA-CalB. The same fragment was present in the digest of dansyl-reacted AHA-CalB, indicating that no dansyl had been attached to this azide moiety. By contrast, a mass shift of 288 Da (corresponding to the weight of dansyl) was detected for the peptide fragment of residues 1−15 containing an azide at residue position 1. It was therefore concluded that this azide, being located at the N-terminus of the processed protein, was accessible for ligation reactions. It was observed that the labeling with dansyl was quantitative, as no residual signal at 1513 Da was detected. Finally, these data show that, as expected, there is a small fraction of methionine present in AHA-CalB (see small peaks at 1055 and 1518 Da in Figure 4B,C). The degree of azidohomoalanine incorporation was shown to be 90%.

The addition of dansyl to AHA-CalB was further analyzed by ESI-TOF mass spectrometry. Only one dansyl molecule was found to be attached to the protein, giving the expected mass of 34 533 Da (Figure 5). The fraction of CalB which contained methionine instead of azidohomoalanine was detected as a residual peak at 34 269 Da.

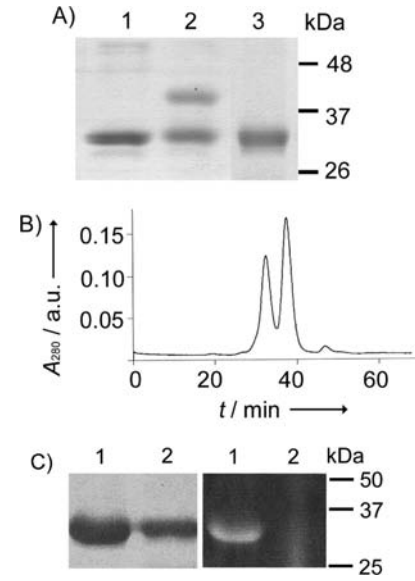

Figure 6. Labeling of AHA-CalB and AHA-CalB(M > G) with PEG5000 and alkynyl−dansyl **3**. (A) PEGylation reactions, analyzed by SDS-PAGE using Coomassie staining: 1, Met-CalB; 2, AHA-CalB; 3, AHA-CalB(M > G). (B) Separation of PEGylated AHA-CalB from nonreacted CalB by size-exclusion chromatography. (C) Click reactions with alkynyl−dansyl, analyzed by SDS-PAGE, and visualized by UV prior to Coomassie staining: 1, AHA-CalB; 2, AHA-CalB(M > G).

Subsequently, alkyne-functionalized PEG(5000) was coupled to AHA-CalB. After removal of the excess PEG(5000) by clicking to azide-functionalized resin (*26*), attachment of the polymer to CalB was analyzed by gel electrophoresis (Figure 6A). A single band shift was detected between 37 and 48 kDa. Nonfunctionalized CalB was separated from the PEGylated fraction by size-exclusion chromatography (Figure 6B). The chromatogram showed two peaks indicating that only one derivative had been produced.

The N-terminal methionine codon was replaced by glycine, indicated as AHA-CalB(M > G). Upon reaction with alkynyl-PEG(5000), no pegylation was observed by gel electrophoresis. Moreover, labeling of AHA-CalB(M > G) with alkynyl−dansyl did not result in a fluorescent band on SDS-PAGE gel (Figure

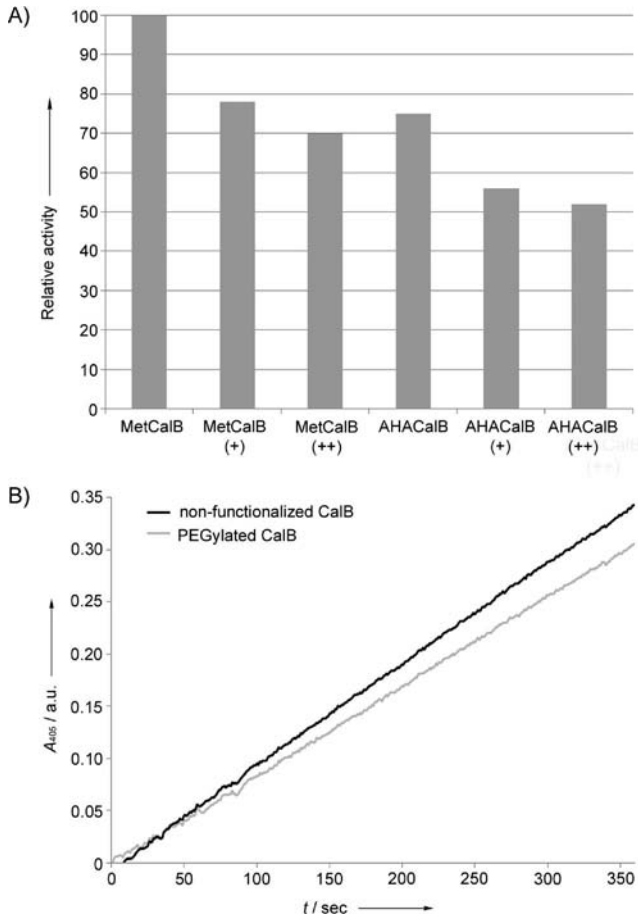

Figure 7. (A) Hydrolytic activity of Met-CalB and AHA-CalB, and the influence of click reagents. Formation of *para*-nitrophenol was monitored by detecting absorbance at 405 nm. (+) = after incubation with $CuSO_4$, ascorbate, and ligand **4**; (++) = after incubation with $CuSO_4$, ascorbate, ligand **4**, and alkynyl−dansyl **3**. (B) Comparison of the hydrolytic activity of PEGylated CalB and the nonfunctionalized fraction. The latter sample consists of a small fraction of Met-CalB together with nonlabeled AHA-CalB.

6C). This confirms that, of all five azides introduced in nonmutated AHA-CalB, only the N-terminal one was accessible for clicking.

The enzymatic activity of different CalB variants was analyzed by hydrolysis of *para*-nitrophenyl butyrate. Formation of *para*-nitrophenol by Met-CalB and AHA-CalB was monitored by measuring absorbance at 405 nm. Upon introduction of azidohomoalanine, hydrolytic activity was retained for 75% (Figure 7A). Additionally, we investigated the effect of the click reaction on enzymatic activity. Met-CalB and AHA-CalB were incubated in the presence of click reagents, with or without alkynyl−dansyl. Subsequent measurements showed that the reagents had some negative effect on the activities of both Met-CalB and AHA-CalB. As shown in Figure 7A, the activity of Met-CalB was decreased to 70%. The activity of AHA-CalB was reduced to 52% after incubation with dansyl and click reagents, which is 69% of the activity of nontreated AHA-CalB.

Additionally, the enzymatic activities of both the PEG-CalB conjugate and the nonpegylated CalB fraction were monitored after size-exclusion chromatography. Comparing the fractions, which were derived from the same click reaction mixture, revealed that there was hardly any loss of activity due to attachment of the polymer itself (Figure 7B).

To conclude, we have developed a convenient method to modify CalB protein in a site-directed way. An azide-bearing methionine analogue was introduced to act as functional handle. Subsequently, other molecules were covalently linked via the highly selective Cu^I-catalyzed click reaction. Although multiple azides were introduced, only one moiety appeared to be reactive under native conditions, as the other residues were buried inside the protein. The method seems to be a good substitute for the less-straightforward amber suppressor strategy.

Our method can be considered a versatile tool to modify proteins in a site-specific way, as long as one solvent-accessible methionine residue is present. In many cases, it will be the N-terminal methionine that is available. It should be noted, however, that the N-terminal methionine or its analogue can be cleaved off during post-translational processing (*27*). If no other methionine is accessible, a novel residue can be introduced via a single mutagenesis step. Therefore, the method is not restricted to N-terminal labeling. It can also be used to modify other regions of the protein surface with absolute control over the site of modification.

After the entire modification procedure, catalytic activity was partially retained. Part of the hydrolytic activity was lost due to the incorporation of the non-proteinogenic amino acid and the use of $CuSO_4$, ascorbate and ligand. Application of a copper-free click reaction such as the Staudinger ligation, the strain-promoted [3 + 2] azide-alkyne cycloaddition, or the reaction between azides and oxanorbornadienes may lead to less loss in activity (*22*, *28*, *29*). As reported elsewhere, the modification strategy has been successfully applied to immobilize CalB on polymersomes (*30*).

ACKNOWLEDGMENT

The authors thank A. J. Dirks for preparing the alkyne-functionalized PEG5000, and R. Brinkhuis and J. Opsteen for providing the alkynyl−dansyl and azide resin, respectively. We thank E. Akpa for providing the CalB gene and P. van Galen and H. op den Camp for help with mass spectrometry analysis. H. Venselaar is thanked for providing the picture of our CalB protein containing the extra methionine and glycine at the N-terminus.

BC800019V

A DNA Duplex-Based, Tailor-Made Fluorescent Sensor for Porphyrin Derivatives

Kazuhisa Fujimoto,* Yu Muto, and Masahiko Inouye*

Graduate School of Pharmaceutical Sciences, University of Toyama, Sugitani 2630, Toyama 930-0194, Japan. Received April 1, 2008; Revised Manuscript Received April 16, 2008

We synthesized a DNA-based fluorescent sensor, tailored to the recognition and signaling for hydrophobic guest molecules. The sensor molecule is made of three functional moieties, per-*O*-methylated *β*-cyclodextrin (per-Me-*β*-CD), DNA, and pyrene as guest-binding, dimerizing, and signaling ones, respectively. Addition of a porphyrin derivative as a hydrophobic guest molecule induced emission switching of the sensor molecule from monomer to excimer due to the DNA hybridization promoted by the host−guest binding.

In host−guest chemistry, most of host molecules have been developed according to preorganization concepts in order to selectively recognize target molecules (*1*, *2*) since the breakthrough of crown ethers by Pedersen (*3*). The preorganization approach, however, demands many designing and synthetic efforts, so that it hardly supplies a series of host molecules with generality and versatility for various biologically important species. In proteins, innumerable combinations of amino acid residues in the primary sequences realize these aspects for recognizing substrates with a specific manner. If we can apply the combination of functional components, as seen in proteins, for designing artificial host molecules, such a design technique will shed fresh light on host−guest chemistry. Recently, we reported a new type of molecular design for host molecules working in water, inspired by the structural motif of antibodies (*4*). The designed host molecules consist of two monomers, each of which possesses three functional regions for guest-binding (recognition units), dimerizing (cDNAs), and signaling (fluorophores). In that study, crown ether and pyrene were used as the guest-binding and signaling sites, respectively, for targeting metal cations. A cooperative binding of the two crown ethers for metal cations promotes the hybridization of the cDNAs to induce a monomer−excimer emission switching from the pyrene fluorophores. This tailormade design method allows a variety of recognition units to be introduced at the ends of DNAs homogeneously or heterogeneously. Here, to demonstrate the generality and versatility of our method, we newly developed a fluorescent sensor **1** (**1a** + **1b**) for porphyrin derivatives on the basis of the design technique mentioned above.

We chose per-*O*-methylated *β*-cyclodextrin (per-Me-*β*-CD) as a recognition moiety in the new fluorescent sensor because

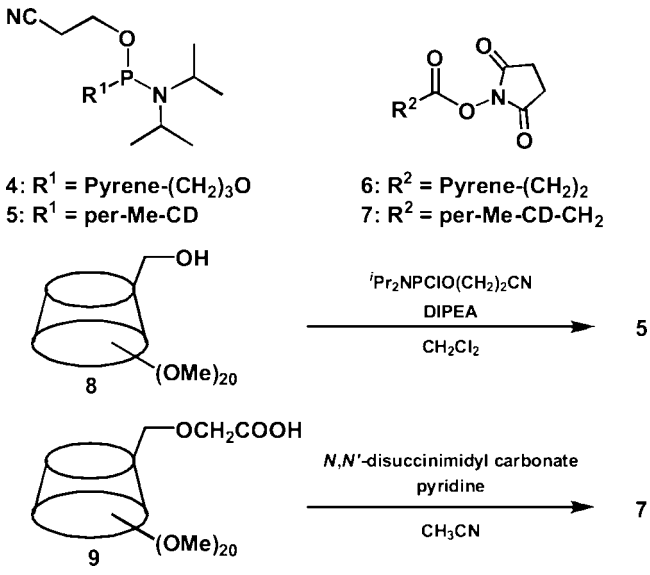
Scheme 1



the skeleton had been reported to strongly recognize porphyrin derivatives such as TPPS **3** in a 2:1 binding manner by Kano et al. (Figure 1) (*5*). Furthermore, per-Me-*β*-CD shows good solubility in water as compared to native *β*-CD, so that it should contribute to improve the water solubilities of **1a** and **1b** as well as the DNA moieties do. As shown in Figure 1b, when the per-Me-*β*-CD moieties capture **3** in a 2:1 binding manner accompanying the duplex formation of the DNA ones, emission switching will occur from the pyrene monomer to excimer. The two monomers **1a** and **1b** comprising complementary 7-mer DNAs were synthesized according to the procedure published previously (*4*). In the DNA moieties of these monomers, **1a** was functionalized with the pyrene-modified phosphoramidite **4** (*6*) and the CD-attached succinimidyl ester **7** at 5′ and 3′ ends, respectively, while **1b** was linked with **5** and **6** in the style opposite that of **1a**. The syntheses of the pyrene derivatives **4** and **6** have been reported in our previous paper (*6*). The CD derivatives **5** and **7** were newly synthesized from mono-6-hydroxy permethylated *β*-cyclodextrin **8** (*7*) and 6^{I}-*O*-carboxymethyl-2^{I-VII},3^{I-VII},6^{II-VII}-eicosa-*O*-methyl-cyclomaltoheptaose **9** (*8*), respectively (Scheme 1). The following reference monomers were prepared for using in control experiments: both **1a′** and **1b′** lack the per-Me-*β*-CD moiety (*4*), and **2** possesses an oxy-ethylene spacer instead of DNA (Figure 1a).

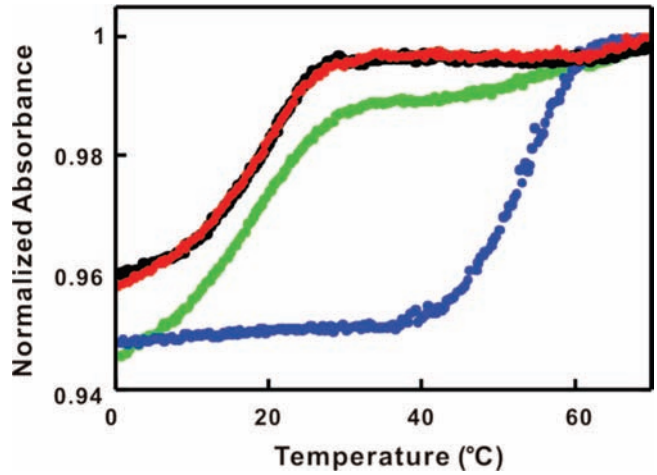


Figure 3. Normalized melting curves at 260 nm. Melting curves were normalized with the division by the each absorbance at 60 °C. The solution for the measurements contained **1** or **1′** (duplex, 2.5 *μ*M) and 20 mM Tris-HCl (pH 8.0) in the presence or absence of **3** (2.5 *μ*M). Blue, **1**+**3**; green, **1**; red, **1′**+**3**; black, **1′**.

To explore the sensing ability of **1** for the porphyrin **3**, fluorescence titration experiments were carried out in an aqueous buffer solution (Figure 2a). As **3** was continuously added to the solution of **1a**/**1b** ([**1a**] = [**1b**] = 200 nM), the monomer emission intensity ($I_{380\ nm}$) decreased while the excimer emission one ($I_{500\ nm}$) increased; the spectral change was completed in the presence of 1.5 equiv of **3** against **1a** or **1b**. In this spectral change, the isoemissive point was observed at 448 nm, which indicates the presence of only two types of fluorescent species in the solution, the single-stranded **1a** (and **1b**) and the associated form. For certifying the 2:1 binding manner of the CD moieties to **3**, control experiments were performed by use of the following combinations **1a**/**1b′**, **1a′**/**1b**, and **1a′**/**1b′**, in which **1a′** and **1b′** lack the CD moieties. The ratio of the emission intensities ($I_{500\ nm}/I_{380\ nm}$) was plotted against the concentration of **3**, and we observed no meaningful changes for the three combinations (Figure 2b). The only combination of **1a**/**1b** showed a significant change in the intensity ratio, meaning that a set of per-Me-*β*-CDs is indispensable for the binding. Therefore, the emission switching is likely to be responsible for the duplex formation between **1a** and **1b** by the addition of **3**. To demonstrate this, melting temperatures (T_m) and CD spectra were measured for **1** and **1′** in the absence and presence of **3**. Figure 3 shows melting curves at 260 nm, normalized with the division by the each absorbance at 60 °C. The T_m value of **1** in the presence of **3** extensively increased up to 53 °C compared with 19 °C for **1** itself, while the value of **1′** hardly changed in the

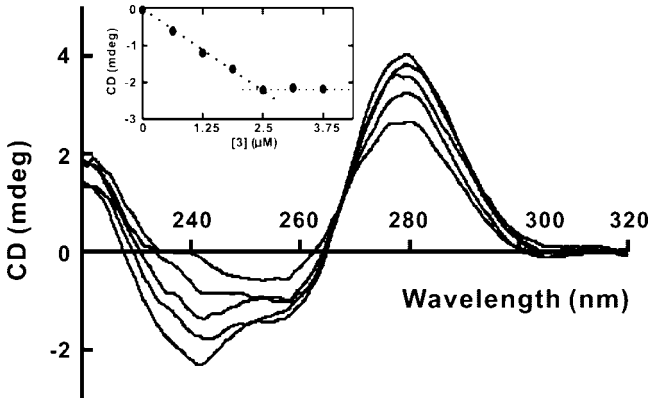

Figure 4. CD titration spectra of **1** (duplex, 2.5 μM; [Tris-HCl], 20 mM, at pH 8.0) on titration with **3** (0−1 equiv). Inset: plots of the CD intensities at 240 nm against the concentration of **3**.

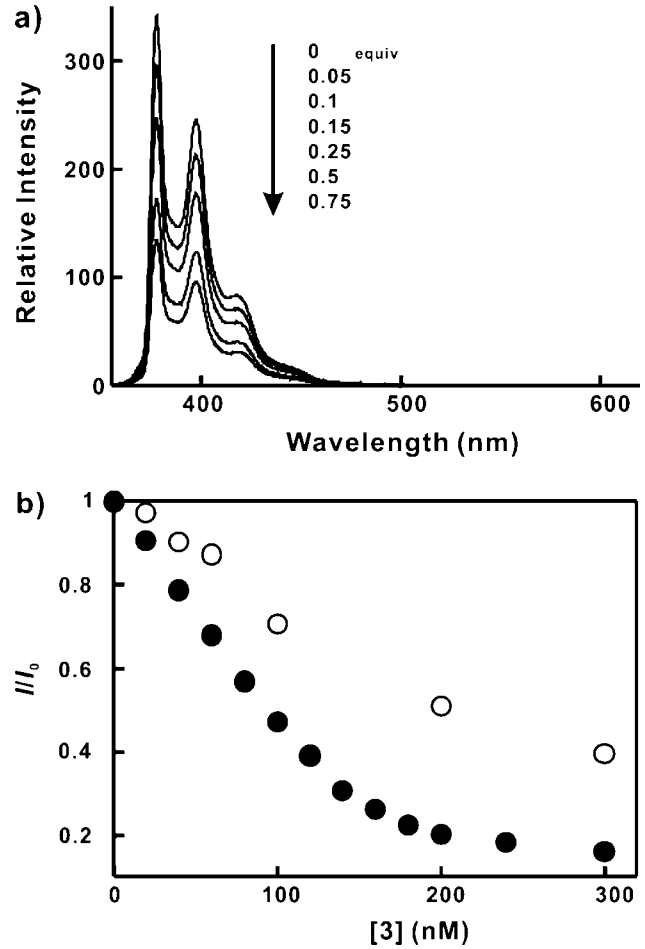

Figure 5. (a) Fluorescence titration spectra of **2** ([**2**] = 400 nM; [Tris-HCl], 20 mM, at pH 8.0) on titration with **3** (0−0.75 equiv). Excitation wavelength was 350 nm. (b) Plots of the monomer emission intensities (I/I_0) at 380 nm against the concentration of **3**. Closed circle, **1** (duplex, 200 nM); open circle, **2** ([**2**] = 400 nM).

presence of **3** (19 °C). The Cotton effects in the DNA-absorptive region of **1** were enhanced by the consecutive addition of **3** (Figure 4). When the CD intensity of **1** at 240 nm was plotted against the concentration of **3**, the intensity change was saturated in the presence of 1 equiv of **3** (Figure 4, inset). The CD titration almost accords with the fluorescent one performed under the more diluted condition in Figure 2. These findings indicate the duplex formation-driven emission switching of **1** in the presence of **3**.

Since per-Me-β-CD itself can bind to TPPS **3** in a 2:1 binding manner, even a fluorescent sensor lacking in DNA moieties may detect **3** by emission switching. Therefore, an additional control experiment was carried out with **2** (Supporting Information Scheme S1) possessing an oxy-ethylene spacer instead of a DNA moiety. The fluorescent titration of **2** is shown in Figure 5a under the same conditions as mentioned in Figure 2 except for [**2**] = 400 nM. When **3** was added to the solution of **2**, the monomer emission was decreased, whereas the corresponding excimer emission never rose. Another emissive band scarcely appeared around 650 nm from the porphyrin core of **3**. These spectral changes might be due to a fluorescence resonance energy transfer (FRET) (*9*) from the pyrene fluorophores to **3** because the monomer emissive region of the pyrenes overlaps with the Soret band of **3**. After the excitation energy of the pyrene monomer had been transferred to **3**, most of the energy might be consumed in nonradiative processes. The rigid duplex moiety in **1** is likely necessary for inhibiting the energy transfer from the pyrene to the bound porphyrin. Next, to display the contribution of the DNA moieties of **1** for binding to **3**, each of the monomer intensities (I/I_0) at 380 nm of **1** and **2** was plotted against the concentration of **3** (Figure 5b). The intensity change of **1** is almost saturated at [**3**] = 200 nM, while that of **2** continues at the concentration of 300 nM. From this comparison between **1** and **2**, the DNA moieties in **1** were found to partially contribute the binding to **3**.

In conclusion, we have developed a new class of fluorescent sensor for hydrophobic target molecules. This DNA-based, tailormade fluorescent sensor could recognize TPPS in a 2:1 binding manner at the per-Me-β-CD moieties, detecting it by monomer−excimer emission switching. We are now introducing new recognition units such as native β-CD into DNA backbones in order to target various biologically important species and to display the practicability of our design technique.

Received November 28, 2007; Revised Manuscript Received March 13, 2008

In the present study, we describe a multimodal QD probe with combined fluorescent and paramagnetic properties, based on silica-shelled single QD micelles with incorporated paramagnetic substances [tris(2,2,6,6-tetramethyl-3,5-heptanedionate)/gadolinium] into the micelle and/or silica coat. The probe was characterized with high photoluminescence quantum yield and good positive MRI contrast, low cytotoxicity, and easy intracellular delivery in viable cells. The intravenous administration of the probe in experimental animals did not affect significantly the physiological parameters and microcirculation (e.g., heart rate, blood pressure, diameter and shape of blood vessels), which makes it appropriate for tracing of blood circulation and *in vivo* multimodal imaging using fluorescent confocal microscopy, two-photon microscopy, and MRI.

INTRODUCTION

The careful design of the architecture of water-soluble QDs enables the creation of nanobioprobes that are compatible with several imaging techniques, so-called multimodal imaging. This opens the door to the existing prospect of simultaneous imaging of QD probes by a variety of techniques including optical imaging, magnetic resonance imaging (MRI), positron emission tomography (PET), computed tomography (CT), and X-ray imaging.

In particular, by fabricating QD probes that exhibit both fluorescent and paramagnetic properties, optical imaging and MRI can be used in a complementary fashion. This is a powerful combination, as the MRI offers an ability to follow the distribution of molecules *in vivo* or provide an anatomical reference, whereas the optical imaging can be applied to obtain detailed information at subcellular levels. The potential applications include monitoring tissue implants and studying the real-time dynamics of tumor metastases and biochemical mediators that might be responsible for many diseases.

The use of a single multimodal probe with two or more imaging techniques has several advantages. The conventional (nonmultimodal) probes, used in PET, MRI, or optical imaging, have different structures and properties, which determine their different target affinity and pharmacodynamics in the organism. Often, the target can be detected by several imaging techniques using several imaging probes with different properties and pharmacodynamics, so the results cannot be easily compared and verified. The researchers and clinicians are faced with the dilemma of which technique to choose and which data to accept as true. The use of a single multimodal probe with two or more imaging techniques minimizes the artifacts and enables a precise comparative analysis of the images, obtained by different techniques.

The existing prospect of using QDs as multimodal imaging probes attracts the interest of researchers in many different scientific fields, and the number of publications on the topic has increased exponentially in recent years (*1*−*21*). However, so far, the results are preliminary and interpretations are still speculative, especially in terms of *in vivo* deep-tissue imaging.

Perhaps the most attractive for development of multimodal imaging probes (optical and paramagnetic) are silica-shelled QDs. The silica is a bioinert material. The silica shell enables incorporation of a large amount of contrast substances inside the silica sphere (e.g., CdSe, CdTe, CdS, InAs, or InP QDs and Fe_2O_3, Fe_3O_4, $CoFe_2O_4$, $MnFe_2O_4$, FePt, or $CoPt_3$ paramagnetic nanoparticles; fluorescent/paramagnetic heterodimers, such as Fe_3O_4-Au, CoPt-Au, FePt-Ag, Fe_3O_4-Au-PbSe, γ-Fe_2O_3-CdS, FePt-CdS, Co/CdS core/shell, Co/CdSe core/shell, CdSe/Zn_{1-x}-Mn_xS; QDs and paramagnetic fatty acids) (*3*, *7*, *13*, *15*, *16*). In addition, paramagnetic substances (e.g., chelators for gadolinium, manganese, etc.) could also be attached on the surface of silica-coated QDs (*5*, *15*, *18*−*20*). The high fluorescent contrast (as a result of high quantum yield of QDs) and the high paramagnetic contrast (as a result of incorporation of a large amount of paramagnetic substances in the small volume of the silica sphere) enable development of a probe that could be detected *in vivo* in a single manner, simultaneously using optical imaging and MRI. In that case, even single cells and molecular targets could be visualized.

Figure 2. (A) Transmission electron micrographs of silica-shelled QD micelles. (B) Retention of gadolinium complex in the silica sphere (probe A) or on the surface of the silica sphere (probe B) after purification via dialysis. (C) Fluorescent and paramagnetic characteristics of probes A and B. The probes were purified using 48 h dialysis. Longitudinal relaxation time (T_1) and transverse relaxation time (T_2) were calculated at equal concentrations of both probes (corresponding to 500 nM QDs). The QD concentration was calculated from the absorbance spectra of multimodal silica-shelled QDs, using the equation of Yu et al. (*38*). The MRI measurements were performed in a 4.7 T magnet (General Electric, CT) interfaced to a Bruker Avance console (Bruker Medical GmbH, Germany). A 30 mm diameter Litz coil (Doty Scientific Inc., SC, USA) was used for measurement of the samples. The sample temperature was maintained at room temperature (~22−24 °C). The measurements were performed in the following order: T_1-weighted imaging using conventional spin−echo (SE) sequence; multiecho SE imaging for T_2 calculations; and inversion−recovery SE imaging for T_1 calculations. For calculation of photoluminescence quantum yield (PL QY), the spectrally integrated emission of particle dispersion in different aqueous solutions (distilled water, PBS, or Tris buffer) was compared with the emission of an ethanol solution of rhodamine 6G (Fluka) of identical optical density (<0.015) at the excitation wavelength 365 nm.

The present study accents the biocompatibility of multimodal QD probes based on silica-shelled single QD micelles with incorporated gadolinium complexes into the micelle and/or silica coat. We tried to clarify the applicability of this probe for blood vessel tracing in the brain, estimating its effect on the major physiological characteristics (such as blood pressure, heart rate, and brain microcirculation) after *in vivo* intravenous (i.v.) administration.

EXPERIMENTAL PROCEDURES

Synthesis and Characterization of Multimodal QDs. Two multimodal QD-based probes were synthesized (Figure 1). The synthesis of the first probe (Figure 1A) was performed as it was described in our previous manuscripts (*21*). The synthesis of the second probe (Figure 1B) was performed according to refs 22, 23 (with slight modifications) (*22*, *23*) Briefly, the gadolinium complex *S*-2-(4-isothiocyanatobenzyl)-1,4,7,10-tetraazacyclododecane tetraacetic acid/gadolinium (DOTA-Bn-NCS/gadolinium) was mixed with amino-functionalized QDs (400:1, mol/mol) in 10 mM PBS (pH 8.0). After 1 h incubation at room temperature, the conjugate was purified using dialysis, as described in our previous manuscript (*21*). DOTA-Bn-NCS/gadolinium complex was purchased from Macrocyclics Co. (USA). The same molar ratio gadolinium complex/QD = 400:1 was used in the synthesis of the first probe. After purification, the gadolinium concentration in the respective probe was measured using ^{1}H-MRI as described below. The structure and size of nanoparticles were characterized by TEM and DLS. Their spectral characteristics were measured using fluorescent spectroscopy, absorbance spectroscopy, and MRI.

Cell Cultures. HeLa cells were cultured in Minimum Essential Medium (MEM, GIBCO, Invitrogen, USA), supplemented with 10% inactivated FBS (Sanko, Japan). A-549 cells, derived from human lung cancer, Jurkat and K-562 cell lines, derived from human acute lymphoblastic leukemia or chronic myeloid leukemia, respectively, were cultured in RPMI-1640 medium (GIBCO, Invitrogen, USA), supplemented with 10% inactivated FBS (Sanko, Japan), 100 U/mL penicillin (GIBCO, Invitrogen, USA), and 100 μg/mL streptomycin (GIBCO, Invitrogen, USA). One day before the treatment with QDs, the cells (1×10^5 cells/mL) were dispensed in 100 μL aliquots in 96-well plates and cultured overnight in medium without FBS and antibiotics, in humidified atmosphere (5% CO_2, 37 °C).

Intracellular Delivery of Multimodal QDs (MRI Measurements and Data Analysis). The MRI measurements were performed in a 4.7 T magnet (General Electric, CT) or a 7.0 T magnet (Kobelco, Japan) interfaced to a Bruker Avance console (Bruker Medical GmbH, Germany). A 30 mm diameter Litz coil (Doty Scientific Inc., SC, USA) or 70 mm diameter volume coil (Bruker) was used for measurement of the samples. The details are indicated in the figure captions. The PCR tubes were mounted on a plastic holder for 4.7 T or on a 70 mm diameter volume coil for 7.0 T and set in the center of the coil. The sample temperature was maintained at room temperature (approximately 22−24 °C). The measurements were performed in the following order: T_1 weighted imaging, using conventional spin−echo (SE) sequence; multiecho SE imaging for T_2 calculations; and inversion−recovery SE imaging for T_1 calculations.

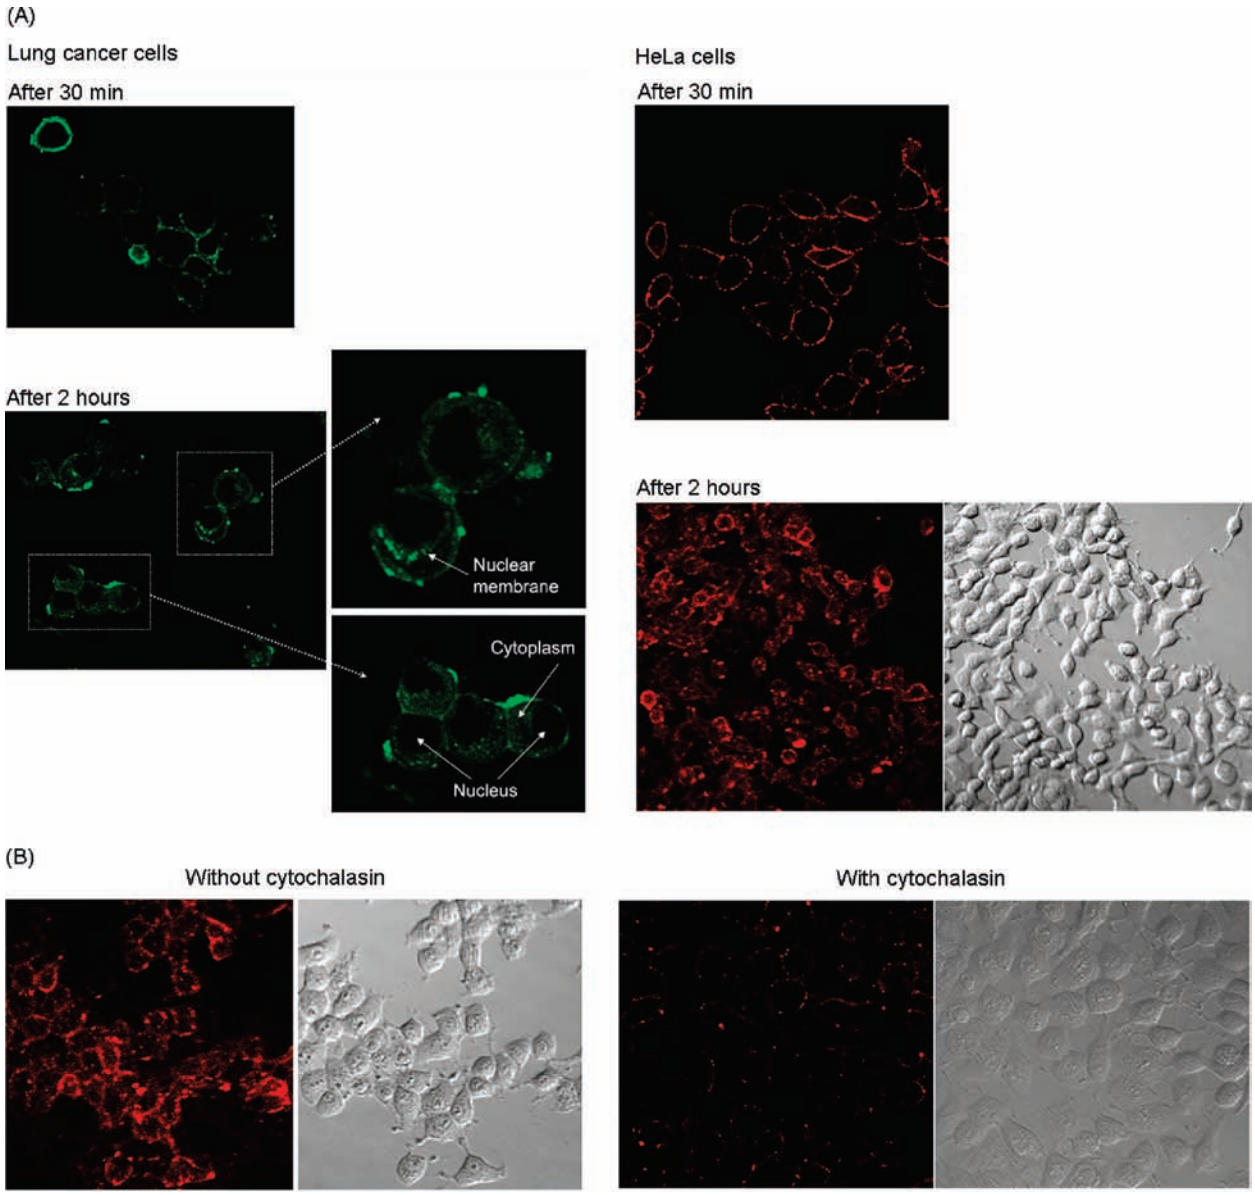

Figure 3. (A) Fluorescent confocal images of the intracellular delivery of multimodal silica-shelled QD probe in living cultured cells. The cells, dispensed in 96-well glass plates, were incubated with the probe (approximately 500 nM of QDs) within 30 min or 2 h in humidified atmosphere (5% CO_2, 37 °C), in the dark. After incubation, the cells were washed three times with PBS and subjected to fluorescent confocal microscopy. (B) Fluorescent confocal images of intracellular delivery of the QD probe in living cells in the absence and in the presence of cytochalasin (5 μg/mL). The cells were incubated with the probe within 2 h in humidified atmosphere (in the dark), washed three times with PBS, and subjected to fluorescence confocal microscopy. In both cases, the images were obtained using an Olympus FV1000 microscope (excitation wavelength, 488 nm; emission filters, 535 nm for lung cancer cells, 615 nm for HeLa cells; differential interference contrast; section scanning).

T_1 weighted imaging: Two dimensional (2D), multislice, T_1 weighted images were obtained using a conventional SE sequence with the following parameters: Pulse repetition time (TR) = 177 or 400 ms, echo time (TE) = 6.65 ms, matrix size = 64 × 64, slice orientation = horizontal, field of view (FOV) = 6.4 × 3.2 mm^2, slice thickness (ST) = 3 mm, and number of acquisitions (NA) = 1.

Multiecho imaging: 2D multislice multiecho imaging were performed to generate T_2 maps with the following parameters: TR = 6000 ms, TE = 6.65, 13.3, 19.95, 26.6, 33.25, 39.9, 46.55, 53.2, 59.85, 66.5, 73.15, 79.8, 86.45, 93.1, 99.75, and 106.4 ms, number of echoes = 16, matrix size = 64 × 64, slice orientation = horizontal, FOV = 6.4 × 3.2 mm^2, ST = 3 mm, and NA = 1.

Inversion−recovery: 2D multislice inversion−recovery MRIs were obtained using a spin−echo acquisition for T_1 map calculation with the following parameters: TR = 6000 ms, TE = 6.65 ms, inversion time = 6.45, 400, 800, 1200, 1600, 2000, 3000, 4000 ms, matrix size = 64 × 64, slice orientation = horizontal, FOV = 6.4 × 3.2 mm^2, ST = 3 mm, and NA = 1.

Quantitative T_1 maps were calculated by a nonlinear least-squares fitting using inversion−recovery MRIs. In addition, quantitative T_2 maps were calculated by a nonlinear least-squares fitting using multiecho imaging. All calculations and analyses were performed using *MRVision* image analysis software (version 1.5.8, MRVision Co., MA) on Solaris (Sun Microsystems, Inc., CA) and Macintosh (Mac OS X, version 10.4, Apple Computer, CA). All data are presented as mean ± SD.

Intracellular Delivery of Multimodal QDs (Fluorescent Confocal Microscopy). 10 μL of QD probe (50 pmol) was incubated with 90 μL cancer cells (containing 1 × 10^5 cells) in medium, within 30 min or 2 h, in a humidified atmosphere. The cell suspension was washed twice by PBS and analyzed by fluorescence confocal microscopy for intracellular delivery

of QDs. An Olympus FV1000 microscope was used in the analysis (excitation wavelength, 488 nm; emission filters, 535 or 615 nm; differential interference contrast; section scanning).

Photosensitization. The cells (90 μL, 2×10^5 cells/mL) were incubated with QDs (50 pmol in 10 μL) in medium,within 24 h, in humidified atmosphere (5% CO_2, 37 °C). The cells were washed twice with fresh medium and subjected to irradiation with laser or UV mercury lamp.

The laser irradiation of the cell suspension was carried out continuously on a confocal microscope for 30 min, changing the plane of irradiation in the well area (96-well plate). The cells were washed twice with PBS, and cell viability was detected using flow cytometry.

The UV irradiation was carried out under the experimental scheme mentioned below, to ensure irradiation with low-intensity UV light without significant heating of the sample and side effects: mercury lamp → UV-filter (UTF-34U, Sigma-Koki) (to restrict the light under 340 nm) → quartz platform → plates with cell suspension. The samples were placed in a fixed position relative to the camera to ensure equal spatial distribution of the energy during irradiation. The irradiation was carried out with the following regime: 10 min irradiation followed by 10 min break, repeated for a total duration of 30 min. Time-dependent monitoring of the level and spatial distribution of the energy during UV irradiation was carried out and was found to be relatively constant during the experiment. The temperature of the sample was also monitored over time and was found to vary in the interval 22−28 °C. After irradiation, the cells were washed twice by PBS, and the cell viability was detected by flow cytometry.

In both cases, the control samples contained QD nontreated cells.

Cytotoxicity Test (Flow Cytometry). The cells (2×10^5 cells/mL) were incubated with QDs (500 nM; $\lambda_{em} = 525$ nm−green fluorescence) in medium, within 24 h, in a humidified atmosphere (5% CO_2, 37 °C), and after that washed twice by PBS. The dead cells were labeled by propidium iodide (PI), and cell viability was analyzed by flow cytometry (flow cytometer Beckman Coulter-Epics XL). The flow cytometer was operated in accordance with the manufacturer's recommendations after fine adjustments for optimization. The forward- and site-scatter parameters were adjusted to accommodate the inclusion of both live and dead cells within the acquisition data with quadrant markers drawn to distinguish PI labeled dead cells (red fluorescence) from PI nonlabeled viable cells. The control sample contained QD nontreated cells. The viability of QD treated cells was calculated as the percentage from viability of nontreated (control) cells. No cells were excluded from the analysis and ∼5000 cells were counted for each sample. The data were collected and analyzed using *XL System II* software.

Pharmacodynamics. Mice (ICR, ∼20−25 g) were injected intravenously through the tail vain with 50 pmol (in 100 μL, a single injection) multimodal silica-shelled QDs. Serial sacrifices were carried out at the sixth and 24th hour after the injection. Several organs (brain, spleen, liver, lung, kidneys) were isolated, homogenized, and analyzed for QD amount, using NMR spectroscopy.

Two-Photon Imaging of Brain Circulation *in Vivo*. The animal (Sprague−Dawley rats, $n = 4$, ∼340 g) was anesthetized with isoflurane (4% for induction, 2% for surgery, and 1.4% during the measurements). The tracheal intubation was performed, and the femoral vein was catheterized for drug administration. The skull over the somatosensory cortex (3 mm × 3 mm) was removed, and the dura was kept intact. The body temperature was maintained (37 °C), and the systemic arterial blood pressure was periodically monitored from the tail artery. The heartbeat and end tidal gas levels were continuously monitored. To visualize brain microcirculation, 5% FITC−Dextran (70 kDa) was intravenously (i.v.) injected (0.3 mL/h), and excited with 900 nm pulse-laser (Maitai HP, Spectral Physics) under a microscope (SP5, Leica) equipped with a 10× objective lens (0.30 numerical aperture). The vessel diameter was then determined by measuring the width of the vessel image projected across the 15 *z*-images (up to ∼0.3 mm from the cortical surface) in each vessel segment. All measured parameters were considered as controls under the conditions mentioned above. After the stoppage of FITC−Dextran infusion, FITC−Dextran was partially washed from the brain circulation by short i.v. infusion of saline solution. Then, QD was injected (single injection, 0.3 mL of 0.5 μM QD concentration) into the rat, and all parameters were measured as described above.

RESULTS AND DISCUSSION

Structure and Characterization of Multimodal Silica-Shelled QDs. Our multimodal QD probe was composed of single QD micelles incorporated in small silica spheres (15−20 nm in diameter) and amphiphilic gadolinium complex [tris(2,2,6,6-tetramethyl-3,5-heptanedionate)/gadolinium, trivial name Resolve Al−Gd] incorporated into the micelle part and/or silica coat (Figure 1A). For comparison, we used a second probe, consisting of QDs conjugated with DOTA-Bn-NCS/gadolinium (Figure 1B).

In the first probe, the micelle around the QD allows an incorporation of strongly hydrophobic paramagnetic substances in the silica sphere. The hydrophobic micelle isolates QD nanocrystal from the polar molecules, penetrating from the environment in the silica sphere, and maintains the fluorescent properties. At the same time, the paramagnetic molecules, incorporated in the silica coat or micelle, are accessible to the water, which is beneficial for ^{1}H MRI contrast agents and, in particular, for gadolinium ions. The surface of the silica sphere was amino-functionalized and ready for bioconjugation. At acidic pH (3.0), the probe (A) had a surface potential of +31 mV (detected by zeta-potential titration), which decreased to −37 mV at pH 10.0. At physiological pH (7.4), the zeta potential was +6.9 mV.

Both probes consist of a single QD per one silica sphere (Figure 2A), which allows normalization of their concentrations to the QD concentration in moles and facilitates the dose-dependent analyses in life science research. Both probes strongly retain about 25−30% of the gadolinium complex added initially to the reaction mixture (Figure 2B). The concentration of the gadolinium complex decreased during purification by dialysis up to 10 h. After this time, there were no changes (Figure 2B), which was an indication for a retention of the complex in the silica coat or on the surface of the silica sphere.

The close distance between QDs and paramagnetic substances (especially paramagnetic nanoparticles) results in a decrease of their fluorescent and paramagnetic characteristics in comparison with the isolated materials (*13, 15*). In the present study, we compared the spectral properties of both multimodal probes, described above (Figure 2C). In probe A, gadolinium ions are in close proximity to QD (Figure 1A), and in probe B, gadolinium ions are far from QD (Figure 1B). The fluorescence quantum yield (QY) of both probes was ∼35−50% in aqueous solution (depending on QD size). It was ∼1.4 times lower than the QY of QDs in organic solvent and the same as the QY of silica-shelled QDs without gadolinium. The incorporation of gadolinium ions into the silica sphere also did not affect the profile of the absorbance and fluorescent spectra of silica-shelled QDs, as well as their paramagnetic characteristics. After purification, T_1 (longitudinal relaxation time) and T_2 (transverse relaxation time) of probe (A) were shorter than T_1 and T_2 of probe (B) (Figure 2C). We calculated that the numbers of

(A) T_1 weighted images

Distilled water: T_2 = 440.0 +/- 9.4 ms. Cells only: T_2 = 368.0 +/- 7.0 ms.

Figure 4. T_1- and T_2-weighted images and quantitative values of samples, containing probe only (A2−A4), cells only (B2−B4), or cells incubated with probe (C2−C4). Incubation conditions: Lung cancer cells (2×10^7) were dispensed in plates, containing 20 mL cultured medium. The probe was added to the plates in different concentrations (1 μM, 0.5 μM, or 0.1 μM QDs, respectively). The incubation was carried out during 2 h in humidified atmosphere (5% CO_2, 37 °C). The cells were collected by centrifugation, washed three times by PBS (containing 1% Trypsin), and finally resuspended in 200 μL PBS. All samples were treated in the same manner. The concentration of the probe in moles was approximate. It was calculated from the absorbance spectra of QD incorporated into the silica spheres, using the equation of Yu et al. (*38*). The MRI measurements were performed in a 7.0 T magnet (Kobelco, Japan) interfaced to a Bruker Avance console (Bruker Medical GmbH, Germany). A 70 mm diameter volume coil (Bruker) was used for measurement of the samples. The sample temperature was maintained at room temperature (~22−24 °C). The measurements were performed as follows: T_1-weighted imaging using conventional spin−echo (SE) sequence and inversion−recovery SE imaging for T_1 calculations. The multiecho SE imaging was measured for T_2-weighted imaging and T_2 calculations.

chelating molecules attached on or incorporated in one silica sphere were approximately same (Gd/QD ~ 18:1 and ~17.6:1, mol/mol, for probe A and probe B, respectively). This indicates that the incorporation of gadolinium in close proximity to QD

does not significantly affect its paramagnetic properties, presumably because of the isolation of both materials from the hydrophobic micelle.

All experiments on viable cells and animals were performed using probe A only.

Direct Intracellular Delivery of Multimodal Silica-Shelled QDs. Figure 3A represents fluorescent images of HeLa and lung cancer cells, labeled with probe A. The amino-functionalized (and positively charged) probe possessed an easy and comparatively fast intracellular delivery without transfection techniques. It was found that the probe penetrates through the cytoplasmic membrane via an endocytotic mechanism. The cytochalasin (an inhibitor of endocytosis) suppressed its intracellular delivery (Figure 3B). The probe was localized into the cytoplasm, uniformly distributed. A concentration of the probe in close proximity to the nuclear membrane was detected, which indicates an interaction with some intracellular compartments. No fluorescence was detected in the nucleus within 4 h incubation.

The facilitated permeability of silica-shelled QDs allows their application in the detection of intracellular targets (antigens, membrane compartments, subcellular organelles, etc.) in viable cells without transfection techniques. Currently, QDs are applied predominantly for labeling of cell surface antigens *in vitro* and *in vivo* or for extra- and intracellular labeling of fixed cells. Their application for labeling of intracellular components in viable cells requires transfection techniques for penetration through plasmatic membrane. The already published data indicate that QDs could be delivered in viable mammalian cells via four different mechanisms: nonspecific endocytosis/pinocytosis facilitated by polycationic transfectants (as lipofectamine); microinjection; electroporation; and peptide-induced transport (*24*−*28*). It is widely accepted that the transfection techniques maintain the risk of artifacts, some of them are toxic, and they have to be replaced with direct approaches for intracellular delivery of QDs. We observed that an appropriate polymer coating of QDs (such as positively charged silica) could facilitate their direct intracellular delivery and random distribution into the cells (*29*), which was also reported by other authors (*30*).

If the cells were washed several times with phosphate-buffered saline, concentrated, and subjected to MRI, a high MRI contrast was observed on the T_1- and T_2-weighted images (Figures 4). The T_1 and T_2 values allow calculation of the approximated absolute amount of multimodal QDs delivered into the cells, using two independent calibration curves. The calibration curve represents the relationship between the pure probe in known concentrations and T_1 or T_2 values, respectively. It was found that approximately 58−75% of the probe was delivered into the cells and/or bound on the cell surface.

Cytotoxicity, Photosensitization, and Pharmacodynamics. All experiments with cultured cells were provided in medium without FBS. The cell viability of A459, Jurkat, K562, and HeLa cells was ∼100% after 24 h incubation with QDs in 500 nM concentration (Table 1). The nanoparticles (500 nM) were also nontoxic under continuous UV or laser irradiation of the cell suspension after preliminary incubation with QDs for 24 h. The cell viability did not change within 30 min of continuous laser irradiation of QD-treated and QD-nontreated (control) cells. Under UV irradiation, the viability of QD-treated and QD-nontreated (control) cells decreased slightly (∼10%) in comparison with nonirradiated cells, as a result of nonspecific effects of UV light on cell viability (Table 1).

Several groups have demonstrated photosensitization of living cells using CdSe or CdTe core QDs (*31*−*35*). However, the overcoating (inorganic or organic) usually suppresses or eliminates the photosensitization effect (*31, 32, 35*).

Regarding cytotoxicity of nanoparticles, it is necessary to note that this parameter is usually clarified on cancer cells that are inherently resistant to many external agents. The data on normal cells are scanty. Currently, there are insufficient data on the metabolism of QDs in live organisms, and it is not clear what will happen if the nanoparticles are accumulated in different organs for a long time. Their excretion through kidneys avoiding any long-term accumulation and metabolism in the liver, bone marrow, or other organs seems to be the best possibility. Choi and colleagues have demonstrated that a hydrodynamic diameter of <5.5 nm of organic-coated QDs results in rapid and efficient renal filtration and urinary excretion from the body. Increasing the diameter by >15 nm usually prevents renal excretion and increases the blood half-life by about 300 times and the whole body half-life by about 700 times (*36*). The authors also have reported that the purely cationic charge is associated with an increase in hydrodynamic diameter of the QDs after incubation with serum.

Our pharmacodynamic study shows that nonPEGylated silica-shelled QDs persist in the blood circulation within an hour after i.v. injection in mice (half-life ∼20 min). Six hours after the injection, a comparatively large amount of QDs were detected in spleen, a very low amount in liver and kidney, and none in lung and brain (data are not shown). A similar result was obtained 24 h after the injection. Recently, Yang and colleagues reported that QDs (commercial Qtracker 705) are accumulated predominantly in spleen, liver, and kidney after i.v. injection in mice, and they do not metabolize within 28 h (*36*).

Effects on Physiological Characteristics and Brain Circulation. The intravenous application of the probe in rat did not affect significantly the physiological parameters, e.g., hart rate, blood pressure, and microcirculation (Figure 5). The multimodal QDs (300 μL of 1 μM stock solution) were injected into the femoral vain. Ten minutes after the injection, the heart rate increased slightly with subsequent normalization to the baseline level within 40 min. The blood pressure was stable within 20 min after the injection and decreased about 10% after 80 min (Table 2). The brain vasculature was visualized in the somatosensory cortex using two-photon microscopy, and the fluorescence was detected up to a 200 μm depth (Figure 5). The probe did not affect the diameter and structure of the blood vessels, which makes it an appropriate tracer for brain vasculature in the study of brain phenomena, e.g., visualization of neuron/astrocyte/blood vessel structure and investigation of neurovascular coupling.

In conclusion, the described strategy of the design of multimodal QDs allows the development of probes with high fluorescent and paramagnetic contrast characteristics and comparatively soft effects on cell homeostasis and animal physiology. The described QD probe is appropriate for *in vitro* and *in vivo* tracing of cells and blood vessels, simultaneously using fluorescent microscopy and MRI. After conjugation with appropriate ligands, the probe could be applied for target-selective molecular imaging *in vitro* and *in vivo*. The easy intracellular

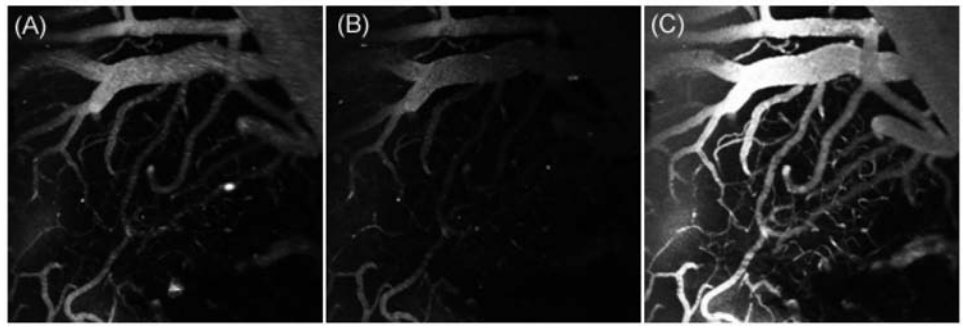

Figure 5. Two-photon images of brain circulation before and after i.v. injection of multimodal silica-shelled QDs in rat. In the images: (A) FITC−Dextran (0.5 mL of 5 μM concentration) was injected in ~340 g rat, and the image was obtained after 20 min at $\lambda_{ex} = 900$ nm and $\lambda_{em} = 525$ nm. (B) FITC−Dextran was washed from the brain vasculature by i.v. infusion of saline solution, and the image was obtained at $\lambda_{ex} = 900$ nm and $\lambda_{em} = 525$ nm. (C) QDs (0.3 mL of 1 μM QD concentration) were injected in the same rat. The image was obtained after 20 min at $\lambda_{ex} = 900$ nm and $\lambda_{em} = 560$ nm. Representative images from three independent experiments are shown in the figure.

Table 2. Physiological Characteristics before and After i.v. Injection of Silica-Shelled QDs in Experimental Animals under Anesthesia[a]

parameter	before	~20 min after i.v. injection
blood pressure, (mmHg)	95.3 +/− 7.8	93.5 +/− 16.2
heart rate, (BPM)	304 +/− 62	348 +/− 43
blood vessel diameter		
arteries, (μm)	26 +/− 8	constant
veins, (μm)	43 +/− 20	constant

[a] $n = 3$ (n = number of rats in the group); QD concentration = 80 pmol (in 300 L).

delivery of these silica-shelled QDs allows avoidance of conventional transfectants that are inherently toxic.

ACKNOWLEDGMENT

The technical assistance of Misao Yoneyama and Jeff Kershaw (NIRS, Chiba, Japan) in MRI measurements and data analysis is gratefully acknowledged. The animal experiments were approved by the Animal Care and Use Committee of NIRS-Chiba.

Received November 29, 2007; Revised Manuscript Received April 16, 2008

Potential receptor imaging agents based on Tc-99m for the in vivo visualization of the peripheral benzodiazepine receptor (PBR) have been designed on the basis of the information provided by the previously published structure−affinity relationship studies, which suggested the existence of tolerance to voluminous substituents in the receptor area interacting with 3-position of the quinoline nucleus of 2-quinolinecarboxamides **5**. In the first step of the investigation, the stereoelectronic features of the above-indicated receptor area were also probed by means of 4-phenyl-3-[(1-piperazinyl)methyl]-2-quinolinecarboxamide derivatives bearing different substituents on the terminal piperazine nitrogen atom (compounds **6a**−**f**). The structure−affinity relationship data confirmed the existence of a tolerance to bulky lipophilic substituents and stimulated the design of bifunctional ligands based on the 4-phenyl-3-[(1-piperazinyl)methyl]-2-quinolinecarboxamide moiety (compounds **6h,j,k,m**). The submicromolar PBR affinity of rhenium complexes **6j,m** suggests that the presence of their metal−ligand moieties with encaged rhenium is fairly compatible with the interaction with the PBR binding site. Thus, in order to obtain information on the in vivo behavior of these bifunctional ligands, ^{99m}Tc-labeled compounds **6h,k** were synthesized and evaluated in preliminary biodistribution and single photon emission tomography (SPET) studies. The results suggest that both tracers do not present a clear preferential distribution in tissues rich in PBR, probably because of their molecular dimensions, which may hamper both the intracellular diffusion toward PBR and the interaction with the binding site.

INTRODUCTION

The peripheral benzodiazepine receptor (PBR) is a 169-amino acid protein (18 kDa) with five trans-membrane domains localized on the mitochondrial outer membrane (*1–3*). PBR is functionally linked to the voltage-dependent anion channel (VDAC) and to the adenine nucleotide translocase (ANT) and might be implicated in the regulation of the opening of the mitochondrial permeability transition pore (MPTP). This receptor is highly expressed in steroidogenic tissues such as adrenal gland, but also in kidney, heart, testis, and at a lower level in the brain parenchyma, ependyma, choroid plexus, and olfactory neurons. Moreover, PBR is overexpressed in a variety of tumors (e.g., certain brain tumors, ovarian cancer, liver tumors, breast carcinoma, colorectal cancer, etc.) and its expression appears to be related to the degree of tumor malignancy (*4–11*). In addition, PBR is overexpressed on activated microglial cells localized in lesioned brain areas of patients with neurodegenerative or neuroinflammatory diseases like Alzheimer's disease, and Huntington's disease or multiple sclerosis (*12–14*).

PK11195 (**1**, Figure 1) is an isoquinolinecarboxamide derivative, which was both found to bind the PBR with nanomolar affinity and is the most widely used pharmacological tool for the study of the expression and the function of PBR. Carbon-11 labeled compound **1** was used for the in vivo imaging of microglial/macrophage activation present in different brain disorders including tumors by means of positron emission tomography (PET) (*15–19*). In addition, a potential role for compound **1** and more in general for PBR in the in vivo monitoring of macrophage infiltration in respiratory disorders has been recently proposed (*20–22*). These results have stimulated the research and development of a large number of potential PET radiotracers based on PBR ligands in different

laboratories all over the world (for a recent review, see ref (*23*)). Among the most significant, labeled DAA1106 (**2a**: R = $^{11}CH_3$), and its fluoromethyl (**2b**: R = $^{18}FCH_2$) and fluoroethyl (**2c**: R = $^{18}FCH_2CH_2$) derivatives were described and [^{18}F]-FEDAA1106 (**2c**) was proposed as a useful PET ligand for PBR which is currently used for the PBR imaging in human brain (*24*).

Potent 2-quinolinecarboxamide PBR ligands **3a**−**c** were ^{11}C-labeled and the biodistribution studies suggested that these compounds are promising PET tracers for the in vivo imaging of PBR (*25*–*27*). Their evaluation in an excitotoxic model of Huntington's disease in rats showed that benzyl derivative **3c** can be considered an interesting candidate for the in vivo PET monitoring of neurodegenerative processes (*28*). Moreover, compound **3c** served as a lead in the design of fluoroderivative **4**, which shows subnanomolar PBR affinity, and was therefore considered for labeling with C-11 and F-18. The results obtained with ^{11}C-labeled **4** in ex vivo biodistribution, inhibition, and small animal YAP-(S)PET studies are very promising (*29*), and the ^{18}F-labeling of **4** is now in progress.

Nevertheless, C-11 and F-18 labeling shows some limitations, since the production of these radioisotopes requires the use of an on-site cyclotron, an apparatus that is not always present in all nuclear medicine centers. On the other hand, technetium-99m is the ideal diagnostic single-photon radionuclide with a 6 h half-life, 140 keV γ-radiation, no particulate radiation, and ready availability in all nuclear medicine centers by means of transportable ^{99}Mo/^{99m}Tc generators (*30*, *31*). These advantages explain the general use of Tc-99m-labeled compounds in routine clinical practice and, at the same time, stimulate the design and synthesis of new PBR ligands labeled with Tc-99m.

The preparation of a receptor−ligand bearing Tc-99m is a difficult undertaking because the compound must satisfy a series of physicochemical requirements in order to reach and interact selectively with the target receptor. For instance, passive transport through biological membranes can be achieved only for complexes having a neutral charge and a suitable lipophilic feature. Furthermore, the molecular shape of the receptor imaging agent has to fit the binding site of the target receptor to allow the establishment of a strong and selective interaction (*32*).

In the design of the receptor imaging agents based on Tc-99m, two main strategies have been developed in recent years (*32*–*34*). The bifunctional chelate approach is based on the conjugation of the bioactive group (receptor−ligand moiety, RLM) to a metal complex through a suitable linkage. Thus, the "bifunctional ligand" can be designed as the result of the combination of a strong chelating group for the radionuclide (metal−ligand moiety, MLM) with the RLM by means of a suitable linker connecting these two molecular portions. After the radionuclide has been coordinated by the chelating system, the resulting conjugate shows RLM as an appended side chain.

The design of new receptor imaging agents based on Tc-99m for the in vivo visualization of the PBR could rely on the information provided by the previously published structure−affinity relationship studies, which suggested the presence of tolerance to voluminous substituents in the receptor area interacting with 3-position of the quinoline nucleus of 2-quinolinecarboxamides **5** (*35*, *36*).

Therefore, bifunctional ligands **6** (Figure 2) could be envisioned to interact with a sufficient potency with PBR given that the binding site would be capable of accommodating the MLM with the encaged radionuclide. In the first step of the investigation, the stereoelectronic features of the above-indicated receptor area was explored by means of probes **6a**−**f** and unlabeled compounds **6j,m** bearing rhenium in their MLM. Rhenium is an excellent model for the radioactive Tc-99m because it forms

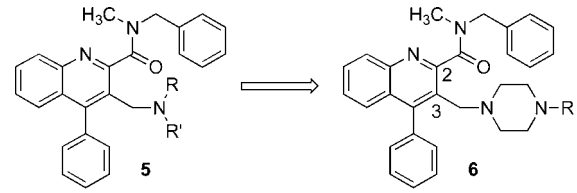

Figure 2. Design of PBR ligands **6**.

equally stable complexes showing lipophilicity and square pyramidal structures very similar to those formed by technetium. In the second phase, potential receptor imaging agents **6h,k** bearing Tc-99m were synthesized and evaluated in preliminary ex-vivo biodistribution and single photon emission tomography (SPET) studies.

EXPERIMENTAL PROCEDURES

Chemistry. All chemicals used were of reagent grade. Yields refer to purified products and are not optimized. Melting points were determined in open capillaries on a Gallenkamp apparatus and are uncorrected. Microanalyses were carried out by means of a Perkin-Elmer 240C or a Perkin-Elmer Series II CHNS/O Analyzer 2400. Merck silica gel 60 (230−400 mesh) was used for column chromatography. Merck TLC plates, silica gel 60 F_{254}, were used for TLC. ^{1}H NMR spectra were recorded with a Bruker AC 200 or a Bruker DRX 400 AVANCE spectrometer in the indicated solvents (TMS as internal standard); the values of the chemical shifts are expressed in ppm and the coupling constants (*J*) in Hz. Mass spectra were recorded on either a Varian Saturn 3 spectrometer or a ThermoFinnigan LCQ-Deca.

***N*-Benzyl-*N*-methyl-4-phenyl-3-[(piperazin-1-yl)methyl]-2-quinolinecarboxamide (6a).** A mixture of **7** (1.2 g, 3.0 mmol) in ethanol (40 mL) with piperazine (0.78 g, 9.0 mmol) was refluxed for 20 min under nitrogen. The solvent was removed under reduced pressure and the resulting residue was diluted with $CHCl_3$. The organic layer was washed with water, dried over sodium sulfate, and evaporated under reduced pressure. The resulting dark residue was purified by flash chromatography with ethyl acetate−TEA−methanol (6:3:1) as the eluent to give **6a** (0.81 g, yield 60%) as a light brown glassy solid. Since the amide nitrogen of this compound bears two different substituents, the ^{1}H NMR spectrum shows the presence of two different rotamers in equilibrium. For the sake of simplification, the integral intensities have not been given. ^{1}H NMR (200 MHz, $CDCl_3$): 2.16 (m), 2.30 (m), 2.50 (m), 2.80 (m), 2.96 (s), 3.03 (s), 3.58 (br s), 4.38 (br s), 4.80 (s), 7.21−7.74 (m), 8.03 (d, J = 8.4), 8.11 (d, J = 8.3). MS(ESI): m/z 451 ($M+H^+$). Anal. ($C_{29}H_{30}N_4O\cdot H_2O$) C, H, N.

1,4-Bis-[[2-[(*N*-benzylmethylamino)carbonyl]-4-phenylquinolin-3-yl]methyl]piperazine (6b). This compound was obtained from the flash chromatography purification of compound **6a** as a less polar fraction [dichloromethane−ethyl acetate (7:3) as the eluent]. Compound **6b** was obtained as a white solid (0.30 g, yield 25%, mp 290−293 °C dec.). Since the amide nitrogen of this compound bears two different substituents, the ^{1}H NMR spectrum shows the presence of different rotamers in equilibrium. For the sake of simplification the integral intensities have not been given. ^{1}H NMR (200 MHz, $CDCl_3$): 2.12 (br s), 2.80 (s), 2.85 (s), 2.89 (s), 2.93 (s), 3.47 (br s), 3.58 (br s), 4.22 (br s), 4.67 (s), 4.73 (s), 7.21−7.70 (m), 7.98−8.12 (m). MS(ESI): m/z 815 ($M+H^+$). Anal. ($C_{54}H_{50}N_6O_2\cdot H_2O$) C, H, N.

3-[[4-(Anilinocarbonyl)piperazin-1-yl]methyl]-*N*-benzyl-*N*-methyl-4-phenyl-2-quinolinecarboxamide (6c). To a solution of **6a** (0.10 g, 0.22 mmol) in $CHCl_3$ (6 mL) cooled at 0−5 °C, a solution of phenylisocyanate (24 μL, 0.22 mmol) in $CHCl_3$ (2 mL) was slowly added. The reaction mixture was stirred for 1 h at room temperature, washed with water, dried over sodium

sulfate, and evaporated under reduced pressure. The residue was purified by flash chromatography with dichloromethane-ethyl acetate (7:3) as the eluent to give **6c** (0.082 g, yield 65%) as a pale yellow glassy solid. Since the amide nitrogen of this compound bears two different substituents, the ^{1}H NMR spectrum shows the presence of two different rotamers in equilibrium. For the sake of simplification, the integral intensities have not been given. ^{1}H NMR (200 MHz, $CDCl_3$): 2.14 (m), 2.28 (m), 2.94 (s), 3.00 (m), 3.35 (m), 3.55 (br s), 4.35 (br s), 4.77 (s), 6.62 (s), 6.90 (m), 7.12−7.71 (m), 8.03 (d, J = 8.3), 8.10 (d, J = 8.4). MS(ESI): m/z 570 ($M+H^+$). Anal. ($C_{36}H_{35}N_5O_2\cdot 0.5H_2O$) C, H, N.

***N*-Benzyl-3-[[4-[2-(1,3-dioxo-2,3-dihydro-1*H*-isoindol-2-yl)ethyl]piperazin-1-yl]methyl]-*N*-methyl-4-phenyl-2-quinolinecarboxamide (6d).** A mixture of **6a** (0.13 g, 0.29 mmol) in DMF (20 mL) with N-(2-bromoethyl)phthalimide (0.11 g, 0.43 mmol) and Na_2CO_3 (0.31 g, 2.9 mmol) was heated at 120 °C for 2 h. The solvent was removed under reduced pressure and the resulting residue was diluted with ethyl acetate. The organic layer was washed with water, dried over sodium sulfate, and evaporated under reduced pressure. The residue was purified by flash chromatography with ethyl acetate as the eluent to give **6d** (0.043 g, yield 24%) as a pale yellow glassy solid. Since the amide nitrogen of this compound bears two different substituents, the ^{1}H NMR spectrum shows the presence of two different rotamers in equilibrium. For the sake of simplification, the integral intensities have not been given. ^{1}H NMR (200 MHz, $CDCl_3$): 2.02−2.45 (m), 2.62 (t, J = 6.5), 2.94 (s), 3.01 (s), 3.40−3.87 (m), 4.36 (s), 4.78 (s), 7.18−7.85 (m), 8.02 (d, J = 8.3), 8.10 (d, J = 8.3). MS(ESI): m/z 624 ($M+H^+$). Anal. ($C_{39}H_{37}N_5O_3\cdot 0.67H_2O$) C, H, N.

***N*-Benzyl-3-[[4-[3-(1,3-dioxo-2,3-dihydro-1*H*-isoindol-2-yl)propyl]piperazin-1-yl]methyl]-*N*-methyl-4-phenyl-2-quinolinecarboxamide (6e).** A mixture of **6a** (0.15 g, 0.33 mmol) in ethanol (20 mL) with *N*-(3-bromopropyl)phthalimide (0.13 g, 0.49 mmol) and Na_2CO_3 (0.35 g, 3.3 mmol) was refluxed for 12 h. The solvent was removed under reduced pressure and the resulting residue was diluted with ethyl acetate. The organic layer was washed with water, dried over sodium sulfate, and evaporated under reduced pressure. Purification of the residue by flash chromatography with ethyl acetate as the eluent gave **6e** as a pale yellow oil, which crystallized on standing (0.10 g, yield 47%, mp 177−179 °C). Since the amide nitrogen of this compound bears two different substituents, the ^{1}H NMR spectrum shows the presence of two different rotamers in equilibrium. For the sake of simplification, the integral intensities have not been given. ^{1}H NMR (200 MHz, $CDCl_3$): 1.72−2.38 (m), 2.90 (s), 2.98 (s), 3.43 (br s), 3.71 (m), 4.32 (br s), 4.75 (s), 7.20−7.76 (m), 8.01 (d, J = 8.3), 8.09 (d, J = 8.4). Radiosynthesis. Negatively charged complex **6h** was prepared by means of the conventional $SnCl_2$ radiolabeling procedure. Briefly, to 0.3 mg of the ligand in 0.30 mL of CH_3CN and 150 μL of 1 M Na_2CO_3 was added 0.50 mg of $SnCl_2 \times 2H_2O$ dissolved in 200 μL of 0.01 N HCl containing 20 mCi of $Na^{99m}TcO_4$. The mixture was heated at 100 °C for 15 min and the radioligand was recovered by solid-phase extraction (SPE) on a preactivated Sep-Pak C-18 cartridge (Millipore). The Sep-Pak was washed with water (10 mL) and eluted with ethanol (2.0 mL). The eluate was concentrated under a nitrogen stream. The residue was dissolved into saline and the resulting solution was sterilized through a sterile 0.22 μm filter (Gelman Acrodisc).

High-performance liquid chromatography (HPLC) was performed with AKTA basic gradient system (GE Health Care) and relative variable-wavelength UV detector in series with radiochemical Bioscan Flow Count detector.

The quality control assays of the unlabeled reference standard **6g** and final radioligand **6h** were performed on a reverse-phase analytical HPLC Chromolith C-18; (100 × 4.6 mm) with the following solvent systems: A, 0.1% TFA in water; B, CH_3CN. Gradient: 0−1 min 100% A, 1−16 min 100% B; 16 min 0% B; 16−20 min 100% B. In the analysis of the ^{99m}Tc labeled compound **6h**, unlabeled reference standard **6g** was used for comparison (Figure 3).

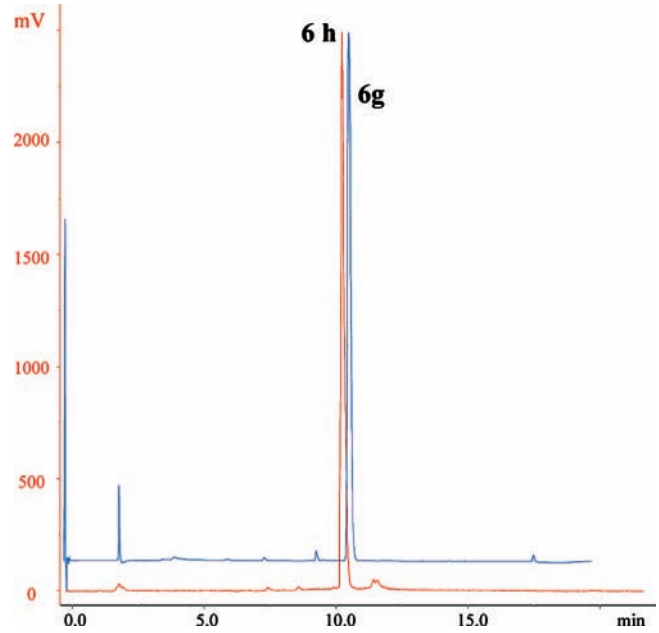

Figure 3. Radiochemical purity of radioligand **6h** (RT = 10.22) in comparison with unlabeled reference standard **6g** (RT = 10.45).

Neutral technetium complex **6k** was prepared by thiol group deprotection and labeling by means of glucoheptonate (GH) as the transfer ligand. Briefly, 0.5 mg of ligand was deprotected in 2.5 mL of EtOH with 0.5 mL of acetone and 0.4 mL of 0.5 N HCl by heating at 100 °C for 15 min. To the deprotected ligand solution was added 0.5 mL of glucoheptonate kit previously labeled with 150−200 mCi of $Na^{99m}TcO_4$, and the reaction mixture was heated at 100 °C for 15 min. The radioligand was recovered by solid-phase extraction (SPE) on preactivated Sep-Pak C-18 cartridge (Millipore). The Sep-Pak was washed with ammonium acetate 0.1 M (5 mL) before eluting with ethanol (2 mL). The eluate was concentrated under a nitrogen stream. The residue was dissolved into saline and the resulting solution was sterilized through a sterile 0.22 μm filter (Gelman Acrodisc).

HPLC was performed with the same system as above. Quality control evaluation of the unlabeled reference standard **6j**, ^{99m}Tc-GH, and final radioligand was performed on a reverse-phase analytical HPLC Alltech C-8 (250 × 4.6 mm, 5 μm) with the following solvent systems: A, 0.1 M ammonium acetate; B, CH_3CN. Gradient: 0−1 min 5% B; 1−16 min 100% B; 16−19 min 100% B; 19 min 5% B; 19−25 min 5% B (Figure 4).

Instant thin-layer chromatography on silica gel (ITLC-SG, Gelman Sciences) was performed by using different mobile phases. Acetone was used to determine ^{99m}Tc-GH (R_f = 0) and the amount of free $^{99m}TcO_4$ (R_f = 1); 50% acetonitrile-water; for ^{99m}Tc colloid (R_f = 0).

In Vitro Binding Assays. Male Sprague−Dawley CD rats (Charles River Italia, Calco, CO, Italy) with body masses of 200−250 g were used. Rats were acclimatized to the new housing conditions for at least one week. They were housed six per cage under an artificial 12-h-light, 12-h-dark cycle at a constant temperature of 22 ± 2 °C and a relative humidity of 65%. They had free access to water and standard laboratory food at all times. Animal care and handling throughout the

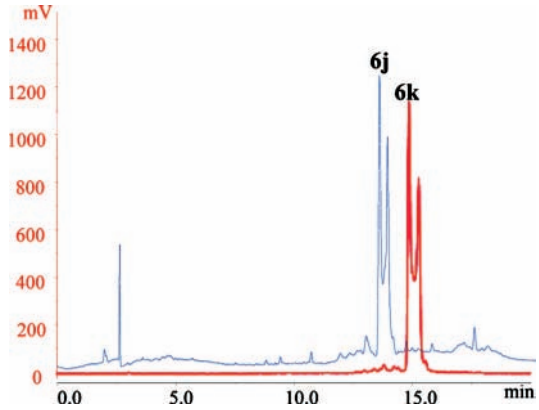

Figure 4. Radiochemical purity of radioligand **6k** (RT = 14.96−15.34) in comparison with unlabeled reference standard **6j** (RT = 14.3). Compounds **6j,k** are resolved into the corresponding rotamers.

experimental procedures were in accordance with the European Communities Council Directive of 24 November 1986 (86/609/EEC).

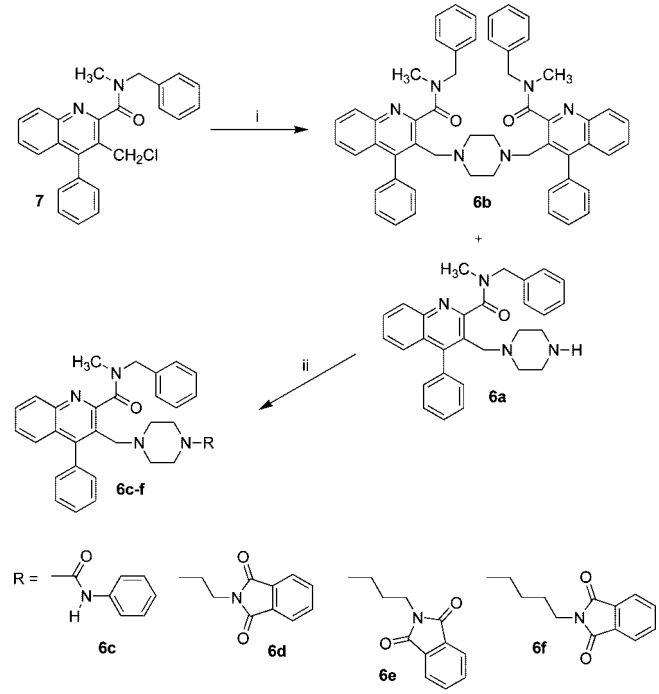
Rats were sacrificed by decapitation and their brains were rapidly dissected into the various areas which were stored at −80 °C until the day of the assay. The binding assays were performed as described in the literature (*44*). The cerebral cortex was subsequently thawed and then homogenized in 50 volumes of ice-cold Dulbecco's phosphate-buffered saline (PBS) pH 7.4 at 4 °C with a Polytron PT 10 disrupter (setting 5 for 20 s). The homogenate was centrifuged at 40 000*g* and 4 °C for 30 min and the resulting pellet was resuspended in the same volume of fresh buffer and recentrifuged. The new pellet was resuspended in 10 volumes of the incubation buffer (PBS) and used for the binding assay.

[^{3}H]PK11195 binding was measured in a final volume of 500 μL, consisting of 50 μL of membrane suspension (0.15−0.20 mg of protein), 50 μL of [^{3}H]PK11195 (s.a. 85.5 Ci/mmol, New England Nuclear; final assay concentration of 1 nM), 5 μL of drug solution or solvent, 395 μL of PBS. The binding reaction was performed at 25 °C for 90 min and began with the addition of membranes. The incubation was terminated by rapid filtration through glass-fiber filters (Whatman GF/B) which had been presoaked with 0.3% polyethyleneimine and placed in a cell harvester filtration manifold (Brandel). The filters were washed five times with 4 mL of ice-cold PBS, after which filter-bound radioactivity was quantified by liquid scintillation spectrometry. Nonspecific binding was defined as binding in the presence of 10 μM of unlabeled PK11195 (Sigma). Specific binding was determined by subtracting the nonspecific from the total binding and was about 80% of the total binding. The concentration of the test compounds that inhibited [^{3}H]ligand binding by 50% (IC_{50}) was determined by means of Jandel Sigmaplot (*45*) program with 6 to 10 concentrations of the displacers, each performed in triplicate.

Kinetic Experiments. Animals. Male CD-1 mice (35−40 g; Charles River, Italy) were used for biodistribution, small-animal SPET imaging, and inhibition studies. Animal experiments were approved by the Ethical Committee for animal care of the San Raffaele Hospital and carried out in agreement with the Italian and EEC recommendations for the care and use of laboratory animals.

Biodistribution. All animal group (n = 3) received an intraperitoneal injection of 0.74−0.92 MBq (20−25 μCi) of [^{99m}Tc]**6h** or [^{99m}Tc]**6k**. The mice were killed by cervical dislocation at 30, 60, and 240 min after intraperitoneal injection of the radiotracer in 200 μL saline vehicle. Blood samples were collected by cardiac puncture. The tissue samples were weighed and their radioactivity was determined in an automated γ-counter

Scheme 1[a]



[a] Reagents: (i) piperazine, EtOH; (ii) phenylisocianate, $CHCl_3$ or N-(2-bromoethyl)phthalimide, Na_2CO_3, DMF or N-(3-bromopropyl)-phthalimide, Na_2CO_3, EtOH or N-(4-bromobutyl)phthalimide, Na_2CO_3, EtOH.

(1282 Compugamma CS; Pharmacia/LKB Nuclear Inc.) and expressed as the percentage of injected dose per gram of tissue (%ID/g).

Small Animal YAP-(S)PET Studies. The kinetics of biodistribution was further explored at later times using a dedicated small animal SPET scanner YAP-(S)PET II (ISE, Pisa, Italy). This small animal tomography is able to perform both PET and SPET modalities. It is made up of four detector heads composed each of a 4 × 4 cm^2 of $YAlO_3$:Ce (YAP:Ce) matrix of 27 × 27 elements, 1.5 × 1.5 × 20 mm^3 each, directly coupled to a PS-PMT (Hamamatsu R2486). The four modules are positioned on a rotating gantry; the opposite detectors are in time coincidence when used in SPET mode. For both PET and SPET modalities, the system operates in 3-D data acquisition mode with an axial field of view (FOV) of 4 cm and a transaxial FOV diameter of 4 cm, providing a set of 27 slices of 1.5 mm thickness. The switching to the SPET modality is made by replacing the tungsten septum (used in PET for shielding the scintillators from the background outside the FOV) with a high-resolution parallel hole, lead collimator (0.6 mm, 0.15 mm septum) in front of each crystal. The default acquisition energy window is 50−850 keV.

Compounds [^{99m}Tc]**6h** and [^{99m}Tc]**6k** were intravenously administered in two CD-1 mice. The animals were scanned in SPET modality at 1, 6, and 24 h after the injection of 3.26 and 2.61 mCi (120.6 and 96.6 MBq), respectively. Each mouse was anesthetized with 1.7% tribromoethanol solution (10 μL/g of weight, i.p.) before scanning and positioned supine on the tomograph bed, with the thorax centered in the FOV. The study was achieved acquiring two bed positions in 1 h approximately. Furthermore, a 30 min brain acquisition was performed 6 h after the injection for compound [^{99m}Tc]**6h** and 1 h after the injection for compound [^{99m}Tc]**6k**. 3D data were reconstructed by the EM (Expectation Maximization) algorithm (*46*).

Inhibition Studies. The specificity of [^{99m}Tc]**6k** uptake was studied in mice pretreated with PK11195 (5 mg/kg, dissolved

[a] Each value is the mean ± SEM of 3 determinations and represents the concentration giving half the maximum inhibition of [^{3}H]**1** (final concentration 1 nM) specific binding to rat cortical membranes. [b] See ref 36. [c] NT: not tested.

RESULTS

Chemistry. The PBR probes **6a−f** were synthesized from the previously described chloromethyl derivative **7** (*36*) as depicted in Scheme 1.

Reaction of **7** with a large excess of piperazine gave piperazinyl derivative **6a** along with a small amount of double alkylation product **6b**, which was separated by flash chromatography. Phenylurea derivative **6c** was prepared by reaction of **6a** with phenylisocyanate, while phthalimidoalkyl derivatives **6d−f** were synthesized by alkylation of **6a** with the appropriate *N*-(bromoalkyl)phthalimides in the presence of sodium carbonate as the base.

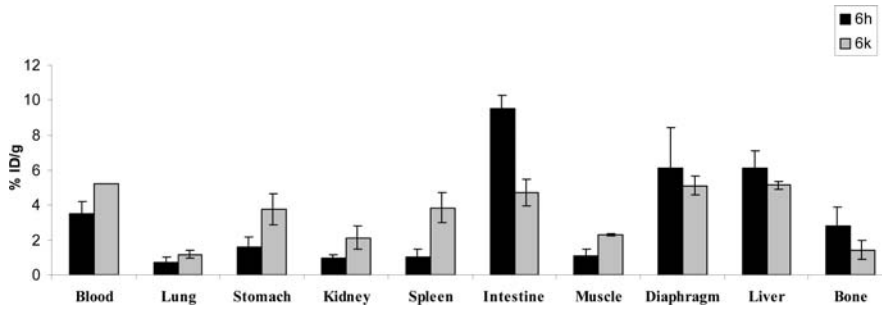

Figure 5. Comparison of tissue distribution of **6h,k** in CD-1 mouse 60 min after the radiotracer injection. The column where the error is not indicated was obtained with two mice.

Table 2. Tissue Distribution of [^{99m}Tc]6h in CD-1 Mouse[a]

tissue	30 min	60 min	240 min
blood	1.65[b]	3.52 ± 0.67	0.23[b]
lung	0.46 ± 0.12	0.71 ± 0.29	0.69[b]
diaphragm	7.26 ± 0.60	6.11 ± 2.31	4.20 ± 1.67
liver	4.84 ± 0.78	6.12 ± 0.94	2.62 ± 1.35
intestine	0.52 ± 0.21	9.52 ± 0.76	3.87 ± 1.47
stomach	0.53 ± 0.10	1.57 ± 0.6	0.41 ± 0.24
spleen	0.69 ± 0.44	1.02 ± 0.44	0.49 ± 0.13
kidney	0.49 ± 0.11	0.93 ± 0.22	0.40 ± 0.25
muscle	0.61 ± 0.21	1.08 ± 0.38	0.71 ± 0.20
bone	1.43 ± 0.53	2.82 ± 1.09	0.61[b]

[a] Radioactivity concentration is expressed as % of injected dose per gram of tissue (%ID/g). Values are expressed as mean ± SD of three rats for each time point. [b] The corresponding values were obtained with two mice.

Table 3. Tissue Distribution of [^{99m}Tc]6k in CD-1 Mouse[a]

tissue	30 min	60 min	240 min
blood	1.08 ± 0.40	5.25[b]	4.44 ± 1.37
lung	1.19 ± 0.24	1.16 ± 0.23	1.05 ± 0.26
diaphragm	4.74 ± 1.3	5.12 ± 0.55	7.92 ± 1.35
liver	3.48 ± 1.65	5.14 ± 0.20	4.80 ± 0.45
intestine	2.26 ± 0.83	4.71 ± 0.77	3.06 ± 1.35
stomach	1.72 ± 0.57	3.77 ± 0.90	2.13 ± 0.32
spleen	2.07 ± 1.32	3.85 ± 0.88	3.43 ± 0.72

bone	1.18 ± 0.32	1.43 ± 0.53	1.56 ± 0.22

[a] Radioactivity concentration is expressed as % of injected dose per gram of tissue (%ID/g). Values are expressed as mean ± SD of three rats for each time point. [b] The corresponding values were obtained with two mice.

Compound **6g** was obtained by conjugation of **6a** with *S*-benzoylmercaptoacetylglycylglycylglycine (*S*-Bz-MAG$_3$, Scheme 2) via activated ester **8** (*37–39*). Negatively charged complex **6h** was prepared by means of conventional radiolabeling procedure with ^{99m}Tc (see Experimental Procedures).

Cross-coupling reaction of synthon **9** (*40–42*) with piperazinylderivative **6a** provided **6i** (Scheme 3), which underwent rhenium incorporation with sodium perrhenate under reductive conditions ($SnCl_2$) in ethanol to give the neutral complex **6j**. On the other hand, neutral technetium complex **6k** was prepared by employing glucoheptonate (GH) as the transfer ligand (see Experimental Procedures).

Finally, neutral rhenium complex **6m** (showing the N_2S_2 MLM of **6j** and the carbonylmethyl spacer of **6 h**) was prepared as shown in Scheme 4. Acid **10** was synthesized as described in the literature (*43*) and conjugated with the piperazinyl derivative **6a** in the presence of HOBt and EDCI to afford **6l**. Neutral complex **6m** was obtained in low yield from **6l** by means of the procedure shown above.

Binding Studies. Compounds **6a−g,j,m** were tested for their potential activity in inhibiting the specific binding of [^{3}H]**1** to rat cortical membrane in comparison with reference compound **1**. The results of the binding studies are shown in Table 1, along with the previously published PBR affinities of 2-quinolinecarboxamide derivatives **5a,b** that are included for comparison.

The structure−affinity relationship (SAFIR) analysis of the compounds designed to probe the receptor tolerance to bulky substituent shows that the introduction of the piperazine substituent of compound **6a** produces a significant decrease in PBR affinity. The comparison between this result and that obtained with previously published *N*,*N*-diethylderivative **5a** suggests that the affinity decrease can be attributed to the presence of the second basic nitrogen atom (the terminal piperazine nitrogen), which confers to compound **6a** hydrophilic characters inappropriate for the interaction with the PBR binding site. This assumption is supported by the affinity shown by phenylurea derivative **6c**, which shows an IC_{50} value similar to that shown by compounds **5a,b**.

Interestingly, the replacement of the −CONHPh group of phenylurea derivative **6c** with a phthalimidoethyl one of **6d** appears to be well-tolerated by the PBR binding site. Furthermore, the nanomolar PBR affinity shown by **6d** appears to be stable to the elongation of the spacer between the terminal piperazine nitrogen and the phthalimide moiety up to three methylene unities (compound **6e**) or four methylene unities (**6f**). These results, taken together with the nanomolar affinity shown by the symmetrically substituted piperazine derivative **6b**, demonstrate that the PBR binding site is capable of accommodating a large variety of molecules based on the 4-phenylquinolin-2-carboxamide scaffold. Thus, the results of the first phase of the investigation confirmed the PBR tolerance to bulky substituents and gave impulse to the development of the second phase.

In the design of the receptor imaging agents based on Tc-99m, the physicochemical characteristics of the final complex were taken into consideration. Thus, neutral **6j,k,m** and negatively charged **6h** complexes were prepared in order to evaluate the difference in the biological properties. Protected precursor **6g** and cold neutral rhenium complexes **6j,m** were studied in the same binding system described for the other ligands belonging to the same class. The submicromolar PBR affinity shown by **6j,m** (IC_{50} values of 127 and 187 nM, respectively) suggests that their MLMs with encaged rhenium interact with PBR binding site less effectively than the phthalimido probe of compounds **6d−f** (IC_{50} values 22−37 nM). However, the reasonable affinity of rhenium complexes **6j,m** and the fact that rhenium has been described to show virtually identical structural properties in its complexes compared to technetium (*31*) motivated the evaluation of technetium-99m labeled complexes **6h,k** in order to obtain information on the in vivo behavior of these bifunctional ligands.

KINETIC STUDIES

Biodistribution. Exvivo biodistribution studies in mice indicate that, after intraperitoneal injection, radiotracer

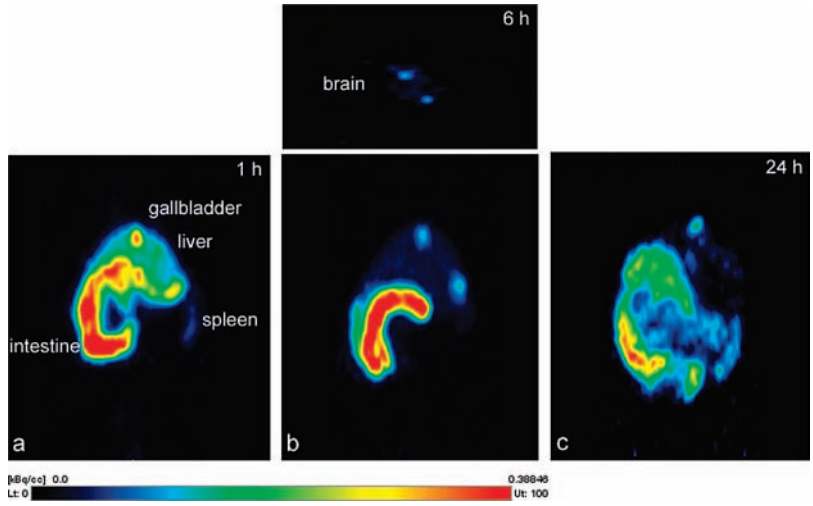

Figure 6. YAP-(S)PET II images of [^{99m}Tc]**6h** distribution in one CD-1 mouse at 1 (a), 6 (b), and 24 h (c) after the i.v. injection of 3.26 mCi of the radiotracer. (a) 1 h. Transaxial view of 3D-rendering reconstruction of whole body acquisition (two beds in present count modality). (b) 6 h. Top, transaxial view of 3D-rendering reconstruction of brain (one bed in present time modality); bottom, transaxial view of 3D-rendering reconstruction of whole body acquisition (two beds in present count modality). (c) 24 h. Transaxial view of 3D-rendering reconstruction of whole body acquisition (two beds in present count modality).

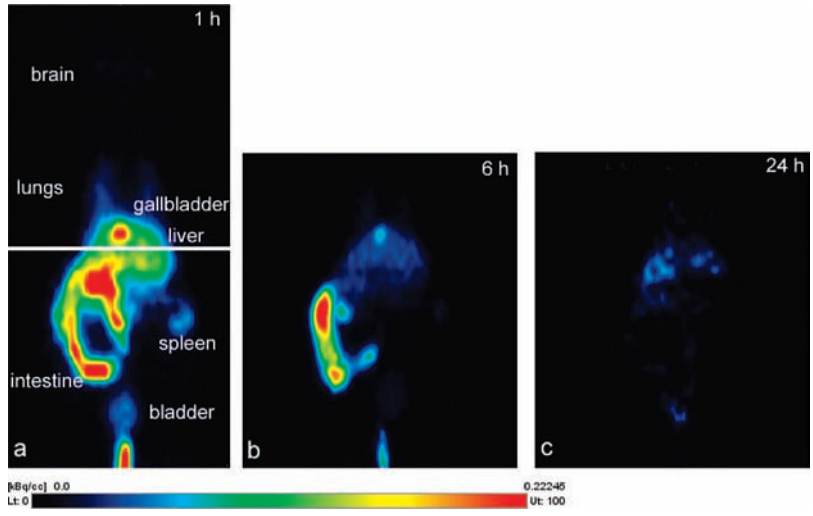

Figure 7. YAP-(S)PET II images of [^{99m}Tc]**6k** distribution in one CD-1 mouse acquired at several time points after the i.v. injection of 2.61 mCi of the radioligand. (a) 1 h. Top, transaxial view of 3D-rendering reconstruction of brain and thorax (one bed in present time modality); bottom, transaxial view of 3D-rendering reconstruction of the abdomen (one bed in present time modality). (b) 6 h. Transaxial view of 3D-rendering reconstruction of whole body acquisition (two beds in present count modality). (c) 24 h. Transaxial view of 3D-rendering reconstruction of whole body acquisition (two beds in present count modality).

[^{99m}Tc]**6h** and [^{99m}Tc]**6k** preferentially accumulate in liver, intestine, and stomach. Similar results are described in the literature for the biodistribution of somatostatin analogue RC-160 labeled with ^{188}Re- or ^{99m}Tc-MAG$_3$ (*39*). However, differently from the negatively charged complex **6h**, neutral **6k** accumulates also in two organs expressing PBR-like spleen and kidney (Figure 5, Tables 2 and 3) although radioactivity was lower than that measured in blood. Maximum levels of radioactivity were observed 60 min after injection of both tracers.

SPET Studies. SPET biodistribution profiles of **6h** and **6k** are shown in Figures 6 and 7. One hour after injection, radioactivity preferentially accumulated in the liver, gallbladder, small intestine, urinary bladder, and spleen, although this last organ was better visualized in the animal injected with neutral complex **6k** (Figure 7). At this time, accumulation of radioactivity was observed in the stomach of the animal injected with **6h** and a small signal of uptake appeared in the lung of the animal injected with **6k**. Six hours after the injection of both radiotracers, the majority of the activity shifted to the first portion of the small intestine especially in the case of compound **6h**. Finally after 24 h, radioactivity was still present in the liver and intestine for **6h** and in liver and urinary bladder for **6k**. For both compounds, we failed to observe a significant radioactivity accumulation in the heart and brain.

Inhibition Studies. The specificity of [^{99m}Tc]**6k** in vivo binding to PBR was evaluated in mice pretreated with PK11195 (5 mg/kg, i.p., $n = 3$) or with the vehicle (i.p., $n = 3$), 1 h before the radioligand administration. The results of the inhibition experiments 4 h after [^{99m}Tc]**6k** injection are shown in Figure 8.

The only significant effect of PK11195 preadministration was observed in the lung, while no significant effects were observed in the remaining tissues.

DISCUSSION AND CONCLUSIONS

The exploration of the PBR binding site by means of 3-substituted-2-quinolinecarboxamide derivatives **6a**−**f** con-

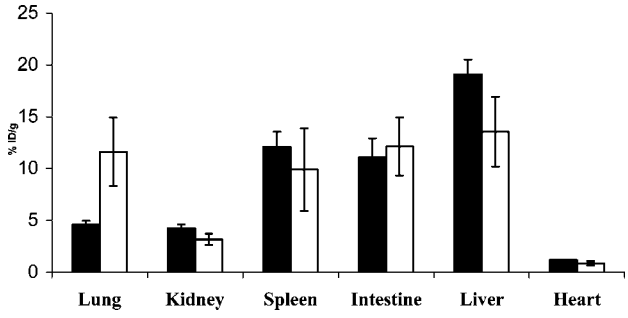

Figure 8. Effect of PK11195 pretreatment on [^{99m}Tc]**6k** radioactivity uptake in peripheral tissues of mice measured 4 h after [^{99m}Tc]**6k** injection. The radioactivity concentration is expressed as % of the injected dose per gram of tissue (%ID/g); 5 mg/kg of PK11195 (pretreated, black) or vehicle (basal, white) were administered 1 h before [^{99m}Tc]**6k** injection.

firmed the existence of a tolerance to bulky lipophilic substituents and stimulated the design and synthesis of bifunctional ligands **6h,j,k,m**. The submicromolar PBR affinity shown by cold rhenium complexes **6j,m** encouraged the preparation of technetium-99m labeled compounds **6h,k** and their evaluation in ex vivo biodistribution and in small animal SPET studies. The results obtained indicate that both tracers do not present a clear preferential distribution in high PBR expressing tissues. In fact, none of them was taken up by the heart, and only neutral complex **6k** displayed activity in spleen, kidney, and lung. In addition, these levels were lower or comparable to those observed in blood and **6k** uptake appeared to be inhibited by unlabeled PK11195 only in lung. A possible explanation is the high molecular weight of these tracers that may hamper transmembrane diffusion and the reaching of the intracellular target receptor. However, compounds **6h,k** show very similar shapes and dimensions (i.e., MW is ca. 800), but different properties in both the spacer and the MLM. In particular, compound **6h** shows the contemporary presence of a negative charge in the MLM and a basic nitrogen atom in the piperazine moiety. The protonation in the physiological environment is likely to produces a zwitterionic character in this MAG_3 derivative that is not present in **6k** and may play a significant role in the membrane passage and, as a consequence, in the biodistribution features. Therefore, **6h** can be ultimately considered a negative control capable of highlighting the relatively favorable properties of **6k.** On the basis of the above results, we believe that negatively charged complex **6h** has inadequate kinetic properties to be further explored as a PBR ligand, while additional experiments on selected animal models are required to establish the potential usefulness in tumor imaging or in the monitoring of lung inflammation of neutral complex **6k** based on the MLM present in technepine, fluoratec, and other interesting tracers (*32, 41, 42*).

ACKNOWLEDGMENT

The authors are grateful to Prof. Stefania D'Agata D'Ottavi for the careful reading of the manuscript and to Prof. Giovanni Biggio and Prof. Alessandra Concas for the binding studies performed on compounds **6a**−**g,j,m**. This work was financially supported by Ministero dell'Università e della Ricerca - PRIN (Programmi di ricerca di Rilevante Interesse Nazionale) and by EMIL (European Molecular Imaging Laboratory), Sixth European Program, Project No: LSHC-CT-2004-503569.

Supporting Information Available: Analytical data for compounds **6a**−**g,i,j,l,m**. This material is available free of charge via the Internet at http://pubs.acs.org.

Received October 20, 2007; Revised Manuscript Received March 31, 2008

In a previous work, we studied the interaction of β-amyloid fibrils (Aβ) with gold nanoparticles (AuNP) conjugated with the peptide CLPFFD-NH_2. Here, we studied the effect of changing the residue sequence of the peptide CLPFFD-NH_2 on the efficiency of conjugation to AuNP, the stability of the conjugates, and the affinity of the conjugates to the Aβ fibrils. We conjugated the AuNP with CLPFFD-NH_2 isomeric peptides (CDLPFF-NH_2 and CLPDFF-NH_2) and characterized the resulting conjugates with different techniques including UV−Vis, TEM, EELS, XPS, analysis of amino acids, agarose gel electrophoresis, and CD. In addition, we determined the proportion of AuNP bonded to the Aβ fibrils by ICP-MS. AuNP-CLPFFD-NH_2 was the most stable of the conjugates and presented more affinity for Aβ fibrils with respect to the other conjugates and bare AuNP. These findings help to better understand the way peptide sequences affect conjugation and stability of AuNP and their interaction with Aβ fibrils. The peptide sequence, the steric effects, and the charge and disposition of hydrophilic and hydrophobic residues are crucial parameters when considering the design of AuNP peptide conjugates for biomedical applications.

INTRODUCTION

Present-day nanomedicine exploits carefully a broad variety of structured nanoparticles. These nanoparticles may serve as diagnostic and therapeutic antiviral, antitumor, or anticancer agents (*1*, *2*). Metallic nanoparticles (NP) can be made so as to respond resonantly to a time-varying magnetic field, with advantageous results related to the transference of energy to the NP. For example, the particles can be made to heat up, leading to its use as a hyperthermia agent, by delivering toxic amounts of thermal energy to targeted bodies such as tumors. The NP can also act as enhanced chemotherapy and radiotherapy agents, where a moderate degree of tissue warming results in more effective destruction of malignant cells. Local heat delivered by NP selectively attached to a target can be used as *molecular surgery* to safely remove toxic and clogging aggregates. Recently, we applied this principle to protein aggregates, concretely to the protein Aβ, involved in Alzheimer's disease (*3*). We redissolved Aβ deposits remotely by using the local heat dissipated by gold nanoparticles (AuNP) conjugated to the peptide CLPFFD-NH_2. The resulting conjugate was selectively attached to the aggregates of Aβ, and then the system was irradiated with low gigahertz electromagnetic fields.

The determinant success in therapeutic and diagnostic use of NP is the ability to deliver them to the desired target. In this sense, NP can be coated with biological molecules to make them recognize the biological target. From the point of view of molecular recognition, peptides have a number of properties participating in ligand−receptor and protein−protein molecular interactions (*4*). For instance, peptides are involved in molecular recognition of antibodies, which is relevant in the field of clinical diagnosis of infectious diseases (*5*) and in the design of new drugs and vaccines (*6*).

Capping AuNP with peptides could increase stability and biocompatibility; however, recently one of the main concerns has become how peptides interact and pack on a NP surface and how the anchorage to the AuNP surface affects molecular recognition of the biological target and the stability of the AuNP (*1*). Thiol-based organic stabilizers have been widely used as capping agents to stabilize AuNP (*7*–*12*). In particular, Levy et al. have developed a family of peptides called CALNN that increases the stability of AuNP (*13*). In our case, the amphipathic peptide CLPFFD-NH_2 also has a cysteine residue (C) which contains a thiol group allowing a strong interaction with the gold surface. This interaction may be additive to that of the N-terminal primary amine, since amino groups are also known to have a strong interaction with gold surfaces (*14*). Moreover, it has been shown by Bellino et al. (*15*) that the presence of the C residue and a positively charged ammonium group in the vicinity of the thiol significantly accelerates the adsorption kinetics of thiols onto citrate-stabilized AuNP. Bare AuNPs are stabilized by citrate anions, which are common electrostatic

stabilizing agents, because the particles are typically synthesized through a citric acid reduction reaction (*13*). Electrostatic stabilization arises from mutual repulsion between neighboring AuNPs resulting from the negative surface charges of the citrate layer. Peptide CLPFFD-NH_2 is bound spontaneously to the AuNP replacing the citrate coating on the AuNP by forming stable Au−S bonds, as seen in the case of other peptides as CALNN (*13*).

In order to direct the AuNP to the toxic Aβ fibrils, in a previous work we conjugated AuNP to the peptide CLPFFD-NH_2, forming the AuNP-CLPFFD-NH_2 conjugate, which selectively attaches to the Aβ fibrils (*3*). This peptide is a fragment corresponding to the physiological molecule Aβ (1−42) and recognizes a particular (hydrophobic) domain of the β-sheet structure (the sequence ^{17}LVF^{20}F which is one of the hydrophobic cores of the native protein Aβ). In that work, we demonstrated that CLPFFD-NH_2 increases the affinity of AuNP for Aβ. The CLPFFD-NH_2 peptide contains at the C-terminal extreme an Asp residue (D) that confers primary amphipathicity to the molecule (i.e., in the C-terminal end of the sequence there is a polar charged residue, and following the sequence there are preponderantly hydrophobic residues), and increases the solubility of the peptide molecule. The presence of the residues Leu (L), Phe (F), and Phe (F), also present in the native sequence, confers to the molecule the ability to recognize the aggregates of Aβ (*16*).

The aim of this work is to explore the effect of changing the residue sequence of CLPFFD-NH_2 on the AuNP peptide conjugation, stability, and affinity to Aβ fibrils. The purpose is to modify the distances between the AuNP surface and the position of the negatively charged hydrophilic residue at pH 7.4 (i.e., the D residue).

EXPERIMENTAL PROCEDURES

Synthesis of AuNP. Citrate-coated AuNPs (12.5 ± 1.7 nm) were prepared by citrate reduction of $HAuCl_4$. An aqueous solution of $HAuCl_4$ (100 mL, 1 mM) was refluxed for 5−10 min, and a warm (50−60 °C) aqueous solution of sodium citrate (10 mL, 38.8 mM) was added quickly. Reflux was continued for another 30 min until a deep red solution appeared. The solution was filtered through 0.45 μm Millipore syringe filters to remove any precipitate, the pH was adjusted to 7.4 using dilute NaOH solution, and the filtrate was stored at 4 °C. AuNP were observed by transmission electronic microscopy (TEM) using a JEOL JEM-1010 microscope. The specimen was prepared by dropping AuNP on Formvar carbon-coated copper microgrids and letting them dry.

Peptide Synthesis. CLPFFD-NH_2, CDLPFF-NH_2, and CLPDFF-NH_2 were synthesized following fluorenylmethyloxycarbonyl (Fmoc) strategy and solid-phase synthesis. Fmoc-protected amino acids were purchased from Novabiochem (Laufelfingen, Switzerland) and Perseptive Biosystems (Framingham, Massachusetts). *O*-(Benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate (TBTU), Fmoc-AM handle, and resin MBHA were also obtained from Novabiochem. Chemical reagents *N*,*N*′-diisopropylcarbodiimide (DIPCI), 1-hydroxy-1*H*-Benzotriazole (HOBt), triethylsilane, and dimethylaminopyridine (DMAP) were from Fluka (Buchs, Switzerland). Manual synthesis including the following steps: (i) resin washing with DMF (5 × 30 s); (ii) Fmoc removal with 20% piperidine/DMF (1 × 1 min + 2 × 7 min); (iii) washing with DMF (5 × 30 s), (iv) washing with DMF (5 × 30 s) and CH_2Cl_2 (5 × 30 s); (v) Kaiser's test (with a peptide−resin sample); (vi) DMF washing (5 × 30 s). Cleavage of the peptide was carried out by acidolysis with trifluoroacetic acid (TFA) using triethylsilane and water as scavengers (94:3:3, v/v/v) for 60−90 min. TFA was removed with N_2 stream and the oily residue precipitated with dry *tert*-butyl ether. Peptide crude was recovered by centrifugation and decantation of the *tert*-butyl ether phase. The solid was redissolved in 10% acetic acid (AcH) and lyophilized. The peptide was analyzed by RP-HPLC [Waters 996 photodiode array detector (λ = 443 nm) equipped with a Waters 2695 separation module (Milford, MA), a Symmetry column (C18, 5 μm, 4.6 × 150 mm), and Millennium software; flow rate = 1 mL/min, gradient = 5−100% B over 15 min (A = 0.045% TFA in H_2O, and B = 0.036% TFA in acetonitrile)]. The peptide was purified by semipreparative RP-HPLC [Waters 2487 Dual Absorbance Detector equipped with a Waters 2700 Sample Manager, a Waters 600 Controller, a Waters Fraction Collector, a Symmetry column (C18, 5 μm, 30 × 100 mm), and Millennium software]. The peptide was finally characterized by amino acid analysis with a Beckman 6300 analyzer and by MALDI-TOF with a Bruker model Biflex III. Amino acid analysis of CLPFFD-NH_2: Asp 1.0 (1), Pro 0.97 (1), Leu 1.0 (1), Phe 2.03 (2) and mass spectrometry MALDI-TOF: CLPFFD-NH_2, $[M+H^+]$=740 and $[M+Na^+]$=762. Stock solutions of the peptides were prepared by dissolution in water. The pH was adjusted to 7.4 using concentrated NaOH, and the resulting 1.3 mM solution was filtered using 0.2 μm PVDF filters and kept as aliquots at −80 °C. An amino acid analysis (Alta Biosciences, Birmingham, U.K.) indicates a final concentration of 1.28 mM after filtering.

Conjugation of Peptides to AuNP. CLPFFD-NH_2, CLPDFF-NH_2, and CDLPFF-NH_2 capped AuNPs were prepared by mixing 5 nM AuNP and peptide stock solution in a volume ratio of 10 to 1. The conjugation was made in the presence of peptide excess in order to ensure full conversion of the AuNP and, consequently, homogeneous conjugation. The AuNP were afterward purified first in a 450 nm filter and then by dialysis (during three days in a membrane Spectra/Por MWCO 6−8000 against 1.2 mM sodium citrate and the solution was changed 6 times) to eliminate the excess of peptide. UV−Vis absorption spectra were recorded at room temperature with a Unicam UV/vis spectrophotometer (UV3). In order to check the absence of nonconjugated peptide, 3 mL of the conjugated solution were centrifuged at 13 500 rpm for 30 min (AuNP peptide sediments) and the supernatant was evaporated to dryness and an analysis of amino acids was carried out. On the other hand, the absence of free peptide both in the supernatant and in the NP pellet (the conjugated AuNP) was also checked by HPLC ES-MS. Separately, the NP pellet and the residue of the supernatant (after the draining) were suspended in 300 μL of 1% TFA and filtered through a 220 nm filter. In any case, the presence of the peptide was detected.

XPS. X-ray photoelectron spectroscopy (XPS) experiments were performed in a PHI 5500 Multitechnique System (from Physical Electronics) with a monochromatic X-ray source (Al Kα line of 1486.6 eV energy and 350 W), placed perpendicular to the analyzer axis and calibrated using the $3d_{5/2}$ line of Ag with a full width at half-maximum (fwhm) of 0.8 eV. The analyzed area was a circle of 0.8 mm diameter, and the selected resolution for the spectra was 187.5 eV of pass energy and 0.8 eV/step for the general spectra and 23.5 eV of pass energy and 0.1 eV/step for the spectra of the different elements. Some measurements were done after some cleaning by sputtering the surface with an Ar^+ ion source (4 keV energy). All measurements were made in an ultrahigh-vacuum chamber pressure between 5×10^{-9} and 2×10^{-8} Torr.

EELS. Electron energy loss spectra (EELS) were obtained in a Gatan Image Filter (GIF 2000) coupled to the JEOL 2010F microscope, with an energy resolution of 1.2 eV.

Estimation of the Number of Peptide Molecules per AuNP. The amount of peptide molecule per NP was estimated by analysis of amino acids and absorption spectrophotometry.

The concentration of AuNP in the solutions was obtained taking into account the molar coefficient of extinction of the 12 nm diameter ($5.7 \times 10^7\ M^{-1}\ cm^{-1}$) AuNP and an analysis of amino acids of the pellet obtained after centrifugation of the conjugates at 13500 rpm for 30 min (in such conditions the NP sediment). The number of peptide molecules per AuNP was obtained by dividing the number of peptide molecules per mL of solution by the number of particles per mL of solution. This ratio was obtained in triplicate in three independent synthesis and conjugation.

Zeta Potential. The zeta potential (Zeta sizer 3000, Malvern Instruments, UK) measurements of the 12 nm diameter AuNP consisted of five repeats of each AuNP solution. The AuNP in 1.2 mM citrate solution were adjusted to pH 7.4 with a 0.1 M buffer phosphate solution, and a final buffer concentration of 10 mM. Because the zeta potential measurements were performed in an aqueous solution, the Smolouchowski approximation was used to calculate the zeta potential from measured electrophoretic mobility.

Electrophoresis. Submarine gel electrophoresis of the AuNP-peptide conjugates was performed in 1.5% agarose gels (Molecular Biology grade, Roche) using as a running 10 mM phosphate buffer in 1.2 mM sodium citrate. The field strength was held constant at 120 V and the current was 97 mA. 50 μL of AuNP solutions were mixed with 50 μL of 1:9 glycerol/buffer solution and loaded in the gels.

Stability of AuNP and Their Conjugates. (a) Characterization of NP aggregation by UV−visible Spectrometry. UV−Vis absorption spectra were recorded at room temperature with a Unicam UV/Vis spectrophotometer (UV3). The aggregation parameter (AP) was defined as follows: $AP = (A - A_0)/A_0$, where A is the integrated absorbance between 600 and 700 nm and A_0 is the integrated absorbance between 600 and 700 nm of the dispersed solution.

(b) Dialysis against water. Ten mL of the colloidal solutions of AuNP were dialyzed in 2 L of water (during 1 day in a membrane Spectra/Por MWCO 6−8000 against water, and the water was changed at 1 h and 3 h).

(c) Stability in running agarose electrophoresis with buffer solutions. 500 μL of each solution were mixed with 500 μL of phosphate buffer and the aggregation parameter (AP) was determined by UV−vis spectrophotometry.

(d) Stability in artificial cerebrospinal fluid buffer (ACSF): 124 mM NaCl, KCl 5 mM, NaH_2PO_4 1.25 mM, $MgCl_2$ 2 mM, $CaCl_2$ 2 mM, $NaHCO_3$ 26 mM, dextrose 10 mM (see ref (*17*)). 50 μL of each 5 nM colloidal solution was mixed with 950 μL of ACSF buffer and the aggregation parameter (AP) was determined by UV−Vis spectrophotometry.

(e) Stability in rat serum. 50 μL of each 5 nM colloidal solution were mixed with 950 μL of serum and the aggregation parameter (AP) was determined by UV−Vis spectrophotometry. For spectrophotometric measurement, a blank with 50 μL of citrate and 950 μL of serum was used. Serum was obtained from blood collected from Sprague−Dawley male rats (200−300 g). The blood was centrifuged (at room temperature) at 3000 rpm and supernatant liquid was collected.

Circular Dichroism (CD). 150 μL of 40 nM colloidal solution was mixed with 50 μL of phosphate buffer saline and 86 μL of trifluoroethanol (TFE) were added. Circular dichroism spectra were recorded with a Jasco J700 spectropolarimeter (Great Dumnow, UK), at a spectral bandwidth of 1 nm, with a time constant of 4 s (scan speed 10 nm/min) and a step resolution of 0.2 nm. Each spectrum was the result of three accumulations and were measured at 25 °C. A blank spectrum of 150 μL of 1.2 mM citrate, 50 μL of phosphate buffer saline and 86 μL of TFE was subtracted from each conjugate spectrum. Mean residue ellipticity, $[\theta]_{MR}$, is given in units by $deg \cdot cm^2 \cdot dmol^{-1}$.

Interaction with Amyloid Fibrils. (a) Preparation of Aβ_{1-42} solution. Aβ_{1-42} was purchased from Peptide Institute, Inc. (Japan). Water−peptide aliquots were lyophilized again in glass vials and stored at −20 °C until used. A variant of Zagorski's protocol was followed in order to obtain a homogeneous Aβ_{1-42} solution free from aggregates (*18*). Summarizing, in the same vial where it was lyophilized, Aβ_{1-42} was treated with TFA in order to eliminate any pre-existing aggregates. TFA was then evaporated under a stream of nitrogen. To thoroughly remove TFA, 1,1,1,3,3,3-hexafluoro-2-propanol was added and evaporated under a nitrogen stream. This last step was repeated three times and the sample was finally left overnight in a desiccator. The desiccated aliquot was carefully and completely resuspended in 18 μL of 10 mM NaOH per each 100 μL of final sample. Finally, 10 μL of 200 mM phosphate buffer and water was added to complete 100 μL (200 μL of the sample was prepared). All solutions are cleaned of small particles by filtration through a 0.20 μm pore size filter (Millipore). At the end of the process, Aβ_{1-42} was at a concentration of 40 μM. The solution was divided into four aliquots of 50 μL each and incubated at 37 °C for 4 h with mechanical shaking.

(b) Interaction of the samples with AuNP and the conjugates. 150 μL of 1 nM AuNP-CLPFFD-NH_2, AuNP-CDLPFF-NH_2, or AuNP-CLPDFF-NH_2 were added to the Aβ_{1-42} solutions and the samples were incubated for 44 additional h at 37 °C with mechanical shaking (nonmature fibrils: i.e. the 2 day old samples) or for 164 additional h at 37 °C with mechanical shaking (mature Aβ precipitated fibrils: i.e., the 7 day old samples). For TEM observations, aliquots of 1 μL of the preparations were diluted in cold (4 °C) with 20 mM PBS buffer (pH 7.4) to a final peptide concentration of 1 μM. Then, the samples were adsorbed for 1 min onto glow discharged carbon-coated colloidal films on 200 mesh copper grids. The TEM grids were then blotted and washed in Milli-Q water before negative staining with 2% uranyl acetate for visualization by TEM (JEOL JEM-1010).

(c) Quantification of gold in fibrils and supernatants. In order to separate the free and bound nanoparticles a centrifugation at 5000 rpm during 5 min was carried out. The pellet was washed with 20 mM phosphate buffer, and the first and the second supernatant were mixed. The concentration of proteins in the total supernatant was determined following the Bradford protocol. The content of gold in both pellet and supernatant was analyzed by ICP-MS after lyophilization.

(d) Determination of gold content in pellets and supernatant. The determinations were carried out in triplicate. The ICP multielement standard was obtained from high purity standards (QCS-26). Samples were digested by using a Millestone MLS-1200 Mega plus EM-45 microwave oven and following USEPA Method IO-3.1. Basically, this consists of extraction of the elements using 10 mL of a nitric acid−hydrogen peroxide (10:1) solution. After the digestion process, gold was determined directly by ICP-MS (Fisons VG-PlasmaQuad) in each fraction. The values obtained in μg/L were expressed in μg in the pellets and supernatants, and finally the ratio between gold in the supernatant (free AuNP) and in the pellet-bound AuNP were calculated. The contents of protein in the pellets of all the samples and in all the supernatants were similar, indicating that the presence of nanoparticles does not affect the fibril formation. In addition to quantify the amount of Aβ fibrils formed in the presence of the AuNPs, thioflavine T assays were performed observing that quantity of Aβ fibrils in the samples of 2 and 7 days (AuNP + fibrils, AuNP-CLPFFD-NH_2 + fibrils, AuNP-CDLPFF-NH_2 + fibrils, and AuNP-CLPDFF-NH_2 + fibrils)

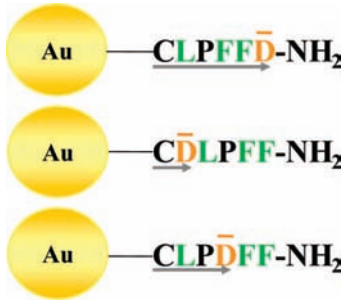

Figure 1. Schematic representation of the peptides conjugated to AuNP at physiological pH 7.4 (The calculated isoelectric point, using the software *Insight II*, of the free peptides is approximately 5.6). In orange is represented the D residues which have a formal negative charge at this pH. In green are represented the hydrophobic residues (LFF). Note that in AuNP-CLPFFD-NH_2 and in AuNP-CDLPFF-NH_2 the hydrophobic residues LFF are uninterrupted by the hydrophilic residue D, which would allow an optimal interaction with the Aβ fibrils. On the other hand, in AuNP-CLPDFF-NH_2 the hydrophobic residues LFF are interrupted by the hydrophilic D. The gray arrows show schematically the distance between the gold surface and the D residue assuming an extended peptide conformation.

were similar, indicating that AuNP does not interfere in the process of Aβ aggregation (data not shown).

RESULTS AND DISCUSSION

Rational Design of the Isomers of CLPFFD-NH_2 for Conjugation with AuNP. For pharmaceutical application of a conjugate AuNP−peptide, it is important to take into account the colloidal stability and the recognition ability of the conjugate AuNP−peptide to the desired target, in this case to the Aβ fibrils. To maintain colloidal stability, it is important that the charge of the AuNP be exposed to the bulk solution to form the double layer that stabilizes the colloid. On the other hand, for recognition purposes it is important that the hydrophobic residues on the conjugate be exposed, in this case L, F, and F residues, to the Aβ fibrils. We chose two isomers of peptide CLPFFD-NH_2, i.e., peptide CDLPFF-NH_2 and peptide CLPDFF-NH_2. When the peptide adopts an extended conformation, the D residue localizes away from the gold surface in the case of CLPFFD-NH_2, while in the case of AuNP-CDLPFF-NH_2, it is near the AuNP surface (Figure 1). In the case of CLPDFF-NH_2, an intermediate situation occurs. In conjugates AuNP–peptide, the stability of the colloid will be modulated by the exposition of the charge to form the double layer and the steric repulsion produced by the peptide capping. On the other hand, the affinity of the conjugates for Aβ fibrils will be modulated by the peptide structure and the exposition of the hydrophobic residues L, F, and F to Aβ fibrils in the cases of CLPFFD-NH_2 and CDLPFF-NH_2, in contrast to CLPDFF-$NH_2$where the L, F, and F residue sequence is interrupted by the hydrophilic charged residue D.

Synthesis and Characterization of AuNP−Peptide Conjugates. AuNP of 12.5 ± 1.7 nm in diameter (Figure 2) were synthesized by reduction of $HAuCl_4$ with sodium citrate in accord with a previous work (*13*).

The AuNP−peptide conjugates were prepared by mixing the colloidal AuNP solution with an excess of peptide to obtain a completely functionalized AuNP surface. The conjugates were exhaustively characterized by using UV−Vis spectrophotometry, EELS, XPS, amino acid analysis, gel electrophoresis, and CD. The peptides were synthesized following a solid-phase synthesis and Fmoc/tbu strategy (*19*). Several dialyses were then performed over three days in order to purge the remaining nonconjugated peptide. Figure 3 shows UV−Vis spectra of the bare AuNP and peptide conjugated to AuNP. The characteristic shift of the surface plasmon resonance band from 519 to 527 nm was observed in the conjugates.

EELS and XPS techniques were used to prove the presence of S−Au bonds on the surface. EELS spectra in the region between 50 and 240 eV were obtained on the AuNP surface from the different samples in order to evaluate the presence of sulfur, and ensure in this way the functionalization of the AuNP with the different peptides (Figure 4A). In Figure 4B, we show a detail of the electron energy loss near edge spectra (ELNES) at the S $L_{2,3}$ edge (165 eV), showing that the edge shape dramatically changes when obtaining the spectrum of the bare AuNP with regard to the peptide-functionalized AuNP. All sample spectra show the typical S $L_{2,3}$-edge slope characteristic of the peptide functionalization (Figure 4B). The spectra obtained on the surface of AuNP in samples AuNP-CLPFFD-NH_2 (red-line spectrum), AuNP-CDLPFF-NH_2 (green-line spectrum), and AuNP-CLPDFF-NH_2 (blue-line) present a clear edge at 165 eV, which is indicative of the presence of sulfur bonded atoms ($L_{2,3}$-edge). This last result corroborates the presence of S atoms at the Au surface, and consequently, the presence of S bonded atoms would imply the functionalization of the AuNP with the peptides in all the samples studied.

Further characterization of the colloids by XPS was performed. In Supporting Information Figure S1, we present survey spectra for four samples taken under similar conditions. In AuNP−peptide conjugates, the expected peaks from S 2p, S 2s, and Au 4f core levels were detected. High-resolution data have also been recorded in the S 2p, S 2s, and Au 4f, spectral regions (Supporting Information Figures S2, S3, and S4). The S 2p signal consists of a broad band with a maximum at 162.2 eV that corresponds to the chemisorptions of sulfur grafted onto gold (*20–23*). A similar trend is also observed with the S 2s photoelectron peak (see Supporting Information Table T1). This peak is a particularly good parameter since it is a singlet, thus making the interpretation straightforward. The S 2s photoelectron binding energy (BE) from bulk peptide with the free thiol and AuNP peptide thiolate are found at 228.2 and 227.3, respectively (Supporting Information Table 1). Similar behavior was reported by Bensebaa et al. (*24*). The accuracy of these BE values is estimated to be ±0.2 eV at the worst. In the case of bare AuNP and capped AuNP, the signal corresponding to Au $4f_{7/2}$ is positioned at 84.2 eV (see Supporting Information Figure S4). The fact that the measured Au $4f_{7/2}$ photoelectron BE is not detected by the sulfur chemisorption is probably because the peak separation is too small. The same result was obtained in capped AuNP with alkanethiolates (*24*).

The number of peptides per AuNP was calculated by dividing the quantity of grafted peptide (obtained by analysis of amino acids of the AuNP pellet) by the amount of AuNP in solution, which was photometrically determined (see Experimental Section). The degree of conjugation follows the order AuNP-CLPFFD-NH_2 > AuNP-CLPDFF-NH_2 > AuNP-CDLPFF-NH_2 (460 ± 30, 420 ± 10, and 203 ± 5 peptide molecules per AuNP). Assuming that (i) the surface of a 12.5 nm in diameter AuNP is 490 nm^2, (ii) the projection of a cylindrical peptide molecule (with cylindrical base) resting along its base on the gold surface in an extended conformation is 0.6 nm^2 (estimated by molecular modeling with the program *Insight II*), and (iii) a hexagonal close-packed lattice in which the maximum number of molecule not exceeding the packing density of 74% is 609 molecules, we conclude that our peptide molecules (for instance, only 460 in the case of AuNP-CLPFFD-NH_2) are not forming a compact self-assembled monolayer (SAM).

Effect of the Residue Sequence in the Stability of the AuNP−Peptide Conjugates. CLPFFD-NH_2, CDLPFF-NH_2, and CLPDFF-NH_2 are more stable than bare AuNP. At 4 °C, AuNP-CLPFFD-NH_2 and AuNP-CLPDFF-NH_2 do not aggregate at pH = 7.4 (in buffer phosphate 10 mM) for one year, but AuNP-CDLPFF-NH_2 and bare AuNP do (see Supporting

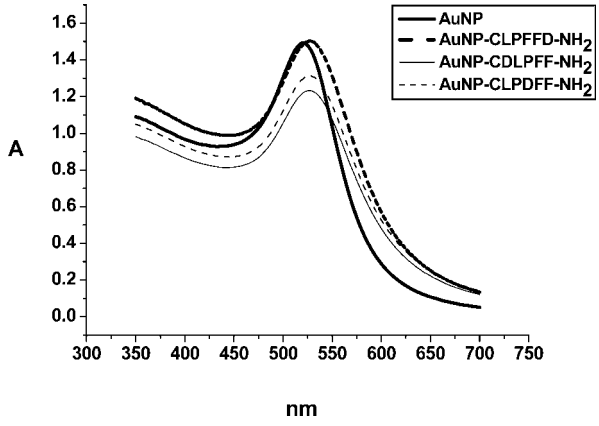

Figure 3. UV−vis spectra of bare AuNP and peptide-capped AuNP.

Information Figure S5). Peptide stabilization of AuNP is a documented phenomenon (*1*), although the effect of the peptide sequence in the stability has been documented for only the peptide CALNN (*13*).

In order to evaluate the stability of the AuNP−peptide conjugates, we measured the UV−Vis spectra for different conditions and determined the AP, in the way defined by Levy et al. (ref (*13*); see Experimental Section). The stability of the AuNP and their conjugates was studied both after fast freezing/defreezing (Figure 5A) and after fast freezing/freeze-drying and reconstitution in water (Figure 5B). AuNP-CLPFFD-NH_2 and AuNP-CLPDFF-NH_2 were more stable than AuNP-CDLPFF-NH_2 and bare AuNP in both conditions (Figure 5A,B). These results also reveal higher exposition of the hydrophobic residues F and F to the solvent (10 mM phosphate buffer, pH 7.4 in 1.2 mM sodium citrate) in the case of AuNP-CDLPFF-NH_2 than in the cases AuNP-CLPFFD-NH_2 and AuNP-CLPDFF-NH_2, a direct consequence of having the F groups in the conjugate AuNP-CDLPFF-NH_2 located far from the influence of the charged aspartic group. Thus, after freezing, the hydrophobic groups of AuNP-CDLPFF-NH_2 particles freely interact through van der Waals interactions (excluding water) producing aggregation and subsequent colloid flocculation.

In colloids there are several interactions that determine the stability. The combination of van der Waals attractive forces and steric forces form the basis for the theory of steric stabilization. Fine particles tend to attract each other due to van der Waals attractive forces that can be neutralized through the addition of charge and/or grafting molecules onto the nanoparticle surface. In the first case, stabilization occurs due to electrostatic repulsion, while in the second case, stabilization occurs due to steric repulsive forces (*25*). Here, we report on two parameters related to the nanoparticle charge, the zeta potential and migration in an electrophoresis gel.

Effect of the Residue Sequence on the Charge of the AuNP−peptide Conjugate. The classical Derjaguin-Landau-Verwey-Overbeekn (DLVO) theory has been widely employed in colloid science for understanding colloidal interaction in liquids (*26–28*). The salient feature of the theory indicates that a colloidal system remains stable if repulsion forces dominate particle interactions over attractive van der Waals forces. However, when attractive forces dominate, then colloidal particles cluster together forming flocculates and aggregates. The origin of stabilizing repulsion forces may be Coulombic, entropic arising from the confinement of thermally mobile surface groups, or a combination. Higher (absolute) values of zeta potentials yield stronger Coulombic repulsion between the particles, thus diminishing the impact of the van der Waals force attractions. Table 1 summarizes the zeta potentials corresponding to bare AuNP and AuNP−peptide conjugates. In general, AuNP−peptide conjugates present lower zeta potential (absolute) values than bare AuNP. We attribute this to the replacement of ion citrates (ion citrates have three dissociated negatively charged carboxylic groups at pH 7.4) with peptide molecules (which bear one formal negative charge at pH 7.4). For instance,

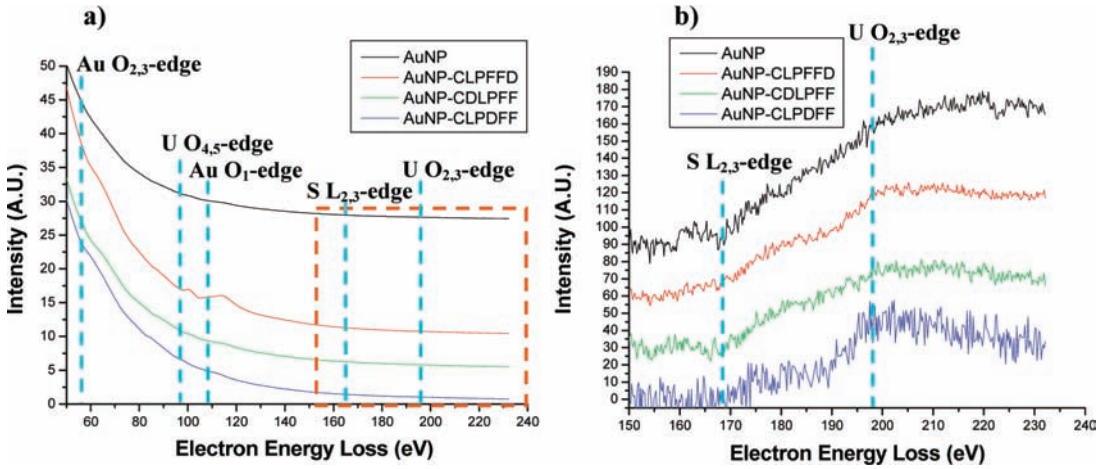

Figure 4. (A) EELS spectra obtained on the surface of 12.5 nm sized AuNP, nonfunctionalized (black line), and functionalized with different peptides (red, blue, and green spectra). (B) Detail of the S $L_{2,3}$ ELNES spectra obtained from the spectra showed in a. Au $O_{2,3}$-edge 54 eV; Au O_1-edge 83 eV; U $O_{4,5}$-edge 96 eV; U $O_{2,3}$-edge 195 eV; S $L_{2,3}$-edge 165 eV.

Table 1. Zeta Potential of Bare and AuNP−peptide Conjugates at pH 7.4 (10 mM phosphate buffer pH 7.4, in 1.2 mM citrate)[a]

colloid	zeta potential mV (std. dev. in mV)
AuNP	−54.3 (2.9)
AuNP-CLPFFD-NH_2	−43.7 (1.5)
AuNP-CDLPFF-NH_2	−34.9 (0.6)
AuNP-CLPDFF-NH_2	−42.8 (1.0)

[a] Low std dev in all cases suggests homogeneous zeta potential distribution and thus capping degree.

the replacement of one peptide molecule with one citrate ion will reduce the total negative charge of the AuNP in two units. However, the diminution of the charge density is not always accompanied by an increase in the peptide grafting density. Remarkably, in the case of AuNP-CDLPFF-NH_2 in which the quantity of peptide molecules covering the surface is lower with respect to the other isomers (203 versus approximately 400 in the other two cases), the zeta potential is lower than that for the other conjugates. In this case, the presence of a carboxylate group belonging to the D residue situated near the surface, seems to induce the exclusion of more molecules of adsorbed citrate (due to the repulsive interaction between D residues and citrate carboxylates) with respect to the other conjugates.

Zeta potential values explain the higher stability of AuNP-CLPFFD-NH_2 and AuNP-CLPDFF-NH_2 with respect to AuNP-CDLPFF-NH_2. Even though in general AuNP−peptides present lower zeta potential values (absolute) with respect to bare AuNPs, the first are more stable than the latter possibly due to the steric stabilization produced by the peptide molecules.

Colloid stability of AuNP−peptide conjugates is enhanced by entropic repulsive interactions of the protruding peptide groups on the particles in water; these groups should not be considered as fixed or rigid, but rather as a superficial layer of flexible segments that expand or collapse on the surface. In this way, van der Waals attractive forces can be neutralized thorough the chemisorption of peptide molecules on the colloid surface and stabilization occurs due to steric repulsive forces as was described for other molecules adsorbed on nanoparticle (*25*, *29*). So, the experimental stability order AuNP-CLPFFD-NH_2 > AuNP-CLPDFF-NH_2 > AuNP-CDLPFF-NH_2 > AuNP would correspond with peptide functionalization that is AuNP-CLPFFD-NH_2 > AuNP-CLPDFF-NH_2 > AuNP-CDLPFF-NH_2 and bare AuNP.

We also ran an electrophoresis agarose gel in phosphate buffer at pH 7.4 (10 mM) (the same conditions under which we studied the interaction with Aβ fibrils; see below). In such conditions the electrophoretic relative mobilities of the nanoparticles follow the order AuNP-CLPFFD-NH_2 ≅ AuNP-CLPDFF-NH_2 > AuNP-CDLPFF-NH_2 > bare AuNP (Figure 6). It is important to mention that bare AuNP presented aggregation in the running conditions in contrast with the AuNP−peptide conjugates. Other works in the literature show that bare AuNP does migrate in agarose gel; however, it does when stabilized with phosphines, compounds which are different from the citrate used here (*30*). On the other hand, the lower mobility of AuNP-CDLPFF-NH_2 with respect to the other conjugates we attribute to the lower resulting surface charge produced by the exclusion of citrate molecules from the surfaces (see previous section). In the case of bare AuNP, particles aggregate (in Figure 6 see the dark coloration corresponding to AuNP in the sample loading position) no matter their high zeta potential (Table 1). This reason is unclear to us; undesired interaction of the citrate ions with the buffer (during the running) in not discarded at this point.

From a pharmaceutical point of view, it is important to determine the stability of AuNP in the absence of citrate, simply because this salt is not present in biological medium. Here, we study the stability of the conjugates and bare AuNP after deprivation of the citrate ion in the media.

Stability of AuNP and Their Conjugates after Citrate Ion Deprivation. The citrate ions play an important role in the stability of the AuNP colloids; however, the interaction of these ions with the gold surface is weak. In the conjugation process of the peptides containing thiols, there is a replacement of citrate ions by peptide molecules forming a stable binding. However, the replacement is not complete because the AuNPs are not capped with a compact SAM; thus on the surface of the AuNP, there are citrate ions and peptide molecules that together contribute to form the stabilizing double layer. To evaluate the stability of AuNP and AuNP−peptide conjugates after citrate ion deprivation, we performed a dialysis against water for 24 h. This deprivation is caused by desorption due to the diffusion process of citrate ions outside the membrane dialysis to equilibrate the chemical potential of AuNP that to the solution. We choose this way to eliminate the citrate in order to avoid centrifugation and reconstitution in a buffer media because a certain degree of aggregation could occur after centrifugation.

After deprivation of the citrate ions, the system reaches thermodynamic equilibrium concentrations inside and outside the membrane; the AP for the AuNP and AuNP−peptide was determined by spectrophotometry after 24 h of dialysis against water. AuNP were unstable (AP = 3.40 ± 0.97) which could be attributed to desorption of weakly interacting adsorbed citrate

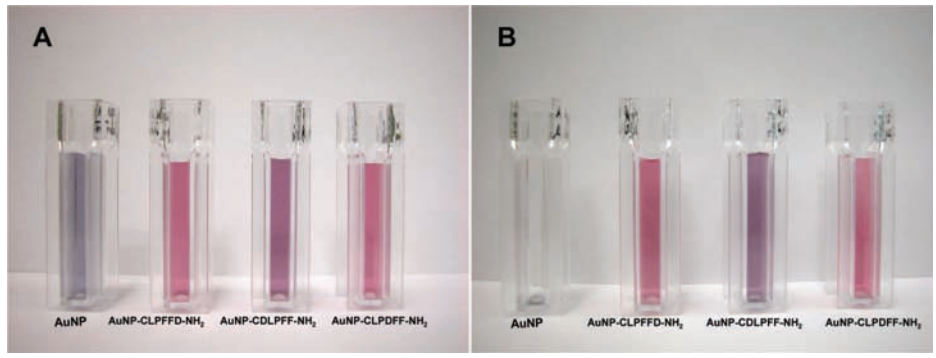

Figure 5. Photographies of colloidal solutions of bare AuNP and conjugated AuNP after: (A) freezing and defreezing and reconstitution in water (AP: 0.09 ± 0.03 for AuNP-CLPFFD-NH_2 and 0.06 ± 0.01 of AuNP-CLPDFF-NH_2, 0.45 ± 0.06 for AuNP-CDLPFF-NH_2, and 5.37 ± 0.24 for bare AuNP). (B) After freezing and freeze-drying the colloidal solutions and reconstitution in water (AP: 0.10 ± 0.05 for AuNP-CLPFFD-NH_2 and 0.14 ± 0.16 for AuNP-CLPDFF-NH_2, 0.35 ± 0.13, for AuNP-CDLPFF-NH_2 and for bare AuNP the AP could not be determined because the sample was totally precipitated).

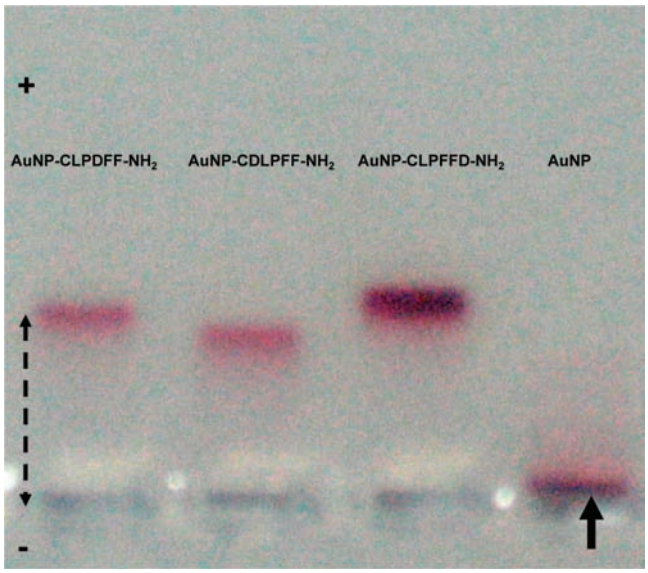

Figure 6. Electrophoresis of AuNP and AuNP−peptide conjugates in agarose gel. Run was performed in 10 mM phosphate buffer pH 7.4 in 1.2 mM citrate at 120 V for 8 min. The arrow indicates the loading sample position of AuNP. The dotted arrow indicates a real distance of 1.5 cm.

ions, which in turn leads to flocculation. AuNP-CDLPFF-NH_2 was also unstable, turning the determination of AP impossible. In contrast, AuNP-CLPFFD-NH_2 and AuNP-CLPDFF-NH_2 (AP = 0.15 ± 0.01 and 0.73 ± 0.01, respectively) were more stable than AuNP and AuNP-CDLPFF-NH_2. The higher stability of AuNP-CLPFFD-NH_2 and AuNP-CLPDFF-NH_2 with respect to AuNP-CDLPFF-NH_2 could be attributed to the higher degree of stable functionalization confered to the AuNP surface, which protects the conjugate against citrate deprivation. Exposition of carboxylic groups belonging to the D residues increases repulsion between the nanoparticles ensuring colloidal stability. In contrast, in AuNP-CDLPFF-NH_2, the degree of functionalization is low, thus leading to low protection against citrate deprivation; as a result, aggregation inevitably occurs due mainly to interaction of hydrophobic groups to exclude water.

The stability of nanoparticles in biological fluids is an important issue for its practical application. We studied the stability of the nanoparticles in less artificial conditions, as in the case of ACSF, a typical buffer used for neurophysiological studies (*17*), and in rat serum.

Stability of AuNP and Their Conjugates in a Medium that Mimics Cerebrospinal Fluid. We determined the AP of bare and capped AuNPs incubated for 48 h, at 4 °C. 5 nM AuNPs were diluted in AuNP/ACSF buffer (1:20). Figure 7 shows that only AuNP-CLPFFD-NH_2 were stable (AP = 0.05 ± 0.01) in ACSF, while the other conjugates and bare AuNP were unstable in such conditions (AP could not be determined due to precipitation).

Stability of AuNP and Their Conjugates in Rat Serum. The AP of bare and capped AuNP was determined in rat serum. The nanoparticle samples were diluted in serum in a 1:20 ratio (nanoparticle/serum) and UV−Vis spectra were obtained (Supporting Information S6). After 48 h, all the samples were stable. It should be noted that a bathochromic shift in all cases was observed before starting incubation (t = 0 h). This shift and stability of all samples could be attributed to nanoparticle capping with serum proteins that stabilizes the colloidal particles.

The secondary structure that adopts the peptide molecules onto the AuNP surface is related to both process, the grafting and the interaction of the anchored peptide molecules with amyloid aggregates. We carried out CD spectra of the conjugates in order to obtain information about the influence of the sequence on the structure of the peptides conjugated to AuNP.

CD Spectra of Conjugates AuNP−Peptide. In an attempt to characterize the possible differences in the secondary structures of the different peptides attached to the surface of AuNP, we have recorded the CD spectra of the conjugates. In the case of CDLPFF, this measurement was not possible due to the weak contribution of peptide yielded by the low degree of AuNP functionalization. On the contrary, Figure 8 shows the CD spectra of AuNP-CLPFFD-NH_2 and AuNP-CLPDFF-NH_2. In the first conjugate, a β structure is present, while a disordered structure is found in the second conjugate. In accordance with our CD experiments, a *hypothetical* model is proposed (Figure 9) that allows visualization of how CLPFFD-NH_2 is grafted on the AuNP surface, allowing the accommodation of a higher number of peptide molecules in relation to the isomer CLPDFF-NH_2. In the case of the peptide CLPFFD-NH_2, which presents primary amphipathicity (*31*), the hydrophilic head (D) is far from the surface and the peptide tends to adopt an extended β conformation. The molecules are orthogonally oriented to the AuNP surface, exposing the D and avoiding the interaction between the gold surface and the terminal amide. This behavior was recently proposed by Pomerantz et al. for the deposit of amphiphilic β-peptides onto gold surfaces (*32*). In the case of peptide CLPDFF-NH_2, in which the primary amphipathicity is not well-defined because the D group is intercalated in the sequence between the hydrophobic residues, the peptide molecules adopt a disordered structure and fewer molecules could be accommodated onto the gold surface. In this case, the terminal amide group could be in contact with the gold surface as proposed for non-amphipathic structures (*32*).

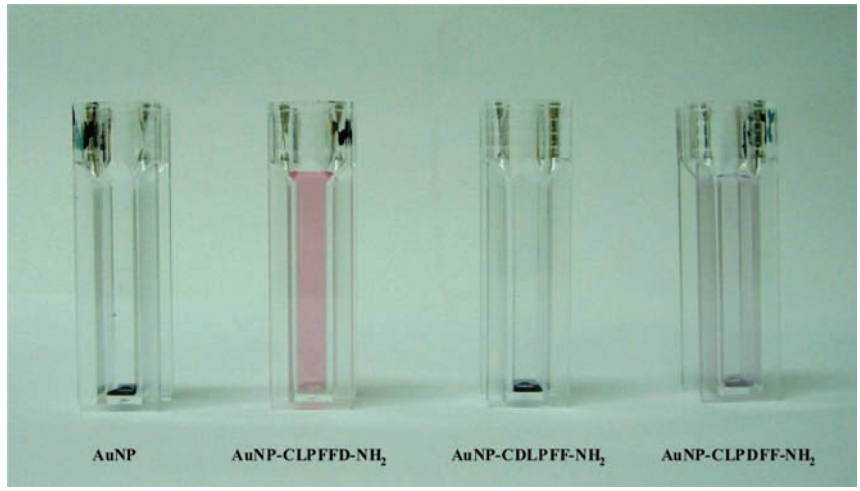

Figure 7. Photographs of colloidal solutions of bare AuNP and conjugated AuNP after incubation in ACSF for 48 h at 4 °C (AP, 0.05 ± 0.01 for AuNP-CLPFFD-NH_2; for bare AuNP and other conjugates, the AP could not be determined because the sample was totally precipitated).

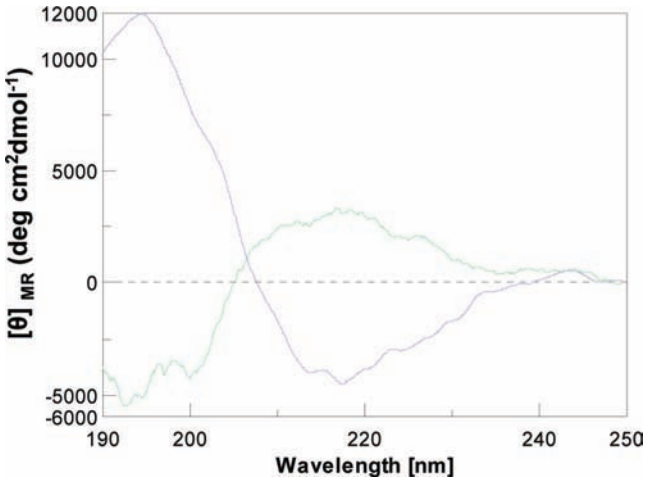

Figure 8. Far-UV CD spectra of AuNP-CLPFFD-NH_2 (blue) and AuNP-CLPDFF-NH_2(green) at pH = 7.4.

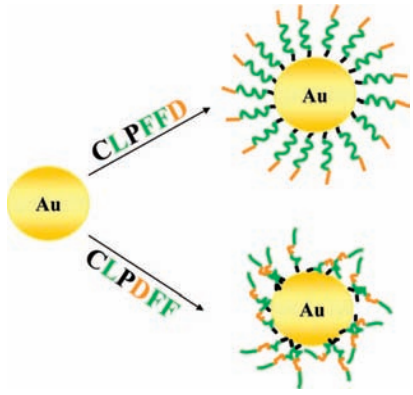

Figure 9. Hypothetical cartoon based on CD results. The hydrophobic groups are represented in green and the hydrophilic groups in orange. In the case of AuNP-CLPFFD-NH_2, the peptide is oriented orthogonally to the gold surface adopting a β secondary structure, while in AuNP-CLPDFF-NH_2, the peptide is in a disordered structure. Note that in the first the degree of functionalization and exposition of D is higher than in the case of AuNP-CLPDFF-NH_2. The scale of the molecules is not in proportion with the nanoparticles.

Interaction of AuNP and AuNP−Peptide Conjugates with Aβ Fibrils. To determine the affinity of AuNP−peptide conjugates for Aβ fibrils, we incubated Aβ with AuNP and their conjugates, for 2 days to form immature fibrils and for 7 days

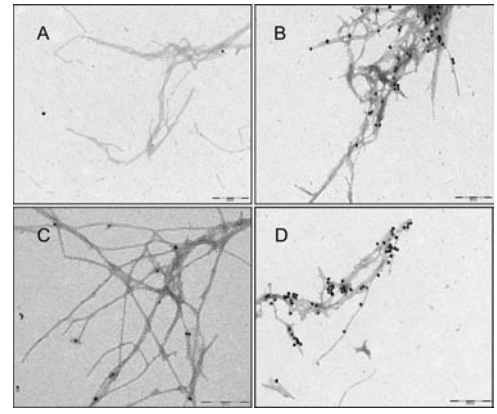

Figure 10. TEM micrograph of 7 day old amyloid fibrils stained with uranil acetate incubated with (A) AuNP, (B) AuNP-CLPFFD-NH_2, (C) AuNP-CDLPFF-NH_2, and (D) AuNP-CLPDFF-NH_2. Bars represent 200 nm.

to form mature fibrils. In both cases of samples, bare AuNP showed by TEM low degree of interaction with the fibril while the three AuNP−peptide conjugates showed a higher degree of interaction (Figure 10). This result could be explained by the presence of hydrophobic groups L, F, and F present in the peptides that which are able to recognize the hydrophobic nucleus in Aβ.

To quantitatively evaluate the affinity or adhesion of each conjugate to the Aβ fibril, we centrifuged the corresponding sample at 2300 *g* for 5 min; under such conditions, the unbound free AuNP remained suspended but the Aβ fibrils bound to AuNP did precipitate forming a pellet. The gold content both in the pellets and in the supernatants was determined by ICP-MS. Gold content ratios between that in the supernatant (unbound free AuNP) and that in the pellet (AuNP attached to the fibrils) are summarized in Table 2. The conjugate AuNP-CLPFFD-NH_2 adheres better to Aβ fibrils than the other conjugates. According to CD results, this peptide adopts a β secondary structure, which could favor the interaction of the residues L F F with Aβ fibrils. In addition, the presence of D groups at the C-terminal position produces the repulsion needed to maintain the peptide chain separation, avoiding self-aggregation between the peptide molecules conjugated to the AuNP. Thus, the adhesive interaction between the conjugate and the Aβ fibril becomes possible. Moreover, the stability of this conjugate in ACSF

Table 2. Proportion of Unbound Gold (AuNP in the supernatant) and Gold Bound to the Aβ fibrils (AuNP in the pellet)[a]

	ratio of gold (supernatant/pellet) (2 d)	ratio of gold (supernatant/pellet) (7 d)
AuNP + Fibrils	6.50 ± 0.05	0.21 ± 0.05
AuNP-CLPFFD +Fibrils	1.50 ± 0.01	0.03 ± 0.02
AuNP-CDLPFF + Fibrils	3.51 ± 0.03	0.11 ± 0.02
AuNP-CLPDFF + Fibrils	3.03 ± 0.03	0.12 ± 0.05

[a] The pellet was washed with 10 mM phosphate buffer pH 7.4 in 1.2 mM citrate and centrifuged (both supernatants were mixed). The pellets and the suppernatants were lyophilized. The gold content in the pellets and in the supernatants was determined by ICP-MS.

and serum is a very important factor in future biomedical applications.

Several conclusions can be drawn from this set of experiments. The peptide sequence influences the degree of conjugation, the stability, and the interaction of AuNP−peptide conjugates. In our opinion, there are two critical factors to be considered: the position of the negative charge and the capacity to adopt a secondary structure. The position of the negative charge could be related with the colloidal stability. In the case of AuNP-CLPFFD-NH_2, the D residues could be located in a more external position contributing to repulsion between particles increasing the colloidal stability. On the other hand, CLPFFD-NH_2 anchored to the AuNP adopts a β secondary structure increasing the ability to interact with Aβ. Following the hypothetical model proposed in Figure 9, the higher number of peptide molecules are accommodated on the surface producing steric hindrance which contribute to colloidal stability. In contrast in the isomer CLPDFF-NH_2, the peptide adopts a more disordered structure avoiding the accommodation of molecules, reducing the degree of functionalization, the stability, and the affinity for Aβ.

The results obtained here provide a first answer to the important concern of the way bioactive peptides could allocate once they are anchored to AuNP surface and the way conjugates could interact with the biological target. However, to determine the conformation of a peptide molecule on the AuNP surface, further experiments are now in progress in our laboratory. Due to the importance that AuNP have in therapy and diagnosis, it is very helpful to understand the parameters governing the stability and interaction with the therapeutic target.

Acute inflammatory diseases are a major cause of death in the world, and effective treatments are greatly needed. Macrophages play a central role in causing acute inflammatory diseases, and there is currently great interest in developing drug delivery vehicles that can target therapeutics to macrophages. Microparticles formulated from aliphatic polyketals have great potential to enhance the treatment of acute inflammatory diseases, due to their ability to passively target therapeutics to macrophages, their acid sensitivity, and their biocompatible degradation products. However, existing aliphatic polyketals are unsuitable for treating acute inflammatory diseases because they require weeks to hydrolyze, and strategies for accelerating their hydrolysis kinetics are greatly needed. In this report, we demonstrate that the hydrolysis kinetics of aliphatic polyketals can be accelerated by increasing their hydrophilic/hydrophobic balance. Aliphatic polyketals of varying hydrophobicity were synthesized, via the acetal exchange reaction, and their hydrolysis kinetics were investigated at the pH values of 4.5 and 7.4. A polyketal termed PK3 was developed, which had the hydrolysis kinetics suitable for treating acute inflammatory diseases. PK3 has a hydrolysis half-life of 2 days at pH 4.5, but requires several weeks to hydrolyze at pH 7.4. Microparticles were formulated with PK3, which encapsulated the anti-inflammatory drug, imatinib. *In vivo* experiments demonstrated that PK3 microparticles were able to significantly improve the efficacy of imatinib in treating acute liver failure. We anticipate that aliphatic polyketals will have numerous applications for the treatment of acute inflammatory diseases, given their pH sensitivity, tunable hydrolysis kinetics, and biocompatible degradation products.

INTRODUCTION

Acute inflammatory diseases such as acute lung injury and acute liver failure cause millions of deaths each year, and effective treatments are greatly needed (*1, 2*). Pro-inflammatory cytokines secreted by macrophages play a central role in mediating acute inflammatory diseases, and drug delivery vehicles that can target therapeutics to macrophages have great clinical potential (*3*). A key drug delivery requirement for the treatment of many acute inflammatory diseases is fast release of drugs to diseased organs, within several hours. This is because, at the time of patient diagnosis, significant tissue damage has already occurred, and organ function is rapidly deteriorating (*4*). It has been challenging to develop clinically acceptable drug delivery vehicles that can target therapeutics to macrophages and release them rapidly. Liposomes are a potential delivery vehicle for treating acute inflammatory diseases, due to their ability to target macrophages (*5*). However, their serum instability and poor storage properties have slowed their progress in clinical trials. Microparticles, based on biodegradable polymers, also have potential to enhance the treatment of acute inflammatory diseases. Microparticles can be freeze-dried, have an excellent shelf life, and can also passively target therapeutics to macrophages (*6, 7*). However, currently used biomaterials for drug delivery are predominantly based on polyesters, which are potentially problematic for treating acute inflammatory diseases because of their slow hydrolysis kinetics and acidic degradation products, which themselves frequently cause inflammation (*8, 9*).

Microparticles formulated from polyketals are a new drug delivery vehicle, which degrade into neutral compounds comprising acetone and diols, and should therefore avoid the inflammatory problems associated with polyester-based materials (*9–13*). At present, only two polyketals have been synthesized for drug delivery, poly(1,4-phenyleneacetone dimethylene ketal) (PPADK) and poly(cyclohexane-1,4-diyl acetone dimethylene ketal) (PCADK) (*12, 13*). PPADK has excellent hydrolysis kinetics for treating acute inflammatory diseases, having a half-life of 35 h at pH 5.0, but degrades into benzene dimethanol, a compound with potential toxicity, due to its aromatic ring. PCADK is an aliphatic polyketal, which degrades into acetone and 1,4-cyclohexanedimethanol, both of which have excellent biocompatibility. However, PCADK has a hydrolysis half-life of 24 days at pH 4.5, which is too slow for applications involving the treatment of acute inflammatory diseases, and therefore strategies that can accelerate its hydrolysis kinetics are greatly needed.

In this report, we demonstrate that the hydrolysis kinetics of PCADK derived aliphatic polyketals can be accelerated by increasing their hydrophilic/hydrophobic balance. Using this principle, we were able to generate a polyketal copolymer, termed PK3, which had a hydrolysis half-life of 2 days at pH 4.5 but several weeks at pH 7.4. Microparticles formulated from PK3 should be suitable for treating acute inflammatory diseases because they should hydrolyze and release therapeutics rapidly in the phagolysosomes of macrophages, but remain stable at

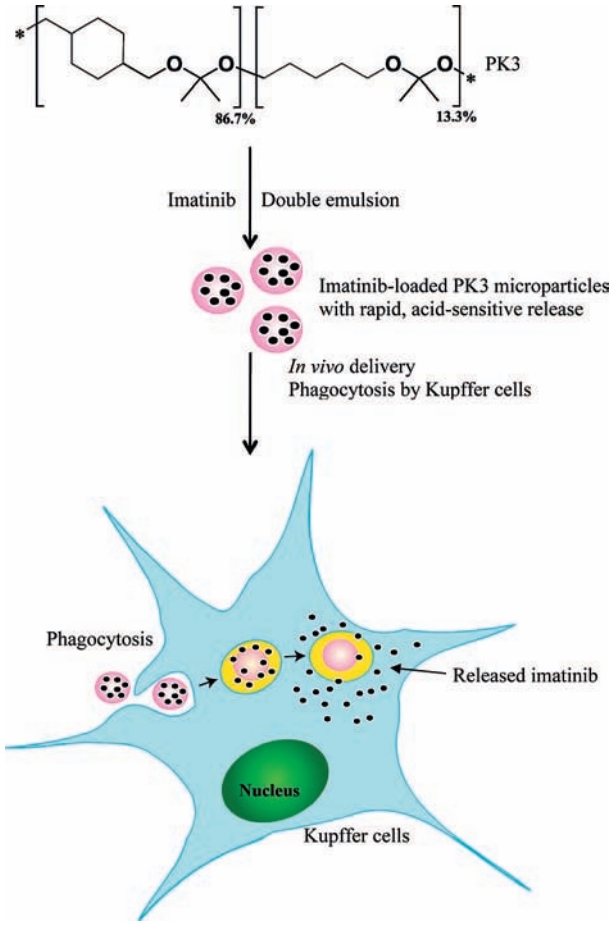
Scheme 1. PK3, a New Biomaterial for Treating Acute Inflammatory Diseases[a]



[a] PK3 is a new polyketal copolymer, which hydrolyzes rapidly at the acidic pH of the macrophage phagosome. PK3 is designed to deliver therapeutics to liver macrophages and enhance the treatment of acute liver failure. PK3 microparticles were capable of enhancing the delivery of imatinib in mice suffering from acute liver failure.

physiological pH. PK3 was used to generate microparticles 1−3 μm in size, which encapsulated the NF_KB inhibitor imatinib, using a solvent evaporation procedure. The therapeutic efficacy of these PK3-imatinib microparticles was investigated in mice, using a Concavalin A (Con A) model of acute liver failure (Scheme 1). The results from these experiments demonstrate that imatinib-loaded PK3 microparticles significantly enhanced the therapeutic efficacy of imatinib, presumably due to their accumulation in liver macrophages (Kupffer cells). Based on these results, we anticipate that aliphatic copolyketals will have numerous applications for the treatment of acute inflammatory diseases.

EXPERIMENTAL SECTION

Materials. All chemicals were purchased from Sigma-Aldrich (St. Louis, MO) and were used as received unless otherwise specified. Benzene and 2,2-dimethoxypropane were purified by distillation. Imatinib was a gift from Novartis.

Animals. Male C57/BL6 mice were purchased from Jackson Laboratory (Bar Harbor, ME). All animal experiments were approved by the Institutional Animal Care and Use Committee (IACUC) of the University of Rochester Medical Center.

Synthesis of Polyketal Copolymers. Polyketal copolymers were synthesized in a 25 mL two-necked flask, connected to a short-path distilling head. The diols, 1,4-cyclohexanedimethanol (1.04 g, 7.25 mmol) and 1,4-butanediol, 1,5-pentanediol, 1,6-hexanediol, or 1,8-octanediol, were dissolved in 20 mL of distilled benzene and kept at 100 °C. Recrystallized *p*-toluenesulfonic acid (5.5 mg, 0.029 mmol) was dissolved in ethyl acetate (500 μL) and added to the benzene solution. The ethyl acetate was distilled off, and the polymerization reaction was initiated by the addition of 2,2-dimethoxypropane (equimolar to the two diols combined). Additional doses of 2,2-dimethoxypropane (500 μL) and benzene (2 mL) were subsequently added to the reaction, every hour for six hours, via a metering funnel, to compensate for 2,2-dimethoxypropane and benzene that had distilled off. After 24 h, the reaction was stopped with triethylamine (100 μL). The copolymers were isolated by precipitation into cold hexanes and analyzed by ^{1}H NMR and GPC. In general, the resulting polymers had number average molecular weights between 2000 to 3000 Da. Table 1 lists the compositions and molecular weights of the polyketal copolymers synthesized. ^{1}H NMR spectra were obtained from a Varian Mercury VX 400 MHz NMR spectrometer (Palo Alto, CA) using $CDCl_3$ as the solvent. PK1 ^{1}H NMR (400 MHz, $CDCl_3$, δ): 3.4−3.18 (m, 4H, CH_2), 1.66 (s, 1.9H, CH), 1.85−0.93 (m, 8H, CH_2), and 1.32 (s, 6H, CH_3). PK2 ^{1}H NMR (400 MHz, $CDCl_3$, δ): 3.4−3.18 (m, 4H, CH_2), 1.66 (s, 1.8H, CH), 1.85−0.93 (m. 8H, CH_2), and 1.32 (s, 6H, CH_3). PK3 ^{1}H NMR (400 MHz, $CDCl_3$, δ): 3.4−3.18 (m, 4H, CH_2), 1.64 (s, 1.7H, CH), 1.85−0.93 (m, 8.2H, CH_2), and 1.32 (s, 6H, CH_3). PK4 ^{1}H NMR (400 MHz, $CDCl_3$, δ): 3.4−3.18 (m, 4H, CH_2), 1.68 (s, 2H, CH), 1.85−0.93 (m, 8H, CH_2), and 1.32 (s, 6H, CH_3). PK5 ^{1}H NMR (400 MHz, $CDCl_3$, δ): 3.4−3.18 (m, 4H, CH_2), 1.67 (s, 1.8H, CH), 1.85−0.93 (m, 8H, CH_2), and 1.32 (s, 6H, CH_3). PK6 ^{1}H NMR (400 MHz, $CDCl_3$, δ): 3.4−3.18 (m, 4H, CH_2), 1.68 (s, 1.8H, CH), 1.85−0.93 (m, 8H, CH_2), and 1.32 (s, 6H, CH_3).

Gel Permeation Chromatography. The molecular weights of the polyketal copolymers were determined by gel permeation chromatography (GPC) using a Shimadzu system (Kyoto, Japan) equipped with a UV detector. Tetrahydrofuran was used as the mobile phase at a flow rate of 1 mL/min. Polystyrene standards (peak M_w = 1060, 2970, and 10680) from Polymer Laboratories (Amherst, MA) were used to establish a molecular weight calibration curve.

Hydrolysis of Polyketal Copolymers. The hydrolysis of the polyketal copolymers was measured according to the procedures of Lee et al. (*13*). Briefly, polymer samples (20 mg) were placed in buffered water (1 mL) at the pH values of 4.5 (100 mM AcOH) and 7.4 (100 mM Na_2HPO_4) at 37 °C. The polymer samples were mixed by gentle shaking and, at specific time points, were extracted into $CDCl_3$ (1 mL). The $CDCl_3$ phase was isolated and analyzed by ^{1}H NMR, to determine the percent hydrolysis.

Release Kinetics of Rhodamine B from PK3 Microparticles. Rhodamine B was encapsulated in PK3 microparticles using single emulsion procedures. Rhodamine B-loaded PK3 microparticles (10 mg) were suspended in pH 4.5 and pH 7.4 buffer solutions (10 mL). The suspensions were kept at 37 °C under gentle shaking. At specific time points, the suspensions (100 μL) were centrifuged at 10 000*g* for 2 min to remove unhydrolyzed particles. The supernatant (3 μL) was then diluted in pH 7.4 buffer (3 mL), which was then analyzed by a Shimadzu spectrofluorophotometer (Kyoto, Japan) to quantify the relative concentration of rhodamine B released form the PK3 microparticles (excitation wavelength = 556 nm, emission wavelength = 573 nm).

Formulation of Imatinib-Loaded PK3 Microparticles. Imatinib-loaded microparticles were formulated from PK3 using a modified water/oil/water emulsion method. Briefly, PK3 (100 mg) was dissolved in dichloromethane (1 mL), and in a separate vial imatinib (40 mg) was dissolved in deionized water (400

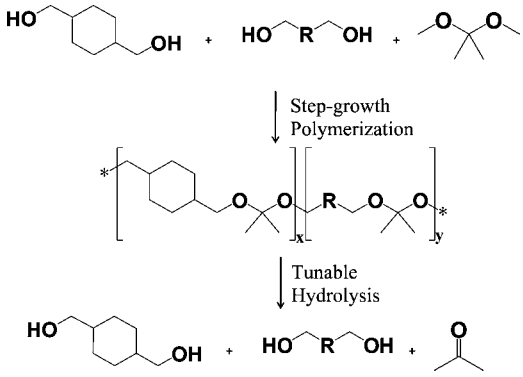

Figure 1. Synthesis of polyketal copolymers from 1,4-cyclohexanedimethanol, a second diol, and 2,2-dimethoxypropane. Hydrolysis kinetics of polyketals can be controlled by manipulating the hydrophilicity of the polyketals through copolymerizing 1,4-cyclohexandimethanol with a more hydrophilic diol.

μL). The aqueous solution of imatinib was mixed with the PK3 solution, and sonicated for 60 s (Misonix Incorporated, Farmigdale, NY). The sonicated mixture was then immersed in liquid nitrogen for 15 s, and a 5% w/w PVA solution (pH 7.45, 12 mL) was added to it. This mixture was homogenized for 120 s with a Powergen 500 homogenizer (Fisher Scientific, Waltham, MA), and then transferred to a beaker containing 1% w/w PVA (pH 7.4, 40 mL). This solution was stirred for 3 h with a magnetic stir bar to evaporate the organic solvent. The particles were isolated by centrifuging at 10 000*g* for 15 min, washed twice with PBS buffer (15 mL), and freeze-dried.

Scanning Electron Microscopy (SEM). SEM images were taken to analyze the morphology of the polyketal microparticles. Briefly, SEM samples were prepared by attaching lyophilized particles onto 12.7 mm diameter aluminum sample mounting stubs (Electron Microscopy Sciences, Hatifield, PA), using conductive double-sided carbon discs (SPI Supplies, West Chester, PA). The samples were coated with a gold sputter coater (International Scientific Instruments, Prahran, Australia) for 2 min under an argon atmosphere. The SEM samples were subsequently analyzed using a Hitachi S-800 scanning electron microscope (Tokyo, Japan).

Determination of Imatinib Loading in PK3 Microparticles. The loading of imatinib in PK3 microparticles was determined by UV spectrometry. A UV calibration curve for imatinib was established at 268 nm, with a Shimadzu UV-1700 spectrometer (Kyoto, Japan) in pH 7.4 buffer. Imatinib-loaded PK3 particles were dissolved in a small amount of methylene chloride, and the imatinib was extracted into pH 7.4 buffer (100 mM Na_2HPO_4). The absorbance of both the aqueous and organic phases was measured to verify that all the imatinib was partitioned into the aqueous phase. The concentration of imatinib loaded into the PK3 microparticles was determined against the established calibration curve as mentioned above.

Treatment of Acute Liver Failure in Mice with Imatinib-Loaded PK3 Microparticles. Male C57/BL6 mice, 6−8 weeks old, were used in these studies. Appropriate doses of imatinib-PK3 particles (containing between 5 μg/kg to 500 μg/kg of imatinib), or an equal quantity of free imatinib, was suspended/dissolved in PBS (200 μL) and was injected intravenously using a 26 G5/8 sterilized needle. One hour later, Con A (15 mg/kg), dissolved in PBS (200 μL), was injected into the intraperitoneal cavity using a 26 G5/8 sterilized needle. Between 4 and 8 mice were used per experimental group. The mice were euthanized 8 h after the Con A injection, by cervical dislocation. Blood was then withdrawn from the heart using a 26 G5/8 sterilized needle, and kept at 4 °C overnight. The serum was isolated by centrifuging at 600*g* for 10 min and sent to the core facility at the University of Rochester for measurement of ALT levels.

RESULTS AND DISCUSSION

There is currently great interest in developing microparticle-based delivery vehicles that have the biocompatibility and hydrolysis kinetics needed to treat acute inflammatory diseases. Microparticles formulated from the aliphatic polyketal PCADK have excellent biocompatibility and degrade under the acidic conditions of the phagolysosome. However, the slow hydrolysis kinetics of PCADK make it unsuitable for treating acute inflammatory diseases, and therefore strategies for accelerating its hydrolysis kinetics are greatly needed. We previously hypothesized that the slow hydrolysis kinetics of PCADK was due to its hydrophobicity, making the diffusion of water into the polymer matrix the rate-limiting step in ketal hydrolysis (*13*). This hypothesis was based on the fact that the hydrolysis half-

Data are presented as mean ± standard deviation. All experiments were conducted in triplicate at 37 °C.

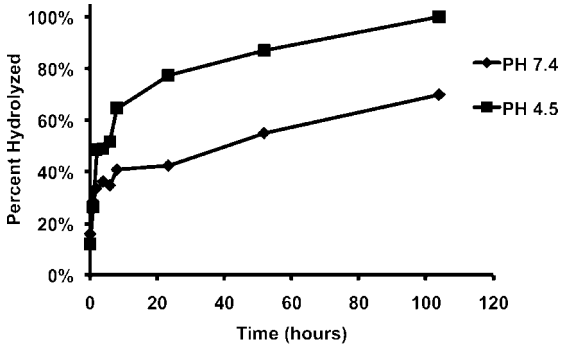

Figure 3. Release kinetics of rhodamine B encapsulated in PK3 microparticles.

life of a water-soluble dimethylacetone-based ketal is only 2 min at pH 5.0, which is 3 to 4 orders of magnitude faster than the hydrolysis of the ketal linkages in PCADK (*14*). Additionally, the hydrolysis kinetics of other water-insoluble polymers, such as polyanhydrides, also scale with their hydrophobicity (*10*). In this report, the role of hydrophobicity in governing the hydrolysis kinetics of polyketals was investigated. This was accomplished by synthesizing polyketal copolymers of varying hydrophobicity and measuring their hydrolysis kinetics.

Six polyketal copolymers were synthesized in this report (PK1−PK6, Table 1), by copolymerizing 1,4-cyclohexanedimethanol with 1,4-butanediol, 1,5-pentanediol, 1,6-hexanediol, or 1,8-octanediol. The hydrophobicity of these diols is different from that of 1,4-cyclohexanedimethanol (log $P = 1.46$, where $P =$ water/octanol partition coefficient), as evidenced by their respective log P values (Table 2). The synthesis of all the polyketal copolymers reported in this study was accomplished using the acetal exchange reaction, and was performed on a multigram scale with yields of 50−60% (Figure 1). In general, the introduction of additional diols other than 1,4-cyclohexanedimethanol did not cause any synthetic complications, and procedures developed for the synthesis of PCADK were suitable for the synthesis of all the copolymers. Importantly, all the polyketal copolymers reported in Table 1 were solid, and therefore have the potential for formulation into microparticles.

The hydrolysis kinetics of PK1 to PK6 were measured at the pH values of 4.5 and 7.4 to determine their behavior in the acidic environment of phagolysosomes and in the blood. Figure 2 demonstrates that all the polyketal copolymers (PK1−PK6) undergo acid-catalyzed hydrolysis, and that their hydrolysis kinetics scale with their hydrophilicity. PK1, PK2, and PK3 are copolymers synthesized from 1,4-cyclohexanedimethanol and 1,5-pentanediol. Their hydrophilicity scales with the amount of 1,5-pentanediol incorporated into the copolymer. This is due to the large difference in hydrophilicity between 1,5-pentanediol and 1,4-cyclohexanedimethanol, as evidenced by their respective log P values of 0.27 and 1.46. Figure 2A demonstrates that 1,5-pentanediol significantly accelerates the pH 4.5 hydrolysis kinetics of 1,4-cyclohexanedimethanol-based polyketals. For example, the hydrolysis half-life of PCADK, a homopolyketal synthesized from 1,4-cyclohexanedimethanol, is 24 days at pH 4.5 (*13*). On the other hand, PK3, a copolymer that incorporates 13 mol % 1,5-pentanediol and 87 mol % 1,4-cyclohexanedimethanol, had a hydrolysis half-life of only 2 days at pH 4.5. Similarly, PK2, another PCADK-derived copolymer, incorporating 7.5 mol % of 1,5-pentanediol, had a hydrolysis half-life of 3 days at pH 4.5, which is faster than PCADK but slower than PK3. PK1, the third copolymer derived from PCADK, incorporating 2 mol % 1,5-pentanediol, was only 30% hydrolyzed after 10 days at pH 4.5, which was expected based on its low incorporation of 1,5-pentanediol[1].

To determine if diols other than 1,5-pentanediol could similarly influence the hydrolysis kinetics of PCADK-derived copolymers, the hydrolysis kinetics of PK4, PK5, and PK6 were also investigated. These polyketals are PCADK-derived copolymers synthesized from 1,4-cyclohexanedimethanol and either 1,4-butanediol, 1,6-hexanediol, or 1,8-octanediol. Figure 2B,D and Table 2 demonstrate that this set of copolymers also has an inverse relationship between hydrophobicity and hydrolysis kinetics. For example, PK4, a copolymer synthesized from 1,4-cyclohexanedimethanol and 1,4-butanediol, has the

[1] Similar copolymers with higher incorporation of 1,5-pentanediol were also generated; however, those copolymers were viscous liquids, which are not suitable for formulation into microparticles for drug delivery. Therefore, we only focused our hydrolysis analysis on the solid polyketal copolymers, PK1, PK2, and PK3.

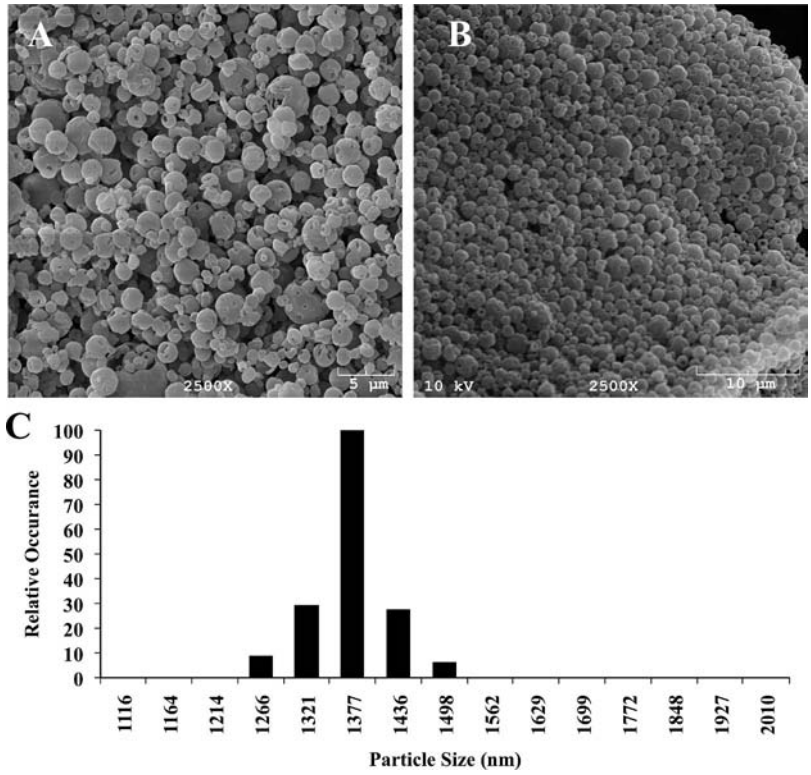

Figure 4. SEM images of particles formulated with PK3. (A) SEM image of empty particles formulated via double emulsion. (B) SEM images of imatinib-loaded PK3 microparticles formulated via double emulsion. (C) Size distribution of imatinib-loaded PK3 microparticles as determined by dynamic light scattering (DLS).

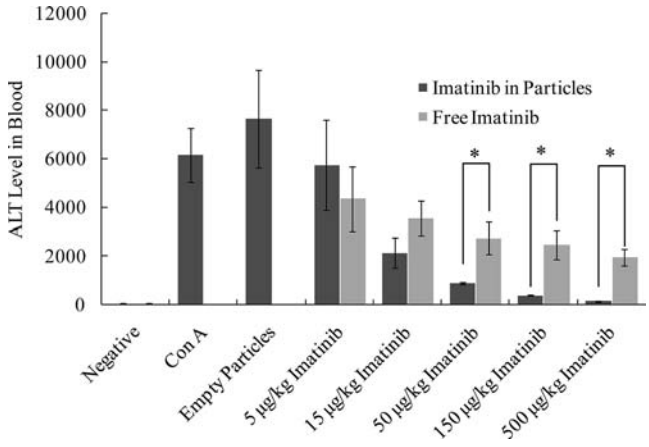

Figure 5. PK3 microparticles improve the efficacy of imatinib in treating acute liver failure in mice. Mice were injected intravenously with either imatinib or imatinib in PK3 microparticles, acute liver failure was then induced by intraperitoneal injection of Con A (15 mg/kg). Eight hours later, ALT levels in the blood were analyzed. * indicates statistical significance (Student's t test, $P > 0.05$, $n = 4$ to 8).

fastest hydrolysis kinetics of all the copolyketals, with a hydrolysis half-life of 1 day at pH 4.5. This is predicted based on the more hydrophilic nature of 1,4-butanediol in comparison to the other diols. On the other hand, PK6, a copolymer composed of 1,4-cyclohexanedimethanol and 1,8-octanediol, had a pH 4.5 hydrolysis half-life of 18.6 days. In summary, these data demonstrate that the hydrolysis kinetics of polyketals can be tuned by varying their hydrophilicity and further support the hypothesis that diffusion of water into the polyketals is the rate-determining step governing their hydrolysis. Importantly, the hydrolysis kinetics of all the polyketal copolymers, PK 1−6, were pH-sensitive; in general, they hydrolyzed at least 1 order of magnitude faster at pH 4.5 than at pH 7.4.

We chose PK3 for further investigation as a drug carrier for the treatment of acute inflammatory diseases because of its suitable hydrolysis kinetics and biocompatible degradation products. The copolymer PK4 has faster hydrolysis kinetics than PK3; however, it degrades into 1,4-butanediol, which is converted into γ-hydroxybutyrate *in vivo*, and subsequently causes toxicity to the central nervous system (*15*). Microparticles were formulated from PK3, using a solvent evaporation procedure. Figure 4A demonstrates that the size range of PK3 microparticles is between 1 and 5 μm, which is suitable for phagocytosis by macrophages.

In order to determine whether or not PK3 microparticles would have suitable drug-release kinetics for treating acute inflammatory diseases, a release study was conducted on PK3 microparticles which encapsulated the fluorescent dye, rhodamine B. Figure 3 demonstrates that the release half-life of rhodamine B from PK3 microparticles is approximately 6 h at pH 4.5 and 40 h at pH 7.4, which is suitable for treating acute liver failure. The drug-release kinetics of PK3 microparticles is 20 times faster than that of PCADK microparticles, which had a release half-life of 5 days at pH 4.5 and over 15 days at pH 7.4 (data not shown).

PK3 microparticles were used to enhance the delivery of imatinib in treating acute liver failure. Imatinib is a kinase inhibitor that inhibits NF-κB activation and has great potential for treating acute inflammatory diseases (*16, 17*). The activation of NF-κB in macrophages leads to the production of cytokines and reactive oxygen species, the central causes of tissue damage during acute inflammatory diseases. Although imatinib has shown promise for treating acute inflammatory diseases in mouse models, there are also numerous side effects associated with imatinib, including heart failure and hepatic toxicity (*18, 19*). PK3 microparticles should enhance the efficacy of imatinib by targeting it to macrophages, thereby increasing its concentration at the target site, and also by reducing the toxic side effects of

imatinib on the heart and liver. Imatinib was encapsulated into PK3 microparticles through double emulsion procedures. These macroparticles were approximately 1.5 μm in size on average, as determined by SEM and DLS, which is suitable for delivering drugs to phagocytic cells such as Kupffer cells (Figure 4B,C). The loading of imatinib in PK3 microparticles was determined to be 0.90 $\pm$ 0.10 μg imatinib per 1 mg of particles ($n = 3$), suggesting that the encapsulation efficiency of imatinib in PK3 microparticles was approximately 0.32%.

The ability of PK3 microparticles to enhance the delivery of imatinib was investigated in mice suffering from Con A-induced acute liver failure. Mice were injected with either imatinib in solution (0.1 μg to 10 μg of imatinib dissolved in 200 μL of saline) or an equivalent amount of imatinib loaded in PK3 microparticles (0.11 mg to 11 mg of imatinib-loaded PK3 microparticles suspended in 200 μL of saline). Acute liver failure was subsequently induced by an intraperitoneal injection of Con A. The severity of liver injury in these mice was determined by measuring the alanine aminotransaminase (ALT) level in their blood, which is a clinical surrogate marker for hepatocyte injury. Figure 5 demonstrates that PK3 microparticles enhanced the treatment efficacy of imatinib in preventing Con A-induced liver damage. For example, a dose of 500 μg/kg of free imatinib resulted in an ALT value of approximately 2000 U, whereas 500 μg/kg of imatinib encapsulated in PK3 microparticles reduced the ALT values to baseline levels of only 50 U. The therapeutic efficacy of 15 μg/kg of imatinib loaded in PK3 microparticles was similar to that of 500 μg/kg of free imatinib. These experiments demonstrate that imatinib-loaded PK3 microparticles significantly enhanced the therapeutic efficacy of imatinib, presumably due to their accumulation in liver macrophages. No noticeable toxicity was observed by injection of empty PK3 microparticles (11 mg suspended in 200 μL of saline), as shown in Figure 5.

CONCLUSIONS

In this report, we demonstrate that the hydrolysis rates of polyketals can be tuned by varying their hydrophilicity. Using this strategy, an aliphatic polyketal copolymer, PK3, was identified, which had a hydrolysis half-life of 2 days at pH 4.5, but was stable for several weeks at pH 7.4. Microparticles were formulated from PK3, which encapsulated the kinase inhibitor, imatinib, and these PK3 microparticles significantly improved the efficacy of imatinib in treating Con A-induced liver damage *in vivo*. Based on these findings, we anticipate numerous applications of copolymers of polyketals for treating acute inflammatory diseases, given their pH sensitivity, rapid and tunable hydrolysis kinetics, and biocompatible degradation products.

Received December 18, 2007; Revised Manuscript Received April 5, 2008

In this report, we present the synthesis and evaluation of the ^{99m}Tc-labeled β-Ala-BN(7−14)NH_2 (ABN = β-Ala-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH_2) as a new radiotracer for tumor imaging in the BALB/c nude mice bearing HT-29 human colon cancer xenografts. The gastrin releasing peptide receptor binding affinity of ABN and HYNIC-ABN (6-hydrazinonicotinamide) was assessed via a competitive displacement of ^{125}I-[Tyr4]BBN bound to the PC-3 human prostate carcinoma cells. The IC_{50} values were calculated to be 24 ± 2 nM and 38 ± 1 nM for ABN and HYNIC-ABN, respectively. HYNIC is the bifunctional coupling agent for ^{99m}Tc-labeling, while tricine and TPPTS (trisodium triphenylphosphine-3,3′,3″-trisulfonate) are used as coligands to prepare the ternary ligand complex [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] in very high yield and high specific activity. Because of its high hydrophilicity (log $P = -2.39 \pm 0.06$), [^{99m}Tc(HYNIC-ABN)(tricine)(TPPS)] was excreted mainly through the renal route with little radioactivity accumulation in the liver, lungs, stomach, and gastrointestinal tract. The tumor uptake at 30 min postinjection (p.i.) was 1.59 ± 0.23%ID/g with a steady tumor washout over the 4 h study period. As a result, it had the best *T*/*B* ratios in the blood (2.37 ± 0.68), liver (1.69 ± 0.41), and muscle (11.17 ± 3.32) at 1 h p.i. Most of the injected radioactivity was found in the urine sample at 1 h p.i., and there was no intact [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] detectable in the urine, kidney, and liver samples. Its metabolic instability may contribute to its rapid clearance from the liver, lungs, and stomach. Despite the steady radioactivity washout, the tumors could be clearly visualized in planar images of the BALB/c nude mice bearing the HT-29 human colon xenografts at 1 and 4 h p.i. The favorable excretion kinetics from the liver, lungs, stomach, and gastrointestinal tract makes [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] a promising SPECT radiotracer for imaging colon cancer.

INTRODUCTION

Colon cancer is the second leading cause of cancer-related deaths. It is estimated that about 130 000 men and women will develop colon cancer and more than 50 000 will die from it each year in the United States (American Cancer Society: http://www.cancer.org). The lifetime risk for individuals to develop colon cancer is ∼6%, but it may increase to 18% among individuals who have a relative (parent, sibling, or child) with colon cancer. Therefore, accurate early detection is highly desirable so that various therapeutic regimens can be given before the primary tumors become widespread.

Bombesin (BN) is a small peptide containing 14 amino acids (Glu-Gln-Arg-Leu-Gly-Asn-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH_2). It was originally isolated from the skin of amphibian *Bombina orientalis* (*1*, *2*). The BN-like peptides have very high binding affinity for the gastrin-releasing peptide (GRP) receptor (*3*–*5*), and produce a wide range of biological responses in peripheral tissues as well as in the central nervous system, including stimulation of gastrointestinal hormone release, exocrine secretion, and maintenance of circadian rhythms. In addition, it has been established that the GRP/BN peptides promote proliferation in cancer cells. The overexpression of GRP receptor (GRPR) has been demonstrated in a large number of tumors, including prostate, breast, colon, and small cell lung cancer (*6*–*13*). The distribution of BN-like peptides and the expression of their receptors have been reviewed (*3*, *4*). Because of its highly restricted overexpression on tumor cells, the GRPR is emerging as an attractive target for both cancer therapy and early detection (*3*, *4*, *14*–*17*).

BN(7−14)NH_2 is the peptide sequence responsible for specific binding of the GRPRs overexpressed on tumor cells. Most of the radiolabeled BN-like peptides are based on or contain the BN(7−14)NH_2 peptide sequence. These radiolabeled BN-like peptides were designed as tumor-specific radiotracers for early diagnosis or systemic radiotherapy of the GRPR-positive tumors, and have been reviewed extensively (*14*–*17*). The radionuclides include ^{111}In (*18*–*20*), ^{177}Lu (*21*–*23*), ^{68}Ga (*24*), ^{64}Cu (*25*–*32*), ^{188}Re (*33*), and ^{99m}Tc (*34*–*47*). While ^{68}Ga and ^{64}Cu are particularly useful for imaging tumors by positron emission tomography (PET), ^{99m}Tc is the radionuclide of choice for tumor imaging by single photon computed tomography (SPECT) due to its excellent nuclear properties ($t_{1/2}$ = 6 h and single photon emission at 140 keV), rich and diverse coordination chemistry, easy availability at low cost, and high specific activity (*48*–*50*).

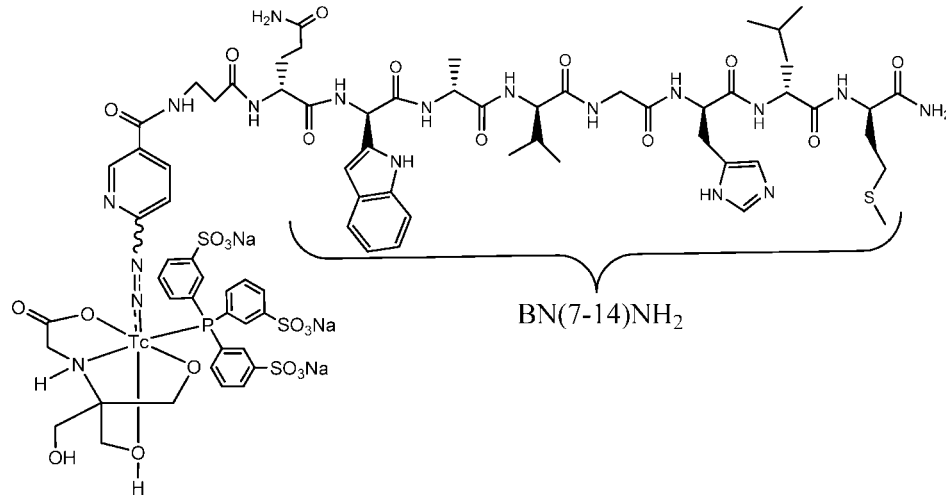

Figure 1. Structure of the ternary ligand complex [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)].

In this study, we used β-Ala-BN(7−14)NH_2 (Figure 1: ABN in short) as the biomolecule for tumor targeting and 6-hydrazinonicotinic acid (HYNIC) as the bifunctional coupling agent (BFC) for the ^{99m}Tc-labeling. Since HYNIC is monodentate in the ^{99m}Tc-HYNIC core, tricine and TPPTS (trisodium triphenylphosphine-3,3′,3″-trisulfonate) are used as coligands to prepare the complex [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] (Figure 1). This ternary ligand system (HYNIC, tricine, and TPPTS) has been successfully used for the ^{99m}Tc-labeling of small biomolecules, including chemotactic peptides (*51*) and LTB_4 receptor antagonists (*52, 53*) for imaging infection and inflammation, integrin $\alpha_v\beta_3$ antagonists for imaging tumor angiogenesis (*54–58*), and GPIIb/IIIa receptor antagonists for imaging deep vein thrombosis (*59*). The BALB/c nude mice bearing HT-29 human colon cancer xenografts were used for both biodistribution and imaging studies. Normal BALB/c nude mice were used for metabolism study. The main objective is to evaluate [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] as a potential new radiotracer for SPECT imaging of colon cancer.

EXPERIMENTAL SECTION

Materials. Tricine and TPPTS were purchased from Sigma/Aldrich (St. Louis, MO), and were used without further purification. The peptide conjugate, HYNIC-β-Ala-BN(7−14)NH_2 (HYNIC-ABN), was obtained from CS Bio Co. (Menlo Park, CA). Na$^{99m}TcO_4$ was obtained from a commercial ^{99}Mo/^{99m}Tc generator **(**Beijing Atom High Tech Co. Ltd., Beijing, China). ^{125}I-[Tyr4]BBN was obtained from Perkin-Elmer Life and Analytical Sciences (North Billarica, MA).

Methods. The radio-HPLC method used a HP Hewlett Packard Series 1100 HPLC system equipped with a Radioflow Detector LB509 and a reversed-phase Zorbax SB-C18 column (4.6 mm × 250 mm, 5 μm). The flow rate was 1.0 mL/min. The mobile phase was isocratic with 90% solvent A (0.01 M phosphate buffer, pH = 6.0) and 10% solvent B (acetonitrile) at 0−5 min, followed by a gradient mobile phase going from 10% solvent B at 5 min to 50% solvent B at 20 min, then to 80% solvent B at 22 min, and back to baseline 10% solvent B at 25 min. The ITLC method used Gelman Sciences silica-gel paper strips and a 1:1 mixture of acetone and saline as eluant. The ^{99m}Tc complexes migrated to the solvent front while $^{99m}TcO_4^-$ and [^{99m}Tc]colloid remained at origin.

Synthesis of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)]. To a clean 5 cc vial were added 100 μL of the HYNIC-ABN solution (100 μg/mL in H_2O), 100 μL of tricine solution (100 mg/mL in 25 mM succinate buffer, pH 5.0), 20 μL of $SnCl_2$ solution (3.0 mg/mL in 0.1 N HCl), and 100 μL of Na$^{99m}TcO_4$ (370 MBq) in saline. The reaction mixture was kept at room temperature for 10 min. To the reaction mixture above was added 120 μL of the TPPTS solution (50 mg/mL in 25 mM succinate buffer, pH 5.0). The vial containing the reaction mixture was sealed, cramped, and heated at 100 °C for 30 min. After cooling to room temperature, a sample of the resulting solution was analyzed by ITLC and radio-HPLC.

Dose Preparation for Animal Studies. [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] was purified using a Sep-Pak C-18 cartridge (Waters, MA) before being used for animal studies. The Sep-Pak C-18 cartridge was activated with ethanol (10 mL) and was washed with water (10 mL). After the radiotracer was loaded, the Sep-Pak C-18 cartridge was washed with saline (10 mL) to remove the unlabeled ^{99m}Tc and excess coligands. The radiotracer was eluted with 80% ethanol (0.4 mL). Doses for animal studies were prepared by dissolving the Sep-Pak purified radiotracer in saline to give a concentration of 150 μCi/mL for biodistribution study, 4.0 mCi/mL for the metabolism study, and 2.0 mCi/mL for the planar imaging study.

Partition Coefficient. The partition coefficient was determined using the following procedure: [^{99m}Tc(HYNIC-ABN)-(tricine)(TPPTS)] was prepared and purified using the Sep-Pak C-18 cartridge. Volatiles in the mobile phase were completely removed under vacuum. The residue was dissolved in a mixture of equal volume (0.5 mL/0.5 mL) *n*-octanol and 25 mM phosphate buffer (pH = 7.4). After vortexing for 2 min, samples in triplicate were obtained from *n*-octanol and aqueous layers and were counted in a γ-counter (Wallac 1470−002, Perkin-Elmer, Finland). The log *P* value is reported as an average of three different measurements.

***In Vitro* Cell-Binding Assay.** *In vitro* GRPR binding affinity and specificity of ABN and HYNIC-ABN were assessed via a competitive displacement assay with ^{125}I-[Tyr4]BBN as the radioligand. Experiments were performed using the GRPR-positive PC-3 prostate carcinoma cells according to the literature method (*32*). The 50% inhibitory concentration (IC_{50}) values were calculated by fitting the data with nonlinear regression using *GraphPad Prism 4.0* (GraphPad Software, San Diego, CA). Experiments were performed twice with triplicate samples. IC_{50} values are reported as an average of these samples plus the standard deviation.

Internalization Kinetics. The internalization assay was performed according to the literature method (*37, 47*) with slight modification. Briefly, the HT-29 cells were incubated in the 24-well plates in quadruplicate with [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] (∼0.1 μCi/well) for 2 h at 4 °C, and then were washed with ice-cold PBS to remove the unbound radioactivity.

After washing, the cells were incubated in the prewarmed culture medium at 37 °C for 0, 5, 15, 30, 60, and 120 min for internalization. The cell-surface bound radiotracer was removed by acid wash (50 mM glycine−HCl/100 mM NaCl, pH 2.8). Subsequently, the cells were solubilized by incubation with 2 M NaOH at 37 °C, and the resulting solution in each well was harvested to determine the internalized radioactivity in a γ-counter (Wallac 1470−002, Perkin-Elmer, Finland). The results were expressed as a percentage of the total radioactivity (surface-bound plus internalized). The same experiment was performed twice with quadruplicate samples.

Efflux Kinetics. The HT-29 cells cultured in 24-well plates were incubated at 37 °C with [^{99m}Tc(HYNIC-ABN)(tricine)-(TPPTS)] (~0.1 μCi/well) for 1 h to allow maximal internalization. The cells were washed three times with ice-cold PBS to remove the unbound radioactivity, then were incubated in the prewarmed culture medium at 37 °C for a specific period of time (0, 15, 30, 60, 120, and 240 min). At the specified time point, the cell-surface bound radioactivity was removed by acid wash (50 mM glycine−HCl/100 mM NaCl, pH 2.8). Subsequently, the cells were solubilized by incubation with 2 M NaOH at 37 °C, and the resulting solution in each well was harvested to determine the internalized radioactivity in a γ-counter (Wallac 1470−002, Perkin-Elmer, Finland). Data are expressed as the percentage of maximal intracellular radioactivity. The same experiment was performed twice with quadruplicate samples.

Animal Model. All animal experiments were performed in accordance with guidelines of Peking University Health Science Center Animal Care and Use Committee. The HT-29 human colon cancer cells were obtained from Professor Xiaoyan Qiu, Peking University Health Science Center, and were maintained at 37 °C and 5% CO_2 in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal bovine serum (FBS). Female BALB/c nude mice (4−5 weeks of age) were purchased from the Department of Experimental Animal, Peking University Health Science Center. The HT-29 cells (5×10^6) were implanted subcutaneously into the right upper flanks of nude mice. When tumors reached ~0.8 cm in mean diameter, the tumor-bearing mice were used for biodistribution and imaging studies. Sixteen tumor-bearing mice were randomly divided into four groups, each of which had four animals. Each tumor-bearing mouse was administered intravenously with [^{99m}Tc-(HYNIC-ABN)(tricine)(TPPTS)] (~15 μCi) dissolved in 0.1 mL of saline via the tail vein. Animals were anesthetized with intraperitoneal injection of sodium pentobarbital at a dose of 45.0 mg/kg, and were sacrificed by cervical dislocation at 0.5, 1, 2, and 4 h postinjection (p.i.). Blood was withdrawn from the eye through a capillary tube. Organs of interest (tumor, heart, liver, spleen, kidney, lung, stomach, intestine, and muscle) were harvested, washed with saline, dried with absorbent tissues, weighed, and measured for radioactivity in a γ-counter (Wallac 1470−002, Perkin-Elmer, Finland). The organ uptake was calculated as a percentage of the injected dose per gram of tissue mass (%ID/g). The biodistribution data and *T*/*B* ratios were reported as an average plus the standard deviation based on the results from four animals at each time point.

Metabolism. The metabolic stability of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] was evaluated using two normal BALB/c nude mice. Each mouse was administered via tail vein the radiotracer (~800 μCi) dissolved in 0.2 mL saline. The urine samples were collected at 1 h p.i. by manual void, and were mixed with an equal volume of saline. The mixture was centrifuged at 8000 rpm for 5 min. The supernatant was collected and filtered through a 0.22 μm Millex-LG syringe-driven filter unit to remove the precipitate and large proteins. The filtrate was analyzed by radio-HPLC. Both the liver and kidney simples were also harvested at 1 h p.i., and were pulped.

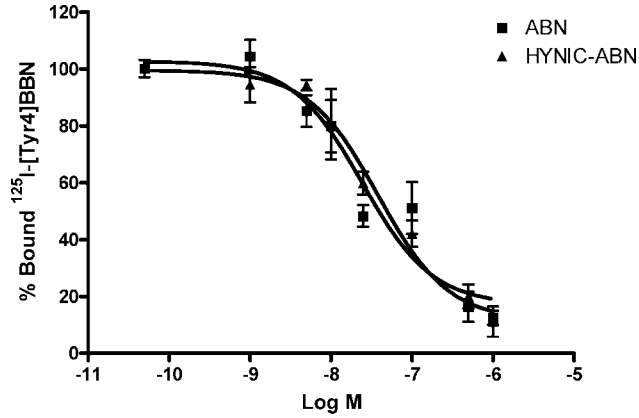

Figure 2. Displacement curves of ^{125}I-[Tyr4]BBN bound to the GRPR-positive PC-3 human prostate carcinoma cells by ABN and HYNIC-ABN. The IC_{50} values were calculated to be 24 ± 2 and 38 ± 1 nM for ABN and HYNIC-ABN, respectively.

The homogenates were mixed with an equal volume of saline, separately. The resulting mixture was vortexed for 5−10 min. After centrifuging at 8000 rpm for 5 min, the supernatant was collected and passed through a 0.22 μm Millex-LG syringe-driven filter unit to remove any precipitate and particles. The filtrate was then analyzed by radio-HPLC.

Scintigraphic Imaging. The imaging study was performed using the female BALB/c nude mice bearing the HT-29 human colon cancer xenografts. Animals were anesthetized with intraperitoneal injection of sodium pentobarbital at a dose of 45.0 mg/kg. Each tumor-bearing mouse was administered intravenously with [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] (~400 μCi) in 0.2 mL saline via tail vein. Animals were placed prone on a two-head γ-camera (SIEMENS, E. CAM) equipped with a parallel-hole, low-energy, and high-resolution collimator. Posterior images were acquired 1 and 4 h p.i. The imaging data were stored digitally in a 128 × 128 matrix. The acquisition count limits were set at 200 K. In the blocking experiment, each tumor-bearing mouse was administered intravenously with excess HYNIC-ABN (300 μg dissolved in 0.1 mL of saline) 30 min prior to administration of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)]. The posterior images were acquired 1 h p.i. using the same procedure above. After completion of imaging, animals were sacrificed by cervical dislocation.

RESULTS

GRP Receptor Binding Affinity of ABN and HYNIC-ABN. The *in vitro* GRPR binding affinities and specificities of ABN and HYNIC-ABN were assessed via a competitive displacement assay using ^{125}I-[Tyr4]BBN as the radioligand. It was found that ABN and HYNIC-ABN were able to compete with ^{125}I-[Tyr4]BBN bound to PC-3 prostate carcinoma cells (Figure 2). The IC_{50} values were 24 ± 2 nM and 38 ± 1 nM for ABN and HYNIC-ABN, respectively. The attachment of HYNIC group seems to slightly reduce the GRPR binding affinity of ABN, but this difference may not be significant within the error of this assay.

Radiochemistry. [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] was prepared in two steps. First, HYNIC-ABN reacted with $Na^{99m}TcO_4$ in the presence of excess tricine and $SnCl_2$ to form the intermediate [^{99m}Tc(HYNIC-ABN)(tricine)$_2$], which was then allowed to react with TPPTS to form the ternary ligand complex [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)]. The specific activity was ~1200 mCi/μmol. The radiochemical purity was >95% after Sep-Pak purification. [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] was analyzed using a reversed-phase HPLC method. A radio-HPLC chromatogram is shown in the top panel

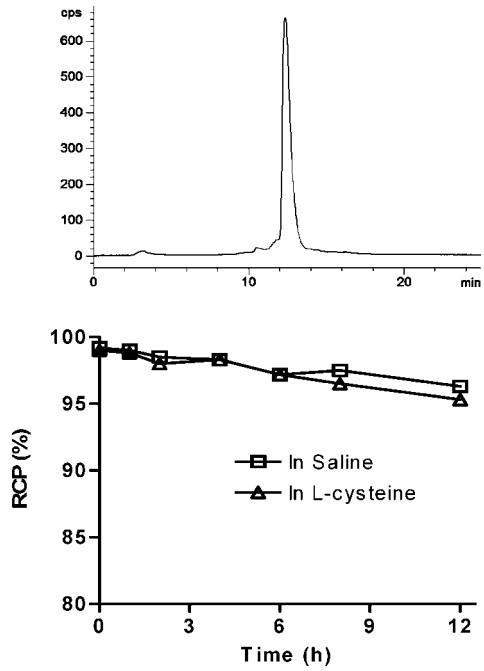

Figure 3. A typical radio-HPLC chromatogram (top) and solution stability data (bottom) for [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] in saline and in the presence of excess cysteine (1 mg/mL, pH = 7.4).

of Figure 3. The HPLC retention time was 12.2 min for [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)]. The partition coefficient was determined in an equal volume mixture of *n*-octanol and 25 mM phosphate buffer (pH = 7.4). The log *P* value was -2.39 ± 0.06. The solution stability of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] was monitored by radio-HPLC in saline and in the presence of excess cysteine (1.0 mg/mL, pH = 7.4). The solution stability data of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] is shown in the bottom panel of Figure 3. It is quite clear that [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] is able to maintain its stability over 12 h in saline and in the presence of excess cysteine.

Internalization and Efflux Kinetics. The internalization and efflux kinetics of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] is shown in Figure 4. The rate of internalization was time and temperature dependent. At 4 °C, the receptor binding took place, but there was no internalization (<1%). At 37 °C, there was a rapid internalization with 35 ± 2% of the cell-associated radioactivity being internalized at 5 min postincubation (Figure 4, left). The maximum was reached with 68 ± 5% of the internalized radioactivity at 30 min postincubation. In spite of the fast internalization, there was no significant retention of radioactivity inside tumor cells since the internalized radioactivity was quickly released. After 15 min incubation at 37 °C, 49 ± 3% of the internalized radioactivity remained. Only ~20% of the internalized radioactivity remained after 1 h (Figure 4, right).

Biodistribution Characteristics. The biodistribution study was performed using the BALB/c nude mice bearing HT-29 human colon cancer xenografts. The selected biodistribution data and T/B ratios for [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] are summarized in Figure 5. In general, [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] had a rapid clearance, predominantly through the renal route. Most of the injected dose was in the urinary system by 1 h p.i. with little radioactivity accumulation in the blood (0.50 ± 0.15%ID/g), liver (0.68 ± 0.16%ID/g), muscle (0.14 ± 0.04%ID/g), and gastrointestinal tract (0.63 ± 0.21%ID/g) at 1 h p.i. The tumor uptake was the highest (1.59 ± 0.23%ID/g) at 30 min p.i., with a steady decrease over the 4 h study period. [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] had the best *T*/*B* ratios for blood (2.37 ± 0.68), liver (1.69 ± 0.41), and muscle (11.17 ± 3.32) at 1 h p.i.

Imaging Studies. Figure 6 illustrates representative planar images of the tumor-bearing mice administered with ~400 μCi of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] at 1 h p.i. (left) and 4 h p.i. (middle), as well as in the presence of excess HYNIC-ABN (right) at 1 h p.i. Arrows indicate the presence of the tumor (T) and kidneys (K). The HT-29 tumor is clearly visualized at 1 h p.i. with excellent tumor-to-background contrast. At 1 h p.i., the "hottest" spots are tumor, kidneys, and bladder. By 4 h p.i., the radioactivity in the chest region almost completely disappears while the tumor is still clearly seen. These data are consistent with those obtained from the *ex vivo* biodistribution study (Figure 5).

The blocking experiment by preinjecting or coinjecting a known receptor−ligand is often used to demonstrate the tumor specificity of the target-specific radiotracers. In this study, we used HYNIC-ABN as the blocking agent. Preinjection of excess HYNIC-ABN result in a significant reduction in the tumor uptake of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] (Figure 6, right), indicating that its tumor localization is at least partially GRPR-mediated. There is also a significant reduction in radiotracer accumulation in several noncancerous organs, such as liver, stomach, intestine, and kidneys, due to the blockage of GRPRs in these organs (*1*, *3*, *4*).

Metabolic Properties. Metabolism study was performed using normal BALB/c mice by analyzing the samples from urine, kidney, and liver. Figure 7 shows typical radio-HPLC chromatograms of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] in the kit matrix before injection (A), in the urine (B), in the kidney (C), and in the liver (D). [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] was completely metabolized in urine, kidney, and liver samples at 1 h p.i. The majority of the injected radioactivity was found in the urine sample at 1 h p.i. Compared with urine sample, the radioactivity level was almost undetectable in the liver and kidney samples.

DISCUSSION

Since colon cancer occurs in the torso area, it is necessary for the radiotracer to have a minimal radioactivity accumulation in the liver, lungs, stomach and gastrointestinal tract. There are several factors influencing the radiotracer excretion kinetics. These include the molecular charge, solution stability, lipophilicity and metabolic stability of the radiotracer. For the last several years, intensive efforts have been made to optimize the radiotracer pharmacokinetics by using different ^{99m}Tc cores (*34*, *36*, *37*, *41*, *44*, *46*), BFCs (*34*, *39*, *44*), and linker groups (*36*, *39*). It was reported that the linker groups, such as β-Ala-β-Ala or 3,6-dioxa-8-aminooctanoic acid, had a significant impact on tumor uptake, excretion kinetics, and metabolic stability of the ^{99m}Tc-labeled BN(7−14)NH_2 (*36*). A major disadvantage of using the ^{99m}Tc$(CO)_3^+$ core for the ^{99m}Tc-labeling of BN(7−14)NH_2 derivatives is that the radiotracer often has high uptake in the liver and intestine (*36*). Recently, NOTA and DOTA were used as BFCs for preparation of the ^{64}Cu-labeled BN-like peptides (*25*–*29*). Results from biodistribution and microPET imaging studies show that the ^{64}Cu-labeled NOTA-BN conjugates have very little accumulation in the liver, lungs, stomach, and intestine (*29*). The BFCs and radiometal chelates can be used to improve the radiotracer clearance from the noncancerous organs.

In this study, we used HYNIC as the BFC and tricine/TPPTS as coligands to prepare [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)]. We found that [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] was excreted rapidly via the renal route with very little radioactivity accumulation in the blood, liver, muscle, and gastrointestinal

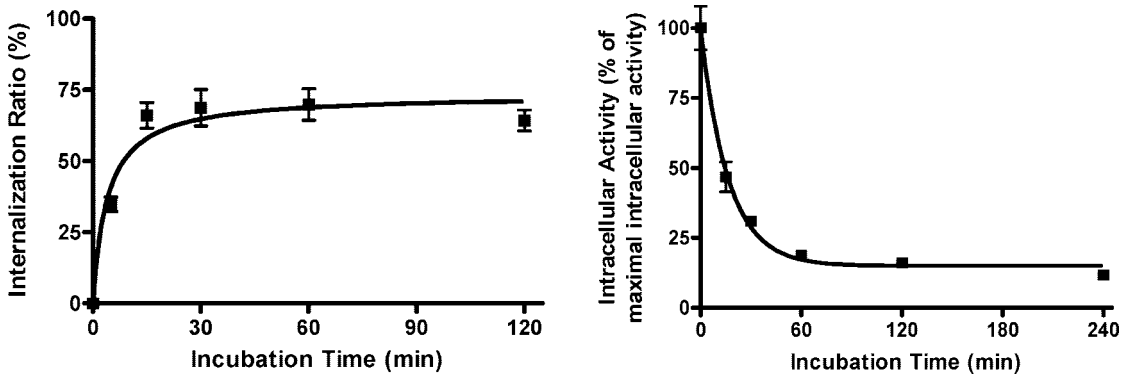

Figure 4. Internalization (left) and efflux (right) kinetics of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)].

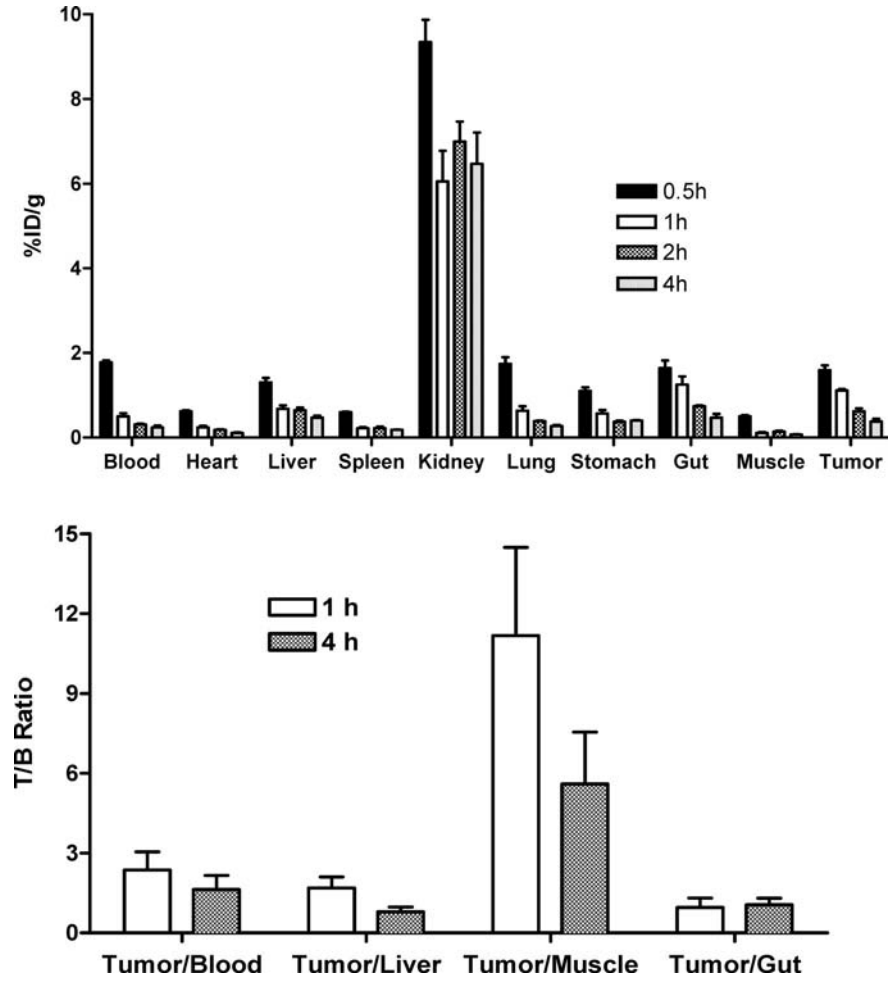

Figure 5. Organ uptake (top) and *T*/*B* ratios (bottom) for [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] in BALB/c nude mice bearing the HT-29 human colon cancer xenografts. Each data point represents an average of biodistribution data in four animals.

tract at >1 h p.i. (Figure 5). The tumor uptake was the highest (1.59 ± 0.23%ID/g) at 30 min p.i. with a steady decrease over the 4 h study period. This radiotracer had the best *T*/*B* ratios in the blood (2.37 ± 0.68), liver (1.69 ± 0.41), and muscle (11.17 ± 3.32) at 1 h p.i. The rapid tumor washout is also seen in images of the tumor-bearing mice (Figure 6), which is consistent with the rapid efflux kinetics of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] (Figure 4). Similar tumor washout was also reported for the ^{99m}Tc(CO)$_3$-labeled BN(7−14)NH$_2$ derivatives (*36*, *37*). Results from the blocking experiment show that the tumor uptake of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] is at least partially GRPR-mediated. The radiotracer uptake decreased in the liver, stomach, and intestine in the presence of excess HYNIC-ABN, which strongly suggests that the GRPRs are also expressed in these organs. Compared with the ^{99m}Tc(CO)$_3$-labeled His-linker-BN(7−14)NH$_2$ (linker = β-Ala-β-Ala or 3,6-dioxa-8-aminooctanoic acid) (*36*), [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] has the advantage with respect to its rapid clearance from blood, liver, muscle, and gastrointestinal tract.

The solution stability data shows that [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] is stable for >12 h in the presence of excess cysteine (Figure 3). However, results from the metabolism study indicate that [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] is completely metabolized at 1 h p.i. in the urine, kidney, and liver samples, probably due to rapid enzymatic degradation. Earlier studies showed that BN-like peptides could be easily metabolized by the neutral endopeptidase E.C.3.4.24.11 and the

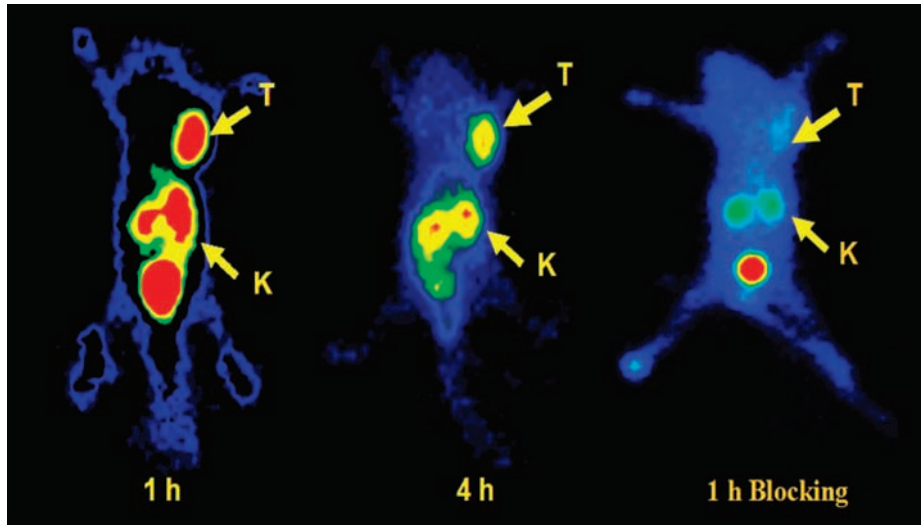

Figure 6. Static planar images of the tumor-bearing mice administered with ~400 μCi of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] at 1 h p.i. (left) and 4 h p.i. (middle), as well as in the presence of excess HYNIC-ABN (right). Arrows indicate the presence of the tumor (T) and kidneys (K).

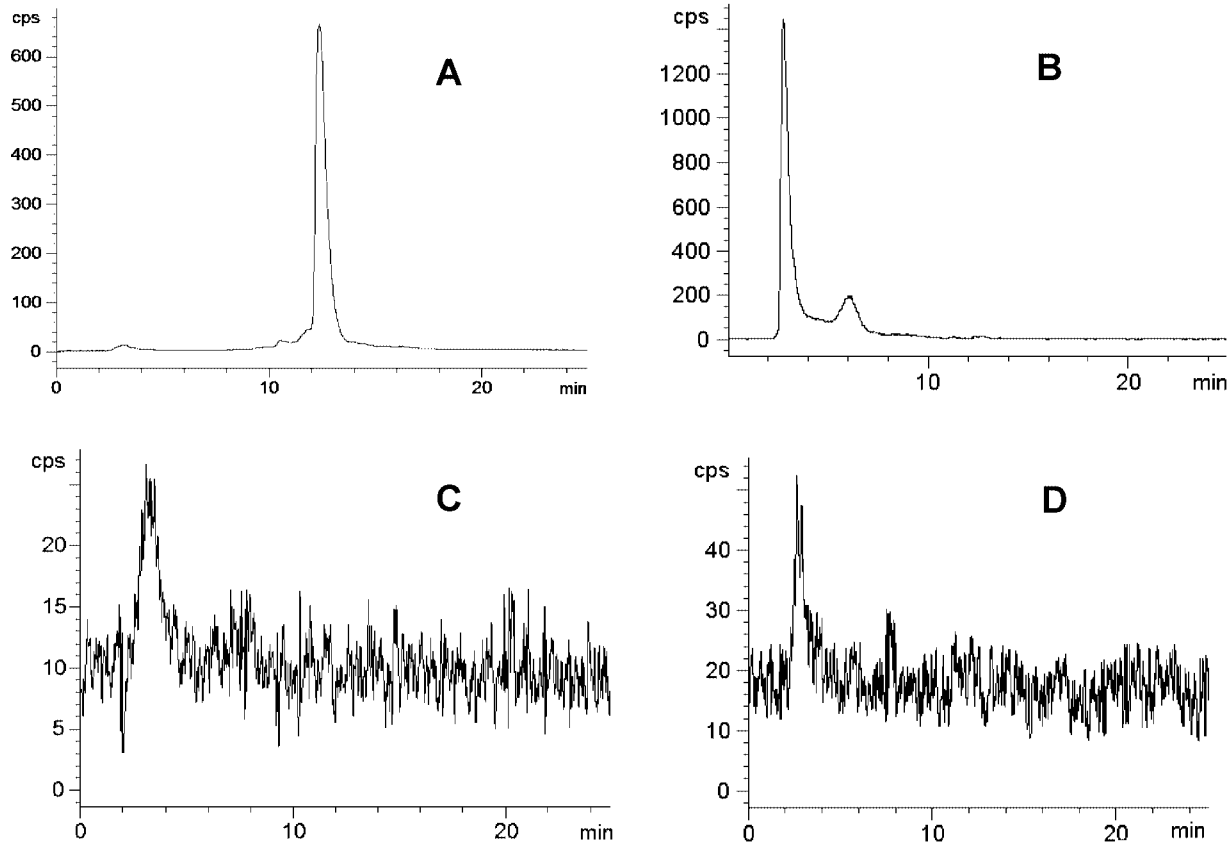

Figure 7. Radio-HPLC chromatograms of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] in the kit matrix before injection (A), in the urine (B), in the liver (C), and in the kidney (D) at 1 h p.i.

angiotensin-converting enzyme (*60–62*). This metabolic instability may contribute, in part, to the rapid washout of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] from tumor and noncancerous organs, such as the liver, lungs, muscle, stomach, and gastrointestinal tract.

The GRPR binding affinities of ABN and HYNIC-ABN are very similar to those reported for DOTA-linker-bombesin(7−14) (linker = triglycine, glycine-serine-glycine, or glycine-serine-serine) (*27*) and those reported for the $Re(CO)_3$ complexes of His-linker-BN(7−14)NH_2 (linker = β-Ala-β-Ala or 3,6-dioxa-8-aminooctanoic acid) (*36*). However, the tumor uptake of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] in HT-29 colon cancer is not as high as the values reported for the ^{64}Cu-labeled DOTA-linker-bombesin(7−14) conjugates (linker = triglycine, glycine-serine-glycine, or glycine-serine-serine) in the PC-3 prostate cancer (*27*). There are two main reasons for the low tumor uptake of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] reported in this study. The expression level of GRPRs on HT-29 cells may not be as high as that on PC-3 prostate cancer cells. The attachment of the ^{99m}Tc chelate (^{99m}Tc, HYNIC, tricine and TPPTS) may significantly reduce the GRPR binding affinity of [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)], which seems to be supported by the fact that the IC_{50} value of ABN (24 ± 2 nM) is slightly lower than that of HYNIC-ABN (38 ± 1 nM). It

must be emphasized that the difference in the tumor-bearing mice (BALB/c versus SCID) may also contribute to the variation of tumor uptake and excretion kinetics of the radiotracer. Therefore, caution must be taken when comparing the biodistribution data obtained by two different research laboratories using two different tumor-bearing animal models.

CONCLUSION

The ternary ligand system (HYNIC, tricine, and TPPTS) has been successfully used for ^{99m}Tc-labeling of β-Ala-BN(7−14)NH_2. [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] can be prepared in high yield and high specific activity. Because of its hydrophilicity (log $P = -2.39 \pm 0.06$), [^{99m}Tc(HYNIC-ABN)(tricine)(TPPS)] is excreted mainly via the renal route with little radioactivity accumulation in the liver, lungs, stomach, and gastrointestinal tract. Its metabolic instability may contribute, in part, to its rapid clearance from the tumor and nontumor organs, such as the blood, liver, lungs, and stomach. As a result, it has the best *T*/*B* ratios in the blood, liver, and muscle at 1 h p.i. The tumor can be clearly visualized as early as 30−60 min p.i. by planar imaging of the BALB/c nude mice bearing the HT-29 human colon xenografts. The combination of relatively high tumor uptake with its extremely favorable pharmacokinetics makes [^{99m}Tc(HYNIC-ABN)(tricine)(TPPTS)] a promising SPECT radiotracer for imaging colon cancer.

ACKNOWLEDGMENT

Authors would like to thank Professor Xiaoyan Qiu, Peking University Health Science Center, for providing the HT-29 human colon cancer cells, and Huiyun Zhao, Peking University Medical Isotopes Research Center, for technical support. This work is supported, in part, by research grants: Z00004105040311 and D0206001041991 (F.W.) from the Beijing Science and Technology Program, 30640067(F.W.) from the NSF, 1R01 CA115883-01A2 (S.L.) from the National Cancer Institute (NCI), and BCTR0503947 (S.L.) from the Susan G. Komen Breast Cancer Foundation.

Received December 21, 2007; Revised Manuscript Received March 25, 2008

We report here, what we believe to be the first time, the successful transport of bioconjugated quantum rods (QRs) across an in vitro blood−brain barrier (BBB) model via a receptor-mediated transport, as well as the use of QR multiplexing technique to compare simultaneously the transmigration efficiency of different biomolecules across the BBB. The migration rate of bioconjugated QRs crossing the in vitro BBB was found to be concentration- and time-dependent. This work illustrates a nanoparticle-based platform that will not only allow a direct visualization of the transmigration ability of various kinds of biomolecules across the BBB, but also facilitate the development of novel diagnostic and therapeutic nanoprobes for early diagnosis and therapy of various disorders of the brain following systemic administration.

INTRODUCTION

The blood−brain barrier (BBB) is a dynamic interface between the body and the brain, which is actively engaged in regulatory functions of the central nervous system (CNS), in addition to its primary role of protecting the brain from harmful substances and fluctuations in blood (*1–3*). Brain microvascular endothelial cells (BMVECs) composing the BBB are underlined by a continuous basement membrane, reinforced by pericytes and astrocytic endfeet, and are connected with adjacent endothelial cells (*4–9*). Owing to the presence of continuous strands of tight junctions between adjacent lateral endothelial membranes, the BBB is almost completely sealed, and therefore, it strictly limits the entrance of systemically circulating endogenous and exogenous compounds into the CNS (*3, 10, 11*). Thus, while the BBB constitutes a natural defense mechanism that safeguards the brain against the invasion of various circulating toxins and infected cells, it also offers a significant impediment toward the delivery of various diagnostic and therapeutic agents in the brain via the systemic route (*4, 12*). Therefore, targeted delivery across the BBB is one of the most challenging fields of research dealing with the treatment of various neurological disorders (*13, 14*).[1]

In general, transport mechanisms across the BBB can be broadly divided into three types, namely, passive, carrier-mediated, and vesicular transport (*6*). For example, lipid-soluble, nonpolar substances can enter the brain by passive diffusion across the BBB. On the other hand, polar substances and small peptides can be transported across the endothelium by carrier-mediated influx. Lastly, the vesicular transport is by either receptor-mediated or absorptive-mediated transcytosis via cationic proteins. However, to date, there are still many unknown and undiscovered parameters that are affecting the permeability of the BBB (*10, 15*). Thus, it is of great importance to systematically investigate the molecular composition, structure, and transport kinetics of the BBB under a variety of conditions in order to comprehend the underlying mechanisms of BBB permeability, which will help us to devise novel strategies for enhanced delivery of various neuropharmaceuticals into the brain.

Currently, nanotechnology is being investigated for overcoming the limited penetration of drugs through the BBB, which is an extremely important and evolving area in CNS pharmacology (*16–20*). To date, various types of nanoparticles and liposomes have been synthesized and used as drug carriers or contrast agents for targeted drug delivery and diagnosis of brain tumors across the BBB (*17, 21–24*). It is generally understood that drug-loaded nanoparticles can cross over the BBB as an intact entity, which will then release the drugs within the CNS. Though few liposomal and polymeric nanoparticles have been used for targeted delivery across the BBB, there have been no reports of using high-quality quantum dots (QDs) or quantum rods (QRs) as targeted probes to monitor the transmigration of specific molecules through BBB. The use of QD/QRs as luminescence probes for numerous biological and biomedical applications has become an area of intense research focus over the past few years (*25–28*). They offer several advantages over organic dyes, including increased brightness, stability against photobleaching, excitation within a broad spectral range, and a tunable and narrow emission spectrum. The QD/QR surface can be functionalized with a variety of biomolecules and have shown the potential to dramatically outperform conventional organic dyes in imaging of cellular and subcellular structures and in a variety of bioassays (*29–31*). Recently, targeted QD/QR-based probes have been modified to carry therapeutic molecules such as anticancer drugs and short interfering (si) RNA (*32, 33*).

Recently, our group has shown that the QR/QD bioconjugates can serve as targeted optical probes for two-photon fluorescence imaging of cancer cells (*34, 35*). Here, we further extended the application of QR bioconjugates as efficient targeted probes for

transmigration across the BBB. A validated endothelial and astrocytic coculture BBB model was used to examine the transmigration of QR bioconjugates across the BBB (*36–38*). It is known that the transferrin receptor (TfR) is a kind of specific BBB transporter that allows selected biomolecules to move across the BBB (*39*). Transferrin (Tf)-conjugated QRs were synthesized and used for transport across the in vitro BBB model via a receptor-mediated transport mechanism. It was found that the migration rate of Tf-conjugated QRs crossing the in vitro BBB is concentration- and time-dependent. Further, another tight-junction protein Claudin-4 was used concurrently to validate the multiplex imaging technique and also to evaluate quasi-quantitatively the comparative transmigration efficiency and specificity of Tf and anti-Claudin 4 antibody (aC4), by conjugating them with red and orange emitting QRs, respectively. The results showed higher transmigration efficiency of Tf-conjugated QRs over the aC4-conjugated ones across the BBB. To the best of our knowledge, this is the first time that the QR multiplexing technique is employed to compare the targeting efficiency of different specific molecules across the BBB. These results illustrate a nanoparticle-based platform that will not only allow a direct visualization and quantification of the transmigration ability of various kinds of biomolecules across the BBB, but also facilitate the development of novel diagnostic and therapeutic nanoprobes for early diagnosis and therapy of various disorders of the brain following systemic administration.

RESULTS AND DISCUSSION

Figure 1a,c shows TEM images of red- and orange-emitting CdSe/CdS/ZnS QRs cast from aqueous media, respectively. The red- and orange-emitting QRs have lengths of 26 and 14 nm, and diameters of 6.5 and 4 nm, respectively. The absorption and PL spectra of the red and orange QRs are also shown in Figure 1b,d, respectively. Absorption spectra of the QRs show the expected structure with absorption onsets of 615 and 589 nm for red- and orange-emitting QRs, respectively. The PL spectra of the red- and the orange-emitting monodispersed QRs show band edge emission at 658 and 608 nm. Thus, we refer to the red- and orange-emitting QRs as 658 nm QRs and 608 nm QRs, respectively. These stored QRs can be directly used for cell staining without any sign of quenching effects. The photoluminescence quantum yields (QY) of 608 and 658 nm

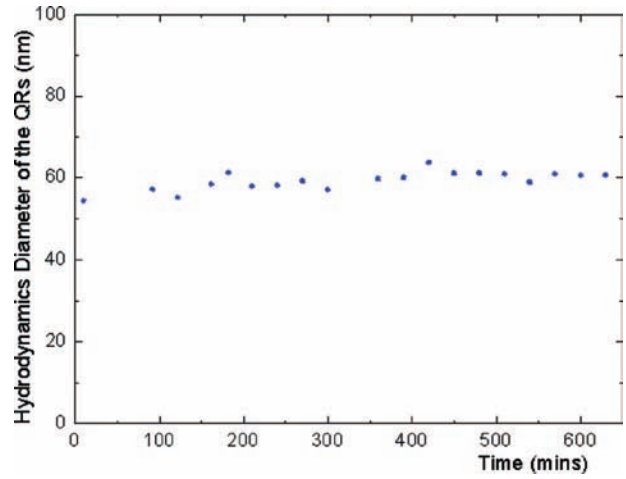

Figure 2. Time-dependent hydrodynamic diameter of lysine coated QRs dispersed in PBS buffer.

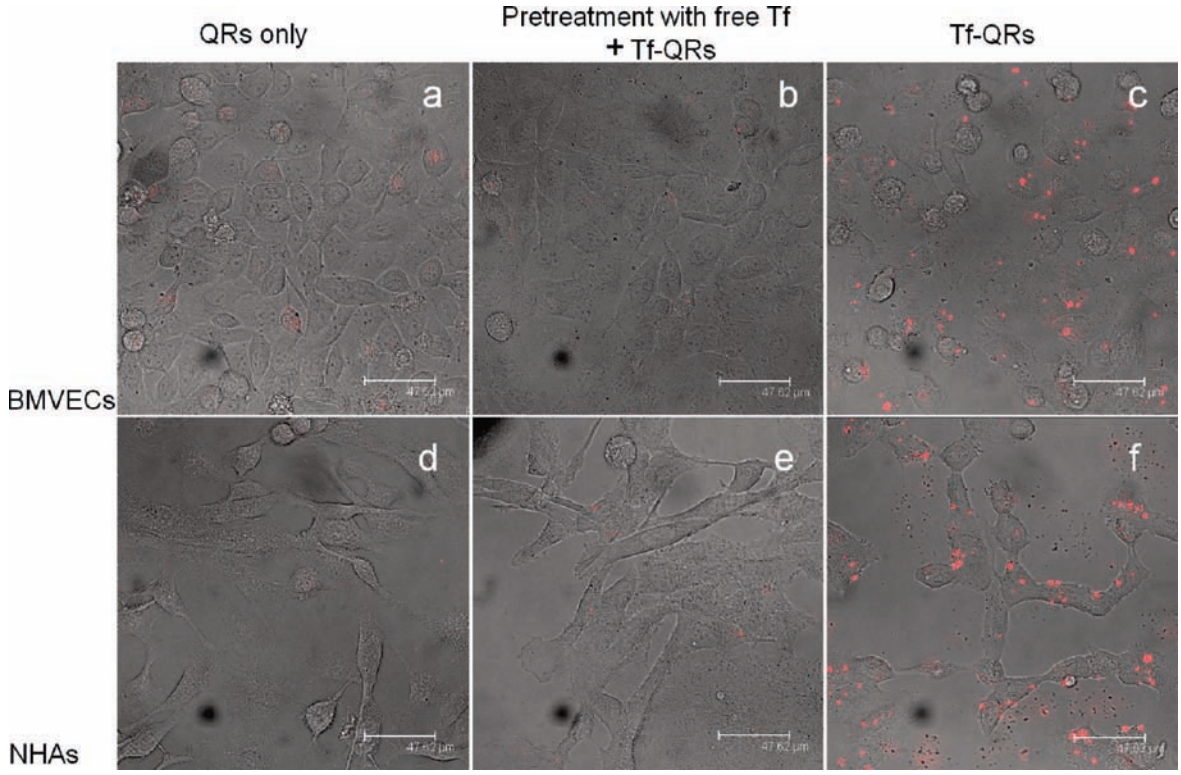

Figure 3. Confocal microscopic images of BMVEC and NHA cells, treated with (a,d) lysine-coated CdSe/CdS/ZnS QRs. (c,f) Tf-conjugated CdSe/CdS/ZnS QRs. Cells in (b) and (e) were saturated with free Tf for 2 h, before treatment with QR-Tf. Confocal microscopy images were obtained with laser excitation at 405 nm.

QRs are estimated to be 30% and 50%, respectively, which are sufficiently high for bioimaging.

In this study, dynamic light scattering (DLS) was also used to determine the colloidal stability of the QRs dispersed in PBS (pH = 7.4). The time-dependent profile of the effective diameter of the QRs is shown in Figure 2. Over the time range from 0 to 600 min, the effective diameter varies by less than 10%, suggesting that their colloidal stability is not affected under physiological pH. It is worth mentioning that the size of the QRs is ~26 nm in length and ~6.5 nm in width and their total hydrodynamic size is further increased by the MUA and lysine coating. Therefore, light scattering data show a total hydrodynamic diameter of ~60 nm. The light scattering analysis assumes that particles are spherical. Thus, the actual sizes determined by light scattering in our case cannot be taken literally. Therefore, we want to stress that the light scattering technique used here is solely to prove the nonaggregation of the QRs under physiological conditions.

To employ QRs as an efficient targeted contrast agent for traversing the BBB, the QRs must be conjugated with specific biorecognition molecules. To date, it is well-known that the transferrin receptor (TfR) is highly localized on the endothelial surfaces of the brain. TfR will generally trigger the receptor-mediated transport across the BBB because it undergoes trancytosis through the BBB. Thus, transferrin (Tf), an iron-transporting protein, was chosen as one of the specific ligands for facilitating transport across the BBB.

Prior to pursuing the in vitro BBB model studies, primary human BMVEC and normal human astrocyte (NHA) cells were individually studied to confirm the selective uptake of the Tf-QR biocojugates. Figure 3c,f represents confocal images showing robust staining of BMVEC and NHA cells, respectively, following treatment with Tf-QRs conjugates. Minimal uptake was observed with unconjugated QRs (Figure 3a,d). This result suggests that the Tf-conjugated QRs are transported within BMVEC and NHA cells through the transferrin receptor-mediated endocytosis pathway. To further confirm the targeted delivery of QR-Tf bioconjugates is receptor-mediated, the BMVEC and NHA were presaturated with free Tf in order to block the available Tf receptors on the cell surface. The results indicated significant reduction in the uptake of QR-Tf bioconjugates (Figure 3b,e), suggesting the specific nature of the uptake (*34*, *35*). In addition to these experiments, we have also performed local spectral analysis in order to quantify the cellular uptake of the nanoparticles in the various conditions given above. The local spectra were plotted as an average of spectral intensity obtained from different random points within the confocal fluorescence images. Figure 4 shows that the fluorescence signal obtained from the cells (both BMVECs and NHAs)

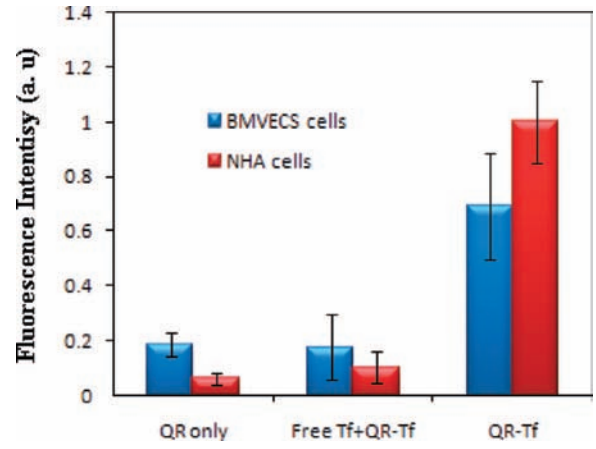

Figure 4. Fluorescence signal distribution collected from BMVEC and NHA cells following treatment with non-bioconjugated (QR only) and bioconjugated (QR-Tf) QRs. The effect of saturating cells with free Tf prior to treatment with QR-Tf is also represented. The error bars represent the range that was obtained for each point from a total of four points.

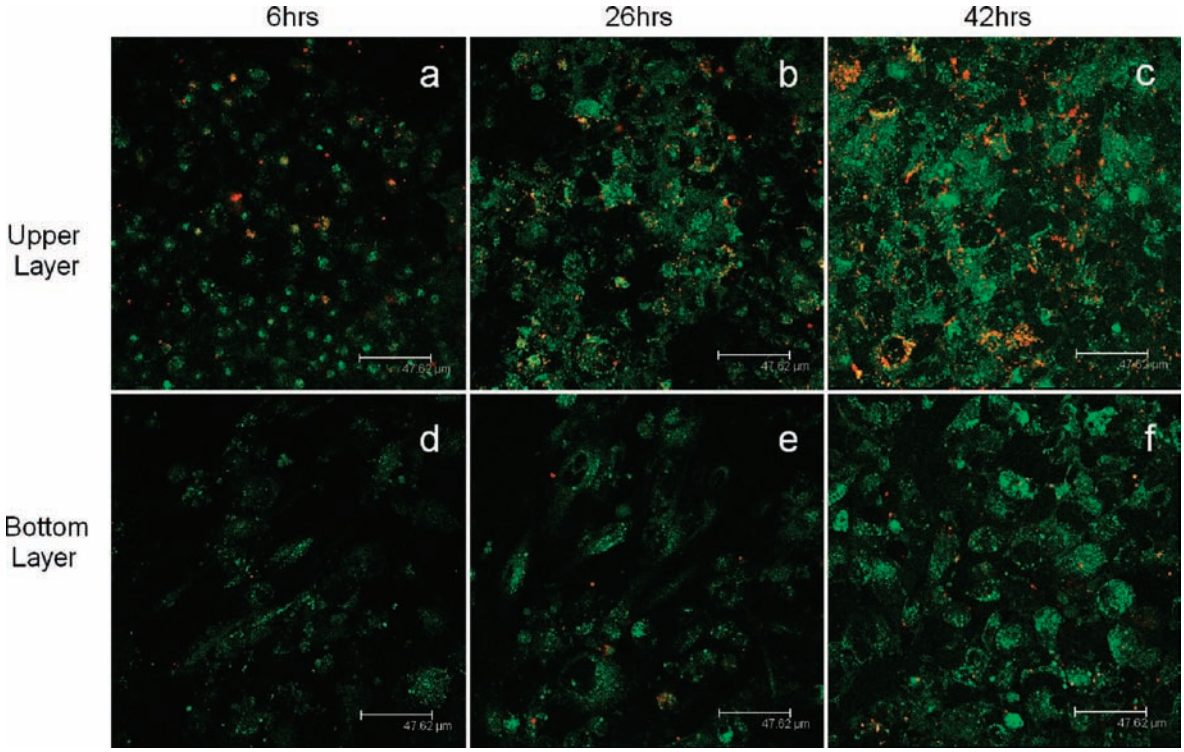

Figure 5. Confocal microscopic image of upper and bottom layer of BBB model treated with Tf-conjugated red QRs. In all cases, green represents emission the autofluorescence and red represents emission from 658 nm QRs.

following treatment with the QR-Tf bioconjugates is significantly higher than that obtained from cells treated with nonbioconjugated QRs and QR-Tf bioconjugates following presaturation with free Tfs. This result presents a semiquantitative estimation that reflects the superiority of the receptor-mediated cellular uptake over passive uptake.

On the basis of the successful in vitro experiment on the individual cell lines, we hypothesized that these bioconjugates could be used as efficient targeted probes for crossing the BBB. In this work, the bioconjugates were used to study the transmigration activity across an in vitro BBB model, which is established using primary human BMVEC and NHA cells. A schematic drawing of the BBB model is presented in the Supporting Information (Scheme 1). This in vitro BBB model consists of two-compartment wells in a culture plate. After formation of the model, Tf-QR bioconjugates were introduced into the upper chamber (blood end of the model) and incubated for different time points and bioconjugate concentrations. Next, the media from upper and bottom (brain end of the model) chambers were separately collected and the photoluminescence (PL) of the media was measured using a spectrofluorimeter in order to estimate the transmigration rate of the bioconjugates across the BBB. Confocal imaging technique was used to study and examine the BMVEC-PET-NHA cell layers (both upper and bottom sides) labeled with the QR bioconjugates.

Figure 5 shows the confocal images of upper and lower sides of the BBB model incubated with the Tf-QR bioconjugates at 6, 26, and 42 h, respectively. The autofluorescence signal (green) from the cells was used as the background for comparison. The upper panel shows confocal images of the BMVEC layer and the bottom panel is for the NHA layer. As shown in Figure 5, the uptake of Tf-QRs in both upper and bottom cell layers increases with the incubation time. This suggests that the migration of the Tf-QR conjugates is driven by both receptor mediated and kinetic processes.

To confirm the receptor-mediated uptake process, control experiments were performed using unconjugated QRs incubated with the BBB model. After 26 h, the upper and bottom layers were carefully rinsed with PBS solution and examined under a confocal microscope. As expected, minimal uptake was observed in the BBB model treated with unconjugated QRs upon comparison to the Tf-QRs (Supporting Information, Figure S1).

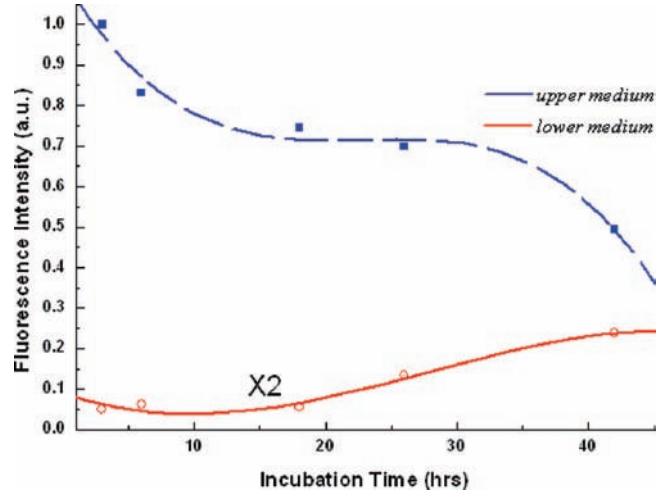

Figure 6. Relationship between fluorescence intensity changes of medium and the incubation time.

To further probe efficiency of permeability of Tf-QRs across the BBB, the PL intensities of the media from the upper and bottom chambers of the BBB model were systematically measured as a function of treatment time and analyzed. Figure 6 shows the band edge emission of the Tf-QRs in the upper and bottom chambers of the BBB model treated for various incubation times. Although there is clear time dependence, the upper medium retains more than 70% of their initial PL intensity, even at 26 h. Over the time range of 26 to 42 h, the PL intensity varies by more than 30%. This suggests that there is a critical period for significant passage of Tf-QRs through the BBB that is greater than 26 h.

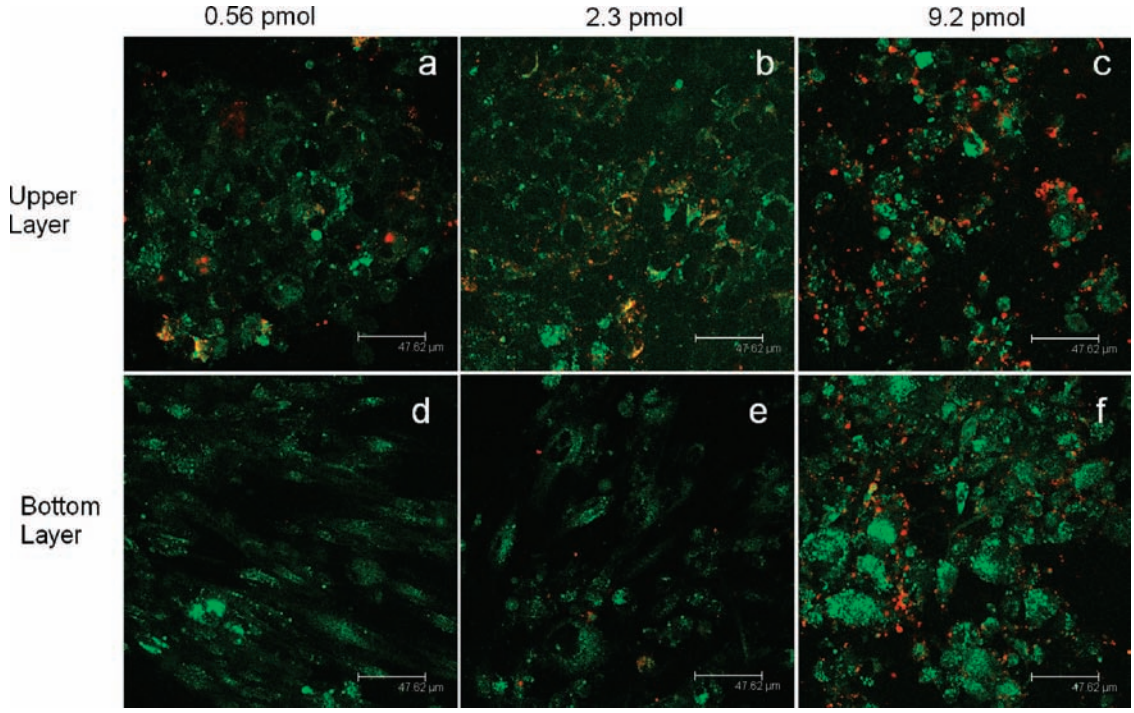

Figure 7. Confocal microscopic image of upper and bottom layers of the BBB model treated with ~0.56, 2.3, and 9.2 pmol of Tf-conjugated red QRs. In all cases, green represents emission of the autofluorescence and red represents emission from 658 nm Tf-QRs.

To better understand the effects of amount of Tf-QR bioconjugates on the permeability and transport kinetics across the in vitro BBB model, three different concentrations of Tf-QRs were used. Figure 7 presents the confocal images of the upper and lower sides of the BBB model incubated with ~0.56, 2.3, and 9.2 pmol of Tf-QRs at 26 h. From the confocal microscopy analysis, we find that the quantities of Tf-QRs labeled on both BMVEC (upper) and NHA (lower) cell layers increase with the increment of the Tf-QR concentration. However, when the Tf-QR concentration exceeded 9.2 pmol, a large amount of morphologically damaged cells was observed, suggesting that this concentration is the maximum tolerated dose prior to the onset of cytotoxicity.

In addition to conjugation of Tf, we have also conjugated aC4 with QRs for evaluating the specificity of different targeting molecules for BMVECs and NHAs. To compare the targeting specificity of aC4 and Tf on the cells, a multiplexed imaging technique was used by employing two different colors of QRs. More specifically, the 608 nm QRs were conjugated with aC4 and the 658 nm QRs were conjugated with Tf for specific targeting to Claudin 4 and transferrin receptors, respectively, on the BBB (and its constituent cells). Figure S2 (Supporting Information) shows confocal images of BMVEC and NHA cells colabeled with 4.0 pmol aC4-QRs (608 nm) and 0.46 pmol Tf-QRs (658 nm). Although the aC4-QRs (608 nm) is added about in a concentration 8.7 times than that for Tf-QRs (658 nm), the uptake of the 658 nm QR bioconjugates is slightly higher than that for the 608 nm QRs, as seen from the localized spectral analysis. The uptake concentration of Tf-QR bioconjugates was estimated to be twice the amount of aC4-QRs for both BMVEC and NHA cells (see Supporting Information Table S1). This experiment clearly demonstrates the Claudin 4 antigen also mediates targeting on BMVEC and NHA cells, but the targeting efficiency is significantly lower than that using the transferrin receptor.

The same formulation was further employed to compare the transmigration efficiency of aC4 and Tf for the in vitro BBB model. Figure 8 shows confocal images and spectra of the upper and bottom cell layers of the intact BBB model, again demonstrating superior staining/transmigration of the Tf-QRs (658 nm) over the aC4-QRs (608 nm). Local spectral analysis of the overall labeling of bioconjugates on the cells confirms that the fluorescence signal from the Tf-QR (658 nm) bioconjugates is more intense than that from the aC4-QR (608 nm) bioconjugates. Here, it was found that the uptake concentration of Tf-QR bioconjugates was three times the concentration of aC4-QRs at the bottom layer (see Supporting Information Table S1). From these results, it appears that it is more efficient to use the Tf-conjugated QRs for transport across the BBB, which agrees with the fact that the transferrin receptors are overexpressed in the BBB cells. Therefore, upon comparing the targeting molecules used in this work, Tf has higher affinity for individual cells lines composing the BBB and better transmigration efficiency across the in vitro BBB model. In comparison the aC4-QRs (608 nm), although can be targeted to the individual cells, are less suited as a nanocarrier to pass through the BBB owing to their lower tansmigration ability. This multiplexing technique can provide a novel nanophotonic method to screen a number of potential ligands for targeted delivery of diagnostics and therapeutics across the BBB, which will shorten the research cycle of CNS drug discovery and screening.

Besides using the QRs as biomarkers, we have also systematically investigated their cyctotoxicity effects on the BMVEC and NHA cell lines. Figure S3 (Supporting Information) shows the in vitro cytotoxicity effects of lysine-coated QRs, Tf-QRs, and aC4-QRs on the BMVEC and NHA cell lines. All the bioconjugates maintained greater than 80% cell viability, even at particle concentration as high as 7.9 pmol. This indicates that such bioconjugates can be used as efficient nanoprobes at noncytotoxic dosages.

In conclusion, we have used photostable, water-dispersible lysine-coated CdSe/CdS/ZnS QRs as efficient targeted probes for monitoring transport across an in vitro BBB model. The lysine-coated QRs can be readily conjugated with Tf and aC4 for specific targeting of the BBB cells. The receptor-mediated uptake of Tf-QR bioconjugates into the BMVEC and the NHA cells was confirmed by presaturating the cells with free Tf,

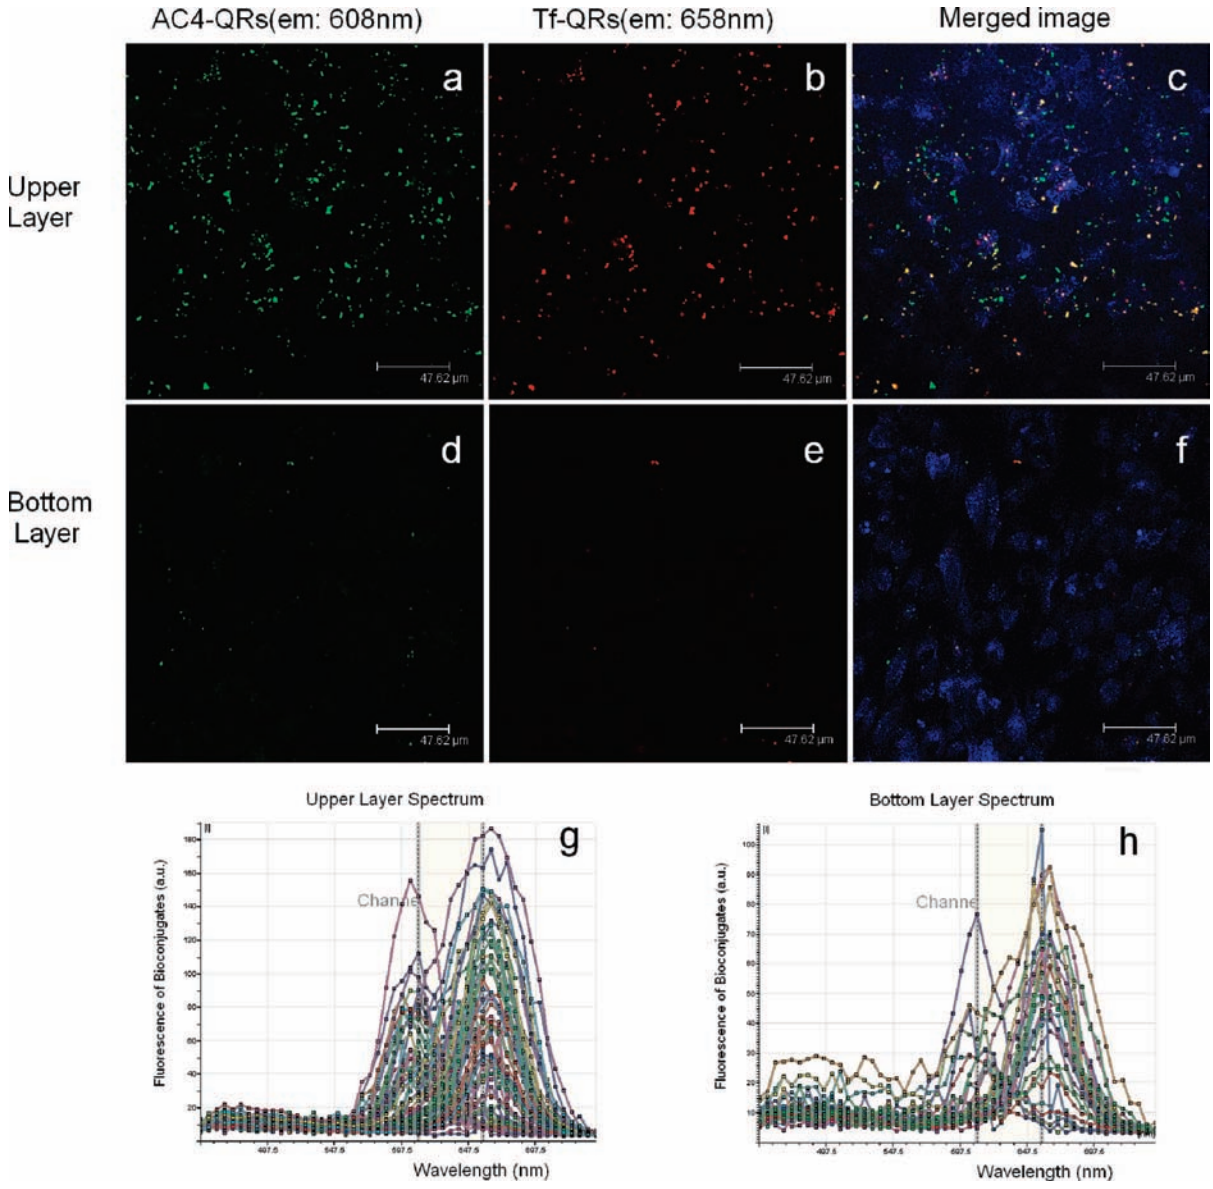

Figure 8. Confocal microscopic images and the local spectra of upper and bottom layer of the BBB model treated with multiplexed bioconjugates. The BBB model was treated with both aC4-conjugated 608 nm QRs and Tf-conjugated 658 nm QRs for 26 h incubation. In all cases, blue represents emission of the autofluorescence, green represents emission from 608 nm QRs, and red represents emission from 658 nm QRs. Confocal microscopy images were obtained with laser excitation at 405 nm. Scale bar: 47.62 μm.

thereby drastically lowering the uptake of the Tf-QR bioconjugates. This work demonstrates a nanoparticle-based platform that will not only allow a direct visualization of the transmigration ability of various kinds of biomolecules across the BBB, but also facilitate the development of novel diagnostic and therapeutic nanoprobes for early diagnosis and therapy of various disorders of the brain, following systemic administration. QRs, owing to their high surface area, can be coincorporated with other diagnostic and therapeutic molecules for targeted therapy of CNS disorders. Development of such multifunctional QRs with combined diagnostic, targeting, and therapeutic molecules are in progress.

We are evaluating PCT imaging in conjunction with NIR dye labeled Herceptin antibody for noninvasive assessment of HER2 expression in tumors. Herceptin was labeled with Alexa Fluor-750 amine reactive dye for characterization of photoacoustic and fluorescence signals. Measurements were performed in solution and after incubation in cultured cell lines that were positive or negative in expression of HER2. The dye to antibody ratio was controlled to achieve a broad range of degree of labeling (DOL = 2 to 15). Photoacoustic signal intensity of Herceptin−dye conjugates in solution increased with increases over the entire DOL range studied. In contrast, fluorescence exhibited significant quenching for higher DOL. In vitro PCT imaging of the labeled HER2 (+) and HER2 (−) cells revealed the targeting specificity of the NIR dye labeled Herceptin. In HER2 (+) cells lines, photoacoustic signal intensity gradually increased with increasing DOL and with increasing number of cells. These results demonstrate that PCT-based measurement of HER2 receptor binding using NIR dye labeled Herceptin is feasible. The absence of a quenching effect with increased DOL advantages this method over traditional methods based on fluorescence measurement.

INTRODUCTION

Recently, there has been growing interest in photoacoustic computed tomography (PCT) imaging (*1–8*). It is a noninvasive imaging modality capable for obtaining both structural and functional information in biological tissues. In PCT, short pulses of stimulating radiation (e.g., laser or radiowaves) are differentially absorbed in tissue, resulting in subsequent thermal expansion and ultrasonic emission. The ultrasonic signals are measured by use of wide-band ultrasonic transducers. Photoacoustic signals thus obtained are free from the deleterious effects of optical scattering in biological tissue. The imaging depth in tissue exceeds standard optical imaging techniques, and systems can be designed to achieve excellent spatial resolution throughout a 3-D volume. Over the last ten years, the technology has advanced from relative obscurity to demonstration levels for a variety of applications including breast imaging and animal brain imaging (*9, 10*). A natural extension of imaging the intrinsic optical contrast of tissue is to demonstrate the ability of photoacoustic imaging to detect contrast agents based on optically absorbing dyes that exhibit well-defined absorption peaks in the near-infrared (NIR). The ultimate goal of this work is to develop a NIR dye based, target-specific contrast agent that can be used as a PCT probe for cancer imaging.

The HER2 gene is among those most frequently altered in human cancer (*11, 12*). HER2 encodes a 185 KDa protein that resides on the surface of the cell and has receptor tyrosine kinase activity. The receptor, which is a member of the EGFR family, is expressed on the cell membrane of a variety of epithelial cell types, and through the binding of specific factors, regulates aspects of cell growth and division. The level of gene amplification is correlated with protein expression (*13, 14*). While HER2 is expressed in normal cells and several types of cancers, it is of particular interest in breast cancer (*15*). It has elevated levels in 25−30% of breast cancers, and is linked to unfavorable prognosis, shorter relapse time, and low survival rate (*11*). A breakthrough in the treatment of metastatic breast cancer occurred with the FDA approval of Herceptin (Genentech, South San Francisco, CA) in 1998. Herceptin is a humanized antibody that has a high binding affinity to the HER2 cell surface receptor. Binding of Herceptin to HER2 prevents the binding of the growth factors to the receptor, resulting in tumor growth inhibition. Herceptin is an excellent candidate for the development of a photoacoustic molecular probe because of its clinical relevance, and because there is currently no imaging methodology available for clinicians to image HER2 binding in humans (*16, 17*). However, the low HER2 receptor density limits the concentration of bound molecular probe, requiring a highly sensitive imaging system for detection. A second complication is the difficulty of identifying a suitable contrast agent for the monoclonal antibody.

NIR dyes of labeled Herceptin molecular probe may increase the localized optical absorption at their point of localization in tissue. When NIR dyes absorb light energy, electrons within the molecules jump to excited states and then promptly dissipate this energy in two prominent ways. A nonradiative pathway produces heat and subsequent thermal expansion in tissue, giving rise to the photoacoustic signal. The second path is a radiative (emission) pathway, known as fluorescence (*18*). Simple energy conservation considerations suggest that what is not released as heat must be released as light (fluorescence): the more fluorescent the sample, the smaller the photoacoustic waveform (*19*).

The fraction of the absorbed light energy that is reradiated as fluorescence is termed fluorescence quantum yield (QY). Often the fluorescence QY for NIR fluorescing dyes is very low, especially in the near-infrared. For example, the fluorescence QY for cyanine dyes that fluoresce within the optical imaging window is typically 10−15% (*20*). The remaining 85−90% of the absorbed energy is available for the photoacoustic waveform. If we increase the number of dye molecules per antibody (generally known as degree of labeling, DOL) to greater than 3, the fluorescence QY of the attached dye molecule will decrease further because of its self-quenching behavior in the excited state (*21*, *22*).

As Herceptin is a large molecule (185 KDa), it was anticipated that cell uptake would not be affected significantly if it is conjugated with several dye molecules. The NIR dyes with very low fluorescence QY appeared to be a good choice for PCT. By labeling Herceptin with several NIR dye molecules, a large NIR absorption may be achieved with less fluorescence. Thus, we hypothesized that NIR dye labeled Herceptin would be a suitable probe to detect breast cancer by PCT. Herein, we report the preparation and evaluation of Herceptin−dye conjugates with a broad range of DOLs as PCT probes for HER2 expressing breast cancer.

MATERIALS AND METHODS

Reagents. The amine-reactive dyes Alexa Fluor 750 (AF750) and AF647 were obtained as a dry powder from Invitrogen. One milligram of the dye was dissolved in 200 μL of anhydrous DMSO (Sigma St. Louis. MO) under reduced light conditions and stored at −80 °C. Herceptin antibody was obtained from Genentech (South San Francisco, CA).

Preparation of Herceptin−Dye Conjugates. All steps were performed under reduced light conditions. Covalent conjugation reactions contained 5 mg/mL Herceptin and various molar ratios of AF750 in 0.1 M bicarbonate buffer, pH 8.5. Reaction volume was ∼200 μL. Conjugation was initiated by addition of AF-750, followed by agitation (without frothing) for 2 h at RT. Dye-labeled Herceptin was purified by size-exclusion chromatography in Sephadex G-25 using (0.1 M) bicarbonate buffer as eluent. Purity of the probe was checked by discontinuous phase gel electrophoresis technique using a solution of free dye as standard. The degree of labeling (DOL) and the concentration of the conjugated Herceptin (mg/mL) were estimated using the extinction coefficients of Herceptin (ϵ_{280nm} = 225 000 M^{-1} cm^{-1}) and AF750 (ϵ_{749nm} = 240 000 M^{-1} cm^{-1}) in 0.1 M bicarbonate buffer, with correction for the 4.0% measured absorbance at 280 nm due to AF750:

$$\mathrm{DOL} = (\mathrm{Abs}_{749nm}/\epsilon_{749nm})/[(\mathrm{Abs}_{280nm} - 0.04 \times \mathrm{Abs}_{749nm})/\epsilon_{280nm}]$$

$$\text{Herceptin conc. (mg/mL)} = [(\mathrm{Abs}_{280nm} - 0.04 \times \mathrm{Abs}_{749nm})/\epsilon_{280nm}] \times \mathrm{MW}_{\mathrm{Herceptin}} \times \text{dilution factor} \quad (1)$$

Herceptin−AF647 conjugates were prepared in a similar way. DOL and concentration of conjugated Herceptin were estimated using the extinction coefficient of AF647 (ϵ_{650nm} = 239 000 M^{-1} cm^{-1}) in 0.1 M bicarbonate buffer, with correction for the 3.0% measured absorbance at 280 nm due to AF647.

$$\mathrm{DOL} = (\mathrm{Abs}_{650nm}/\epsilon_{650nm})/[(\mathrm{Abs}_{280nm} - 0.04 \times \mathrm{Abs}_{650nm})/\epsilon_{280nm}]$$

$$\text{Herceptin conc. (mg/mL)} = [(\mathrm{Abs}_{280nm} - 0.04 \times \mathrm{Abs}_{650nm})/\epsilon_{280nm}] \times \mathrm{MW}_{\mathrm{Herceptin}} \times \text{dilution factor} \quad (2)$$

Instrumentation for Probe Imaging in Solution. A protocol was developed to image AF-750 dye and dye−herceptin conjugates in solution. The imaging system was the Photoacoustic Spectrometry System (PASS) developed by OptoSonics, Indianapolis. Figure 1 shows the schematic diagram and imaging setup for the PASS system. The transducer array (custom 5.0 MHz, 128-element, Imasonic, France) was oriented vertically. The sample solution was held within a thin-walled FEP tube (Zeus, South Carolina, ID = 2.2 mm), and placed vertically in front of the array. The optical fiber was mounted so that

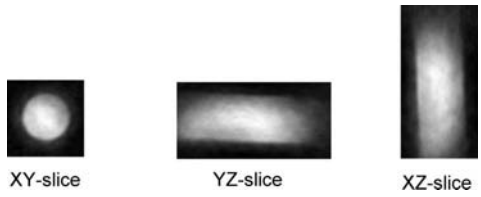

Figure 2. Representative PCT images of the Herceptin−AF750 conjugate in solution.

excitation light entered the side of the tank through a transparent glass window and hit the sample tube. The fiber output was first collimated with a lens and then reduced in intensity with a 12% neutral density (ND) filter thereby delivering a fluence of 6.2 mJ/cm^2 to the sample, which is about an order of magnitude greater than the fluence used typically in our fluorescence imaging device. Mylar film (0.0021/2 aluminized PET, >99% reflectance) was placed in front of the array to protect it from scattered light. The imaging tank was filled with water to provide an acoustic path. The imaging field of view (FOV) was roughly a cube with side length of 6 mm.

The first step in the reconstruction process is to compute the first temporal derivatives of the incident pressure waveforms $p_{\mathbf{r}}(t)$ from each of the 128 signals $p'_{\mathbf{r}}(t)$ recorded with the linear array. In practice, we do not measure $p_{\mathbf{r}}(t)$ directly, because the impulse response of the transducers used to record the thermoacoustic pressure was not a delta function. What we measure instead is $p_{\mathbf{r}}(t)$:

$$p'_{\mathbf{r}}(t) = p_{\mathbf{r}}(t) * i_{\mathbf{r}}(t) \tag{3}$$

where $i_{\mathbf{r}}(t)$ is the impulse response of the transducer at position $\mathbf{r}$ and * denotes convolution. We then compute $[\partial p_{\mathbf{r}}(t)]/\partial t$ in a single *filtering* step:

$$\frac{\partial p_{\mathbf{r}}(t)}{\partial t} \approx \mathrm{IFFT}\left[\frac{j\omega P'_{\mathbf{r}}(\omega)}{I_{\mathbf{r}}(\omega)}\right]\left[\frac{1+\cos\left(\frac{\pi\omega}{\omega_C}\right)}{2}\right] \tag{4}$$

where $I_{\mathbf{r}}(\omega)$ and $P'_{\mathbf{r}}(\omega)$ are the Fourier transforms of the transducer impulse responses and signals recorded by each transducer element, respectively, and $\mathbf{r}$ denotes the spatial locations at which each of the 128 pressure signals were recorded. The apodizing function $[1 + \cos(\pi\omega/\omega_C)]/2$ was used to bandwidth limit the signal to ω_c; in this case, $\omega_c = 8$ MHz. The last step in the reconstruction process is to back-project each of the $[\partial p_{\mathbf{r}}(t)]/\partial t$ computed using eq 4 over circular paths of radii $\tau_{\mathbf{r}}(x,y.z)*v_s$, where $\tau_{\mathbf{r}}(x,y.z)$ are the transit times for acoustic waves to travel from each volume element $(x,y.z)$ to each detector location $\mathbf{r}$, and v_s is the velocity of sound.

Dual-wavelength subtraction was used to remove reconstruction artifacts. Data were acquired at 32 evenly spaced angles by rotating the sample tube. Images were obtained at each angle at 745 and 810 nm. Four laser (Vibrant NIR OPOTEK, www.optek.com) pulses were averaged together at each wavelength to reduce the noise. A custom-designed laser output monitor used a reflective window to extract a small percentage of the laser light for measurement with an integrating sphere and photodiode. This allowed compensation for the variation of the laser output with wavelength and number of pulses. The image at 810 nm was subtracted from the 745 image with an experimentally determined scaling factor (k) based on measurements of the photoacoustic contrast of the DMSO buffer and the plastic holder at each wavelength. For these experiments, k was fixed to a value of 1.4, at which nearly all of the extraneous signals were removed as verified by analysis of the weighted PCT difference image in the absence of labeled cells. *In vivo* measurements would require a different scaling factor to account for the presence of hemoglobin. The measured resolution of the system was about 0.18 mm, significantly lower resolution than the reconstruction voxel size of 0.05 mm. For this reason, adjacent slices of the reconstructed image were averaged together before making quantitative measurements. A region-of-interest (ROI) tool was used to select a region in the center of the tube of the subtracted *XY*-slice image (Figure 2) and record the average and standard deviation values. Sample optical densities measured before and after the photoacoustic experiments were found to be the same, indicating that no photobleaching had occurred during photoexcitation.

Instrumentation for Cell Measurements. Figure 3 shows the imaging tank for the PCT-LIN system. The linear transducer array was mounted below the bottom of the clear PVC sample holder and oriented vertically upward. The optical fiber was mounted to the top of the sample holder assembly to deliver the laser directly down through the sample. The fiber output was first collimated and reduced in intensity with a 12% ND filter before reaching the sample. Mylar film in front of the array protected it from the direct beam. The sample holder assembly was positioned so the tip of the holder was at the region of greatest sensitivity, approximately 2 cm from the array face, as shown in Figure 3. The tank was filled with water to a level just below the sample holder. Figure 4 shows a detail of the sample holder assembly. The clear PVC sample holder had a thickness of approximately 0.02 in at the tip. It had a low optical absorption and gave a minimal photoacoustic signal in the NIR wavelengths. The diameter of the tip was less than 2 mm and the available sample volume was 100−150 μL. Figure 4a shows the exploded view of the assembly. The sample holder was suspended in the assembly so that no structural pieces were within the imaging field of view. The sample holder was conical and self-centering in the bottom aperture of the assembly. The cylindrical section was placed in the assembly after the sample holder and locked with a set screw to fix the holder in place.

We investigated two different techniques to resolve the signal of interest from the competing signals from artifacts and background sources. The first was dual-wavelength subtraction as previously described. The second was blank subtraction, whereby the sample holder was emptied, filled with buffer, imaged again, and the resultant image subtracted from the cell-filled image. In principle, the blank subtraction yielded a subtraction with somewhat higher signal, but it was sensitive to repositioning errors. In practice, we obtained the most robust results using the dual-wavelength technique.

Relative Quantum Yields (rQY). Relative fluorescence quantum yields (rQY-fl) or fluorescence per fluorophore of each dye−antibody conjugate were determined in comparison to that of the corresponding free dye, which was assumed to be 1. Fluorescence emission spectra were obtained from the samples of matched absorbance at the excitation wavelength (710 nm), and the integrated signals were normalized to that of the free dye to calculate rQY-fl. Absorbance was measured with an independent laboratory UV−vis spectrophotometer (Varian Cary 50, Palo Alto, CA). Fluorescence was measured with a Cary-Eclipse fluorimeter for AF750 conjugates.

In a similar way, the relative photoacoustic quantum yields (rQY-PA) or acoustic signal intensity per dye of each conjugate were determined by PASS in comparison to that of the corresponding free dye, which was assumed to be 1. Acoustic signals were obtained from the samples of matched absorbance at the excitation wavelength (745 nm for AF-750 conjugates) using photoacoustic instruments developed by OptoSonics Inc. Signals thus obtained were normalized to that of the free dye to calculate relative photoacoustic QY.

Fluorescence Measurement by Flow Cytometry. Fluorescence of the labeled HER2(+) cells was measured by flow

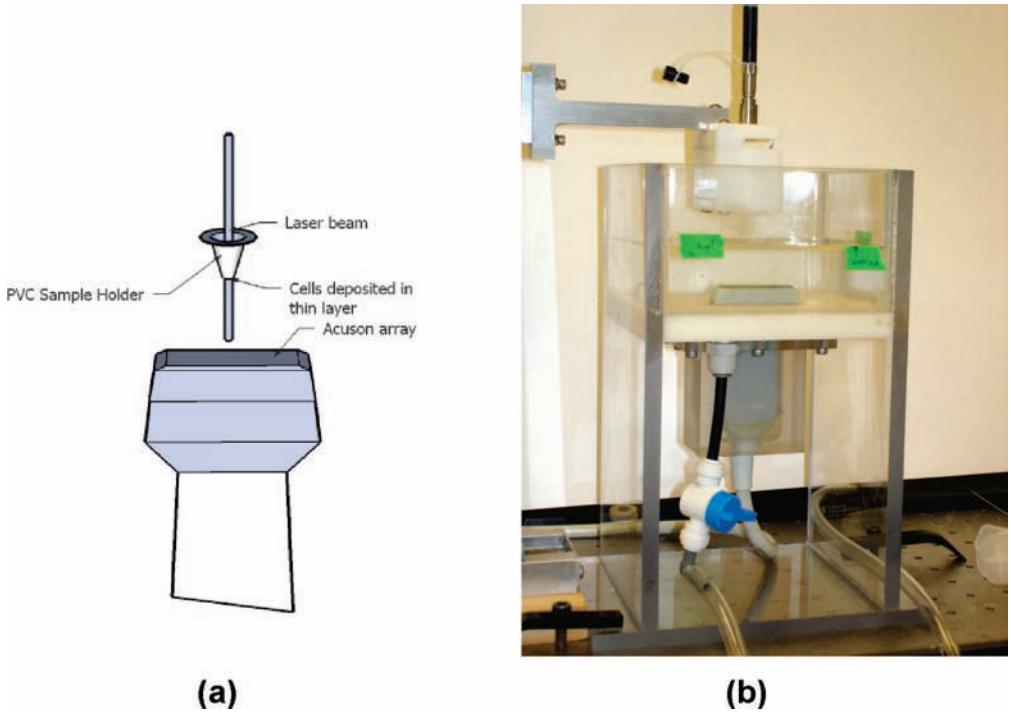

Figure 3. (a) Schematic diagram for PCT imaging of cells. (b) Instrument for PCT cell imaging.

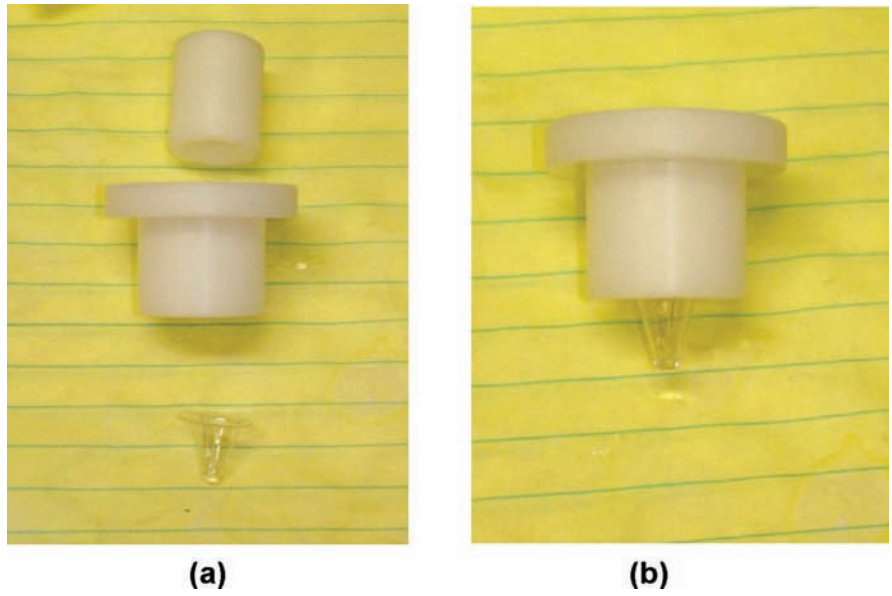

Figure 4. Sample holder assemblies for cell imaging.

cytometry. A direct comparison of fluorescence and photoacoustic signal could not be made using AF750-labeled Herceptin because the flow cytometer (FACS Calibur) could not operate at wavelengths exceeding 635 nm. For this reason, Herceptin was conjugated with AF647 dye in equivalent labeling conditions to those used for AF750. Approximately 0.5×10^6 breast cancer cells were incubated with ~50 μg probe (Herceptin-AF647) at 37 °C for 1.5 h. After labeling, cells were washed out three times by PBS, then the labeled cells were suspended in ~500 μL of PBS for flow cytometry measurements. Three measurements were made at each DOL. Suspension of corresponding unlabeled cells was used as control.

Cell-Binding Measurements by PCT. Both HER2 positive (MCF-7 and BT-474) and HER2 negative (MCF-7-PC-DMA and MDA-MB-231) cell lines were utilized for binding of the dye−Herceptin conjugates following standard cell culture protocols. Cells were maintained at 37 °C and 5% CO_2 in a humidified atmosphere. Approximately 0.5×10^6 breast cancer cells were incubated with ~50 μg probe (Herceptin-AF 750) at 37 °C for 1.5 h. After labeling, cells were washed out three times by PBS, then the labeled cells were suspended in PBS. Cells were counted in a Beckman Coulter cell counting machine before transferring to the sample holder. Finally, the cells were pelleted to the bottom of the sample holder by centrifugation.

For the AF-750−Herceptin-labeled cells, a 0.1 M solution of sodium bicarbonate in 25% DMSO was used. The labeled cells were transferred to the PCT sample holder so that the entire population could be contained in 100 μL of appropriate buffer. The sample was then centrifuged at 4000 rpm for 10 min. The cells formed a small layer at the tip of the holder. The sample holder was carefully placed in the assembly using the provided tool and one side of the holder was marked to designate this

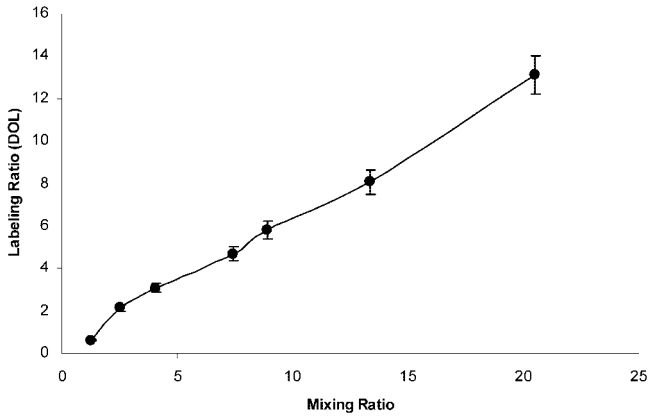

Figure 5. The dye (AF750) to protein (Herceptin) molar labeling ratio was measured at various dyes to protein molar mixing ratios.

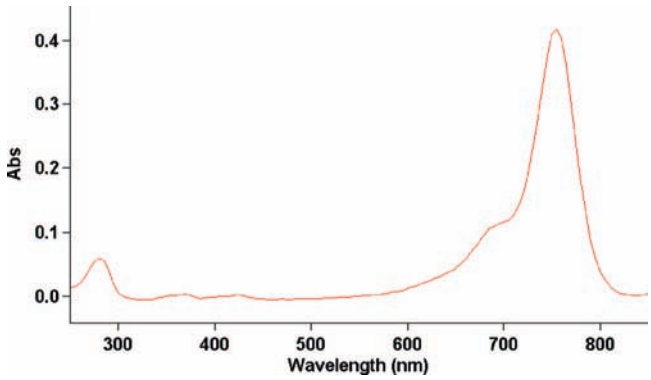

Figure 6. Representative UV−vis spectrum of Herceptin−AF750 conjugate (DOL 7) in 0.1 M bicarbonate buffer.

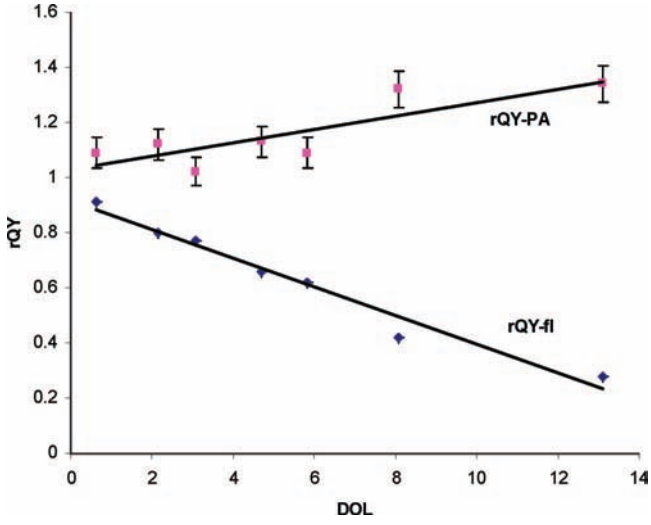

Figure 7. Per dye photoacoustic and per dye fluorescence signal intensity comparison with increase in DOL of Herceptin−AF750 conjugates.

orientation as 6 o'clock. The cylinder was inserted and locked in place. It was then placed in the imaging tank and rotated to align the index marks.

Images were acquired for the sample at 745 and 810 nm with 32 laser pulses per image. Then the 810 nm image was subtracted from the 745 nm image with an experimentally determined scaling factor (*k*) based on the varying absorption of the DMSO buffer (about 1.2 for PVC in 25% DMSO buffer). Nearly all of the extraneous signals were removed. The holder assembly was removed carefully by loosening the screw and

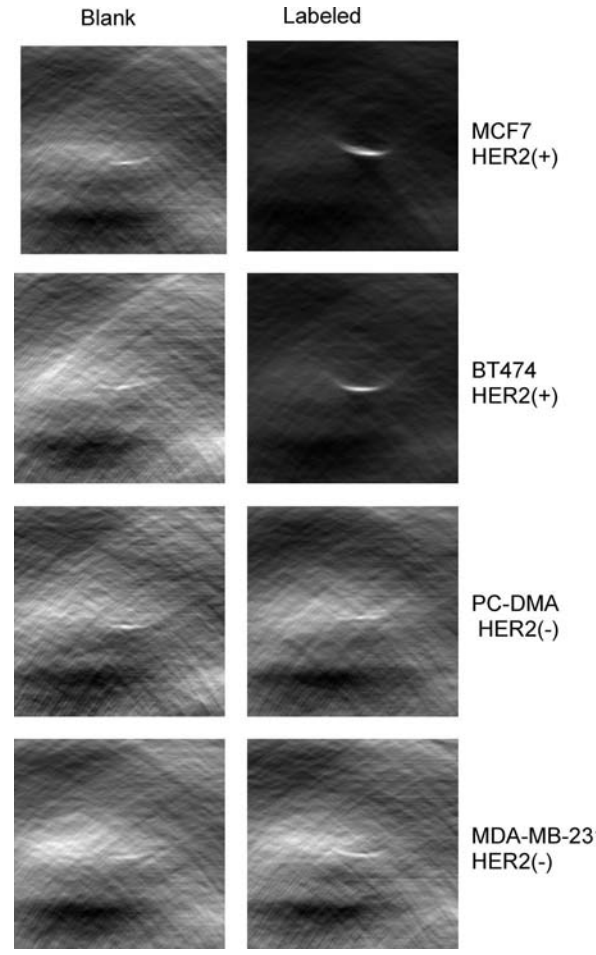

Figure 8. PCT images of HER2 positive and HER2 negative cell lines.

rotating the sample holder by 90° (3 o'clock) and two more images were obtained and subtracted as before. The same procedure was followed for the orientations at 180° (12 o'clock) and 270° (9 o'clock) from the initial position. We found no significant evidence of photobleaching of the sample for these 4 orientations. The ROI tool was used to take a small, thin ROI at the tip of the holder that corresponded to the layer of cells and the maximum value of photoacoustic intensities were measured. All 4 measurements from the different orientations were averaged together.

RESULTS AND DISCUSSION

After reactions of AF-750 or AF-647 with Herceptin, the products were isolated by gel filtration to a purity ≥98%. Increasing the dye to Herceptin molar ratio in the conjugation reaction over the range 2−21:1 resulted in increasing actual dye to antibody ratios, or degree of labeling (DOL), of 1−13:1 (Figure 5). A representative UV−vis spectrum of Herceptin−dye conjugate is shown in Figure 6.

In solution imaging of the probe, 25% DMSO in bicarbonate buffer was used to minimize the microbubble formation. Dye absorption maxima were at 745 nm, so the image obtained at this wavelength was due to dye and background (sample holder, microbubbles, etc.). At 810 nm, dye absorption was negligible; images obtained at this wavelength were indicative of the background. Corrected images of dye absorption were obtained by subtracting 810 nm image from the corresponding 745 nm images. For both solution and cell-binding measurements, the lambda subtraction technique worked effectively to eliminate background variation including microbubbles from the image.

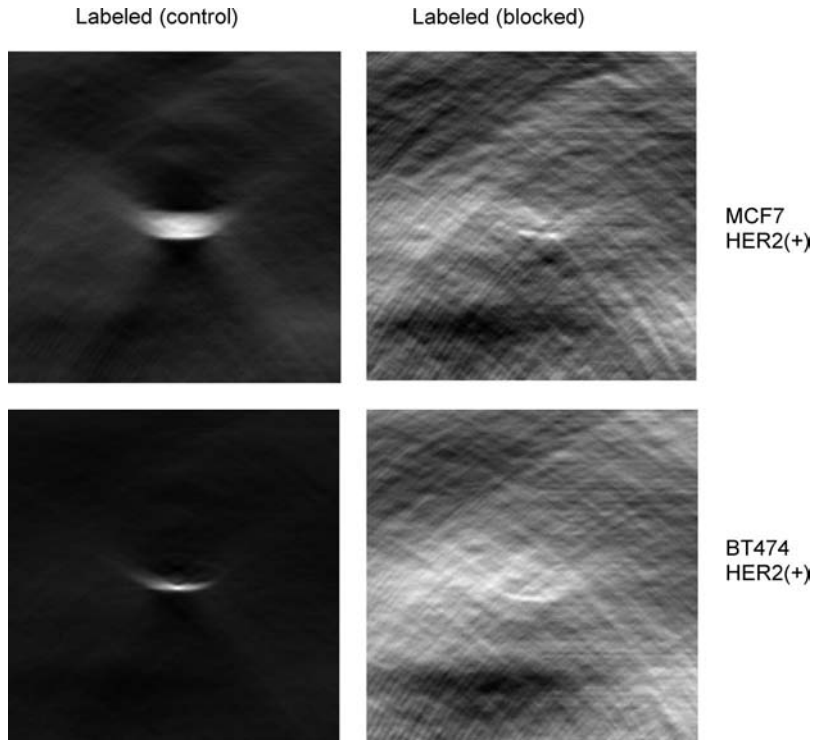

Figure 9. PCT images of unblocked and blocked HER2(+) cells.

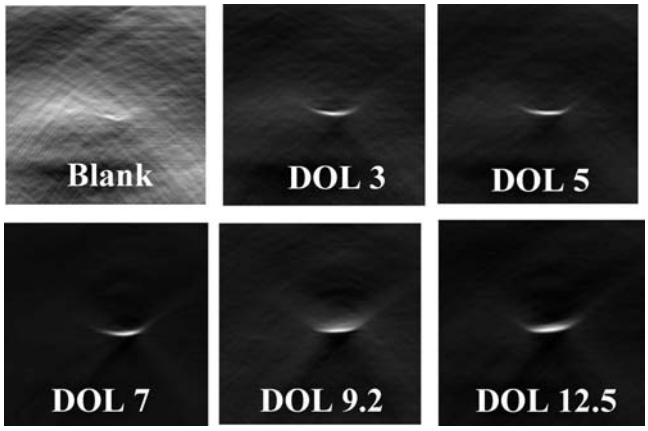

Figure 10. Representative PCT images of MCF7 HER2 positive cell lines at different DOL at constant no. of cells (0.2×10^6).

In cell-binding measurements, cells were packed to form a thin layer at the bottom of the sample holder by centrifuging using a hanging bucket rotor. Loose packing produced low-quality images. The sample holder could accommodate up to 0.3 million cells at the bottom to form a uniform layer. If the number exceeded 0.3 million, the layer became thicker, and the acoustic signal did not scale with the number of cells.

rQY-fl vs rQY-PA of AF750−Herceptin Conjugates. As the DOL increased, the fluorescence of any single fluorophore decreased when compared with free AF750 in solution. Comparative measurement between free Alexa Fluor dye molecules and Herceptin−Alexa Fluor conjugates in solution showed that with increasing DOL from 1 to 13, fluorescence intensity per dye (rQY-fl) gradually decreased (up to ~70%). Measurement of corresponding photoacoustic signal intensity (rQY-PA) per dye produced meaningful results. Though the data showed considerable noise, we observed that rQY-PA was gradually increased (up to ~25%) with increase in DOL (Figure 7). It is suggested that increased heat generated due to fluorescence quenching is the source of increased photoacoustic signal intensity per dye molecule.

Receptor Specificity of the Probe by PCT. HER2 positive (BT-474 and MCF-7) and HER2 negative (MCF-7-PC-DMA and MDA-MB-231) cell lines were incubated with Herceptin−dye conjugates (DOL 5). Approximately 0.2×10^6 cells of each cell line were used for cell imaging by PCT. In addition, blank samples, for which cells were not exposed to the probe, were imaged.

Figure 8 shows representative images of blank and labeled cell lines. Only HER2 positive cell lines gave high-intensity acoustic images. Signal intensity of HER2 negative cell lines was similar to that of corresponding unlabeled cells.

In a blocking experiment, HER2 positive (BT-474 and MCF-7) cells were at first incubated with unlabeled Herceptin for 1 h at 37 °C, then equal amount of Herceptin−dye conjugate (DOL 5) was added and incubated again for another 1.5 h.

PCT image intensities (Figure 9) showed that unlabeled Herceptin blocked >95% of the Herceptin−dye conjugate binding to the HER2 positive cells, demonstrating the specificity of labeled Herceptin binding to HER2. (Figure 10).

PCT Imaging of HER2 Positive Cells. In order to evaluate NIR dye labeled Herceptin as a PCT probe, HER2 positive cell lines were incubated with Herceptin−dye conjugates having different DOL, followed by PCT imaging. Equal numbers of cells (0.2×10^6) were used to determine the variation of acoustic signal intensity with increase in DOL of the probe. In Figure 10, cell imaging of MCF7 cells is shown. After subtraction of the PCT intensity corresponding to a sample with no probe (blank), signal intensity increased with increasing DOL (Figure 11). In contrast to this finding, fluorescence signal intensity from cells generally decreases for DOL greater than 3 (*21–23*). There was a slight upward exponential trend of the intensity vs DOL plots (Figure 11), indicating the tendency toward an increase in photoacoustic signal intensity per dye (Figure 7) as DOL is increased. The results also indicate that cell uptake of the probe does not appear to suffer from saturation effects at the HER2 receptors.

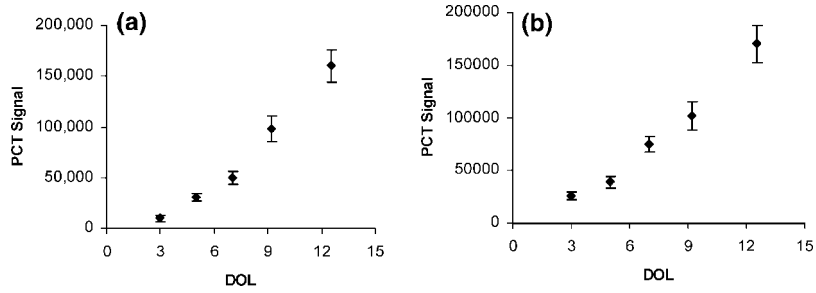

Figure 11. DOL vs peak photoacoustic signal intensity (arb. unit) of PCT images obtained by using ROI tool. Plot (a) is for MCF7 and plot (b) is for BT474 cell lines labeled with Herceptin−AF750 conjugates.

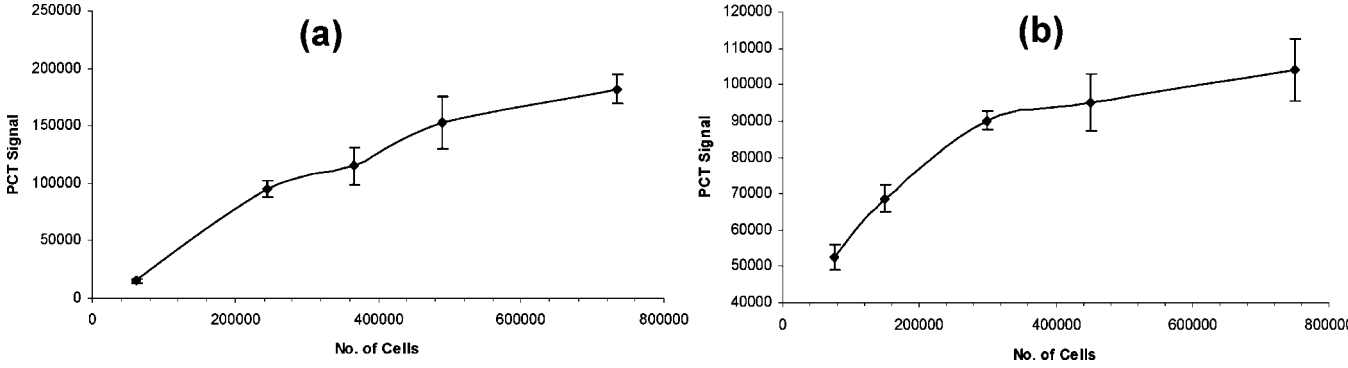

Figure 12. Change of PCT signal intensity with no. of cells at constant DOL: plot (a) BT474 HER2(+), DOL 6 (b) MCF7 HER2(+), DOL 4.5, and plot.

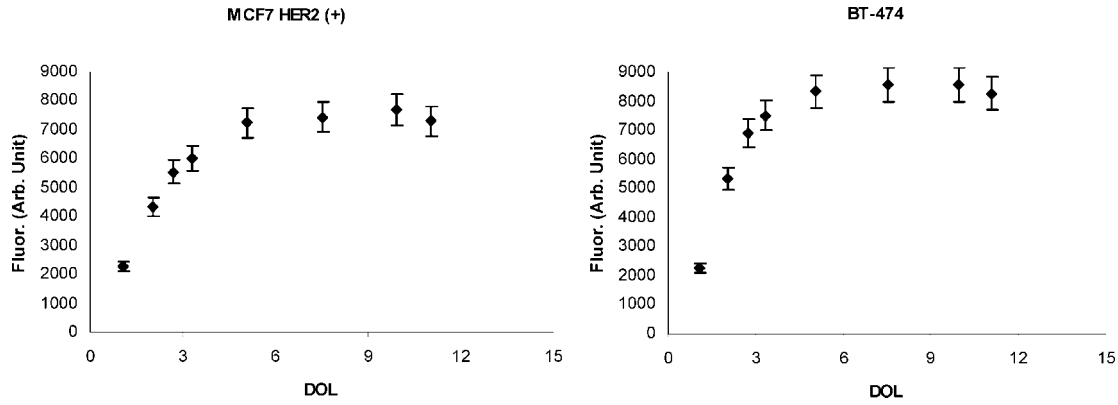

Figure 13. Fluorescence vs DOL of HER(+) cells labeled with Herceptin−AF647 conjugates obtained by flow cytometry.

Acoustic signal intensity was also varied with number of cells per sample while keeping DOL constant. The acoustic signal gradually increased with the number of cells up to of 0.3 million (Figure 12). Because of the narrow sample holder tip, when the number of cells exceeded 0.3 million, the cell layer became substantially thicker. The resultant signal plateaued because the layer was no longer contained within a thickness equivalent to the spatial resolution of the PCT system, i.e., 0.2 mm. This was verified by analyzing the apparent thickness of the PCT image of the cells. Experiments in the two HER2 positive cell lines yielded similar results.

The uncertainties of the PCT signals shown in Figures 11 and 12 were derived from four measurements made at different orientations for each sample. The signal was clearly dependent on the orientation the holder. For example, orientations at 6 and 12 o'clock gave similar PCT signal values, as did 3 and 9 o'clock orientations, but the two groups were distinct. The dependence on orientation was a function of the position relative to the linear array. For larger number of cells in the tube (Figure 12), the distinction of PCT signal between two groups became larger because the cells were less uniformly deposited on the bottom. We could typically see the layer creeping up one side of the tube as the number of cells increased. Our solution to this problem was to measure at four orientations and average the measurements.

Fluorescence and PCT Signal vs DOL of HER2(+) Cells. In order to compare PCT signal with fluorescence signal of the cells labeled by Herceptin−dye conjugates, we performed flow cytometry experiments to determine the fluorescence intensity per labeled cell. Because the flow cytometer (FACS Calibur) could not excite beyond 635 nm, AF647 was substituted for AF750 as labeling dye. AF647 and AF750 are almost equivalent in terms of their molecular weight and molar extinction coefficient. The flow cytometry data (Figure 13) for both cell lines indicated that fluorescence signal intensity reached a plateau higher DOL values, whereas PCT signal intensity (Figure 11) increased with DOL over the entire DOL range.

CONCLUSION

From this *in vitro* study, we have successfully demonstrated potential for NIR dye labeled Herceptin to be used as a PCT

probe for breast cancer. A large PCT signal with respect to control (cells with no probe) was obtained by labeling Herceptin with several dye molecules per molecule of protein. Unlike fluorescence, the photoacoustic signal gradually increased with increasing DOL of the dye. Moreover, it was shown that cellular binding to HER2 positive cell lines was maintained with increase in DOL of the dye over the range of 2 to 13. *In vivo* and *in vitro* studies with different low-fluorescence QY dyes are underway. It is believed that this labeling and detection scheme will be applicable to a broad class of biomolecules.

Before this technique can be translated to clinical applications, we will have to deal with two issues: obtaining sufficient SNR at depths of 2−3 cm in the breast, and accounting for hemodynamic variation within tumors. Phantom experiments suggest that we can detect dye concentrations in the 50−100 nM range at a depth of 30 mm. The confounding issues of hemodynamic variability can be mitigated to a large degree by choosing a differential pair of wavelengths that are 20−40 nm apart and straddle the falling edge of the dye absorption curve. In this case, the differential dye signal is maximized, while the differential hemoglobin signal is minimized. Work is ongoing to quantify these properties in greater detail.

ACKNOWLEDGMENT

Authors are thankful to Dr. Kathy D. Miller for providing breast cancer cell lines. This work is supported by National Institutes of Health: R01-CA108620 and R44-CA114839.

Functionalized Thermoresponsive Micelles Self-Assembled from Biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA for Tumor Cell Target

Cheng Cheng, Hua Wei, Jing-Ling Zhu, Cong Chang, Han Cheng, Cao Li, Si-Xue Cheng, Xian-Zheng Zhang,* and Ren-Xi Zhuo

Key Laboratory of Biomedical Polymers of Ministry of Education and Department of Chemistry, Wuhan University, Wuhan 430072, China. Received January 4, 2008; Revised Manuscript Received March 30, 2008

Novel micelles, comprising hydrophilic PEG shells, hydrophobic PMMA cores, and thermosensitive P(NIPAAm-*co*-HMAAm) segments were self-assembled from the biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA triblock copolymer. The thermosensitive micelles exhibited superior stability and showed thermotriggered drug release behavior upon temperature alterations. The fluorescence spectroscopy and confocal microscopy studies confirmed that the self-assembled biotinylated micelles can be specifically and efficiently bonded to cancer cells with the administration of biotin−transferrin, suggesting that the multifunctional micelles have great potential as drug carriers for tumor targeting chemotherapy.

INTRODUCTION

Traditional cancer chemotherapy relies on the premise that rapidly proliferating cancer cells are more likely to be killed by anticancer drugs. However, the nonspecific actions of the anticancer agents lead to systemic toxicity, causing undesirable severe side effects such as damage to liver, kidney, hair loss, and bone marrow (*1*). To reduce the side effects and to increase the local drug concentration at the targeting site, biotin−avidin systems (BAS) have been introduced to drug delivery systems to realize pretargeting in tumor chemotherapy (*2, 3*). Due to the considerable binding affinity between biotin and avidin, BAS can serve as a universal linkage between biotinylated polymeric drug carriers and other proteins. In the pretargeting approach, the biotinylated therapeutic carrier is administered after an appropriate delay, followed by the administration of active targeting ligands, such as avidin-conjugated monoclonal antibodies (*4*).

In the past decade, amphiphilic block copolymers have been extensively investigated with respect to fundamental research as well as biomedical applications (*5–14*). The unique character of the amphiphilic block copolymers enables them to self-assemble in an aqueous solution to form micelles (*15–20*). Due to the small size and the hydrophilic surface, polymeric micelles are not easily recognized and captured by the reticuloendothelial systems (RES) (*21, 22*). Accordingly, the polymeric micelles have a relatively long circulation time after intravenous administration and, as a result, they enrich in tumor tissues due to the enhanced permeation and retention effect (EPR effect) (*23*). Very recently, intelligent polymeric materials have been developed to be drug carriers for controlled release, such as stimuli-responsive polymeric micelles (*24–27*) and bioactive site-specific targeting carriers (*4, 28*). To date, as far as we know, very few studies deal with multifunctional drug carriers especially self-assembled polymeric micelles with both environmental sensitivity and specific targeting function (*29, 30*).

In this study, we designed and prepared a new type of multifunctional micelle as the drug carrier which not only has thermosensitivity, but also can be functionalized with a variety of ligands. The micelles were self-assembled by biotinylated amphiphilic biotin−poly(ethylene glycol)-*block*-poly(*N*-isopropylacrylamide-*co*-*N*-hydroxylmethylacrylamide)-*block*-poly(methyl methacrylate) (biotin-PEG-*b*- P(NIPAAm-*co*-HMAAm)-*b*-PMMA) triblock copolymer. The self-assembly and thermally induced change of the triblock copolymer micelle are schematically illustrated in Scheme 1. In the triblock copolymer, the PEG block was introduced as a hydrophilic segment due to its good biocompatibility and ability to stabilize the micelles and to protect them from being cleared up by the RES (*31*). Since the PEG shell was hydrophilic regardless of the temperature, the micelles self-assembled from the triblock copolymer would be more stable in water due to the fact that the PEG shell would prevent the aggregation of conventional PNIPAAm-based micelles once reaching the temperature above the LCST (*20, 32, 33*). Besides, the flexible PEG spacer offered an optimized accessibility for ligands (*28*). The PMMA block was used as a hydrophobic segment. The purpose to incorporate the poly(*N*-isopropylacrylamide-*co*-*N*-hydroxylmethylacrylamide) block was to endow the copolymer with thermosensitivity. Poly(*N*-isopropylacrylamide) (PNIPAAm) is known for exhibiting a reversible thermoresponsive phase transition in an aqueous solution at around 32 °C, termed lower critical solution temperature (LCST). However, such a LCST is not always favorable for biomedical applications since the physiologic temperature is around 37 °C. Herein, the hydrophilic *N*-hydroxylmethylacrylamide (HMAAm) was employed to adjust the LCST of the copolymer, since HMAAm is more hydrophilic, and an increase in its content would lead to a higher LCST. The

P(NIPAAm-*co*-HMAAm) block was hydrophilic when the temperature was lower than the LCST, and became hydrophobic when the temperature was higher than the LCST.

Furthermore, the biotin molecule was introduced to the micelle drug delivery system and BAS can be further used as reagents for pretargeting method in chemotherapy to increase the local concentration of drug at the target site resulting from the fact that active recognizing ligands can be incorporated into the drug delivery system through biotin−avidin interactions. In the pretargeting approach, the biotinylated drug carrier is administered after an appropriate delay, following the recognizing ligands conjugated with avidin, instead of coupling with them directly which may cause the denaturation of these ligands during the synthesis process in organic solvent. In addition, the delay allows for the antibody to localize and concentrate in the specific tissues, and then the thermoresponsive drug carrier can perform the controlled thermotriggered release by changing the environmental temperature.

MATERIALS AND METHODS

Materials. *N*-Isopropylacrylamide (NIPAAm), 3-mercaptopropionic acid (MPA), and 2-amino-ethanethiol hydrochloride (AET·HCl) purchased from Acros were used as received. Rhodamine B, *N*-hydroxymethylacrylamide (HMAAm), *N*-hydroxysuccinimide (NHS), and dicyclohexylcarbodiimide (DCC) were obtained from Tianjin Chemical Reagent Co. (Tianjin, China) and used as received. Biotin, dithiobis (succinimidyl propionate) (DSP), and fluorescein isothiocyanate-labeled avidin (FITC-avidin) were purchased from Pierce, and used as received. 1,1-Carbonyldiimidazole (CDI) and biotinylated transferrin (biotin-trasferrin) obtained from Sigma-Aldrich were used as received. *N*,*N*′-Dimethylformamide (DMF), methyl methacrylate (MMA), tetrahydrofuran (THF), and 1,4-dioxane obtained from Shanghai Chemical Reagent Co. were used after distillation. Diamine poly(ethylene glycol) (H_2N-PEG-NH_2) with a molecular weight of 3000 g/mol (in THF) and 4,4′-azobis-4-cyanovaleric acid (ACVA) were purchased from Fluka and used as received. Dithiothreitol (DTT) was obtained from Shanghai BoAo Biotechnical Co. Ltd. and used as received. *N*,*N*′-Azobisisobutyronitrile (AIBN) provided by Shanghai Chemical Reagent Co. (Shanghai, China) was used after recrystallization from 95% ethanol. MTX was kindly gifted by SuRi Biochem Co. Ltd. (Suzhou, China). All other reagents and solvents were used without further purification.

Preparation of Biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA. Amino-terminated biotinylated poly(ethylene glycol) (biotin-PEG-NH_2) was synthesized according to the literature (*24*). Biotin-PEG-NH_2 (1.77×10^{-4} mol) was dissolved in 3 mL DMSO. DSP (8.85×10^{-5} mol) in 3 mL of DMF was then added to the reaction flask to obtain biotin−PEG dimer and biotin−PEG was connected by disulfide bonds. The reaction mixture was stirred for 24 h at room temperature. The dimer was reduced by adding DTT (2.66×10^{-4} mol) to the reaction mixture and the reaction was carried out at room temperature for 24 h to obtain sulfhydryl-terminated biotinylated PEG (biotin-PEG-SH).

Carboxyl-terminated biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm) block was synthesized by copolymerizing NIPAAm and HMAAm (the molar ratio of NIPAAm and HMAAm is 10:1) by using ACVA as an initiator (*30, 31*) and biotin-PEG-SH as a macromolecular chain transfer reagent. Amino-terminated PMMA (PMMA-NH_2) was prepared by radical polymerization by using AET·HCl as a chain transfer agent. MMA (4.8×10^{-2} mol), AET·HCl (1.92×10^{-3} mol), and AIBN (2.4×10^{-4} mol) were dissolved in 20 mL DMF. The solution was degassed by bubbling with nitrogen for 30 min. Polymerization was carried out at 60 °C for 6 h. After reaction, the product was purified by repeated precipitation in water, and then the product was dried in vacuum.

The resulting carboxyl-terminated biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm) (0.10 g), PMMA-NH_2 (0.10 g), and NHS (4.0×10^{-5} mol) were dissolved in 4 mL dioxane. DCC (4.0×10^{-5} mol) in 1 mL dioxane was added dropwise to the solution under nitrogen atmosphere. After 24 h reaction at room temperature, the product was precipitated in excess diethyl ether and dried in vacuum after filtration.

GPC Measurements. Number-average molecular weight (M_n) of PMMA-NH_2, biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-COOH, and biotin-PEG-*b*-P(NIPAAm -*co*-HMAAm)-*b*-PMMA were determined by gel permeation chromatographic (GPC) system equipped with a Waters 2690D separations module and a Waters 2410 refractive index detector. THF was used as the eluent at a flow rate of 0.3 mL/min. Waters millennium module software was used to calculate molecular weight on the basis of a universal calibration curve generated by polystyrene standard with narrow molecular weight distribution.

Optical Absorption Measurements. Optical absorbance of the biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-COOH and biotin-PEG-*b*-P(NIPAAm-*co*- HMAAm)-*b*-PMMA copolymer aqueous solution (600 mg/L) at various temperatures was measured at 542 nm with a Lambda Bio40 UV−vis spectrometer (Perkin-Elmer). Sample cell was thermostatted in a refrigerated circulator bath at a predefined temperature prior to measurements. The LCST of the polymer solution was defined as the temperature producing a half-increase of the total increase in optical absorbance.

In Vitro Cytotoxicity Study. For each well in a 96-well plate, 200 μL of human vein endothelial cell line (ECV304) in RPMI1640, with a concentration of 2.5×10^5 cells/mL, was added. After incubation for 24 h in incubator (37 °C, 5% CO_2), The culture medium was changed to 200 μL of RPMI1640 containing biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA copolymer with a particular concentration and the mixture was further incubated for 48 h. Then, RPMI1640 with polymer was replaced by fresh RPMI1640 and 20 μL of MTT solution (5 mg/mL) and was added to the ECV304. After incubation for 4 h, 200 μL of DMSO was added and shaken at room temperature. The optical density (OD) was measured at 570 nm with a Microplate Reader (model 550).

Micelle Formation. Membrane-dialysis method was used to prepare micelles through self-assembly of biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA copolymer. In brief, the triblock copolymer (10 mg) was dissolved in 2 mL DMF. The solution was put into a dialysis tube (molecular weight cutoff: 8000−10 000 g/mol) and subjected to dialysis against 1000 mL distilled water for 24 h, then lyophilized before further examinations.

FT-IR and ^{1}H NMR Characterizations. FT-IR spectra were recorded on an AVATAR 360 spectrometer. Samples were pressed into potassium bromide (KBr) pellets. ^{1}H NMR spectra were recorded on a Mercury VX-300 spectrometer at 300 Hz using $CDCl_3$ and D_2O as the solvents.

Fluorescence Measurements. Fluorescence spectra were recorded on a LS55 luminescence spectrometer (Perkin-Elmer) and pyrene was used as a hydrophobic fluorescent probe (*20*). Aliquots of pyrene solutions (6×10^{-6} M in acetone,1 mL) were added to containers, and the acetone was allowed to evaporate. Ten-milliliter aqueous polymer solutions at different concentrations were then added to the containers containing the pyrene residue. It should be noted that all the aqueous sample solutions contained excess pyrene residue at the same concentration of 6×10^{-7} M. The solutions were kept at room temperature for 24 h to reach the solubilization equilibrium of

pyrene in the aqueous phase. Excitation was carried out at 340 nm, and emission spectra were recorded ranging from 350 to 600 nm. Both excitation and emission bandwidths were 10 nm. From the pyrene emission spectra, the intensities (peak height) of I_{373nm} were analyzed as a function of the polymer concentration.

Transmission Electron Microscopy (TEM). A drop of micelle suspension stained by a drop of 1% (w/v) phosphotungstic acid was placed on a copper grid with Formvar film and dried before observation on a JEM-100CXa transmission electron microscope (TEM) at an acceleration voltage of 80 kV.

Size Distribution Measurements. The size distribution of micelles was determined by a Nano Series Nano-ZS (MALVERN Instrument) zetasizer. The micelle aqueous solution (100 mg/L) was passed through a 0.45 μm pore-sized syringe filter and kept in the thermostat of the apparatus at 37 °C (±0.05 °C) for 20 min to reach the equilibrium prior to the measurements.

Drug Loading and In Vitro Drug Release. Biotin-PEG-*b*-P(NIPAAm-*co*- HMAAm)-*b*-PMMA triblock copolymer (10 mg) and MTX (5 mg) were dissolved in 2 mL DMF. The solution was put into a dialysis tube and subjected to dialysis against 1000 mL distilled water at 25 °C for 24 h. To determine the EE, the drug-loaded micelles solution was lyophilized, and then dissolved in DMF and analyzed by UV absorbance at 303 nm.

After dialysis, the dialysis tube was directly immersed into 400 mL distilled water. Aliquots of 4 mL were withdrawn from the solution periodically. The volume of solution was held constant by adding 4 mL distilled water after each sampling. The amount of MTX released from micelles was measured at different temperatures using UV absorbance at 303 nm.

Fluorescence Dye Loading. Biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA triblock copolymer (10 mg) and rhodamine B (5 mg) were dissolved in 2 mL DMF. The solution was put into a dialysis tube and subjected to dialysis against 1000 mL distilled water at 25 °C for 24 h. Then, the dye-loaded micelles were lyophilized before further measurements.

Cell Uptake Study. The dye-loaded freeze-dried micelles (200 μg) and FITC-avidin 100 μg were dissolved in 1.0 mL 0.01 M phosphate buffer saline (PBS, pH 7.4), respectively. Then the two solutions were mixed and shaken at room temperature for 30 min. The solution was centrifuged (10 000−12 000 r/min) for 15 min, and then the sediment was washed with cold PBS three times, and suspended again in 2.0 mL PBS as the FITC-labeled micelle samples. HeLa, A549, and ECV304 cells were seeded into a 24-well plate (1×10^5 cells/well) containing 1 mL of DMEM media to grow to ~70% confluence after 24 h incubation. 100 μL biotin−transferrin (200 μg/mL) was then added in each well and incubated with cells for 2 h at 37 °C. After the incubation, the medium was removed and cells were washed with cold PBS three times. Then, 1 mL DEME medium containing 100 μL FITC-avidin-rhodamine B loaded micelle complex was added in each well and incubated with cells for another 2 h at 37 °C. After that, medium was again removed and cells were washed with cold PBS three times. In addition, another plate of HeLa sample was administrated without the biotin−transferrin step for comparison. Finally, 1 mL of DMSO was added in each well to lyse cells. Fluorescence emission intensities of FITC at 490 nm and rhodamine B at 570 nm (LS55 luminescence spectrometer, Perkin-Elmer) provided means for the measurement of internalized FITC and rhodamine B levels.

Confocal Microscopy Observation. Cells were seeded into specific confocal investigation plates containing 1 mL DMEM media (1×10^5 cells/plate). Then the samples were treated in the same way of fluorescent spectroscopy analysis. The fluorescent images of cells were analyzed using laser scanning confocal microscopy (Leica TCS SP2AOBS, Germany).

Scheme 2. Synthesis of Biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA Triblock Copolymer

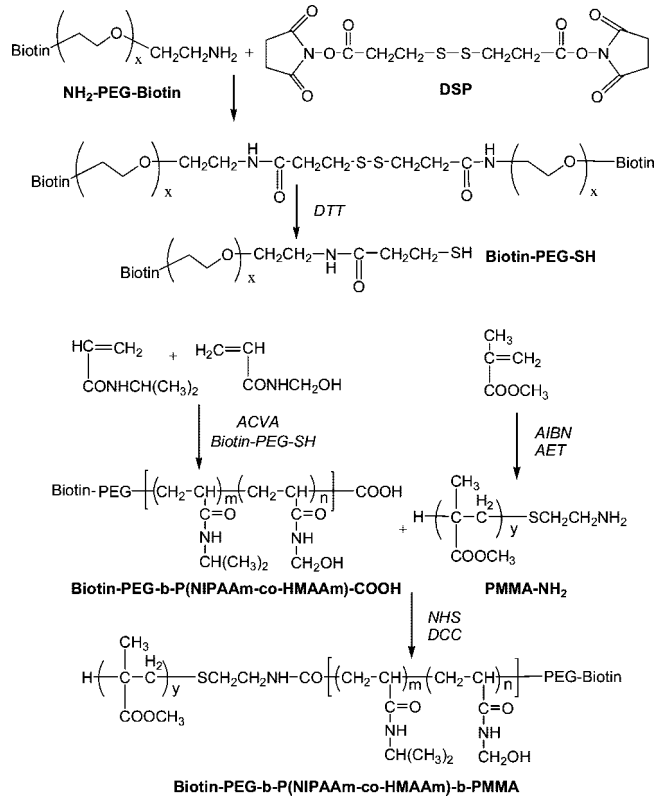

Table 1. GPC Data of Biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-COOH, PMMA-NH_2, and Biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA

sample	M_n	M_w/M_n
biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-COOH	11 032	1.6
PMMA-NH_2	5 473	1.7
biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA	15 484	1.8

RESULTS AND DISCUSSION

Synthesis of Biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA. Carboxyl-terminated biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm) block (biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-COOH) was synthesized by copolymerizing NIPAAm and HMAAm by using ACVA as an initiator and biotin-PEG-SH as a macromolecular chain transfer reagent. And amino-terminated PMMA (PMMA-NH_2) was prepared by radical polymerization by using AET·HCl as a chain transfer agent. Finally, the triblock copolymers of biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA were obtained by a condensation reaction between the carboxylic end groups of biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm) and amino end groups of PMMA. The detailed synthesis procedure is illustrated in Scheme 2. The block coupling was confirmed by molecular weights determined by GPC (Table 1) and ^{1}H NMR spectrum of biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA in $CDCl_3$ (Figure 4a), which reveals the presence of signals from PEG, P(NIPAAm-*co*-HMAAm), and PMMA blocks.

In addition, it can be seen from Figure 1 that the LCSTs of biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-COOH and biotin-PEG-*b*-P(NIPAAm- *co*-HMAAm)-*b*-PMMA were determined to be 43.1 and 40.8 °C, respectively.

Cytotoxicity Study. Cytotoxicity study was performed to evaluate the cytotoxicity of the biotinylated triblock copolymer.

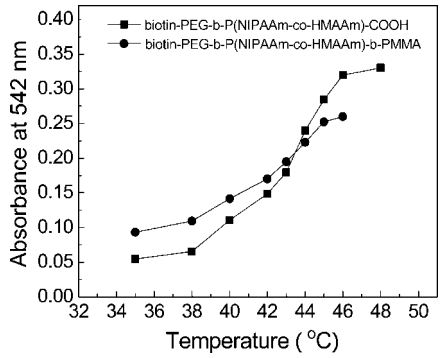

Figure 1. Optical absorbance of biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-COOH and biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA triblock copolymer in aqueous solutions/suspensions at various temperatures. (Polymer concentration was 600 mg/L).

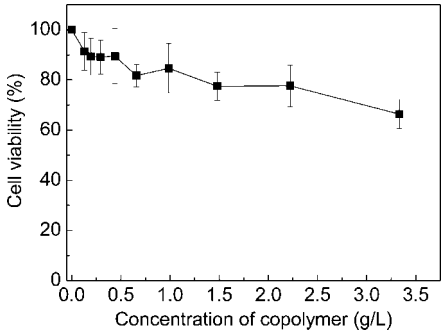

Figure 2. Cytotoxicity study of biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA triblock copolymer.

The effect of the polymer concentration on the proliferation of human vein endothelial cells (ECV304) was studied and it can be seen from Figure 2 that the cell viability was above 60% even when the copolymer concentration was as high as 3.3 g/L, suggesting that the copolymer exhibits no apparent cytotoxicity.

Micelle Formation. The structures of biotin-PEG-*b*-P(NIPAAm-*co*- HMAAm)-COOH, PMMA-NH_2, biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA block copolymer, and the resulting micelles were characterized by FT-IR. As exhibited in the FT-IR spectra, the absorbance of amide carbonyl groups in P(NIPAAm-*co*-HMAAm) occurs at 1650 cm^{-1}, and bending frequency of amide N−H appears at 1550 cm^{-1} (Figure 3a). Stretch vibration for C═O in ester in PMMA-NH_2 appears at 1730 cm^{-1} (Figure 3b). All the peaks mentioned above can be seen from the spectrum of biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA polymer (Figure 3c), which supports the formation of the triblock copolymers. Furthermore, it has been found that the absorbance of C═O in the ester segments is quite weak in the spectrum of biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA micelles (Figure 3d), as compared with that in the spectrum of copolymer. However, the typical peaks at 1550 and 1650 cm^{-1} from the P(NIPAAm-*co*-HMAAm) segment in the spectrum of micelle (Figure 3d) are as strong as those in the spectrum of biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-COOH regardless of the formation of micelles (Figure 3a). According to our previous study (*33*), the reason is that block copolymers form core−shell micellar structure with completely isolated hydrophobic inner cores and hydrophilic outer shells. Consequently, the peak for stretch vibration of C═O in the ester segments of micelles is apparently weakened.

^{1}H NMR analyses can provide another insight into the self-assembly process since aggregation may result in a decreased mobility of the core-forming block and a resultant suppression of the NMR signal intensities. The blocks in amphiphilic biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA possess disparate solubilities in selective solvents. Consequently, the NMR signals originating from all three blocks can be recorded when using $CDCl_3$. In contrast, the use of water as NMR solvent results in insufficient mobility and a suppression of the signals pertinent to PMMA block. In fact, as shown in Figure 4b, the use of water results in the total absence of characteristic NMR signals originating from PMMA block. This result indicates the formation of the well-defined core−shell structure of the block copolymer in aqueous solution, which exhibits a shell of biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm) and a core of PMMA.

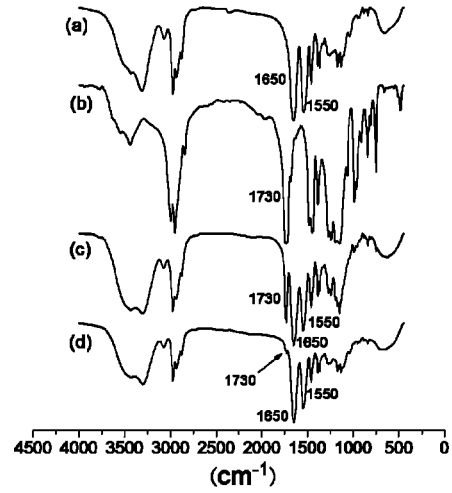

Figure 3. FT-IR spectra of (a) biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-COOH; (b) PMMA-NH_2; (c) biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA block copolymer; and (d) biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA micelles.

The formation of micelles from the triblock copolymers was also verified by a fluorescence probe technique using pyrene. In the emission spectra (Figure 5a), fluorescence intensity increases with increasing copolymer concentration, due to the fact that pyrene in water has a very small absorption, which increases when it is transferred into a hydrophobic environment. This effect also supports the proposed micelle formation. From the plot of fluorescence intensity versus polymer concentration (Figure 5b), fluorescence intensity is essentially constant at low concentration. Above a certain concentration, intensity increases dramatically, indicating formation of micelles and the transfer of pyrene into the hydrophobic core of the micelles. This concentration can be defined as the critical micellar concentration (cmc). The cmc value of the triblock copolymer obtained in this study is a low concentration of 8.5 mg/L, implying that the micelles could be used in very dilute aqueous media such as body fluids.

In a word, the results of fluorescence are in good agreement with those of FT-IR and ^{1}H NMR. From these results, we conclude that the triblock copolymers do form micelles in the aqueous media, which further conforms that the triblock copolymer was successfully synthesized because a physical mixture of the three polymers would lead to the separation in water.

Characterization of Polymeric Particles. As can be visualized by transmission electron microscopy (TEM) (Figure 6a), the self-assembled micelles are well-dispersed as individual particles with a regularly spherical shape. As shown in Figure 6b, the micelles exhibited a narrow size distribution with an average diameter of 195 nm (PDI 0.115). Compared with the size determined by the particle-size analyzer, the particle size observed by TEM is smaller. The variation in particle size measured by TEM and particle-size analyzer is attributed to the fact that dynamic light scattering (DLS) measurement of

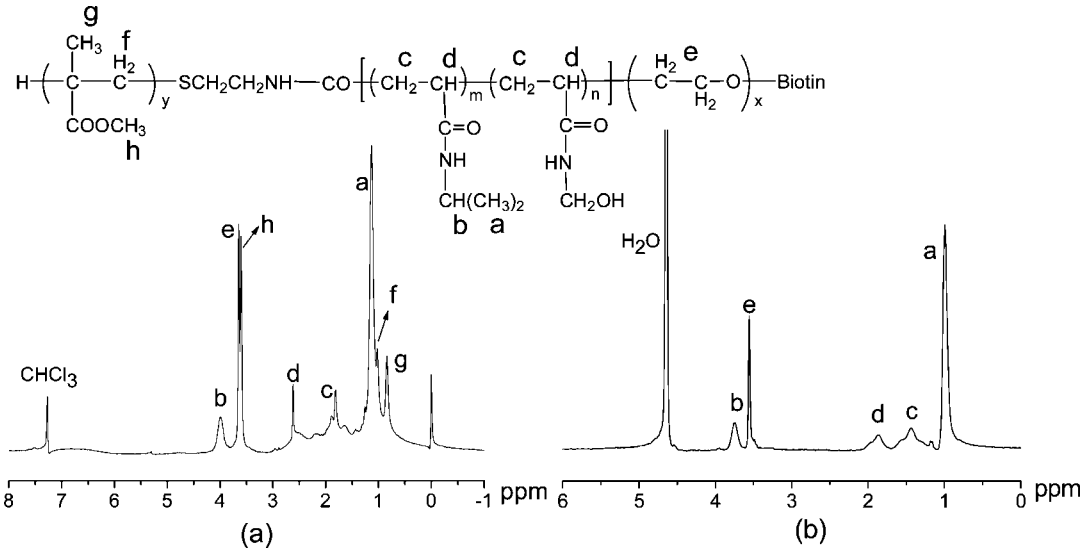

Figure 4. [1]HNMR spectra of biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA in (a) $CDCl_3$ and (b) D_2O, respectively.

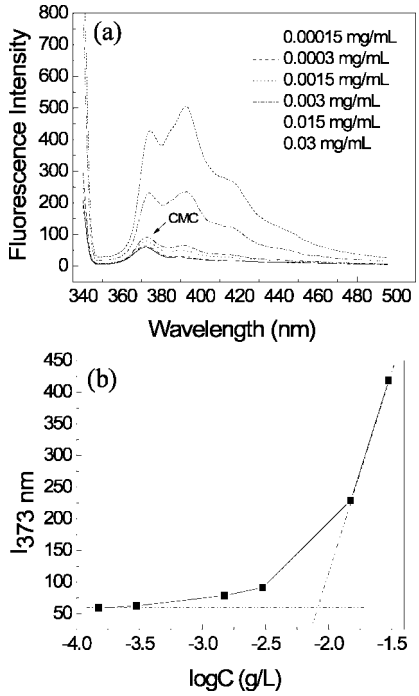

Figure 5. (a) Fluorescence emission spectra of pyrene with increasing concentration of biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA; (b) the intensity of I_{373} nm in the emission spectra as a function of logarithm of copolymer concentration.

the particle-size analyzer gives the hydrodynamic diameter rather than the actual diameter of the dried particles. Similar discrepancy in size was also reported in the literature (*34*, *37*, *38*). In order to provide direct evidence of the stability of the micelles formed by the triblock copolymers, we kept the micelles aqueous solution for 40 days at room temperature. No obvious change in the morphology of the micelles was observed after 40 days (Figure 6c), indicating the micelles have superior stability in aqueous solution at room temperature. Consistent with the TEM observation, it was found that the size (average diameter 186 nm) and the size distribution (PDI 0.070) were very similar to that obtained 40 days before (Figure 6d). This suggests that the superior stability of the micelles would be favorable for the practical biomedical applications.

In Vitro Drug Release. The thermotriggered drug release behavior of the biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA micelles was also investigated in this study. Methotrexate (MTX), a poorly water-soluble anticancer drug, was loaded in the micelles by the membrane-dialysis method at room temperature with entrapment efficiency (EE) of around 10%. The in vitro drug release property of the biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA micelles was evaluated at temperatures below (37 °C) and above (43 °C) the LCST of biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA micelle. The drug release profiles show drastic changes with temperature alterations as presented in Figure 7. Compared with the release at 37 °C, the drug release is accelerated dramatically at 43 °C due to the temperature-induced structural changes of the micelles. When the temperature increased above the LCST, the P(NIPAAm-*co*-HMAAm) segment becomes hydrophobic, which makes the hydrophilic shell of the micelle structure become thinner. As a result, the drug diffuses out quickly and about 92% of the drug is released from the micelles during 96 h at 43 °C.

Cell Uptake Study. Cervical cancer HeLa cells have been extensively characterized for intracellular delivery through receptor-mediated endocytosis using the iron-carrying protein transferrin for targeting (*39–41*). In the two-step pretargeting protocol, we used HeLa cells to study the intracellular uptake of the triblock copolymer micelles in vitro. Rhodamine B, a versatile fluorescence dye, was initially entrapped in the micelles during the dialysis at room temperature as a probe. FITC-labeled avidin was then associated with the rhodamine B loaded biotinylated micelles. Then after the preincubation of biotin−transferrin and HeLa cells, FITC-avidin-rhodamine B loaded micelle complex was infused to "chase" biotin−transferrin through the biotin−avidin interaction. Based on the fluorescence emission intensities of rhodamine B at 570 nm and FITC at 490 nm, the cell uptake of the FITC-avidin-rhodamine B loaded micelle was calculated as follows (*42*):

Uptake = [(concentration of the dye internalized into cells in each well)/(concentration of the dye added in each well)] × 100%

Human lung cancer cells (A549) and vein endothelial cells (ECV304) with the same administration procedure as well as the HeLa samples free of the preincubating with biotinylated transferrin were also studied for comparison. The cell uptake calculated by both fluorescence probes is presented in Figure 8. Based on the fluorescence probe of FITC, with the presence of biotin−transferrin, cell uptake values are 30.6% for HeLa, 9.4% for A549, and 8.7% for ECV304, respectively. On the

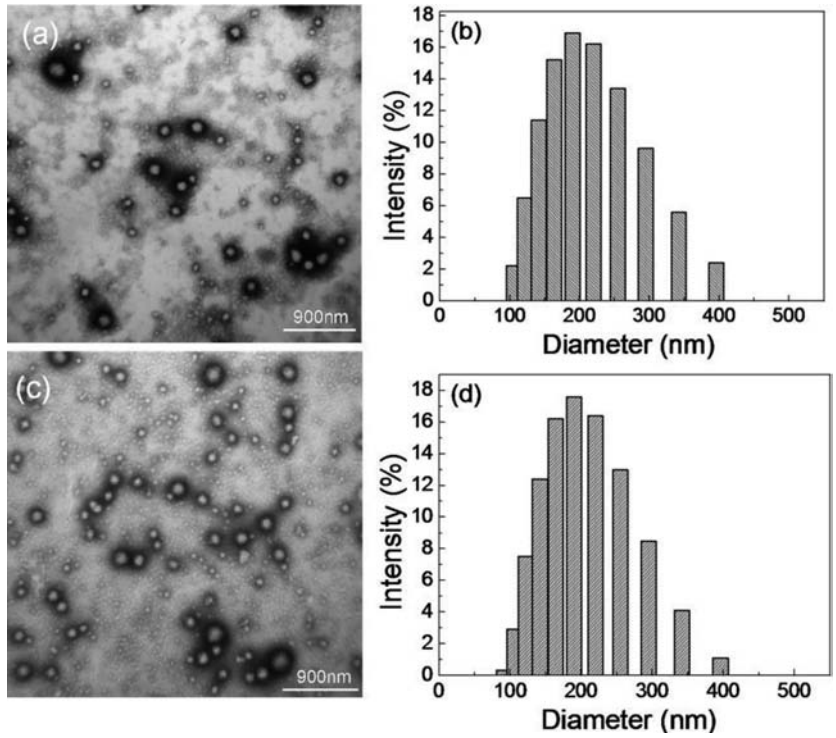

Figure 6. (a) TEM image and (b) size distribution of biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA micelles; (c) TEM image and (d) size distribution of biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA micelles self-assembled in an aqueous medium after 40 days.

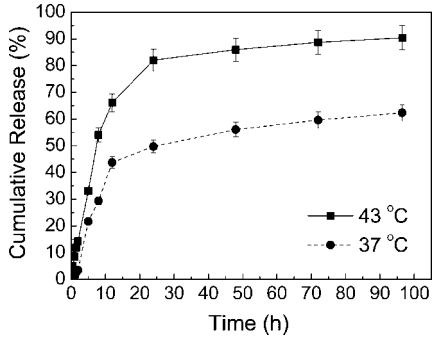

Figure 7. Drug release from the thermoresponsive biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA micelles loaded with MTX at different temperatures (37 and 43 °C).

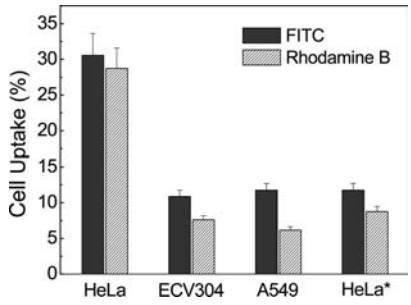

Figure 8. The rate of double fluorescence probes labeled triblock copolymer micelle drug carriers uptaken by different cells at 37 °C. HeLa* means Hela cells without the biotin-transferrin preincubating was used as the control.

contrary, in the absence of biotin−transferrin, the HeLa cell uptake is merely around 9.4%. And the above four results calculated from rhodamine B are 28.7%, 6.1%, 4.9%, 7.0%, respectively. These results were in close accord with that of the other fluorescence probe.

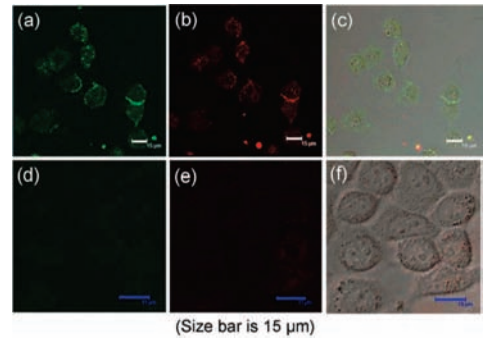

Figure 9. Confocal microscopy images of HeLa cells with pretargeting treatment incubated with FITC-avidin and rhodamine B loaded micelles under different observation conditions (a−c). Confocal microscopy images of HeLa cells without pretargeting treatment incubated with FITC-avidin and Rhodamine B loaded micelles under different observation conditions (d−f). The green fluorescence in images (a) and (d) represent the existence of FITC (FITC labeled avidin), and the red fluorescence in images (b) and (e) represent the existence of rhodamine B (rhodamine B loaded biotinylated micelle). (c) and (f) are the coalescent of bright-field and double fluorescence images, and the yellow fluorescence in them indicate the coexistence of green (FITC) and red fluorescence (rhodamine B).

Confocal Microscopy Observation. The internalization of the triblock copolymer micelles into HeLa cells was also visualized by confocal microscopy. After 2 h incubation with FITC-avidin-rhodamine B loaded micelle complex at 37 °C, HeLa cells pretreated with biotin−transferrin (Figure 9a,b,c) show remarkably more intense fluorescence in both cell membrane and cell cytoplasm than those free of biotin−transferrin pretreatment (Figure 9d,e,f), confirming the facilitation of the cell binding and internalization for the pretagerting approach. In the confocal images, the green fluorescence belongs to FITC (FITC labeled avidin), while the red fluorescence belongs to rhodamine B (rhodamine B loaded biotinylated micelle). Furthermore, the yellow fluorescence in Figure 9c shows the coexistence of green (FITC) and red fluorescence (rhodamine

B) indicating the intracellular delivery of dye (as poorly soluble drug model) by triblock copolymer micelles as well as the biotin molecule does exist in the copolymer since the micelle conjugate with FITC labeled avidin through the action of biotin. In addition, the confocal microscopy investigations of A549 and ECV304 are in a similar situation to Figure 9d,e,f. Overall, the qualitative results from double-fluorescence probe microscopy studies are in good agreement with the quantitative results obtained from fluorescence spectroscopy, substantiating the involvement of transferrin-mediated internalization in the cellular uptake of triblock copolymer micellar drug carrier.

CONCLUSIONS

In summary, novel micelles, comprising hydrophilic PEG shells, hydrophobic PMMA cores, and thermosensitive P(NIPAAm-*co*-HMAAm) segments were self-assembled from the biotin-PEG-*b*-P(NIPAAm-*co*-HMAAm)-*b*-PMMA triblock copolymer. The TEM observation and size distribution analysis illustrated the superior stability of the thermosensitive micelles. The polymeric micelles showed a thermotriggered drug release behavior upon temperature alterations ascribed to the thermoinduced structural change of the micellar structure. The pretargeting delivery property of the triblock copolymer micelles was investigated by fluorescence spectroscopy as well as confocal microscopy, and the results confirmed that the self-assembled micelles can be specifically and efficiently bonded to cancer cells with the administration of biotin−transferrin, suggesting that the multifunctional micelles have great potential as drug carriers for the tumor targeting chemotherapy.

Synthesis and Application of [^{18}F]FDG-Maleimidehexyloxime ([^{18}F]FDG-MHO): A [^{18}F]FDG-Based Prosthetic Group for the Chemoselective ^{18}F-Labeling of Peptides and Proteins†

2-[^{18}F]Fluoro-2-deoxy-D-glucose ([^{18}F]FDG) as the most important PET radiotracer is available in almost every PET center. However, there are only very few examples using [^{18}F]FDG as a building block for the synthesis of ^{18}F-labeled compounds. The present study describes the use of [^{18}F]FDG as a building block for the synthesis of ^{18}F-labeled peptides and proteins. [^{18}F]FDG was converted into [^{18}F]FDG-maleimidehexyloxime ([^{18}F]FDG-MHO), a novel [^{18}F]FDG-based prosthetic group for the mild and thiol group-specific ^{18}F labeling of peptides and proteins. The reaction was performed at 100 °C for 15 min in a sealed vial containing [^{18}F]FDG and *N*-(6-aminoxy-hexyl)maleimide in 80% ethanol. [^{18}F]FDG-MHO was obtained in 45−69% radiochemical yield (based upon [^{18}F]FDG) after HPLC purification in a total synthesis time of 45 min. Chemoselecetive conjugation of [^{18}F]FDG-MHO to thiol groups was investigated by the reaction with the tripeptide glutathione (GSH) and the single cysteine containing protein annexin A5 (anxA5). Radiolabeled annexin A5 ([^{18}F]FDG-MHO-anxA5) was obtained in 43−58% radiochemical yield (based upon [^{18}F]FDG-MHO, $n = 6$), and [^{18}F]FDG-MHO-anxA5 was used for a pilot small animal PET study to assess in vivo biodistribution and kinetics in a HT-29 murine xenograft model.

INTRODUCTION

Compounds labeled with short-lived positron-emitting radionuclides have extensively been utilized to target selective physiological and biochemical processes at the molecular and cellular level in vivo by means of positron emission tomography (PET) as the most advanced noninvasive imaging methodology. Besides numerous small molecular weight compounds, in recent years several radiolabeled molecules such as peptides, proteins, and aptamers have been proposed as highly target-specific PET imaging probes. In this context, various radiolabeled peptides and proteins, including antibodies and antibody fragments, have been used in nuclear medicine for imaging of tumors and inflammatory processes.

Within the spectrum of available positron emitters, fluorine-18 (^{18}F) is a particularly attractive radionuclide due to its favorable nuclear and chemical properties. ^{18}F can be produced in high amounts via several nuclear reactions in particle accelerators (cyclotrons) at high specific radioactivity. The low positron energy of 0.64 MeV results in low radiation doses and short tissue range, and the relatively long 109.7 min half-life allows complex and multistep radiosyntheses and scanning protocols extending 4 to 6 h. However, radiochemistry with ^{18}F focused on peptide and protein labeling also implies specific challenges. Thus, direct incorporation of ^{18}F at high specific radioactivity as [^{18}F]fluoride into peptides and proteins is hampered due to the harsh reaction conditions occurring during [^{18}F]fluoride labeling reactions. In order to circumvent this obstacle, peptide and protein labeling with ^{18}F is usually carried out by means of prosthetic groups, also referred to as bifunctional labeling agents (*1–6*). This approach involves ^{18}F incorporation into a small organic molecule capable of being linked to peptides, proteins, antibodies, and oligonucleotides under mild conditions. Such linkage of ^{18}F-labeled prosthetic groups can be accomplished via acylation (*6–18*), amidation (*19*), imidation (*20*), alkylation (*19–32*), photochemical conjugation (*6, 33–35*), and oxime (*36, 37*) or hydrazone formation (*38, 39*). Every linking method has its own advantage and limitations. Depending on the conjugation mechanism and the multitude of functional groups abundant in proteins (e.g., lysine residues), the chemoselective and regioselective introduction of the radiolabel into a defined position represents a special challenge. Moreover, the laborious, time-consuming, and multistep synthesis of most ^{18}F-labeled prosthetic groups represents another drawback, which has limited the availability and applicability of prosthetic groups in routine ^{18}F-labeling reactions.

As a consequence, the routine ^{18}F labeling of molecules like peptides and proteins should preferentially involve simple and efficient radiolabeling methods based on readily available prosthetic groups while allowing the chemo- and regioselective introduction of the radiolabel.

2-[^{18}F]Fluoro-2-deoxy-D-glucose ([^{18}F]FDG) is the most important radiotracer for PET imaging in nuclear medicine. Its highly efficient radiosynthesis makes this radiotracer available in almost every PET center worldwide. However, despite the convenient automated synthesis and almost unlimited availability of [^{18}F]FDG there are only very few examples using [^{18}F]FDG and peracetylated [^{18}F]FDG (1,3,4,6-tetra-*O*-acetyl-2-[^{18}F]fluoro-2-deoxyglucose) as building blocks for the radiosynthesis of ^{18}F-labeled compounds (Figure 1).

One of the first reports dealing with [^{18}F]FDG as ^{18}F building block was written by Borman et al. on the synthesis of β-*O*-D-galactopyranosyl-(1,4′)-2′-[^{18}F]fluoro-2′-deoxy-D-glucopyra-

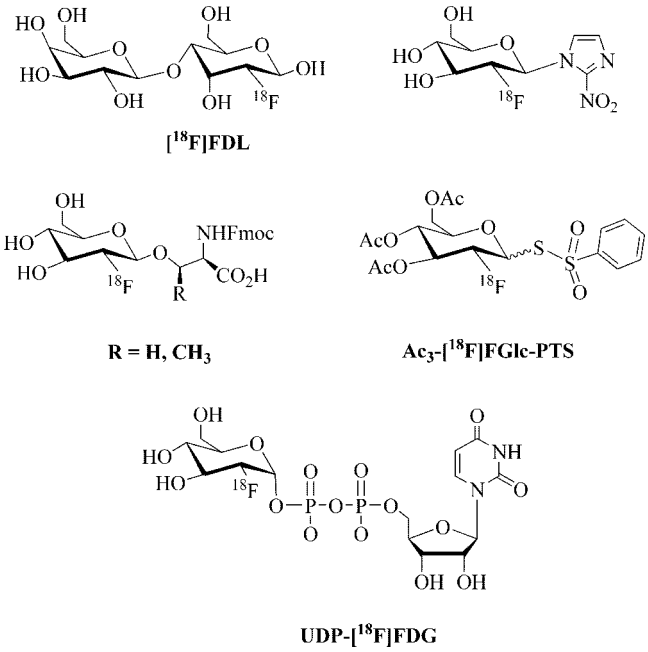

Figure 1. Structures of ^{18}F-labeled radiotracers synthesized starting from [^{18}F]FDG or peracetylated [^{18}F]FDG.

nose (2′-[^{18}F]fluoro-deoxylactose, [^{18}F]FDL) using an enzymatic reaction starting from [^{18}F]FDG (*40*). Although the obtained radiochemical yield was quite low (3.4% decay-corrected, starting from [^{18}F]FDG), the authors could perform preliminary biological evaluation of [^{18}F]FDL involving biodistribution studies in mice. Starting from peracetylated [^{18}F]FDG as ^{18}F building block, Patt and co-workers developed a FDG-based radiotracer for imaging hypoxia (*41*). HPLC-purified peracetylated [^{18}F]FDG was treated with 2-nitroimidazole in the presence of $Hg(CN)_2$ as a source for cyanide anion and the Lewis acid $SnCl_4$ to give a glucose-coupled 2-nitroimidazole intermediate. After removal of the acetyl protecting groups of the intermediate applying reaction conditions similar to the [^{18}F]FDG production method, the desired [^{18}F]FDG-coupled 2-nitroimidazole could be isolated and used in subsequent biological studies.

The use of peracetylated [^{18}F]FDG as building block in the radiosynthesis of ^{18}F-glycosylated amino acids serine and threonine has been reported by Prante et al. (*42, 43*). The authors describe two different reaction pathways involving either the reaction of an intermediate glucopyranosyl bromide with Fmoc-Ser-OH or Z-Ser-OBn in the presence of AgOTf or direct conversion of peracetylated [^{18}FDG] with Fmoc-protected serine or threonine in the presence of Lewis acid BF_3 into glycosylated amino acids. The glycosylation reaction involving a glucopyranosyl bromide intermediate according to a Koenigs-Knorr reaction afforded radiochemical yields of 67%, whereas the BF_3-mediated method provided significantly lower radiochemical yields of 27% suggesting the suitability of Koenig-Knorr reaction conditions for ^{18}F-glycosylation of protected bioactive peptides.

Another reaction with peracetylated [^{18}F]FDG was described by the same author aiming at the enzymatic synthesis of uridine-5′-diphospho-2-deoxy-2-[^{18}F]fluoro-α-D-glucopyranose (UDP-[^{18}F]FDG) (*44*). Starting from peracetylated [^{18}F]FDG, a MacDonald synthesis was used to prepare [^{18}F]FDG-1-phosphate which was successfully subjected to an enzymatic reaction to prepare UDP-[^{18}F]FDG. This method is also discussed as a highly selective and mild ^{18}F-labeling method for glycosylated biomolecules.

Very recently, 3,4,5-tri-*O*-acetyl-2-[^{18}F]fluoro-2-deoxy-D-glucopyranosyl 1-phenylthiosulfonate (Ac_3-[^{18}F]FGLc-PTS) was reported as a novel thiol-reactive reagent for the chemoselective ^{18}F-glycosylation of peptides (*45*). Ac_3-[^{18}F]FGLc-PTS was prepared in three steps in radiochemical yield of 33%. The feasibility of using Ac_3-[^{18}F]FGLc-PTS as a thiol-reactive agent was demonstrated through chemoselective bioconjugation to a cycteine-containing model pentapeptide and to the integrin $\alpha_V\beta_3$-affine peptide c(RGDfC). Both peptides could be labeled in conjugation yields greater than 90%.

The present study aims at the use of [^{18}F]FDG as a ^{18}F building block for the convenient synthesis of a thiol-reactive prosthetic group for the chemoselective conjugation to cysteine-containing peptides and proteins. In recent years, several maleimide-functionalized prosthetic groups have been shown to be especially suitable as chemoselective agents for the site-specific ^{18}F labeling of cysteine-containing peptides under mild reaction conditions (*19–22, 32, 46*).

Herein, we report on the use of [^{18}F]FDG as a suitable building block for the synthesis of ^{18}F-labeled peptides and proteins. The presented approach involves the design and synthesis of [^{18}F]FDG-maleimidehexyloxime ([^{18}F]FDG-MHO) as a novel [^{18}F]FDG-based prosthetic group for the mild and thiol group-specific ^{18}F labeling of peptides and proteins. The feasibility of [^{18}F]FDG-MHO as thiol group-reactive prosthetic group was assessed through the reaction with cycteine-containing tripeptide glutathione and with single thiol group-containing protein annexin A5 (anxA5). The present work is concluded with a pilot small animal PET study to assess biodistribution and kinetics of chemoselectively radiolabeled anxA5 in a human colorectal adenocarcinoma (HT-29) murine xenograft model in vivo.

EXPERIMENTAL METHODS

General. All commercial reagents and solvents were used without further purification unless otherwise specified. Nuclear magnetic resonance spectra were recorded on a Varian Unity 300 MHz spectrometer. ^{1}H and ^{19}F chemical shifts were given in ppm and were referenced with the residual solvent resonances relative to tetramethylsilane (TMS). Mass spectra were obtained on a Quattro/LC mass spectrometer (MICROMASS) by electrospray ionization. Thin-layer chromatography (TLC) was performed on Merck silica gel F-254 aluminum plates, with visualization under UV (254 nm).

[^{18}F]FDG was prepared according to refs (*47, 48*). HPLC analyses were carried out with a SUPELCOSIL LC-18S column (4.6 × 250 mm, 5 mm) using isocratic elution with CH_3CN/0.1 M ammonium formate (30/70) gradient pump L2500 (Merck, Hitachi) with a flow rate of 1 mL/min. The products were monitored by an UV detector L4500 (Merck, Hitachi) at 254 nm and by γ-detection with a scintillation detector GABI (X-RAYTEST). Semipreparative HPLC was performed with a Merck LiChroCart 250−10 column at a flow rate 4 mL/min. Solvent A: CH_3CN; solvent B: 0.1 M ammonium formate. The following gradient was used: 0 min 15% A, 20 min 70% A, 30 min 70% A. Radio-TLC analyses of glutathione coupling with [^{18}F]FDG-MHO was performed on Merck RP18 F-254 aluminum plates. Radio-sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) was performed according to published literature procedure (*32*). Aminooxy-maleimide hydrochloride **1** (*32*) and [^{18}F]FDG (*47, 48*) were prepared according to literature.

2-Fluoro-3,4,5,6-tetrahydroxyhexanal-*O*-[3-(2,5-dioxo-2,5-dihydropyrrol-1-yl)hexyl]oxime (FDG-MHO). 2-Fluorodeoxyglucose (50 mg, 275 μmol) and aminooxymaleimide × HCl **1** (69 mg, 277 μmol) were dissolved in 5 mL of EtOH/H_2O (4:1) and the resulting solution was refluxed for 1 h. The mixture was concentrated under reduced pressure. After the addition of water (50 mL), the mixture was passed through a C18 SepPak

cartridge. The cartridge was washed with water (10 mL) and the product was eluted with EtOH (2 mL). The solvent was evaporated to give 77 mg (75%) of the desired compound FDG-MHO as a colorless glass. ^{1}H NMR (400 MHz, CD_3OD) δ 7.48 (dd, 1H, J_{H-F} = 7.5 Hz, J_{H-H} = 6.1 Hz; =NHOR), 6.79 (s, 2H, CH=CH), 5.03 (dt, 1H, J_{H-F} = 48.4 Hz, J_{H-H} = 7.5 Hz; CH-F), 4.08 (dd, 1H, J = 7.1 Hz, J = 1.6 Hz), 4.05 (t, 2H, J = 6.6 Hz; =NO−CH_2), 3.77 (dd, 1H, J = 11.2 Hz, J = 3.4 Hz), 3.69 (m, 1H), 3.58−3.66 (m, 2H), 3.48 (t, J = 7.1 Hz, 2H; CH_2-maleimide), 1.53−1.67 (m, 4H, CH_2), 1.26−1.42 (m, 4H, CH_2). ^{13}C NMR (100 MHz, CD_3OD) δ 26.1, 27.3, 28.6, 29.3, 38.5, 62.5, 71.2 (d, J_{C-F} = 7.9 Hz), 71.7, 72.5, 91.4 (d, J_{C-F} = 169.9 Hz), 134.2, 145.8 (d, J_{C-F} = 23.7 Hz), 172.7. ^{19}F-NMR (376 MHz, CD_3OD) δ −61.67 (ddd, J = 45.8 Hz, J = 12.2 Hz, J = 6.1 Hz), LR-MS (ESI, positive): m/z 377.4 $[M+H]^+$, 399.3 $[M+Na]^+$.

2-[^{18}F]Fluoro-3,4,5,6-tetrahydroxyhexanal-*O*-[3-(2,5-dioxo-2,5-dihydropyrrol-1-yl)hexyl]oxime ([^{18}F]FDG-MHO). [^{18}F]-FDG solution in saline (1 mL, 400−700 MBq) was added to vial containing aminooxymaleimide hydrochloride **1** (5 mg, 13.3 μmol) in EtOH (4 mL). The vial was sealed and heated at 100 °C for 15 min. After evaporation of the solvent and addition of water (20 mL), the mixture was passed through a SepPak cartridge. The crude prudct was eluted with acetonitrile (1 mL) and subjected to semipreparative HPLC for purification. The peak eluting at 18−19 min was collected, diluted with water (20 mL), and passed through a SepPak cartridge. Elution with EtOH (1 mL) gave the desired product in high radiochemical purity (>95%). In a typical experiment, starting from 420 MBq of [^{18}F]FDG, 135 MBq of [^{18}F]FDG-MHO (42% radiochemical yield based upon [^{18}F]FDG) could be obtained within 45 min.

Radiolabeling of Gluthathione with [^{18}F]FDG-MHO. [^{18}F]FDG-MHO in ethanol (25 μL, 8 MBq) was added to 900 μL of glutathione solutions (1.0 mg/mL up to 10 ng/mL) in phosphate-buffer (pH = 7.2) and incubated at room temperature. The progress of the reaction was monitored by radio-TLC after 10 min. Radio-TLC: R_f = 0.8, CH_3CN/water (80/20).

Radiolabeling of anxA5 with [^{18}F]FDG-MHO. [^{18}F]FDG-MHO in ethanol (25 μL, 18−20 MBq) was added to 100 μL of anxA5 solution (1.0 mg/mL recombinant AnxA5 (kind gift from Dr. Nediljko Budisa), isolated from *Escherichia coli* B834 (DE3), transformed with plasmid pASET-pp4, as described by Burger et al. (*49*)) in 0.05 mol/L Tris-HCl (pH 7.4) and incubated for 30 min at room temperature. The reaction mixture was applied to size exclusion chromatography (Äkta Prime plus, HiTrap Desalting column 5 mL) and eluted with phosphate-buffered saline (pH 7.2; 0.5 mL/min). The collected high molecular weight fractions were combined to give 6−8 MBq (44−58%, decay-corrected, based upon [^{18}F]FDG-MHO) of radiolabeled anxA5. Radiochemical purity radiolabeled anxA5 was greater 95% as determined by radio-sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). The isolated product was directly used for small animal PET imaging studies.

Small Animal PET Imaging of ^{18}F-labeled anxA5. Dynamic small animal PET studies were performed with a dedicated PET scanner for small animals (microPET P4, Siemens Preclinical Solutions, Knoxville, TN, USA). For imaging studies, mice were anesthetized with a desflurane 10% oxygen/40% air mixture and catheters with hypodermic needle were placed into a tail vein. The animals were then positioned and immobilized prone with their medial axis parallel to the axial axis of the scanner on a heated bed. In a typical experiment, 1 MBq of [^{18}F]FDG-MHO-anxA5 was administered in a total volume of 0.5 mL over 1 min using a programmable syringe pump 30 s after start of the PET data acquisition. Dynamic PET scanning was carried out for 14 400 s (4 h), using the following time intervals (frames) for sinogram generation: 15 × 10 s, 5 × 30 s, 5 × 60 s, 4 × 300 s, and 21 × 600 s. The PET data were reconstructed using a 3D OSEM MAP iteration algorithm provided by the PET scanner producer. The image data were evaluated with the program ROVER (ABX GmbH, Radeberg, Germany) to get 3D regions of interest (ROI) of tissues of interest. The time activity concentration curves and the activity amounts were further processed using software written in the R language (R Development Core Team: R: A Language and Environment for Statistical Computing, http://www.R-project.org, R Foundation for Statistical Computing, Vienna, Austria (2007). ISBN 3−900051−07−0.).

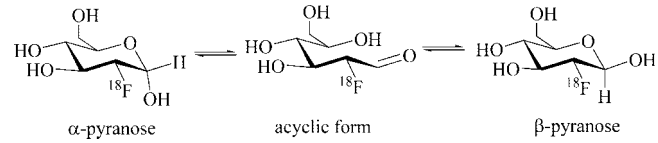

Figure 2. Proposed mutarotation of glucose analogue [^{18}F]FDG via an acyclic form.

RESULTS AND DISCUSSION

[^{18}]FDG as the most important PET radiotracer for in vivo imaging of glycolysis in nuclear medicine has found multiple applications in the fields of oncology, neurology, and cardiology. In aqueous solutions, [^{18}F]FDG consists of a mixture of α/β anomers. The process behind the equilibration between the α anomer and the β anomer is known as mutarotation. Mechanistically, the isomerization must proceed with ring opening via a small concentration of the acyclic form (Figure 2). To the best of our knowledge, however, the exact amount of each isomeric form of [^{18}F]FDG in aqueous solution is still not known yet.

In the case of D-glucose, in aqueous solution at room temperature the amounts of the α and β anomers were determined to be 38% and 62%, respectively. The amount of the acyclic form is reported to be as little as 0.003% (*50*).

A comparable situation should be expected for the glucose analogue [^{18}F]FDG. Although presumably available in only very small amounts, in principle the open chain aldehyde form of [^{18}F]FDG should allow chemoselective aldehyde group-based reactions. A very prominent and chemoselective reaction represents the aminooxy−aldehyde coupling reaction to yield the corresponding oxime. Recently, the chemoselective oxime formation was shown to be a promising and versatile approach for both the convenient synthesis of ^{18}F-labeled prosthetic groups (*20, 32*) and the direct ^{18}F-labeling of aminooxy group-functionalized peptides (*36*) with readily available 4-[^{18}F]fluorobenzaldehyde.

Likewise, chemoselective reaction between the acyclic aldehyde form of [^{18}F]FDG with aminooxy group-containing compound **1** should lead to the corresponding oxime derivative [^{18}F]FDG-MHO. However, in the case of hexoses as aldehyde components in the aminooxy−aldehyde coupling reaction the formation of isomeric products must be considered. Hence, Ramsay et al. observed the formation of three isomeric products with identical molecular mass when they investigated the reaction of *O*-(4-(nitrobenzyl)-hydroxylamine with glucose at pH 4 (*51*). The observed isomers were proposed to be a mixture of *E*- and *Z*- acyclic oximes and α- and β-cyclic products (pyranoses and furanoses, respectively.). Accordingly, chemoselective condensation between the hexose FDG and aminooxy-functionalized maleimide **1** should also lead to a mixture of isomers as shown in Figure 3.

Synthesis of the Reference Compound FDG-MHO. Reference compound FDG-MHO was prepared by heating equimolar amounts of [^{19}]FDG and aminooxy compound **1** in EtOH/H_2O (4:1) for two hours. After solid-phase extraction using a C18

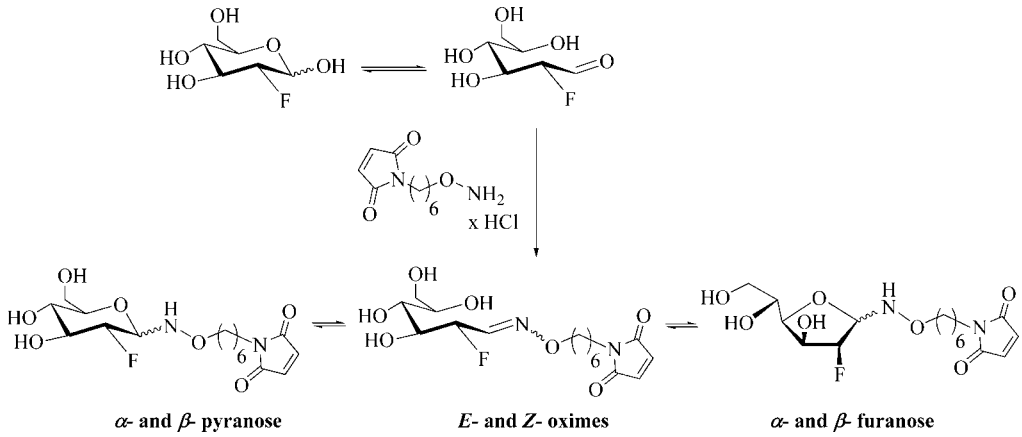

Figure 3. Proposed isomer formation through aminooxy−aldehyde coupling reaction involving FDG.

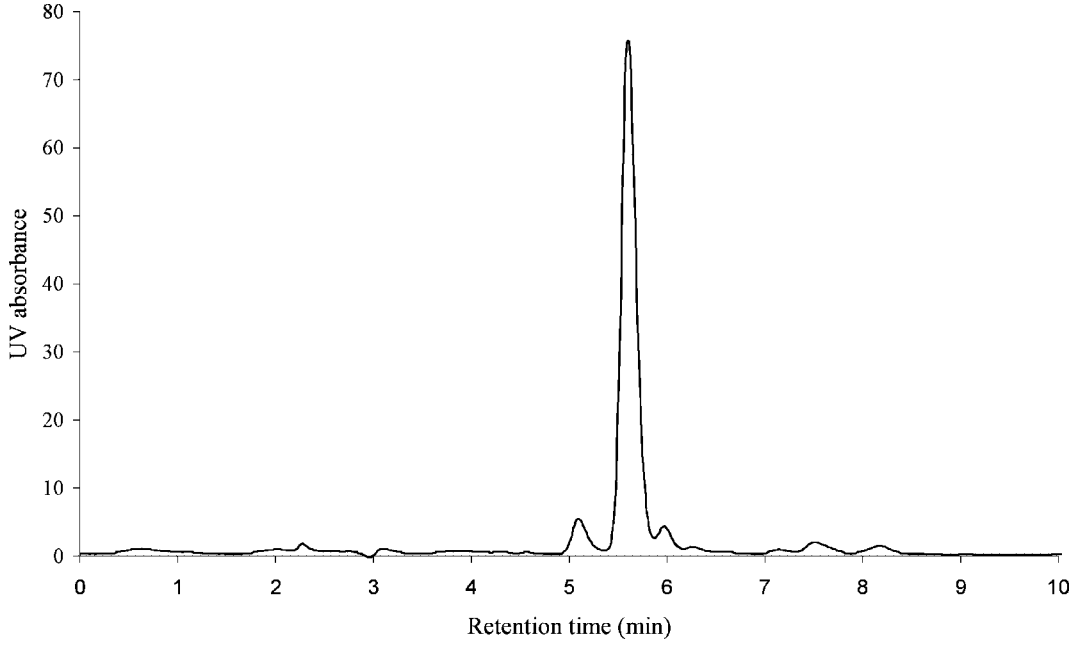

Figure 4. HPLC analysis of isolated product of the aminooxy−aldehyde coupling reaction with FDG.

SepPak cartridge and evaporation of the solvent, the desired reference compound FDG-MHO was obtained as a glass in 79% yield. HPLC analysis of the product indicated, however, the formation of several compounds consisting of a major product (>90%, t_R = 5.6 min) accompanied by at least two smaller peaks at retention times of 5.1 and 6.0 min, respectively (Figure 4).

The three peaks were collected and subjected to mass spectrometric analysis (ESI, positive). The peaks at 5.1 and 5.6 min showed identical mass peaks of *m*/*z* 377.4 ([M+H]$^+$) and *m*/*z* 399.35 ([M+Na]$^+$), respectively, suggesting the formation of at least two isomers. The formation of isomers during the aminooxy−aldehyde conjugation reaction between the hexose FDG and aminooxy compound **1** in aqueous media is in accordance with the report by Ramsay et al. (*51*). However, NMR analysis of the isolated reaction product in CD_3OD shows only one distinct compound. In the ^{1}H NMR spectra, the observed characteristic doublet−doublet coupling pattern (J_{H-F} = 7.5 Hz, J_{H-H} = 6.1 Hz) at 7.48 ppm correlates with one proton as expected for an oxime proton (=N*H*−OR). No signals were found which would refer to the formation of related pyranose or furanose isomers as depicted in Figure 3. It is known from the literature that oxime protons of *E*- and *Z*-isomers show characteristic chemical shift differences, being, e.g., 7.56 ppm for the *E*-isomer and 6.95 ppm for the *Z*-isomer (*52*). The observed more downfield shifted signal at 7.48 ppm would agree with an *E*-isomer oxime proton. Consequently, we conclude that the product possesses an open-chain *E*-oxime structure.

Radiosynthesis of [^{18}F]FDG-MHO. The radiosynthesis of [^{18}F]FDG-MHO is given in Figure 5.

The reaction is based on treatment of a [^{18}F]FDG solution, which was prepared according to the well-established [^{18}F]FDG synthesis (*47*, *48*), with aminooxy-functionalized compound **1**. Notably, the used [^{18}F]FDG solution contains substantial amounts of D-glucose (50−70 μg per milliliter [^{18}F]FDG solution) as typically formed during the [^{18}F]FDG production process starting from mannose triflate and subsequent basic hydrolysis. Therefore, formation of the corresponding glucose product must be considered. The formation of the glucose product was confirmed through LC-MS (ESI, positive) analysis of the collected mass peak (*m*/*z* 375.2 [M+H]$^+$, *m*/*z* 397.4 [M+Na]$^+$) in the semipreparative HPLC (t_R = 19−21 min). To avoid complete consumption of the amino-oxy labeling precursor by the reaction with glucose, the amount of labeling precursor has to be sufficiently high to give the desired [^{18}F]FDG-MHO compound in satisfactory radiochemical yields. Thus, best results were obtained when at least 10 mg (40 μmol) of compound **1** per milliliter [^{18}F]FDG solution was used. The

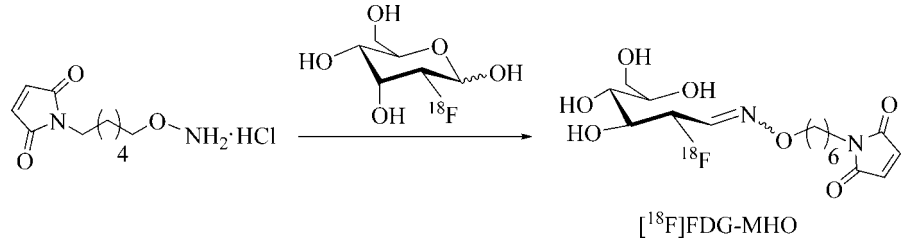

Figure 5. Radiosynthesis of [^{18}F]FDG-MHO.

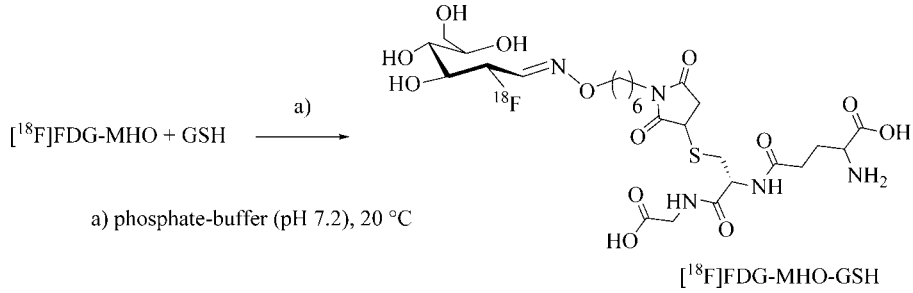

Figure 6. Radiolabeling of GSH with [^{18}F]FDG-MHO.

Table 1. Radiolabeling of GSH with [^{18}F]FDG-MHO

GSH concentration	1 mg/mL	100 μg/mL	10 μg/mL	1 μg/mL	100 ng/mL	10 ng/mL	1 ng/mL
% Product	>95	>95	>95	>95	92	47	38

reaction proceeded best in 80% ethanol as the solvent at 100 °C for 15 min. After semipreparative HPLC purification desired [^{18}F]FDG-MHO could be isolated in 45−69% radiochemical yield based upon [^{18}F]FDG (decay-corrected) within 45 min in high radiochemical purity (greater than 95%).

The obtained radiochemical yield of 45−69% for [^{18}F]FDG-MHO is comparable with related maleimide-containing ^{18}F prosthetic groups such as *N*-{4-[(4-[^{18}F]fluorobenzylidene)-aminooxy]butyl}maleimide (*20*), [^{18}F]FBAM (*32*), [^{18}F]FPyME (*21*), and [^{18}F]FBEM (*46*). However, the facile availability of [^{18}F]FDG as the labeling precursor in the coupling reaction circumvents the laborious preparation of ^{18}F-labeled precursors such as 4-[^{18}F]fluorobenzaldehyde, [^{18}F]fluoropyridine derivatives, or [^{18}F]SFB as intermediates required for the synthesis of *N*-{4-[(4-[^{18}F]Fluorobenzylidene)aminooxy]butyl}maleimide, [^{18}F]FBAM, [^{18}F]FPyME, and [^{18}F]FBEM, respectively. Thus, the simple single step reaction sequence starting from easily available [^{18}F]FDG make the synthesis of [^{18}F]FDG-MHO a very attractive alternative to previously published maleimide-containing ^{18}F prosthetic groups.

Radiolabeling of Glutathione (GSH). Various thiol-reactive agents containing a maleimide group have successfully been used for the chemoselective modification of peptides and proteins. Thiol-specific Michael reaction of maleimide-containing prosthetic groups provides high chemoselectivity when compared with amine and carboxylate-reactive labeling agents. The labeling properties of the bifunctional labeling agent [^{18}F]FDG-MHO for chemoselective conjugation toward thiol groups was exemplified by the reaction with the cysteine-containing tripeptide glutathione (GSH) and the single thiol group-containing protein anxA5 (Figure 6).

The ^{18}F-labeling reaction was performed at room temperature for 10 min in a phosphate buffer solution (pH 7.2) containing various GSH concentrations ranging from 1 ng/mL to 1.0 mg/mL. Conversion of [^{18}F]FDG-MHO into conjugate [^{18}F]FDG-MHO-GSH was monitored by radio-TLC analysis as previously reported (*32*). The conversion refers to as the percentage of radioactivity area of coupling product [^{18}F]FDG-MHO-GSH relative to the total radioactivity area. The results are summarized in Table 1.

More than 95% of the labeling reagent [^{18}F]FDG-MHO was converted into the corresponding GSH conjugate at GSH concentrations ranging from 1.0 mg/mL to 1 μg/mL after 10 min at room temperature. At lower GSH concentrations of 100, 10, and 1 ng/mL, the conversions were still good to moderate, being 92%, 47%, and 38%, respectively. The dependency of the radiochemical yield upon the peptide concentration has also been reported in previous publications describing the ^{18}F-labeling of peptides via prosthetic group labeling strategies (*13*). The labeling efficiency of [^{18}F]FDG-MHO toward GSH in this work is superior to recently reported results in the literature involving maleimide-containing prosthetic groups for ^{18}F-labelings, especially at very low GSH concentrations (*20, 32*). The determined radiochemical yields of 92% and 47% at 100 ng/mL and 10 ng/mL for [^{18}F]FDG-MHO are significantly higher compared to the 20% and 5% radiochemical yield observed at similar GSH concentrations of 100 and 10 ng/mL in the case of the prosthetic group [^{18}F]FBAM (*32*). Thus, the obtained excellent radiochemical yields even at very low GSH concentrations after 10 min at room temperature make the bifunctional labeling agent [^{18}F]FDG-MHO an excellent ^{18}F prosthetic group for the efficient labeling of thiol groups under mild reaction conditions compatible with peptides and proteins.

Radiolabeling of Annexin A5 (anxA5). The feasibility of [^{18}F]FDG-MHO as a thiol-reactive bifunctional labeling agent was further assessed by using the single thiol group-containing protein annexin A5 (anxA5) as a model. The mature human anxA5 is a 36 kDa, 319 amino acid protein which belongs to a family of calcium-dependent phospholipid-binding interfacial membrane proteins.

In the past decade, anxA5 binding has become one of the standard procedures to measure apoptosis in histopathology (*55*). Moreover, an increasing number of reports deal with radiolabeled anxA5 as molecular probes for imaging apoptosis in vivo (*56*). In this line, ^{99m}Tc-, ^{68}Ga-, ^{18}F-, ^{123}I-, and ^{124}I-labeled annexin derivatives have been prepared and studied. In the case

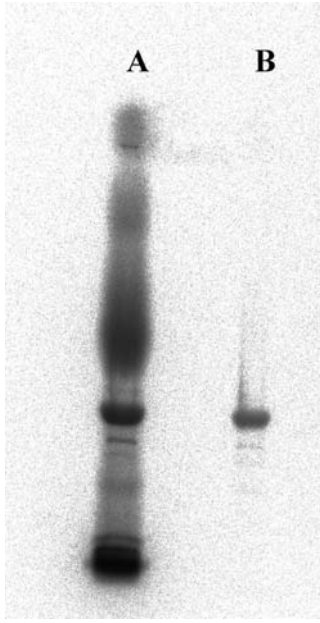

Figure 7. Representative radio-SDS-PAGE pattern of the reaction mixture (A) and the purified ^{18}F-labeled anxA5 (B). The figure shows radioactivity distribution as determined by radioluminography using a BAS 5000 scanner (Fujix, Japan). The radioluminograms were analyzed with the AIDA software package (Raytest GmbH, Germany).

of ^{18}F-labeled anxA5 derivatives, all described radiosyntheses were based on the reaction of anxA5 with the amine-group reactive prosthetic group [^{18}F]SFB (*57–61*). Consequently, incorporation of the ^{18}F label was achieved via nonchemoselective, random [^{18}F]fluorobenzoylation of variations of the total 22 lysine residues or the chemically accessible N-terminus of anxA5. On the other hand, mature anxA5 contains only one chemically accessible cysteine residue at position 315 (position 316, often cited in the literature, refers to the unprocessed precursor). Therefore, anxA5 should prove a suitable model for the chemoselective ^{18}F radiolabeling of proteins possessing one single cysteine residue. Radiolabeling of anxA5 with the thiol-group reactive agent [^{18}F]FDG-MHO is expected not to lead to adverse modification of anxA5. Moreover, modification of the cysteine residue in anxA5 should not alter the biological activity and functionality of the protein. This assumption is supported by recent data from the patent literature reporting the same binding affinity of anxA5 or annexin conjugates for phosphatidylserine-containing membranes when cysteine 315 is deleted or replaced with serine or other non-sulfur-containing amino acids (*62, 63*).

The radiolabeling of anxA5 was performed through chemoselective alkylation of the cysteine residue in anxA5 with maleimide [^{18}F]FDG-MHO. Treatment of anxA5 (100 μg, 2.8 nmol) in Tris buffer (pH = 7.4) with [^{18}F]FDG-MHO and subsequent size-exclusion chromatography afforded 43−58% (decay-corrected, based upon [^{18}F]FDG-MHO, n = 6) of [^{18}F]FDG-MHO-anxA5 within 60 min. Considering the low anxA5 concentration used (2.25 μM) and the presence of a single cysteine residue as the sole potential reaction site, the radiochemical yield is remarkably good. The high efficiency of the chemoselective introduction of the ^{18}F label via maleimide-containing prosthetic group [^{18}F]FDG-MHO into anxA5 is further confirmed when comparing the obtained 43−58% radiochemical yields with the reported yields of [^{18}F]SFB-based anxA5 derivatives. Thus, conjugation reaction with [^{18}F]SFB using a comparable amount of anxA5 (100 μg) gave only a 10% radiochemical yield based upon [^{18}F]SFB (*58*). Higher radiochemical yields of up to 70% for the conjugation step were only achievable when fairly high protein concentrations of up to 6 mg/mL were used (*57, 60, 61*). Moreover, conjugation reaction of anxA5 with [^{18}F]SFB can rely on the availability of 22 lysine residues and the N-terminus in the protein as potential reaction sites. This leads to a highly random [^{18}F]fluorobenzoylation of the available primary amines abundant in anxA5, thus avoiding a regioselective and chemoselective introduction of the ^{18}F label as in the case of [^{18}F]FDG-MHO-anxA5. Moreover, in some instances the use of the amine-reactive agent [^{18}F]SFB for protein labeling can fail completely. As an example, steric hindrance of the *N*-terminal region of apoB-100 due to oxidative modification of apoB-100 by myeloperoxidase or hypochlorous acid prevents radiolabeling with the acylation agent [^{18}F]SFB (*32*).

Starting from 20 MBq of [^{18}F]FDG-MHO, the effective specific activity of purified ^{18}F-labeled anxA5 was calculated to be 2−4 GBq/μmol at the end of synthesis (related to anxA5, M_r = 36 000 Da). Purification of the reaction mixture by size-exclusion chromatography gave radiochemically pure [^{18}F]FDG-MHO-anxA5, which could be completely separated from unreacted [^{18}F]FDG-MHO and other radioactive byproduct not further identified. The quality of purified [^{18}F]FDG-MHO-anxA5 was suitable to be used directly for subsequent small animal PET studies. Radiolabeling and purification of radiolabeled anxA5 was monitored by radio-SDS-PAGE. Figure 7 shows representative radio-SDS-PAGE patterns of the reaction mixture (lane A) and purified ^{18}F-labeled anxA5 fraction (lane B).

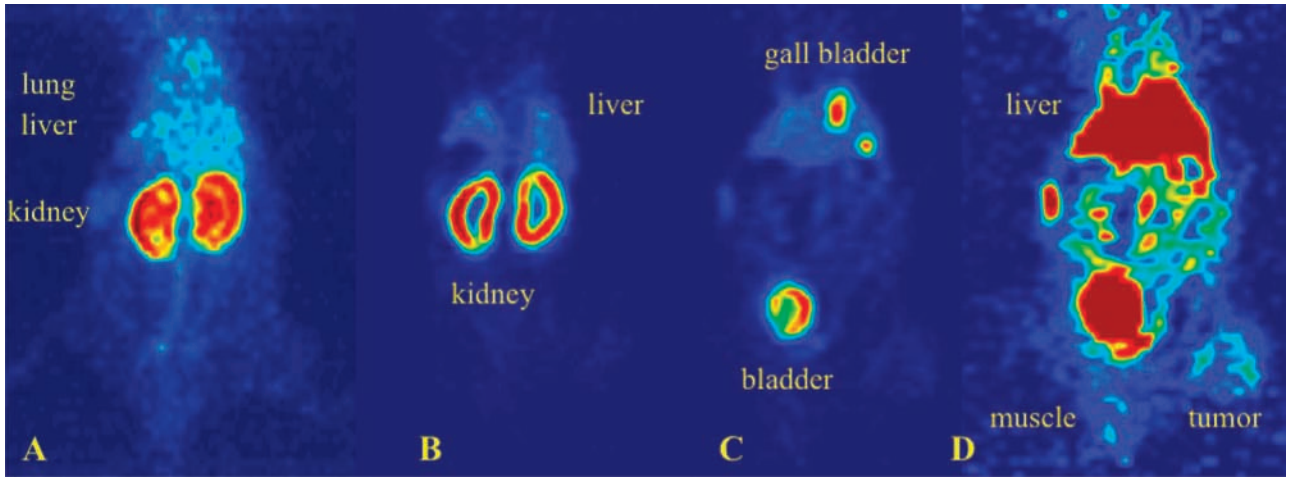

Figure 8. Small animal PET images of [^{18}F]FDG-MHO-anxA5 at 2 min (A) and 4 h (B,C,D) after tracer application. (B) Coronal section on the level of kidneys. (C) Coronal section on the level of xenographted tumor. (D) Coronal section as (C) but expanded scale intensity.

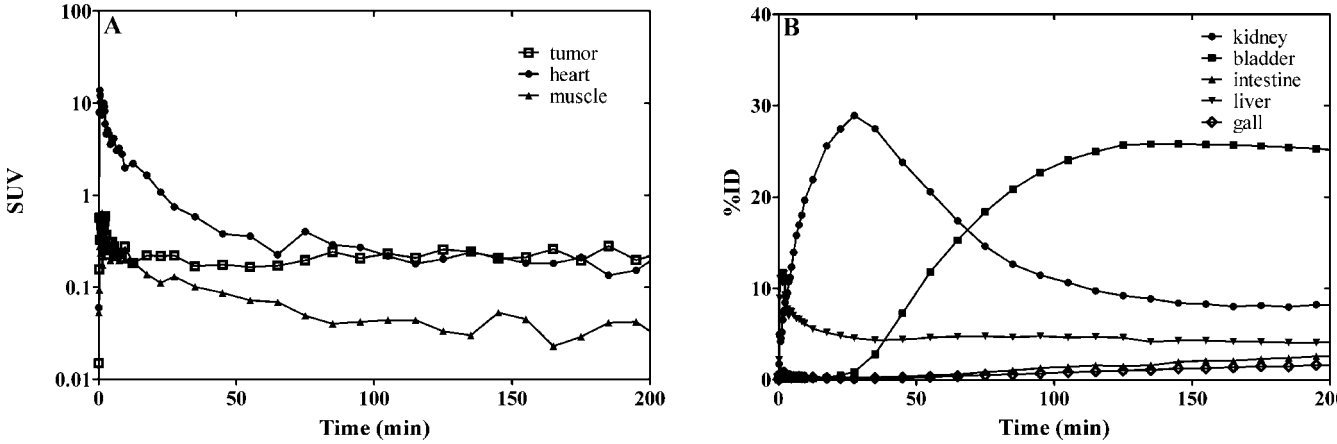

Figure 9. Representative time−activity curves from one animal after single intravenous application of [^{18}F]FDG-MHO-anxA5. (A) Time−activity concentration (SUV) curves of the heart, tumor, and muscle (note the semilogarithmic scale). (B) Time−activity (%ID) curves of liver, intestine, gall bladder, kidney, and urinary bladder.

Small Animal PET Imaging of [^{18}F]FDG-MHO-anxA5. Biodistribution and kinetics of [^{18}F]FDG-MHO-anxA5 was evaluated in a pilot small animal PET study in a human colorectal adenocarcinoma (HT-29) murine xenograft model. The murine xenograft model was not treated with an apoptosis inducing agent. Figure 8 shows small animal PET images at 2 min and 4 h after injection of [^{18}F]FDG-MHO-anxA5.

Figure 9 depicts representative time−activity curves for heart (blood pool), tumor, and muscle (A), liver, intestine, gall bladder, kidney, and urinary bladder (B).

After intravenous application of [^{18}F]FDG-MHO-anxA5, the radiotracer was rapidly distributed in the blood pool. [^{18}F]FDG-MHO-anxA5 showed a blood clearance with a mean half-life of 6.5 min, which is slower in comparison to the 2.6 min half-life as determined for [^{18}F]fluorobenzoylated anxA5 (R. Bergmann et al., unpublished results). Thus, chemoselective labeling of the cysteine residue in anxA5 with [^{18}F]FDG-MHO leads to a ^{18}F-labeled anxA5 derivative with a longer residence time in the blood pool resulting in a better availability of the radiotracer for in vivo imaging of apoptosis.

Radiolabeled anxA5 was mainly accumulated in the kidney cortex, reaching 8.2%ID at 200 min p.i. The high activity accumulation in the renal excretory system is consistent with reports in the literature using ^{18}F-labeled anxA5 derivatives in normal rats (*59*, *61*). At the same time point, approximately 4%ID of the injected activity was found in the liver. A part of activity was eliminated into the bile (1.6%ID at 200 min p.i.) and intestine (2.6%ID at 200 min p.i.). The activity in the xenografted tumor increased over the time reaching a tumor-to-muscle ratio of about 3 at 200 min p.i. Therefore, although the absolute activity in the HT-29 tumor was relatively low (SUV = 0.12) the tumor could be clearly delineated in the PET images (Figure 9).

CONCLUSION

We have developed a novel thiol-reactive prosthetic group ([^{18}F]FDG-MHO) based upon the readily available PET radiotracer [^{18}F]FDG. The straightforward access to [^{18}F]FDG makes this procedure especially attractive, e.g., for research groups without a complete PET facility. The novel prosthetic group was used for the chemoselective ^{18}F-labeling of glutathione as a thiol-containing model peptide and single cysteine residue containing anxA5 as a model protein. The use of [^{18}F]FDG-MHO as thiol group reactive prosthetic group allows the exclusive labeling of cysteine 315 in anxA5 while providing excellent radiochemical yields for the conjugation step even at very low protein concentration. Moreover, [^{18}F]FDG-MHO-anxA5 represents the first example of a defined, chemoselectively ^{18}F-labeled annexin derivative.

Taken together, the ease of preparation and the excellent yields of the conjugation step with cysteine residues make [^{18}F]FDG-MHO a very interesting and promising novel prosthetic group for chemoselective ^{18}F labeling of thiol group-containing peptides and proteins.

ACKNOWLEDGMENT

The authors wish to thank S. Preusche for radionuclide production, T. Krauss for technical assistance, K. Schumann, D. Pfitzmann, and R. Herrlich for assistance in animal experiments. We are grateful to Dr. N. Budisa, Max Planck Institute of Biochemistry, Molecular Biotechnology, for the kind gift of recombinant Annexin A5. The project was partly supported by the EU project BioCare No. 505785 and by a grant from the Deutsche Forschungsgemeinschaft (DFG; grant no. PI304/1-1).

NanoFerrite Particle Based Radioimmunonanoparticles: Binding Affinity and In Vivo Pharmacokinetics

A. Natarajan,*[,†] C. Gruettner,[‡] R. Ivkov,[§] G. L. DeNardo,[†] G. Mirick,[†] A. Yuan,[†] A. Foreman,[§] and S. J. DeNardo[†]

School of Medicine, University of California Davis, Sacramento, California, Micromod Partikeltechnologie, GmbH, Rostock-Warnemuende, Germany, and Triton BioSystems, Inc., Chelmsford, Massachusetts. Received January 11, 2008; Revised Manuscript Received May 2, 2008

Dextran and PEG-coated iron oxide nanoparticles (NP), when suitably modified to enable conjugation with molecular targeting agents, provide opportunities to target cancer cells. Monoclonal antibodies, scFv, and peptides conjugated to 20 nm NP have been reported to target cancer for imaging and alternating magnetic field (AMF) therapy. The physical characteristics of NPs can affect their in vivo performance. Surface morphology, surface charge density, and particle size are considered important factors that determine pharmacokinetics, toxicity, and biodistribution. New NanoFerrite (NF) particles having improved specific AMF absorption rates and diameters of 30 and 100 nm were studied to evaluate the variation in their in vitro and in vivo characteristics in comparison to the previously studied 20 nm superparamagnetic iron oxide (SPIO) NP. SPIO NP 20 nm and NF NP 30 and 100 nm were conjugated to ^{111}In-DOTA-ChL6, a radioimmunoconjugate. Radioimmunoconjugates were conjugated to NPs using 25 μg of RIC/mg of NP by carbodiimide chemistry. The radioimmunonanoparticles (RINP) were purified and characterized by PAGE, cellulose acetate electrophoresis (CAE), live cell binding assays, and pharmacokinetics in athymic mice bearing human breast cancer (HBT 3477) xenografts. RINP (2.2 mg) were injected iv and whole body; blood and tissue data were collected at 4, 24, and 48 h. The preparations used for animal study were >90% monomeric by PAGE and CAE. The immunoreactivity of the RINP was 40−60% compared to ^{111}In-ChL6. Specific activities of the doses were 20−25 μCi/2.2 mg and 6−11 μg of mAb/2.2 mg of NP. Mean tumor uptakes (% ID/g ± SD) of each SPIO 20 nm, NF 30 nm, and 100 nm RINP at 48 h were 9.00 ± 0.8 (20 nm), 3.0 ± 0.3 (30 nm), and 4.5 ± 0.8 (100 nm), respectively; the ranges of tissue uptakes were liver (16−32 ± 1−8), kidney (7.0−15 ± 1), spleen (8−17 ± 3−8), lymph nodes 5−6 ± 1−2), and lung (2.0−4 ± 0.1−2). In conclusion, this study demonstrated that 100 nm NF NP could be conjugated to ^{111}In-mAb so that the resulting RINP had characteristics suitable for AMF therapy. Although 100 nm RINP targeted tumor less than 20 nm SPIO RINP, their heating capacity is typically 6 times greater, suggesting the 100 nm NF RINP could still deliver better therapy with AMF.

INTRODUCTION

Dextran and PEG-coated magnetic iron oxide nanoparticles linked to a fluorescent or radiolabeled molecular targeting agent have been used to (a) deliver heat selectively at the microenvironment of tumors with external AMF, (b) construct the multiple mono- or bispecific targeting units, and (c) image and trace the NP kinetics in vivo (*1*–*5*). Systemic delivery of nanoparticles specifically to cancer tissues in concentrations sufficient to achieve a therapeutic thermal dose induced by external alternating magnetic field has also been demonstrated to be predicted by calculated heat dosimetry (*5*, *6*). This can allow specific heating of cancer tissues using RINP by AMF, providing a promising treatment modality (*7*). Radioactivity quantitation should provide sufficient concentration of the particles retained in the tumor tissue relative to nearby normal tissues, and the characteristic specific AMF absorption rates (SAR) of the particles, to allow calculations of selective heat generation in tumor with moderate AMF amplitudes.

Exposure of tissue to alternating magnetic fields results in the deposition of heat through the induction of eddy currents in tissues that is dependent upon the field frequency, amplitude, duration of exposure, and area of exposed tissue (*5*). This induced heating can be controlled and minimized through judicious selection of AMF parameters and, when combined with appropriately targeted particles, can lead to successful therapy. Thus, successful therapy requires that an appropriate combination of AMF parameters be directed to tumor tissue containing a sufficiently high concentration of particles capable of producing therapeutic heat at the chosen AMF amplitudes, and minimizing both AMF exposure and particle concentrations in nearby surrounding tissues. In this manner, cytotoxic heat can be deposited specifically into the tumor microenvironment while simultaneously minimizing the nonspecific heating of surrounding healthy tissues.

The elevation of tissue temperature to between 40 and 45 °C is often called hyperthermia (*8*). There is a clear rationale for using hyperthermia in cancer treatment because hyperthermia is known to cause direct cytotoxicity and because it also acts as a radiation and chemo sensitizer (*8*). However, there is generally no intrinsic difference between hyperthermia sensitivity of normal and tumor cells, except for hematological malignancies (*9*). On the other hand, selective tumor cell kill can be achieved in vivo in this range because of characteristic differences between normal and tumor physiology. The architecture and vasculature in solid tumors is chaotic, producing

hypoxic and low-pH [2−4] conditions that sensitize cells to thermal damage.

The effect of hyperthermia depends upon the achieved temperature and time of exposure. At temperatures above 42.5−43 °C, the exposure time can be halved with each 1 °C temperature increase to give an equivalent cell kill (*9, 10*). Hyperthermia inhibits cellular repair of sublethal radiation damage and also induces increasing radiosensitivity due to tumor reoxygenation. Despite the beneficial attributes of hyperthermia for cancer treatment, its clinical application has been limited because of a general inability to (a) deliver sufficient heat selectively to the tumor tissue and (b) accurately predict or measure heat dose deposited in the tumor (*8–10*).

Tumor-targeted heat therapy using the combination of NP and AMF has the potential to overcome both these limitations. In a previous study, 20 nm dextran matrix nanoparticles containing superparamagnetic iron oxide were linked to breast cancer targeting chimeric L6 (ChL6) monoclonal antibody (bioprobe), demonstrating the feasibility of delivering thermoablation to cancer cells (*5*). More key to clinical application of NP/AMF therapy, the demonstration of heat thermal dosimetry was predictive of tumor response and minimal normal tissue toxicity (*7*).

In order to further raise the therapeutic index of tumor response without normal tissue toxicity, an increased heat dose is needed. The heat dose (J/g of tumor tissue) can be increased by a combination of increased particle concentration in the tumor and/or increased heat output of the particles. The latter can be achieved only with higher SAR particles, because increasing heat from the particles by using higher AMF amplitudes or duration of exposure increases the potential for nonspecific heating (*5, 7, 11*).

New NF particles with high specific AMF absorption rates were synthesized by high-pressure homogenization according to a core−shell method, having a range of sizes 20−100 nm (*12*). Selected NF particles 30 and 100 nm were synthesized and characterized for the present study; measured specific absorption rates (SAR) demonstrated 7−10× higher SAR at various AMF amplitudes and 150 kHz over 20 nm SPIO particles (*12*). The NF particles possess an iron oxide core (density >5 g/cm^3) (10−60 nm) that is surrounded by a dextran shell. The iron content of the particles is >50% w/w, and they are separable with a permanent magnet. The dextran shell was further modified by cross-linking and addition of carboxyl-terminated PEG (PEG-COOH) for antibody conjugation (*12*).

By contrast, the previously described 20 nm SPIO particles are produced by the precipitation of ferric and ferrous chlorides in the presence of dextran (*13–15*). These particles consist of <40% w/w iron in a dextran matrix that is not cross-linked. Separation can be achieved only with the use of a high gradient magnetic field; thus, they are not separable with a permanent magnet. SAR values produced by these particles have been measured to range 27−105 W per gram of iron (*12*), several times lower than that observed with the NF particles.

Because of the significantly different physical and magnetic characteristics exhibited by the NF and SPIO particles, the potential utility of NF-based RINPs for cancer therapy must be validated with a study of their in vivo performance after conjugation with a monoclonal antibody (ChL6). This report describes the development of ^{111}In-ChL6 linked to various NPs: 20 nm SPIO, 30 nm NF, and 100 nm NF to produce RINP. Mean RINP diameter and size distributions were measured by photon correlation spectroscopy. In vitro and in vivo targeting and pharmacokinetics (PK) of the RINPs were characterized. The in vivo tumor targeting and in vitro SAR data were compared for the various RINPs to predict thermal dose deliverable at the cancer tissues by various AMF amplitudes (at 150 kHz) to enhance further development of optimal particles for future NP-AMF thermal therapy.

EXPERIMENTAL PROCEDURES

Materials. Carrier-free ^{111}In (MDS Nordion, Ontario, Canada) was purchased as $^{111}InCl_3$ in 0.05 M HCl. Chimeric L6 (ChL6), human-mouse monoclonal antibody chimera (Bristol-Myers Squibb Pharmaceutical Research Institute, Seattle, WA), reacts with an integral membrane glycoprotein highly expressed on human breast, colon, ovary, and lung carcinomas (*16, 17*). ChL6 was specified as greater than 95% pure monomeric IgG by polyacrylamide gel electrophoresis (PAGE). High gradient magnetic field (HGMF) columns and separator, Nanomag-D-SPIO 20 nm (product #79−56−201), and COOH-functionalized dextran and poly(ethylene glycol) (PEG) coated NF particles of 30 nm (84−56−301) and 100 nm (84−56−102) in suspension (15−25 mg/ml) were obtained from micromod Partikeltechnologie, GmbH (Rostock, Germany). MES (2-(4-morpholino) ethanesulfonic acid), EDC (1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide HCl), NHS (*N*-hydroxysuccinimide), glycine, and PBS were purchased from Sigma Chemical Co., St. Louis, MO. EDC activated NPs were purified by membrane dialyzer 3400 kDa cutoff (Pierce, Rockford, IL) dialysis bags. *S*-2-(4-Isothiocyanatobenzyl)-1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA-Bz-SCN) was purchased from Macrocyclics (Dallas, TX).

Preparation of SPIO and NanoFerrite particles (NF). SPIO particles were prepared by the precipitation of ferric and ferrous chlorides in the presence of dextran (*13, 14*). NF particles (International and European patents WO 2005006356, WO 20050271745, and DE 10331439) were synthesized by high-pressure homogenization by the core−shell method (*12*). Briefly, a monodisperse aqueous iron oxide suspension (25 mg/mL) was homogenized with an excess of dextran at pressures above 500 bar and at temperatures above 70 °C, for 30 min. NF particles with iron content 45% (w/w) were obtained after magnetic sedimentation in a crystallization disk at an NdFeB permanent magnet and washing with deionized water. The NF particles were cross-linked by a modified Josephson method (*18*) with a mixture of poly(ethylene glycol) diglycidyl ether and epichlorohydrin at pH 11−12 for 24 h at room temperature. After magnetic separation, particles were washed with deionized water, and NF particle suspension with an iron concentration of 20−25 mg/mL was obtained. The particles were functionalized with amino groups by shaking with ammonia at room temperature for 24 h. The amine-functionalized NF particles were further washed three times with deionized water by magnetic separation and filtered through 0.22 mm Millex-GP filters (Millipore). These NF particles were further modified by EDC and poly(ethylene glycol) 600 diacid using MES buffer (pH 6.3) and incubated for 2 h at room temperature for COOH functionalization. The narrow size distributions of the NF particles obtained were in two diameter ranges 20−40 and 80−100 nm (*12*).

Preparation of Radioimmunoconjugate (RIC). The immunoconjugate (DOTA-Bz-ChL6) was prepared by the previously described method (*19*), with slight modifications. Conjugation was carried out with final concentrations of 0.15 mM ChL6 (20 mg/mL) and 2.0 mM DOTA-Bz-SCN mixed in 0.1 M tetramethylammonium phosphate, pH 9, at 37 °C with 2 h incubation. The DOTA-Bz-ChL6 conjugate was purified by G50 molecular sieving chromatography and transferred to 0.1 M ammonium acetate, pH 5.3. The RIC preparation was carried out using ^{111}In chloride in 0.05 M HCl (0.2 GBq) buffered in 0.1 M ammonium acetate at pH 5.3, and DOTA-Bz-ChL6 (2.5

mg) added. The solution was incubated for 30 min at 37 °C, and then 0.1 M sodium ethylene diamine tetraacetate (EDTA) (Fisher Scientific, Pittsburgh, PA) was added to a final concentration of 10 mM to scavenge nonspecifically bound ^{111}In. ^{111}In-DOTA-Bz-ChL6 was purified from ^{111}In-EDTA by molecular sieving chromatography.

The reaction mixture of RIC was purified by a molecular sieving (Penefsky) column. Purity was estimated by HPLC (Beckman Coulter System Gold 128, Fullerton, CA) with a radioactive detector (Raytest USA, Wilmington, NC) using an SEC 3000 column (GE Health care) eluted at 1 mL per minute by phosphate buffer solution. The yield and quality assurance (QA) of the RIC were evaluated by HPLC and cellulose acetate electrophoresis (CAE) strips (Gelman Sciences Inc., Ann Arbour, MI) performed on 0.05 M sodium barbital buffer at pH 8.6. The RIC bands on CAE strips and TLC plates were exposed on phosphor imager plates and scanned by Fuji Film imager (BAS 1800 II). The data were converted to digital peaks by Fuji film MultiGaugeV2.1 software.

Preparation of RINP. Three lots of nanoparticles, 20 nm SPIO and 30 and 100 nm NF (*12*), were used for the conjugation of RIC in in vitro targeting effect and in vivo mouse studies. ^{111}In-DOTA-Bz-ChL6 was conjugated with the nanoparticles via amide linkage to the carboxyl (COOH) terminated coating to prepare the ^{111}In-ChL6 NP. For each of the preparations, 6 mg of EDC and 12 mg of NHS in 0.5 mL of 0.5 M MES buffer were mixed with 5 mL of 10 mg/mL of NP. This suspension was incubated for 1 h at RT with continuous mixing, then placed into 3400 MWCO dialysis bags, and dialyzed against 4 L of saline for 1 h. ^{111}In-DOTA-Bz-ChL6 (0.5 mCi/0.2 mg/0.2 mL of PBS) suspended in 0.3 mL of 0.1 M MES buffer was mixed with the activated SPIO and NF particle suspension and incubated for 1 h at RT with continuous mixing (20−25 μg ^{111}In-ChL6/mg of NP). The preparations of 20 nm SPIO and 30 nm NF particles conjugated ^{111}In-DOTA-Bz-ChL6-NP, 2 mL, were again placed into dialysis bags (3400 MWCO) (3 mL), and dialyzed against 4 L of saline at RT for 1 h. The 100 nm BNF particles were purified by magnetic separation. The RINP products were mixed with 20 mL of 25 mM glycine in PBS at RT (15 min), and then purified by high grade magnetic field (HGMF) column (20 and 30 nm) and magnetic separator (100 nm) using PBS to remove the nonbound ^{111}In-DOTA-Bz-ChL6. Non-immunoreactive RINP (negative control) was prepared by a similar method, except the RIC used for conjugation to NP was non-immunoreactive.

The final suspensions that were collected from the magnetic column or separator with PBS wash after removing from the magnetic field were brown and yielded 3−5 μg of ^{111}In-ChL6/mg with specific activities of 6−10 μCi/mg of RINP. The concentration of the particles was estimated by UV/vis spectrophotometry at a wavelength of 492 nm using unconjugated beads as a reference, and protein concentration was estimated at a wavelength of 280 nm and also calculated from decay-corrected radioactivity. 2 μL aliquots of final products were applied to multiple CAE strips for electrophoresis of 11 and 45 min.

Preparation of Nontargeted Radionanoparticles (RNP). The nontargeted RNP (negative control) was prepared by conjugation of radiolabeled ^{111}In-DOTA-Bz-NH_2 to COOH functionalized 20 nm NP via amide linkage according to published procedure (*20*). Briefly, the ^{111}In-DOTA-Bz-NH_2 (1.5×10^{16} molecules; 5 mCi/20 μg) diluted in 0.5 mL of 0.1 mM MES buffer was mixed to a carbodiimide-activated NP suspension, and incubated for 2 h at room temperature with continuous mixing (reaction ratio was 6×10^{14} molecules of DOTA/mg of NP). The radiolabeled ^{111}In-DOTA-Bz-NP was purified by a 3400 MW cutoff dialysis membrane against 4 L of saline at RT for 1 h. After 1 h, the dialyzed product was quenched with glycine (25 mM) for 15 min to terminate the remaining active sites on the particle surface. This suspension was further purified by high gradient magnetic field column using saline as both washing and final eluent buffer. The specific activity of the RNP was 10−15 μCi/mg of RNP.

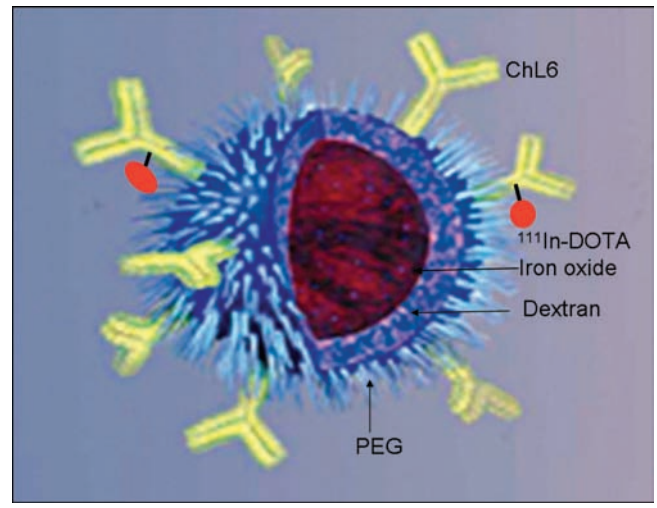

Figure 1. Simple diagram of a BNF-type particle coated with PEG to link ^{111}In-ChL6 to construct RINP. The particle core (reddish-brown sphere in center) is iron oxide.

In Vitro Cell Binding Assay of RINP. Purified RINP of each lot was evaluated by in vitro immunoreactivity as % of RINP bound to HBT 3477 cells. Relative immunoreactivity was established by comparing with reference ^{111}In-ChL6 alone used in these studies (*21*). The ^{111}In-DOTA-ChL6, RINP, and viable cells (2×10^7 cells/mL) were diluted to the desired concentrations in phosphate buffered saline (pH 7) to find the maximal binding percentage corresponding to the reported method (*22*). ^{111}In-DOTA-ChL6 (10 ng) and RINP of each (50 μl, 0.04 mg/mL) were added to triplicate tubes. One million cells (50 μL) were added to the triplicates, vortexed, and incubated for 1 h at room temperature. The cells were pelleted by centrifugation at $300 \times g$ for 10 min, and the supernatant and cells were counted. The percentage bound was calculated as follows: [cell bound cpm/(cell cpm + supernatant cpm)] × 100.

RINP Size Measurement. RINP size was measured by dynamic light scattering (photon correlation spectroscopy) using a Zetasizer 3000 (Malvern Instruments Ltd., UK) after suspensions had undergone 0.45 m filtration. This instrument uses a 5 mW He Ne laser (633 nm) and measures particle sizes from 2 to 3000 nm. Fluctuations in the intensity of scattered light (at 90° to the incident) are analyzed through the use of autocorrelation functions.

Animal Studies. Female (7−9 week old) athymic Balb/c nu/nu mice (Harlan Sprague−Dawley, Inc., Frederick, MD) were maintained according to University of California animal care guidelines on a normal diet ad libitum and under pathogen-free conditions. HBT 3477 cells were harvested in log phase; 3.0×10^6 cells were injected subcutaneously on both sides of the abdomen of mice for the PK study. Five groups of mice with 9 animals per group and 2 HBT3477 tumors per mouse were used for the PK study, and 3 mice with bilateral HBT3477 were used for WBAR study. RNP negative control (group 1) and non-immunoreactive RINP (group 2) were studied at 24 and 48 h; and 20, 30, and 100 RINP experimental groups (groups 3−5) were studied at 4, 24, and 48 h time points. All mice studies were initiated 2 to 4 weeks after implantation when the tumor volume was 100−350 mm^3. PK and WBAR studies were performed using RINP doses of 20−25 μCi per mg of RINP,

Table 1. Specification of RINP[a]

NP size (nm)	initial NP (mg)	[Fe]/[NP] mg/mg	RINP yield (mg)	[RIC] μg/mg of NP	SA μCi/mg of RINP	QA		
						CAE 45′ %	PAGE %	RIR %
20	50	0.46	26	5	8	95	90	79
30	50	0.63	26	4	7	75	85	57
100	50	0.6	35	3	6	90	90	60

[a] SA: specific activity. RIR: relative immunoreactivity.

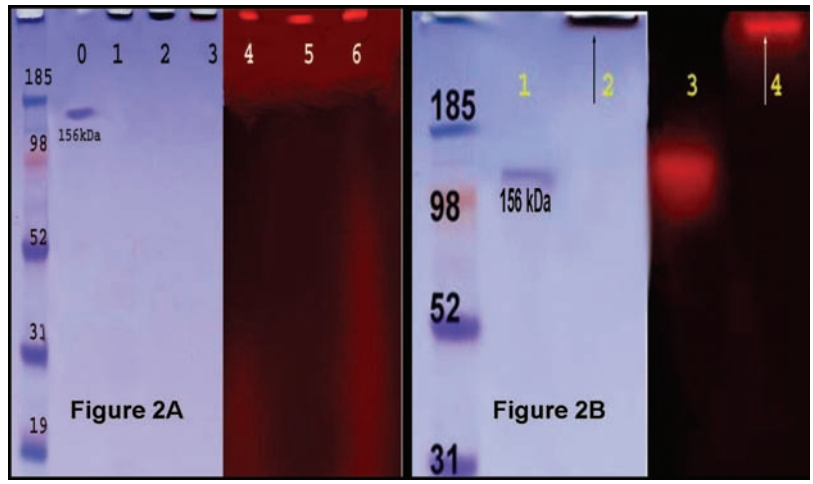

Figure 2. RINP on 4−12% SDS−PAGE spectrum. Left: CB stained for protein detection. Right: same PAGE scanned on Fuji phosphor Imager for radioactivity detection. (A) RINP (20, 30, and 100 nm) on 4−12% SDS−PAGE spectrum: lane 0, ^{111}In-DOTA-Bz-ChL6; lanes 1−3, RINP (20, 30, and 100 nm)—brown band at origin, no unconjugated ^{111}In-ChL6 observed; lanes 4−6: radioactivity bands at origin correspond to RINP (20, 30, and 100 nm). (B) Lane 1, ^{111}In-DOTA-Bz-ChL6; lane 2, RINP (100 nm)—brown band at origin; lane 3, ^{111}In-DOTA-Bz-ChL6; and lane 4, radioactivity band at origin corresponds to RINP.

injected iv into a lateral tail vein with an additional 50 μg ChL6 (cold) in 200 μL saline.

Whole Body Autoradiography (WBAR). WBAR was conducted as previously described (*23, 24*). 24 h after tail vein injection of 50 μg/50 μCi/200 μL/5 mg of RINP, mice were anesthetized using an intravenous injection of 50 mg/mL of 100 μL aqueous solutions of sodium pentobarbital, then flash-frozen in a hexane/dry ice bath. The frozen mice were embedded in 4% carboxymethylcellulose and sagittal sections were generated with a Leica Polycut at −20 °C. Sections of 50 μm thickness were obtained to show tumors, spleen, kidney, liver, and the midline of the vertebral column. Radiographs of the sections were prepared by exposing the sections to X-ray film (Kodak BioMax MS, Rochester, NY).

Pharmacokinetic Study. RINP doses were injected iv in 200−250 μL saline. In the pharmacokinetic studies, whole body activity was measured in a dose calibrator (CRC-12, Capintech, Inc., Pittsburgh, PA) immediately, and again at 1, 4, 24, and 48 h; and values were expressed as %ID. Blood activity, expressed as %ID/mL, was determined by counting 2 μL blood samples, collected at 5 min and 1, 4, 24, and 48 h after injection in a gamma well counter (Pharmacia LKB, Piscataway, NJ) calibrated using ^{111}In standards in the appropriate sample configuration and volumes. The mice were sacrificed and organs and tissue samples collected. Activity, expressed as %ID/g, was measured in a gamma well counter in a manner similar to that used for blood activity (*25*). Specific activity and dose used for animal study was 20−25 μCi/5−10 μg of mAb/2.2 mg RINP or non-immunoreactive RINP.

RESULTS

Preparation, Characterization, and Quality Assurance of RIC, RNP, and Various RINP. Figure 1 shows a simple schematic diagram of a representative NF-type RINP. Table 1 indicates the specification of various sizes of RINP. The purified

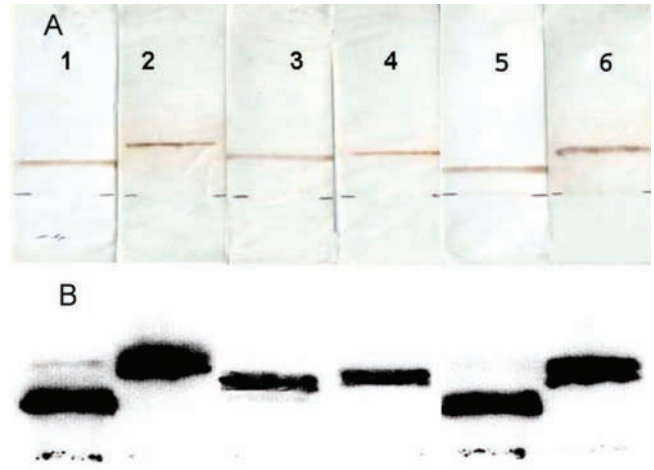

Figure 3. CAE characterization of RINPs.^{111}In-ChL6 modified NPs of 20 nm (lanes 1,2), 30 nm (lanes 3,4), and 100 nm (lanes 5,6) were tested on CAE strips, using pH 8.5 buffer, 300 V, at 11 min (lanes 1, 3, and 5) and 45 min (lanes 2, 4, and 6) time points. (A) RINPs tested on CAE strips were scanned by laser scanner (brown bands correspond to iron oxide of NPs visible at different distance from the origin (2 cm above from bottom of the strip). (B) The same CAE strips were scanned on Fuji Imager to analyze the migration pattern of RINPs by size and charge effect traced by radioactivity. The migration distances of each lot of NPs have identical distance by radioactivity and band stain. RINP preparations were greater than 95% pure. The purity of the RINP on CAE 11 min and 45 min showed greater than 90% monomeric product. RINP preparation does not contain aggregated particles or free ^{111}In-ChL6 molecules.

RIC molecule of ^{111}In-DOTA-Bz-ChL6 was evaluated by CAE, HPLC, and PAGE prior to conjugation to NP. The specific activity of the RIC was 0.5 μCi/μg with greater than 95% monomeric by HPLC, CAE, and PAGE (Figure 2A, lane 0, and Figure 2B, lanes 1 and 3). The absolute binding of RIC in the

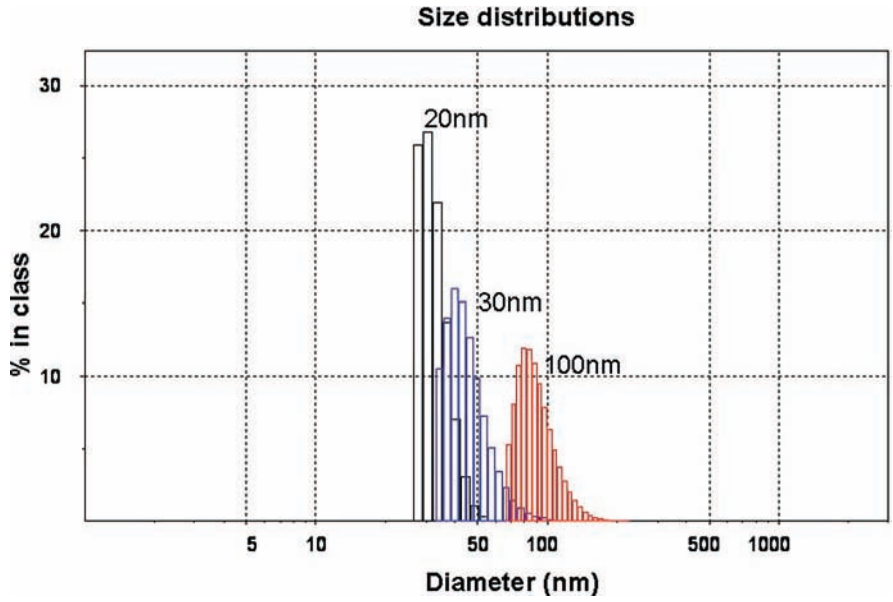

Figure 4. RINP size distributions were measured by photon correlation spectroscopy (Zetasizer 3000, Malvern Instruments, Ltd.).

live cell assay was >70% and equal to 100% compared to ^{125}I-ChL6 as reference standard. The RIC used for non-immunoreactive RINP (20 nm) was 4% compared to ^{125}I-ChL6 as reference standard. Using carbodiimide chemistry, RINP products were prepared by conjugation of ^{111}In-DOTA-Bz-ChL6 to COOH functionalized NP of 20, 30, and 100 nm particles; and the amounts of ^{111}In-ChL6 linked to NPs were 5, 4, and 3 (μg/mg), respectively. In the case of non-immunoreactive RINP, the ^{111}In-ChL6 (non-immunoreactivity) was linked to 20 nm NP with 6 μg/mg of NP. Similarly, particles without targeting molecules, such as nontargeting 20 nm NP (RNP), were prepared for the negative control (10 μCi/mg) using ^{111}In-DOTA-Bz-NH_2 and 20 nm NP.

All of the RINPs were greater than 90% monomeric by PAGE (Figure 2A,B) and CAE (Figure 3). Each purified RINP was a dark brown, homogeneous suspension and remained at the origin of PAGE. The RINPs (20, 30, and 100 nm) shown in Figure 2A, by Coomassie in lanes 1−3 and radioactivity in lanes 4−6, did not migrate due to the high molecular weight. However, no unbound ChL6 or ^{111}In-DOTA-ChL6 was observed, corresponding to the control protein in Figure 2A lane 0 and Figure 2B lane 1 or control radiolabeled ChL6 in lane 3. Figure 3 shows the evaluation of the RINP mobility by CAE at 11 min (lanes 1, 3, and 5) and 45 min (lanes 2, 4, and 6). These preparations are >90% monomeric with no aggregation or unbound free ChL6. The specific activity of the final purified RINP was 6−8 μCi/3−5 μg of ^{111}In-ChL6/mg of NP. The concentration of ^{111}In-ChL6 conjugated to NP was estimated by decay-corrected specific activity of the RINP, and the ^{111}In-ChL6 conjugated to each NP was as 6−10 molecules per bead.

Using photon correlation spectroscopy, the sizes of the RINPs were (Figure 4) distributed to narrow diameter ranges 20−30, 30−40, and 70−100 nm. RINP sizes did not change compared to NP size prior to conjugation with ^{111}In-mAb (*12*). Thus, RIC conjugation on NP did not influence or alter the initial particle diameters.

In Vitro Cell Binding Assay. The radioimmunoassay (RIA) of RIC and RINP was tested using HBT 3477 human breast cancer cells. Relative immunoreactivity of the RINP showed 57−79% compared to control RIC tested on HBT 3477 (Table 1).

WBAR and PK in Mice. The WBAR obtained from a mouse sacrificed 24 h after injection of the 100 nm RINP showed that the particles were able to target tumor in vivo (Figure 5). Blood and body clearances of the RINP (Figures 6 and 7) and mean RINP concentrations (%ID/g) in lung, kidney, and lymph node (Figure 8) were similar to ^{111}In-ChL6-NP as previously reported (*7*). In vivo tumor targeting of RINPs were compared with RNP (without the targeting mAb molecules) and non-immunoreactive RINP (20 nm). Figure 8 shows that mean concentrations of RINP of each preparation in tumor in the PK study were between 4 and 9% ID/g over 2 days. RNP 20 nm NP with no targeting molecules and non-immunoreactive RINP (20 nm) were used as a negative control and demonstrated (Figure 8) tumor

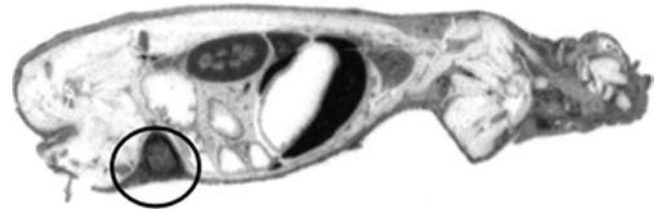

Figure 5. Sagittal section of the WBAR image obtained from euthanized mice 24 h after tail vain injection of ^{111}In-ChL6-NP (100 nm BNF). The HBT3477 tumor (human breast cancer) bearing nude mice received 50 μCi/5 mg of RINP dose. Accumulations of RINPs are mostly in kidney, liver, and tumor (circle).

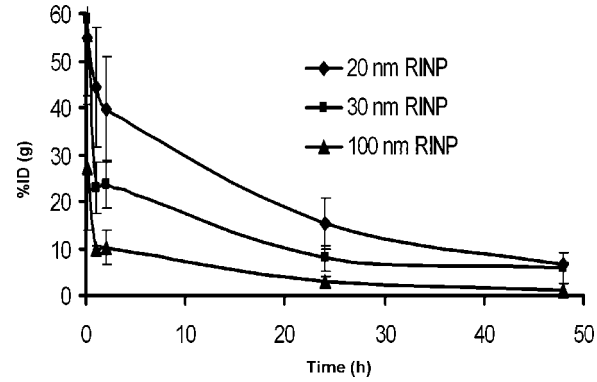

Figure 6. Pharmacokinetic study of RINPs in mice with HBT3477 human breast cancer xenografts (nine animals per group; three groups total). Three RINP blood clearances were compared at various time points: 5 min, and 1, 2, 4, 24, and 48 h.

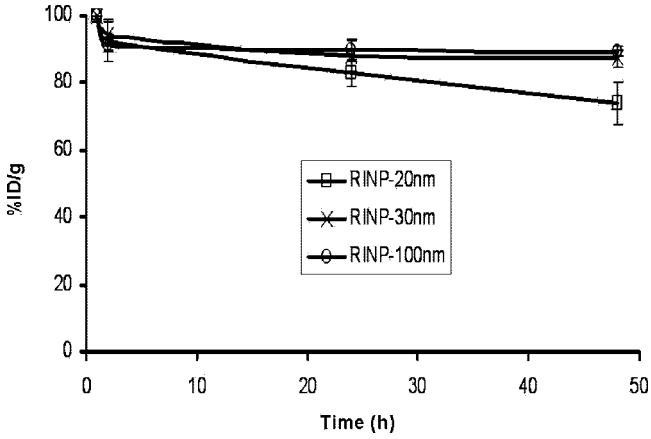

Figure 7. The pharmacokinetic study of three RINPs (20, 30, and 100 nm) in mice with HBT3477 human breast cancer xenograft. Body clearances were compared at various time points of 2, 4, 24, and 48 h. (Nine animals per group; total five groups were used; non-immunoreactive RINP (20 nm) and RNP (20 nm) negative control groups were not represented in these data.)

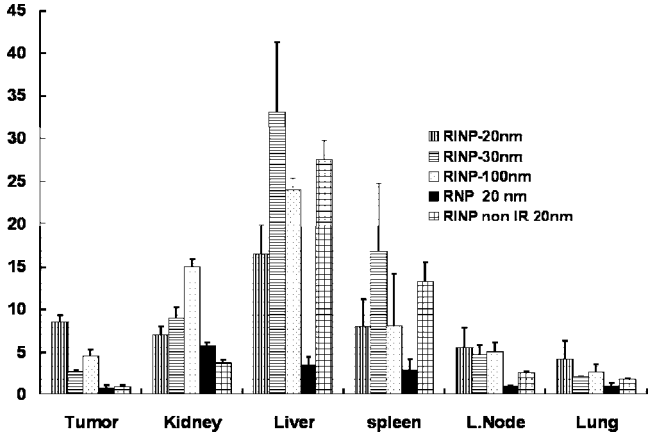

Figure 8. Pharmacokinetic biodistribution of the RINPs (20, 30, and 100 nm size), negative controls of RNP (20 nm) NP without targeting molecules, and RINP (20 nm) non-immunoreactive were measured as %ID/g in various organs after 48 h injection. The difference between targeted (RINP) and nontargeted particles (RNP) and non-immunoreactive RINP (*5*) should be noted. The mean ± SD (error bars) were calculated based on three animals ($n = 3$) in each study group. IR = immunoreactive.

accumulation of less than 0.5% ID/g. The differences in tumor uptake observed between the targeted and nontargeted NPs were substantial. The 20 nm RINP tumor uptake was consistent with previous observations (*5, 7*). Both 30 nm and 100 nm BNF particles demonstrated a lower tumor uptake than SPIOs, with little difference between the two.

DISCUSSION

Focused hyperthermia (FH) can be achieved at selective cancer tissues by ligand directed magnetic nanoparticles using AMF to activate NP to deliver heat (*26*). This treatment modality is more advantageous than other thermotherapies, because heat is induced locally by external AMF application through activation of cancer-targeted nanoparticles which are preferentially retained in the microenvironment of the tumor tissues at higher concentrations than in the immediately surrounding normal tissues (*27, 28*). In this approach, the AMF is preferentially directed to the regions containing cancer (*11*), and the field amplitude can be adjusted to provide NP heat lethal only at the cancer tissues while minimizing the heat deposited elsewhere, thus sparing the surrounding normal tissues. To enhance the FH, high SAR NF-type particles were developed (*12*). Two sizes of these NF-type particles were evaluated in this study to characterize their in vivo performance in comparison with a previously used 20 nm SPIO particle. Future selection of a preferred RINP will be based on two criteria: (1) concentration of the particles targeted at the tumor; and (2) particle SAR heat after AMF activation.

Table 2. SAR Values for BNF- and SPIO-type Particles As Reported in Ref (*12*)

nanoparticle type (diameter)	SAR[a] (W/g iron)			
	29 kA/m	58 kA/m	86 kA/m	104 kA/m
20 nm SPIO	27	66	76	105
30 nm BNF	90	253	380	438
100 nm BNF	140	437	528	642

[a] SAR values measured for different mean diameter NPs as a function of the amplitude of the AMF.

Three types of RINP were created using the 20 nm (SPIO) and 30 and 100 nm (NF) particles linked to ^{111}In-ChL6 to target breast cancer in mice. In our previous study, we demonstrated that RINPs based on 20 nm SPIO particles were successfully utilized for thermal therapy in a mouse model (*7*). However, the SPIO particle SAR value was not sufficient to induce enough heat to eradicate the cancer completely with modest amplitudes of AMF at a frequency of 150 kHz.

In this study, we have compared 30 and 100 nm RINP from NF particles with previously tested 20 nm SPIO RINP. All of these preparations had a high purity and excellent immunoreactivity and were similar to the preparation used in the earlier therapy studies. The in vivo PK and WBAR study showed that 100 nm RINP accumulation in tumor was 50% that of 20 nm SPIO RINP. However, the SAR value of 100 nm particles has been measured to be up to 6 times higher (Table 2) than that of 20 nm SPIO particles. Therefore, the calculated net heat induction for any specific AMF in cancer tissue by 100 nm RINP is expected to be 3 times higher than that produced by 20 nm RINP (SPIO).

Important characteristics of magnetic NP for FH applications are narrow particle size distribution and high SAR values providing substantial heat at lower AMF (*29*). In general, RINP accumulation at the tumor tissues depends on the RINP affinity, the presence of abundant cancer cell targets for the molecules linked to NP, circulation half-time, and tumor vessel permeability. The NP of SPIO and NF preparations were different in surface morphology, physical characteristics (density), surface charge, PEG concentration, and functional modification, which may affect the PK. The cellular and tissue uptake was affected by several characteristics of the nanoparticles, e.g., particle size, coatings, and charge, as demonstrated by Wu et al. (*30*). In another study, surface properties had a larger impact on cellular uptake of SPIO particles rather than particle size (*31*). In our study, ^{111}In-DOTA conjugated RNP (negative control) showed less than 5% uptake in liver and spleen compared to RINPs, which showed above 10% as shown in Figure 8. This may be due to increased anionic charge of the RNP. However, this was not the focus of this study. NP design and chemical conjugation were optimized in such a way that RINP preparations were fully functional to target the antigen both in vitro and in vivo. The particles were also coated with PEG molecules to increase plasma half-time and decrease uptake in normal tissues. The present study clearly confirms that the NF-based 100 nm RINP are able to penetrate the tumor vessels sufficiently well for moderate tumor accumulation (see Figures 5 and 8). In conclusion, we have created RINP

of varying sizes using SPIO and NF NP to target breast cancer for focused hyperthermia. Analytical methods have been developed to characterize the RINP. Radiotracer was utilized on NP to establish RINP targeting in the tumor, to predict thermal dose in the tumor, and to quantify RINP tissue biodistributions. Although 100 nm NF RINP targeted tumor less than 20 nm SPIO RINP, because their heating capacity was 6 times higher, 100 nm BNF RINP should provide 3 times greater heat dose in tumor with AMF activation. A complete characterization of the physical and magnetic properties of these particles and how these are affected by the chemical modifications of the surface coatings is underway.

Received January 12, 2008; Revised Manuscript Received March 31, 2008

We have developed a reduction-triggered fluorescence probe with a new fluorogenic compound derivatized from Rhodamine for sensing oligonucleotides. The chemistry to activate the compound involves the reaction between the azide group of rhodamine derivatives and the reducing reagents, with the fluorescence signal appearing after reduction of the azide group. The signal/background ratio of this fluorogenic compound reached 2100-fold enhancement in fluorescence intensity. Dithio-1,4-threitol or triphenylphosphine as reducing reagents were successfully utilized for this chemistry to be introduced into the DNA probe. The genetic detection requires that two strands of DNA bind onto target oligonucleotides, one probe carrying a reducible fluorogenic compound while the other carries the reducing reagents. The reaction proceeds automatically without any enzymes or reagents under biological conditions to produce a fluorescence signal within 10−20 min in the presence of target DNA or RNA. In addition, the probe was very stable under biological conditions, even such extreme conditions as pH 5 solution, pH 10 solution, or high temperature (90 °C) with no undesirable background signal. The probes were successfully applied to the detection of oligonucleotides at the single nucleotide level in solution and endogenous RNA in bacterial cells.

INTRODUCTION

Fluorescent-labeled oligonucleotides are becoming important tools for detecting oligonucleotide sequences (*1, 2*). A possible application is the detection of RNA species in cells by in situ hybridization (*3–5*). However, standard fluorescent probes require careful handling to avoid nonspecific signals. Fluorogenic probes with a fluorescence on/off mechanism have been developed to avoid this problem (*6–13*). Some of these probes have been applied to the detection of RNA in cells (*14–17*). Examples are molecular beacon (MB) (*15, 16*) or target-assisted chemical ligation (*14, 18*). Target-dependent fluorescence enhancement of these methods is based on the resonance energy transfer (RET) mechanism, for which a pair of quencher and fluorescence dyes is normally used. However, higher sensitivity for the detection method is still required to monitor gene expression in cells. Recently, various fluorogenic compounds have been developed for the detection of small biological substances (*19–23*). For example, diaminofluorescein when used for the detection of nitric oxide (NO) reacts with NO to yield a fluorescent compound through triazole formation (*21*). The boronate fluorescein derivative for detection of hydrogen peroxide (H_2O_2) reacts with H_2O_2 to yield a fluorescent form through cleavage of the carbon−boron bond (*20*). In these examples, detection is triggered by a chemical reaction accompanied by transformation of the chemical structure of the fluorogenic compound. Fluorescence modulation is caused by photoinduced electron transfer or absorption change. The signal/background (*S*/*B*) ratio of this type of molecule could exceed that of the RET mechanism (*24*). However, there are few reports that describe chemical reaction-triggered fluorogenic molecules for oligonucleotide sensing, although this method offers high sensitivity (*25*). Here, we report a reduction-triggered fluorescence (RETF) probe that shows a high *S*/*B* ratio for sensing oligonucleotides (Figure 1). A new fluorescence molecule, rhodamine azide, that we designed and synthesized is activated only by a specific reducing reagent on the oligonucleotide target and is very stable under biological conditions, showing little background fluorescence. The probe was applied to the sensing of nucleic acids in vitro and of endogenous RNA in bacterial cells.

EXPERIMENTAL PROCEDURES

t-Boc-Rhodamine 110 Azide (2). t-Boc-Rhodamine 110 (48.0 mg, 0.112 mmol) was dissolved in CH_3CN (8 mL) and CH_2Cl_2 (4 mL) under Ar (g). TFA (12.4 μL, 0.167 mmol) was added, followed by addition of isopentyl nitrite (17.8 μL, 0.134 mmol) at 0 °C. After stirring for 2 h at 0 °C, sodium azide (15.0 mg, 0.223 mmol) was added to the resulting solution, followed by stirring for 1 h at ambient temperature. The reaction was quenched with saturated aqueous $NaHCO_3$. The aqueous layer was extracted with AcOEt (×2), and the combined organic layers were dried over Na_2SO_4, concentrated, and subjected to flash column chromatography (silica gel, 6:1 hexane/EtOAc) to give azide-Rhodamine 110-t-Boc (**2**) as a pale yellow crystalline solid (36.5 mg, 80.0 μmol, 71%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 1.53 (9H, s), 6.61 (1H, brs), 6.68 (1H, d, J = 3.2 Hz), 6.71 (1H, d, J = 3.2 Hz), 6.77 (1H, d, J = 8.5 Hz), 6.87 (1H, dd, J = 2.2 Hz, 8.8 Hz), 6.93 (1H, d, J = 1.9 Hz), 7.12 (1H, brd, J = 7.3 Hz), 7.56 (1H, brs), 7.62 (1H, dt, J = 1.0 Hz, 7.5 Hz), 7.66 (1H, dt, J = 1.2 Hz, 7.6 Hz), 8.02 (1H, brd, J = 7.3 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ 28.36, 81.25, 82.19, 105.97, 107.21, 112.87, 114.26, 114.74, 115.59, 123.70, 125.07, 126.22, 128.45, 129.43, 129.78, 135.04, 140.56, 142.37, 151.47, 152.08, 152.95, 169.13. QSTAR (Applied Biosystems/MDS SCIEX) (ESI): [MH+] $C_{25}H_{21}N_4O_5$: calculated 457.1512, found 457.1509.

Rhodamine 110-Azide (3). Azide-Rhodamine 110-t-Boc (**2**) (30.8 mg, 67.5 μmol) was dissolved in 4.0 M HCl solution in dioxane (3 mL). The resulting solution was stirred at ambient temperature for 3 h. Solvent was removed under reduced pressure, and the residue was purified by TLC plate (9:1 $CHCl_3$/MeOH). Azide-Rhodamine 110 (**3**) was isolated as a pale pink crystalline solid (23.8 mg, 66.8 μmol, 99%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 3.92 (2H, s), 6.36 (1H, dd, J = 2.4 Hz, 8.5 Hz), 6.52 (1H, d, J = 2.2 Hz), 6.55 (1H, d, J = 8.5 Hz), 6.67 (1H, dd, J = 2.2 Hz, 8.5 Hz), 6.74 (1H, d, J = 8.5 Hz), 6.92 (1H, d, J = 2.2 Hz), 7.16 (1H, d, J = 7.6 Hz), 7.61 (1H, dt, J = 1.0 Hz, 7.3 Hz), 7.66 (1H, dt, J = 1.2 Hz, 7.5 Hz), 8.01 (1H, d, J = 7.6 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ 82.82, 101.15, 106.95, 108.15, 111.67, 114.39, 115.82, 123.63, 124.80, 126.54, 128.93, 129.38, 129.48, 134.73, 142.03, 148.62, 151.97, 152.11, 152.73, 169.06. QSTAR (Applied Biosystems/MDS SCIEX) (ESI): [MH+] $C_{20}H_{13}N_4O_3$: calculated 357.0988, found 357.0988.

Bromoacetylamide-Rhodamine 110-Azide (4). Azide-Rhodamine 110 (**3**) (17.9 mg, 50.2 μmol) was dissolved in $CHCl_3$ (4 mL). Anhydrous potassium bicarbonate (138.2 mg, 1.0 mmol) was added. The reaction mixture was cooled to 0 °C, followed by addition of bromoacetyl bromide (43.7 μL, 0.50 mmol). The resulting solution was stirred at ambient temperature for 12 h, and the reaction was quenched with saturated aqueous Na_2CO_3. The aqueous layer was extracted with $CHCl_3$ (×2), and the combined organic layers were dried over Na_2SO_4, concentrated, and subjected to flash column chromatography (silica gel, 3:1 hexane/EtOAc) to give bromoacetylamide-Rhodamine 110-azide (**4**) (22.6 mg, 47.4 mmol, 94%) as a pale yellow crystalline solid. ^{1}H NMR (400 MHz, CDCl3) δ 4.03 (2H, s), 6.71 (1H, dd, J = 2.2 Hz, 8.6 Hz), 6.75 (1H, d, J = 8.5 Hz), 6.79 (1H, d, J = 8.6 Hz), 6.95 (1H, d, J = 2.2 Hz), 7.05 (1H, dd, J = 2.2 Hz, 8.8 Hz), 7.13 (1H, brd, J = 7.6 Hz), 7.64 (1H, dt, J = 1.0 Hz, 7.6 Hz), 7.68 (1H, dt, J = 1.2 Hz, 7.6 Hz), 7.74 (1H, d, J = 1.9 Hz), 8.04 (1H, brd, J = 6.8 Hz), 8.33 (1H, brs). ^{13}C NMR (100 MHz, $CDCl_3$) δ 29.21, 81.89, 107.11, 107.82, 114.86, 115.15, 115.43, 123.57, 125.03, 125.87, 128.38, 129.26, 129.82, 135.12, 138.86, 142.46, 151.09, 151.77, 152.68, 163.60, 169.11. QSTAR (Applied Biosystems/MDS SCIEX) (ESI): [MH+] $C_{22}H_{14}BrN_4O_4$: calculated 477.0198, found 477.0196.

t-Boc-Rhodamine 110-Triphenylphosphine-aza-ylide (5a). t-Boc-rhodamine 110 azide (**2**) (13.4 mg, 29.4 μmol) was dissolved in anhydrous THF (1.1 mL). Triphenylphosphine (9.1 mg, 34.7 μmol) was added. After 2 h reaction, solvent was removed under reduced pressure, and the residue was purified by PLC plate (1:1 hexane/AcOEt). t-Boc-rhodamine 110-triphenylphosphine-aza-ylide (20.3 mg, 29.4 mmol, quantative) was obtained as a red crystalline solid. ^{1}H NMR (400 MHz, CDCl3) δ 1.50 (9H, dd, J = 3.8 Hz, 5.3 Hz), 6.34 (1H, m), 6.47 (1H, m), 6.56 (1H, m), 6.64 (1H, m), 6.73 (1H, m), 6.81 (1H, m), 7.13 (1H, m), 7.47 (6H, m), 7.54 (4H, m), 7.60 (1H, m), 7.66 (3H, m), 7.73 (3H, m), 7.97 (1H, m). QSTAR (Applied Biosystems/MDS SCIEX) (ESI): [MH+] 691.2362, found 691.2374.

Reaction of Compound 2 with DTT. t-Boc-rhodamine 110 azide (**2**) (0.37 mg, 0.8 μmol) was dissolved in methanol (2.0 mL). Dithiothreitol (30.6 mg, μmmol) was added. The reaction was monitored by fluorescence and UV spectra. The maximum wavelength of fluorescent emission was observed at 525 nm. Mass spectrometry analysis showed that the product was rhodamine amine (**1**). ([MH+] $C_{25}H_{23}N_2O_5$: 431.161, MALDI-TOF MS found: 431.167).

Reaction of Compound 2 with TPP. t-Boc-rhodamine 110 azide (**2**) (11.1 mg, 24.3 μmol) was dissolved in anhydrous THF (2.43 mL). Triphenylphosphine (7.0 mg, 30.5 μmol) was added. The reaction was monitored by fluorescence and UV spectra (fluorescence measurements were conducted by diluting 1.5 μL reaction mixture with 1500 μL methanol. Absorption measurements were conducted by diluting 4.0 μL reaction mixture with 196 μL methanol.). As showed in Figure 5A, the maximum wavelength of fluorescent emission was observed at 550 nm 10 min later. After 1 h reaction, the fluorescent emission at 550 nm was saturated and no additional fluorescent emission was

observed. Mass spectrometry analysis showed that the product was aza-ylide (**5a**). ([MH+] $C_{43}H_{36}N_2O_5P$: 691.236, MALDI-TOF MS found: 691.304).

Synthesis of Unmodified Oligonucleotides. All oligonucleotides were synthesized on a 0.2 μmol scale on a DNA synthesizer (H-8-SE; Gene World) using standard phosphoroamidite coupling chemistry. Deprotection and cleavage from the CPG support was carried out by incubation in concentrated ammonia for 4 h at 55 °C. Following deprotection, the oligonucleotides were purified by reverse-phase column chromatography (MicroPure II column; Biosearch Technologies), and quantitated by UV absorbance using the nearest-neighbor approximation to calculate molar absorptivities.

3′-Rhodamine-Azide-Conjugated Oligonucleotide (probe 1). The bromoacetyl group of the rhodamine-azide (**4**) was reacted with the phosphorothioate group on the ODNs. For 3′ phosphorothioate sequences, the 3′-phosphate CPG was sulfurized by the sulfurizing reagent (Glen Research) after the first nucleotide was added. 75 nmol of the 3′-phosphorothioate oligonucleotide in 50 μL of 400 mM triethylammonium bicarbonate buffer were shaken for 5 h at room temperature with 750 nmol of rhodamine-azide (**4**) in 200 μL of dimethylformamide. The reacted products were collected by ethanol precipitation. Next, the products were purified by reverse-phase HPLC (0−80% acetonitrile/50 mM triethylammonium acetate gradient). The probe structure was confirmed by ESI-TOF mass spectrometry. 5′-GCCGGCGG-Rh-azide-3′: calculated mass, $C_{104}H_{126}N_{33}O_{51}P_9$ 2942.5; found 2942.5.

5′-Dithiothreitol (DTT)-Linked Oligonucleotide (probe 2). Dithiol phosphoroamidite (DTPA; Glen Research) was used to prepare 5′-DTT-modified oligonucleotide. Deprotection and cleavage from the CPG support was carried out by the standard method. Following deprotection, the oligonucleotide was purified by reverse-phase column chromatography and quantitated by UV absorbance. To cleave the disulfide bond, 10 nmol of purified oligonucleotide was treated with 250 μL of 100 mM TCEP in phosphate buffer (pH 6.0). The reacted products were collected by ethanol precipitation, and then preserved in 100 μM DTT solution. The probe structure was confirmed by MALDI-TOF mass spectrometry. 5′-DTT-TGTGGGCA-3′: calculated mass, $C_{83}H_{108}N_{32}O_{51}P_8S_2$ 2980.4; found 2979.7.

5′ Triphenylphosphine (TPP)-Linked Oligonucleotide (probe 3). Carboxy-triphenylphosphine (TPP) NHS ester was reacted with 5′-amino-modified oligonucleotide. 5′-amino-modifier C6 (Glen Research) was used to prepare 5′-amino-modified oligonucleotide. 50 nmol of the 5′-amino-modified oligonucleotide in 135 μL of 93 mM sodium tetraborate (pH 8.5) was shaken for 5 h at room temperature with 2 μmol of TPP NHS ester in 115 μL of dimethylformamide. The reacted products were collected by ethanol precipitation. Next, the collected products were purified by reverse-phase HPLC (0−50% acetonitrile/50 mM triethylammonium acetate gradient). The probe structure was confirmed by ESI-TOF mass spectrometry. 5′-TPP-TGTGGGCA-3′: calculated mass, $C_{104}H_{126}N_{33}O_{51}P_9$ 2931.6; found 2932.6. A peak corresponding to the oxidized product (+O) was also seen and presumed to arise from oxidation during purification.

Fluorescence Measurement. Reactions on the DNA template were performed in 1.2 mL of tris-borate buffer (70 mM, pH 8.0) containing 10 mM $MgCl_2$ with target DNA (500 nM), probe 1 (500 nM), and probe 2 (1 μM) or probe 3 (500 nM) at 25 °C. In the case of probe 2, DTT (100 μM) was added to the reaction mixture. The increase of fluorescence intensity produced by reduction of rhodamine-azide on probe 1 was continuously monitored at time intervals. Reactions were observed by fluorescence spectrometry (FP-6500; JASCO). Fluorescence spectra were measured under the following conditions: excitation, 490 nm. For the time course of the azide reduction, the fluorescence intensity was measured for 0.5 s at 1 min intervals: excitation, 490 nm; emission, 550 nm (TPP) or 530 nm (DTT).

Imaging of RNA in Fixed *E. coli* Cells. *Escherichia coli* K12 (NBRC 3301) was grown aerobically on a rotary shaker in Luria−Bertani broth (WAKO) at 30 °C for 20 h. The cells were centrifuged and were fixed with 4% paraformaldehyde−PBS solution for 2 h before being washed with PBS and resuspended in PBS/ethanol (1:1; vol/vol). Fixed cells were stored at −20 °C. Oligonucleotide probes were targeted to nucleotides 968−997 in 23S rRNA of *E. coli* K12 since Fuchs et al. described the accessibility of this site was superior to other sites (*26*). Both rhodamine-azide probe (5′-CTGGCGGTCTGGGTT-Rh-azide-3′) and triphenylphosphine probe (5′-TPP-GTTTCCCTCT-TCACG-3′) were 15 nt in length. After attaching fixed *E. coli* on the glass slide, 9 μL of hybridization buffer (20 mM Tris−HCl pH 7.2, 0.9 M NaCl, 0.1% SDS, 440 nM rhodamine-azide probe, 440 nM triphenylphosphine probe, and 0.025% PEG6000) were applied to each well. After incubation at 37 °C for 30 min, hybridization buffer was briefly removed with distilled water without the conventional washing step, air-dried, and mounted in Slow Fadeβ Gold antifade reagent (Invitrogen). Fluorescence images were obtained through a fluorescence microscope (Carl Zeiss Axioskop 2 Plus) with mercury lamp, using digital camera (Carl Zeiss AxioCam HRm) and imaging software (Carl Zeiss *AxioVision 3.0*). Microscope settings were as follows: ex. 480/40 band-pass filter; ex. 510 nm with long-pass filters, exposure time 2 s.

RESULTS

Principle of Fluorescence Emission of the RETF Probe. The RETF probe consists of two separated DNA strands, with one probe having a reducible fluorogenic compound, while the other probe has reducing reagents. The chemistry of the RETF probe involves reaction between the azide group of nonfluorescent rhodamine derivatives and reducing reagents on an oligonucleotide template (Figure 1A). This reaction proceeds only in the presence of complementary oligonucleotide templates. After reduction of the azide group (**I**), the rhodamine derivative with the aza-ylide group (**III**) or the amino group (**IV**) emits fluorescence. Dithiothreitol (DTT) or triphenylphosphine (TPP) can be used as reducing reagent for this chemistry. DTT directly reduces the an azide group (**I**) to an amino group (**IV**) with the formation of a disulfide bond (Figure 1B). The Staudinger reaction using TPP as a reducing reagent produces an aza-ylide (**III**), which hydrolyzes to give a primary amine (**IV**) and the corresponding phosphorus compound (Figure 1C). This reaction works orthogonally in biological conditions or even in cells.

Synthesis of Rhodamine Azide. The synthesis of rhodamine azide derivatives (**4**) is shown in Scheme 1. The previously reported mono-Boc-rhodamine 110 (**1**) (*27*) was transformed to the diazo derivative by treatment with $NaNO_2$, and the diazo group was replaced with an azide group by the addition of NaN_3 to the reaction mixture. Treatment with trifluoroacetic acid to remove the Boc group of compound **2** did not give the desired product **3** because of damage to the azide group. The Boc group was successfully deprotected by treatment with 4 M HCl/dioxane solution, followed by introduction of the bromoacetyl group by treatment with bromoacetyl bromide and sodium bicarbonate to give the desired compound **4**. Compound **4** was introduced into the DNA probe.

Reaction of Rhodamine Azide (2) with Reducing Reagents. Rhodamine azide **2** showed no absorbance at wavelengths longer than 310 nm in methanol, but the corresponding rhodamine amine **1** showed a maximum absorption at 490 nm. When a high concentration of DTT or TPP was added to a solution of

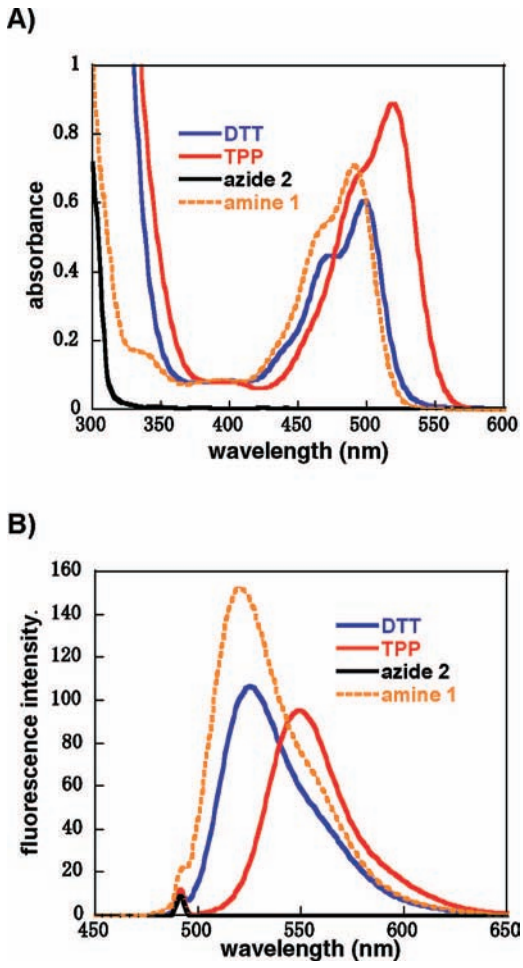

Figure 2. (A) Absorption spectra of 200 μM azide 2 after treatment with DTT (blue solid line) or TPP (red solid line), azide 2 (black solid line) without any treatment, or amine 1 (orange broken line) in methanol. (B) Fluorescent emission spectra with excitation at 490 nm of 10 μM azide 2 by treatment with DTT (blue solid line) or TPP (red solid line), azide 2 (black solid line) without any treatment, or amine 1 (orange broken line) in methanol.

azide **2**, a peak having a maximum at 495 or 518 nm increased, respectively, resulting from reduction of the azide group (Figure 2A). The fluorescence properties of rhodamine derivatives were also examined. No significant fluorescence with excitation at 490 nm was observed for azide **4**. On the other hand, rhodamine amine **1** showed strong fluorescence emission at around 520 nm. After the addition of DTT or TPP to the solution of azide **4**, a strong emission appeared around 520 or 550 nm, respectively, where the emission was enhanced almost 2100-fold (Figure 2B). We isolated these products and analyzed the structures by NMR spectroscopy and mass spectrometry. The product resulting from the DTT treatment was amine **1**. In contrast, TPP treatment gave aza-ylide **5a** (Scheme 1). It seems that not **5a** but **5b** with longer π-conjugation in the equilibrium structures emits fluorescence at 550 nm. Thus, we conclude that both reducing reagents can transform rhodamine azide into a

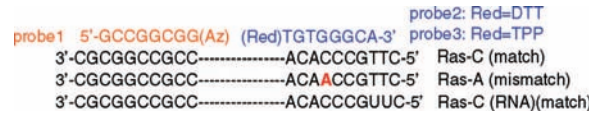

Figure 3. Probe 1 is an 8-mer ODN modified with rhodamine azide **4** (Az) at the 3′-terminal. Probes 2 and 3 are 8-mer ODNs modified with DTT or TPP as reducing reagents (Red) at the 5′-terminal. The DNA targets are 20-mer ODNs with a fully matched sequence (Ras-C) and a one-base mismatched sequence (Ras-A). Ras-C (RNA) is the fully matched RNA target.

fluorescent form by intermolecular reaction at the small compound level.

Design of the RETF Probe. To test the utility of the RETF system for fluorescence-based oligonucleotide detection, we designed three new DNA probes (Figure 3). Probe 1 was modified at the 3′-terminal with rhodamine azide **4**, where the bromoacetyl group of **4** was reacted with the phosphorothioate group at the 3′-end of the DNA probe. Probe 2 was modified at the 5′-terminal with DTT using commercially available phosphoramidite reagents. Probe 3 was modified at the 5′-terminal with 2′-carboxytriphenylphosphine (TPP), which was conjugated with the 5′-amino linker of the DNA probe through amide bond formation. Two DNA templates originating from the human Ras gene sequence, which is known as an oncogene, were designed containing Ras-C with a full match sequence and Ras-A with a one-base mismatch, respectively (Figure 3). Ras-C (RNA) was also designed, corresponding to the Ras-C DNA strand.

Reaction of the RETF Probe. An important issue for the detector probe is that it shows neither background fluorescence nor a false signal under biological conditions, in order to achieve a high *S*/*B* ratio. The probe should be very stable in any biological conditions. To determine the stability of the RETF probe, we treated the probe under various extreme conditions and checked the resulting signal. As a consequence, it was found that probe 1 with rhodamine azide was fully stable under acidic or basic conditions at pH 5−10 and under light irradiation at 490 nm, and at a high temperature of 90 °C for at least 10 min, as indicated by the lack of increase in fluorescence (Figures 4 and 5). However, when a high concentration of tris(2-carboxyethyl)phosphine (TCEP) was added to a solution of probe 1, a strong fluorescence signal appeared as the result of reduction of rhodamine azide on probe 1. Thus, we conclude that probe 1 with rhodamine azide was fully stable under various biological conditions to show no undesired fluorescence signal and was responsive to only the specific reducing reagents.

Next, we tested whether the RETF probe can detect target DNA or RNA sequences to produce a fluorescence signal (Figure 5). When 500 nM probe 1 and 1 μM probe 2 were incubated in pH 8.0 tris-borate buffer, the fluorescence signal at 530 nm increased in the presence of a target Ras-C over 60 min by reduction of the azide group to the amino group of probe 1, and no significant increase in fluorescence was observed in the absence of Ras-C (Figure 5A). When 500 nM probe 1 and 500 nM probe 3 were incubated in buffer, the increase in fluorescence at 550 nm was monitored. Probe 3 reacted with probe 1 in the presence of target Ras-C much faster than did

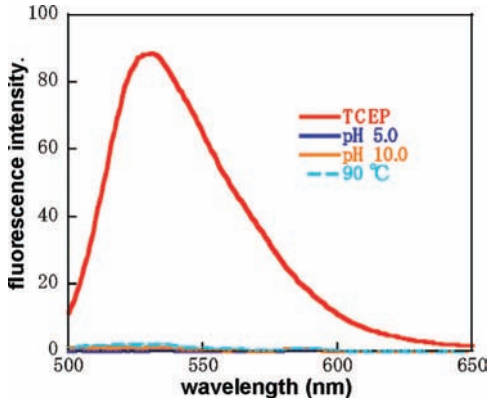

Figure 4. Stability of probe 1 under various conditions. The stability of the rhodamine-azide probe (probe 1) was tested at pH 5.0, 10.0, and high-temperature (90 °C) conditions. Probe 1 was incubated at pH 5.0 (blue solid line) or 10.0 (orange solid line) tris-borate buffer for 30 min at room temperature or in pH 8.0 tris-borate buffer for 10 min at 90 °C (light blue broken line). No significant fluorescence with excitation of 490 nm was observed in these conditions by comparison with the spectra after the treatment of TCEP (red solid line).

probe 2, and the signal at 550 nm reached the saturation phase within 20 min (Figure 5A). The signal did not increase in the absence of Ras-C over 30 min, even under continuous light irradiation at 490 nm.

The ability to achieve single base discrimination is important for diagnostic applications. The reaction of probe 1 with probe 3 in the presence of one-base-mismatched target Ras-A was carried out and showed good single base mismatch discrimination, dropping in initial rate by 18.8-fold, compared with fully matched Ras-C (Figure 5B).

RNA is an important target for detection, especially for imaging cellular RNA. However, because RNA−DNA duplexes form a different helical structure from DNA−DNA duplexes, there is no guarantee that such a chemical reaction on the template would proceed in the same way when detecting RNA as happened with DNA. Thus, we prepared an RNA target, Ras-C (RNA), and compared the reaction rates with the corresponding DNA target, Ras-C. When Ras-C (RNA) was targeted, almost identical time-course spectra as for Ras-C (DNA) were obtained from both probe 2 and probe 3 (Figure 5C). The fluorescence signal at 550 nm from the reaction of probe 1 and probe 2 with Ras-C (RNA) reached the saturation phase in 20 min, similar to the Ras-C, DNA target. Thus, the RETF probe seems to be capable of detecting both DNA and RNA targets.

Figure 6A shows the time-dependent fluorescence intensities at 530 and 550 nm in the reaction of probe 1 and probe 3 in the presence of the Ras-C template over 600 min. The signal at 550 nm quickly increased in the initial stage and slightly dropped after 30 min, but the signal at 530 nm continuously increased over the 600 min. The maximum wavelength in the fluorescence spectra shifted from 550 to 530 nm (Figure 6B). HPLC (Figure 7A,B) and MALDI-TOF mass analysis (Supporting Information Figure S1) showed that 67% of probe 1 had reacted with probe 3 after 10 min to give the corresponding ligated product with an aza-ylide bond (**III**) (peak 2: 52%) and reduced probe 1 with an amino group (**IV**) (peak 3: 15%) (Figures 1 and 7A). After 24 h, the aza-ylide peak completely disappeared and the product with an amino group was obtained in 86% yield (peak 1, Figure 7B). In contrast, reaction with probe 2 (DTT) showed only reduced product in 36% yield after 2 h (Figure 7C). Thus, we conclude that, in the reaction of probe 1 and probe 3, the increase in fluorescence at 530 nm indicates the formation of reduced probe 1 with the amino group of rhodamine (**IV**) from the hydrolysis of the aza-ylide product (**III**) (*28*). In contrast, probe

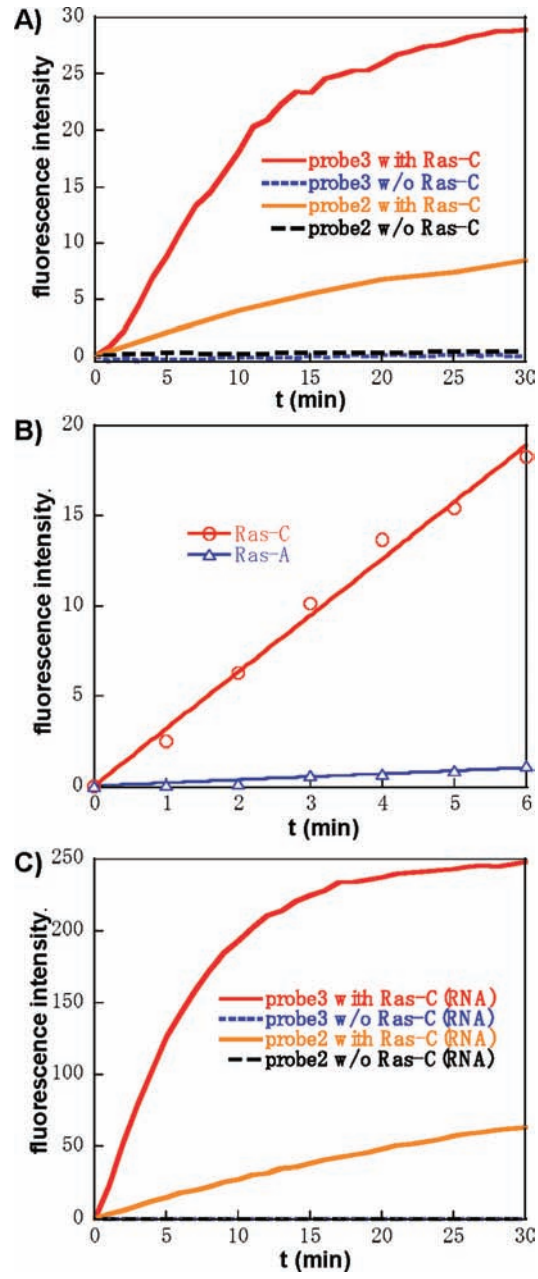

Figure 5. (A) Time course of the fluorescence intensity in the reaction of probe 1 with probe 2 or probe 3. Fluorescence emission at 530 nm (probe 2) or 550 nm (probe 3), respectively, was monitored by excitation at 490 nm. The reactions were carried out under the following conditions in pH 8.0 tris-borate buffer containing 10 mM $MgCl_2$, 1 μM probe 2, 100 μM DTT, and 500 nM probe 1 with (orange solid line) or without (black broken line) Ras-C, or 500 nM probe 3 and 500 nM probe 1 with (red solid line) or without (blue broken line) Ras-C. (B) The time course of the fluorescence intensity in the reaction of probe 1 with probe 3 in the presence of Ras-C (match; circle) or Ras-A (mismatch; triangle). The reaction conditions were the same as above. (C) Time course of the fluorescence intensity in the reaction of probe 1 with probe 2 or probe 3 with RNA target. The reactions were carried out with 500 nM probe 1 with (orange solid line) or without (black broken line) Ras-C (RNA), or 500 nM probe 3 and 500 nM probe 1 with (red solid line) or without (blue broken line).

2 directly reduces the azide group of probe 1 to the corresponding amine (**IV**).

Imaging of RNA in Bacterial Cells. Fluorescence in situ hybridization (FISH) is becoming broadly adopted by microbiologists because of the existence of a growing database of rRNA (rRNA) sequences. However, the standard fluorescent probes require a careful washing step in the protocol to remove

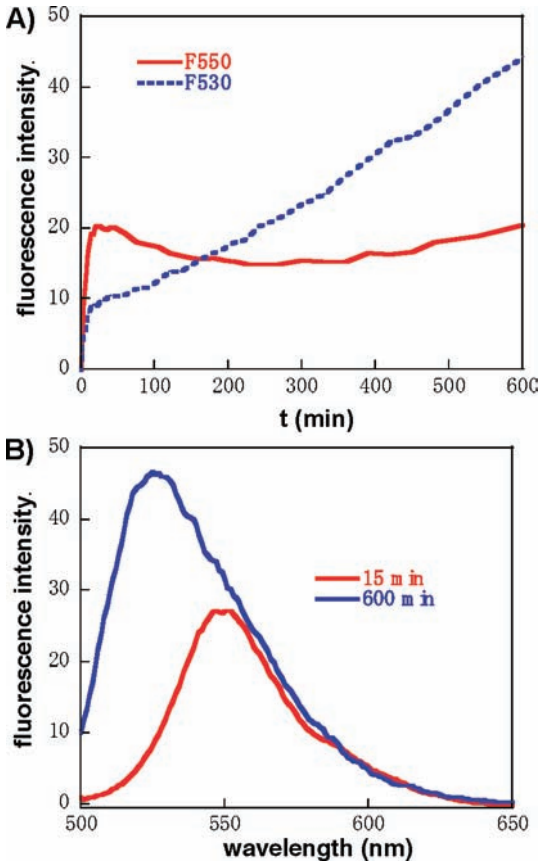

Figure 6. (A) Time course of the fluorescence intensity in the reaction between 500 nM probe 1 and 500 nM probe 3 in the presence of 500 nM Ras-C. Emissions at 550 nm (red solid line) and 530 nm (blue broken line) were monitored simultaneously. (B) Fluorescence spectra were measured after 15 min (red solid line) and 600 min (blue solid line) incubation with probes 1 and 3 in the presence of Ras-C. The maximum wavelength in the fluorescence spectra shifted from 550 to 530 nm.

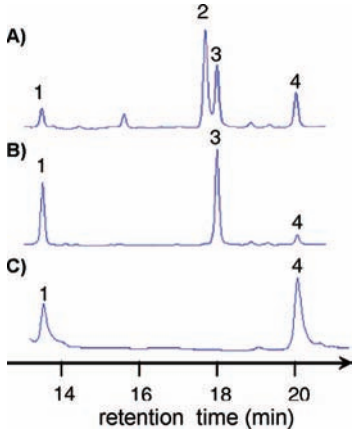

Figure 7. HPLC analysis of the reaction mixture. (A) 10 min reaction with probe 3, (B) 24 h reaction with probe 3, (C) 2 h reaction with probe 2. nonspecific signals. Here, we tested a nonwashing protocol for detection of 23S rRNA in the *Escherichia coli* K12 strain (NBRC3301) by use of an RETF probe. Probes were designed for targeting sequence 968−997 on 23S rRNA, which is known to be accessible by the standard FISH probe (*26*). The rhodamine azide probe and the TPP probe with matched sequence are both

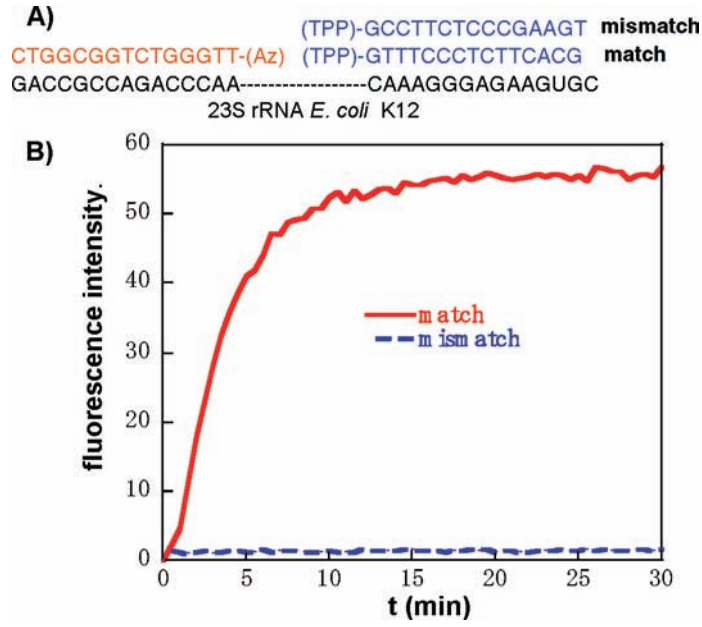

Figure 8. (A) Probe sequences for 23S rRNA of *E. coli* K12. Designed 15-mer probes are a rhodamine-azide probe with fully matched sequence, TPP probe with fully matched sequence, and TPP probe with mismatched sequence. (B) Time course of the fluorescence intensity in the reaction between 500 nM rhodamine-azide probe and 500 nM matched TPP probe or mismatched TPP probe in the presence of 500 nM target DNA. Reaction was monitored by excitation at 490 nm and emission at 550 nm.

15 bases long (Figure 8A). The TPP probe with mismatched sequence was tested as a control. Before imaging experiments, probes were tested in in vitro experiments to target corresponding DNA sequences (Figure 8B). The matched probe pair produced a strong fluorescent signal and completed the reaction within 10 min, and no significant signal was observed from a mismatched probe pair (Figure 8B).

We then proceeded to test the probes in bacterial cells. Cells were fixed with paraformaldehyde according to literature methods and were incubated with probes at 37 °C for 30 min. Cell mixtures were directly spotted on a slide glass without a washing step and observed using a microscope. Figure 9A−D show fluorescence images and bright-field transmission images of cells. A strong fluorescent signal was observed in the case of the matched probe pair (Figure 9A), but no signal was observed from the mismatched probe pair (Figure 9B). The data show that the RETF probe can be used to detect specific RNA sequences in structured biological targets in cells. This suggests the possibility of their general use in identifying bacterial pathogens by their rRNAs.

DISCUSSION

Many fluorogenic probes for sensing oligonucleotides have been developed, such as MBs (*6*, *16*) and quenched autoligation (QUAL) probes (*14*, *18*, *29*). These probes produce a fluorescent signal based on the RET mechanism, for which a pair of quencher and fluorescence dyes is normally used. The quenching efficiency reaches a maximum of 98%, if the position of a pair of dyes is carefully optimized (*24*). The corresponding *S*/*B* ratio is 50:1. In contrast, rhodamine azide of the RETF probe emits by an absorption change triggered by a chemical reaction. The *S*/*B* ratio reaches 2100:1 (Figure 2). This property is clearly helpful for sensing. Another issue for an MB is that protein binds to the beacon to yield a false fluorescent signal (*30*). QUAL probes also have the potential to yield false fluorescent signals through automatic hydrolysis of the quencher. A novel

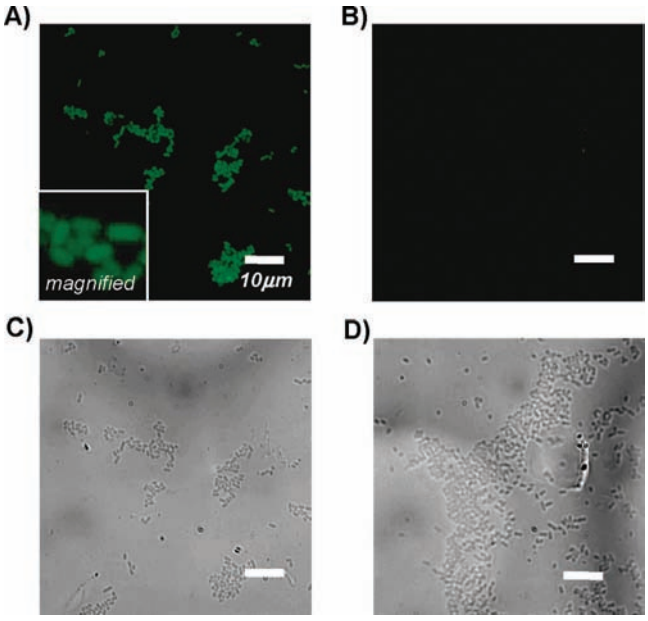

Figure 9. Imaging of 23S rRNA in fixed *E. coli* K12 (NBRC3301). Pictures showed a specific signal with a matched probe pair and little or no signal with a mismatched pair. Microscope settings were as follows: excitation, 480/40 band-pass filter; emission, 510 nm with long-pass filters; exposure time, 2 s. (A) Rhodamine-azide probe/matched TPP probe. (B) Rhodamine-azide probe/mismatched TPP probe. (C) Bright-field picture under the conditions of (A). (D) Bright-field picture under the conditions of (B).

fluorogenic system has been reported, that is, nucleic acid-triggered fluorescent probe activation by the Staudinger reaction, and showed that the fluorescence signal emerged subsequent to cleavage of the ester bond, which produces the possibility of yielding background fluorescence by automatic or enzymatic hydrolysis of the ester bond (*25*). The method has not been applied to the detection of cellular RNAs. On the other hand, the RETF probe accepts not only TPP in the Staudinger reaction, but also other reducing reagents, such as DTT, for reduction of the azide group to switch the fluorescence on and has no hydrolysis problems, which results in minimization of background fluorescence. In addition, as shown in Figure 4, the RETF probe has proven to be fully stable under various conditions such as pH 5−10, light irradiation at 490 nm, and high temperature of 90 °C. This result implies that the RETF probe operates under wide biological conditions without producing an undesirable false fluorescence signal. An issue of our method to be solved is oxidative deactivation of the reducing reagent on the probe in solution, although that does not produce a false signal. We showed one example of a single base discrimination study. The discrimination ability depends on the identity of the mutation and its nearest neighbors, as well as the length of the probe. Therefore, the probe should be carefully designed in each case to achieve single nucleotide resolution.

We carefully analyzed the reaction mechanism between rhodamine azide and reducing reagents. The DTT probe directly reduces rhodamine azide on the probe to fluorescent rhodamine amine (Figure 1). On the other hand, the reaction of the TPP probe initially produces a fluorescent ligation product with an aza-ylide bond, then gives a fluorescent product with rhodamine amine through hydrolysis of the aza-ylide bond (Figure 1). The key finding here is that the rhodamine aza-ylide derivative is fluorescent. This mechanism was supported by several experimental results. In a small compound, rhodamine azide **2** is directly reduced to amine **1** by DTT. The rhodamine aza-ylide derivative **5b** was isolated from the reaction of **2** with TPP (Scheme 2). Aza-ylide **5b** with open lactone form was stable in methanol and showed fluorescence emission at 550 nm, as opposed to amine **2**, which emits fluorescence at 520 nm (Figure 2). Interestingly, when the trialkylphosphine TCEP was employed as a reducing reagent, rhodamine azide **2** was directly reduced to amine **2** without formation of the aza-ylide product in methanol (Figure 4). This result suggests that TPP as a triarylphosphine can stabilize the aza-ylide intermediate because of the presence of long π-conjugation. The reaction of the rhodamine azide probe with the reducing probe on the DNA template proceeded in a similar manner as the reaction of rhodamine azide **2** in the small compound. The existence of a ligated product with an aza-ylide linkage was verified by HPLC and mass spectrometric analysis shown in Figure 7 and Supporting Information Figure S1. Further spectroscopic analysis clearly indicates hydrolysis of the aza-ylide bond in solution with increasing emission signal at 530 nm resulting from the formation of the amino rhodamine probe (Figure 6).

Fluorescence activation by reduction of the azide group of rhodamine is a new molecular mechanism as a fluorogenic compound. After reduction of the azide group, the rhodamine derivative opens the lactone ring to form a carboxylate and emits fluorescence. The reaction of the TPP probe is complete within 10−15 min with both DNA and RNA targets. The reaction speed is faster than other DNA-templated chemical reactions that are able to produce fluorescence. As we have shown, the method was successfully applied to visualization of 28S rRNA in *E. coli* by a nonwashing protocol with probes. It could be applied to detect RNA species in living cells. Future work will be aimed at making new azide fluorescent compounds for multiple color detection and sensing RNA species in living cells.

CONCLUSION

We developed a reduction-triggered fluorescence (RETF) probe for sensing oligonucleotides. The chemistry involves the reaction between the azide group of rhodamine derivatives and reducing reagents on a DNA template. A new fluorogenic compound, rhodamine azide **4**, was designed and synthesized for this chemistry. After reduction of the azide group to the amino group, the rhodamine derivative emits fluorescence. DTT, TPP, or other reducing reagents can be used for this chemistry. Reaction of the RETF probe proceeded without any enzymes or reagents, and offered a high signal and very low background fluorescence under biological conditions. We successfully applied the probe to detection of oligonucleotides in solution and endogenous RNA in bacterial cells.

Development of a Thyroid Hormone Receptor Targeting Conjugate

Jianfei Zheng, Atsushi Hashimoto,[†] Marc Putnam,[‡] Katherine Miller, and John T. Koh*

Department of Chemistry and Biochemistry, University of Delaware, Newark, Delaware 19716. Received January 24, 2008; Revised Manuscript Received March 14, 2008

Molecular conjugates of hormone receptor−ligands with molecular probes or functional domains are finding diverse applications in chemical biology. Whereas many examples of hormone conjugates that target steroid hormone receptors have been reported, practical ligand conjugates that target the nuclear thyroid hormone receptor (TRβ) are lacking. TR-targeting conjugate scaffolds based on the ligands GC-1 and NH-2 and the natural ligand triiodothyronine (T3) were synthesized and evaluated in vitro and in cellular assays. Whereas the T3 or GC-1 based conjugates did not bind TRβ with high affinity, the NH-2 inspired fluorescein-conjugate JZ01 showed low nanomolar affinity for TRβ and could be used as a nonradiometric probe for ligand binding. A related analogue JZ07 was a potent TR antagonist that is 13-fold selective for TRβ over TRα. JZ01 localizes in the nuclei of TRβ expressing cells and may serve as a prototype for other TR-targeting conjugates.

INTRODUCTION

Advances in chemical biology have led to many important new applications of hormone conjugates as tools to probe nuclear receptor biology. The high affinity and specificity of small-molecule hormones can be used to selectively direct new bimolecular functions to the sites of nuclear hormone receptors (NHR) action. Notable examples include testosterone-based PROTAC conjugates that can down-regulate AR stability by recruiting ubiqitin ligases (*1, 2*), or peptoid activation domain conjugates of dexamethasone that can be used to activate transcription from GR (glucocorticoid receptor) independent of its normal coactivator proteins (*3*). Other examples include fluorescent NHR agonists or ligand−fluorophore conjugates that have been used as nonradiometric methods for detecting NHR binding (*4*). Yet another new and exciting discovery in this area is hormone conjugates that selectively regulate non-nuclear hormone actions by limiting cellular penetration and localization (*5*).

The development of hormone conjugates for NHRs is not always straightforward, as NHR agonist ligands are generally completely encapsulated by the protein in their bound forms. Many NHR antagonist have been shown to have molecular appendages or "extensions" that displace the active conformation of helix-12, an essential element of the coactivator binding site (*6–9*). In some cases, these appendages extend to the receptor surface providing a potential handle for generating new hormone conjugates. Structure−activity relationship studies revealed that the design of such molecular extensions is more complicated than simply introducing steric bulk at an appropriate site on the ligand, as subtle structural modifications to these extensions can have a substantial effect on ligand activity (*10–12*). Therefore, a priori, it is not obvious how to modify an agonist structure in a manner that would allow reporter groups or functional domains to be presented from the receptor surface while maintaining high-affinity binding.

The thyroid hormone receptors are important regulators of genes involved in metabolic regulation and homeostasis, as well as critical events in development (*13*). Mutations of TRβ have been implicated in RTH (resistance to thyroid hormone) as well as certain forms of cancer (*14–17*). New molecular probes of thyroid hormone action may help understand the molecular roles of TR in normal development and in these TR-associated disease states. Examples of thyroxine−fluorophore conjugates have been reported that change properties upon binding antithyroxine (T4) antibodies or detergent; however, no TR-targeting conjugates have been developed that effectively target the nuclear thyroid hormone receptor (TR) (*18, 19*).

Recently, several TR antagonists and partial agonists prompted us to investigate the development of TR-targeting hormone conjugates. Of the recently described antagonists, the compound NH-3 and the closely related agonist NH-2 (Figure 1) were of particular interest because the 5′-arylethynyl appendages could be expected to point toward helix-12 and have demonstrated subnanomolar affinity for TRβ (*11*). Although NH-2 is reported to be a TR agonist, the additional *n*-pentyl substitution of NH-2 could be envisioned to access the protein surface from the ligand binding site of TR through displacement of helix-12 or from repositioning of helix-11 as has been observed in some TR−ligand cocrystal structures (*20*). Scaffold I was therefore proposed as a conjugate scaffold for presentation of molecular probes from TR (Figure 1). To evaluate the properties of scaffold I as a means to synthesize TR-targeting conjugates, we generated the fluorescein conjugated probe JZ01 and evaluated its ability to bind to TRβ.

EXPERIMENTAL PROCEDURES

Synthesis of JZ01 and JZ07 5-(2,6-dimethyl-4-(triisopropylsilyloxy)benzyl)-3-isopropyl-2-(methoxymethoxy)benzaldehyde (2). Compound **1**was made as previously described (*21*). To a solution of **1** (2.3 g, 4.9 mmol) in a 2:1 (v/v) mixture of anhydrous THF and hexane (48 mL) at −78 °C under N_2 was added 5.4 mL 2 M *n*-BuLi solution in anhydrous hexane (10.8 mmol). The solution was allowed to warm to room temperature and stirred for 2 h before DMF (1.15 mL, 14.7 mmol) was added dropwise to the stirring solution. After an hour, the solution was poured over 1 N cold HCl solution (100 mL) and the mixture was extracted with ethyl acetate (2 × 50 mL). The organic extracts were washed with water (20 mL) and brine (20 mL), dried over

MgSO4, filtered, and evaporated under reduced pressure. The resulting crude product was purified by flash column chromatography on silica gel (1:10 ethyl acetate/hexane) to give compound **2** (1.68 g, 3.37 mmol, 69%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 10.22 (s, 1H), 7.34 (d, J = 1.6 Hz, 1H), 7.13 (d, J = 1.6 Hz, 1H), 6.63 (s, 2H), 5.02 (s, 2H), 3.96 (s, 2H), 3.58 (s, 3H), 3.32 (heptet, J = 6.8 Hz, 1H), 2.16 (s, 6H), 1.27 (heptet, J = 6.8 Hz, 3H), 1.15−1.11 (m, 24H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 191.09, 155.65, 154.22, 142.80, 138.03, 137.13, 132.24, 129.42, 128.76, 125.96, 119.68, 101.74, 57.76, 33.77, 26.18, 23.49, 20.37, 18.00, 12.54. HRMS (CI) calculated for $[C_{30}H_{46}O_4Si + H]^+$ 499.3244, found 499.3209.

(4-(3-ethynyl-5-isopropyl-4-(methoxymethoxy)benzyl)-3,5-dimethylphenoxy)triisopropylsilane (3). To a solution of diisopropylamine (0.46 g, 4.5 mmol) in anhydrous THF (10 mL) at −78 °C was added 1.8 mL 2.0 M solution of *n*-BuLi in anhydrous hexane (3.6 mmol). The solution was allowed to warm up to 0 °C and stirred for 30 min before it was cooled to −78 °C. Then 1.8 mL 2.0 M solution of TMS−diazomethane in anhydrous hexane was added dropwise to the solution at −78 °C and the solution was stirred for 30 min. To the reaction solution at −78 °C, **2** (1.5 g, 3.0 mmol) in 10 mL anhydrous THF was added dropwise and the solution was stirred at −78 °C for 1 h. Then the solution was allowed to reflux for 2.5 h, cooled to room temperature, and poured over ice−water. The mixture was extracted with ethyl acetate (2 × 50 mL), and organic extracts were washed with water (20 mL) and brine solution (20 mL), dried over $MgSO_4$, and evaporated under reduced pressure. The resulting residue was purified by flash column chromatography on silica gel (1:10 ethyl acetate/hexane) to give **3** (0.9 g, 1.8 mmol, 60%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 6.90 (d, J = 2 Hz, 1H), 6.86 (d, J = 2 Hz, 1H), 6.60 (s, 2H), 5.17 (s, 2H), 3.88 (s, 2H), 3.60 (s, 3H), 3.36 (heptet, J = 6.8 Hz, 1H), 3.17 (s, 1H), 2.15 (s, 6H), 1.25 (heptet, J = 6.8 Hz, 3H), 1.23−1.10 (m, 24H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 154.50, 154.07, 141.95, 138.13, 136.06, 130.52, 128.99, 127.04, 119.55, 115.39, 99.89, 81.21, 80.55, 57.55, 33.65, 26.34, 23.34, 20.36, 18.00, 12.71. HRMS (CI) calculated for $[C_{31}H_{46}O_4Si + H]^+$ 495.3294, found 495.3275.

Methyl 6-(4-((5-(2,6-dimethyl-4-(triisopropylsilyloxy)benzyl)-3-isopropyl-2-(methoxymethoxy)phenyl)ethynyl)phenyl)hexanoate (5). Compound **4** was prepared as previously described. CuI (17 mg, 0.086 mmol) and bis(triphenylphosphine)palladium(II) chloride (61 mg, 0.086 mmol) were added into a Schlenk flask, and the flask was vacuumed then backfilled with N_2 atmosphere 3 times. Compound **3** (850 mg, 1.72 mmol) and compound **4** (630 mg, 1.89 mmol) were dissolved in 20 mL distilled piperidine and the solution was added to the Schlenk flask. The reaction mixture was stirred overnight at 40 °C. The reaction mixture was poured over 100 mL cold 0.1 N HCl solution and extracted ethyl acetate (2 × 50 mL). The organic extracts were washed with water (30 mL) and brine solution (30 mL), dried over $MgSO_4$, and evaporated under reduced pressure. The resulting crude product was purified by flash column chromatography on silica gel (1:10 ethyl acetate/hexane) to give **5** (950 mg, 79%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.39 (d, J = 8 Hz, 2H), 7.12 (d, J = 8 Hz, 2H), 6.89 (d, J = 0.8 Hz, 2H), 6.63 (s, 2H), 5.26 (s, 2H), 3.91 (s, 2H), 3.64 (s, 3H), 3.60 (s, 3H), 3.39 (heptet, J = 6.8 Hz, 1H), 2.60 (t, J = 7.6 Hz, 2H), 2.29 (t, J = 7.6 Hz, 2H), 2.17 (s, 6H), 1.64 (m, 4H), 1.34−1.23 (m, 5H), 1.16 (d, J = 7.2 Hz, 6H), 1.11 (d, J = 7.2 Hz, 18H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 174.12, 154.07, 153.81, 142.93, 141.84, 138.18, 135.99, 131.38, 129.81, 129.20, 128.48, 126.40, 120.73, 119.59, 116.61, 99.78, 92.94, 86.39, 57.55, 51.47, 35.66, 33.97, 33.75, 30.87, 28.70, 26.43, 24.79, 23.40, 20.42, 18.04, 12.74. HRMS (ESI) calculated for $[C_{44}H_{62}O_5Si + Na]^+$ 721.4264, found 721.4231.

Methyl 6-(4-((5-(4-Hydroxy-2,6-dimethylbenzyl)-3-isopropyl-2-(methoxymethoxy) phenyl)ethynyl)phenyl)hexanoate (6). To a solution of compound **5** (140 mg, 0.2 mmol) in 2 mL THF was added 0.4 mL 1 M solution of Bu_4NF in THF (0.4 mmol). The solution was stirred for 30 min and poured over 0.1 N HCl (30 mL). The mixture was extracted with ethyl acetate (2 × 30 mL). The organic portions were combined, washed with water (15 mL) and brine solution (15 mL), dried over $MgSO_4$, and evaporated under reduced pressure. The resulting crude product was purified by flash column chromatography on silica gel (1:4 ethyl acetate/hexane) to yield **6** (96 mg, 88%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.40 (d, J = 8.4 Hz, 2H), 7.12 (d, J = 8.4 Hz, 2H), 6.96 (d, J = 2 Hz, 1H), 6.86 (d, J = 2 Hz, 1H), 6.56 (s, 2H), 5.26 (s, 2H), 5.21 (s, 1H), 3.89 (s, 2H), 3.67 (s, 3H), 3.61 (s, 3H), 3.41 (heptet, J = 6.8 Hz, 1H), 2.60 (t, J = 8 Hz, 2H), 2.31 (t, J = 8 Hz, 2H), 2.17 (s, 6H), 1.64 (m, 4H), 1.35 (m, 2H), 1.17 (d, J = 6.8 Hz, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 174.49, 153.78 (*2*), 142.97, 141.87, 138.67, 136.01, 131.38, 129.54, 128.70, 128.47, 126.64, 120.61, 116.66, 114.90, 99.76, 93.03, 86.30, 57.60, 51.62, 35.63, 34.02, 33.76, 30.83, 28.68, 26.46, 24.77, 23.43, 20.40. HRMS (ESI) calculated for $[C_{35}H_{42}O_5 + Na]^+$ 565.2930, found 565.2946.

Methyl 6-(4-((5-(4-(2-*Tert*-butoxy-2-oxoethoxy)-2,6-dimethylbenzyl)-3-isopropyl-2-(methoxymethoxy)phenyl)ethynyl)phenyl)hexanoate (7). To the solution of **6** (49 mg, 0.09 mmol) and cesium carbonate (117 mg, 0.36 mmol) in 4 mL 1:1 (v/v) mixture of anhydrous THF and DMF was added *tert*-butylbromoacetate (0.029 mL, 0.18 mmol). The reaction mixture was allowed to stir for 6 h at room temperature, then poured over 15 mL of cold 0.1 N HCl and extracted with ethyl acetate (3 × 15 mL). The combined organic extracts were washed with water (10 mL) and brine solution (10 mL) and concentrated under reduced pressure to afford crude product, which was purified by flash column chromatography on silica gel (1:4 ethyl acetate/hexane) to yield **7** (54.1 mg, 92%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.39 (d, J = 8 Hz, 2H), 7.12 (d, J = 8 Hz, 2H), 6.94 (d, J = 2 Hz, 1H), 6.85 (d, J = 2.4 Hz, 1H), 6.63 (s, 2H), 5.25 (s, 2H), 4.52 (s, 2H), 3.91 (s, 2H), 3.67 (s, 3H), 3.61 (s, 3H), 3.41 (heptet, J = 6.8 Hz, 1H), 2.61 (t, J = 7.6 Hz, 2H), 2.31 (t, J = 7.6 Hz, 2H), 2.21 (s, 6H), 1.68−1.61 (m, 4H), 1.49 (s, 9H), 1.35 (m, 2H), 1.17 (d, J = 7.2 Hz, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 174.19, 168.35, 156.03, 153.85, 142.95, 141.88, 138.48, 135.76, 131.37, 129.69, 129.56, 128.44, 126.57, 120.63, 116.64, 114.22, 99.76, 92.97, 86.27, 82.18, 65.74, 57.58, 51.51, 35.64, 33.98, 33.83, 30.04, 28.68, 28.06, 26.44, 24.76, 23.40, 20.59. HRMS (ESI) calculated for $[C_{41}H_{52}O_7 + Na]^+$ 679.3611, found 679.3644.

6-(4-((5-(4-(2-*Tert*-butoxy-2-oxoethoxy)-2,6-dimethylbenzyl)-3-isopropyl-2-(methoxymethoxy)phenyl)ethynyl)phenyl)hexanoic acid (8). To the solution of **7** (40 mg, 0.06 mmol) in 0.3 mL of THF was added 0.66 mL of 0.1 N LiOH solution over 2 h. The reaction mixture was stirred for 24 h, poured over 5 mL of cold 0.1 N HCl, and extracted with ethyl acetate (2 × 15 mL). The organic extracts were washed with water (2 × 10 mL) and brine solution (10 mL), dried over $MgSO_4$, and evaporated under reduced pressure. The resulting crude was purified by flash column chromatography on silica gel (1:2 ethyl acetate/hexane) to yield **8** (22.4 mg, 58%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.39(d, J = 8.4 Hz, 2H), 7.12 (d, J = 8.4 Hz, 2H), 6.94 (d, J = 2 Hz, 1H), 6.85 (d, J = 2 Hz, 1H), 6.63 (s, 2H), 5.25 (s, 2H), 4.51 (s, 2H), 3.91 (s, 2H), 3.60 (s, 3H), 3.41 (heptet, J = 6.8 Hz, 1H), 2.61 (t, J = 7.6 Hz, 2H), 2.35 (t, J = 7.6 Hz, 2H), 2.21 (s, 6H), 1.69−1.61 (m, 4H), 1.49 (s, 9H), 1.39−1.37 (m, 2H), 1.80 (d, J = 6.8 Hz, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 179.53, 168.40, 156.03, 153.85, 142.90, 141.88, 138.48, 135.77, 131.39, 129.69, 129.58, 128.31, 126.58, 120.66, 116.65, 114.23, 99.76, 92.98, 86.29, 82.21, 65.75, 57.58, 35.63, 33.88, 33.84, 30.85, 28.62, 28.06, 26.44, 24.49, 23.41, 20.60. HRMS (ESI) calculated for $[C_{40}H_{50}O_7$+Na$]^+$ 665.3454, found 665.3436.

Perfluorophenyl 6-(4-((5-(4-(2-*Tert*-butoxy-2-oxoethoxy)-2,6-dimethylbenzyl)-3-isopropyl-2-(methoxymethoxy)phenyl)ethynyl)phenyl)hexanoate (9). To **8** (18 mg, 0.029 mmol) in anhydrous THF was added triethyl amine (0.0045 mL, 0.032 mmol) and then pentafluorophenyl trifluoroacetate (0.006 mL, 0.035 mmol). The solution was stirred for 30 min and diluted with 3 mL of ethyl acetate before pouring over cold 0.1 N HCl. The mixture was extracted with ethyl acetate (2 × 10 mL), washed with water (2 × 5 mL) and brine solution (5 mL), dried over $MgSO_4$, and concentrated under reduced pressure to yield **9** (22 mg, 94%) without further purification. ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.41 (d, J = 8 Hz, 2H), 7.13 (d, J = 8.4 Hz, 2H), 6.94 (d, J = 2.4 Hz, 1H), 6.85 (d, J = 2.0 Hz, 1H), 6.63 (s, 2H), 5.25 (s, 2H), 4.51 (s, 2H), 3.91 (s, 2H), 3.61 (s, 3H), 3.41 (heptet, J = 6.8 Hz, 1H), 2.66 (m, 4H), 2.21 (s, 6H), 1.83−1.63 (m, 4H), 1.49−1.40 (m, 11H), 1.83 (d, J = 6.8 Hz, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 169.48, 168.43, 156.02, 153.85, 142.86, 141.89, 138.48, 135.78, 131.42, 131.34, 129.70, 129.57, 128.43, 126.61, 120.75, 116.62, 114.22, 99.76, 92.92, 86.33, 82.24, 65.73, 57. 58, 35.58, 33.83, 33.23, 30.71, 28.38, 28.05, 26.44, 24.60, 23.39, 20.58. HRMS (ESI) calculated for $[C_{46}H_{49}F_5O_7 + Na]^+$ 831.3296, found 831.3322.

***N*-Fluoresceinylmethyl 6-(4-((5-(4-(2-*Tert*-butoxy-2-oxoethoxy)-2,6-dimethylbenzyl)-3-isopropyl-2-(methoxymethoxy)-phenyl)ethynyl)phenyl)hexanamide (10).** To the solution of **9** (18.5 mg, 0.023 mmol) and 10 mg 5-(aminomethyl)fluorescein, hydrochloride (Invitrogen, catalog number A1353) in 1 mL of 1:1 (v/v) mixture of anhydrous THF and DMF was added TEA (6.8 μL, 0.048 mmol) and the solution was allowed to stir at room temperature for 2 h. The reaction mixture was pour over cold water (5 mL), extracted with ethyl acetate (2 × 10 mL), washed with brine solution (2 × 5 mL), dried over $MgSO_4$, and evaporated under reduced pressure. The resulting crude product was purified by column chromatography on silica gel (1:9 MeOH/CH_2Cl_2) to yield **10** (7.7 mg, 34%) and recovered 9.0 mg of **9** (49%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.81 (s, 1H), 7.57 (d, J = 8 Hz, 1H), 7.26 (d, J = 8 Hz, 2H), 7.08−7.03 (m, 3H), 6.89 (d, J = 1.6 Hz, 1H), 6.72 (d, J = 2 Hz, 1H), 6.57−6.54 (m, 4H), 6.48−6.42 (m, 4H), 5.10 (s, 2H), 4.45 (s, 2H), 4.42 (s, 2H), 3.86 (s, 2H), 3.46 (s, 3H), 3.32 (heptet, J = 6.8 Hz, 1H), 2.53 (t, J = 6.4 Hz, 2H), 2.19 (t, J = 6.8 Hz, 2H), 2.10 (s, 6H), 1.62−1.54 (m, 4H), 1.37 (s, 9H), 1.37−1.30 (m, 2H), 1.07 (d, J = 6.8 Hz, 6H). HRMS (ESI) calculated for $[C_{73}H_{53}NO_6 + Na]^+$ 702.3771, found 702.3759.

***N*-Fluoresceinylmethyl 6-(4-((5-(4-(Carboxymethoxy)-2,6-dimethylbenzyl)-2-hydroxy-3-isopropylphenyl)ethynyl)phenyl)hexanamide (JZ01).** To the solution of **10** (3.8 mg, 0.0039 mmol) in 0.5 mL of THF was added 1 mL of 6 N HCl (aq). The reaction mixture was allowed to stir at 40 °C for 3 h and then extracted with ethyl acetate (3 × 5 mL). The organic extracts were washed with H_2O (2 mL) and brine solution (2 mL), dried over $MgSO_4$, and concentrated under reduced pressure. The resulting residue was purified by reverse-phase HPLC (Higgins, C8, 5 μm, 40−60% acetonitrile/water) to yield JZ01 (0.73 mg, 21%). Purity was assessed by HPLC (UV, 254 nm) to be >98%. ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.85 (s, 1H), 7.51 (d, J = 7.6 Hz, 1H), 7.31 (d, J = 8 Hz, 2H), 7.12−7.03 (m, 3H), 6.83 (s, 1H), 7.73−7.20 (m, 2H), 7.57−7.55 (m, 5H), 6.45 (d, J = 8.8 Hz, 2H), 4.42 (s, 2H), 4.26 (s, 2H), 3.79 (s, 2H), 3.54 (s, 2H), 3.38 (heptet, J = 6.8 Hz, 1H), 2.54 (t, J = 7.6 Hz, 2H), 2.19 (t, J = 7.6 Hz, 2H), 2.10 (s, 6H), 1.63−1.52 (m, 4H), 1.31−1.25 (m, 2H), 1.02 (d, J = 6.4 Hz, 6H), HRMS (ESI) calculated for $[C_{55}H_{51}NO_{10} + H]^+$ 886.3591, found 886.3608.

(*Tert*-butyl-2-(4-(3-isopropyl-4-(methoxymethoxy)-5-((4-(6-oxo-6-(prop-2-ynylamino)hexyl)phenyl)ethynyl)benzyl)-3,5-dimethylphenoxy)acetate) (11). To a solution of 39.0 mg of **9** (0.048 mmol) and 26 mg of propargyl amine (0.48 mmol) in 0.9 mL of anhydrous THF was added a solution of 6 mg of TEA in 0.1 mL of anhydrous THF. After 30 min at ambient temperature, the solution was diluted with 15 mL of ethyl acetate and washed with 2 × 5 mL of 0.1 N HCl (aq) and 2 × 5 mL of brine, dried over Mg_2SO_4, and evaporated under reduced pressure. The residue was purified by flash column chromatography on silica gel (1:1 ethyl acetate/hexane) to yield 29.2 mg of **11** (89%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.40 (d, J = 8.0 Hz, 2H), 7.11 (d, J = 8.0 Hz, 2H), 6.94 (d, J = 2.4 Hz, 1H), 6.85 (d, J = 2.0 Hz, 1H), 6.63 (s, 2H), 5.74 (s, 2H), 4.51 (s, 2H), 4.04−4.02 (m, 2H), 3.91 (s, 2H), 3.41 (heptet, J = 6.8 Hz, 1H), 2.60 (t, J = 7.6 Hz, 2H), 2.22−2.15 (m, 9H), 1.70−1.59 (m, 4H), 1.49 (s, 9H), 1.35−1.20 (m, 2H), 1.18 (d, J = 6.8 Hz, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 172.57, 168.37, 156.04, 153.84, 142.95, 141.89, 138.47, 135.77, 131.37, 129.70, 129.56, 128.45, 126.59, 120.63, 116.64, 114.24, 99.75, 92.98, 86.31, 82.19, 79.67, 71.53, 65.75, 57.57, 36.27, 35.63, 33.83, 30.87, 29.13, 28.74, 28.06, 26.44, 25.31, 23.40, 20.58. HRMS (ESI) calculated for $[C_{37}H_{41}NO_5+Na]^+$ 602.2882, found 602.2875.

(2-(4-(4-Hydroxy-3-isopropyl-5-((4-(6-oxo-6-(prop-2-ynylamino)hexyl)phenyl)ethynyl)benzyl)-3,5-dimethylphenoxy)-acetic acid) (JZ07). To a solution of 14.6 mg of **11** in 1 mL of THF was added 1 mL of 6 N HCl (aq) . The reaction mixture was stirred at 40 °C for 8 h. The reaction mixture was cooled, diluted with 15 mL ethyl acetate, washed with 3 × 5 mL H_2O (×3) and 5 mL of brine (×2), dried over Mg_2SO_4, and evaporated under reduced pressure. The resulting residue was purified by flash column chromatography on silica gel (1:15 MeOH/DCM) to yield 11.6 mg of JZ07 (95%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.40 (dd, J = 7.6 Hz, 1.6 Hz, 2H), 7.12 (d, J = 8.4 Hz, 2H), 6.94 (d, J = 1.6 Hz, 1H), 6.69 (d, J = 1.6 Hz, 1H), 6.65 (s, 2H), 5.68 (bs, 1H), 4.66 (s, 2H), 4.05−4.03 (m, 2H), 3.88 (s, 2H), 3.26 (heptet, d, J = 6.8 Hz, 1H), 2.60 (t, d, J = 7.6 Hz, 2H), 2.23−2.14 (m, 9H), 1.69−1.61 (m, 4H), 1.36−1.30 (m, 2H), 1.22 (d, d, J = 7.2 Hz, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 172.95, 172.44, 155.51, 152.05, 143.43, 138.75, 134.12, 131.54, 131.36, 130.62, 128.57, 127.31, 127.01, 119.75, 114.18, 109.09, 96.05, 83.32, 79.44, 71.72, 64.91, 36.25, 35.60, 33.64, 30.77, 29.27, 28.64, 27.55, 25.30, 22.34, 20.55. HRMS (ESI) calculated for $[C_{37}H_{41}NO_5+Na]^+$ 602.2882, found 602.2875.

Plasmid Construction. Expression vectors pET15b-TRβ wild-type, F451Δ and C446Δ mutant was constructed by subcloning the wild-type and mutant sequences for thyroid hormone receptor into the BamH I and Nde I sites of pET15b (Novagen), using the cloning primers 5′-GGAAAATTCCATATGACCCCCAACAGTATGACAGAAAATGGC-3′ and 5′-CGCGGATCCCTAATCCTCGAACACTTCCAGGAACAAAGG-3′ (w.t.).

Protein Expression and Purification. Full-length histidine-tagged recombinant thyroid receptor protein was expressed in *E. coli* and purified by Ni-NTA affinity chromatography. Rosetta (DE3)pLysS cells (Novagen) were transformed with pET15b-TRβ (wt or mutant). The cells were grown at 18 °C in 500 mL Luria Broth containing 100 μg/mL ampicillin and 34 μg/mL chloramphenicol to an OD of 0.3, at which point protein expression was induced with 1 mM IPTG and continued for 20 h at 18 °C. The cells were harvested by centrifugation at 4000 *g* for 30 min at 4 °C and the cell pellet was immediately frozen at −80 °C. Cells were resuspended with 5 mL lysis buffer (50 mM Tris, pH 8.0, 300 mM NaCl, 12 mM 2-mercaptoethanol, 10% glycerol, and Roche complete EDTA free protease inhibitors) and sonicated on ice (15 s bursts, 4 times). The lysate was centrifuged for 10 min at 14 000 *g* (4 °C) and the soluble supernatant was loaded onto Ni-NTA resin (Qiagen) from which thyroid receptor was eluted with 250 mM imidazole. Protein concentration was determined by Bradford assay (BioRad) and purity was assessed by SDS-PAGE and Western blot with thyroid hormone receptor monoclonal antibody C3 (Covance). Yield was approximately 1 mg purified protein per liter of culture.

Binding Assay and Competition Assay. A 0.7 mM stock solution of JZ01 in DMSO was prepared, which was diluted with binding buffer containing 50 mM sodium phosphate, 150 mM NaCl, 1 mM DTT, 1 mM EDTA, 0.01% Nonidet P-40, and 10% glycerol (pH = 7.2) to obtain a 5.0 nM solution. Solutions of TRβ with different concentrations ranging from 1 μM to 0.3 nM were prepared with the same buffer. 90 μL aliquots of the TRβ solutions were mixed with 10 μL of 5.0 nM JZ01 solution in individual triplicate wells of a 96-well plate and incubated at room temperature for 1 h. Fluorescence polarization value (mP) was measured on Fusion plate reader (Perkin-Elmer, excitation = 485 nM, emission = 535 nM). As a control, solutions of ovalbumin with concentrations ranging from 1 μM to 1 nM were prepared, then mixed with the solution of JZ01 and measured with fluorescence polarization value similarly to TRβ. The probe JZ01 bound to TRβ with an apparent EC_{50} = 21.4 ± 5.6 nM and the dynamic range about 250 mP. Ovalbumin showed only a very small change of fluorescence polarization even at a high concentration of 1 μM. (Note: BSA should not be used as a control as it has known thyronine binding capacity).

The ligands T3 and GC-1 were evaluated for their ability to competitively displace the probe JZ01 from TRβ. A solution of TRβ (43 μL, 2.8 μM) was added to 6 mL of 0.1 nM probe JZ01 in the binding buffer containing 50 mM sodium phosphate, 150 mM NaCl, 1 mM DTT, 1 mM EDTA, 0.01% Nonidet P-40, and 10% glycerol (pH = 7.2) and aliquoted into individual wells of a 96-well plate (90 μL/well). The solutions were incubated at room temperature for 30 min before adding the solutions of ligands. The stock solutions of the ligands were diluted with the same buffer to achieve different concentrations ranging from 100 μM to 1 nM. Then 10 μL of the solutions of ligands were added to the wells containing 90 μL of solution of JZ01 and TRβ and incubated at room temperature for 1 h before taking the FP value. The assay was conducted in triplicate. The measured FP value (mP) was plotted against the concentration of the ligands. The IC_{50} values for T3 and GC-1 were determined to be 429.3 ± 249.2 nM and 214.23 ± 134.7 nM, respectively.

Cellular Reporter Gene Assays. Cellular reporter gene assays were performed as described previously (*22*). Briefly, HEK293 cells were transiently transfected (Calcium phosphate method) with pSG5-TRβ (or pSG5-TRα), DR4-tk-Luc (reporter), and pRL-CMV (control). Ligand-dependent transcription response was measured by dual-luciferase assay (Promega) following manufacturer's protocol. Under these assay conditions, T3 is slightly more potent in TRα (EC_{50} = 0.61 nM) than in TRβ (EC_{50} = 1.4 nM).

Cellular Localization Studies. Cellular localization studies were performed with NIH3T3 cells seeded at 45 000 cells per well in 24-well plates. Cells were transfected with pSG5-TRβ using Lipofectamine 2000 (Invitrogen) following the manufacturer's protocol. After 24 h, the cells were washed and treated with 50 nM of JZ01 in PBS buffer at 37 °C for 1 h. Direct DAPI treatment without fixation/permeabilization was achieved by treatment with 600 nM of DAPI (Invitrogen) at room temperature for 2 min followed by PBS wash (500 μL × 2). Fixation/permeabilization was performed by treatment with 4% formaldehyde in PBS at 37 °C for 15 min, washed 2× in PBS,

followed by treatment with 0.2% Triton X-100 in PBS for 10 min and 2× rinse with PBS. DAPI solution (600 nM in PBS) was then applied to the fixed/permeabilized cells, incubated for 2 min, and washed 2× in PBS according to the Invitrogen protocol.

RESULTS

In the course of developing JZ01, we developed two additional scaffolds having flexible tethers attached via the 5′-position of T3 and the halogen-free thyromimetic GC-1 (Figure 1, scaffolds II and III) (*21*). Model conjugate AH-20 based on the structure of T3 and the peptide conjugate MP01 based on GC-1 were also conjugated via the 5′-position but showed poor affinity by radioligand displacement assays (Figure 2; see Supporting Information). AH-20 showed no appreciable binding to TRβ wild-type below 1 μM, suggesting that the T3 core itself is not sufficient to provide high-affinity binding to TRβ when it has a flexible alkyl tether at the 5′-position. The GC-1 based

peptide conjugate, MP01, shows submicromolar binding to TRβ wild-type (K_i = 580 nM) but is over 2500× less potent than T3 or GC-1.

To further explore the properties of MP01, we evaluated its binding to truncated forms of the receptor TRβC446Δ and TRβF451Δ in radioligand displacement assays. These nonsense mutants completely lack the c-terminal helix-12 but have previously been shown to retain low nanomolar binding affinity for T3 (*23*, *24*). MP01 had modest but improved binding to the nonsense mutants TRβC446Δ, K_i = 73.8 nM (log K_i = 1.86 ± 2.37), and TRβF451Δ, K_i = 237 (log K_i = 2.37 ± 1.27 nM) (*25*). The improved affinities of MP01 for the these receptors lacking helix-12 imply that this scaffold forms unfavorable interactions with helix-12 in its bound conformation. Together, these examples further illustrate that the development of high-affinity scaffolds for TR targeting conjugates is nontrivial and often depends on subtle aspects of the ligand structure.

Synthesis of JZ01, a Fluorescent Conjugate Based on NH-2. The fluorescent probe, JZ01, was synthesized from the differentially protected bisphenol **1** by formylation of the methoxymethyl (MOM) protected phenol followed by Corey-Fuchs alkynylation. Sonogoshira coupling afforded the diarylalkyne **5** in good yield. Desilylation and alkylation of the triisopropyl silyl (TiPS) protected phenol followed by selective hydrolysis of the methyl ester afforded compound **8**, which served as the protected form of our scaffold. The scaffold **8** can be coupled to amine probes such as 5-(aminomethyl)fluorescein via the pentafluorophenyl ester. Deprotection with 6 N aqueous HCl in THF afforded the target fluorescent probe compound JZ01 (Scheme 1).

Fluorescence Polarization Assays with JZ01. The affinity of JZ01 for TRβ can be measured directly by fluoresence polarization (FP) assay (Figure 3A). The polarization of the fluorescent probe JZ01 (0.5 nM) was measured as a function of increasing concentration of full-length TRβ. A sigmoidal dose−response of the FP value (mP) was observed with TRβ but not with ovalbumin control. The titration curve showed that the probe JZ01 bound to TRβ with K_d = 21.4 ± 5.6 nM. These results suggest that the NH-2-inspired conjugate scaffold was a high-affinity probe for TRβ, that could accommodate even relatively bulky substitutions such as fluorescein. As a probe for binding the conjugate, JZ01 provided a relatively large dynamic range even at probe concentrations below 1 nM.

To further explore the utility of JZ01, we evaluated its ability to serve as a nonradiometric probe for TR binding of ligands through competition. Competition assays were conducted with the native TR ligand, T3, and GC-1 as the competing ligands. The measured FP value (mP) was plotted against the concentration of the competing ligands (Figure 3B). T3 and GC-1 have been reported to have similar potencies toward TRβ and were determined to have IC_{50} values of 152.9 ± 87 nM and 93.5 ± 26 nM (average of two determinations ± min/max), respectively, using fluorescence polarization. JZ01 provides a facile nonradiometric means to compare the potency of TRβ ligands by competition.

Subtype Selective Antagonist. The agonist and antagonist activities of JZ01 for TRα and TRβ were further determined by cellular reporter gene assays in HEK293 cells transiently transfected with pSG5TRα or pSG5TRβ and a DR4-luc reporter. JZ01 showed no detectable agonist activity at or below 250 nM (data not shown). JZ01 does have significant antagonist activity at 250 nM (38% reduction in activity) against 1 nM T3 in cells expressing TRβ but only slight antagonist activity (15% reduction) with 1 nM T3 in cells expressing TRα (Figure 4A). Concerns about potential fluorescein aggregation of JZ01 at high concentrations precluded us from establishing an accurate measure of its potency (IC_{50}).

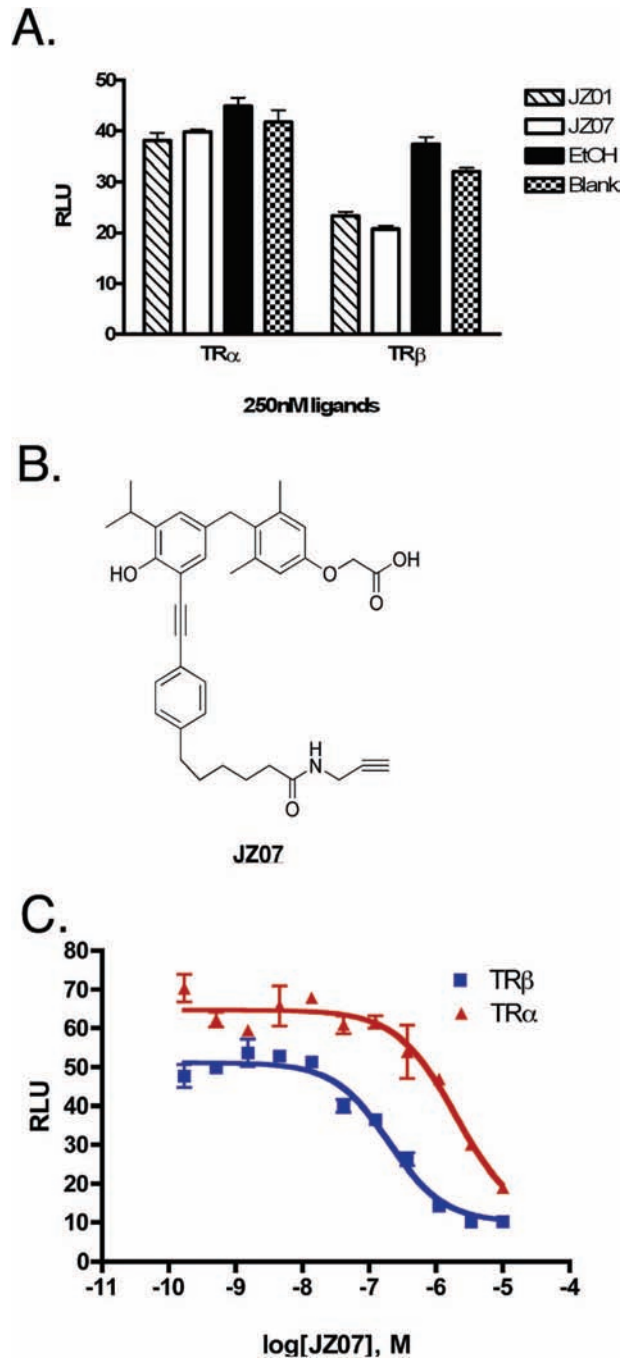

Figure 4. Antagonist activities of ligands in cellular luciferase reporter gene assays. (A) 250 nM ligands with 1 nM T3 andTRα or TRβ. (B) Structure of JZ07. (C) Cellular dose−response behavior of JZ07 vs 1 nM T3 and TRα (σ) or TRβ (ν).

To assess the generic subtype selectivity of Scaffold I, the analogue JZ07, having a propargyl group in place of the fluorescein of JZ01, was prepared by coupling propargyl amine to intermediate **9** (**11**, R_3═$NHCH_2CCH$) followed by deprotection (Figure 4B). The smaller propargyl amide can be used to assess the intrinsic selectivity of the scaffold in the absence of potential influence of the much larger fluorescein group of JZ01. JZ07 had nearly identical activity to JZ01 at 250 nM in antagonist assays with TRβ wt and T3 (Figure 4A). The analogue JZ07 showed no signs of cellular toxicity at concentrations up to 10 μM and is a full antagonist of TRα (IC_{50} = 2.83 ± 0.3 μM) and TRβ (IC_{50} = 221 ± 76 nM) (Figure 4C). This is in contrast to the parent compound NH-2 that was reported as a weak TRβ agonist (*26*). In addition to being more potent

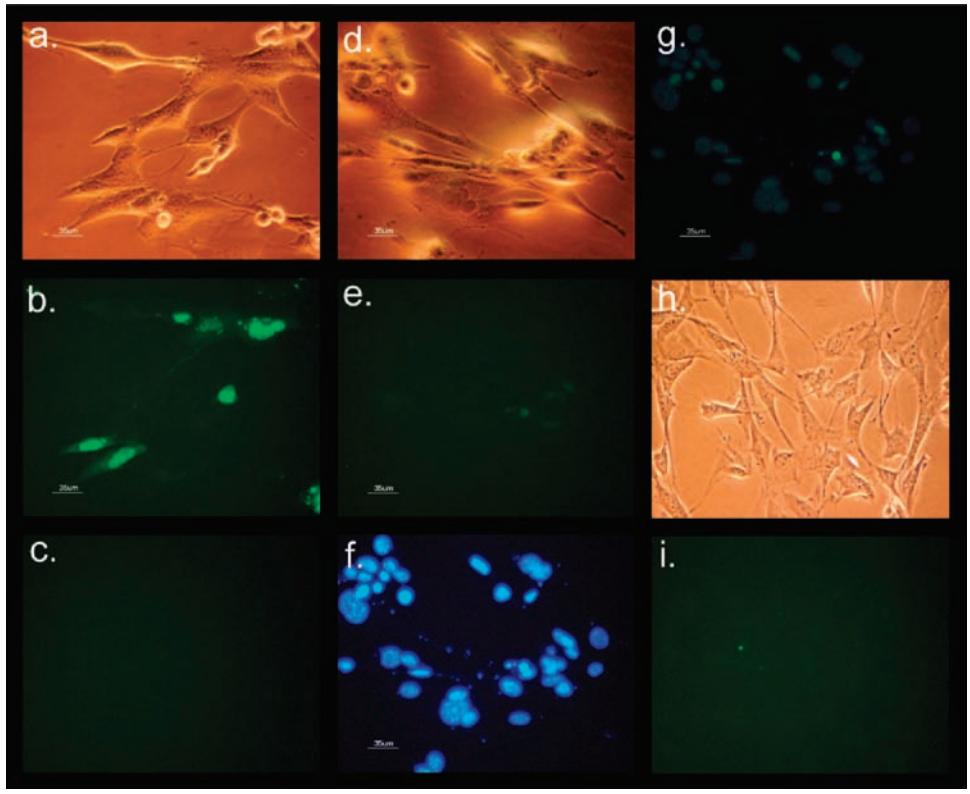

Figure 5. (a) 3T3 cells transfected with pSG5-TRβ with 50 nM of JZ01 and stained with DAPI; (b) cells from panel viewed under fluorescein filter (Nikon B-2E/C); (c) DAPI-stained pSG5-TRB transfected 3T3 cells view under fluorescein filter; (d) pSG5-TRB transfected 3T3 cells with 50 nM, fixed and DAPI-stained; (e) cells from panel d viewed under fluorescein filter; (f) cells from panel d observed under DAPI-filter; (g) merge of panels e and f; (h) 3T3 cells (no TRβ) with JZ01; (i) same as panel h observed under fluorescein filter.

than the structurally related nitro-substituted antagonist NH-3, the compound JZ07 is as subtype selective as the most selective TR antagonist reported to date ($IC_{50}\alpha/IC_{50}\beta = 12.8$) (*27–30*).

Subcellular localization of JZ01 was further examined in NIH3T3 cells treated with 50 nM JZ01 and visualized by fluorescence microscopy (Figure 5). Strong intracellular JZ01 fluorescence was visible only in NIH3T3 cells transfected with pSG5TRβ (compare Figure 5b and f). This cellular fluorescence is almost completely blocked by the addition of 500 nM T3, further supporting that staining is TR-specific (see Supporting Information). JZ01's localization was further demonstrated to be nuclear and coincident with DAPI nuclear stain. Whereas efficient DAPI staining requires first fixing the cells, the fixation process caused significant loss of the intracellular but noncovalently bound JZ01 (compare Figure 5b to e). Nonetheless, although the JZ01 fluorescence is diminished JZ01 is clearly coincident with the DAPI nuclear stain (Figure 5g). In the absence of transfected TRβ, JZ01 is more diffuse and less intense, suggesting that JZ01 is indeed binding TRβ in cells (Figure 5i).

DISCUSSION

Studies with the fluorescent probe JZ01 and antagonist JZ07 demonstrate that Scaffold I represents, to our knowledge, the first thyroid hormone conjugate capable of high-affinity binding of the nuclear thyroid hormone receptor TRβ. Conceptually similar molecular scaffolds based on the natural hormone T3 or the halogen-free thyromimetic GC-1 were not found to be as effective. The compound JZ01 can serve as an efficient probe for direct visualization of TRβ expression in cells and as a nonradiometric probe for ligand binding in vitro. The analogue JZ07 is a potent and highly β-subtype-selective TR antagonist. These findings suggest that scaffold I may be employed as a general scaffold for making β-selective TR-targeting hormone conjugates for a variety of applications in chemical biology.

ACKNOWLEDGMENT

We thank the National Institutes of Health DK054257 for support of this work. A.H. was supported by Mitsubishi Pharma Corp.

Supporting Information Available: Complete synthetic details for the preparation ad characterization of of MP01 and AH-20 along with additional cellular imaging methods are available. This material is available free of charge via the Internet at http://pubs.acs.org.

One-Electron Oxidation of Condensed DNA Toroids: Injection-Site Dependent Charge (Radical Cation) Mobility

Prolay Das and Gary B. Schuster*

School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, Georgia 30332. Received January 26, 2008; Revised Manuscript Received March 18, 2008

DNA condensates were formed by treating linear pUC19 plasmids ligated to an AQ-containing oligomer with spermidine. The condensates are toroid-shaped objects having a radius of 70 to 100 nm. Irradiation of the condensates with UV light (absorbed by the anthraquinone) causes the one-electron oxidation of the DNA and concomitant reaction at GG steps of the oligomer. Analysis of the distance dependence of the reaction at guanine in these condensates reveals a dependency on the position of the AQ. This observation is attributed to a reduction in the rate for trapping of the radical cation in the relatively dehydrated interior of the condensate.

INTRODUCTION

A clear understanding of the mechanisms for oxidative damage to DNA is essential because these processes are considered to be responsible for mutations, aging, and some diseases (*1*). Extensive experimentation has shown that a radical cation (electron "hole") introduced into a duplex DNA oligomer in solution by one-electron oxidation will migrate long distances by hopping before being irreversibly trapped by reaction with water or molecular oxygen at a remote nucleobase (*2–5*). In this process, the radical cation is self-stabilized in a distortion of the DNA and its nearby solvent and counterion environment that spreads the charge over several bases (a polaron). Thermal activation (by phonons) causes the polaron to hop from one site to a neighboring site. Trapping of the radical cation occurs at the most reactive nucleobase, which is typically a guanine, G_n-site ($n = 2, 3$) or, in the absence of guanine, a thymine (*6, 7*). The site at which the radical cation is trapped is typically revealed by chemical or enzymatic treatment that results in strand cleavage at the damaged base (*8*).

Most reported studies of long-distance radical cation transfer in DNA have been carried out using short oligomers in solution (*9–12*). For example, the UV irradiation of an anthraquinone group (AQ) that is covalently linked to a 5′-terminus of a duplex DNA oligomer results in oxidative damage to remote bases. We recently reported the results from a set of experiments in which DNA from a linearized plasmid was ligated to an AQ-containing oligomer, formed into a condensate, and then irradiated (*13*). Condensates are nanometer-scale particles produced from extended DNA chains in the presence of multivalent cations such as spermine or spermidine (*14–19*). They are sometimes used as models for studying gene packing in viruses, bacteria, or eukaryotic cells. Our previous investigation showed that the charge migration effectiveness decreased in the condensate compared with that in a similar short oligomer in solution. This observation was attributed to a reduction in the formation of charge-transfer effective states in the condensate (*13*). In that study, by design, the AQ group was at a terminal position of the duplexes that comprise the condensate. Clearly, those are unique positions and the reactions of radical cations near those sites may not represent the properties of the majority of the nucleobases in the condensate. In the current study, we prepared condensates from an oligomer that is doubly ligated to two linearized pUC19 plasmids. This construction causes the AQ group to be in an interior position of the condensate. The pattern of oxidative damage in this system reveals a complex competition between charge hopping and charge trapping within the condensate.

EXPERIMENTAL PROCEDURES

Materials and Methods. The pUC19 plasmid, T4 DNA ligase, *Hin*dIII, *Eco*RI, PaeR7 I restriction endonucleases, and T4 polynucleotide kinase were purchased from New England Biolabs. [γ-^{32}P]ATP and nonradioactive ATP were purchased from Amersham Biosciences. Gel extraction kits were purchased from Qiagen. Gelase agarose gel-digesting preparation was obtained from Epicenter Biotechnologies, and spermidine hydrochloride was obtained from Aldrich. DNA oligomers and the uridine AQ were synthesized by standard procedures on an Expedite 8909 DNA synthesizer (*20*). The phosphorylation of the 5′-end of DNA2 was achieved in the DNA synthesizer with chemical phosphorylation reagent II, obtained from Glen Research (Sterling, VA). The oligonucleotides were purified by reverse-phase HPLC on a Hitachi (Tokyo) preparative HPLC system using a Dynamax C18 column. Purified oligomers were desalted with Sep-Pak columns and characterized by mass spectroscopy. UV melting and cooling curves were recorded on a Cary 1E spectrophotometer (Varian) equipped with a multicell block, temperature controller, and sample transport accessory. Buffer-exchanging spin columns, enzyme removal, and other spin columns are obtained from Millipore Corporation (Bedford, MA).

Restriction Digestion and Alkaline Phosphatase Treatment of Plasmid. A 2 μg sample of pUC19 plasmid was treated with 5 μL of *Hin*dIII restriction endonuclease in a microcentrifuge tube (total volume of 50 μL) containing 1 × *Hin*dIII buffer and incubated overnight at 37 °C. To this solution, 0.5 μL sample of shrimp alkaline phosphatase (SAP) was added at the same restriction buffer concentration. The reaction mixture was incubated at 37 °C for an additional 30 min, followed by heating at 65 °C for 15 min. The SAP-treated restriction digest was passed through a Micropure-EZ centrifugal filter device to eliminate the restriction enzyme and SAP. The restriction buffer was replaced with nanopure water by means of buffer-exchange spin columns. The linearized plasmid samples were precipitated with ethanol, washed twice with 80% ethanol, and air-dried. The SAP-treated linearized plasmid was resuspended in water, and its concentration was measured by UV−vis spectroscopy. The same procedure was carried out for restriction digestion of

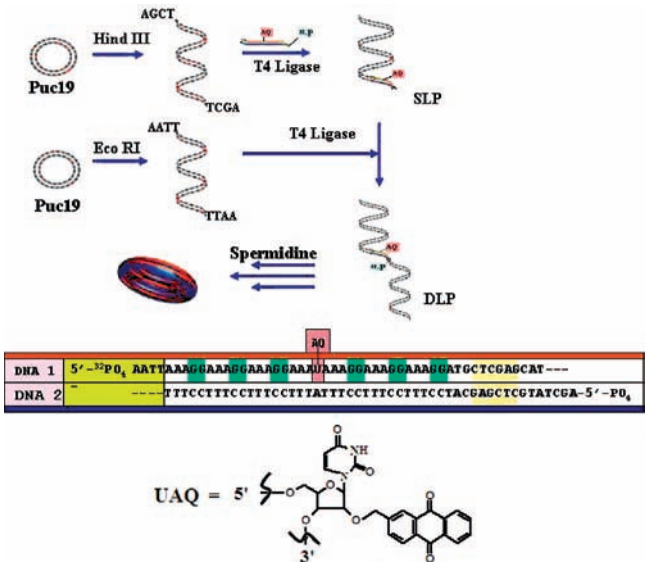

Figure 1. A schematic representation of the experimental design for the DNA constructs used in this work. pUC19 is cut with Hind III enzyme and ligated to the *Hind*III compatible ends of DNA1/ DNA2, to form SLP. Further ligation of SLP with *Eco*RI linearized pUC19 give DLP. Treatment of SLP and DLP with spermidine leads to toroid-shaped condensate formation, DNA1/DNA2 is a double-stranded DNA oligomer that has two cohesive ends; one of them is complementary to Hind III cut linearized pUC19 (shown as dark yellow) and the other complementary to *Eco*RI cut linearized pUC19. The oligomer duplex also has an AQ group linked covalently to a uridine (AQ, structure shown), a 5′-^{32}P radiolabel, and a palindromic sequence which is cut by Pae R7 I (shown as canary yellow).

pUC19 with *Eco*RI enzyme and SAP treatment. In all cases, analytical, nondenaturing, low-melting agarose gels were run to identify and compare the linearized plasmids from uncut relaxed and supercoiled plasmid and also to confirm inhibition of self-ligation by SAP. The single- (SLP) and double- (DLP) ligated plasmid condensates were treated with PaeR7 I restriction endonuclease after irradiation. The restriction digestions were carried out in the presence of NEB buffer 4 and were supplemented by 5 μg of bovine serum albumin and incubated at 37 °C for 1 h. The reaction mixtures were used without further purification for subsequent piperidine treatment.

Preparation of Radiolabeled DNA. The DNA1 oligomer (Figure 1) was radiolabeled with [γ-^{32}P] ATP and T4-polynucleotide kinase enzyme (PNK) and isolated by standard methods on a 20% denaturing polyacrylamide gel. The DNA was precipitated by addition of cold ethanol, vortexed, placed on dry ice, and then centrifuged. The DNA sample was washed twice with 80% ethanol and then air-dried. The air-dried DNA pellets were redissolved in water and passed through buffer-exchange spin columns to eliminate ammonium, magnesium, and acetate ions from the gel elution buffer.

Ligation of Plasmids with Radiolabeled Oligonucleotides. Equimolar concentrations (3 μM) of radiolabeled DNA1 and complementary sequence DNA2 were mixed in 10 mM sodium phosphate buffer at pH 7.0, annealed by heating for 10 min at 90 °C, and then cooled very slowly to room temperature. The oligomer was ligated to the Hind III linearized pUC19 plasmid (10:1 molar ratio) with T4 DNA ligase, 10 mM ATP in 1 × T4 ligase buffer at 16 °C overnight in a Neslab RTE-7 incubator (Newington, NH). The success of the ligation reaction was assessed by autoradiography on an analytical, nondenaturing low-melting agarose gel following standard procedures (*21*).

The DNA in the reaction mixture was washed with ethanol and mixed with nondenaturing dye containing bromophenol blue and xylene cyanol in water and glycerol (4:1). The ligated plasmid DNA band was isolated from a nondenaturing 1% preparative agarose gel in 1 × TAE buffer (Tris−acetate−EDTA) containing ethidium bromide for visualization. The gel pieces were collected in centrifuge tubes and heated at 65 °C for 10 min, followed by addition of 1 μL of 50 × reaction buffer of gelase agarose gel-digesting enzyme, per 50 μL of molten agarose. The solutions were incubated overnight after the addition of one unit of gelase enzyme per 200 mg of molten agarose. The gelase digestions were washed with ethanol and then passed through Qiagen nucleotide removal spin columns for elimination of the last traces of agarose.

The gel-extracted SLP was subjected to a second phase ligation by the addition of equimolar amounts of linearized pUC19 plasmid, cut with *Eco*RI restriction enzyme, in the presence of T4 DNA ligase and 10 mM ATP in 1 × T4-ligase buffer at 20 °C. Preparative agarose gel and gel extraction procedures, as above, were performed to obtain purified double-ligated plasmid (DLP).

Dynamic Light Scattering Study. A solution of doubly ligated plasmid containing the sandwiched oligomer duplex-DNA1/DNA2 (25 μg) was added to an equal volume of spermidine solutions (50−600 μM at increments of 50 uM). All experiments were performed in 10 mM sodium phosphate buffer (pH 7.2). All solutions were filtered through Amicon UltraFree MC centrifugal filters (diameter, 0.22 μm; Millipore) before introducing them into the light scattering instrument. After 5 min of gentle agitation, the samples were analyzed by dynamic light scattering using a Dynapro MS X dynamic light-scattering instrument (Proterion, Piscataway, NJ). Decondensation experiments were performed by addition of NaCl (final concentration 2 M) to the solutions containing the DNA and spermidine at appropriate concentrations.

Transmission Electron Microscope Studies. DNA condensates were prepared according to the standard procedure (*22*); doubly ligated plasmids were deposited on a carbon-coated copper grid (Ted Pella, Redding, CA) and allowed to settle for 10 min. The grids were stained by the direct addition of 5 μL of a 2% uranyl acetate solution, rinsed in 95% ethanol, and then air-dried. Images of the DNA condensates at room temperature were collected on film using a JEOL-100C transmission electron microscope at 100 000× magnification.

UV Irradiation and Strand-Cleavage Analysis. DNA solutions of the radiolabeled oligomer duplex, SLP and DLP were irradiated in microcentrifuge tubes (20 μL, 10 mM sodium phosphate buffer) containing varying concentrations of spermidine at ca. 30 °C in a Rayonet Photoreactor (Southern New England Ultraviolet, Barnsford, CT) equipped with 16 × 350 nm lamps. After irradiation, the samples were washed with ethanol, dried, and treated at 90 °C with 1 M piperidine for 30 min. The piperidine was evaporated, and the samples were dried and suspended in denaturing loading buffer and analyzed by electrophoresis on a 20% 19:1 acrylamide/bis-acrylamide containing 7 M urea Tris−borate−EDTA buffer. Cleavage sites were visualized by autoradiography and quantified by phosphorimagery.

RESULTS

Preparation of Internally Linked AQ-DNA. We constructed a linear DNA oligomer (DLP; see Figure 1) that is composed of an AQ-containing duplex oligomer (DNA1/DNA2) linked at both ends to linearized pUC19 plasmids. The duplex is formed from strands DNA1 and DNA2 and it has two cohesive ends. The 5′-end of DNA1 has a 5′-AATT-3′ overhang that is compatible with the EcoR1 restriction-cut ends of pUC19. This 5′-end also contains a [^{32}P]-radiolabeled phosphate group that will permit visualization of the experimental results by autoradiography. The 3′-end of DNA1 forms a four-base

recessed cohesive end in the DNA1/DNA2 duplex that is complementary to the overhang of a *Hin*dIII cut pUC19 plasmid. DNA1 also has an AQ group linked covalently to a uridine in a central location. In addition, the DNA1 strand contains six GG steps (three on each side of the AQ) that will serve as indicator sites for the reactions of the radical cation.

The DNA1/DNA2 duplex was prepared by following standard techniques that have been reported previously (*12*). The melting temperature (T_m) for this AQ-containing duplex is 68 °C, which is 3.5 °C higher than that of the corresponding duplex where the uridine-linked AQ has been replaced by a thymine. This indicates that the AQ group stabilizes the duplex oligomer, probably by intercalation (*20*).

DLP was prepared in two steps from DNA1/DNA2. In the first step, ligation of DNA1/DNA2 with *Hin*dIII linearized pUC19 gives SLP (see Figure 1). The *Hin*dIII cuts pUC19 at a unique position (base number 447) leaving two overhanging 5′-AGCT-3′ cohesive ends. This 2680 base pair linearized plasmid was treated with shrimp alkaline phosphatase (SAP) before reaction with DNA1/DNA2 to inhibit self-ligation. The T4 DNA ligase catalyzed reaction of DNA1/DNA2 with the *Hin*dIII cut plasmid gives the SLP construct in ca. 50% yield having an AQ group close to its terminus. SLP was purified by preparative agarose gel electrophoresis to remove unligated and self-ligated DNA1/DNA2 (see Figure 2). In the second step of formation of DLP, pUC19 linearized by reaction with EcoR1, which cuts the plasmid at the unique 5′-AATT-3′ sequence site (base number 396), was ligated (after treatment with SAP) to SLP to give DLP, which was further purified by gel electrophoresis. Thus formed, the DLP construct is a linear DNA polymer containing 5407 base pairs that has the DNA1/DNA2 AQ-containing oligomer in the central position between the two linearized pUC19 plasmids. Finally, it should be noted that the *Hin*dIII compatible end of DNA1/DNA2 contains a 5′-CTC-GAG-3′/3′-GAGCTC-5′ restriction site for PaeR7 endonuclease. This sequence does not occur in pUC19. This fact allows for the selective disassembly of the SLP and DLP constructs for analytical purposes after their irradiation.

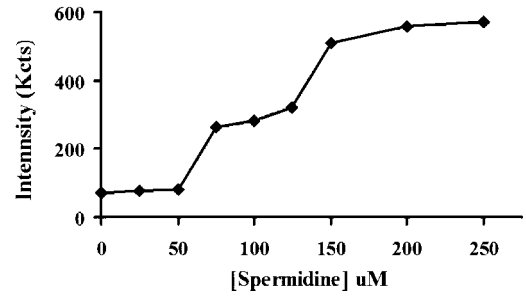

Figure 3. Dynamic light scattering experiment: Plot of the intensity of scattered light against the concentration of spermidine in DLP.

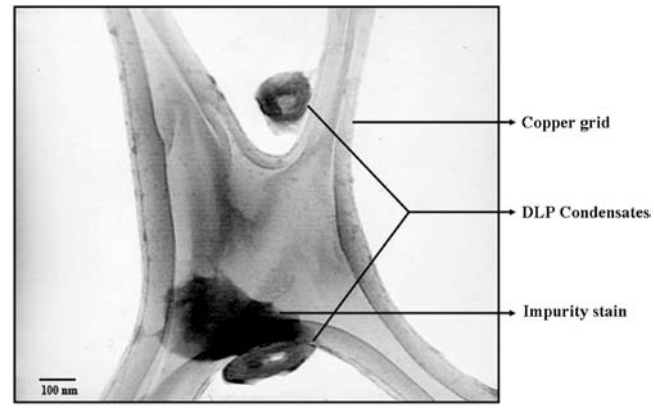

Figure 4. Transmission electron microscopic image of DNA condensate formed from DLP at pH = 7 with 100 μM spermidine in 1 × Tris−EDTA buffer. Scale indicates 100 nm. Images are taken at 100 000 magnification in a JEOL 100C TEM instrument.

Formation of DNA Condensates from DLP with Spermidine (DLP-Condensate). It is well-known that treatment of DNA with polycations such as spermidine can lead to the formation of condensate structures (*14*, *15*). We converted DLP to condensates in this way and characterized those structures by dynamic light scattering and by transmission electron microscopy.

Dynamic light scattering experiments were conducted to assess the effect of spermidine on SLP and DLP. Solutions of purified SLP and DLP oligomers were prepared with various concentrations of spermidine, and their hydrodynamic radii were measured by light scattering. In the absence of spermidine, solutions of SLP and DLP do not show meaningful scattering. The data for DLP are shown in Figure 3; the behavior of SLP (not shown) is essentially identical to that of DLP. With the addition of spermidine, the light scattering intensity of DLP solutions increases, indicating that particles are being formed and their hydrodynamic radii increase with the spermidine concentration. At spermidine concentrations between 25 and 50 μM, the light scattering intensity is low and derived particle radii ranges 40−50 nm. With an increase in spermidine concentration to the range between 75 and 125 μM, the light scattering intensity increases and then reaches a plateau, which indicates the formation of stable particles having calculated radii of 70 to 90 nm. We refer to these particles as DLP-condensates. At higher spermidine concentration, the light scattering experiment indicates the formation of larger aggregates that eventually precipitate from solution. As expected (*17*), the light scattering experiments show that condensate formation is reversed by the addition of NaCl (2 M) to the solution of DLP and spermidine. The formation of condensates by DLP with the spermidine concentration at 100 μM was confirmed by transmission electron microscopy (Figure 4), which reveals stable, toroid-like structures with radii of 80−100 nm.

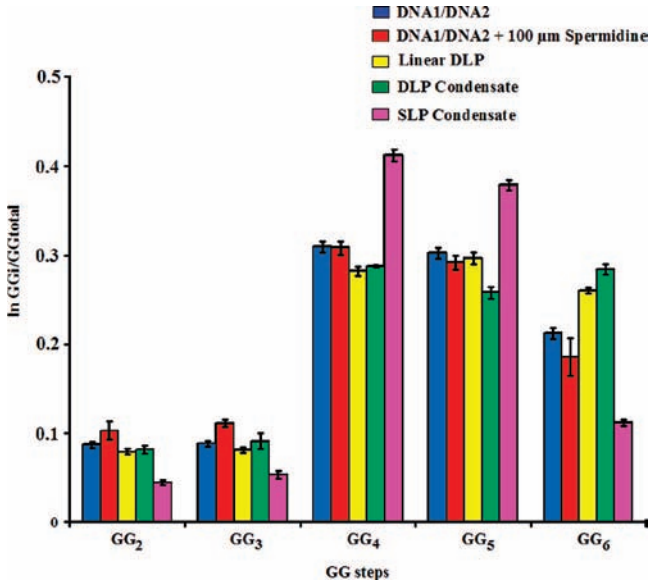

Figure 5. Normalized damage ratios for DNA1/DNA2, DLP, and SLP irradiated in the presence or absence of spermidine, as indicated. Each bar corresponds to a GG step. The AQ is between GG3 and GG4. Damage ratios for DNA1/DNA2 are after 45 min of irradiation and those for DLP and SLP are after 2 h of irradiation.

UV Irradiation of UAQ-DNA1/DNA2, SLP, and DLP. It is known that UV irradiation of an AQ that is covalently linked to duplex DNA at an internal position introduces a nucleobase radical cation and results in reaction far removed from the anthraquinone (*20*). Those reactions are routinely revealed as strand cleavage at remote GG sites by treatment of the irradiated sample with piperidine (*23*). We carried out experiments on DNA1/DNA2, SLP, SLP-condensate, DLP, and DLP-condensate to assess the effect of condensate formation on the migration and reaction of the radical cations introduced by UV irradiation of the covalently linked AQ group.

Solutions of DNA1/DNA2, DLP, and SLP, with and without spermidine, were irradiated with UV light to low conversion (single hit conditions) and then analyzed to assess the amount of reaction that occurred at each of the GG steps of the DNA1/DNA2 oligomer. Analysis by high-resolution PAGE requires the deconstruction of the ligated plasmid. This was accomplished by its treatment with endonuclease PaeR7 I and Sac I, which excises the oligomer portion from the plasmid−oligomer−plasmid system. These results are shown in the form of a histogram in Figure 5. Autoradiograms from the PAGE analyses of irradiated samples of SLP and DLP after deconstruction and treatment with piperidine are shown in Supporting Information (Figures S1 and S2).

These experiments show that UV irradiation and piperidine treatment of DNA1/DNA2, DLP, and SLP result in strand cleavage at GG steps on both the 3′ and 5′ sides of the AQ in each of the constructs both in the linear form and as the condensate. As has been previously observed, the efficiency of reaction to the 5′ side of the AQ is greater than to its 3′ side (*20*). This is true for DNA1/DNA2, as well as SLP and DLP. As expected, the efficiency of strand cleavage generally falls off the farther the GG step is located from the AQ. As a control experiment, solutions of DNA1/DNA2 containing spermidine were irradiated and analyzed. Piperidine treatment and PAGE analysis of the irradiated samples show (see Figure 5) that the presence of the spermidine (100 μM) does not affect the relative reactivity of the GG steps of the oligomer. In contrast, comparison of the results from irradiation of SLP without added spermidine to those containing 100 μM of spermidine reveals a strand cleavage pattern showing that condensate formation results in an increased distance dependence for reaction at GG steps; that is, GG damage decrease more sharply with distance from the AQ for SLP-condensate compared with DNA1/DNA2 and SLP. This finding is consistent with previous experiments in which the AQ group is at the terminal position of the DNA that forms the condensate (*13*).

Comparison of the relative reactivity of radical cations at the GG steps of DLP and DLP-condensate provides a remarkable finding. Unlike the case for SLP, condensate formation has little effect on the distance dependence of reaction for DLP (see Figure 5). A close look at the GG damage pattern for DLP-condensate (in the presence of 100 μM of spermidine) reveals that reactions at the guanines are essentially identical to those observed for linear DLP (no spermidine) and for DNA1/DNA2 with or without spermidine present. Evidently, the position of the AQ in the condensate has a powerful affect on the distance dependence of radical cation migration efficiency. When the AQ is at or near the end of the DNA strands that comprise the condensate, remote reaction of GG steps is inhibited, but when the AQ at the middle of the DNA stand, condensate formation has no measurable effect on the efficiency of remote reaction.

DISCUSSION

The one-electron oxidation of DNA generates a radical cation that migrates by a thermally activated hopping process requiring local structural distortion of DNA (*24*). These local structural distortions include the redistribution of surrounding water molecules and counterions, which are responsible for stabilizing the self-trapped radical cation (*25*). If the rate for hopping of the radical cation (k_{hop}) is greater than for its irreversible trapping (k_{trap}) at guanine-rich regions of the DNA, then the radical cation will be distributed approximately equally (thermodynamic control) to all equivalent sites. However, if the rate of trapping of the radical cation is greater than that for hopping, then the probability of reaction at remote sites typically falls off exponentially with distance (kinetic control) (*5*).

In an earlier report (*13*), we showed that when the AQ is located at a terminal position the efficiency of charge hopping decreases significantly when linear DNA is converted to a toroidal condensate by the addition of spermidine. In the present case, we find a similar result for SLP-condensate, which has the AQ group near the terminus of the DNA chain. However, no such effect is observed for DLP-condensate where the AQ group is in the center of a long DNA chain. Clearly, the efficiency of radical cation hopping is affected by an environmental change associated with condensate formation that is different near the ends of the chain than it is at the middle.

It is not possible to reach a unique explanation for this observation from these experiments because their outcome is determined by the ratio of the rates of hopping and trapping (*5*). That is, the observed effect might be a result of an increase in the magnitude of the rate of hopping near the center of the condensate, or it could be a result of the trapping rate becoming smaller (or some combination of these two effects). Nevertheless, valuable insight into the nature of radical cation migration and trapping in complex DNA structures results from these findings.

In SLP, where the AQ group is 22 base pairs from a terminus, the GG damage falls off normally with distance. Evidently, positioning the AQ group at an internal position near a terminus does not change the behavior compared with the case when the AQ is at the terminus, as it is in the previously reported example (*13*). Thus, the factors responsible for differentiation of the behavior of SLP and DLP-condensates cannot be directly tied to the specific nature of the chemical linkage of the AQ to the DNA strand.

It has been reported that the surface-to-surface spacing between adjacent DNA helices in condensed structures is ca.

1−2 water molecules in diameter (*26*). This indicates that the DNA molecules that comprise condensates are considerably dehydrated compared with DNA oligomers in solution. Thus, there is a relative absence of water in the interior of the DLP-condensate. Water and to a lesser extent O_2 are the reagents responsible for the trapping of the radical cation that leads eventually to strand cleavage. A lower concentration of these trapping reagents in the interior of the condensate would lead to a decrease in the rate of trapping of the migrating radical cation. As a result of this factor, the radical cations formed in dehydrated regions of the condensate would migrate with reduced distance dependence compared to those formed in well-hydrated regions. This explanation accounts for the findings with the DLP-condensate if it is assumed that the interior regions of the condensate are less hydrated, which seems reasonable. Interestingly, it has been suggested that the amazing resistance to radiation damage exhibited by the bacterium *Deinococcus radiodurans* is related to toroid-like structures found in its DNA that inhibit diffusion (*27*).

Alternatively, the reduced distance dependence observed for DLP-condensate might be caused by an increase in the rate of hopping, although this seems less likely. Multivalent cations such as spermidine not only cause condensation but also modify the local structure of the DNA (*28*). If these local structural changes are different in the interior of the condensate than near the terminus of a DNA chain, and if these changes accelerate the rate of radical cation hopping, then these factors could account for the difference we observe between SLP and DLP condensates. Although it seems less likely, this explanation can not be ruled out with the available data.

CONCLUSION

DNA condensates were formed from constructs created by ligating an AQ-containing oligomer to one or two linearized pUC19 plasmids. In the first case (SLP), the oligomer is near a terminal position of the DNA chain. In the second case (DLP), the oligomer is in the central position between two linearized plasmids. Both constructs are converted to condensates when they are treated with spermidine. The condensates were characterized by dynamic light scattering and TEM and found to be toroid-shaped objects having a radius of 70 to 100 nm. Irradiation of the condensates with UV light (absorbed by the AQ) causes the one-electron oxidation of the DNA resulting in the conversion of a nucleobase to its radical cation. The radical cation migrates along the DNA chain and is trapped at GG steps where it reacts irreversibly with H_2O or O_2. The site of reaction is revealed (after enzymatic deconstruction of the condensate) by autoradiography. Analysis of the distance dependence of radical cation migration in these condensates reveals a dependency on the position of the AQ. The radical cation migrates more efficiently in DLP-condensate than in SLP. This observation is attributed to a reduction in the rate for trapping of the radical cation in the relatively dehydrated interior of the DLP condensate compared with SLP. Alternatively, this effect could be due to a unique local structural change in the interior of the DLP condensate that increases the rate of radical cation hopping. These findings illuminate the challenge of extrapolating results obtained for linear DNA oligomers in solution to more complex DNA structures.

ACKNOWLEDGMENT

We thank Prof. Andrew Lyon (School of Chemistry and Biochemistry, Georgia Institute of Technology) for assistance with dynamic light scattering experiments; Dr. Sriram Kanvah for synthesizing the DNA oligomer strands. This work was supported by a grant from National Science Foundation and by the Vassar Woolley Foundation.

Supporting Information Available: Autoradiogram showing results from the irradiation of DNA1/DNA2, DLP and SLP and their condensates are shown in Figures S1 and S2.This material is available free of charge via the Internet at http://pubs.acs.org.

Conjugation to Hyperbranched Polyglycerols Improves RGD-Mediated Inhibition of Platelet Function in Vitro

RGD (arginine-glycine-aspartic acid) is a known peptide sequence that binds platelet integrin GPIIbIIIa and disrupts platelet−fibrinogen binding and platelet cross-linking during thrombosis. RGD peptides are unsuitable for clinical applications due to their high 50% inhibitory concentration (IC_{50}) and low in vivo residence times. We addressed these issues by conjugating RGD peptides to biocompatible macromolecular carriers: hyperbranched polyglycerols (HPG) via divinyl sulfone. The GPIIbIIIa binding activity of RGD was maintained after conjugation and the effectiveness of the HPG−RGD conjugate was dependent upon molecular weight and the number of RGD peptides attached to each HPG molecule. These polyvalent inhibitors of platelet aggregation decreased the IC_{50} of RGD in an inverse linear manner based on the number of RGD peptides per HPG. Since HPG−RGD conjugates do not cause platelet activation by degranulation and certain substitution ratios do not increase fibrinogen binding to resting platelets, HPG−RGD may serve as a model for a novel class of antithrombotics.

INTRODUCTION

Peptidomimetics are short amino acid sequences that have shape and hydropathic profiles that provide epitope behavior such that they can be selectively screened for ligand- or receptor-like activity to target specific binding sites. The prospect of deploying such polypeptides in a therapeutic setting presents a promising lead in rational drug design; for example, a peptidomimetic was used to induce apoptosis of malignant leukemic cells without affecting healthy tissue (*1*) or to inhibit thrombin (*2*). In addition, Arg-Gly-Asp (RGD)-coupled liposomes were used to target activated platelets as a method for vascular drug delivery (*3*).

The RGD peptide sequence is a motif found in fibronectin, vitronectin, osteopontin, collagens, thrombospondin, fibrinogen, and von Willebrand factor and can mediate integrin adhesion and cellular communication (*4*). The RGD motif disrupts platelet aggregation by binding to the platelet glycoprotein IIb/IIIa integrin receptor (GPIIbIIIa) to cause competitive exclusion of fibrinogen from its binding site (*5*); hence, RGD and RGD-containing conjugates are effective antithrombotics (*6*) as fibrinogen-mediated bridging and platelet aggregation are essential steps in primary hemostasis. The GPIIbIIIa−fibrinogen interaction is clinically relevant and a new generation of antithrombotics specifically targets this interaction (*7*). To this end, a number of laboratories have defined the pharmacophore of RGD (*8*), and explored a wide variety of chemical modifications on simple peptidomimetic structures designed to compete with fibrinogen, in order to improve either their binding affinity for GPIIbIIIa or their pharmacokinetic profile (*1, 6–10*). RGD, RGD variants, and RGD mimics have proven to be successful antithrombotics both in vitro and in vivo (*11, 12*).

In order to be clinically useful, a mimetic compound must evade rapid elimination from the host and demonstrate high efficacy at comparatively low doses. RGD, RGD variants, and RGD mimics suffer from limited in vivo retention due to their small size. A well-known solution to this problem is to couple such peptides to long-circulating materials. Studies have described the conjugation of RGD to albumins (*13*), to polyethylenimine−poly(ethylene glycol) (*14*), and to liposomes (*15*). Other macromolecules, such as hyperbranched polyglycerols (HPG), are also potentially viable choices as carriers.

HPG are water-soluble, biocompatible polyether polyols (*16, 17*) that can be synthesized in a controlled manner with predetermined molecular weights and narrow molecular weight distributions (*18*). Recently, some of us reported the synthesis of very high molecular weight HPGs (MW values up to 1.48×10^6) with low polydispersities (PDI): PDI $= M_w/M_n = 1.1-1.4$, where M_w and M_n are the weight-average and number-average molecular weights, respectively (*18*). These polymers show excellent biocompatibility properties both in vitro (*19*) and in vivo (*20*). The plasma circulation half-lives were found to depend on the molecular weight, and half-lives as high as 60 h were achieved for high molecular weight polymers (*20*). As the number of hydroxyl groups approximately equals the degree of polymerization, synthesis of higher molecular weight HPGs is a major development given the difficulty of synthesizing high molecular weight dendrimers. These materials have numerous applications in nanomedicine, and one such application is the use of HPGs as carriers of peptides for biomedical applications where multivalency/polyvalency can be exploited.

We now report the conjugation of RGD-containing peptides to hyperbranched polyglycerol (HPG), and the effects of these constructs on platelet aggregation. We conjugated HPGs of different molecular weights with peptides carrying the RGD motif (*21*) and examined the in vitro activity of the conjugates. We used the ability of the RGD-conjugated HPG to inhibit the GPIIbIIIa−fibrinogen receptor−ligand interactions to determine the suitability of HPG as a viable carrier in this setting. We compared the HPG−RGD conjugates to the unconjugated HPG and the free peptide for inhibition of fibrinogen binding to platelets as a prelude to disaggregation studies. We also

demonstrated RGD-dependent ligand-like association of the conjugates with the GPIIbIIIa receptor complex.

We found that both the HPG molecular weight at identical substitution levels and its level of substitution influence the subsequent function of such macromolecular constructs, and that certain combinations are suitable for inhibition of platelet−platelet binding and thus have antithrombotic potential.

EXPERIMENTAL PROCEDURES

Peptides and Proteins. The peptidomimetic CGGGGGRGDF, (MW = 882) was synthesized by the University of BC's Nucleic Acid and Peptide Synthesis unit to >90% purity as tested by HPLC. Lyophilized material was weighed and used to make standardized stock solutions.

Polyglycerols and Conjugation. Hyperbranched polyglycerols of molecular weights 3, 100, and 515 kDa were synthesized as described previously (*18*). The conjugation of the peptide to the HPG was achieved through cysteine coupling to vinyl sulfone functionalized polymers. A typical reaction procedure (HPG−RGD conjgate C-7) was as follows. Initially, the HPG-515 kDa polymer (100 mg) was dissolved in 3 mL dimethyl sulfoxide (DMSO) and up to 20% of the $n \sim 7000$ theoretical hydroxyl groups were deprotonated with 20 mg potassium hydride (30 wt % dispersion in mineral oil, Sigma-Aldrich, Canada). Divinyl sulfone (20 μL, corresponding to a polymer−peptide ratio of 1:1000) was added and stirred at 22 °C for 12 h. After the reaction, methanol was added and the reaction mixture was passed through an Amberlite IRC-150 cation exchange column (Sigma-Aldrich, Canada) to remove the potassium ions. The polymer was then precipitated in acetone and dried. For the peptide coupling, 5 mg vinyl sulfone functionalized polymer was dissolved in 2 mL DMSO (Sigma-Aldrich, Canada) and stirred with an excess amount of peptide (15 mg) for 2 days at 22 °C. The excess peptide was removed by dialysis (cellulose acetate membrane, MW cutoff 1000, Spectrum Laboratories Inc., USA) against HEPES buffered saline (HBS, 10 mM HEPES, 150 mM NaCl, pH 7.40) and the conjugate was collected by lyophilization (Figure 1). The other conjugates were synthesized using appropriate amounts (Table 1) of divinyl sulfone. For subsequent experiments, stock solutions were made from weighed, lyophilized material.

Table 1. Synthesis, Characterization, and Evaluation of RGD and RGD−HPG Conjugates

name	HPG platform MW	UV spec. RGD peptides per HPG	estimated resultant MW	IC_{50} (M)	[RGD] used to achieve IC_{50} (M)
RGDF	—	—	0.882 kDa	5.0×10^{-5}	5.0×10^{-5}
C-1	3 kDa	0.11	3.1 kDa	5.0×10^{-4}	5.5×10^{-5}
C-2	3 kDa	0.05	3.0 kDa	5.0×10^{-3}	2.5×10^{-4}

C-6	515 kDa	1.42×10^{3}	1770 kDa	1.4×10^{-8}	2.0×10^{-5}
C-7	515 kDa	1.51×10^{3}	1850 kDa	1.2×10^{-8}	1.8×10^{-5}

Characterization of the HPG−RGD Conjugates. The HPG−RGD conjugates were characterized for substitution levels by UV absorption at 278 nm on an ND-1000 spectrophotometer (Nanodrop Technologies, USA). A calibration curve was made using standards made from the free peptide molecules at varying concentrations (1.0×10^{-7} M to 6.0×10^{-3} M). For each conjugate, solutions containing a range of concentrations were measured and related to the standard curve.

Preparation of Human Platelets. As approved by the CBS Ethics Board, samples of whole blood were drawn from healthy, consenting donors into 2.7−4.0 mL citrated tubes (BD, USA). Platelet-rich plasma (PRP) was extracted by centrifugation in a Beckman (CS-6R) benchtop centrifuge (Beckman Coulter, USA) of whole blood at 850 rpm ($r = 203.57$ mm) for 15 min. Platelet-rich plasma from a number of unrelated donors was evaluated on an Adiva 120 Hematology Analyzer (Bayer, Canada) and standardized to a concentration of 300×10^9 cells/L in HBS.

Effects of the Unconjugated HPG on Resting and Activated Platelets. First, we examined the effect of the various molecular weights of unconjugated HPG on resting and activated platelets. For resting platelets, 45 μL aliquots of HBS were mixed with 5 μL PRP and 5 μL of 3, 100, and 500 kDa HPG polymers at each of 1.0×10^{-3}, 1.3×10^{-7}, and 2.9×10^{-8} M concentrations and incubated for 40 min, and then 5 μL of human fibrinogen (Sigma-Aldrich, Canada), at 5 mg/mL dissolved in bicarbonate buffer (100 mM $NaHCO_3$, pH 8.30) was added and the incubation continued for 30 min before the addition of 5 μL 1.5 mg/mL fluorescein isothiocyanate (FITC)-conjugated monoclonal mouse antihuman fibrinogen IgG (Biocytex, France) and continued incubation in the dark for 30 min. Similarly, to assay the effect of unconjugated HPG on activated platelets, 5 μL 10 mM $MnCl_2$ to activate GPIIbIIIa (*22*) was included in the above assay.

Effects of the Conjugated HPG on Resting Platelets. Thereafter, we determined whether the conjugated HPGs were capable of activating resting platelets. For this, the fibrinogen−antifibrinogen detection system of the above assay was replaced by 5 μL 2 mg/mL of phycoeryhtrin (PE)-conjugated mouse antihuman CD62 IgG1 (Beckman-Coulter, Canada) to detect P-Selectin expression on the platelet surface.

Effects of the Conjugated HPG on Activated Platelets. Finally, we examined the effect of the RGD-conjugated HPGs first on resting platelets ability to bind fibrinogen, then on activated platelets using appropriate modifications of the above assay systems. Negative controls included incubating with mouse IgG-FITC of the same isotype, and/or omitting the conjugate, and/or omitting the addition of $MnCl_2$ to activate platelet GPIIbIIIa which allows for the detection of baseline binding to fibrinogen. Positive controls for platelet fibrinogen binding did not contain conjugates. After the incubations, the samples were diluted and fixed with 0.2% formolsaline (0.2% formaldehyde, 150 mM NaCl, pH 7.20) before being submitted for analysis on the FACS flow cytometer (BD, USA).

Enzyme Cleavage. RGD conjugated to the 3 kDa HPG was dissolved in HBS to a final concentration of 1 mM and treated with 1 mM Trypsin-TPCK (Sigma-Aldrich, Canada) for 15 min at 37 °C. Enzyme cleavage was stopped with the addition 2 mM soybean trypsin-inhibitor (SBTI, Sigma-Aldrich, Canada) for another 15 min. Controls included premixed and incubated trypsin-TPCK with SBTI added to platelets only, to peptides only, and to the RGD-conjugated HPG. Enzyme treatment was followed by flow cytometry as already described.

Microscopy. In a standard ELISA plate, PRP was incubated at 37 °C for 100 min with 10 μL 100 mM $MnCl_2$, and an amount of conjugate with a final conjugate concentration equal to the conjugate 50% inhibitory concentration (IC_{50}) and a final platelet concentration of 300×10^9 cells/L in a 200 μL volume. Negative controls consisted of platelets incubated alone, while positive controls included 10 μL 100 mM $MnCl_2$ as a platelet agonist. These samples were examined at 400× magnification on a Leica DMIL inverted microscope (Leica Microsystems, Germany) with 1-S55 filter. Pictures were taken with Micropublisher 3.3 Cooled RTV and the QCapture program (Q-Imaging, Canada).

Aggregometry. PRP (300×10^9 cells/L, final concentration) was incubated at 37 °C for 100 min with conjugates or unsubstituted HPG at a final concentration equal to the IC_{50} of that conjugate, in a total volume of 315 μL. The samples were loaded in the aggregometer (Chrono-Log, USA) and compared to a platelet-poor plasma derived from the same blood source, produced by high-speed centrifugation. To initiate aggregation, 25 μL of 100 mM $MnCl_2$ was added and the aggregation curve was recorded for 12 min.

RESULTS

Synthesis and Characterization of HPG−Peptide Conjugates. Peptides carrying the RGD motif were conjugated to HPGs of different molecular weights (Table 1). As the number of hydroxyl groups approximately equals the degree of polymerization a large number of peptide moieties can be coupled to the high molecular weight HPG which are thus ideal for realizing polyvalency. It is to be noted that the hydrodynamic radii of these branched molecules increase only marginally with molecular weights and are in the range 7−10 nm as described earlier (*18*). The extent of functionalization was kept below 20% of the total hydroxyl groups as highly deprotonated HPGs are insoluble in DMSO (*23*). The alkoxide groups were reacted with divinyl sulfone, and the resulting vinyl sulfone end groups were utilized to couple the cysteine-terminated peptides (Figure 1).

The presence phenylalanine residues allows for the quantitative determination of the degree of substitution of the peptide by UV spectrophotometry. The degrees of substitution were determined to be 0.05−0.1 for the 3 kDa conjugates, 125−150 for 100 kDa conjugates, and 1000−1500 for 515 kDa conjugates.

Effects of the Unconjugated HPG on Resting and Activated Platelets. Naked, unconjugated HPGs do not induce fibrinogen binding to platelets above normal levels (Figure 2), nor do they inhibit fibrinogen binding to either resting or activated platelets (Figure 2). Furthermore, the RGD peptides and conjugated HPGs did not cause any platelet activation as

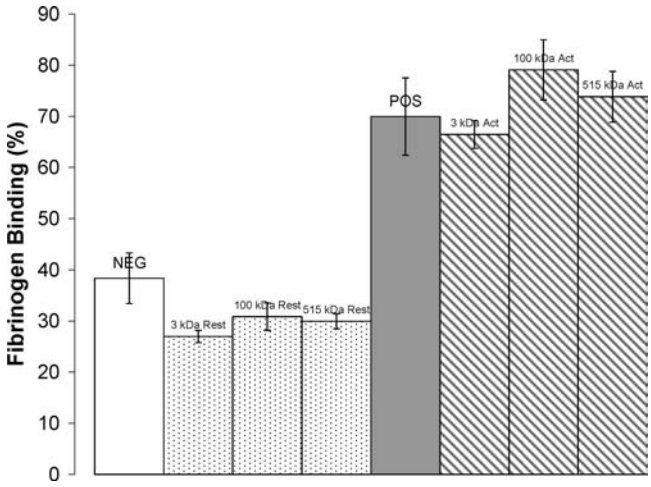

Figure 2. Evaluation of unconjugated HPGs. NEG (*1*): resting platelets; 3 kDa, 100 kDa, and 515 kDa rest. Dotted histograms: resting platelets incubated with 3, 100, and 515 kDa HPG, respectively. detected by degranulation and consequent CD62 surface expression above control levels.

Effects of the Conjugated HPG on Resting Platelets. Conjugated HPG increased fibrinogen binding to resting platelets in a size- and substitution-dependent manner. Free RGD peptide and smaller (3 kDa) conjugates did not increase the levels of fibrinogen bound to resting platelets; however, the larger conjugates (100 kDa and 515 kDa) significantly enhanced ($p < 0.05$) fibrinogen binding. This trend also applied to large conjugates in a substitution-dependent manner: platelet fibrinogen binding was increased significantly ($p < 0.05$) with increasing degrees of substitution by RGD peptides (Figure 3a). Tryptic removal of the RGD conjugated to the HPG confirmed that the inhibition of fibrinogen binding was RGD-dependent (Figure 3b).

Effects of the Conjugated HPG on Activated Platelets. Conjugated HPGs inhibition of fibrinogen binding to platelets is concentration-, size-, and substitution-dependent. This was true especially for the 100 kDa and 515 kDa conjugates (Figure 4). That this inhibition was specific and required the presence of the RGD motif was confirmed by the loss of function after enzymatic removal of the RGD (Figure 3b). Based on the titration curves, we derived IC_{50} values that are shown in Table 1. The relationship among HPG size, substitution, and resultant IC_{50} is summarized in Figure 5.

Macroscopic Platelet Aggregation. In general, both the free RGD peptides and the RGD-conjugated HPG inhibited agonist-induced, macroscopic platelet aggregation whether the aggregation was assessed visually via light microscopy or semiquantitated by lumiaggregometry (Table 1). We also found that HPG−RGD conjugates do not cause spontaneous aggregation of resting platelets as could have been suggested by the increased fibrinogen binding by platelets incubated with conjugates of high substitution (C-7).

DISCUSSION

The attachment of RGD peptides to HPG confers unique attributes to the resulting construct: the HPG gains specificity and thereby function; while the peptidomimetic gains polyvalency and thereby binding avidity.

Characterization. Peptide attachment increases the theoretical molecular weight of the HPG-conjugates depending on the number of available sites that can be functionalized on the

surface of the HPG polymer. The branch density of the HPG varies directly with the molecular weight of the polymer while the Stokes' radius of the molecule remains relatively stable at about 7−10 nm for the 100 kDa and 515 kDa HPG molecules (*18*). The peptidomimetic is <1 nm in length, thus based on the level of substitution, peptide conjugation can approximately triple the theoretical MW of the 515 kDa HPG polymer to up to 1850 kDa for the HPG−RGD conjugate. Since attachment of the peptides is through divinyl sulfone, a reaction with limited yields, it is not surprising that the 3 kDa HPG (C-1 and C-2) carried few RGD peptides after conjugation. The achieved peptide density has steric implications for subsequent function due to its polyvalent binding to multiple GPIIbIIIa receptors on the platelet surface.

The design of the peptide included an N-terminal cystine for attachment and five glycine residues to facilitate the RGD motif's access to the GPIIbIIIa binding pocket (*5*). The RGDF sequence was considered by Foster et al. (*24*) to be the most

potent of the small RGD-peptidomimetics ($IC_{50} = 8 \times 10^{-3}$ M) and the phenylalanine was also useful for detection and UV tracking of the peptide (*24*).

Function. In order to evaluate whether RGD-conjugated HPGs have specific interactions with platelets, the naked, unconjugated HPGsb were examined first. Both the original studies (*19*, *20*) and the assays presented here involving either resting or activated platelets show no significant alterations of fibrinogen binding to platelets. Although plasma fibrinogen concentration, platelet surface GPIIbIIIa levels, and degree of preparation-induced platelet activation vary with the individual, similar IC_{50} values were obtained with the plasma and cells of all blood donors. Furthermore, neither the naked HPG nor the RGD-conjugated HPG caused platelet activation as defined by degranulation and CD62 expression. However, the RGD-conjugated HPG promoted some fibrinogen binding to resting platelets in a manner that could be related to both HPG molecular size and degree of RGD substitution: the more dense RGD brushes on HPG increased fibrinogen binding to platelets more so than diffuse RGD brushes. This can be attributed to cooperativity of GPIIbIIIa binding of RGD motifs such that RGD binding to a GPIIbIIIa receptor enhances the ability of other GPIIbIIIa molecules to bind fibrinogen (*25*, *26*).

The most important finding was that fibrinogen binding to activated platelets and subsequent platelet aggregate formation is inhibited by RGD-conjugated HPG in a manner related to HPG size (Figure 4) and to its degree of substitution (Figure 4). As the 3 kDa conjugates carried few RGD peptides, higher concentrations were needed to achieve the same degree of inhibition as obtained for free RGD peptides. However, both the 100 kDa and 515 kDa HPG conjugates carry 100−1500 RGD peptides, and thus they are able to reduce the IC_{50} of free RGD peptides by 2 to 3 orders of magnitude. Extrapolating from this data (Figure 5), it is possible to derive the substitution/MW relationship to achieve optimal platelet inhibition.

The large decrease of the IC_{50} and the corresponding increase of the HPG-conjugated RGD peptides' inhibitory effect may be a matter of kinetics. As a result of the polyvalent presentation of the RGD conjugated to HPG, the binding of RGD to platelet GPIIbIIIa is enhanced due to both a higher local concentration of RGD peptides and a slowed dissociation due to several concurrent dynamic associations of HPG−RGD with two or more GPIIbIIIa integrins. In addition, there is cooperativity among GPIIbIIIa receptors, such that a single bound RGD changes the GPIIbIIIa conformation to increase the likelihood of further ligand binding (*25*, *26*).

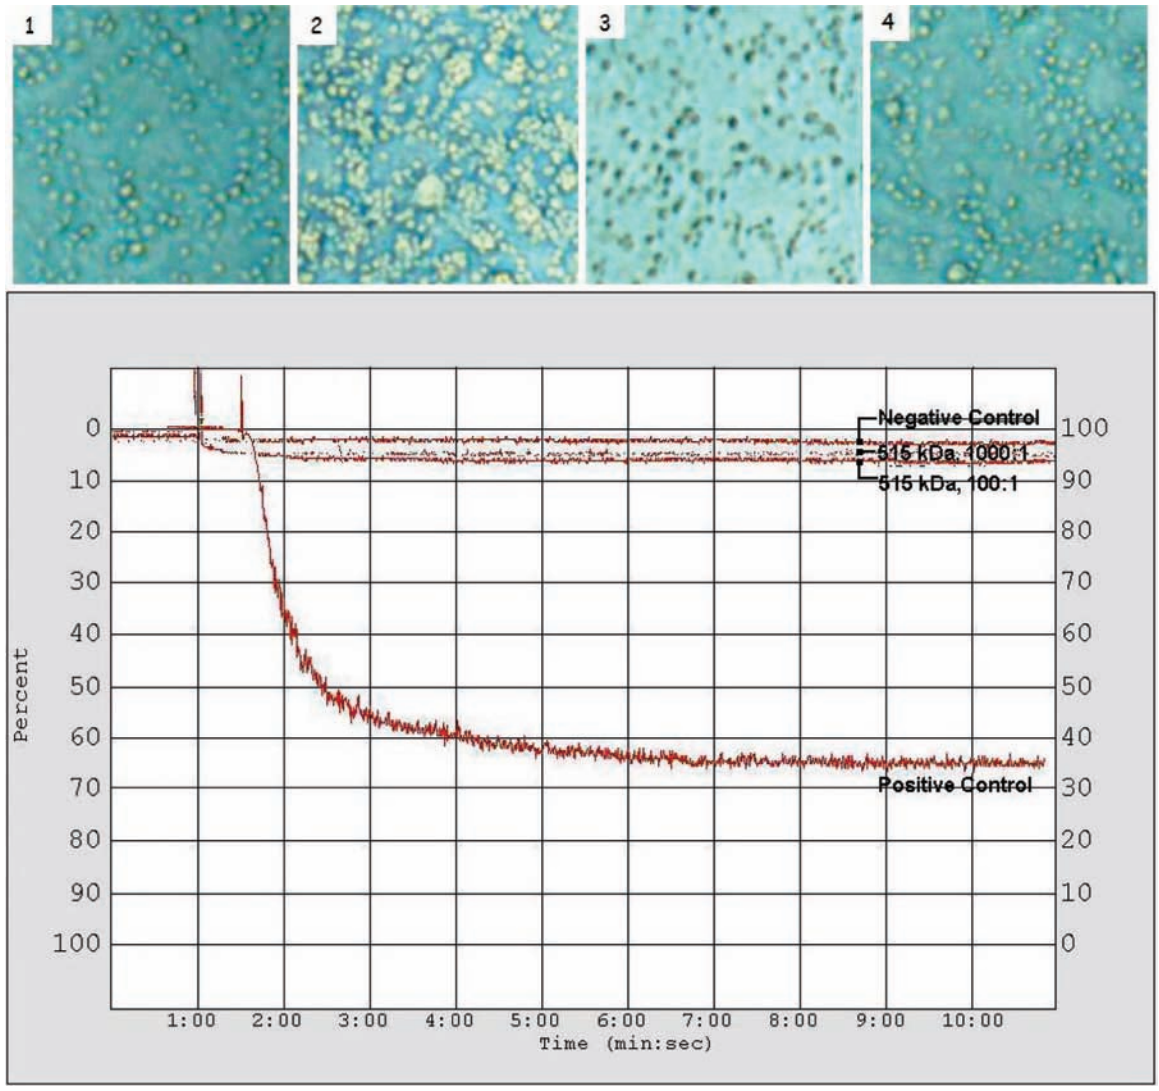

Figure 6. Light microscopy and aggregometry. Compound light microscopy 400×: panel 1, resting platelets; panel 2, Mn^{2+} activated platelets; panel 3, Mn^{2+} activated platelets incubated in C-5 HPG−RGD; panel 4, Mn^{2+} activated platelets incubated with C-7 HPG−RGD. Aggregometry graph: negative control, resting platelets; positive control, Mn^{2+} activated platelets; C-5 HPG−RGD, platelets incubated with RGD conjugate and activated with Mn^{2+}; C-7 HPG−RGD, platelets incubated with RGD conjugate and activated with Mn^{2+}.

It is known that free RGD peptides can activate the GPIIbIIIa receptors such that an increased number of the receptors are converted to the "open" configuration that is capable of binding fibrinogen (*25*, *26*). Thus, it is not unlikely that the HPG-carried RGD generate a similar activating effect. The increased fibrinogen binding seen on flow cytometry with resting platelets caused by high molecular weight, high-substitution HPG−RGD does not seem to cause spontaneous platelet aggregation macroscopically, as observed by light microscopy and lumiaggregometry. They do, however, still inhibit the macroscopic aggregation of Mn^{2+} activated platelets as detected both macroscopically (Figure 6; Table 2) and by flow cytometry (Figure 4).

CONCLUSIONS

We have demonstrated that RGD-based peptidomimetics can be conjugated to HPG polymers of varying molecular weight via divinyl sulfone and still retain receptor binding activity. The inhibitory effects of the HPG conjugates vary directly with the size and degree of substitution by the RGD peptides. We were able to increase the platelet inhibitory function of RGD by 2 to 3 orders of magnitude through conjugation to a macromolecular carrier, thereby increasing its local concentration as well as decreasing its dissociation kinetics. In addition, we found that, at high levels of RGD substitution, HPG conjugates may enhance platelet−fibrinogen binding to a certain extent and yet not result in activation by degranulation. Only in extreme cases do platelets aggregate spontaneously at a microscopic level: the use of the higher molecular weight carriers with moderate levels of conjugated peptides, such as C-5 and C-6, are suitable for

the development of an antithrombotic drug. Further studies of RGD and other peptidomimetics and their enhanced effectiveness through conjugation to macromolecular carriers are being investigated.

Received February 26, 2008; Revised Manuscript Received May 3, 2008

In the study, chitosan (CS) was conjugated with trimethyl groups for the synthesis of *N*-trimethyl chitosan (TMC) polymers with different degrees of quaternization. Nanoparticles (NPs) self-assembled by the synthesized TMC and poly(γ-glutamic acid) (γ-PGA, TMC/γ-PGA NPs) were prepared for oral delivery of insulin. The loading efficiency and loading content of insulin in TMC/γ-PGA NPs were 73.8 $\pm$ 2.9% and 23.5 $\pm$ 2.1%, respectively. TMC/γ-PGA NPs had superior stability in a broader pH range to CS/γ-PGA NPs; the *in vitro* release profiles of insulin from both test NPs were significantly affected by their stability at distinct pH environments. At pH 7.0, CS/γ-PGA NPs became disintegrated, resulting in a rapid release of insulin, which failed to provide an adequate retention of loaded insulin, while the cumulative amount of insulin released from TMC/γ-PGA NPs was significantly reduced. At pH 7.4, TMC/γ-PGA NPs were significantly swelled and a sustained release profile of insulin was observed. Confocal microscopy confirmed that TMC40/γ-PGA NPs opened the tight junctions of Caco-2 cells to allow the transport of insulin along the paracellular pathway. Transepithelial-electrical-resistance measurements and transport studies implied that CS/γ-PGA NPs can be effective as an insulin carrier only in a limited area of the intestinal lumen where the pH values are close to the pK_a of CS. In contrast, TMC40/γ-PGA NPs may be a suitable carrier for transmucosal delivery of insulin within the entire intestinal tract.

INTRODUCTION

The oral route is the most convenient and comfortable means of administering protein/peptide drugs such as insulin, because the pain caused by injection could be avoided, leading to a higher patient compliance (*1*, *2*). However, protein/peptide drugs are readily degraded by the low pH of gastric medium in the stomach. Additionally, different digestive enzymes in the stomach and small intestine may lead to degradation of protein/peptide drugs (*3*–*5*). Therefore, a pH-responsive drug delivery system that is stable in the gastrointestinal (GI) tract and can swell significantly or disintegrate and subsequently release the loaded drug when adhering and infiltrating into the mucus of the intestinal tract is desired.

Chitosan (CS) and poly(γ-glutamic acid) (γ-PGA) have been used for the purpose of gene or drug delivery (*6*–*11*). In our recent study, a nanoparticle (NP) system composed of CS and γ-PGA for oral delivery of insulin via the paracellular transport was developed (*12*, *13*). We found that the prepared NPs remained intact in the pH range 2.5−6.6; however, outside this range, they became unstable and disintegrated, thus limiting the efficacy of insulin delivery. It is known that the natural pH environment in the GI tract varies from acidic in the stomach to slightly alkaline in the small intestine (*14*). CS lacks the advantage of good solubility at neutral pH values. It aggregates in solutions at pH values above 6.5, and only protonated CS (i.e., in its uncoiled configuration) can trigger the opening of tight junctions, thereby facilitating the paracellular transport of hydrophilic compounds (*15*). To overcome these problems, CS was conjugated with trimethyl groups for the synthesis of *N*-trimethyl chitosan (TMC) polymers with different degrees of quaternization. The partially quaternized TMC, which shows higher aqueous solubility than CS in a much broader pH range (*15*), was used in this study to prepare NPs.

The synthesized TMC polymers were analyzed by the proton nuclear magnetic resonance (^{1}H NMR) and Fourier transformed infrared (FT-IR) spectroscopy. Preparation of NPs self-assembled by TMC and γ-PGA (TMC/γ-PGA NPs) was reported and their mean particle sizes as well as zeta potential values in response to simulated GI media were examined by dynamic light scattering. Molecular dynamic (MD) simulations were used to investigate the structural changes of the self-assembled TMC/γ-PGA complex at distinct pH environments. Evaluation of test NPs in enhancing the intestinal paracellular transport was investigated *in vitro* in Caco-2 cell monolayers. The change of transepithelial electrical resistance (TEER) for the tightness of cell monolayers was measured and the paracellular transport of insulin was visualized using confocal laser scanning microscopy (CLSM) and quantified by enzyme-linked immunosorbent

assay (ELISA). Additionally, the release profiles of insulin from test NPs were studied in simulated GI media.

MATERIALS AND METHODS

Synthesis and Characterization of TMC. CS (MW 60 kDa) with a degree of deacetylation of approximately 85% was acquired from Koyo Chemical Co. Ltd. (Japan). TMC55 with a degree of quaternization of about 55% was synthesized from CS using a two-step methylation procedure described by Sieval et al. (*16*). By varying the number of reaction steps and the amount of base used, TMC25 and TMC40 with degrees of quaternization of approximately 25% and 40%, respectively, were synthesized by a method reported by Polnok et al. (*17*). The obtained TMC was purified by dialysis against water for 3 days and then freeze-dried. The purified TMC was analyzed by ^{1}H NMR (Varian Unityionva 500 NMR Spectrometer, Missouri) and FT-IR (Perkin-Elmer Spectrum RX1 FT-IR System, Buckinghamshire, England). Degrees of quaternization of the synthesized TMC polymers were estimated using ^{1}H NMR spectra (*17*).

Preparation and Characterization of NPs. TMC/γ-PGA NPs were prepared using a simple ionic-gelation method under magnetic stirring at room temperature. In brief, an aqueous γ-PGA (Vedan, Taichung, Taiwan, MW 60 kDa, 1.0 mg/mL, 2 mL) was added by flush mixing with a pipet tip into an aqueous TMC [1.2 mg/mL, 10 mL, in deionized (DI) water, pH 6.0]. The self-assembled NPs were collected by centrifugation at 15 000 rpm for 50 min. Supernatants were discarded and NPs were resuspended in DI water for further studies. The mean particle sizes and zeta potential values of NPs were measured using a Zetasizer (3000HS, Malvern Instruments Ltd., Worcestershire, UK). The characteristics of NPs were investigated at distinct pH values (simulating the pH environments in the GI tract) (*18*–*20*).

MD Simulation of NPs at Distinct pH Environments. MD simulations were performed with the program NAMD (*21*) using parameters adapted from the CHARMM (*22*) force field. TMC and γ-PGA used in simulations were oligomers consisting of 10 monomers. The models were minimized to remove unfavorable contacts, brought to 310 K by velocity rescaling and equilibrated for 1 ns. Before any MD trajectory was run, 40 ps of energy minimization was performed to relax conformational and structural tensions. This minimum structure was the starting point for MD simulations. For this purpose, the molecule was embedded into a cubic simulation box of 80 Å. A cutoff distance of 12 Å was employed for the nonbonded and electrostatic interactions. The heating process was performed from 0 to 310 K through Langevin damping with a coefficient of 10 ps^{-1}. A time step of 2 fs was employed for rescaling the temperature. After 20 ps heating to 310 K, equilibration trajectories of 1 ns were recorded, which provided the data for the structural and thermodynamic evaluations. The equations of motion were integrated with the Shake algorithm with a time step of 1 fs. Figures displaying atomistic pictures of molecules were generated using VMD (*23*).

Preparation of Insulin-Containing NPs. A sample of 100 mg of insulin (from bovine pancreas, 27.4 IU/mg, Sigma-Aldrich, St. Louis, MO) was dissolved in 10 mL of 0.01 N HCl, and this solution was neutralized with 0.1 N NaOH (*24*). The insulin solution was then diluted with DI water to make a 3 mg/mL insulin stock solution. The insulin stock solution (1 mL) was premixed with an aqueous γ-PGA (3 mg/mL, 1 mL). Subsequently, $MgSO_4$ (6 mg/mL, 1 mL) was blended into the mixture and thoroughly stirred for 30 min. The mixed solution was added into an aqueous TMC (1.2 mg/mL, 10 mL) under magnetic stirring at room temperature as described before.

To determine their insulin loading content and loading efficiency, NPs were collected by centrifugation at 15 000 rpm, 4 °C for 50 min, and the insulin concentration in the supernatant was assayed by high-performance liquid chromatography (HPLC). The drug loading content and loading efficiency of NPs were determined as follows (*12*, *13*).

$$\text{Loading Content (\%)} = \frac{\text{total amount of insulin} - \text{free insulin}}{\text{weight of NPs}} \times 100\%$$

$$\text{Loading Efficiency (\%)} = \frac{\text{total amount of insulin} - \text{free insulin}}{\text{total amount of insulin}} \times 100\%$$

The release profiles of insulin from test NPs were investigated in distinct dissolution media (pH 2.5, 6.4, 7.0, and 7.4, simulating the pH environments in the GI tract) at 37 °C under agitation (100 rpm, DISTEK-2230A, North Brunswick, NJ). At particular time intervals, samples were taken out and centrifuged and supernatants were used for the HPLC analysis. The amount of insulin released was expressed as a percentage of the total insulin associated with NPs as calculated from the loading efficiency (*25*). The stability of the released insulin was determined by analyzing its conformation using an Aviv 202 spectropolarimeter (Aviv Associates, Lakewood, NJ) and comparing the spectrum with that of standard insulin (*26*).

TEER Measurements and Transport Studies. Caco-2 cell monolayers were cultured on the tissue-culture-treated polycarbonate filter (diameter 24.5 mm, growth area 4.7 cm^2) in Costar Transwell 6 wells/plates (Corning Costar Corp., NY) and were used for transport experiments approximately 21 days after seeding (TEER values in the range 600−800 Ω cm^2). Evaluation of test NPs (0.2 mg/mL, 1 mL) in enhancing the intestinal paracellular transport at pH 6.6, 7.0, and 7.4 (in the donor compartment; at pH 7.4 in the receiver compartment) was investigated in Caco-2 cell monolayers (*27*). The change of TEER for the tightness of cell monolayers was measured with a Millicell-Electrical Resistance System (Millipore Corp., Bedford, MA). Simultaneously, samples (50 μL) were collected from the receiver compartment at distinct time intervals and the insulin concentrations were measured using ELISA (bovine insulin kit, Mercodia AB, Uppsala, Sweden) (*28*). The transport of insulin through Caco-2 cell monolayers was expressed as the cumulative insulin transport (*29*).

Fluorescent NP Preparation and CLSM Visualization. Cy3-labeled insulin (Cy3-insulin) was synthesized by a method described in the literature (*30*). To remove the unconjugated Cy3, the synthesized Cy3-insulin was dialyzed in the dark against 5 L of 0.01 N HCl and replaced on a daily basis until no fluorescence was detected in the supernatant. The resultant Cy3-insulin was lyophilized in a freeze−dryer. Fluorescent NPs loaded with Cy3-insulin were then prepared for the CLSM study as per the procedure described above. The transport medium (pH 7.0) containing fluorescent NPs (0.2 mg/mL, 1 mL) was introduced into the donor compartment of Caco-2 cell monolayers, while the medium in the receiver compartment was maintained at pH 7.4 (*31*). After incubation for specific time intervals at 37 °C, test samples were aspirated. Cells were then washed twice with prewarmed phosphate buffered saline (PBS) before they were fixed in 3.7% paraformaldehyde (*32*). Subsequently, the fixed cells were examined under a CLSM (TCS SL, Leica, Germany).

Visualization of Opening Tight Junctions. Caco-2 cell monolayers were incubated with test NPs (0.2 mg/mL, 1 mL). After 120 min, the incubated NPs were removed and cells were fixed in 3.7% paraformaldehyde. Cells were washed three times with PBS and permeabilized with 0.2% Triton X-100 and RNase (100 μg/mL) for 15 min at 37 °C. The wash was repeated and cells were blocked with 5% normal goat serum (Jackson ImmunoResearch Laboratories, West Grove, PA) in PBS for

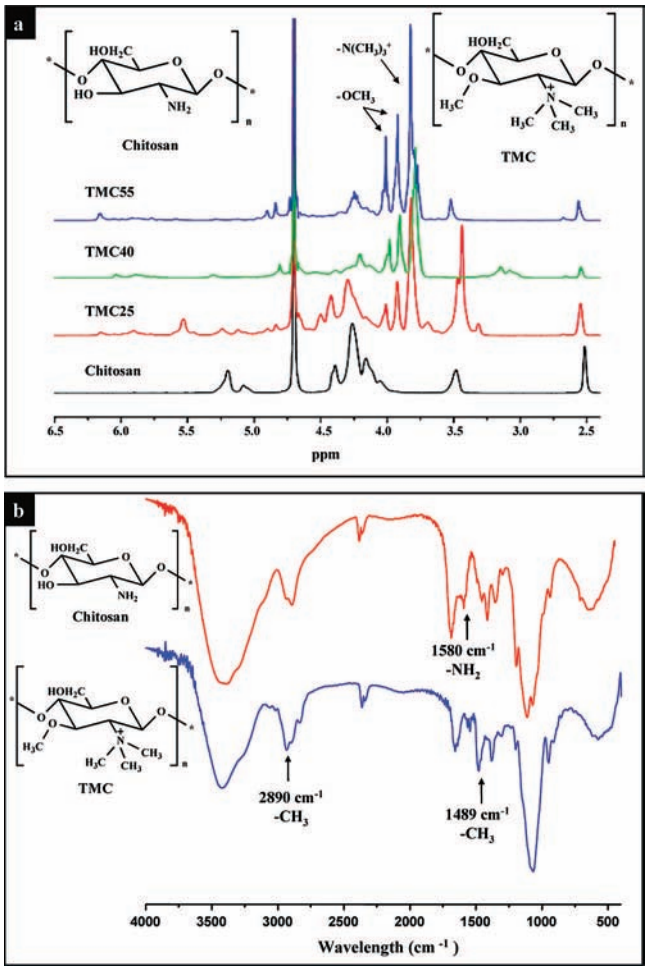

Figure 1. (a) ^{1}H NMR spectra of chitosan (CS) and *N*-trimethyl chitosan (TMC) polymers with different degrees of quaternization; (b) FT-IR spectra of CS and TMC40.

60 min at 37 °C. Subsequently, cells were treated with the rabbit anti-ZO-1 mAb (Zymed Laborates, San Francisco, CA) at 1:50 dilution for 60 min at 37 °C. After washing three times with PBS, cells were incubated in the Cy-5 conjugated goat antirabbit IgG at 1:100 dilution (Jackson ImmunoResearch Laboratories). Additionally, cells were costained to visualize nuclei by propidium iodide (PI, P4864, Sigma-Aldrich, St. Louis, MO). The stained cells were evenly mounted on slides and examined under a CLSM. Superimposed images were performed with LCS Lite software (version 2.0).

Statistical Analysis. Comparison between two groups was analyzed by the one-tailed Student's *t*-test and multiple group comparison was performed by one-way ANOVA followed by Fisher's LSD using statistical software (SPSS, Chicago, IL). All data are presented as a mean value with its standard deviation indicated (mean ± SD). Differences were considered to be statistically significant when p values were less than 0.05.

RESULTS AND DISCUSSION

Characterization of TMC. Figure 1a,b shows the ^{1}H NMR and FT-IR spectra of CS and the synthesized TMC, respectively. As shown in Figure 1a, TMC showed a new signal at 3.82 ppm [$-N(CH_3)_3^+$], while those observed at 3.82−4.04 ppm corresponded to $-OCH_3$ (*13*, *33*). In the FT-IR spectra, the intensity of the characteristic peak (2890 cm^{-1}, C−H stretch) increased and a new peak at 1489 cm^{-1} ($-CH_3$ antisym deformation) was observed on TMC, while the characteristic peak (1580 cm^{-1}) of $-NH_2$ on CS decreased (*33*). These results indicated that TMC was successfully synthesized. Degrees of quaternization of the synthesized TMC polymers, estimated from the obtained ^{1}H NMR spectra, were 24.8% (TMC25), 42.8% (TMC40), and 54.5% (TMC55), respectively.

Table 1. Mean Particle Sizes, Zeta Potential Values, and Polydispersity Indices of Nanoparticles (NPs) Self-Assembled by TMC Polymers with Different Degrees of Quaternization and γ-PGA (n = 5 batches)[a]

	mean particle size (nm)	zeta potential (mV)	polydispersity index
CS/γ-PGA NPs	104.1 ± 1.2	36.2 ± 2.5	0.11 ± 0.02
TMC25/γ-PGA NPs	101.3 ± 3.1	30.9 ± 2.1	0.13 ± 0.04
TMC40/γ-PGA NPs	106.3 ± 2.3	32.3 ± 2.1	0.15 ± 0.14
TMC55/γ-PGA NPs	114.6 ± 2.3	30.6 ± 3.8	0.12 ± 0.03

[a] TMC: *N*-trimethyl chitosan. CS: Chitosan. γ-PGA: Poly(γ-glutamic acid).

Preparation of NPs. In the study, NPs were self-assembled instantaneously upon addition of an aqueous γ-PGA into an aqueous TMC (with a TMC/γ-PGA weight ratio of 6:1) under magnetic stirring at room temperature. The amount of positively charged TMC significantly exceeded that of negatively charged γ-PGA; some of excessive TMC molecules were entangled onto the surfaces of NPs, thus displaying a positive surface charge (Table 1). The degree of quaternization on TMC had little effects on the mean particle size and zeta potential of NPs.

pH-Responsive Characteristics of NPs. The stomach pH is about 1.0−2.0 in the presence of food, while the fasting pH of the stomach is 2.5−3.7 (*18–20*). The pH values in the duodenum and the jejunum and proximal ileum are 6.0−6.6 and 6.6−7.0, respectively, while the mean pH in the distal ileum and in the body fluid at intercellular spaces between enterocytes is about 7.4 (*14*, *19*, *20*). Therefore, characterization of test NPs in response to distinct pH environments must be investigated.

Peppas et al. prepared poly(methacrylic acid-*g*-ethylene glycol) (PMAA-g-EG) NPs for oral administration of insulin (*24*, *34*, *35*). It was shown that the prepared NPs were pH-responsive and mucoadhesive. The results of TEER measurements and transport studies implied that PMAA-g-EG NPs were effective as a transmucosal carrier and able to open the tight junctions between Caco-2 cells.

In contrast to PMAA, TMC is a positively charged polymer and has been used as an intestinal permeation enhancer (*29*), and its mechanism of opening tight junctions is similar to that of protonated CS (*15*). Additionally, TMC showed no indication of epithelial damage or cytotoxicity (*15*). The mucoadhesive characteristics of the CS-coated NPs (FITC-labeled) in vivo were previously reported by our group (*36*). In this study, the FITC-labeled CS NPs were orally administered in a rat model and the intestinal segments were retrieved 3 h afterwards. It was found that the administered CS NPs were colocalized with ZO-1 proteins at the epithelial junctions. Also, it has been reported that TMC-containing formulations exceeded the potency of CS in mucoadhesion (*29*). The mucoadhesive properties of CS and TMC have also been reported in large animals such as pigs (*37*).

The basic concept of the study is that the orally administered NPs with excessive mucoadhesive TMC (*29*) on their surfaces may adhere and infiltrate into the mucus of the intestinal tract, and then mediate transiently opening the tight junctions between enterocytes (Figure 2). It is known that the tight junctions opened by absorption enhancers are less than 20 nm in width (*38–40*). Consequently, the NPs infiltrated into the mucus must become unstable (swelling or disintegration); thus, their loaded insulin can be released and permeated through the paracellular pathway to the bloodstream.

It is known that the pK_a values of CS (amine groups) and γ-PGA (carboxylic groups) are 6.5 and 2.9, respectively (*12*).

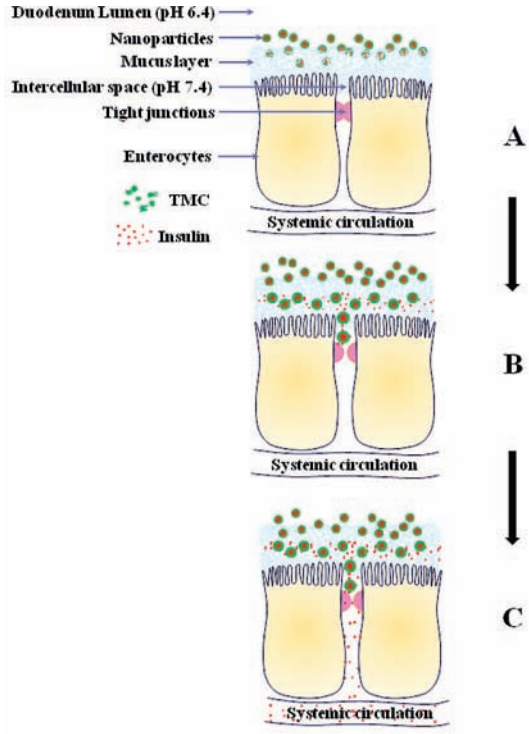

Figure 2. Schematic illustrations of the presumed mechanism of opening tight junctions by test nanoparticles and transporting of their encapsulated drug (using duodenum as an example).

In the study, NPs were prepared in DI water (pH 6.0). At pH 6.0, CS (TMC25) and γ-PGA were ionized. The ionized CS (TMC25) and γ-PGA could form polyelectrolyte complexes, which resulted in a matrix structure with a spherical shape. At pH 1.2−2.0, most carboxylic groups on γ-PGA were in the form of −COOH. Hence, there was little electrostatic interaction between CS (TMC25) and γ-PGA; thus, NPs became disintegrated (Table 2). Similarly, at pH values above 6.6, the free amine groups on CS (TMC25) were deprotonated, thus leading to the disintegration of NPs. This might limit the efficacy of drug delivery and absorption in the small intestine.

With increasing the degree of quaternization on TMC (TMC40 and TMC55), the stability of NPs in the pH range 6.6−7.4 increased significantly. However, the swelling of TMC55/γ-PGA NPs at pH 7.4 was minimal (due to the highly quaternized TMC55), which might limit the release of loaded drugs. In contrast, TMC40/γ-PGA NPs swelled significantly with increasing pH value (Figure 3). Therefore, TMC40/γ-PGA NPs were chosen to load insulin and used for the rest of the study. As shown in Table 2, TMC40/γ-PGA NPs still retained a positive surface charge with a zeta potential value of 17.3 mV at pH 7.4.

The results of MD simulations showed that the molecular chains of TMC40 (in blue) and γ-PGA (in red) in their self-assembled complex were tightly entangled to each other at pH 6.0 (Figure 4). The surface of the complex was dominated by TMC40 molecules. Relaxations of TMC40 and γ-PGA molecular chains at pH 2.5 (pH 7.4) resulted in a moderate (significant) swelling of the TMC40/γ-PGA complex, while its surface was still dominated by the positively charged TMC molecules, thus retaining a positive surface charge.

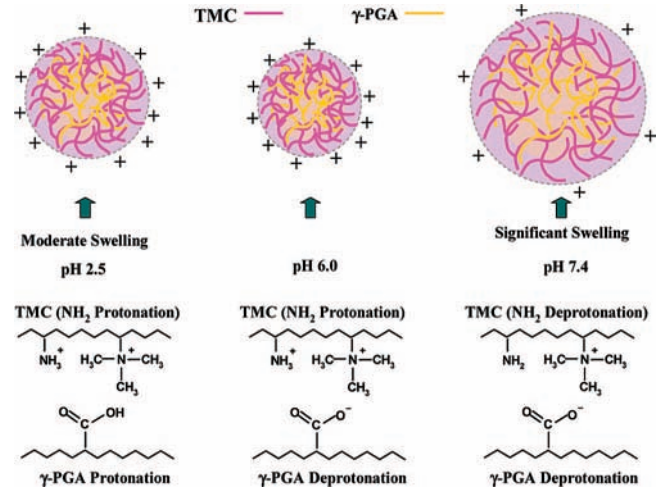

Figure 3. Schematic illustrations of the pH-responsive characteristics of TMC40/γ-PGA NPs at distinct pH environments. TMC: *N*-trimethyl chitosan. γ-PGA: poly(γ-glutamic acid).

Characteristics of Insulin-Containing NPs and Their Release Profiles. In the study, we found that the loading efficiency and loading content of insulin in TMC40/γ-PGA NPs were only 20.8 ± 1.9% and 4.2 ± 1.6% (n = 5 batches), respectively. To increase the amount of insulin loaded, Mg^{2+} was blended in the premixed aqueous insulin/γ-PGA in the

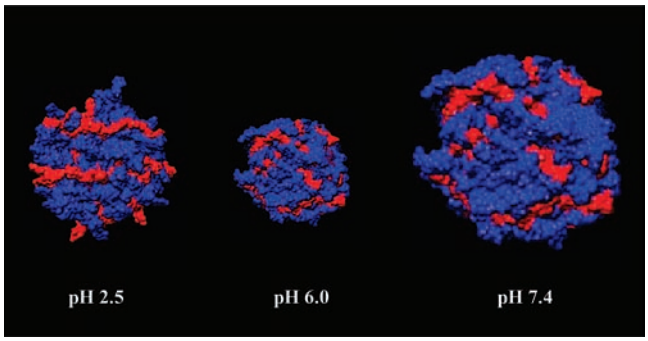

Figure 4. Structural changes of the self-assembled TMC40/γ-PGA complex at distinct pH environments obtained by molecular dynamic simulations. TMC: *N*-trimethyl chitosan (in blue). γ-PGA: poly(γ-glutamic acid) (in red).

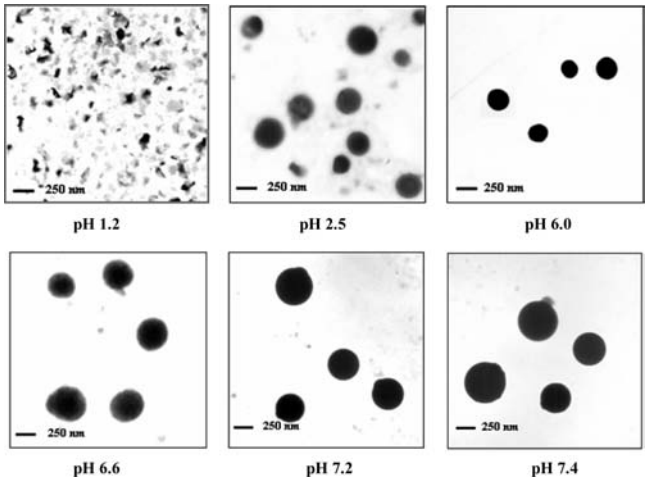

Figure 5. TEM micrographs of the insulin-containing TMC40/γ-PGA nanoparticles at distinct pH environments. TMC: *N*-trimethyl chitosan. γ-PGA: poly(γ-glutamic acid).

preparation of NPs. It was reported in our previous study that insulin could conjugate with γ-PGA via divalent metal ions such as Zn^{2+} (*13*, *36*), thus increasing the drug loading efficiency and loading content in NPs. In the present study, we found that the NPs prepared with Mg^{2+} had a better stability than their counterparts with Zn^{2+} (data not shown). Mg^{2+} is one of the most abundant ions present in living cells. It was reported that daily Mg^{2+} administration in diabetic patients improves insulin-mediated glucose uptake (*41*). In the presence of Mg^{2+}, the insulin loading efficiency (73.8 ± 2.9%) and loading content (23.5 ± 2.1%, $n = 5$ batches) in TMC40/γ-PGA NPs increased significantly.

The morphology, mean particle sizes, zeta potential values, and polydispersity indices of the insulin-containing TMC40/γ-PGA NPs at distinct pH values are shown in Figure 5 and Table 3, respectively. As shown, the pH-responsive characteristics of the insulin-containing TMC40/γ-PGA NPs were similar to their empty counterparts (Table 2).

Figure 6a shows the release profiles of insulin from the insulin-containing CS/γ-PGA and TMC40/γ-PGA NPs at pH 2.5, 6.4, 7.0, and 7.4, simulating the pH environments in the stomach before a meal (similar to the conventional injectable insulin therapy), the small intestine, and the body fluid at intercellular spaces between enterocytes, respectively. As mentioned already, the insulin-containing TMC40/γ-PGA NPs were prepared at pH 6.0, which was close to the pI of native insulin. It has been reported that at this pH value, insulin associated with CS/TPP NPs primarily through hydrophobic interactions and the associated insulin released rapidly and

completely in aqueous media at pH 2.0 to 7.4 (*25*). Therefore, the release of insulin from the prepared NPs should be mainly influenced by their pH-dependent swelling property.

At pH 2.5 (the stomach before meal) and 6.4 (the duodenum), the release profiles of insulin from both test NPs were similar. At pH 7.0 (the jejunum and the proximal ileum), CS/γ-PGA NPs became disintegrated (Table 2), resulting in a rapid release of insulin, which failed to provide an adequate retention of loaded insulin (approximately 85% of the loaded insulin was released). In contrast, for TMC/γ-PGA NPs, the cumulative amount of insulin released was significantly reduced to about

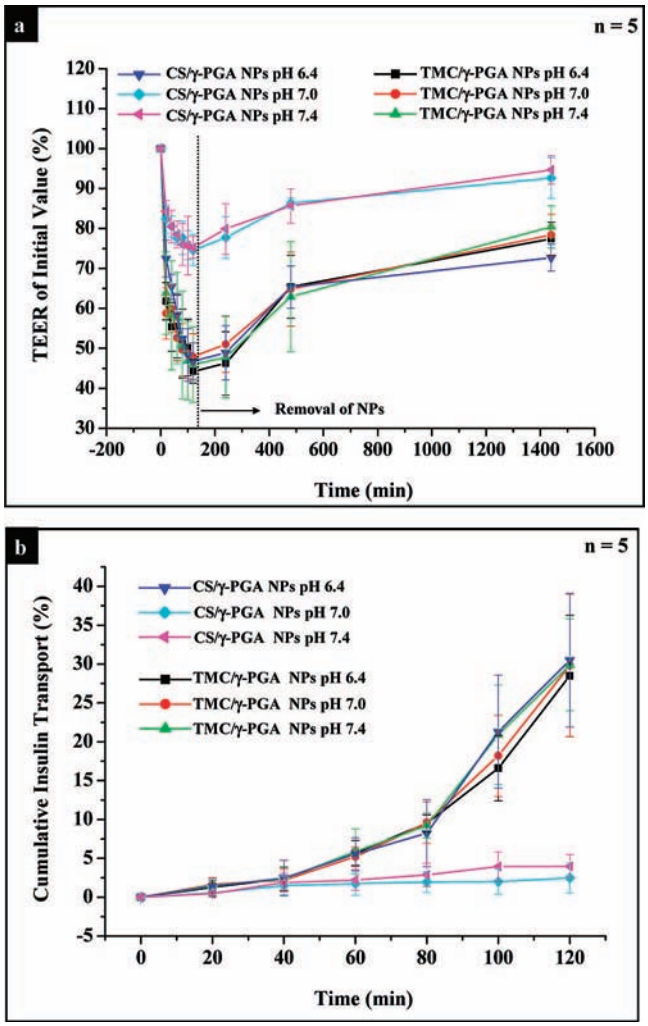

Figure 7. (a) Effects of CS/γ-PGA and TMC40/γ-PGA nanoparticles (NPs) on TEER values of Caco-2 cell monolayers at distinct pH values. (b) Cumulative amounts of insulin transported through Caco-2 cell monolayers incubated with test nanoparticles as a function of time at distinct pH values. CS: chitosan. TMC: *N*-trimethyl chitosan. γ-PGA: poly(γ-glutamic acid).

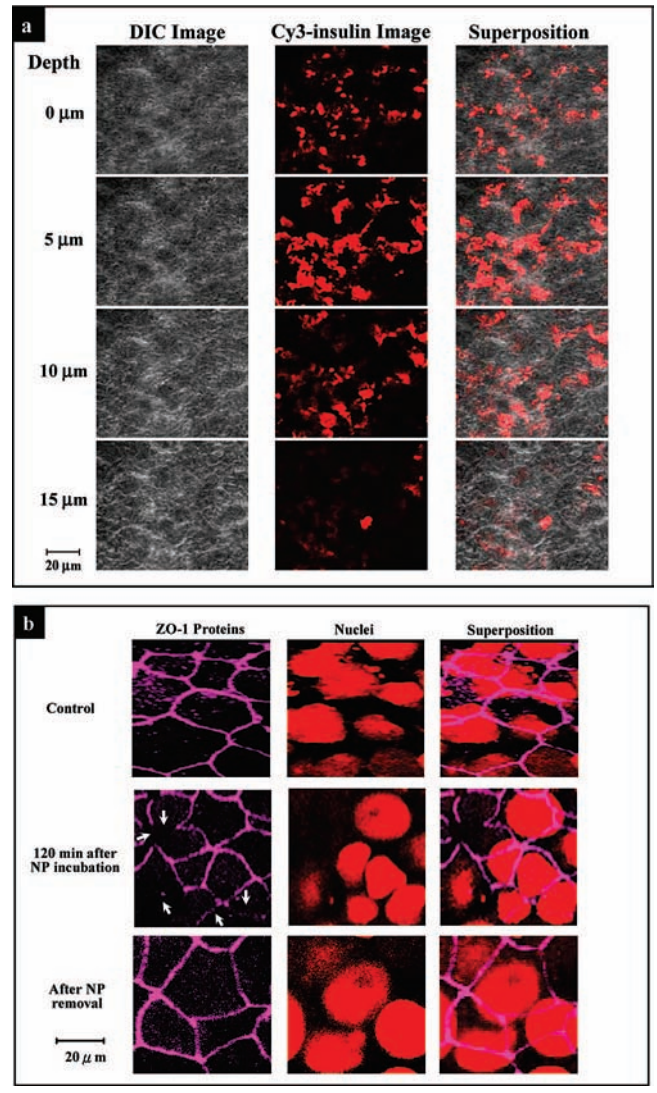

Figure 8. (a) DIC and fluorescence images (taken by an inverted confocal laser scanning microscope) of four optical sections (at different depths) of Caco-2 cell monolayers 120 min after incubation with the Cy3-insulin containing TMC40/γ-PGA NPs. (b) Fluorescence images of Caco-2 cell monolayers immunofluorescently stained for ZO-1 proteins after incubation with TMC40/γ-PGA NPs for 120 min. TMC: *N*-trimethyl chitosan. γ-PGA: poly(γ-glutamic acid).

30%, due to their comparative stability at pH 7.0. At pH 7.4 (the distal ileum and the body fluid at intercellular spaces), TMC/γ-PGA NPs were significantly swelled and a sustained release profile of insulin was observed. As indicated by the circular dichroism spectra (Figure 6b), no significant conformation change was observed for the insulin released from TMC/γ-PGA NPs at pH 7.4 as compared to the standard insulin.

TEER Measurements and Insulin Transport Studies. Effects of CS/γ-PGA and TMC40/γ-PGA NPs on the TEER and the amount of insulin transported across Caco-2 cell monolayers as a function of time at distinct intestinal pH environments are shown in Figure 7a,b. As shown, incubation of CS/γ-PGA NPs on the apical side of Caco-2 cell monolayers at pH 6.4 led to an immediate reduction in TEER and a significant amount of insulin transported. However, at pH 7.0 and 7.4, the reduction in TEER and the amount of insulin transported through Caco-2 cells were significantly limited. These results implied that CS/γ-PGA NPs can be effective as an insulin carrier only in a limited area of the intestinal lumen (the duodenum) where the pH values are close to the pK_a of CS.

In contrast, TMC40/γ-PGA NPs significantly decreased the TEER and increased the amount of insulin transported across Caco-2 cell monolayers at all test intestinal pH environments, indicating a specific interaction of the cationic NPs (Table 3) with components of the tight junctions at neutral pH values. These findings suggested that TMC40/γ-PGA NPs may be a suitable carrier for transmucosal delivery of protein/peptide drugs within the entire intestinal lumen (the duodenum, jejunum, and ileum). After removal of the incubated test particles, a gradual increase in TEER was observed, indicating that the effect of TMC40/γ-PGA NPs on the tight junction's regulation is transient and reversible.

CLSM Visualization. Figure 8a shows the differential interference contrast (DIC) and fluorescence images of 4 optical sections of Caco-2 cell monolayers 120 min after incubation with the Cy3-insulin-containing TMC40/γ-PGA NPs using CLSM. This noninvasive method allows for optical sectioning and imaging of the transport of insulin across Caco-2 cell monolayers, without disrupting their structure (*42*). As shown, fluorescent images were observed at intercellular spaces between adjacent cells, suggesting that TMC40/γ-PGA NPs opened the tight junctions of Caco-2 cells to allow the transport of insulin by passive diffusion along the paracellular pathway. These

findings confirmed the results observed in our TEER measurements and insulin-transport experiments (Figure 7a,b).

The opening of the tight junctions of cell monolayers by TMC40/γ-PGA NPs was shown in Figure 8b. As shown, the staining for ZO-1 tight junction proteins showed a continuous ring appearance between adjacent cells before incubation with test NPs (control). After incubation with test NPs, the staining for ZO-1 proteins appeared discontinuous (indicated by white arrows), indicating the opening of cell tight junctions. ZO-1 proteins are thought to be a linkage molecule between occludin and actin cytoskeleton and play important roles in the rearrangement of cell−cell contacts (*43*, *44*). After removal of NPs, the discontinuous staining for ZO-1 proteins appeared again, indicating the restoration of cell tight junctions.

CONCLUSIONS

A pH-responsive NP system self-assembled by TMC and γ-PGA for oral delivery of insulin was successfully prepared in the study. TEER experiments showed that TMC/γ-PGA NPs were able to open the tight junctions between Caco-2 cells, and their effect on the tight junction's integrity appeared to be reversible. CLSM confirmed that TMC/γ-PGA NPs opened the tight junctions of cell monolayers to allow the transport of insulin along the paracellular pathway at all test intestinal pH environments. These findings suggested that TMC40/γ-PGA NPs may be a suitable carrier for transmucosal delivery of protein/peptide drugs within the entire intestinal lumen.

Development of Novel ^{68}Ga- and ^{18}F-Labeled GnRH-I Analogues with High GnRHR-Targeting Efficiency

Margret Schottelius,* Sebastian Berger, Thorsten Poethko, Markus Schwaiger, and Hans-Jürgen Wester

Nuklearmedizinische Klinik and Poliklinik, Klinikum rechts der Isar, Technische Universität München, 81675 München, Germany. Received February 12, 2008; Revised Manuscript Received April 28, 2008

A large majority of tumors of the reproductive system express the gonadotropin releasing hormone receptor (GnRHR). Blockade and activation of this receptor with various antagonistic and agonistic analogues of native GnRH-I (pGlu^1-His^2-Trp^3-Ser^4-Tyr^5-Gly^6-Leu^7-Arg^8-Pro^9-Gly^{10}-NH$_2$), respectively, has shown efficient suppression of tumor growth. In this study, the GnRH-receptor system has been evaluated with respect to its suitability as a target for in vivo peptide receptor targeting using radiolabeled GnRH-analogues, and in parallel, new ^{18}F- and ^{68Ga}-labeled GnRH analogues have been developed. In vitro radioligand binding assays performed with various GnRHR-expressing human cell lines using [^{125}I]Triptorelin (D-Trp^6-GnRH-I) as the standard radioligand revealed a very low level of GnRH receptor expression on the cell surface. Generally, total cellular activity was very low (~3% of the applied activity), and only a small fraction (max. 40%) of cell-associated activity could be attributed to receptor-specific radioligand binding/internalization. However, substitution of fetal calf serum by NU serum in the culture medium led to increased and stable GnRHR-expression, especially in the ovarian cancer cell line EFO-27, thus allowing for a stable experimental setup for the evaluation of the new radiolabeled GnRH-I analogues. The new radiolabeled GnRH-I analogues developed in this study were all based on the D-Lys^6-GnRH-I-scaffold. For ^{68}Ga-labeling, the latter was coupled with DOTA at D-Lys^6. To allow ^{18}F-labeling via chemoselective oxime formation, D-Lys^6-GnRH-I was also conjugated with Ahx (aminohexanoic acid) or β-Ala, which in turn was coupled with Boc-aminooxyacetic acid. ^{18}F-labeling via oxime formation with 4-[^{18}F]fluorobenzaldehyde was performed using the Boc-protected precursors. Receptor affinities of [^{68}Ga]DOTA-GnRH-I, D-Lys^6-Ahx([^{18}F]FBOA)-GnRH-I, and D-Lys^6-βAla([^{18}F]FBOA)-GnRH-I (FBOA = fluorobenzyloxime acetyl) were determined using GnRHR-membrane preparations, and internalization efficiency of the new radioligands was determined in EFO-27 cells. Both quantities were highest for D-Lys^6-Ahx([^{18}F]FBOA)-GnRH-I ($IC_{50} = 0.50 \pm 0.08$ nM vs 0.13 ± 0.08 nM for Triptorelin; internalization: 86 ± 16% of the internal reference [^{125}I]Triptorelin), already substantially reduced in the case of the -βAla([^{18}F]FBOA)-derivative ($IC_{50} = 0.86 \pm 0.13$ nM; internalization: 42 ± 3% of [^{125}I]Triptorelin), while the [^{68}Ga]DOTA-analogue showed almost complete loss of binding affinity and ligand internalization ($IC_{50} = 13.3 \pm 1.0$ nM; internalization: 2.6 ± 1.0% of [^{125}I]Triptorelin). Generally, the lipophilic residue [^{18}F]FBOA is much better tolerated as a modification of the D-Lys^6-side chain, with receptor affinity of the respective analogues strongly depending upon spacer length between the D-Lys^6-side chain and the [^{18}F]FBOA-moiety. In summary, D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I shows the highest potential for efficient GnRHR-targeting in vivo of the compounds investigated. Unfortunately, however, the very low cell surface expression of GnRH-receptors and thus very low radioligand uptake by GnRHR-positive tumor cells found in vitro was also confirmed by a preliminary biodistribution study in OVCAR-3 xenografted nude mice using the standard GnRHR radioligand [^{125}I]Triptorelin. Tumor uptake was lower than blood activity concentration at 1 h p.i. (0.49 ± 0.05 vs 0.96 ± 0.13 for tumor and blood, respectively). These data seriously challenge the suitability of the GnRHR-system as a suitable target for in vivo peptide receptor imaging using radiolabeled GnRH-I derivatives, despite the availability of high-affinity radiolabeled receptor−ligands such as D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I.

INTRODUCTION

Neuropeptide receptors are overexpressed on a wide variety of human tumors. Due to their expression on the cell surface, they represent excellent molecular targets for radiolabeled neuropeptide analogues—their specific accumulation in receptor expressing tumors not only often allows high-contrast visualization of human malignancies, but also constitutes the basis for endoradiotherapeutic approaches. The somatostatin (sst) receptor system represents a prototype for successful peptide receptor targeting: the receptor, its function, and its expression pattern in normal and neoplastic tissues have been thoroughly investigated, and an increasing number of optimized receptor−ligands labeled with a variety of radionuclides are available for both diagnostic and therapeutic applications (*1–6*).

The success and increasing clinical impact of sst-targeting in nuclear oncology has prompted intensified research with respect to the identification of novel peptide receptors as potential candidates for in vivo tumor targeting (*7*, *8*), and novel and/or optimized radioligands are currently being developed for–among others–bombesin (*9*, *10*), cholecystokinin (*11*), and glucagon-like peptide-1 receptors (*12*), to mention only a few.

Another receptor, which represents an interesting novel target in this field, is the gonadotropin releasing hormone receptor (GnRHR), also known as luteinizing hormone releasing hormone receptor (LHRHR). Its two subtypes, GnRHR-I and GnRHR-II, have been shown to be strongly expressed on the majority

of tumors of the human reproductive system, either one subtype exclusively or both together: 80% of endometrial, 78% of ovarian, 52% of mammary, and 86% of prostate cancers are GnRHR-positive (*13, 14*). Expression of GnRHRs has also been demonstrated in human tumor specimens and cancer cell lines originating from liver (*15*), lanrynx (*16*), pancreas (*17*), kidney (*18*), brain (*19*), blood cells (*20, 21*), and skin (*22, 23*).

The GnRH receptor system has been studied intensely as a target for peptidic drugs during the past decade. A broad palette of agonistic and antagonistic analogues derived from the native decapeptide ligand GnRH-I is clinically used for effective suppression of the pituitary−gonadal axis and consequently of the growth of hormone-dependent cancers (*24*). However, based on the finding that GnRH analogues also exert direct antiproliferative effects on GnRHR-expressing tumor cells (*13, 24*), cytotoxic analogues such as the 2-pyrrolidino-doxorubicin-coupled D-Lys^6-GnRH-derivative AN-207 have been developed and show high therapeutic efficiency in animal models (*21, 25–27*).

Despite the clinical success of the pharmacological application of GnRH-derivatives (*28*), the GnRHR-system has not been exploited as a target for scintigraphic imaging using radiolabeled ligands yet. To date, only one ^{99m}Tc-labeled GnRH-analogue is known which has been specifically developed as a potential SPECT tracer (*29*). Unfortunately, the introduction of the radiometal via backbone cyclization of the peptide was accompanied by a dramatic loss of binding affinity, hampering the applicability of this analogue as an in vivo imaging agent.

This study was therefore conducted to address two major open questions: First, is the GnRH-receptor system a suitable target for in vivo receptor imaging? And second, which structural prerequisites have to be met for the development of high-affinity radiolabeled GnRH analogues?

To address the first question, several human cancer cell lines, i.e., the ovarian cancer cell lines EFO-27 and SKOV-3, the breast cancer cell lines MDA-MB 231 and SKBR-3, as well as the prostate cancer cell lines LNCaP and DU-145, all know to express either GnRHR-I and/or GnRHR-II (*30–34*), were screened for GnRHR-expression using the standard radioligands [^{125}I]Triptorelin (pGlu-His-Trp-Ser-[^{125}I]Tyr-D-Trp-Leu-Arg-Pro-Gly-NH_2) for GnRHR-I (expressed on EFO-27, MDA-MB 231, SKBR-3, and LNCaP cells) or [^{125}I]D-Lys6-GnRH-II (pGlu-His-Trp-Ser-His-D-Lys-Trp-[^{125}I]Tyr-Pro-Gly-NH_2) or GnRHR-II (expressed on SKOV-3 and DU-145 cells), and the extent of receptor-specific ligand binding was determined. Furthermore, the dependence of specific radioligand binding, reflecting the level of receptor expression, on the medium supplement, which had been previously documented for DU-145 cells (*35*), was investigated for all six cell lines. The cells were grown in parallel both with fetal calf serum (FCS) or with Nu-Serum as serum supplements. Nu-Serum is a semisynthetic serum supplement containing, among other components, EGF, ECGS, insulin, human transferrin, triiodothyronine, progesterone, estradiol-17β, and testosterone, thus mimicking much more closely the physiological tumor cell growth conditions than FCS.

In parallel, new radiolabeled GnRH analogues were developed. Previous studies had demonstrated that both the N- and the C-terminus of GnRH-ligands are responsible for receptor binding, and that their amino acid sequences are responsible for the agonistic or antagonistic profile of the peptide (*36, 37*). The development of a multitude of highly potent GnRH-I analogues further yielded important structure−activity relationships: first, introduction of a D-amino acid in position 6 leads to a substantial stabilization of the peptide toward degradation in vivo and an increased receptor affinity, and second, the amino acid in position 6 shows remarkable tolerance toward even bulky chemical modifications, both in GnRH agonists and antagonists (*37–39*).

Since agonism is an important prerequisite for ligand internalization, ideally leading to high intracellular tracer accumulation and enhanced tumor to nontumor ratios in vivo, the GnRH-I-agonist D-Lys^6-GnRH-I (pGlu-His-Trp-Ser-Tyr-D-Lys-Leu-Arg-Pro-Gly-NH_2) was chosen as a scaffold for radioligand development. To investigate the flexibility of the ligand with respect to the type of moiety attached to D-Lys^6, two different synthetic approaches toward GnRH-I-analogues labeled with positron emitters were chosen: (A) the macrocyclic chelator DOTA (1,4,7,10-tetraazacyclododecane-*N′*,*N″*,*N‴*,*N⁗*-tetraacetic acid) was directly attached for ^{68}Ga-labeling; and (B) the structure of the high-affinity cytotoxic analogue AN-207 ((*25*); Figure 1) was used as a lead structure for the development of ^{18}F-labeled GnRH-I-derivatives. To investigate the impact of spacer length between the peptide core and the hydrophobic moiety ([^{18}F]FBOA (4-[^{18}F]fluorobenzyloxim acetyl-) in the case of the ^{18}F-analogues), two different spacers, aminohexanoic acid (Ahx) and β-alanine (β-Ala), were coupled to D-Lys^6 and further functionalized with (Boc)aminooxyacetic acid for chemoselective ^{18}F-labeling via oxime formation with 4-[^{18}F]fluorobenzaldehyde (*40*) (Figure 1).

The new radiolabeled compounds were evaluated in vitro, both using cell membranes to determine receptor affinity and using GnRH-I-expressing EFO-27 cells to assess internalization efficiency. In addition, an exemplary in vitro serum stability study was performed for D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I.

Furthermore, a preliminary evaluation of the OVCAR-3 cell line as a transplantable xenograft model for in vivo GnRH-I-targeting was carried out using the reference ligand [^{125}I]Triptorelin.

MATERIALS AND METHODS

General Conditions. Most Fmoc (9-fluorenylmethoxycarbonyl-) amino acids, N-Boc-aminooxyacetic acid, and Rink amide resin (100−200 mesh) were purchased from Novabiochem (Merck Biosciences, Schwalbach, Germany). Boc-Pyr-OH (N-Boc-pyroglutamic acid) and Boc-β-Ala-OH were supplied by Bachem (Heidelberg, Germany). 6-Boc-Ahx-OSu was purchased from Fluka (Neu-Ulm, Germany). DOTA (1,4,7,10-tetraazacyclododecane-*N′*,*N″*,*N‴*,*N⁗*-tetraacetic acid) was obtained from Macrocyclics (Dallas, Texas, USA). Solvents and all other organic reagents and were purchased from Merck Eurolab (Darmstadt, Germany), Aldrich or Fluka (Neu-Ulm, Germany).

Solid-phase peptide synthesis was carried out manually using a flask shaker (St. John Associates Inc., USA).

Analytical RP-HPLC was performed on a Nucleosil 100 C18 (5 μm, 125 × 4.0 mm) column (CS Chromatographie Service, Langerwehe, Germany) using a Sykam gradient HPLC System (Sykam GmbH, Fürstenfeldbruck, Germany). The peptides were eluted applying different gradients of 0.1% (v/v) TFA (trifluoroacetic acid) in H_2O (solvent A) and 0.1% TFA (v/v) in acetonitrile (solvent B) at a constant flow of 1 mL/min (specific gradients are cited in the text). UV detection was performed at 220 nm using a 206 PHD UV−vis detector or an UVIS 200 photometer (Linear Instruments Corporation, Reno, NV).

Preparative RP-HPLC was performed on the same HPLC system using a YMC J'Sphere ODS-H80 (150 × 20 mm, S-4 μm, 8 nm) column (YMC Europe, Schermbeck, Germany) at a constant flow of 9 mL/min.

Both retention times t_R as well as the capacity factors K' are cited in the text. K' is calculated as follows:

$$K' = \frac{t_R - t_0}{t_0} \qquad t_R = \text{retention time}$$

$$t_0 = \frac{\text{dead volume of the column [mL]}}{\text{flow [mL} \times \text{min}^{-1}\text{]}}$$

Figure 1. Structures of some selected GnRHR-binding compounds and of the new radiolabeled GnRH-I analogues developed in this study. FBOA = fluorobenzyloxime acetyl, DOTA = 1,4,7,10-tetraazacyclododecane-*N′*,*N″*,*N‴*,*N⁗*-tetraacetic acid.

Mass spectra were recorded on the LC-MS system LCQ from Finnigan (Bremen, Germany) using the Hewlett-Packard series 1100 HPLC system.

Peptide Synthesis. *Triptorelin (D-Trp^6-GnRH-I).* Coupling of the first amino acid, Fmoc-Gly-OH, to the resin was performed as specified by the manufacturer. Briefly, the resin was allowed to preswell in NMP (*N*-methylpyrrolidon) for 30 min. Then, the *N*-terminal Fmoc-protecting group was cleaved off using 20% piperidine in DMF (dimethyl formamide). After thoroughly washing the resin with NMP, Fmoc-Gly-OH was coupled to the resin using HOBt (1-hydroxybenzotriazol) and TBTU (*O*-(1*H*-benzotriazol-1-yl)-*N*,*N*,*N′*,*N′*-tetramethyluronium-tetrafluoroborate) as coupling reagents and DIPEA (*N*-ethyl diisopropylamine) as a base. The subsequent assembly of the peptide sequence pGlu(Boc)-His(Trt)-Trp(Boc)-Ser(tBu)-Tyr(tBu)-D-Trp(Boc)-Leu-Arg(Pbf)-Pro- on the resin-bound amino acid was performed according to standard Fmoc-protocol. Cleavage from the resin was carried out using a mixture of 95% TFA, 2.5% water, and 2.5% triisobutylsilane (v/v/v). The fully deprotected crude peptide was precipitated using diethyl ether and dried. A small fraction of crude Triptorelin was then purified via preparative HPLC (22−37% B in 20 min). Triptorelin (40 mg) was obtained in a purity (220 nm) >98%. Triptorelin: HPLC (10 → 35% B in 20 min): t_R = 12.3 min; K' = 6.65. Calculated monoisotopic mass ($C_{64}H_{82}N_{18}O_{13}$): 1310.6. found: m/z = 1312.1 $[M+H]^+$, 1333.9 $[M+Na]^+$.

D-Lys^6-GnRH-I. D-Lys^6(Dde)-GnRH-I was synthesized via SPPS (solid phase peptide synthesis) in analogy to Triptorelin with the sole difference that Fmoc-D-Trp(Boc)-OH was replaced by Fmoc-D-Lys(Dde)-OH during SPPS. After cleavage from the resin, D-Lys^6(Dde)-GnRH-I was precipitated using diethyl ether, dried, and stored at −20 °C. For further derivatization, the Dde-protecting group in D-Lys^6(Dde)-GnRH-I was removed using 2% hydrazine hydrate (30%) in DMF. After 10 min, deprotected D-Lys^6-GnRH-I was precipitated using diethyl ether, washed with ether, and dried. The crude peptide was used for subsequent derivatizations without further purification. D-Lys^6-GnRH-I: HPLC (10 → 35% B in 20 min): t_R = 7.1 min; K' = 3.94. Calculated monoisotopic mass ($C_{59}H_{84}N_{18}O_{13}$): 1252.7. found: m/z = 1253.8 $[M+H]^+$, 1275.7 $[M+Na]^+$.

D-Lys^6-GnRH-II. The synthesis of D-Lys^6(Dde)-GnRH-II (pGlu-His-Trp-Ser-His-D-Lys-Trp-Tyr-Pro-Gly-NH_2) was carried out entirely in analogy to D-Lys^6(Dde)-GnRH-I. After Dde-deprotection, the crude peptide was purified via preparative RP-HPLC. D-Lys^6-GnRH-II: HPLC (15 → 45% B in 20 min): t_R = 9.0 min; K' = 4.86. Calculated monoisotopic mass ($C_{64}H_{78}N_{18}O_{13}$): 1306.6. found: m/z = 1307.9 $[M+H]^+$, 1330.0 $[M+Na]^+$.

D-Lys^6(DOTA)-GnRH-I. The macrocyclic chelator DOTA was coupled to the side chain of D-Lys^6 in D-Lys^6-GnRH-I according to a previously published protocol (*41*). Briefly, DOTA (2 equiv, 0.37 mmol) was preactivated with NHS (*N*-hydroxysuccinimide, 2.5 equiv), EDCI (1-ethyl-3-(3′-dimethylaminopropyl)-carbodiimide, 2.5 equiv) and DIPEA (5 equiv) in water for 30 min. Then, D-Lys^6-GnRH-I (1 equiv, 0.18 mmol) dissolved in DMF was slowly added under vigorous stirring. After 90 min, the solvents were evaporated in vacuo, the residue was resuspended in methanol, and the suspension was centrifuged. The super-

natant methanolic solution was concentrated in vacuo and added dropwise to an excess of diethyl ether. The precipitate (crude D-Lys^6(DOTA)-GnRH-I) was dried and subsequently purified using preparative HPLC (14−30% B in 20 min). D-Lys^6(DOTA)-GnRH-I (47 mg) was obtained in 16% yield and a purity (220 nm) of 97.6%. D-Lys^6(DOTA)-GnRH-I: HPLC (10 → 35% B in 20 min): $t_R = 10.9$ min; $K' = 5.19$. Calculated monoisotopic mass ($C_{75}H_{110}N_{22}O_{20}$): 1638.8. found: $m/z = 1640.0$ $[M+H]^+$, 821.1 $[(M+2H)/2]^{2+}$, 1662.0 $[M+Na]^+$, 1677.9 $[M+K]^+$.

D-Lys^6(Ahx-AOA(Boc))-GnRH-I. Coupling with Boc-Ahx-OH and Deprotection. Boc-Ahx-OSu (1.5 equiv, 0.52 mmol), HOBt (1.5 equiv, 0.52 mmol), and TBTU (1.5 equiv, 0.52 mmol) were dissolved in DMF; DIPEA (4 equiv, 2.08 mmol) was added, and the mixture was preactivated for 15 min. Then, this solution was added to a solution of D-Lys^6-GnRH-I (1 equiv, 0.35 mmol) in DMF. After 30 min of stirring at RT (room temperature), the crude product was precipitated using diethyl ether, washed, and dried (D-Lys^6(Ahx(Boc))-GnRH-I: HPLC (20 → 70% B in 15 min): $t_R = 10.3$ min; $K' = 4.35$). For Boc-deprotection, the dried residue was redissolved in a 1:1 mixture (v/v) of TFA and dichloromethane. Usually, deprotection was complete within 15 min. The deprotected peptide was then precipitated using diethyl ether, washed, and redissolved in water/MeOH for subsequent preparative HPLC purification (16−27% B in 20 min). D-Lys^6(Ahx)-GnRH-I: HPLC (20 → 70% B in 15 min): $t_R = 4.8$ min; $K' = 1.83$. Calculated monoisotopic mass ($C_{65}H_{95}N_{19}O_{14}$): 1365.6. found: $m/z = 1366.7$ $[M+H]^+$, 684.2 $[(M+2H)/2]^{2+}$, 1388.7 $[M+Na]^+$.

Coupling with N-(Boc)-Aminooxyacetic Acid. N-(Boc)-aminooxyacetic acid (AOA(Boc)) was coupled to D-Lys^6(Ahx)-GnRH-I under optimized coupling conditions (*42*). Briefly, AOA(Boc) (1.2 equiv, 0.030 mmol) was preactivated for 15 min with HOAt (1-hydroxy-7-azabenzotriazole, 1.2 equiv, 0.030 mmol), DIC (diisopropylcarbodiimide, 1.2 equiv, 0.030 mmol), and pyridine (2 equiv, 0.052 mmol) in DMF. This solution was added to a solution of D-Lys^6(Ahx)-GnRH-I (1 equiv, 0.026 mmol) in DMF. After stirring at RT for 35 min, the product peptide was precipitated using diethyl ether, washed, and isolated using preparative HPLC purification (24−52% B in 20 min). D-Lys^6(Ahx-AOA(Boc))-GnRH-I was obtained in 50% yield and a purity > 90%. D-Lys^6(Ahx-AOA(Boc))-GnRH-I: HPLC (20 → 70% B in 15 min): $t_R = 9.2$ min; $K' = 4.21$. Calculated monoisotopic mass ($C_{72}H_{106}N_{20}O_{18}$): 1538.5. found: $m/z = 1539.6$ $[M+H]^+$, 1439.7 $[M\text{-Boc}+H]^+$.

D-Lys^6(β-Ala-AOA(Boc))-GnRH-I. Coupling with Boc-β-Ala-OH and Deprotection. Coupling of Boc-β-Ala-OH to D-Lys^6-GnRH-I as well as subsequent Boc-deprotection were performed in analogy to the Ahx-analogue. After preparative HPLC purification (16−23% B in 20 min), D-Lys^6(β-Ala)-GnRH-I was obtained in 21% yield. D-Lys^6(β-Ala)-GnRH-I: HPLC (20 → 70% B in 15 min): $t_R = 2.8$ min; $K' = 0.58$. Calculated monoisotopic mass ($C_{62}H_{89}N_{19}O_{14}$): 1323.7. found: $m/z = 1324.8$ $[M+H]^+$, 1346.7 $[M+Na]^+$.

Coupling with N-(Boc)-Aminooxyacetic Acid. N-(Boc)-aminooxyacetic acid (AOA(Boc)) was coupled to D-Lys^6(β-Ala)-GnRH-I as described for the Ahx-derivative. After preparative HPLC purification (22−46% B in 20 min), D-Lys^6(β-Ala-AOA(Boc))-GnRH-I was obtained in 49% yield and a purity > 90%. D-Lys^6(β-Ala-AOA(Boc))-GnRH-I: HPLC (20 → 70% B in 15 min): $t_R = 8.5$ min; $K' = 3.73$. Calculated monoisotopic mass ($C_{69}H_{100}N_{20}O_{18}$): 1496.5. found: $m/z = 1497.6$ $[M+H]^+$, 1397.7 $[M\text{-Boc}+H]^+$.

Synthesis of the Reference Compounds. *D-Lys^6(Ga-DOTA)-GnRH-I.* D-Lys^6(DOTA)-GnRH-I was dissolved in 0.1 N NaOAc (pH = 4.5), and an equimolar amount of $GaNO_3$ was added. After heating to 90 °C for 30 min, the reaction mixture was cooled to RT, and D-Lys^6(Ga-DOTA)-GnRH-I was immediately purified using preparative HPLC (14−30% B in 20 min). The peptide was obtained in 97% purity (220 nm). D-Lys^6(Ga-DOTA)-GnRH-I: HPLC (10 → 35% B in 20 min): $t_R = 7.6$ min; $K' = 3.61$. Calculated monoisotopic mass ($C_{75}H_{108}N_{22}O_{20}Ga$): 1705.7. found: $m/z = 1705.9$ $[M]^+$, 854.0 $[(M+H)/2]^{2+}$, 570.2 $[(M+2H)/3]^{3+}$.

D-Lys^6(Ahx-FBOA)-GnRH-I and D-Lys^6(β-Ala-FBOA)-GnRH-I. Immediately prior to the reaction with 4-fluorobenzaldehyde, D-Lys^6(Ahx-AOA(Boc))GnRH-I and D-Lys^6(β-Ala-AOA(Boc))-GnRH-I were deprotected using a 1:1 mixture (v/v) of TFA and dichloromethane. After 15 min, the deprotected peptides were precipitated using diethyl ether, washed, and redissolved in water/MeOH. Then, an equimolar amount of 4-fluorobenzaldehyde was added. After 30 min at 60 °C, the respective coupling product was purified using RP-HPLC (D-Lys^6(Ahx-FBOA)GnRH-I: 20−66% B in 20 min, D-Lys^6(β-Ala-FBOA)-GnRH-I: 22−60% B in 20 min). The purity (220 nm) of both the Ahx- and β-Ala-reference compound was >98%. D-Lys^6(Ahx-FBOA)GnRH-I: HPLC (20 → 70% B in 15 min): $t_R = 10.3$ min; $K' = 4.84$. Calculated monoisotopic mass for D-Lys^6(Ahx-FBOA)GnRH-I ($C_{74}H_{101}N_{20}O_{16}F$): 1544.5. found: $m/z = 1545.9$ $[M+H]^+$, 773.9 $[(M+2H)/2]^{2+}$, 1567.7 $[M+Na]^+$. D-Lys^6(β-Ala-FBOA)GnRH-I: HPLC (20 → 70% B in 15 min): $t_R = 9.6$ min; $K' = 4.55$. Calculated monoisotopic mass for D-Lys^6(β-Ala-FBOA)GnRH-I ($C_{71}H_{95}N_{20}O_{16}F$): 1502.5. found: $m/z = 1503.8$ $[M+H]^+$, 752.8 $[(M+2H)/2]^{2+}$, 1525.5 $[M+Na]^+$.

Radiolabeling. *Instrumentation.* Radio-HPLC was performed on a Nucleosil 100 C18 (5 μm, 125 × 4.0 mm) column using a Sykam gradient system (Sykam GmbH, Fürstenfeldbruck, Germany) and an UVIS 200 photometer (Linear Instruments Corporation, Reno, NV). For radioactivity measurement, the outlet of the UV-photometer was connected to a Na(Tl) well-type scintillation counter Ace Mate 925-Scint (EG&G Ortec, München, Germany).

[^{125}I]Triptorelin and D-Lys^6-[^{125}I]GnRH-II. Iodogen Method. A solution of approx 200 μg of peptide in 200 μL of TRIS-HCl buffer (25 mM, 0.4 M NaCl, pH 7.5) was transferred to an Eppendorf tube coated with 50 μg of Iodogen (Pierce, Rockford, USA). After the addition of 5−20 μL (18.5−74 MBq) of n.c.a. [^{125}I]NaI in 0.05 M NaOH (Hartmann Analytic, Brauschweig, Germany), the cap was vortexed, and the labeling reaction was allowed to proceed for 15 min at RT. The peptide solution was then removed from the insoluble oxidizing agent, and the radiolabeled peptide was separated from unreacted precursor via RP-HPLC using an isocratic solvent mixture of 24% (D-Lys^6-[^{125}I]GnRH-II) or 32% ([^{125}I]Triptorelin) EtOH (0.5% AcOH) in water (0.5% AcOH). Radiochemical yields after purification ranged from 35% to 65%.

Chloramine T Method. Triptorelin (100 μg) was dissolved in 100 μL of TRIS-HCl buffer (25 mM, 0.4 M NaCl, pH 7.5). After addition of 10 μL (37 MBq) of n.c.a. [^{125}I]NaI in 0.05 M NaOH and 50 μL of a Chloramine T solution (1 mg/mL), the labeling reaction was allowed to proceed for 15 min at RT. Then, 10 μL of a $Na_2S_2O_5$ solution (1 mg/mL) and 120 μL of TRIS-HCl buffer were added, and [^{125}I]Triptorelin was purified via RP-HPLC as described above. Radiochemical yields after purification ranged from 79% to 87%.

For use in the in vitro experiments, the HPLC eluate was evaporated to dryness, and [^{125}I]Triptorelin was redissolved in RPMI-1640 medium containing 5% BSA (activity concentration of approx 100 000 cpm/10 μL). [^{125}I]Triptorelin: 32% EtOH isocratic: t_R (range) = 6.6−8.5 min; K' (range) = 3.77−4.83. [^{125}I]D-Lys^6-GnRH-II: 24% EtOH isocratic: t_R (range) = 7.7−9.5 min; K' (range) = 4.13−5.33.

D-Lys^6([^{68}Ga]DOTA)-GnRH-I. $^{68}GaCl_3$ was eluted with 0.1 N HCl from an in-house OBNINSK ^{68}Ge/^{68}Ga-generator (1.48 GBq; Chemotrade Chemiehandelsgesellschaft mbH, Leipzig,

Germany). To 1.3 mL of the generator eluate were added 150 μL of HEPES (2.5 M) and 7 μg (4.25 nmol) of D-Lys^6(DOTA)-GnRH-I in 7 μL of water, and the reaction mixture was heated to 95 °C for 20 min. After cooling to RT, the reaction mixture was diluted with 2 mL of water, and D-Lys^6([^{68}Ga]DOTA)-GnRH-I was immobilized on a Sep-Pak Plus C-18 cartridge (Waters, Eschborn, Germany), washed with 10 mL of water, and eluted with 2 mL of ethanol. The solvent was then evaporated in vacuo and the product was redissolved in RPMI-1640 medium (Biochrom, Berlin, Germany) containing 5% BSA (bovine serum albumin) and diluted to an activity concentration of approx 500 000 cpm/10 μL for use in internalization studies. Quality control was performed using a standard TLC system.

D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I and D-Lys^6(β-Ala-[^{18}F]-FBOA)-GnRH-I. The synthesis of 4-[^{18}F]fluorobenzaldehyde from 4-formyl-*N*,*N*,*N*-trimethylanilinium triflate was performed as described previously (*40*). For peptide labeling, 10 μL of a 10 mM solution of D-Lys^6(Ahx/β-Ala-AOA(Boc))-GnRH-I in water was added to 20−40 μL of a freshly prepared methanolic 4-[^{18}F]fluorobenzaldehyde solution. Then, 1 μL of TFA was added. After 15 min at 75 °C and product isolation via RP-HPLC (15−50% B in 20 min, analytical column), both [^{18}F]FBOA-GnRH-I-analogues were obtained in radiochemical yields of 74−85% (based on 4-[^{18}F]fluorobenzaldehyde) and an overall synthesis time of approx 60 min. For use in in vitro studies, the HPLC eluate was evaporated to dryness, and the [^{18}F]FBOA-peptides were redissolved in RPMI-1640 medium containing 5% BSA (activity concentration of approx 250 000 cpm/10 μL). D-Lys^6(Ahx-[^{18}F]FBOA)GnRH-I: HPLC (15 → 50% B in 20 min): t_R = 16.7 min; K' = 9.14. D-Lys^6(β-Ala-[^{18}F]FBOA)GnRH-I: HPLC (15 → 50% B in 20 min): t_R = 15.2 min; K' = 8.77.

Lipophilicity. To a solution of approx 2 kBq of radiolabeled peptide in 500 μL of PBS (pH 7.4), 500 μL of octanol were added (n = 6). Vials were vortexed vigorously for 3 min. To achieve quantitative phase separation, the vials were centrifuged at 14 600 × g for 6 min in a Biofuge 15 (Heraeus Sepatech, Osterode, Germany). The activity concentrations in 100 μL samples of both the aequous and organic phases were measured in a γ-counter. Both the partition coefficient P_{ow}, which is defined as the molar concentration ratio of a single species A between octanol and water at equilibrium and log P_{ow}, which is an important parameter used to characterize lipophilicity of a compound (*43*), were calculated.

Cell Culture. The ovarian cancer cell line EFO-27 was purchased from DSMZ (Braunschweig, Germany). OVCAR-3 ovarian cancer cells were a kind gift from Dr. A. Krüger, Institute of experimental oncology, Klinikum rechts der Isar, TU München, Germany. The prostate cancer cell lines DU-145 and LNCaP as well as the breast cancer cell lines MDA-MB 231 and SKBR-3 were kindly supplied by the group of Prof. R. Senekowitsch-Schmidtke, Department of Nuclear Medicine, Klinikum rechts der Isar, TU München, Germany. All cell lines except SKBR-3 were grown in RPMI-1640 medium supplemented with either 10% FCS (fetal celf serum; Biochrom, Berlin, Germany) or 10% Nu-Serum (BD Bioscience, Heidelberg, Germany). SKBR-3 cells were grown in Gibco DMEM/Nutrition Mix F-12 with Glutamax-I (1:1) (invitrogen, Karlsruhe, Germany) supplemented with the same two sera mentioned above. Cultures were maintained at 37 °C in a 5% CO_2/humidified air atmosphere. For cell counting, a CASY1-TT cell counter and analyzer system (Schärfe System GmbH, Reutlingen, Germany) was used.

Determination of the Serum Dependence of [^{125}I]Triptorelin Binding. One day prior to the experiment, cells that had been grown in medium containing either FCS or Nu-Serum were harvested using Trypsin/EDTA (0.05% and 0.02%) in PBS, centrifuged, resuspended with culture medium, transferred into 24-well plates (1 mL/well), and placed in the incubator overnight.

On the day of the experiment (cell count: 160 000−220 000 cells/well), the culture medium was removed and the cells were washed once with 250 μL of medium (unsupplemented RPMI-1640) before being left to equilibrate in 190 μL of medium at 37 °C for a minimum of 15 min before the experiment. Then, 50 μL per well of medium containing 5% BSA (n = 3, control experiment, nca conditions) or of a 25 μM solution of Triptorelin in the same medium (n = 3, determination of nonspecific binding) were added. This was followed by the addition of ∼100 000 cpm [^{125}I]Triptorelin in 10 μL of medium (5% BSA). The cells were then incubated for 60 and 120 min, respectively, at 37 °C in a 5% CO_2/humidified air atmosphere. Incubation was terminated by removal of the incubation medium. Cells were thoroughly rinsed with 250 μL of fresh medium. The wash medium was combined with the supernatant of the previous step. This fraction represents the amount of free radioligand. To determine the amount of bound radioligand, cells were lysed by the addition of 300 μL of 1 N NaOH, transferred to vials, and combined with 250 μL of PBS used for rinsing the wells. Quantification of the amount of free and bound activity was performed in a γ-counter (Wallach, Turku, Finland).

Internalization Studies. In general, the internalization experiments were performed in strict analogy to the experiments described above. However, because all internalization experiments were performed as dual tracer experiments, cells were not only incubated with the reference [^{125}I]Triptorelin, but with a mixture of radioligands, i.e., of ∼100 000 cpm [^{125}I]Triptorelin and either ∼250 000 cpm of the respective [^{18}F]FBOA-GnRH-I-analogue or ∼500 000 cpm D-Lys^6([^{68}Ga]DOTA)-GnRH-I. After the addition of the radioligands, the cells were incubated for 10, 30, 60, and 120 min at 37 °C. After removal of the incubation medium and washing with medium, an additional acid wash step was performed to remove surface-bound (acid-releasable) radioactivity. Cells were incubated with 250 μL of ice cold acid wash buffer (0.02 M NaOAc buffered with AcOH to pH = 5), and after removal of the acid wash buffer, the cells were thoroughly rinsed with another 250 μL of ice cold acid wash buffer. Both acid wash fractions were combined. The internalized activity was released by incubation with 250 μL of 1 N NaOH as described above. Quantification of the amount of free, acid-releasable, and internalized activity was performed in a γ-counter.

Determination of IC_{50} Using Cell Membranes. Cell membrane preparations of cells expressing the human GnRHR were obtained from Chemicon International (Hampshire, UK). Assembly of the competition binding curves was performed in close analogy to the manufacturer's protocol. Briefly, solutions of unlabeled competitor (Triptorelin, D-Lys^6(Ga-DOTA)-GnRH-I, D-Lys^6(Ahx-FBOA)-GnRH-I, and D-Lys^6(β-Ala-FBOA)-GnRH-I; 20 μL, concentration range from $1\cdot10^{-11}$ to $1\cdot10^{-5}$ M, n = 3, per concentration and peptide) in binding buffer (50 mM HEPES, 5 mM $MgCl_2$, 1 mM $CaCl_2$, 0.2% BSA, buffered to pH 7.4 using 1 N NaOH) were pipetted into a 96-well plate. To each well, 20 μL of [^{125}I]Triptorelin in binding buffer (approx 100 000 cpm) was added. Then, 10 μg of cell membrane in 60 μL of binding buffer was added and incubated for 90 min at RT. The final radioligand concentration in the incubation mixture was 0.42 nM. Membranes were then aspired onto a glass fiber filtermat (Printed Filtermat B, Wallach, Turku, Finland), which had been preconditioned with 0.33% polyethylenimine for 30 min and then washed five times with 200 μL (per well) of wash buffer (50 mM HEPES, 500 mM NaCl, 0.1% BSA, buffered to pH 7.4 using 1 N NaOH), using a Mach II M Harvester 96 (Tomtec CE, Etten-Leur, The Netherlands).

Membranes were washed 15 times with 100 μL (per well) of wash buffer. The filtermat was then cut into squares containing the membrane from the respective wells, and membrane bound activity was counted in a γ-counter.

Serum Stability. To four 500 μL samples of freshly prepared human serum was added 50 μL of a solution containing 4.6 MBq of D-Lys^6(Ahx-[^{18}F]FBOA)GnRH-I in PBS (pH = 7.5). The mixtures were incubated in a 5% CO_2 environment at 37 °C. After 10, 30, 60, and 120 min, respectively, the samples were removed from the incubator and diluted with 10 mL of water. The solution was applied to a Sep-Pak Plus C-18 cartridge, and the eluate was collected (fraction I). Then, the cartridge was washed with 10 mL of water. The eluate was again collected (fraction II). After drying with 10 mL of air, the cartridge was eluted with 2 mL of 70% EtOH containing 1% (v/v) 0.1 N HCl (fraction III). The radioactivity in all eluates (fractions I−III) as well as the activity remaining bound to the cartridge material were counted in a Capintec. The activity collected in the EtOH-eluate was further analyzed via analytical RP-HPLC (5 → 90% B in 20 min).

Biodistribution Study. To establish tumor growth, OVCAR-3 cells were detached from the surface of the culture flasks using 1 mM EDTA in PBS, centrifuged, and resuspended in serum-free culture medium. Concentration of the cell suspension was $5 \cdot 10^6$ cells/100 μL medium. Nude mice (Swiss nu/nu, female, 6−8 weeks; Charles River, Sulzfeld, Germany) were injected with 100 μL of the cell suspension subcutaneously into the flank. Six weeks after tumor transplantation, all mice showed solid palpable tumor masses (tumor weight 0.15−0.8 g) and were used for the experiments.

For biodistribution studies, mice ($n = 3$) were intravenously injected with 0.37 MBq [^{125}I]Triptorelin in 100 μL PBS into the tail vein. To determine nonspecific tracer accumulation, 25 μg of unlabeled Triptorelin was coinjected ($n = 3$). At 60 min after radioligand injection, mice were sacrificed and dissected. The organs of interest were removed, weighed, and counted in a γ-counter (Wallach, Turku, Finland). Data are expressed as percent injected dose per gram tissue (%iD/g).

RESULTS

Peptide Synthesis. Triptorelin (pGlu-His-Trp-Ser-Tyr-D-Trp-Leu-Arg-Pro-Gly-NH_2), D-Lys^6-GnRH-I (pGlu-His-Trp-Ser-Tyr-D-Lys-Leu-Arg-Pro-Gly-NH_2) as well as D-Lys^6-GnRH-II (pGlu-His-Trp-Ser-His-D-Lys-Trp-Tyr-Pro-Gly-NH_2) were assembled on Rink Amide resin via a standard Fmoc-protocol. Cleavage from the resin was carried out using 95% trifluoroacetic acid (TFA), leading to concomitant side chain deprotection. Triptorelin and D-Lys^6-GnRH-II were then purified via preparative HPLC and were obtained in purities > 98% (220 nm).

D-Lys^6-GnRH-I was further derivatized on the Lys^6-side chain, either by direct coupling with unprotected DOTA (*41*) to yield D-Lys^6(DOTA)-GnRH-I or by coupling with different spacers (aminohexanoic acid (Ahx) or β-Ala), deprotection, and subsequent coupling with (Boc)aminooxyacetic acid ((Boc)Aoa) (Figure 1).

After workup and product isolation via preparative HPLC, D-Lys^6(DOTA)-GnRH-I was obtained in 16% yield. Due to impurities in the starting peptide and resulting formation of side products, necessitating an intermediate HPLC purification step, yields of D-Lys^6((Boc)Ahx)- and D-Lys^6((Boc)β-Ala)GnRH-I were also comparably low (approx 20%). The respective (Boc)Aoa-derivatives, however, were obtained in 50% yield after preparative HPLC isolation. Purities of these compounds were somewhat lower than for the other peptides synthesized in this study (90 vs >98%), which is occasioned by unavoidable cleavage of the Boc-protecting group from the Aoa-functionality during solvent evaporation after preparative HPLC, the 10% impurity consisting of the respective Ahx-Aoa- and β-Ala-Aoa-peptides. However, since the Aoa-deprotected peptides are the reactive species during ^{18}F-labeling and are in any case generated in situ during the labeling reaction, no attempt was made to further purify the seemingly impure D-Lys^6(Ahx-(Boc)Aoa)- and D-Lys^6(β-Ala-(Boc)Aoa)GnRH-I preparations, and they were used as such for the labeling reaction.

Radiolabeling. Radioiodination of Triptorelin and D-Lys^6-GnRH-II was initially carried out using the Iodogen method. However, under these conditions, radiochemical yields were comparably low (35−65% after HPLC purification) due to the formation of radiolabeled side products, and an optimized protocol based on a method described in the literature (*44*) was developed. Using chloramine T as an oxidant, the incorporation of radioiodide into the peptide was improved, and the formation of radioiodinated side products was successfully suppressed, leading to radiochemical yields of [^{125}I[Triptorelin of 82−89% after HPLC isolation. Because unreacted precursor was completely separated from both radioiodinated peptides, respectively, via HPLC, the specific activity of the radioiodinated compounds was assumed to be that of the radioiodide used for their preparation, i.e., 74 TBq/mmol.

^{18}F-labeling via oxime formation with 4-[^{18}F]fluorobenzaldehyde was performed in analogy to a previously published method (*40*), but with one major modification. Instead of first preparing and purifying the deprotected aminooxy-functionalized peptides and then using them for the labeling reaction, they were generated in situ from the protected (Boc)Aoa-precursors in the acidic (pH = 2) reaction milieu at 75 °C. Compared to the original labeling protocol, this necessitated a higher peptide concentration in the reaction mixture (2.5 vs 0.5 mM), since Boc-deprotection was not quantitative under the reaction conditions. However, D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I and D-Lys^6(β-Ala-[^{18}F]FBOA)-GnRH-I were obtained in high yields (74−85% based on 4-[^{18}F]fluorobenzaldehyde) and high radiochemical purities (>99%) in an overall synthesis time of approx. 60 min (including RP-HPLC purification). Identity of the [^{18}F]FBOA-peptides was confirmed via coinjection with the ^{19}F-reference compounds (Figure 2). The variance in peak symmetry between the UV and the radiochromatogram, i.e., tailing of the activity peak, is due to suboptimal lead shielding of the detector.

^{68}Ga-labeling of D-Lys^6(DOTA)-GnRH-I was carried out according to a standard radiometalation strategy. After purification via a RP-18 cartridge, D-Lys^6([^{68}Ga]DOTA)-GnRH-I was obtained in 94% radiochemical yield and >99% radiochemical purity and a specific activity of 18.1 TBq/mmol.

Lipophilicity. For all radiolabeled peptides, the partition coefficient *P* between *n*-octanol and PBS (0.01 M, pH 7.4) and log *P* as a standard quantity to describe ligand lipophilicity (*43*) were determined. Lipophilicities of [^{125}I]Triptorelin and D-Lys^6-(Ahx-[^{18}F]FBOA)-GnRH-I were similar ([^{125}I]Triptorelin: log $P = -0.247 \pm 0.016$, D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I: log $P = -0.395 \pm 0.016$), whereas it was lower in the case of D-Lys^6(β-Ala-[^{18}F]FBOA)-analogue due to the reduced length of the aliphatic chain compared to its Ahx-counterpart (log $P = -0.686 \pm 0.060$). With a log *P* of -3.703 ± 0.019, D-Lys^6([^{68}Ga]DOTA)-GnRH-I was the most hydrophilic of the compounds investigated.

In Vitro Studies. *Serum Dependence of [^{125}I]Triptorelin/D-Lys^6-[^{125}I]GnRH-II Binding.* All cell lines investigated (EFO-27, SKOV-3, LNCaP, DU-145, MDA-MB 231, SKBR-3) were cultured in parallel with different medium supplements, i.e., fetal calf serum (FCS) and Nu-Serum, a semisynthetic serum supplement. To evaluate the influence of culture conditions on GnRHR-expression, cells, that had been grown in the presence of the different serum supplements, were incubated with the

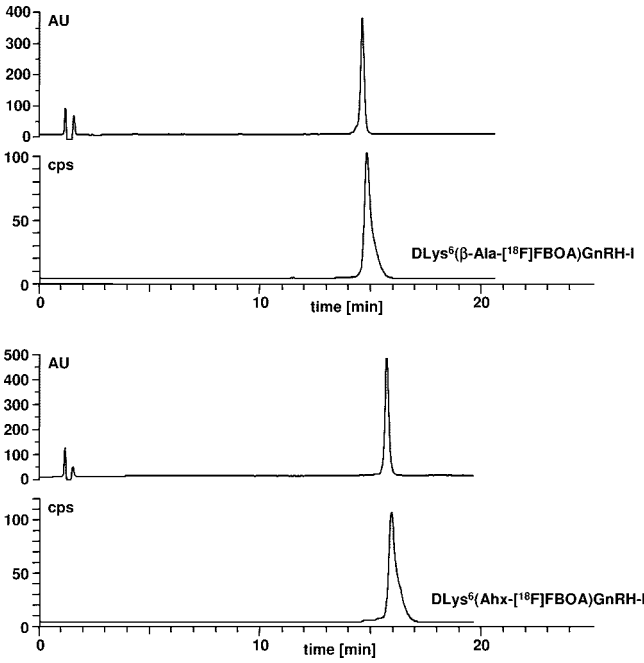

Figure 2. Analytical chromatograms of the coinjection of D-Lys^6(β-Ala-[^{18}F]FBOA)-GnRH-I (upper panel) and D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I (lower panel) with their respective ^{19}F-analogues, i.e., D-Lys^6(β-Ala-FBOA)-GnRH-I and D-Lys^6(Ahx-FBOA)-GnRH-I. RP-HPLC was performed using a Nucleosil 100 C18 column and a gradient of 15 → 50% B in 20 min (A = 0.1% TFA, B = 0.1% TFA in acetonitrile).

respective standard radioligand for 60 and 120 min, and total as well as nonspecific radioligand uptake in the presence of an excess of cold competitor (5 μM) at the respective time point were determined. For EFO-27, LNCaP, MDA-MB 231, and SKBR-3 cells, which express the GnRH-I-receptor (*14*, *30*, *31*, *33*, *34*), [^{125}I]Triptorelin was used as the radioligand. The cell lines SKOV-3 and DU-145 have been shown to express the putative GnRH-II-receptor (*30, 32*), and thus the GnRH-II analogue D-Lys^6-[^{125}I]GnRH-II, was used as the radioligand to evaluate whether potential effects of the serum supplement on receptor expression could also be observed in the case of the receptor type II.

Data obtained for the cells grown with Nu-Serum and FCS are shown in Figure 3. Generally, cellular uptake of [^{125}I]Triptorelin or D-Lys^6-[^{125}I]GnRH-II was low (≤3.5% of total activity), and the extent of nonspecific binding was high (55−80% of total binding). This is reflected by the low percentage of specific ligand binding (in % of total binding) shown in Figure 3. However, substitution of FCS in the culture medium by Nu-Serum increased the fraction of specifically bound ligand in all cell lines and independently of the receptor subtype, indicating stronger GnRHR expression under these culture conditions. The observed increase in specific binding was highest (increase by a factor of ∼2) in EFO-27, LNCaP, and MDA-MB 231 cells. Of the cell lines investigated, EFO-27 cells showed the highest absolute radioligand uptake (3.01 ± 0.19% and 3.11 ± 0.18% of the applied activity after 60 and 120 min, respectively; LNCaP, 2.49 ± 0.15% and 2.55 ± 0.18%; MDA-MB, 1.53 ± 0.07% and 2.15 ± 0.18%), and thus EFO-27 cells cultured with Nu-Serum were chosen as the in vitro model for the evaluation of the new radioligands developed in this study.

Internalization Studies. Since high cellular uptake of radiolabeled peptide agonists greatly enhances the tumor to background ratio in peptide receptor imaging, the new ^{68}Ga- and ^{18}F-labeled GnRH-I analogues were also evaluated with respect to their internalization into EFO-27 cells. All studies were

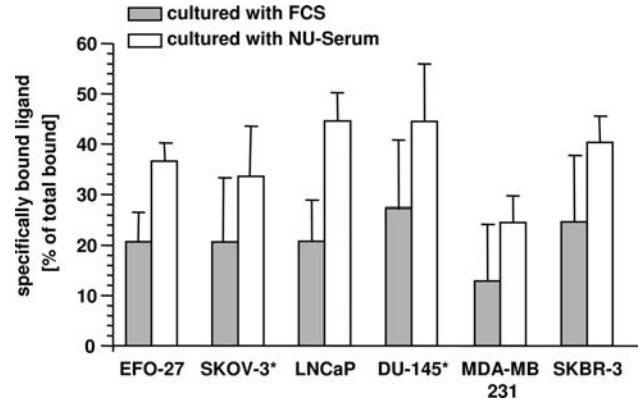

Figure 3. Dependence of radioligand uptake into different human GnRHR-positive cell lines on the serum supplement. Cells were grown using either fetal calf serum (FCS) or semisynthetic Nu-Serum for several weeks. They were then transferred into 24-well plates and incubated for 60 min with either the GnRHR-I ligand [^{125}I]Triptorelin or the GnRHR-II ligand [^{125}I]D-Lys^6-GnRH-II (GnRHR-II expressing cells are labeled with an asterisk (*)). Data are means of triplicate experiments (n = 3) and are given as specifically bound radioligand (= total − nonspecifically bound) in % of total binding. Nonspecific binding was determined in the presence of an excess (5 μM) of cold ligand.

performed in triplicate as dual tracer experiments with the respective ^{68}Ga- and ^{18}F-labeled peptides and [^{125}I]Triptorelin as an internal reference. This experimental setup assures comparability of the data obtained for the ^{68}Ga- and ^{18}F-labeled peptides, because the differences in specific activity between the radiometallated (c.a.) and radiofluorinated (n.c.a.) peptides are significant and may lead to large variations in cellular ligand uptake. However, uptake data for [^{125}I]Triptorelin in all experiments showed that the internalization of the reference peptide is unchanged by the different final peptide concentrations in the assay wells (1.8 nM for D-Lys^6([^{68}Ga]DOTA)-GnRH-I, subnanomolar for the ^{18}F-labeled peptides). Furthermore, performing the internalization studies as dual tracer experiments also allows elimination of systematic errors due to variable cell count or cell viability.

In the case of slowly internalizing receptors such as GnRHR (*45, 46*), it is of particular importance to be able to discriminate between internalized and receptor-bound radioligand. Thus, an acid wash was performed after the incubation step to release receptor-bound radioligand before lysis of the cells. Then, both acid-releasable (receptor-bound) and internalized activity were quantified.

Of the new compounds investigated, D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I showed the highest internalization into EFO-27 cells. However, its cellular uptake was slightly lower than that of the reference [^{125}I]Triptorelin (85.8 ± 16.0% and 84.9 ± 5.6% of the internalization found for [^{125}I]Triptorelin in the same experiment at 60 and 120 min, respectively) (Table 1). The D-Lys^6(β-Ala-[^{18}F]FBOA)-analogue, however, showed less than half of the internalization found for [^{125}I]Triptorelin, and for D-Lys^6([^{68}Ga]DOTA)-GnRH-I almost no internalization was detected.

As already observed in the initial uptake studies (serum depencence of GnRHR-I expression), nonspecific receptor binding and internalization in the presence of an excess of unlabeled Triptorelin (5 μM) was high. For the two ^{18}F-labeled analogues, only approx 10% of the acid-releasable activity was specifically bound to the cell membrane at 60 min ([^{125}I]Triptorelin: 17%), and only 20−30% ([^{125}I]Triptorelin: 37%) of the internalized activity was found to be taken up specifically. In the case of D-Lys^6([^{68}Ga]DOTA)-GnRH-I, no specific receptor binding or internalization was observed.

Table 1. Internalization of the Different Radiolabeled GnRH-I-Analogues into GnRHR-Expressing EFO-27 Ovary Carcinoma Cells[a]

peptide	internalization [% of [^{125}I]Triptorelin]
[^{125}I]Triptorelin	100
D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I	86 ± 16
D-Lys^6(β-Ala-[^{18}F]FBOA)-GnRH-I	42 ± 3
D-Lys^6([^{68}Ga]DOTA)-GnRH-I	2.6 ± 1.0

[a] Cells were coincubated with both the ^{18}F- or ^{68}Ga-labeled compound and the reference [^{125}I]Triptorelin for 60 min at 37° C (n = 3). Data are given in % of the internalization of the reference [^{125}I]Triptorelin in the same experiment and are means ± SD (triplicate determination).

Table 2. Binding Affinities of the Reference Triptorelin and the Three New GnRH-I-Analogues to the Human GnRHR[a]

peptide	IC_{50} [nM]
Triptorelin	0.13 ± 0.01
D-Lys^6(Ahx-FBOA)-GnRH-I	0.50 ± 0.08
D-Lys^6(β-Ala-FBOA)-GnRH-I	0.86 ± 0.13
D-Lys^6(Ga-DOTA)-GnRH-I	13.27 ± 1.01

[a] Competitive binding studies were performed using a membrane preparation of GnRHR-expressing cells (10 μg membrane/sample) with [^{125}I]Triptorelin as the radioligand (n = 3 for each peptide concentration). Experiments were carried out in triplicate. Data are means ± SD.

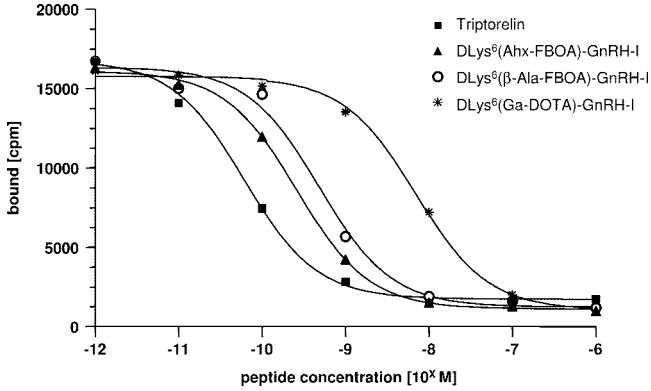

Figure 4. Exemplary IC_{50}-curves obtained for the different new GnRH-I analogues and the reference Triptorelin using GnRHR-membrane preparations (10 μg/well, n = 3; error bars are omitted for better clarity) and [^{125}I]Triptorelin as the radioligand. Data represent one of three separate determinations.

The internalization data for D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I were also confirmed in the ovarian cancer cell line OVCAR-3, which in contrast to the EFO-27 cell line is a well-established tumor model and was chosen as a model for the potential future in vivo evaluation of the new GnRH-I analogues. In OVCAR-3 cells, D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I showed 85.3 ± 15.8% and 89.1 ± 15.0% of the internalization of [^{125}I]Triptorelin at 60 and 120 min, respectively. In OVCAR-3 cells, however, the fraction of nonspecifically bound/internalized ligand (approx 90% in both cases) is even higher than in EFO-27 cells.

Determination of IC_{50}. The GnRH-receptor affinities of Triptorelin, D-Lys^6(Ahx-FBOA)-GnRH-I, D-Lys^6(β-Ala-FBOA)-GnRH-I, and D-Lys^6(Ga-DOTA)-GnRH-I were determined using a commercially available membrane preparation of GnRHR-I-expressing cells and [^{125}I]Triptorelin as the radioligand. Results are summarized in Table 2. While the Ga-DOTA-analogue shows a loss of binding affinity by a factor of ~100 compared to the reference Triptorelin, both FBOA-analogues display only slightly reduced receptor affinities, which are still in the subnanomolar range (Figure 4). The order of affinities, however, reflects the trend already observed for the internalization efficiencies of the respective GnRHR-ligands, i.e., Triptorelin > D-Lys^6(Ahx-FBOA)-GnRH-I > D-Lys^6(β-Ala-FBOA)-GnRH-I ≫ D-Lys^6(Ga-DOTA)-GnRH-I.

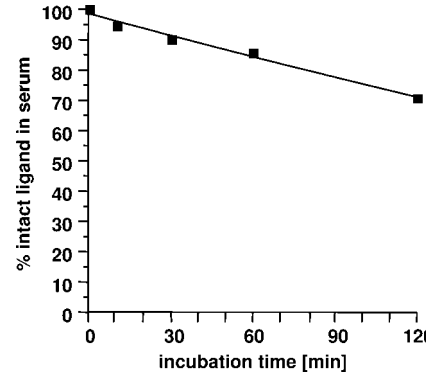

Figure 5. Stability of D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I in human serum. Data represent the amount of intact tracer found in serum after incubation at 37 °C for 30 to 240 min. A one-phase exponential fit yielded a calculated serum half-life of 254 ± 18 min for D-Lys^6-(Ahx-[^{18}F]FBOA)-GnRH-I.

Table 3. Biodistribution of [^{125}I]Triptorelin in OVCAR-3 Tumor Bearing Nude Mice 60 min p.i. (n = 3)[a]

organ	activity accumulation [%iD/g]
blood	0.96 ± 0.13
heart	0.54 ± 0.01
lung	1.49 ± 0.28
liver	2.39 ± 1.03
intestine	13.56 ± 3.57
stomach	2.64 ± 0.64
kidney	2.82 ± 0.67
spleen	0.54 ± 0.10
pancreas	0.52 ± 0.10
muscle	0.22 ± 0.05
OVCAR-3 tumor	0.49 ± 0.05

[a] Data are given in % injected dose per gram tissue (%iD/g).

Serum Stability. The new GnRH-I-analogue with the highest receptor affinity and internalization efficiency, D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I, was investigated with respect to its stability in human serum (Figure 5). The radiolabeled peptide was incubated with human serum for up to 120 min, followed by extraction of the radioactivity using a RP-18 cartridge. The cartridge eluate was analyzed using RP-HPLC.

Over time, an increasing amount of a hydrophilic metabolite with no retention on the RP-18-material of the extraction cartridge was formed (5.4%, 9.9%, 14.4%, and 29.3% of the total activity applied to the cartridge after 10, 30, 60, and 120 min incubation, respectively). This metabolite was always eluted in the washing step with water and was not further characterized. At all time points investigated, however, the activity immobilized on the cartridge (elution with a slightly acidified ethanolic solution) was analyzed using RP-HPLC and was found to consist exclusively of intact tracer. Formation of further metabolites was not observed.

The decrease of the amount of intact D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I over time is illustrated in Figure 5. A one-phase exponential fit of the data yielded a serum half-life of 254 ± 18 min for this ligand.

In Vivo Biodistribution Study. To evaluate the potential of OVCAR-3 xenografts as an in vivo model for GnRHR-imaging, a preliminary biodistribution study for the reference ligand [^{125}I]Triptorelin was performed in OVCAR-3 tumor bearing nude mice. Data are summarized in Table 3.

The highest accumulation of [^{125}I]Triptorelin was observed in the organs of the gastrointestinal tract, probably due to a predominant hepatobiliary clearance of the tracer, and in the kidneys. Unfortunately, uptake of [^{125}I]Triptorelin in the

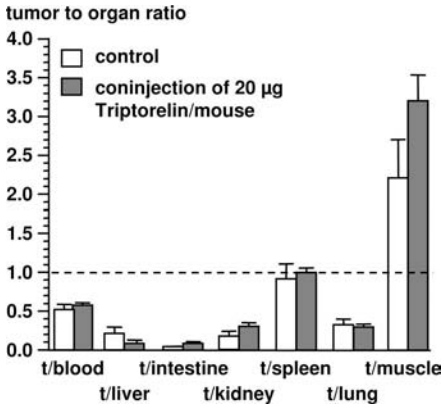

Figure 6. Tumor to organ ratios for [^{125}I]Triptorelin in OVCAR-3 tumor bearing nude mice at 60 min p.i.. White bars represent the control experiment (tracer only, $n = 3$); gray bars represent blocking conditions (coinjection of 20 μg Triptorelin, $n = 3$).

OVCAR-3 tumors was as low as nonspecific tracer accumulation in heart, spleen, and pancreas (~0.5%iD/g). This leads to very low tumor-to-organ ratios of 0.51, 0.21, 0.04, 0.17, and 2.22 for blood, liver, intestine, kidney, and muscle, respectively (Figure 6).

Furthermore, a blocking study was performed, in which 20 μg of unlabeled Triptorelin was coinjected. In this study, absolute tracer accumulation in all organs was approx threefold higher than observed in the control experiment (data not shown), which might be occasioned by a slowed tracer excretion due to some pharmacological effect caused by Triptorelin. However, tumor to organ ratios were nearly identical to those found in the control experiment (Figure 6), demonstrating that tracer accumulation in OVCAR-3 tumors is not receptor-mediated.

DISCUSSION

Due to their high incidence on human tumors of the reproductive system, GnRH-receptors have been successfully used for direct targeting with potent GnRH-analogues, leading to tumor growth suppression (*24*). However, to our knowledge only one attempt to exploit this receptor system as a target for in vivo peptide receptor imaging has been reported to date (*29*).

One possible reason for this circumstance is the fact that almost no data are available concerning the level of GnRH-receptor protein expression in human tumor cell lines, since for most studies investigating, e.g., GnRH receptor function transiently transfected cells are used (*45, 47*), and receptor expression in cancer cell lines or tumor specimens is almost exclusively determined using mRNA blotting techniques or hormonal response studies (*34*). For the evaluation of GnRH-radiotracers, however, receptor expression on the respective human tumor cell lines is a crucial quantity, because high cellular radioligand uptake and thus the possibility for high-contrast GnRHR-imaging depends on high intrinsic membrane presentation of the target receptor.

Furthermore, the capacity of the receptor to internalize the radioligand is helpful to achieve high activity accumulation in tumor tissue. Among all G-protein coupled receptors that have been cloned to date, the type I mammalian GnRHR is the only receptor fully lacking the C-terminal cytoplasmatic tail, which is highly important for effective receptor internalization (*45, 46*). Nevertheless, the human GnRHR-I is internalized (*45, 48*), albeit slowly. In a very recent study, it has been demonstrated that this internalization is constitutive and not–as previously assumed–agonist-induced, and also cannot be stimulated above constitutive level in the presence of various GnRH-analogues (*49*). In contrast, the type II mammalian and nonmammalian GnRHRs, which possess intracellular C-tails of varying length, are rapidly internalized (*45, 46*).

From this point of view, the type II GnRHR seems more suitable for targeting with radiolabeled GnRH-analogues than the type I receptor. However, it is still a matter of ongoing debate whether a functional human GnRHR-II exists at all. Some studies suggest GnRHR-II mediated actions of ant/agonistic GnRH-I or GnRH-II analogues on GnRHR-expressing cancer cells (*50, 51*), others indicate ligand-selective active conformations of GnRHR-I, explaining the different ligand-induced signaling observed for GnRH-I and -II analogues (*52*), and others demonstrate modulation of GnRHR-I function by expression of GnRHR-II gene fragments (*53*).

Therefore, the focus of this study was directed toward the evaluation of the GnRH-I receptor as a potential target for radiolabeled GnRH-I-analogues as well as the parallel development of high-affinity GnRH-I analogues labeled with positron-emitting radionuclides (^{18}F, ^{68}Ga) for potential use in GnRHR-imaging via PET.

First, several GnRHR-expressing cell lines derived from human ovarian (EFO-27, SKOV-3, OVCAR-3), breast (MDA-MB 231, SKBR-3), and prostate cancer specimens (LNCaP, DU-145) were screened for GnRHR-expression using a radioligand binding assay. While EFO-27, MDA-MB 231, SKBR-3, and LNCaP cells have been reported to express GnRHR-I only (*14, 30, 31, 33, 34*), OVCAR-3 cells express both the human type I and type II GnRHR (*30*), and DU-145 and SKOV-3 cells have been shown to express the type II GnRHR (*30, 32*). Although, based on the argumentation above, the focus of this study was the evaluation of the GnRH-I receptor as a potential target for peptide receptor imaging, the latter two cell lines were also included in this study and screened for GnRHR-II expression using the corresponding standard radioligand D-Lys^6-[^{125}I]GnRH-II. This allows comparison of two receptor subtypes, GnRHR-I and the putative GnRHR-II, with respect to the level of receptor expression and efficiency of radioligand uptake, and thus identification of the more suitable target receptor for the intended purpose.

Unfortunately, GnRHR-expression and thus radioligand uptake was low in all cell lines investigated ($\leq$3.5% of the applied activity after a 120 min incubation) and independent of the receptor subtype. Furthermore, the level of nonspecific binding, which was determined in the presence of an excess of unlabeled peptide (5 μM), was >55% for all cell lines. These data are consistent with a previous study, in which GnRHR-expression on different breast cancer cell line membranes was investigated using [^{125}I][D-Ala^6-N$_\alpha$MeLeu^7-Pro^9-NEt]-GnRH-I as the radioligand (*31*). Similar results were obtained using membranes of SKBR-3 and MDA-MB 231 cells: very low receptor binding (~1.5% of applied activity) and a high level ($\geq$50%) of nonspecific binding was found.

Another problem encountered during the in vitro studies presented here was that absolute radioligand uptake did not correlate with the cell count in the respective assay in most cases, indicating variable levels of receptor expression or receptor presentation on the cell surface (data not shown), even when cell culture conditions were kept constant for the different assays. However, reliability of the in vitro system can be partially improved by the choice of the appropriate serum supplement used for cell culture. Substituting fetal calf serum (FCS) by a semisynthetic serum supplement, Nu-Serum, leads to an increase in the fraction of specifically bound radioligand in all cell lines, independently of the GnRH receptor type investigated, indicating enhanced receptor expression under these conditions (Figure 3). This had already been documented previously for DU-145 cells (*35*), and seems, based on the data obtained in this study, a suitable means to enhance and stabilize

GnRHR-expression in cell culture, thus providing reliable in vitro systems for the evaluation of new radiolabeled GnRHR-ligands. In this study, EFO-27 cells were chosen as the optimal in vitro model due to their comparably high and constant receptor expression.

Generally, the low GnRH receptor protein expression, that has been observed in this study, is explainable by the results of recent studies elucidating the regulation of human GnRHR-expression. Obviously, a large proportion of the human GnRHR protein is inefficiently processed by the cell under physiological conditions and is retained at the site of production, the endoplasmatic reticulum, or an intracellular pool (*49*). This inefficient routing to the plasma membrane seems to be due to a high degree of protein misfolding which can be partly overcome by the action of so-called "pharmacoperones", small membrane-permeable antagonistic molecules that stabilize the correct receptor conformation and thus allow efficient routing to the plasma membrane (*54–56*). In contrast to the GnRHRs of other species, that show high plasma membrane expression, the human receptor seems to have specifically evolved by point mutation to be inefficiently folded and thus retained intracellularly. However, despite its very low membrane expression (approx 2000 receptors/cell in MCF7 and LNCaP cells (*56*)) signaling of the human GnRHR is very robust, suggesting that a proportion of the intracellular receptors might traffic to the cell surface during stimulation and thus providing a rationale for the successful application of GnRH-analogues for suppression of tumor growth (*24*).

In parallel to the evaluation of the different cell lines as potential in vitro models, three novel GnRH-I analogues were developed (Figure 1): D-Lys^6([^{68}Ga]DOTA)-GnRH-I, D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I, and D-Lys^6(β-Ala-[^{18}F]FBOA)-GnRH-I.

While radiolabeling of the first was performed according to a standard protocol, the strategy for ^{18}F-labeling via oxime formation with 4-[^{18}F]fluorobenzaldehyde was modified as compared to a previous method (*40*). Instead of the deprotected aminooxy-functionalized peptides, their respective Boc-protected precursors, i.e., D-Lys^6(Ahx-(Boc)AoA)-GnRH-I and D-Lys^6(β-Ala-(Boc)AoA)-GnRH-I, were used for the labeling reaction. One substantial problem with using the deprotected peptides is the very high reactivity of the aminooxy group toward ketones and aldehydes of any kind, leading to the formation of unwanted conjugates with even traces of acetone or formaldehyde and softeners during workup or storage of the purified peptides. This problem can be avoided using the Boc-protected precursors. In this study, deprotection of the aminooxy group was carried out in situ during the labeling reaction, and the [^{18}F]FBOA-peptides were obtained in high radiochemical yields, identical to those obtained when the deprotected precursors were used (*40*). It is important to note, however, that a 5-fold higher peptide concentration was needed for efficient labeling as compared to deprotected aminooxy-peptides. However, this potential drawback is balanced by the much greater ease of peptide precursor preparation and handling as well as facilitated HPLC purification of the corresponding [^{18}F]FBOA-peptides due to a significantly lower fraction of unlabeled impurities in the case of the Boc-protected analogues.

In vitro evaluation of D-Lys^6([^{68}Ga]DOTA)-GnRH-I, D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I, and D-Lys^6(β-Ala-[^{18}F]FBOA)-GnRH-I yielded unexpected results with respect to the sensitivity of the D-Lys^6-GnRH-I scaffold toward chemical modification of the D-Lys^6-side chain. While data from the literature had indicated that even very large molecules such as proteins (*37, 39*) could be conjugated to this position without significantly affecting receptor affinity, the modifications introduced in this study had substantial effects on receptor affinity and ligand internalization. Interestingly, introduction of a highly hydrophilic moiety, i.e., [^{68}Ga]DOTA, on the D-Lys^6-side chain led to a hundredfold decrease in receptor affinity compared to the reference peptide Triptorelin, while the effect of conjugation with the lipophilic residue [^{18}F]FBOA via different spacers (Ahx, β-Ala) was very small, i.e., a loss of binding affinity by a factor of 4 to 6 (Table 2). These data indicate first that only lipophilic modifications are well-tolerated in this position, and second that spacer length between the D-Lys^6-side chain and the lipophilic moiety has significant impact on the receptor affinity of D-Lys^6-modified GnRH-I analogues.

The receptor binding data obtained via membrane binding assays correlate well with the internalization data from studies using EFO-27 cells (Table 1). Receptor-mediated internalization of the [^{68}Ga]DOTA-analogue was negligible, corresponding to the very low receptor affinity of this compound, while cellular uptake of D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I was close to that of the reference [^{125}I]Triptorelin, reflecting the similar receptor affinity of these radioligands.

Because D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I showed the most promising in vitro profile of the new compounds evaluated, its in vitro stability in human serum was investigated in preparation for future in vivo evaluation. The calculated serum half-life of this compound is >4 h, indicating both sufficient stability of the peptide scaffold as well as of the oxime bond between the aminooxy-functionalized peptide and 4-[^{18}F]fluorobenzaldehyde and thus suitable stability for in vivo application for imaging purposes.

Another step toward the future in vivo evaluation of D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I was the search for an appropriate in vivo tumor model. Because EFO-27 cells are not tumorigenic in mice, internalization of D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I and of the standard ligand [^{125}I]Triptorelin were also investigated in OVCAR-3 cells, a well-established GnRHR-expressing transplantable tumor model. For both peptides, absolute radioligand uptake was identical to that observed in EFO-27 cells, and the difference in internalization efficiency between the two peptides was also identical in both cell lines, indicating the suitability of OVCAR-3 cells as a transplantable tumor model for the future in vivo evaluation of new radiolabeled GnRH-I analogues.

To confirm this, a preliminary biodistribution study was performed in OVCAR-3 tumor bearing nude mice. Because [^{125}I]Triptorelin has an even higher receptor affinity than D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I and therefore can be viewed as a "gold standard"-GnRH-ligand, [^{125}I]Triptorelin was used as the radioligand for the evaluation of the OVCAR-3 tumor model. The comparably high lipophilicity of [^{125}I]Triptorelin leads to predominant hepatobiliary clearance of the radioligand, as illustrated by the very high uptake in intestine and also substantial hepatic accumulation (Table 3). Because the lipophilicity of D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I is similar to that of [^{125}I]Triptorelin, the excretion patterns of both radioligands will probably be very similar. Consequently, a high extent of hepatobiliary excretion and thus high background activity can also be expected for the fluorinated peptide. Therefore, based on the experience from studies with different glycosylated somatostatin receptor−ligands, which have demonstrated that only ligands with a log $P < 1.6$ show a suitable excretion pattern for high-contrast peptide receptor imaging (*57, 58*), pharmacokinetic ligand optimization is warranted before performing in vivo studies with D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I.

With respect to receptor-specific tracer accumulation, the biodistribution data of [^{125}I]Triptorelin (Table 3) parallel the in vitro data found for all GnRHR-expressing cell lines investigated in this study: the level of GnRHR-expression on the respective tumor cells seems to be very low. Tumor uptake of [^{125}I]Triptorelin was as low as nonspecific tracer accumulation in organs such as heart, spleen, and pancreas (~0.5%iD/g) and is even

lower than blood activity concentration at the same time point (0.96%iD/g at 60 min p.i.). A blocking study revealed the absence of receptor-mediated tumor accumulation (Figure 6). However, to confirm this observation and to be able to quantify GnRH-I-receptor expression in OVCAR-3 tumors more precisely, ex vivo GnRHR-autoradiography or immunohistochemistry after excision of the implanted tumor would be necessary.

Nevertheless, this observation seriously challenges the suitability of the GnRH receptor system as a target for peptide receptor imaging, since the obvious lack of receptor-mediated tracer accumulation will not allow high-contrast imaging and sensitive detection of GnRHR-positive lesions, even if overall tracer pharmacokinetics are substantially improved.

CONCLUSION

The in vitro evaluation of the three new radiolabeled GnRH-I analogues investigated in this study, D-Lys^6([^{68}Ga]DOTA)-GnRH-I, D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I, and D-Lys^6(β-Ala-[^{18}F]FBOA)-GnRH-I, yielded interesting insights into the structural requirements for the development of high-affinity radiolabeled GnRH-I agonists. Obviously, in this study only the conjugation of lipophilic residues to the D-Lys^6-side chain is well-tolerated by the peptide scaffold without significant loss of binding affinity, and spacer length between the D-Lys^6-side chain and the hydrophobic moiety has substantial impact on the receptor affinity of the radioligand.

Of the new compounds investigated, D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I shows the highest receptor affinity and internalization efficiency into GnRHR-expressing tumor cells, bearing the highest structural homology to a previously developed high-affinity cytotoxic GnRH-I analogue. D-Lys^6(Ahx-[^{18}F]FBOA)-GnRH-I illustrates again the versatility and ease of the newly developed ^{18}F-labeling method via chemoselective oxime formation with 4-[^{18}F]fluorobenzaldehyde, especially when the Boc-protected aminooxy-peptide is used as the labeling precursor, and represents the first radiolabeled GnRH-I analogue with suitable binding characteristics for efficient GnRHR-targeting.

Unfortunately, both the in vitro radioligand binding assays performed with various GnRHR-expressing human cancer cell lines as well as the initial in vivo biodistribution study carried out using OVCAR-3 tumor-bearing nude mice indicated a very low level of GnRHR expression on the cell surface. While this obviously does not seem to hamper application of nonradiolabeled GnRH-analogues for the effective suppression of tumor growth, as demonstrated in a variety of studies, it has a deleterious impact on the suitability of the GnRHR system as a suitable target for peptide receptor imaging using radiolabeled GnRH-analogues. In our opinion, GnRH receptors represent a highly interesting target for pharmacological interventions, but do not fulfill the prerequisites for successful peptide receptor imaging, even when suitable receptor−ligands as developed in this study are available.

Minisequencing with Acyclonucleoside Triphosphates Tethered to Lanthanide(III) Chelates

Pia Ollikka, Alice Ylikoski, Annukka Kaatrasalo, Heli Harvala, Harri Hakala, and Jari Hovinen*

PerkinElmer Life and Analytical Sciences, Turku Site, POB 10, FI-20101 Turku, Finland. Received March 3, 2008; Revised Manuscript Received April 14, 2008

Four acyclic nucleoside triphosphates (derivatives of cytosine, thymine, 7-deazaadenine, and 7-deazaguanine) labeled with nonluminescent europium, terbium, dysprosium, and samarium chelates of 2,2′,2″,2‴-[[4-(4-isothiocyanatophenyl)ethyl]pyridine-2,6-diyl]bis(methylenenitrilo)]tetrakis(acetic acid) were applied to minisequencing using two mutations (Δ*F* 508 and 1717−1 G to A) of cystic fibrosis as a model system. When synthetic targets were used, all four alleles involved could be analyzed in a single reaction using four terminating substrates labeled with four different lanthanide(III) chelates and DELFIA technology for detection. Blood spot samples without DNA isolations were used for PCR amplification and genotyping the target mutations by minisequencing. The single- and dual-labeled minisequencing assays were robust, while the four-label assay still requires further optimization of the multiplexed PCR amplification.

INTRODUCTION

Over 15 years ago, a method called minisequencing was introduced for the detection of point mutations in DNA (*1, 2*). The method involves hybridization of a single-stranded target DNA with a primer that ends immediately before the site of mutation, and elongation of the chain with a single-labeled dideoxyribonucleoside 5′-triphosphate (ddNTP). Parallel runs with each of the four possible labeled nucleotides enable identification of the mutated base. Originally, only radioactive detection was employed (*2–6*). Later, the detection has been predominantly based on fluorescence, where the ddNTPs are labeled with dyes and the identification of the single nucleotide polymorphisms (SNPs) is based on the signal intensity of each dye-specific emission wavelength (*7–13*). Nowadays, SNPs can be genotyped using multiplex, four-color fluorescent minisequencing in a microarray format (*11, 12*). However, application of fluorescence techniques in SNP analysis suffers from low detection sensitivity and problems associated with the properties of the labeled triphosphates to act as good substrates for DNA polymerases. Furthermore, the organic fluorophores as labels have several drawbacks, such as Raman and Rayleigh scattering, short Stokes' shift, low water solubility, and concentration quenching. By contrast, the unique properties of lanthanide(III) chelates such as strong long-decay time luminescence make them ideal markers for numerous applications (*14–16*). Furthermore, the large Stokes' shift and very sharp emission bands enable the simultaneous use of four lanthanides (i.e., Eu, Tb, Sm, and Dy) in the analysis. Time-resolved fluorimetric assays based on lanthanide(III) chelates have found applications in diagnostics, research, and high-throughput screening. The heterogeneous DELFIA technique is applied especially in assays requiring exceptional sensitivity, robustness, and multilabel approach. Up to now, this technology has not been applied for sequencing, although each of four DNA bases could be analyzed with the four different lanthanide(III) ions commonly used in DELFIA based assays.

We report here the preparation of four different acyclonucleoside triphosphates labeled with different lanthanide(III) chelates. Also, their applicability in detection of mutations in a model system (cystic fibrosis mutations Δ*F* 508 and 1717−1 G to A) has been demonstrated.

EXPERIMENTAL PROCEDURES

General. The PCR primers, minisequencing primers, and synthetic 5′-biotinylated targets for optimization of the minisequencing reactions (cystic fibrosis mutations Δ*F* 508 in exon 10 and 1717−1 G to A in exon 11 of CFTR gene) were purchased from Sigma-Genosys (HPLC purified). The sequences of synthetic targets and primers are shown in Table 1. HPLC purifications of the labeled acyclonucleoside triphosphates were performed using a Merck-Hitachi L-7100 instrument and a reversed-phase column (Termoquest Hypersil 4.6 μm). Mobile phase: Buffer A, 0.02 M triethylammonium acetate (pH 7.5); Buffer B, A in 50% (v/v) acetonitrile. Gradient: from 0 to 30 min from 10% to 45% B and from 30 to 35 min from 45% to 100% B. Flow rate was 1.0 mL min^{-1}. ESI-TOF mass spectra were recorded on an Applied Biosystems Mariner instrument. For PCR, DNA polymerase (DyNAzyme II), buffer solution, and $MgCl_2$ solution were purchased from Finnzymes, and dNTPs were from GE Healthcare. For minisequencing, DNA polymerase (AcycloPol), dilution buffer, unlabeled acycloterminators, streptavidin-coated microtiter plates, assay buffer, DELFIA Wash Solution, DELFIA Enhancement solution, DELFIA Enhancer, and lanthanide(III) chelates were from PerkinElmer Life and Analytical Sciences. Wallac DBS puncher, DELFIA Plateshake, Platewash, Plate Dispense, and Victor D Multilabel Counter were from PerkinElmer Life and Analytical Sciences. PCR and minisequencing reactions were performed on a GeneAmp 9700 Instrument (Applied Biosystems) and an IEMS incubator (Labsystems), respectively.

Synthesis of Labeled Acyclonucleoside Triphosphates (acycloNTP-Lns). The acycloterminators tethered to propargylamino group (1.0 nmol) (*17*) and 2,2′,2″,2‴-[[4-(4-isothiocyanatophenyl)ethyl]pyridine-2,6-diyl]bis(methylenenitrilo)]tetrakis(acetic acid) lanthanide(III) (*18*) (3.0 nmol) were dissolved in sterile water (40 μL). Pyridine (90 μL) and triethylamine (2 μL) were added, and the reaction was allowed to proceed overnight at ambient temperature. The products were isolated by precipitation with acetone (5 mL). The precipitate was dried,

PCR. For the analysis of the mutations, dried blood samples on a filter paper were used. From a dried blood spot sample, a 3.2 mm disk was punched directly into the PCR tube and 100 μL of master mix was added. The 100 μL amplification reactions contained 1× Dynazyme buffer, nucleotides (0.2 mM), $MgCl_2$ (2.5 mM), primers, and 1 U of Dynazyme II Polymerase enzyme. For single- and dual-label minisequencing assays, the PCR mixtures contained either Δ*F* 508 or 1717−1 G to A primer pairs. For four-label minisequencing, the PCR mixture contained all four PCR primers. The primer concentrations for Δ*F* 508 amplifications were 0.2 μM, while the primer concentrations for 1717−1 G to A amplification were 0.1 μM. In the positive control reactions, the blood disk was substituted with 200−300 ng of purified DNA. The negative control reaction contained only the reaction mixture. The PCR program used was the following: preheating to 95 °C followed by 30 cycles of 95 °C for 1 min, 56 °C for 1 min, and 72 °C for 1 min. When the amplification was completed, the PCR products were cooled to 4 °C and stored at −20 °C. Both the mutations in exons 10 and 11 were amplified using the same reaction conditions.

Minisequencing Reactions Using Synthetic Oligonucleotides. The minisequencing reaction was optimized using synthetic targets simulating the wild-type and mutated alleles of the exons 10 and 11. The biotinylated synthetic targets were allowed to bind to the streptavidin-coated wells (10^{11} target molecules per well in 50 μL of DELFIA Assay Buffer containing 1 M NaCl and 0.1% Tween 20) for 30 min with shaking at ambient temperature. Unbound targets were removed using DELFIA Wash Solution and Platewash (3 washings). The minisequencing reaction conditions were optimized as the function of concentration of reaction components (primers, acyclonucleotides, and enzyme), reaction time, reaction volume and temperature, and the focus was on the signal levels and specificity of the reaction. The minisequencing reaction was allowed to proceed in sealed plates with shaking for 20 min at 50 °C. The reactions contained 1 pmol of sequencing primers, 1−5 pmol of *acyclo*NTP-Lns, and 50 μL of reaction buffer. The optimized reaction buffer consisted of 10 mM Tris-HCl, pH 8.5, 50 mM NaCl, 50 μM EDTA, 7.5 mM $MgCl_2$, 0.1 mg/mL BSA, and 0.4 U/mL AcycloPol polymerase. When the reactions were completed, the wells were rinsed 6 times with DELFIA Wash Solution. Analyses of reactions were performed according to DELFIA protocol using Victor D Multilabel Counter. Shortly, lanthanide ions were released to solution using DELFIA Enhancement Solution (200 μL) and shaking for 25 min. In the case of Tb and Dy, additional incubation of 5 min after the addition of 50 μL DELFIA Enhancer was used. Luminescent chelates formed during this period of time were measured with Victor D Multilabel Counter.

Minisequencing of PCR Products. The minisequencing reaction optimized with synthetic oligonucleotides was tested with PCR products. The capture of the PCR product was performed in a total volume of 50 μL as described above. A 25 μL aliquot of PCR product together with 25 μL of DELFIA Assay Buffer containing 1 M NaCl and 0.1% Tween 20 was transferred and allowed to bind onto streptavidin-coated microtiter plates, and after the washing the products bound to the wells were denatured by shaking for 5 min in the presence of NaOH (10 mM) and EDTA (300 μM). The unbound single-stranded DNA and the denaturation solution were removed by washing three times. The minisequencing reaction was performed in 50 μL as described above. The control reactions were the following: positive PCR control containing purified DNA, negative PCR control containing only the PCR reaction mixture, and a positive minisequencing control containing 10^{11} molecules of the synthetic target. The negative minisequencing control was performed in the reaction buffer in the absence of the enzyme.

RESULTS

Synthesis of the Labeled Acyclonucleoside Triphosphates. The acycloterminators labeled with four different lanthanide(III) chelates were synthesized by allowing the acycloterminators tethered to propargylamino group to react with europium, terbium, samarium, and dysprosium chelates of the DELFIA DNA labeling chelate, 2,2′,2″,2‴-[[4-(4-isothiocyanatophenyl)-ethyl]pyridine-2,6-diyl]bis(methylenenitrilo)]tetrakis(acetic acid). After precipitation from acetone, the crude products were

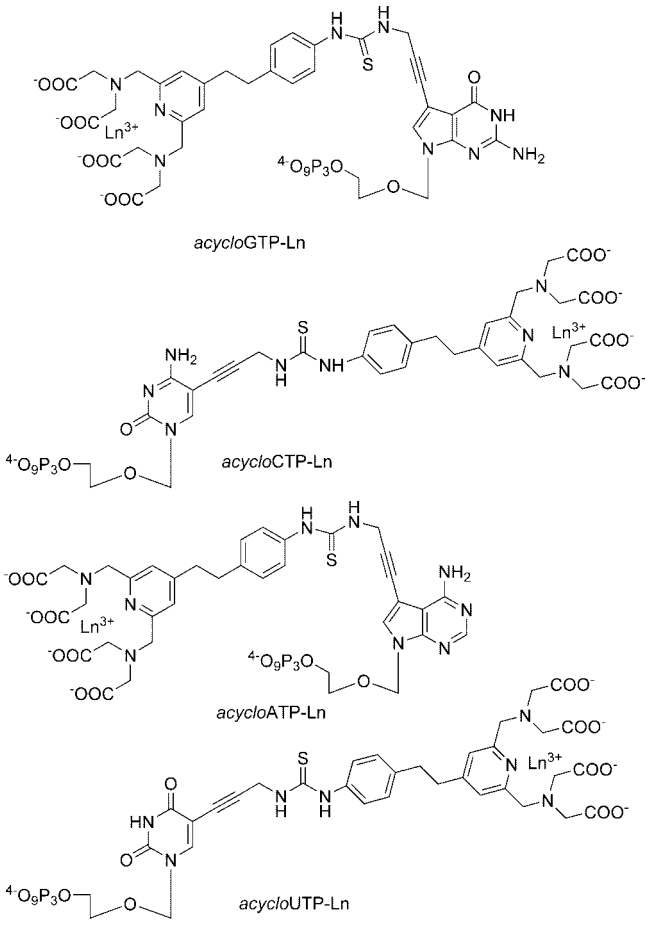

Figure 1. Structures of the acycloterminators labeled with lanthanide(III) chelates. Ln is Eu, Tb, Sm, and Dy.

redissolved in water and purified on HPLC. The labeled triphosphates were analyzed on mass spectrometry, and the observed molecular weights were in accordance with the proposed structures (Figure 1). Accordingly, in all the cases the ligand structure is the same, and each of the four nucleobases can be identified by using the specific signal derived from europium, samarium, terbium, and dysprosium.

Optimization of Minisequencing. The minisequencing reaction conditions were optimized using synthetic oligonucleotides as the function of reaction components, temperature, and time. For Δ*F* 508 mutation, the best results were obtained using a 22-base primer; the use of longer primers caused significant cross reactivity, and the shorter sequences, in turn, resulted in decrease of the specific signal. For 1717−1 G to A mutation, the primer did not have a significant effect on the signal-to-noise ratio, and a 24-mer primer was chosen. With respect to both mutations, 1 pmol of primer per well was enough, and the use of higher amounts did not give better results.

In single-label assays with synthetic oligonucleotides, one of the acyclonucleotides was labeled with europium (5 pmol per well) and the other three acyclonucleotides were unlabeled (5 pmol per well). In dual- and four-label assays, the suitability of each label to each nucleotide was investigated. In the dual-label assay for detection of Δ*F* 508 mutation, the best results were obtained using *acyclo*CTP-Eu and *acyclo*UTP-Tb, wherein *acyclo*ATP and *acyclo*GTP were unlabeled, and when each of which was 1 pmol per well. For detection of 1717−1 G to A mutation, in turn, the best results were obtained using *acyclo*GTP-Eu and *acyclo*ATP-Tb (1 pmol of each per well) and 5-fold excess of the unlabeled *acyclo*CTP and *acyclo*UTP. In four-label assays, where both of the mutations were analyzed from a single reaction, the following labels were chosen: *acyclo*CTP-Eu (5 pmol), *acyclo*UTP-Tb (1 pmol), *acyclo*GTP-Sm (5 pmol), and *acyclo*ATP-Dy (5 pmol). In all cases, the best results were obtained at 50 °C using a 20 min reaction time. The most suitable reaction volume was 50 μL.

Minisequencing of PCR Products. In the first set of experiments, PCR amplified products of 32 blood spots were analyzed using single-label assays. Only the mutant and wild-type alleles of Δ*F* 508 mutation were analyzed, each in their own reactions using *acyclo*CTP-Eu specific to the wild type-allele, and *acyclo*UTP-Eu specific to the mutant allele. The differentiation of wild-type, carrier, and mutant was based on the data obtained with the synthetic model developed above, and the result was calculated as a ratio of mutant *acyclo*UTP signal to wild-type *acyclo*CTP signal. Here, the UTP/CTP ratio for wild-type samples was below 1, for mutants over 5, and for carriers 1.5−2.5 (Figure 2). Accordingly, the single-label method allows us to detect all mutants, carriers, and wild-type samples from the blood spots.

In dual-label assays, both the wild-type and mutant alleles of the same target area were analyzed from a single reaction. Genotyping of Δ*F* 508 and 1717−1 G to A mutations from 16 blood spot samples was performed using two dual-label assays.

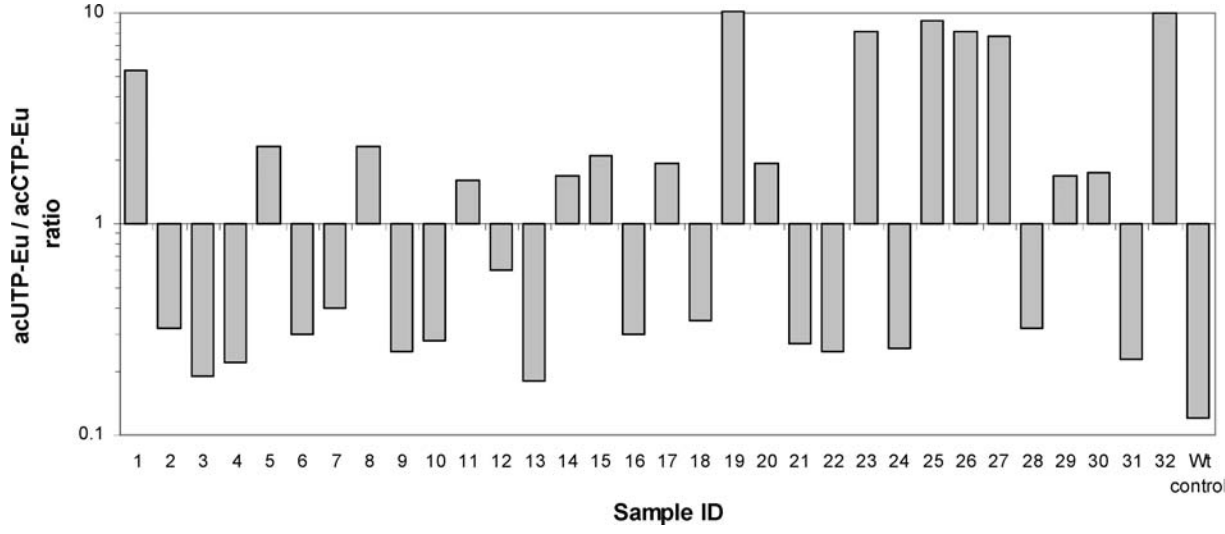

Figure 2. Minisequencing of blood disk samples with a single-label assay. The single-label assays utilized *acyclo*CTP-Eu for the detection of wild-type allele and *acyclo*UTP-Eu for the detection of mutant allele. The UTP/CTP ratio for wild-type, mutant, and carrier samples were below 1, over 5, and 1.5−2.5, respectively.

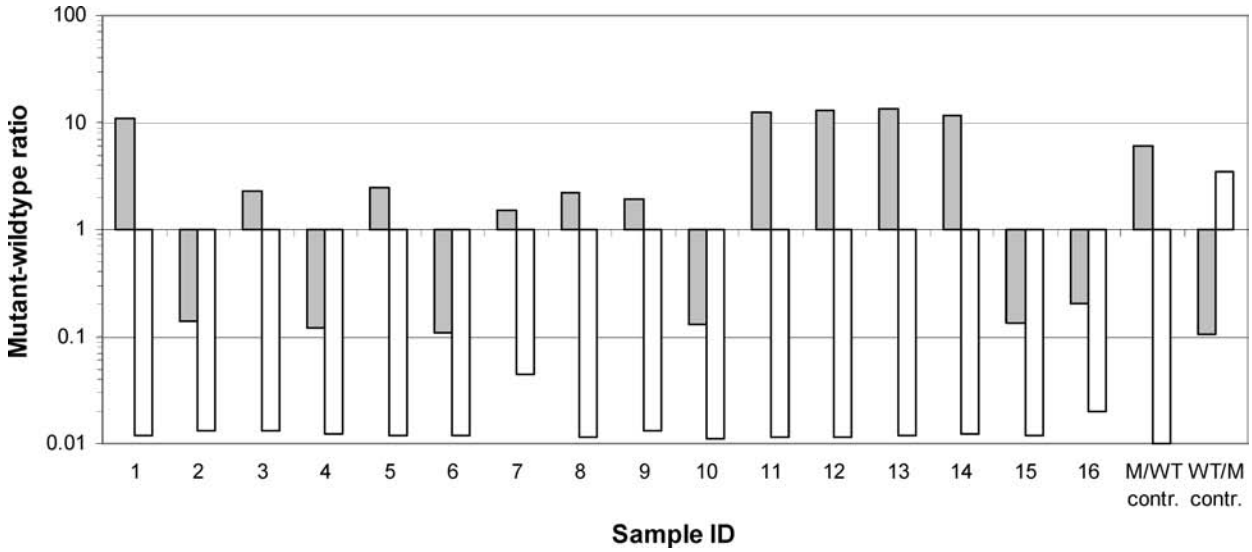

Figure 3. Minisequencing of blood disk samples with a dual-label assay. The dual-label assay for Δ*F* 508 utilized *acyclo*CTP-Eu for the detection of wild-type allele and *acyclo*UTP-Tb for the detection of mutant allele. The dual-label assay for 1717−1 G to A utilized *acyclo*GTP-Eu for the detection of wild-type allele and *acyclo*ATP-Tb for the detection of mutant allele. The control samples were mutant (M)/wild-type (WT) and wild-type (WT)/mutant (M) with respect to Δ*F* 508/1717−1 G to A. For the Δ*F* 508 assay (gray bars), the UTP/CTP ratios for wild-type, mutant, and carrier samples were below 1, over 5, and 1.5−2.5, respectively. For the 1717−1 G to A assay (white bars), the ATP/GTP ratios for wild type was below 0.1, for mutant over 1, and that for carrier was not determined due to lack of carrier samples.

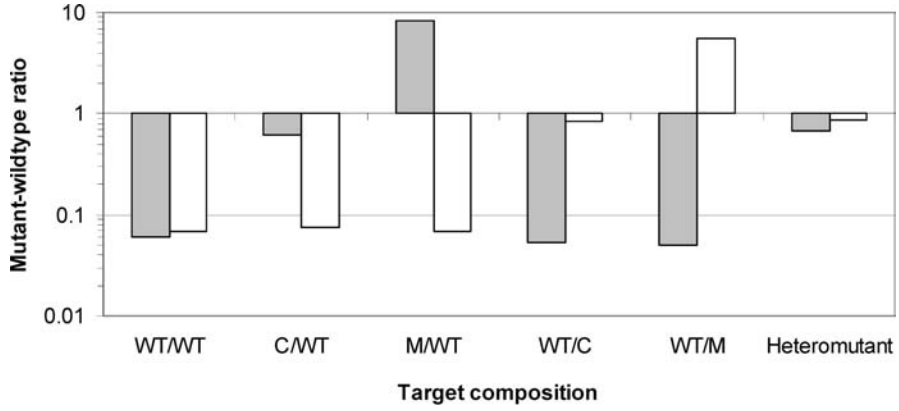

Figure 4. Minisequencing of synthetic DNA samples with a four-label assay. The four-label assay utilized *acyclo*CTP-Eu for wild type Δ*F* 508, *acyclo*UTP-Tb for mutant Δ*F* 508, *acyclo*GTP-Sm for wild-type 1717−1 G to A, and *acyclo*ATP-Dy for mutant 1717−1 G to A. *X*-axis shows the target composition in respect to Δ*F* 508/1717−1 G to A. WT, C, and M denote wild-type, carrier, and mutant, respectively. Gray bars show the Δ*F* 508 (UTP/CTP ratio) and white bars the 1717−1 G to A (ATP/GTP ratio) results. The mutant/wild-type signal ratio for wild type, mutant, and carrier samples was below 0.1, over 5, and 0.5−1, respectively.

The *acyclo*CTP-Eu/*acyclo*UTP-Tb pair and *acyclo*GTP-Eu/*acyclo*ATP-Tb pair was chosen for Δ*F* 508 and 1717−1 G to A mutations, respectively. GTP and ATP were specific nucleotides for wild-type and mutated sequences of the 1717−1 G to A mutation. The UTP/CTP ratio for Δ*F* 508 samples was comparable to the single-label assay (Figure 3). The ATP/GTP ratio in the 1717−1 G to A wild-type samples was always below 0.05 (mean of 16 samples 0.015) (Figure 3). Accordingly, the dual-label minisequencing reaction easily differentiates the wild-type and mutated sequences.

The four-label system was first tested with synthetic oligonucleotides. By mixing Δ*F* 508 and 1717−1 G to A target sequences, we could simulate the conditions in real patient samples. The concentration of oligonucleotide targets used (2×10^{11} molecules/well) was comparable to PCR product concentration used in earlier experiments. The Δ*F* 508 and 1717−1 G to A mutations were measured using *acyclo*CTP-Eu and *acyclo*UTP-Tb for wild-type and mutated Δ*F* 508, respectively, and *acyclo*GTP-Sm and *acyclo*ATP-Dy for the wild-type and mutated 1717−1 G to A, respectively. The four-label assay clearly discriminates the four different targets in the same reaction: UTP/CTP for wild-type, carrier, and mutated Δ*F* 508, and ATP/GTP for wild-type, carrier, and mutated 1717−1 G to A were clearly divided into three groups (Figure 4). For the four-label assay with synthetic targets, the mutant/wild-type signal ratio was below 0.1, 0.5−1, and over 5 for the wild-type, carrier, and mutant samples, respectively. Although the results with the synthetic targets were very promising, our four-label system could not discriminate PCR-amplified products from blood-spot samples.

DISCUSSION

To study the applicability of acyclonucleoside triphosphates labeled with lanthanide(III) chelates to minisequencing, we selected the major mutation Δ*F* 508 (frequency 66%) as well as the mutation 1717−1 G to A (frequency 0.6%), which is among the eight most common mutations of CF in the world. Δ*F* 508 is a three base deletion in the exon 10 of CFTR gene codon 508, while in 1717−1 G to A there is a single transversion of G to A in the position before exon 11. The three base deletion in Δ*F* 508 causes the loss of phenylalanine in CFTR protein,

and the transversion of G to A at position 1717 has an effect on breakdown of the mRNA produced by the gene.

We knew in advance that out of the 32 samples 7 were Δ*F* 508 mutant homozygotes, 9 were Δ*F* 508 heterozygote carriers, and the genotypes of the remaining 16 samples were unknown. By using the single-label assay, we could easily determine the genotype for Δ*F* 508 mutation for all 32 samples. The results of the known samples were in accordance with the previous information. However, since this approach requires the determination of each allele in separate reactions, it is time-consuming and requires significant amounts of rather expensive reagents.

In the dual-label assays, we could determine both wild-type and mutated alleles of each mutation in a single reaction. Accordingly, for determination of Δ*F* 508 and 1717−1 G to A mutations, only two reactions were needed. The results of the Δ*F* 508 analysis were in accordance with the results obtained in the single-label assays. All the samples were analyzed as 1717−1 G to A wild types. Although we did not know in advance any of the genotypes of 1717−1 G to A mutations, it is not likely that any of the samples were 1717−1 G to A carriers or mutants due to the extremely low abundance of that mutation (0.6% of population). Although we did not have blood spot samples of 1717−1 G to A carriers or mutants, the results obtained with synthetic mutated sequences show that the system is sensitive enough to analyze 1717−1 G to A mutations. Due to lack of carrier samples, we did not estimate the carrier ranges for 1717−1 G to A.

Although the four-label assay was sensitive enough to differentiate the synthetic targets, we were not able to perform the same assay with blood spot specimens. Since the minisequencing is working well with the synthetic targets, the problem with blood spot samples is, in all likelihood, derived from PCR amplification, which has been shown to be the bottleneck of minisequencing (*1*). For the four-label assay, we had to amplify the sequences of both the mutations in the same PCR reaction, i.e., there were two biotinylated and two nonbiotinylated primers in the same reaction. Accordingly, and in contrast to single- and dual-label assays, we had two different mutation sequences as well as two different pairs of PCR primers in a single well, which can bind to each other. Therefore, in order to use four-label assay for blood spot samples, optimization of multiplex-PCR amplification is required. Alternatively, a software program enabling data extraction should be developed.

The major goal of the present work was to develop a method based on minisequencing where we could determine the genotype of the patient two mutations in a single reaction using four different lanthanide-labeled nucleotides. Although this goal has not been reached yet, we have clearly demonstrated that the dual-label assay is well-suited for detection of Δ*F* 508 and 1717−1 G to A mutations involved in CF: the assay is simple, and the mutations can be determined directly from the products of PCR-amplified blood spot samples. The method is also suitable for detection of four alleles simultaneously.

Enhanced Loading Efficiency and Retention of ^{225}Ac in Rigid Liposomes for Potential Targeted Therapy of Micrometastases

Min-Yuan Chang,[†] Jonathan Seideman,[‡] and Stavroula Sofou*[,†]

Othmer-Jacobs Department of Chemical and Biological Engineering, Polytechnic University, 6 MetroTech Center, Brooklyn, New York 11201, and Molecular Pharmacology and Chemistry, Memorial Sloan-Kettering Cancer Center, 1275 York Ave, New York, New York 10021. Received November 29, 2007; Revised Manuscript Received April 22, 2008

Targeted α-particle emitters are promising therapeutics for micrometastatic disease. Actinium-225 has a 10-day half-life and generates a total of four α-particles per parent decay rendering ^{225}Ac an attractive candidate for α-therapy. For cancer cells with low surface expression levels of molecular targets, targeting strategies of ^{225}Ac using radiolabeled carriers of low specific radioactivities (such as antibodies) may not deliver enough α-particle emitters at the targeted cancer cells to result in killing. We previously proposed and showed using passive ^{225}Ac entrapment that liposomes can stably retain encapsulated ^{225}Ac for long time periods, and that antibody-conjugated liposomes (immunoliposomes) with encapsulated ^{225}Ac can specifically target and become internalized by cancer cells. However, to enable therapeutic use of ^{225}Ac-containing liposomes, high activities of ^{225}Ac need to be stably encapsulated into liposomes. In this study, various conditions for active loading of ^{225}Ac in preformed liposomes (ionophore-type, encapsulated buffer solution, and loading time) were evaluated, and liposomes with up to 73 ± 9% of the initial activity of ^{225}Ac (0.2−200 μCi) were developed. Retention of radioactive contents by liposomes was evaluated at 37 °C in phosphate buffer and in serum-supplemented media. The main fraction of released ^{225}Ac from liposomes occurs within the first two hours of incubation. Beyond this two hour point, the encapsulated radioactivity is released from liposomes slowly with an approximate half-life of the order of several days. In some cases, after 30 days, ^{225}Ac retention as high as 81 ± 7% of the initially encapsulated radioactivity was achieved. The ^{225}Ac loading protocol was also applied to immunoliposome loading without significant loss of targeting efficacy. Liposomes with surface-conjugated antibodies that are loaded with ^{225}Ac overcome the limitations of low specific activity for molecular carriers and are expected to be therapeutically useful against tumor cells having a low antigen density.

INTRODUCTION

α-Particle emitters hold great promise as therapeutics for micrometastatic disease. Because of their high-energy deposition of approximately 80 keV/μm and short range that is consistent with the dimensions of micrometastases (50 to 100 μm), α-particles, when specifically targeted to cancer cells, can combine high cell-killing efficacies with minimal normal-tissue irradiation. Cell survival studies have shown that as few as one to three tracks across the nucleus may result in cell death and is also independent of oxygenation state or cell-cycle during irradiation (*1*–*3*). Actinium-225 has a 10-day half-life and generates three α-particle emitting daughters (^{221}Fr ($t_{1/2}$ = 4.9 min), ^{217}At ($t_{1/2}$ = 32.3 ms), ^{213}Bi ($t_{1/2}$ = 45.59 min)), and a total of 4 α-particles per decay, that render ^{225}Ac an attractive candidate for α-therapy of micrometastatic disease.

For the particular case of cancer cells with low surface-expression levels of molecular targets (*4*), delivery of ^{225}Ac mediated by radiolabeled antibodies may not reach adequately high delivered activities at the targeted cancer cells. This is due to the generally low specific activity of radiolabeled antibodies with ^{225}Ac (*5*–*7*), with reported values to as high as 1 conjugated ^{225}Ac atom per 2300 antibodies (*8*). Tumor targeting liposomes with high activities of encapsulated ^{225}Ac could provide an alternative carrier for such cases where tumor localization also coincides with areas of usual liposome accumulation (liver, bone marrow) (*9*, *10*) or for targeting of micrometastatic clusters or single cancer cells that circulate in the bloodstream or reside in confined areas such as the peritoneal cavity. Liposomes are closed self-assembled structures of lipids, the nontoxic amphiphilic molecules of natural origin, and have been extensively studied for applications in drug delivery (*11*, *12*). Compared to using antibodies or other molecular carriers, liposomes have the substantial advantage of high drug-to-carrier (or ligand) ratios (*11*). In addition, the liposome surface can be used as a platform to conjugate targeting ligands resulting in ligand multivalency with possibly enhanced binding efficacies (*11*, *13*).

Liposomes have been previously considered for diagnostic and therapeutic delivery of radionuclides (*14*–*17*). We have previously investigated passive encapsulation of ^{225}Ac in liposomes as a means of retaining ^{225}Ac and its α-particle-emitting daughters within liposomes during delivery (*8*, *18*). We have shown that liposomes can stably retain encapsulated ^{225}Ac for 30 days. However, only passive radionuclide entrapment was used in these studies that resulted in low encapsulated activities. To enable the therapeutic use of ^{225}Ac, high activities of ^{225}Ac need to be encapsulated into liposomes.

In this study, PEGylated liposomes, composed of rigid membranes to enable long blood circulation times (*19*, *20*), were developed and characterized for size and stability. Different conditions (ionophore-type, encapsulated buffer solution, and loading time) were evaluated to maximize the yield of active loading of ^{225}Ac into preformed liposomes. Retention of encapsulated ^{225}Ac by liposomes was evaluated at 37 °C over

time in model conditions (phosphate buffer) and in serum-containing media.

For potential targeted α-particle therapy, liposomes conjugated to tumor targeting antibodies (immunoliposomes) were developed and their binding to cancer cells was evaluated *in vitro*. However, to efficiently load liposomes with ^{225}Ac, the suspension needs to be annealed to relatively high temperatures (at least 60 °C) to allow formation of a stable chelant between ^{225}Ac and the liposome-encapsulated DOTA[1] (*7*). In addition, elevated temperatures above the lipid membrane glass transition temperature (58 °C) are also required to increase the permeability of the liposomal membrane bilayer to the radionuclide−ionophore complexes (*21*). These relatively high temperatures may interfere either with the activity of liposome-conjugated antibodies or with the reactive groups on liposomes that will be used as linkers to antibodies at a following bioconjugation step. In our studies, maleimide-functionalized lipids are used presenting, therefore, a temperature limitation due to their potential hydrolysis (*22*). Consequently, the sequences of liposome immunolabeling and of liposome radionuclide loading were interchanged in order to determine the order that optimizes the development of immunolabeled liposomes combining maximum binding efficiency with maximum encapsulated ^{225}Ac activities.

MATERIALS AND METHODS

Reagents. 1,2-Dinonadecanoyl-*sn*-glycero-3-phosphocholine (DNPC), 1,2-distearoyl- *sn*-glycero-3-phosphoethanolamine-*N*-[methoxy(poly(ethylene glycol))-2000] (DSPE-PEG-2000), 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[maleimide-(poly(ethylene glycol))2000] (DSPE-PEG-Maleimide lipid), 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(Lissamine Rhodamine B Sulfonyl) (rhodamine-lipid), were purchased from Avanti Polar Lipids (Alabaster, AL). Phosphate buffered saline (PBS), Sephadex G-50, Sepharose 4B, ascorbic acid, tetramethylammonium acetate, sucrose, diethylenetriaminepentaacetic acid (DTPA), calcium ionophore A23187, and 8-hydroxyquinoline (Oxine) were obtained from Sigma-Aldrich (Atlanta, GA). Ethylenediaminetetraacetic acid (EDTA), disodium salt, sodium hydroxide (NaOH), and HEPES were purchased from Fisher Scientific (Pittsburgh, PA). Hydrochloric acid (HCl) was purchased from Spectrum (New Brunswick, NJ). *p*-Isothiocyanatobenzyl-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) was purchased from Macrocyclics (Dallas, TX). Actinium-225 was provided by Dr. George Sgouros and Dr. David Scheinberg. RPMI 1640 medium and fetal bovine serum (FBS) were purchased from Irvine Scientific (Santa Ana, CA). Cholesterol powder, Traut's Reagent, BSA Assay Kit, and Ellman's Assay Kit, were purchased from Pierce (Rockford, IL).

Liposome Preparation. Lipids in chloroform (DNPC (70 mol % of total lipid), DSPE-PEG-2000 (3 mol % of total lipid), cholesterol (30 mol % total lipid), rhodamine-lipid (1 mol % of total lipid), and DSPE-PEG-Maleimide lipid (2 mol % of total lipid for immunoliposomes)) were combined in a 25 mL round-bottom flask. Chloroform was evaporated in a Buchi rotavapor R-200 (Buchi, Flawil, Switzerland) for 10 min at 55 °C followed by evaporation under N_2 stream for 5 min. For liposomes to be loaded with ^{225}Ac, the dried lipid film was then hydrated in 1 mL acetate buffer (150 mM tetramethylammonium acetate, containing 5 mg/mL DOTA and 2.25 mg/mL ascorbic acid, pH 4.5) or 1 mL of citrate buffer (225 mM citrate buffer, containing 5 mg/mL DOTA and 2.25 mg/mL ascorbic acid, pH 4.0) for 2 h at 50 °C. The lipid suspension (10 mM lipid) was then extruded 21 times through 2 stacked polycarbonate filters of 200 nm pore diameter (Avestin Inc., Ottawa, Canada) followed by 21 times through 100 nm pore diameter. Extrusion was carried at 65 °C for DNPC liposomes in a water bath. After extrusion, exchange of the liposomes' surrounding buffer was performed by size exclusion chromatography (SEC) using a Sephadex G-50 column (11 cm length) eluted with isosmolar HEPES buffer (20 mM HEPES, 200 mM sucrose, pH 7.4). All solutions were chelexed before liposome and buffer preparation.

For liposome loading with the fluorophore calcein, the dried lipid film was hydrated in 1 mL of 1 mM calcein solution containing 2.5 mM HEPES, 75 mM NaCl, and 50 μM EDTA (pH 7.4) for 1 h at 50 °C. The lipid suspension (10 mM lipid) was then extruded 21 times as above, and unentrapped calcein was removed by SEC using a Sephadex G-50 column (11 cm length) eluted with isosmolar HEPES buffer.

Liposome Size Distribution Determination. Dynamic light scattering (DLS) of liposome suspensions was studied with an N4 plus autocorrelator (Beckman-Coulter, Fullerton, CA), equipped with a 632.8 nm He−Ne laser light source. Scattering was detected at 23.0°, 30.2°, 62.6°, and 90°, and particle size distributions at each angle were calculated from autocorrelation data analysis by CONTIN (*23*). The average liposome size was calculated to be the *y*-intercept at zero angle of the measured average particle size values versus $\sin^2(\theta)$ (*24*). All buffer solutions used were filtered with 0.22 μm filters just before liposome preparation. The collection times for the autocorrelation data were 1−10 min.

Differential Scanning Calorimetry. DSC scans of liposome suspensions (0.5 mL, 2.5 mM total lipid) in phosphate buffer (pH = 7.4) were performed using a VP-DSC Instrument (MicroCal, LLC, Northampton, MA) from 25 to 85 °C at a scan rate of 5 °C /h. The thermograph of the corresponding buffer was also acquired at identical conditions, and was subtracted from the excess heat capacity curves.

Liposome Loading with Actinium-225. Immediately before liposome active loading, ^{225}Ac (0.2−200 μCi) was dissolved in 30 μL HCl (3 mM) and was mixed with different ionophores: Oxine (3 μL of 11 mM oxine in ethanol with 97 μL of 20 mM sodium acetate) or A23187 (0.4 mg A23187 in 50 v/v water/ethanol). Then, the ionophore/radionuclide solution was incubated with liposomes (1 mL of 5 μmol total lipid/mL) in a dry bath at 65 °C. At different incubation times (15, 30, and 60 min), lipid samples were removed from the parent liposome suspension, and were mixed with DTPA (0.3 mM final concentration) after being cooled in ice-cold water for 5 min. Unentrapped ^{225}Ac was separated from liposomes by SEC using a Sephadex G-50 column (11 cm length, equilibrated and eluted with PBS, 1 mM EDTA, pH 7.4). Entrapment efficiency was calculated from the ratio of activities retained within the liposomes after SEC divided by the activities contained by the liposome suspension before SEC. Activities were measured 20 h later to allow for equilibrium to be reached before counting the γ-emissions of bismuth-213 (^{213}Bi) decay.

In these studies, the major upper temperature limitation is the preservation of the functionality of antibodies that are already conjugated via maleimide groups on the surface of liposomes, or of the maleimide groups if the bioconjugation reaction succeeds the liposome radiolabeling. Even if a different chemistry was used for antibody conjugation to liposomes, the liposome radiolabeling stage would still be restricted toward the upper temperature limit due to the potential thermal hydrolysis of phospholipids and PEGylated lipids comprising the liposome membranes that would not allow use of high temperatures (*25*).

In these studies, complexes of ^{225}Ac with the encapsulated chelant DOTA are potentially formed after diffusion of the

[1] *p*-Isothiocyanatobenzyl-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA).

^{225}Ac-ionophore complex from the solution across the bilayer membrane into the encapsulated aqueous core of liposomes during the loading period of liposomes. In order to evaluate the extent of formation of ^{225}Ac complexes with the chelant DOTA during the time period of liposome loading and to compare with the extent of formation of ^{225}Ac complexes with each ionophore, radioactivity was incubated separately with the chelant, and with each ionophore, and also with both the chelant and the ionophore in conditions identical to those of the encapsulated aqueous volume during liposome loading, and the extent of formation of each type of complex was assessed using cation exchange chromatography. The concentrations of ionophores in the incubation mixture were calculated to agree with the concentrations used for loading liposome suspensions in the presence of the acetate or of the citrate buffers that were encapsulated in liposomes (please see above paragraph). The mole ratio of DOTA to ionophores in the incubation mixture was calculated to be the same as during radionuclide loading of liposomes. For these calculations, since DOTA was passively encapsulated into liposomes, the maximum encapsulation efficiency of 5% of total volume, and initial DOTA used, was assumed (*26*). After a 15 min and 60 min incubation at 65 °C, each mixture was then passed through a cation exchange column (SP Sephadex C-25, Pharmacia Biotech, Sweden), equilibrated, and eluted with acetate or citrate buffer. The ion exchange group in the column is a sulfopropyl group that remains charged over the pH range of 4.0 to 13.0, therefore, maintaining high capacity to capture cations. This column was chosen to challenge the ^{225}Ac-ionophore complexes but not the ^{225}Ac-DOTA complexes. The eluted samples were allowed to reach equilibrium before γ-photon counting.

Measurement of Retention of Encapsulated Actinium-225 by Liposomes. The protocol to measure the retention of ^{225}Ac is described, in detail, elsewhere (*18*). Briefly, the γ-emissions (radioactivity equilibrium values) of ^{213}Bi were measured in liposome fractions, which were separated, at different times, from the parent liposome population and the free radionuclides by SEC (Sephadex G-50). The samples were counted using a Cobra γ-counter (Packard Instrument Co., Inc.). For monitoring ^{225}Ac, the window 150−600 keV was used, which includes the chief ^{213}Bi photopeak. Repeated measurements were performed on three different liposome preparations of each combination of ionophore and encapsulated acidic buffer. Retention of activity by liposomes was monitored for 30 days. This time period was chosen on basis of the focus of this work, which is to evaluate retention of radionuclide contents by the liposomal delivery carriers during circulation of the carriers in the body before their blood clearance and accumulation at particular tissues and their cellular uptake. In particular, the average blood circulation half-life of i.v. administered liposomes is 20 to 30 h in mice (*27*) and between 30 and 90 h in humans (*28*).

Liposome Immunolabeling. The protocol to immunolabel liposomes is described elsewhere (*29*). Briefly, Trastuzumab purified from Herceptin (Genentech, South San Francisco, CA) was activated with Traut's reagent (1 mL of 0.5 mg/mL antibody in PBS buffer (1 mM EDTA, pH 8) with 0.15 mg Traut's reagent for 1.5 h), was purified by a PD-10 column (Amersham Biosciences, Piscataway, NJ) eluted with PBS buffer (1 mM EDTA, pH 7.4), and was reacted with maleimide-lipids contained in liposomes (2 mol % of total lipid) in a nitrogen atmosphere for 40 min at room temperature (the ratio of liposomes to antibody was 0.5 mg activated antibody to 7.5 μmol lipids in a total volume of 1 mL). Unbound antibodies were separated from immunoliposomes by SEC using a Sepharose 4B column (11 cm length) eluted with PBS buffer (1 mM EDTA, pH 7.4). In purified immunoliposome suspensions, a protein assay was used to quantify the concentration of antibodies, and lipid concentration was determined by the fluorescence intensity of rhodamine-lipids contained in liposomes. Using the measured values of conjugated antibodies per lipid, the average number of antibodies per liposome was calculated (*29*) using for input values the mean size of liposomes (as measured by DLS) and the headgroup surface area per lipid (70 Å^2) (*26*).

Cell Line. The metastatic ovarian carcinoma cell line, SKOV3-NMP2 was derived from serial passage of the parental SKOV3 cell line in nude mice (*30*), and was propagated at 37 °C, in 5% CO_2 in RPMI 1640 media supplemented with 10% fetal bovine serum, 100 units/mL penicillin, and 100 μg/mL streptomycin. Cell concentration was determined by counting trypsinized cells with a hemocytometer.

Flow Cytometry. Immunoliposome binding was evaluated in the ovarian cancer SKOV3-NMP2 line for Trastuzumab-labeled liposomes. Cells were grown to confluency and were resuspended and adjusted to 5.6 million cells per milliliter in ice-cold FACS buffer (PBS with 1 mM EDTA, 0.5% BSA, and 0.02% sodium azide). Liposome suspensions (0.25 μmol lipid in 0.1 mL) were mixed with 180 μL of cell suspensions on ice. After incubation at 4 °C for variable times, samples were washed with ice-cold FACS buffer. Cell pellets were separated from the supernatant by centrifugation (three times) and were then resuspended in 400 μL of FACS buffer, and their fluorescence was measured by flow cytometry following the intensity of the liposome-encapsulated fluorescent calcein (FC 500 System, Beckman culture, Fullerton, CA).

Liposome Annealing before Immunolabeling. Maleimide-containing PEGylated liposomes were annealed at 65 °C in a dry bath for one hour. After annealing (that is required for the radionuclide loading and chelation), liposomes were allowed to cool in ice-cold water for 5 min before the liposome immunolabeling reaction with antibodies was initiated.

Liposome Immunolabeling before Annealing. After liposome immunolabeling as described above, immunoliposomes were annealed at 65 °C in a dry bath for one hour. After annealing (that is required for the radionuclide loading and chelation), liposomes were allowed to cool before evaluation of their binding efficacy to cells.

RESULTS

The size of PEGylated liposomes measured by DLS was 121 ± 6 nm in diameter.

Efficiency of Actinium-225 Loading in Preformed Liposomes. The optimal temperature range for chelation of ^{225}Ac to DOTA is reported between 55 and 60 °C (*7*). We chose to perform liposome loading and chelation of ^{225}Ac with the encapsulated DOTA at 65 °C to also ensure adequate permeability of the lipid bilayer membrane to the radionuclide−ionophore complex. The DSC thermogram of the lipid composition exhibits significant thermotropic responsiveness (greatest change in the heat capacity) at temperatures below 65 °C, indicating that the lipid membranes should be mostly in fluid phase at temperatures at or above 65 °C (Figure 1). Higher loading temperatures were not explored since they present an instability source for the structure and binding efficacy of conjugated antibodies on immunoliposomes (vide infra).

The loading efficiency of ^{225}Ac in PEGylated liposomes is shown in Figure 2A,B for liposomes with encapsulated acetate and citrate buffer, respectively, for two types of ionophores (Oxine and A23187) and with increasing loading times (15, 30, and 60 min). Liposomes encapsulating acetate buffer (Figure 2A) exhibited loading efficiencies that increase with increasing incubation time to similar extents for both ionophones studied: from 28 ± 7% to 63 ± 13% for oxine, and from 38 ± 3% to

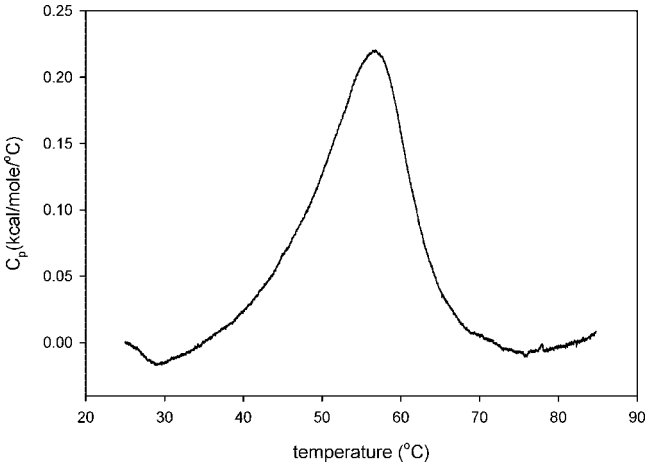

Figure 1. DSC thermogram of the PEGylated liposomes composed of DNPC lipids and cholesterol in phosphate buffer.

61 ± 18% for A23187. Longer loading times (1.5 h) did not result in a significant increase of loading yield and were, therefore, not explored systematically (data not shown). Liposomes encapsulating citrate buffer (Figure 2B) exhibited time-independent loading of ^{225}Ac that is, however, a strong function of the ionophore type. Oxine-mediated loading resulted in low radiation entrapment efficacies (average value: 15 ± 2%), and A23187-mediated loading resulted in significantly greater extents (62 ± 10%).

Studies of ^{225}Ac loading into liposomes in suspensions containing PBS buffer resulted in considerably lower loading yields than the yields in suspensions containing HEPES buffer which was, therefore, explored in this work.

The preferential formation of ^{225}Ac complexes with the chelant DOTA compared to ^{225}Ac complexes with each ionophore was evaluated in acetate and citrate buffer over time in conditions identical to liposome loading. In acetate buffer, in the presence of oxine, the extent of complex formation between ^{225}Ac and the chelant DOTA increases with time. The yield becomes 47% after 15 min, and after 60 min of incubation, all radiation is eluted from the cation exchange column, suggesting complete chelation of the radionuclide with DOTA (Figure A, Supporting Information). When both DOTA and the ionophore A23187 are present, 31% and 47% of the total radioactivity is in the form of ^{225}Ac-DOTA chelates after 15 and 60 min of incubation, respectively (Figure B, Supporting Information). The cation exchange column used in these studies was unable to challenge the complexes formed between ^{225}Ac and the citrate buffer, which seems to behave as a chelating agent for the radionuclide (*31*, *32*).

Efficiency of Actinium-225 Retention by Liposomes. After ^{225}Ac loading, the retention efficiency of ^{225}Ac by all PEGylated liposomes was studied and is shown in Figures 3 to 6 for liposome suspensions incubated at 37 °C in PBS and 10% serum-supplemented media over time. The main fraction of released ^{225}Ac from all liposomes occurs within the first two hours of incubation, and beyond this point, the retained radioactivity is stably carried by liposomes for approximately 30 days.

All liposome suspensions with encapsulated acetate buffer (Figures 3 and 4) exhibited more extensive release (within the first two hours of incubation) of radioactive contents compared to liposomes encapsulating citrate buffer (Figures 5 and 6). In particular, for oxine-mediated loading (Figure 3A,B,C), extensive content release was observed both in PBS and in serum supplemented media. Increase in loading time correlates with higher retention of radioactive contents by liposomes during the first two hours of incubation at 37 °C (Figure 3A,B,C). When A23187 was used to mediate active ^{225}Ac loading into liposomes with encapsulated acetate buffer (Figure 4A,B,C), radionuclide retention was independent of the loading time and decreased by approximately 50% within the first two hours of incubation in PBS and by approximately 64% in serum.

In liposomes encapsulating citrate buffer following oxine-mediated loading (Figure 5A,B,C), within the first two hours of incubation at 37 °C, liposomes exhibit higher content retention with increasing loading time, as is the case when acetate buffer and oxine are used (Figure 3A,B,C). Liposomes encapsulating citrate buffer that were loaded using A23187 exhibited the greatest content retention that increases with loading time (Figure 6A,B,C). In particular, these liposomes retained the encapsulated ^{225}Ac at levels that range from 54% to 81% (when liposomes were incubated in PBS) and from 35% to 56% when liposomes were incubated in serum-supplemented media. Actinium-225 was stably retained by these liposomes for a period of 20−30 days (Figure 6A,B,C).

For both types of encapsulated buffers used, A23187 always results in higher retention of radioactivity by liposomes compared to when oxine is used to load liposomes. With increasing incubation times, oxine-mediated loading results in radionuclide retention that approaches the retention exhibited by A23187-mediated loading. Only when A23187 is used in acetate buffer is the retention independent of loading time.

Cell Binding Specificity of Immunoliposomes. The conjugation reaction resulted in 68 ± 13 bound antibodies per liposome. Using flow cytometry, a significant shift in fluorescence counts was detected only when immunoliposomes were incubated with SKOV3-NMP2 cells with unblocked HER2/neu receptors (please see Supporting Information, Figure C).

Effect of Heating and Bioconjugation Sequence on the Cell Binding Efficacy of Immunoliposomes. The average ratios of conjugated antibodies per liposome were measured to be 14 ± 2 (or 15.6 ± 1.7 g of bound antibody per mole of lipid) when bioconjugation preceded the annealing at 65 °C for one hour, and 7 ± 1 (or 7.5 ± 0.2 g of bound antibody per mole of lipid) when annealing (of one hour) preceded the bioconjugation step.

It is shown in Figure 7 that when annealing of liposomes (that is required for loading of liposomes with ^{225}Ac) takes place after the bioconjugation reaction, immunoliposomes bind to cancer cells (bar indicated as b) with 80% of the maximum efficacy (bar indicated as c); this maximum value corresponds to immunoliposome binding when no additional annealing takes place. When annealing at 65 °C takes place before the bioconjugation reaction, then the specific binding of immunoliposomes to SKOV3-NMP2 cells decreases to 60% (bar indicated as a) of the maximum binding efficacy. Hydrolysis of the maleimide groups at the elevated annealing temperature before conjugation to antibodies could be a potential explanation for the decreased number of conjugated antibodies and, therefore, of cell specific binding of immunoliposomes (*22*). Antibody denaturation during annealing after liposome immunoconjugation could also play a role in decreasing immunoliposome binding. This relatively small decrease in binding efficacy seems disproportional to the decrease of liposome-bound antibodies. It has been shown that immunoliposome binding efficacy increases with higher surface densities of liposome-conjugated antibodies, but beyond some critical value of grafting densities, more surface-conjugated antibodies do not result in higher binding efficacies of immunoliposomes (*29*). If the initial grafting density corresponding to 68 ± 13 bound antibodies per liposome is beyond this critical value, then the small

Figure 2. decrease in liposome binding at such significantly lower antibody densities could possibly be explained.

DISCUSSION

Actinium-225 is a promising α-particle generator for the therapy of micrometastatic cancer since it emits a total of four α-particles per parent decay. Liposomes have been studied for the delivery of ^{225}Ac and were shown to adequately retain the parent nuclide (*8, 18*). However, passive entrapment of radionuclides into liposomes will only yield approximately 5% loading of initially used radioactivity, rendering this approach economically unfeasible and producing radioactive liposomes with low specific activities. High encapsulated activities of ^{225}Ac by liposomes are required in order to enable consideration of these drug carriers for α-particle therapy of cancer. In this work, PEGylated liposomes composed of rigid membranes were developed to allow for long circulation times in the bloodstream with minimal release of encapsulated contents. Different conditions were evaluated for optimizing (1) the radionuclide loading into preformed liposomes, (2) the retention of radioactivity by these carriers over time, and (3) the binding efficacy of antibody-conjugated liposomes (immunoliposomes) for potential specific targeting of cancer cells.

In particular, two types of ionophores (oxine and A23187) and two different types of liposome-encapsulated buffers (citrate buffer and acetate buffer) were studied for variable loading intervals to encapsulate ^{225}Ac in PEGylated liposomes composed of DNPC and cholesterol. Oxine has previously been reported to facilitate transport of trivalent cations (indium-111 and gallium-67) through the lipid membrane of liposomes composed

of high T_g lipids (*32*), and A23187 has been reported for the transport of divalent radium-223 and trivalent actinium-228 (*17*), and of indium-111 (*21*) through liposome membranes. In the present studies, both commercially available A23187 and oxine were evaluated in order to maximize the potential loading efficiency of actinium-225 in liposomes. A23187 and oxine are lipophilic molecules and act as ionophores by forming complexes with cations resulting in effective shielding (camouflage) of their charge. These complexes can diffuse across the hydrophobic region of the lipid bilayer membranes. It is possible that more than one molecule of A23187 or oxine forms a complex with the radionuclides (*21, 33, 34*). Complexes containing different numbers of ionophores per radionuclide will result in different configurations with variable diffusion rates across the lipid bilayer (*33*). Potentially different rates of diffusion across the bilayer could affect the yield of liposome loading with radionuclides. In addition, to effectively load liposomes, the complexes of the encapsulated chelant DOTA and the transported radionuclides should be more stable than the complexes of radionuclides with the ionophores used to facilitate the radionuclide transport across the liposome membrane. DOTA is described to form stable chelates with ^{225}Ac (*7*), and was therefore encapsulated into liposomes. The encapsulated buffers studied in this work (acetate and citrate) were chosen on the basis of literature reports (*7, 17*), and the pH of the aqueous liposome phase (4.0 to 4.5) was chosen to agree with typical reported conditions for optimal chelation of ^{225}Ac by DOTA (*7*) and to completely avoid potential hydrolysis of the ^{225}Ac cations. The absence of encapsulated chelators in liposomes is reported to not result in loading of liposomes with radionuclides (*33*). In our studies, the loading temperature was set above the T_g of the liposome membranes, evaluated by DSC, in order to increase the membrane fluidity, and, therefore, the permeability of the ionophore/radionuclide complex across the bilayer (*21*). In our studies, the optimal loading temperature was found to be 65 °C. At this temperature, significant membrane transport of the radionuclide/ionophore complexes is observed and chelation of actinium-225 by the encapsulated DOTA occurs with minimal thermal hydrolysis of the lipids comprising the membrane (*25*), and the conjugated antibodies or attached maleimide groups (*22*).

This study shows that ^{225}Ac is loaded to a higher yield in preformed liposomes and is more stably retained over time when the ionophore A23187 is used with liposomes encapsulating citrate buffer. We did not distinctly measure the transport rates across the lipid bilayer of each ionophore−radionuclide complex. However, the diffusion rates of both complexes of ^{225}Ac

with ionophores across the lipid bilayer should be comparable, since in liposomes encapsulating acetate buffer, the loading efficacies are identical for both ionophores over all time points studied. In liposomes containing citrate buffer, oxine resulted in extremely low and time-independent loading of ^{225}Ac. This result could potentially be attributed to slow kinetics of formation of the chelate between ^{225}Ac and the encapsulated DOTA in the presence of citrate buffer. Contrary to oxine, when A23187 delivers the radionuclide in the presence of both acetate and citrate buffers, the chelation reaction to DOTA seems to proceed faster.

All liposomes exhibited significant release of encapsulated contents mainly within the first two hours after the start of incubation into PBS and serum supplemented media at 37 °C. This behavior does not seem to depend on the specific ionophore/buffer combination used, and it is possibly due to the sudden temperature change of the lipid bilayer membranes when liposomes are introduced to 37 °C from room temperature. Heating of the liposomal membrane at temperatures close to the bilayer's transition temperature has been reported to increase the permeability of the bilayer that has been attributed to the presence of grain boundaries (due to lipid packing defects) that melt at these temperatures (*35*, *36*). The membrane of DNPC-cholesterol lipids contains 30 mol % cholesterol and is shown by the DSC thermogram (Figure 1). Cholesterol decreases the range of temperature response of the DNPC-based membrane from 72 °C ($=T_g$ of DNPC lipid) to lower values that extend to the vicinity of 37 °C. Therefore, a hypothesis of formation of transient local melted lipid domains within the lipid bilayer could explain the increased bilayer permeability at the onset of incubation of the liposome suspension from 25 to 37 °C. Alternatively, the initial increased release of contents could be due to differences in osmolarity between the encapsulated liposome contents and the surrounding environment.

Membrane permeability to radionuclides is expected to be a function of the size of radionuclide complex, and the complex's net charge or hydrophobicity. Free radionuclides are charged species and are expected to diffuse across the bilayer membrane very slowly over the period of several days due to the hydrophobic barrier presented by the lipid acyl chains (*37*). In addition, trivalent cations can electrostatically adsorb on the phosphatidyl choline headgroups of lipid membranes (*18*, *33*). It is expected that, for fluid membranes, the membrane permeability to ^{225}Ac-DOTA chelates should be lower than the membrane permeability to ^{225}Ac-ionophore complexes (*21*, *33*, *34*), since ionophores are lipophilic molecules that upon complexation may camouflage the radionuclide's charge, exhibiting increased membrane permeabilities. However, gel phase bilayer membranes, such as those used in the present studies, are expected to exhibit considerably lower diffusivities to all species. Our studies, after the first two hours of incubation at 37 °C, exhibit generally slow release of radioactive contents for 30 days. On the contrary, during the first part of incubation at 37 °C, the extent of formation of transient lipid packing discontinuities due to sudden melting of grain boundaries across the bilayer membrane can be potentially large and comparable to either complexed form of the radionuclide. Such transient structures should allow release of any form of complexed ^{225}Ac.

In the studies of content release from liposomes, the complexed form of the radionuclide (^{225}Ac-DOTA or ^{225}Ac-ionophore) that is released from liposomes was not directly identified. In parallel studies, however, the extent of formation of ^{225}Ac-DOTA chelants compared to ^{225}Ac-ionophore complexes was evaluated in conditions identical to those of the encapsulated aqueous volume during liposome loading. The species of radionuclide complexes were identified using a cation exchange column that selectively challenges the ^{225}Ac-ionophore complexes. Our findings suggest that, after 60 min of incubation in acetate buffer when both the chelant DOTA and the ionophore oxine are present, all of ^{225}Ac is in the form of ^{225}Ac-DOTA chelates. When A23187 is used, after 60 min of incubation (corresponding to 60 min of liposome loading) 47% of the total radioactivity is in the form of ^{225}Ac-DOTA chelates. These studies could be indicative of the complexed forms of the released radioactivity from liposomes during content retention studies. In the presence of citrate buffer, the cation exchange column that was used could not challenge the complexes formed with ^{225}Ac, probably due to the excess of citrate buffer that could be acting as a weak chelant to the radionuclide (*31*, *32*). Nevertheless, it is possible for the enhanced formation of ^{225}Ac-DOTA chelants versus ^{225}Ac-ionophore complexes with increasing incubation times that was observed in the case of acetate buffer to also occur in the case of citrate buffer, independently of the inability of the cation exchange column to selectively challenge and quantitate the different species of complexes.

We developed liposomes and showed that it is possible to achieve as high as 55−73% loading efficacies using PEGylated liposomes containing DNPC lipids and cholesterol. In some cases, after the first 24 h in serum-supplemented media at 37 °C, the remaining radioactivity (as high as 74% of the encapsulated ^{225}Ac for 55% loading yield) is stably retained by liposomes for several weeks. Thus, for 370 MBq (10 mCi) ^{225}Ac initial activity, and 41% ^{225}Ac overall loading/retention efficacy (the product of the aforementioned 55% loading yield and 74% retention), we can project that we can stably encapsulate three ^{225}Ac nuclides per every two liposomes (for 3.3×10^{13} liposomes, starting with 5 μmol lipid, with a mean diameter of 100 nm based on our protocols). Assuming an average number of 50 antibodies per liposome, then each immunoliposome construct results in 1 ^{225}Ac nuclide per 34 lipid-conjugated antibodies. Analogous to immunoreactivity of radiolabeled antibodies that can exceed 80−90% (*6*), immunoliposomes have significantly lower binding capacity (2−4.5%) (*8*, *29*). However, the drug-to-ligand ratios are significantly enhanced for immunoliposomes (1:34) compared to radiolabeled antibodies (1:2300). Although many other factors determine the actual delivered dose at the targeted cancer cells *in vivo*, high encapsulated activities by liposomes could potentially make feasible the α-particle therapy using ^{225}Ac delivered by liposomes. Specific targeting of ^{225}Ac can also be achieved using these liposomes, and as shown in this study, it is possible to develop such immunolabeled liposomes for the delivery of radionuclides while also retaining 80% of their binding efficacy to cancer cells.

Liposome biodistributions and pharmacokinetics commonly include significant uptake by the liver, spleen, and bone marrow. Minimization of toxicities using these delivery vehicles could be achieved by specifically targeting liposomes to cancer cells using surface conjugated antibodies or other targeting ligands forming immunoliposomes. Immunoliposomes can be used for the targeted therapy of circulating micrometastases or of single cancer cells, or for locoregional administration. Direct administration of immunoliposomes at the site where cancer cells reside could lead to faster binding to the target. This may allow for lower liposome doses to be administered, eventually resulting in lower localization at normal organs with lower toxicities.

Our studies on the stability of liposomes in serum-supplemented media could only be indicative of their stability in human blood. It is expected that in the bloodstream the presence of divalent cations and enzymes could contribute to additional liposome destabilization *in vivo* and could result in further release of radioactive contents. Additional studies *in vivo* for

the optimization of these liposome membranes regarding radionuclide retention are in progress.

Micrometastatic disease is still a treatment challenge. Depending on the disease localization throughout the body, targeted liposomes could be potentially used to carry ^{225}Ac which is a powerful α-particle generator. This work suggests that immunoliposomes bearing high specific activities of ^{225}Ac with adequate binding efficacy and specificity to cancer cells can be developed and may potentially be used for targeted α-particle therapy of micrometastatic cancer. *In vivo* evaluation of the stability and targeting specificity of these liposomes is necessary.

ACKNOWLEDGMENT

We thank Dr. George Sgouros at Johns Hopkins University for providing Actinium-225, Dr. David Scheinberg at Memorial Sloan-Kettering Cancer Center (MSKCC) for providing Actinium-225 and for use of his laboratory facilities, Dr. Michael McDevitt (MSKCC) for reading the manuscript and his suggestions, and Mr. Shrirang Karve (Polytechnic University) for assistance with the DSC studies. This study was supported by Polytechnic University and the Othmer Major Project Initiative.

Structure−Activity Investigation on the Gene Transfection Properties of Cardiolipin Mimicking Gemini Lipid Analogues

Avinash Bajaj,[†] Bishwajit Paul,[†] Paturu Kondaiah,[‡] and Santanu Bhattacharya*[,†,§]

Department of Organic Chemistry and Department of Molecular Reproduction, Development and Genetics, Indian Institute of Science, Bangalore 560 012, India, and Chemical Biology Unit of JNCASR, Bangalore 560 064, India. Received December 19, 2007; Revised Manuscript Received March 14, 2008

A structure−activity relationship has been explored on the gene transfection efficiencies of cardiolipin mimicking gemini lipid analogues upon variation of length and hydrophilicity of the spacer between the cationic ammonium headgroups and lipid hydrocarbon chain lengths. All the gemini lipids were found to be highly superior in gene transfer abilities as compared to their monomeric lipid and a related commercially available formulation. Pseudoglyceryl gemini lipids bearing an oxyethylene ($-CH_2-(CH_2-O-CH_2)_m-CH_2-$) spacer were found to be superior gene transfecting agents as compared to those bearing polymethylene ($-(CH_2)_m-$) spacers. The major characteristic feature of the present set of gemini lipids is their serum compatibility, which is most often the major hurdle in liposome-mediated gene delivery.

INTRODUCTION

Gene therapy refers to the introduction of foreign genes into cells with the aim of providing a therapeutic effect (*1*). Several strategies like suicide gene therapy (*2*), corrective gene therapy, and antisense oligonucleotide therapy (*3*) have been used under the umbrella of gene therapy. One of the major hurdles that must however, be overcome in order to succeed in gene therapy is the development of efficient gene delivery vehicles. Natural or engineered viruses are very competent vectors (*4*) toward this end. However, such biological materials have a high risk of being infectious or immunogenic as compared to their synthetic counterparts. This has imposed serious limits on their use. Unlike viral vectors, lipid−DNA complexes are easy to prepare, have no limit in the size of genes that can be delivered, and have low toxicity and significantly low immunogenicity (*5–10*). Various nonviral formulations have been developed with modification at the headgroup region, linker, and hydrophobic parts (*11–30*). We have shown that the use of an ether linkage leads to a significant increase in the transfection efficiency as compared to its ester- or urethane-based cholesterol lipid analogues (*31, 32*).

However, the rational search for new molecular entities for gene delivery continues. For instance, gemini surfactants, possessing two surfactant units covalently joined by a spacer, have been shown to possess unusual aggregation and biological properties (*21, 33–41*). Similarly, gemini lipids constitute a dimeric class of lipids, where two monomeric lipid molecules are joined together through a suitable spacer. The length and the nature of the spacer (e.g., flexibility, hydration, etc.) dramatically influence the aggregation properties of the resulting gemini lipids (*42, 43*). Since the spacer is in the dynamic interfacial region in vesicular aggregates, changes in the length and the nature of the spacer modulate the aggregation properties significantly (*44–46*).

Nature has always been instructive for molecular designers. Cardiolipin (glycerol-bridged phosphatidic acid) constitutes a class of complex phospholipids that occur in the heart and skeletal muscles (*47–49*). Taking the inspiration from the cardiolipins, we reported for the first time the synthesis and membrane-forming properties of pseudoglyceryl backbone based gemini cationic lipids with different spacers (*42, 43*). It was shown that the aggregation behavior, membrane organization, and lipid packing of gemini lipids strongly depend upon the length and the nature of the spacer (*50–52*). We have recently exploited cholesterol and aromatic-based gemini lipids for the delivery of the DNA into mammalian cells and this works efficiently even in the presence of serum; (*53*). These investigations reveal that the gene delivery activity is more efficient with gemini lipids and its efficiency strongly depends on the length and the nature of the spacer between the headgroups (*53–56*). Efficient transfection profiles of the above gemini lipids inspired us to examine the gene transfection properties of the gemini lipids based on the pseudoglyceryl backbone, although a corresponding monomeric lipid (DOTMA) is known to be a commercially available transfection reagent. The aggregation properties of gemini lipids had been reported already (*50, 51*), but there has been no attempt to examine the effect of the length and nature of the spacer on the gene transfection activity.

Toward this end, we have synthesized eight cationic gemini lipids possessing a polymethylene spacer and six additional cationic gemini lipids possessing an oxyethylene spacer between the cationic ammonium headgroups. Thus, we have varied the length and the nature of the spacer between the headgroups, from hydrophobic polymethylene [$-(CH_2)_m-$] to hydrophilic oxyethylene [$-CH_2-(CH_2-O-CH_2)_m-CH_2-$] units (Figure 1). In these two series, we have also examined the effect of variation of the chain length from tetradecyl (n-$C_{14}H_{29}$) to hexadecyl (n-$C_{16}H_{33}$) chains. Though synthetically more demanding, ether functionality was chosen to link the hydrocarbon chains with the pseudoglyceryl backbone to ensure long-term chemical stability of these lipids. We have investigated the transfection properties of all the cationic lipids in detail in HeLa cells both in the absence and in the presence of serum; and compared them

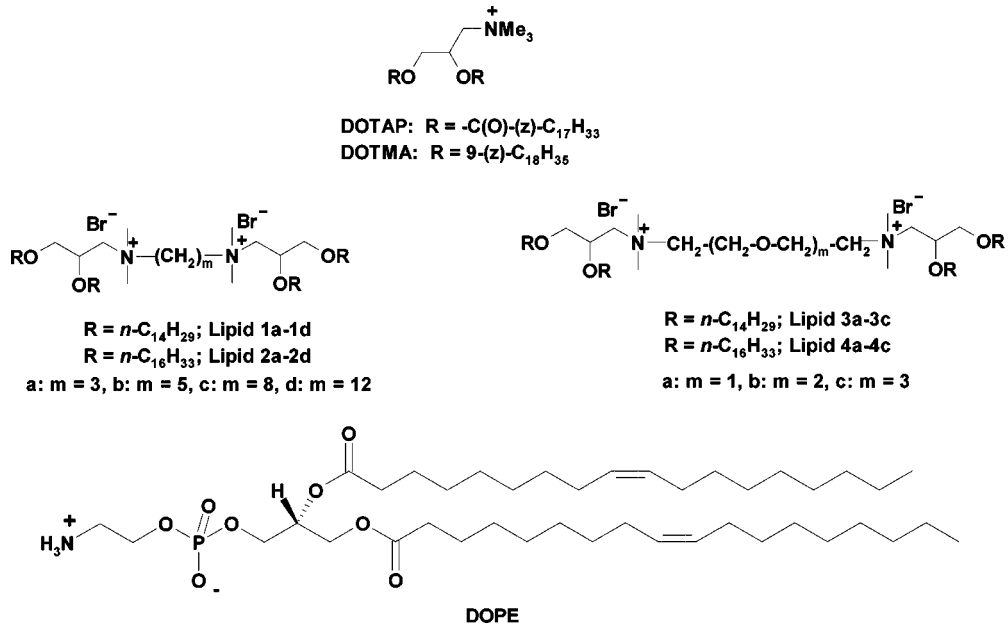

Figure 1. Molecular structures of gemini lipids synthesized and studied in this work, and the structures of DOTMA, DOTAP, and DOPE.

with that of Lipofectin, which is a commercially available 1:1 (w/w) liposomal formulation of DOTMA and DOPE.[1]

EXPERIMENTAL PROCEDURES

Materials and Methods. All reagents, solvents, and chemicals used in this study were of the highest purity available. The solvents were dried prior to use. Column chromatography was performed using 60−120 mesh silica gel. NMR spectra were recorded using a Jeol JNM λ-300 (300 MHz for ^{1}H) spectrometer. The chemical shifts (δ) are reported in ppm downfield from the internal standard: TMS, for ^{1}H NMR. Mass spectra were recorded on a Kratos PCKompact SEQ V1.2.2 MALDI-TOF spectrometer or on a MicroMass ESI-TOF spectrometer or Shimadzu table-top GC-MS or ESI-MS (HP1100LC-MSD). Infrared (IR) spectra were recorded on a Jasco FT-IR 410 spectrometer using KBr pellets or neat. Gemini lipids were synthesized and characterized fully by their ^{1}H NMR, mass spectra, and elemental analysis.

Synthesis. *2,3-Bis-hydroxy-1-benzyloxypropanol (**6**) (**43**).* 1,2-*O*-Isopropylidene glycerol **5** (10 g, 75.6 mmol) was mixed with powdered KOH (8.8 g, 156.6 mmol) in 45 mL of dry benzene. The solution first turned yellow and then rose red within 5 min. Benzyl chloride (19.8 g, 156.6 mmol) was added into the reaction mixture, and the resulting mixture was refluxed for 24 h. The water formed during the reaction was removed by Dean−Stark apparatus. The reaction mixture was allowed to cool down to room temperature, and it was then diluted further with benzene (100 mL) and washed successively with water (80 mL), 0.2 N HCl (50 mL), 3% $NaHCO_3$ (50 mL), and again with water. The benzene layer was separated by separatory funnel, and it was dried over anhydrous Na_2SO_4, and solvent was removed under reduced pressure. The crude product, 1,2-*O*-isopropylidene glycerol benzyl ether, was taken up in 100 mL of MeOH−H_2O (2:1), and *p*-TsOH (5.75 g, 30.3 mmol) was added into it and the mixture was stirred at room temperature for 5 h. The reaction mixture was neutralized with solid $NaHCO_3$. The mixture was filtered and washed with $CHCl_3$, and then the organic layer was evaporated under reduced pressure. The reaction mixture was dissolved in $CHCl_3$ (200 mL) and washed successively with saturated aqueous $NaHCO_3$ (100 mL), water (100 mL), and then saturated brine solution (100 mL). The organic layer was separated, dried over anhydrous Na_2SO_4, and the required compound (R_f∼0.8 at MeOH−$CHCl_3$ (2:98)) was purified by column chromatography over silica gel (60−120 mesh size) using MeOH/$CHCl_3$ (3:97). The isolated yield of **6** was 57%. FT-IR (neat): 3100−3650 cm^{-1} (OH str.). ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 2.65 (br s, 2H, 2 × O*H*), 3.45−3.71 (m, 4H, 2 × CH_2O), 3.75−4.02 (m, 1H, OC*H*), 4.05 (s, 2H, OCH_2Ph), 7.35 (s, 5H, ArH). ESI-MS for $C_{10}H_{14}O_3$: calcd 182.22; found 205 [M + Na$^+$] (*43*).

*2,3-Bis(alkyloxy)-1-benzyloxypropanol (**7a**, **7b**).* A mixture of 2,3-bis-hydroxy-1-benzyloxypropanol, **6**, (16.48 mmol), powdered potassium hydroxide (3.8 g, 65.9 mmol), and appropriate long chain alkyl bromide (49.45 mmol) in dry benzene (50 mL) was refluxed for 24 h with continuous stirring. The water formed during the reaction was removed by using a Dean−Stark apparatus. The reaction mixture was cooled and diluted with ethyl acetate (100 mL), and it was washed successively with water (50 mL), 1 N HCl (50 mL), and 2.5% $NaHCO_3$ solution (50 mL) and again with water. The organic layer was dried over anhydrous Na_2SO_4. The product was purified by column chromatography over silica gel (60−120 mesh) using EtOAc/hexane (5:95). A viscous oily compound was isolated in 85−90% (9.2 g) yield.

*2,3-Bis(tetradecyloxy)-1-benzyloxypropanol (**7a**).* FT-IR (neat): 1115 cm^{-1} (asym. str. of C−O−C). ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 0.78−0.83 (t, 6H, 2 × -CH_3, J = 6 Hz), 1.18 (br m, 44H, 2 × -(CH_2)$_{11}$-), 1.45−1.52 (m, 4H, 2 × -O−CH_2−CH_2), 3.33−3.55 (m, 9H, 4 × -OCH_2 and 1 × -OC*H*), 4.6 (s, 2H, -OCH_2−Ar), 7.21 (s, 5H, Ar*H*). ESI-MS for $C_{38}H_{70}O_3$: calcd 574.98; found 598 [M + Na$^+$].

[1]Abbreviations: DOPE, 1,2-dioleoyl-L-α-glycero-3-phosphatidylethanolamine; DOTMA, *N*-[1-(2,3-dioleyloxy)propane]-*N*,*N*,*N*-trimethylammonium chloride; DOTAP, *N*-[1-(2,3-dioleoyloxy)]-*N*,*N*,*N*-trimethylammonium propane chloride; MFI, mean fluorescence intensity; FACS, fluorescence-activated cell sorting; FBS, fetal bovine serum; DMEM, Dulbecco's Modified Eagle's Medium; MTT, 3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyltetrazolium bromide; GFP, green fluorescence protein; TEM, transmission electron microscope; ESI-MS, electron spray ionization mass spectrometry; MALDI-TOF, matrix assisted laser desorption/ionization time-of-flight; N/P represents the charge ratio of lipid/DNA, where N denotes the charge on lipid because of ammonium headgroup and P represents the charge on DNA because of phosphate.

*2,3-Bis(hexadecyloxy)-1-benzyloxypropanol (**7b**).* FTIR (neat): 1115 cm^{-1} (asym. str. of C−O−C). ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.90 (t, 6H, 2 × -C*H*$_3$), 1.10 (br s, 52H, 2 × -(C*H*$_2$)$_{13}$-), 1.50−1.80 (m, 4H, 2 × -OCH$_2$−C*H*$_2$), 3.40−3.75 (m, 9H, 4 × -OC*H*$_2$ and -OC*H*), 4.55 (s, 2H, -C*H*$_2$Ph), 7.27−7.34 (m, 5H, Ar*H*). ESI-MS for $C_{42}H_{78}O_3$: calcd 631.09; found 630 [M^+] (*43*).

*2,3-Bis(alkyloxy)propanol (**8a**, **8b**).* A solution of appropriate 2,3-bis(alkyloxy)-1-benzyloxypropanol (**7a**, **7b**) (12.94 mmol) in (1:1) mixture of methanol and ethyl acetate (50 mL) was hydrogenated using 10% Pd−C catalyst (0.2 g) for 24 h, at 40 Psi pressure, during which almost all the starting material was converted to the alcohol. Then, Pd−C was filtered off and the solvent was removed. The solid obtained was dissolved in hot ethyl acetate and kept at room temperature for recrystallization. The solid was filtered and washed with hexane. The resulting solid was recrystallized several times to get pure, white solid. The rest of the compound, which was in filtrate, was purified by column chromatography over silica with EtOAc/hexane (1:9) as the eluting solvent ($R_f \sim 0.4$ in EtOAc/hexane (1:9)). The overall yield after purification was 90−94%.

*2,3-Bis(tetradecyloxy)propanol (**8a**).* FT-IR (Nujol): 1115 cm^{-1} (asym. str. of C−O−C), 3471 cm^{-1} (O−H str.). ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.83−0.87 (t, 6H, 2 × -C*H*$_3$, $J = 6$ Hz), 1.23 (br. m, 44H, 2× -(C*H*$_2$)$_{11}$-), 1.52 (m, 4H, 2 × -O−CH$_2$−C*H*$_2$), 3.39−3.68 (m, 9H, 4 × -OC*H*$_2$ and 1 × -OC*H*). ESI-MS for $C_{31}H_{64}O_3$: calcd 484.85; found 484 [M^+].

*2,3-Bis(hexadecyloxy)propanol (**8b**).* FT-IR (Nujol): 1115 cm^{-1} (asym. str. of C−O−C), 3471 cm^{-1} (O−H str.). ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.89 (t, 6H, 2 × -C*H*$_3$), 1.15−1.40 (br. s, 52H, 2 × (C*H*$_2$)$_{13}$-), 1.50−1.80 (m, 4H, 2 × -OCH$_2$−C*H*$_2$), 3.40−3.75 (m, 9H, 4 × -OC*H*$_2$ and 1 × - OC*H*). ESI-MS for $C_{35}H_{72}O_3$: calcd 540.96; found 540 [M^+] (*43*).

*2,3-Bis(alkyloxy)propylbromide (**9a**, **9b**).* To a well-stirred solution of 2,3-bis(alkyloxy)propanol (**8a**, **8b**) (3.7 mmol) and CBr_4 (2.46 g, 7.4 mmol.) in dry CH_2Cl_2 (85 mL) at ∼15 °C, a solution of Ph_3P (1.47 g, 5.6 mmol.) in dry CH_2Cl_2 (7 mL) was added dropwise over a period of 30 min. The reaction mixture was stirred at room temperature for another 12 h until TLC showed the disappearance of the spot due to starting material. Dichloromethane was removed under vacuum and the residual mass was repeatedly extracted using hexane. The combined extract was evaporated to dryness. The required compound was purified by column chromatography over a silica gel (60−120 mesh) column using hexane and EtOAc mixture. The fraction, which was collected using EtOAc/hexane (1:50) on removal of organic solvent, afforded a viscous liquid in quantitative yield. It solidified on standing. The pure compound gave a spot with R_f value of 0.8 in EtOAc/hexane (1:4).

*2,3-Bis(tetradecyloxy)propylbromide (**9a**).* FT-IR (Nujol): 1121 cm^{-1} (asym. str. of C−O−C). ^1H NMR ($CDCl_3$ 300 MHz) δ: 0.86−0.90 (t, 6H, 2 × -C*H*$_3$, $J = 6$ Hz), 1.26 (br. m, 44H, 2 × -(C*H*$_2$)$_{11}$-), 1.51−1.58 (m, 4H, 2 × -OC*H*$_2$-CH$_2$), 3.43−3.58 (m, 9H, 3 × -OC*H*$_2$, 1 × -OC*H*, 1 × -C*H*$_2$Br). MALDI-TOF for $C_{31}H_{63}BrO_2$: calcd 547.75; found 546.5 [M^+].

*2,3-Bis(hexadecyloxy)propylbromide (**9b**).* FT-IR (Nujol): 1121 cm^{-1} (asym. str. of C−O−C). ^1H NMR ($CDCl_3$ 300 MHz) δ: 0.89 (t, 6H, 2 × -C*H*$_3$), 1.15−1.40 (br. s, 52H, 2 × -(C*H*$_2$)$_{13}$-), 1.54−1.8 (m, 4H, 2 × -OCH$_2$−C*H*$_2$), 3.33−3.50 (m, 9H, 3 × -OC*H*$_2$, 1 × -OCH, 1 × -OC*H*$_2$Br). MALDI-TOF for $C_{35}H_{71}BrO_2$: calcd 603.86; found 626.5 [M + Na]$^+$ (*43*).

*D,L-[1,2-Di-O-alkyloxy-3-(N,N′-dimethylamine)] Propane (**10a**, **10b**).* Dry NMe_2 gas was dissolved in anhydrous ethanol (5.0 mL) in a screw-top pressure tube at 0 °C, so that volume increased to 15 mL. To this solution, individual bromohydrin **9a** or **9b** (1.66 mmol) in dry ethanol (3.0 mL) was added (3.0 mL) at 0 °C. The tube was heated with stirring at 80 °C for 48 h. Solvent was removed to furnish a crude white mass, which was recrystallized several times from $CHCl_3$/acetone/EtOAc (1:10:1) mixture.

*D,L-[1,2-Di-O-tetradecyloxy-3-(N,N′-dimethylamine)] Propane (**10a**).* ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.83−0.87 (t, 6H, 2 × -C*H*$_3$, $J = 6$ Hz), 1.23 (br m, 44H, 2 × -(C*H*$_2$)$_{11}$-), 1.54 (m, 4H, 2 × -OCH$_2$−C*H*$_2$), 2.24 (s, 6H, -N(C*H*$_3$)$_2$), 2.30−2.38 (m, 2H, -C*H*$_2$N), 3.38−3.60 (m, 7H, 3 × -OC*H*$_2$, 1 × -OC*H*). ESI-MS for $C_{33}H_{69}NO_2$: calcd 511.92; found 512.54 [M + H^+].

*D,L-[1,2-Di-O-hexadecyloxy-3-(N,N′-dimethylamine)] Propane (**10b**).* ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.83−0.87 (t, 6H, 2 × -C*H*$_3$, $J = 6$ Hz), 1.26 (br m, 52H, 2 × -(C*H*$_2$)$_{11}$-), 1.54 (m, 4H, 2 × -OCH$_2$−C*H*$_2$), 2.28 (s, 6H, -N(C*H*$_3$)$_2$, 2.29−2.43 (m, 2H, -C*H*$_2$N), 3.38−3.58 (m, 7H, 3 × -OC*H*$_2$, 1 × -OC*H*). ESI-MS for $C_{37}H_{77}NO_2$: calcd 568.03; found 568.6 [M^+].

General Method for the Synthesis of Gemini Lipids. A solution of **10a** or **10b** (1.0 mmol) and appropriate dibromoalkane (0.33 mmol) in dry MeOH−EtOAc mixture was refluxed over a period of 48−96 h. It was cooled, and solvent was evaporated to give a crude solid. It was repeatedly washed with dry acetone to remove the traces of unreacted starting material and finally subjected to repeated crystallizations from a mixture of either acetone and methanol (∼9:1) or ethyl acetate and methanol (∼9:1). Repeated crystallizations afforded a white compound found to be pure by TLC, R_f ∼020−0.30 in $CHCl_3$/MeOH, 10:1 (yield 50−70%). All compounds were found to be hygroscopic, and a few of them also crystallized as hydrates despite prolonged drying under vacuum. They gave satisfactory ^1H NMR, ESI-MS, and elemental analysis.

Pertinent spectroscopic data are given below.

*Lipid **1a**: Propanediyl-α,ω-bis[D,L-N-(1,2-di-O-tetradecyl-3-propyl)-N,N-dimethylammonium bromide].* ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.85 (t, 12H, 4 × -C*H*$_3$), 1.25−1.50 (br. s, 88H, 4 × -(C*H*$_2$)$_{11}$-), 1.55−1.80 (br. m, 8H, 4 × -O−CH$_2$−C*H*$_2$), 2.70−2.73 (br m, 2H, -N$^+$CH$_2$C*H*$_2$CH$_2$N$^+$-), 3.36−4.14 (m, 34H, 2 × -N$^+$(C*H*$_3$)$_2$, 6 × −O−C*H*$_2$−CH$_2$, 2 × −O−C*H*−CH$_2$, and 2 × -C*H*$_2$NC*H*$_2$-). ESI-MS for $C_{69}H_{144}N_2O_4Br_2$: calcd 1225.73; found 532.6 [M^{+2}/2], 1146.0 [M^{+2} + Br^-] Elemental analysis (%) for $C_{69}H_{144}N_2O_4Br_2$: calcd C 67.61, H 11.84, N 2.29; found C 67.34, H 11.65, N 2.37.

*Lipid **1b**: Pentanediyl-α,ω-bis[D,L-N-(1,2-di-O-tetradecyl-3-propyl)-N,N-dimethylammonium bromide].* ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.85 (t, 12H, 4 × -C*H*$_3$), 1.25−1.50 (br m, 88H, 4 × -(C*H*$_2$)$_{11}$-), 1.51 (br m, 8H, 4 × -O−CH$_2$−C*H*$_2$), 1.98 (br m, 6H, -N$^+$CH$_2$C*H*$_2$C*H*$_2$C*H*$_2$CH$_2$N$^+$-), 3.36−4.0 (m, 34H, 2 × -N$^+$(C*H*$_3$)$_2$, 6 × -O−C*H*$_2$−CH$_2$, 2 × -O−C*H*−CH$_2$, and 2 × -C*H*$_2$NC*H*$_2$-). ESI-MS for $C_{71}H_{148}N_2O_4Br_2$: calcd 1253.78; found 546.62 [M^{+2}/2], 1174.1 [M^{+2} + Br^-]. Elemental analysis (%) for $C_{71}H_{148}N_2O_4Br_2$: calcd C 68.02, H 11.90, N 2.23; found C 67.99, H 11.65, N 2.66.

*Lipid **1c**: Octanediyl-α,ω-bis[D,L-N-(1,2-di-O-tetradecyl-3-propyl)-N,N-dimethylammonium bromide].* ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.85 (t, 12H, 4 × -C*H*$_3$), 1.25−1.50 (br m, 100H, 4 × -(C*H*$_2$)$_{11}$- and -N$^+$CH$_2$(C*H*$_2$)$_6$CH$_2$N$^+$-), 1.55 (br m, 8H, 4 × -O−CH$_2$−C*H*$_2$), 3.33−4.03 (m, 34H, 2 × -N$^+$(C*H*$_3$)$_2$, 6 × -O−C*H*$_2$−CH$_2$, 2 × -O−C*H*−CH$_2$, and 2 × -C*H*$_2$NC*H*$_2$-). ESI-MS for $C_{74}H_{154}N_2O_4Br_2$: calcd 1295.86; found 567.7 [M^{+2}/2], 1216.1 [M^{+2} + Br^-]. Liposome Preparation. Individual lipid or its mixture with DOPE in the desired mole ratio was dissolved in chloroform in autoclaved Wheaton glass vials. Thin films were made by evaporation of the organic solvent under a steady stream of dry nitrogen. Last traces of organic solvent were removed by keeping these films under vacuum overnight. Freshly autoclaved water (Milli-Q) was added to individual film such that the final concentration of the cationic lipid was 1 mM. The mixtures were kept for hydration at 4 °C for 10−12 h and were repeatedly freeze−thawed (ice-cold water to 70 °C) with intermittent vortexing to ensure hydration. Sonication of these suspensions for 15 min in a bath sonicator at 70 °C afforded closed cationic liposomes as evidenced from transmission electron microscopy. Liposomes were prepared and kept under sterile conditions. Formulations were stable and, if stored frozen, possessed long shelf-life.

Transmission Electron Microscopy. Freshly prepared aqueous suspensions of each cationic lipid (1 mM) or lipoplex were examined under transmission electron microscopy by negative staining using 1% uranyl acetate. A 10 μL sample of the suspension was loaded onto Formvar-coated, 400 mesh copper grids and allowed to remain for 1 min. Excess fluid was wicked off the grids by touching their edges to filter paper, and 10 μL of 1% uranyl acetate was applied on the same grid after which the excess stain was similarly wicked off. The grid was air-dried for 30 min, and the specimens were observed under TEM (JEOL 200-CX) operating at an acceleration voltage of 120 keV. Micrographs were recorded at a magnification of 5000−20 000×.

Plasmid DNA. pEGFP-c3 (Clontech, USA), which encodes for an enhanced green fluorescence protein (GFP) under a CMV promoter, was amplified in *Escherichia coli* (DH5α) and purified using Qiagen Midi Prep Plasmid Purification protocol (Qiagen, Germany). Purity of the plasmid was checked by electrophoresis

on 1.0% agarose gel. Concentration of the DNA was estimated spectroscopically by measuring the absorption at 260 nm and confirmed by gel electrophoresis. The plasmid preparations showing a value of $OD_{260}/OD_{280} > 1.8$ were used.

Cell Culture. Cells (HeLa) were cultured in Dulbecco's Modified Eagle's Medium (DMEM; Sigma) supplemented with 10% fetal bovine serum (FBS) in T25 culture flasks (Nunc, Denmark) and were incubated at 37 °C in a humidified atmosphere containing 5% CO_2. Cells were regularly passaged by trypsinization with 0.1% trypsin (EDTA 0.02%, dextrose 0.05%, and trypsin 0.1%) in PBS (pH 7.2).

Cytotoxicity. Toxicity of each cationic lipid formulation toward HeLa cells was determined using 3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyltetrazolium bromide (MTT) reduction assay following literature procedures (*57, 58*). Cytotoxicity levels of the lipid formulations optimal for transfection experiments were found out under conditions exactly similar for transfection conditions. Nearly 12 000 cells/well were plated in 96 well plates. After 24 h, optimized lipid/DOPE formulations were complexed with 0.2 μg of the DNA at various N/P ratios for 30 min. DNA−lipid complexes were added to the cells in the absence of serum. After 6 h of incubation, lipoplexes were removed and 200 μL of media with 10% FBS was added. After 42 h, 20 μL of MTT solution was added and the cells were incubated further for 4 h. Blue formazan crystals were seen when checked under microscope. Media was removed and 200 μL of DMSO was added per well. The absorbance was measured using a microtiter plate reader. The % viability was then calculated as $[\{A_{590}(\text{treated cells}) - \text{background}]/[A_{590}(\text{untreated cells}) - \text{background}\}] \times 100$.

Transfection Procedure. All transfection experiments were carried out in HeLa Cells in antibiotic-free media unless specified otherwise. In a typical experiment, 24-well plates were seeded with 45 000 cells/well in antibiotic-free media 24 h before transfection such that they were at least ~70% confluent at the time of transfection. For transfection, lipid formulation and DNA were serially diluted separately in DMEM containing no serum to have the required working stocks. DNA was used at a concentration of 0.8 μg/well unless specified otherwise. The lipid and DNA were complexed in a volume of 200 μL by incubating the desired amount of lipid formulation and DNA together at room temperature for about 30 min. The lipid concentrations were varied so as to obtain the required lipid/DNA (N/P) charge ratios. Charge ratios here present the ratio of charge on cationic lipid (in mol) to nucleotide base molarity and were calculated by considering the average nucleotide mass of 330. After 30 min of complexation, 200 μL of media was added to the complexes (final DNA concentration = 12.12 μM). Old media was removed from the wells, cells were washed with DMEM, and lipid−DNA complexes in 200 μL media were added to the cells. The plates were then incubated for 6 h at 37 °C in a humidified atmosphere containing 5% CO_2. At the end of incubation period, media was removed and cells were washed with DMEM; 500 μL of DMEM containing 10% FBS was added per well. Plates were further incubated for a period of 42 h before checking for the reporter gene expression. GFP expression was examined by fluorescence microscopy and was quantified by flow cytometry analysis. Control transfections were performed in each case by using commercially available transfection reagent Lipofectin using standard conditions specified by the manufacturer. All the experiments were done in duplicate, and results presented are the average of at least two such independent experiments done on two different days.

For transfections in the presence of serum, lipid and DNA were separately diluted in serum-free media as already mentioned and the complexation was done in serum-free media (200 μL) for 30 min. The complex was then diluted to 400 μL with DMEM containing 20% FBS so as to achieve a final serum concentration of 10%. The cells were then incubated with this complex for 6 h. At the end of the incubation period, medium was removed and cells were washed with DMEM; 200 μL of DMEM containing 10% FBS was added per well.

Gel Retardation. To examine the complexation of DNA with cationic lipid suspensions at different lipid-DNA ratios, we prepared lipid−DNA complexes at different lipid−DNA charge ratios in an identical manner as was done with transfection experiments. After 30 min of incubation, these complexes were electrophoretically run on a 1.0% agarose gel. The uncomplexed DNA moved out of well, but the DNA that was complexed with lipid remained inside the well (*59*).

Flow Cytometry. The reporter gene expression was examined by fluorescence microscopy at regular intervals and was quantified 48 h post-transfection by flow cytometry. Percentages of transfected cells were obtained by determining the statistics of cells fluorescing above the control level whereas nontransfected cells were used as the control. Approximately 10 000 cells were analyzed to achieve the statistical data, which have been presented as the average of at least two independent measurements. For flow cytometry analysis, ~48 h post-transfection, old media was removed from the wells; cells were washed with PBS and trypsinized by adding 100 μL of 0.1% trypsin. To each well, 200 μL of PBS containing 20% FBS was added. Duplicate cultures were pooled and analyzed by flow cytometry immediately using a Becton and Dickinson flow cytometer equipped with a fixed laser source at 488 nm.

FACS Analysis. FACS data were analyzed by public domain *WinMDI* software to eliminate data from cell debris (particles smaller than cells), dead cells, and clumps of two or more cells. Subcellular debris and clumps can be distinguished from single cells by size (estimated by the intensity of low angle forward scatter). Dead cells have lower forward scatter and higher side scatter than living cells. The FACS scans had been configured to display the fluorescence signals only from those particles with a specified set of scatter properties, namely, living single cells. This is called a scatter-gated fluorescence analysis. Therefore, the data from dead cells had been eliminated by gating out brightly fluorescent cells.

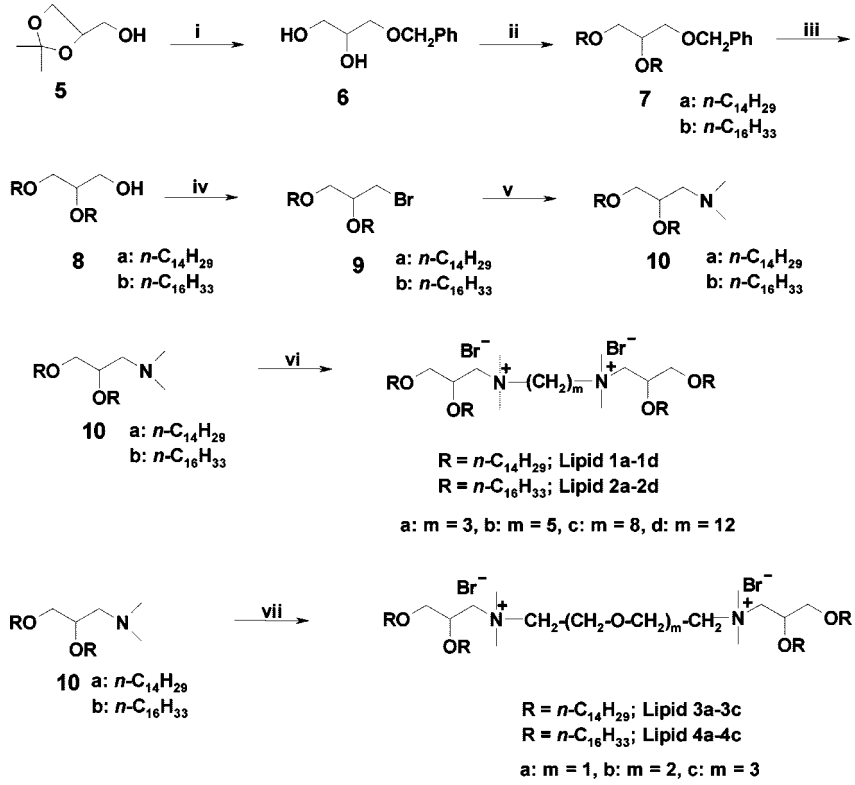
Membrane Hydration Studies. Membrane hydration studies on lipid vesicles were performed using Paldan as a hydrated probe (*50*). All the fluorescence experiments were carried out on sonicated lipid suspensions using a lipid-to-probe ratio 1000:3. The width of excitation and emission slit was 5 nm. Generalized polarization of emission (GP) was calculated using the equation

$$GP_{em} = \frac{I_{440} - I_{490}}{I_{440} + I_{490}} \quad (1)$$

where I_{440} and I_{490} represent the fluorescent intensities at 440 and 490 nm. For the GP values reported herein, an excitation wavelength of 350 nm was used. The lower the GP value is, the higher the hydration (*50*). Therefore, we calculated the parameter called membrane hydration by inversing and normalizing the GP values such that the parameter values increase with increase in membrane hydration.

Differential Scanning Calorimetry. Multilamellar vesicles of 1 mM concentration were prepared in degassed water as mentioned above, and their thermotropic behavior was investigated by high-sensitivity differential scanning calorimetry using a CSC-4100 model, multicell differential scanning calorimeter (Calorimetric Science Corporation, Utah, USA). A baseline thermogram was obtained using degassed water (0.5 mL) in all the ampoules including the reference cell to normalize cell to cell differences. Samples were taken in the cells such that the differences in weight with the baseline experiment to the sample

Scheme 1[a]



[a] Reagents and Conditions. (i) (a) KOH, $PhCH_2Cl$, benzene, reflux, 24 h; and (b) *p*-TsOH, MeOH−H_2O, rt, 5 h; overall 57% isolated yield. (ii) *n*-$C_{14}H_{29}Br$ or *n*-$C_{16}H_{33}Br$, KOH, benzene (Dean-Stark), reflux, 24 h, 85−90%; (iii) 10% Pd−C, H_2 (40 psi), MeOH−EtOAc (1:1), 24 h, 90−94%; (iv) CBr_4, Ph_3P, CH_2Cl_2, 10 °C (30 min), rt (12 h), quantitative yield; (v) Me_2NH (excess), MeOH−EtOAc, rt, 24 h, 95%; (vi) $Br(CH_2)_mBr$, MeOH−EtOAc (2:1), 80 °C, screw-top pressure tube, 48−96 h, 40−50%; (vii) $BrCH_2(CH_2OCH_2)_mCH_2Br$, MeOH−EtOAc (2:1), 80 °C, screw-top pressure tube, 48−96 h, 40−50%.

run were less than 0.001 g in the respective ampoules. The measurements were carried out in the temperature range 20−90 °C. The scan rate was 20 °C per hour for all the lipids. The thermograms for vesicular suspensions were obtained by subtracting the respective baseline thermogram from the sample thermogram using the software CpCalc provided by the manufacturer.

Ethidium Bromide Intercalation Assay (*60*). Fluorescence emission due to ethidium bromide (EB) at 590 nm was monitored in a Hitachi model F-4500 spectrofluorimeter (λ_{ex} = 526 nm with 10 nm slit widths for both excitation and emission). Typically, emission was measured for EB (25 μM) in 5 mM HEPES, 0.1 M NaCl, pH 7.4 buffer. To this, CT-DNA (40 μM) was added and again emission due to EB upon intercalative complexation with DNA was measured at 25 °C. Then, an aliquot of a given liposome (2 μM) was added into performed EB/CT−DNA complex in 5 mM HEPES (pH 7.4) buffer. This resulted in the fluorescence quenching due to displacement of EB molecules from intercalated sites caused due to distortion in the DNA double-helix upon addition of cationic lipid aggregates. Progressive addition of SDS (2 μM aliquot) to cationic lipid/DNA complex formed as described resulted in the release of DNA from cationic lipid/DNA complex. Due to release of DNA, EB gets reintercalated and fluorescence emission increases. If F_0 is the fluorescence intensity (FI) of unintercalated and F_{max} is the FI of fully intercalated EB, and F_x is the FI for a given concentration of liposome or SDS, then % FI = $(F_x - F_0)/(F_{max} - F_0)$.

RESULTS AND DISCUSSION

Chemistry. The pseudoglyceryl backbone, which is similar to the glycerol-based, naturally occurring phospholipids, was considered for the synthesis of new gemini cationic lipids. Fourteen gemini lipids differing in the hydrocarbon chains and the length and nature of the spacers between the cationic headgroups have been synthesized using previously reported procedures (*61*). First, the CH_2OH group of the primary building block, 1,2-isopropylidene glycerol **5**, was protected in the form of benzyl ether (Scheme 1). Then, the isopropylidene group was removed by treatment with *p*-TsOH in aqueous MeOH to obtain **6** in 57% isolated yield (Scheme 1). The diol **6** was fully alkylated using 3 equiv of *n*-tetradecyl bromide (*n*-$C_{14}H_{29}Br$) or *n*-hexadecyl bromide (*n*-$C_{16}H_{33}Br$) in the presence of KOH under reflux conditions to give **7a** or **7b** in 85−90% yields, which upon hydrogenolysis at 40 psi pressure in the presence of 10% Pd−C afforded **8a**/**8b** in quantitative yields. In a subsequent step, alcohols (**8a**, **8b**) were converted to the corresponding bromides (**9a**, **9b**) in quantitative yields by reaction with PPh_3/CBr_4 in dry dichloromethane. Bromides **9a**, **9b** were then reacted with Me_2NH in EtOAc−MeOH (1:1) mixture to give **10a** and **10b** in ∼95% yields. The gemini lipids have been synthesized from the precursor 1,2-di-*O*-tetradecyl-3-(dimethylamino)]propane (**10a**) or 1,2-di-*O*-hexadecyl-3-(dimethylamino)]propane (**10b**) by reacting it with corresponding α,ω-dibromoalkanes or α,ω-dibromoethoxyalkanes in pressure tube at 80 °C for 48−96 h. All the newly synthesized lipids including gemini lipids have been purified by repeated precipitation with mixtures of MeOH, EtOAc, and acetone. The resulting lipids were characterized by ^1H NMR, mass spectroscopy, and elemental analysis, and the spectral and analytical data were consistent with their assigned structures.

Aggregate Formation from Cationic Gemini Lipids and Mixed Liposome formation with DOPE. Liposomes could be conveniently prepared from each gemini lipid alone or with

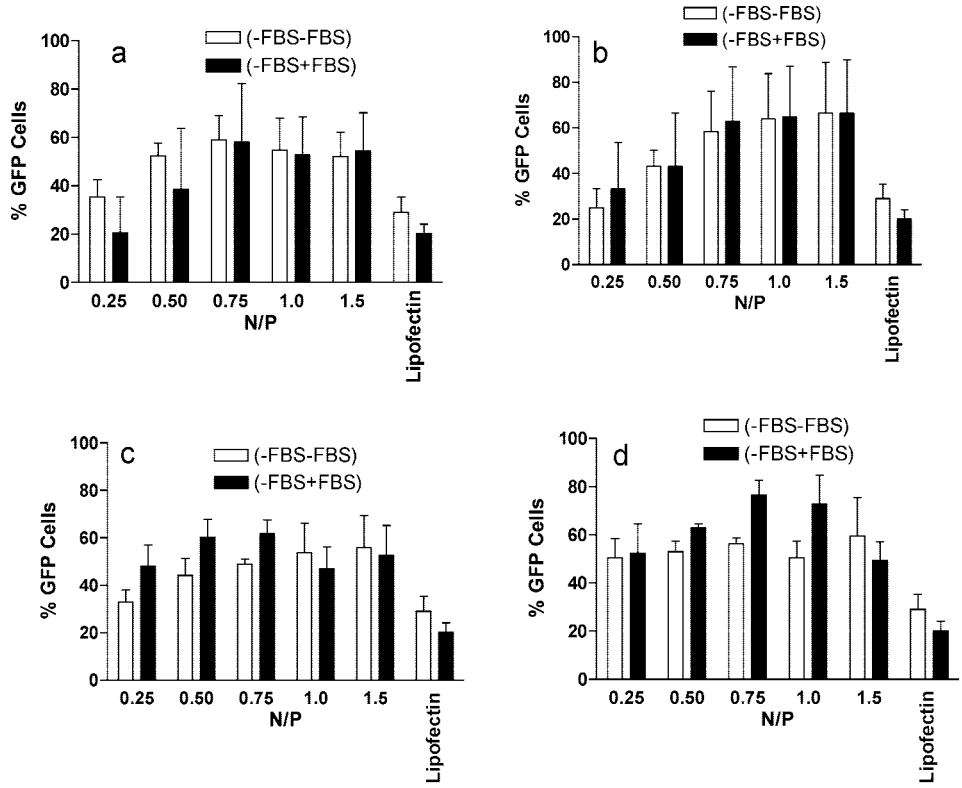


Figure 2. Transfection efficiencies of gemini lipids using optimized lipid/DOPE formulations at various N/P ratios in the absence (-FBS − FBS) and the presence (-FBS + FBS) of serum. (a) **1a**; (b) **1b**; (c) **1c**; (d) **1d**. Concentration of the DNA = 0.8 μg/well. Data expressed as number of GFP positive cells as obtained from flow cytometry analysis.

naturally occurring helper lipid 1,2-dioleoyl-L-α-glycero-3-phosphatidyl ethanolamine (DOPE) by first subjecting the films of lipid mixtures to hydration, repeated freeze−thaw cycles, followed by sonication at 70 °C for 15 min. All the lipid molecules mentioned here formed stable, optically clear suspensions in water. Gemini lipids with oxyethylene spacers have been found to get dispersed more easily than the lipids with polymethylene spacers. Generally, TEM examination of air-dried, aqueous suspensions revealed the existence of closed aggregate structures for all the gemini lipids (not shown) (*50, 51*). Vesicles were prepared under sterile conditions and were resonicated for 5 min at room temperature before transfection experiments. The vesicular suspensions were sufficiently stable, and no precipitation was observed within three months if stored at 4 °C.

Transfection Biology. *Optimization of Lipid/DOPE Ratio.* The neat lipid suspensions were found to show low transfection efficacies (not shown). Naturally occurring lipids such as DOPE has been known to increase the efficiency of transfection in lipid-mediated gene transfer applications (*62*) Accordingly gemini lipid/DOPE mixed lipid suspensions were examined for transfection. In order to determine the most effective formulation, transfections with identical lipid/DNA mole ratio (or N/P ratio) by variation of the mole ratios of gemini lipids in DOPE were done. To determine the optimized transfection efficiency, both the number of transfected cells and the mean fluorescence intensity were considered. The mean fluorescence intensities (MFI) defined for GFP-positive cells reveal that the level of GFP expression with a higher MFI value correlates positively with high GFP expression (*19*). These data were obtained from flow cytometric analysis. All the lipids except lipid **3c** showed maximum transfection efficiency at a lipid/DOPE mole ratio of 1:2, whereas the lipid/DOPE optimization ratio for lipid **3c** was found to be 1:3.

Optimization of Lipid/DNA Charge Ratio. The cationic liposomes of gemini lipids were prepared in an optimized lipid/DOPE mole ratio, and EGFP-c3 plasmid DNA was used as the reporter gene across the lipid/DNA charge ratios from 0.25:1 to 1.5:1. It should be noted that 1 mol of cationic gemini lipid possesses two units of charges. Therefore, the transfections were performed in lipid/DNA mole ratios from 0.125:1 to 0.75:1. Gemini lipids showed significantly enhanced transfection efficiency as compared to commercially available reagent, Lipofectin. Lipofectin is a monomeric lipid, structurally related to the present set of lipids, and is based on a 1:1(w/w) ratio of DOTMA/DOPE formulation. Among gemini lipids, transfection efficiency was found to be dependent upon the length and nature of the spacer between headgroups and also on the hydrocarbon chain lengths.

Polymethylene Spacer-Based Gemini Lipids. Among lipids **1a**−**1d**, lipid **1b** possessing a pentamethylene (-$(CH_2)_5$-) spacer was found to be the best transfecting agent, and with the further increase in the length of the spacer, the transfection efficiency decreased as shown in Figure 2. However, in the presence of serum, lipid **1d** possessing a longer spacer (-$(CH_2)_{12}$- showed enhanced transfection efficiency, transfecting nearly 70% of the cells. DOPE mixed lipid **1a**−**1d** formulations possessing *n*-$C_{14}H_{29}$ chains were found to be better transfecting agents than the lipid formulations **2a**−**2d** bearing *n*-$C_{16}H_{33}$ chains. Among lipids **2a**−**2d**, **2a** and **2b** were found to be better transfecting agents than other analogues as presented in Figure 3. However, the major drawback of gemini lipid **2a** formulation was its lack of compatibility with serum, as the transfection efficiency decreased drastically in the presence of 10% serum. In case of other lipid (**2b**−**2d**) formulations, there was little decrease in the transfection efficacies in the presence of 10% serum. Lipid **1a**−**1d** formulations showed maximum transfection efficiency at lipid/DNA charge ratio of 1.0 and transfection profiles

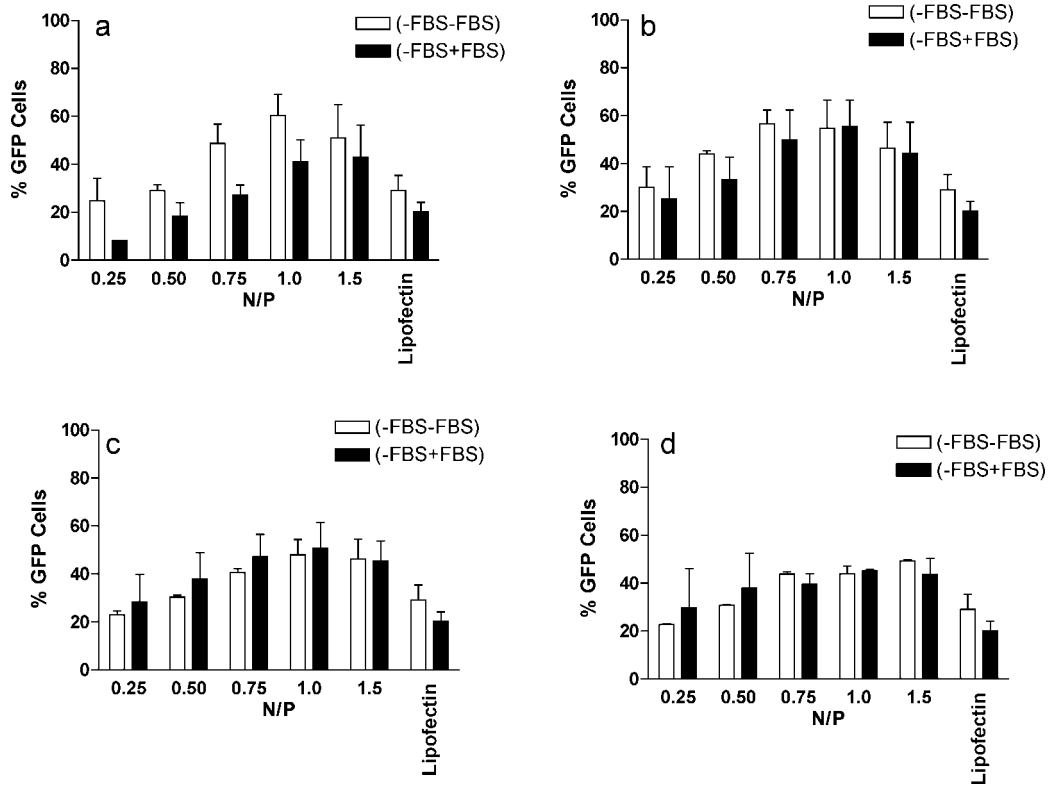

Figure 3. Transfection efficiencies of gemini lipids using optimized lipid/DOPE formulations at various N/P ratios in the absence (-FBS − FBS) and the presence (-FBS + FBS) of serum. (a) **2a**; (b) **2b**; (c) **2c**; (d) **2d**. Concentration of the DNA = 0.8 μg/well. Data expressed as number of GFP positive cells as obtained from flow cytometry analysis.

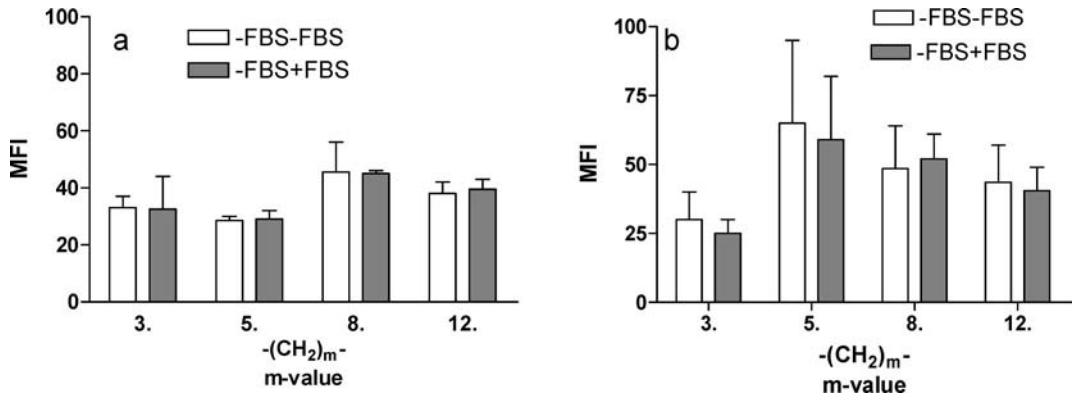

Figure 4. Effect of the length of the spacer on the MFI observed in the case of gemini lipid formulations in the absence (-FBS − FBS) and the presence (-FBS + FBS) of serum (a) *n*-$C_{14}H_{29}$ based gemini lipids (b) *n*-$C_{16}H_{33}$ based gemini lipids. Concentration of the DNA = 0.8 μg/well. Data expressed as MFI as obtained from flow cytometry analysis.

followed a bell-shaped graph. With lipid **2a**−**2d** formulations, maximum transfection efficiencies were achieved at the lipid/DNA charge ratio of 1.5. Comparative transfection profiles showed that the gemini lipids bearing *n*-$C_{14}H_{29}$ chains were better transfecting agents as compared to the lipids bearing *n*-$C_{16}H_{33}$ chains and the optimized length of the spacer was -$(CH_2)_5$- toward this end.

Mean fluorescence intensities (MFI) observed from the FACS scans after the transfection with gemini lipid formulations in the absence and presence of serum is shown in Figure 4. MFI provides an estimate of the average amount of protein expressed inside the transfected cells, which also indirectly indicates the amount of the DNA delivered inside the cells. MFI results suggest that the amount of the DNA delivered by gemini lipid **1a**−**1d** formulations was comparatively less than that in case of **2a**−**2d**. Gemini lipid **2b** formulation possessing *n*-$C_{16}H_{33}$ chains and a -$(CH_2)_5$- spacer showed maximum MFI. With an increase in the length of the spacer in the gemini lipid, the MFI decreased. As mentioned earlier, the gemini lipid **1b** possessing *n*-$C_{14}H_{29}$ chains with a -$(CH_2)_5$- spacer showed maximum transfection activity in terms of the number of cells, but the MFI observed here was nearly half that of lipid **2b/DOPE** formulation. These results suggest that the lipid **1b/DOPE** formulation transfects the maximum number of cells, whereas lipid **2b/DOPE** transfects maximum amount of the DNA into the cells among the polymethylene spacer-based gemini lipids.

Oxyethylene Spacer-Based Gemini Lipids. Transfection efficacy of oxyethylene spacer based gemini lipids are shown in Figures 5–8. In the absence of serum, DOPE-containing lipid (**3a**−**3c**) formulations were found to be as effective as Lipofectin in terms of the number of transfected cells (Figure 5), whereas to our great surprise, in the presence of 10% serum, the transfection efficacy of gemini lipids (**3a**−**3c**) increased dramatically. Lipid **3a-DOPE** formulation was able to transfect

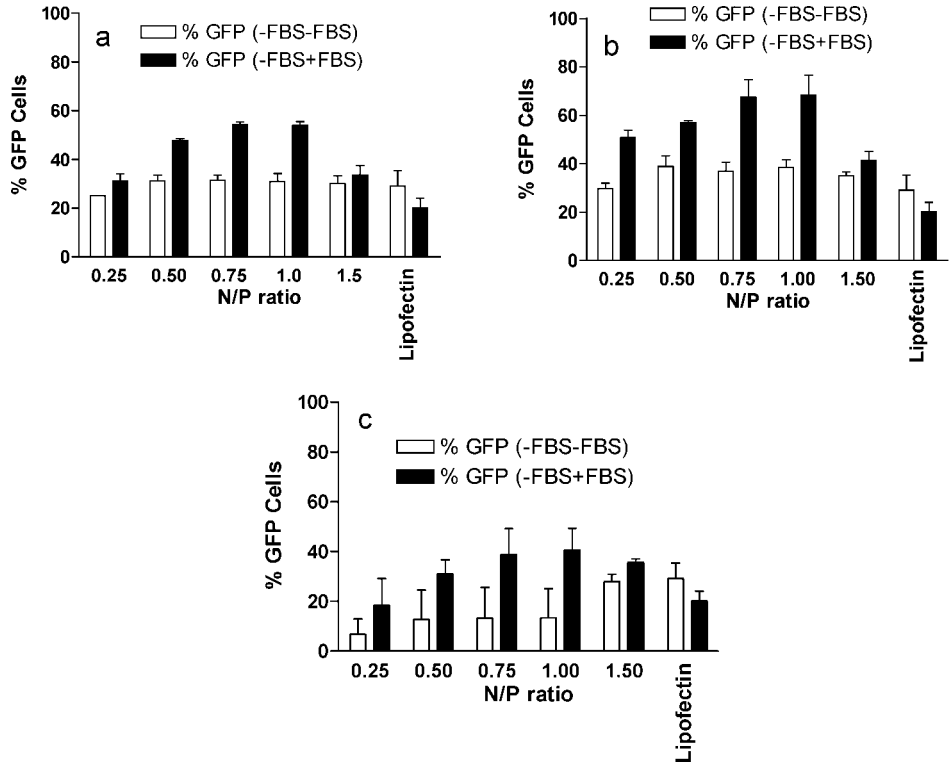

Figure 5. Transfection efficiencies of gemini lipids using optimized lipid/DOPE formulations at various N/P ratios in the absence (-FBS − FBS) and the presence (-FBS + FBS) of serum. (a) **3a**; (b) **3b**; (c) **3c**. Concentration of the DNA = 0.8 μg/well. Data expressed as number of GFP-positive cells as obtained from flow cytometry analysis.

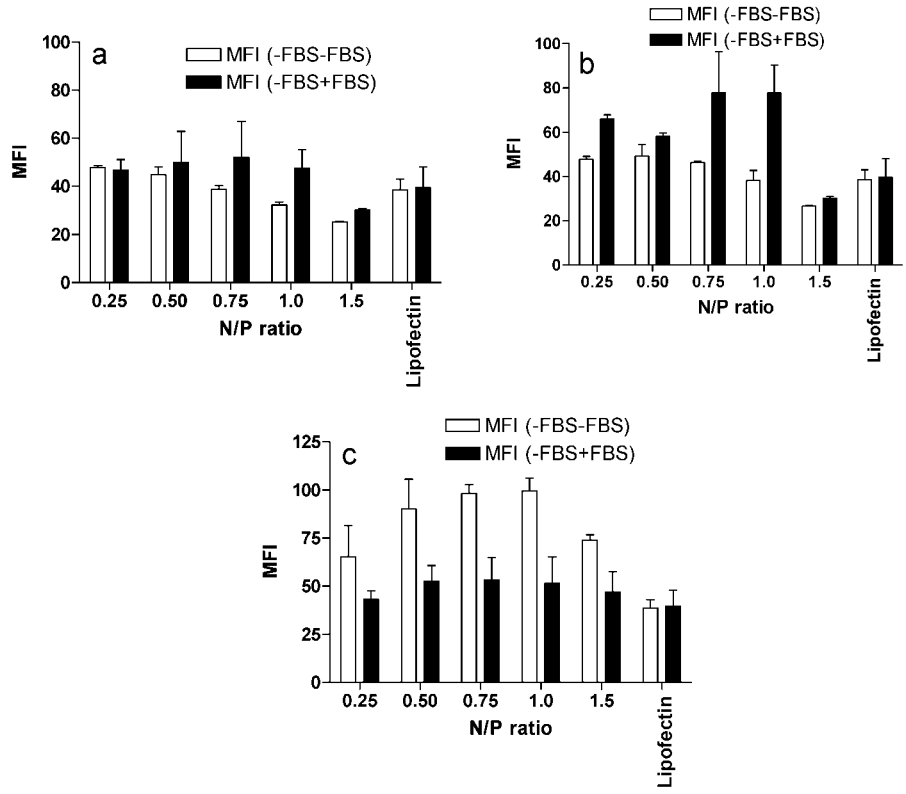

Figure 6. Transfection efficiencies of gemini lipids using optimized lipid/DOPE formulations at various N/P ratios in the absence (-FBS − FBS) and the presence (-FBS + FBS) of serum. (a) **3a**; (b) **3b**; (c) **3c**. Concentration of the DNA = 0.8 μg/well. Data expressed as MFI as obtained from flow cytometry analysis.

nearly 45% of cells as compared to ∼15% transfection efficacy of Lipofectin in presence of 10% serum conditions. More than 60% of the cells transfected in the case of lipid **3b** formulation in the presence of serum as compared to ∼40% without serum. Lipid **3c-DOPE** formulation was found to be less efficient in gene delivery both in the absence and in the presence of serum conditions. MFI observed from flow cytometric analysis for transfections by gemini lipids **3a**−**3c** are shown in Figure 6. In

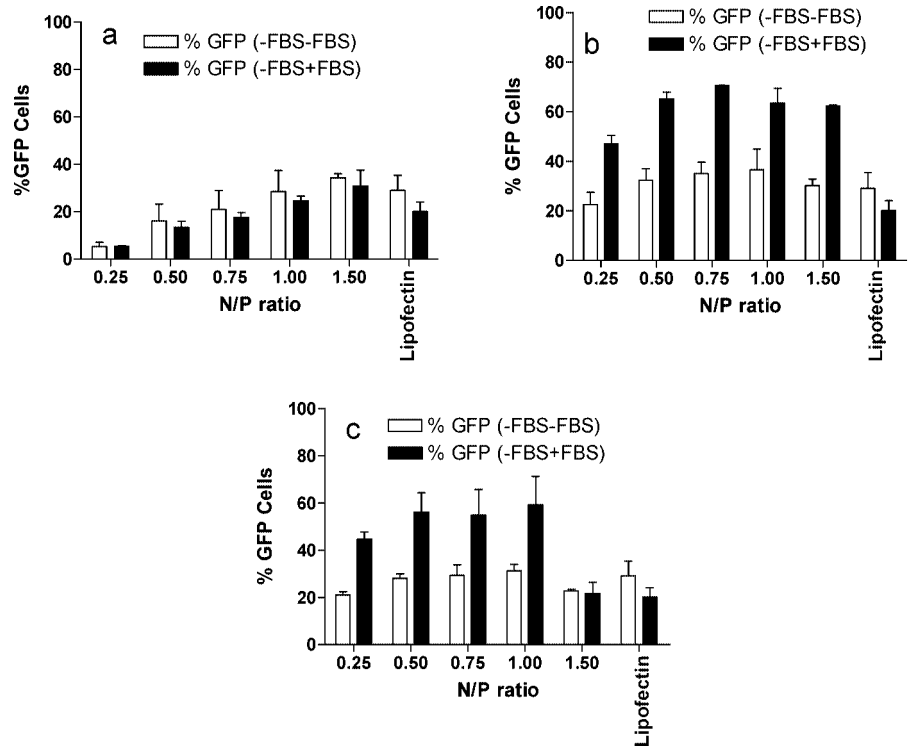

Figure 7. Transfection efficiencies of gemini lipids using optimized lipid/DOPE formulations at various N/P ratios in the absence (-FBS − FBS) and the presence (-FBS + FBS) of serum. (a) **4a**; (b) **4b**; (c) **4c**. Concentration of the DNA = 0.8 μg/well. Data expressed as number of GFP-positive cells as obtained from flow cytometry analysis.

the absence of serum, lipid **3a** and **3b** formulations showed nearly the same MFI as observed in the case of Lipofectin, whereas lipid **3c** formulation was able to deliver more than twice the DNA compared to Lipofectin in the absence of serum as observed by MFI from flow cytometric analysis. In the presence of serum, there was no change in MFI in the case of lipid **3a** formulation, whereas lipid **3b** formulation showed 2-fold enhancement in the MFI in the presence of serum. However, in case of lipid **3c** formulation, there was a decrease in MFI in the presence of serum. Overall, lipid **3b** formulation was able to transfect nearly twice the number of cells with more than two times the MFI as compared to Lipofectin, and lipid **3c** formulation was able to transfect less cells with nearly three times the MFI as compared to Lipofection in the absence of serum.

Among DOPE-containing **4a**−**4c** formulations, all were found to be as effective as Lipofectin in the absence of serum (Figure 7), whereas at least 4-fold enhancement was observed in the number of transfected cells in case of lipid **4b** formulation in the presence of serum (Figure 8). Lipid **4c** formulation showed nearly 2-fold enhancement in the number of transfected cells in the presence of serum as compared to Lipofectin. In terms of MFI, all (**4a**−**4c**) formulations were found to be as effective as Lipofectin with or without serum, except lipid **4c** formulation, which showed nearly 2-fold increase in MFI as compared to Lipofectin. Overall, lipid formulations **4b** and **4c** were highly effective in the presence of serum as compared to that without serum and Lipofectin.

Cell Viability. MTT-based cell viability assays were performed in HeLa cells at the optimized lipid/DNA charge ratios (N/P) used in the transfection experiments. Percentage cell viabilities of all the gemini lipids except lipids **1c** and **2d** were found to be more than 75% (Figure 9). Lipid **1c** and **2d** formulations showed nearly 70% cell viability.

Characterization of Lipid/DNA Complexes. *Gel Electrophoresis.* To characterize the electrostatic binding interactions between the plasmid DNA and the mixed cationic liposomes as a function of different N/P charge ratios (or lipid/DNA mole ratios), we performed conventional electrophoretic gel retardation assays using optimized cationic lipid/DOPE liposomes (Figures 10 and 11). Polymethylene spacer-based gemini lipid formulations except **1d** and **2d** were able to retard the plasmid DNA from the well at N/P ratio of 0.75, whereas **1d** and **2d** showed retardation at N/P ratio of 1.0. Among oxyethylene spacer-based gemini lipids, **4a** and **4c** were found to be most effective in DNA retardation, showing complexion at N/P ratio of 0.75, whereas in case of other lipid formulations, plasmid DNA retardation was observed at N/P ratio of 1.0. It should be noted that every gemini lipid molecule possesses two hard cationic charges, which indicates that the whole plasmid DNA gets retarded at lipid/DNA mole ratio of 0.375−0.5.

Electron Microscopy. To get further insights into the lipid−DNA complexation, we examined these complexes at the optimized lipid/DNA charge ratios by transmission electron microscopy (*11*, *35*, *39*, *63–66*). Representive electron micrographs of the lipid−DNA complexes are shown in Figures 12 and 13. Most of the lipid formulations formed spherical lipid−DNA complexes, whereas lipid **1d** lipoplexes did not possess regular shapes. Lipoplexes from lipid **4a** and **4d** showed the existence of clustering of small spheres and were found to be smaller than other lipoplexes observed.

Role of Surface Hydration. Cationic lipids interact with the plasmid DNA *via* electrostatic interactions, mainly between the headgroup region of the lipid molecules and the phosphate backbone of the DNA. Therefore, the alterations in the headgroups should influence the interactions of the liposomes with the DNA. In turn, this lipid−DNA complexation directly influences the transfection activities of the liposomes. In the case of gemini lipids, we have another parameter that influences these interactions, which is the spacer between the headgroups in each gemini lipid. As in the case of gemini lipids, this spacer is embedded between the headgroups; it influences the hydration behavior of the headgroups in gemini lipid liposomes depending on its folding at the interfaces. The hydration on the membrane

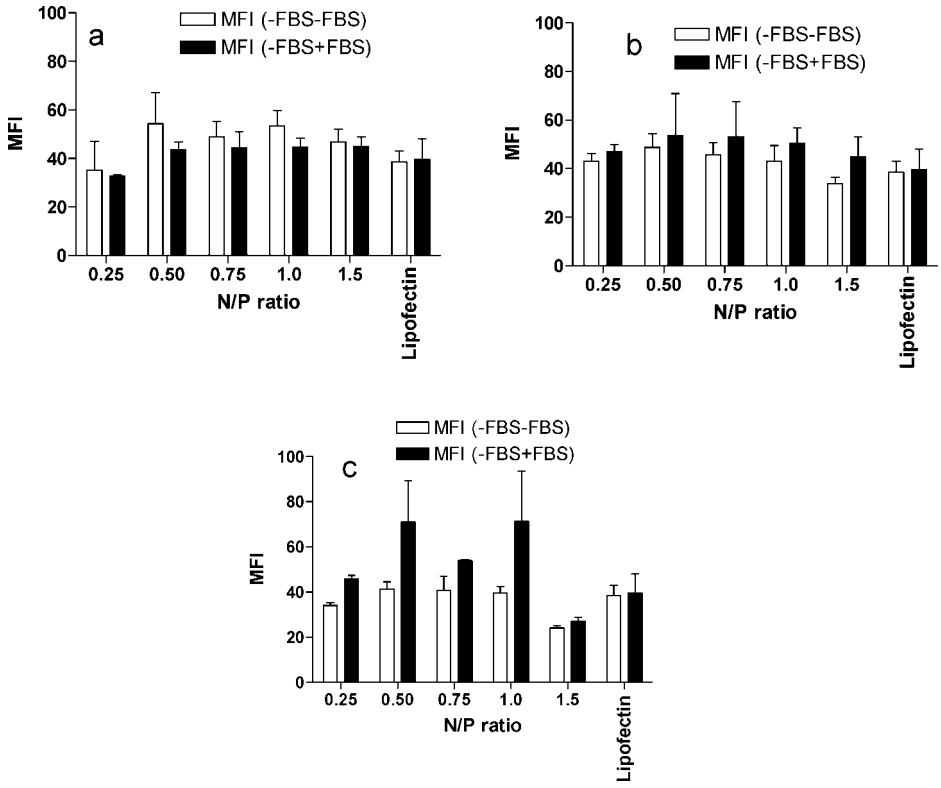

Figure 8. Transfection efficiencies of gemini lipids using optimized lipid/DOPE formulations at various N/P ratios in the absence (-FBS − FBS) and the presence (-FBS + FBS) of serum. (a) **4a**; (b) **4b**; (c) **4c**. Concentration of the DNA = 0.8 μg/well. Data expressed as MFI as obtained from flow cytometry analysis.

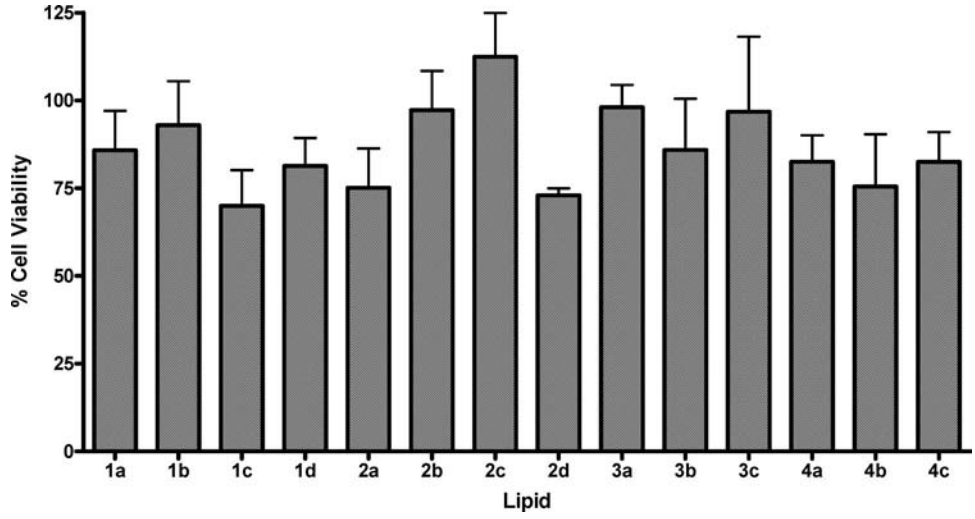

Figure 9. MTT assay-based cellular cytotoxicity of gemini lipids against HeLa cells. The percent viability values shown are averages of duplicate experiments performed on the same day.

surface will also have direct bearing on the complexation between the DNA and the liposomes. DNA has a spine of hydration, and during its complexation with lipid counterion, the "ordered" water molecules are released, giving rise to an entropic gain. When lipid membranes are highly hydrated, there is also a possibility of exchange of water molecules bound to DNA with that associated with membranes depending on the hydration requirements. The balance of these two aspects determines the efficiency of liposome−DNA complexation.

In the present investigation, as we have varied the length and the nature of the spacer from flexible hydrophobic polymethylenic to hydrophilic oxyethylene segments, we also investigated the effect of hydration environment around the liposomes on transfection activities. In case of lipid molecules **1a**−**1d**, transfection activities were found to increase with the decrease in hydration, as maximum transfection activity was found with lipid **1c** formulation having -$(CH_2)_8$- spacer, which also demonstrated the minimum hydration in this series of lipids (Figure 14). Similarly in the case of lipid molecules **2a**−**2d**, lipid **2b** afforded maximum transfection activity as compared to other lipid molecules in the series, which (except **2a**) showed high hydration as compared to **2b** liposomes. Low transfection activity of lipid **2a** formulation in spite of low hydration could be because of the high phase transition temperature of its liposomes (see below). In the case of the gemini lipids possessing an oxyethylene spacer, we found that, in general, with an increase in apparent hydration, the transfection activity increased as compared to the gemini lipids possessing a

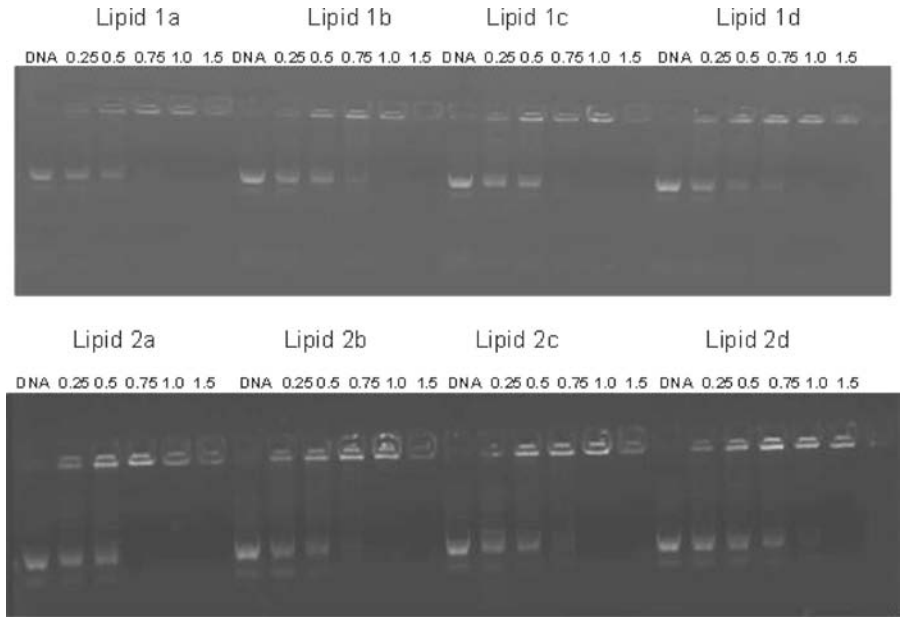

Figure 10. Electrophoretic gel patterns for lipoplex-associated DNA in gel retardation for gemini lipids possessing polymethylene spacers. The N/P ratios are indicated at the top of each lane.

polymethylene spacer, where transfection activity increased with a decrease in the membrane hydration (Figure 14). In the case of lipid molecules **3a**−**3c**, the transfection activities increased with an increase in hydration around the liposomes. Similarly, in the case of **4a**−**4c**, the transfection activity decreased with a decrease in lipid surface hydration, except **4c** where transfection decreased despite the increase in lipid hydration. However, the lipid **4c** formulation was the one found to be the most effective recipe even in the presence of high percentages of serum. This complex behavior of this lipid formulation is immediately apparent. This opposite behavior of oxyethylene spacer-based liposomes with respect to its polymethylene counterpart indicates that the DNA complexation by gemini lipids strongly depends upon the nature of the spacer, as oxyethylene spacers might be folded in a way facilitating some different mode of interaction with DNA as compared to those with polymethylene spacers.

Lipid Melting Temperatures and Transfection Activity. Lipid phase transition temperatures (T_m) for lipid formulations are shown in Table 1. As expected, the lipids possessing *n*-$C_{16}H_{33}$ chains showed higher T_m compared to the lipids bearing *n*-$C_{14}H_{29}$ chains. Among the polymethylene spacer based gemini lipids, **1a** and **2a** bearing a -$(CH_2)_3$- spacer possessed the highest T_m among its other analogues having the same hydrocarbon chain lengths. The high T_m values of the lipid aggregates could be responsible for their low transfection activity, as at 37 °C, the corresponding membranes may be too "rigid" to effect good transfection. Similarly, among oxyethylene spacer based gemini lipids, **3a** and **4a** bearing a -CH_2−CH_2−O−CH_2−CH_2- spacer possessed the highest T_m among all the lipids in the series. It was found that lipid **3a** showed the lowest transfection activity within the series, whereas lipid **4a** showed reasonable MFI but the number of transfected cells was very low.

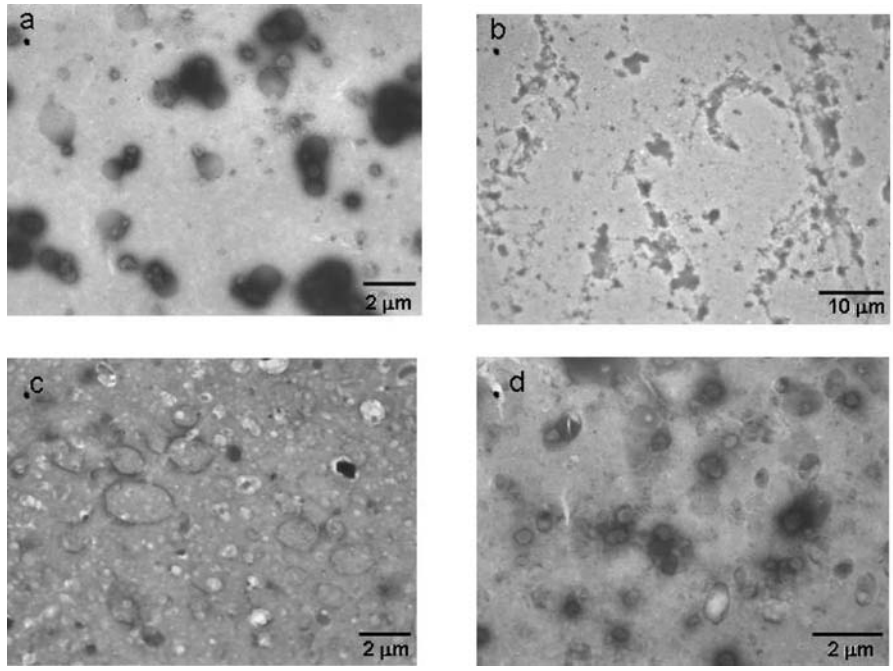

Figure 12. Representive transmission electron micrographs for the lipoplexes prepared from gemini lipid/DOPE liposome/DNA complexes at the optimized N/P ratio. (a) **1b**; (b) **1d**; (c) **2b**; (d) **2c**.

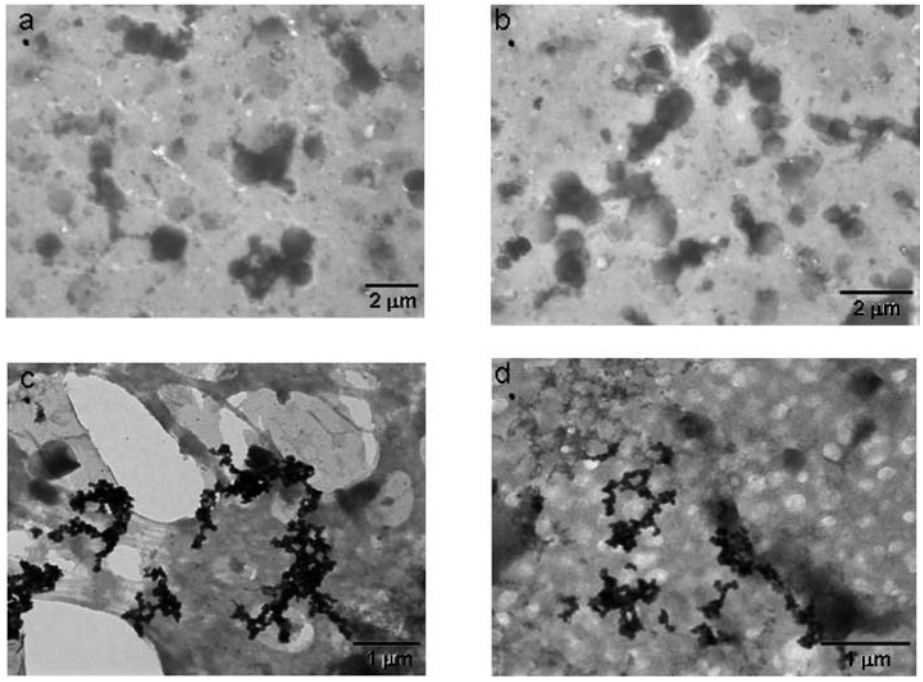

Figure 13. Representive transmission electron micrographs for the lipoplexes prepared from gemini lipid/DOPE liposome/DNA complexes at the optimized N/P ratio. (a) **3a**; (b) **3b**; (c) **4a**; (d) **4d**.

It is evident from the hydration and calorimetric studies that the transfection properties of pseudoglyceryl gemini lipid formulations are dependent upon the hydration and T_m of their liposome formulations, which are in turn controlled by hydrocarbon chain lengths and the length and nature of the spacer between the cationic ammonium headgroups. Although gene trafficking inside eukaryotic cells is a very complicated phenomenon, in order to understand variation in the transfection activity and lipid−DNA complexation of different lipids, we performed ethidium bromide exclusion assay and anionic SDS induced release of the DNA from preformed lipid−DNA complexes.

DNA Complexation by Cationic Liposomes. Various complexes of cationic liposomes with calf-thymus DNA (CT-DNA) were examined using several physical methods to gain insight into the nature of interaction among the various components. We first looked into the effect of the addition of different positively charged liposomes to CT-DNA. For this, the fluorescence experiments were performed by exposing *ds*-DNA molecules to ethidium bromide (EB) that acts as a fluorescent probe upon intercalation with DNA base pairs. Progressive addition of a given cationic liposome into the EB/CT-DNA complex led to a gradual quenching of the EB fluorescence eventually leading to saturation. Quenching of the

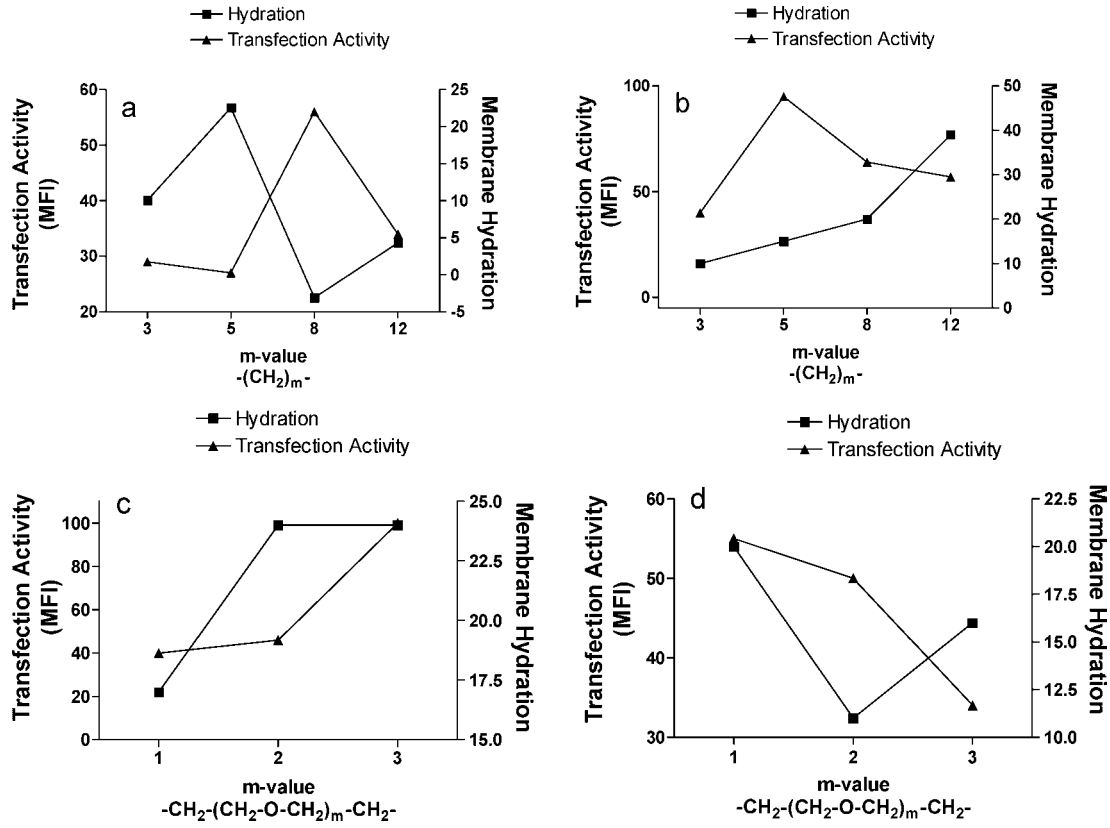

Figure 14. Effect of hydration of the gene transfection efficacies of pseudoglyceryl gemini lipids differing in the nature and length of the spacer and possessing different hydrocarbon chain lengths. (a) and (c) *n*-$C_{14}H_{29}$ hydrocarbon chain based lipids, (b) and (d) *n*-$C_{16}H_{33}$ hydrocarbon chain based lipids. Membrane hydration was calculated from the GP values using Paldan as membrane probe as discussed in the Experimental Procedures section.

Table 1. Phase Transition Temperatures of Gemini Lipid Aggregates

lipid	T_m	lipid	T_m	lipid	T_m	lipid	T_m
1a	43.2	**2a**	59.3	**3a**	38.9	**4a**	53.9
1b	28.6	**2b**	46.2	**3b**	26.6	**4b**	44.2
1c	30.6	**2c**	48.6	**3c**	27.1	**4c**	44.9
1d	29.6	**2d**	47.3				

fluorescence intensity (FI) at 590 nm upon addition of cationic liposomes is due to the gradual release of free EB out of the EB/CT-DNA complex (*67*). This could be explained on the basis of the cationic liposome induced compaction formation of DNA, which facilitates the dissociation of EB from the EB−DNA complex. Although the fluorescence quenching was seen in all the instances, there were significant differences in the minimum concentration (*c*) of the liposomes required for inducing saturation in the fluorescence quenching. The percentage decreases of FI (FI %) until saturation for given liposomes also were found to depend on the molecular structure of the cationic lipid. Figure 15 shows how various cationic lipid suspensions promote dissociation of EB from EB−DNA complexes.

Lipid **2d** induced nearly 90% dissociation of EB at N/P ratio of 1.0, whereas **2a** was able to induce ∼90% dissociation at N/P ratio of 2.0. The maximum ethidium bromide dissociation for liposomes from **2b** and **2c** were found to be at N/P ratio 1.0−2.0. For all the liposomes showing complexion with DNA, the saturation value of FI that could be attained ranged from 80% to 90% of the original value. This value is plotted as the percentage decrease in FI as shown in Figure 15. The % decrease in FI is a direct measure of the strength of the DNA−cationic liposome complex. This also reflects the ability of the given cationic liposome to complex with DNA. However, the ability of a lipid aggregate to attain saturation appeared to be related to the lipid molecular structure. The ease of the abilities of the cationic lipids possessing *n*-$C_{16}H_{33}$ chains to bring about compaction of the DNA followed the order **2d** > **2c** > **2b** > **2a**. It indicates that the binding of the liposomes depends on the spacer length between the cationic headgroups in a gemini lipid. Lipids bearing longer spacers bind at lower N/P ratios, whereas those with shorter spacers bind at higher N/P ratios. However, there was no such pronounced effect of the spacer on DNA complexation when liposomes of *n*-$C_{14}H_{29}$ chain-based lipids were used, as such lipid suspensions showed ∼90% decrease in FI at N/P ratio of 0.75. Among oxyethylene spacer-based lipids, the order was **3a** > **3b** > **3c**. Among the oxyethylene spacer-based lipids with *n*-$C_{16}H_{33}$ chains, the order was **4a** > **4c** > **4b**. This clearly indicates that, among oxyethylene spacer-based gemini lipids, lipids possessing shorter oxyethylene spacers are more efficient at DNA binding.

SDS-Induced Release of DNA from Cationic Liposome−DNA Complexes. It is generally believed that the endosomal layers of the cell, which are rich in negatively charged lipids, facilitate release of DNA from its complexes with cationic liposomes. To study this aspect in a model situation, we have used negatively charged SDS micelles to induce release of DNA from various cationic liposome−DNA complexes. An aqueous solution of EB (25 μM) gave a broad λ_{max} at 590 nm when excited at 526 nm. In the presence of CT-DNA (40 μM base molarity), the FI at 590 nm due to intercalated EB increases more than 5-fold. Addition of an aqueous solution of a given cationic liposome to the EB/DNA complex resulted in quenching of the FI as discussed previously. Progressive addition of SDS triggers the dissociation of cationic lipids from the cationic liposome/DNA complex. This in turn facilitates the reintercalation of EB into CT-DNA that gets released from the lipoplex. The increase in the fluorescence intensity reached a plateau at

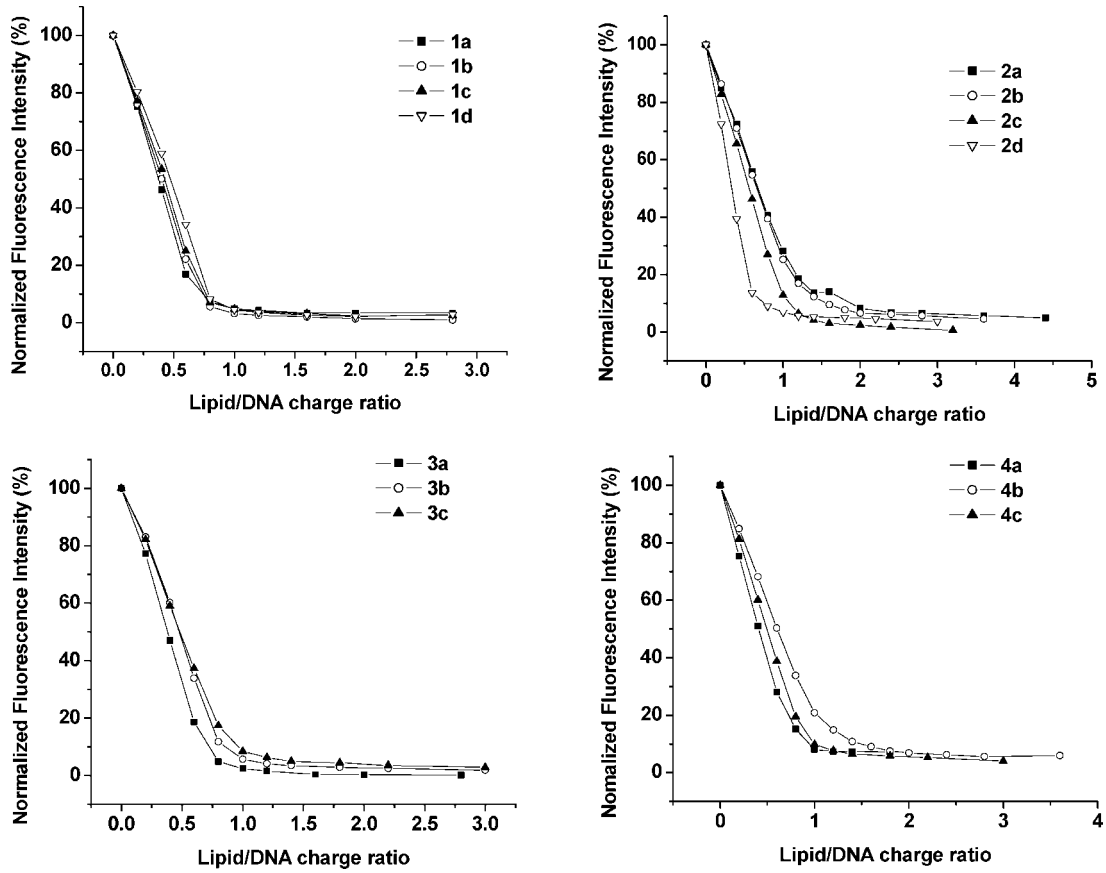

Figure 15. Release of the ethidium bromide (EB) from the DNA−EB complexes upon addition of the liposomes at different lipid/DNA charge ratios.

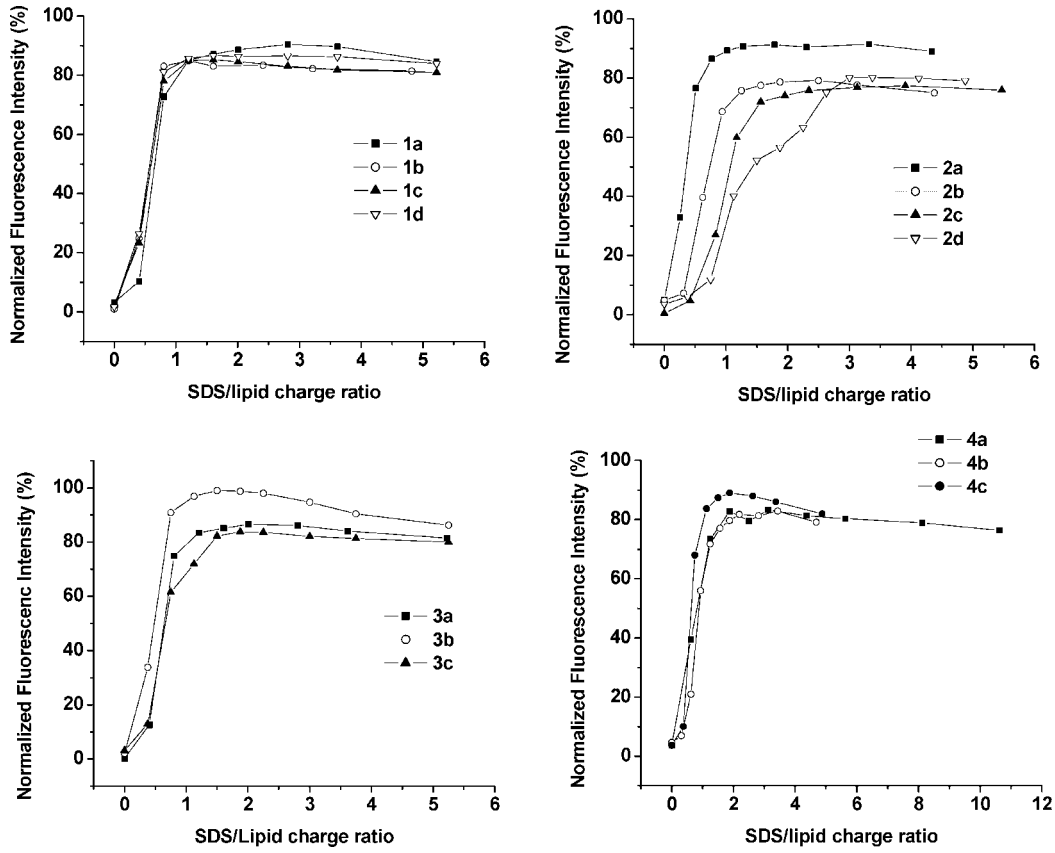

Figure 16. Reintercalation of the ethidium bromide to the DNA upon release of the DNA from lipid/DNA complexes upon addition of SDS at different SDS/lipid charge ratios.

a particular concentration of SDS for a given cationic liposome/DNA complex. Beyond this concentration, further addition of SDS did not result in any additional extent of fluorescence recovery as shown in Figure 16.

Examination of the profiles obtained by SDS promoted the DNA release from a given cationic liposome/DNA complex revealed significant differences. For instance, the amount of SDS required to reach a saturation value of FI was not the same for different cationic liposome/DNA complexes. The complexes of liposomal **2a** with DNA showed 90% recovery of FI at SDS/lipid charge ratio of 1.0, whereas **2d** liposomes needed the highest SDS concentration for DNA release from complexes. The order of ease of fluorescence recovery upon addition of SDS was **2a** > **2b** > **2c** > **2d**. At SDS/lipid charge ratio of 0.75, the order of recovery of fluorescence among n-$C_{14}H_{29}$ chain-based lipids was **1b** > **1d** > **1c** > **1a**, and among oxyethylene-based gemini lipids **3b** > **3a** > **3c**. Among oxyethylene spacer-based gemini lipids with n-$C_{16}H_{33}$ chains, addition of SDS induced release of liposomes **4c** from the DNA much more easily as compared to other lipids of the series. It should be noted that this lipid-based formulation was found to be the best transfecting agent in the presence of serum.

CONCLUSIONS

We have undertaken a chemical biological investigation on the gene delivery efficacies of pseudoglyceryl-based gemini lipid based liposomes. Fourteen gemini lipids, differing in the hydrocarbon chain lengths and the nature of spacer between the headgroups, were investigated. These lipids formed stable suspensions in water easily. These gemini lipid formulations showed a significant enhancement in the gene transfection activities as compared to that of Lipofectin, a monomeric lipid related to this series of gemini lipids investigated herein.

Serum is known to be a major impediment to the applications of cationic lipids for their use in vivo (*68*). So, there is always a challenge to design such cationic lipids, which can be useful for transfection studies in the presence of serum. The present set of gemini lipids were found to be serum compatible, and even the presence of serum caused enhancement of the gene transfection activities of the lipid **3b**, **4b**, and **4c** formulations. We have been able to reduce their cytotoxicity and enhance the transfection efficiency significantly. The simplicity of the use of pseudoglyceryl backbone and their high chemostability and long shelf-lives make these formulations particularly attractive for further applications in biological research.

Although the DNA delivery to eukaryotic cells involves several steps (*69*) and the precise mechanisms of many of these steps are not clearly understood at the molecular level at this point in time, it would be important to note that some correlation could be achieved between the molecular structures of these new gemini lipids and their membrane level properties and transfection properties. Regardless of the actual mechanism for transfection mediated by this class of gemini lipid formulations, the results obtained with these gemini lipids should be of interest to researchers working in the design of non-viral vectors.

A Novel Prosthetic Group for Site-Selective Labeling of Peptides for Positron Emission Tomography

Dag Erlend Olberg,*[,†] Ole Kristian Hjelstuen,[†,‡] Magne Solbakken,[‡] Joseph Arukwe,[‡] Hege Karlsen,[‡] and Alan Cuthbertson[‡]

University of Tromsø, Institute of Pharmacy, Department of Pharmaceutics and Biopharmaceutics, N- 9037 Tromsø, Norway, and GE Healthcare, Medical Diagnostics Discovery Research, P.O. Box 4220, 0401 Oslo, Norway. Received January 7, 2008; Revised Manuscript Received April 4, 2008

Efficient methodologies for the radiolabeling of peptides with [^{18}F]fluoride are a prerequisite to enabling commercialization of peptide-containing radiotracers for positron emission tomography (PET) imaging. It was the purpose of this study to investigate a novel chemoselective ligation reaction comprising conjugation of an [^{18}F]-*N*-methylaminooxy-containing prosthetic group to a functionalized peptide. Twelve derivatives of general formula R_1-CO-NH-Lys-Gly-Phe-Gly-Lys-OH were synthesized where R_1 was selected from a short list of moieties anticipated to be reactive toward the *N*-methylaminooxy group. Conjugation reactions were initially carried out with nonradioactive precursors to assess, in a qualitative manner, their general suitability for PET chemistry with only the most promising pairings progressing to full radiochemical assessment. Best results were obtained for the ligation of *O*-[2-(2-[^{18}F]fluoroethoxy)ethyl]-*N*-methyl-*N*-hydroxylamine **18** to the maleimidopropionyl-Lys-Gly-Phe-Gly-Lys-OH precursor **10** in acetate buffer (pH 5) after 1 h at 70 °C. The non-decay-corrected isolated yield was calculated to be 8.5%. The most encouraging result was observed with the combination **18** and 4-(2-nitrovinyl)benzoyl-Lys-Gly-Phe-Gly-Lys-OH, **9**, where the conjugation reaction proceeded rapidly to completion at 30 °C after only 5 min. The corresponding non-decay-corrected radiochemical yield for the isolated ^{18}F-labeled product **27** was 12%. The preliminary results from this study demonstrate the considerable potential of this novel strategy for the radiolabeling of peptides.

INTRODUCTION

In recent years, ^{18}F-labeled peptides have gained increasing interest as an important class of radiotracer well-suited to functional imaging with PET (*1–3*). The intrinsic pharmacokinetic properties, high affinity, and versatility of solid-phase chemistry make small proteins and peptides attractive candidates for diagnostic imaging.

The short-lived positron emitter fluorine-18 is currently the radionuclide of choice from the perspective of radiotracer manufacturability and distribution. It has excellent physical characteristics including a relatively low positron energy of 635 keV and a half-life of 109.7 min. This allows for extended radiochemical synthesis times and prolonged PET imaging protocols. There are, however, still considerable challenges to finding faster, more efficient methods for radiolabeling of peptides with this radionuclide. Although direct labeling routes have been described (*4*), the most common method utilizes a two-step process whereby the fluorine-18 is first introduced into a prosthetic group followed by conjugation to the peptide. This strategy separates the harsh reaction conditions required for [^{18}F]fluoride incorporation from the mild conditions preferred for conjugation, ameliorating the risk of significant degradation of the peptide precursor. A variety of ^{18}F-labeled prosthetic groups have been developed for incorporation into peptides, exploiting many different chemical reactions. These include acylation, alkylation, oxime formation, hydrazone formation, and 1,3-dipolar cycloaddition (*4–7*). Although alkylation and Michael-type reactions are often used in conjugation chemistry, there are limited cases reported for peptide labeling with ^{18}F-containing prosthetic groups. Examples include the [^{18}F]thiol conjugation to α-haloacetylated or maleimide-modified peptides and [^{18}F]maleimide conjugation to peptides bearing a free thiol group (*7, 8*). Thiols however, have the potential to oxidize to disulfides and readily take part in exchange reactions under a variety of conditions leading to complex mixtures (*9*). 4-[^{18}F]Fluorobenzaldehyde has been demonstrated to be a useful prosthetic group in the labeling of peptides bearing an aminooxy function (*10–13*). Oxime-bond formation proceeds rapidly and in good yield but often requires heating during the conjugation step, leading in some cases to the accelerated degradation of the peptide. In addition, the high reactivity of the aminooxy group complicates the routine handling and storage of the precursors and demands high quality standards for the reagents and solvents used in the process.

In contrast to aminooxy, the *N*-methylaminooxy group is unreactive toward aldehydes and ketones but reacts with Michael acceptors and a wide range of alkyl halides (*14*). The *N*-methylaminooxy nitrogen can also be selectively reacted with active esters at slightly acidic pH in the presence of competing nucleophiles such as the thiol group of cysteine or amino group of lysine (*15*). Peptides containing *N*-methylaminooxy amino acids have been chemoselectively alkylated with allylic, benzylic, and α-haloacetyl, *N*-ethylmaleimide, and hexyl acrylate groups in mildly acidic aqueous/organic solutions (*14, 16*). It was therefore postulated that an ^{18}F-labeled *N*-methylaminooxy prosthetic group could provide a useful addition to the toolbox of PET labeling strategies. This study reports on the radiosynthesis of the novel prosthetic *O*-[2-(2-[^{18}F]fluoroethoxy)ethyl]-*N*-methyl-*N*-hydroxylamine **18** and demonstrates its suitablility for radiolabeling in a model peptide system. Conjugation proceeded rapidly to completion in acetate buffer at pH 5 with

4-(2-nitrovinyl)benzoyl-Lys-Gly-Phe-Gly-Lys-OH, **9**, at 30 °C after only 5 min. The desired conjugate **27** was isolated after purification with a non-decay-corrected radiochemical yield of 12%.

MATERIAL AND METHODS

General. 9-Fluorenylmethoxycarbonyl (Fmoc) amino acids, Fmoc-Lys(Boc)-Sasrin resin, and peptide coupling reagents were purchased from Novabiochem, Bachem, and Applied Biosystems, respectively. All other reagents and solvents were purchased from Acros, Fluka, and Sigma-Aldrich. Mass spectra were recorded on a LCQ DECA XP MAX instrument using electrospray ionization (ESI) operated in positive mode at 4.5 kV and scan rate 5500 Da/s coupled to Finnigan Surveyor PDA chromatography system. Accurate mass spectra were recorded on a QToF-micro orthogonal acceleration time-of-flight mass spectrometer (Micromass UK Ltd., Manchester, UK) coupled to an Agilent 1100 chromatography system (Agilent Technology, Stockport, UK) using Leucine Enkephalin (Sigma Aldrich, St Louis, MO, USA) as reference compound. Data acquisition and processing were performed using *Masslynx 4.0* data system.

All NMR-spectra were recorded at 25 °C in 5 mm tubes on a Varian Unity Inova 500 NMR spectrometer using a ^{1}H{broadband} indirect detection pfg probe.

Thin layer chromatography (TLC) was run on precoated plates of silica gel 60F_{254} (Merck). Analytical and preparative reversed-phase HPLC runs were performed on Finnigan, Shimadzu, and Beckman chromatography systems. Purification of nonradioactive compounds, with the exception of the peptide derivatives, was performed using standard manual flash chromatography or an automated flash chromatography instrument (Combiflash companion, Teledyne ISCO). Details on HPLC and LC-MS conditions and analytical results are deposited as Supporting Information.

Preparation of Peptide Precursors. Assembly of the resin-bound amino acid sequence Lys(Boc)-Gly-Phe-Gly-Lys(Boc)-OH was done using fully automated synthesis (ABI 433A synthesis machine) on Fmoc-Lys(Boc)-Sasrin resin (0.25 mmol) with 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethylaminium hexafluorophosphate (HBTU) activation. Further derivatization of the peptide to yield compounds **1**−**12** was performed on the solid phase using a manual nitrogen bubbler apparatus (0.05−0.1 mmol peptide loading). Anhydride formation was mediated by *N*,*N*′-dicyclohexylcarbodiimide in dichloromethane. Coupling reactions were monitored by the Kaiser test (*17*). Simultaneous removal of the peptides from the resin and deprotection of side-chain protecting groups was carried out in trifluoroacetic acid containing triisopropylsilane and water (95:2.5:2.5 v/v/v). After filtration, the solution was concentrated under reduced pressure and the residue was washed with diethyl ether. Crude products were purified by reversed-phase preparative HPLC and isolated by lyophilization.

Chloroacetyl-Lys-Gly-Phe-Gly-Lys-OH (1). Freshly prepared chloroacetic anhydride (0.4 mmol) and diisopropylethylamine (DIPEA) (0.4 mmol) were added to a suspension of the resin-bound peptide (0.05 mmol) in dimethylformamide (DMF) (5 mL). The reaction was run until complete conversion was achieved (1 h). After cleavage, the crude material was purified yielding 13 mg (42%).

Bromoacetyl-Lys-Gly-Phe-Gly-Lys-OH (2). The compound was synthesized as described for the corresponding chloro compound **1** yielding 17 mg (52%) after purification.

Acryloyl-Lys-Gly-Phe-Gly-Lys-OH (3). Acrylic acid (0.25 mmol) was preactivated for 3 min using (7-azabenzotriazol-1-yloxy)tripyrrolidinophosphonium hexafluorophosphate (PyAOP) (0.25 mmol) and DIPEA (0.4 mmol) in DMF (3 mL). The mixture was added to the resin-bound peptide (0.06 mmol) and left to react until complete conversion (2 h). Yield after cleavage and purification was 18 mg (51%).

2-Fluoroacryloyl-Lys-Gly-Phe-Gly-Lys-OH (4). A solution of freshly prepared 2-fluoroacrylic anhydride (0.2 mmol) in DMF (5 mL) was added to the resin-bound peptide (0.05 mmol) and left to react for 2 h. The procedure was repeated until complete conversion was achieved. After cleavage, the crude material was purified affording 24 mg (79%).

2-(Trifluoromethyl)acryloyl-Lys-Gly-Phe-Gly-Lys-OH (5). 2-(Trifluoromethyl)acryloyl chloride was prepared from 2-(trifluoromethyl)acrylic acid following the procedure by Yamazaki et al. (*18*). Coupling of the acid chloride (0.3 mmol) to the resin-bound peptide (0.1 mmol) in dry dichloromethane containing sym-collidine (0.1 mmol) was performed as described by Volonterio et al. (*19*) at 0 °C for 1 h and was repeated until complete conversion was achieved. After cleavage, the crude product was purified affording 13 mg (23%).

4-Bromocrotonoyl-Lys-Gly-Phe-Gly-Lys-OH (6). Freshly prepared 4-bromocrotonic anhydride (0.3 mmol) was added to a suspension of the resin-bound peptide (0.1 mmol) in DMF (3 mL) and left to react until complete conversion was achieved (2 h). After cleavage, the crude material was purified affording 50 mg (70%).

4-(Bromomethyl)benzoyl-Lys-Gly-Phe-Gly-Lys-OH (7). 4-(Bromomethyl)benzoic acid (0.15 mmol) was preactivated for 3 min using a solution of PyAOP (0.15 mmol) and DIPEA (0.3 mmol) in DMF (3 mL). The mixture was added to the resin-bound peptide (0.05 mmol) and left to react until complete conversion was achieved (2 h) followed by cleavage. The product was identified but decomposed during purification.

4-(Bromoacetyl)benzoyl-Lys-Gly-Phe-Gly-Lys-OH (8). Freshly prepared 4-(bromoacetyl)benzoic acid anhydride (0.3 mmol) was added to the resin-bound peptide (0.1 mmol) and left to react until complete conversion was achieved (2 h). After cleavage, the crude product was purified affording 17 mg (22%).

4-(2-Nitrovinyl)benzoyl-Lys-Gly-Phe-Gly-Lys-OH (9). 4-[(1*E*)-2-Nitrovinyl]benzoic acid (0.3 mmol), prepared according to a method of Park and Pei (*20*), was preactivated for 3 min in a solution of PyAOP (0.3 mmol) and DIPEA (0.6 mmol) in DMF (5 mL). The mixture was added to the resin-bound peptide (0.1 mmol) and left to react until complete conversion was achieved (1 h). After cleavage, the crude material was purified affording 50 mg (70%).

3-(Maleimido)propionyl-Lys-Gly-Phe-Gly-Lys-OH (10). To a suspension of the resin-bound peptide (0.1 mmol) in DMF (3 mL) were added 3-(maleimido)propionic acid *N*-hydroxysuccinimide ester (0.3 mmol) and DIPEA (0.35 mmol). The mixture was left to react until a complete conversion was achieved (4 h). After cleavage, the crude product was purified affording 60 mg (87%).

Vinylsulfonyl-Lys-Gly-Phe-Gly-Lys-OH (11). The vinylsulfonyl derivative was prepared following a procedure by Li et al. (*21*). To a stirred suspension of the resin-bound peptide (0.05 mmol) in dichloromethane (3 mL) cooled to 0 °C were added 2-chloroethanesulfonyl chloride (0.375 mmol) and triethylamine (0.375 mmol). The mixture was stirred for 1 h at room temperature. Triethylamine (3.75 mmol) was added and the mixture was stirred for 1 h to effect elimination and formation of the vinylsulfone. The product was cleaved off the resin and purified to give 24 mg (76%).

2-Methyloxirane-2-carbonyl-Lys-Gly-Phe-Gly-Lys-OH (12). 2-Methyloxirane-2-carboxylic acid was prepared by hydrolysis of methyl 2-methyloxirane-2-carboxylate following a procedure by Roush et al. (*22*). Freshly prepared 2-methyloxirane-2-caboxylic acid anhydride (0.4 mmol) was added to the resin-bound peptide (0.1 mmol) in DMF and left to react until

a complete conversion was achieved (1 h). After cleavage, the crude product was purified affording 28 mg (45%).

Methyl[4-[[(4-methylphenyl)sulfonyl]oxy]butoxy]carbamic Acid *t*-Butyl Ester (13). *N*-Boc-*N*-methylhydroxylamine was synthesized from *N*-methylhydroxylamine after a procedure by Tamura et al. (*23*).

To a solution of 4-bromo-1-butanol (2.80 g, 18.0 mmol) and DIPEA (10 mL) in dichloromethane (10 mL) was added diphenyl-*t*-butylsilyl chloride (5.0 mL, 18 mmol) under argon atmosphere. The solution was stirred at room temperature for 2 h, concentrated *in vacuo*, and purified by flash chromatography (hexane/ethyl acetate, 10:1) to afford (4-bromobutoxy)(*t*-butyl)-diphenylsilane as a colorless oil (4.39 g, 62%). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.05 (9H, s, (CH_3)$_3$), 1.69 (2H, m, CH_2), 1.98 (2H, m, CH_2), 3.42 (2H, t, J = 6.8 Hz, CH_2Br), 3.69 (2H, t, J = 6.1 Hz, CH_2O), 7.41 (3H, m, 3 × Ar*H*), 7.66 (2H, m, 2 × Ar*H*).

A solution of *N*-Boc-*N*-methylhydroxylamine (0.74 g, 5.0 mmol) in DMF (10 mL) was treated with sodium hydride (200 mg, 60% dispersion in mineral oil, 4.80 mmol) and stirred for 1 h under argon. To the mixture was added a solution of (4-bromobutoxy)(*t*-butyl)diphenylsilane (1.56 g, 4.00 mmol) in DMF (10 mL) at 0 °C. The reaction mixture was stirred at 0 °C for 3 h and then concentrated. The residue was taken up in ethyl acetate (150 mL) and washed with 0.1 M NaOH (5 × 50 mL), water (50 mL), 0.1 M $KHSO_4$, and brine (50 mL), and dried ($MgSO_4$). After concentration, the residue was purified by flash chromatography (hexane/ethyl acetate, 10:1) affording [4-[[(*t*-butyl)diphenylsilyl]oxy]butoxy]methylcarbamic acid *t*-butyl ester as a colorless oil (0.59 g, 24%). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.04 (9H, s, (CH_3)$_3$), 1.48 (9H, s, (CH_3)$_3$), 1.69 (4H, m, 2 × CH_2), 3.07 (3H, s, CH_3O), 3.68 (2H, t, J = 6.2 Hz, 2 × CH_2O), 3.83 (2H, t, J = 6.2 Hz, 2 × CH_2O), 7.39 (6H, m, 6 × Ar*H*), 7.66 (4H, m, 4 × Ar*H*). ESI-MS: found m/z = 457.8 $(MH)^+$, calcd m/z = 458.3.

Tetrabutylammonium fluoride (TBAF) (1 M solution in THF, 1.6 mL, 1.6 mmol) was added to a solution of [4-[[(*t*-butyl)diphenylsilyl]oxy]butoxy]methylcarbamic acid *t*-butyl ester (0.59 g, 1.2 mmol) in dry THF (20 mL). The reaction was stirred overnight under argon. Saturated ammonium chloride solution (40 mL) was added to the mixture and THF was evaporated off. The product was extracted into dichloromethane and dried (Na_2SO_4). The organic phase was removed under reduced pressure and the residue was purified by flash chromatography (hexane/ethyl acetate 1:1) affording (4-hydroxybutoxy)methylcarbamic acid *t*-butyl ester as a colorless oil (0.17 g, 63%). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.49 (9H, s, (CH_3)$_3$), 1.71 (4H, m, 2 × CH_2), 1.78 (1H, t, J = 5.3 Hz, O*H*), 3.10 (3H, s, CH_3O), 3.69 (2H, m, CH_2OH), 3.89 (2H, m, CH_2O). ESI-MS: found m/z = 241.9 $(M+Na)^+$, calcd m/z = 242.1.

To a stirred solution of (4-hydroxybutoxy)methylcarbamic acid *t*-butyl ester (170 mg, 0.800 mmol) and triethylamine (161 μL, 1.16 mmol) in dry dichloromethane (10 mL) was added tosyl chloride (191 mg, 1.00 mmol) in dry dichloromethane (5 mL). The reaction mixture was stirred overnight under argon. The organic phase was washed with 10% $NaHCO_3$ (3 × 10 mL) and dried ($MgSO_4$). After concentration, the residue was purified by flash chromatography (hexane/ethyl acetate 8:2) to give **13** as a colorless oil (64 mg, 22%). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.47 (9H, s, (CH_3)$_3$), 1.64 (2H, m, CH_2), 1.79 (2H, m, CH_2), 2.45 (3H, s, ArCH_3), 3.05 (3H, s, CH_3N), 3.79 (2H, t, J = 6.1 Hz, CH_2O), 4.07 (2H, t, J = 6.3 Hz, CH_2O), 7.34 (2H, m, 2 × Ar*H*), 7.79 (2H, m, 2 × Ar*H*). ESI-MS: found m/z = 396.1 $(M+Na)^+$, calcd m/z = 396.2.

(4-Fluorobutoxy)methylcarbamic Acid *t*-Butyl Ester (14). A mixture of potassium fluoride (4.64 mg, 0.0800 mmol) and 4,7,13,16,21,24-hexaoxa-1,10-diazabicylo[8.8.8]hexacosane (Kryptofix 222) (30.1 mg, 80.0 μmol) in dry acetonitrile (0.75 mL) was stirred for 5 min. A solution of **13** (15 mg, 40 μmol) in dry acetonitrile (0.250 mL) was added and the mixture was heated at 60 °C for 1 h. After concentration, the residue was purified by flash chromatography (hexane/ethyl acetate, 1:1) affording **14** as a colorless oil (4.5 mg, 51%). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.49 (9H, s, (CH_3)$_3$), 1.73 (2H, m, CH_2), 1.82 (2H, m, CH_2), 3.10 (3H, s, CH_3N), 3.87 (2H, t, J = 6.2 Hz, CH_2O), 4.49 (2H, d of t, J_{HF} = 47.2 Hz, J = 6.0 Hz, CH_2F). ESI-MS: found m/z = 221.7 $(M+H)^+$, calcd m/z = 222.2.

Methyl[2-[2-[[(4-methylphenyl)sulfonyl]oxy]ethoxy]ethoxy]carbamic Acid *t*-Butyl Ester (16). To a stirred solution of diethylene glycol (22.0 g, 208 mmol) and triethylamine (10.5 g, 104 mmol) in dichloromethane (100 mL) was added tosyl chloride (9.9 g, 52 mmol). The solution was stirred at room temperature for 1 h. The reaction mixture was washed with aqueous 0.1 M $KHSO_4$ and 5% $NaHCO_3$ and dried (Na_2SO_4). After concentration, the residue was purified by flash chromatography (hexane/ethyl acetate, 1:1) to give 2-(2-hydroxyethoxy)ethyl tosylate as a colorless oil (7.62 g, 56%). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.86 (1H, s, O*H*), 2.45 (3H, s, ArCH_3), 3.54 (2H, m, CH_2O), 3.67 (2H, m, CH_2O), 3.70 (2H, m, CH_2O), 4.20 (2H, m, CH_2O), 7.35 (2H, m, 2 × Ar*H*), 7.81 (2H, m, 2 × Ar*H*). ESI-MS: found m/z = 261.3 $(M+H)^+$, calcd m/z = 261.1.

To a solution of 2-(2-hydroxyethoxy)ethyl tosylate (7.62 g, 29.3 mmol) in dichloromethane (30 mL) containing DIPEA (6.0 mL, 35 mmol) were added diphenyl-*t*-butylsilyl chloride (9.0 mL, 35 mmol) and a catalytic amount of 4-dimethylaminopyridine under argon atmosphere. The solution was stirred at room temperature for 48 h. The reaction mixture was diluted with dichloromethane (100 mL) and washed with water (2 × 100 mL) and brine (2 × 50 mL) and dried ($MgSO_4$). After concentration, the residue was purified by automated flash chromatography (RediSep 120 g column, flow 85 mL/min) using a gradient of 0−50% ethyl acetate in hexane over 30 min affording 2-[2-[[(*t*-butyl)diphenylsilyl]oxy]ethoxy]ethyl tosylate as a colorless oil (9.2 g, 63%). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.03 (9H, s, (CH_3)$_3$), 2.41 (3H, s, ArCH_3), 3.52 (2H, m, CH_2O), 3.67 (2H, m, CH_2O), 3.73 (2H, m, CH_2O), 4.17 (2H, m, CH_2O), 7.28 (2H, m, 2 × Ar*H*), 7.37 (4H, m, 4 × Ar*H*), 7.42 (2H, m, 2 × Ar*H*), 7.66 (4H, m, 4 × Ar*H*), 7.78 (2H, m, 2 × Ar*H*). ESI-MS: found m/z = 499.2 $(M+H)^+$, calcd m/z = 499.2.

A solution of *N*-Boc-*N*-methylhydroxylamine (1.53, 1.04 mmol) in THF (5 mL) was added slowly to a stirred suspension of sodium hydride (60% in mineral oil, 0.48 g, 12 mmol) in THF (5 mL) under argon. The reaction mixture was stirred for 30 min until no more gas evolution was observed and then cooled to 0 °C. 2-[2-[[(*t*-Butyl)diphenylsilyl]oxy]ethoxy]ethyl tosylate (4.0 g, 8.0 mmol) was added and the solution was stirred at 0 °C for 30 min and then at room temperature overnight. After concentration, the residue was taken up in ethyl acetate (200 mL) and washed consecutively with 0.1 M NaOH (5 × 50 mL), water (50 mL), 0.1 M $KHSO_4$ (50 mL), and brine (50 mL); dried ($MgSO_4$), and concentrated. The product was purified by flash chromatography (RediSep 40 g column, flow 40 mL/min) using a gradient 0−20% methanol in dichloromethane over 20 min affording [2-[2-[[(*t*-butyl)diphenylsilyl]oxy]ethoxy]ethoxy]methylcarbamic acid *t*-butyl ester as a colorless oil (3 g, 78%). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.05 (9H, s, (CH_3)$_3$), 1.48 (9H, s, (CH_3)$_3$), 3.09 (3H, s, CH_3N), 3.61 (2H, m, CH_2O), 3.68 (2H, m, CH_2O), 3.81 (2H, m, CH_2O), 3.98 (2H, m, CH_2O), 7.37 (4H, m, 4 × Ar*H*), 7.42 (2H, m, 2 × Ar*H*), 7.68 (4H, m, 4 × Ar*H*). ESI-MS: found m/z = 496.1 $(M+Na]^+$, calcd m/z = 496.3.

TBAF (1 M solution in THF, 6.8 mL, 6.8 mmol) was added to a stirred solution of [2-[2-[[(*t*-butyl)diphenylsilyl]oxy]ethoxy]ethoxy]methylcarbamic acid *t*-butyl ester (3.0 g, 6.0 mmol) in dry THF (15 mL). The reaction was stirred overnight at room

temperature. After concentration, the residue was taken up in dichloromethane and washed consecutively with saturated ammonium chloride solution (40 mL), water (2 × 50 mL), and brine (2 × 50 mL); dried ($MgSO_4$), and concentrated. The product was purified by automated flash chromatography (RediSep 40 g column, flow 30 mL/min) using gradient 0−5% methanol in dichloromethane over 20 min affording [2-(2-hydroxyethoxy)ethoxy]methylcarbamic acid *t*-butyl ester as a colorless oil (1.36 g, 91%). ^{1}H NMR (CD_2Cl_2, 500 MHz) δ 1.46 (9H, s, (CH_3)$_3$), 2.41 (1H, t, J = 6.2 Hz, O*H*), 3.08 (3H, s, CH_3N), 3.57 (2H, m, CH_2O), 3.65 (2H, m, CH_2O), 3.67 (2H, m, CH_2O), 3.97 (2H, m, CH_2O). ESI-MS: found m/z = 258.2 $(M+Na)^+$, calcd m/z = 258.1.

A solution of tosyl chloride (1.6 mg, 8.5 mmol), [2-(2-hydroxyethoxy)ethoxy]methylcarbamic acid *t*-butyl ester (1.0 g, 4.3 mmol), and triethylamine (1.25 mL, 9.00 mmol) in dry dichloromethane (30 mL) was stirred under argon overnight. Dichloromethane (50 mL) was added and the reaction mixture was washed consecutively with 5% $NaHCO_3$ (100 mL), brine (100 mL), and water (2 × 100 mL); dried ($MgSO_4$) and concentrated. The product was purified by automated flash chromatography (RediSep 40 g column, flow 40 mL/min) using gradient 10−65% ethyl acetate in hexane over 20 min to give **16** as a colorless oil (1.23 g, 74%). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.48 (9H, s, (CH_3)$_3$), 2.45 (3H, s, ArCH_3), 3.07 (3H, s, CH_3N), 3.62 (2H, m, CH_2O), 3.70 (2H, m, CH_2O), 3.95 (2H, m, CH_2O), 4.17 (2H, m, CH_2O), 7.34 (2H, m, 2 × Ar*H*), 7.80 (2H, m, 2 × Ar*H*). ESI-MS: found m/z = 412.0 $(M+Na)^+$, calcd m/z = 412.2.

[2-(2-Fluoroethoxy)ethoxy]methylcarbamic Acid *t*-Butyl Ester (17). A mixture of potassium fluoride (58 mg, 1.0 mmol) and Kryptofix 222 (376 mg, 1.00 mmol) in dry acetonitrile (3 mL) was stirred for 5 min. A solution of **16** (230 mg, 0.600 mmol) in dry acetonitrile (2 mL) was added and the mixture was heated at 80 °C for 1 h. After concentration, the residue was purified by flash chromatography (hexane/ethyl acetate, 1:1) affording **17** as a colorless oil (83 mg, 58%). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.49 (9H, s, (CH_3)$_3$), 3.12 (3H, s, CH_3N), 3.73 (2H, m, CH_2O), 3.76 (2H, d of m, J_{HF} = 29.5 Hz, FCH_2CH_2O), 4.03 (2H, m, CH_2O), 4.57 (2H, d of m, J_{HF} = 47.6 Hz, FCH_2CH$_2$O). ESI-MS: found m/z = 260.0 $(M+Na)^+$, calcd m/z = 260.1.

Compounds 10−31. General Conjugation Procedure. To a conical vial charged with **14** or **17** (2 mg, 8 μmol) was added 2 M HCl in diethylether (0.3 mL), and the reaction mixture was left at room temperature for 5 min removing the Boc-groups quantitatively to give **15** and **18**, respectively. The solution was concentrated to dryness under reduced pressure and a solution of peptide derivative (3 mg, 2.8−5.1 μmol) in 0.4 M sodium acetate buffer pH 5 (0.8 mL) was added. Progress of the reaction was monitored by LC-MS analysis. If formation of conjugate could not be detected after reaction at room temperature for 30 min, temperature was increased to 70 °C and aliquots were analyzed at 45, 60, 90, and 120 min reaction times. Analytical results are deposited as Supporting Information.

Radiochemistry. All anhydrous chemicals were purchased from Sigma-Aldrich (Norway). HPLC solvents were obtained from Merck KGaA (VWR). Radiochemistry and semipreparative HPLC purifications were performed using the TracerLab Fx_{FN} (GE Medical Systems) with manual interventions when required. Thin layer chromatography (TLC) was run on precoated plates of silica gel $60F_{254}$ (Merck) developed in hexane/ethyl acetate (1:1). Instant Imager (Packard BioScience) was used to measure the Radio-TLC scan. Analytical HPLC was performed on an Agilent system (1100 series) with UV detection equipped in series with a γ-detector (Bioscan flow-count). Preparative purification was run on a TracerLab HPLC system. [^{18}F]Fluoride was produced by a cyclotron (GE PETtrace 6) using ^{18}O(p,n)^{18}F nuclear reaction with a 16.5 MeV proton irradiation of an enriched [^{18}O]H_2O target.

Preparation of the K[^{18}F]F−K_{222} Complex. Aqueous [^{18}F]fluoride (1 mL, 150−250 MBq) was passed through an anion-exchange resin (Sep-Pak light Waters Accell Pluss QMA Cartridge, preconditioned with K_2CO_3). The [^{18}F]fluoride was then eluted from the resin into the TracerLab reaction vessel using a solution of Kryptofix 222 (56 mg) and K_2CO_3 (10 mg) in a mixture of water (215 μL) water and acetonitrile (785 μL). The solution was then concentrated to dryness by heating at 100 °C under reduced pressure and a flow of nitrogen for 2 min. Acetonitrile (0.8 mL) was added and evaporated off as above. This step was repeated twice.

(4-[^{18}F]Fluorobutoxy)methylcarbamic Acid *t*-Butyl Ester ([^{18}F]14). To the dried K[^{18}F] F−K_{222} complex was added a solution of **13** (3 mg, 8 μmol) in acetonitrile (1 mL). The sealed reaction vessel was heated at 70 °C for 20 min and then analyzed by TLC and HPLC. The reaction mixture was passed through an alumina column (Sep-Pak, Waters) removing free [^{18}F]F^-. Finally, the reaction vessel was rinsed with acetonitrile (1 mL) and this solution was passed through the same alumina column to isolate as much of the labeled material as possible.

[2-(2-[^{18}F]Fluoroethoxy)ethoxy]methylcarbamic Acid *t*-Butyl Ester ([^{18}F]17). To the dried K[^{18}F] F−K_{222} complex was added a solution of **16** (3.0 mg, 7.7 μmol or 5.0 mg, 12.5μmol) acetonitrile (1 mL). The sealed reaction vessel was heated to 90 °C for 10 min. and then analyzed by TLC and HPLC. The reaction mixture was diluted with water (9 mL) and loaded onto an Oasis HLB Sep-Pak column (Waters). The column was rinsed with 25% methanol in water solution (50 mL) and then dried with a flow of nitrogen. The labeled product was eluted off the column using acetonitrile (1.5 mL).

[^{18}F]23. Conjugation of Prosthetic Group [^{18}F]15 to Peptide 10. The solution of [^{18}F]**14** in acetonitrile (2 mL) from the labeling procedure was evaporated to dryness at 70 °C under vacuum. To the residue was added 2 M HCl in diethyl ether (1 mL) and the reaction mixture was stirred for 5 min. The mixture was concentrated at 65 °C under reduced pressure with a flow of nitrogen. To the residue was added a solution of peptide **10** (5.0 mg, 7.3 μmol) in 0.4 M sodium acetate buffer pH 5 (0.8 mL). The reaction mixture was heated to 70 °C and aliquots were removed after 20, 40, and 60 min reaction time. HPLC analysis showed reappearance of free [^{18}F]fluoride, unreacted [^{18}F]**15**, and the desired peptide conjugate [^{18}F]**23**.

[^{18}F]27. Conjugation of Prosthetic Group [^{18}F]18 to Peptide 9. To the solution of [^{18}F]**17** in acetonitrile (1.5 mL) from the labeling procedure was added 2 M HCl in diethyl ether (0.2 mL) and the reaction mixture was stirred for 5 min. The mixture was concentrated at 65 °C under reduced pressure with a flow of nitrogen for 3 min. Acetonitrile (0.8 mL) was added and the concentration procedure was repeated. To the residue was added a solution of peptide **9** (5 mg, 7 μmol) in 0.4 M sodium acetate buffer pH 5 (0.8 mL). The reaction mixture was heated at 30 °C for 5 min, diluted with water (3 mL), and analyzed by HPLC showing unreacted [^{18}F]**18** and desired conjugate [^{18}F]**27**. The labeled peptide was purified on a preparative HPLC and shown to coelute with reference standard **27**.

[^{18}F]28. Conjugation of Prosthetic Group [^{18}F]18 to Peptide 10. The deprotection of Boc-protected [^{18}F]**17** and removal of the organic solvents was carried out in the same manner as that described in the section above. The dry residue was reconstituted in 0.8 mL of 0.4 M sodium acetate buffer containing 5 mg (7.3 μmol) of peptide derivative **10**. The reaction mixture was left for 60 min at 70 °C. After diluting the reaction mixture with 3 mL of water, an aliquot was analyzed

Table 1. Structures of the Peptide Derivatives Studied

by HPLC showing [18F]**18** and [18F]**28**. The reaction mixture was subjected to preparative HPLC and the isolated fraction was shown to colelute with reference standard **28**.

RESULTS AND DISCUSSION

The aim of this study was to investigate the utility of two novel 18F-containing prosthetic groups bearing the *N*-methylaminooxy functionality as a new methodology for the radiolabeling of peptides. Because of the alpha effect, *N*-methylaminooxy compounds are much more powerful nucleophiles than the ε-amino group of lysine, allowing site-specific conjugation under mildly acidic conditions (*24*). Furthermore, although structurally related, the *N*-methylaminooxy group has a quite different set of reactivities compared to aminooxy being unreactive toward aldehydes and ketones (*14*).

Carrasco et al. reported site-specific ligations of *N*-methylaminooxy groups in peptide systems to Michael-type acceptors and halides through nucleophilic substitution (*16*). One potential drawback however in applying this chemistry to the labeling of peptides for PET imaging was the relatively long reaction times reported for the conjugation step. We therefore adopted a strategy designed to rapidly screen a range of reactive groups linked to the *N*-terminal end of the model peptide KGFGK. Our approach was to assess, in a qualitative manner, the suitability and general applicability to PET chemistry. The conjugation reactions were first carried out using nonradioactive compounds with promising chemistries transferred to full radiochemical evaluation with [18F]fluoride. Table 1 shows a list of peptide derivatives synthesized for the initial conjugation studies.

The reactivity of peptide precursors **1**−**12** were then assessed using the two prosthetic groups **15** and **18** whose structures and synthetic routes are illustrated in Scheme 1 below.

Starting from 4-bromo-1-butanol, **13** was readily prepared in 4 steps by protection of the hydroxyl group as the *t*-butyl diphenyl silyl ether followed by reaction with the anion of *N*-Boc-*N*-methylhydroxylamine generated by sodium hydride, removal of the silyl ether with TBAF and reaction with tosyl chloride. The Boc-protected product **14** was obtained by direct fluorination of **13** with the KF-Kryptofix complex. Subsequent removal of the Boc-group with 2 M HCl in ether produced **15** in quantitative yield.

In a similar manner, **16** was prepared from diethylene glycol by monotosylation of the diol followed by protection as the *t*-butyl diphenyl silyl ether. Once again, reaction with the anion of *N*-Boc-*N*-methylhydroxylamine generated by sodium hydride, TBAF mediated removal of the silyl ether, and subsequent reaction with tosyl chloride gave the desired product in acceptable yield. The fluorinated compound **18** was prepared by reaction of **16** with KF-Kryptofix 222 followed by removal of the Boc-group with 2 M HCl in ether.

Nonradioactive conjugations were performed with prosthetic groups **15** and **18** and peptide derivatives **1**−**12** dissolved in 0.4 M acetate buffer at pH 5. The reactions were initially stirred for 30 min at room temperature and an aliquot analyzed by LC-MS. In cases where no detectable product had formed, the temperature of the solution was elevated to 70 °C and further aliquots removed for LC-MS analysis at 45, 60, 90, and 120 min. The reactions were performed on a milligram scale using 2 equiv of the prosthetic group and conjugation yields and product identity were confirmed by HPLC and mass spectrometry respectively.

Table 2 summarizes the test reactions carried out with peptide derivatives **1**, **3**, **5**, **6**, and **10** in combination with prosthetic group **15**.

Precursors **1** and **3** reacted sluggishly with **15**, forming only low yields of the conjugates **19** and **20** and were not selected for further evaluation. Although the 2-trifluormethyl derivative **5** gave product **21** in a 17% yield after 45 min at 70 °C, significant degradation of the starting material was observed by HPLC, complicating the analysis of the product mixture. A similar observation was made for peptide derivative **6**. Indeed, the complexity of the product mixtures led us to exclude these derivatives, and no attempt at radiochemical assessment was made. In contrast, the maleimide derivative **10** gave a 28% yield of **23** after 90 min at 70 °C, and the conjugate could be readily isolated from the starting material by HPLC.

In a similar set of experiments, the prosthetic group **18** was used to prepare conjugates with the peptide derivatives **2**, **4**, **8**, **9**, **10**, **11**, and **12**, and the yields are shown in Table 3 below.

Interestingly, the conjugation yields were in general higher using **18** compared to **15**. The maleimide derivative **10** was converted in 50% yield to product **28** with heating to 70 °C for 45 min. Most significantly, the 4-(2-nitrovinyl)benzoyl derivative **9** was converted to conjugate **27** in greater than 90% yield at 30 °C. Indeed, the reaction time could be reduced from 30 min to only 5 min with no significant impact on yield. The vinylsulfonamide **11** gave a clean reaction product, but the reaction was slower than for both maleimide and 4-(2-nitrovinyl)benzoyl-functionalized peptides. Once again, significant degradation of all other derivatives was observed, and from the initial round of screening, derivatives **9** and **10** were selected for full radiochemical assessment.

Radiochemical Assessment. Incorporation of [18F]fluoride into precursor **13** using [18F]KF-Kryptofix/ carbonate in acetonitrile at 70 °C for 20 min typically gave ~60% yield of [18F]**14** as analyzed by radio-TLC. Removal of free fluoride was performed on an alumina column (Sep-Pak, Waters) before cleavage of the Boc group with 2 N HCl in diethyl ether to quantitatively liberate [18F]**15**. The organic phase was evaporated *in vacuo* and the product reconstituted by addition of sodium acetate buffer pH 5. On subsequent reaction with the maleimide derivative **10** at 70 °C, the presence of a new

radioactive peak corresponding to the desired product **23** was observed (peak C, Figure 1). However, a second, more prominent peak was also present eluting in the void volume (peak A, Figure 1). This byproduct could be explained by

15 **31**

liberation of [^{18}F]fluoride through cyclization of the prosthetic group to give the six-membered ring **31** as shown in Scheme 2. Figure 1 shows the radiochromatograms of [^{18}F]**15** (peak B) on heating for 20 and 60 min at 70 °C in the presence of peptide derivative **10**. The presence of product **31** in the reaction mixture was confirmed by mass spectrometry. This was surprising, as direct nucleophilic substitution on alkyl fluorides is relatively uncommon; one example found in the literature relates to their reactivity with hydrazines (*25*). As a result of these findings, no further work was carried out on [^{18}F]**15**.

Radiolabeling of precursor **16** gave [^{18}F]**17** in typical radiochemical yields ranging 60−80% (n = 9) starting with 5 mg (12.9 μmol) of precursor at 90 °C for 5 min in 1 mL acetonitrile. Increasing the reaction time to either 10 or 15 min had no detectable impact on yield, as the tosylate **16** appeared to rapidly

hydrolyze to the alcohol. This was not observed for **13** and may reflect a neighboring group effect of the ether oxygen. Purification was carried out by trapping the products of the reaction mixture on an Oasis HLB Sep-Pak cartridge, first eluting the excess alcohol with five aliquots of 10 mL 25% aqueous MeOH. Product [18F]**17** was then eluted in 1.5 mL acetonitrile with a radiochemical purity of greater than 95% and a preparation time of 35 min. This compares well with the 50% radiochemical yield and synthesis time of 30−55 min reported for [18F]FB-CHO by Phoetko et al. (*10*). The amount of alcohol carried over to the conjugation stage was found to have an impact on the final conjugation yield. Reducing the amount of precursor **16** to 3 mg (8 μmol) gave an isolated yield of [18F]**17** after Oasis Sep-Pak purification (decay-corrected) of 43 ± 4% (n = 13).

Removal of the Boc group was performed by addition of 0.2 mL 2 M HCl in diethyl ether as previously described, liberating [18F]**18**. Excess solvent was removed *in vacuo* at 65 °C under a stream of nitrogen for 3 min. To the residue was added a further 0.8 mL aliquot of acetonitrile and the drying process repeated before progressing to the next step. Conjugation was then initiated by dissolving [18F]**18** in 0.4 M acetate buffer pH 5 (0.8 mL), followed by addition of either **9** or **10**. In contrast to the [18F]**15**, [18F]**18** was found to be stable with no observable cyclization in solution following Boc deprotection. Efficient conjugation with the maleimide precursor **10** was achieved by heating for 1 h at 70 °C giving [18F]**28** in yields ranging 64−78% (n = 3) as analyzed by radio-HPLC. In contrast, peptide **9**, which in the nonradioactive experiments had proven to be the most reactive compound, demonstrated excellent reactivity at 30 °C forming [18F]**27** in yields ranging 80−89% (n = 5) after only 5 min (Figure 2a, 10.8 min). Indeed, the clean conjugation of the prosthetic group to the precursor was considered noteworthy, as closely eluting radioactive byproducts can be difficult to remove even by HPLC. These results generally compare favorably with other methodologies currently being employed in PET chemistry such as the [18F]Galacto-RGD radiosynthesis using the prosthetic group [18F]fluoropropionate, which has a reported RCY for the acylation step of ~85% (*26*). The thiol-based prosthetic groups gave comparable conjugation yields but required heating to 70−80 °C for 30 min (*7*). Likewise, for an aminooxy-modified somatostatin analogue, conjugation with [18F]FB-CHO gave a 60% RCY after 15 min at 60 °C, and for an RGD peptide, 60−80% RCY after 10−15 min at 60 °C has been reported (*10*).

Table 4. Radiochemical Yields (not corrected for decay) for [18F]27 and [18F]28

peptide conjugate	reaction temp (°C)	conjugation time (min)	% isolated yield[a]	total synthesis time[b] (min)	% RCP[c]
27	30	5	12.0 (n = 3)	80	>99
28	70	60	8.5 (n = 3)	140	>99

[a] Yields of isolated [18F]fluoropeptide, based on starting [18F]fluoride (not corrected for decay). [b] Time of synthesis measured from incoming [18F]fluoride to end of purification. [c] Radiochemical purity analyzed by radio-HPLC.

The overall efficiency of the reaction sequence was calculated from starting activity of [18F]fluoride following isolation of final product by reversed-phase chromatography. Isolated yields of 12.0% and 8.5% were achieved for [18F]**27** and [18F]**28**, respectively, as summarized in Table 4.

The major significance of these preliminary findings were the rapid kinetics demonstrated by the *N*-methylaminooxy prosthetic group [18F]**18** in combination with peptide precursor **9** at 30 °C. By avoiding high-temperature conjugation reactions, we can improve the chemical purity of the final conjugation mixture and reduce the complexity of the purification process. Peptides are known to have an inherent instability at elevated temperatures, and strategies which minimize the formation of byproduct are advantageous. We therefore anticipate that the methodology described in this study will provide a useful alternative for radiolabeling sensitive peptides for PET imaging.

CONCLUSION

18F-Containing *N*-methylaminooxy compounds are useful prosthetic groups suitable for labeling of peptides. The 4-(2-nitrovinyl)benzoyl moiety covalently linked to a model peptide was found to be highly reactive and selective toward the prosthetic group, enabling efficient labeling at 30 °C after 5 min in sodium acetate buffer at pH 5. This protocol therefore represents a novel methodology for the radiolabeling of peptides.

ACKNOWLEDGMENT

We would like to thank David Grace and Tone Hauk Fritzell (GE Healthcare) for kindly supplying the NMR spectra. We finally thank Roger Smeets and the staff at Kjeller for technical assistance.

Aptamer-Targeted Gold Nanoparticles As Molecular-Specific Contrast Agents for Reflectance Imaging

David J. Javier,[†] Nitin Nitin,[†] Matthew Levy,[‡] Andrew Ellington,[‡] and Rebecca Richards-Kortum*[,†]

Department of Bioengineering, Rice University, Houston, Texas 77005, and Institute for Cellular and Molecular Biology, University of Texas at Austin, Austin, Texas 78712. Received March 25, 2008; Revised Manuscript Received April 22, 2008

Targeted metallic nanoparticles have shown potential as a platform for development of molecular-specific contrast agents. Aptamers have recently been demonstrated as ideal candidates for molecular targeting applications. In this study, we investigated the development of aptamer-based gold nanoparticles as contrast agents, using aptamers as targeting agents and gold nanoparticles as imaging agents. We devised a novel conjugation approach using an extended aptamer design where the extension is complementary to an oligonucleotide sequence attached to the surface of the gold nanoparticles. The chemical and optical properties of the aptamer−gold conjugates were characterized using size measurements and oligonucleotide quantitation assays. We demonstrate this conjugation approach to create a contrast agent designed for detection of prostate-specific membrane antigen (PSMA), obtaining reflectance images of PSMA(+) and PSMA(−) cell lines treated with the anti-PSMA aptamer−gold conjugates. This design strategy can easily be modified to incorporate multifunctional agents as part of a multimodal platform for reflectance imaging applications.

I. INTRODUCTION

Most contrast agents for molecular imaging couple a targeting molecule to a reporter moiety. For example, monoclonal antibodies are frequently used as targeting agents coupled to reporting agents. Recently, the use of aptamers for molecular targeting has been advocated due to several advantages relative to traditional antibody-based approaches (*1, 2*). Aptamers are generally smaller in size (3−5 nm) than antibodies (∼12−15 nm). The high affinity and specificity of aptamers make them ideal targeting agents. In contrast to antibodies, aptamers can be chemically synthesized in bulk amounts at a reasonable price. Another advantage of aptamers is that they can be generated using modified nucleotides, and the incorporation of these non-natural analogues can greatly increase nuclease stability. Moreover, oligonucleotide extensions can be easily incorporated in the aptamer's backbone to separate the conjugating arm from the targeting arm. This eliminates the need for direct modifications to the aptamer binding site. In the case of antibodies, the addition of reporting molecules is normally accomplished by modifying functional groups on the peptide backbone which can potentially compromise the affinity of the antibody.

The use of gold nanoparticles as reporting agents for reflectance-based molecular imaging applications has recently been reported as alternative to fluorescence-based methods (*3–5*). Gold nanoparticles have strong localized surface plasmon resonance that makes them ideal for reflectance imaging. The extinction coefficients of gold nanoparticles are higher than organic fluorophores; the scattering signal from a single nanoparticles is approximately equivalent to 10^6 fluorophores in a homogeneous environment (*6, 7*). Gold nanoparticles are good candidates for in vivo applications since their material composition is less cytotoxic compared to organic fluorescent dyes and quantum dots. Moreover, generation of reflectance imaging using gold nanoparticles also requires less complicated instrumentation compared to fluorescence methods.

In a previous study, we demonstrated the development of aptamer-based quantum dot conjugates for molecular imaging where the conjugation of the aptamers to the quantum dot is facilitated using biotin−avidin interactions (*8*). In this paper, we developed aptamer-targeted gold nanoparticles for use as contrast agents for reflectance imaging. In this approach, shown schematically in Figure 1, conjugation of the aptamers to gold nanoparticles is accomplished using an extended aptamer design where the extension is complementary to an oligonucleotide sequence attached to the surface of gold nanoparticles. This novel approach provides a simple conjugation method and offers the potential for multiplexing capabilities.

We demonstrate this conjugation approach to create a contrast agent designed for the detection of prostate-specific membrane antigen (PSMA). PSMA is a cell surface antigen commonly present in prostate cancer cells. Anti-PSMA aptamers were conjugated to 20 nm gold nanoparticles and the optical and chemical properties of the conjugates were characterized. The potential of the conjugates for molecular imaging was demonstrated by obtaining reflectance images of PSMA(+) and PSMA(−) cell lines treated with the anti-PSMA aptamer−gold conjugates.

II. MATERIALS AND METHODS

A. Synthesis of Aptamer−Gold Conjugates. The anti-PSMA aptamer used in the study is an A9 RNA aptamer. The selection and characterization of A9 RNA aptamers have been previously described in another paper (*9*). Here, we added an extension to the aptamer to serve as a hybridization site for complementary oligonucleotide-coated gold nanoparticles. The sequence of the A9 RNA aptamer showing the extended sequence (underlined) is 5′ GGG AGG ACG AUG CGG ACC GAA AAA GAC CUG ACU UCU AUA CUA AGU CUA CGU UCC CAG ACG ACU CGC CCG AGA AUU AAA UGC CCG CCA UGA CCA G. The extended A9 aptamer (100 μM concentration) was obtained from the Ellington laboratory at the University of Texas at Austin.

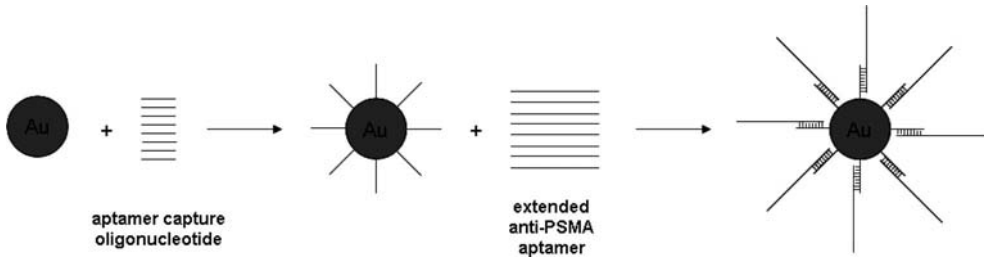

Figure 1. Schematic diagram for the conjugation of anti-PSMA aptamers to gold nanoparticles.

Gold nanoparticles (20 nm gold nanospheres, citrate-stabilized, Ted Pella, Inc.) were coated with capture oligonucleotide which was complementary to the aptamer extension sequence. The aptamer capture oligonucleotide was functionalized with thiol group (C6 S−S spacer) and hexa(ethylene glycol) (18-atom spacer) on the 5′ terminal position. The HPLC-purified aptamer capture oligonucleotide was obtained from IDT DNA Technologies with the following sequence: 5′/ThioMC6-D/Sp18/CTG GTC ATG GCG GGC ATT TAA TTC. To prepare the capture oligonucleotide-coated gold nanoparticles, 5 uM of aptamer capture oligonucleotide was reduced with TCEP (tris(2-carboxyethyl)phosphine hydrochloride, Pierce Chemical) for 30 min and added to 1.0 mL of 20 nm colloidal gold nanoparticles (7.0×10^{11} Au nanoparticles per mL). The conjugate was slowly aged with increasing concentration of PBS for 24 h until a 1× PBS concentration was reached. The unreacted capture oligonucleotide was removed from the oligonucleotide-coated gold nanoparticles by centrifugation (2×) at 12 000 *g* for 30 min. The detailed oligonucleotide coating process is described in a previous paper (*10*).

The anti-PSMA aptamer (50 μL of 100 μM stock solution or 5 nmol) was hybridized to 1.0 mL of capture oligonucleotide-coated gold nanoparticles (suspended in 1× PBS) by initially heating the solution at 70 °C for 5 min followed by incubation at room temperature for 30 min. The unreacted anti-PSMA aptamers were removed from the aptamer−gold conjugates by centrifugation (2×) at 12 000 *g* for 30 min.

B. Characterization of Aptamer−Gold Conjugates. The characterization experiments were designed to determine the size of the conjugates and the amount of aptamer-capture oligonucleotide and the extended anti-PSMA aptamers conjugated to the gold nanoparticles. We used 1.0 mL of 20 nm Au nanoparticles (7.0×10^{11} Au nanoparticles per mL) for all experiments.

The hydrodynamic size of the functionalized gold nanoparticles was measured using dynamic light scattering (Brookhaven Instruments). Triplicate runs were performed at 25 °C and 3 min analysis time to determine the average hydrodynamic diameter of the conjugates.

The amount of aptamer-capture oligonucleotide coated to gold nanoparticles was determined by fluorescence measurements using the Quant-iT OliGreen ssDNA assay kit from Invitrogen. The gold nanoparticles were first dissolved in 500 μM KCN before performing the assay. A standard curve was generated using the aptamer-capture oligonucleotide. The fluorescence intensity ($\lambda_{exc} = 480$ nm, $\lambda_{em} = 520$ nm) of the samples and standards was measured using a plate reader (SpectraMax, Molecular Devices).

The amount of extended anti-PSMA aptamer hybridized to the gold nanoparticles coated with capture oligonucleotides was estimated by using a fluorescently labeled oligonucleotide. Gold nanoparticles coated with capture oligonucleotides were hybridized with a shorter analogue of the anti-PSMA aptamer with a Cy5 modification on the 5′ terminus. The sequence of the oligonucleotide obtained from IDT DNA Technologies is 5′ Cy5\GAA TTA AAT GCC CGC CAT GAC CAG. The oligonucleotide-Cy5 was also used as a standard to generate a calibration curve. The amount of the aptamers hybridized to the gold nanoparticles was estimated by measuring the fluorescence intensity of the oligonucleotide-Cy5 upon dissolution of the gold nanoparticles with KCN and comparing the measured intensity to the standard curve. The solution was treated with KCN to dissolve the gold and release the oligonucleotides, thus preventing the plasmon resonance of gold nanoparticles from interfering with fluorescence measurements.

C. Optical Imaging of Aptamer−Gold Conjugates. LNCaP cells and PC3 prostate cancer cells were obtained from ATCC. LNCaP is used as PSMA(+) cell line, while PC3 served as PSMA(−) cell line. The cells were grown in RPMI media with 5% FBS at 37 °C until they were 80−90% confluent. The cells were trypsinized, washed, and resuspended in 1× PBS before labeling. For cell labeling, the aptamer−gold conjugates (500 μL each) were added to LNCaP and PC3 cell suspensions for 30 min at 37 °C. The cells were centrifuged twice (1 min, 800 *g*) to remove unbound aptamer−gold conjugates. Reflectance imaging of the labeled cells was performed with confocal microscopy (Zeiss LSM510) in reflectance mode (633 nm laser, 63× objective). *Image J* software was used to compare the signal intensity of the reflectance images obtained from the two cell lines.

III. RESULTS AND DISCUSSION

Figure 1 illustrates the steps involved in conjugating anti-PSMA aptamers to gold nanoparticles. Gold nanoparticles are first coated with aptamer capture oligonucleotides via the gold−sulfur interactions between the lattice structure of the gold nanoparticles and the thiol groups of the aptamer capture oligonucleotide. Due to the strong gold−sulfur binding energy (*11*), most conjugation approaches to gold nanoparticles are based on this interaction. A PEG spacer is added between the thiol and the complementary capture sequence of the oligonucleotide to improve hybridization efficiency by minimizing steric hindrance between the gold surface and the hybridization site. The use of oligonucleotide coating on gold nanoparticles has several advantages. First, the negatively charged phosphate groups present on the oligonucleotides prevent aggregation of the nanoparticles via electrostatic repulsion. This results in stable gold nanoparticles that do not aggregate even in high salt environments (i.e., physiological buffers). Second, the presence of the capture oligonucleotides on the gold nanoparticles can be used to easily conjugate other targeting moieties which incorporate a complementary sequence. In this study, an extended anti-PSMA aptamer is then hybridized to the aptamer-capture oligonucleotides on the gold nanoparticles. A major advantage of this conjugation approach is that it prevents any direct modification of the aptamer sequence involved in the binding process, since conjugation to gold nanoparticles is facilitated via the oligonucleotide extension. A longer spacer composed of PEG, polyA's, or polyT's can also be used if larger gold nanoparticles (40−100 nm diameter) are desired. Larger

Table 1. Characterization of Aptamer−Gold Conjugates

	hydrodynamic size (diameter), nm	number of oilgonucleotide per Au nanoparticle
bare Au nanoparticle	19.3 ± 0.6	N/A
Au nanoparticle + aptamer capture oilgonucleotide	25.5 ± 1.2	376 ± 25 (aptamer capture)
Au nanoparticle + aptamer capture oilgonucleotide + anti-PSMA aptamer	39.6 ± 3.8	213 ± 12 (anti-PSMA aptamer)

nanoparticles can provide higher contrast images but can present difficulties during delivery and clearance routes.

Table 1 summarizes the characteristics of the gold nanoparticle conjugates used in this study. The bare gold nanoparticles were measured to have an average hydrodynamic diameter of 19.3 nm. The addition of the aptamer-capture oligonucleotide resulted in nanoparticles with an average diameter of 25.5 nm, an increase of 6.2 nm. This is consistent with the expected size contribution of the added aptamer-capture oligonucleotide (24 nucleotides + hexa(ethylene glycol) spacer) of about ∼3 nm on each side based on the predicted hairpin structure. Upon hybridization of the anti-PSMA aptamers, the average nanoparticle size was 39.6 nm, an increase of 20.3 nm compared to the bare gold nanoparticles. Again, the expected size contribution of the added extended A9 anti-PSMA aptamer (94 nucleotides) is between 8 and 10 nm on each side based on the predicted m-fold RNA secondary structure. In summary, the measured sizes of the functionalized gold conjugates are within the expected size contribution of the added oligonucleotides. Determining the size of the gold conjugates is an important consideration in the delivery and clearance of the contrast agents for imaging applications.

We also determined the average number of oligonucleotides (both aptamer capture and anti-PSMA aptamers) present per gold nanoparticle (Table 1). Based on measurements using the oligonucleotide quantitation assay, there are approximately 376 aptamer-capture oligonucleotides per gold nanoparticle. This number represents the possible number of hybridization sites for the anti-PSMA aptamers and is consistent with literature values for oligonucleotide coating on various sizes of Au nanoparticles (*12*). Using a fluorescently labeled anti-PSMA aptamer analogue, we determined that there are approximately 213 anti-PSMA aptamer analogues per gold nanoparticle. This represents a 57% conjugation efficiency which can be attributed to the steric hindrance upon hybridization between the aptamer capture oligonucleotide and the anti-PSMA aptamer analogue. The efficiency may be further reduced when using larger oligonucleotides like the extended A9 anti-PSMA aptamer. We did not determine this efficiency directly because of difficulties in modifying the aptamer with fluorescent dyes. Direct quantitation of the aptamer conjugated to gold nanoparticles using oligonucleotide assays is difficult because of the contribution of the aptamer capture oligonucleotide. However, we validated the incorporation of the extended A9 anti-PSMA aptamers on the gold nanoparticles using reflectance imaging. Ideally, only a few copies of the aptamers per gold nanoparticles are necessary to develop a molecular-specific contrast agent for reflectance imaging.

Figure 2 shows the brightfield and reflectance confocal images of PSMA negative (PC3) and PSMA positive (LNCaP) cells labeled with anti-PSMA aptamer−gold conjugates. The reflectance images of the LNCaP positive cell lines show strong labeling with the aptamer−gold conjugates. Minimal labeling was observed for the PC3 negative cell lines. The labeling on the LNCaP positive cells occurs around the cellular membrane, consistent with the expected pattern, since the PSMA target is a membrane-bound glycoprotein. The reflectance images also

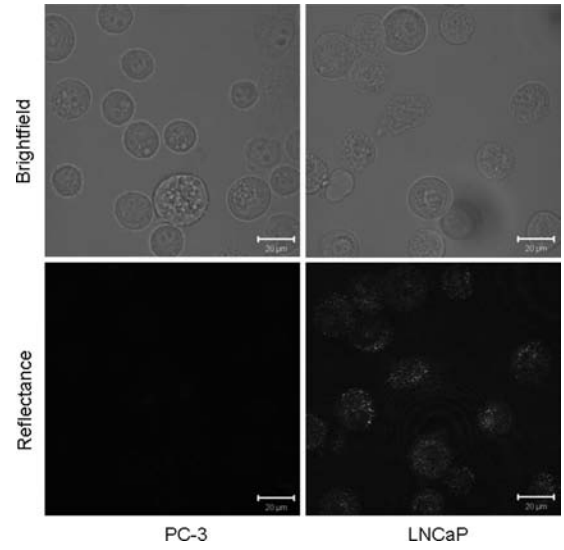

Figure 2. Reflectance imaging using aptamer−gold conjugates. Scale bar is 20 μm.

suggest possible endocytosis of the aptamer−gold conjugates during the labeling process. Analysis of signal intensity using *Image J* software shows a 3−5-fold increase in the reflectance intensity of the positive cell lines compared to intensity of the negative cell lines. For imaging applications, an increase of 1.5- to 3.0-fold in contrast intensity is considered significant (*13*).

There are other important considerations in the use of aptamer−gold conjugates as molecular-specific contrast agents for clinical imaging. For example, the cytotoxicity of the contrast agents should be carefully evaluated. In a previous paper, we evaluated the cytotoxicity of the oligonucleotide-coated gold nanoparticles using standard cell viability assays (*14*). Delivery and clearance routes of the contrast agents are also important factors. We are currently exploring these areas in order to facilitate translation of this type of contrast agents for molecular imaging applications.

IV. CONCLUSION

The study illustrates the feasibility of using aptamer−gold nanoparticles as molecular-specific contrast agents for reflectance imaging. We introduced a new method for conjugating aptamers via hybridization reactions on oligonucleotide-coated gold nanoparticles. An alternative approach for introducing aptamers to gold nanoparticles is the direct use of thiolated aptamers, which has recently been reported (*15*). However, the approach presented in this study has several advantages over the use of thiolated aptamers. First, the integrity and stability of the aptamers is easily preserved during the bioconjugation process since the aptamers are only introduced for a short period of time during the hybridization process. Second, a smaller amount of aptamers can be used for binding to gold nanoparticles, in contrast to thiolated aptamers where significant amounts of aptamers are necessary to coat and stabilize the gold nanoparticles. In our approach, the use of shorter and cheaper complementary oligonucleotides facilitates better coating and stabilization of the gold nanoparticles prior to bioconjugation of the aptamers. Last, our approach offers possible multiplexing capabilities where other types of molecules (targeting, delivery, imaging, or therapeutic) can be incorporated in the design of the contrast agents. In a previous study, we have demonstrated a multimodal reporting system (reflectance and fluorescence) using oligonucleotide−dye conjugates hybridized on complementary oligonucleotides functionalized on gold nanoparticles (*14*). Moreover, therapeutic molecules can be incorporated to

the aptamer-gold nanoparticles to develop multimodal theranostic agents. For example, protein-based therapeutic agents (*16*) can be functionalized via oligonucleotide−protein linkage to aptamer−gold conjugates with the advantage of controlling the amount of therapeutic agents per nanoparticle. The ability to incorporate multifunctional agents into a single construct can be a useful technique in developing multimodal platforms for various clinical applications.

TECHNICAL NOTES

Evaluation of Ketone-Oxime Method for Developing Therapeutic On-Demand Cleavable Immunoconjugates

Pappanaicken R. Kumaresan,* Juntao Luo, Aimin Song, Jan Marik, and Kit S. Lam. Received January 17, 2008; Revised Manuscript Received March 31, 2008

The use of antibody molecules in immunoassay, molecular targeting, or detection techniques encompasses a broad variety of applications affecting nearly every field of medical science. In cancer therapy, monoclonal antibodies (mAb) have been used as vehicles to deliver radionuclides, toxins, or drugs to the target cancer cells. New conjugation methods are most needed to conjugate a wide variety of targeting small molecules and peptidomimatic compounds. Here, we exploited a keto-oxime method for conjugation of protease susceptible linkers to an antibody. This modified method involves two steps: (i) introduction of methyl ketone linkers (referred to as linker moiety) to the primary amines present in the antibody and (ii) conjugation of ketone linkers to aminoxy functional group present in the conjugated moiety (referred to as functional moiety). We have optimized this conjugation method and shown that ~10 functional moieties can be conjugated to antibody. Conjugation was verified by MALDI-TOF MS and Western blot analysis. The acidic pH conditions used in this method did not change the immune reactivity of the Ab. In addition, *in vitro* protease susceptibility assay was performed to validate this method for prodrug release assay as well as to remove excess radioimmune conjugates from circulation. This orthogonal method is compatible with peptides containing a thiol, amino, or carboxyl groups in the conjugation moiety.

1. INTRODUCTION

Ketones selectively react with amino-oxy groups and form oxime bonds at slightly acidic pH. This type of chemoselective ligation is more preferable for making bioconjugates because it does not require anhydrous conditions, excessive heat, or any catalyst (*1, 2*). It is also tolerant of a wide range of functional groups that are found in proteins and oligonucleotides. This ligation has been successfully used in various applications such as making small molecule drug conjugates (*3*), peptide and oligonucleotide conjugates (*4*), protein conjugates (*5*), glycoconjugates (*2*), polymer conjugates (*6, 7*), and coating biomolecules on plannar microarray slides (*8*) and sialoglycoproteins present on cell wall (*9, 10*). Except for N-terminal labeling (*11*), this ligation method has not been used to make antibody drug conjugates especially in the area of cancer targeted therapy. Antibodies are important biomolecules developed by nature to protect hosts by eliminating disease-causing pathogens. Several conjugation methods have been developed to conjugate radionuclides, toxins, or drugs to antibody for cancer therapy (*12–17*). Here, we report conjugation of tissue plasminogen activator (t-PA) substrate rqYKYkf (*18*) to ChL6 antibody by the keto-oxime method. Chemical synthesis of methylketo linkers, aminoxy-functional peptides and optimization of conjugation method and its bioapplications are discussed.

2. MATERIALS AND METHODS

Rink amide MBHA resin (0.45 mmol/g) was purchased from Tianjin Nankai Hecheng (Tianjin, China). Levulinate *N*-succinimidyl ester was prepared using our previously published procedure (*8*). All the amino acid derivatives and HOBt (1-hydroxybenzotriazole) were purchased from CPC (San Jose, CA). DIC (diisopropylcarbodiimide) was purchased from Advanced ChemTech (Louisville, KY). DMF (*N*,*N*-dimethylformamide) was purchased from VWR (Brisbane, CA). DCM (dichloromethane), MeOH (methanol), diethyl ether, and acetonitrile were purchased from Fisher (Houston, TX). All other chemical reagents were purchased from Aldrich (Milwaukee, WI). Analytical HPLC analyses (Vydac column, 4.6 mm × 250 mm, 5 μm, 300 Å, C_{18}, 1.0 mL/min, 25 min gradient from 100% aqueous media (0.1% TFA) to 100% CH_3CN (0.1% TFA), 214, 220, 254, and 280 nm) and preparative HPLC purification (Vydac column, 20 mm × 250 mm, 5 μm, 300 Å, C_{18}, 7.0 mL/min, 45 min gradient from 100% aqueous media (0.1% TFA) to 100% CH_3CN (0.1% TFA), 254 nm) were performed on a Beckman System Gold HPLC system (Fullerton, CA). MALDI-TOF MS analysis was performed on a Bruker BIFLEX III mass spectrometer (Billerica, MA). All of the experiments are carried out at room temperature unless otherwise noted. ChL6 (Bristol-Myers Squibb Pharmaceutical Research Institute, Seattle, WA) was a chimera consisting of human IgG1-constant regions and the murine L6 mAb antigen-binding site.

2.1. Synthesis of Biotin-rqYKYkf-spacer-K(Aoa)-NH_2 Peptide. Solid-phase synthesis of biotin-rqYKYkf was carried out using Rink amide MBHA resin after the treatment of resin with 20% piperidine solution in DMF (2 mL) for 15 min to remove Fmoc protecting group. Onto the Rink resin (200 mg, 0.09 mmol) with free amino groups, Fmoc-Lys(Alloc)-OH (122.2 mg, 0.27 mmol) was coupled following the standard Fmoc chemistry using HOBt (36.5 mg, 0.27 mmol) and DIC (42.3 μL, 0.27 mmol) as coupling agents. The coupling was monitored using ninhydrin test agents until a negative result was obtained. The resin was washed with DMF, MeOH, and DCM 3 times,

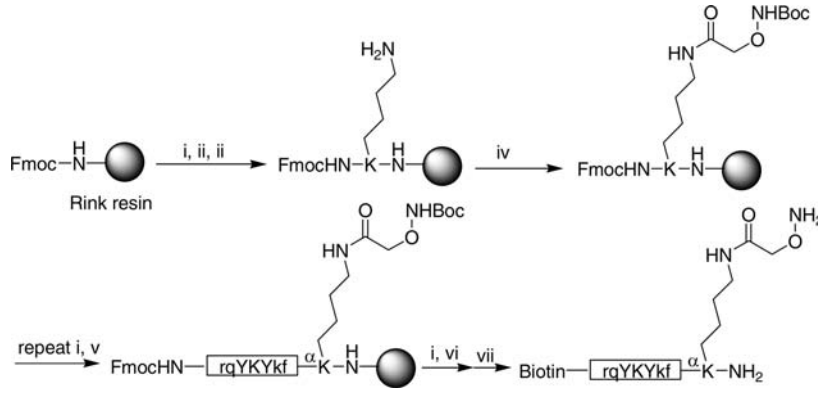

Figure 1. Schematic representation of the synthesis of aminoxy peptide. (i) 20% Piperidine in DMF; (ii) Fmoc-Lys(Alloc)-OH, DIC/HOBt; (iii) $Pd(PPh_3)_4/PhSiH_3$; (iv) Boc-Aoa-OH, DIC/HOBt; (v) Fmoc-AA_i, DIC/HOBt; (vi) Biotin, HBTU/DIEA; (vii) K Reagent (TFA/phenol/thioanisole/water/propylsilane, 82.5/7.5/5/5/2.5, v/w/v/v/v.

respectively. The resin was treated twice with $Pd(PPh_3)_4$ (26.0 mg, 0.0225 mmol) in the presence of excessive $PhSiH_3$ (266.5 μL, 2.16 mmol) in DCM under argon for 30 min to remove the alloc protecting groups on the side chain of lysine. After thoroughly washing the resin with DCM, DMF, MeOH, and DMF, Boc-Aoa-OH (51.6 mg, 0.27 mmol) was coupled onto the resin using HOBt (36.5 mg, 0.27 mmol) and DIC (42.3 μL, 0.27 mmol) as coupling agents until the ninhydrin test was negative. After deprotection of Fmoc groups by piperidine treatment, a linear hydrophilic linker was coupled to the α-amino group of the lysine as a spacer following a published procedure (*19*). The peptide was constructed on the linker using standard Fmoc chemistry using DIC/HOBt as coupling agents (*20*). After the coupling of the last amino acid, the N-terminus Fmoc protection group was removed by piperidine treatment. The resin was treated with a solution of biotin (44.0 mg, 0.18 mmol), DIEA (diisopropylethylamine, 42.3 μL, 0.36 mmol), and HBTU (*O*-(benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate, 68.3 mg, 0.18 mmol) in DMF (2 mL) until the ninhydrin test was negative. The resin was thoroughly washed with DMF, MeOH, and DCM, and then dried *in vacuo*. To the dried resin was added 4 mL of cleavage mixture (TFA (trifluoroacetic acid)/phenol/thioanisole/water/TIS (triisopropylsilane), 82.5:7.5:5:5:2.5, v/w/v/v/v) at ice-bath temperature. The mixture was slowly warmed to room temperature and allowed to agitate for 6 h. The supernatant was then collected and the resin was washed with TFA (3 × 1 mL). The combined supernatants were concentrated to 1 mL under a stream of nitrogen. The peptide was precipitated by dilution with cold ethyl ether (10 mL), collected by centrifuge, washed with ethyl ether, and dried *in vacuo*. The crude peptide was analyzed and purified by HPLC, and characterized by MALDI-TOF MS.

2.2. Antibody Conjugation. This keto-oxime method has two steps. First, ketone linkers will be conjugated to primary amines of the antibody followed by conjugation of functional derivatives such as DOTA chelators, immunotoxin, or chemotoxin. Before conjugation, the required amounts of antibody were purified by passing through a Sephadex-G100 molecular sieving column to remove impurities and are equilibrated with 40 mM of ketone linker conjugation buffer triethanolamine (pH 7.8). The linker conjugation can be done with phosphate buffer 50 mM (pH 7.8). In order to identify optimum ketone group introduction to Ab, conjugation was done with antibody at different molar ratios (10:1, 20:1, 30:1, and 300:1) for 1 h at room temperature. After conjugation, the excess free linkers were removed by passing through the Sephadex-G100 spin columns. In the second step, aminoxy functional conjugates were conjugated to the ketone linker of Ab with different molar ratios of linker to Ab (10:1, 20:1, and 30:1) at RT for 4 h in the present of TEA (40 mM, pH 5.5). We have selected a biotin-tagged

rqYKYkf peptide, which is cleavable by tissue plasminogen activator (t-PA, recombinant version of t-PA, trade name TNKase) (*18*), as a functional derivative to verify this conjugation method for antibody studies. Conjugation was confirmed by determining the mass of the antibody and peptide conjugated antibody by using MALDI-TOF mass spectrometry.

2.3. Western Blot Analysis and Protease Cleavage Studies. Breast adenocarcinoma cancer cell targeting antibody (ChL6) (*21*) and biotin-rqYKYkf-conjugated ChL6 was separated at 10% SDS-PAGE gel and transferred onto nitro cellulose membrane. The transferred membrane was blocked with 1% BSA for 3 h at RT and incubated with HRPO-conjugated avidin for 30 min. Unbound avidin was removed by washing three times with TBS containing 0.2% Tween-20 and bands were developed by ECL method (Perkin-Elmer life Sciences). Biotinylated anti-insulin antibody was used as control. For protease susceptibility studies, biotin-rqYKYkf-conjugated ChL6 was incubated with TNKase at different concentrations (0, 10, and 25 μg/mL) in TBS buffer pH 8.0 for 1 h at 37 °C. Digested

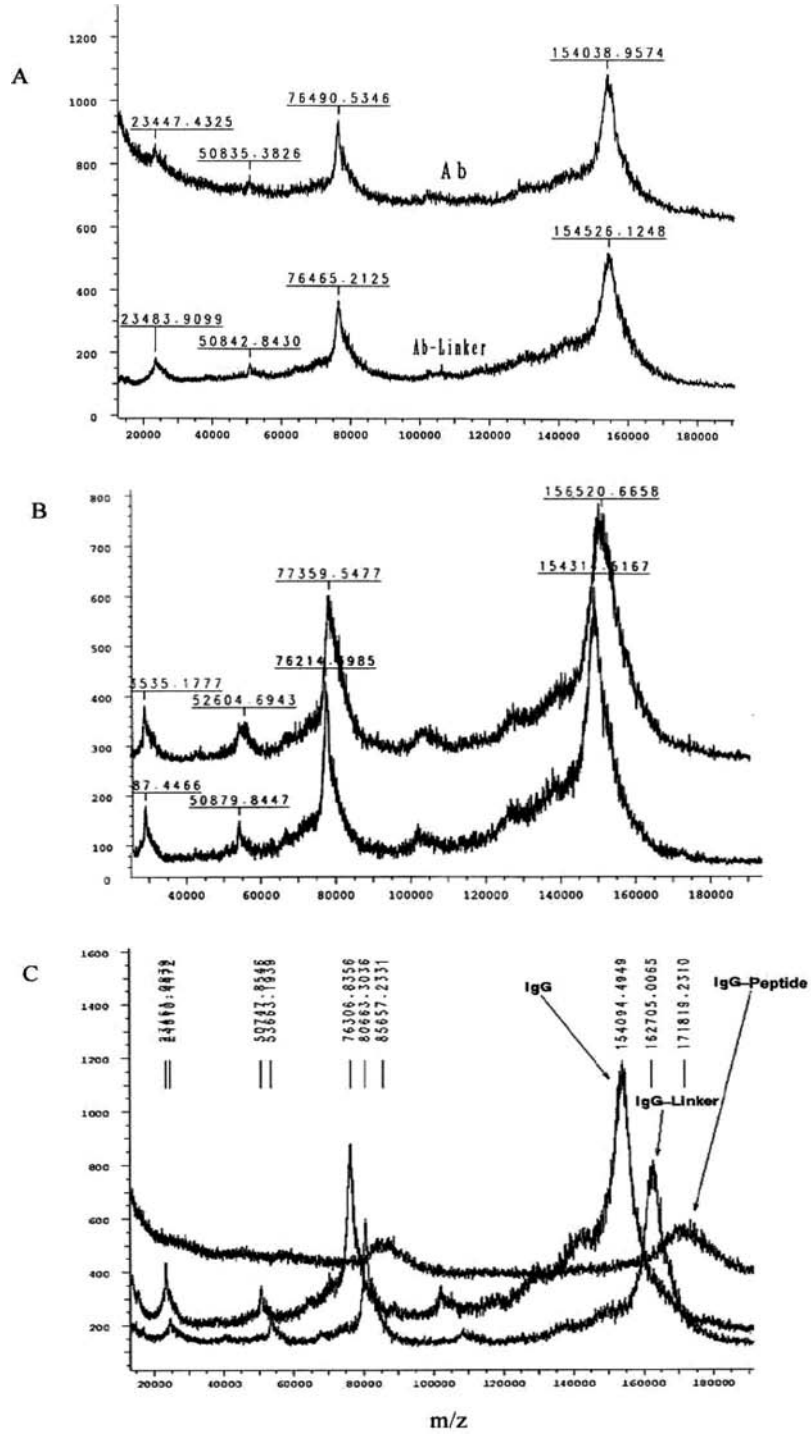

Figure 3. MALDI-MS analysis of ChL6 Ab, ChL6-linker moiety, and ChL6-functional moiety: (A) At 30:1 molar ratio of linker to Ab, ~5−6 linker moiety was conjugated to ChL6 Ab. (B) At 30:1 molar ratio, ~1−3 functional moiety (MW 1688) was conjugated to ChL6. (C) At 300:1 molar ratio, ~7−11 functional moieties were conjugated. The average incorporated values are shown. At this ratio, ChL6 with linker moiety showed a distinct peak suggesting that most of the primary amines in ChL6 are conjugated with linker moiety.

products are separated, transferred to membrane, and stained with avidin-HRPO as described above.

2.4. Immunohistochemistry. Breast adenocarcinoma cancer cells were seeded on a six-well plate one day before the experiments were performed. 1 μg of ChL6 and biotin-rqYKYkf-conjugated ChL6 were added directly into 1 mL of growth media in duplicate and kept for 1 h on ice. Unbound antibodies were removed by washing three times with PBS containing 1% BSA. FITC-conjugated streptavidin was added to each well and kept on ice for 30 min, followed by washing three times with PBS containing 1% BSA to remove the unbound streptavidin. Fluorescent staining was observed under the fluorescence microscope in green filter (U-M51004 F/R-V2; Olympus).

3. RESULTS AND DISCUSSION

3.1. Characterization of Biotin-rqYKYkf-spacer-K [Aminoxy (Aoa)]-NH_2 Peptide. The methyl ketone linker (Levulinate *N*-succinimidyl ester) was synthesized according to the reported procedure using levulinic acid and *N*-hydroxyl succinimide as starting materials and 85% yield was obtained (*8, 22*). Synthetic

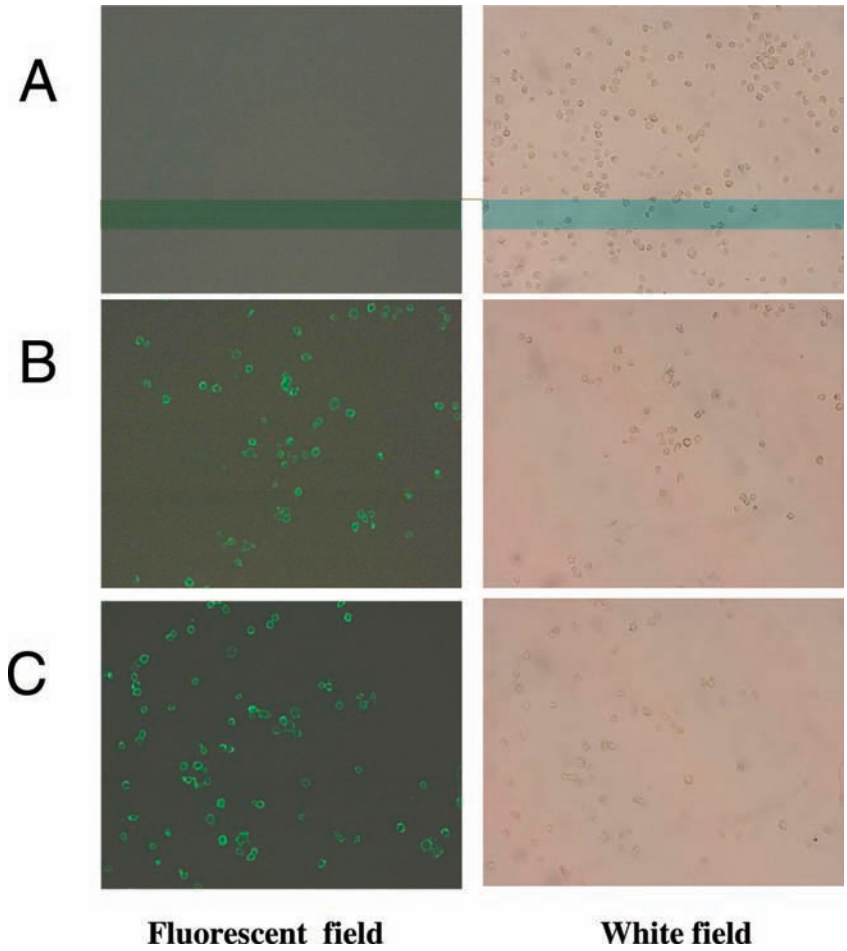

Figure 4. Immunoreactivity assay: Breast cancer cells (HBT) were incubated with ChL6 (B) and ChL6 conjugated to functional moiety (C) followed by FITC conjugated murine antihuman Ab. ChL6 conjugated with functional moiety (C) showed binding as good as native unaltered ChL6 (B). FITC conjugated murine antihuman IgG did not show any binding (A).

scheme of biotin-rqYKYkf-spacer-K(Aoa)-NH_2 peptide was shown in Figure 1. A total of 25 mg of biotin-rqYKYkf-spacer-K(Aoa)-NH_2 was obtained from 200 mg of resin (yield: 16%). The synthetic product was verified by MALDI-TOF MS $(M+H)^+$ calculated: 1688.9; found: 1688.5.

3.2. Optimization of Ketone-Oxime Conjugation. This modified ketone-oxime method has two steps. (i) introduction of the NHS-ketone linkers (referred as linker moiety) to the primary amines present in the antibody and (ii) conjugation of ketone group to aminoxy functional group present in the conjugated moiety (referred to as functional moiety). Steps involved in this conjugation are shown in Figure 2.

First, ketone linkers were introduced by reacting the NHS group with primary amines of the antibody at various molar ratio (L/Ab 5:1, 10:1, 30:1, and 300:1). MALDI-MS results revealed that antibody derivatives occurred when a 20-fold excess or more of ketone linker was used in the initial antibody modification step. No conjugation was observed when 5:1 or 10:1 molar ratio of L/Ab was used. Table 1 summarizes the level of antibody derivatives under various L/Ab ratios. At 30:1 (L/Ab) ratio, ~5−6 linker moieties were conjugated to each Ab molecule (Figure 3A). The same preparation will yield 1−3 functional conjugates (Figure 3B). At (L/Ab) ratio of 300:1, mass spectrometry analysis of ChL6 Ab showed a distinct peak (Figure 3C) suggesting that most of the primary amines present in the Ab were conjugated. When functional moiety is conjugated at 30 molar ratio to an antibody, ~3 functional moieties were generated from this preparation. Previous reports have shown that, in order to retain the biological function of antibodies, conjugation of a functional moiety should not exceed 8. Therefore, we have selected 30:1 L/Ab ratio to perform our conjugation studies.

3.3. Immunoreactivity Assay. CHL6, a chimeric antibody that targets a breast cancer antigen, was used for conjugation studies (*21*). To verify that this conjugation method does not alter antigen binding properties of CHL6 antibody, it was conjugated with biotin-tagged peptide at 30:1 L/Ab ratio, and immunoreactivity assay was performed on breast cancer cells (HBT). Figure 3 shows that both conjugated and unconjugated ChL6 antibody were binding HBT breast cancer cells with similar intensity, confirming that the conjugation method did not alter the antigen binding property of CHL6 (Figure 4).

3.4. Protease Susceptibility Assay. In clinics, antibodies have been used for targeting as well as delivering therapeutic drugs, especially prodrugs to eliminate infected and transformed cells. These nontoxic prodrugs get converted to a toxic metabolite when it is cleaved by a specific protease such as Cathepsin-B at the target site (*23*). A similar strategy has been used in radioimmunotherapy (RIT), to remove circulating radioimmunoconjugates after tumor targeting. This will boost the therapeutic potential of RIT which was greatly limited by exposure of radiation to vital organs (liver, bone marrow) during the treatment. These linkers can be cleaved either internally by proteases expressed in vital organs such as the liver (e.g., Cathepsin-D) (*24*) or externally by administering enzymes such as β-lactamase (*25*) and TNKase (*18*). We have selected TNKase as an on-demand cleavable enzyme because it is already in clinical use to dissolve fibrin clots (*26, 27*). Protease susceptibil-

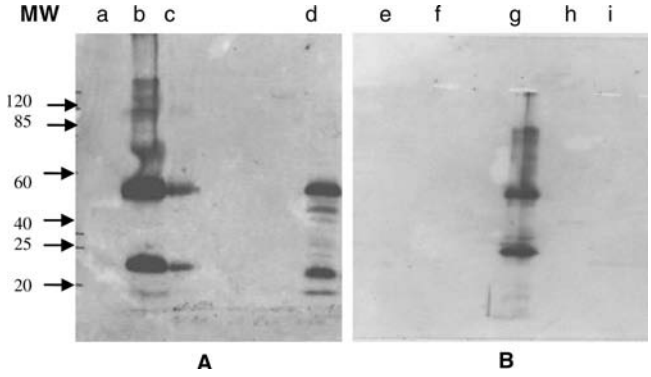

Figure 5. Western blot and protease susceptibility analysis: (A) ChL6−10μg (a), ChL6-conjugated with biotin-rqYKYkf−10μg (b), ChL6-conjugated with biotin-rqYKYkf−1μg (c), biotinylated anti-insulin Ab (d) was electrophoresed in 10% SDS-PAGE gel and developed using ECL after transferring to a nylon membrane. Positive bands appeared only on conjugated ChL6 (b,c,d) and not the native ChL6 (a). (B) To evaluate protease susceptibility of the functional moiety (t-PA substrate), conjugated ChL6 was incubated with various concentrations of TNKase, 0 μg/mL (g),10 μg/mL (h), and 25 μg/mL (i). The band has disappeared in TNKase-treated lanes (h,i) and not in untreated lanes (g). Native ChL6 and TNKase were run together as a negative control. Standard MW markers are shown on the left side of the figure.

ity was evaluated by incorporating t-PA substrate "rqYKYkf", identified by screening one-bead−one-compound combinatorial chemistry libraries in linker moiety with biotin tag (*18*). After conjugation with ChL6 at 30:1 molar ratio, 5 μg/mL samples were taken in triplicate and digested with 0, 10, and 25 μg/mL of recombinant t-PA (TNKase) for 2 h at RT. Digested samples were identified by Western blot analysis as described in the Materials and Methods section. ECL showed bands only in the conjugated ChL6 and not with ChL-6 alone or in TNKase-digested conjugated ChL6 samples, suggesting that biotin was removed by protease digestion. This confirms that this method can be used as an alternative method to conjugate therapeutic drugs, especially prodrugs (Figure 5).

CONCLUSION

Previously, we used the methods described here to print peptides and small molecules in microarrays over a planar surface (*8*). Previously, *in vivo* small molecule drug conjugate studies have demonstrated oxime bond stability at the physiological pH of body fluids (*28*, *29*). Here, we have demonstrated this method to conjugate protease (TNKase) cleavable peptides to antibodies without affecting their antigen binding properties. We also showed that conjugated substrates were susceptible to TNKase at the clinical dosage. We conclude that the ketone-oxime method can be substituted in place of other methods like maleimide (*12*) and click chemistry conjugation (*30*) for making therapeutic antibody conjugates. This method is compatible with peptides containing a thiol, amino, or carboxyl group in the conjugation moiety.

ACKNOWLEDGMENT

Author greatly appreciated Dr. Sally Denardo for providing ChL6 antibody and HBT cells and Dr. Seth Dixon for proofreading. This study was supported by funds from NIH Grant P01-CA047829-15A2 and DOD-CM064046.

Chemical conjugates of paclitaxel and hyaluronic acid (HA) were synthesized by utilizing a novel HA solubilization method in a single organic phase. Hydrophilic HA was completely dissolved in anhydrous DMSO with addition of poly(ethylene glycol) (PEG) by forming nanocomplexes. Paclitaxel was then chemically conjugated to HA in the DMSO phase via an ester linkage without modifying extremely hydrophilic HA. A series of HA−paclitaxel conjugates with different conjugation percentages were synthesized and characterized. HA−paclitaxel conjugates self-assembled in aqueous solution to form nanosized micellar aggregates, as characterized by dynamic light scattering (DLS), atomic force microscopy (AFM), and transmission electron microscopy (TEM). An intact form of paclitaxel was regenerated from HA−paclitaxel conjugate micelles at acidic pH conditions. HA−paclitaxel conjugate micelles exhibited more pronounced cytotoxic effect for HA receptor overexpressing cancer cells than for HA receptor deficient cells, suggesting that they can be potentially utilized as tumor-specific nanoparticulate therapeutic agents.

INTRODUCTION

Paclitaxel is a powerful anticancer drug originally isolated from the bark of pacific yew (*Taxus brevifolia*) and is well-known for its antimitotic activity that promotes tubulin assembly into stable microtubules (*1*–*3*). Paclitaxel prevents the depolymerization of polymerized microtubules, thus inhibiting cell replication in the late G_2/M phase of the cell cycle (*4*, *5*). Although paclitaxel has shown remarkable potential as an anticancer drug, its poor solubility in water has limited widespread use in cancer therapy. Current clinical formulation such as Taxol contains a 50:50 mixture of Cremophore EL and ethanol to enhance the solubility of paclitaxel in water. However, a large number of studies have reported various side effects of Cremophore EL such as hypersensitivity, neurotoxicity, and neuropathy (*6*–*8*). Previous attempts to overcome the serious side effects include formulating paclitaxel in various carriers such as polymer conjugates, liposomes, polymeric micelles, emulsions, and nanospheres (*9*–*12*).

Among them, drug−polymer conjugates have distinctive advantages over conventional polymeric nanosized carriers by demonstrating high drug content and good solubility in water, increasing drug half-life in the body, and enhancing antitumor effects (*13*). Although various water-soluble synthetic polymers have been widely exploited for conjugation of hydrophobic drugs, naturally occurring polymers with intrinsic cell specific binding capacity have tremendous potential as a target specific drug carrier. For example, hyaluronic acid (HA), a naturally occurring polysaccharide composed of *N*-acetyl-D-glucosamine and D-glucuronic acid, has a strong affinity with cell-specific surface markers such as CD44 and RHAMM (*14*). HA plays important roles in biological functions, such as stabilizing and organizing the ECM, regulating cell adhesion and motility, and mediating cell proliferation and differentiation (*15*–*17*). HA is also closely related to angiogenesis in many types of tumors, in which HA receptors (CD44 and RHAMM) are abundantly overexpressed on the surface. Thus, malignant cells with high metastatic activities often exhibit enhanced binding and uptake of HA (*18*–*20*). More recently, HA and its derivatives have been popularly used as target-specific drug delivery vehicles for various therapeutic agents (*21*–*23*).

Chemical modification and conjugation of HA have been achieved in aqueous solution by utilizing reactive functional groups in HA such as carboxylic groups and hydroxyl groups and a reducing end (*24*–*26*). However, its extreme hydrophilicity and poor solubility in most organic solvents restrict the direct conjugation of HA with hydrophobic polymers, drugs, and lipids. To circumvent the above problems, various solubilization methods were utilized to obtain a homogeneous mixture of HA and hydrophobic reactants in a common solvent. For example, a mixture of polar organic solvent and water (i.e., DMSO/H_2O or DMF/H_2O) was used to codissolve *N*-hydroxysuccinimide-activated paclitaxel and adipic dihydrazide functionalized HA for conjugation (*27*). Polyanionic HA was physically complexed with aliphatic quaternary ammonium compounds or chemically blocked to enhance the solubility of HA in the mixed organic solvents for further modification (*28*). However, the above methods have shown some limitations such as multiple activation steps required for conjugation in mixed water/organic solvent phase and utilizing environmentally cytotoxic ammonium surfactants that are not preferred for biomedical and drug delivery applications.

Previously, we reported the solubilization of DNA in organic solvents using biocompatible poly(ethylene glycol) (PEG) by forming nanoscale complexes (*29*). More recently, other hydrophilic biomacromolecules such as proteins and carbohydrates could also be solubilized in organic solvents by using PEG as a nanocomplexing agent (*30*). Since PEG can act as both hydrogen bonding donor and acceptor, it was hypothesized that the addition of PEG in organic solvents could also facilitate the formation of HA/PEG nanocomplexes by inter- and intrahydrogen bonds (*31*). In the present study, HA was solubilized in anhydrous DMSO by complexing with dimethoxy poly(ethylene glycol) (dmPEG). It was expected that HA soluble in DMSO could be readily conjugated by various hydrophobic drugs, thus generating HA−drug bioconjugates with high yield without using any salts and blocking agents. A typical water-insoluble anticancer drug, paclitaxel, was chosen for HA−drug conjuga-

tion in organic solvents. HA−paclitaxel conjugate was synthesized and their self-assembly properties in aqueous solution were characterized using dynamic light scattering (DLS), atomic force microscopy (AFM), and transmission electron microscopy (TEM). Critical aggregation concentration (CAC) was also determined by employing hydrophobic fluorescence probes. Target-specific antitumor activities were comparatively evaluated using HA-receptor positive and negative cells.

EXPERIMENTAL PROCEDURES

Materials. Hyaluronic acid (HA) sodium salt (MW: 64 kDa) was purchased from Lifecore Biomedical (Chaska, MN). Poly(ethylene glycol) dimethyl ether (dmPEG) (MW: 2000 Da), 1,3-dicyclohexylcarbodiimide (DCC), 4-dimethylaminopyridine (DMAP), propidium iodide (PI), pyrene, and anhydrous dimethyl sulfoxide (DMSO) were all obtained from Sigma-Aldrich (St. Louis, MO). Paclitaxel was purchased from TCI (Tokyo, Japan). Cell counting kit-8 (CCK-8) was obtained from Dojindo laboratories (Kumamoto, Japan). All other chemicals and reagents were of analytical grade and used as received.

Preparation of HA/dmPEG Complexes and Solubilization of HA/dmPEG in DMSO. For desalting process, 1 g of HA (64k Da) was dissolved in 100 mL of deionized water, dialyzed (MWCO: 1k Da) for 24 h, and lyophilized. A blend mixture of desalted HA and dmPEG at four different dmPEG/HA weight ratios (0.5, 1, 5, and 10) was added in 25 mL of deionized water. The solution was well-stirred and lyophilized to obtain dry HA/dmPEG complex powder. A total of 600 mg of lyophilized HA/dmPEG complexes was added in 5 mL of anhydrous DMSO under dry N_2. After the solution was vigorously stirred at 80 °C for 2 h, the transmittance value was measured at 400 nm using a spectrophotometer (UV-1601, Shimadzu, Japan) to verify the solubilization of HA/dmPEG complexes in DMSO as a function of added dmPEG amount.

Synthesis of HA−Paclitaxel Conjugate. A total of 600 mg of HA/dmPEG powder prepared at 5 weight ratios of dmPEG/HA was dissolved in 5 mL of anhydrous DMSO with addition of DCC and DMAP at different molar ratios. The solution was stirred for 1 h to activate carboxylic groups of HA. Paclitaxel with different amounts (10 and 20 mg) was dissolved in 1 mL of anhydrous DMSO and slowly added to the above solution using a syringe under dry N_2. The mixture was then stirred for 2 days at 40 °C. The resultant solution was dialyzed against DMSO for 1 day and deionized water for 3 days using a dialysis membrane (MWCO: 3500 Da) to remove unreacted paclitaxel and dmPEG. HA−paclitaxel conjugate was collected and lyophilized for 3 days and analyzed. Five different HA−paclitaxel conjugates were synthesized depending on the molar ratio of paclitaxel, DCC, and DMAP. ^{1}H NMR spectra of HA−paclitaxel conjugate was obtained by a Bruker 400 MHz NMR spectrometer (Bruker, Germany) using D_2O and DMSO-d_6. The amount of paclitaxel conjugated to HA was determined by an HPLC (1100 series, Agilent Technologies, Palo Alto, CA, USA) using a reversed-phase column (Waters Spherisorb ODS2: 4.6 mm ID × 250 mm). The mobile phase consisting of acetonitrile/water (50/50 (v/v)) was used to fully expose conjugated paclitaxel molecules in the cosolvent phase for UV detection. The solvent was delivered at a flow rate of 0.8 mL/min for the HPLC analysis and eluted peaks were monitored (λ_{max}: 227 nm, $\epsilon = 2.81 \times 10^4$ $M^{-1}cm^{-1}$). Free paclitaxel was used to generate a standard curve for the estimation of paclitaxel content in HA−paclitaxel conjugates. There was no difference in the molar extinction coefficient of paclitaxel molecule before and after the conjugation.

Characterization of Self-Assembled HA-Paclitaxel Conjugate Micelles in Aqueous Solution. The formation of HA−paclitaxel conjugate micelles in aqueous solution was characterized by measuring their hydrodynamic diameter using a dynamic light scattering instrument (Zeta-Plus, Brookhaven, NY). The size measurement was carried out ($n = 6$) at a concentration of 5.0 mg/mL of HA−paclitaxel conjugate (sample #4 in Table 1) in deionized water at 25 °C. Nanosized HA−paclitaxel micelles were also visualized by atomic force microscopy (AFM) and transmission electron microscopy (TEM). For AFM image, 100 μL of HA−paclitaxel micelle solution (5.0 mg/mL) was placed on a clean mica surface and then air-dried overnight. The image was obtained with a PSIA XE-100 AFM system (Santa Clara, CA) in a noncontact mode with a scanned area of 5 × 5 μm. For TEM image, HA−paclitaxel micelles were analyzed by Zeiss Omega 912 transmission electron microscope (TEM) (Carl Zeiss, Germany). TEM sample was prepared by depositing 20 μL of HA−paclitaxel solution (5.0 mg/mL) on a 300 mesh copper TEM grid with a carbon film and air-dried at room temperature. Critical aggregation concentration (CAC) of HA−paclitaxel conjugate was estimated by employing a hydrophobic fluorescence probe, pyrene, as described previously (*32*). A pyrene stock solution prepared in deionized water was prepared at a concentration of 6.0×10^{-7} M. Different amounts of HA−paclitaxel conjugate ranging from 0.1 μg to 1 mg/mL were dissolved in the pyrene stock solution. At an emission wavelength at 390 nm, excitation spectra of HA−paclitaxel micelle solution with pyrene were monitored by a spectrofluorometer (Shimadzu, Japan).

pH Dependent Release of Paclitaxel from HA−Paclitaxel Conjugate Micelles. HA−paclitaxel conjugate micelles were formed in deionized water at a concentration of 10 mg/mL. pH of the sample solution was adjusted from 1 to 7 using 0.1 M NaOH or HCl. After gentle mixing for 3 h at 37 °C, the solution was filtered using a 0.45 μm syringe filter. The amount of paclitaxel cleaved from the conjugate was monitored by HPLC as described above using a reverse-phase column (Waters Spherisob ODS2: 4.6 mm ID × 250 mm) with a refractive index (RI) detector (RI-71, Shodex, Japan).

***In Vitro* Antitumor Activities of HA−Paclitaxel Conjugate Micelles.** HCT-116 and MCF-7 cells were used as CD44 overexpressing cancer cell lines to verify *in vitro* cell-specific targeted delivery of HA−paclitaxel conjugate micelles (*21, 27*). NIH-3T3 cells were used as a CD44 deficient cell line. Cells were plated in a 96-well plate at a density of 1×10^4 cells per well and grown in RPMI medium supplemented with 10% (v/v) fetal bovine serum for 24 h at 37 °C. Cytotoxicity of HA−paclitaxel conjugate micelles was evaluated by treating cells with different concentrations of HA−paclitaxel conjugates for 2 days at 37 °C. For comparison, Taxol was prepared as described elsewhere and used as a positive control (*32*). Cell viability were determined by a CCK-8 cell viability assay kit (*33*).

An apoptotic event such as DNA fragmentation was observed using a confocal laser microscope (LSM 510, Carl-Zeiss Inc., USA) and a flow cytometer (FACSCalibur, USA). HCT-116 cells were

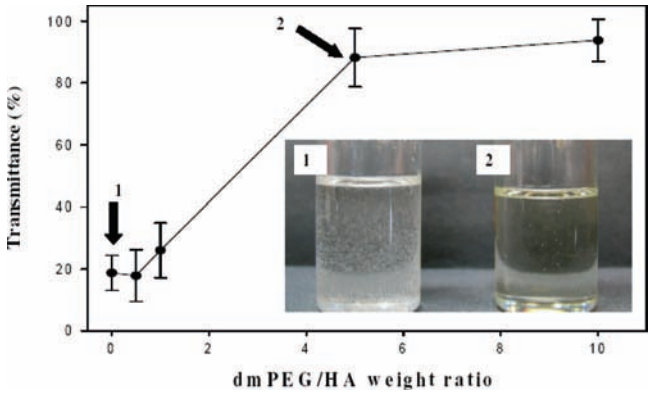

Figure 1. Transmittance of HA/dmPEG solubilized DMSO after 2 h of mixing at 80 °C as a function of dmPEG amount. Note that the inset shows the photographic image of DMSO solution at the pointed samples.

plated in a chamber slide at a density of 1.0×10^5 cells/mL and treated with Taxol formulation or HA−paclitaxel conjugate micelle formulation at an equivalent paclitaxel concentration of 1 μg/mL for 24 h at 37 °C. The cells were fixed with 1% paraformaldehyde and then incubated with a propodium iodide (PI) staining solution (0.25 mg/mL PI and 0.1 mg/mL RNase A in PBS solution) at a concentration of 1×10^6 cells/mL for 30 min at 37 °C. Stained cells were visualized at an excitation wavelength of 543 nm using a confocal microscope. For flow cytometric analysis, the stained cells were collected and resuspended in 1.5 mL PBS solution (pH 7.4). The PI fluorescence of each nucleus was analyzed using *CELLQUEST* software (PharMingen, USA).

RESULTS AND DISCUSSION

The formulation of paclitaxel with biocompatible materials has been examined in depth to increase its solubility in aqueous solution. Among the formulations using nanoscale particulates and polymer conjugates, polyglutamic acid and polypeptides were previously used to chemically conjugate paclitaxel to enhance the solubility (*34–36*). Paclitaxel-conjugated polyglutamic acid, as a prodrug, showed promising antitumor effect *in vivo* and is now in clinical trial. HA, a naturally occurring biocompatible polysaccharide, was also used for the conjugation of paclitaxel. Adipic dihydrazide functionalized HA was reacted with active ester derivatized paclitaxel in DMF/H_2O mixture for HA−paclitaxel conjugation (*27*). Although HA−paclitaxel conjugates prepared in the mixed-solvent system showed enhanced solubility of paclitaxel in aqueous medium with good cytotoxicity results, their synthetic method required multiple cumbersome steps for direct conjugation of paclitaxel on the backbone of HA. This is because HA is not soluble in most organic solvents mainly due to extremely hydrophilic nature with strong inter/intramolecular hydrogen bonding (*14,15*). To make HA soluble in polar organic solvents, HA was physically complexed with cationic salts and surfactants to shield highly anionic carboxylic acid groups and to disrupt inter/intramolecular hydrogen bonds in HA. Alternatively, functional groups in HA were partially protected by hydrophobic blocking agents and deprotected after the conjugation with hydrophobic molecules (*25, 28*).

We recently discovered a novel solubilization method of various biomacromolecules, such as plasmid DNA, proteins, and carbohydrates, in selected organic solvents by nanocomplexing with poly(ethylene glycol) (PEG) (*29, 30*). In this study, HA was solubilized using dmPEG as nanoscale complexes in anhydrous DMSO. Figure 1 shows transmittance value of the DMSO solution as a function of dmPEG/HA weight ratio. The inset displays photographs of the DMSO solution containing dmPEG/HA mixture taken at the indicated points. The dmPEG/HA/DMSO solution at a dmPEG/HA weight ratio of 5 became transparent with a transmittance value greater than 90%, while the HA/DMSO solution without adding dmPEG was turbid with a much lower transmittance value as expected. It is likely that HA and dmPEG interacted together to form HA/dmPEG nanocomplexes in DMSO phase via hydrogen bonding as reported earlier (*30*). The size of HA/dmPEG complexes was 120 ± 6.3 nm in DMSO, as determined by dynamic light scattering technique, sufficiently small to not scatter visible light, resulting in a homogeneous and clear solution. Paclitaxel was then conjugated to HA/dmPEG nanocomplexes finely dispersed in the DMSO phase.

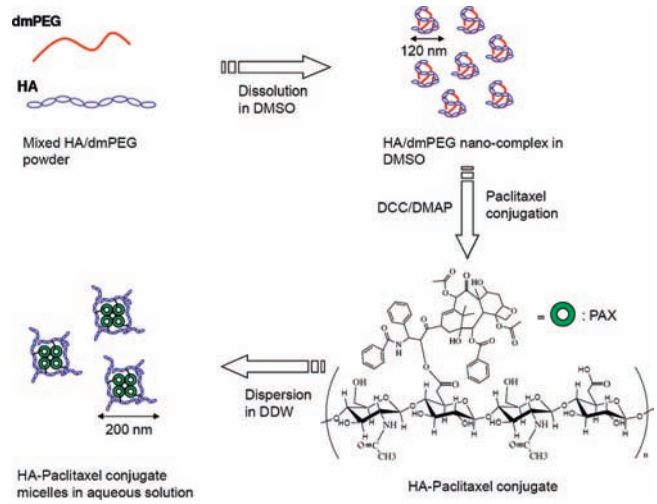

Figure 2. Synthetic scheme of HA−paclitaxel conjugation.

A synthetic scheme for the HA−paclitaxel conjugate is shown in Figure 2. Hydroxyl groups of paclitaxel were directly conjugated to carboxylic groups of HA in a single organic phase using DCC/DMAP as coupling agent (*37, 38*). The resultant HA−paclitaxel conjugate had an acid-cleavable ester linkage. In this study, dimethoxy-PEG (dmPEG) was used for solubilization of HA in DMSO instead of dihydroxyl-PEG to avoid any unfavorable conjugation of hydroxyl group terminated PEG to HA during the HA−paclitaxel conjugation. It should be noted that HA in the HA/dmPEG nanocomplexes was also partially cross-linked by the DCC/DMAP coupling process because it has both hydroxyl and carboxylic acid groups. However, it was most likely that paclitaxel was conjugated to HA mainly at the surface of compactly formed nanocomplexes, limiting self-cross-linking between dmPEG-bound HA molecules. The synthesis of HA−paclitaxel conjugate was verified by ^{1}H NMR analysis (Figure 3). Two different solvents were used to obtain characteristic proton peaks of paclitaxel and HA. In the case of D_2O, a strong acetyl (-NHCOCH_3) peak was identified at 1.86 ppm along with glucosidic H (10*H*) at 3.0−4.0 ppm and anormeric H (2*H*) at 4.30 and 4.40 ppm, while characteristic peaks of paclitaxel such as multiplets in aromatic rings (7.37−7.58 and 7.74−7.85 ppm) were minimal. When DMSO-d_6 was used as a solvent, the characteristic peaks of paclitaxel strongly appeared in the ^{1}H NMR spectra along with the disappearance of HA specific acetyl peaks at 1.86 ppm and reduced anormeric H (2*H*) peak at 4.33 ppm. However, the specific conjugation site in paclitaxel could not be identified. According to the previous reports, it appears that the 2′-hydroxyl group in paclitaxel was preferentially conjugated to HA rather than the 7′-hydroxyl group because it is less sterically hindered (*34*). From the ^{1}H NMR results, it is conceivable that HA−paclitaxel conjugate micelles were formed in aqueous solution by hydrophobic interaction between paclitaxel molecules conjugated to the HA backbone. Although the paclitaxel specific peaks were observed

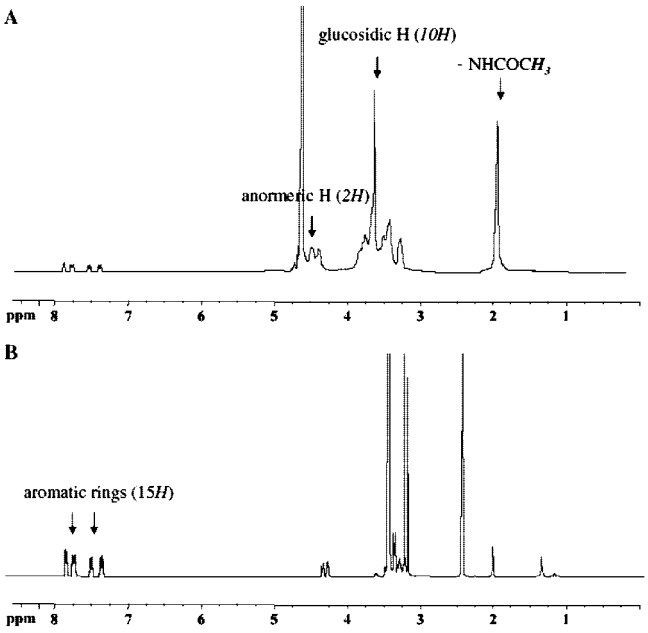

Figure 3. ^{1}H NMR spectra of HA−paclitaxel in (A) D_2O and (B) DMSO-d_6. HA and paclitaxel specific peaks are indicated with arrows.

in ^{1}H NMR in the polar organic phase, the shielding and deshielding effects of paclitaxel and HA peaks made it difficult to accurately estimate the conjugation extent of paclitaxel to HA. Therefore, the conjugation percent of paclitaxel to HA and the yield of each batch sample were determined by an HPLC using a 50:50 mixture of acetonitrile and water as a cosolvent, and the results were summarized in Table 1. As the molar excess of DCC/DMAP increased, the yield of HA−paclitaxel conjugate increased and reached about 60%. The most paclitaxel conjugated sample exhibited ca. 10.8% of paclitaxel loading content (w/w %), which means approximately nine paclitaxel molecules were bound to each HA chain. These data demonstrate that the feed ratio of DCC/DMAP was a critical factor in conjugating paclitaxel to HA.

The size of HA−paclitaxel conjugate micelles was measured by DLS (Figure 4A). The HA−paclitaxel conjugate micelles showed an average diameter of 196 ± 9.6 nm with a narrow size distribution. It is well-known that amphiphilic copolymers, such as Pluronic copolymers, poly(lactic-*co*-glycolic acid) (PLGA)-PEG block copolymers, and PLGA-poly(L-lysine) graft copolymers self-assemble to produce nanosized micelles in aqueous solution via hydrophobic interactions (*39–41*). To visualize HA−paclitaxel conjugate micelles, AFM and TEM images were obtained (Figure 4B,C). From AFM images, round-shaped HA−paclitaxel conjugate micelles were observed with an average diameter of 232.0 ± 28.2 nm (n = 30), which corresponds well to the size as measured by DLS. TEM image also provided evidence for the spherical morphology (183 ± 17.8 nm, n = 30). HA−paclitaxel conjugate micelles were likely to have a core/shell structure composed of a hydrophobic inner core containing aggregated paclitaxel molecules and a hydrophilic HA shell layer.

The self-assembly behavior of HA−paclitaxel conjugate in aqueous solution was characterized by measuring the critical aggregation concentration (CAC) of HA−paclitaxel conjugate using pyrene as a hydrophobic fluorescence probe (*32*, *42*). It is known that pyrene can partition into the hydrophobic core of polymer micelles and exhibits aggregation-induced enhanced emission (AIEE) in aqueous solution. Excitation spectra were measured and the intensity ratio of I_{339}/I_{334} of pyrene was evaluated as a function of HA−paclitaxel conjugate concentration (Figure 4D). A rapid increase of fluorescence intensity and a red shift of pyrene were observed when increasing the concentration of HA−paclitaxel conjugate. From the plot of intensity ratios (I_{339}/I_{334}), the CAC value was estimated to be 7.8 μg/mL. This value is similar to those of polymeric micelles such as poly(L-lactic acid) grafted chondroitin sulfate (5.0 μg/mL) and PLGA grafted poly(L-lysine) (1.0−9.6 μg/mL), but significantly lower than those of Pluronic copolymers (1−24

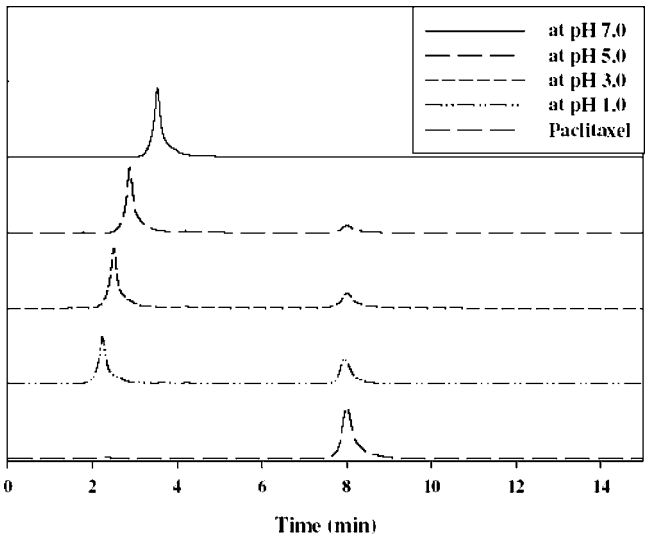

Figure 5. HPLC measurement of released paclitaxel from HA−paclitaxel conjugate micelles after 3 h incubation at different pH values. Paclitaxel is used as a positive control.

mg/mL) (*41*, *43*). Since paclitaxel was conjugated to HA via an acid-cleavable ester linkage, an intact form of paclitaxel was cleaved from the conjugate at slightly acidic environments such as extracellular solid tumor tissues and intracellular endosomal and lysosomal vesicles. After 3 h incubation of the HA−paclitaxel conjugate at four different pH conditions, the release of paclitaxel was monitored using reversed-phase HPLC. As shown in Figure 5, an intact paclitaxel peak appears to a greater extent at more acidic pH. In addition, the gradual left-shift of the HA−paclitaxel conjugate peak was also observed at acidic pH, because the hydrophobicity of the HA−paclitaxel conjugate started to decrease with the gradual cleavage of paclitaxel. It is likely that the release of free paclitaxel from the conjugate micelles was also dependent on the incubation pH. Since acidic physiological condition is in the range of pH 5.0 to 6.0, slow release of paclitaxel from HA−paclitaxel conjugates was observed. Therefore, the pH-dependent release behavior would play a favorable role in enhancing the cytotoxicity effect of free paclitaxel to acidic tumor cells.

In vitro cytotoxicity of HA−paclitaxel conjugate micelles was monitored by a cell viability assay using CCK-8 (Figure 6) (*21*, *33*). As compared to the commercially available Taxol formulation, HA−paclitaxel conjugate micelles exhibited more cytotoxicity for HCT-116 and MCF-7 cells, but reduced cytotoxicity for NIH-3T3 cells. HCT-116 and MCF-7 cells are known to overexpress HA recognizable CD44 receptors on the cell membrane, while NIH-3T3 cells do not overexpress CD44 receptors. Our data suggested that HA−paclitaxel conjugate micelles were internalized to a greater extent within HCT-116 and MCF-7 cells via HA receptor-mediated endocytosis than paclitaxel in the Taxol formulation, resulting in higher cytotoxic effect. Taxol is supposed to transport into cells by a passive diffusion mechanism, but HA−paclitaxel conjugate micelles are likely to be internalized within cells via a HA-receptor-mediated endocytosis process. The cytoxicity effect of HA−paclitaxel conjugate micelles was lower than that of the Taxol formulation for NIH-3T3 cells, probably due to their reduced extent of cellular uptake. It seems that negatively charged HA prohibits the anticancer effect of paclitaxel to HA receptor-deficient cells like NIH-3T3 by reducing nonselective uptake of HA−paclitaxel conjugate micelles.

Previously, we showed that HA nanogels physically encapsulating small interfering RNA (siRNA) could be delivered to HCT-116 cells in a HA receptor-mediated, target-specific

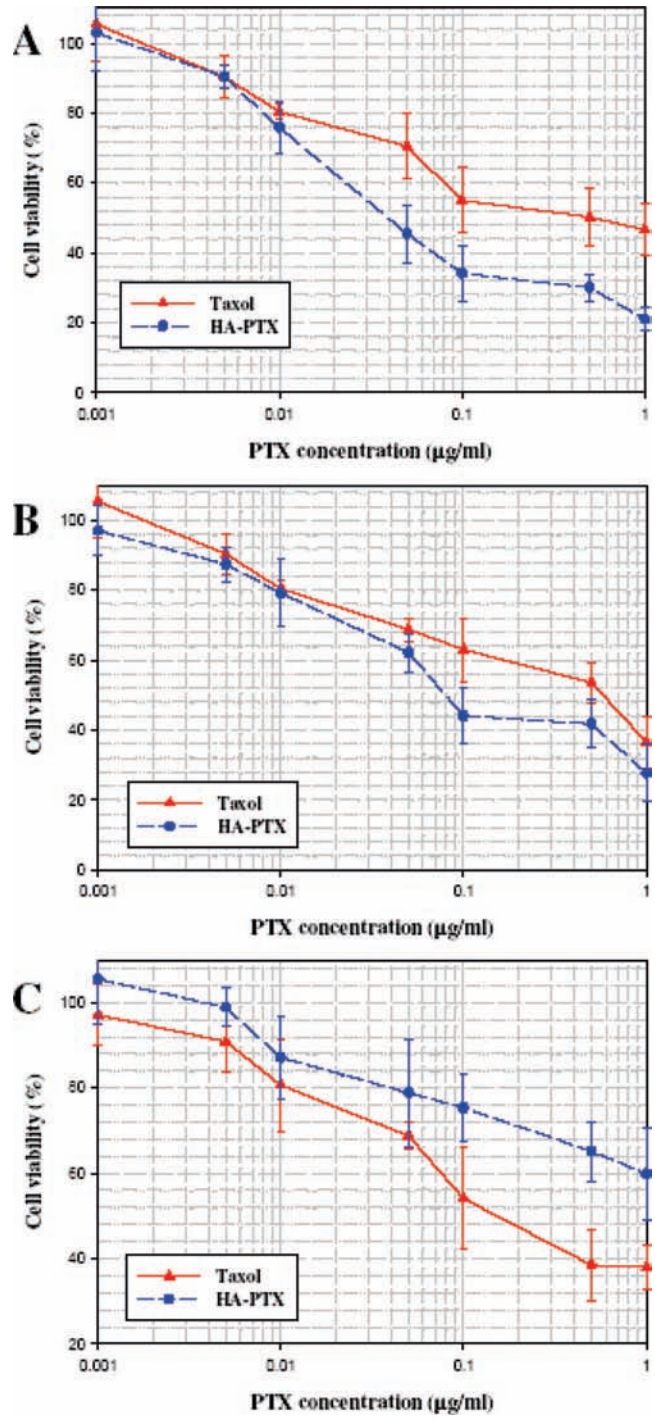

Figure 6. *In vitro* cytotoxicity of HA−paclitaxel conjugate micelles and Taxol against three different cell lines (A) HCT-116, (B) MCF-7, and (C) NIH-3T3.

manner (*21*). Similarly, it is conceivable that HA−paclitaxel conjugate micelles could be utilized for targeted delivery of paclitaxel to many tumor cells overexpressing HA receptors. To verify the apoptosis-inducing effect of HA−paclitaxel conjugate micelles, confocal microscopy and flow cytometric analyses were performed for HCT-116 cells. Figure 7 illustrates the confocal microscopic images of HCT-116 cells followed by incubation with various paclitaxel formulations at an equivalent paclitaxel concentration of 1 μg/mL. Morphological change of the cell nuclei such as DNA fragmentation was visualized by propodium iodide (PI) staining to confirm paclitaxel-induced apoptotic cell death. Since HCT-116 cells treated with the control formulation (20 μg/mL of HA) without

All paclitaxel formulations have 1 μg/mL of equivalent paclitaxel concentration.

paclitaxel were nonapoptotic, strong red fluorescence was detected homogeneously within the nucleus (Figure 7A). In contrast, after incubation with Taxol or HA−paclitaxel conjugate micelles, HCT-116 cells displayed apparent evidence of apoptosis such as segregation and fragmentation of cell nucleus into dense and tiny granules (Figure 7 B,C). It was thought that the activation of endogenous nucleases was associated during the apoptosis which cleaved chromosomal DNA into oligonucleosomal fragments (*44*, *45*). The extent of apoptosis was quantitatively assessed by flow cytometric analysis. Since the cytotoxic activity of paclitaxel is mainly due to its stabilizing effect on polymerized microtubules necessary for spindle formation and cell division, paclitaxel has been shown to cause a cell cycle arrest in the G2/M phase and finally cell death through an apoptotic mechanism (*4*, *5*). As shown in Figure 7D−F, HA−paclitaxel conjugate micelles induced a significant increase in G2/M cell population (64.9%), compared to that of the control (16.1%) and Taxol (31.2%). Consequently, these results demonstrate that HA−paclitaxel conjugate micelles were readily taken up by CD44 overexpressing cells and significantly enhanced the extent of apoptosis-inducing cell death. Nanosized and self-assembled HA−paclitaxel conjugate micelles could be utilized as efficient all-in-one carriers not only for the solubilization of paclitaxel, but also for its passive and active targeted delivery to cancer cells.

CONCLUSIONS

In this study, paclitaxel, a very hydrophobic anticancer drug, was directly conjugated to HA in DMSO by forming HA/PEG nanocomplexes without using any ionic surfactants, salts, and blocking agents to functional groups in HA. HA−paclitaxel conjugates were self-assembled to form nanosized spherical micelles in aqueous solution. HA−paclitaxel conjugate micelles exhibited greater cytotoxicity to HA recognizable CD44 overexpressing cells than the conventional paclitaxel formulation, suggesting that they could be efficiently delivered to cancer cells that overexpress HA receptors.

REVIEWS

Re-Engineering Biopharmaceuticals for Delivery to Brain with Molecular Trojan Horses

William M. Pardridge*

Department of Medicine, University of California at Los Angeles, Los Angeles, California 90024. Received April 9, 2008; Revised Manuscript Received May 7, 2008

Biopharmaceuticals, including recombinant proteins, monoclonal antibody therapeutics, and antisense or RNA interference drugs, cannot be developed as drugs for the brain, because these large molecules do not cross the blood−brain barrier (BBB). Biopharmaceuticals must be re-engineered to cross the BBB, and this is possible with genetically engineered molecular Trojan horses. A molecular Trojan horse is an endogenous peptide, or peptidomimetic monoclonal antibody (mAb), which enters brain from blood via receptor-mediated transport on endogenous BBB transporters. Recombinant neurotrophins, single chain Fv antibodies, or therapeutic enzymes may be re-engineered as IgG fusion proteins. The engineering of IgG-avidin fusion proteins enables the BBB delivery of biotinylated drugs. The IgG fusion proteins are new chemical entities that are dual or triple function molecules that bind multiple receptors. The fusion proteins are able both to enter the brain, by binding an endogenous BBB receptor, and to induce the desired pharmacologic effect in brain, by binding target receptors in the brain behind the BBB. The development of molecular Trojan horses for BBB drug delivery allows the re-engineering of biopharmaceuticals that, owing to the BBB problem, could not otherwise be developed as new drugs for the human brain.

INTRODUCTION

Biopharmaceuticals include recombinant proteins, monoclonal antibodies (mAb), and antisense drugs including RNA interference (RNAi) therapeutics. However, short of a trans-cranial injection of drug into the brain, biopharmaceuticals cannot presently be developed as new drugs for human brain diseases, because these drugs do not cross the brain capillary endothelial wall, which forms the blood−brain barrier (BBB) in vivo. While it is generally assumed that small molecules cross the BBB, in fact, <2% of all small molecules cross the BBB in pharmacologically active amounts (*1*). The BBB is the most important factor limiting the development of new drugs for the brain, and particularly, large molecule biopharmaceuticals.

The BBB phenomenon is illustrated in Figure 1A, which is a whole body autoradiogram of a mouse 30 min after the intravenous injection of radiolabeled histamine, a small molecule of just 111 Da (*2*). The histamine readily crosses the porous vascular barrier in all organs of the body except for the brain and spinal cord. The capillaries in the brain lack the pores found in microvessels in peripheral tissues (*3*). The microvasculature of the brain is shown in Figure 1B, which is a vascular cast of the human brain cortex (*4*). The distance between brain capillaries is about 40 μm, which provides space for approximately 2 neurons between 2 capillaries in the brain.

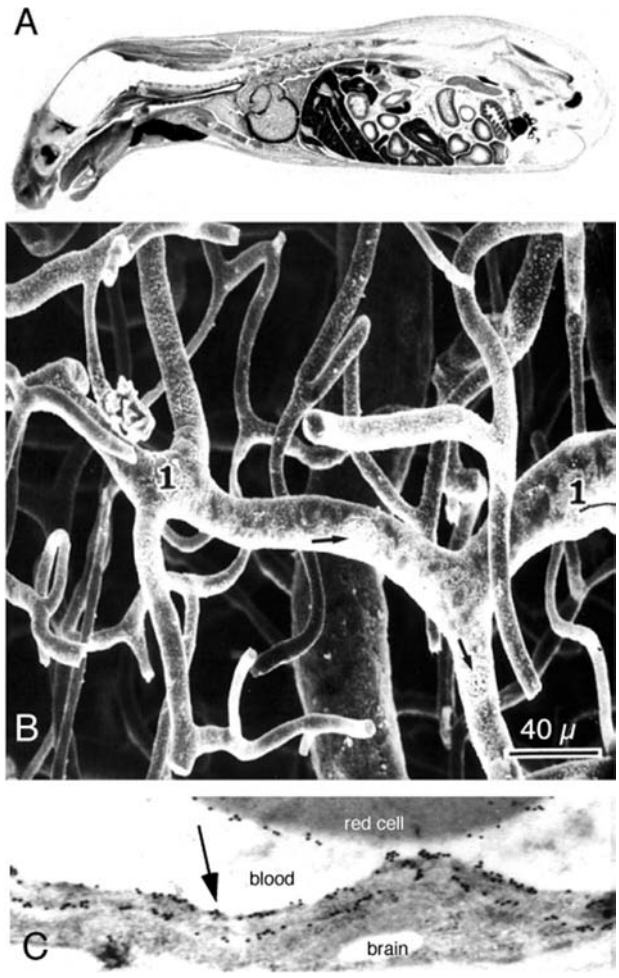

Figure 1. Location of endogenous BBB transporters. (A) Whole body autoradiogram of an adult mouse sacrificed 30 min after intravenous injection of radiolabeled histamine, a small molecule that readily traverses the capillary barrier in all organs of the body, except for the brain and spinal cord. From ref (*2*). (B) Scanning electron micrograph of the human cortex. The distance between capillaries in the human brain is approximately 40 μm. From ref (*4*). (C) Electron microscopic immunogold study of human brain with a rabbit polyclonal antibody to the human GLUT1 glucose transporter, and a secondary antibody conjugated with 10 nm gold. The localization of the gold particles (arrow) shows the expression of a model endogenous BBB transporter (the GLUT1 glucose transporter) at the luminal and abluminal membranes of the brain capillary endothelial cell. GLUT1 is also visible on the plasma membrane of an erythrocyte within the capillary lumen. From ref (*8*).

Therefore, each neuron in perfused by its own blood vessel. Once the biopharmaceutical crosses the brain microvascular barrier, the drug is delivered to the "doorstep" of every neuron in the brain. Diffusion plays a minimal role in the distribution of drugs within the brain following entry via the trans-vascular route, owing to the short intercapillary distance.

The BBB is expressed in the brain of all vertebrates, and is laid down within the first trimester of human fetal life (*5*). The anatomical basis of the BBB is the presence of epithelial-like tight junctions within the capillary endothelial cells of the brain (*3*). Unlike capillaries in peripheral tissues, which have porous endothelial barriers, the endothelial cells of brain microvessels are fused together by the high-resistance tight junctions. The electrical resistance across the brain capillary endothelial cell is as high as 8000 ohm$\cdot$cm^2 (*6*), which is as high as any cellular barrier in biology. Owing to the presence of the endothelial tight junctions at the cerebral microvasculature, circulating molecules gain access to brain interstitial fluid only via one of two transport

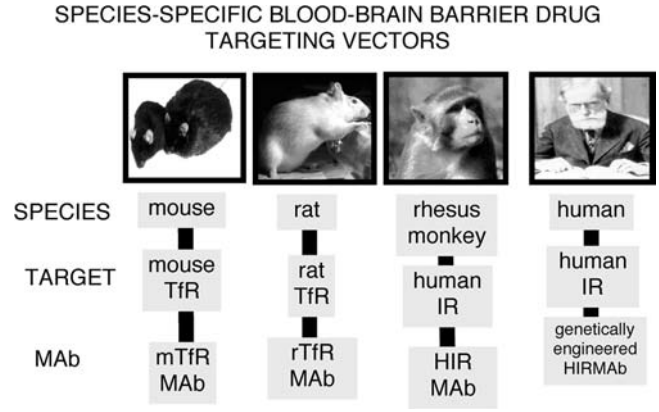

Figure 2. BBB molecular Trojan horses. Panel of species-specific monoclonal antibodies (mAb) against either the rodent transferrin receptor (TfR) or the human insulin receptor (IR). From ref (*19*).

pathways: lipid-mediated free diffusion, which is available to a restricted class of lipid-soluble small molecules; and catalyzed transport via endogenous BBB transporters.

There are two broad classes of endogenous BBB transporters that mediate the uptake of circulating molecules by brain. Carrier-mediated transporters (CMT) allow for the selective uptake of water-soluble small molecule nutrients that have an affinity for specialized CMT systems within the BBB, including the glucose transporter, the amino acid transporter, and other transporters (*7*), which are generally expressed by genes within the solute carrier (SLC) gene family (*1*). The expression of the GLUT1 glucose transporter on the luminal and abluminal membranes of the brain capillary endothelial cell is illustrated with the electron microscopic immunogold study shown in Figure 1C (*8*). The endogenous transporter is expressed on both luminal and abluminal membranes, which are separated by about 200 nm of endothelial cytoplasm. Similar to CMT systems, such as the glucose transporter, the BBB also expresses endogenous receptor-mediated transport (RMT) systems for certain endogenous large molecules in the circulation, such as the insulin receptor or the transferrin receptor (TfR) (*9*). The rapid receptor-mediated transport of insulin or transferrin across the BBB in vivo was demonstrated with thaw mount autoradiography of brain following the intracarotid arterial infusion of radiolabeled insulin or transferrin (Tf) (*10, 11*). The RMT pathway was shown to be a transcytosis process with electron microscopy of brain following the intracarotid arterial infusion of conjugates of 5 nm gold and a mAb against the TfR (*12*).

BLOOD−BRAIN BARRIER MOLECULAR TROJAN HORSES

The discovery of endogenous RMT systems within the BBB, such as the insulin receptor or the TfR, led to the development of the molecular Trojan horse hypothesis. Certain endogenous peptides, such as insulin or Tf, could be used as molecular Trojan horses to ferry drugs across the BBB following attachment of the drug to the endogenous insulin or Tf. In addition, certain peptidomimetic MAbs to the endogenous BBB RMT systems could also be used as molecular Trojan horses. A panel of species-specific molecular Trojan horses has been developed for mice, rats, Rhesus monkeys, and humans, as shown in Figure 2. A rat mAb to the mouse TfR is used as a Trojan horse for drug delivery in the mouse (*13*). This mAb is not active in rats or other species. A murine mAb to the rat TfR is used for drug delivery in rats (*14*), and this mAb is not active in mice or other species. A murine mAb to the human insulin receptor (HIR) cross reacts with the insulin receptor of Old World primates such as the Rhesus monkey (*15*). The murine HIRMAb is not

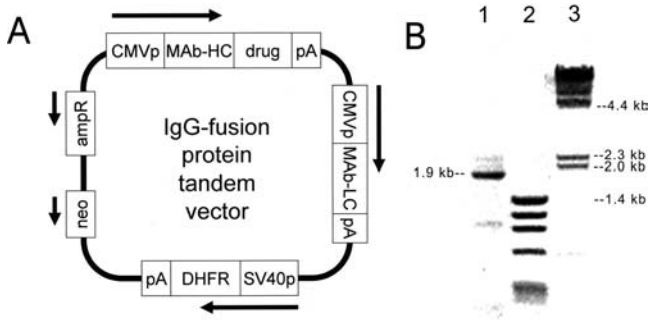

Figure 3. Tandem vector for expression of IgG fusion proteins. (A) A tandem vector contains the separate expression cassettes for the IgG heavy chain (HC) fusion gene, the IgG light chain (LC) gene, the dihydrofolate reductase (DHFR) gene, and the neomycin resistance gene (neo). The HC and LC genes are bordered by the cytomegalovirus (CMV) promoter and the bovine growth hormone (BGH) polyA (pA) transcription termination sequence. The DHFR gene is bordered by the SV40 promoter (SV40p) and the hepatitis B virus pA sequence; ampR = ampicillin resistance gene. (B) PCR amplification of the 1.9 kb cDNA encoding the human α-L-iduronidase (IDUA) (lane 1); DNA size standards are shown in lanes 2 and 3. From ref (*20*).

active in New World primates such as the squirrel monkey. The murine HIRMAb cannot be used for drug delivery in humans owing to immune reactions to a mouse protein. Therefore, both a chimeric HIRMAb and a humanized HIRMAb have been developed for drug delivery in humans (*16*). A genetically engineered TfRMAb could be used for drug delivery across the human BBB. However, the HIRMAb is 900% more active as a BBB drug delivery vector than any known mAb to the human TfR (*17*). The TfRMAb is used as a molecular Trojan horse in rodents, because there is no known mAb to the rat or mouse insulin receptor that can be used as a molecular Trojan horse for drug delivery in these species.

The availability of the genes encoding the heavy chain (HC) and the light chain (LC) of the genetically engineered HIRMAb allows for the bioengineering of IgG fusion proteins for drug delivery of recombinant proteins and MAbs across the human BBB (*16*). The recombinant protein or single chain Fv (ScFv) monoclonal antibody is fused to the heavy chain, or light chain, of the HIRMAb. If the therapeutic protein functions as a dimer, then fusion of the amino terminus of the therapeutic protein to the carboxyl terminus of the heavy chain of the HIRMAb restores the natural dimeric configuration of the therapeutic protein. Many proteins, such as neurotrophins, ScFv antibodies, or avidin, have preferred dimeric configurations. To facilitate the isolation of high expressing mammalian host cell systems, the genes encoding the heavy chain fusion gene and the light chain gene, as well as the gene encoding for a selectable marker such as dihydrofolate reductase (DHFR), are placed on a single piece of DNA called a tandem vector (Figure 3A). The HC expression cassette, the LC expression cassette, and the DHFR expression cassette, are are all contained within the tandem vector, which also encodes the neomycin resistance gene and the ampicillin resistance gene (*18*). The heavy chain expression cassette and the light chain expression cassette are both driven by tandem cytomegalovirus (CMV) promoters and both expression cassettes have separate and tandem bovine growth hormone (BGH) polyA (pA) transcription termination sequences. A unique restriction endonuclease sequence is engineered at the 3′ end of the heavy chain expression cassette. This allows for the facile insertion of a cDNA encoding the therapeutic protein into the tandem vector for expression of a new fusion protein, which is composed of the HIRMAb heavy chain fused to the nontransportable therapeutic protein. The cDNA encoding for the nontransportable therapeutic protein is generated by the polymerase chain reaction (PCR) and the PCR amplification of the cDNA encoding human α-L-iduronidase (IDUA) is shown in Figure 3B. Following the engineering of the tandem vector, the engineering of new vectors expressing new HIRMAb fusion proteins is a relatively rapid process.

Table 1. Partial Lists of Protein Drugs That Could Enter Drug Development Should the Protein be Enabled to Cross the Blood−Brain Barrier[a]

recombinant proteins

There are almost an endless number of therapeutic proteins that could be fused to the HIRMAb to create new chemical entities, which are composed of the HIRMAb fused to the therapeutic protein. A partial list of recombinant proteins that could be developed for drugs for the brain is given in Table 1, and these are broadly classified as recombinant proteins, recombinant monoclonal antibodies, or recombinant lysosomal enzymes. There are many highly neuroprotective neurotrophins which could be developed as neuropharmaceuticals for a variety of brain diseases (*21*), should these molecules be made transportable through the human BBB, and a partial list is shown in the recombinant protein section of Table 1. There are multiple therapeutic monoclonal antibodies that could be developed for brain diseases, and a partial list is shown in the monoclonal antibody section of Table 1. There are different approaches that could be used for the genetic engineering of a fusion antibody

Table 2. IgG Fusion Proteins and Therapeutic Applications for the Brain[a]

therapeutic protein	therapeutic application
BDNF	stroke, neurodegeneration
GDNF	stroke, Parkinson's disease, motor neuron disease
Aβ ScFv	Alzheimer's disease
IDUA	MPS type I
Avidin	biotinylated drugs, including siRNA

[a] BDNF = brain-derived neurotrophic factor; GDNF = glial derived neurotrophic factor; ScFv = single chain Fv antibody; IDUA = iduronidase; MPS = mucopolysaccharidosis; siRNA = short interfering RNA.

composed of the HIRMAb and a therapeutic antibody (*22*, *23*). The approach described below involves the fusion of a therapeutic ScFv to the heavy chain of the HIRMAb. In addition, many enzymes are potential therapeutic proteins for brain diseases such as lysosomal storage disorders or other conditions, and a partial list of potential enzyme therapeutics for the brain is given in the lysosomal enzyme section of Table 1. This review will discuss the recent genetic engineering and testing of HIRMAb fusion proteins which encode for neurotrophins such as brain-derived neurotrophic factor (BDNF), glial derived neurotrophic factor (GDNF), a ScFv against the Aβ amyloid peptide of Alzheimer's disease (AD), the lysosomal enzyme IDUA, and avidin (Table 2).

BLOOD−BRAIN BARRIER DELIVERY OF IgG-NEUROTROPHIN FUSION PROTEINS

Neurotrophins are potential neuroprotective agents for the brain (Table 1), including stroke. However, neurotrophins do not cross the BBB, and have not been effective in the treatment of human stroke. In experimental stroke, or other brain diseases, it is necessary to deliver the neurotrophin to brain via a transcranial injection, owing to the BBB problem. Recently, two model neurotrophins, BDNF (*18*) and GDNF (*24*), have been re-engineered for delivery across the human BBB.

Glial-Derived Neurotrophic Factor (GDNF). The cDNA encoding human prepro GDNF was produced by PCR and cDNA generated from RNA isolated from human U87 glioma cells (*24*). The cDNA encoding the mature 134 amino acid GDNF was subsequently produced by PCR from the prepro GDNF template and subcloned into the HIRMAb heavy chain expression cassette. COS cells were dual lipofected with separate expression plasmids encoding the HIRMAb light chain and the fusion gene of the HIRMAb heavy chain and the GDNF (*24*). The HIRMAb-GDNF fusion protein was purified from conditioned serum-free medium with protein A affinity chromatography. Western blot analysis with primary antibodies to either human IgG or human GDNF is shown in Figure 4. The size of the HC of the HIRMAb-GDNF fusion protein is about 15 kDa larger than the HC of the original HIRMAb using either the antihuman IgG primary antibody or the antihuman GDNF primary antibody (Figure 4). Both the HIRMAb and the HIRMAb-GDNF fusion protein have the same immunoreactive light chain in the IgG Western blot, since both proteins share the same light chain. The GDNF antibody is immunoreactive with the HIRMAb-GDNF fusion protein and with recombinant human GDNF, but not with the HIRMAb (Figure 4). Similarly, the antihuman IgG primary antibody is immunoreactive with the HIRMAb and the HIRMAb-GDNF fusion protein, but not with recombinant GDNF (Figure 4). The affinity of the HIRMAb-GDNF fusion protein for the HIR extracellular domain (ECD) was determined with a ELISA-based binding assay following the initial affinity purification of the HIR ECD from serum-free medium conditioned by Chinese hamster ovary (CHO) cells permanently transfected with the cDNA encoding

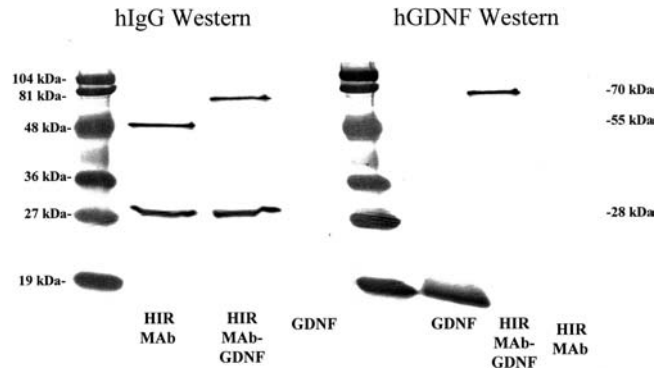

Figure 4. GDNF Western blot. Western blot with either antihuman (h) IgG primary antibody (left panel) or an antihuman GDNF primary antiserum (right panel). The immunoreactivity of the HIRMAb-GDNF fusion protein is compared to the HIRMAb and to recombinant GDNF. Both the HIRMAb-GDNF fusion protein and the HIRMAb have identical light chains on the anti-hIgG Western. The HIRMAb-GDNF fusion heavy chain reacts with both the anti-hIgG and the antihuman GDNF antibody, whereas the HIRMAb heavy chain only reacts with the anti-hIgG antibody. The size of the HIRMAb-GDNF fusion heavy chain, 70 kDa, is about 15 kDa larger than the size of the heavy chain of the HIRMAb, owing to the fusion of the 15 kDa GDNF to the 55 kDa HIRMAb heavy chain. From ref (*24*).

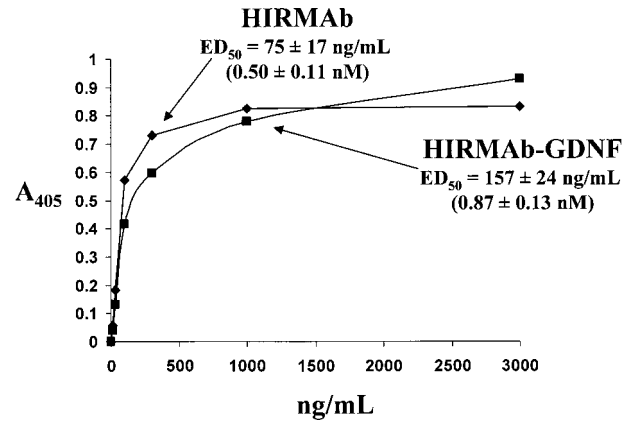

Figure 5. Fusion protein binding to the human insulin receptor. Binding of either the HIRMAb or the HIRMAb-GDNF fusion protein to the HIR extracellular domain (ECD) is saturable. The ED50 of HIRMAb-GDNF binding to the HIR ECD is comparable to the ED50 of the binding of the HIRMAb. From ref (*24*).

the HIR ECD (*25*). The HIR binding assay shows that the affinity of the HIRMAb-GDNF for the HIR is comparable to the original HIRMAb and both proteins have high affinity for the insulin receptor with an ED50 of 0.5−1.0 nM (Figure 5). The binding of the HIRMAb-GDNF fusion protein to the GDNF receptor was demonstrated with a separate binding assay, which measured the affinity of the fusion protein for the ECD of the human GDNF receptor (GFR)-α1. In a cell free binding assay, human GDNF bound to the recombinant GFR-α1 ECD with an ED50 of 1.03 ± 0.18 nM. The affinity of the HIRMAb-GDNF fusion protein for the GFR-α1 was also high with ED50 of 1.68 ± 0.17 nM (*24*). The original HIRMAb had no affinity for the GFR-α1. The activation of the GFR-α1 dependent signal transduction pathways within human neural cells by the HIRMAb-GDNF fusion protein was evaluated in a cell-based bioassay (Figure 6A). Human neural SK-N-MC cells were dual transfected with a cDNA encoding for the c-ret kinase and a luciferase reporter gene driven by the tyrosine hydroxylase (TH) promoter (*28*). Addition of GDNF to the medium of these cells activates the TH promoter via the GFR-α1/c-ret kinase system, and this leads to increased cellular luciferase expression (Figure

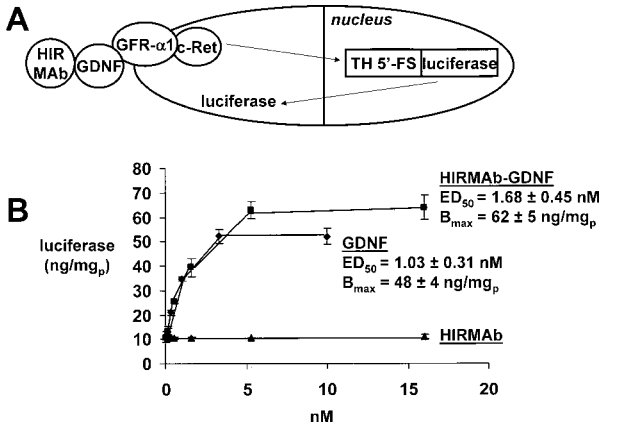

Figure 6. Cell-based bioassay of fusion protein potency. (A) Binding by either GDNF or the HIRMAb-GDNF fusion protein to the GFRα1 on the cell membrane of c-ret kinase transfected human neural SK-N-MC cells activates the tyrosine hydroxylase (TH) 5′-flanking sequence (FS), which drives luciferase gene expression. (B) Both GDNF and the HIRMAb-GDNF fusion protein activate luciferase gene expression in a saturable manner, with comparable ED50 values. There is no activation of luciferase gene expression by the HIRMAb. From ref (*24*).

6B). GDNF increased luciferase expression with an ED50 of 1.03 ± 0.31 nM, and the HIRMAb-GDNF also increased luciferase expression with an ED50 of 1.68 ± 0.45 nM (Figure 6B). The original HIRMAb was biologically inactive in this bioassay (Figure 6B). The biological activity of the HIRMAb-GDNF fusion protein was also evaluated with an in vivo bioassay using a middle cerebral artery occlusion (MCAO) stroke model in the adult rat (*24*). Since the HIRMAb portion of the HIRMAb-GDNF fusion protein does not recognize the rat insulin receptor, the HIRMAb-GDNF fusion protein could not be delivered to rat brain following intravenous administration. However, the fusion protein was delivered to ischemic rat brain following permanent occlusion of the middle cerebral artery with an intracerebral injection for the purposes of demonstrating neural cell neuroprotection in vivo. The intracerebral injection of the HIRMAb-GDNF fusion protein resulted in a 77% reduction in the hemispheric stroke volume from 331 ± 33 mm^3 to 77 ± 22 mm^3 (as shown in Figure 7A), and this reduction in stroke volume was significant at the $p < 0.001$ level. Similarly, the stroke volume in the cortex was significantly reduced 86% and the subcortical stroke volume was reduced significantly 52% by the administration of the HIRMAb-GDNF fusion protein (Figure 7A). The volume of the infarcted area in brain was measured by histochemistry using 2% 2,3,5-triphenyltetrazolium chloride (TTC). A representative TTC stain of the rat brain 24 h after occlusion of the middle cerebral artery and intracerebral injection of either saline or the HIRMAb-GDNF fusion protein is shown in Figure 7B,C, respectively (*24*). The neurologic deficit score was 3.0 ± 0.7 and 1.3 ± 0.6 in the saline treated and HIRMAb-GDNF treated rats, respectively, and this difference is statistically significant (*24*). The recent work with HIRMAb-GDNF fusion protein demonstrates that GDNF can be re-engineered to enable transport across the human BBB so that this neurotrophin can be pharmacologically active in brain following intravenous administration. GDNF could be a new pharmaceutical for the treatment of both acute and chronic brain diseases including acute stroke, Parkinson's disease, or motor neuron disease (Table 2).

Brain-Derived Neurotrophic Factor (BDNF). BDNF is a potent neuroprotective molecule when injected directly into the brain (*29, 30*). However, BDNF is not pharmacologically active in the brain following intravenous administration in the absence of BBB disruption (*31, 32*), because BDNF does not cross

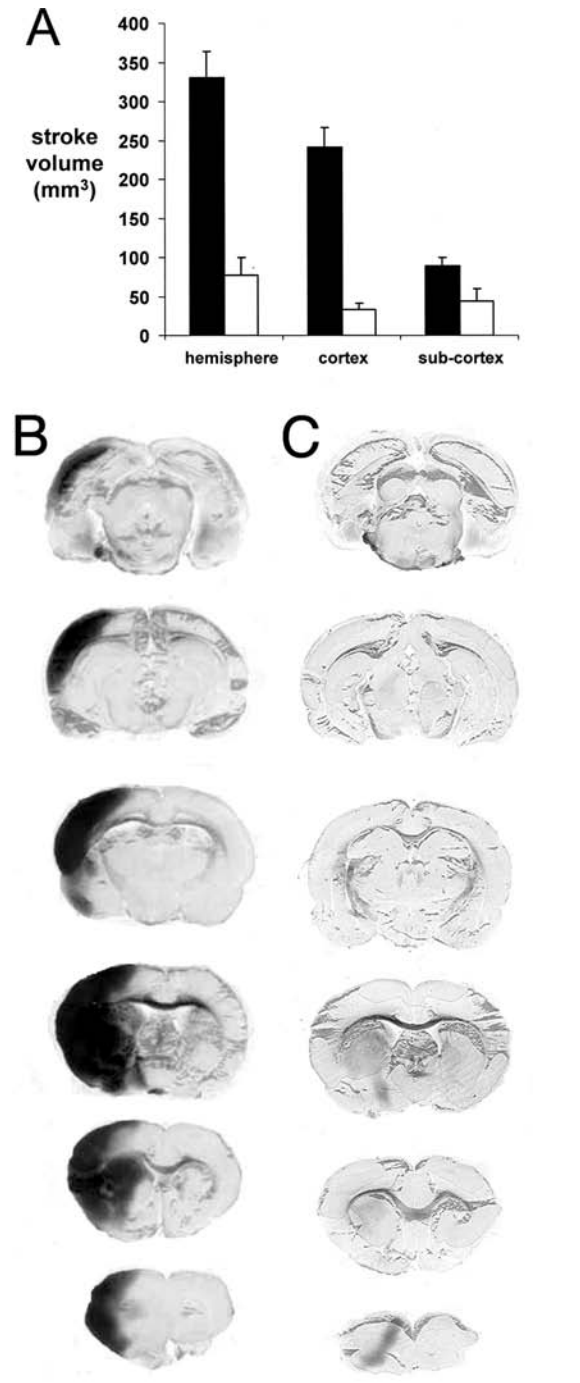

Figure 7. In vivo bioassay of fusion protein potency. (A) Stroke volumes in rats subjected to a 24 h permanent middle cerebral artery occlusion (MCAO) and treated with either intracerebral saline (closed bar) or the HIRMAb-GDNF fusion protein (open bar). Data are mean ± SE ($n = 5-6$ rats per group). (B, C) TTC stains of serial coronal sections of rat brain at 24 h after permanent MCAO and intracerebral saline (B) or HIRMAb-GDNF fusion protein (C). A representative stain is shown for 1 rat from each treatment group. In these inverted gray-scale images, the infarcted brain is black, and the healthy brain is white. The most rostral section is top and the most caudal section is bottom. From ref (*24*).

the BBB (*33*). Therefore, if BDNF is to be developed as a new pharmaceutical for the brain, the BDNF must be re-engineered to cross the human BBB. A HIRMAb-BDNF fusion protein was genetically engineered and a tandem vector encoding this fusion protein was permanently inserted into CHO cells with electroporation (*18*). Following amplification of cell lines with methotrexate (MTX) and dilutional cloning of the cell line, a

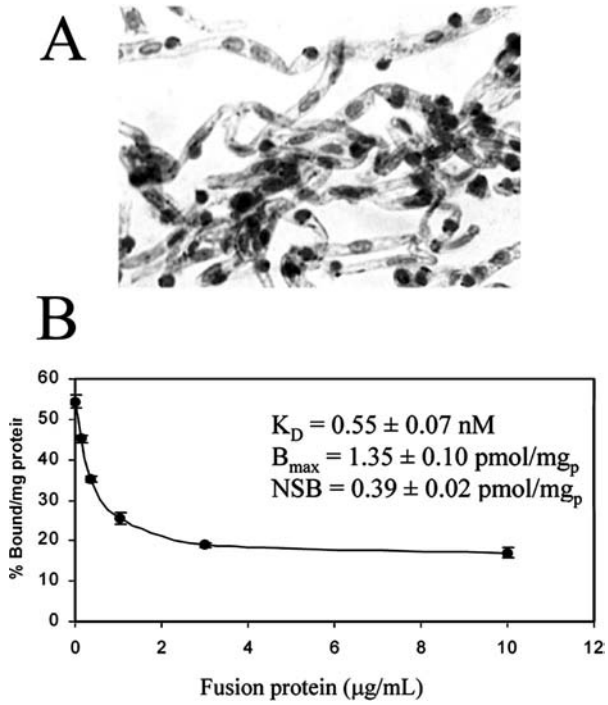

Figure 8. Fusion protein binding to the human BBB. (A) Light micrograph of capillaries isolated from human brain, used as an in vitro model system of the human BBB. (B) Radio-receptor assay of binding of [^{3}H]-HIRMAb-BDNF fusion protein to the HIR on the human BBB; the binding is self-inhibited by unlabeled fusion protein. Fitting the saturation data to a Scatchard plot with a nonlinear regression analysis yields the binding parameters: $K_D = 0.55 \pm 0.07$ nM, $B_{max} = 1.35 \pm 0.10$ pmol/mg_p, NSB $= 0.39 \pm 0.02$ pmol/mg_p, where B_{max} is the maximal saturable binding, and NSB is the nonsaturable binding. From ref (*18*).

high producing CHO line was isolated. The fusion protein was affinity purified by protein A affinity chromatography. The high-affinity binding of the HIRMAb-BDNF fusion protein to the human BBB was evaluated with a radioreceptor assay (RRA) using isolated human brain microvessels. Capillaries can be isolated from human autopsy brain free of adjoining brain tissue, as illustrated in Figure 8A. Binding of ligands to the endogenous human BBB insulin receptor can be measured with the isolated human brain capillary RRA. The fusion protein was tritiated with [^{3}H]-*N*-succinimidylpropionate. The binding of the [^{3}H]-HIRMAb-BDNF fusion protein to isolated human brain capillaries was saturable and the K_D was 0.55 ± 0.07 nM (Figure 8B). This K_D is identical to the K_D of binding of the original murine HIRMAb to the isolated human brain capillary (*15*). These observations indicate there is no change in affinity of the HIRMAb for binding to the intact HIR at the human BBB following fusion of a BDNF molecule to each of the two heavy chains of the HIRMAb. The transport of the HIRMAb-BDNF fusion protein across the BBB in the Rhesus monkey in vivo was measured following the intravenous injection of the [^{3}H]-HIRMAb-BDNF fusion protein (*18*). The fusion protein was rapidly cleared from blood at a rate comparable to the rate of clearance of the original murine HIRMAb (Figure 9A). The comparable clearance of the HIRMAb-BDNF fusion protein, and the HIRMAb, demonstrates that fusion of a highly cationic protein, such as BDNF, to the HIRMAb does not cause an acceleration of the removal of the IgG from the bloodstream. In contrast, the highly cationic BDNF is rapidly removed from blood, and is rapidly degraded following an intravenous administration (*33*). The metabolic stability of BDNF in vivo is increased following fusion of the neurotrophin to the IgG. The differential trichloroacetic acid (TCA) precipitability of the serum radioactivity of radiolabeled HIRMAb-BDNF fusion protein and native BDNF is shown in Figure 9B. The much higher TCA precipitability of the HIRMAb-BDNF fusion protein, as compared to BDNF, shows that the metabolic stability of the BDNF is increased following re-engineering of the neurotrophin as an IgG fusion protein. The concentration of the HIRMAb-BDNF fusion protein in primate brain following intravenous administration of a subtherapeutic dose of fusion protein is many-fold greater than the concentration of endogenous BDNF (Figure 9C). This demonstrates that brain BDNF can be elevated by administration of the HIRMAb-BDNF fusion protein. The increased brain uptake of the HIRMAb-BDNF is due to actual transport through the microvascular barrier, and into brain parenchyma. This was demonstrated with the capillary depletion technique (Figure 9D). The equivalence of the volume of distribution (VD) of the labeled fusion protein in the total brain homogenate versus the postvascular supernatant (Figure 9D) indicates the HIRMAb-BDNF fusion protein is not sequestered within the microvascular compartment of brain (*18*). In summary, recent work shows that BDNF can be developed as a new pharmaceutical for human brain disease, providing this neurotrophin is re-engineered to cross the human BBB. BDNF could be used for the treatment of acute stroke or head injury, or for the treatment of chronic neurodegeneration.

BLOOD−BRAIN BARRIER DELIVERY OF THERAPEUTIC MONOCLONAL ANTIBODIES

A new therapeutic for the treatment of AD is a mAb against the Aβ amyloid peptide of Alzheimer's disease. The dementia of AD correlates with the deposition of Aβ amyloid plaques in brain (*34*), which accumulate over many years prior to the development of dementia. AD transgenic mouse models have been developed which similarly demonstrate Aβ amyloid deposits in brain as well as deterioration of neuro-behavioral function which progresses in parallel with accumulation with age of Aβ amyloid plaque in brain (*35*). The intracerebral injection of a monoclonal antibody against the Aβ peptide results in rapid disaggregation of the Aβ amyloid plaque (*36, 37*). This plaque disaggregation is followed by repair of dystrophic neurites in the region previously occupied by the amyloid plaque (*36, 37*), which correlates with improvement in neuro-behavioral function. Similar results were reported with passive immune therapy in AD transgenic mice, which involves the systemic administration of large doses of an anti-Aβ mAb (*38, 39*). However, the passive immune therapy of AD does not address the question as to how the circulating anti-Aβ mAb gains access to the brain amyloid plaque, which resides behind the BBB. The pharmacologic effects of passive immune therapy in transgenic mouse models of AD may be due to inadvertent BBB disruption. A consistent finding of passive immune therapy in rodents is the development of cerebral microhemorrhage (*40, 41*). Such BBB disruption would allow the circulating anti-Aβ mAb to gain access to brain amyloid. The cause of cerebral microhemorrhage is not known. However, it is known that the plasma level of the Aβ peptide increases from very low levels to nearly 1 μM following the intravenous administration of an anti-Aβ mAb for the passive immune therapy of AD (*42*). It is also known that elevations in the plasma concentration of the Aβ peptide following the infusion of Aβ peptide into the blood of rodents also results in microhemorrhage and BBB disruption (*43*). These findings suggest that the cerebral microhemorrhage of passive immune therapy may be caused by the large increase in plasma Aβ concentration. Therefore, it is possible that passive immune therapy will lead to cerebral microhemorrhage in humans similar to that observed in rodents. What is needed is a re-engineering of the anti-Aβ mAb, such that the therapeutic mAb gains access to plaques in brain following receptor-

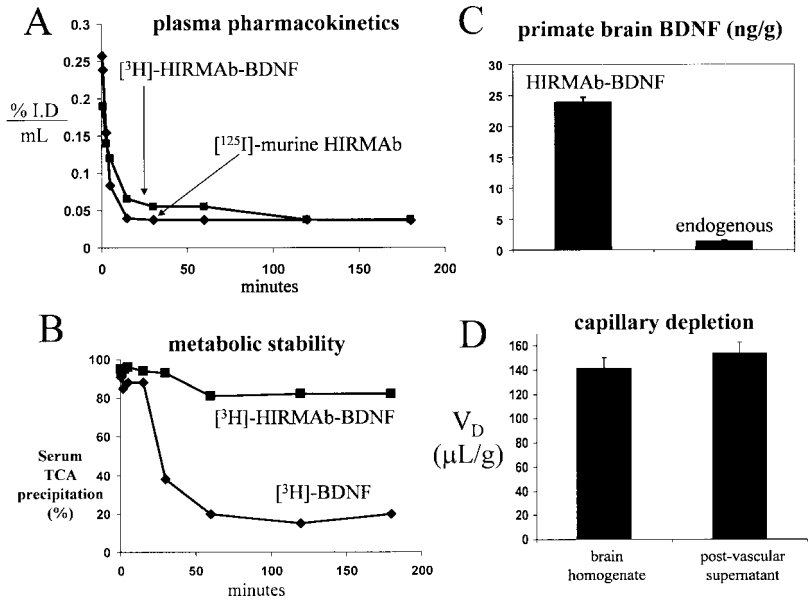

Figure 9. Fusion protein pharmacokinetics and brain uptake in the Rhesus monkey. Pharmacokinetics and brain uptake of HIRMAb-BDNF fusion protein in the adult Rhesus monkey. (A) The serum concentration of [^{3}H]-HIRMAb-BDNF, or [^{125}I]-murine HIRMAb, is plotted vs time after a single intravenous injection of either protein in anesthetized adult Rhesus monkeys. (B) The serum radioactivity that is precipitable by trichloroacetic acid (TCA) is plotted vs time after a single intravenous injection of either [^{3}H]-HIRMAb-BDNF in the anesthetized adult Rhesus monkey, or [^{3}H]-BDNF in the anesthetized adult rat. (C) Primate brain concentrations of HIRMAb-BDNF fusion protein at 180 min after an intravenous injection of 70 μg/kg fusion protein, as compared to the endogenous concentration of BDNF in the adult primate brain. (D) Capillary depletion analysis of brain volume of distribution (V_D) at 180 min after a single intravenous injection of the [^{3}H]-HIRMAb-BDNF fusion protein in the anesthetized adult Rhesus monkey. The V_D is shown for the total brain homogenate and the postvascular supernatant. From ref (*18*).

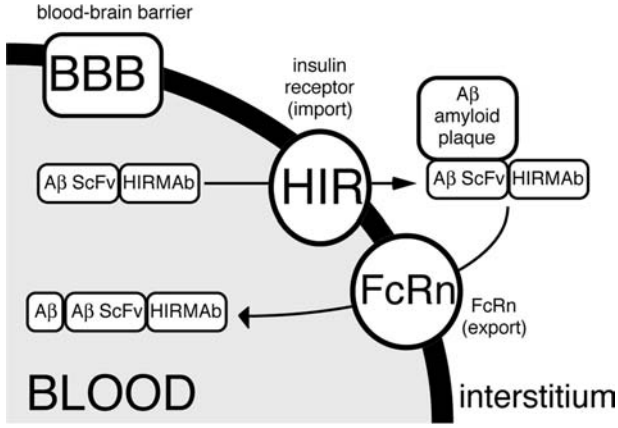

Figure 10. Import−export model of Aβ antibody therapeutics. The fusion antibody of the HIRMAb and the anti-Aβ single chain Fv antibody (ScFv) clears amyloid from brain in AD via 3 sequential steps, and each of these 3 sequential steps uses separate parts of the fusion antibody molecule. Step 1 is the influx of the fusion antibody from blood to brain across the BBB, which is mediated by binding of the fusion antibody to the BBB HIR. Step 2 is binding of the fusion antibody to the amyloid plaque in AD, which promotes disaggregation of the amyloid plaque, and this binding to the plaque is mediated by the anti-AβScFv part of the fusion antibody. Step 3 is the efflux of the fusion antibody from brain to blood across the BBB, which is mediated by binding of the fusion antibody to the BBB FcRn at the CH_2-CH_3 interface of the Fc region of the fusion antibody. From ref (*26*).

mediated transport across the BBB. Such a molecule would be rapidly cleared from the blood, as compared to a conventional anti-Aβ mAb (*26*), and this rapid clearance would minimize the accumulation of the Aβ peptide in the blood compartment.

The bidirectional BBB transport of a fusion antibody of the HIRMAb and an anti-Aβ ScFv is illustrated in Figure 10, which depicts the influx of the fusion antibody from blood into brain via transport on the endogenous HIR (*26*). Once in brain, the fusion antibody is free to bind to the Aβ amyloid plaque and promote disaggregation of the plaque. However, there must also be also a mechanism for efflux of the fusion antibody from brain to blood; otherwise, there would be no net decrease in the brain Aβ amyloid peptide burden. The fusion antibody is able to rapidly exit the brain via reverse transcytosis across the BBB, because the BBB expresses an Fc receptor (FcR), which functions as an IgG efflux system (*44*). IgG molecules injected directly into the brain are rapidly transported to blood via reverse transcytosis across the BBB, which is mediated by the brain microvascular FcR (*44*). The most widely expressed FcR on the BBB is the neonatal FcR, also called the FcRn (*45*). The BBB FcR mediates the asymmetric reverse transcytosis of IgG molecules from brain back to blood, but does not mediate the uptake or influx of IgG molecules in the blood to brain direction. The FcRn binding site on an IgG molecule is the CH_2-CH_3 interface (*46*). This region of the IgG molecule is retained following the engineering of the HIRMAb-ScFv fusion antibody, which is depicted in Figure 11. The genes encoding the variable region of heavy chain (VH) and the variable region of light chain (VL) of a murine mAb against the amino terminal portion of the Aβ peptide were spliced together with a linker peptide to form a ScFv molecule (*26*). The amino terminal portion of this anti-Aβ ScFv was fused to the carboxyl terminus of the CH_3 region of the HIRMAb to produce the fusion antibody shown in Figure 11. The fusion antibody is a trifunctional molecule that binds the HIR on the BBB to mediate influx from blood into the brain; binds to the BBB FcRn at the CH_2-CH_3 interface to mediate efflux from brain back to blood; and binds and disaggregates the Aβ amyloid plaque of AD. These three functionalities of the fusion antibody were all demonstrated in vivo in different animal models (*26*). The fusion antibody was radiolabeled with 125-iodine, and coinjected intravenously into the adult Rhesus monkey with [^{3}H]-labeled anti-Aβ mAb (*26*). The HIRMAb-ScFv fusion antibody was rapidly removed from blood, similar to the rapid removal from blood of the HIRMAb-BDNF fusion protein shown in Figure 9A. In contrast, the conventional anti-Aβ mAb had a very long blood residence time,

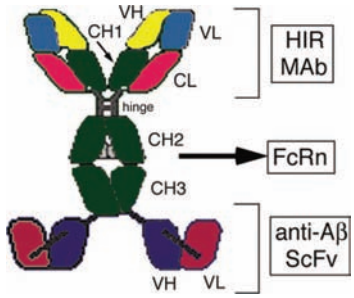

Figure 11. Antibody fusion protein with 3 functional domains. The first domain, the HIRMAb, binds the BBB HIR to trigger influx across the BBB. The second domain, the anti-AβScFv fused to the CH_3 region, binds to the Aβ amyloid peptide of AD to cause disaggregation of amyloid plaque in brain. The third domain, the CH_2-CH_3 interface of the Fc region, binds to the BBB FcRn to trigger efflux of the fusion antibody from brain back to blood, resulting in a net depletion of amyloid plaque in brain. From ref (*26*).

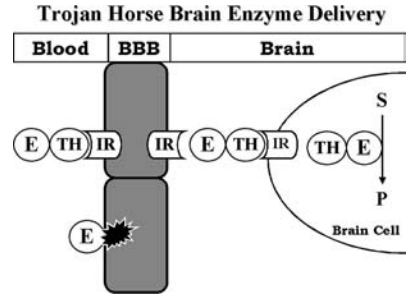

Figure 12. Antibody−lysosomal enzyme fusion protein. The fusion protein is composed of an engineered mAb to the human insulin receptor (IR), which acts as a molecular Trojan horse (TH), and IDUA, a lysosomal enzyme (E). By itself, the IDUA does not cross the blood−brain barrier (BBB). However, following fusion of the IDUA to the TH, the enzyme is able to cross the BBB, and the brain cell membrane, by trafficking on the IR, which is expressed at both membranes in the brain. Once inside brain cells, the IDUA moiety of the fusion protein degrades lysosomal storage substrate (S) into low molecular weight products (P). From ref (*20*).

and was not measureably removed from blood during the experimental time period (*26*). As expected, the anti-Aβ mAb was not taken up by brain (*26*). In contrast, high brain uptake of the fusion antibody was observed owing to transport into brain on the endogenous insulin receptor of the primate BBB (*26*). Although the rat insulin receptor does not recognize the HIRMAb, the rat FcRn does recognize human IgG (*47*). Therefore, the rapid efflux of the fusion antibody from the brain to blood compartments across the BBB could be demonstrated with the brain efflux index method following the intracerebral injection of the fusion antibody into adult rat brain (*26*). The binding of the fusion antibody to the $A\beta^{1-40}$ peptide was confirmed with an immunoradiometric assay in vitro (*26*). The binding of the fusion antibody to the Aβ amyloid plaque was demonstrated in vivo following the intracerebral injection of the fusion antibody into the brain of a double transgenic mouse model of AD (*26*). A single intracerebral injection of 20 pmol of the fusion antibody into the transgenic mouse brain resulted in a 40% reduction in amyloid plaque in both the hippocampus and the cortex within 48 h. In summary, if mAb therapeutics, such as a mAb against the Aβ amyloid of Alzheimer's disease, are to be developed as human neurotherapeutics, these therapeutic MAbs must be reengineered to cross the human BBB. The ability of the fusion antibody to traverse the BBB in both directions may be controlled by the genetic engineering. If the intent is to minimize efflux from brain, then the fusion antibody could be engineered without a constant region CH_2-CH_3 interface, so as to eliminate affinity of the fusion protein for the BBB FcR IgG efflux system. There are multiple genetic engineering approaches that can be taken to develop antibody fusion proteins that cross the BBB in either direction.

BLOOD−BRAIN BARRIER DELIVERY OF THERAPEUTIC ENZYMES

There are over 40 lysosomal storage disorders and approximately 75% of these affect the brain (*48*). The standard therapy for lysosomal storage disorders is enzyme replacement therapy (ERT) (*49*). However, recombinant enzymes do not cross the BBB and do not treat the brain in patients with lysosomal storage diseases. A common lysosomal storage disorder is mucopolysaccharidosis (MPS) type I, also called Hurler's syndrome, which is caused by the mutation of the gene encoding for the IDUA lysosomal enzyme. Recombinant human IDUA is produced in CHO cells (*50, 51*) for the ERT of Hurler's syndrome. The delivery of IDUA from blood to a neuronal lysosomal compartment requires transport of the lysosomal enzyme across two membranes in series: the BBB and the neuronal plasma membrane, as shown in Figure 12. Owing to the high expression of the insulin receptor on the neuronal plasma membrane (*52*), the HIRMAb acts as a molecular Trojan horse to ferry the lysosomal enzyme not only across the BBB, but also across the neuronal plasma membrane (Figure 12). Following the PCR amplification of a 1.9 Kb cDNA encoding for the human IDUA, minus its signal peptide (Figure 3B), the IDUA cDNA was fused to the 3′-terminus of the cDNA encoding the heavy chain of the HIRMAb (*20*). The HIRMAb-IDUA fusion protein was expressed in COS cells and purified from conditioned serum-free medium with protein A affinity chromatography. The HIRMAb-IDUA fusion protein was added to the medium of MPS type I fibroblasts and the localization of the fusion protein within these cells 24 h later was detected with confocal microscopy and primary antibodies to either human IDUA (Figure 13A) or human lysosomal associated membrane protein (LAMP)-1 (Figure 13B). As shown in the overlay study (Figure 13C), there is localization of the HIRMAb-IDUA fusion protein in the lysosomal compartment of MPS type I fibroblasts. Figure 13D is an overlap image of the negative control primary antibodies. The HIRMAb-IDUA fusion protein was radiolabeled with 125-iodine and chloramine T. The [^{125}I]-HIRMAb-IDUA fusion protein was injected intravenously into the adult Rhesus monkey. At 2 h after injection, the animal was euthanized, the brain was removed, and 20 μm frozen sections were prepared for film autoradiography. The brain autoradiography study demonstrated a robust uptake of the HIRMAb-IDUA fusion protein in all parts of the Rhesus monkey brain following intravenous administration with a higher uptake in gray matter as compared to white matter (Figure 13E). Owing to the greater microvascular density of gray matter as compared to white matter, there is a higher vascular density of insulin receptor in gray matter as compared to white matter (*15*). The primate brain uptake of the HIRMAb-IDUA fusion protein was 1.05 ± 0.05% of injected dose (ID) per 100 g brain (*20*). Since the size of the Rhesus monkey brain is approximately 100 g, the amount of injected fusion protein that distributed to primate brain was approximately 1%. A standard dose of intravenous common IDUA in the ERT of Hurler's syndrome is 0.6 mg/kg (*53*). Given this injection dose in a 50 kg patient, and given the brain uptake of the fusion protein expressed as percent of injected dose per gram, and given the IDUA enzyme-specific activity of 363 units/μg protein for the HIRMAb-IDUA fusion protein (*20*), the brain IDUA enzyme activity is predicted to be 1.1 units of IDUA enzyme activity per mg of protein following the intravenous administration of the therapeutic dose of the HIRMAb-IDUA fusion protein (*20*). This level of IDUA enzyme activity is normal for the human brain, where the IDUA

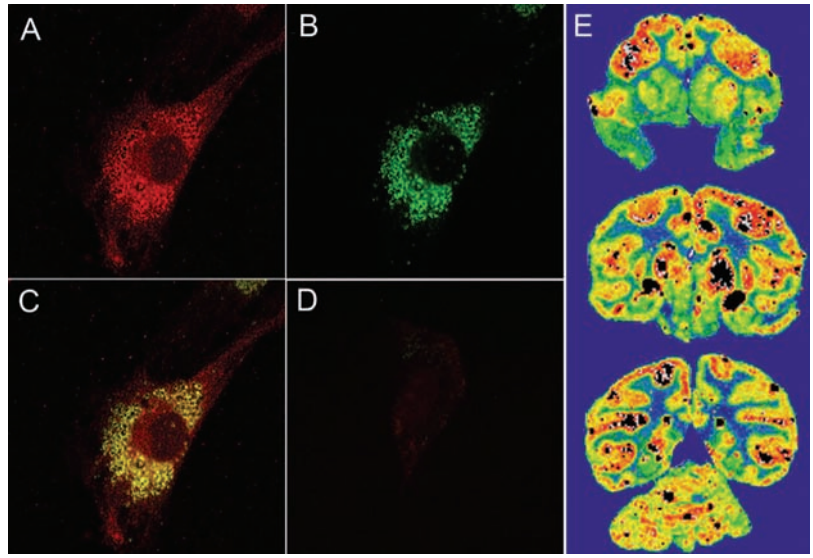

Figure 13. Delivery of IDUA by Trojan horse in cell culture and in vivo in the Rhesus monkey brain. (A, B, C, D) Hurler fibroblasts were incubated with HIRMAb-IDUA fusion protein for 24 h and then fixed and immune stained for confocal microscopy. The fixed cells were stained with an antibody to human IDUA (panel A: red channel), and a mouse monoclonal antibody to human lysosomal associated membrane protein (LAMP)-1 (panel B: green channel). The overlap image in panel C shows sequestration of the HIRMAb-IDUA fusion protein within lysosomes. Panel D is an overlap image of negative control primary antibodies. (E) Film autoradiography of Rhesus monkey brain removed 2 h after an intravenous administration of [^{125}I]-HIRMAb-IDUA fusion protein. Coronal sections through the forebrain (top panel), midbrain (middle panel), and hindbrain/cerebellum (bottom panel) are shown. Gray matter is red−yellow and white matter is blue−green. From ref (*20*).

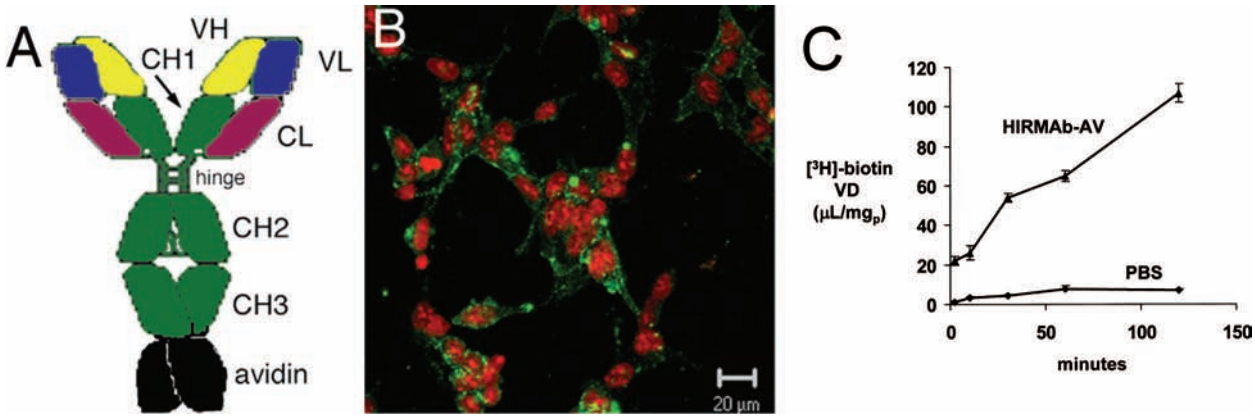

Figure 14. Antibody-avidin fusion protein. (A) Structure of the HIRMAb-avidin fusion protein showing fusion of the amino terminus of the mature avidin (AV) monomer to the carboxyl terminus of the CH_3 region of the heavy chain of the engineered HIRMAb. The fusion protein is a bifunctional molecule. The fusion protein binds the HIR at the BBB, to mediate transport into the brain, and binds biotinylated pharmaceuticals, to mediate high-affinity attachment of the pharmaceutical to the HIRMAb molecular Trojan horse. (B) Confocal microscopy of human 293 cells showing the intracellular distribution (green) of fluorescein-biotin conjugated to the HIRMAb-AV fusion protein. The nuclei are stained by propidium iodide (red). (C) Volume of distribution (VD) of [^{3}H]-biotin in human 293 cells at 2 to 120 min of incubation at 37 °C after comixture of the labeled biotin with either phosphate buffered saline (PBS) or the HIRMAb-AV fusion protein. Data points are mean ± SE (n = 4 dishes per time point). From ref (*27*).

enzyme activity ranges from 0.5 to 1.5 units/mg protein (*54*). Therefore, the IDUA enzyme activity in the brain of patients with Hurler's syndrome may be normalized following the intravenous administration of therapeutic doses of the HIRMAb-IDUA fusion protein. This is made possible following the re-engineering of IDUA to enable transport of this recombinant enzyme across the human BBB (Table 2).

ENGINEERING OF IgG-AVIDIN FUSION PROTEINS FOR DELIVERY OF BIOTINYLATED DRUGS

It is not feasible to engineer IgG fusion proteins for certain types of biotherapeutics including oligopeptides, antisense drugs, or short interfering RNA (siRNA). However, the delivery of monobiotinylated therapeutics or siRNA across the BBB is possible with the genetic engineering and expression of a HIRMAb-avidin fusion protein. Avidin has been administered to humans without immunologic reactions (*55, 56*). The binding of biotin by avidin is characterized by very high affinity, with a $K_D = 10^{-15}$ M and a dissociation $t_{1/2} = 89$ days (*57*). Therefore, the avidin−biotin system provides the high stability of the bond between the drug and the Trojan horse that is required for in vivo drug delivery. The avidin cDNA was produced by PCR and following engineering of the heavy chain-avidin fusion gene, and transfection of COS or CHO cells, the HIRMAb-avidin (AV) fusion protein was expressed and purified (*27*). The amino terminus of the avidin monomer was fused to the carboxyl terminus of the CH_3 region of the HIRMAb heavy chain, as depicted in Figure 14A. Engineering the IgG-avidin fusion protein in this manner places the avidin monomer in a dimeric configuration which replicates the natural configuration of avidin, which is a dimer of dimers (*58*). A high producing CHO line was isolated, which allowed for purification of the

HIRMAb-avidin fusion protein. Initial work showed the biotin binding site of the HIRMAb-AV fusion protein was completely saturated by the high biotin content of cell culture medium. However, the CHO line could be maintained for up to a month in biotin-free medium, and the HIRMAb-AV fusion protein produced under these conditions avidly bound biotin (*27*). The biologic activity of the HIRMAb-avidin fusion protein was demonstrated in cell culture using human 293 epithelial cells. The intracellular distribution of biotin-fluorescein in 293 cells was demonstrated with confocal microscopy following attachment of the biotin-fluorescein to the HIRMAb-AV fusion protein (Figure 14B). There is no measurable cell uptake of the biotin-fluorescein in the absence of the HIRMAb-AV fusion protein (*27*). The uptake by these cells of ^{3}H-biotin was increased many-fold following attachment of the biotin to the HIRMAb-AV fusion protein as compared to biotin alone (Figure 14C). The use of avidin−biotin technology in drug delivery has advantages over other methods for attachment of ligands to an antibody transport vector and may be particularly advantageous in the delivery of siRNA therapeutics. The BBB delivery of siRNA was validated with an intracranial brain cancer model in rats. Rat glial tumors permanently transfected with the luciferase gene were implanted in adult rat brain. A monobiotinylated siRNA against the luciferase mRNA was attached to a conjugate of streptavidin and the mAb against the rat TfR (*59*). Intravenous administration of the siRNA alone caused no knockdown in brain tumor luciferase gene expression. However, the biotinylated siRNA caused a 69−81% reduction in luciferase gene expression following intravenous administration of the siRNA conjugated to the TfRMAb molecular Trojan horse (*59*). Therefore, the availability of the HIRMAb-AV fusion protein may allow for the delivery of siRNA across the human BBB. The HIRMAb-AV fusion protein is a universal Trojan horse, and almost any monobiotinylated drug could be delivered to brain with this delivery system. The formulation of human therapeutics with the IgG-avidin fusion protein technology is facilitated by a "two-vial" approach. The HIRMAb-AV fusion protein is formulated in one vial, and the monobiotinylated therapeutic is formulated in a second vial. The two vials are mixed just prior to administration. Owing to the very high affinity of avidin binding of biotin, there is instantaneous capture of the biotinylated drug by the HIRMAb-AV fusion protein.

CONCLUSIONS

The BBB problem has been the rate-limiting step in brain drug development. Prior attempts to deliver pharmaceuticals to the brain include BBB disruption, by either osmotic (*60*) or biochemical agents (*61*), or trans-cranial approaches using intracerebroventricular (ICV) injection (*62*) or convection-enhanced diffusion (CED) (*63*). BBB disruption is associated with chronic neuropathologic changes (*64*), which may be related to the toxic effects of plasma proteins on brain cells (*65*). Administration of drug by ICV injection only distributes drug to the ependymal surface of the brain, and this approach was not successful in the delivery of GDNF for Parkinson's disease (PD) (*66*). The delivery of GDNF for PD via CED was not successful in clinical trials (*67*), and this was subsequently shown to be due to limited distribution of the neurotrophin in brain distal to the perfusion catheter (*68*). An alternative approach to either the disruption of the BBB, or the trans-cranial delivery of drug to the brain, is the targeting of drug to brain via the trans-vascular route utilizing endogenous BBB transporters. This approach requires the re-engineering of biopharmaceuticals so that these molecules can access the endogenous BBB receptor-mediated transport systems.

The re-engineering of therapeutic proteins for drug delivery across the human BBB represents a merger of biopharmaceutical drug discovery and drug delivery. The presence of the BBB, and the fact that all large molecule biopharmaceuticals do not cross this barrier, represents an insurmountable barrier for CNS drug developers. Brain drug development programs that are focused solely on CNS drug discovery, in the absence of a parallel effort in CNS drug delivery, are destined to fail, owing to the BBB problem. There are many protein drugs for the brain that have already been discovered (Table 1). However, these drugs do not cross the BBB, and cannot enter into a CNS drug development program because of the BBB problem. The availability of these drugs allows a CNS drug delivery program to short-circuit CNS drug discovery. The drugs have already been discovered; the problem is BBB drug delivery. The BBB drug delivery problem can be solved by re-engineering existing biopharmaceuticals for transport across the human BBB using genetically engineered molecular Trojan horses. Future clinical trials with fusion proteins will address immunogenicity in humans, and off-target side effects. However, human Fc:soluble extracellular domain receptor fusion proteins such as etanercept (*69*) are FDA approved biopharmeuticals, and have low immunogenicity in humans, and safety profiles consistent with minimal off-target side effects (*70*).

ACKNOWLEDGMENT

The author is indebted to colleagues Drs. Ruben Boado, Yun Zhang, and Yufeng Zhang, of ArmaGen Technologies, for many valuable discussions.

Design of an Optical Switch for Studying Conformational Dynamics in Individual Molecules of GroEL

Gabriel A. Frank,[†,§] Yakov Kipnis,[§] Elena Smolensky,[§] Shirley S. Daube,[‡] Amnon Horovitz,*[,§] and Gilad Haran*[,†]

Departments of Chemical Physics, Chemical Research Support, and Structural Biology, Weizmann Institute of Science, Rehovot 76100, Israel. Received March 21, 2008; Revised Manuscript Received May 15, 2008

We describe the design of an optical switch in the chaperonin GroEL that is opened and closed by its ATP- and cochaperonin GroES-driven conformational changes. The switch, based on a fluorophore and a quencher, is engineered into the single-ring variant of the chaperone, and shows dramatic modulation of its fluorescent intensity in response to the transition of the protein between its allosteric states. It, therefore, forms a sensitive probe for the dynamics of the allosteric transitions of this machine, both in the bulk and in single molecules.

Many proteins operate as molecular machines, using chemical energy to drive them through a functional cycle that involves multiple conformational states (*1*). The *E. coli* molecular chaperone GroEL is a machine that assists protein folding by undergoing allosteric transitions between protein substrate binding (T) and release (R) states (*2*). Fluorescence spectroscopy has been used for studying the functional cycle of GroEL in both ensemble (*3, 4*) and single-molecule experiments (*5*). However, it has been difficult to devise methods that allow probing the conformational dynamics of the chaperone itself at the single-molecule level. We designed an optical switch that is opened and closed by the conformational changes of GroEL, showing a dramatic modulation of its fluorescent intensity. This optical switch was demonstrated to be a sensitive probe of ATP- and cochaperone-driven allosteric transitions, both in the bulk and in individual molecules.

GroEL is made up of two homoheptameric rings, stacked back-to-back, with a cavity at each end (*6*), in which protein folding can take place. GroEL functions in conjunction with a heptameric ring-shaped cochaperonin, GroES, that caps the cavity of the so-called *cis* ring, thereby triggering dissociation of bound protein substrates into the cavity (*7*). The allosteric transitions of GroEL are induced by ATP binding that occurs with positive cooperativity within rings and negative cooperativity between rings (*8*). The intraring positive cooperativity is an outcome of a concerted switch of its rings between the T and R conformations. The structure of the GroEL-GroES-ADP_7 complex has been determined at atomic resolution (*9*). A single-ring version of GroEL (SR1) displays similar positive cooperative behavior with respect to ATP binding (*10*) but, unlike GroEL, its complex with GroES is long-lived since the trigger for GroES dissociation is ATP binding to the opposite ring (*11*). In the rest of this Communication, we concentrate on SR1.

The switch we built into the structure of SR1 is based on the quenching of oxazine derivatives by tryptophan (Trp) (*12*). This electron transfer-based quenching reaction has been used previously to study folding dynamics in peptides and small proteins (*13, 14*). It requires the formation of a ground-state complex between an appropriate fluorophore (attached to the side chain of an amino acid residue) and the side chain of a tryptophan residue, and can thus operate only if the two are in close proximity to each other. The quenched state has low fluorescence intensity. A conformational change that increases the distance between the fluorophore and the quencher should, in principle, lead to a large increase in emission. The design of the optical switch that is described below was based on our knowledge of the structures of two conformations of GroEL (*9*).

The fluorophore we used in this work was the maleimide derivative of the oxazine dye Atto 655 (Atto-tec). The switch based on this dye requires inserting a cysteine residue (to be labeled) and a Trp residue at appropriate positions. To identify such positions, we first listed all pairs of amino acid residues (either within one subunit or in neighboring subunits) that are separated by a distance short enough to allow contact formation between the fluorophore and the Trp side chain in the T conformation, but too long for quenching to take place in the R′ (GroES-bound) conformation. All pairs in this list in which the interaction between the fluorophore and the Trp in the T conformation might be hindered by other amino acids were discarded. This analysis resulted in 51 suitable pairs that are listed in Table 1 of the Supporting Information. Pairs of mutations that were not likely, on the basis of the literature, to affect the protein's stability and activity are highlighted in Table 1. One of these pairs, on which we focused, involves residue 44 in one subunit and residue 327 in the nearest-neighbor subunit in the counterclockwise direction. The mutations F44W and K327C were each characterized before and found to have only minor effect on the protein's stability and activity (*15, 16*). In the T conformation, the distance between the C_α atoms of these residues is ∼17 Å, allowing interaction of a dye molecule with the Trp side chain. In the R′ conformation, this distance grows to ∼46 Å, thereby preventing this interaction. A molecular graphics program was used to build a subset of the fluorophore's rotamers into the two structures of GroEL with the above

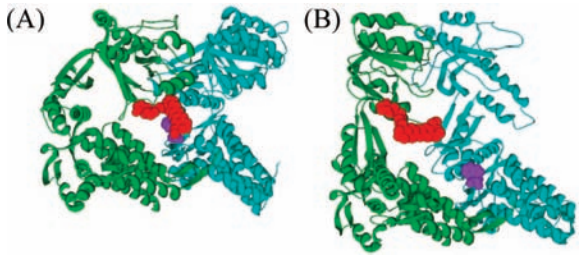

Figure 1. The optical switch in single-ring GroEL (SR1) molecules. (A) The fluorescence of the oxazine dye at position 327 (in red) is quenched by Trp44 (in violet) in the T conformation of GroEL. (B) In the R′ conformation, the quenching is removed. The structures shown in A and B are those of two adjacent subunits in the *trans* and *cis* rings, respectively, of the GroEL-GroES-ADP_7 complex (*9*).

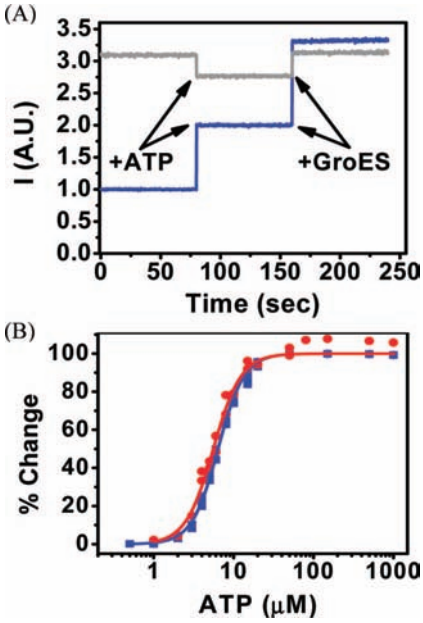

Figure 2. Response of the optical switch to conformational changes. (A) Response of SR1WC (blue) and SR1C (gray) to the addition of 1 mM ATP followed by addition of 50 nM GroES. (B) ATP titration curves of labeled SR1WC molecules obtained in the bulk (blue) and on a glass surface (red). Data were fitted to the Hill equation (lines).

mutations, and test that the fluorophore is indeed in contact with the Trp side chain in the T conformation (Figure 1).

We generated SR1 molecules with the replacements F44W and K327C (SR1WC), using standard site-directed mutagenesis techniques, and labeled Cys327 with Atto655. Under the labeling conditions we used, wild-type cysteines are essentially unreactive (*17*). Care was taken so that less than one subunit in each SR1 molecule would be labeled on average. We also purified and labeled the Trp-lacking single mutant SR1-K327C (SR1C) as a control.

The addition of 1 mM ATP to 25 nM labeled SR1WC molecules generated a strong response, doubling the fluorescence intensity (Figure 2A, blue line). Addition of 50 nM GroES shortly after the addition of ATP (Figure 2A) essentially doubled the signal again. In contrast, the baseline fluorescence of labeled SR1C molecules (without ATP and GroES) was almost as high as the maximal fluorescence of SR1WC molecules in the presence of both additives (Figure 2A, gray line). Addition of ATP and GroES to the Trp-lacking molecules barely changed their fluorescence, thereby showing that the fluorescence changes observed in SR1WC molecules are related to the removal of Trp quenching. In the absence of GroES and as ATP was consumed with time, SR1WC molecules reverted to their initial

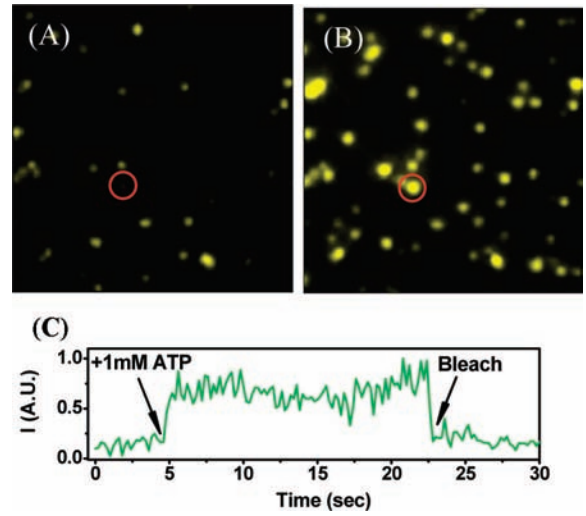

Figure 3. Activity of the optical switch in labeled SR1WC molecules deposited on a glass surface, monitored at the single molecule level. Changes in fluorescence after addition of (A) buffer only and (B) 1 mM ATP. (C) Temporal trajectory of the molecule marked with a red circle in (A) and (B).

conformation and the fluorescence returned essentially to its baseline (not shown). The optical switch, thus, operates as designed.

The observation that the fluorescence intensity of labeled SR1WC, in the presence of ATP and GroES, is similar to the baseline fluorescence of the Trp-lacking mutant suggests that the SR1-GroES complex is in a conformation in which the interaction between Trp44 and the label is not possible. On the other hand, the fluorescence intensity attained with a saturating concentration of ATP is only about half of the value when GroES is also present. This suggests that ATP-bound SR1 molecules are in dynamic equilibrium with conformations in which the quenched state can be formed. This intriguing observation awaits further study.

ATP titration experiments with the labeled double mutant revealed a gradual increase in fluorescence with a sigmoidal dependence on ATP concentration (Figure 2B, blue points), indicating a cooperative behavior. Fitting the data to the Hill equation yielded a Hill coefficient of 2.65 ± 0.05, similar to a previously published value for SR1 based on its ATPase activity (2.87 ± 0.16) (*10*), thus showing that the labeled protein is fully functional.

In order to test the applicability of the design for single-molecule experiments, we deposited labeled SR1WC molecules on a glass slide and observed them under a fluorescence microscope. First, a dense molecular layer was formed, and a titration curve was obtained by registering fluorescence changes upon gradual addition of ATP. The surface titration curve was similar to the bulk titration curve (Figure 2B, red), indicating that the deposition of the protein on the surface does not significantly change its activity. Washing the surface following ATP addition led to a return of the fluorescence intensity to baseline levels, establishing reversibility of the optical switch.

A sparse layer of protein molecules was then formed, and fluorescence changes were monitored on the single-molecule level. Figure 3 shows a typical microscope field before (A) and after (B) addition of 1 mM ATP. A strong increase in the fluorescence of many of the molecules is readily observed. The temporal trajectory of the fluorescence of one of these (circles in Figure 3A,B) is shown in Figure 3c.

We have shown here how an optical switch can be incorporated into the structure of GroEL to report on its structural changes. This switch has several advantages over other fluo-

rescence-based methods for probing conformational transitions. First, it provides a very large dynamic range, as the signal is large in one conformation and essentially null in the other. Second, labeling with only one dye is required in contrast with FRET which usually necessitates labeling with two different dyes. The optical switch built into SR1 now provides us with a convenient and powerful route for studying its dynamics on the single-molecule level, which we hope to report soon.

Charge Dependence of Ligand Release and Monolayer Stability of Gold Nanoparticles by Biogenic Thiols

Apiwat Chompoosor, Gang Han, and Vincent M. Rotello*

Department of Chemistry, University of Massachusetts, 710 North Pleasant Street, Amherst, Massachusetts 01003, Department of Chemistry, University of Massachusetts, Amherst 01003. Received February 22, 2008; Revised Manuscript Received May 19, 2008

The effect of surface charge on the stability of gold nanoparticles (AuNPs) to the biogenic thiols glutathione (GSH), dihydrolipoic acid (DHLA), and cysteine was quantified. It was observed that the rate of release of fluorescein-tagged ligand was determined by the surface charge of the AuNPs, with cationic particles much more labile than anionic analogues. This ability to tune stability is significant for the design of both delivery vehicles and intracellular probes.

The design of functional materials that are capable of controlled release of therapeutic materials is of great importance in biomedical and materials chemistry (*1, 2*). Numerous drug release strategies have been employed, including those relying on external stimuli (e.g., photochemical (*3, 4*) or ultrasound *5, 6*) or intracellular environment (e.g., enzymes (*7, 8*) or pH *9, 10*).

One of the most promising intracellular release strategies relies on glutathione (GSH) (*11, 12*). GSH is the most abundant thiol species inside the cell and plays an essential role in protecting organisms from free radical damage and oxidative stress through balancing the GSH/oxidized glutathione (GSSG) equilibrium (*13*). The concentration of GSH is significantly lower in the extracellular environment than inside the cell (10 μM in blood plasma (*14*) vs 10 mM in liver cells (*15*)). This 1000-fold difference in concentration makes GSH a promising trigger for intracellular release, a method that has been exploited through disulfide-bond based drug delivery systems (*16*). Other biogenic thiols are found in cells, including DHLA (*17*) and cysteine (*18*).

Recent interest has been focused on drug delivery using gold nanoparticles (AuNPs). The core of AuNPs are essentially inert and nontoxic, and the capability to tune the core size and surface functionalities provide convenient access to explore and optimize delivery parameters (*19, 20*). These materials also offer controlled release of payload through place-exchange of GSH with thiols on the AuNP surface, thus leading to efficient protein (*21*), DNA (*22*), and small molecular drug payload release *in vitro* and inside cells (*11*). However, it will be very desirable to develop a simple approach to modulate payload release kinetics by systemic alteration of functionalities of AuNPs (*23*).

Here, we report the use of a series of fluorophore-labeled gold nanoparticles with varied surface charges to investigate the role of particle charge on the stability of gold nanoparticles to thiols. Our hypothesis was that the systemic tuning of the surface charge on AuNP would affect the electrostatic interaction between AuNPs surface and anionic GSH molecule, thus alternating concomitant payload release. In addition, intracellular thiols DHLA and cysteine were systematically examined.

Monolayer-protected AuNPs of 2 nm diameter featuring controlled surface charge were synthesized by the Brust-Schiffrin reduction (*24*) followed by the Murray place-exchange reaction (*25*). The charges on these particles range from positive to negative (Figure 1). Briefly, the cationic AuNPs (**NP1**−**NP4**) were fabricated with different ratios of tetra(ethylene glycol) (TEG) ligands onto 1-pentanethiol AuNPs, while the anionic AuNP (**NP5**) was obtained in analogous fashion using a carboxylate-terminated tetra(ethylene glycol) (TCOOH) ligand (see Supporting Information). In placed-exchanged protocol, the fluorophore was also incorporated onto these water-soluble nanoparticles (≤1% loading as determined by NMR) with fluorescein-functionalized thiol **FITC-SH**. The obtained AuNPs were subjected to dialysis to remove excess fluorophore and displaced ligands. The ligand ratios for the cationic and neutral ligands were determined through NMR endgroup analysis; the fluorescein ligand was at concentrations too low to quantify. As expected, the zeta potential tracked qualitatively with ligand ratio for the particles (Figure 1).

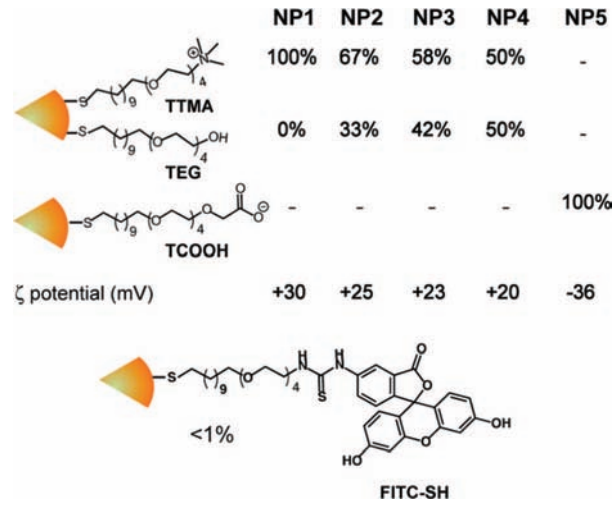

Figure 1. Ligand ratios as determined by NMR for **NP1**−**NP5**.

The rate of ligand release from the nanoparticles was determined using fluorescence spectroscopy, exploiting the efficient quenching of fluorophores by the Au core of the particles. The increase in light emission observed upon GSH-mediated displacement of the fluorophores provides a direct tool for the quantification of release *in vitro* and in the cellular environments (*11*). The fluorophore-conjugated AuNPs **NP1**−**NP5** were treated with GSH solution (Figure 2). Upon place exchange with GSH, the fluorescent ligands are released from the AuNP surface and the fluorescence recovered. The

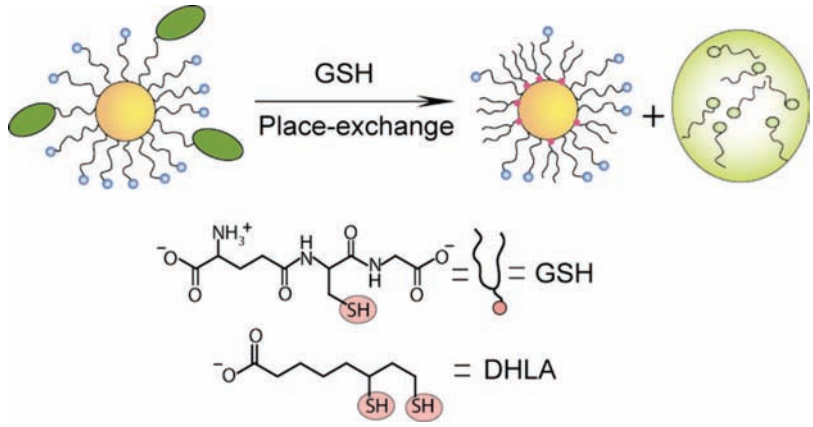

Figure 2. Schematic representation of GSH-mediated ligand release.

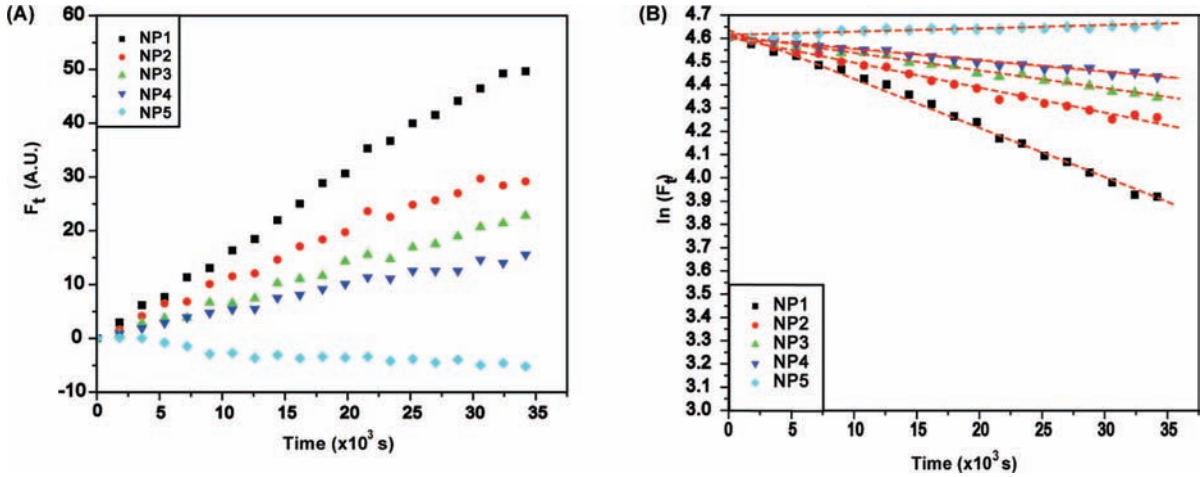

Figure 3. Percentage (A) and rate (B) for GSH-mediated release of fluorophores from different NPs. The fraction of the released **FITC-SH** ligand (F_t) at a given incubation time point (t). The concentration of AuNPs was 1.5 μM in PBS buffer (pH $\sim$ 7.4) at 37 °C.

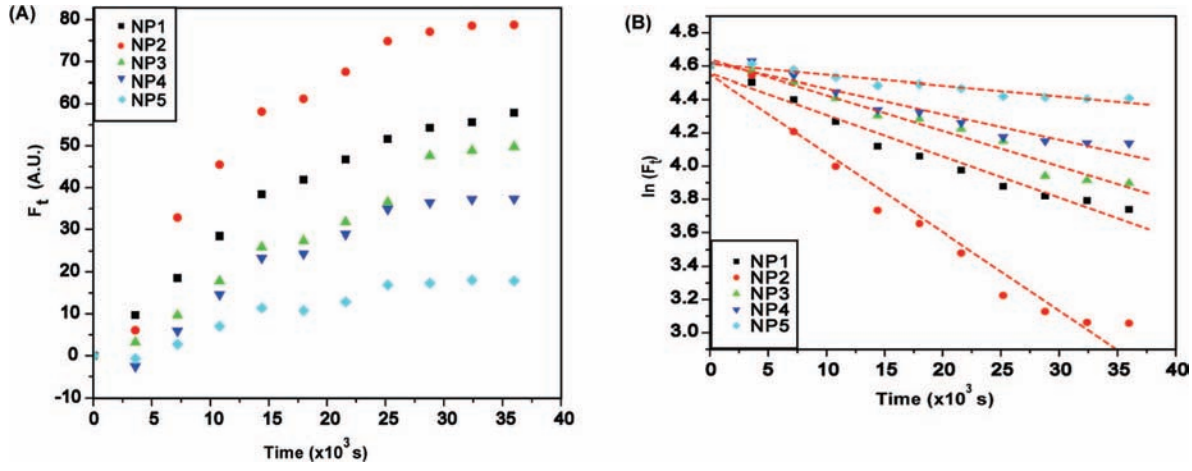

Figure 4. Percentage (A) and rate (B) for DHLA-mediated release of fluorophore. The fraction of the released **FITC-SH** ligand (F_t) at a given incubation time point (t). The concentration of AuNPs was 1.5 μM in PBS buffer (pH $\sim$ 7.4), at 37 °C.

fluorescence intensity thus corresponds to the amount of fluorophore that is released from the NP surface (Figure 3).

From Figure 3, it is evident that fluorophore release from the AuNPs surface is time- and charge-dependent. Moreover, the kinetic analysis of the parameter of ln F_t (logarithm of the normalized percentage of fluorophore release) as a function of time shows a linear dependency with respect to time, indicating pseudo first-order kinetics (see Supporting Information).

In addition to GSH, the AuNPs were investigated in the presence of other biologically relevant free thiols, i.e., DHLA and cysteine. In comparison with GSH, dihydrolipoic acid (DHLA) features two thiols and a higher degree of hydrophobicity and has been used to functionalize nanoparticles, including quantum dots. The results from DHLA-mediated release of FITC from AuNP surface are shown in Figure 4. Cysteine, a zwiterionic thiol, was likewise tested (Figure 5). In both cases, pseudo first-order kinetics were observed.

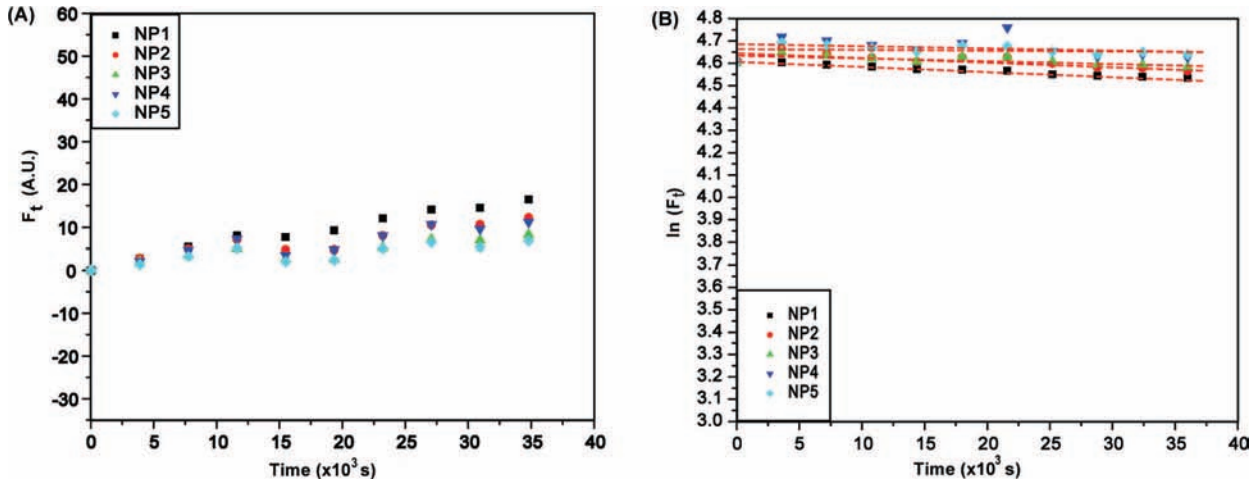

Figure 5. Percentage (A) and rate (B) for cysteine-mediated release of fluorophores from different NPs. The fraction of the released **FITC-SH** ligand (F_t) at a given incubation time point (t). The concentration of AuNPs was 1.5 μM in PBS buffer (pH $\sim$ 7.4). at 37 °C.

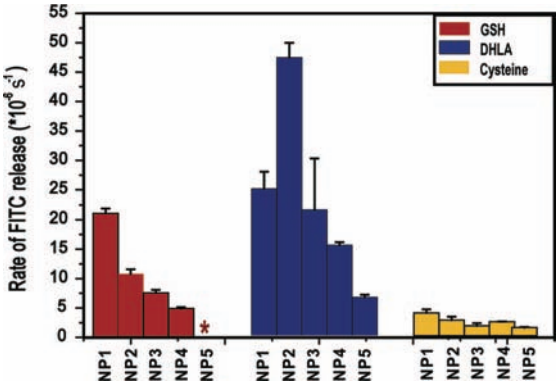

Figure 6. Summary of release rates at 20 mM thiol concentration.

The pseudo first-order rate constants of **NP1**−**NP5** with GSH, DHLA, and cysteine are shown in Table 1 and summarized in Figure 6. Of the particles, **NP1** (100% positively charged) shows the highest release rate with GSH, presumably due to the strong electrostatic interaction between the positive charge on the particle surface and the negative charge on the thiol molecule (Figure 7). The rate of release with the other positively charged NPs show that increasing positive charge results in more rapid fluorophore release. In the case of negatively charged AuNPs, no measurable change in fluorescence was observed, indicating complete nanoparticle stability. This low reactivity presumably arises due to repulsion between the negatively charged NP surface and negative charge on the GSH (Figure 7).

DHLA-mediated release was qualitatively similar to that observed with GSH. The one major difference is that **NP2** shows

Table 1. Summary Rate of FITC Release Mediated by Different Thiol Species at 20 mM Concentration

	rate of release ($\times 10^{-6}$ s^{-1})		
AuNPs	GSH	DHLA	cysteine
NP1	21.10	24.90	3.90
NP2	10.80	47.20	2.69
NP3	7.59	21.40	1.72
NP4	4.91	15.40	2.42
NP5	-	6.55	1.41

the highest release rate. This behavior suggests that the hydrophobic properties and electrostatic interaction of **NP2** interact in a cooperative fashion. As expected, release by DHLA is more rapid than with GSH, as DHLA is both more hydrophobic and contains a dithiol in the molecule facilitating interactions with the AuNP core. Cysteine, while zwitterionic, will be partially anionic (pI = 5.07) under the conditions studied. The rate of release with cysteine was very slow, with the most rapid release occurring with **NP1**, as expected based on electrostatic arguments presumably the slow rate of exchange arises from the lack of hydrophobicity of the highly charged amino acid.

In summary, we found that the stability of gold nanoparticles toward thiols is governed by the surface charge of AuNPs. The ability to control the rate of release of ligands via place exchange provides a potentially potent tool for drug delivery applications. Likewise, these studies provide a strategy for enhancing the stability of nanoparticles in cells, and important consideration for the design of imaging agents.

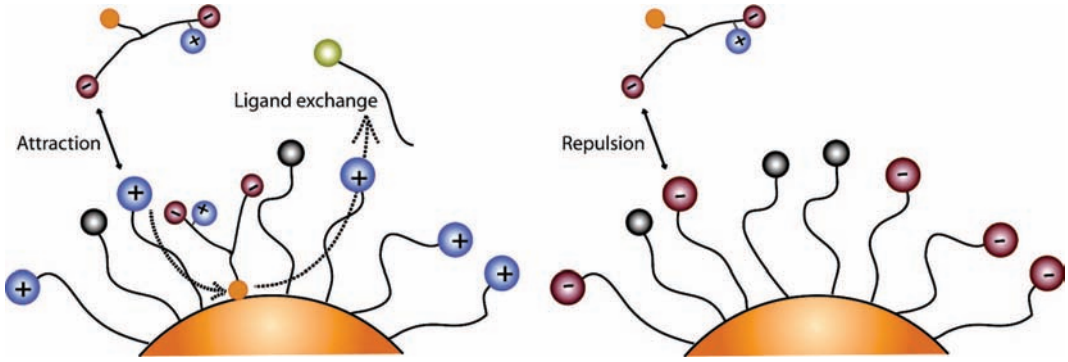

Figure 7. Proposed mechanism for GSH-mediated FITC release from cationic and anionic AuNPs surface.

Received April 28, 2008; Revised Manuscript Received May 19, 2008

We describe new DOC (sodium deoxycholate)−heparin nanoparticles for *in vivo* tumor targeting and inhibition of angiogenesis based on chemical conjugation and the enhanced permeability and retention (EPR) effect. Heparin has been used as a potent anticoagulant agent for 70 years, and has recently been found to inhibit the activity of growth factors which stimulate the smooth muscle cells around tumor. From the results, DOC and heparin were conjugated by bonding carboxyl groups of heparin with amine groups of aminated sodium deoxycholate. Larger antitumor effects of the DOC−heparin VI (8.5 mol of DOC coupled with 1.0 mol heparin) were achieved in animal studies, compared to heparin alone. We confirmed that the conjugated heparin retained its ability to inhibit binding with angiogenic factor, showing a significant decrease in endothelial tubular formation. These results provide new insights into the nontoxic anticancer drug carrier as well as the design of multifunctional bioconjugates for targeted drug delivery.

INTRODUCTION

Tumors produce a number of growth factors stimulating angiogenesis via affinity for receptors on endothelial cells. Low molecular weight heparin (LMWH) appears to have a greater inhibitory effect on angiogenesis than unfractioned heparin (*1–4*). It has been shown that LMWH, as a result of its smaller size and in contrast to unfractioned heparin, can reduce binding of growth factors to their receptors. Fragments of fewer than 18 saccharides reduce the activity of vascular endothelial growth factor (VEGF), and fragments of fewer than 10 saccharides inhibit the activity of basic fibroblast growth factor (bFGF) (*5, 6*). Small molecular heparins (smaller than 6000 Da) are more effective than unfractionated heparin (UFH) for inhibition of VEGF- and bFGF-mediated angiogenesis *in vivo* (*3, 4*).

Heparin has highly hydrophilic properties due to the negatively charged group such as sulfonyl, carboxyl, and hydroxyl within its structure (*7–9*). To treat tumor with heparin, we need new structure designs to allow the use of a reduced dose to achieve the same therapeutic response with a consequent decrease in systemic toxicity and side reactions. Recently, a heparin-based drug carrier has been developed to deliver an anticancer drug to tumor sites by the EPR effect (*10, 11*). In our previous study, a chemically modified unfractionated heparin derivative for delivery of the anticancer doxorubicin was developed and proven a safe drug carrier without the risk of inducing hemorrhage and other side effects (*11*). Other studies have developed polysaccharides such as chitosan and curdlan as anticancer drug carriers with inhibition of tumor growth (*12, 13*).

In this study, we propose a new anticancer drug conjugate system for the treatment of tumor and tumor vasculature by using DOC−heparin nanoparticles. To obtain the optimized anticancer effect of heparin, we designed DOC−heparin conjugates by modification of the C3-hydroxyl group of DOC with 4-nitrophenyl chloroformate (4-NPC) and ethylenediamine (EDA). Through the conjugation method, many DOC molecules were allowed to bind freely with one heparin structure. In addition, the conjugated heparin retained its ability to inhibit binding with angiogenic factors, which can induce proliferation of smooth muscle cells. The rationale for conjugating DOC to the polysaccharide heparin was to specifically target tumor and tumor vasculature and to circumvent adverse reactions from drug toxicity and bleeding by reducing the binding affinity with anticoagulant factors such as factor Xa.

MATERIALS AND METHODS

Materials. Fraxiparin (101 IU/mg, heparin) of average molecular weight ca. 5000 Da was purchased from GlaxoSmith-Kline (Brentford, Middlesex, UK). Sodium deoxycholate (DOC), 4-nitrophenyl chloroformate, triethylamine, dicyclohexylcarbodiimide (DCC), hydroxysuccinimide (HOSu), 4-methylmorpholine, ethylene diamine, dimethyl sulfoxide (DMSO), and ethyl acetate were purchased from Sigma Chemical Co. (St. Louis, MO). Formamide was obtained from Merck (Darmstadt, Germany). Coatest Factor Xa assay kits were from Chromogenix

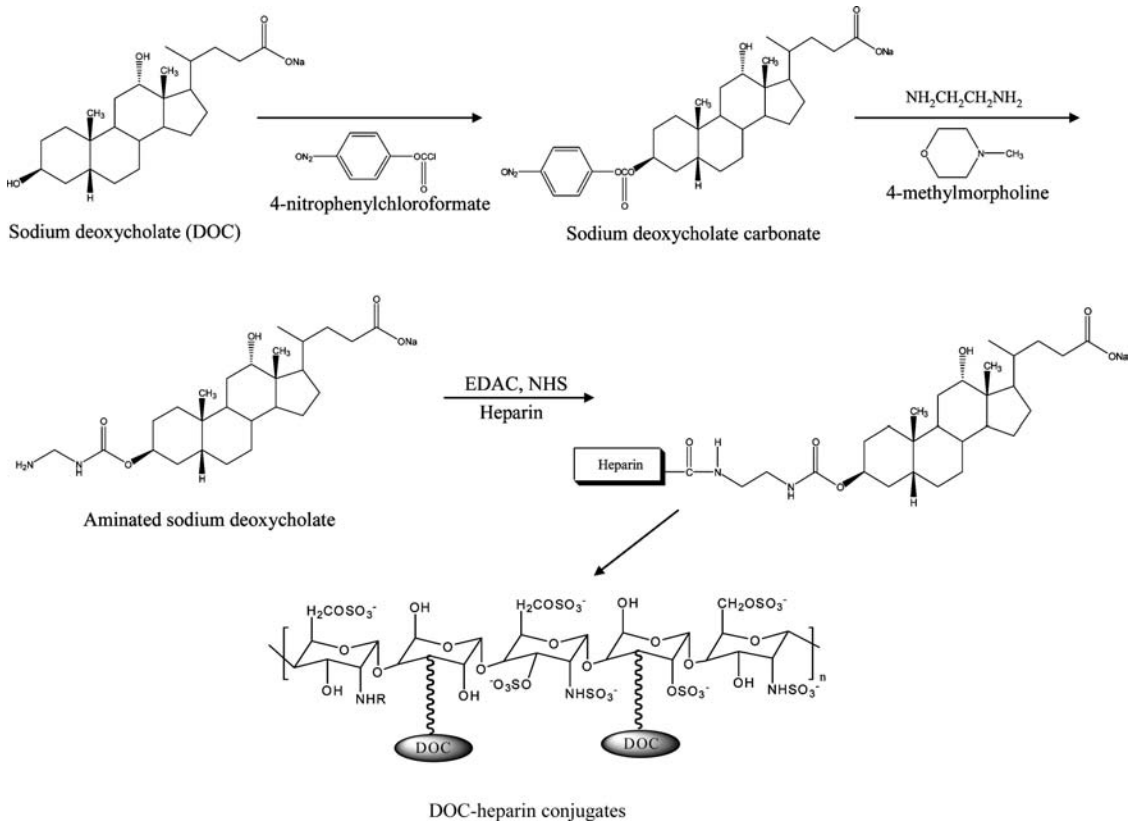

Figure 1. Synthesis and schematic structure of DOC−heparin conjugate.

(Milano, Italy). All reagents were of analytical grade and were used without further purification.

Preparation of DOC−Heparin Conjugates (Figure 1). For amination of sodium deoxycholate (DOC), DOC (0.93 mmol) in 5 mL DMSO was reacted with 4-nitrophenyl chloroformate (4-NPC, 4.65 mmol) and triethylamine (5.58 mmol) for 6 h at room temperature. After reaction, the precipitant was removed by 0.45 μm filter membrane. The filtrate was extracted with 25 mL ethyl acetate and 25 mL water. The crude product from aqueous solution was washed with ethyl acetate three times, and then DOC carbonate was obtained as a powder type after freeze-drying. To obtain aminated DOC, DOC carbonate was reacted with 4-methylmorpholine (1.42 mmol) and ethylenediamine (0.071 mmol) overnight at room temperature. The product was concentrated by rotary evaporation and then precipitated by adding acetonitrile. The precipitated product was dried under vacuum for 24 h.

For preparation of the DOC-heparin conjugate, heparin (0.01 mmol) was dissolved in water and adjusted to pH 5.0 by adding 0.1 M HCl solution. The solution was mixed with EDAC (0.04 mmol), NHS (0.04 mmol), and aminated DOC (0.044 mmol). After 30 min, the mixture was dialyzed (MWCO: 2000) against water to remove unreacted NHS, EDAC, and aminated DOC. The final product, DOC−heparin, was obtained and stored at 4 °C after freeze-drying. The dried DOC−heparin conjugate was analyzed by ^{1}H NMR and FT-IR (Bruker, Germany). Values for ^{1}H NMR of heparin (D_2O) were: δ 5.38 [H1 of glucosamine residue (A)], δ 5.04 [H1 of iduronic acid residue (I)], δ 4.84 [I-5], δ 4.36−4.23 [A-6], δ 4.12−4.40 [I-3], δ 4.08 [I-4], δ 4.02 [A-5], δ 3.78 [I-2], δ 3.71 [A-4], δ 3.65−3.69 [A-3], δ 3.24 [A-2]. Values for ^{1}H NMR of aminated DOC (D_2O) were: δ 1.2−1.9 [m, five and six rings of DOC, 1H], δ 2.1−2.3 [m, CH_3 of DOC, 1H], δ 3.15[d, 12α-OH of DOC, 2H], δ 8.0 [H of CONH]. Values of 1H-NMR of DOC−heparin conjugates (D_2O) were: δ 1.2−1.9 [m, five and six rings of DOC, 1H], δ 3.24−5.38 [A or I of heparin], δ 8.0−8.2 [H of CONH of DOC−heparin].

Ninhydrin Colorimetric Method. For the coupling ratio of DOC in the DOC−heparin conjugate, the ninhydrin colorimetric method was used as described previously (*14*). In brief, 80 μL of the ninhydrin solution was added to 300 μL aminated DOC and the test tube covered with a piece of paraffin film to avoid the loss of solvent due to evaporation. With gentle stirring, the solution was heated for 5 min at 100 °C. After cooling to room temperature in a cold water bath, the absorbance was recorded with a spectrophotometer at 570 nm in wavelength. With the standard curves of aminated DOC, the coupling ratios of DOC−heparin conjugates were determined by subtracting the OD values of remaining aminated DOC.

Anticoagulant Activity of DOC−Heparin Conjugates. DOC−heparin conjugate (100 μL) was mixed with 100 μL of antithrombin III (ATIII) solution to make DOC−heparin conjugate−ATIII complexes, where ATIII concentration was in excess of the DOC−heparin conjugate concentration. The solution was incubated at 37 °C for 3 min, and 100 μL of FXa was added to the solution. The resulting solution was then incubated for an additional 30 s. The concentration of FXa was also in excess of the DOC−heparin conjugate concentration. The substrate (200 μL, 0.8 μmol/mL) was then added and incubated at 37 °C for 3 min. The reaction was terminated by adding 300 μL of 20% acetic acid. The bioactivity and the concentration of DOC−heparin conjugate were calculated from the absorbance at 405 nm.

Endothelial Tubular Formation. Human endothelial cells were resuspended at 4×10^5 cells/mL phenol red−free RPMI containing glutamine (2 mM). Then, 100 μL growth factor-free Matrigel with or without SDF-1α (200 ng/mL) was plated into 96-well plates (Costar, Corning, NY) and incubated at 37 °C for 30 min for gelation. Thereafter, cells were seeded in gelated Matrigel in the presence of different stimuli. Plates were

Table 1. Reaction Condition and Coupled Ratio of DOC in DOC−Heparin Conjugates

	DOC−heparin I	DOC−heparin II	DOC−heparin III	DOC−heparin IV	DOC−heparin V	DOC−heparin VI
Fraxiparin (Ca^{2+},mol)	1	1	1	1	1	1
EDAC (mol)	1.2	2.4	3.6	4.8	6	12
HOSu (mol)	1.2	2.4	3.6	4.8	6	12
Aminated DOC (mol)	1.3	2.6	4	5.2	6.7	13.3
Coupling ratio	0.9	2.1	3.2	3.9	4.2	8.5

incubated for 24 h, and then tubular formation was analyzed after 6 h of incubation. For inhibition experiments, heparin or DOC−heparin conjugates were used at 10, 50, and 250 μg/mL and added together with the cells before seeding the cells on Matrigel. After 6 h of incubation, cell growth and three-dimensional organization were observed through a reverse-phase-contrast photomicroscope (Olympus 1 × 71), and the results were expressed as the mean number of junctions/5 fields at × 100 original magnification. Tubular formation and inhibition of tubular formation experiments were performed in duplicate and repeated at least 3 times.

Human Tumor Xenograft. Four- to six-week-old Athymic BALB/c-nu/nu female nude mice (14−18 g) were purchased from SLC Inc. (Japan) and maintained under specific pathogen-free conditions. All experiments were approved by the institutional guidelines of the Institutional Animal Care and Use Committee (IACUC) of the Catholic University of Korea College of medicine in accordance with the NIH Guidelines. Cultured KB cells (ATCC, Rockville, MD) were trypsinized, washed twice with serum-free EMEM medium (ATCC), and suspended at 1 × 10^7cells/mL PBS buffer. 50 μL of the suspended cells was subcutaneously injected into the back of the mice. On day 12−15 after tumor injection, the resulting tumors reached a volume of 45−55 mm^3. According to body weight and tumor size, the animals were divided into four experimental groups of five mice each: groups A, B, C, and D, respectively, received through the tail vein injections of 100 μL of saline as control (Group A, $n = 5$), heparin (10 mg/kg, Group B, $n = 5$), DOC−heparin VI (5 mg/kg, Group C, $n = 5$), and DOC−heparin VI (10 mg/kg, Group D, $n = 5$). Each drug was administered twice a week for four weeks after tumor inoculation. Data are expressed as means ± SE. One-way ANOVA was used to compare groups, where P values of <0.05 were considered significant.

RESULTS AND DISCUSSION

We synthesized DOC−heparin conjugates for cancer targeting and angiogenesis inhibition by linking the polysaccharide heparin (about 5000 Da) with sodium deoxycholate (DOC). Conjugation between the carboxyl groups of polysaccharide heparin and the amine groups of DOC was confirmed by the presence of signals at δ 8.0−8.2 ppm in the ^{1}H NMR spectrum. The selective modification of C3-OH was conducted by a suitable protected side chain of C12-OH group. It also took advantage of the known reactivity order of the two hydroxyl groups in DOC structure, C3-OH > C12-OH (*15*). We also found a sharp peak at δ 2.0 ppm, indicating the presence of a hydroxyl group at the C12-OH position. The amount of DOC conjugated to polysaccharide heparin estimated by the ninhydrin colorimetric method was maximized to 8.5 mol based on 1 mol of heparin (DOC-heparin VI) as shown in Table 1. By changing feed mole ratio of heparin, EDAC, HOSu, and aminated DOC, we controlled the coupling ratio between DOC and heparin. When dissolved in water, the DOC−heparin conjugates produced a clear solution at a concentration of 50 mg/mL. AFM and size measurement showed that the particles formed uniform spheres with a narrow size distribution as shown in Figure 2. The mean diameter of the nanoparticles (DOC-heparin IV) was 185 nm with a standard deviation of 2.8 nm, as determined by dynamic light scattering. A nanoparticle size of about 100−300 nm is considered to be suitable for passive targeted delivery utilizing the EPR effect. Several research groups using liposomes and other macromolecules have shown that particles with small size (less than 400 nm and ideally less than 200 nm) are more efficient in cell targeting than larger particles (*16*).

Table 2. Bioactivity of DOC−Heparin Conjugates

sample	absolute bioactivity (IU/mg)	SD
Fraxiparine (Ca^{2+})	101 IU/mg	-
DOC−heparin I	106.7 IU/mg	1.5
DOC−heparin II	109.8 IU/mg	2.1
DOC−heparin III	92.6 IU/mg	2.0
DOC−heparin IV	86.5 IU/mg	5.7
DOC−heparin V	86.0 IU/mg	2.7
DOC−heparin VI	75.1 IU/mg	1.0

Biological Activity. Antifactor Xa activity of DOC−heparin conjugates measured by chromogenic assay decreased with the increase of coupled DOC in DOC−heparin as shown in Table 2. When the carboxyl group of heparin is modified by conjugation, its affinity to factor Xa and/or antithrombin and thus its anticoagulant activity diminishes (*17–19*). The conjugated heparin presents several advantages as an anticancer drug carrier: (i) More DOC−heparin conjugates can access cancer cells, bypassing the coagulation cascade. (ii) Conjugation to DOC in DOC−heparin reduces the amount of negative charges of heparin, decreasing side effects such as heparin-induced thrombocytopenia (HIT) or bleeding that arise from the charge and size of heparin (*20*, *21*). (iii) Through the intact sulfate group, the conjugated heparin retains its ability to inhibit binding with angiogenic factors, which can induce proliferation of smooth muscle cells. It is widely known that a high degree of sulfation and optimum saccharide chain length are essential for recognition of angiogenic growth factors such as bFGF and VEGF (*22–27*). All of the advantages suit our purpose to develop a biocompatible novel drug carrier that acts as an efficient antitumor agent, and is free of undesired interactions with blood and vessel components.

DOC−Heparin Conjugates Inhibit Tumor Vasculature

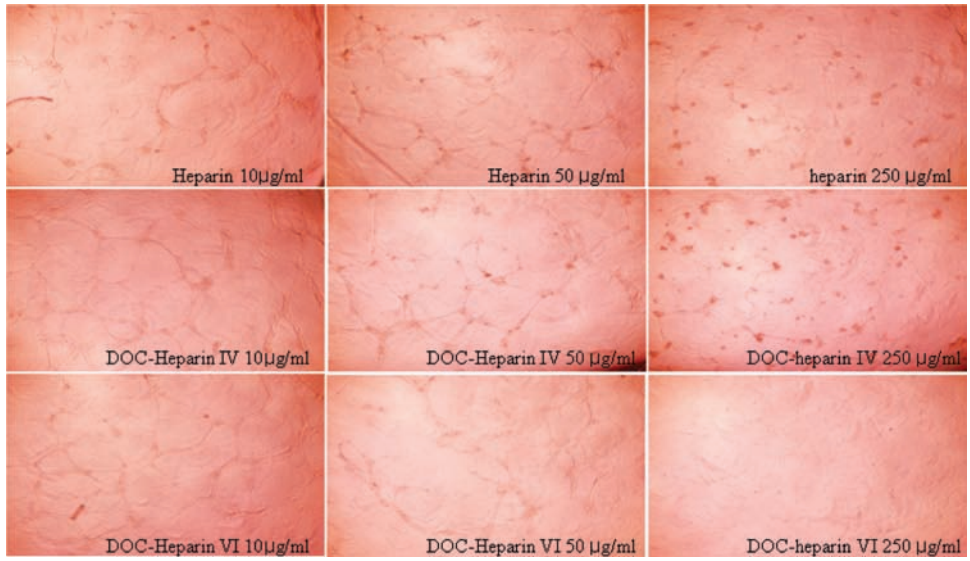

Figure 3. Inhibition of tubular formation by heparin and DOC−heparin conjugates at different concentrations.

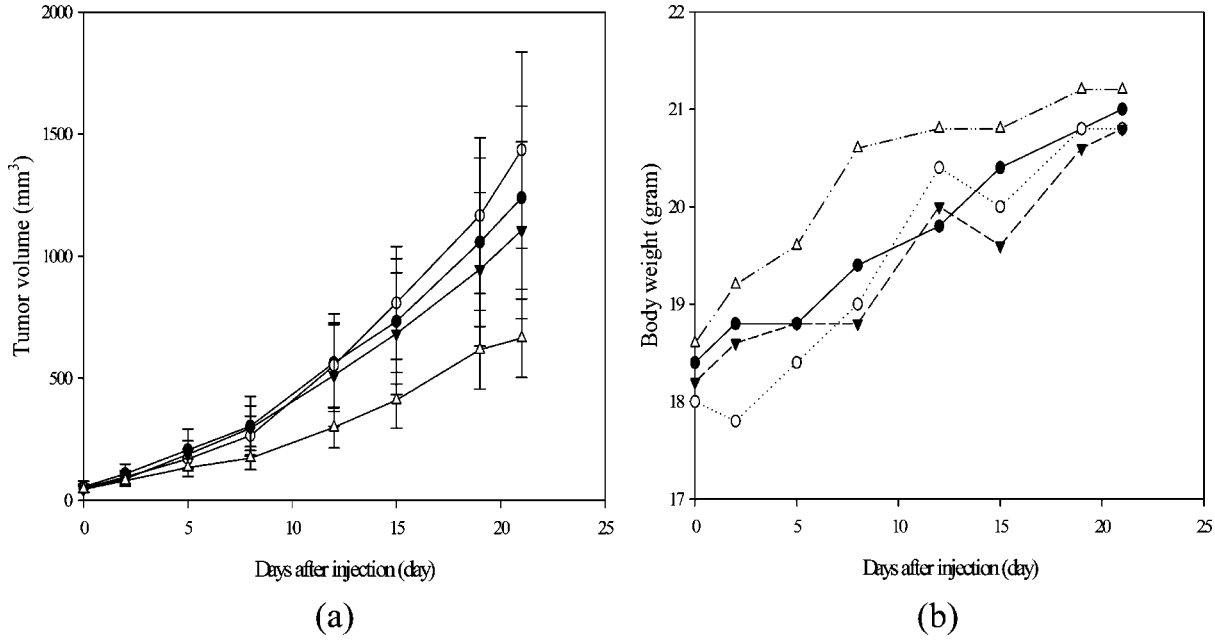

Figure 4. Antitumor effects of DOC−heparin conjugates. (a) Shrinkage in tumor volume and (b) changes in body weight after treatment with saline (□), 10 mg/kg heparin (•), 5 mg/kg of DOC−heparin VI (▼), and 10 mg/kg of DOC−heparin VI (Δ), respectively. All data represent mean ± s.e.

Growth. We sought to determine whether DOC−heparin conjugates would block angiogenesis that accompanies tumor growth. After heparin or DOC−heparin conjugates were added on Matrigel that included human endothelial cells, we observed the endothelial tubular formation and counted the number of tubes formed by a reverse-phase contrast photomicroscope as shown in Figure 3. When treated with heparin at 10, 50, and 250 μg/mL, no inhibitory effect of tubular formation was observed. On the other hand, DOC−heparin VI showed significant decrease in tubular formation at 50 μg/mL. For endothelial cells treated with 250 μg/mL of DOC−heparin VI, tubular formation was completely removed.

From the results, we believe that blood vessels surrounding the tumor treated with DOC−heparin VI have almost disappeared whereas a number of capillaries near the tumor excised from nude mice treated with saline remained intact (data not in shown). A significant decrease of angiogenesis was seen in *in vitro* treatment with DOC−heparin VI, indicating that DOC−heparin inhibits tumor vasculature growth in mice.

DOC−Heparin Conjugate Showed Remarkable Tumor Growth Inhibition. To determine whether heparin or DOC−heparin conjugates can reduce tumor growth rate, athymic BALB/c-nu/nu female nude mice bearing KB tumors (human epidermoid carcinoma cells) were used. Tumor growth and body weight were monitored after treatment. The antitumor effect of DOC−heparin conjugate against KB tumor cells was remarkably better than that of heparin. The tumor volume of mice treated with injection of DOC−heparin VI was about 550 mm^3, indicating shrinkage in initial tumor volume and inhibition of tumor growth by 37% ($p < 0.01$) compared to the control group (saline injection) as shown in Figure 4. The DOC−heparin conjugates did not induce death due to toxicity or body weight loss during treatment.

By itself, however, polysaccharide heparin is ineffective in inhibiting solid tumor growth. When intravenously injected at 10 mg/kg, most of the polysaccharide heparin will be systemically distributed into blood vessels, bind preferably with Factor Xa, and act as a highly potent anticoagulant, leaving only a few polysaccharide heparin molecules available to reach cancer cells. A high concentration of heparin or anticancer drug may circumvent this problem, but not without the accompanying side effects such as bleeding, thrombocytopenia, and general complications similar to those of chemotherapy. Therefore, the need arises for a strategy to facilitate specific interaction between polysaccharide heparin and tumor cells. The binding affinity to Factor Xa is markedly diminished when the carboxyl groups of heparin are modified to anchor DOC (Figure 1). The extent of antiangiogenesis *in vitro* would be ranked as follows: DOC−heparin VI > DOC−heparin IV > heparin > saline. The reduction of tumor vasculature when treated with the DOC−heparin VI implies that heparin, in addition to its targeted carrier role, may strongly interact with angiogenic stimulators to inhibit tumor vasculature growth. From the slowly halted tumor growth at 21 days, we concluded that it was likely that most of the residual solid tumors perished after treating with DOC−heparin VI for 21 days. The treated tumor cells had irregular structure with nuclei exposed to the outside of the cell membrane, indicating necrosis and cell malfunction.

In addition, this study introduces new prospects for the delivery of macromolecular drugs. As an antitumor agent, DOC−heparin conjugate can efficiently be delivered to solid tumors via intravenous injection. The conjugates were shown to produce certain therapeutic effects on human tumor implanted in BALB/c mice. It may become a new compound, but further studies still need to be conducted to explore *in vivo* metabolic profiles. Also, this approach can be used as a method to prove certain interaction between angiogenesis and tumor growth.

CONCLUSION

This study demonstrated that the DOC−heparin conjugate can specifically target tumor and tumor vasculature with minimized side effects. The main advantage of these novel biomolecular nanoparticles is the superior antitumor effect *in vivo*. By design, the self-assembled nanoparticles accumulate in tumors by passive targeting mechanisms. The conjugate inhibited tumor growth in mice without decrease in body weight. Our findings in animal studies suggest that the DOC−heparin VI has high antitumor activity and selective toxicity, yielding 34% tumor inhibition compared with tumor volume treated heparin. The results are consistent with tumor angiogenesis inhibition, showing a less detectable tumor vasculature after DOC−heparin VI treatment.

PEGylation of Human Serum Albumin: Reaction of PEG-Phenyl-Isothiocyanate with Protein

Fantao Meng,[†] Belur N. Manjula,[†] Paul K. Smith,[§] and Seetharama A. Acharya*[,†,‡]

Department of Physiology and Biophysics and Department of Medicine, Albert Einstein College of Medicine, Bronx, New York 10461, and BioAffinity Systems, Rockford, Illinois 61109. Received October 18, 2007; Revised Manuscript Received May 21, 2008

Successful and cost-effective PEGylation protocols require pure functionalized PEG reagents, which can be synthesized by simple and efficient procedures, exhibit high stability against hydrolysis, and maintain a level of reactivity with protein functional groups under mild reaction conditions. PEG-phenyl-isothiocyanate (PIT-PEG) is a new functionalized PEG having these characteristics, and has been synthesized by condensation of the bifunctional reagent 4-isothiocyanato phenyl isocyanate with monomethoxy PEG (mPEG). The data of ^{1}H NMR and colormetric analysis of the new PEG reagent establish that the mPEG has been quantitatively functionalized. The $t_{1/4}$ values for the hydrolysis of PIT-PEG5K in 100 mM phosphate solution at pH 6.5 and 9.2 are about 95 and 40 h, respectively. Incubation of human serum albumin (HSA, 0.5 mM) with a 10-fold molar excess of PIT-PEG (3K or 5K) at pH 6.5 and 9.2 generated PEG-HSA conjugates with average of 3.5 and 6.0 PEG chains per HSA molecule, respectively. The circular dichroism spectra of the conjugates showed that PEGylation of HSA has little influence on the secondary structure of HSA. The hexaPEGylated HSA, $(TCP\text{-}PEG5K)_6$-HSA, exhibited very high hydrodynamic volume, and the molecular radius of HSA increased from 3.95 to 6.57 nm on hexaPEGylation. The hexaPEGylation also increased the viscosity of 4% HSA from 1.05 to 2.10 cP, and the colloid osmotic pressure from 15.2 to 48.0 mmHg. The large increase in the hydrodynamic volume and the solution properties of $(TCP\text{-}PEG5K)_6$-HSA suggest that it could be a potential candidate as a plasma volume expander. PIT-PEG is a useful addition to the spectrum of functionalized PEG reagents available for surface decoration of proteins with PEG.

INTRODUCTION

Advances in biotechnology, in particular recombinant DNA technology, have made a large number of proteins available for application as novel drugs. Most of these therapeutic proteins suffer from short circulating life due to their proteolytic degradation and/or rapid clearance. Immunogenic reaction of the therapeutic proteins is another major concern in developing protein-based drugs. This in effect decreases their therapeutic efficacy (*1*). Covalent attachment of natural or synthetic polymers to therapeutic proteins with the purpose of generation of hybrid biomacromolecules with unique and improved molecular properties has become a popular approach to overcome these limitations of therapeutic proteins (*2*). Many polymers have been studied for these applications, and the most popular one is poly(ethylene glycol) (PEG), which is nontoxic, nonimmunogenic, highly soluble in water, and FDA approved. Since the pioneering experiments on PEGylation of proteins by Abuchowski et al. (*3, 4*), the application of this strategy to improve the therapeutic efficacy of protein drugs has been very clearly demonstrated (*1, 5, 6*).

PEGylation of a protein, peptide, or nonpeptide molecule involves the covalent attachment of one or more copies of PEG chains to the desired molecule. Functionalization of the PEG chain with a choice reactive functional group is the first step in carrying out PEGylation of macromolecules. Several PEG reagents, which facilitate the formation of bioconjugates (*7–9*), have been developed over the years, and are commercially available now.

Active esters of PEG, in particular the *N*-hydroxysuccinimde (NHS) esters of PEG acids are the most commonly used PEG reagents to target PEGylation to surface amino groups of protein. The half-life of the NHS esters of PEG acids for hydrolysis is in the range from 1 min (or less) to about 45 min at pH 8.0 and 25 °C (*10, 11*). As the reactivity of PEG-NHS toward amino groups of proteins goes up, the half-life of the PEG reagent in aqueous buffer decreases. Accordingly, a large excess of PEG reagents over protein have to be used for achieving desired levels of PEGylation.[1]

In contrast to the NHS ester of PEG acid, a maleimide-activated PEG, which reacts with the thiols of cysteine residues of protein to form stable thioether linkage with the protein, exhibits a much higher stability against hydrolysis, and accordingly PEG-maleimide reagents have been one of most desired PEGylation reagents. The maleimide moiety reacts rapidly with the thiol group without hydrolysis around neutral pH. The reaction is very selective as well as nearly quantitative. Accordingly, we have developed a new strategy that takes advantage of the high selectivity and efficiency of the thiol-

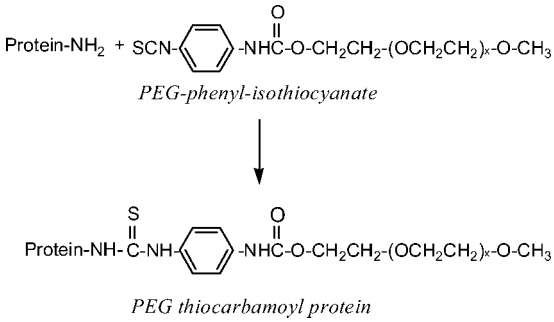

Figure 1. Schematic representation of the reaction of PEG-phenyl-isothiocyanate with protein amino groups.

maleimide reaction to develop a new PEGylation platform, referred to as the extension arm facilitated (EAF) PEGylation. This procedure targets the PEGylation reaction to the reactive surface amino groups of the proteins. Hemoglobin, albumin, and red blood cell have been surface-decorated with multiple copies of PEG chains very efficiently using this simple and cost-effective PEGylation protocol (*12–15*). In this PEGylation protocol, protein can be incubated with both the thiolating reagent (2-iminothiolane) and PEG-maleimide simultaneously. As new thiol groups are generated *in situ* as a result of reaction of iminothiolane with protein amino group, they are trapped by the PEG-maleimide. The application of this protocol for surface decoration of protein and cells is further facilitated by the development of a single-step procedure for functionalization of the mPEG as PEG-maleimide. An easy and nearly quantitative reaction of aromatic isocyanates with aliphatic hydroxyl that generates a carbamate linkage has been used to functionalize the PEG (*16, 17*). This approach of using a low molecular weight bifunctional reagent, phenyl isocynanate, carrying the desired functional group at the *p*-position is advanced as a modular approach for functionalizing PEG.

Phenyl isothiocyanate is a well-known reagent for carrying out Edman degradation (*18*) and amino acid analyses by HPLC (*19*). Some isothiocyanates were used to modify hemoglobin (Hb) in an attempt to correlate the structure with function (*20, 21*) and to introduce cross-links into Hb (*22, 23*). In all these reactions, isothiocyanates showed a high reactivity with the N-terminal valine residues of Hb. Isothiocyanate reacts with nucleophiles such as amines, sulfhydryls, and the phenolate ion of tyrosine side chains. The only stable product of these reactions, however, is with the primary amino groups (*24*). Therefore, isothiocyanate compounds are very selective reagents for modifying ϵ- and N-terminal amines in proteins. Besides, phenyl isothiocyanate is a stable reagent that can be stored at room temperature. Accordingly, it is reasonable to expect that PEG activated with a phenyl isothiocyanate group will exhibit high stability against hydrolysis and also a good level of reactivity with the α-amino groups and the low pK_a amino groups of proteins to generate thiocarbamoyl protein conjugate (Figure 1). Under the conditions where the NHS esters of PEG acids readily undergo hydrolysis, PEG-isothiocyanate could serve as an alternate reagent for PEGylation.

To functionalize PEG with isothiocyanato moiety, we have translated the one-step modular approach that we had developed earlier to functionalize PEG with a maleimide moiety, i.e., condensation of *p*-maleimide phenyl isocyanate with mPEG (*16,17*). Accordingly, for functionalizing mPEG with an isothiocyanato moiety, the synthesis of *p*-isothiocyanato phenyl isocyanate and the condensation of this reagent with mPEG have been pursued (*25*). The application of this reagent for PEGylation of protein has been investigated using human serum albumin (HSA) as a model protein.

HSA is an abundant negatively charged plasma protein, with ligand binding and transport functions, antioxidant functions, and enzymatic activities (*26, 27*). We choose HSA as a model protein for PEGylation with multiple copies of PEG chains using this new reagent, in view of our interest in the application of PEGylated albumin as a plasma volume expander to improve microcirculatory function in various clinical settings (*28, 29*).

Here, we describe the functionalization of PEG as PEG-phenyl-isothiocyanate (PIT-PEG), its stability against hydrolysis, its reactivity with HSA, and optimization of its reaction with HSA for generation of hexaPEGylated albumin. To assess the feasibility of using these new PEG-HSA conjugates as plasma volume expanders, the solution properties (including hydrodynamic molecular radius, viscosity, and colloid osmotic pressure) of the new PEG-HSA conjugates, influence of PEGylation on the secondary structure, and overall conformation of HSA have also been studied.

MATERIALS AND METHODS

Synthesis of PEG-Phenyl-Isothiocyanate. Monomethoxy PEG-phenyl-isothiocyanate, namely, PIT-PEG, was synthesized as described earlier (*25*). As shown in Figure 2A, the synthesis of PIT-PEG can be achieved in a one-step reaction, activating the mPEG with a small molecular weight bifunctional reagent, 4-isothiocyanato-phenyl isocyanate. The synthesis of the bifunctional reagent can be divided into three steps as schematically represented in Figure 2B: (i) synthesis of 4-carboxy phenyl isothiocyanate from *p*-amino benzoic acid; (ii) the conversion of 4-carboxy phenyl isothiocyanate to 4-isothiocyanato benzoyl azide; (iii) the synthesis of 4-isothiocyanato phenyl isocyanate.

(i) Synthesis of 4-Carboxy Phenyl Isothiocyanate. Para-aminobenzoic acid (0.2 mol; 26 g) was dissolved in acetone (400 mL) at room temperature. Activated carbon, (about 5 g, Darco, G60) was added and the mixture was stirred (using magnetic stir bar) for 5 to 10 min. The entire solution was filtered, yielding a much lighter colored solution of *p*-aminobenzoic acid. Sodium acetate (0.3 mol, 26 g) was dissolved in about 200 mL of deionized water, and added to the above filtrate of *p*-aminobenzoic acid, now contained in a 4 L vacuum flask. A vacuum was applied to the flask with an intermediate dry ice/acetone trap connected between the flask and the vacuum pump.

Thiophosgene (about 40 g of neat red liquid) was added to the cooled acetone stripped slurry of *p*-aminobenzoic acid, while stirring rapidly with an overhead paddle stirrer. A tan precipitate formed almost immediately upon the addition of the thiophosgene along with considerable foaming. After the foaming subsided (about 10 min), the insoluble precipitate was filtered and dried under vacuum to get a powdery material. The crude product was recrystallized from hot (80 °C) glacial acetic acid to yield yellow needles of 4-carboxy phenyl isothiocyanate (about 16 g) after drying under vacuum.

Elemental analysis of the yellow crystals yielded: Carbon (found 53.38%, theory 53.63%); hydrogen (found 2.76%, theory 2.79%); nitrogen (found 7.58%, theory 7.82%). The crystals darkened but did not melt at 220 °C.

(ii) Synthesis of 4-Isothiocyanato Benzoyl Azide. 15 g of the 4-carboxyphenyl isothiocyanate was suspended in 200 mL of dry methylene chloride in a 1 L sidearm vacuum flask, along with 16 g of pyridine (0.2 M), phenyl dichlorophosphate (0.1 M), and 6.5 g of sodium azide (0.1 M). This mixture was stirred overnight at room temperature. The stirred mixture was then washed in a separatory funnel with 200 mL of water and then with 200 mL of 0.05 M sulfuric acid. The acid-washed methylene chloride layer was dried with anhydrous magnesium sulfate. The dried methylene chloride reaction solution was evaporated under vacuum in a rotary evaporator at room temperature. The resulting light tan crystals were dissolved in

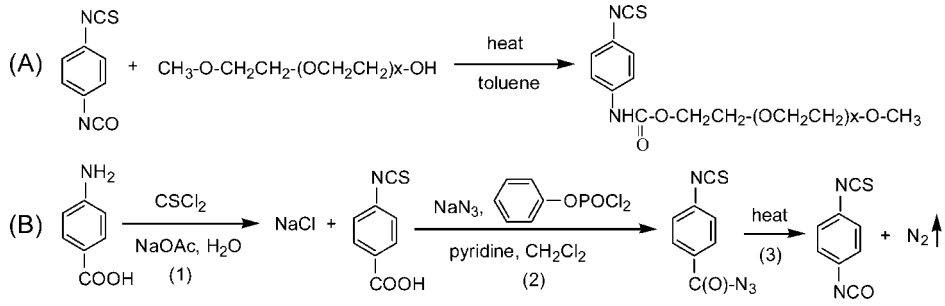

Figure 2. Schematic representation functionalization of mPEG as PEG-phenyl-isothiocyanate. (A) The one-step functionalization procedure. (B) The synthesis of 4-isothiocyanato phenyl isocyanate.

a minimal amount of ethyl ether at room temperature. The recrystallization solution was treated with activated carbon (Darco G 60) and filtered. The resulting light-colored solution was evaporated to dryness at room temperature. White crystals were obtained which melted at 68 to 72 °C with the evolution of nitrogen consistent with azide decomposition.

The elemental analysis of the 4-isothiocyano benzoyl azide crystals gave the following results: Carbon (found 46.85%, theory 47.05%); hydrogen (found 2.09%, theory 1.96%); nitrogen (found 26.87%, theory 27.45%). The infrared spectrum of the crystals (FTIR) conformed to 4-isothiocyanobenzoyl azide (e.g., strong broadband from about 2000 to about 2200 cm^{-1} is from N═C═O and N═C═S stretching modes; and a strong absorption due to azide at about 980−1000 cm^{-1}). The compound is stable at room temperature but was stored in the freezer.

(iii) Synthesis of 4-Isothiocyanato Phenyl Isocyanate. The 4-isothiocyanobenzoyl azide was thermally decomposed at about 75−104 °C (Curtius rearrangement) smoothly and quantitatively as a solution in dry refluxing of a toluene solution to 4-isothiocyanato phenyl isocyanate. The 4-isothiocyanate phenyl isocyanate was not isolated, but reacted as formed *in situ* with the hydroxyl-containing PEG according to the following description. An infrared spectrum of the composition containing 4-isothiocyanate phenyl isocyanate showed the decrease in the azide band at about 980−1000 cm^{-1} along with increased complexity of the absorbance in the N═C═O and N═C═S region of the spectrum from about 2000 to about 2300 cm^{-1}.

(iv) Functionalization of mPEG to PIT-PEG. 50 g of mPEG5K having a low diol content (NOF Corporation, Japan) was dissolved in 500 mL of toluene in a 2 L, three-necked flask equipped with a thermometer, overhead stirrer with motorized drive, and a Dean−Stark trap and condenser. The solution was stirred and heated to reflux (about 104 °C) and any water present was azeotropically removed as it accumulated in Dean−Stark trap. When no more additional water could be removed, the refluxing was discontinued and the contents were cooled under a dry nitrogen blanket to about 60 °C. To this reaction mixture, *p*-isothiocyanato benzoyl azide (0.5 g) was added and heating was resumed. Nitrogen was evolved during the initial 15 to 30 min after the heating was resumed. Heating was continued (reflux) for an additional hour. Heating was discontinued and the contents of the flask was allowed to cool to room temperature, and the reaction mixture now contained the desired product, PEG5K-phenyl-isothiocyanate. The reaction mixture was concentrated under vacuum using a rotary evaporator into viscous oil. This was treated with anhydrous ethyl ether to induce the crystallization of the activated mPEG5K. Ethyl ether also extracted the unreacted *p*-isothiocyanatophenyl isocyanate.

The crude PIT-PEG was purified with filtration in water, extraction with methylene chloride twice, then recrystallization in mixed solvent of methylene chloride/anhydrous ether twice. Finally, the purified white solid (48 g) was dried at room temperature under vacuum overnight. The purity of PIT-PEG was estimated as described below.

Estimation of Phenyl Isothiocyanato Moiety in Functionalized PEG. The concentration of phenyl isothiocyanato moiety in PIT-PEG was assayed by a colorimetric method developed by Zhang et al. (*30*). The principle of the method is that phenyl isothiocyanate reacts with 1,2-benzenedithiol to yield 1,3-benzodithiole-2-thione (λ_{max} = 365 nm and ϵ_m = 23 000 M^{-1} cm^{-1}). A final volume of 2.0 mL reaction mixture contains 900 μL of 100 mM potassium phosphate solution (pH 8.5), 900 μL of methanol, 100 μL of a solution of the isothiocyanate to be determined (0.5 mM), and 100 μL of 80 mM 1,2-benzenedithiol in methanol. The reactions were carried out in 5 mL of screwtop glass vials. The vials containing the reaction mixture were heated at 65 °C for 1 h and then cooled to room temperature. The absorbance at 365 nm was determined against a solvent blank. Each sample to be analyzed was accompanied by a paired blank containing all ingredients, except 1,2-benzedithiol. Each set of determinations also included a control vessel that contained the 1,2-benzedithiol but no isothiocyanate. A typical calibration curve for 0.1−1.0 mM phenyl isothiocyanate was generated with each testing of samples.

Hydrolysis Kinetics of Isothiocyanate of PIT-PEG5K. 25.9 mg of PIT-PEG5K dissolved into 1 mL (5 mM) of 100 mM potassium phosphate solution at different pH values, i.e., 5.5, 6.5, 7.4, and 9.2. The PIT-PEG5K solutions were incubated at room temperature. 40 μL of aliquots were pipetted out from the 5 mM of PIT-PEG5K solution at regular time intervals, and the concentrations of isothiocyanate in the incubation mixtures were estimated by colorimetric method as described above.

PEGylation of HSA with PIT-PEG. 0.5 mM HSA (Sigma, 99.9% free from acid) was incubated with a desired concentration of PIT-PEG reagent in 0.5 mL of 10 mM phosphate solution, at pH 8.5, at room temperature. The unreacted PIT-PEG was removed by centrifugal filtration using Centricon (50 KD cutoff membrane, Millipore Corp.) at 5000 rpm for 30 min four times. To study the kinetics of PEGylation (pH 9.2), 40 μL of reaction mixture was pipetted out at regular time intervals and diluted to 300 μL, and then analyzed by size exclusion chromatography (SEC) to measure the amount of unreacted PIT-PEG. For large preparation of PEGylated HSA, 1 g of HSA was incubated with 0.48 g of PIT-PEG3K or 0.78 g of PIT-PEG5K (HSA: PIT-PEG = 0.5:5 mM) in 30 mL of 10 mM phosphate solution, pH 6.5 or 9.2, at room temperature for 6 h. The unreacted PIT-PEG was removed by tangential flow ultrafiltration against phosphate buffer serum (PBS), using Minim from PALL Corporation and a 70 KD cutoff membrane. The progress of the removing of unreacted PIT-PEG from the products was monitored by the absorbance at 280 nm using a SEC.

Analytical Methods. SEC was performed on a Pharmacia FPLC system, at 25 °C using two HR10/30 Superose 12 columns connected in series with a 100 μL loop. The columns

were equilibrated and eluted with PBS, pH 7.4, at a flow rate of 0.5 mL/min. The effluent was monitored at 280 nm. SDS-PAGE analysis was carried out using a 6% Tris-glycine gel from Invitrogen Corp. as described previously (*31*).

HSA Content Assay. The concentration of HSA was determined from the absorbance at 279 nm (1 mg/mL, OD = 0.531; $\epsilon_m = 35\,300\ M^{-1}\ cm^{-1}$). The concentrations of PEG-HSA conjugates were determined by the standard procedure of Bio-Rad protein assay (*32*).

^{1}H NMR Analysis. ^{1}H NMR spectra were recorded using D_2O as the solvent and terimethylsilopropionate as the internal standard on a Bruker DRX 300 NMR spectrometer at 300 MHz. 10 mg samples (either PIT-PEG reagents or PEG-HSA conjugates) were dissolved in 0.1 mL of D_2O and their ^{1}H NMR spectra were scanned for 1.3 s. Pure sample of mPEG (10 mg) in D_2O (0.1 mL) served as standard. The integrated signal characteristic for mPEG was recorded for all samples, and by reference to the standard, the amount of functionalized group in PIT-PEG or the amount of mPEG in the conjugates was calculated (*33*).

Solution Properties of PEGylated HSA. The hydrodynamic molecular radius of the PEGylated HSA was determined at 22 °C at 1 mg/mL by dynamic light scattering measurements on a DynaPro molecular sizing instrument (Protein Solutions, Charlottesville, VA). The viscosity of the PEGylated HSA was measured with a cone and plate rheometer (Brookfield, Middleboro, MA) at 37 °C in PBS. The instrument was calibrated with water prior to measurements of the viscosity of the HSA samples. The colloid osmotic pressure (COP) of the PEGylated HSA was determined using a Wescor 4420 Colloidal Osmometer (Wescor, Logan, UT, USA) with a 30 KD Mw cutoff membrane at room temperature in PBS. The instrument was calibrated with Osmocoll reference standard prior to measurements of the samples. Each sample was measured at least twice and the average of the measurements is presented.

Spectroscopic Studies of PEGylated HSA. CD (circular dichroism) spectra for HSA and PEGylated HSA were recorded on a JASCO-720 spectropolarimeter (Tokyo, Japan) at 25 °C using a 0.2 cm light path cuvette (310 μL). All the samples (3 μM) were scanned in the range 200−250 nm in PBS, pH 7.4. The CD results were expressed in terms of mean residue ellipticity (MRE) [θ] in deg.cm^2/dmol. The fluorescence measurements of HSA and PEGylated HSA samples (3 μM) were performed using a Shimadzu RF-5301 spectrofluorimeter at room temperature. The emission spectra were recorded from 305 to 400 nm using an excitation wavelength of 295 nm. A cuvette with a 1 cm path length was used in all these stuides.

RESULTS

Isolation and characterization of PIT-PEG. PIT-PEG was isolated by recrystallization as described in Methods and Materials. The ^{1}H NMR spectrum of mPEG5K functionalized with 4-isothiocyanato phenyl isocyanate is compared with that of mPEG5K in Figure 3. The ^{1}H NMR spectrum of the functionalized PEG clearly "fingerprints" the signature of phenyl ring introduced, and the methylene groups of PEG that are connected to the phenyl ring through a carbamate linkage. The NMR data confirmed the expected molecular structure of PIT-PEG. The chemical shifts and assignments of the protons in the PEG reagent are as follows: δ 3.3 (s, 3H, mPEG, CH_3O-); δ 3.5−3.8 (s, PEG backbone, -CH_2CH_2O-); δ 4.3 (t, 2H, carbamate PEG linker, -CH_2-OC(O)-); and δ 7.2−7.5 (q, 4H, phenyl ring, -C_6H_4-).

Purity of PIT-PEG. The purities of PIT-PEGs are calculated from the estimation of isothiocyanato moiety in the functionalized PEG by colorimetric method and by ^{1}H NMR method (*34*), and presented in Table 1. The colorimetric method

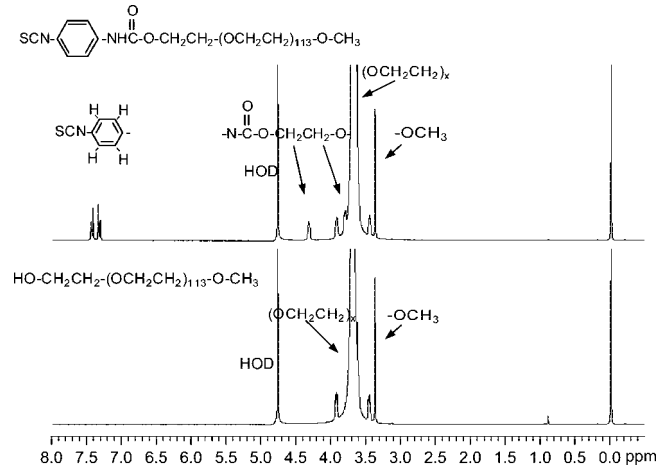

Figure 3. ^{1}H NMR spectra (D_2O, 300 MHz) of mPEG5K and PIT-PEG5K.

Table 1. Extent of Functionalization of PEG by Isothiocyanato Phenyl Isocyanate

	extent of functionalization	
	colorimetry method	^{1}H NMR method
PIT-PEG3K	109%	93%
PIT-PEG5K	112%	96%

estimates the purity higher than 100%. ^{1}H NMR spectroscopy estimates the purity of PIT-PEG3K and PIT-PEG5K as about 93% and 96%, respectively. The purity of PIT-PEG5K was obtained by quantitating the integrated areas of hydrogen of backbone PEG (113 × 4H) with that of phenyl ring (4H). The purities estimated by both methods indicate that the mPEG appears to be essentially fully functionalized.

Stability of PIT-PEG. The PEG-isothiocyanate is an electrophilic reagent, which can react with a weak nucleophile like hydroxyl ion. In neutral aqueous solution, the hydrolysis of PIT-PEG is relatively very slow, but proceeds more rapidly in aqueous alkaline solutions. The hydrolysis of PEG-isothiocyanate forms corresponding PEG-aniline, carbon dioxide, and hydrogen sulfide (*35*). The kinetics of hydrolysis of PIT-PEG5K (5 mM) in 100 mM phosphate solution as a function of pH is shown in Figure 4. The hydrolysis rate of PIT-PEG5K increases with the increase of pH. It may be noted that only a negligible amount of PIT-PEG5K hydrolyzed at all the pH within the first 12 h. The $t_{1/4}$ for the hydrolysis of PIT-PEG5K in different buffers of pH 5.5, 6.5, 7.4, and 9.2 (curve a, b, c, and d, respectively) are approximately 105, 95, 70, and 40 h, respectively.

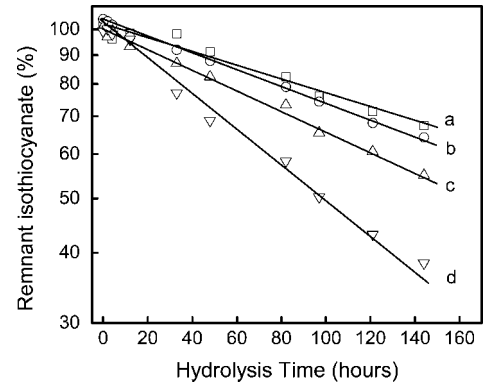

Figure 4. Hydrolysis kinetics of PIT-PEG5K (5 mM) in 100 mM of phosphate solutions at different pH (pH 5.5, 6.5, 7.4, and 9.2; curves a−d) at room temperature.

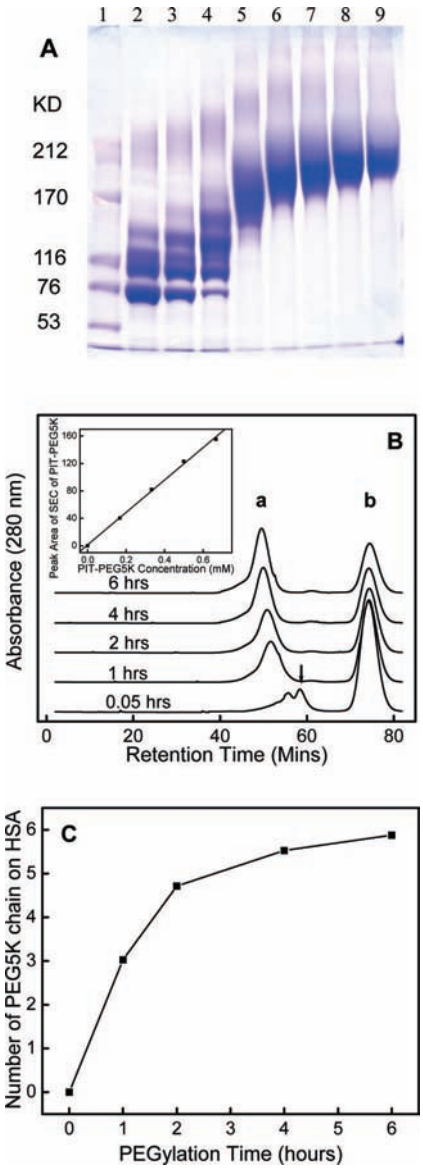

Figure 5. (A) The SDS-PAGE analysis of HSA and PEG-HSA conjugates prepared at the different ratio in 10 mM phosphate solution at pH 8.5 at room temperature for 6 h. Lane 1, marker; Lanes 2 to 9, 0.5 mM albumin reacted with 0.25, 0.5, 1.0, 4.0, 8.0, 10.0, 15.0, and 20.0 mM PIT-PEG5K, respectively. (B) SEC analysis of HSA (0.5 mM) reacted with PIT-PEG5K (5 mM) in 10 mM phosphate solution (pH 9.2) at room temperature. 20 μL of reaction mixture was diluted to 150 μL and uploaded into SEC (100 μL of loop) at 0.05, 1, 2, 4, and 6 h. The arrow points at the unmodified HSA. Inset is the standard curve of the peak area in SEC as a function of concentration of PIT-PEG5K. (C) The kinetic curve of PEGylation of HSA with PIT-PEG5K (0.5:5 mM) reacted in 10 mM phosphate solution (pH 9.2) at room temperature.

Reactivity of PIT-PEG. *(i) Modification of HSA by PIT-PEG5K as a Function of Molar Excess of the Reagent.* The reactivity of the isothiocyanato moiety of PIT-PEG with a protein amino group has been investigated using HSA as the model protein. SDS-PAGE pattern of HSA (0.5 mM) incubated with 0.5- to 40-fold molar equivalents of PIT-PEG5K (0.25 to 20 mM) in 10 mM phosphate solution, pH 8.5, at room temperature for 6 h is shown in Figure 5A. As the molar equivalents of PIT-PEG5K to HSA increase, HSA with an apparent molecular size of approximately 70 KD is converted into higher molecular weight species. Apparently, the new protein bands generated in these reactions represent PEG-HSA conjugates with number of PEG chains. When the PIT-PEG is only 0.5 equiv (0.25 mM, lane 2 in Figure 5A), most of the HSA remains unPEGylated, but three well-resolved bands are present besides the unmodified HSA. When the PIT-PEG is increased to 1 equiv (lane 3 in Figure 5A), the amount of the HSA band decreases with a concomitant increase in the other three bands and the generation of the fourth band. As the PIT-PEG5K increased further to 2 equiv (lane 4 in Figure 5A), the HSA band becomes a minor species, with generation of the new fifth band (diffused) of higher molecular size. This reflects the high reactivity of PEG-isothiocyanate with the amino groups of HSA. When the PIT-PEG is increased to 8 equiv (lane 5 in Figure 5A), PEGylated HSA moves as a diffused band in the apparent molecular weight range of 130 to 170 kD. With 16-fold molar equiv (lane 6 in Figure 5A) of PIT-PEG, almost all modified HSA appears as a diffused band in the molecular weight range 170−212 kD. Further increase in the amount of PIT-PEG does not increase the apparent molecular mass of the modified PEG significantly, but the product moves as a more compact band.

(ii) Kinetics of PEGylation of HSA by PIT-PEG. The kinetics of PEGylation of HSA with PIT-PEG5K (0.5:5 mM) in 10 mM phosphate solution (pH 9.2) at room temperature is studied by SEC and shown in Figure 5B. The decrease in the retention time and the increasing peak area of albumin as reflect by the absorbance at 280 nm (peak **a** in Figure 5B), suggest that the molecular size of albumin and its absorbance at 280 nm increase as PEG is coupled to HSA gradually with the incubation time increasing (the linkage between the PEG and HSA has a strong UV absorption due to presence of the phenyl ring and thiourea bond). Meanwhile, the amount of the PIT-PEG5K (peak **b** in Figure 5B) decreases as the reaction proceeds.

In view of the high stability of PIT-PEG (Figure 4), peak **b** represents the unreacted PIT-PEG in the reaction mixture, and it is conceivable that quantitation of this peak can be used to estimate the PEGylation of the protein. The inset curve in the Figure 5B depicts the linear correlation of that the peak area of PIT-PEG5K in SEC as a function of its concentration loaded into SEC (100 μL of loop). From the standard curve and the integrated area of unreacted PIT-PEG5K (peak **b** in Figure 5B), the amount of PIT-PEG5K coupled to albumin (the number of PEG5K chains on HSA) in each of the PEG-HSA conjugate can be calculated.

The kinetic curve of PEGylation of HSA with PIT-PEG5K is shown in Figure 5C. The PEGylation proceeds very fast in the first 2 h, and is almost complete with about 5 copies of PEG chains coupled to albumin molecule. As the reaction is going on, the rate of PEGylation slows down, and only about 1 copy of additional PEG chain is coupled on each molecule in the following 4 h. After 6 h of reaction, there are about 5.9 copies of PEG5K chains attached on HSA molecule. In view of the high stability of the reagent, and the fact that only 50% of the reagent is used by 2 h, the second phase of the kinetics of PEGylation represents an increasing resistance of PEG-HSA conjugate as the number of PEG chains on the protein molecule increases.

(iii) Influence of pH and Length of PEG Chain on the PEGylation of HSA. The influences of reaction pH and length of PEG chain on the PEGylation of HSA have been studied by incubating HSA with PIT-PEG3K and PIT-PEG5K at pH 6.5 and 9.2. Incubation of 0.5 mM HSA with 5 mM PIT-PEG3K or PIT-PEG5K in 10 mM phosphate solution, at pH 6.5 and 9.2, at room temperature for 6 h, resulted in a quantitative modification of HSA as anticipated, and a concomitant significant enhancement in apparent molecular size of HSA as shown by SEC pattern (Figure 6A). The HSA modified with PIT-PEG3K at pH 6.5 (curve 2) elutes close to the position of HSA dimer, while the PEG-HSA generated at pH 9.2 with PIT-

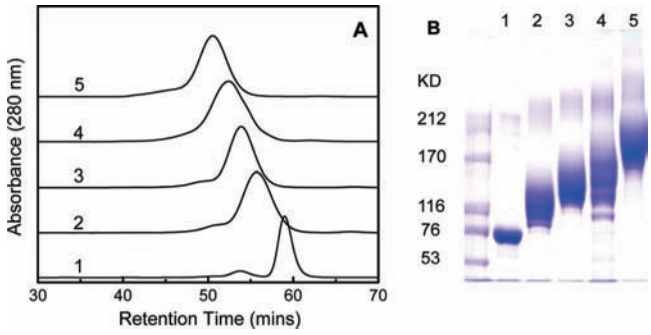

Figure 6. SEC analysis (A) and SDS-PAGE analysis (B) of native HSA (1), PEG3K-HSA generated at pH 6.5 (2), PEG3K-HSA generated at pH 9.2 (3), PEG5K-HSA generated at pH 6.5 (4), and PEG5K-HSA generated at pH 9.2 (5). The reaction condition is described in context. The unreacted PIT-PEG were removed using tangential flow ultrafiltration.

Table 2. Influence of Reaction pH and PEG Chain Length of PIT-PEG on the PEGylation of HSA

		average copies of PEG chains on HSA molecule	
pH	ITP-PEGMw	SEC method	^{1}H NMR method
6.5	PEG3K	3.3	3.6
6.5	PEG5K	3.7	3.4
9.2	PEG3K	5.5	5.9
9.2	PEG5K	6.0	6.0

PEG3K (curve 3) is slightly larger than the HSA dimer. Similarly, the hydrodynamic molecular size of PEG5K-HSA conjugate generated at pH 6.5 (curve 4) is smaller than that of PEG5K-HSA conjugate generated at pH 9.2 (curve 5). The numbers of PEG chains on the four PEGylated samples are calculated from their SEC results (data not shown) before removing unreacted PIT-PEG and presented in Table 2. In the reactions at pH 9.2, approximately 6 copies of PEG chains (either PEG3K or 5K) are conjugated to HSA, whereas in the reactions at pH 6.5, about 3.5 copies of PEG chains are linked to HSA. Therefore, it is clear that modulation of pH of the reaction mixture will be a good approach to control the extent of PEGylation, and that the PEG chain length of PIT-PEG has little influence on the PEGylation of HSA.

The SDS-PAGE analysis of the four PEG-HSA conjugates are shown in Figure 6B. From the gel, it is confirmed that the PEG-HSA conjugates generated at pH 9.2 (Lanes 3 and 5) exhibit higher level of PEGylation than the PEG-HSA conjugates generated at pH 6.5 (Lanes 2 and 4). The distribution of the PEGylated materials (based on the number of PEG chains) of Lanes 2 and 4 (conjugates generated at pH 6.5) is wider as compared to the distribution of the PEGylated material in Lanes 3 and 5 (conjugates generated at pH 9.2). Therefore, the PEG-HSA conjugates generated at pH 6.5 appear to be much more heterogeneous as compared to the products generated at pH 9.2.

The SEC and SDS-PAGE results suggest that the level of PEGylation increases with the increase of the pH of the PEGylation reaction, as more ϵ-amino groups of HSA are deprotonated at higher pH.

Solution Properties of PEG-HSA Conjugates. Four PEG-albumin conjugates were prepared in large scale (1 g HSA) and purified using tangential flow ultrafiltration. Two PEG-HSA conjugates have been generated at pH 6.5 using PIT-PEG3K and PIT-PEG5K, respectively, and the another two conjugates have been generated at pH 9.2 again using the same two PEG reagents.

(i) Molecular Mass of PEG Conjugated to Albumin. The amount of PEG conjugated to albumin in the four PEG-HSA conjugates have been calculated by the ^{1}H NMR approach (*33*) and compared with the amount calculated by spectrophotometric/SEC approach in Table 2. The PEGylation at pH 6.5 couples an average of 3.5 PEG chains on each albumin molecule. Comparatively, the PEGylation at pH 9.2 couples 6 copies of PEG chains. According to the number of PEG chains attached on HSA molecule, the PEG-HSA conjugates generated at pH 6.5 are referred to as tetraPEGylated HSA [named (TCP-PEG3K)$_4$-HSA or (TCP-PEG5K)$_4$-HSA], and those generated at pH 9.2 as hexaPEGylated HSA [named (TCP-PEG3K)$_6$-HSA or (TCP-PEG5K)$_6$-HSA].

Table 3. Comparison of Solution Properties of PEG-HSA Conjugates

sample HSA	hydrodynamic[a] radius/nm	PEG mass[b] /kD (n PEG)	viscosity[c] /cP	COP[d] /mmHg
HSA	3.95	0	1.05	15.2
(TCP-PEG3K)$_4$-HSA	4.83	10.8 (3.6)	1.12	21.3
(TCP-PEG5K)$_4$-HSA	5.79	17.0 (3.4)	1.34	33.2
(TCP-PEG3K)$_6$-HSA	5.57	17.7 (5.9)	1.46	26.9
(TCP-PEG5K)$_6$-HSA	6.57	30.0 (6.0)	2.03	46.8

[a] Measured by DynaPro, concentration = 1.0 mg/mL, 22 °C. [b] Calculated by ^{1}H NMR. [c] Albumin concentration = 4.0 g/100 mL, 37 °C. [d] Albumin concentration = 4.0 g/100 mL, 25 °C.

(ii) Solution Properties of PEGylated Albumins. Molecular Radius of the PEGylated Albumins. The molecular radius of native HSA is around 3.95 nm (Table 3). The hexaPEGylated HSA with PEG5K chains, (TCP-PEG5K)$_6$-HSA, has the largest radius of 6.57 nm. The tetraPEGylated HSA with the least amount of PEG, (TCP-PEG3K)$_4$-HSA exhibits the smallest molecular radius, i.e., 4.83 nm. (TCP-PEG3K)$_6$-HSA has a molecular radius of 5.57 nm, while (TCP-PEG5K)$_4$-HSA exhibits a radius of 5.79 nm (Table 3). It may be noted that, although (TCP-PEG3K)$_6$-HSA carries a little more amount of PEG on HSA than that on (TCP-PEG5K)$_4$-HSA (17.7 KD vs 17.0 KD, Table 3), the former conjugate exhibits a smaller radius than the latter conjugate (5.57 nm vs 5.79 nm in Table 3, and Curve 3 vs 4 in Figure 6A). This is probably because, although (TCP-PEG3K)$_6$-HSA carries more PEG chains than (TCP-PEG5K)$_4$-HSA does, the PEG shell of the former conjugate is fixed on the albumin surface through 6 anchors and the PEG shell of the latter one is fixed through fewer locating sites, 4 anchors. The PEG shell of (TCP-PEG3K)$_6$-HSA, therefore, appears more compact than that of (TCP-PEG5K)$_4$-HSA. This result is different from that reported by Fee et al. (*36*), who suggested that the hydrodynamic radii of PEGylated proteins depend on the total weight of grafted PEG but not on PEG molecular weight, or PEG-to-protein molar grafting ratio.

Colloid Osmotic Pressure of PEGylated Albumins. The COP of PEGylated albumins hs been studied as a function of protein concentration and compared with that of unmodified albumin (Figure 7A). The COP of albumin shows only a marginal increase when measured as a function of the protein concentration, and this small increase is linear over the range of the protein concentration studied. On the other hand, the COP values of PEGylated albumin samples are higher than that of native HSA and exhibit an exponential increase as a function of the protein concentration. The increased COP resulting from PEGylation as a function of PEG mass conjugated to HSA at different protein concentration is shown in the inset of Figure 7A. The increase in COP as a function of PEG mass conjugated is also exponential.

Viscosity of PEGylated Albumins. The viscosities of PEGylated albumins are compared with that of unmodified albumin as a function of the protein concentration (Figure 7B). The viscosity of HSA does not increase significantly upon increasing the protein concentration. On the other hand, the viscosities of the four PEGylated albumins exhibit an exponential increase as a function of the protein concentration. The correlation of

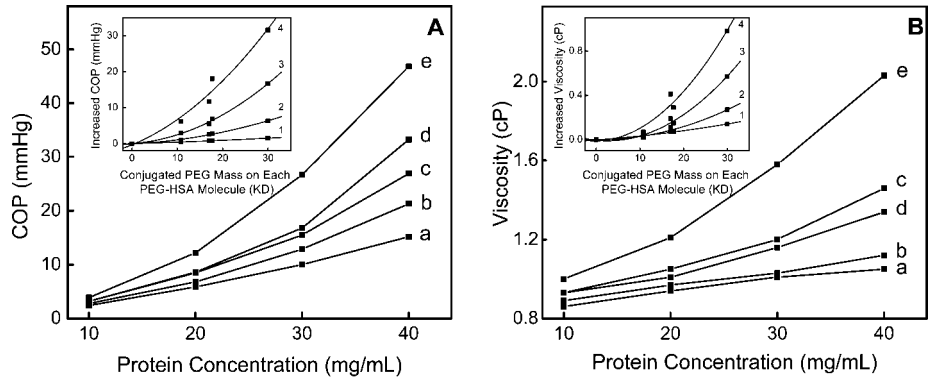

Figure 7. Colloid osmotic pressure (A) and viscosity (B) of HSA (a) and PEG-HSA conjugates, $(TCP\text{-}PEG3K)_4$-HSA (b), $(TCP\text{-}PEG5K)_4$-HSA (c), $(TCP\text{-}PEG3K)_6$-HSA (d), and $(TCP\text{-}PEG5K)_6$-HSA (e) as a function of the protein concentration. Inset A, relationships of conjugated PEG masses on PEG-HSA conjugates and the increased COP at different protein concentrations. Inset B, relationships of conjugated PEG masses on PEG-HSA conjugates and the increased viscosity at different protein concentrations. Curve 1, 1 g/dL; curve 2, 2 g/dL; curve 3, 3 g/dL; curve 4, 4 g/dL.

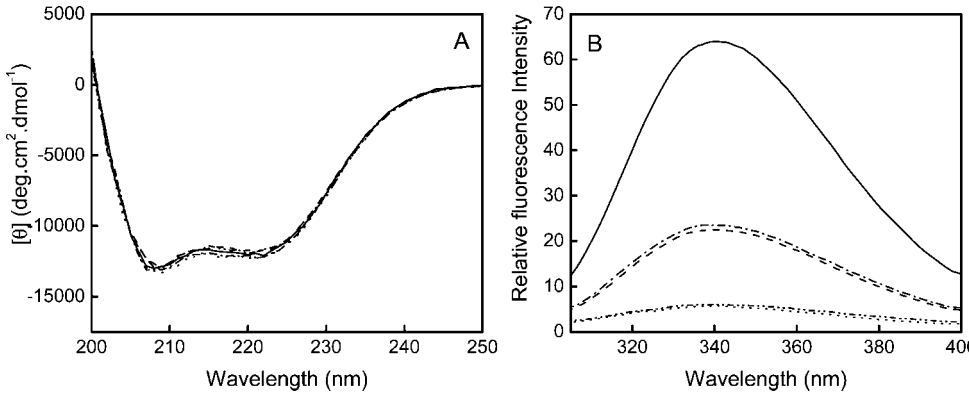

Figure 8. Circular dichroism (A) and intrinsic fluorescence emission (B) spectra of HSA (solid line) and conjugates $(TCP\text{-}PEG3K)_4$-HSA (dash), $(TCP\text{-}PEG3K)_6$-HSA (dot), $(TCP\text{-}PEG5K)_4$-HSA (dash dot), and $(TCP\text{-}PEG5K)_6$-HSA (dash dot dot).

increased viscosity as a function of PEG mass conjugated to HSA is presented in the inset of Figure 7B. Again, the viscosity as a function of the molecular mass of PEG in the conjugate increased exponentially, especially at high protein concentration.

(iii) Influence of PEGylation on the Conformation of HSA: Influence of PEGylation on the Secondary Structure of HSA. The CD spectra of PEGylated HSA in the far-UV region (200 to 250 nm) is compared with that of the unmodified HSA (Figure 8A). The CD spectra of PEG-HSA conjugates and albumin in the far ultraviolet region are essentially identical. Only very few changes are seen in the CD spectra, particularly in terms of the values of mean residue ellipticity [θ] at 208 and 222 nm, as a consequence of PEGylation. The results suggest that the α-helical conformation of HSA is not influenced by the PEGylation. Thus, the secondary structure of HSA is not adversely influenced on its PEGylation with PIT-PEG.

Intrinsic Fluorescence Measurement. The intrinsic fluorescence spectra of the PEG-HSA conjugates are analyzed to evaluate the conformational changes around the tryptophan residue (Trp 214) in HSA. When excited at 295 nm, all the PEGylated samples and HSA showed maximum emission intensity at the same wavelength (340 nm) (Figure 8B). The fluorescence intensity of PEGylated HSA, however, showed a significant decrease as compared to that of HSA, indicating that attachment of PIT-PEG on HSA quenched the intrinsic fluorescence of the Trp 214 residue of HSA. The fluorescence intensities of the two conjugates generated at pH 6.5 (using PIT-PEG3K and PIT-PEG5K) are similar; the PEG-HSA adducts generated at pH 9.2 also have a similar level of fluorescence quenching. Thus, the total amount of coupled PEG on the surface of HSA molecule does not dictate fluorescence of PEGylated HSA. The level of quenching of fluorescence is dictated by the pH of PEGylation reaction, i.e., by the extent of PEGylation. The quenching effect is apparently a consequence of the specific formation of thiocarbamoyl-phenyl linker between protein amino group and PEG chain. The hydrophobic phenyl linker section binds near the Trp 214 or its proximity and acts like some small hydrophobic molecules quenching the fluorescence of Trp 214 (*37, 38*). The quenching of the Trp 214 fluorescence clearly indicates that the conformation of the hydrophobic binding pocket in the second α-helix domain is affected.

DISCUSSION

Functionalizing PEG chains by quantitative modification of the hydroxyl group of methoxy PEG is a very crucial step in achieving a high-purity, reliable, and reproducible PEGylation reagent. If mPEG is subjected to multiple steps of organic synthetic reactions during the process of functionalization, the yield and/or purity of the final PEG reagent will decrease. A one-step functionalization process using a small molecular weight heterobifunctional reagent will minimize the exposure of mPEG to a multistep synthetic protocol. A quantitative modification of mPEG by the heterobifunctional reagent will significantly simplify the subsequent purification of the funationalized PEG. We have now developed such a one-step protocol for functionalizing the mPEG with a desired functional group. The reaction of phenyl isocyanate with hydroxyl group of mPEG is simple and quantitative and can serve as a prototype reaction for attaching a bifunctional reagent that carries the desired functional group at its distal end to the mPEG. The one-step functionalization of PEG by isothiocyanato phenyl isocy-

anate as PEG-phenyl-isothiocyanate proceeds very efficiently. The functionalization of both mPEG3K and mPEG5K are nearly quantitive as assayed by the colorimetric method and ^{1}H NMR method (Table 1).

The isolation of the small molecular bifunctional reagent, isothiocyanato phenyl isocyanate, is not required in the synthesis of PIT-PEG, because its precursor, an azide, can be quantitively converted *in situ* before its reaction with mPEG. However, in the case of synthesis of PEG-maleimides by this approach, the isolation of the small molecular weight bifunctional reagent, *p*-maleimido phenyl isocyanate, is preferred, as it gives a better preparation of PEG-maleimide (*39*).

The PIT-PEG exhibits a high stability against hydrolysis at room temperature. When PIT-PEG was dissolved in phosphate solution of different pH values (from pH 5.5 to 9.2) at room temperature, only a negligible level of hydrolysis occurred within the first 12 h. The high stability of the PIT-PEG permits the use of the high pH as well as room temperature for PEGylation, as far as the protein is stable under these conditions. The high stability of the PIT-PEG has also made it possible to develop an analytical procedure to calculate the amount of consumed PEG in reaction (i.e., conjugated to protein) using a SEC, that facilitates the easy calculation of the extent of PEGylation.

Generally, when a protein chemical modification reagent exhibits a high stability against hydrolysis, it will exhibit a low reactivity for PEGylation of protein. In spite of the high stability of the PEG-isothiocyanate against hydrolysis, it displays an acceptable level of reactivity to modify HSA at room temperature. Incubation of 0.5 mM HSA and a 10-fold molar excess of PIT-PEG at room temperature for 6 h at pH 9.2 generates hexaPEGylated HSA, i.e., 60% of PEG reagent is utilized and conjugated to HSA. The reaction of PEG-isothiocyanate with an amino group in albumin involves the nucleophilic attack of the amino group and the generation of a stable linkage, thiocarbamoyl linkage, between the PEG and the albumin. PIT-PEG reacts better at slightly alkaline pH, as more amino groups on proteins will be unprotonated. Nearly identical levels of PEGylation of HSA by PIT-PEG3K and PIT-PEG5K at both pH 6.5 and 9.2 reflect that the PEGylation reaction is correlated to the pH and the length of PEG chain of PIT-PEG has limited influence on the PEGylation reaction under the present reaction condition.

PEGylation of HSA with PIT-PEG proceeds very fast in beginning, and then slows down after 2 h reaction (Figure 5C). The PEGylation is expected to target the single α-amino group of amino-terminal Asp and the ε-amino groups of internal Lys residues. HSA has a single free SH group, which is a nucleophile. To establish whether the thiol has been conjugated with PEG, we measured the number of SH group on HSA (lyophilized powder, the thiol group was blocked to prevent dimerization) by reaction with 4-PDS (40), and it is 0.32. After hexaPEGylation, the number of SH groups on modified HSA is about 0.31. The results suggested that the PIT-PEG does not react with the thiol group on HSA. The observation that PEGylation of HSA proceeds very fast in the beginning and then slows down after 2 h reaction can be a reflection of one or both of these aspects: (i) the reaction rate slows down as the low pK_a amino groups have been modified; and (ii) PEG chains that are already conjugated to albumin molecules make it difficult to conjugate new PEG chains to the PEGylated albumin molecule. As a combination of these molecular aspects of the PEGylation of HSA with PIT-PEG, at pH 9.2 the hexaPEGylation of HSA appears to be complete under the present experimental condition. Increasing the concentration of PEG reagent from 20- to 40-fold molar excess of HSA has very little influence on the extent of PEGylation (Lanes 7 to 9, Figure 5A), which is consistent with the above conclusion. This suggests that the strong rule of steric factors is slowing down the PEGylation reaction on hexaPEGylation of proteins of molecular size of 65 KD. A similar conclusion has been made with regard to the hexaPEGylation of Hb (*41*).

The PEGylation studies of Hb exposed that the unique molecular properties could be engineered into proteins by the conjugation of PEG chains, namely, unusually enhanced hydrodynamic volume, high viscosity, and high COP (*12, 14, 15, 40–42*). These molecular properties, which are also the unique properties of plasma volume expanders that endow unique microvascular properties to the molecules, have been attributed to the nonhypertensive property of PEGylated Hb (*12*). Accordingly, we have considered the PEGylated albumin generated by extension arm facilitated protocol as plasma volume expanders; and the studies of both dodecaPEGylated and hexaPEGlated albumin with animal models have indeed established that PEGylated albumin is a new therapeutic protein with some unique potential as a plasma volume expander (*28, 29*). Therefore, we suggest that $(TCP\text{-}PEG5K)_6$-HSA is also potential therapeutic protein as a plasma volume expanders.

PEGylation of HSA has little influence on the secondary structure of HSA. On the other hand, the fluorescence of HSA (Trp 214) is influenced by PEGylation. The extent of quenching of fluorescence is dependent on the extent of PEGylation, that is, the number of copies of PEG chains conjugated, however, not on the size of PEG chain conjugated. Apparently, it is the phenyl linker that quenched the fluorescence of Trp-214 on HSA, and clearly suggests the proximity of the conjugated chains to the Trp reside.

In summary, we have designed and developed a novel PEGylation reagent, PEG-phenyl-isothiocyanate. The new PEG reagent displays a high stability against hydrolysis around neutral pH, and also displays a good level of chemical reactivity with protein amino groups.

ACKNOWLEDGMENT

We thank Dr. Parimala Nacharaju, Dr. Tao Hu, Dr. Dongxia Li, and Dr. Ananda U for critical review of this paper prior to submission. We would like to acknowledge the assistance of Dr. Sean Cahill for the help in ^{1}H NMR analysis. This work was supported by a grant-in-aid from the American Heart Association Heritage Affiliate 9951021T, the National Institutes of Health grants HL58247, HL71064, and U.S. Army grant PR023085.

Peptide−Oligonucleotide Conjugates Form Stable and Selective Complexes with Antibody and DNA

Tuula Tennilä, Maxim Antopolsky, Alex Azhayev, and Elena Azhayeva*

Department of Pharmaceutical Chemistry, University of Kuopio, FIN-70211 Kuopio, Finland. Received December 12, 2007; Revised Manuscript Received April 9, 2008

The present work demonstrates that the relatively low molecular weight synthetic peptide−oligonucleotide conjugates are capable of stable and selective three-component complex formation with complementary 72−100mer DNA oligonucleotides and a cardiac troponin I monoclonal antibody. Neither the Watson−Crick-type interaction between peptide−oligonucleotide conjugate and DNA nor the conjugate−antibody interaction dramatically hampers the other. These interactions remain selective and specific in the presence of several other conjugates not specific to cardiac troponin I monoclonal antibody as well as in the presence of control 100mer DNA oligonucleotides. The data herein demonstrate the feasibility of the synthetic peptide−oligonucleotide conjugates as convenient molecular tools, e.g., for antibody epitope mapping.

INTRODUCTION

Applications for semisynthetic nucleic acid−protein conjugates (NAPCs) (*1–4*) in array technology (*5, 6*) and nanobiotechnology (*7, 8*) have received increasing interest. Moreover, immuno-PCR (*9–11*) and even magneto-immuno-PCR (*12*) employing NAPCs are established and substantially developed.

Methods for the covalent synthesis of peptide−oligonucleotide conjugates (POCs) have drawn a considerable amount of attention during the past 20 years (*13–17*). Undoubtedly, low molecular weight POCs are easier to obtain (*13–17*) and properly characterize (*18*) by chemical methods than high molecular weight NAPCs.

Nowadays, linear POCs where the N- or C-terminus of a peptide is covalently linked to either 3′- or 5′-terminus of an oligonucleotide are available commercially on virtually any scale from Thermo Scientific (www.thermo.com/biopolymers). Moreover, the oligonucleotide moiety of these custom-synthesized oligomers may incorporate modified nucleosides as well as additional dye modification (fluorescein, Cy3, etc.). In other words, it seems fair to claim that at least small libraries of POCs are easily available for a variety of applications as molecular tools.

Limited data are currently available on the applicability of POCs as molecular tools for the life sciences. To our knowledge, the only publication closely related to the subject of this investigation was the demonstration that oligodeoxyribonucleotides, PNA−peptide conjugates (PPCs), and antibodies form stable ternary complexes that can be used for quantification of antibodies (*19*).

Recently, a high-complexity, multiplexed solution-phase assay for profiling protease activity on microarrays was reported (*20*). In this assay, the sets of peptide sequences that serve as protease substrates were conjugated to oligonucleotide sequences (from 100 to 1000 POCs in a set) complementary to the oligo tags on randomly assembled bead arrays. The assay was successfully employed for the measurement of protease activity in complex samples.

POC libraries may also find use for epitope mapping, employing immuno-PCR. Obviously, it is possible to construct POC libraries where every oligonucleotide unequivocally corresponds to certain peptide. With the help of such libraries, the task of the epitope mapping can be thus translated into oligonucleotide sequence estimation provided that the antibody−POC−DNA triple complex is strong and specific enough.

The objective of this work was to demonstrate the feasibility of a predesigned complex formation, based on simultaneous antigen−antibody and Watson−Crick interactions. We investigated DNA−POC−mAb complexes involving two different DNA templates capable of binding one or four POCs. In an attempt to study possible applications of the complexes mentioned above, we constructed a very simple model system, comprising a small library of several POCs, a small library of longer DNA oligomers, and an immobilized mAb. The small POC library incorporated a single POC, bearing a peptide sequence specific to the solid phase bound mAb, while the POCs of the control library contained only nonspecific peptides. The aim of the experiment was to show that incubation of the POC library with the support-bound mAb and DNA library results in the formation of a specific triple complex with the single antibody-specific POC and the single DNA. This DNA (and the oligonucleotide part of POC accordingly) sequence was estimated after PCR amplification of the bound oligonucleotide. In the control case, no amplification of the longer DNA sequence was observed, since no POC was capable of binding the antibody. In our opinion, this simple testing revealed the ability of POCs to simultaneously display efficient and selective Watson−Crick base-pairing and efficient and selective epitope−antibody recognition. Our experiments, described below, may serve as a basis for future development of more complex essays, exploiting the three-component complex formation.

EXPERIMENTAL PROCEDURES

General Procedures. Cardiac Troponin I monoclonal antibody, clone 19C7 (**mAb1**), Sepharose-bound **mAb1**, and Sepharose-bound antibody to precursor of brain natriuretic peptide (**mAb2**) were from HyTest. γ-^{32}P ATP and γ-^{33}P ATP was from Perkin-Elmer; polynucleotide kinase and CycleReader DNA Sequencing Kit were from Fermentas. Oligonucleotides were assembled on the Biosset ASM 800 synthesizer, using

10.1021/bc700457y CCC: $40.75 © 2008 American Chemical Society
Published on Web 06/05/2008

reagents from Glen Research. Peptide−oligonucleotide conjugates were prepared and characterized as reported earlier (*14*, *15*, *18*). PAGE was run on a Hoefer SE600 unit. PCR experiments were conducted on a BioRad iCycler. Manual DNA sequencing was performed on a Pharmacia Biotech Macrophor electrophoresis unit with a thermostatic plate.

Labeling of the Oligonucleotides and POCs. Mixtures of 250 pmol of the oligonucleotide or **POC1**, 1 μM ATP, 1 mM cystamine, 5−10 units of polynucleotide kinase, 70 μCi of γ-^{32}P ATP in buffer, containing 10 mM Tris-acetate, 10 mM magnesium acetate, and 50 mM potassium acetate, were incubated at 37 °C for 30−60 min, heated 5 min at 65 °C, centrifuged, and finally kept on ice.

Template T72-POC1-mAb1 Complexes. Complex formation was performed in two steps. In the first step, 100−130 pmol of the oligonucleotide **T72** and 400−530 pmol of **POC1**, 2.5 pmol of 5′-^{32}P-**POC1**, or 5′-^{32}P- **T72** were mixed. Samples were annealed in buffer, containing 10 mM Tris, 15 mM $MgCl_2$, and 150 mM NaCl, pH 7.5, by heating to 85 °C and slowly decreasing the temperature to 25 °C. The resulting samples were stored at 4 °C. In the second step, **mAb1** was incubated with template−conjugate complexes at different **mAb1**/complex ratios. Each sample usually contained 128 pmol of **T72**, 512 pmol of **POC1**, and **mAb1** at 2:1, 1:1, 0.5:1, and 0.1:1 ratios. Samples were incubated for 30−60 min at room temperature and finally analyzed by nondenaturing 5−20% (or 3−17%) gradient PAGE. The gel was autoradiographed and subsequently stained with Coomassie Blue.

Template T75-POC3-mAb1 Complexes. Complex formation was performed essentially as described above. In the case of **POC3**, the peptide moiety was linked to the 5′-terminus of oligonucleotide; only the 5′-^{32}P-**T75** was employed in the present experiment.

Complex Formation on the Sepharose-Bound Cardiac Troponin I mAb. Sets of samples, containing 1 μM of oligonucleotide−peptide conjugates and DNA template **T100a**, as well as different control mixtures with control templates in the PCR buffer, were prepared for annealing. After heating for 3 min at 87 °C, the samples were left for 6 h in a thermoblock and then transferred to 4 °C. Several small columns were packed with 50 μL of Sepharose-bound **mAb1**, washed with 2 × 900 μL of 0.1 M glycine buffer, and then equilibrated with 3 × 900 μL of PCR buffer (10 mM Tris−HCl, 50 mM KCl, 3 mM $MgCl_2$, pH 8.3). 100 μL of annealed samples were applied and incubated with Sepharose for 2 h at room temperature (samples were shaken every 0.5 h). Control Sepharose-bound **mAb2**was treated in the same way. After incubation, the unbound template−conjugate complexes were washed off with 2 × 900 μL of the PCR buffer, then with 900 μL of PCR buffer containing 0.3 M NaCl, and finally with 4 × 900 μL of PCR buffer. 70 μL of PCR buffer was added and 30 μL Sepharose suspension containing antibody/conjugate/template complexes was transferred to Eppendorf tubes and taken for PCR. **Pr1** and **Pr2** were used for the initial amplification of the complex-bound template. The PCR was run in touchdown mode, at an initial annealing temperature of 50 °C, at 15 cycles with 1 °C decrease per cycle, T_{amp} 72 °C, and 25 additional cycles with T_{ann} 36 °C, T_{amp} 72 °C. After PCR amplification, samples were analyzed by 15% PAGE (ethidium bromide staining). The final verification of amplified product was performed by sequencing. **Pr1** or **Pr3** was labeled with γ-^{33}P ATP and polynucleotide kinase, and subsequently used in conjunction with the CycleReader DNA Sequencing Kit, where 8 μL of amplified product was used as a template in the sequencing mixture. The reaction was run as follows: 94 °C for 3 min; 35 cycles at 94 °C for 30 s, 50 °C for 30 s, and 72 °C for 1 min. Samples were applied to the sequencing gel, which was autoradiographed after electrophoresis. A similar experiment was conducted with the consequent application of conjugates and templates. Initially, 1 μM conjugates or mixtures of conjugates were applied to Sepharose-bound **mAb1** and incubated at room temperature for 1−1.5 h. After incubation, the columns were washed with 2 × 900 μL of PCR buffer, then with 900 μL of PCR buffer containing 0.3 M NaCl, and finally with 4 × 900 μL of PCR buffer. Mixtures containing 1 μM oligonucleotides **T100a**−**T100e** or their mixtures were applied, incubated for 2−3 h, and washed with 2 × 900 μL of PCR buffer, then with 900 μL of PCR buffer containing 0.3 M NaCl, and finally with 4 × 900 μL of PCR buffer. Samples were subjected to PCR as previously described herein and sequenced.

RESULTS AND DISCUSSION

Three-Component Complex formation. Ketomäki and Lönnberg (*19*) have demonstrated applicability of ternary complexes formed by oligodeoxyribonucleotides, PPCs, and mAbs for quantification of antibodies. In their study, they employed conjugates of PNAs and peptides rather than POCs and demonstrated the possibility of quantification of antibodies. Although this approach seems to be undoubtedly attractive, in some cases, PPCs may display certain disadvantage, when applied for broader use in diagnostics. Noteworthy are the higher costs associated with PNA synthesis and the potentially poor solubility of PNAs (*21*, *22*) and some PPCs in aqueous solutions (when compared to highly soluble POCs). It seems also important to consider a potential hydrophobic interaction of some PNA moieties with certain peptides or stabilization of PNA−DNA duplex formation by polycationic peptide moieties of some PPCs (*23*, *24*). Evidently, no data are available on the influence of these factors upon the selectivity and stability of ternary complexes formed by oligodeoxyribonucleotides, PPCs, and antibodies. In principle, however, these interactions may hamper selective antibody−epitope recognition.

Likewise, no knowledge is available on the selectivity and stability of three-component complexes formed by oligodeoxyribonucleotides, POCs, and antibodies. According to Harrison and Balasubramanian (*25*), the polycationic peptide moiety of POC is able to considerably stabilize duplex formation by preferable association with the single-stranded overhand of 16mer oligonucleotide. This phenomenon in principle may seriously affect the antibody−epitope interaction and, as a result, oligodeoxyribonucleotide, POC, and antibody ternary complex formation.

Our initial objective was to demonstrate the feasibility of a predesigned complex formation, based on simultaneous antigen−antibody and Watson−Crick interactions. Thus, the components of the complex included **POC1** (Figure 1), 72mer DNA oligonucleotide **T-72**, and **mAb1**. **POC1** contained peptide sequence **P1**, capable of specific and selective interaction with **mAb1** and a 14mer oligonucleotide sequence (complementary to the 72mer DNA oligonucleotide **T-72**). **T-72** contained four identical short stretches for interaction with conjugate **POC1** (Figure 2A). Complexes were preformed in two steps as discussed below.

In the first step, Watson−Crick complexes of **T72** and **POC1** were formed, with a molar ratio of **POC1** to **T72** of 4:1, in accordance with the number of complementary stretches on the 72mer. Either **POC1** or oligomer **T72** was radioactively 5′-^{32}P-labeled. In the second step, **mAb1** was incubated with the previously formed template−conjugate duplexes at antibody−Watson−Crick complex ratios of 2:1, 1:1, 0.5:1, and 0.1:1. Theoretically, in such a case, each antibody may bind up to two POCs. A maximum of four **POC1** molecules may bind to the 72-base oligonucleotide template. In other words, a variety of multicomponent complexes and even supramolecular struc-

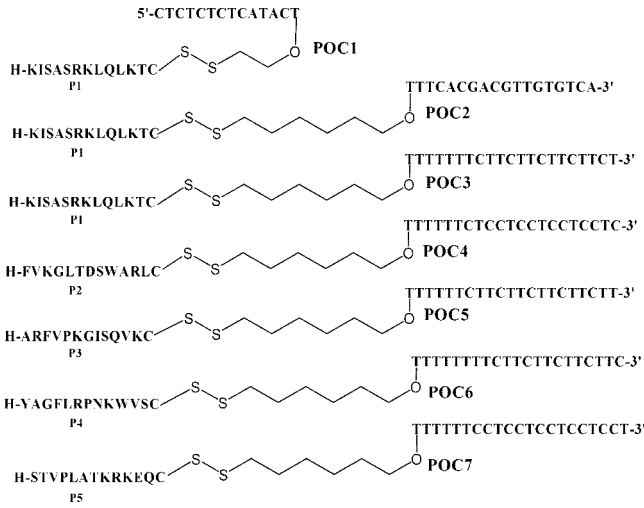

Figure 1. Structures of **POC1**−**POC7**, employed in the present study. Peptide sequences are abbreviated as **P1**, **P2**, **P3**, **P4**, and **P5**, correspondingly.

tures may exist in POC−template−antibody mixture. One of these three-component complexes, incorporating only a single template molecule, with up to four POC molecules and up to four antibodies is shown in Figure 2A.

Thus, the resulting complexes from this experiment were analyzed by a nondenaturing gradient (3−17%) PAGE. After electrophoresis, the gel was autoradiographed and subsequently stained with Coomassie Blue. Figure 3 was obtained by overlaying two images of this PAGE.

In Figure 3, it can be seen that the **POC1** demonstrates a distinct interaction with **mAb1** (Figure 3, lanes 9−11) and the resulting complex migrates some distance further on the gel, probably due to the increased total negative charge, whereas no interactions of **mAb1** and 5′-**T72** template are evident (Figure 3, lanes 12−14). Lanes 3−5 (**mAb1**-**T72**-5′-^{32}P-**POC1** mixtures) as well as lanes 6−8 (**mAb1**−5′-^{32}P-**T72**−**POC1** mixtures) characterize the mixture of two-component and three-component complexes. The presence of the radioactive bands (Figure 3, lanes 3, 4, 5 and 6, 7, 8) close to or coinciding with two-component antibody−conjugate complexes (Figure 3, lanes 9, 10, 11) in the case of mixtures containing labeled **T72** template (Figure 3, lanes 6, 7, 8) but not the labeled conjugate (Figure 3, lanes 3, 4, 5) can only be explained by the formation of the three-component complexes. The mobility rates of **mAb1**-**T72**-**POC1** complexes are influenced by both the large molecular mass of the antibody molecule (probably one in this case) and a significant combined negative charge of the 72-mer template and the 14-mer conjugate. It seems rather difficult to precisely characterize the exact molecular composition of the described three-component complexes, due to their intricate behavior under conditions of electrophoresis.

As follows from Figure 3, lane 5, some slower-moving radioactive structures were observed to migrate similarly to **mAb1** alone, or even slower (red arrow). These complexes may be attributed to some higher degree of complexity for the three-component structures. One can also notice certain associates not entering the gel, but which were stained by Coomassie Blue and incorporated the radioactive label (green arrow). At higher **mAb1** concentrations (Figure 3, lanes 3, 4 and 7, 8), the three-component structures having a low degree of complexity (blue arrow) disappear. In parallel to that, the amount of radioactive structures migrating on the gel similarly to the antibody alone (red arrow), but more slowly than **mAb1**-(5′-^{32}P-**POC1**) complex (blue arrow), distinctly increases. In addition, the amount of material both radioactive and stained by Coomassie Blue and not entering the gel (green arrow) also increases. We are tempted to speculate that the data discussed above points to the presence of multiple types of three-component structures of diverse complexity. As for the non-entering components on the gel, both radioactive and stained with Coomassie Blue, these may correspond to multicomponent supramolecular species that exist in **POC1**−**T72**-**mAb1** mixtures.

In a similar experiment, the 75mer DNA oligonucleotide **T75** incorporated only one region, complementary to the oligonucleotide moiety of **POC2** (Figure 2B). Apparently, a somewhat simpler three-component structure may be expected in the case of the **POC2**-**T75** complex interaction with **mAb1** (Figure 2B).

The resulting complexes from this experiment were analyzed by a nondenaturing gradient (3−17%) PAGE (Figure 4), as described above. Again, the presence of radioactivity at the **mAb1**-**POC2** two-component associate position (Figure 4, lanes 2, 3, 4; blue arrow) supports our interpretation of these bands as being a mixture of two- and three-component complexes. It is assumed that the component composition of complexes in these bands is characterized by the ratio 1:2:2 (**mAb1**-**POC2**-**T75**). The bands indicated by the red arrow in Figure 4 may be interpreted accordingly as the three-component complexes with the ratio composition of 1:1:1 (**mAb1**-**POC2**-**T75**).

The detailed study of the three-component complex stoichiometry was not an aim of the present work. In fact, the feasibility of a stable selective DNA−POC−antibody complex formation was the primary focus, as a basis for the further development of practical applications. Both experiments described above, however interesting, do not give any clear-cut answer to the main question of this work—i.e., are the POC−DNA −antibody complexes stable and selective enough to be employed as reliable molecular tools?

Indeed, from a thorough inspection of numerous gradient nondenaturing PAGEs, similar to those given in Figures 3 and 4, it became obvious that the presence or absence of radioactive and Coomassie Blue stained spots corresponded to various types of three-component complexes (simpler triple complexes, complexes of a higher order, and possibly even supramolecular structures) were strongly dependent on the exact conditions while conducting the electrophoresis. Therefore, it seemed apparent that certain additional experiments were absolutely imperative to understand if the stability and selectivity of POC−DNA−antibody complexes would be suitable for development of a simple model system for the immuno-PCR-based antibody epitope mapping.

Complex Formation on the Sepharose-Bound Cardiac Troponin I mAb. For the additional experiments, a 100mer template **T100a** was synthesized to incorporate three regions that were complementary to three different peptide−oligonucleotide conjugates (**POC1**−**POC3**), and bearing peptide moiety **P1** (Figure 5). The main difference among these peptides was that, whereas the **POC1** was a 3′-conjugate and incorporated a shorter disulfide linker, bridging the peptide **P1** directly with the oligonucleotide sequence complementary to template **T100a**, **POC2** and **POC3** were 5′-conjugates and incorporated a longer disulfide linker, bridging the peptide **P1** with the oligonucleotide sequence complementary to template **T100a** *via* two (**POC2**) or five (**POC3**) noncomplementary thymidine residues. By employing these three different conjugates, we hoped to understand whether the orientation of conjugation and the linker size would noticeably affect our results.

The complementary sequences were designed in the central region of the template in order to enable the sequencing of this region at the final stage of the experiment. For this purpose, **T100a** incorporated regions, complementary to initial PCR (**Pr1**, **Pr2**) and sequencing (**Pr1**, **Pr3**) primers (Figure 6A). In addition, four 100mer control templates (**T100b**−**T100e**) were synthesized. These control templates contained the same PCR

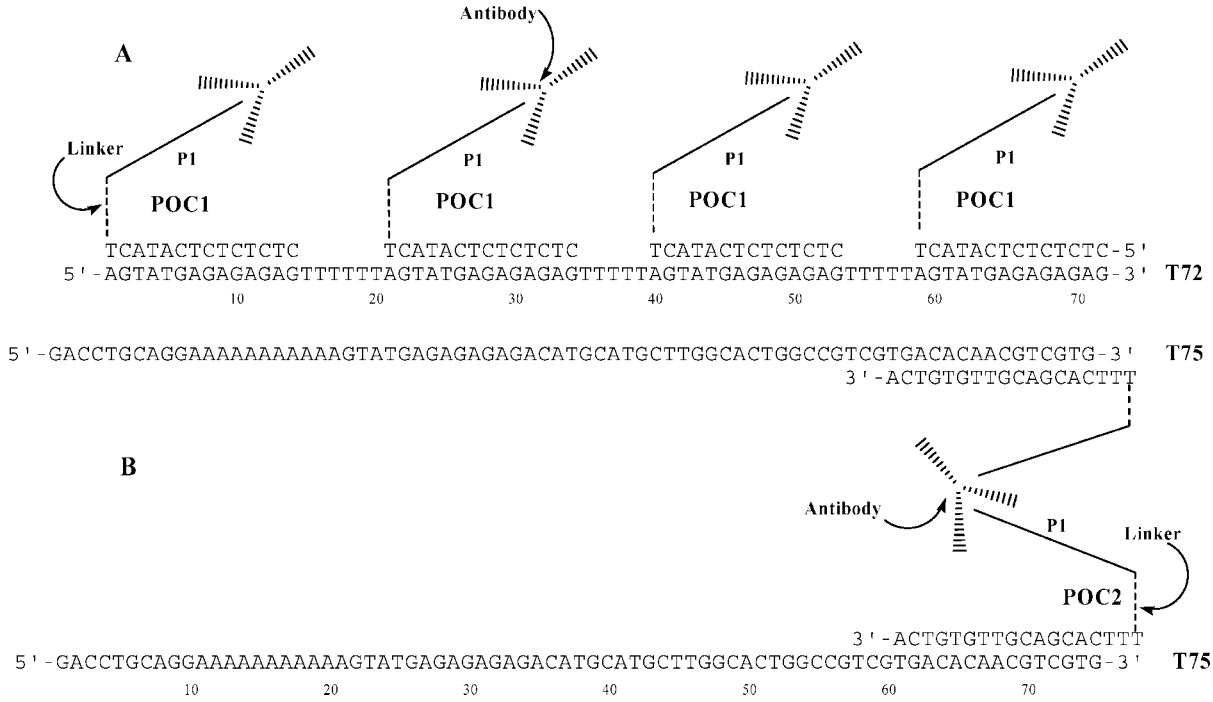

Figure 2. (A) Three-component complex, incorporating only a single template **T72** molecule, four **POC1** molecules, and four antibodies **mAb1**. (B) Three-component complex, incorporating only a single antibody **mAb1**, two template **T75** molecules, and two **POC2** molecules.

Controls: Lane 1,**mAb1**; Lane 2, 5′-^{32}P-**T72**; Lanes 12−14, **mAb1** and 5′-^{32}P-**T72** mixtures (2:1; 1:1; 0.5:1 correspondingly). Two-component complexes: Lane 15, **T72**-5′-^{32}P-**POC1** complex (1:4); Lanes 9−11, **mAb1**-5′-^{32}P-**POC1** complexes (2:1; 1:1; 0.5:1 correspondingly). Three-component complexes: Lanes 3−5, **mAb1**-(**T72**-5′-^{32}P-**POC1**) complexes (2:1; 1:1; 0.5:1 correspondingly); Lanes 6−8, **mAb1**-(5′-^{32}P-**T72**−**POC1**) complexes (2:1; 1:1; 0.5:1 correspondingly). Blue arrow: three-component low-complexity structures. Red arrow: three-component higher-complexity structures. Green arrow: multicomponent associates not entering the gel.

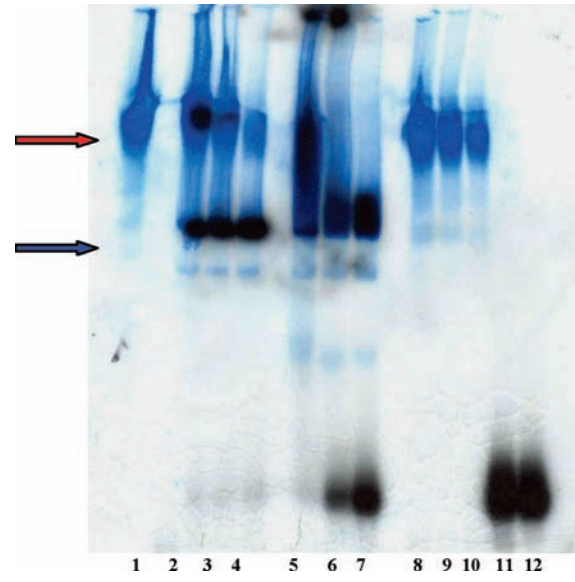

Figure 4. Overlay of two images of autoradiographed and Coomassie Blue stained 3−17% gradient nondenaturing PAGE of the **T75-POC2-mAb1** three-component complexes. Controls: Lane 1, **mAb1**; Lanes 8−10, **mAb1** and 5′-^{32}P-**T75** mixtures (2:1; 1:1; 0.5:1 correspondingly). Two-component complexes: Lanes 11, 12, 5′-^{32}P-**T75-POC2** complex (1:1 and 1:4 correspondingly). Three-component complexes: Lanes 2−4, **mAb1**-5′-^{32}P-**T75**−**POC2** complexes (2:1:1; 1:1:1; 0.5:1:1 correspondingly); Lanes 5−7, **mAb1**-5′-^{32}P-**T75**−**POC2** complexes (2:1:4; 1:1:4; 0.5:1:4 correspondingly). Blue arrow: three-component low-complexity structures. Red arrow: three-component higher-complexity structures.

and sequencing primer regions as **T100a**, but no complementary regions for the POCs (Figure 6B). Four control conjugates (**POC4**−**POC7**, Figure 1) were also prepared that incorporated 13mer peptide moieties (**P2**, **P3**, **P4**, **P5**), which displayed no affinity to **mAb1**, and the oligonucleotide sequences were noncomplementary to **T100a** (Figures 1, 5).

Sets of samples containing POCs, template **T100a**, as well as different control mixtures with control templates in PCR buffer were prepared, annealed, and applied onto the **mAb1**-Sepharose columns. The control **mAb2**-Sepharose columns were treated in the same way. After 2 h incubation at room

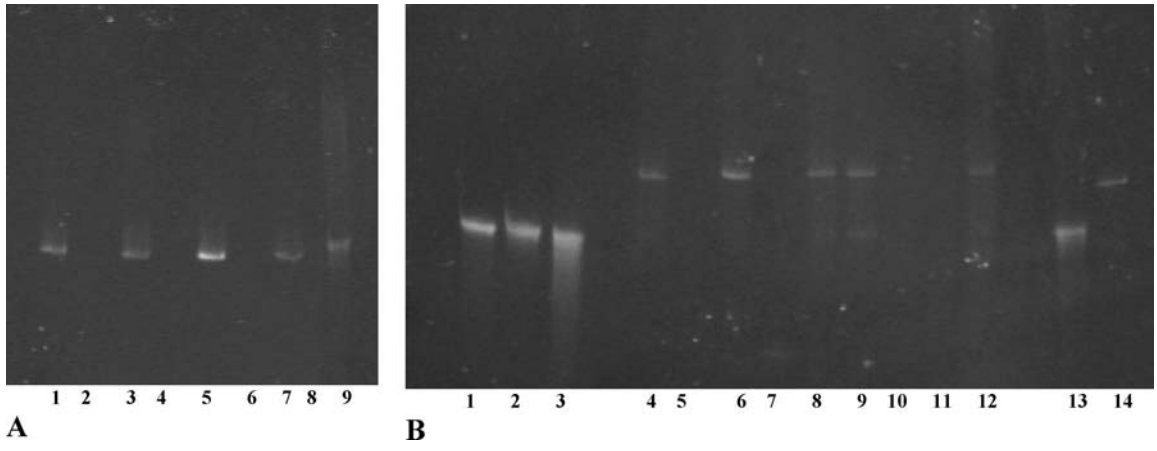

Figure 7. PCR products, obtained after selective three-component complex formation on Sepharose-bound **T100a**. PCR products, resulting from selective interaction of 100mer matrix/POC Watson−Crick complexes and Sepharose-bound **mAb1**. Watson−Crick complexes of 100mer matrixes and POCs were formed by annealing, applied to the columns, containing Sepharose-bound **mAb1**. Columns were washed, and Sepharose with bound complexes was subjected to PCR (see Experimental Procedures). (A) Standard: Lane 9, template **T100a**. PCR products resulting from annealed mixtures, containing: Lane 1, 1 μM of **POC3** and 1 μM of **T100a**; Lane 2, 1 μM of **POC3**; Lane 3, 1 μM of **POC2** and 1 μM of **T100a**; Lane 4, 1 μM **POC2**; Lane 5, 1 μM **POC1** and 1 μM of **T100a**; Lane 6, 1 μM of **POC1**; Lane 7, 1 μM of each-**POC3**, control conjugates **POC4**−**POC7** with 1 μM of **T100a**; Lane 8, 1 μM of each - **POC3**, control conjugates **POC4**−**POC7** without template. (B) Standards: Lane 1, control template **T100b**; Lane 2, control **T100c**; Lane 3, control **T100d**; Lane 13, **T100a**; Lane 14, control PCR with **T100a** as template. PCR products resulting from annealed mixtures, containing: Lane 4, 1 μM of **POC3** and 1 μM of **T100a**; Lane 5, 1 μM of **POC3**; Lane 6, 1 μM of **POC2** and 1 μM of **T100a**; Lane 7, 1 μM **POC2**; Lane 8, 1 μM of **POC3** and 1 μM of each **T100a**, **T100b**, **T100c**, **T100d**, **T100e**; Lane 9, 1 μM of each **POC1**, **POC2**, **POC3** with 1 μM of each **T100a**, **T100b**, **T100c**, **T100d**, **T100e**; Lane 10, 1 μM of each control conjugates **POC4**−**POC7** and 1 μM of **T100a**; Lane 11, 1 μM of each control conjugates **POC4**−**POC7** and 1 μM of each **T100b**, **T100c**, **T100d**, **T100e**; Lane 12, 1 μM of each **POC2**, control conjugates **POC4**−**POC7** and 1 μM of each **T100a**, **T100b**, **T100c**, **T100d**, **T100e**. All PCR mixtures contained 30 μL of Sepharose suspension, 0.1 μM primers, and 10 μM dNTPs. PCR products in part B are double-stranded, as they were not efficiently denatured during electrophoresis, which explains higher band position on the gel.

temperature, the samples of Sepharose were thoroughly washed, equilibrated with the PCR buffer, suspended in the PCR buffer, and taken for PCR, using **Pr1** and **Pr2** (Figure 6A) as initial amplification primers. Several sets of primers with different melting temperatures were previously tested in order to optimize the selectivity of PCR.

The results of the PCR experiments are shown in Figure 7A,B. Neither template (not shown) nor conjugate alone treated samples (Figure 7A, lanes 2, 4, 6; Figure 7B, lanes 5, 7), nor any samples with control **mAb2**-Sepharose (data not shown) resulted in any detectable PCR product. The mixture of control POCs (**POC4**−**POC7**) annealed with (a) control templates

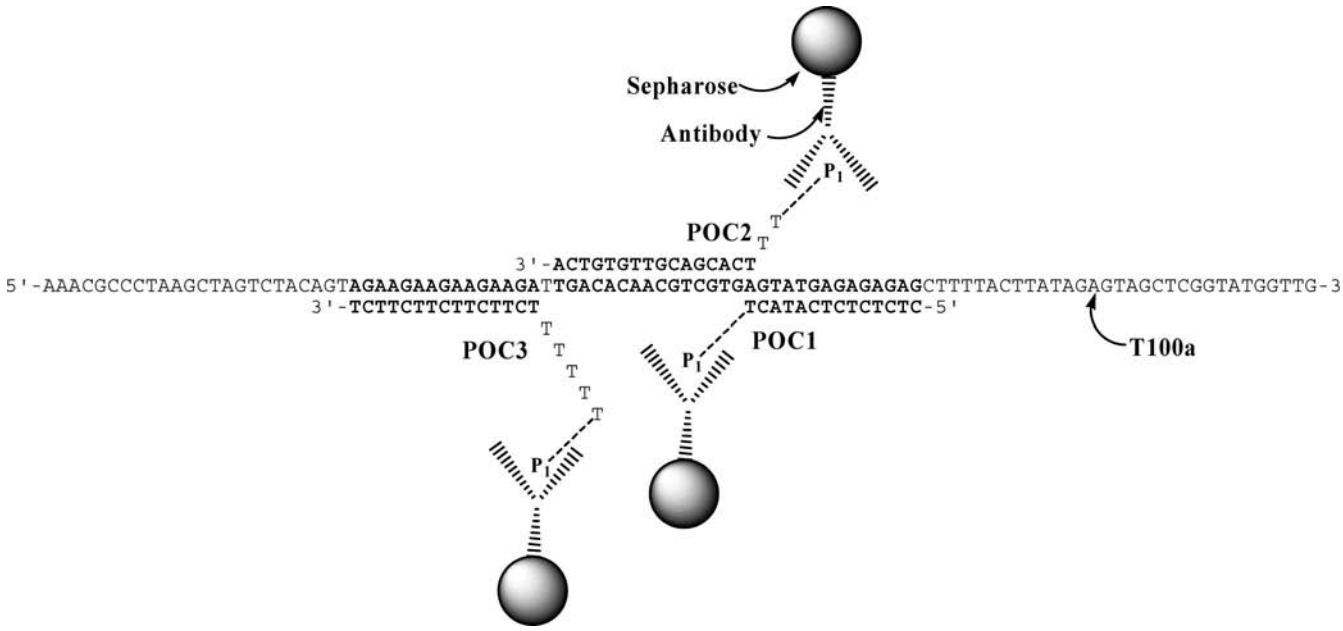

Figure 8. Three-component complex, incorporating Sepharose-bound antibody **mAb1**, template **T100a** and **POC1**, **POC2**, or **POC3**.

T100b−**T100e** (Figure 7B, lane 11) and (b) template **T100a** (Figure 7B, lane 10) also did not result in any detectable PCR product. All three conjugates were studied individually: **POC3** (Figure 7A, lane 1; Figure 7B, lane 4), **POC2** (Figure 7A, lane 3; Figure 7B, lane 6), and **POC1** (Figure 7A, lane 5), or in the mixture (Figure 7A, lane 7; Figure 7B, lanes 8, 9), and were able to form the three-component complexes with template **T100a** and Sepharose-bound **mAb1**, thus resulting in the 100-mer PCR product. From the mixture of various **POC1**−**POC7**, only those incorporating **mAb1** specific peptide **P1** were selectively binding to the complex (compared with no product in Figure 7B, lines 10, 11).

The final verification of the amplified product was performed by sequencing, using either ^{33}P-**Pr3** and **Pr1** or ^{33}P-**Pr1** and **Pr3** primers and CycleReader DNA Sequencing Kit (Fermentas). Results obtained confirmed that the product amplified from the three-component Sepharose-bound **mAb1**/**POC1**, **POC2**, or **POC3**/template DNA complex had a sequence of **T100a** (Supporting Information).

Additionally, the same experiment was conducted with the consequent application of conjugates and templates. Initially, individual conjugates **POC1**, **POC2**, or **POC3** or mixtures of POCs (**POC1**−**POC7**) were applied to the Sepharose-bound **mAb1** column. After incubation for 1−1.5 h at room temperature, the columns were washed and the oligonucleotide templates or their mixtures were applied, incubated for 2−3 h, and finally washed. Samples were subjected to PCR and sequenced as described previously herein. These results confirmed that the amplified sequences were that of **T100a** (Supporting Information). This experiment clearly demonstrates not only that preformed POC−template duplexes are capable of selectively and efficiently binding the antibody, but also that the formation of a selective POC−mAb complex does not hamper the Watson−Crick base pairing between the oligonucleotide template and complementary oligonucleotide moiety of **POC1**, **POC2**, or **POC3** (Figure 8). It is noteworthy that differences in orientation of conjugation and linker size had no effect on our result with **POC1**−**POC3**. Within our experiments, all three POCs were capable of engaging in selective three-component complex formation, leading to identical results, when used in a model system for the immuno-PCR-based antibody epitope mapping.

In the investigation of 49 POCs library (*25*), positively charged peptides incorporated in POCs along within 8mer oligonucleotide parts were causing the additional electrostatic rather than sequence-dependent interactions with overhang of complementary 16mer oligonucleotide. However, no data are available on how the DNA−POC (bearing the polycationic peptide) interaction may influence the antibody−peptide recognition, when forming ternary complexes.

In this study, the 12mer peptide portion **P1** of **POC1**−**POC3** incorporated 4 basic (two Lys and two Arg) and 8 neutral amino acid residues. These 4 basic residues according to (*25*) had to be engaged in the association of **POC1**−**POC3** and the single-stranded overhangs of oligomers **T72**, **T75**, and **T100a**. However, at least under the conditions of our experiments, this kind of interaction did not dramatically hamper the **P1**−**mAb1** recognition, and we were capable of testing the simple model system for the immuno-PCR based antibody epitope mapping. To our mind, experiments described herein may be extended to construction of considerably more complex protocols for epitope mapping that employ representative POC libraries.

CONCLUSIONS

The present work demonstrates that the relatively low molecular weight POCs that incorporate, for example, 14mer peptide and 13−15 oligonucleotide moieties are capable of a stable and selective three-component complex formation with DNA and mAb. Neither the Watson−Crick type interaction between POC and DNA nor the POC-antibody interaction dramatically hamper the other. In our experiments, the selectivity of three-component complex formation resulted in only one 100mer oligonucleotide **T100a**, associated with Sepharose-bound **mAb1** *via* **POC1**, **POC2**, or **POC3**, bearing peptide moiety **P1**. It was noteworthy that any of these POCs or their mixture brought about a similar result. Neither the control POCs nor control 100mer oligonucleotides interfered with this process, and, as a result, only a single sequence of **T100a** was clearly readable on the verification gel.

We conclude that the synthetic POCs may be successfully employed in a variety of practical applications, e.g., the immuno-PCR based antibody epitope mapping, employing representative POC libraries.

ACKNOWLEDGMENT

We are grateful to Dr. Maria Severina and Dr. Alexei Katrukha of HyTest Ltd. for providing antibodies and valuable discussions. We thank Dr. James Callaway for reading the manuscript. Financial support by the Finnish Funding Agency for Technology and Innovation (TEKES) is gratefully acknowledged.

Novel Thermoresponsive Nonviral Gene Vector: P(NIPAAm-*co*-NDAPM)-*b*-PEI with Adjustable Gene Transfection Efficiency

Han Cheng, Jing-Ling Zhu, Yun-Xia Sun, Si-Xue Cheng, Xian-Zheng Zhang,* and Ren-Xi Zhuo

Key Laboratory of Biomedical Polymers of Ministry of Education and Department of Chemistry, Wuhan University, Wuhan 430072, P. R. China. Received December 21, 2007; Revised Manuscript Received May 7, 2008

A thermoresponsive cationic copolymer, poly(*N*-isopropylacrylamide-*co*-*N*-(3-(dimethylamino)propyl)methacrylamide)-*b*-polyethyleneimine (P(NIPAAm-*co*-NDAPM)-*b*-PEI), was designed and synthesized as a potential nonviral gene vector. The lower critical solution temperature (LCST) of P(NIPAAm-*co*-NDAPM)-*b*-PEI in water measured by UV−vis spectroscopy was 38 °C. P(NIPAAm-*co*-NDAPM)-*b*-PEI as the gene vector was evaluated in terms of cytotoxicity, buffer capability determined by acid−base titration, DNA binding capability characterized by agarose gel electrophoresis and particle size analysis, and in vitro gene transfection. P(NIPAAm-*co*-NDAPM)-*b*-PEI copolymer exhibited lower cytotoxicity in comparison with 25 kDa PEI. Gel retardation assay study indicated that the copolymer was able to bind DNA completely at N/P ratios higher than 30. At 27 °C, the mean particle sizes of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes decreased from 1200 to 570 nm corresponding to the increase in N/P ratios from 10 to 60. When the temperature changed to 37 °C, the mean particle sizes of complexes decreased from 850 to 450 nm correspondingly within the same N/P ratio range due to the collapse of thermoresponsive PNIPAAm segments. It was found that the transfection efficiency of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes was higher than or comparable to that of 25 kDa PEI/DNA complexes at their optimal N/P ratios. Importantly, the transfection efficiency of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes could be adjusted by altering the transfection and cell culture temperature.

INTRODUCTION

For human gene therapy, genes are introduced to cells to be transfected and produce therapeutic proteins (*1–6*). However, due to the lack of vectors that can safely and efficiently deliver nucleic acids to the target cells, gene therapy has not fulfilled its potential. Both viral and nonviral delivery systems for delivering genes into cells have been extensively investigated. Since viral vectors are limited due to the issues of safety, immunogenicity, and mutagenesis, there is a limited amount of genomic information, although they have high efficiency (*7–10*). Nonviral vectors such as liposomes and cationic polymers have been developed to overcome these limitations (*1, 11*). Water-soluble cationic polymers such as poly(ethyleneimine)s (PEIs) and their block copolymers have been studied as nonviral vectors for effective and safe gene delivery systems (*11, 12*). Although cationic polymers can carry much larger pieces of DNA as compared with the viral vectors, they also exhibit some problems such as the aggregation of complexes at physiological conditions and possible cytotoxicity on the target cells due to the high surface charge.

The transfection efficiency and cytotoxicity of PEIs depend on the molecular weight greatly. As we know, the high molecular weight PEIs exhibit high transfection activity as well as high cytotoxicity compared with the low molecular weight PEIs. For example, the well-known commercial linear and branched 25 kDa PEIs, as an effective transfection reagent in vitro and in vivo, have high transfection efficiency but have high cytotoxicity at the same time. In order to enhance the transfection efficiency and decrease the cytotoxicity, synthetic cationic copolymers based on PEIs and stimuli-responsive polymers were investigated as nonviral gene vectors. The introduction of the stimuli-responsive polymers not only reduces the excess positive charge but also shows variable physiochemical characteristics under different cellular environments. Among various stimuli-responsive polymers, the most popular thermoresponsive polymer is poly(*N*-isopropylacrylamide) (PNIPAAm), which exhibits a phase transition at its lower critical solution temperature (LCST) around 32−33 °C. Several research groups reported temperature-sensitive vectors based on the PNIPAAm-derived polymers (*13–17*).

In this study, a novel thermoresponsive P(NIPAAm-*co*-NDAPM)-*b*-PEI copolymer as gene vector was synthesized by a coupling reaction between P(NIPAAm-*co*-NDAPM)-COOH and 800 Da PEI. The copolymer as the gene vector was evaluated based on the cytotoxicity, buffer capability determined by acid−base titration, DNA binding capability characterized by agarose gel electrophoresis and particle size analysis, and in vitro gene transfection. It was found that the copolymer exhibited different binding capabilities with DNA upon temperature changes. In addition, the temperature-dependent transfection efficiency demonstrated that P(NIPAAm-*co*-NDAPM)-*b*-PEI copolymer had great potential as a nonviral gene vector with low cytotoxicity and adjustable gene transfection efficiency.

EXPERIMENTAL PROCEDURES

Materials. *N*-Isopropylacrylamide (NIPAAm) and 3-mercaptopropionic acid (MPA) were purchased from ACROS and used as received. *N*,*N*′-Carbonyldiimidazole (CDI) and branched PEIs (25 kDa and 800 Da) were purchased from Sigma and used as received. *N*-(3-(Dimethylamino)propyl)methacrylamide (NDAPM) was purchased from Japan Mark lot. *N*,*N*′-Dimethylformamide (DMF) was obtained from Shanghai Chemical Reagent Co. and used after distillation under reduced pressure.

N,*N*′-Azobisisobutyronitrile (AIBN) was purchased from Shanghai Chemical Reagent Co., China, and used after recrystallization with 95% ethanol. Plasmid pGL-3 control with SV40 promoter and enhancer sequences encoding luciferase was obtained from Promega, Madison, WI, USA. Plasmid pEGFP-C1 encoding a red-shifted variant of wild-type green fluorescent protein (GFP) was purchased from Clontech, Mountain View, CA, USA. All other chemicals were analytical grade and used as received.

Plasmid DNA Preparation and Purification. PGL-3 and EGFP-C1 plasmids were used for in vitro gene transfections. The former was transformed in *E. coli* JM109 and the latter was transformed in *E. coli* DH5α. Both plasmids were amplified in Luria−Bertani (LB) medium at 37 °C overnight at 250 rpm. Then, the plasmids were purified as described by means of EndoFree plasmid purification. The purified plasmids were diluted by TE buffer solution and stored at −20 °C. The integrity of the plasmid was confirmed by agarose gel electrophoresis. The purity and concentration of plasmids were determined by ultraviolet (UV) absorbance at 260 and 280 nm.

Synthesis of P(NIPAAm-*co*-NDAPM)-*b*-PEI. P(NIPAAm-*co*-NDAPM)-COOH was synthesized by free-radical copolymerization of NIPAAm (2.74 g) and NDAPM (150 μL) in DMF (10 mL) using AIBN (0.021 g) and MPA (0.418 g) as an initiator and a chain transfer reagent, respectively. After all the reactants were dissolved in DMF, the solution was degassed by bubbling with nitrogen for 30 min. Then the polymerization reaction was carried out at 70 °C under N_2 atmosphere for 24 h. The P(NIPAAm-*co*-NDAPM)-COOH was obtained by precipitating the reaction mixture into diethyl ether. The precipitated polymer was isolated by filtration, dried under vacuum, and then reprecipitated from diethyl ether. Subsequently, resultant P(NIPAAm-*co*-NDAPM)-COOH (0.8348 g) and CDI (28 mg) were dissolved in DMSO (10 mL) and stirred for 3 h at room temperature. The solution was added quickly to a large excess of 800 Da PEI in DMSO (5 mL) with vigorous stirring. After 24 h, the product was precipitated in diethyl ether. The precipitated polymer was isolated by filtration and dried in a vacuum. Then, the dried polymer was further purified by dialysis against distilled water (MWCO 8000−12000) to remove the unreacted 800 Da PEI and other residues.

Characterizations. Fourier transformed infrared (FTIR) spectra were recorded on a Lambda Bio40 UV−vis spectrometer (Perkin-Elmer). ^{1}H nuclear magnetic resonance (NMR) spectra were recorded on a Varian Unity 300 MHz spectrometer using $CDCl_3$ as a solvent.

LCST Measurement. Optical absorbance of P(NIPAAm-*co*-NDAPM)-COOH, P(NIPAAm-*co*-NDAPM)-*b*-PEI, and P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes at various temperatures was measured at 542 nm using a Lambda Bio40 UV−vis spectrometer (Perkin-Elmer). Sample cells were thermostatted in a refrigerated circulator bath at different temperatures from 31 to 60 °C prior to measurement. The heating rate was set at 0.1 °C/min. The LCSTs of the polymers and complexes were defined as the temperature showing a 50% change in the total optical absorbance.

Cell Culture. Human embryonic kidney 293 cells (HEK293) were incubated in Dulbecco's Modified Eagle's Medium (DMEM) containing 10% fetal bovine serum (FBS) and 1% antibiotics (penicillin−streptomycin, 10000 U/mL) at 37 °C in a humidified atmosphere containing 5% CO_2.

Cell Viability Assay. For cell viability assay, the HEK293 cells (2500 cells/well) were seeded into 96-well plates. The cells were then incubated in culture medium containing polymer with a particular concentration for 48 h. After that, the medium was replaced with 200 μL of fresh medium, and 20 μL of sterile filtered MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide) (5 mg/mL) stock solution in PBS was added to each well, reaching a final concentration of 0.45 mg/mL. After 4 h, unreacted dye was removed by aspiration. The formazan crystals were dissolved in 200 mL DMSO per well and measured spectrophotometrically in an ELISA plate reader (model 550, Bio-Rad) at a wavelength of 570 nm. The cell survival was expressed as follows.

$$\text{cell viability} = (\text{OD}_{\text{treated}}/\text{OD}_{\text{control}}) \times 100\%$$

where $\text{OD}_{\text{control}}$ was obtained in the absence of polymers and $\text{OD}_{\text{treated}}$ was obtained in the presence of polymers.

Acid−Base Titration. The buffer capability of PEIs and P(NIPAAm-*co*-NDAPM)-*b*-PEI were determined by acid−base titration assay over the pH from 10 to 2 as described by Benns et al. (*18, 19*). Briefly, 0.2 mg/mL of each sample solution was prepared in 30 mL 150 mM NaCl solution. The pH value of the sample solution was adjusted to 10 by adding 0.1 M NaOH, and then the solution was titrated by 0.1 M HCl. During titration, the pH value of the mixture was measured using a microprocessor pH meter (pH 211, Germany).

Polymer/DNA Complex Formation. P(NIPAAm-*co*-NDAPM)-*b*-PEI was dissolved in NaCl solution (150 mM, pH 7.4) to form a solution with a concentration of 1 mg/mL. A plasmid DNA stock solution (120 ng/μL) was prepared in Tris-HCl buffer solution (pH 7.4). The total volumes of polycation solution and DNA stock solution were adjusted to 50 μL with 150 mM NaCl solution, respectively, and then two solutions were mixed together to form complexes with different N/P (the primary amino groups of PEI in the P(NIPAAm-*co*-NDAPM)-*b*-PEI to phosphate groups) ratios. The formation of complexes was carried out for 30 min at 37 °C after vortexing polymer/DNA mixture for 5 s.

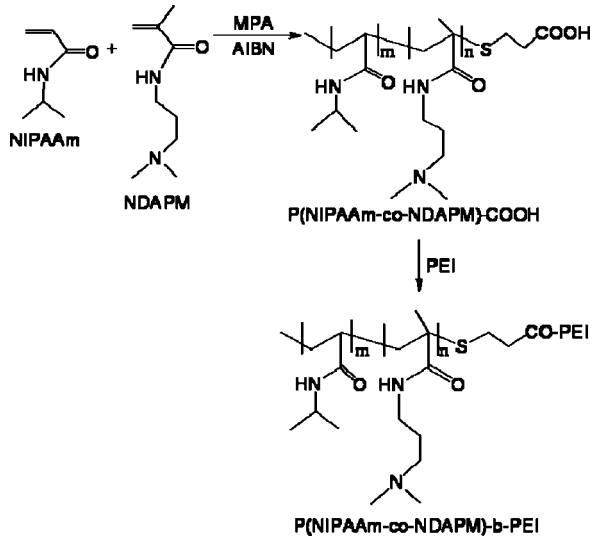
Agarose Gel Retardation Assay. The complexes at different N/P ratios were prepared by adding appropriate volumes of P(NIPAAm-*co*-NDAPM)-*b*-PEI (in 150 mM NaCl solution) to 96 ng of plasmid EGFP-C1 DNA (120 ng/μL in 40 mM Tris-HCl buffer solution), and the complexes were diluted by 150 mM NaCl solution to 6 μL, then the complexes were incubated at 37 °C for 30 min. After that, the complexes were loaded on the 0.7% (w/v) agarose gel containing GelRed with Tris-acetate (TAE) running buffer at 80 V for 80 min. DNA was visualized with a UV lamp using a Vilber Lourmat imaging system (France).

Particle Size Measurements. The P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes at various N/P ratios were prepared by adding appropriate volumes of P(NIPAAm-*co*-NDAPM)-*b*-PEI (in 150 mM NaCl solution) to 10 μg of plasmid DNA (in 40 mM Tris-HCl buffer solution), then the complexes were diluted by 150 mM NaCl solution to 1 mL and incubated at 27 and 37 °C for 30 min, respectively. The particle size was measured by Nano-ZS ZEN3600 (MALVERN Instruments) at 27 and 37 °C, respectively.

Gene Transfection. For in vitro transfection study, the HEK293 cells were split one day prior to transfection and seeded in 24-well plates at a density of 5×10^4 cells/well. Before transfection, the cell culture medium was replaced with serum-free DMEM. The cells were transfected with P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes containing 1 μg of plasmid DNA at 25 and 37 °C for 4 h, respectively. Then, the complexes were removed and incubated in fresh DMEM with 10% FBS at 37 °C for another 48 h. Altogether, for the thermo-controlled assay, the complexes were incubated following the two different temperature programs: (1) 37 °C (4 h) → 37 °C (48 h) and (2) 27 °C (4 h) → 37 °C (48 h).

Cell Tracing Assay. GelRed was used as a molecular probe to show the transport of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes into cells. Complexes were incubated with serum-free DMEM in 24-well plates following the above two tem-

Scheme 1. Schematic Illustration of the Synthesis of P(NIPAAm-*co*-NDAPM)-*b*-PEI



perature-controlled programs for 4 h. After that, the GelRed solution (at 1/5000 volume of the transfection medium) was added to 24-well plates and incubated 10 min before the serum-free DMEM was replaced by fresh DMEM with 10% FBS. Then, the cells were directly observed by an inverted microscope (TE-2000U, NIKON, JAPAN) after incubation for 4 and 12 h in DMEM with 10% FBS.

Luciferase Assay. The cells were washed by PBS and lysed with the reporter lysis buffer (Promega, USA). The luciferase activity in cell extracts was measured using a luciferase assay kit (Promega, USA). Each measurement was carried out for 10 s in a single-well luminometer (Berthold Lumat LB 9507, Germany). The relative light units (RLU) were normalized by the total protein concentration of the cell extracts, and the total protein was measured with a BCA protein assay kit (PERBIO, USA). Luciferase activity was expressed as RLU/mg protein.

GFP Detection. The cells which expressed green fluorescent proteins were directly observed by inverted microscope (IX 70, OLYMPUS, JAPAN).

RESULTS AND DISCUSSION

Synthesis of P(NIPAAm-*co*-NDAPM)-*b*-PEI. PNIPAAm has been frequently used as a thermoresponsive segment to form block polymers with the LCST of around 32−33 °C (*20*). In the present study, a block copolymer of P(NIPAAm-*co*-NDAPM)-*b*-PEI was prepared. The hydrophilic NDAPM units were used to adjust the LCST of P(NIPAAm-*co*-NDAPM)-*b*-PEI copolymer. The synthesis of the P(NIPAAm-*co*-NDAPM)-*b*-PEI copolymer involved two steps as illustrated in Scheme 1. P(NIPAAm-*co*-NDAPM)-COOH was synthesized by free-radical polymerization using AIBN as an initiator, and MPA as a chain transfer agent. Then, P(NIPAAm-*co*-NDAPM)-*b*-PEI was prepared by coupling reaction between P(NIPAAm-*co*-NDAPM)-COOH and PEI, using CDI as a coupling reagent. During the coupling reaction, the large excess 800 Da PEI was added to make sure that one PEI molecule would react with one P(NIPAAm-*co*-NDAPM)-COOH molecule, and the P(NIPAAm-*co*-NDAPM)-COOH would be consumed completely.

The structure of polymers was confirmed by FTIR and ^{1}H NMR spectroscopies. As shown in Figure 1, the absorbance of amide carbonyl groups in P(NIPAAm-*co*-NDAPM)-COOH occurred at 1630 cm^{-1} and the bending frequency of the amide N−H appeared at 1580 cm^{-1}. The FTIR spectrum of P(NIPAAm-*co*-NDAPM)-*b*-PEI was similar to that of P(NIPAAm-*co*-NDAPM)-COOH due to the fact that the amide N−H peak of PEI overlapped the one of PNIPAAm. However, it was found that the absorbance of amide N−H in P(NIPAAm-*co*-NDAPM)-*b*-PEI was greatly enhanced (Figure 1b) as compared with that of P(NIPAAm-*co*-NDAPM)-COOH, which indicated that the PEI was successfully grafted on P(NIPAAm-*co*-NDAPM)-COOH.

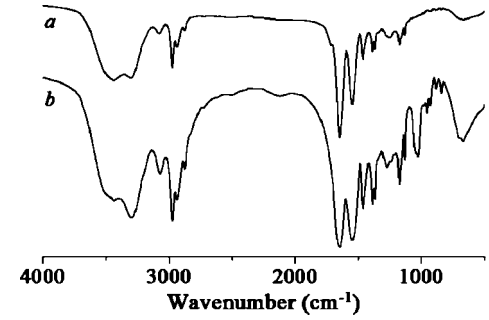


Figure 1. FTIR spectra of P(NIPAAm-*co*-NDAPM)-COOH (a) and P(NIPAAm-*co*-NDAPM)-*b*-PEI (b).

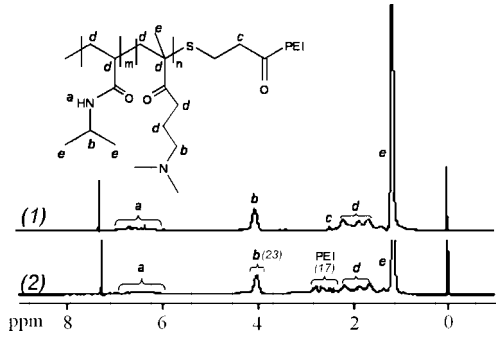

Figure 2. The ^{1}H NMR spectra of (1) P(NIPAAm-*co*-NDAPM)-COOH and (2) P(NIPAAm-*co*-NDAPM)-*b*-PEI in $CDCl_3$.

The ^{1}H NMR spectra of P(NIPAAm-*co*-NDAPM)-COOH and P(NIPAAm-*co*-NDAPM)-*b*-PEI in $CDCl_3$ are shown in Figure 2. Figure 2(1) and (2) both showed a single peak at δ 3.9−4.1 ppm, which could be attributed to the hydrogen of NC*H*$(CH_3)_2$ in the PNIPAAm segment. Besides, there existed a signal at around δ 1.0 ppm which could be assigned to the methyl in the PNIPAAm. In Figure 2(2), the broad peak δ 2.5−3.3 ppm was assigned to the methylene of branched 800 Da PEI. The integrals of signal δ 3.9−4.1 ppm and signal δ 2.5−3.3 ppm were 23 and 17, respectively. In addition, the molecular weights (M_n) of the polymers were calculated from the ratio of these two integrals. The M_n of P(NIPAAm-*co*-NDAPM)-COOH and P(NIPAAm-*co*-NDAPM)-*b*-PEI were 1.14×10^4 and 1.22×10^4, respectively.

LCST Determination. The phase transition of thermoresponsive polymers in aqueous solution is attributed to a change in the hydrophilic/hydrophobic equilibrium of the polymers with respect to their hydrogen bonding between the polymer chains and water molecules. The light transmittance of a polymer solution could be examined as a function of temperature, and the LCST of the polymer was defined as the temperature producing a half-decrease of the total decrease in light transmittance. Generally, PNIPAAm itself exhibits a temperature-induced phase transition at around 32−33 °C (*20*), and the complete transition occurs within a narrow temperature range. As shown in Figure 3, the LCST values of P(NIPAAm-*co*-NDAPM)-COOH, P(NIPAAm-*co*-NDAPM)-*b*-PEI, and P-(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes are around 42, 38, and 37 °C, respectively. A well-recognized mechanism for the phase transition of the PNIPAAm polymer is the result of

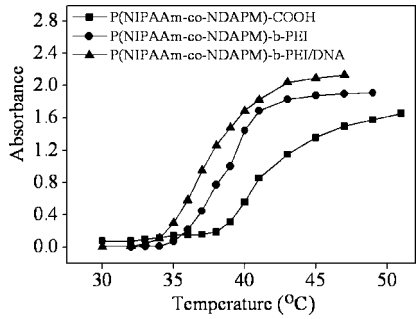

Figure 3. Thermoresponsive behavior of P(NIPAAm-*co*-NDAPM)-COOH, P(NIPAAm-*co*-NDAPM)-*b*-PEI, and P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes.

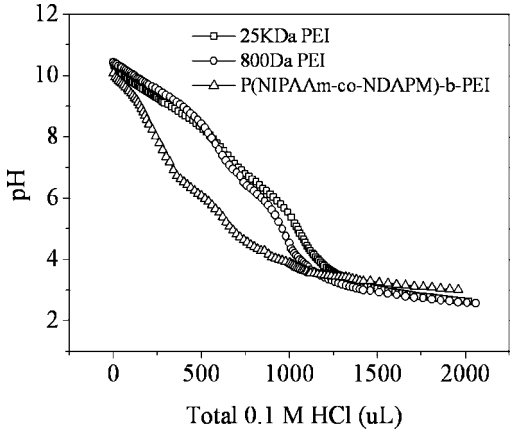

Figure 4. Acid−base titration curves of 25 kDa PEI, 800 Da PEI, and P(NIPAAm-*co*-NDAPM)-*b*-PEI in 150 mM NaCl solution.

a balance between hydrophilicity and hydrophobicity in the polymer chain. When a hydrophilic moiety is copolymerized into a PNIPAAm segment, the hydrophilic/hydrophobic balance shifts to a more hydrophilic nature, and the LCST would shift to a higher temperature accordingly (*21*, *22*).

The P(NIPAAm-*co*-NDAPM)-COOH and P(NIPAAm-*co*-NDAPM)-*b*-PEI exhibited higher LCSTs compared with pure PNIPAAm, ascribed to the incorporation of hydrophilic NDAPM units. The fact that the LCST of P(NIPAAm-*co*-NDAPM)-COOH was higher than that of P(NIPAAm-*co*-NDAPM)-*b*-PEI is due to the end group effect of terminal carboxylic acid groups (*23*, *24*).

Acid−Base Titration. The buffer capabilities of 25 kDa PEI, 800 Da PEI, and P(NIPAAm-*co*-NDAPM)-*b*-PEI are shown in Figure 4. It was found that the buffer capabilities of 25 kDa and 800 Da PEIs are similar, that is to say that the buffer capability is not directly correlated with the molecular weight. It was reported that the buffer capability depends on the primary, secondary, and ternary amines. Hence, the buffer capability of P(NIPAAm-*co*-NDAPM)-*b*-PEI, which is slightly lower than that of PEIs, could be ascribed to the reduction of positive charge density owing to the introduction of neutral PNIPAAm chains.

Characterization of Polymer/DNA Complexes. The binding capability between the polycation and DNA is a prerequisite for the gene vector. When the DNA is condensed by the polycation, the condensed form can protect the DNA against digestion by enzymes. In addition, the compact unit facilitates the escape of the complex from endosomes into the cytoplasm, and then the DNA accumulates in the nucleus of the targeted cell where the gene is expressed. In order to study the ability of the polymer to condense DNA, the agarose gel assay was conducted. As shown in Figure 5, the plasmid DNA was retarded partly at the N/P ratio of 10. With an increase in N/P ratio, the

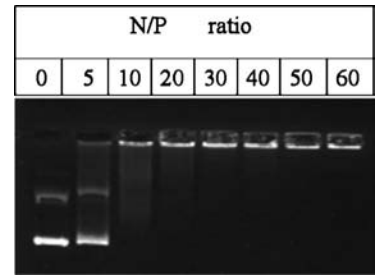

Figure 5. Agarose gel electrophoresis retardation assay of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes at different N/P ratios of 0, 5, 10, 20, 30, 40, 50, and 60.

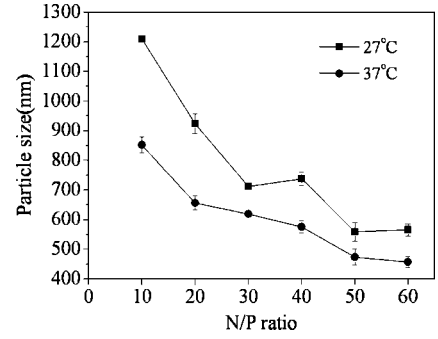

Figure 6. Particle size of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes at N/P ratios ranging from 10 to 60 at different temperatures (27 and 37 °C). Data were shown as mean ± SD ($n = 3$).

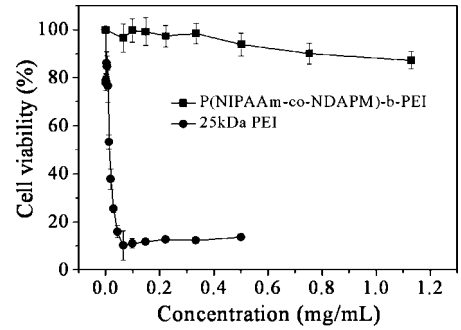

Figure 7. Cytotoxicity of P(NIPAAm-*co*-NDAPM)-*b*-PEI for HEK293 cells in comparison to 25 kDa PEI.

DNA binding capability of P(NIPAAm-*co*-NDAPM)-*b*-PEI was improved and the copolymer was able to bind DNA completely at N/P ratio higher than 30.

Particle Size Measurement. The particle sizes of the polymer/DNA complexes at different N/P ratios at 27 and 37 °C are shown in Figure 6. The effect of the N/P ratio on the complex size shows a similar trend at 27 and 37 °C. At 27 °C, with an increase in the N/P ratio from 10 to 60, the particle size decreases from 1200 to 600 nm. At 37 °C, with an increase in N/P ratio from 10 to 60, the particle size decreases from 860 to 450 nm.

It is obvious that the particle size of complexes depends on the temperature, and the particle size at 27 °C is larger than that at 37 °C at the same N/P ratio. As we know, at a higher temperature, the PNIPAAm chains collapse to form highly compact structure. At a lower temperature, the PNIPAAm chains get expanded to promote the dissociation of complexes. In the current study, at a lower N/P ratio, the complexes at both 27 and 37 °C form larger particles attributed to the weaker electrostatic interaction between P(NIPAAm-*co*-NDAPM)-*b*-PEI and DNA. With increasing N/P ratio, the electrostatic interaction becomes stronger and more compact complexes are

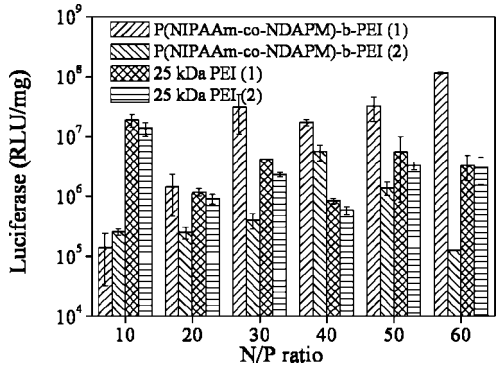

Figure 8. Transfection efficiency of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA and 25 kDa PEI/DNA complexes evaluated at N/P ratios range from 10 to 60 at two different cultured temperature programs: (1) 37 °C (4 h) → 37 °C (48 h); (2) 27 °C (4 h) → 37 °C (48 h). Data were shown as mean ± SD ($n = 3$).

formed (*25*), and so, the particle size at 37 °C is smaller than that at 27 °C (*25*, *26*), which implies that the particle size of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes might be adjusted by changing the temperature.

Cytotoxicity of Polymers. Low cytotoxicity is a very important requirement for gene vectors. In this study, the cytotoxicity of P(NIPAAm-*co*-NDAPM)-*b*-PEI was evaluated in HEK293 cells by MTT assay using 25 kDa PEI as the control. As shown in Figure 7, the viability of HEK293 cells treated with P(NIPAAm-*co*-NDAPM)-*b*-PEI at the concentration of 1.1 mg/mL is above 80%, indicating that the cytotoxicity of P(NIPAAm-*co*-NDAPM)-*b*-PEI is lower than that of 25 kDa PEI. Moreover, the cytotoxicity of P(NIPAAm-*co*-NDAPM)-*b*-PEI increases slightly with increasing polymer concentration.

The cytotoxicity of a polymer is correlated with the molecular weight as well as the cell binding between the polymer and cellular surfaces (*27*). The lower cytotoxicity of P(NIPAAm-*co*-NDAPM)-*b*-PEI is attributed to the lower molecular weight of PEI and the shielding function of PNIPAAm chains, which can partially prevent the combination between P(NIPAAm-*co*-NDAPM)-*b*-PEI and cellular surfaces.

In Vitro Transfection. The commercially available branched 25 kDa PEI was used as the positive control due to its high transfection efficiency in vitro and in vivo. The plasmid PGL-3 was used as a reporter gene. In order to examine the influence of temperature on the transfection efficiency, the complexes were incubated following two different temperature programs: (1) 37 °C (4 h) → 37 °C (48 h) and (2) 27 °C (4 h) → 37 °C (48 h). The efficiency of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes was evaluated at N/P ratios from 10 to 60, and the efficiency of 25 kDa PEI at the optimal ratio (N/P = 10) was used as the control. As shown in Figure 8, the luciferase activities of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes at various N/P ratios are 1.38×10^5 RLU/mg, 1.44×10^6 RLU/mg, 3.11×10^7 RLU/mg, 1.72×10^7 RLU/mg, 3.21×10^7 RLU/mg, and 1.16×10^8 RLU/mg under the constant temperature program (1). However, under the condition of nonconstant temperature program (2), the luciferase activities of P(NIPAAm-*co*-NDAPM)-*b*-PEI decrease 0.5−1000-fold as compared with that of the constant temperature program (1). As also shown in Figure 8, the efficiency of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes at certain N/P ratios is higher than that of 25 kDa PEI/DNA complexes at its optimal N/P ratio under constant temperature program (1).

To further illuminate the effect of temperature on the transfection efficiency, the tracing analysis was carried out using fluorescent microscopy, showing transport of the complexes into the cells. As shown in Figure 9, the GelRed labeled P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes initially dispersed on the cell surface after incubation in DMEM with 10% FBS for 4 h following two temperature programs (Figure 9a,c, arrows). After the complexes were incubated in DMEM with 10% FBS for 12 h, the labeled DNA was clearly restricted to the periphery

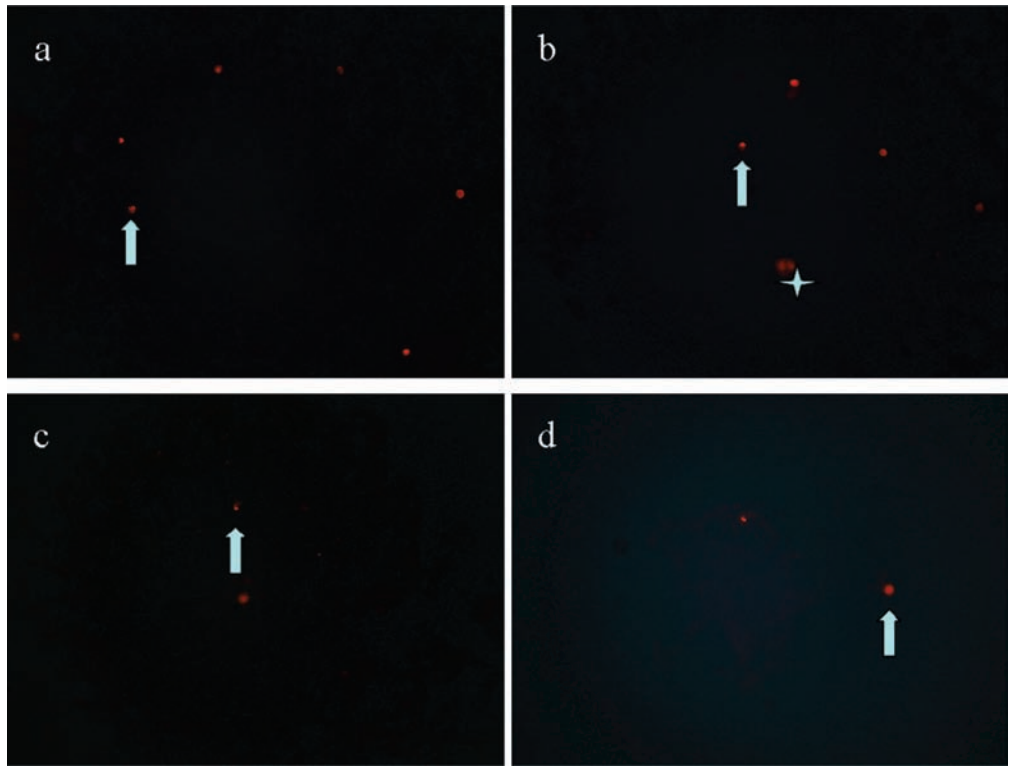

Figure 9. Cell tracing of GelRed labeled P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes in HEK293 cells at two different cultured temperature programs: (1) 37 °C (4 h) → 37 °C (48 h) for 4 h (a) and 12 h (b); (2) 27 °C (4 h) → 37 °C (48 h) for 4 h (c) and 12 h (d). The images were obtained at magnification of 100×.

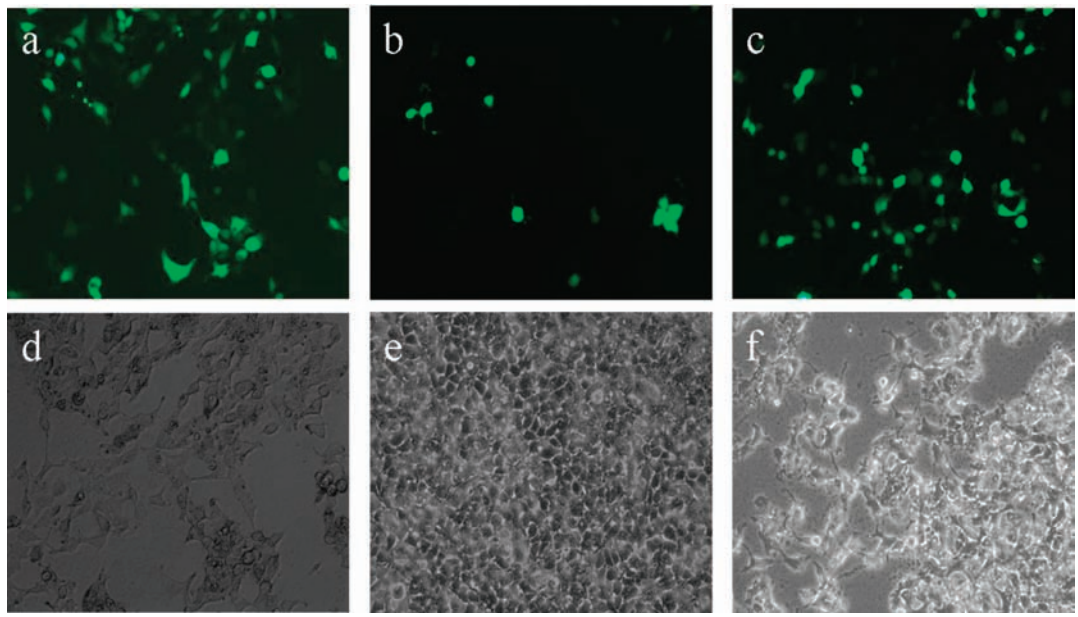

Figure 10. The transfected HEK293 cells by P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes and 25 kDa PEI/DNA complexes observed by inverted microscope. The images in a, b, and c are the fluorescent images, and the images in d, e, and f are the bright-field images. The images (a, d) of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes were obtained under the temperature program (1) with N/P ratio of 60, images (b, e) of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes under the temperature program (2) with N/P ratio of 60, and images (c, f) of 25 kDa PEI/DNA complexes with N/P ratio of 10. The images were obtained at magnification of 100×.

of the nucleus following temperature program (1) (Figure 9b, asterisk). However, it was difficult to identify any labeled DNA entering the cells, and it was still dispersed on the cell surface after incubation in DMEM with 10% FBS for 12 h following temperature program (2) (Figure 9d, arrow). The results indicate that the transfection efficiency of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes is adjustable through temperature control.

However, the transfection result of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes is partially different from that of the previously studied thermoresponsive complexes at two different temperature programs (*13, 28*). The difference was attributed to the different transfection methods. In this study, when the P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes were incubated in DMEM for 4 h at 37 °C, the complexes got associated compactly for cell uptake and prevention of DNA degradation; hence, the gene expression was conducted successfully. When the P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes were incubated in DMEM for 4 h at 27 °C, the P(NIPAAm-*co*-NDAPM)-*b*-PEI could not condense DNA compactly, as demonstrated by the particle size analysis and tracing assay. The transgene expression was limited and thus resulted in low transfection efficiency at 27 °C. In the literature reports (*13, 28*), the thermoresponsive complexes were first incubated for a few hours at 37 °C, and the complexes got associated tightly for cell uptake. After that, the complexes were further incubated for a couple of hours at temperatures below the LCST, resulting in the dissociation of the complexes, and then the free DNA would enter the nucleus easily. As a result, the transfection efficiency of the complexes incubated for a couple of hours at temperatures below the LCST is higher than that at temperature above the LCST. In a word, the transfection efficiency of thermoresponsive polymer/DNA complexes could be adjusted by altering the cultured temperature.

In order to directly visualize the infected cells expressing GFP, EGFP-C1 encoded a red-shifted variant of wild-type GFP with optimized brighter fluorescence and higher expression in mammalian cell was used as a reporter gene. The cells expressing green fluorescence were observed by inverted microscope at the optimal N/P ratio for the polymer/DNA complexes. The transfection results are presented in Figure 10. Figure 10a,b,c represents the fluorescent images, and Figure 10d,e,f represents the bright-field images. GFP is successfully expressed in HEK293 cells, the number of green fluorescent cells increases with increasing N/P ratio, and the nonconstant temperature program results in less GFP expression compared with the constant temperature program, which is consistent with luciferase reporter system.

CONCLUSIONS

A novel thermoresponsive P(NIPAAm-*co*-NDAPM)-*b*-PEI block copolymer was prepared by the coupling reaction between P(NIPAAm-*co*-NDAPM)-COOH and 800 Da PEI. Compared with 25 kDa PEI, P(NIPAAm-*co*-NDAPM)-*b*-PEI copolymer exhibits much lower cytotoxicity. The particle size of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes could be adjusted by varying the culture temperature. In vitro gene transfection reveals that the transfection efficiency of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes is comparable to or even higher than that of 25 kDa PEI/DNA complex (N/P = 10). Importantly, the gene transfection efficiency of P(NIPAAm-*co*-NDAPM)-*b*-PEI/DNA complexes could be adjusted by altering the transfection and incubation temperature, suggesting that the P(NIPAAm-*co*-NDAPM)-*b*-PEI has great potential as an intelligent and effective nonviral gene vector.

Received January 17, 2008; Revised Manuscript Received April 15, 2008

The calpain enzymes play important roles in numerous processes in the cell. *In vivo* analysis of calpain activity might be useful for clarification of their role in different diseases. Our early results suggested that a peptide substrate, *Dabcyl*-TPLKSPPPSPR-*EDANS*, based on the calpain cleavage sequences is suitable for developing a new cell-penetrating calpain substrate. This conjugate with the Dabcyl and EDANS fluorophores as a FRET pair is specific for calpain even in cell lysate, but unfortunately has poor cell uptake. Therefore, we have modified this sequence by C-terminal elongation with heptaarginine unit possessing cell-penetrating activity. In order to preserve the necessary distance between the two FRET partners, we inserted a Glu residue between the substrate and heptaarginine parts of the peptide. Thus, the cell-penetrating substrate *Dabcyl*-TPLKSPPPSPRE(*EDANS*)R_7 was synthesized. This peptide not only retained the substrate property, but was a better substrate of Calpain B enzyme. The cell uptake of the substrate conjugate was studied by fluorescence microscopy and flow cytometry. The results showed that the conjugate enters COS-7 cells more efficiently than the peptide substrate without heptaarginine. The uptake occurs already at low concentration and the compound is distributed homogeneously inside cells. These observations might indicate that this new cell-penetrating substrate could be useful for determining calpain activity in cell lysate or in intact cells of various origins.

INTRODUCTION

Calpains are intracellular cysteine proteases whose catalytic site is analogous to that of the papain-like protease domain (*1, 2*). The family has 14 members showing various patterns of expression. The ubiquitous forms of them are the μ- and m-calpains (calpains 1 and 2, respectively). Calpains play crucial roles in cell adhesion and motility, exocytosis, signal transduction, cell cycle progression, and regulation of gene expression (*3–7*). Calpain overactivation is associated with the pathogenesis of a wide range of disorders (*8*). For *in vitro* study of calpain activity, short peptide sequences were used with modification by a fluorophore (*9*). Since these substrates are not specific to calpain and are quite poor in kinetic terms, there have been attempts to create better substrates for specific applications. The study of a huge number of cleavage sites of calpain in different substrates resulted in an amino acid preference matrix in the P1−P7′ position (*10*). From the most preferred amino acids, a new substrate, *Dabcy*l-TPLKSPPPSPR-*EDANS*, was prepared. By this peptide substrate, it was possible to measure calpain activation in COS-7 cell lysates, and only after lipofection intracellular calpain activity in *Drosophila* S2 cells. However, this construct was not able to penetrate cells.

For *in vivo* measurement of calpain activity, Vanderklish et al. (*11*) constructed a vector encoding for an 11 amino acid long sequence of α-spectrin flanked by two fluorescent protein domains to serve as an *in vivo* FRET substrate. This construct led to identifying dendritic spines in which calpain is activated during the excitatory synaptic activity. Mittoo et al. followed a similar approach to design two FRET substrates using the same α-spectrin sequence (*12*). In the third case, protein−substrate of calpain, MAP2, labeled with DTAF to monitor calpain continuously was used (*13*).

Another strategy is the application of a small labeled dipeptide calpain substrate (Boc-LM-CMAC) for *in vivo* activity measurement. In this case, calpain activity could be determined by measuring the hydrolysis of the dipeptide substrate using fluorescence microscopy (*14*) with the excitation and emission wavelengths $\lambda = 350$ and $\lambda = 430$ nm, or by flow cytometry (*15*). After the internalization, the nonfluorescent dipeptide substrate is conjugated to an intracellular thiol group via chloromethyl group of aminocoumarin (CMAC), resulting in a membrane-impermeable form allowing substrate accumulation within the cell (*16*). The proteolytic cleavage of this peptide by calpain produces aminocoumarin derivative, which possesses blue fluorescence.

Several oligopeptides of natural and/or synthetic origin have been discovered with cell membrane penetrating capability. The first peptide sequences came from the HIV-1 Tat (*17, 18*) and the Antennapedia protein of *Drosophila* (*19*). Based on the polycationic nature of the cell-penetrating peptides, the ability to enter cells of oligomers of 3−9 Arg, Lys, Orn, or His residues were tested. It was found that hexa- and octaarginine were taken up far more effectively than other polycationic oligopeptides of equal length (*20–22*). These peptides could go through the cell membrane with different covalently attached cargos (peptides, peptide-nucleic acid, oligonucleotide) (review (*23*)).

Our aim was to synthesize a new cell-penetrating substrate of calpain, based on the *Dabcyl*-TPLKSPPPSPR-*EDANS* peptide, by conjugation with octaarginine. Considering that the sequence contains one Arg at the C-terminal, and it is not necessary to have all eight Arg residues in one block in the sequence (*24*), in our design−*Dabcyl*-TPLKSPPPSPRE-(*EDANS*)R_7−a Glu residue was inserted between the substrate and the heptaarginine parts of the target peptide−conjugate. Thus, in this construct we also preserved the necessary distance between the two FRET partners. The substrate properties of the

new construct were studied by using calpain B enzyme. We report here also that the cell-penetrating variant not only retained the substrate properties, but was even better than the free peptide substrate. In contrast to the free peptide, we found that the conjugate internalized efficiently and distributed nearly homogeneously in COS-7 cells as demonstrated by fluorescent microscopy studies. As the concentration dependence of internalization studied by flow cytometry indicates, the conjugate had already penetrated with high efficiency at low concentration. We have also demonstrated that the enzyme activity could be suitably measured in cell lysate and living cells by this new conjugate. These data suggest its potential for measurements of calpain activity *in vivo*.

EXPERIMENTAL PROCEDURES

Materials. All amino acid derivatives were purchased from Bachem (Bubendorf, Switzerland) and Reanal (Budapest, Hungary), while thioanisole, ethandithiol (EDT), *N*-diisopropylethylamine (DIEA), 1-hidroxybenztriazole (HOBt), benztriazol-1-yloxy)tris(dimethyl-amino)phosphonium-hexafluorophosphate (BOP), *N*,*N*′-diisopropylcarbodiimide (DIC), piperidine, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), trifluoracetic acid (TFA), and 5(6)-carboxyfluorescein (cf) were Fluka (Buchs, Switzerland) products. The Rink-amide MBHA resin and *N*-{4-[4′-(dimethylamino)phenylazo]benzoyloxy}succinimide (Dabcyl-OSu) were purchased from Novabiochem (Laufelfingen, Switzerland). The 5-(2-aminoethylamino)-1-naphtalenesulfonic acid (EDANS) was purchased from Sigma-Aldrich Kft. (Budapest, Hungary). Solvents (DMF, DCM, diethyl ether, acetonitrile) for synthesis and purification were obtained from Reanal (Budapest, Hungary).

The fluorescent substrate LY-AMC (catalog no. S 1153) and all other chemicals used in biological experiments were purchased from Sigma. The buffers were prepared with ion-exchanged distilled water.

Analytical RP-HPLC. Analytical HPLC was performed on a Knauer (Herbert Knauer GmbH, Berlin, Germany) system using a Phenomenex SYNERGI MAX-RP column (250 × 4.6 mm i.d., 4 μm silica, 80 Å pore size) (Torrance, CA) as a stationary phase. Linear-gradient elution (0 min 0% B; 5 min 0% B; 50 min 90% B) was generated using 0.1% TFA in water as eluent A and 0.1% TFA in acetonitrile−water (80:20, V/V) as eluent B. A flow rate of 1 mL/min was applied at ambient temperature. Peaks were detected at $\lambda = 220$ nm. The samples were dissolved in eluent B. The crude products were purified on a semipreparative Phenomenex Jupiter C18 column (250 × 10 mm i.d., 10 μm silica, 300 Å pore size) (Torrance, CA). The flow rate was 4 mL/min. Peaks were detected at $\lambda = 220$ nm.

Mass Spectrometry. The molecular mass of the conjugates was measured by ESI-MS. Positive ion electrospray ionization mass spectrometric analysis was performed on a Bruker Daltonics Esquire 3000 plus (Germany). The samples were dissolved in acetonitrile−water (50:50, V/V), containing 0.1% acetic acid.

Synthesis of Dabcyl-TPLKSPPPSPRE(EDANS)RRRR-RRR-NH_2 Peptide. This conjugate was synthesized manually by solid-phase methodology on Rink-amide resin (0.230 g, 0.7 mmol/g) by Fmoc/^{t}Bu strategy. Fmoc protection from the N^α-amino group was removed with 2% piperidine and 2% DBU in DMF (2 + 2 + 5 + 10 min) followed by washing with DMF (8 × 0.5 min). Amino acid derivatives, DIC, and HOBt were dissolved in DMF in 3 molar excess for the resin capacity to the coupling proceeded for 60 min at RT. Then, the resin was washed (DMF (2 × 0.5 min), DCM (3 × 0.5 min)). The efficiency of the coupling was checked by ninhydrin (*25*) or isatin (*26*) tests. After the removal of the last N^α-Fmoc group, a Dabcyl group was introduced to the *N*-terminus of the peptidyl-resin by 1.5 equiv Dabcyl-OSu dissolved in DMF. The reaction was carried out overnight. Peptide was cleaved by 10 mL TFA, using 0.75 g phenol, 0.5 mL distilled ion-exchanged water, 0.5 mL thioanisole, and 0.25 ethandithiol as scavengers. Crude product was precipitated by dry diethyl ether, dissolved in 10% acetic acid, and freeze-dried. Crude *Dabcyl*-TPLKSPPPSPRERRRRRRR-NH_2 (21 mg, 8 μmol) was dissolved in 1 mL DMF, and 2 equiv Fmoc-OSu (5 mg, 16 μmol) and 1 equiv DIEA (2 μL, 8 μmol) were added to the solution. The reaction was performed for 3 h; after the mixture was purified by RP-HPLC, gradient was 0 min 20% B, 7 min 20% B, 52 min 85% B. The EDANS was coupled to the *Dabcyl*-TPLK(*Fmoc*)SPPPSPRERRRRRRR-NH_2 peptide (20 mg, 7 μmol) in 1 mL DMF. 2 equiv EDANS (4 mg, 14 μmol), BOP (6 mg, 14 μmol), HOBt (2 mg, 14 μmol), and 4 equiv DIEA (5 μL, 28 μmol) were used in the coupling reaction. After 1 day, the solution was purified by RP-HPLC, gradient was 0 min 35% B, 7 min 35% B, 52 min 80% B. The product was not pure but this fraction was used in the next step. Fmoc group was removed by 20% piperidine in DMF. After acidification, the cleavage mixture was purified by RP-HPLC; gradient was 0 min 20% B, 7 min 20% B, 52 min 85% B.

Synthesis of 5(6)-Carboxyfluorescein Labeled Peptides. The *H*-TPLKSPPPSPRE-NH_2 peptide amide was synthesized by solid-phase methodology on Rink-amide resin (50 mg, 0.72 mmol/g) using Fmoc chemistry on a Syro (Multisyntech, Written, Germany) peptide synthesizer. The Fmoc protection from the N^α-amino groups was removed with 40% piperidine in DMF (2 + 15 min) followed by washing with DMF (6 × 0.5 min). For coupling, amino acid derivatives, DIC and HOBt dissolved in DMF were used in 4 molar excess for the resin capacity. The reaction proceeded for 60 min at RT. Then, the resin was washed (DMF (4 × 0.5 min) and the coupling process was repeated. After the removal of last N^α-Fmoc group, a Dabcyl group was introduced to the *N*-terminus of the peptidyl-resin by 1.5 equiv Dabcyl-OSu dissolved in DMF. The reaction was carried out overnight. Peptide was cleaved by 10 mL TFA, using 0.75 g phenol, 0.5 mL D.I. water, 0.5 mL thioanisole, and 0.25 ethandithiol as scavengers. Crude product was precipitated by dry diethyl ether, dissolved in 10% acetic acid, and freeze-dried. The crude product was purified on FPLC System (Pharmacia, Uppsala, Sweden). 5 mg (3.2 μmol) *Dabcyl*-TPLKSPPPSPRE-NH_2 was reacted with 2.5 mg (4 μmol) pentachlorophenyl ester of 5(6)-carboxyfluorescein (cf-OPcp) in 0.5 mL DMF in the presence of 0.8 μL (4.8 μmol) DIEA overnight. The cf labeled substrate was purified by RP-HPLC. Linear gradient elution was applied: 0 min 25% B, 8 min 25% B, 53 min 75% B.

Dabcyl-TPLK(*cf*)SPPPSPRERRRRRRR-NH_2 was prepared in solution. 5 mg (2 μmol) *Dabcyl*-TPLKSPPPSPRERRRRRRR-NH_2 was reacted with 2 mg (3.2 μmol) cf-OPcp in DMF in the presence of 0.5 μL (3 μmol) DIEA overnight. The reaction mixture was purified by RP-HPLC system. Linear gradient elution was applied: 0 min 5% B, 10 min 25% B, 55 min 70% B.

Enzyme Assay. Kinetic analysis was carried out with cell-penetrating substrate using *Drosophila* Calpain B enzyme in a Jasco FP-6300 spectrofluorometer (Essex, U.K.), in a 3 × 3 mm quartz cuvette at room temperature. The excitation wavelength was $\lambda = 320$ nm, and emission was monitored at $\lambda = 480$ nm. The reactions were carried out in 50 μL calpain buffer (50 mM TRIS, 150 mM NaCl, 1 mM EDTA, pH 7.5), which contained 20 mM $CaCl_2$, 0.5 μM Calpain B, and the cell-penetrating substrate with concentration in the range 1−200 μM. The reaction was followed by continuously recording the increase of fluorescence intensity corresponding to the cleavage of the substrate. The initial rate of change of the fluorescence

intensity was determined from the progress curves, using *MicroCal Origin* software.

Analysis of Cellular Uptake by Fluorescent Microscopy. COS-7 cells were grown in Dulbecco's modified Eagle's medium (Sigma-Aldrich Kft, Budapest, Hungary) at 37 °C and 5% CO_2 content. The substrates were dissolved in 0.01 M PBS (pH = 7.4) and used at a final concentration of 330 μM. Cells were incubated for 4 h with substrates, then washed with PBS. The fluorescence of cells after fixation (3% *para*-formaldehyde for 10 min) mounted with MOWIOL 4−88 (Calbiochem, MERCK Kft., Budapest, Hungary) was analyzed by a Leica DMLS fluorescent microscope equipped with a Spot RT color digital camera (Diagnostic Instruments, Livingston, U.K.).

Analysis of Cellular Uptake by Flow Cytometry. COS-7 cells were plated into 24 well plates 24 h prior to treatment. Cells were washed twice with serum-free medium. The cells were incubated with the labeled peptides and conjugates for 3 h at 37 °C. Following the incubation, cells were trypsinized with PBS containing 5 mg/mL trypsin and 2 mg/mL EDTA. The change of cellular fluorescence was analyzed by flow cytometry on a BD LSR II cytometer. Data were analyzed with FACSDiVa and *WinMDI 2.9* software. Fluorescence mean values of untreated control were subtracted from the mean fluorescence of treated samples. Statistical analysis of data was performed using Student's *t* test at the 95% confidence level.

Measurement of Intracellular Calpain Activity. *Drosophila melanogaster* Schneider S2 cells ($1-1.5 \times 10^7$) were collected by centrifugation at 2000 rpm for 5 min and washed three times with 10 mL of 0.01 M PBS (pH 7.4). Collected cells were resuspended in 300 μL 0.05 M TRIS buffer containing 0.15 M NaCl, 10 mM EDTA, 10 mM β-mercaptoethanol, 10 mM benzamidine, and 1 mM phenylmethylsulphonyl fluoride, and then were sonicated (16 μm, MSE sonicator, West Sussex, U.K.) four times for 10 s with 1 min breaks at 0 °C. After sonication, the cell lysate was centrifuged at 100 000 × *g* for 20 min at 4 °C, and the supernatant was used for fluorometric calpain activity measurement. In the case of the induction of the exogenous calpain gene, cells were incubated with 0.7 μM $CuSO_4$ for 12−16 h before collection.

1 mM LY-AMC or 100 μM *Dabcyl*-TPLKSPPPSPRE(*EDANS*)RRRRRRR-NH_2 were used as substrate for fluorometric calpain activity measurement in 50 μL calpain buffer (50 mM TRIS, 150 mM NaCl, 1 mM EDTA, pH 7.5), which contained 25 μL S2 cell lysate, 5 mM EDTA, or 10 mM free Ca^{2+}. The final concentration of the inhibitor (Calpain Inhibitor I) was 20 μM. The excitation and emission wavelengths were $\lambda = 320$ nm and $\lambda = 480$ nm, respectively.

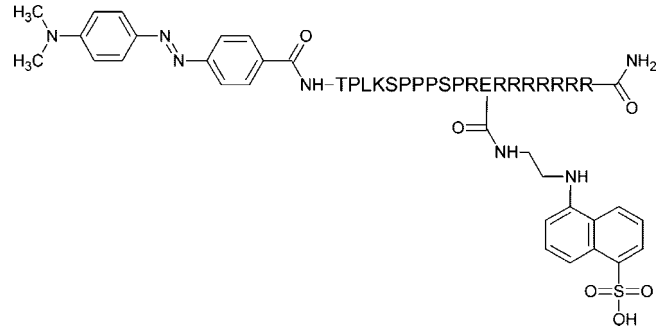

Figure 1. Structure of cell-penetrating calpain substrate.

Activity Measurement with Cells Incubated with Cell-Penetrating Substrate. Confluent S2 cells were incubated with 150 μM *Dabcyl*-TPLKSPPPSPRE(*EDANS*)RRRRRRR-NH_2 substrate in 1 mL Drosophila-SFM medium at 25−28 °C for 20 h. After incubation, cells were washed with 0.01 M PBS (pH 7.4) three times and then gently suspended in 1 mL calpain buffer (50 mM TRIS, 150 mM NaCl, 1 mM EDTA, pH 7.5) without EDTA. Cells were collected by centrifugation (2000 rpm × 5 min) and washed calpain buffer without EDTA until the supernatant became colorless. Washed cells, $1-1.2 \times 10^7$ in 300 μL calpain buffer without EDTA, were separated into two: one-half of them were used for *in vivo* activity measurement (with the cells intact) and the other half were lysed and used for fluorometric calpain activity measurement as described above.

In vivo activity measurements were carried out in a Jasco FP-6300 spectrofluorometer (Essex, U.K.), in a 3 × 3 mm quartz cuvette at room temperature using 50 μL cell suspension. Fluorescence intensity was monitored continuously from the start, and at about 1000 s after the initiation of the measurement, 20 μM ionomycin (from 1 mM stock solution) was added. After 1200 s, the fluorimeter was restarted, keeping the cuvette untouched, and an additional 500 s later, the cells were stirred up and the measurement was continued.

RESULTS

Synthesis of Cell-Penetrating Calpain Substrate. For the synthesis of new cell-penetrating calpain substrate, the peptide substrate (*10*) was elongated by a Glu and seven Arg residues at its C-terminus (Figure 1). The modified substrate sequence was prepared by solid-phase peptide synthesis using Fmoc/^{t}Bu strategy as outlined in Scheme 1. After the cleavage of the last N^{α}-Fmoc protecting group, Dabcyl fluorophore was coupled to the *N*-terminal amino group of resin-bound peptide by using

[a] Column: Phenomenex Jupiter C18 (250 × 4.6 mm, 5 μm, 300 Å). Linear gradient elution (0 min 0% B; 5 min 0% B; 50 min 90% B) with eluent A (0.1% TFA in water) and eluent B (0.1% TFA in acetonitrile−water (80:20, V/V)) was used at a flow rate of 1 mL/min at ambient temperature. Peaks were detected at λ = 220 nm. [b] ESI-MS, masses presented as $[M+H]^+$ were calculated from multiple charged ions.

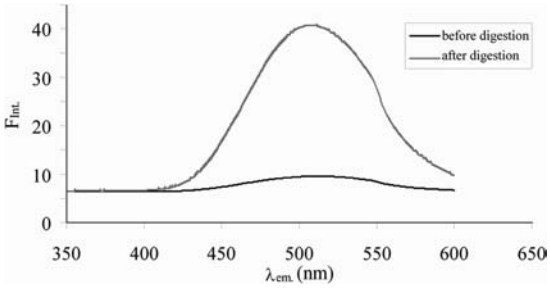

Figure 2. Fluorescence intensity before and after digestion of cell-penetrating substrate by isolated Calpain B enzyme. The substrate (200 μM) was digested by Calpain B enzyme (0.5 μM) in calpain buffer (50 mM TRIS, 150 mM NaCl, 1 mM EDTA, pH 7.5) for 40 min, and the fluorescence spectrum of the substrate was recorded before (solid line) and after (dashed line) digestion.

its active ester derivative (Dabcyl-OSu). The substrate containing Dabcyl group was cleaved from the resin by TFA cleavage mixture. The crude peptide was used in the next reactions without purification. The ϵ-amino group of Lys residue in the sequence was temporarly protected by Fmoc group, coupled in solution. Then, the EDANS fluorophore was attached to the semiprotected peptide by BOP/HOBt coupling reagent. The cell-penetrating FRET substrate was isolated by RP-HPLC purification after the cleavage of Fmoc group (Scheme 1). The compounds were characterized by analytical RP-HPLC and ESI-MS (Table 1). Their purity was higher than 95% based on analytical HPLC.

Enzyme Kinetics. The kinetic parameters of cell-penetrating FRET substrate (*Dabcyl*-TPLKSPPPSPRE(*EDANS*)RRRRRRR-NH_2) were studied by using Calpain B enzyme. Data are summarized in Figure 2. Before cleavage by calpain, the level of fluorescence is low, but calpain cleavage results in an about 4-fold increase in fluorescence intensity. The increase in the fluorescence intensity indicated that cell-penetrating substrate is cleaved by Calpain B enzyme and this level of the change is enough for the kinetic measurements.

Kinetic parameters were determined with digestion of cell-penetrating substrate using it in the 1−200 μM concentration range. The change of fluorescence intensity was recorded and parameters were calculated. Based on the kinetic parameters one could appreciate that the cell-penetrating substrate conjugate is an appropriate substrate of Calpain B enzyme (k_{cat} = 0.2 s^{-1} and k_{cat}/K_M = 5000 M^{-1} s^{-1}). In comparison to the free peptide substrate (*Dabcyl*-TPLKSPPPSPR-*EDANS*) (k_{cat} = 0.17 s^{-1} and k_{cat}/K_M = 680 M^{-1} s^{-1}) (*10*), the conjugation with heptaarginine not only preserved but increased the sensitivity of Calpain B enzyme. However, the molar change in the fluorescence intensity is dependent on the initial concentration of cell-penetrating

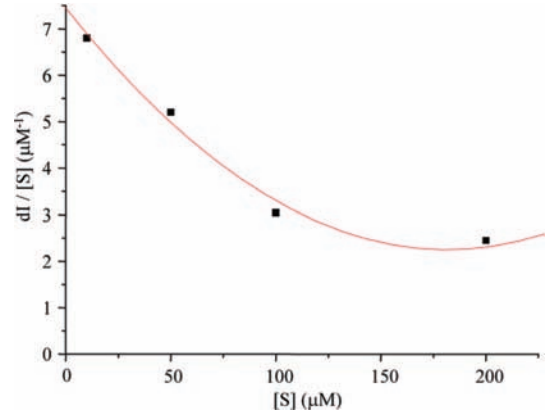

Figure 3. Molar change of fluorescence intensity as a function of the initial concentration of cell-penetrating substrate conjugate. The substrate at different concentrations was digested by Calpain B enzyme (0.5 μM) in calpain buffer (50 mM TRIS, 150 mM NaCl, 1 mM EDTA, pH 7.5) for 10 min, and the fluorescence spectrum of the substrate was recorded.

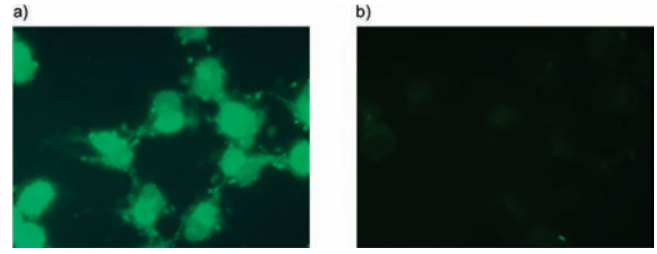

Figure 4. Internalization of substrates into COS-7 cells. The COS-7 cells were treated with 330 μM solution of (a) cell-penetrating substrate conjugate, (b) free peptide substrate for 4 h at 37 °C, and then the fixed cells were examined by fluorescence microscopy.

substrate (Figure 3). At low concentration, the degree of change was decreased steeply and at c = 100 μM reached minimum value.

Internalization of Calpain Substrates into COS-7 Cells. The internalization properties of the substrates were studied first by fluorescence microscopy. COS-7 cells were treated by the peptide substrate (*Dabcyl*-TPLKSPPPSPR-*EDANS*) and cell-penetrating substrate conjugate (*Dabcyl*-TPLKSPPPSPRE(*EDANS*)RRRRRRR-NH_2), then the fluorescence intensity of cells was recorded (Figure 4). In case of the free peptide substrate, the cells had almost no fluorescence intensity. When the cells were treated by cell-penetrating substrate conjugate, high fluorescence was detected and the fluorescence intensity was found to be homogeneous in cells.

The concentration dependence of cell uptake of cf labeled substrates was studied by flow cytometry. COS-7 cells were treated with the labeled substrates (*Dabcyl*-TPLK(*cf*)SPPPSPRE-NH_2 and *Dabcyl*-TPLK(*cf*)SPPPSPRERRRRRRR-NH_2), and then cells were trypsinised and their fluorescence intensity was measured by flow cytometry (Figure 5). Peptide substrate showed poor internalization at 10 μM concentration (F_{mean} = 334), which could be increased by elevation of the concentration (at 50 μM concentration F_{mean} = 1159.5). On the other hand, uptake of cell-penetrating substrate conjugate was significant (F_{mean} = 15 097.5) at 10 μM concentration. At higher concentration, the efficiency of penetration was at a similar level (at 50 μM, F_{mean} = 12 724.5).

Measurement of Intracellular Calpain Activity. Considering that the cell-penetrating substrate conjugate seemed to be a good substrate *in vitro* (Figure 2) and could translocate into COS-7 cells (Figures 4 and 5), we extended our studies to evaluate its applicability for measurements of intracellular

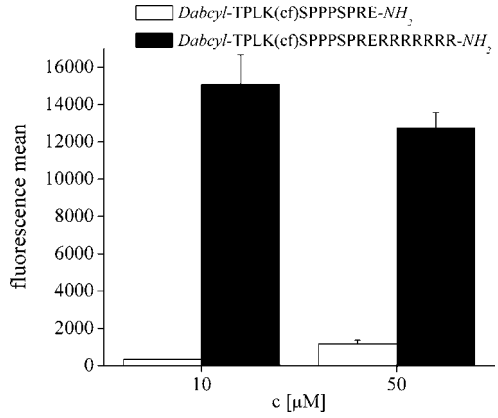

Figure 5. Concentration-dependent cell uptake of *Dabcyl*-TPLK(cf)-SPPPSPRE-NH_2 and *Dabcyl*-TPLK(cf)SPPPSPRERRRRRRR-NH_2 by COS-7 cells. COS-7 cells were incubated with the solution of substrates at $c = 10$ or 50 μM for 3 h. Then, the cells were trypsinized and fluorescence intensity was measured by flow cytometry.

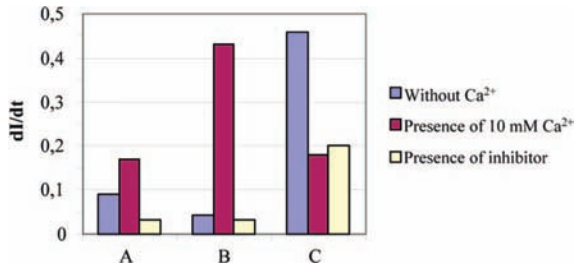

Figure 6. Change in the fluorescence intensity of *Dabcyl*-TPLKSP-PPSPRE(*EDANS*)RRRRRRR-NH_2 A. *Dabcyl*-TPLKSPPPSPRE(*EDAN-S*)RRRRRRR-NH_2 added to S2 cell lysate. B. *Dabcyl*-TPLKSP-PPSPRE(*EDANS*)RRRRRRR-NH_2 added to lysate of S2 cell overexpressing calpain. C. LY-AMC added to lysate of S2 cell overexpressing calpain.

calpain activity. Therefore, first we used cell-penetrating substrate to determine calpain activity in the lysate of *Drosophila melanogaster* S2 cells. The cell-penetrating substrate conjugate was added to the cell lysate and the change in the fluorescence intensity was measured. We found that the substrate was cleaved in the cell lysate, which could be inhibited by Calpain inhibitor I (Figure 6 column A). The increase of the fluorescence intensity was the largest in presence of Ca^{2+}. In order to prove the calpain cleavage of substrate, lysate of cells overexpressing calpain was used (Figure 6 column B). We observed the same phenomenon as in case of normal cells. It is interesting to note that the differences between the fluorescence intensity changes recorded in the absence or in the presence of Ca^{2+} were more expressed. As control, the commercially available LY-AMC substrate was also included into experiments with cell lysate of calpain-overexpressing cells (Figure 6 column C). No change in the fluorescence intensities was detected in relation to calpain activity.

What happens with the substrate in the cells is an important question. Does it remain intact or is it digested intracellular by enzyme? To address this, the S2 cells were treated with the solution of cell-penetrating substrate conjugate and were lysed. The activity of endogenous calpain in the lysate was measured after Ca^{2+} activation. Data are summarized in Figure 7. In the absence of Ca^{2+} ion, only the base fluorescence intensity was detected. This was not altered until the time point of Ca^{2+} ion addition (0−700 s). The addition of Ca^{2+} initiated the increase in the fluorescence intensity, an indication of the activation of calpain.

In the third experiment, the activity of endogenous calpain was measured in living cells. The S2 cells were treated with

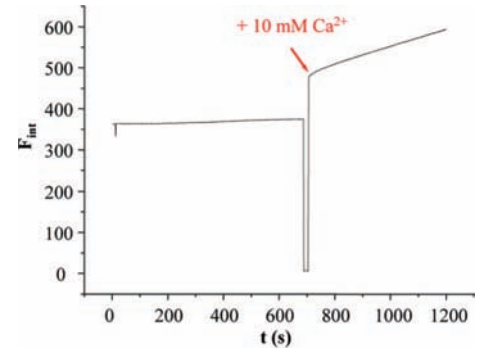

Figure 7. Change of fluorescence intensity of lysate of cells treated with cell-penetrating substrate conjugate. The change of fluorescence intensity in the presence of Ca^{2+} indicates the difference of enzyme activity in the lysate of S2 cells after treatment by cell-penetrating substrate. $\lambda_{ex.} = 320$ nm, $\lambda_{em.} = 480$ nm.

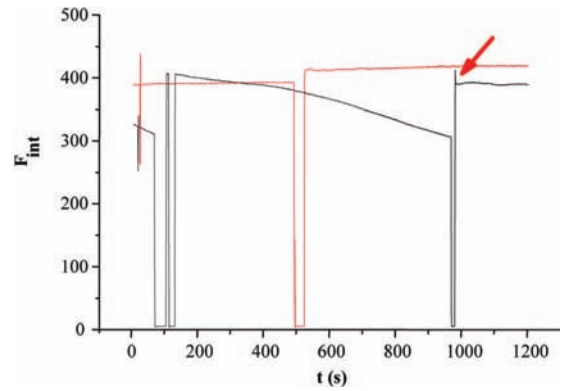

Figure 8. Change in the fluorescence intensity of the S2 cell suspension. The S2 cells were incubated with cell-penetrating substrate and the fluorescence intensity of cell suspension was detected. The black curve shows the decreasing fluorescence intensity, due to the sedimentation of cells. After addition of ionomicin (red arrow), a slight increase in the fluorescence intensity was measured (red curve).

cell-penetrating substrate; then, ionomycin was added to the cells and the fluorescence intensity was monitored. Results outlined in Figure 8 show that the fluorescence intensity is decreased (black curve) due to the sedimentation of cells. After the addition of 10 μM ionomycin (red arrow), the fluorescence intensity slightly increased, indicating calpain activation and substrate cleavage.

DISCUSSION

The calpains, Ca^{2+} dependent Cys proteases, play important roles in many different physiological and pathological processes. To study their function, dipeptide substrates are widely used. To understand better the calpain cleavage specificity, the preferred amino acids in the P_4-P_7' position of 101 calpain cleavage site was studied and a preference matrix was constructed (*10*). We found earlier that the FRET derivative of peptide (*Dabcyl*-TPLKSPPPSPR-*EDANS*) derived from the preference matrix was a better substrate than the LY-AMC dipeptide (*10*).

Our aim was to prepare a conjugate of the matrix substrate to enhance the internalization efficiency and to measure the activity of intracellular calpain by conjugation with heptaarginine. Considering the presence of an Arg residue in the substrate sequence, seven Arg residues were attached to the C-terminus of substrate. For the FRET analysis, the chromophore and the fluorophore must be within a given distance. In the free substrate peptide, the distance of the two groups was appropriate for FRET. In our cell-penetrating

substrate conjugate, incorporation of seven Arg residues between the chromophores might diminish FRET. To avoid this, a Glu residue was inserted between the substrate and the heptaarginine part. In this case, the eight Arg residues do not connect continuously. It was demonstrated before that the number of Arg residues in the sequence is important for sufficient penetration, but not their linear connection (*24*). The Dabcyl chromophore was attached at the *N*-terminus of the cell-penetrating peptide, while the EDANS fluorophore to the γ-carboxylic group of Glu residue.

Though the sequence of substrate was only slightly modified in respect to FRET pairs, first the FRET phenomenon was studied. Our result suggests that the distance between the FRET pair was not higher than their Förster radius (33 Å), and the change in fluorescence intensity was sufficient for the detection of calpain activation *in vitro*.

Next, the substrate properties of the conjugate were studied. We observed that the presence of seven Arg residues does not interfere with the substrate properties, but rather improves them. The k_{cat}/K_M of cell-penetrating substrate was higher, indicating that it is a better substrate than the free peptide. The mechanism of the effect of heptaarginine had not been studied. Considering that this part of the conjugate is outside the sequence responsible for FRET, cleavage(s) in this part of the molecule were not detected in the experiments. It is attractive to speculate that the presence of heptaarginine results in such a conformer, which could fit better into the substrate pocket, or the positively charged heptaarginine could improve the substrate binding to the enzyme. The molar fluorescence intensity change is dependent on the concentration of cell-penetrating substrate. At low concentrations, the change was higher and decreased steeply on increasing concentration.

The internalization and distribution of the conjugate in COS-7 cells were followed by fluorescent microscopy. As expected, the free peptide substrate did not exhibit internalization; the cells had no fluorescence. In contrast, if the cells were treated with cell-penetrating substrate conjugate, high fluorescence intensity was observed. The internalized cell-penetrating substrate distributed nearly homogeneously in the cytosol. Based on these results, one could conclude that the conjugation of seven Arg residues resulted in marked and detectable internalization of the peptide substrate.

For studying the effect of substrate concentration, cell uptake was also monitored by flow cytometry. It should be noted that for the sake of comparison the Glu-modified substrate, as a component of the cell-penetrating substrate conjugate, was used. The free substrate peptide showed poor internalization at 10 μM concentration. The conjugation of seven Arg residues resulted in highly efficient translocation even at this concentration. The increase of concentration (to 50 μM) could slightly improve the cell uptake of substrate peptide; however, the cell-penetrating substrate internalized almost with the same efficiency. The results suggest that the cell-penetrating substrate can efficiently penetrate into cells even at low concentration.

The substrate properties of new cell-penetrating substrate conjugate and its efficient internalization into COS-7 cells suggest that this compound could be suitable for *in vivo* measurement of calpain activity. To study the specificity of the new substrate, calpain activity was measured in S2 cell lysate in comparison with commercially available LY-AMC substrate. While the dipeptide substrate did not signal calpain activation, the conjugate was able to detect calpain activity after addition of Ca^{2+} ion. The differences between the signal with and without Ca^{2+} addition suggest that this substrate is appropriate for activity measurement in cell lysate. To prove the calpain function in the substrate cleavage, lysate of S2 cells overexpressing calpain was also examined. In this case, the fluorescence intensity change in the presence of Ca^{2+} was remarkably higher as compared to the effect observed in the absence of the ion.

In order to have some information about the fate of the conjugate after internalization, S2 cells were treated with the cell-penetrating substrate conjugate and lysed after. We found that Ca^{2+} addition resulted in increased fluorescence intensity. This might be indicative of retained substrate integrity and cleavage only after activation of calpain. The fluorescence intensity of cell-penetrating substrate conjugate treated S2 cell suspension increased significantly after addition of ionomycin. This result indicates that intracellular release of Ca^{2+} could induce activation as well and might suggest that the new cell-penetrating substrate conjugate is suitable for measurement of intracellular calpain activity.

Received January 31, 2008; Revised Manuscript Received May 15, 2008

D-Penicillamine (D-pen) is an established copper chelator. We have recently shown that the copper-catalyzed D-pen oxidation generates concentration-dependent hydrogen peroxide (H_2O_2). Additionally, D-pen coincubated with cupric sulfate resulted in cytotoxicity in human leukemia and breast cancer cells due to the extracellular generation of reactive oxygen species (ROS). The inherent physicochemical properties of D-pen such as its short *in vivo* half-life, low partition coefficient, and rapid metal catalyzed oxidation limit its intracellular uptake and the potential utility as an anticancer agent *in vivo*. Therefore, to enhance the intracellular delivery and to protect the thiol moiety of D-pen, we designed, synthesized, and evaluated a novel gelatin-D-pen conjugate. D-pen was covalently coupled to gelatin with a biologically reversible disulfide bond with the aid of a heterobifunctional cross-linker (*N*-succinimidyl-3-(2-pyridyldithio)-propionate) (SPDP). Additionally, fluorescein-labeled gelatin-D-pen conjugate was synthesized for cell uptake studies. D-pen alone was shown not to enter leukemia cells. In contrast, the qualitative intracellular uptake of the conjugate in human leukemia cells (HL-60) was shown with confocal microscopy. The conjugate exhibited slow cell uptake (over the period of 48 to 72 h). A novel HPLC assay was developed to simultaneously quantify both D-pen and glutathione in a single run. The conjugate was shown to completely release D-pen in the presence of glutathione (1 mM) in approximately 3 h in PBS buffer, pH 7.4. The gelatin−D-pen conjugate resulted in significantly greater cytotoxicity compared to free D-pen, gelatin alone, and a physical mixture of gelatin and D-pen in human leukemia cells. Further studies are warranted to assess the potential of D-pen conjugate in the delivery of D-pen as a ROS generating anticancer agent.

INTRODUCTION

D-Penicillamine (D-pen) is a copper chelating agent that is currently approved by the FDA for the treatment of Wilson's disease and rheumatoid arthritis. In recent years, there has been immense interest in the use of copper chelators including D-pen as antiangiogenic agents (*1*, *2*). This is due to the now-established role of copper in angiogenesis. Copper is known to act as a cofactor for a variety of important endogenous pro-angiogenic compounds such as fibroblast growth factor (FGF) and vascular endothelial growth factor (VEGF) (*2*). Thus, it has been proposed that copper chelation by D-pen could lead to an antiangiogenic effect. It is also known that the interaction of D-pen with copper during chelation leads to the generation of hydrogen peroxide (H_2O_2) and other reactive oxygen species (ROS) (*1*, *3*, *4*). We have recently confirmed, both qualitatively and quantitatively, that copper-catalyzed D-pen oxidation generated concentration-dependent H_2O_2 (*5*). In addition, we have shown that D-pen coincubated with cupric sulfate resulted in concentration-dependent cytotoxicity in both human breast cancer (MCF-7, BT474) and leukemia cells (HL-60, HL-60/VCR) in culture (*6*).

As copper levels have been reported to be significantly elevated in the serum (*7*, *8*) and the tumor tissue (*9*–*11*) of cancer patients, we believe that our studies in the investigation of D-pen cytotoxicity in the presence of copper have significant potential. Therefore, we hypothesized that novel formulation strategies that could increase the intracellular delivery of D-pen would potentially lead to the use of D-pen as a dual anticancer agent via (1) cytotoxicity, through the intracellular generation of H_2O_2 and other ROS, (2) antiangiogenesis, through the well-known copper chelation process. However, the physicochemical properties of D-pen would limit the anticancer efficacy of D-pen *in vivo*. These limiting properties include (i) extreme hydrophilicity (Log $P = -0.39$) (*12*), thus limiting its intracellular uptake in cancer cells (*13*, *14*), (ii) rapid elimination from the blood exhibiting biphasic kinetics (*15*, *16*), and (iii) sensitivity to oxidation. The thiol group of D-pen is critical to both copper chelation and H_2O_2 generation; however, D-pen is prone to oxidation resulting in the formation of inactive D-pen disulfide or mixed disulfides. Therefore, the efficacy of D-pen as an anticancer agent would depend on its successful delivery to cancer cells in its reduced form or a modified form which could then be reversibly converted intracellularly to bioactive D-pen.

We have previously reported on a novel D-pen-nanoparticle formulation for metal chelation therapy (*17*). Also, Chvapil et al. recently reported on the synthesis of a hexyl-D-pen-ester that converted D-pen to a more lipophilic form (Log $P = 1.61$) (*12*, *18*). The ester prodrug strategy for D-pen delivery could potentially have problems such as (i) the lack of protection

of the critical thiol group and (ii) the slow rate of D-pen release from the lipophilic ester prodrug. This could result in less than effective free D-pen concentrations *in vivo*. To overcome these potential problems, we designed a novel conjugate of D-pen wherein D-pen was linked to a macromolecular polymer via a biologically reversible disulfide bond. In recent years, the covalent conjugation of low molecular weight drugs with soluble macromolecular carriers (peptides, protein, and polymers) has been the focus of considerable research (*19, 20*).

Gelatin is a partially hydrolyzed form of collagen (*19*). Gelatin has been used in oral delivery technologies such as hard and soft capsules and is recently being examined as a carrier in novel drug delivery (*21*). Gelatin has been reported to be both biocompatible and biodegradable (*21, 22*). These and other desirable physiochemical properties of gelatin make it a suitable carrier for the delivery of genes (*23–25*), and chemotherapeutic agents formulated as conjugates (*19, 20, 26, 27*), nanoparticles (*21, 28–31*), complex coacervates (*24*), and as microspheres (*21, 25*). Both the carboxyl and the amino groups of gelatin have been modified for drug conjugation (*22, 27*).

In the present studies, we describe the synthesis of a soluble gelatin-D-pen conjugate through the modification of gelatin with the aid of a heterobifunctional cross-linker, sulfosuccinimidyl 6-(3′(2-pyridyldithio)-propionamido) hexanoate (sulfo-LC-SPDP) (water-soluble derivative of SPDP). Gelatin was coupled to D-pen using SPDP to form a potentially biologically reversible disulfide bond. The disulfide bond was an attractive strategy for D-pen delivery due to (i) enhanced protection of the thiol group of D-pen from oxidation before it reaches the site of action, (ii) its potential for intracellular reversibility (due to the presence of ∼1−11 mM of glutathione inside the cells) (*32–34*), and (iii) its reported relative stability in plasma (*35*).

The overall objectives of the present studies were to (1) synthesize and characterize a novel disulfide gelatin−D-pen conjugate; (2) evaluate the *in vitro* release of D-pen from the gelatin-D-pen conjugate as a function of glutathione concentration, time of incubation with glutathione, and pH; (3) evaluate the intracellular uptake of free D-pen and fluorescein labeled gelatin−D-pen conjugate in human leukemia cells (HL-60); and (4) investigate the *in vitro* cytotoxicity of gelatin−D-pen conjugate in HL-60 cells compared to free D-pen, gelatin alone, and the physical mixture of gelatin with D-pen.

EXPERIMENTAL PROCEDURES

Materials. Type B gelatin (75 bloom strength) with 100−115 mmol of carboxylic acid per 100 g of protein, an isoelectric point of 4.7−5.2, and an average molecular weight of 20 000−25 000 Da, D-penicillamine (D-pen), D-penicillamine disulfide, glutathione, glutathione disulfide, dithiothreitol (DTT) were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO). Sulfosuccinimidyl 6-(3′(2-pyridyldithio)-propionamido) hexanoate (Sulfo-LC-SPDP), 2,4,6-trinitrobenzene sulfonic acid (TNBS) reagent, *N*-hydroxysuccinimide-fluorescein (NHS-Fluorescein), M-PER mammalian cell extraction reagent were purchased from Pierce Biotech Inc. (Rockford, IL). Acetonitrile and *o*-phosphoric acid (85%) were purchased from Fisher Scientific (Pittsburgh, PA). Microcon (YM-10, MWCO: 10 kDa) centrifugal filter devices were purchased from Millipore (Billerica, MA). All aqueous solutions were prepared in deionized distilled water (MilliQ, Millipore Inc.).

Cell Lines and Culture Conditions. The human leukemia cell line (HL-60) was purchased from American type Cell Culture Collection (ATCC, Rockville, MD). Cells were routinely cultured in RPMI-1640 media (Invitrogen, Carlsbad, CA) supplemented with 100 U/mL penicillin, 100 μg/mL streptomycin, and 10% fetal bovine serum (FBS) (ATCC, Rockville, MD) and maintained at 37 °C in a humidified 5% CO_2 incubator. Plasmocin (5 μg/mL) (InvivoGen, San Diego, CA) was added to the cell culture media as a prophylactic measure to prevent mycoplasma contamination. Cell viability was regularly determined by Trypan blue dye (0.4% in phosphate buffered saline) (ATCC, Rockville, MD).

Synthesis and Purification of the Gelatin−D-Pen Conjugate. A heterobifunctional cross-linker (sulfo-LC-SPDP) was employed to conjugate D-pen with gelatin. Sulfo-LC-SPDP has an amine reactive *N*-hydroxysuccinimide (NHS) and a thiol-reactive 2-pyridylthio group. The conjugate synthesis was performed in two steps. Briefly, gelatin (2 mg/mL) was incubated with SPDP for 2 h at room temperature in PBS, pH 7.4. After incubation, excess SPDP was separated from gelatin with microcon centrifugation devices (MWCO: 10 kDa). As described below, the pyridine-2-thione and the TNBS assays were performed to determine the degree of SPDP modification of gelatin. The SPDP-modified gelatin was then incubated with excess D-pen. The gelatin−D-pen conjugate was separated from the unconjugated D-pen with microcon centrifugal devices. The HPLC assay as described below was performed on the filtrate and retentate to determine the amount of D-pen conjugated to gelatin.

The complete and efficient separation of gelatin from unreacted SPDP or D-pen was performed with microcon centrifugation filter devices (MWCO: 10 kDa). Briefly, 500 μL of reaction mixture was added to the microcon filter device, the mixture was centrifuged at 14 000 *g* for 30 min at room temperature. The filtrate was then collected and the retentate was washed twice with 400 μL of fresh PBS buffer. The retentate was finally collected by centrifuging at 3000 *g* for 5 min. Gelatin and D-pen concentration both in the filtrate and in the retentate were quantified as described below.

Synthesis and Purification of the Fluorescein Labeled Gelatin−D-Pen Conjugate. The fluorescent labeling of the conjugate was performed with the aid of an amine-reactive fluorescent probe, NHS-fluorescein. Briefly, NHS-fluorescein was added to gelatin in a 1:1 mol ratio and the mixture was incubated with constant shaking for 1 h at room temperature. The unreacted free fluorescein was separated from fluorescein−gelatin using the microcon centrifugal filter devices. The fluorescein−gelatin was washed three times with PBS, pH 7.4, until the free fluorescein was completely removed. The fluorescein−gelatin was then used to synthesize the conjugate as described above.

CHARACTERIZATION OF THE GELATIN−D-PEN CONJUGATE

Amino Content Determination. 2,4,6-Trinitrobenezene sulfonic acid (TNBS) is a rapid and sensitive assay reagent employed for the determination of free amino groups. Briefly, 50 μL of 0.01% (w/v) TNBS was added to 100 μL of either gelatin or SPDP-modified gelatin in PBS buffer, pH 7.4, and was incubated for 2 h at 37 °C. 25 μL of 1 N HCl was added to stop the reaction. The resulting absorbance was recorded at 335 nm with the Synergy 2 Multi-Detection Microplate Reader (Biotek, Winooski, VT). A standard curve for amino groups was generated using known concentrations of D-pen. The primary amino group was expressed as the amount of TNBS reactive amino groups in 1 g of gelatin. The % amino groups conjugated was calculated as follows: % amino groups conjugated = (amino groups of SPDP modified gelatin/amino groups in gelatin alone) × 100%.

Gelatin Determination. The gelatin concentration was analyzed using the Coomassie Plus assay. Briefly, 10 μL of standard or sample was added to 150 μL of Coomassie Plus Protein Assay Reagent (Pierce Biotech, Rockford, IL), mixed

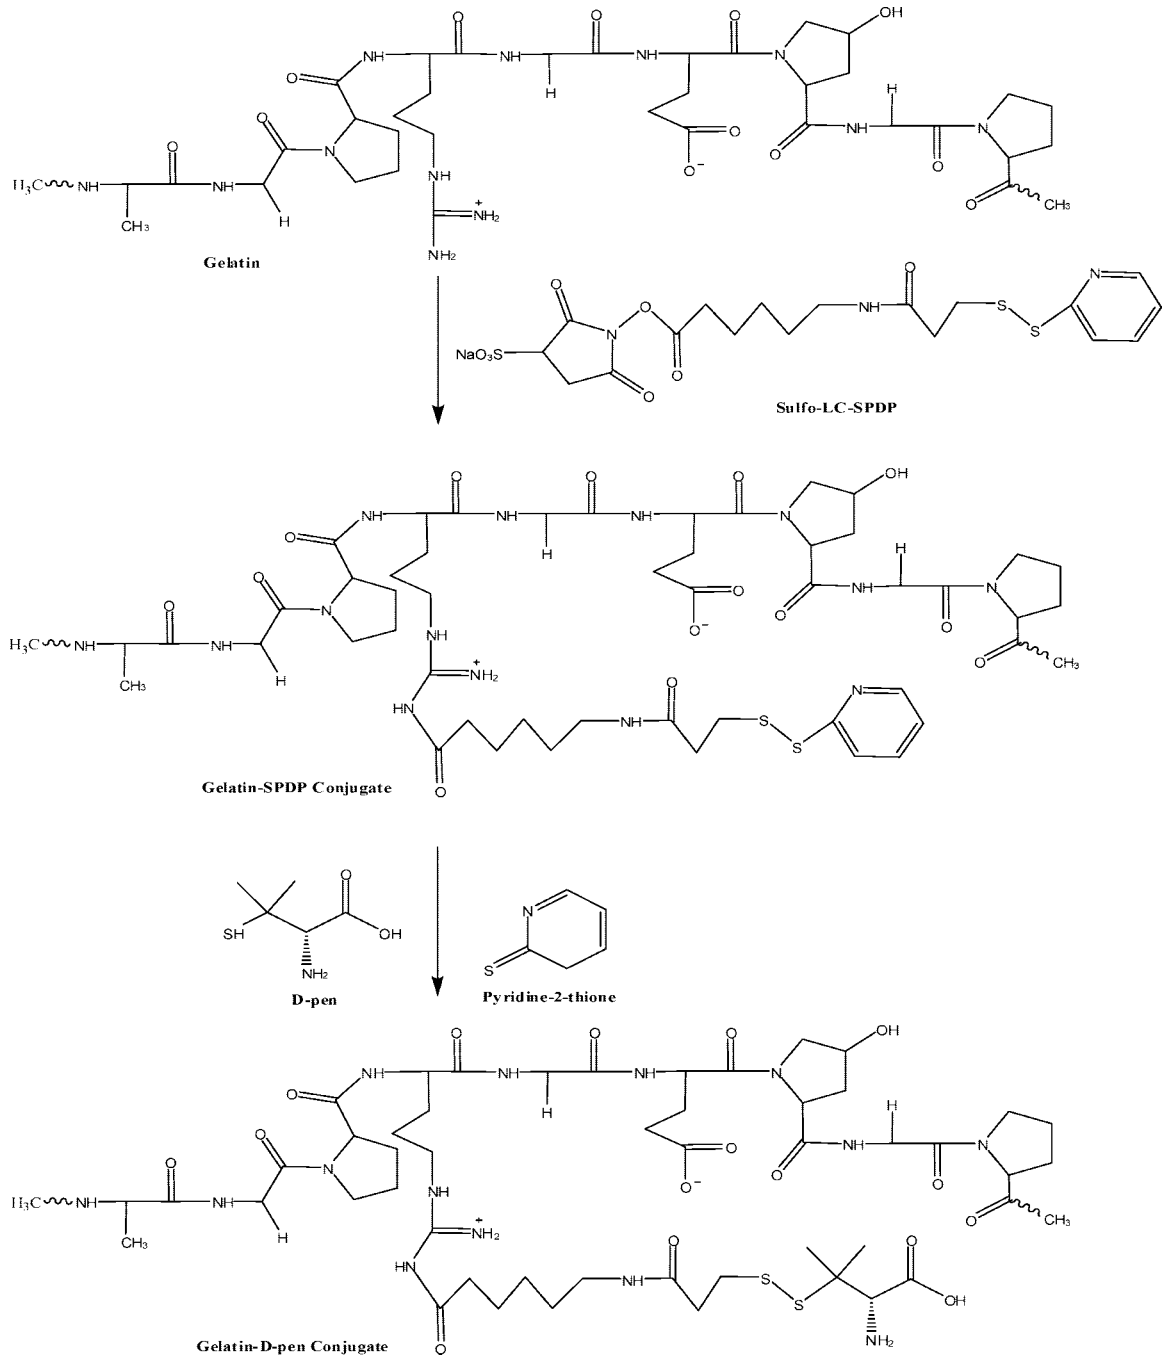

Figure 1. Schematic illustration of gelatin−D-pen conjugate synthesis. The amino group of gelatin was modified with the amine-reactive *N*-hydroxysuccinimide (NHS) portion of sulfo-SPDP and D-pen was conjugated to the SPDP modified gelatin by reacting with sulfhydryl reactive 2-pyridothione.

and incubated for 10 min at room temperature and the absorbance was read at 595 nm with the microplate reader.

Determination of the Level of SPDP Modification. The degree of SPDP modification of gelatin was determined by quantifying the release of pyridine-2-thione group after exposure of the SPDP-modified gelatin with DTT. Briefly, 100 μL purified SPDP-modified gelatin was diluted to 1 mL with PBS buffer, pH 7.4. 10 μL DTT (15 mg/mL) was added and samples were incubated for exactly 15 min, and the absorbance was recorded at 343 nm with the microplate reader. The molar ratio of SPDP to gelatin modification was calculated as follows = ($\Delta A \times 8080$) $\times$ (average MW of gelatin $\times$ mg/mL of gelatin), where the value 8080 reflects the extinction coefficient (8.08×10^3 M^{-1} cm^{-1}) for pyridine-2-thione at 343 nm.

HPLC Determination of D-Pen and Glutathione. D-pen and glutathione were simultaneously analyzed with a modification of our previously reported HPLC method (*5*). Briefly, a HPLC system (Finnigan Surveyor System (Thermo Electron Corp., San Jose, CA)) was used and the data were analyzed with *ChromQuest* software version 4.2. The mobile phase employed was a 50:50% v/v mixture of solvent A (50 mM *o*-phosphoric acid) and solvent B (50 mM *o*-phosphoric acid + 5% acetonitrile), both adjusted to pH 2.5, and pumped at a flow rate of 1 mL/min. Both D-pen and glutathione were detected by UV absorption at 214 nm with retention times of 3.1 ± 0.01 and 2.79 ± 0.01 min, respectively. Sample concentrations (μM) were obtained from the regression line of peak area versus standard sample concentration (μM). These were calculated

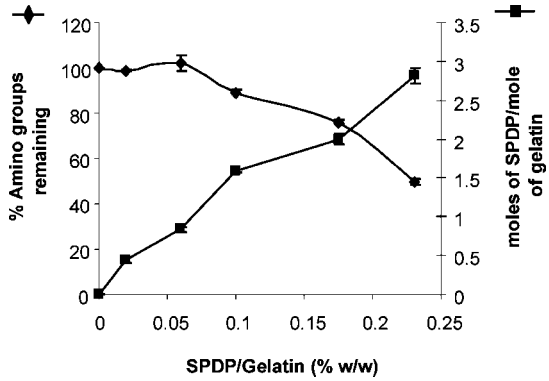

Figure 2. Effect of increasing SPDP concentration on the modification of gelatin. The amine groups and moles of SPDP conjugated to gelatin. The pyridine-2-thione assay was used to determine the SPDP modification of gelatin. The TNBS assay was used to determine the level of SPDP modification of gelatin. Each value represents mean ± SD.

Table 1. Effect of SPDP/Gelatin Concentration on the Amount of D-Pen Conjugated to Gelatin[a]

SPDP/gelatin (% w/w)	D-pen (μmol)/gelatin (g) ± SD	D-pen (mg)/gelatin (g) ± SD
0.02	20.5 ± 0.5	3.1 ± 0.07
0.06	52.8 ± 2.0	7.8 ± 0.3
0.1	58.8 ± 0.9	8.7 ± 0.14
0.18	84.3 ± 9.1	12.6 ± 1.3
0.23	102.4 ± 1.4	15.3 ± 0.2

using a ten-point calibration curve of D-pen and glutathione dissolved in PBS buffer, pH 7.4.

D-Pen Release from the Conjugate under Reducing Conditions. To evaluate the amount of D-pen released from the conjugate under reducing conditions, the gelatin−D-pen conjugate was incubated in PBS buffer, pH 6.2 and 7.4, with increasing concentrations of glutathione (0, 0.1, 1, and 10 mM) for 2 h at 37 °C. Additionally, D-pen release from the conjugate at various times was also determined in PBS at pH 6.2 and 7.4 after incubation in the presence of 1 mM of glutathione at 37 °C.

CANCER CELL UPTAKE STUDIES

Quantitative Cell Uptake of Free D-Pen. The quantitative cell uptake of free D-pen was investigated in HL-60 cells. Briefly, D-pen (100 μM) was incubated with HL-60 (1×10^6) cells in PBS, pH 7.4, at 37 °C in a 5% CO_2 incubator. Cells were incubated for 1−4 h. At a predetermined time, the cells were separated by centrifugation and the supernatant was analyzed for the remaining concentration of D-pen present as either free D-pen or D-pen disulfide using the HPLC assay previously described (5).

Intracellular Uptake of the Conjugate. The uptake of the fluorescein-gelatin-D-pen conjugate was determined qualitatively using confocal microscopy. HL-60 cells (1×10^5) were suspended in a 24 well plate in the medium alone (control) or containing either fluorescein-gelatin (fluorescein-labeled gelatin) (control) or fluorescein-gelatin-D-pen conjugate. At 4, 24, 48, and 72 h post-treatment, cells were transferred to a centrifuge tube, washed twice with PBS, and resuspended in 200 μL fresh Phenol red free media. Cells were transferred onto a slide for visualizing using Zeiss 510 Meta laser scanning confocal microscope (Carl Zeiss, Thornwood, NY). Differential interference contrast (DIC) images, fluorescence images, and the overlapped images taken from the microscope were visualized using the Zeiss AIM Viewer (Carl Zeiss, Thornwood, NY).

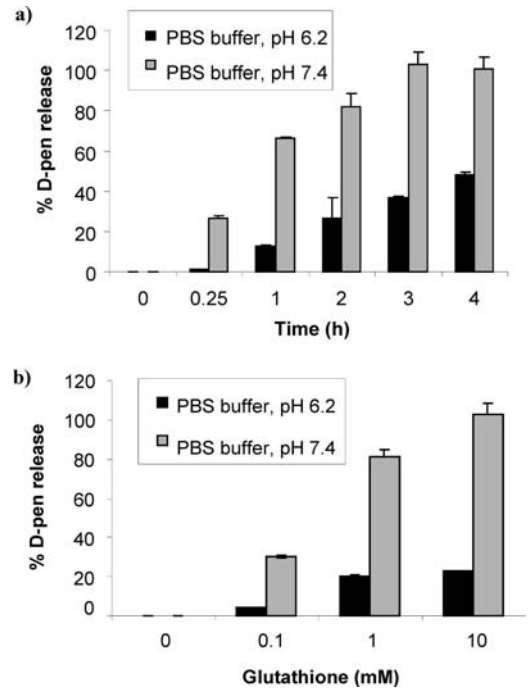

Figure 3. Release of D-pen from the gelatin−D-pen conjugate under reducing conditions. (a) The gelatin−D-pen conjugate was incubated with glutathione (1 mM) at 37 °C in phosphate buffer saline (PBS, pH 7.4 and pH 6.2) and the release of D-pen was analyzed with HPLC. Each value represents mean ± SD ($n = 3$). (b) The gelatin−D-pen conjugate was incubated with increasing concentration of glutathione (0, 0.1, 1, 10 mM) at 37 °C for 2 h. D-pen release was analyzed with HPLC. Each value represents mean ± SD ($n = 3$).

Additionally, to support the qualitative cell uptake of the conjugate, we measured the lysate fluorescence of the fluorescein-gelatin-D-pen conjugate treated HL-60 cells. Briefly, after treatment and washing with PBS as described above the HL-60 cells were lysed with M-PER mammalian cell extraction reagent. The fluorescence of the cell lysate was measured at 485 ± 20 nm (excitation) and 520 ± 25 nm (emission).

Gelatin−D-Pen Conjugate Cytotoxicity. HL-60 cells were plated in 48 well plates at 20 000 cells/well. The cells were treated with the gelatin−D-pen conjugate (1 mg/mL conjugate, corresponding to 100 μM D-pen), D-pen (100 μM), gelatin (1 mg/mL), a physical mixture of gelatin (1 mg/mL) plus D-pen (100 μM). The medium was replaced every 2 days, and no further dose of any treatment group was added. Cytotoxicity was determined on the 2nd, 4th, 6th, 8th, and 10th day using the MTT assay.

Statistical Analysis. Statistical analysis was performed with GraphPad *Prism 4* software (GraphPad software Inc., San Diego, CA). The data represented in Figure 7 were analyzed with two-way analysis of variance (ANOVA) followed by Bonferonni's post test, where significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

Synthesis of Gelatin−D-Pen Conjugate. The gelatin−D-pen conjugate was prepared by a simple two-step reaction as shown in Figure 1: (i) gelatin was modified with the heterobifunctional cross-linker (sulfo-LC-SPDP); (ii) D-pen was conjugated to the modified gelatin (SPDP-gelatin) with simple thiol exchange. The choice of the amine-thiol reactive heterobifunctional cross-linker (sulfo-LC-SPDP) was based on two important properties: (i) availability of amino groups in gelatin for chemical modification, (ii) the protection of the thiol group of D-pen, through a reversible bond between polymer (gelatin) and

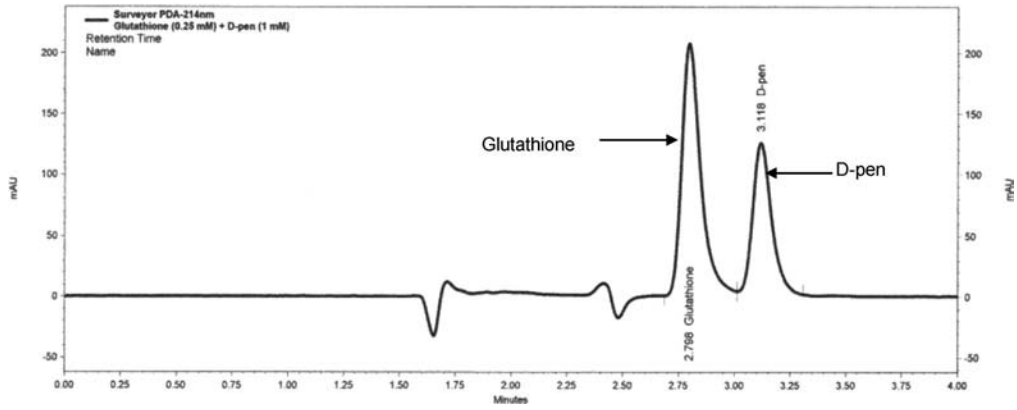

Figure 4. HPLC chromatogram showing glutathione and D-pen elution.

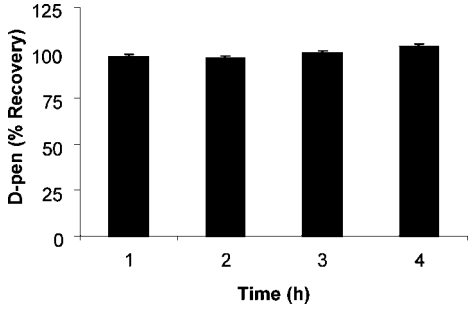

Figure 5. Cell uptake of D-pen. D-pen (100 μM) was added to HL-60 (1×10^6) cells in PBS (pH 7.4) in a 24 well plate at 37 °C in 5% CO_2 incubator. Cells were separated by centrifugation and the supernatant was analyzed by HPLC assay for D-pen concentration. Data represent mean ± SD ($n = 4$).

the drug (D-pen). A disulfide bond compared to the irreversible (maleimide) bond provides potential biological reversibility.

As shown in Figure 2, the amino group content of gelatin was reduced to approximately 50% of the original gelatin as the ratio of SPDP added to gelatin increased to 0.23% w/w. To confirm and quantify the amount of SPDP modification of gelatin in the process of loss of amino groups, the SPDP-modified gelatin was incubated with DTT to release the pyridine-2-thione group. Figure 2 shows that approximately 3 mol of SPDP was conjugated per mole of gelatin as SPDP added to gelatin increased to 0.23% w/w. This corresponded to 20.5 ± 0.5 to 102.4 ± 1.4 μmol D-pen/g gelatin or 3.1 ± 0.07 to 15.3 ± 0.2 mg D-pen/g gelatin as the ratio of SPDP to gelatin was increased from 0.02% to 0.23% w/w (shown in Table 1).

Synthesis of Fluorescein Labeled Gelatin−D-Pen Conjugate. A fluorescein-gelatin-D-pen conjugate was synthesized for cell uptake studies. The degree of labeling of fluorescein on gelatin was 0.1 mol of fluorescein per mole of gelatin. Gelatin was labeled with fluorescein through the reaction of the NHS-fluorescein with gelatin to form fluorescein-labeled gelatin. The fluorescein-gelatin was then conjugated to D-pen as described above to form the fluorescein-gelatin-D-pen conjugate. Fluorescein-gelatin alone was used as a control for cell uptake studies.

D-Pen Release in the Presence of Glutathione. The stability of the disulfide bond between D-pen and gelatin was investigated using glutathione, an endogenous reducing agent. The intracellular glutathione concentration has been reported to range from 1 to 11 mM (*33*). Therefore, *in vitro* release studies were performed in the presence of both low (1 mM) and high (10 mM) concentrations of glutathione. The selection of pHs 6.2 and 7.4 were based on the reported pH of the early endosome and cytosol, respectively. In the presence of 1 mM glutathione

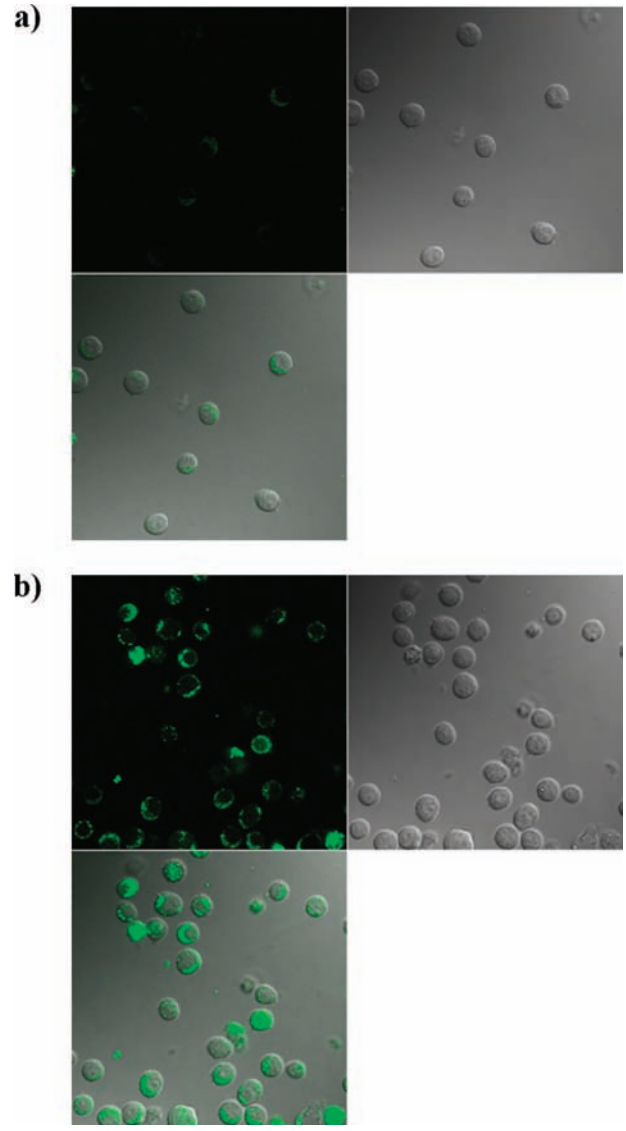

Figure 6. Intracellular uptake of gelatin−D-pen conjugate. HL-60 cells were incubated with the fluorescein-labeled gelatin−D-pen conjugate at 37 °C for (a) 4 and (b) 72 h. Cells were washed twice with PBS and cells then suspended in Phenol red free RPMI media. Cells were imaged by confocal laser scanning microscopy. Fluorescence (left), differential contrast (DIC) (right), and overlapped images (bottom).

in pH 7.4, D-pen was completely released in 4 h, while only ~50% D-pen was released at pH 6.2 (Figure 3a). As shown in Figure 3b, 2 h incubation of the conjugate with glutathione

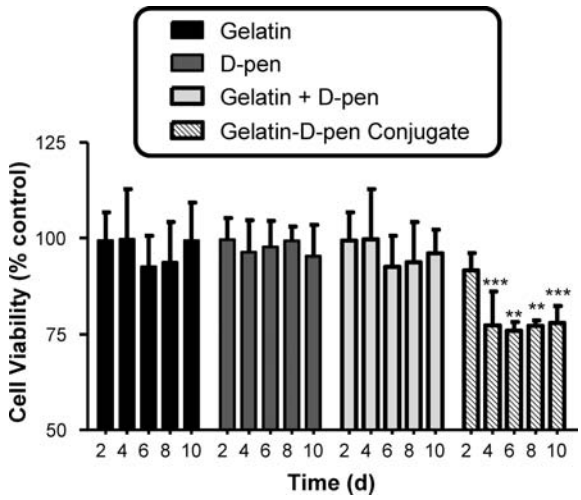

Figure 7. Cytotoxicity of the gelatin-D-pen conjugate in HL-60 cells. Cells (2×10^4) were incubated with gelatin alone (1 mg/mL), D-pen alone (100 μM), gelatin (1 mg/mL) plus D-pen (100 μM), and gelatin−D-pen conjugate (1 mg/mL) After every 2 day interval, media was replaced with fresh media. MTT assay was performed on day 2, 4, 6, 8, and 10. Data represent mean ± SD ($n = 6$). $^{**}p < 0.01$ and $^{***}p < 0.001$ compared to gelatin plus D-pen ($n = 3$).

(0.1−10 mM) at pH 7.4 resulted in the release of approximately 30%, 80%, and 100% of D-pen in the presence of 0.1, 1, and 10 mM glutathione, respectively. In contrast, the D-pen release at pH 6.2 was approximately 5%, 20% in the presence of 0.1, 1, and 10 mM glutathione, respectively. D-pen and glutathione were simultaneously quantitated as shown in Figure 4. These studies underline the significance of interaction of the conjugate at favorable pH and local concentration of glutathione for successful D-pen release and the subsequent cytotoxicity.

Intracellular Uptake of Free D-Pen. Lodemann et al. reported the inability of D-pen to cross cell membrane of mammalian cells (*36*). The inability to be transported is likely explained by the three highly ionizable functional groups of D-pen. The novel HPLC assay developed provides accurate determination of both D-pen and D-pen disulfide. As shown in Figure 5, when the supernatant was analyzed for remaining D-pen at 1, 2, 3, and 4 h postincubation, approximately 100% D-pen was recovered. These results support the previously reported studies by Lodemann et al. (*36*) and signify the need for developing a novel delivery system for D-pen to enhance intracellular delivery.

Gelatin−D-Pen Conjugate Uptake. The intracellular uptake of the gelatin−D-pen conjugate and fluorescein-labeled gelatin alone in HL-60 cells was studied using confocal laser scanning microscopy. The fluorescein-gelatin-D-pen conjugate uptake into HL-60 cells was a slow process with maximum uptake seen at the 72 h (Figure 6b) compared to 4 h (Figure 6a). Similar slow cell uptake was seen with the fluorescein-labeled gelatin (data not shown). Both the conjugate and gelatin alone were seen to accumulate in the cells in a uniform, nonpunctate manner. However, there was a trend for increased fluorescence associated with the cell membrane as compared to the cytoplasm. There were no apparent differences between the cellular uptake of gelatin and the gelatin−D-pen conjugate. Ofner et al. previously showed a similar cellular distribution and slow uptake (over 96 h) of fluorescein-labeled gelatin in HL-60 cells (*20*). We have confirmed the cell uptake of the conjugate by measuring the cell lysate fluorescence of the conjugate-treated HL-60 cells (data not shown). We are currently examining the cellular uptake profiles of other polymers such as polyglutamic acid to further improve intracellular D-pen delivery. For example, we have preliminary data that the uptake of the polyglutamic acid−D-pen conjugate is much more rapid than that of gelatin−D-pen conjugate and results in dose-dependent increase in intracellular ROS leading to cytotoxicity in HL-60 cells within 8 h. Moreover, the levels of ROS produced by gelatin−D-pen conjugate (equivalent to 500 μM D-pen dose) is comparable to that caused by 100 μM H_2O_2 (data not shown), whereas free D-pen causes no increase in intracellular ROS since it is cell-impermeable.

Conjugate Cytotoxicity in HL-60 Cells. We have reported that D-pen alone in the presence of cupric sulfate was more cytotoxic in leukemia cells compared to breast cancer cells (*6*). The data suggest that this may be due to the higher innate copper levels in the cultured leukemia cells compared to breast cancer cells (unpublished data). Therefore, the cytotoxicity of the conjugate was evaluated in human HL-60 leukemia cells. HL-60 cells were treated with gelatin and D-pen alone, a physical mixture of gelatin plus D-pen and the gelatin-D-pen conjugate. As the conjugate was shown to enter the cells, the differences in cytotoxicity of the conjugate were compared with the free gelatin and D-pen and the physical mixture of gelatin plus D-pen in the presence of innate levels of intracellular copper in HL-60 cells. During the studies, media was replaced every two days. As shown in Figure 7, the conjugate exhibited significantly increased cytotoxicity compared to all the controls ($p < 0.001$ on days 4 and 10 and $p < 0.01$ on days 6 and 8, respectively). As we have reported earlier, the mechanism of D-pen cytotoxicity is due to the generation of H_2O_2 and other ROS in the presence of copper (*5*, *6*). Thus, the intracellular efficacy of D-pen is dependent upon two important processes, namely, (i) the interaction of the conjugate with glutathione and the subsequent release of D-pen and (ii) the interaction of the released D-pen with the intracellular innate copper present in leukemia cells to produce its cytotoxic effect. We are presently investigating the intracellular D-pen release from the conjugate and the localization of intracellular copper to improve the conjugate anticancer effect. Other conjugates are being designed and synthesized that may increase the rate and extent of uptake and the subsequent D-pen release.

CONCLUSIONS

A method for the synthesis and characterization of a novel gelatin−D-pen conjugate is described. The disulfide bond between gelatin and D-pen in the conjugate provides protection of D-pen from oxidation. Additionally, the disulfide bond in the conjugate was shown to be biologically reversible through the complete release of D-pen only in the presence of biologically relevant concentration of glutathione. It was shown that free D-pen does not enter cells. The delivery of D-pen as a novel gelatin-D-pen conjugate was shown to increase the intracellular accumulation of conjugate in cancer cells over time, and this directly led to enhanced cytotoxicity in human leukemia cells. The cytotoxicity of the conjugate in leukemia cells was sustained and significant compared to the physical mixture of gelatin and D-pen, indicating the importance of the disulfide bond between gelatin and D-pen. To further improve the conjugate cytotoxicity, we are currently examining the intracellular interaction of the D-pen released from the conjugate with the cellular copper either free or bound to proteins.

ACKNOWLEDGMENT

The authors would like to thank Wendy Salmon at the Michael Hooker Microscopy Facility at the University of North Carolina at Chapel Hill for her help and guidance in the confocal microscopy studies.

Received February 16, 2008; Revised Manuscript Received May 11, 2008

Transplantation of islets of Langerhans (islets) is a promising technique for treating insulin-dependent diabetes mellitus (type I). One unresolved issue is early graft loss due to inflammation triggered by blood coagulating on the surface of islets after transplantation into the portal vein. Here, we describe a versatile method for modifying the surface of islets with an ultrathin membrane carrying the fibrinolytic enzyme urokinase or the anticoagulant heparin. The surface of islets was modified with a poly(ethylene glycol)−phospholipid conjugate bearing a biotin group (biotin-PEG-lipids, PEG MW: 5000). Biotin-PEG-lipids were anchored to the cell membranes of islets, and the PEG-lipid layer on the islets was further covered by streptavidin and biotin−bovine serum albumin conjugate using a layer-by-layer method. The surface was further activated with oxidized dextran. Urokinase was anchored to the islets through Schiff base formation. Heparin was anchored to the islets through polyion complex formation between anionic heparin and a cationic protamine coating on the islets. No practical islet volume increase was observed after surface modification, and the modifications did not impair insulin release in response to glucose stimulation. The anchored urokinase retained high fibrinolytic activity, which could help to improve graft survival by preventing thrombosis on the islet surface.

INTRODUCTION

The success achieved with the Edmonton protocol has established clinical islet transplantation as an alternative to pancreas transplantation (*1*, *2*). Transplantation of islets of Langerhans (islets) has been proposed as a safe and effective method for treating patients with insulin-dependent diabetes mellitus (type I). However, it still remains an experimental procedure for late-stage diabetics who can no longer control diabetes with insulin injection. Some improvements in islet transplantation are needed, including increasing islet isolation efficiency, improving islet preservation, increasing the efficacy of immunosuppressive drug dosage protocols, and reducing islet loss in the early phase following transplantation. Among these, graft loss poses the most serious limitations for current islet transplantation protocols. Even though sufficient numbers of islets from multiple donors are transplanted to one patient, only 30% of patients treated become insulin-independent (*2*), suggesting that many islets are lost early after intraportal transplantation.

Innate immune reactions are involved in the destruction of islets exposed to blood in the portal vein (*3*–*6*). The blood coagulation and complement systems are activated when islets are exposed to fresh blood in the portal vein. Chemotactic factors, tissue factor, chemokines, and other inflammatory mediators are released during this early phase. These factors induce instant blood-mediated inflammatory reactions that result in graft loss (*7*). Some methods of regulating early coagulation and blood-mediated inflammatory reactions have been investigated, such as administering the thrombin inhibitor Melagatran (*8*), activated protein C (*9*), dextran sulfate (*10*), and the water-soluble domain of complement receptor I (*11*). Control of these reactions has promoted the transplantation success by reducing islet loss in animal models; however, it is difficult to apply these methods in the clinical environment because systemic administration is associated with an increased risk of bleeding. Recently, Nilsson et al. proposed an original method for preventing instant blood-mediated inflammatory reactions by coating islets with heparin to inhibit surface thrombosis formation following transplantation (*12*). Although it is a challenging method to reduce islet loss in the early phase of transplantation, it has been experimentally under examination. At this point, it is valuable to propose several alternative methods to modify islet surface.

In our previous studies (*13*, *14*), islets were enclosed in a thin synthetic polymer membrane through poly(ethylene glycol)-conjugated phospholipid (PEG−lipids) derivatives that had been anchored in the membranes of islets cells. The PEG−lipid derivatives can be immobilized on the cell surface through hydrophobic interactions between the lipid bilayer and the PEG−lipid, without any effect on cell viability or function. The polymer membrane can be covered further using the layer-by-layer method (*13*, *14*). In this report, we propose a versatile method for immobilizing enzyme and glycosaminoglycans, such as urokinase and heparin, to the surface of islets utilizing this layer-by-layer method. In addition, the results of detailed studies on the fibrinolytic properties of islet-anchored urokinase are reported.

EXPERIMENTAL PROCEDURES

Materials. α-*N*-Hydroxysuccinimidyl-*ω*-*tert*-butoxycarbonyl poly(ethylene glycol) (NHS-PEG-Boc, MW 5000) was purchased from Nektar Therapeutics (San Carlos, CA). 1,2-Dipalmitoyl-*sn*-glycerol-3-phosphatidylethanolamine (DPPE) was purchased from NOF Corporation (Tokyo, Japan). Dichloromethane, chloroform, *N*,*N*-dimethylformamide (DMF), diethyl ether, *N*,*N*′-dicyclohexylcarbodiimide (DCC), D-biotin, streptavidin from Streptomyces avidin, dextran (MW 200 000−300 000), protamine sulfate (from Salmon), and heparin sodium salt were purchased from Nacalai Tesque (Kyoto, Japan). date ($NaIO_4$) was purchased from Wako Pure Chemcal (Osaka, Japan). Fluorescein isothiocyanate (FITC) was purchased from Dojindo Laboratories (Kumamoto, Japan). Urokinase was purchased from Calbiochem Inc. (La Jolla, CA). Biotinylated bovine serum albumin (biotin-BSA, biotin/BSA = 9, by molar ratio) was purchased from Pierce Biotechnology Inc. (Rockford, IL). Fibrinogen (human) and FITC-labeled BSA (FITC-BSA) were purchased from Sigma-Aldrich Co. (St Louis, MO). Thrombin was purchased from Kayaku CO. Ltd. (Saitama, Japan). FITC-streptavidin was purchased from Zymed laboratories (South San Francisco, CA). Biotinylated poly(ethylene glycol) alkanethiol was purchased from SensoPath Technologies Inc. (Bozeman, MT). Minimum essential medium (MEM), HEPES buffer solution, and Medium 199 were purchased from Invitrogen Co. (Carlsbad, CA). Fetal bovine serum (FBS) was purchased from BioWest (Miami, FL). Phosphate-buffered saline (PBS) was purchased from Nissui Pharmaceutical Co. Ltd. (Tokyo, Japan).

Synthesis of Biotinylated PEG-Conjugated DPPE. NH_2-PEG-lipid was synthesized from DPPE and NHS-PEG-Boc, which carries an activated ester (NHS) to react with an amino group of DPPE, and a protective group (Boc) for the amino group, as reported previously (*13*). Briefly, NHS-PEG-Boc (175 mg) and DPPE (21 mg) were dissolved in 5 mL of dichloromethane solution, and stirred for 3 days at room temperature (RT). Then, a solution of TFA (2 mL) was added and stirred for 20 min at 4 °C to remove Boc groups. The crude product was purified by precipitation with diethyl ether. After extraction into chloroform and evaporation, NH_2-PEG-lipid was obtained as a white solid (115 mg, yield 66%). D-Biotin (20 mg) and DCC (21 mg) were dissolved into DMF and stirred for 3 h at RT. Then, NH_2-PEG-lipid (22 mg) was added to the solution and stirred for 7 days at RT. This solution was filtered through a glass filter and the DMF was evaporated *in vacuo*; then, chloroform was added. After precipitation with diethyl ether, biotin-PEG-lipid was obtained as a white powder (10 mg, yield 40%). Biotin-PEG-lipid: ^1H NMR ($CDCl_3$, 400 MHz, δ ppm): 0.88 (t, 6H, -CH_3), 1.25 (br, 52H, -CH_2-, DPPE), 3.18 (d, 2H, C-CH_2-S, biotin), 3.24 (q, 1H, S-CH(-C)-C, biotin), 3.64 (br, 460H, PEG). 4.52 (m, 2H, C-CH(-C)-N, biotin), 5.15 (s, 2H, C-NH-C, biotin).

Forming Biotin-BSA and Streptavidin-Based Multilayers. A multilayered protein membrane was formed with biotin-BSA and streptavidin using the layer-by-layer method. To examine the formation of the multilayered membrane, we employed an in-house-designed surface plasmon resonance (SPR) instrument (*15*). Gold-coated BK-7 glass plates were immersed in a biotin-SAM (1 mM) methanol solution for 24 h, and the biotin-SAM formed on the surface of the gold-coated glass plates. Before SPR measurements, the plates were sequentially washed thoroughly with pure water and 2-propanol. A glass plate was set in an SPR flow cell, and a solution of strepavidin (20 μg/mL in PBS) was allowed to flow onto the surface, followed by a solution of biotin-BSA (40 μg/mL in PBS). These procedures were repeated several times to form multiple layers of BSA and streptavidin by the layer-by-layer method. The reaction solutions and PBS were allowed to circulate through the flow cell at 4.0 mL/min, and all SPR measurements were performed at 30 °C.

Modifying a Single Cell Surface with Biotin-PEG-Lipid and Streptavidin Complex. CCRF-CEM cells (acute lymphoblastic leukemia T-cells) were used as model cells for the surface modification of single cells. Biotin-PEG-lipids were dispersed in MEM and added to a CCRF-CEM cell suspension (1×10^6 cells in MEM, [biotin-PEG-lipids] = 100 μM), the cell suspension was incubated for 30 min at RT. The cells were washed with MEM and centrifuged at 180 $\times$ *g* for 5 min at RT. This procedure was repeated twice. The biotin-PEG-modified cells were resuspended in 80 μL of MEM. Then, 20 μL of FITC-labeled streptavidin was added to the cell suspension (100 μg/mL) and incubated at RT for 5 min. Cell viability was assessed by the Trypan blue exclusion method. FITC-labeled streptavidin-modified cells were observed by confocal laser scanning microscopy (FLUOVIEW FV500, Olympus, Tokyo).

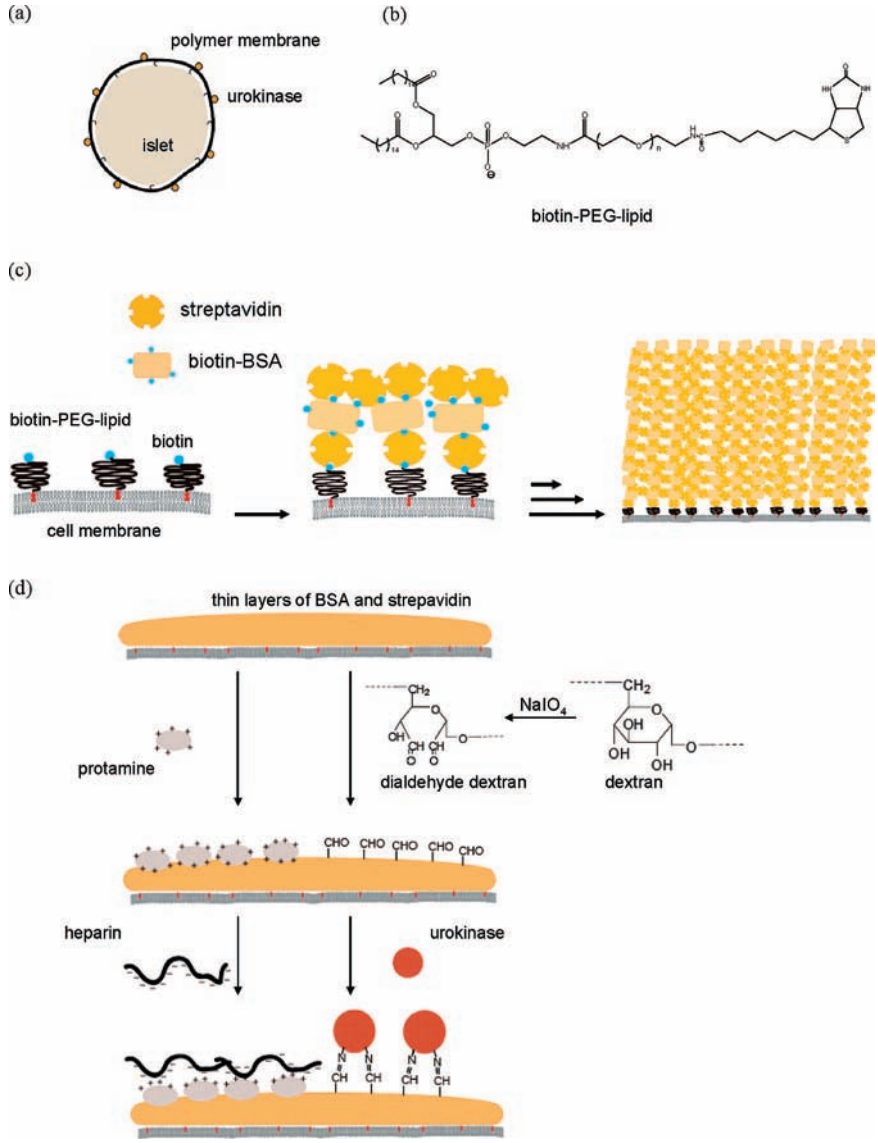
Islets Surface Modification. Islets were isolated from the pancreas of Syrian hamsters (7−8 weeks old, female, Japan SLC, Inc., Shizuoka, Japan) by the collagenase digestion method (*24*). The islets were maintained in culture medium (Medium 199 with 10% FBS, 8.8 mM HEPES buffer, 100 units/mL penicillin, 100 μg/mL streptomycin, and 8.8 U/mL heparin). A large amount release of insulin was observed from damaged islets during a few days culture after the islet isolation. Isolated islets were cultured for 7 days to remove damaged cells before surface modification. Effect of surface modification on islet functions could be clearly seen after this 7 days culture. A biotin-PEG-lipid solution was added to islets suspended in MEM (100 islets, [biotin-PEG-lipid] = 500 μM 100 μL of MEM), and the mixture was incubated at RT for 1.5 h. After washing three times with MEM, the biotin-PEG-lipid modified islets were mixed with a solution of streptavidin (50 μg/mL in PBS) and allowed to react for 10 min at RT. Streptavidin-modified islets were washed three times with MEM. The modified islets were then added to a solution of biotin-BSA (100 μg/mL in PBS) and left for 10 min at RT. The layer-by-layer modification with streptavidin and biotin-BSA was repeated 10 times to form 20 layers on the surface of the islets. In order to visualize the surface of islets by confocal laser scanning microscopy), FITC-labeled streptavidin (30 μg/mL in PBS) was used for the 21st layer.

Anchoring Bioactive Molecules onto the Surface-Modified Islets. The surface-modified islets were further modified with the fibrinolysis enzyme urokinase or with heparin, using dialdehyde dextran (*16*) or protamine. $NaIO_4$ (107 mg) was added to a dextran (250 mg) solution in pure water (5 mL) and the reaction mixture was stirred for 2 h at RT. Oxidation of dextran by $NaIO_4$ causes cleavage of the carbon−carbon bonds within each monosaccharide unit of the dextran chain, transforming the 1−2 hydroxyl groups into dialdehyde groups. After precipitation with acetone and dialysis against PBS, dialdehyde dextran was obtained as a white solid (220 mg). Biotin-BSA/streptavidin-modified (20 layers) islets were then activated using the dialdehyde dextran solution (5 mg/mL in PBS) for 30 min at 37 °C, and then incubated in urokinase solution (1000 IU/mL in PBS) for 60 min at 37 °C to anchor the urokinase onto the islets. Urokinase-islets were cultured in Medium 199 supplemented with FBS, heparin, and HEPES for a specified number of days at 37 °C in 5% CO_2.

Fibrinolytic activity of the anchored urokinase was determined by the fibrin plate method (*17*). Briefly, 10 mL of a fibrinogen solution (10 mg/mL in saline) (ϕ = 9.5 cm) and 60 μL of a thrombin solution (60 IU/mL) was mixed well. Plasminogen was not added to the fibrinogen solution, because plasminogen is included in fibrinogen prepared by the standard preparation (*17*). Naïve islets and urokinase-anchored islets (50 islets) collected after 0, 1, 3, and 7 days of culture were spotted onto the fibrin plate and incubated at 37 °C for 12 h. The size of the area of dissolved fibrin around the islet spot was determined as a measure of urokinase fibrinolytic activity.

For anchoring heparin, the BSA and streptavidin-modified islets (total layers, 10) were further treated with polycation, protamine (150 μg/mL in HBSS), for 5 min at RT. Most of polycations are cytotoxic toward many cell types. In this study, protamine was used as a polycation, because it is the least cytotoxic polycation as could be expected from the fact that it

Scheme 1[a]



[a] (a) Scheme for anchoring urokinase on surface of islets by constructing a multilayered membrane composed of streptavidin and biotin-BSA. (b) Chemical structure of biotin-PEG-conjugated DPPE (biotin-PEG-lipid). (c) Biotin-BSA/streptavidin multilayered membrane formation. The first biotin-PEG layer was anchored to the surface through hydrophobic interactions. Then, streptavidin and biotin-BSA were chemically reacted to the surface, layer-by-layer. (d) Dextran was oxidized to produce aldehyde groups on the surface of islets, providing a means for urokinase immobilization through Schiff base formation. Heparin was anchored to the surface of islets after treatment with protamine.

is administered to reverse heparin action in the clinical setting. Then, heparin was added for 15 min at RT (5 mg/mL in HBSS). For visualization, the heparin had been labeled with FITC. Heparin (40 mg/mL in pure water) was reacted with FITC (2.6 mg in 100 μL of DMSO) for 3 h at RT, precipitated in acetone at −20 °C for 24 h, evaporated, and washed three times with acetone. Finally, the precipitate was dialyzed against PBS for 2 days (MWCO; 3500 Da) to obtain FITC-heparin (FITC/heparin = 2.5 by molar ratio).

Glucose Stimulation Test. A static glucose-responsive insulin assay (*13*) was performed on biotin-BSA/streptavidin-encapsulated islets, activated dextran modified-encapsulated islets, and urokinase-immobilized islets after 1 and 7 days in culture. After the modified islets were washed several times with Krebs-Ringer solution, they were incubated in 0.1 g/dL, 0.3 g/dL, and then 0.1 g/dL glucose in Krebs-Ringer solution for 1 h each at 37 °C. The insulin concentration in the supernatant at each step was determined by an enzyme-linked immunosorbent assay (ELISA; Shibayagi Co. Ltd., Gunma, Japan).

Statistical Analyses. Comparisons between two groups were performed by Student's *t* test. $P < 0.05$ was considered statistically significant. All statistical calculations were performed using the software *JMP v.5.1.1*.

RESULTS

Forming Multilayered Biotin-BSA and Streptavidin Membranes on Surface of Islets. A nanometer-thick membrane composed of streptavidin and biotin-BSA layers formed on cell surfaces using biotin-PEG-lipid and the layer-by-layer method, as shown in Scheme 1. Biotin and streptavidin interact to form a stable conjugate (association constant was $\sim 10^{15}$ M^{-1}) under physiological conditions, so this system can be used to form a multilayered membrane without damaging the surface of the living cell. To confirm the formation of a multilayered biotin-BSA and streptavidin membrane, the SPR method, which can detect small changes in refractive index on the surface of a gold thin film in real time, was employed. Figure 1 shows the SPR profiles of layer-by-layer reactions between streptavidin and

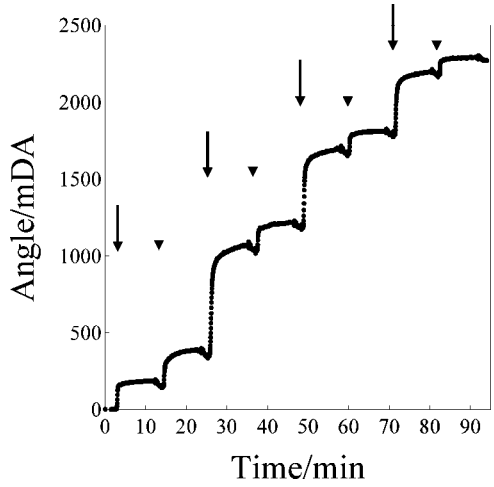


Figure 1. SPR-monitoring of multilayered streptavidin and biotin-BSA membrane formation on the biotin-SAM surface. Stepwise SPR profile indicates sequential formation of a protein multilayer. Arrows and arrowheads indicate the addition of streptavidin and biotin-BSA solutions, respectively.

biotin-BSA. A solution of streptavidin was flowed onto an SPR sensor with a self-assembled monolayer of biotinylated poly(ethylene glycol) alkanethiol (biotin-SAM) as indicated by the first arrow in Figure 1 and Supporting Information Figure S1. The streptavidin layer was formed on a biotin-SAM formed on the sensor surface. Then, biotin-BSA was flowed onto the surface (indicated by the first arrowhead), and BSA was trapped on the streptavidin layer through the biotin/streptavidin reaction. Afterward, streptavidin and biotin-BSA solutions were alternately applied to the surface. The refractive index increased in a stepwise manner indicating the formation of a multilayered membrane composed of streptavidin and biotin-BSA. After this procedure was repeated 10 times, the thickness of the multilayered membrane was about 30 nm as indicated by an SPR shift when the refractive index of the BSA and streptavidin layer was assumed to be 1.45.

Modifying the Surface of Islets with the Multilayered Membrane. In order to construct a biotin-BSA/streptavidin multilayer on the membranes of islets, a hydrophobic lipid chain conjugated hydrophilic PEG chain carrying a biotin molecule was applied to the cell suspension. When a biotin-PEG-lipid dispersion is mixed with the islets suspension, it is expected to incorporate into cell membranes spontaneously via hydrophobic interactions between the hydrophobic part of biotin-PEG-lipid and the lipid bilayer of the cell membrane. Hydrophilic PEG chains remain on the outer surface of the cell, as illustrated in Scheme 1.

First, the surface of single CCRF-CEM cells (floating cells, acute lymphoblastic leukemia T-cells) was treated with biotin-PEG-lipid to confirm the occurrence of the reaction. After incubation of the cells in biotin-PEG-lipid dispersion, FITC-labeled streptavidin was applied. Figure 2a shows the microscopic images of cells modified with FITC-labeled streptavidin/biotin-PEG-lipid. Fluorescence from FITC-streptavidin was visible at the periphery of the each cell, indicating that FITC-streptavidin had formed a complex with the biotin-PEG-lipid on the cell membrane. No fluorescence was observed for cells not treated with biotin-PEG-lipid. Thus, the hydrophobic lipid of the biotin-PEG-lipid was anchored in the lipid bilayer of the cell membrane as shown in Scheme 1. Cell viability as assessed by Trypan blue exclusion was 89% after the modification. There was no statistically significant difference in cell viability between cells modified with streptavidin/biotin-PEG-lipid conjugates and cells prior to modification. Therefore, the surface modification was not toxic to the living cells.

Islets were sequentially treated with biotin-PEG-lipid and FITC-streptavidin. Their fluorescent images taken with a confocal laser-scanning microscope are shown in Figure 2b. Clear fluorescence is seen at the periphery of each islet; no fluorescence was observed on islets treated with FITC-streptavidin when the biotin-PEG-lipid treatment was skipped. These observations indicate that biotin groups can be introduced on the surface of islets using biotin-PEG-lipid and that streptavidin can be anchored to the islet surface via biotin without damaging islet morphology. To form a multilayered membrane of streptavidin and biotin-BSA, the biotinylated islet surface was treated sequentially with streptavidin and biotin-BSA; this procedure was repeated several times. Finally, FITC-streptavidin was used for the 21st layer to allow visualization under a confocal laser-scanning microscope. Figure 2c shows fluorescent images of islets encapsulated with 21 layers of biotin-BSA and streptavidin. A strongly fluorescing layer was observed at the periphery of all islets, indicating the presence of multilayered membranes of biotin-BSA and streptavidin.

Immobilization of Bioactive Molecules to the Surface of Encapsulated Islets. Urokinase is a serine protease that activates plasminogen. Activation of plasminogen triggers a proteolysis cascade that participates in thrombolysis. Immobilizing urokinase on the surface of islets is expected to help dissolve small blood clots that may form on islets, thereby suppressing blood-mediated inflammatory reactions. Multilayered membrane-modified islets were further modified with dialdehyde dextran to introduce aldehyde groups on the surface of islets. Urokinase was immobilized on the islets surface through Schiff base formation between the aldehyde groups with primary amines of urokinase. FITC-labeled BSA was reacted with the aldehyde groups in place of urokinase, allowing direct visualization (Figure 2d). Fluorescence from FITC-BSA was observed at the periphery of all islets, indicating the presence of FITC-BSA. On the other hand, no fluorescence was observed on islets without treatment with activated dextran (Supporting Information Figure S2 (a)). Islets after treatment with biotin-BSA and streptavidin were also used to immobilize heparin at the surface. Protamine was immobilized on islets with biotin-BSA as an outermost surface and then anionic heparin was immobilized on the protamine layer through polyion complex formation. Fluorescence from FITC-heparin was observed at the periphery of all islets (Figure 2e), indicating the presence of FITC-heparin on the islets. There was no fluorescence on islets without the protamine layer (Supporting Information Figure S2 (b)). Thus, our technique enables various bioactive molecules to be immobilized on the surface of islets.

A fibrin plate-based assay was performed to assess the function of the urokinase anchored on the islets. Urokinase transforms plasminogen into active plasmin, which can dissolve fibrin. To assess the activity of the membrane-anchored urokinase, we spotted the modified islets on a fibrin gel, and measured the area of dissolved fibrin around the spotted urokinase-islets. Figure 3a shows the fibrin plate at 12 h after urokinase-islets spotting. A large transparent area was observed around the urokinase-islets, indicating urokinase activity. The transparent area was small around naïve islet spots. The small transparent area might be due to small amounts of urokinase secreted by the islet itself (*18*). Islets with anchored urokinase were cultured in Medium 199 supplemented with 10% FBS. Urokinase activity during culture was followed and is shown in Figure 3b. The fibrinolytic activity of urokinase was retained for 3 days, and then decreased to 25% after 7 days in culture. The stability of the surface modifications was also examined by observing the morphology of islets treated with a multilayered membrane (total layer number = 20). Their outermost layer was treated with FITC-streptavidin and fixed with dialdehyde dextran. Figure 4

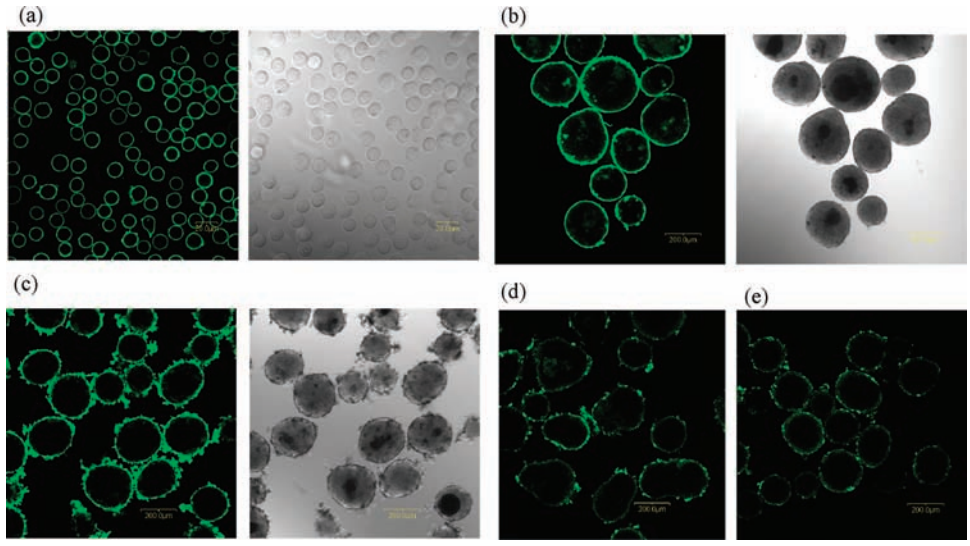

Figure 2. Images of surface-modified cells and islets observed under confocal laser and differential interference microscopy. (a) CCRF-CEM cells were sequentially modified with biotin-PEG-lipid and FITC-labeled streptavidin. (b) Hamster islets were sequentially modified with biotin-PEG-lipid and FITC-labeled streptavidin. (c) Hamster islets modified with biotin-PEG-lipid were sequentially coated with streptavidin and biotin-BSA (20 times); the 21st layer was FITC-streptavidin. (d) Islets covered with a multilayered biotin-BSA/streptavidin membrane were activated with oxidized dextran. FITC-BSA was anchored to the islets through Schiff base formation. (e) Multilayered islets were coated with cationic protamine and FITC-labeled heparin (anionic) was immobilized on the islets through polyion complex formation. Scale bars: 20 μm for (a), and 200 μm for (b), (c), (d), and (e).

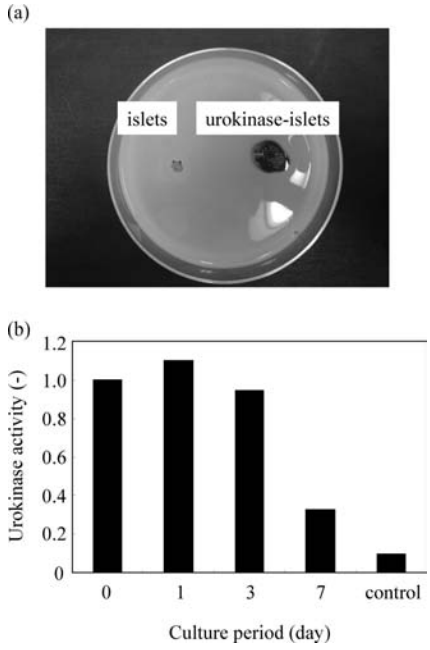

Figure 3. Fibrin plate assay for islet-anchored urokinase. (a) 100 naïve islets and 100 urokinase-modified islets were spotted on the left and right sides of a fibrin plate, respectively, and incubated at 37 °C for 12 h. (b) Bar graph illustrating the change in islet-anchored urokinase activity during culture in medium. Activity is expressed as the area of dissolved fibrin around urokinase-islet spots normalized to the area at day zero (see Experimental Section).

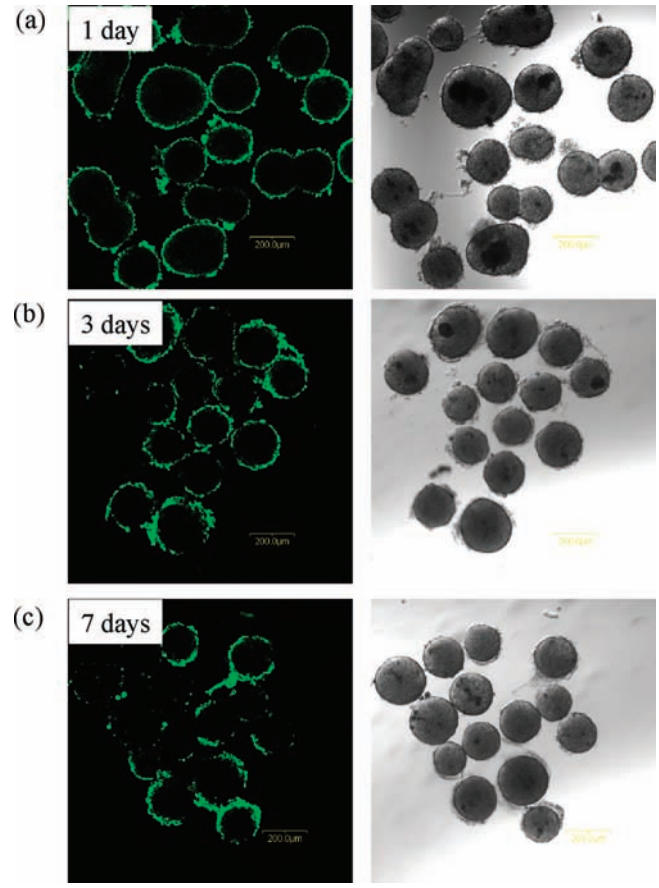

Figure 4. Changes in multilayered membranes on islets after (a) 1, (b) 3, and (c) 7 days in culture. Islets had been coated with a multilayered biotin-BSA/streptavidin membrane on biotin-PEG-lipid modified surface, followed by reaction with activated dextran and culture in Medium 199.

shows the microphotographs of islets at 1, 3, and 7 days of culture. The membrane gradually deteriorated over time, although islet morphology was well-maintained. Thus, urokinase could have detached from the islets, which could account for the decrease in urokinase activity.

Glucose-Stimulated Insulin Release by Surface-Modified Islets. A glucose stimulation test was performed in order to examine the ability of the modified islets to control insulin release in response to glucose level changes; the results are summarized in Figure 5. When the glucose concentration was increased from 0.1 g/dL to 0.3 g/dL, islets in all groups increased insulin release from basal levels. Insulin release returned to the basal level when islets were re-exposed to 0.1 g/dL, indicating

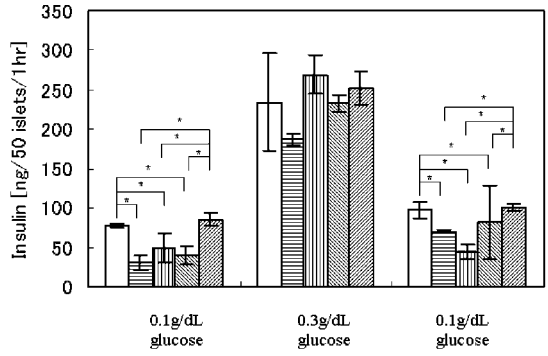

Figure 5. Glucose stimulation test. Bars from left indicate (1) islets without surface modification, (2) islets modified with a multilayered biotin-BSA/streptavidin membrane, (3) periodate-activated dextran-treated islets, (4) urokinase-anchored islets at day zero, and (5) urokinase-anchored islets after 7 days of culture in Medium 199 at 37 °C. The amounts of insulin secreted from modified islets in response to glucose concentration changes (0.1, 0.3, and 0.1 g/dL) were determined by ELISA. ($n = 3$). * indicates a statistically significance difference ($p < 0.01$).

that islets after surface modification normally response to the glucose changes. At low glucose level, the insulin secretion rates in groups of islets after surface modification are slower than that of control group, whereas it was the same level among all groups at high glucose level. However, the all insulin secretion rates were recovered to the basal level after seven days culture. These results indicate that the surface modifications and urokinase anchoring did not influence the islets' ability to regulate and release insulin.

DISCUSSION

Recently, Nilsson et al. reported that the graft survival of porcine islets could be improved by modifying the surface of islets with heparin (*12*), and Chaikof et al. reported immobilizing thrombomodulin to the surface of islets (*19*). In their approaches, biotin molecules were conjugated to amino groups of islets surface proteins in order to cover the surface with avidin for immobilizing heparin, and it is necessary to covalently conjugate phosphine molecules to surface protein amino groups to anchor thrombomodulin. Although they reported some improvements in the graft survival by their modification methods, their method is not sufficient enough to solve all of the problems related with the graft loss in the islet transplantation. It is meaningful to increase options to modify islet surface.

In this study, we develop a versatile method for anchoring bioactive substances onto the surface of islets. First, biotin-PEG-lipid was anchored to the lipid bilayer of the cell membrane through hydrophobic interactions. This modification had no influence on cell viability. The biotin molecule on the cell surface was used to add multilayered membranes of streptavidin and biotin-BSA. Then, a fibrinolytic enzyme, urokinase or anticoagulant heparin, was immobilized to the outermost surface to prevent the instant blood-mediated inflammatory reaction. Our methods can much more easily immobilize enzymes and polysaccharide on islet surfaces. The surface modifications did not influence the glucose-responsive insulin-secreting ability of islets, and anchored urokinase retained its fibrinolytic properties at least for 7 days. Therefore, thrombosis that form immediately after transplantation would be prevented from using these modified islets for transplantation. Immobilizing urokinase and heparin on the surface of islets is an attractive method because it would prevent systemic administration of anticoagulants, which is associated with an increased risk of bleeding after intraportal transplantation.

As shown Figure 2c, a strong fluorescence layer was observed at the periphery of all islets. Multilayered membranes of biotin-BSA and streptavidin seem to be formed on islets from the microphotographs and SPR monitoring shown in Supporting Information Figure S1. Although the surface of islets treated with a single layer was smooth, the surface became rough and some debris-like material was found on the surface of islets coated with the 21 layers. The internal tension in the coated membranes is expected to increase with a number of the layer-by-layer sequences. The layer formed was peeled off when the internal tension became larger than the anchoring strength of the PEG-lipid into the lipid bilayer. Bovine serum albumin is a globular protein and is expected not to form a mechanical strong film. We will examine synthetic linear polymers, such as poly(vinyl alcohol) and cellulose derivatives, which have been used to prepare tough membranes in industrial applications.

The number of amino groups in urokinase (25 lysine residues in a molecule) is less than that of BSA (59 lysine residue in a molecule) and the reaction used to immobilize proteins was Schiff base formation which is considered to be a reversible reaction. Although urokinase seems to be easily released from the islet surface, the fibrinolytic activity of urokinase immobilized on islets retained 25% of its initial activity after 7 days in culture. Activated dextran carries a number of aldehyde groups in a molecule. The interaction between the activated dextran and urokinase becomes stronger and more stable due to multibond formation between these molecules, even though each Schiff base is unstable by itself. Our technique using activated dextrane enables various bioactive proteins to be immobilized on the surface of islets.

Islets microencapsulated within an alginate-poly-(L-lysine) membrane and an agarose hydrogel membrane have been investigated for use as a bioartificial pancreas (*20–26*). Many groups have reported that a long-term normoglycemia in a diabetic small animal, such as a mouse or a rat, can be realized by transplanting microencapsulated islets into its peritoneal cavity. However, in clinical settings, about 10 mL of islet suspension should be injected through a catheter into the portal vein in liver. The diameter of microencapsulated islets was several times larger than that of islets, which could result in plugged vessels if infused into the portal vein. As shown in Figure 1 for SPR examinations, the thickness of the membrane increases stepwise using the streptavidin/biotin-BSA multilayer method. We examined the possibility of enclosing islets within a thin membrane using this layer-by-layer method. After forming 21 layers, the multilayer thickness reached tens of nanometers, as evaluated by SPR method and microscopy (Figures 1 and 2). The thickness was enough to the cover islet surface, but the islets' volume increase was small. Our method holds promise as a means to enclose islets without increasing volume. Immunoisolative efficacy of the layer-by-layer membrane is carefully being examined in islet transplantation studies; the results will be reported.

We examined membrane stability and found that the membrane gradually deteriorated over time (Figure 4). Either the mechanical strength of the streptavidin and biotin-BSA membrane is not strong enough for long-term encapsulation or enzymes secreted from the cells degraded the membranes. In addition, it would be necessary to carefully examine the effect of urokinase and heparin immobilized to the surface of islets *in vivo*. Future work will focus on maintaining the integrity of the multilayer membrane for longer periods and graft survivals will be carefully examined.

In conclusion, thin-layered membranes were formed on the surface of islets via biotin-PEG-lipids and the biotin/streptavidin system without increasing cell volume. Further, urokinase was anchored to the membrane, and its high fibrinolytic ability was maintained for seven days in culture. This novel method for

constructing a bioartificial pancreas provides a promising means for improving graft survival following intraportal transplantation.

Surface-Modified and Internally Cationic Polyamidoamine Dendrimers for Efficient siRNA Delivery

Mahesh L. Patil,[†] Min Zhang,[†] Seema Betigeri,[†] Oleh Taratula,[‡] Huixin He,[‡] and Tamara Minko*[,†]

Department of Pharmaceutics, Rutgers, The State University of New Jersey, Piscataway, New Jersey 08854, and Department of Chemistry, Rutgers, The State University of New Jersey, Newark, New Jersey 07102. Received February 22, 2008; Revised Manuscript Received May 27, 2008

A novel internally quaternized and surface-acetylated poly(amidoamine) generation four dendrimer (QPAMAM-NHAc) was synthesized and evaluated for intracellular delivery of siRNA. The proposed dendrimer as a nanocarrier possesses the following advantages: (1) modified neutral surface of the dendrimer for low cytotoxicity and enhanced cellular internalization; (2) existence of cationic charges inside the dendrimer (not on the outer surface) resulting in highly organized compact nanoparticles, which can potentially protect nucleic acids from degradation. The properties of this dendrimer were compared with PAMAM-NH_2 dendrimer, possessing surface charges, and with an internally quaternized charged and hydroxyl-terminated QPAMAM-OH dendrimer. Atomic force microscopy studies revealed that internally charged and surface neutral dendrimers, QPAMAM-OH and QPAMAM-NHAc, formed well-condensed, spherical particles (polyplexes) with siRNA, while PAMAM-NH_2 resulted in the formation of nanofibers. The modification of surface amine groups to amide significantly reduced cytotoxicity of dendrimers with QPAMAM-NHAc dendrimer showing the lowest toxicity. Confocal microscopy demonstrated enhanced cellular uptake and homogeneous intracellular distribution of siRNA delivered by the proposed QPAMAM-NHAc nanocarrier. The results clearly demonstrated distinct advantages of developed QPAMAM-NHAc/siRNA polyplexes over the existing nucleic acid dendrimeric carriers.

INTRODUCTION

Short or small interfering RNA (siRNA) is a class of short double-stranded RNA molecules composed of 20−25 nucleic acids. siRNA is involved in the RNA interference (RNAi) pathway to inhibit gene expression of a specific gene (*1–3*). In addition, siRNA also acts in RNAi-related pathways, e.g., as an antiviral mechanism or in shaping the chromatin structure of a genome. Despite several potential therapeutic applications, the efficiency of siRNA *in vivo* is limited by its low resistance against enzymatic degradation, limited permeability across cell membrane, and substantial liver and renal clearance (*4*). Therefore, in order to exploit potential therapeutic applications of siRNA, the effective delivery of siRNA to the site of action and into targeted cells is required. While considerable efforts have recently been made to develop new siRNA carriers, the research on the delivery of siRNA is still in a preliminary stage (*5–11*).

One of the most common methods used for the delivery of charged nucleic acids involves their electrostatic interaction with cationic carriers. Several types of cationic carriers such as liposome/lipids, dendrimers, and polymeric amines have been successfully used for the delivery of plasmid DNA and oligonucleotides (*12, 13*). Even though siRNA is structurally similar to plasmid DNA with negatively charged anionic phosphodiester backbones, electrostatic interaction of siRNA largely differs from that of plasmid DNA (*14*). The molecular weight and molecular topography of siRNA and plasmid DNA play an important role in their electrostatic interaction with cationic agents. Nonviral vectors, and especially polymers, form looser complexes with siRNA than with plasmid DNA, and incomplete encapsulation of the nuclear acid leads to the exposure of siRNA to enzymatic or physical degradation prior to delivery to the targeted cells. Consequently, carriers that are successfully used for the delivery of plasmid DNA cannot be efficiently employed for the delivery of siRNA, and a different approach is required.

Polycationic dendrimers such as poly(amidoamine) (PAMAM) dendrimers have been extensively studied as efficient vehicles for the delivery of genes and therapeutic drugs (*15–17*). Dendrimers are a type of regular and highly branched, monodisperse, spherical nanomaterials with dense peripheral groups that can be functionalized with drugs, targeting moieties, and other biologically active components (*18, 19*). Biodistribution studies showed that the higher molecular mass and/or more branched dendrimers exhibited longer circulation half-lives due to slower excretion into the urine when compared with lower molecular mass carriers, less branched dendrimers, or linear polymers (*20*). Dendrimers such as poly(amidoamine) and poly(propylenimine) possess cationic primary amine groups at the surface, which participate in the DNA binding process and increase the cellular uptake of DNA by transforming the entire complex into nanoscale polyplexes (*12–15, 17*). However, these highly efficient delivery systems have been less explored for siRNA delivery. It has been shown that PAMAM dendrimers or their conjugates are more efficient in delivering antisense oligonucleotides or plasmid DNA than siRNA (*21*).

Lee et al. have demonstrated synthesis of internally quaternized PAMAM-OH dendrimers and their efficiency in the delivery of plasmid DNA (*22, 23*). Although the internally charged PAMAM dendrimers formed stable polyplexes with plasmid DNA, their transfection ability was far lower than polyplexes of the poly(ethyleneimine) or PAMAM dendrimer.

It is generally believed that the neutral surface of a dendrimer results in low transfection efficiency. In contrast, cationic dendrimers with positive surface charge interact with negatively charged cell membranes and permeate more easily than the neutral or anionic dendrimers. However, such a positive surface charge renders cytotoxicity to the cationic dendrimers, which limits their clinical applications. Recently, it has been shown that modification of surface amine groups of PAMAM dendrimer reduced their cytotoxicity (*22, 24*).

Herein, we describe synthesis of surface-modified and an internally quaternized PAMAM dendrimer that possesses low cytotoxicity and at the same time offers internal positive charges for electrostatic interaction with negatively charged siRNA. A novel QPAMAM-NHAc dendrimer in which surface amine groups were modified with acetyl group and internal tertiary nitrogens were quaternized was prepared and evaluated for siRNA delivery.

EXPERIMENTAL PROCEDURES

Materials. Generation four PAMAM-NH_2 (Mw ~14 214 Da, 64 amine end groups), generation four PAMAM-OH dendrimer (Mw ~14 277 Da, 64 hydroxyl end groups), acetic anhydride and methyl iodide were purchased from Sigma-Aldrich Co. (St. Louis, MO). Spectra/Pore dialysis membrane with molecular weight cutoff of 2000 Da was obtained from Spectrum Laboratories, Inc. (Rancho Dominguez, CA). Fluorescent RNA duplex−siRNA labeled with Pierce NuLight DY-547 fluorophores (si*GLO* Red Transfection Indicator, red fluorescence) was obtained from Applied Biosystems (Ambion, Inc., Foster City, CA). All other chemicals were purchased from Fisher Scientific (Fairlawn, NJ).

Cell Line. The human ovarian carcinoma A2780 cell line was obtained from Dr. T. C. Hamilton (Fox Chase Cancer Center). Cells were cultured in RPMI 1640 medium (Sigma, St. Louis, MO) supplemented with 10% fetal bovine serum (Fisher Scientific, Fairlawn, NJ). Cells were grown at 37 °C in a humidified atmosphere of 5% CO_2 (v/v) in air. All experiments were performed on cells in the exponential growth phase.

Synthesis of Internally Quaternized QPAMAM-OH Dendrimer. A slightly modified previously described procedure was used for synthesis of QPAMAM-OH dendrimer (*23*). Briefly, PAMAM-OH generation four (172 mg, 0.012 mmol) was dissolved in *N*,*N*′-dimethylformamide (DMF, 1 mL) and excess methyl iodide (MeI, 0.5 mL) was added. The reaction mixture was sealed and stirred at 50 °C for 48 h. The reaction mixture was then precipitated into diethyl ether to obtain a solid, which was dried under a vacuum and redissolved in water (1 mL). The resulting solution was dialyzed against 2 M NaCl and deionizer water successively using dialysis membrane (molecular mass cutoff 2000 Da) and then lyophilized to afford a white solid (Figure 1A).

Synthesis of Acetylated PAMAM-NHAc Dendrimer (Figure 1B). Triethylamine (0.17 mL, 1.2 mmol) was added to a stirred solution of PAMAM-NH_2 generation four (172 mg, 0.012 mmol) dissolved in anhydrous methanol (10 mL) followed by the addition of excess acetic anhydride (0.1 mL, 0.96 mmol). The resulting mixture was stirred at room temperature for 24 h. Methanol was evaporated under reduced pressure and the resulting residue was dissolved in water (2 mL). Further purification by extensive dialysis against deionizer water using dialysis membrane (molecular mass cutoff 2000 Da) and freeze-drying afforded acetylated PAMAM dendrimer.

Synthesis of Acetylated and Internally Quaternized QPAMAM-NHAc Dendrimer (Figure 1B). PAMAM-NHAc (100 mg, 0.0059 mmol) was dissolved in DMF (1 mL) and excess methyl iodide (0.5 mL) was added. The reaction mixture was sealed and stirred at 50 °C for 48 h. The reaction mixture was then precipitated into diethyl ether to obtain a solid, which was dried under a vacuum and redissolved in water (1 mL). The resulting solution was dialyzed against 2 M NaCl and deionizer water successively using dialysis membrane (molecular mass cutoff 2000 Da) and then lyophilized to afford a white solid.

Proton nuclear magnetic resonance spectroscopy (^{1}H NMR). ^{1}H NMR was performed on a Varian VNMRS 400 MHz NMR spectrometer (Varian, Inc., Palo Alto, CA). The chemical shift was expressed as parts per million (ppm) and a solvent peak was used as reference (D_2O, 4.8 ppm). The following abbreviations are used in the Results section to identify multiplicities: s, singlet; m, multiplet; br, broad.

Atomic Force Microscopy. The samples of siRNA/dendrimer condensates were imaged with a tapping mode atomic force microscope (Nanoscope III A, Veeco Digital Instruments, Chadds Ford, PA). During imaging, a 125 μm long rectangular silicon cantilever/tip assembly was used with a spring constant of 40 N/m, resonance frequency of 315−352 kHz, and tip radius of 5−10 nm. The images were generated by the change in amplitude of the free oscillation of the cantilever as it interacts with the sample. The height differences on the surface are indicated by the color code: lighter regions indicate higher heights. In order to image siRNA condensates, 5 μL of dendrimer/siRNA solutions was deposited on freshly cleaved mica. After 3−5 min of incubation, the mica surface was rinsed with 3 drops of deionized water 4 times and dried under a flow of nitrogen.

Gel Electrophoresis. The complexes of dendrimers (PAMAM-NH_2, QPAMAM-OH, and QPAMAM-NHAc) and siRNA were prepared in water at N/P (negative to positive) charge ratios ranging 0−1.5 and incubated at room temperature for 30 min. The charge ratio was calculated by relating the number of positive charges on dendrimer (primary amine groups of PAMAM-NH_2 and quaternary amine groups of QPAMAM-OH and QPAMAM-NHAc) with the number of negatively charged phosphate groups of siRNA. Dendrimer-free siRNA was used as the control. Double-stranded RNA ladder (New England Biolabs) with the smallest number of base pairs at 21 was used as a size reference. The samples were further diluted with DPBS buffer and electrophoresed with ethidium bromide in 4% agarose gel at 100 V for 50 min in Tris-Borate-EDTA buffer. siRNA bands on the gel were visualized under ultraviolet light.

Dynamic Light Scattering (DLS) Analysis. Three types of complexes with N/P charge ratios of 1, 1.5, and 3 were prepared from dendrimers (PAMAM-NH_2, QPAMAM-OH, and QPAMAM-NHAc) and siRNA in water. The resulting complexes were incubated for 30 min and the size was determined using the DynePro-MS800 dynamic light scattering/molecular sizing instrument with argon laser wavelength $\lambda = 830$ nm, a detector angle 90°, and typical sample volume of 20 μL. Each light scattering experiment consisted of 20 or more independent readings, each 10 s in duration. Data analysis was conducted using DynaPro Instrument Control Software for Molecular Research DYNAMICS (version 5.26.60). The obtained DLS data represents the average of three runs.

Cellular Internalization of siRNA and Dendrimer/siRNA Complex. To analyze cellular internalization and intracellular localization of siRNA, fluorophore-labeled siRNA (si*GLO* Red, red fluorescence) either free or complexed with dendrimer (N/P = 3) was incubated for 75 min with living A2780 human ovarian cancer cells. Fluorescence and its distribution within the cell were examined every minute using a confocal microscope. Fluorescent images were digitally scanned and fluorescence inside cells (that reflects cellular accumulation of labeled siRNA) was expressed in arbitrary units.

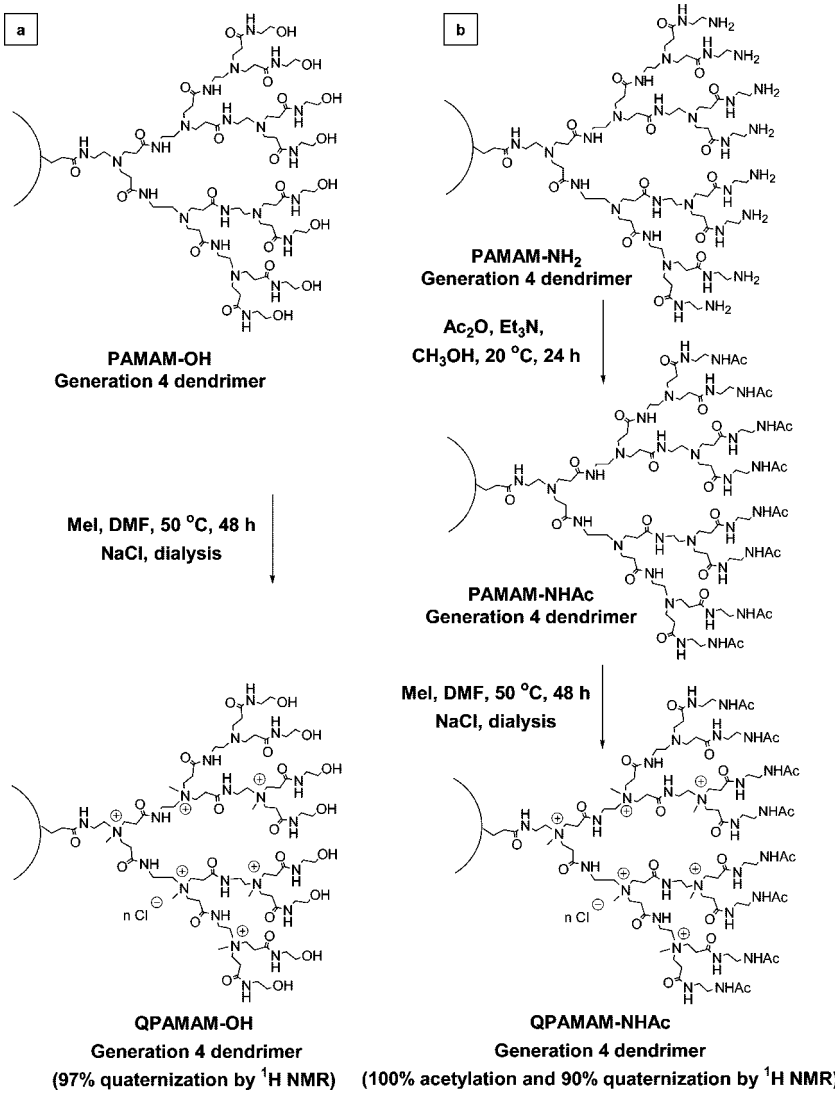

Figure 1. Synthesis of dendrimers. (a) PAMAM-OH dendrimer was internally quaternized to form QPAMAM-OH dendrimer with inner cationic charges. (b) PAMAM-NH_2 dendrimer was acetylated to form PAMAM-NHAc dendrimer. Surface acetylated PAMAM-NHAc dendrimer was internally quaternized to form QPAMAM-NHAc dendrimer possessing internal cationic charges.

***In Vitro* Cytotoxicity.** A modified MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay was used to assess the cyctotoxicity of three dendrimers as previously described (*25*). To measure cytotoxicity, cells were separately incubated in a microtiter plate with different concentrations of PAMAM-NH_2, QPAMAM-OH, and QPAMAM-NHAc dendrimers. Control cells received an equivalent volume of fresh medium. The duration of incubation was 24 h. On the basis of these measurements, cellular viability was calculated for each dendrimer concentration. A decrease in the cellular viability indicated an increase in dendrimer toxicity.

RESULTS

Synthesis and Characterization of Internally Quaternized PAMAM Dendrimer (QPAMAM-OH). The internal quaternization of PAMAM-OH dendrimer was carried out according to a previously described procedure (*23*) with a slight modification (Figure 1A). Excess methyl iodide was added to ensure complete quaternization of internal tertiary amine groups. Analysis of dendrimer by ^{1}H NMR (400 MHz, D_2O) revealed the following major peaks (Figure 2): δ 2.83−2.98 (br m, $\underline{CH_2}CONH$), 3.16 (br s, $N^+\underline{CH_3}$), 3.32−3.38 (br m, $\underline{CH_2}CH_2OH$), 3.46−3.57 (br m, $CONHCH_2\underline{CH_2}N^+$), 3.62−3.78 (br m, $N^+\underline{CH_2}CH_2CONH$ and $\underline{CH_2}OH$). The degree of quaternization was confirmed by ^{1}H NMR spectroscopy. Proton peaks arising from the (-$CH_2\underline{CH_2}$N-) methylene group adjacent to

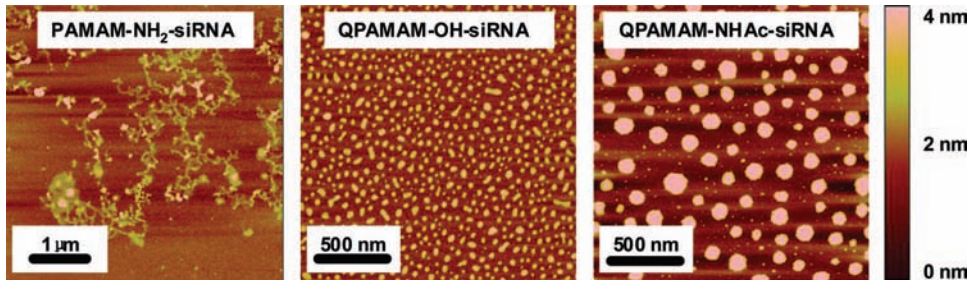

Figure 4. Typical atomic force microscope images of the condensates formed by siRNA in the presence of different dendrimers. The images were made in a tapping mode. The height differences on the surface are indicated by the color code: lighter regions indicate higher heights.

tertiary nitrogen were completely shifted, suggesting almost complete quaternization. Furthermore, the exact degree of quaternization (97%) was determined by comparing the integrated peak area of newly introduced methyl group (N^+-CH_3) at δ 3.16 to that of the unmodified methylene protons (−$\underline{CH_2}CH_2OH$) at δ 3.32−3.38.

Synthesis and Characterization of Surface-Modified and Internally Quaternized PAMAM Dendrimer (QPAMAM-NHAc). The surface-modified and internally quaternized dendrimer QPAMAM-NHAc was synthesized in two steps (Figure 1B). During the first step, the primary amine groups of PAMAM-NH_2 dendrimer were modified with acetyl group to yield fully acylated PAMAM-NHAc (*23*). ^{1}H NMR (400 MHz, D_2O) spectral data for this dendrimer are (Figure 2): δ 1.98 (s, CO$\underline{CH_3}$), 2.40−2.50 (br m, $\underline{CH_2}$CONH), 2.62−2.73 (br m, CONHCH$_2\underline{CH_2}$N), 2.82−2.92 (br m, N$\underline{CH_2}CH_2$CONH), 3.26−3.37 (m, CONH$\underline{CH_2}$ and $\underline{CH_2}$NHCOCH$_3$). The degree of acetylation was confirmed by ^{1}H NMR spectra by relating the integrated peak area of signal appeared at δ 1.98 ppm (-NHCO$\underline{CH_3}$) to that of methylene protons of PAMAM dendrimer (δ 2.40−3.37). During the second step, internal tertiary amine groups of the surface-modified PAMAM-NHAc dendrimer were quaternized by treatment with excess methyl iodide in *N*,*N*′-dimethylformamide at 50 °C. ^{1}H NMR (400 MHz, D_2O) spectral data for this dendrimer are as follows (Figure 2): δ 2.00 (s, CO$\underline{CH_3}$), 2.81−2.99 (br m, $\underline{CH_2}$CONH), 3.16 (br s, $N^+\underline{CH_3}$), 3.29−3.38 (br m, CONH$\underline{CH_2}$ and $\underline{CH_2}$NHCOCH$_3$), 3.47−3.58 (br m, CONHCH$_2\underline{CH_2}N^+$), 3.66−3.81 (br m, $N^+\underline{CH_2}$-CH_2CONH). The degree of quaternization was estimated using ^{1}H NMR spectroscopy by comparing the integrated peak area of newly introduced methyl group (N^+-CH_3) at δ 3.16 to that of the unmodified methylene protons (CONH$\underline{CH_2}$ and $\underline{CH_2}$NHCOCH$_3$) at δ 3.29−3.38.

Analysis of Dendrimer/siRNA Complex Formation by Agarose Gel Electrophoresis. Three types of dendrimers, PAMAM-NH_2, QPAMAM-OH, and QPAMAM-NHAc, were mixed with siRNA in water at various N/P charge ratios and were subjected to electrophoresis in agarose gel (Figure 3a). The complex formation was observed for all three dendrimers as evidenced by oligonucleotide bands disappearance from agarose gels. Interestingly, QPAMAM-OH and QPAMAM-NHAc dendrimers displayed a comparable ability to form complexes with siRNA, and no significant difference was observed in their band intensities.

Analysis of Particle Size of Dendrimer/siRNA complexes. The particle size of each of the dendrimer/siRNA complexes was determined by dynamic light scattering. Measured sizes of dendrimer/siRNA complexes at charge ratios ranging from 1 to 3 rel. units are shown in Figure 3b. The complexes formed using PAMAM-NH_2 and QPAMAM-OH dendrimers exhibited a decrease in particle size as the charge ratio was increased. These results are in agreement with previous studies by Lee et al. on dendrimer/pDNA polyplexes, where the particle size decreased systematically as the charge ratio was increased (*23*). The complexes formed with QPAMAM-NHAc dendrimer showed an initial decrease in average particle size from 165 to 72 nm as N/P ratio increased from 1 to 1.5 rel. units. However, the particle size did not decrease further with the increase in the N/P ratio to 3 rel. units.

Atomic Force Microscopy. The size and morphology of all three dendrimer/siRNA complexes at N/P ratio of 3 rel. units were also determined by atomic force microscopy (Figure 4).

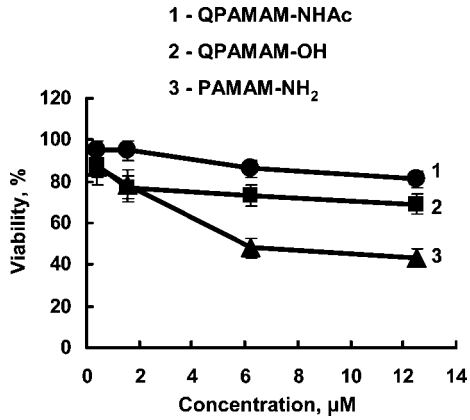

Figure 5. Cytotoxicity of dendrimers. Cellular viability was evaluated by the modified MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay. Means ± SD are shown.

It was found that well-condensed spheroidal particles were formed with internally quaternized QPAMAM-OH and QPAMAM-NHAc dendrimers, while the PAMAM-NH_2 dendrimer resulted in nanofiber-shaped structures. The particle size distribution was consistent with the dynamic light scattering data.

***In Vitro* Cytotoxicity.** The cytotoxicity evaluation of each dendrimer at various concentrations revealed a relationship between dendrimer surface charge and cellular cytotoxicity (Figure 5). An increase in surface charge led to the increase in cytotoxicity of the dendrimer. The PAMAM-NH_2 dendrimer showed highest toxicity, while a significant decrease in toxicity was observed for QPAMAM-OH dendrimer. Notably, among all three dendrimers, QPAMAM-NHAc was the least toxic even at higher concentrations.

Cellular Uptake of siRNA. The cellular uptake of fluorophore-labeled siRNA (si*GLO* Red, red fluorescence) either naked or complexed with different dendrimers (N/P = 3) was analyzed using confocal fluorescent microscopy. In this series, A2780 human ovarian cancer cells were separately incubated 80 min with naked siRNA or dendrimer−siRNA complexes, and fluorescence distribution within the cell was examined every minute using a confocal microscope. The naked siRNA without any complexation with cationic dendrimers failed to internalize cells, which was evident by the absence of measurable red fluorescence in the cell cytoplasm and nuclei (Figure 6). Similarly, PAMAM-NH_2/siRNA and QPAMAM-OH/siRNA complexes did not penetrate into cellular cytoplasm within the incubation time. In contrast, the QPAMAM-NHAc-siRNA complex was internalized by the cells and distributed uniformly inside the cytoplasm and nuclei by the end of the incubation period.

DISCUSSION

Given the ability to knock down any gene of interest, siRNA has generated a considerable interest as a novel and very effective tool for basic research and applied medicine. However, poor cell penetration ability and facile enzymatic degradation of siRNA limit its effective use (*14*). The presence of a hydroxyl group at the 2′ position of the pentose ring in the RNA favors hydrolysis of the phosphodiester backbone of nucleic acid by serum nucleases (*26*). Consequently, the development of efficient delivery systems which will protect siRNA from degradation during the voyage in the bloodstream and organs and facilitate its uptake by the targeted cells is one of the major challenges in the therapeutic application of siRNA.

Similar to the delivery of plasmid DNA, electrostatic interaction of siRNA with cationic carriers is expected to enhance cellular uptake and protect it from enzymatic degradation. Cationic liposomes and dendrimers are considered two of the most promising nanocarriers for the effective delivery of plasmid DNA, antisense oligonucleotides, and siRNA. Cationic liposomes interact with siRNA leading to a relatively large size of complexes due to uncontrolled and incomplete encapsulation of nucleic acid, thereby exposing siRNA to enzymatic degradation prior to delivery to the cell (*27*). Dendrimers have been extensively studied for the efficient delivery of plasmid DNA and antisense oligonucleotides. However, they have been explored less for the delivery of siRNA. Moreover, the relatively high cytotoxicity of cationic PAMAM-NH_2 dendrimer due to nonspecific interaction of primary amine groups with the cell membrane is the main concern for their potential applications as nanocarriers.

In the present study, two different approaches have been used to reduce the cytotoxicity of PAMAM dendrimers. First, an internally quaternized PAMAM dendrimer (QPAMAM-OH) that forms less toxic complexes with negatively charged plasmid DNA (*23*) was prepared and tested as a nanocarrier to deliver siRNA. Second, the surface primary amine groups of the PAMAM-NH_2 dendrimer were modified by acetylation followed by internal quaternization resulting in novel internally quaternized QPAMAM-NHAc dendrimer. While most traditional cationic nanocarriers have an electrical charge on their surface, both of the developed dendrimers possess neutral outer surfaces with internal positive charges. Therefore, one can hypothesize that siRNA could be internalized (at least partially) inside the dendrimer. This hypothesis is based on a report by Lee et al. (*23*) that large plasmid DNA can be incorporated in the inner space of dendrimers. Since siRNA are smaller than DNA, we suggest that it can easily penetrate between dendrimer branches. It is possible that siRNA was partially accommodated inside the dendrimer branches and the remaining part of siRNA was internalized in another molecule of dendrimer. Thus, at N/P ratio 1, an interpolyelectrolyte complex would be formed which is supported by the fact that siRNA/dendrimer complex at N/P charge ratio 1 showed a larger diameter. On the other hand, at higher N/P charge ratio, several dendrimer molecules were available to accommodate siRNA in parts and thus exhibited a decrease in diameter. These results might suggest that siRNA is partially internalized in dendrimer branches and is covered by several dendrimers, thus limiting the exposure of siRNA to nucleases. Therefore, siRNA is likely to be shielded by the dendrimer surface, which in turn limited the exposure of siRNA to a hazardous environment. This could potentially improve the stability of the entire system during its journey toward the site of action. Present experimental data confirmed that acetylated quaternized dendrimers containing siRNA are taken up to a higher extent than other dendrimers or siRNA alone.

Agarose gel retardation studies clearly indicated that both synthesized QPAMAM-OH and QPAMAM-NHAc dendrimers, as well as commercially available PAMAM-NH_2 dendrimer, interacted with siRNA irrespective of internal or surface positive charges. As anticipated, surface modification of PAMAM-NH_2 dendrimers significantly reduced their cytotoxicity. It was found that the QPAMAM-NHAc dendrimer showed the least toxicity among all three tested nanocarriers. These results are consistent with previously published data (*24*) and confirm that prevention of nonspecific nanocarrier−cell interactions caused by surface amine groups decreases the cytotoxicity of the PAMAM dendrimer. Furthermore, dynamic light scattering studies revealed condensation of siRNA into particles of nanometer dimensions when complexed with the dendrimers. The particle size dramatically decreased with an increase in N/P, which is in good agreement with the assumption that the dendrimer acts as a cross-linker, and the particle size increases if the complexation is not complete. It is interesting that hydroxyl-terminated

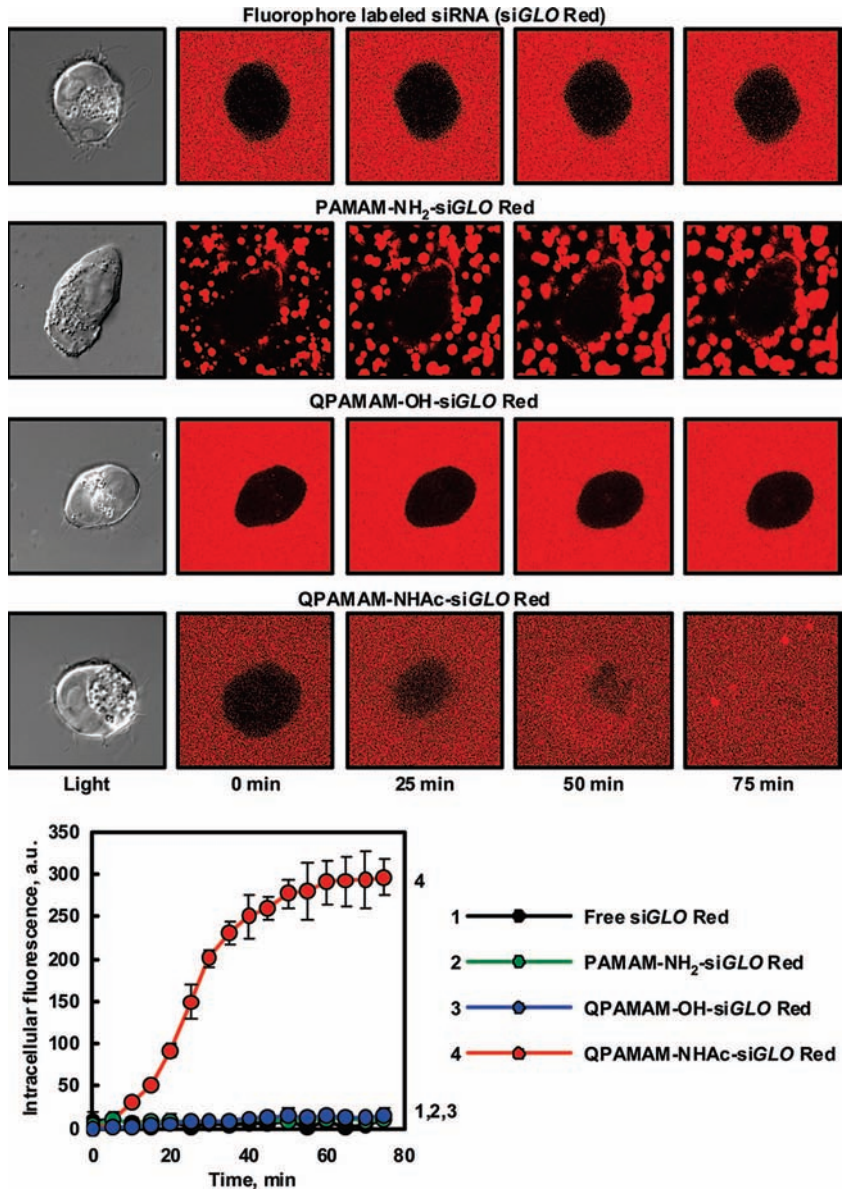

Figure 6. Cellular internalization of free siRNA and siRNA delivered by different dendrimers. Typical confocal microscopy images of living A2780 cells incubated with fluorophore-labeled siRNA (si*GLO* Red, red fluorescence) and dendrimer−siRNA complexes and time course of fluorescence intensity of si*GLO* accumulated inside cells. Means ± SD are shown.

dendrimers have lower average diameters at 1.5 and 3 N/P ratios. These results are consistent with observations made by Lee et al. (*23*). It is believed that at N/P ratio 1 the dendrimer acts as a cross-linker leading to a large-sized interpolyelectrolyte complex. Such a mechanism is supported by the fact that a siRNA/dendrimer complex at N/P charge ratio 1 showed a larger diameter. On the other hand, at higher N/P charge ratio, a higher number of dendrimers are available to form complexes with siRNA. Therefore, the net number of dendrimer/siRNA would be considerably reduced in the complex, which in turn decreased the diameter of the particles. The reason for the slight increase in particle size of the QPAMAM-NHAc/siRNA complex at charge ratio of 3 rel. units is unknown. However, all dendrimer/siRNA complexes were small enough to be internalized by cells via an adsorptive nonspecific endocytosis pathway (*28*).

The particle size distribution of synthesized nanocarriers was further supported by atomic force microscope experiments, which also revealed very interesting morphological features of the studied dendrimer/siRNA complexes at charge N/P ratio of 3.0 rel. units. The internally quaternized and surface-neutral dendrimers QPAMAM-OH and QPAMAM-NHAc formed complexes with siRNA resulting into more compact spherical nanometer particles. In contrast, the PAMAM-NH_2 dendrimer possessing cationic amino groups at the surface formed ribbon-like nanofibers, probably originating from the interpolyelectrolyte complexation with siRNA. Previous studies on understanding the condensation mechanism of DNA and dendrimers proposed a model that involves binding of one dendrimer molecule to two or more DNA chains (*29*). Apparently, such complexation leads to the formation of nanofiber-shaped structures (*30*); however, the dendrimer generation and charge ratio could also contribute to determining the morphology of the complexes. Based on these observations, we believe that internal positive charges in QPAMAM-OH or QPAMAM-NHAc dendrimer play a significant role in controlling the morphology of the complexes by shielding siRNA with the dendrimer surface. Apparently, at high N/P ratios, siRNA could be encapsulated by several QPAMAM-OH or QPAMAM-NHAc dendrimers to produce compact and spherical particles. On the other hand, surface-charged PAMAM-NH_2 probably is involved in linking two or more siRNA molecules to form higher molecular weight polymer chains.

In addition to enzymatic degradation, low cellular uptake of naked siRNA is one of the serious problems that limit their potential applications. Since siRNAs are negatively charged in the physiological range of pH, the cellular internalization of naked siRNA through a negatively charged cell membrane is considerably low. In fact, our confocal microscope studies demonstrated that naked siRNAs are not internalized by cells. Similar to plasmid DNA, complexation of siRNA with cationic agents such as polymers, liposomes, or dendrimers increases cell permeability. Alternatively, the backbone of all bases in oligonucleotides (DNA and RNA) can potentially be modified to neutralize their electric charge, enhance nuclease resistance, and increase the incorporation efficacy into liposomes or other neutral nanocarriers (*31–33*). Previously, we successfully used both approaches utilizing neutral and cationic liposomes for effective delivery of P-ethoxy antisense oligonucleotides and siRNA, respectively (*34–37*). In the present study, we exploited complexation of siRNA to the cationic outer surface or inner core of dendrimers in order to facilitate the uptake of siRNA by cells. However, our data showed that the complexation of siRNA with surface-charged PAMAM-NH_2 and internally charged QPAMAM-OH dendrimers could not improve the siRNA cell permeability. Although the exact reason for inefficiency of these types of dendrimers is unknown, we believe that size and morphology of siRNA/PAMAM-NH_2 complex and neutral surface of QPAMAM-OH dendrimers contributed to the registered low cellular uptake. In contrast, the surface-modified and internally quaternized QPAMAM-NHAc showed excellent cell permeability resulting in a substantial accumulation of siRNA in cells within 80 min. These results are in agreement with the observations made by Kolhatkar and coauthors that surface-acetylated PAMAM dendrimers showed good permeability across the cell membrane (*24*). The authors suggested a paracellular transport route for increased permeability of acetylated dendrimers due to reduced nonspecific interaction of dendrimers with cell membrane leading to an increase in concentration of dendrimers across the apical side of the membrane. It is possible that a similar mechanism was responsible for a higher uptake of acetylated dendrimers. Cellular uptake is a complex mechanism and involves several important factors that include concentration of penetrating material across the cell membrane, surface charge, and hydrogen bonding with the cell membrane. Increased permeability of surface-modified dendrimers due to reduced nonspecific interaction of dendrimers with cell membranes leading to an increase in concentration of dendrimers across the apical side of the membranes was suggested (*24*). Alternatively, amide groups on the surface of the dendrimer may also offer hydrogen bonding with cell membranes to enhance the cellular uptake of the complex. Wender et al. demonstrated the importance of hydrogen bonding in the mechanism of translocation of guanidinium-rich peptides into cells (*38*). It was found that charge is necessary, but not sufficient for cellular uptake, and hydrogen bonds with H-bond acceptor functionality on the cell surface increased uptake significantly. It is possible that these mechanisms could also be responsible at least in part for higher penetration ability of the QPAMAM-NHAc/siRNA complex. However, further studies are required to elucidate the exact mechanism for cell permeability of acetylated and internally quaternized QPAMAM-NHAc dendrimer and its complex with siRNA.

CONCLUSIONS

In summary, we have demonstrated surface-modified and internally quaternized PAMAM dendrimers as novel siRNA delivery systems. Three types of dendrimers were examined for their cytotoxicity and siRNA delivery in A2780 ovarian cancer cells. The modification of surface amine groups of PAMAM dendrimers to amide and internal quaternization proved to play a critical role for the reduced cytotoxicity and efficient cell permeability of the dendrimer−siRNA complex.

Controlling the Reactivity of Ampiphilic Quantum Dots in Biological Assays through Hydrophobic Assembly of Custom PEG Derivatives

Michael R. Warnement, Ian D. Tomlinson, Jerry C. Chang, Michael A. Schreuder, Courtney M. Luckabaugh, and Sandra J. Rosenthal*

Department of Chemistry, Vanderbilt University, Station B, 351822, Nashville, Tennessee, 37235-1822. Received March 12, 2008; Revised Manuscript Received April 28, 2008

Modifications of the quantum dot (QD) surface are routinely performed via covalent biomolecule attachment, and poly(ethylene glycol) (PEG) derivatization has previously been shown to limit nonspecific cellular interactions of QD probes. Attempts to functionalize ampiphilic QDs (AMP-QDs) with custom PEG derivatives having a hydrophobic terminus resulted in self-assembly of these PEG ligands to the AMP-QD surface in the absence of covalent coupling reagents. We demonstrate, via electrophoretic characterization techniques, that these self-assembled PEG-QDs exhibit improved passivation in biological environments and are less susceptible to unwanted protein adsorption to the QD surface. We highlight the artifactual fluorescent response protein adsorption can cause in biological assays, and discuss considerations for improved small molecule presentation to facilitate specific QD interactions.

INTRODUCTION

Quantum dots (QDs) were first reported as improved fluorophores for biological imaging applications in 1998 (*1, 2*), and have since seen increasing incorporation into numerous biological assays ranging from multiplexed fluorescent detection (*3, 4*) to tumor targeting *in vivo* (*5, 6*). Their remarkable photostability has permitted biological processes to be observed on time scales unattainable with conventional organic fluorophores (*7*). Recently, an increasing number of reports have utilized QDs to visualize trafficking dynamics of individual proteins (*8–11*); these processes are readily observable due to the enhanced brightness of these QD probes, with attainable quantum yields approaching unity (*12*). Their inorganic composition, which gives rise to these robust, size-dependent optical properties, is not conducive, however, to direct integration into biological assays. Surface modifications are initially required to permit dispersion in aqueous environments, and further functionalization is necessary to facilitate specific biological interactions. Initial attempts at water solubilization generally involved the displacement of organic capping ligands present on the quantum dot surface (*1, 2, 13*), but these approaches generally had a deleterious effect on the QD optical properties as well as reduced colloid stability. Retention of these organic capping ligands seemingly results in improved fluorophores; as such, encapsulation in phospholipids (*14*) or ampiphilic polymers (*15, 16*) has been widely used to confer water solubility. Biological specificity can subsequently be introduced through biomolecule attachment (see (*17*) for a comprehensive review). Consequently, the surface of a biologically active QD probe is surprisingly complex, with alternating regions of hydrophobicity and hydrophilicity, the possibility of a net positive or negative surface charge depending on functionalization, as well as the presence of numerous reactive chemical functionalities. A better understanding of this potentially reactive surface is required and will ultimately result in improved surface passivation and the elimination of undesirable biological interferences.

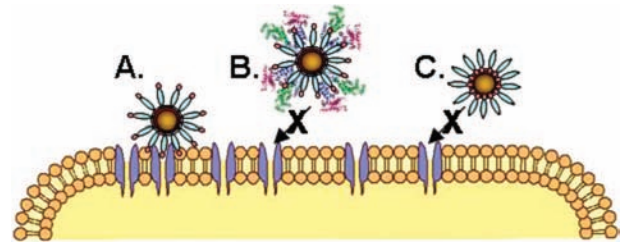

Figure 1. Cartoon schematic illustrating (a) small molecule QD targeting approach, (b) potential interferences due to protein adsorption and (c) ineffective ligand presentation as a result of ligand interaction with the QD surface.

A majority of fluorescent imaging applications involving QD probes utilize antibody conjugation to introduce biological specificity. Our own laboratory has demonstrated the utility of biologically active small molecule QD conjugates for targeting membrane-associated receptors (*13, 18*). Small molecule conjugates have the potential to provide several advantages over antibody recognition. Notably, the large size of antibodies (~150 kDa) adds significant steric bulk to an already sizable QD probe, whereas small molecule attachment provides minimal additional bulk. Despite the fact that antibodies can be designed to recognize virtually any biological target, the antibody−antigen interaction varies dramatically from antibody to antibody, and the associated cost of antibody production significantly limits their utility. Small molecules, on the other hand, can have significantly reduced costs associated with synthesis, and the strength of the ligand−receptor interaction can be optimized through iterative ligand development. Additionally, a wide variety of cellular targets are available based on drug candidates from the known pharmocopia, and these improved probes would be of immediate benefit for various drug discovery applications. Our small molecule QD targeting approach is schematically illustrated in Figure 1a. This ligand design incorporates a biologically active drug derivative (pink) on one end of a poly(ethylene glycol) (PEG) chain (blue). The PEG chain acts to reduce nonspecific interactions (*19–21*) as well as provide additional degrees of freedom for the drug derivative to interact with its cellular target. The terminus of the PEG chain is

designed with a chemical functionality to facilitate attachment to the QD surface. Generally, a terminal amine is utilized in conjunction with standard carbodiimide coupling chemistry to covalently modify carboxylic acid derivatized AMP-QDs (ITK Qdots, Invitrogen Corp., formerly Quantum Dot Corp.). Alternately, a biotin can be introduced at this terminus to assemble ligands on commercially available streptavidin QDs, utilizing the extremely high affinity streptavidin−biotin interaction. Fluorescent imaging applications utilizing this small molecule architecture have remained elusive, however, due to technical difficulties involving ligand design and associated ligand presentation on the QD surface.

It is apparent that ligand presentation on the QD surface must be optimized to facilitate specific binding of the small molecule−QD conjugate to a cellular target. Furthermore, nonspecific protein adsorption to the QD surface, specifically adsorption of the serum protein albumin, significantly inhibits the ability of a ligand to interact with a cellular target. Albumin, a 66 kDa serum protein present in standard blocking solutions and widely used in biological protocols, has previously been shown to complex to reactive QD surfaces and facilitate QD endocytosis (*22*). This protein adsorption, or "biofouling" as it has been called, on the QD surface is less problematic in the case of the larger antibody (∼150 kDa) or streptavidin (∼50 kDa) QD conjugates, but it has a dramatic effect for the ligand−QD conjugates due to the added size and steric bulk of adsorbed protein (illustrated schematically in Figure 1b). PEG modification reportedly prevents serum protein adsorption (*23*), but in this manuscript, we demonstrate continued protein adsorption despite PEG surface modification. Additionally, we show that PEG derivatives with increasingly hydrophobic targeting functionalities have the ability to self-assemble to the surface of ampiphilic QDs in the absence of any added coupling reagents (Figure 1c). This hydrophobic ligand self-assembly results in a passivated, nontargeted QD surface better suited to prevent nonspecific protein adsorption. In this manuscript, we discuss electrophoretic characterization techniques useful for the identification of adsorbed proteins on the QD surface and demonstrate improved surface passivation resulting from the hydrophobic self-assembly of PEGylated ligands. Fluorescence microscopy further demonstrates the utility of these improved probes in reducing the QD background signal *in vitro*, and illustrates the artifact endosomal fluorescence staining which results from albumin adsorption.

EXPERIMENTAL METHODS

Reagents. Ampiphilic poly(acrylic acid) polymer-coated quantum dots, commercially available as ITK Qdots, were purchased from the Invitrogen Corporation (Carlsbad, CA). Core/shell cadmium selenide/zinc sulfide quantum dots emitting at 605 nm were utilized in this study. Quantum dot concentrations were determined by UV−vis spectroscopy using a NanoDrop ND-1000 spectrophotometer (Nanodrop Technologies, Wilmington, DE). Concentrations were calculated from absorbance readings at 350, 405, 488, and 532 nm, each with reported extinction coefficients of 4 400 000, 2 800 000, 1 100 000, and 580 000 M^{-1} cm^{-1}, respectively (*24*), and then averaged to yield a final concentration. 5-Methoxyindol, 5-cyanoindol, 4-piperidone hydrochloride monohydrate, octanoic acid, *N*-hydroxy succinimide (NHS), methoxy-PEG2000, 2-(2-bromoethyl)isoindoline-1,3-dione, 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC), and dicyclohexylcarbodimide (DCC) were obtained from the Sigma Aldrich corporation (Milwaukee, WI). Boc-PEG3400-NHS and biotin-PEG5000-NHS were obtained from Nektar Therapeutics (Huntsville, AL). Borate buffer, supplied as a 5× concentrate, was obtained from Polysciences, Inc. (Warrington, PA). Ultrapure agarose and Tris-acetate-EDTA (TAE) buffer were purchased from Invitrogen, while all equipment and supplies required for polyacrylamide gel preparation (30% acrylamide solution, Tris-HCl buffer, ammonium persulfate (APS), *N*,*N*,*N*′,*N*′,-tetramethyl ethylenediamine (TEMED), Tris-borate-EDTA (TBE) running buffer, and Coomassie brilliant blue staining and destaining solutions) were purchased from Bio-Rad Laboratories. SephadexTM G-50 from Amersham Biosciences (Uppsala, Sweden) and 100K molecular weight centrifugal filters from Millipore (UFV5BHK00, Billerica, MA) were used for QD conjugate purification. Deuterium oxide for NMR experiments was purchased from Cambridge Isotope Laboratories (Andover, MA). Unless otherwise noted, all reagents were used as supplied without further purification.

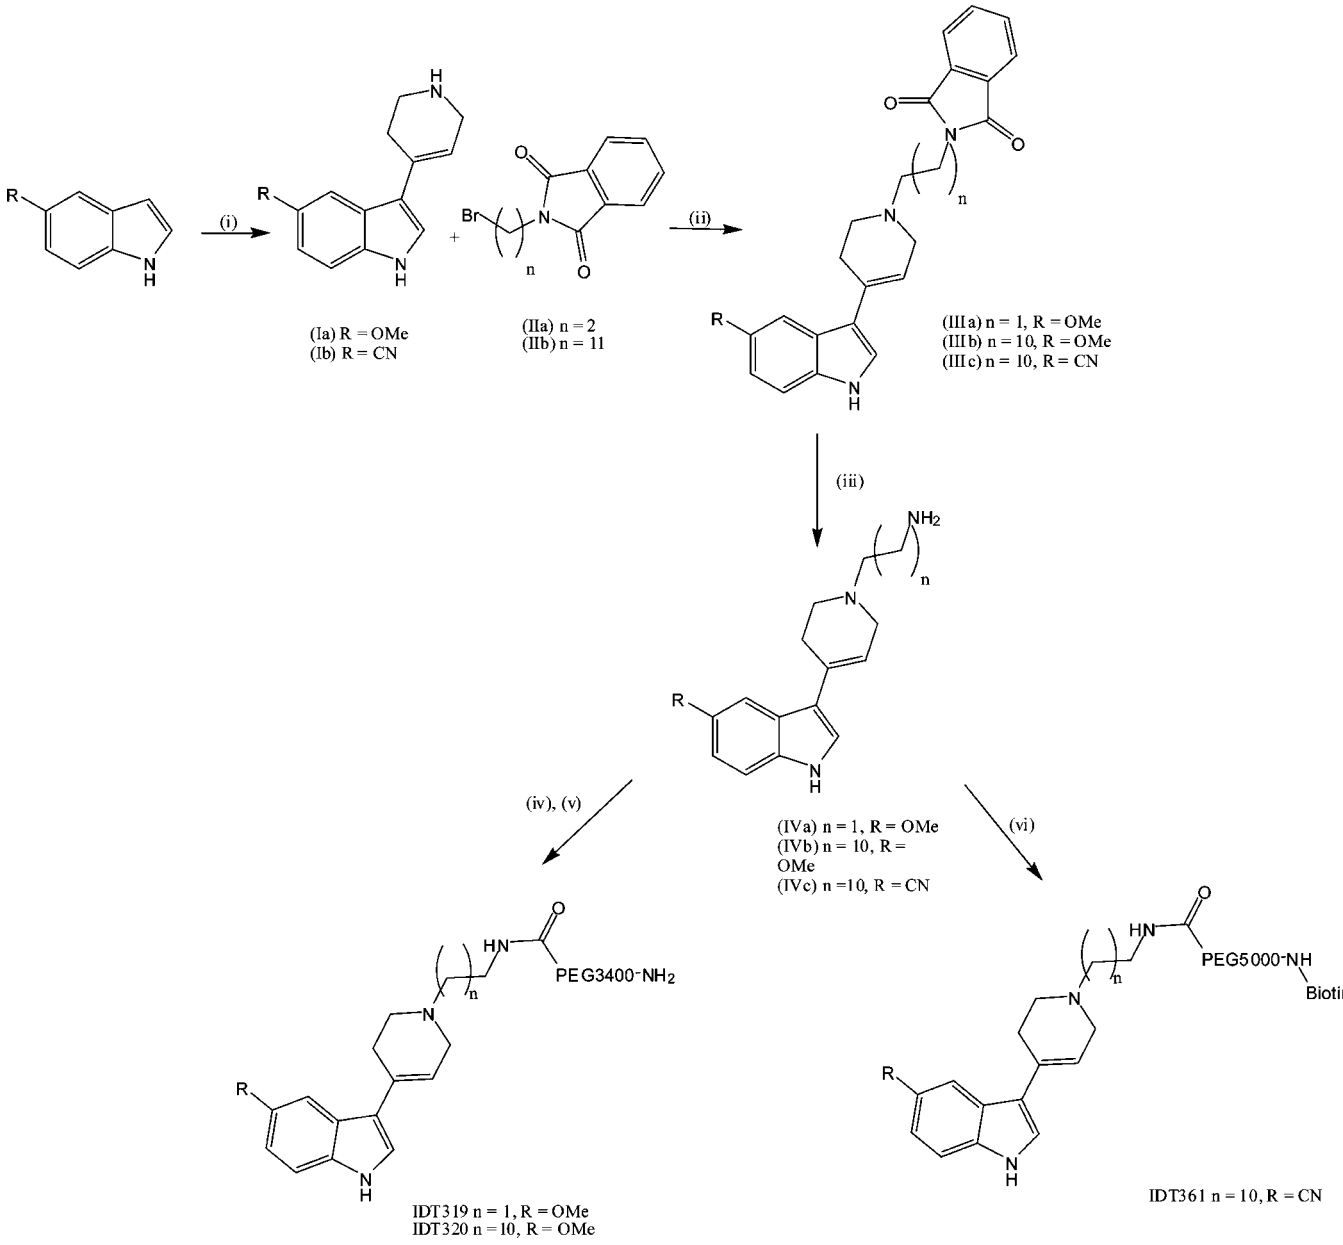
Ligand Synthesis. The synthesis of custom PEG derivatives utilized in this study is outlined in Scheme 1. This approach initially involves the synthesis of 3-(4-piperidinyl)indole derivatives, previously shown to have a high affinity for the serotonin transporter (SERT) (*25*, *26*), and their subsequent attachment to either amine- or biotin-terminated PEG chains. The use of either 2-(2-bromoethyl)isoindoline-1,3-dione (**IIa**) or 2-(11-bromoundecyl)isoindoline-1,3-dione (**IIb**), as described by Tomlinson et al. (*25*), allows for the incorporation of a variable-length alkyl spacer between the SERT-selective 3-(4-piperidinyl)indole derivative and the PEG chain. This alkyl spacer region appears to have a significant effect on the ligand's affinity for SERT, and ongoing investigations are focused toward specifically targeting SERT utilizing QD conjugates which incorporate a long alkyl chain spacer. Additionally, alternate PEG derivatives without SERT-specificity (IDT352, IDT353, and IDT363) were synthesized in a one-step coupling to either a mono-amino-methoxy-terminated PEG2000, as previously described (*20*), or a biotin-PEG5000-NHS. These nontargeting ligands were used to determine the chemical functionality required to drive the interaction with the QD surface, and not employed for any biological labeling application. Specific synthetic details are as follows:

5-Methoxy-3-(1,2,3,6-tetrahydropyridin-4yl)-1*H*-indole (Ia). 5-Methoxyindole (5 g, 34 mmol) was dissolved in methanol (200 mL) containing potassium hydroxide (22.4 g, 0.4 mol). 4-Piperidone hydrochloride monohydrate (14 g, 91 mmol) was added to the resulting solution and the mixture was heated at reflux for 18 h, after which it was cooled to ambient temperature and added to deionized water (2000 mL). The product crystallized from solution over a 48 h period and was removed by filtration to give 2.3 g (30% yield) of 5-methoxy-3-(1,2,3,6-tetrahydropyridin-4yl)-1*H*-indole (**Ia**) as a pale brown sold. This was used without further purification.

3-(1,2,3,6-Tetrahydropyridin-4-yl)-1*H*-indole-5-carbonitrile (Ib). 5-Cyanoindole (5 g, 35 mmol) and 4-piperidone hydrochloride monohydrate (14 g, 91 mmol) were heated at reflux for 18 h in methanol (200 mL) containing potassium hydroxide (22.4 g, 0.4 mol). The solution was cooled and added to deionized water (1000 mL). The aqueous solution was extracted with methylene chloride (3 × 200 mL) and the combined organic extracts were dried over magnesium sulfate. The organic solution was filtered and evaporated to yield a brown solid which was purified by column chromatography on silica eluted with ethyl acetate to give 1.8 g of the desired product in a 22% yield.

2-(2-(4-(5-Methoxy-1*H*-indol-3-yl)-5,6-dihydropyridin-1(2*H*)-yl)ethyl)isoindoline-1,3-dione (IIIa). 5-Methoxy-3-(1,2,3,6-tetrahydropyridin-4yl)-1*H*-indole (2 g, 8.7 mmol) was dissolved in acetonitrile (100 mL). Triethylamine (2 mL) and 2-(2-bromoethyl)isoindoline-1,3-dione (2.7 g, 10 mmol) were added and the mixture was heated at reflux for 18 h, after which the solvent was evaporated under reduced pressure and the product

Scheme 1. Synthesis of Ligand-Conjugated PEG Derivatives[a]



[a] (i) KOH, methanol, 4-piperidone hydrochloride monohydrate, reflux 18 h; (ii) triethylamine, acetonitrile, reflux 18 h; (iii) (a) Hydrazine monohydrate, ethanol, ambient temperature, 2 h, (b) methylene chloride, ambient temperature, 18 h; (iv) BOC-PEG3400-NHS, methylene chloride, ambient temperature, 18 h; (v) TFA; (vi) Biotin-PEG5000-NHS, (**IVc**), methylene chloride ambient temperature.

was recrystallized from methanol to give 2-(2-(4-(5-methoxy-1*H*-indol-3-yl)-5,6-dihydropyridin-1(2*H*)-yl)ethyl)isoindoline-1,3-dione (**IIIa**) in a 29% yield as a pale brown solid.

2-(2-(4-(5-Methoxy-1*H*-indol-3-yl)-5,6-dihydropyridin-1(2*H*)-yl)undecyl)isoindoline-1,3-dione (IIIb). 5-Methoxy-3-(1,2,3,6-tetrahydropyridin-4yl)-1*H*-indole (2 g, 8.7 mmol) was dissolved in acetonitrile (100 mL). Triethylamine (10 mL) and 2-(11-bromoundecyl)isoindoline-1,3-dione (3.8 g, 10 mmol) were added and the mixture was heated at reflux for 18 h. Upon cooling, the solvent was removed under reduced pressure and the product was recrystallized from acetonitrile to give 1.7 g of 2-(2-(4-(5-methoxy-1*H*-indol-3-yl)-5,6-dihydropyridin-1(2*H*)-yl)undecyl)isoindoline-1,3-dione as a pale brown solid in a 36% yield.

3-(1-(11-(1,3-Dioxoisoindolin-2-yl)undecyl)-1,2,3,6-tetrahydropyridin-4-yl)-1*H*-indole-5-carbonitrile (IIIc). 3-(1,2,3,6-Tetrahydropyridin-4-yl)-1*H*-indole-5-carbonitrile (0.9 g, 4 mmol) was added to 2-(11-bromoundecyl)isoindoline-1,3-dione (1.7 g, 4.4 mmol) in acetonitrile (100 mL) and triethylamine (5 mL). The mixture was heated at reflux for 18 h, cooled, and then evaporated to yield the crude product as a yellow solid. This was purified by column chromatography on silica gel eluted with ethyl acetate/methanol (95:5) followed by recrystallization from acetonitrile to give 1 g (50%) of the product as a pale yellow solid.

2-(4-(5-Methoxy-1*H*-indol-3-yl)-5,6-dihydropyridin-1(2*H*)-yl)ethanamine (IVa). 2-(2-(4-(5-Methoxy-1*H*-indol-3-yl)-5,6-dihydropyridin-1(2*H*)-yl)ethyl)isoindoline-1,3-dione (0.9 g, 0.2 mmol) was dissolved in absolute ethanol (50 mL) and hydrazine monohydrate (3 mL) was added. The solution was stirred at ambient temperature for 18 h, then evaporated under reduced pressure. Methylene chloride (100 mL) was added and the solution was stirred for 18 h. The resulting 2,3-dihydrophthalazine-1,4-dione was removed by filtration and the filtrate was evaporated under reduced pressure. 2-(4-(5-Methoxy-1*H*-indol-3-yl)-5,6-dihydropyridin-1(2*H*)-yl)ethanamine was recrystallized

from acetonitrile to give 0.5 g of the desired product as a pale brown solid in a 90% yield.

11-(4-(5-Methoxy-1*H*-indol-3-yl)-5,6-dihydropyridin-1(2*H*)-yl)undecan-1-amine (IVb). Using the same procedure as was used to synthesize (**IVa**), 11-(4-(5-methoxy-1*H*-indol-3-yl)-5,6-dihydropyridin-1(2*H*)-yl)undecan-1-amine was obtained in a 100% yield as a brown solid from 2-(2-(4-(5-methoxy-1*H*-indol-3-yl)-5,6-dihydropyridin-1(2*H*)-yl)undecyl)isoindoline-1,3-dione (**IIIb**).
